Selenometallates, such as tetraselenomolybdate and tetraselenotungstate, have been extensively used in the synthesis of transition metal selenides [1,2]. A number of coinage-metal/MSe_4 heteroselenometallic cluster compounds with various structural types including linear, butterfly, cubane, incomplete-cubane, co-planar T-frame, and open cross-frame, crown, cage, and pin-wheel shapes have been isolated from the interactions of $[MSe_4]^{2-}$ (M = Mo, W) anions with a series of coinage-metal species [3–9]. For the Mo(W)–Se–Ag system, a few discrete heteroselenometallic cluster compounds have been obtained to date, such as linear trinuclear $[(\mu\text{-}WSe_4)(AgPR_3)_2]$ (R = Ph or Cy, Cy = cyclohexyl) [4,10] and $[(\mu\text{-}WSe_4)(AgPPh_3)\{Ag(PPh_3)_2\}]$ [11], incomplete cubic $[(\mu\text{-}WSe_4)(AgPPh_3)_2(\mu\text{-}C_5H_5NS)]$ [5], cubane-like $[(\mu_3\text{-}MSe_4)(AgPR_3)_3\text{-}(\mu_3\text{-}X)]$ (M = Mo, W; R_3 = Ph_3, $PhMe_2$, Cy_3; X = Cl, Br, I) [4,12,13], open butterfly $[(\mu_3\text{-}WSe_4)Ag_3(\mu_3\text{-}I)(\mu\text{-}dppm)_2]$ [4], and hexanuclear $[(\mu_3\text{-}WSe_4)_2Ag_4(\mu\text{-}dppm)_3]$ [dppm = bis(diphenylphosphino)methane] [4], but polymer compounds of this kind are much fewer. The only one example is a one-dimensional helical polymer cluster compound $\{[La(Me_2SO)_8][(\mu_3\text{-}WSe_4)_3Ag_3]\}_n$ [14]. Wu and his coworkers have found that the assembling of $[WS_4]^{2-}$ and Ag^+ is flexible through non-bonding interactions with complementary small molecules (or cations) and the solvent, which can assemble into polymeric clusters with different configurations, such as single linear, zigzag and helical and double chains [15–20]. With this idea in mind, we are interested to extend the study of polymeric heterometallic

compounds from sulfides to selenides within our long-term interest in heterometallic cluster compounds based on the $[MSe_4]^{2-}$ anions [2]. A reasonable speculation originates from the fact that selenium-containing compounds have important applications, such as precursors for low-band-gap semiconductors [21] and non-linear optics [22], and in part the reactivity of selenide compounds parallels that of their sulfur counterparts [23]. Herein, we report the syntheses, structures and optical properties of the polymer compounds $\{[Et_4N][(\mu\text{-}WSe_4)Ag]\}_n$ (**1**) and $\{[Ln(Me_2SO)_8][(\mu_3\text{-}WSe_4)_3Ag_3]\}_n$ (Ln = Pr **2**, Er **3**).

2. Results and discussion

2.1. Synthetic reaction

Reaction of $[Et_4N]_2[WSe_4]$ and $AgNO_3$ in a 1:1 molar ratio in a mixed MeCN/DMF (1:10) solution resulted in the formation of the linear polymer compound $\{[Et_4N][(\mu\text{-}WSe_4)Ag]\}_n$ (**1**) as dark red crystals in 77% yield. Treatment of **1** in Me_2SO with $Ln(NO_3)_3 \cdot 3H_2O$ gave a dark brown solution, from which black block crystals of the helical chain polymer compounds $\{[Ln(Me_2SO)_8][(\mu\text{-}WSe_4)_3Ag_3]\}_n$ (Ln = Pr **2**, Er **3**) were obtained in about 70% yield. In the present reaction, the oxygenphilic Ln^{3+} cations may coordinate the oxygen atoms of the Me_2SO solvent to form the larger complex trivalent cations $[Ln(Me_2SO)_8]^{3+}$ which can displace the relatively small organic univalent cation $[Et_4N]^+$, accordingly the original univalent cluster anion $[(\mu\text{-}WSe_4)Ag]^-$ self-assembles into the trivalent cluster anions $[(\mu\text{-}WSe_4)_3Ag_3]^{3-}$ with a large size so as to match the complex cations. From the results reported here and previously, it is clear that a trend of the dependence of the cluster anion geometric sphere, which may be of a novel structure, on the size of the counterion appears to emerge. Larger cations, such as bivalent $[Ca(Me_2SO)_6]^{2+}$ and trivalent $[Ln(Me_2SO)_8]^{3+}$, effect a polynuclear W/Se(S)/Ag cluster anion polymer (e.g. $\{[W_4S_{16}Ag_4]^{4-}\}_n$ zigzag chain [17] and $\{[W_3Se_{12}Ag_3]^{3-}\}_n$ helical chain [14]), while small ones, such as univalent $[Et_3NH]^+$ and $[Et_4N]^+$, favor a binuclear cluster anion polymer (e.g. $\{[WS_4Ag]^-\}_n$ [15,16], and $\{[WSe_4Ag]^-\}_n$ linear chains).

The W–Se stretching modes of the polymeric clusters **1**–**3** can be identified since they appear as strong and sharp bands in the low wavenumber region, below 400 cm^{-1} [3,4]. The terminal W–Se_t absorptions at 312 cm^{-1} for **2** and 314 cm^{-1} for **3** appear at relatively high wavenumbers compared to the ν(W–Se) absorption at 305 cm^{-1} in $[WSe_4]^{2-}$ [1]. However, the bridging W–μ_n-Se ($n = 2$–3) vibrations in the range 295–300 cm^{-1} are observed at relatively lower wavenumbers from that of $[WSe_4]^{2-}$ [1]. The IR spectra of **2** and **3** also show bands in the range 990–1010 cm^{-1} which can be assigned to ν(S=O) of the Me_2SO solvent ligands.

2.2. Crystal structures

The structure determination shows that the cluster **1** is composed of independent $[Et_4N]^+$ cations and polymeric linear chains of $[(\mu\text{-}WSe_4)Ag]^-$ anions. An ORTEP drawing of a portion of the linear chain structure is shown in Fig. 1, with the packing diagram of the unit cell shown in Fig. 2. Although a similar structure has been seen previously in heterothiometallic systems such as $[Ph_4P]_n[MoS_4Ag]_n$ [24], $[\alpha\text{-MepyH}]_n[MoS_4Ag]_n$ (py = pyridine) [25], $[WS_4Ag \cdot NH_4]_n$ [15] and $[WS_4Ag \cdot NH_3C(CH_2OH)_3 \cdot 2DMF]_n$ [16], the current arrangement appears to be the

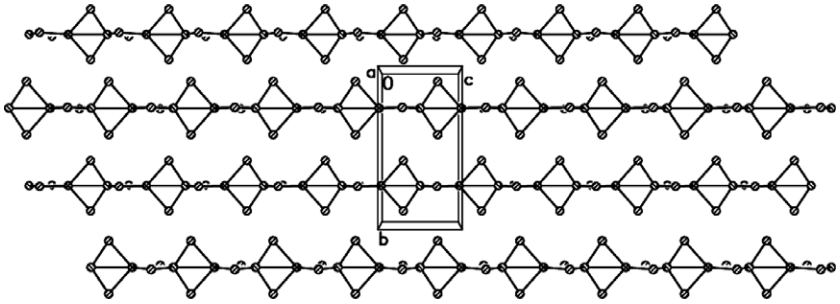

Fig. 2. Packing diagram of the linear chain polymeric $\{[(\mu\text{-}WSe_4)Ag]^-\}_n$ anion in **1**, $[Et_4N]^+$ cations are omitted for clarity.

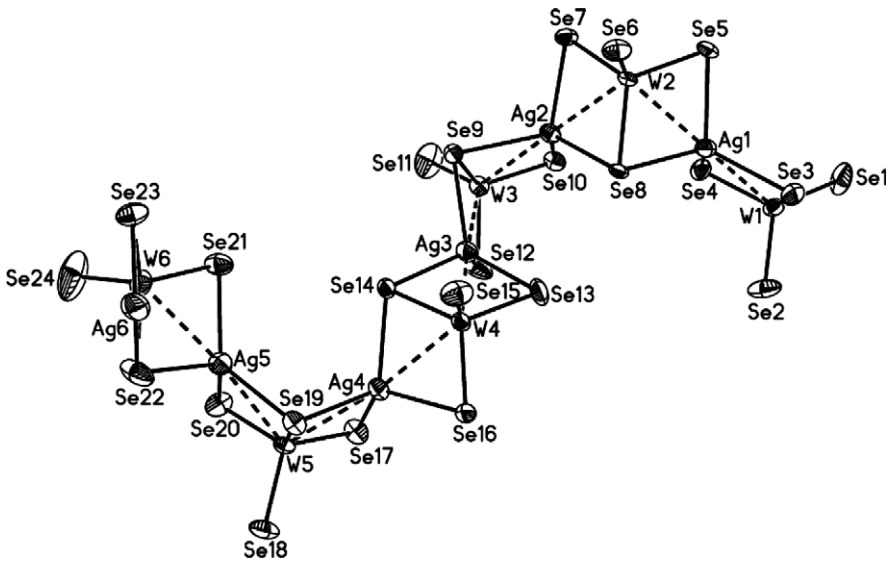

Fig. 3. ORTEP drawing of a portion of the $\{[(\mu\text{-}WSe_4)_3Ag_3]^{3-}\}_n$ anion in **2**, thermal ellipsoids are drawn at the 50% probability level.

first example of a heteroselenometallic compound with a polymeric linear chain. Both metal atoms display tetrahedron coordination in a selenium-rich environment, comparatively, the coordination geometry of the silver atoms [Se–Ag–Se: 97.00(4)–116.04(2)°] is more distorted than the tungsten atoms [Se–W–Se: 107.65(2)–113.18(5)°]. The chain has a straight linear configuration with a Ag–W–Ag angle of 180°. The W–μ-Se and Ag–μ-Se bond lengths are 2.3404(9) and 2.6085(9) Å, respectively. The $AgSe_2W$ units are co-planar, and neighboring ones are perpendicular to each other. The W–Ag distance of 3.0169(2) Å in **1** is comparable to those in $[(\mu\text{-}WSe_4)(AgPCy_3)_2]$ (av. 2.928(2) Å) [4] and $[(\mu\text{-}WSe_4)(AgPPh_3)\{Ag(PPh_3)_2\}]$ (av. 2.996(1) Å) [11].

Single-crystal X-ray diffraction analyses reveal that clusters **2** and **3**, with the same space group, have different units in the cells. Both are composed of non-interacting $\{[Ln(Me_2SO)_8]^{3+}\}_n$ (Ln = Pr **2**, Er **3**) cations and $\{[(\mu_3\text{-}WSe_4)_3Ag_3]^{3-}\}_n$ macroanions. A similar structure has been reported previously in $\{[Ln(Me_2SO)_8][(\mu_3\text{-}MS_4)_3Ag_3]\}_n$ (Ln = Nb, La; M = W, Mo) [18,19] and $\{[La(Me_2SO)_8][(\mu_3\text{-}WSe_4)_3Ag_3]\}_n$ [14]. The basic repeating unit is a butterfly-type $SeWSe_3Ag_2$ unit, containing a bridging WSe_4 group which is linked through interactions with the Ag atom of one fragment and a Ag atom of another to form an intriguing helical array of repeating $[(\mu_3\text{-}WSe_4)_3Ag_3]^{3-}$ cluster units. Fig. 3 shows a view of an individual helical chain in cluster **2**. Fig. 4 represents the packing of the $\{[(\mu_3\text{-}WSe_4)_3Ag_3]\}_n^{3n-}$ chain in the unit cell with the $[Er(Me_2SO)_8]^{3+}$ ions in cluster **3**. This chain is made up of two sets of helices which alternatively propagate along the chain. The tetrahedral tungsten atoms have Se–W–Se angles in the range 105.51(11)–114.23(9)° for **2** and 106.94(3)–113.80(3)° for **3**, and three types of W–Se bond lengths, W–Se_t (2.261(3) Å for **2** and 2.282(1) Å for **3**), W–μ-Se (2.324(3) Å for **2** and 2.336(1) Å for **3**) and W–μ_3-Se (2.377(3) Å for **2** and 2.375(1) Å for **3**). The geometry about the Ag atoms may be described as highly distorted tetrahedral, with angles in the range 95.47(8)–130.00(10)° for **2** and 96.08(3)–126.03(3)° for **3**. The average W–Ag distances [3.004(2) Å for **2** and 3.027(1) Å for **3**] are close to those observed in related heteroselenometallic W–Se–Ag clusters. The larger trivalent cations $[Ln(Me_2SO)_8]^{3+}$ are arrayed amongst the anionic helical chains and are well separated from each other and the anionic chains. Each Ln(III) atom is eight-coordinated by oxygen atoms of eight Me_2SO molecules. The average Pr–O bond length is 2.428(13) Å and the O–Pr–O angles range from 69.9(4)–146.8(4)° in **2**, while the average Er–O bond length is 2.344(4) Å and the O–Er–O angles range from 71.2(2)° to 143.7(2)° in **3**.

2.3. Optical properties

The non-linear optical (NLO) properties of **1** were investigated in DMF using a *z*-scan technique [26,27]. The open and closed *z*-scan data are given in Fig. 5. The observed curves clearly show the presence of both non-linear optical

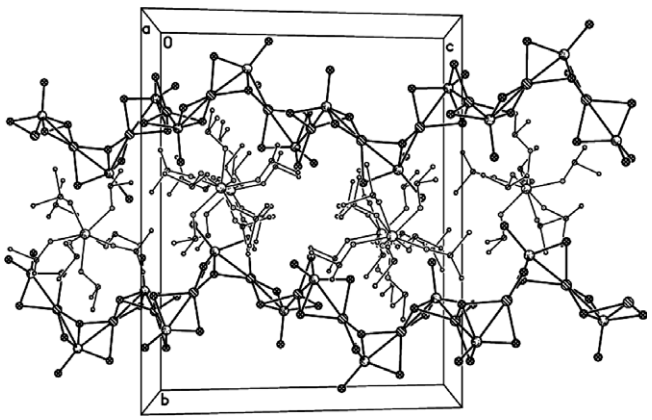

Fig. 4. Packing drawing of **3** down the *b*-axis.

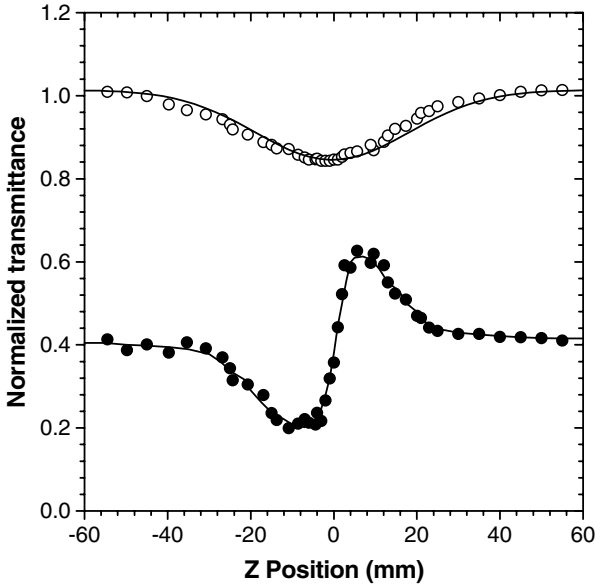

Fig. 5. z-Scan data of 1.78×10^{-4} M **1** at 532 nm with $I_0 = 1.65\times10^{-9}$ W/m^2. (a) The data shown by open circles are those collected under an open aperture configuration, and the solid curve is a theoretical fit based on $T(Z) = \frac{1}{\pi^{1/2}q(Z)}\int_{-\infty}^{\infty}\ln[1+q(z)]e^{-\tau^2}d\tau$ and $q(Z) = \alpha_2 I_i(Z)\frac{(1-e^{-\alpha_0 L})}{\alpha_0}$. (b) The data shown by filled circles were obtained by dividing the normalized z-scan data measured under a closed aperture configuration by the normalized z-scan data of (a).

absorption and non-linear optical refraction. The valley-peak pattern of the normalized transmittance curve obtained under a close aperture configuration shows characteristic self-focusing behavior of propagating light in the sample. The non-linear absorption component was evaluated under an open aperture configuration. The theoretical curve of transmittance against the z position was fitted to the observed z-scan data by varying the α_2 value, where the experimentally measured α_0, L and $I_i(z)$ values were adopted. The solid curve in Fig. 5 (top) was the theoretical curve calculated with $\alpha_2 = 1.2\times10^{-10}$ m W^{-1} for **1**. The non-linear refractive component of **1** was assessed by dividing the normalized z-scan data obtained under the closed aperture configuration with those obtained under the open aperture configuration. The theoretical curve in Fig. 5 (bottom) is superimposed for comparison, where the estimated n_2 value is 3.6×10^{-15} m^2 W^{-1}. The DMF solution of **1** caused self-focusing of the propagating light, while DMF solvent itself is known to show a negative dn/dT of -5.6×10^{-4} K^{-1} [28]. Therefore, the observed NLO properties are not due to a solvent thermal effect. By a comparison with the NLO properties of polymer compound $\{[La(Me_2SO)_8][(\mu\text{-}WSe_4)_3Ag_3]\}_n$ [14], both non-linear optical absorptive and refractive effects of linear polymer compound **1** are inferior to those found in the polynuclear polymer compound $\{[La(Me_2SO)_8][(\mu\text{-}WSe_4)_3Ag_3]\}_n$, which has a helical chain, suggesting that aggregation of metal atoms in heteroselenometallic clusters may possibly assist to improve the NLO properties of the clusters. Whether the structural variation from linear chain to helical chain might influence the NLO properties of the clusters will be further studied by way of the designed syntheses of this class of cluster with different structural types [22,29].

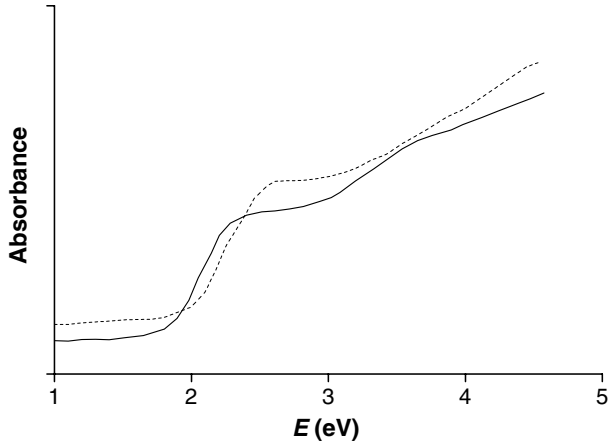

Fig. 6. Solid-state UV–Vis spectra of **1** (dashed line) and **2** (solid line), recorded as suspensions in Nujol.

To gain insight into the optoelectronic properties of **1** and **2**, we measured the UV–Vis solid-state absorption spectra of the polymeric clusters **1** and **2** (see Fig. 6). The absorption onsets of **1** and **2** were observed at $E = 1.92$ eV (647 nm) and 2.11 eV (590 nm), respectively, which may be tentatively assigned to the optical bandgap energy at the lowest electronic excitation in the solid state. On comparison to heteroselenometallic polymer compounds with ternary metal-selenide compounds [30], the differences in the optical bandgaps may probably be attributed to differences in the coordination environment as well as the nature of the organic and metal-complex cations of **1** and **2** [31].

In summary, we have synthesized and structurally characterized inorganic polymer complexes, one-dimensional linear $\{[Et_4N][(\mu\text{-}WSe_4)Ag]\}_n$ and helical $\{[Ln(Me_2SO)_8][(\mu_3\text{-}WSe_4)_3Ag_3]\}_n$ (Ln = Pr, Er). The present heteroselenometallic W–Se–Ag polymer compounds, without peripheral ligands, show middling non-linear optical absorption and refraction in solution and a normal optical bandgap energy at the lowest electronic excitation in the solid state. We are currently investigating more structural types of heteroselenometallic W–Se–Ag polymer complexes and clusters and are further studying their optical and electronic properties so that some desired optoelectronic functions with new inorganic cluster materials will be achieved.

3. Experimental

3.1. Materials and measurements

All syntheses were performed in oven-dried glassware under a purified nitrogen atmosphere using standard Schlenk techniques. The solvents were purified by conventional methods and degassed prior to use. $[Et_4N]_2[WSe_4]$ was prepared by a modification of the literature method

[32]. $AgNO_3$, $Pr(NO_3)_3 \cdot 6H_2O$, and $Er(NO_3)_3 \cdot 6H_2O$ were purchased from Strem Ltd. and were used without further purification. All elemental analyses were carried out using a Perkin–Elmer 2400 CHN analyzer. Infrared spectra were recorded on a Digilab FTS-40 spectrophotometer with the use of pressed KBr pellets. UV–Vis spectra were recorded on a Perkin–Elmer spectrometer Lambda 900, employing the double-beam technique. The samples were measured in Nujol, prepared by grinding single crystals in a drop of Nujol. The mixture was placed between two quartz plates and rapidly brought into the UV–Vis beam.

A DMF solution of cluster **1** was placed in a 1 mm quartz cuvette for non-linear optical measurements, which were performed with linearly polarized 7 ns pulses at 532 nm generated from a Q-switched frequency-doubled Nd:YAG laser. The cluster is stable toward air and laser light under the experimental conditions. The spatial profiles of the pulsed laser were focused on the sample cell with a 30 cm focal length mirror. The spot radius of the laser beam was measured to be 55 μm (half-width at $1/e^2$ maximum). The incident and transmitted pulse energies were measured simultaneously by two energy detectors (Laser Precision Rjp-735), which were linked to a computer by an IEEE interface [26,27]. The NLO properties of the samples were manifested by moving the samples along the axis of the incident laser irradiance beam (z-direction) with respect to the focal point and with the incident laser irradiance kept constant (z-scan methods). The closed-aperture curves are normalized to the open aperture curves. An aperture of 0.2 mm radius was placed in front of the detector to measure the transmitted energy when assessment of the laser beam distortion was needed. To eliminate scattering effects, a lens was mounted after the samples to collect the scattered light.

Ag(2)–W(1)–Ag(1)	90.32(2)	W(2)–Ag(2)–W(1)	160.84(2)
W(2)–Ag(3)–W(3)	168.83(3)	W(1)–Ag(1)–W(3)#2	176.62(2)

Symmetry codes: #1 $x+\frac{1}{2}, -y+\frac{1}{2}, z+\frac{1}{2}$; #2 $x-\frac{1}{2}, -y+\frac{1}{2}, z-\frac{1}{2}$.

3.2. Preparation of $\{[Et_4N][(\mu\text{-}WSe_4)Ag]\}_n$ (1)

A solution of $AgNO_3$ (42.5 mg, 0.25 mmol) in MeCN (1 mL) was added dropwise to a solution of $[Et_4N]_2[WSe_4]$ (190 mg, 0.25 mmol) in DMF (10 mL). The mixture was stirred for a while at room temperature, resulting in a purple-red solution with a small amount of black precipitate, and then filtered to afford a dark red filtrate. Dark-red prism crystals of **1** were obtained after allowing the filtrate to stand at room temperature for three days. Yield: 117 mg (77%). IR (KBr, cm^{-1}): ν(W–Se) 297 (m). *Anal.* Calc. for $C_8H_{20}NSe_4WAg$: C, 13.0; H, 2.71; N, 1.90. Found: C, 12.8; H, 2.66; N, 1.92% (Table 1).

3.3. Preparations of $\{[Ln(Me_2SO)_8][(\mu\text{-}WSe_4)_3Ag_3]\}_n$ (Ln = Pr 2, Er 3)

To a solution of **1** (111 mg, 0.15 mmol) in 10 mL Me_2SO was added a solution of $Pr(NO_3)_3 \cdot 6H_2O$ (62 mg, 0.20 mmol) or $Er(NO_3)_3 \cdot 6H_2O$ (68 mg, 0.20 mmol) in 5 mL of Me_2SO with slow stirring. A brown solution was gradually formed along with a little black precipitate. The clear filtrate was allowed to stand at room temperature for two days to afford black block crystals suitable for a single-crystal X-ray diffraction analysis, which were identified as **2** or **3**, respectively. For **2**: Yield: 94 mg (70%). IR (KBr, cm^{-1}): ν(S=O) 1003 (s), 997 (s); ν(W–Se), 297 (m). *Anal.* Calc. for $C_{16}H_{48}O_8S_8Se_{12}W_3Ag_3Pr$: C, 7.42; H, 1.85. Found: C, 7.38; H, 1.82%. For **3**: Yield: 90 mg (68%). IR (KBr, cm^{-1}): ν(S=O) 1001 (s), 992 (s); ν(W–Se), 296 (m). *Anal.* Calc. for $C_{16}H_{48}O_8S_8Se_{12}W_3Ag_3Er$: C, 7.34; H, 1.84. Found: C, 7.32; H, 1.85% (Tables 2 and 3).

3.4. X-ray crystallography

Well developed single-crystals of **1** ($0.25 \times 0.15 \times 0.10\ mm^3$), **2** ($0.16 \times 0.13 \times 0.10\ mm^3$), and **3** ($0.18 \times 0.16 \times 0.10\ mm^3$) were mounted in a random orientation on glass fibers. Diffraction data were collected on a Bruker APEX CCD area-detecting diffractometer equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) by using an ω-scan technique (for **1**, $1.53° < \theta < 28.20°$; for **2**, $1.53° < \theta < 25.00°$; for **3**, $1.37° < \theta < 25.00°$). The collected frames were processed with the software SAINT [33]. The data were corrected for absorption using the program SADABS [34]. Structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELXTL software package [35]. All non-hydrogen atoms were refined anisotropically. The positions of all hydrogen atoms were generated geometrically (C–H bond fixed at 0.96 Å), assigned isotropic thermal parameters and allowed to ride on their respective parent C atoms before the final cycle of least-squares refinement. For **2** and **3**, sulfur and carbon atoms in two of Me_2SO groups were clearly observed to be disordered. Their site occupancies were each initially set to 0.5, but they were then refined with the restriction that their sum should add up to unity, which resulted in site occupancy values (see Supporting information). The large peaks in the final difference maps had a height of 2.698 e Å^{-3} for **1** and 2.947 e Å^{-3} for **2**, and are in the vicinity of the W atoms. The final cycle of full-matrix least squares refinement converged to give R_1 and wR_2 values which along further details of the structure analyses are listed in Table 4.

Abstract

Four cyano bridged Cu(II)–Pd(II) heterometallic complexes, $[Cu(dpt)Pd(CN)_4]_n$ (**1**), $\{[Cu_2(medpt)_2Pd(CN)_4](ClO_4)_2 \cdot 3H_2O\}_n$ (**2**), $\{[Cu_2(dien)_2Pd(CN)_4](ClO_4)_2 \cdot 2CH_3OH\}_n$ (**3**) and $\{[Cu_2(i\text{Prdien})_2Pd(CN)_4](ClO_4)_2 \cdot 2H_2O\}_n$ (**4**) [dpt = 3,3′-iminobispropylamine; medpt = 3,3′-diamino-*N*-methyldipropylamine; dien = diethylenetriamine and *i*prdien = *N*′-isopropyldiethylenetriamine] have been synthesized and characterized by single crystal X-ray diffraction analysis, magnetic measurement and thermal study. Complexes **1**, **2** and **3** are 1D coordination polymers, while **4** presents a 2D network. In **1**, the *cis*-directed cyanide ligands of $[Pd(CN)_4]^{2-}$ anions link two Cu(dpt) units to form a neutral coordination polymer, whereas in **2**, **3** and **4**, all the cyanide groups of $[Pd(CN)_4]^{2-}$ take part in bonding with four adjacent Cu(II) ions, resulting in cationic coordination polymers counterbalanced by perchlorate anions. The structures are compared with those of analogous $[Ni(CN)_4]^{2-}$ derivatives. The magnetic behavior shows antiferromagnetic interactions in all the complexes.

Keywords: Cu(II); Tetracyanopalladate; Triamine; Crystal structure; Magnetic behavior

1. Introduction

Recently the design and synthesis of coordination polymers with specific properties have received significant attention in the field of material science [1]. The formation of polymeric structures depends on several factors [2] i.e.; (i) stereo electronic molecular information encoded in the ligand(s); (ii) reading of the information by metal ions having a set of coordination numbers and stereochemical preferences depending on their size, charge and electronic structure; and (iii) external conditions, e.g. solvent, counterions, which have a strong influence in the crystallization process as well as on the solid-state architecture.

Cyanometallate complexes have been intensively investigated in view of their potential application in the design of molecule-based magnets [3] or microporous inorganic materials mimicking zeolites [4]. It has been observed that when the second coordination center is a transition metal ion, $\sigma \rightarrow \pi$ back donation stabilizes the resulting complexes making them robust [5].

Cyanometallate anions may be either diamagnetic or paramagnetic, and the latter center generates unique multidimensional structures with useful magnetic properties, even magnetic ordering [3], when combined with suitable coordination metal centers. On the other hand, diamagnetic cyanometallate entities do not show noticeable magnetic properties, but due to the rigidity of the structure, these frameworks are potentially useful as analogues to zeolites [6]. Square planar tetracyanometallates, which are generally formed by d^8 metal ions, have received little

attention for designing coordination polymers and a literature survey reveals that reports on coordination polymers using $[Pd(CN)_4]^{2-}$ or $[Pt(CN)_4]^{2-}$ as building blocks are scarce [7,8].

Recently our group reported [5] a novel porous framework, $\{[Cu_2(medpt)_2Ni(CN)_4](ClO_4)_2 \cdot 2.5H_2O\}_n$ [medpt = bis(3-aminopropyl)methylamine], where all the CN groups of $Ni(CN)_4^{2-}$ are involved in bridging, and this material retains crystallinity upon removal of water guest molecules. The dehydrated species shows novel zeolitic properties. Related heterometallic frameworks of Cu(II) with $Ni(CN)_4^{2-}$ along with their magneto structural correlations have also been reported by us [9]. Thus, as an extension of our work on these systems we report here the synthesis, crystal structure, thermal study and magnetic behavior of $[Cu(dpt)Pd(CN)_4]_n$ (**1**), $\{[Cu_2(medpt)_2Pd(CN)_4](ClO_4)_2 \cdot 3H_2O\}_n$ (**2**), $\{[Cu_2(dien)_2Pd(CN)_4](ClO_4)_2 \cdot 2CH_3OH\}_n$ (**3**) and $\{[Cu_2(i\text{prdien})_2Pd(CN)_4](ClO_4)_2 \cdot 2H_2O\}_n$ (**4**) [dpt = 3,3′-iminobispropylamine; medpt = 3,3′-diamino-*N*-methyldipropylamine; dien = diethylenetriamine and *i*prdien = *N*′-isopropyldiethylenetriamine]. Of these, complex **4** is a rare example of a 2D coordination polymer in tetracyanometallato-bridged systems.

2. Experimental

2.1. Materials

High purity 3,3′-iminobispropylamine (dpt); 3,3′-diamino-*N*-methyldipropylamine (medpt); diethylenetriamine (dien); *N*′-isopropyldiethylenetriamine (*i*prdien) and potassium tetracyanopalladate(II) trihydrate were purchased from the Aldrich Chemical Co. Inc. and were used as received. All other chemicals were of AR grade.

2.2. Physical measurements

Elemental analysis (carbon, hydrogen and nitrogen) was performed using a Perkin–Elmer 240C elemental analyzer. IR spectra were measured from KBr pellets on a Nicolet 520 FTIR spectrometer. Magnetic measurements were carried out in the "Servei de Magnetoquímica (Universitat de Barcelona)" on polycrystalline samples (30 mg) with a Quantum Design SQUID MPMS-XL magnetometer working in the 2–300 K range, the magnetic field was 0.1 T. The diamagnetic corrections were evaluated from Pascal's constants. Thermal analysis was done on a Perkin–Elmer Pyris Diamond system.

2.3. Synthesis

Suitable single crystals of complexes **1**–**4** were obtained from the filtrate derived after mixing the reactants and stirring for 30 min. Syntheses were conducted in water–methanol (2:1) and the chemical reactions are schematically given below:

$$2n\text{Cu}(\text{ClO}_4)_2 \cdot 6\text{H}_2\text{O} + 2n\text{dpt} + n\text{K}_2[\text{Pd}(\text{CN})_4] \rightarrow [\text{Cu}(\text{dpt})\text{Pd}(\text{CN})_4]_n \quad (1)$$

$$2n\text{Cu}(\text{ClO}_4)_2 \cdot 6\text{H}_2\text{O} + 2n\text{medpt} + n\text{K}_2[\text{Pd}(\text{CN})_4] \rightarrow \{[\text{Cu}_2(\text{medpt})_2\text{Pd}(\text{CN})_4](\text{ClO}_4)_2 \cdot 3\text{H}_2\text{O}\}_n \quad (2)$$

$$2n\text{Cu}(\text{ClO}_4)_2 \cdot 6\text{H}_2\text{O} + 2n\text{dien} + n\text{K}_2[\text{Pd}(\text{CN})_4] \rightarrow \{[\text{Cu}_2(\text{dien})_2\text{Pd}(\text{CN})_4](\text{ClO}_4)_2 \cdot 2\text{CH}_3\text{OH}\}_n \quad (3)$$

$$2n\text{Cu}(\text{ClO}_4)_2 \cdot 6\text{H}_2\text{O} + 2ni\text{prdien} + n\text{K}_2[\text{Pd}(\text{CN})_4] \rightarrow \{[\text{Cu}_2(i\text{prdien})_2\text{Pd}(\text{CN})_4](\text{ClO}_4)_2 \cdot 2\text{H}_2\text{O}\}_n \quad (4)$$

2.3.1. *[Cu(dpt)Pd(CN)$_4$] (1)*

A methanolic solution (10 ml) of 3,3′-iminobispropylamine (dpt) (2 mmol, 0.262 g) was added dropwise to an aqueous solution (10 ml) of $Cu(ClO_4)_2 \cdot 6H_2O$ (2 mmol, 0.740 g) with constant stirring over a few minutes. To the resulting deep blue solution, an aqueous solution (10 ml) of $K_2[Pd(CN)_4] \cdot 3H_2O$ (1 mmol, 0.342 g) was added slowly and the reaction mixture was stirred for 30 min and then filtered, and the filtrate was kept in a $CaCl_2$ desiccator. Shiny deep blue single crystals suitable for X-ray analysis were obtained after a few days. Yield: 80%. *Anal.* Calc. for $C_{10}H_{17}CuN_7Pd$ (405.25): C, 29.61; H, 4.19; N, 24.18. Found: C, 29.13; H, 4.03; N, 23.81%. The infrared spectra exhibited the following absorptions: 3304(vs), 3219(s), 3144(vs), 2932(vs), 2864(s), 2183(s), 2140(vs), 1594(s), 1434(w), 1275(w), 1151(s), 1028(w), 999(vw), 896(vw), 697(vw), 512(vw) cm^{-1}.

2.3.2. *[Cu$_2$(medpt)$_2$Pd(CN)$_4$](ClO$_4$)$_2$ · 3H$_2$O (2), [Cu$_2$(dien)$_2$Pd(CN)$_4$](ClO$_4$)$_2$ · 2CH$_3$OH (3) and [Cu$_2$(iPrdien)$_2$Pd(CN)$_4$](ClO$_4$)$_2$ · 2H$_2$O (4)*

The complexes were synthesized following the procedure adopted for complex **1** using 3,3′-diamino-*N*-methyldipropylamine (medpt) (2 mmol, 0.290 g), diethylenetriamine (dien) (2 mmol, 0.206 g) and *N*′-isopropyldiethylenetriamine (*i*prdien) (2 mmol, 0.284 g) for **2**, **3** and **4**, respectively instead of dpt. Suitable blue crystals of **2**, **3** and **4** for X-ray diffraction analysis were obtained from the filtrate kept in a $CaCl_2$ desiccator. The yields were 72%, 70 % and 74% for **2**, **3** and **4**, respectively.

Elemental analyses are in good agreement with the calculated values. *Anal.* Calc. for $C_{18}H_{44}Cl_2Cu_2N_{10}O_{11}Pd$ (**2**) (881.01): C, 24.51; H, 4.99; N, 15.89. Found: C, 24.82; H, 4.81; N, 16.12%. 2.4. Crystallographic data collection and refinement

Diffraction data of complex **4** were collected at room temperature on a Brucker Kappa CCD imaging plate mounted on a Nonius FR591 rotating anode ($\lambda = 1.54178$ Å), those of **1**, **2** and **3** on a Nonius DIP-1030H system with Mo Kα radiation ($\lambda = 0.71073$ Å). Cell refinement, indexing and scaling of the data sets were carried out using programs DENZO [10] and SCALEPACK [10]. All the structures were solved by Patterson and Fourier analyses [11] and refined by the full-matrix least-squares method based on F^2 with all observed reflections [11]. The ΔF maps of **2** revealed some residuals interpreted as three water oxygens (0.5 occupancy each, H atoms not assigned), while a molecule of water (H atoms from Fourier map) and one of methanol was found in the crystal structures of **4** and of **3**, respectively. The hydrogen atoms were placed at geometrically calculated positions, except those of water molecules as indicated above. Crystallographic data and experimental details are reported in Table 1. All the calculations were performed using the WINGX System, Ver 1.70.01 [12].

3. Results and discussion

3.1. Description of the structures

The X-ray structure determinations of complexes **1**–**4** reveal coordination polymers built up by Cu(triamine) units connected through bridging tetracyanopalladate anions. In all of these structures the copper(II) atom exhibits a distorted square pyramidal coordination sphere accomplished by the tridentate amine ligand and a cyanide nitrogen in the basal plane, whereas the apex is occupied by another CN group from a symmetry related $[Pd(CN)_4]^{2-}$ anion. The coordination bond lengths and angles are reported in Table 2 together with other relevant geometrical data. These values compare well with those found in the analogous $[Ni(CN)_4]^{2-}$ complexes [9].

3.1.1. Complex *1*

Complex **1** is isomorphous and isostructural to the $[Ni(CN)_4]^{2-}$ derivative [13] and it consists of neutral $-[Cu(dpt)–Pd(CN)_4]_n-$ polymers having a zigzag arrangement developed along the *b*-axis, where $Pd(CN)_4^{2-}$ anions connect Cu(dpt) units in a *cis* fashion (Figs. 1 and 2). The Cu–N bond distances in the basal plane of the square pyramidal geometry (range 2.006(4)–2.039(3) Å) are significantly shorter than that observed for the apical Cu–N bond, 2.193(4) Å. The donor atoms in the base display a slight tetrahedral distortion (±0.084 Å) with the copper displaced by about 0.266(2) Å towards the vertex of the

of the square pyramid, respectively. It is obvious that the configuration of this and other polymers depend on the latter values and also on the orientation assumed by the $Pd(CN)_4$ plane with respect to the copper environment. The formation of weak H-bonding interactions (Table 3) between the $–NH_2$ groups and uncoordinated cyano nitrogen atoms of adjacent chains gives rise to a 3D supramolecular architecture.

3.1.2. Complexes 2 and 3

These structures appear very similar at a first glance, showing cationic 1D coordination polymeric chains, $–[Pd(CN)_4Cu_2(L)_2]_n–$ (L = medpt for **2** and dien for **3**), where the tetracyanopalladate groups have all μ-bridging CN ligands (Fig. 3). However the Pd atoms in the case of **2** have a zigzag arrangement (Pd···Pd···Pd angle 155.80°) separated by 7.597 Å, whilst in **3** they are collinear (Pd···Pd···Pd = 180.0°) at a distance of 7.952 Å (Table 2). The charge is counterbalanced by perchlorate anions.

The ORTEP drawings of the Cu(II) coordination sphere with the atom labeling scheme are shown in Figs. 4 and 5. In both complexes the square pyramidal coordination environment shows the basal Cu–N bond distances significantly shorter with respect to the apical ones, which are 2.191(4) and 2.337(4) Å in **2** and **3**, respectively, and the latter is the longest among those reported by us for CN–Cu bond lengths. The square planar basal plane displays almost coplanar nitrogen donors with the Cu ion slightly displaced by about 0.259(2) and 0.229(2) Å in **2** and **3**, respectively, towards the vertex of the pyramid. The palladium atom in the $Pd(CN)_4^{2-}$ anions is located on a crystallographic symmetry plane in **2** and on a inversion center in **3**. The Pd–C bond distances are comparable within 3σ, varying in the range 1.996(4)–2.015(4) Å. The cyanide groups reveal different coordination geometries, being almost linearly coordinated to copper (175.9(4)–178.1(4)°), with the exception of that located at the apical position of the square pyramidal sphere of copper in **2** (C(5)–N(5)–Cu 154.6(4)°). The polymers are involved in a H-bonding (Table 3), evolved through the amine groups, the perchlorate anions and the lattice water molecules in **2**, which enhances the dimensionality to 3D. The packing appears to be determined by the number of methylene units and the methyl groups at the ancillary medpt triamine

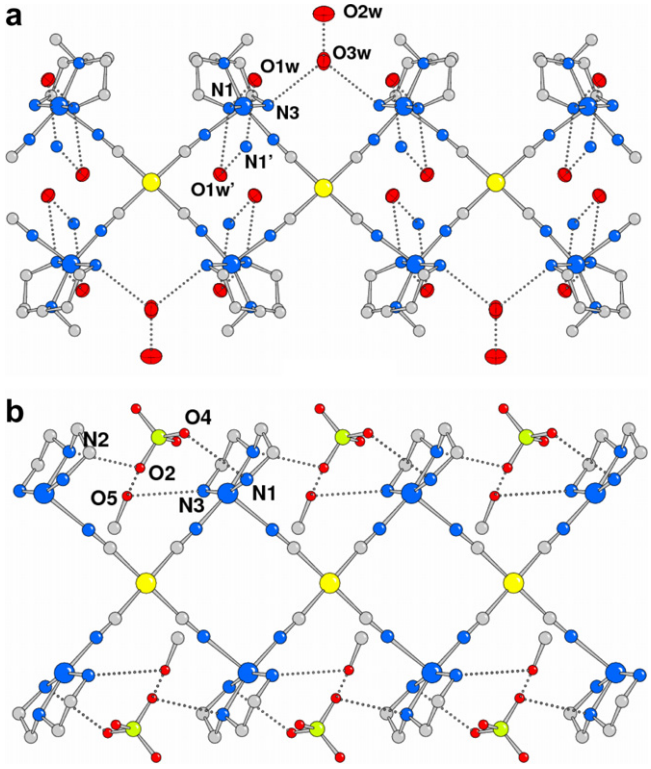

Fig. 3. Coordination polymer of complexes **2** and **3** with H-bonds (dotted lines) involving lattice amine groups with water molecules (a) and perchlorate and methanol molecules (b).

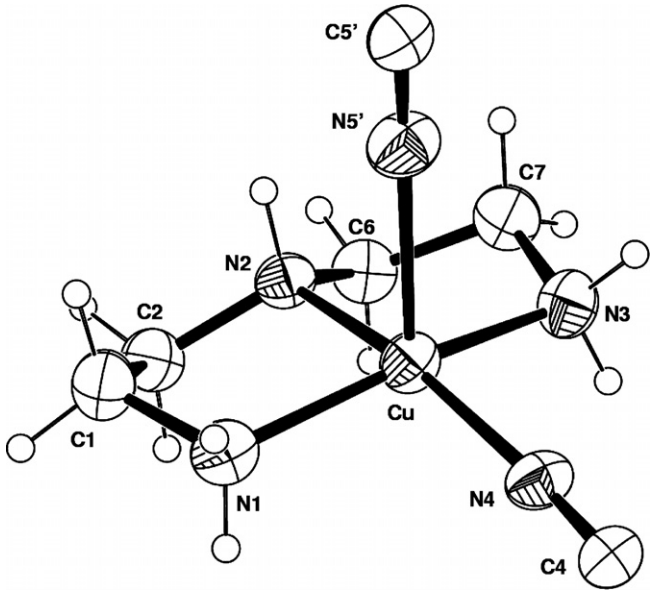

Fig. 5. ORTEP drawing (40% probability level) of the copper coordination sphere of complex **3**.

ligand, the void space (amongst the chains) being occupied by the counter anions and ultimately by solvent molecules.

Complex **2** is isomorphous and isostructural to the tetranickellate derivative [5], differing only by a small amount due to the disordered lattice water molecules. The water molecule O(3w) (which is appended to O(2w)) bridges through H-bonding to symmetry related N(3) atoms, while O(1w) enhances the dimensionality to 3D by connecting N(1) amines of adjacent chains (Fig. 3). On the other hand, it is worth noting that complex **3**, with dien ligands, crystallizes in a different space group than that detected with $Ni(CN)_4^{2-}$ anions [9]. This is due to the presence of a lattice methanol, used for crystallization, rather than a water molecule which also modifies the topological arrangement of the dien ligands along the chain. Beside the intra-chain H-bonds depicted in Fig. 3, the methanol –OH group acts also as a H acceptor towards N(1), connecting close packed polymers. Although these interactions appear rather weak (Table 3), they give rise to a 3D arrangement. The H-bonding interaction involving the amine groups with the guest methanol molecules and perchlorate anions results in a different orientation assumed by the CuL moieties and thus affects the crystal symmetry. We have provided a simple scheme to indicate the polymer topology through an oriented vector indicating the Cu–N(2) bond [9], as shown in Fig. 6.

3.1.3. Complex *4*

The crystal structure includes 2D rhomboid grid sheets extended in the *bc* plane, perchlorate anions and lattice water molecules. The Pd(II) ions, located on inversion centers, occupy the knots of the grid and are linked by the –CN–Cu(*i*prdien)–NC– units at a distance of 8.471(2) Å (Fig. 7). A side view (Fig. 7, down) indicates a pattern very similar to that of the 1D polymers **2** and **3**. In the distorted square pyramidal geometry of copper (Fig. 8), the central Cu–N(*i*prdien) bond distance, of 2.007(8) Å, is shorter than the others 2.049(9), 2.044(10) Å, and the Cu–N(nitrile) in

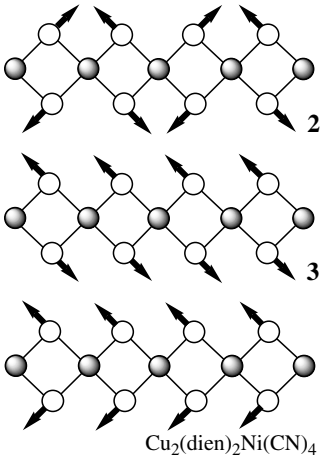

Fig. 6. Coordination polymer topologies of **2**, **3** and of $-[Cu_2(dien)_2Ni(CN)_4]_n^-$ [9].

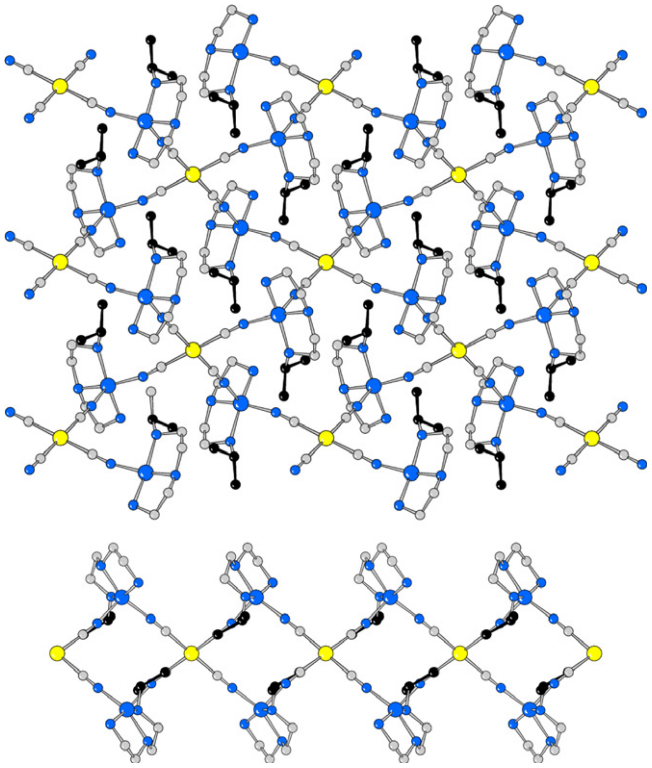

Fig. 7. 2D layered structure of **4** extended in the *bc* plane and side view down the *b* axis (*i*-propyl group of triamine ligand evidenced in black).

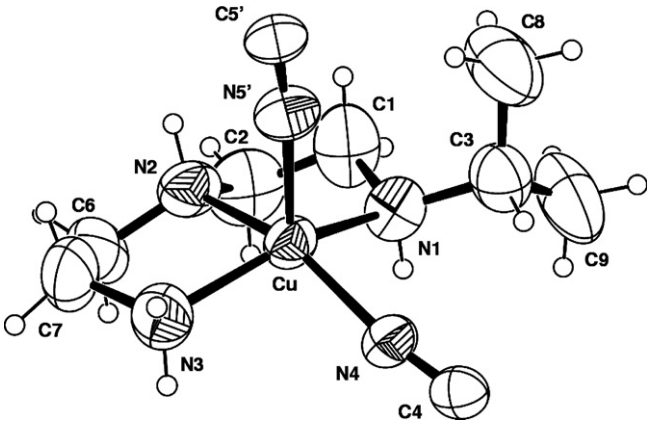

Fig. 8. ORTEP drawing (40% probability level) of the copper coordination sphere of complex **4**.

the pyramid base is considerably shorter (1.974(8) Å) with respect to the apical one (2.166(11) Å). The packing shows an H-bonding motive built by $-[H_2O-(ClO_4)]_n-$ chains running along the *b* axis, (Fig. 9), where each lattice water molecule plays a crucial role in giving rise to a 3D network arrangement, acting as a double H-bond donor towards ClO_4^- oxygens and double acceptor towards N(2) and N(3) amine groups (Table 3).

With regard to structures **2** and **3**, and to the strictly related 1D polymers built up by $[Ni(CN)_4]^{2-}$ anions, complex **4**, represents an unexpected outcome since it has the same molecular formula. It is difficult to rationalize how

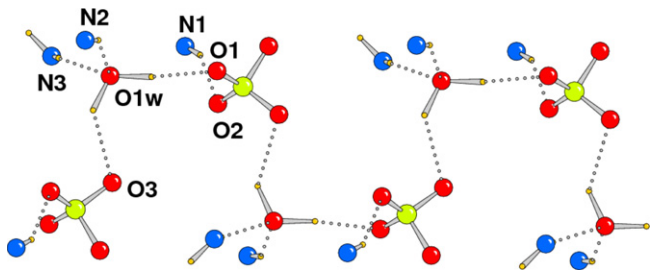

Fig. 9. The H-bonding motive involving water molecules, ClO_4^- anions and amine nitrogens from different layers.

the bulkiness of the ancillary ligand *i*prdien may affect the orientation of the $[Pd(CN)_4]^{2-}$ mean plane in the copper coordination and ultimately the crystal packing towards a 2D architecture. As a matter of fact the complex $[Ni_2(tren)_2Pt(CN)_4](ClO_4)_2$ (tren = tris(2-aminoethyl)amine) [8e], of the same formulation as **2**–**4**, still presents a 1D polymeric structural motif. A few examples of 2D layered structures containing tetracyano anions have been reported. Among them it is worth noting that the neutral structures reported by Gutierrez [7a], [Ni(dien)M(CN)$_4$] (M = Pd, Pt), were formed by hexacoordinated Ni(II) units that have more degrees of freedom in the network assembly with respect to pentacoordinated Cu(II).

3.2. Magnetic properties

The magnetic properties of complexes **1**–**4** as $\chi_M T$ vs T plots (χ_M is the molar magnetic susceptibility for one Cu(II) ion) and the reduced magnetization ($M/N\beta$ vs H) are shown in Figs. 10–13. The values of $\chi_M T$ at 300 K varies from 0.41 to 0.43 $cm^3\ mol^{-1}$ K for complexes **1**–**4** respectively, as expected for one magnetically quasi-isolated spin doublet ($g > 2.00$). Starting from room temperature, the $\chi_M T$ values are practically constant to 50 K and below this temperature they quickly decrease to 0.34–0.40 $cm^3 mol^{-1}$K at 2 K. This feature indicates a very weak antiferromagnetic interaction. The reduced molar magnetization at 2 K (Figs. 11–13 inset) clearly corroborates that the antiferromagnetic coupling is very small. The $M/N\beta$ value at 5 T is close to 1.0 $N\beta$ in all four cases and the curve follows the Brillouin function for a g value close to 2.10.

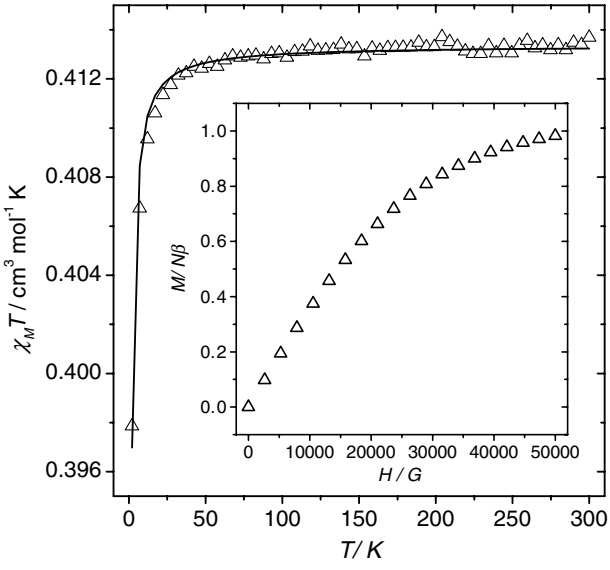

Fig. 10. Plot of $\chi_M T$ vs T for complex **1** (solid line indicates the best fit). Inset: plot of the reduced magnetization ($M/N\beta$) vs T at 2 K.

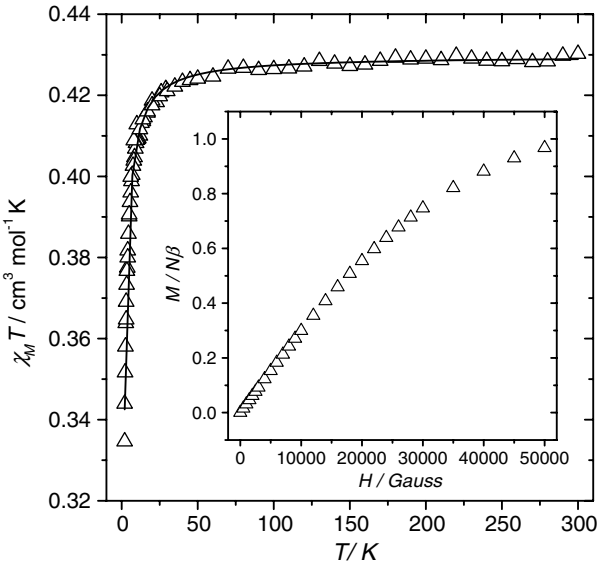

Fig. 11. Plot of $\chi_M T$ vs T for **2** (solid line indicates the best fit). Inset: plot of the reduced magnetization ($M/N\beta$) vs T at 2 K.

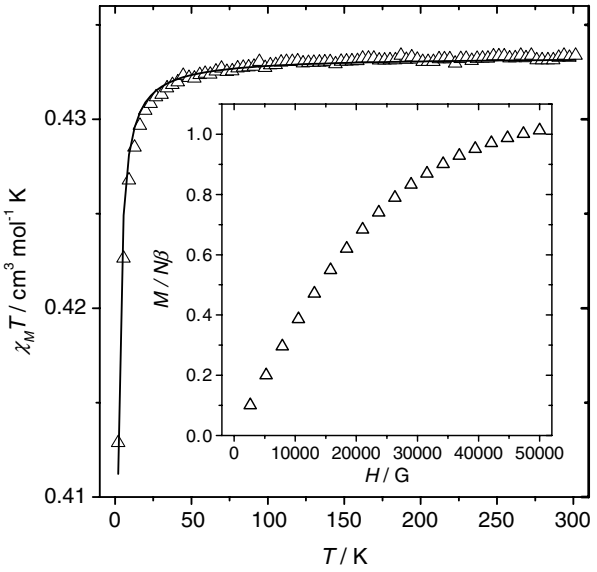

Fig. 12. Plot of $\chi_M T$ vs T for **3** (solid line indicates the best fit). Inset: plot of the reduced magnetization ($M/N\beta$) vs T at 2 K.

Complexes **1**–**4** are actually 1D and 2D copper(II) entities with $[Pd(CN)_4]^{2-}$ as bridging ligand, and all the copper(II) ions show a distorted square planar geometry. For **1**–**3** (1D systems) we have fitted the experimental data

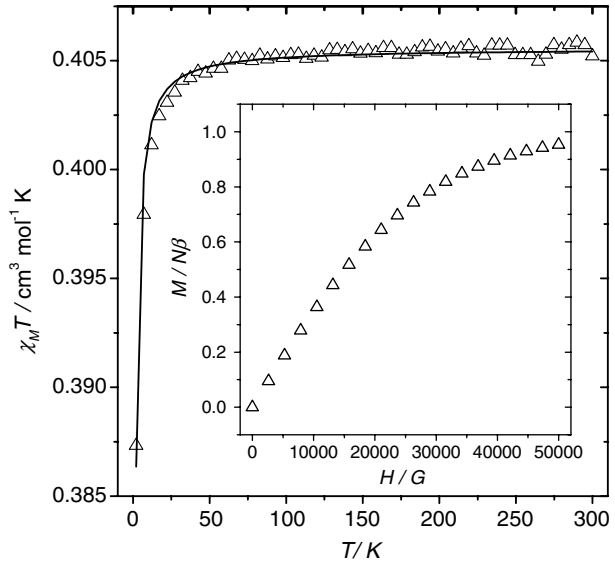

Fig. 13. Plot of $\chi_M T$ vs T for **4** (solid line indicates the best fit). Inset: plot of the reduced magnetization (M/Nβ) vs T at 2 K.

applying the formula for a uniform 1D copper(II) system, given by Bonner and Fisher [14]. The main structural data are indicated in Table 4 together with the best-fit parameters obtained. The 2D layer of complex **4** can be considered as a pseudo-quadratic net. Taking into account these structural features, we have fitted the susceptibility data by the expression given by Rushbrooke and Wood for a Heisenberg square planar system [15]. The calculated J and g values are given in Table 4. The small (almost negligible) J values for the four complexes can be interpreted as a consequence of the almost nil overlap between the copper(II) ions through the long diamagnetic $[Pd(CN)_4]^{2-}$ bridge. These too small J values do not allow any attempt to draw magneto-structural correlations, because in all cases the intermolecular interactions have not been taken into account in the formulae used. These interactions can have the same order of magnitude of the main J values. Looking at the literature, we note several copper(II) systems with diamagnetic $[M(CN)_4]^{2-}$ bridging ligands (M = Ni, Pd, Pt), but without magnetic studies [16b,16c,16d,16e]. The number of analogous complexes with magnetic studies is scarce, giving always very small antiferromagnetic coupling [7b,16a].

The magnetism of these four new Pd–Cu complexes is similar (but in general, smaller) to those previously reported for the analogous $[Ni(CN)_4]^{2-}$ derivatives. Considering the small J values in both series (Ni and Pd) it is impossible to draw any conclusion, because together with the intra-chain coupling, there are also inter-chains magnetic pathways that, due to the diamagnetic character of the cyanide bridge, can be of a similar order. Thus these diamagnetic ligands do not allow a strong (or medium) magnetic coupling, as expected.

3.3. Thermal studies

Complex **1** is stable up to 150 °C and it collapses beyond this temperature. The TG profile of complex **2** shows

(Fig. 1S) that the loss of lattice water molecules starts at 30 °C and the sample becomes completely deaquated at 40 °C. The deaquated species is stable up to 170 °C and shows decomposition upon further heating. Thermogravimetric analysis (Fig. 2S) of complex **3** reveals that it starts to lose solvent molecules at 65 °C and the process completes at 225 °C. The desolvated species collapses immediately upon further heating. The range of temperatures of desolvation and the collapse of the network immediately after desolvation corroborate the participation of lattice methanol in constructing the 3D supramolecular architecture. Complex **4** shows deaquation (Fig. 3S) in the temperature range 40–100 °C, and the corresponding dehydrated species is stable up to 150 °C, showing decomposition beyond this temperature.

4. Conclusion

We have demonstrated that square planar tetracyanometallates are proper building blocks for designing polynuclear cyano-bridged complexes in conjunction with suitable Cu(II)-triamine units, having the copper ion in a square pyramidal coordination geometry. The structure determinations reveal **1** and **2** are isomorphous to the corresponding $[Ni(CN)_4]^{2-}$ derivatives, but the presence of methanol used in the crystallization of **3** modifies the polymer topology. Finally, in **4** the use of *i*prdien as an ancillary ligand results in an unexpected 2D layered structure. The H-bonding interactions enhance the dimensionality to 3D and play a key role in designing the topology of the coordination polymers.

Abstract

The syntheses of the pentadentate ligand 1,4-bis(carboxymethyl)-1,4,7-triazacyclononane ($\mathbf{LH_2}$) and its use in the preparation of $[LHCu]ClO_4$ (**1**), and a mononuclear iron(III) complex ([LFeCl] **(2)**) are reported. The hydrolysis of **2** in the presence of an excess of $NaClO_4$ resulted in the crystallization of a binuclear complex, $[Fe_2(\mu\text{-}O)L_2] \cdot (NaClO_4)_3 \cdot CH_3OH \cdot 3H_2O$ **(3)**. The crystal structures of **1**–**3** have been determined by single-crystal X-ray crystallography. In complex **1**, the Cu(II) centre is in square based pyramidal environment, with two nitrogen atoms from the tacn ring and two oxygen atoms from two different carboxylate groups lying in the basal plane and the third nitrogen atom occupying the apical position. One pendant acetic acid group is protonated and, instead of coordinating to the copper(II) centre, participates in hydrogen bonding interactions with the perchlorate counter-ion. The coordinated carboxylate group forms a bridge to the copper atom of an adjacent $[LHCu]^+$ molecule, thus generating 1D-helical chains. The compound exhibits weak ferromagnetic coupling probably due to weak interactions between $[LHCu]^+$ molecules. In complex **2**, the iron(III) centre is in a distorted octahedral geometry, with the *fac*-coordinated triamine ring, two carboxylate groups and one chloride ligand occupying the coordination sphere. In the binuclear complex **3**, two iron(III) centres are bridged by one oxygen atom to form a μ-oxo-diiron(III) complex with an Fe···Fe distance of 3.423(3) Å and a non-linear Fe–O–Fe angle of 144.4°. This binuclear complex features strong antiferromagnetic coupling between the two iron(III) centres.

1. Introduction

Binuclear (and higher nuclearity) transition metal complexes featuring bridging groups between the metal centres have been widely studied over the past few decades. The drive for these studies derives from many quarters, with one major focus being complexes with novel molecular structures and magnetic behaviour [1–6]. Polynuclear complexes have also been actively pursued as models for multimetal centre units found at the active sites of important enzymes [7–10]. For example, oxo-bridged iron complexes have attracted considerable interest because diiron centres have been found at the active site of a variety of non-heme proteins (hemerythrin, purple acid phosphatase, ribonucleotide reductase, methane monooxygenase) [11–16].

Ligands based on 1,4,7-triazacyclononane, tacn, are particularly effective for forming binuclear (and higher nuclearity) complexes because they bind strongly to one

face of the metal polyhedron while at the same time leaving one or more accessible coordination sites for the introduction of bridging ligands. The tacn macrocycle also lends itself readily to further structural elaboration through attachment of potentially coordinating pendant arms (e.g. pyridyl, carboxylate, phosphonate) or non-coordinating organic groups to one or more of the three secondary nitrogens of the tacn ring. Variation in the number and types of pendant groups incorporated into the ligand framework therefore offers a potential means of controlling metal complex stability, selectivity for particular metal ions, as well as the redox potential and stereochemistry of coordinated metal ions. In terms of the formation of multinuclear complexes, the number of pendant groups dictates the number of coordination sites left available for auxiliary ligands to bridge between the metal centres. In some cases, the pendant groups may themselves act as endogenous bridging groups.

Complexes featuring ligands with pendant carboxylate groups [1,2] are of interest because the carboxylate moiety is found in many metalloproteins where aspartate or glutamate side chains act as coordinating groups. In addition, the presence of carboxylate groups increases the probability of forming complexes with interesting magnetic properties because these groups can adopt a variety of coordination modes, ranging from terminal monodentate to several different bridging configurations (*syn–syn*, *syn–anti*, etc.) [17].

We, and others, recently described the synthesis and characterization of stable metal complexes of the ligand, 1,4,7-triazacyclononane-*N*-acetate, that include mononuclear complexes [1,18–20], binuclear complexes [1,20] and helical chains, in which copper(II) atoms are bridged by the carboxylate pendant arms [21]. We have now begun to investigate the coordination behaviour of another carboxylate-bearing tacn ligand, 1,4-bis(carboxymethyl)-1,4,7-triazacyclononane ($\mathbf{LH_2}$). Herein we report an efficient and high yielding synthetic route to $\mathbf{LH_2}$, together with the synthesis and properties of a Cu(II) complex, [(LH)Cu](ClO$_4$) (**1**) and two novel Fe(III) complexes, [LFeCl] (**2**) and [Fe$_2$(μ-O)L$_2$] · (NaClO$_4$)$_3$ · CH$_3$OH · 3H$_2$O (**3**) of this ligand.

2. Experimental

2.1. Materials

All chemicals were purchased from commercial suppliers and used without purification with the exception of 1,4,7-triazacyclononane trihydrochloride (tacn · 3HCl) [22] and 1,4,7-triazatricyclo[5.2.1.0^{4,10}]decane (tacn orthoamide) [23,24], which were prepared by literature methods.

2.2. Physical measurements

NMR spectra were obtained on a Bruker AV 200 or DPX 300 (CDCl$_3$) spectrometer, IR spectra were recorded using KBr pellets on a Perkin–Elmer 1600 FTIR spectrometer at a resolution of 8 cm^{-1}. Electronic spectra were recorded on a Cary 5G UV–Vis–NIR spectrophotometer in 1 cm quartz cells. Mass spectra were obtained using a Micromass platform mass spectrometer with an electrospray source. Microanalyses were performed by the Campbell Microanalytical Service, University of Otago, New Zealand. Magnetic susceptibilities were measured on powdered samples contained in calibrated gelatine capsules using a Quantum Design MPMS 5 Squid magnetometer operating in a field of 1 T. The instrument was calibrated against a standard Pd sample supplied by the company and against a chemical calibrant (CuSO$_4$ · 5H$_2$O).

2.3. Syntheses

Caution: Although no problems were encountered during this work, perchlorate salts of transition metal complexes are potentially explosive and should be handled with extreme care and be prepared only in small quantities.

2.3.1. 1-Ethylacetato-4-formyl-1,4,7-triazacyclononane (II)

A solution of bromoethylacetate (3.6 g, 22 mmol) in acetonitrile (40 mL) was added to a solution of tacn orthoamide (3 g, 22 mmol) in acetonitrile (40 mL). The mixture was stirred at room temperature overnight. The resulting white product **I** was collected by filtration, washed with diethyl ether (2 × 30 mL) and air dried. The solid was then dissolved in water (100 mL) and heated to reflux for 4 h. After removal of the solvent by rotary evaporation and drying at 90 °C for 2 h, a dark red-orange oil of **II** was obtained. Yield: 2.50 g, 93%. Selected IR bands (KBr, cm^{-1}): 3426 [ν(O–H)], 2935 [ν(C–H)], 1730 [ν(CO ester)], 1660 [ν(CO formyl)]. ^{1}H NMR spectrum (CDCl$_3$): δ (ppm) 1.28 and 1.29* (3H, t, C*H*$_3$–CH$_2$), 2.93–3.89 (12H, m, CH$_2$-ring), 3.55 and 3.7* (2H, s, N–C*H*$_2$–COOEt), 4.2 and 4.18* (2H, q, CH$_3$–C*H*$_2$), 8.38 and 8.18* (1H, s, CHO), 9.18 (1H, s, N–*H*). * splitting of signals due to two resonance forms of the formyl group.

2.3.2. 1,4-Bis(ethylacetato)-7-formyl-1,4,7-triazacyclononane (III)

Compound **II** (2.8 g, 10 mmol) was dissolved in acetonitrile (40 mL) and a solution of bromoethylacetate (2.02 g, 10 mmol) in acetonitrile (40 mL) slowly added. Sodium carbonate (7 g) was added and the mixture stirred overnight under reflux. The suspension was filtered to remove the insoluble inorganic salts and the solvent was removed from the filtrate under reduced pressure to yield a very viscous brown oil. This was placed under high vacuum to remove volatile impurities. Yield: 3.1 g, 89%. ^{1}H NMR spectrum (CDCl$_3$): δ (ppm) 1.26 and 1.27* (6H, t, C*H*$_3$–CH$_2$–O), 2.68, 2.76, 3.00, 3.21, 3.31, 3.51 (6 × 2H, 6m, ring-NC*H*$_2$), 3.4 (4H, s, N–C*H*$_2$–COOEt), 4.15 and 4.16* (4H, q, C*H*$_2$–CH$_3$), 8.06 (1H, s, N–C*H*O). ^{13}C NMR spectrum (CDCl$_3$): δ (ppm) 14.57 *C*H$_3$–CH$_2$–O, 47.33 and 50.44* ring-N*C*H$_2$ next to CHO, 54.4 and 58.11*, 55.03

and 58.30* ring-N*C*H$_2$, 55.3 and 58.46* N–*C*H$_2$–COOEt, 60.7 CH$_3$–*C*H$_2$–O, 164 *C*HO, 172 *C*OO. * splitting of signals due to two resonance forms of the formyl group.

2.3.3. 1,4- Bis(carboxymethyl)-1,4,7-triazacyclononane (*LH$_2$*)

Compound **III** (3.08 g, 8.01 mmol) was dissolved in 5 M HCl (80 mL) and the solution refluxed for 2 days. Removal of the solvent gave a light brown oil, which was dissolved in 50 mL of water and decolorized by heating with activated charcoal. The solution was filtered, reduced to dryness and re-dissolved in water (50 mL). The water was then removed on a rotary evaporator and the residue taken up in 33% hydrobromic acid (10 mL) and glacial acetic acid (5 mL). The white precipitate that formed immediately was filtered, washed with acetone (2 × 20 mL) and dried under nitrogen to yield the product as a white solid. Yield: 4.47 g, 86%. Selected IR bands (KBr, cm^{-1}): 3450 [ν(O–H)], 2951 [ν(C–H)], 1739vs, [ν_{as}(CO)], 1422vbr, [ν_s(CO)]. ^{1}H NMR spectrum (NaOD/D$_2$O): δ (ppm) 3.43 (4H, s, NC*H*$_2$), 3.58 (8H, m, NC*H*$_2$), 4.03 (4H, s, C*H*$_2$–COOH), ^{13}C NMR spectrum (CDCl$_3$): δ (ppm) 42.9 ring-N*C*H$_2$ next to CHO, 50.36, 50.98 ring-N*C*H$_2$, 56.46 N–*C*H$_2$–COOH, 172 *C*OO. Electrospray mass spectrum (*m*/*z* for **LH$_2$**): Calc.: 245. Found: 246 [M+H]$^+$. Microanalysis Calc. for C$_{10}$H$_{23}$N$_3$O$_4$Br$_4$ · 4H$_2$O: C, 18.7; H, 4.8; N, 6.6; Br, 49.8. Found: C, 18.7; H, 4.9; N, 6.7; Br, 48.6%.

2.3.4. [LHCu](ClO$_4$) (*1*)

The pH of a warm aqueous solution of **LH$_2$** (0.22 g, 0.34 mmol in 10 mL water) was adjusted to 7 with NaOH (0.5 M) and Cu(ClO$_4$)$_2$ · H$_2$O (0.33 g, 0.89 mmol) was added. The pH of the solution dropped to ~2 and after cooling to room temperature, thin blue crystals suitable for X-ray analysis formed. These were filtered, washed with ethanol and diethyl ether and air dried. Yield: 92 mg, 68%. Selected IR bands (KBr, cm^{-1}): 3300 [ν(N–H)], 1756, 1628 and 1575 [ν_{as}(CO)], 1442 and 1404 [ν_s(CO)], 1101 and 624 [ν(ClO$_4$)]. UV–Vis spectrum (H$_2$O) [λ_{max}, nm (ε_{max}, l mol^{-1} cm^{-1})]: 667 (106); 1032, (24); 267 (3340). Microanalysis Calc. for C$_{10}$H$_{17}$N$_3$O$_4$CuClO$_4$: C, 29.5; H, 4.2; N, 10.3. Found: C, 29.5; H, 4.5; N, 10.3%.

2.3.5. [LFeCl] (*2*)

To an aqueous solution of **LH$_2$** (0.62 g, 0.95 mmol) was added NaOH (0.5 M) to adjust the pH to 7. The solution was warmed to 50 °C and Fe(NO$_3$)$_3$ · 9H$_2$O (0.38 g, 0.95 mmol) was added, whereupon the color changed to deep orange and the pH dropped to ~2. Orange crystals suitable for X-ray analysis were obtained upon slow cooling overnight. These were filtered and washed with ethanol and diethyl ether. Yield: 0.24 g, 74%. Selected IR bands (KBr, cm^{-1}): 3213 [ν(N–H)], 1658 [ν_{as}(CO)], 1329 [ν_s(CO)]. UV–Vis spectrum (H$_2$O) [λ_{max}, nm (ε_{max}, l mol^{-1} cm^{-1})]: 235 (900); 272 (700); 308 (520). Microanalysis Calc. for C$_{10}$H$_{17}$N$_3$O$_4$FeCl: C, 35.9; H, 5.1; N, 12.6. Found: C, 36.0; H, 5.1; N, 12.6%.

2.3.6. [Fe$_2$(μ-O)L$_2$] · (NaClO$_4$)$_3$ · CH$_3$OH · 3H$_2$O (*3*)

Compound **2** (0.21 g, 0.6 mmol) was dissolved in water (5 mL) at 50 °C. An aqueous solution (10 mL) containing sodium acetate (0.50 g, 6.1 mmol) and sodium perchlorate

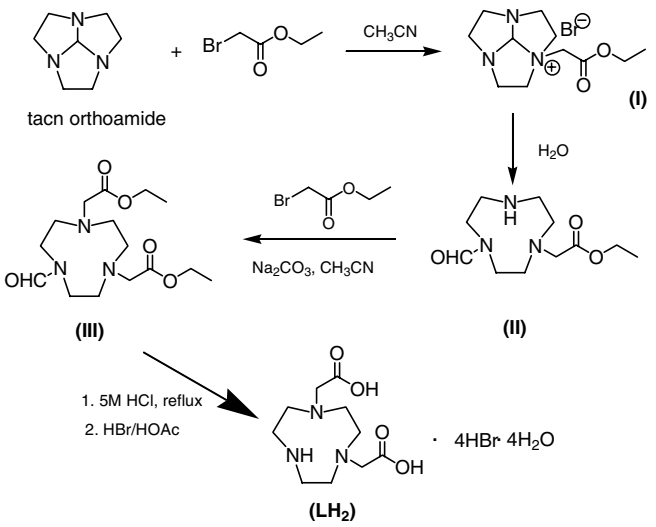
(0.50 g, 4.1 mmol) was added dropwise. A dark brown solution was obtained whose volume was reduced to 5 mL. Vapour diffusion of methanol produced a dark green crystalline product which was filtered, washed with ethanol and diethyl ether and air dried. Yield: 0.46 g, 66%. Selected IR bands (KBr, cm^{-1}): 3450 [ν(O–H)], 3370 [ν(N–H)], 1654 [ν_{as}(CO)], 1364 [ν_s(CO)], 1079 and 629 [ν(ClO_4)], 813 [ν Fe–O–Fe]. UV–Vis spectrum (H_2O): [λ_{max}, nm (ε_{max}, $l\,mol^{-1}\,cm^{-1}$)], 600 (131); 491 (436); 313 (13200); 273 (12100); 233 (14300). Microanalysis Calc. for $C_{20}H_{36}N_6O_9Fe_2Na_3 \cdot (ClO_4)_3 \cdot CH_3OH \cdot 3H_2O$: C, 21.5; H, 3.6; N, 7.2. Found: C, 21.5; H, 3.4; N, 7.2%.

2.4. Crystallography



Single-crystals of **1**, **2** and **3** were mounted on thin glass fibres. X-ray crystallography data were obtained on an Enraf-Nonius CAD4 diffractometer with monochromated Mo Kα radiation. ($\lambda = 0.71073$ Å) at 123(2) K using phi and/or omega scans. Data were corrected for Lorentz and polarization effects. The structures were solved by direct method and all crystallographic calculations were performed with use of the programs SHELXS-97 [25] and SHELXL-97 [25], respectively. All non-hydrogen atoms were located on Fourier difference-maps and were refined anisotropically. For all complexes, the methylene hydrogen atoms were located on Fourier difference maps and restrained to idealized geometries with d(C–H) = 0.99 Å, as were the amine hydrogen atoms for complex **1** and **3** (d(N–H) = 0.93 Å). All solvent water protons were located on Fourier difference maps and restrained to idealized geometries. The program X-Seed [26] was used as an interface to the SHELX programs and to prepare the figures. In the ORTEP [27] plots thermal ellipsoids for non-hydrogen atoms have been drawn at the 30% probability level and hydrogen bonds are presented by dashed lines. Cell parameters and details of data collection and structure solution are given in Table 1. For complex **3**, three of the carbon atoms of the macrocycle ring (C(12), C(13), and C(15)) and oxygen atoms (O(6), O(7), O(8), O(11), O(12), O(10)) of the perchlorates (C(l2) and C(l3)) were disordered over two positions. Each disordered position is given half occupancy and the atoms involved were refined isotropically.

3. Results and discussion

3.1. Syntheses

3.1.1. Ligand

The ligand 1,4-bis(carboxymethyl)-1,4,7-triazacyclononane (**LH_2**) has been reported previously [28–31]. The published syntheses, however, can yield a mixture of di- and trisubstituted products [30,31]. We therefore developed a new synthetic route, which yielded the tetrahydrobromide salt of **LH_2**, that uses 1,4,7-triazatricyclo[5.2.1.$0^{4,10}$]decane (tacn orthoamide) [23,24], a synthon that has been used to prepare a variety of functionalized tacn derivatives [18].

Scheme 1. Synthetic pathway leading to 1,4-bis(carboxymethyl)-1,4,7-triazacyclononane.

Our approach, depicted in Scheme 1, involves four straight forward steps, which produce the various intermediates in high yield. In each case, the intermediates were sufficiently pure to proceed directly to the next step. The reaction of tacn orthoamide with ethyl bromoacetate in acetonitrile gave the insoluble monoamidinium bromide salt **I** [32], which was hydrolyzed to yield the formyl-monoester derivative **II**. The IR spectrum showed absorption bands at 1730 and 1660 cm^{-1} due to ν(C=O) stretches associated with the ester and formyl group, respectively. As indicated by Blake et al. [33], the formyl group can have two conformational isomers as a result of slow rotation about the C–N amide bond. These can be seen at 8.38 ppm and 8.18 ppm in the ^{1}H NMR spectrum of compound **II**.

The second pendant carboxylate group was attached in similar fashion to step 1, but in the presence of a base. Hydrolysis of **III** in 5 M HCl removed the formyl and ester groups and the final ligand, **LH_2** was isolated from a HBr/glacial acetic acid mixture. Microanalytical data were consistent with the composition for $LH_2 \cdot 4HBr \cdot 4H_2O$, which indicated that the three amines are protonated and that there was an extra molecule of HBr in the crystal lattice. The ESI mass spectrum showed a signal for the parent molecular ion $[M+H]^+$ at $m/z = 246$, and the spectroscopic data (^{1}H NMR and ^{13}C NMR spectrum) were as expected.

3.1.2. Metal complexes

The blue complex, [**LHCu**](**ClO_4**) (**1**), was obtained on addition of copper(II) perchlorate to a neutralized aqueous solution of the $LH_2 \cdot 4HBr$ salt. The formation of a dark blue solution and an instant pH change from pH 7 to 2 were observed, indicating the formation of a copper(II) complex. Slow evaporation of the dark blue solution gave blue thin crystals suitable for X-ray-crystallography.

In the IR spectrum of **1**, a band at 3300 cm^{-1} is attributable to the N–H stretches of the secondary amine in the

ligand and several bands in the range of 1400–1800 cm^{-1}, which are due to ($\nu_{as}C{=}O$) and ($\nu_{s}C{=}O$) stretches of the carboxylate groups. While some of these bands are quite weak and difficult to assign, strong asymmetric vibrations due to the protonated carboxylate and the relatively uncommon *syn*, *anti* bridging carboxylate conformation [34,35] can be found at 1756, 1628 and 1575 cm^{-1}. The UV–Vis spectrum of **1** displays absorption maxima at 667 nm ($\varepsilon = 106\ l\ mol^{-1}\ cm^{-1}$) and 1032 nm ($\varepsilon = 24\ l\ mol^{-1}\ cm^{-1}$), which indicates that in solution the copper(II) centres are in a square pyramidal ligand environment with a $(d_{x^2-y^2})^1$ electronic structure [1].

Complex **2**, [LFeCl], was prepared by reacting iron(III) nitrate with a neutralized aqueous solution of the $\mathbf{LH_2}$ salt (pH 7). An instant color change to dark yellow and decrease in pH to ~2 were indicative of immediate complex formation. Orange crystals of **2** precipitated overnight from this solution, which were suitable for single X-ray crystallography. In the IR spectrum, bands due to the asymmetric and symmetric stretching mode of the carboxylate groups were observed at 1658 cm^{-1} and 1329 cm^{-1}. The large separation between the bands ($\Delta\nu = 329\ cm^{-1}$) is indicative of monodentate coordination mode.

Dark green crystals of the oxo-bridged complex **3**, $[Fe_2(\mu\text{-}O)L_2]\cdot(NaClO_4)_3\cdot CH_3OH\cdot 3H_2O$, deposited slowly from a solution prepared by dissolving complex **2** in an aqueous solution of sodium perchlorate and sodium acetate. As expected for iron(III) and other μ-oxo-bridged complexes, which feature asymmetric ν_{as}(M–O–M) stretches in the 800–850 cm^{-1} region, complex **3** exhibited a strong absorption band at 813 cm^{-1} [36] The IR spectrum of **3** also showed a ν_{as}(COO)] stretch at 1654 cm^{-1} and a ν_{s}(COO)] stretch at 1364 cm^{-1}, which are indicative of monodentate carboxylate coordination [37,38].

The electronic absorption spectrum of **3**, recorded in acetonitrile, is shown in Fig. 1. The electronic transitions of μ-oxo-diiron complexes have been studied intensively and assigned from analyses of absorption and CD spectra [39], polarized single-crystal spectra [40,41] and Raman excitation profiles [42]. These studies have been reviewed in detail [7,8,36,43,44]. The electronic spectrum of **3**, recorded in acetonitrile is shown in Fig. 1. In the 200–400 nm, the transitions can be assigned as oxo → Fe^{3+} ligand to metal charge-transfer transitions (LMCT) [39]. The lower energy, lower intensity band found at 408 nm ($10\,560\ l\ mol^{-1}\ cm^{-1}$) can be assigned to exogenous ligand → metal charge-transfer transitions [39,42,45] and to forbidden oxo-Fe^{3+} charge-transfer transitions which enhance the intensity of the weaker ligand field transition. For **3**, these bands are less intense than those in spectra of (μ-oxo)bis(μ-X)diiron(III) complexes [1,10,46]. The sharp absorbance band at 491 nm ($436\ l\ mol^{-1}\ cm^{-1}$) has been assigned to transitions into higher energy levels, $^6A_1 \rightarrow {}^4A_1, {}^4E$, [47] and has also been observed in the spectrum of metHr [48]. A broad band at 600 nm ($131\ l\ mol^{-1}\ cm^{-1}$) was rather unexpected because for a high spin iron(III) d^5 configuration, d–d electronic transitions in an octahedral ligand field are spin forbidden. Since no d–d-transitions were present in the UV–Vis spectrum of the mononuclear Fe^{3+} complex, **2**, these observed transitions must be due to the unique structure of the dimeric unit [41,43].

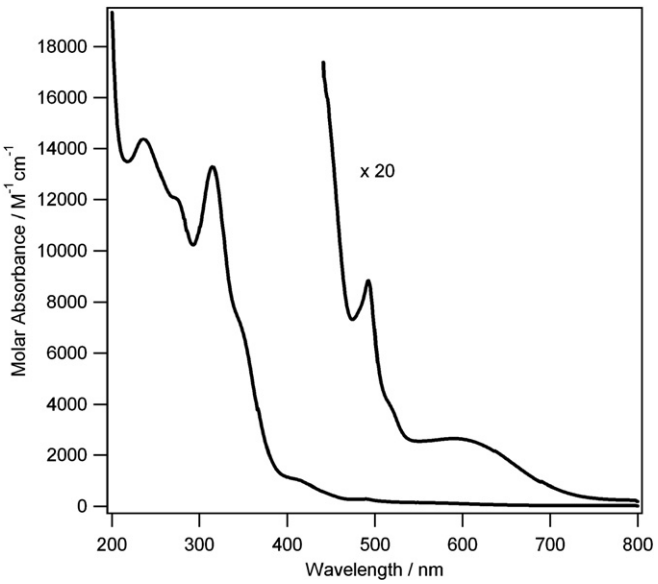


Fig. 1. Electronic spectrum of μ-oxo-diiron(III) complex.

3.2. Crystal structure determinations

The structures of **1**–**3** were determined by X-ray crystallography (see Section 2) and selected crystallographic data are found in Table 1.

3.2.1. [LHCu](ClO4) (1)

Fig. 2 shows the molecular structure of the complex cation of **1**, while Table 2 lists selected bond lengths and angles. The Cu(II) centre is in a distorted square-pyramidal geometry formed by the three nitrogen atoms from the macrocycle, one oxygen atom (O(2)) from the carboxylate group and a second O-atom (O*(1)) from the equivalent

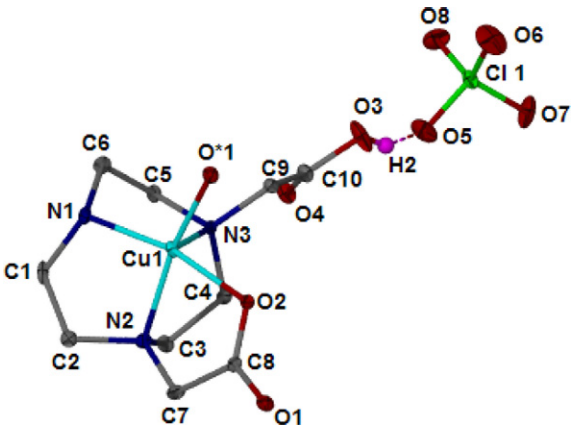

Fig. 2. Asymmetric unit of **1**. C–*H* and N–*H* atoms have been omitted for clarity.

carboxylate on an adjacent complex unit. Interestingly, the second pendant acetic acid arm of the ligand remains protonated and does not coordinate, but is instead bent away from the copper centre and participates in H-bonding interactions (see below). A similar structure has been observed in VO_2(LH) [30] where again only one pendant arm was coordinated to the V(V) centre.

As observed in copper(II) complexes of other tacn derivatives the two nitrogen atoms, N(1) and N(2), that are part of the base of the pyramid have shorter Cu–N bond length [1.984(3) Å and 2.051(4) Å, respectively] than the third apical nitrogen atom [Cu–N(3) = 2.232(3) Å]. The formation of the five-membered Cu–O–C–C–N ring may induce a shortening of the in-plane Cu–N bonds in order to reduce the strain within this chelate ring [30].

Each coordinated carboxylate group bridges between two Cu(II) centres in a *syn*, *anti*-fashion, thus forming 1D-helical chains [21] (Fig. 3). The bond lengths Cu–O*(1) and Cu–O(2) are identical [1.967(3) and 1.972(3) Å] (Table 2).

The oxygen atom (O(3)) from the uncoordinated carboxylate group is protonated and forms a hydrogen bond to the perchlorate oxygen atom O(5) [O(3)···O(5) 2.769(5) Å]. There is also a hydrogen bond between the protonated secondary macrocyclic amine N(1) and the oxygen atom O(2) from the coordinated acetate group of an adjacent complex [N(1)···O(2)# 2.819(5) Å]. Hydrogen bond interactions occur only within the chain and there are no such interactions between the strands. The intra-strand Cu···Cu distance is 4.9898(4) Å, whereas the shortest strand-to-strand Cu···Cu distance is 13.10 Å (Fig. 4).

3.2.2. *[LFeCl] (**2**)*

The crystal structure of the mononuclear complex **2** shows that the iron(III) centre is in a highly distorted octahedral coordination environment (Fig. 5). In the equatorial plane, there are two tacn ring nitrogens and two oxygens, one from each of the carboxylate groups. One axial position is occupied by the third nitrogen atom from the tacn ring, while a chloride ligand, lying in the opposite axial position, completes the octahedral coordination sphere.

The asymmetry of the iron(III) coordination sphere is highlighted by the fact that the three Fe–N and two Fe–O distances (Table 3) involving the ligand donor atoms are all different. In particular, the Fe(1)–N(1) bond is sig-

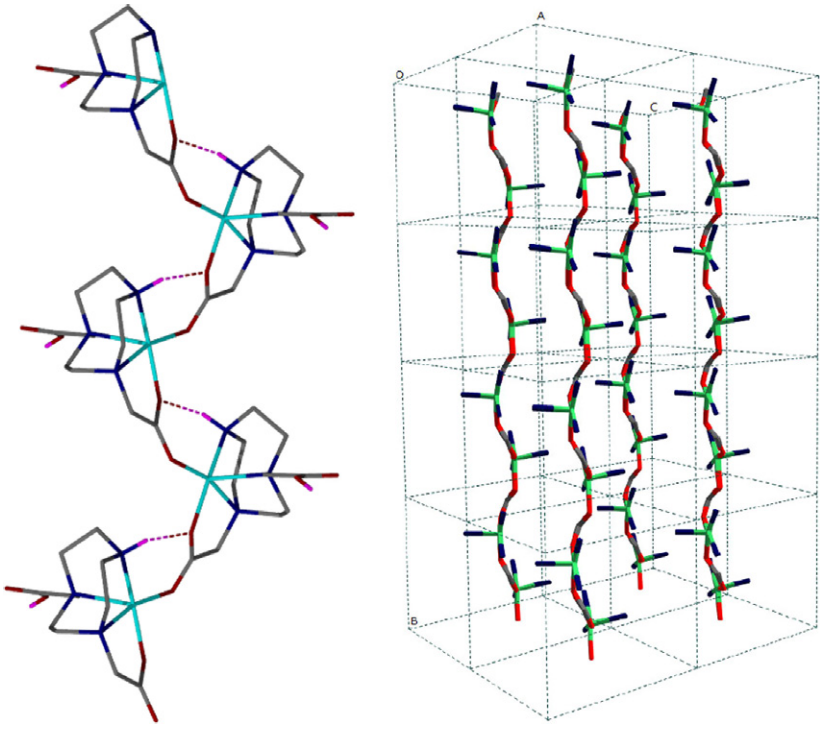

Fig. 3. Left: Segment of a 1D-chain formed by [LHCu] units in the crystal structure of **1**. Hydrogen atoms and perchlorate anions have been omitted for clarity. Right: Helical chains in unit cells (dashed lines). C, N and O atoms which are not part of the chains have been removed for clarity.

nificantly shorter [2.137(2) Å] probably because this atom is less sterically hindered compared to the Fe(1)–N(2) [2.186(2) Å] and Fe(1)–N(3) [2.218(2) Å] bonds. The two Fe–O bond lengths are also different but only slightly so [1.9796(2) Å and 1.9493(2) Å]. The longer Fe(1)–N(3) distance, cf. Fe(1)–N(2), could be a reflection of the quite high affinity of the *trans* chloro ligand for Fe(III). The three N–Fe–N chelate ring angles are all well below 90°, as expected for a non-idealized octahedral structure. An interesting

intermolecular hydrogen bonding network is created including the nitrogen atom N(1) to two oxygen atoms of carboxylate moieties of two adjacent [LFeCl] unit with distances of 3.104(3) Å [N(1)–H(3)···O(2)#1] and 3.141(3) Å [N(1)–H(3)···O(1)#1]. The network is supported by quite short C–H···O hydrogen bond interactions which range from 3.1 Å to 3.5 Å (see Table 4). Of note is the [C(4)–H(4B)···O(4)] interaction which links chains together and creating a 2D-network (Fig. 6).

3.2.3. $[Fe_2(\mu\text{-}O)L_2]\cdot(NaClO_4)_3\cdot CH_3OH\cdot 3H_2O$ (**3**)

The crystal structure determination of **3** verified that the compound has two Fe(III) centres linked *via* a single μ-oxo-bridge (see Fig. 7). Selected bond angles and bond distances are summarized in Table 5. The Fe···Fe distance of 3.422(3) Å and a non-linear Fe–O–Fe angle of 144.4° are quite similar to those observed for $[(salen)Fe]_2O$ and other related binuclear complexes (see Table 6). The comparison of the structural parameters of the Fe–O–Fe core for a selection of mono-oxo-bridged Fe(III) complexes (Table 6) reveals that the differences in the Fe···Fe distances in these compounds can be attributed exclusively to the variation in the Fe–O–Fe angles, as all Fe–O distances are virtually identical.

In the structure of complex **3**, the three nitrogen donors coordinate facially to each iron(III) centre, two further coordination sites are occupied by two carboxylate oxygens and the sixth (*trans* to the secondary amine) is taken up by a bridging oxygen atom. As in compound **2**, the geometry around the iron(III) centres is significantly distorted from octahedral. The iron(III) centre is located slightly out of the plane (0.356 Å) formed by two nitrogen atoms of the macrocyclic ring and two oxygen atom of the pendant carboxylate arms. The relatively short Fe–O_{oxo} bond 1.797(1) Å (average of both Fe–O_{oxo} bonds) indicates substantial double bond character. The μ-oxo group exerts a strong *trans* influence which results in elongation of the Fe(1)–N(3) [2.284(4) Å] and Fe(2)–N(6) [2.261(4) Å] bonds. The two in-plane Fe–N distances in each unit are much shorter [2.136(3)–2.184(3) Å] than the axial distance and the distance to the secondary nitrogen atoms, N(1) and N(4), is shorter than that to the tertiary nitrogen atoms N(2) and N(5), as was the case for complex **2**. It is interesting to note that, apart from the longer Fe–N bonds *trans* to the bridging oxo group all other distances are similar to those in complex **2**. However, the two Fe–N distances to the two secondary nitrogen atoms are clearly different [Fe(1)–N(1), 2.136(3) Å] than N(4) [Fe(2)–N(4), 2.168(4) Å]. This may be due to the involvement of the hydrogen atom on N(1) in hydrogen bonding with an oxygen atom of a perchlorate anion [N(1)–H(1)···O(12P)#1, 3.069(5) Å, 167°] (see Table 7).

Complex **3** crystallizes with one methanol and three water molecules of solvation as well as three sodium ions and three perchlorate ions, which are located between two $[Fe_2(\mu\text{-}O)L_2]$ units. The two water molecules O(2W) and O(3W) are hydrogen bonded to the oxygen atoms of

the carboxylate groups of the macrocyclic ring and the methanol molecule is coordinated to sodium ion Na(3). Two sodium cations Na(1) and Na(2), are seven-coordinate, while the third, Na(3), is six-coordinate (Fig. 8). These sodium atoms are linked together by Na–O–Na bridges with Na–O distances in the range of 2.310(3) Å to 2.764(5) Å (see Table 5) for which the oxygen atoms are primarily provided by the carboxylate groups of two binuclear Fe(III) units (Fig. 8). Additional coordination sites are occupied by perchlorate oxygens, which act as counter-ions, as well as oxygens from water solvent molecules. These water molecules also participate in various H-bonding interactions (Table 7).

The geometry of Na(1) is defined by five carboxylate oxygens atoms, two of them, O(8) and O(1), are from one [Fe_2-(μ-O)L_2] unit, the other three oxygen atoms, O(3), O(4) and O(6) from another [Fe_2(μ-O)L_2] unit (Fig. 8). Consequently, this unique sodium atom not only links the two Fe(III) units of one binuclear μ-oxo complex via an O(1)–Na(1)–O(8) bridge, it also connects the [Fe_2(μ-O)L_2] complexes. In addition, Na(1) is the only sodium atom, which is chelated by the carboxylate oxygen atoms O(3)* and O(4)*. These interactions join two macrocyclic complexes together forming a chain, whereas the oxygen atom O(6PA) from the perchlorate anion provides a link to another chain, resulting in an one-dimensional ensemble, where clusters of composition [$Na_6(ClO_4)_4$] are flanked by [Fe_2(μ-O)L_2] units (Fig. 9). These 1D-chains are connected by only one hydrogen bond [O(10)–H(10)···O(5P)#, 3.053(5) Å, 167°] which is of particular interest as it is the only interaction holding the 1D-chains together.

Complex **3** exhibits a number of carboxylate coordination modes (Fig. 10), some of which were recently reported for the copper(II) complex of 1-propylamino-4-acetato-1,4,7-triazacyclononane [54]. In **3**, binding modes Ia to Ic

are characterized by one oxygen atom of the carboxylate group coordinating to the iron(III) centre, whereas the second oxygen atom binds to two sodium atoms. However, these modes differ in the number of water molecules hydrogen bonded to one or both oxygen atoms of the carboxylate group. The type II mode is unique in that it features one sodium atom chelated by the same carboxylate group.

3.3. Magnetism

The temperature dependence of the magnetic susceptibility of diiron(III) complex **3** (Fig. 11) measured from 2 to 300 K, indicates that strong antiferromagnetic coupling exists between the two iron(III) centers. As a consequence of this strong coupling, the magnetic moment calculated at room temperature (298 K) is $1.99\mu_B$, decreasing to $0.4\mu_B$ at 4 K. The susceptibility data were fitted with an expression derived from the Heisenberg–Dirac–van Vleck spin exchange Hamiltonian [55]. $H = -2JS_1 \cdot S_2$, where $S_1 = S_2 = 5/2$. The agreement between the observed and calculated data was very good and the best fit values were $g = 2.06$, $J = -101\ cm^{-1}$, including a correction for a small amount (0.2%) of monomeric impurity. The J value ($-101\ cm^{-1}$) is in good agreement with literature values observed for other single μ-oxo-diiron(III) compounds, which have been found to be between -80 and $-105\ cm^{-1}$ (see for example, Refs. [2,8,36]). As may have been anticipated, the linking of the dinuclear molecules by $NaClO_4$ moieties does not affect the J values.

Table 7

Symmetry transformations used to generate equivalent atoms: #1 x, $y+1$, z; #2 $-x$, $-y+1$, $-z+1$.

Fig. 12 shows the temperature dependence of the effective magnetic moment of the copper(II) complex **1**. At temperatures above 70 K, simple Curie behaviour (1.94 μ_B/Cu at room temperature), indicative of an uncoupled system with $S = 1/2$ is observed. Below 70 K the magnetic moment increases to a maximum of $2.6\mu_B$ at 3 K. Fitting of the data to a 1/2 Fisher chain model (solid line in Fig. 12) yielded parameters for $g = 2.19$, $J = 3.05\ cm^{-1}$ and $TIP = 60 \times 10^{-6}\ cm^3\ mol^{-1}$, indicative of weak ferromagnetic coupling. This coupling arises from the exchange route between the copper(II) centres, which occur *via* the acetate group where the carboxylate group connects the $d_{x^2-y^2}$

Table 6
Comparison of structural parameters for **3** with those of related mono-oxo-bridged diiron(III) complexes

Complex	α(Fe–O–Fe) (°)	Fe–oxo[a] (Å)	Fe···Fe (Å)	Ref.

Abstract

Mannich aminomethylation reactions involving $M(aa)_2$, where M = Cu, Ni and aa = glycine(gly), DL-alanine(DL-ala), L-alanine-(L-ala), with formaldehyde and diethylmalonate have been carried out, resulting in carboxylate appended systems in high yield. All the compounds have been characterized by UV-Vis spectroscopy, infrared spectroscopy and elemental analysis. One of the synthesized complexes, (5,5-dicarboxyethyl-3,7-diazanonanedioato)copper(II) monohydrate, has been characterized by single crystal XRD and has been used as catalyst in the hydrogen peroxide-induced degradation of pyrocatechol violet (PCV) dye. The variations in the rate of degradation of the dye with respect to change in concentration of hydrogen peroxide, dye, catalyst and pH have been studied. Effect of addition of NaCl has been studied and a suitable mechanism based on the formation of free radical species during the degradation process has been proposed.

Keywords: Diethylmalonate; Metal complexes; Mannich aminomethylation; Pyrocatechol violet dye

1. Introduction

Mannich aminomethylation reactions involving chelated metal complexes, formaldehyde and a 'carbon acid' bridging group have been extensively studied during the past several years [1]. Nitroalkanes and malonic esters have been predominantly used as ring-closing agents leading to nitro- and carboxylate-appended macrocycles. Several other compounds such as primary amines [2], amides and sulfonamides [3] have also been used as nucleophiles. Chelated amino acid complexes undergo aldol condensation or Mannich aminomethylation reactions depending upon the pH and the nature of the α-alkyl substituents [4]. Mannich aminomethylation reaction of chelated amino acid complexes using diethylmalonate as the carbon acid is yet unreported in the literature. Hence, this paper reports Mannich aminomethylation reaction of a series of bis(α-amino acidato) metal(II), $M(aa)_2$, with formaldehyde and diethylmalonate as the carbon acid under both acidic and alkaline conditions which would further help in understanding the chemistry of the chelated amino acid complexes.

Study of the catalytic effect of metal complexes has been the subject of extensive research during the past several decades. Coordination complexes have been successfully used as catalysts in several organic reactions [5]. One of the important and useful areas of investigation is the recycling of textile wastewater by decolorization techniques for its subsequent use in dyeing processes [6]. There are several decolorization techniques such as adsorption, coagulation, electrochemical method, chlorination and ozonation, advanced oxidation using UV/TiO_2 and biological oxidation [7]. The need to reduce the amount of toxic wastes and byproducts arising from chemical processes requires increasing emphasis on the use of less toxic and environmentally compatible materials. In this aspect, our attempt to use one of the synthesized Mannich aminomethylation products as a catalyst in the hydrogen peroxide induced degradation of pyroctechol violet (PCV) dye appears to suggest a promising technique.

PCV, a phenolic organic compound, is used as a model in this study as it is a recommended reagent in spectrophotometric studies and has enhanced analytical potential towards metal ion extraction and determination [8]. H_2O_2 is the widely used oxidizing agent in the degradation processes [9]. Transition metal complexes are found to activate H_2O_2 by releasing highly active and nonspecific hydroxyl radicals that oxidize organic pollutants [10].

This paper reports the synthesis of products containing carboxylate bridging groups starting from amino acid complexes of Cu and Ni and one of the synthesized Mannich aminomethylation product, (5,5-dicarboxyethyl-3,7-diazanonanedioato)copper(II) monohydrate, has been tested for its catalytic activity in the H_2O_2 induced degradation of PCV.

2. Experimental

Glycine(gly), DL-alanine(DL-ala), L-alanine(L-ala) and 2-propanol were supplied by SRL laboratories, diethylmalonate and pyrocatechol violet {2-[(3,4-dihydroxyphenyl)-(3-hydroxy-4-oxocyclohexa-2,5-dien-1-ylidene)methyl] benzenesulphonic acid} (PCV) was obtained from Lancaster chemicals, 37% aqueous formaldehyde solution and AR grade hydrogen peroxide (30%) free of inhibitors were obtained from Merck. The initial concentration of H_2O_2 was determined iodometrically using a standard solution of sodium thiosulphate. $Cu(aa)_2$ and $Ni(aa)_2$ were prepared as reported in the literature [11].

2.1. Physical measurements

Electronic spectra of the complexes and the kinetic measurements were carried out on a Zhimadzu UV-160A spectrophotometer. The infrared spectra were recorded on a Themo Mattson Satellite FT-IR spectrophotometer from 4000 to 450 cm^{-1} as KBr discs. Elemental analyses were carried out with an Elementar Vario EL III Carlo Erba 1108 analyzer available at CDRI, Lucknow. ESR measurements were done using BRUKER X-Band EMX-EPR spectrometer available at CLRI, Chennai. About 3 mM solutions of the complexes in DMSO were used for measurements at 77 K.

2.2. Reactions and syntheses

All reactions of $M(aa)_2$, where M = Cu, Ni and aa = glycine, DL-alanine and L-alanine, with formaldehyde and diethylmalonate were carried out in the absence of base and in the pH range between 6.0 and 9.0. The pH of each reaction mixture was adjusted by the addition of aqueous Na_2CO_3 solution.

2.2.1. (5,5-Dicarboxyethyl-3,7-diazanonanedioato)-copper(II) (**1a**)

A reaction mixture consisting of $Cu(gly)_2 \cdot H_2O$ (1 g, 4.4 mmol), formaldehyde (6.6 ml, 0.08 mol) and diethylmalonate (1.3 ml, 8.8 mmol) in 100 ml of water:methanol mixture (3:1) was stirred thoroughly at room temperature for 2 days. The reaction mixture on concentration (~30 ml) using rotary evaporator and on standing at room temperature yielded deep blue crystalline product. The crystals were collected by filtration, washed with cold ethanol and diethyl ether and finally dried over $CaCl_2$ for 2 h. Yield: 1.23 g, 68%. Elemental *Anal.* Calc. for $C_{13}H_{20}N_2O_8Cu.H_2O$: C, 37.75; H, 5.31; N, 6.77. Found: C, 37.61; H, 5.30; N, 6.92%. $\lambda_{max}(H_2O)$/nm 248 (ε/$dm^3\ mol^{-1}\ cm^{-1}$ 447.5) and 615 (47.9). IR (cm^{-1}): 3612, 3433, 3249, 3184, 2980, 2935, 1733, 1655, 1586, 1455, 1382, 1345, 1276, 1239, 1195, 1146, 1080, 1027, 974, 942, 856, 775, 746, 644, 583, 510, 465. This complex could be synthesized between pH 4.0 and 7.0. Yield of the product decreases above pH 7 (<10%) and no product could be isolated above pH 8. Reactions carried out with different mole ratios of the reactants did not enhance the yield of the product.

2.2.2. (5,5-Dicarboxyethyl-2,8-dimethyl-3,7- diazanonanedioato)copper(II) (**1b**)

A reaction mixture consisting of $Cu(DL\text{-}ala)_2 \cdot H_2O$ (1 g, 3.8 mmol), formaldehyde (5.8 ml, 0.07 mol) and diethylmalonate (1.2 ml, 7.7 mmol) in 100 ml water:methanol mixture (3:1) was stirred thoroughly at room temperature for 5 days. On concentration by rotary evaporator (~30 ml) and on standing at room temperature, deep blue crystalline product was obtained. The crystals were collected by filtration, washed with cold ethanol and diethyl ether and finally dried over $CaCl_2$ for 2 h. Yield: 1.02 g, 61%. Elemental *Anal.* Calc. for $C_{15}H_{24}N_2O_8Cu.H_2O$: C, 40.79; H, 5.88; N, 6.34. Found: C, 40.62; H, 5.92; N, 6.29%. $\lambda_{max}(H_2O)$/nm 284 (ε/$dm^3\ mol^{-1}\ cm^{-1}$684.4) and 604 (99.3). IR (cm^{-1}): 3428, 3343, 3233, 3180, 2984, 2943, 1728, 1622, 1464, 1443, 1378, 1313, 1292, 1239, 1207, 1178, 1109, 1019, 913, 885, 856, 783, 669, 658, 607, 522, 453. This complex could be synthesized between pH 4.0 and 7.0. Yield of the product decreases above pH 7

(<10%) and no product could be isolated above pH 8. Reactions carried out with different mole ratios of the reactants did not enhance the yield of the product.

2.2.3. (5,5-Dicarboxyethyl-2,8-dimethyl-3,7-diazanonanedioato)copper(II) (**1c**)

A reaction mixture consisting of Cu(L-ala)$_2$ (0.5 g, 2.0 mmol), formaldehyde (0.8 ml, 0.01 mol) and diethylmalonate (0.3 ml, 2.0 mmol) in 100 ml water:methanol mixture (3:1) was stirred thoroughly at room temperature for 5 days. On concentration by rotary evaporator (~30 ml) and on standing at room temperature, a deep blue product was obtained. The product was collected by filtration, washed with cold ethanol and diethyl ether and finally dried over $CaCl_2$ for 2 h. Yield: 0.37 g, 42%. Elemental *Anal.* Calc. for $C_{15}H_{24}N_2O_8Cu$: C, 42.52; H, 5.66; N, 6.61. Found: C, 42.41; H, 5.61; N, 6.52%. $\lambda_{max}(H_2O)$/nm 282 (ε/dm^3 mol^{-1} cm^{-1} 665.0) and 607 (91.0). IR (cm^{-1}): 3233, 3182, 2987, 2919, 1733, 1623, 1451, 1437, 1382, 1315, 1292, 1239, 1203, 1182, 1105, 1019, 913, 890, 852, 791, 678, 606, 520, 460. Product yield is poor above pH 7.0 (~5%).

2.2.4. (5,5-Dicarboxyethyl-3,7-diazanonanedioato)-nickel(II) (**2a**)

A reaction mixture consisting of Ni(gly)$_2 \cdot 2H_2O$ (1 g, 4.1 mmol), formaldehyde (6.2 ml, 0.08 mol) and diethylmalonate (1.2 ml, 8.2 mmol) in 250 ml water:methanol mixture (4:1) was stirred thoroughly at 40 °C for 6 h. On concentration by rotary evaporator (~50 ml) and on standing at room temperature, a pale blue crystalline product was obtained which was collected by filtration, washed with cold ethanol and diethyl ether and finally dried over $CaCl_2$ for 2 h. Yield: 0.70 g, 40%. Elemental *Anal.* Calc. for $C_{13}H_{20}N_2O_8Ni.2H_2O$: C, 36.58; H, 5.62; N, 6.56. Found: C, 36.61; H, 5.73; N, 6.71%. $\lambda_{max}(H_2O)$/nm 288 (ε/dm^3 mol^{-1} cm^{-1} 7.7), 365 (9.8), 603 (6.0) and 742 (6.5). IR (cm^{-1}): 3408, 3286, 3241, 2976, 2935, 1729, 1610, 1451, 1394, 1370, 1341, 1309, 1284, 1252, 1227, 1199, 1150, 1060, 1027, 962, 930, 860, 742, 644, 616, 575, 510, 432. This complex could be synthesized between pH 4.0 and 6.0. No product could be isolated above pH 8.0.

2.2.5. (5,5-Dicarboxyethyl-2,8-dimethyl-3,7-diazanonanedioato)nickel(II) (**2b**)

The complex was prepared according to the synthetic method described for the analogous **2a**, using Ni(DL-ala)$_2 \cdot 3H_2O$ as starting material. Yield: 1.03 g, 63%. Elemental *Anal.* Calc. for $C_{15}H_{24}N_2O_8Ni.3H_2O$: C, 38.10; H, 6.34; N, 5.92. Found: C, 38.18; H, 6.26; N, 5.72%. $\lambda_{max}(H_2O)$/nm 289 (ε/dm^3 mol^{-1} cm^{-1}6.5), 349 (8.3), 602 (5.0) and 742 (8.2). IR (cm^{-1}): 3416, 3270, 3217, 2997, 2945, 1729, 1606, 1464, 1390, 1347, 1279, 1239, 1170, 1148, 1075, 1027, 969, 948, 860, 778, 743, 638, 592, 501, 461. Yield of the product is maximum in the pH range 4.0–7.0.

2.2.6. (5,5-Dicarboxyethyl-2,8-dimethyl-3,7-diazanonanedioato)nickel(II) (**2c**)

The complex was prepared according to the synthetic method described for the analogous **2a**, using Ni(L-ala)$_2 \cdot 3H_2O$ as starting material. Yield: 0.94 g, 58%. Elemental *Anal.* Calc. for $C_{15}H_{24}N_2O_8Ni \cdot 3H_2O$: C, 38.10; H, 6.34; N, 5.92. Found: C, 38.21; H, 6.24; N, 5.81%. $\lambda_{max}(H_2O)$/nm 289 (ε/dm^3 mol^{-1} cm^{-1}6.4), 351 (7.7), 605 (4.8) and 748 (7.4). IR (cm^{-1}): 3427, 3363, 3256, 3230, 2984, 2938, 1737, 1590, 1460, 1411, 1366, 1339, 1256, 1226, 1165, 1117, 1062, 1036, 931, 909, 860, 771, 733, 627, 543. Yield of the product is maximum at pH 7.0.

2.3. Degradation of PCV using **1a**

In each experiment, a conical flask of volume 100 cm^3 containing definite quantity of the catalyst together with 20 cm^3 of double distilled water was placed in water thermostat for 30 min. To the flask was added the required quantity of PCV/H_2O_2 mixture and zero time was noted at half the addition point. The reaction mixture was stirred continuously using a magnetic stirrer. At regular time intervals, an aliquot was withdrawn and the absorbance at $\lambda_{max} = 441$ nm ($\varepsilon = 15.766$ dm^3 mol^{-1} cm^{-1}) was recorded. The absorbance of PCV/H_2O_2 mixture remains constant for several hours in the absence of the catalyst.

2.4. Structure determination of **1a**

A blue crystal of size $0.44 \times 0.34 \times 0.04$ mm was used for intensity data collection on a Bruker SMART APEX2 CCD area-detector diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å) at 100 K. Empirical absorption correction was applied by using the SADABS program [12]. The structure was solved by direct methods and refined by full-matrix least-squares techniques on F^2 by using SHELXTL [13] with 3252 reflections ($2.51° \leqslant \theta \leqslant 26.00°$) and 236 parameters. All non-hydrogen atoms were refined anisotropically, and C and N-bound hydrogen atoms were positioned geometrically and refined using a riding model. The hydrogen atoms of the water molecules were located in a difference map and refined isotropically with distance restraints. The final cycle of the refinement converged with

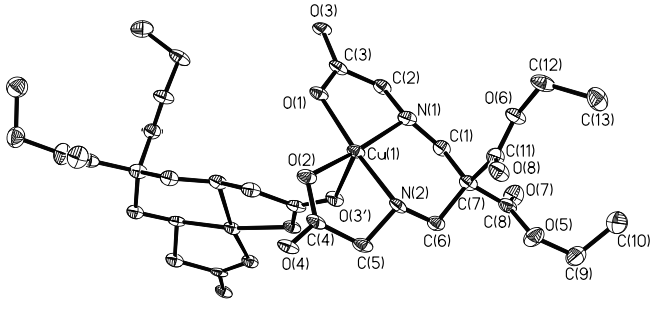

Fig. 1. An ORTEP plot of **1a** from the crystal structure analysis. The water molecule is not shown in the figure.

$R = 0.072$. The highest residual density peak (2.72 e/Å^3) and the deepest hole (−1.84 e/Å^3) are located 0.96 and 0.86 Å, respectively, from Cu(1) atom. The poor residuals may be as a result of the plate-like nature of the crystal. No disorder is found in the carboxyethyl groups or in the water molecule. The structure is illustrated as an ORTEP [14] plot in Fig. 1. Crystal data, selected bond lengths and angles are listed in Tables 1 and 2.

3. Results and discussion

Chelated amino acid complexes undergo condensation reactions, via two different pathways such as aldol-type condensation reaction resulting in the formation of oxazolidine ring-containing compound [15] or Mannich aminomethylation in the presence of formaldehyde and a third compound containing labile protons [4].

In the present study, Mannich aminomethylation of glycine and alanine chelated to Cu and Ni with formaldehyde and diethylmalonate has been carried out. More than 60% yield of the Mannich aminomethylation products were obtained when Cu(gly)$_2$, Cu(DL-ala)$_2$ and Ni(DL-ala)$_2$ are used as the starting materials.

The products obtained from the reactions of Cu(aa)$_2$ and Ni(aa)$_2$ with formaldehyde and diethylmalonate are schematically shown below.

M(aa)$_2$

1a – 2c

1a, R = H, M = Cu
1b, R = CH_3, M = Cu
1c, R = CH_3, M = Cu
2a, R = H, M = Ni
2b, R = CH_3, M = Ni
2c, R = CH_3, M = Ni

Details of the reactions of copper(II) and nickel(II) complexes of glycine, DL and L forms of alanine with formaldehyde and diethylmalonate at different pH conditions are described in Section 2. The reactions of Cu(gly)$_2 \cdot H_2O$, Cu(DL-ala)$_2 \cdot H_2O$ and Ni(gly)$_2 \cdot 2H_2O$ with formaldehyde and diethylmalonate yielded crystalline products **1a**, **1b** and **2a**, respectively, and their structures are assigned based on their IR and elemental analysis data. The structure of the product **1a** is characterized by X-ray diffraction studies. The product, **1c**, obtained for Cu(L-ala)$_2$ with formaldehyde and diethylmalonate has been identified as (5,5-dicarboxyethyl-2,8-dimethyl-3,7-diazanonanedioato)copper(II) from the IR spectrum and elemental analysis data.

The reactions of Cu(L-ala)$_2$, Ni(DL-ala)$_2 \cdot 3H_2O$ and Ni(L-ala)$_2 \cdot 3H_2O$ with formaldehyde and diethylmalonate

yielded blue colored products. However, the crystals were not suitable for X-ray analysis and our best attempts to grow single crystals of the complexes were unsuccessful. The products **2a**, **2b** and **2c** were assigned structures similar to that of their analogous **1a**, **1b** and **1c** from their IR and elemental analysis data.

The IR spectra of all the complexes exhibit a sharp band at ~3250 cm^{-1}, indicating the presence of an N–H group. Hence, only one proton of the $–NH_2$ group of the chelated amino acids takes part in the Mannich aminomethylation reaction which is consistent with the results reported previously [1,16]. The ester carbonyl stretching is observed at ~1730 cm^{-1} for all the products. All the synthesized complexes **1a**, **1b**, **1c**, **2a**, **2b** and **2c** exhibit typical coordinated carboxylate asymmetric stretching and symmetric stretching frequencies at ~1600 cm^{-1} and ~1400 cm^{-1}, respectively. The absence of a triplet in the IR region 1200–1050 cm^{-1}, attributed to an oxazolidine ring system, shows that the α-carbon protons in the products are unaffected by the formaldehyde attack in the pH range 4.0 and 7.0. All the complexes, except **1c**, exhibit bands at ~3450 cm^{-1} indicating the presence of water molecules. Thus, it is clear from the IR data that the products are the result of the reactions of their corresponding chelated amino acids, $Cu(aa)_2$ or $Ni(aa)_2$, with formaldehyde and diethylmalonate. Furthermore, microanalytical data support the postulated formulae of these complexes.

The formation of the products in all the cases must necessarily involve the initial loss of amino protons of bis(amino acidato)M(II), a phenomenon which has been well documented [17]. This step leads to electrophilic attack on the nitrogen atom by formaldehyde molecules, followed by subsequent condensation with diethylmalonate resulting in the formation of a heterocyclic ring system. Diethylmalonate is weakly acidic ($pK_a \sim 13.3$), and is found to be reactive [18].

No role of chirality is observed in this work, as both DL and L-alaninato complexes of Cu(II) and Ni(II) were found to undergo Mannich aminomethylation to give the same product, in contrast to the earlier reports [19].

3.1. Description of the crystal structure of *1a*

In the coordination polymer (Fig. 1), each copper atom is five-coordinated by two carboxyl O atoms and two N atoms from two glycine units and one carboxyl O atom from a symmetry-related ligand; the local coordination environment around each copper atom can be best described as a distorted square-pyramidal geometry, with atoms O(1), O(2), N(1) and N(2) defining the basal plane, and the copper atom deviates by 0.184(2) Å from that plane, in the direction of the O(3′) atom which occupies the apical site, with a Cu(1)–O(3′) bond distance of 2.288(4) Å. This coordination results in the formation of a one-dimensional chain structure along the crystallographic *b* axis. In the chain, the shortest Cu···Cu distance is 5.910(1) Å. But there exists a long semi-coordinate Cu(1)–O(2″) bond of 2.754(4) Å between the adjacent symmetry related chain. If this longer coordination is considered to be significant, then the coordination around each copper atom may be alternatively explained as distorted octahedral and it results in the formation of two-dimensional coordination polymer (Fig. 2) extending along the crystallographic bc plane, with a short Cu(1)···Cu(1″) contact of 3.383(1) Å. The three *trans* angles at each copper centre lie in the range 169.04(17)°–170.57(13)°. All other angles subtended at each copper atom are ranging from 79.42(15)° to 102.11(15)°, which indicates a distorted octahedral geometry of atom Cu(1). N–H···O and O–H···O hydrogen bonds involving the carboxylate and solvate water O atoms are observed within the layer (range of N···O = 2.951(6)–3.128(6) Å and that of O···O = 2.856(7)–3.179(7) Å). No interaction is observed between the layers.

3.2. Solution spectroscopy of the copper(II) complexes

The ESR spectra of **1a** and **1b** have been recorded in DMSO solution at liquid nitrogen temperatures. The solution ESR spectrum of the complex **1a** (Fig. 3) looks very similar to that of an earlier report [4d] and is typical of a square planar CuN_2O_2 coordination geometry with weakly bound axial ligand. This is in agreement with the crystal structure of **1a**. Apparently, the sample contains both monomeric and dimeric Cu centers.

The ESR spectrum of **1b** (Fig. 3a) appears to be a typical triplet state spectrum arising from a dimer. A computer simulation of the ESR spectrum (Fig. 3b) was attempted using the approach of Pilbrow [20]. A computer program reported was used [21]. The interaction between the Cu

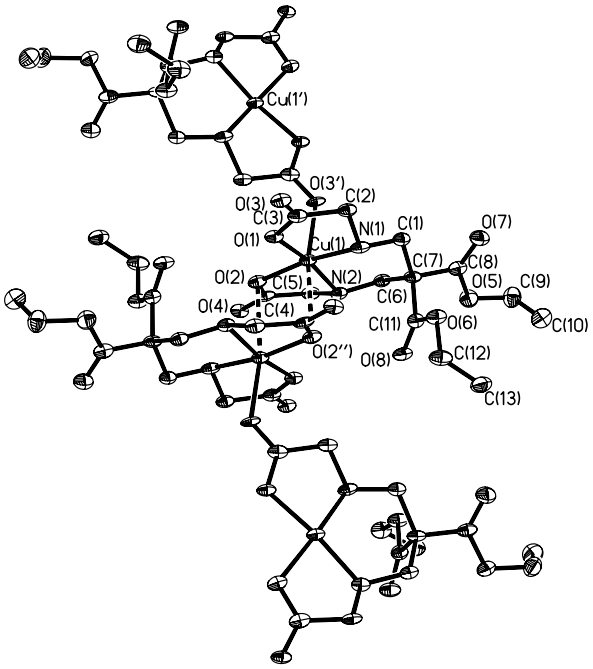

Fig. 2. Two-dimensional view of the coordination polymer.

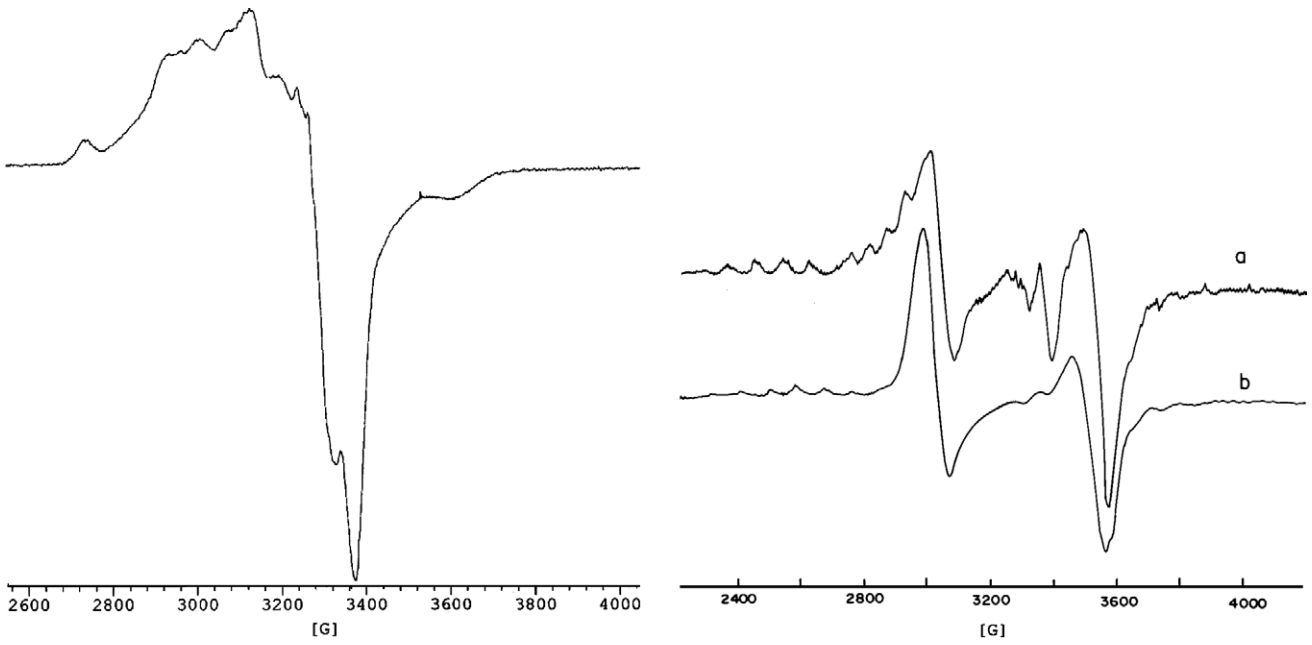

Fig. 3. ESR spectrum of **1a** at 77 K in DMSO at microwave frequency of 9.502 GHz and field modulation frequency of 100 kHz. (a) ESR spectrum of **1b** at 77 K in DMSO at microwave frequency of 9.502 GHz and field modulation frequency of 100 KHz. (b) Computer simulated ESR spectrum of **1b**.

centers is assumed to arise predominantly from dipolar interactions. An exchange coupling of about $-2\ cm^{-1}$(ferromagnetic) in the simulation was obtained. A distance of 3.9 Å between the two Cu centers gave a good agreement between the experimental and the computer simulated spectrum. The computer simulated spectrum of **1b** yielded the parameters $g_{11} = 2.220$, $g_{\perp} = 2.080$, $A_{11} = 191.0 \times 10^{-4}\ cm^{-1}$ and $A_{\perp} = 35.0 \times 10^{-4}\ cm^{-1}$.

3.3. Catalytic activity

Spectrophotometric measurements in phosphate buffer solutions revealed that no absorbance change was observed when H_2O_2 is mixed with PCV at concentrations used in this work. However on addition of the catalyst the absorbance at 441 nm was found to decrease at a much higher rate than the uncatalyzed reaction (Fig. 4).

The kinetic measurements were carried out under pseudo-first-order conditions with respect to [PCV]. The value of the rate constant, k, is obtained from the slope of the straight lines of the equation, $\ln A_t = \ln A_0 - kt$, where A_t is the absorbance at time t, A_0 is the absorbance at time = 0.

Experiments carried out at constant temperature and pH to determine the order of reaction with respect to PCV and H_2O_2 revealed that the reaction rate increases with a first order dependence on H_2O_2 (Fig. 5) in the range 0.009–0.12 M at 30 °C. Thus, activation of H_2O_2 by the catalyst leads to the formation of hydroxyl or perhydroxyl radicals which attack PCV and degrade it. The influence of [PCV] on the rate of reaction was studied by varying $[PCV]_0$ in the range $0.5–3.8 \times 10^{-4}$ M at 30 °C (Fig. 6) at constant $[H_2O_2]_0$ and pH value. The reaction obeyed a first order dependence on $[PCV]_0$ at lower concentrations.

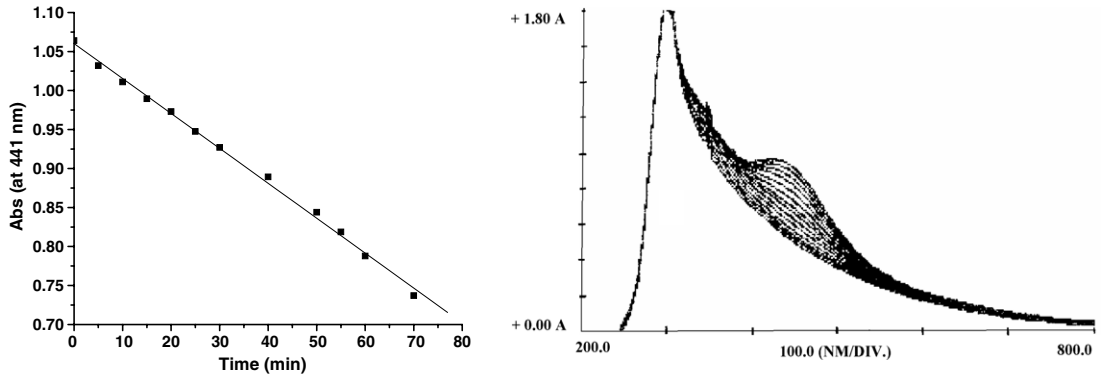

Fig. 4. The variation of absorbance for the reaction of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

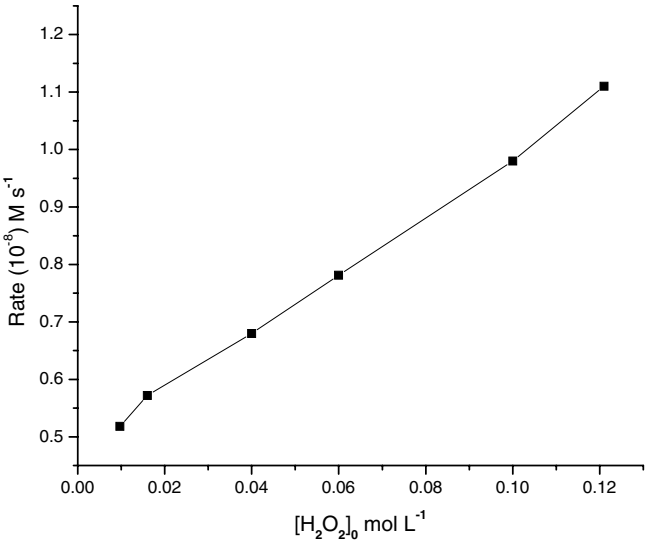

Fig. 5. Dependence of the initial rate on the $[H_2O_2]_0$ for the reaction of 1.2×10^{-4} M $[PCV]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

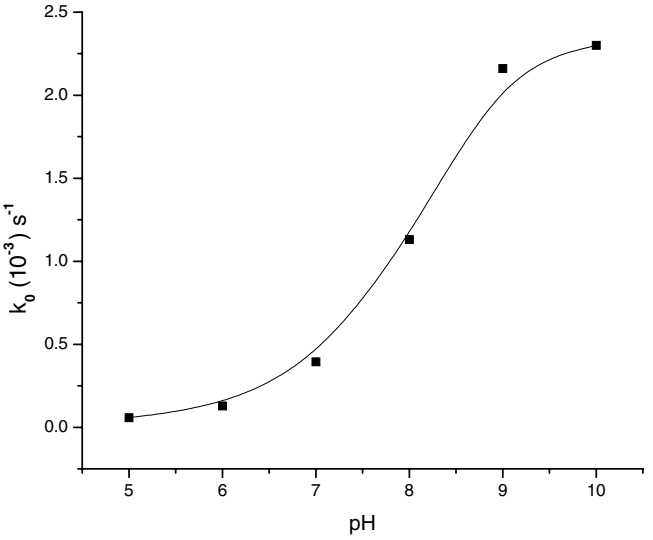

Fig. 7. Dependence of the rate constant on pH for the reaction of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$in the presence of 0.01 g of the catalyst at 30 °C.

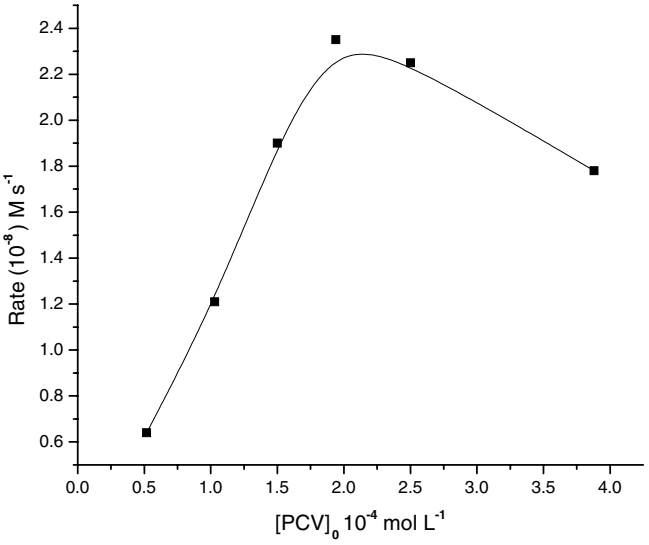

Fig. 6. Dependence of the initial rate on the $[PCV]_0$ for the reaction of 0.01 M $[H_2O_2]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

However, the order reached almost zero at higher concentrations.

Rate of the reaction is found to increase with increase in concentration of the catalyst. The effect of increase in the concentration of the catalyst on the degradation of the dye was studied by fixing $[PCV]_0$ and $[H_2O_2]_0$ at constant values and taking 0.01, 0.02 and 0.03 g of the catalyst. The absorbance value is found to decrease with increase in the concentration of the catalyst, thereby increasing the rate of the reaction.

The effect of pH on the rate of reaction was studied using phosphate buffer in the range 5–9, and NaOH for pH > 9 at 30 °C. PCV, a tetraprotic acid (H_4L) exists in the form H_3L^- (yellow) under weakly acidic condition (pH 3–7) and shows maximum absorbance at $\lambda_{max} =$ 441 nm. Under alkaline conditions (pH > 7), PCV exists in the form H_2L^{2-} (violet) having maximum absorbance at 596 nm [8]. The value of the rate constant increases slowly at the beginning and then attains maximum value at pH 9.0, after which it levels off resulting in an S-shape curve (Fig. 7). This increase in the reaction rate could be attributed to the deprotonation of H_2O_2 which in turn favors the formation of the peroxo intermediate [22]. Thus, the generation of the active peroxo species brings about easy oxidation of PCV. The change in the electronic configuration of PCV under alkaline condition would have made it more susceptible for oxidation. However, at pH > 10, the solution turned turbid thereby making the experimental determination of the absorbance difficult.

The effect of chloride ions on the reaction rate was studied at fixed concentrations of $[PCV]_0$, $[H_2O_2]_0$ and the catalyst. The rate constant was found to increase with increasing [NaCl] (Fig. 8). This increase in rate may be attributed to the oxidation of chloride ions by H_2O_2 to produce other oxidizing agents such as OCl^- and Cl_2 that assist in the oxidation of PCV [23].

The formation and the role of the free radical species such as $OH^{\cdot}$ and $HO_2^{\cdot}$ by the decomposition of H_2O_2 by transition metal complexes has already been confirmed by spectroscopic methods [24]. Also, organic radical scavengers like 2-propanol and a chromogen 2,2′-azino-bis(3-ethylbenz-thiazoline)-6-sulphonate diammonium salt (ABTS) were used as a probe to confirm the generation of free radical species [25]. Our attempt to use 2-propanol as the radical scavenger also proved the formation of free radical species during the degradation process. Addition of 2-propanol to the reaction mixture resulted in a drastic decrease in the rate of the reaction. The rate of the reaction with the addition of 2-propanol was found to be approximately 10

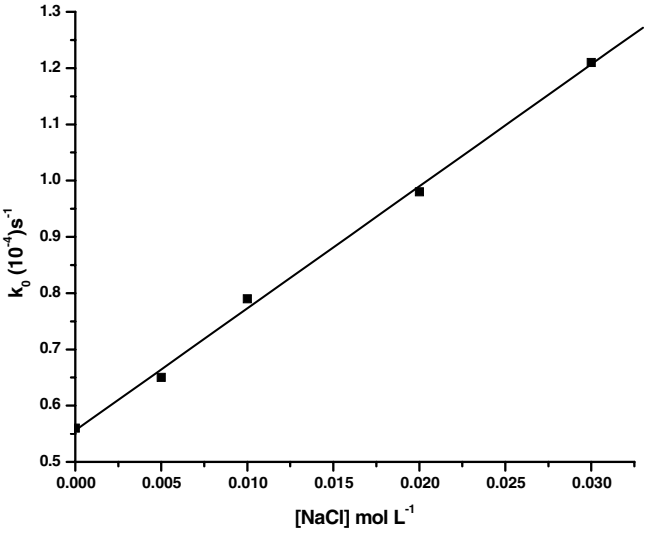

Fig. 8. Variation of rate constant with [NaCl] for the reaction of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$ and 0.01 g of the catalyst at 30 °C.

times less than the rate of the reaction without the addition of 2-propanol (Fig. 9). This confirms the generation of radical species by the transition metal complex from H_2O_2. Based on the results and discussion given above, the reaction mechanism which involves the formation of the highly active hydroxyl radical, formed by the interaction of the catalyst with H_2O_2, has been proposed. The hydroxyl radical, which is an active oxidant, attacks PCV forming PCV-radical adduct which gets decomposed in the rate-determining steps resulting in the formation of the final oxidation products as given under:

$$[Cu^{II}L] + H_2O_2 \underset{k_{-1}}{\overset{k_1}{\leftrightarrows}} [Cu^{II}L(HO_2^-)] + H^+ \quad (1)$$

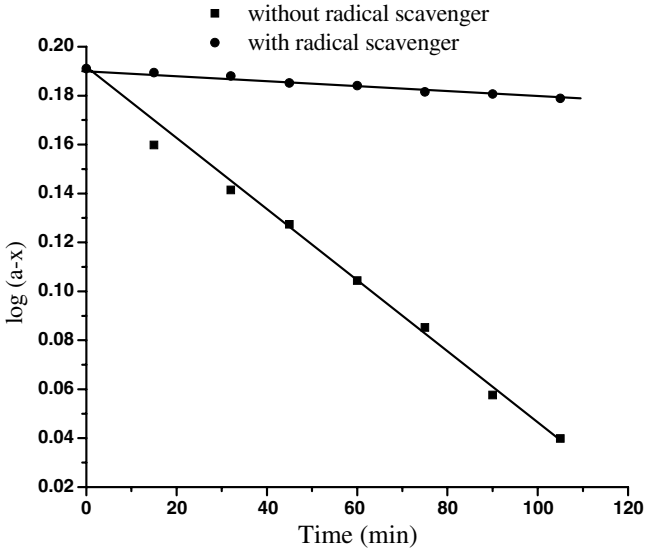

Fig. 9. Effect of the radical scavenger on the rate of the reaction.

$$[Cu^{II}L(HO_2^-)] \xrightarrow{k_2} [Cu^{I}L] + OH^{\cdot} + \frac{1}{2}O_2 \quad (2)$$

$$PCV + (HO^{\cdot})] \xrightarrow{k_3} \underset{\text{Dye-radical adduct}}{[PCV(HO^{\cdot})]} \quad (3)$$

$$[PCV(HO^{\cdot})] \underset{\text{slow}}{\xrightarrow{k_4}} \text{Oxidation products,} \quad (4)$$

$$[Cu^{I}L] + HO^{\cdot} \xrightarrow{k_5} [Cu^{II}L] + OH^- \quad (5)$$

$$OH^- + H^+ \rightarrow H_2O \quad (6)$$

From Eq. (1), the concentration of the peroxo complex is given by

$$[[Cu^{II}L(OH_2^-)]] = K_1[[Cu^{II}L]][H_2O_2]/[H^+] \quad (7)$$

where $K_1 = k_1/k_{-1}$.

Applying steady-state approximation for the determination of $[OH^{\cdot}]$ and $[PCV(HO)^{\cdot}]$

$$\frac{d[OH^{\cdot}]}{dt} = k_2[[Cu^{II}L(OH_2^-)]] - k_3[PCV][HO^{\cdot}] - k_5[[Cu^{I}L]][OH^{\cdot}] = 0 \quad (8)$$

$$\frac{d[PCV(OH^{\cdot})]}{dt} = k_3[PCV][HO^{\cdot}] - k_4[PCV(HO^{\cdot})] = 0. \quad (9)$$

Assuming, $[Cu^{II}L(HO_2^-)] = [Cu^{I}L]$ and substituting from Eq. (7) into Eq. (8) we get,

$$[HO^{\cdot}] = \frac{k_2K_1[[Cu^{II}L]][H_2O_2]}{k_3[PCV][H^+] + k_5K_1[[Cu^{II}L]][H_2O_2]}. \quad (10)$$

Substituting for $[HO^{\cdot}]$ from Eq. (10) in (9) we get,

$$[PCV(HO^{\cdot})] = \frac{k_2k_3K_1[PCV][[Cu^{II}L]][H_2O_2]}{k_3k_4[PCV][H^+] + k_4k_5K_1[[Cu^{II}L]][H_2O_2]}. \quad (11)$$

From Eq. (4),

$$\text{Rate} = k_4[PCV(HO^{\cdot})]. \quad (12)$$

Substituting for $[PCV(HO^{\cdot})]$ in Eq. (12) we get,

$$\text{Rate} = \frac{k_2k_3K_1[PCV][[Cu^{II}L]][H_2O_2]}{k_3[PCV][H^+] + k_5K_1[[Cu^{II}]][H_2O_2]}. \quad (13)$$

Expressing the initial concentration of both reactants, $[PCV]_0$ and $[H_2O_2]_0$

$$[H_2O_2]_0 = [H_2O_2] + [[Cu^{II}L(HO_2^-)]] + [OH^{\cdot}] \quad (14)$$

$$[PCV]_0 = [PCV] + [PCV(OH^{\cdot})]. \quad (15)$$

Substituting from Eqs. (7) and (10) assuming $k_3[PCV][H^+ \ll k_5K_1\ [[Cu^{II}L]][H_2O_2]$

$$[H_2O_2] = \frac{[H^+]\{k_5[H_2O_2]_0 - k_2\}}{k_5[H^+] + k_5K_1[[Cu^{II}L]]}. \quad (16)$$

Substituting from Eq. (11) in Eq. (15) and assuming $k_3k_4[PCV][H^+] \ll k_4k_5K_1[[Cu^{II}L]][H_2O_2]$

$$[PCV] = \frac{k_4k_5[PCV]_0}{k_4k_5 + k_2k_3}. \quad (17)$$

Substituting for $[H_2O_2]$ and [PCV] in Eq. (13), we get

$$\text{Rate}=\frac{k_2k_3k_4k_5K_1[\text{PCV}]_0[[\text{Cu}^{\text{II}}\text{L}]][\text{H}_2\text{O}_2]_0}{k_3k_4k_5[\text{PCV}]_0\{[\text{H}^+]+K_1[[\text{Cu}^{\text{II}}\text{L}]]\}+K_1k_5[[\text{Cu}^{\text{II}}\text{L}]][\text{H}_2\text{O}_2]_0\{K_1k_5k_4+k_2K_3\}}.$$

Assuming $k_4k_5K_1 \gg k_2k_3$

$$\text{Rate}=\frac{k_2k_3K_1[\text{PCV}]_0[[\text{Cu}^{\text{II}}\text{L}]][\text{H}_2\text{O}_2]_0}{k_3[\text{PCV}]_0\{[\text{H}^+]+K_1[[\text{Cu}^{\text{II}}\text{L}]]\}+K_1^2k_5[[\text{Cu}^{\text{II}}\text{L}]][\text{H}_2\text{O}_2]_0} \quad (18)$$

From Eq. (18) it is clear that the rate of the reaction is first-order with respect to $[PCV]_0$ and $[H_2O_2]_0$ at lower concentrations and attains a limiting value at higher concentrations which is also found to be the same from the results obtained from the kinetic studies. The rate of dye degradation also increases with increasing pH and attains maximum value at pH 9.0 (Fig. 7).

4. Conclusion

Straightforward syntheses of Mannich aminomethylation products using diethylmalonate as the carbon acid have been carried out. The experimental procedure reported here proves to be the suitable condition for the synthesis of Mannich aminomethylation products in high yield by minimizing side reactions such as hydrolysis and decarboxylation reactions that normally occur with this carbon acid as in earlier reports. Competing processes normally occur in the reactions of $M(aa)_2$ with formaldehyde and carbon acids yielding products resulting from Mannich aminomethylation or aldol-type condensation reactions. The nature of α-substituents and the pH of the reaction determine the preferred pathway. The experimental conditions used in this work result only in Mannich aminomethylation reaction and no aldol condensation take place at all. It may be noted here, that in the case of amino acid chelates used in this work, the proton under attack is sufficiently labile even under weakly acid or near neutral conditions and at room temperature, whereas, in the reports in the literature, alkaline conditions have been necessary, as also elevated temperatures with diethylmalonate as the carbon acid. The Mannich aminomethylation also works with Ni(II) complexes, hitherto unreported. No difference in reactivity is observed with DL-ala and L-ala in the course of the reaction.

One of the Mannich aminomethylation products have been successfully used as a catalyst in the color removal of the pyrocatechol violet dye. Hydrogen peroxide alone could not degrade PVC but in the presence of the catalyst immediate degradation and color removal is observed. The rate of degradation of the dye is correlated with the variation in the concentration of the dye, H_2O_2 and catalyst. Variation of rate with pH and [NaCl] is also given and the mechanism is proposed based on the formation of the highly active hydroxyl radical.

Abstract

The chemical interactions of 1-methyl-3-hydroxy-4-pyridinecarboxylic acid (1M3H4P) and 1-methyl-4-hydroxy-3-pyridinecarboxylic acid (1M4H3P) with Fe(III) were investigated in aqueous 0.6 m (Na)Cl at 25 °C by means of potentiometric titrations and UV–Vis spectrophotometry. A large number of complexes were formed in solution with stoichiometry FeL_xH_y, $x = 1, 2, 3$ and $y = 0, -1, -2$. In view of a possible application to Fe(III) chelation therapy, the efficiencies of the ligands to chelate the metal ion were evaluated *in vitro* at physiological pH. 1M3H4P and 1M4H3P show a lower complexation efficiency with Fe(III) than that of other available chelators, but higher than that of their non-methylated analogs 3H4P and 4H3P.

1. Introduction

The therapy for metal overload pathologies usually involves the administration of suitable chelating agents to selectively remove the metal from the body. Regarding Fe(III) and Al(III), there is a need for new, safe, inexpensive, efficient, and orally effective chelators [1–3], because the existing ones, *i.e.* desferrioxamine (DFO) and deferiprone (L1), have a number of drawbacks, including oral inefficacy and the high cost for the former [4–6], and several toxic side effects and controversial efficiency for the latter [5–8].

In previous work (*e.g.* [9–11]) we proposed hydroxypyridinecarboxylic acids as new possible orally active chelating agents for Fe(III) and Al(III). Our results showed that the unsubstituted derivatives 3-hydroxy-4-pyridinecarboxylic acid (3H4P) and 4-hydroxy-3-pyridinecarboxylic acid (4H3P) [9,10] cannot be regarded as possible alternatives to DFO and L1, because they do not adequately complex Fe(III) and Al(III) at physiological pH. As a strategy to improve the metal complexation ability, without affecting the beneficial properties, alkylation of the pyridinic ring was proposed [9], because the electron-donor properties of alkyl substituents can be expected to increase the basicity of chelating oxygens and therefore to increase the affinity towards hard metal ions, such as Fe(III) and Al(III).

Recently, we studied the complexation between Al(III) and either 1-methyl-3-hydroxy-4-pyridinecarboxylic acid (1M3H4P) or 1-methyl-4-hydroxy-3-pyridinecarboxylic acid (1M4H3P) (Fig. 1) [11]. A significant increase of complex stability was observed for 1M3H4P compared to 3H4P. In the present paper, the complexing ability of 1M3H4P and 1M4H3P towards Fe(III) has been assessed

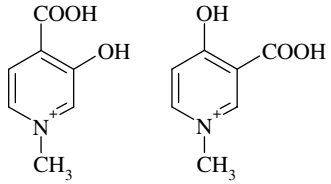

Fig. 1. 1-Methyl-3-hydroxy-4-pyridinecarboxylic acid (1M3H4P) and 1-methyl-4-hydroxy-3-pyridinecarboxylic acid (4H3P), shown in their protonated forms (H_2L^+).

in aqueous solution by means of potentiometric titrations. The speciation data obtained have been compared to the results of studies using UV–Vis. The efficiency of the ligands to chelate Fe(III) at physiological pH has been determined *in vitro* [10].

2. Experimental

2.1. Thermodynamic study

The experimental apparatus, reagents and measurement methods are summarized in the following. Details are reported only when different from those previously described [12].

2.1.1. Apparatus

All potentiometric measurements were performed with a Radiometer ABU93 Triburette apparatus. UV–Vis spectra were recorded with a Perkin–Elmer Lambda 40 instrument. Elemental analyses were performed with a Perkin–Elmer 903 atomic absorption spectrometer for Fe, and with a Perkin–Elmer Elemental Analyzer Model 240B for C, N and H.

2.1.2. Reagents

All concentrations for potentiometric and UV–Vis measurements are expressed in molality (mol/kg of water), and the ionic strength of all the solutions was adjusted to 0.6 m (≈0.594 M) (Na)Cl. Working solutions of HCl (0.2 m), NaOH (0.2 m), Fe(III) (0.05 m in 0.27 m HCl) and ligands 1M3H4P and 1M4H3P (0.015 m) were prepared and standardised as described [10–12].

2.1.3. Potentiometric measurements

Titrations were carried out at 25.0 ± 0.1 °C. Duplicate potentiometric measurements were obtained by using two different glass electrodes (Radiometer pHG201 and BDH 309/1015/02). The glass electrodes were standardised in the concentration scale. As the reference, a Ag/AgCl/0.6 m NaCl electrode with a J-shaped junction was used [13–15].

The HCl–NaOH titrations allowed the standardisation of the base and the evaluation of the autoprotolysis constant for water ($pK_w = 13.707 \pm 0.002$, means ± standard deviation of the mean). This value is in agreement with previous reports [9–12,15,16] at the same temperature and ionic strength conditions, thus confirming the reliability of the present experimental results.

Titrations of solutions containing one of the ligands and the metal ion with NaOH were executed at different ligand and metal concentrations: for 1M3H4P, $[L]_0 = 1.15–3.75 \times 10^{-3}$ m and $[M]_0 = 0.29–1.04 \times 10^{-3}$ m. For 1M4H3P, $[L]_0 = 1.26–4.09 \times 10^{-3}$ m and $[M]_0 = 0.41–1.12 \times 10^{-3}$ m. Metal-to-ligand ratios ranged from 1:1 to 1:8. The precipitation of the metal hydroxide was always observed at slightly basic pH values ($pH \leqslant 9$). All stability constants were calculated using the computer programme PITMAP [17]. The programme minimises the sum of the squares of the differences between experimental and calculated *e.m.f.* values. Optimization is performed using pitmapping [18] or simplex [19] as nonlinear least squares algorithms. Mass balance equations are solved, *i.e.* species concentration at equilibrium are obtained, by means of Newton–Raphson method [19].

2.1.4. UV–Vis measurements

Spectra were obtained at very acidic pH values (ranging from 0.22 to 1.48) for solutions containing known concentrations of ligand and metal ion. The pH of these solutions was computed directly from the stoichiometric concentration of added HCl [10]. Additional spectra at higher pH values (ranging from 1.60 to 6.71) were obtained for Fe/1M4H3P. Logβ values were computed as described [15]. Spectra of the ligands and of the metal alone, required for this method, have been obtained previously [11,15].

2.2. Solid state study

Solid A: 50 mL of a solution containing 0.1 m Fe(III), 0.3 m 1M4H3P, and *ca.* 10^{-2} m HCl were basified to pH 4.5 by adding NaOH 1 M. An orange powder-like precipitate was formed. It was washed three times with water and dried by lyophilization before being analyzed. Results: C = 45.32, N = 7.41, H = 3.50, Fe = 11.10%. The molar ratios Fe/C and Fe/N suggest a 1:3 metal-to-ligand stoichiometric ratio (Fe/C = 0.24 and Fe/N = 1.50; expected ratios for FeL_3: Fe/C = 0.22, Fe/N = 1.32).

Solid B: 50 mL of a solution containing 0.1 m Fe(III), 0.3 m 1M4H3 P, and *ca.* 10^{-2} m HCl were basified to pH 3.5 by adding NaOH 1 M. An orange powder-like precipitate was formed. It was washed three times with water and dried by lyophilization before being analyzed. Results: C = 40.54, N = 6.94, H = 3.82, Fe = 11.71%. The molar ratios Fe/C and Fe/N suggest a 1:2 metal-to-ligand stoichiometric ratio (Fe/C = 0.29 and Fe/N = 1.69; expected ratios for FeL_2: Fe/C = 0.33, Fe/N = 1.98).

2.3. In vitro study

The method employed to assess chelation efficiency in vitro is a modification of a similar method previously developed for aluminium [20].

An octanol/aqueous system containing 125 mM NaCl, 25 mM $NaHCO_3$, 4.5 mM KCl and 50 mM HEPES at pH 7.4 was used. Equal volumes (typically four milliliters) of the aqueous phase and 1-octanol (Sigma Scientific Co., St. Louis, MO) were placed in a screw-cap polypropylene tube. The octanol phase was saturated with the aqueous solution before use, to avoid a larger redistribution of hydrophilic compounds into the octanol phase: as the aqueous phase (containing test compound) saturates the octanol phase, a falsely elevated concentration of ligand in the octanol phase would be obtained. The opposite (*i.e.* the saturation of the aqueous phase with octanol) was not needed for these hydrophilic ligands.

For each experiment to assess a ligand, duplicate tubes were prepared to contain (1) only the octanol and the aqueous phase; (2) as (1) plus 1–2 mg of basic ferric acetate (Pfaltz & Bauer Inc., Waterbury, CT) to provide an excess of undissolved Fe, thus saturating the aqueous and octanol phases with Fe; (3) as (1) plus the ligand introduced into the aqueous phase at 1×10^{-3} M; (4) as (3) plus 1–2 mg of basic ferric acetate. The tubes were agitated overnight at room temperature to establish equilibrium.

The tubes were centrifuged (~3400*g*, 10 min), both phases were filtered together through a 5.0 μm hydrophilic nitrocellulose membrane and then analyzed by electrothermal atomic absorption spectroscopy, using a Perkin–Elmer 4100 ZL spectrophotometer, to determine Fe concentration.

The amount of Fe in each liquid phase of tubes with added Fe but no ligand minus the amount of Fe in tubes without added Fe or ligand represented Fe solubility from basic ferric acetate. The increase in Fe in each liquid phase in the presence of ligand over that seen in the absence of the ligand was taken as complexation of Fe by the ligand.

Chelator efficiency was calculated by

$$\frac{x[\text{sum of the M Fe concentration in each phase}]}{1 \times 10^{-3}\ \text{M}}$$

where x equals the ligand-to-iron ratio. For DFO, where at pH 7.4 a 1:1 ligand:iron complex was anticipated, $x = 1$. DFO was included in this study as a positive, internal control to confirm the reliability of this method, with the expectation that a value close to 100% chelator efficiency would be obtained when $x = 1$. For a bidentate ligand, that exists totally as a 3:1 ligand:Fe complex, $x = 3$. For a bidentate ligand for which 50% of the complexation species are 2:1 ligand:Fe complexes and 50% are 3:1 ligand:Fe complexes, $x = 2.5$.

3. Results and discussion

For both ligands, metal–ligand complexation was nearly quantitative at the starting pH value (*ca.* 2) of the potentiometric titrations. As potentiometric results below pH 2 are inherently inaccurate, very acidic solutions were investigated by means of UV–Vis spectrophotometry. Fig. 2a shows the spectra for Fe/1M3H4P. Spectra are very similar

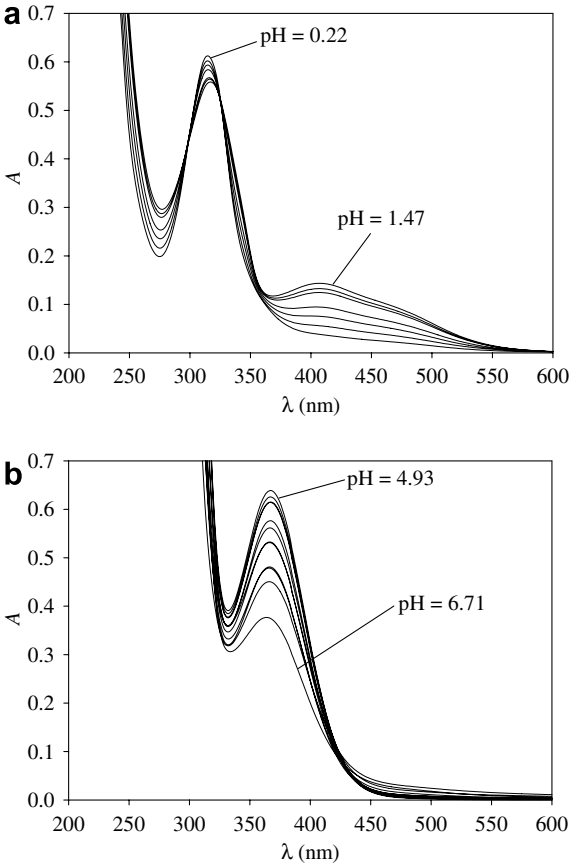

Fig. 2. (a) UV–Vis spectra for Fe/1M3H4P. $[M]_0 = [L]_0 = 1.00 \times 10^{-3}$ m (path cell 0.1 cm), pH: 0.22, 0.40, 0.59, 0.77, 1.16, 1.28, and 1.47. Calculations were performed at $\lambda = 273$, 312, 337, 404, 416 nm. (b) UV–Vis spectra for Fe/1M4H3P. $[M]_0 = 1.07 \times 10^{-4}$ m, $[L]_0 = 1.964 \times 10^{-3}$ m (path cell 0.1 cm), pH: 4.93, 5.26, 5.38, 5.56, 5.80, 5.96, 6.13, 6.24, 6.36, 6.40, 6.52, and 6.71. Calculations were performed at $\lambda = 367$ nm.

to those obtained for 3H4P and 4H3P [10]. For 1M3H4P, the main peak at 312 nm is due to pyridinic ring $\pi \rightarrow \pi^*$ transitions, and by increasing the pH a weak charge-transfer peak appears at 416 nm. For 1M4H3P, the same signals are observed at lower wavelengths. For both ligands, UV–Vis spectra allowed the detection of the species FeL^{2+} and the calculation of the corresponding stability constant $\beta_{1,1,0}$ (Table 1, first line). The value of $\beta_{1,1,0}$ was kept constant in the subsequent elaboration of potentiometric data.

Table 1
Stability constants for Fe–L complexes, at 25 °C in aqueous (Na)Cl 0.6 m (reactions: $m\text{Fe}^{3+} + a\text{L}^- + h\text{H}^+ \rightleftharpoons \text{Fe}_m\text{L}_a\text{H}_h^{3m-a+h}$)

* The reported uncertainty is the standard deviation of the mean (for potentiometric titrations) or of the weighted mean (for UV–Vis spectra).

Potentiometric data were elaborated in a sequential manner, as described previously [9], to avoid the difficulties produced by the strong correlation between the parameters to be optimised in the presence of a large number of metal–ligand species. Each species is considered to be present if its inclusion in the speciation model improves fitting quality by at least 20–30%.

The metal–ligand $\log\beta$ results are reported in Table 1 (here and in the following, charges are omitted for simplicity). The acidic properties of the ligands have been determined previously [11]: for 1M3H4P $pK_{H2L} = 0.28 \pm 0.05$, $pK_{HL} = 6.6326 \pm 0.0008$; for 1M4H3P $pK_{H2L} = 0.12 \pm 0.02$, $pK_{HL} = 5.9578 \pm 0.0006$ (reported standard deviations measure the spread of experimental results, and they probably underestimate the typical uncertainty of potentiometric and UV–Vis experimental data, especially for very low pK_a values). The stability constants for Fe(III)/hydroxo complexes have been taken from the literature: $\log\beta_{FeOH} = -2.87$, $\log\beta_{Fe(OH)_2} = -6.16$ [15], $\log\beta_{Fe(OH)_3} = -12.16$, $\log\beta_{Fe(OH)_4} = -22.16$, $\log\beta_{Fe_2(OH)_2} = -2.9$, $\log\beta_{Fe_3(OH)_4} = -6.3$, $\log\beta_{Fe_{12}(OH)_{34}} = -48.9$ [21]. After data elaboration of metal–ligand titrations we found that Fe(III)/hydroxo species have always a negligible concentration, apart at the start of hydroxide precipitation (points discarded in the calculation).

For Fe/1M4H3P UV–Vis spectra at various pH values (some are reported in Fig. 2b) were obtained to verify the unexpected presence of the species FeL_3H_{-1} (see below). From spectroscopic data, the following stability constants could be computed: $\log\beta_{1,2,0}$ (16.07 ± 0.03), $\log\beta_{1,3,0}$ (21.8 ± 0.3), and $\log\beta_{1,3,-1}$ (15.7 ± 0.3) (other complexes could not be detected because they have a very low concentration at the conditions chosen for the UV–Vis measurements). These results compare well with the corresponding potentiometric values reported in Table 1. This agreement suggests the absence of systematic errors in the results.

Typical distribution diagrams for Fe/1M3H4P and for Fe/1M4H3P are shown in Fig. 3. The two speciations are very similar at acidic pH values, whereas significant differences are evident in slightly acidic and neutral solutions. In particular, FeL_2H_{-1} and FeL_2H_{-2} prevail for Fe/1M3H4P above pH 6. For Fe/1M4H3P these mixed hydroxo-species are much less important at all pH values (FeL_2H_{-2} could not even be detected), and at pH values between 3 and 6 the prevailing species is FeL_3. The latter deprotonates above pH 6 to form FeL_3H_{-1}.

Although potentiometric and UV–Vis data do not give any structural information, it is reasonable that in all complexes the ligands coordinate the metal ion with the hydroxyl and carboxyl oxygens (bidentate chelation), and that Fe(III) is hexa-coordinated, as it is generally the case [22]. The formation of hepta-coordinated Fe(III) complexes is not very rare (*e.g.* [23] and references therein). In the species FeL_3H_{-1} (found in Fe(III)/1M4H3P solutions by both potentiometric titrations and UV–Vis measurements), as no deprotonation can occur from the bound ligand, the presence of a coordinated water molecule must be assumed. Therefore, Fe(III) is probably hepta-coordinated. The alternative structural hypothesis, *i.e.* that Fe(III) is hexa-coordinated and a ligand is bound monodentately, is less probable, because it is not compatible with the high stability of FeL_3H_{-1} (it is the prevailing species above pH 6).

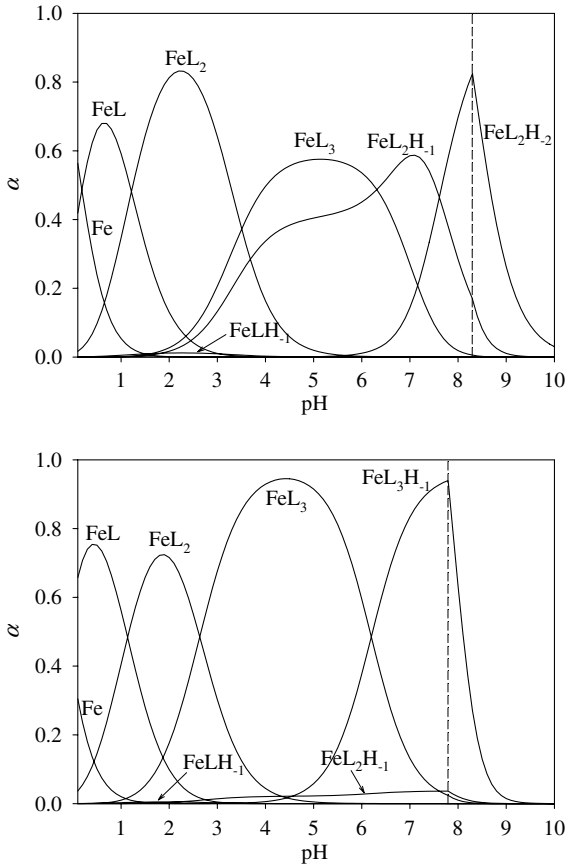

Fig. 3. Distribution diagrams of the most important iron species in the presence of 1M3H4P (above) and 1M4H3P (below) in aqueous (Na)Cl 0.6 m, $T = 25$ °C; $[Fe]_0 = 5 \times 10^{-4}$ m, $[L]_0 = 4 \times 10^{-3}$ m. Dashed lines show the theoretical starting pH for hydroxide precipitation.

The octanol/water distribution coefficients of 1M3H4P and 1M4H3P at pH 7.4 were 0.0054 ± 0.0042, and 0.0015 ± 0.0013, respectively [11]. For Fe(III)/ligand complexes lower $D_{o/a}$ values were obtained at physiological pH, *i.e.*, the complexes were even more hydrophilic than the free ligands.

The results obtained in the chelation efficiency studies are shown in Table 2. Results for 3H4P and 4H3P [10] are reported for comparison. The chelation efficiencies for 1M3H4P and 1M4H3P are lower than that of DFO, although higher than those observed for 3H4P and 4H3P.

The affinities of the various hydroxypyridinecarboxylic acids (3H4P, 4H3P, 1M3H4P and 1M4H3P) towards the metal can be compared by computing pFe ($=-\log[Fe^{3+}]$) *versus* pH at a given metal and ligand concentration: the stronger the complexes the higher the pFe. In Fig. 4, pFe plots are shown, together with that of L1 (data at 25 °C, KCl 0.1 M [25]). Among the hydroxypyridinecarboxylic

Table 2
Fe(III) chelation efficiencies of DFO, 3H4P [10], 4H3P [10], 1M3H4P, and 1M4H3P

Chelator	Chelator efficiency (%)[a]
DFO	82 ± 8
3H4P	6 ± 1
4H3P	11 ± 3
1M3H4P	21 ± 6
1M4H3P	19 ± 2

[a] Data are shown as the means of four experiments, each conducted in duplicate. For DFO, x in the chelator efficiency calculation was = 1, for 3H4P and 4H3P x was = 3 [10], and for 1M3H4P $x = 2.15$ and for 1M4H3P $x = 3$, based on potentiometric results.

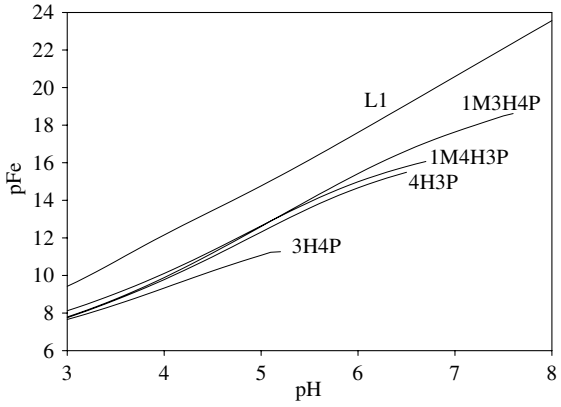

Fig. 4. pFe for several ligands (see text); $[Fe]_0 = 10^{-6}$ m, $[L]_0 = 5 \times 10^{-5}$ m [24].

acids, the complex stability increases in the order 3H4P < 4H3P < 1M4H3P < 1M3H4P. This result is in agreement with the chelation efficiency data, and it confirms our hypothesis, *i.e.*, that alkylation of the pyridinic ring can be a good strategy towards the synthesis of stronger Fe(III) chelators. If Al(III) results are also considered [11], it appears that for both metal ions the alkylation of 3H4P produced a larger increase of complexation strength than the alkylation of 4H3P. Other derivatives should be investigated to further test this beneficial effect of alkyl addition to 3-hydroxy-4-carboxylic and to 4-hydroxy-3-carboxylic pyridinic ring.

Both Fig. 4 and Table 2 show that the pFe and the chelation efficiencies of all hydroxypyridinecarboxylic acids are lower than those of DFO and L1. For 1M3H4P, and to a lesser extent also for 1M4H3P, the chelation strength difference is not very large, *e.g.*, its pFe is only about 2 orders of magnitude lower than that of L1.

4. Conclusions

Both 1M3H4P and 1M4H3P form strong complexes in solution with Fe(III). Potentiometric data allowed the determination of the stoichiometry and stability constants of the species. UV–Vis spectra studies gave the stability constants of FeL, and additional spectra for 1M4H3P confirmed the $\log\beta$ values of the major species obtained by potentiometry. The *in vitro* chelation efficiencies are significant, and they are in agreement with thermodynamic data (pFe values) at physiological pH.

The metal–ligand complexes are very hydrophilic at physiological pH. This should be regarded as a positive property. Although chelating agents having $D_{o/w}$ values around 0.2 were hypothesized to be most suitable as iron chelators [26], in our evaluation of a series of 3,4-hydroxypyridinones we found that very hydrophilic compounds can be the most orally bioavailable and effective chelators [27–29].

On the other hand, the iron complexes formed by 1M3H4P and 1M4H3P are weaker than those formed by DFO and L1 at all pH values. Therefore, 1M3H4P and 1M4H3P are probably not as effective iron chelators *in vivo* as DFO and L1.

The relative complexation strength of 1M3H4P and 1M4H3P in comparison with the unsubstituted derivatives 3H4P and 4H3P, especially as regards 3-hydroxy-4-carboxylic compounds, is significantly higher. The same results were obtained for Al(III) [11]. This suggests that further alkylation of the pyridinic ring can be a good strategy towards the synthesis of stronger Fe(III) chelators. To not significantly reduce the high hydrophilicity of the complexes, methyl derivatives seem to be promising. Towards this goal, the syntheses of 2-methyl and 1,2-dimethyl derivatives of 3H4P and 4H3P, and the thermodynamic and *in vitro* studies of the complexation with Fe(III), are in progress.

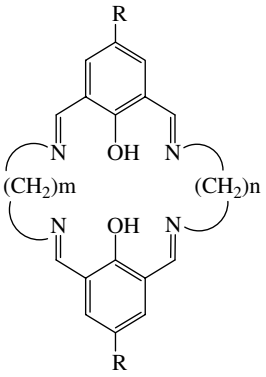
Abstract



Three dimetallic complexes of the unsymmetrical macrocycle $(L)^{2-}$, $[M_1M_2L]^{2+}$ (M_1M_2 = NiNi, CuZn, CuCd), have been synthesized by cyclocondensation between *N*,*N*′-bis(3-formyl-4-*n*-butylsalicylidene)ethylenediimine and 1,3-diaminopropane in the presence of M_1^{2+} and M_2^{2+}.The crystal structure of the complex $[Ni_2L^4(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$ was determined by X-ray diffraction techniques.The asymmetric unit contains two complete macrocyclic complexes which are nevertheless quite similar to one another.The nickel–nickel separations, bridged by the two phenoxides, are 2.977 Å and 2.982 Å.In each molecule, the Ni(II) located in the ethylene chain linked site has a square planar geometry whereas the Ni(II) located in the propylene chain linked site has an octahedral environment.The results of ES-MS and cycle voltammograms confirm that Cu–Zn, Ni–Ni form stable complexes with the macrocyclic ligand L, however the complex composed of Cu–Cd was unstable, and easily lost Cd^{2+} from the complex in methanol solution.The cyclic voltammograms of the complexes show that each complex undergoes a stepwise reduction process, e.g.$[Ni_2L]^{2+}$ with $E^1_{1/2} = -0.862$ V and $E^2_{1/2} = -1.20$ V.Magnetic measurements in the 2–300 K range indicate weak antiferromagnetism for the dinuclear nickel(II) complex with the exchange constant$J = -0.90\ cm^{-1}$.

Keywords: Crystal structure; Electrochemistry; Dinuclear macrocyclic complexes; Magnetism

The Okawa-style phenoxide Schiff base unsymmetrical macrocycles (Scheme 1) with ($R = CH_3$), synthesized by the condensation of 2,6-diformyl-4-methyl-phenol and alkylenediamine, have a powerful coordinating interaction with transition metal ions and are extensively used for synthesizing homo- and heterodinuclear complexes and mixed-valence complexes [1–3]. With short distances between the two metal ions in the complexes, they show special electrical and magnetic properties. Much attention has been paid to this kind of complexes to understand the relationship between structure and properties. Previous works showed that the electron density on ligands can be transmitted directly to the metal centers [4], and influence the magnetic exchange due to the fact that they adopt a flat structure and form a highly delocalized framework in most cases [5]. So changing the R group would cause a change of the electron-density in the macrocycle and subsequently affect the electron-density on metals, thereby alter the properties of the complexes. It is well known that the electron donating ability of the butyl group is greater than that of the methyl group, hence it is reasonable to believe that the electronic density around the metal ions in the complexes with R = butyl would be higher than that in the

Scheme 1. Chemical structures of H_2L ($m = 2$, 3, $n = 3$–5 and R = CH_3, here, $m = 2$, $n = 3$ and R = *n*-butyl).

complexes with R = CH_3. Therefore, the $E_{1/2}$ value of the former complexes should be more negative than the latter ones, and this was proved by our previous study [6]: the $E_{1/2}$ values of two dinuclear copper(II) complexes with similar macrocyclic ligands (H_2L: $m = 2$, $n = 2$, R = CH_3, R = *n*-butyl), in which the only difference was that they have different substitutes on the phenyl group, show a similar trend. Derived from the electron-density around the metal ions, the $E_{1/2}$ value of the complex with R = *n*-butyl is more negative than the related complex with R = CH_3. Furthermore, in the processes of synthesizing phenoxide Schiff base macrocyclic complexes, we have found that a base is required in the reaction systems to prevent the destruction of azomethine when R is *n*-butyl on the phenyl ring [7], whilst for the other analogous system, R = CH_3, it is not especially needed [8,9]. This is because when the phenolate groups are deprotonated and coordinate to the metal ions, the protons may attack the rich-electron C=N bond and destroy it, and the bigger the electron-density around C=N, the more likely it is to be attacked. Due to the fact that C=N in the macrocyclic ligand with R = *n*-butyl has richer electron-density than that with R = CH_3, a base must be added to protect the C=N bond from being attacked.

The magneto-structural relationships of phenoxide-bridged dinuclear nickel complexes have been extensively studied. The research showed that complexes with centrosymmetric structures have a linear dependence of J on the Ni–O–Ni bridge angle and Ni–Ni distance, and the magnetism of complexes with no centrosymmetric structure largely depends on their structures [10,11]. Although S. Mohanta reported the synthesis and the room temperature magnetic moment of an asymmetric dinickel macrocyclic complex with $m = 2$, $n = 3$ and R = CH_3 [12], its crystal structure and variable-temperature magnetism have not been reported. To understand the effect of the substituents of phenoxide macrocyclic ligands on the coordination environments, and the relationship between the magnetism and the structure of the complexes, we synthesized three unsymmetric macrocyclic complexes: $[M_1M_2L](ClO_4)_2$ (M_1M_2 = Ni Ni, Cu Zn, Cu Cd). ES-MS, spectroscopy, electrochemistry and magnetic properties of the complexes were investigated and the X-ray crystal structure of $[Ni_2L(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$ was also determined.

1. Experimental

1.1. Materials

All solvents and chemicals were of analytical grade and were used as received, except for methanol that was purified to absolute one by a general method. 2,6-Diformyl-4-*n*-butyl-phenol and *N*,*N*′-bis(3-formyl-5-*n*-butyl-salicylidene)ethylenediimine ($\mathbf{L}^1$) were prepared according to the literature methods [13].

1.2. Preparation of the complexes

$[Ni_2L(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$ (***1***). A suspension of $\mathbf{L}^1$ (0.218 g, 0.5 mmol) in 30 ml absolute methanol was added a methanol solution of $Ni(OAc)_2 \cdot 2H_2O$ (0.105 g, 0.5 mmol), and the mixture was stirred at ambient temperature for about 3 h, then triethylamine (5 ml) and a methanol solution (5 ml) containing $Ni(ClO_4)_2 \cdot 6H_2O$ (0.183 g, 0.5 mmol) were added, and the mixture was further stirred for about 10 h. A methanol solution (10 ml) containing 1,3-diaminopropane (0.037 g, 0.5 mmol) was added dropwise over 40 min, the mixture was refluxed for 1 h to give a red solution. Red needle crystals of $[Ni_2L(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$, suitable for X-ray diffraction, were obtained by slow diffusion of diethyl ether into the mother solution over one week (yield:12%). *Anal.* Calc. for $C_{29.5}H_{42}N_4O_{12.5}Cl_2Ni_2$: C, 42.13; H, 5.03; N, 6.66; Ni, 13.96. Found: C, 42.10; H, 5.08; N, 6.60; Ni, 13.52%. IR (KBr, ν/cm^{-1}), 3452 (O–H), 1643 (C=N), 1090 and 626 (ClO_4^-).

$[CuZnL](ClO_4)_2 \cdot 3H_2O$ (***2***). **2** was prepared by a similar procedure as described above, except that $Cu(OAc)_2 \cdot 2H_2O$ and $Zn(ClO_4)_2 \cdot 6H_2O$ were used instead of $Ni(OAc)_2 \cdot 2H_2O$ and $Ni(ClO_4)_2 \cdot 6H_2O$, respectively. Yield: 36%. *Anal.* Calc. for $C_{29}H_{42}N_4O_{13}Cl_2CuZn$: C, 40.76; H, 4.95; N, 6.56; Cu, 7.43; Zn, 7.65. Found: C, 40.37; H, 4.61; N, 6.72; Cu, 7.31; Zn, 7.42%. IR (KBr, ν/cm^{-1}): 3440 (O–H), 1644 (C=N), 1086.6 and 623.9 (ClO_4^-).

$[CuCdL](ClO_4)_2 \cdot 3H_2O$ (***3***). **3** was prepared by a similar procedure as described above, except that $Cu(OAc)_2 \cdot 2H_2O$ and $Cd(ClO_4)_2 \cdot 6H_2O$ were used instead of $Ni(OAc)_2 \cdot 2H_2O$ and $Ni(ClO_4)_2 \cdot 6H_2O$, respectively. Yield: 32%. *Anal.* Calc. for $C_{29}H_{42}N_4O_{13}Cl_2CuCd$: C, 38.64; H, 4.70; N, 6.21; Cu, 7.05; Cd, 12.47. Found: C, 38.23; H, 4.52; N, 5.96; Cu, 7.13; Cd, 12.47%. IR (KBr, ν/cm^{-1}): 3446.9 (O–H), 1645.06 (C=N), 1087.66 and 621.48 (ClO_4^-).

1.3. Physical measurements

IR spectra were recorded on a Vector 22 FI-IR spectrophotometer using KBr discs. Electronic spectra were

performed on an UV-2450 spectrophotometer. Elemental analyses were measured with a Perkin–Elmer 240 analyzer. The contents of metals in the complexes were determined by a general method in which samples were decomposed by dilute hydrogen nitrate, and then titrated with EDTA. Electrospray mass spectra (ES-MS) were determined on a Finnigan LCQ ES-MS mass spectrograph using methanol as the mobile phase with a concentration of approximate 1.0 mmol dm^{-3}. This diluted solution was electrosprayed at a flow rate of 5×10^{-6} dm^3 min^{-1} with a needle voltage of +4.5 kV. The temperature of the heated capillary in the interface was set at 200 °C and a fuse silica sprayer was used. Thermoanalyses of the complexes were performed on a SDT 2960 TA thermoanalyzer under an argon atmosphere at a rate of 10 °C min^{-1}.

Magnetic susceptibilities of a crystalline-powdered samples were measured on a SQUID-based sample magnetic meter in the temperature range 2.0–300 K, and diamagnetic corrections were made according to Pascal's constants. EPR spectra were recorded at room temperature and 110 K on a Bruker EMX-10/12 spectrometer operating at 9.4 GHz with DPPH as an external calibrant. Cyclic voltammograms were run on a CHI model 750 B electrochemical analyzer in a DMF solution containing tetra(*n*-butyl)ammonium perchlorate (TBAP) as the supporting electrolyte. A three-electrode cell was used, which was equipped with a glassy carbon-working electrode, a platinum wire as the counter electrode and a Ag/AgCl electrode as the reference electrode. Scanning rates were in the range 20–200 mV s^{-1}. The solution was deaerated for 15 min before measurements. The half-wave potentials were calculated approximately from $(E_{pa} + E_{pc})/2$, and the measured error was ±2 mV.

1.4. Crystal structure determination

Diffraction intensity data were collected on a SMART-CCD area-detector diffractometer at 293 K using graphite monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å). Data reduction and cell refinement were performed by SMART and SAINT programs [14]. The structure was solved by direct methods (Bruker SHELXTL) and refined on F^2 by full-matrix least squares (Bruker SHELXTL) using all unique data [15]. The non-H atoms in the structure were treated as anisotropic. Hydrogen atoms were located geometrically and refined in a riding mode.

2. Results and discussion

2.1. Synthesis and characterization

Because of hydrolysis of the Schiff base in the macrocycle, there are two by-products in the systems, and the yields of the complexes are lower than other analogs [16]. In the IR spectra of the complexes, the strong band at 1680 cm^{-1} in $\mathbf{L}^1$ has disappeared [7], and sharp C=N stretching vibration bands corresponding to four imine groups of the macrocyclic framework are observed at 1643 cm^{-1} for **1**, 1644 cm^{-1} for **2** and 1645 cm^{-1} for **3**, indicating that macrocyclic complexes are formed. In addition, the very strong bands centered at 1090 and 621 cm^{-1}, 1087 and 623 cm^{-1}, and 1088 and 621.48 cm^{-1} can be ascribed to the vibration of ClO_4^- groups for **1**, **2** and **3**, respectively. The ν_3 vibration of the perchlorate ion appeared as a sharp band around 1090 cm^{-1} in complex **1**, implying that the anion is not coordinated to the nickel(II) ion, and the vibrations of ClO_4^- in complexes **2** and **3** exhibit broad bands centered at 1087 and 1088 cm^{-1}, respectively, implying that the ClO_4^- groups are coordinated to metal ions in the solid state [17].

The electronic spectra of the complexes are measured in acetonitrile solution. In complex **1**, the bands at ca 545 and 386 nm can be attributed to the octahedral nickel(II) center with $^3A_{2g} \rightarrow {}^3T_{1g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transitions, respectively. The intensity of the absorption at 386 nm indicates that the $^3A_{2g} \rightarrow {}^3T_{1g}(P)$ transition must be admixed with the intraligand $\pi \rightarrow \pi^*$ transition and a charge transfer process [12,16]. The band at ca 315 nm was assigned to the charge transition from Ni(II) in a different coordination environment to azomethine. The band of the π–π* transition was observed at 253 nm. Comparing with analogs [8,12,16]] (Table 1), the absorption band at 900 nm in this complex is not observed because the measured range of the instrument used is 200–800 nm. The bands at 564 and 568 in complexes **2** and **3** are clearly due to the d–d transition of the copper(II) center because zinc and cadmium have no d–d transitions, having d^{10} electronic configurations. The bands at 360 and 384 nm were ascribed to the absorptions of Zn(II) and Cu(II) to azomethine in complex **2**, and the bands at 420 and 395 nm were ascribed to the Cd(II) and Cu(II) to azomethine in complex **3**, respectively, which indicate that the mixed metal complexes **2** and **3** are formed [12]. The additional band at 190–225 nm in acetonitrile solution may be the π–π* absorption peak of C≡N,

Table 1
UV–Vis, IR, magnetic and electrochemical data for the complexes and their analogs

Complex	UV–Vis λ (nm)	Electrochemical data $E_{1/2}$ (V)	μ_{eff}/μ_B	Ref.
$[Ni_2L^{2,4}(ClO_4)_2 \cdot H_2O \cdot i\text{PrOH}$	383, 525sh	−1.01, −1.23 (110) in DMSO	3.25 (298 k)	[8]

implying that acetonitrile is coordinated to the metal ions in solution.

2.2. Electrospray mass spectra

The ES-MS spectrum of complex **1** in MeOH solution is shown in Fig. 1. It shows that the peak at m/z 294.5, corresponding to $[Ni_2L]^{2+}$, is dominant and can be ascribed to the molecule ionic peak of complex **1**, confirming the formation of the macrocyclic complex. The peak at m/z 701.1 is due to the new species $[NiL(H_3O)_2(ClO_4)MeOH]^+$, whose relative abundance is lower than 25%, indicating that there is little opportunity for the complex to lose one Ni^{2+} in MeOH solution. The other peaks in the ES-MS of complex **1** are not discussed for they have relatively low abundance (<5%). The ES-MS spectra of complexes **2** and **3** show that $[CuZnL]^{2+}$ is very stable in MeOH solution, and $[CuCdL]^{2+}$ is unstable in MeOH solution and easily to loses Cd^{2+} to give [CuLH] [13]. The results are consistence with UV–Vis and thermogravimetric analyses.

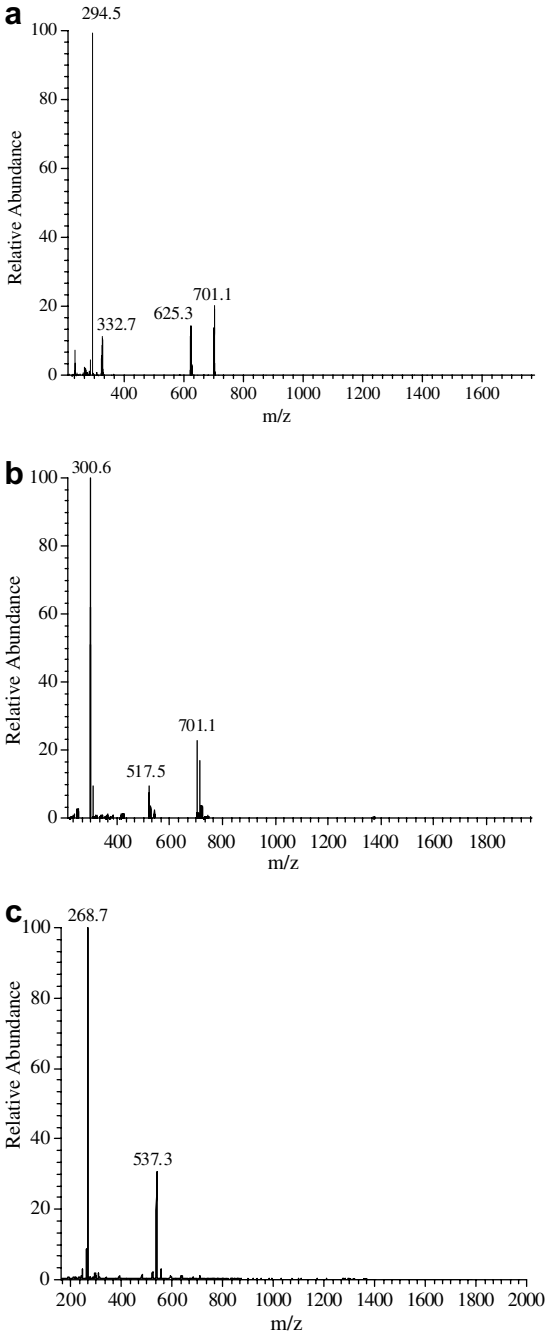

Fig. 1. (a) The ES-MS spectrum of complex **1** in MeOH solution. (b) The ES-MS spectrum of complex **2** in MeOH solution. (c) The ES-MS spectrum of complex **3** in MeOH solution.

Thermogravimetric analyses show the number of water molecules in the complexes. In the thermogram of complex **1**, there are two weight loss processes in the range 25–120 °C. Complex **1** begins to lose 2.0% and 4.4% of its weight at 80–90 °C and 100–115 °C, corresponding to the loss of 0.5 methanol molecules and two water molecules, respectively. The thermograms of complexes **2** and **3** are similar to complex **1**. The complexes begin to lose 6.2% and 6.0% of their weights at about 105–115 °C of their weights for **2** and **3**, respectively, corresponding to the loss of three water molecules. The results are consistent with the elemental analyses and ES-MS spectra of the complexes, which demonstrate that the unsymmetrical complexes were formed. All the complexes decomposed above 250 °C.

2.3. Crystal structure of $[Ni_2L(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$ (1)

The perspective view of $[Ni_2L(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$ (**1**) is given in Fig. 2, together with the atom numbering scheme. Crystallographic data and details about the data collection are presented in Table 2. The asymmetric unit contains two complete macrocyclic complexes which are quite similar to one another. Selected bond lengths and angles relevant to the nickel coordination spheres of the two molecules are listed in Table 3. Except for the *n*-butyl groups which are disordered, the macrocyclic molecules adopt essentially a flat structure. In molecule B, the nickel–nickel separation bridged by the two phenolic oxygens is 2.982 Å, and the coordination polyhedra of the two nickel(II) centres are different, where Ni(3) and Ni(4) are better described approximately as square planar and octahedral with Ni–O–Ni angles of 100.04° and 100.38°, respectively. The distances between nickel Ni(3) and the coordinated atoms near the ethylene chain fall in the range 1.778–1.877 Å and nickel Ni(3) departs by 0.0202 Å from the mean N_2O_2 basal plane, while the distances of nickel Ni(4) and coordinated atoms near the propylene chain fall in the range 1.985–2.015 Å and (Ni(4)) deviates 0.0085 Å from the mean N_2O_2 basal plane. This is consistent with the expectations for the low spin and high spin electronic configurations of square planar and octahedral Ni(II) sites, respectively. The coordination polyhedra around each Ni(II) in complex **1** are the same as the ones in the counterpart of the complex $[Ni_2L]^{2+}$ with $m = 2$, $n = 3$ and $R = CH_3$ [12]. Two water molecules occupy the apical positions in an arrangement with somewhat longer contacts,

2.143 Å and 2.145 Å. It is interesting that the two water molecules in turn form hydrogen bonds with the oxygen atoms of the perchlorate anions with distances 2.310 Å (O(19)–H(8D)O(8)) and 2.069 Å (O(13)–H(7B)O(7)), on opposite sides of the macrocyclic plane.

Molecule A contains two nickel(II) ions which are coordinated by four and six atoms, with an intermetallic distance of 2.977 Å and Ni–O–Ni angles of 101.50° and 101.09°. The coordination polyhedra of Ni(1) and Ni(2) are almost the same as the relative ones of Ni(3) and Ni(4), in which the two coordinated waters also form hydrogen bonds with the oxygen atoms of the perchlorate

anions (O(10)···H(4B)O(4), 2.437 Å and O(24)···H(3B)O(3), 2.400 Å), the difference is that one of the water molecules makes a hydrogen bond with an oxygen atom from a methanol molecule (O(25)–H(3A) 1.918 Å). This is the reason why the formula of the complex contains 0.5 molecule of methanol, because only one methanol molecule exists in the two molecules of the unit. From the two molecular structures A and B, it is clearly observed that the torsion angles consisting of N(1), C(8), C(9), N(2) as well as N(5), C(37), C(38), N(6), close to the four coordinated Ni(II) in the molecules A and B, are different (−36.4° and −4.9°, respectively), and it may be a partial reason as to the difference of the bond distances and angles in the two molecules.

The spacial arrangement of the two molecules A and B is shown in Fig. 3. For distinction, the atoms marked Ni(1) and Ni(2) are in the same molecule, so are the atoms marked Ni(3) and Ni(4). The molecules containing Ni(3) and Ni(4) are parallel to each other and are connected by hydrogen bond interactions between the hydrogen atoms in coordinated water molecules and the oxygen atoms in perchlorate anions, which can be regarded as a bridging group (O(12)···H(7A)O(7), 2.020 Å and O(9)···H(8C)O(8), 2.060 Å), and weak coordination interactions between the oxygen atoms of the perchlorate anions and Ni(II)(O(12)–Ni(3), 3.044(3) Å) (Fig. 3a). The different molecules A and B are also linked by perchlorate anions (Fig. 3b) (O(24)···H(3B)O(3), 2.400 Å and O(23)···H(54)C(54),

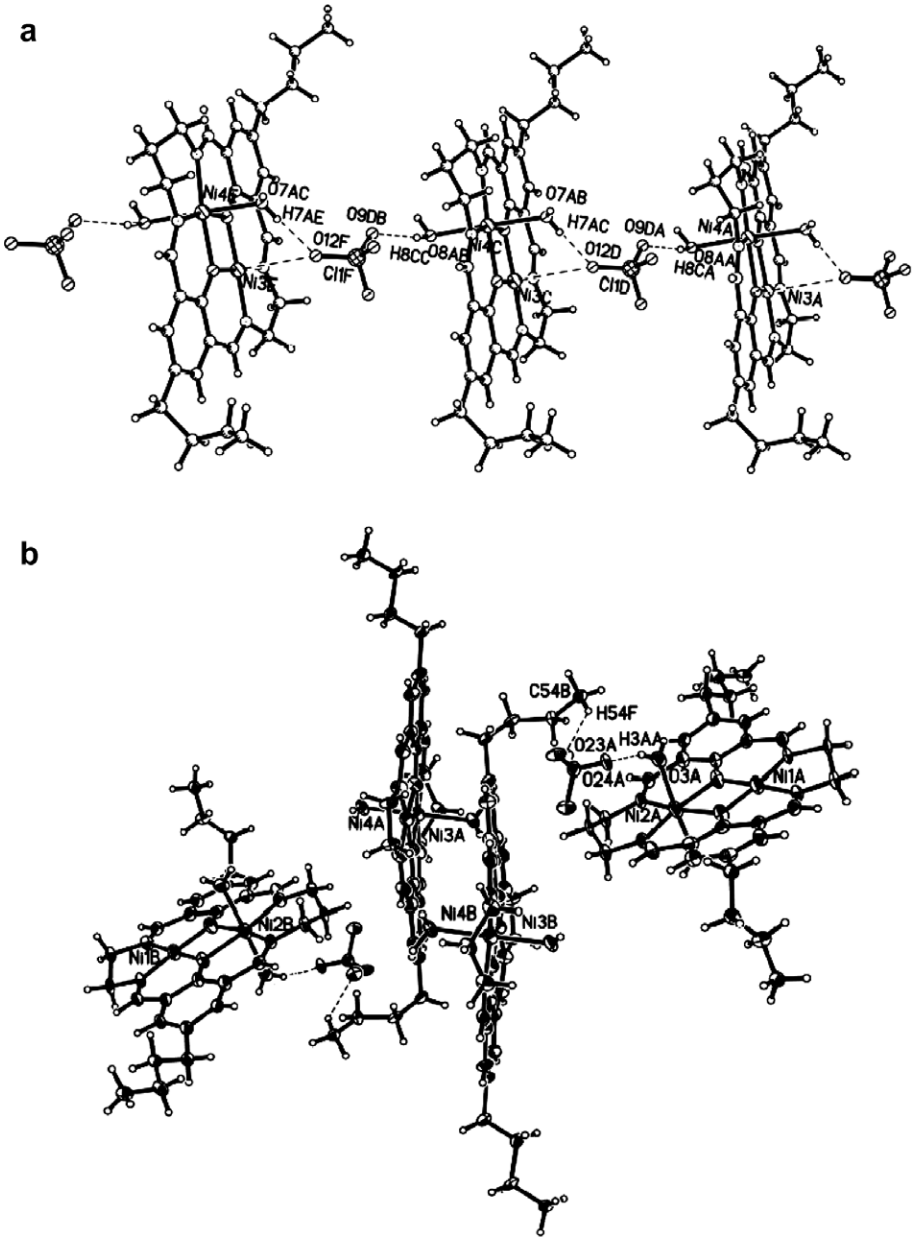

Fig. 3. The H-bonding patterns in complex **1**. (a) Viewed along the *b* axis, (b) viewed along the *a* axis.

2.523 Å), a similar hydrogen bond was found in Ref. [18]. The molecules containing Ni(1) and Ni(2) have a large intermolecular distance and no interactions between the molecules were found, but they are parallel to each other. Table 2 shows that the maximum and minimum residual electron density are both high despite nice R_1 and wR_2 values, the reason is that the residual electron density is located on the nearside of Ni(II), which can be ascribed to the cut-tail effect of nickel(II).

2.4. Electrochemical properties of the complexes

The electrochemical properties of **1**–**3** have been studied by the cyclic voltammetry technique in DMF solvent containing 0.1 M tetra(*n*-butyl)ammonium perchlorate. A typical cyclic voltammogram of complex **1** in DMF is given in Fig. 4 and the numerical data of complexes **2** and **3** are summarized in Table 1. For complex **1**, when scanning from 0 to −1.5 V, the cyclic voltammogram shows two pairs of anodic and cathodic peaks. The cathodic and anodic peak currents appearing at half-wave potentials ($E_{1/2}$) −0.862 V are almost equal. The value of $i_{pc}/v^{1/2}$ remained constant when the scan rate was varied between 50 and 150 mV s^{-1}, indicating that this process was controlled by diffusion, and was pseudo-reversible with $\Delta E = 111$ mV at $v = 50$ mV s^{-1}. The first electron transfer reaction in the complex can be ascribed to the square-planar nickel(II) site [11], because it is an easier site to be reduced than that of Ni(II) in an octahedral configuration. The second couple appearing at the half wave potential −1.201 V is also pseudo-reversible ($\Delta E = 108$ mV). With enhancement of the scan rates, the ratio of $i_{pc}/v^{1/2}$ increases and the value of E_{pc} becomes more negative, furthermore an augmentation in height of the anodic peak occurs to a greater extent relative to that of the cathodic peak. These facts reveal that the reduced Ni(I)Ni(I) species is weakly adsorbed on the electrode surface. The electrochemical properties are similar to the related analogs [8,12] in spite of the fact that they have a different substituent on the phenyl ring (see Table 1); this may be caused by the different solution used in the CV experiments. The redox processes may be tentatively considered as:

$$[\mathrm{Ni(II)Ni(II)L}] \underset{-e}{\overset{+e}{\rightleftharpoons}} [\mathrm{Ni(I)Ni(II)L}] \underset{-e}{\overset{+e}{\rightleftharpoons}} [\mathrm{Ni(I)Ni(I)L}]$$

The electrochemistry of the heterodinuclear complex **2** shows one pseudo-reversible redox couple, with an $E_{1/2}$ value of −0.398 V in the potential range 0.0 to −1.2 V, and an irreversible reduction peak. For complex **3**, a similar process was observed, with $E_{1/2} = -0.382$ and $E_{pc} = -0.810$ V, but two additional cathodic peaks also are displayed at −0.643 V and −1.062 V, which can be assigned to two reduction processes caused by the mononuclear copper(II) complex of the same ligand, which is consistence with the results of the ES-MS. The four redox processes may be described as follows:

$$[\mathrm{Cu(II)Cd(II)L}] \underset{-e}{\overset{+e}{\rightleftharpoons}} [\mathrm{Cu(I)Cd(II)L}] \overset{+e}{\rightarrow} [\mathrm{Cu(0)Cd(II)L}]$$

$$[\mathrm{Cu(II)L}] \overset{+e}{\rightarrow} [\mathrm{Cu(I)L}] \overset{+e}{\rightarrow} [\mathrm{Cu(0)L}]$$

The differences of the redox processes between complexes **1**, **2** and **3** are partially due to the stability of the complexes in solution. The ES-MS results of the complexes show that complexes **1** and **2** are relative stable but complex **3** easily loses Cd^{2+} to form a mononuclear copper(II) complex, so the cyclic voltammogram of complex **3** has two more cathodic peaks than those of complexes **1** and **2**.

2.5. Magnetic properties of complex *1*

The temperature dependence of the magnetic susceptibility of complex **1** from 300 to 2 K is shown in Fig. 5 in the form of a $\chi_M T$ versus T plot with non-linear least-square fitting of the theoretical Eq. (1) [19] to the experimental data. The magnetic parameters of complex **1** can be estimated as $g = 2.24, J = -0.90\ \mathrm{cm}^{-1}$ and $\rho = 0.061$, with $R = 1.1 \times 10^{-4}$

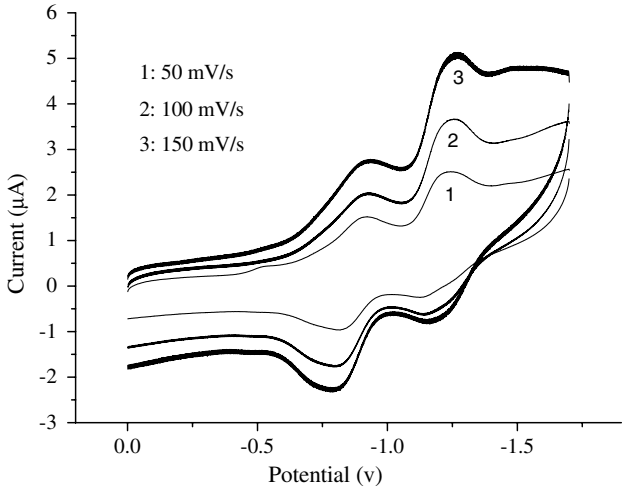

Fig. 4. Cyclic voltammogram of complex **1** in DMF solution at different scan rates.

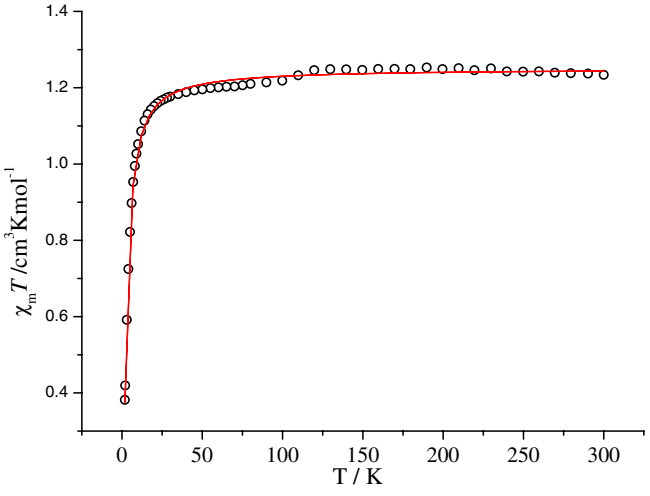

Fig. 5. Experimental and calculated plots of $\chi_M T$ vs. T. The solid line shows the fit with Eq. (1).

(R is an agreement factor defined as $R = \sum[(\chi_M T)_{calc} - (\chi_M T)_{obs}]^2 / \sum(\chi_M T)^2_{obs}$), and these values are indicative of a relatively weak antiferromagnetic coupling between the two nickel(II) ions in complex **1**

$$\chi = \frac{Ng^2\beta^2}{kT} \times \frac{[5 + \exp(-4J/kT)](1-\rho)}{5 + 3\exp(-4J/kT) + \exp(-6J/kT)} + \frac{(2Ng^2\beta^2)\rho}{3kT} \quad (1)$$

where χ and g have their usual meanings and ρ is the ratio of the paramagnetic impurity.

According to the effective magnetism quadrature formula $\mu_{eff} = 2.83(\chi_M T)^{1/2}$, the experimental effective magnetic moment of the complex equals 3.17 emu K mol^{-1} at room temperature, where $\chi_M T = 1.26$ emu K mol^{-1}, which is equal to the theoretic value of 3.17 emu K mol^{-1} calculated from $\mu_{eff} = g[S(S+1)]^{1/2}$ (when $g = 2.24$, $S = 1$) based on a NiNi unit without any interaction between the two nickel ions ($J < 1$ cm^{-1}). Alternatively it can be said that it is consistent with the value expected for a combination of a low-spin ($S = 0$) and a high-spin ($S = 1$) nickel(II) center and it agrees well with the crystal structure in which the two nickel(II) centres are in square planar and octahedral coordination polyhedra, respectively, and similar magnetic behavior was observed for the structurally characterized analogous dinickel(II) complexes [12]. The $\chi_M T$ value of 1.26 emu K mol^{-1} is practically constant in the range 300–20 K, and then rapid decreases to 0 emu K mol^{-1} due to zero field splitting. The magnetic parameters of complex **1** obey the rule reported by Thompson and Nag, as well as Okawa, where the Ni–O–Ni angle in a phenoxide-bridged molecule is larger than 97° [11,20]. It exhibits antiferromagnetic behavior, but the antiferromagnetic exchange interaction J of complex **1** is very small, which does not follow the trend [11] that for centrosymmetric complexes J increases with increasing Ni–O–Ni angles and Ni–Ni distance (Table 4). The magnetic parameters of complex **1** are somewhat like other complexes with no centrosymmetric structure (Table 4), in which the smaller J value in complex **1** is produced by the special coordination polyhedra around each Ni(II) centre.

2.6. EPR spectra

The X-band EPR spectrum for complex **1** is shown in Fig. 6. The complex exhibits a broad band centered at approximately $g = 2.23$, which is in agreement with the magnetic parameters, indicating that there is an unpaired electron in complex **1**.

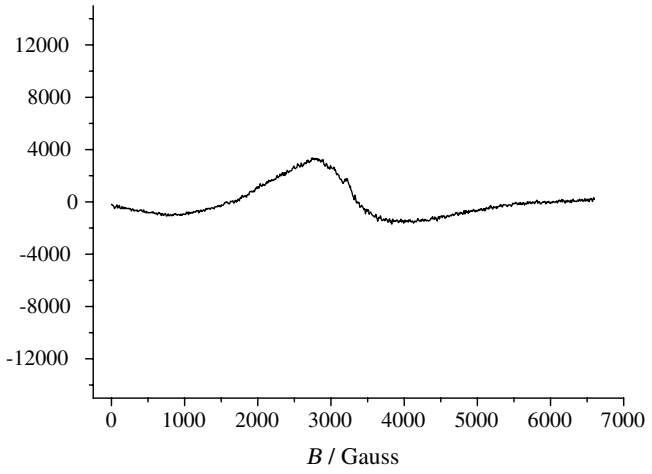

Fig. 6. EPR spectra of **1** determined at room temperature on a crystalline powder sample ($f = 9.4853$ GHz).

The X-band EPR spectra of the crystalline powder and ethanol solution of complex **2** were measured at room temperature and 110 K, as shown in Figs. 7 and 8. No detectable zero field splitting or half-filled signal were observed. Fig. 8 shows four lines with a nuclear hyperfine spin 3/2 due to hyperfine splitting. From the observed g and A values

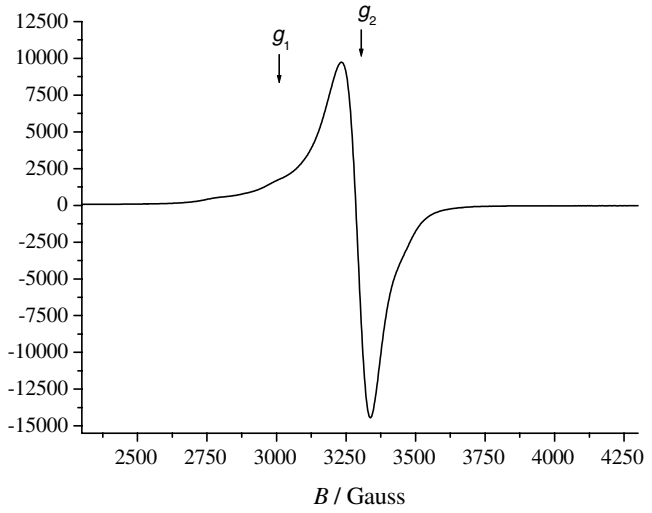

Fig. 7. EPR spectra of **2** determined at 110 K on a crystalline powder sample ($f = 9.4875$ GHz).

Table 4
Magneto-structural parameters for complex **1** and its analogs

Complex	Bond distance (Å)	Bond angle (°)	Coordination number	Magnetism data (J cm^{-1})
$[Ni_2L^{2,2}(CH_3COO)_2] \cdot 10H_2O$	3.005	95.6	six[a]	$J = 10.1$, $g = 2.15$ [19]
$[Ni_2L^{3,3}(\mu\text{-}O_2CCH_2NH_3)(H_2O)_2](ClO_4)_2 \cdot 2H_2O$	3.066	95.0, 92.6	six	$J = -1.1$, $g = 2.21$ [10]
$[Ni_2L(H_2O)_4](ClO_4)_2 4NH_2CONH_2$	3.100	99.5	six[a]	$J = -17.0$, $g = 2.15$ [10]
$[Ni_2(H_2L)(H_2O)_2Cl_2] \cdot 2H_2O$	3.10	101.5	six[a]	$J = -23$ [15]
$[Ni_2L(py)_2](ClO_4)_2$	3.206	105.7	five[a]	$J = -67.1$, $g = 2.24$ [10]
$[Ni_2L(H_2O)_2](ClO_4)_2 \cdot 0.5CH_3OH$	2.977	101.5, 101.1	four and six	$J = -0.9$, $g = 2.24$, this work

[a] Centrosymmetric.

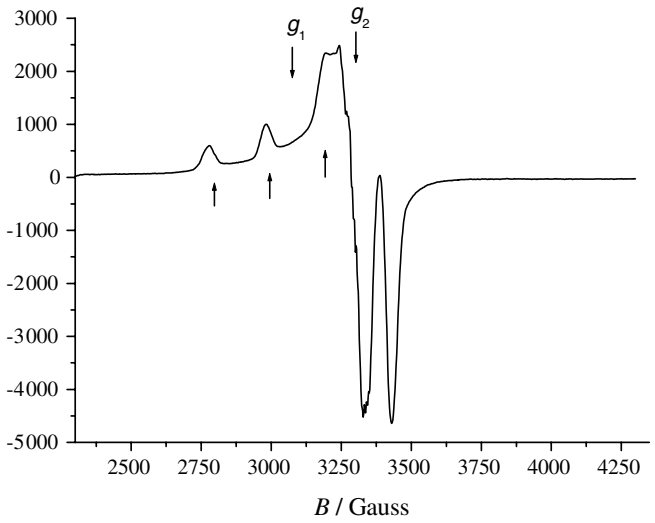

Fig. 8. EPR spectra of **2** determined at 110 K on an ethanol solution of the crystalline powder sample ($f = 9.4853$ GHz).

($g_{\parallel} = 2.20$, $g_{\perp} = 2.06$, $A_{\parallel} = 0.0188\ \mathrm{cm}^{-1}$ and $A_{\perp} = 0.0091$), it is evident that the unpaired electron predominantly occupies the $d_{x^2-y^2}$ orbital and the copper(II) ion is in a tetragonal pyramidal environment [21], which is in agreement with the crystal structure [13].

3. Conclusion

Three unsymmetrical macrocyclic complexes $[M_1M_2L]^{2+}$ (M_1M_2 = Ni Ni, Cu Zn, Cu Cd) have been obtained by adding triethylamine in the synthetic processes. Studies on the crystal structure and temperature-dependence of the magnetic susceptibility of complex **1** show that the two nickel(II) ions are located in square planar and octahedral centers with low spin and high spin electronic configurations, respectively. The results of ES-MS and cycle voltammograms show that the stability of the complexes decreases in the order CuZn > NiNi > CuCd. The R group is unlikely to change the coordination polyhedra for the dinuclear nickel(II) complex in the macrocyclic ligand (H_2L) described here.

Abstract

Reactions of the lithium or sodium salt, $[HC(CMeNDipp)_2]M$ (Dipp = 2,6-diisopropylbenzene, M = Li or Na), with PBr_3 or PCl_3 affords a series of phosphenium cations that were characterized in the solid state by X-ray crystallography. Solid-state analysis reveals that for compounds **1** and **2**, C–H activation of the ligand occurs and the phosphorus is bound to a nitrogen and carbon atom of the ligand. Compound **3** exhibits the more traditional nitrogen chelation of the ligand to the phosphorus atom.

1. Introduction

Research on β-diketiminato ligands (often abbreviated to nacnac = $[HC(CMeNDipp)_2]$ (Dipp = 2,6-diisopropylbenzene)) has increased dramatically over recent years [1]. The combination of these ligands with main group elements has afforded a series of low oxidation state compounds that often exhibit novel bonding arrangements [2].

Until recently, *NN′* chelation of the group 15 elements with β-diketiminato (nacnac) ligands remained uncharacterized. The research of Burford and Lappert [3] revealed that the preferred coordination mode of the phosphorous was at the γ-carbon (Fig. 1A).

Recently, Cowley et al. reported the first example of a phosphenium cation supported by *N*,*N′* chelation of a β-diketiminato ligand [4] (Fig. 1B) followed by a second report of a N–C bonded phosphenium cation [5] formed via C–H activation that shows structural similarity to our previous antimony studies [6] (Fig. 1C).

Herein we report the isolation of two N, C bonded phosphenium ions, compounds **1** and **2** and an *N*,*N′* coordinated phosphenium ion with an anionic arsenic counter-ion. Compounds **1** and **3** are prepared by a facile one pot synthesis that can be compared to the earlier more sophisticated methods [4,5]. Compound **2** is isolated in low yield but exhibits previously unobserved coordination of a rearranged β-diketiminato ligand with phosphorus(III) bromide.

2. Experimental

Solvents used were dried over sodium or potassium and degassed before use. All manipulations were performed under anaerobic conditions using standard Schlenk techniques. NacnacH and the corresponding lithium and sodium salts were prepared according to published procedures [7]. All other reagents were purchased from Aldrich and used as received.

3. Preparation of compound 1

A THF solution of nacnacNa (0.5 g, 1.13 mmol) was added dropwise at −78 °C to a stirred THF solution of PBr_3 (0.11 mL, 1.13 mmol). The resulting yellow solution was immediately removed from the dry-ice bath and allowed to warm to ambient temperature. Stirring was maintained overnight. Following the removal of THF in vacuo, the pale yellow solid was extracted in hexane and filtered. Concentration under reduced pressure of the hexane

3.1. Preparation of compound 2

NacnacLi (0.5 g, 1.18 mmol) had 1.1 equiv. of PBr_3 (0.11 ml, 1.3 mmol) added neat in the dry-box. An immediate reaction was observed. The yellow colored solid was dissolved in toluene and stirred over night. The reaction mixture was filtered from the lithium bromide. Concentration to ~5 ml followed by storage at room temperature for 5 days, yielded large yellow crystals of **2**. M.p. 144–148 °C Due to the low yield, no further spectroscopic data were obtained.

3.2. Preparation of compound 3

NacnacLi (0.5 g, 1.18 mmol) had 1.1 equiv. of PCl_3 (0.11 ml, 1.3 mmol) added neat in the dry-box. An immediate reaction was observed. The yellow colored solid was dissolved in THF, and cooled to −78 °C. $AsBr_3$ (0.37 g, 1.18 mmol), dissolved in THF, was added drop-wise. There was no observable color change and the resulting yellow colored solution was brought to ambient temperature and stirred overnight. Following the removal of THF in vacuo, the yellow solid was extracted in toluene. Concentration of the solution and storage at −5 °C afforded compound **3** in moderate yield (67%, based on PCl_3). M.p. 96–99 °C. ^1H NMR (C_6D_6, 25 °C): δ (ppm) 0.725 (d, 12H, CHMe*Me*′), 0.776 (d, 12H, CH*Me*Me′), 1.057 (m, 4H, C*H*MeMe′), 1.489 (s, 6H, CH_3 backbone), 5.746 (s, 1H, CH backbone), 6.788 (6H, H $_{aryl}$); ^{13}C NMR (C_6D_6, 25 °C): δ (ppm) 21.709 (*Me*–C_α), 23.391 (CHMe*Me*′), 26.925 (CH*Me*Me′), 28.791 (*C*HMeMe′), 92.959 (C_β), 117.953 (C_m), 118.392 (C_p), 139.036 (C_o), 147.458 (C–N), 197.545 (C_α); $^{31}P\{^1H\}$ NMR (C_6D_6, 25 °C): δ (ppm) 130. 243 (s).

4. Results and discussion

To a −78 °C THF solution of PBr_3, a THF solution of nacnacNa was added drop-wise (Scheme 1).

Following work-up of the reaction mixture in hexanes, compound **1** was isolated as colorless needles. (Crystal data for compounds **1** to **3** is given in Table 1.)

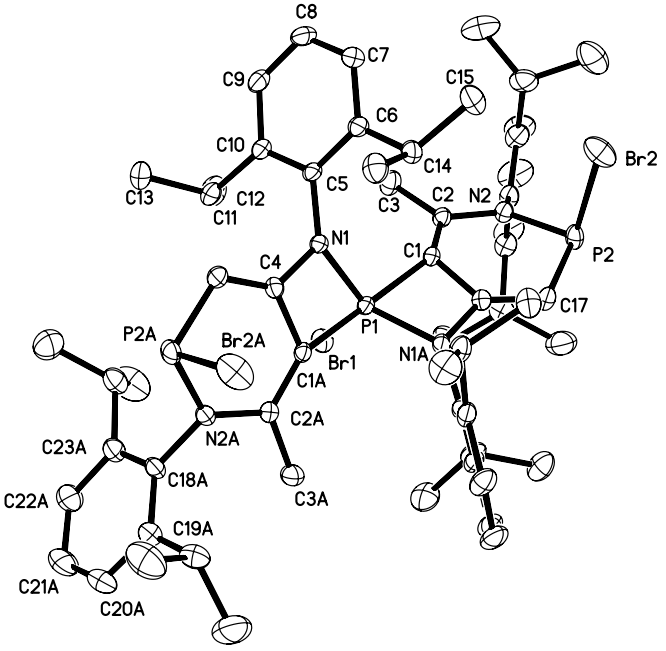

Fig. 3. ORTEP of compound **2**, the upper projection shows the asymmetric unit, and the lower, the full molecule. Thermal ellipsoids are shown at 30% probability; the two toluene molecules and hydrogen atoms are removed for clarity.

The unit cell parameters were determined and the data collected with a Bruker SMART diffractometer in $\theta/2\theta$ scan mode using graphite monochromatized molybdenum radiation ($\lambda = 0.7107$ Å). The data were corrected for absorption. The structure was solved by direct methods using the SHELXS-97 program [8] and refined [9] via full-matrix least squares. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions and were assigned thermal parameters equal to those of the atom to which they were bonded (see Table 1).

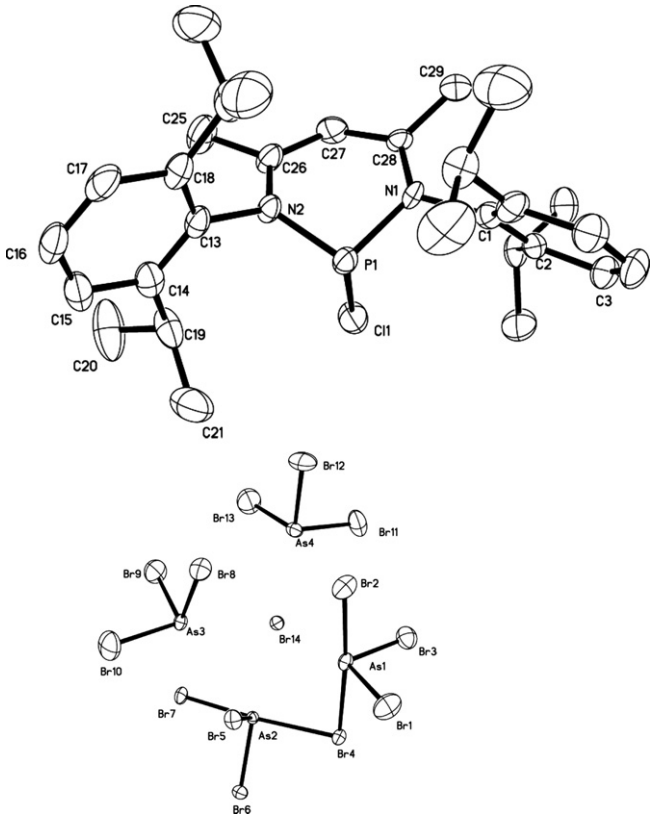
Single crystal X-ray analysis revealed that the backbone of the nacnac ligand in compounds **1** and **2** had undergone intramolecular C–H activation (Figs. 2 and 3). This is not a new phenomenon for these ligands, however, is usually associated with more reactive species, for example the early transition elements [10] and the nacnac compounds of the alkaline earth metals [2a]. The intramolecular C–H activation is thought to be attributed to the presence of the reactive P–X (X = halide) [11] and the reaction conditions. Compound **1** is analogous to (B) [5] (Fig. 1), and has remarkably similar bond lengths and angles. The major difference is the bromide counter-ion that sits at a distance of 4.675 Å from the cation phosphorus center. The closest interaction is 3.935 Å with the isopropyl group, (Table 2).

In the course of experimental work leading to the formation of compound **1**, compound **2** was isolated in low yield (Fig. 3). Given the interesting structural features of this molecule, we feel it noteworthy to report, (see Table 3).

Compound **2** was isolated from the reaction of solid nacnacLi with 1 equiv. of neat PBr_3 (*l*) added in the drybox. An immediate reaction was observed. Toluene was added to the solid, resulting in a yellow colored solution that was stirred overnight. Following filtration and concentration of the reaction mixture, yellow crystals were obtained of compound **2** after storage at room temperature for 12 h. The solid-state analysis of **2** is exhibited in Fig. 3. The P–N, and P–C bond lengths are slightly longer than observed in **1**, but indicate single bonds around the phosphorus center. The P–Br bonds show no noteworthy discrepancies. The geometry around the P(III) center is distorted trigonal pyramidal. The bond lengths of 1.339(3) and 1.384(3) Å between C(1)–C(2) and C(6)–C(7), respectively, are indicative of double bond character.

The exact mechanism that leads to formation of compounds **1** and **2** is unclear. From the repeated isolation of compound **1** this is assumed the primary product.

In order to elucidate the mechanism for formation of compounds **1** and **2**, numerous experiments were performed under varied conditions. Following the isolation of compound **2**, we believed that C–H activation occurred



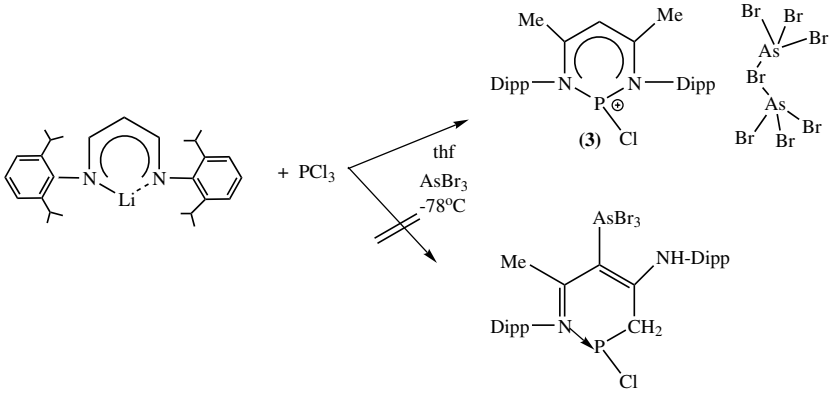


Fig. 4. ORTEP of compound **3**, thermal ellipsoids at 30% probability, hydrogen atoms are removed for clarity.

Scheme 2. Formation of compound **3** expected and obtained products.

Table 4
Selected bond lengths (Å) and angles (°) for compound **3**

P(1)–N(1)	1.742(9)

initially and then compound **2** resulted from subsequent activation of the γ carbon. To this end, the reaction of nacnacLi with PCl_3, was performed in a similar manner as described for compound **2**. Following addition of thf, the reaction mixture was cooled to −78 °C, and 1.2 equiv. of $AsBr_3$ were added drop-wise (Scheme 2).

It was anticipated that addition of $AsBr_3$, would lead to a product similar to that shown in Scheme 2. Instead, compound **3**, (Fig. 4) was isolated in moderate to high yield (68%), and could be obtained whether the initial reaction was performed in toluene or thf. It shows structural similarity to the *NN′*phosphenium cation discussed earlier reported by Cowley and co-workers [4]. Compound **3** crystallizes in the triclinic space group $P\bar{1}$, with two phosphenium cations present in the asymmetric unit. The charge is counterbalanced by the presence of an arsenic anion, $[As_2Br_7]^-$, and a free bromide ion, located between the anion and two neutral $AsBr_3$ molecules. The phosphorus atom sits in the pocket and is coordinated to two nitrogen atoms, the P–N bonds are very similar in length. Selected bond lengths and angles are given in Table 4.

5. Conclusion

Three phosphorus complexes derived from reactions with β-diketiminato ligands are described. Two of the reported structures compliment the existing published work of Cowley et al. Compound **2** reveals a novel arrangement of the C–H activated nacnac ligand. Further experimental efforts are underway to elucidate a more definitive mechanism.

Electronic structure of dinuclear iron nitrosyl complexes with different ligands at two iron centers

Maria Jaworska *

Institute of Chemistry, University of Silesia, Szkolna 9, 40-006 Katowice, Poland

Received 13 December 2006; accepted 2 March 2007
Available online 27 March 2007

Abstract

The electronic structures of three dinuclear iron complexes were determined with the DFT method. The complexes contain a $\{Fe(NO)_2\}^9$ unit and thiolate, nitrosyl, carbonyl and amine ligands at the second iron atom. The two iron atoms are bridged by thiolate ligands. In the lowest energy states of these complexes, the iron atoms possess spin $S = 1$, 3/2 or 5/2, depending on the coordinated ligands and their mutual arrangement. Nitrosyl is coordinated as NO^- antiferromagnetically coupled to iron, and the two iron units are antiferromagnetically coupled to each other.

Keywords: Iron; Carbonyl; Nitrosyl; DFT

1. Introduction

Iron nitrosyl complexes are studied as models for nitric oxide interaction with heme and non-heme enzymes [1–8]. Their potential use as NO delivery or absorbing agents in medicine is also widely investigated [9–13]. The electronic configuration of a metal–nitrosyl unit is described as $\{MNO\}^n$ in the Feltham–Enemark notation [14], where n stands for the number of d electrons on the metal center plus the one unpaired electron of the nitrosyl group. Because of the presence of an unpaired electron, nitric oxide can bind to a metal ion as a cationic, anionic or neutral ligand. The electronic structure of iron–nitrosyl complexes has also been studied by theoretical methods [15–19]. For many high-spin $\{FeNO\}^7$ complexes and iron enzyme centers, theoretical calculations and experimental data show antiferromagnetic coupling between the high-spin Fe(III) ion and NO^- ligand with spin $S = 1$ [15,16,18–21]. The electronic structure of nitrosyl–metal complexes is important from the point of view of their reactivity and photochemistry.

Sulfur ligands are low field ligands and they usually promote a high spin central atom in complexes. However, many five and six-coordinate both high-spin and low-spin iron–sulfur complexes are known [22–26]. This is also relevant for thiolate containing iron enzymes, which can occur in a low-spin (e.g. nitrile hydratase [27]) or high-spin (e.g. superoxide reductase [28]) electronic configuration. The low-spin state of a nitrile hydratase model complex was explained by the interaction of in-plane sulfur π orbitals with the iron d_{xy}, $d_{x_2-y_2}$ orbitals [23]. CO ligated iron centers show a strong preference for a low-spin configuration. This is pertinent to the low-spin and low oxidation states in iron hydrogenase enzyme, in which iron atoms are complexed by sulfur, carbonyl and cyanide ligands [29].

The aim of the present paper was to investigate the electronic structure of structurally similar dinuclear iron complexes with nitrosyl and carbonyl ligands with the use of the DFT method. We were interested in the character of Fe–NO and metal–metal bonding and at which metal center the unpaired electrons are placed in the case of non-singlet states. The influence of the ligand environment on the

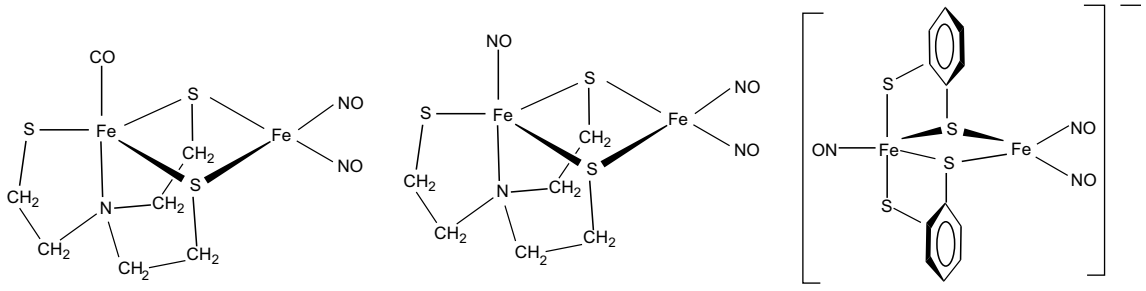
doi:10.1016/j.poly.2007.03.021

electronic structure of the investigated complexes was examined.



2. Calculational details

The calculations were carried out with the use of the GAUSSIAN03 program [30]. The geometry optimization was carried out with the DFT/BLYP method [31,32]. The 6-311G* basis set was employed in the calculations. The electronic structure of the investigated complexes was calculated with the unrestricted B3LYP method [33] (UB3LYP). In the case of singlet spin states the respective wave functions were obtained with the use of the STABLE keyword in the GAUSSIAN program.

3. Results and discussion

The investigated dinuclear complexes are models of the synthetic compounds $[Fe(NO)_2\{Fe(NS_3)(CO)\}$-S,S′], $[Fe(NO)_2\{Fe(NS_3)(NO)\}$-S,S′] [34] and $[(NO)Fe(S,S\text{-}C_6H_4)_2\text{–}Fe(NO)_2]^-$ [35], where NS_3 denotes the $N(CH_2CH^2S)_3^{3-}$ ligand (Scheme 1). The model complexes are presented in Fig. 1. In the models **1**–**3** the ethylene chains in NS_3 and the benzylidene group were replaced by hydrogen atoms at nitrogen and methyl groups at sulfur. All three complexes contain the $Fe(NO)_2$ unit. The second iron center is coordinated by carbonyl, nitrosyl, amine and thiolate ligands. It is interesting how a different ligand environment influences the electronic structure of such complexes. DFT calculations for the symmetric systems Roussin Red Salt ($Fe_2S_2(NO)_4^{2-}$) and Roussin Red Ester ($Fe_2SR_2(NO)_4$) showed that the two iron atoms are antiferromagnetically coupled to two NO^- ligands, and two such units are antiferromagnetically coupled to each other [18,19].

Complex **1** has an odd number of electrons and its effective magnetic moment is 2.91 μ_B at 293 K [34], which indicates that there is a spin equilibrium between the $S = 1/2$ and $S = 3/2$ states. **2** has a magnetic moment of 2.81 μ_B [34], indicating a triplet ground state, while **3** has a singlet ground state [36]. The geometries of all the complexes were optimized with the B3LYP and BLYP methods in the low-spin states (doublet for **1**, singlet for **2** and **3**). The BLYP optimized geometries for **1** and **3** are in good agreement with the experimental data, better than by the B3LYP method, and these geometries were used in the calculations of the electronic structure. The optimized geometrical parameters are gathered in Table 1. In the optimization, C_s symmetry was used for **1** and C_2 for **3**. As it can be seen from Table 1, the calculated geometrical parameters for **1** and **3** are in very good agreement with experimental data, although the Fe–S bond lengths are somewhat longer than the experimental ones. The geometry optimized for the singlet state of **2** was different from the experimental results, which is due to the fact that this is not the ground state. The optimization of the triplet state led to a much too long Fe–Fe distance (calculated 2.92 Å, versus experimental 2.766 Å), which did not agree with the crystal structure of **2**. Because of that, the experimental geometry was used for **2**. The same was found for the triplet state of **3**, where the optimization leads to a very long Fe–Fe distance of 3.357 Å, and for this reason the same geometry was used for the low-spin and high-spin states in the cal-

Scheme 1.

culations. Similarly, the same geometry was used for the low and high spin states of **2**. The problem of geometry optimization using the spin unrestricted DFT method was analyzed by Blasco et al. [37] for sulfur bridged dinuclear iron complexes. If there is a direct metal–metal bond in such a complex, the optimization leads to a much longer bond distance than the experimental one. This was explained by the fact that in the unrestricted spin wave function there is an admixture of a higher spin state which leads to bond elongation.

The electronic structures of **1**–**3** were calculated with the UB3LYP method. The B3LYP functional was used, since it was shown that it is able to reproduce correctly the ground spin states of iron sulfur complexes [38]. In Table 2 the energies, atomic charges and spin densities of the two lowest spin states of the investigated complexes are collected. One may note the large expectation values of the $\hat{S}^2$ operator and of atomic spin densities in Table 2. This is typical for the spin-unrestricted approach (broken-symmetry approach) where orbitals of different spin become localized on different parts of a molecule. This usually takes place in the case of weak metal–metal or metal–ligand bonds. In this way non-dynamical electron correlation is taken into account. In the broken-symmetry wave function spin densities different from zero are obtained, even for the singlet states. Spin densities of opposite sign on adjacent atoms indicate antiferromagnetic electron coupling. Such broken-symmetry calculations are used to study the electronic structure and magnetic properties of transition metal complexes [39–42].

From the UB3LYP wave functions the natural orbitals are generated for **1**–**3**. The natural orbitals are used, since they are more easy to analyze than the broken-symmetry molecular orbitals. Their occupation numbers are between 0 and 2. Selected natural orbitals are depicted in Figs. 2–4. The spin density plots from UB3LYP calculations for **1**–**3** are presented in Fig. 5, the relevant spin structures are depicted in Scheme 2.

3.1. Complex *1*

For **1**, the calculated doublet state has a lower energy than the quartet state of 10.2 kcal/mol (Table 2). The atomic charges on both iron atoms are positive in the doublet state, the Mulliken charge is more positive on Fe1, The NBO charge is smaller on Fe2. The charges on the nitrosyl ligands are negative. The spin densities on the iron atoms in the doublet state of **1** are of opposite sign, with a smaller absolute value on Fe1. There are large spin densities on the nitrosyls, of the opposite sign to the spin densities of the iron atom to which they are bound. The pictures of the natural orbitals of **1** in Fig. 2 show that the singly occupied orbital is d_{xy} of Fe1 (NO91). The d_{z_2} orbital of Fe1 is empty (NO99). The d_{yz} and d_{xz} orbitals of Fe1 (NO84, NO85) are doubly occupied as the result of donor–acceptor bonding with the carbonyl ligand. NO90 and NO92 are respective bonding and antibonding orbitals of the weak, antiferromagnetic metal–metal bond. The plots of spin densities and a schematic description of the electronic configurations are depicted in Fig. 5 and Scheme 2, respectively. Some negative spin density on CO can be noted from Table 2 and Fig. 5. Such spin densities on carbonyl ligands were also found in other iron complexes [43].

Complex **1** in the doublet state can be described as a $Fe^{2+}(S = 1)$ CO unit antiferromagnetically coupled to a $\{Fe(NO)_2\}^9(S = 1/2)$ unit. In $\{Fe(NO)_2\}^9$, the Fe^{3+} cation is antiferromagnetically coupled to two NO^- ligands, each with $S = 1$. The $\{Fe(NO)_2\}^9$ fragment has a similar electronic structure to Roussin Red Ester and Roussin Red Salt [18,19]. The mononuclear iron complex with NS_3 and CO ligands has a triplet spin state [35]. Calculations indicate that such a unit is antiferromagnetically bonded to the $\{Fe(NO)_2\}^9$ fragment in the dimeric complex.

The atomic charges and spin density values for the quartet state of **1** are similar but with one important difference, that is the spin densities on both irons are of the same sign, indicating ferromagnetic coupling of both units. It means

that in the quartet state, the two electrons engaged in the metal–metal bond are decoupled.

3.2. Complex *2*

For **2** the triplet state is lower in energy than the singlet state, in agreement with the experiment [34]. The calculated energy difference is 12.8 kcal/mol (Table 2). From the atomic spin density values and natural orbital plots presented in Fig. 3, the electronic structure of the triplet state can be described as a $Fe^{3+}(S = 5/2)NO^{-}(S = 1)$ unit with a spin state $S = 3/2$ antiferromagnetically coupled to a $\{Fe(NO)_2\}^9$ unit of spin 1/2 (see Scheme 2). The resulting spin state of the molecule is $S = 1$, two unpaired electrons

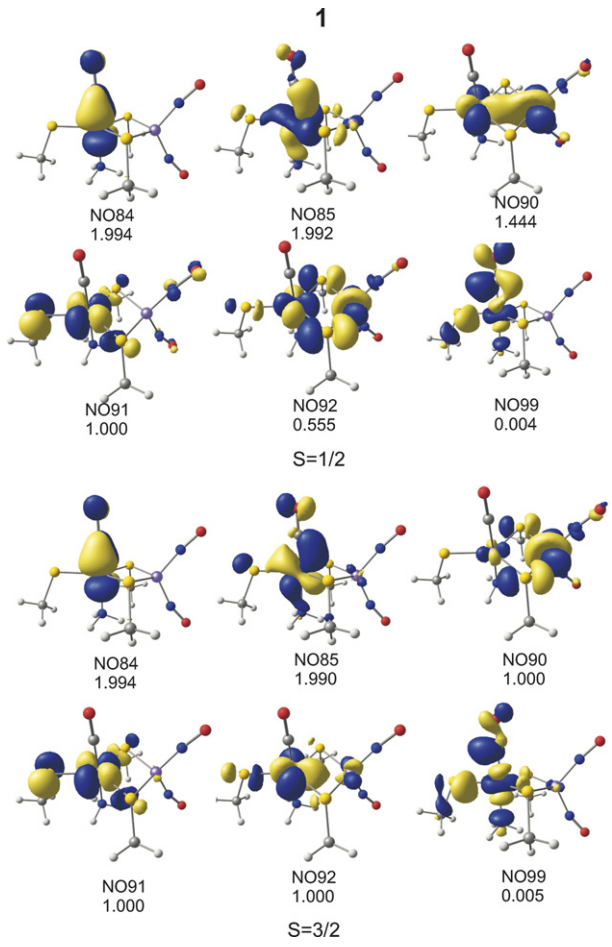

Fig. 2. Selected natural orbitals and their occupation numbers of **1**.

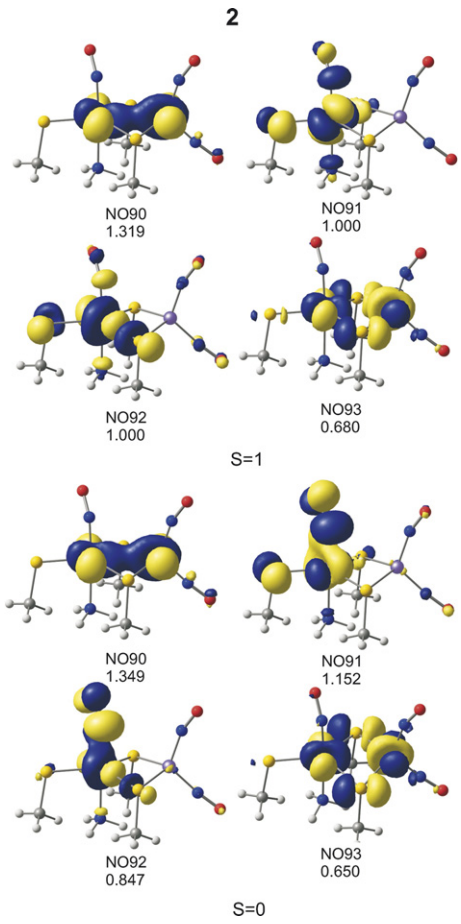

Fig. 3. Selected natural orbitals of **2**.

are placed in the d_{xy} and d_{z_2} orbitals of Fe1 (NO91 and NO92 in Fig. 3), which are rotated to avoid interaction with the electron density of axial ligands at Fe1. The absolute value of spin density on Fe1 is larger than that on Fe2 (Table 2), since the d_{xy}, d_{z_2} electrons are not engaged in forming any bonds. The mononuclear complex of iron with NO and NS_3 is also known [35], and it possesses three unpaired electrons. Antiferromagnetic coupling between Fe^{3+} and NO^- is suggested for this complex [35]. This agrees with the results of the present calculations, according to which the $Fe(NO)(NS_3)$ unit with $S = 3/2$ is antiferromagnetically coupled to the $\{Fe(NO)_2\}^9$ unit with $S = 1/2$.

The energetically higher singlet state of **2** may be described as possessing an intermediate $S = 3/2$ spin state Fe1 center, where two unpaired electrons on the d_{xy}, d_{z_2} (NO91, NO92) orbitals are coupled to the singlet state, as can be seen in Fig. 3. In addition these two natural orbitals contain a large admixture of nitrosyl orbitals.

3.3. Complex *3*

The calculated low energy state of **3** is a singlet, which is in accordance with the experimental data [36]. The triplet state is higher in energy by 11.2 kcal/mol (Table 2). In the singlet state, the d_{yz} orbital on Fe1 (NO90 in Fig. 4) is doubly occupied, and the d_{z_2} orbital is empty (NO107).The fact that the d_{z_2} orbital is unoccupied is a result of avoiding electrostatic repulsion with the electron density from the axial thiolate ligands on Fe1. In **2** there is an amine ligand in the axial position (modelled by ammonia) whose electron density is much more compact, which reduces the repulsing interaction. In the triplet state both these orbitals are singly occupied (NO99 and NO100). On the basis of the natural orbital occupancy and atomic spin densities and charges from Table 2, the electronic structure of **3** can be described as $Fe^{3+}(S = 3/2)NO^-(S = 1)$ with spin 1/2, antiferromagnetically coupled to $\{Fe(NO)_2\}^9$, which results in a total spin of the molecule of $S = 0$. The magnetic measurements also indicate that the two iron atoms are antiferromagnetically coupled [36].

The spin densities and charges in **3** show antiferromagnetic coupling of NO^- to Fe1, which is also visible in the spin density drawings in Fig. 5. This is atypical, as the NO1 ligand has a linear arrangement, which is often considered as an indication of NO cationic character, and the bent NO group as NO^- or $NO^{\cdot}$. However in the octahedral, high-spin $\{FeNO\}^7$ configuration the bending may result from avoiding repulsion between the electron on the d_{z_2} orbital of Fe and on π^* orbitals of NO. In complex **3** the

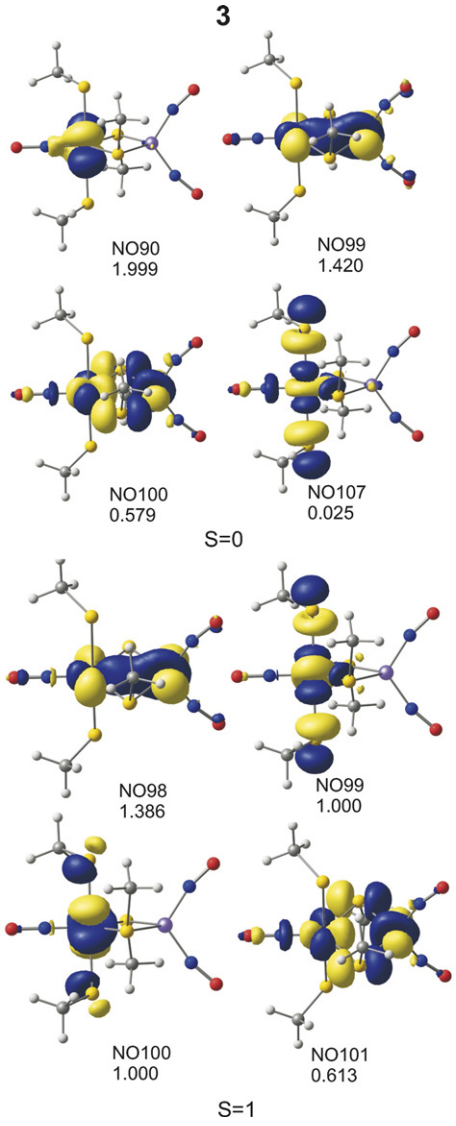

Fig. 4. Selected natural orbitals of **3**.

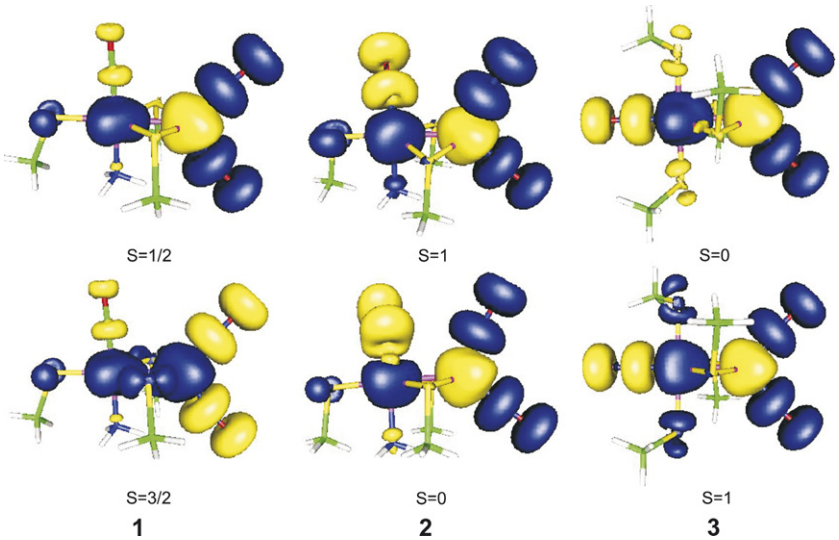
iron *d* orbital placed along the Fe1–NO1 axis, $d_{x_2-y_2}$, (NO99) has its maximum value directed towards Fe2, to form weak antiferromagnetic bonding with a similar orbital on Fe2. As a result, the interaction of this electron with electrons on NO1 is reduced. On the other hand, in may be noted that the negative charge and spin densities on NO1 are somewhat smaller than those on NO2 and NO3.

The triplet state of **3** is higher in energy (Table 2). Fig. 4 shows that the singly occupied orbitals are d_{z_2} and d_{yz} (NO99, NO100) on Fe1, hybridized to avoid a repulsive interaction with the electron density of sulfur atoms S3 and S4.

The low energy states are correctly determined by the B3LYP method for **1**, **2** and **3**. The three complexes **1**–**3** are examples of dinuclear iron compounds with nitric oxide and thiolate ligands. In each of them, two iron atoms are antiferromagnetically bonded. The electronic structure of the $\{Fe(NO)_2\}^9$ fragment is basically the same in all three complexes. In the low energy state the Fe1 cation exists in the $S = 1$ (**1**), $S = 5/2$ (**2**) or $S = 3/2$ (**3**) spin state. In **1** the CO ligand, which is a strong π-acceptor, causes the low-spin state of Fe1. The other ligands and the mutual position of the thiolate ligands also influence the spin state of Fe1 in **2** and **3**.

The interesting difference between **1** and **2**, **3** is that in the high-spin state the two iron atoms are ferromagnetically coupled in **1**, in contrast to **2** and **3** where antiferromagnetic coupling between the two iron atoms exists in the low and high-spin states, which means that in the two latter complexes the change in Fe1 configuration is energetically easier than in **1**. In **2** and **3** the low-spin–high-spin transition is related to one iron atom (Fe1). It shows that in polynuclear iron complexes, both one-center spin transitions and two-center antiferromagnetic–ferromagnetic transitions are possible, which one is more facile depends on the ligand environment of the iron atoms. Such flexibility in the electronic structure change as a result of the



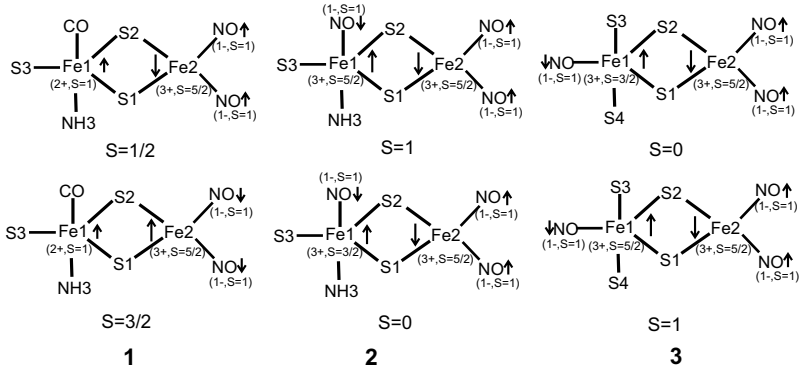


Fig. 5. Spin density plots for **1**–**3**.

Scheme 2.

dependence on the attached ligands is why iron can be used in many enzymes performing diverse biological functions.

4. Conclusions

The electronic structures of three dinuclear iron complexes containing the $\{Fe(NO)_2\}^9$ unit have been determined with the DFT method. The second iron atom is coordinated by carbonyl, nitrosyl, thiolate and amine ligands. The two iron atoms are bridged by thiolate ligands. According to the calculations the low-spin–high-spin transition in the carbonyl complex is related to an antiferromagnetic–ferromagnetic coupling change between the iron atoms, while in the nitrosyl complexes it is the low-spin–high-spin one iron center change. The total spin state of the investigated complexes depends on the coligands (amine, thiolate) and their mutual arrangement.

Abstract

The polymer–copper(II) complex samples, $[Cu(phen)(L\text{-}Thr)(BPEI)]ClO_4 \cdot 2H_2O$ (L-Thr = L-theronine, phen = 1,10-phenanthroline and BPEI = branched polyethyleneimine), with varying degrees of copper(II) chelate content in the polymer chain, were prepared by ligand substitution method in water–ethanol medium and characterized by Infra-red, UV–Vis, EPR spectral and elemental analysis methods. The binding of these complex samples with calf thymus DNA (CT-DNA) has been investigated by absorption spectroscopy and emission spectroscopy and gel electrophoresis techniques. The experimental results indicate that the polymer–copper(II) complex is an avid DNA binder and the binding constant increased with the increase in amount of copper(II) chelate content in the polymer chain. Besides the electrostatic interaction between a negatively charged DNA molecule and a positively charged polymer–copper(II) complex molecule, other binding modes, such as van der Waals interaction, hydrogen bonding and partial intercalation binding modes may also exist in this system. A sample of polymer–copper(II) complex was tested for its antibacterial and antifungal activity and it was found to have good antibacterial and antifungal activities.

Keywords: Polymer–copper(II) complexes; L-Theronine; 1,10-Phenanthroline; DNA binding

1. Introduction

The interaction of transition metal complexes with DNA has long been the subject of intense investigation in relation to the development of new reagents for biotechnology and medicine [1–3]. In these complexes, metal or ligands can be varied in an easily controlled way to facilitate the individual applications. There are several types of sites in the DNA molecule where binding of metal complexes can occur: (i) between two base pairs (intercalation), (ii) in the minor groove, (iii) in the major groove, and (iv) on the outside of the helix [4].

Copper(II) complexes have been found to be possible medical uses in the treatment of many diseases including cancer [5]. Among the various copper complexes so far investigated, those containing phenanthroline and its derivatives have attracted much attention for their various biological activities such as anticandida [6], antimycobacterial [7] and antimicrobial [8] activities. Amino acids are the basic structural units of proteins that recognize a specific base sequence of DNA. Metal complexes with amino acid ligands are involved in the exchange and transport mechanisms of trace metal ions in the human body [9]. Copper complexes containing amino acids have been studied as models for the behaviour of copper enzymes [10] and some copper complexes with amino acid ligands were reported to exhibit potent antitumor and artificial nuclease activities [11,12].

Significant developments have occurred in recent years in the field of biopolymers and biomaterials. Especially interesting are the investigations of

doi:10.1016/j.poly.2007.03.001

pharmacologically active compounds as drugs or carriers for normal pharmaceutical agents [13–15]. Drug–polymer conjugates are potential candidates for the selective delivery of anticancer agents to tumor tissues [16] and only a very few reports are available for the use of polymer–metal complexes as anticancer drugs [17]. Polyethyleneimine (PEI) is a cationic polymer exhibiting the highest positive charge density potential [18] and recently PEI has appeared as a possible alternative to viral and liposomal routes of gene delivery [19]. PEI possesses quite a number of advantages as polymer chelating agent, such as good water solubility, high content of functional groups and good physical and chemical stability and suitable molecular weights [20]. Recently we have reported some interesting results on the various interacting natures of some surfactant-metal and polymer-metal complexes with DNA [21,22].

In this paper, we have reported the synthesis of some novel water-soluble polymer (PEI)–copper(II) complex samples (containing both 1,10-phenanthroline and L-theronine ligands) with varying degrees of copper(II) complex content in the polymer chain. The binding properties of these complexes to calf thymus DNA have been carried out using different physico-chemical methods and the binding modes are discussed. The experimental results show that these polymer–copper(II) complex samples can be candidates for DNA-binding reagents, as well as laying the foundation for the rational design of new useful DNA probes. We have also reported the antimicrobial activities of a sample of polymer–copper(II) complex against Gram +ve and Gram −ve bacteria and fungus.

2. Experimental

2.1. Materials

Calf thymus DNA and branched polyethyleneimine (BPEI) (M_w ca. 25000) were obtained from Sigma-Aldrich, Germany, and were used as such. Copper(II) chloride dihydrate, 1,10-phenanthroline were purchased from Merck, India and L-threonine was obtained from Loba Chemie, India. The spectroscopic titrations were carried out in the buffer (50 mM NaCl–5 mM Tris–HCl, pH 7.1) at room temperature. A solution of calf thymus DNA in the buffer gave a ratio of UV absorbance at 260 and 280 nm of ~1.8–1.9:1, indicating that the DNA was sufficiently free of protein [23]). Plasmid pBR322 DNA was purchased from Genei, India. Milli-Q water was used to prepare the solutions. The complex, [Cu(phen)(L-Thr)(H_2O)]ClO_4, was prepared as reported earlier [24].

2.2. Physical measurements

The carbon, hydrogen and nitrogen contents of samples were determined at SAIF, Lucknow, India. Absorption spectra were recorded on a UV–Vis–NIR Cary300 Spectrophotomer using cuvettes of 1-cm path length, and emission spectra were recorded on a JASCO FP 770 spectrofluorimeter. FT-IR spectra were recorded on a FT-IR Perkin Elmer spectrophotometer with samples prepared as KBr pellets. EPR spectra were recorded on Varian E-112 EPR spectrometer at room temperature and at LNT (77 K), the field being calibrated with diphenylpicryl hydrazyl (DPPH, $g = 2.0037$) at SAIF, I.I.T., Chennai, India. Electrochemical measurements were made on a Princeton EG and G-PARC model potentiostat. A three-electrode system comprising a glassy carbon working electrode, a platinum wire auxillary electrode and a saturated calomel reference (SCE) electrode was used for voltammetric work. The buffer (5 mM Tris–HCl/50 mM NaCl, pH 7.2) solution was used as supporting electrolyte. The antimicrobial screening studies were carried out at Pharmaceutical laboratory, Periyar College of Pharmaceutical Sciences, Tiruchirappalli, India and the bacteria and fungus species were obtained from National Chemical Laboratory (NCL), Pune, India.

2.3. Synthesis of polymer–copper(II) complexes

To a solution of 0.15 g of BPEI dissolved in 15 mL of ethanol, 1.5 g of [Cu(phen)(L-Thr)(H_2O)]ClO_4 in 15 mL of water was added slowly with stirring. The mixture was heated between 50 and 60 °C for 6–12 h in a water bath. After being warmed enough, the dark blue coloured mixture was filtered and the filtrate was dialyzed against cold water for days together. Afterwards the solvent was evaporated by a rotary evaporator under reduced pressure at room temperature. A dark bluish filmy substance was obtained. This was pulverized and dried. Yield, 0.25 g. (*Anal*. Calc.: C, 39.94; H, 8.05; N, 18.23. Found: C, 39.94; H, 8.20; N, 18.59% and $x = 0.203$ (where x is the degree of coordination)). The other polymer–copper(II) complex samples with various degrees of coordination were synthesised with slight modifications, like changing the concentration of reagents, and the reaction time, in the experimental procedure.

2.4. DNA-binding experiments

The DNA-binding experiments were performed at 30.0 ± 0.2 °C. The DNA concentration per nucleotide was determined by electronic absorption spectroscopy using the known molar extinction coefficient value of 6600 M^{-1} cm^{-1} at 260 nm [25]. Absorption titration experiments of polymer–copper(II) complexes in buffer (50 mM NaCl–5 mM Tris–HCl, pH 7.1) were performed by using a fixed complex concentration to which increments of the DNA stock solutions were added. Polymer–copper(II) complex–DNA solutions were allowed to incubate for 10 min before the absorption spectra were recorded.

For fluorescence quenching experiments DNA was pretreated with ethidium bromide (EB) for 30 min. The polymer–copper(II) complexes were then added to this mixture and their effect on the emission intensity was measured.

Samples were excited at 450 nm and emission was observed between 500 and 700 nm.

For the gel electrophoresis experiments, supercoiled pBR322 DNA (0.1 μg) was treated with the polymer–copper(II) complex in 50 mM Tris–HCl, 18 mM NaCl buffer, pH 7.2. The samples were electrophoresed for 3 h at 50 V on a 0.8% agarose gel in Tris–acetic acid–EDTA buffer. The gel was stained with 0.5 μg/mL of ethidium bromide and photographed under UV light.

2.5. Microbial assay

The in vitro antimicrobial screening of the polymer–copper(II) complex ($x = 0.203$) was tested for its effect on certain human pathogenic bacteria and fungus by disc diffusion method. The complex was stored dry at room temperature and dissolved in DMSO. Both the Gram + (*Staphylococcus aureus*, *Bacillus subtilis*) and Gram – (*Escherichia coli*, *Pseudomonas aeruginosa*) bacteria were grown in nutrient agar medium and incubated at 37 °C for 48 h followed by frequent subculture to fresh medium and was used as test bacteria. The fungi *Candida albicans* grown in sabourad dextrose agar medium were incubated at 27 °C for 72 h followed by periodic subculturing in fresh medium and were used as test fungus. Then the petriplates were inoculated with a loop full of bacterial and fungal culture and spread throughout the petriplates uniformly with a sterile glass spreader. To each disc the test samples (10 ppm) and reference ciprofloxacin (1 μg/disc for bacteria) or clotrimazole (10 μg/disc for fungus) were added with a sterile micropipette. The plates were then incubated at 35 ± 2 °C for 24–48 h and 27 ± 1 °C for bacteria and fungus, respectively. Plates with disc containing respective solvents served as control. Inhibition was recorded by measuring the diameter of the inhibitory zone after the period of incubation. All the experiments were repeated thrice and the average values were presented.

3. Results and discussion

3.1. Degree of coordination

The structure of the polymer–copper(II) complex is shown in Fig. 1. In this figure 'x' represents degree of coordination. The degree of coordination, (x), means the number of moles of copper(II) chelate per mole of the repeating unit (amine group) of polymeric ligand. If all the repeating units (amine groups) in the polymer are coordinated to copper, then the value of x is 1. The degree of coordination, (x), of the copper chelate in the polymer–copper(II) complex was calculated either from the carbon content [26,27] or copper content [28]. The degree of coordination (x) thus obtained for the polymer–copper(II) complexes synthesised are 0.141, 0.169 and 0.203. Even if the copper chelate was added in large excess or the reaction mixture was warmed for more than 10 h, we could not obtain polymer–copper(II) complex sample with degree of coordination more than 0.203. This may be ascribed to the steric hindrance between metal complex units in the polymer chain which prevents further coordination [26].

3.2. Spectral and electrochemical characterization

In the IR region, the bands around 1518 cm^{-1} and 1425 cm^{-1} can be attributed to the ring stretching frequencies [ν(C=C) and ν(C=N)] of 1,10-phenanthroline [24]. The IR values, δ (C–H) 853 cm^{-1} and 737 cm^{-1} observed for phenanthroline are red shifted to 849 cm^{-1} and 725 cm^{-1}. These shifts can be explained by the fact that each of the two nitrogen atoms of phenanthroline ligands donate a pair of electrons to the central copper metal forming a coordinate covalent bond [29]. The bands around 2925 cm^{-1} can be assigned to C–C stretching vibration of aliphatic CH_2 of BPEI. The broad band observed around 3428 cm^{-1} is assigned to the N–H stretching of BPEI [20] and the band around 1091 cm^{-1} has been assigned to ν(Cl–O) of perchlorate anions [24].

In the UV–Vis region, the intense absorption bands appeared from 200 to 300 nm are attributed to intraligand transitions. Another band which appeared around 638 nm is assigned to ligand field transitions.

The solid state EPR spectra of the polymer–copper(II) complex ($x = 0.203$) was recorded in X-band frequencies at room temperature as well as in frozen solution (77 K) (Fig. 2). At room temperature the complex exhibits well defined single isotropic feature near $g = 2.053$. Such isotropic lines are usually the results of intermolecular spin exchange, which broaden the lines. This intermolecular

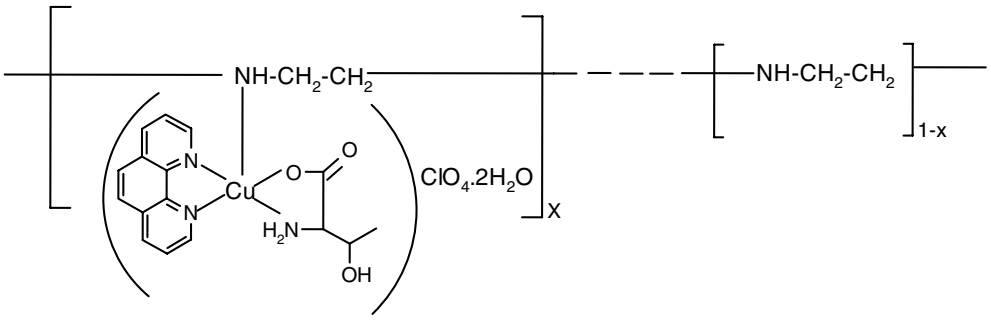

Fig. 1. Structure of [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ ($x = 0.203$, where x is the degree of coordination).

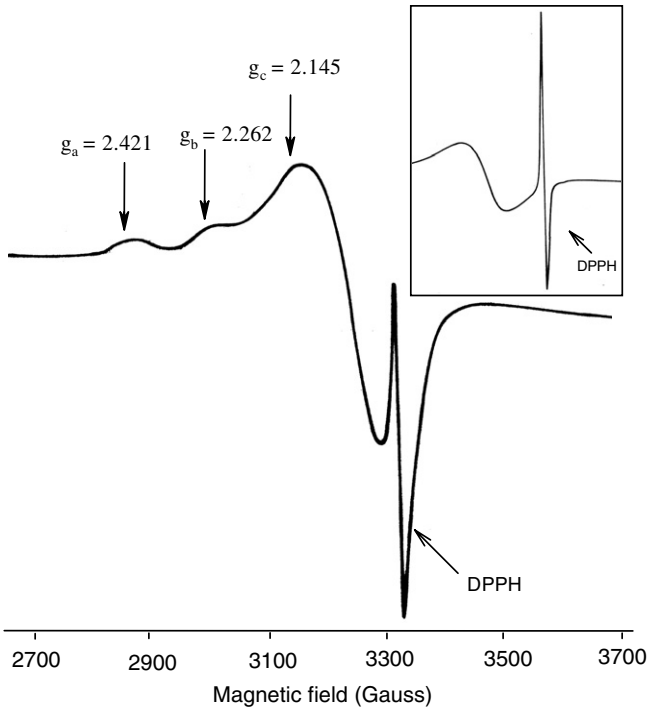

Fig. 2. EPR spectrum of [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ ($x = 0.203$) in DMSO at liquid nitrogen temperature (Inset: solid state EPR spectrum at room temperature).

type of spin exchange is caused by the strong spin coupling which occurs during a coupling of two paramagnetic species.

At 77 K we observed three peaks with the third being broad. This is because the copper complex units have been mounted on a polymer chain resulting in some spin–spin coupling between the copper complex units which leads to a small amount of broadening.

The cyclic voltammogram of the polymer–copper(II) complex ($x = 0.203$) in Tris–HCl buffer is shown in Fig. 3. The complex displays a quasireversible cyclic voltammetric response which can be assigned to the Cu(II)/Cu(I) couple. The cathodic peak potential (E_{pc}) and the anodic peak potential (E_{pa}) are −253.98 and −11.28 mV, respectively. The separation of the anodic and cathodic peak potentials (ΔE_p) is 242.7 mV. The formal peak potential, $E_{1/2}$, taken as the average of E_{pa} and E_{pc}, is −0.133 V.

3.3. DNA binding studies

3.3.1. Electronic spectral studies

Electronic absorption spectroscopy was an effective method to examine the binding mode of DNA with metal complexes [30–32]. In general, hypochromism and red-shift are associated with the binding of the complex to the helix by an intercalative mode involving strong stacking interaction of the aromatic chromophore of the complex between the DNA base pairs. Fig. 4 shows the UV absorption spectra of polymer–copper(II) complex ($x = 0.203$) in the absence and presence of DNA. In the ultraviolet region

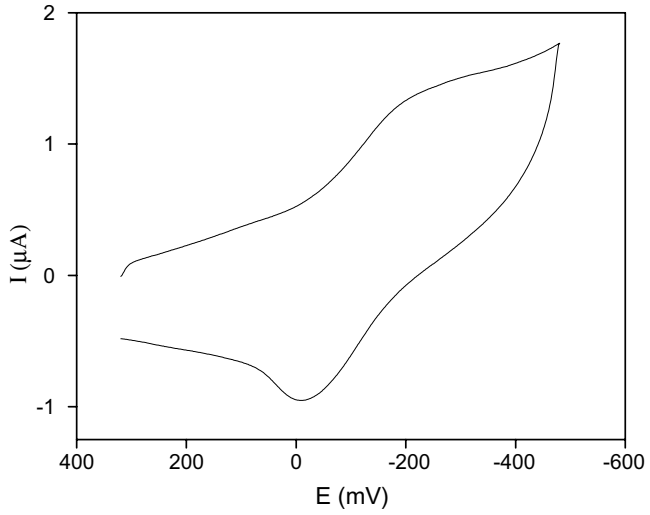

Fig. 3. Cyclic voltammogram of [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ ($x = 0.203$), 5 mM) in buffer containing 50 mM NaCl–5 mM Tris–HCl, pH 7.2. Scan rate: 100 mV s^{-1}.

from 200 to 300 nm, the complex had strong absorption peaks at 272 nm, besides a shoulder band around 294 nm. The absorption intensity of the polymer–copper(II) complex sample increased (hyperchromism) evidently after the addition of DNA, which indicated the interactions between DNA and the complex.

The polymer–copper(II) complex can bind to the double stranded DNA in different binding modes on the basis of their structure and charge and type of ligands. As DNA double helix possesses many hydrogen bonding sites which are accessible both in the minor and major grooves, it is likely that the amine groups of polyethyleneimine and –OH groups of L-theronine ligand in the copper(II) complex form hydrogen bonds with DNA, which may contribute to

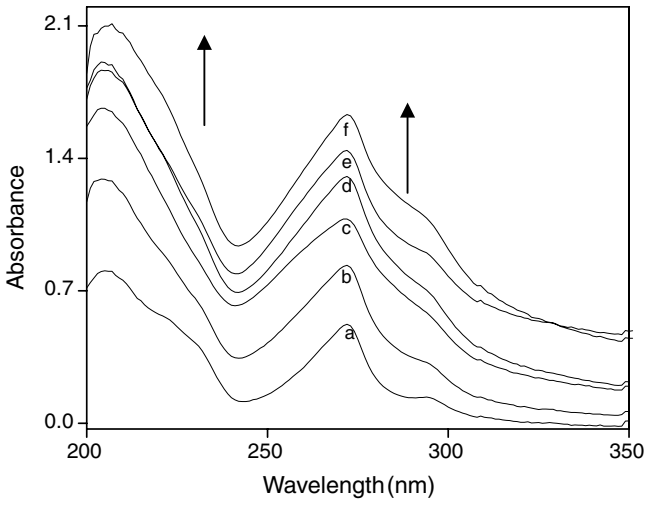

Fig. 4. Absorption spectra of [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ ($x = 0.203$) in the absence (a) and in the presence of increasing amounts of DNA (b–f), [Complex] = 12 μM, [DNA] = 0.2–1 μM. Arrow shows the absorbance changes upon increasing DNA concentrations.

the hyperchromism observed in the absorption spectra. On the other hand, our polymer–copper(II) complex, which possesses several methylene groups of the branched polyethyelene (BPEI) can bind to DNA by van der Waals interactions between the methylene groups and the thymine methyl groups [33] . The hyperchromic effect may also be due to the electrostatic interaction between positively charged polymer (BPEI) and the negatively charged phosphate backbone at the periphery of the double helix CT DNA [34]. In our complex, the copper(II) chelates are randomly coordinated to the branched polymer, hence complete intercalation of the phenanthroline ligand between a set of adjacent base pairs is sterically impossible, but some type of partial intercalation can be envisioned [35]. But this needs further clarification of the DNA binding mode of the complex by viscosity measurements. But as our copper complexes are polymeric and DNA being another polymer we were not able to use viscosity method, because changes in the structure of these polymer systems would change the viscosity. It is almost impossible to resolve the changes in the viscosity behaviour.

Determinations of intrinsic binding constants, K_b, based upon these absorption titrations may be made with the following equation [4]:

$$[\mathrm{DNA}]/(\varepsilon_a - \varepsilon_f) = [\mathrm{DNA}]/(\varepsilon_b - \varepsilon_f) + 1/K_b(\varepsilon_b - \varepsilon_f),$$

where [DNA] is the concentration of DNA in base pairs, ε_a, ε_f and ε_b correspond to A_{obsd}/[total copper complex units], the extinction coefficient of the free polymer–copper(II) complex and the extinction coefficient of the complex in the fully bound form, respectively. A plot of [DNA]/$(\varepsilon_a - \varepsilon_f)$ versus [DNA], gives K_b as the ratio of the slope to the intercept (Fig. 5). The K_b values of polymer–copper(II) complexes, thus obtained with different degrees of coordinated copper(II)-chelates are shown in Table 1. As reflected in the K_b values, the significant difference in DNA binding affinity of polymer–copper(II) complexes with different copper(II) complex chelates can be understood as a result of the fact that the polymer–copper(II) complex with higher degree of copper(II) chelate binds strongly with DNA. This may be due to the high positive charges and large number of copper(II) chelates present in the complex which cooperatively act to increase the overall binding ability of the polymer–copper(II) complex molecule to DNA. The K_b values obtained for our polymer–copper(II) complex samples are very much higher than those for any other known simple mononuclear or binuclear copper(II) complexes including complexes such as $[Cu_2phen_2Cl_4]$ (K_b, 4.75×10^4 M^{-1}) [36], $[Cu(phen)_2Cl_2]$ (K_b, 2.70×10^3 M^{-1}) [37] and $[Cu(phen)(L\text{-}Thr)(H_2O)]ClO_4$ (K_b, 6.35×10^3 M^{-1}) [24].

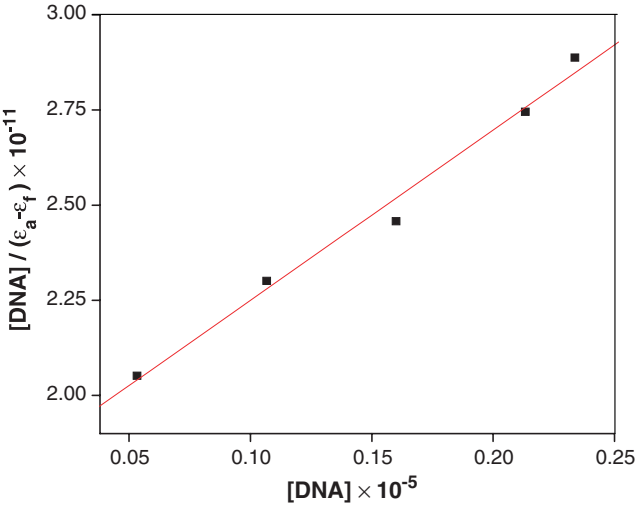

Fig. 5. Plot of [DNA]/$(\varepsilon_a - \varepsilon_f)$ vs. [DNA].

Table 1
The intrinsic binding constants (K_b) of $[Cu(phen)(L\text{-}Thr)(BPEI)]\text{-}ClO_4 \cdot 2H_2O$ with calf thymus DNA

Degree of coordination (x)	K_b (M^{-1})
0.141	1.32×10^5
0.169	1.78×10^5
0.203	2.48×10^5

3.3.2. Fluorescent spectral studies

No fluorescence was observed for the polymer–copper(II) complex samples either in aqueous solution or in the presence of calf thymus DNA. So the binding of polymer–copper(II) complex samples with DNA cannot be directly presented in the emission spectra. So the binding of polymer–copper(II) complex samples to CT-DNA have been studied by competitive ethidium bromide (EB) binding experiments. The molecular fluorophore, EB, is known to show intense fluorescence light when bound to DNA, due to its strong intercalation between the adjacent DNA base pairs [38]. In earlier literature, it was reported that the fluorescent light of EB–DNA system can be reduced by the addition of a second molecule [39], indicating the competition of second molecule with EB in binding to DNA. Recently Ni et al. [40] found that fluorescence reduction of fluorophore NR (neutral red dye) in the presence of DNA by $Cu(phen)^{2+}$ may be due to the replacement of the DNA intercalator, NR. This means that the complex interacts with the same site as NR does. Zhang et al. [36] also indicate that a binuclear copper(II) complex of 1,10-phenanthroline ligand competitively binds to the EB–DNA system by intercalation. On the other hand, Bronich et al. [41] have reported that the addition of a pure organic copolymer (i.e. polyethyleneglycol–polyethyleneimine (PEI)) to EB–DNA complex results in quenching of the fluorescence due to the displacement of EB by the copolymer. Xiao et al. [34] have studied the effect of polymeric schiff base–nickel complexes on the fluorescence of EB–DNA system and they suggested that a portion of the metal complex, possessing a planar aromatic moiety, intercalates to adjacent base pairs, which inhibits EB binding to calf thymus DNA competitively. In our studies the addition of the polymer–copper(II) complexes to DNA pretreated with EB causes appreciable reduction in the emission

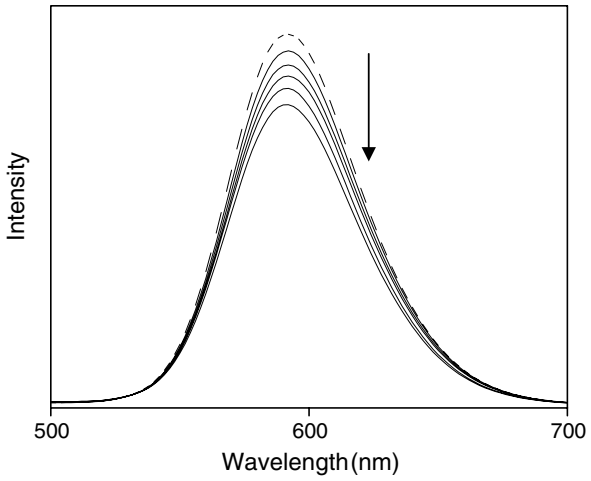

Fig. 6. Emission spectra of EB bound to DNA in the absence (---) and in the presence of [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ (—) ($x = 0.203$), [EB] = 4 μM, [DNA] = 4 μM, [Complex] = 0–4 μM.

intensity (Fig. 6), indicating that the replacement of the EB fluorophore by the polymer–copper(II) complex, results in a decrease in the emission intensity. The polymer–copper(II) complex with higher degree of coordination has lead toa large reduction in emission intensity in the presence of DNA. This may be due to the larger number of copper(II) chelates present in the polymer chain, which hinder intercalation of EB into DNA and thus decreasing the binding ability between EB and calf thymus DNA.

3.3.3. Gel electrophoresis studies

Preliminary results from the absorption and fluorescence spectral studies show that the polymer–copper(II) complex with high copper(II) chelate content binds strongly to DNA. Binding of this complex with DNA was also studied by gel electrophoresis using plasmid pBR 322 DNA. This DNA moves on agarose gel under the influence of electrical field. This movement is retarded when they are bound to other molecules.

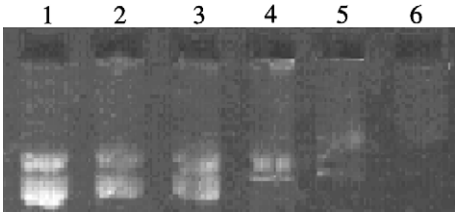

Fig. 7. Gel retardation behaviour of pBR322 DNA by [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ ($x = 0.203$). Lane 1: DNA alone, Lanes 2–6: DNA + polymer–copper(II) complex in the concentration of 20, 30, 40, 50 and 60 μM.

Many polycationic organic polymer molecules interact with DNA through electrostatic interactions between phosphate groups of the DNA and oppositely charged groups of polymer [42,43,18]. Forrest et al. [44] and Vinogradov et al. [45] have reported that the organic polymer, polyethyleneimine (PEI), retards the DNA migration in agarose gel electrophoresis and they have suggested that the binding between DNA and polyethyleneimine (PEI) have occurred mainly through electrostatic interactions among the participating species. Recently Annaraj et al. [46] observed that the phenanthroline containing mixed ligand copper(II) complexes retard the mobility of DNA due to the intercalation of the planar phenanthroline groups. Similar retardation in the DNA mobility is also observed due to the intercalation by ruthenium complexes [47]. In order to substantiate the binding of our polymer–copper(II) complexes to DNA, gel electrophoresis has been performed with a sample of the polymer–copper(II) complex ($x = 0.203$) (Fig. 7). Lane 1 is pure DNA not treated with complex. Lanes 2–6 represent the DNA treated with the polymer–copper(II) complex of various solution concentrations. As reported by previous workers on the interaction of DNA-polyethyleneimine alone, in our work also the migration of the DNA band is retarded as the concentration of polymer–copper(II) complex in the solution is increased. This clearly demonstrates that the cationic segments of the branched polyethyleneimine neutralize the negative charges of DNA, which could have facilitated further due to the increased planar phenanthroline groups of copper(II) complex moieties present in the polymer chain.

3.4. Antibacterial and antifungal screening

The polymer–copper(II) complex ($x = 0.203$) was screened in vitro for its microbial activity against certain pathogenic bacterial and fungal species using disc diffusion method. The complex was found to exhibit considerable

Table 2
Anti-microbial activities of [Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$ ($x = 0.203$)

Test organisms	Diameter of zone inhibition (mm)				
	Cu(phen)(L-Thr)$(H_2O)]ClO_4$	BPEI	Standard	Cu(phen)(L-Thr)(BPEI)]$ClO_4 \cdot 2H_2O$	Standard
Staphylococcus aureus	4	7	15	11	16
Bacillus subtilis	2	9	16	13	17
Escherichia coli	3	8	17	10	16
Pseudomonas auregenosa	4	7	17	12	17
Candida albicans	3	6	10	10	12

Standard – Ciprofloxacin for bacteria and Clotrimazole for fungus.
Solvent – DMSO (showed nil effect against the microorganisms under test).

activity against Gram +ve and Gram −ve bacteria and the fungus *C. albicans*. The test solutions were prepared in dimethyl sulphoxide and the results of the antimicrobial activities are summarized in Table 2.

Zoroddu et al. [48] have reported that neither phenanthroline ligand alone nor copper(II) chloride itself showed any significant activity against the Gram +ve and Gram −ve bacteria but the copper(II)–phenanthroline complex has exhibited considerable activity against Gram +ve *S. aureus* and Gram −ve *E. coli*, but inactive against Gram −ve *P. aeruginosa*. In our biological experiments, using polymer–copper(II) complex ($x = 0.203$), we have observed considerable antibacterial activity against Gram +ve bacteria *S. aureus* and *B. subtilis* and Gram −ve bacteria *E. coli* and *P. aeruginosa*. The polymer–copper(II) complex has shown a high activity against Gram +ve than Gram −ve bacteria. The polymer–copper(II) complex is also active against the fungus *C. albicans*. Also we carried out the tests with polymer (BPEI) and ordinary copper complex $[Cu(phen)(L\text{-}Thr)(H_2O)]ClO_4$ separately. Both showed some activity against all microorganisms but the effect is very small compared to polymer–copper complex. It may be concluded that our polymer–copper(II) chelate inhibits the growth of bacteria and fungi to a greater extent.

4. Conclusion

We described here the synthesis of some novel water-soluble polymer–copper(II) complex samples with varying amounts of copper(II) chelate content in the polymer chain. The characterization of complex sample was achieved through Infra-red, UV–Vis, EPR spectral and elemental analysis methods. Spectroscopic studies suggest that the presence of multiple copper(II) complex moieties and free NH groups, in a single big size polymer molecule, can enhance the various binding ability i.e. with CT-DNA. The polymer–copper(II) chelates could bind to DNA molecules mainly by electrostatic interaction. Besides this, ionic interaction, van der Waals interaction, hydrogen bonding and other partial intercalation binding modes may also exist in this system. The polymer–copper(II) complex sample showed good antimicrobial activity against Gram +ve and Gram −ve bacteria and fungi.

Abstract

Five copper(II) complexes with *N*(4)-*ortho*, *N*(4)-*meta* and *N*(4)-*para*-tolyl thiosemicarbazones derived from 2-formyl and 2-acetylpyridine were obtained and thoroughly characterized. The crystal structure of *N*(4)-*meta*-tolyl-2-acetylpyridine thiosemicarbazone (H2Ac4mT) was determined, as well as that of its copper(II) complex [Cu(2Ac4mT)Cl], which contains an anionic ligand and a chloride in the coordination sphere of the metal. The *in vitro* antimicrobial activities of all thiosemicarbazones and their copper(II) complexes were tested against *Salmonella typhimurium* and *Candida albicans*. Upon coordination a substantial decrease in the minimum inhibitory concentration, from 225 to 1478 μmol L^{-1} for the thiosemicarbazones to 5–30 μmol L^{-1} for the complexes was observe against the growth of *Salmonella typhimurium* and from 0.7–26 to 0.3–7 μmol L^{-1} against the growth of *C. albicans*, suggesting that complexation to copper(II) could be an interesting strategy of dose reduction.

1. Introduction

Thiosemicarbazones present a wide range of pharmacological applications as anticancer, antiviral and antimicrobial agents [1–3]. The biological properties of thiosemicarbazones are often related to metal coordination. Firstly, lipophilicity, which controls the rate of entry into the cell, is modified by coordination. Also, the metal complex can be more active than the free ligand, or the metal complex can be a vehicle for activation of the ligand as the cytotoxic agent [1–3].

The antimicrobial action of thiosemicarbazones against a variety of bacteria and fungi has been investigated. The activity of 2-formyl and 2-acetylpyridine thiosemicarbazones has been demonstrated in clinical isolates of bacteria [1,4]. Significant activity has been found toward gram positive bacilli but poor antibacterial activity has been shown toward gram negative cultures [1,4,5]. In addition, the *in vitro* inhibitory activity of 2-acetylpyridine-derived thiosemicarbazones has been demonstrated against clinically significant bacterial cultures, including isolates with known antibiotic resistance [1,4,5]. A variety of metal complexes of these ligands has also shown to present potent antibacterial activity [1]. Less attention has been given to 2-benzoylpyridine-derived thiosemicarbazones.

Some 2-formyl and 3-formylpyridine thiosemicarbazones and their metal complexes were tested against *Candida albicans* and *Apergillus fumigatus*. In addition, *N*(4)-alkyl and *N*(4)-dialkyl-2-acetylpyridine thiosemicarbazones showed marked inhibitory activity of *A. niger* growth. Moreover, metallocene derivatives of titanium and zirconium with

doi:10.1016/j.poly.2007.03.002

thiosemicarbazones derived from 2-acetylpyridine, 2-acetylfuran, 2-acetylthiophene and 2-acetylnaphtalene were tested against a number of pathogenic fungi and bacteria. All the complexes were more active against the studied organisms than the free thiosemicarbazones [1].

It has been demonstrated that the presence of a bulky group at *N*(4) strongly improves the biological activity of thiosemicarbazones [2,3], probably due to an increase in lipophilicity.

In previous works, we started an evaluation of the antimicrobial and cytotoxic activities of pyridine-derived thiosemicarbazones and their metal complexes. *N*(4)-alkyl- and *N*(4)-phenyl-substituted 2-benzoylpyridine thiosemicarbazones have been prepared, as well as their palladium(II), tin(IV) and iron(II) complexes [6–8].

Taking into consideration that copper(II) complexes have found possible medical uses in the treatment of many diseases including microbial infections [2,3,9] we recently prepared *N*(4)-tolyl thiosemicarbazones derived from 2-benzoylpyridine as well as their copper(II) complexes. Both ligands and complexes proved to be active against the growth of *C. albicans* with low values of minimum inhibitory concentration. The activity is improved upon coordination to copper [10].

Salmonella sp. is a *gram*-negative facultative rod-shaped bacterium which causes infections about 12–24 h following ingestion of contaminated food. Strains of *Salmonella* which are resistant to a range of antimicrobials, including first-choice agents for the treatment of humans have emerged, and are threatening to become a serious public health problem [11]. The same occurs with strains of fungi. Among the azole drugs used against infections caused by *C. albicans*, fluconazole and itraconazole exhibit satisfactory safety and efficacy. However, the emergence of clinical resistance during long-term therapy is well known [12].

Resistance results from the use of antimicrobials both in humans and animal husbandry. Multi-drug resistance to critically important antimicrobials is compounding the problems [13]. Therefore, preparation of new antimicrobials with activity in low doses is extremely important.

In the present work, we studied the activity of *N*(4)-*ortho*-, *N*(4)-*meta*- and *N*(4)-*para*-2-formyl (hereafter named H2Fo4oT, H2Fo4mT, H2Fo4pT), 2-acetyl (H2Ac4oT, H2Ac4mT, H2Ac4pT) and 2-benzoylpyridine thiosemicarbazones (H2Bz4oT, H2Bz4mT, H2Bz4pT) (see Fig. 1) and their copper(II) complexes against the growth of *Salmonella typhimurium* and *C. albicans*.

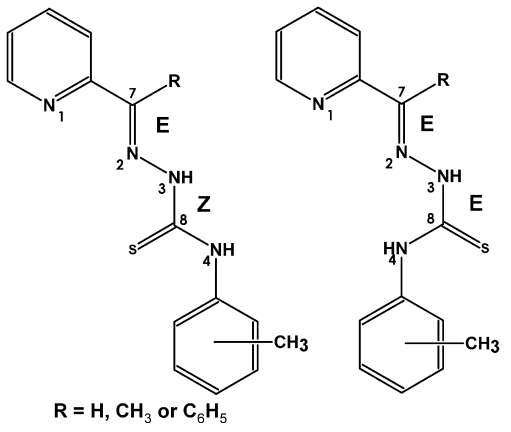

Fig. 1. General structure of *N*(4)-*ortho*-, *N*(4)-*meta*- and *N*(4)-*para*-tolyl 2-formyl 2-acetyl and 2-benzoylpyridine thiosemicarbazones, *E* and *Z* configurations.

2. Experimental

2.1. Apparatus

Partial elemental analyses were performed on a Perkin Elmer CHN 2400 analyzer. Infrared spectra were recorded on a Perkin Elmer FT-IR Spectrum GX spectrometer using CsI/nujol; an YSI model 31 conductivity bridge was employed for molar conductivity measurements. Magnetic susceptibility measurements were carried out on a Johnson Matthey MSB/AUTO balance. Electron paramagnetic resonance (EPR) spectra of samples in frozen DMF solution were obtained in quartz tubes of 3 mm of internal diameter at liquid N_2 temperature (77 K) on a Bruker ESP300E equipment with modulation frequency of 100 kHz operating at 9.5 GHz (X-band). Spectra simulations were performed using the WINSIMFONIA Bruker package. Crystal structures of H2Ac4mT and its copper complex [Cu(2Ac4mT)Cl] (see below) were investigated using single-crystal X-ray diffractometry. Data have been collected at room temperature in a Kappa CCD diffractometer, Mo Kα monochromated radiation, $\lambda = 0.71073$ Å. Crystal data, data collection procedure, structure determination methods and refinement results are summarized in Table 1. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares using the SHELX 97 [14,15] program in a WINGX system [16,17]. Although some of the hydrogen atoms could be identified in a Fourier difference map, in the final model they were geometrically positioned and refined using a riding model. All non-H atoms were refined anisotropically.

2.2. Synthesis of the copper(II) complexes with 2-formyl- and 2-acetylpyridine N(4)-tolyl thiosemicarbazones

The thiosemicarbazones were prepared as described in the literature [18]. The copper(II) complexes were obtained by refluxing an ethanol solution (25 mL) of the desired thiosemicarbazone (3 mmol) with $CuCl_2 \cdot 2H_2O$ (Aldrich) in 1:1 ligand-to-metal molar ratio for 5 h. The resulting solids were filtered then washed with ethanol followed by diethyl ether, and dried *in vacuo*. Crystals of H2Ac4mT were grown by slow diffusion from ethanol solution and crystals of its copper(II) complex from a 1:9 DMSO/acetone solution.

The copper(II) complexes will be hereafter numbered as follows: [Cu(H2Fo4oT)Cl_2] (**1**), [Cu(2Fo4mT)Cl] (**2**),

Molar conductivity (1×10^{-3} mol L^{-1}, DMF): 37 Ω^{-1} cm^2 mol^{-1}. Effective magnetic moment = 2.03 BM. Yield: 87%.

2.3. Antibacterial activity

Antibacterial activity was evaluated by minimum inhibitory concentration (MIC) using the macro dilution test [19–21]. *S. typhimurium* ATCC13311 stored in Brain Heart Infusion (BHI) broth was subcultured for testing in the same medium and grown at 37 °C. Then the bacterial cells were suspended, according to the McFarland protocol in saline solution [21], to produce a suspension of about 10^5 CFU mL^{-1} (colony-forming units per mL). Serial dilutions of the test compounds, previously dissolved in dimethyl sulfoxide (DMSO), were prepared in test tubes to final concentrations of 512, 256, 128, 64, 32, 16, 8, 4, 2, and 1 μg mL^{-1}; 100 μL of a 24-h-old-inoculum was added to each tube. The MIC, defined as the lowest concentration of the test compound, which inhibits the visible

growth after 20 h, was determined visually after incubation for 20 h at 37 °C. Tests using chloramphenicol as reference and DMSO as negative control were carried out in parallel. All tests were performed in triplicate with full agreement between results.

As previously, antifungal activity was evaluated by minimum inhibitory concentration (MIC) using the macro dilution test [19–21]. *C. albicans* (ATCC 18804) stored in Sabouraud broth, was subcultured for testing in the same medium and grown at 37 °C. Then the yeast cells were suspended, according to the McFarland protocol in saline solution [21], to produce a suspension of about 10^5 CFU mL^{-1}. Serial dilutions of the test compounds, previously dissolved in dimethyl sulfoxide (DMSO), were prepared in test tubes to final concentrations of 512, 256, 128, 64, 32, 16, 8, 4, 2, 1, 0.5, 0.3 and 0.1 μg mL^{-1}. 100 μL of a 24-h-old inoculum was added to each tube. The MIC was determined visually after incubation for 18 h at 37 °C and DMSO was used as negative control. All tests were performed in triplicate.

3. Results and discussion

Microanalyses suggest the formation of [CuLCl] for complexes **2**–**6**, in which the thiosemicarbazones coordinate as anionic ligands. The molar conductivity data reveal that the complexes are non-electrolytes [22], in accordance with the proposed formulations. The values of magnetic moments in the 1.73–2.03 BM range are close to the calculated value of 1.73 BM, characteristic of the presence of one unpaired electron as in copper(II) complexes.

Complexes **1** and **7**–**9** obtained previously [18,10] were formulated as $[Cu(HL)Cl_2]$, in which the thiosemicarbazones coordinate as neutral ligands. Once again the complexes are non-electrolytes, in agreement with the presence of two chlorides in the metal coordination sphere.

3.1. Structural characterization of H2Ac4mT and [Cu(2Ac4mT)Cl] (5)

The structure of H2Ac4mT was refined in the monoclinic system, $P2_1/c$ and that of [Cu(2Ac4mT)Cl] (**5**) in the triclinic system, $P\bar{1}$, both with one molecule in the asymmetric unit. Selected intra-molecular bond distances and angles are given in Table 2; hydrogen bond distances and angles are detailed in Table 3 and angles between planes in Table 4. The asymmetric units are shown in perspective in Figs. 2 and 3.

H2Ac4mT adopts the *EE* configuration in relation to the C7–N2 and C8–N3 bonds (see Fig. 1). In complex **5** the ligand adopts the *EZ*, configuration, to match the sterical requirements of coordination through the N_{py}–N–S chelating system. The C8–N3 bond distance goes from 1.359(3) Å in the free base to 1.311(5) Å in the complex, due to deprotonation at N3 and formation of new predominantly double bond. The C8–S bond changes from 1.671(3) Å in H2Ac4mT to 1.749(4) Å in complex **5** in agreement with deprotonation at N3 and formation of a thiolate bond. Significant modifications have also been observed in the bond angles upon coordination (see Table 2). For example, the N2–N3–C8 bond angle changes from 118.5(2)° in the free base to 111.6(3)° in the complex, and N3–C8–S goes from 120.3(2)° to 125.2(3)° (see Table 2).

The bond distances and angles in **5** are comparable to those related in the literature for copper(II) complexes containing anionic thiosemicarbazones [23].

In H2Ac4mT N3-H forms an intermolecular hydrogen bond with a sulfur of an adjacent molecule, N3–H···S1 ($-x$, $-y+1$, $-z+1$). In [Cu(2Ac4mT)Cl] (**5**) N4 is hydrogen bonded to a thiolate sulfur of a second adjacent molecule forming dimers (see Fig. 4); N4–H···S ($-x+1$, $-y+1$, $-z+2$), d(D–H) = 2.68 Å, ∠DHA = 173.4° and d(D···A) 3.539(3) Å (Table 3).

The C7–N2–N3–C8S1–N4 skeleton is approximately planar in the structures of both H2Ac4mT and complex **5**, with mean deviation from planarity of 0.0591 Å in the free thiosemicarbazone and 0.0132 Å in **5**.

The angle between the pyridine plane and the thiosemicarbazone moiety is 17.2° in H2Ac4mT and 2.6° in complex **5**. Similarly, the angle between the thiosemicarbazone chain and the tolyl ring is 65.4° in H2Ac4mT and 3.2° in **5**, due to the almost planar structure of the complex (see Table 4).

3.2. Infrared spectra

The ν(C=C) + ν(C=N) composed mode observed in the 1608–1564 cm^{-1} in the spectra of the thiosemicarbazones shifts 1607–1538 cm^{-1} in the spectra of the complexes, indicating coordination of the azomethine nitrogen N2 [6–8,10].

The ν(C=S) absorption at 870–821 cm^{-1} in the spectra of the uncomplexed thiosemicarbazones is observed at 782–757 cm^{-1} in those of the complexes, in accordance with coordination through a thiolate sulfur. The 88–64 cm^{-1} shift observed upon complexation is compatible with coordination of an anionic thiosemicarbazone in all cases [6–9]. The pyridine in-plane deformation mode at 639–595 cm^{-1} in the spectra of the ligands shifts to 624–601 cm^{-1} in those of the complexes, suggesting coordination of the heteroaromatic nitrogen [6–8,10]. In addition, new absorptions at 460–416 cm^{-1} and 374–343 cm^{-1} have been attributed to ν(Cu–N) and ν(Cu–N_{py}), respectively,

and bands in the 341–329 cm^{-1} range have been assigned to ν(Cu–S). An absorption at 318–308 cm^{-1} has been attributed to ν(Cu–Cl) [23,24].

The infrared data for the complexes indicate coordination of the thiosemicarbazones through the N_{py}–N–S chelating system.

3.3. Electronic spectra

In the electronic spectra of the thiosemicarbazones (DMSO) the π–π* absorptions at ca. 37 000 cm^{-1} are not significantly modified upon complexation. The absorption at 31 153–30 395 cm^{-1} in the spectra of the free bases was attributed to n–π* transitions associated to the azomethine and thioamide [6–8,10] functions which overlap under the same envelope. In the spectra of complexes three absorptions were observed at 31 250–30 860 cm^{-1}, 27 780–26 600 cm^{-1} and 24 750–24 210 cm^{-1}. The first two were assigned to n–π* transitions of the azomethine and thioamide functions, and the latter to N–Cu^{II} and S–Cu^{II} ligand-to-metal charge transfer transitions [10,24]. Ligand field transitions were found at 16 650–16 304 cm^{-1} [10,24]. The electronic spectra of the solids are not significantly different, particularly in the d–d region.

3.4. ESR spectra

Fig. 5 shows the experimental EPR spectra in frozen DMF solution, liquid nitrogen (77 K), for the studied complexes. The Hamiltonian parameters obtained from the spectra, together with the d–d ligand field transitions, are resumed in Table 5.

The g values are in agreement with the relation $g_{\parallel} > g_{\perp} > 2$, indicating the presence of $d_{x^2-y^2}$ ground states. The $g_{\parallel}/A_{\parallel}$ ratio can be used as a convenient empirical index of distortion from square-planar structure. This value ranges from ca. 105 to 135 cm for square-planar structure, and this quotient increases on the introduction of tetrahedral distortion to the chromospheres [25]. The values of the $g_{\parallel}/A_{\parallel}$ ratio (Table 5) indicate nearly square-planar environments for complexes **2**–**6**, some with small distortions, which is in good agreement with the X-ray determined structure for complex **5**. The relatively low g values of the studied compounds are characteristic of an N enriched environment around the Cu(II) ions [26].

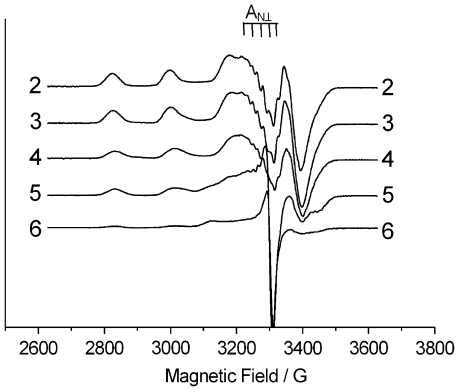

Fig. 5. X-band EPR spectra of [Cu(2Fo4mT)Cl] (**2**), [Cu(2Fo4pT)Cl] (**3**), [Cu(2Ac4oT)Cl] (**4**), [Cu(2Ac4mT)Cl] (**5**) and [Cu(2Ac4pT)Cl] (**6**) in DMF at 77 K (Inset: five perpendicular super-hyperfine interaction lines – $A_{N\perp} \approx 16 \times 10^{-4}$ cm^{-1} – of two ^{14}N ($I = 1$) atoms with the Cu(II) ions from each complex).

An interesting feature of the spectra is the appearance of nitrogen super-hyperfine lines (five lines) in the $g_{\perp}$ region, which generally mirror the number of nitrogen donors ($2nI + 1$, where $I = 1$ for nitrogen and n is the number of nitrogen atoms in the same chemical environment). The five lines correspond to two nitrogen donor atoms in the equatorial positions. The $A_{N\perp}$ values, around 16×10^{-4} cm^{-1} are in agreement with the imine/amine N coordination to the Cu(II) ions [27].

3.5. Antimicrobial activity

Table 6 lists the minimum inhibitory concentration (MIC) of the thiosemicarbazones and their copper(II) complexes against the growth of *S. typhimurium* and Table 7 lists the MIC against *C. albicans*. Included in this section are values previously obtained for 2-benzoylpyridine *N*(4)-tolyl thiosemicarbazones and their copper(II) complexes [10].

For the antibacterial action, MIC values in the 225–1478 μmol L^{-1} range were found for the thiosemicarbazones. Upon coordination, a substantial decrease in MIC was observed, with values in the 5–30 μmol L^{-1} range. Among the thiosemicarbazones, the lowest values of MIC were found for the 2-acetylpyridine derivatives, but in the complexes the lowest values were found for those with the 2-benzoylpyridine-derived thiosemicarbazones (**7**–**9**). The most significant decrease upon coordination occurred for these same complexes (Table 6). Interestingly, in the latter a neutral ligand is attached to the metal center, along with two chloride ions, forming species with coordination number five and with geometries which are different from that of complexes **2**–**6**.

To our knowledge this is one of the few cases of thiosemicarbazones' activity against *gram* negative bacilli, which indicates new possibilities of applications for this class of compounds.

Much lower values of MIC were obtained for the thiosemicarbazones against *C. albicans* (0.5–26 μmol L^{-1}) (Table 7), indicating selectivity. Upon coordination a decrease of the MIC values was observed as well, although not as significant as in the case of the antibacterial action, probably because the free thiosemicarbazones were already very active.

On complexation modifications of lipophilicity can occur [1,2]. Also, the rigid structure of the ligand in the complex could facilitate its interaction with the biological target, so that the metal complex may be a vehicle for activation of the ligand as the antimicrobial agent. Since the copper salt presents antimicrobial action as well, a syner-

gistic effect of both ligand and metal acting together is also possible.

It is interesting to compare the values of MIC found for the studied complexes (5–30 μmol L^{-1} in the case of the antibacterial action and 0.3–7 μmol L^{-1} in the case of the antifungal action) with the values observed for the clinically used drugs chloramphenicol (12 μmol L^{-1}) and amphotericin (4.4 μmol L^{-1}). As already mentioned, resistance to used drugs has increased due to the increased and indiscriminate use of antibiotics and antifungal agents in the treatment of humans and animals [13].

These results suggest that coordination of the studied thiosemicarbazones with copper(II) could be an interesting strategy for preparing new antimicrobial agents which could be used against clinically significant bacteria and fungi cultures presenting resistance. In the case of the antifungal action, the free *N*(4)-tolyl thiosemicarbazones could be promising drug candidates, as well as their copper(II) complexes.

Structure–activity relationship analyses are presently underway in our laboratory as well as an investigation on the mechanisms of action of the studied compounds.

4. Supplementary material

CCDC 632461 and 632460 contain the supplementary crystallographic data for H2Ac4mT and [Cu(2Ac4mT)Cl] (**5**). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Synthesis and spectral characterization of some complexes of platinum(II) containing η^2-methyleugenol

Tran Thi Da, Nguyen Thi Tuyet Minh, Nguyen Thi Thanh Chi, Nguyen Huu Dinh *

Department of Chemistry, Hanoi National Pedagogic University, Hanoi, Vietnam

Received 7 February 2007; accepted 3 March 2007
Available online 21 March 2007

Abstract

Several complexes of the formula *trans*-[Pt(Meug)(Am)Cl_2], Meug: methyleugenol (4-allyl-1,2-dimethoxybenzene), a η^2-coordinated olefin, and Am: ammine, methylamine, diethylamine, *o*-toluidine, *m*-toluidine, *p*-toluidine, *o*-anisidine, *m*-anisidine and *p*-anisidine have been prepared. UV, IR, Raman, ^{1}H NMR, ^{13}C NMR and 2D NMR spectra of the complexes were recorded and analyzed.

Keywords: Platinum complexes; Olefin complexes; Methyleugenol; ^{1}H NMR; ^{13}C NMR

1. Introduction

Platinum–olefin complexes quite long ago attracted the attention of chemists [1,2]. Various olefin ligands have been used. Amongst the arylolefin ligands, phenylethylene (styrene) and substituted phenylethylenes were widely studied [3,4], but phenylpropylenes were rare. Today substituted phenylpropylenes, which are easily available from natural resources, have been used as valuable starting materials in various synthetic processes [5]. In many cases transition metals-olefin complexes are present as key intermediates.

Eugenol, izoeugenol and methyleugenol (4-allyl-1,2-dimethoxybenzene) represents interesting phenylpropylenes, extracted from essential clove oil, which can be transformed into coniferyl aldehyde, coniferyl alcohol, vanilin and vanillic acid, compounds commonly used in the flavour and fragrance industry [6]. In this paper we describe some platinum(II) complexes containing methyleugenol, which are prepared as follows:

$$K[Pt(C_2H_4)Cl_3] \xrightarrow{\text{Methyleugenol}} \underset{(\mathbf{1})}{K[Pt(Meug)Cl_3]} \xrightarrow{\text{Amine}} \underset{(\mathbf{2})\text{–}(\mathbf{10})}{\textit{trans}\text{-}[Pt(Meug)(Am)Cl_2]}$$

Meug: Methyleugenol (4-allyl-1,2-dimethoxybenzene, formula I).
Am: NH_3 (**2**), CH_3NH_2 (**3**), $(C_2H_5)_2NH$ (**4**), *o*-$CH_3C_6H_4NH_2$ (**5**), *m*-$CH_3C_6H_4NH_2$ (**6**), *p*-$CH_3C_6H_4NH_2$ (**7**), *o*-$CH_3OC_6H_4NH_2$ (**8**), *m*-$CH_3OC_6H_4NH_2$ (**9**), *p*-$CH_3OC_6H_4NH_2$ (**10**).

2. Results and discussion

The complexes [Pt(Meug)(Am)Cl_2] were prepared by replacement of a Cl ligand from K[Pt(Meug)Cl_3] (**1**) by an amine, Am. According to the *trans*-effect, the Cl ligand in the opposite position to Meug is replaced by the amine. For volatile amines such as methylamine, diethylamine and NH_3, the reaction was carried out at 10–15 °C, with 1.2 mmol of amine per 1 mmol of **1**. For toluidines and anisidines, the reaction was carried out at 25–30 °C, with 1.1 mmol of amine per 1 mmol of **1**. The neutral complexes [Pt(Meug)(Am)Cl_2] precipitate out and can be easily

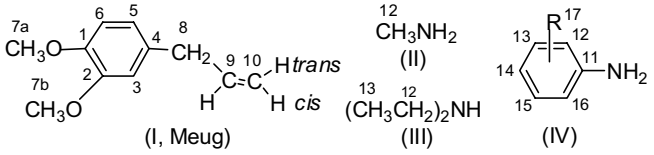
doi:10.1016/j.poly.2007.03.017



isolated, then purified by recrystallizing from aqueous EtOH solution.

The molar conductivity (μ) of 10^{-4} M K[Pt(Meug)Cl_3] solution is 95 Ω^{-1} cm^2 mol^{-1}. The molar conductivity (μ) of a $5.10^{-5} - 10^{-4}$ M solution of *trans*-[Pt(Meug)(Am)Cl_2] is in the range 15–22 Ω^{-1} cm^2 mol^{-1}, indicating its non-electrolytic nature (Table 1).

The electronic spectra of the synthesized complexes are given in Table 1. All the examined complexes are slight soluble. Their spectra were recorded at a concentration as small as 10^{-4} M in 96% by volume aqueous EtOH. Thus only charge-transfer and ligand spectra were obtained.

In Table 1, the *v*(Pt–N), *v*(Pt–Cl) values were taken from the Raman spectra. Because the intensity of *v*(NH) in the Raman spectra was too weak, the *v*(NH) value was taken from the IR spectra. These values are in general agreement with those in the literature [1,7].

The NMR data of the examined compounds are presented in Tables 2–4. The numeration of the examined compounds for the analysis of the NMR spectra is as follows:

The assignment of the NMR signals is based on their chemical shift, spin-spin splitting patterns, HMQC, HMBC and NOESY spectra. For example, the assignment of some ambiguous signals from the ^{13}C NMR spectrum of complex **8** and then the signals of H7a, H7b, H17 have been assigned as illustrated in Fig. 1.

In Fig. 1, the signals of all the protons, except H-7a, H-7b and H-17, have been unambiguously assigned, the signals of ring carbons are thus identified. Two cross peaks *a* and *b* of H-16 (7.29 ppm) show that two signals at 152.0 and 127.0 ppm belong to C-12 and C-14, respectively. Two cross peaks *c*, *d* of H-14 (7.15 ppm) show signals of C-12 (152.0), C-16 (124.1). Two cross peaks *e*, *f* of H-13 (6.98 ppm) show signals of C-11 (130.52), C-15 (121.81). Two cross peaks *g*, *h* of H-5 (6.96 ppm) show signals of C-1 (148.83), C-3 (113.88). Two cross peaks *i*, *k* of H-6 (6.86 ppm) show signals of C-2 (150.11), C-4 (132.3). Two cross peaks *l*, *m* of H-15 (6.88 ppm) show signals of C-11 (130.52), C-13 (112.88). The cross peaks of C-12, C-2 and C-1, in turn, allow one to distinguish the signals of H-17, H-7b and H-7a.

Upon coordination to Pt(II), the resonances of the ethylenic protons (H-9, H-10 *cis* and H-10 *trans*, Table 2) are upfield in comparison to those of non-coordinated methyleugenol (5.86, 4.96 and 4.98 ppm, respectively). The ^{195}Pt satellites in the signals from H-9 are broadened beyond detection, but two satellites in the signals from H-10 *cis* and H-10 *trans* are clear, with a $^2J_{PtH}$ value of 60–70 Hz (Table 2). The resonances of the ethylenic carbons (C-9, C-10) are upfield too (Table 4). These indicate that methyleugenol is present as an η^2-coordinated olefin.

For non-coordinatinated methyleugenol, two protons H-8 (formula I) give rise to a doublet at 3.22 ppm with $^3J = 6.5$ Hz, but in the spectra of the examined complexes we usually observed one doublet of doublets centered at 3.38–3.55 ppm for H-8a and another doublet of doublets centered at 3.01–3.21 ppm for H-8b. This is expected since upon coordination to Pt(II), atom C-9 becomes a chiral center, and H-8a and H-8b become diastereotopic.

It is interesting that in ^1H NMR and ^{13}C NMR spectra of *trans*-[Pt(Meug)(Et_2NH)Cl_2] (**4**), recorded in d_6-acetone, two CH_2 groups of diethylamine give rise to two complicated proton signals (one multiplet centered at 2.88 ppm and another at 3.17 ppm, H12a and H12b in Fig. 2) and two ^{13}C signals at 49.67 and 49.69 ppm; two CH_3 groups give rise to two triplets (one centered at 1.400 and another at 1.395 ppm) and the two ^{13}C signals are at 14.67 and 14.74 ppm. This anomaly also happens in the spectra of **4** recorded in CD_3CN. It is noted that we have just prepared *trans*-[Pt(Saf)(Et_2NH)Cl_2] (**4a**) and *trans*-[Pt(Saf)(Me_2-NH)Cl_2] (**4b**) (Saf: 4-allyl-1,2-methylendioxybenzene, Et: $-CH_2CH_3$, Me: CH_3). In the spectra of **4a** recorded in d_6-acetone, two CH_2 groups of diethylamine give rise to two complicated proton signals (one multiplet centered at

[a] Solvent, a: CD_3OD, b: $CDCl_3$, c: CD_3COCD_3, d: CD_3CN.

2.87 ppm and another at 3.18 ppm) and two ^{13}C signals at 49.67 and 49.71 ppm; two CH_3 group give rise to one proton signal (at 1.408 ppm) but two ^{13}C signals (at 14.64 and 14.74 ppm). In the spectra of **4b** recorded in d_6-acetone, two CH_3 groups of dimethylamine give rise to two proton signals (at 2.65 and 2.70 ppm) and two ^{13}C signals (at 40.09 and 41.99 ppm). The analogous appearance was still observed when d_6-acetone was replaced by CD_3CN or CD_3Cl. Whilst for *cis*-[Pt(Morpholine)(Et_2NH)Cl_2], the two CH_2 groups of ethylamine give rise to one proton signal, and the two CH_3 groups of ethylamine also give rise to one proton signal [7], for *trans*-[$PtCl_2(C_2H_4)(Et_2NH)$] the two CH_2 groups of ethylamine give rise to one carbon signal (at 48.979 ppm), and the two CH_3 groups of ethylamine also give rise one carbon signal (at 14.699 ppm) and one proton signal (at 1.573 ppm). This asks the question, what causes the two ethyl groups in *trans*-[Pt(Meug)(Et_2NH)Cl_2] to become non-equivalent?

To answer this, we recorded NOESY spectra of **4**, **4a**, **4b**, **7** and **8**. The signals of H-9, H-10 *cis and* H-10 *trans* of all the 10 complexes are shaped and resolved. The cross peaks *n* and *p* (Fig. 2) indicate that only group CH_2-a (H-12a) is adjacent

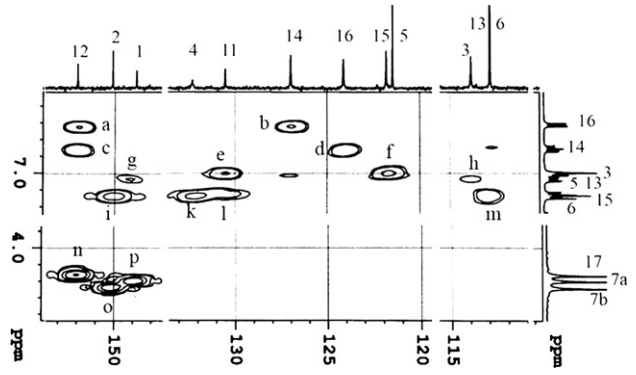

Fig. 1. A part of the HMBC spectrum of [Pt(Meug)(*o*-CH_3O-$C_6H_4NH_2$)Cl_2] (**8**).

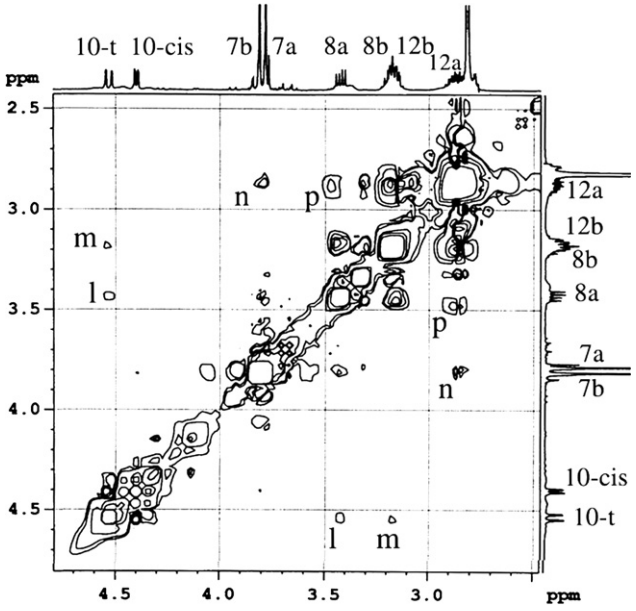

Fig. 2. A part of the NOESY spectrum of [Pt(Meug)(Et_2NH)Cl_2] (**4**).

to the protons H-7b and H-8a, while group CH_2-b (H-12b) is not. This demonstrates that a rotation around the coordination axes (Pt–olephin bond and Pt–N bond) does not occur on the NMR timescale at the recorded temperature. Thus the atom Pt becomes asymmetrical.

3. Experimental

Elemental analysis: Pt was analyzed according to the weight method [8], and C, H, N analyses were performed at the Ho Chi Minh City Center of Analytical Service. Experimentation used an automatic elemental analyzer. The molar conductivity was measured using a conductivity Meter HI 88119 N. The UV spectra were recorded on a GCB Instrument-2855 spectrophotometer. The Raman spectra were carried out on a Micro Raman LABRAM in the range 4000–100 cm^{-1}, using excited radiation at 632.8 nm from a heli-neon laser. The IR spectra were recorded on an IMPACK-410 NICOLET spectrometer in KBr discs in the range 400–4000 cm^{-1}. The NMR spectra were recorded on a Bruker AVANCE 500 MHz, all at 298–300 K, with TMS as the internal standard in a suitable solvent (Tables 2 and 3).

3.1. 4-Allyl-1,2-dimethoxybenzene (Methyleugenol, Meug)

Methyleugenol is prepared by reaction of eugenol (from *Ocimum Sanetum* L.) with dimethyl sulfate in alkaline medium, Bp. (15 mm Hg), 125–126 °C; (125–127 °C, according to [9]). ^1H NMR ($CDCl_3$, δ, ppm, J, Hz, formula I): 6.61, d, ^4J 1.8, 1H: H3; 6.62, dd, ^3J 8, ^4J 1.8, 1H: H5; 6.68, d, ^3J 8, 1H: H6; 3.73, s, 3H, 3.75, s, 3H: H7a, H7b; 3.22, d, ^3J 6.5, 2H: H8; 5.86, m, 1H: H9; 4.96, m, *J cis* 7, 1H: H10 *cis*; 4.98, m, *J trans* 12.5, 1H: H10 *trans*.

3.2. Potassium trichloro(methyleugenol)platinat(II), K[Pt(Meug)Cl$_3$] (**1**)

To a stirred solution of 3.68 g (10 mmol) of Zeise's salt in 80 ml of ethanol was slowly added a solution of 2.5 ml (16 mmol) of methyleugenol in 20 ml of ethanol. The reaction mixture was stirred at 40–45 °C for an hour. Then it was allowed to cool to room temperature. Yellow plate crystals were collected and washed with cool water, then cool ethanol, and were then dried in a vacuum at 50 °C for 2 h. The yield was 4.15 g (80%). For ^{1}H and ^{13}C NMR see Tables 2–4. *Anal.* Calc. for $KPtC_{11}H_{14}O_2Cl_3$: Pt + K_2SO_4, 54.39; C, 24.46; H, 2.70. Found: Pt + K_2SO_4, 54.75; C, 24.18; H, 2.54%.

3.3. trans-Dichloro(methyleugenol)(ammine)platinum(II), [Pt(Meug)(NH$_3$)Cl$_2$] (**2**)

K[Pt(Meug)Cl$_3$] (0.518 g, 1 mmol) was dissolved in 16 ml of 50% by volume aqueous EtOH. To this solution 8 ml of 1.5 M NH_3 solution was slowly added over 30 minutes and stirred at 10–15 °C for an additional 3 h. The resulting yellow precipitate was collected, washed with a solution of 0.1 N HCl, cool water, cool ethanol and recrystallized from 75% by volume aqueous EtOH. The light yellow crystals were dried in a vacuum at 50 °C for 2 h. The yield was 0.32 g (70%). *Anal.* Calc. for [$PtC_{11}H_{17}NO_2Cl_2$]: Pt, 42.30; C, 28.63; H, 3.69; N, 3.04. Found: Pt, 42.58; C, 28.40; H, 3.88; N, 2.82%.

3.4. trans-Dichloro(methyleugenol)(methylamine)-platinum(II), [Pt(Meug)(MeNH$_2$)Cl$_2$] (**3**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$] and 1.3 ml aqueous solution of 30% methylamine (1.2 mmol), according to the procedure for the preparation of **2**. The yield was 0.36 g (75%), light yellow crystals. *Anal.* Calc. for [$PtC_{12}H_{19}NO_2Cl_2$]: Pt, 41.05; C, 30.32; H, 4.00; N, 2.95. Found: Pt, 41.30; C, 29.98; H, 4.12; N, 2.76%.

3.5. trans-Dichloro(methyleugenol)(diethylamine)-platinum(II), [Pt(Meug)(Et$_2$NH)Cl$_2$] (**4**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.13 ml (1.2 mmol) diethylamine, according to the procedure for the preparation of **2**. The yield was 0.36 g (70%), light yellow crystals. *Anal.* Calc. for [$PtC_{15}H_{25}NO_2Cl_2$] (%): Pt, 37.72; C, 34.82; H, 4.83; N, 2.71. Found: Pt, 37.58; C, 34.98; H, 4.62; N, 2.89%.

3.6. trans-Dichloro(methyleugenol)(o-toluidine)platinum(II), [Pt(Meug)(o-$CH_3C_6H_4NH_2$)Cl$_2$] (**5**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.12 ml (1.1 mmol) *o*-toluidine, at 25–30 °C, according to the procedure for the preparation of **2**. The yield was 0.44 g (80%), light yellow crystals. *Anal.* Calc. for [$PtC_{18}H_{23}NO_2Cl_2$]: Pt, 35.39; C, 39.20; H, 4.17; N, 2.54. Found: Pt, 35.52; C, 39.48; H, 4.32; N, 2.32%.

3.7. trans-Dichloro(methyleugenol)(m-toluidine)-platinum(II), [Pt(Meug)(m-$CH_3C_6H_4NH_2$)Cl$_2$] (**6**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.118 g (1.1 mmol) *m*-toluidine, at 25–30 °C, according to the procedure for the preparation of **2**. The yield was 0.40 g (75%), light yellow crystals. *Anal.* Calc. for [$PtC_{18}H_{23}NO_2Cl_2$]: Pt, 35.39; C, 39.20; H, 4.17; N, 2.54. Found: Pt, 35.25; C, 39.37; H, 4.35; N, 2.65%.

3.8. trans-Dichloro(methyleugenol)(p-toluidine)-platinum(II), [Pt(Meug)(p-$CH_3C_6H_4NH_2$)Cl$_2$] (**7**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.118 g (1.1 mmol) *p*-toluidine, at 25–30 °C, according to the procedure for the preparation of **2**. The yield was 0.38 g (70%), light yellow crystals. *Anal.* Calc. for [$PtC_{18}H_{23}NO_2Cl_2$]: Pt, 35.39; C, 39.20; H, 4.17; N, 2.54. Found: Pt, 35.51; C, 39.38; H, 4.36; N, 2.72%.

3.9. trans-Dichloro(methyleugenol)(o-anisidine)-platinum(II), [Pt(Meug)(o-$CH_3OC_6H_4NH_2$)Cl$_2$] (**8**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.11 ml (1.1 mmol) *o*-anisidine, at 25–30 °C, according to the procedure for the preparation of **2**. The yield was 0.48 g (84%), light yellow crystals. *Anal.* Calc. for [$PtC_{18}H_{23}NO_3Cl_2$] (%): Pt, 34.39; C, 38.09; H, 4.06; N, 2.47. Found: Pt, 34.54; C, 38.22; H, 4.21; N, 2.33%.

3.10. trans-Dichloro(methyleugenol)(m-anisidine)-platinum(II), [Pt(Meug)(m-$CH_3OC_6H_4NH_2$)Cl$_2$] (**9**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.11 ml (1.1 mmol) *m*-anisidine, at 25–30 °C, according to the procedure for the preparation of **2**. The yield was 0.45 g (81%), light yellow crystals. *Anal.* Calc. for [$PtC_{18}H_{23}NO_3Cl_2$] (%): Pt, 34.39; C, 38.09; H, 4.06; N, 2.47. Found: Pt, 34.21; C, 38.25; H, 3.87; N, 2.62%.

3.11. trans-Dichloro(methyleugenol)(p-anisidine)-platinum(II), [Pt(Meug)(p-$CH_3OC_6H_4NH_2$] (**10**)

This complex was prepared starting from 0.52 g (1 mmol) K[Pt(Meug)Cl$_3$], 0.123 g (1.1 mmol) *p*-anisidine, at 25–30 °C, according to the procedure for the preparation of **2**. The yield was 0.46 g (82%), light yellow crystals. *Anal.* Calc. for [$PtC_{18}H_{23}NO_3Cl_2$] (%): Pt, 34.39; C, 38.09; H, 4.06; N, 2.47. Found: Pt, 34.26; C, 37.91; H, 4.26; N, 2.29%.

Abstract

A new complex, $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$ (sulfameter = 4-amino-*N*-(5-methoxy-2-pyrimidinyl)benzenesulfonamide), has been synthesized. Its structure has been determined by single-crystal X-ray diffraction and its spectroscopic properties (EPR, IR, Raman, UV–Vis) have been analyzed. The structure presented three different dimeric units in the unit cell and the EPR spectra, characteristic of antiferromagnetically coupled dimers, revealed two magnetically different dimeric environments.

1. Introduction

There are many topics of considerable importance in sulfonamide coordination chemistry. In the analytical area, sulfonamides have been investigated as reagents for the separation, concentration, and selective determination of many of the first-row transition metal cations [1–3]. As a result, analytical tests using reactions with sulfonamides, have been included in modern pharmacopoeias (Ph.Eur, BP, USP). Moreover, some sulfonamide complexes have proved to be relevant catalysts in chemical reactions, such as Zn-sulfonamide complexes that catalyzes enantioselective cyclopropanations [4] and also as reagents for the cleavage of nucleic acids [5–7]. On the other hand, numerous sulfonamide complexes have been studied as simple models of metal–protein interactions [8–11].

In addition, some metal sulfonamides have drawn much attention due to the fact that they are used in medicine especially as antibacterial drugs. It is known that coordination with metals can modify the toxicological and pharmacological properties of free sulfonamides [12–17].

In all the above reported areas knowledge of the structure of the involucrate sulfonamide complexes is extremely useful for understanding their activity.

Due to their versatility, these ligands can act as monodentate, bidentate or polydentate coordinating groups, providing monomeric structures, dimeric, and polymeric arrangements [8,18–21]. Sulfameter (4-amino-*N*-(5-methoxy-2-pyrimidinyl)benzenesulfonamide), a well-known antibacterial sulfadrug, has several groups with donor atoms that can interact with metal ions, such as the ^{4}N from aryl amine, the ^{1}N and O from the sulfonamide group, and heterocyclic N (N_h) as shown in Fig. 1. In spite of the fact that a copper complex with sulfameter is reported [22] until now no single-crystal X-ray diffraction studies have been performed.

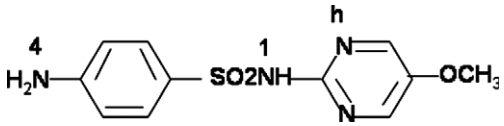

Fig. 1. Sulfameter (4-amino-*N*-(5-methoxy-2-pyrimidinyl)benzenesulfonamide) scheme.

As a part of our work on biologically interesting copper complexes [21,23–25] and with the aim to contribute with structural information useful for the general understanding of the microbiological behavior of metal–sulfonamide complexes, the synthesis and structural characterization of $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$ were reported. Its structure was analyzed and compared with spectroscopic results. Although there are different molecules with sulfonamides reported with similar dimeric Cu–Cu interactions [26–31], this structure presented three dimeric units in the unit cell and the EPR spectra revealed two magnetically different dimeric environments.

2. Experimental

2.1. Materials and methods

Sulfameter and $CuSO_4 \cdot 5H_2O$ were provided by SIGMA and Fluka, respectively, and all reagents were of analytical grade.

The decomposition point was measured with a Gallenkamp apparatus.

The elemental analysis was performed with a Carlo Erba EA1108 elemental analyzer. The copper content was determined by iodometric method.

X- (9.5 GHz) and Q-band (35 GHz) EPR measurements were carried out on polycrystalline samples using a Varian E109 spectrometer and cavities with 100 kHz field modulation. The measurements were performed at room temperature and a Cr(III) ($g = 1.9797$) sample was used for field calibration. The *g*-values and zero-field splitting (D and E terms) of the spin Hamiltonian were obtained from the simultaneous spectral simulation of the X- and Q-band spectra using the EasySpin program.

IR spectra, in the range between 4000 and 200 cm^{-1}, were recorded on a BOMEM M 102 FTIR spectrophotometer using the KBr pellet technique.

Raman spectra were scanned on a Brucker FRA 106 instrument mounted on an IFS 66 Fourier transform optical bench. A Nd/YAG laser (power = 100 mW) was used for excitation.

Electronic spectra were registered on a Beckman DU 70 spectrophotometer using a suspension in Nujol.

2.2. Synthesis of $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$

The complex was synthesized according to the procedure described by Bult et al. [32]. A solution of NaOH 1 M was added drop wise over a suspension of sulfameter (2.8 g, 10 mmol) in 100 mL of water until total dissolution (pH 9–10). To the resulting solution 50 mL of 0.5 M $CuSO_4 \cdot 5H_2O$ was added with stirring. After half an hour the brown precipitate formed was filtered, washed with water, dried at room temperature and protected from light. The complex was recrystallized from acetone. Yield (4.6 g, 73%). The decomposition point was 226 °C. The results of the elemental analysis were: *Anal*. Calc. for $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$ ($C_{132}H_{137}N_{48}O_{38.5}S_{12}Cu_6$): C, 41.97; N, 17.81; H, 3.63; S, 10.17; Cu, 10.10. Found: C, 41.86; N, 17.70; H, 3.70; S, 9.93; Cu, 10.22%.

2.3. Crystal structure determination

Low temperature X-ray diffraction data collection was performed at 150(2) K, on an Enraf-Nonius Kappa-CCD diffractometer equipped with an Oxford Cryosystem liquid N_2 device, using graphite-monochromated MoKα radiation (0.71073 Å). Data were collected up to 50.8° in 2θ, with a redundancy of 4 in the ϕ scans mode. The final unit cell parameters were based on all reflections. Data collections were made using the COLLECT program [33]. Integration and scaling of the reflections were performed with the HKL Denzo–Scalepack system of programs [34]. Multi-scan absorption correction was applied [35].

The structures were solved by direct methods with SHELXS-97 [36]. The models were refined by full-matrix least squares on F^2 with SHELXL-97 [37]. All the hydrogen atoms were stereochemically positioned and refined with the riding model [37]. Hydrogen atoms of the CH and CH_2 groups were set isotropic with a thermal parameter 20% greater than the equivalent isotropic displacement parameter of the atom to which each one was bonded. This percentage was set to 50% for the hydrogen atoms of the CH_3 groups and the water molecules. Data collections and experimental details for the complexes are summarized in Table 1. The programs SHELXL-97 and ORTEP-3 [38] were used within WinGX [39] to prepare materials for publication. Atomic coordinates, bond lengths and angles, and thermal parameters have been deposited at the Cambridge Crystallographic Data Centre.

3. Results and discussion

The synthesis of the complex was performed in an alkaline medium were the deprotonation of the amide group took place, additionally favored by the coordination through this group. Consequently, the copper complex was neutral.

The experimental elementary analysis values are in reasonable agreement with the calculated ones.

3.1. Crystal structure determination of $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$

The unit cell comprises three slightly different dimeric units. Fig. 2 presents an ORTEP diagram of one of these

dimeric units, showing the atoms labeling and the 30% probability ellipsoids.

Each copper atom of the dinuclear unit is four-coordinated with a slightly distorted square planar environment. It is bonded to four sulfameter ligands through two N_h pyridazine atoms from two sulfameter molecules and two ^{1}N atoms from the other sulfameter ligands as scheme in Fig. 3 shows. In the coordination polyhedra both N_h atoms are in trans position and consequently the ^{1}N atoms show the same disposition.

In addition, each copper interacts with two sulfonamide O atoms, as Fig. 3 shows and as it can be inferred from the IR spectrum. This coordination environment is different from that previously suggested for a similar copper complex ($[Cu(sulfameter)_2] \cdot 3H_2O$) were the spectroscopic data indicated the coordination through the sulfonyl oxygen and sulfonamide nitrogen [22]. The two copper ions of each unit are bridged by four-triatomic ^{1}N–C–N_h chemical path (see Fig. 3).

Fig. 4 shows the disposition of the three slightly different dimeric units in the unit cell.

Selected bond distances and angles around the copper atoms for the three dimeric units are presented in Table 2. For the sake of clarity the N atoms are labeled with the nomenclature noted in Fig. 1 and not to the ORTEP diagram.

As shown in Table 2, in some copper centers the Cu–N_h bond distances are shorter than the Cu–N^1 ones, while in other centers the opposite behavior is observed. However, in all cases the Cu–N_h ($\Delta = 1.951$–2.025 Å) and the Cu–^{1}N ($\Delta = 1.993$–2.036 Å) bond lengths are in the range of those previously reported in similar copper complexes with sulfonamides [19,21,5]. The Cu–Cu distances in the unit 1 and 2 are similar to those of most of the structurally related complexes [19,28,40,41]. On the opposite, unit 3 presented a short Cu–Cu distance (2.535 Å) comparable with those of several complexes like $[Cu_2(CH_3COO)_4(H_2O)_2] \cdot 2dmf$ (2.541 Å) [42], $[Cu_2(N\text{-}p\text{-tolylsulfonyl pyridine})_4]$ (2.516 Å), and $[Cu_2(1,3\text{-di-phenyltriazenato})_4]$

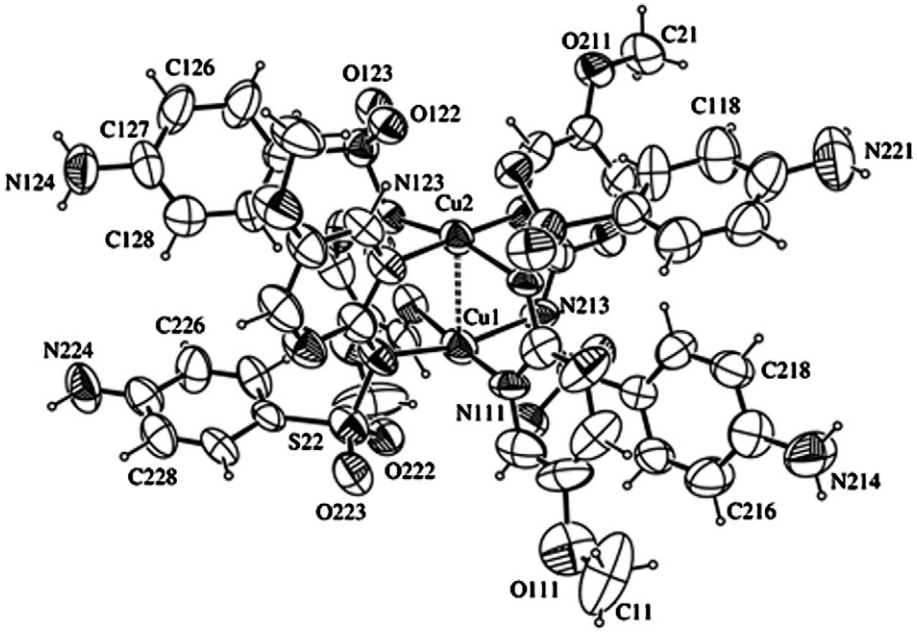

Fig. 2. ORTEP view of a dimeric unit of $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$, showing the atoms labeling and the 30% probability ellipsoids.

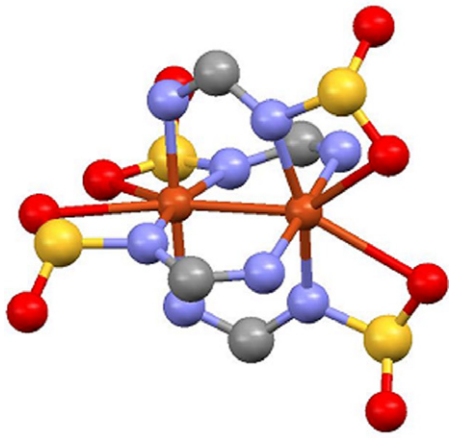

Fig. 3. Scheme of copper coordination environment.

(2.441 Å) [43]. This different Cu–Cu bond length in unit 3 seems to be related to an increment in two of the four Cu–O distances (see Table 2). It is interesting to observe that, in the three units, the sulfonamidic O atoms participate in a short interaction with the pyrimidinic N atoms, not bonded to the metal (ranging between 2.85(1) and 3.04(1) Å), forming a five member ring.

The square planar geometry of all copper ions presents distortions as it is shown in the Cu–N_4 plane distances in Table 2.

The bond angles of the Cu–N_4 square plane are close to 90°. The Cu–N_4 planes of each dimeric unit are almost coplanar and perpendicular to the Cu–Cu axes. Besides, the angles between the Cu–Cu axes for units 1 and 3 are almost parallel ($\alpha = 17.79(4)°$) while for unit 1 and 2 are almost perpendicular ($\alpha = 89.90(3)°$). The N1–C–Nh angles of the unit 3 bridge are slightly greater than those of the dimeric units 1 and 2.

Taking into account these results, it can be said that units 1 and 2 present little difference between each other, differing by the orientation of the cyclic groups and their substituents while unit 3 differs in several bond distances and angles, principally in the Cu–Cu distance.

The study of the crystal packing shows that the three-dimensional structure is stabilized by several networks of inter- and intra-molecular interactions (see Table 3). The structure shows four H-bond intra-unit between the Nh and the sulfonic O of the same sulfonamide. Besides, three H-bond inter-unit are formed: one of them between the sulfonic O of one unit and the ^{4}N of the second unit, the second one between the O from the –OCH_3 of one unit and the N_h of the other unit, and the third between two sulfonic oxygen of different units. The water molecules bond the dimeric units 2 and 3 through moderated hydrogen bonds [44] involving the O atoms from the –SO_2 groups, whereas unit 1 does not have any interaction with the water molecules. An interesting feature of this complex's crystal packing is that ligand arrangement gives rise to a hydrophilic region formed by the NH_2–Ar, the –SO_2N–, and the –OCH_3 groups placed to the external surface of a cylindrical area with a hydrophobic region in the inside. However, no stacking between the aromatic rings is observed.

3.2. Vibrational spectra

The IR and Raman spectra of the complex were compared with those of previously reported complexes

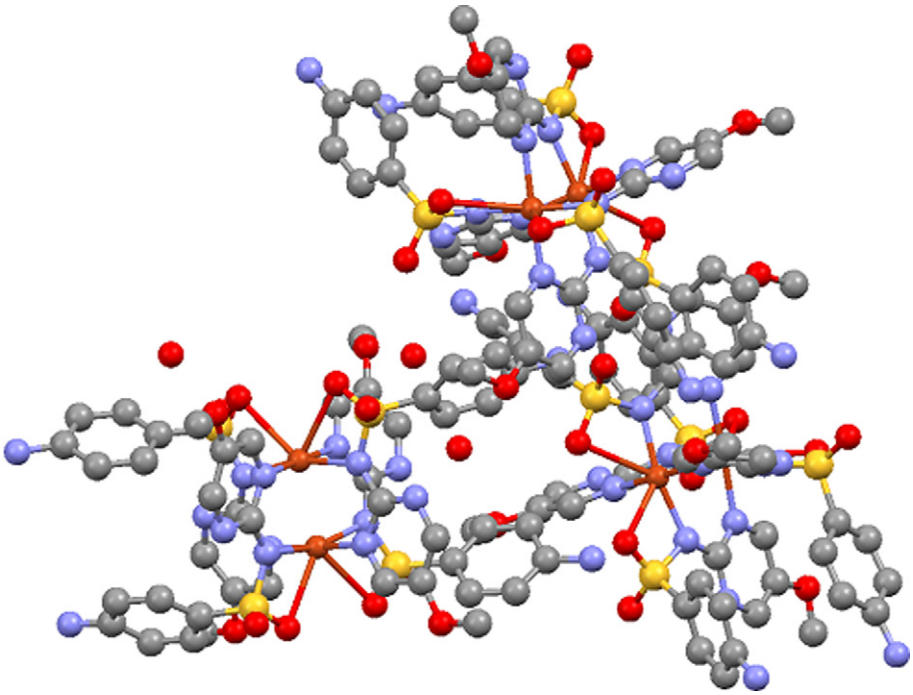

Fig. 4. ORTEP view of the asymmetric unit of $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$.

[14,18,20,45–53]. Table 4 summarizes the main bands and their proposed assignments.

In Table 4, the bands of the complex assigned to ν_a(NH) and ν_s(NH) appeared at similar frequencies to those obtained for the free sulfameter, which agree with the fact that the amino group did not participate in the coordination. The Raman spectrum of the complex did not show these bands in accordance with the bibliographic data [53]. Furthermore, δNH_2 bands are almost unchanged in the IR spectra and have exhibited no Raman signals.

The free ligand spectrum presented a strong broad band at 3230 cm^{-1} possibly involving the NH stretching of the sulfonamide group and other vibrational modes characteristic of ligand. In the complex spectrum this band changed to a medium-intensity signal at 3238 cm^{-1}. The change in this band is probably due to the disappearance of the ν(NH) of the sulfonamide group after deprotonation, remaining the other vibrational modes of the molecule. This behavior was previously reported in other copper complexes with sulfonamides [54].

The heteroaromatic ring motions cannot be interpreted as simple vibrational modes as most of them are of complex origin and involve different vibrational types. Some ring absorption bands can shift upon complexation to metal ions through the nitrogen atom, but most of them are not metal-dependent. As shown Table 5, only one band presented a significant shift ($\Delta = 21$ cm^{-1}) to lower frequencies, while in most bands no change was observed.

The asymmetric and symmetric $-SO_2$ group stretching vibrations shifted to lower frequencies in the copper complex ($\Delta = 40$ cm^{-1} and $\Delta = 27$ cm^{-1}, respectively). This behavior is in accordance with the fact that each copper interacts with two sulfonamide O atoms from two different sulfameter molecules as shown in Fig. 2.

Furthermore, complex spectrum showed a broad band at 3580 cm^{-1} assigned to the presence of a water molecule in the complex. Other bands corresponding to water molecule modes could not be assigned due to the fact that they were overlapped with other signals.

3.3. Electronic spectrum

The copper complex presented three wide bands at 358, 557, and 841 cm^{-1}. According to some authors, the band at

358 cm^{-1} is related to a binuclear nature of copper complexes [32], while other authors assigned it as either metal–ligand [14,45] or ligand–metal [50] charge transfers. In this case, the first assignment is in accordance with the structure found for the complex. In spite of this, there are different copper-sulfonamide complexes which present

this band and do not bear dimeric structure [21]. The other two bands correspond to d–d transitions [51].

3.4. EPR measurements

The X-band EPR spectrum (Fig. 5A) of the title complex shows major lines centered at ~150, ~270, ~315, and ~380 mT. This set of resonances can be rationalized in terms of a coupled dimmer ($S = 1$) of Cu(II) ions. The copper coupling is antiferromagnetic as determined from the absence of EPR signal at 4 K, which indicates a $S = 0$ ground state for the spin system. The $g = 2$ (~315 mT) resonance in this case is most likely due to mononuclear impurities in the sample.

In the $S = 1$ case, the zero-field contribution gives rise to two allowed transitions per principal direction (x, y, z) [55], thus yielding a six-line pattern in the EPR spectrum [56]. The resonance fields for each of those transitions are denoted H_{x1}, H_{x2}, H_{y1}, H_{y2}, H_{z1}, H_{z2}, and expressions for them can be found elsewhere [57]. The two major lines observed in Fig. 5A result from the overlap at X-band of resonance corresponding to H_{x1} and H_{y1} (~270 mT) and H_{x2} and H_{y2} (~380 mT). The H_{z2} EPR signal is barely seen as a slight shoulder around ~420 mT. Another resonance is observed at ca. 150 mT (Fig. 5A) and is due to a collapse of the half-field transition ($\Delta M_s = \pm 2$), present in coupled systems, with the H_{z1} resonance. At Q-band (Fig. 5B), the otherwise overlapped signals corresponding to the half-field (~580 mT) and H_{z1} (~990 mT) transitions are clearly resolved. The other resonance in the $g \sim 2$ region can also be unambiguously assigned to the additional peaks observed in the spectrum ($H_{x1}, H_{y1} \sim 1150$ mT and $H_{x2}, H_{y2} \sim 1250$ mT). Moreover, the Q-band spectrum reveals extra peaks that indicate the existence of a second magnetically non-equivalent copper dimer (see calculated spectra for each component in Fig. 5B). This second less intense component presents the same pattern of resonance fields discussed above.

To further investigate the origin of the spectra at both frequencies, we firstly performed spectral simulation of the Q-band spectrum (Fig. 5B) using the EasySpin package [58]. This software has been recently made available to the EPR community and is designed to address several types of EPR simulations including solid-state spectra of both single crystals and disordered systems with any electronic spin S. In our case, the spin Hamiltonian includes the following interactions:

$$\mathscr{H} = \beta B \cdot g \cdot S + S \cdot D \cdot S + S \cdot A \cdot I$$

where B is the applied magnetic field, g is the gyromagnetic tensor, D is the *zero-field interaction* or spin–spin tensor and A is the hyperfine interaction. The experimental spectrum was simulated with two sets of g-values (Table 5), which yielded a very reasonable calculated spectrum (Fig. 5B), thus confirming our initial assumption of two non-equivalent types of dimers. The g, A, and D parameters determined from the Q-band simulation were then used to simulate the X-band spectrum and resulted in a very good agreement (Fig. 5A – short dotted line). Minor adjustments in the linewidth parameters were made to achieve the best simulated spectra. The g- and D-values obtained from our simulation are in agreement with values previously determined for other copper dimers [42,19,59].

In our EPR spectrum we can then distinguish two sets of dimers (species 1 and 2), whose differences in coupling mechanism could be related to difference in the Cu–Cu distance as observed from the X-ray data. As described by

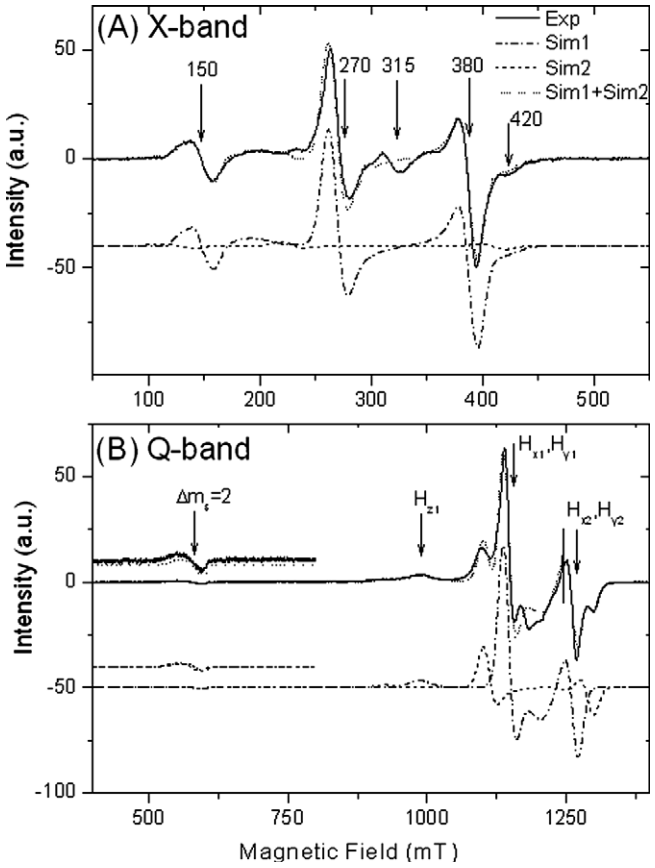

Fig. 5. (A) X- and (B) Q-band EPR spectra (solid lines) of polycrystalline sample of $[Cu_2(sulfameter)_4]_3 \cdot 2.5H_2O$ and their respective simulations (short dotted lines) obtained using the EasySpin software. The calculated spectra for each component (sim1 and sim2) are also shown in the figure. Arrows indicate the resonance fields discussed in the text.

Casanova et al. [40], in this kind of copper arrangement this distance plays an important role in the exchange coupling.

4. Conclusions

This work showed a new copper(II) complex with sulfameter as ligand. Its structure presented three dimeric units in the asymmetric unit. Two of them are similar whilst the other presented structural differences. The EPR spectra indicated the copper coupling is antiferromagnetic and showed the existence of two magnetically non-equivalent dimers. The IR spectra is in accordance with the coordination of copper(II) through the sulfonamidic N and the heterocyclic N and the electronic spectra agreed with the structure found.

Abstract

Two acyclic Schiff-base ligands, bis-5,5′-(1,3-propanediyldiimino)-2,2-dimethyl-4-hexene-3-one and bis-5,5′-(1,3-ethanediyldiimino)-2,2-dimethyl-4-hexene-3-one, were used to complex homoleptic triethylaluminum and tris[bis(trimethylsilyl)amino]aluminum, respectively. The acid–base reactions proceeded in excellent yields with elimination of ethane or bis(trimethylsilyl)amine during *in situ* deprotonation of the protio Schiff-base. The colorless aluminum complexes crystallized from *n*-pentane and were characterized by standard methods including single crystal X-ray diffraction. Polymerization of racemic lactide, with addition of alcohol, yielded PLA with narrow polydispersities but low molecular weights.

1. Introduction

Schiff-bases (SB) constitute one of the oldest chelator classes in inorganic chemistry and continue to receive considerable attention. One active research area is the binding of Group 13 elements to SBs affording 5-coordinate species where bonding occurs through classical N_2O_2 ligation [1]. Analogously, we have been interested in assessing the extent to which steric factors of the Schiff-base, as well as those of other ligands bound to the metal (typically monodentate monoanions) can influence catalysis [1]. Previously, our focus concentrated on modifying the frontal, ''saturated'' SB steric bulk, and now we sought to include direct comparisons of linker length (Fig. 1). Indeed, much of the resurgence associated with similar complexes is attributable to their activity in numerous catalytic cycles and relativity low envirotoxicity (for Al^{3+}) [2]. Particularly relevant is the use of aluminum centers with aromatic Salen-type ligands for the polymerization of biodegradable and biocompatible polymers, such as those derived from lactones, lactides, carbon dioxide and epoxides, and other renewable resources [3–7]. Recent reviews by Atwood [1] and Lewinski and Zachara [8] serve as testament to the burgeoning activity in this area. In our hands we, for the first time, wanted to evaluate ''saturated'' SB Al^{3+} complexes for the polymerization of racemic lactide. The advantages of these complexes would be the lack of aromaticity and tunable peripheral steric bulk, both precluding the possibility of oligomerization in the solution and solid-state species [9].

Our secondary interest in these Group 13 complexes stems from their utility as benchmarks to isoelectronic five-coordinate rare earth Schiff-base complexes [9]. The present study was also designed to compare Al^{3+} structural features and activities with those of these heavier congeners. To this end, we synthesized a new ligand (bis-5,5′-(1,3-ethanediyldiimino)-2,2-dimethyl-4-hexene-3-one, **(1)**

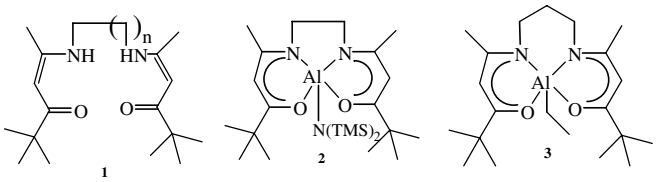

Fig. 1. "Saturated" Schiff-base ligand (**1**) and the two Al^{3+} complexes (**2** and **3**).

and two, five-coordinate metal complexes (**2** and **3**) exploiting *in situ* deprotonation reactions. Marked structural differences exist between **2** and **3** and amongst their square pyramidal rare earth counterparts. The Al^{3+} coordination polyhedron is rigorously trigonal bipyramidal in **3** and distorted trigonal pyramidal in **2**; this difference is due at least in part to the Schiff-base ethylene spacer in **2** that is less flexible than the propylene spacer in **3**.

2. Experimental

2.1. Materials and methods

Standard Schlenk techniques and a Vacuum Atmospheres N_2-filled glovebox were used throughout the isolation and handling of all aluminum complexes. 1,2-diaminoethane (Acros), absolute ethanol (EtOH, Pharmco), Et_3Al solution (Aldrich) and benzene (C_6H_6) were used as received whereas alkali earth bis(trimethylsilyl)amides (Gelest) and *rac*-lactide were first purified by double sublimation at $\sim 10^{-5}$ Torr. 2,2-Dimethyl-3,5-hexanedione [10] and bis-5,5′-(1,3-propanediyldiimino)-2,2-dimethyl-4-hexene-3-one [9] were synthesized using literature methods. Toluene (C_7H_8) and deuterated benzene (C_6D_6) with sodium metal and pentane (C_5H_{12}, CaH_2) were dried and distilled immediately before use. Polymerization reactions followed Nomura's procedure [6], and dry MeOH was added to activate the catalysts. ^1H and ^{13}C NMR were recorded on a GE 300 MHz (^1H) and processed using NUTS software. The solid-state molecular structures of **2** and **3** were determined by single crystal X-ray diffraction at Wake Forest University (Table 1) and elemental analyses were performed at Midwest Microlabs (Indianapolis, IN). Melting points were determined using a modified Mel-Temp II with digital thermocouple readouts and are uncorrected.

2.2. Synthesis of bis-5,5′-(1,3-ethanediyldiimino)-2,2-dimethyl-4-hexene-3-one (*1*)

Under ambient conditions, to a 250 mL 24/40 1-neck round bottom flask charged with 50 mL EtOH and 17.3 g (122 mmol) 2,2-dimethyl-3,5-hexanedione was added 3.7 g (61 mmol) 1,3-diaminoethane in 35 mL EtOH dropwise over 30 minutes. Following this, a condenser replaced the 125 mL addition funnel and the reaction heated at reflux overnight, after which time it was diluted with 100 mL *d*H_2O and extracted twice with 30 mL Et_2O. The organics were washed with 4×20 mL H_2O, dried over Na_2SO_4, filtered, and removed in vacuo yielding a dull-yellow wax. This crude product was subjected to a C_6H_6 azeotrope and recrystallized from C_7H_{16} affording colorless crystals of **1** in unoptimized yields between 60% and 80%; ^1H NMR (δ, $CDCl_3$): 1.21 (s, 18H), 1.92 (m, 6H), 3.40 (m, 4H), 5.15 (s, 2H), 11.1 (b, 2H); ^{13}C NMR (δ, $CDCl_3$): 19.3, 28.0, 41.5, 43.6, 91.5, 163.8, 204.7; *Anal.* Calc. for $C_{18}H_{32}N_2O_2$: C, 70.09; H, 10.46; N, 9.08. Found C, 69.85; H, 10.06; N, 9.03%.

2.3. Bis-5,5′-(1,3-ethanediyldiimino)-2,2-dimethyl-4-hexene-3-onato aluminum bis(trimethylsilyl)amino (*2*)

Forty milliliters of C_7H_{16} dissolved 0.316 g (1.02 mmol) anhydrous **1** and simultaneously, in a 100 mL, 1-neck round bottom flask 0.528 g (1.04 mmol) $Al[N(TMS)_2]_3$ [11] was dissolved in 10 mL C_7H_{16}. The ligand solution was then added to the flask containing $Al[N(TMS)_2]_3$ via syringe in one portion and the reaction stirred at reflux overnight, after which time the solvent was removed in vacuo. The white solids were then recrystallized from minimal C_5H_{12} in a −20 °C freezer for 2 days to afford colorless crystals. Yield 92%; m.p. 141–143 °C (dec.); ^1H NMR (C_6D_6): δ 0.39 (s, 9H); 1.29 (s, 9H); 1.35 (s, 3H); 2.66 (m, 1H); 3.28 (m, 1H); 5.21 (s, 1H); ^{13}C NMR (C_6D_6): δ 5.5; 21.2; 28.6; 39.1; 45.7; 95.4; 171.3; 188.8; *Anal.* Calc. for $C_{24}H_{48}N_3O_2Si_2Al$: C, 58.37; H, 9.80; N, 8.51. Found: C, 56.88; H, 9.23; N, 8.01%.

2.4. Bis-5,5′-(1,3-propanediyldiimino)-2,2-dimethyl-4-hexene-3-onato ethylaluminum (*3*)

4.75 mL of 1.0 M $AlEt_3$ (4.75 mmol) was slowly added, via a syringe, to a 100 mL Schlenk flask containing a solution of 1.54 g (4.77 mmol) **1** in 35 mL dry C_7H_8. Addition of $AlEt_3$ caused the reaction to become yellow and evolve ethane gas. After stirring (~5 min) the solution returned to colorless. The reaction was heated at reflux overnight and solvent removed in vacuo to afford an off-white solid. The product crystallized from C_5H_{12} to present large, clear, colorless plates. Yield 94%; m.p. 124–125 °C (dec.); ^1H NMR (C_6D_6): δ 0.48 (m, 1H); 1.25 (m, 1H); 1.34 (s, 9H); 1.58 (s, 3H); 1,64 (m, 3H) 2.29 (m, 1H); 2.75 (m, 1H); 3.01 (m, 1H); 5.22 (s, 1H). ^{13}C NMR (C_6D_6): δ 11.5; 21.7; 26.2; 28.6; 39.1; 49.4; 94.7; 172.0; 188.9 *Anal.* Calc. for $C_{21}H_{37}N_2O_2Al$: C, 66.99; H, 9.90; N, 7.44. Found: C, 66.56; H, 9.76; N, 7.39%.

2.5. Polymeriation of racemic lactide

Two 25 mL Schlenk flasks under N_2 were each charged with 720 mg (5.0 mmol) *rac*-lactide, 10 mL toluene, and a stir bar. To one, 0.2 mL of MeOH was added and both flasks heated to 70 °C until the *rac*-lactide dissolved. Following this 0.0188 g (0.05 mmol) of **3** was added to each

as a 0.05 M toluene solution. The reaction flasks remained immersed in an oil bath heated to 70 °C and polymerization progress monitored by ^{1}H NMR. Near completion (~90% conversion by disappearance of monomer) each flask containing polymer and catalyst were precipitated and quenched with MeOH, respectively and dried in vacuo.

3. Results and discussion

3.1. Ligands

Organic **1** originates from a non-commercial diketone and the large frontal ^{t}Bu groups afford only one of three possible structural isomers following the Schiff-base condensation. A noteworthy and requisite ketoiminate purification step is a benzene azeotrope to remove all spurious H_2O (the reaction byproduct), as anhydrous starting materials are essential or metallation will fail. Overall, ligand choice was predicated by our previous successes in isolating and structurally characterizing anhydrous, 5-coordinate Schiff-base lanthanide (III) complexes that all exhibited mononuclear, slightly distorted square pyramidal metal coordination geometry (vide supra). Since the metal coordination in $(C_2H_5)Al(sal_2en)$ was reported to also be distorted square-pyramidal [1], we (incorrectly) anticipated a distorted square-pyramidal coordination for the Al^{3+} ion in **2** and **3** [12]. With the ligand set in **2** being nearly identical to that in some of our earlier studies with lanthanide(III) complexes, a structural characterization of **2** would allow us to assess the effects of reducing metal size on coordination geometry. Structural comparisons of **2** with **3**, would also allow us to explore the extent to which changes in steric factors of the ligand set can effect metal coordination geometry: The SB in **3** has one more methylene group and the terminally-bonded ligand is considerably less bulky.

3.2. Complexes

Al^{3+} introduction occurs using commercial Et_3Al solution or $Al(N[TMS]_2)_3$ [13], the latter was synthesized and purified using literature preparations [11]. Addition of either to a heptane solution of the protio Schiff-base briefly causes a light-yellow color and then the reactions return to their transparent, colorless appearance. With Et_3Al, evolution of C_2H_6 is rapid and obvious (as evidenced by bubbling of the isolated the Schlenk N_2 bubbler), whereas for bulkier $Al(N[TMS]_2)_3$ steric factors slow the acid–base reaction. To assure completion, both reactions were heated

overnight at reflux. Once purified by recrystallization in C_5H_{12} the colorless compounds exhibit melting points proportional to increased monoanion molecular dissymmetry and molecular weight (i.e. m.p. **2** > **3**), and each decomposes before volatilizing at $<10^{-5}$ Torr. There is no spectroscopic (NMR) or structural evidence to support complex dimerization or oligomerization [1,2], and the lack of ligand aromaticity promotes the formation of mononuclear species in both solution and the solid-state [14–16], although fluxional behavior is suggested by the methylene proton splittings.

The X-ray diffraction-derived molecular structures of **2** and **3** are shown in Fig. 2. Both compounds contain a 5-coordinate Al^{3+} ion that is terminally-bonded to a monoanion and complexed to all four donor atoms of an N_2O_2 Schiff-base (Table 2). While the bis(trimethylsilyl)amino monoanion [16] in **2** is considerably bulkier than the ethyl monoanion in **3**, the ethylene bridged Schiff-base in **2** is slightly more compact and more restricted than the propylene-bridged N_2O_2 Schiff-base of **3**. The Al^{3+} coordination geometry in both complexes is best described as trigonal bipyramidal with a distorted polyhedron ($\tau = 0.65$) in **2** and a nearly ideal polyhedron ($\tau = 1.00$) in **3** [12]. Axial atoms O(1) and N(2) subtend angles of 162.4(1)° and 173.6(1)° in **2** and **3**, respectively. The less ideal trigonal bipyramidal coordination geometry in **2** probably results from the smaller "bite" angle and increased rigidity attributable to its ethylene spacer as well as the increased bulk of its terminally-bonded anion when compared to **3**. This anion Al–N(3) bond length of 1.86 Å is one of the shortest "apical" bond lengths amongst this class of compounds, and more closely resemble that of the hindered organometallic imido Cp*AlNSiPh$_3$ [1,17]. The wrapping pattern adopted by the Schiff-base in both complexes is the one expected: it spans 3 contiguous polyhedral edges that would ideally subtend a 90° angle at the metal. Furthermore, the SB Al–O and Al–N distances in **2** and **3** all exhibit the sterically-anticipated trigonal-bipyramidal trend of longer bonds to axial ligands than to equatorial ligands. Interestingly, these differences in SB Al–O and Al–N distances are considerably larger for the nearly ideal **3** (0.066–0.106 Å) than the more distorted **2** (0.029–0.031 Å). The C–C bond lengths within the ketoiminato rings [C(2)–C(3) < C(3)–C(4), C(8)–C(9) < C(7)–C(8) in **2** and C(2)–C(3) < C(3)–C(4), C(9)–C(10) < C(8)–C(9) in **3**] suggest more enolic character [3] with the primary resonance structure favoring the harder oxygen atoms upon chelation in both complexes. The remaining C–O, C–N and C–C bond lengths in **2** and **3** are unremarkable.

While complex **2** contains a terminally-bonded bis(trimethylsilyl)amido group and an ethylene-bridged Schiff-base, organometallic complex **3** has a terminally-bonded ethyl group and a propyl-bridged Schiff-base [1,16]. The equatorial plane has a slight deformation [12] with C(21) canted from an idealized N_2O_2 normal although equally centered between N(2) and O(1). It resides forward toward O(2)

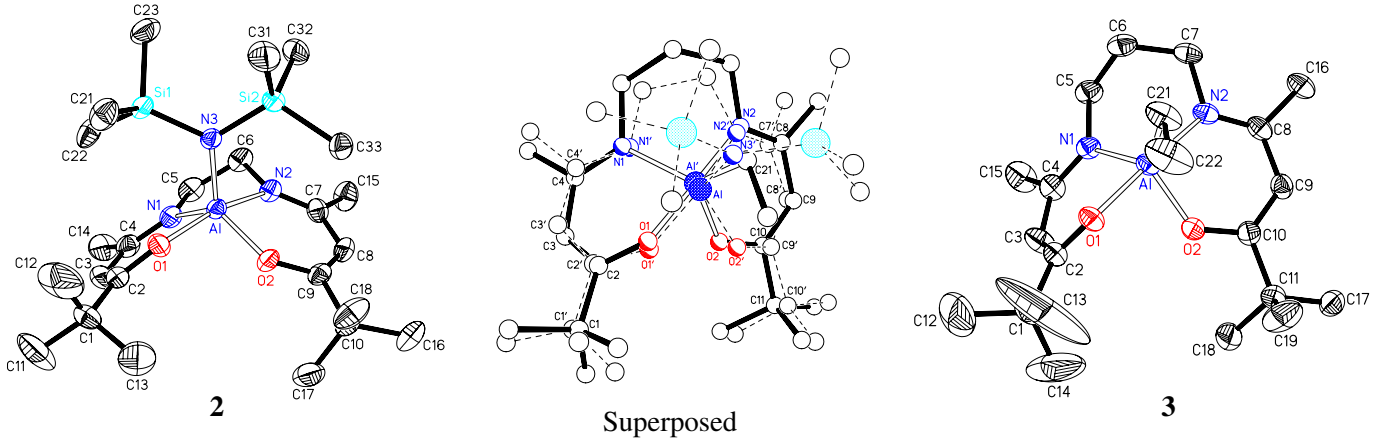

Fig. 2. X-ray diffraction-derived molecular structures of **2** and **3** and each coordination environment superposed. Relevant bond lengths and angles can be found in Table 2 and discussions throughout the text. Hydrogen atoms were removed for clarity and thermal ellipsoids are at 30% probability.

and the C(21)–Al–O(2) and C(21)–Al–N(1) angles are 119.9 ° and 126.9 °, respectively. This distortion is most likely due to the frontal steric constraints forming an unsymmetric pocket above one of the ^{t}Bu groups and removal of the eclipsed hydrogen conformation along the methylenes of the larger C_3 linker [1]. This C_3 backbone of the propyl bridge in **3** forms a six-membered chelate ring, Al–N(1)–C(6)–C(7)–C(8)–N(2), that adopts the boat conformation. Fig. 2 also shows a superposition of **2** and **3.** The labeled atoms from the ketoiminato halves, the coordinated atoms from the monodentate ligands, and the exocyclic carbons have an rms deviation of 0.283 Å and a maximum deviation of 0.482 Å. One of the Schiff-base ^{t}Bu groups in each molecule also superimposes quite closely. The regions where the two Schiff-bases in **2** and **3** do not superimpose are near the linker groups and the second ^{t}Bu group which is rotated about the C(1)–C(2) bond in **2** relative to **3**. Although the ligand set in **2** is virtually identical (with the exception of one less methylene group in the linker) to that for the earlier trivalent lanthanide complexes [9], the ionic radius of 5-coordinate Al^{3+} is smaller. The net result of replacing a trivalent lanthanide ion with the smaller Al^{3+} ion is therefore to ''pull'' all of the ligands radially toward the central metal ion. This produces shorter intraligand contacts unless the relative orientations of the ligands change. A minor reorientation (linked-ligand Berry pseudo-rotation) of the square-pyramidal lanthanide amido/Schiff-base ligand set would give distorted trigonal bipyramidal Al^{3+} coordination in **2** with shorter metal–ligand distances.

Lactide polymerizations to produce polylactic acid (pLA) are an intensely active area within green chemistry. Inspired by Nomura and others using Al Salen complexes [4–7] we began evaluating our ''saturated'' complexes as polymerization catalysts for this biocompatible material. Initially, **2** and **3** were used to initiate polymerization, however no activity was observed with **2** and only modest turnovers with **3**. Furthermore, polymers derived from **3** exhibited low molecular weights, broad polydispersities, and no stereocontrol. Following these efforts, and anticipating that the apical ligand and metal center were too encumbered with peripheral steric bulk to allow monomer insertion, we began activating the Al Schiff-base complexes with methanol and benzyl alcohol. Although our efforts are only beginning, using the aforementioned systems (with various loadings) we have recovered atactic pLA with molecular weight control (up to 20,000 Da) and monomodal polydispersities (<1.3). Currently, we are optimizing reaction conditions, performing more detailed mechanistic studies, and attempting to control tacticity [6].

4. Conclusions

This report presents our initial results on a new organic Schiff-base (**1**) and the molecular structures of two new Al^{3+} complexes bearing ''saturated'' Schiff-bases (**2** and **3**). Unlike the square pyramidal geometry of their isoelectronic rare earth congeners, both aluminum complexes adopt ideal and slightly distorted trigonal bipyramidal coordination environments. Initial polymerization results with either the terminal ethyl or bis(trimethylsilyl)amino ligand failed; however, activation with trace MeOH yielded biodegradable polymers with some control over both molecular weights and polydispersity.

Available online 7 March 2007

Abstract

Raman spectroscopy complimented with supplementary infrared spectroscopy has been used to characterise the vibrational spectrum of aurichalcite a zinc/copper hydroxy carbonate $(Zn,Cu^{2+})_5(CO_3)_2(OH)_6$. XRD patterns of all specimens show high orientation and indicate the presence of some impurities such as rosasite and hydrozincite. However, the diffraction patterns for all samples are well correlated to the standard reference patterns. SEM images show highly crystalline and ordered structures in the form of micron long fibres and plates. EDAX analyses indicate variations in chemical composition of Cu/Zn ratios ranging from 1/1.06 to 1/2.87. The symmetry of the carbonate anion in aurichalcite is C_s and is composition dependent. This symmetry reduction results in multiple bands in both the symmetric stretching and bending regions. The intense band at 1072 cm^{-1} is assigned to the $\nu_1(CO_3)^{2-}$ symmetric stretching mode. Three Raman bands assigned to the $\nu_3(CO_3)^{2-}$ antisymmetric stretching modes are observed for aurichalcite at 1506, 1485 and 1337 cm^{-1}. Multiple Raman bands are observed in 800–850 cm^{-1} and 720–750 cm^{-1} regions and are attributed to ν_2 and ν_4 bending modes confirming the reduction of the carbonate anion symmetry in the aurichalcite structure. An intense Raman band at 1060 cm^{-1} is attributed to the δ OH deformation mode.

1. Introduction

The mineral aurichalcite $(Zn,Cu^{2+})_5(CO_3)_2(OH)_6$ is one of a large number of highly coloured copper bearing minerals [1–3]. Aurichalcite forms in the oxidation zones of zinc–copper deposits. Crystals are acicular and fibrous and often found in aggregates. The color is an attractive grass green to pale blue–green. Aurichalcite will often partially cover red limonite and be associated with such colorful minerals as rosasite, azurite, smithsonite and malachite. Aurichalcite may be confused with rosasite minerals because of their similar appearance. Rosasite minerals including glaukosphaerite; kolwezite; mcguinnessite are usually more massive and not lamellar. Other related hydroxy carbonates are nullaginite and pokrovskite. It appears that aurichalcite is similar to hydrozincite and both minerals are formed under the same conditions when copper is present in the solution [4]. Williams further states that up to one quarter of the cation sites are occupied by Cu^{2+}. Greater concentrations of copper give rise to other discrete phases such as malachite and rosasite. Interestingly the range of substitution of other transition metal ions in the aurichalcite lattice is very limited. The minerals in the hydroxy carbonate group have been synthesised because of their potential as catalysts [2]. Further studies of synthetic hydroxy carbonates incorporated Al^{3+} into the structures [5]. The mineral is monoclinic as are many of the other hydroxy carbonates such as malachite. Anthony et al. (2003) reports aurichalcite to be acicular to lath-like crystals with prominent crystal growth along the [0 1 0] axis, commonly straited parallel to [0 0 1] axis. The mineral is of point group $2/m$ and space group $P2_1/m$ [6]. The model for the structure of aurichalcite based upon the crystallographic studies of this mineral using

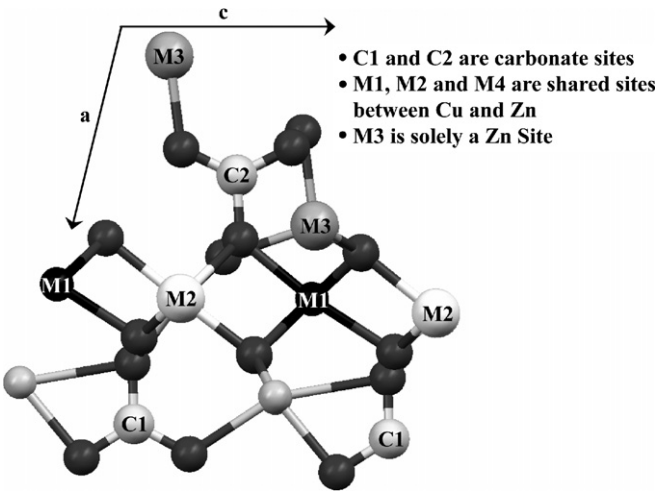

Fig. 1. Model of the structure of aurichalcite.

synchrotron radiation by Harding et al. [8] is shown in Fig. 1. Based on this structure the symmetry of the carbonate anion is C_s. The accurate X-ray crystallography of aurichalcite is difficult to obtain because of its very small interwoven needles which makes obtaining single crystal studies difficult [3,6–8]. Harding et al. showed the positions in the structure of aurichalcite are octahedrally coordinated. The atom positions occupied by zinc have tetrahedral coordination [8].

Spectroscopic studies of aurichalcites and related minerals have been sparse. Reports regarding the chemical analysis, ESR, electronic and some limited infrared spectroscopic studies have been published [9]. These workers reported optical spectra revealing the presence of copper in D_{4h} symmetry with crystal field (Dq) and tetragonal field (Ds and Dt). This research was further extended in a comparison of rosasite and aurichalcite [10]. Optical and EPR spectra of aurichalcite accounted for Cu^{2+} ion in the distorted octahedron site [10]. Stoilova et al. [29] reported the infrared spectra of a series of synthetic hydroxy carbonates containing Cu^{2+}.

Raman spectroscopy has proven very useful for the study of minerals [11–13]. Indeed Raman spectroscopy has proven most useful for the study of diagentically related minerals as often occurs with carbonate minerals [14–18]. Some previous studies have been undertaken by the authors using Raman spectroscopy to study complex secondary minerals formed by crystallisation from concentrated sulphate solutions [19]. The authors have undertaken some comprehensive studies of selected carbonate minerals [20–24]. The importance of this work rests with the application of Raman spectroscopy to the study of minerals and inorganic compounds which show no or limited symmetry. As part of our comprehensive research on the molecular structure of secondary minerals, we report the Raman spectroscopic study complemented by X-ray diffraction and electron microscopy of selected aurichalcites from different origins.

2. Experimental

2.1. Mineral samples

Selected minerals were obtained from the Mineralogical Research Company and other sources including Museum Victoria, Victoria, Australia. The samples were phase analysed by X-ray diffraction and for chemical composition by EDX measurements.

2.2. X-ray diffraction

X-ray diffraction patterns were collected using a Philips X'pert wide angle X-ray diffractometer, operating in step scan mode, with Cu Kα radiation (1.54052 Å). Patterns were collected in the range 5–90 ° 2θ with a step size of 0.02° and a rate of 41.75 s per step. Samples were prepared as powders and pressed into a depression quartz low background plate.

2.3. SEM and EDX

Mineral samples were coated with a thin layer of evaporated carbon and secondary electron images were obtained using a scanning electron microscope (FEI Quanta 200 SEM, FEI Company, Hillsboro, OR, USA). For X-ray microanalysis (EDX), three samples were embedded in Araldite resin and polished with diamond paste on Lamplan 450 polishing cloth using water as a lubricant. The samples were coated with a thin layer of evaporated carbon for conduction and examined in a JEOL 840A analytical SEM (JEOL Ltd., Tokyo, Japan) at 25 kV accelerating voltage. Preliminary analyses of the carbonate mineral samples were carried out on the FEI Quanta SEM using an EDAX X-ray microanalyser, and microanalyses of the clusters of fine crystals were carried out using a full standards quantitative procedure on the JEOL 840 SEM using a JEOL-2300 energy-dispersive X-ray microanalysis system (JEOL Ltd., Tokyo, Japan). Oxygen was not measured directly but was calculated using assumed stoichiometry to the other elements analysed.

2.4. Raman microprobe spectroscopy

The crystals of aurichalcite were placed and oriented on the stage of an Olympus BHSM microscope, equipped with 10× and 50× objectives and part of a Renishaw 1000 Raman microscope system, which also includes a monochromator, a filter system and a charge coupled device (CCD). Raman spectra were excited by a He–Ne laser (633 nm) at a resolution of 2 cm^{-1} in the range between 100 and 4000 cm^{-1}. Repeated acquisition using the highest magnification was accumulated to improve the signal to noise ratio. Spectra were calibrated using the 520.5 cm^{-1} line of a silicon wafer. In order to ensure that the correct spectra are obtained, the incident excitation radiation was scrambled. Details of the technique have been published by the authors.

2.5. Mid-IR spectroscopy

Infrared spectra were obtained using a Nicolet Nexus 870 FTIR spectrometer with a smart endurance single bounce diamond ATR cell. Spectra over the 4000–525 cm^{-1} range were obtained by the co-addition of 128 scans with a resolution of 4 cm^{-1} and a mirror velocity of 0.6329 cm/s. Spectra were co-added to improve the signal to noise ratio.

Spectral manipulation such as baseline adjustment, smoothing and normalisation were performed using the Spectracalc software package GRAMS (Galactic Industries Corporation, NH, USA). Band component analysis was undertaken using the Jandel Scientific 'Peakfit' software package which enabled the type of fitting function to be selected and allows specific parameters to be fixed or varied accordingly. Band fitting was done using a Lorentz–Gauss cross-product function with the minimum number of component bands used for the fitting process. The Gauss–Lorentz ratio was maintained at values greater than 0.7 and fitting was undertaken until reproducible results were obtained with squared correlations of r^2 greater than 0.995. The reason for using this type of mathematical function is that this function best fits vibrational spectroscopic data where the central peak is Lorentzian and the wings of the peak are Gaussian. It should be noted that where sharp bands are obtained in the Raman spectra fitting is unique. If one starts with different starting parameters, then the fit will converge to a unique result. When bands are broad the uniqueness of the fit is open to question. Band fitting offers a procedure to determine the exact position of bands.

3. Results and discussion

3.1. X-ray diffraction

The X-ray diffraction patterns of the three mineral samples together with likely impurities are shown in Fig. 2. The XRD patterns of the samples from Durango and Chihuahua are highly oriented (ref. Pattern 17-0743). The XRD patterns match that of the standard reference pattern The aurichalcite from Arizona does show some impurities of rosasite (ref. Pattern 36-1475). To make an XRD pattern all material on the surface of the host rock is scraped off for analysis, so it is not unexpected that the XRD patterns will show some impurity. In terms of both Raman spectroscopy and SEM analysis a group of crystals or even a single crystal may be collected for spectroscopic analysis.

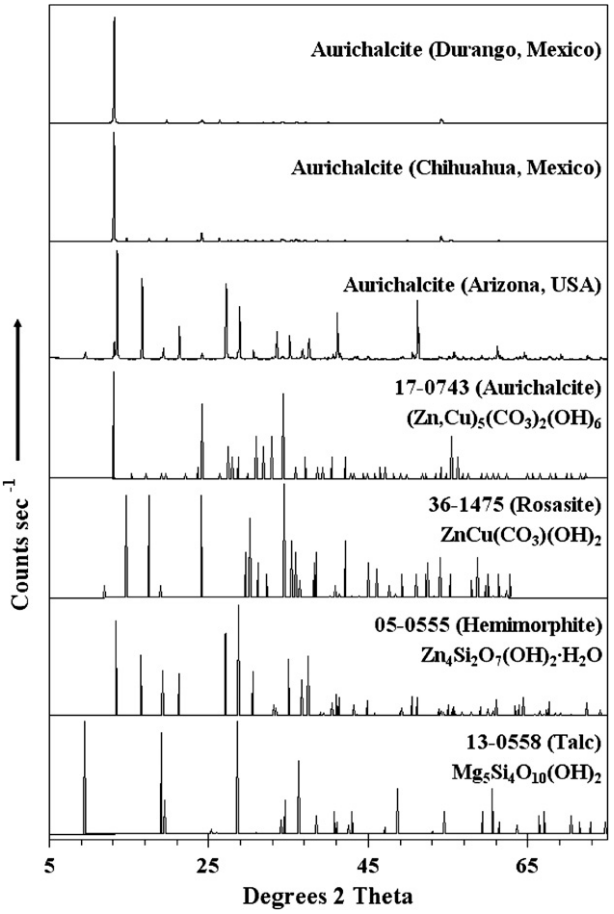

Fig. 2. X-ray diffraction patterns of aurichalcite minerals.

3.2. SEM and EDX

The SEM pictures of the three aurichalcite minerals studied in this work are shown in Fig. 3 (Durango), (b) (Chihuahua) and (c) (Arizona). The aurichalcite minerals appear to exist in two different forms (a) acicular as for Durango and (b) lath-like as is illustrated by the SEM images of the Chihuahua and Arizona samples. Often the acicular crystals appear to radiate from one centre. This suggests crystal growth from solution occurs from one nucleation point. The crystals are directed along [0 1 0] and appear often to have wedge like terminations. The crystals are quite large and may be several microns long. Crystals are acicular or fibrous and found in tufted aggregates. The crystal forms enable the mineral to be distinguished from other copper–zinc hydroxy carbonates such as malachite.

EDX measurements for the Durango aurichalcite show a Cu/Zn ratio of 1/1.06; for the Chihuahua sample the Cu/Zn ratio is 1/1.85; and for the Arizona sample is 1:/2.87. It is proposed that the morphology of the aurichalcite mineral is controlled by the Cu/Zn ratio. When the ratio is close to 1, the acicular morphology is obtained. If the Cu/Zn ratio is close to 2 or even 3, then the lath-like crystals are obtained.

3.3. Raman spectroscopy

Only a very limited number of Raman studies have been reported on the carbonate anion in hydrozincite type minerals [1,25,26]. When the carbonate species is present as a free ion not involved in any bonding it will exhibit a space

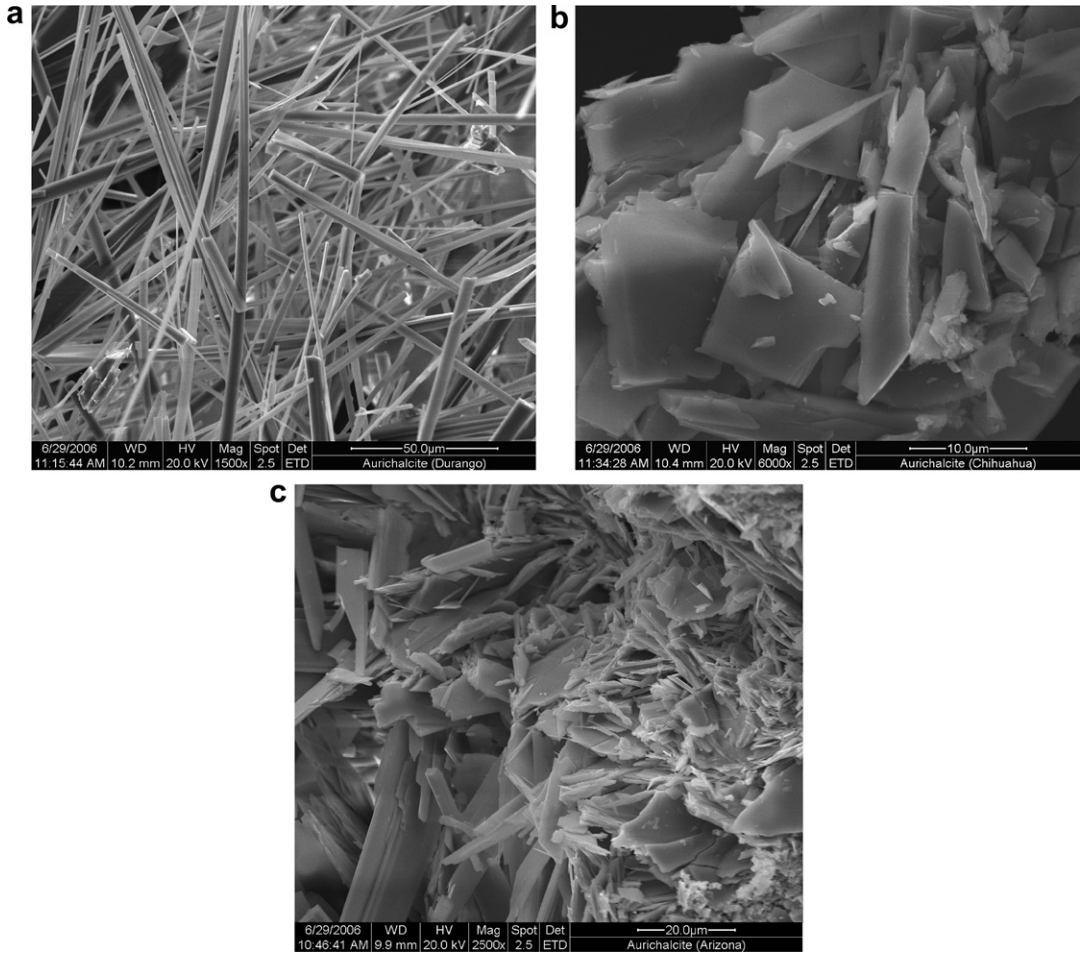

Fig. 3. SEM images of aurichalcite minerals: (a) Durango; (b) Chihuahua; (c) Arizona.

group of D_{3h}. In the Raman spectrum one will observe $v_1(A'1)$, $v_3(E')$ and $v_4(E')$. As a result three bands, the bending non-planar mode $v_2(A''2)$, the anti-symmetrical stretching mode $v_3(E')$ and the bending angular mode $v_4(E')$, will be observed in the infrared spectrum around 880, 1415 and 680 cm^{-1}, while the symmetric stretching mode $v_1(A'1)$ is infrared inactive. However, changes can be expected when the carbonate ion is bonded in a mineral structure as it will be affected by interactions with water molecules and OH-groups. In comparison with free CO_3^{2-} a shift towards lower wavenumbers is generally observed for the carbonate anion in minerals. Interaction between interlayer water molecules and the carbonate ion is reflected by the presence of bands in the OH-stretching region of the infrared spectrum around 3000–3100 cm^{-1}. The shift towards lower wavenumbers indicates a loss of freedom compared to free CO_3^{2-} and as a consequence a lowering of the carbonate symmetry from D_{3h} to probably C_{2v} or C_s.

3.4. Raman spectroscopy

The Raman spectra of aurichalcite in the 650–1700 cm^{-1} region are shown in Fig. 4. The results of the band component analysis of the Raman spectra are reported in Table 1. Two intense Raman bands are observed at 1072 and 1060 cm^{-1}. Some variation in the peak position is observed for different mineral samples especially for the second peak at around 1060 cm^{-1}. The first band at 1072 cm^{-1} is assigned to the v_1 symmetric stretching mode of the carbonate unit and the intense Raman band at ~1060 cm^{-1} is assigned to the Raman activated δ OH deformation mode. Little information on the Raman spectra of aurichalcite is available. Bouchard and Smith [45] published a Raman spectrum of an aurichalcite of unknown origin with an intense peak observed at 1074 cm^{-1}. An additional band is observed for the aurichalcite from Durango, Mexico. It is likely that this band is due variations in the chemical composition of the mineral . It is noted that the Cu/Zn ratio for the Durango aurichalcite is 1/1. In the infrared spectrum low intensity band is observed at around 1084 cm^{-1} (Fig. 6) as a shoulder on a infrared spectral profile which is dominated by bands at around 1032 cm^{-1} attributed to the δ OH deformation mode. Raman spectra of aurichalcite should be similar to that of the other hydroxy carbonates such as the rosasite mineral group [21]. For rosasite two intense Raman bands were observed at 1096 and 1056 cm^{-1}. In the infrared spectrum of Arizona aurichalcite two intense bands are observed at 1084

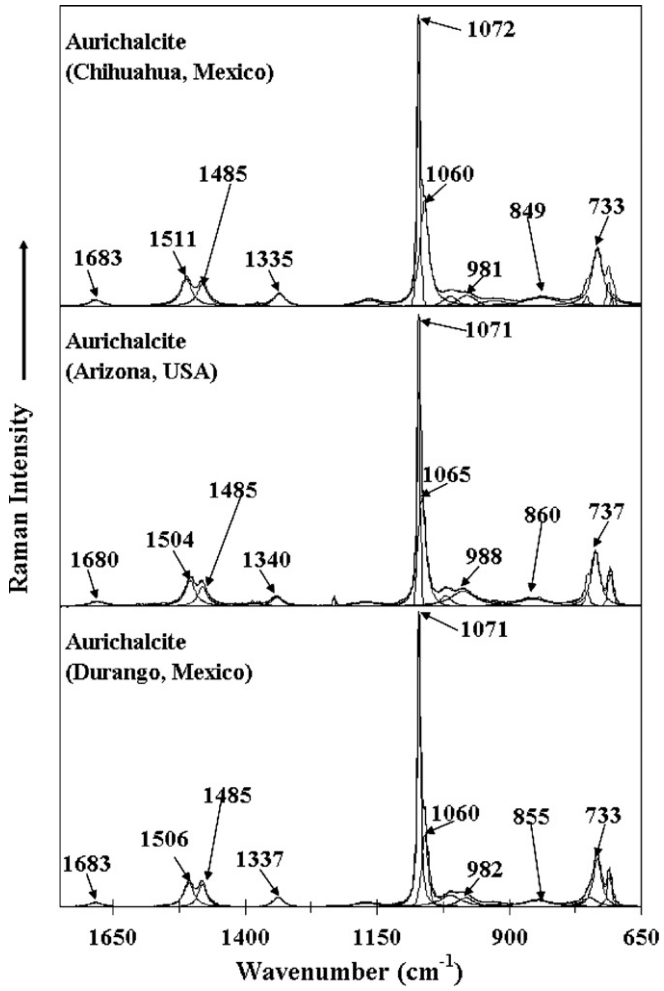

Fig. 4. Raman spectra of aurichalcite in the 650–1700 cm^{-1} region.

and 1029 cm^{-1} with an additional band at 924 cm^{-1} (Fig. 6). The first band at 1084 cm^{-1} is assigned to the v_1 symmetric stretching mode of the carbonate unit.

Bands have been observed in the infrared spectra of malachite at 1095 cm^{-1} and for azurite 1090 cm^{-1} [30,31]. The infrared spectrum of hydrocerrusite showed an intense band at 1090 cm^{-1} [32]. Interestingly the $(CO_3)^{2-}$ v_1 band of the aurichalcite mineral should not be infrared active. However because of symmetry reduction of the carbonate anion the band becomes activated. The intense Raman band observed at 1096 cm^{-1} for rosasite is assigned to the $v_1(CO_3)^{2-}$ symmetric stretching vibration. The intense Raman band at 1029 cm^{-1} is assigned to the δ OH deformation mode.

A number of low intensity bands are observed in the 1300–1500 cm^{-1} region (Fig. 4). These bands may be ascribed to the $v_3(CO_3)^{2-}$ antisymmetric stretching modes. Three bands are observed for the Durango aurichalcite at 1506, 1485 and 1337 cm^{-1}. Additional low intensity bands are observed at 1683, 1382 and 1170 cm^{-1}. Bands are observed at 1504, 1485 and 1340 cm^{-1} for the Arizona aurichalcite. For the Chihauhau aurichalcite bands in this region are observed at 1683, 1511, 1485, 1335 and 1165 cm^{-1}. The number of bands in this spectral region is attributed to the lack of symmetry of the carbonate anion in the aurichalcite structure. In the spectrum reported by Bouchard and Smith [45] two bands were reported at 1511 and 1479 cm^{-1}. Their spectra showed low signal to noise ratio and any low intensity bands would not be observed. Infrared spectra show multiple bands in the 1200–1600 cm^{-1} region (Fig. 5). For the Durango aurichalcite infrared bands are observed at 1563, 1503 1471, 1406 1353 and 1308 cm^{-1}. A similar pattern is observed for the Chihauhau aurichalcite with bands observed at 1567, 1503, 1477, 1406, 1343 and 1304 cm^{-1}. These bands are attributed to the infrared active $v_3(CO_3)^{2-}$ antisymmetric stretching vibrations.

The bands for the Arizona aurichalcite appear to be shifted to higher wavenumbers. The band at 1633 cm^{-1} is attributed to water bending modes. The band is not observed for the other aurichalcite minerals. The question arises as to whether water is bonded in the structure of the aurichalcite replacing some of the OH units. The infrared spectral patterns are similar for all three minerals. The complexity of the infrared spectra in this spectral region may be attributed to the combination of spectra from two different carbonate units. The 1557 cm^{-1} band may be associated with the 1412 cm^{-1} band. The second band at 1509 cm^{-1} is likely to be associated with bands at 1366 and 1361 cm^{-1}.

3.5. Comparison with the spectra of other hydroxy carbonates

A comparison may be made with the spectra of other hydroxy carbonate minerals. For rosasite $[(Cu,Zn)_2(CO_3)(OH)_2]$ [33–35] Raman bands for the 298 K spectrum are observed at 1516, 1493, 1458 and 1364 cm^{-1}. The Raman spectrum of malachite in this spectral region displays bands at 1516, 1493 and 1363 cm^{-1}. The band positions for rosasite and related minerals strongly resemble that of malachite. These results indicate two concepts: (a) the identification of more than one carbonate anion in the structure as implied from the symmetric stretching vibrations and (b) the crystal structure the reduction of symmetry of the carbonate anion [8]. These two factors combine to give multiple bands in this spectral region. Spectra may be compared with that of the other rosasite minerals: The Raman spectrum of kolwezite $[(Cu,Co)_2(CO_3)(OH)_2]$ [36] in $v_3(CO_3)^{2-}$ antisymmetric stretching region shows bands at 1515, 1495, 1456, 1426 and 1363 cm^{-1}. The Raman spectrum of glaukosphaerite $[(Cu,Ni)_2(CO_3)(OH)_2]$ [37–39] showed four bands at 1522, 1496, 1460 and 1367 cm^{-1}. For the mineral nullaginite $[(Ni)_2(CO_3)(OH)_2]$ [40–42], the Raman spectrum of the 1300–1500 cm^{-1} region showed an intense sharp band at 1426 cm^{-1} (with band width 15.0 cm^{-1}) with an additional higher wavenumber component at 1441 cm^{-1}. Although

these bands are in different positions to that of rosasite the bands are attributed to the $v_3(CO_3)^{2-}$ antisymmetric stretching vibrations.

The bands for aurichalcite are shown in Fig. 4. The v_2 bending modes for carbonates vary from around 890 to 850 cm^{-1}. A single band is observed for the Durango aurichalcite at 855 cm^{-1} assigned to the v_2 bending mode. The band is observed at 860 cm^{-1} for the Arizona aurichalcite and 849 cm^{-1} for the Chihuahua aurichalcite. It is probable that more than one band is observed in this region; however the intensity of the band is so low, it makes band fitting difficult. In the Raman spectra of the rosasite group of minerals in the 850–800 cm^{-1} region only very low intensity bands are also observed. The observation of more than one v_2 mode suggests symmetry reduction of the carbonate anion in the structure. For the Durango spectrum two Raman bands may be resolved at 860 and 845 cm^{-1}. Multiple bands are observed for the carbonate v_4 in phase bending modes in the Raman spectrum of aurichalcite. For the Durango aurichalcite three bands are observed at 752, 733 and 708 cm^{-1}; for the Arizona aurichalcite 748, 737 and 710 cm^{-1}; and for the Chihuahua aurichalcite 753, 733 and 711 cm^{-1}. These bands are ascribed to the v_4 bending modes.

For azurite two bands are observed 834 and 765 cm^{-1} and are attributed to the v_2 out of phase and v_4 in phase

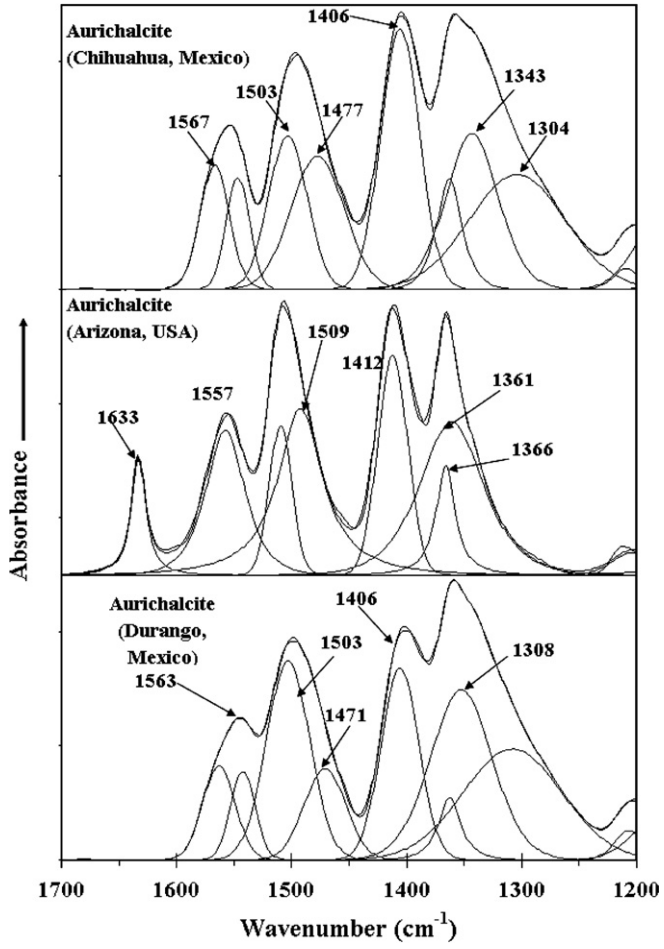

Fig. 5. Infrared spectra of aurichalcite in the 1200–1700 cm^{-1} region.

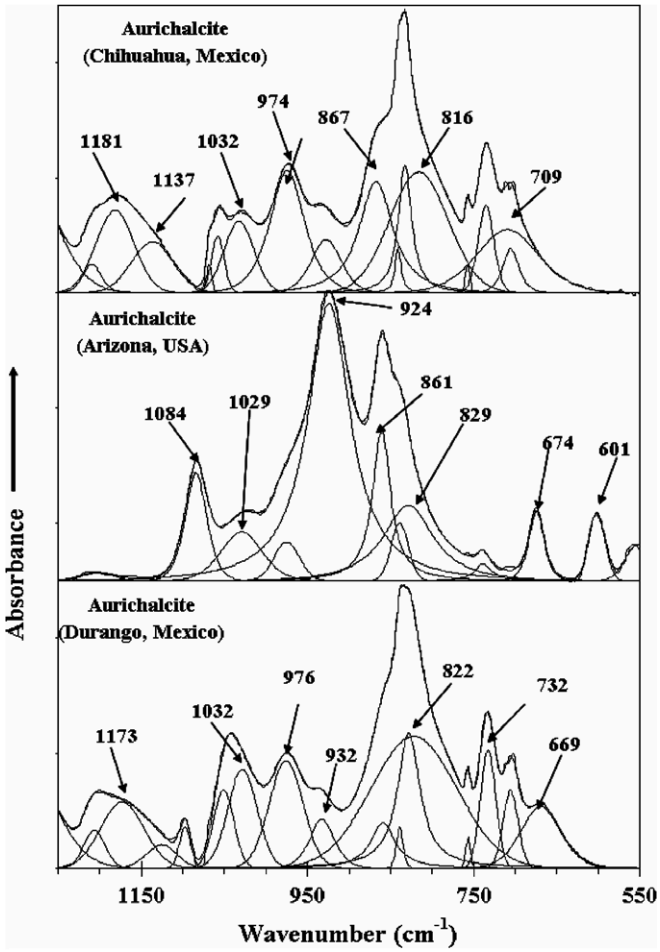

Fig. 6. Infrared spectra of aurichalcite in the 550–1150 cm^{-1} region.

bending modes of carbonate in azurite [30]. A component band is observed at 739 cm^{-1} and is also assigned to the v_4 mode. The number of bands observed in this spectral region may be attributed to the structural distortion of the mineral. Only a single band at 817 cm^{-1} is observed in this region for malachite. The FTIR spectrum of malachite showed two bands at 879 and 821 cm^{-1} [30]. This FTIR spectral region is more complex for azurite with bands observed at 872, 837, 815 and 796 cm^{-1}. This complexity is again ascribed to the loss of degeneracy. The equivalent Raman bands for malachite are observed at 752 and 717 cm^{-1}. In the infrared spectra bands are observed at 779, 754 and 701 cm^{-1} for azurite and at 780, 750 and 715 cm^{-1} for malachite [30].

The Raman spectra of the low wavenumber region are reported in Fig. 7. It is expected that bands in this region are associated with CuO and ZnO stretching and bending vibrations. Strong bands are observed at around 498, 460 and 390 cm^{-1}. In the structure as shown in Fig. 1, there are three structurally distinct MO stretching vibrations. The M3 site is a solely Zn site. The M1, M2 and M4 sites are shared randomly between Cu and Zn [43]. The above bands are associated with these CuO and ZnO stretching modes. Bouchard and Smith [45] reported Raman bands at 503, 463, and 389 cm^{-1} which are in agreement with the band positions reported here; however no assignments were offered. The number of bands observed in this spectral region may be attributed to the structural distortion of the mineral. Two intense bands are observed at around 166 and 142 cm^{-1}. These bands are assigned to the OCuO and OZnO bending vibrations.

3.6. Raman spectroscopy of the hydroxyl stretching region

The Raman spectra of the OH-stretching region of the three aurichalcite mineral samples are shown in Fig. 8. A single symmetric band is observed for the Durango aurichalcite at 3338 cm^{-1} which may be compared with the value of 3348 cm^{-1} for Arizona aurichalcite and 3355 cm^{-1} for the Chihuahua aurichalcite. A comparison can be made with rosasite where two distinct bands are observed at 3387 and 3319 cm^{-1}. The bands are assigned to the OH-stretching vibration. Bouchard and Smith [45] reported a noticeably broad band in the Raman spectrum of aurichalcite at 3331 cm^{-1}. This value is in good agreement with the results reported in this work. In the infrared spectra, more complexity is observed. Infrared bands for the Durango aurichalcite are observed at 3491, 3350,

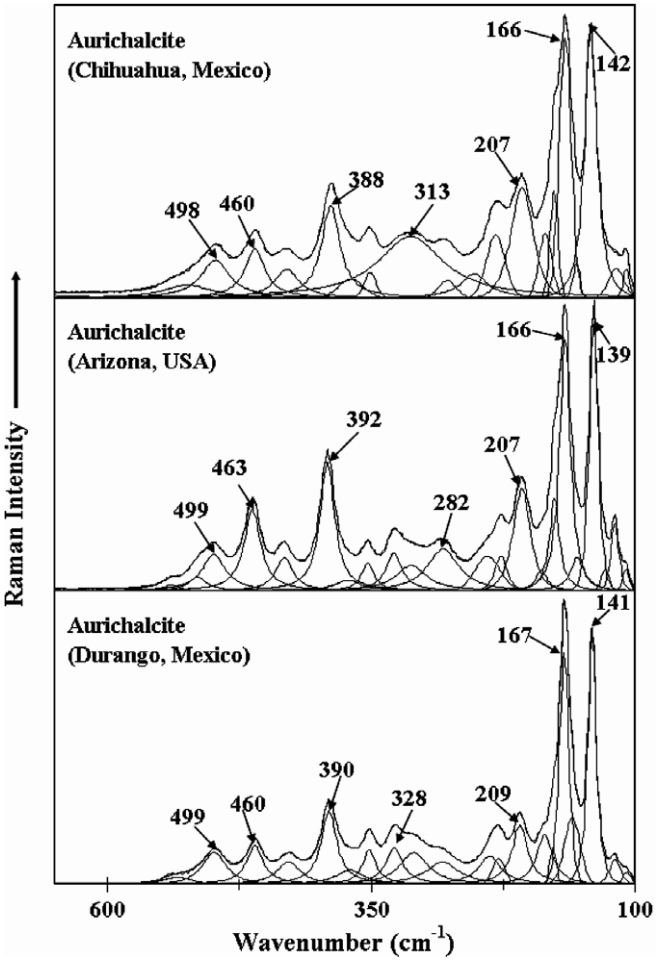

Fig. 7. Raman spectra of aurichalcite in the 100–600 cm^{-1} region.

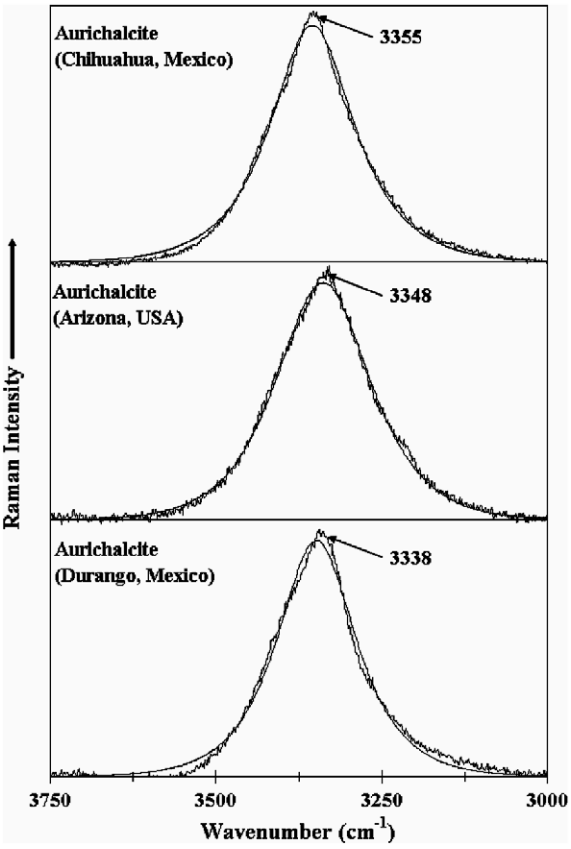

Fig. 8. Raman spectra of aurichalcite in the 3000–3750 cm^{-1} region.

3244 and a broad band at 3173 cm^{-1}. The infrared spectrum of the sample from Chihuahua gave bands at 3359, 3249 and 3106 cm^{-1}. The broad band at around 3163 cm^{-1} may be ascribed to adsorbed water. The first two bands are assigned to OH-stretching vibrations.

The question can be asked as to why the bands in the hydroxyl stretching region occurs in various positions for the different minerals. The reason is attributed to variation in hydrogen bond distances between the OH units and the oxygens of adjacent carbonate units. If a Libowitzky type formula [44] is employed an estimate of the hydrogen bond distances can be made. The two IR band positions for the Chihuahua aurichalcite gives H-bond distances of 2.77_3 and 2.72_1 Å. A comparison of hydrogen bond distances may be made with either hydroxy carbonates such as rosasite and malachite. Hydrogen bond distances vary for rosasite from 2.78_0 to 2.86_7 Å. These values are in harmony with the values for malachite which are 2.863_6 and 2.801_7 Å. Further the hydrogen bond distances for pokrovskite are significantly longer with values between 2.83 and 3.28_0 Å. It is concluded that the hydrogen bond distances for aurichalcite are shorter than for the other hydroxy carbonates.

3.7. A comparison with other minerals

The spectra are composition dependent and additional bands may be ascribed to divalent cation content. The generic formula for aurichalcite is $(Zn,Cu^{2+})_5(CO_3)_2(OH)_6$. The ratio of Zn to Cu may vary between samples and some Zn may be replaced by Ca and other cations. The composition of the aurichalcite from mapimi, Duarango, Mexico is 20.8% CuO, 53.2% ZnO, 16.1% CO_2, 9.9% H_2O [6]. This leads to a formula of $Zn_{3.6}Cu_{1.4}(CO_3)_2(OH)6$. Another analysis of aurichalcite from Salida, Chaffee Co., CO, USA gave a formula of $Zn_{3.75}Cu_{1.25}(CO_3)_2(OH)_6$. Variation in the ZnO content varies from 55.8% to 44.8% by weight whilst CuO varies from 18.2% to 14.5%. Further minor amounts of other cations may influence the spectra. Studies by Charnock et al. [46] have shown using EXAFS techniques that only divalent cations are in the crystal structure of aurichalcite and that the Cu may take up more than one position in that structure. The Cu:Zn ratio may vary between 1:3 and 1:1.5. Charnock et al. have shown using EXAFS that the copper atoms preferentially enter the Jahn–Teller elongated, octahedral (M2) and trigonal bipyramidal (M4) sites, with the zinc atoms entering the more regular octahedral (M1) and tetrahedral (M3) site. Furthermore, substantial solid solution towards the zinc rich region is

facilitated by the substitution of copper by zinc on the M2 and M4 sites [43].

4. Conclusions

Raman spectroscopy complimented with infrared data, X-ray diffraction, electron microscopy and EDAX have been used to characterise the structure and chemical composition of the mineral aurichalcite. The spectra are correlated with the structure of the mineral. Compositional variation for aurichalcite is observed for minerals of different origin. This compositional variation affects the Raman spectral profile. A similar cation substitution reliance is observed for the hydroxyl stretching vibrational modes. This is related to the hydrogen bond distances of the OH units and the adjacent carbonate units in the aurichalcite structure.

The XRD patterns of all three samples (but more so for the specimens from Durango and Chihuahua) indicate high orientation and contain some expected impurities such as rosasite and hydrozincite but never the less match the standard reference patterns. SEM analysis of the non-mechanochemically activated sample confirms the XRD orientation of the ground sample findings as images show highly crystalline and ordered structures in the form of micron long fibres and plates. EDAX analysis indicates vast differences in metal ion chemical composition (Cu/Zn ratios) ranging from 1/1.06 to 1:/2.87.

The question arises as to why there are similar Raman spectral patterns for aurichalcite as compared with other hydroxy carbonate minerals such as hydrozincite and members of the rosasite mineral group. The answer must infer that the minerals must have the same structure or at least related structures. Aurichalcite is monoclinic as is malachite with point group $2/m$. The rosasite mineral group has spectra similar to that of malcachite. Therefore it can be suggested that the structure of the rosasite group of minerals is monoclinic, although at this point in time remains unproven. This conclusion is in agreement with the assumptions of Anthony et al. (2003) who state that rosasite and related minerals have monoclinic structure by analogy with malachite.

Abstract

N-(2-Hydroxybenzyl)aminopyridines (L^i) react with Cu(II) and Pd(II) ions to form complexes in the compositions $Cu(L^i)_2(CH_3COO)_2 \cdot nH_2O$ ($n = 0, 2, 4$), $Pd(L^i)_2Cl_2 \cdot nC_2H_5OH$ ($n = 0, 2$) and $Pd(L^2)_2Cl_2 \cdot 2H_2O$. In the complexes, the ligands are neutral and monodentate which coordinate through pyridinic nitrogen. Crystal data of the complexes obtained from 2-amino pyridine derivative have pointed such a coordinating route and comparison of the spectral data suggests the validity of similar complexation modes of other analog ligands. Cu(II) complex of *N*-(2-hydroxybenzyl)-2-aminopyridine (L^1), $[Cu(L^1)_2(CH_3COO)_2]$ has slightly distorted square planar *cis*-mononuclear structure which is built by two oxygen atoms of two monodentate carboxylic groups disposed in *cis*-position and two nitrogen atoms of two pyridine rings. The remaining two oxygen atoms of two carboxylic groups form two Cu and H bridges containing cycles which joint at same four coordinated copper(II) ion. IR and electronic spectral data and the magnetic moments as well as the thermogravimetric analyses also specify on mononuclear octahedric structure of complexes $[Cu(L^2)_2(CH_3COO)_2 \cdot 2H_2O]$ and $[Cu(L^3)_2(CH_3COO)_2 \cdot 4H_2O]$ where L^2 and L^3 are *N*-(2-hydroxybenzyl)-2- or 3-aminopyridines, respectively.

X-ray analysis for $[Pd(L^1)_2Cl_2 \cdot 2C_2H_5OH]$ show square planar environment around Pd(II) ion formed by two chlorine atoms in *trans* position and two nitrogen atoms of pyridine rings. The spectral data indicate structural similarity in the complexes obtained via ligand exchange between $PdCl_2(PhCN)_2$ and 3-amino and 4-aminopyridine derivatives.

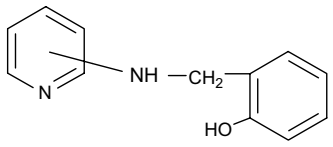
1. Introduction

Aminopyridines and their derivatives in most cases act as monodentate ligands which coordinate the metal ions through the nitrogen of the ring [1–4], though there are several works on 2-aminopyridine complexes in which the amino group also participates in coordination [5,6]. The 2-amino group was reported to participate in H-bond with phenol oxygen, which stabilizes the complex unit but no direct coordination to metal ion was observed [6].



Many works on transition metal complexes with Schiff bases of aminopyridines have been reported [7–18]. In all of these compounds metal ion is coordinated via phenolic oxygen and azomethine nitrogen albeit endocyclic nitrogen atom usually does not participate in coordination. In the former reports, there are very few data on the complexes of "hydrogenated" analogues of the above-stated compounds [19,20]. The reduction of azomethine bond which interferes π conjugation between phenolic oxygen and azomethine nitrogen atoms should change the coordinating ability of such compounds.

We have investigated the coordinating behaviour of *N*-(2-hydroxybenzyl)aminopyridines which have been received by the reduction of corresponding Schiff's bases obtained from salicylaldehyde and aminopyridines. Very

few complexes of *N*-(2-hydroxybenzyl)aminopyridines have been reported in the chemical literature [19,20]. The ligands have three electron donating atoms (NNO) and mono- and dianionic forms of the ligands present in the complexes. In our work, copper(II) acetate which is known to have binuclear structure which partially decomposes in the presence of water, is used to allow to keep the acetate as ligand in the complexes, since the preservation of acetate leads the formation of complexes with different coordination modes. Palladium(II) complexes of neutral ligands have been synthesized by the ligand exchange reactions of $PdCl_2(PhCN)_2$. The structures of complexes have been elucidated by spectral means, TGA and magnetic measurements. X-ray crystal data have also been obtained for the copper(II) and palladium(II) complexes of *N*-(2-hydroxybenzyl)-2-aminopyridine (L^1).

2. Experimental

2.1. Physical and chemical measurements

IR. IR spectra were recorded on a Specord-M80 (Charles Zeiss Jena) infrared spectrophotometer as KBr tablets in the range of 4000–400 cm^{-1}.

UV–Vis. The electronic spectra were recorded on spectrophotometers Specord-M40 and Shimadzu UV–Vis 240.

Magnetic susceptibility measurements were carried out at room temperature on Faraday magnetic balance with $Hg[Co(SCN)_4]$ as standard.

Thermogravimetric measurements were made on derivatograph MIM (Hungary).

Elemental analyses. The elemental analyses were performed in the analytical laboratory Tübitak, Ankara on LECO CHNS 932.

X-ray data have been obtained on a STOE IPDS 2 diffractometer with graphite monochromated Mo Kα radiation at 296 K.

2.2. Syntheses of ligands and complexes

2.2.1. Reagents

Aminopyridines, salicylaldehyde, sodium borohydride and the solvents used in the preparations were all Merck p.a. products.

Schiff bases have been synthesized by the reaction of aminopyridines with salicylaldehyde in ethanolic solutions The properties of the Schiff bases coincided with those of given in the literature [17,18].

2.2.2. Borohydride reduction of Schiff bases

N-(2-Hydroxybenzyl)aminopyridines have been obtained by the reduction of corresponding Schiff bases by sodium borohydride in ethanolic solutions. A typical procedure for the reduction is given below.

2.2.2.1. N-(2-Hydroxybenzyl)-2-aminopyridine (L^1). Into a solution of *N*-2-pyridylsalicylaldimine (25 mmol, 5 g) in 15 mL ethanol was added sodium borohydride in small portions until initial yellow-orange colour of the solution was discoloured. The mixture was poured into 60 mL water, mixed well and left to crystallize for 3 h. Fine needle crystals have been filtered, washed well with water up to neutral reaction against litmus. The crystals have been dried and recrystallized from ethanol to yield 3.2 g L^1 (65%). White powder. Mp: 104 °C. ^{1}H NMR (DMSO-d_6, δ): 10.55 (s, 1H, Ph–OH); 6.45–7.96 (m, 8H, arom.CH); 4.35 (s, 2H, CH_2), 3.50 (s, 1H, NH). *Anal.* Calc. for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99. Found: C, 71.55; H, 5.68; N, 13.59%.

2.2.2.2. N-(2-Hydroxybenzyl)-3-aminopyridine (L^2). White powder. Mp: 196 °C. ^{1}H NMR (DMSO-d_6, δ): 9.65 (s, 1H, Ph–OH); 6.25–8.15 (m, 8H, arom.CH); 4.25 (s, 2H, CH_2); 3.4 (s, 1H, NH). *Anal.* Calc. for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99. Found: C, 71.12; H, 5.95; N, 13.73%.

2.2.2.3. N-(2-Hydroxybenzyl)-4-aminopyridine (L^3). White powder. Mp: 177 °C. ^{1}H NMR (DMSO-d_6, δ): 8.05 (s, 1H, Ph–OH); 6.50–8.15 (m, 8H, arom.CH); 4.25 (s, 2H, CH_2); 3.2 (s, 1H, NH). *Anal*. Calc. for $C_{12}H_{12}N_2O$: C, 71.98; H, 6.04; N, 13.99. Found: C, 71.48; H, 5.45; N, 13.54%.

2.2.3. Copper(II) complexes of N-(2-hydroxybenzyl)-aminopyridines

A typical procedure for copper(II) complexes of *N*-(2-hydroxybenzyl)aminopyridines is given below.

2.2.3.1. Diacetato-bis(N-(2-hydroxybenzyl)-2-aminopyridine)-copper(II) [$Cu(L^1)_2(CH_3\ COO)_2$]. L^1 (1 mmol, 0.20 g) in 10 mL ethanol was mixed with copper acetate monohydrate (0.5 mmol, 0.10 g) solution in 5 mL water and the mixture was heated at 50–60 °C for 30 min. During cooling to room temperature, dark blue rhombic crystals were collected from dark green solution, washed with water and dried in vacuo (0.27 g, 90% yield). Mp: 170–175 °C (decomp.). $\mu_{eff} = 1.78$. TGA data (°C) (weight loss%) (Calc. weight loss%) [Endo. peak temp. °C]: (50–174 °C) (5.65) (5.15, calc. for −0.5AcOH); (174–244 °C) (18.05) (15.46, −1.5AcOH); (244–485 °C) (32.39); (485–735 °C) (28.05); [170; 244; 465 °C].

Anal. Calc. for $C_{28}H_{30}N_4O_6Cu$: C, 57.77; H, 5.19; N, 9.62; Cu, 10.91. Found: C, 57.86; H, 4.87; N, 9.77; Cu, 10.35%.

2.2.3.2. Diacetato-bis(N-(2-hydroxybenzyl)-3-aminopyridine)-copper(II)dihydrate [Cu(L^2)$_2$(CH_3COO)$_2$] · 2H_2O. Green powder. Mp: 160–165 °C (decomp.). $\mu_{eff} = 1.90$. TGA data (°C) (weight loss%) (Calc. weight loss%) [Endo. peak temp. °C]: (50–130 °C) (2.52) (2.91, calc. for –H_2O); (130–175 °C) (2.87) (2.91, –H_2O); (175– 251 °C) (43.3); (351–819 °C) (36.52); [170, 296; 422 °C]. *Anal.* Calc. for $C_{28}H_{34}N_4O_8Cu$: C, 54.39; H, 5.54; N, 9.06; Cu, 10.28. Found: C, 53.42; H, 5.62; N, 8.85; Cu, 10.20%.

2.2.3.3. Diacetato-bis(N-(2-hydroxybenzyl)-4-aminopyridine)copper(II)tetrahydrate[Cu(L^3)$_2$(CH_3COO)$_2$] · 4H_2O. Blue powder. Mp: 121–125 °C (decomp.). $\mu_{eff} = 1.81$. TGA data (°C) (weight loss%) (Calc. weight loss%) [Endo. peak temp. °C]: (50–130 °C) (3.24) (2.75, calc. for –H_2O); (130–198 °C) (6.82) (8.26, –3H_2O); (198–268 °C) (9.44) (9.17, –AcOH); (778 °C) (51.12); [130, 198, 268; 645 °C]. *Anal.* Calc. for $C_{28}H_{38}N_4O_{10}Cu$: C, 51.41; H, 5.85; N, 8.56; Cu, 9.71. Found: C, 51.17; H, 5.22; N, 8.11; Cu, 9.39%.

Refluxing the reaction mixture for 5 h yields Cu_2O as by-product. Oxidative dehydrogenations of the ligands to give *N*-(2-pyridyl)salicylaldimines were not observed.

2.2.4. Palladium(II) complexes of N-(2-hydroxybenzyl)-aminopyridines

A typical procedure for palladium(II) complexes of *N*-(2-hydroxybenzyl)aminopyridines is given below.

2.2.4.1. Dichloro-bis(N-(2-hydroxybenzyl)-2-aminopyridine)palladium(II)diethanol [Pd(L^1)$_2$Cl$_2$] · 2C_2H_5OH. L^1 (2 mmol, 0.40 g) in 10 mL ethanol was mixed with Pd(C_6H_5CN)$_2$Cl$_2$ (1 mmol, 0.383 g) solution in 15 mL ethanol. The mixture was heated at ~40 °C for 30 min, filtered hot and left for crystallization. Light yellow crystals were collected and dried in vacuo (0.44 g, 65% based on Pd). Yellow crystals. Mp: 127–130 °C (decomp.).

^{1}H NMR (DMSO-d_6, δ): 10.55 (b, 1H, Ph–OH); 9.75 (s, 1H, Ph–OH); 8.61 (d, 1H, arom.CH); 8.3 (d, 1H, arom.CH); 6.25–7.60 (m, 14H, arom.CH); 4.55 (s, 4H, CH_2–OH); 4.35 (s, 4H, CH_2); 3.40, 3.42 (s, 2H, NH) 1, 17 (s, 6H, CH_3).

Mass data (70 equiv) (*m*/*z*) (%): 623.95 (0.1, M*−EtOH); 577.9 (0.4, M*−2EtOH); 543 (25.9, PdL$_2$Cl+H); 542 (11.0, PdL$_2$Cl); 541 (25.4, PdL$_2$Cl–H); 540 (17.3, PdL$_2$Cl–2H); 203.15 (1.2); 202.1 (13.6, L+2H); 201.1 (100.0, L+H); 130.2 (4.7); 107.1 (14.4, Pd); 96.1 (4.3). TGA data (°C) (weight loss%) (Calc. weight loss%) [Endo. peak temp. °C]: (95–146 °C) (14.07) (13.75, calc. for –2C_2H_5OH); (146–345 °C) (33.11); (345–926 °C) (39.42); [146; 213; 345 °C]. *Anal.* Calc. for $C_{28}H_{36}N_4O_4Cl_2Pd$: C, 50.20; H, 5.42; N, 8.36; Pd, 15.89. Found: C, 50.02; H, 4.61; N, 8.66; Pd, 15.93%.

2.2.4.2. Dichloro-bis(N-(2-hydroxybenzyl)-3-aminopyridine)palladium(II)dihydrate [Pd(L^2)$_2$Cl$_2$] · 2H_2O. Yellow powder. Mp: 231–235 °C (decomp). ^{1}H NMR(DMSO-d_6, δ): 9.75 (s, 2H, Ph–OH); 8.20 (d, 1H, arom.CH); 7.85 (d, 1H, arom.CH); 6.7–7.4 (m, 14H, arom.CH); 4.20 (s, 4H, CH_2); 3.15, 3.18 (s, 2H, NH). TGA data (°C) (weight loss%) (Calc. weight loss%) [Endo. peak temp. °C]: (148–284 °C) (8.58) (8.87, calc. for –(HCl+H_2O)); (284–329 °C) (3.19) (2.94, –H_2O); (329–374 °C) (27.90); (374–638 °C) (40.60); [240; 273; 329; 638; 832 °C]. *Anal.* Calc. for $C_{24}H_{28}N_4O_4Cl_2Pd$: C, 46.96; H, 4.60; N, 9.13; Pd, 17.34. Found: C, 46.66; H, 3.11; N, 9.62; Pd, 18.25%.

2.2.4.3. Dichloro-bis(N-(2-hydroxybenzyl)-3-aminopyridine)-palladium(II) [Pd(L^3)$_2$Cl$_2$]. Yellow powder. Mp: 303–305 °C (decomp). ^{1}H NMR(DMSO-d_6, δ): 9.70 (s, 2H, Ph–OH); 6.2–8.2 (m, 16H, arom.CH); 4.22 (s, 4H, CH_2); 3.15, 3.18 (s, 2H, NH); TGA data (°C) (weight loss%) (Calc. weight loss%) [Endo. peak temp. °C]: (69–198 °C) (6.34) (6.31, calc. for –HCl); (198–290 °C) (7.31) (6.31, –HCl); (290–411) (22.93); (411–651 °C) (53.66); [242; 391; 476 °C]. *Anal.* Calc. for $C_{24}H_{24}N_4O_2Cl_2Pd$: C, 49.89; H, 4.18; N, 9.69; Pd, 18.42. 2.3. X-ray structural analyses of complexes

Blue plate [Cu(II) complex of L^1] and colorless prism [Pd(II) complex of L^1] single crystals suitable for data collection were mounted on a glass fiber and data collection processes were performed on a STOE IPDS 2 diffractometer with graphite monochromated Mo Kα radiation at 296 K. Details of crystal data, data collection and refinement results for the two crystals [21] are given in Table 1. The structures were solved by direct-methods using SHELXS-97 [22] and refined by full-matrix least-squares methods on F^2 using SHELXL-97 [20]. Molecular drawings were obtained using ORTEP-III [23] for Windows. Materials were prepared for publication using software WinGX [24].

2.3.1. Crystal structure of diacetato-bis(N-(2-hydroxybenzyl)-2-aminopyridine)copper(II) [Cu(L^1)$_2$(CH_3COO)$_2$]

The compound, namely diacetato-bis[*N*-(2-hydroxybenzyl)-2-aminopyridine]copper(II), crystallize in triclinic space group $P\bar{1}$ and molecular structure of this compound is shown in Fig. 1. Title compound has intramolecular and intermolecular hydrogen bonds; geometric parameters are given in Table 2. In three-dimensional networks, the molecules are linked by two intramolecular N–H···O and two intermolecular O–H···O hydrogen bonds. Fig. 2 shows the packing of molecules in unit cell. All hydrogen atoms except for H4A and H5A were refined using a riding model and H bond distances were set to 0.930 Å for CH, 0.960 Å for CH_2, 0.970 Å for CH_3 and 0.820 Å for OH (Table 3).

Crystal data and refinement results are listed in Table 1. Atomic coordinates and equivalent isotropic displacement parameters and the geometric parameters of molecule are available from the Cambridge Crystallographic Data Center, CCDC 605890.

Data collection: X-AREA; Cell refinement: X-AREA; Data reduction and absorption correction: X-RED32 [21].

anisotropic parameters. All hydrogen atoms were refined using a riding model and H bond distances were set to 0.930 Å for CH, 0.960 Å for CH_2, 0.970 Å for CH_3, 0.820 Å for OH and 0.860 Å for NH.

The palladium ion is four coordinated by two Cl atoms and N atoms of two pyridine rings. In Pd(II) complex, the coordination environment of metal is very slightly distorted square planar. There is no significantly deviation from Pd1/Cl1/N1/Cl1^i/N1^i plane.

The N–Pd–N1 angle is 180° and N–Pd–Cl angles are 89.67° and 90.33°. Pd–N and Pd–Cl distances are 2.0155 Å and 2.3052 Å, respectively.

Crystal data and refinement results, selected bond lengths and angles are listed in Tables 1 and 3. Atomic coordinates and equivalent isotropic displacement parameters and the geometric parameters of molecule are available from the Cambridge Crystallographic Data Center, CCDC 605890.

3. Results and discussion

3.1. Infrared spectra of the ligands

The absorption bands of secondary amine N–H stretching vibrations appear at different frequencies depending on their positions in the pyridine ring, e.g., 3328 cm^{-1} for L^1; 3360 cm^{-1} for L^2 and 3355 cm^{-1} for L^3. Phenolic O–H stretching bands appear clearly at 3400 cm^{-1} only for L^3.

Prominent feature of *N*-(2-hydroxybenzyl)aminopyridines is the presence of two broad absorption bands in the region of 2500–1650 cm^{-1}, which notify the presence of intramolecular hydrogen bond between phenolic hydroxyl and secondary amino group. Although position of the band at around 2500 cm^{-1} do not change for all ligands, position of the low-frequency band shifts depending on the basicity of secondary amino group. Log *K* of amino group of aminopyridines depends on its position in the pyridine ring and has the values of 7, 6; 6.1 and 1.5 for 2-amino-; 4-amino- and 3-aminopyridine, respectively [25]. It can be inferred that similar sequence should be observed for secondary amino groups in 2-hydroxybenzyl derivatives of aminopyridines. L^1 with the least basic amino group shows maximum absorption at ~1780 cm^{-1}, L^3 at 1840 cm^{-1} and L^2 at 1860 cm^{-1}. These bands, apparently, may be attributed to the deformation vibrations of protonated secondary amino group NH_2^+.

O–H bending and C–O stretching absorptions of phenols appear at 1210–1270 cm^{-1} and 1330–1360 cm^{-1} range, respectively.

3.2. Characterization of the complexes

3.2.1. Cu(II) complexes of N-(2-hydroxybenzyl)-aminopyridines

In the IR spectra of Cu(II) complexes, displacements of absorption bands to lower frequencies were observed, by which broad peaks assigned for O–H and N–H stretching vibrations with maximum absorptions at ~3328, ~3260 and 3280 cm^{-1} appeared for $[Cu(L^1)_2(CH_3COO)_2]$, $[Cu(L^2)_2(CH_3COO)_2]\cdot 2H_2O$ and $[Cu(L^3)_2(CH_3COO)_2]\cdot 4H_2O$ complexes, respectively. 3420 and 3400 cm^{-1} bands in the spectra of L^2-Cu(II) and L^3-Cu(II) complexes assigned for the coordination water O–H stretching appear as weak and strong peaks, respectively.

The broad bands of the ligands around 2500 and 1850 cm^{-1} which are assigned for proton transfer or hydrogen bonding between phenolic OH and secondary amine NH disappear in the spectra of all complexes.

The carboxylic group stretching v_{as} in the copper complexes are obscured with ligand bands at 1624 and 1584 cm^{-1}. For complex $[Cu(L^1)_2(CH_3COO)_2]$, v_{sym} of COO^- is observed at 1448 cm^{-1}. $\Delta v = v_{as} - v_{sym} =$ 176 cm^{-1} and corresponds to bridge structure [26] which in the complex should be placed between Cu(II) ion and secondary amino group. v_{sym} of COO^- in complexes $[Cu(L^2)_2(CH_3COO)_2]\cdot 2H_2O$ and $[Cu(L^3)_2(CH_3COO)_2]\cdot 4H_2O$ are observed at 1392 cm^{-1} and 1420 cm^{-1} with $\Delta v = 192$ and 204 cm^{-1}, respectively, by which monodentate character of acetate and the absence of bridge structures in those complexes are noticed [27].

O–H bending and C–O stretching bands of phenol in 1220–1260 cm^{-1} range and at 1340, 1350 cm^{-1} frequencies, respectively, do not change their position in Cu(II) complexes to indicate the nonparticipation of phenolic O–Hs in complexation which was also clearly observed in X-ray studies of L^1-Cu(II) complex.

According to the data of elemental analyses and thermogravimetric measurements Fig. 3, ligands L^2 and L^3 form Cu(II) complexes in the composition of $[Cu(L^2)_2(CH_3COO)_2]\cdot 2H_2O$ and $[Cu(L^3)_2(CH_3COO)_2]\cdot 4H_2O$.

Electronic spectra of Cu(II) complexes in DMF solution contain three absorption bands around 400 (ε 18 $M^{-1}\,cm^{-1}$), 488 (sh) (ε 6 $M^{-1}\,cm^{-1}$) and 690 (ε 4 $M^{-1}\,cm^{-1}$) nm which accordingly can be attributed to charge transfer band and d–d transition. In the electronic spectra of $[Cu(L^2)_2(CH_3COO)_2]\cdot 2H_2O$ and $[Cu(L^3)_2(CH_3COO)_2]\cdot 4H_2O$ taken in DMF the absorption bands at 410 (ε 20 $M^{-1}\,cm^{-1}$), 488 (ε 7 $M^{-1}\,cm^{-1}$) and 699 (ε 5 $M^{-1}\,cm^{-1}$) nm and at 365 (ε 25 $M^{-1}\,cm^{-1}$), 488 (ε 6 $M^{-1}\,cm^{-1}$) and 730 (ε 4 $M^{-1}\,cm^{-1}$) nm are observed, respectively. The obtained data allow assuming that coordination routes with acetate and pyridine ligands in complexes are same. For L^2 and L^3 complexes of Cu(II), coordination of Cu(II) up to the extended octahedron is possible due to the water molecules.

Magnetic moments of the complexes are between 1.78–1.90 BM which correspond to bivalent copper complexes and specify the absence of antiferromagnetic interaction.

The X-ray study of $[Cu(L^1)_2(CH_3COO)_2]$ obtained from *N*-(2-hydroxybenzyl)-2-aminopyridine has shown that the coordination environment around Cu(II) is slightly distorted from square planar and is composed from two oxygen atoms of two monodendate carboxylic groups, disposed in *cis*-position and two nitrogen atom of two pyridine rings. In complex L^1-Cu(II), the remaining two oxygen atoms of two carboxylic groups form two 8-membered cycles both of which contain Cu and H bridges through hydrogen atoms of secondary amine groups. Earlier such cycles with Cu and H bridges have been reported for binuclear Cu(II) complexes of 2-aminopyridine such as $[Cu_2(CH_3COO)_4(NH_2C_6H_4N)_2]$ and $[Cu_2(CH_3COO)_4\cdot(NH_2C_6H_4N)_2\cdot C_4H_8O_2]$ [28] in which acetate ion acted as bidentate bridging ligand. However, mononuclear copper(II) complex $[Cu(L^1)_2(CH_3COO)_2]$ has two 8-membered cycles which are joint at the same four coordinated copper ion with square planar environment.

3.2.2. Pd(II) complexes of N-(2-hydroxybenzyl)-aminopyridines

The spectral data of the Pd(II) complexes have been supported by the XRD data. In the IR spectra of Pd(II) complexes, secondary amino group absorption of the ligand does not shift by complexation and appears at 3373 cm^{-1} for $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$ and 3352 cm^{-1} for $[Pd(L^2)_2Cl_2]\cdot 2H_2O$ and $Pd(L^1)_2Cl_2$, by which nonparticipation of amino group in coordination with palladium ion is notified.

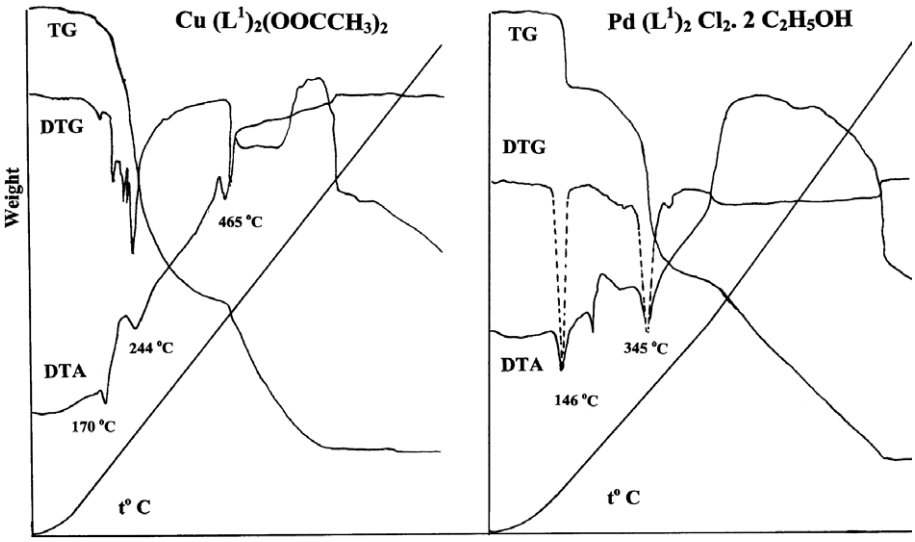

Fig. 3. TG, DTG and DTA diagrams of $[Cu(L^1)_2(CH_3COO)_2]$ and $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$.

Since the absorption bands of phenolic hydroxyl appear in 3350–3500 cm^{-1} range for stretching and 1210–1270 cm^{-1} range for bending modes in all Pd(II) complexes, ligand coordination should be built through endocyclic nitrogen atom which was also proved by XRD studies (Figs. 4 and 5).

Another indication for the participation of pyridine nitrogen in coordination has been shown earlier, the band groups in the region of 1600–1340 cm^{-1}, referring to pyridine ring absorption by complex formation displaces aside high frequencies in comparison with the same bands of free ligands [29,30]. However, in work [14], it has been shown that high frequency shift of IR absorption bands of pyridine ring not always can be a reliable indication on the participation of pyridine nitrogen in coordination. In [14] it was reported that in the Schiff bases of aminopyridine derivatives high-energy shift of pyridine ring bands was observed, however the X-ray data have shown the absence of coordination with endocyclic nitrogen. Regarding those band groups, our studies showed that the frequency shifts of the bands are not reliable in discussions about the contribution of pyridinic nitrogen into coordination. IR analysis of Pd complexes with *N*-(2-hydroxybenzyl)aminopyridines shows that stretching frequencies of pyridine rings decreased in $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$, while increased in $[Pd(L^3)_2Cl_2]$. For complex $[Pd(L^2)_2Cl_2]\cdot 2H_2O$ irregular band shifts were observed.

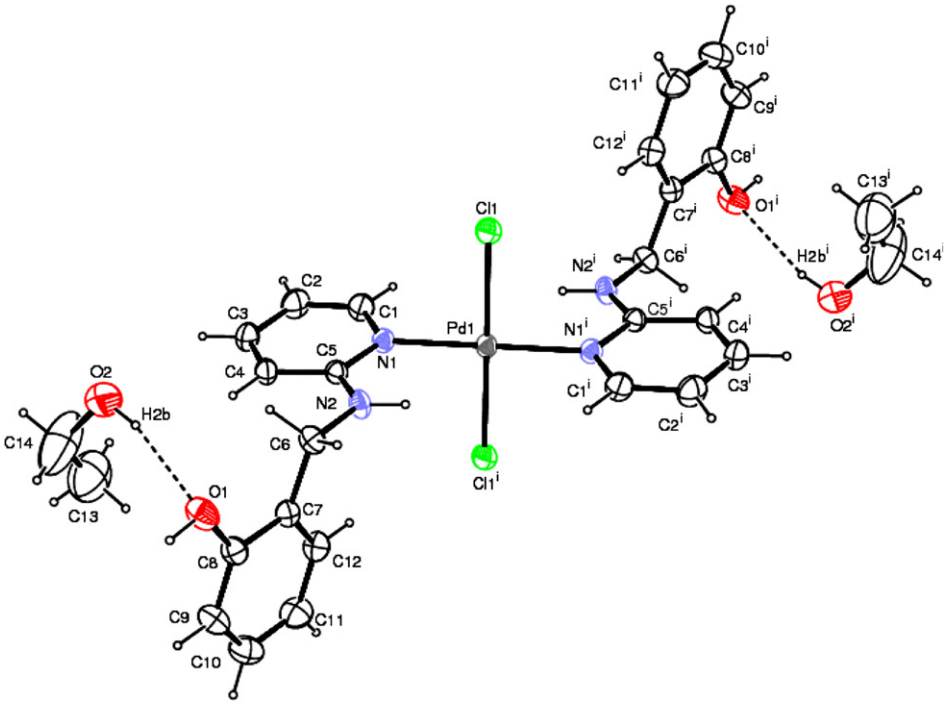

Fig. 4. An ORTEP3 view of $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$, with the atom-numbering scheme and 30% probability displacement ellipsoids. H atoms are shown as small spheres of arbitrary radii.

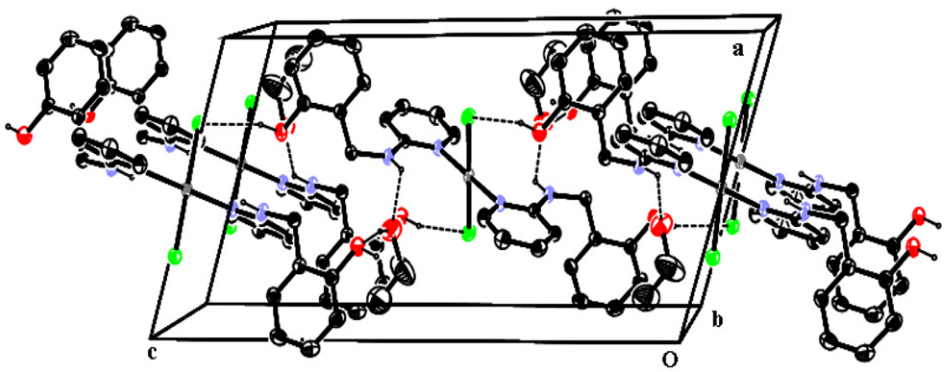

Fig. 5. A packed diagram of $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$. Dashed lines show the intra- and intermolecular hydrogen bonds. The hydrogen atoms which have no contribution in bonding were omitted for clarity.

Elemental analyses and TG data in Fig. 3 indicated the presence of two ethanol solvate molecules in complex $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$. In X-ray crystallography, the second ethanol on the outside of the unit cell was not observed. In the IR spectrum of L^1-Pd(II) complex, O–H stretching and methyl CH_2 bands of ethanol which is hydrogen bonded to phenolic oxygen and found in unit cell appear at 3311 and 1392 cm^{-1}, respectively. The free ethanol O–H stretching appears at 3544 cm^{-1} as a strong sharp peak. The C–O stretching of alcohol absorbs at 1060 cm^{-1}. ^1H NMR data also indicate the presence of two ethanol molecules in the complex.

In electronic spectra of Pd(II) complexes dissolved in DMF, two weak absorption bands at 425 and 500 nm were observed, which can be attributed to d–d transitions in square planar complexes of palladium [26].

3.3. Discussion

N-(2-Hydroxybenzyl)aminopyridines (L) (L^1: 2-amino; L^2: 3-amino; L^3: 4-amino derivative) react with Cu(II) acetate and $Pd(C_6H_5CN)_2Cl_2$ to give mononuclear complexes in which accompanying anions and neutral ligands coordinate the metal ions

$$Cu_2(CH_3COO)_4\cdot 2H_2O + 4L + (2n-2)H_2O \rightarrow 2([CuL_2(CH_3COO)_2]\cdot nH_2O) \quad (n=0,2,4)$$

$$Pd(C_6H_5CN)_2Cl_2 + 2L + nC_2H_5OH \rightarrow PdL_2Cl_2\cdot nC_2H_5OH + 2C_6H_5CN \quad (n=0,2)$$

$$Pd(C_6H_5CN)_2Cl_2 + 2L_2 + 2H_2O \rightarrow Pd(L_2)_2Cl_2\cdot 2H_2O + 2C_6H_5CN$$

However, distinctive feature of *N*-(2-hydroxybenzyl)aminopyridines is their low coordinating ability. We have attempted to obtain complexes with other metal ions such as Co(II), Ni(II), Mn(II), etc., but because of instability of these compounds, we could not succeed in their isolation in pure state.

N-(2-Hydroxybenzyl)aminopyridines have three electron donating atoms (NNO): pyridinic nitrogen, secondary amine nitrogen and phenolate oxygen. During complexation, aromatic hydroxyl and also secondary amine NH can be deprotonated to give mono and dianionic ligands. Pyridinic nitrogen can also participate in the coordination of metal. Thus, complexation behaviour of ligands depends on the reaction conditions as well as the kind of the metal.

In alkaline solutions, *N*-(2-hydroxybenzyl)-2-aminopyridine behave as tridentate ligand, as in the Ru-complex, in which secondary amino NH also deprotonates to make the ligand dianionic tridentate [19]. However, in acetone solution of the reactants, as in the formation of Re-complex, the secondary amino NH group has not been deprotonated, pyridinic nitrogen does not coordinate the metal and consequently the ligand acts as a monoanionic didentate chelate [20].

Contrary to above mentioned results, our work showed that, in both Pd(II) complexes and acetate containing complexes of Cu(II), *N*-(2-hydroxybenzyl)-2-aminopyridine as well as its 3-amino and 4-aminopyridine analogs behaved as monodentate ligand coordinating only through pyridinic nitrogen while the phenolic hydroxyl and secondary amino groups have not participated in coordination. The ligands form neutral ligand complexes. Neither secondary amine NH nor aromatic hydroxyl is deprotonated. These groups have been stabilized *via* intra- or intermolecular hydrogen bonding. This coordinating behaviour is the basic difference from corresponding Schiff bases which coordinate metal ions through phenolic oxygen and azomethine nitrogen while pyridine nitrogen has not any role in coordination. The crystal data of the complexes obtained from 2-aminopyridine derivative have supported these observations and comparison of the spectral data suggested the validity of similar complexation modes with other analog ligands.

The reactant copper(II) acetate $Cu_2(CH_3COO)_4\cdot 2H_2O$ is known to have binuclear structure which consists of four three atom bridges of carboxylate groups uniting two contiguous copper(II) ions [31]. Two water molecules occupy the terminal positions. Although its dimeric structure is destroyed in water to form monomeric hydrated Cu(II) acetate in ionic and molecular form, this destruction can be avoided in alcohol like organic solvents which have much weaker coordinating power than the water molecule [32]. The bonds between the carboxylate and Cu(II) ions should be strong enough in such solvent systems.

In our work, we have used ethanol/water (2:1) solvent mixture so that partial decomposition of dimeric structure of copper(II) acetate may take place and the acetate bridges are mainly cleaved by the attack of ligand's pyridinic nitrogen, without elimination of acetates from simultaneously formed mononuclear complex. In the working solution, interaction between the free acetate which is in the low concentration and Ar–OH would be at minimum level and consequently the bonding competition between acetate and phenolate might be negligible. Thus, the participation of deprotonated phenolic O–H in coordination is not favored. XRD data confirmed such kind of coordinating behaviour of the ligands in copper complexes.

In Cu(II) complex of L^1 (Fig. 1), hindering the Cu(II) ion from phenolate coordination via the formation of Cu, H eight membered two cycles through hydrogen bonding between acetate oxygen and secondary amine NH, may be an additional but minor reason. High yields (around 90%) of the acetatoCu(II) complexes of neutral ligands support this reaction pathway. The complexes $[Cu(L^2)_2(CH_3COO)_2]\cdot 2H_2O$ and $[Cu(L^3)_2(CH_3COO)_2]\cdot 4H_2O$ have similar structure with $[Cu(L^1)_2(CH_3COO)_2]$, but apparently without Me, H cycles.

In similar way, Pd(II) complexes are obtained in aqueous ethanol (90%) via the attack of pyridinic nitrogen to substitute benzonitrile ligand of $Pd(C_6H_5–CN)_2Cl_2$. *N*-(2-hydroxybenzyl)-aminopyridines yield light yellow

complexes in compositions of $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$, $[Pd(L^2)_2Cl_2]\cdot 2H_2O$ and $[Pd(L^3)_2Cl_2]$. XRD data of $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$ indicate coordination through pyridinic nitrogen. $[Pd(L^1)_2Cl_2]\cdot 2C_2H_5OH$ with slightly distorted square planar coordination of Pd(II) ion is realized by two nitrogen atoms of pyridine rings and two chlorine atoms in *trans*-position. Similar spectroscopic data have been obtained for the other complexes.

Appendix A. Supplementary material

CCDC 605889 and 605890 contain the supplementary crystallographic data for Pd(II) and Cu(II) complexes. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.03.015.

Abstract

The titled compounds were synthesized in high purity and yield by passing an ozone/oxygen mixture (5 vol% O_3 in O_2) through aqueous solutions of different Ag(I) salts at 273–298 K. Ag_3O_4 is obtained by ozonolysis of neutral or mildly acidic solutions of AgF (0.05 M) or $AgBF_4$ (0.05 M) at 273 K. Ozonolysis of aqueous solutions of $AgNO_3$, $AgClO_4$, Ag_2SO_4 and CH_3COOAg at 273–298 K afforded $Ag_7O_8NO_3$, $Ag_7O_8ClO_4$, $Ag_7O_8HSO_4$ and Ag_2O_2, respectively. Products were characterized by XRD, SEM, XPS, FT-IR, Raman spectroscopy and DSC. The spectroscopic data show that Ag_3O_4 and the Ag_7O_8X salts behave as metals at room temperature, due to overlap between valence and conduction bands in their electronic structure. The correct valence formulations for these compounds are $(Ag^{2.67+})_3O_4$ and $(Ag^{2.67+})_6O_8 \cdot Ag^+X^-$, respectively. The thermal stability in air of the ozonolysis products was determined by DSC and also complementary XRD, FT-IR and Raman measurements. Ag_3O_4 was the least stable product, and thermally decomposed to $1.5Ag_2O_{2(s)} + 0.5O_{2(g)}$ within 20 h at 298 K. Thermal stabilities in air increased in the order $Ag_3O_4 < Ag_7O_8ClO_4$, $Ag_7O_8HSO_4 < Ag_7O_8NO_3 < Ag_2O_2$. This work resolves long-standing debate about the valence states of silver in Ag_3O_4 and Ag_7O_8X salts, and also provides valuable new spectroscopic information for these compounds. Attempts to prepare Ag_2O_3 by the ozonolysis route proved unsuccessful.

Keywords: Silver oxides; Ozone; Ag_3O_4; $Ag_7O_8NO_3$; XPS; FT-IR; Raman

1. Introduction

The oxides of silver are a structurally diverse group of compounds that attract attention due to the widespread use of Ag_2O and Ag_2O_2 as cathode materials in Zn–silver oxide "button cell" batteries [1–3]. To date, five binary oxides have been isolated and structurally characterized in the silver–oxygen system [4–12]; Ag_6O_2, Ag_2O, Ag_2O_2, Ag_3O_4, and Ag_2O_3. It should be noted that Ag_2O_2 and Ag_3O_4 are both mixed-valence compounds (formally written as $Ag^+Ag^{3+}O_2$ and $Ag^{2+}(Ag^{3+})_2O_4$, respectively), and that Ag_2O_2 crystallizes in two different polymorphic forms [6–11]. The existence of other binary oxide phases, such as Ag_4O_3 and a hexagonal form of Ag_2O have been suggested [13,14], although supporting evidence for these phases is lacking.

Due to their technological importance, Ag_2O and Ag_2O_2 have been the subjects of numerous structural and spectroscopic investigations [5–9,14–23]. Accordingly, literature pertaining to these two compounds is extensive and generally reliable. By comparison, data for Ag_3O_4 and Ag_2O_3 is extremely limited [10–12,22,23], which stems largely from the thermal instability of these two compounds. Thermal stability decreases rapidly with increasing silver oxidation state (cf. Ag_2O, Ag_2O_2 and Ag_2O_3; $\Delta_f G^0 = -11.2$, 27.6 and 121.4 kJ mol^{-1}, respectively) [24]. Ag_2O_3 decomposes completely to Ag_2O_2 in less than 1 h at 298 K, whereas Ag_2O is stable indefinitely at this temperature. Crystalline specimens of Ag_3O_4 and Ag_2O_3 have been obtained by electrolytic deposition from aqueous solutions of different Ag(I) salts at 273 K [10–12], and their crystal structures solved. Ag_2O_3 crystallizes in the

doi:10.1016/j.poly.2007.03.006

orthorhombic system Fdd2 with $Z = 8$, and is isomorphous with Au_2O_3 [12]. The structure contains approximately square-planar AgO_4 groups linked together via common oxygen atoms in a three-dimensional network, with an average Ag–O bond length of 2.02 Å. Ag_3O_4 crystallizes in the monoclinic system $P2_1/c$ with $Z = 2$ [10,11], and has the formal valence electron configuration $Ag^{2+}(Ag^{3+})_2O_4$. The crystal structure comprises a three-dimensional network of distorted edge- and corner-sharing square-planar AgO_4 units. Silver cations occupy two crystallographically independent sites; Ag^{3+} cations are square-coordinated by four oxygens at an average distance of 2.07 Å, while Ag^{2+} cations have four nearest neighbours at 2.03 Å. This result is somewhat anomalous, since shorter Ag–O bond lengths are expected about the Ag^{3+} cations. Recently, van Wüllen et al. reported ^{109}Ag solid state magic angle spinning (MAS) NMR spectra for a number of binary and ternary silver oxides [23]. The ^{109}Ag MAS NMR spectrum for Ag_3O_4 showed only one broad isotropic signal at −795 ppm, which was tentatively assigned to Ag^{3+} centres (cf. Ag^{3+} centres in Ag_2O_2 and Ag_2O_3 showed chemical shifts of 1970 and 2015 ppm, respectively). No signal was observed for the Ag^{2+} cations in Ag_3O_4. Results of the X-ray crystallographic and ^{109}Ag MAS NMR investigations can be rationalized if an alternative valence configuration of $(Ag^{2.67+})_3O_4$ is considered for the compound. O'Keefe calculated Madelung potentials at Ag and O sites in a number of binary silver oxides [25]. Madelung potentials are approximately proportional to valence and may be used to determine valences in mixed-valence oxides. In the case of Ag_3O_4, no preferred valence configuration was found between $Ag^{2+}(Ag^{3+})_2O_4$ and $(Ag^{2.67+})_3O_4$, evidence of electron delocalization and metallic behaviour. Further work is necessary to clarify the electronic structure of Ag_3O_4. Also, important spectroscopic data for Ag_2O_3 and Ag_3O_4 has yet to be reported (such as FT-IR and Raman spectra), clearly justifying further work in this area.

Closely related to the binary silver oxides are the silver oxide clathrate salts of empirical formula Ag_7O_8X ($X = NO_3^-, ClO_4^-, HSO_4^-, HCO_3^-$ or HF_2^-) [26–36]. The formal valence configuration for these compounds is $(Ag^{2+})_2(Ag^{3+})_4O_8 \cdot Ag^+X^-$, although their physical properties and structural data suggest a $(Ag^{2.67+})_6O_8 \cdot Ag^+X^-$ formulation is more accurate [26–32]. At room temperature, all Ag_7O_8X salts have a *fcc* crystal structure (space group $Fm\bar{3}m$, $Z = 4$, $a = 9.82$–9.94 Å) based on face-sharing, 26-sided, cubo-octahedra [26–32]. Oxygen anions in the 'Ag_6O_8' structural unit are located at the 24 corners of the cubo-octahedra (each is common to three cubo-octahedral units). The six Ag cations in the 'Ag_6O_8' unit occupy structurally equivalent positions in the square faces common to two cubo-octahedra (each is square-planar coordinated by oxygen with Ag–O = 2.05 Å). As these cations are structurally indistinguishable, an intermediate valency of 2.67 is implied. Ag^+ ions in the Ag_7O_8X lattice occupy cubic sites between the cubo-octahedra, and are coordinated 8-fold by oxygen at an average Ag–O distance of 2.52 Å. Anions occupy sites at the centre of the cubo-octahedra. Fundamental interest in these compounds relates to their fascinating physical properties which include metallic conductivity ($\rho = 2.5 \times 10^{-3}$ Ω cm for $Ag_7O_8NO_3$ at 300 K) and low temperature superconductivity ($T_c = 1.04$ K for $Ag_7O_8NO_3$) [27,28]. The metallic properties of Ag_7O_8X salts are attributed to promotion of two electrons from the face-sharing 'Ag_6O_8' structural units into a conduction band that utilizes Ag 4d and O 2p orbitals. The Ag_7O_8X salts are two electron class III-B mixed-valence compounds under the classification system of Robin and Day [30], and as such are expected to show an absorption edge (typically in the infrared) and metallic reflectivity in the visible region. Accordingly, they should be very interesting materials to study by FT-IR and Raman spectroscopy. To date, no reliable vibrational spectroscopic data have been reported for these salts, and minimal experimental data exists examining their electronic structure (e.g. XPS, UPS or XANES) [35]. Further spectroscopic studies of the Ag_7O_8X compounds are needed to fill these gaps.

Traditionally, Ag_3O_4, Ag_2O_3 and Ag_7O_8X salts have been synthesized by electrochemical routes (e.g. by anodic polarization of a platinum electrode). The disadvantage of the electrochemical approach is the fact that crystal growth rates are slow and yields typically low (scale-up procedures are not practical due to the high cost of Pt electrodes). Chemical routes, rather than electrochemical, are thus more attractive for the large-scale synthesis of these compounds. O_3 is one of the strongest oxidants known ($O_2/O_3\varepsilon_0^{acid} = 2.075$ V) and capable of oxidising Ag^+ to Ag^{2+} ($Ag^+/Ag^{2+}\varepsilon_0^{acid} = 1.980$ V) and Ag^+ to Ag^{3+} ($Ag^+/AgO^+\varepsilon_0^{acid} = 2.00$ V) [24]. The application of ozonolysis to synthesize Ag_2O_2 from metallic Ag or Ag_2O has already been demonstrated [9,19,20,37,38]. The synthesis of Ag_2O_2, Ag_3O_4, Ag_2O_3 and Ag_7O_8X salts by ozone-oxidation of aqueous Ag^+ is also theoretically viable (Eqs. (1)–(4) below). Minimal reliable work has been reported in this area to date [39], clearly justifying further research effort.

$$2Ag^+_{(aq)} + O_{3(g)} + H_2O_{(l)} \rightarrow Ag_2O_{2(s)} + O_{2(g)} + 2H^+_{(aq)} \quad (1)$$

$$6Ag^+_{(aq)} + 5O_{3(g)} + 3H_2O_{(l)} \rightarrow 2Ag_3O_{4(s)} + 5O_{2(g)} + 6H^+_{(aq)} \quad (2)$$

$$2Ag^+_{(aq)} + 2O_{3(g)} + H_2O_{(l)} \rightarrow Ag_2O_{3(s)} + 2O_{2(g)} + 2H^+_{(aq)} \quad (3)$$

$$7Ag^+_{(aq)} + X^-_{(aq)} + 5O_{3(g)} + 3H_2O_{(l)} \rightarrow Ag_7O_8X_{(s)} + 5O_{2(g)} + 6H^+_{(aq)} \quad (4)$$

For the reasons outlined above, a comprehensive study of the aqueous Ag^+/O_3 system was undertaken. We aimed to synthesize Ag_2O_2, Ag_3O_4, Ag_2O_3 and Ag_7O_8X salts by the ozonolysis route (Eqs. (1)–(4)), then comprehensively characterize the reaction products using a variety of spectroscopic and thermo-analytical methods. Particular emphasis is placed on examination of the vibrational spectra and electronic structure of these compounds.

2. Experimental

2.1. General

Silver(I) salts were purchased from Aldrich and used without further purification. Ag_2O and Ag_2O_2 powders were prepared from $AgNO_3$ in accordance with established procedures [40,41], and used as reference materials.

2.2. Synthesis of the binary silver oxides and Ag_7O_8X salts

During preliminary studies, we determined that the product obtained during ozonolysis of aqueous solutions of Ag^+ at 298 K was highly dependent on the anion of the silver salt used to prepare the silver solution. Ozonolysis of aqueous solutions of $AgNO_3$, $AgClO_4$ and Ag_2SO_4 afforded $Ag_7O_8NO_3$, $Ag_7O_8ClO_4$ or $Ag_7O_8HSO_4$, respectively, whereas ozonolysis of 0.05 M aqueous solutions of AgF or $AgBF_4$ yielded Ag_3O_4. To prevent thermal decomposition of Ag_3O_4 during the synthesis, the ozonolysis of aqueous solutions of AgF or $AgBF_4$ was performed at 273 K. Monoclinic Ag_2O_2 was the product collected by ozonolysis of aqueous solutions of CH_3 COOAg at 273–298 K.

The general procedure used to prepare these compounds was as follows. Aqueous solutions of the silver salts were prepared using milli Q water. Ag^+ concentrations used in the ozonolysis experiments were determined by the respective solubilities of the different silver salts in H_2O at 273–298 K. The pH of the Ag^+ solution was measured, after which it was transferred to a 1 L. glass round-bottomed flask; fitted with a stirrer, a sintered glass frit bubbler for introducing gaseous O_3-O_2 mixtures and a gas outlet tube. The flask was then placed in a thermostated water bath and allowed to equilibrate for 1 h at a specified temperature in the range 273–298 K. An O_3–O_2 gas mixture (5 vol% O_3 in O_2, total flow rate $O_3 + O_2 = 200$ L h^{-1}), generated from dry O_2 using a commercial ozone generator (Fischer model 502), was then bubbled through the silver(I) solution for a specified time (0.5–15 h). After the specified time, ozonolysis was discontinued and the solid product collected by vacuum filtration on a pre-weighed sintered glass crucible (porosity 4). The filtrate was retained and its pH measured. The solid product was then washed repeatedly with ice-cold deionised water, then acetone. Ag_7O_8X salts ($X = NO_3^-$, ClO_4^-, HSO_4^-) were dried at 313 K under vacuum for 2 h. After drying, the sample and sintered glass crucible were reweighed, and the yield of product determined by difference. Ag_3O_4 powders were not vacuum dried, and instead were immediately transferred to a freezer at 255 K to prevent thermal decomposition before spectroscopic analysis.

2.3. Product characterization

2.3.1. XRD

Powder X-ray diffraction patterns were acquired using a Philips PW-1130 diffractometer, equipped with a Cu anode X-ray tube and curved graphite filter monochromator. XRD data was collected at room temperature, using monochromatized Cu K_α X-rays ($\lambda = 1.5418$ Å). Additional acquisition parameters were: 2θ range, 2–90°; step size, 0.02°; and scan rate, 2° min^{-1}. Diffraction patterns were referenced against the JCPDS database for sample identification [42–47].

2.3.2. SEM

Sample morphology was examined using a Philips XL-30 field emission gun scanning electron microscope (FEG-SEM). All micrographs were collected at an electron gun accelerating voltage of 5 kV. Specimens were mounted on black carbon tape for analysis.

2.3.3. XPS

XPS spectra were collected using a Kratos XSAM800 instrument equipped with an analytical chamber of base pressure $\sim 5 \times 10^{-10}$ Torr, a dual anode X-ray source (Mg/Al), and a hemispherical electron energy analyzer with multi-channel detector. For analysis, samples were lightly pressed to form a pellet then mounted on stainless steel stubs using carbon sticky dots. Spectra were excited using Mg Kα radiation ($h\nu = 1253.6$ eV). The hemispherical analyzer was operated in the fixed analyzer transmission (FAT) mode, and the analyzer axis was normal to the sample surface. Survey spectra were collected at an analyzer pass energy of 65 eV. Multiplet spectra were collected over narrow spectral regions at a pass energy of 38 eV. All XPS spectra were referenced against the Fermi edge. Elemental compositions were determined from the survey spectra by standard quantification procedures using peak areas and spectrometer-modified Scofield cross-sections. Estimated uncertainty in the percentage atomic concentration reported for each element is approximately 1–2%.

2.3.4. FT-IR

Far-infrared measurements were performed on a Digilab FTS-60 series spectrometer. Incorporated equipment included an FTS-60V vacuum optical bench with a 5 lines/mm wire mesh beam splitter, a mercury lamp source and a pyroelectric triglycine sulfate detector. Spectra were recorded at 2 cm^{-1} resolution over the range 50–700 cm^{-1} using 500 signal-averaged scans. Prior to data collection, the optical bench was evacuated to a pressure of $\sim 10^{-2}$ Torr. Mid-infrared studies were carried out using a Digilab FTS-60 series spectrometer employing a DTGS detector. Acquisition parameters were: range = 400–4000 cm^{-1}; resolution = 2 cm^{-1}; number of signal-averaged scans, = 500. Samples were analyzed using the polyethylene disk sampling method (solid state ion exchange reactions between the silver compounds and KBr precluded the use of the KBr disk technique). Fresh sample (5 mg) was mixed with polyethylene powder (20 mg) then compressed at a pressure of 5 ton per-square-inch for 5–10 min to form thin disks of diameter 13 mm. Pellets were

mounted in a stainless steel disc holder for the collection of infrared spectra.

2.3.5. Raman

Raman spectra were taken on a Renishaw RM-2 Raman microscope system, fitted with an Olympus 20× objective lens. Raman spectra were excited using either 785 nm radiation from a diode laser or 488 nm radiation from an argon ion laser, and scattered light was collected at an angle 180° to the incident beam direction (180° backscattering sampling geometry). The laser power at the sample for routine data collection was ~0.3 mW, although higher powers were also used to study the photosensitivity of selected samples. Spectra were collected over the range 200–2000 cm^{-1} and at a resolution of *ca.* 2 cm^{-1}. To improve the signal-to-noise ratio of the data reported 20 consecutive scans were added to produce a spectrum.

2.3.6. DSC

DSC data was obtained on a DSC-2 instrument (Rheometric Scientific Ltd.). Samples (10–15 mg) were weighed into open aluminium crucibles, and referenced against an empty aluminium crucible during calorimetric measurements. DSC traces were recorded at a heating rate of 10 K min^{-1}, under a dry air purge.

3. Results and discussion

3.1. Ozone-mediated synthesis of binary silver oxides and Ag_7O_8X salts

3.1.1. Effect of silver(I) salt

The first objective of this study was to identify of the product(s) formed by sparging ozone through aqueous solutions of different Ag(I) salts. Table 1 summarizes our key findings. Results are discussed in conjunction with Fig. 1, which shows XRD patterns for the various reaction products isolated. As mentioned in Section 2.2, the anion of the silver(I) salt had a strong influence on the ozonolysis product. Ozonolysis of neutral or mildly acidic solutions of $AgNO_3$, $AgClO_4$ or Ag_2SO_4 at 298 K afforded $Ag_7O_8NO_3$, $Ag_7O_8ClO_4$ and $Ag_7O_8HSO_4$, respectively. XRD patterns for these clathrate compounds were indistinguishable (Fig. 1a–c), in agreement with the fact that the crystallographic parameters for all Ag_7O_8X salts are similar (space group $Fm\bar{3}m$, $Z = 4$, $a = 9.82$–9.94 Å) [26–32]. For each synthesis, the molar yield ratio H^+/Ag_7O_8X ($X = NO_3^-, ClO_4^-, HSO_4^-$) was in the range 5.8–5.9, close to the theoretical ratio of 6 predicted by Eq. (4). The nature of the anion appears to be important for the stabilization of the Ag_7O_8X clathrate structure. Polyoxoanions appear to be ideal in this regard. Ozone treatment of aqueous solutions of AgF or $AgBF_4$ at 273 K yielded Ag_3O_4 in high purity (Fig. 1d and e). This is an exciting result and the first reported synthesis of Ag_3O_4 by non-electrochemical routes. The molar yield ratio H^+/Ag_3O_4 for both experiments was 2.9, in good accord with the theoretical value of 3 (Eq. (2)). Monoclinic Ag_2O_2 was the product obtained by ozonolysis of aqueous solution of silver acetate at 273–298 K (Fig. 1f). Acetate ions acted to buffer the solution, since the pH of the solution decreased only from 8.7 to 5.9 after 3 h ozonolysis. Ag_2O_2 may have formed directly as described by Eq. (1), or alternatively is a decomposition product of a higher silver oxide, possibly Ag_2O_3. The latter is very thermally unstable at 298 K [12]. Our attempts to prepare Ag_2O_3 by ozonolysis of aqueous solutions of $AgClO_4$ or $AgBF_4$ at low temperature, as has been achieved electrochemically [11,12], have proved unsuccessful to date.

To examine the effect of other experimental parameters on the ozone-mediated syntheses, the precipitation of $Ag_7O_8NO_3$ was examined in further detail.

Table 1
Products obtained by the ozonolysis of aqueous solutions of different Ag(I) salts

* At pH 14, Ag(I) precipitates from solution as Ag_2O, which is oxidized by O_3 to monoclinic Ag_2O_2.

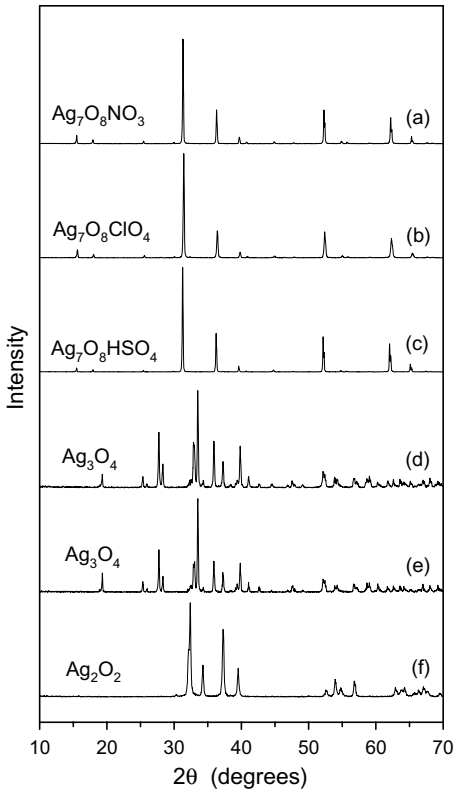

Fig. 1. Powder XRD patterns for the products obtained by ozonolysis of aqueous solutions of (a) $AgNO_3$ (0.1 M, 298 K, 5 h); (b) $AgClO_4$ (0.1 M, 298 K, 5 h); (c) Ag_2SO_4 (0.015 M, 298 K, 5 h); (d) AgF (0.05 M, 273 K, 3 h); (e) $AgBF_4$ (0.05 M, 273 K, 3 h) and (f) CH_3COOAg (0.05 M, 273 K, 3 h). Silver salt concentrations, reaction temperatures and ozonolysis times are given in parentheses. Products identified are listed next to the XRD patterns.

3.1.2. Effect of ozonolysis time

Ozonolysis of 0.1 M $AgNO_3$ (initial pH 5.5) at 298 K for 0.5–15 h yielded $Ag_7O_8NO_3$ as the only solid phase (Table 1). The yield of $Ag_7O_8NO_3$ increased almost linearly with time during the first 5 h of reaction, but tended towards an asymptotic limit of approximately 55% at longer reaction times. A yield of 52.7% was achieved after 15 h. The pH of the solution decreased sharply during the initial stages of the reaction, but maintained an almost constant value of ~1.4 after 15 h. The molar yield ratio $H^+/Ag_7O_8NO_3$ at all times was between 5.7 and 5.9, again close to the theoretical value of 6 predicted by Eq. (4).

Results suggest that the precipitation of $Ag_7O_8NO_3$ is likely affected by competing dissolution processes at low pH. To test whether competing precipitation-dissolution phenomena were a factor in our studies, we determined a dissolution curve for $Ag_7O_8NO_3$ powder in aqueous HNO_3 (not shown). The stability of $Ag_7O_8NO_3$ particles in HNO_3 solution decreased sharply in the pH range 1–2. This confirmed that competitive precipitation and dissolution of $Ag_7O_8NO_3$ particles was likely during ozonolysis at low pH values, and this limits the yield of product achievable.

3.1.3. Effect of initial pH

To investigate the effect of initial pH on the synthesis of $Ag_7O_8NO_3$, we prepared 0.1 M $AgNO_3$ solutions in either dilute HNO_3 (pH 0–4) or NaOH (pH 8–14) and used these in the ozonolysis experiments. $NaNO_3$ was also added to achieve a constant ionic strength (1.1 M).

The data in Table 1 shows that the initial pH had a strong influence on product composition and yields. For initial pH 0–10, ozonolysis yielded $Ag_7O_8NO_3$ exclusively. Product yields increased with initial pH in this range. For pH 10–13, the precipitation of Ag_2O and the oxidation by O_3 of Ag_2O to Ag_2O_2 compete with $Ag_7O_8NO_3$ formation. The proportions of Ag_2O and Ag_2O_2 in the product increased with increasing initial pH. At pH 13 and above, only Ag_2O and Ag_2O_2 formed. At pH 14, complete oxidation of the initially formed Ag_2O precipitate to Ag_2O_2 was achieved in 10 h.

3.2. SEM characterization of the ozonolysis products

The growth morphology of the products was examined by SEM. Fig. 2a–d shows the morphological evolution of $Ag_7O_8NO_3$ particles as a function of ozonolysis time. Particles formed after 30 min were predominantly of cubic shape (exposing 6 square {1 0 0} faces) and submicron size (Fig. 2a). With increasing ozonoloysis time, the particles became larger and developed an octahedral habit (exposing 8 triangular {1 1 1} faces) or forms derived from octahedra by truncation of corners and edges (Fig. 2b–d). After 15 h ozonolysis, the $Ag_7O_8NO_3$ particles were typically of truncated octahedral habit, twinned and of average size ~5 μm (Fig. 2d). Similar growth morphologies were observed for the $Ag_7O_8ClO_4$ and $Ag_7O_8HSO_4$ powders (SEM micrographs not shown).

Ag_3O_4 obtained by ozonolysis of aqueous solutions of AgF at 273 K displayed a rhombohedral prismatic habit (Fig. 2e). Monoclinic Ag_2O_2 resulting from the ozonolyis of aqueous silver acetate crystallized in the form of irregular platelets (Fig. 2f).

3.3. Electronic structure, vibrational spectra and thermal decomposition of Ag_7O_8X salts

As stated in the introduction, Ag_7O_8X salts are metals and the only known clathrates to exhibit low temperature superconductivity [28,29]. Minimal spectroscopic information is available for these compounds, motivating a detailed investigation here.

3.3.1. XPS characterization of $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$

Information about the electronic states of silver in these compounds can be deduced from the high-resolution XPS spectra shown in Fig. 3. The spectra are discussed in conjunction with Table 2, which provides XPS data summaries for the Ag_7O_8X salts and reference data collected for metallic silver and other relevant silver compounds. It is useful to note that the spectra presented in Fig. 3 are in

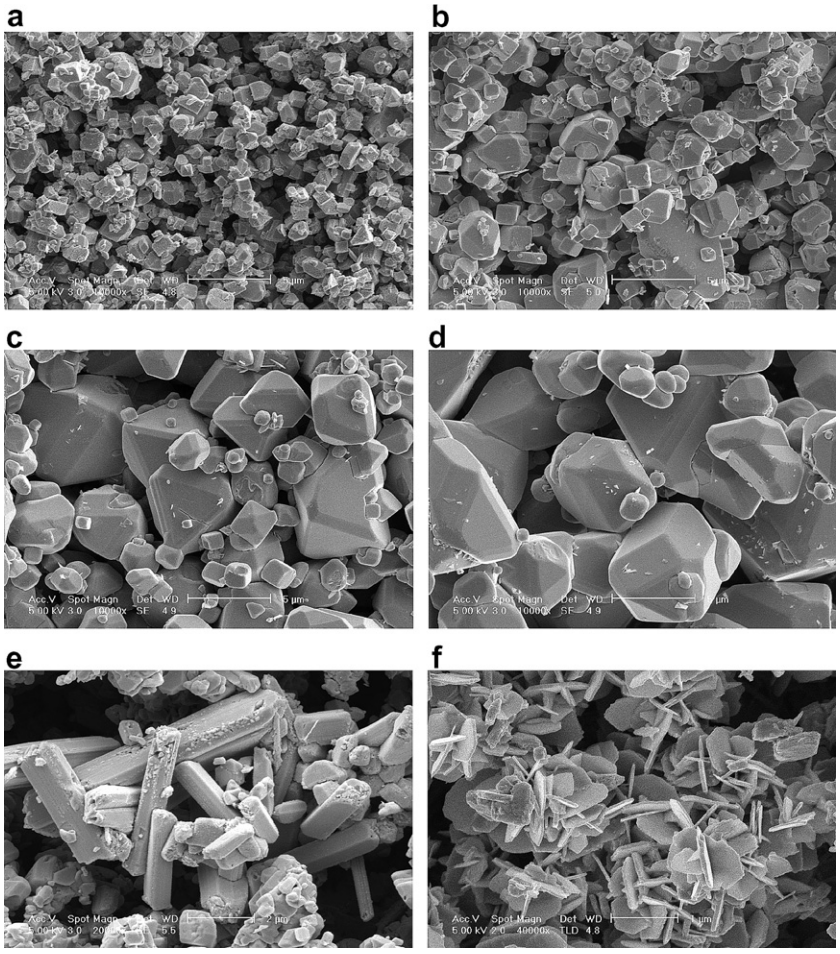

Fig. 2. SEM micrographs of $Ag_7O_8NO_3$ powders obtained by the ozonolysis of 0.1 M $AgNO_3$ at 298 K for (a) 0.5 h; (b) 2 h; (c) 5 h and (d) 15 h. Fig. 2e shows the Ag_3O_4 powder obtained by ozonolysis of 0.05 M AgF at 273 K for 3 h and Fig. 2f monoclinic Ag_2O_2 precipitated by ozonolysis of 0.05 M CH_3COOAg at 273 K for 3 h. Image magnifications are 10000, 10000, 10000, 10000, 20000 and 40000×, respectively.

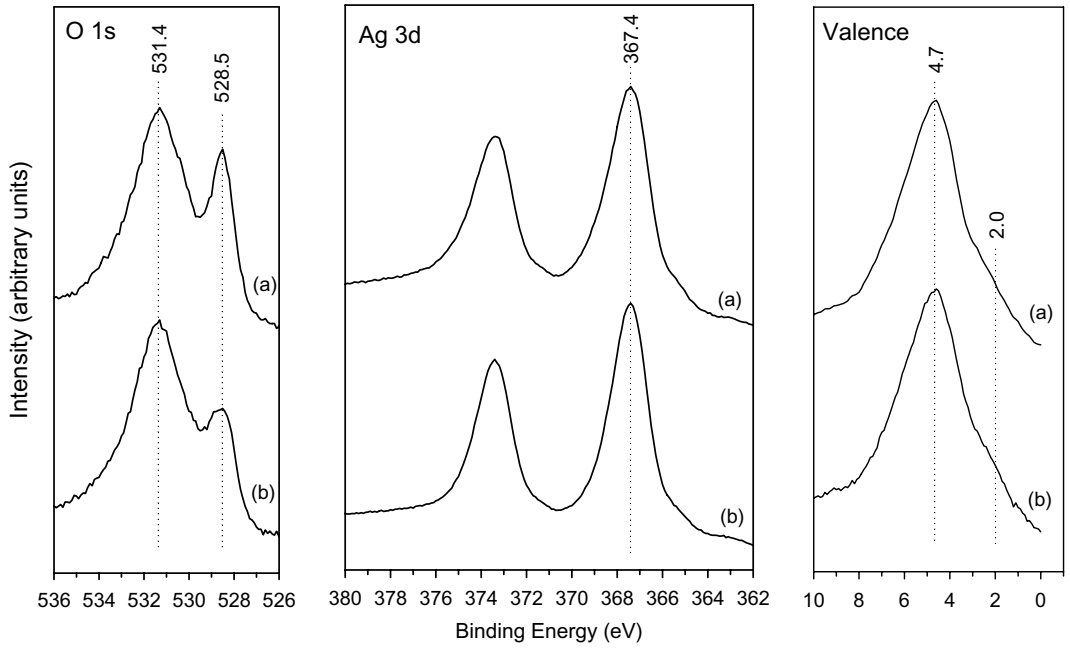

Fig. 3. XPS O 1s, Ag 3d and valence-band spectra for (a) $Ag_7O_8NO_3$ and (b) $Ag_7O_8HSO_4$. Spectra were referenced relative to the Fermi edge ($E_F = 0$ eV).

Table 2
Summarized XPS data for metallic silver and various silver compounds

Sample	Atomic composition (%)					O/Ag ratio		Binding energy (eV)			
	Ag	O	N	S	C	Theor.	Exp.	Ag $3d_{5/2}$	O 1s	N 1s	S $2p_{3/2}$
Ag	60.9	19.0			20.1	0	0.31	368.2	531.0		
Ag_2O	38.9	22.4			38.7	0.5	0.58	367.8	529.6		
$AgNO_3$	15.5	46.8	15.7		22.0	3.0	3.02	368.0	532.1	406.1	
Ag_2SO_4	24.6	48.9		12.2	14.3	2.0	1.99	367.9	531.7		168.0
Ag_2O_2	36.8	39.9			23.3	1.0	1.08	367.4	528.6		
$Ag_7O_8NO_3$	21.9	40.3	3.1		34.3	1.57	1.84	367.4	528.5	405.8	
$Ag_7O_8HSO_4$	21.4	41.8		3.2	33.6	1.71	1.95	367.4	528.5		167.6

excellent qualitative agreement with data reported by Bao et al. for electrochemically synthesized $Ag_7O_8NO_3$ [35].

XPS spectra collected for non-metallic samples typically need to be corrected for specimen charging during X-ray irradiation, unless precautions are taken to dissipate the build up of positive charge (such as flooding the specimen surface with low energy electrons during data acquisition). No such charging correction was necessary for spectra taken from the Ag_7O_8X salts, evidence of their metallic character.

The elemental composition determined by quantitative XPS analysis for $Ag_7O_8NO_3$ was Ag (21.9%), O (40.3%), N (3.1%) and C (34.3%) (Table 2). The carbon impurity results predominantly from the adsorption of residual hydrocarbons in the UHV chamber of the XPS instrument. The experimental Ag/N ratio was close to 7, consistent with the empirical formula of the compound. The O/Ag ratio of 1.84 exceeded the theoretical value of 1.57. Independent ICP-MS and thermogravimetric analyses of the compound revealed a composition very close to $Ag_7O_8NO_3$, indicating that the oxygen excess determined by XPS was likely localized at the specimen surface (XPS is surface-analytical technique). The cause of this oxygen excess is examined below. The elemental composition data for $Ag_7O_8HSO_4$ was similar (Table 2), in that the Ag/S ratio was approximately 7, but the O/Ag ratio of 1.95 slightly exceeded the theoretical value of 1.71.

The core-level Ag 3d spectra for $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$ show broad, asymmetric peaks at 373.4 eV and 367.4 eV (FWHM = 2.0 eV), which are readily assigned to core-level Ag $3d_{3/2}$ and Ag $3d_{5/2}$ photoemissions, respectively. The Ag 3d peaks are shifted by −0.8 eV relative to a those of Ag metal (Ag $3d_{5/2}$ = 368.2 eV), the magnitude and direction of the shift typical for highly oxidized states of silver [16–20,35]. Silver is unusual in that its core-levels photoemissions shift to lower binding energy with increasing oxidation state (cf. Table 2, Ag $3d_{5/2}$ binding energies for Ag, Ag_2O and Ag_2O_2 are 368.2, 367.8 and 367.4 eV, respectively). For most metals, positive binding energy shifts are observed when the metal is oxidized, on account of the extra coulombic attraction of core-level electrons towards the nucleus in the oxidized state. The negative binding energy shift observed for silver with increasing oxidation state is rationalized in terms of the large contribution of final state relaxation effects to the XPS chemical shift [16–18]. The Ag 3d peaks for $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$ were also broad compared to those measured for Ag and Ag_2O (FWHM = 1.25 eV and 1.47 eV, respectively), and of similar width to those of measured for Ag_2O_2 (FWHM = 1.9 eV), strong evidence that Ag_7O_8X compounds contain silver in several different oxidation states. The Ag 3d spectra for the Ag_7O_8X salts also show satellites on the low binding energy side of the Ag $3d_{3/2}$ and Ag $3d_{5/2}$ peaks, arising from final state relaxation effects.

The O 1s spectra contain two distinct peak maxima. The narrow peak at 528.5 eV (FWHM 1.4 eV) is typical for lattice oxygen (formally O^{2-}) in silver oxides [15–20], and in excellent agreement with XPS data reported here for bulk Ag_2O_2 (Table 2). We assign this feature to oxide ions of the face-sharing Ag_6O_8 structural units in $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$. The feature at ~531.4 eV in the O 1s spectra of both compounds is very broad (FWHM 2.8 eV), suggesting the presence of multiple oxygen species. The polyoxoanions of the Ag_7O_8X salts will contribute to this feature (cf. $AgNO_3$ O 1s = 532.1 eV; Ag_2SO_4 O 1s = 531.7 eV), as also will surface hydroxyl species (531.7 eV) and possibly chemisorbed H_2O (533.0 eV) since the compounds were prepared from aqueous solution [18–20]. For both compounds, spectroscopic evidence was found in the C 1s spectrum for a surface carbonate species (C 1s = 289.0 eV), which typically gives an O1s peak between 530.5 and 531 eV [19,20]. Carbonate formation results from the reaction between surface oxygen atoms and atmospheric CO_2, and is a characteristic common to all silver oxides (cf. Table 2, carbonate formation is responsible for the high O/Ag ratios observed experimentally for Ag_2O and Ag_2O_2). The presence of surface hydroxyl and carbonate species, and possibly chemisorbed H_2O, satisfactorily explain the high O/Ag ratios determined by quantitative XPS analysis for the Ag_7O_8X salts.

N 1s and S $2p_{3/2}$ binding energies measured for the NO_3^- and HSO_4^- ions in $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$, respectively, were in excellent agreement with those determined for the same anions in the $AgNO_3$ and Ag_2SO_4 (Table 2). S 2p binding energies are similar for metal salts containing HSO_4^- and SO_4^{2-} (both S^{6+}) [48].

Valence-band spectra for $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$ (Fig. 3) comprise an intense peak at 4.7 eV and a weaker feature at 2.0 eV. The 4.7 eV peak exhibits asymmetry on

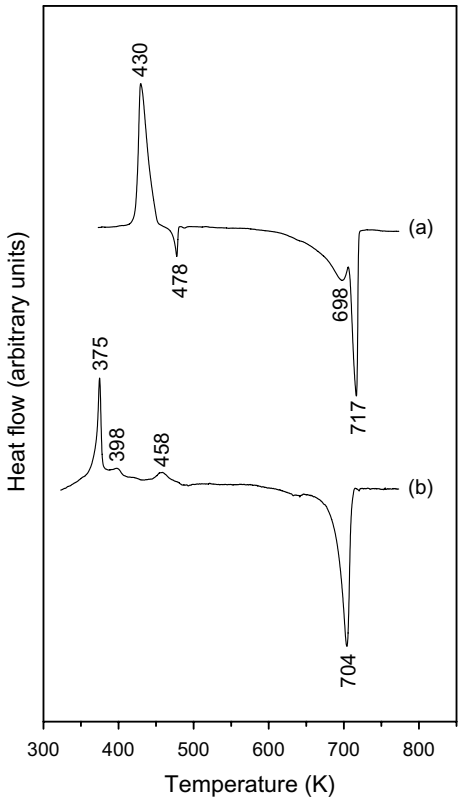

Fig. 4. DSC curves for (a) $Ag_7O_8NO_3$ and (b) Ag_3O_4. All data was collected at a heating rate of 10 K min^{-1} under a dry air purge.

the high binding energy side, consistent with presence of more than one component. By comparison with valence-band spectra reported for other silver compounds [15–20], we assign the 4.7 eV peak to orbitals of Ag 4d character. The broadness and asymmetry of the peak reflect the mixed-valence nature of the Ag_7O_8X compounds. The feature at about 2.0 eV originates from valence orbitals of mostly O 2p character. The metallic conductivity of Ag_7O_8X salts is attributed to promotion of two electrons from the face-sharing Ag_6O_8 structural units into a conduction band involving Ag 4d–O 2p orbitals (i.e. electron hopping between metal centres of the 'Ag_6O_8' units via bridging oxygen atoms). Consistent with this proposal, the valence-band spectra of the $Ag_7O_8NO_3$ and $Ag_7O_8HSO_4$ show overlap between valence and conduction bands at the Fermi edge ($E_F = 0$ eV). The XPS data thus strongly supports the mixed-valence formulation $(Ag^{2.67+})_6O_8 \cdot Ag^+X^-$ for these compounds.

3.3.2. Thermal decomposition of $Ag_7O_8NO_3$ in air under dynamic heating conditions

Detailed knowledge about the thermal stability of the Ag_7O_8X salts synthesized in this work is important as these compounds show commercial application potential in several areas; most notably in antibacterial coatings on account of the enormous oxidising power of Ag^{2+} and Ag^{3+} centres [36]. Here, we examined the thermal decomposition of $Ag_7O_8NO_3$ in air under both dynamic heating conditions (DSC) and stepwise isothermal heating conditions (XRD and FT-IR spectroscopy, Section 3.3.3. below).

The DSC trace for $Ag_7O_8NO_3$ (Fig. 4a) comprises a large exothermic peak at 430 K, two small endothermic peaks at 478 K and 698 K, and a large endothermic peak at 717 K. The trace is qualitatively similar to that reported for electrochemically synthesized $Ag_7O_8NO_3$ [33], and the peaks assigned accordingly. The large exothermic peak at 430 K is due predominantly to the thermal decomposition of $Ag_7O_8NO_3$ (Eq. (5)), but will also contains contributions from the thermal decomposition of Ag_2O_2 (Eq. (6)) and the orthorhombic → tetragonal phase transition of $AgNO_3$ [21,33].

$$Ag_7O_8NO_{3(s)} \rightarrow 3Ag_2O_{2(s)} + AgNO_{3(s)} + O_{2(g)} \quad (5)$$

$$3Ag_2O_{2(s)} \rightarrow 3Ag_2O_{(s)} + 1.5O_{2(g)} \quad (6)$$

The endothermic peaks at 478 K, 698 K and 717 K in Fig. 4a result from the melting of tetragonal $AgNO_3$, the thermal decomposition of $AgNO_3$ (Eq. (7)) and the thermal decomposition of Ag_2O (Eq. (8)), respectively.

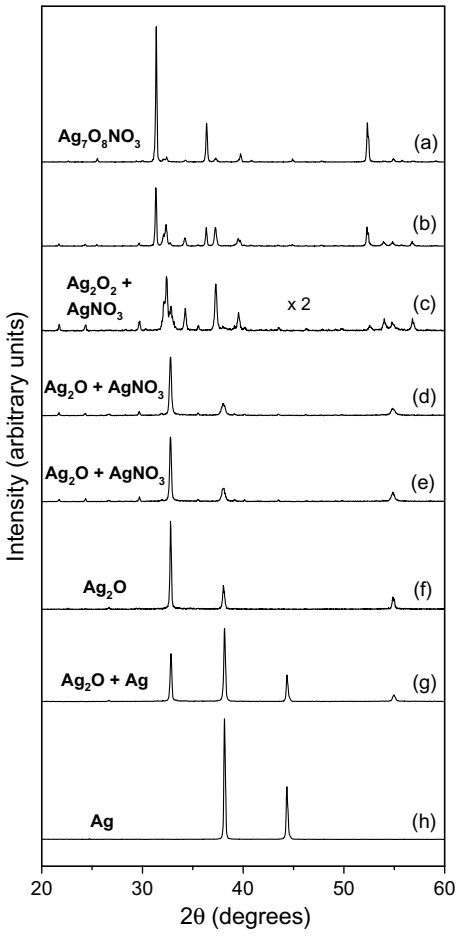

Fig. 5. XRD patterns for the thermal decomposition of $Ag_7O_8NO_3$ in air. Fresh samples were calcined 1 h at (a) 363 K; (b) 388 K; (c) 398 K; (d) 423 K; (e) 573 K; (f) 623 K; (g) 648 K and (h) 673 K. All data was collected at room temperature. The main phases identified are listed on the left side of the figure.

$$AgNO_{3(l)} \rightarrow 0.5Ag_2O_{(s)} + NO_{2(g)} + 0.25O_{2(g)} \quad (7)$$

$$3.5Ag_2O_{(s)} \rightarrow 7Ag_{(s)} + 1.75O_{2(g)} \quad (8)$$

The overall decomposition reaction for $Ag_7O_8NO_3$ in air is thus

$$Ag_7O_8NO_{3(s)} \rightarrow 7Ag_{(s)} + NO_{2(g)} + 4.5O_{2(g)} \quad (9)$$

DSC curves for $Ag_7O_8ClO_4$ and $Ag_7O_8HSO_4$ heated in air were also collected (not shown). The curves were similar in most respects to that presented in Fig. 4a for $Ag_7O_8NO_3$, although the onset temperature for the thermal decomposition of these compounds was *ca.* 5 K lower than that observed for $Ag_7O_8NO_3$, suggesting they have slightly lower thermal stability.

3.3.3. Vibrational spectra and thermal decomposition of $Ag_7O_8NO_3$ in air under isothermal heating conditions

Structural changes occurring during the thermal decomposition of $Ag_7O_8NO_3$ in air under isothermal conditions were followed by powder XRD (Fig. 5) and FT-IR spectroscopy (Fig. 6). Freshly prepared $Ag_7O_8NO_3$ powders were calcined for 1 h at selected temperatures in the range 323–773 K, then quickly cooled to room temperature and analyzed by the two techniques. Due to the nature of the heating program, onset temperatures for reactions 5–8 registered by XRD and FT-IR spectroscopy were considerably lower than those determined by DSC.

The XRD pattern obtained following calcination of $Ag_7O_8NO_3$ at 363 K (Fig. 5a) was identical to that collected for the freshly prepared salt (cf. Fig. 1a), indicating no decomposition occurred during this treatment. The corresponding mid-IR and far-IR spectra for the compound dispersed in a low-density polyethylene disk are shown in Fig. 6a The spectra contain no discernable peaks, and were identical to that of a pure polyethylene disk of the same thickness (not shown), except for the fact they showed significantly increased absorbance (i.e. relative to the spectrum of pure polyethylene, spectra for $Ag_7O_8NO_3$ in polyethylene were shifted up the absorbance axis by an amount proportional to the $Ag_7O_8NO_3$ loading). The fact that bands due to the component ions of $Ag_7O_8NO_3$ are not evident in Fig. 6a is indicative of metallic behaviour and lends further support for the valence formulation $(Ag^{2.67+})_6O_8 \cdot Ag^+NO_3^-$.

The thermal decomposition of $Ag_7O_8NO_3$ commenced around 373 K, in agreement with literature reports that $Ag_7O_8NO_3$ is transformed to $3Ag_2O_2 + AgNO_3 + O_2$ with prolonged immersion in boiling water [7]. Spectroscopic evidence to support this is found in Fig. 5a–c, where XRD peaks characteristic for $Ag_7O_8NO_3$ disappeared on increasing the calcination from 363 K to 398 K. Simultaneously, new peaks appeared and were indexed to monoclinic Ag_2O_2 [43], orthorhombic $AgNO_3$ [44] and Ag_2O [45]. The same changes manifest themselves in the FT-IR

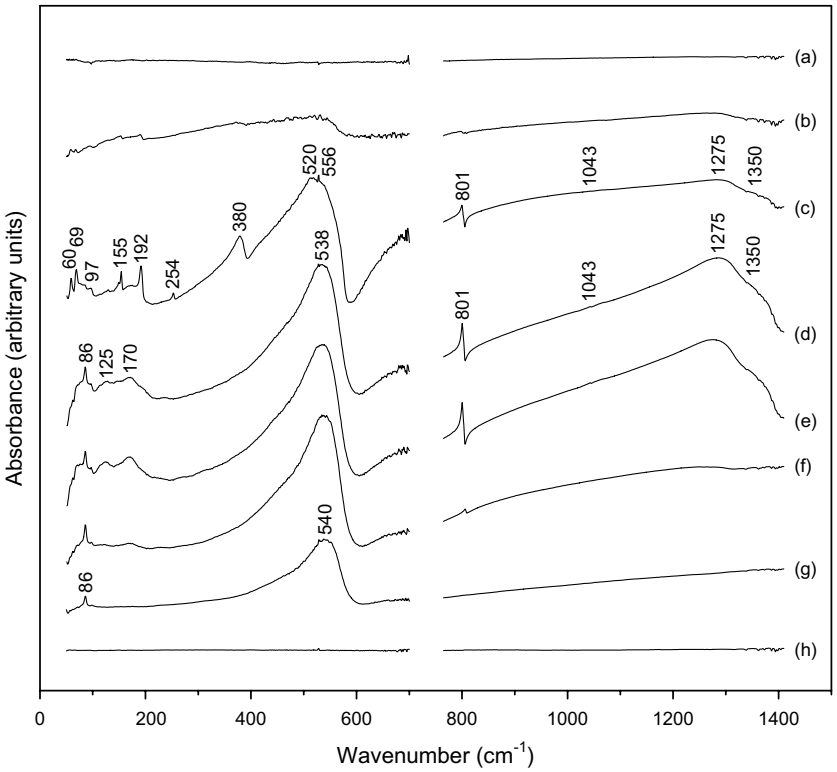

Fig. 6. FT-IR absorbance spectra for the thermal decomposition of $Ag_7O_8NO_3$ in air. Fresh samples were calcined 1 h at (a) 363 K; (b) 388 K; (c) 398 K; (d) 423 K; (e) 573 K; (f) 623 K; (g) 648 K and (h) 673 K. All data was collected at room temperature using the pressed polyethylene disk sampling method. The spectrum of the polyethylene disk was removed by subtraction.

spectra of Fig. 6a–c, where bands characteristic for monoclinic Ag_2O_2 (60, 69, 97, 155, 192, 254, 380, 520, 556 cm^{-1}) and orthorhombic $AgNO_3$ (80, 103, 125, 170, 801, 1043, 1275, 1350 cm^{-1}), then Ag_2O (86, ~540 cm^{-1}), develop with increasing calcination temperature up to 398 K. Assignments for these bands may be found in Refs [21,49,50]. The XRD and FT-IR data obtained following sample heating at 423 K (Figs. 5d and 6d, respectively) were those of Ag_2O and $AgNO_3$, indicating that complete thermal decomposition of the initially formed Ag_2O_2 was effected by this treatment.

Diffraction peaks and IR bands characteristic for $AgNO_3$ lost intensity with temperature between 573 K and 623 K (Figs. 5e–f and 6e–f), which is explained by the thermal decomposition of $AgNO_3$ (Eq. (7)) [51]. With increasing temperature above 623 K, spectral data typical of Ag_2O was progressively replaced by that of Ag metal (Figs. 5f–h and 6f–h), reflecting the thermal decomposition of Ag_2O to its component elements (Eq. (8)). Silver was the only phase identified by XRD after sample calcination at 673 K (Fig. 5h). Note the similarity between the FT-IR spectra of $Ag_7O_8NO_3$ (Fig. 6a) and silver metal (Fig. 6h).

3.3.4. Raman spectra for $Ag_7O_8NO_3$

Fig. 7a shows a Raman spectrum for $Ag_7O_8NO_3$ excited at 785 nm and low laser power (~0.3 mW at sample). The spectrum shows no discernable features, and was identical to a spectrum collected at the same laser power using 488 nm excitation (not shown). Results confirm the metallic reflectivity of $Ag_7O_8NO_3$ powders over the visible and near-infrared regions. Excitation at 785 nm and higher laser power (*ca.* 10 mW at sample) produced the spectrum shown in Fig. 7b, which contains bands at 219, 300, 376, 428, 467, 485, 525 (broad), 972 and 1043 cm^{-1}. By comparison with Raman spectra collected for monoclinic Ag_2O_2 (Fig. 7c), and orthorhombic $AgNO_3$ (Fig. 7d), it is clear that the use of a high laser power caused sample heating and the thermal decomposition of $Ag_7O_8NO_3$ to $3Ag_2O_2 + AgNO_3 + O_2$ (Eq. (5)). The broad band at 525 cm^{-1} is characteristic for Ag_2O [19–21], indicating partial decomposition of Ag_2O_2 also occurred (Eq. (6)). Fig. 7b is qualitatively similar to a spectrum reported by Pettinger et al. for electrochemically synthesized $Ag_7O_8NO_3$ [34], suggesting laser damage to the sample also occurred in that study (a laser power of 20 mW was used for data acquisition).

3.4. Electronic structure, vibrational spectra and thermal decomposition of Ag_3O_4

The synthesis of Ag_3O_4 in high purity is a key finding of the present study. In view of fact that the electronic structure of Ag_3O_4 is unclear and minimal spectroscopic information is available for the compound, we used DSC,

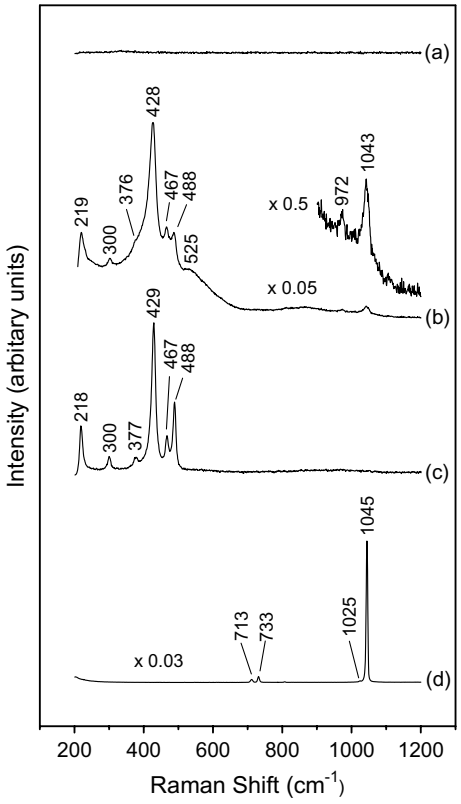

Fig. 7. Raman spectra excited at 785 nm for (a) $Ag_7O_8NO_3$, 0.3 mW; (b) $Ag_7O_8NO_3$, 10 mW; (c) monoclinic Ag_2O_2, 5 mW and (d) orthorhombic $AgNO_3$, 5 mW. Laser powers at the sample are also given.

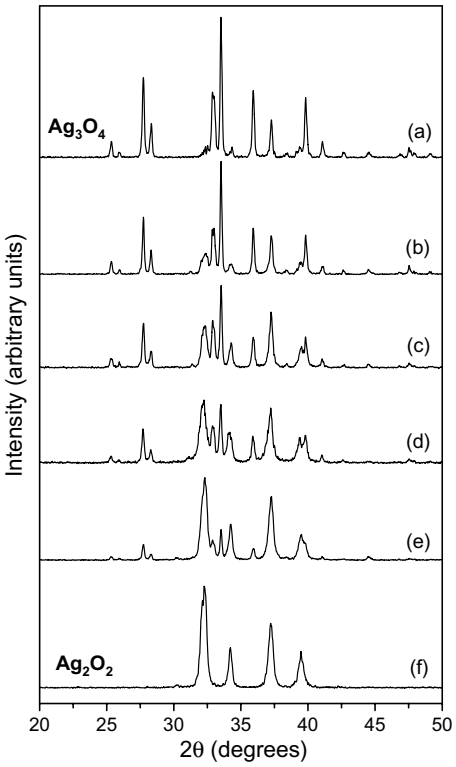

Fig. 8. XRD patterns for the thermal decomposition of Ag_3O_4 in air at 298 K. Time after preparation was (a) 0.5 h; (b) 4 h; (c) 8 h; (d) 12 h; (e) 16 h and (f) 20 h.

XRD, FT-IR and Raman spectroscopy to examine the thermal decomposition of Ag_3O_4 in air. From the vibrational spectra, we hoped to establish the correct valence structure for the compound. Attempts to collect XPS data for Ag_3O_4 proved unsuccessful due to the thermal instability of the compound.

3.5. Thermal decomposition of Ag_3O_4 in air under dynamic heating conditions

The DSC trace for Ag_3O_4 (Fig. 4b) shows a large exotherm at 375 K, several weak exotherms at 398 K and 458 K, and a large endotherm at 704 K. These peaks are assigned as follows. The endotherm at 375 K results from thermal decomposition of Ag_3O_4 (Eq. (10)); the weak endotherm at 398 K is due to crystallization of monoclinic Ag_2O_2; the endotherm at 458 K is due to thermal decomposition of Ag_2O_2 (Eq. (11)); and the strong exotherm at 704 K reflects thermal decomposition of Ag_2O to its elements (Eq. (12)).

$$Ag_3O_{4(s)} \rightarrow 1.5Ag_2O_{2(s)} + 0.5O_{2(g)} \quad (10)$$

$$1.5Ag_2O_{2(s)} \rightarrow 1.5Ag_2O_{(s)} + 0.75O_{2(g)} \quad (11)$$

$$1.5Ag_2O_{(s)} \rightarrow 3Ag_{(s)} + 0.75O_{2(g)} \quad (12)$$

The overall decomposition reaction for AgO_4 in air is thus

$$Ag_3O_{4(s)} \rightarrow 3Ag_{(s)} + 2O_{2(g)} \quad (13)$$

3.5.1. Vibrational spectra and thermal decomposition of Ag_3O_4 in air at 298 K

XRD, FT-IR and Raman spectroscopy were used to document the thermal decomposition of Ag_3O_4 to $1.5Ag_2O_2 + 0.5O_2$ in air at 298 K. Freshly prepared Ag_3O_4 powders were left in air at 298 K for 24 h. At regular time intervals, samples were taken and quickly analyzed using the three techniques. The data obtained is shown in Figs. 8–10, respectively.

Fig. 8a shows the XRD pattern collected for freshly prepared Ag_3O_4, and is identical to that presented in Fig. 1d. On standing in air at 298 K, the XRD peaks characteristic for Ag_3O_4 were progressively replaced by those typical for monoclinic Ag_2O_2 (Fig. 8a–f). Complete decomposition of Ag_3O_4 was achieved after about 20 h.

Fig. 9a shows the far-IR spectrum of Ag_3O_4 powder dispersed in a low-density polyethylene disk. The spectrum contains no discernable bands and was similar to that reported in Fig. 6a for metallic $Ag_7O_8NO_3$. Similarly, the Raman spectrum collected at low laser power for Ag_3O_4

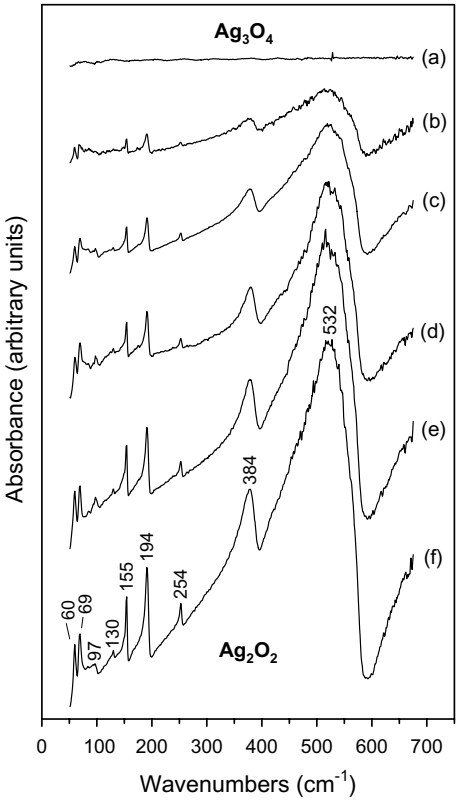

Fig. 9. FT-IR absorbance spectra for the thermal decomposition of Ag_3O_4 in air at 298 K. Time after preparation was (a) 0.5 h; (b) 4 h; (c) 8 h; (d) 12 h; (e) 16 h and (f) 20 h. The data was collected using the pressed polyethylene disk sampling method. The spectrum of the polyethylene disk was removed by subtraction.

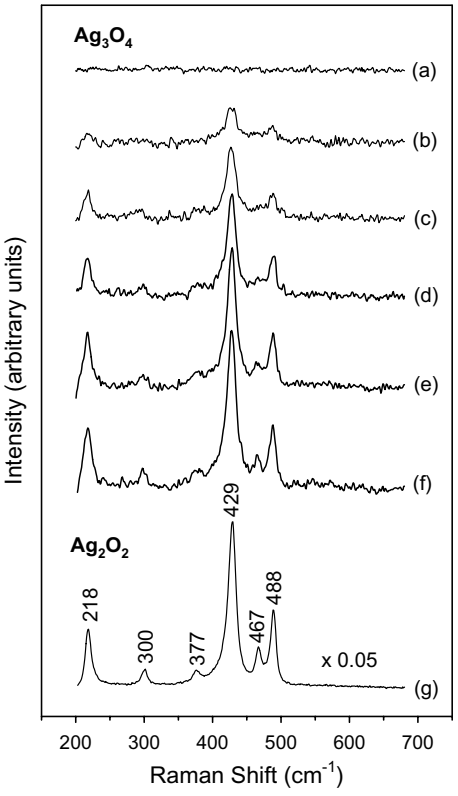

Fig. 10. Raman spectra excited at 785 nm for the thermal decomposition of Ag_3O_4 in air at 298 K. Time after preparation was (a) 0.5 h; (b) 4 h; (c) 8 h; (d) 12 h; (e) 16 h and (f) 20 h. The laser power at the sample for all measurements was ~0.3 mW. Fig. 10g was taken from the same sample as Fig. 10f, at a laser power of 5 mW.

(Fig. 10a) contained no bands. The fact that no discrete vibrational bands are observed in the FT-IR or Raman spectra for Ag_3O_4, even though some are expected based on a factor group analysis of the oxide's crystallographic structure, is clear proof that Ag_3O_4 behaves as a metal at 298 K. From the metallic properties it follows that one electron per Ag_3O_4 formula unit is delocalized over the Ag_3O_4 lattice, and the correct valence formulation for this compound is $(Ag^{2.67+})_3O_4$ rather than $Ag^{2+}(Ag^{3+})_2O_4$. The observation that Ag_3O_4 behaves as a metal is not unexpected, given that the unit cell formula for the oxide Ag_6O_8 is identical to that of the face-sharing Ag_6O_8 polyhedral units responsible for the metallic conductivity of Ag_7O_8X salts. The grey colour and metallic lustre of both Ag_3O_4 and the Ag_7O_8X salts is further evidence of similarities in the electronic structure of these compounds.

With increasing time at 298 K, the FT-IR and Raman spectra characteristic for Ag_3O_4 are slowly replaced by those of monoclinic Ag_2O_2 (Figs. 9a–f and 10a–f, respectively). Fig. 10f and g was taken sequentially from the same sample, the latter at a higher laser power and longer acquisition time to achieve a better signal-to-noise ratio. The value of using XRD and vibrational spectroscopic methods in combination to characterize silver compounds and follow their thermal decomposition is highlighted by this study.

4. Conclusions

(1) Ozonolysis of neutral or mildly acidic solutions of Ag(I) represents a simple and effective route for the sythesis of Ag_2O_2, Ag_3O_4 and Ag_7O_8X salts ($X = NO_3^-, ClO_4^-, HSO_4^-$). Previously, Ag_3O_4 and Ag_7O_8X compounds have only been accessible by electrochemical routes. Attempts to prepare Ag_2O_3 were unsuccessful.

(2) FT-IR and Raman spectra were reported for the first time for Ag_3O_4 and $Ag_7O_8NO_3$. The vibrational spectra indicate these compounds are metallic, a result also confirmed by XPS for the $Ag_7O_8NO_3$. Based on structural and spectroscopic considerations, the electron configurations of these compounds can be formulated as $(Ag^{2.67+})_3O_4$ and $(Ag^{2.67+})_6O_8 \cdot Ag^+NO_3^-$.

(3) The thermal decomposition of Ag_3O_4 and $Ag_7O_8NO_3$ powders in air was examined by DSC, XRD, FT-IR and Raman spectroscopy. The thermal stabilities of compounds prepared by ozonolysis were comparable to samples prepared by traditional electrochemical routes.

Abstract

The synthesis, photophysical and photochemical properties of the tetra- and octa-[4-(benzyloxyphenoxy)] substituted gallium(III) and indium(III) phthalocyanines are reported for the first time. The new compounds have been characterized by elemental analysis, IR, ^{1}H NMR spectroscopy and electronic spectroscopy. General trends are described for quantum yields of photodegredation, fluorescence quantum yields and lifetimes, triplet lifetimes and triplet quantum yields as well as singlet oxygen quantum yields of these compounds in dimethylsulfoxide (DMSO). Substituted indium phthalocyanine complexes (**7b**–**9b**) showed much higher quantum yields of triplet state and shorter triplet lifetimes, compared to the substituted GaPc derivatives due to enhanced intersystem crossing (ISC) in the former. The gallium and indium phthalocyanine complexes showed phototransformation during laser irradiation due to ring reduction. The singlet oxygen quantum yields (Φ_Δ), which give an indication of the potential of the complexes as photosensitizers in applications where singlet oxygen is required (Type II mechanism) ranged from 0.51 to 0.94. Thus, these complexes show potential as photodynamic therapy of cancer.

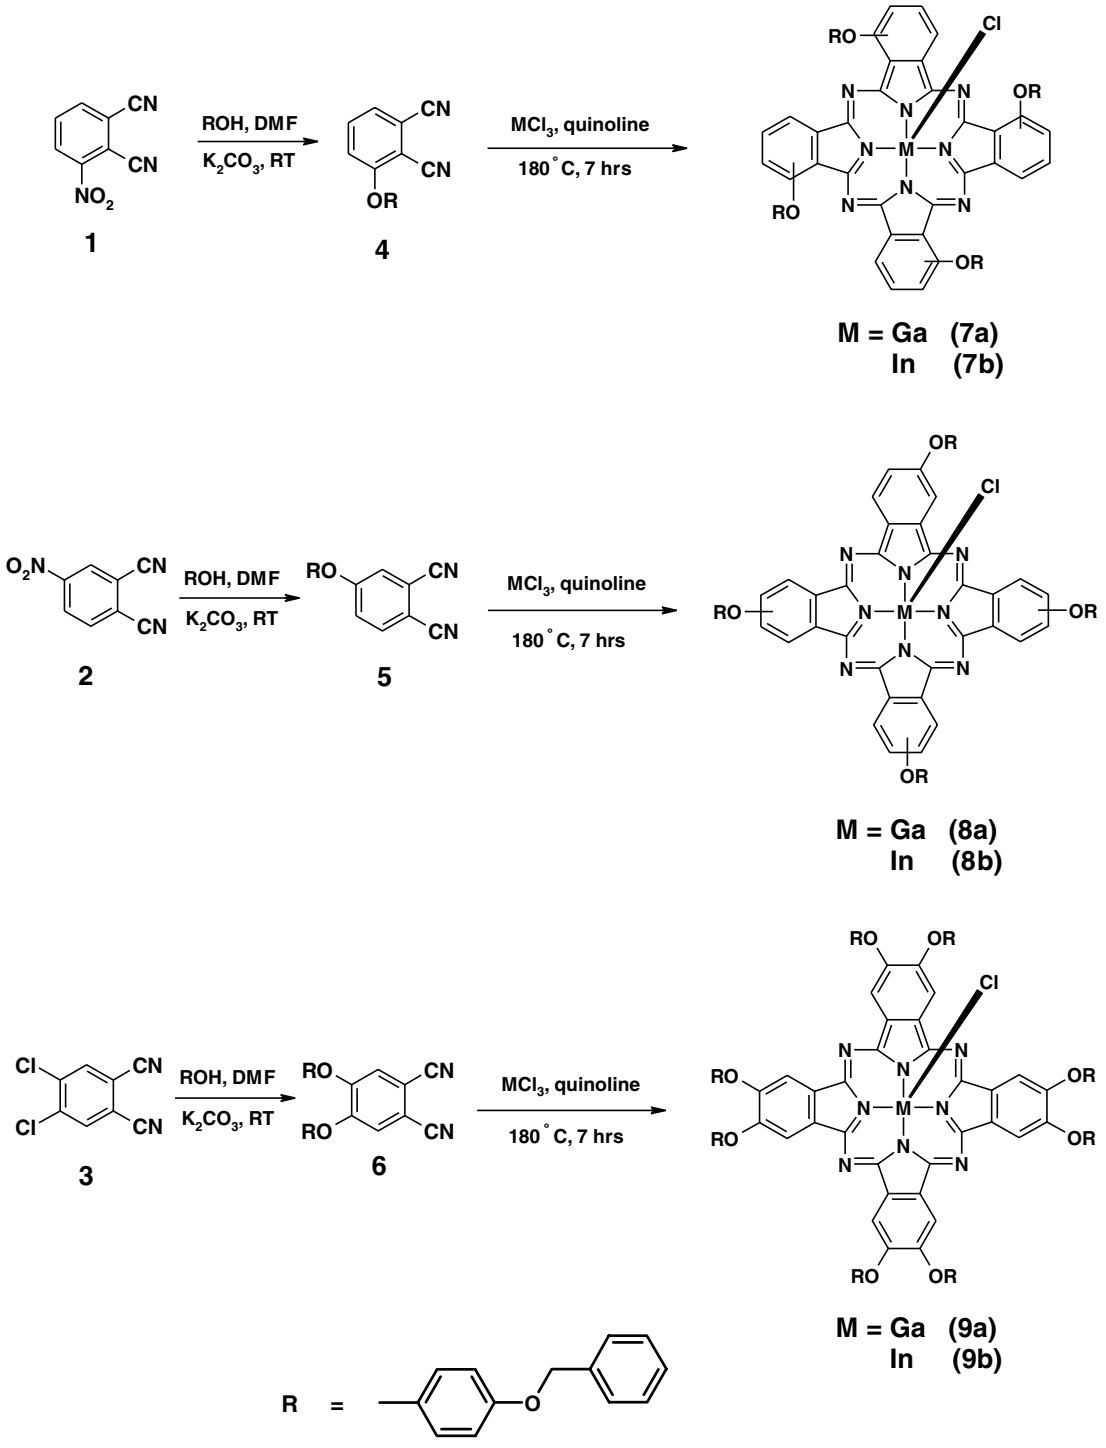
1. Introduction



Phthalocyanines, a family of aromatic macrocycles based on an extensive delocalized 18-π electron system, are known not only as classical dyes in practical use but also as modern functional materials in scientific research [1]. There has been growing interest in the use of phthalocyanines in a variety of new high technology fields including semiconductor devices [2], Langmuir–Blodgett films [3], electrochromic display devices [4], gas sensors [5], liquid crystals [6], non-linear optics [7] and various catalytic processes [8]. The attractive characteristics of phthalocyanines in these applications arise from their great diversity, thermal and chemical stability, redox versatility and intense colour.

One of their most important applications is functioning as photosensitizers for photodynamic therapy (PDT) [9–12]. Due to the intense absorption in the visible region, high efficiency to generate reactive oxygen species (such as singlet oxygen), and low dark toxicity, phthalocyanines have been used in this avenue for the treatment of various cancers and photoinactivation of viruses [13–15]. However, their insolubility in common organic solvents causes difficulties for many applications, rendering the syntheses of soluble derivatives an important task. Phthalocyanine derivatives of increased solubility have been obtained using substituents such as alkyl, alkoxy, alkylthio chains and bulky groups. Peripheral substitution with bulky groups or long alkyl, alkoxy or alkylthio chains leads to phthalocyanine products which are soluble in apolar solvents. Sulfo or quaternary ammonium groups enhance solubility in aqueous media over a wide pH range of aqueous solutions. The size and the nature of the substituents are not

doi:10.1016/j.poly.2007.03.007

the only criteria for the solubility of the substituted phthalocyanines; the change in symmetry caused by the substituents is also important. Generally, tetra substituted phthalocyanines are more soluble than symmetrically octa-substituted ones due to the formation of four positional isomers in the case of tetra substituted analogues [16]. According to their substituent positions two types of tetra-substituted macrocycles which show significant differences in their chemical and physical behaviour can be distinguished. Substitution at the more sterically crowded α (non-peripheral) position show reduced aggregation tendencies more than substitution at β (peripheral) position [17,18]. It has been established that non-aggregated phthalocyanines are extremely important and potentially useful for PDT applications [19]. Molecular aggregation of phthalocyanines, which is an intrinsic property of these

Scheme 1. Synthesis of 4-benzyloxyphenoxy tetra- and octa-substituted gallium and indium phthalocyanine complexes.

large πconjugated systems, provides an efficient non-radiative energy relaxation pathway, thereby shortening the excited state lifetimes and greatly reducing the photosensitizing efficiency [20,21]. The nature of peripheral substituents influences the degree of aggregation, with bulky groups reducing this phenomenon [22].

There is a continuous effort to extend the chemistry of metallophthalocyanines. Nonetheless, gallium(III) and indium(III) phthalocyanine chemistry appears not to have been fully explored especially when compared to the development of aluminium (which is the other group IIIA metal) phthalocyanine complexes. Aluminium phthalocyanine complexes have been used as PDT agents. However there are only a few studies about the photochemical and photophysical properties of gallium and indium phthalocyanine compounds [23–25]. Closed shell, diamagnetic ions, such as Zn^{2+}, Al^{3+} and Ga^{3+}, give phthalocyanine complexes with both high triplet quantum yields and long lifetimes [26].

To our knowledge, octasubstituted gallium or indium phthalocyanines have not been reported before. This is first report about synthesis of octasubstituted gallium and indium phthalocyanines. 4-Benzyloxyphenoxy substitution on gallium and indium-based phthalocyanines have not been reported before also. Thus we report on the synthesis of 4-benzyloxyphenoxy-substituted gallium (ClGaPcs) and indium (ClInPcs) phthalocyanines, tetrasubstituted at the non-peripheral (**7a**,**b**), peripheral (**8a**,**b**) positions and peripherally octasubstituted (**9a**,**b**) with 4-benzyloxyphenoxy group (Scheme 1). The development and elucidation of photophysical and photochemical properties of new phthalocyanine complexes are of fundamental importance, hence this work presents the study of these parameters. Specific phthalocyanines can thus be tailored such that they consist of certain properties which are required for various applications since the possibility of combining an unlimited number and type of substituents with a great number of central metals is infinite.

2. Experimental

2.1. Materials

Quinoline, dimethylsulfoxide (DMSO), methanol, hexane, chloroform ($CHCl_3$), dichloromethane (DCM), tetrahydrofuran (THF), acetone, ethanol and dimethylformamide (DMF) were dried as described in Perrin and Armarego [27] before use. Gallium(III) chloride, indium(III) chloride, deuterated $CDCl_3$, 1,3-diphenylisobenzofuran (DPBF) and 4-benzyloxyphenol were purchased from Aldrich. Column chromatography was performed on silica gel 60 (0.04–0.063 mm) and preparative thin layer chromatography was performed on silica gel 60 P F_{254}. 3-Nitrophthalonitrile (**1**) [28], 4-nitrophthalonitrile (**2**) [29], 4,5-dichlorophthalonitrile (**3**) [30], 3-(benzyloxyphenoxy)phthalonitrile (**4**) [31], 4-(benzyloxyphenoxy)phthalonitrile (**5**) [31], 4,5-bis-(benzyloxyphenoxy)-phthalonitrile (**6**) [31], unsubstituted gallium(III) phthalocyanine [32] and unsubstituted indium(III) phthalocyanine [32] were synthesized and purified according to literature procedures.

2.2. Equipment

UV–Vis spectra were recorded on a Cary 500 UV–Vis/NIR spectrophotometer. Fluorescence excitation and emission spectra, were recorded on a Varian Eclipse spectrofluoremeter using 1 cm pathlength cuvettes at room temperature. IR spectra (KBr pellets) were recorded on a Perkin–Elmer spectrum 2000 FTIR spectrometer. ^1H NMR spectra were recorded using a Bruker EMX 400 MHz NMR spectrometer. Elemental Analyses were performed at the University of Cape Town.

Photo-irradiations were done using a General electric Quartz line lamp (300 W). A 600 nm glass cut off filter (Schott) and a water filter were used to filter off ultraviolet and infrared radiations respectively. An interference filter (Intor, 700 nm with a band width of 40 nm) was additionally placed in the light path before the sample. Light intensities were measured with a POWER MAX5100 (Molelectron detector incorporated) power meter. Triplet absorption and decay kinetics were recorded on a laser flash photolysis system, the excitation pulses were produced by a Quanta-Ray Nd: YAG laser providing 400 mJ, 90 ns pulses of laser light at 10 Hz, pumping a Lambda-Physik FL3002 dye (Pyridin 1 dye in methanol). Single pulse energy was 7 mJ. The analyzing beam source was from a Thermo Oriel xenon arc lamp, and a photomultiplier tube was used as a detector. Signals were recorded with a two-channel digital real-time oscilloscope (Tektronix TDS 360); the kinetic curves were averaged over 256 laser pulses.

2.3. Photophysical parameters

2.3.1. Fluorescence quantum yields and lifetimes

Fluorescence quantum yields (Φ_F) were determined by the comparative method (Eq. (1)) [33,34],

$$\Phi_F = \Phi_F(\mathrm{Std})\frac{F \cdot A_{\mathrm{Std}} \cdot \eta^2}{F_{\mathrm{Std}} \cdot A \cdot \eta^2_{\mathrm{Std}}} \quad (1)$$

where F and F_{Std} are the areas under the fluorescence emission curves of the samples (**7a**,**b**, **8a**,**b** and **9a**,**b**) and the standard, respectively. A and A_{Std} are the respective absorbances of the samples and standard at the excitation wavelengths, respectively. η and η_{Std} are the refractive indexes of the solvents used for the sample and standard, respectively. Unsubstituted ZnPc (in DMSO) ($\Phi_F = 0.18$) [35] was employed as the standard. Both the samples and standard were excited at the same wavelength. The absorbance of the solutions at the excitation wavelength ranged between 0.04 and 0.05.

Fluorescence (τ_F) and natural radiative (τ_0) lifetimes were determined using PhotochemCAD program which uses the Strickler–Berg equation [36].

2.3.2. Triplet quantum yields and lifetimes

The de-aerated solutions of the respective gallium(III) and indium(III) phthalocyanine complexes were introduced into a 1 cm pathlength spectrophotometric cell and irradiated at the Q-band maxima with the laser system described above. Triplet quantum yields (Φ_T) were determined by a comparative method using triplet decay [23], Eq. (2):

$$\Phi_T^{Sample} = \Phi_T^{Std} \frac{\Delta A_T^{Sample} \cdot \varepsilon_T^{Std}}{\Delta A_T^{Std} \cdot \varepsilon_T^{Sample}} \quad (2)$$

where ΔA_T^{Sample} and ΔA_T^{Std} are the changes in the triplet state absorbances of the samples (**7a**,**b**, **8a**,**b** and **9a**,**b**) and standard, respectively; ε_T^{Sample} and ε_T^{Std}, the triplet state extinction coefficients for the samples (**7a**,**b**, **8a**,**b** and **9a**,**b**) and standard, respectively. The standard employed was ZnPc in DMSO, $\Phi_T^{Std} = 0.65$ [37].

Quantum yields of internal conversion (Φ_{IC}) were obtained from Eq. (3), which assumes that only three processes (fluorescence, intersystem crossing and internal conversion), jointly deactivate the excited singlet state of peripherally and non-peripherally tetra- and octa-substituted gallium(III) and indium(III) phthalocyanine complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**):

$$\Phi_{IC} = 1 - (\Phi_F + \Phi_T) \quad (3)$$

Triplet lifetimes were determined by exponential fitting of the kinetic curves using OriginPro 7.5 software.

2.3.3. Singlet oxygen and photodegradation quantum yields

Singlet oxygen (Φ_Δ) and photodegradation (Φ_d) quantum yield determinations were carried out using the experimental set-up described above [38,39]. Typically, a 2 mL portion of the respective peripheral and non-peripheral tetra- and octa-substituted gallium(III) and indium(III) phthalocyanine (**7a**,**b**, **8a**,**b** and **9a**,**b**) solutions containing the singlet oxygen quencher was irradiated in the Q-band region with the photo-irradiation set-up described above [38,39]. Φ_Δ values were determined in air using the relative method with DPBF as singlet oxygen chemical quencher in DMSO (Eq. (4)):

$$\Phi_\Delta = \Phi_\Delta^{Std} \frac{R \cdot I_{abs}^{Std}}{R^{Std} \cdot I_{abs}} \quad (4)$$

where Φ_Δ^{Std} is the singlet oxygen quantum yield for the standard (ZnPc in DMSO, $\Phi_\Delta^{ZnPc} = 0.67$) [40], R and R_{Std} are the DPBF photobleaching rates in the presence of the respective samples (**7a**,**b**, **8a**,**b** and **9a**,**b**) and standard, respectively; I_{abs} and I_{abs}^{Std} are the rates of light absorption by the samples (**7a**,**b**, **8a**,**b** and **9a**,**b**) and standard, respectively. To avoid chain reactions induced by DPBF in the presence of singlet oxygen [41], the concentration of DPBF was lowered to $\sim 3 \times 10^{-5}$ mol dm^{-3}. Solution of sensitizer (absorbance ~1.5 at the irradiation wavelength) containing DPBF were prepared in the dark and irradiated in the Q-band region using the set-up described above. DPBF degradation at 417 nm was monitored. The light intensity used for Φ_Δ determinations was found to be 9.21×10^{15} photons s^{-1} cm^{-2}. The error in the determination of Φ_Δ was ~10% (determined from several Φ_Δ values). Photodegradation quantum yields (Φ_d) were determined using Eq. (5)

$$\Phi_d = \frac{(C_0 - C_t) \cdot V \cdot N_A}{I_{abs} \cdot S \cdot t} \quad (5)$$

where C_0 and C_t are the samples (**7a**,**b**, **8a**,**b** and **9a**,**b**) concentrations before and after irradiation respectively, V is the reaction volume, N_A the Avogadro's constant, S the irradiated cell area and t the irradiation time. I_{abs} is the overlap integral of the radiation source light intensity and the absorption of the samples (**7a**,**b**, **8a**,**b** and **9a**,**b**). A light intensity of 3.07×10^{16} photons s^{-1} cm^{-2} was employed for Φ_d determinations.

2.4. Synthesis

*2.4.1. 1,(4)-Tetrakis(4-benzyloxyphenoxyphthalocyaninato) gallium(III) (**7a**)*

A mixture of anhydrous gallium(III) chloride (0.40 g, 2.3 mmol), 3-(benzyloxyphenoxy)phthalonitrile (**4**) (1.50 g, 4.6 mmol) and quinoline (5 mL, doubly distilled over CaH_2) was stirred at 180 °C for 7 h under nitrogen atmosphere. After cooling, the solution was dropped into the ethanol. The green solid product was precipitated and collected by filtration and washed with ethanol. The crude product was dissolved in CH_2Cl_2 and then filtered. After filtering and concentrating, the dark green waxy product was purified by passing through a silica gel column, using THF as the eluting solvent. Furthermore this product was purified with preparative thin layer chromatography (silica gel) using $CHCl_3$ solvent system. Yield: 0.42 g (26%). UV–Vis (DMSO): λ_{max} nm ($\log\varepsilon$) 353 (4.62), 643 (4.48), 716 (5.20). IR [(KBr) ν_{max}/cm^{-1}]: 3055 (Ar–CH), 3027 (Ar–CH), 2945–2852 (CH), 1586 (C=C), 1194 (C–O–C). ^{1}H NMR ($CDCl_3$): δ, ppm 8.40–8.91 (4H, m, Pc–H), 7.63–7.93 (4H, m, Pc–H), 7.31–7.57 (24H, m, Phenyl–H, Pc–H), 7.04–7.28 (12H, m, Phenyl–H), 6.81–6.98 (4H, m, Phenyl–H), 5.11 (8H, m, CH_2). *Anal.* Calc. for $C_{84}H_{56}ClGaN_8O_8$: C, 71.52; H, 4.00; N, 7.94. Found: C, 71.06; H, 3.91; N, 7.81%.

*2.4.2. 1,(4)-Tetrakis(4-benzyloxyphenoxyphthalocyaninato) indium(III) (**7b**)*

Synthesis and purification was as outlined for **7a** except anhydrous $InCl_3$ was employed instead of anhydrous $GaCl_3$. The amounts of the reagents employed were: **4** (1.50 g, 4.6 mmol), indium(III) chloride (0.51 g, 2.3 mmol) and quinoline (5 ml). Yield: 0.37 g (22%). UV–Vis (DMSO): λ_{max} nm ($\log\varepsilon$) 355 (4.58), 641 (4.44), 716 (5.18). IR [(KBr) ν_{max}/cm^{-1}]: 3057 (Ar–CH), 3027 (Ar–CH), 2949–2856 (CH), 1582 (C=C), 1192 (C–O–C). ^{1}H NMR ($CDCl_3$): δ, ppm 8.79–9.18 (4H, m, Pc–H), 7.86–

8.12 (4H, m, Pc–H), 7.31–7.58 (28H, m, Phenyl–H, Pc–H), 7.23–7.28 (4H, m, Phenyl–H), 7.10–7.18 (4H, m, Phenyl–H), 6.88–6.97 (4H, m, Phenyl–H), 5.12 (8H, m, CH_2). *Anal.* Calc. for $C_{84}H_{56}ClInN_8O_8$: C, 69.31; H, 3.88; N, 7.70. Found: C, 69.19; H, 3.80; N, 7.60%.

2.4.3. 2,(3)-Tetrakis(4-benzyloxyphenoxyphthalocyaninato) gallium(III) (8a)

Synthesis and purification was as outlined for **7a** except **5** was employed instead of **4**. The amounts of the reagents employed were: **5** (1.50 g, 4.6 mmol), gallium(III) chloride (0.40 g, 2.3 mmol) and quinoline (5 ml). Yield: 0.62 g (38%). UV–Vis (DMSO): λ_{max} nm ($\log\varepsilon$) 354 (4.82), 622 (4.55), 693 (5.24). IR [(KBr) ν_{max}/cm^{-1}]: 3057 (Ar–CH), 3027 (Ar–CH), 2947–2854 (CH), 1617 (C=C), 1193 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 8.21–8.82 (8H, m, Pc–H), 7.61–7.77 (4H, m, Pc–H), 7.36–7.58 (28H, m, Phenyl–H), 7.16–7.23 (8H, m, Phenyl–H), 5.16 (8H, m, CH_2). *Anal.* Calc. for $C_{84}H_{56}ClGaN_8O_8$: C, 71.52; H, 4.00; N, 7.94. Found: C, 71.24; H, 3.79; N, 7.96%.

2.4.4. 2,(3)-Tetrakis(4-benzyloxyphenoxyphthalocyaninato) indium(III) (8b)

Synthesis and purification was as outlined for **7a** except **5** was employed instead of **4** and anhydrous $InCl_3$ was employed instead of anhydrous $GaCl_3$. The amounts of the reagents employed were: **5** (1.50 g, 4.6 mmol), indium(III) chloride (0.51 g, 2.3 mmol) and quinoline (5 ml). Yield: 0.59 g (35%). UV–Vis (DMSO): λ_{max} nm ($\log\varepsilon$) 361 (4.78), 625 (4.46), 697 (5.16). IR [(KBr) ν_{max}/cm^{-1}]: 3056 (Ar–CH), 3027 (Ar–CH), 2950–2857 (CH), 1617 (C=C), 1192 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 8.29–8.91 (8H, m, Pc–H), 7.58–7.77 (4H, m, Pc–H), 7.41–7.56 (28H, m, Phenyl–H), 7.15–7.22 (8H, m, Phenyl–H), 5.16 (8H, m, CH_2). *Anal.* Calc. for $C_{84}H_{56}ClInN_8O_8$: C, 69.31; H, 3.88; N, 7.70. Found: C, 69.38; H, 3.74; N, 7.49%.

2.4.5. 2,3-Octakis(4-benzyloxyphenoxyphthalocyaninato) gallium(III) (9a)

Synthesis and purification was as outlined for **7a** except **6** was employed instead of **4**. The amounts of the reagents employed were: **6** (2.00 g, 3.8 mmol), gallium(III) chloride (0.33 g, 1.9 mmol) and quinoline (5 ml). Yield: 0.84 g (40%). UV–Vis (DMSO): λ_{max} nm ($\log\varepsilon$) 358 (4.98), 620 (4.68), 692 (5.43). IR [(KBr) ν_{max}/cm^{-1}]: 3058 (Ar–CH), 3027 (Ar–CH), 2949–2857 (CH), 1602 (C=C), 1190 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 8.62–9.16 (8H, m, Pc–H), 8.09–8.41 (8H, m, Phenyl–H), 7.36–7.61 (48H, m, Phenyl–H), 7.15–7.24 (16H, m, Phenyl–H), 5.12 (16H, d, CH_2). *Anal.* Calc. for $C_{136}H_{96}ClGaN_8O_{16}$: C, 74.13; H, 4.39; N, 5.09. Found: C, 74.01; H, 4.79; N, 5.24%.

2.4.6. 2,3-Octakis(4-benzyloxyphenoxyphthalocyaninato) indium(III) (9b)

Synthesis and purification was as outlined for **7a** except **6** was employed instead of **4** and anhydrous $InCl_3$ was employed instead of anhydrous $GaCl_3$. The amounts of the reagents employed were: **6** (2.00 g, 3.8 mmol), gallium(III) chloride (0.42 g, 1.9 mmol) in quinoline (5 ml). Yield: 0.92 g (43%). UV–Vis (DMSO): λ_{max} nm ($\log\varepsilon$) 362 (5.02), 623 (4.69), 696 (5.43). IR [(KBr) ν_{max}/cm^{-1}]: 3058 (Ar–CH), 3027 (Ar–CH), 2951–2859 (CH), 1600 (C=C), 1187 (C–O–C). ^1H NMR ($CDCl_3$): δ, ppm 8.60–9.21 (8H, m, Pc–H), 8.18–8.59 (8H, m, Phenyl–H), 7.31–7.57 (48H, m, Phenyl–H), 7.03–7.22 (16H, m, Phenyl–H), 5.15 (16H, ss, CH_2). *Anal.* Calc. for $C_{136}H_{96}ClInN_8O_{16}$: C, 72.65; H, 4.30; N, 4.98. Found: C, 72.83; H, 4.76; N, 5.05%.

3. Results and discussion

3.1. Synthesis and characterization

Phthalocyanines are prepared by cyclotetramerization of phthalonitriles or 1,3-diimino-1*H*-isoindoles. Octasubstituted phthalocyanines can be synthesized from 4,5-dichlorophthalonitriles [30]. 2(3),9(10),16(17),23(24)-Tetrasubstituted phthalocyanines can be synthesized from 4-substituted phthalonitriles while 1(4),8(11),15(18),22(25)-tetrasubstituted phthalocyanines are obtained from 3-substituted analogues [42]. In both cases a mixture of four possible structural isomers are obtained for tetrasubstituted phthalocyanines. The four probable isomers can be designed by their molecular symmetry as C_{4h}, C_{2v}, C_s and D_{2h} [43]. In this study, synthesized tetrasubstituted phthalocyanine compounds are obtained as isomer mixtures as expected. No attempt was made to separate the isomers of **7a**,**b** and **8a**,**b**.

The preparation of phthalocyanine derivatives from the aromatic nitriles occur under different reaction conditions. The syntheses of metallophthalocyanine complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) were achieved by treatment of phthalonitriles **4**, **5** and **6** with $InCl_3$ or $GaCl_3$ in freshly distilled quinoline (Scheme 1). Because gallium and indium are large atoms, high energy is required to insert the metal ion into the phthalocyanine ring, thus a high-boiling solvent (such as quinoline) is used to achieve this purpose. Complexes **7a** and **7b** are non-peripherally (α), and **8a** and **8b** are peripherally (β) tetrasubstituted, whereas complexes **9a** and **9b** are peripherally octasubstituted. Column and preparative thin layer chromatography with silica gel was employed to obtain the pure products from the reaction mixtures.

Generally, phthalocyanine complexes are insoluble in most organic solvents; however introduction of substituents on the ring increases the solubility. All complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) exhibited excellent solubility in organic solvents such as dichloromethane, chloroform, THF, toluene, DMSO. The new compounds were characterized by UV–Vis, IR and NMR spectroscopies and elemental analysis. The analyses are consistent with the predicted structures as shown in the experimental section. After conversion into gallium or indium phthalocyanines, the characteristic C≡N stretch at ~2230 cm^{-1} of

phthalonitriles **4**, **5** and **6** disappeared, indicative of metallophthalocyanine formation. The complexes showed characteristic vibrations due to ether groups (C–O–C) 1187–1194 cm^{-1}, aromatic CH stretching at ca. 3058–3027 cm^{-1} because the compounds contain different aromatic rings and aliphatic CH stretching at ca. 2949–2857 cm^{-1}.

The ^{1}H NMR spectra (Fig. 1) of tetrasubstituted phthalocyanine derivatives (**7a**,**b** and **8a**,**b**) show complex patterns due to the mixed isomer character of these compounds and they have different aromatic protons. Octasubstituted derivative (**9a**,**b**) also show complex patterns due to the different aromatic protons. The complexes were found to be pure by ^{1}H NMR with all the substituents and ring protons observed in their respective regions. The resonances belonging the phthalocyanine ring protons of non-peripherally tetrasubstituted complexes were observed between 8.40–8.91, 7.63–7.93 and 7.31–7.57 ppm (overlap with phenyl protons) for **7a**; 8.79–9.18, 7.86–8.12 and 7.31–7.58 ppm (overlap with phenyl protons) for **7b** (Fig. 1), integrating to a total of 12 protons expected for both non-peripheral and peripheral protons. The phenyl protons were observed between 7.31–7.57, 7.04–7.28 and 6.81–6.98 ppm integrating for 24 (overlap with 4 phthalocyanine ring protons), 12 and 4, respectively and totalling 36 protons as expected for **7a** and between 7.31–7.58, 7.23–7.28, 7.10–7.18 and 6.88–6.97 ppm integrating for 28 (overlap with 4 phthalocyanine ring protons), 4, 4 and 4, respectively and totally 36 protons as expected for **7b** (Fig. 1). For the peripherally tetrasubstituted complexes the resonance belonging the phthalocyanine ring protons were observed between 8.21–8.82 and 7.61–7.77 ppm for **8a** and between 8.29–8.91 and 7.58–7.77 ppm for **8b** integrating for 8 and 4 protons respectively giving a total of 12 protons as expected for both peripherally tetrasubstituted complexes. The phenyl protons were observed between 7.36–7.58 and 7.16–7.23 ppm for **8a** and between 7.41–7.56 and 7.15–7.22 ppm for **8b**, integrating for 28 and 8 protons respectively and giving a total of 36 protons for each complex as expected. The resonances belonging to phthalocyanine ring protons of octasubstituted complexes were observed between 8.62–9.16 ppm for **9a** and 8.60–9.21 ppm for **9b**, integrating 8 protons as expected. The phenyl protons for octasubstituted complexes were observed between 8.09–8.41, 7.36–7.61, 7.15–7.24 ppm for **9a** and between 8.18–8.59, 7.31–7.57, 7.03–7.22 ppm for **9b**, integrating for 8, 48 and 16, respectively, giving a total of 72 protons as expected. The methyl protons were observed at ca. 5.10 ppm, integrating 8 protons for tetrasubstituted (**7a**,**b**, **8a**,**b**) and 16 protons for octasubstituted (**9a**,**b**) complexes. The methyl protons were observed as multiplets for tetrasubstituted complexes (**7a**,**b**, **8a**,**b**) due to the mixed isomer character of these complexes. They were observed as two singlets for octasubstituted complexes (**9a**,**b**), due to the two type of CH_2 protons, with one of them near the Cl atom and the far from Cl atom.

3.1.1. Ground state electronic absorption and fluorescence spectra

The ground state electronic absorption spectra showed monomeric behaviour evidenced by a single (narrow) Q-band, typical of metallated phthalocyanine complexes (Fig. 2) [44]. In DMSO, the Q-bands were observed at: 716 (**7a**), 716 (**7b**), 693 (**8a**), 697 (**8b**), 692 (**9a**) and 696 (**9b**), Table 1. The Q-bands of the α-tetrasubstituted complexes (**7a** and **7b**) are red-shifted by 23–19 nm, when compared to the corresponding β-tetrasubstituted (**8a** and **8b**), and by 24 and 20 nm when compared with octasubstituted

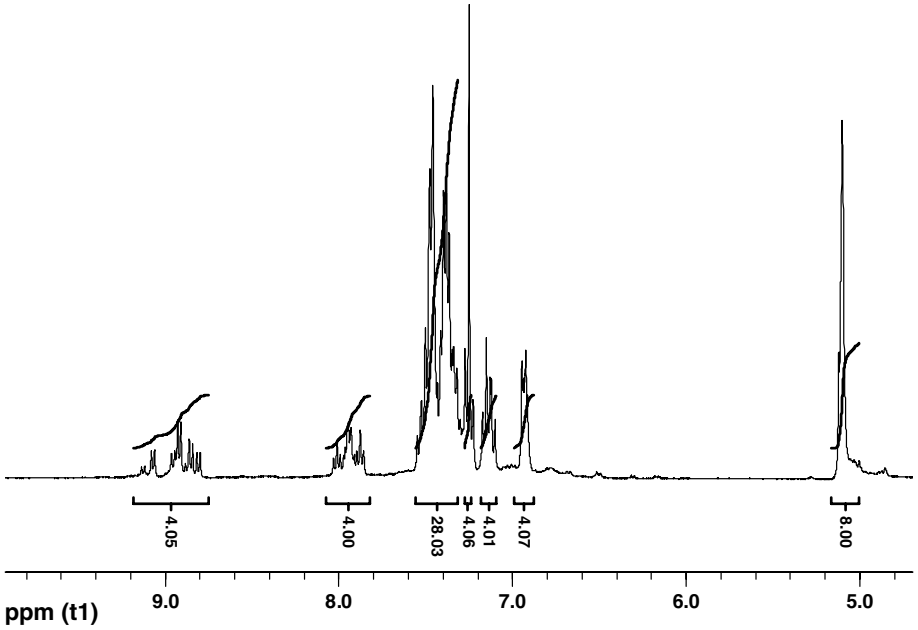

Fig. 1. ^{1}H NMR spectrum of complex **7b** in $CDCl_3$.

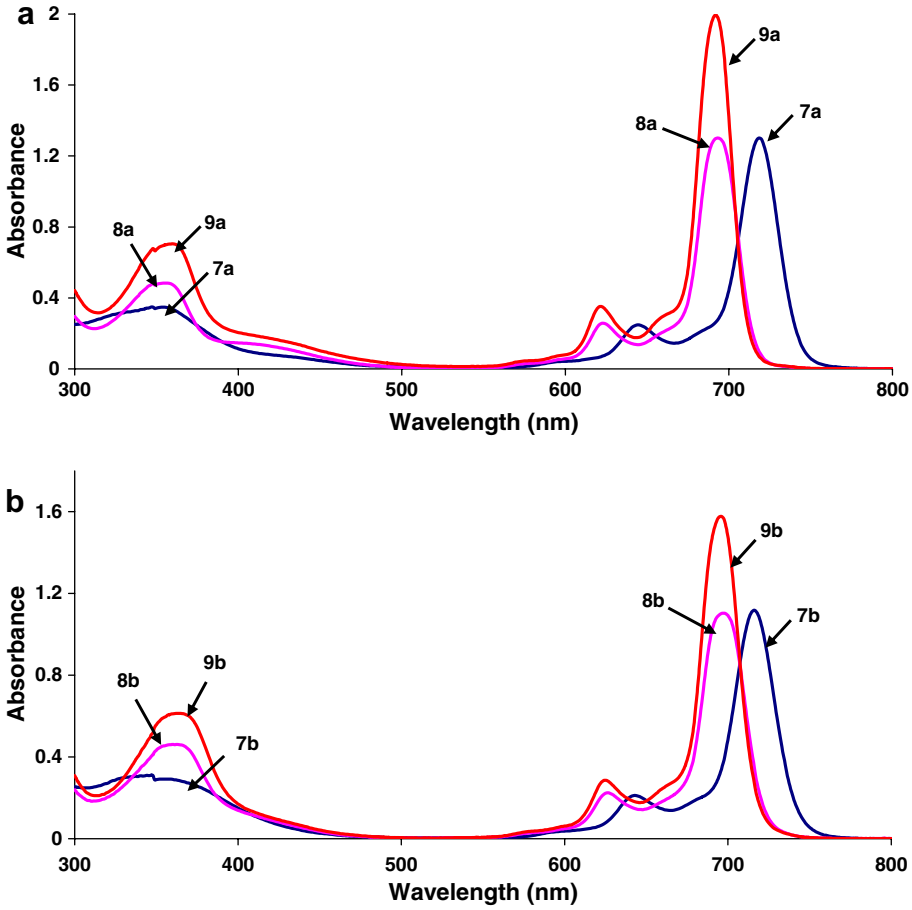

Fig. 2. Absorption spectra of: (a) **7a**, **8a** and **9a**; (b) **7b**, **8b** and **9b** in DMSO. Concentration = 4×10^{-6} mol dm^{-3}.

(**9a** and **9b**) complexes in DMSO (Table 1). The observed red spectral shift is typical of phthalocyanines with substituents at the non-peripheral positions and has been explained [45,46] to be due to linear combinations of the atomic orbitals (LCAO) coefficients at the non-peripheral positions of the HOMO being greater than those at the peripheral positions. As a result, the HOMO level is destabilized more at the non-peripheral position than it is at the peripheral position. Essentially, the energy gap (ΔE) between the HOMO and LUMO becomes smaller, resulting in a bathochromic shift. The shoulder between 400 and 450 nm may be due to charge transfer from the electron-rich ring to the electron-poor metal. The B-bands are broad due to the superimposition of the B_1 and B_2 bands in the 330–360 nm region [45].

Aggregation is usually depicted as a coplanar association of and it is dependent on the concentration, nature of the solvent, nature of the substituents, complexed metal ions and temperature [47,48]. The aggregation behaviour of the phthalocyanine complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) was also investigated at different concentrations in DMSO. In DMSO, as the concentration was increased, the intensity of absorption of the Q-band also increased and there were no new bands (normally blue shifted) due to the aggregated species for all complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) (Fig. 3 for complex **7a**). Beer–Lambert law was obeyed for all of the

compounds in the concentrations ranging from 1.4×10^{-5} to 4×10^{-6} mol dm^{-3}.

The ClGaPc derivatives (**7a**, **8a**, **9a**) showed the same fluorescence behaviour, which was different from the ClInPc derivatives. The latter complexes (**7b**, **8b**, **9b**) also showed fluorescence behaviour which was similar to each other. Fig. 4 shows fluorescence emission, absorption and excitation spectra of complexes **8a** and **8b** as examples of the ClGaPc and ClInPc derivatives, respectively. Fluorescence emission peaks were observed at: 728 nm for **7a**, 704 nm for **8a**, 702 nm for **9a**, 739 nm for **7b**, 716 nm for **8b** and 713 nm for **9b** in DMSO (Table 1). The observed Stokes shifts are typical of MPc complexes (Table 1).

The shape of the excitation spectra were similar to absorption spectra and both were mirror images of the fluorescent spectra for the ClGaPc complexes (Fig. 4a). However in terms of wavelength, the excitation spectra was slightly red-shifted when compared to the absorption spectra, suggesting that the nuclear configurations change following excitation.

For the tetra- and octa-substituted indium phthalocyanine complexes **7b**, **8b** and **9b**, the shape of excitation spectra was different from the absorption spectra in that the Q-band of the former showed splitting, Fig. 4b, unlike the narrow Q-band of the latter. This suggests that there are changes in the molecule following excitation most likely due to loss of symmetry. The fluorescence spectra of complexes **7b**, **8b** and **9b** were also broad. Thus the Q-band maxima of the excitation and absorption spectra were different (Table 1) due to the difference in the ground and excited state species. This was however not observed for the ClGaPc complexes. The difference in the behaviours of ClGaPc and ClInPc on excitation could be due to the larger indium metal being more displaced from the core of the phthalocyanine ring, and the displacement being more pronounced on excitation hence a loss of symmetry.

Table 2
Photophysical and photochemical parameters of unsubstituted, tetra- and octa-substituted gallium and indium phthalocyanine compounds in DMSO

Compound	τ_T (μs)	Φ_F	Φ_T	Φ_{IC}	Φ_d ($\times 10^{-5}$)	Φ_Δ	S_Δ

3.2. Photophysical properties

3.2.1. Fluorescence lifetimes and quantum yields

The fluorescence quantum yields (Φ_F) of ClGaPc complexes **7a**, **8a** and **9a** are typical of MPc complexes, but are lower than for the unsubstituted ClGaPc (Table 2). This suggests that the substituents quench the excited singlet state. The peripherally tetrasubstituted complex **8a** show marginally larger Φ_F values, suggesting less quenching of the excited singlet state by peripheral tetrasubstitution compared to non-peripheral tetra- and octasubstitution. For the ClInPc complexes (**7b**, **8b** and **9b**), the Φ_F values were very low due to enhancement of intersystem crossing (ISC) by the presence of a heavier indium atom in these complexes. The enhanced ISC will also result in increased triplet quantum yields and decreased triplet lifetimes as will be discussed below.

Lifetimes of fluorescence (τ_F, Table 3) were calculated using the Strickler–Berg equation. Using this equation, a good correlation has been [34] found between experimentally and the theoretically determined lifetimes for the unaggregated molecules as is the case in this work. Thus we believe that the values obtained using this equation are a good measure of fluorescence lifetimes. The τ_F values were within the range reported for MPc complexes [34]. τ_F values were lower for substituted complexes **7a**,**b**, **8a**,**b** and **9a**,**b** when compared to unsubstituted derivatives, Table 3, suggesting quenching of fluorescence by the ring substituents. For the substituted complexes, longer τ_F values were

Table 3

Compound	Fluorescence lifetime, τ_F (ns)	Natural radiative lifetime, τ_0 (ns)	k_F^a (s^{-1}) ($\times 10^8$)	k_{ISC}^b (s^{-1}) ($\times 10^9$)	k_{IC}^c (s^{-1}) ($\times 10^8$)	k_d^d (s^{-1})
ClGaPc	3.71	11.96	0.83	0.18	0.03	4.60
7a	1.39	9.3	1.07	0.55	0.57	0.96
8a	1.90	8.26	1.21	0.39	0.10	9.10
9a	0.70	5.49	1.82	1.05	1.85	2.50
ClInPc	0.90	50.20	0.19	1.01	0.77	68.60
7b	0.12	9.03	1.07	8.08	1.14	7.50
8b	0.16	9.35	1.09	5.68	4.56	19.40
9b	0.09	5.34	1.87	9.88	10.33	3.80

[a] k_F is the rate constant for fluorescence. Values calculated using $k_F = \Phi_F/\tau_F$.
[b] k_{ISC} is the rate constant for intersystem crossing. Values calculated using $k_{ISC} = \Phi_T/\tau_F$.
[c] k_{IC} is the rate constant for internal conversion. Values calculated using $k_{IC} = \Phi_{IC}/\tau_F$.
[d] k_d is the rate constant for photodegredation. Values calculated using $k_d = \Phi_d/\tau_T$.

obtained for the peripherally tetrasubstituted complexes **8a** and **8b** compared to non-peripherally tetrasubstituted (**7a** and **7b**) and octasubstituted complexes (**9a** and **9b**), suggesting more quenching by peripheral tetrasubstitution when compared to non-peripheral ones and octasubstitution. The τ_F values ClInPc complexes were lower than for the ClGaPc complexes due to the fact that indium atom is larger than gallium atom. The natural radiative lifetime (τ_0) values of substituted complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) were lower than unsubstituted complexes (ClGaPc and ClInPc). The rate constants for fluorescence (k_F) however increased on going from unsubstituted ClGaPc (or ClInPc) to the corresponding substituted complexes **7a**,**b**, **8a**,**b** and **9a**,**b** (Table 3). There was an increase in k_F values on going from tetrasubstituted to octasubstituted ClGaPc and ClInPc complexes. Substituted complexes **7a**–**9a** and **8b**–**9b** also showed larger rate constants for internal conversion (k_{IC}, Table 3), compared to unsubstituted derivatives. There was no clear trend found for k_{IC} (Table 3) and quantum yields for internal conversion (Φ_{IC}, Table 2). In addition larger rate constants for intersystem crossing (k_{ISC}) for complexes **7a**–**9a** and **7b**–**9b** compared to the respective unsubstituted ClGaPc and ClInPc complexes confirmed improved intersystem crossing to the triplet state for the former.

3.2.2. Triplet lifetimes and quantum yields

Transient differential spectrum for complex **8a** in DMSO is shown in Fig. 5, and shows a maximum at 520 nm, hence the triplet lifetimes and yields were determined at this wavelength. Fig. 6 shows the triplet decay curves of the complexes (using complex **8a** in DMSO as an example). Table 2 shows that the triplet lifetimes for the ClGaPc complexes ranged from 200 to 280 μs, with unsubstituted ClGaPc showing the lowest triplet quantum

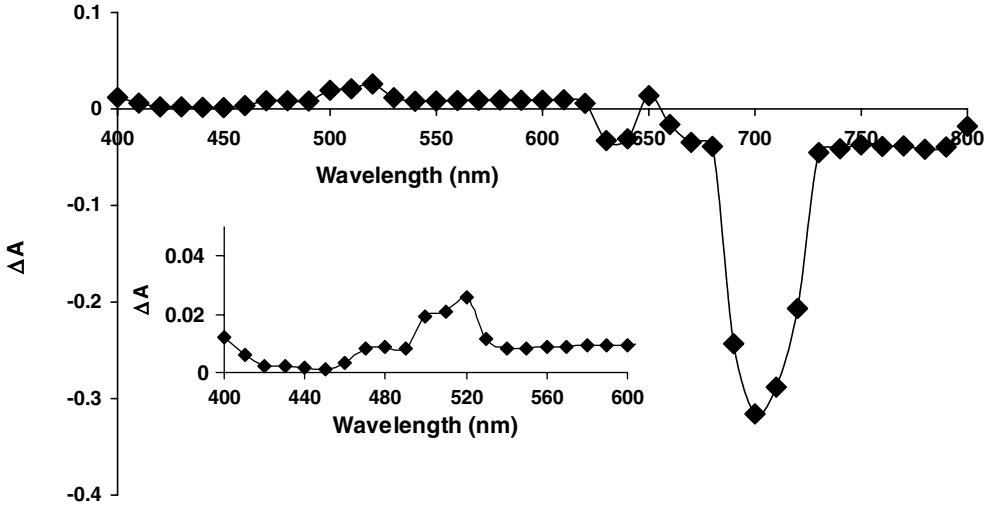

Fig. 5. Transient differential spectrum of complex **8a** in DMSO.

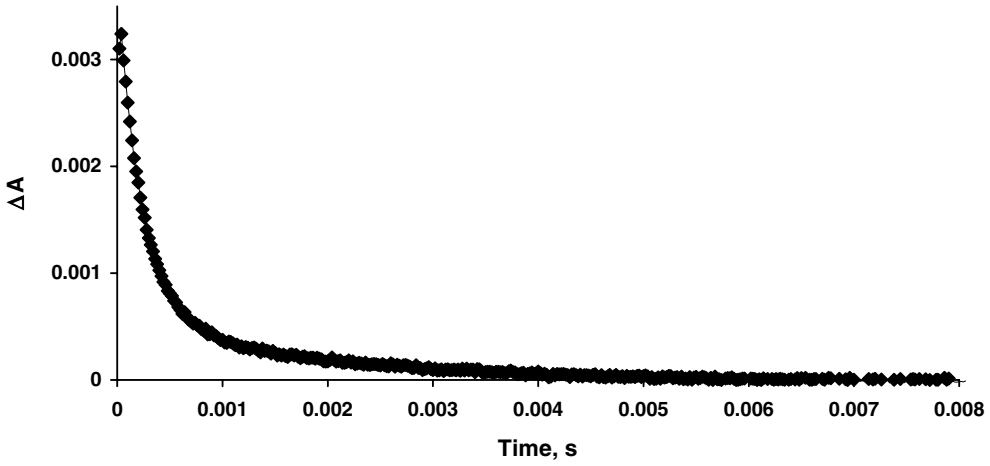

Fig. 6. Triplet decay curve of **8a** in DMSO at 520 nm. Excitation wavelength = 693 nm.

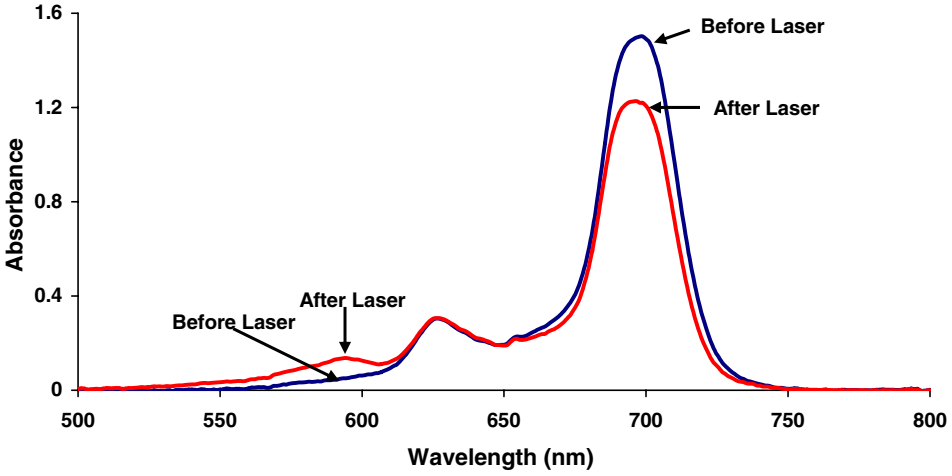

Fig. 7. Absorption spectral changes of compound **8b** before and after laser irradiation.

yield (Φ_T) when compared to substituted complexes **7a**–**9a**. Due to enhanced ISC, indium phthalocyanine complexes (ClInPc and **7b**–**9b**) showed much higher quantum yields of triplet state and shorter triplet lifetimes when compared to corresponding gallium phthalocyanine (ClGaPc and **7a**–**9a**) complexes. There is not a huge difference between Φ_T of octa- and tetra-substituted derivatives of each of ClGaPc or ClInPc.

Fig. 7 shows that for substituted complexes (**7a**–**9a** and **7b**–**9b**) and unsubstituted derivatives, there was a change is spectra following laser irradiation. The spectral changes involved the decrease in the Q-band and an increase in the absorption near 590 nm. However, on exposure of the solution to air, the Q-band increased in intensity and the band around 590 nm decreased suggesting that this band is due to a reduction products of the complexes. The first ring reduction in MPc complexes is characterized by a decrease in the Q-band and the formation of weak bands between 500 and 600 nm [49]. Thus during laser irradiation, the ClGaPc and ClInPc derivatives were partly transformed to an anion (Pc^{-3}) species. The suggested mechanism for the formation of Pc^{-3} in the presence of H donors is shown by Eqs. (6)–(8):

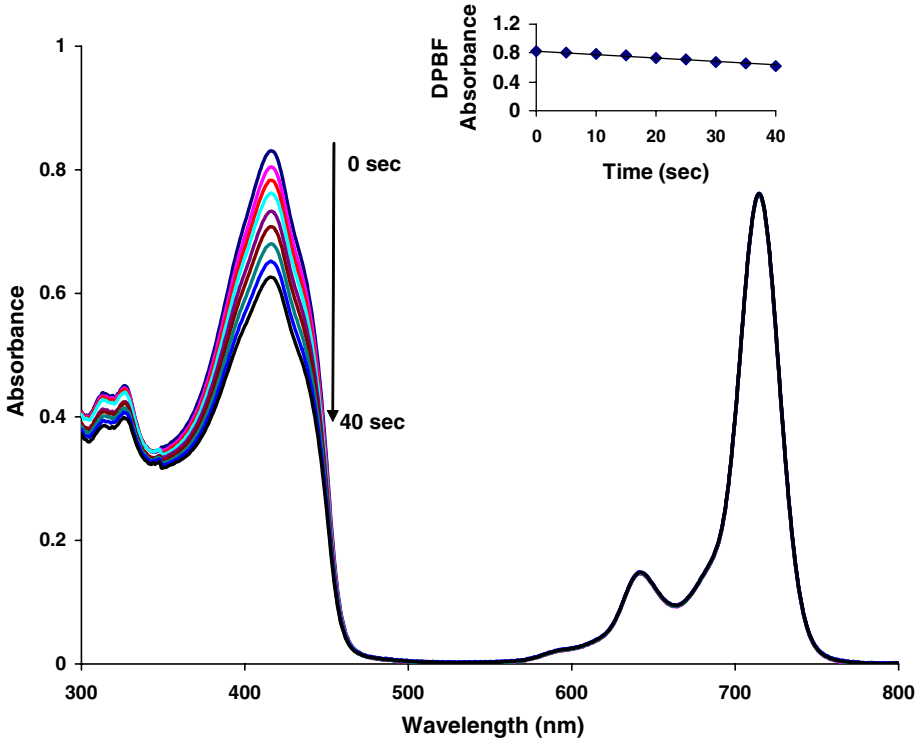

Fig. 8. A typical spectrum for the determination of singlet oxygen quantum yield. This determination was for compound **7a** in DMSO at a concentration of 3×10^{-5} mol dm^{-3}.

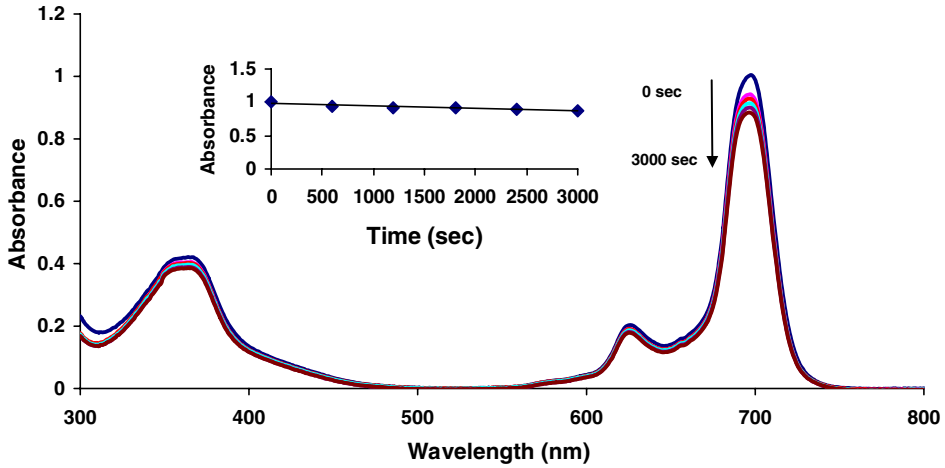

Fig. 9. The photodegredation of compound **8b** in DMSO showing the disappearance of the Q-band at 10 min intervals.

$$MPc + h\nu \rightarrow {}^{3}MPc^{*} \quad (6)$$

$${}^{3}MPc^{*} + S\text{–}H \rightarrow MPc^{\cdot -} + S\text{–}H^{\cdot +} \quad (7)$$

$$MPc^{\cdot -} + O_2 \rightarrow MPc + O_2^{\cdot -} \quad (8)$$

S = solvent

3.3. Photochemical properties

3.3.1. Singlet oxygen quantum yields

Singlet oxygen quantum yields (Φ_Δ) were determined in DMSO using DPBF as a chemical quencher. The disappearance of DBPF was monitored using UV–Vis spectrometer. Many factors are responsible for the magnitude of the determined quantum yield of singlet oxygen including; triplet excited state energy, ability of substituents and solvents to quench the singlet oxygen, the triplet excited state lifetime and the efficiency of the energy transfer between the triplet excited state and the ground state of oxygen.

Because of the presence of oxygen during the determination of singlet oxygen quantum yields (Φ_Δ) the photoreduction of complexes was not observed during singlet oxygen studies as shown by Fig. 8 for complex **7a** (as an example) in DMSO. There was no decrease in the Q-band of formation of new bands. The values of Φ_Δ were higher for complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) when compared to respective unsubstituted ClGaPc or ClInPc complexes. The trend of singlet oxygen quantum yields among the corresponding substituted complexes was non-peripherally tetrasubstituted (**7a**,**b**) > peripherally tetrasubstituted (**8a**,**b**) > octa-substituted (**9a**,**b**) for both of substituted gallium and indium phthalocyanine complexes in DMSO. The magnitude of the S_Δ ($=\Phi_\Delta/\Phi_T$) represents the efficiency of quenching of the triplet excited state by singlet oxygen. Most of the substituted complexes showed S_Δ of near unity (Table 2), suggesting efficient quenching of the triplet state by singlet oxygen. The S_Δ values were less than unity for unsubstituted ClGaPc and ClInPc complexes, suggesting inefficient quenching of the triplet state by singlet oxygen.

3.3.2. Photodegradation studies

Degradation of the molecules under irradiation can be used to study their stability and this is especially important for those molecules intended for use as photo catalysts. The collapse of the absorption spectra without any distortion of the shape confirms clean photodegradation not associated with phototransformation. The spectral changes observed for all the complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) during irradiation are as shown in Fig. 9 (using complex **8b** as an example in DMSO) and hence confirm photodegradation occurred without phototransformation.

All the complexes showed about the same stability with Φ_d of the order of 10^{-5}. Again there was no photoreduction of the complexes during photodegradation studies in the presence of oxygen, hence the magnitudes of the observed Φ_d are not due to phototransformation. The rate constant for photodegradation (k_d) values were lower for substituted indium phthalocyanine complexes **7b**, **8b** and **9b**, compared to unsubstituted ClInPc, while there was no clear trend for the ClGaPc derivatives (Table 3).

4. Conclusions

In conclusion, we have synthesized new peripherally and non-peripherally tetra-, and octa-(4-benzyloxyphenoxy) substituted gallium and indium phthalocyanines. These phthalocyanine complexes are monomeric in solution. The difference in the behaviours of ClGaPc and ClInPc complexes on excitation could be due to the larger indium metal being more displaced from the core of the phthalocyanine ring, and the displacement being more pronounced on excitation hence a loss of symmetry. Although the fluorescence quantum yields (Φ_F) of ClGaPc complexes are typical of MPc complexes, the Φ_F values for the ClInPc complexes were very low due to presence of a heavier indium atom in these complexes. 4-Benzyloxyphenoxy substituted gallium phthalocyanine complexes (**7a**–**9a**) showed long triplet lifetimes and high triplet quantum

yields. Due to enhanced ISC, 4-benzyloxyphenoxy indium phthalocyanine complexes (**7b**–**9b**) showed much higher quantum yields of triplet state and shorter triplet life times. The gallium and indium phthalocyanine complexes showed phototransformation when using laser irradiation due to the ring reduction. The substituted complexes (**7a**,**b**, **8a**,**b** and **9a**,**b**) gave good singlet oxygen quantum yields ranging from 0.51 (for **9a**) and 0.94 (for **7b**). The singlet oxygen quantum yields (Φ_Δ), which give an indication of the potential of the complexes as photosensitizers in applications where singlet oxygen is required (Type II mechanism). Thus, these complexes show potential as Type II photosensitizers for photodynamic therapy of cancer.

Abstract

The *fac*-[Re(CO)$_3$(2,2′-biquinoline)Cl] complex has been obtained in reaction of Re(CO)$_5$Cl with 2,2′-biquinoline. The compound has been studied by IR, UV–Vis spectroscopy and X-ray crystallography. The molecular orbital diagram of the tricarbonyl has been calculated with the density functional theory (DFT) method. The spin-allowed singlet–singlet electronic transitions of [Re(CO)$_3$(2,2′-biquinoline)Cl] have been calculated with the time-dependent DFT method, and the UV–Vis spectrum of the title compound has been discussed on this basis.

1. Introduction

For many years the diimine chelates (e.g., 2,2-bipyridine, 1,10-phenanthroline and their derivatives) of d^6 metals have been the subject of much attention. The interest of researchers has been attracted mostly by their unique photophysical and photochemical properties, crucial for numerous potential and already introduced practical applications. The most frequently studied compounds belonging to this group are complexes of general formula *fac*-[Re(CO)$_3$(diimine)(E)]$^{0/+}$, where E stands for a halogen atom or other ligand approximately axial to the heteroaromatic rings plane. The photobehaviour of the Re(I) carbonyl–diimine complexes may be discussed in terms of four types of excited states: (i) M → diimine metal-to-ligand charge transfer (MLCT) states, (ii) E → diimine ligand-to-ligand charge transfer (LLCT) states; (iii) transition from the M–E σ-bonding orbital to the diimine ligand, (iv) intraligand (IL) states. The last ones appear to lie at rather high energies in the *fac*-[Re(CO)$_3$(diimine)(E)]$^{0/+}$ complexes, and they are of little photochemical importance. The early studies has shown that the excited states of [Re(CO)$_3$(diimine)(E)]$^{0/+}$ complexes are both strong reductants and oxidants. The high reactivity of the reduced species may be utilized in photocatalysis. For example, photoexcitation of [Re(CO)$_3$(bipy)Cl] in the presence of triethylamine produces [Re(CO)$_3$(bipy)Cl]$^-$, which loses the chloride ligand. The further reaction with CO_2 results in the photocatalytic CO_2 reduction to CO. The excited states of [Re(CO)$_3$(diimine)(E)]$^{0/+}$ complexes are often sufficiently long-lived to become engaged in energy transfer reactions. Currently, several *fac*-Re(CO)$_3^+$ complexes are used as electroluminescent materials in OLED-type devices [1–12].

As the spectroscopic and redox behaviour of the Re(I) complexes are ligand dependent and can be tuned by varying the identity of their chelate ligands, there is a clear need to synthesize and investigate novel species of this type.

Here, we present the synthesis, crystal, molecular and electronic structure of the *fac*-[Re(CO)$_3$(2,2′-biquino-

line)Cl] complex. The molecular orbital diagram of the title complex has been calculated with the density functional theory (DFT) calculations. This method meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [13].

The spin-allowed singlet–singlet electronic transitions of *fac*-[Re(CO)$_3$(2,2′-biquinoline)Cl] have been calculated with the time-dependent DFT method (TDDFT method), and a good assignment with the experimental spectrum has been observed.

2. Experimental

2.1. General procedure

The reaction was performed under argon atmosphere. The solvents were dried before use, using the appropriate drying reagents. Re(CO)$_5$Cl and 2,2′-biquinoline were purchased from Aldrich, and they were used as received.

IR spectrum was recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectrum was measured on a spectrophotometer Lab Alliance UV–VIS 8500 in the range 900–200 nm in dichloromethane solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of [Re(CO)$_3$(2,2′-biquinoline)Cl]

Re(CO)$_5$Cl (0.2 g, 0.55 mmol) and 2,2′-biquinoline (0.15 g, 0.58 mmol) in toluene (50 cm^3) were refluxed for 6 h. The resulting reaction mixture was reduced in volume to ~10 ml and allowed to cool to room temperature. An off-orange solid was filtered off, washed with hexane, diethyl ether, and dried; yield 90%.

IR (KBr, cm^{-1}): ν_{NO} = 2014, 1895 and 1884 cm^{-1}; ν_{CN} and $\nu_{C=C}$ = 1616, 1595, 1578 and 1509 cm^{-1}.

Anal. Calc. for $C_{21}H_{12}N_2O_3ClRe$: C, 44.88; H, 2.15; N, 4.98. Found: C, 44.70; H, 2.20; N, 4.80%.

2.3. Crystal structures determination and refinement

Single crystals of complex [Re(CO)$_3$(2,2′-biquinoline)Cl] were grown by the slow diffusion of diethyl ether into a solution of the complex dissolved in chloroform. A orange crystal of [Re(CO)$_3$(2,2′-biquinoline)Cl]·CHCl$_3$ was mounted on a KM-4-CCD automatic diffractometer equipped with a CCD detector, and used for data collection. X-ray intensity data were collected with graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at temperature of 293.0(2) K, with ω scan mode. Twenty-six-seconds exposure time was used and reflections were collected up to 2θ = 50.01°. The unit cell parameters were determined from 7044 strongest reflections respectively. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and empirical absorption corrections [14] were applied. The structure was solved by the Patterson method and subsequently completed on the basis of the difference Fourier maps calculated after four

cycles of refinement. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. The hydrogen atoms were treated as ''riding'' on their parent carbon atoms [d(C–H$_{HCCl3}$) = 0.96 Å, d(C–H$_{2,2'\text{-biquinoline}}$) = 0.93 Å] with U_{iso}(H) = 1.2 U_{eq}(C). SHELXS97 [15], SHELXL97 [16] and SHELXTL [17] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

Cg(1), Cg(2), Cg(3), Cg(4) indicates the centroids of aromatic rings containing N(1), N(2), C(12), C(21) atoms respectively, α is a dihedral angle between planes I and J, β is an angle between Cg(I)–Cg(J) vector and normal to plane I and d_p is a perpendicular distance of Cg(I) on ring J plane.
The stacked six-membered rings are indicated by (*).
Symmetry equivalent used to generate rings #1 $-x$, $-y$, $-z+1$, #2 $-x$, $y+1/2$, $-z+1/2$, #3 $-x$, $y-1/2$, $-z+1/2$.

2.4. Computational details

GAUSSIAN03 program [18] was used in the calculations. The geometry optimization was carried out with the DFT method with the use of B3LYP functional [19,20]. The electronic spectrum was calculated with the TDDFT method [21]. The calculations were performed by using ECP basis set on the rhenium atom, the standard 6-31+G** basis for chlorine, oxygen, nitrogen and carbon, and 6-31G basis for hydrogen atoms. The Xe core electrons of Re were replaced by an effective core potential and DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [22] was used for the valence electrons. Additional d function with exponent $\alpha = 0.3811$ and f function with exponent $\alpha = 2.033$ on the rhenium atom were added.

3. Results and discussion

3.1. Preparation and infrared data

The [Re(CO)$_3$(2,2′-biquinoline)Cl] complex was prepared by refluxing the [Re(CO)$_5$Cl] compound with a small

Table 4
Atomic charges and spin densities of [Re(CO)$_3$(2,2′-biquinoline)Cl]

Atom	Atomic charge

C(3)	0.535
O(1)	−0.475
O(2)	−0.475
O(3)	−0.503

excess of 2,2′-biquinoline in toluene. The complex was isolated as air-stable, microcrystalline solid, soluble in common organic solvents. The infrared spectrum of the complex displays three bands in the carbonyl stretching region: a sharp intense band at 2014 cm^{-1} and two lower-energy bands closely spaced (1895 and 1884 cm^{-1}), typical of Re(I) diimine tricarbonyl complexes [23]. The characteristic bands of the C–C and C–N stretching modes are observed in the range 1620–1500 cm^{-1} [24].

3.2. Crystal structure

The title complex crystallises as the solvate $[Re(CO)_3$-(2,2′-biquinoline)Cl$] \cdot CHCl_3$. The crystallographic data

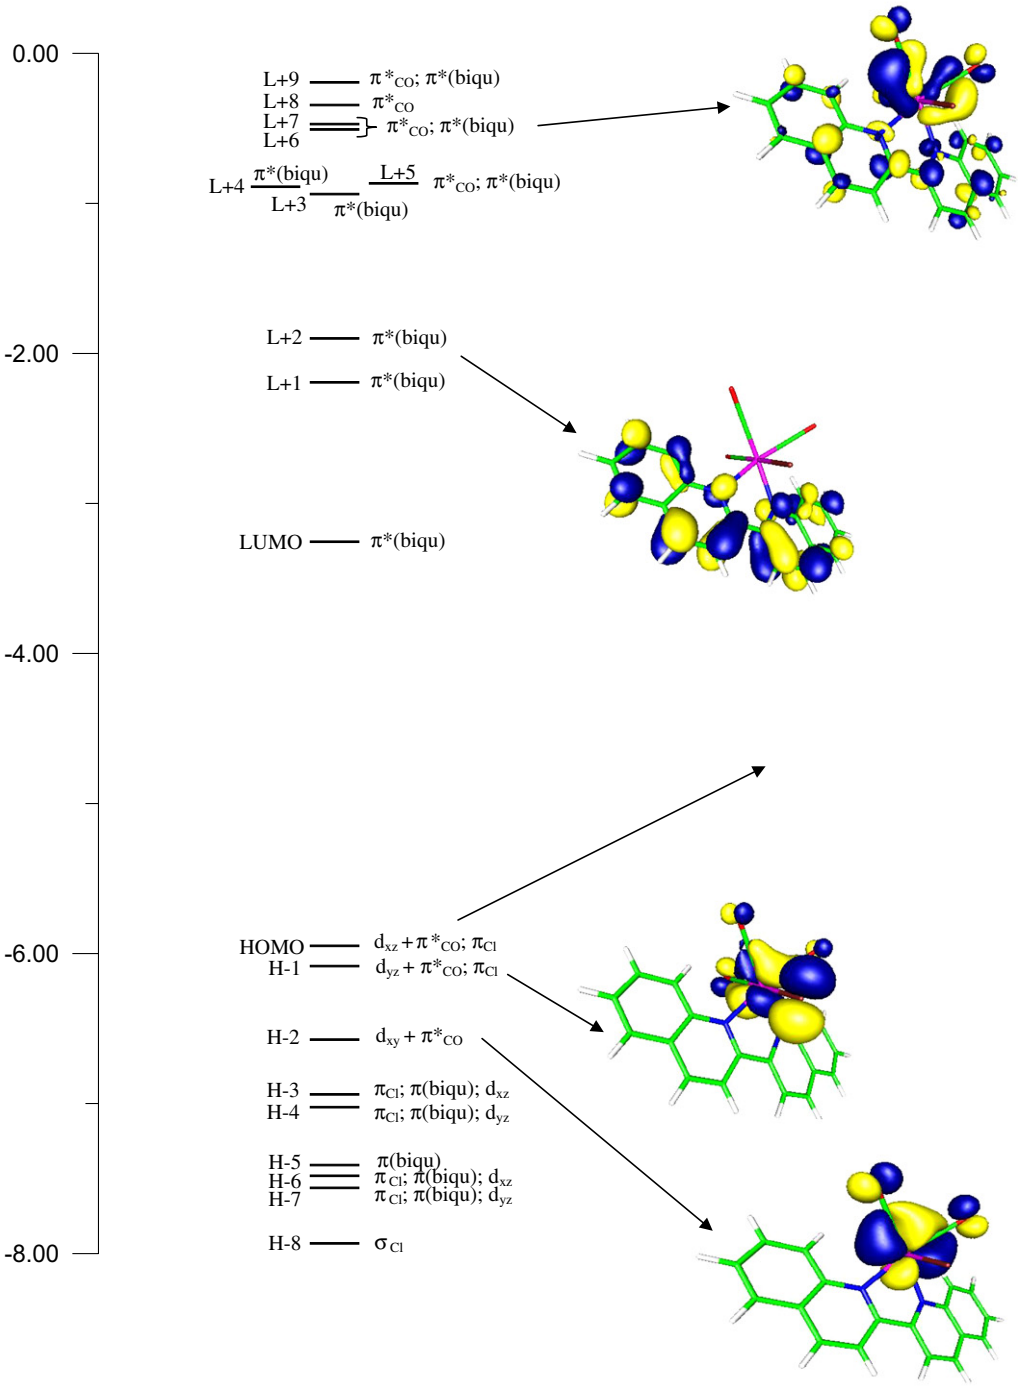

Fig. 2. The energy (eV), character and some contours of the unoccupied molecular orbitals of $[Re(CO)_3$(2,2′-biquinoline)Cl].

are given in Table 1, and the perspective drawing of [Re(CO)$_3$(2,2′-biquinoline)Cl] with atomic numbering is shown in Fig. 1. The three carbonyl ligands are arranged in a *facial* arrangement, and the rhenium coordination sphere can be described as slightly distorted tetragonal bipyramid. The deviation from ideal geometry mostly originates from geometric retrains imposed by chelating ligand (Table 2). The selected bond lengths and angles of [Re(CO)$_3$(2,2′-biquinoline)Cl] are given in Table 2. The Re–C and Re–N bond distances are close to those reported for the relative rhenium structures with 2,2′-biquinoline [25] and 2,2′-biquinoline substituted in the 3 and 3′ positions [26–28]. In the structure can not be found any intermolecular short contacts, which can be considered as classical hydrogen bonds, but one C(91)–H(91)···Cl(1) contact can be considered as very weak hydrogen bond [29,30] (D···A distance = 3.545(8) Å, H···A distance = 2.62 Å and D–H···A angle = 157.7°). Additionally in the structure exist stacked 2,2′-biquinoline molecules connected *via* π···π interactions (Table 3) [31]. These interactions expand molecules to stacked piles along crystallographic *b*0*c* plane.

3.3. Optimised geometry

The geometry of [Re(CO)$_3$(2,2′-biquinoline)Cl] was optimised in a singlet state by the DFT method with the B3LYP functional. The optimised geometric parameters are gathered in Table 2. The calculated bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

3.4. Charge distribution

The atomic charges from the natural population analysis (NPA) for [Re(CO)$_3$(2,2′-biquinoline)Cl] are shown in Table 4. The calculated charge on the rhenium atom of [Re(CO)$_3$(2,2′-biquinoline)Cl] is lower than the formal charge +1, as a result of significant charge donation from the ligands. The charges on the carbon atoms of the carbonyl ligands are positive, whereas the oxygen atoms are negatively charged. The carbon atom in the *trans* position to the chloride ion (π-donor ligand) has the smallest positive charge.

3.5. Electronic structure

The [Re(CO)$_3$(2,2′-biquinoline)Cl] complex is a closed-shell structure. Its molecular orbital diagram with several occupied and virtual molecular orbital contours is presented in Fig. 2. The HOMO–LUMO gap equals to 2.69 eV. The low-lying virtual orbitals correspond to π^*_{biqu} and π^*_{CO}, and the energy of the π^*_{biqu} is lower than π^*_{CO} orbitals. The three highest occupied molecular orbitals are predominately localized on the rhenium atom, corresponding to the $(5d_{xy})^2$ $(5d_{yz})^2$ $(5d_{xz})^2$ occupation of the central ion. They are, to a large extent, formed by Re 5d orbitals mixed with CO π* orbitals. The HOMO and HOMO − 1 orbitals contain also an admixture of chloride p_π orbitals.

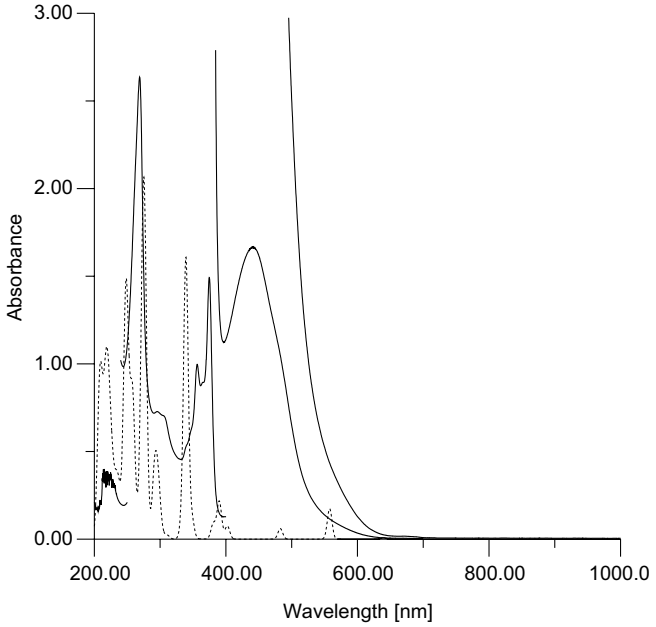

Fig. 3. The experimental (——) and calculated (----) electronic absorption spectrum of [Re(CO)$_3$(2,2′-biquinoline)Cl].

3.6. Electronic spectrum

The experimental and calculated electronic spectra of [Re(CO)$_3$(2,2′-biquinoline)Cl] are presented in Fig. 3. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}.

Table 5 shows the spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method for [Re(CO)$_3$(2,2′-biquinoline)Cl]. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.010 are listed in Table 5.

The assignment of the calculated transitions to the experimental bands is based on the criterion of the energy and oscillator strength of the calculated transitions. In the description of the electronic transitions only the main components of the molecular orbital are taken into consideration.

The broad low-energy absorption band centered at 445.4 nm is attributed to *MLCT* transitions occurring from the rhenium center to the π-antibonding orbitals of the chelating ligand ($d \rightarrow \pi^*_{biqu}$). The strong experimental absorption bands in the range 400–200 nm result from *metal–ligand charge transfer* (occurring from the rhenium ion to the π-antibonding orbitals of the N–N ligand or π-antibonding orbitals of the carbonyl group) and *ligand–ligand charge transfer* transitions. The last one are of intra- and interligand character.

biqu: 2,2′-biquinoline.

4. Conclusions

The [$Re(CO)_3$(2,2′-biquinoline)Cl] complex has been structurally and spectroscopically characterized. X-ray and IR studies confirm a *facial* geometry of the carbonyl ligands in the [$Re(CO)_3$(2,2′-biquinoline)Cl] complex. The molecular orbital diagram of the tricarbonyl has been calculated with the density functional theory (DFT) method. The HOMO, HOMO − 1 and HOMO − 2 orbitals are predominantly of d_{Re} orbital character corresponding to the $(5d_{xy})^2$ $(5d_{yz})^2$ $(5d_{xz})^2$ occupation. The low-lying virtual orbitals correspond to π^*_{biqu} and π^*_{CO}. The spin-allowed electronic transitions of *fac*-[$Re(CO)_3$(2,2′-biquinoline)Cl] have been calculated with the time-dependent DFT method (TDDFT method), and a good agreement between calculated and experimental spectra is observed.

5. Supplementary material

CCDC 623826 contains the supplementary crystallographic data for $C_{22}H_{13}Cl_4N_2O_3Re$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Mixed cobalt–nickel oxydiacetate $[Co_xNi_{1-x}(oda)(H_2O)_3]\cdot 1.5H_2O$ compounds (oda = $O(CH_2COO)_2^{2-}$; $x = 0.3$, 0.4, 0.6) were synthesized from the reaction of aqueous solutions of a mixture of nickel dichloride and cobalt dichloride with a 1:1 mixture of Na_2CO_3 and oxydiacetic acid, $O(CH_2COOH)_2$. In particular, compound $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$ (**1**) was characterized by single-crystal X-ray analysis. Complex **1** is a co-crystallization of $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ and $[Co(oda)(H_2O)_3]\cdot 1.5H_2O$ compounds, the latter species being a new hydrated form of cobalt oxydiacetate that shows a *fac*-coordination for the oda ligand. These compounds can be used for the preparation of mixed metal oxides. For instance, thermal decomposition of **1**, carried out under a nitrogen atmosphere, produces essentially $Co_{0.4}Ni_{0.6}O$ oxide.

1. Introduction

From a structural point of view, the information about oxydiacetate compounds ($O(CH_2COO)_2^{2-}$, oda) has increased significantly in recent decades. Besides the lanthanide elements, first row transition metals containing this ligand are those more studied by X-ray crystallography [1,2]. We have produced several contributions concerning the chemistry of oda complexes [3–6], and in this paper we have centred our attention on the simplest compounds of the general empirical formula $[M(oda)(H_2O)_x]\cdot nH_2O$. They are composed of a divalent first-row transition metal ion, the oda ligand and water (as a coligand or/and hydration molecule). Our interest came from the fact that these compounds are known to yield the corresponding transition metal oxides by thermal decomposition [2f,7] and, consequently, they can be selected as precursors for the synthesis of these materials.

In recent years, a renewed interest in the methodologies for the preparation of transition metal oxides has emerged, particularly nanoparticles, due to their importance in applications [8]. For instance, Pericàs and co-workers have recently described an elegant process for the room temperature synthesis of pure CoO nanoparticles [9]. These new methodologies are also applied to the preparation of mixed metal oxides (MMO) that have important practical applications in several fields [10]. A number of procedures have been employed in order to achieve precise control on the composition of the MMO powders. This is due to the influence that the homogeneous composition at the atomic length scale may have in the properties of the resulting material. A recent improvement in classical methodologies is to make use of a single source instead of a multicomponent mixture [11]. The single component may be a bimetallic compound which is capable of affording simultaneously both metal compounds into the desired final mate-

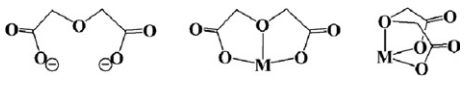
doi:10.1016/j.poly.2007.03.020

rial in a single step. Alternatively, the single precursor may be a solid solution of a compound with mixed metal composition, which permits the fine-tuning of properties such as magnetism [12].



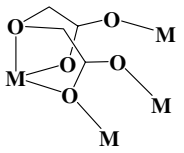
Here, we report the synthesis and properties of mixed Co–Ni oxydiacetate compounds. One of these complexes, namely $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$ (**1**), has been selected for study of its properties. Complex **1**, which has been characterized by single-crystal X-ray analysis, is a co-crystallization of $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ and $[Co(oda)(H_2O)_3]\cdot 1.5H_2O$. The latter species is a new hydrated form of cobalt oxydiacetate that shows a *fac*-coordination for the oda ligand. In the absence of the Ni counterpart, the Co-oda complex displays a different $[M(oda)(H_2O)_x]\cdot nH_2O$ stoichiometry and a *mer* oda conformation. Therefore, the presence of the Ni species in **1** controls the composition of the Co complex in the crystal and also guides the conformation of the oda ligand. Furthermore, compound **1** can be used as single precursor to the mixed $Co_{0.4}Ni_{0.6}O$ oxide, which was obtained by thermal decomposition of $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$ (**1**) under a nitrogen atmosphere.

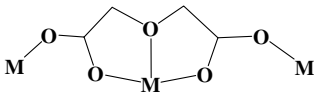
2. Results and discussion

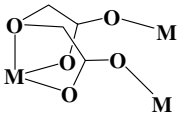
2.1. Structural features of oxydiacetate $[M(oda)(H_2O)_x]\cdot nH_2O$ compounds

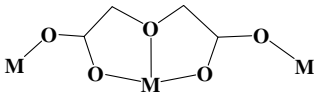
The oxydiacetate dianion contains five atoms as potential donors, of which four come from two carboxylate groups and one from the ether function (Scheme 1). If this ligand binds a single metal in a tridentate way, two "exo" oxygen donor atoms of the carboxylate groups remain and they are capable of additional coordination toward another metal or external electrophiles. This permits the formation of homo- and hetero-metallic extended solids or the formation of stabilizing hydrogen bonds. Concerning the tridentate coordination, two limiting situations exists (see Scheme 1): the oda ligand may be planar (*mer* coordination) or folded about the M–O vector (*fac* coordination). These two characteristics: the flexibility of oda [6] and the large capacity of this ligand to form coordination polymers (for instance, through hydrogen networks with water as a ligand or solvated [13]), make possible the formation of a rich assortment of 3D architectures notwithstanding the simplicity of a formula such as $[M(oda)(H_2O)_x]\cdot nH_2O$.

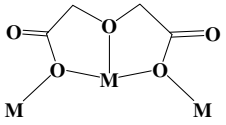
Table 1 collects the structurally characterized examples of $[M(oda)(H_2O)_x]\cdot nH_2O$ compounds and displays the corresponding oxydiacetate bonding mode. We have restricted the entries of the table to first-row transition metals, but there are also known examples of group 2 [14], cadmium [15,16] and other metals [17]. From the inspection of the table, it is evident that cobalt is the most frequent metal. In fact, there are three complexes $[Co(oda)]_n$ [7], $[\{Co(oda)(H_2O)\}\cdot H_2O]_n$ [2e,7] and $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [2e,18,19], and six X-ray determinations. All of them are polymeric in nature and differ in the number of water molecules in their composition. Recently, Hung, Lu and co-workers have illustrated the influence that the water content in the synthesis reaction may have in the topology of metal frameworks based on pyridine-3,5-dicarboxylate [20]. Concerning the Co-oda system, a somewhat related relationship can be established. Scheme 2 displays a representation of the different coordination modes of oxydiacetate in structurally characterized cobalt complexes containing water. An increase in the number of water molecules that are acting as ligands produces a diminution in the connectivity of oda as a ligand. The synthesis and characterization of compound **1**, which displays a *fac*-conformation (see below), completes the series.

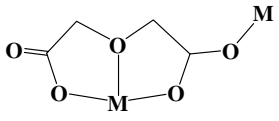


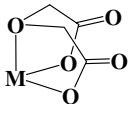




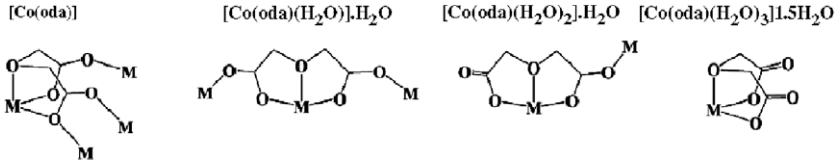








Scheme 1.



2.2. Synthesis and characterization

Following the procedure described by us for the synthesis of related oxydiacetate complexes [4], the treatment of aerobic aqueous solutions of a 1:1 mixture of nickel dichloride and cobalt dichloride with a 1:1 mixture of Na_2CO_3 and oxydiacetic acid, $O(CH_2COOH)_2$, results, after the appropriate work-up, in the formation of grey crystals of complex **1** in good yields. The chemical microanalysis indicates the composition $[M(oda)(H_2O)_3]\cdot 1.5H_2O$ for this complex. The UV–VIS spectrum of an aqueous solution of **1** (see Section 3) is the same as the spectrum of a 1:1 mixture of aqueous solutions of $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ and $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [2e,18,19]. These data suggest to us the formation of a mixed cobalt–nickel species. Similar compounds have been reported in the bibliography and some of them have been prepared by a related procedure [21]. The crystal morphology of **1** (see Fig. 1) is similar to that observed for the known complex $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ [2f], although it differs from that observed for the related Co complex $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [2e,18,19], confirming that this compound is not a mixture but a ca. 1:1 co-crystallization of $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ and $[Co(oda)(H_2O)_3]\cdot 1.5H_2O$. The Co:Ni ratio found in **1** is $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$, which was determined by X-ray fluorescence and SEM microscopy (EDAX), using a crystalline-solid sample. Following the same experimental procedure, but employing mixtures of nickel dichloride and cobalt dichloride with different Co:Ni ratios, the mixed compounds $[Co_{0.6}Ni_{0.4}(oda)(H_2O)_3]\cdot 1.5H_2O$ and $[Co_{0.3}Ni_{0.7}(oda)(H_2O)_3]\cdot 1.5H_2O$ were also obtained.

The IR spectrum of $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$ (**1**) shows the characteristic absorptions due to the oxydiacetate ligand [22]: an intense broad band at 1605 cm^{-1}, due to the antisymmetric vibrations of the carboxylate group, and a sharp signal centred at 1091 cm^{-1} corresponding to

Table 1
Structural features of $[M(oda)(H_2O)_x]\cdot nH_2O$ compounds (M = first-row transition metal)

Formula	M	Nature	Coordination mode of oda	Ref.

$[M(oda)(H_2O)_2]\cdot H_2O$	Fe Co Zn	polymer		[5] [2e,18,19] [2h]
$[M(oda)(H_2O)_3]\cdot 1.5H_2O$	Ni	monomer		[2f]

Scheme 2.

the COC stretching of oda. Compounds $[Co_{0.6}Ni_{0.4}(oda)(H_2O)_3]\cdot 1.5H_2O$ and $[Co_{0.3}Ni_{0.7}(oda)(H_2O)_3]\cdot 1.5H_2O$ display similar spectra. In previous works [3,6], we have shown that the position of the latter band depends on the disposition of this ligand in the coordination sphere. Thus, when the signal appears above 1100 cm^{-1}, the oda ligand adopts a planar conformation (*mer*-disposition). In other cases, the arrangement is non-planar (*fac*-disposition). In **1**, the position of this absorption is in good agreement with the *fac*-coordination mode observed in the X-ray analysis (see below). We have realized that the IR spectrum of a compound of the type $[M(oda)(H_2O)_x]\cdot nH_2O$ can be used

Fig. 1. SEM micrograph of compound **1**.

as a fingerprint that identifies the 3D arrangement of the compound. For instance, the IR spectrum of the complex $[\{Co(oda)(H_2O)\}\cdot H_2O]_n$, structurally identified by Wang [2e] and Cheetham [7], is superimposable on that of the isomorphous Mn compound described by us, $[\{Mn(oda)(H_2O)\}\cdot H_2O]_n$ [4,7]. In addition, complex $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [6], whose structure has been recently re-determined twice [2e,19], shows an identical IR spectrum to that of the isomorphous derivatives $[\{M(oda)(H_2O)_2\}\cdot H_2O]_n$ (M = Fe [5], Mg [23] and Zn [2h]). Since the IR spectra of the mixed Co–Ni compounds are identical to that recorded for $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ [2f], we suggest that these compounds have the same structure and 3D arrangement. This proposal has been confirmed through an X-ray study of **1**.

2.3. Structural study

Compound **1** has been structurally characterized by single crystal X-ray diffraction analysis. A drawing with 50% thermal ellipsoids is shown in Fig. 2 and selected geometric parameters are collected in Table 2. X-ray diffraction cannot readily distinguish between Ni(II) and Co(II) ions and they appear delocalized on the same crystallographic site in the whole lattice. A relative ratio of 1:1 was considered, corresponding to the stoichiometry employed in the reaction from which the crystals were obtained, and refinements on the occupancies at the metal centres were carried out with this scheme (see Section 3). Compound **1** is a monomer, displaying the oda ligand in a *fac* disposition, and it is isomorphous with the Ni homologous complex. The bonding parameters around the metal centre and also the structural data within the oda ligand are similar to other characterized Ni and Co compounds [24]. For instance, the observed M–O lengths for the metal–oda moiety (M(1)–O(1) 2.0543(10), M(1)–O(2) 2.1443(11) and M(1)–O(3) 2.0223(11) Å) fit well within the range observed for oxydiacetates of Ni and Co (2.01–2.26 Å). However, the conformation of the oda ligand merits some comment. There are 17 X-ray determinations of oxydiacetate complexes of Ni and Co and only four of them display the

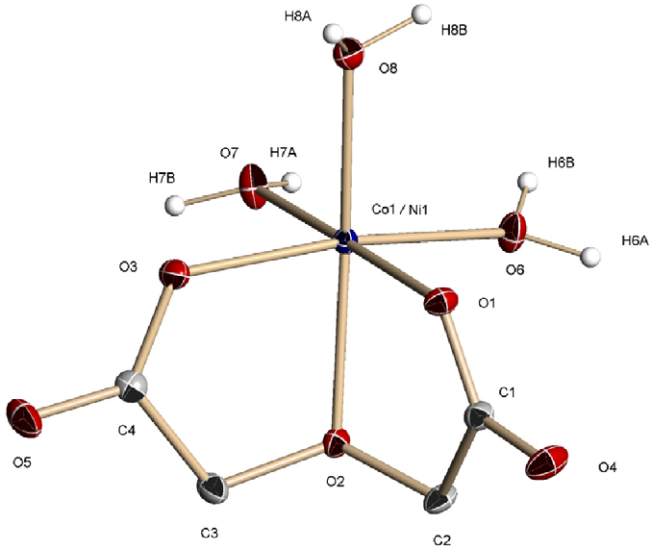

Fig. 2. ORTEP view of one of the symmetrically independent $[M(oda)(H_2O)_3]$ molecules (M = Co or Ni) present in the asymmetric unit of **1**.

fac-coordination. The remaining examples show angles between the M–O–CH_2–C(O)–O planes in the 165–180° range, a characteristic feature of a planar ligand. We have previously determined through DFT computational methods the energy differences between the two possible oda conformations in the $[Ni(oda)(H_2O)_3]$ model [6] (and also in $[VO(oda)(H_2O)_2]$ [3]). We concluded that there is a small ΔE value between the two isomers (of the order of 2 kcal mol^{-1} for the Ni compound). Under these circumstances, non-covalent interactions, such as hydrogen bond networks involving water crystallization molecules, likely determine the specific conformation of the oxydiacetate ligand. The formation of **1** is a definitive proof of the importance of the crystalline packing forces in the conformation of oda. In fact, if the synthesis of **1** is carried out under identical experimental conditions, but with the absence of Co chloride, the isolated final product is $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ [2f]. However, if the same reaction is carried out with the absence of Ni chloride, again under identical experimental conditions, the resulting oda compound has a different formula, $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [2e,18,19], displaying a planar oda ligand (*mer*-), and no evidence of the formation of $[Co(oda)(H_2O)_3]\cdot 1.5H_2O$ is found. We conclude that the presence of the Ni derivative (*fac*-) during the co-crystallization with the Co derivative specifically organizes the stoichiometry and the oda conformation in the solid state of the Co species.

2.4. Thermal decomposition of compound 1

The effect of the experimental conditions on the composition and properties of the nickel cobalt oxide series has been studied recently and several preparation techniques for getting the oxides have been evaluated [25]. The mixed

[a] M = Co or Ni.

complex $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$ (**1**) can be a new valid precursor for the synthesis of $CoNiO_2$ oxide and thus we have studied the thermal decomposition of compound **1**, carried out under a nitrogen atmosphere in order to prevent the formation of the spinel $NiCo_2O_4$ [25]. The DTA profile essentially shows two endothermic peaks (Fig. 3). The first peak covers the 130–180 °C range and results from the loss of both coordinated and hydration water molecules, while the second at 396 °C is due to pyrolysis of the oda ligand. These observations parallel those of the isomorphous Ni species [2f] and related $[\{Co(oda)(H_2O)\}\cdot H_2O]_n$ complex [7]. The loss of hydration water molecules begins to occur at relatively low temperatures and this fact can be rationalized on the basis of the specific metal organic framework found in crystalline **1** (Fig. 4). The network of crystallization water molecules occupy channels parallel to the *a*-axis (approximate dimensions: $a = \infty$, $b = 5$ and $c = 8$ Å), which favours the removal of such molecules.

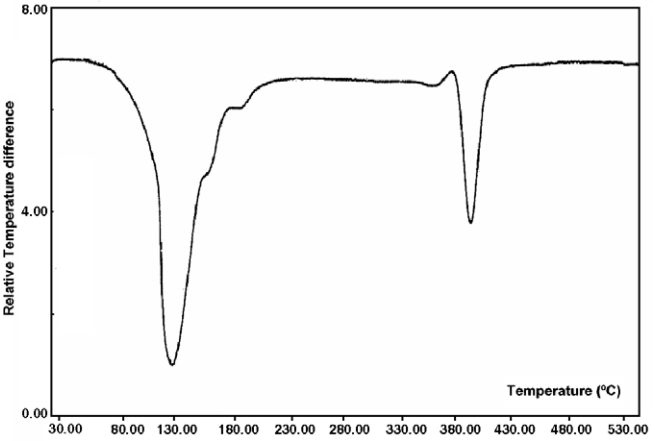

Fig. 3. DTA profile of **1**.

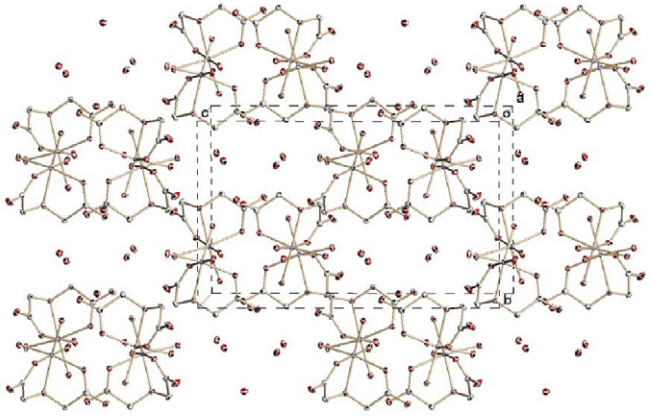

Fig. 4. Crystal packing of **1** viewed along the *a*-axis.

Chemical analysis of the sample, resulting from the thermal decomposition of **1**, (EDAX quantification by SEM and X-ray fluorescence, see details in Section 3) confirms that the composition of the solid is mainly $Co_{0.4}Ni_{0.6}O$ (a micrograph is also shown in Fig. 5), although small amounts of metallic Ni are observed by X-ray powder

Fig. 5. SEM micrograph of the mixed oxide material obtained after thermal decomposition of **1** under nitrogen.

diffraction data (peaks at 2.03 and 1.76 Å), while the oxide is rather amorphous.

3. Experimental

3.1. General

All preparations and other operations were carried out under aerobic conditions. Oxydiacetic acid and other chemicals were obtained from commercial sources and were used without further purification. The known compounds $[\{Co(oda)(H_2O)_2\}\cdot H_2O]_n$ [2e,18,19] and $[Ni(oda)(H_2O)_3]\cdot 1.5H_2O$ [2f] were prepared by the same experimental procedure described for the synthesis of **1**, but using $NiCl_2\cdot 6H_2O$ and $CoCl_2\cdot 6H_2O$, respectively.

3.2. Physical measurements

Infrared spectra were recorded on a Perkin–Elmer Model 883 spectrophotometer (Nujol emulsion in NaCl plates). Magnetic moments were measured in the solid state, at room temperature, with a Sherwood Scientific (Cambridge Research Laboratory) magnetic balance. UV–VIS spectra were recorded on a Perkin–Elmer Lambda 25 spectrophotometer. The following measurements were carried out by the "Servicios Generales de Investigación" (CITIUS) of the University of Sevilla. Microanalyses (C, H) were performed on an Elemental LECO CHNS 93 analyzer. X-ray fluorescence analyses were performed in an Axios PW4400 instrument (μSX Panalytical). SEM micrographs (SE) and chemical analysis with EDAX quantification were obtained in a Philips XL-30 instrument (silicium detector and UTW window). In both cases the samples were previously covered with graphite. Powder X-ray diffraction patterns were recorded on a Bruker D8I diffractometer.

3.3. Synthesis of $[Co_{0.4}Ni_{0.6}(oda)(H_2O)_3]\cdot 1.5H_2O$ (1) and other mixed Co–Ni compounds

To a solution of $O(CH_2COOH)_2$ (1.27 g, 12 mmol) in water (30 mL) was added a solution of Na_2CO_3 (1.61 g, 12 mmol) in water (30 mL). The mixture was stirred until the evolution of CO_2 ceased and then this mixture was added onto a 40 mL water solution of a 1:1 mixture of $NiCl_2\cdot 6H_2O$ (1.43 g; 6 mmol) and $CoCl_2\cdot 6H_2O$ (1.43 g; 6 mmol). The resulting solution was stirred for 15 min and then concentrated until ca. 40 mL. Acetone (40 mL) was added and the solution was kept at room temperature overnight. Grey crystals of complex **1** were formed, filtered off, washed with acetone, Et_2O and dried in air (2.5 g, 76%). IR (cm^{-1}): 3500–3000 br, 1605 s, 1467 s, 1431 sh, 1353 w, 1330 m, 1288 w, 1261 m, 1146 w, 1091 s, 1082 s, 1054 w, 1004 m, 967 w, 935 m, 728 s, 673 w. UV–VIS (ca. 0.05 M in water, nm): 661.1, 526.9, 398.5. $\mu_{eff} = 4.3$ μ_B at 22 °C. *Anal.* Calc. for $C_4H_{13}O_{9.5}Ni_{0.6}Co_{0.4}$: C, 17.67; H, 4.82. Found: C, 17.77; H, 4.82%. X-ray fluorescence analysis: $C_4H_{13}O_{9.5}Ni_{0.6}Co_{0.4}$: Ni/Co ratio, 1.50; found 1.51. Following the same experimental procedure, but using different ratios of $NiCl_2\cdot 6H_2O$ and $CoCl_2\cdot 6H_2O$ starting materials, the mixed compounds $[Co_{0.6}Ni_{0.4}(oda)(H_2O)_3]\cdot 1.5H_2O$ (X-ray fluorescence analysis: $C_4H_{13}O_{9.5}Ni_{0.4}Co_{0.6}$: Ni/Co ratio, 0.67; found 0.61) and $[Co_{0.3}Ni_{0.7}(oda)(H_2O)_3]\cdot 1.5H_2O$ (X-ray fluorescence analysis: $C_4H_{13}O_{9.5}Ni_{0.7}Co_{0.3}$: Ni/Co ratio, 2.33; found 2.44) were obtained, which display similar IR spectra.

3.4. Thermal analysis: synthesis of $Co_{0.4}Ni_{0.6}O$

Data were collected on a Perkin–Elmer System 714 (model 1700) instrument in flowing N_2 (40 cm^3 min^{-1}) at a heating rate of 6 °C min^{-1} by heating a crystalline solid sample of **1** (50 mg). The resulting material was identified as $Co_{0.4}Ni_{0.6}O$, according to the analysis by EDAX quantification (SEM), carried out on several particles of the oxide displaying different morphologies (average results: Co, 43; Ni, 57), and also by X-ray fluorescence: Co, 31.52; Ni, 47.09; O, 21.39. Found Co, 31.79; Ni, 43.34; O, 23.56%.

Table 3
Crystallographic data for **1**

Empirical formula	$C_4H_{13}O_{9.5}Co_{0.5}Ni_{0.5}$
Formula weight	543.93
Temperature (K)	100(2)
Wavelength (Å)	0.71073
Crystal system	orthorhombic
Space group	$Pna2_1$
Unit cell dimensions

b (Å)	10.2643(4)
c (Å)	16.5393(6)
α (°)	90
β (°)	90
γ (°)	90
Volume (Å^3)	2008.92(13)
Z	4
D_{calc} (Mg m^{-3})	1.798
Absorption coefficient (mm^{-1})	1.853
$F(000)$	1124
Crystal size (mm^3)	$0.20\times 0.18\times 0.14$
θ Range for data collection (°)	2.90–30.52.
Index ranges	$-16\leqslant h\leqslant 16$, $-14\leqslant k\leqslant 14$, $-23\leqslant l\leqslant 23$
Reflections collected	26774
Independent reflections [R_{int}]	6128 [0.0304]
Completeness to $\theta = 30.52°$	99.8%
Absorption correction	semi-empirical from equivalents
Maximum and minimum transmission	0.7814 and 0.7082
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	6128/19/317
Goodness-of-fit on F^2	1.037
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0226$, $wR_2 = 0.0569$
R indices (all data)	$R_1 = 0.0233$, $wR_2 = 0.0572$
Absolute structure parameter	0.291(6)
Largest difference in peak and hole (e Å^{-1})	1.689 and −0.287

3.5. X-ray structural study of **1**

A summary of the crystal data of compound **1** is given in Table 3. The X-ray data were collected at 100 K on a Bruker–Nonius X8APEX-II CCD diffractometer equipped with a graphite monochromator and Mo Kα radiation. The data were reduced [26] and corrected for Lorentz polarisation effects and absorption by the multiscan method, applied by SADABS [27]. The structure was solved by direct methods (SIR-2002 [28]) and refined against all F^2 data by full-matrix least-squares techniques (SHELXTL-6.12 [29]). The occupancy factors for the Ni and Co metal sites were first refined and later both fixed to 0.5. All the non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were included in calculated positions and refined riding on their respective carbon atoms with isotropic displacement parameters.

Abstract

Our two original approaches, the first based on the topological (connectivity) index $^3\chi^v$ and the second based on the model of overlapping spheres (OS), were applied for the estimation of stability constants of copper(II) complexes (CuL) with ethylenediamines ($N = 14$) and diethylenetriamines ($N = 8$), and mixed complexes (CuLA) of amino acids and diethylenetriamines ($N = 18$). The stability constants of the ethylenediamine complexes were predicted "indirectly" from calibration models developed on diethylenetriamines and vice versa, and also by a more direct method using the leave-one-out procedure of cross validation (*cv*). By averaging all the estimates, stability constants were reproduced with a *rms* error of 0.56 and 0.43 $\log K$ units for diethylenetriamines and ethylenediamines, respectively.

Stability constants of the mixed complexes (CuLA) were estimated with $S.E._{cv} = 0.69 \log K$ units (the best linear regression) and $S.E._{cv} = 0.53 \log K$ units (the best binomial regression). The best bivariate regression with the indicator variable, $\mathrm{In} = 1$ for CuLA, $\mathrm{In} = 0$ for CuL, combining stability constants of CuL and CuLA, gave $S.E._{cv} = 0.67 \log K$ units.

1. Introduction

Predicting the stability of coordination compounds is, no doubt, one of the most important problems in coordination chemistry [1]; however there is no general method for its solution. The reason for this is obvious: there are many different factors that determine the thermodynamic stability of coordination compounds. Besides electronic (strength of the metal–ligand bond), stereochemical (mode of coordination) and sterical (conformational) influences, thermodynamic stability of coordination compounds is also determined by solvation (hydration) of the metal, ligand, complex, etc. Simple empirical rules (Irving–Williams order [2], cation [3,4] and HSAB classification [5,6]) have been used in crude predictions of the stability of complexes with various metals and ligands differing in bite atoms. For structurally related complexes, models based on "interaction parameters" between the atoms in the first coordination sphere [7–9] have been used, along with methods based on a molecular mechanics [10–16] or molecular dynamics [17] approach. Also, various kinds of quantitative structure–property relationship (QSPR) models have been applied for the prediction of stability constants [18,19], along with quantum mechanical methods, i.e. model of continuous distribution of solvent [20,21] and density functional theory (DFT) [22,23].

In our study on the stability of coordination compounds, we used two new approaches. The first approach, based on the overlapping spheres (OS) model, assumes that

doi:10.1016/j.poly.2007.03.050

the stability of coordination compounds depends on the free volume within the sphere situated at a characteristic point of the molecule (usually the central atom). The method was applied originally for the calculation of Gibbs energy of solvation [24–27]. Latter it was used in drug design [28–30], and as a tool for finding out the most stable molecular conformations [31–35]. We used the OS method for the estimation of stability constants of copper(II) chelates with amino acids and their derivatives [36], and subsequently the stability constants of copper(II) and nickel(II) complexes with 1,2-diaminoethanes [37] and mixed amino acid chelates [38]. The method was also applied for the estimation of enantioselectivity and diastereoselectivity effects in copper(II) chelates with amino acids and their *N*-alkyl derivatives [39,40].

Topological indices have found application in various fields of chemistry, starting from the classical problem of estimation of boiling points [41,42] and properties of conjugated systems [43,44] to QSAR and drug design [45,46]. We found these simple descriptors of molecular topology («constitutional formula») very suitable for the estimation of stability constants of copper(II) and nickel(II) chelates with amino acids, their *N*-alkyl derivatives and diamines [47–50]. In contrast to the method of overlapping spheres, where the three-dimensional structure (conformation) of molecule must be known, to solve a problem by the method of topological indices, only the constitution of the complex is needed. This not only facilitates the calculations, but also rules out many ambiguities that stem from the plethora of conformations attributed to the studied molecules.

In our last paper in this journal [50], it was shown that the method of topological indices yielded results of the same quality as the much more demanding OS method. It was also pointed out that both methods give in many respects complementary results, and thus the best way to estimate the stability constants appears to be the calculation of the average of the results obtained by these methods.

The aim of this paper is to take a step further; i.e. to find out whether it is possible to successfully estimate stability constants of one class of compounds from the calibration models developed on another class of complexes. For this purpose we chose copper(II) complexes with ethylenediamines and diethylenetriamines, and the mixed complexes of the later class of ligands with naturally occurring amino acids. The later chelates were studied as a model system for metal-catalyzed hydrolysis of amino acid esters [51,52], but from our point of view they are interesting for their terdentate ligand coordination and as a good model for mixed complexes of structurally unrelated ligands.

2. Methods

2.1. Method of overlapping spheres

The overlapping spheres (OS) approach is based on the evaluation of the function [53]:

$$V^* = \sum V_j(S_v \cap s_j) \tag{1}$$

where V^* is the sum of overlapping volumes of the central sphere S_v and volumes of van der Waals spheres s_j of the neighbouring atoms:

$$V_j = 1/3\pi[2R_v^3 + 2r_j^3 + r_{vj}^3] - \pi[R_v^3 x^* + (r_{vj} - x^*)(r_j^2 + r_{vj}x^*)] \tag{2}$$

where

$$x^* = (R_v^2 - r_j^2 + r_{vj}^2)/r_{vj} \tag{3}$$

In Eqs. (2) and (3) r_j stands for the van der Waals radius of atom j penetrating the central sphere with radius R_v, and r_{vj} is the distance between the centers of atom j and the central sphere. Eq. (3) holds only for a partial overlaps; otherwise $V_j = 0$ for $R_v + r_j \leqslant r_{vj}$, and $V_j = 4/3\ r_j^3\pi$ for $r_j + r_{vj} \leqslant R_v$.

The central sphere is situated at the central copper atom (Fig. 1). Usually, its value is set to 3 or 4 Å [38], but in this paper we used its best value in the range 2–5 Å. Also, as usual, we chose the conformations with the lowest V^* [36,37]. The sets of the van der Waals radii, r_j, are given elsewhere [32,53].

Calculation of the overlapping volume V^* (Eq. (1)) was performed by a special FORTRAN program. All the molecular mechanics calculations, needed to find the conformers of the copper(II) chelates, were done with the program developed by Rasmussen and co-workers [54–56], using the force field denoted as FF3 [57].

2.2. Calculation of topological indices

The calculations of topological indices were performed with a program system DRAGON 2.1, written by Todeschini and coworkers, [58] which is capable of yielding 262 topological indices in a single run, along with many other molecular descriptors. The connectivity matrix was constructed with the program CORINA, [59] developed by Sadowski, Schwab and Gasteiger.

All calculations were done with the Randić index ${}^3\chi^v$ (the valence molecular connectivity index of the 3rd order), which gives generally the most consistent results of all topological indices [48,50]:

$${}^3\chi^v = \sum_{\text{path}} \{\delta(i)\delta(j)\delta(k)\delta(l)\}^{-0.5} \tag{4}$$

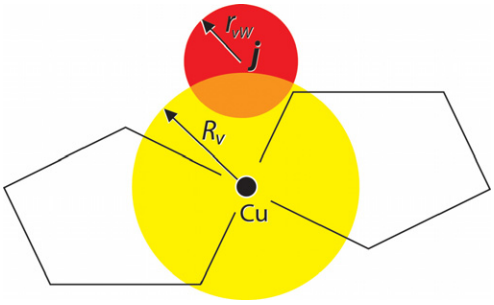

Fig. 1. General scheme of the model of overlapping spheres (cf. Eq. (1)).

where $\delta(i)$, $\delta(j)$, $\delta(k)$ and $\delta(l)$ are weights (valence-delta values) of vertices (atoms) i, j, k and l, making up the path of length 3 (three consecutive chemical bonds) in a vertex-weighted molecular graph [60,61]. The valence-delta value, $\delta(i)$, of a vertex i is defined by

$$\delta(i) = [Z^v(i) - H(i)]/[Z(i) - Z^v(i) - 1] \quad (5)$$

where $Z^v(i)$ is the number of valence electrons belonging to the atom corresponding to vertex i, $Z(i)$ is its atomic number and $H(i)$ is the number of hydrogen atoms attached to it. For instance, delta values for primary, secondary, tertiary and quaternary carbon atoms are 1, 2, 3 and 4, respectively; for oxygen in an OH group it is equal to 5, and for the NH_2 group $\delta(N) = 3$ (it has to be pointed out that $^3\chi^v$ is only a member of the family of valence connectivity indices, $^n\chi^v$, which differ from each other by path length, i.e. the number of factors δ's in the summation term, Eq. (4)).

All the diamine and triamine structures were treated as model ML^{aq} [50], i.e. assuming the binding of ligand water, up to the coordination number 4.

2.3. Regression calculations

Regression calculations, including the leave-one-out procedure of cross validation, *cv*, were done with the CROMRsel program [62]. The standard error of cross validation estimate is defined as

$$S.E._{cv} = (\sum \Delta X^2/N)^{0.5} \quad (6)$$

where ΔX and N denote *cv* residuals and number of reference points, respectively.

Because of the different coordination of diamines and triamines (2 and 3, respectively) their $\log K_1$ values were corrected if estimated "indirectly", *i.e.* from a calibration model developed on another class of compounds. The correction term is taken to be equal to −slope/3 and +slope/2 for the estimation of $\log K_1$ values of diamines and triamines, respectively ("slope" is the slope of the calibration line).

3. Results and discussion

3.1. N-Methyl and N-ethyl substituted diethylenetriamine copper(II) complexes

As the first test of the validity of our models, we chose eight copper(II) complexes with *N*-(2-aminoethyl)-1,2-ethanediamine (diethylenetriamine, dien), and its derivatives substituted at one, two or all three nitrogen atoms (Fig. 2). For all the complexes, their stability constants, K_1, were known [51]. To make a systematic comparison of both methods ($^3\chi^v$ and OS), as well as to check their predictive power for different classes of molecules, we made altogether six analogous regressions with both models (Tables 1 and 2).

Generally, the stability constants were better, but not substantially better, when estimated by the models based on connectivity indices (mean *S.E.* value is 0.60 and 0.68 $\log K$ units for all $^3\chi^v$ and OS models, respectively, Table 3). For instance, calibration lines for the diethylenetriamines yielded $S.E._{cv}$ values of 0.62 and 0.67 $\log K$ units for the $^3\chi^v$ and OS models, respectively (regr. 1 and 7, Tables 1 and 2), but the prediction of stability constants for the diamine complexes was virtually the same for both models (0.51 and 0.47 $\log K$ units, respectively, Table 3).

Mean			0.60	0.68	0.56

This is also reflected in the basic calibration lines for the $^3\chi^v$ and OS models, which very closely resemble each other (Fig. 3).

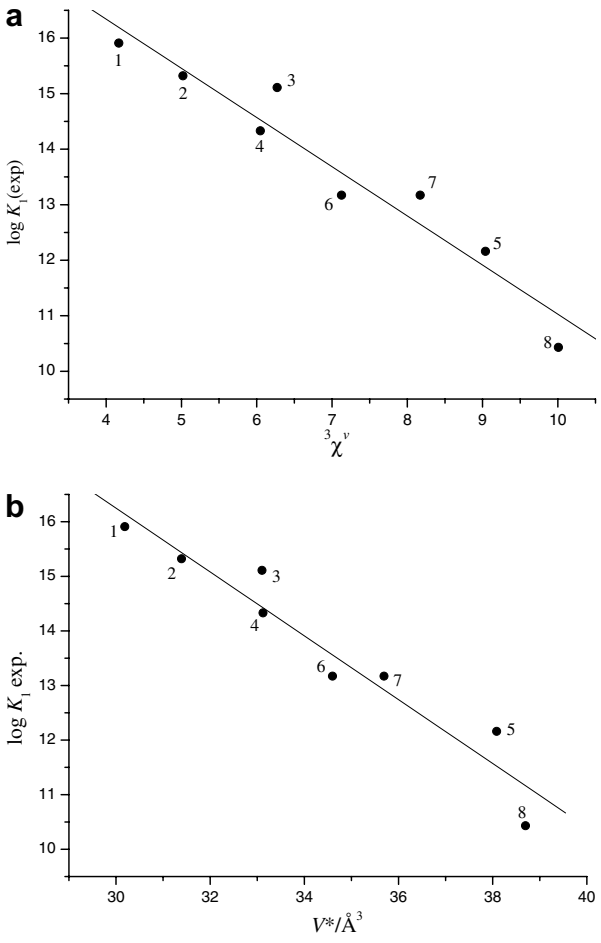

Fig. 3. The calibration lines, (a) regr. 1, Table 1 and (b) regr. 7, Table 2, for the estimation of stability constants ($\log K_1$) of copper(II) complexes with diethylenetriamines, as denoted in Table 5; (a) $\log K_1 = 19.88(71) - 0.885(98)\ ^3\chi^v$, (b) $\log K_1 = 33.8(23) - 0.585(66)\ V^*$.

Grouping of complexes with closely related ligands did not substantially enhance the results (Tables 1 and 2). For the $^3\chi^v$ variable calibration, *N*-methyl substituted diethylenetriamines ($N = 5$) yielded lines of equal quality ($S.E._{cv} = 0.61$ versus $0.62 \log K$ units), but in the case of the OS variable, substantially better results were obtained ($S.E._{cv} = 0.41$ versus $0.67 \log K$ units). It is interesting to note that calibration lines derived only from methyl derivatives were successful in the estimation of stability constants of ethyl derivatives, and vice versa (Regr. 5 and 11, 6 and 12, Table 3). This is in contrast to the simple model, $\log K_1$ versus number of methyl substitutents [51], which is intrinsically incapable of dealing with ethyl derivatives. Moreover, in spite of its very low error for diethylenetriamines ($S.E._{cv} = 0.35 \log K$ units), the model based on the number of methyl substituents yielded a very high error ($S.E. = 0.96 \log K$ units) for the prediction of the stability of copper(II) complexes with another class of ligands, methylated diaminoethanes.

3.2. Mixed copper(II) complexes with amino acids and diethylenetriamines

For the study of mixed complexes, we chose $\log \beta_2$ constants of altogether 20 mixed chelates of diethylenetriamine and its six *N*-methyl and *N*-ethyl derivatives (the same ligands as referred to in Section 3.1, cf. Table 5) with three naturally occurring α-amino acids (glycine, valine and sarcosine, i.e. *N*-methylglycine), Fig. 4 [52]. Two mixed complexes, with 1,1,4,7,7-Me_5dien and Gly or Val, were found, in contrast to the complexes of other ligands, to undergo a color change during the mixed-complex formation, which is attributed to extensive distortion of the coordination polyhedron [52]. In spite of this (quite tentative) argument, our molecular-mechanical calculation did not find any extraordinary distortion of the coordination polyhedron in the molecules of the two complexes. Moreover, the reproduction of experimental constants of these two complexes was in no way exceptional. Despite the finding that the complex with glycine shows, in regression on the OS volume ($R_v = 2.5$ Å), the highest residual ($1.34 \log K$ units), the complex with valine yielded one of the lowest

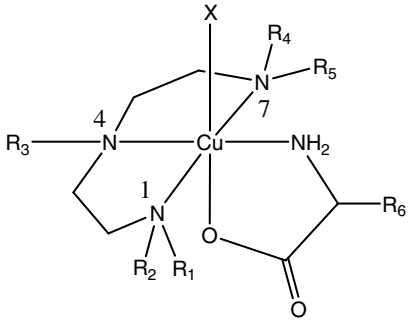

Fig. 4. General structure of mixed copper(II) complexes with amino acids and diethylenetriamines (cf. Table 5). *X* denotes "dummy" atoms needed in molecular-mechanics calculations [57].

values (0.38 log K units). In regressions with respect to $^3\chi^v$, however, residuals for these two chelates (0.73 and 1.01 log K units for the glycine and valine complexes, respectively) are close to the average value of the set ($S.E. = 0.71 \log K$ units). By discarding these two chelates, substantially better results were obtained; $S.E.$ drop from 0.71 to 0.65 and from 0.69 to 0.60 log K units for the $^3\chi^v$ and OS model, respectively (regr. 13 and 16, Table 4). All these findings strongly suggest that the stability constants for these two complexes, as referred to in Ref. [52], were poorly determined, possibly due to formation of MLA complexes of different structures.

Table 4
Statistical parameters for linear regressions of $\log\beta_2$ values[a] of copper(II) mixed complexes with amino acids (Gly, Val, Sar) and diethylenetriamines on the connectivity index $^3\chi^v$ and the OS volumes (V^*), $R_v = 2.5$ Å

Independent variable	Regression no.	Ligands	N	r	$S.E.$	$S.E._{cv}$
$^3\chi^v$	13	mixed complexes	18	0.890	0.65	0.71
	14	mixed complexes (binomial)	18	0.890	0.65	0.74
	15	mixed complexes + all diethylenetriamines	26	0.974	0.61	0.67
V^*	16	mixed complexes	18	0.908	0.60	0.69
	17	mixed complexes (binomial)	18	0.948	0.46	0.53
	18	mixed complexes + all diethylenetriamines	26	0.964	0.71	0.83
	19	mixed complexes + all diethylenetriamines ($R_v = 2.1$ Å)	26	0.940	0.91	1.00

[a] $\beta_2 = [\mathrm{CuLA}][\mathrm{Cu}]^{-1}[\mathrm{L}]^{-1}[\mathrm{A}]^{-1}$; L and A denote the diethylenetriamine and amino acid ligands, respectively.

The regressions of $\log\beta_2$ on $^3\chi^v$ and V^* for the CuLA complexes (Table 4, Fig. 5) do not differ very much, slightly favoring the OS model in respect to all parameters (r, $S.E.$ and $S.E._{cv}$). The values of the $S.E.$ parameter (0.65 and 0.60 log K units for the $^3\chi^v$ and OS models, respectively) are higher than the corresponding parameters for the ML complexes (0.45 and 0.46 log K units, for the $^3\chi^v$ and OS models, respectively; Tables 1 and 2), but not substantially. The same holds true for $S.E._{cv}$ (0.71 versus 0.62 and 0.69 versus 0.67 for the $^3\chi^v$ and OS models, respectively).

To improve the prediction power of our method, we introduced binomial regression of $\log\beta_2$ on both, $^3\chi^v$ and V^* variables (regr. 14 and 17, Table 4). For the regression on the first variable, no improvement was obtained, but the binomial regression of $\log\beta_2$ on V^* yielded substantial improvement in both $S.E.$ (0.46 versus 0.60 log K units) and $S.E._{cv}$ (0.53 versus 0.69 log K units). Regression with the indicator variable, by combining the stability constants of the ML and MLA complexes, yielded better results with $^3\chi^v$ (Fig. 6) than with the V^* variable ($S.E._{cv}$ is 0.67 and 0.83 log K units). The optimal R_v value for the mixed complexes ($R_v = 2.1$ Å) yielded results of lesser quality than the optimal value for ethylenetriaminoethanes ($R_v = 2.5$ Å).

3.3. Estimation of stability constants by combining the models

In our recent paper [50] we proposed a general method for estimation of stability constants by averaging the values obtained by all the reliable methods. To prove the validity of our approach for new systems, we estimated the $\log K_1$ values of all eight copper(II) diethylenetriamine complexes (Table 5) by using various ways of averaging. The mean of the estimated values from the calibration lines on $^3\chi^v$ and V^* (regr. 1 and 7, Tables 1 and 2) yielded a *rms* deviation

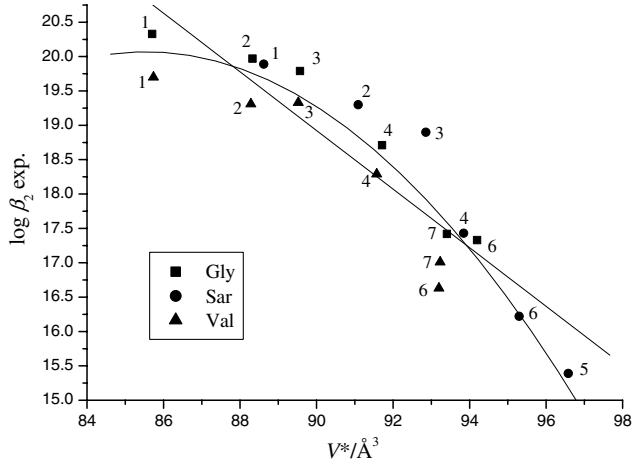

Fig. 5. The calibration models (regr. 16 and 17, Table 4) for the estimation of stability constants ($\log\beta_2$) of the mixed copper(II) complexes with amino acids and ethylenetriaminoethanes ($N = 18$). Ethylenetriaminoethanes are denoted as in Table 5, and amino acids by the graphic code presented in the picture. Regr. 16: $\log\beta_2 = 57.3(45) - 0.426(49)\ V^*$ regr. 17: $\log\beta_2 = -273(100) + 6.9(22)\ V^* - 0.040(12)\ (V^*)^2$.

(*R*,*S*)-2,3-Diaminobutane (**20**)	10.72	10.43	10.22	10.59	10.47	10.37
(*R*,*R*)-2,3-Diaminobutane (**21**)	11.39	10.56	10.22	10.63	10.58	10.33
2-Methyl-1,2-diaminopropane (**22**)	10.53	10.54	10.51	10.71	10.58	10.64
rms		0.44	0.53	0.46	0.43	0.48
Error range		0.04–1.12	0.01–1.09	0.06–1.03	0.05–1.10	0.02–1.10

of 0.63 $\log K$ units, which is even worst than the value of 0.50 $\log K$ units obtained by the less direct method, namely from the calibration lines developed for diamine complexes (regr. 2 and 8, Table 3). Moreover, the indirect method yielded less of a maximum error than that by the direct method (1.09 versus 1.17 $\log K$ units). No improvement of estimation was obtained by calculating the mean or median value of all four estimates (*rms* is 0.56 and 0.57 $\log K$ units, for the mean and median values, respectively), as well as in terms of maximum error (1.13 $\log K$ units). The method of averaging substantially bettered extreme estimates. For instance, the error for the residual of complex **8** dropped by averaging from 1.67 to 1.09–1.13 $\log K$ units, and that of complex **4** from 0.70 to 0.17–0.23 $\log K$ units (regr. 2, Table 2).

The worst overall estimate is attributed to complex **8**, 1,1,7,7-$(Et)_4$dien, assuming it to be 1.09–1.13 $\log K$ units more stable than that found experimentally, and the best predictions were obtained for complex **2**. (By discarding complexes **8** from the set in Table 5, the *rms* error of the mean estimate for all models dropped to 0.43, and the maximum error to 0.74 $\log K$ units.) The poor estimations for complex **3** (in contrast to the fair estimation for complex **4**) could be tentatively attributed to enantioselectivity, because two epimeric complexes, 1(*S*),4(*S*) and 1(*S*),4(*R*), have the same $^3\chi^v$ and virtually the same V^* parameters.

The method of averaging was also checked on copper(II) complexes with diaminoethanes (Table 6). The indirect method of estimation of stability constants (from regr. 1, 3, 4, 7, 9, 10, Tables 1 and 2) proved even better than the direct method, based only on two values (regr. 2 and 8, Table 3). The result was further, but not substantially, improved by averaging the values calculated by all models. However, by discarding the two worst estimates (for ligands **15** and **21**) the *rms* values dropped to 0.25–0.34, and the maximum error to 0.49–0.75 $\log K$ units.

4. Conclusion

Taking into account all the presented estimates, it can be concluded that the method based on topological indices ($^3\chi^v$) leads in many cases to complementary results (cf.

Tables 1, 2, and Fig. 3) and generally to results of the same quality as the more demanding method of overlapping spheres. However, the best results were obtained by combining both methods, which is demonstrated on the copper(II) complexes with diamines and triamines (Tables 5 and 6). Also, it was shown (Table 3) that indirect estimation (from a different class of complexes) leads to results of the same quality as the estimation from the same class of compounds (Tables 1 and 2).

Despite the possible objection that our method for estimation of stability constants yields, in some cases, unacceptable estimates (cf. **15** and **21**, Table 6), the results clearly show that stability constants can be generally reproduced within the error limit of $0.5 \log K$ units, even not knowing any stability constants in the class to which the studied chelate belongs.

Abstract

Three monochlorotitanium complexes Cp′Ti(2,4-^{t}Bu$_2$-6-(CPh$_2$O)C$_6$H$_2$O)Cl [Cp′ = η^5-C$_5$H$_5$ (**2**), η^5-C$_5$(CH$_3$)$_5$ (**3**), η^5-C$_5$H$_2$Ph$_2$CH$_3$ (**4**)] have been synthesized in high yields (>90%) by the reaction of corresponding Cp′TiCl$_3$ with the dilithium salt of ligand 2,4-^{t}Bu$_2$-6-(CPh$_2$OH)C$_6$H$_2$OH (**1**). When activated by [Ph$_3$C]$^+$[B(C$_6$F$_5$)$_4$]$^-$ and Al^{i}Bu$_3$, complexes **2**–**4** exhibit reasonable catalytic activity for ethylene polymerization, producing polyethylenes with moderate molecular weights and melting points. Addition of excess water to complex **2** gave the oxo-bridged complex [Ti(η^5-C$_5$H$_5$)(2,4-^{t}Bu$_2$-6-(CPh$_2$O)C$_6$H$_2$O)]$_2$O (**5**). Complexes **4** and **5** were characterized by single crystal X-ray diffraction.

1. Introduction

Polyolefins are the largest volume synthetic materials used in the world, and have been almost applied in every aspect of our daily lives and productions. One of the most active areas of polyolefins research over the past decades has been the discovery and development of Ziegler–Natta catalysis for polymerization of ethylene and α-olefins. Since Kaminsky et. al. discovered the highly active zirconocene dichloride/methylaluminoxane (MAO) catalytic system for olefin polymerization [1], intensive research work has been focused on developing new Group 4 metallocene catalysts for improving catalytic activities and polymer properties [2,3]. Most of Group 4 metallocene and related complexes for olefin polymerization typically have two or more alkyl (or halide) groups attached to the metal. Examples of precatalysts containing only one such group are scarce [4], although they are active for olefin polymerization and are also of potential interest in the context of single-site olefin polymerization catalysis. Therefore, our current focus is the development of this class of monochlorotitanium complexes, and investigation of the influence of different substituents at cyclopentadienyl (Cp) on their catalytic activity.

In this work, a new bidentate chelating ligand 2,4-^{t}Bu$_2$-6-(CPh$_2$OH)C$_6$H$_2$OH (**1**) was firstly synthesized and introduced into the monochlorotitanium system, based on the following considerations: (i) the phenoxy-alkoxo bidentate ligand comprising the alkoxo group linked with the phenol group has two different active oxygen functionalities in the metalation reaction, therefore increasing the selectivity of forming the desired complexes in the synthetic reaction; (ii) recently, Doherty et al. have reported that introducing phenyl groups on the alkoxo ligand are able to increase catalytic activity of the precatalysts [CpTi{NC$_5$H$_4$(CR$_2$O)-2}Cl$_2$] [5], so here we choose the alkoxo ligand containing phenyl groups. With the new ligand, we successfully obtained a series of monochlorotitanium complexes

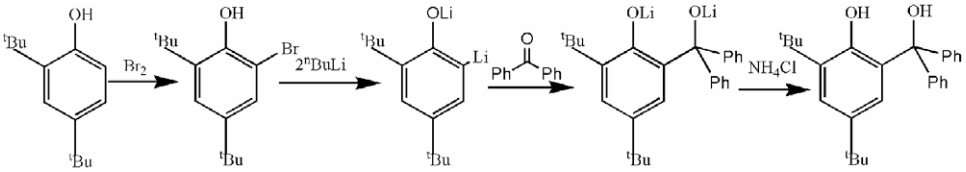
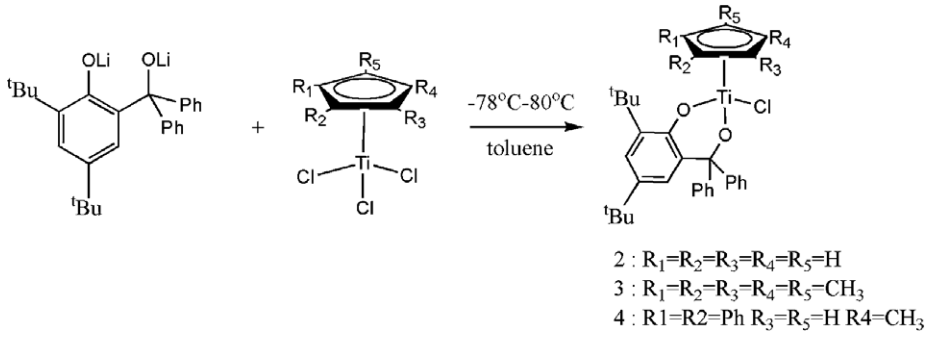
$Cp'Ti(2,4\text{-}^tBu_2\text{-}6\text{-}(CPh_2O)C_6H_2O)Cl$ ($Cp' = \eta^5\text{-}C_5H_5$ (**2**), $\eta^5\text{-}C_5(CH_3)_5$ (**3**), $\eta^5\text{-}C_5H_2Ph_2CH_3$ (**4**)) which have different substituents in cyclopentadienyl in high yield (>90%), and studied their application in ethylene polymerization and their hydrolysis reactions.



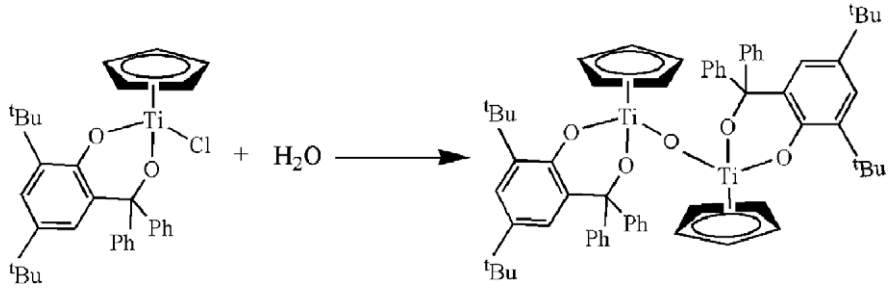
2. Results and discussion

2.1. Synthesis and characterization



The new bidentate ligand **1** was synthesized with 2,4-di-*tert*-butylphenol as the starting material. 2-Bromo-4,6-di-*tert*-butylphenol was easily prepared from the reaction of Br_2 with 2,4-di-*tert*-butylphenol in $CHCl_3/CCl_4$ at 0 °C. The reaction of dilithium phenoxide, obtained by treating 2-bromo-4,6-di-*tert*-butylphenol with 2 equiv. of ^{n}BuLi, with benzophenone in Et_2O at −15 °C, followed by hydrolysis with saturated NH_4Cl produced the ligand **1** in a moderate yield (Scheme 1). The monochlorotitanium complexes **2**–**4** were prepared by reaction of $Cp'TiCl_3$ ($Cp' = \eta^5\text{-}C_5H_5$, $\eta^5\text{-}C_5(CH_3)_5$, $\eta^5\text{-}C_5H_2Ph_2CH_3$) with equimolar amount of dilithium salt of $2,4\text{-}^tBu_2\text{-}6\text{-}(CPh_2OH)C_6H_2OH$ in toluene in high yields (Scheme 2). These complexes were found to be easily hydrolyzed. Addition of excess water to toluene solution of complex **2** gave the oxo-bridged complex $[Ti(\eta^5\text{-}C_5H_5)(2,4\text{-}^tBu_2\text{-}6\text{-}(CPh_2O)C_6H_2O)]_2O$ (**5**) (Scheme 3). However, the same reaction with complexes **3** and **4** caused complete decomposition of both complexes to a mixture of unknown composition in which no organometallic complexes were isolated. All complexes were characterized by elemental analysis and NMR spectroscopy. Complexes **4** and **5** were characterized by single crystal X-ray diffraction.

2.2. Crystal Structures of *4* and *5*



Crystals of complexes **4** and **5** suitable for single-crystal X-ray diffraction study were grown by cooling the saturated solutions of **4** and **5** in mixed CH_2Cl_2/hexane. The ORTEP drawings of the molecule structures are shown in Figs. 1 and 2. The selected bond lengths and angles are summarized in Table 1. The geometry around titanium in **4** can be described as a pseudo-tetrahedral coordination environment, which is defined by a substituted Cp ring

Scheme 1. Synthetic procedure of ligand **1**.

Scheme 2. Synthetic procedure of complexes **2**–**4**.

Scheme 3. Synthetic procedure of complex **5**.

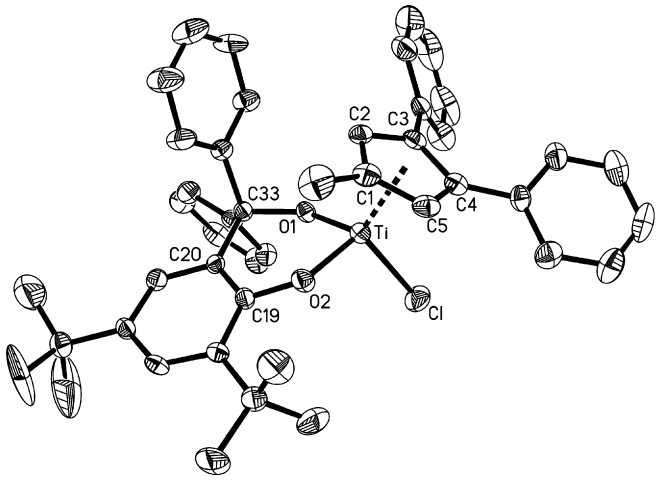


Fig. 1. Molecular structure of complex **4**.

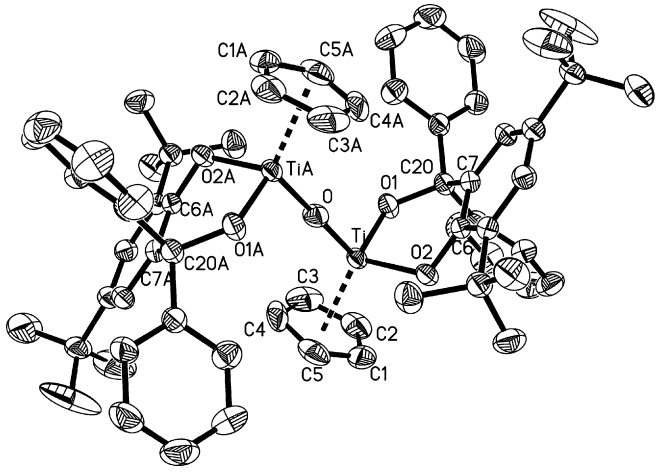

Fig. 2. Molecular structure of complex **5**.

(assuming Cp to occupy one coordination site), a chlorine atom, and two oxygen atoms from the phenol-alkoxo ligand. The phenol-alkoxo ligand adopts a puckered chelate disposition with the typical *boat* conformation. The Ti–C bond lengths range from 2.336 to 2.445 Å, and Ti–C4 (2.445 Å) are longer than those of known Ti–C (Cp ring carbon) bond lengths in similar monochlorotitanium complexes [4]. The C–C bond lengths in the substituted Cp ring range from 1.408 to 1.447 Å, and the C3–C4 (1.447 Å) bond length is the longest among these values, which could be explained by the steric and conjugate effects of the two phenyl groups on the Cp-ring.

The molecular structure of complex **5** consists of two [Ti(η^5-C_5H_5)(2,4-^{t}Bu$_2$-6-(CPh$_2$O)C$_6$H$_2$O)] units linked by Ti–O–Ti bridge. Each titanium is coordinated in a pseudo-tetrahedral geometry by a Cp ring, and three oxygen atoms (one from the oxo-bridge, and the other two from the phenoxy-alkoxo ligand). The C–C bond lengths in the Cp ring are close to the ones observed in know Ti–Cp ring carbon distances. The conformation of the phenol-alkoxo ligand 2,4-^{t}Bu$_2$-6-(CPh$_2$O)C$_6$H$_2$O in **5** is similar to complex **4**, showing a *boat* structure. The Ti–O (alkoxo) bond lengths of 1.778 Å in **4** and 1.803 Å in **5** are shorter than Ti–O (phenoxy) bond lengths of 1.831 Å in **4** and 1.848 Å in **5**, respectively, which may reflect O(pπ)–Ti(dπ) donation of alkoxo groups to the metal [5].

2.3. Ethylene polymerization studies

The experimental results of ethylene polymerization with complexes **2**–**4** as precatalysts were summarized in Table 2. Upon activation with Al^{i}Bu$_3$ and [Ph$_3$C]$^+$-[B(C$_6$F$_5$)$_4$]$^-$, complexes **2**–**4** show good catalytic activity for ethylene polymerization, producing polyethylenes with moderate molecular weights and melting points. For complexes **2**–**4** the catalytic activity increases with the increase of Al/Ti ratio, and reaches the highest catalytic activity with the ratio Al/Ti of 150, while further increasing the Al/Ti ratio results in a decrease in catalytic activity. It is possible that excessive Al^{i}Bu$_3$ would consume so much [Ph$_3$C]$^+$[B(C$_6$F$_5$)$_4$]$^-$ that catalysts could not be efficiently activated [6]. The catalytic activity of all complexes increases with the increase of polymerization temperature, and reaches the highest value at 80 °C. Further increase in the polymerization temperature results in a decrease in the catalytic activity. The order of catalytic activity for ethylene polymerization under similar conditions (see run 2, 7 and 12 in Table 2) is **3** > **4** > **2**, which implies that both the electronic and steric factors of substituents on the cyclopentadienyl group play roles in determining catalytic activity of these complexes.

[d] Determined by DSC at a heating rate of 10 °C min^{-1}.

3. Experimental

3.1. General comments

Reactions with organometallic reagents were carried out under an argon atmosphere (ultra-high purity) using standard Schlenk techniques [7]. Solvents were dried and distilled prior to use [8]. Polymerization grade ethylene was further purified by passage through columns of 10 Å molecular sieves and MnO. Al^{i}Bu$_3$, ^{n}BuLi and $TiCl_4$ were purchased from Aldrich. [η^5-C_5H_5]$TiCl_3$ [9], [η^5-$C_5(CH_3)_5$]$TiCl_3$ [10], [η^5-$C_5H_2Ph_2CH_3$]$TiCl_3$ [11], and $[Ph_3C]^+[B(C_6F_5)_4]^-$ [12] were prepared according to the literature procedures. NMR spectra were measured using a Varian Mercury-300 NMR spectrometer.

3.2. Synthesis of 2,4-^{t}Bu$_2$-6-(CPh_2OH)C_6H_2OH (**1**)

A solution of Br_2 (5.2 ml, 95 mmol) in $CHCl_3$ (20 ml) was added dropwise to a solution of 2,4-Di-*tert*-butylphenol (19.6 g, 95 mmol) in $CHCl_3$ (20 ml) and CCl_4 (20 ml) over 2 h at 0 °C. The mixture was stirred for 1 h at this temperature. The organic phase was separated, and washed six times with water (50 ml), dried with $MgSO_4$. Pure product (24.4 g, 90%) was obtained by column chromatography over silica (hexanes) as white crystals. A solution of 2-bromo-4,6-di-*tert*-butylphenol (5.71 g, 20 mmol) in Et_2O (40 ml) was added dropwise to a solution of ^{n}BuLi (40 mmol) in Et_2O (40 ml) at −15 °C. The mixture was slowly warmed to room temperature and stirred overnight. The solution was cooled to −15 °C, and a solution of benzophenone (7.32 g, 40 mmol) in Et_2O (20 ml) was added dropwise. The reaction mixture was stirred overnight and then quenched with 60 ml of saturated NH_4Cl (aq). The organic layer was separated, dried over $MgSO_4$, filtered, and concentrated by distillation under reduced pressure. Pure product (4.90 g, 64%) was obtained by column chromatography over silica (hexanes) as white needles. *Anal.* Calc. for $C_{27}H_{32}O_2$ (388.54): C, 83.46; H, 8.30. Found: C, 83.38; H, 8.24%. ^{1}H NMR ($CDCl_3$, 300 MHz; 298 K): δ 8.27 (s, 1H, Ph–OH), 7.17–7.35 (m, 11H, Ph), 6.33 (d, 1H, Ph), 3.47 (s, 1H, OH), 1.39 (s, 9H, Ph–^{t}Bu), 1.11 (s, 9H, Ph–^{t}Bu). C^{13} NMR ($CDCl_3$, 75.4 MHz) δ, ppm: 153.4, 145.6, 140.2, 136.9, 129.4, 128.1, 127.8, 127.7, 125.4, 124.0, 85.5, 35.5, 34.5, 31.9, 30.3.

3.3. Synthesis of [Ti(η^5-C_5H_5)(2,4-^{t}Bu$_2$-6-(CPh_2O)C_6H_2O)Cl] (**2**)

A solution of ^{n}BuLi in n-hexane (1.6 M, 1.6 ml) was added to a solution of 2,4-^{t}Bu$_2$-6-(CPh_2OH)C_6H_2OH (1.00 g, 2.57 mmol) in toluene (10 ml) at −78 °C. The reaction mixture was warmed to room temperature and stirred for 1 h to give a solution of 2,4-^{t}Bu$_2$-6-(CPh_2OLi)C_6H_2OLi. This reaction mixture was added to a solution of $CpTiCl_3$ (0.56 g, 2.57 mmol) in toluene (5 ml) at −78 °C, and the reaction mixture was warmed slowly to room temperature and then heated for another 6 h at 80 °C. After allowing the mixture to cool to room temperature, the mixture was filtered, the solution was evaporated in vacuo, and the resultant solid was extracted with *n*-hexane. The extract was concentrated and placed in the freezer. The pale yellow microcrystals were collected. Yield 91% (1.25 g, 2.34 mmol). *Anal.* Calc. for $C_{32}H_{35}ClO_2Ti$ (534.94): C, 71.85; H, 6.59. Found: C, 71.91; H, 6.49%. ^{1}H NMR ($CDCl_3$, 300 MHz; 298 K): δ 7.11–7.39 (m, 11H, Ph), 6.52 (d, 1H, Ph), 6.35 (s, 5H, Cp), 1.36 (s, 9H, Ph–^{t}Bu), 1.18 (s, 9H, Ph–^{t}Bu). C^{13} NMR ($CDCl_3$, 75.4 MHz) δ, ppm: 158.1, 147.6, 146.2, 142.9, 128.6, 128.1, 127.2, 126.5 125.4, 123.3, 118.3, 99.9, 35.3, 34.6, 31.1, 30.7.

3.4. Synthesis of [Ti(η^5-$C_5(CH_3)_5$)(2,4-^{t}Bu$_2$-6-(CPh_2O)C_6H_2O)Cl] (**3**)

Complex **3** was synthesized in the same way as described above for the synthesis of **2** with [η^5-$C_5(CH_3)_5$]$TiCl_3$ (0.74 g, 2.57 mmol) as the starting material. Pure complex **3** was obtained as yellow crystals. Yield 90% (1.40 g, 2.31 mmol). *Anal.* Calc. for $C_{37}H_{45}ClO_2Ti$ (605.07): C, 73.45; H, 7.50. Found: C, 73.37; H, 7.42%. ^{1}H NMR ($CDCl_3$, 300 MHz; 298 K): δ 7.08–7.45 (m, 11H, Ph), 6.48 (d, 1H, Ph), 1.99 (s, 15H, Cp–Me), 1.39 (s, 9H, Ph–^{t}Bu), 1.03 (s, 9H, Ph–^{t}Bu). C^{13} NMR ($CDCl_3$, 75.4 MHz) δ, ppm: 156.1, 146.3, 145.2, 141.6, 128.8, 128.5, 127.4, 126.3, 125.4, 123.6, 118.8, 98.6, 35.3, 34.9, 31.8, 30.1, 12.6.

3.5. Synthesis of [Ti(η^5-$C_5H_2Ph_2CH_3$)(2,4-^{t}Bu$_2$-6-(CPh_2O)C_6H_2O)Cl] (**4**)

Complex **4** was synthesized in the same way as described above for the synthesis of **2** with [η^5-$C_5H_2Ph_2CH_3$] $TiCl_3$

(0.99 g, 2.57 mmol) as the starting material. Pure complex **4** was obtained as yellow crystals. Yield 95% (1.71 g, 2.44 mmol). *Anal.* Calc. for $C_{45}H_{45}ClO_2Ti$ (701.16): C, 77.08; H, 6.47. Found: C, 77.14; H, 7.54%. ^{1}H NMR ($CDCl_3$, 300 MHz; 298 K): δ 7.06–7.46 (m, 21H, Ph), 6.51 (d, 1H, Ph), 6.32 (d, 1H, Cp), 6.19 (d, 1H, Cp), 1.98 (s, Cp–Me), 1.28 (s, 9H, Ph–^{t}Bu), 1.06 (s, 9H, Ph–^{t}Bu). C^{13} NMR ($CDCl_3$, 75.4 MHz) δ, ppm: 158.4, 148.2, 146.6, 143.2, 135.0, 134.2, 133.6, 132.8, 131.3, 129.7, 129.5, 129.4, 129.1, 128.8, 128.6, 128.4, 128.3, 128.2, 128.1, 128.0, 127.9, 127.7, 127.6, 127.4, 123.3, 118.9, 118.2, 99.5, 35.6, 34.5, 31.5, 30.5, 15.5.

3.6. Synthesis of [Ti(η^5-C_5H_5)(2,4-^{t}Bu$_2$-6-(CPh$_2$O)C$_6$H$_2$O)]$_2$O (5)

To a solution of complex **2** (0.60 g, 1.12 mmol) in toluene (20 ml) was added H_2O (0.04 g, 2 mmol) at room temperature. The reaction mixture was stirred for 12 h at room temperature, and the solvent was removed under vacuum. The residue was extracted with **n**-hexane. The extract was concentrated and placed in the freezer. The yellow microcrystals were collected. [Ti(η^5-C_5H_5)(2,4-^{t}Bu$_2$-6-(CPh$_2$O)-C_6H_2O)]$_2$O (**5**): Yield 80% (0.91 g, 0.90 mmol). *Anal.* Calc. for $C_{64}H_{70}O_5Ti_2$ (1014.97): C, 75.73 H, 6.95. Found: C, 75.66; H, 7.01%. ^{1}H NMR ($CDCl_3$, 300 MHz; 298 K): δ 7.06–7.46 (m, 22 H, Ph), 6.51 (d, 2H, Ph), 5.91 (s, 10H, Cp), 1.36 (s, 18H, Ph–^{t}Bu), 1.07 (s, 18H, Ph–^{t}Bu). C^{13} NMR ($CDCl_3$, 75.4 MHz) δ, ppm: 158.8, 148.1, 146.7, 142.1, 129.1, 128.5, 127.7, 126.1, 125.0, 123.1, 118.9, 107.6, 35.1, 34.2, 31.9, 30.2.

3.7. X-ray structure determinations of 4 and 5

Single crystals of complexes **4** and **5** suitable for X-ray structural analysis were obtained from the mixture of CH_2Cl_2/hexane. The data were collected at 293 K on Rigaku R-AXIS RAPID IP diffractometer for complexes **4** and **5** with Mo Kα ($\lambda = 0.71073$ Å). Details of the crystal data, data collections, and structure refinements are summarized in Table 3. Both structures were solved by direct methods [13] and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in idealized position. All calculations were performed using the SHELXTL [14] crystallographic software packages.

3.8. Ethylene polymerization

A dry 250 ml steel autoclave was charged with 50 ml of toluene, thermostated at desired temperature and saturated with ethylene (1.0 bar). The polymerization reaction was started by injection of a mixture of catalyst and Al^{i}Bu$_3$ in toluene (5 ml) and a solution of $[Ph_3C]^+[B(C_6F_5)_4]^-$ in toluene (5 ml) at the same time. The vessel was repressurized to needed pressure with ethylene immediately and the pressure was kept by continuously feeding of ethylene. After 5 min, the polymerization was quenched by injecting acidified methanol [HCl (3M)/methanol = 1:1], and the polymer was collected by filtration, washed with water, methanol, and dried at 60 °C in vacuo to a constant weight.

4. Conclusions

We have synthesized and characterized three new monochlorotitanium complexes based on mono-Cp and phenoxy-alkoxo mixed ligands. These complexes were found to be stable in air, but can be easily hydrolyzed. The reaction of complex **2** with excess water gave the oxo-bridged complex **5**. When activated with $[Ph_3C]^+[B(C_6F_5)_4]^-$ and Al^{i}Bu$_3$, these monochlorotitanium complexes exhibit good catalytic activity for ethylene polymerization and produce moderate molecular weight polyethylene. These new catalysts represent a valuable addition to the limited list of monochlorotitanium ethylene polymerization catalysts.

5. Supplementary material

CCDC 623912 and 623913 contain the supplementary crystallographic data for **4** and **5**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Mononuclear oxomolybdenum(V) complexes with thiosemicarbazonato ligands as condensation products of aldehydes (salicylaldehyde, 2-hydroxynaphthaldehyde) with thiosemicarbazides ($H_2NNHC{:}SNHR$; R = H, CH_3, C_6H_5) were prepared. The $[MoOCl_2HL]$ complexes (HL = thiosemicarbazonato ligand) were characterized by chemical analysis, IR spectroscopy, thermogravimetry and two of them, $[MoOCl_2\{C_6H_4(O)CH{:}NNHC{:}SNHC_6H_5\}]$ and $[MoOCl_2\{C_{10}H_6(O)CH{:}NNHC{:}SNHC_6H_5\}]\cdot CH_3CN$, by single-crystal X-ray structural analysis. In both complexes the MoO^{3+} core is coordinated by a monobasic tridentate ONS thiosemicarbazonato ligand and two chloro ligands. The coordination around the molybdenum atom is a distorted octahedron. $NH_4[MoOCl_4(CH_3CN)]$ and unstable $(C_5H_5NH)_2[MoOCl_5]\cdot CH_2Cl_2$ were isolated from the acetonitrile solution of $(NH_4)_2[MoOCl_5]$ and from the acetonitrile and dichloromethane (1:1) solution of $(C_5H_5NH)_2[MoOCl_5]$, respectively.

Isolation and structural characterization of $NH_4[MoOCl_4(CH_3CN)]$ from the acetonitrile solution suggests the $[MoOCl_4(CH_3CN)]^-$ anion to be the reaction intermediate in the synthesis of molybdenum(V) thiosemicarbazonato complexes.

$(C_5H_5NH)_2[MoOCl_5]\cdot CH_2Cl_2$ is a rare example of a structurally characterized simple oxohalomolybdate(V) with a six-coordinate octahedral $[MoOCl_5]^{2-}$ anion.

Keywords: Oxomolybdenum(V) complexes; Thiosemicarbazone; X-ray crystal structure

1. Introduction

The chemistry of molybdenum is of great interest because its large number of accessible oxidation states offers a wide variety of complexes with diverse coordination numbers and stereochemistries [1]. Molybdenum is important in many biological processes [2,3], for example, it is well known that catalytic reactions of molybdoenzymes involve molybdenum in its +6 and +4 oxidation states. Some studies established that during the process of electron transfer to or from the redox centres, Mo(V) coexists with Mo(VI) and Mo(IV) [4–7]. In spite of the fact that investigations of oxomolybdenum(VI), (V) and

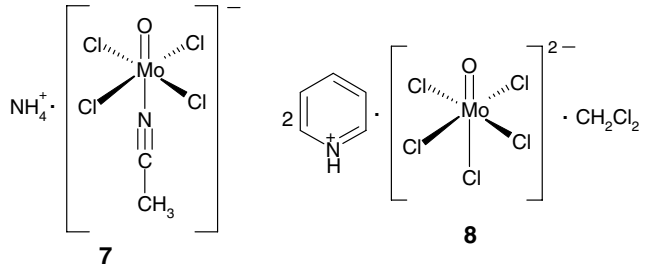
doi:10.1016/j.poly.2007.03.028



(IV) complexes with NS, SS and ONS donor ligands can give useful information on the active sites of molybdoenzymes, there are just a few studies on oxomolybdenum(V) complexes of thiosemicarbazones as NS/ONS donors [8,9].

Our interest in the chemistry of the oxomolybdenum(V) cation ligated to ONS donors has prompted us to pursue the present work. In this paper we report eight new Mo(V) complexes, six of them coordinated by monoanionic tridentate thiosemicarbazonato ligands, {C_6H_4(O)CH:NNHC:SNHR′ or $C_{10}H_6$(O)CH:NNHC:SNHR′; R′ = H, CH_3, C_6H_5}, derived from salicylaldehyde or 2-hydroxynaphthaldehyde. These ligands are of interest because their complexes with the MoO^{3+} core can be of the form MoOL, possessing coordination sites that can be utilized for substrate binding.

We obtained and characterized Mo(V) complexes of the general formula $[MoOCl_2HL]$ {HL = C_6H_4(O)CH:NNHC:SNH_2 (**1**), C_6H_4(O)CH:NNHC:$SNHCH_3$ (**2**), C_6H_4(O)CH:NNHC:$SNHC_6H_5$ (**3**), $C_{10}H_6$(O)CH:NNHC:SNH_2 (**4**), $C_{10}H_6$(O)CH:NNHC:$SNHCH_3$ (**5**)} and $[MoOCl_2HL]\cdot CH_3CN$ {HL = $C_{10}H_6$(O)CH:NNHC:$SNHC_6H_5$} (**6**).

R′	H	CH_3	C_6H_5
Type I	**1**	**2**	**3**
Type II	**4**	**5**	**6** (without cocrystallized CH_3CN)

7 **8**

Complexes **3** and **6** were also structurally characterized by single crystal X-ray diffraction. $NH_4[MoOCl_4(CH_3CN)]$ (**7**) and $[C_5H_5NH]_2[MoOCl_5]\cdot CH_2Cl_2$ (**8**), isolated and structurally characterized during our study, are part of the reaction pathway in the syntheses of the Mo(V) thiosemicarbazonato complexes.

2. Experimental

The starting molybdenum(V) salts $(NH_4)_2[MoOCl_5]$ and $(C_5H_5NH)_2[MoOCl_5]$, and the thiosemicarbazones were prepared as described in the literature [10–12]. Acetonitrile and dichloromethane were dried over phosphorus pentoxide, methanol over magnesium ethoxide.

The Analytical Services Laboratory of the Rudjer Bošković Institute provided C, H, N and S analyses. Molybdenum and chlorine were determined according to the already known methods [13,14] (Table 1). Infrared spectra were recorded in KBr discs with a Spectrum RX I spectrophotometer in the 4500–450 cm^{-1} region. Thermogravimetric analyses were measured on a Mettler TG 50 thermobalance using aluminium crucibles under oxygen atmosphere with a heating rate of 5 °C min^{-1}. In all experiments the temperature ranged from 25 to 600 °C. The results were developed by applying the Metler STAR^e 6.1 program.

2.1. Syntheses of molybdenum(V) complexes

2.1.1. Syntheses of thiosemicarbazonato molybdenum(V) complexes: *1–6*

A mixture of $(NH_4)_2[MoOCl_5]$ (0.20 g, 0.65 mmol) and the appropriate thiosemicarbazone (0.65 mmol) in dry acetonitrile (20 cm^3) (under an argon atmosphere) was heated under reflux for 4–5 h. Brown crystals of $[MoOCl_2HL]$ (**1**–**5**) or $[MoOCl_2HL]\cdot CH_3CN$ (**6**) and white NH_4Cl were deposited during the heating of the reaction mixture. The obtained products were filtered off and washed with cold water. For analytical data and selected spectroscopic data, see Table 1.

Only the crystals of **3** and **6** were suitable for single crystal X-ray structural analyses.

2.1.2. Crystallization of $NH_4[MoOCl_4(CH_3CN)]$ (7) and $(C_5H_5NH)_2[MoOCl_5]\cdot CH_2Cl_2$ (8)

The green crystalline product of **7** was deposited from a solution of $(NH_4)_2[MoOCl_5]$ (0.10 g, 0.33 mmol) in dry acetonitrile (10 cm^3), while unstable green prismatic crystals of **8** deposited from a solution of $(C_5H_5NH)_2[MoOCl_5]$ (0.10 g, 0.22 mmol) in a mixture of dry acetonitrile and dichloromethane (10 cm^3:10 cm^3). The crystalline products were obtained, filtered off and washed with cold acetonitrile (for complex **7**) or a mixture of acetonitrile and dichloromethane (for complex **8**).

2.2. X-ray crystallography

The X-ray data were collected on an Oxford Diffraction Xcalibur 3 CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The crystallographic data are summarized in Table 2. The X-ray data for **8** were measured from a crystal coated with a thin layer of silicone grease (due to its instability). The data reduction (including the absorption correction) was performed using the CRYSALIS software package [15]. Solution, refinement and analysis of the structures were done using the programs integrated in the WINGX system [16]. The structures were solved by direct methods (SHELXS) [17] and refined by the full-matrix least-squares method based on F^2 against

$U_{iso}(H) = 1.2U_{eq}(C)$. For the methyl H-atoms in **6** only the torsion angles were refined, keeping the methyl-group geometry fixed, while the positions of the methyl H-atoms in **7** were kept fixed during refinement. The methyl H-atoms were assigned isotropic thermal parameters, $U_{iso}(H) = 1.5U_{eq}(C)$. Geometrical calculations were performed using PLATON [19]. The figures were made using ORTEP-3 [20].

3. Results and discussion

3.1. Syntheses of the complexes

The brown complexes $[MoOCl_2\{RCH{:}NNHC{:}SNHR'\}]$ [$R = C_6H_4(O)$ or $C_{10}H_6(O)$; $R' = H$, CH_3, C_6H_5] (**1**–**5**) and $[MoOCl_2\{C_{10}H_8(O)CH{:}NNHC{:}SNH{-}C_6H_5\}]\cdot CH_3CN$ (**6**) were obtained by the reaction of $(NH_4)_2[MoOCl_5]$ with a stoichiometric amount of the appropriate thiosemicarbazone (H_2L) in dry acetonitrile, under an argon atmosphere, as follows:

$$(NH_4)_2[MoOCl_5] + H_2L \xrightarrow{CH_3CN} MoOCl_2HL + 2NH_4Cl + HCl$$

All products were washed with cold water to remove ammonium chloride as the by-product of all the synthetic reactions. We were able to isolate brown single crystals of $[MoOCl_2\{C_6H_4(O)CH{:}NNHC{:}SNHC_6H_5\}]$ (**3**) and $[MoOCl_2\{C_{10}H_6(O)CH{:}NNHC{:}SNHC_6H_5\}]\cdot CH_3CN$ (**6**) from the acetonitrile solution at room temperature. In both complexes molybdenum is octahedrally coordinated by the monoprotonated tridentate ONS thiosemicarbazonato ligand, two chloro ligands and one oxygen atom. The thiosemicarbazonato complexes **1**–**6** could not be obtained if $(C_5H_5NH)_2[MoOCl_5]$ was used instead of $(NH_4)_2[MoOCl_5]$ in the synthetic trials.

All the complexes were characterized by IR spectroscopy and selected spectral data are given in Table 1. The IR spectra of complexes **1**–**6** showed characteristic vibrations for this type of compound and the data are in accordance with that in the literature [21].

The ν(OH) band at about 3440 cm^{-1} of the free ligands disappears upon the formation of the complexes and indicates that the deprotonated phenolic oxygen is involved in the molybdenum coordination. The intense bands in the region 1610–1640 cm^{-1}, associated with the C=N stretching frequency of the free ligands, are shifted to 1578 (**1**), 1602 (**2**), 1576 (**3**), 1618 (**4**), 1600 (**5**) and 1601 (**6**) cm^{-1} in the corresponding complexes and indicate coordination of the azomethine nitrogen to the molybdenum [12]. Ligand bands in the region 1515–1540 cm^{-1}, due to ν(C–O), are shifted to 1546 (**1**), 1542 (**2**), 1540 (**3**), 1560 (**4**), 1536 (**5**) and 1538 (**6**) cm^{-1} in the complexes, indicating the coordination of the oxoaryl oxygen. Appearance of a strong single band in the region 940–974 cm^{-1} confirmed the presence of $\nu(Mo{=}O_t)$. The bands at about 815–830 cm^{-1} in the free thiosemicarbazones, assigned as ν(C=S), appear at lower frequencies (760–746 cm^{-1}) in the complexes, suggesting coordination through the sulfur atom.

Isolation and structural characterization of $NH_4[MoOCl_4(CH_3CN)]$ (**7**) from an acetonitrile solution of $(NH_4)_2[MoOCl_5]$ suggests $[MoOCl_4(CH_3CN)]^-$ to be the reaction intermediate in the synthesis of the Mo(V) thiosemicarbazonato complexes. The chloro ligand *trans* to the double bonded oxygen atom in $[MoOCl_5]^{2-}$ is substituted by the acetonitrile solvent molecule, and so crystalline NH_4Cl and the $[MoOCl_4(CH_3CN)]^-$ anion are formed. The same $[MoOCl_4(CH_3CN)]^-$ anion has been found in several oxomolybdates(V), e.g. in $Tl[MoOCl_4(CH_3CN)]$ [22] and $(AsPh_4)_2[(MoOCl_4)_2(CH_3CN)]$ [23]. In the final reaction step, an acetonitrile and two mutually *trans* chloro ligands in $[MoOCl_4(CH_3CN)]^-$ are substituted by a molecule of the monodeprotonated thiosemicarbazone.

The unstable crystals of $(C_5H_5NH)_2[MoOCl_5]\cdot CH_2Cl_2$ (**8**) were obtained from an acetonitrile and dichloromethane (1:1) solution of $(C_5H_5NH)_2[MoOCl_5]$. The crystals desolvate rapidly, particularly upon prolonged exposure to air. Oxohalomolybdates(V) have been extensively studied since 1927 [24–28], however this is a rare example of a structurally characterized simple oxohalomolybdate(V) with a six-coordinated, octahedral $[MoOCl_5]^{2-}$ anion. The X-ray structure analysis of $(C_5H_5NH)_2[MoOCl_5]$ [24–28], prepared by modified literature methods [11,24–28], showed its true identity as $(C_5H_5NH)_5[MoOCl_4(H_2O)]_3Cl_2$. However, our investigation suggests that $[MoOCl_5]^{2-}$ could be one of the anions present in the acidic solution of $(C_5H_5NH)_2[MoOCl_5]$. We could further assume that the solution of $(C_5H_5NH)_2[MoOCl_5]$ in acetonitrile and dichloromethane (1:1) also contains $[MoOCl_4(CH_3CN)]^-$ anions, according to the literature data [24–28]. So, if there are $[MoOCl_4(CH_3CN)]^-$ anions in the acetonitrile solution of $(C_5H_5NH)_2[MoOCl_5]$ and these anions are the postulated reaction intermediate in the synthesis of the Mo(V) thiosemicarbazonato complexes, it is not completely obvious why the thiosemicarbazonato complexes **1**–**6** could not be obtained using this pyridinium salt as the starting material. One of the possible reasons could be the different solubility of the by-product chloride salts in acetonitrile. The low solubility of ammonium chloride in acetonitrile and the ammonium chloride crystals thus formed can act as the driving force for the removal of the chloro ligands from the $[MoOCl_4(CH_3CN)]^-$ intermediate, and the subsequent formation of the Mo(V) thiosemicarbazonato complexes. On the contrary, pyridinium chloride is much more soluble in acetonitrile, so crystals of pyridinium chloride do not occur and the chloride anions stay in the solution or bonded in the starting Mo(V) complex anions.

3.2. Thermal analysis

The thermal behaviour of the molybdenum(V) complexes **1**–**5** is in agreement with our previous findings on thiosemicarbazonato complexes of molybdenum(VI) [29,30]. The TG data of the complexes showed that their

ligands decomposed in the range 196–569 °C (**1**), 245–591 °C (**2**), 241–591 °C (**3**), 191–591 °C (**4**), 217–596 °C (**5**) and 213–588 °C (**6**).

The thermal studies of complexes **6** and **8** reveals two processes:

(1) loss of acetonitrile within the range 25–105 °C for complex **6** and loss of dichloromethane within the range 27–62 °C for complex **8**;
(2) decomposition of complex **6** within the range 213–588 °C and loss of C_5H_5NHCl for complex **8** within the range 228–557 °C.

The TG studies of complex **7** showed that it sublimates at 346 °C.

All experimental values for mass loss on the TG curve are in good agreement with the calculated values.

3.3. Structural studies

3.3.1. Structures of $[MoOCl_2\{C_6H_4(O)\text{-}CH{:}NNHC{:}SNHC_6H_5\}]$ (3) and $[MoOCl_2\{C_{10}H_6(O)\text{-}CH{:}NNHC{:}\ SNHC_6H_5\}]\cdot CH_3CN$ (6)

The molecules found in the crystal structures of **3** and **6** are shown in Figs. 1 and 2, respectively. The structures of the complex molecules in **3** and **6** are very similar and are discussed together. In **6**, complex molecules co-crystallise with molecules of acetonitrile.

In both structures, Mo(V) is coordinated by an oxo group, two chloro ligands and a monodeprotonated tridentate thiosemicarbazonato ligand. The two chloro ligands are mutually in *trans* positions, while the corresponding thiosemicarbazone molecule is meridionally bonded in its thioketo-amino tautomeric form through the thione sulfur (S), imine nitrogen (N1) and the deprotonated phenolic oxygen (O2) atoms, thus forming 5- and 6-membered chelate rings. As indicated by the bond angles (Table 3), the coordination around Mo(V) is a distorted octahedron with the Mo atom displaced from the least-squares plane of Cl1, Cl2, S and O2 atoms towards the oxo group O1 [by 0.35406(18) Å in **3** and by 0.3417(3) Å in **6**]. In both structures the bond lengths Mo = O1, Mo–Cl1 and Mo–Cl2 are similar to those found in other structures with a *trans*-$[Mo^{V}OCl_2]^{+}$ core [31–33]. The two Mo–Cl bond distances in each complex molecule are significantly different. This feature was also found in some other *trans*-$[MoOCl_2]^{+}$ complexes [31–33]. The Mo–S, Mo–N1 and Mo–O2 distances fall in the range of the corresponding bond distances observed for thiosemicarbazonato-*O*,*N*,*S* complexes with a *cis*-$[MoO_2]^{2+}$ core [29,30,34–39].

Each thiosemicarbazonato ligand in **3** and **6** consists of three planar parts: the oxoaryl (salicyl in **3**: C11–C16, C1 and O2; or 2-oxonaphthyl in **6**: C11–C20 and O2), thiosemicarbazonyl (N1, N2, C3, S and N4) and *N*-phenyl (C5–C10) moieties. Dihedral angles between the least-squares planes of the oxoaryl and the thiosemicarbazonyl fragments are 17.46(7)° and 24.22(10)° in **3** and **6**, respectively. The planarity of these two fragments allows a high

[a] Cg is the centroid of the ring C11–C12–C13–C14–C15–C16 (in both **3** and **6**).

degree of π-electron delocalization throughout them (as suggested by the corresponding bond distances; Table 3). Such π-electron delocalisation is also observed in the structures of similar free thiosemicarbazone ligand molecules [29,40–46] as well as in their *cis*-$[MoO_2]^{2+}$ complexes [29,34–39]. The π-electron delocalization is interrupted at the single N4–C5 bond [1.432(3) and 1.434(5) Å] which is, therefore, significantly longer than the (formally) single C3–N4 bond [1.329(3) and 1.331(5) Å]. Consequently, the *N*-phenyl ring is inclined to the thiosemicarbazonyl moiety [44.99(9)° in **3** and 46.97(15)° in **6**].

In **3** the two complex molecules are connected by N2–H2N···Cl1 ($2-x$, $-y$, $1-z$) hydrogen bonds, thus forming a centrosymmetrical $R_2^2(10)$ ring (Fig. 3). There is also a C6–H6···π interaction between the *N*-phenyl ring of one molecule and the salicyl ring of the other member of the centrosymmetrical dimer. Each complex molecule is also a part of a $C_1^1(6)$ chain parallel to the *a* axis formed by N4–H4N···Cl2 ($x-1/2$, $1/2-y$, $1-z$) hydrogen bonds. The salicyl ring of each molecule forms π···π interactions with the *N*-phenyl ring of the neighbouring member in the $C_1^1(6)$ chain. Additionally, the terminal oxygen atom (O1) participates in two weak C–H···O interactions (Table 4).

In **6** each acetonitrile molecule is bound to the complex molecule *via* N2–H2N···N5 and C1–H1··· N5 hydrogen bonds (Fig. 2, Table 4). Also, the acetonitrile C≡N group is involved in π···π interactions with the *N*-phenyl ring of one complex molecule and the naphthyl ring of the other, with which the acetonitrile methyl group additionally forms a C–H···π hydrogen bond. Similarly as in **3**, the complex molecules are connected into $C_1^1(6)$ chains parallel to [1 0 1] by forming N4–H4N···Cl2 ($1/2+x$, $1/2-y$, $1/2+z$) hydrogen bonds (Fig. 4). The naphthyl ring of each molecule exhibits π···π interactions with the *N*-phenyl ring of the neighbouring molecule in the $C_1^1(6)$ chain.

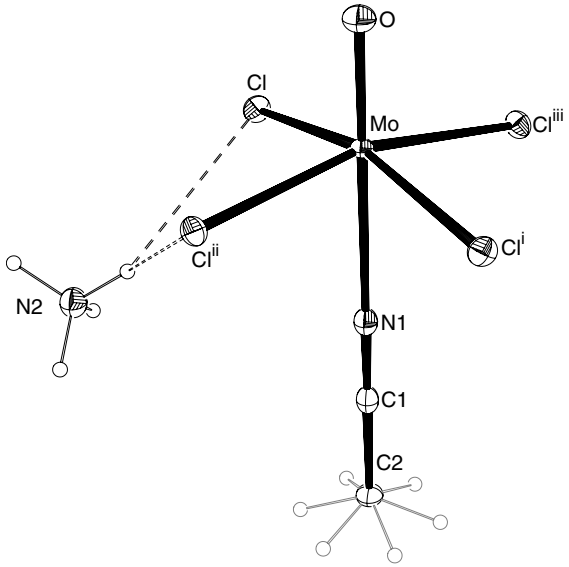

Fig. 5. The structure of $NH_4[MoOCl_4(CH_3CN)]$ (**7**) with the numbering scheme and displacement ellipsoids drawn at the 50% probability level. The methyl group is disordered between the two equally occupied sites (shown in grey). Hydrogen bonds are represented by the dashed lines. Symmetry codes: (i) $-x$, y, $z+1/2$; (ii) x, y, $-z+1/2$; (iii) $-x$, y, z.

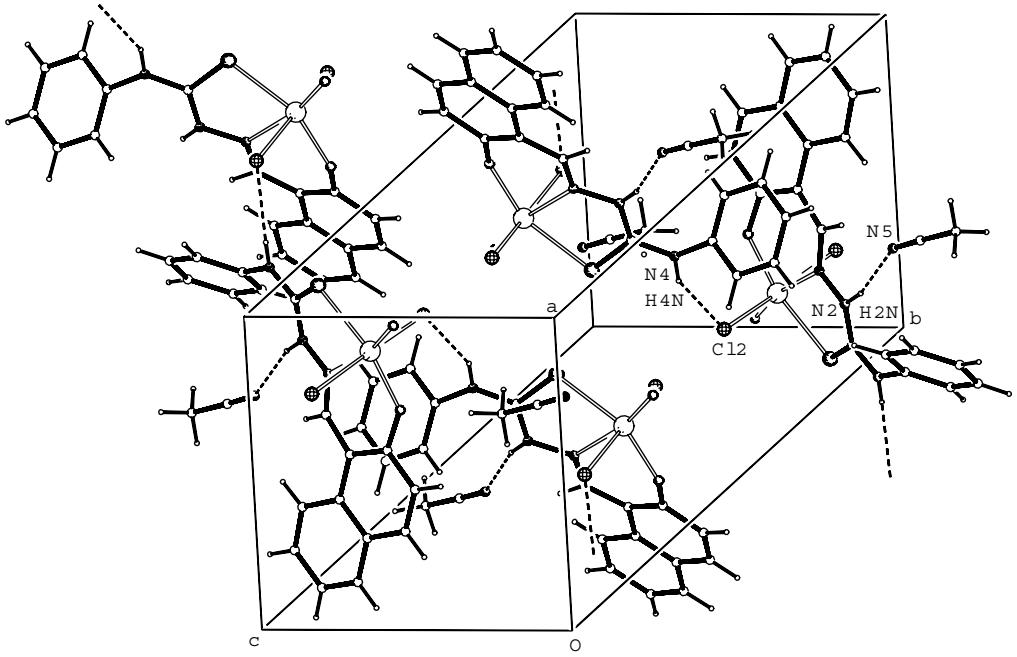

Fig. 4. The crystal packing in **6**. Each acetonitrile molecule is hydrogen-bonded to the complex molecule. Chains of the complex molecules are formed in the [1 0 1] direction.

3.3.2. Structures of $NH_4[MoOCl_4(CH_3CN)]$ (7) and $(C_5H_5NH)_2[MoOCl_5]\cdot CH_2Cl_2$ (8)

In the crystal structure of $NH_4[MoOCl_4(CH_3CN)]$ (Fig. 5) all non-hydrogen atoms lie on a twofold axis (intersection of two mirror planes), except for the chlorine atom which is in a general position. The ammonium hydrogen atoms lie in the mirror planes, while the methyl hydrogen atoms are disordered between the two equally occupied sites mutually related by the twofold axis. In the $[MoOCl_4(CH_3CN)]^-$ anion, Mo(V) is coordinated by four chloride ions, a terminal oxo group and an acetonitrile molecule, which is *trans* to the oxo group. The selected structural parameters for the $[MoOCl_4(CH_3CN)]^-$ anion are given in Table 5. Mo(V) is in a distorted octahedral environment and is displaced by 0.3697(3) Å from the plane of the four chloro ligands towards the oxo group.

Table 5
Selected bond distances (A) and angles (°) for **7**

Mo–O	1.661(3)	Cl–Mo–N1	81.06(1)
Mo–Cl	2.3789(5)	Cl–Mo–Cl^{i}	162.12(2)
Mo–N1	2.397(3)	Cl–Mo–Cl^{ii}	88.25(2)
Cl–Mo–O	98.94(1)	Cl–Mo–Cl^{iii}	88.98(2)
		O–Mo–N1	180

Symmetry codes: (i) $-x$, y, $1/2-z$; (ii) x, y, $1/2-z$; (iii) $-x$, y, z.

The bond distances Mo = O, Mo–Cl and Mo–N1 are similar to those observed in the structure of $[AlCl_2(15\text{-crown-}5)][MoOCl_4(CH_3CN)]\cdot CH_3CN$ [47] – the only other known crystal structure with the $[MoOCl_4(CH_3CN)]^-$ anion. The most striking difference between the geometries of $[MoOCl_4(CH_3CN)]^-$ anions in **7** and in $[AlCl_2(15\text{-crown-}5)][MoOCl_4(CH_3CN)]\cdot CH_3CN$ is the orientation of the bonded acetonitrile molecule: while in **7** the non-hydrogen acetonitrile atoms are in line with the Mo=O bond (as all of them lie on the twofold axis), in the latter structure an axis through the non-hydrogen atoms of the acetonitrile ligand is inclined by ~6° to the Mo=O bond.

In **7**, each NH_4^+ is connected with five $[MoOCl_4(CH_3CN)]^-$ anions (and *vice versa*) by forming a bifurcated N–H···Cl hydrogen bond with each of the four anions and a chelated N–H···O hydrogen bond with the fifth one (Table 4, Fig. 6). In addition, the methyl group of the acetonitrile ligand forms weak C–H···Cl hydrogen bonds with symmetrically related complex molecules.

The primitive orthorhombic unit cell of **8** consists of eight pyridinium cations, four $[MoOCl_5]^{2-}$ anions and four solvate CH_2Cl_2 molecules. Mo, O, Cl1, Cl3 and Cl4 atoms of $[MoOCl_5]^{2-}$ and the CH_2Cl_2 methylene group (C7 and its hydrogen atoms) lie in the mirror plane (Fig. 7). Similarly as in **7**, Mo(V) is in a distorted octahedral environ-

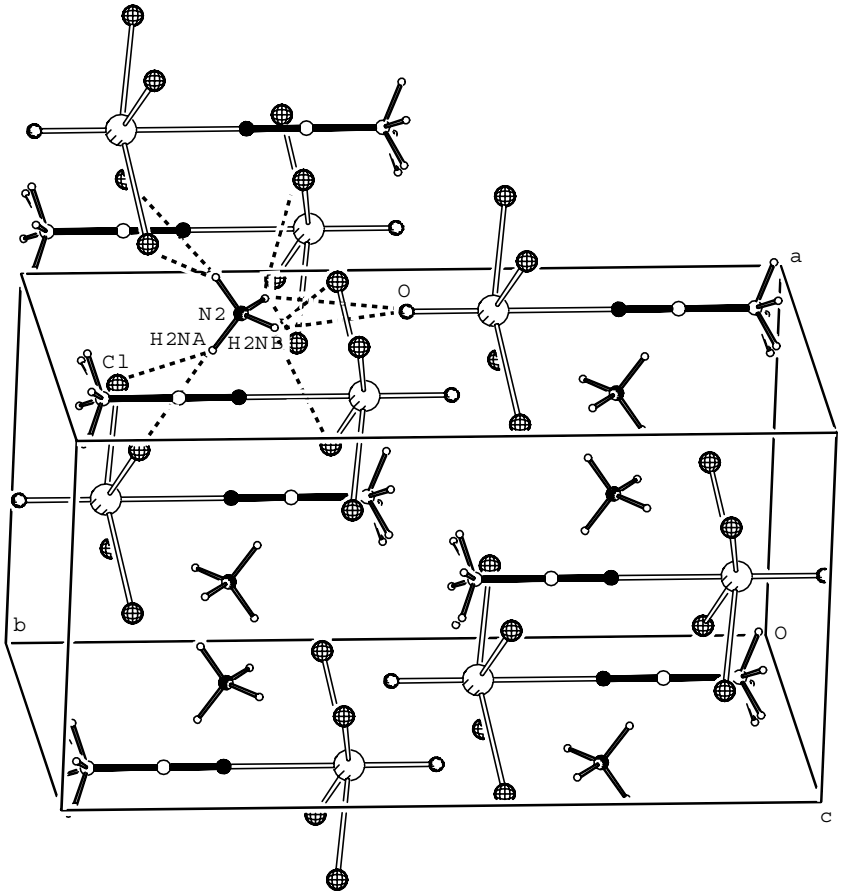

Fig. 6. The crystal packing in **7**. Each NH_4^+ cation is hydrogen-bonded to five $[MoOCl_4(CH_3CN)]^-$ anions.

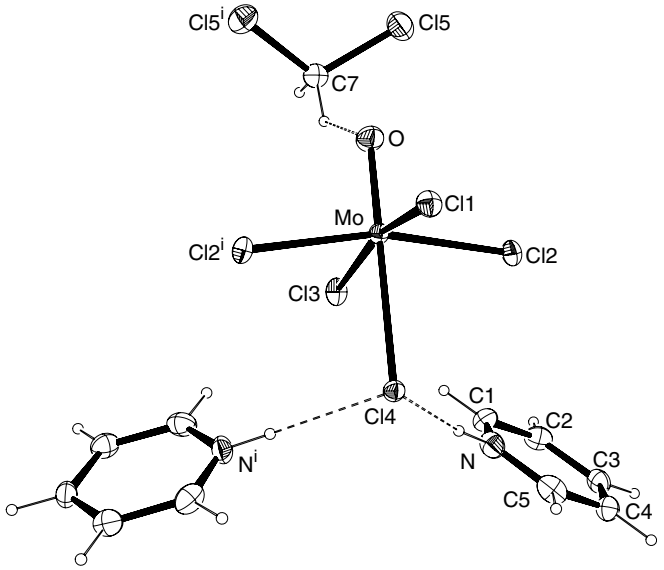

Fig. 7. The structure of $[C_5H_5NH]_2[MoOCl_5]\cdot CH_2Cl_2$ (**8**) with the numbering scheme and displacement ellipsoids drawn at the 50% probability level. Hydrogen bonds are indicated by the dashed lines. Symmetry code: (i) $x, -y+1/2, z$.

ment and is displaced by 0.2937(2) Å from the least-squares plane of four equatorial chloro ligands [Cl_{eq} = Cl1, Cl2, Cl2 ($x, -y+1/2, z$) or Cl3] towards the oxo group. The bond distances Mo = O and Mo–Cl_{eq} are similar to those found in other known structures which contain monomeric $[MoOCl_5]^{2-}$ anions [48–50]. The Mo–Cl4 bond [2.6910(6) Å] – being *trans* to the oxo group – is significantly longer than the Mo–Cl_{eq} bonds [2.3729(6)–2.4147(6) Å]. Selected geometric parameters for $[MoOCl_5]^{2-}$ are given in Table 6.

An exhaustive list of the hydrogen bonding interactions in the crystals of **8** is provided in Table 5. The axial chloro ligand (Cl4) is connected with two pyridinium cations *via* N–H···Cl hydrogen bonds (Fig. 7). These hydrogen-bonding interactions could be the reason why the Mo–Cl4 bond in the structure of **8** is longer than the corresponding bond in the other three known structures with the $[MoOCl_5]^{2-}$ anion {2.564(2) Å in $[HP(Ph)_3]_2[MoOCl_5]$ [48], 2.533(5) Å in $(PyH)_{10}[(Mo_2O_4Cl_4)_2(\mu_4\text{-hda})][MoOCl_5]Cl_2$ ($hda^{2-} = {}^{-}OOC(CH_2)_5COO^{-}$) [49], 2.5569(10) Å and 2.5790(9) Å in $[N(CH_3)_4]_2[MoOCl_5]\cdot CH_3CN$ [50]}. Namely, the chlorine atom *trans* to the oxo group in both $[HP(Ph)_3]_2[MoOCl_5]$ and $(PyH)_{10}[(Mo_2O_4Cl_4)_2(\mu_4\text{-hda})][MoOCl_5]Cl_2$ is involved in hydrogen-bonding interactions, but these are weaker than those in **8**. Additionally, each pyridinium cation forms three weak C–H···Cl interactions with the $[MoOCl_5]^{2-}$ anions. The co-crystallized CH_2Cl_2 molecules are bound to $[MoOCl_5]^{2-}$ anions by weak C–H···O and C–H···Cl hydrogen bonds. The presence of only these weak interactions between the solvent CH_2Cl_2 molecules and the other components of the crystal is the main reason why CH_2Cl_2 readily leaves the crystals of **8** and thus they rapidly disintegrate outside the mother liquor. The crystal packing of **8** is shown in Fig. 8.

Table 6
Selected bond distances (Å) and angles (°) for **8**

Mo–O	1.664(2)	Cl1–Mo–O	96.72(7)
Mo–C11	2.3729(6)	C12–Mo–$C12^{i}$	165.29(2)
Mo–C12	2.3810(5)	C12–Mo–C13	88.15(1)
Mo–C13	2.4147(6)	C12–Mo–C14	82.71(1)

4. Conclusion

In this study it was shown that the thiosemicarbazones, {$C_6H_4(O)CH{:}NNHC{:}SNHR'$ or $C_{10}H_6(O)CH{:}NNHC{:}SNHR'$; R′ = H, CH_3, C_6H_5}, coordinate molybdenum(V) as monomeric tridentate ligands. The complexes **1**–**6** could not be obtained if $[C_5H_5NH]_2[MoOCl_5]$ was used instead of $[NH_4]_2[MoOCl_5]$ as the reaction precursor. One of the reasons could be the different solubility of the by-product chloride salts, ammonium chloride and pyridinium chloride, in acetonitrile. The formed ammonium chloride crystals can act as the driving force for removal of the chloro ligands from the $[MoOCl_4(CH_3CN)]^{-}$ intermediate and the subsequent formation of the mononuclear Mo(V) thiosemicarbazonato complexes. Isolation and characterization of complexes **7** and **8** suggests the presence of different oxohalomolybdate anions in acetonitrile solution, e.g. $[MoOCl_4(CH_3CN)]^{-}$ or $[MoOCl_5]^{2-}$.

Supplementary material

CCDC 625748, 625749, 625750 and 625751 contain the supplementary crystallographic data for **7**, **8**, **3** and **6**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

New bis(phosphinoamine) and bis(phosphinite) derivatives of 2,2′-bipyridine were prepared through a single step reaction of 3,3′-diamino-2,2′-bipyridine or 3,3′-dihydroxy-2,2′-bipyridine with diphenylchlorophosphine, respectively. Their P = E chalcogenides (E = O, S, Se) were also prepared. All the new compounds were characterized by elemental analysis, IR and NMR spectroscopies. The molecular structure of 3,3′-bis(diphenylthiophosphinite)-2,2′-bipyridine was elucidated by single-crystal X-ray crystallography.

1. Introduction

The chemistry of aminophosphines and phosphinites has been intensively explored in recent years [1] and they have been the subject of review papers [2]. These compounds are extremely attractive as potential ligands since various structural modifications are accessible via simple P–N and P–O bond formation [3]. Many modified phosphine ligands and a variety of chiral aminophosphine–phosphinite ligands have important applications in organometallic chemistry and catalysis, giving selective catalysts for hydroformylation, hydrosilylation and asymmetric transfer hydrogenation [2c,4–6]. As the pyridylphosphine and pyridylaminophosphine derivatives can act as bidentate ligands containing both hard (nitrogen) and soft (phosphorus) donor atoms [7], their coordination chemistry has been extensively studied [8]. The catalytic activity of complexes containing phosphinopyridyl ligands has received much attention and these complexes have recently been employed as catalysts for the hydrogenation of ketones, asymmetric transfer hydrosilylation, asymmetric hydroboration, allylic substitution and carbonylation [2b,9]. While much effort has been devoted to the synthesis of chelating bis(phosphines) and their transition metal complexes, similar studies on the analogous bis(phosphinites) are less extensive [10], even though some of their complexes have proved to be efficient catalysts [11].

Herein we report the synthesis of new 3,3′-bis(diphenylphosphinoamine)-2,2′-bipyridine and 3,3′-bis(diphenylphosphinite)-2,2′-bipyridine compounds through a single step reaction of 3,3′-diamino-2,2′-bipyridine and 3,3′-dihydroxy-2,2′-bipyridine with diphenylchlorophosphine, respectively. These compounds could be isolated from the reaction solution and characterized by elemental analysis, IR and NMR spectroscopies. Furthermore, we

report the crystal and molecular structure of one of the products, 3,3′-bis(diphenylthiophosphinite)-2,2′-bipyridine, $(Ph_2P(S)O)_2–C_{10}H_6N_2$, elucidated by single crystal X-ray diffraction.

2. Experimental

2.1. General remarks

All reactions and manipulations were performed under an atmosphere of dry nitrogen or argon using standard Schlenk techniques unless otherwise stated. Ph_2PCl, 2-chloro-3-nitropyridine and 2-bromo-3-hydroxypyridine were purchased from Fluka and were used as received. The starting materials 3,3′-diamino-2,2′-bipyridine [12] and 3,3′-dihydroxy-2,2′-bipyridine [13] were prepared according to previously reported procedures. Solvents were dried and distilled by standard methods prior to use. Spectra were recorded on the following instruments: NMR, Bruker Avance 400 (162.0 MHz for ^{31}P, 400.1 MHz for ^{1}H and 100.6 MHz for ^{13}C); Elemental analysis, Fisons Model EA 1108; IR, Mattson UNICAM-FTIR Model 1000 spectrometer; Melting points, Gallenkamp Model apparatus with open capilleries.

2.2. 3,3′-Bis(diphenylphosphinoamine)-2,2′-bipyridine, $(Ph_2PNH)_2–C_{10}H_6N_2$ (**1**)

Ph_2PC1 (0.59 g, 2.68 mmol) was added slowly to a solution of 3,3′-diamino-2,2′-bipyridine (0.25 g, 1.34 mmol) and Et_3N (0.29 g, 2.87 mmol) in CH_2C1_2 (45 mL) at 0 °C. The resulting yellow solution was stirred for 2 h, and the solvent was removed under reduced pressure. The residue was washed with THF and precipitated triethylamine hydrochloride was removed by filtration through a sintered Schlenk tube. THF was removed under reduced pressure, the product was washed with diethyl ether (2×20 mL) and then dried in vacuo to give a yellow solid. Yield 0.45 g, 61%. m.p. 141–143 °C; *Anal.* Calc. for $C_{34}H_{28}N_4P_2$: C, 73.65; H, 5.05; N, 10.11. Found: C, 73.40; H, 4.83; N, 10.02%. ^{1}H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 7.82 (m, H-4 and H-6, 4H), 7.57 (m, H-10, 8H), 7.36 (m, H-11 and H-12, 12H), 7.10 (dd, H-5, 2H, J 4.8 and 7.6); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$): 148.62 (C-3), 139.30 (C-6), 132.80 (C-12), 132.05 (C-11), 131.40 (C-9), 128.80 (C-10), 128.50 (C-12), 127.30 (C-4), 122.80 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in $CDCl_3$): 26.8 (s). Selected IR (KBr pellet in cm^{-1}): υ(N–H) 3150, υ(CN) 1561, υ(P–N) 913, υ(P–Ph) 1434.

2.3. 3,3′-Bis(diphenyloxophosphinoamine)-2,2′-bipyridine, $(Ph_2P(O)NH)_2–C_{10}H_6N_2$ (**1a**)

A THF solution (15 mL) of **1** (0.05 g, 0.09 mmol) and aqueous H_2O_2 (30% w/w, 0,018 mL) was stirred for 2 h at room temperature. The solution was filtered through Celite to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **1a** as a bright yellow solid which was collected by suction filtration. Yield 0.038 g, 72%. m.p. 197–199 °C; *Anal.* Calc. for $C_{34}H_{28}N_4O_2P_2$: C, 69.62; H, 4.78; N, 9.55. Found: C, 69.48; H, 4.59; N, 9.42%. ^{1}H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 7.94 (m, H-10, 8H), 7.80 (m, H-6 and H-4, 4H), 7.56 (m, H-11 and H-12, 12H), 7.05 (dd, H-5, 2H, J 4.4 and 8.2); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$): 140.20 (C-3), 137.38 (C-6), 132.91 (C-2), 132.21 (C-11), 131.60 (C-9), 128.85 (C-10), 128.36 (C-12), 127.33 (C-4), 123.68 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in $CDCl_3$): 18.0 (s). Selected IR (KBr pellet, in cm^{-1}): υ(N–H) 3209, υ(CN) 1562, υ(P–N) 947, υ(P–Ph) 1437, υ(P═O) 1198.

2.4. 3,3′-Bis(diphenylthiophosphinoamine)-2,2′-bipyridine, $(Ph_2P(S)NH)_2–C_{10}H_6N_2$ (**1b**)

To a solution of **1** (0.05 g, 0.09 mmol) in THF (20 mL), S_8 (0.006 g, 0.18 mmol) was added and this mixture was refluxed for 6 h. The solution was filtered through Celite while hot to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **1b** as a dark yellow solid which was collected by suction filtration. Yield 0.043 g, 77%. m.p. 251–253 °C; *Anal.* Calc. for $C_{34}H_{28}N_4S_2P_2$: C, 66.02; H, 4.53; N, 9.06; S, 10.36. Found: C, 65.88; H, 4.30; N, 8.91; S, 10.16%. ^{1}H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 8.07 (m, H-10, 8H), 7.77 (d, H-6, 2H, J 7.6), 7.67 (d, H-4, 2H, J 4.0), 7.53 (m, H-11 and H-12, 12H), 7.03 (dd, H-5, 2H, J 4.4 and 8.0); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$): 140.12 (C-3), 137.12 (C-6), 132.70 (C-2), 131.94 (C-11), 131.49 (C-9), 128.75 (C-10), 128.12 (C-12), 127.10 (C-4), 123.18 (C-5); ^{31}P NMR(δ in ppm rel. to H_3PO_4 in $CDCl_3$): 49.3 (s). Selected IR (KBr pellet, in cm^{-1}): υ(N–H) 3036, υ(CN) 1551, υ(P–N) 944, υ(P–Ph) 1439, υ(P═S) 649.

2.5. 3,3′-Bis(diphenylselenophosphinoamine)-2,2′-bipyridine $(Ph_2P(Se)NH)_2–C_{10}H_6N_2$ (**1c**)

Grey Se (0.014 g, 0.18 mmol) was added to a solution of **1** (0.05 g, 0.09 mmol) in THF (20 mL) and this mixture was refluxed for 6 h. The solution was filtered through Celite while hot to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **1c** as a white solid which was collected by suction filtration. Yield 0.052 g, 81%. m.p. 233–235 °C; *Anal.* Calc. for $C_{34}H_{28}N_4Se_2P_2$: C, 57.30; H, 3.93; N, 7.87. Found: C, 57.11; H, 3.70; N, 7.64%. ^{1}H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 8.08 (m, H-10, 8H), 7.78 (d, H-6, 2H, J 8.2), 7.67 (d, H-4, 2H, J 4.0), 7.53 (m, H-11 and H-12, 12H), 7.06 (dd, H-5, 2H, J 4.4 and 7.2); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$): 140.20 (C-3), 136.82 (C-6), 132.71 (C-2), 131.83 (C-11), 131.40 (C-9), 128.62 (C-10), 128.09 (C-12), 127.20 (C-4), 123.22 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in

$CDCl_3$): 43.5 (s), $J(^{31}P–^{77}Se) = 756$ Hz. Selected IR (KBr pellet, in cm^{-1}): υ(N–H) 3147, υ(CN) 1551, υ(P–N) 945, υ(P–Ph) 1440, υ(P=Se) 547.

2.6. 3, 3′-Bis(diphenylphosphinite)-2,2′-bipyridine, $(Ph_2PO)_2–C_{10}H_6N_2$ (2)

Ph_2PC1 (0.53 g, 2.66 mmol) was added slowly to a solution of 3,3′-bis(dihydroxy)-2,2′-bipyridine (0.25 g, 1.33 mmol) and Et_3N (0.27 g, 2.67 mmol) in toluene (45 mL) at 0 °C. The resulting white suspension was stirred for 2 h after which time it was filtered through a sintered Schlenk tube to remove precipitated triethylamine hydrochloride. The filtrate was taken to dryness under reduced pressure, leaving a viscous material. The product was washed with diethyl ether (2 × 20 mL) and then dried in vacuo to give **2** as a white viscous material. Yield 0.51 g, 69%. *Anal.* Calc. for $C_{34}H_{26}N_2O_2P_2$: C, 73.38; H, 4.68; N, 5.04. Found: C, 73.21; H, 4.61; N, 4.92%. ^1H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 8.40 (d, H-6, 2H, J 4.2), 8.07 (dd, H-4, 2H, J 1.1 and 8.2), 7.77 (m, H-11, 8H), 7.61 (m, H-12, 4H), 7.43 (m, H-10, 8H), 7.26 (dd, H-5, 2H, J 4.6 and 8.7); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$):149.10 (C-3), 146.71 (C-9), 144.74 (C-6), 133.90 (C-2), 132.83 (C-4), 132.11 (C-12), 130.90 (C-11), 128,32 (C-10), 123.51 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in $CDCl_3$): 116.3 (s). Selected IR (KBr pellet, in cm^{-1}): υ(CN) 1573, υ(P–O) 952, υ(P–Ph) 1445.

2.7. 3,3′-Bis(diphenyloxophosphinite)-2,2′-bipyridine, $(Ph_2P(O)O)_2–C_{10}H_6N_2$ (2a)

A toluene solution (15 mL) of **2** (0.4 g, 0.72 mmol) and aqueous H_2O_2 (30% w/w, 0.18 mL) was stirred for 2 h at room temperature. The solution was filtered through Celite to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **2a** as a white solid which was collected by suction filtration. Yield 0.31 g, 74%. m.p. 125–128 °C; *Anal.* Calc. for $C_{34}H_{26}N_2O_4P_2$: C, 69.39; H, 4.42; N, 4.76. Found: C, 69.18; H, 4.23; N, 4.54%. ^1H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 8.69 (d, H-6, 2H, J 4.3), 8.07 (dd, H-4, 2H, J 1.1 and 8.2), 7.73 (m, H-10, 8H), 7.58 (m, H-12, 4H), 7.45 (m, H-10, 8H), 7.30 (dd, H-5, 2H, J 4.8 and 8.4); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$):156.21 (C-3), 139.90 (C-9), 135.93 (C-6), 132.62 (C-2), 131.91 (C-4), 130.74 (C-12), 128.80 (C-11), 125.92 (C-10), 124.90 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in $CDCl_3$): 22.8 (s). Selected IR (KBr pellet, in cm^{-1}): υ(CN) 1574, υ(P–O) 951, υ(P–Ph) 1445, υ(P=O) 1195.

2.8. 3,3′-Bis(diphenylthiophosphinite)-2,2′-bipyridine, $(Ph_2P(S)O)_2–C_{10}H_6N_2$ (2b)

To a solution of **2** (0.4 g, 0.72 mmol) in toluene (20 mL), S_8 (0.046 g, 1.44 mmol) was added and this mixture was refluxed under argon atmosphere for 6 h. The solution was filtered through Celite while hot to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **2b** as a dark yellow solid which was collected by suction filtration. Yield 0.34 g, 76%. m.p. 155–157 °C; *Anal.* Calc. for $C_{34}H_{26}N_2O_2S_2P_2$: C, 65.81; H, 4.19; N, 4.52; S, 10.32. Found: C, 65.63; H, 4.08; N, 4.36; S, 10.17%. ^1H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 8.40 (d, H-6, 2H, J 4.4), 7.83 (dd, H-4, 2H, J 1.2 and 8.4), 7.71 (m, H-11, 8H), 7.42 (m, H-12, 4H), 7.30 (m, H-10, 8H), 7.22 (dd, H-5, 2H, J 4.4 and 8.4); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$):148.35 (C-3), 146.50 (C-9), 145.05 (C-6), 134.02 (C-2), 133.10 (C-4), 132.05 (C-12), 131.27 (C-11), 128.40 (C-10), 123.68 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in $CDCl_3$): 82.8 (s). Selected IR (KBr pellet, cm^{-1}): υ(CN) 1580, υ(P–O) 913, υ(P–Ph) 1445, υ(P=S) 649.

2.9. 3,3′-Bis(diphenylselenophosphinite)-2,2′-bipyridine, $(Ph_2P(Se)O_2)–C_{10}H_6N_2$ (2c)

Grey Se (0.12 g, 1.52 mmol) was added to a solution of **2** (0.4 g, 0.72 mmol) in toluene (20 mL) and this mixture was refluxed under argon atmosphere for 6 h. The solution was filtered through Celite while hot to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **2c** as a white solid which was collected by suction filtration. Yield 0.36 g, 72%. m.p. 134–136 °C. *Anal.* Calc. for $C_{34}H_{26}N_2O_2Se_2P_2$: C, 57.14; H, 3.64; N, 3.92. Found: C, 56.96; H, 3.54; N, 3.86%. ^1H NMR (δ in ppm rel. to TMS, J Hz, in $CDCl_3$): 8.42 (d, H-6, 2H, J 4.3), 8.08 (dd, H-4, 2H, J 1.1 and 8.1), 7.75 (m, H-11, 8H), 7.43 (m, H-12, 4H), 7.30 (m, H-10, 8H), 7.28 (dd, H-5, 2H, J 4.4 and 8.4); ^{13}C NMR (δ in ppm rel. to TMS in $CDCl_3$):157.20 (C-3), 144.43 (C-9), 134.32 (C-6), 133.31 (C-2), 132.20 (C-4), 131.43 (C-12), 130.74 (C-11), 128.21 (C-10), 124.16 (C-5); ^{31}P NMR (δ in ppm rel. to H_3PO_4 in $CDCl_3$): 86.0 (s), $J(^{31}P–^{77}Se) = 782$ Hz. Selected IR (KBr pellet, in cm^{-1}): υ(CN) 1573, υ(P–O) 887, υ(P–Ph) 1440, υ(P=Se) 547.

3. X-ray diffraction structure analysis

To determine the crystal structure of 3,3′-bis(diphenylthiophosphinite)-2,2′-bipyridine (**2b**), X-ray diffraction data were collected at room temperature with graphite monochromated Cu Kα radiation on an Enraf-Nonius CAD4 diffractometer operating in the $\omega/2\theta$ scan mode. The lattice parameters and their estimated standard deviations were determined from a least-squares refinement of 17 centered reflections in the range of $12.71 \leqslant \theta \leqslant 42.34°$ by using CAD4 Express [14]. Data reduction was carried out using XCAD4 [15]. The structure was solved by the direct method and refined by the full-matrix least-square technique using the programs SHELXS97 and SHELXL97, respectively [16].

Table 1
Crystal data and results of the structure refinement for **2b**

Formula	$[C_{17}H_{13}NOPS]_2$
Formula weight (g/mol)	620.63
Temperature (K)	293(2)
Wavelength (Å)	1.54184
Crystal system, space group	triclinic, $P\bar{1}$
Unit cell dimensions	
a (Å)	9.490(1)
b (Å)	13.031(2)
c (Å)	14.501(5)
α (°)	114.13(2)
β (°)	91.58(2)
γ (°)	106.36(1)
Cell volume (Å^3)/Z	1549.3(6)/2
Calculated density (g/cm^3)	1.33
Crystal colour/shape/size (mm)	colourless/prism/0.3 × 0.3 × 0.2
$F(000)$	644
Absorption coefficient (mm^{-1})	2.805
Absorption correction type	psi-scan
T_{max}/T_{min}	0.571/0.496
θ Range for data collection (°)	3.38–74.24
Limiting indices	$-11 \leqslant h \leqslant 11$, $-16 \leqslant k \leqslant 14$, $0 \leqslant l \leqslant 18$
Reflections collected/Unique	6085/5854 ($R_{int} = 0.0504$)
Refinement method	full-matrix least-squares on F^2
Data/parameters	5854/379
Goodness-of-fit on F^2	1.009
Final R indices ($I > 2\sigma(I)$)	$R_1 = 0.0847$, $wR_2 = 0.2159$
Largest differences in peak and hole (e/Å^3)	0.78, −0.35

Additional material available from the Cambridge Crystallographic Data Center as deposition No.: CCDC 634701 comprises H-atom coordinates, thermal parameters, and remaining bond lengths and angles.

For all non-hydrogen atoms anisotropic displacement parameters were refined and all hydrogen atoms were placed geometrically with $U_{iso}(H) = 1.2\ U_{eq}(C)$. Results of the X-ray structure determination are presented in Tables 1–3 and Figs. 1 and 2.

4. Results and discussion

The reaction of 3,3′-diamino-2,2′-bipyridine with two equivalents of diphenylchlorophosphine in the presence of triethylamine in dichloromethane affords 3,3′-bis(diphenylphosphinoamine)-2,2′-bipyridine, $(Ph_2PNH)_2$-$C_{10}H_6N_2$ (**1**), in moderate yield (Scheme 1), which was isolated from the solution as an analytically pure yellow solid. The IR spectrum of **1** shows characteristic bands at 3150, 1561, 1434 and 913 cm^{-1} due to υ(N–H), υ(CN), υ(P–Ph) and υ(P–N) stretchings, respectively. The ^{31}P–{^1H} NMR spectrum of **1** shows a single resonance at 26.8 ppm, indicating that the two phosphorus atoms in the molecule are equivalent. Treatment of **1** with H_2O_2 solution in THF affords the oxo-derivative, $(Ph_2P(O)NH)_2$–$C_{10}H_6N_2$, (**1a**). The ^{31}P NMR spectrum of **1a** shows also a singlet at 18.0 ppm, which is shielded by 8.8 ppm compared to the parent compound **1**. The reaction of **1** with two equivalents of sulfur or selenium in THF under refluxing conditions yields the corresponding sulfur, $(Ph_2P(S)NH)_2$–$C_{10}H_6N_2$ (**1b**), and selenide analogues, $(Ph_2P(Se)NH)_2$–$C_{10}H_6N_2$ (**1c**), respectively (Scheme 1). The ^{31}P NMR spectrum of **1b** shows a single resonance at 49.3 ppm. The ^{31}P NMR signal of **1c** shows a singlet at 43.5 ppm with selenium satellites, $^1J(^{31}P$–$^{77}Se) = 756$ Hz, as observed in similar tetra coordinated pentavalent phosphine selenides [7b,11a,17].

The reaction of 3,3′-dihydroxy-2,2′-bipyridine with two equivalents of diphenylchlorophosphine in the presence of triethylamine, proceeds in toluene to give 3,3′-bis(diphenylphosphinite)-2,2′-bipyridine, $(Ph_2PO)_2$–$C_{10}H_6N_2$ (**2**) in moderate yield (Scheme 1). The IR spectrum of **2** exhibits characteristic bands at 1573, 1445 and 952 cm^{-1} due to υ(CN), υ(P–Ph) and υ(P–O) stretchings, respectively. The ^{31}P–{^1H} NMR spectrum of **2** shows a single resonance at 116.3 ppm, indicating that the two phosphorus atoms in the molecule are equivalent. The oxo-deriveative, $(Ph_2P(O)O)_2$–$C_{10}H_6N_2$ (**2a**) was easily prepared by

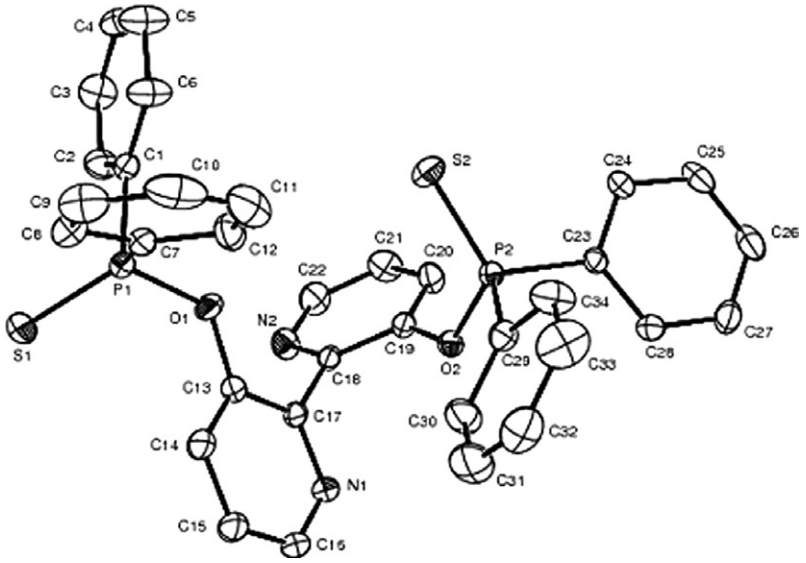

Fig. 1. ORTEP diagram of 3,3′-bis(diphenylthiophosphinite)-2,2′-bipyridine, $(Ph_2P(S)O)_2$–$C_{10}H_6N_2$ (**2b**). H atoms have been omitted for clarity.

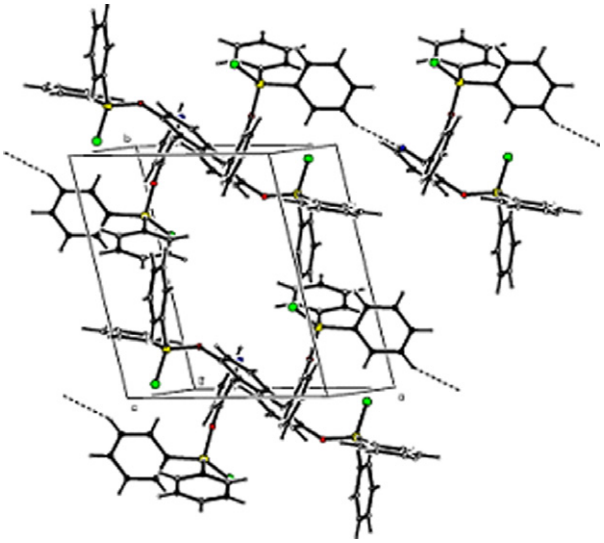

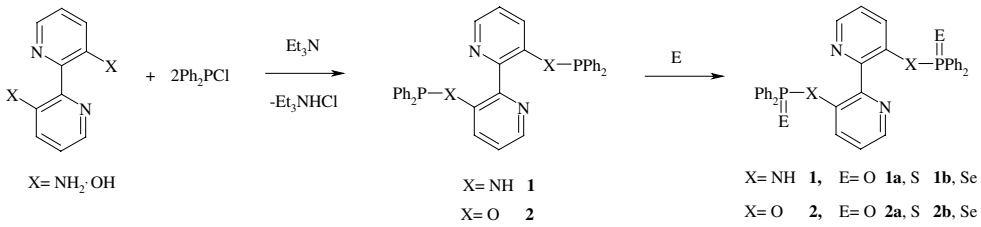

Fig. 2. Packing view of compound **2b**.

addition of excess aqueous hydrogen peroxide in toluene. The ^{31}P NMR spectrum of **2a** shows also a singlet at 22.8 ppm, remarkably shielded (by 93.5 ppm) compared to the parent compound **2**. The sulfur, $(Ph_2P(S)O)_2$–$C_{10}H_6N_2$ (**2b**), and selenide, $(Ph_2P(Se)O)_2$–$C_{10}H_6N_2$ (**2c**), analogues were prepared by addition of elemental sulfur or selenium to **2** in toluene (Scheme 1). ^{31}P–$\{^1H\}$ NMR showed single resonances at 82.6 and 86.0 ppm for the sulfide and selenide, respectively with selenium satellites ^1J (^{31}P–^{77}Se) = 782 Hz, as observed in similar P=Se compounds [7b,11a,17].

The solid-state structure of 3,3′-bis(diphenylthiophosphinite)-2,2′-bipyridine, $(Ph_2P(S)O)_2$–$C_{10}H_6N_2$ (**2b**), was determined by single-crystal X-ray diffraction study. The triclinic unit cell contains two molecules of 3,3′-bis(diphenylthiophosphinite)-2,2′-bipyridine, $[C_{17}H_{13}NOPS]_2$, with symmetry showing an inversion center (Fig. 1).

The coordination around the two phosphorus atoms (P1 and P2) are distorted tetrahedral, involving one S, one O and two C atoms from phenyl rings. In the coordination spheres, the P–S and P–O bond lengths are 1.915(2), 1.908(2) Å, and 1.620(4), 1.621(4) Å, respectively. The P–C coordination bond lengths are in the range of 1.794(6)–1.811(4) Å. The bond angles in the coordination spheres of the P1 and P2 atoms are in the range 99.9(2)–115.86(15)°, the smallest value belonging to the O2–P2–C29 angle and the largest value to the O2–P2–S2 angle. Steric effects could explain these deviations from the ideal tetrahedral angle value of 109.5°. The aromatic rings in the molecule as expected have usual bond lengths and angles. The P1…P2 distance is 5.820 Å.

Scheme 1. The formation of $(Ph_2PNH)_2$–$C_{10}H_6N_2$, $(Ph_2P(E)NH)_2$–$C_{10}H_6N_2$, $(Ph_2PO)_2$–$C_{10}H_6N_2$ and $(Ph_2P(E)O)_2$–$C_{10}H_6N_2$ (E = O, S, Se).

As shown in Fig. 2, there is an intermolecular hydrogen bonding set involving the two molecules: [C11–H11···N2]^{i} H-bond with a C11···N2 distance of 3.434(13) Å and C11–H11···N2 angle of 154° [symmetry code: (i) $1+x$, y, z]. The molecule also has two intramolecular hydrogen bonds between the oxygen atoms and one of the phenyl hydrogen atoms: [C12–H12···O1] and [C30–H30···O2] with C12···O1 and C30···O2 distances of 2.975(10), 2.904(9) Å, respectively and C12–H12···O1 and C30–H30···O2 angles of 107°. In the crystal structure, there exists a weak intermolecular interaction through hydrogen bonding involving some of the rings. The shortest intermolecular contact is observed between Cg(1)–Cg(1)^{ii} [Cg(1) = N(1)–C(16)–C(15)–C(14)–C(13)–C(17)]. The distance Cg(1)–Cg(1)^{ii} is 3.908(4) Å (symmetry code ii: $1-x$, $2-y$, $1-z$).

Abstract

The spectroscopic and magnetic properties, and crystal structure of dark-blue $[Cu(2\text{-pca})_2]_n$ (**1**), (2-pca = pyridine-2-carboxylate ion) are described. The copper(II) ions are in strongly tetragonally distorted octahedral environments. They are sequentially bridged by a double out-of-plane carboxylate bridge, resulting in the formation of an infinite chain (1D). The equatorial Cu–O bonds (1.957(3) Å) are significantly shorter than the axial bonds (2.737(4) Å). The crystal structure of the compound is stabilized by interchain hydrogen bonds of the C–H···O type. The intrachain copper–copper separation is 5.178(3) Å, whereas the shortest interchain copper–copper distance is 7.614(6) Å. The magnetic properties, investigated in the temperature range 1.8–300 K, revealed the occurrence of a weak intrachain antiferromagnetic coupling, $J = -1.04\ cm^{-1}$, and an interchain exchange interaction, $zJ' = 0.34\ cm^{-1}$. The title compound appears to be a polymorphic form of the blue-violet compound (**2**) of identical stoichiometry, the X-ray structure of which was recently reported. Magneto-structural correlations in **1** have been made considering both the carboxylato bridging group and the existence of interchain hydrogen bonds. The structure and magnetic properties of **1** are compared with those of the polymorphic form **2**.

1. Introduction

Copper(II) carboxylates are structurally a very diverse group of coordination compounds due to the various coordination modes of the carboxylato ligands [1,2]. Different coordination modes of the carboxylate group lead to the formation of mononuclear and polynuclear structures. Polynuclear complexes of copper(II) with the carboxylate as a bridging group have been extensively studied in view of their interesting magnetic properties [3–5]. It is well known that the carboxylate group is able to create hydrogen bonds leading to the formation of supramolecular networks which play an important role in the transmission of magnetic interactions. Thus particular interest has also recently been focused on the development of supramolecular structures created by hydrogen bonds of different types in order to study their magnetic behaviour [6]. A variety of ligands containing N or O as donor atoms have been employed for preparation of such systems.

In our recent publications [3–5] the study of copper(II) complexes with the pyridine-2-carboxylate ligand containing N,O-donor atoms has been presented. In this work, we present the spectroscopic and magnetic properties, and the X-ray single-crystal analysis of a dark-blue form of $Cu(2\text{-pca})_2$ (**1**), where 2-pca = pyridine-2-carboxylate. We would like to emphasize that the studied compound **1** is a new crystal form of the Cu(II) compound with pyridine-2-carboxylate, structurally and magnetically characterized by us. Previously we obtained and characterized other polymorphic forms of Cu(pyridine-2-carboxylate)$_2$, namely a blue-violet (**2**) [5] and a violet (**3**) [3] form. Form **3** is a square-planar copper(II) compound in which crystal packing is due to π–π stacking and hydrogen bonds giving rise to a polymeric network arrangement. However, an interesting feature of structure **2** was found, resulting from

doi:10.1016/j.poly.2007.03.024

the fact that the copper(II) ions are sequentially doubly out-of plane bridged by carboxylate groups to form an infinite linear one-dimensional polymeric chain. The structure is stabilized by weak C–H···O hydrogen bonds.

Here, we describe the spectroscopic and magnetic properties of **1** in the light of the structure description. The magnitudes of the exchange interactions between neighbouring copper ions are estimated and discussed in terms of the bond properties, in particular the carboxylate bridge and the characteristics of the hydrogen bonds. In this paper we also compare the structure and magnetic properties of both **1** and **2** forms of Cu(pyridine-2-carboxylate)$_2$.

2. Experimental

2.1. Reagents and physical measurements

The starting materials and solvents for the synthesis were obtained commercially and were used as received. Metal content was determined using a Carl–Zeiss–Jena atomic absorption spectrophotometer. Elemental analyses were carried out using a Perkin–Elmer elemental analyzer 2400CHN. Infrared spectra (100–4000 cm^{-1}) were recorded on a Bruker IFS 113v spectrophotometer using KBr pellets, and solid-state electronic spectra (28000–4000 cm^{-1}) were recorded on a Cary 500 spectrophotometer. The EPR spectra of powder samples were recorded (at 295 and 77 K) on a Bruker ESP 300E spectrometer operating at X-band and equipped with a Bruker NMR gaussmeter ER 035 M and a Hewlett–Packard microwave frequency counter HP 5350B. The EPR parameters were calculated by computer simulation of the experimental spectra of the powder samples using Bruker's WIN-EPR SimFonia Version 1.25.

Magnetization measurements of polycrystalline samples were carried out with a Quantum Design SQUID magnetometer (MPMSXL-5 type) at a magnetic field of 0.5 T over the temperature range 1.8–300 K. Magnetization measurements versus magnetic field (0–5 T) were made at 2 K. The corrections for diamagnetic contributions were based on subtracting the sample-holder signal and estimating the contribution χ_D from Pascal constants [7]. The effective magnetic moments were calculated from $\mu_{eff} = 2.83(\chi_M T)^{1/2}$ using a temperature-independent paramagnetism of 60×10^{-6} cm^3 mol^{-1} for Cu(II).

2.2. X-ray crystallography of Cu(2-pca)$_2$ (*1*)

The crystallographic measurements were performed on a κ-geometry Xcalibur PX automated four-circle diffractometer with graphite–monochromatized Cu Kα radiation. The data for the crystal were collected at 100(2) K using the Oxford Cryosystems cooler. A summary of the conditions for the data collection and the structure refinement parameters are given in Table 1. The data were corrected for Lorentz and polarization effects. An analytical absorption correction was applied. Data collection, cell refinement and data reduction and analysis were carried out with the Xcalibur PX software (Oxford Diffraction Poland): CrysAlis CCD and CrysAlis RED, respectively [8a]. The structure was solved by direct methods using the SHELXS-97 program [8b] and refined by a full-matrix least-squares technique using SHELXL-97 [8c] with anisotropic thermal parameters for non-H atoms. All H atoms were found in difference Fourier maps. In the final refinement cycles, the H atoms were treated as riding atoms, with C–H distances of 0.95 Å, and with U_{iso} values of $1.2U_{eq}$(C). All figures were made using the XP program [8d].

Refinement on	F^2
R ($F_o^2 > 2\sigma(F_o^2)$)	$R_1 = 0.0423$, $wR_2 = 0.1055$
R (all data)	$R_1 = 0.0514$, $wR_2 = 0.1095$
Goodness-of-fit = S	1.068
Weighting parameter a/b	0.0645/0.1022
$\Delta\rho_{max}/\Delta\rho_{min}$ (e Å^{-3})	0.62/−0.52

2.3. Synthesis of Cu(2-pca)$_2$ (*1*)

This compound was obtained from the reaction of $CuCl_2$ with the diethyl 2-pyridylmethylphosphonate ligand according to the procedure described in details elsewhere [3]. In this reaction the ligand undergoes an oxidative P-dealkylation/dephosphorylation reaction according to scheme: R–CH$_2$–P(O)(OEt)$_2$ → R–COOH + OH–P(O)(OEt)$_2$, where R = C$_5$H$_4$N The final products of this process are the complexes of composition Cu(2-pca)$_2$ and Cu(2-pca)Cl (2-pca = pyridine-2-carboxylate). Slow evaporation of the solvent led to the formation of dark-blue crystals of Cu(2-pca)$_2$, suitable for X-ray studies.

Anal. Calc. for $[C_{12}H_8N_2O_4Cu]$: C, 46.54; H, 2.63; N, 8.84; Cu 20.55; Found: C, 46.32; H, 2.58; N, 8.95; Cu, 20.79%.

3. Results and discussion

3.1. Description of the crystal structure of Cu(2-pca)$_2$ (1)

Crystallographic parameters are summarized in Table 1 and selected bond distances and angles are listed in Table 2. The structure of the Cu(2-pca)$_2$ compound with the crystallographic numbering is depicted in Fig. 1.

As can be seen from Fig. 1, the structure is a one-dimensional polymeric chain, $[Cu(2\text{-pca})_2]_n$. Each Cu(II) ion is connected to the two adjacent metal ions by two out-of-plane carboxylate bridges, creating a polymeric chain along the *a* axis in which the Cu···Cu distance within the chain is 5.178(3) Å. This distance is near the range of reported values of ca. 5 Å observed for polyatomic bridges [9]. The copper(II) atom lies on a center of symmetry. The coordination polyhedron around the copper atom can be described as a strongly distorted octahedron. The equatorial plane is composed of the oxygen and nitrogen atoms of the two chelating picolinate ions. The apical positions are occupied by two oxygen atoms [O(2)B and O(2)C] belonging to the carboxylate groups of the adjacent molecules in the chain (symmetry codes are given in Table 2). The Cu–O and Cu–N distances in the basal plane agree well with those found in other square-planar copper(II) complexes [10] but the apical distances are very long [Cu···O(2)B, O(2)C = 2.737(4) Å]. Regarding the carboxylate group, the two C–O distances are different [O(1)–C(1) 1.302(5) Å, O(2)–C(1) 1.236(4) Å], while the Cu(1)–O(1), O(1)A distances are identical (1.957(3) Å). As previously noted, each carboxylate group bridges two copper(II) ions through its O(2) oxygen atom, resulting in non-planarity of the Cu–O–C–O–Cu′ fragment. The bridging pathway is asymmetric not only in its conformation but also with respect to the C–O bond lengths. The crystal structure of compound **1** is stabilized by weak hydrogen bonds of the C–H···O type in accordance with the well-known ability of carboxylate moieties to generate hydrogen-bonding motifs in complexes. The crystal packing is shown in Fig. 2. These hydrogen bond interactions (Table 3), lead to the formation of a 2D sheet structure. The shortest interchain Cu···Cu separations are 7.614(6), 7.751(7), 8.109(6) and 8.316(7) Å (Table 2).

As mentioned earlier, the title compound **1** is a polymorphic form of Cu(pyridine-2-carboxylate)$_2$ (**2**) recently reported [5]. In both complexes the copper(II) ions are sequentially doubly bridged by carboxylate groups to form infinite one-dimensional polymeric chains. Both compounds are of parallel-planar type with out-of-plane carboxylate bridges. This type, characteristic especially for those compounds bridged by chloride ions [11], is unique among the carboxylate bridged chain compounds.

Table 2
Selected interatomic distances (Å) and valence angles (°) in Cu(2-pca)$_2$ (**1**)

Cu(1)–O(1)	1.957(3)	Cu(1)···Cu(1)C, Cu(1)D	5.178(3)
Cu(1)–N(1)	1.960(3)	Cu(1)···Cu(1)E	7.614(6)
Cu(1)–O(2)B	2.737(4)	Cu(1)···Cu(1)F	7.751(7)
O(1)–C(1)	1.302(5)	Cu(1)···Cu(1)G	8.109(6)

Symmetry codes: (A) $-x+1, -y+1, -z+1$; (B) $-x+2, -y+1, -z+1$; (C) $x-1, y, z$; (D) $x+1, y, z$; (E) $x, y-1, z$; (F) $x-1, y+1, z$; (G) $x, y, z-1$; (H) $x-1, y, z+1$.

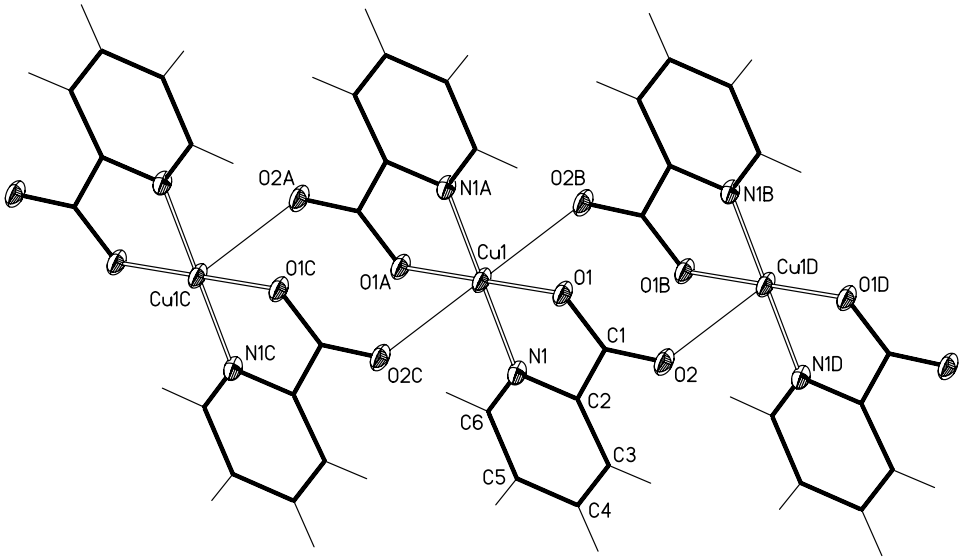

Fig. 1. The fragment of the polymeric $[Cu(2\text{-pca})_2]_n$ chain along the *a*-axis. Symmetry codes are given in Table 2.

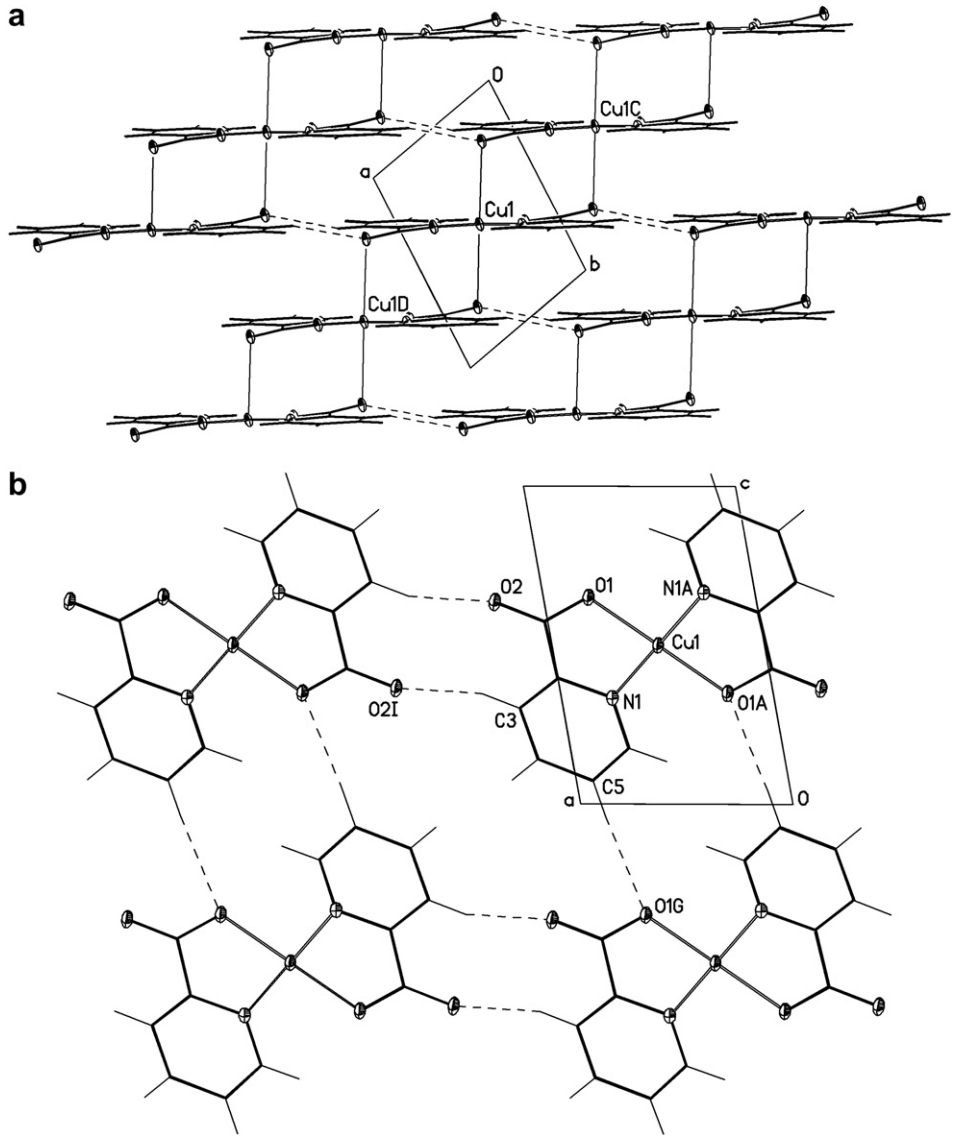

Fig. 2. (a) Crystal packing in (**1**) showing the interchain C–H···O interactions and layers formed by the planar Cu(2-pca)$_2$ fragments from adjacent chains. (b) Arrangement of Cu(2-pca)$_2$ within the 2D layer; viewed down the *b*-axis. Hydrogen contacts of the C–H···O type are shown as dashed lines. Symmetry codes are given in Tables 2 and 3.

Table 3
Geometry of C–H···O hydrogen bonds for Cu(2-pca)$_2$ (**1**)

D–H···A	D–H (Å)	H···A (Å)	D···A (Å)	D–H···A (°)
C(3)–H(3)···O(2)I	0.95	2.43	3.287(5)	150
C(5)–H(5)···O(1)G	0.95	2.49	3.419(5)	166

Symmetry codes: (G) $x, y, z-1$; (I) $-x+3, -y, -z+1$.

Bond distances and related angles in the ligand do not noticeably differ from those reported by us for **2**, in which the ligand, within the mononuclear units, is coordinated in the same fashion as in the complex discussed here.

The 1D chain structures of **1** and **2** are very similar but some subtle structural differences are observed. The Cu(II) atom in **1** lies strictly in the basal plane, whereas the copper(II) atom in **2** is displaced by 0.02 Å. The long out-of-plane Cu–O bond distance is slightly shorter (2.737(4) Å) than that reported in **2** (2.745(8)–2.770(8) Å). The in-plane Cu–O bond distance in **1** is 1.957(3) Å, however in **2** the values are 1.964(8) and 1.944(8) Å. Two related C–O distances in **1** are very different [1.302(5), 1.236(4) Å], whereas in **2** they are similar [1.270(14) and 1.267(14) Å]. The O(1)–C(1)–O(2) angle of 125° in both **1** and **2** is typical [12]. Crystal packing (H-bonds) in **1** and **2** are significantly different. Further structural parameters will be discussed in Section 3.4.

3.2. Spectroscopic properties of Cu(2-pca)$_2$ (*1*)

The earlier infrared spectroscopy study [3] on the title compound **1** indicates bond formation between the copper ion and the nitrogen atom of the pyridine ring and oxygen atom of the carboxylate group, and suggests a *trans* square-planar copper environment. The IR spectrum shows strong

asymmetric and symmetric stretching vibrations of the coordinated carboxylate groups [13], ν_{as}(COO) and ν_s(COO), at 1646 cm^{-1} and 1349 cm^{-1}, respectively with a shoulder at about 1650 cm^{-1}, overlapping with the stretching vibration of ν(C=N) of the pyridine ring. This shoulder may be the result of the presence of hydrogen bonding, as confirmed by the crystal structure [14]. The large difference between the two bands of the carboxylate group ($\Delta\nu = 297\ cm^{-1}$), as discussed earlier [5] for compound **2**, can be viewed as a pseudo-monodentate coordination, which is consistent with the structure.

A broad asymmetric band centered at 16 580 cm^{-1} observed in the ligand-field spectrum is characteristic of a tetragonally distorted octahedral complex [15], consistent with the structural analysis.

The X-band EPR spectrum of a polycrystalline sample of Cu(2-pca)$_2$ is of the axial type with g values of $g_\parallel = 2.22_0$, $g_\perp = 2.07_2$. The $g_\parallel$ value is in agreement with that observed for a CuN_2O_2 chromophore with strong planar and weaker axial bonds [5,16]. The spectra are independent of temperature. The g-values obtained from a computer simulation procedure (powder spectrum simulation) indicate basically a $d(x^2–y^2)$ ground state for Cu(II), as observed for other copper–amino acid complexes [5,17]. The hyperfine structure expected for Cu(II) ions is not observed, suggesting the existence of exchange interactions coupling the paramagnetic ions [18].

It is worth mentioning that the differences in packing arrangements of **1** and **2** are manifested mainly in their d-d spectra. The $g_\parallel$ values for both complexes are similar. However, a small shift of the d–d band observed for **1** (16 580 cm^{-1}) with respect to **2** (16 670 cm^{-1}) is in full agreement with difference in Cu–O axial bond lengths for **1** (2.737(4) Å) and for **2** (2.745(8) and 2.770(8) Å) [5].

3.3. Magnetic properties of Cu(2-pca)$_2$ (*1*)

The magnetic properties of the compound were investigated in the temperature range 1.8–300 K. The magnetic susceptibility results for the polycrystalline sample obey the Curie–Weiss law between 25 and 300 K, $\chi = C/(T-\theta)$, where χ is the magnetic susceptibility per copper atom, the Curie constant $C = Ng^2\beta^2S(S+1)/3k$ and $S = 1/2$. The best fit values of the Curie (C) and Weiss (θ) constants are equal to 0.375 $cm^3\ K\ mol^{-1}$ and −0.63 K, respectively. The negative Weiss constant value suggests a weak antiferromagnetic interaction between the copper(II) ions. The temperature variation of χT is depicted in Fig. 3.

The magnetic moment at room temperature (1.73 μ_B) is typical of the normal value for an uncoupled copper(II) system and might suggest the absence of spin exchange, but the χT value decreases slowly with temperature, lowering from 0.373 $cm^3\ K\ mol^{-1}$ at 300 K to 0.259 $cm^3\ K\ mol^{-1}$ at 1.8 K. This suggests the existence of a weak antiferromagnetic exchange interaction between the copper(II) ions at low temperatures.

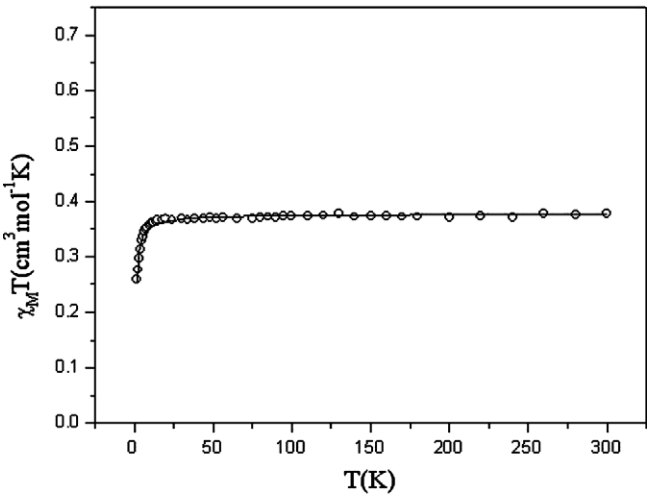

Fig. 3. Plot of $\chi_{Cu}T$ (○) vs. T for Cu(2-pca)$_2$. The solid line represents the best fit of the experimental data to the Bonner–Fisher chain model with the parameters reported in the text.

Taking into account the crystal structure of the compound, the magnetic properties could be explained by the Heisenberg linear-chain model of the magnetic interaction arising from the isotropic model $S = 1/2$ described by the Hamiltonian $H = -2J\sum_{i=1}^{n} S_i \cdot S_{i+1}$. The magnetic data were analyzed using the polynominal expression (1) developed by Hall [19] which describes well the results of Bonner and Fisher [20] on a uniformly-spaced linear chain of spin 1/2, assuming a first-order molecular-field correction (2), namely:

$$\chi_{Cu} = \frac{Ng^2\beta^2}{kT} \times \frac{0.25 + 0.14995x + 0.30094x^2}{1 + 1.9862x + 0.68854x^2 + 6.0626x^3} \quad (1)$$

$$\chi_{Cu}^{corr} = \frac{\chi_{Cu}}{1 - \frac{2zJ'}{N\beta^2 g^2}\chi_{Cu}} \quad (2)$$

where $\chi = |J|/kT$, χ_{cu} is the susceptibility of the copper(II) centers in a Heisenberg chain, zJ' is the interchain exchange, and the other parameters have their usual meanings. In the frame of this model, the best-fit parameters obtained by a least-squares fit are as follows: $J = -1.04\ cm^{-1}$, $zJ' = 0.34\ cm^{-1}$, $g = 2.01$ with $R = 4.22 \times 10^{-5}$, where R is the agreement factor defined as:

$$R = \sqrt{\sum \frac{1}{(\chi_i^{exp})^2}(\chi_i^{exp} - \chi_i^{calc})^2 \Big/ \sum \frac{1}{(\chi_i^{exp})^2}}$$

The molar magnetization M of a powder sample of the studied complex was measured as a function of the applied magnetic field H at 2 K (Fig. 4). No differences were observed between the $M(H)$ curves measured with increasing or decreasing magnetic field.

The magnetization (M Nμ_B) per Cu(II) ion at 5 T tends to 0.88 electrons (Nμ_B) and this value is less than that expected for an isolated Cu(II) ion (1 Nμ_B). The shape of the curve formed by the experimental points does not follow the Brillouin formula for an isolated Cu(II) ion and

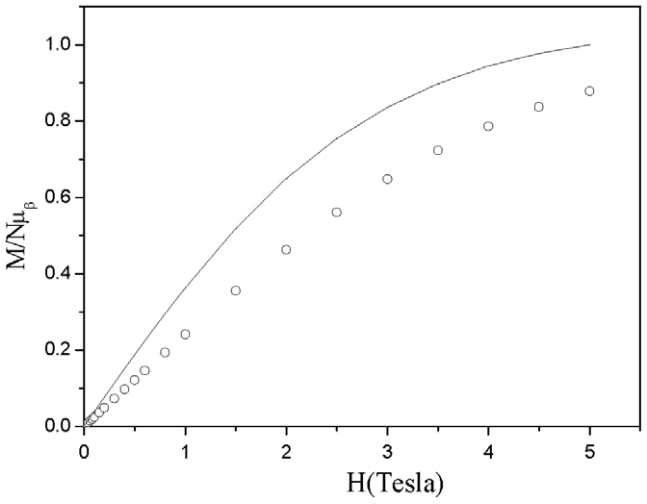

Fig. 4. A plot of the molar magnetization in $N\mu_B$ units, as a function of the magnetic field: experimental (○) and Brillouin curve for isolated Cu(II) ion (solid line).

is indicative of the dominant small antiferromagnetic coupling between the copper(II) ions.

3.4. Magneto-structural correlations

3.4.1. Intermolecular interactions through the carboxylato bridging ligand

The magnetic coupling for all known out-of-plane polynuclear copper(II)compounds is relatively weak, (J from $\sim$0.5 to ~ -1 cm^{-1}) because of the near-orthogonality of the magnetic orbitals, as has been shown for the chloro- [21], carbonato- [22] and oximato- [23] bridged compounds, and for some carboxylato-bridged complexes in which carboxylate bridges from the basal to the axial position exist with a long Cu–O distance (2.28–2.68 Å) [24]. In the case of the interactions in apical-equatorial bond modes, the orthogonality of the magnetic orbitals leads to a coupling which must be weakly antiferromagnetic, zero or weakly ferromagnetic.

For the title compound **1**, similar to compound **2**, the weak antiferromagnetic coupling observed between the copper atoms is expected in light of the same following electronic and structural features: (i) relatively long Cu–O axial distance, (ii) non-planarity of the Cu–O–C–O–Cu′ fragment (an out-of-phase exchange pathway), (iii) each carboxylate bridge involves an axial position on a copper(II) ion, where the spin density of the unpaired electron is very small (in a square-based geometry the unpaired electron is in $d(x^2-y^2)$). All these features observed in **1** and **2** are unfavorable for the propagation of strong interactions.

The magnetic behaviour of both compounds with carboxylate out-of-plane bridges can be explained as a result of the magnetic exchange within the chain through long Cu–O axial bonds (2.737(4) Å for **1** and 2.745(8)–2.770(8) Å for **2** [5]). In **1** and **2** weak antiferromagnetic interactions between the copper(II) ions through the carboxylate bridge have been found (-1.04 and -0.73 cm^{-1}, respectively).

3.4.2. Intermolecular interactions through hydrogen bonds

It is worth mentioning that studies of very weak non-covalent intermolecular interactions, such as hydrogen bonds [25a,25b,25c], stacking of aromatic rings [25d,25e,25f,25g] and intramolecular cation–π interactions [25h,25i,25j,25k], are of fundamental importance not only for further development of inorganic supramolecular chemistry and the prediction of crystal structures [25], but these contacts also generate interesting supramolecular properties, such as electrical, optical and magnetic ones [25c], and play a major role in the function of biological macromolecules. Additionally, metal–amino acid and metal–peptide complexes mimic some of the weak bonds that are important in proteins [25l,25m].

It is well known that the role played by hydrogen bonds in the transmission of magnetic interactions is still not fully understood. For many years, hydrogen bonds have been thought to propagate essentially antiferromagnetic interactions between metal centres [26], but presently, the number of ferromagnetically coupled hydrogen-bonded systems is growing [27].

In order to show which structural features may be responsible for the observed ferromagnetic coupling through hydrogen bonds in the studied compound, we decided to compare the Cu(2-pca)$_2$ complex presented here (**1**) with the other Cu(2-pic)$_2$ (**2**) previously reported by us [5]. The intermolecular hydrogen bonds for complexes **1** and **2** are listed in Tables 3 and 4, and are shown in Figs. 2 and 5.

Despite the usual weak character of the C–H···O hydrogen bonds, different superexchange couplings provided by them in **1** ($zJ' = 0.34$ cm^{-1}) and **2** ($zJ' = -0.06$ cm^{-1}) are observed. Although the ligands are the same in both complexes and the Cu(II) ions are doubly bridged by carboxylate out-of-plane bridges (1D chains), the packing of the two complexes is different. Complexes **1** and **2** form two different supramolecular structures in which the chains are linked by weak C–H···O hydrogen bonds, leading to the formation of 2D sheet structures. Therefore, in these compounds not only are the H-bonding networks different, but also their magnetic properties, generated by the hydro-

Table 4

Symmetry codes: (J) $-x+2$ $-y+1$, $-z$; (K) $-x$, $y+1$, $-z+1$; (L) $x-1$, $-y+1/2$, $z+1/2$; (M) $x+1$, $-y+1/2$, $z-1/2$.

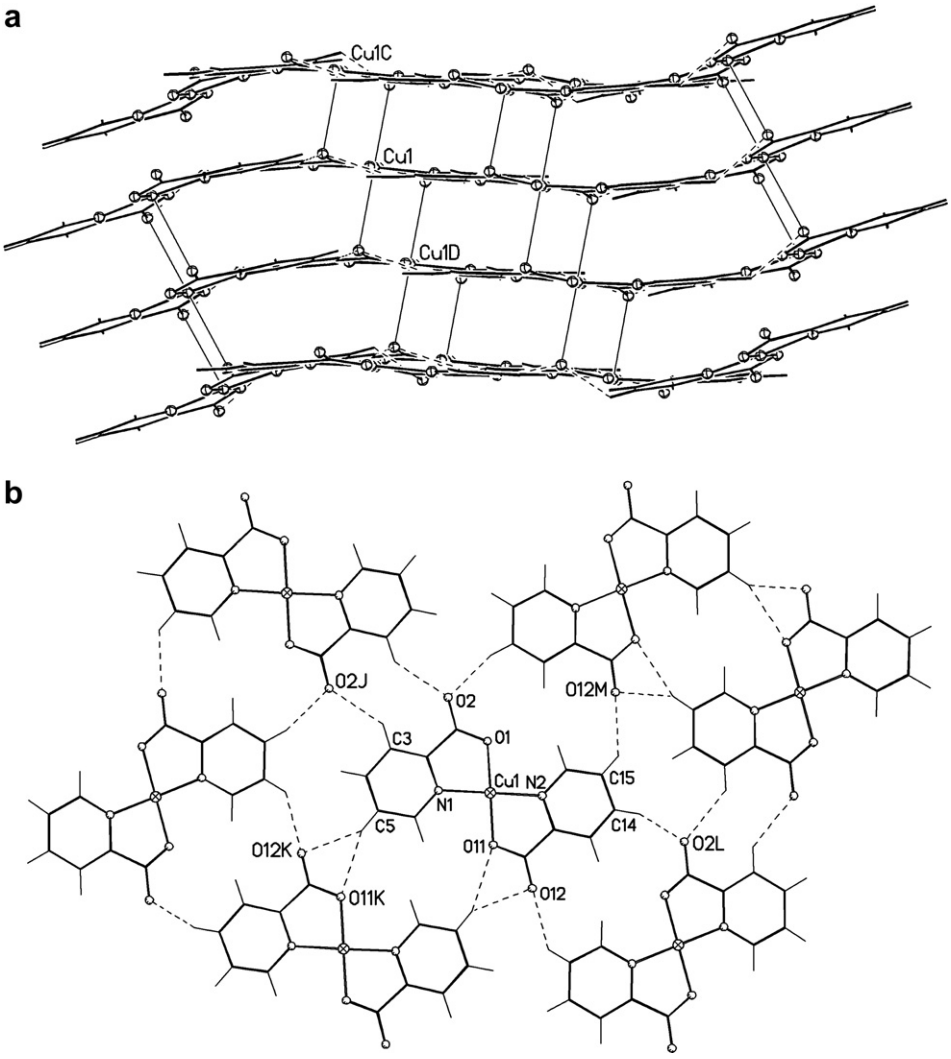

Fig. 5. (a) Crystal packing in (**2**) showing the interchain C–H···O interactions and corrugated layers formed by the planar $Cu(2\text{-pic})_2$ from adjacent chains. (b) Arrangement of $Cu(2\text{-pic})_2$ (**2**) within the 2D layer. Hydrogen contacts of the C–H···O type are shown with dashed lines [5]. Symmetry codes are given in Tables 2 and 4.

gen bonds, differ (F and AF, respectively). The shortest interchain Cu···Cu separations are 7.614(6)–8.316(7) Å in **1** and 7.43 Å and 8.09 Å in **2**.

Inspection of Tables 3 and 4 indicates some structural differences in the intermolecular C–H···O hydrogen bonds in **1** and **2**. It is worth mentioning that the H-bonds can only support very weak magnetic interactions. Because the H(5) atom in **2** is involved in weak hydrogen-bond-like contacts (three-centered bonds with a bifurcated donor) with the H···O distance >2.5 Å, the exchange interactions by these pathways are probably minor. Therefore, its possible contribution to zJ' may be neglected. Thus these contacts in **2** are excluded from the discussion. Both compounds show intermolecular hydrogen bonds with an O···H distance in the range 2.43–2.49 Å in **1** and 2.40–2.49 Å in **2**. The relative bond angles in **1**, C(3)–H(3)···O(2)I and C(5)–H(5)···O(1)G, are 150 and 166°, respectively. The relative bond angles in **2**, C(3)–H(3)···O(2)J, C(15)–H(15)···O(12)M and C(14)–H(14)···O(2)L, are 140°, 137° and 143°, respectively. Hence the binding angles in compound **1** are more favourable for transmission of the magnetic interaction through the H-bonds than those in compound **2**. On the other hand, the relative C···O separations in the C–H···O hydrogen bonds in **2** are shorter (3.161(14)–3.278(14) Å) than those (3.287(5)–3.419(5) Å) in compound **1**. This fact could explain the differences in the sign of the superexchange couplings observed in compounds **1** and **2**, because the stronger coupling corresponds to the shorter hydrogen bonded donor–acceptor distance [28]. Nevertheless, it should be underlined that other subtle structural parameters may also be responsible for the magnetic properties of copper(II) compounds with H-bond systems [25f,29].

4. Concluding remarks

The present study has provided a new example of an out-of-plane double carboxylato-bridged copper(II)

compound which is of the structurally parallel-planar type. This compound (**1**) and those (**2**) also mentioned in this work are polymorphic forms of Cu(pyridine-2-carboxylate)$_2$. The 1D chains structures in both compounds are very similar, but the deviation of the copper(II) ion from the basal plane (0.02 Å) in **2** and the small difference in Cu–O axial bond lengths observed in **1** and **2** seem to be responsible for attainment of different supramolecular structures and magnetic behaviour. Two key factors control the crystal structures of **1** and **2**, the bridging coordination and the interchain hydrogen bonds. These hydrogen bonds generate a supramolecular structure, govern the stability of the complexes and have an important role in the magnetism by a further increase in the dimensionality of the overall structure. From a magnetic point of view, it is interesting that despite the weak character of the C–H···O interactions, this magnetic pathway, as indicated by experimental results, is not negligible. The superexchange coupling provided by them may have weak antiferromagnetic or weak ferromagnetic character, as described in this work. In summary, this paper exhibits that the differences between the crystal packing of **1** and **2** are important and account for the differences in their magnetic properties.

Abstract

Mannich aminomethylation products have been prepared from one-pot template condensation of bis(glycinato)metal(II) complexes, $M(gly)_2$, with formaldehyde and nitromethane. The synthesized compounds were characterized by suitable spectroscopic and analytical methods such as UV–Vis, infrared spectroscopy, elemental analysis, FAB mass, ESR, cyclic voltammetry, TGA and NMR. One of the synthesized products has been used as catalyst in the hydrogen peroxide induced degradation of pyrocatechol violet (PCV) dye.

Keywords: Metal(II) complexes; Mannich aminomethylation; Nitromethane; Pyrocatechol violet dye

1. Introduction

Mannich aminomethylation reaction has become established as a versatile route towards synthesis of macrocyclic compounds and complexes with pendant-arm ligands [1–4]. Compounds such as amides (carboxamides and sulphoxamides), amines, diesters and nitroalkanes have been successfully used as active hydrogen containing compounds in Mannich reactions [5]. The ring-closing agents used have been dominated by nitroalkanes and malonic esters leading to nitro- and carboxylate-appended systems [6,7]. Mannich reaction involving chelated amino acids as an amine component [8,9] or as a substrate with active hydrogen has been studied extensively [10,11]. The products formed were found to vary with the pH and the α-alkyl substituents of the chelated amino acid complexes [12].

Mannich aminomethylation reaction involving nitromethane as the carbon acid has received scant attention during the past several years [13,14]. Herein, we report syntheses of new compounds using nitromethane as the carbon acid.

Use of transition metal complexes as catalysts has been the area of interest for many researchers during the past several decades. Activation of H_2O_2 by transition metal complexes has been widely applied to chemical synthesis, environmental studies, effluent treatment and sterilization processes, etc. [15–21]. This method has gained much importance, particularly in the area of oxidation of dyes [22–24], due to its technical and environmental efficiency compared to the existing physicochemical techniques that are economically unattractive.

Our attempt to use one of the synthesized Mannich aminomethylation products as catalysts in the H_2O_2 induced degradation of pyrocatechol violet dye, taken as a model compound, has been proved to be successful.

2. Experimental

Glycine (AR) and 2-propanol was supplied by SRL laboratories, nitromethane and pyrocatechol violet

{2-[(3,4-dihydroxyphenyl)(3-hydroxy-4-oxocyclohexa-2,5-dien-1-ylidene)methyl] benzenesulphonic acid} (PCV) were obtained from Lancaster chemicals, 37% aqueous formaldehyde (HCHO) solution and AR grade hydrogen peroxide (30%) free of inhibitors were obtained from Merck. The initial concentration of H_2O_2 was determined iodometrically using a standard solution of sodium thiosulphate. Tetra(*n*-butyl)ammonium perchlorate (TBAP) was obtained from Fluka chemicals. Reference chromogen, 2,2′-azino-bis(3-ethylbenz-thiazoline)-6-sulphonate diammonium salt (ABTS), was purchased from Aldrich chemicals. $Cu(gly)_2 \cdot H_2O$, $Ni(gly)_2 \cdot 2H_2O$ and $Zn(gly)_2 \cdot H_2O$ complexes were prepared as reported in literature [25].

2.1. Physical measurements

Electronic spectra of the complexes and kinetic measurements were carried out in a Shimadzu UV-160A spectrophotometer. For the electronic and ESR spectral analysis, solutions of *ca.* 1×10^{-3} M concentration of the complexes were used and the pH was adjusted by the addition of microlitres of HCl and $HClO_4$ solutions respectively. The infrared spectra were recorded on a Thermo Mattson Satellite FT-IR spectrophotometer with KBr discs in the frequency range 4000–450 cm^{-1}. Elemental analyses were carried out using an Elementar Vario EL III Carlo Erba 1108 analyzer available at CDRI, Lucknow. FAB mass spectra were recorded on a Jeol SX-102 analyzer available at CDRI, Lucknow. ESR measurements were done using BRUKER X-Band EMX-EPR spectrometer available at CLRI, Chennai. About 3 mM solutions of the complexes in DMSO were used for ESR measurements at 77 K. Cyclic Voltammograms were obtained on CHI600A electrochemical analyzer. The measurements were carried out under oxygen-free conditions using a three-electrode cell, in which a glassy carbon electrode was the working electrode, a saturated Ag/AgCl electrode was the reference electrode and a platinum wire was used as the auxiliary electrode. TBAP was used as the supporting electrolyte. Thermogravimetric analyses (TGA) for the complexes were obtained using SDT Q600 V8.0 Build 95 thermal analyzer from 30 °C to 700 °C at a heating rate of 10 °C min^{-1} under nitrogen atmosphere. [^{1}H] and [^{13}C] NMR spectra were recorded at ambient temperature with a Jeol GSX 400 MHz and 100 MHz NMR spectrometer respectively in DMSO-d_6 with TMS as internal reference.

2.2. Reactions and syntheses

All reactions of $M(gly)_2$, where M = Cu, Ni and Zn, with formaldehyde and nitromethane were carried out in the absence of base and at pH 9.0, maintained using aqueous Na_2CO_3 solution.

2.2.1. [(1,7-dinitro-3,5-dioxa-9,12-diazabicyclo[5.3.3]-tridecane)diacetato]copper(II) (**1a**)

To a solution of $Cu(gly)_2 \cdot H_2O$ (1 g, 4.35 mmol) in 100 ml of water/methanol mixture (3:1), formaldehyde (5.2 ml, 0.07 mol) and nitromethane (0.9 ml, 17.4 mmol) were added dropwise with constant stirring. After complete addition of formaldehyde and nitromethane, the reaction mixture was stirred continuously at room temperature for another 10 h. The reaction mixture was then concentrated to one-third of its volume (~30 ml) using rotary evaporator and filtered. Purple colored product formed after several days on standing at room temperature was filtered from solution, washed with ethanol and ether and dried over $CaCl_2$. Yield: 1.22 g, 61%. *Anal.* Calc. for $C_{13}H_{18}N_4O_{10}Cu \cdot 0.5H_2O$: C, 33.72; H, 4.10; N, 12.10; O, 36.32. Found: C, 33.54; H, 4.23; N, 11.98; O, 36.94%. λ_{max}(DMSO)/nm 294 (ε/dm^3 mol^{-1} cm^{-1} 3399.9) and 638 (266.4). Selected IR peaks (cm^{-1}): 3415, 3069, 2992, 2967, 2895, 2879, 1661, 1541, 1437, 1361, 1152, 1142, 1110, 1055, 940, 906, 836, 782, 563, 509, 460. Mass (FAB) $m/z = 462$ (M^+).

2.2.2. [N,N′-1,3-(2-nitropropanediyl)bis(oxazolidine-4-carboxylato)]copper(II) (**1b**)

To a solution of $Cu(gly)_2 \cdot H_2O$ (1 g, 4.35 mmol) in 100 ml of water/methanol mixture (3:1), formaldehyde (5.2 ml, 0.07 mol) and nitromethane (0.9 ml, 17.4 mmol) were added dropwise with constant stirring. The pH of the solution was maintained at 9.0 using dilute Na_2CO_3 solution. After complete addition of formaldehyde and nitromethane, the reaction mixture was stirred continuously at room temperature for 24 h. The solution was then concentrated to one-third of its volume (~30 ml) using rotary evaporator and filtered. Blue colored product formed after several days on standing at room temperature was filtered from solution, washed with ethanol and ether and dried over $CaCl_2$. Yield: 0.92 g, 56%. *Anal.* Calc. for $C_{11}H_{15}N_3O_8Cu$: C, 34.68; H, 3.94; N, 11.03; O, 33.63. 1284, 1235, 1195, 1113, 1072, 1015, 1006, 946, 909, 856, 775, 681, 612, 559, 506. No product could be isolated under alkaline condition at pH 9.0.

2.2.4. *[(1,7-dinitro-3,5-dioxa-9,12-diazabicyclo[5.3.3]-tridecane)diacetato]zinc(II) (**3a**)*

To a solution of $Zn(gly)_2 \cdot H_2O$ (1 g, 4.32 mmol) in 100 ml of water/methanol mixture (3:1), formaldehyde (5.2 ml, 0.07 mol) and nitromethane (0.9 ml, 17.3 mmol) were added dropwise with constant stirring. After complete addition of formaldehyde and nitromethane, the reaction mixture was stirred continuously at room temperature for 24 h. The reaction mixture was then concentrated to half its volume (~50 ml) using rotary evaporator and filtered. The product formed on standing at room temperature was filtered from solution, washed with ethanol, ether and dried over $CaCl_2$. Yield: 1.31 g, 62%. *Anal.* Calc. for $C_{13}H_{18}N_4O_{10}Zn \cdot 2H_2O$: C, 31.74; H, 4.47; N, 11.39; O, 39.07. Found: C, 31.88; H, 4.53; N, 11.45; O, 39.39%. $\lambda_{max}(H_2O)$/nm 290 (ε/dm^3 mol^{-1} cm^{-1} 200.3). Selected IR peaks (cm^{-1}): 3581, 3298, 2866, 1651, 1533, 1460, 1394, 1337, 1284, 1239, 1195, 1150, 1113, 1068, 1019, 995, 946, 913, 856, 775, 616, 554, 514. No product was formed under alkaline condition. ^{1}H NMR (DMSO-d_6): δ 4.47 (d, 2H, —O—CH_2—O—), 4.24 (t, 4H, —C—CH_2—O—), 3.80 (d, 2H, —N—CH_2—C—), 3.69 (s, 4H, —N—CH_2—C—), 3.60 (d, 2H, —N—CH_2—C—), 3.13 (d, 4H, —N—CH_2—C=O). ^{13}C NMR (DMSO-d_6): δ 173.80, 86.76, 82.88, 67.74, 63.98, 54.57, 52.63.

2.3. Degradation of PCV using *1a*

To a number of conical flasks of volume 100 cm^3 containing PCV/H_2O_2 mixture in double distilled water, thermostatted in water for 30 min, was added definite quantity of the catalyst and zero time was noted. The solution was stirred continuously using a magnetic stirrer. At regular time intervals, aliquots were withdrawn and the absorbance at $\lambda_{max} = 441$ nm, $\varepsilon = 15{,}766\ l\ mol^{-1}\ cm^{-1}$ was recorded. The absorbance of PCV/H_2O_2 mixture remains constant for several hours in the absence of the catalyst.

3. Results and discussion

Reactions of $M(gly)_2$ complexes with HCHO and nitromethane yielded only a single major product under the experimental conditions mentioned in this work. In the absence of a base (pH 4.5), $Cu(gly)_2$, $Ni(gly)_2$ and $Zn(gly)_2$ gave **1a**, **2a** and **3a** respectively as their products. Under alkaline condition (pH 9.0), reaction of $Cu(gly)_2$ with formaldehyde and nitromethane gave **1b** as the product and no stable product could be isolated from the reactions of $Ni(gly)_2$ and $Zn(gly)_2$ complexes.

All the synthesized complexes are stable in aqueous acid for several hours, as indicated by the electronic spectra of the complexes. The electronic spectra of the complexes do not show any shift in the position of the d–d band on lowering the pH to 2. Increased stability of bridged complexes has been proved from their constant d–d band position in the electronic spectrum at low pH values [26]. Since Cu(II) and Ni(II) complexes reported here also show constant d–d band position even at low pH values, these complexes are proposed to have a bridged structure. The ESR spectra of the copper complexes at low pH values also agree with the electronic spectral observations. The ESR spectra of the complexes **1a** and **1b** show the expected four-line ($2I + 1$) ESR pattern under both neutral and at low pH values as a result of coupling of the electron spin dipole ($s = 1/2$) with the copper nucleus dipole ($I = 3/2$). The ESR spectrum of a representative complex, **1b**, at two different pH values is shown in Fig. 1 which corroborates the results obtained for other bridged complexes [26]. Hence, both electronic and ESR spectral studies suggest a bridged structure for the complexes and the non-formation of species such as $[CuL]^+$ at lower pH values.

The IR spectra of the complexes show strong absorptions at ~1550 cm^{-1} and 1350 cm^{-1} corresponding to —NO_2 stretching vibrations. Peaks corresponding to —NH vibrations are absent in the IR spectrum of all the four complexes confirming the absence of free amino protons in the products. In the complexes **1a**, **2a** and **3a**, the

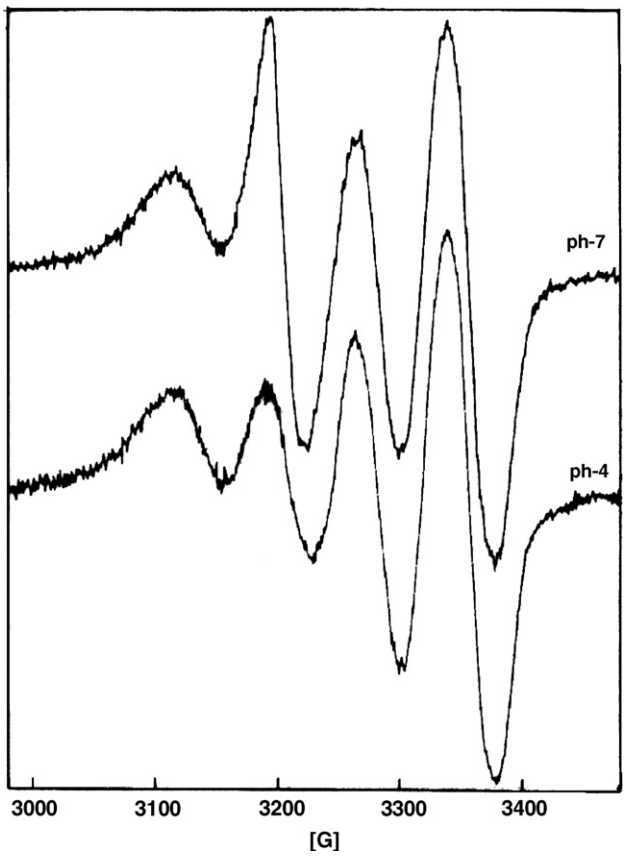

Fig. 1. Room temperature ESR spectra of **1b** at two different pHs at microwave frequency of 9.692 GHz and field modulation frequency of 100 kHz.

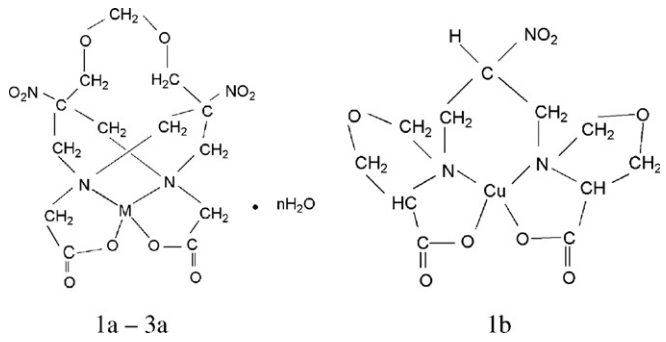

Fig. 2. Proposed structure for the synthesized complexes **1a**: M = Cu, $n = 0.5$; **2a**: M = Ni, $n = 3$; **3a**: M = Zn, $n = 2$.

peak corresponding to ether function, —CH_2—O—CH_2—, is present around ~1113 cm^{-1} and is absent in the spectrum of **1b**. The IR spectrum of **1b** shows three closely spaced peaks between ~1200 cm^{-1} −1050 cm^{-1} corresponding to oxazolidine ring [12c] and is absent in the spectra of all the other products. Based on these observations, the proposed structures of the products are shown in Fig. 2. The proposed structures of the complexes **1a**, **1b**, **2a** and **3a** are further supported by microanalysis and FAB mass spectra of the complexes.

The formation of the products from the reaction of $M(gly)_2$ with NO_2CH_3 and HCHO can be explained as follows:

In the absence of a base, $M(gly)_2$ undergoes Mannich aminomethylation reaction with nitromethane and HCHO replacing all the four amino protons of the chelated amino acid complexes. The remaining acidic protons [6] of the two nitromethane molecules react further with three other molecules of HCHO resulting in the formation of product of the type, **1a**, containing ether type linkages. Product with similar structure has also been isolated by the reaction of $Ni(gly)_2$ with HCHO and ammonia [12d]. Thus, nitromethane also undergoes active condensation reaction with chelated amino acid complexes similar to ammonia.

Under alkaline conditions, nitromethane undergoes Mannich aminomethylation reaction replacing one proton of each amino group of the metal(II) complexes. This is followed by aldol condensation of the HCHO molecules with the α-carbon protons to give oxazolidine ring containing compound **1b**.

Thermal analysis of the complexes shows weight loss at very high temperatures, all above 150 °C. Compound **1a** is found to be the most thermally stable product showing a weight loss of 1.9% above 221 °C and remains stable without any loss in weight up to 700 °C. The other three products show different percentages of weight loss at various higher temperatures. The percentage weight losses for initial decomposition of all the compounds are given in Table 1.

Table 1
Thermal decomposition of the complexes

Complexes	Range of decomposition (°C)	Weight loss (%)
1a	221–254	1.9
1b	300–350	63.4
2a	230–255	38.6
3a	188–235	42.2

3.1. ESR spectroscopy

The ESR spectrum of the product **1a** shows three hyperfine splitting lines and the fourth line is merged with the $g_\perp$ line indicating that the product exists as a monomer in solution and some slight rhombic character appears to be present. Because of the poor resolution of the ESR spectrum, computer simulation was not attempted. The spectral parameters indicate approximately square planar co-ordination around the copper(II) ion. Fig. 3a shows the ESR spectrum of the complex **1a** with $g_\parallel = 2.32$, $g_\perp = 2.06$, $A_\parallel = 175.5 \times 10^{-4}$ cm^{-1}. In the ESR spectrum of **1b**, the lines marked with arrows correspond to the triplet state ESR lines arising from dimerization of the Cu complex. We have arrived at this conclusion based on the discussion in an earlier report [27] where, a clear indication of dimeriza-

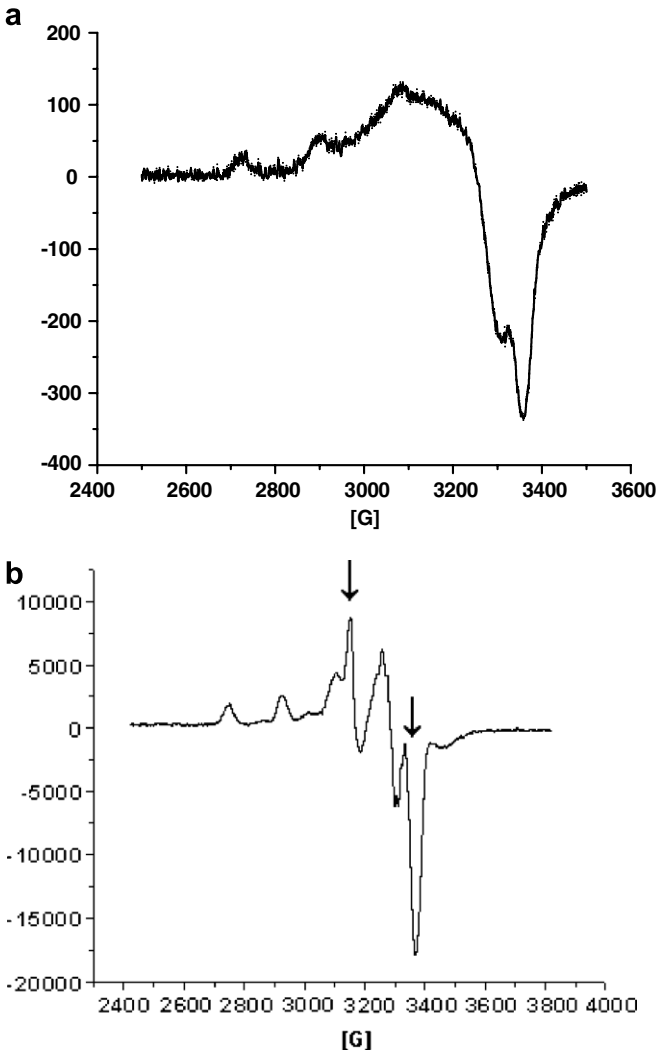

Fig. 3. X-band ESR spectrum of **1a** (a) and **1b** (b) at 77 K in DMSO at microwave frequency of 9.492 GHz and field modulation frequency of 100 kHz.

tion to form a triplet state has been shown to be present by computer simulation. From the ESR spectrum, we could clearly identify hyperfine coupling from two equivalent ^{63,65}Cu nuclei. In the ESR studies on this and related systems, we observed that the complex **1a** exists mainly as monomeric species in solution and complex **1b** exists as a mixture of monomer and dimeric units in solution. A similar identification of coexistence of monomer and dimeric Cu species in solution has been made by earlier workers [28]. Fig. 3b shows the ESR spectrum of the complex **1b** with $g_{\parallel} = 2.27$, $g_{\perp} = 2.09$ and $A_{\parallel} = 185.4 \times 10^{-4}$ cm^{-1}.

3.2. NMR spectroscopy

The ^{1}H NMR spectrum of **3a** in DMSO-d_6 shows peaks corresponding to six magnetically different protons. The assignment of the δ values for the protons is given under the experimental section. The ^{13}C NMR spectrum shows seven signals corresponding to seven different carbon atoms. The δ values exactly match that from the environment of the carbon atoms. Thus, NMR spectra of the compound lend further support to the proposed structure for the complex, **3a**.

3.3. Electrochemical studies

The electrochemical properties of the complexes were studied using cyclic voltammetry in DMSO solution containing TBAP as the supporting electrolyte. The electrochemical data of the complexes are given in Table 2. The cyclic voltammograms of the complexes are shown in Fig. 4.

All the complexes show a quasi-reversible two step electron transfer process as is evidenced from the following: The $E_{1/2}$ values are independent of scan rate; ΔE_p increases with increasing scan rate and is greater than 60 mV. The peak currents i_{pc} and i_{pa} are not equal. All complexes show metal and ligand (—NO_2) reduction peaks in the cathodic potential range −0.43 to − 0.71 V and −1.55 to −1.78 V respectively. Hence the complexes contain two reducible species which undergo reduction at two different cathodic potentials. The complexes **1a**, **2a** and **3a** show single oxidation peak at potentials +1.58, +1.19 and +1.24 V respectively. High cathodic potential values and irreversibility

Table 2
Electrochemical data[a] of the complexes

Complexes	E^1_{pc} (V)	E^1_{pa} (V)	ΔE^1_p (mV)	$E^1_{1/2}$ (V)	E^2_{pc} (V)	E^2_{pa} (V)	ΔE^2_p (mV)	$E^2_{1/2}$ (V)
1a	−0.43				−1.78			
1b	−0.71	−0.62	90	−0.66	−1.62			
2a	−0.68	−0.61	70	−0.64	−1.55	−1.44	110	−1.49
3a	−0.70				−1.77			

[a] Measured on a Pt working electrode vs. a non-aqueous Ag/Ag$^+$ reference electrode; scan rate 75 mV s^{-1}; supporting electrolyte, tetra-*N*-butylammonium perchlorate (0.1 mol dm^{-3}); complex concentration, 1 mmol dm^{-3}; E_{pc} and E_{pa} are the cathodic and anodic peak potentials for the metal (1) and ligand (2) reduction processes respectively.

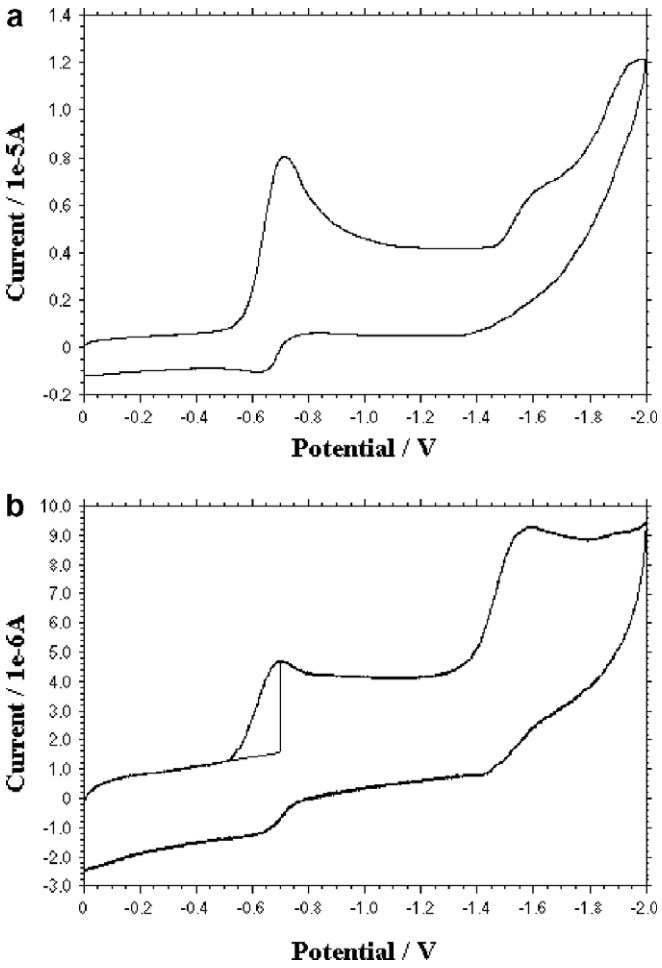

Fig. 4. Cyclic Voltammograms of the complexes **1b** (a) and **2a** (b).

of the M(II)/M(I) reduction process are characteristic of metal complexes having planar geometry [29]. Bridged complexes tend to possess planar geometry and show irreversible electrochemical metal reduction process due to stabilization of metal ion in its higher oxidation state. All the synthesized complexes reported here also show irreversible M(II)/M(I) reduction at high negative values confirming the planar geometry and a bridged structure for all the complexes.

3.4. Catalytic activity

Spectrophotometric measurements in phosphate buffer solutions showed no change in absorbance for the PCV/H_2O_2 mixture for several hours. However, an immediate decrease in absorbance at 441 nm was observed by the introduction of the catalyst (Fig. 5).

The kinetic measurements were carried out under pseudo-first-order conditions with respect to [PCV]. The value of the rate constant, k, is obtained from the slope of the straight lines of the equation, $\ln A_t = \ln A_0 - kt$, where A_t is the absorbance at time t, A_0 is the absorbance at time = 0.

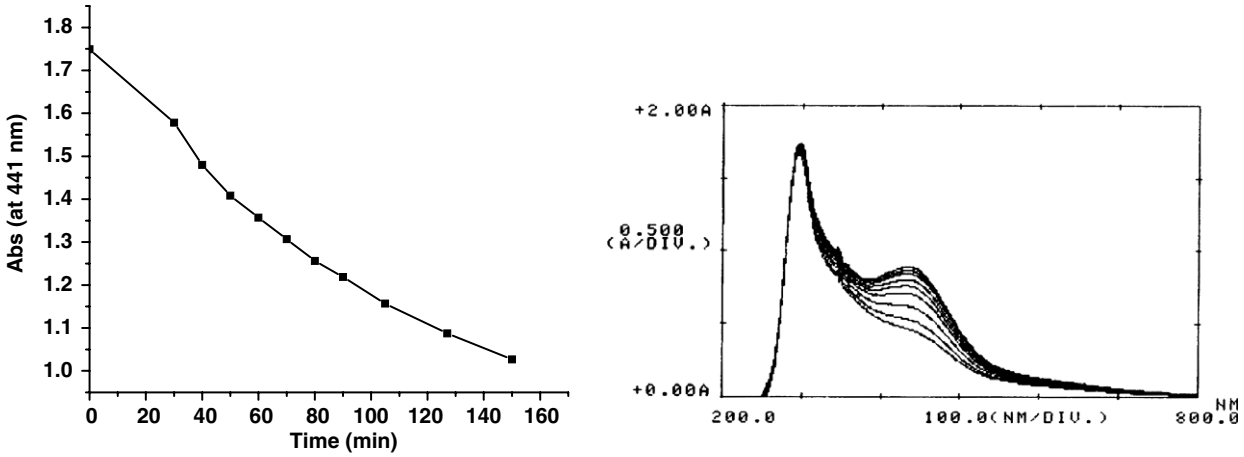

Fig. 5. The variation of absorbance for the reaction of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

The order of the reaction with respect to $[H_2O_2]_0$ and $[PCV]_0$ was determined by carrying out experiments at constant temperature and pH. The order of the reaction was found to be one with respect to $[H_2O_2]$ by varying the concentration of $[H_2O_2]_0$ in the range 0.009–0.02 M at 30 °C (Fig. 6) at constant $[PCV]_0$. Thus the catalyst activates H_2O_2 and releases hydroxyl or perhydroxyl radical which attacks PCV leading to its degradation. The influence of [PCV] on the rate of reaction was studied by varying $[PCV]_0$ in the range $0.5–3.8 \times 10^{-4}$ M at 30 °C (Fig. 7) at constant $[H_2O_2]_0$. The reaction obeyed a first-order dependence at lower concentrations of $[H_2O_2]_0$ and $[PCV]_0$ and the rate of the reaction decreases at higher concentrations.

The rate of the reaction was found to increase with increase in the concentration of the catalyst. The effect of catalyst concentration on the degradation of the dye was studied by fixing $[PCV]_0$ and $[H_2O_2]_0$ at constant values and taking 0.01, 0.02, 0.03 g and 0.04 g of the catalyst.

The effect of pH on the reaction rate was studied using phosphate buffer solution in the pH range 5–9 and for pH > 9, drops of NaOH solution was added to the buffer solution. Under acidic condition, pH < 7, PCV exists in the form, H_3L^- (yellow), having maximum absorbance at 441 nm whereas, in alkaline medium, pH > 7, it exists as H_2L^{2-} (violet), having maximum absorbance at 596 nm [30]. The rate constant value increases with pH up to 8.0 and then starts decreasing at higher pH values (Fig. 8). The increase in the rate of the reaction under alkaline condition could be attributed to the deprotonation of H_2O_2 which effectively produce peroxo intermediate [31]. Thus rate of degradation of PCV is enhanced by the formation of the active radical species. Moreover, changes in the electronic configuration of H_2L^{2-} anion of PCV also facilitate its rapid degradation.

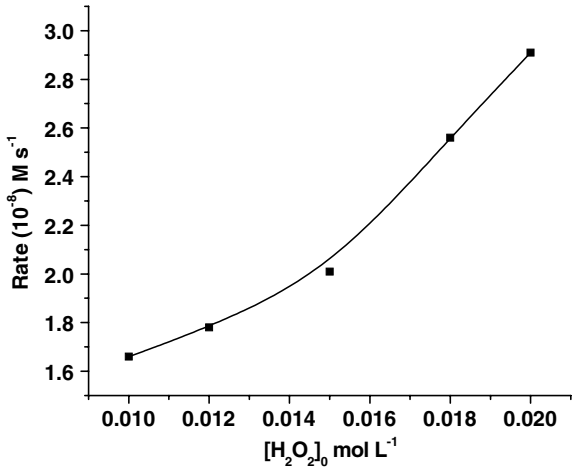

Fig. 6. Dependence of the initial rate on the $[H_2O_2]_0$ for the reaction of 1.2×10^{-4} M $[PCV]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

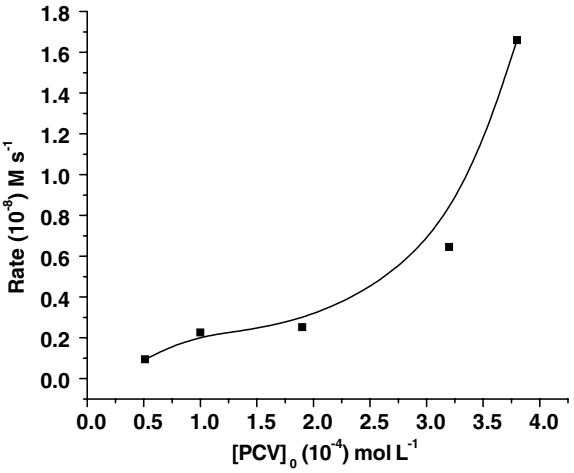

Fig. 7. Dependence of the initial rate on the $[PCV]_0$ for the reaction of 0.01 M $[H_2O_2]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

The effect of chloride ions on the reaction rate was studied at fixed concentrations of $[PCV]_0$, $[H_2O_2]_0$ and the catalyst. The rate constant was found to increase with increasing [NaCl] (Fig. 9). This increase in rate can be attributed to the oxidation of chloride ions by H_2O_2 to produce other oxidizing agents such as OCl^- and Cl_2 that assist in the oxidation of PCV [32].

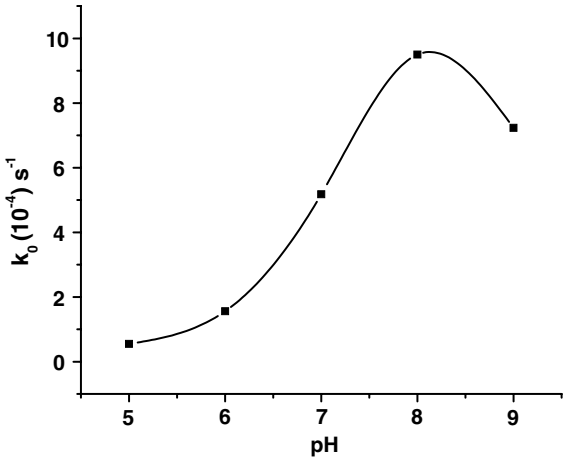

Fig. 8. Dependence of the rate constant on pH for the reaction of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

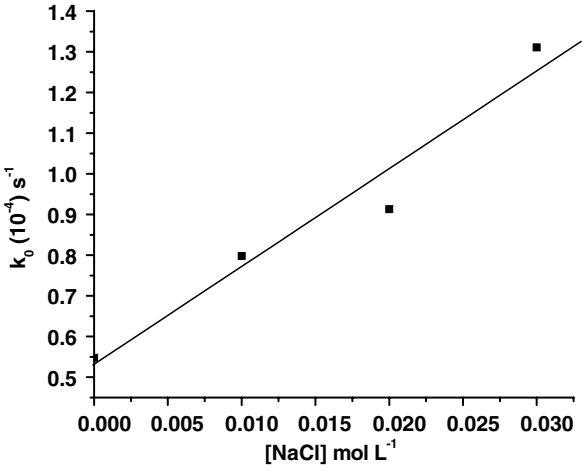

Fig. 9. Variation of rate constant with [NaCl] for the reaction of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$ and 0.01 g of the catalyst at 30 °C.

Decomposition of H_2O_2 by transition metal complexes producing free radicals has already been proved by spectroscopic methods [33]. Generation of free radical species from H_2O_2 decomposition using transition metal complex has already been proved using organic radical scavenger, 2-propanol and a chromogen 2,2′-azino-bis(3-ethylbenzthiazoline)-6-sulphonate diammonium salt (ABTS) [34]. We confirmed the generation of free radical from H_2O_2 decomposition during the degradation process using different techniques. Addition of 2-propanol, a known organic radical scavenger [34d], decreased the rate of the reaction to approximately 50% of the original rate obtained without the addition of 2-propanol (Fig. 10). The decrease in the rate of the reaction is due to quenching of radicals, generated during the degradation process, by the radical scavenger.

The generation of free radical was also confirmed using the chromogen ABTS. It is known that the chromogen

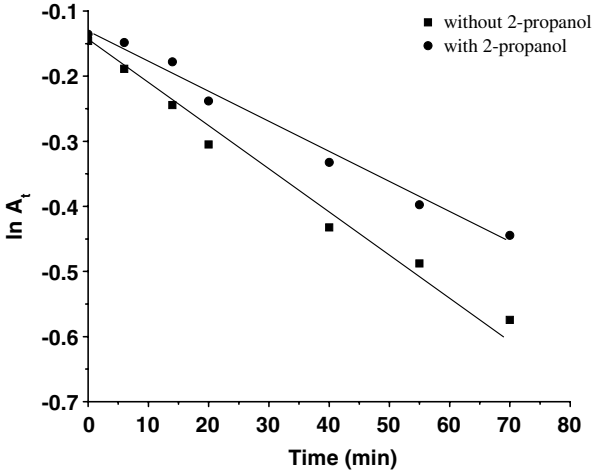

Fig. 10. Effect of addition of the radical scavenger 2-propanol on the rate of the reaction.

ABTS undergo oxidation in the presence of inorganic free radicals such as OH· [35], i.e. $ABTS + OH^{\cdot} \rightarrow ABTS^{+\cdot} + OH^-$, to give the persistent radical cation $ABTS^{+\cdot}$. In the present investigation, formation of $ABTS^{+\cdot}$ is used to confirm the generation of radical species during the degradation process. Fig. 11 shows the absorption signal of the radical cation $ABTS^{+\cdot}$ at 414 nm and 660 nm, generated in the presence of 1 mmol dm^{-3} of the complex, 4 mmol dm^{-3} ABTS and 3 mmol dm^{-3} H_2O_2. The radical cation $ABTS^{+\cdot}$ was found to be generated only when both the catalyst and H_2O_2 are present in ABTS solution.

It is well established that irradiation of H_2O_2 by UV-light leads to the formation of OH radical [36]. In the present investigation, enhancement of the reaction rate by 40% upon irradiation of the reaction mixture with UV-light ($\lambda = 254$ nm) also proves that the degradation process proceed via a free radical mechanism. The increase in the rate of the reaction by irradiation of UV-light, $\lambda = 254$ nm, is shown in Fig. 12.

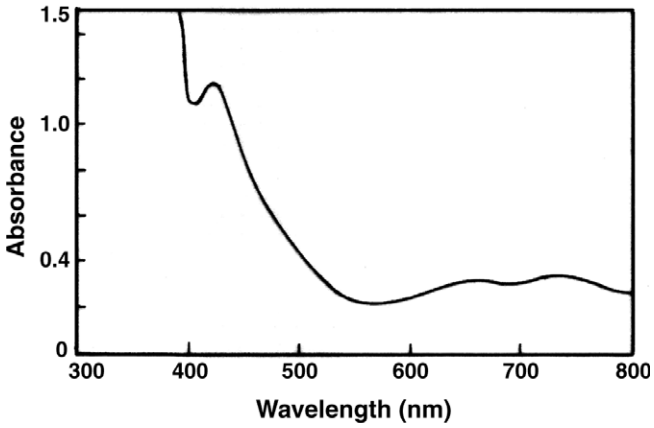

Fig. 11. Absorption spectrum of the radical cation $ABTS^{+\cdot}$ generated in the presence of 1 mmol dm^{-3} of the complex, 4 mmol dm^{-3} ABTS and 3 mmol dm^{-3} H_2O_2.

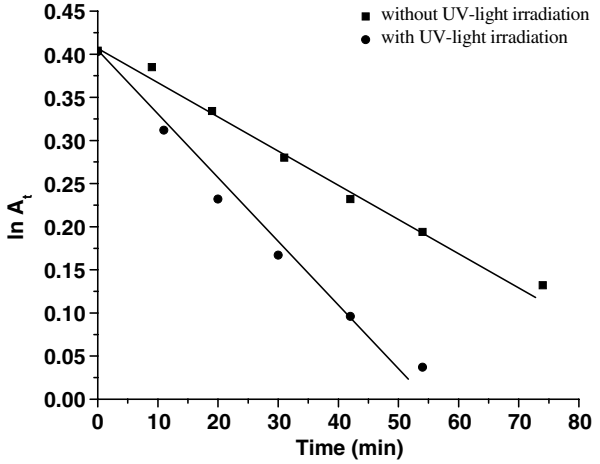

Fig. 12. Effect of irradiation of UV-light on the reaction mixture of 1.2×10^{-4} M $[PCV]_0$ with 0.01 M $[H_2O_2]_0$ in the presence of 0.01 g of the catalyst at 30 °C.

Thus, from the experimental results and discussion, it is clear that the degradation process follows a free radical mechanism involving the formation of highly active hydroxyl radical by the interaction of the catalyst with H_2O_2. These oxidizing agents attack PCV leading to its degradation and formation of other oxidation products as follows:

$$[Cu^{II}L] + H_2O_2 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \underset{\text{peroxo complex}}{[Cu^{II}L(HO_2^-)]} + H^+ \quad (1)$$

$$[Cu^{II}L(HO_2^-)] \xrightarrow{k_2} [Cu^{I}L] + OH^{\cdot} + \frac{1}{2}O_2 \quad (2)$$

$$PCV + HO^{\cdot} \xrightarrow{k_3} \underset{\text{Dye-radical adduct}}{[PCV(HO^{\cdot})]} \quad (3)$$

$$[PCV(HO^{\cdot})] \xrightarrow[\text{slow}]{k_4} \text{Oxidation products} \quad (4)$$

$$[Cu^{I}L] + HO^{\cdot} \xrightarrow{k_5} [Cu^{II}L] + OH^- \quad (5)$$

$$OH^- + H^+ \rightarrow H_2O \quad (6)$$

From Eq. (1), the concentration of the peroxo complex is given by

$$[[Cu^{II}L(HO_2^-)]] = K_1[[Cu^{II}L]][H_2O_2]/[H^+] \quad (7)$$

where $K_1 = k_1/k_{-1}$.

Applying steady-state approximation for the determination of $[HO^{\cdot}]$ and $[PCV(OH^{\cdot})]$,

$$\frac{d[OH^{\cdot}]}{dt} = k_2[[Cu^{II}L(HO_2^-)]] - k_3[PCV][HO^{\cdot}] - k_5[[Cu^{I}L]][OH^{\cdot}] = 0 \quad (8)$$

$$\frac{d[PCV(HO^{\cdot})]}{dt} = k_3[PCV][HO^{\cdot}] - k_4[PCV(HO^{\cdot})] = 0 \quad (9)$$

Assuming $[Cu^{II}L(HO_2^-)] = [Cu^{I}L]$ and by substituting from Eq. (7) into Eq. (8) we get,

$$[HO^{\cdot}] = \frac{k_2K_1[[Cu^{II}L]][H_2O_2]}{k_3[PCV][H^+] + k_5K_1[[Cu^{II}L]][H_2O_2]} \quad (10)$$

Substituting for $[HO^{\cdot}]$ from Eq. (10) in (9) we get,

$$[PCV(HO)^{\cdot}] = \frac{k_2k_3K_1[PCV][[Cu^{II}L]][H_2O_2]}{k_3k_4[PCV][H^+] + k_4k_5K_1[[Cu^{II}L]][H_2O_2]} \quad (11)$$

From Eq. (4),

$$\text{Rate} = k_4[PCV(HO)^{\cdot}] \quad (12)$$

Substituting for $[PCV(HO^{\cdot})]$ in Eq. (12) we get,

$$\text{Rate} = \frac{k_2k_3K_1[PCV][[Cu^{II}L]][H_2O_2]}{k_3[PCV][H^+] + k_5K_1[[Cu^{II}L]][H_2O_2]} \quad (13)$$

Expressing the initial concentration of both reactants, $[PCV]_0$ and $[H_2O_2]_0$

$$[H_2O_2]_0 = [H_2O_2] + [[Cu^{II}L(HO_2^-)]] + [OH^{\cdot}] \quad (14)$$

$$[PCV]_0 = [PCV] + [PCV(HO^{\cdot})] \quad (15)$$

Substituting from Eqs. (7) and (10) and assuming $k_3[PCV][H^+] \ll k_5K_1[[Cu^{II}L]][H_2O_2]$

$$[H_2O_2] = \frac{[H^+]\{k_5[H_2O_2]_0 - k_2\}}{k_5[H^+] + k_5K_1[[Cu^{II}L]]} \quad (16)$$

Substituting Eq. (11) in Eq. (15) and assuming $k_3k_4[PCV][H^+] \ll k_4k_5K_1[Cu^{II}L]][H_2O_2]$

$$[PCV] = \frac{k_4k_5[PCV]_0}{k_4k_5 + k_2k_3} \quad (17)$$

Substituting for $[H_2O_2]$ and $[PCV]$ in Eq. (13) we get,

$$\text{Rate} = \frac{k_2k_3k_4k_5K_1[PCV]_0[[Cu^{II}L]][H_2O_2]_0}{k_3k_4k_5[PCV]_0\{[H^+] + K_1[[Cu^{II}]]\} + K_1k_5[[Cu^{II}L]][H_2O_2]_0\{K_1k_5k_4 + k_2k_3\}}$$

Assuming $k_4k_5K_1 \gg k_2k_3$,

$$\text{Rate} = \frac{k_2k_3K_1[PCV]_0[[Cu^{II}L]][H_2O_2]_0}{k_3[PCV]_0\{[H^+] + K_1[[Cu^{II}L]]\} + K_1^2k_5[[Cu^{II}L]][H_2O_2]_0} \quad (18)$$

According to Eq. (18), the rate of the reaction is first-order with respect to $[PCV]_0$ and $[H_2O_2]_0$ at lower initial concentrations and is found to be the same experimentally, in the concentration ranges selected for the study (Figs. 6 and 7). The rate of the reaction attains a limiting value at higher concentrations. The rate also increases with increasing pH and attains a maximum value at pH 8.0 after which it decreases.

4. Conclusion

Mannich aminomethylation reactions involving $M(gly)_2$, HCHO and nitromethane have been carried out. Different products were obtained under acidic and alkaline pH conditions. Mannich aminomethylation reaction was

found to take place under both acidic and alkaline conditions, whereas, aldol condensation was found to occur only under alkaline condition, particularly with $Cu(gly)_2$ complex and not with the other glycinato complexes such as $Ni(gly)_2$ and $Zn(gly)_2$. The Mannich aminomethylation product obtained using $Cu(gly)_2$, HCHO and nitromethane under acidic condition has been used as catalyst in the H_2O_2 induced degradation of pyrocatechol violet dye and has been found to be effective. Hydrogen peroxide alone could not bring about degradation of PCV, but the addition of the catalyst increased the rate of decomposition of H_2O_2 producing hydroxyl radical which efficiently degraded the dye. The rate of degradation has also been correlated with variations in $[PCV]_0$, $[H_2O_2]_0$, pH, NaCl and catalyst concentration and a mechanism has been proposed based on the experimental observations.

Aminoalkylbis(phenolate) [O,N,O] donor ligands for uranyl(VI) ion coordination: Syntheses, structures, and extraction studies

Harri Sopo, Kamal Goljahanpoor, Reijo Sillanpää *

Department of Chemistry, University of Jyväskylä, P.O. Box 35, FIN-40351, Jyväskylä, Finland

Received 16 February 2007; accepted 13 March 2007
Available online 30 March 2007

Abstract

The syntheses of five new aminoalkylbis(phenolate) ligands (as hydrochlorides) and their uranyl complexes are described. The reaction between uranyl nitrate hexahydrate and phenolic ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-1-aminopropane) · HCl], $H_2L1 \cdot HCl$, forms a uranyl complex $[UO_2(HL1)_2] \cdot 2CH_3CN$ (**1**). The ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-1-aminobutane) · HCl], $H_2L2 \cdot HCl$, forms a uranyl complex with a formula $[UO_2(HL2)_2] \cdot 2CH_3CN$ (**2**). The ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methyl benzyl)-1-aminohexane) · HCl], $H_2L3 \cdot HCl$, yields a uranyl complex with a formula $[UO_2(HL3)_2] \cdot 2CH_3CN$ (**3**) and the ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-cyclohexylamine) · HCl], $H_2L4 \cdot HCl$, yields a uranyl complex with a formula $[UO_2(HL4)_2]$ (**4**). The ligand [(*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-benzylamine) · HCl], $H_2L5 \cdot HCl$, forms a uranyl complex with a formula $[UO_2(HL5)_2] \cdot 2MeOH$ (**5**). The molecular structures of **1**, **2′** (**2** without methanol), **3, 4** and **5** were verified by X-ray crystallography. The complexes **1**–**5** are neutral zwitterions which form in a molar ratio of 1:2 (U to L) in the presence of a base (triethylamine) and bear similar mononuclear, distorted octahedral uranyl structures with the four coordinating phenoxo ligands forming an equatorial plane and resulting in a centrosymmetric structure for the uranyl ion. In uranyl ion extraction studies from water to dichloromethane with ligands $H_2L1 \cdot HCl$–$H_2L5 \cdot HCl$, the ligands $H_2L2 \cdot HCl$ and $H_2L4 \cdot HCl$ are the most effective ones.

Keywords: Uranyl complex; Bisphenolate; Crystal structure; Uranyl extraction

1. Introduction

About 25–30% of the world's supply of electrical power is generated using nuclear sources [1]. This produces a vast amount of nuclear wastes to take care of and a risk of environmental contamination by radioactive material. The industrial procedure used to reprocess spent nuclear fuel is called PUREX in which the irradiated fuel is dissolved into nitric acid and an organic solvent composed of 30% tributyl phosphate in kerosene is used to recover the uranium and plutonium [2]. This liquid–liquid extraction method was developed in the 1950s and it is still the industry standard, although the process remains far from perfect [3]. The separation of uranium from sources such as phosphate rocks has been the subject of intense research worldwide [4]. In view of this extensive use of actinide extractors for different applications, it is logical to search for other options, either new methods or new selective ligands [5a–c]. For this purpose numerous kinds of solutions, e.g. expanded porphyrins [6], calixarenes [7], polyphenols [8], crown ethers [9a,9b], etc. have been presented. These types of compounds are quite bulky and some of them require the threading of the UO_2^{2+}-ion through a ring, which may be difficult. Thus there is a need for smaller and less rigid molecules containing O- or N-donor atoms or both, allowing a more flexible coordination of the UO_2^{2+}-ion. We have earlier reported that the aminoalcoholbis(phenolate) [O,N,O,O′] donor ligands of a relatively small size have good uranyl ion complexing properties [10a,10b]. Furthermore, the structure of these ligands offers a possibility to attach them on silica-gel, as described in an article

H_2L2	butyl
H_2L3	hexyl
H_2L4	cyclohexyl
H_2L5	benzyl

Scheme 1. The ligands under study.

by Barbette et al. [11]. In the present study, we have prepared five new ligands by substituting the alcohol part of the aminoalcoholbis(phenolate) molecule with different alkyl groups, thus reducing the number of possible donor atoms in the coordinating molecules. This procedure also removes one polar atom (O) from the "outer sphere" of the coordinated molecule, making its exterior lipophilic after complexation and promoting the solubility of the formed complex into organic solvents which is an important feature in the extraction [2,12]. The ligand family under study is depicted in Scheme 1. Burke et al. [13] have prepared similar alkyl compounds with different phenol groups.

We have chosen 4-*tert*-butyl-2-methylphenol as a starting phenol due to the solubility behavior of the new ligands containing this phenol group. We have found that the ligands containing these groups form better crystalline solids as free ligands or uranyl complexes than the ligands containing 2,4-dimethylphenols.

The syntheses of these new ligands and their uranyl ion complexes are reported below. Also the X-ray diffraction structures are presented for the five uranyl complexes. In addition the ability of these ligands to extract uranyl ion from water to dichloromethane in different physical and chemical circumstances has been studied as it has been shown that various ligands have different optimal extraction conditions [14–18]. The effect of the anion used (uranyl nitrate versus uranyl acetate) on the extraction properties has also been studied in order to get a better understanding of the two-phase extraction system. The distribution pattern of the ligands and ions at a liquid/liquid interface may significantly contribute to the extraction rates [2,19].

2. Experimental

2.1. General information

1-Aminopropane (Sigma), 1-aminobutane (Merck), 1-aminohexane, cyclohexylamine (Fluka), benzylamine (Merck), triethylamine (Riedel-de Haën), 4-*tert*-butyl-2-methylphenol (Fluka), 37% formaldehyde (Merck), uranyl acetate dihydrate (Riedel-de Haën) and uranyl nitrate hexahydrate (Merck) were used as supplied. The ligands $H_2L1 \cdot HCl$–$H_2L5 \cdot HCl$ were synthesized by following mainly the procedure for methylamino-*N*,*N*-bis(1-methylene-2-naphthol) [13]. During the separation process the ligands were transformed to their hydrochlorides by treating them with HCl. The details of the syntheses are described below. The NMR spectra were recorded on a Bruker AVANCE DPX 250 FT NMR spectrometer or Bruker AVANCE DRX 500 FT NMR spectrometer. The ^1H and ^{13}C NMR spectra were recorded either in $CDCl_3$ or DMSO-d_6 at 30 °C. The chemical shifts are reported in ppm and referenced internally using the residual protio solvent resonances relative to tetramethylsilane ($CDCl_3$ δ 7.26, ^1H NMR; δ 77.0, ^{13}C NMR; DMSO-d_6 δ 2.50, ^1H NMR; δ 39.50, ^{13}C NMR). The mass spectrometric measurements were performed using a Micromass LCT time of flight (TOF) mass spectrometer with electrospray ionization (ESI-MS). Elemental analyses were performed using a VarioEl III elemental analyzer. The melting points were measured by Mettler Toledo FP62 Melting Point instrument and Perkin–Elmer Pyris Diamond TG/DTA Thermogravimetric/Differential Thermal Analyzer. The uranyl extraction samples were analyzed with inductively coupled plasma optical emission spectrometry (ICP-OES) at 385.958 nm using a Perkin–Elmer Optima 4300DV instrument. The pH's were measured with an Orion 720A pH-meter.

The synthesis of the ligand $H_2L1 \cdot HCl$ is described in detail below. The syntheses of the rest of the ligands followed the same procedure. Also, only the preparation of uranyl complex **1** is described in detail; the syntheses of the other complexes follow the same concept.

2.2. $H_2L1 \cdot HCl \cdot 1.5H_2O$[(*N*,*N*-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-1-aminopropane · HCl) · $1.5H_2O$]

To a solution of 4-*tert*-butyl-2-methylphenol (3.28 g, 0.020 mol) in methanol (15 ml) (EtOH 15 ml in case of $H_2L3 \cdot HCl$, $H_2L4 \cdot HCl$ and $H_2L5 \cdot HCl$) and water (3 ml) was added aqueous formaldehyde (37%, 3.26 g, 0.040 mol), 1-aminopropane (0.60 g, 0.010 mol) and triethylamine ($V = 0.500$ ml, 0.004 mol). The resulting solution was kept in a water bath (50 °C) with stirring for 74 h (168 h in case of $H_2L2 \cdot HCl$). After that the solution was left to stand in the freezer for 24 h (48 h in case of $H_2L2 \cdot HCl$ and 94 h in case of $H_2L4 \cdot HCl$). During that time an oil phase separated from the main liquid. The liquid was decanted off and the oil was dissolved in 10 ml of cold MeOH. 4 ml of 6 M HCl was then added to the solution with stirring, leading to a formation of a white solid. The solid was filtered and washed with water (4×50 ml), recrystallized with EtOH (7 ml), washed with diethylether (10 ml) and dried. The yield was 2.15 g (45%). Mp: 156–157 °C. ^1H NMR ($CDCl_3$, 250 MHz): 0.93 (t, $J = 7.4$ Hz, 3H, alkyl CH_3), 1.25 (s, 18H, aryl *t*-butyl), 1.86 (m, 2H, $CH_3CH_2CH_2$), 2.44 (s, 6H, aryl

CH_3), 2.99 (m, 2H, NCH_2CH_2), 4.22 (d, 4H, NCH_2-aryl), 6.96 (d, 2H, aryl), 7.20 (d, 2H, aryl). ^{13}C NMR ($CDCl_3$, 63 MHz): 10.9 (alkyl CH_3), 17.2 (aryl CH_3), 17.3 ($CH_3CH_2CH_2$), 31.4 (aryl $C(CH_3)_3$), 34.0 (aryl $C(CH_3)_3$), 54.4 (NCH_2CH_2), 56.5 (NCH_2-aryl), 116.3–151.1 (aryl). ESI-MS: $m/z = 412.27$ $[H_2L1+H]^+$. The calculated value: $m/z = 412.32$ $[H_2L1+H]^+$. Elemental *Anal.* Calc. for $C_{27}H_{45}NO_{3.5}Cl$: C, 68.26; H, 9.55; N, 2.95. 2.4. $H_2L3 \cdot HCl \cdot 1.5H_2O$ [(N,N-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-1-aminohexane · HCl) · $1.5H_2O$]

Recrystallized with EtOH (10 ml). Yield: 2.28 g (44%). Mp: 141–143 °C. ^1H NMR ($CDCl_3$, 250 MHz): 0.80 (t, $J = 7.0$, 3H, alkyl CH_3), 1.16 (m, 4H, $CH_3CH_2CH_2CH_2$) 1.24 (s, 18H, aryl *t*-butyl), 1.77 (m, 2H, $CH_3(CH_2)_2CH_2$), 2.08 (m, 2H, NCH_2CH_2), 2.42 (s, 6H, aryl CH_3), 3.00 (m, 2H, NCH_2CH_2), 4.23 (s, 4H, NCH_2-aryl), 6.97 (d, 2H, aryl), 7.19 (d, 2H, aryl). ^{13}C NMR ($CDCl_3$, 63 MHz): 13.8 (alkyl CH_3), 17.2 (aryl CH_3), 22.2 ($CH_3CH_2CH_2CH_2$), 23.0 ($CH_3CH_2CH_2CH_2$), 25.8 ($CH_3(CH_2)_2CH_2CH_2$), 30.8 (NCH_2CH_2), 31.4 (aryl $C(CH_3)_3$), 33.9 (aryl $C(CH_3)_3$), 52.1 (NCH_2CH_2), 56.3 (NCH_2-aryl), 116.2–151.2 (aryl). ESI-MS: $m/z = 454.34$ $[H_2L3+H]^+$. The calculated value: $m/z = 454.37$ $[H_2L3+H]^+$. Elemental *Anal.* Calc. for $C_{30}H_{51}NO_{3.5}Cl$: C, 69.67; H, 9.94; N, 2.71. Found: C, 69.22; H, 10.08; N, 2.51%.

2.5. $H_2L4 \cdot HCl$ [(N,N-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-cyclohexylamine · HCl)]

Recrystallized with the solution of MeOH (7 ml) and EtOH (1 ml). Yield: 1.40 g (29%). Mp: 160–163 °C. ^1H NMR ($CDCl_3$, 250 MHz): 1.13–2.20 (m, 10 H, cyclohexyl-CH_2), 1.26 (s, 18H, aryl *t*-butyl), 2.47 (s, 6H, aryl CH_3), 3.14 (m, 1H, cyclohexyl-CH), 4.14 (m, 4H, NCH_2-aryl), 6.90 (d, 2H, aryl), 7.20 (d, 2H, aryl), 9.14 (s, 2H, aryl-OH), 9.32 (m, 1H, NH^+). ^{13}C NMR ($CDCl_3$, 63 MHz): 17.3 (aryl CH_3), 25.0, 25.1, 26.7, 61.1 (cyclohexyl-*C*), 31.5 (aryl $C(CH_3)_3$), 34.0 (aryl $C(CH_3)_3$), 53.0 (NCH_2-aryl), 116.1–151.1 (aryl). ESI-MS: $m/z = 452.28$ $[H_2L4+H]^+$. The calculated value: $m/z = 452.35$ $[H_2L4+H]^+$. Elemental *Anal.* Calc. for $C_{30}H_{46}NO_2Cl$: C, 73.81; H, 9.50; N, 2.87. Found: C, 73.25; H, 9.62; N, 2.68%.

2.6. $H_2L5 \cdot HCl$ [(N,N-bis(2-hydroxy-5-tert-butyl-3-methylbenzyl)-benzylamine · HCl)]

Recrystallized with MeOH (5 ml). Yield: 1.82 g (37%). Mp: 176–178 °C. ^1H NMR ($CDCl_3$, 250 MHz): 1.26 (s, 18H, aryl *t*-butyl), 2.47 (s, 6H, aryl CH_3), 4.19 (m, 6H, NCH_2-aryl), 6.93 (d, 2H, aryl), 7.19 (d, 2H, aryl), 7.45 (m, 5H, phenyl). ^{13}C NMR ($CDCl_3$, 63 MHz): 17.2 (aryl CH_3), 31.5 (aryl $C(CH_3)_3$), 34.0 (aryl $C(CH_3)_3$), 56.4 (NCH_2-aryl), 56.7 (NCH_2-phenyl), 115.9–151.1 (aryl, phenyl). ESI-MS: $m/z = 460.26$ $[H_2L5+H]^+$. The calculated value: $m/z = 460.32$ $[H_2L5+H]^+$. Elemental *Anal.* Calc. for $C_{31}H_{42}NO_2Cl$: C, 75.05; H, 8.53; N, 2.82. Found: C, 74.58; H, 8.58; N, 2.60%.

2.7. $[UO_2(HL1)_2] \cdot 2CH_3CN$ (**1**)

The complex **1** was prepared dissolving 0.040 g (0.090 mmol) of $H_2L1 \cdot HCl \cdot 1.5H_2O$, 24.8 μL (0.180 mmol) of Et_3N and 0.023 g (0.045 mmol) of $UO_2(NO_3)_2 \cdot 6H_2O$ in 10 ml of CH_3CN (15 ml of CH_3CN in the case of (**4**) and 5 ml MeOH in the case of (**2′**) and (**5**)). $H_2L1 \cdot HCl \cdot 1.5H_2O$ is not readily soluble in CH_3CN but after addition of NEt_3 it dissolves. The resulting orange solution was kept at room temperature for one week leading to the formation of the orange (red for (**5**)) crystals. The crystals were filtered off and washed twice with 5 ml of cold ethanol and air-dried. Yield: 0.035 g (66%). The crystals are very soluble in $CHCl_3$, pyridine and toluene and slightly soluble in DMSO. ^1H NMR ($CDCl_3$, 250 MHz): 0.82 (t, $J = 7.3$ Hz, 6H, $NCH_2CH_2CH_3$), 1.31 (s, 9H, aryl *t*-butyl), 1.32 (s, 27H, aryl *t*-butyl), 1.68 (m, 4H, NCH_2CH_2), 2.41 (s, 9H, aryl CH_3), 2.52 (s, 3H, aryl CH_3), 3.05 (m, 4H, NCH_2CH_2), 3.90, 4.13, 4.84, 5.22 (m, 8H, N-CH_2-aryl), 6.98, 7.28 (m, 8H, aryl), 11.71, 12.05 (m, 2H, NH^+). ^{13}C NMR ($CDCl_3$, 63 MHz): 10.9 (alkyl CH_3), 15.4 (NCH_2CH_2), 16.9, 17.2 (aryl CH_3), 31.8 (aryl $C(CH_3)_3$), 33.6 (aryl $C(CH_3)_3$, 49.9 (NCH_2CH_2), 58.3 (N-CH_2-aryl), 116.9–167.6 (aryl). ESI-MS: $m/z = 1091.71$ [(**1**)+H]$^+$. The calculated value: $m/z = 1091.66$ [(**1**)+H]$^+$. Elemental *Anal.* Calc. for $C_{54}H_{80}N_2O_6U$: C, 59.43; H, 7.39; N, 2.57. Found: C, 59.18; H, 7.41; N, 2.36%. A single crystal X-ray analysis was performed on one of these crystals.

2.8. $[UO_2(HL2)_2] \cdot 2CH_3CN$ (**2**)

Yield: 0.036 g (67%). The crystals are very soluble in $CHCl_3$, pyridine and toluene and slightly soluble in DMSO. ^1H NMR ($CDCl_3$, 250 MHz): 0.78, 0.80 (t,

$J = 7.3$ Hz, 6H, $N(CH_2)_3CH_3$), 1.26 (m, 4H, $N(CH_2)_2CH_2$), 1.31 (s, 9H, aryl *t*-butyl), 1.32 (s, 27H, aryl *t*-butyl), 1.66 (m, 4H, NCH_2CH_2), 2.41 (s, 9H, aryl CH_3), 2.52 (s, 3H, aryl CH_3), 3.07 (m, 4H, NCH_2CH_2), 3.90, 4.13, 4.84, 5.23 (m, 8H, N-CH_2-aryl), 6.99, 7.28 (m, 8H, aryl), 11.69, 12.00 (m, 2H, NH^+). ^{13}C NMR ($CDCl_3$, 63 MHz): 13.4 (alkyl CH_3), 16.9, 17.3 (aryl CH_3), 19.6 ($NCH_2CH_2CH_2$), 23.4 (NCH_2CH_2), 31.9 (aryl $C(CH_3)_3$), 33.7 (aryl $C(CH_3)_3$), 47.5 (NCH_2CH_2), 58.0 (N-CH_2-aryl), 117.6–167.7 (aryl). ESI-MS: $m/z = 1119.76$ [(**2**)+H]$^+$. The calculated value: $m/z = 1119.69$ [(**2**)+H]$^+$. Elemental *Anal.* Calc. for $C_{56}H_{84}N_2O_6U$: C, 60.09; H, 7.56; N, 2.50. Found: C, 59.55; H, 7.51; N, 2.30%. A single crystal X-ray analysis was done on one of these crystals, but the quality of the crystals from this preparation was poor. Much better crystals were obtained from methanol; the full structural analysis for a crystal obtained from methanol is labelled **2′**.

2.9. $[UO_2(HL3)_2]\cdot 2CH_3CN$ (*3*)

Yield: 0.035 g (63%). The crystals are very soluble in $CHCl_3$, pyridine and toluene and slightly soluble in DMSO. ^{1}H NMR ($CDCl_3$, 250 MHz): 0.80, 0.81 (t, $J = 6.7$ Hz, 6H, alkyl CH_3), 1.17 (m, 12H, $NCH_2CH_2CH_2CH_2CH_2$), 1.65 (m, 4H, NCH_2CH_2), 1.31 (s, 9H, aryl *t*-butyl), 1.32 (s, 27H, aryl *t*-butyl), 2.41 (s, 9H, aryl CH_3), 2.52 (s, 3H, aryl CH_3), 3.06 (m, 4H, NCH_2CH_2), 3.89, 4.13, 4.83, 5.23 (m, 8H, N-CH_2-aryl), 6.99, 7.28 (m, 8H, aryl), 11.66, 12.01 (m, 2H, NH^+). ^{13}C NMR ($CDCl_3$, 63 MHz): 13.8 (alkyl CH_3), 16.9, 17.3 (aryl CH_3), 21.3, 22.2, 25.9, 30.9 ($NCH_2CH_2CH_2$-CH_2CH_2), 31.9 (aryl $C(CH_3)_3$), 33.7 (aryl $C(CH_3)_3$), 47.9 (NCH_2CH_2), 58.1 (N-CH_2-aryl), 117.0–167.7 (aryl). ESI-MS: $m/z = 1175.99$ [(**3**)+H]$^+$, $m/z = 1198.00$ [(**3**)+Na]$^+$ and $m/z = 1214.00$ [(**3**)+K]$^+$. The calculated value: $m/z = 1175.75$ [(**3**)+H]$^+$, $m/z = 1197.74$ [(**3**)+Na]$^+$ and $m/z = 1213.71$ [(**3**)+K]$^+$. Elemental *Anal.* Calc. for $C_{60}H_{92}N_2O_6U$: C, 61.31; H, 7.89; N, 2.38. Found: C, 61.27; H, 7.89; N, 2.14%. A single crystal X-ray analysis was done on one of these crystals.

2.10. $[UO_2(HL4)_2]$ (*4*)

Yield: 0.020 g (38%). The crystals are very soluble in $CHCl_3$, pyridine and toluene and slightly soluble in DMSO. ^{1}H NMR ($CDCl_3$, 250 MHz): 1.00–2.00, 3.33 (m, 22H, cyclohexyl-*H*), 1.31 (s, 18H, aryl *t*-butyl), 1.32 (s, 18H, aryl *t*-butyl), 2.52 (s, 6H, aryl CH_3), 2.55 (s, 6H, aryl CH_3), 4.19 (m, 4H, N-CH_2-aryl), 4.81 (m, 4H, N-CH_2-aryl), 6.97 (d, 4H, aryl), 7.27 (d, 4H, aryl), 11.58 (m, 2H, NH^+). ^{13}C NMR ($CDCl_3$, 126 MHz): 17.3, 17.4 (aryl CH_3), 25.3, 25.4, 27.0, 27.1, 55.3, 60.5, 60.6 (cyclohexyl-*C*), 31.9 (aryl $C(CH_3)_3$), 33.6 (aryl $C(CH_3)_3$), 55.8 (N-CH_2-aryl), 117.3–168.0 (aryl). ESI-MS: $m/z = 1172.05$ [(**4**)+H]$^+$. The calculated value: $m/z = 1171.72$ [(**4**)+H]$^+$. Elemental *Anal.* Calc. for $C_{60}H_{88}N_2O_6U$: C, 61.52; H, 7.57; N, 2.39. Found: C, 60.65; H, 7.50; N, 2.12%. A single crystal X-ray analysis was done on one of the crystals from the synthesis vessel.

2.11. $[UO_2(HL5)_2]\cdot 2MeOH$ (*5*)

Prepared as **1**, but the solvent was methanol (5 ml). The red solution produced red crystals, which were washed twice with methanol (5 ml). Yield: 0.045 g (80%). The crystals are soluble in $CHCl_3$, pyridine, toluene and DMSO. ^{1}H NMR ($CDCl_3$, 250 MHz): 1.33 (s, 9H, aryl *t*-butyl), 1.38 (s, 27H, aryl *t*-butyl), 2.40 (s, 9H, aryl CH_3), 2.54 (s, 3H, aryl CH_3), 3.90, 4.10, 4.73, 5.09 (m, 8H, N-CH_2-aryl), 4.29 (m, 4H, N-CH_2-phenyl), 7.00, 7.07, 7.28, 7.30 (m, 8H, aryl), 7.41 (m, 10H, phenyl), 12.52, 12.80 (m, 2H, NH^+). ^{13}C NMR ($CDCl_3$, 126 MHz): 17.0, 17.3 (aryl CH_3), 31.90, 31.94 (aryl $C(CH_3)_3$), 33.68, 33.74 (aryl $C(CH_3)_3$), 51.0, 57.3, 57.8 (N-CH_2-aryl), 116.6–167.8 (aryl). ESI-MS: $m/z = 1187.93$ [(**5**)+H]$^+$, $m/z = 1209.93$ [(**5**)+Na]$^+$ and $m/z = 1225.89$ [(**5**)+K]$^+$. The calculated value: $m/z = 1187.66$ [(**5**)+H]$^+$, $m/z = 1209.64$ [(**5**)+Na]$^+$ and $m/z = 1225.62$ [(**5**)+K]$^+$. Elemental *Anal.* Calc. for $C_{62}H_{80}N_2O_6U$: C, 62.72; H, 6.79; N, 2.36. Found: C, 62.49; H, 6.81; N, 2.17%. A single crystal X-ray analysis was done on one of these crystals.

2.12. X-ray crystallography

Crystals suitable for single crystal X-ray measurements were obtained directly from the reaction vessels. The crystal data for compounds **1**–**5** are summarized in Table 1 along with other experimental details. The crystallographic data were collected at 173 K on an Enraf Nonius Kappa CCD area-detector diffractometer using graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). The data were collected using φ and ω scans and processed using a DENZO-SMN v 0.93.0 [20]. A SHELXA [21] absorption correction was applied to the data of **1**–**5**. The structures were solved by direct methods using the SHELXS-97 program [22] and full-matrix least-squares refinements on F^2 were performed using the SHELXL-97 program [22]. For all compounds the heavy atoms were refined anisotropically. The CH hydrogen atoms were included at fixed distances using fixed displacement parameters from their host atoms while other H atoms were refined using fixed displacement parameters. Structure figures were drawn using ORTEP-3 for Windows [23].

2.13. Uranyl extraction

Two-phase uranyl ion extraction studies from water to dichloromethane were performed at ambient room temperature (22–24 °C) to determine the extraction ability of the ligands and the influence of several factors on the extraction. The study consisted of six different tests: (1) the extraction ability of the prepared ligands, (2) the effect of the amount of the extractor solvent, (3) the effect of stirring

Table 1
Summary of crystallographic data for compounds **1**–**5** at 173(2) K

Compound	**1**	**2′**	**3**	**4**	**5**

[b] Values in parentheses for reflections with $I > 2.0\sigma(I)$.
[c] $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$ and $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP)]$, where $P = (2F_c^2 + F_o^2)/3$.

the extractor solvent during the process, (4) the effect of the pH of the water solution, (5) the role of the uranyl salt used, and (6) the extraction ability of the known extractor, tributylphosphate (TBP), for comparative purposes. The ligands were $H_2L1 \cdot HCl$–$H_2L5 \cdot HCl$, $H_3L6 \cdot 1/3$toluene (*N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-2-aminoethanol · 1/3toluene), $H_3L7 \cdot HCl$ (*N*,*N*-bis(2-hydroxy-3,5-dimethylbenzyl)-4-amino-1-butanol · HCl), $H_3L8 \cdot HCl$ (*N*, *N*- bis(2-hydroxy- 5-*tert*-butyl- 3-methylbenzyl)-4-amino -1-butanol · HCl) and $H_3L9 \cdot HCl$ (*N*,*N*-bis(2-hydroxy-5-*tert*-butyl-3-methylbenzyl)-6-amino-1-hexanol · HCl). The last four ligands were prepared previously [10a,10b].

In the first experiment with ligands $H_2L1 \cdot HCl$–$H_2L5 \cdot HCl$ the experimental setup was the following: into a test tube were placed 3 ml of CH_2Cl_2 with the ligand (0.210 mmol) and NEt_3 (0.210 mmol, to neutralize HCl) and on the top of this CH_2Cl_2 layer was placed 2 ml of a water solution of uranyl nitrate hexahydrate (0.0525 mmol) leading to a U:ligand ratio of 1:4. Also one otherwise identical test tube containing no ligand and no base was prepared. The samples for ICP ($V = 50$ μL, diluted to 10 ml of H_2O) were taken from the water layer within a 480 h period of time. After taking of the samples of during hours (48 h) of extraction, 1 ml of CH_2Cl_2 was added to each test tube containing the ligand (making the total volume of CH_2Cl_2 of 4 ml) to confirm that the CH_2Cl_2 solution was not oversaturated. Finally, after taking samples during 120 h of extraction, 0.5 ml of CH_3CN was added to each test tube to provoke possible crystal formation of the extracted complexes in CH_2Cl_2. The samples were analyzed with ICP-OES at 385.958 nm using a Perkin–Elmer Optima 4300DV instrument in every experiment.

In the second experiment with ligands $H_2L2 \cdot HCl$, $H_2L4 \cdot HCl$, $H_3L7 \cdot HCl$ and $H_3L9 \cdot HCl$ the experimental setup was as follows: into a test tube was placed 6 ml of CH_2Cl_2 with the ligand (0.210 mmol) and Et_3N (0.210 mmol, to neutralize HCl) and on the top of this layer was placed 2 ml of water with uranyl nitrate (0.0525 mmol) leading to a U:ligand ratio of 1:4. One test tube containing no ligand was also prepared. The samples for ICP ($V = 50$ μL, diluted to 10 ml) were taken from the water layer during an 80 h period of time.

The third experiment was performed like the second experiment with ligands $H_2L4 \cdot HCl$ and $H_3L7 \cdot HCl$, with the exception that the test tubes were stirred with a magnetic stirrer (300–500 rpm) throughout the experiment. Before the samples were taken, the stirring was interrupted and the solutions were allowed to settle for 5 min.

The fourth experiment with ligands $H_3L6 \cdot 1/3$toluene, $H_3L7 \cdot HCl$ and $H_3L9 \cdot HCl$ was performed like the first one using 3 ml of CH_2Cl_2 without acetonitrile addition, but now uranyl acetate dihydrate was used as the uranyl salt. The samples for ICP ($V = 50$ μL, diluted to 10 ml) were taken from the water layer during a 77-h period of time.

The fifth experiment was performed like the first one using 3 ml of CH_2Cl_2 without acetonitrile addition with ligands $H_2L2 \cdot HCl$ and $H_3L8 \cdot HCl$, but now the uranyl salt (uranyl acetate dihydrate) was dissolved in an acetate buffer. The extraction effectiveness of both ligands was studied under three different buffer solutions with pH values 3.4, 4.3 and 5.2. In all cases the solutions were stirred throughout the experiment with a magnetic stirrer (300–500 rpm). The samples for ICP ($V = 50$ μL, diluted to

10 ml) were taken from the water layer during a 48 h period of time.

The sixth experiment was performed with tributylphosphate, which is used in the PUREX process, to compare the extraction ability of a known compound to our ligands in the extraction system used by us. The experimental setup was as follows: into test tube 1 was placed 2 ml of water with uranyl nitrate (0.0525 mmol) and on the top of this layer was placed 3.5 ml kerosine with 0.9 ml TBP (3.380 mmol) leading to a U:TBP ratio of 1:64. Into test tube 2 was placed 2 ml of CH_2Cl_2 with 1.0 ml TBP (3.676 mmol) and on the top of this layer was placed 2 ml of water with uranyl nitrate (0.0525 mmol) leading to a U:TBP ratio of 1:70. The samples for ICP ($V = 50$ μL, diluted to 10 ml) were taken from the water layer during a 52-h period of time.

3. Results and discussion

3.1. Syntheses of ligands and uranyl complexes

The progress of the reactions in the formation of the ligands was followed by HPLC. Generally we could observe the formation of three products: the amine with one phenol moiety (this product could be identified by ^{1}H NMR from the material obtained during the separation process of $H_2L2 \cdot HCl$ in a yield about 28%), the amine with two phenol moieties (the desired product) in a yield about 44%, and a third unidentified product, which was detected in HPLC. On the basis of our other studies we suspect that the unidentified compound is an amine with one phenol moiety with a methylene bridge between the nitrogen atom and the phenolic oxygen atom forming a six-membered ring at a yield about 16% (HPLC). Also, at the end of the reaction one could see that some unreacted phenol was present. Thus the yields of the reported ligand syntheses obtained with this method can be said to be at practical levels.

The preparation reactions for all the ligands $H_2L1 \cdot HCl$–$H_2L5 \cdot HCl$ were performed by two different methods: by refluxing at the solvent boiling temperature, and by keeping the reaction solution in a water bath at 50 °C. The progress of these reactions were followed by HPLC and from the data we could deduce that for the best yield of the desired product (amine with two phenol moieties) the method of choice was the latter one (reaction at 50 °C) with NEt_3 added as a catalyst.

The reason for lower yields of $H_2L4 \cdot HCl$ and $H_2L5 \cdot HCl$ compared to $H_2L1 \cdot HCl$–$H_2L3 \cdot HCl$ during the same reaction time (about 75 h) is the slower reaction speed. According to the HPLC reaction follow-up in the synthesis of $H_2L4 \cdot HCl$ and $H_2L5 \cdot HCl$, the compound with one phenol moiety was the main product (about 41% and 58%, respectively), and amine with two phenol moieties formed with 29% and 37% yield, respectively.

In order to make the separation process easier the reaction mixtures were treated with HCl (6 M) to form the ligand hydrochlorides, which generally solidified out as white precipitates in the reaction vessels.

Although all the ligands were dried in vacuo, $H_2L1 \cdot HCl$–$H_2L3 \cdot HCl$ contained 1.5 water molecules for one ligand unit. Those water molecules did not leave the products until the ligands were heated to their melting point. This was confirmed by TG/DTA analysis.

Generally, the complexes formed quite easily after the dissolution of the uranyl nitrate hexahydrate in acetonitrile (or in methanol or ethanol) together with an appropriate amount of the ligand and a base (triethylamine). The quick formation of the complex was clearly indicated by the immediate change in colour of the solution from yellow (uranyl nitrate) to orange or red. The crystals started to form quite quickly, but the reaction vessels were left to stand at room temperature for up to two weeks to allow for the formation of crystals. The filtrates, though, were still orange or red in colour after removal of the crystals, indicating that the crystallization was incomplete. The solutions of complexes in methanol and ethanol were much redder in colour than those in acetonitrile. The reason for the red colour is the formation of U=O···HO hydrogen bonds as shown in the structural part later. In many cases the complexes in the crystalline state formed adducts with solvents (acetonitrile, methanol or ethanol). Some of the adducts formed crystals of better quality for X-ray analysis purposes than the parent complexes without solvent molecules, but not always. Especially **4** formed methanol and ethanol adducts, which were also analysed by X-ray methods, but the calculations gave quite high *R*-values; the best results were obtained from unsolvated crystals.

The crystals of **1**, **2**, **3** and **5**, which contain solvent molecules, decompose slowly after they are removed from the reaction solution, indicating that solvent molecules are quite loosely bonded in these crystals; this is confirmed by X-ray studies.

The solubility of the complexes into organic solvents was good. The ESI-MS measurements for compounds **1**–**5** were done in a solution of $CHCl_3$ and CH_3CN (1:3) or MeOH and CH_3CN (3:1); in this procedure the compounds **1**–**5** broke down mainly into corresponding ligands but the complex ions of compounds **1**–**5** could be still identified, although the peaks were of low intensity.

3.2. NMR studies

The ^{1}H NMR spectra of the compounds **1**–**3** and **5** in $CDCl_3$ were quite similar. One of the compounds (compound 3) was completely analyzed with ^{1}H–^{1}H COSY, NOESY, ^{1}H–^{13}C HMQC and ^{1}H–^{13}C HMBC NMR techniques to find out the behavior of the complexes in $CDCl_3$. According to these data it seems that in $CDCl_3$ the conformational changes of the N-CH_2-aryl part of the compounds **1**–**3** and **5** lead to a splitting of the ^{1}H signals of the aryl ring and the N-CH_2-aryl protons in a ratio of 1:3 at 30 °C. A measurement of the ^{1}H NMR of **3** in $CDCl_3$ as a function of temperature from −60 °C to +60 °C with

increments of 10 °C (Fig. 1) verifies that the splitting pattern is due to conformational changes of the N-CH_2-aryl part of the molecule.

In compound **4** the splitting ratio of the corresponding ^{1}H signals is 1:1 at 30 °C. The reason for this difference is probably that in **4** the N-alkyl part of the molecule does not contain the flexible N-CH_2-alkyl joint which is present in the compounds **1**–**3** and **5**. Furthermore, additional NMR measurements of **1** were made in pyridine and of **3** and **5** in DMSO and toluene. From those data it is evident that in pyridine and in DMSO all these compounds break down to two components, namely $[UO_2(HLn)(Solvent)_x]^+$ (Solvent = DMSO or pyridine, and $x = 2$ or 3) and HLn^- ($n = 1$–5). Analogous results were obtained in the ^{1}H NMR studies of similar aminoalcohol substituted ligands in DMSO [10b]. The ^{1}H NMR spectra of **3** and **5** in toluene resembled those obtained in $CDCl_3$, as expected. Thus it seems that if a solvent could offer a strongly coordinating hard Lewis donor atoms (O, N), it will eject one ligand from the uranyl complex, while in the noncoordinating solvents the ligands stay attached to the uranyl ion.

3.3. Structural studies of the uranyl complexes

The solid-state structures of compounds **1**–**5** were verified by single crystal X-ray analysis. The crystals of **1, 3** and **4** were obtained from an acetonitrile solution and the crystals of **2′** and **5** from a methanol solution. The triclinic unit cells of **1** and **3** contain one complex unit with two acetonitrile molecules. The triclinic unit cell of **2′** contains one complex unit. The monoclinic unit cell of **4** contains two complex units. The triclinic unit cell of **5** contains one complex unit and two methanol molecules.

All the complexes have a centrosymmetric structure in which the uranium(VI) ion has a compressed octahedral symmetry (Figs. 2–6). Selected bond parameters for these five molecules are presented in Table 2. The asymmetric unit of all compounds contains a UO^+ unit with a negative HLn^- ligand ($n = 1$–5), which binds to the UO^+ unit via two phenoxide groups. The aliphatic nitrogen atom accepts a proton and thus it does not form a bond with the U(VI) ion. The proton on the nitrogen atom, however, forms weak intramolecular H-bonds to O2 and/or O3 (Table 3). The complexes are neutral zwitterionic units with four negative charges at the oxygen atoms, two positive charges at the uranyl ion and two positive charges on the nitrogen atoms (one per nitrogen). The overall structures are similar to the uranyl homoazacalixarene complex [24], where the uranyl ion is located inside the cage, and to the earlier reported complexes of uranyl ion with aminoalcohol ligands [10a,10b].

The U=O distances are almost the same in all compounds studied; they range from 1.789(3) to 1.808(3) Å. Only in **5** the solvent molecule (methanol) forms a hydrogen bond to O1 (see Table 3) causing a slight lengthening of the U=O bond.

The extreme values of the U–O(phenoxide) bond distances are from 2.231(3) to 2.311(3) Å in the compounds studied. These values are near the estimated "ideal" value of 2.2 Å found in U(VI) compounds with unrestricted, unidentate alkoxide ligands [25,26]. Similar values have been found also in U(VI) compounds with Schiff base

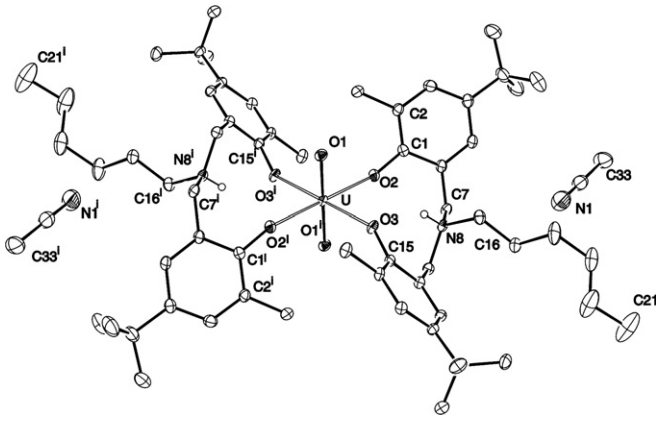

Fig. 4. Molecular structure of $[UO_2(HL3)_2]\cdot 2CH_3CN$ (**3**). Thermal ellipsoids have been drawn at 30% probability level. Symmetry operation i = −*x*, −*y*, −*z*. The CH hydrogens are not shown.

ligands [27]. This suggests that the now reported ligands bind to the UO_2^{2+} ion quite effectively.

The U–O–C angles vary from 132.0(3)° to 165.8(3)° and the corresponding U–O distances are 2.311(3) and 2.258(3) Å, respectively. These numerical values follow the general trend: the smaller is the U–O–C angle, the longer is the U–O bond.

Analysis of the bond lengths and angles in the structures **1**–**5** (see Table 2) shows only modest variations between compounds indicating that the coordination process happens quite similarly for all ligands. In the solid state the dihedral and torsion angles (see Tables 2 and 4) indicate that the ligands still have sufficient freedom to accommodate slightly different conformations for packing reasons.

3.4. Uranyl ion extraction studies

The decrease of the uranyl ion concentration in the water layer during the extraction studies at room temperature (22–24 °C) with the new ligands $H_2L1\cdot HCl$–$H_2L5\cdot HCl$ is shown in Fig. 7. The extraction was done without stirring the extraction tubes at the pH of the uranyl nitrate in water solution (around 3). The concentration ratio of the uranyl ion to the ligand was 1:4 during the extraction process. The concentration of the uranyl ion in the water layer of the control samples was constant during the follow-up.

The uranyl ion extraction efficiency of the ligands in an equilibrium situation can be described using the distribution coefficient (*D*), which expresses the ratio of the total

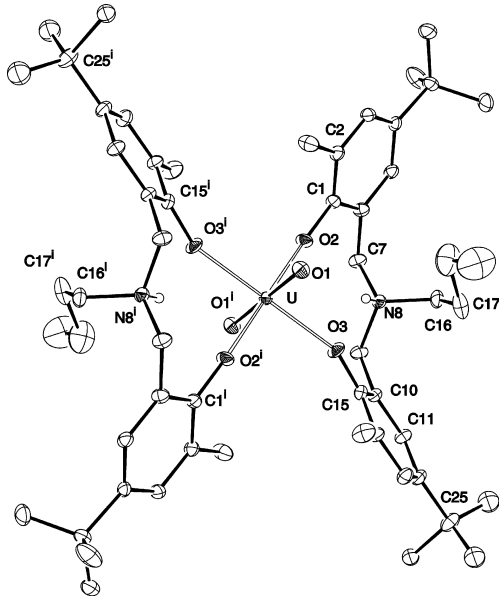

Fig. 3. Molecular structure of $[UO_2(HL2)_2]$ (**2′**). Thermal ellipsoids have been drawn at 30% probability level. Symmetry operation i = −*x*, −*y*, −*z*. The CH hydrogens are not shown.

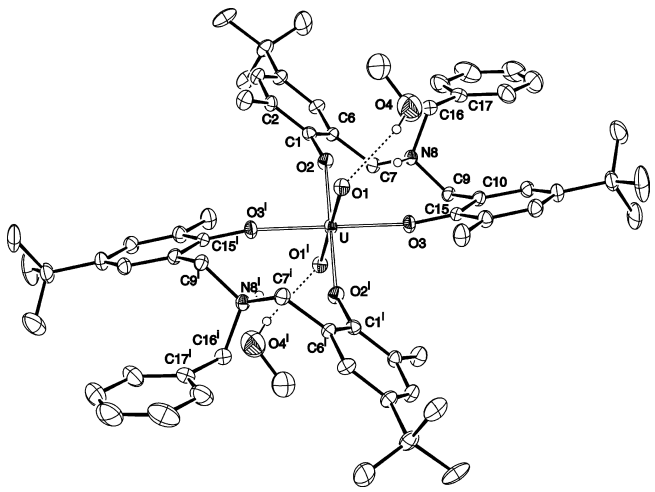

Fig. 6. Molecular structure of $[UO_2(HL5)_2]\cdot 2MeOH$ (**5**). Thermal ellipsoids have been drawn at 30% probability level. Symmetry operation i = $-x$, $-y$, $-z$. The CH hydrogens are not shown.

mass of the extracted substance in all of its possible forms in the organic and aqueous layers. It was calculated by modifying the equation given in Ref. [11]:

$$D = \frac{m(\mathrm{U})_\mathrm{o}}{m(\mathrm{U})_\mathrm{w}}, \quad (1)$$

where $m(\mathrm{U})_\mathrm{o} = m(\mathrm{U})$ in all possible forms in the CH_2Cl_2 layer at equilibrium (480 h); $m(\mathrm{U})_\mathrm{w} = m(\mathrm{U})$ in the water layer at equilibrium (480 h).

The results in Fig. 7 and in Table 5 show that the transfer of the uranyl ion from the water layer to the CH_2Cl_2 layer during 480 h was best with $H_2L2\cdot HCl$ (95%) and $H_2L4\cdot HCl$ (95%), although $H_2L1\cdot HCl$ and $H_2L3\cdot HCl$ were close to that efficiency level (92% and 94%, respectively). $H_2L5\cdot HCl$ is clearly the worst extractor.

Although ligands $H_2L1\cdot HCl$–$H_2L4\cdot HCl$ are almost equally effective in uranyl extraction and after 48 h all had transferred about 70% of uranyl ion into the organic solvent, after 120 h ligands $H_2L1\cdot HCl$, $H_2L2\cdot HCl$ and $H_2L4\cdot HCl$ had reached about 90% ($H_2L3\cdot HCl$ was still about 70%). After 480 h all ligands except $H_2L5\cdot HCl$ had reached an extraction level higher than 90%. However, the slow extraction rate is a problem with these ligands and in order to reach results in a reasonable time the extraction should be speeded up by stirring.

D	12.3	17.9	16.9	17.9	1.3

No crystals were formed in the CH_2Cl_2 phase during experiment 1 despite the addition of CH_3CN to the extraction solution, although uranyl complexes of ligands H_2L1–H_2L3 formed acetonitrile adducts in acetonitrile solution. In our previous extraction studies [10a] with aminoalcohol tail ligands, crystals were formed in the CH_2Cl_2 layer in some cases. This indicates that the uranyl complexes formed are more soluble in organic solvents than the uranyl complexes with similar long aminoalcohol tail ligands [10b].

The comparison of the uranyl extraction efficiency of the ligands presented in this paper with the extraction ability of the known compound (TBP) (experiment 6) revealed that during 48 h of extraction with TBP about 15% of uranyl ions (20% with TBP in kerosene) were extracted from water layer to CH_2Cl_2 layer, while the ligands $H_2L1 \cdot HCl$–$H_2L4 \cdot HCl$ extracted about 70% of uranyl ions and the ligands presented in our earlier paper [10b] extracted about 93% of uranyl ions during the same time period. Thus these new ligands are much better uranyl ion extractors than TBP in the circumstances studied.

In the extraction experiments 2 and 3 the amount of CH_2Cl_2 was increased and thus the concentration of the ligand in the organic layer was lower. Experiment 2 was done without stirring the solution and experiment 3 with stirring. Increase of the solvent led to a slower extraction rate with ligands $H_2L2 \cdot HCl$, $H_3L7 \cdot HCl$ and $H_3L9 \cdot HCl$, but to a faster rate with $H_2L4 \cdot HCl$ after 48 h of extraction (Table 6). When the solutions of ligands $H_2L4 \cdot HCl$ and $H_3L7 \cdot HCl$ were stirred during the extraction process, the system reached an equilibrium state almost within 2 h, while the process took about 80–100 h without stirring.

We also studied the influence of the uranium salt used by changing uranyl nitrate hexahydrate to uranyl acetate dihydrate in the water phase. We did the experiment with our best ligands: $H_3L6 \cdot 1/3$toluene, $H_3L7 \cdot HCl$ and $H_3L9 \cdot HCl$. This led to a better extraction efficiency with all three ligands examined: from 71% with uranyl nitrate to 92% with uranyl acetate by ligand $H_3L6 \cdot 1/3$toluene, from 93% to 98% by ligand $H_3L7 \cdot HCl$ and from 94% to

48.0	22	13	11	20	15	7

97% by ligand $H_3L9 \cdot HCl$ after 48 h of extraction. The solutions were stirred during the extraction.

As the water solution of uranyl nitrate has a lower pH (about 2.9) than that of uranyl acetate (about 3.2), we studied the effect of pH on the extraction efficiency of ligands $H_2L2 \cdot HCl$ and $H_3L8 \cdot HCl$ in three different acetate buffers. One can clearly see from Table 7 that the extraction efficiency improves as the pH is raised from 3.4 to 5.2 (e.g. from 80% to 93% in the pH range 3.4–5.2 with $H_3L8 \cdot HCl$ after 48 h of extraction). However, high pH values can cause precipitation of uranyl hydroxide without the presence of large amounts of acetate ions and the ligand. Thus the pH value must be optimized for the best extraction results in one experiment.

4. Conclusions

The family of aminoalkylbis(phenolate) [O,N,O] donor ligands formed similar complexes with uranyl ion as the aminoalcoholbis(phenolate) [O,N,O,O′] donor ligands presented earlier [10a,10b]. The complexes presented in this paper are in the solid-state neutral uranyl complexes in which the uranyl ion is almost ideally bonded to four phenolato oxygen atoms of two ligands. The complexes formed are zwitterions, where one of the phenolic protons moves to the nitrogen atom. Changes in the aminoalkyl part of the ligand have only a minor effect on the actual coordination sphere around the uranyl ion.

The solubility of these uranyl complexes in organic solvents is very good. The uranyl extraction effectivity of these new aminoalkylbisphenolates is almost the same as that of the aminoalcoholbisphenolates, but their extraction rate is relatively slow. The reason for the slower rate compared to the aminoalcoholbisphenolates [10a,10b] is probably the higher hydrophobicity of the aminoalkylbisphenolate ligands, leading to a slower penetration rate of the ligand molecule into the water phase to react with the uranyl ion. The slow extraction rate can be compensated by mechanical stirring. However, without stirring one gets a better understanding of the effectiveness and speed of the whole extraction process.

The influence of the pH on the extraction was also studied since it is obvious that the deprotonation of the ligand influences the complex formation. We observed that when uranyl acetate dihydrate was used as uranyl salt instead of uranyl nitrate hexahydrate under the same extraction conditions, the ligands were able to extract more uranyl ions from the water phase into the CH_2Cl_2 phase. This is probably due to the fact that acetate ions in the water phase increase the pH of the solution, which increases the deprotonation of the ligand and thus improves the complexation of the uranyl ion.

According to the ^1H NMR studies in $CDCl_3$ the complexes in CH_2Cl_2 have the formula $[UO_2(HL)_2]$ (L = L1–L5). In order to get more information about the extraction process, an effort was made to find out if the uranyl complex of H_2L2 is formed in 1:1 ratio and possibly then extracted in the 1:1 form into the dichloromethane phase. This was studied by making a solution of $H_2L2 \cdot HCl$: Et_3N: $UO_2(CH_3COO)_2 \cdot 2H_2O$ in a ratio of 1:2:1 in MeOH, EtOH and acetonitrile. However, the crystals formed in these solvents were normal 1:2 complexes of UO_2^{2+} and $HL2^-$ with no indication of the formation of solid 1:1:1 complexes of UO_2^{2+}, $HL2^-$ and CH_3COO^-.

The ligands presented in this work, and also ligands studied earlier [10], are quite good uranyl ion extractors. The next phase is to study how selective these ligands are in the presence of other metal ions. Such studies are underway.

Acknowledgments

We are grateful to Prof. Matti Nurmia for correcting the language of this paper, to Elina Hautakangas for performing the elemental analyses, to Reijo Kauppinen for his assistance with NMR measurements and to Dr. Ari Väisänen for performing the ICP-measurements.

Abstract

The complexes $(\mu_3\text{-}L^1/L^2)[Ru(acac)_2]_3$, $acac^- = 2,4$-pentanedionato, $L^1 = 2,3,8,9,14,15$-hexachlorodiquinoxalino[2,3-*a*:2′,3′-*c*]phenazine and $L^2 = 2,3,8,9,14,15$- hexamethyldiquinoxalino[2,3-*a*:2′,3′-*c*]phenazine, undergo stepwise one-electron oxidation involving a total of three electrons and stepwise one-electron reduction with three (L^2) or four electrons (L^1). All reversibly accessible states were characterized by UV–Vis–NIR spectroelectrochemistry. Oxidation leads to mixed-valent intermediates $\{(\mu_3\text{-}L)[Ru(acac)_2]_3\}^+$ and $\{(\mu_3\text{-}L)[Ru(acac)_2]_3\}^{2+}$ of which the $Ru^{III}Ru^{II}Ru^{II}$ combinations exhibit higher comproportionation constants K_c than the $Ru^{III}Ru^{III}Ru^{II}$ states – in contrast to a previous report for the unsubstituted parent systems $\{(\mu_3\text{-}L^3)[Ru(acac)_2]_3\}^{+/2+}$, $L^3 =$ diquinoxalino[2,3-*a*:2′,3′-*c*]phenazine. No conspicuous inter-valence charge transfer absorptions were observed for the mixed-valent intermediates in the visible to near-infrared regions. The monocations and monoanions were characterized by EPR spectroscopy, revealing rhombic ruthenium(III) type signals for the former. Electron addition produces ruthenium(II) complexes of the reduced forms of the ligands L, a high resolution EPR spectrum with ^{14}N and $^{35,37}Cl$ hyperfine coupling and negligible *g* anisotropy was found for $\{(\mu_3\text{-}L^1)[Ru(acac)_2]_3\}^-$. DFT calculations of $(\mu_3\text{-}L^1)[Ru(acac)_2]_3$ confirm several ligand-centered low-lying unoccupied MOs for reduction and several metal-based high-lying occupied MOs for electron withdrawal, resulting in low-energy metal-to-ligand charge transfer (MLCT) transitions.

1. Introduction

In contrast to the vast number of mixed-valent ligand-bridged diruthenium complexes [1] there have been relatively few reports on the electron transfer reactivity of symmetrically trinuclear compounds [2–8]. If the common Ru^{III}/Ru^{II} redox pairs are involved, this arrangement leads to two homovalent and to two different mixed-valent states, the odd-electron form $Ru^{III}Ru^{II}Ru^{II}$ and the even-electron species $Ru^{III}Ru^{III}Ru^{II}$. Electron transfer to or from a trigonally symmetrical system can involve partial occupation of degenerate orbitals with the resulting tendency for distortion.

Following a previous report [8] on the synthesis and spectroelectrochemical characterization of unsubstituted $(\mu_3\text{-}L^3)[Ru(acac)_2]_3$ (**3**), a trinuclear complex of the extended π ligand $L^3 =$ diquinoxalino[2,3-*a*:2′,3′-*c*]phenazine, we now describe the results for the redox systems $\{(\mu_3\text{-}L^1)[Ru(acac)_2]_3\}^n$, $\mathbf{1}^n$, and $\{(\mu_3\text{-}L^2)[Ru(acac)_2]_3\}^n$, $\mathbf{2}^n$, with the hexasubstituted ligands L^1 and L^2 (Scheme 1).

Scheme 1.

DFT calculation results are reported for the hexachloro-substituted **1**, involving structure optimization and MO description. Voltammetric methods were employed to establish multistep reversible electron transfer while spectroelectrochemistry in the UV–Vis–NIR region as well as EPR in the X band (9.5 GHz) were used to characterize the intermediates.

2. Experimental

2.1. Materials

The precursor compounds $Ru(acac)_2(CH_3CN)_2$ [9], 2,3,8,9,14,15-hexachlorodiquinoxalino[2,3-*a*:2′,3′-*c*]phenazine (L^1) [10] and 2,3,8,9,14,15-hexamethyldiquinoxalino[2,3-*a*:2′,3′-*c*]phenazine (L^2) [11][1] were prepared according to the reported procedures. Other chemicals and solvents were reagent grade and used as received. For spectroscopic and electrochemical studies HPLC grade solvents were used.

2.2. Physical measurements

UV–Vis–NIR spectroelectrochemical studies were performed in CH_3CN/0.1 M Bu_4NPF_6 at 298 K using an optically transparent thin layer electrode (OTTLE) cell [12] in connection with a J&M TIDAS spectrophotometer. FT-IR spectra were taken on a Nicolet spectrophotometer with samples prepared as KBr pellets. Solution electrical conductivity was checked using a Systronic 305 conductivity bridge. ^1H NMR spectra were obtained with a 400 MHz Varian FT spectrometer. The EPR measurements were made in a two-electrode capillary tube [13] with an X-band Bruker system ESP300, equipped with a Bruker ER035M gaussmeter and a HP 5350B microwave counter. Cyclic voltammetric, differential pulse voltammetric and coulometric measurements were carried out using a PAR model 273A electrochemistry system. Platinum wire working and auxiliary electrodes and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. The supporting electrolyte was 0.1 M Et_4NClO_4 and the solute concentration was $\sim 10^{-3}$ M. The half-wave potential E°_{298} was set equal to $0.5(E_{pa} + E_{pc})$, where E_{pa} and E_{pc} are the anodic and cathodic cyclic voltammetric peak potentials, respectively. A platinum wire-gauze working electrode was used in the coulometric experiments. The elemental analysis was carried out with a Perkin–Elmer 240C elemental analyzer. Electrospray mass spectra were recorded on a Micromass Q-ToF mass spectrometer.

2.3. Preparation of complexes *1* and *2*

2.3.1. $[\{(acac)_2Ru^{II}\}_3(\mu\text{-}L^1)]$ (*1*)

The starting complex $Ru(acac)_2(CH_3CN)_2$ (100 mg, 0.26 mmol) and the ligand L^1 (52 mg, 0.087 mmol) were added to 20 ml of ethanol, and the mixture was heated to reflux for 6 h under a dinitrogen atmosphere. The initial orange solution gradually changed to dark green. The solvent was evaporated to dryness and the residue was purified by using a silica gel column. Initially, a red compound corresponding to $Ru(acac)_3$ was eluted by CH_2Cl_2–CH_3CN (25:1 v/v). With CH_2Cl_2–CH_3CN (20:1 v/v), a green compound corresponding to **1** was then separated. Yield: 45 mg, 35%. *Anal.* Calc. for $C_{54}H_{48}Cl_6N_6O_{12}Ru_3$: C, 43.55; H, 3.25; N, 5.65. Found: C, 43.20; H, 3.10; N, 5.32%. ^1H NMR (400 MHz) in $(CD_3)_2SO$ δ (ppm), 8.29/8.27, 8.21/8.19 (s, ($CH(L^1)$), 5.67/5.66/5.64 (s, CH(acac)), 2.34; 1.68/1.67 (s, CH_3(acac)). The positive ion electrospray mass spectrum of **1** shows the molecular ion peak centered (*m*/*z*) at 1489.58, corresponding to $\mathbf{1}^+$ (calculated molecular mass, 1488.94) and a peak centered (*m*/*z*) at 1388.53 corresponding to $\{\mathbf{1}\text{-acac}\}^+$ (calculated molecular mass, 1389.83).

2.3.2. $[\{(acac)_2Ru^{II}\}_3(\mu\text{-}L^2)]$ (*2*)

The complex $Ru(acac)_2(CH_3CN)_2$ (100 mg, 0.26 mmol) and L^2 (41 mg, 0.087 mmol) were added to 20 ml of ethanol and the mixture was heated to reflux for 12 h under a dinitrogen atmosphere. The initial orange solution gradually changed to bluish green. The solvent was evaporated and the residue purified by using a silica gel column. Initially, a red compound corresponding to $Ru(acac)_3$ was eluted by CH_2Cl_2–CH_3CN (25:1 v/v). With CH_2Cl_2–CH_3CN (5:1 v/v), a blue compound corresponding to **2** was separated. Yield: 55 mg, 46%. *Anal.* Calc. for $C_{60}H_{66}N_6O_{12}Ru_3$: C, 52.62; H, 4.86; N, 6.14. Found: C, 52.83; H, 4.85; N, 6.22%. ^1H NMR (400 MHz) in $(CD_3)_2SO$ δ (ppm), 8.34/8.28; 8.15/7.94 (s, $CH(L^2)$), 5.76/5.52 (s, CH(acac)), 2.41/2.21/1.56 (multiplet, CH_3). The positive ion electrospray mass spectrum of **2** shows the molecular ion peak centered (*m*/*z*) at 1365.95, corresponding to $\mathbf{2}^+$ (calculated molecular mass, 1366.43).

[1] The heterocyclic system was referred to as 5,6,11,12,17,18-hexaazatrinaphthalene (Ref. [11]).

2.4. Computational details

Complete geometry optimization without symmetry constraints was carried out for **1** in the Δ_3/Λ_3 configuration, using the density functional theory method at the B3LYP level. The Δ_3/Λ_3 configuration was chosen for convenience, isomerism was shown to affect the electronic structure very little [1f,1i,1j,3]. All elements except ruthenium were assigned a 6-31G* basis set. The Stuttgart–Dresden effective core potential (ECP), representing 19 core electrons, along with valence basis sets (SDD) was used for the ruthenium atoms [14a,14b]. Calculations were performed with GAUSSIAN 98 [14c]. Vertical electronic excitations based on B3LYP optimized geometries were computed using the time-dependent density functional theory (TD-DFT) formalism [14d,14e] with the B3LYP functional using the above combination of basis sets. Extinction coefficients were obtained from calculated oscillator strengths using Gaussian line shape and a full width at half maximum (fwhm) of 0.4 eV = 3228 cm^{-1} [14f]. The molecular orbital compositions have been determined using the programme AOMIX using the B3LYP/SDD,6-31G* wave function [14g]. Visual inspection of all key orbitals was done with MOLDEN [14h] to assign the nature of various electronic transitions.

3. Results and discussion

Regardless of the molar ratio of the reactants, the trinuclear complexes **1** and **2** were invariably obtained from reactions between $Ru(acac)_2(CH_3CN)_2$ and either of the free ligands. The well established [9,15] π electron donor capacity of the $Ru^{II}(acac)_2$ complex fragment is held responsible for enhancing the metal affinity of mono- and dinuclear intermediates through extensive π conjugation until full charge transfer supported coordinative saturation [16] is achieved.

Positive ion electrospray mass spectroscopy of **1** (Fig. 1a) and **2** (Fig. 1b) support the identity of the new hexasubstituted complexes. The ^1H NMR spectra of **1** and **2** exhibit two sets of signals both for the aromatic CH protons of L^1 and L^2 and for the CH/CH_3 groups of the $acac^-$ ligands (Fig. 2, Section 2). The presence of two sets of signals in each case indicates the existence of mixtures of two diastereoisomers (Δ_3/Λ_3 or $\Delta_2\Lambda/\Lambda_2\Delta$) in solution. The two closely spaced singlets for all protons involved with a particular diastereoisomeric form result from the pseudo C_3-symmetry of the molecule. In related cases such isomerism was shown to affect the electrochemical and spectroscopic response only slightly [1f,1i,1j,3], we therefore used the product distributions as obtained and as characterized by NMR (Fig. 2).

Full geometry optimization of complex **1** in the Δ_3/Λ_3 configuration was carried out at the B3LYP level of theory by using the SDD basis set for Ru and the 6-31G* basis for all other atoms (Fig. 3). Important optimized structural parameters of complex **1** are summarized in Tables S1

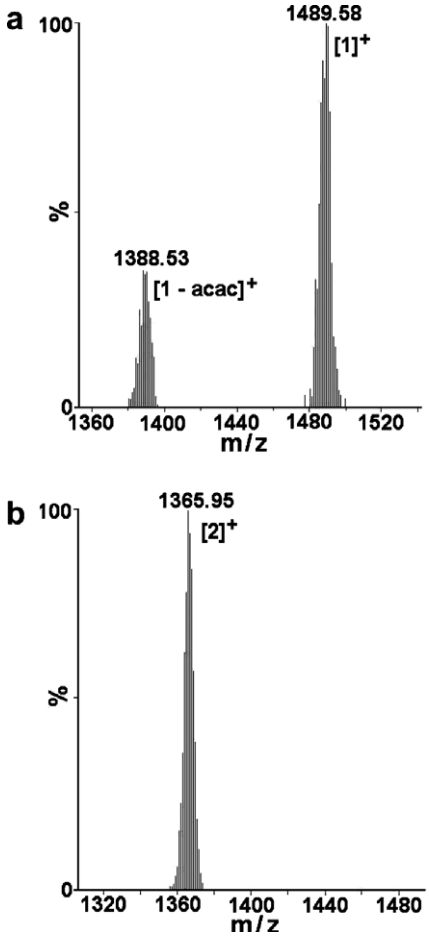

Fig. 1. Electrospray mass spectra of: (a) **1** and (b) **2** in CH_3CN.

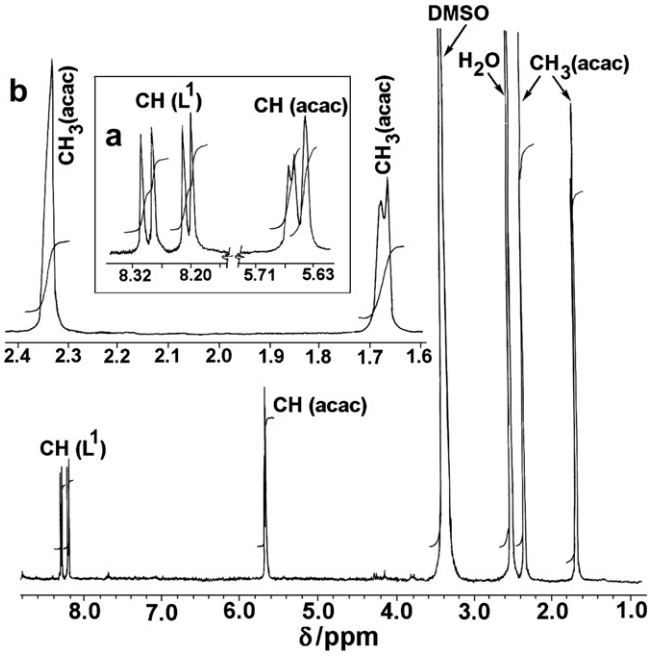

Fig. 2. ^1H NMR spectrum of **1** in $(CD_3)_2SO$. Inserts show expanded parts of the spectrum in the range of: (a) 5.5–8.5 ppm and (b) 1.5–2.5 ppm.

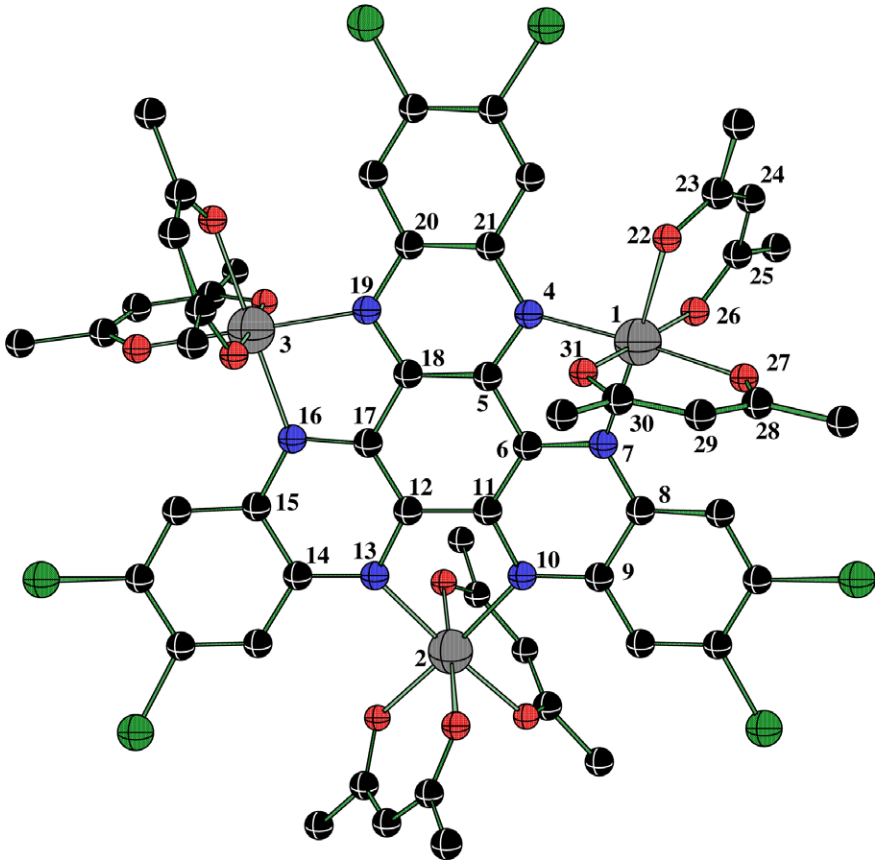

Fig. 3. Optimized structure of complex **1** at the B3LYP level of theory by using the SDD basis set for Ru and 6-31G* for all other atoms (no symmetry constraints).

and S2. The Ru–N and Ru–O(acac) distances are found to vary only slightly and range between 2.06 and 2.08 Å. The N(4)–C(5) and N(7)–C(6) π bonds are found to be elongated by about 0.023 Å in **1** as compared to the free ligand L^1, and this N–C π bond elongation is nearly the same at each ruthenium center which signifies the comparable extent of π back-bonding from each Ru^{II} ion (*vide infra*). The metal centers were found to be separated by about 6.9 Å (Table S1).

Electrochemically the complexes **1** and **2** exhibit multiple reversible one-electron reduction waves which are associated with the highly conjugated bridging ligands (L^1/L^2); the potentials also vary systematically with the electronic nature of the substituents, Me or Cl. In case of **1**, four distinct reduction processes were observed whereas only three waves were detected for **2** (Table 1, Fig. 4). In addition, **1** and **2** display three successive oxidation processes corresponding to the reversible transitions $Ru^{II}Ru^{II}Ru^{III} \rightleftharpoons Ru^{II}Ru^{II}Ru^{II}$ (couple I), $Ru^{II}Ru^{III}Ru^{III} \rightleftharpoons Ru^{II}\ Ru^{II}Ru^{III}$ (couple II), and $Ru^{III}Ru^{III}Ru^{III} \rightleftharpoons Ru^{II}Ru^{III}Ru^{III}$ (couple III) (Table 1, Fig. 4). These potentials are lower for R = Me (complex **2**) than for R = Cl (complex **1**) (Table 1), as expected from the different electron donating and withdrawing abilities. Remarkably, the separation between the redox potentials for complex oxidation leads to larger comproportionation

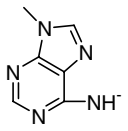
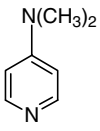
constants for the first intermediate (K_{c1}) than for the second form, $Ru^{II}Ru^{III}Ru^{III}$ (K_{c2}), both for $\mathbf{1}^{n+}$ and $\mathbf{2}^{n+}$, respectively ($RT\ln K_c = nF(\Delta E)$ [1]). Usually, the opposite is observed (Table 2) due to increasing Coulombic interactions; for instance, K_c values for the corresponding parent complex $\mathbf{3}^{n+}$ with R = H have been reported at $10^{5.7}$ (K_{c1}) < $10^{8.0}$ (K_{c2}). In comparison to $\mathbf{3}^{n}$ K_{c1} appears to be slightly greater for $\mathbf{1}^{n+}$ or $\mathbf{2}^{n+}$, however, K_{c2} is much larger for $\mathbf{3}^{n+}$ than for $\mathbf{1}^{n+}$ or $\mathbf{2}^{n+}$.



The electrolyte-dependent [17a,17b] comproportionation constants K_c reflect several different effects such as the electrostatic interaction, an inductive factor, the resonance exchange, the antiferromagnetic exchange stabilization, and ion-pairing effects [17c,17d,17e]. Their comparative interpretation is thus not always as straightforward as commonly believed. In the present case, the smaller range for the dicationic, i.e. rather highly charged $Ru^{II}Ru^{III}Ru^{III}$ forms may reflect diminished Coulombic effects due to enhanced charge delocalization by the six π donating Cl ($\mathbf{1}^{2+}$) or inductively electron donating Me substituents ($\mathbf{2}^{2+}$). Not unexpectedly, the potentials for corresponding diastereoisomers are rather similar [3,18,19]. Nevertheless, the profile of the cyclic voltammograms, in particular for **2**, suggests the existence of two diastereoisomers in solution as has also been observed by ^{1}H NMR (Fig. 2, Section 2).



The EPR spectra taken of monocations and monoanions are in agreement with expectations [8] for the frontier orbital situation and with the DFT calculated orbital

compositions (see Table 4). The cations exhibit rhombic Ru^{III} type signals with considerable g anisotropy in the immobilized state (Fig. 5, Table 3); this and the average g above 2 are indicative of low-spin d^5 species in a distorted octahedral situation [20].

In contrast, the monoanions exhibit EPR features without detectable g anisotropy at X band frequency (9.5 GHz), the isotropic g values near 2.00 (Table 3) signify vanishing participation of atoms with large spin–orbit coupling constants at the spin distribution [21]. The complex anion $\mathbf{1}^{\cdot-}$ was even found to exhibit hyperfine structure caused by coupling with ^{14}N ($I = 1$) and $^{35,37}Cl$ nuclei ($I = 3/2$) at the order of about 1 G (Fig. 6). These values are compatible with the composition of the lowest unoccupied MO (see Fig. 8), small, unresolved hyperfine interaction with the total of 18 methyl hydrogen atoms is likely to obscure the hyperfine structure for $\mathbf{2}^{\cdot-}$. Evidence for symmetry lowering on the EPR time scale has not been observed, there is probably rapid equilibration of any distortions.

The signal detectability at room temperature, the small line-width allowing for EPR resolution, the isotropic g factors close to the free electron value of 2.0023, and the absence of metal ($^{99,101}Ru$, $I = 5/2$) hyperfine splitting and of g anisotropy at 9.5 GHz are all in agreement with an almost exclusively ligand-centered spin [21]. In fact, the results suggest much less metal participation than in complexes of $[Ru(bpy)_2]^{2+}$ with anion radical ligands [13], probably because of the donor characteristics of $Ru(acac)_2$ in comparison to $[Ru(bpy)_2]^{2+}$.

The energies and the composition of the frontier Kohn–Sham orbitals (Figs. 7 and 8) have been examined using the AOMIX programme [14g,22]. The filled levels (between HOMO and HOMO − 6) are predominantly metal-centered orbitals with total Ru contributions of around 65% and additional mixing with the π orbitals of $acac^-$ (Table 4). The unfilled levels, on the other hand, are primarily located over the L^1 unit, having π^*

characteristics[2]. Atomic orbital contributions from the metal centers towards the LUMO are successfully adopted in explaining the back-bonding within metal complexes in more quantitative fashion [23]. In the present case, the con-

[2] We have identified the π^* orbital of L^1 as the one in the xy-plane by careful analysis of the MO coefficient of the LUMO, which is mainly located on π^* of L^1 (66%) with minor contribution from dπ on Ru. Further, the d-orbital in the same plane as that of L^1 is taken as the d_{xy} and the remaining orthogonal d-orbitals as d_{xz} and d_{yz}.

[a] Values in parentheses indicate orbital energy in cm^{-1}.

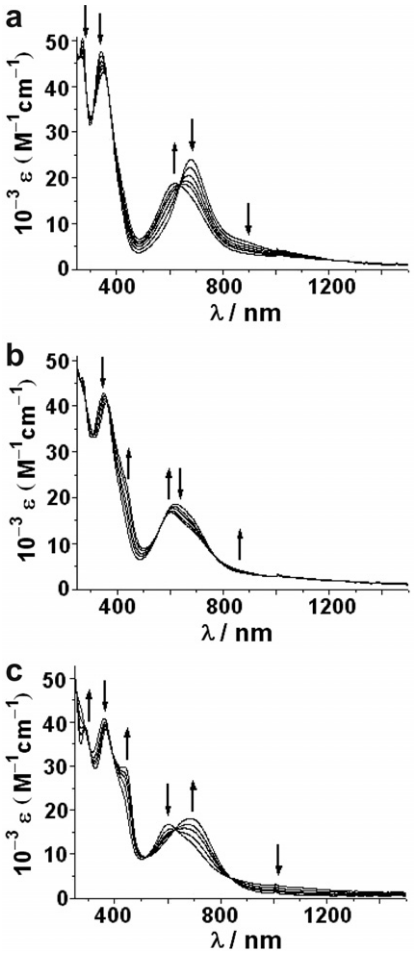

Fig. 9. UV–Vis–NIR spectroelectrochemistry for the conversions: (a) $\mathbf{1} \rightarrow \mathbf{1}^{+}$, (b) $\mathbf{1}^{+} \rightarrow \mathbf{1}^{2+}$ and (c) $\mathbf{1}^{2+} \rightarrow \mathbf{1}^{3+}$in CH_3CN/0.1 M Bu_4NPF_6.

tributions from the ruthenium atoms towards the LUMO are found to be about the same on average, the effective trigonal symmetrical situation being further confirmed by the optimized geometrical parameters around the ruthenium atoms. Nonetheless, the metals contribution especially to the calculated LUMO seems to be overestimated, considering the EPR results with their suggestion of marginal ruthenium influence.

UV–Vis–NIR absorption spectroelectrochemistry was performed for the multistep series $\mathbf{1}^{3+}$–$\mathbf{1}^{4-}$ (Figs. 9 and 10) and $\mathbf{2}^{3+}$–$\mathbf{2}^{3-}$ (Table 5).

The results show similar trends for both series in agreement with the donor effect of both kinds of substituents. The free ligands have long-wavelength π–π* absorption bands at about 412 nm (ε ca. $6 \times 10^4\ M^{-1}\,cm^{-1}$) whereas the lowest energy absorption maxima of **1** and **2** lie around 660 nm (ε ca. $1.8 \times 10^4\ M^{-1}\,cm^{-1}$). These bands are assumed to derive from allowed metal-to-ligand charge transfer (MLCT) transitions, given by the experimentally and computationally suggested presence of several high-lying occupied d levels and low-lying unoccupied ligand π* orbitals.

A selected list of computed vertical excitation energies using the time-dependent density functional theory (TD-DFT) is therefore given in Table S2. For **1**, two transitions with fairly high oscillator strengths and calculated extinction coefficients have been obtained, one at 781 nm ($\varepsilon = 2914\ M^{-1}\,cm^{-1}$) and another at 771 nm ($\varepsilon = 4993\ M^{-1}\,cm^{-1}$). The quantitative assessment of these orbital overlap-favored MLCT processes compares with experimental values for **1** of 890 nm(sh) and 680 nm ($\varepsilon = 23900\ M^{-1}\,cm^{-1}$). As must be expected for

[a] In CH_3CN/0.1 M Bu_4NPF_6.

a situation with several filled d orbitals from three d^6 metal centers and a number of ligand π^* MOs (Fig. 4) there are several other MLCT transitions of lower energy but much smaller oscillator strengths (poor orbital overlap) which are not experimentally detectable (Table S2). A similar reason may preclude [8] the detection of the inter-valence charge transfer (IVCT) bands of the mixed-valent forms $\mathbf{1}^{+}$, $\mathbf{1}^{2+}$, $\mathbf{2}^{+}$ and $\mathbf{2}^{2+}$ in the typical near-infrared region [1,3]. In spite of careful spectral search even in the mid-infrared region we could not establish such bands (Table 5), although $[Ru(bpy)_2]^{2+}$ complexes of the related 1,4,5,8,9,12-hexaazatriphenylene ligands exhibit such features [3b,3c]. This absence of detectable long-wavelength absorption for otherwise clearly identified Ru^{II}/Ru^{III} mixed-valent intermediates has been noted before not only for $\mathbf{3}^{+}$ and $\mathbf{3}^{2+}$;8 dinucleating chelate acceptor bridges connecting ruthenium complex fragments, especially $Ru(acac)_2$, have previously been described to yield "IVCT silent" mixed-valent species [24]. An alternative interpretation [3a] involving the obscuring of the IVCT band by the MLCT absorptions in the visible would imply an usually strong metal–metal interaction which we consider less likely.

Within the spectroelectrochemically monitored electron transfer series (Figs. 9,10, and Table 5) it is remarkable that the second oxidation and reduction involve very little spectral changes. This may suggest spin pairing of the doubly reduced or oxidized forms in agreement with the absence of EPR triplet features. Although they can be generally assigned as MLCT and, at higher energies, as intra-ligand (IL) absorptions, the detailed identification of the major bands of the spectroelectrochemically generated complex ions (Table 5) will not be attempted and will have to await open-shell calculations. Given the photophysical and intercalating potential of such large π systems [25] further investigations of their electronic structures are warranted.

4. Conclusion

We have shown that EPR spectroscopy in conjunction with electrochemistry can provide an alternative way to identify mixed-valent intermediates, especially when the expected inter-valence CT bands in the long-wavelength region are not observable. The six fold substitution of the large heterocyclic π system clearly affects the physical properties, allowing not only for multiple oxidation at the metals but also for several ligand based reduction processes.

Abstract

2-Hydroxy-3-carboxy-dihydrocinnamic acid (H_3L) is proposed as a simple salicylic acid derivative able to form tridentate complexes with Al(III) and Fe(III). H_3L was synthesized, and its complexation properties towards Al(III) and Fe(III) have been studied by means of potentiometric titrations, UV–Vis and NMR measurements at 25 °C in aqueous (Na)Cl 0.6 m. pK_a values of the ligand are 2.68 ± 0.02 (H_3L) and 4.49 ± 0.01 (H_2L^-). The complexes with the following stoichiometry (and stability constant, log beta values) were identified: $AlLH^+$ (3.888 ± 0.003), AlL (-0.273 ± 0.003), and AlL_2^{3-} (-2.93 ± 0.06) for Al(III), and $FeLH^+$ (6.54 ± 0.04), FeL (3.0 ± 0.1), $FeL_2H_2^-$ (10.5 ± 0.1), and FeL_2H^{2-} (7.34 ± 0.08) for Fe(III). Most of the Al(III) and Fe(III) species are either bidentate (salicylate-like), or mixed ligand-hydroxo complexes. The tridentate chelation is displayed in the AlL species. Molecular modeling confirmed experimental results.

1. Introduction

The therapy for metal overload pathologies usually involves the administration of suitable chelating agents to selectively remove the metal from the body. Regarding Al(III) and Fe(III), there is a need for new, safe, inexpensive, efficient, and orally effective chelators [1–8]. The chemical contribution on this topic consists in the synthesis of new ligands, and in the study of their metal–ligand complexation properties [9], especially under physiological conditions.

Hexadentate ligands possess very high selectivity towards Al(III) and Fe(III), but usually they have a poor oral bioavailability [10]. Bidentate ligands have opposite behaviour, *i.e.* lesser selectivity but higher oral bioavailability. Tridentate ligands could simultaneously display the advantages of both hexadentate and bidentate molecules, and therefore they could represent the ideal type of chelating agent. Up to now, strong tridentate ligands having three oxygen donors as chelating groups are not known [10]: at least one of the three chelating sites is a nitrogen atom. The presence of nitrogen in the metal coordination sphere, in the case of Fe(III), may favour the Fe(II) redox state and could reduce the redox potential of the complex, with possible occurrence of Fenton-type reactions in vivo and generation of hydroxyl radicals [10].

In previous works [11, and references therein] we proposed selected hydroxypyridinecarboxylic acids (Fig. 1) as new possible bidentate chelating agents for Al(III) and Fe(III) in view of several promising properties. The possibility to prepare new tridentate chelating agents by substituting the hydroxypyridinecarboxylic acid moiety is the aim of the present work. The $(CH_2)_nCOOH$ derivative in

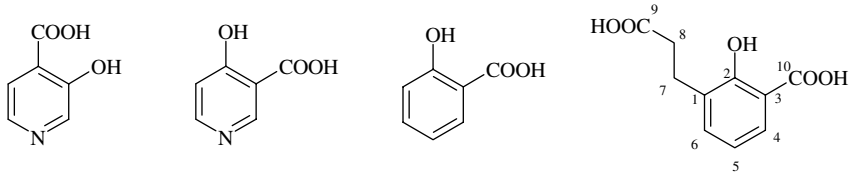

Fig. 1. From the left to the right, 3-hydroxy-4-pyridinecarboxylic acid, 4-hydroxy-3-pyridinecarboxylic acid, salicylic acid, 2-hydroxy-3-carboxy-dihydrocinnamic acid (shown in the H_3L form).

ortho with respect to the phenolic oxygen was considered in view of the relative easy of its synthesis. However, because hydroxypyridinecarboxylic acids are not commercially available, a first synthetic and complexation study attempt has been made starting with a similar, commercially available molecule, salicylic acid (Fig. 1).

A preliminary molecular modeling study allowed to individuate 2-hydroxy-3-carboxy-dihydrocinnamic acid (H_3L, Fig. 1) as the aliphatic carboxylate derivative of salicylic acid which should have the highest probability to display a tridentate chelation geometry, and therefore improved complexation affinity towards Al(III) and Fe(III). Then, because H_3L is not commercially available, it has been synthesized and characterized. In the last step, the complexation study of H_3L with Al(III) and Fe(III) has been performed by means of potentiometric titrations, UV–Vis and NMR measurements.

2. Experimental

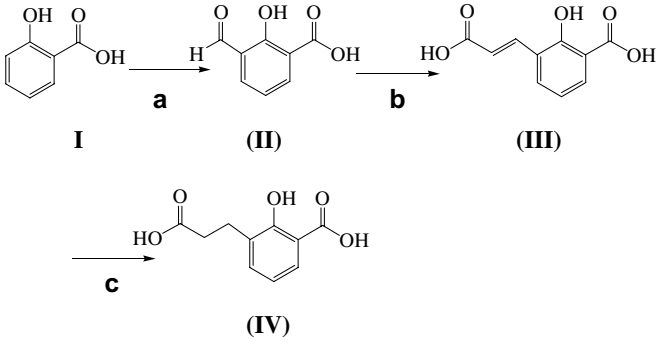
2.1. Molecular modeling

All quantum chemistry calculations were performed by using SPARTANO2 [12] and GAUSSIAN98 [13] softwares. The ground state geometry of all, charged and uncharged, aluminium and iron complexes were fully optimized without geometry constraints using RHF/PM3 calculations. Vibrational frequency analysis was used to characterize the minima stationary points (zero imaginary frequencies). We apply the COSMO [14] using the gas phase PM3 fully optimized geometries to obtain the corresponding solvation energy ΔE_{solv}.

2.2. Synthesis and solution equilibria

2.2.1. Chemicals

All chemicals were commercially available and of pure grade. Salicylic acid, sodium hydroxide, phosphorus pentoxide, copper(II) sulphate pentahydrate, sulphuric acid (95–97% weight) and ethyl ether were Fluka (Germany) reagents. Sodium hydrogen sulphite solution (38–40% weight) and hydrochloric acid (37% weight) were purchased by Riedel de Haen (Germany). Chloroform was purchased by Janssen. Magnesium sulphate anhydrous was a Baker Analyzed Reagent (Holland) product. Ammonia solution (30%) was purchased by Carlo Erba. HCl (Prolabo), NaOH (Fluka, nominal purity 98%+, CO_2 max. 0.5%), aluminium wire (Aldrich, nominal purity 99.999%) and iron granules (Aldrich, nominal purity 99.999%) were used to prepare solutions for potentiometric and UV–Vis measurements. For the NMR measurements, D_2O (Aldrich, 99.9 atoms% D), $AlCl_3$ (Fluka, $\geqslant$99%), KOD (Aldrich, 40% sol. in D_2O, 99.9 atom% D) and DCl (Janssen, 20% wt. sol. in D_2O, 99+ atom% D) were used.



2.2.2. Apparatus

IR spectra were registered on a FT-IR Perkin–Elmer spectrophotometer mod. 237 as a nujol suspension. The ^1H and ^{13}C NMR measurements were made at room temperature with a Bruker Avance 300 operating in FT mode using 5 mm tubes. The chemical shifts were given with respect to Me_4Si (TMS) when organic deuterated solvents were employed, and to $Me_3SiCH_2CH_2COONa$ (TSP) when D_2O was used as solvent. HPLC-MS analyses were made with an Agilent instrument mod 1100 equipped with a Luna C-108 column (15 cm × 5 mm i.d.) and an ion-trap quadrupolar mass detector. The eluent was a solution of $HCOONH_4$ 2.1 mM and HCOOH 0.026 mM.

All potentiometric measurements were performed with a Metrohm 765 Dosimat apparatus. UV spectra were recorded with a Perkin–Elmer Lambda 25 spectrophotometer.

2.2.3. Synthesis of 2-hydroxy-3-carboxy-dihydrocinnamic acid (H_3L)

H_3L was prepared in three steps following the literature data.

In the first step (a), 30 g of salicylic acid (**I**) (0.27 mol) were converted to 3-formylsalycilic acid (**II**) in 15% yield by reaction with 114.7 mL $CHCl_3$ (0.68 mol) and 250 mL NaOH 1.0 M (0.25 mol) added drop wise. Reaction is com-

pleted in 5 h [15]. In step (b), 2.1 g of **II** (0.013 mol) was allowed to react with 3.0 g of malonic acid (0.028 mol) in pyridine (7.0 mL) added with three drops of aniline to form 2-hydroxy-3-carboxy-cinnamic acid (**III**) in 63% yield [16]. In the last step (c), palladium-catalyzed hydrogenation under 5 bar pressure of **III** (0.45 g, 23.7 mmol) in 30 mL of ethanol gave after four hours and crystallization with cold water the titled pure compound 2-hydroxy-3-carboxy-dihydrocinnamic acid (**IV** = H_3L) in 73% yield [16]. All the products **II**–**III**–**IV** were fully characterized by elemental analysis, melting point, IR and ^1H, ^{13}C NMR measurements and the results were in good agreement with those of literature. In addition, analysis of **II** with HPLC-MS ion-trap was used to confirm the purity of the prepared compound.

Main chemical–physical data for H_3L: Elemental *Anal.* Calc. for $C_{10}H_{10}O_5$: C, 57.14; H, 4.83. Found: C, 57.02; H, 4.50%. M.p.: 211–213 °C (literature 202–205 °C [16]); IR (KBr) = 1693 (stretching as. COO), 1637 and 1623 (stretching C=C aromatic), 1465, 1435 and 1413 cm^{-1} (stretching sim. COO). ^1H NMR in $(CD_3)_2CO$, δ: 2.61 (t, 2H, methylene protons), 2.93 (t, 2H, methylene protons), 6.87 (t, 1H, aromatic protons), 7.47 (d, 1H, aromatic proton) and 7.77 (d, 1H, aromatic proton) ppm. ^{13}C NMR in $(CD_3)_2CO$, δ (see Fig. 1): 25.98 (C-8), 33.54 (C-7), 112.56 (C-3), 119.48 (C-5), 129.31 (C-1), 136.94 (C-6), 161.04 (C-2), 173.10 (C-10) and 174.06 (C-9) ppm.

2.2.4. Synthesis of an Al–H_3L complex

An acidic solution of H_3L (105.2 mg in 10 mL, 0.05 mmol/L) was brought to pH 6.50 upon addition of KOH 0.1 M. An Al(III) solution ($AlCl_3$ 0.05 mmol/L, pH 3.37) was added drop wise under stirring (final pH 5.50). After few minutes a white precipitate formed, which was filtered, washed and dried overnight under vacuum. M.p. = 344–346 °C, IR (KBr) = 1605, 1577, 1476, 1451, 1406, 1259, 1082, 874, 765 cm^{-1}. Elemental analysis: 30.28% C, 3.85% H, 6.54% Al (by AAS). Although elemental analysis was not able to indicate the exact stoichiometry of the complex, the molar ratio Al/C = 0.216 obtained in the analysis suggests a 1:1 metal-to-ligand stoichiometric ratio (calculated ratio: 0.224). The complex is probably the neutral species $AlC_{10}H_7O_5 \cdot xH_2O$ with the copresence of some KCl.

2.2.5. Solution equilibria

The measurement method was almost the same as reported previously [17]. In the following, a summary will be given. Details are reported only when different from those already described.

All analyte concentrations were expressed in the molality scale (mol/kg of water).

For potentiometric and UV measurements, working solutions of HCl (0.1 m), NaOH (0.2 m), $AlCl_3$ (0.05 m, containing HCl 0.3 m) [17] and $FeCl_3$ (0.05 m, containing HCl 0.2 m) [18] were prepared and standardized. H_3L was used as synthesized to prepare a 0.005 m solution, brought to pH *ca.* 8.5 to ensure water solubility (at autogenic pH, *i.e.* below 3, the ligand has a too low water solubility, *ca.* 7×10^{-4} m). There was no evidence of ligand lactonization. The starting solution and all working solutions contained known amounts of NaCl to assure a constant (Na)Cl 0.6 m (0.594 M) ionic strength during the titrations. Solutions for ^1H NMR measurements were prepared by dissolving in D_2O weighed amounts of ligand, $AlCl_3$ and NaCl. The pD was adjusted by the addition of concentrated KOD and/or DCl solutions.

Potentiometric titrations are summarized in Table 1. Temperature was 25.0 ± 0.1 °C. Duplicate potentiometric measurements were executed by using two different glass electrodes (Metrohm 6.0150.100 and VWR 662-1792) and a Ag/AgCl/0.6 m NaCl reference electrode [19,20] with a J–shaped junction. Titrations were discarded if the relative e.m.f. values measured by the two electrodes differed by more than 0.2 mV (*ca.* 0.003 pH units). The acidic liquid junction potential of the reference electrode has been determined previously [18], and it can be represented by the equation [20] $E_j = -S \cdot \log(1+J \cdot C_{H^+})$, with $J = 3.69 \pm 0.08$. As a check of the accuracy of the entire experimental system, the pK_w value for water in (Na)Cl 0.6 m was computed from HCl + NaOH titrations. The values obtained from different series of experiments (pK_w = 13.699 ± 0.002, 13.701 ± 0.002, and 13.690 ± 0.003) compare well with the literature value [21] in Na(Cl) 0.6 M at 25 °C (13.727 ± 0.001). All stability constants were calculated using the computer program PITMAP [22]. The following metal-hydroxo species have been considered and the corresponding log β values kept fixed during the elaboration of the data: AlH_{-1} (logβ = −5.52), AlH_{-2} (−11.3), AlH_{-3} (−17.3), AlH_{-4} (−23.46), Al_3H_{-4} (−13.57), $Al_{13}H_{-32}$ (−109.2) [23], FeH_{-1} (logβ = −2.87), FeH_{-2} (−6.16) [18], FeH_{-3} (−12.2), FeH_{-4} (−22.2), Fe_2H_{-2} (−2.9), Fe_3H_{-4} (−6.3) [24].

UV measurements (Table 2) were carried out for solutions containing the ligand alone, and for solutions containing the ligand and the metal ion, at various pH values (cell path 1 cm). In the case of Al(III), a large metal excess was necessary to enhance the complex formation. When the pH of the solution was below 2.5, it was computed from the stoichiometric concentration of HCl, because the $[H^+]$ modifications produced by the other species (*i.e.* the free ligand, the free metal ion, and the metal–ligand complexes) were negligible under these conditions. In other cases the pH was measured with the same electrodes and procedures as for potentiometric titrations.

Table 1
Potentiometric titrations

System	Conditions			
	$C_M/10^{-3}$ m	$C_L/10^{-3}$ m	C_L/C_M	pH
(1) H_3L		0.77		2.1–11.0
(2) Al(III)/H_3L	0.28–0.77	0.77–1.13	1, 2, 3, 4	2.3–5.5
(3) Fe(III)/H_3L	0.24–0.96	0.77–1.17	1, 2, 3, 4, 5	1.8–3.7

Table 2
UV–Vis measurements

System	Conditions			
	$C_M/10^{-3}$ m	$C_L/10^{-3}$ m	pH	λ (nm) for calculation
H_3L		0.20	0.57, 1.79	
Al(III)/H_3L	1.95	0.19	1.53–2.93	265; 308
Fe(III)/H_3L	1.19	1.22	1.60–3.40	550

The $\log\beta$ values for some metal–ligand complexes were computed by the program PITMAP.

^{1}H NMR spectra of H_3L were collected at various pD values in D_2O solutions containing only the free ligand ($C_L = 0.0012$ m), and the ligand together with Al(III) at two different metal concentrations ($C_L = 0.0012$ m, $C_{Al} = 0.00052$ m and 0.0012 m). The pD was measured with a glass electrode BDH 309/1025/02 previously calibrated in buffered solutions at pH 4 and pH 7, and 0.41 pH units were added to the pH-meter readings to correct for isotopic and solvent effects [25].

3. Results and discussion

3.1. Potentiometric results

In principle H_3L is a triprotic acid (see Fig. 1). Table 3 summarizes the pK_a values obtained from our potentiometric titrations. Under the experimental conditions here used, only pK_{a1} and pK_{a2} can be detected. The former corresponds to the deprotonation of the benzoic COOH, the latter to the deprotonation of the dihydrocinnamic COOH residue. The pK_{a1} obtained by us is very similar to the one obtained for salicylic acid by Öhman et al. (p$K_{a1} = 2.724 \pm 0.001$ [26]) in very similar conditions ($T = 25$ °C, aqueous Na(Cl) 0.6 M). The pK_{a3}, which corresponds to the deprotonation of the phenol-like OH group, could be measured neither by us nor by Öhman because it is too high. Therefore, we disregarded this last proton dissociation process and considered HL as the complex-forming species in the formation equilibrium $pM + qHL + rH = M_pL_qH_{r+q}$ (for simplicity, charges will be generally omitted from the formulae, except in the Tables). In this way, more accurate formation constants were obtained, although their numerical values differ by the value of the last pK_a from those calculated in the usual way for the equilibrium $pM + qL + rH = M_pL_qH_r$.

The potentiometric titrations of solutions containing the metal and the ligand allowed the identification of the complexes AlLH, AlL, and AlL_2, for Al(III)–H_3L, and FeLH, FeL, FeL_2H_2, and FeL_2H, for Fe(III)–H_3L. The values of their stability constants are reported in Table 3. Typical distribution diagrams are reported in Fig. 2a for Al(III) and 2b for Fe(III). In the case of Al(III), a 1:1 species, probably the neutral complex AlL, was isolated as solid at slight acidic pH values.

Table 3
pK_a values of H_3L (reactions: $H_nL \rightleftharpoons H_{n-1}L + H$), and $\log\beta$ values for metal–ligand complexes at 25 °C in aqueous (Na)Cl 0.6 m (reactions: $pM + qHL + rH = M_pL_qH_{r+q}$)

Species	$\log\beta$	pK_a
H_3L		2.68 ± 0.02
H_2L^-		4.49 ± 0.01
$AlLH^+$	3.888 ± 0.003	
AlL	-0.273 ± 0.003	
AlL_2^{3-}	-2.93 ± 0.06	
$FeLH^+$	6.54 ± 0.04	
FeL	3.0 ± 0.1	
$FeL_2H_2^-$	10.5 ± 0.1	
FeL_2H^{2-}	7.34 ± 0.08	

Values are shown as the mean and standard deviation of the mean.

Some structural features of the complexes can be deduced from the stoichiometry of the species and from their stability constants. AlLH, FeLH and FeL_2H_2 likely have the dihydrocinnamic carboxylate in the protonated form, and therefore they are probably bidentate salicylate-like complexes (Fig. 3. See also UV–Vis and NMR sections).

The pK_a corresponding to the deprotonation AlLH = AlL + H ($pK_{a(AlLH)} = \log\beta_{AlLH} - \log\beta_{AlL} = 4.16$) is more

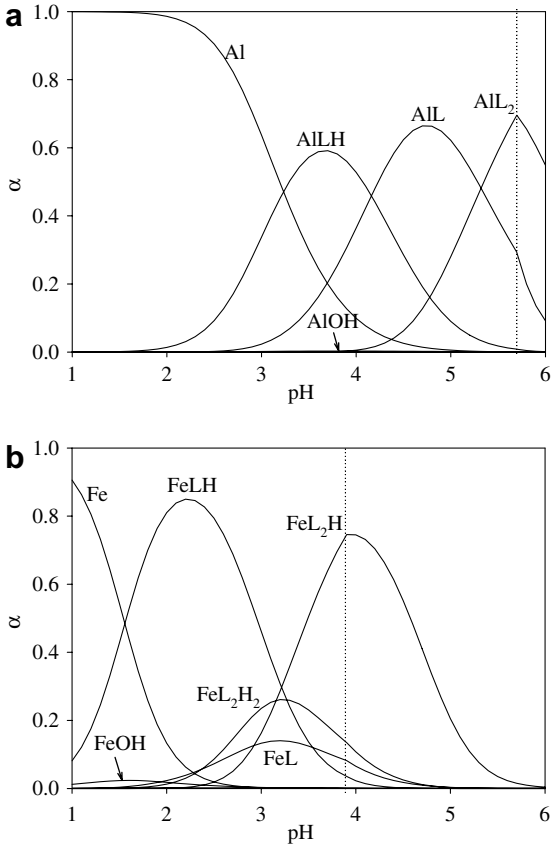


Fig. 2. Distribution diagrams of the H_3L complexes of Al(III) (a) and Fe(III) (b) in aqueous (Na)Cl 0.6 m, $T = 25$ °C; $C_M = 10^{-3}$ m, $C_L = 4 \times 10^{-3}$ m. The dotted line indicates the theoric start of metal hydroxide precipitation.

similar to the pK_{a2} of the free ligand (4.49) than to the pK_1 of $Al(H_2O)_6^{3+}$ (5.52): this suggests that the deprotonation occurs at the dihydrocinnamic carboxylic group. Moreover, as $pK_{a(AlLH)}$ is lower than the pK_{a2} of the free ligand, it is reasonable to suppose the participation of the dihydrocinnamic arm to the metal chelation (see also NMR data below).

As regards Fe(III) complexes, the pK_a values corresponding to the deprotonations $FeLH = FeL + H$ (3.54) and $FeL_2H_2 = FeL_2H + H$ (3.16) are comparable to that of $Fe(H_2O)_6^{3+}$ (2.87), and much lower than that of dihydrocinnamic carboxylate (4.49). These pK_a values could be due to the deprotonation of the dihydrocinnamic carboxylate group, its acidity being enhanced by the metal binding (thus giving rise to tridentate FeL and FeL_2H complexes). However, this pK_a enhancement is not followed by a similar increase of the stability of the complexes in comparison with those formed by salicylic acid (see below). Therefore, it is more probable that the deprotonation is due to Fe(III)-coordinated water, and FeL and FeL_2H are the mixed ligand-hydroxo-species FeLH(OH) and $FeL_2H_2(OH)$ with the dihydrocinnamic carboxylate still in the protonated form (Fig. 3).

In order to evaluate if the insertion of the dihydrocinnamic group in the salicylate moiety produced a stabilization of the metal complexes, it is necessary to compare our quantitative metal–H_3L complexation data with those of metal–salicylate. The quantitative comparison can be accomplished by computing pM (= −log [M′], with $[M'] = [M] + [MOH] + \ldots$) *versus* pH at a given metal and ligand concentration (e.g. $C_M = 10^{-6}$ m and $C_L = 5 \times 10^{-5}$ m [27]). A number of studies are available for the complexation of both metal ions with salicylate, in very different solvents and ionic media [28]. As regards Al(III), Öhman and Sjöberg [26] obtained data in Na(Cl) 0.6 M, *i.e.* in a very similar medium as ours ((Na)Cl 0.6 m), and therefore the comparison is particularly rigorous. As Fig. 4 shows, pAl values of Al(III)–H_3L are very

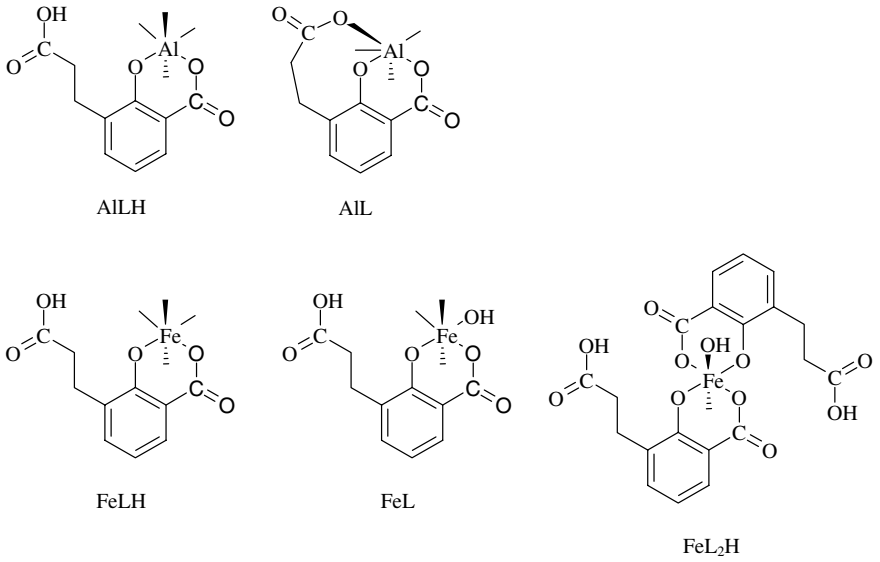

Fig. 3. Probable structures of some Al(III)–H_3L and Fe(III)–H_3L complexes.

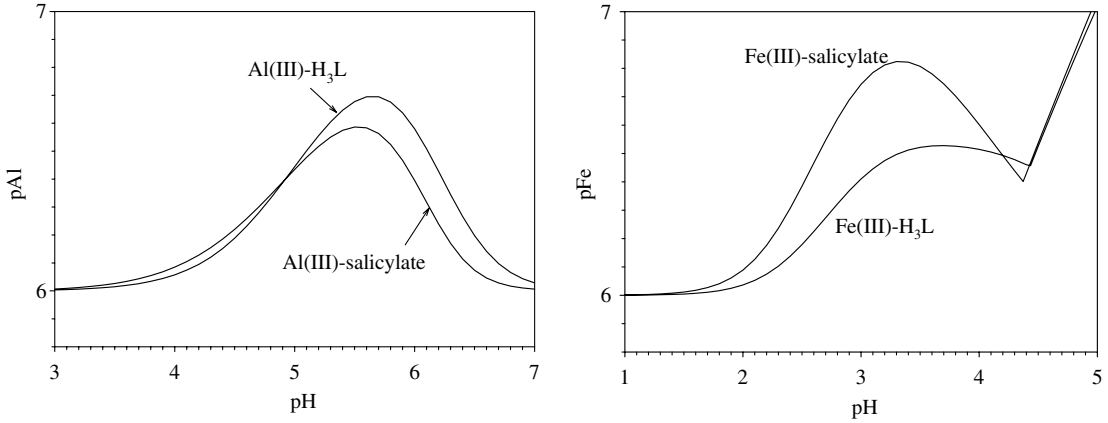

Fig. 4. pM *vs.* pH for M(III)–H_3L (present work) and M(III)–salicylate [26,29] ($C_M = 10^{-6}$ m, $C_L = 5 \times 10^{-5}$ m).

similar to those of Al(III)–salicylate. At pH values above 5 the pAl of Al(III)–H_3L is slightly higher (maximum 0.15 log units at pH ~ 6). This difference can be due to a tridentate coordination mode of AlL and AlL_2, which stabilizes Al(III)–H_3L complexes slightly more than Al(III)–salicylate ones. As regards Fe(III), the ionic medium which most closely resembles our (Na)Cl 0.6 m is KCl 0.1 M, which was used in a very old work by Akselrud and Fialkov [29]. pFe values (Fig. 4) are very similar for the two Fe(III)–ligand complexes, and slightly higher for Fe(III)–salicylate (up to 0.35 log units at pH 3). This little difference could be due to the quite different ionic strength employed to obtain the two sets of data.

In any case our potentiometric data give no evidence for a significant extra-stabilization of Al(III)- and Fe(III)–H_3L complexes with respect to the corresponding metal–salicylate ones.

3.2. Molecular modeling

To clarify the coordination geometry of Al(III) and Fe(III) complexes, a theoretical study has been carried out. In particular, the complexation reactions corresponding to the formation of tridentate ML starting from bidentate MLH were analyzed in order to take into account the interaction modes of Al(III) and Fe(III) with H_3L. The possible coordination sites of the free ligand were investigated and the interaction energies calculated in the gas phase and water solution. Quantum chemistry study confirms that the coordination of the third arm of the dihydrocinnamic ligand to both Al(III) and Fe(III) is accessible from a conformational point of view but, conversely, this additional coordination is controlled by an endothermic process. The formation of AlL seems to be, at least in water, slightly favourable with respect to the formation of the corresponding FeL derivative. The structure of fully optimized complexes and the corresponding interaction energy values are collected in Fig. 5.

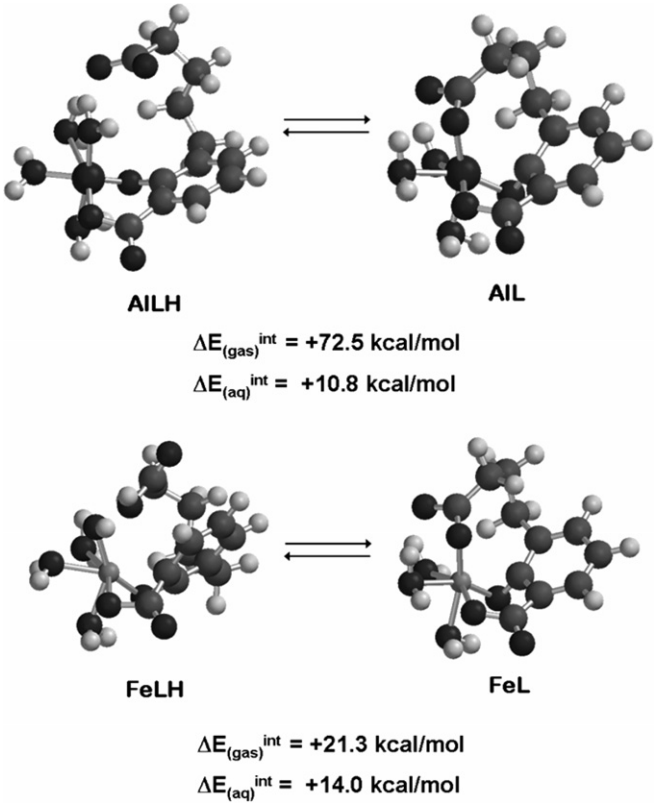

Fig. 5. PM3 fully optimized structure of the AlLH/AlL and FeLH/FeL complexes. Interaction energies (ΔE^{int}) for the complexation reaction are also reported. To simplify the picture, the water molecule replaced by the third arm of the dihydrocinnamic ligand is arbitrarily omitted.

3.3. UV–Vis results

Selected UV–Vis spectra for the Al(III)–H_3L and Fe(III)–H_3L solutions are reported in Fig. 6. In the case of Al(III)–H_3L, the increase of pH causes a slight blue shift of the main peaks and a general decrease of the absorption coefficients. These effects are in agreement with the gradual formation of the metal complexes, which are more positively charged, thus electron-poorer, than the free ligand. In the case of Fe(III)–H_3L, the metal–ligand coordination produces a charge-transfer peak centered at 550 nm ($\varepsilon = 1559\ M^{-1}\ cm^{-1}$). In the investigated pH range, the peak height is well correlated with the concentration of FeLH (compare Fig. 6b with 2b). Therefore FeLH is assumed to be the absorbing species, and the other Fe(III)–H_3L complexes do not absorb at these wavelengths. A very similar behaviour was observed for Fe(III)–salicylate complexes: the species FeL produces a charge-transfer peak (*e.g.* at 530 nm, $\varepsilon = 1660\ M^{-1}\ cm^{-1}$ in $NaClO_4$ 0.1 M [30]), and the other complexes do not absorb at the same wavelengths ([30] and references therein). Therefore, it is strongly suggested that the H_3L–FeLH species has the same bidentate structure of the salicylate–FeL species, with no role for the dihydrocinnamic arm in the metal complexation.

In the elaboration of the UV–Vis data, the formation constant of only one species could be optimized: $\log\beta_{1,1,0} = 0.5 \pm 0.3$ for Al(III)–H_3L ($\lambda = 265,\ 308$ nm), $\log\beta_{1,1,1} = 6.67 \pm 0.02$ for Fe(III)–H_3L ($\lambda = 550$ nm). The quite large error associated to the Al(III)–H_3L $\log\beta_{1,1,0}$ value, and the difference with the corresponding potentiometric constant ($\log\beta_{1,1,0} = -0.273 \pm 0.003$), are due to the similarity of the UV–Vis spectra of AlL at various pH values (Fig. 6a). The $\log\beta$ value of FeLH compares reasonably well with the corresponding potentiometric one ($\log\beta_{1,1,1} = 6.54 \pm 0.04$ for Fe(III)).

3.4. ^1H NMR results

The ^1H NMR spectra of D_2O solutions containing the free ligand and Al(III)–H_3L in a 1:1 molal ratio at two diagnostic pD values are reported in Fig. 7a and b. Proton assignments are reported (refer to Fig. 1).

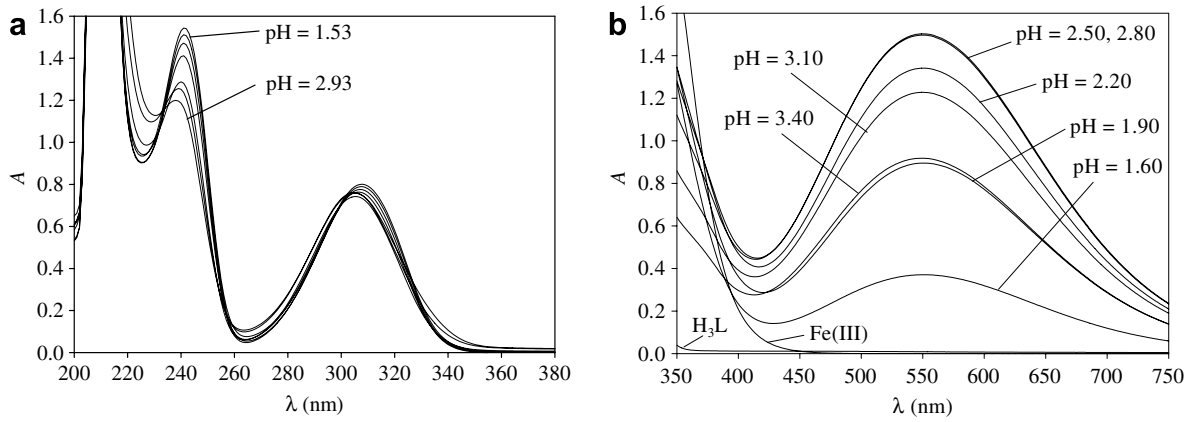

Fig. 6. UV–Vis spectra of Al(III)–H_3L (a) and Fe(III)–H_3L (b) at various pH values.

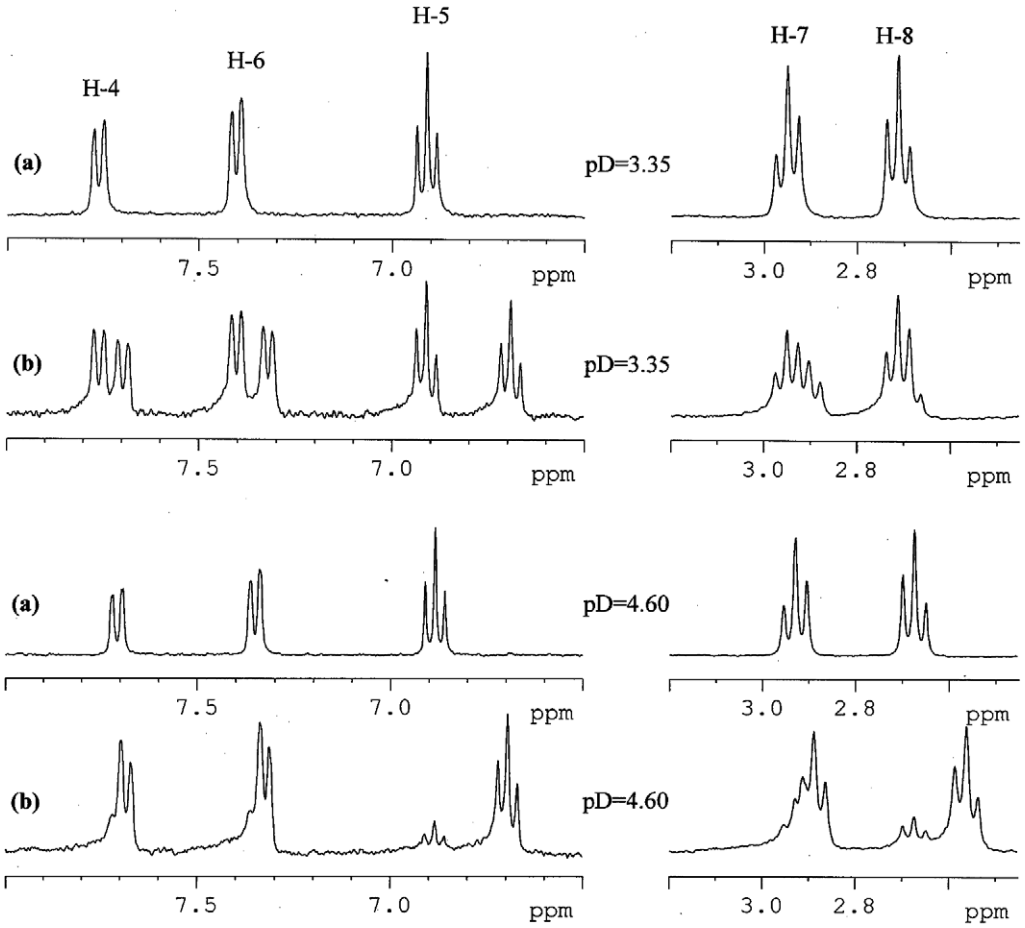

Fig. 7. ^1H NMR spectra of D_2O solutions at various pD values containing H_3L 0.0012 m (a), Al(III) 0.0012 m and H_3L 0.0012 m (b).

For the free ligand, the chemical shifts show a little pD dependence (compare Fig. 7a at pD 3.35 with Fig. 7a at pD 4.60), which is maximum for values higher than 5 (spectra not shown), where the deprotonation of dihydrocinnamic carboxylic group occurs.

Upon addition of Al(III), no modification is observed with respect of the free ligand outside the pD range 2.5–6.5, indicating that no complexation occurs at these pD values. This is in agreement with the potentiometric data, see e.g. Fig. 2a. Conversely, the appearance of new signals are observed within this pD range (compare Fig. 7a with b). At pD 3.35, a new set of signals centered at 7.70, 7.32 and 6.69 ppm is clearly visible in the aromatic region together with the signals of the free ligand. Also in the aliphatic region, new signals centered at 2.70 ppm (H-7 protons) clearly appear even if partially overlapped with

those of free ligand. These new sets of signals are assigned to the complex AlLH, which according to potentiometric data predominates at this pD value. The shift of the proton signals observed in the complex with respect to those in the free ligand indicates that the phenolic and the benzoic oxygens are involved in the metal chelation. On the other hand, the H-8 protons in AlLH must be very similar to the ones of the free ligand, as their signals are almost completely overlapped: from this it can be stated that the dihydrocinnamic carboxylate is not chelated to the metal center. This result confirms the structural hypothesis drawn for AlLH in Fig. 3.

At pD 4.60 the signals of the aromatic protons of the free ligand in the presence of Al(III) almost vanished, and the signals of the complex are predominating. By comparing this spectrum with the one a pD 3.35, also in the presence of Al(III), it can be noticed that the complex signals in the aromatic region and the signal of the H-7 protons do not shift with pD. The main change regards the appearance of a new set of signals centered at 2.55 ppm, well separated from the signals of the free ligand. Reasonably, this set can be assigned to the H-8 protons of the methylene group adjacent to the carboxylate group of the dihydrocinnamic arm (see Fig. 1). Here, it is evident that H-8 protons feel a very different chemical surrounding from those experienced by the Al(III) complex at pD 3.35, whereas all other protons have the same chemical shifts at both pD values. On the basis of potentiometric results, the NMR pattern at pD 4.60 is explained with the presence of the predominating species AlL, where also the dihydrocinnamic carboxylate is involved in the metal chelation together with the phenolate-like $-O^-$ as well as the benzoate-like COO^-. Therefore, NMR results strongly suggest a tridentate chelation at the metal in the complex AlL (this does not mean that the parallel formation of a mixed ligand-hydroxo-species AlLH(OH) is excluded, but at least that the tridentate coordinated species represents a significant fraction of AlL).

Other ^1H NMR measurements have been made for Al(III)–H_3L in a 1:2 molal ratio at several pD values (spectra not shown), in order to check the presence in solution of the complex AlL_2. We were not able to detect this species. This is due to the small amount of complex which forms in solution (apart for large excess of ligand over metal ion, and at pD values close to the start of aluminium hydroxide precipitation, see e.g. Fig. 2a).

4. Conclusions

The complexes formed in Al(III)–H_3L solutions are AlLH, AlL, and AlL_2. Potentiometric titrations allowed to obtain stoichiometry and stability constant values. UV–Vis gave a value for the stability constant of AlL, which is in fair agreement with the corresponding potentiometric result. ^1H NMR data confirmed the complex formation, and gave strong evidence of the involvement of the dihydrocinnamic carboxylate in the metal chelation. NMR and potentiometric data indicate that AlLH is a salicylate-like bidentate species, with no role of the dihydrocinnamic arm. For AlL, potentiometric data suggested and NMR supported a tridentate coordination, *i.e.* with dihydrocinnamic carboxylate chelated to the metal center together with the phenolate and the benzoate-like oxygens.

The complexes formed in Fe(III)–H_3L solutions are FeLH, FeL, FeL_2H_2, and FeL_2H. Potentiometric titrations allowed to obtain stoichiometry and stability constant values, and UV–Vis gave a value for the stability constant of FeLH, which is in reasonable agreement with the potentiometric one. The presence of an UV–Vis charge-transfer peak similar to the one encountered in Fe(III)–salicylate solutions indicates FeLH to be a salicylate-like, bidentate species. On the basis of stability constant values, it can be suggested that the dihydrocinnamic carboxylate does not chelate Fe(III) at any pH and in any complex, and that FeL and FeL_2H are mixed ligand-hydroxo-species. Anyway, the tridentate coordination, even if with a lesser relevance than in the case of Al(III), cannot be excluded.

Quantum chemistry calculations confirm experimental results: they indicate that the coordination of the third arm of the dihydrocinnamic ligand to both Al(III) and Fe(III) is accessible from a conformational point of view, and that this additional coordination is slightly more endothermic for Fe(III) than for Al(III).

As regards the chelation strength of H_3L, the presence of the dihydrocinnamic arm slightly increases the stability constant values of Al(III) complexes. The synthesis of 5-dihydrocinnamic derivatives of 3-hydroxy-4-pyridinecarboxylic acid and 4-hydroxy-3-pyridinecarboxylic acid, and the study of their Al(III) and Fe(III) complexing properties, are now in progress.

Abstract

New complexes of Cd(II), Zn(II) and Ni(II) with 2-quinolinecarboxaldehyde selenosemicarbazone (Hqasesc) were synthesized and structurally characterized. The structure of the ligand, Cd(II) and Zn(II) complexes was determined by NMR and IR spectroscopy, elemental microanalysis and molar conductivity measurements. Both complexes occur in solution in two forms, the major tetrahedral and minor octahedral. In the major Cd(II) complex one qasesc$^-$ ligand is coordinated as a tridentate, the fourth coordination site being occupied by acetate, while in the major Zn(II) complex two qasesc$^-$ ligands are coordinated as bidentates. In both minor complexes two qasesc$^-$ ligands are coordinated as tridentates forming the octahedral geometry around the central metal ion. The only paramagnetic complex in the series is Ni(II) complex for which X-ray structure analysis was performed. The complex has the angularly distorted octahedral geometry with two qasesc$^-$ ligands coordinated as tridentates, in a similar way as in the minor complexes of Cd(II) and Zn(II).

Keywords: Cd(II), Zn(II) and Ni(II) complexes; Selenosemicarbazone; 2-Quinolinecarboxaldehyde; X-ray structure; NMR; Biological activity

1. Introduction

Semicarbazones and thiosemicarbazones have been extensively studied as antibacterial, antiviral and antitumor agents [1–6]. There are only few studies on biological activity of selenosemicarbazones, indicating their similar or grater activity in comparison with sulphur analogues, while oxygen analogues showed a lower activity [7–12]. Selenosemicarbazones of cinnamaldehydes, benzaldehydes and 5-hydroxy-2-formylpyridine show strong antitumor activity [7,11], selenosemicarbazones of benzaldehydes and furfural strong antimicrobial activity [9,10], and 2-acetylpyridine selenosemicarbazone antiviral activity [8]. A much greater number of complexes were synthesized with semi- and thiosemicarbazones than with selenosemicarbazones. The complexes were also studied as antibacterial, antiviral and antitumor agents [1–6].

The ligand systems used for preparation of the selenosemicarbazone complexes were selenosemicarbazones of: aliphatic acyclic and cyclic ketones [13–19], aromatic aldehydes [13,14,16,20–32], diacetyl monoxime [33–37], keto acids [32,38,39], and diketones [40–42]. Of almost

200 synthesized complexes, only four were characterized by X-ray structural analysis. Biological activity studies were not performed with any of the complexes.

In our previous paper, synthesis of the first heteroaromatic bis(selenosemicarbazone), 2,6-diacetylpyridine bis(selenosemicarbazone) (H_2dapsesc) and the corresponding Cd(II) and Zn(II) complexes was reported [42]. The attempted synthesis of the Ni(II) complex gave an unexpected result, namely elimination of hydrogen selenide from one side chain, affording the Ni(II) complex with the ligand 2-{1-[6-(1-selenosemicarbazonoethyl)-2-pyridyl]ethylidene}-hydrazine carbonitrile (H_2hcn), the structure of which was determined by X-ray structural analysis [42]. Such a reaction had not been reported previously.

In the present work synthesis of the heteroaromatic monoselenosemicarbazone ligand 2-quinolinecarboxaldehyde selenosemicarbazone (Hqasesc) and its Ni(II), Cd(II) and Zn(II) complexes, as well as their structure determination by X-ray crystallography and multinuclear 2D NMR spectroscopy are reported. The biological activity evaluation of the new complexes, as well as of some previously synthesized ones is also a part of this work.

2. Experimental

2.1. Materials and measurements

Selenosemicarbazide and 2-quinolinecarboxaldehyde were obtained from Acros Organics (BVBA, Geel, Belgium). $Ni(AcO)_2 \cdot 4H_2O$, $Zn(AcO)_2 \cdot 2H_2O$ and $Cd(AcO)_2 \cdot 2H_2O$ were obtained from Fluka Chemie GmbH (Germany). All solvents (ethanol, dimethyl sulfoxide, *N*,*N*-dimethylformamide) were reagent grade and used without further purification. Elemental analysis (C, H, N and S) was performed by the standard micro method using the ELEMENTARVario ELIII C.H.N.S=O analyser. IR spectra were recorded on Perkin–Elmer FT-IR 1725X spectrophotometer by the KBr technique in the region 4000–400 cm^{-1}. Molar conductivity of DMF solutions was measured at room temperature (298 K) on the digital conductometer JENWAY-4009. The magnetic measurements were performed at 298 K by the Evans' method using a MSB-MK1 balance (Sherwood Scientific Ltd.).

2.2. NMR spectroscopy

NMR spectral assignments and structural parameters were obtained by combined use of ^{1}H homonuclear spectroscopy (2D DQF-COSY, 2D TOCSY, 2D NOESY, 2D ROESY) [43–46] and multinuclear proton-detected spectroscopy (2D HSQC, 2D HMQC, 2D HMBC) [47–49]. ^{1}H homonuclear 1D and 2D spectra were obtained in DMSO-d_6 using Bruker 600 equipped with cryo-probe. 2D NOESY spectra were collected with eight scans per t1-increment and mixing time of 1 s, 2D TOCSY with mixing time of 80 ms and 2D ROESY with mixing time of 500 ms. ^{1}H–^{13}C heteronuclear 2D HSQC and HMBC experiments were obtained on the same spectrometer and samples but with an increase number of scans (64) per t1-increment. ^{1}H–^{113}Cd heteronuclear 2D HSQC spectrum was obtained on 500 MHz spectrometer equipped with a broad-band inverse probe (32 scans per 512 t1-increments). Directly detected 1D ^{113}Cd and ^{77}Se (^{113}Cd at 111 MHz, ^{77}Se at 95 MHz) spectra were obtained on the same spectrometer equipped with a broad-band direct probe (30 000 scans for ^{113}Cd and 5000 scans for ^{77}Se). Chemical shifts (δ) are given in ppm using direct (^{1}H) or indirect (hetero nuclei) referencing to tetramethylsilane as ^{1}H standard.

2.3. X-ray crystallography

Mo Kα radiation ($\lambda = 0.71073$ Å), $T = 293$ K was used on a SMART AXS 1000 CCD diffractometer for $[Ni(qasesc)_2] \cdot 2DMSO$. Lorentz, polarization, and absorption corrections were applied [50]. Structures were solved by direct methods using SIR97 [51] and refined by full-matrix least-squares on all F^2 using SHELXL97 [52] implemented in the WINGX package [53]. Hydrogen atoms were partly located on Fourier difference maps and refined isotropically and partly introduced in calculated positions. Anisotropic displacement parameters were refined for all non-hydrogen atoms. Hydrogen bonds have been analyzed with SHELXL97 [52] and PARST97 [54], and extensive use was made of the Cambridge Crystallographic Data Centre packages [55] for the analysis of crystal geometry. The bischelate $[Ni(qasesc)_2]$ complex crystallizes with two DMSO solvation molecules, for one of which the sulphur atom is disordered over two sites. Table 1 summarizes crystal data and structure determination results.

2.4. Preparation of 2-quinolinecarboxaldehyde selenosemicarbazone (Hqasesc)

To a suspension of selenosemicarbazide (0.20 g, 1.45 mmol) in ethanol (25 mL), a solution of 2-quinolinecarboxaldehyde (0.26 g, 1.65 mmol) in 6 mL ethanol–glacial acetic acid mixture (1:1) was added. The reaction mixture was refluxed with stirring for 1 h followed by cooling to a room temperature. A yellow precipitate was filtered off and washed with cold ethanol. Yield 0.34 g (86%). *Anal.* Calc. for $C_{11}H_{10}N_4Se$: C, 47.66; H, 3.64; N, 20.21. Found: C, 47.69; H, 3.48; N, 20.03%. 2.5. Preparation of $[Cd(qasesc)(AcO)] \cdot H_2O$ (**1**)

To a solution of Hqasesc (0.05 g, 0.18 mmol) in ethanol (10 mL), a solution of $Cd(AcO)_2 \cdot 2H_2O$ (0.05 g, 0.19 mmol) in ethanol (2 mL) was added. The reaction mixture was heated at 65 °C with stirring for 1 h followed by cooling to a room temperature. A yellow precipitate was filtered off and washed with cold ethanol. Yield 0.06 g

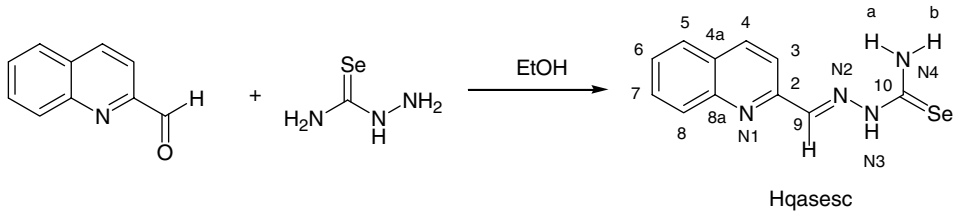
Λ_M (1×10^{-3} M, DMF): 2.35 Ω^{-1} cm^2 mol^{-1}. μ (293 K) = 3.15 BM.

2.8. Preparation of H_2dapsesc, [Cd(dapsesc)] (4), [Zn(dapsesc)] (5) and [Ni(hcn)] (6)

The ligand H_2dapsesc and complexes **4–6** were prepared as described previously [42]. In short, ligand H_2dapsesc was obtained by condensation of 2,6-diacetylpyridine and selenosemicarbazide in the molar ratio of 1:2. The complexes **4–6** were synthesized by adding aqueous solution of $Cd(AcO)_2\cdot 2H_2O$, $Zn(AcO)_2\cdot 2H_2O$, or $Ni(AcO)_2\cdot 4H_2O$, respectively, into suspension of H_2dapsesc in ethanol.

2.9. Biological activity evaluation



A teaspoon of lyophilized eggs of the brine shrimp *Artemia salina* was added to 1 L of the artificial sea water containing several drops of yeast suspension (3 mg of dry yeast in 5 mL distilled water), and air was passed through the suspension thermostated at 301 K, under illumination for 24 h. The tested substances were dissolved in DMSO. In a glass vial, into 1 mL of artificial sea water 1–2 drops of yeast extract solution (3 mg in 5 mL of distilled water) and 10–20 hatched nauplii were added, and finally solutions of all derivatives to the appropriate concentrations. For each concentration, two determination were performed. The vials were left at 301 K under illumination for 24 h, and afterwards live and dead nauplii were counted. $LC_{50}$was defined as the concentration of a drug that causes death of 50% nauplii. DMSO was inactive under applied conditions.

3. Results and discussion

3.1. Synthetic aspects

The new ligand system, 2-quinolinecarboxaldehyde selenosemicarbazone (Hqasesc), was obtained by condensation reaction of 2-quinolinecarboxaldehyde and selenosemicarbazide (1:1) (Scheme 1). Hqasesc is a yellow microcrystalline product soluble at room temperature in DMF and DMSO, and at elevated temperatures also in EtOH, MeOH and MeCN.

By reaction of nickel, cadmium and zinc acetates with Hqasesc in equimolar ratio (1:1) the corresponding complexes were obtained. The mole ratio of the reacting species did not influence the composition of the products. The nickel complex is soluble in MeOH, EtOH, MeCN, DMF and DMSO at room temperature, the cadmium complex

Scheme 1.

in DMSO at room temperature and in EtOH and DMF at elevated temperatures, and the zinc complex in DMSO at room temperature.

All the synthesized complexes are non-electrolytes, as determined by molar conductivity measurements.

Elemental microanalysis showed that in the molecules of Zn(II) and Ni(II) complexes there are two deprotonated ligand molecules, while in the molecule of Cd(II) complex there is only one deprotonated ligand molecule and an acetate ion.

Magnetic measurements showed that the Ni(II) complex is paramagnetic.

3.2. IR spectra

The absence of the ν(Se–H) band at 2300 cm^{-1} in the IR spectrum of the ligand is an evidence of the selenone tautomeric form. Coordination of azomethine nitrogen can be assumed on the basis of the shift of the band originating from ν(C=N) vibration toward higher frequencies in the complexes (1607 cm^{-1} in the ligand and 1637 cm^{-1}, 1614 cm^{-1} and 1611 cm^{-1} in **1**, **2** and **3**, respectively). In the Cd(II) complex, bands of the coordinated acetate (1553 cm^{-1} and 1417 cm^{-1}), and in the Ni(II) complex, band at 1037 cm^{-1} originating from non-coordinated DMSO molecules can be seen.

3.3. NMR spectral data

The (*E*)-configuration of the hydrazone moiety in the ligand can be evidenced from 2D ROESY spectrum (Fig. 1) in which protons 9 and N3 are correlated.

The Cd(II) and Zn(II) complexes are diamagnetic and their structure in solution was determined by NMR spectroscopy. The Ni(II) complex is paramagnetic.

The Cd(II) complex was characterized by ^{1}H, ^{13}C, ^{77}Se and ^{113}Cd NMR spectra as well as by two-dimensional heteronuclear correlation spectra (^{1}H–^{13}C, ^{1}H–^{113}Cd), Figs. 2–4. In all spectra there are two series of signals, indicating the presence of two complex species. Since the ratio of intensities of the signals in ^{113}Cd spectrum is 6:1, and in ^{77}Se and ^{1}H spectra 3:1, it implies that the ratio of amounts of two complexes is 6:1, whereby in the major complex one

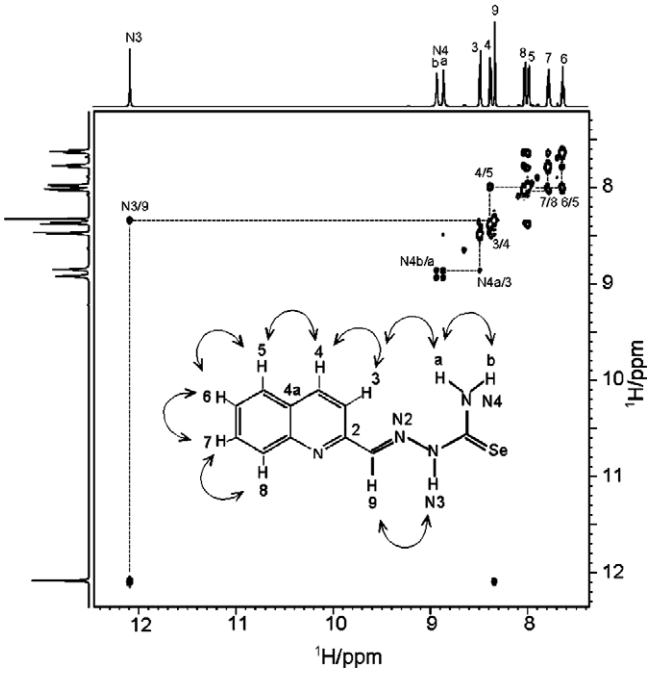


Fig. 1. 2D ROESY of Hqasesc in DMSO-d_6 at 298 K (mixing time 500 ms) recorded on Bruker 600 MHz spectrometer equipped with cryo-probe. Connectivity by spatial proximity is indicated by dashed lines in the spectrum and by arrows in the Hqasesc structure model.

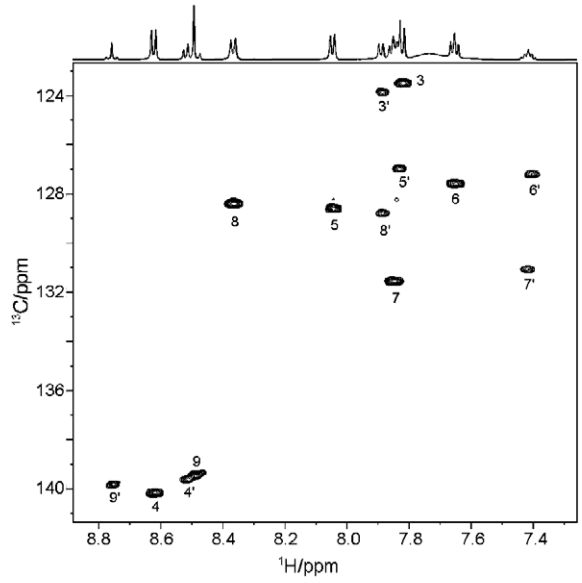

Fig. 2. {^{1}H–^{13}C}-HSQC chemical shift correlation spectrum of Cd(II) complex (DMSO-d_6, 298 K), recorded on Bruker 600 MHz spectrometer equipped with cryo-probe. Spectral peaks numbering is same as in Fig. 1; minor component is denoted by primed numbers.

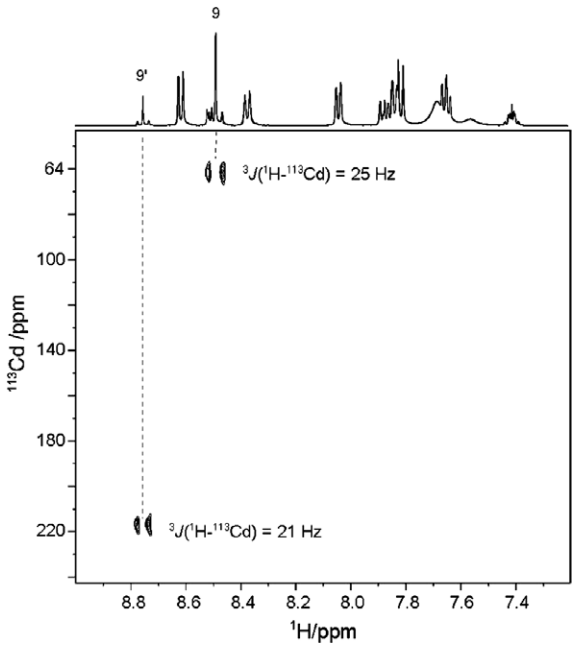

Fig. 3. {^{1}H–^{113}Cd}-HSQC chemical shift correlation spectrum of Cd(II) complex (DMSO-d_6, 298 K), recorded on Bruker 500 MHz spectrometer equipped with inverse broad-band probe. Spectral peaks numbering is same as in Fig. 1; minor component is denoted by primed numbers. Note that natural abundance of ^{113}Cd (20%) gives doublet splitting in proton spectrum at about 20% intensity.

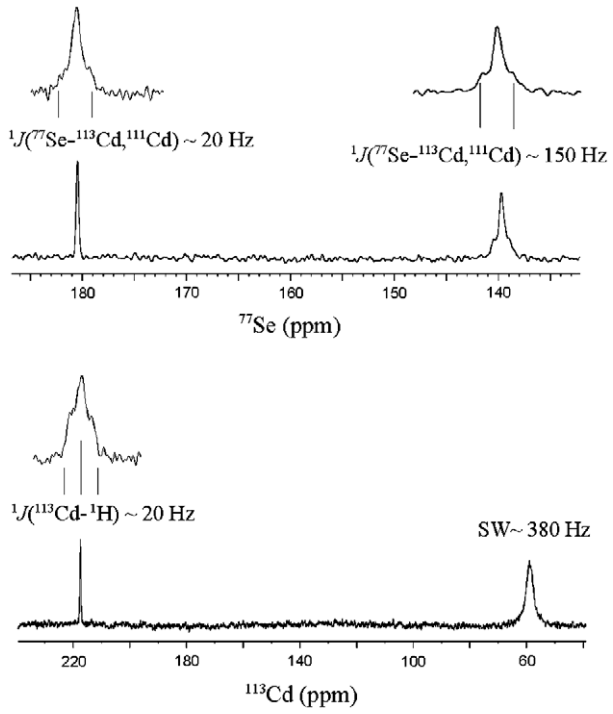

Fig. 4. ^{113}Cd (bottom) and ^{77}Se (top) spectra of Cd(II) complex (DMSO-d_6, 298 K), recorded on Bruker 500 MHz spectrometer equipped with broad-band probe. Note that natural abundance of ^{113}Cd (20%) gives doublet splitting in ^{77}Se spectrum at about 20% intensity.

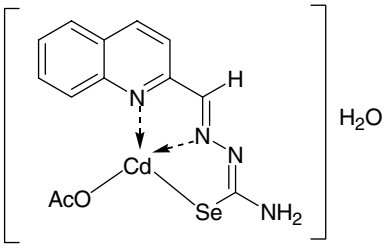
ligand molecule is bound to Cd(II), while the minor one contains two ligand molecules bound to Cd(II).

The presence of two ligands in the minor complex can also be evidenced by coupling of ^{113}Cd with protons. The sharper line at 220 ppm is a triplet (Fig. 4), indicating two identical protons. When this coupling is observed in the ^{1}H spectrum (signal at 8.8 ppm), a doublet with the same coupling constant (~20 Hz) is seen (Fig. 3). That means that the minor complex has two symmetrical ligands. The chemical shifts of ^{113}Cd indicate a larger number of coordinated nitrogen atoms in the minor complex than in the major one (Cd shift of 220 ppm in the former and 60 ppm in the latter one).

The major complex has a strongly coordinated selenium, since there is a strong coupling of ^{77}Se with ^{113}Cd (a broad line at 140 ppm in 1D ^{77}Se spectrum), with a coupling constant of 150 Hz (Fig. 4). The corresponding signal in the minor complex (180 ppm) has a small $^{1}J(^{77}Se–^{113}Cd)$ coupling constant of 20 Hz, indicating a weak coordination of selenium. In both complexes azomethine nitrogen is coordinated as shown by the forementioned coupling of proton 9 (doublets with intensity of ~20%). Signal of proton 9 (Fig. 2) has a large downfield shift in comparison to the ligand. In both complexes there are large relative shifts of several protons in the quinoline molecules, indicating coordination of the quinoline nitrogen. In the major complex, quinoline nitrogen is weakly coordinated. Assignments of signals in ^{1}H and ^{13}C NMR spectra are given in Tables 2 and 3.

Based on the presented evidence, the major complex has a tetrahedral geometry with one ligand coordinated in deprotonated form *via* selenium, azomethine and quinoline nitrogens, the fourth coordination site being occupied by acetate ion (singlet at 1.79 ppm in ^{1}H spectrum) (Scheme 2). In the minor complex two deprotonated ligands are bound *via* selenium, azomethine and quinoline nitrogen atoms each, forming octahedral geometry (Scheme 3). Cadmium(II) complex with pyridine-2-carbaldehyde thiosemicarbazone, obtained from cadmium acetate, has a similar octahedral geometry, in which two deprotonated ligands are bound *via* sulphur, azomethine and pyridine nitrogen atoms [56]. Since the microanalysis is in complete accordance with the proposed structure of the major complex, it is likely that in DMSO solution the complex undergoes chemical change and a small quantity (15%) of the minor complex is formed.



According to NMR spectral evidence (Fig. 5), the Zn(II) complex in solution also exists in two forms. Based on the intensity of the signal of C9 proton (85:15), the relative ratio of the major and minor complex is 5.7:1, assuming that in both of them there are two molecules of the ligand in one molecule of the complex. It is likely that the major complex has a tetrahedral geometry in which the ligands are coordinated *via* selenium and azomethine nitrogens (Scheme 4), while the minor complex has an octahedral geometry with two ligand molecules coordinated in the same way as in the minor Cd(II) complex (Scheme 5).

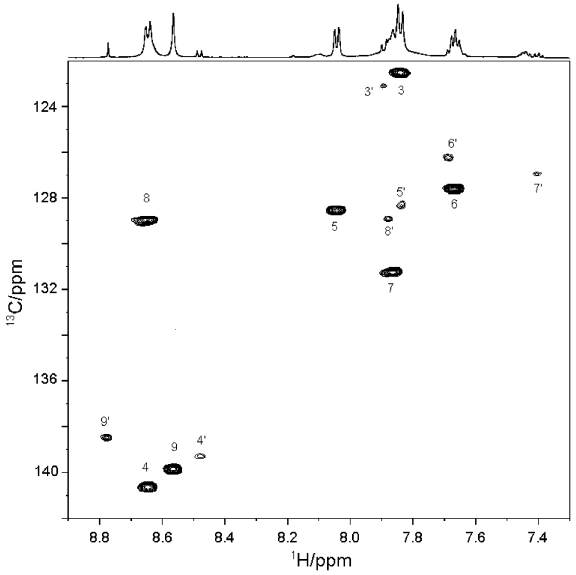
Scheme 2.

Scheme 3.



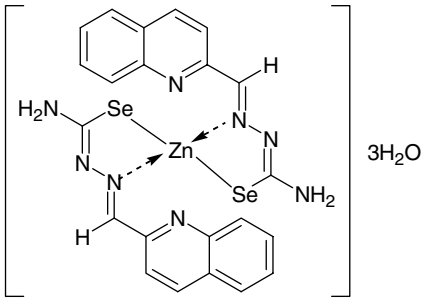


Fig. 5. {^{1}H–^{13}C}-HSQC chemical shift correlation spectrum of Zn(II) complex (DMSO-d_6, 298 K), recorded on Bruker 600 MHz spectrometer equipped with cryo-probe. Spectral peaks numbering is same as in Fig. 1; minor component is denoted by primed numbers.

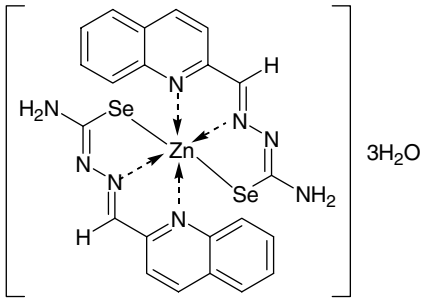

The structure in solution differs from the structure in solid state. Proton NMR spectrum of the freshly prepared solution has additional signals with fairly broad lines (Fig. 6), indicating an oligomeric structure. Since the colour changes, it is obvious that in solid state there is some (probably stacking) interaction which disappears in solution.

3.4. Crystal structure

Single crystal X-ray analysis shows that the nickel ion coordinates two deprotonated qasesc$^-$ ligands giving the octahedral bischelate complex [Ni(qasesc)$_2$]. Fig. 7 shows a perspective view of the neutral complex, and Table 4 reports the most relevant bonding parameters. The qasesc$^-$

Scheme 4.

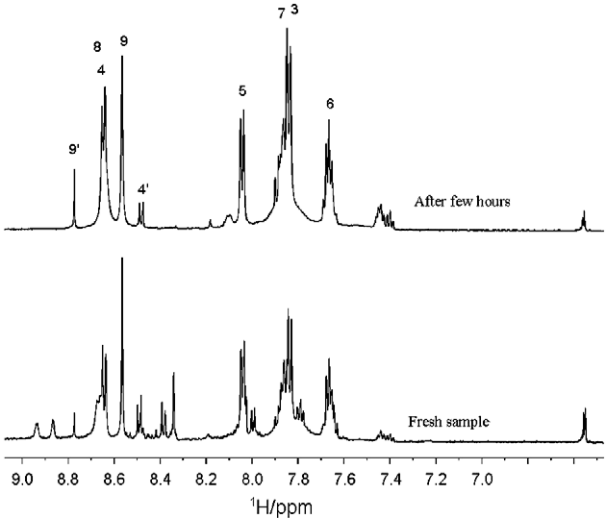

Fig. 6. ^{1}H spectrum (bottom) of freshly dissolved Zn(II) complexes and spectrum after few hours (top) (DMSO-d_6, 298 K), recorded on Bruker 600 MHz spectrometer. Spectral peaks numbering is same as in Fig. 1; minor component is denoted by primed numbers.

ligands coordinate the metal in a tridentate fashion by means of the selenium, the quinoline and the hydrazonic nitrogen atoms, forming two five membered chelate rings. The resulting octahedral coordination geometry is angularly distorted according to the bite angles of the chelate rings, ranging between 78.03(7) and 81.73(5)°. In this complex the ligand skeletons are essentially planar within 0.08 and 0.12 Å for C1–C11–N1–N4 and C12–C22–N5–N8, respectively, while the selenium atoms deviate slightly from the average planes, by 0.14 and 0.32 Å, respectively, for Se1

N(4)–Ni–Se(2)	89.31(5)
Se(1)–Ni–Se(2)	97.39(1)

and Se2. This slight distortion from planarity is due to an intramolecular repulsion between the selenium atoms, which are forced by the bischelate coordination geometry to come closer than the sum of their Van der Waals radii (Se1...Se2 = 3.795(5) Å, r_{Se} = 1.90 Å). The Ni–Se distances (Ni–Se1 = 2.5221(4) Å, Ni–Se2 = 2.5306(4) Å) are remarkably longer than the one observed in the similar isothiocyanato-[2-(diphenylphosphino)benzaldehyde selenosemicarbazonato]-nickel(II) [25] (CSD refcode: ISIPUV, Ni–Se = 2.269 Å), where the chalcogen is *trans* to a phosphine donor, and free from steric tension. Similarly, the Ni–N(quinoline) bonds (Ni–N4 = 2.206(2) Å, Ni–N8 =

2.198(2) Å) are significantly longer than the average (2.08(4) Å) found in a search on quinoline–Ni systems performed through the Cambridge Structural Database [55]. A structurally related thiosemicarbazonato *iso*-quinoline bischelate Ni(II) complex has been structurally characterized (CSD refcode: ICQTNI) [57].

The crystal packing is based on the association of pairs of neutral [Ni(qasesc)$_2$] complexes by formation of hydrogen bonds between the –NH$_2$ group of one molecule and the imminic nitrogen of the second one (N5–H...N6(i), N...N = 3.004(3) Å, N–H...N = 174(2)°, (i) = $-x$, $-y+1$, $-z+2$). A centrosymmetric dimeric pattern is obtained (Fig. 8). This molecular recognition process involves only one of the two ligands of each complex, leaving three –NH hydrogen bond donors per molecule available to interact with two DMSO guest molecules; each complex fulfills its hydrogen bonding capability by forming the contacts N1–H...O2 (N...O = 2.918(5) Å, N–H...O = 145(4)°) and N5–H...O1 (N...O = 2.895(3) Å, N–H...O = 147(2)°) (Fig. 8).

3.5. Biological activity

Biological activity of all three complexes and the corresponding ligands was tested by the brine shrimp test (toxicity to *A. salina*). This test is in good correlation with cytotoxic activity [58]. For comparison, brine shrimp test was also performed with previously synthesized complexes with H$_2$dapsesc ligand and the corresponding ligand. All the compounds showed moderate activity, the complexes being more active than the ligands (Table 5). The only exception was [Ni(hcn)], where the ligand was modified during complexation. The higher activity of the complexes is probably a consequence of the non-ionic nature of all complexes, which might facilitate their diffusion through biological membranes. The results justify further study of biological effects of the complexes.

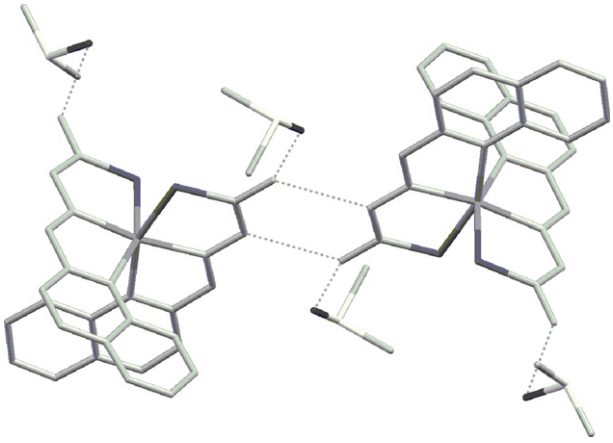

Fig. 8. Crystal association of [Ni(qasesc)$_2$] complex and DMSO guest molecules by hydrogen bonds. Hydrogen atoms omitted for clarity.

Table 5

Abstract

The *trans*(O^6) isomer of the Ba[Co(1,3-pddadp)] · $8H_2O$ complex (where 1,3-pddadp represents hexadentate 1,3-propanediamine-*N*,*N*′-diacetate-*N*,*N*′-di-3-propionate ion) has been prepared and characterized by X-ray crystallography. In the crystal structure the complex cations and anions are bridged by carboxylate oxygen atoms from the in-plane coordinated glycinate rings (G-rings) of $[Co(1,3\text{-pddadp})]^{2-}$ and by the barium-coordinated water molecules, thus forming 1D polymeric chains, separated by infinite water tapes hydrogen bonded to the $[Co(1,3\text{-pddadp})]^{2-}$ carboxylate oxygens from the out-of-plane β-alaninate rings (R-rings). Conformational analysis of the three possible geometrical isomers: *trans*(O^5), *trans*(O^5O^6), and *trans*(O^6) of the $[Co(1,3\text{-pddadp})]^{2-}$ complex, with ligand acting as hexadentate, as well as of the corresponding complexes of Ni(II) and Cr(III) has been performed using the consistent force field (CFF) method, with the parameters developed previously for edta-type complexes of chromium(III) and supplemented with new parameters for cobalt(II) and nickel(II). The energy-minimized structure of the *trans*(O^5O^6) isomer represents the global minimum for the $[M(1,3\text{-pddadp})]^{n-}$ (M = Co(II), Ni(II), and Cr(III)) species. The occurrence of the least energetically favored *trans*(O^6) isomer in a crystal and the exceptional conformation of the axially oriented β-alaninate rings can be accounted for by the stabilizing role of the infinite tapes of planar cyclic water pentamers and hexamers which act as a ''glue'' to reinforce the coordination polymeric chains.

doi:10.1016/j.poly.2007.03.029

due to the fact that these complexes may have very intricate stereochemistry, particularly when the pentadentate coordination mode of the ligand is involved [1]. Complexes of 1,3-pddadp (1,3-pddadp = 1,3-propanediamine-*N*,*N*′-diacetate-*N*,*N*′-di-3-propionate ion, Scheme 1), in which 1,3-pddadp acts as a hexadentate ligand, can exist theoretically in three isomeric forms designated as *trans*(O^5), *trans*(O^5O^6), and *trans*(O^6) (where O^5 and O^6 refer to the five- and six-membered N,O rings, respectively, Scheme 1). In the synthetic reactions of Co(III), Rh(III), and Ni(II) with the 1,3-pddadp ligand, two out of three possible geometrical isomers of $[M(1,3\text{-pddadp})]^{n-}$ complex (*trans*(O^5O^6) and *trans*(O^6) for Co(III) [2–5], and *trans*(O^5) and *trans*(O^5O^6) for Rh(III) [6,7], and Ni(II) [8]) have been isolated and characterized. However, for the $[Cr(1,3\text{-pddadp})]^-$ complex all three geometrical isomers (*trans*(O^5), *trans*(O^5O^6), and *trans*(O^6)) have been reported [9]. In addition, only one dominant isomer of the 1,3-pddadp complex (*trans*(O^6)) of Cu(II) has been described [10]. In most cases, the geometry of the complex was confirmed by X-ray methods, and the X-ray data are available so far for the *trans*(O^6)-$[Cr(1,3\text{-pddadp})]^-$ [9], *trans*(O^6)-$[Co(1,3\text{-pddadp})]^-$ [3,4], *trans*(O^5O^6)-$[Co(1,3\text{-pddadp})]^-$ [5], *trans*(O^5)-$[Rh(1,3\text{-pddadp})]^-$ [7], *trans*(O^5O^6)-$[Rh(1,3\text{-pddadp})]^-$ [7], *trans*(O^5)-$[Ni(1,3\text{-pddadp})]^{2-}$ [8], and *trans*(O^6)-$[Cu(1,3\text{-pddadp})]^{2-}$ [10] structures, which were all reported by us previously except for the *trans*(O^6)-$[Cr(1,3\text{-pddadp})]^-$. Conformational analysis of the systems: $[Co(1,3\text{-pddadp})]^-$ [5] and $[Rh(1,3\text{-pddadp})]^-$ [1], with ligand acting as hexadentate, revealed that the *trans*(O^5O^6) isomer is the most stable one for either complex species. Presented in this paper are the results of X-ray structure determination of the *trans*(O^6) isomer of $[Co(1,3\text{-pddadp})]^{2-}$ complex, supplemented by a detailed stereochemical analysis of $[Co(1,3\text{-pddadp})]^{2-}$, $[Ni(1,3\text{-pddadp})]^{2-}$, and $[Cr(1,3\text{-pddadp})]^-$ complexes using the methods of molecular mechanics (MM). The obtained results are compared with those previously reported for the analogous $[Co(1,3\text{-pddadp})]^-$ [5], and $[Rh(1,3\text{-pddadp})]^-$ [1] systems.

Scheme 1.

2. Experimental

All commercially obtained reagent-grade chemicals were used without further purification. The preparation of barium 1,3-propanediamine-*N*,*N*′-diacetate-*N*,*N*′-di-3-propionate octahydrate, $Ba_2(1,3\text{-pddadp})\cdot 8H_2O$, has been reported elsewhere [2].

2.1. Preparation of barium (1,3-propanediamine-N,N′-diacetato-N,N′-di-3-propionato) cobaltate(II) octahydrate, trans(O^6)-Ba[Co(1,3-pddadp)] · 8H_2O

The *trans*(O^6)-$Ba[Co(1,3\text{-pddadp})]\cdot 8H_2O$ complex was prepared by the similar procedure as that applied for the preparation of $[Mg(H_2O)_6][Co(1,3\text{-pddadp})]\cdot H_2O$ [11].

2.81 g (0.01 mol) of $CoSO_4\cdot 7H_2O$ was dissolved in 25 cm^3 of H_2O at 60 °C. To this solution, solid $Ba_2(1,3\text{-pddadp})\cdot 8H_2O$ (7.49 g, 0.01 mol) was added and the reaction mixture was heated (60 °C) with stirring for 30 min. The precipitated $BaSO_4$ was then removed by filtration. The dark pink filtrate was poured into a 5 × 60 cm column containing Dowex 1-X8 (200–400 mesh) anion-exchange resin in the Cl^- form. After elution with 0.1 M $BaCl_2$ (*ca.* 0.5 cm^3/min) two bands were detectable on the column after two days. The second eluate, which represents the *trans*(O^6) isomer of $[Co(1,3\text{-pddadp})]^{2-}$, was reduced by evaporation to 10 cm^3 at 40 °C and desalted by passage through a G-10 Sephadex column, with distilled water as the eluant. The eluate was concentrated to a small volume, and the *trans*(O^6)-$Ba[Co(1,3\text{-pddadp})]\cdot 8H_2O$ complex was crystallized by adding of ethanol, and cooling in a refrigerator. *Anal.* Calc. for *trans*(O^6)-$Ba[Co(1,3\text{-pddadp})]\cdot 8H_2O$, $C_{13}H_{34}N_2O_{16}BaCo$ (FW = 670.69): C, 23.28; H, 5.11; N, 4.18. Found: C, 23.38; H, 5.15; N, 4.19%.

2.2. Crystallographic data collection and refinement of the structure

The crystal data for the $Ba[Co(1,3\text{-pddadp})]\cdot 8H_2O$ complex, and the parameters of data collection are summarized in Table 1. The intensity data were measured with a KM4CCD kappa-geometry diffractometer [12] using graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at 295.0(2) K. The structure was solved by direct methods using SHELXS86 [13] and refined by least-squares techniques with SHELXL97 [14]. The intensity data were corrected for absorption. Anisotropic atomic displacement parameters were employed for the non-hydrogen atoms. Hydrogen atoms connected to carbon atoms have been placed at calculated positions, while those attached to the water oxygen atoms have been located on subsequent difference Fourier maps. Although refined at the earlier stages of structure determination, the hydroxyl hydrogens were eventually fixed at a distance of 0.85 Å from their respective oxygen atoms because some of the bond lengths and angles involving these hydrogens as well as their displacement parameters refined to unrea-

sonable values. All hydrogen atoms were allowed to ride on the atoms to which they were attached and their isotropic displacement parameters were given values 30% higher than the isotropic equivalent for the atom to which the H-atom was bonded. The two largest difference peaks (1.03 and 1.01 e Å^{-3}) are located in between two Ba(II) cations related by the center of symmetry at 000 and bridged by O2 carboxylate oxygens. The structure was viewed and analyzed, and drawings were prepared with Siemens computer graphics program XP [15a] and with the program MERCURY [15b].

2.3. Computational method

Molecular mechanics (MM) calculations of the three geometrical isomers of $[M(1,3\text{-pddadp})]^{n-}$ system, in which M = Co(II), Ni(II), and Cr(III) and ligand acts as hexadentate, were carried out with the consistent force field (CFF) program package [16] using the all-atom representation. The force field parameters hither used throughout the study were parameterized specifically for edta-type complexes [1,5,17,18]. Validity of the force field for the (poly)amino(poly)carboxylate modeling was proven in a number of applications [1,5,19]. The new parameters for cobalt and nickel atoms were optimized to obtain the best fit between experimental X-ray data and the modeling studies (Table 2). Potential functions for bond stretching, angle bending, torsional, non-bonded and electrostatic contributions are given in the footnote to Table 2. The force field of a maximally diagonal type is parameterized on the basis of two different types of carbon atom (sp^3 – (C) and sp^2 – (C′) carbons), two different types of oxygen atom (coordinated (O) and carbonyl (O′) oxygens), one type of hydrogen (H), nitrogen (N) and the central metal atom (Co(II) or Ni(II)). The same parameters were used for aliphatic carbons from glycinate, β-alaninate, and 1,3-propanediamine chelate rings.

Point charge parameters in the present force field were adjusted on the basis of single point DFT calculations. They were performed using the Becke three-parameter exchange (B3) [20] and the Lee–Yang–Parr correlation functional (LYP) [21]. The B3LYP calculations have been carried out with the GAUSIAN98 program [22]. The LANL2DZ basis set was chosen for all atoms. The atomic charges of Co(II) ($S = 3/2$) and Ni(II) ($S = 1$) complexes were calculated using the natural bond orbital method developed by Weinhold [23], from B3LYP optimized wave function.

MM calculations were carried out with the same molecular modeling methodology used by us in the studies of other coordination compounds [17,24]. The starting structures for geometric isomers were obtained by manipulation of the coordinates of metal complexes to generate all the permissible conformations of 1,3-propanediamine and β-alaninate rings. By this strategy we believe that we have achieved a comprehensive and reliable spanning of all geometrical isomers of the investigated complexes. Details of the procedure were described previously [17].

Geometry optimizations were carried out using a combination of the steepest-descent, Davidon–Fletcher–Powell and Newton–Raphson methods. The steepest-descent and Davidon–Fletcher–Powell methods were mostly used, in that order, for initial exploratory searches and minimizations of conformations farther from equilibrium. To approach the true minima the Newton–Raphson iterations were always employed. Geometry optimizations were carried out until convergence was attained for a gradient of $<10^{-6}$ kJ/mol Å. Siemens computer graphics program XP was used for the presentation of energy-minimized structures [15a]. Chelate ring puckering parameters were calculated using PLATON [25] and PARST [26] packages and a locally developed computer program based on the equations given by Cremer and Pople [27]. A complete list of

Table 2

[b] Parameters for M–O–C′ angles in six-membered chelate rings.
[c] Parameters for M–O–C′ angles in five-membered chelate rings.

the Cremer and Pople puckering parameters for all chelate rings together with the endocyclic torsion angles is presented in Supplementary material Tables S1–S9.

3. Results and discussion

3.1. The crystal structure of the trans(O^6)-Ba[Co(1,3-pddadp)] · 8H$_2$O complex

The ORTEP diagram of the *trans*(O^6)-[Co(1,3-pddadp)]$^{2-}$ complex anion and the coordination polyhedron around the barium cation are depicted in Fig. 1a and b, where the numbering scheme adopted for the respective atoms is also given. The basic supramolecular motifs found in the crystal lattice and the modes they bind together are illustrated in Figs. 2a–c. Selected bond distances and valence angles are listed in Table 3.

The Co(II) ion is encircled by all of the donating atoms (2N and 4O) of the 1,3-pddadp ligand to form an octahedral geometry. The complex anion [Co(1,3-pddadp)]$^{2-}$ represents the *trans*(O^6) isomer with two β-alaninate rings coordinated in the *trans* positions (R rings) and two glycinate rings coordinated in the *girdle* plane (G rings), thus making in-plane a 5–6–5 ring system (Fig. 1a). The format for describing the various chelate rings formed in these kinds of chelates is credited to Weakliem and Hoard [28]. Conformations of the six-membered chelate rings are: a nearly ideal twist-boat for the 1,3-propanediamine ring (T ring), and nearly ideal boats for both β-alaninate rings (R_1 and R_2), with the coordinated carboxylate oxygen and C_β carbon atoms in flagpole positions. The five-membered glycinate rings (G_1 and G_2) are envelope and twist,

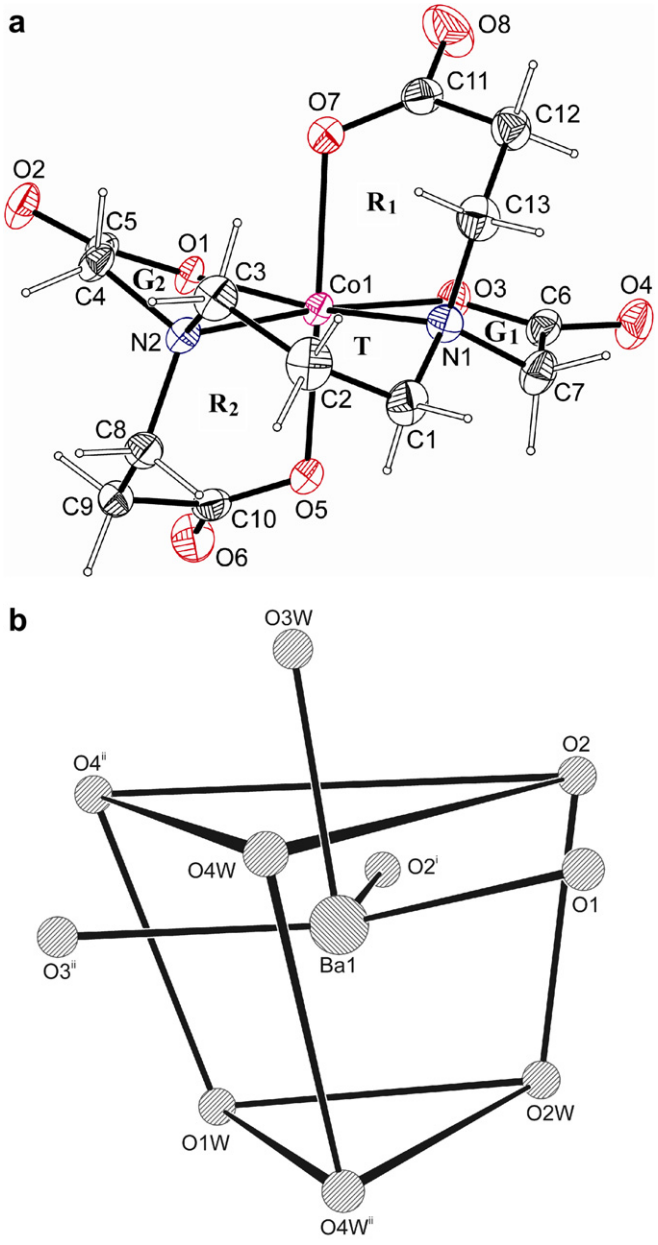

Fig. 1. (a) Molecular structure of the complex anion *trans*(O^6)-[Co(1,3-pddadp)]$^{2-}$with thermal ellipsoids drawn at the 40% probability level, (b) Tenfold coordination of barium cation (symmetry codes: (i) $-x$, $2-y$, $-z$, (ii) $1-x$, $2-y$, $-z$).

respectively (Table S3 Supplementary material). Worth to notice is the observed non-planarity of the Co–O–C=O entities belonging to the β-alaninate rings, signaled by the absolute values of the Co1–O7–C11–O8 and Co1–O5–C10–O6 torsion angles of 116.1(3)° and 116.9(2)°. A search of the Cambridge Crystallographic Data Base [29] for the M–O–C=O torsion angle magnitudes in the β-alaninate rings (M = any metal) provides 289 observations with the values in the range 107.6–180.0° but concentrated around 180°, with the mean value of 162.5(9)° and the median of 167.8°. In only 2% of cases (six observations) this torsion angle is smaller than 120.0°. This statistics illustrates that

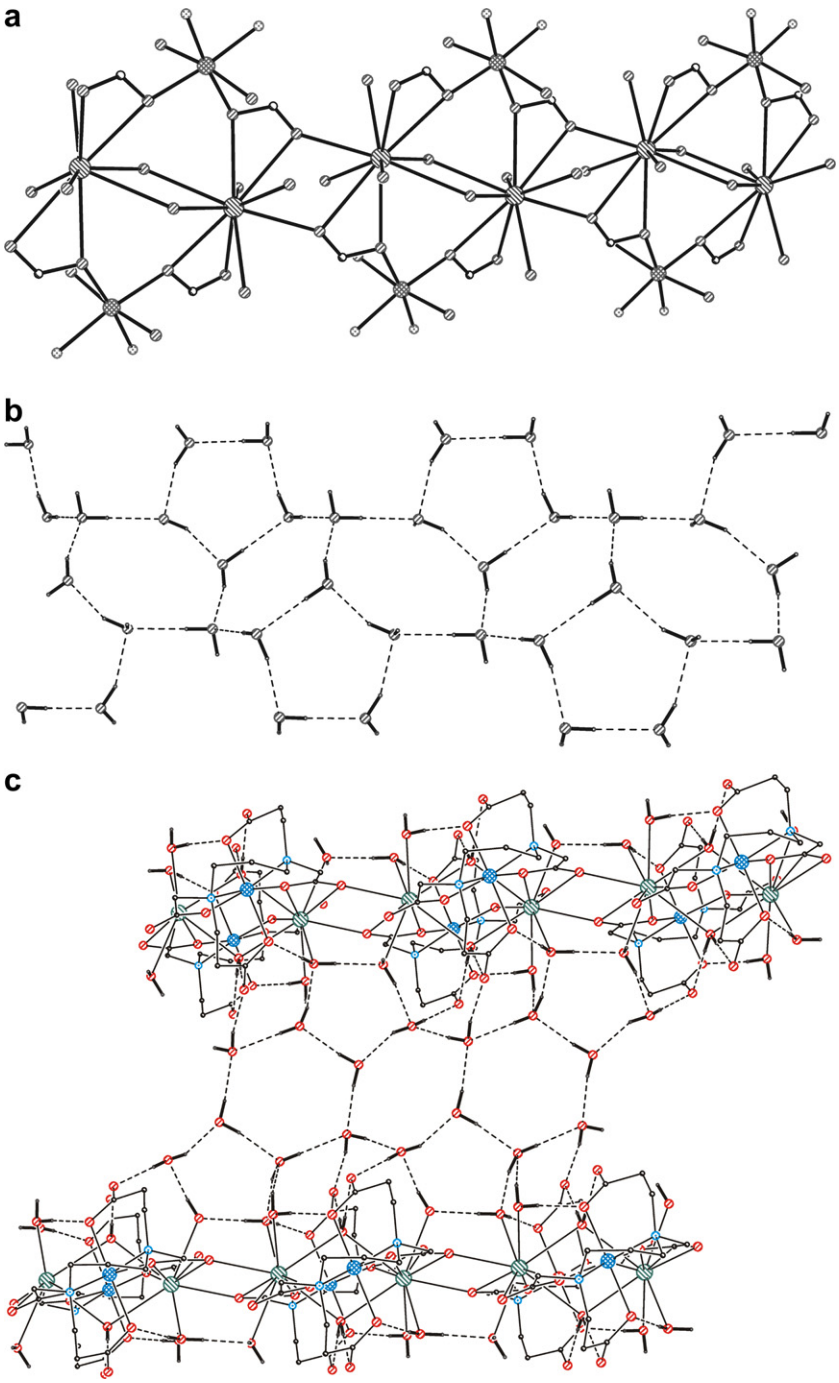

Fig. 2. Supramolecular motifs in the crystal lattice of *trans*(O^6)-Ba[Co(1,3-pddadp)] · $8H_2O$. (a) 1D coordination polymer based on the six-coordinate Co(II) and ten-coordinate Ba(II) nodes (for clarity, only atoms directly bonded to metal ions are shown), (b) tapes of water pentamers and hexamers extending along the *a*-direction, (c) illustration of the mediating role of β-alaninate carboxylates in hydrogen-bond interactions between water cluster and the metal-organic-one-dimensional framework (the only hydrogen atoms shown are those belonging to water molecules).

carboxylate groups from the β-alaninate rings generally bind metal ions in the plane of this group and in an *anti* mode, and hence the drastic non-planarity of the Co–O–C=O fragment, observed in the *trans*(O^6)-[Co(1,3-pddadp)]$^{2-}$ complex anion is exceptional. Moreover, a closer look at the six structures that possess a highly non-planar M–O–C=O fragments revealed that in all these complexes the β-alaninate rings display the bridging function. Although in the investigated crystal structure the two axially oriented β-alaninate rings are not directly involved in bridging the Co(II) and Ba(II) metal ions, they are involved in several hydrogen-bond interactions with water molecules (O1W···O5, O4W···O6, O7W···O6 and O2W···O7, O4W···O8, O6W···O8) by utilizing both carboxylate oxygens as hydrogen-bond acceptors (Table 4). Particularly important seems to be the role the two

Symmetry codes: (i) $-x, 2-y, -z$; (ii) $1-x, 2-y, -z$.

carboxylate groups play in establishing connections between metal-organic chains and infinite water tapes that propagate parallel to each other along the *a*-direction (Figs. 2a–c). More specifically, the investigated crystal structure of the *trans*(O^6)-Ba[Co(1,3-pddadp)]·$8H_2O$ complex can be considered as arising from self assembly of tetrametallic building blocks, composed of two Co(II) and two Ba(II) cations related by the center of symmetry at $\frac{1}{2}\,0\,0$ and bridged by water molecules and by the G-ring carboxylate groups. The tetrametallic units are further connected *via* the G-ring carboxylate groups (related by the center of symmetry at 0 0 0) into one-dimensional polymers (Fig. 2a). Parallel to these chains propagate infinite water tapes build of six water molecules (O2W, O3W, O5W, O6W, O7W, and O8W) forming cyclic pentamers and two distinct hexamers fused together. The rings are planar, and the average O···O distances in the three types of rings are 2.77(2), 2.81(5), 2.87(9) Å, respectively, while the average of the O···O···O angles are 108(1), 120(13), and 115(5)°. According to Infantes' classification [30] these water tapes have the symbol T5(2)6(2)6(2). Within the tapes one can distinguish the bay regions created by the T5(2)6(2)6(2)5(2) units. This is where the carboxylate groups from the β-alaninate R rings are situated, forming a hydrogen-bond linkage between the metal-organic chains and the water tapes. The coordinated and uncoordinated β-alaninate oxygen atoms act, respectively, as single and double acceptors of strong hydrogen bonds. Such extensive hydrogen-bond interactions provide explanation for the exceptional non-planarity of the Co–O–C=O fragments. The very bent Co–O–C=O moiety accompanies the boat form of the β-alaninate ring (*vide infra*).

Barium ion is deca-coordinated with five carboxylate oxygen atoms (O1, O2, O2^{i}, O3^{ii}, and O4^{ii}; where i = $-x$, $2-y$, $-z$ and ii = $1-x$, $2-y$, $-z$) and with five water molecules (O1W, O2W, O3W, O4W, and O4W^{ii}). The coordination polyhedron formed around the Ba1 is irregular four-capped trigonal prism with O1, O2^{i}, O3^{ii} and O3W constituting the caps. The uncapped trigonal prism face is one of the two triangular faces (Fig. 1b).

3.2. Strain analysis of related Co(III), Cr(III), Rh(III), Ni(II), and Co(II) edta-type chelates

The results of a comparative study of the strain characteristics of Co(III), Cr(III), Rh(III), Ni(II), and Co(II) complexes containing analogous edta-type ligands: 1,3-pddadp and 1,3-pdta (1,3-pdta = 1,3-propanediaminetetraacetate) are given in Table 5. The major contributions to strain were considered to be: (i) the octahedral angles around the metal ion, (ii) the ring angle sums of the various kinds of rings, (iii) the M–O–C bond angles, and (iv) the bond angles that the chelating nitrogen atom makes with its connectors.

The total deviation of the octahedral angles ($\sum \Delta O_h$) increases with increasing size of the metal ion radius [31] within each series of complexes ([M(1,3-pddadp)]$^{n-}$ and [M(1,3-pdta)]$^{n-}$) with exceptions for the *trans*(O^6)-[Cr(1,3-pddadp)]$^{-}$ and *trans*(O^5O^6)-[Rh(1,3-pddadp)]$^{-}$. These values vary from 36° to 67° for [M(1,3-pddadp)]$^{n-}$ and from 34° to 71° for [M(1,3-pdta)]$^{n-}$ complexes. Expanding of the two glycinate rings lowers the octahedral strain in the case of Cr(III), Rh(III), and Co(II) complexes, as can be seen while comparing the $\sum \Delta O_h$ values for the corresponding complexes (**5**) (42°) [9] *vs.* (**4**) (56°) [32]; (**7**) (42°) [7] and (**8**) (55°) [7] *vs.* (**6**) (57°) [32]; (**12**) (66°) *vs.* (**11**) (71°) [33]. However, when the two glycinate rings in [Co(1,3-pdta)]$^{-}$ system are expanded to give rise to [Co(1,3-pddadp)]$^{-}$ the opposite effect is registered (compare $\sum \Delta O_h$ values calculated for complexes (**2**) (36°) [5] and (**3**) (38°) [3] with those of (**1**) (34°) [34]). The total devi-

[a] Ionic radius for C.N. = 6 [31].
[b] $\sum\Delta(O_h)$ is the sum of the absolute values of the deviations from 90° of the L–M–L′ bite angles. All values rounded off to the nearest degree.
[c] $\Delta\sum$(ring) is the deviation from the ideal of the corresponding chelate rings' bond angle sum. A mean value of the two rings (R or G) is reported for complexes having an approx. C_2 molecular symmetry.
[d] Δ(M–O–C) (ring) is the mean value of the deviation of the corresponding rings' M–O–C bond angle from 109.5°.
[e] $\sum\Delta$(N) is the sum of the absolute values of the deviations from 109.5° of the six bond angles made by the nitrogen atoms. A mean value for the two nitrogens is reported.
[f] The average values are given for the two complexes: Co[Co(1,3-pdta)] · $8H_2O$ and Mg[Co(1,3-pdta)] · $8H_2O$ that form isomorphic crystals.

ation of the octahedral angles for the $[Ni(1,3\text{-pdta})]^{2-}$ (**9**) [35] and *trans*(O^5)-$[Ni(1,3\text{-pddadp})]^{2-}$ (**10**) [8] complexes is the same and amounts 60°.

As expected, the five-membered glycinate rings of the G type are much more strained than those of the R type. The total deviation from the ideal chelate ring bond angle sum (538.5°) varies from −9° to −12° for the G rings, while for the R rings it is approx. zero except for the *trans*(O^5)-$[Rh(1,3\text{-pddadp})]^-$ [7], where this deviation of −6° av. is unusually large as far as the axially coordinated glycinates are concerned. The bond angles of the M–O–C fragment are expected to lie between 109.5° and 120°, depending on the degree of covalence of the M–O bond [36]. In general, the deviations are larger for the β-alaninate rings of the G type than for the β-alaninate rings of the R type. For edta-type chelates that are considered in this paper these values are in the range 14–24° and 4–19°, respectively (Table 5). In the reported here *trans*(O^6) isomer of $[Co(1,3\text{-pddadp})]^{2-}$ the average deviation of the Co–O–C bond angles in β-alaninate rings is very small (+4°) being of the same order of magnitude as that for the corresponding bond angles in glycinate rings.

Another important source of stain in edta-type complexes is the bonding geometry made by the chelating nitrogens. Each N atom makes four bonds with six ideally 109.5° bond angles. The greatest effect of chelation on the distortion of the tetrahedral bonding geometry of the nitrogen atoms has been registered for the Co(III) and Cr(III) complexes (Table 5).

3.3. Molecular mechanics

Energy minimization and geometry optimization procedure resulted in a few stable conformations for each geometrical isomer (*trans*(O^5), *trans*(O^5O^6), and *trans*(O^6)) of each $[M(1,3\text{-pddadp})]^{n-}$ complex (M = Co(II), Ni(II), and Cr(III)), starting from an exhaustive set of initially generated conformations [17]. Calculated energies for the most stable energy-minimized structures, as well as a comparison with the previously reported data [1,5] for the corresponding Co(III) and Rh(III) complexes are presented in Table 6. Figs. 3–5 illustrate the resulting energy-minimized structures of the three geometrical isomers of $[M(1,3\text{-pddadp})]^{n-}$ complexes (M = Co(II), Ni(II), and Cr(III)), together with the results of a least-squares fit to M (M = Co, Ni, or Cr), N1 and N2 atoms of the corresponding X-ray structures. Structural parameters for the most stable energy-minimized conformers together with the crystallographic data for the *trans*(O^6)-$[Co(1,3\text{-pddadp})]^{2-}$, *trans*($O^5$)-$[Ni(1,3\text{-pddadp})]^{2-}$ [8], and *trans*(O^6)-$[Cr(1,3\text{-pddadp})]^{-}$ [9] complexes are summarized in Tables S10 and S11 (Supplementary material). Geometries of the calculated structures are in good agreement with the corresponding values obtained from the X-ray results, if available.

Table 6
Relative energies (ΔE) and energy contributions (in kcal/mol) for the energy-minimized structures of the three geometrical isomers of $[M(1,3\text{-pddadp})]^{n-}$ complex (M = Co(II), Ni(II), Cr(III), Co(III), and Rh(III))

	ΔE	E_{total}	E_b	E_θ	E_ϕ	E_{nb}	E_c	Ref.

$[Ni(1,3\text{-pddadp})]^{2-}$								
trans(O^5O^6)	0	34	7	34	2	17	−26	this work
trans(O^5)	1	35	8	33	1	19	−26	
trans(O^6)	13	47	8	39	5	17	−22	
$[Co(1,3\text{-pddadp})]^{2-}$								
trans(O^5O^6)	0	36	6	27	12	18	−27	this work
trans(O^5)	3	39	8	30	7	22	−28	
trans(O^6)	9	45	7	32	11	17	−22	

For each $[M(1,3\text{-pddadp})]^{n-}$ system (M = Co(II), Ni(II), Cr(III), Co(III) [5], and Rh(III) [1]), the lowest energy conformer corresponds to the *trans*(O^5O^6) configuration. The total energy of the minimized structures for three geometrical isomers of $[M(1,3\text{-pddadp})]^{n-}$ (M = Co(II), Ni(II), and Rh(III)) increases in the order $E_{total}(trans(O^5O^6)) < E_{total}(trans(O^5)) < E_{total}(trans(O^6))$. However, the stability order of the two less stable isomers (*trans*(O^5) and *trans*(O^6)) for Co(III) and Cr(III) 1,3-pddadp complexes is inverse compared to the corresponding Co(II), Ni(II), and Rh(III) complexes. Analysis of the distribution of strain contributions shows that in all three isomers of $[M(1,3\text{-pddadp})]^{n-}$ (M = Co(III), Cr(III), Rh(III), Co(II), and Ni(II)) complexes the strain is mainly localized in glycinate rings i.e. in M–O–C(sp^2) bond angles, as well as in N–M–O bite angles (*trans*(O^5) isomer of Co(II) and Ni(II) complexes and *trans*(O^5O^6) isomer of Cr(III), Rh(III), Co(II), and Ni(II) complexes), and in O–M–O open angles (*trans*(O^5) isomer of Co(III) and Cr(III) complexes). The energy differences between isomers are rather small, except for the two less stable isomers of Ni(II) and Co(II) complexes (*trans*(O^5) and *trans*(O^6) isomers, respectively). For

Fig. 3. Fig. 4. Illustrations of the energy-minimized structures of the three isomers of $[Ni(1,3\text{-pddadp})]^{2-}$ (open line) and X-ray crystal structure (full line): (a) *trans*(O^5O^6) isomer; (b) the result of a least-squares fit to Ni1, N1 and N2 atoms of the X-ray structure and the energy-minimized structure of *trans*(O^5) isomer; (c) *trans*(O^6) isomer.

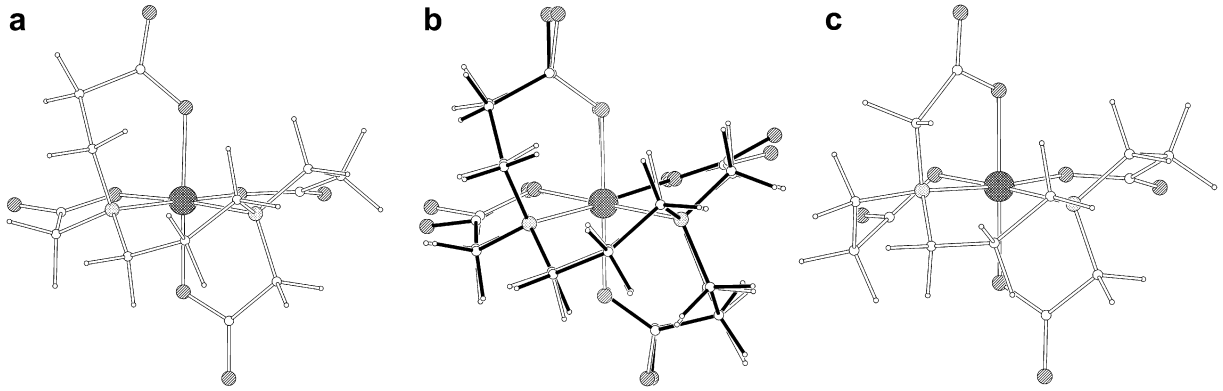

Fig. 5. Illustrations of the energy-minimized structures of the three isomers of $[Cr(1,3\text{-pddadp})]^{-}$ (open line) and X-ray crystal structure (full line): (a) *trans*(O^5O^6) isomer; (b) the result of a least-squares fit to Cr1, N1 and N2 atoms of the X-ray structure and the energy-minimized structure of *trans*(O^6) isomer; (c) *trans*(O^5) isomer.

$[M(1,3\text{-pddadp})]^{n-}$ (M = Co(III), Cr(III), Rh(III), and Co(II)) complexes energy differences between isomers originate mostly from the torsional contributions to the total energy, and in the case of Ni(II) from the angular contributions to the total energy. The analysis of the torsional contributions to the total strain shows that in Co(III), Cr(III), Rh(III), and Co(II) structures the strain is pronounced mainly in endocyclic torsions involving M–O and O–C(sp^2) bonds in the β-alaninate rings of both type (G and R).

3.4. Chelate ring conformations

In $[M(1,3\text{-pddadp})]^{n-}$ structures (M = Co(II), Ni(II), and Cr(III)) the six-membered diamine rings (T rings) adopt predominantly a twist-boat conformation except for the *trans*(O^5)-$[Co(1,3\text{-pddadp})]^{2-}$ and *trans*(O^5)-$[Cr(1,3\text{-pddadp})]^{-}$ in which boat and intermediate between boat and twist-boat forms have been observed, respectively. The axially coordinated glycinate rings (R rings) are usually almost flat while those coordinated in the equatorial plane (G rings) are highly puckered irrespective of their conformations (envelope or twist). In the case of β-alaninate rings, a twist-boat form predominates (12 out of 21 cases, see Table S12c in the Supplementary material) for both types of rings (G and R). The M–O–C=O fragments in this type of β-alaninate rings are roughly planar, as the corresponding torsion angle magnitudes span the narrow range of 144.7–155.7° (18 out of 21 cases listed in Table S12c). However, in some axially oriented β-alaninate rings (R-rings) we note a significant non-planarity of the M–O–C=O fragments, described by the values of the corresponding torsion angle magnitudes in the range of 116.1–122.5°, and associated with it pure boat conformation of the β-alaninate R-ring. This suggests that there exists a correlation between the chelate ring conformation and the M–O–C=O torsion angle magnitude. Moreover, for this pure boat conformation deviations (average value +17) from the ideal ring's bond angle sum (648) are significantly smaller than in other β-alaninate R-rings (Table 5), as are the deviations (average value +4°) of the Co–O–C bond angles from the ideal value of 109.5° (Table 5). These observations might indicate that the nearly ideal boat conformation of the β-alaninate R-ring is favored not only because it enables multiple interactions with the nearest neighbors (coordination or hydrogen bond, *vide supra*)

but also from the point of view of the ring strain. As far as the diaminopolycarboxylate edta-like complexes are concerned, the very bent M–O–C=O moiety and, connected with it, the pure boat conformation of the β-alaninate ring seem to be present only in eddadp and 1,3-pddadp types of chelates, and only in the axially oriented β-alaninate rings.

4. Conclusions

Structural preferences of transition metal complexes with diaminopolycarboxylate edta-type ligands have been compared based on our present and previous results [1,5,17,18]. For each $[M(1,3\text{-pddadp})]^{n-}$ system (M = Co(III), [5] Cr(III), Rh(III), [1] Ni(II), and Co(II)) the lowest energy conformer corresponds to the *trans*(O^5O^6) configuration with the 5–6–6 combination of the chelate rings in the G-plane. Moreover, the lowest energy isomer of the pentadentate $[Rh(1,3\text{-pddadp})Cl]^{2-}$ system (*cis*-polar, *trans*(Cl,O^5) (*N*′(R), *N*″(R)) isomer) [1] also displays the 5–6–6 configuration of the chelate rings in the G-plane, as does the lowest energy conformer of Cr(III) complex with the pentadentate 1,3-propanediamine-*N*,*N*′-diacetate-*N*-3-propionate (1,3-pddap) ligand [19]. However, the stability order of the other two isomers (*trans*(O^5) and *trans*(O^6)) is inverse for $[M(1,3\text{-pddadp})]^{-}$ (M = Co(III) and Cr(III)) with respect to the Co(II), Ni(II), and Rh(III) complexes, indicating that the effect of the metal ion size on the stability order of the two less stable isomers of $[M(1,3\text{-pddadp})]^{n-}$ system is a decisive one. The occurrence of the least energetically favored *trans*(O^6) isomer in the crystal and the unusual conformation, and geometry, of the axially oriented β-alaninate rings can be accounted for by the stabilizing role of extended tapes of planar cyclic water pentamers and hexamers which act as a "glue" to reinforce the coordination polymeric chains, consisting of complex cations and anions bridged together by carboxylate and water oxygens.

Abstract

The synthesis and characterization of new dinuclear Mn^{III} and tetranuclear Cu^{II} complexes, $[HL^1Mn(DMSO)]_2$ (**1**) and $[H_2L^2Cu_2(MeO)_2]_2$ (**2**), are reported (H_4L^1 = 2-hydroxy-*N*-[2-({2-[(2-hydroxybenzoyl)amino]ethyl}amino)ethyl]benzamide and H_4L^2 = 2-hydroxy-*N*-[3-({3-[(2-hydroxybenzoyl)amino]propyl}(methyl)amino)propyl]benzamide). Single crystal X-ray structures have been determined for **1** and **2**. In **1** only one of the two amide functions of H_4L^1 is deprotonated in addition to the phenol ones, while in **2** all the amide functions of H_4L^2 are protonated and none of the potential nitrogen donors (amide and amine) is involved in the coordination to copper. HL^1 and H_2L^2 do not play the role of compartmental ligands and do not wrap around one Mn and one Cu ion, respectively, but embrace two metal centers yielding, with the respective assistance of auxiliary DMSO and methoxo ligands, dinuclear manganese and tetranuclear copper complexes, respectively. **1** includes two well isolated Mn^{III} ions ($Mn\cdots Mn' = 7.33$ Å) that do not interact magnetically. The intermolecular $Mn\cdots Mn''$ distance along the 1D chains (10.17 Å) is also too large to allow extended magnetic interactions. The pairwise magnetic interactions between the copper(II) ions in the tetranuclear complex **2** are so large that the $\chi_M T$ product is already equal to zero at room temperature, implying that the antiferromagnetic interaction is around $-1000\ cm^{-1}$, as observed previously for di-μ-hydroxo–dicopper complexes.

Keywords: Heptadentate amide ligands; Dinuclear Mn^{III} complex; Tetranuclear Cu^{II} complex; Single-crystal X-ray structures; Magnetic studies

1. Introduction

Complexes based on polydentate ligands resulting from amide condensations are not numerous: they include different families depending on the purpose for which the complexes were prepared. In many cases, the polydentate amido ligands from which these complexes are built were purposely designed and synthesized for a given complex (or family of complexes) with specific shape, denticity, nature and functionality of donor atoms. The ligands, including amido and catecholato donors reported by Raymond et al., and their various metal complexes constitute an exemplary illustration of this approach [1]. Several other such examples are of interest in areas as diverse as catalysts, reducing or oxidizing agents, mimics of metalloproteins and enzymes, luminescent or magnetic materials. (i) From potentially tri-anionic tetradentate ligands including amido and phenoxo donors, mononuclear Mn^{IV}, Mn^{V}, Co^{III} and Co^{IV} complexes [2] as well as dicopper-(II,II), -(II,III) and -(III,III) complexes [3] were prepared. (ii) From related potentially mono-, di- or tri-anionic tetradentate ligands including amido and imidazolato and/or

doi:10.1016/j.poly.2007.03.051

pyridyl and/or phenoxo and/or thiolato donors, mononuclear Fe^{III} and dinuclear Ni^{II} complexes were prepared [4]. (iii) From potentially tetra-(tri-)anionic hexa-(penta-) dentate ligands including amido (imino) and phenoxo donors were prepared: a dinuclear Cr^{III} complex [5] and mononuclear Os^{II}, Os^{III}, Os^{IV} and Os^{VI} complexes as reducing and oxidizing agents [6], mononuclear Ru^{IV}, dicobalt-(II,II), -(II,III) and -(III,III) complexes as epoxidation catalysts [7], diiron(II,II) and mononuclear Bi^{III}, Cr^{III} and Fe^{III} complexes as catalysts for the controlled oxidation of organic molecules by O_2 [8], dianionic Cu^{II} ligand complexes as precursors to di- and tetra-heteronuclear 3d–3d and 3d–4f magnetic materials [9], and nitrido-Ru^{VI} and nitrido-Os^{VI} complexes as oxidizing agents [10]. (iv) From potentially tetra-anionic hexadentate ligands including amido and thiolato (or sulfinato) donors were prepared mononuclear Co^{III} [11] and Fe^{III} [12] complexes as mimics of nitrile hydratases, and a trinuclear cobalt(III,II,III) complex [13]. (v) Potentially tri-(penta-) anionic heptadentate ligands including alkoxo, amido and pyridyl (phenoxo) donors allowed the preparation of mono- and dinuclear Cu^{II}, and dinuclear Mn^{III} complexes [14]. (vi) From potentially tetra-anionic octadentate ligands including amido, amino and phenoxo donors, mononuclear Mn^{IV} [15] and dinuclear lanthanide [16] complexes were prepared for their redox, oxidizing and luminescence properties, respectively. (vii) A related potentially penta-anionic nonadentate ligand including amido, imidazolidino and phenoxo donors allowed the preparation of dinuclear Fe_2^{III} and Fe^{III},Zn^{II} complexes [17]. While all the above complexes were thoroughly characterized, most often including a single crystal molecular structure, the scarcity of Cu^{II} [18] and Fe^{III} [19] complexes prepared from related potentially tetra-anionic heptadentate ligands including amido, amino and phenoxo donors, could not be extensively characterized, and especially no single crystal molecular structure has yet been determined for any complex in this series. We have thus explored the chemistry of two such ligands (H_4L^1 = 2-hydroxy-*N*-[2-({2-[(2-hydroxybenzoyl)amino]ethyl}amino)-ethyl]benzamide and H_4L^2 = 2-hydroxy-*N*-[3-({3-[(2hydroxybenzoyl)amino]propyl}(methyl)amino)propyl]-benzamide) with transition metal complexes with the aim of exploring their nuclearities, supramolecular structure and magnetic properties. In this contribution we describe the synthesis, crystal structure and properties of two novel complexes, the dimanganese(III) and tetracopper(II) discrete species $[HL^1Mn(DMSO)]_2$ (**1**) and $[H_2L^2Cu_2(MeO)_2]_2$ (**2**), respectively.

2. Experimental

2.1. Materials

Diethylenetriamine, 3,3′-diamino-*N*-methyldipropylamine, phenylsalicylate, piperidine, triethylamine, $Cu(Ac)_2 \cdot H_2O$, $Mn(Ac)_2 \cdot 4H_2O$ (Aldrich) were used as purchased. High-grade solvents (acetonitrile, diethylether, DMSO, 2-propanol and methanol) were used for the syntheses of the ligands and complexes without further purification.

2.2. Syntheses

2.2.1. Ligands

The ligands were characterized by ^1H and by ^{13}C NMR in DMSO-d_6 (δ, ppm; s, singlet; d, doublet; dd, doublet of doublets; t, triplet ; td, triplet of doublets; q, quadruplet).

2.2.1.1. Synthesis of 2-hydroxy-N-[2-({2-[(2-hydroxybenzoyl)amino]ethyl}amino)ethyl]benzamide, H_4L^1. A mixture of phenylsalicylate (2.14 g, 1×10^{-2} mol), diethylenetriamine (0.51 g, 0.5×10^{-2} mol) and triethylamine (1 g, 1×10^{-2} mol) in 2-propanol (40 mL) was refluxed for 2 h with stirring. The white precipitate which appeared after cooling was filtered off, washed with 2-propanol and diethylether. Yield: 1.33 g (77.6%). m.p. 130 °C. *Anal.* Calc. for $C_{18}H_{21}N_3O_4$: C, 63.0; H, 6.2; N, 12.2. Found: C, 63.3; H, 6.1; N, 12.2%. ^1H NMR (250 MHz, 20 °C) δ: 9.06 (t, $J = 6.4$ Hz, 2H, OCN*H*), 7.96 (dd, $J = 1.5$ and 7.8 Hz, 2H, C(6) *H*), 7.48 (td, $J = 1.5$ and 7.8 Hz, 2H, C(4)*H*), 6.99(d, $J = 7.8$ Hz, 2H, C(3)*H*), 6.99(t, $J = 7.8$ Hz, 2H, C(5)*H*), 3.52 (q, $J = 6.4$ Hz, 4H, OCNHCH_2), 2.89 (t, $J = 6.4$ Hz, 4, NHCH_2). $^{13}C\{^1H\}$ NMR (62.896 MHz, 20°C): δ 39.1 (s, *C*H_2NHCO), 48.0 (s, *C*H_2NH), 115.7 (s, Ar*C*), 117.6 (s, Ar*C*(5)H), 118.3 (s, Ar*C*(3)H), 128.1 (s, Ar*C*(6)H), 133.6 (s, Ar*C*(4)H), 160.4 (s, Ar*C*(2)OH), 169.0 (s, O*C*NH). Characteristic IR absorptions (KBr): 3446, 3222, 1603 cm^{-1}.

2.2.1.2. Synthesis of 2-hydroxy-N-[3-({3-[(2hydroxybenzoyl)amino]propyl}(methyl)amino)propyl]benzamide] H_4L^2. The same experimental procedure as for H_4L^1, but using 3,3′-diamino-*N*-methyldipropylamine instead of diethylenetriamine, yielded H_4L^2 as an oily product. Yield: 1.0 g (52%). *Anal.* Calc. for $C_{21}H_{27}N_3O_4$: C, 65.4; H, 7.1; N, 10.9. Found: C, 65.0; H, 6.9; N, 10.5%. ^1H NMR (250 MHz, 20 °C) δ: 9.11 (s, 2H, OCN*H*), 7.94 (dd, $J = 1.5$ and 8 Hz, 2H, C(6) *H*), 7.47 (td, $J = 1.5$ and 8 Hz, 2H, C(4)*H*), 7.00 (d, $J = 8$ Hz, 2H, C(3)*H*), 6.98(t, $J = 8$ Hz, 2H, C(5)*H*), 3.46 (t, $J = 6.8$ Hz, 4H, OCNHCH_2), 2.48 (t, $J = 6.8$ Hz, 4H, CH_3NCH_2), 2.27 (s, 3H, CH_3NCH_2), 1.81 (q, $J = 6.8$ Hz, 4H, CH_2). $^{13}C\{^1H\}$ NMR (62.896 MHz, 20°C): δ 26.7 (s, *C*H_2), 37.6 (s, *C*H_2NHCO), 41.8 (s, CH_2NCH_3), 55.1 (s, *C*H_2NCH$_3$), 115.6 (s, Ar*C*), 117.6 (s, Ar*C*(5)H), 118.3 (s, Ar*C*(3)H), 127.8 (s, Ar*C*(6)H), 133.6 (s, Ar*C*(4)H), 160.6 (s, Ar*C*(2)OH), 169.0 (s, O*C*NH). Characteristic IR absorptions (thin film): 3380, 3212, 1600 cm^{-1}.

2.2.2. Complexes

*2.2.2.1. $[HL^1Mn(DMSO)]_2$ (**1**).* To a stirred methanolic solution (25 mL) of the H_4L^1 ligand (0.343 g, 1×10^{-3} mol) with piperidine (0.340 g, 4×10^{-3} mol), was added $Mn(Ac)_2 \cdot 4H_2O$ (0.245 g, 1×10^{-3} mol). The solution darkened immediately and was stirred for 3 h at

room temperature. A dark brown precipitate was then filtered off, and washed with methanol. A DMSO/acetonitrile solution of the powder yielded brown crystals 1 month later. Yield: 0.14 g (30%). *Anal.* Calc. for $C_{40}H_{48}Mn_2N_6O_{10}S_2$: C, 50.7; H, 5.1; N, 8.9; Mn, 11.6. Found: C, 50.4; H, 5.0; N, 8.8; Mn, 11.5%. Characteristic IR absorptions (KBr): 3431, 1617, 1596, 1570, 1526, 1437, 1016, 764 cm^{-1}.

*2.2.2.2. $[H_2L^2Cu_2(MeO)_2]_2$ (**2**).* To a stirred methanolic solution (25 mL) of the H_4L^2 ligand (0.385 g, 1×10^{-3} mol) was first added KOH (0.224 g, 4×10^{-3} mol) and, ten minutes later, $Cu(Ac)_2 \cdot H_2O$ (0.398 g, 2×10^{-3} mol). The mixture was stirred with heating for 2 h. A green precipitate which formed was filtered off, and washed several times with methanol. Blue–green crystals were isolated from a DMSO/methanol solution 1 month later. Yield: 0.20 g (35%). *Anal.* Calc. for $C_{46}H_{62}Cu_4N_6O_{12}$: C, 48.2; H, 5.5; N, 7.3; Cu, 22.2. Found: C, 47.9; H, 5.2; N, 7.1; Cu, 22.1%. Characteristic IR absorptions (KBr): 3305, 1609, 1579, 1538, 1526, 1241, 748 cm^{-1}.

2.3. Physical measurements

Elemental analyses were carried out on a Perkin–Elmer 2400 series II device (C, H, N) at the Microanalytical Laboratory of the Laboratoire de Chimie de Coordination in Toulouse, France, and on a Perkin–Elmer 300 Atomic Absorption Spectrophotometer (Mn, Cu) at the LCSCO laboratory of the Department of Chemistry of the University Abou Beker Belkaid in Tlemcen, Algeria. 1D ^1H and ^13C NMR spectra were recorded on an AC 250 FT spectrometer (Bruker). Chemical shifts are given in ppm versus TMS (^1H and ^{13}C) using DMSO-d_6 as the solvent. IR spectra were measured in the 400–4000 cm^{-1} range on a 9800 FTIR spectrometer (Perkin–Elmer). Samples were run as KBr pellets. Variable temperature magnetic susceptibility data were collected on powdered samples on a MPMS-55 Quantum Design SQUID magnetometer under applied magnetic fields lower than 0.5 T. Diamagnetic corrections were applied by using Pascal's constants [20].

2.4. Crystallographic data collection and structure determination for *1* and *2*

The X-ray data for compound **1** were collected on a Stoe Imaging Plate Diffractometer System (IPDS) equipped with an Oxford Cryosystems cooler device using a graphite monochromator ($\lambda = 0.71073$ Å). Data were collected [21] using φ rotation movement with the crystal-to-detector distance equal to 70 mm ($\varphi = 0.0$–$270°$, $\Delta\varphi = 1.5°$). Diffraction data for **2** were collected using an Oxford-Diffraction XCALIBUR CCD diffractometer equipped with a graphite monochromated Mo Kα radiation source. The crystal was placed 50 mm from the CCD detector. More than the hemisphere of reciprocal space was covered by a combination of four sets of exposures; each set had a different φ-angle (0, 90, 180, 270°) and each exposure of 20 s covered 0.75° in ω. Coverage of the unique set is 99.5% complete up to $2\theta = 63.22°$. The unit cell determination and data integration were carried out using the CRYSALIS package of Oxford Diffraction [22]. All structures were solved by direct methods using SIR92 [23] and refined by full-matrix least-squares on F_o^2 with SHELXL-97 [24], using anisotropic displacement parameters for non-hydrogen atoms. The hydrogen atoms were placed in calculated positions (C–H 0.96 Å) and they were included in the refinement in the riding-model approximation with $U_{iso} = 1.1\ U$(atom of attachment). Scattering factors were taken from the standard compilation [25]. The molecular plots were obtained using the CAMERON and ORTEP programs [26]. Semi-empirical absorption corrections were applied for **1** and **2** using the program DIFABS [27]. The final full-matrix least-squares refinement, minimizing $[\sum w(|F_o^2| - |F_c^2|)^2]^2$, converged at the values of R and wR listed in Table 1, presented together with the main crystallographic parameters. For both compounds, it was not possible to resolve the diffuse electron-density residuals (crystallization solvent molecules). Treatment with the SQUEEZE facility from PLATON [28] resulted in a smooth refinement. Since a few low order reflections are missing from the data set, the electron count is underestimated. Consequently, the values given for ρ_{calc}, $F(000)$ and the molecular weight are only valid for the ordered part of the structure. The relatively high R-factor for complex **1** is due to the low quality of the crystals:

Table 1

[a] $R = \sum||F_o| - |F_c||/\sum|F_o|$.
[b] $wR = [\sum w(|F_o^2| - |F_c^2|)^2/\sum w|F_o^2|^2]^{1/2}$.

among several sets of diffraction data obtained from different crystals, which all diffracted poorly, the best one was used to solve this structure. The disorder of the ligand in **2** was treated with the PART option of SHELX97.

3. Results

3.1. Syntheses

The potentially tetra-anionic heptadentate ligands H_4L^1 and H_4L^2, including two terminal phenoxo, two amido and one central amino donor, were expected to act as dinucleating ligands upon reaction with metal salts. Thus, we reacted them aerobically with Cu^{II} and Mn^{II} acetate in a 1:2 ligand/metal ratio. While the obtained Cu^{II} complex **2** had the expected 1:2 ligand/metal ratio, the Mn^{III} complex **1** was characterized by a 1:1 ligand/metal ratio. This latter reaction was then optimized by carrying it out with a 1:1 ligand/metal ratio. By carrying out these reactions in basic media we also expected to favor bridging of the metal centers through full deprotonation of the ligand. However, the analytical data, charge balance, as well as IR spectroscopy suggested the absence of bridging oxo or acetato anions or a counter-cation, implying that the ligand is not fully deprotonated in the Mn^{III} complex. This was confirmed by the single-crystal X-ray molecular structure of **1** which showed that only one of the two amide functions of H_4L^1 is deprotonated in addition to the phenol ones, yielding $[HL^1Mn(DMSO)]_2$. It is remarkable that this ligand is not fully deprotonated in spite of the propensity of amido ligands to favor high oxidation states of the metal centers to which they are coordinated [2,3,6,10,15]. On the other hand, the molecular structure of **2** confirmed another peculiarity suggested by the analytical data, charge balance and IR spectroscopy, namely none of the two amide functions of H_4L^2 are deprotonated, yielding $[H_2L^2Cu_2(MeO)_2]_2$ where the phenoxo and amido oxygen atoms of the H_2L^2 ligands are involved in the coordination to the Cu^{II} cations whilst, at variance with **1**, the central amino nitrogen atoms are not coordinated to the metal centers (see Fig. 1).

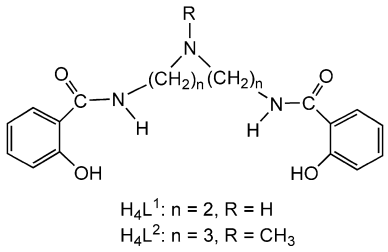

Fig. 1. Schematic representation of ligands H_4L^1 and H_4L^2.

3.2. Description of the structures

A CAMERON plot of **1** and an ORTEP plot of **2** are sketched in Figs. 2 and 3, respectively. Selected inter-atomic distances and angles are collated in Tables 2 and 3, respectively. The crystal structures confirm that HL^1 and H_2L^2 do not play the role of compartmental ligands and do not wrap around one Mn and one Cu ion, respectively. These ligands embrace two metal centers yielding, with the respective assistance of auxiliary DMSO and methoxo ligands, dinuclear manganese and tetranuclear copper complexes, respectively.

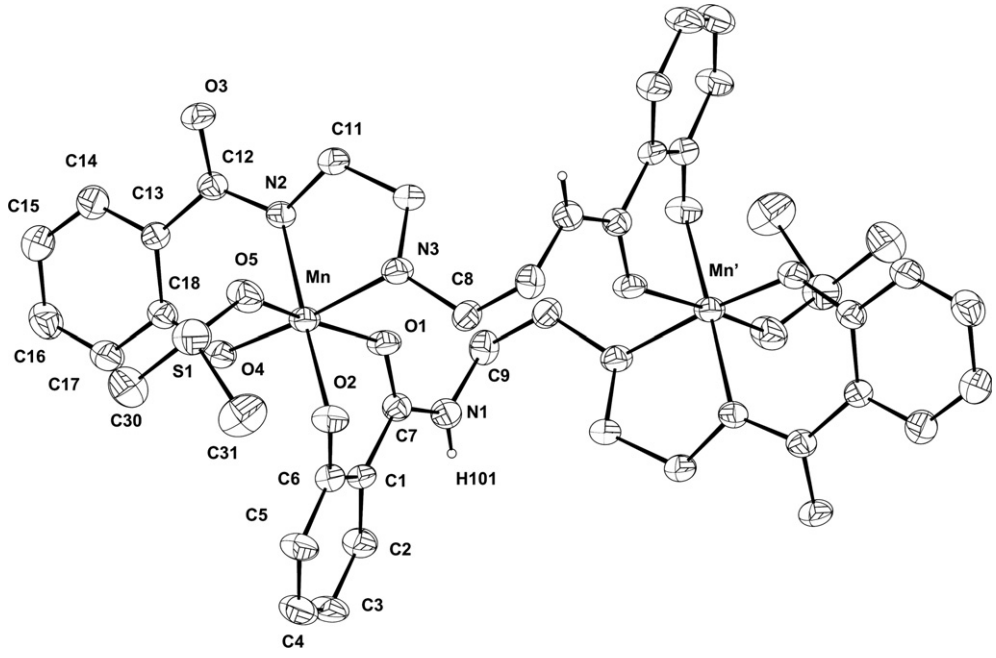

Fig. 2. ORTEP plot of the complex molecule $[HL^1Mn(DMSO)]_2$ (**1**) at the 30% probability level ($' = x + 1, -y, -z$). Carbon bonded H-atoms have been omitted for clarity.

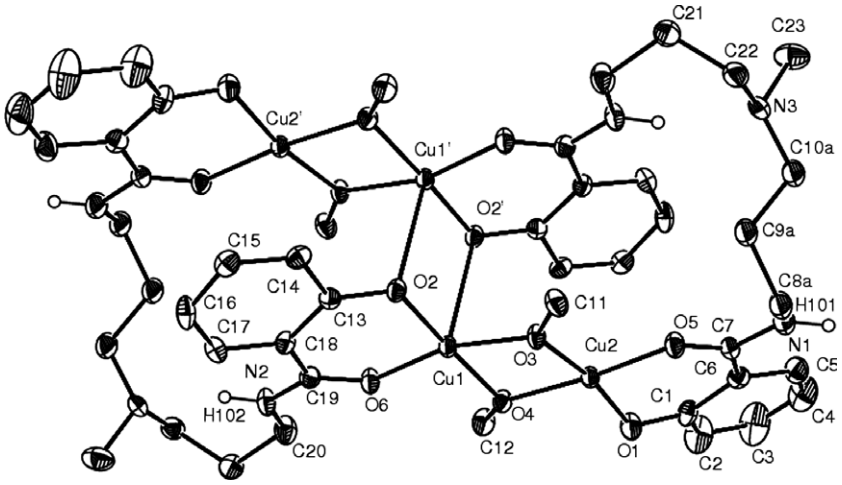

Fig. 3. ORTEP plot of $[H_2L^2Cu_2(MeO)_2]_2$ (**2**) at the 30% probability level ($' = -x+1, -y, -z$). Carbon bonded H-atoms have been omitted for clarity.

The asymmetric unit of the dinuclear complex **1** includes half the $[HL^1Mn(DMSO)]_2$ molecule. The Mn^{III} cations are thus symmetry related and each Mn^{III} is surrounded by four oxygen and two nitrogen atoms originating from two ligands and one DMSO molecule. One ligand is coordinated through one phenoxo oxygen and its deprotonated amido nitrogen atoms and the secondary amino nitrogen atom; the second ligand is chelated to the metal center through one phenoxo and one amido (belonging to the protonated amide function) oxygen atom. Consequently, each ligand is trianionic. The apical positions of the Mn coordination octahedron are occupied by the amido and the DMSO oxygen atoms. The four basal N_2O_2 donor atoms deviate from the mean coordination plane by less than 0.0138 Å. The apical Mn–O bond lengths (2.259(4) and 2.198(4) Å) are larger than the equatorial Mn–O (1.863(4) and 1.894(4) Å) and Mn–N bonds, although the $Mn–N_{amino}$ bond (2.124(5) Å) is larger than the $Mn–N_{amido}$ one (1.949(4) Å), in agreement with the Jahn–Teller elongation expected for the Mn^{III} cation. The $Mn–O_{amido}$ coordination is accompanied by a decrease of the corresponding C=O bond length (0.028 Å), more pronounced than the decrease of the C–N amido bond length following deprotonation and complexation (0.017 Å). The Mn ions belong to a 14-membered macrocycle, with a Mn···Mn′ distance of 7.330(3) Å. This dinuclear structure is reminiscent of a Cu^{II} dimer based on the pentadentate saldien ligand (2-[(*E*)-{[2′-(propylamino)ethyl]imino}methyl]phenol-2-(iminomethyl)-phenol) [29] and of the Mn^{III} dimer $[Mn_2O(5\text{-}NO_2\text{-saldien})_2]$ based on a similar 5-NO_2-salicylaldimine substituted ligand [30]. The crystal packing evidences chains of dinuclear complex molecules developing along the *b*-axis through hydrogen bonds connecting the N1(H) amide nitrogen to the O3 amide oxygen atoms of an adjacent molecule (N1–H = 0.86 Å, H(N1)···O3 = 2.18 Å, N1···O3 = 3.022(6) Å, N1–H···O3 = 165(7)° ($x, y+1, z$)). The resulting intermolecular Mn···Mn″ distance along the chains is 10.1645(19) Å.

The asymmetric unit of the tetranuclear complex **2** includes half of the $[H_2L^2Cu_2(MeO)_2]_2$ molecule. Only two Cu^{II} cations are thus crystallographically independent. Cu1 is in a square pyramidal environment: the four basal donor atoms include one amido and one phenoxo oxygen atom from H_2L^2 and two bridging methoxo oxygen atoms from the symmetry related (′) $[H_2L^2Cu_2(MeO)_2]$ half complex molecule. The apical donor is a bridging phenoxo oxygen atom from the H_2L^2 ligand of the symmetry related (′) $[H_2L^2Cu_2(MeO)_2]$ half complex molecule. Cu2 is in a square planar environment including one amido and one phenoxo oxygen atom from H_2L^2 and two bridging methoxo oxygen atoms. In complex **2**, all the amide functions are protonated and none of the potential nitrogen donors (amide and amine) are involved in the coordination to copper. Cu1 (Cu1′) is bridged to Cu2 (Cu2′) through two methoxo oxygen atoms yielding two $Cu(\mu\text{-}OMe)_2Cu$ pairs in which the Cu···Cu distance is 2.9627(7) Å. In addition, Cu1 is bridged to Cu1′ through two phenoxo oxygen atoms (one from each of the two H_2L^2 ligands in the tetranuclear $[H_2L^2Cu_2(MeO)_2]_2$ molecule) yielding one $Cu(\mu\text{-}O_{phenoxo})_2Cu$ pair in which the Cu···Cu distance is 3.3678(11) Å. The basal Cu–O bond lengths are in the tiny 1.881(3) to 1.926(3) Å range while the apical Cu–O is, as expected, significantly elongated (2.608(3) Å). Consequently, while the $Cu(\mu\text{-}OMe)_2Cu$ cores are practically perfect lozenges with equivalent Cu–OMe–Cu bridging angles (100.99(13) and 101.38(13)°), the $Cu(\mu\text{-}O_{phenoxo})_2Cu$ core is a symmetry imposed rectangle. This overall arrangement results in a 32 metalla-macrocycle, with the two phenolato rings (one from each H_2L^2 ligand) coordinated to one $Cu(\mu\text{-}OMe)_2Cu$ pair in a *trans* configuration. Two symmetry related intramolecular hydrogen bonds between N2(H) and N3 (N2–H = 0.854(10) Å, H(N2)···N3 = 2.05(2) Å, N2···N3 2.822(5) Å, N2–H···N3 = 150(4)° ($-x+1$, $-y$, $-z$)) participate in the stabilization of this tetranuclear arrangement. The crystal packing of **2** does not evidence any significant intermolecular interactions.

3.3. Magnetic studies

The thermal variation of the magnetic susceptibility χ_M has been explored for complexes **1**–**2** in the 300–2 K temperature range. The $\chi_M T$ data for complex **1** are practically constant in the 300–10 K temperature range (5.92–5.63 $cm^3\,mol^{-1}\,K$), which is close to the spin-only value for two non-interacting S = 2 metal centers (6.00 $cm^3\,mol^{-1}\,K$). Below 10 K, the $\chi_M T$ product decreases down to 3.45 $cm^3\,mol^{-1}\,K$ at 2 K. This $\chi_M T$ decrease at very low temperature results from the single ion zero field splitting associated with the Jahn–Teller elongation of the octahedral symmetry around Mn^{III}, mentioned in the molecular crystal structure section. The $\chi_M T$ data for complex **2** are virtually equal to zero in the whole temperature range suggesting strong antiferromagnetic interactions among the $Cu(\mu\text{-}OMe)_2Cu$ pairs described in the molecular crystal structure section.

4. Discussion

These results indicate that, independent of their protonation state, the diamide ligands H_4L^1 and H_4L^2, which contain seven potential donor atoms, do not wrap around the metal ions, as was the case for Ln complexes of the pentadentate saldien Schiff base $[\{Ln(saldien)(NO_3)\}_2]$ (Ln = Gd, Tb) [31] and for 3d complexes of a related Schiff base [M(mbp)] (M = Cu, Ni; mbp = *N*,*N*′-bis[(2-hydroxy-5-methyl-phenyl)phenylmethylene]-4-azaheptane-1,7-diamine) [32]. Neither do they act as common dinucleating ligands. The net result is the obtention of metalla-macrocycles (14-(HL^1 with Mn^{III}) or 32-membered macrocycles (H_2L^2 with Cu^{II})). On comparison with Schiff bases, two supplementary factors are present – the isomerism of the amide function and the number of anionic sites. It is also surprising to see that with Mn^{III} ions, three of the four possible deprotonations occurred while for Cu^{II} ions two deprotonations are observed. In both cases, neutral complexes have been isolated. The presence of methoxo bridges is also puzzling for the deprotonation of the amide function is usually easier than that for methanol. A recent example of a di-μ-methoxo bridge evidences that fairly strong basic conditions are needed for its obtention [33].

From a magnetic point of view, the complex molecule **1** includes two well isolated Mn^{III} ions (Mn···Mn′ = 7.33 Å) that do not interact magnetically. The intermolecular Mn···Mn″ distance along the 1D chains (10.17 Å) is also too large to allow extended magnetic interactions. On the contrary, the pairwise magnetic interactions between the copper(II) ions in the tetranuclear complex **2** are so large that the $\chi_M T$ product is already equal to zero at room temperature. This implies that the antiferromagnetic interaction is around $-1000\,cm^{-1}$. The Cu1–O4–Cu2 and Cu1–O3–Cu2 θ angles (101.0(2) and 101.4(2)°) are in line with previous experimental results for di-μ-hydroxo–dicopper complexes [34]. Antiferromagnetic interaction parameters J were observed for θ angles larger than 98°, their absolute value increasing with θ. Finally, it is remarkable that the magnetic behavior observed for **2** suggests a larger *J* value than those found for similar θ angles in di-μ-hydroxo–dicopper complexes [34].

Abstract

The reactions of $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ with 2-(2′-hydroxyphenyl)-2-benzoxazoline (Hhbo) have been examined and $[ReOX_2(hbo)(AsPh_3)]$ and $[ReOX_2(hbo)(PPh_3)]$ (X = Cl, Br) complexes have been obtained. The crystal and molecular structures of $[ReOCl_2(hbo)(AsPh_3)]$ (**1**) and $[ReOBr_2(hbo)(PPh_3)]$ (**4**) have been determined. The electronic structures of **1** and **4** have been calculated with the density functional theory (DFT) method. The spin-allowed electronic transitions of **1** and **4** have been calculated with the time-dependent DFT method, and the UV–Vis spectra of these complexes have been discussed.

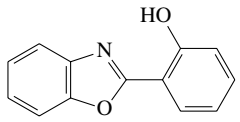
1. Introduction

For many years inorganic compounds containing an oxygen atom multiply bonding to a transition metal have been in the centre of interest to those scientists engaged in basic research and to those trying to employ these complexes in catalytic processes. Oxygen atom transfer chemistry has been implicated in various reactions of industrial and biological importance, including olefin epoxidation and catalysis by cytochrome P-450 [1–3].

The chemistry of oxo rhenium complexes arouses particular interest among these compounds. It results from the favourable nuclear properties of ^{186}Re and ^{188}Re nuclides, which make the radioisotopes useful for diagnostic nuclear medicine and applications in radioimmunotherapy [4,5].



In this context, the design, synthesis and reactivity of novel rhenium oxocomplexes has become the aim of several laboratories, including ours.

Previously, we investigated the reactivity of oxorhenium(V) species-$[ReO(OEt)X_2(PPh_3)_2]$, $[ReOX_3(PPh_3)_2]$ and $[ReOX_3(AsPh_3)(OAsPh_3)]$ (X = Cl or Br) - towards pyrazole, 3,5-dimethylopyrazole and benzotriazole [6]. In this report we focus on the examinations of the reactions of $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ with 2-(2′-hydroxyphenyl)-2-benzoxazoline (Hhbo, Scheme 1).

Although oxazolines have been used widely in many areas of chemistry, given the versatility of this ring which acts as a protector group, coordinating ligand, and activation moiety, studies on rhenium oxocomplexes

Scheme 1. Structure of Hhbo ligand.

incorporating such ligands have been relatively rare [7]. Additionally, we were encouraged by the recent reports concerning investigations of the reactivity of $[ReOCl_3(PPh_3)_2]$ towards 2-, 5-, and/or 7-substituted 8-quinolinolato and pyridinecarboxylate ligands. Several oxocomplexes of general $[ReOCl_2(O–N)(PPh_3)]$ formula have been isolated in these reactions and structurally and spectroscopically characterized [8–11]. The oxorhenium(V) chelates $[ReOCl_2(O–N)(PPh_3)]$ with pyridinecarboxylate ligands have been also examined as catalysts for the carboxylation of ethane by CO in the presence of potassium peroxodisulfate $K_2S_2O_8$ [11].

Here we present synthesis and spectroscopic data for $[ReOCl_2(hbo)(AsPh_3)]$ (**1**), $[ReOBr_2(hbo)(AsPh_3)]$ (**2**), $[ReOCl_2(hbo)(PPh_3)]$ (**3**) and $[ReOBr_2(hbo)(PPh_3)]$ (**4**) complexes. X-Ray studies have been performed for **1** and **4**, and electronic structures of **1** and **4** have been calculated with the density functional theory (DFT). The spin-allowed singlet-singlet electronic transitions of **1** have been calculated with the time-dependent DFT method (TDDFT method), and the UV–Vis spectra of these complexes have been discussed on this basis.

Currently density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [12]. Recent calculations with TD-DFT method for open- and closed-shell of 5d-metal complexes (including rhenium complexes) have also supported the TD-DFT method to be applicable for such systems giving good assignment of experimental spectra [13,14].

2. Experimental

2.1. General procedure

All the reagents used to the synthesis were commercially available and were used without further purification. The $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ complexes were prepared according to the literature methods [15].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 1000–200 nm in chloroform solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer. ^1H NMR spectra were obtained in $CDCl_3$ using Bruker Avance 400 spectrometer.

2.2. Preparation of $[ReOCl_2(hbo)(AsPh_3)] \cdot MeCN$ (**1** · MeCN)

A mixture of $[ReOCl_3(AsPh_3)_2]$ (0.50 g, 0.54 mmol), Hhbo (0.13 g, 0.62 mmol) and acetone (70 ml) was stirred for 3 h. 50 ml of acetone was distilled off and 100 ml of diethyl ether was added. $[ReOCl_2(hbo)(AsPh_3)]$ was filtered off, washed with ethanol, diethyl ether, dried and recrystallized from acetonitrile. Yield 86%.

IR (KBr; ν/cm^{-1}): 1606 (m), 1595(sh), 1571 (w), 1538 (m) ν_{CN} and $\nu_{C=C}$; 966(s) $\nu_{Re=O}$.

UV–Vis ($CHCl_3$; λ_{max} [nm] (ε; [$dm^3\ mol^{-1}\ cm^{-1}$])): 681.0 (60), 414.3 (3010), 307.9 (2.375×10^4) and 249.5 (3.93×10^4).

^1H NMR (20 °C, $CDCl_3$, ppm); hbo related resonances: 6.80 (d, 1H); 6.89 (t, 1H); 7.10 (m, 2H); 7.40–7.55 (m, 3H) and 7.98 (d, 1H); $AsPh_3$ related resonances: 7.39–7.19 (m, 15H).

Anal. Calc. for $C_{33}H_{26}AsCl_2N_2O_3Re$: 47.72; H, 3.16; N, 3.37. Found: C, 47.80; H, 3.30; N, 3.45%.

2.3. Preparation of $[ReOBr_2(hbo)(AsPh_3)] \cdot MeCN$ (**2** · MeCN)

A procedure similar to that for $[ReOCl_2(hbo)(AsPh_3)]$ was used with $[ReOBr_3(AsPh_3)_2]$ (0.50 g, 0.47 mmol) and Hhbo (0.12 g, 0.55 mmol). Crystalline precipitate of $[ReOBr_2(hbo)(AsPh_3)] \cdot MeCN$ was collected in 88% yield.

IR (KBr; ν/cm^{-1}): 1604 (m), 1593 (sh), 1574 (w), 1538 (s) ν_{CN} and $\nu_{C=C}$; 967(s) $\nu_{Re=O}$.

UV–Vis ($CHCl_3$; λ_{max}[nm] (ε; [$dm^3\ mol^{-1}\ cm^{-1}$])): 681.5 (60), 429.5 (2.0×10^3), 310.0 (2.0×10^4) and 249.8 (5.09×10^4).

Anal. Calc. for $C_{33}H_{26}AsBr_2N_2O_3Re$: 43.11; H, 2.85; N, 3.05. Found: C, 43.25; H, 2.75; N, 2.99%.

2.4. Preparation of $[ReOCl_2(hbo)(PPh_3)] \cdot MeCN$ (**3** · MeCN)

A procedure similar to that for $[ReOCl_2(hbo)(AsPh_3)]$ was used with $[ReOCl_3(PPh_3)_2]$ (0.50 g, 0.6 mmol) and Hhbo (0.15 g, 0.7 mmol). Crystalline precipitate of $[ReOCl_2(hbo)(PPh_3)] \cdot MeCN$ was collected in 85% yield.

IR (KBr; ν/cm^{-1}): 1606 (m), 1596 (sh), 1570 (w), 1536 (s) ν_{CN} and $\nu_{C=C}$; 964 (s) $\nu_{Re=O}$.

UV–Vis ($CHCl_3$; λ_{max}[nm] (ε; [$dm^3\ mol^{-1}\ cm^{-1}$])): 681.8 (50), 400.9 (4.8×10^3), 308.7 (2.8×10^4) and 255.0 (3.6×10^4).

Anal. Calc. for $C_{33}H_{26}PCl_2N_2O_3Re$: 50.39; H, 3.33; N, 3.56. Found: C, 50.60; H, 3.25; N, 3.48%.

2.5. Preparation of $[ReOBr_2(hbo)(PPh_3)] \cdot MeCN$ (**4** · MeCN)

A procedure similar to that for $[ReOCl_2(hbo)(AsPh_3)]$ was used with $[ReOBr_3(PPh_3)_2]$ (0.50 g, 0.52 mmol) and Hhbo (0.09 g, 0.62 mmol). Crystalline precipitate of $[ReOBr_2(hbo)(PPh_3)] \cdot MeCN$ was collected in 90% yield.

2.6. Crystal structures determination and refinement

The X-ray intensity data of **1** and **4** were collected on a KM-4-CCD automatic diffractometer equipped with CCD detector and graphite monochromated Mo-Kα radiation ($\lambda = 0.71073$ Å) at room temperature. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and absorption correction [16] were applied. The structures were solved by the Patterson method and subsequently completed by the difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. The hydrogen atoms were treated as, riding'' on their parent carbon atoms and assigned isotropic temperature factors equal 1.2 times the value of equivalent temperature factor of the parent atom. SHELXS97 [17], SHELXL97 [18] and SHELXTL [19] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

3. Computational details

GAUSSIAN03 program [20] was used in the calculations. The geometry optimisations of **1** and **4** were carried out with the DFT method with the use of B3LYP functional [21,22]. The electronic spectra of **1** and **4** were calculated with the TDDFT method [23]. The calculations were performed by using ECP basis set on the rhenium atom, the standard 6-31+G** basis for halogen, oxygen, arsine, phosphorous and nitrogen, 6-31G* for carbon and 6-31G for hydrogen atoms. The Xe core electrons of Re were replaced by an effective core potential and DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [24] was used for the valence electrons. Additional d function with exponent $\alpha = 0.3811$ and f function with exponent $\alpha = 2.033$ on the rhenium atom were added.

Natural bond orbital (NBO) calculations were performed with the NBO code [25] included in GAUSSIAN03.

4. Results and discussion

4.1. Preparation and infrared data

The $[ReOX_2(hbo)(EPh_3)]$ (X = Cl, Br; E = As, P) complexes were prepared in good yields by ligand exchange reactions starting from $[ReOX_3(EPh_3)_2]$ complexes and 2-(2′-hydroxyphenyl)-2-benzoxazoline in acetone:

$$[ReOX_3(Eph_3)_2] + Hhbo \rightarrow [ReOX_2(hbo)(Eph_3)] + HX + Eph_3 \quad X = Cl, \quad Br;\ E = As, P$$

They were isolated as green microcrystalline solids, soluble in common organic solvents.

The strong ν(Re=O) stretching band of $[ReOX_2(hbo)(EPh_3)]$ is found at 964–967 cm^{-1}, at a relatively high wavenumber, which suggests that the Re–hydroxy bond *trans* to the oxo ligand does not compete effectively for the Re_d orbitals and the bond is relatively weak. Moreover, the range in which the ν(Re=O) bands appear is very similar to those observed for Re(V)-oxo complexes with an monoanionic oxygen (RO^- and $R–COO^-$,) *trans* to the oxo group [26].

4.2. Crystal structures

Both complexes are isostructural and they crystallise as acetonitrile solvates in the triclinic space group $P\bar{1}$. No specific intermolecular interactions [27,28] with enough strength to govern molecule conformation were found in the crystals of **1** and **4**.

The molecular structure of **1** is presented in Fig. 1, and the selected bond distances and angles of **1** and **4** are collected in Tables 3 and 4, respectively.

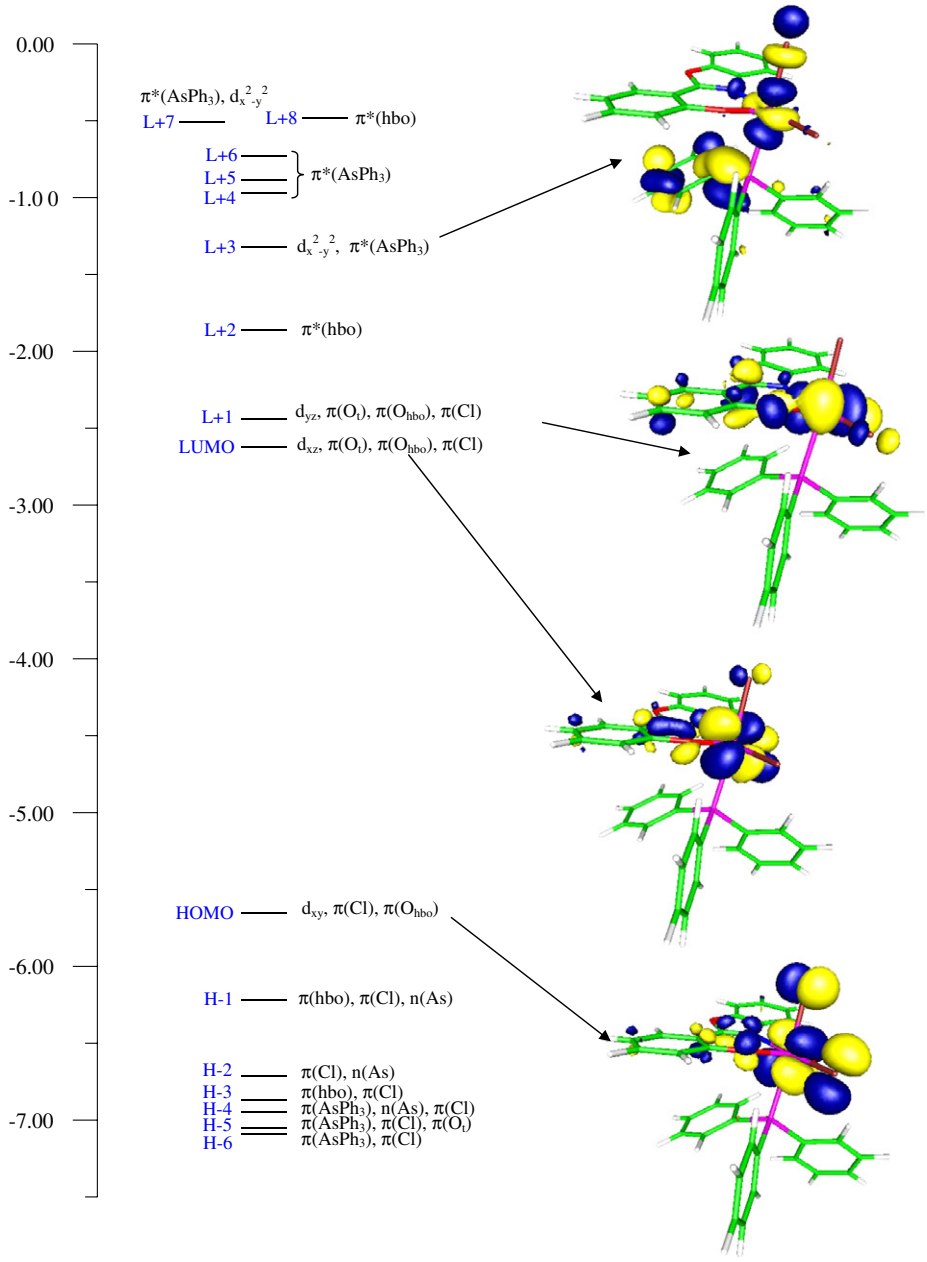

Fig. 2. The energy (eV), character and some contours of the unoccupied molecular orbitals of **1**. Positive values of the orbital contour are represented in blue (0.04 au) and negative values – in yellow (−0.04 au). (For interpretation of colour with respect to this figure caption the reader is referred to the web version of this article.)

Both complexes show octahedral geometry about the central rhenium atom defined by the terminal oxo-group, two halide ions in *cis* arrangement, the phosphorus or arsine of EPh_3 molecule, and the bidentate N,O donors of the hbo ligand. The Re(1) atoms derive 0.1326(6) and 0.1298(10) Å respectively from the equatorial N(1)/As(1)/Cl(1)/Cl(2) (compound **1**) and N(1)/P(1)/Br(1)/Br(2) (compound **4**) least squares planes. The oxygen atom of hbo is coordinated in *trans* position to the terminal oxo ligand. The multiple bonding ligand (terminal oxo) and narrow bite angle of the chelating ligand contribute to clear distortions of the pseudooctahedral environment of Re center in the $[ReOX_2(hbo)(EPh_3)]$ complexes. The high concentration of electronic density along the Re–O axis strongly influences the positions of the adjacent halogen atoms, which are pushed away.

The similar coordination geometry is observed for the other $[ReOCl_2(O–N)(PPh_3)]$ complexes with quinolinolato and pyridinecarboxylate derivatives [8–11]. Another geometry about the central atom can be noticed in dibromooxo(*N*-phenylsalicylideneaminato)(triphenylphosphine)–rhenium(V) complex [29]. Similar to the $[ReOCl_2(O–N)(PPh_3)]$ complexes with 8-quinolinolato ligands the oxygen atom of *N*-phenylsalicylideneaminato ion occupies *trans* position to the terminal oxo ligand, but bromide ions are in *trans* arrangement and PPh_3 molecule is opposite the

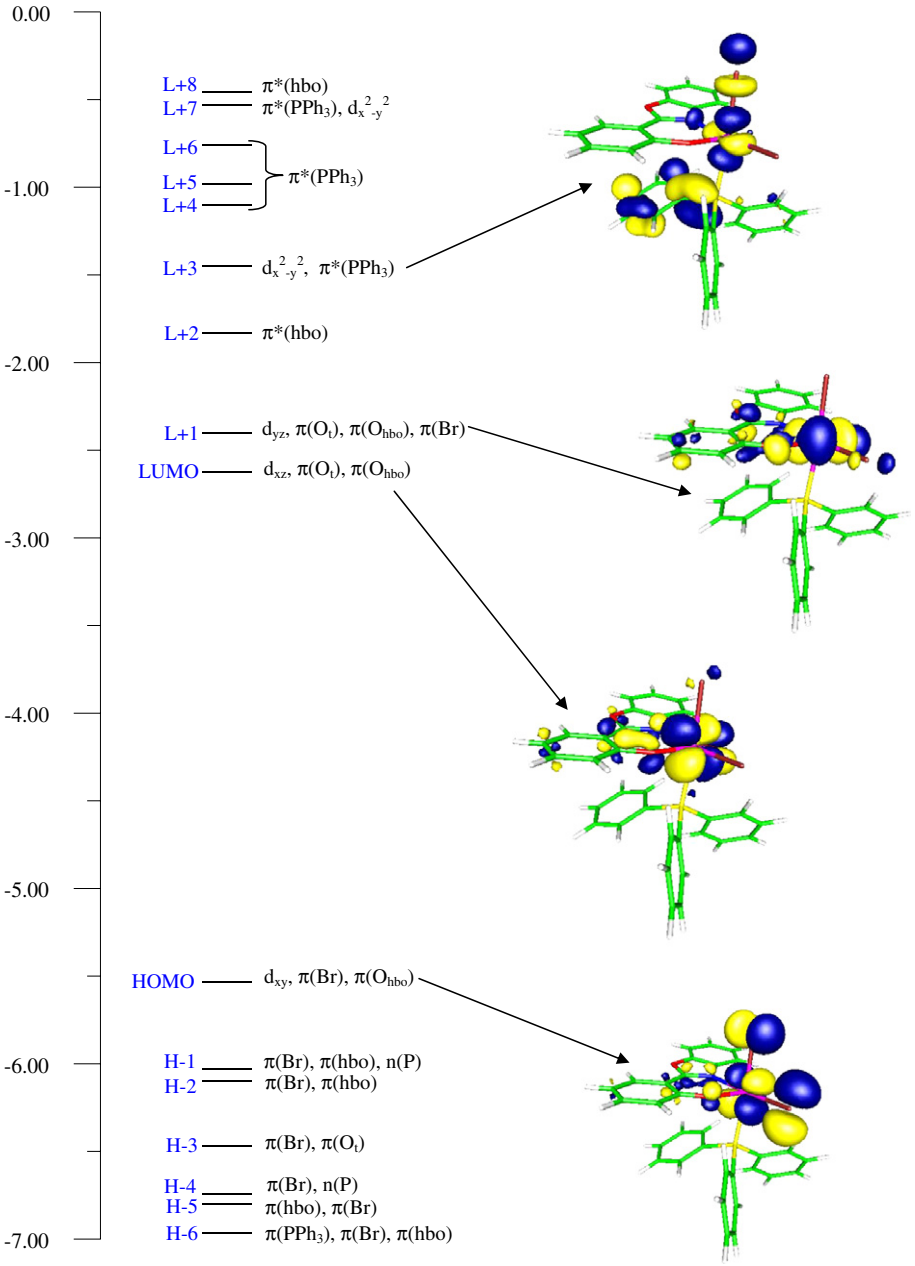

Fig. 3. The energy (eV), character and some contours of the unoccupied molecular orbitals of **4**. Positive values of the orbital contour are represented in blue (0.04 au) and negative values – in yellow (−0.04 au). (For interpretation of colour with respect to this figure caption the reader is referred to the web version of this article.)

nitrogen atom of *N*-phenylsalicylideneaminato ligand. It seems that electrostatic (not steric) factors are responsible for changing geometry about the central atom in dibromooxo(*N*-phenylsalicylideneaminato)(triphenylphosphine)–rhenium(V) in comparison with the discussed 8-quinolinolato oxocomplexes. The pyridine ring of the 8-quinolinolato ligand is good π acceptor, whereas the nitrogen atom of *N*-phenylsalicylideneaminato ion is pure donor.

The Re–O(1) and Re–O(3) distances of **1** and **4** are in good agreement with the corresponding values found for the oxorhenium(V) chelates $[ReOCl_2(O–N)(PPh_3)]$ with 2-, 5-, and/or 7-substituted 8-quinolinolato and pyridine-carboxylate ligands [8–11]. The Re–O_t bond lengths fall in the range 1.639-1.76 Å, typical of mononuclear complexes of rhenium(V) having $[ReO]^{3+}$ core, and indicate the presence of a triple bond Re≡O [30]. The interatomic distances between the rhenium atom and the oxygen atom of hbo ligand are longer the Re–O_{alkoxy} in the $[ReO(OR)X_2(PPh_3)_2]$ complexes [31], and only somewhat shorter than an ideal single Re–O bond length. The last one, predicted by the use of Pauling's covalent radius for oxygen and Cotton and Lippard's value for the octahedral covalent radius of rhenium(V), should be ca. 2.04 Å [32].

Table 5
The occupancy and composition of the calculated natural bond orbitals (NBOs) between the rhenium and the oxo ligand for **1** and **4**

BD	Occupancy	Composition of NBO	BD*	Occupancy
1				
Re–O_t	1.990	$0.564(d)_{Re} + 0.826(p)_O$	$0.826(d)_{Re} - 0.564(p)_O$	0.255
Re–O_t	1.987	$0.570(d)_{Re} + 0.822(p)_O$	$0.822(d)_{Re} - 0.570(p)_O$	0.300
4				
Re–O_t	1.993	$0.565(d)_{Re} + 0.825(p)_O$	$0.825(d)_{Re} - 0.565(p)_O$	0.269
Re–O_t	1.987	$0.571(d)_{Re} + 0.821(p)_O$	$0.821(d)_{Re} - 0.571(p)_O$	0.293

BD denotes 2-center bond.
* Denotes antibond NBO.

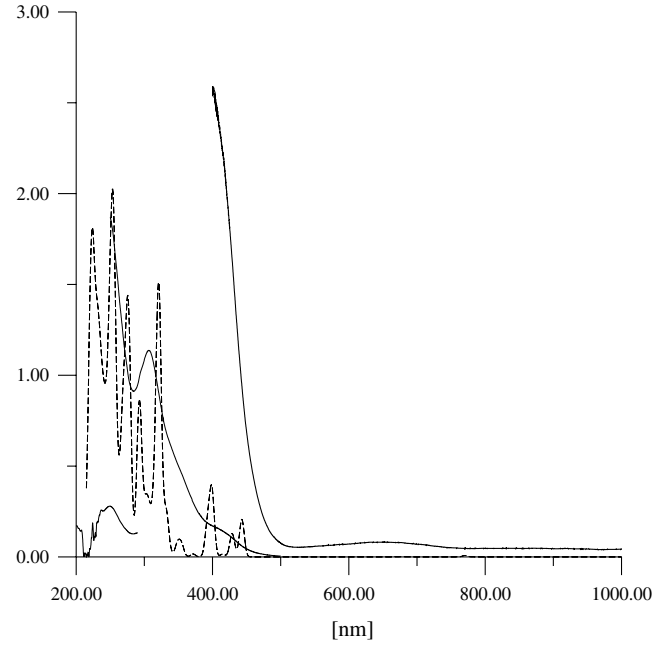

Fig. 4. The experimental (—) and calculated (---) electronic absorption spectra of **1**.

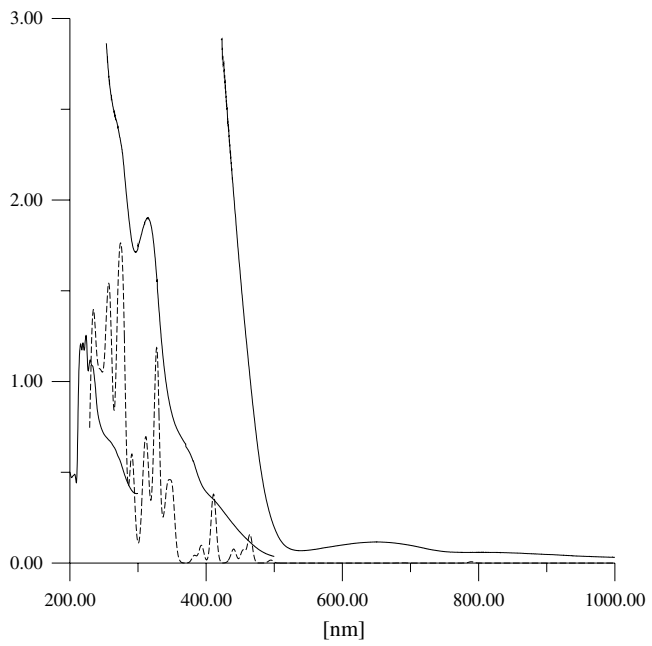

Fig. 5. The experimental (—) and calculated (---) electronic absorption spectra of **4**.

The Re1–X(1) distances *trans* to the phosphorus or arsine atom of EPh_3 molecule are slightly longer than the Re1–X(2) bonds *trans* to the nitrogen atom of the hbo^- ligand. It indicates *structural trans* effect of the EPh_3 ligands. A similar trend was observed in the oxorhenium(V) chelates $[ReOCl_2(O–N)(PPh_3)]$ with 2-, 5-, and/or 7-substituted 8-quinolinolato and pyridinecarboxylate ligands [8–11].

4.3. Geometry optimisation, charge distribution, electronic structure and NBO analysis

The geometries of **1** and **4** were optimised in a singlet state by the DFT method with the B3LYP functional. The optimized geometric parameters of **1** and **4** are gathered in Tables 2 and 3, respectively. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

Table 4 presents the atomic charges from the natural population analysis (NPA) for **1** and **4**. The calculated charges on the rhenium atoms in **1** and **4** are considerably lower than the formal charge 5+, and the populations of the d_{xy}, d_{xz}, d_{yz}, $d_{x^2-y^2}$ and d_{z^2} rhenium orbitals are following: 0.846, 1.044, 0.926, 1.159 and 1.543 for **1** and 0.992, 0.958, 1.128, 1.603 and 0.901 for **4**. It confirms significant charge donation from the ligands. The As and P atoms are positively charged, and the charges on the terminal oxo, halide and oxygen atom of hbo^- are significantly smaller than −2, −1 and −1, respectively. The terminal oxo ions are less negative in comparison with the oxygen atoms of hbo^-ligand. It indicates the higher electron density delocalization from the terminal ligands towards the rhenium centers and corresponds to differences in the Re–O(3) and Re–O(1) bond lengths.

The complexes **1** and **4** are closed-shell structures. Their molecular orbital diagrams with several highest HOMO and lowest LUMO contours are presented in Figs. 2 and 3, respectively. The HOMO–LUMO gaps equal to 3.03

and 2.9 eV for **1** and **4**, respectively. The highest occupied MOs of **1** and **4** are of d_{xy} type with some contributions from p_π chloride and hbo^- orbitals. The remaining four d-type orbitals of rhenium are found among unoccuppied MOs. It confirms d^2 configuration of the rhenium atoms in **1** and **4**.

The rhenium–oxygen interaction in **1** and **4** is described as a triple bond. Assuming that rhenium uses its six valence orbitals, $5d_{x^2-y^2}$, $5d_z{}^2$, 6s, $6p_x$, $6p_y$ and $6p_z$ to form σ-bonds with the six ligands, empty $5d_{xz}$ and $5d_{yz}$ orbitals are available to overlap with $2p_x$ and $2p_y$ orbitals on the terminal oxygen to form an effective triple bond. The LUMO and LUMO + 1 (Figs. 2 and 3) are ascribed as π-antibonding rhenium–oxygen molecular orbitals.

Additional information about nature rhenium–terminal oxygen bonding has been obtained by NBO analysis. The occupancy and composition of the calculated Re–O_t natural bond orbitals (NBOs) are given in Table 5.

Each natural bond orbital (NBO) σ_{AB} can be written in terms of two directed valence hybrids (NHOs) h_A and h_B on atoms A and B:

$$\sigma_{AB} = c_A h_A + c_B h_B$$

where c_A and c_B are polarization coefficients. Each valence bonding NBO must in turn be paired with a corresponding valence *anti*-bonding NBO:

$$\sigma^*_{AB} = c_B h_A - c_A h_B$$

ε – molar absorption coefficient [dm^3 mol^{-1} cm^{-1}]; f – oscillator strength; H – highest occupied molecular orbital; L – lowest unoccupied molecular orbital.

to complete the span of the valence space. The Lewis-type (donor) NBOs are thereby complemented by the non-Lewis-type (acceptor) NBOs that are formally empty in an idealized Lewis picture. The interactions between 'filled' Lewis-type NBOs and 'empty' non-Lewis NBOs lead to loss of occupancy from the localized NBOs of the idealized Lewis structure into the empty non-Lewis orbitals, and they are referred to as 'delocalization' corrections to the zeroth-order natural Lewis structure [33].

The detected natural Re–O_t bond orbitals of **1** and **4** complexes are orbitals of π character – the p_x and p_y oxygen orbitals and d_{xz} and d_{yz} rhenium orbitals are involved in their formation. Not detected σ_{Re-O_t} bond has character of predominant Coulomb-type interactions between the central ion and ligands [34]. Accordingly, NBO analysis confirms a triple bond between the rhenium and the terminal oxygen ligand.

4.4. Electronic spectrum

The experimental and calculated electronic spectra of **1** and **4** are presented in Figs. 4 and 5, respectively. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}. The positions of absorption bands for the other [$ReOX_2$(hbo)(EPh_3)] complexes are given in the experimental part.

The spin-allowed singlet-singlet electronic transitions calculated with the TDDFT method for **1** and **4** are gathered in Tables 6 and 7, respectively. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.015 are listed in Tables 6 and 7.

The longest wavelength experimental bands at 681.0 and 663.2 nm for **1** and **4** are attributed to the transitions of d → d character with small oscillator strengths.

Table 7
The energy and molar absorption coefficients of experimental absorption bands and the electronic transitions calculated with the TDDFT method for **4**

The absorption bands with maxima at ~410 and ~310 nm are assigned to the *Metal–Ligand Charge Transfer* (occurring from the rhenium ion to the π-antibonding orbitals of the hqn ligand and EPh_3 ligands) and *Ligand–Metal Charge Transfer* ($\pi_{hqn}/\pi_{EPh_3}/\pi_{Cl}/\pi_O \rightarrow d$) transitions.

The experimental bands below 300 nm result mainly from *Ligand–Ligand Charge Transfer* and interligand (IL) transitions.

Supplementary material

CCDC 634528 and 634529 contain the supplementary crystallographic data for $C_{33}H_{26}AsCl_2N_2O_3Re$ and $C_{33}H_{26}PBr_2N_2O_3Re$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +(44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Complexes of the general formula $[Re^{III}(L)Cl(PPh_3)_2]$ have been synthesised by reacting H_2L and $[ReOCl_3(PPh_3)_2]$ in ethanol. Here H_2L represents imines of α-amino acids (glycine, L-alanine, L-valine, L-phenylalanine) derived from salicylaldehyde and naphthaldehyde. The crystal structure of one complex has been determined. The complexes are mononuclear, paramagnetic and display paramagnetic ^1H NMR in $CDCl_3$ solution. Their spectral and redox properties are scrutinised.

Keywords: Rhenium(III); α-Amino acids; Schiff base

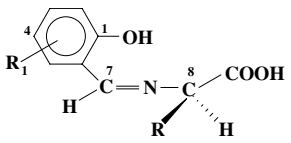
1. Introduction

Considerable attention has been given to the coordination chemistry of rhenium due to its widespread application in catalysis [1] as well as its β-emitting (Re^{186}, Re^{188}) isotopes which are used as therapeutic agents in nuclear medicine [2,3]. A sizable number of tridentate Schiff bases [4] have been used to investigate the chemistry of rhenium. However the chemistry of rhenium using aldimines of α-amino acids is not known. This has motivated us to initiate research of the chemistry of rhenium with the Schiff bases of α-amino acid.

The stability of α-amino acid Schiff base complexes depends on various factors, such as the amino acid side chain polarity [5], the metal, pH, solvent and temperature [6]. Moreover racemic complexes are also observed even in the case of optically active amino acid Schiff bases [5,7,8]. Herein we describe a successful synthesis of a hitherto unknown family of mononuclear Re(III) species chelated by aldimines of α-amino acids (glycine, L-alanine, L-valine, L-phenylalanine), starting from $[ReOCl_3(PPh_3)_2]$. The X-ray structure of one representative case is reported. Their spectral and redox behavior are discussed.

2. Experimental

2.1. Materials



All the starting chemicals were analytically pure and were used without further purification. The Schiff bases were synthesized using the reported procedure [9].

2.2. Physical measurements

UV–Vis spectra were recorded on a Perkin–Elmer LAMBDA 25 spectrophotometer. IR spectra were measured with a Perkin–Elmer L-0100 spectrophotometer. ^1H NMR and ^{31}P spectral measurements were carried out on a Bruker FT 300 MHz spectrometer with TMS as an internal reference and Bruker FT 500 MHz spectrometer, respectively. The atom-numbering scheme used for ^1H NMR is the same as that used in the crystallography and in Chart 1. Electrochemical measurements were performed (acetonitrile solution) on a CH620 electrochemical analyzer

using a platinum electrode under a dinitrogen atmosphere. Tetraethylammonium perchlorate (TEAP) was used as a supporting electrolyte and the potentials are referenced to the standard calomel electrode (SCE) without junction correction. Magnetic susceptibilities were measured on a PAR-155 vibrating-sample magnetometer. Microanalyses (C, H, N) were obtained from a Perkin–Elmer 2400 Series II elemental analyzer. CD spectra were recorded on a JASCO-715 polarimeter and mass spectra (70 eV) were recorded on a Qtof Micro YA263 spectrometer.

2.3. Synthesis of the complexes

The complexes $[Re^{III}(L)Cl(PPh_3)_2]$ were prepared by using a general method with $[ReOCl_3(PPh_3)_2]$ [10] as the starting material. Details are given below for one representative case (**1a**).

$[Re^{III}(L^1)Cl(PPh_3)_2]$ **1a**. 42 mg (0.18 mmol) of H_2L^1 were added to a solution of 100 mg (0.13 mmol) of $[ReOCl_3(PPh_3)_2]$ in 20 ml dry ethanol in the presence of excess PPh_3. The reaction mixture was refluxed for 6 h, producing a red precipitate. This was filtered and the solid mass was then dissolved in a minimum volume of dichloromethane and subjected to column chromatography on a silica gel column (12 × 1 cm, 60–120 mesh). A red-orange band was eluted using benzene–acetonitrile (10:1) mixture. A red-orange solid was obtained after removal of solvent from the eluate under reduced pressure. Yield: 88 mg (68%). *Anal.* Calc. for $C_{49}H_{39}NClO_3P_2Re$: C, 60.40; H, 5.04; N, 1.44. Found: C, 60.32; H, 4.98; N, 1.39%. 2.4. X-ray structure determination

X-ray quality single crystals for the complex $[Re^{III}(L^1)Cl(PPh_3)_2]$ were grown by slow diffusion of diethyl ether into a dichloromethane solution. The X-ray intensity data were measured at 293 K on a Bruker AXS SMART APEX CCD diffractometer (Mo Kα, $\lambda = 0.71073$ Å). The detector was placed at a distance of 6.03 cm from the crystal. A total of 606 frames were collected with a scan width of 0.3° with different settings of φ. The data were reduced in SAINTPLUS [11] and an empirical absorption correction was applied using the SADABS package [12]. The metal atom was located by direct methods using SIR92 [12]. The structure was refined by the full matrix least-square method using SHELXL97 [13], that was present in the program suite WINGX (Version 1.63.04a) [14]. All non-hydrogen atoms were refined anisotropically. The azomethine hydrogen atom was directly located in difference Fourier maps and the remaining hydrogen atoms were included in calculated positions. Significant crystal data are given in Table 1.

3. Result and discussion

3.1. Synthesis

Aldimines of four α-amino acids (glycine, L-alanine, L-valine and L-phenylalanine) have been used in the present work. The aldimine ligands will be abbreviated as H_2L (Chart 1), the two H atoms (phenolic and carboxylic) being potentially dissociable. The abbreviations for specific Schiff bases are given in Chart 1.

The stoichiometric reaction of $[ReOCl_3(PPh_3)_2]$ with the appropriate ligand in boiling ethanol afforded orange-red coloured complexes of the general formula $[Re^{III}(L)Cl(PPh_3)_2]$. It is noted that when the reaction is carried out in the presence of excess PPh_3 there is an increase in yield of $[Re^{III}(L)Cl(PPh_3)_2]$. This observation indicates that the reduction from Re(V) to Re(III) takes place via the abstraction of the Re=O oxygen atom by PPh_3 [4e].

The characterization data of the complexes are given in the Section 2. A strong C=N stretch is observed at ~1670 cm^{-1}. Carboxylate monocoordination [15,16] is consistent with the presence of one symmetric (~1310 cm^{-1}) and two asymmetric (~1620 and 1660 cm^{-1}) stretches. The Re–Cl and Re–P stretches occur at ~325 and ~745 cm^{-1} respectively.

Electro spray ionization mass spectrometry (ESI-MS) of compound **1a** displayed the highest *m*/*z* peak at 972.90, unambiguously assigned to the $[Re^{III}(L^1)Cl(PPh_3)_2]$ parent ion on the basis of the isotopic distribution of ^{35,37}Cl and ^{185,187}Re. The pattern for $(M–H)^+$ is also observed.

3.2. Crystal structure

The crystal structure of $[Re^{III}(L^1)Cl(PPh_3)_2]$ has been determined. The molecular view is shown in Fig. 1 and selected bond parameters are given in Table 2.

The tridentate meridionally disposed $[L^1]^{2-}$ contains two excellently planar segments ($OC_{10}H_6CHN$ and CCO_2; mean deviation <0.02 Å) and the dihedral angle between them is 5.8 Å. In the distorted ReO_2NClP_2 octahedral environment two oxygen atoms, one chlorine atom

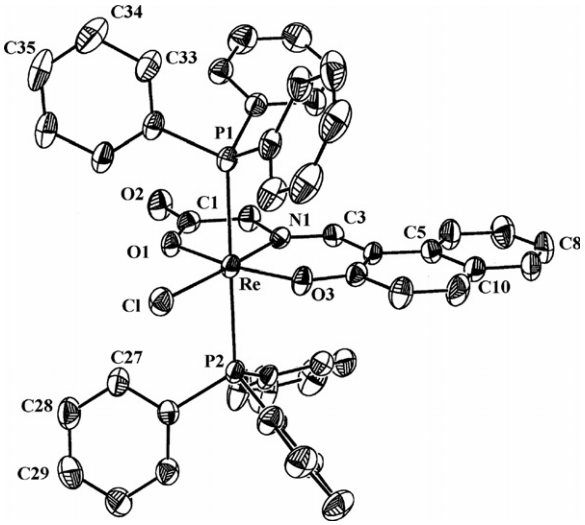

Fig. 1. Perspective view and atom-labelling scheme for the molecule $[Re^{III}(L^1)Cl(PPh_3)_2]$. All non-hydrogen atoms are represented by their 30% thermal probability ellipsoids.

and one nitrogen atom lie in the equatorial plane, whereas the axial positions are occupied by two phosphine ligands. The two Re–O bond distances are not similar and span the range 1.89–1.98 Å. The Re–P bond distances are slightly larger than for previously reported rhenium(III) mixed ligand phosphine Schiff base complexes [17]. The Re–Cl and Re–N bond distances are usual [18] (Table 2).

3.3. Electrochemical studies

The redox properties of the Re(III) α-amino acid Schiff base complexes have been examined by cyclic voltammetry using platinum as the working electrode and SCE as the reference electrode. The cyclic voltammogram was recorded at a scan rate of 50 mV/s. The relevant data are given in Section 2 and a representative voltammogram is shown in Fig. 2.

All the complexes exhibit one quasi-reversible and one irreversible one-electron wave in acetonitrile solution.

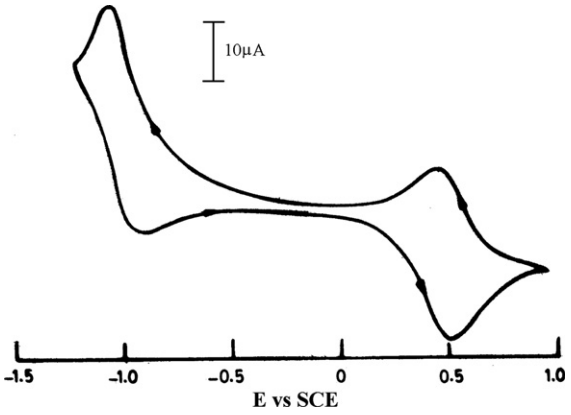

Fig. 2. Cyclic voltammogram of ca. 10^{-3} M solution of $[Re^{III}(L^2)Cl(PPh_3)_2]$ in acetonitrile.

The anodic signal (~0.50 V) at a more positive potential is assigned to the oxidation couple $Re^{IV/III}$ while the couple at ~−1.10 V is believed to be the $Re^{III/II}$ reduction. This redox behavior is consistent with previously known Re(III) complexes [17,19,20].

3.4. Magnetism and NMR spectra

The complexes show a magnetic moment value of ~1.94 BM, corresponding to mononuclear octahedral rhenium(III) d^4 species. The low value of the magnetic moment can be attributed to the large spin–orbit coupling of the rhenium(III) ion [21,22]. The complexes display well-resolved paramagnetic ^1H NMR resonances in $CDCl_3$ solution and the chemical shifts are observed within the range ~−25.00 to +50.00 ppm. The resonances are assigned on the basis of spin–spin structure and spin intensity of the respective rhenium(III) complexes.

In the present case, the absence of phosphorous-proton coupling is probably due to a rapid relaxation of the phosphorous nuclei through an electron-nuclear mechanism to the paramagnetic Re(III) center [23–28]. The paramagnetically shifted ^1H NMR spectrum of a representative case is shown in Fig. 3 and the chemical shift values of the

O(1)–Re(1)–P(2)	89.60(12)		

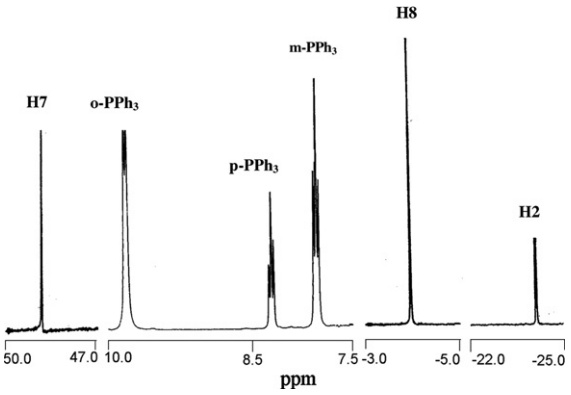

Fig. 3. ^1H NMR spectrum of $[Re^{III}(L^1)Cl(PPh_3)_2]$ in $CDCl_3$ at room temperature.

complexes are given in Section 2. The numbering scheme is as in Chart 1 and Fig. 1. In solution, the azomethine hydrogen occurs as a singlet at ~49.00 ppm. The ortho protons of the coordinated phosphine appear as a doublet at ~9.50 ppm ($J = 7$–8 Hz). The meta and para protons are observed as triplets at ~7.80 and 8.40 ppm respectively, with a coupling constant $J = 7$–9 Hz. All other aromatic H-atoms fall in the range +25.00 to −25.00 ppm. The α-hydrogen atom of the amino acid residue appears as singlet/multiplet in the negative region.

The ^{31}P NMR signals for the phosphines coordinated to the Re(III) center were not observed and the result is consistent with previously reported paramagnetic Re(III) complexes [26,29,30].

3.5. Electronic and CD spectra

The electronic and CD spectra were recorded in dichloromethane solution. The electronic and CD spectral data are given in Section 2. The CD spectra of the Re(III) chelates of amino acid Schiff bases below 550 nm are given in Fig. 4.

The low energy d–d absorption of the complexes is found near 1000 and 1470 nm. A moderately intense absorption band is observed at ~360 nm and this can be attributed to the π–π* transition originating mainly from the azomethine chromophore. The bathochromic shift of this band compared to the free amino acid Schiff bases [31]is due to the increase of conjugation in the molecule upon coordination. The intense absorption band at higher energy, ~270 nm, is presumably from the π–π* transition of the benzene/naphthalene ring of the Schiff bases. The CD spectra are more informative than the corresponding absorption spectra. A careful comparison of the CD spectra of the Re(III) amino acid Schiff base complexes reveal that the sign and pattern of three bands or shoulder in the UV region as well as the Cotton effect is same within the entire family. This observation clearly indicates that the coordinating ligands adopt a common conformation. It has been recognized that a negative azomethine CD band corresponds to the L-absolute configuration of the amino acid residue. The present results are consistent with previously reported complexes using aldimines of α-amino acids [6,32].

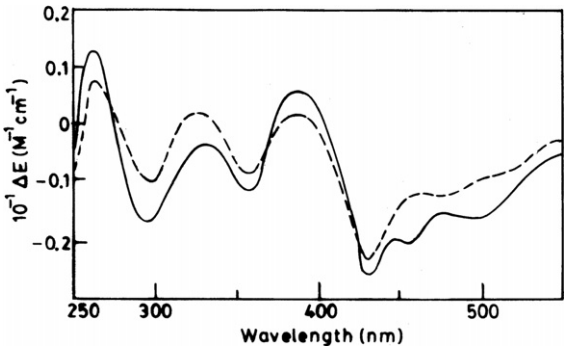

Fig. 4. Circular dichroism spectra of **1b** (——) and **1c** (—) in dry dichloromethane solution.

4. Conclusion

The Schiff bases of salicyladehyde/naphthaldehyde and α-amino acids (glycine, L-alanine, L-valine, L-phenylalanine) react with $[ReOCl_3(PPh_3)_2]$ toafford Re(III) complexes of the general formula $[Re^{III}(L)Cl(PPh_3)_2]$. The species $[Re^{III}(L)Cl(PPh_3)_2]$ represent the first example of structurally characterized Re(III) complexes incorporating α-amino acid Schiff bases as a coligand. The CD spectra confirm the L-absolute configuration of the amino acids in the complexes. Our search for new rhenium complexes of Schiff bases of different amino acids and peptides are in progress.

Abstract

The reactions of a series of 5-alkyl-2-thiophenedithiocarboxylates with nickel(II) chloride afforded two types of complexes, blue nickel(II) complexes with two terminal dithiocarboxylate ligands, $[Ni(S_2CTR)_2]$ and violet nickel(II) complexes with perthio- and dithiocarboxylate ligands, $[Ni(S_2CTR)(S_3CTR)]$ (where T = 2,5-disubstituted thiophene, R = C_nH_{2n+1}, $n = 4, 6, 8, 12, 16$). The blue monomers are preferred for the shorter chains (C_4 and C_6) and the violet compounds form exclusively for the longer chains (C_8, C_{12}, and C_{16}) in the alkylthiophene complexes. In addition to the above series, $[Ni(S_2CTCH_3)_2]$, was prepared in a one-pot reaction in THF and both the blue and violet products were isolated. It was possible to convert the blue complexes $[Ni(S_2CTR)_2]$ (R = butyl, hexyl) into the corresponding violet complexes $[Ni(S_2CTR)(S_3CTR)]$ after stirring in THF solutions for prolonged periods of time. Liquid-crystalline properties of these complexes were examined by DSC and POM. The violet complexes with C_8 and C_{12} alkyl chains showed liquid-crystalline properties.

1. Introduction

An important class of nickel(II) complexes are those with sulfur donor-atoms such as thiols, dithiolene and dithiocarboxylate as ligands [1,2]. Earlier literature (1963–1975) has revealed nickel(II) complexes displaying a variety of coordination numbers and many different coordination modes for thiol, dithiocarboxylate, dithiocarbamate and trithiocarboxylate ligands [1]. Square-planar, tetrahedral, 5-coordinate, and octahedral geometries are known for nickel(II) with dithiocarboxylate ligands. It has been widely demonstrated that square-planar or square-pyramidal coordination leads to the appearance of liquid-crystalline properties, whereas tetrahedral geometry, it was assumed, inhibits mesophase formation. This assumption has recently been refuted [3]. Examples of complexes with two bidentate dithiocarboxylate or dithiocarbamate ligands surrounding one nickel(II) metal have been documented before and a crystal structure determination of $[Ni\{S_2CPh\}_2]$ revealed a flat, square-planar mononuclear nickel(II) complex [4].

Nickel(II) ions in complexes containing different coordination modes and structural features must not be underestimated for potential applications as liquid-crystalline materials [5,6]. The first mesogenic nickel(II) complexes were those with dithiolene ligands and were studied by Giroud and Müller-Westerhoff in [7]. The nickel(II) complexes displayed enantiotropic mesophases, which were nematic for the shorter chains and smectic for the longer alkyl chains. In addition to the calamitic (rod-like) metallomesogens, Ohta and co-workers reported disc-shaped

metallomesogens for nickel(II) with dithiolenes [8]. Of the piperazine dithiocarbamate complexes of palladium, nickel, copper and zinc only the nickel and copper derivatives showed liquid-crystalline behaviour [9]. The mesogenic properties of bis(*p*-alkylphenyldithiolate) complexes of nickel(II) and platinum(II) were reported by Müller-Westerhoff in [10].

Adams and co-workers synthesized the mesomorphic 4-alkyloxydithiobenzoate derivatives of Ni(II), Pd(II) and Zn(II) [11]. The mesomorphism of nickel(II) and palladium(II) complexes were similar, showing smectic C phases for longer alkyl chains. Later on Ohta and co-workers employed alkyldithiocarboxylate as ligands to form dimeric nickel(II) complexes that exhibited monotropic smectic phases [12].

In this study, the reactions of a series of 5-alkyl-2-thiophenedithiocarboxylates with nickel(II) chloride were investigated to see if the inclusion of thiophene in the chain would affect the outcome of the reactions and play a role in determining the melting point behaviour and properties of mesophases. It is envisaged that the geometry of the rod-like structures of the complexes will be affected by the presence of thiophene in the molecule in stead of benzene and that the electronic properties of these complexes will be different than the benzene analogues in their electronic influence on the CS_2 moiety.

2. Experimental

2.1. General

Solvents were dried and distilled under nitrogen prior to use. Diethyl ether, tetrahydrofuran and hexane were distilled from sodium metal, with benzophenone as indicator in the case of ethereal solvents. Dichloromethane was distilled from phosphorus pentoxide. Thiophene was purified as described by Spies and Angelici [13]. Reactions were performed in an inert atmosphere of either nitrogen or argon using standard Schlenk and vacuum-line techniques. Column chromatography was carried out under a nitrogen-atmosphere using silica gel (particle size 0.063–0.200 nm) as stationary phase. All other reagents were purchased from commercial suppliers and used without further purification. All NMR spectra were recorded in degassed deuterated chloroform on a Bruker ARX-300 spectrometer. Chemical shifts were referenced to chloroform. ^{1}H and ^{13}C NMR spectra were measured at 300.133 and 75.469 MHz, respectively. Infrared spectra were recorded on a Perkin–Elmer Spectrum RX1 FT-IR spectrophotometer with a NaCl cell using hexane as solvent. Liquid-crystalline properties were examined on a differential scanning calorimeter (DSC) Q 100 V8.2 Build 268 and hot-stage polarising optical microscope (POM) Olympus BX60 equipped with a Linkam THMS600 hot stage and a Linkam TMS93 programmable temperature controller.

2.2. Synthesis

2.2.1. Synthesis of 5-alkyl-2-thiophenedithiocarboxylate ligands

2.2.1.1. Preparation of 2-alkylthiophene (RT). The procedure used was similar to the one described by Brandsma [14]. *n*-Butyl lithium (15.6 mL, 25.0 mmol) was added to a mixture of THF (50.0 mL) and hexane (30.0 mL), which was cooled to −20 °C. Thiophene (1.68 g, 20.0 mmol) was introduced over 10 min with cooling between 0 °C and 10 °C. The cooling bath was removed and the mixture was allowed to warm to room temperature. The alkyl bromide (2.74 g for butyl bromide, 20.0 mmol) was added in one portion without external cooling. The temperature of the solution was raised to 50 °C and kept at this temperature for a further 30 min. The rest of the procedure was carried out in air. Ice water (100 ml) was added with vigorous stirring. Two layers formed and were separated. Two further extractions with 20 mL diethyl ether of the aqueous phase gave a combined organic solution that was dried over anhydrous $MgSO_4$. The mixture was concentrated in a rotary evaporator to afford the crude product. Yield = 2.38 g; 85% for R = butyl.

2.2.1.2. Preparation of 5-alkyl-2-thiophenedithiocarboxylic acid ($RTCS_2H$). *n*-Butyl lithium (12.5 mL, 20.0 mmol) was added to a solution of THF (50.0 mL) and hexane (30.0 mL), which was cooled to −20 °C. 2-Alkyl thiophene (R = butyl, 2.38 g, 17.0 mmol) was introduced over 10 min with cooling between 0 °C and 10 °C. The cooling bath was removed and the mixture that warmed to room temperature was stirred for a further 10 min. The solution was cooled to 0 °C and copper(I) bromide (0.10 g) added. Carbon disulfide (1.29 g, 17.0 mmol) was added drop-wise to the stirred mixture. The colour of the reaction mixture changed to deep-red. The cooling bath was removed and the mixture was allowed to warm to room temperature while stirring was continued for a further 1 h. Ice water (100.0 mL) was added followed by dilute hydrochloric acid (20.0 mL, 1 mol/dm^3). The organic layer was separated in air and the product extracted into diethyl ether (70.0 mL) and washed with 2 × 50.0 mL of water. The product was dried over $MgSO_4$ and the solvent removed *in vacuo*. Yield = 3.30 g; 89.8% for R = butyl.

2.2.1.3. Preparation of sodium 5-butyl-2-thiophenedithiocarboxylate ($C_4H_9TCS_2Na$). Sodium metal (0.35 g, 15.3 mmol) was added over 10 min to vigorously stirred methanol (50.0 mL) to form sodium methoxide. When all the sodium had dissolved, additional (20.0 mL) methanol was added. 5-Alkyl-2-thiophenedithiocarboxylic acid (for R = butyl, 3.30 g, 15.3 mmol) was added over 5 min to the mixture and left stirring for 30 min. The solvent was removed under reduced pressure, affording, for R = butyl, the sodium 5-butyl-2-thiophenedithiocarboxylate as an orange-brown solid. Yield = 3.09 g; 85%.

*2.2.2. Synthesis of bis(5-butyl-2-thiophenedithiocarboxylato) nickel(II) [$Ni(S_2CTC_4H_9)_2$] (**1a**)*

The procedure was similar to that of Adams et al. [15], who prepared dithiobenzoate complexes. The reaction was done in air. To a stirred solution of sodium 5-butyl-2-thiophenedithiocarboxylate (1.55 g, 6.5 mmol) in water (25.0 mL) was added, drop-wise, a pale green solution of $NiCl_2 \cdot 6H_2O$ (0.71 g, 3.0 mmol) in water (10.0 mL) at room temperature. The colour of the solution turned blue-violet and the mixture was left to stir for 3 h. The mixture was concentrated to 25.0 mL on a rotary evaporator and 20.0 mL of methanol was added. The precipitate was separated by filtration and dried. Further purification was done on a silica gel column and the product was purified with hexane/CH_2Cl_2 (4:1) as the eluent. A blue powder was obtained on evaporation of the solvent. Yield = 0.49 g; 66%.

5b, R = $C_{16}H_{33}$: ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ in ppm; J in Hz) 7.70 (d, 2H, H3, $J = 3.9$), 7.48 (d, 2H, H3′, $J = 3.9$), 6.86 (d, 2H, H4, $J = 3.9$), 6.75 (d, 2H, H4′, $J = 3.9$), 2.76 (dt, 8H, H6 and H6′, $J = 7.8/7.5$), 1.69 (m, 8H, H7 and H7′), 1.28 (m, 104H, H8–H20 and H8′–H20′), 0.86 (t, H21 and H21′, $J = 6.5/7.0$); ^{13}C NMR (ppm) 227.9, 214.9 (C1 and C1′), 159.0, 156.2, 139.3, 129.8, 129.2, 127.1, 127.0 (C2–C5 and C2′–C5′), 31.9, 31.1, 31.0, 30.7, 30.6, 30.2, 29.9, 29.8, 29.7, 29.7, 29.7, 29.6, 29.5, 29.4, 29.2, 29.2, 29.0, 22.7, 14.1 (C6–C21 and C6′–C21′); IR (cm^{-1}) 2922 (vs), 1458 (vs), 1375 (s), 1049 (m) 977 (m), 925 (w), 720 (s).

*2.2.4. Second method of synthesis (one-pot reaction) for **6a** and **6b***

In a second method (one-pot reaction), 2-methylthiophene (1.96 g, 20.0 mmol) was lithiated by the addition of *n*-butyl lithium (13.8 mL, 22.0 mmol) at −20 °C in THF. The colour of the solution immediately changed to orange on addition of the BuLi, but changed gradually to yellow after stirring for 30 min. The mixture was cooled to −50 °C and carbon disulfide (1.52 g, 20.0 mmol) was added. The mixture became dark red in colour and was stirred for 30 min. Anhydrous nickel(II) chloride (1.30 g, 10.0 mmol) was added in small portions and the mixture was allowed to reach room temperature. The yellow solid material gradually dissolved on reacting and the solution changed first to green then to blue and thereafter to violet over a period of 3 h. The blue-violet product was purified by filtration of the reaction mixture through a plug of silica gel once the solvent was changed to dichloromethane and afforded **6** in very high yield (the yield was more than 80%). From this mixture both blue and violet compounds were isolated by column chromatography with mixtures of hexane and dichloromethane as eluents. The blue compound **6a** was less soluble in organic solvents compared to the violet compound **6b**.

6a, R = CH_3: *Anal.* Calc. for $C_{12}H_{10}S_6Ni$: C, 35.56; H, 2.49. Found: C, 35.71; H, 2.63%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ in ppm; J in Hz) 7.72 (d, 2H, H3, $J = 4.0$), 6.82 (d, 2H, H4, $J = 3.9$), 2.43 (s, 3H, Me); ^{13}C NMR (ppm) 228.0 (C1), 159.0, 139.3, 129.2, 127.1 (C2–C5), 14.1 (C6); IR (cm^{-1}) 2919 (vs), 1460 (vs), 1375 (s), 1049 (m), 978 (m), 721 (s).

6b, R = CH_3: *Anal.* Calc. for $C_{12}H_{10}S_7Ni$: C, 32.95; H, 2.30. Found: C, 33.17; H, 2.52%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ in ppm; J in Hz) 7.76 (d, 2H, H3, $J = 3.8$), 7.47 (d, 2H, H3′, $J = 3.6$), 6.85 (d, 2H, H4, $J = 3.7$), 6.74 (d, 2H, H4′, $J = 3.6$), 2.47 (s, 3H, Me), 2.43 (s, 3H, Me′); ^{13}C NMR (ppm) 227.9, 214.9 (C1 and C1′), 159.0, 156.2, 140.1, 139.3, 129.8, 129.2, 127.1, 127.0 (C2–C5 and C2′–C5′), 14.2, 14.1 (C6 and C6′); IR (cm^{-1})

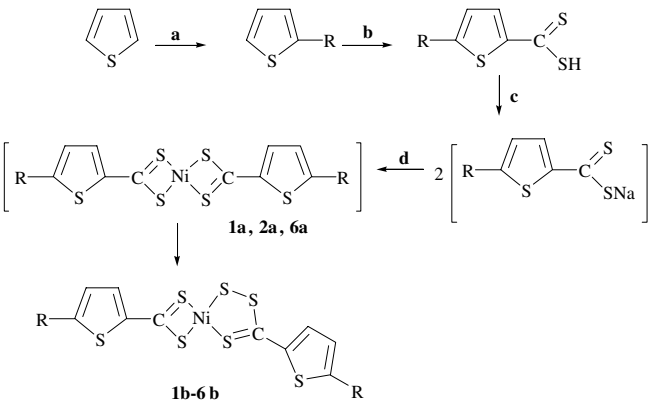
2920 (vs), 1458 (vs), 1375 (s) 1046 (m), 999 (w), 978 (m), 721 (s).

2.2.5. Conversion of *1a* and *2a* into *1b* and *2b*

The blue complexes **1a** and **2a** were converted to the violet complexes **1b** and **2b**, respectively, by stirring 0.5 g of the blue complex, **1a** or **2a**, in 20 mL of THF for 12 h at room temperature.

1b, R = C_4H_9: ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ in ppm; J in Hz) 7.78 (d, 2H, H3, $J = 3.9$), 7.49 (d, 2H, H3′, $J = 4.1$), 6.87 (d, 2H, H4, $J = 3.9$), 6.75 (d, 2H, H4′, $J = 3.9$), 2.80 (t, 4H, H6, $J = 7.2$), 2.74 (t, 4H, H6′, $J = 7.2$), 1.67 (q, 4H, H7, $J = 7.5'$), 1.66 (q, 4H, H7′, $J = 7.5$), 1.40 (m, 4H, H8, $J = 7.4$), 1.39 (m, 4H, H8′, $J = 7.4$), 0.93 (t, 6H, H9, $J = 7.2$), 0.92 (t, 6H, H9′, $J = 7.2$); ^{13}C NMR (ppm) 227.9, 214.9 (C1 and C1′), 160.1, 158.2, 149.4, 148.6, 131.3, 129.8, 127.6, 127.2 (C2–C5 and C2′–C5′), 33.6, 31.4, 22.6, 13.9 (C6–C9 and C6′–C9′); IR (cm^{-1}) 2921 (vs), 1461 (vs), 1375 (s), 1049 (m), 970 (m), 925 (w), 721 (s).

2b, R = C_6H_{13}: ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ in ppm; J in Hz) 7.77 (d, 2H, H3, $J = 3.2$), 7.48 (d, 2H, H3′, $J = 3.2$), 6.86 (d, 2H, H4, $J = 3.1$), 6.75 (d, 2H, H4′, $J = 3.1$), 2.82 (dt, 8H, H6 and H6′, $J = 7.2$), 1.71 (m, 8H, H7 and H7′), 1.32 (m, 24H, H8–H10 and H8′–H10′), 0.91 (t, 12H, H11 and H11′, $J = 7.2$); ^{13}C NMR (ppm) 227.8, 214.8 (C1 and C1′), 159.0, 156.2, 147.4, 144.6, 139.3, 128.8, 127.1, 127.0 (C2–C5 and C2′–C5′), 30.8, 29.9, 28.9, 27.9, 21.6, 13.1 (C6–C11 and C6′–C11′); IR (cm^{-1}) 2920 (vs), 1460 (vs), 1375 (s), 1097 (m), 1050 (m) 978 (m), 720 (s).



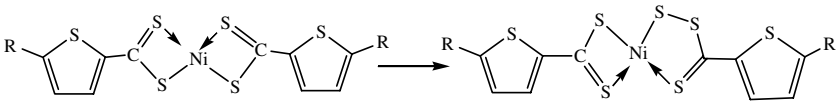
3. Results and discussion

3.1. Synthesis and characterization

Five complexes of the type $[Ni(S_2CTR)_2]$ (where T = 2,5-disubstituted thiophene, R = alkyl group; C_4H_9 (**1**), C_6H_{13} (**2**), C_8H_{17} (**3**), $C_{12}H_{25}$ (**4**), $C_{16}H_{33}$ (**5**)) were synthesized via a four-step reaction sequence as shown in Scheme 1.

The sodium 5-alkyl-2-thiophenedithiocarboxylate precursors were synthesized according to the literature procedures [14]. The final step was similar to that of Adams and co-workers who prepared complexes with dithiobenzoate ligands [15].

The formation of violet vs blue compounds in this study was dependent on the solvent, as well as the length of the alkyl chain. Using the first method of synthesis, the blue monomers are preferred for the shorter chains (C_4 and C_6) and the violet compounds for the longer chains (C_8, C_{12} and C_{16}). In a third experiment, pure blue complex **1a** was dissolved in THF and stirred at room temperature. A sample was taken after 1 h and the ^{1}H NMR spectrum was recorded in deuterated chloroform. The solution consisted of 83% blue and 17% violet complex by comparing the integration ratios of the different signals.



Scheme 1. Reagents: **a** *n*-BuLi, RBr; **b** *n*-BuLi, CS_2, HCl; **c** Na/MeOH; **d** $NiCl_2 \cdot H_2O$.

As stirring continued the colour of the reaction mixture gradually changed from blue to violet. After 12 h the conversion was complete and only the violet complex could be isolated from the reaction mixture. A similar result was achieved after stirring **2** for 10 h. The blue compound converted into the violet compound. The mass peak at m/z-value of 632 (^{58}Ni, 3%) corresponds to the mass of **3b** and represents the molecular ion, $[Ni(S_3CTR)(S_2CTR)]^+$ (R = C_8H_{17}). Chemical analysis supported the structures proposed for the violet complexes. Based on the physical and spectroscopic data and literature results, it was concluded that **1b–6b** were the mononuclear nickel(II) complexes with perthio- and dithiocarboxylate ligands as shown in Scheme 2. The only outstanding issue was the source of additional sulfur for insertion. The formation of perthiocarboxylate complexes of nickel(II) have previously been achieved by thermal conditions and the addition of polysulfides, elemental sulfur or by a photolytic procedure in dichloromethane or chloroform [16,17].

It is unclear how the sulfur-inserted ligand was formed under such mild reaction conditions, and in the absence of an oxidant and warrants further investigations. Studies involving the mechanism of the sulfur insertion process using labeled ^{34}S revealed that the sulfur atom is inserted between a C–S bond and not between a M–S bond [18,19]. Based on this, an intermolecular mechanism whereby a sulfur atom from one dithiocarboxylate molecule was inserted into a second one to form perthiocarboxylate, was proposed by Fackler and Fetchin [19]. It was previously noted that temperature plays an important role for the transformation of a dithiocarboxylate into a perthiocarboxylate ligand, and in this study it can be assumed that the thiophene facilitated the sulfur inclusion under the mild reaction conditions. This could be achieved by the stabilization of the electrophilic CS_2-carbon in the intermediate by electron charge transfer from the thiophene ring.

3.2. Characterization of the complexes

The complexes were characterized by NMR and infrared spectroscopy and representative examples by mass

Scheme 2. Structures of novel nickel(II) complexes.

spectra, uv and elemental analysis [20]. The blue complexes, **1a**, **2a** and **6a**, displayed two doublets in the thiophene region of the spectra, while the violet complexes, **1b**–**6b**, displayed four doublets in this area. This can be ascribed to the difference in electronic environment of the thiophene protons in the unsymmetrical perthio-, thiocarboxylate complexes compared to the symmetrical dithiocarboxylate complexes. For **3b**, the four doublets are at 7.77, 7.49, 6.86 and 6.75 ppm, respectively. Interestingly, the triplet of the CH_2 group attached to the thiophene of the octyl chain is also duplicated for the two types of ligands emphasising the large differences in the coordination modes of the perthio- and dithiocarboxylato ligands (see Fig. 1). The resonances in the ^{13}C NMR spectra of **1**–**6b** were assigned based on a 2D HETCOR spectrum recorded for **3b.** The ^{13}C NMR spectrum of **3b** showed the resonances of CS_2 as one peak for **1a**, **2a** and **6a** and two peaks for **1**–**6b**. The lower chemical shift value was assigned to the CS_2 of the perthiocarboxylate ligand. These resonances are typically at 228 ppm for identical dithiocarboxylate ligands and at 214 and 227 ppm for the complexes with mixed dithio- and perthiocarboxylate ligands. The thiophene resonances as well as the carbon atoms of the alkyl chain are also duplicated for the two different ligands in **1b**–**6b** and are unique for both types of complexes.

The infrared data supported the structures of the complexes and compared well with literature values [21–23]. The peaks at 1049 and 977 cm^{-1} were assigned for C–S stretching frequencies. Usually the stretching frequencies of the dithiocarboxylic acid are around 1100 and 900 cm^{-1} for the C=S and C–S stretching frequencies. We ascribe the lowering of the higher wave number and the increase in the lower wave number to the transfer of charge from the thiophene unit to the coordinating CS_2-moiety. In the electronic spectrum of the blue complex **1a** the d–d transitions of nickel(II) was at 602 nm and the value is similar to that reported by Furlani for monomeric dithiocarboxylate complexes of nickel(II) [24]. The d–d transitions of nickel(II) in the violet complex **1b** was at 551 nm and this value is similar to the literature value of a mixed dithiobenzoato and perthiobenzoato nickel(II) complex [25].

3.3. Thermal properties

Thermal properties of the complexes were investigated by using differential scanning calorimetry (DSC) and hot-stage polarising optical microscopy (POM). All the complexes were subjected to thermal analysis by DSC. The scanning rate was 10 °C per minute. No double melting behaviour was observed for **1a**, **1b**, **2a**, **2b** and **5b** whereas double melting behaviour was observed for **3b** and **4b**. Two endothermic peaks could be observed at 77 °C and 88 °C for **3b**. The peak at 88 °C is compatible with the melting point and the peak at 77 °C is for crystal-to-crystal transition. The clearing point was not observed in the DSC. Complex **4b** also showed two endothermic peaks at 102 °C and 117 °C.

Complexes **3b**, **4b** and **5b** were also examined using hot-stage polarising optical microscopy. Complex **3b** (Fig. 2) is an enantiotropic liquid crystal and it exhibits a nematic phase. Enantiotropic liquid crystals show mesomorphism upon heating the solid as well as on cooling the isotropic liquid. The transition temperature of **3b** was between 92 °C and 116 °C.

The optical texture of **3b** is similar to the nematic phase of 4-nonyloxybenzoic acid [26]. Complex **4b** was a mixture of dark highly viscous liquid and opaque crystals. The liquid was not birefringent and therefore it was not a liquid crystal. The opaque crystals however melted to a nematic phase. Transition temperatures of the complexes **1**–**5** are given in Table 1. It is shown that the melting temperatures increase from the shortest chain to C_{12} and then decreases sharply for C_{16}.

Complexes **1**, **2** and **5b** directly melted to the isotropic liquids without passing through any mesophases. The transition temperature range for **3b** was between 92 °C and 116 °C (N → I) whereas for the benzene analogue [Ni(8-ottb)$_2$], the range was between 122 °C and 186 °C (N → I) [15]. The lower transition temperature observed for **3b** may be ascribed to the thiophene in the complex, due to the greater disorder in the packing of this complex compared to the rod-like benzene analogues. The thiophene complexes are not straight rods but have more of a ''step-rod'' structure [27]. This deviation from linearity may be the reason for the lower transition temperatures observed. It was reported that thiophene systems have generally lower melting points than their benzene counter parts due to reduced packing efficiency in the molecules [28].

Complexes **1a**, **1b**, **2a**, **2b** and **5b** had no mesogenic behaviour whereas complexes **3b** and **4b** showed nematic mesophases. The optimum chain length suitable for mesomorphism for the alkyl thiophene dithiocarboxylate complexes was C_8.

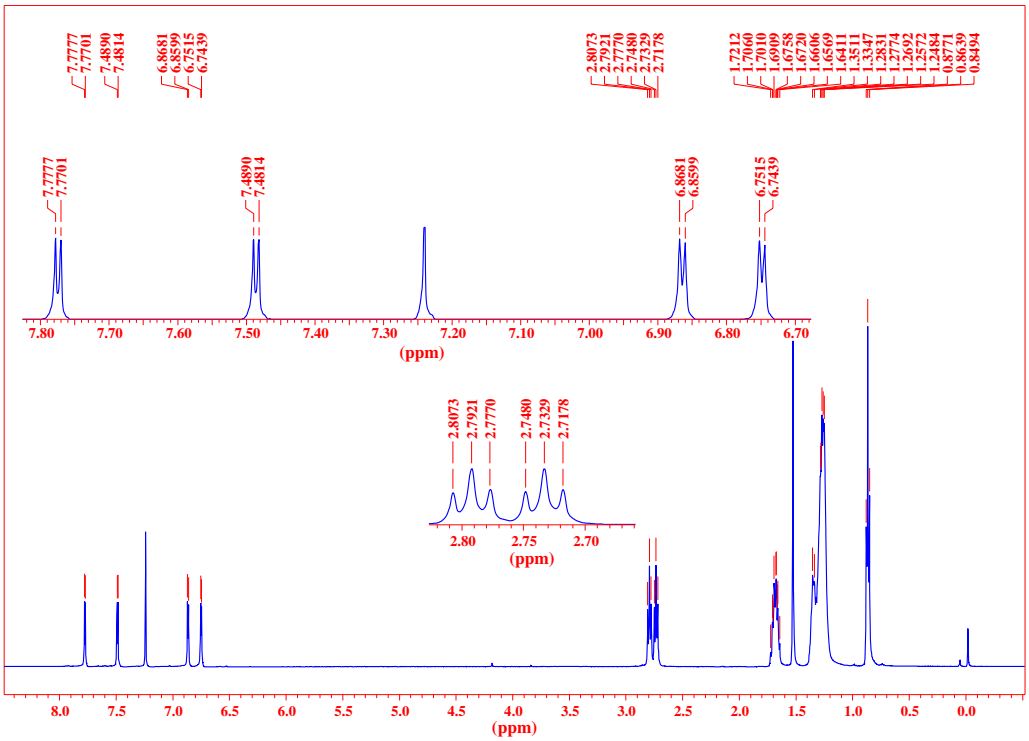


Fig. 1. The ^{1}H NMR spectrum ($CDCl_3$) of **3b**.

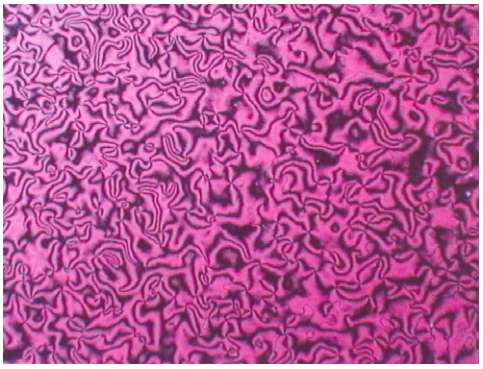

Fig. 2. Nematic phase of [Ni($S_3CTC_8H_{17}$)($S_2CTC_8H_{17}$)] **3b** at 105 °C (200× magnification).

Table 1
Transition temperatures of **1**–**5**

Complex	Chain	Transition	Temperature (°C)
1a	C_4H_9	Cr → I	52
2a	C_6H_{13}	Cr → I	65
3b	C_8H_{17}	Cr → N	92
		N → I	116
4b	$C_{12}H_{25}$	Cr → N	117
		N → I	102
5b	$C_{16}H_{33}$	Cr → I	61

Cr, crystal; N, nematic phase; and I, isotropic liquid.

4. Conclusion

The reactions of a series of 5-alkyl-2-thiophenedithiocarboxylates with nickel(II) chloride formed two types of complexes, mononuclear nickel(II) complexes with two terminal dithiocarboxylate ligands (blue) and mononuclear nickel(II) complexes with perthio- and dithiocarboxylate ligands (violet). The formation of violet vs blue compounds in this study was dependent not only on the properties of the solvent, but also by the length of the alkyl chain and the conversion from **a**- to **b**-type products enhanced by the presence of thiophene in the chain. Using the first method of synthesis the blue monomers are preferred for the shorter chains (C_4 and C_6) and violet compounds for the longer chains (C_8, C_{12} and C_{16}). It was previously noted that temperature plays an important role for the transformation of dithiocarboxylate to a perthiocarboxylate ligand [19]. The blue compounds are less soluble than the violet compounds. Thermal studies with DSC and POM showed that the complexes with C_8 and C_{12} alkyl chains are liquid crystals (metallomesogens). The mesomorphism of the two complexes was similar, as both complexes showed nematic phases. Unfortunately it was not possible to obtain **a**-type complexes of **3** and **4** to compare and study their melting behaviours. The dark colour of the complexes made phase characterization very difficult. The transition temperatures of these complexes are lower than the benzene analogues, as predicted [15]. Complexes **3b** and **4b** are the first examples of metallomesogens of nickel(II) complexes with 5-alkyl-2-thiophenedithiocarboxylate as ligands. In future, further work will be done on the optical and conducting properties of these complexes.

Abstract

Layered double hydroxides (LDHs) of the type $[Mg_{1-X}Al_X(OH)_2]^{X+}[(CO_3^{2-})_{X/2} \cdot mH_2O]$ with variable Mg/Al molar ratios have been prepared by co-precipitation of Mg^{2+} and Al^{3+} ions at constant pH. The ability of these compounds to adsorb Acid Blue 9 has been evaluated by UV–Vis spectrophotometry, FT-IR spectroscopy, powder X-ray diffraction analysis, N_2 adsorption/desorption analysis, scanning electron microscopy, energy-dispersive X-ray analysis, X-ray photoelectron spectroscopy and atomic absorption spectroscopy. Optimum adsorption of Acid Blue 9 (AB9) was achieved for LDHs produced from mixtures containing Mg and Al in molar ratios varying from 3.1 to 4.4. LDHs with such compositions giving an equilibrium binding constant (K_a) of ca. $1.2 \times 10^5\ M^{-1}$ with a maximum monolayer coverage (C_m) of ca. 7.6×10^{-2} mmol g^{-1}. This observation was correlated to the surface area, phase purity, pore size and volume, particle size and the surface morphology of the LDHs. Powder XRD analysis after adsorption of 1.85 mM Acid Blue 9 in 20% (v/v) glycerol–H_2O solvent system indicated that the dye was not intercalated between the brucite-like layers as no change was evident in the $d_{(003)}$ spacing. Thus, at this low concentration surface adsorption of the dye is occurring. Powder XRD analysis revealed that intercalation was achieved at 76 mM dye concentration in the same solvent system for materials with Mg:Al molar ratios between 3.1 and 5.6. This results in an expansion of the interlayer spacing from ca. 8 Å to 19 Å to accommodate the AB9 anion. For the sample produced from a 3:1 mixture of Mg/Al, thermal gravimetric and elemental/micro analyses revealed that the new hybrid material has the composition $[Mg_{3.0}Al_{1.0}(OH)_{7.5}][(CO_3)_{0.62} \cdot 3.2H_2O \cdot 1.5\text{Glycerol} \cdot 0.1\text{Acid Blue 9}]$.

1. Introduction

Layered solids have attracted the attention of many researchers because of their possible use in a variety of applications [1–3]. These compounds may be classified as neutral layers which are held together by van der Waals interactions, negatively charged layers which are separated by mobile cations, and positively charged layers which are separated by anions [4]. They have distinctive properties that are characterized by the strong intralayer bonds and weak interlayer interactions.

Positively charged layer compounds are known as layered double hydroxide (LDH), or hydrotalcite-like compounds. Their empirical formula is $[M^{2+}_{1-X}M^{3+}_X\text{-}(OH)_2]^{X+}[(A^{n-})_{X/n} \cdot mH_2O]$ where M^{2+} and M^{3+} are di- and trivalent cations, respectively, A^{n-} is an exchangeable anion, and x is the molar ratio, $M^{3+}/(M^{2+} + M^{3+})$, that determines layer charge density [5,6]. These compounds exist in two dimorphic forms, rhombohedral hydrotalcite and hexagonal manasseite. In the hydrotalcite structure, three double-layers are present per unit cell, whilst in the manasseite structure, two double-layers are present [7].

The crystal structure consists of positively charged brucite-like octahedral hydroxide layers due to the isomorphous replacement of some divalent metal cation by trivalent metal cation [8]. Positive charges on the surface of the layer are neutralised by interlayer anions. When LDHs are immersed in aqueous solutions some of the interlayer anions can move into the solution and can be exchanged with other ions [9].

There have been many studies focussing on the application of layered double hydroxides as adsorbent material using different interlayer anions [10–15] and as a host for intercalation chemistry [16–21]. Remarkably absent in the literature is the optimisation of adsorption and intercalation properties through fine tuning of the divalent/trivalent metal molar ratios. In this paper, we report the adsorption affinity of Acid Blue 9 (AB9) to hydrotalcite-like compounds of the type $[Mg_{1-X}Al_X(OH)_2]^{X+}[(CO_3^{2-})_{X/2}\cdot mH_2O]$ herein referred to as Mg–Al–LDH–CO_3 (Fig. 1) in which the Mg/Al content was varied with a view to improving the adsorption (surface) and intercalation (interlamellar) properties of the LDH material (in the context of this study, adsorption is taken to indicate chemisorption since the exact nature of binding is not known). We demonstrate that anion exchange can still be achieved even if the original interlayer anion is carbonate – an ion that can be difficult to exchange from the LDH interlayer region.

AB9 was chosen as the dye for our investigation as it has many important practical applications. For example, it is used in textile industry for dyeing textile fibres and, as a consequence, studies [22,23] have been conducted to reduce the colour of the dye-containing effluents through treatments involving adsorption onto low-cost materials, such as LDHs. Intercalation of this dye into an LDH could also be used for slow-dying process technology, i.e., slow release of the dye from the inorganic lamella into a solution [13]. AB9 has also been studied [24] as film dopant to act as photosensitive chromophore for optics and laser technology application. Finally, AB9 has also been used for ink jet technology [25] so its adsorption and/or intercalation into LDHs is of commercial significance.

2. Experimental

2.1. Synthesis

Mg–Al–LDH–CO_3 materials were prepared by the co-precipitation method described previously [26]. Solution A containing $Mg(NO_3)_2\cdot 6H_2O$ and $Al(NO_3)_3\cdot 9H_2O$ (Sigma–Aldrich) with Mg^{2+}/Al^{3+} molar ratios varying from 2.0 to 10.0 were dissolved in 150 mL of distilled water to give solutions with a Mg^{2+} concentration of 1.6 M. Solution B containing NaOH and Na_2CO_3 (Merck) was prepared by dissolving the salts in 150 mL distilled water. The concentrations of reagents in solution B were related to the concentrations of metal ions in solution A as follows: $[NaOH] = 1.6[Mg^{2+}+Al^{3+}]$ and $[Na_2CO_3] = 2.0[Al^{3+}]$.

Solution A (150 mL) and solution B (150 mL) were added dropwise to a vessel containing stirred distilled water (120 mL) at such a rate that the pH of the reaction mixture was maintained at 9.5 (±0.05). The addition process was controlled by a Metrohm 736 GP Titrino auto titrator and carried out at room temperature. The resulting slurry was aged at 100 °C for 16 h. The precipitate was then filtered, washed three times with distilled water, and dried at 100 °C for 24 h. All products were then ground with an agate mortar and pestle prior to analysis and use in dye adsorption testing. Hydromagnesite ($Mg_5(CO_3)_4(OH)_2\cdot 5H_2O$; Sigma–Aldrich) was included in the analysis for discussion purposes.

A typical intercalation reaction leading to sample 5 (see Table 5) was performed based on a modified method [27] that involved reacting 0.5 g of Mg–Al–LDH–CO_3 (Mg/Al = 3.1 and without prior removal of CO_3^{2-} ions) with 5 mL, 76 mM disodium salt of Acid Blue 9 (disodium α-(4-(*N*-ethyl-3-sulfonatobenzylamino)phenyl)-alpha-(4-*N*-thyl-3-sulfonatobenzylamino,cyclohexa-2,5-dienylidene)toluene-2-sulfonate) (Fig. 2; Saujanya Dyechem company) in a 5:1 (v/v) H_2O:glycerol solvent system. The overall process is the same as the dye affinity test outlined below. The molecular structure and size of the dye was estimated in the gas phase using the Hyperchem software. This was

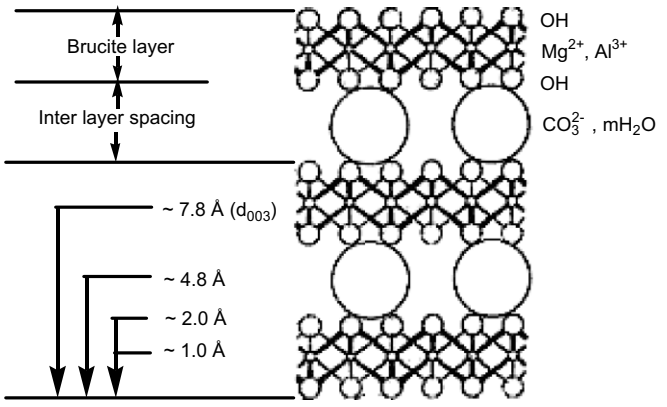

Fig. 1. 2D – Schematic representation of Mg–Al–LDH–CO_3 system [10].

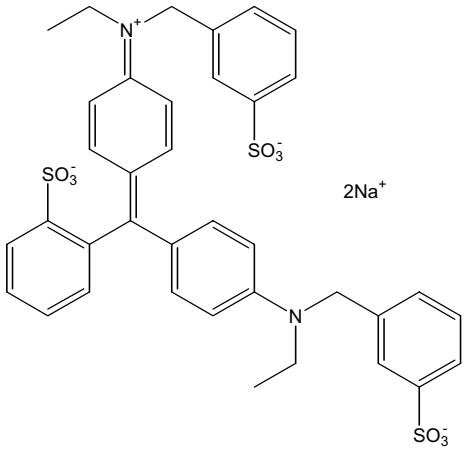

Fig. 2. Disodium salt of Acid Blue 9.

done by finding the lowest energy conformation prior to energy minimization. It should be pointed out that single crystal X-ray analysis of the dye could not be done due to the amorphous nature of Acid Blue 9. The solid produced was recovered by centrifugation and dried under air atmosphere for 24 h at 100 °C.

2.2. Dye affinity test

The change in the adsorbed amounts of Acid Blue 9 with time was measured for up to 7 days. It was found that the adsorbed amount was the same after mixing (vortex) for 1 min. and after vigorous stirring (magnetic stirrer) for 7 days. On the basis of these results, the adsorption for the determination of adsorption isotherms was carried out for 1 min. using a vortex (2500 rpm).

A 9.23×10^{-6} M solution of the dye prepared in 20% glycerol/Milli-Q water solvent mixture was found to exhibit a λ_{max} at 629 nm and $\varepsilon = 1.37 \times 10^5\ M^{-1}\ cm^{-1}$. The Mg–Al–LDH–$CO_3$ with different Mg/Al ratios were then subjected to a dye affinity test (three replicates) according to published methodologies [28], using Acid Blue 9 solution (1.85 mM). The dye solution (5 mL) was added to the Mg–Al–LDH–CO_3 system (0.5 g) in a centrifuge tube. The tube was agitated using a vortex mixer for 1 min followed by centrifugation (4600 rpm, 5 min.). The supernatant liquid was removed carefully and the mass of liquid was recorded. An aliquot of supernatant liquid (25 μL) was diluted with Milli-Q water (5 mL) giving a ratio of 1:200 and analysed using CARY 100 Bio UV–Vis spectrophotometer. It should be pointed out that for Mg–Al–LDH–CO_3 with Mg:Al ratios of 3.0, 3.1, 4.4, and 5.6, a dilution factor lower than 200 was used so that the final absorbance reading was in the range of 0.5–1.0.

The absorbance of the diluted supernatant was recorded at the wavelength of maximum absorption (629 nm). The value was then divided by the absorbance for the untreated dye, giving a relative absorbance value. A ratio greater than one indicates that the supernatant has a high dye concentration post treatment whilst a ratio of less than one indicates good affinity of the dye for the Mg–Al–LDH–CO_3 system.

For Mg–Al–LDH–CO_3 systems that exhibited the best affinity of Acid Blue 9, adsorption isotherms were measured and the Langmuir equation [14], originally derived for gas adsorption on planar surfaces [29], was then used to estimate the dye adsorption properties of the material, $C_s = C_m K_a C_p/(1 + K_a C_p)$, where C_s (mmol/g) is the amount of dye adsorbed to the surface, C_p (mmol/mL) is the amount of dye remaining in the solution, C_m (mmol/g) is the maximum adsorption capacity at a monolayer coverage, and K_a ($M^{-1} = (mmol/mL)^{-1}$) is the equilibrium binding constant.

2.3. Characterization

The synthesized LDH materials were analysed by powder X-ray diffraction using a Philips 1140 diffractometer under the following conditions: 40 kV, 25 mA, Cu Kα ($\lambda = 0.15406$ nm) radiation. The samples, as unoriented powders, were scanned in steps of 0.02° (2θ) in the range from 2° to 70° at a speed of 2°/min.

Metal analyses were carried out using three different techniques. Energy dispersive X-ray spectroscopy at a voltage of 15 kV using Link ISIS manufactured by Oxford Instruments. X-ray photoelectron spectroscopy using Kratos AXIS HSi spectrometer with a monochromated Al Kα source at a power of 180 W (12 kV × 15 mA) and a hemispherical analyser operating in the fixed analyser transmission mode. The total pressure in the main vacuum chamber during analysis was $\sim 10^{-8}$ mbar. Each sample was analysed at an electron take-off angle of 90° relative to the sample surface. The Mg 2s and Al 2p photoelectrons were identified and quantified from survey spectra acquired at 320 eV pass energy. Atomic absorption spectroscopy analyses were conducted using a VARIAN SpectrAA-400 spectrophotometer.

Elemental analysis was performed by the Campbell Microanalytical Laboratory, University of Otago, New Zealand and Chemical & MicroAnalytical Services Pty. Ltd., Australia.

Infrared experiments were carried out using EQUINOX–IFS 55 spectrometer. Samples were mixed with KBr to produced a disc with a 1% compound loading. The spectra was recorded between 4000 and 400 cm^{-1}. Fifty scans were recorded with a resolution of 2 cm^{-1}.

Thermogravimetric analyses were performed on a Perkin–Elmer Pyris 1 TGA instrument. Ten to twenty milligrams of samples was heated in a platinum crucible between 25 and 800 °C at a heating rate of 10 °C/min under a stream of air.

Surface morphologies and particle size distribution were studied using Philips XL30 field emission scanning electron microscope manufactured by Oxford Instruments at a voltage of 5 kV.

Surface area, pore size, and pore volume were studied using an Omnisorp 360 CX manufactured by Coulter using nitrogen adsorption–desorption at 77 K.

The density was determined by helium pycnometry technique using AccuPyc 1330 gas displacement pycnometer manufactured by Micromeritics.

3. Results and discussion

3.1. Surface adsorption studies

Three different methods were utilized to determine the metal content as well the Mg to Al molar ratio of the synthetic Mg–Al–LDH–CO_3 materials. These methods were in close agreement to each other giving a relative standard deviation (RSD) of <0.2 for LDHs with Mg:Al molar ratios of less than 5.0. Higher RSD were observed for Mg:Al molar ratio of 6.0 and above (Table 1) due to the aluminium content being below the threshold that can be accurately measured by EDX and XPS techniques. AAS values are used throughout the discussion of the results

Table 1
Mg/Al ratios using energy dispersive X-ray spectroscopy (EDX), X-ray photoelectron spectroscopy (XPS) and atomic absorption spectroscopy (AAS)

Calculated Mg:Al molar ratio[a]	Experimental			RSD
	EDX	XPS	AAS

9.3	0.43	1.4×10^{-1}
10.7	0.47	2.2×10^{-1}

[a] Calculated according to the formula: 6.02×10^{23} (moldye$_{total}$–moldye$_{supernatant}$)/(0.5 g × surface area)/1×10^{-18}.

presented herein. At the higher Mg/Al molar ratio ($\geqslant 5$) some of the Mg must come from hydromagnesite that formed during the synthesis.

The results of the dye affinity test shown in Fig. 3, indicate that the Mg–Al–LDH–CO_3 system exhibits excellent dye affinity for samples with composition in the range of Mg/Al molar ratios of 3.1–5.6. Above and below these values the dye affinity decreases. The equilibrium concentration of Acid Blue 9 left in the supernatant was subtracted from the initial Acid Blue 9 concentration to determine the adsorbed dye in a given fixed amount of LDH as a function of the surface area of LDH (Table 2). No change in the interlayer spacing as measured by powder XRD was observed indicating that the Acid Blue 9 is adsorbed onto the surface of the material and not intercalated between the interlayer.

It is apparent from Table 2 that Mg/Al molar ratios of 3.1–5.6 adsorbed almost all the dye from the solution (<0.3% remaining solution). Even though most of the dye is adsorbed from solution, the surface coverage of the adsorbed dye is low (~0.10 mol/nm^2) for these ratios. This is due to higher surface area (see Table 4) of these materials plus the fact that the concentration (1.85 mM) of dye used was fixed and insufficient to achieve monolayer coverage for Mg:Al molar ratios of 3.1–5.6.

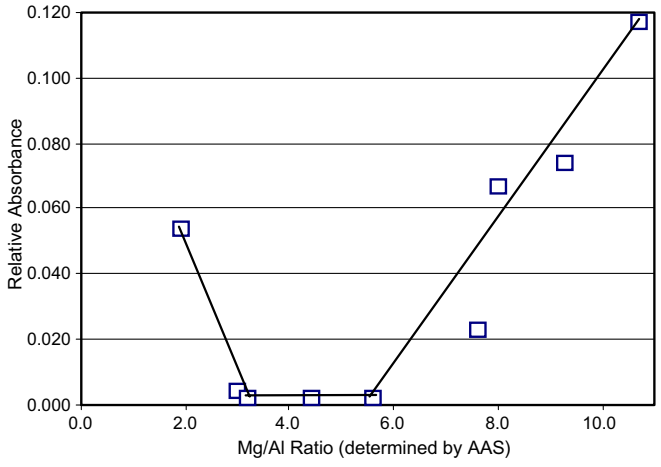

Fig. 3. Relative absorbance of solutions used to adsorb Acid Blue 9 on Mg–Al–LDH–CO_3 system with varying Mg/Al ratios.

The maximum adsorption capacity and binding constants of these materials were determined by measuring the amount of dye adsorbed as a function of concentration of Acid Blue 9. The data, shown in Fig. 4, could be fitted very well using the Langmuir model. According to Giles et al. [30] these are of L-2 curves which indicates that the Acid Blue 9 molecules are most likely to be adsorbed to the surface of the LDH by very strong intermolecular interactions. It should be noted, however, that since the initial part of the isotherm is nearly vertical, one may consider such a curve as belonging also to an H-2 class which is a special case of the L curves. This further demonstrates that Acid Blue 9 has such a high affinity for the LDH that it is adsorbed even from dilute solutions. The plateau may represent the formation of a complete monolayer coverage from which maximum adsorption capacity can be derived. The long plateau of these materials suggest that after the surface has been saturated to the first degree a high energy barrier needs to be overcome before additional adsorption can occur on new sites, or even the interlayer region.

The Langmuir model parameters (C_m and K_a) are listed in Table 3 and reveal interesting trends. These three LDH materials have much the same affinity for Acid Blue 9 as indicated by the similar K_a values of ca. 1.2×10^5 M^{-1}. However, the optimum adsorption was exhibited by the materials with Mg/Al molar ratios of 3.1 and 4.4, both of which gave C_m values of ca. 7.6×10^{-2} mmol/g. A significant decrease in the C_m value was observed for the material with a molar ratio 5.6 and it can be concluded that this type of LDH material exhibits the best adsorption properties for metal molar ratios in the range 3.1–4.4.

To rationalize this behavior, the powder X-ray diffractograms (Fig. 5) of these compounds were closely examined.

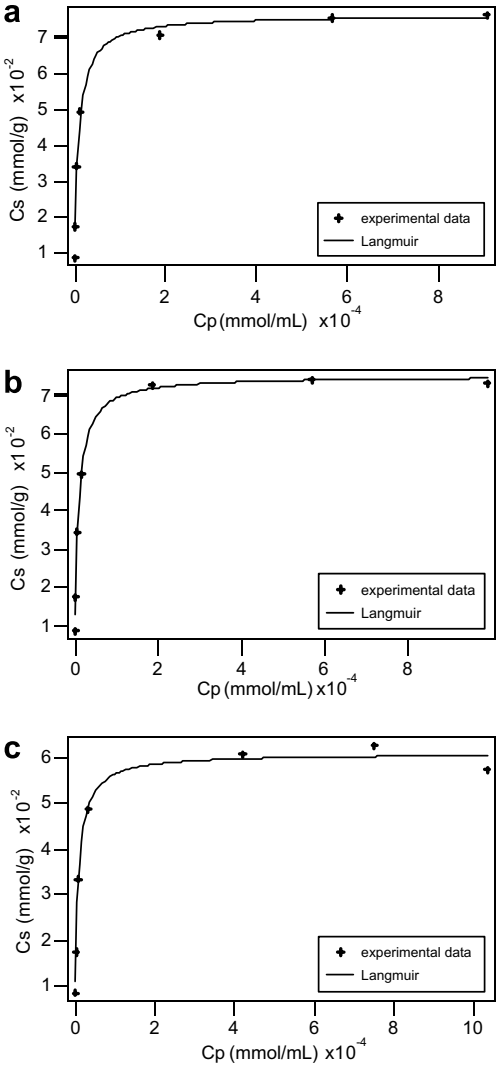

Fig. 4. Adsorption isotherms for Acid Blue 9 binding to Mg–Al–LDH–CO_3 system at a Mg/Al (a) 3.1; (b) 4.4 and (c) 5.6. Fitting of the data to the Langmuir equation is represented by the full line.

Table 3
Langmuir model parameters for Acid Blue 9 binding to the Mg–Al–LDH–CO_3 system at ratios 3.1, 4.4, and 5.6

Mg:Al molar ratio	C_m (mmol/g)	K_a (M^{-1})
3.1	$7.62\ (\pm 0.29) \times 10^{-2}$	$1.18\ (\pm 0.20) \times 10^{5}$
4.4	$7.51\ (\pm 0.16) \times 10^{-2}$	$1.19\ (\pm 0.11) \times 10^{5}$
5.6	$6.09\ (\pm 0.12) \times 10^{-2}$	$1.24\ (\pm 0.13) \times 10^{5}$

It was found that a pure hydrotalcite-like compound can only be produced within a very narrow range of x values ($M^{3+}/[M^{2+} + M^{3+}]$), between 0.24 (Mg/Al = 3.1) and 0.34 (Mg/Al = 1.9) which is within the range of most reliable limits reported in previous studies (viz. $0.2 \leqslant x \leqslant 0.4$) [5,7,31,32].

Fig. 5 shows that the (hkl) reflections where $l \neq 0$ of the hydrotalcite-like phase are slightly shifted to the lower 2θ as the x value is decreased. This is due to an increase in the interlayer spacing, as evident from a change in c values,

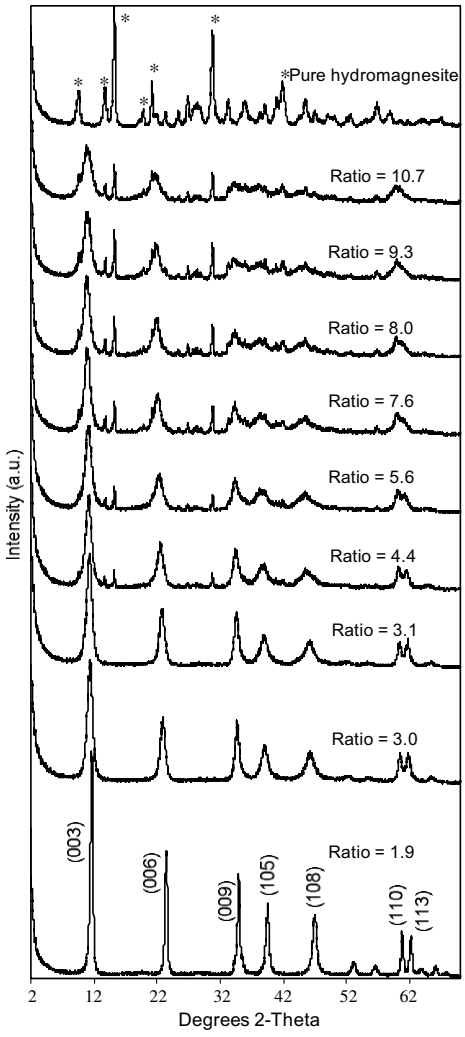

Fig. 5. X-ray powder diffractograms of Mg–Al–LDH–CO_3 system at different Mg/Al values and for pure hydromagnesite.

i.e., from $c = 7.6$ Å for $x = 0.34$ (ratio = 1.9) up to $c = 8.1$ Å for $x = 0.09$ (ratio = 10.7) (see Supplementary material, Table S1). Therefore, a less compact Mg–Al–LDH–CO_3 system results at a lower value of x. This has been proposed [31] to be due to the decrease in charge density which consequently results in a lower electrostatic attraction between positive brucite-like layers and negative interlayer species. This less compact textural property could be contributing for the better dye affinity of these materials but other factors like surface area (vide infra) will be more important. We note also that this will be valid only if the compound in question is hydrotalcite-like. As can be seen from Fig. 5, starting from a Mg:Al molar ratio of 4.4, a new phase can be observed in the powder XRD as revealed in the emergence of new set of reflections in the diffraction pattern, notably at 2θ values of 9.6°, 13.8°, 15.2°, 19.9°, 21.2°, 30.8° and 41.9° (*shown in asterisks*). At the same time the reflections for hydrotalcite-like phase becomes less intense. Analysis of these new reflections revealed that it is a hydromagnesite compound which has the formula of $Mg_5(CO_3)_4(OH)_2 \cdot 5H_2O$ (*JCPDS #:*

70-1177). This compound may be formed via the following reactions:

$$Mg^{2+} + 2OH^- \Longleftrightarrow Mg(OH)_2 \quad (1)$$

$$5Mg(OH)_2 + 4CO_2 + H_2O \rightarrow Mg_5(CO_3)_4(OH)\cdot 5H_2O \quad (2)$$

The formation of this compound at a molar ratio of 4.4 is probably triggered by two factors: (1) the interlayer spacing (7.9 Å) is already too high such that interlamellar anions are no longer effective in holding the brucite layers, leading to a collapse of some interlamellar domains of the hydrotalcite-like compound [31] favoring the formation of a new phase, and (2) the deficiency of trivalent metal ions necessary in the formation of hydrotalcite-like compounds. Interestingly, as the Mg/Al molar ratio is further increased (lower x value) the adsorption ability of the material decreases. This suggests that the good adsorption behavior can be ascribed to the presence of a hydrotalcite phase and not of the hydromagnesite phase. The materials with Mg:Al molar ratios of 4.4 and 5.6 still exhibit good dye adsorption properties due to the fact that they consist predominantly of the hydrotalcite phase. In this context, the dye affinity of the material with Mg:Al molar ratio of 5.6 is excellent, but the capacity to adsorb the dye has dropped by ca. 25% (see Table 3).

The (003), (006) and (009) reflections of the hydrotalcite-like phase get broader as the x value gets smaller (Fig. 5). Application of the Scherrer equation [33], $t = 0.9\lambda/B\cos\theta_B$, where t is the crystallite size, λ is the wavelength of the radiation used, B is the full width at half maximum (FWHM) and θ_B is the Bragg diffraction angle, leads to the conclusion that the average crystallite size of the hydrotalcite phase material is decreasing. This implies that the material has a greater surface area, and consequently, better adsorbance.

Table 4 summarizes the surface area, pore diameter/pore volume and density of Mg–Al–LDH–CO_3 system at different Mg/Al molar ratios as determined using the BET (Brunauer, Emmett and Teller) theory, B.J.H. (Barret, Joyner and Halenda) method and helium pycnometry, respectively. It is clear that the adsorptive capacity of these materials increases with the surface area reaching a maximum that has a Mg/Al molar ratio of 3.1 (SA = 123 m^2/g). The surface area value at Mg/Al = 3.1 is in excellent agreement with that reported by Reichle [34] of 120 m^2/g, although the crystallization temperature used in this study was 100 °C (24 h) (cf. 65–75 °C (18 h) by Reichle). Beyond a Mg/Al molar ratio of 4.4, the surface area starts to decrease and so does the adsorptive capacity (see Table 3). It can be concluded that as hydromagnesite starts to form, dye adsorption by the material decreases, due to a decrease in surface area and for the poorer dye adsorptive properties of hydromagnesite.

The change in surface area influences the pore volume of these materials. Obviously, the larger the volume, the larger the surface area, and therefore more dye would be needed to achieve monolayer adsorption on the surface can take place. In fact, the highest pore volumes were measured for materials with the best dye affinity, i.e., at Mg:Al molar ratios of 3.1 and 4.4.

Table 4
Textural properties of Mg–Al–LDH–CO_3 materials at different Mg/Al values

Mg/Al[a]	Surface area[c] (m^2/g)	Ave. pore diameter[d] (Å)	Corrected pore vol.[e] (cm^3/g)	Ave. density[f] (g/cm^3)
1.9	40	284	0.28	2.10
3.0	118	263	0.78	2.00
3.1	123	266	0.82	2.03

With respect to the pore diameter, there was no correlation with adsorptive capacity of the material. It is clear however, that all of these materials can be considered mesoporous, i.e., having pores at 2–50 nm [35]. It should also be noted that, despite the significant change in surface area and pore size, all of the materials studied have much the same average density of ca. 2 g cm^{-3}. Fig. 6 shows the adsorption and desorption isotherms of selected materials and they can be classified as type IV isotherms which are typical of mesoporous materials [31,36] such as hydrotalcite and hydromagnesite. The same type of isotherms were exhibited by the other materials prepared in this study. The shapes of pores can usually be inferred from the form of the adsorption–desorption isotherm. All synthesised materials including the pure hydromagnesite do not show a limiting adsorption capacity at high relative pressures, thus, according to Sing et al. [37] this is a H3 type hysteresis which is characteristic of aggregates of plate-like particles leading to slit-shaped pores. This conclusion is supported by scanning electron microscope analysis (Fig. 7).

For the material with Mg/Al = 1.9, the SEM shows a hexagonal platelet morphology consistent with previous studies [34,38]. It appears also that the average particle size ($\sim 50 \times 250$ nm) is quite uniform, implying a narrow particle size distribution. However, starting from a molar ratio of 3.0 and up to a molar ratio of 9.3, mixing of a coral-like morphology with large lamellar shaped materials is evident, the latter becoming more pronounced as the Mg/Al molar ratio increases. A closer examination of the coral-like surface micrographs reveal that these are just plate-like

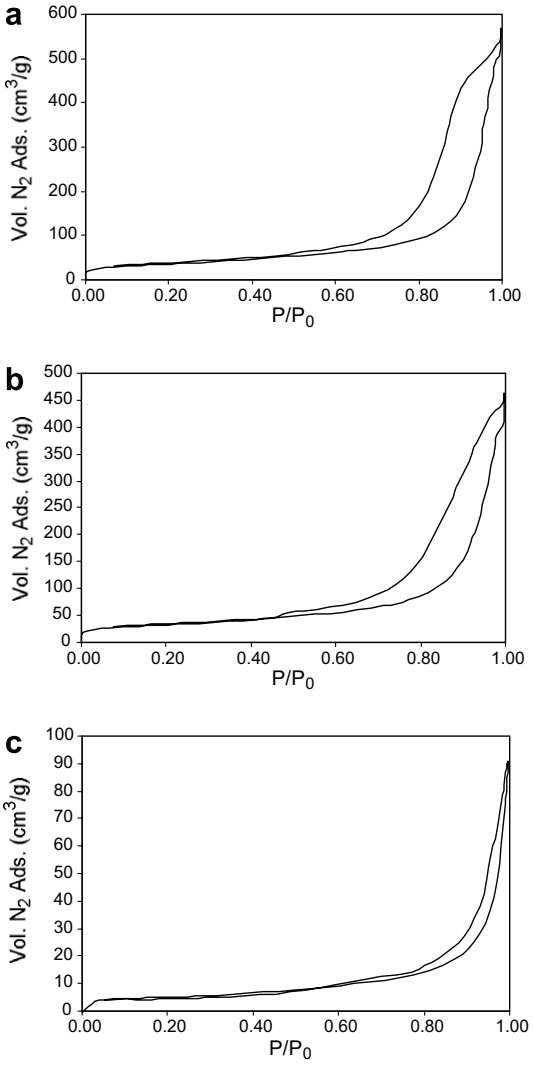

Fig. 6. N_2 Adsorption–desorption isotherms of: (a) Mg–Al–LDH–CO_3 at ratio 3.1 (b) Mg–Al–LDH–CO_3 at ratio 4.4 and (c) pure hydromagnesite (PHM).

particles arranged in a "hollow-block" fashion (see Fig. 7). Interestingly, this hollow-block fashion arrangement becomes most evident at Mg/Al = 3.1 and decrease in prominence above Mg/Al = 5.6. At and above this molar ratio, a wide particle size distribution (100–670 nm in diameter) is more evident. At Mg/Al = 10.7, the surface morphology becomes more characteristic of hydromagnesite, that is, lamellar plates are stacked parallel to each other. Since pure hydromagnesite was found to exhibit the least adsorptive capacity of all the materials studied (not shown in Fig. 3), it can be concluded that the presence of hydromagnesite is a further factor (in addition to a reduction in surface area) causing reduction in the dye adsorption properties of the materials. In fact, hydromagnesite exhibited the least surface area (18 m^2/g) and pore volume (0.14 cm^3/g) of all materials studied and the presence of this material is likely to be contributing to a reduction in surface area.

3.2. Intercalation (interlamellar anionic exchange)

Previous studies [27,39] showed that the use of a swelling agent, such as glycerol, assists the intercalation of Keggin-type polyoxometalate anions into layered double hydroxides. In such studies glycerol (1:2 (v/v) H_2O:glycerol) was used to increase the interlayer spacing prior to the intercalation reaction. Carbonates were also removed before intercalation by heating the LDH material to 500 °C and then reconstructing it under N_2 atmosphere. The possibility of whether anion intercalation can occur in our dye affinity test procedure was examined using a 5:1 (v/v) H_2O:glycerol (low glycerol loading) in the presence of carbonate and hydroxide anions. To probe whether Acid Blue 9 molecules are intercalated between the interlayer spacing or just a surface adsorption, the dye treated pigment during the dye affinity test was collected. This pigment was then dried at 100 °C for 24 h, ground with an agate mortar and pestle and subjected to PXRD analysis. Acid Blue 9 in its original form was also subjected for PXRD analysis. Fig. 8 shows the diffractograms of Mg–Al–LDH–CO_3 system at different Mg/Al molar ratios treated with 1.85 mM dye showed no change in the $d_{(003)}$ basal spacing (see Supplementary material, Table S1) of the LDH before and after dye treatment. This means that Acid Blue 9 was not intercalated. However, two important observations can be made from the diffraction peaks. Firstly, the appearance of a broad background peak at 2θ of ca. 20° is due to Acid Blue 9 which exhibits a diffuse or amorphous X-ray pattern. Most likely, the dye has precipitated as microcrystals on the surface. Secondly, the reflection at $2\theta = 9.6°$ (*for hydromagnesite*) that starts to appear for a Mg:Al molar ratio of 4.4 for untreated LDH, disappears for the treated LDH as the Mg:Al molar ratio increases (e.g., at Mg:Al molar ratio of 9.3 and 10.7). This reflection and the (0 0 3) reflection of hydrotalcite results in one broadened diffraction line which is the only one experimentally observable. The transformation of symmetric and sharp reflections into broad and asymmetric diffraction bands after treatment with glycerol (see also Fig. 9a) is an indication of the presence of stacking faults. Although incorporation of glycerol into the hydrotalcite did not increase the gallery height, it is believed, however, that uneven expansion leads to planar defects (i.e. stacking faults) that may facilitate the intercalation of bulky anions, such as Acid Blue 9.

One could argue that intercalation is still possible considering especially that the dye has the same charge as the carbonate ion. Since preliminary investigations have shown that Mg:Al molar ratios of 3.1–5.6 exhibit the best dye adsorption properties on these materials. These were treated with a more concentrated (76 mM; 1.5 meq/g ion-exchange capacity) Acid Blue 9 solution. This concentration is ten times greater than that needed for a complete monolayer coverage (7.6×10^{-2} mmol/g) for the material that exhibits the best adsorption properties. Fig. 9b shows the diffractograms of Mg:Al molar ratios of 3.1–5.6 treated

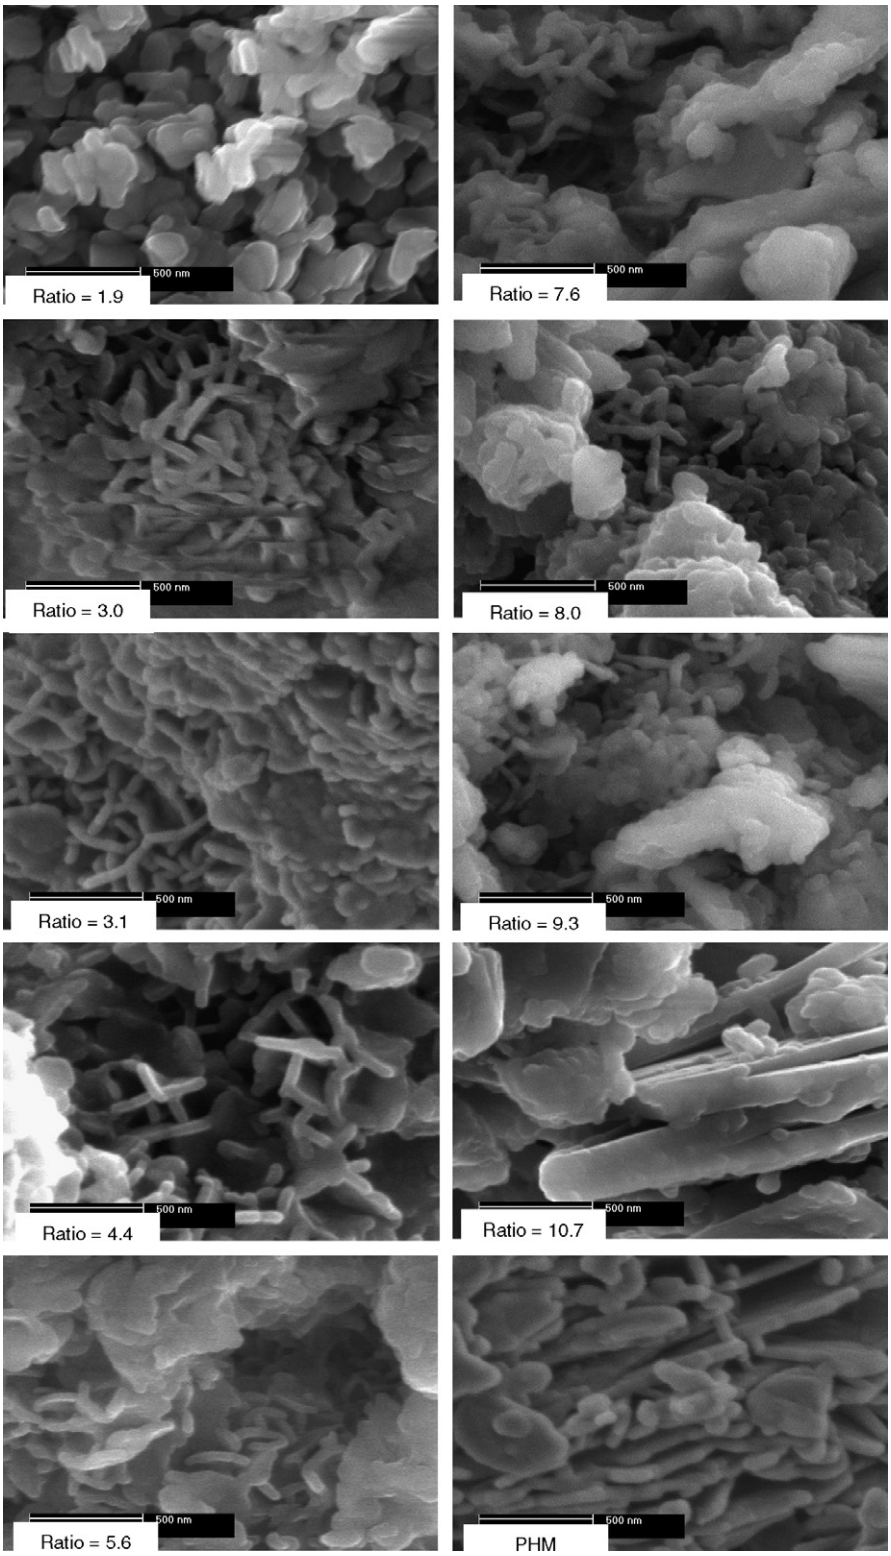

Fig. 7. Scanning electron micrographs of Mg–Al–LDH–CO_3 systems at varying ratios and pure hydromagnesite compound (PHM).

with 76 mM Acid Blue 9 in pure H_2O solvent. Clearly, no evidence of intercalation can be observed as there are no changes in peak position and intensity (cf. original hydrotalcite materials, Fig. 5). This is despite an increase in the Acid Blue 9 content of the materials (see Table 5).

Since this amount (76 mM) of dye is less than the specific ion-exchange capacity of LDH used that is 2.2 meq/g, the LDH was treated with more concentrated aqueous solutions of AB9 having an ion-exchange capacities of 3.0 and 6.1 meq/g. Again, there was no sign of intercalation

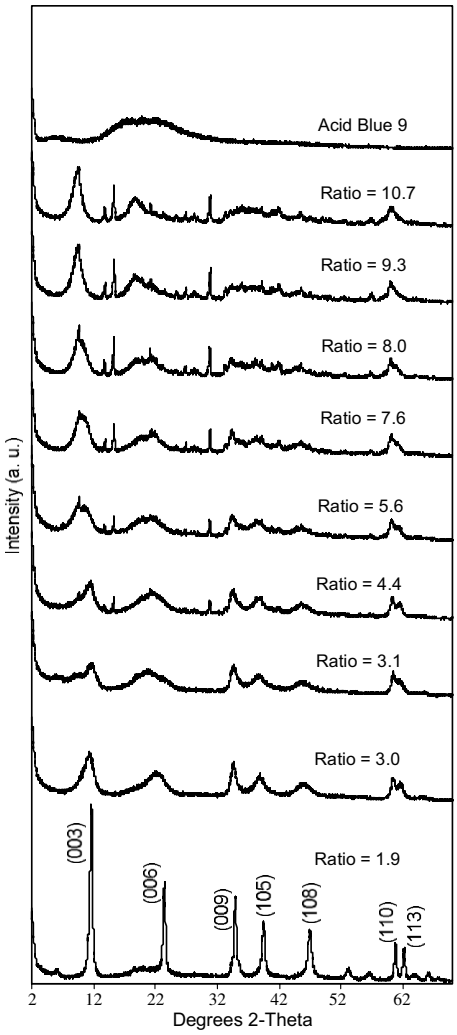

Fig. 8. X-ray powder diffractograms of Mg–Al–LDH–CO_3 system at different Mg/Al values after dye (1.85 mM) treatment and for Acid Blue 9.

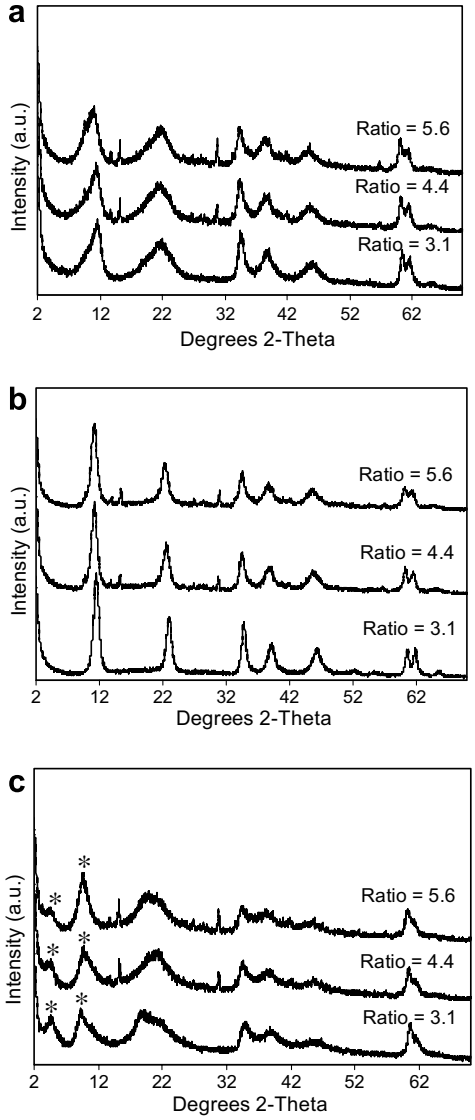

Fig. 9. X-ray powder diffractograms of Mg–Al–LDH–CO_3 system at Mg/Al values of 3.1, 4.4 and 5.6 upon treatment of: (a) 20% (v/v) glycerol–H_2O; (b) Acid Blue 9 solution. (76 mM) in pure H_2O solvent; (c) Acid Blue 9 solution. (76 mM) in 20% (v/v) glycerol–H_2O solvent system. *New reflections at 2θ of 4.6° and 9.5° indicating a d spacing of 19.3 Å and 9.3 Å, respectively.

as shown by the diffractograms (see Supplementary Material, Figure S1). This indeed shows that CO_3^{2-} is very strongly held within the interlayer [40] and that this, and the small interlayer spacing, prevents exchange of AB9 ions for the carbonate precursor anion [41].

Interestingly, when the same materials were treated with only 76 mM Acid Blue 9 in 20% (v/v) glycerol–H_2O solvent system, intercalation was observed (Fig. 9c). New reflections were found at 2θ of ca. 4.6 and 9.5θ (*shown in asterisks*) that gave a d spacing of ca. 19.0 Å (1.9 nm) and 9.5 Å (1.0 nm) respectively. The d spacing at $2\theta = 4.6°$ could correspond to the basal spacing of a new less ordered layered material being formed through intercalation of the dye which is topotactic to the Mg–Al–LDH–CO_3 system precursor. At Mg:Al molar ratio of 3.1, this less ordered intercalate is more dominant, but at Mg:Al molar ratios of 4.4 and 5.6, it is less evident due to the presence of hydromagnesite in the starting material. A basal spacing of 19.0 Å corresponds to an interlayer spacing of 14 Å. This corresponds extremely well to the length of the Acid Blue 9, which in the gas phase has the dimensions of a nanosized molecular box of $x = 10.3$ Å; $y = 10.0$ Å; $z = 12.8$ Å. In addition two of the sulfonate groups are approximately located along the z-axis. For intercalation to occur, the SO_3^- ends of the guest are likely to orient themselves towards the metal cations of the host so as to maximise electrostatic interactions. Consequently, the z and y axes of the molecular box would be slightly tilted in a counter clockwise direction (Fig. 10). This orientation of AB9 in the interlayer of LDH was inferred only based on X-ray data on the AB9 intercalated LDH material and the 3D-structure of AB9 calculated using computational chemistry. Hansen and Taylor [42] have proposed three hypotheses of how the presence of glycerol may facilitate easy intercalation of anions with lower charge density using Mg(II)–

Table 5
Variation in composition and basal spacing of Mg–Al–LDH–CO_3 with a Mg/Al = 3.1 with treatment conditions

Sample	Treatment	Composition[a]	d_{003} (Å)[b]

FT-IR spectra of the (a) Pure Mg–Al–LDH–CO_3 with Mg/Al = 3.1, (b) Mg–Al–LDH–CO_3 added with 20% (v/v) glycerol–H_2O system, (c) Mg–Al–LDH–CO_3 added with 1.85 mM Acid Blue 9 in 20% (v/v) glycerol–H_2O solvent system, (d) Mg–Al–LDH–CO_3 added with 76 mM Acid Blue 9 in pure water, (e) Mg–Al–LDH–CO_3 added with 76 mM Acid Blue 9 in 20% (v/v) glycerol–H_2O solvent system, and (f) Acid Blue 9.

Fe(III) hydroxycarbonate as LDH, some of which could be used to explain how bulky anions, such as AB9, can be exchanged into the Mg(II)–Al(III) LDH in the presence of glycerol and even when carbonate is the interlayer anion. Firstly, swelling of the interlayer between the brucite-like sheets, following penetration by glycerol into the interlayer, decreases the strength of the electrostatic and H-bonding interactions between carbonate and the brucite layers. This anion is then exchangeable with anions present in high concentrations outside the interlayer region. Secondly, negatively charged glycerolate anions, could form under dehydrating conditions in reactions involving the interlayer CO_3^{2-}, e.g. when the materials are treated with liquid glycerol as represented in Eq. (3)

$$2(CH_2OH\text{–}CHOH\text{–}CH_2OH) + CO_3^{2-} \Longleftrightarrow CO_{2(g)} + 2(CH_2OH\text{–}CHOH\text{–}CH_2O)^- + H_2O \quad (3)$$

With the decomposition of the CO_3^{2-} and its liberation as CO_2, it has been suggested that the glycerolate anions are retained in the interlayer as the charge compensating anion.

Table 5 shows the calculated compositions based on elemental/micro and TGA analyses data, (see Supplementary material, Table S2 and Figures S2–S7) as well as the corresponding basal spacings of Mg–Al–LDH–CO_3 (Mg/Al ~ 3.1) at different treatment conditions. As pointed out previously, no change in the basal spacings were observed in any conditions employed except when a more concentrated (76 mM) solution of Acid Blue 9 in a 20% glycerol–H_2O was used to treat the layered double hydroxides. This results in ca. 14% Acid Blue 9 (surface and interlamellar) loading of the new material. Although the amount of added Acid Blue 9 is insufficient to replace all

the carbonates originally present in the system (also confirmed via FT-IR analyses), it does cause a major change in the basal spacing from 7.8 Å to 19.0 Å (see Fig. 8c).

Fig. 11 shows the IR spectra of pure Mg–Al–LDH–CO_3 with Mg/Al = 3.1, Mg–Al–LDH–CO_3 treated with 20% (v/v) glycerol–H_2O solution, Mg–Al–LDH–CO_3 treated 1.85 mM Acid Blue 9 in 20% (v/v) glycerol–H_2O solvent system, Mg–Al–LDH–CO_3 treated with 76 mM Acid Blue 9 in pure water, Mg–Al–LDH–CO_3 intercalated with Acid Blue 9, and Acid Blue 9. Pure Mg–Al–LDH–CO_3 (Fig. 11a) exhibited peaks at 691 and 1372 cm^{-1} which are due to vibration of the interlayer CO_3^{2-}.

When Mg–Al–LDH–CO_3 is treated with 20% glycerol (Fig. 11b), the C–O stretches of glycerol between 1000 and 1210 cm^{-1} are evident indicating a high loading of glycerol, which is consistent with the elemental analyses. Fig. 11c shows the spectra of Mg–Al–LDH–CO_3 treated 1.85 mM Acid Blue 9 in 20% (v/v) glycerol–H_2O solvent system. Vibrations due to glycerol still dominate the spectrum but vibrations between 1522 and 1623 cm^{-1} starts to appear that could be due to C=C ring stretches of surface bound Acid Blue 9. When Mg–Al–LDH–CO_3 is treated with a higher concentration of Acid Blue 9 in water (Fig. 11d), vibrations due to Acid Blue 9 becomes more apparent in the 1522–1623 cm^{-1} and additional C–N and S–O stretches are also evident in the range 1039–1150 cm^{-1}. It should be noted that although Acid Blue 9 vibrations are so evident, powder X-ray analyses (see Fig. 9b) indicated that intercalation had not occurred. Fig. 11e shows the spectra of Mg–Al–LDH–CO_3 intercalated with Acid Blue 9 (see Fig. 9c also) in which vibrations due to Acid Blue 9 are evident, In particular, the strong absorption centered at 1200 cm^{-1} is present and could only be due to SO_3^- vibration of Acid Blue 9 species.

Intercalation of a negatively charged species in a layered double hydroxide system can occur in three ways: reconstruction method [8], self-assembly technique [10,12] and anion exchange methods [43]. Anion exchange follows the order, $CO_3^{2-} > SO_4^{2-} \gg OH^- > F^- > Cl^- > Br^- > NO_3^- > ClO_4^-$. In keeping with this, we have further demonstrated here that carbonate-LDHs are excellent precursors for surface adsorption since the interlayer carbonates will not be involved in the exchange process, whereas, the surface carbonates or hydrogen carbonates are easily replaced by anionic dyes [27].

4. Conclusions and future studies

In this study, surface adsorption of Acid Blue 9 to Mg–Al–LDH–CO_3 materials was observed when a 1.85 mM dye solution in a 20% (v/v) glycerol–H_2O mixture was used. This system exhibited excellent surface adsorption (chemisorption) properties when the Mg/Al molar ratios were between 3.1 and 4.4, the compositions corresponding to the pure hydrotalcite phase. The adsorption behaviour correlates with the surface area, phase purity, surface morphology, particle size distribution and packing density. Interlamellar anion exchange was observed using 76 mM Acid Blue 9 solution in the same glycerol/water solvent system but was not observed when pure water was used as the solvent. This means that, through the use of glycerol, partial intercalation of bulky anions can take place even when carbonates are used as interlayer anions and even when the amount of anions added is well below the specific ion-exchange capacity of the LDH material. This method affords a facile synthesis of organic–inorganic hybrid materials using a very stable and easy to produce type of layered double hydroxide. To our knowledge, this is the first work that demonstrates the use of the anion exchange method to intercalate bulky anionic molecules into Mg–Al layered double hydroxides with carbonate as interlayer anions. However, in order to achieve this, an agent such as glycerol is needed to assist in the expansion of the hydrotalcite interlayer. Further studies aimed at improving the dye adsorption characterization of the LDH material are in progress.

Reactivity of mercury(II) halides with the unsymmetrical phosphorus ylide $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)Ph: Crystal structure of $\{HgI_2[PPh_2CH_2CH_2PPh_2$=C(H)C(O)Ph$]\}_n$

Abstract

The unsymmetrical phosphorus ylide, $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)Ph is shown to react with Hg(II) halides to form polymeric products with the composition $\{HgX_2[PPh_2CH_2CH_2PPh_2C(H)C(O)Ph]\}_n$, where X = Cl (**1**), Br (**2**), I (**3**). The complexes have been characterized by elemental analysis, IR, ^1H, ^{31}P NMR spectra as well as by ESI mass spectra. In product **1** the ylide exhibits a P, C-bridging mode of coordination, while in **2** and **3** it shows a monodentate P-coordination with the dangling ylide. The structure of complex **3** has been characterized crystallographically. The monomeric –Hg–I–Hg– bridging in **3** leads to a zig-zag polymeric chain in which mercury assumes a distorted tetrahedral geometry.

1. Introduction

Resonance stabilized phosphorus ylides are versatile ligands for heavy metal ions [1–5]. The α-keto stabilized ylides derived from bisphosphines, viz., $Ph_2PCH_2PPh_2$=C(H)C(O)R, $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)R (R=Me, Ph or OMe) [6] and PhC(O)C(H)=$PPh_2CH_2CH_2PPh_2$=C(H)C(O)Ph [7] form an important class of such ligands which can exist in ylidic and enolate forms. These ligands can therefore engage in different types of bonding as illustrated in Chart 1 for $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)Ph.

The bonding mode (f) had been previously observed for Pd(II), Pt(II) and Rh(I) [6–13]. In addition, Rh(I) was shown to exhibit the P-bonding mode (a) [13]. We have been interested in investigating the different bonding modes adopted by ylides when ligated to Hg(II) and U(VI) [14]. Hg(II) forms C-coordinated complexes with Ph_3P=C(H)C(O)Ph [15,16] and Ph_3P=C(H)CO(OEt) [17]. On the other hand, regiospecific O-coordination of the acetyl oxygen has been observed for the reaction of Hg(II) halides with Ph_3P=C(COPh)(COMe). The remarkable change in reactivity arises from a subtle variation in the molecular-electronic structure of the ylide due to the presence of additional keto stabilization. Further, although $HgBr_2$ and HgI_2 form 1:1 dimeric halobridged complexes with the above ylide, $HgCl_2$ forms a 1:2 monomeric square planar complex [18]. Motivated by the above chemistry, we decided to study the interaction of Hg(II) halides with mixed ylide-phosphine ligands. In this paper, we report the reactivity of the ligand $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)Ph, Benzoylmethylenediphenyl-2-diphenylphosphinoethylphosphorane (BDEP), towards mercury(II) halides.

2. Experimental

All reactions were carried out under an atmosphere of dry nitrogen. Reactants and reagents were obtained from Aldrich Chemical Company and used without further purification. The solvents were dried and distilled using standard methods [19].

2.1. Instrumentation

The ^1H and ^{31}P–{^1H} NMR spectra were recorded on a Bruker DPX400 or Varian Gemini 200 spectrometer, referenced relative to residual solvent and external 85% H_3PO_4, respectively. The IR spectra in the interval of 4000–400 cm^{-1} were recorded on a Perkin–Elmer 1720X FT-IR spectrophotometer using KBr pellets. ESI-mass spectra were measured on a Bruker FTMS 4.7T BioAPEX II instrument using the solution of the complexes in acetonitrile. Elemental analyses were performed at the Ecole d'ingénieurs de Fribourg, Switzerland.

2.2. Synthesis of compounds

2.2.1. $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)Ph

The ligand was prepared by the treatment of triethylamine on the monophosphonium bromide derived from 1,2-bis(diphenylphosphino)ethane (dppe) as reported previously [6]. IR (cm^{-1}): 3054, 2912, 1585, 1521, 1482, 1434, 1396, 1308, 1175, 1108, 1061, 1025, 998, 898, 882, 794, 746, 739, 722, 701, 653, 507, 490. ^1H NMR (200 MHz, $CDCl_3$): 2.20–2.33 (m, 2H), 2.79–2.94 (m, 2H), 4.26 (d, 1H, $^2J_{P-H} = 23.0$), 7.33–8.01 (m, 25H). ^{31}P NMR (162 MHz, $CDCl_3$): −12.20 (d, $^3J_{P-P} = 47.5$), 17.54 (d, $^3J_{P-P} = 47.5$).

2.2.2. Synthesis of $\{HgX_2[PPh_2CH_2CH_2PPh_2C(H)C(O)Ph]\}_n$ {X = Cl (1), Br (2), I (3)}

The following general procedure was used for preparing the complexes. To a solution of HgX_2 (0.38 mmol) in methanol (10 ml), a solution of $PPh_2CH_2CH_2PPh_2CHCOPh$ (0.2 g, 0.38 mmol) also in methanol (10 ml) was added dropwise at 0 °C and stirred for 2 h. The resulting solid, admixed with grey material was treated with dichloromethane (25 ml) and filtered through celite. Addition of excess methanol to the concentrated filtrate caused the precipitation of the products as white solids. The complexes were purified by repeating the precipitation three times and the solid dried under vacuum.

2.3. X-ray crystallography

Single crystals of **3** were obtained as colourless needles, when a hot 1-butanol solution containing the complex was allowed to stand at room temperature for a week. The intensity data were collected at 173 K (−100 °C) on a Stoe Mark II-Image Plate Diffraction System [20] equipped with a two-circle goniometer using Mo Kα graphite monochromated radiation. Image plate distance 100 mm, ω rotation scans 0–180° at ϕ 0°, and 0–20° at ϕ 90°, step $\Delta\omega = 1.0°$, 2θ range 2.29–59.53°, d_{min}–d_{max} = 17.779–0.716 Å. The structure was solved by direct methods using the program SHELXS-97 [21]. The refinement and all further calculations were carried out using SHELXL-97 [22]. The H-atoms were included in calculated positions and treated as riding atoms using SHELXL default parameters. The non-H atoms were refined anisotropically, using weighted full-matrix least-squares on F^2. An empirical absorption correction was applied using the MULscanABS routine in PLATON [23]; transmission factors: $T_{min}/T_{max} = 0.2744/0.6083$. A region of disordered electron density was squeezed out using the SQUEEZE routine in PLATON; 68 electrons for a volume of 346.9 Å^3, which was equated to 0.5 molecule of 1-butanol per asymmetric unit. Further crystallographic data are given in Table 2.

3. Results and discussion

The reactions of mercury(II) halides with unsymmetrical phosphorus ylide, $Ph_2PCH_2CH_2PPh_2$=C(H)C(O)Ph in 1:1 molar ratio yield two different polymeric products. While mercury(II) chloride forms a P, C-coordinated bridging complex [type (d), Chart 1], the mercury(II) bromide, and iodide, produce monodentate P-coordinated complexes with dangling ylide [type (a), Chart 1].

Complexes **1** and **2** are moderately soluble in acetonitrile and DMSO whereas the solubility of the complex **3** is higher in chloroform than in DMSO or acetonitrile. The yields of **1** and **2** are low due to some decomposition during the reaction. The IR spectrum of **1** shows the ν(CO) absorption at 1637 cm^{-1}, in the region typical for the C-bonded phosphonium ylides [24]. Similarly, in the ^{1}H NMR spectrum, both the downfield shift of the signal due to the PCH group and the decrease in the coupling constant are ascribed to C-coordination of the ylide (Table 1). The ^{31}P NMR spectrum of **1** exhibits two broad doublets at 23.78 and 35.88 ppm, which are assigned to the coordinated P=CHCOPh and PPh_2 groups, respectively. The spectral data thus indicate the bidentate coordination of the ligand through both P and C atoms. Although, complex **1** gives satisfactory elemental analysis for the 1:1 metal to ligand stoichiometry, the ESI-mass spectrum in acetonitrile solvent shows, in addition to the parent pseudomolecular ion, $[HgCl_2L–Cl]^+$ observed at m/z 753 as the base peak, another peak at m/z 1269 (83%) which is attributed to an $[HgCl_2(L)_2–Cl]^+$ ion. Such an observation is best explained by the polymeric structure with bridging mode of coordination of the ylide where both 1:1 and 1.2 (metal: ligand) fragmentation is possible.

In the IR spectra of **2** and **3**, the ν(CO) absorptions are shifted only slightly from that of the free ligand (Table 1). As noted previously [15], the coordination of the ylide through carbon or oxygen causes a significant increase or decrease, respectively, in the ν(CO) frequency. In the ^{1}H NMR spectra of **2** and **3**, the doublets due to the methine proton at 4.68 and 4.34 ppm, respectively, appear in the same region as observed for the free ligand (4.26 ppm). The ^{31}P NMR signals due to P=CHCOPh group are not much shifted from the corresponding value for the free ylide (Table 1). However, the signals due to PPh_2 group exhibit the expected downfield shifts for coordination. Thus, IR and NMR data indicate that interaction of ligand to $HgBr_2$ and HgI_2 is only through the phosphine part, as proved for the crystal structure of **3**. This is corroborated by the absence of any species containing two ligands in the ESI Mass spectra in acetonitrile for both **2** and **3**. The absence of ^{199}Hg satellites in the ^{31}P NMR spectra of all the complexes can be attributed to the fast exchange of ligand with metal, as noted previously for Hg(II)–phosphine complexes [25,26].

3.1. Crystal structure of complex 3

The molecular structure of **3** is shown in Fig. 1 and selected bond lengths and angles are given in Table 3. The X-ray analysis reveals the coordination of the ligand through the phosphorus atom only. The Hg(II) atom is

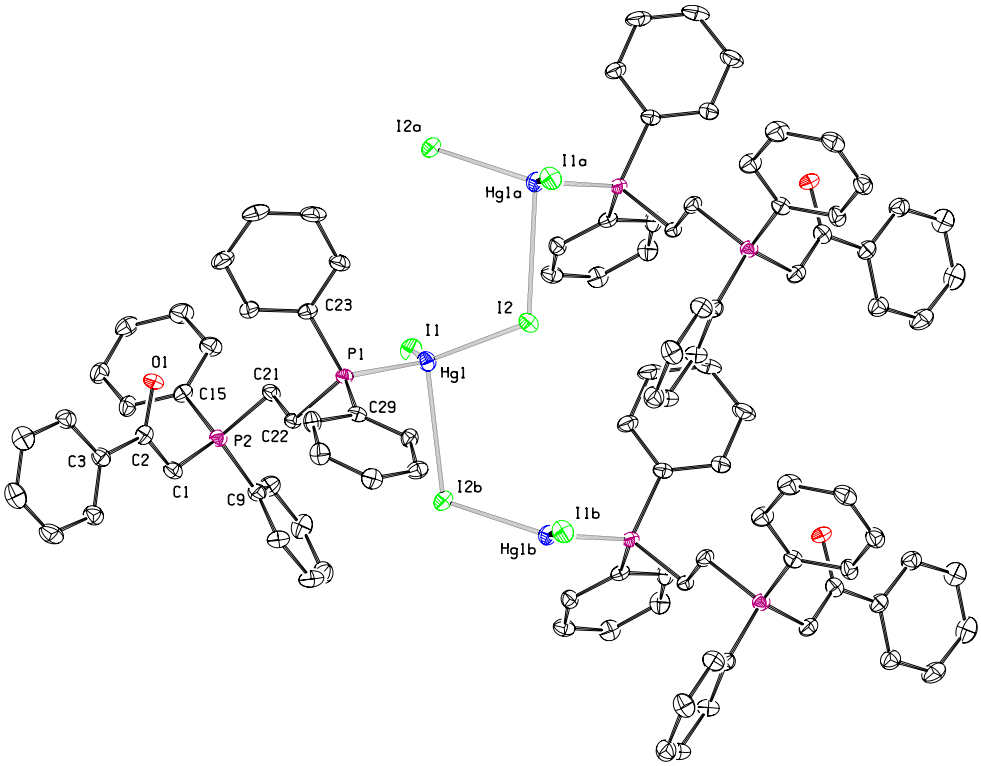

Fig. 1. Polymeric structure of **3** showing part of the chain running parallel to *b*-axis. The hydrogen atoms have been omitted for clarity. (*Symmetry codes*: $a = -x, -1/2 + y, 1/2-z$; $b = -x, 1/2 + y, 1/2-z$.)

located in a distorted tetrahedral environment with one 'P', one terminal 'I' and two bridging 'I' atoms, resulting in an one-dimensional polymeric chain. The Hg–P bond length of 2.472(2) Å is consistent with the values reported for monomeric mercury(II)–phosphine complexes [27]. However, this distance is shorter when compared to those in the polymeric complex, $[Hg(CN)_2dppe]_n$ [2.606(3) Å and 2.534(4) Å] containing the bridging phosphine ligand [28]. The Hg–I(terminal) bond distance [2.705(1) Å] is comparable to those of 2.727(2) and 2.693(2) Å found in $[Hg\{Ph_2P(S)CH_2PPh_2\}I_2]$ [29]. The asymmetric bridging nature of the other two iodo ligands is indicated by the two different Hg–I(bridging) distances of 2.728(1) and 3.321(1) Å. The latter distance being rather long, indicates a weak Hg–I(bridging) interaction. The bond angles around Hg atom (Table 3) indicate a severe distortion from ideal tetrahedral geometry. The deviation of atom Hg1 from the best least-squares plane defined by atoms I1, I2 and P1, is only 0.254 Å. This is comparable to the previous observations in the complexes $[HgX_2\{Ph_2PCH_2CH_2P(O)Ph_2\}]_n$ (X = Br, I) [30] and $[HgI_2\{Ph_2P(S)CH_2PPh_2\}]$ [29], where a weak coordination of the one of the ligands lead to a flattened tetrahedral geometry as shown by the small deviations (ranging from 0.244 to 0.406 Å) of the Hg atom from the plane defined by other three strongly bonded atoms. On the basis of the high solubility of complex **3** in most of the solvents and the long Hg–I(bridging) distance, it is possible that the polymer could dissociate to form a monomeric species in solution as indicated by the ESI mass spectral data. The ylidic moiety shows no interaction with mercury. The bond angles around C1 (~120°) and the P2–C1 distance [1.716(7) Å] indicate that the ylidic carbon remains unprotonated. Similarly, the short C1–C2 and long C=O distances show the resonance delocalization in the free ylide. As observed previously for α-stabilized phosphorus ylides [31], the phosphorus and oxygen atoms are *cis* oriented due to significant interaction between P^+ and O^- centres, as shown by the appropriate length and torsion angle (Table 3).

Symmetry transformation: (i) $-x, y + 1/2, -z + 1/2$.

4. Conclusions

In this study, we have shown that Hg(II) halides react with the unsymmetrical phosphorus ylide, Ph_2PCH_2-CH_2PPh_2=C(H)C(O)Ph, to form complexes in which the ylide exhibits different coordination modes. The difference can be accounted for by hardness associated with $HgCl_2$ compared to the softness of other two mercuric halides. Further, it is interesting to note that the monodentate P-coordination to mercury in the complexes **2** and **3**, with dangling ylide moiety, is in stark contrast to the product of the same ligand with $UO_2(NO)_2 \cdot 6H_2O$. The latter displays a monodentate O-coordination with the dangling phosphino group [32].

Abstract

The dilithiated derivative **2** of 1,1′-bis(trimethylsilylamino)ferrocene (**1**) reacts with the pyridine adducts of the aluminum trihalides AlX_3 (X = Cl, Br, I) to give the respective 1,3,2-diazaalumina-[3]ferrocenophanes (**4b**, **c**, **d**) as pyridine adducts. The fluoride **4a** could not be obtained in this way. The reaction of 1,1′-bis(trimethylsilylamino)ferrocene (**1**) with the dimethyl(ethyl)amine- or pyridine adduct of aluminium trihydride gave the 1,3,2-diazaalumina-[3]ferrocenophanes (**5**) and (**6**) as the amine and pyridine adducts, respectively. Treatment of **5** with trimethyltin fluoride afforded the adduct **7** with an Al–F function. Addition of pyridine converted **7** into the desired pyridine adduct of the fluoride (**4a**). The molecular structures of the pyridine adducts **4a**, **4b**, **4c** and **6** were determined by X-ray analysis. The pyridine is in the *trans*-position relative to the N–Si bond vectors, and temperature dependent solution-state NMR spectra prove that prominent structural features are retained in solution.

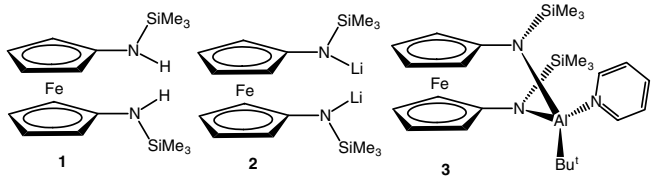
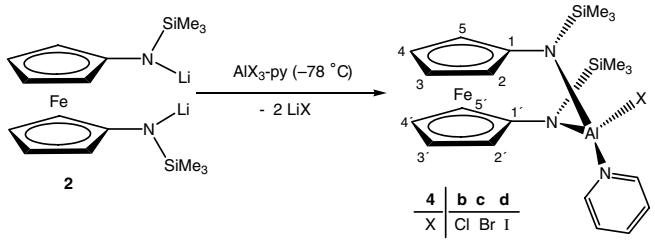
Keywords: Aluminum amides; [3]Ferrocenophanes; NMR; X-ray structure



1. Introduction

The principle structures as well as the reactivity of neutral aluminum amides can be tuned by the appropriate choice of the amino groups. There are rare structurally characterised examples containing tri-coordinate aluminum linked to rather bulky amino groups [1]. On the other hand, there are numerous examples containing penta-coordinate [2] or tetra-coordinate aluminum [1a,3]. In the latter cases, the majority of the compounds are either dimers [1c,4], in which two amino groups form bridges between the aluminum atoms, or intramolecular coordination takes place [4a,5]. Alternatively, the structures of few examples of tetra-coordinate aluminum amides with intermolecular coordination have been studied with suitable donors such as trimethylamine [6], pyridine [7] or some other Lewis bases [3c,6b,7b]. There is also some structural information available on tetra-coordinate aluminum amides with *N*-silylamino groups, again with intramolecular [4a,4b,4f,5a,5b,5d] or intermolecular coordination [1e,4a,4c,4d,4e,4f,6c,8]. The presence of amino groups together with halogeno or hydrido functions at aluminum deserves interest, since such compounds are known as catalysts for various organic transformations [5a,5b,5c,9] or as hydroaluminating [10] or selective reducing reagents [11].



We are interested in the conversion of 1,1′-diaminoferrocene [12] into suitable chelating ligands in order to build [3]ferrocenophanes containing the N–M–N bridge. For this purpose, the 1,1′-bis(trimethylsilylamino)ferrocene **1** is a useful starting compound [13], since it can be readily metalated e.g. to give the dilithiated derivative **2** (Scheme 1). The latter reacts with numerous dihalides to give the corresponding [3]ferrocenophanes containing the $N(SiMe_3)$–M–$N(SiMe_3)$ bridge, where M can be a main group element [14–18] or a transition metal [13,19]. Alternatively, **1** can react with metal hydrides to give the desired products by elimination of H_2, as known for other amines and aluminum hydrides [3d,5a,6a,6b,20].

Scheme 1.

Scheme 2.

Recently, we have reported on the first examples of 1,3,2-diazaalumina-[3]ferrocenophanes bearing a bulky organyl group at aluminum such as **3** [21] (Scheme 1). Certainly, the introduction of an exocyclic function at the site of aluminum is an attractive object. Indeed, the formation of the chloride **4b** (Scheme 2), as a side product has already been observed in the course of the previous study [21]. This prompted us to attempt the direct synthesis of such aluminum halides and of the hydride as adducts.

2. Experimental

2.1. General

The syntheses of starting materials and products as well as all handling of the samples were carried out observing necessary precautions to exclude traces of air and moisture. Carefully dried solvents and oven-dried glassware were used throughout. The deuterated solvents CD_2Cl_2 and $CDCl_3$ were distilled over CaH_2 in an atmosphere of Ar. All other solvents were distilled from Na metal in an atmosphere of argon. The starting materials were prepared as described in the literature, i.e. 1,1′-bis(trimethylsilylamino)ferrocene (**1**) [13], *N*,*N*′-dilithio-1,1′-bis(trimethylsilylamino)ferrocene (**2**) ($fc(NSiMe_3)_2Li_2$) [16]. Trimethyltin fluoride, Me_3SnF [22], was sublimed at 130–135 °C (0.02 Torr) prior to use. NMR measurements: Bruker ARX 250: ^1H, ^{13}C, ^{27}Al, ^{29}Si NMR (refocused INEPT [23] based on $^2J(^{29}Si,^1H) = 7$ Hz); Varian INOVA 400: ^1H, ^{13}C, ^{19}F NMR; Bruker DRX 500: ^{15}N NMR; chemical shifts are given with respect to Me_4Si [$\delta^1H(CHDCl_2)$ 5.33, $(C_6D_5CD_2H) = 2.08$; $\delta^{13}C(CD_2Cl_2) = 53.8$, $(C_6D_5CD_3) = 20.4$; $\delta^{29}Si = 0$ for $\Xi(^{29}Si) = 19.867184$ MHz]; external neat $CFCl_3$ [$\delta^{19}F = 0$ for $\Xi(^{19}F) = 94.094003$ MHz]; external neat $MeNO_2$ [$\delta^{15}N = 0$ for $\Xi(^{15}N) = 10.136767$ MHz]; external 1.1 M $Al(NO_3)_3$ in D_2O [$\delta^{27}Al = 0$ for $\Xi(^{27}Al) = 26.056890$ MHz]. In the cases of the compounds **4b**, **4c**, **6**, the crystalline solids as well as reaction solutions were studied by NMR. For **4a**, **4d**, **5**, **7** NMR spectra of reaction solutions were measured. EI-MS spectra: Finnigan MAT 8500 spectrometer (ionisation energy 70 eV) with direct inlet; the *m*/*z* data refer to the isotopes ^1H, ^{12}C, ^{14}N, ^{27}Al, ^{28}Si, and ^{56}Fe. IR spectra: Perkin–Elmer Spectrum 2000 FTIR. The melting points (uncorrected) were determined using a Büchi 510 melting point apparatus.

2.2. 1,3-Bis(trimethylsilyl)-2-halogeno-2-pyridine-1,3,2-diazaalumina-[3]ferrocenophanes (**4**)

2.2.1. 1,3-Bis(trimethylsilyl)-2-chloro-2-pyridine-1,3,2-diazaalumina-[3]ferrocenophane (**4b**)

Freshly prepared $fc(NSiMe_3)_2Li_2$ (**2**) (292 mg, 0.78 mmol) was taken up in toluene (20 mL); the solution was cooled to −78 °C, and a solution of freshly prepared $AlCl_3$-py [from $AlCl_3$ (105 mg, 0.78 mmol) and pyridine (0.063 mL, 0.78 mmol) in toluene (10 mL)] was added drop wise. After stirring the reaction mixture for 1 h at −78 °C and then for 18 h at ambient temperature, insoluble materials were separated by centrifugation, and the clear liquid was collected. Volatile materials were evaporated and the remaining oil was washed with hexane (10 mL), and a solid was obtained. Thus was dried in a vacuum to give **4b** as a brown powder (236 mg; 60%). Crystallisation from toluene-[d_8], after 2 days at −20 °C, gave orange crystals of **4b** (132 mg; 34%); m.p. >260 °C (decomposition). ^1H NMR (250.1 MHz; CD_2Cl_2; 25 °C): $\delta = -0.10$ (s, 18H, Me_3Si), 3.72 (br) (m, 4H, $H^{2,2',5,5'}$), 3.81 (m, 4H, $H^{3,3',4,4'}$), 7.78 (m, 2H, H_β), 8.20 (m, 1H, H_γ), 9.09 (d, 2H, H_α, $J = 4.5$ Hz). ^1H NMR (250.1 MHz; CD_2Cl_2; −50 °C): $\delta = -0.20$ (s, 18H, Me_3Si), 3.38, 3.86 (m, m, 2H, 2H, $H^{2,2'}$, $H^{5,5'}$), 3.70, 3.78 (m, m, 2H, 2H, $H^{3,3'}$, $H^{4,4'}$), 7.80 (m, 2H, H_β), 8.23 (m, 1H, H_γ), 8.94 (m, 2H, H_α).

2.2.2. 1,3-Bis(trimethylsilyl)-2-bromo-2-pyridine-1,3,2-diazaalumina-[3]ferrocenophane (**4c**)

Freshly prepared $fc(NSiMe_3)_2Li_2$ (**2**) (260 mg, 0.70 mmol) was taken up in toluene (20 mL); the solution was cooled to −78 °C, and $AlBr_3$ (186 mg, 0.70 mmol) and pyridine (0.060 mL, 0.75 mmol) was added. After stirring the reaction mixture for 1 h at −78 °C and then for 14 h at ambient temperature, insoluble materials were separated by centrifugation, and the clear liquid was collected. Volatile materials were removed in vacuo (0.001 torr) to give **4c** as a brown solid (358 mg; 94%). Crystallisation from toluene-[d_8], after 2 days at −20 °C, gave red-orange crystals of **4c** (195 mg; 51%); m.p. >270 °C (decomposition). ^1H NMR (250.1 MHz; CD_2Cl_2; 25 °C): $\delta = -0.18$ (s, 18H, Me_3Si), 3.83 (br) (m, 4H, $H^{2,2',5,5'}$), 3.87 (m, 4H, $H^{3,3',4,4'}$), 7.85 (br) (m, 2H, H_β), 8.22 (m, 1H, H_γ), 9.18 (br) (m, 2H, H_α). ^1H NMR (250.1 MHz; CD_2Cl_2; −40 °C): $\delta = -0.27$ (s, 18H, Me_3Si), 3.61, 3.86 (m, m, 2H, 2H, $H^{2,2'}$, $H^{5,5'}$), 3.77, 3.80 (m, m, 2H, 2H, $H^{3,3'}$, $H^{4,4'}$), 7.80 (m, 2H, H_β), 8.23 (m, 1H, H_γ), 9.01 (m, 2H,

H_α). EI-MS (70 eV) for $C_{21}H_{32}N_3AlSi_2Fe$ (465.13): *m/z* (%) = 360 (100) [fc(N(H)SiMe$_3$)$_2$], 328 (53), 288 (55), 272 (5), 256 (25), 216 (15), 194 (8), 178 (6), 147 (50), 136 (8), 103 (13).

2.2.3. 1,3-Bis(trimethylsilyl)-2-iodo-2-pyridine-1,3,2-diazaalumina-[3]ferrocenophane (*4d*)

The synthesis was carried out in the same way as for **4c**, starting from 164 mg (0.44 mmol) of fc(NSiMe$_3$)$_2$Li$_2$ (**2**), AlI_3 (180 mg, 0.44 mmol) and pyridine (0.05 mL, 0.62 mmol), to give 287 mg of a mixture containing **4d** (ca. 70%) and several unidentified side products as brown oily material. ^{1}H NMR (250.1 MHz; CD_2Cl_2; 25 °C): $\delta = -0.28$ (s, 18H, Me_3Si), 3.81, 3.98 (br) (m, m, 2H, 2H, $H^{2,2'}$, $H^{5,5'}$), 3.87 (br) (m, 4H, $H^{3,3',4,4'}$), 7.81 (br) (m, 2H, H_β), 8.25 (m, 1H, H_γ), 9.22 (br) (m, 2H, H_α). ^{1}H NMR (250.1 MHz; CD_2Cl_2; −40 °C): $\delta = -0.40$ (s, 18H, Me_3Si), 3.81, 3.95 (m, m, 2H, 2H, $H^{2,2'}$, $H^{5,5'}$), 3.83 (m, m, 2H, 2H, $H^{3,3'}$, $H^{4,4'}$), 7.80 (m, 2H, H_β), 8.25 (m, 1H, H_γ), 9.13 (m, 2H, H_α).

The products **4b**, **c**, **d** decompose slowly as solids under Ar at room temperature to green-black powders, which are insoluble in CD_2Cl_2 and inaccessible for NMR spectroscopic characterisation.

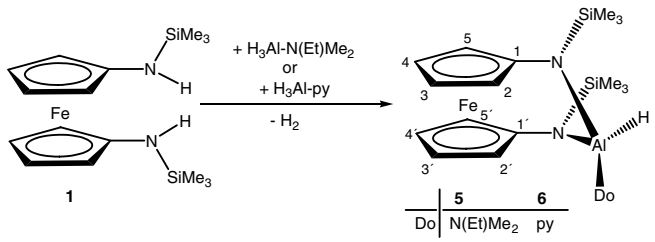
2.2.4. Reaction of the N,N′-dilithio-1,1′-bis(trimethylsilylamino)ferrocene (*2*) with AlF_3 and pyridine

When the synthesis was carried out as described for **4c**, starting from 216 mg (0.58 mmol) of fc(NSiMe$_3$)$_2$Li$_2$ (**2**), AlF_3 (49 mg, 0.58 mmol) and pyridine (0.05 mL, 0.62 mmol), a crude reaction mixture (248 mg) was obtained containing **1** (ca. 70%) and fc(NSiMe$_3$)$_2$Li$_2$-2py (ca. 30%) as a brown, oily-material. The absence of ^{19}F NMR signals indicated that an appreciable amount of soluble fluorine-containing materials was not present.

2.3. 1,3-Bis(trimethylsilyl)-2-hydro-1,3,2-diazaalumina-[3]ferrocenophane adducts (*5*) and (*6*)

2.3.1. 1,3-Bis(trimethylsilyl)-2-dimethyl(ethyl)amine-2-hydro-1,3,2-diazaalumina-[3]ferrocenophane (*5*)

A solution of 1,1′-bis(trimethylsilylamino)ferrocene (**1**) (176 mg, 0.49 mmol) in toluene (10 mL) was cooled to 0 °C, and a solution of AlH_3-N(Et)Me$_2$ (0.98 mL of a 0.5 M solution in toluene, 0.49 mmol) was added drop wise. While stirring, gas evolution was observed. The reaction mixture was stirred at 0 °C for 1 h, then allowed to reach ambient temperature and kept stirring for 20 h. Volatile materials were removed *in vacuo*, the remaining yellow-green oil was dissolved in hexane (20 mL) and centrifugated. Then, the solvent was removed *in vacuo* to give 190 mg (85%) of **5** as a yellow-orange oil. ^{1}H NMR (250.1 MHz; toluene-[d_8]; 25 °C; *J*/Hz): $\delta = 0.26$ (s, 18H, Me_3Si), 0.63 (t, 3H, CCH_3, $J = 7.3$ Hz), 2.08 (s, 6H, NCH_3), 2.70 (q, 2H, NCH_2), 3.44 (m, 2H, $H^{2,2'}$), 3.86 (m, 4H, $H^{3,3',4,4'}$), 4.00 (m, 2H, $H^{5,5'}$). IR (toluene-[d_8]) ν(Al–H) = 1818 (br) cm^{-1}.



2.3.2. 1,3-Bis(trimethylsilyl)-2-hydro-2-pyridine-1,3,2-diazaalumina-[3]ferrocenophane (*6*)

The synthesis was carried out as described for **5**, starting from 216 mg (0.60 mmol) of fc(N(H)SiMe$_3$)$_2$ (**1**) and a

solution of freshly prepared AlH_3-py [from AlH_3-$N(Et)Me_2$ (1.20 mL of a 0.5 M solution in toluene, 0.60 mmol) and pyridine (0.048 mL, 0.60 mmol) in toluene (10 mL)], to give 303 mg of a mixture containing **6** (70%) and **1** (ca. 30%). Crystallisation from CD_2Cl_2, after 2 days at −20 °C, gave orange crystals of **6** (115 mg, 41%); m.p. 170 °C (decomposition). The product decomposes slowly as a solid under Ar at room temperature to green-black powder, which is insoluble in CD_2Cl_2 and inaccessible for NMR spectroscopic characterisation. ^{1}H NMR (250.1 MHz; CD_2Cl_2; 25 °C): $\delta = 0.05$ (s, 18H, Me_3Si), 3.54 (br) (m, 4H, $H^{2,2',5,5'}$), 3.70 (m, 4H, $H^{3,3',4,4'}$), 7.74 (m, 2H, H_β), 8.13 (m, 1H, H_γ), 8.96 (d, 2H, H_α, $J = 3.5$ Hz). ^{1}H NMR (250.1 MHz; CD_2Cl_2; −60 °C): $\delta = 0.002$ (s, 18H, Me_3Si), 3.42 (br) (m, 4H, $H^{2,2',5,5'}$), 3.61 (m, 4H, $H^{3,3',4,4'}$), 3.95 (br) (s, 1H, AlH), 7.73 (m, 2H, H_β), 8.13 (m, 1H, H_γ), 8.76 (m, 2H, H_α). EI-MS (70 eV) for $C_{21}H_{32}N_3AlSi_2Fe$ (465.13): m/z (%) = 392 (1) [M^+−$SiMe_3$], 360 (100) [$fc(N(H)SiMe_3)_2]^+$, 288 (20).

2.4. 1,3-Bis(trimethylsilyl)-2-fluoro-1,3,2-diazaalumina-[3]ferrocenophane adducts (7) and (4a)

A solution of **5** (120 mg; 0.26 mmol) in toluene-[d_8] (1 mL) was added to Me_3SnF (64 mg; 0.35 mmol). The mixture was stirred for 2 h and centrifugated to separate the excess of Me_3SnF. The resulting mixture contained about 70% of the dimethyl(ethyl)amine adduct **7** together

Scheme 4.

2.5. Crystal structure determinations of the 1,3-bis(trimethylsilyl)-1,3,2-diazaalumina-[3]ferrocenophane pyridine adducts (*4a*, *4b*, *4c*, and *6*)

Details pertinent to the crystal structure determinations are listed in Table 1. Crystals of appropriate size were sealed under Ar in Lindemann capillaries. The data collections were carried out at 20 °C.

3. Results and discussion

3.1. Synthesis

The reaction of the aluminum trihalides in the presence of pyridine (py) with **2** (Scheme 2) provides a straightforward route to the chloride **4b**, bromide **4c** and iodide **4d**, whereas the formation of the fluoride **4a** was not observed. The dilithiated species **2** did not react with aluminum trifluoride, and the reaction solution contained only **1**, as a result of hydrolysis, and **2**, shown by ^{29}Si NMR, and ^{19}F

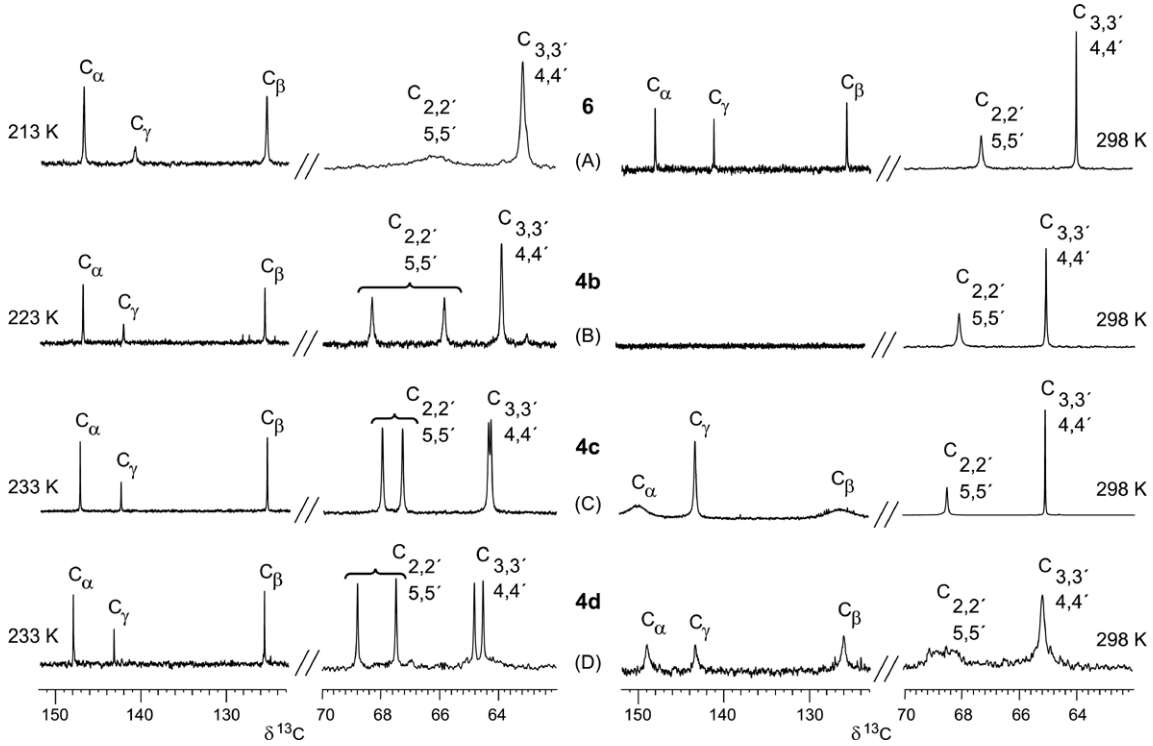

Fig. 1. Parts of the room temperature (right trace) and low temperature (left trace) 62.9 MHz $^{13}C\{^1H\}$ NMR spectra of the 1,3-bis(trimethylsilyl)-2-X-2-pyridine-1,3,2-diazaalumina-[3]ferrocenophane (**6**, **4b**, **4c**, and **4d**) (CD_2Cl_2). (A) **6** (R = H). (B) **4b** (R = Cl). (C) **4c** (R = Br). (D) **4d** (R = I).

NMR indicated the absence of any soluble aluminum fluoride.

The compounds **4b**, **c**, **d** are orange solids, extremely sensitive towards traces of moisture. Crystalline materials suitable for X-ray analysis were obtained for the chloride **4b** and the bromide **4c** (*vide infra*).

The reaction of aluminum trihydride adducts with **1** opens the most convenient way to the hydride adducts **5** and **6** (Scheme 3), of which **6** could be isolated for single crystal X-ray diffraction studies (*vide infra*). Both **5** and **6** are sensitive to moisture, appear to be very reactive, and the ease of their essentially quantitative formation is promising for further applications.

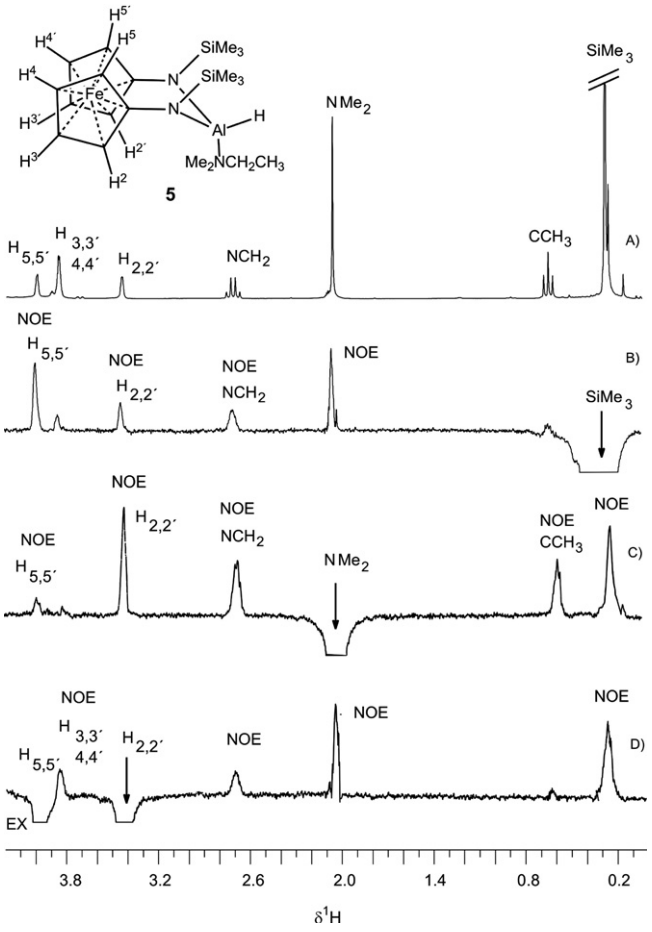

Fig. 2. 400 MHz $^{1}H\{^{1}H\}$ NOE difference spectra (gradient enhanced [27]) of **5** (10% in toluene-[d_8] at 23 °C; relaxation delay 1.5 s; mixing time 0.6 s; 30 min of spectrometer time). The irradiated resonance signals are marked by arrows; the resulting intensities arising from NOE or EXchange are marked. (A) Normal ^{1}H NMR spectrum. (B) The $NSiMe_3$-resonance was irradiated and response is shown: $H^{5,5'}$(++) and $H^{2,2'}$(+) of the cyclopentadienyl groups, NCH_2 and NMe_2 of the dimethyl(ethyl)amine ligand. (C) The NMe_2-resonance of the dimethyl(ethyl)amine ligand was irradiated and response is shown: $H^{5,5'}$(+) and $H^{2,2'}$(++) of the cyclopentadienyl groups, NCH_2CH_3 of the dimethyl(ethyl)amine ligand, and the $SiMe_3$ group. (D) The $H^{2,2'}$-resonance of the cyclopentadienyl groups was irradiated and response is shown: magnetisation transfer [25] takes place between $H^{2,2'}$ and $H^{5,5'}$, whereas NOE is observed for $H^{3,3',4,4'}$(+) of the cyclopentadienyl groups, NCH_2 and NMe_2 of the dimethyl(ethyl)amine ligand, and the $SiMe_3$ group.

The reaction of **5** with Me_3SnF in toluene-[d_8] leads to the aluminium monofluoride adduct **7** in moderate to good yields [6a,24]. The formation of some side products may arise because of reactions of the tin hydride with **5** or **7**. Pyridine displaces the amine from the adduct **7**, and the pyridine adduct **4a** is formed and crystallises from the reaction solution (see Scheme 4).

3.2. NMR spectroscopy

The NMR data given in Tables 2 and 3 and in Section 2 are in support of the proposed structures for the compounds **4**–**7**. The Fe, C^1, $C^{1'}$, *N*, *N*′, Al atoms form non-planar rings, and the ring inversion becomes slow as compared to the NMR time scale at lower temperatures for the pyridine adducts (Fig. 1), and is already slow at room temperature for the amine adduct **5** (Fig. 2). However, the structure of **5** in solution is not rigid as shown by magnetisation transfer [25] (Fig. 2D), and this is also evident from the 2D $^{13}C/^{13}C$ EXSY experiment (Fig. 3) [26]. Apparently, the bulky amine prevents fast inversion at the site of the aluminium. $^{1}H/^{1}H$ NOE difference spectra [27] indicate that the position of the pyridine or the amine $Me_2(Et)N$ is opposite to the N-$SiMe_3$ groups, as found for the solid state (*vide infra*). This is exactly the other way round when compared with **3** (Scheme 1), where the bulky *tert*-butyl group avoids close contacts with the $SiMe_3$

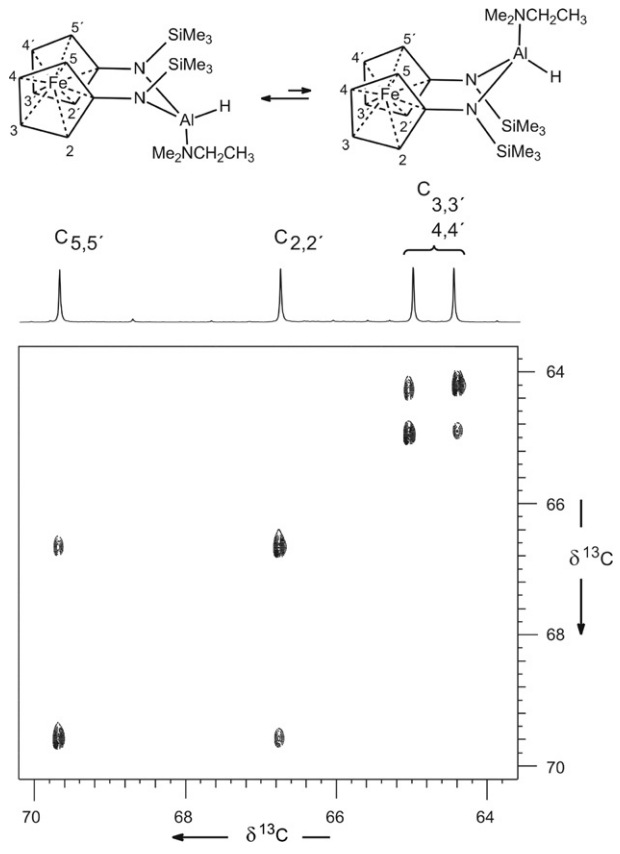

Fig. 3. ^{13}C 2D EXSY NMR spectrum [26] of compounds **5** (100.5 MHz, 10% in toluene-[d_8], at 23 °C), relaxation delay 2.0 s; mixing time 1.0 s.

groups, both in solution and in the solid state [21]. The NOE experiments, together with 2D $^{1}H/^{13}C$ shift correlations, also serve conveniently for the assignment of ^{1}H and ^{13}C NMR signals of the cyclopentadienyl groups.

Frequently, ^{1}H NMR signals of aluminum hydrides are not reported, since these signals tend to be weak and broad, and may be hidden underneath other intense signals. This is also true for **5**, whereas in the case of **6**, the signal could be observed at low temperature in the range typical of other ^{1}H(Al–H) NMR signals [5a,6b,6c]. Similarly, the ^{19}F NMR signals of **4a** and **7** are broad and fit into the range known for terminal Al–F bonds ($\delta^{19}F$ −145 to −180) [6a,24].

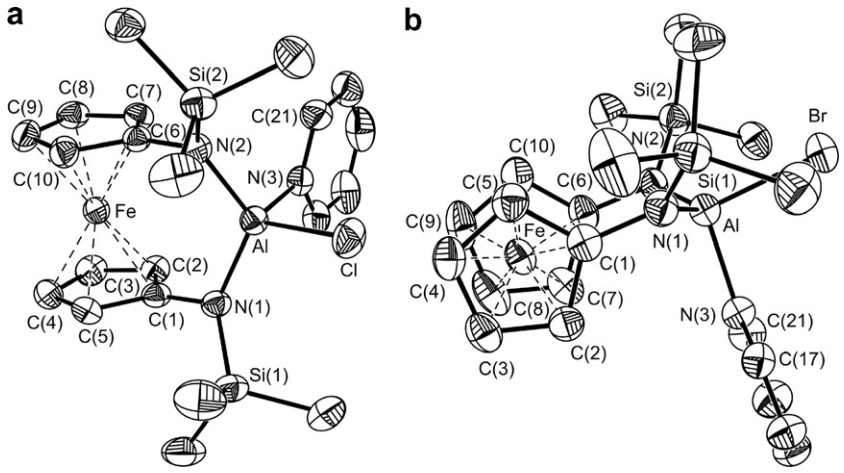

Fig. 4. Molecular structures of **4b** (a) and **4c** (b) (ORTEP plot, 40% probability, hydrogen atoms are omitted for clarity), see Table 4 for structural parameters. The molecular structures of **4a** and **6** are analogous.

[b] If the H-atom was refined without restraints, the distance Al–H is 161(4) pm.
[c] Mean deviation from plane.

3.3. X-ray crystallography

The molecular structures of the adducts **4b** and **4c** (all molecular structures of **4a**, **b**, **c** and **6** are analogous) are shown in the Fig. 4, and selected structural parameters are compiled in Table 4. Intermolecular interactions appear to be negligible. The tetrahedral surroundings of the aluminum atoms enforce non-planar arrangements in the cycles containing the atoms Al, N(1), C(1), Fe, C(6), N(2), and the pyridine ligand avoids contacts with the $SiMe_3$ groups in all cases studied here. Thus, these structures differ from that of **3** (Scheme 1), where the steric interactions pyridine/$SiMe_3$ are less repulsive than for *tert*-Bu/$SiMe_3$ groups. Expectedly, the Al–N(amino) are shorter than Al–N(pyridine) bonds. The surroundings of the amino nitrogen atoms deviate slightly from trigonal planarity as shown by the respective sum of the bond angles: 357.6°, 357.3° for **4a**, 356.9°, 358.0° for **4b**, 358.8°, 358.6° for **4c**, and 357.8°, 257.5° for **6**. Remarkably, changes in all Al–N bond lengths in the series **4a**, **b**, **c** and **6** are rather small, almost within the error limits. Reported Al–N(pyridine) bond lengths of pyridine adducts range from 186.3(4) to 203.0(4) pm [7b,7c], and it appears that steric repulsion is the major influence for extended bond lengths, as in the cases of **3** 202.7(4) pm [21], tmp_2AlBr(py) (203.0(4) pm [7b]) or tmp_2AlI(py) (202.2(3) pm [7b]).

The cyclopentadienyl rings adopt almost exactly eclipsed conformations, and the rings differ only slightly from a parallel orientation [28] which appears to be typical for these [3]ferrocenophanes [13–19,21]. In **4a**, the distances F···C(Si) (327.2, 317.8 pm) indicate for the carbon atoms being closest in space to the Al–F unit that attractive Al–F···H–C interactions [29] may have to be considered.

4. Supplementary material

CCDC 634696, 634693, 634694, and 634695 contain the supplementary crystallographic data for **4a**, **4b**, **4c**, and **6**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

New mononuclear phthalocyanines [Zn(II) **4** and Co(II) **6**] and ball-type bisphthalocyanines [Zn(II) **5** and Co(II) **7**] have been synthesized from the corresponding compound **3**, which can be obtained from the reaction of 4-nitrophthalonitrile **1** with 1a,8b-dihydronaphtho[*b*]naphthofuro[3,2-*d*]furan-7,10-diol **2**. The novel compounds have been characterized by elemental analysis, UV/Vis, IR, ^{1}H NMR and MASS spectroscopy. The electrochemical measurements show the formation of various mixed-valence oxidized and reduced species, due to intramolecular interactions between the two phthalocyanine units in the ball-type binuclear metallophthalocyanines. Detailed studies of the effect of temperature on the electronic properties of the films were investigated by dc conductivity and impedance spectroscopy techniques at temperatures between 290 K and 460 K. Thermally activated conductivity dependence on temperature was observed from the dc measurements. The ac results give a power law behavior in which the frequency exponent decreases with temperature. It was observed that the impedance spectra consist of a curved line at low temperature. These curved lines transform into a full semicircle with increasing temperature.

1. Introduction

Binuclear phthalocyanines (Pcs) have attracted great attention because of their unique spectroscopic, electrochemical and electrical properties. In this respect, binuclear Pcs linked by various kinds of bridges, i.e., lanthanoid and actinoid sandwich dimmers [1–3], covalently linked cofacial dimmers [4–6], planar homo- and hetero-dimers sharing a common aromatic ring or linked by other units [7–11] and linear dimers linked by flexible alkyl chains [12,13] have been synthesized. These dimers and multimers, especially those with rigid cofacial configurations, usually show spectroscopic electrochemical and electrical properties which differ significantly from the parent monomers. A strong interaction between the halves of the molecule is usually detected in electronic absorption and MCD spectroscopy and electrochemistry. The redox couples observed in monomeric species are usually split into two couples. It

doi:10.1016/j.poly.2007.03.047

was suggested that electron cloud overlap is important for a strong interaction.

The first synthesis of ball-type binuclear Pcs was reported in 2003 by the Zefirov group [14]. However, the studies on this type of Pc did not continue until we recently reported the synthesis, characterization and electrical, electrochemical and gas sensing properties of ball-type *t*-butylcalix-[4]arene bridged [15] and 1,1′-methylene-di-naphthalen-2-ol bridged [16] metal free and/or metallophthalocyanines. These novel compounds showed interesting mixed-valence behavior.

For a long time, binuclear Pcs have been obtained by the tetramerization of phthalonitrile (or its derivatives) with basic catalysts in a suitable solvent such as pentanol, hexanol, dimethylformamide or *o*-dichlorobenzene at 180–200 °C. Recently investigators have used new reaction techniques such as microwawe irradiation or heating of the solid phase to obtain binuclear Pcs. In this paper, in our continuing efforts, we have used the "heating of the solid phase" method for the synthesis of novel ball-type four 1a,8b-dihydronaphtho[*b*]naphthofuro-[3,2-*d*]furan-7,10-diol bridged zinc(II) and cobalt(II) phthalocyanines (Scheme 1).

Scheme 1. (i) K_2CO_3, DMSO; (ii) a: $Zn(CH_3COO)_2 \cdot 2H_2O$, 300 °C; b: $Co(CH_3COO)_2 \cdot 4H_2O$, 280 °C.

The electrical and electrochemical properties of the compounds are also presented.

2. Experimental

The starting materials **1** and **2** were synthesized by the methods described previously in the literature [17–20]. IR spectra were recorded on a Shimadzu FTIR-8300 spectrophotometer as KBr pellets. Electronic spectra were recorded on a Shimadzu UV-1601 spectrophotometer. Elemental analyses were performed by the Instrumental Analysis Laboratory of Tubitak–Ankara. ^{1}H NMR spectra were recorded in *d*-chloroform, *d*-dimethylsulfoxide and *d*-acetone with a Mercury-Vx 400 MHz instrument. Mass spectra were acquired on a Voyager-DE™ PRO MALDI-TOF mass spectrometer (Applied Biosystems, USA) equipped with a nitrogen UV-Laser operating at 337 nm. Spectra were recorded either in reflectron and linear modes with an average of 50 shots.

2.1. Synthesis

2.1.1. 4,4′-(1a,8b-Dihydronaphtho[b]naphthofuro[3,2-d]-furan-7,10-diyl)bis(oxy)diphthalonitrile (3)

A mixture of 4-nitro-1,2-dicyanobenzene **1** (0.657 g, 3.8×10^{-3} mol) and 4,4′-(1a,8b-dihydronaphtho[*b*]naphthofuro[3,2-*d*]furan-7,10-diyl)bis(oxy)diphthalonitrile **2** (0.650 g, 1.9×10^{-3} mol) in 20 mL dry dimethylsulfoxide (DMSO) was stirred at room temperature under N_2. K_2CO_3 (0.828 g, 6×10^{-3} mol) was added into the mixture over a period of 2 h. After stirring the reaction mixture for a further 24 h, the undissolved salt was removed by filtration. The reaction mixture was poured into water (100 mL) and stirred. The precipitate was filtered and washed with water. The residue was chromatographed by silica gel and eluted with CH_2Cl_2 (DCM). Yield: 1.14 g (96%). This compound is soluble in $CHCl_3$, DCM, tetrahydrofuran (THF), dimethylformamide (DMF), acetone and acetonitrile. Mp: 152 °C. IR (KBr pellet) ν_{max}/cm^{-1}: 833, 968, 1056, 1134, 1184, 1249, 1280, 1307, 1361, 1419, 1454, 1485, 1519, 1593, 1631, 2229, 3082. *Anal.* Calc. for $C_{38}H_{18}N_4O_4$: C, 76.76; H, 3.05; N, 9.42. Found: C, 76.33; H, 2.95; N, 9.83%. ^{1}H NMR (chloroform-*d*) δ, ppm: 5.4 (d, $J=5.85$ Hz 1H), 7.01 (d, $J=8.58$ Hz, 2H), 7.01 (d, $J=8.19$ Hz, 2H), 7.15 (s, 2H), 7.27 (d, $J=5.85$ Hz, 1H), 7.29 (d, $J=8.58$ Hz, 2H), 7.60 (d, $J=8.19$ Hz, 2H), 7.65 (br ds, 2H), 7.84 (d, $J=8.97$ Hz, 2H), 7.95 (d, $J=8.97$ Hz, 2H).

2.1.2. [2,10,16,24-Tetrakis(1a-hydronaphtho[b]-naphthofuro[3,2-d]-7,10-dyl-4-oxyphthalo-nitrile)-phthalocynaninatozinc(II)] (4) and [1′a,8′b-tetrakis-bis{(2′,10′,16^I,24′)-phthalocyaninatozinc(II)}dioxynaphtho-[b]-naphthofuro[3,2-d]furan-7,10-diyl] (5)

A mixture of compound **3** (0.2 g, 0.3×10^{-3} mol) and $Zn(OAc)_2\cdot2H_2O$ (0.100 g, 2.4×10^{-3} mol) was powdered in a quartz crucible and heated in a sealed glass tube for 5 min under dry N_2 atmosphere at 300 °C. After cooling to room temperature, 5 mL of DMF was added to the residue to dissolve the product. The reaction mixture was precipitated by adding water. The precipitate was filtered, multiply washed at first with hot water and then with hot ethanol in order to eliminate the unreacted starting materials, and dried *in vacuo*. Then, the crude product was washed with acetic acid, methanol, ethanol, acetonitrile and acetone for 12 h, respectively, in a soxhlet apparatus. The residue was coarsely fractionated on a silica gel column eluting with chloroform and a gradient of chloroform–THF up to 100% THF. This compound is soluble in chloroform (slightly), THF, DMF and DMSO. Mp > 350 °C. Yield of **4**: 6 mg (5%). Yield of **5**: 30 mg (15%).

Compound **4** is slightly soluble in DCM and $CHCl_3$, and soluble in THF, DMF and DMSO. Mp > 350 °C. IR (KBr pellet) ν_{max}/cm^{-1}: 835, 945, 1041, 1085, 1184, 1220, 1249, 1332, 1394, 1446, 1487, 1514, 1606, 1722, 2231, 2850, 2925, 3066. *Anal.* Calc. for $C_{152}H_{72}N_{16}O_{16}Zn$: C, 74.71; H, 2.97; N, 9.17. Found: C, 74.02; H, 3.02; N, 9.21%. ^{1}H NMR (DMSO-d_6) δ, ppm: 8.25–7.60 (m, 32H, arom.), 7.50–6.85 (m, 32H, arom.), 7.32 (m, 4H, O–CH–O), 5.80 (m, 4H, Ar–CH–Ar). MS (MALDI-TOF): *m*/*z* 2446 (M+H).

Compound **5** is soluble in THF, DMF and DMSO. Mp > 350 °C. IR (KBr pellet) ν_{max}/cm^{-1}: 834, 946, 1042, 1094, 1179, 1223, 1257, 1361, 1394, 1454, 1476, 1517, 1606, 1654, 2850, 2925, 3025. *Anal.* Calc. for $C_{152}H_{72}N_{16}O_{16}Zn_2$: C, 72.76; H, 2.89; N, 8.93. Found: C, 72.53; H, 3.08; N, 9.23%. ^{1}H NMR (DMSO-d_6) δ, ppm: 8.18–6.80 (m, 64H, arom.), 6.85 (m, 4H, O–CH–O), 5.70 (m, 4H, Ar–CH–Ar). MS (MALDI-TOF): *m*/*z* 2510 (M+H).

2.1.3. [2,10,16,24-Tetrakis(1a-hydronaphtho-[b]naphthofuro[3,2-d]-7,10-dyl-4-oxyphthalo-nitrile)-phthalocynaninatocobalt(II)] (6) and [1′a,8′btetrakis-bis{(2′,10′,16^I,24′)-phthalocyaninatocobalt(II)}-dioxynaphtho-[b]-naphthofuro[3,2-d]furan-7,10-diyl] (7)

A mixture of compound **3** (0.200 g, 0.337 mmol) and $Co(OAc)_2\cdot4H_2O$ (0.130 g, 0.522 mmol) was powdered in a quartz crucible and heated in a sealed glass tube for 5 min under dry N_2 atmosphere at 280 °C. After cooling to room temperature, the blue-green reaction product was obtained, isolated and purified with using the same procedure explained above for **4** and **5**. Yield of **6**: 5 mg (4.5%). Yield of **7**: 28 mg (14%).

Compound **6** is slightly soluble in DCM and $CHCl_3$, and is soluble in THF, DMF and DMSO. Mp > 350 °C. IR (KBr pellet) ν_{max}/cm^{-1}: 752, 956, 1053, 1090, 1179, 1228, 1253, 1361, 1453, 1476, 1517, 1610, 1628, 2231, 2850, 2925, 3059. *Anal.* Calc. for $C_{152}H_{72}N_{16}O_{16}Co$: C, 74.91; H, 2.98; N, 9.20. Found: C, 74.77; H, 2.87; N, 9.15%. MS (MALDI-TOF): *m*/*z* 2438 (M+H).

Compound **7** is soluble in chloroform (slightly), THF, DMF and DMSO. Mp > 350 °C. IR (KBr pellet) ν_{max}/

cm^{-1}: 833, 956, 1056, 1094, 1118, 1181, 1226, 1253, 1363, 1407, 1452, 1473, 1518, 1609, 1655, 2850, 2925, 3059. *Anal.* Calc. for $C_{152}H_{72}Co_2N_{16}O_{16}$: C, 73.14; H, 2.91; N, 8.98. Found: C, 73.05; H, 2.88; N, 8.73%. MS (MALDI-TOF): *m*/*z* 2496 (M+H).

2.2. Electrochemical measurements

The cyclic voltammetry (CV) and controlled potential coulometry (CPC) measurements were carried out with a Princeton Applied Research Model VersaStat II potentiostat/galvanostat controlled by an external PC and utilizing a three-electrode configuration at 25 °C. The working electrode was a Pt plate with a surface area of 0.10 cm^2. The surface of the working electrode was polished with a H_2O suspension of Al_2O_3 before each run. The last polishing was done with a particle size of 50 nm. A Pt wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode and separated from the bulk of the solution by a double bridge. The ferrocene/ferrocenium couple (Fc/Fc^+) was also used as an internal standard. Electrochemical grade tetrabutylammonium perchlorate (TBAP) in extra pure DMSO and DCM was employed as the supporting electrolyte at a concentration of 0.10 mol dm^{-3}. High purity N_2 was used for deoxygenating the solution at least 20 min prior to each run and to maintain a nitrogen blanket during the measurements. For controlled (CPC) studies, a Pt gauze working electrode (10.5 cm^2 surface area), Pt wire counter electrode, separated by a glass bridge, and a SCE as the reference electrode were used.

2.3. Electrical conductivity and impedance measurements

For the electrical characterization, an interdigital comb structure with 100 μm gap on a glass substrate was used. Thin films of the compounds were obtained by the spin-coating method. The substrate temperature was kept constant at 290 K during deposition of the materials over the electrodes. Dc conductivity and impedance spectra measurements were performed between 290 and 460 K using a Keithley 617 electrometer. Ac conductivity and impedance measurements were carried out with a Keithley 3330 LCZ meter in the frequency range 40 Hz to 10^5 Hz, in the temperature range from 290 to 460 K. Both dc and ac conductivity measurements were performed under 10^{-3} mbar in the dark. The conductivity data were recorded using an IEEE 488 data acquisition system incorporating a personal computer.

3. Results and discussion

3.1. Synthesis

The synthesis of the bisphthalodinitriles is based on the reaction of diols with an excess of compound **1** (DMF or DMSO in the presence of dry K_2CO_3 as a base, at 25 °C, 20–96 h) [17]. Our key starting material is compound **3** which can be obtained via the reaction of compound **1** and **2**, in dry DMSO in the presence of dry K_2CO_3. **4**, **5** and **6**, **7** were synthesized by heating **3** with $Zn(OAc)_2 \cdot 2H_2O$ and $Co(OAc)_2 \cdot 4H_2O$, respectively, in a sealed tube under a N_2 atmosphere (Scheme 1).

Elemental analysis, IR, ^{1}H NMR, MASS and UV/Vis spectra confirm the proposed structures of the compounds. Compounds **3**, **4** and **6** show a sharp intense CN vibration band at 2229–2231 cm^{-1} in the IR spectra. The spectra of compounds **3**–**7** showed Ar–O–Ar peaks at 1220–1285 cm^{-1}, C=C (in the phenyl and naphthalene rings) peaks at 1560–1655 cm^{-1}, C=N peaks at 1670–1720 cm^{-1}, aromatic CH peaks at 3060–3070 cm^{-1} and aliphatic CH peaks at 2840–2945 cm^{-1}. The ^{1}H NMR spectra were also in good correlation with the structure of the synthesized compounds. In the ^{1}H NMR spectrum of compound **3**, which was taken in chloroform-*d*, the phenyl protons appeared at 7.65 (br s), 7.60 (d) and 7.13 (br d) ppm, naphthalene protons at 7.95 (d), 7.84 (d), 7.29 (d), 7.15 (s) and 7.01 (br d) ppm, and CH protons at 7.27 (d) and 5.40 (d) ppm. In addition, in the ^{1}H NMR spectra of **4** and **5**, which were taken in DMSO-d_6, the aromatic protons appeared in the range 8.25–6.80 (m) ppm and the aliphatic CH peaks 5.70–5.80 (m) ppm.

The UV–Vis spectra of **4**–**7** in DMF showed characteristic absorptions between 610 and 710 nm in the Q-band region. The Q-band observed for the compounds was attributed to the $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the Pc ring. The other bands (B) in the UV region at 300–350 nm were observed due to transitions from the deeper π levels to the LUMO (Table 1).

An α-cyano-4-hydroxycinnamic acid (ACCA) (10 mg/mL in acetonitrile–water mixture, 1:1 v/v) matrix for **6** and 2,5-dihydroxy benzoic acid (DHB) (20 mg/mL acetonitrile) MALDI matrices were prepared. MALDI samples were prepared by mixing the complex (2 mg/mL in tetrahydrofuran for **6** and **7**, and in dichloromethane for **4** and **5**) with the matrix solution (1:20 v/v) in a 0.5 mL eppendorf® micro tube. Finally 1 μL of this mixture was deposited on

the sample plate, dried at room temperature and then analyzed.

3.2. Electrochemistry

The redox properties of the complexes were examined by cyclic voltammetry, differential pulse voltammetry and controlled potential coulometry in DMSO/TBAP. A summary of the relevant electrochemical data is given in Table 2. Typical voltammograms for the mononuclear metallophthalocyanines [Zn(II)Pc(−2) **4**, Co(II)Pc(−2) **6**] and ball-type dinuclear phthalocyanines {[Zn(II)Pc(−2)]$_2$ **5**, [Co(II)Pc(−2)]$_2$ **7**} are shown in Figs. 1 and 2. The CPC studies showed that all the redox processes for the complexes involve the transfer of one electron.

Complex **4** displayed three quasi-reversible reduction waves at $E_{1/2} = -0.69$, $E_{1/2} = -1.00$ and $E_{1/2} = -1.35$ V vs. SCE, with considerably high anodic to cathodic peak separations, and a nearly reversible oxidation peak with a relatively low peak separation, Fig. 1A. These phthalocyanine ring-based redox processes were examined as a function of potential scan rate in order to determine the mode of mass transport. The peak currents for the processes R1, R2, R3 and O1 increased in direct proportion to the square root of the scan rate between 0.025 and 0.500 V/s, thus suggesting that the relevant reactions are controlled by diffusion.These redox processes are probably ligand based since zinc is not redox active in phthalocyanine complexes. The redox potentials measured for **4** are consistent with the general redox characteristics reported previously for similar Pcs [21].

The voltammogram for **5** at 0.100 V s^{-1} is shown in Fig. 1B. It appears that characteristic Pc(−2)/Pc(−3) redox process of monophthalocyanines is not well-split due to

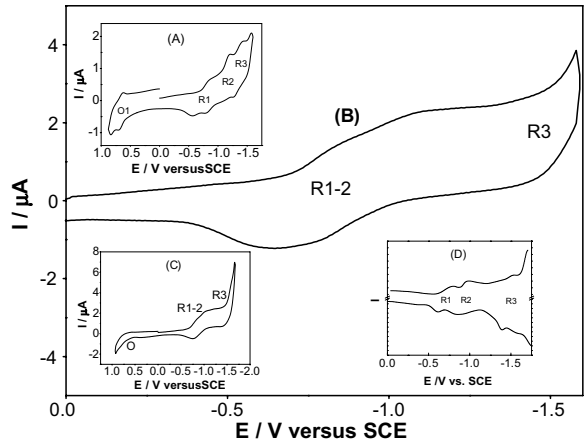

Fig. 1. Voltammograms of **4** and **5** in DMSO/TBAP. A: CV of **4** at 0.100 V s^{-1}. B: CV of **5** at 0.100 V s^{-1}. C: CV of **5** at 0.010 V s^{-1}. D: DPV of **5** at 0.100 V s^{-1}.

weak interactions between the two cofacial phthalocyanine rings in **5**, and thus a rounded-shaped voltammogram is observed. The redox processes of this complex are better defined in the voltammogram recorded at 0.010 V s^{-1}, Fig. 1C. Unfortunately, the oxidation process/processes are still ill-defined. However, the differential pulse voltammogram of the complex enabled us to detect the splitting of the first reduction process clearly, Fig. 1D. The observed redox potentials suggest that the mixed-valence splitting energy for the Pc(−2)/Pc(−3) process in **5** (0.22 V) is lower as compared with that reported recently (0.43 V) for ball-type four 1,1′-methylenedinaphthalen-2-ol bridged metallophthalocyanine, [Zn(II)Pc(−2)]$_2$ [16]. This provides additional support for relatively weak interactions between the phthalocyanine rings in **5**, and is consistent with the

Table 2
The electrochemical data for **1**–**4** in DMSO[a]

Complex	Redox processes		$E_{1/2}$ (V)	ΔE_p (V)	ΔE (V)	ΔE_s (V)
4	$[Zn(II)Pc(-1)]^+/Zn(II)Pc(-2)$	O1	0.66	0.06	1.35

	$[Zn(II)Pc(-3)]_2^{2-}/[Zn(II)Pc(-3)\cdot Pc(-4)]^{3-}$	R3	−1.46[b]	0.12[b]		
7	$[Co(II)Pc(-2)\cdot Co(III)Pc(-2)]^+/[Co(II)Pc(-2)]_2$	O1	0.50	0.08	0.86	
	$[Co(II)Pc(-2)]_2/[Co(II)Pc(-2)\cdot Co(I)Pc(-2)]^-$	R1	−0.36	0.20		0.39
	$[Co(II)Pc(-2)\cdot Co(I)Pc(-2)]^-/[Co(I)Pc(-2)]_2^{2-}$	R2	−0.75	0.34		
	$[Co(I)Pc(-2)]_2^{2-}/[Co(I)Pc(-2)\cdot Co(I)Pc(-3)]^{3-}$	R3	−1.34	0.08		

[a] Half-wave potentials in DMSO versus the Fc/Fc$^+$ couple correspond approximately with the above **4**–**7** data minus 0.50 V. $E_{1/2}$ values were measured by cyclic voltammetry [$E_{1/2} = (E_{pa} + E_{pc})/2$. The peak separation values ($\Delta E_p = E_{pa} - E_{pc}$) are reported at 0.100 V s^{-1}. ΔE is the potential difference between the first oxidation and first reduction potentials. It represents the HOMO–LUMO gap for **4** and **5**, but the charge transfer transition for **6** and **7** involving redox-active metal centers. ΔE_s indicates the mixed-valence splitting energy for the relevant split redox couple.

[b] Measured by differential pulse voltammetry.

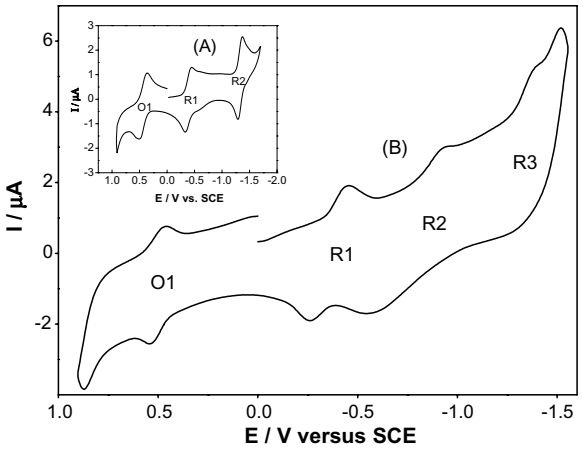

Fig. 2. Cyclic voltammograms of **6** (A) and **7** (B) at $0.100\ \mathrm{V\ s^{-1}}$ in DMSO/TBAP.

difference in the bridges in **5** and the recently reported [Zn(II)Pc(−2)]$_2$. It is expected that the distance between the cofacial phthalocyanine rings is higher in **5** than that in [Zn(II)Pc(−2)]$_2$.

Voltammetric behavior of **6** is different from that of **4**, in terms of redox potentials. It indicates two well-defined one-electron reduction processes at $E_{1/2} = -0.39$ and $E_{1/2} = -0.67$ V versus SCE, and a one-electron oxidation process at $E_{1/2} = 0.43$ V versus SCE, Fig. 2A. Some metallophthalocyanines vary in their electrochemical behavior according to their environment, i.e., the oxidation of Co(II)Pc(−2) can lead to [Co(III)Pc(−2)]$^+$ or [Co(II)Pc(−1)]$^+$ depending on whether there are any available suitable coordinating species that would stabilize the Co(II) center [21]. Such electrochemistry, especially of Co(II)Pc(−2) and Fe(II)Pc(−2) is split into two sections, that referring to donor solvents and that referring to non-donor solvents. The main difference lies in whether the metal or the ring is oxidized first. Donor solvents strongly favor Co(III)Pc(−2) by coordinating along the axis to form six coordinate species. If such donor solvents are absent, then oxidation to Co(III) is inhibited and ring oxidation occurs first. Thus, the first oxidation and the first reduction processes of **6** are probably metal based and correspond to Co(II)Pc(−2)/[Co(III)Pc(−2)]$^+$ and Co(II)Pc(−2)/[Co(I)Pc(−2)]$^-$, respectively,while the second reduction is ring based, since the voltammetric measurements were carried out in DMSO/TBAP.

The ball-type **7** displays three one-electron quasi-reversible reduction couples and a reversible one-electron oxidation couple within the potential limits of the DMSO/TBAP medium, Fig. 2B. A comparison of the first two reduction potentials of **7** with those of **6** clearly suggests the formation of mixed valence species. The difference between the first and second reduction potentials of **7** is 0.39 V, whilst it is 0.92 V for **6**. The two one-electron reduction couples can be attributed to the stepwise reduction of the two Co(II) centers in **7**, and thus to the formation of mixed valence [Co(II)Pc(−2) · Co(I)Pc(−2)]$^-$ species in the first step and doubly oxidized [Co(I)Pc(−2)]$_2^{2-}$ species in the second step. The splitting observed for the Co(II)/Co(I) process in this study may be attributed to the interactions between the two cobalt centers, which are probably held in close proximity by the cofacial ligand geometry, resulting in overlap of their d_{z^2} orbitals along the cobalt–cobalt axis. The third reduction and the first oxidation couples can be assigned to the formation of [Co(I)Pc(−2) · Co(I)Pc(−3)]$^{3-}$ and [Co(II)Pc(−2) · Co(III)Pc(−2)]$^+$ respectively, since all redox couples involve the transfer of one electron. The formation of a fully reduced ligand and a fully oxidized metal species could not be observed. These processes appear to be out of the available solvent/electrolyte limited potential range. The splitting of metal or phthalocyanine based redox processes as a result of the interaction between the cofacial phthalocyanine units has also been reported recently for ball-type four 1,1′-methylenedinaphthalen-2-ol bridged [Co(II)Pc(−2)]$_2$ [16]. The observed redox potentials suggest that the mixed-valence splitting energy, ΔE_s, for the Co(II)/Co(I) process in **7** (0.39 V) is smaller as compared with that reported recently for ball-type four 1,1′-methylenedinaphthalen-2-ol bridged [Co(II)Pc(−2)]$_2$ (0.44 V). This implies relatively weak interactions between the phthalocyanine rings in **7**, and is consistent with the difference between the bridges in **7** and the recently reported [Co(II)Pc(−2)]$_2$. It may be concluded that the distance between the cofacial phthalocyanine rings or metal centers in **7** is higher than that in [Co(II)Pc(−2)]$_2$. Moreover, it appears that Co(II)/Co(I) mixed-valence species in **7** are more stable than the Pc(−2)/Pc(−3) mixed-valence species in **5**.

3.3. Electrical conductivity and impedance spectroscopy

The temperature dependent dc behavior of the films was determined from the slope of the current–voltage (*I–V*) measurements by using the following relation:

$$\sigma_{dc} = \frac{I}{V}\frac{d}{(2n-1)l \cdot h}$$

where I is the measured current, V is the bias voltage, d is the electrode spacing, n is the number of electrode finger pairs, l is the overlap length of the electrode fingers and h is the thickness of the electrodes. A linear *I–V* behavior was found in the voltage range of −1 V to 1 V, indicating no rectifying properties. Well defined straight lines were obtained from Arrhenius plots (logarithms of dc conductivity versus inverse temperature). This linear temperature dependence of the dc conductivity suggest the presence of only one conduction mechanism, assuming that the dominant levels are the conduction and valence bands in the whole temperature range for the films of **4**–**7**. The observed electrical conductivity values at room temperature for **4**–**7** are 2.7×10^{-12}, 5.1×10^{-12}, 4.2×10^{-12} and 1.6×10^{-12} S/cm, respectively. The order of dc conductivities observed for these compounds are **5** > **6** > **4** > **7** for all temperatures investigated. The value of the activation energy was derived

from the slope of the $\log \sigma_{dc}$ vs. $1/T$ graph, and is 0.67 eV for **4**, 0.75 eV for **5**, 0.83 eV for **6** and 0.55 eV for **7**.

The ac conductivity and impedance spectrum measurements were performed in the temperature range 290–460 K and for frequencies between 40 and 10^5 Hz. Fig. 3 shows the frequency dependence of the measured ac conductivity at 373 K for films of **4**–**7**. The figure indicates the strong conductivity dependence on frequency at around room temperature, with weaker frequency dependence at high temperatures for the films. It can be seen from Fig. 3 that the ac conductivity increases with frequency. The frequency dependence of the conductivity can be represented by the universal power law for all compounds

$$\sigma_{ac} = A\omega^s \quad (1)$$

where ω is the angular frequency, A and the frequency exponent, s, are material dependent constants. This type of frequency dependent ac conduction has been explained on the basis of two distinct mechanisms for carrier conduction. One of them is the Quantum Mechanical Tunelling model (QMT). According to this model, the conduction occurs by means of thermally assisted Quantum Mechanical Tunelling. The other model, which is also known as the Correlated Barrier Hopping (CBH) model, is based on the concept of charged defects and in this method bipolarons hop between two charged defect states D^+ and D^- over the barrier separating them, rather than tunneling through the barrier. In these two models, the frequency exponent s is found to have two different trends with temperature and frequency [22]. Our calculations showed that s is definitely a function of temperature for all compounds and shows a general tendency to increase with decreasing temperature. This is in agreement with the prediction of the CBH model. The decrease in s with temperature is in contradiction with the QMT model.

To ensure complete electrical properties of the compounds, the impedance spectroscopy technique was used in the frequency range 40–10^5 Hz. Fig. 4 shows the temperature dependence of the real part of the impedance, $Z(\omega) = R(\omega) + iX(\omega)$, at indicated frequencies for compound **5**. The observed $R(T)$ reveals that there is an obviously different tendency for different ranges of temperature. Namely, over the temperature range from 290 K to the critical temperature there appears a positive temperature coefficient (PTC), and a negative temperature coefficient (NTC) is seen above this temperature. The crossover occurs between 375 and 411 K. It is clear from Fig. 4 that in the transition region from PTC to NTC, there is a peak of $R(T)$. At a frequency of 2 kHz, it is clearly found that a peak of $R(T)$ displays at about 411 K, which is considered as a switching point from PTC to NTC. This peak weakens slowly and shifts to the low temperature region with increasing frequency. On the other hand, it was found from the analysis of the temperature dependence of the imaginary part of the impedance that $X(T)$ displays a negative temperature coefficient for all frequencies. Similar results of the impedance spectra were obtained for all temperatures investigated. The measured impedance curves are composed of a not fulfilled quasi-vertical line at low

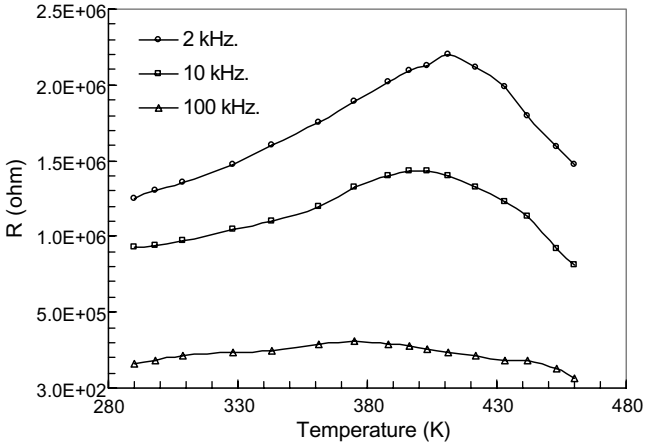

Fig. 4. Temperature dependence of the real part of the impedance for compound **5**.

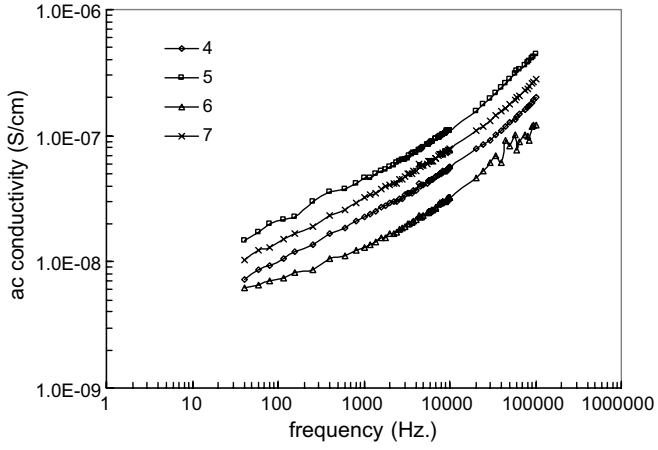

Fig. 3. Frequency dependence of the ac conductivity at 373 K for the films of **4**–**7**.

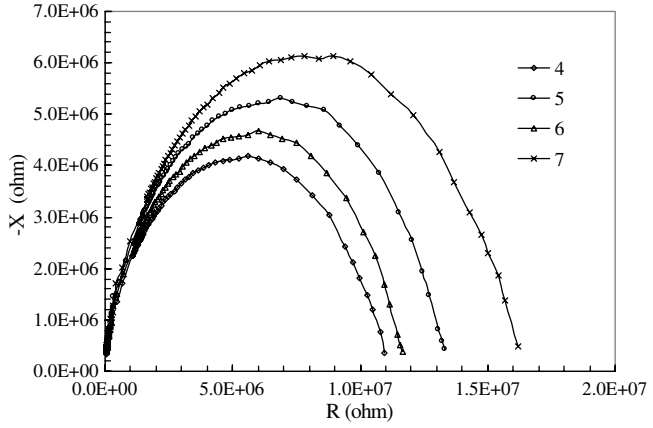

Fig. 5. Impedance spectra of the compounds at 400 K.

temperatures, suggesting pure capacitive behavior. On the complex plane plot at high temperatures, only a depressed semicircle with different radii were observed, Fig. 5, for compounds **4**–**7** at higher temperatures, indicating deviation from the Debye dispersion relation. In the case of a depressed semicircle in the impedance spectra, the relaxation time is considered as a distribution of values, rather than a single relaxation time.

molar ratios of diamine and carbonyl compounds is not the only determining factor for mono-condensation or di-condensation of such Schiff bases. However, an explanation for such hydrolytic behaviour is still lacking.

In the present paper, we report the synthesis, structural features and spectroscopic characterization of some new complexes of Ni(II) perchlorate and Ni(II) thiocyanate with neutral mono-Schiff bases or di-Schiff bases derived from the condensation of 1,2-propanediamine or 1,3-propanediamine with pyridine-2-carboxaldehyde or 2-acetylpyridine. Here, we observe that the formation of tetradentate or tridentate ligands is directed by the counter anions. We attempt to rationalise the syntheses in the light of anion modulation of cation templating effect. Although, templated reactions are known for many years, the use of anions as templates is still a relatively young [10] and to our knowledge, there is no report where an anion directed cation templating effect has been taken into account to provide an explanation for the synthesis of complexes of tridentate and tetradentate Schiff bases.

2. Experimental

All chemicals were of reagent grade and used without further purification.

Caution!!! Although no problems were encountered in this work, perchlorate salts containing organic ligands are potentially explosive. Only a small amount of the material should be prepared and they should be handled with care.

2.1. Preparations

2.1.1. Synthesis of ligands

Two sets of ligands, set-1 and set-2 were prepared by refluxing the respective diamine (1,3-diaminopropane or 1,2-diaminopropane) (10 mmol) with 2-acetylpyridine or pyridine-2-carboxaldehyde (10 mmol for set-1 and 20 mmol for set-2) in methanol solution (20 cm^3) for ca. 3 h. The ligands were not isolated. The methanol solutions were used for the syntheses of the complexes.

2.1.2. Synthesis of the complexes $[Ni(L^1)_2](ClO_4)_2$ (**1**) {L^1 = N^1-(1-pyridin-2-yl-ethylidine)-propane-1,3-diamine}, $[Ni(L^2)_2](ClO_4)_2$ (**2**) {L^2 = N^1-pyridine-2-ylmethylene-propane-1,3-diamine} and $[Ni(L^3)_2](ClO_4)_2$ (**3**) {L^3 = N^1-(1-pyridine-2-yl-ethylidine)-propane-1,2-diamine}

To prepare complexes **1**–**3**, a methanol solution (20 cm^3) of Ni(II) perchlorate hexahydrate (5 mmol, 1.825 g) was added to the methanol solution (10 mmol) of the respective set-1 ligands (1,3-diaminopropane and 2-acetylpyridine for **1**; 1,3-diaminopropane and pyridine-2-aldehyde for **2**; 1,2-diaminopropane and 2-acetylpyridine for **3**) and refluxed for 1 h. Orange red precipitate was separated in each case on cooling the mixture and was collected by filtration. Diffraction quality single crystals were obtained after a few days by slow evaporation of an orange acetonitrile solution of compound **1** and **3** in open atmosphere, but all efforts to grow suitable single crystals of **2** failed.

Complex **1** (Yield: 2.14 g, 70%). *Anal.* Calc. for $C_{20}H_{30}Cl_2N_6NiO_8$: C, 39.25; H, 4.94; N, 13.73; Ni, 9.59. 2.1.3. Synthesis of the complexes $[Ni(L^4)](SCN)_2$ (**4**) {L^4 = N,N′-bis-(1-pyridine-2-yl-ethylidine)-propane-1,3-diamine}, $[Ni(L^5)](SCN)_2$ (**5**) {L^5 = N,N′-bis(pyridine-2-ylmethyline)-propane-1,3-diamine} and $[Ni(L^6)](SCN)_2$ (**6**) {L^6 = N,N′-bis-(1-pyridine-2-yl-ethylidine)-propane-1,2-diamine}

A methanol solution (20 cm^3) of nickel thiocyanate tetrahydrate (10 mmol, 2.47 g) was added to the methanol solution (10 mmol) of respective set-2 ligands (1,3-diaminopropane and 2-acetylpyridine for **4**; 1,3-diaminopropane and pyridine-2-aldehyde for **5**; 1,2-diaminopropane and 2-acetylpyridine for **6**) and refluxed for 2 h. Pale yellowish green crystals were separated in each case on cooling the mixture and were collected by filtration. Complexes **4** and **5** were re-crystallised from methanol solution to obtain needle shaped greenish yellow single crystals suitable for X-ray diffraction. No suitable single crystals could be obtained for complex **6**.

Complex **4** (Yield: 2.96 g, 65%). *Anal.* Calc. for $C_{19}H_{20}N_6NiS_2$: C, 50.13; H, 4.43; N, 18.46; Ni, 12.89. Found: C, 50.2 ; H, 4.7; N,17.9; Ni, 11.9%; UV–Vis, λ_{max} (nm), (ε_{max} ($dm^3\,mol^{-1}\,cm^{-1}$)) (acetonitrile), 505 (118), 795 (129). Magnetic moment, $\mu_{eff} = 3.1$ BM.

Complex **5** (Yield: 3.16 g, 74%). *Anal.* Calc. for $C_{17}H_{16}N_6NiS_2$: C, 47.8; H, 3.78; N, 19.67; Ni, 13.74. Found: C, 47.6; H, 4.1; N, 19.5; Ni, 13.9%; UV–Vis, λ_{max} (nm), (ε_{max} ($dm^3\,mol^{-1}\,cm^{-1}$)) (acetonitrile), 501 (198), 872 (178). Magnetic moment, $\mu_{eff} = 3.1$ BM.

Complex **6** (Yield: 2.50 g, 55%). *Anal.* Calc. for $C_{19}H_{20}N_6NiS_2$: C, 50.13; H, 4.43; N, 18.46; Ni, 12.89. Found: C, 50.2 ; H, 4.7; N,18.4; Ni, 13.1%; UV–Vis, λ_{max} (nm), (ε_{max} ($dm^3\,mol^{-1}\,cm^{-1}$)) (acetonitrile), 514 (164), 881 (213). Magnetic moment, $\mu_{eff} = 3.1$ BM.

2.2. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 240C elemental analyzer. The nickel content in all the complexes was estimated

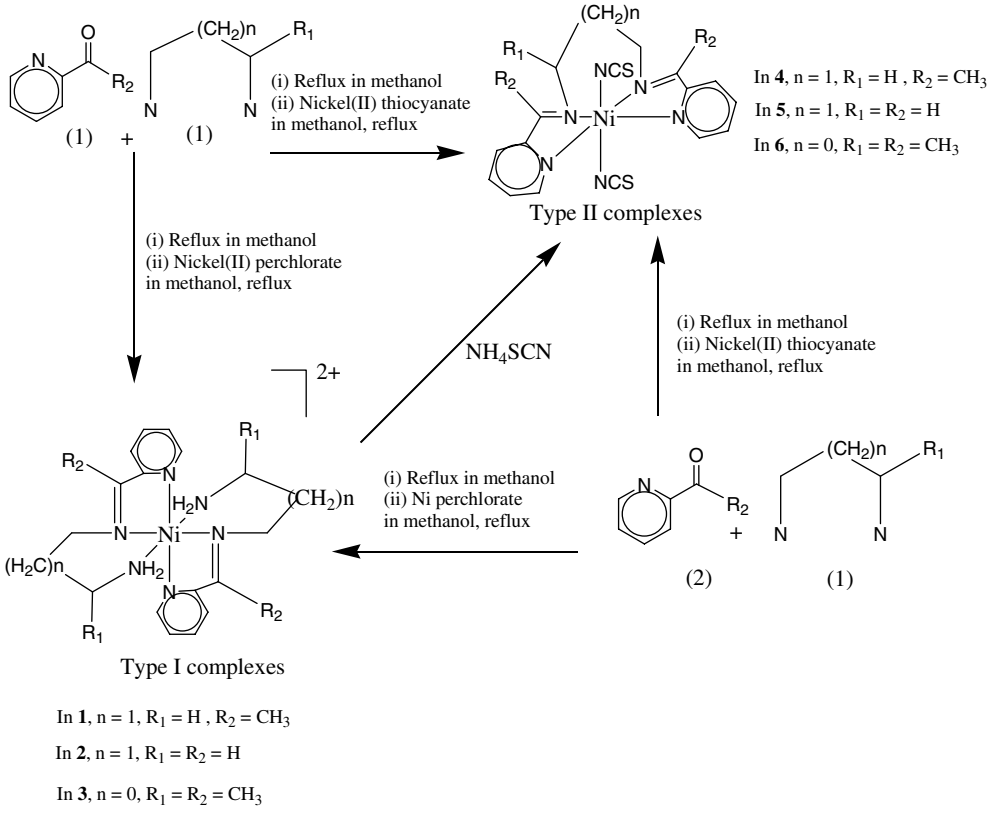
magnetometer, model 155 at room temperature and diamagnetic corrections were made using Pascal's constants. Electrochemical measurements were performed under a dry nitrogen atmosphere in a three-electrode configuration using Pt disc working electrode, Pt auxiliary electrode and standard calomel reference electrode on a PAR Versastat-2 electrochemistry system in this work and were uncorrected for junction contribution. The value for the ferrocenium–ferrocene couple under our conditions is 0.42 V.



2.3. X-ray crystallography

Crystal data are given in Tables 1 and 2. Intensity data were measured at 150 K using the Oxford X-Calibur CCD System with Mo Kα radiation. The crystals were positioned at 50 mm from the CCD. 321 frames were measured with a counting time of 3 s. Data analyses were carried out with the CRYSALIS program [11]. The structures were solved using direct methods with the SHELX97 program [12]. The non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. Absorption corrections were carried out using the ABSPACK program [13]. The structures were refined on F^2 using SHELX97 [12]. The R value of **5** is rather high because of the poor quality of the crystals. In **5**, all four perchlorates were disordered and two sets of oxygen tetrahedra were refined with occupancies of x and $1-x$ with $x = 0.62(1)$, $0.60(1)$, $0.58(1)$, $0.57(1)$, respectively. Also one of the carbon atoms in one of the two independent cations was disordered and two sets of positions were refined similarly with x converging to 0.51(1).

3. Results and discussion

3.1. Syntheses

Two sets of ligands (Set-1: L^1, L^2 and L^3 and Set-2: L^4, L^5 and L^6) have been employed for the synthesis of complexes with Ni(II) perchlorate and Ni(II) thiocyanate (Scheme 1). For the set-1 and set-2 ligands, the respective diamine and carbonyl compounds were mixed in 1:1 and 1:2 ratios, respectively in methanol and refluxed for 3 h. The ligands were not isolated and the methanol solutions were used for the synthesis of complexes. When the methanol solution of any of the set-1 ligands is added to methanol solution of Ni(II) perchlorate bis-complexes (type-1; **1**–**3**) of the respective tridentate ligands are produced in high yield. Similarly, set-2 ligands yield type-2 complexes of tetradentate di-Schiff base ligands; **4**–**6**, when methanol solution of Ni(II) thiocyanate is added. From these results one may assume that the diamine:carbonyl compound ratio is the only important factor to determine the nature of the products formed. In fact, during the synthesis of Cu(II) complexes of such ligands, we isolated the

Scheme 1.

complexes of mono- and di-Schiff bases simply by changing the diamine carbonyl compound ratios [14,6c]. However, in the present systems when we add set-1 ligands to methanol solution of $Ni(SCN)_2$ we do not obtain any type-1 complex; type-2 compounds are the sole products. Similarly, set-2 ligands on addition to methanol solution of Ni(II) perchlorate yield exclusively type-1 complexes. Thus, it is obvious that the nature of Schiff bases present in the complexes does not depend upon the ratios of the diamine:carbonyl compounds (set-1 or set-2) used for their preparation; instead the counter anions present in the Ni(II) salt dictate their composition. Another interesting observation is that when a methanol solution of ammonium thiocyanate is added to the solution of type 1 complexes (2:1 molar ratio), they transform into type-2 complexes i.e. complexes of mono-Schiff base transforms into di-Schiff base complexes in presence of thiocyanate confirming the importance of anion on the type of Schiff base complexes formed.

The formation of the Schiff base complexes can be rationalised in the light of templating effect of Ni(II) modulated by the counter anions. A templating agent can be said to contain the required information to organize a collection of building blocks so that they can be linked together in a specific manner [10]. The nitrogen donor ligands usually form octahedral Ni(II) complexes. In perchlorate salts, Ni(II) prefers to be coordinated with two tridentate ligands to satisfy its six coordination sites leaving the weakly coordinating perchlorate as counter ion. On the other hand, the thiocyanate ions that have similar crystal field stabilization energy as the Schiff base occupy two coordination sites leaving the other four sites to be coordinated by the Schiff base and that can be achieved most efficiently by a tetradentate Schiff base ligand. The driving force for the formation of tetradentate Schiff base in presence of Ni(II) and thiocyanate is also obvious when addition of thiocyanate ion to complexes **1**, **2** or **3** transforms them to **4**, **5** or **6**, respectively. The lower solubility of **4**, **5** or **6** compare to **1**, **2**, **3** in methanol seems also contribute positively in this transformation.

However, during the synthesis of Cu(II) complexes, we observed that the ratio of carbonyl compound and diamine was important for the formation of complexes of tridentate or tetradentate Schiff bases as mentioned earlier [14,6c]. When the ratio was 1:1, complexes of tridentate and when 1:2, complexes of tetradentate Schiff bases were formed irrespective of the nature of the anions present. The apparent anomaly may be rationalized considering the active Jahn–Teller effect present in Cu(II) that makes its coordination number and geometry much more flexible.

3.2. Description of the structures

3.2.1. Complex *1*

The structure of **1** together with the atomic numbering scheme is shown in Fig. 1. The structure consists of discrete $[NiL^1_2]^{2+}$ cations together with perchlorate anions. There

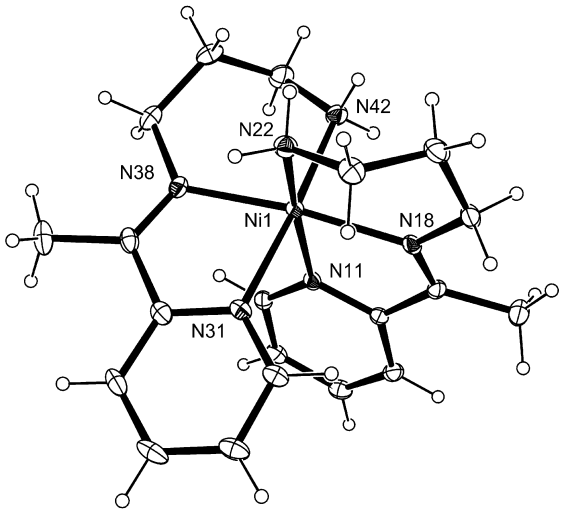


Fig. 1. The structure of one of the $[NiL^1_2]^{2+}$ independent cations in **1**, ellipsoids at 25% probability. Only the coordinating atoms along with central metal are labelled for clarity. The second molecule in the asymmetric unit has an equivalent geometry.

are two cations in the asymmetric unit with equivalent geometries, together with four perchlorate anions, one of which is shown in Fig. 1. The metal atoms are in six-coordinate octahedral environments being bonded to the two tridentate ligands which occupy mer positions. The Ni(1)–N bond lengths are all equivalent ranging from 2.083(2) to 2.110(2) Å. Selected bond lengths and bond angles are given in Table 2. The conformations of the six membered saturated rings of both the molecules present in the asymmetric unit are intermediate between boat and twist boat.

There are eight available H atoms on the four NH_2 groups (N22, N42 in molecule 1 and N62, N82 in molecule 2) for H-bond formation. Amongst them, H42b, attached to N42 in molecule 1 is involved in a strong H-bond with symmetry related $(x-1/2,-y+1/2,-z)$ perchlorate oxygen ($O33^c$). Another O atom of the same perchlorate ($O34^c$) forms a relatively weak H bond with H62b (N62) of molecule 2. H62a and H82a form H bonds with O41 and O43 respectively, whereas H42a, H22a, H22b and H82b are involved in H bonding with symmetry related perchlorate oxygen atoms $O11^a$ $(-x+1/2,y-1/2,z)$, $O12^a$ $(-x+1/2,y-1/2,z)$, $O21^b$ $(x-1/2,y,-z+1/2)$ and $O32^d$ $(-x+2,-y,-z)$, respectively (Fig. 2). The details of hydrogen bonds are given in Table 4.

3.2.2. Complex *3*

The structure of **3** contains discrete $[NiL^3_2]^{2+}$ cations together with perchlorate anions. There are two cations with equivalent geometries, one of which is shown in Figure S1 (Supplementary material), together with four anions in the asymmetric unit. Selected bond lengths and bond angles are given in Table 2. The conformations of the five membered saturated rings of both the molecules present in

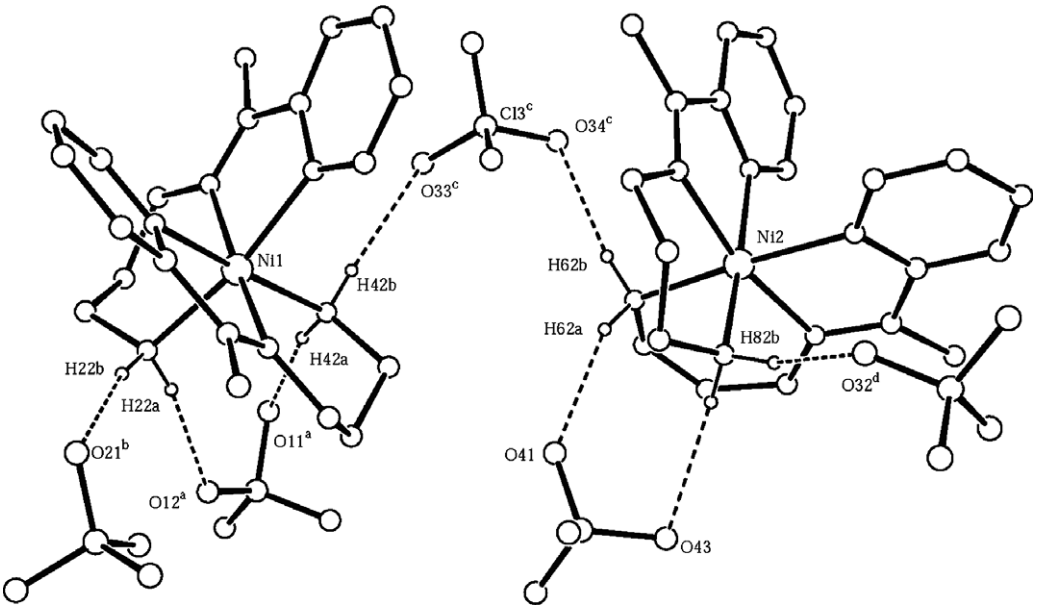

Fig. 2. The packing of **1** showing how the two independent cations are linked by hydrogen bonds to bridging perchlorate anions.

the asymmetric unit are intermediate between boat and twist boat.

The metal atoms are bonded to two tridentate ligands in the mer conformation and the structure is therefore similar to **1**. This environment of the metal atom is more distorted from octahedral than in **1**, presumably because there are only two carbon atoms between the donor nitrogen atoms N(18) and N(21) and also N(38) and N(41) thus forming two five-membered chelate rings compared to three carbon atoms between the donor nitrogen atoms N(18) and N(22) and also N(38) and N(42) which form six-membered chelate rings in **1**. The geometries of the two cations are compared in Table 3 and one obvious difference is that the chelating angles in **3** average to 81° compared to 95° in **1**. Also the bond lengths to the imine nitrogens N(18) and N(38) are much shorter in **3** than in **1** averaging at 2.016 Å compared to 2.091 Å. It would appear therefore that the lengthening of these bonds in **1** is due to the steric strain of the extra carbon atom creating the six-member chelate ring. The Ni–N distances to the NH_2 groups in **3** are slightly longer (average 2.132 Å) compared to the analogous distances in **1** (average 2.094 Å). However the distances to the pyridine nitrogen atom N(11) are equivalent.

The hydrogen bond pattern in the structure is complicated because of the disorder in one of the cations and in all four perchlorates. Because of the former disorder, there are two sets of alternate positions for the two hydrogens bonded to N21, namely H21a, H21b and H21c and H21d and because of the anion disorder there are alternate hydrogen bonds for most of the amines. Details are pro-

Note that because of the disorder in the perchlorates there are two alternate positions for each perchlorate oxygen atom and therefore for each hydrogen bond.
(Symmetry transformation: [a] $= -x+1, -y+1, -z+1$; [b] $= x+1/2, y, -z+3/2$). D, donor; H, hydrogen; A, acceptor.
[A] In this case only, the alternative oxygen atom does not form a hydrogen bond.

vided in Table 5 and illustrated in Fig. 3. Again the hydrogen bonds between the cations and anions allow the perchlorates to bridge between the cations.

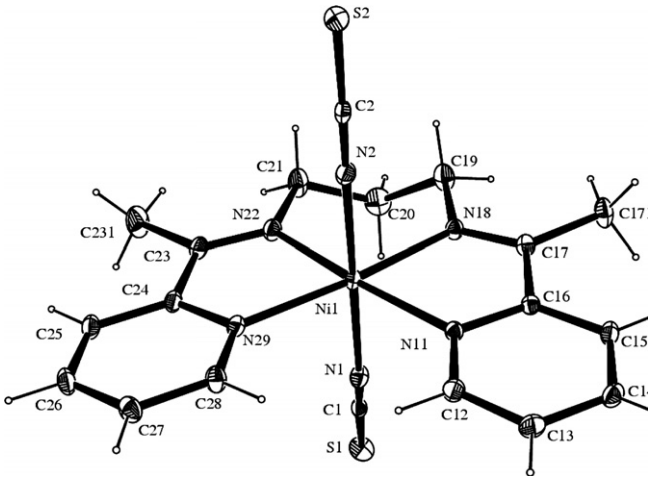

Fig. 4. The structure of **4** together with the atom numbering scheme, ellipsoids at 20% probability.

3.2.3. Complexes *4* and *5*

The structure of **4** is shown in Fig. 4 together with the atom numbering scheme (complex **5** has very similar molecular structure: Figure S2, Supplementary material). The structures of **4** and **5** consist of discrete $NiL^4(NCS)_2$ and $NiL^5(NCS)_2$ molecules, respectively.

The nickel atom is in a slightly distorted octahedral site in **4** with the ligand (L^4) occupying the equatorial plane and the N-bonded thiocyanate anions in axial positions at

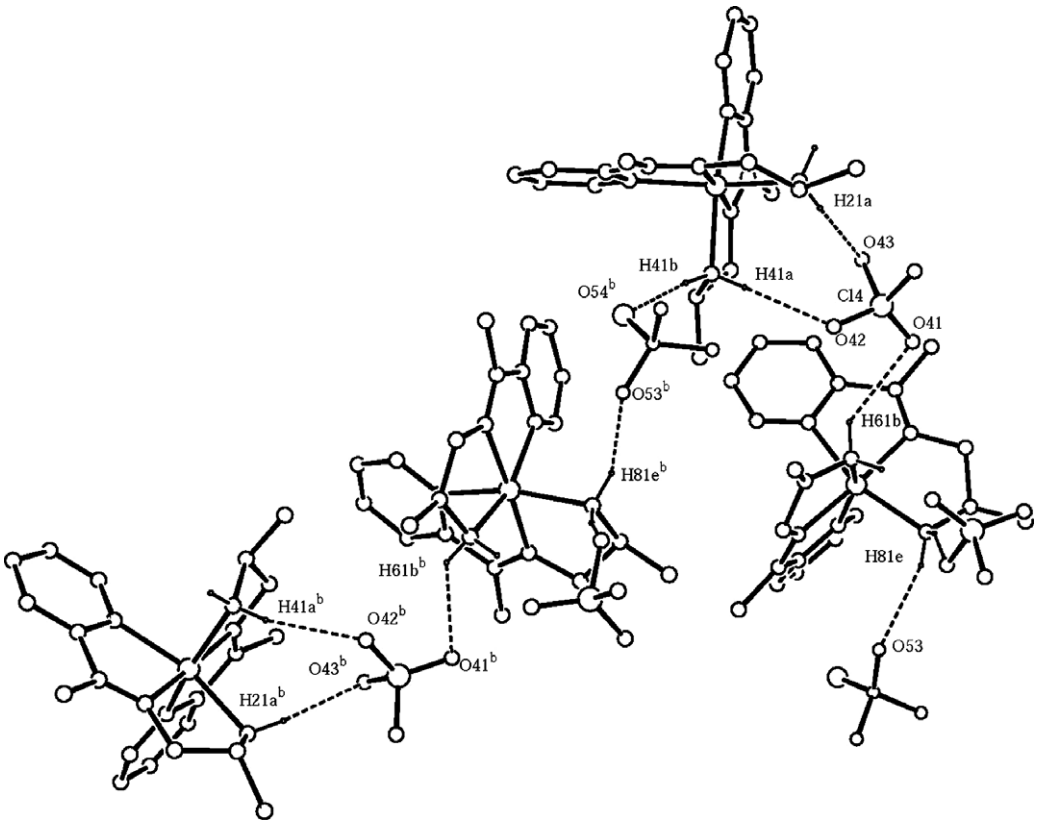

Fig. 3. H-bonds in complex **3**. Only one tetrahedron of the disordered perchlorates is shown.

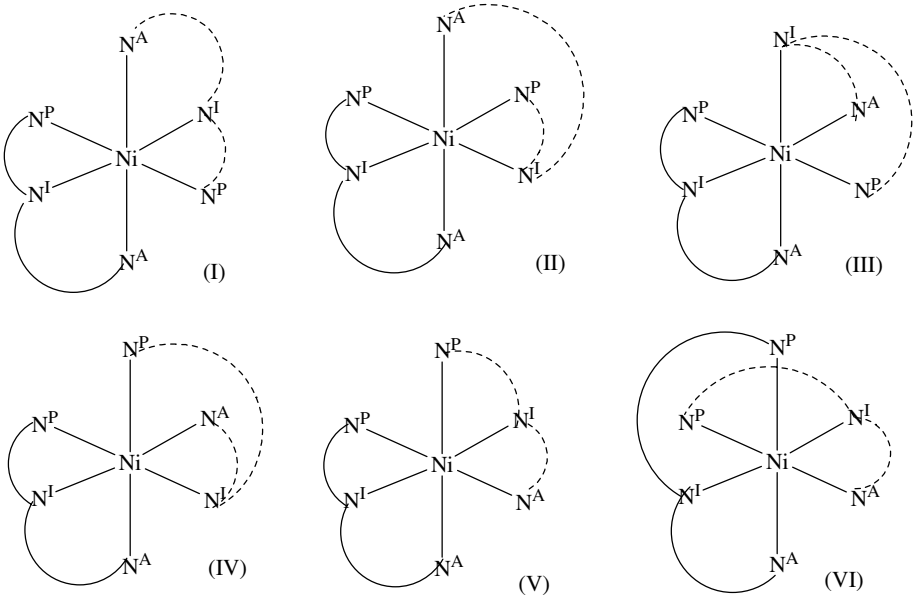
distances of 2.066(2), 2.086(2) Å. The Ni–N bond lengths to the pyridine nitrogen atoms are slightly longer [2.119(2), 2.120(2) Å] than those to the imino nitrogens [2.076(2), 2.069(2) Å]. The CuN_4 equatorial plane has an r.m.s. deviation of 0.021 Å. The saturated six membered ring [Ni(1)–N(18)–C(19)–C(20)–C(21)–N(22)–Ni(1)] has an envelope conformation with puckering parameters [15] $Q = 0.563(3)$, $\theta = 119.6(3)$, $\phi = 354.1(3)$.

The metal atom in **5** is also six-coordinate being bonded to the tetradentate ligand (L^5) which occupies an equatorial plane together with two iso-thiocyanate groups in axial positions. The Ni(1)–N bond lengths to ligand donor atoms are to N(11) 2.115(8), N(18) 2.078(9), N(22) 2.076(9), N(29) 2.127(9) Å. The Ni(1)–N(1) and Ni(1)–N(2) bond lengths to the axial thiocyanate [2.025(8) and 2.153(9) Å] differ significantly and this difference in axial bond lengths may be correlated with the difference in Ni(1)–N–C angles which are 177.9(9) for Ni(1)–N(1)–C(1) and 135.7(8)° for Ni(1)–N(2)–C(2). The saturated six member ring [Ni(1)–N(18)–C(19)–C(20)–C(21)–N(22)–Ni(1)] has an envelope conformation with puckering parameters [15] $Q = 0.575(11)$, $\theta = 127.4(10)$, $\phi = 359.3(13)$. Selected bond lengths and bond angles of **4** and **5** are given in Table 3.



3.3. Geometrical preferences

The four complexes whose structures have been determined are found to have distorted octahedral geometry. In type 1 complexes (**1** and **3**) two tridentate ligands encapsulate Ni(II) through six ligating nitrogen atoms from one pyridyl, one imine and one amino group of each ligand. In the bis complexes of such asymmetric tridentate ligands there is possibility of formation of six geometrical isomers – one meridional and five facial (Scheme 2). However, only the meridional one which has the pyridyl nitrogen atoms in the cis positions, the imine nitrogen atoms in the trans positions and amino nitrogen atoms in cis positions has been formed exclusively for both the complexes as is confirmed by X-ray analysis. Electronic factor cannot explain the stability of the mer isomer as here the trans disposition of two imine groups causes competition between them for the same metal d-orbitals, minimizing the back-bonding stabilization. However, the non-bonding interaction in the mer isomer is expected to be low (as two chelate rings are orthogonal to each other) and this along with the requirement of efficient crystal packing seems to be responsible for its exclusive formation.

In case of complexes **4** and **5**, the tetradentate Schiff base encapsulates the equatorial plane leaving the two axial trans positions to be coordinated by the thiocyanate group and this trans isomer is the exclusive product in both cases. The extra stability of this isomer probably comes from both steric and electronic effects as in this configuration, the cis orientation of the two imine groups allows maximized back-bonding stabilization (as evident from the Ni–N^i bond shortening) from 2.099(2), 2.096(3) Å for Ni–N(18); 2.088(2), 2.080(2) Å for Ni–N(38) in the two molecules of **1** to 2.069(2) Å for Ni–N(18) and 2.076(2) for Ni–N(22) in **4** and at the same time, steric repulsion is minimized by the trans disposition of two NCS moieties.

3.4. Electronic and IR spectra

The electronic spectra of all the six complexes (**1**–**6**) were recorded in acetonitrile solution. A broad band is observed near 800 nm, well separated from the second transition at about 510 nm for all the complexes. The third d–d band

Scheme 2. Possible geometrical isomers of the complexes $[NiL_2]^{2+}$ ($L = L^1$, L^2, and L^3); I–V are facial isomers, whereas VI is the meridional one (N^I, N^A and N^P indicate imine, amine and pyridyl nitrogen atoms, respectively).

at lower wavelength cannot be observed as it is obscured by a strong charge transfer transition in each case. The two absorption peaks are assigned to as $^3T_{2g} \leftarrow {}^3A_{2g}$ and $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ transitions. The calculated values of Dq lie in the ranges 1250–1260 cm^{-1} for all complexes and are in good agreement with literature values [16].

In the IR spectra of all the six complexes, the imine (C=N) stretch appears at about 1650 cm^{-1}. The two NH_2 stretching modes are observed in complexes of tridentate ligands (**1**–**3**) near 3340 and 3290 cm^{-1} as sharp bands (doublet) for the asymmetric and symmetric stretching vibrations, respectively. Concerning the ClO_4^- anion, the ν_3 mode at 1089, 1088 and 1093 cm^{-1} for **1**–**3** respectively, is somewhat broadened, but the ν_4 band at 622.4, 622 and 622.3, respectively, is devoid of any splitting and are consistent with the IR active normal modes for T_d symmetry suggesting that these anions are not coordinated to the nickel ions as substantiated by the crystal structures of **1** and **3**. The strong bands at 2009, 2006 and 2001 cm^{-1} in the IR spectra of **4**–**6**, respectively, indicate the presence of N-bonded thiocyanate [17].

3.5. Luminescence studies

Complexes **1**–**3** do not display any fluorescence probably because the small energy gap between the ground state and first excited state favouring non-radiative decay. On the other hand, complexes **4**–**6** show fluorescence. These are assigned as intra-ligand fluorescence $^1(\pi \rightarrow \pi^*)$. The spectroscopic data are given in Table 6 (without solvent correction).

3.6. Electrochemistry

The redox behaviour of all the complexes were studied by using cyclic voltammetry (CV) in acetonitrile (0.1 M NEt_4ClO_4) in the potential range ±2 V by using platinum auxiliary electrode and Pt disc working electrode at ambient temperature (300 K) with no trace of decomposition as reflected in smooth curve. The reported potentials (Tables 7 and 8) are referenced to the saturated calomel electrode (SCE).

Complexes **1**–**3** displayed two one electron cyclic voltammetric responses at about 0.95 and 1.70 V. The irreversible redox signal encountered near 1.70 V is attributable to the $Ni^{4+/3+}$ response, whereas quasi reversible ($\Delta E_p \sim 118$ mV) one electron oxidative response at about 0.95 V is attributable to the $Ni^{3+/2+}$ couple. The absence of any satellite response is consistent with the exclusive occurrence of single isomer in the solution. No voltammetric response consistent with $Ni^{2+/+}$ reduction is observed.

Table 6
Photophysical data for the complexes **1**–**6**

Complex	Absorption	Emission
1	376	
2	367	
3	405	
4	280	458
5	281	435
6	280	449

Table 7
Electrochemical data for complexes **1**–**3**

Compound	$E_{1/2}$/V (ΔE_p/mV)[a]	
	$Ni^{III/II}$ couple	$Ni^{IV/III}$ couple
1	0.97(110)	1.69
2	0.95(115)	1.71
3	0.96(118)	1.68

[a] $E_{1/2}$ is calculated as the average of anodic (E_{pa}) and cathodic (E_{pc}) peak potentials; $\Delta E_p = (E_{pa} - E_{pc})$.

Table 8
Electrochemical data for complexes **4**–**6**

Compound	$E_{1/2}$/V (ΔE_p/mV)[a]	
	$Ni^{II/I}$	couple $Ni^{III/II}$ couple
4	−0.95(60)	0.64(120)
5	−0.95(78)	0.70(130)
6	−0.90(82)	0.61(125)

[a] $E_{1/2}$ is calculated as the average of anodic (E_{pa}) and cathodic (E_{pc}) peak potentials; $\Delta E_p = (E_{pa} - E_{pc})$.

Complexes **4**–**6** do not follow a similar trend as that of **1**–**3**. Compound **4** shows two quasi reversible redox couples at $E_{1/2} = 0.64$ and −0.95 V (vs. SCE). The redox reaction at $E_{1/2} = +0.64$ V corresponds to the first electron abstraction from the complex and is consistent with $[NiL^2(SCN)_2]^+/[NiL^2(SCN)_2]$ couple. The redox couples at $E_{1/2} = -0.95$ can be assigned to the electron addition to Ni^{II} complex to form Ni^{I} species. The similar pattern of cyclic voltammogram of **4**–**6** indicates the similarity of their structures (Table 8).

All the redox signals remain virtually invariant under different scan rates (0.01–1.0 V s^{-1}) in the temperature range 300–280 K. Solvent dependent shift and change in electrochemical reversibility of redox couples are not significant.

3.7. Magnetic properties

The effective magnetic moments (ranging from 3.03 to 3.12 BM) of the complexes **1**–**6** clearly confirm the presence of two unpaired electrons ($S = 1$) in a pseudo-octahedral environment, in agreement with a high-spin configuration ($t_{2g}^6 e_g^2$) as was also observed in similar systems [6f].

4. Conclusion

The syntheses of Ni(II) complexes with mono-condensed tridentate or tetradentate di-Schiff base have been rationalised by anion directed cation templating effect. When all six coordination numbers of the Ni(II) are to

be fulfilled by the Schiff base ligand, the tridentate mono-Schiff base is formed so that two such ligands can result in discrete octahedral complex. But when two of the coordination sites are occupied by strongly coordinating anions, tetra-coordinated di-Schiff base is formed to satisfy the remaining four coordination sites.

temperature range of 1 or 2 K. Abrupt transitions in particular can also exhibit thermal hysteresis when measured in warming and cooling modes. An abrupt transition reflects cooperativity between the spin centres in the solid, which are in close proximity to each other [13]. As such, this is a reflection of the intermolecular packing within the solid material; different crystal polymorphs of the same compound can exhibit very different thermal spin-crossover regimes. It is an open question to what degree it should be possible to control the form of a spin transition, by manipulating the crystal packing of the solid [14]. Such considerations are very important for producing materials that could be used for the applications listed in the previous paragraph [9].

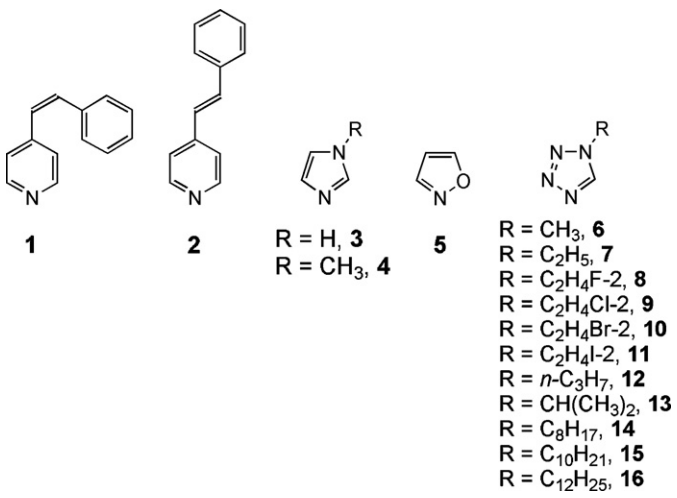
Although thermal spin-transitions are most heavily-studied, spin crossover in transition metal compounds can also be induced by other physical stimuli. The first to be discovered chronologically was that a high → low spin change can be effected by the application of pressure to the sample [3]. This depends on the fact that the volume of the low-spin state of a molecule is always smaller than its high-spin form. Since this is favoured at higher pressures, increasing pressure results in the thermal transition temperature $T_{1/2}$ being shifted to higher temperature as the low-spin state is stabilised [16,17]. More recently, it was noted that placing a sample in a very strong magnetic field has the reverse effect of stabilising its high-spin state [18]. The field can interact more strongly with the high-spin form of the compound, which is always more paramagnetic, causing $T_{1/2}$ to shift to lower temperature as the field strength is increased [19]. Very high magnetic fields of 30 T or above are required to decrease $T_{1/2}$ by more than a fraction of a degree, however.

More importantly, it was discovered in 1984 that spin-state conversions can also be induced in the solid by laser irradiation [20–22]. Most commonly the low-spin form of a spin-transition compound is converted using a green laser to its high-spin form, which is metastable at the temperature of the experiment, typically below 30 K. If the temperature is held below its activation barrier for thermal relaxation, then the sample can only relax back to its low-spin ground state by quantum-mechanical tunnelling. Since tunnelling is slow when the ground and excited states of a compound have very different structures, some samples can retain their excited spin-state for weeks at low enough temperatures. This has been termed the "light-induced excited spin-state trapping" (LIESST) effect [23]. It is not unusual for photogenerated high-spin forms of iron(II) materials to be long-lived below 50 K, but examples are also known where excited spin-states remain trapped at higher temperatures [24–28], the current record for a molecular species being 130 K [28]. The thermal stability of LIESST excited states in the solid state is inversely related to their thermal crossover temperature $T_{1/2}$, and seems to be controlled more by the molecular structure of the materials studied, than by any longer range cooperativity phenomena. This opens interesting possibilities that spin-crossover molecular materials showing light-induced bistability at higher temperatures might be designed [29].

Metastable high-spin forms of spin-transition materials at low temperature can also sometimes be trapped by thermal quenching; that is, very rapid cooling of the sample to ca. 5 K [30]. They can also be observed following nuclear decay of a ^{57}Co nucleus in a high-spin cobalt(II) complex, to the metastable high-spin form of the corresponding ^{57}Fe compound, in a Mössbauer emission spectroscopy experiment (the "nuclear decay-induced excited spin-state trapping" or NIESST effect) [31]. The resultant metastable high-spin states formed by both techniques usually exhibit the same thermal stability and relaxation kinetics as their light-induced counterparts for a given material, where these have been compared.

The low temperatures required for the observation of spin-state trapping phenomena might restrict their practical application. However, switching spin states at higher temperatures by irradiation can also be achieved, for materials that are genuinely bistable at the temperature of measurement. That is, if the experiment is performed at a temperature inside the thermal hysteresis loop of a cooperative spin-transition. This phenomenon has been observed occasionally at low temperatures [32,33], but very recently the first fully reversible, room temperature light-activated switch of this type was attained. That is, a material that can be shuttled between its bistable low- and high-spin forms at room temperature, by pulses of the *same* laser radiation [34]. This is not a spin-trapping process, but is a genuine, reversible light-induced colour switch that has clear potential applications.

By far the majority of known spin-transition compounds are octahedral iron(II) compounds, of general formula $[FeL_6]^{n+}$ or $[Fe(NCX)_2L_4]$. The 'L' ligand here is a nitrogen donor, usually from a heterocyclic group which may be monodentate or part of a larger polydentate ligand framework, while NCX^- is isothiocyanate (X = S) or, sometimes, isoselenocyanate (X = Se) or a related pseudohalide. Of all the metal ions [35] and ligands that are known to give spin-crossover complexes, the iron(II)/N–ligand combination leads to the greatest change in metal–ligand bond lengths between the high- and low-spin states [36]. Greater structural changes induce larger cooperativity between spin centres during spin-crossover, leading to more abrupt thermal transitions that may show hysteresis. Hence abrupt spin-transitions that take place within a temperature range of <5 K, are well-known for solid iron(II)/N–ligand complexes but rare for compounds of other metal ions or ligand types [37]. Similarly, iron(II) compounds with N-donor ligands give by far the longest-lived photochemical excited spin-states, since the large structural changes involved inhibit relaxation of these excited states by quantum mechanical tunnelling. For example, the rate of tunnelling relaxation of photogenerated high-spin states of spin-crossover iron(II) complexes in low-temperature matrices is ca. 10^7 times slower than for comparable iron(III) compounds [38].



The potential applications of spin-crossover materials, and the range of physical phenomena they can exhibit,

mean that the synthesis and structural and physical chemistry of new spin-crossover compounds is of great current interest worldwide. Reflecting its current popularity, the chemistry and physics of spin-crossover phenomena has been reviewed extensively in recent years [1,13,17,18,23,29,35,39–44]. These literature articles mostly describe the novel structural [12,35,40] and physical [17,18,23,41–44] chemistry that has been discovered in spin-transition materials; or, efforts to design new spin-transition materials de novo to have technologically useful thermochromic or photochromic properties [13,29,40]. Ref. [1] is particularly highlighted as an accessible, general introduction to spin-crossover phenomena, and Ref. [39] as a recent series of three volumes covering all aspects of spin-transition chemistry. Several individual chapters from Ref. [39] are also cited during this review.

The aim of this article is different, being to survey the range of metal complexes that have been shown to exhibit spin-transitions. This will provide a convenient guide to what materials have been made before (and which have not), highlighting those that exhibit interesting spin-transitions or structural chemistry. Since most spin-crossover chemistry has been achieved using mononuclear iron(II) complexes with N-donor ligation (see above), the review concentrates on that class of compounds. The discussion is organised by ligand type, and described in order of increasing ligand donacity. Polynuclear and polymeric iron(II) spin-transition compounds are not described here, but have been reviewed elsewhere [13,40,44].

2. Monodentate ligands

The solid compounds "$Fe(py)_6X_2$" (py = pyridine; $X^- = Br^-$, I^- or NCO^-) in fact have the composition $[FeX_2(py)_4]\cdot 2py$ [45]. However, three solid salts of the $[Fe(py)_6]^{2+}$ dication have been isolated, namely $[Fe(py)_6]X_2$ ($X^- = PF_6^-$, [46], picrate [47] and $1/2[Fe_4(CO)_{13}]^{2-}$ [48]). A crystal structure of the latter compound at room temperature shows a high-spin, centrosymmetric octahedral iron centre. $[Fe(py)_6][picrate]_2$ is also high-spin at room temperature, as are its 4-picoline and 3-picoline-containing analogues [47]. The PF_6^- salt loses pyridine in MeCN solution, forming $[Fe(py)_x(NCMe)_{6-x}]^{2+}$ ($x \approx 5$) [46]. Interestingly these solutions are thermochromic, changing from pale yellow at room temperature to dark red when frozen. It is uncertain whether this reflects the onset of a spin-state transition, however. Molecular mechanics calculations suggest that the apparent instability of octahedral $[Fe(py)_6]^{2+}$ is a consequence of steric hindrance between the 2- and 6-H atoms on adjacent pyridine ligands [49]. No other homoleptic Fe(II) complexes of six-membered azinyl ligands have yet been synthesised. While $[Fe(NCS)_2(py)_4]$ is high-spin at ambient pressure, a partial spin-crossover can be induced in this compound under 5–7 GPa pressure at room temperature [50]. Although $[Fe(NCB\{C_6H_5\}_3)_2(\mathbf{1})_4]$ is also high-spin, $[Fe(NCB\{C_6H_5\}_3)_2(\mathbf{2})_4]$ undergoes a quite abrupt thermal spin-transition centred at 190 K. Irradiation of these compounds in a cellulose acetate film at 140 K causes their interconversion through photoisomerisation of the ligand styryl group, with a concomitant change in the spin-state of the iron centre [51]. This was the first time a ligand-driven, light-induced spin-transition had been demonstrated. Several related complexes containing other 4-(*trans*-styryl)pyridine derivatives also undergo more gradual thermal spin-crossover, with $155 < T_{1/2} < 200$ K [51].

A much larger number of complexes containing monodentate azole ligands have been prepared. All known $[FeL_6]^{2+}$ or $[Fe(NCS)_2L_4]$ complexes of pyrazole [52,53], imidazole [46,52,54–57] or thiazole [58] ligands are high-spin at room temperature. Of these only $[Fe(\mathbf{3})_6][NO_3]_2$, $[Fe(\mathbf{4})_6]Cl_2$ [54], $[Fe(\mathbf{4})_6]S_8$ [56] and some $[Fe(NCS)_2L_4]$ (L = pyrazole or a 5-alkylpyrazole) compounds [53] have been shown to remain high-spin on cooling, however. In contrast, all known $[FeL_6]^{2+}$ salts of *iso*-oxazole (**5**) or 1-alkyltetrazole (**6**–**16**) 'L' ligands undergo spin-state transitions at low temperatures (Table 1) [59]. This apparent ordering of ligand donor strengths:

[tetrazole,*iso*-oxazole] > imidazole

does not correspond to the ordering of pK_as of the conjugate acids of the free heterocycles:

imidazole > tetrazole > *iso*-oxazole.

Molecular mechanics calculations on $[Fe(pz)_6]^{2+}$ (pz = pyrazole) suggest that it instead reflects intramolecular, interligand steric hindrance between the C–H or N–H groups adjacent to the coordinated N-donor on each ligand [49]. This disfavours the Fe–N bond contraction associated with a spin-state transition. Such steric repulsion will be less significant for *iso*-oxazole or tetrazole complexes, which have only one C–H or N–H group adjacent to their ligand N-donors, than for imidazoles which have two. All known iron(II) complexes of 1,2,4-triazoles have polynuclear or polymeric structures and are outside the scope of this article, but have been reviewed in [59].

[f] Brill = Brillouin spectroscopy; Cal = calorimetry; Dielec = variable temperature dielectric constant measurements; DFT = density functional calculations; EPR = variable temperature EPR of trace copper(II) or manganese(II) dopant ions; HF-EPR = high-frequency EPR of the high-spin iron(II) complex; HF-Mag = low → high spin conversion using a very strong magnetic field; IE = deuterium isotope effect measurements; INS = inelastic neutron scattering; IR = variable temperature infrared spectroscopy; LIESST = light-induced excited spin state trapping experiments; Mag = variable temperature magnetic susceptibility; MM = molecular mechanics calculations; Möss = Mössbauer spectroscopy; μSR = muon spin resonance; PND = polarised neutron diffraction; Pos = positronium annihilation lifetime measurements; PD = variable temperature powder diffraction; Press = magnetic susceptibility or Mössbauer spectroscopy measurements under high pressure; Quen = thermal trapping of high-spin state at low temperatures by rapid cooling; Sol = spin-crossover temperature determination in solution by variable temperature UV/Vis or Evans method measurements; stress = magnetic susceptibility measurements under mechanical stress; T_1 = variable temperature solid-state NMR T_1 measurements; TEM = transmission electron microscopy; Vis = diffuse reflectance or single crystal absorption UV/Vis/NIR; XAS = X-ray absorption spectroscopy (EXAFS or XANES).

Single crystals of $[Fe(\mathbf{5})_6][BF_4]_2$ (space group $P\bar{3}$) contain two independent complex dications, both with crystallographic C_3-symmetry, one of which has twice the occupancy of the other [59]. This compound shows a gradual, two-step spin-state transition; two-thirds of the iron centres become low-spin at 192 K, and the other one-third at 91 K [60,61], leaving a 13% residual high-spin content below 50 K. At 130 K the crystalline compound has undergone a crystallographic phase transition to $P\bar{1}$ [60]. The low temperature phase contains three independent complex molecules, all now on general positions: two of these contain low-spin iron centres, while

the third one is high-spin. Interestingly, while $[Fe(\mathbf{5})_6][ClO_4]_2$ is isostructural with the BF_4^- salt at room temperature [60], it undergoes a very different spin-crossover. This proceeds in a single abrupt step with a 9 K hysteresis loop centred at 213 K, to 94% completeness [61,62]. Single crystals of this material do not undergo the crystallographic phase transition that operates for the BF_4^- salt [60], and clearly all the iron centres in $[Fe(\mathbf{5})_6][ClO_4]_2$ that undergo a spin-state transition, do so at the same time. The $[Fe(\mathbf{5})_6]^{2+}$ moieties in the double salt $[Fe(\mathbf{5})_6][Fe(\mathbf{5})_4(OH_2)_2][BF_4]_4$ undergo spin-crossover at 173 K [59]. Density functional (DF) [63] and hybrid density functional/molecular mechanics (DF/MM) calculations [64] have both predicted a high-spin ground state for $[Fe(\mathbf{5})_6]^{2+}$ at 0 K, contrary to what is observed.

The spin-crossover behaviour of homoleptic Fe(II) 1-alkyltetrazole complexes has been heavily studied [59,65]. A complete list of known materials of this type is given in Table 1. Only those examples that show unusual structural or physical chemistry will be discussed in detail, however. In addition to the compounds in Table 1, seven other $[Fe(Rtz)_6][BF_4]_2$ (Rtz = a 1-alkyltetrazole with R ranging from *n*-butyl to *n*-octadecyl) complexes have been studied by variable temperature IR spectroscopy with a view to determining their spin transition temperatures. However, while the spectra are described in detail, the measured $T_{1/2}$ values were not reported [66].

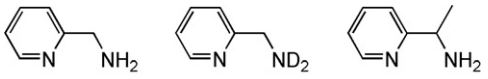
The salts $[Fe(\mathbf{6})_6]X_2$ ($X^- = BF_4^-$ [67] and ClO_4^- [68]) exhibit very similar spin-transitions, which occur gradually at very low temperatures, centred near 70 K. In both cases, the transition only proceeds to 50% completeness. Crystalline $[Fe(\mathbf{6})_6][BF_4]_2$ and $[Fe(\mathbf{6})_6][ClO_4]_2$ are isostructural, containing two unique centrosymmetric half-molecules in their asymmetric unit that are both high-spin at higher temperatures [69]. At 10 K, however, one of the two iron sites in the BF_4^- salt has become low-spin while the other remains high-spin [70]. The spin-states of each iron site in both salts at 10 K can be shuttled between their different spin-states by irradiation with the appropriate laser wavelength, selectively affording fully high-spin and fully low-spin forms of the materials [68,70,71]. Single crystal structures of all three forms of the compound (high-spin, low-spin and mixed) were obtained at 10 K [70]. The relaxation of both forms of $[Fe(\mathbf{6})_6][BF_4]_2$ back to their 1:1 high:low-spin ground state shows complicated kinetics, consistent with a high degree of cooperativity between the two sites. The different zero-point energy differences between the high- and low-spin states ($\Delta E^0_{HL} = E^0_{HS} - E^0_{LS}$) for the two molecules in the BF_4^- crystal at 20 K was determined, at $+120\ cm^{-1}$ for the low-spin site and $-60\ cm^{-1}$ for the high-spin one [71]. The fully high-spin form of $[Fe(\mathbf{6})_6][BF_4]_2$ can also be trapped quantitatively at 10 K by thermal quenching [72]. Thermal spin-crossover and LIESST phenomena in the diluted materials $[Fe_xM_{1-x}(\mathbf{6})_6][ClO_4]_2$ (M = Zn [75] and Ni [76]) have also been studied.

At room temperature, $[Fe(\mathbf{6})_6][CF_3SO_3]_2$ contains a single, unique high-spin iron environment [78,79] which, between 175 and 195 K, undergoes a change to a second high-spin crystallographic phase of unknown structure that also only contains one iron site [78]. Upon further cooling, a cooperative spin-transition is observed centered at 173 K with a 12 K hysteresis loop is observed that is only 33% complete [78,79]. No structural information below the transition temperature is available. While $[Fe(\mathbf{6})_6][CF_3SO_3]_2$ does not exhibit a LIESST effect, its fully high-spin form can be trapped by thermal quenching to 5 K. The quenched metastable material has an indefinite lifetime below the unusually high temperature of 103 K [79].

Only the BF_4^- salt of $[Fe(\mathbf{7})_6]^{2+}$ has been described to date [67]. At room temperature the crystalline material contains two different complex molecule environments: one centrosymmetric half-molecule, and one whole molecule on a general crystallographic site [80]. Upon cooling, the wholly occupied molecular site undergoes a gradual high → low-spin transition centred at 105 K; the second, half-occupied molecule remains high-spin at all temperatures. Spin-crossover in the bulk material is therefore only 67% complete at 5 K [67,80]. The high-spin site remains high-spin at 60 K, under applied pressures of up to 1.2 kbar [80]. As for $[Fe(\mathbf{6})_6][BF_4]_2$ (see above), however, metastable fully high-spin *and* fully low-spin forms of $[Fe(\mathbf{7})_6][BF_4]_2$ can be produced by laser irradiation at 20 K [32,80]. This implies that spin-crossover at the half-occupied iron site is thermodynamically accessible, but may exhibit too wide a thermal hysteresis to be observed on thermal cooling. Analysis of the relaxation kinetics of this site implies that its thermal transition temperature in warming mode is ca. 77 K [32].

Powder diffraction has shown that $[Fe(\mathbf{9})_6]X_2$ ($X^- = BF_4^-$ and ClO_4^-), $[Fe(\mathbf{10})_6][BF_4]_2$ and $[Fe(\mathbf{11})_6][BF_4]_2$ are all isostructural [81–84], and the structures of the high-spin and low-spin forms of all four salts have been solved and refined from synchrotron powder diffraction data [82–84]. These compounds retain the same unit cell and crystal symmetry at all temperatures, and contain a single centrosymmetric half-molecule in their asymmetric unit. It is therefore unusual that $[Fe(\mathbf{9})_6]X_2$ ($X^- = BF_4^-$, ClO_4^- and PF_6^-) [81] and the BF_4^- and ClO_4^- salts of $[Fe(\mathbf{8})_6]^{2+}$, $[Fe(\mathbf{10})_6]^{2+}$ and $[Fe(\mathbf{11})_6]^{2+}$ [85] all undergo gradual thermal spin-crossover, many of which show pronounced plateaus at around 50% conversion. The appearance of this transition is very dependent on the form of the solid samples for the $[Fe(\mathbf{9})_6]^{2+}$ salts [81]. Most dramatically, $[Fe(\mathbf{9})_6][ClO_4]_2$ undergoes a complete, two-step thermal spin-crossover as a powder, one of which shows a pronounced hysteresis loop; but only the first of these steps is observed in crystalline samples of the same material, whose transition is therefore only 50% complete [81]. No sample-dependent behaviour for the other compounds in this series was reported [85]. The different types of thermal spin-crossover shown by these isostructural complexes have been reproduced theoretically, by models describing

the effects of small changes in elastic intermolecular interactions between each molecule and its two nearest neighbours in the solid [86].



High-spin, crystalline $[Fe(\mathbf{12})_6][BF_4]_2$ contains a single one-third-occupied molecule site lying on a site of $\bar{3}$ crystal symmetry [69]. Rapid cooling of the sample retains this crystal form, producing an isostructural low-spin material [87,88] whose structure has been refined from powder diffraction data [89]. Under these conditions, spin-crossover occurs abruptly at 125 K without hysteresis [90]. However, cooling the sample more slowly to below 135 K over a 30 min period causes a small upward shift in $T_{1/2}$ with the appearance of a small hysteresis loop [67]. The low-spin form of the material under these conditions has greatly reduced crystallinity and cannot be solved by diffraction methods [69], although it may have lowered crystallographic symmetry [91]. The ''ordered'', super-cooled low-spin form can be converted to this ''disordered'' phase by annealing above 120 K [65], or by exposure to a synchrotron X-ray beam below a certain critical incident wavelength [88]. LIESST and reverse-LIESST interconversion of the spin-states in ''ordered'' low-spin $[Fe(\mathbf{12})_6][BF_4]_2$ (see below) does not convert it to its ''disordered'' phase, however [92]. Interestingly, rewarming the ''disordered'' low-spin phase cleanly regenerates the fully crystalline high-spin material [65]. Doped materials $[Fe_xZn_{1-x}(\mathbf{12})_6][BF_4]_2$ show the same cooling-controlled spin-crossover as the neat iron material for $x > 0.44$, but more dilute solids with $x < 0.44$ form the ''ordered'' low-spin phase only [90,93]. While $[Fe(\mathbf{12})_6][ClO_4]_2$ is isostructural with the BF_4^- salt at room temperature [69], its thermal spin transition is much more gradual [94].

Despite its complex behaviour, $[Fe(\mathbf{12})_6][BF_4]_2$ is one of the best characterised of all molecular spin-crossover compounds (Table 1), as it has often been used as a prototype material in the development of new physical techniques relating to spin-crossover. In particular, the first demonstration of the LIESST effect employed this compound (its relaxation temperature is 60 K) [20,22,24], as did the first ''reverse-LIESST'' high → low-spin photoconversion experiment [95]. These and other experiments on it provided the basis for interpretation of the physics of trapped spin-state relaxation [96]. More recently, the same compound has provided the first demonstration of optical hysteresis in the rates of laser-induced interconversion of high- and low-spin states [97]; and, the only spin-density map of a spin-crossover compound (by single crystal polarised neutron diffraction) obtained to date [98].

3. Bidentate ligands

3.1. 2-(Aminomethyl)pyridine

The salts $[Fe(\mathbf{17})_3]X_2$ ($X^- = Cl^-$, Br^- and I^-) were some of the first spin-crossover iron(II) compounds to be discovered (Table 2) [5]. The unsolvated chloride and bromide salts both show a relatively gradual spin-transition centred near 110 K, which proceeds to completion for the chloride salt but is only ca. 60% complete for the bromide. The iodide salt exists as an approximately 1:1 high-spin:low-spin mixture below ca. 250 K, but a small increase in μ_{eff} at 300 K implies the existence of a thermal spin-transition centred above room temperature [5]. A room temperature crystal structure determination of $[Fe(\mathbf{17})_3]I_2$ showed that its asymmetric unit contains a 1:1 mixture of the *fac* and *mer* isomers of the complex [109]. The *mer* molecule in the crystal is high-spin, while the Fe–N bond lengths in the *fac* molecule imply that it is predominantly low-spin, but with a significant high-spin fraction that was estimated at 30%.

17 **18** **19**

Much more heavily studied have been the hydrates and alcohol solvates of the chloride and bromide salts of the $[Fe(\mathbf{17})_3]^{2+}$ cation (Table 2). The monohydrate $[Fe(\mathbf{17})_3]Cl_2 \cdot H_2O$ exhibits an abrupt spin-transition centred at 250 K, with a very wide thermal hysteresis loop of 91 K by Mössbauer spectroscopy [110]. Although structural data from this phase are not available, a recent adiabatic heat capacity calorimetry study has implied that the initial high → low-spin transition in cooling mode at 199 K initially affords a metastable low-spin phase, which undergoes the reverse low → high-spin conversion in warming mode at 211 K [111]. Hence, rapid scanning of the spin-transition with descending–ascending temperature ramp gives a thermal hysteresis loop of only 12 K. However, the metastable low-spin material transforms slowly to a second, stable low-spin structure when annealed at 200 K for two weeks. This new, stable low-spin phase undergoes the reverse low → high-spin conversion in warming mode at 280 K, similar to that observed in the earlier Mössbauer study. Hence, the width of the thermal hysteresis loop shown by $[Fe(\mathbf{17})_3]Cl_2 \cdot H_2O$ depends on the conditions used to measure it. In contrast to this behaviour, the dihydrate $[Fe(\mathbf{17})_3]Cl_2 \cdot 2H_2O$ is low-spin at room temperature and below [110]. Crystals of this compound contain the *fac* isomer of the complex dication [109,113].

Although they are not perfectly isostructural, the solvates $[Fe(\mathbf{17})_3]Cl_2 \cdot MeOH$ and $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ adopt the same *mer* geometry at their iron site and essentially identical intermolecular hydrogen bonding networks in the crystal [14,114]. The methanol solvate exhibits a gradual thermal spin-crossover centred at 153 K [14,110,113,114], and does not undergo a crystallographic phase change during the transition [113,115]. Spin-crossover in the ethanol solvate is more abrupt, and is notable

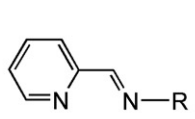
[c] Hysteresis only observed when high-spin fraction of the sample is between ca. 70% and 90%.
[d] Hysteresis only observed when high-spin fraction of the sample is >50%.

for being the first example of a discontinuous spin-crossover to be discovered [122]. The transition proceeds over two steps at 114 and 121 K, with a plateau between them corresponding to 50% spin conversion [123]. This narrow discontinuity had been missed in earlier studies of this material [110,114,118]. Statistical modelling predicted that the plateau region corresponds to an intermediate state containing short-range ordering of high-spin/low-spin pairs of molecules [124]. Consistent with this, early crystallographic studies [114,115,125], including one determination within the plateau region at 115 K [115], had indicated that the spin-transition in $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ proceeds without any change in crystal symmetry. However, a more recent variable temperature study using synchrotron radiation detected a discreet, long-range-ordered intermediate crystal phase within the plateau region, that has the same $P2_1/c$ space group as the fully high- and low-spin material, but a unit cell that has doubled along the c direction so that Z has increased from 4 to 8 [126]. The asymmetric unit of the intermediate phase contains one high-spin and one low-spin molecular environment, alternating within the 2D hydrogen-bonded layers in the lattice. The intermolecular processes responsible for ordering the high-spin/low-spin molecular pairs in the intermediate phase have been modelled theoretically [127]. Thermal spin-crossover in the doped materials $[Fe_xCo_{1-x}(\mathbf{17})_3]Cl_2 \cdot EtOH$ ($x \leqslant 0.65$) [128] and $[Fe_{0.73}Zn_{0.27}(\mathbf{17})_3]Cl_2 \cdot EtOH$ [123] proceeds smoothly and without any apparent discontinuity.

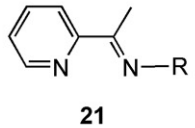
The LIESST effect has been demonstrated in $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$, although its trapped high-spin state is only long-lived below 25 K [21]. The metastable high-spin state of a single crystal of the compound at 10 K has the same structure as the fully high- and low-spin material, and appears to decay back to its low-spin state without passing through the ordered intermediate crystal phase [129,130]. The kinetics of this LIESST relaxation imply that short-range correlations between high-spin/low-spin molecular pairs play a significant role in this process, however [131]. Continuous irradiation of the

crystal in its intermediate phase at 118 K also appears to yield the fully high-spin phase, although a full crystallographic determination was not possible [130]. While the Fe–N vibrations in the far-IR spectra of the thermal and photochemical high-spin states of $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ are similar [132], their ligand vibrations in the IR fingerprint region show significant differences [133]. In the light of the above crystallographic results, this has been ascribed to local differences in intermolecular interactions between ligands in the two materials [132]. The quantum efficiency of the low → high-spin conversion in $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ under LIESST conditions has been measured as being almost 100% [134]. Although its thermal spin-transition temperature is barely perturbed inside a strong, 7 T magnetic field, the lifetime of the LIESST excited state of $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ at 10 K is increased by 50% under these conditions [135]. The LIESST effect in $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ has also been studied by non-resonant inelastic neutron scattering [136], EXAFS [137], photoelectron spectroscopy [138], X-ray spectroscopy [139] and EPR (of cobalt(II) ions doped into the iron(II) host material) [140].



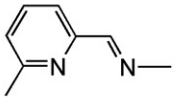
The spin transitions undergone by the deuterated materials $[Fe(\mathbf{18})_3]Cl_2 \cdot CH_3OD$ [118] and $[Fe(\mathbf{18})_3]Cl_2 \cdot C_2H_5OD$ [118,141] both take place at ca. 15 K higher temperature than for their protio-congeners, while exhibiting a similar degree of cooperativity [118]. This was the first time that an isotope effect on spin-crossover had been detected. The origin of the effect was unclear, but may reflect the influence of M–L vibrational modes in the cooperativity of the transitions; or, a change in the intermolecular hydrogen bond geometry in the crystals upon deuteration. Consistent with these explanations, deuteration at the methylene group or pyridine ring of $[Fe(\mathbf{17})_3]Cl_2 \cdot C_2H_5OH$ had a much smaller effect on $T_{1/2}$ [18]. Measurements of thermal spin-transitions [119,123,128], and rates of relaxation of the LIESST metastable high-spin states at low temperatures [120,121], in a series of doped solids $[Fe_xM_{1-x}(\mathbf{17})_3]Cl_2 \cdot MeOH$ and $[Fe_xM_{1-x}(\mathbf{17})_3]Cl_2 \cdot EtOH$ (M = Zn, Co or Mn) have been used to develop theories of cooperative transitions in bulk materials [96].

Four other alcohol solvates $[Fe(\mathbf{17})_3]Cl_2 \cdot ROH$ (R = *n*Pr, *i*Pr, allyl and *t*Bu) have also been prepared [14]. The propan-1-ol, propan-2-ol and allyl alcohol solvates are isostructural with $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$ above, while the *t*-butanol solvate is not but shows the same 2D layered hydrogen-bonded network structure as the others. Intriguingly, the spin-transition regimes exhibited by these materials, and the methanol and ethanol solvates, are very different. The allyl alcohol solvate shows a gradual transition in two steps, centred at 92 and 131 K, with no plateau between them. Spin-crossover in the $[Fe(\mathbf{17})_3]Cl_2 \cdot i$PrOH is triggered by a crystallographic phase transition at 196 K to an intermediate phase, that also contains a doubled unit cell but differs from the one in $[Fe(\mathbf{17})_3]Cl_2 \cdot EtOH$. This intermediate phase undergoes a gradual high → low-spin conversion upon cooling to 157 K (where the material is still ca. 90% high-spin), when the original unit cell of the material is restored and the remaining transition proceeds much more rapidly on further cooling to 90 K. A narrow hysteresis loop is observed where the high-spin fraction of the material is between ca. 70% and 90% only. Finally, the propan-1-ol and *tert*-butanol solvates remain fully high-spin on cooling to 5 K. Given the near-identical crystal packing in these compounds, their very different spin-transition regimes led to the conclusion that it is currently impossible to engineer a spin-crossover compound from first principles, based purely on its molecular and long-range structure [14]. The bromide salt $[Fe(\mathbf{17})_3]Br_2 \cdot EtOH$ [114] is also isostructural with its chloride-containing congener [143] and shows an apparently smooth spin-transition from magnetic measurements, in one step centred at 123 K [114,144]. However, a narrow thermal hysteresis loop of 2 K was revealed from Mössbauer measurements, which is only present when the sample is >50% high-spin. A variable temperature unit cell study did not reveal the source of this anomaly, but showed that the low-spin and high-spin forms of the compound were isostructural [144].



Spin-crossover in several salts of $[Fe(\mathbf{17})_3]^{2+}$ has also been measured in solution. The thermodynamics of this transition differ to a small extent in different solvents, with more polar solvents stabilising the high-spin state by accepting stronger hydrogen bonds from the complex amino groups [145,146]. The solution-phase spin-crossover does not depend on the identity of the counterions present, however [145].

3.2. 2-(Carbaldimino)pyridine derivatives and related ligands



Nearly all known salts of type $[Fe(\mathbf{20})_3]^{2+}$ [151–156] and $[Fe(\mathbf{21})_3]^{2+}$ [155–158] are low-spin at room temperature, whether 'R' is H, or an alkyl or aryl group. Only one such compound has been crystallographically characterised, which contains a *mer* iron(II) complex dication [155]. However, NMR data imply that both *fac* and *mer* isomers are present in solutions of this class of complex [154,155] which, in one case, have been separated by chromatography [158]. The compound $[Fe(\mathbf{22})_3][ClO_4]_2$ shows a gradual thermal spin-transition centred near 160 K, that is 70% complete at 5 K from susceptibility and Mössbauer measurements [159]. Interestingly, $[Fe(\mathbf{23})_3]I_2 \cdot 2H_2O$ [152] and $[Fe(\mathbf{24})_3][ClO_4]_2$ [153] are both high-spin at room temperature, although no variable temperature studies were undertaken.

While a large number of complexes of type $[Fe(NCS)_2L_2]$ and $[Fe(NCSe)_2L_2]$ (L = a ligand of type **20**) have been shown to undergo thermal spin-transitions, only a few of them have been characterised in detail (Table 3). Most heavily studied have been complexes with ligands bearing extended aromatic Schiff base substituents like **36**–**38** and **40** [160]. All examples of this type that have been structurally characterised crystallise in one of two closely related crystal forms, in the space groups $P2_1/c$ or *Pccn*. Indeed, $[Fe(NCS)_2(\mathbf{37})_2]$ undergoes a crystallographic phase change from one form to the other during its spin transition (which contributes to the unusually wide thermal hysteresis loop shown by this compound [187]), while $[Fe(NCS)_2(\mathbf{36})_2]$ can be obtained in either polymorph from methanol solution, depending on the rate of crystallisation [181]. The α-form (*Pccn*) [30,179,180] undergoes a very abrupt thermal transition at 170 K, with a 6 K hysteresis loop [179], while the β-form ($P2_1/c$) [182] exhibits a much more gradual spin-crossover, centred at a higher temperature of 198 K [181]. The same trend does not extend to other compounds in the series, however, since $[Fe(NCS)_2(\mathbf{38})_2]$

All compounds in this series that have been crystallographically characterised contain *cis*-isothiocyanate ligands. See also Refs. [162,167,169–173] for more examples, and Table 1 for the abbreviations of physical techniques.

[a] The high-spin:low-spin ratio in the sample was essentially invariant between 78 and 298 K by Mössbauer spectroscopy and/or susceptibility measurements.

and $[Fe(NCS)_2(\mathbf{40})_2]$ respectively adopt the $P2_1/c$ and *Pccn* crystal forms, but both exhibit very gradual thermal spin-crossover [188]. Rather, the width of the thermal spin-transition in these compounds appears to correlate with two structural parameters. First, the transition becomes more cooperative as intermolecular steric contacts to the thiocyanate ligand S atoms become shorter [160,182]. Second, the cooperativity also increases with increasing trigonal distortion of the octahedral N_6 donor sphere about the high-spin iron atom (see below) [182,192].

The α- and β-forms of $[Fe(NCS)_2(\mathbf{36})_2]$ also show different LIESST behaviour, with the metastable high-spin state of the β-form being formed less efficiently under irradiation at 10 K, and less thermally stable [180]. The metastable high-spin state of α-$[Fe(NCS)_2(\mathbf{36})_2]$ can also be generated by thermal quenching, and has been crystallographically characterised in this way [30]. Comparison of their crystal structures with those of other $[Fe(NCS)_2L_2]$ complexes (L = **37**, **38**, **40**, **41** or another bidentate N-donor chelate) implied that the thermal stability of their trapped high-spin states and, by extension, their thermal spin-crossover temperatures $T_{1/2}$ are controlled by the degree of structural rearrangement of the ligand sphere taking place during spin conversion. This was quantified by an angle ('Θ') defining the degree of trigonal distortion of the six N donor atoms away from an ideal octahedral geometry [192]. A large angular rearrangement of the ligand sphere during spin-crossover results in a large difference in Θ between the low- and

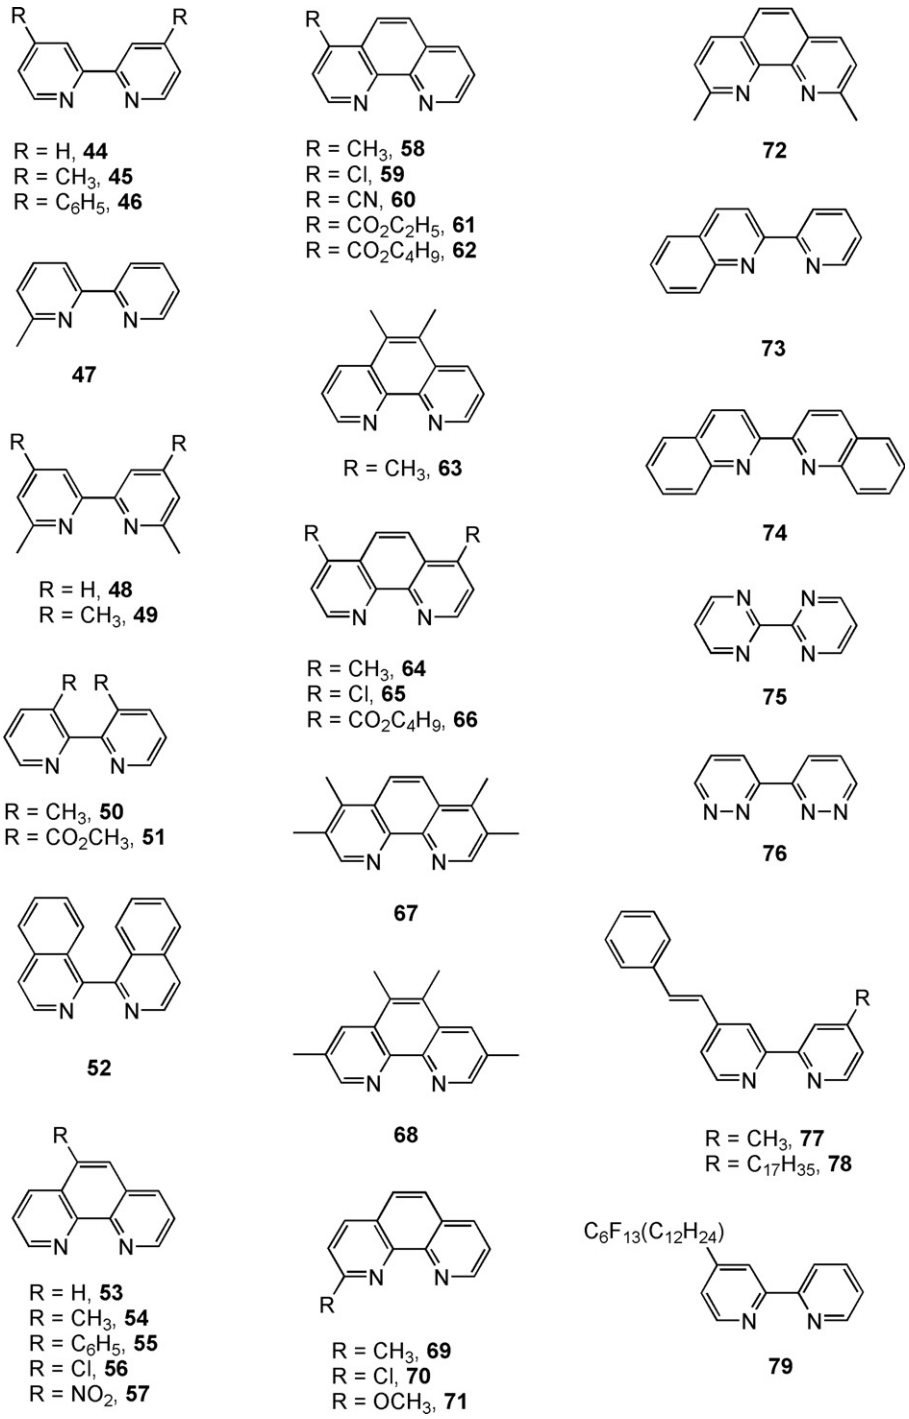
Where it is known, the geometric isomer adopted by the iron centres in those compounds containing unsymmetric chelate ligands is given. Homoleptic complexes of unhindered 2,2′-bipyridines (e.g. **44**–**46** and related ligands) and 1,10-phenanthrolines (e.g. **80**–**97** and related ligands), which are all low-spin [193], are not listed. See Ref. [248] for an additional example, and Table 1 for the abbreviations of physical techniques.

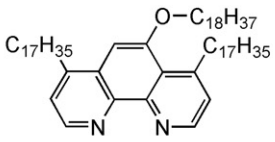
[a] Crystals contained half an equivalent of uncoordinated ligand.

[b] Crystallographic disorder of the coordinated ligands meant that it could not be determined whether the compound adopts the *fac* or *mer* geometric isomer.

[c] The "gradual" phase of this compound transforms to the "abrupt" phase upon heating to 323 K.

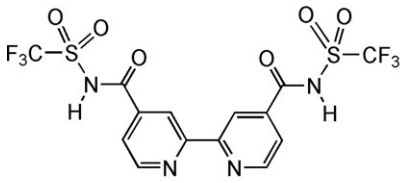


high-spin forms ('$\Delta\Theta$'). There is an almost linear correlation of $\Delta\Theta$ with $T_{1/2}$ in this series of materials [192]. The low → high-spin conversion of α-[Fe(NCS)$_2$(**36**)$_2$] has also been achieved by irradiation at 170 K, inside its thermal spin-transition hysteresis loop where the high- and low-spin forms of the compound are indefinitely stable [33]. However, [Fe(NCS)$_2$(**26**)$_2$] does not undergo the LIESST effect upon laser irradiation at 10 K [166].



The compounds [M(NCS)$_2$(**36**)$_2$] and [M(NCS)$_2$(**37**)$_2$] (M = Mn, Fe, Co, Ni and Zn) show second-order hyperpolarisabilities β of up to 800×10^{-30} esu in acetonitrile solution [176]. The magnitude of β increases in the order Mn > Fe > Co > Ni > Zn, correlating with the number of unpaired electrons at the metal ion (assuming they are all high-spin in solution; [Fe(NCS)$_2$(**39**)$_2$] is high-spin at room temperature at room temperature in this solvent). The iron compounds [Fe(NCS)$_2$L$_2$] with different 'L' ligands show the trends in β of **40** > **36** > **27**; and, **42** > **37** > **27** [176]. Acetonitrile solutions of [Fe(NCS)$_2$(**36**)$_2$] at room temperature also show a very high third-order non-linear optical susceptibility γ, of -130000×10^{-36} esu [186].

3.3. Bipyridines and other, directly linked, bis-heterocyclic ligands



As for [Fe(**20**)$_3$]$^{2+}$ in the previous section, many [FeL$_3$]$^{2+}$ complexes with *bis*-pyridyl donor 'L' ligands are low-spin [193]. The reduction in ligand field required to afford a spin-transition centre with this ligand type has been achieved in three ways, however. First, is by substitution at the 6-position of *one* of the pyridyl rings, as in [FeL$_3$]$^{2+}$ (L = **47** and **69**–**71**). This induces steric repulsion within the coordination shell, making the high-spin state (with its longer Fe–N bonds) more favourable. Bipyridyls disubstituted at the 6 and 6′ positions (as in **48**, **49** and **74** for example) are too bulky for a homoleptic [FeL$_3$]$^{2+}$ complex to form [195,200]. Second, is by inducing conformational strain into the bipyridyl backbone. Hence, salts

of $[FeL_3]^{2+}$ with L = **50**–**52** all undergo thermal spin-transitions centred at 250 K or above, which has been ascribed to sterically-induced twisting of the bipyridyl ligands [195,196]. This reduces covalent overlap between the metal ion and the ligand lone pairs, which are no longer oriented towards the metal d-orbitals. Finally, replacement of one or both pyridyl donors in the bidentate ligand by a less basic heterocycle (usually an azole) can also afford a homoleptic iron(II) spin-crossover complex. The majority of the compounds listed in Table 4 are of this type. A transient high-spin state of $[Fe(\mathbf{44})_3]^{2+}$ doped into other $[M(\mathbf{44})_3]^{2+}$ hosts can be photogenerated, if the host metal centre 'M' is larger than iron(II), since the reduced chemical pressure of the lattice surrounding each iron centre will favour its larger high-spin form. The (rapid) high → low-spin relaxation rates of the resultant high-spin $[Fe(\mathbf{44})_3]^{2+}$ centres correlate perfectly with the radius of the host metal 'M' [424]. High-spin states

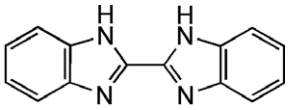
of $[Fe(\mathbf{44})_3]^{2+}$ and $[Fe(\mathbf{53})_3]^{2+}$ have also been detected by Mössbauer emission spectroscopy following nuclear decay of their corresponding, high-spin ^{57}Co analogues (the NIESST effect) [31,210].



Only five $[FeL_3]^{2+}$ complex salts in Table 4 have been reported to undergo a cooperative thermal spin-transition, namely: anhydrous $[Fe(\mathbf{89})_3][CF_3SO_3]_2$ [218]; $[Fe(\mathbf{98})_3][ClO_4]_2$ [228]; one of the two solid forms of $[Fe(\mathbf{110})_3][ClO_4]_2$ [250]; one of three apparently different crystal phases of $[Fe(\mathbf{120})_3][ClO_4]_2$ [254]; and, $[Fe(\mathbf{129})_3][ClO_4]_2$ [261]. The only one of these compounds to exhibit significant thermal hysteresis in its spin transition is $[Fe(\mathbf{89})_3][CF_3SO_3]_2$. A crystallographic study of $[Fe(\mathbf{98})_3][ClO_4]_2$ showed that its abrupt spin-crossover is not mediated by a crystallographic phase change [228]; no structural data are available for the rest of the compounds. Aerial oxidation of $[Fe(\mathbf{129})_3][ClO_4]_2$ yields the iron(III), mono-deprotonated ligand complex $[Fe(\mathbf{129}–H)(\mathbf{129})_2][ClO_4]_2$ which also undergoes a

thermal spin-transition [261]. Self-exchange between these two compounds, and oxidation of TEMPO by the iron(II) complex, both proceed by hydrogen-atom transfer [262].

All the other complexes in Table 4 that undergo spin-crossover do so in a gradual and often incomplete manner, that in at least some cases varies significantly between samples. Complex salts of **92**–**96** exhibit heterogeneous iron environments by Mössbauer spectroscopy in the solid, which undergo spin-crossover at different rates, or to differing degrees, upon cooling [220,223,225]. In only one case has this information been combined with a variable temperature crystallographic investigation, for $[Fe(\mathbf{92})_3][BF_4]_2 \cdot 2H_2O$, which undergoes a gradual spin-crossover centred at 135 K that is only 70% complete [221,223,224]. Crystals of this compound contain just one unique iron site, with anions and solvent molecules that are very badly disordered in layers between the complex dications. The

symmetry and intermolecular packing of this structure do not change across the temperature range of the spin-transition, which led to the conclusion that the multiple iron sites detected in this material by Mössbauer spectroscopy simply reflect local heterogeneities in their intermolecular environments, caused by the aforementioned anion and solvent disorder [223]. It is unclear whether this conclusion can be generalised towards other complexes of **92**–**96**, or to other compounds in Table 4 that show poorly-defined spin-transitions, most of which have only a single type of iron site by Mössbauer (see e.g. [195,216,218,228,239,254]). Other possible origins of the gradual, often incomplete spin-crossover in the compounds in Table 4 could include: the co-crystallisation of *fac* and *mer* isomers in the bulk material; linkage isomerism (for ligands like **92**–**95**, **117** and **118** for example, which could coordinate through the triazole *N*2 or *N*4 atoms); and/or, co-crystallisation of racemic and optically pure polymorphs of these chiral molecules.

Bidentate ligands that form low-spin $[FeL_3]^{2+}$ complexes can often yield compounds of the $[Fe(NCS)_2L_2]$ type that do show spin-crossover (Table 5). The compounds $[Fe(NCS)_2(\mathbf{44})_2]$ [263] and $[Fe(NCX)_2(\mathbf{53})_2]$ (X = S and Se) [4] were among the first iron(II) spin-crossover compounds to be identified. Early reports described that the appearance of the thermal spin-transition in all these materials varies considerably between samples, which led to the suggestion that these materials crystallise as more than one polymorph [4,263,264]. Since more recent studies showed that their spin-crossover is very dependent on sample history [269,287,289], and there are no structural data from a putative second polymorph, this remains an open question [50,112,304]. The spin-transition in unground samples of each compound is very abrupt, and shows a small hysteresis loop of no more than 1 K. The crystal forms that have been characterised for all three compounds are all isostructural (in the orthorhombic space group *Pbcn*), contain *cis*-octahedral iron(II) centres, and do not undergo a crystallographic phase change during spin-crossover [275,276,285,286,308]. While the unit cell of a second orthorhombic polymorph of $[Fe(NCS)_2(\mathbf{44})_2]$ has also been reported [263], no more detailed structural information on this form is available. Attempts to synthesise $[Fe(NCSe)_2(\mathbf{44})_2]$ yielded instead a product of formula $[Fe_3(\mathbf{44})_7(NCSe)_6]$, whose structure is uncertain but which contains two low-spin and one high-spin iron centres [277].

Both $[Fe(NCS)_2(\mathbf{44})_2]$ and, in particular, $[Fe(NCS)_2(\mathbf{53})_2]$ are some of the best characterised spin-crossover complexes (Table 5), and have often been used as prototype materials in the demonstration of new aspects of the spin-crossover phenomenon. Particular highlights in their chemistry include some of the first studies of the LIESST phenomenon [21,271]; the first demonstration of the NIESST effect in a spin-crossover compound [270,287]; the first conclusive observation of the perturbation of a thermal spin-transition by a strong, continuous or pulsed, magnetic field [291]; and, the demonstration that spin-crossover in $[Fe(NCS)_2(\mathbf{53})_2]$ (and $[Fe(NCS)_2(\mathbf{122})_2]$) is also reflected in changes in their dielectric constants, leading to potential applications in dielectric memory devices [11]. The low- and (trapped) high-spin forms of $[Fe(NCS)_2(\mathbf{53})_2]$ [286] and $[Fe(NCSe)_2(\mathbf{53})_2]$ [308] have been crystallographically characterised at very low temperatures. Interestingly, the metastable high-spin forms of both compounds at ca. 30 K show small, but significant, differences from their thermally stabilised high-spin forms at room temperature, particularly in the Fe–NCX bond length and the intermolecular contacts in the crystal. That has been attributed to anisotropic contraction of their crystals on cooling between the two very different temperatures of the experiments. This leads to different intermolecular crystal pressures in the two structures, resulting in changes in the way the molecules pack together and deformation of the ligand shell about the rather plastic high-spin iron(II) ions.

Like $[Fe(NCS)_2(\mathbf{44})_2]$ and $[Fe(NCS)_2(\mathbf{53})_2]$, most of the other complexes in Table 5 that have been crystallographically characterised also have *cis*-isothiocyanate (or analogous) ligands. However, all except one example [340] of complexes of the (pyrid-2-yl)triazolyl-donor ligands **111** and **113**–**115** instead adopt a *trans* stereochemistry [251,334–340]. Most heavily studied of these is the series $[FeX_2(\mathbf{113})_2]$ ($X^- = NCS^-$, $NCSe^-$, $\{NC\}_2N^-$, $tcnq^-$). The thiocyanate and selenocyanate compounds both crystallise in two different unsolvated polymorphs with the same $P2_1/n$ crystal symmetry. The α-polymorph of both compounds undergoes a relatively gradual but well-defined thermal spin-crossover on cooling [334,335], but the β-polymorph remains high-spin at all temperatures [337]. While the geometries of the complex molecules in the two polymorphs are very similar, it is noteworthy that the Fe–N bonds in the β-crystals are consistently longer than in the α-form, by up to 0.04 Å [337]. The increased structural rearrangement that would be required to produce a putative low-spin form of the β-polymorph may be responsible for its remaining high-spin on cooling. A similar polymorphism between spin-crossover and high-spin crystal forms is also shown by $[Fe(NCS)_2(\mathbf{112})_2]$, although this compound adopts the *cis*-geometric isomer [348].

The thermal spin-transition in $[Fe(N\{CN\}_2)_2(\mathbf{113})_2]$ has very low $T_{1/2}$ of 86 K, with a pronounced discontinuity at around 50% conversion, and only proceeds to 63% completeness at a normal rate of cooling [338]. The discontinuity may reflect the fact that two distinct crystal phases of this material have been identified, which could both be present in the bulk material [339]. The high-spin state of this material can be trapped at low temperatures by irradiation or thermal quenching. Importantly, the thermally trapped material relaxes to a fully low-spin form upon rewarming to ca. 50 K, showing that the low-spin state of this material is accessible. This implies that its incomplete spin-crossover reflects partial kinetic trapping of the high-spin state at the very low temperatures involved. Single crystal structures of the trapped metastable high-spin state of $[Fe(N\{CN\}_2)_2(\mathbf{113})_2]$ at 15 K have been reported, by

Where it is known, the disposition of the isothiocyanate (or similar) ligands about the iron centres in these compounds is indicated. See Refs. [161,215,274,278] for more examples, and Table 1 for the abbreviations of physical techniques.

[a] N. Sinclair, S. R. Batten, B. Moubaraki, K. S. Murray, private communication.

[b] From a solvated crystal structure.

[c] The bulk material probably contains a mixture of both crystal phases, accounting for its spin-crossover discontinuity.

both irradiation and thermal quenching of a single crystal [339]. While its spin-transition is unexceptional in itself, [Fe(tcnq)$_2$(**113**)$_2$] is unusual as a spin-crossover compound containing two organic radical anion [tcnq$^{\bullet}$]$^-$ ligands [340].

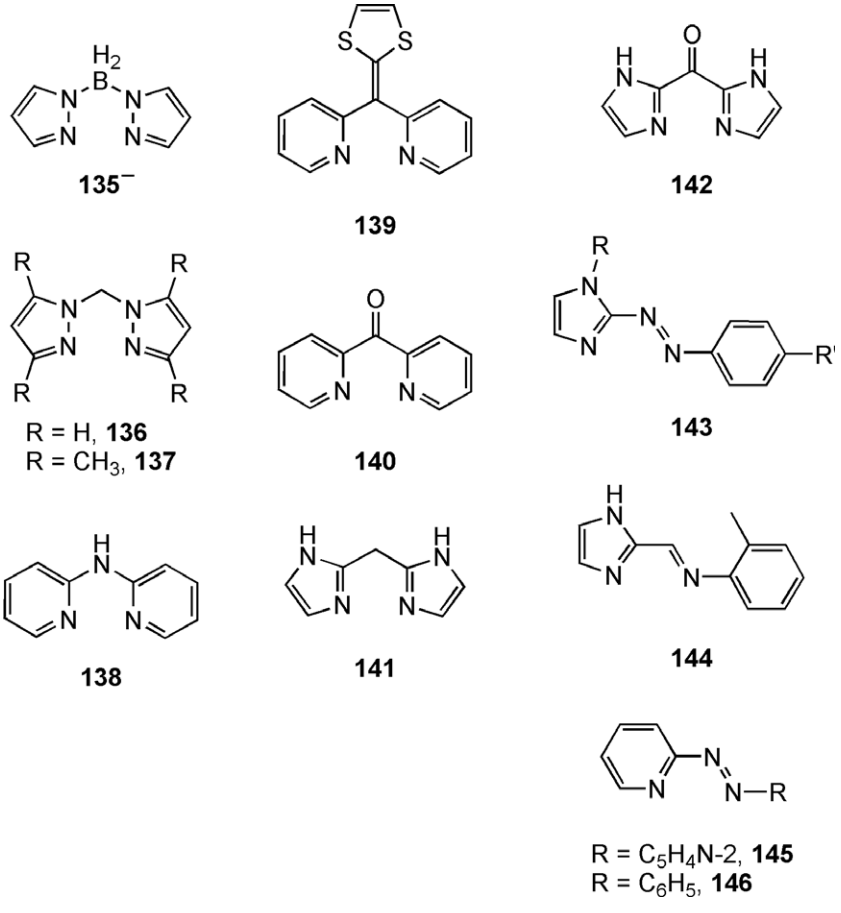
UV irradiation of the *trans*-styryl group in CH_3CN solutions of [Fe(NCS)$_2$(**77**)$_2$] at room temperature results in its photoisomerisation to the *cis*-geometric isomer. UV/Vis spectra show that this change is accompanied by the appearance of an increased high-spin iron fraction in the solution, the first time that a ligand-driven, light-induced spin-crossover (LD-LISC) had been demonstrated at room temperature [322,323]. Gradual thermal spin-crossover in Langmuir–Blodgett films of [Fe(NCS)$_2$(**78**)$_2$] [323–326], [Fe(NCS)$_2$(**79**)$_2$] [327] and [Fe(NCS)$_2$(**80**)$_2$] [295] has been observed. The spin-transition in monolayer samples [Fe(NCS)$_2$(**78**)$_2$] [325] and [Fe(NCS)$_2$(**79**)$_2$] [327] closely resembles that in the neat solid, although in the latter compound spin-crossover is only achieved if the film is first annealed at 370 K, the melting point of the semi-fluorinated chain substituents. However, although Langmuir–Blodgett films of [Fe(NCS)$_2$(**80**)$_2$] undergo a gradual thermal spin-transition centred at 260 K, the neat solid complex is high-spin above liquid nitrogen temperatures [295]. Laser irradiation of unannealed Langmuir–Blodgett films of [Fe(NCS)$_2$(**79**)$_2$] results in ca. 20% photoconversion to its metastable high-spin form [328]. The LIESST excited state in the film decays more rapidly than in the neat solid compound, which may reflect the different pressure experienced by molecules in a monolayer compared to the solid state. The complex [Fe(NCS)$_2$(**81**)$_2$] has been patented for use as a dye in solar cells, although its spin-state properties were not recorded [354].

Several other [Fe(NCS)$_2$L$_2$] compounds, not listed in Table 5, exhibit magnetic moments of intermediate value at room temperature, that often do not vary significantly on cooling. This led to several early suggestions that they adopt an intermediate, $S = 1$ spin state [161,274,278,279,309]. Although intermediate-spin iron(III) complexes are well-established [355], genuine $S = 1$ iron(II) compounds are very rare and none of the established examples is octahedral [356]. It was subsequently shown that one of the putative intermediate-spin iron(II) compounds in Table 5 in fact contains a mixture of high- and low-spin iron sites that interconvert rapidly on the Mössbauer timescale, leading to a single averaged Mössbauer doublet for the material near room temperature [309] (see also Section 7). More generally, an intermediate spin-state would imply that the energy gap between the $d_{x^2-y^2}$ and d_{z^2} orbitals is large enough to overcome the unfavourable electron pairing energy (to prevent a high-spin state from forming), but that Δ_{oct} is small so the compound is not low-spin. That requirement implies that the $\Delta E\{d_{x^2-y^2} \rightarrow d_{z^2}\} > \Delta_{oct}$, which is extremely unlikely in an octahedral ligand field. Hence, reports of putative $S = 1$ [Fe(NCS)$_2$L$_2$] compounds should be treated with caution.

3.4. Selected complexes of other bidentate ligands

The compounds [Fe(**44**)(**135**)$_2$] and [Fe(**53**)(**135**)$_2$] are isostructural at room temperature, and undergo abrupt thermal spin-transitions at almost the same temperature with $160 \leqslant T_{1/2} \leqslant 163$ K [357]. However, [Fe(**53**)(**135**)$_2$] undergoes a crystallographic phase change upon spin-crossover, from $C2/c$ (high-spin) to $P\bar{1}$ (low-spin), while [Fe(**44**)(**135**)$_2$] retains the $C2/c$ crystal form in both spin states [358]. This different phase behaviour is also probably retained in these two compounds during spin-crossover under pressure [359]. Laser irradiation of [Fe(**53**)(**135**)$_2$] at 30 K produces a metastable high-spin form of its low-

temperature $P\bar{1}$ phase. That explains the lower LIESST relaxation temperature exhibited by this complex (44 K) compared to [Fe(**44**)(**135**)$_2$] (52 K), since the metastable high-spin state of the latter adopts the $C2/c$ crystal form [358]. The homoleptic complex [Fe(**135**)$_3$]$^-$ can only be isolated in the presence of a large excess of **135**$^-$ ligand; its tetraethylammonium salt is high-spin at 300 K [360]. The only other homoleptic iron(II) complexes of *bis*-pyrazolylborate ligands have a [FeL$_2$] stoichiometry [361,362] and are often very air-sensitive. They have been assigned tetrahedral structures from their IR spectra [363]. The *bis*-pyrazolylmethane complexes *trans*-[Fe(NCS)$_2$(**136**)$_2$] [364] and [Fe(NCS)$_2$(**137**)$_2$] [365] are high-spin at room temperature, although the visible spectrum of the latter compound implies that it may undergo a spin-crossover equilibrium in CH_3NO_2 solution.



While [Fe(N{CN}$_2$)$_2$(**138**)$_2$] is high-spin [366], *cis*-[Fe(NCS)$_2$(**138**)$_2$] shows a gradual thermal spin-transition upon cooling, centred at the low temperature of 88 K [366,367]. In contrast, *cis*-[Fe(NCS)$_2$(**139**)$_2$]·1/2CH_3OH exhibits a very abrupt spin-crossover at 132 K, which was attributed to lattice cooperativity mediated by intermolecular S···S contacts in the crystal [368]. The compound undergoes quantitative photoconversion to a trapped high-spin form at 5 K, which relaxes upon rewarming to 66 K. The related complex [Fe(NCS)$_2$(**140**)$_2$] is low-spin at room temperature [369]. [Fe(**141**)$_3$][ClO_4]$_2$ is high-spin, and is oxidised to [Fe(**142**)$_3$][ClO_4]$_2$ upon exposure to air [370]. The latter compound appears to undergo a thermal spin-crossover in solution by Evans' method, being almost fully high-spin at 307 K.

While complexes of type [Fe(**143**)$_3$]$^{2+}$ (R = H or alkyl, R′ = H, alkyl or Cl) are all low-spin [371], [Fe(NCS)$_2$(**143**)$_2$] are high-spin at room temperature [372]. A full variable temperature magnetic study of the thiocyanato complex with R = CH_3 and R′ = C_2H_5 confirmed that it remains high-spin on cooling to 5 K. [Fe(NCS)$_2$(**144**)$_2$] is also high-spin, and has *cis*-isothiocyanate ligands in the crystal [373]. The dipyridylhydrazone ligands in low-spin [Fe(NCS)$_2$(**145**)$_2$] chelate to the metal through one pyridyl and one azo N donor [374]. Salts of homoleptic [Fe(**146**)$_3$]$^{2+}$ are also low-spin [375].

4. Tridentate ligands

4.1. Tripodal ligands

Several iron(II) complexes of *tris*-pyrazolyl-borate and methane ligands exhibit thermal spin-transitions (Table 6) [376]. The parent compound [Fe(**147**)$_2$] is low-spin at room

temperature, but undergoes a complete low → high spin-crossover on warming [377]. An initial heating:cooling cycle shows a gradual transition with a 33 K hysteresis loop, with $T_{1/2}\uparrow = 393$ K and $T_{1/2}\downarrow = 360$ K [377,378]. Subsequent heating:cooling cycles on the same sample follow the pathway of the cooling curve, with no hysteresis now being observed. DSC measurements suggested that [Fe(**147**)$_2$] undergoes an irreversible crystallographic phase transition upon initial heating to 393 K; consistent with this, its single crystals shatter at this temperature [378].

Table 6
Iron(II) complexes of *tris*-pyrazolylborate, *tris*-pyrazolylmethane and related ligands

	Spin-state or $T_{1/2}$ (K)	Form of spin-state transition	Spin states of crystal structure(s)	Other measurements	Refs.

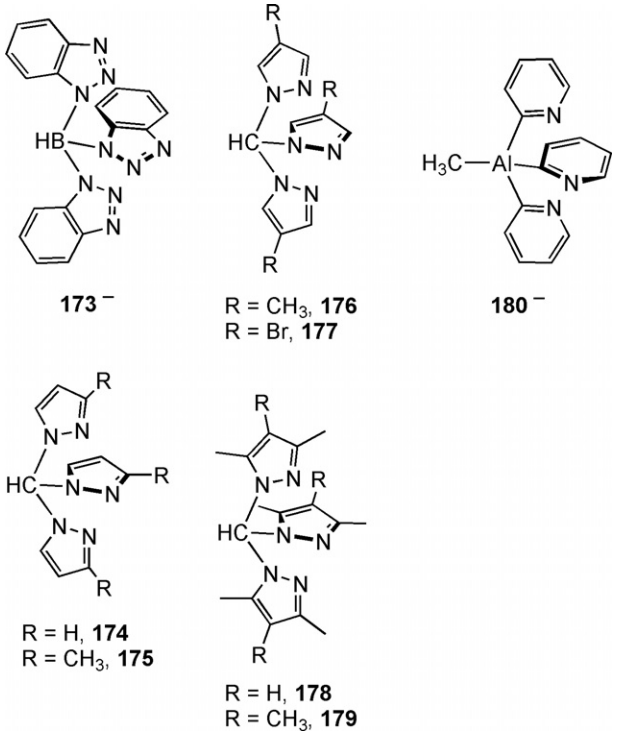
See also Refs. [361,385,401,406] for additional examples, and Table 1 for the abbreviations of physical techniques.



[a] From a solvated crystal structure.

[b] Compound forms two crystalline polymorphs, which have similar magnetic behaviour and were both crystallographically characterised.

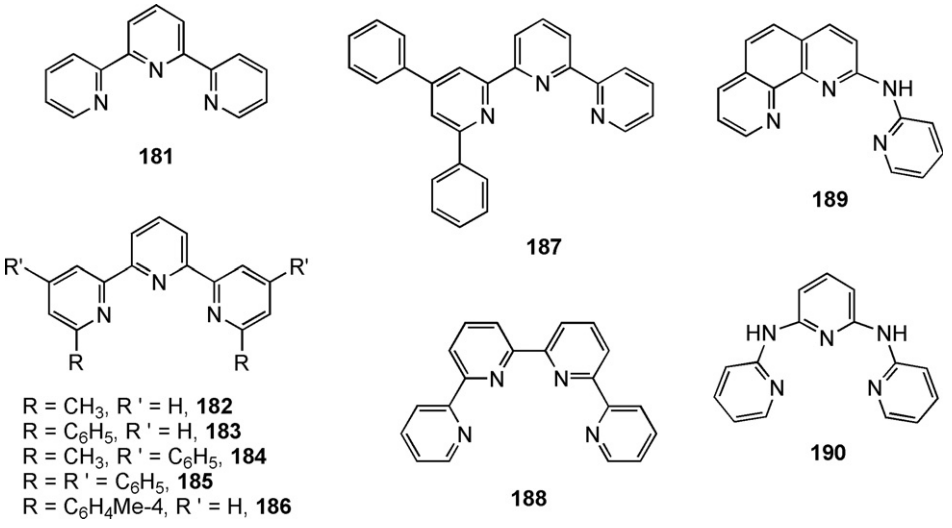
[c] Powder precipitated from CH$_2$Cl$_2$. The same compound precipitated from acetone, undergoes a similar spin-state transition that is only 12% complete.

The methylated complex [Fe(**148**)$_2$] undergoes a partial spin-state transition upon cooling by Mössbauer spectroscopy, from HS at room temperature to a 3:2 HS:LS ratio at 4.2 K [385]. This may reflect that crystals of the material contain two independent molecules per asymmetric unit, both of which are high-spin at room temperature. It is possible that one of these molecules undergoes a partial spin-crossover upon cooling while the other does not, although this remains to be investigated further. Solid [Fe(**155**)$_2$] undergoes a gradual, complete spin-state transition centred at 195 K [389], while [Fe(**149**)$_2$] and [Fe(**160**)$_2$] also exhibit gradual spin-transitions at slightly lower temperatures, that are only 50% complete. This reflects the fact that the crystalline compounds both contain two distinct iron sites [393]. In chlorinated solvents [Fe(**147**)$_2$] ($T_{1/2} \approx 340$ K), [Fe(**157**)$_2$] ($T_{1/2} > 290$ K), [Fe(**158**)$_2$] ($T_{1/2} \approx 290$ K) and [Fe(**155**)$_2$] (HS above 215 K) show sequentially lowered spin-crossover temperatures [396,398], which reflects steadily increasing steric hindrance between the pyrazole-3-methyl substituents in the methylated complexes [49]. Consistent with this explanation, the fully methylated compound [Fe(**156**)$_2$] is high-spin in the solid above 4.2 K [390,393], while [Fe(**153**)$_2$] is low-spin at room temperature [387].

The compounds [Fe(**159**)$_2$] [49,382], [Fe(**163**)$_2$] [49] and [Fe(**164**)$_2$] [399] are all low-spin at room temperature in the solid and in solution. Crystal structures and molecular mechanics calculations on [Fe(**163**)$_2$] have implied that this reflects steric repulsion between the non-coordinated pyrazolyl or phenyl boron substituent and the coordinated pyrazole rings, which enforces narrow N–B–N angles between the coordinated pyrazole groups [49]. Interestingly, however, photoelectron spectroscopy on [Fe(**159**)$_2$] has implied that this compound is high-spin in the gas phase below 290 K [397]. The compound [Fe(**166**)$_2$] has been isolated as two unsolvated polymorphs, and one CH_2Cl_2 solvate [399]. One of the unsolvated forms is high-spin, while the other undergoes an abrupt thermal spin-transition at 131 K. This behaviour was attributed to the different patterns of intermolecular π–π interactions between the pendant iodophenyl groups in the crystal. These are clearly more geometrically favourable in the high-spin polymorph, which may result in a higher activation barrier for the structural rearrangement required for spin-crossover in this form. In addition to the compounds listed in Table 6, several other homoleptic iron(II) complexes of sterically hindered *tris*- or *tetrakis*-pyrazolylborates are known that are presumably high-spin or low-spin at room temperature from their colouration and/or NMR behaviour [361,401,406]. However, Mössbauer spectra and EXAFS studies imply that [Fe(**161**)$_2$] instead adopts a tetrahedral structure with bidentate ligands [407].

Where they undergo spin-crossover (see below), *bis*-(*tris*pyrazolylmethane) complexes of iron(II) undergo spin-state transitions at generally similar temperatures to their *bis*-(*tris*pyrazolylborate) analogues containing the same pattern of pyrazole substitution (Table 6). This shows that the zwitterionic nature of iron *tris*pyrazolylborate compounds has little effect on the electronic character of the iron centre. The preference of [Fe(**174**)$_2$]$^{2+}$ for a low-spin state at 0 K has been successfully reproduced by density functional (DF) calculations incorporating non-hybrid BLYP or PW91 basis sets [63]. The same BLYP DF method correctly predicted that [Fe(**174**)$_2$]$^{2+}$ and [Fe(**177**)$_2$]$^{2+}$ should undergo spin-crossover at similar temperatures [408].

The salt [Fe(**178**)$_2$][BF$_4$]$_2$ undergoes an abrupt spin-state transition at 206 K, without hysteresis, that is only 50% complete [410]. This is a result of a crystallographic phase change at this temperature [413]: from a high-temperature form in $C2/c$ that contains one formula unit per asymmetric unit, that is fully high-spin at 220 K; to a low-temperature form in $P\bar{1}$ containing two crystallographically independent molecules, one of which is low-spin at 173 K while the other is apparently fully high-spin. The analogous complexes [M(**178**)$_2$][BF$_4$]$_2$ (M = Co, Ni, Cu) are isomorphous with the iron compound at room temperature and also undergo the same phase transition upon cooling, although this has no impact on their variable temperature magnetic moment [415]. [Fe(**178**)$_2$]I$_2$, when crystallised from CH_2Cl_2, undergoes a spin-state transition at 203 K that is ca. 80% complete; the remaining 20% of the sample become low-spin upon further cooling to ca. 60 K. In contrast, the same compound when crystallised from acetone undergoes spin-crossover at the same temperature, but that is only about 12% complete [416]. The trapping of some forms of [Fe(**178**)$_2$]$^{2+}$ in the high-spin state was rationalised by comparing crystal structures of two polymorphs of [Fe(**178**)$_2$]I$_2$ that crystallise from CH_2Cl_2. These were a solvent-free form, that undergoes spin-crossover at 195 K, at which point the crystals shatter; and, a solvate of formula [Fe(**178**)$_2$]I$_2$ · 4CH_2Cl_2 that remains high-spin at 110 K [416]. The main difference between these two compounds at room-temperature lies in the pitch of their pyrazole rings, as expressed by the Fe–N–N–C torsion angles. In the unsolvated crystals of [Fe(**178**)$_2$]I$_2$ this torsion averages to 171° for the six pyrazole groups, while for the solvate the average torsion is 161° [416]. A similarly low average Fe–N–N–C torsion of 162° is seen in the molecule in the low-temperature polymorph of [Fe(**178**)$_2$][BF$_4$]$_2$, that is trapped in a high-spin state. In contrast, the low-spin molecule in the same structure shows an average torsion of 179°, reflecting the smaller size of the low-spin Fe(II) ion [413]. Apparently, in a crystalline environment molecules of [Fe(**178**)$_2$]$^{2+}$ with strongly tilted pyrazole rings are insufficiently flexible to accommodate the change in size of the coordinated iron ion, that would accompany a spin-state transition. Similar conclusions about the influence of pyrazole ring pitch on spin-state were drawn from a survey of known high-spin iron(II) *tris*pyrazolylborate complexes [393,400].



Homoleptic iron(II) complexes of several other tripodal ligands containing three pyrid-2-yl, pyrazol-1-yl or imidazol-2-yl donors in various combinations have also been reported, and are nearly all low-spin [409,410,418]. One possible exception is [Fe(**180**)$_2$], which is 'paramagnetic at room temperature' but shows a unique Fe–N bond length of 2.054(3) Å at 180 K that would indicate a predominantly low-spin state at that temperature [419].

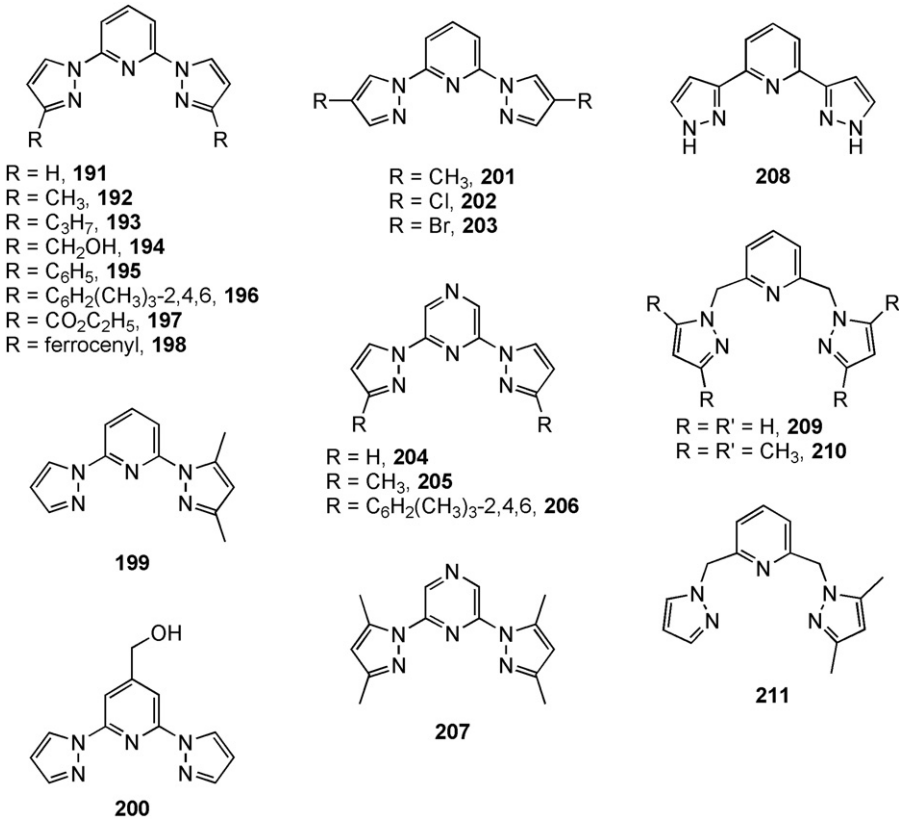
4.2. Terpyridines

All $[FeL_2]^{2+}$ salts, where L is **181** or a derivative substituted at the 4- or 5-positions of one or more of the pyridine rings, are low-spin [420,421]. However, metastable high-spin states of $[^{57}Fe(\mathbf{181})_2]Cl_2 \cdot 5H_2O$ and $[^{57}Fe(\mathbf{181})_2][ClO_4]_2 \cdot 1/2H_2O$ have been detected at low temperatures by Mössbauer emission spectroscopy, as intermediates in the nuclear decay of the corresponding salts of $[^{57}Co(\mathbf{181})_2]^{2+}$ [422]. The rates of relaxation of these metastable high-spin $[Fe(\mathbf{181})_2]^{2+}$ species, down to their low-spin ground state, are inversely proportional to the ligand field strength experienced by the Co(II) ions in the starting materials [422]. This is the same trend as seen in the relaxation of photogenerated metastable high-spin species (Sections 1 and 8). Irradiation of a doped solid $[Fe_{0.02}Mn_{0.98}(\mathbf{181})_2][ClO_4]_2$ converts the (low-spin) Fe fraction of the material into its metastable high-spin state that is indefinitely long lived at 10 K [423]. In contrast, pure $[Fe(\mathbf{181})_2][ClO_4]_2$ does not undergo spin-conversion upon irradiation under the same conditions. This is the first time that a low-spin complex has been fully activated towards the LIESST spin-trapping effect by doping into a host material (although an increase in the lifetime of the transient photogenerated high-spin form of a low-spin complex, doped it into a host lattice, had been demonstrated before [424]).

In contrast, $[FeL_2]^{2+}$ complexes of 6-substituted-2,2′:6′,2″-terpyridines have more varied electronic structures. The complexes of **182**–**185** are high-spin in solution, while $[Fe(\mathbf{185})_2][ClO_4]_2 \cdot CH_3CN \cdot H_2O$ is high-spin in the crystal at 223 K [425]. Salts of $[Fe(\mathbf{186})_2]^{2+}$ undergo spin-crossover on cooling in CH_3CN, but show more complex behaviour in the solid state: $[Fe(\mathbf{186})_2]PF_6]_2$ is completely high-spin above 5 K, while $[Fe(\mathbf{186})_2][ClO_4]_2$ is low-spin at room temperature [425]. This dichotomy was explained by structure determinations of solvated crystals of these compounds. Low-spin $[Fe(\mathbf{186})_2][ClO_4]_2$ has a fairly regular octahedral geometry with near-perpendicular terpyridyl ligands, that shows only small deviations from local D_{2d}-symmetry if the ligand phenyl substituents are ignored. However (high-spin) $[Fe(\mathbf{187})_2][PF_6]_2 \cdot 2(CH_3)_2CO$ has an unusual, twisted coordination geometry, in which the dihedral angle between the terpyridyl frameworks of the two ligands is only 64.0°. The same twisted high-spin structure is also shown by $[Fe(\mathbf{185})_2][ClO_4]_2 \cdot CH_3CN \cdot H_2O$ [425] and $[Fe(\mathbf{186})_2][FeCl_4]_2$ [426]. A theoretical study on a related system (Section 4.3) has shown that this structure corresponds to an angular Jahn–Teller distortion of the high-spin d^6 ^5E configuration (in O_h symmetry), which traps the iron centre in a high-spin state [15].

The crystal structure of $[Fe(\mathbf{188})_2][ClO_4]_2$ at room temperature shows a high spin Fe(II) centre with each quaterpyridyl ligand binding in a tridentate manner [427]. The coordination geometry of this compound is highly distorted, in a manner that partly resembles that of $[Fe(\mathbf{187})_2][PF_6]_2$ [424]. In $[Fe(\mathbf{188})_2][ClO_4]_2$, however, this distorted structure leaves space for an additional long Fe···N contact of 2.819(9) Å to the fourth pyridyl ring of one of the two ligands, resulting in a [6+1] coordination geometry overall. No low temperature crystallographic or

magnetic investigation of this compound was undertaken. Solid [Fe(**189**)$_2$]X$_2$ (X$^-$ = NO$_3^-$ and BF$_4^-$), [Fe(**189**–H)$_2$] [428] and [Fe(**190**)$_2$]Cl$_2$ · 2MeOH [429] are all low-spin.



4.3. 2,6-Di(pyrazolyl)pyridines and related ligands

Iron(II) complexes of **191** and several of its substituted derivatives have been prepared (Table 7) [430]. Solid [Fe(**191**)$_2$][BF$_4$]$_2$ exhibits an abrupt spin transition at 261 K in the solid [15,26,431–433], but the ClO$_4^-$ [434], PF$_6^-$ [15] and SbF$_6^-$ [434] salts of the same complex, which are isostructural with each other, remain fully high-spin above 5 K. This behaviour is explained by the crystal structures of the two compounds: while [Fe(**191**)$_2$][BF$_4$]$_2$ has a six-coordinate geometry at iron with near-regular D_{2d} symmetry, the other salts adopt an unusual C_2-distorted, twisted molecular structure that traps the complex in a high-spin state. DF calculations showed that the C_2 structure represents an angular Jahn-Teller distortion of the high-spin d^6 manifold [15]. The same structural distortion is also exhibited, to differing degrees, by high-spin [Fe(**191**)$_2$]I$_{0.5}$[I$_3$]$_{1.5}$ [435], [Fe(**194**)$_2$]X$_2$ (X = BF$_4^-$ [434] and ClO$_4^-$ [437]), [Fe(**195**)$_2$][BF$_4$]$_2$ [434] and [Fe(**204**)$_2$]-[SbF$_6$]$_2$ [442], and by high-spin iron(II) complexes of three terpyridine derivatives (Section 4.2) [425,426]. The salt [Fe(**191**)$_2$][Co(C$_2$B$_9$H$_{11}$)$_2$]$_2$ is also notable, in containing equal numbers of angularly distorted and undistorted molecules in the crystal [435]. As expected, this material undergoes a thermal spin transition that is only 50% complete. Interestingly, recrystallisation of [Fe(**191**)$_2$][BF$_4$]$_2$ at a temperature below its thermal spin-transition yielded a different low-spin phase [Fe(**191**)$_2$][BF$_4$]$_2$ · xCH$_3$NO$_2$ ($x \approx 3$) Crystals of this material become high-spin, with concomitant decomposition, at essentially the same temperature as the spin-transition undergone by the solvent-free material [15].

See Table 1 for the abbreviations of physical techniques.
[a] From a solvated crystal structure.
[b] Structure refinement from powder diffraction data.

Unlike the solvent-free material (see above), crystalline $[Fe(\mathbf{194})_2][ClO_4]_2 \cdot x$MeCN ($x \approx 0.75$) is high-spin at 200 K but undergoes a partial spin-state transition upon cooling to 100 K, resulting in a colour change and the appearance of ligand conformational disorder [437]. Refinement of this disorder implied that the transition was 42% complete at this temperature. The packing diagram at 100 K revealed that one of the disordered ligand hydroxyl groups is only 1.456(17) Å from its nearest neighbour when both molecules are low-spin. This steric clash implies that only one complex molecule in this pair can be low-spin, and places a natural limitation of 50% completeness on the spin-state transition.

The salts $[Fe(\mathbf{204})_2]X_2$ ($X = BF_4^-$ and ClO_4^-) both show abrupt high $\rightarrow$ low spin-state transitions upon cooling, with $T_{1/2} = 223$ K and 206 K, respectively [441]. Powder diffraction measurements showed that $[Fe(\mathbf{204})_2][ClO_4]_2$ is isostructural with $[Fe(\mathbf{191})_2][BF_4]_2$ at room temperature but, unlike the latter compound, it undergoes a crystallographic phase change at the spin-crossover temperature [442]. The high- and low-spin forms have the same apparent crystal symmetry, but the unit cell *a* axis has doubled in length in the low-temperature phase. The similarly abrupt nature of the spin-transitions exhibited by these three compounds, and by $[Fe(\mathbf{201})_2][ClO_4]_2$, $[Fe(\mathbf{202})_2][BF_4]_2$ and $[Fe(\mathbf{203})_2][BF_4]_2$ has been attributed to the layered "terpyridine embrace" crystal packing motif that they all adopt [440]. Thermal spin-crossover in $[Fe(\mathbf{205})_2]X_2$ ($X = BF_4^-$ and ClO_4^-) involves two discrete steps [441], despite their only containing a single unique iron environment [444]. The first part of the transition is triggered by an ordering of an anion site in the crystal, which allows an apparently random distribution of half the iron centres to undergo spin-crossover without causing a change in crystal symmetry. The remaining high-spin fraction then undergoes spin-crossover much more gradually as the temperature is further lowered [444].

Several compounds in Table 7 exhibit quantitive photoconversion to their LIESST high-spin states, which have relaxation temperatures of up to 100 K [26,433]. The trapped high-spin forms of $[Fe(\mathbf{191})_2][BF_4]_2$ [432] and $[Fe(\mathbf{200})_2]X_2$ ($X = BF_4^-$ [439] and ClO_4^- [433]) have also been crystallographically characterised at 30 K. In contrast to $[Fe(NCX)_2(\mathbf{53})_2]$ ($X = S$ [286] and Se [308]; Section 3.3), for all these compounds the thermally populated high-spin state at room temperature and the photochemically trapped high-spin state at 30 K show no significant structural differences at the iron centre. The reason why these two sets of crystalline materials behave differently in the LIESST experiment may be related to the different crystal packing motifs they adopt.

Many hydrated and anhydrous salts of $[Fe(\mathbf{208})_2]^{2+}$ also undergo thermal spin-crossover (Table 8). The highly hydrated salts are low-spin at room-temperature, but often become high-spin on heating with concomitant water loss. The less hydrated or anhydrous materials usually undergo

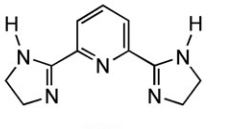
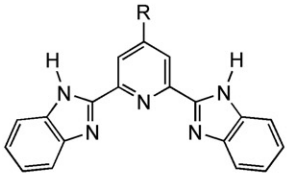
[a] Transition is accompanied by water loss from the sample.

spin-crossover below room-temperature. Anhydrous [Fe(**208**)$_2$][BF$_4$]$_2$ exhibits an abrupt spin transition at 176 K, with a hysteresis loop of between 10 and 16 K depending on the measurement [25,449,450]. The trapped high-spin state of [Fe(**208**)$_2$][BF$_4$]$_2$ can be generated below 80 K by thermal quenching or irradiation; this was the first compound whose LIESST thermal relaxation was shown to deviate from first-order kinetics owing to cooperativity in the solid [450]. In contrast, [Fe(**208**)$_2$][CF$_3$SO$_3$]$_2$ · H$_2$O exhibits in cooling mode an abrupt and complete high → low-spin transition at 140 K. However, upon rewarming the low → high-spin conversion takes place in two steps: a gradual transition centred at 170 K during which ca. 1/3 of the sample becomes high-spin; and, a more abrupt change at 285 K [454]. This leads to the bulk of the sample showing a very wide spin-crossover hysteresis width of ca. 140 K. The high-spin form of [Fe(**208**)$_2$][CF$_3$SO$_3$]$_2$ · H$_2$O can also be generated at 77 K by thermal trapping or irradiation although, unlike the BF_4^- salt, the thermal relaxation kinetics of these two forms of the metastable high-spin state are very different [454]. This implies that freeze-quenching the sample preserves the high-temperature crystallographic phase, while LIESST excitation generated a metastable high-spin form of the low-temperature phase. Consistent with this suggestion, an EPR study implied that spin-crossover in both [Fe(**208**)$_2$][BF$_4$]$_2$ and [Fe(**208**)$_2$][CF$_3$SO$_3$]$_2$ · H$_2$O is accompanied by a change in crystallographic symmetry [451].



The gradual thermal spin-transition in [Fe(**208**)$_2$][NCS]$_2$ · 2H$_2$O is split into two steps which, unusually, both exhibit pronounced hysteresis [447,448]. Repeated cycling through this transition changes its form to a single, more abrupt spin-crossover at 232 K; annealing of the sample at room temperature for 24 h led to its reversion to the original behaviour. Powder diffraction measurements showed that this reflects a sample-dependent distribution of two crystal phases in the bulk material, which can be thermally interconverted [448]. Spin-crossover in three different salts of $[Fe(\mathbf{208})_2]^{2+}$ in acetone solution is essentially independent of the anion present, occurring at $T_{1/2} \approx 260$–270 K [446].

Eight different hydrated or anhydrous salts of $[Fe(\mathbf{208})_2]^{2+}$ exhibit efficient LIESST excitation on irradiation at 10 K, yielding trapped high-spin materials with relaxation temperatures of between 40 and 110 K [25]. LIESST relaxation in a $[Fe(\mathbf{208})_2]^{2+}$/Nafion film takes place in the same temperature range as the neat solids, showing that intermolecular cooperativity has only a minor influence on the stability of a metastable high-spin state [458].



$[Fe(\mathbf{209})_2][ClO_4]_2 \cdot H_2O$ undergoes a gradual thermal spin-transition centred near 250 K [459,460]. Salts of $[Fe(\mathbf{210})_2]^{2+}$ [459,461] and $[Fe(\mathbf{211})_2]^{2+}$ [459,462] are high-spin, which probably reflects steric crowding about the iron centres [462]. A small low-spin population was detected in $[Fe(\mathbf{210})_2][ClO_4]_2 \cdot CH_3CN$ and $[Fe(\mathbf{210})_2][B(C_6H_5)_4]_2 \cdot 2CH_3CN$, however, whose relative abundance varies with temperature in a manner inconsistent with a simple spin-crossover equilibrium. This was attributed to a thermally induced interconversion of spin-states in a fraction of the sample, triggered by a change in ligand conformation [461]. Photoexcitation of $[Fe(\mathbf{209})_2][ClO_4]_2 \cdot H_2O$ at 10 K affords its trapped high-spin state, which decays at the relatively low temperature of 38 K [463]. The high → low-spin reverse-LIESST effect in $[Fe(\mathbf{210})_2][ClO_4]_2 \cdot CH_3CN$ has also been demonstrated, albeit with a conversion efficiency of <30% [464]. Relaxation of the trapped excited spin-states in both materials occurs via a distribution of rate constants rather than simple sigmoidal kinetics, which was suggested to reflect the presence in the bulk solid of both *fac* and *mer* complex isomers, and/or different conformers of the unusually flexible tridentate ligand [463,464].

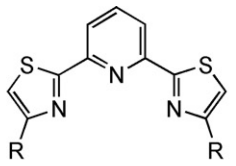
4.4. 2,6-Di(imidazolyl)pyridines, 2,6-di(benzimidazolyl)pyridines and related ligands

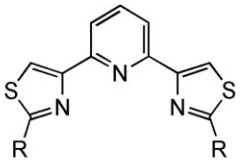
The complex $[Fe(\mathbf{212})_2][ClO_4]_2$ undergoes a spin-transition in CD_3OD solution upon cooling from room temperature to 200 K, although no further magnetochemical characterisation of this material was reported. Basic, aerobic methanol solutions of this compound rapidly convert to a low-spin iron(III) complex of the deprotonated ligand, isolated as $Na[Fe(\mathbf{212}\text{–}2H)_2]\cdot 2H_2O$ [465]. The salt $[Fe(\mathbf{213})_2][ClO_4]_2$ is low-spin [466].

Freshly prepared crystalline samples of $[Fe(\mathbf{214})_2][ClO_4]_2\cdot 1/4H_2O$ undergo an abrupt spin-crossover at 403 K with a 12 K hysteresis loop [467–470]. However, susceptibility measurements of rapidly precipitated or aged samples exhibit a variable, reduced population of this transition, superimposed onto a much broader feature centred at lower temperature [469]. These effects do not appear to reflect loss of the water content of the aged and powder samples [469], but may be caused by the presence of iron(III) contaminants [467]. These observations may explain the somewhat variable behaviour found in earlier reports of this material [471,472]. Solid $[Fe(\mathbf{214})_2][BPh_4]_2\cdot xH_2O$ is high-spin when $x = 0$ and 2, but undergoes a gradual spin-crossover centred near 325 K when $x = 4$ [468,473]. The crystalline complex $[Fe(\mathbf{214}\text{–}H)_2]\cdot H_2O$ can be precipitated from aqueous ethanol in the presence of NEt_3, and also exhibits a gradual spin-transition centred at 424 K [474,475]. Further heating results in loss of water from the solid, accompanied by a stabilisation of the high-spin state. Several other solid salts of $[Fe(\mathbf{214})_2]^{2+}$ also undergo spin-crossover above room-temperature, but have been less well characterised [471,473]. Polyethene [476] and polyvinylalcohol [477,478] films containing $[Fe(\mathbf{214})_2][ClO_4]_2$ also undergo spin-crossover by far-IR and UV/Vis spectroscopy. Stretching the PVA films causes the complex molecules to orient themselves within the polymer, allowing their polarisation absorption spectra to be obtained [478].



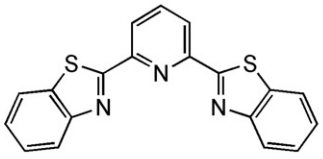
Spin crossover of $[Fe(\mathbf{214})_2]^{2+}$ in solution is complicated by ligand dissociation equilibria, ligand deprotonation and the formation of $[Fe(\mathbf{214})_3]^{2+}$, all of which has been studied in some detail [12,479–481]. Although the mid-point temperature of this transition in all solvents is >350 °C [480,481], the room temperature magnetic moment of this compound depends strongly on concentration and solvent used [480]. The high- and low-spin states of $[Fe(\mathbf{214})_2]^{2+}$ and $[Fe(\mathbf{214}\text{–}H)_2]$ in methanol/ethanol mixtures show different fluorescence maxima, whose relative intensities change as the temperature is lowered and spin-crossover progresses [478]. The energy difference of the two fluorescence peaks implied that the high- and low-spin states in $[Fe(\mathbf{214})_2]^{2+}$ are separated by ca. 350 cm^{-1}. Although $[Fe(\mathbf{216})_2]^{2+}$ and $[Fe(\mathbf{217})_2]^{2+}$ are high-spin in MeOH solution [481,482], solid-state far-IR spectra show that $[Fe(\mathbf{215})_2][ClO_4]_2$ is high-spin and $[Fe(\mathbf{216})_2][ClO_4]_2$ low-spin, while $[Fe(\mathbf{216})_2][ClO_4]_2\cdot 3H_2O$ shows thermal spin-crossover [483]. In contrast, $[Fe(\mathbf{216}\text{–}H)_2]\cdot 2C_2H_5OH\cdot H_2O$ and $[Fe(\mathbf{217}\text{–}H)_2]\cdot 2C_2H_5OH\cdot H_2O$ are predominantly low-spin in solution [484] and the solid state [485]. The complex $[Fe(\mathbf{219})_2][ClO_4]_2\cdot 2H_2O$ undergoes a very abrupt spin-crossover at 323 K, with a 35 K hysteresis loop. The morphology of this material prevented its structural characterisation, however [475]. The stability constants of the 1:1 and 2:1 iron(II) complexes of **218** and **220** have been communicated [486]. The *N*,*N*′-dialkylated ligand complexes $[FeL_2][ClO_4]_2$ (L = **221** [471] and **222**–**224** [487]) are all low-spin.

4.5. Selected complexes of other tridentate ligands



While $[Fe(\mathbf{225})_2][ClO_4]_2$is low-spin, steric repulsion from the ligand methyl groups reduces the ligand field in $[Fe(\mathbf{226})_2][ClO_4]_2$ so that it exhibits a gradual thermal spin-crossover centred below 91 K [465]. Similar behaviour is shown by $[Fe(\mathbf{227})_2]X_2$ (low-spin) and $[Fe(\mathbf{228})_2]X_2$ (spin-crossover; $X^- = BF_4^-$ and ClO_4^-), with $T_{1/2}$ for the latter being 350–360 K [488]. Solid $[Fe(\mathbf{229})_2][ClO_4]_2$shows sample-dependent behaviour, sometime undergoing a gradual spin-transition and sometimes remaining high-spin [470,471,489]. A Mössbauer study identified four different iron environments in the solid compound, whose relative distributions varied between samples and appeared to be very dependent on the solvent content [471]. The salts $[Fe(\mathbf{229})_2]Br[FeBr_4]$ [489], $[Fe(\mathbf{229})_2][BPh_4]_2$ [490] and $[Fe(\mathbf{230})_2][ClO_4]_2$ [471] are high-spin although, interestingly, the susceptibility of five-coordinate $[Fe(\mathbf{53})(\mathbf{229})][ClO_4]_2$ is consistent with a partial spin-transition near 170 K [490].

The hydrates $[Fe(\mathbf{231})_2]Cl_2\cdot 6H_2O$ [443] and $[Fe(\mathbf{231})_2]Cl_2\cdot 3H_2O$ [491] are both high-spin, but the anhydrous compound is low-spin and hygroscopic [491]. The latter has been proposed as a moisture detector, particularly for use in space probes [492]. Five other hydrated salts of $[Fe(\mathbf{231})_2]^{2+}$ are high-spin, as are salts of $[Fe(\mathbf{232})_2]^{2+}$ and $[Fe(\mathbf{234})_2]^{2+}$. However, $[Fe(\mathbf{233})_2]X_2\cdot H_2O$ ($X^- = BF_4^-$ and ClO_4^-) both show gradual thermal spin-crossover centred above 80 K [491]. A high-spin state is enforced in $[Fe(\mathbf{235})_2][PF_6]_2$ [493] and $[Fe(\mathbf{236}\text{–}H)_2]$ [494] by conformational strain, associated with the central five-membered ring in the ligands. However, the BF_4^- and ClO_4^- salts of $[Fe(\mathbf{237})_2]^{2+}$ [495,496] both show gradual spin-transitions by susceptibility and Mössbauer measurements, although these were only ca. 60% complete at the lowest temperature measured, 77 K [497].



Different salt hydrates of $[Fe(\mathbf{238})_2]^{2+}$ [495] are either high-spin [498,499], or undergo gradual spin-crossover with $T_{1/2}$ ranging from ca. 250 to >400 K [498,500]. A more thorough study of $[Fe(\mathbf{238})_2][NO_3]_2$ showed that its spin-transition is inhibited by a significant activation energy of 18.8 kJ mol^{-1} below 190 K [501]. If the sample is cooled slowly, the transition is centred at 246 K and proceeds to completeness, with a pronounced hysteresis loop of 34 K. More gradual and incomplete spin-crossover is observed with more rapid temperature ramps, as in earlier studies [498,500]. Unfortunately the structural basis for this unu-

248

sual behaviour is unknown. Aqueous solutions of [Fe(**238**)$_2$]Cl_2 undergo spin-crossover, with a mid-point below 287 K [502]. Interestingly, neutral [Fe(**238**–H)$_2$] also undergoes gradual, incomplete thermal spin-crossover, at temperatures rather lower than the dicationic species [503,504]. The form of this transition is very dependent on the presence or absence of solvent in the material, with $T_{1/2}$ varying from ca. 210 to <83 K [504]. The NO_3^- and BF_4^- salts of $[Fe(\mathbf{239})_2]^{2+}$ undergo spin-crossover above room temperature when hydrated, and below room temperature when anhydrous, while the $CF_3SO_3^-$ salt also shows $T_{1/2} > 383$ K [505]. Spin-crossover in [Fe(**239**–H)$_2$] resembles that in [Fe(**238**–H)$_2$], with a similar dependence on solvent content and sample history [506]. Comparison of the cationic and neutral complexes of **238** and **239** shows that the pyrazine ring in the latter tends to stabilise the

low-spin form of its compounds. This is particularly obvious in solution, when comparing $T_{1/2}$ of [Fe(**238**–H)$_2$] (215 K) and [Fe(**239**–H)$_2$] ($\gg$299 K) in CD_3OD [506].

Solid [Fe(**240**)$_2$][ClO_4]$_2$ exhibits a gradual thermal spin-crossover centred at 173 K [507]. Susceptibility measurements on [Fe(**242**)$_2$]X_2 ($X^- = BF_4^-$ and PF_6^-) [496], [Fe(**243**)$_2$][BF_4]$_2$, [Fe(**244**)$_2$][BF_4]$_2$ [508], [Fe(**247**)$_2$][BF_4]$_2 \cdot 2H_2O$, [Fe(**247**–H)$_2$]$\cdot CHCl_3$ and [Fe(**248**)$_2$][BF_4]$_2 \cdot H_2O$ [509] all show gradual spin-transitions on heating, mostly centred significantly above 363 K. The magnetic moment of [Fe(**245**)$_2$][BF_4]$_2$ decreases very slowly on cooling from 4.8 BM at 363 K to 4.2 BM at 83 K, while [Fe(**241**)$_2$][BF_4]$_2$ is low-spin [496] and [Fe(**246**)$_2$][BF_4]$_2$ (which presumably contains tridentate **246** ligands) is high-spin [508]. Solid [Fe(**249**)$_2$]$X_2 \cdot H_2O$ ($X^- = BF_4^-$ and ClO_4^-) are predominantly low-spin at room temperature [510], while the PF_6^- salts of [Fe(**249**)$_2$]$^{2+}$ [511] and [Fe(**250**)$_2$]$^{2+}$ [512] are both low-spin in acetone solution. However, three different salt hydrates of [Fe(**251**)$_2$]$^{2+}$ exhibit gradual spin-transitions centred at, or slightly above, room temperature [513]. Acetone solutions of [Fe(**252**)$_2$][PF_6]$_2$ are low-spin, but those of [Fe(**253**)$_2$][PF_6]$_2$ give $\mu_{eff} = 4.1$ BM at room temperature, indicating spin-equilibrium behaviour [512].

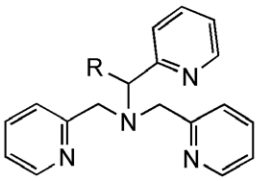
Hydrated or anhydrous salts of $[FeL_2]^{2+}$ (L = **254**–**257** [514] and **262** [517]) are high-spin at room temperature, although in each case a small low-spin population appears on heating to up to 383 K. While the complexes of **254**–**257** are all low-spin in solution as well [514], the high-spin state of $[Fe(\mathbf{262})_2]^{2+}$ predominates in acetone at room temperature, allowing the activation volume for its spin-transition to be determined [518]. Solid salts of $[FeL_2]^{2+}$ (L = **258**–**261**) show more variable behaviour, with nearly all of those examined exhibiting gradual thermal spin-crossover, albeit at widely variable $T_{1/2}$ values ranging from <89 to >373 K [515,516]. Best studied is $[Fe(\mathbf{261})_2][ClO_4]_2$, whose spin-transition is centred near 265 K when anhydrous but which crystallises in two different hydrated forms. Crystal structures showed that $[Fe(\mathbf{261})_2][ClO_4]_2 \cdot H_2O$ exists as a mixture of high- and low-spin molecules at room temperature, consistent with the magnetic and Mössbauer spectroscopic data from the anhydrous material, but that $[Fe(\mathbf{261})_2][ClO_4]_2 \cdot 2/3H_2O$ is low-spin [516]. $[FeL_2][ClO_4]_2$ (L = **258**–**261**) also undergo spin-transitions in acetone solution, mostly centred near room-temperature [515].

While $[Fe(\mathbf{263})_2]F_2$ is essentially high-spin [519,520], a gradual spin-transition involving 6% of the sample was detected at low temperatures. A theoretical study implied that the ground-state of the molecule is in fact high-spin, but that the energy gap between the high- and low-spin states of the compound is unusually small at ca. 40 cm^{-1}. The weak spin-crossover in this system is therefore driven by transitions between molecular vibrational energy levels with temperature, rather than by the usual factors [519]. Several other salts of $[Fe(\mathbf{263})_2]^{2+}$ undergo complete gradual thermal spin-transitions on cooling [520–523]. A comprehensive study of the four halide salts of this cation showed that $T_{1/2}$ followed the trend in counterion of $I^- > Br^- > Cl^- > F^-$. DF calculations implied that this trend reflects the different electronegativities of the anions, which interact with the iron centres through strong N–H···X (X^- = halide) hydrogen bonds [520]. Relaxation of the LIESST excited state of $[Fe(\mathbf{263})_2]Cl_2$ [520,522] takes place at 42 K, and displays complicated kinetics below 30 K implying that a range of quantum mechanical tunneling frequences are involved in the relaxation process [524].

Although $[Fe(\mathbf{266})_2]^{2+}$ is low-spin [525], salts of $[Fe(\mathbf{267})_2]^{2+}$ and $[Fe(\mathbf{268})_2]^{2+}$ do undergo thermal spin-transitions. The behaviour of $[Fe(\mathbf{267})_2][BF_4]_2$ [525–557] and $[Fe(\mathbf{267})_2][ClO_4]_2$ [344,527,528] is very similar, each compound undergoing abrupt spin-crossover centred at 283 K ($X^- = BF_4^-$) and 252 K ($X^- = ClO_4^-$) with a hysteresis loop of 8 K. Powder diffraction measurements showed that both transitions are accompanied by a crystallographic phase change, although single crystal data are not available. The width of the hysteresis in these spin-transitions *increases* with increasing pressure, contrary to the expectations of mean field theory. This anomaly can be accounted for if the bulk modulus of the material varies with pressure [529]. Iron(II) complexes of *N*′,*N*′-disubstituted hydrazones related to **266**–**268** [525], and of **265** [530] and **269** (which was proposed to contain tridentate **269** ligands) [531] are all high-spin, while those of $[Fe(\mathbf{264})_2]^{2+}$ are low-spin [530]. Solid $[Fe(\mathbf{270})_2][BF_4]_2$ exhibits a gradual, complete thermal spin-crossover centred around 220 K, but iron(II) complexes of related Schiff

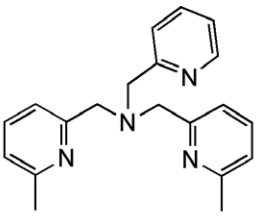
bases with smaller imino *N*-substituents are all low-spin [532]. The pK_a of [Fe(**271**)$_2$]$^{2+}$ has been determined, but no solid state properties of this complex were reported [533]. Ligands **272**, **273** and their *N*-substituted derivatives form low-spin complexes with iron(II), where the ligands afford a *N*,*N*,*O* or *N*,*N*,*S* donor set [534].

The complexes [Fe(**274**)$_2$][ClO$_4$]$_2$ [535] and [Fe(**275**)$_2$]Br$_2$ [536] are low-spin, as are salts of [FeL$_2$]$^{2+}$ (L = **277**–**287**, and related diimines derived from 2,6-diacetylpyridine) [537]. The pK_as and electrochemistry of [Fe(**276**)$_2$]$^{2+}$ and [Fe(**276**–H)$_2$] have been reported, but not their solid-state behaviour [538]. Coordination polymers with tridentate metal-binding domains related to **274** have been prepared by reacting 2,6-pyridinedicarbaldehyde with a range of straight-chain diaminoalkanes in the presence of iron(II) salts. These are structurally amorphous and contain a mixture of low-spin iron(II) and high-spin iron(III) centres [536]. Similar iron(II) polymers, with metal binding sites related to **277**, have also been prepared from 2,6-diacetylpyridine and four different diaminoalkanes [539]. Despite its dark brown colouration, [Fe(**288**)$_2$]Cl$_2$ · 2 H$_2$O is high-spin at room temperature by crystallography [540]. The synthesis of iron(II) catenanes containing tridentate metal-binding motifs related to **274** [541] and rotaxanes related to **288** [542] have been reported but no characterisation data were provided.



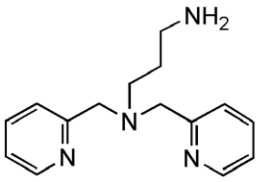
Salts of [Fe(**289**)$_2$]$^{2+}$ [471,543,544] and [FeL$_2$][ClO$_4$]$_2$ (L = **292**–**294**) [535] are low-spin, but [Fe(NCS)$_2$(py)(**289**)] is predominantly high-spin at 80 K and above [545] and [Fe(**290**)$_2$][PF$_6$]$_2$ [544,546] and [Fe(**291**)$_2$][ClO$_4$]$_2$ [546] are high-spin at room temperature. The iron centre in [Fe(**295**–H)$_2$] is low-spin [547], and remains low-spin when additional metal ions are coordinated to its O-donors [548]. Its iron(III) congener [Fe(**295**–H)$_2$]$^+$ is a spin-crossover system, however [547]. The complex [Fe(**296**)$_2$]Cl$_{1.3}$Br$_{0.7}$ is high-spin above 30 K [64,549], while [Fe(**297**)$_2$][ClO$_4$]$_2$ has been synthesised but its spin-state was not reported [550]. The voltammograms of [Fe(**298**)$_2$]Cl$_3$ and [Fe(**299**)$_2$]Cl$_3$ in MeCN show iron(III/II) couples of −0.21 and −0.74 V versus Ag/Ag$^+$ respectively, suggesting that their iron(II) congeners (which have not been reported) might not be air-stable [551]. While salts of [Fe(**300**)$_2$]$^{2+}$ are low-spin in the solid state [552], in solution the complex dication undergoes thermal spin-crossover centred at 335 K in (CD$_3$)$_2$NCDO, and 349 K in D$_2$O [553]. More sterically encumbered 1,4,7-triazacyclononanes like **301**–**303** only form 1:1 metal:ligand complexes with iron(II) [554]. While several larger ring triazamacrocycles are known, their iron(II) complexes have not been described.

5. Tetradentate ligands



The complexes [Fe(NCS)$_2$(**304**)] and [Fe(NCS)$_2$(**305**)] undergo a very gradual thermal spin-transition centred near 150 K [545]. The fully low-spin state of [Fe(NCS)$_2$(**304**)] can be prepared following slow cooling to 5 K [555], and its spin-crossover has been studied by variable temperature Mössbauer [555,556] and FTIR [555] spectroscopies, EXAFS [557], nuclear resonant and inelastic scattering [557,558] and DF calculations [63]. The LIESST excited state of [Fe(NCS)$_2$(**304**)] is generated quantitatively at 10 K, and relaxes back to its near 50 K [559]. Spin-crossover in [Fe(NCS)$_2$(**308**)] is similarly gradual, being centred near 190 K [560], but [Fe(NCS)$_2$(**307**)] is high-spin [545]. Spin-crossover in [Fe(NCS)$_2$(**315**)] occurs abruptly, without hysteresis, at 138 K [561]. Three polymorphs of [Fe(NCS)$_2$(**317**)] can be crystallised. One of these undergoes a quite gradual thermal spin-transition centred at 176 K (polymorph A, space group $P\bar{1}$ at 298 K), one is high-spin (polymorph B, $P2_1/c$) while the third exhibits an abrupt transition at 116 K, with a hysteresis width of 8 K (polymorph C, *Pbca*) [562]. Room-temperature crystal structures of the three polymorphs show that the same geometric isomer was present in all three structures, with *cis*-pyridyl donors, but that the Fe–N{pyridyl} distances increase in the trend A < C < B. That is consistent with the observed increasing stabilisation of the high-spin state along this series. This structural difference can also be reproduced theoretically, if the different Madelung constants of the three lattices are considered in the calculation [563]. Solid [Fe(NCS)$_2$(**320**)] is high-spin at room temperature [564].

Salts of [Fe(NCCH$_3$)$_2$L]$^{2+}$ are low-spin when L is **304** [565–567], **309** and **310** [566], but high-spin when L is **306** [566,567], **307** [568], **311** and **312** [566,567]. Solutions of [Fe(NCCH$_3$)$_2$L]$^{2+}$ (L = **313**, **314** [566], **316** and **318** [569]) in CD$_3$CN are high-spin, although these were not isolated as solids, while [Fe(NCCH$_3$)$_2$(**304**)]$^{2+}$ apparently undergoes a thermal spin-transition upon warming in the same solvent [565]. The crystalline triflate salt of the *bis*-ligand complex [Fe(**304**)$_2$]$^{2+}$ is octahedral and high-spin at 173 K, with one dangling pyridyl donor per ligand (cf. [Fe(**290**)$_2$]$^{2+}$ and [Fe(**291**)$_2$]$^{2+}$, Section 4.5) but the [B(C$_6$H$_5$)$_4$]$^-$ salt of the same compound is eight-coordinate [565].



Solid [Fe(**127**)(**315**)][ClO$_4$]$_2$ · 1/2H$_2$O exhibits a rather gradual spin-transition in two distinct steps, centred at 171 and 218 K. These steps are explained by the presence of two independent complex molecule sites observed in the crystalline compound [570]. While the trapped LIESST excited state of [Fe(**127**)(**315**)][ClO$_4$]$_2$ · 1/2 H$_2$O can be generated, the photoconversion is only 40% efficient. Decay of the resultant trapped high-spin content of the sample upon warming also occurs in two steps, at 21 and 36 K. In contrast, spin-crossover in [Fe(**113**)(**319**)][ClO$_4$]$_2$ takes place abruptly at 176 K with a 10 K hysteresis loop. This hysteresis is not caused by a crystallographic phase change during the spin-transition. Rather, it may reflect the extensive hydrogen bonding and π–π stacking in the structure, or an order/disorder transition of one of the **319** ligand propyl groups that was observed to take place on cooling [571]. DF calculations implied that both ligand conformations in this complex should give rise to similar spin-transition temperatures [572].

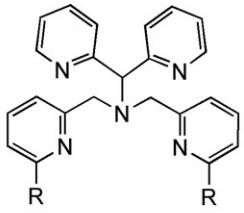
suggestion, ca. 70% of the iron content in the powder can be trapped in its high-spin state by rapid quenching from 150 to 20 K; the yield of trapped high-spin material following laser irradiation at 20 K was only 40%, however [573]. The LIESST relaxation temperature of the compound is around 40 K. $[Fe(NCSe)_2(\mathbf{321})]$ [573] and $[Fe(NCBH_3)_2(\mathbf{321})]$ [575] undergo spin-crossover at progressively higher temperatures, of 181 and 362 K respectively; the former compound does not exhibit the LIESST phenomenon [573]. Powdered $[Fe(NCS)_2L]$ (L = **322**, **325**, **326** [574], **331** and **332** [576]) are all high-spin, but $[Fe(NCS)_2(\mathbf{333})]$ is low-spin [577] and $[Fe(NCS)_2(\mathbf{330})]$ exhibits a very gradual spin crossover with a midpoint near 185 K [63,555,574,578]. Although no magnetic data are available, the C≡N vibrations in the IR spectrum of $[Fe(NCS)_2(\mathbf{336})]$ (at 2069 and 2077 cm^{-1}) imply it is high-spin at room temperature [579].

The complex $[Fe(NCCH_3)_2(\mathbf{322})][ClO_4]_2$ undergoes a spin-transition in CD_3CN solution, centred at around 290 K [569,580,581]. The anomalously high enthalpy of this transition (40 kJ mol^{-1}) implies that the spin-transition competes with ligand substitution equilibria in solution, possibly involving coordination of the perchlorate anions [581]. The same compound is low-spin in the crystal with *cis*-MeCN ligands [582], as is $[Fe(NCCH_3)_2(\mathbf{324})][ClO_4]_2$ [583]. Other $[Fe(NCCH_3)_2L]^{2+}$ complexes with L = **327** [579], **328** and **329** [584] have been reported to be paramagnetic in CD_3CN solution, but have not been isolated as solids, while $[Fe(NCCH_3)_2(\mathbf{323})]^{2+}$ (which should contain *trans*- rather than *cis*-MeCN ligands) has also been briefly mentioned [585]. A theoretical study implied that $[Fe(NCCH_3)_2L]^{2+}$ should be a spin-crossover compound when L = **322** (as observed), but will be high-spin when L = **327** or one of several other 6,6″-disubstituted derivatives of **322** [586]. The solid complex $[Fe(\mathbf{334})(\mathbf{321})][BF_4]_2 \cdot 2H_2O \cdot 1/2(C_2H_5)_2O$ exhibits a thermal spin-transition on heating, with a midpoint above 400 K [587], while crystalline $[Fe(\mathbf{45})(\mathbf{335})][ClO_4]_2$ [588] and *trans*-$[Fe(NCCH_3)_2(\mathbf{335})][ClO_4]_2$ [589] are both low-spin. The latter compound rapidly reacts with CH_3CN or other nitriles to form a tripodal pentadentate ligand complex (Section 6), through nucleophilic attack of the (transiently) deprotonated β-diimine moiety at the C≡N bond [588,589]. The quaterpyridine complex $[Fe(\mathbf{188})_2]^{2+}$, which contains tridentate **188**, has been discussed in Section 4.2.

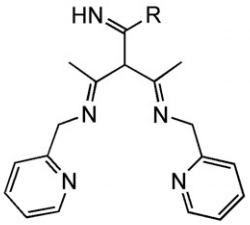
Macrocyclic complexes of type $[FeL_2(\mathbf{337})]^{n+}$ (L = NCS^-, CN^-, $n = 0$; L = CH_3CN, $n = 2$) are all low-spin [590], as are analogues with C-alkylated or unsaturated 14-membered macrocycles [591–594]. One possible exception to that is $[Fe(\mathbf{53})(\mathbf{338})][ClO_4]_2$, which exhibits an intermediate magnetic moment at room temperature (although its instability made characterisation difficult) [591]. However, increasing or decreasing the macrocycle ring size, as in $[Fe(NCS)_2L]$, (L = **339**–**341**) and $[Fe(NCCH_3)_2L][PF_6]_2$ (L = **340** and **341**) affords compounds that are high-spin at room temperature [593]. Only one six-coordinate complex of this type with an *N*-alkylated cyclam appears to have been reported, namely high-spin $[Fe(NCS)_2(\mathbf{342})]$ [595]; 1,4,8,11-tetramethylcyclam itself forms high-spin five-coordinate complexes with iron(II) [596]. Six-coordinate iron(II) porphyrin [597] and phthalocyanine [598] complexes with axial amine or imine bases are low-spin, while most other classes of tetrapyrrole macrocycle (including corrins and corroles) favour higher oxidation states of iron.

6. Pentadentate ligands



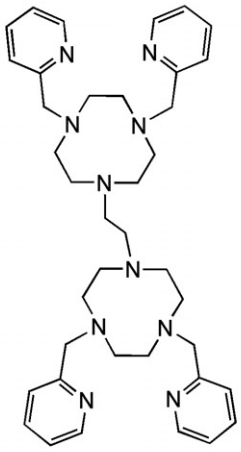
Several complexes of type $[Fe(NCCH_3)L]^{2+}$ (L = **343**–**346** and related derivatives substituted at one, two or four pyridine rings) have been synthesised, as pro-catalysts for organic oxidation reactions. All are low-spin in the solid and solution phases, where this has been determined [599,600]. The spin-state of $[FeL(\mathbf{348})]^{n+}$ depends on L, being low-spin when L = CH_3CN, pyridine or CN^- but high-spin when L is an O-donor [601,602]. Crystalline $[FeN_3(\mathbf{348})]CF_3SO_3 \cdot 2H_2O$ undergoes a gradual thermal spin-crossover with a mid-point of 156 K, that is 80% complete at low temperatures [602]. Crystallographic studies showed that this spin-transition is accompanied by contraction of the five Fe–N bonds to ligand **348**, but apparently not the Fe–N_3 bond. Interestingly, after mild grinding the spin-transition is lost and the material remains high-spin on cooling. The same compound also undergoes spin-crossover in CD_3OD, with $T_{1/2} = 207$ K. Crystalline $[Fe(HOCH_3)(\mathbf{348})][CF_3SO_3]_2$ [603] undergoes a more abrupt spin-crossover at 90 K, which is <50% complete below that temperature and shows significant sample-dependent hysteresis [602]. Water-soluble $[Fe(NCCH_3)(\mathbf{347})]^{2+}$ has been prepared, but its spin-state was not determined [604].

The UV/Vis spectrum of $[Fe(NCS)(\mathbf{349})]PF_6$ has been reported, which does not unequivocally establish its spin-state [605]. However, $[Fe(N\{CN\}_2)(\mathbf{350})]PF_6 \cdot CH_3OH$ is low-spin in the solid state, while dinuclear $[\{Fe(\mathbf{350})\}_2(\mu\text{-}N\{CN\}_2)][PF_6]_2 \cdot xH_2O$ undergoes an abrupt spin-transition that is sample-dependent and only 50% complete when $x = 1$, but which proceeds to completion in two discrete steps when $x = 0$ [606]. Salts of $[Fe(NCCH_3)L]^{2+}$ (L = **351** [607], **352** [608], **353**, **354** [589], **356** [609] and **357** [600]) and $[Fe(NCS)L]^+$ (L = **355** [577], **356** [609], **358** [610]) are all low-spin, while $[\{Fe(NCS)\}_2(\mu\text{-}\mathbf{359})][ClO_4]_2$ is high-spin at room temperature [610]. Quinquepyridines **360** and **361** afford seven-coordinate high-spin iron(II) complexes with two axial acetonitrile ligands [604]. In contrast, $[Fe(NCS)_2L]$ (L = **362**–**364**) are all high-spin and six-coordinate, with tetradentate bispidene ligands [576].



Solid $[Fe(CN)_2(\mathbf{365})] \cdot H_2O$ exhibits very complex and sample-dependent spin-crossover and LIESST behaviour. Powder samples of this compound show an abrupt thermal spin-transition that is 50% complete, centred at 212 K with a hysteresis width of 25 K [28,611,612]. However, an initial

cooling/warming scan of the crystalline high-spin compound [28,613] instead results in a 100% complete, abrupt spin-crossover at 166 K, with a 13 K hysteresis loop [28,614]. Subsequent scans of the crystalline sample instead resemble the data from the powder material, as the crystals decompose during the spin-transition [28]. However, if the same sample is stored at room temperature for 8 h before re-examination, the original complete spin-crossover behaviour is restored [614].



Since crystalline $[Fe(CN)_2(\mathbf{365})] \cdot H_2O$ is seven-coordinate at room-temperature [613], this behaviour may reflect a geometry change during spin-crossover, from seven-coordinate high-spin to six-coordinate low-spin iron centres [611,612]. Such a structure change would also have to involve a change in crystal symmetry [613]. Rewarming the low-spin complex would initially generate a six-coordinate high-spin form, which could only revert slowly to its original seven-coordinate phase. It is the six-coordinate

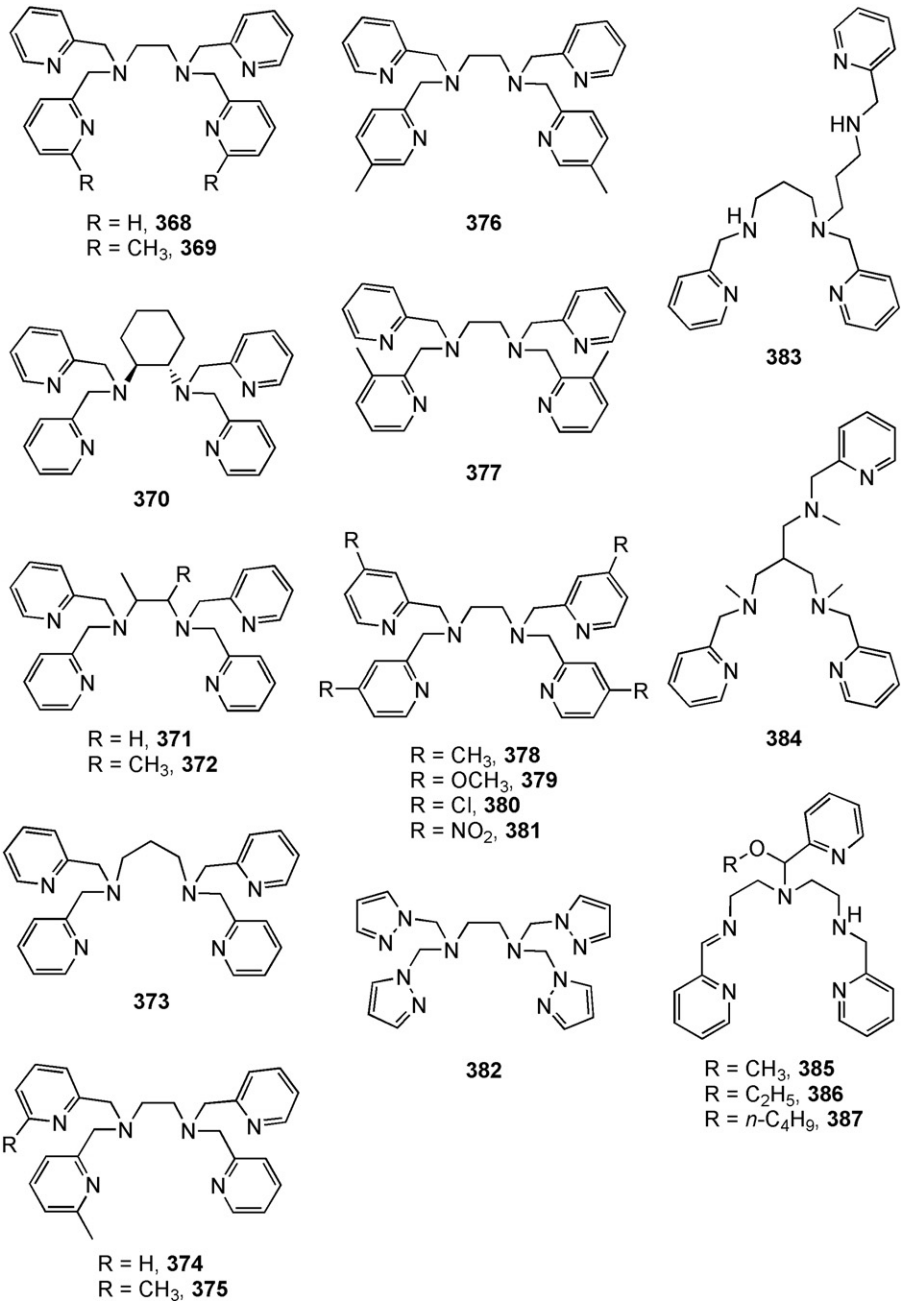
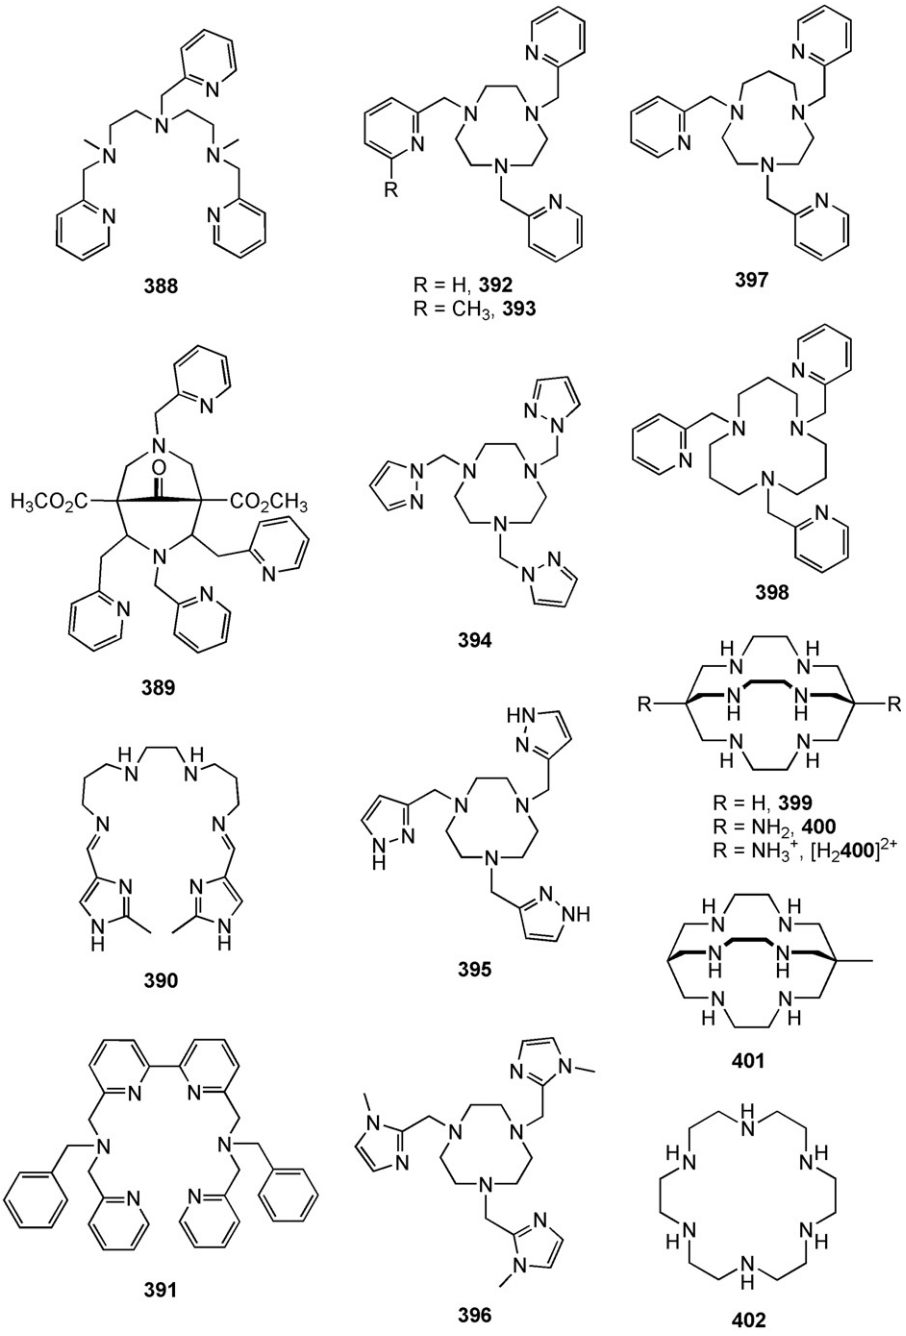
high-spin phase that undergoes the incomplete thermal spin-transition observed in powder samples. Both the low-spin, and 1:1 high:low-spin, low-temperature phases of $[Fe(CN)_2(\mathbf{365})] \cdot H_2O$ exhibit the LIESST effect, undergoing relaxation at 132 and 73 K, respectively [28,614–616]. The former temperature is the highest T(LIESST) value yet recorded in a molecular species [29]. The 1:1 high:low-spin phase also undergoes the reverse-LIESST effect, albeit with only ca. 15% conversion efficiency [615]. Laser irradiation of the 1:1 high:low-spin material at 216 K generates a high-spin species, which decays *irreversibly* back to a partially low-spin form upon annealing at 203 K for 2 h [617]. A 1-D chain complex was produced by linking $[Fe(CN)_2(\mathbf{365})]$ centres with $[Mn(hfac)_2]$ moieties (hfacH = 1,1,1,5,5,5-hexafluoro-2,4-pentanedione), which also undergoes a 50% complete spin-transition, at 110 K, albeit this time gradually and without hysteresis [618]. $[Fe(CN)_2(\mathbf{366})]$ and related complexes of pentaaza macrocycles are low-spin [611], but $[Fe(NCS)_2L]$ (L = **365** [619], **366** [620] and **367** [621]) are all high-spin at room temperature, and also seven-coordinate.

7. Hexadentate ligands



Solid $[Fe(\mathbf{368})][ClO_4]_2 \cdot xH_2O$ ($x = 1/2$–1) has a slightly variable water content, and exhibits a gradual, complete spin transition with a midpoint near 365 K [622–624]. Unusually, only a single, temperature-dependent Mössbauer doublet is observed in this compound at all temperatures, showing that its high- and low-spin states interconvert more quickly that the Mössbauer timescale [623]. Photolysis experiments established that this spin-state exchange takes place on a sub-picosecond timescale in aqueous solution [625]. This rapid spin-interconversion was suggested to reflect a trigonal twist in the six-coordinate coordination sphere, leading to an increase in spin–orbit interaction between the different spin-states of the molecule [623]. While the kinetics of light-induced spin-interconversion in $[Fe(\mathbf{368})][ClO_4]_2$ in solution have been studied in some detail [625,626], its LIESST properties in the solid state have not been reported. An anhydrous material, $[Fe(\mathbf{368})][ClO_4]_2$, has also been described, whose spin-transition is still gradual and shifted to significantly higher temperatures than the hydrate [623,626], while its $T_{1/2}$ for spin-crossover in dmf solution has been measured at 363 K. The $[Fe(\mathbf{368})]^{2+}$ dication has been used as a model in several theoretical studies of spin-crossover systems [63,64,627]. The complex $[Fe(NCS)(\mathbf{369})]PF_6$ is high-spin at room temperature by IR ($\nu_{C\equiv N} = 2055\ cm^{-1}$), with one dangling 6-methylpyridyl group [605].



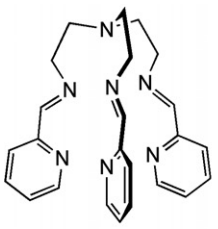
Spin-crossover in $[Fe(\mathbf{370})][ClO_4]_2 \cdot 2H_2O$ [622,628] and $[Fe(\mathbf{371})][ClO_4]_2 \cdot xH_2O$ ($x = 2/3$–1) [622,627] is gradual and centred significantly above 400 K, while $[Fe(\mathbf{373})][ClO_4]_2 \cdot H_2O$ is low-spin, and $[Fe(\mathbf{369})][ClO_4]_2 \cdot H_2O$ [622] and $[Fe(\mathbf{374})][ClO_4]_2 \cdot xH_2O$ ($x = 2/3$–1) [622,627] are high-spin. $[Fe(\mathbf{372})][ClO_4]_2$ undergoes thermal spin-crossover in dmf solution (as do $[Fe(\mathbf{370})][ClO_4]_2$ and $[Fe(\mathbf{371})][ClO_4]_2$), but its solid state properties were not reported [236]. Spin-interconversion in $[Fe(\mathbf{370})][ClO_4]_2$ in methanol solution shows biphasic kinetics, which was attributed to the existence of two conformations of the ligand cyclohexyl ring [236,628]. Interestingly, all other known examples of this phenomenon (discussed below) also involve iron complexes of hexadentate ligands that completely encapsulate the metal ion. Iron(II) complexes of **375**–**381** have been synthesised, but their spin-states were not recorded [629]. In contrast to the six-coordinate complexes of the tetrapyridyl ligands, $[FeX(\mathbf{382})]X \cdot H_2O$ ($X^- = BF_4^-$ and ClO_4^-) are seven-coordinate and high-spin above 4 K [630].

Spin-crossover in $[Fe(\mathbf{383})][BF_4]_2$ is discontinuous. The first step is gradual, centred at 181 K and involves 50% of the sample. The second step is abrupt, at 121 K with a 4 K hysteresis; below that temperature, about 90% of the material is in its low-spin state. The high- and low-spin forms of the compound are isostructural, but differ in that one of the amino donors is disordered in the high-spin crystal, but crystallographically ordered in the low-spin state. This order:disorder transition is probably the cause of the cooperativity in the low-temperature spin-crossover step [631]. Stereochemically similar $[Fe(\mathbf{384})][ClO_4]_2$ is also a spin-crossover compound, exhib-

iting a gradual, complete transition centred at 196 K in the solid state and 230 K in propionitrile [632]. An inelastic neutron scattering study has been performed on this complex [633]. Crystalline $[FeL][B(C_6H_5)_4]_2$ (L = **385**–**387**) are all low-spin [634], while $[Fe(\mathbf{388})][BF_4]_2$ [635] and $[Fe(NCS)_2(\mathbf{389})]$ [576] are high-spin, the latter compound having a tetradentate bispidene ligand with two dangling pyridyl donors.

The compound $[Fe(\mathbf{390})][ClO_4]_2$ undergoes an abrupt thermal spin-transition, with $T = 172$ K and a 5 K hysteresis loop [636]. This reflects a crystallographic phase change during spin-crossover, caused by a conformational change in one of the the six-membered chelate rings. The bipyridyl-containing ligand complex $[Fe(\mathbf{391})][PF_6]_2$ exists as an approximately 1:3 high:low-spin mixture, which is almost invariant between 77 and 293 K. Its crystal structure reveals two independent iron sites, one of which is low-spin while the other suffers strongly from disorder and was proposed to contain a mixture of high- and low-spin centres [637].

Salts of the macrocylic complexes $[Fe(\mathbf{392})]^{2+}$ [64,635,638], and $[Fe(\mathbf{395})]FeCl_4$ [639] and $[Fe(\mathbf{396})][B(C_6H_5)_4]_2$ [640], are all low-spin. However, $[Fe(\mathbf{393})][ClO_4]_2$ exhibits a very gradual spin-transition centred significantly above room temperature [641], while salts of $[Fe(\mathbf{394})]^{2+}$ are high-spin at room temperature [639,640]. Although it is low-spin in the solid state, $[Fe(\mathbf{397})][ClO_4]_2$ shows a thermal spin-transition in $MeCN/H_2O$ mixed solvent systems. Transient spin-interconversion in this solvent exhibits biphasic kinetics, the rate of one of the processes being invariant with temperature (that is, it has no activation barrier) [642]. This was proposed to reflect the conformational stiffness of the macrocyclic ligand framework (cf. $[Fe(\mathbf{370})][ClO_4]_2$, see above). The larger, 12-membered macrocycle **398** forms high-spin iron(II) complexes [635,643]. The solid macrobicyclic complexes $[FeL][CF_3SO_3]_2$ (L = **399** and **401**) and $[Fe(H_2\mathbf{400})]Cl_2Br_2 \cdot 4H_2O$ are high-spin, but $[Fe(\mathbf{400})][CF_3SO_3]_2$ is low-spin [644,645]. All three of the triflate salts undergo spin-transitions in CD_3CN, however [644]. The magnetic moment of the high-spin compound $[Fe(\mathbf{402})][B(C_6H_5)_4]_2$ is slightly temperature-dependent, which was interpreted on the basis of partial electron transfer between the iron(II) dications and tetraphenylborate anions [646].



8. Higher denticity ligands

Iron(II) complexes of heptadentate Schiff bases derived from *tris*-(2-aminoethyl)amine (tren) have been heavily studied (Table 9). The high-spin forms of these compounds typically adopt [6+1] coordination geometries, with the tertiary amino donor capping one face of a compressed octahedron with a Fe–N distance of 2.5–3.3 Å (tabulated in [678]). The stereochemistries of the low-spin forms of these compounds tend to be more rigorously octahedral, with the capping N donor being >3.4 Å from the iron atom [648,649,657,665,670–674]. There is no apparent correlation between the distance of this additional ligand donor from the iron centre, and whether or not the compound undergoes spin-crossover [678].

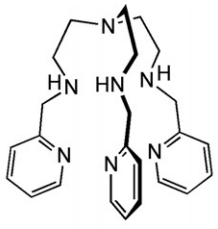


Table 9
Iron(II) complex salts of potentially heptadentate Schiff bases derived from *tris*-(2-aminoethyl)amine and related ligands

	Spin-state or $T_{1/2}$ (K)	Form of spin-state transition	Spin states of crystal structure(s)	Other measurements	Refs.
[Fe(**403**)]X_2 ($X^- = BF_4^-$, ClO_4^-)	LS		RT (LS, both salts)	Mag, Möss	[647–650]

Two crystal phases of [Fe(**403**)][PF_6]$_2$ have been isolated [658]. One of these is low-spin (as are other salts of this cation), but the other undergoes a gradual spin-transition centred near 150 K that is about 50% complete. The spin-crossover $T_{1/2}$ in acetone and DMSO solutions for [Fe(**404**)][PF_6]$_2$ and [Fe(**405**)][PF_6]$_2$ is almost identical to their solid state values but [Fe(**406**)][PF_6]$_2$ is high-spin in these solvents [651,653], despite also being a spin-crossover compound in the sold state. The kinetics of light-induced spin-interconversion and decay in [Fe(**405**)][ClO_4]$_2$ doped into polymer films [661], solutions of [Fe(**404**)]$^{2+}$, [Fe(**405**)]$^{2+}$ and [Fe(**406**)]$^{2+}$ [662], and the doped solids [Fe_xZn_{1-x}L][PF_6]$_2$ (L = **403**–**406**; $x = 0.00025$–0.0005) [120,664], have been studied in detail. The first of these

studies provided the first direct experimental evidence for the involvement of quantum mechanical tunnelling in the relaxation of metastable spin-states [661]. Ultrafast EXAFS measurements in solution have revealed that the low → high-spin conversion in [Fe(**403**)][PF_6]$_2$ is complete within 70 ps following laser irradiation [656]. The complex [Fe(**407**)]$^{2+}$ is air-sensitive, and undergoes conversion to [Fe(**403**)]$^{2+}$ in aerobic solution [658].

A series of salts of [Fe^{II}L][Fe^{II}(L–3H)]$^+$ and [Fe^{II}L]-[Fe^{III}(L–3H)]$^{2+}$ (L = **409** and **410**) have been studied in detail. While [Fe(**409**)][Fe(**409**–3H)]BF_4 undergoes spin-crossover in one gradual step centred near room temperature [670], the spin-transitions of [Fe(**410**)][Fe(**410**–3H)]X (X$^-$ = NO_3^-, BF_4^-, ClO_4^-, PF_6^-, AsF_6^- and SbF_6^-) all show two discrete steps arising from the [Fe(**410**)]$^{2+}$ and [Fe(**410**–3H)]$^-$ sites in the lattice [674,675]. The iron(III) sites in the mixed-valent compounds [Fe(**409**)][Fe(**409**–3H)]X_2 (X$^-$ = NO_3^- [671] and BF_4^- [670]) exhibit gradual spin-transitions centred above room temperature, while their iron(II) centres show a more abrupt transition at 160–190 K. Iron(III) spin-crossover in [Fe(**410**)][Fe(**410**–3H)][NO_3]$_2$ is similarly broad but shifted to lower temperature, as expected on steric grounds, while its iron(II) content remains high-spin [674]. All these compounds crystallise in the chiral space groups *P*3 or *R*3, with two distinct iron environments lying on C_3 axes. Both iron centres in [Fe(**410**)][Fe(**410**–3H)]BF_4 exhibit the LIESST effect, giving ca. 75% total photoconversion at 5 K and a relaxation temperature near 50 K [675]. Conversely, only the iron(II) content of [Fe(**409**)][Fe(**409**–3 H)][NO_3]$_2$ undergoes LIESST photoconversion, relaxing between 50 and 100 K [671]. The LIESST phenomenon was also detected in [Fe(**409**)]-[Fe(**409**–3H)]BF_4 [670] and [Fe(**410**)][Fe(**410**–3H)]AsF_6 [675], but was much less efficient. Thermal and photochemical spin-crossover has also been studied in several salts of the simple mononuclear analogues [Fe(**409**)]$^{2+}$ [665,669,670] and [Fe(**410**)]$^{2+}$ [672,673].

Crystals of the potentially octadentate complex [Fe(**416**)][PF_6]$_2$ contain two unique iron sites. One of these is octahedral with two dangling pyridyl groups, while the other is best described as having a [6+1] coordination geometry with one long Fe···N pyridyl interaction of 3.1 Å [637]. The complex is predominantly high-spin in the solid state and in CD_3CN solution, but with a ca. 25% low-spin fraction that does not change significantly with temperature. The kinetics of high → low-spin state relaxation of [Fe(**416**)][PF_6]$_2$ in solution are biphasic, demonstrating that the two high-spin coordination geometries found in the solid state are also present in solution [637]. Crystals of [Fe(**417**)][ClO_4]$_2$ contain seven-coordinate complex molecules that appear to remain high-spin on cooling to 80 K. As for [Fe(**416**)]$^{2+}$, its UV/Vis spectrum suggests the presence of a six-coordinate iron centre in solution, however [680]. The crystal structure of [Fe(**418**)][ClO_4]$_2$ at room temperature is seven-coordinate and high-spin [681], while eight-coordinate [Fe(**419**)]-[ClO_4]$_2$ remains high-spin on cooling to 5 K [682]. Solid [Fe(**420**)][ClO_4]$_2$ · 3H_2O is also high-spin at room temperature; although no crystal structure is available, its manganese(II) analogue is only six-coordinate [683]. A small number of other iron(II) complexes with potential, or actual, [FeN_7]$^{2+}$ or [FeN_8]$^{2+}$ donor sets have also been reported but their spin-state behaviour was not described [684].

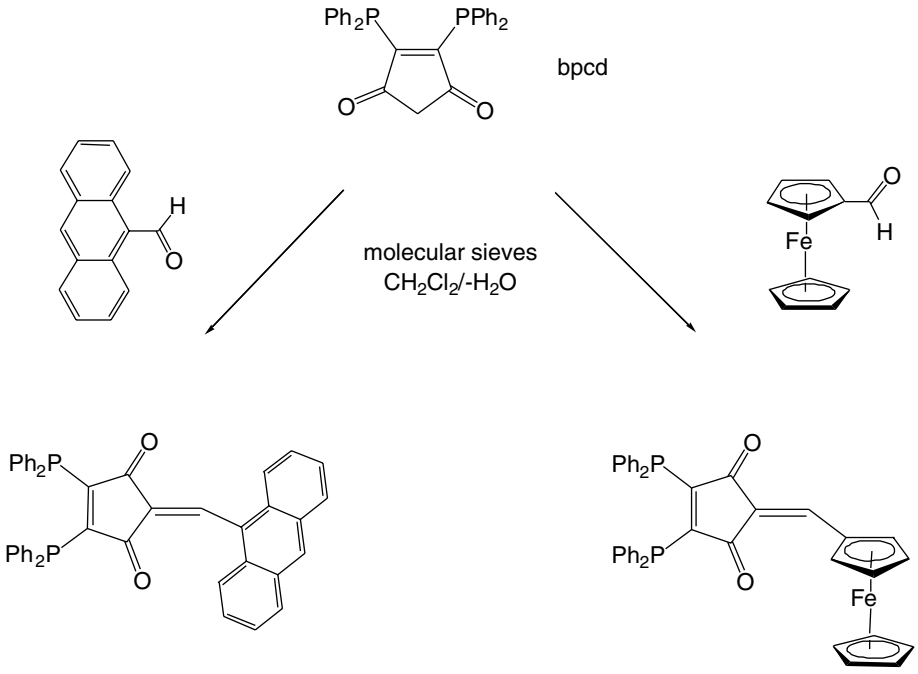
(bma) [4], 4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (bpcd) [5], and 2,3-bis(methylthio)pyrrolo[1,2-a]benzimidazol-1-one (bmpb) [6], the structures of which are shown below.

fac-BrRe(CO)$_3$(bma) *fac*-ClRe(CO)$_3$(bpcd) *fac*-BrRe(CO)$_3$(bmpb)

In terms of the diphosphine ligand bpcd, we recently confirmed that facile and significant structural modifications of the central dione platform could easily be achieved through Knoevenagel condensation reactions. Two such reactions involving the union of 9-anthracenecarboxaldehdye and ferrocenecarboxaldehyde are depicted in Scheme 1 [7,8]. The resulting second-generation ligands derived from bpcd can be custom- or fine-tuned to produce compounds that have a fixed or specific redox potential(s) by simply controlling the extent of π-electron delocalization within the diphosphine ligand platform. With the attachment of suitable donor–acceptor groups to the original dione scaffold, new ligands with the ability to function as directed energy transfer agents can be expected.



Wishing to extend our functionalization studies of the bcpd ligand to other aldehydes that could, in principle, function as multidentate ligand systems, we have studied the condensation reaction between thiophene-2-carboxaldehyde and bpcd. Herein we present our data on the synthesis of the new diphosphine ligand 2-(2-thienylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (tbpcd). The reactivity of this ligand with BrRe(CO)$_5$ and BrRe(CO)$_3$(THF)$_2$ has been examined and found to give *fac*-BrRe(CO)$_3$(tbpcd) in high yield. Both new compounds have isolated and their solid-state structures determined. The redox properties and photophysics of the tbpcd ligand and its rhenium(I) complex have been investigated and the results are discussed relative to MO calculations at the extended Hückel level.

2. Experimental

2.1. General

The starting diphosphine ligand bpcd was prepared from 4,5-dichloro-4-cyclopenten-1,3-dione and Ph_2PSiMe_3 [9], while BrRe(CO)$_3$(THF)$_2$ was synthesized from BrRe(CO)$_5$ [10]. The thiophene-2-carboxaldehyde was purchased from Aldrich Chemical Co. and used as received. All reaction and NMR solvents were distilled from an appropriate drying agent using Schlenk techniques and stored under argon in storage vessels equipped with high-vacuum Teflon stopcocks [11]. The tetra-*n*-butylammonium perchlorate (TBAP) electrolyte was purchased from Johnson Matthey Electronics and was recrystallized from ethyl acetate/hexane, followed by drying under high vacuum for at least 36 h.

The IR spectral data were recorded on a Nicolet 20 SXB FT-IR spectrometer in sealed 0.1 mm NaCl cells, while the

Scheme 1.

^{1}H spectral data were recorded at 200 MHz on a Varian Gemini-200 spectrometer. The ^{31}P NMR spectra were collected in the proton-decoupled mode on a Varian 300-VXR spectrometer at 121 MHz, with the reported chemical shifts referenced to external H_3PO_4 (85%), taken to have $\delta = 0$. The absorption spectra were recorded on a HP 8453 ChemStation (Marshall) or a HP 8425A diode array spectrometer (UNT). The emission data were recorded on a Jobin Fluorolog FL 3-22 spectrometer equipped with DataMax software. The ESI-APCI mass spectra were recorded at the University of the Pacific in the positive ionization mode for **1** and the negative ionization mode for **2**.

2.2. Synthesis of tbpcd (*1*)

To a small Schlenk vessel was added 0.20 g (0.43 mmol) of bpcd, followed by 25 mL of CH_2Cl_2, 0.39 mL (excess) thiophene-2-carboxaldehyde, and ca. 4.0 g of molecular sieves (4 Å). Stirring over night under argon led to the complete consumption of the bpcd ligand, as assessed by TLC analysis. The presence of the desired product was confirmed by TLC examination of the reaction solution. Here the tbpcd ligand was observed as an orange spot having a $R_f = 0.30$ using CH_2Cl_2/petroleum ether (3:2) as the eluent. The molecular sieves were filtered away and the solution concentrated to ca. 0.5 mL, after which the crude product was subjected to chromatographic separation over silica gel using the aforementioned solvent system to give tbpcd as an orange solid in 90% yield (0.22 g). IR (CH_2Cl_2): ν(CO) 1719 (m, symm dione), 1673 (vs, antisymm dione) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 7.05 (dd, 1H, thiophene, $^3J_{H-H} = 7$, 5 Hz), 7.22–7.46 (m, 20H, phenyls), 7.56 (s, 1H, vinyl), 7.68 (d, 1H, thiophene, $^3J_{H-H} = 7$ Hz), 7.90 (d, 1H, thiophene, $^3J_{H-H} = 5$ Hz). ^{31}P NMR ($CDCl_3$): δ −24.23 (AB quartet, $J_{P-P} = 25$ Hz). ESI-APCI MS (*m*/*z*): 581.086 [**1**+Na]$^+$, 558.995 [**1**]$^+$.

2.3. Synthesis of fac-BrRe(CO)$_3$(tbpcd) (*2*) from tbpcd and BrRe(CO)$_3$(THF)$_2$

To a Schlenk tube under argon was charged 0.10 g (0.20 mmol) of $BrRe(CO)_3(THF)_2$ and 0.11 g (0.20 mmol) of **1**, after which 20 mL of CH_2Cl_2 was added via cannula. The contents were stirred at room temperature for 3 h and examined by TLC, which revealed the complete consumption of the starting materials and only the presence of the desired product as a yellow spot at $R_f = 0.20$ using CH_2Cl_2 as the mobile phase. The solvent was concentrated and compound **2** subsequently isolated by column chromatography over silica gel using CH_2Cl_2. Yield of **2**: 0.14 g (80%). IR (CH_2Cl_2): ν(CO) 2039 (s), 1966 (s), 1912 (s), 1728 (vw, symm dione), 1684 (s, antisymm dione) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 7.21 (dd, 1H, thiophene, $^3J_{H-H} = 7$, 5 Hz), 7.32–7.90 [m, 22H, vinyl (1H), thiophene (1H), and phenyls (20H)], 8.06 (d, 1H, thiophene, $^3J_{H-H} =$ 5 Hz). ^{31}P NMR ($CDCl_3$): δ 18.09 (s, 1P), 19.18 (s, 1P). ESI-APCI MS (*m*/*z*): 907.821 [**2**]$^-$, 938.922 [**2**+MeO]$^-$.

2.4. X-ray diffraction structures

Single crystals of the tbpcd ligand were grown from a CH_2Cl_2 solution containing tbpcd that had been layered with hexane, while X-ray quality crystals of *fac*-BrRe(CO)$_3$(tbpcd) were grown from an acetone solution containing *fac*-BrRe(CO)$_3$(tbpcd) that was layered with Et_2O. The reported X-ray data for both compounds were collected on a Bruker SMART™ 1000 CCD-based diffractometer at 213 K. The frames were integrated with the available SAINT software package using a narrow-frame algorithm [12], and the structures were solved and refined using the SHELXTL program package [13]. The molecular structures were checked by using PLATON [14], and solved by direct methods with all nonhydrogen atoms refined anisotropically. All carbon-bound hydrogen atoms were assigned calculated positions and allowed to ride on the attached heavy atom, unless otherwise noted. Refinement for tbpcd converged at $R = 0.0641$ and $R_w = 0.1187$ for 6379 independent reflections with $I > 2\sigma(I)$, with **2** · acetone yielding convergence values of at $R = 0.0358$ and $R_w = 0.0873$ for 8558 independent reflections with $I > 2\sigma(I)$. Tables 1 and 2 summarize the pertinent X-ray data for compounds **1** and **2** · acetone.

2.5. Electrochemistry

The cyclic voltammetric data were recorded on a PAR Model 273 potentiostat/galvanostat, equipped with positive feedback circuitry to compensate for *i*R drop. The

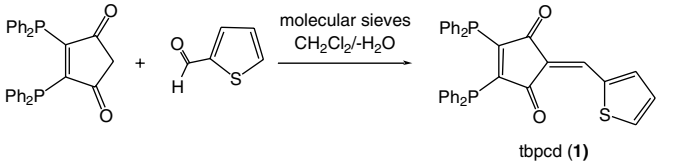
homemade three-electrode cell that was used allowed the cyclic voltammograms to be recorded under oxygen- and moisture-free conditions. A platinum disk (area = 0.0079 cm^2) was employed as the working and auxiliary electrode. The reference electrode utilized a silver wire as a quasi-reference electrode, with the reported potential data standardized against the formal potential of the Cp_2Fe/Cp_2Fe^+ (internally added) redox couple, taken to have $E_{1/2} = 0.307$ V [15].



2.6. Extended Hückel MO calculations

The extended Hückel calculations on tbpcd and *fac*-$BrRe(CO)_3$(tbpcd) were carried out using the original program developed by Hoffmann [16], as modified by Mealli and Proserpio [17]. The weighted H_{ij}'s contained in the program were used in the calculations. The input *Z*-matrices for the model compounds tbpcd-H_4 and *fac*-$BrRe(CO)_3$(tbpcd-H_4) were constructed from the X-ray data of **1** and **2** · acetone, employing hydrogens in the place of the four ancillary phenyl groups and setting the P–H bond distances to 1.41 Å [18].

3. Results and discussion

3.1. Synthesis, spectroscopic data, and X-ray diffraction structure of tbpcd (*1*)

Knoevenagel condensation of the diphosphine ligand bpcd with thiophene-2-carboxaldehyde (excess) proceeds readily in CH_2Cl_2 at room temperature in the presence of added molecular sieves to afford the new diphosphine ligand 2-(2-thienylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (tbpcd) in near quantitative yield. Simply stirring the two reagents without added molecular sieves showed no evidence for the formation of tbpcd (**1**), as assessed by TLC and IR analyses, which clearly underscores the need to drive the reaction to completion through the removal of the water that accompanies the Knoevenagel reaction. Compound **1** was subsequently isolated as a relatively air-stable orange solid after chromatographic separation over silica using CH_2Cl_2/petroleum ether (3:2) as the eluent. Eq. (1) illustrates the reaction leading to the tbpcd ligand.

(1)

The tbpcd ligand was fully characterized in solution by IR and NMR spectroscopies, ESI mass spectrometry, and X-ray diffraction analysis. The ^{1}H NMR spectrum of **1** confirmed the loss of the methylene hydrogens from the bpcd ligand and the formyl hydrogen from the thiophene-2-carboxaldehyde. The ^{31}P NMR spectrum displays a classic four-line AB quartet centered at δ −24.23 in keeping with the inequivalent phosphine moieties in **1**. The vibrationally coupled dione carbonyl groups of the tbpcd ligand give rise to symmetric and antisymmetric ν(CO) bands at 1719 (m) and 1673 (vs) cm^{-1} [19], that are 23 and 32 cm^{-1} lower in energy, respectively, relative to the ν(CO) bands of bpcd ligand [9,20], which in turn indicates that the tbpcd ligand is slightly more electron rich than the bpcd ligand. The UV-vis spectrum of **1** in CH_2Cl_2 is shown in Fig. 1, where a single absorbance at 374 nm ($\varepsilon = 18\,000$) is observed. The absorbance is insensitive to the nature of the solvent as the UV–vis band exhibits a small shift to 371 nm ($\varepsilon = 20\,000$) when the spectrum was recorded in MeCN solvent. The ESI mass spectrum of **1** that was recorded in the positive ion mode revealed *m*/*z* peaks at 581.086 and 558.995 for the singly charged sodium adduct of tbpcd $[\mathbf{1} + Na]^+$ and the parent ion of $[\mathbf{1}]^+$, respectively, consistent with the proposed ligand product.

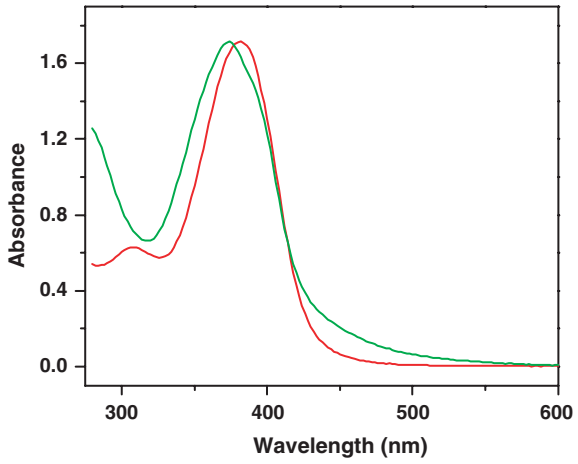


Fig. 1. UV–Vis spectra of the tbpcd ligand (green) and *fac*-BrRe(CO)$_3$(tbpcd) (red) in CH_2Cl_2 at room temperature. Both compounds were recorded at a concentration of ca. 10^{-4} M. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The solid-state structure of tbpcd was determined by single-crystal X-ray diffraction analysis, with the thermal ellipsoid plot of **1** shown in Fig. 2. The union of the bpcd ligand to the formyl carbon atom of the thiophene-2-carboxaldehyde is confirmed by the presence of the exocyclic alkene moiety defined by the C(1)–C(30) vector, whose 1.352(3) Å bond length is in excellent agreement with the 1.355(3) Å bond distance found for the C(3)–C(4) π bond in the dione platform. The internuclear P(1)···P(2) bond distance of 3.330(1) Å is slightly longer than the 3.278(3) Å P···P distance reported for unsaturated diphosphine ligand (*Z*)-$Ph_2PCH{=}CHPPh_2$ [21], while the O(2)···S(2) internuclear distance of 2.861(2) Å is shorter than the sum of the van der Waals radii for oxygen and sulfur atoms by ca. 0.36 Å [22]. These structural trends indicate that the molecule is not subject to significant adverse perturbations. The two five-membered rings are essentially coplanar based on an interplanar angle of 9.1(1)°. The remaining bond distances and angles are unremarkable and require no comment.

3.2. Syntheses, spectroscopic data, and X-ray diffraction structure of *fac*-BrRe(CO)$_3$(tbpcd) (**2**)

The reactivity of the tbpcd ligand was next examined with the rhenium(I) compounds $BrRe(CO)_5$ and $BrRe(CO)_3(THF)_2$ given our aforementioned interest in ligand-substituted rhenium compounds [4,6]. Our initial substitution studies employed $BrRe(CO)_5$ as a starting material. Heating an equimolar mixture of $BrRe(CO)_5$ and tbpcd at ca. 60–70 °C in either toluene or 1,2-dichloroethane furnished *fac*-$BrRe(CO)_3$(tbpcd) in good yields. TLC and IR analyses confirmed that **2** was formed as the major product. The same product was also obtained using the labile compound $BrRe(CO)_3(THF)_2$ in place of $BrRe(CO)_5$. In the case of $BrRe(CO)_3(THF)_2$, the reaction with added tbpcd ligand proceeded rapidly at room temperature to produce **2** in quantitative yield. While both rhenium starting materials give compound **2**, the use of the $BrRe(CO)_3(THF)_2$ has a slight advantage in that the reaction is cleaner and the solvent can be removed directly to give pure **2** for immediate use, if desired. The thermolysis reactions were accompanied by small amounts of unreacted

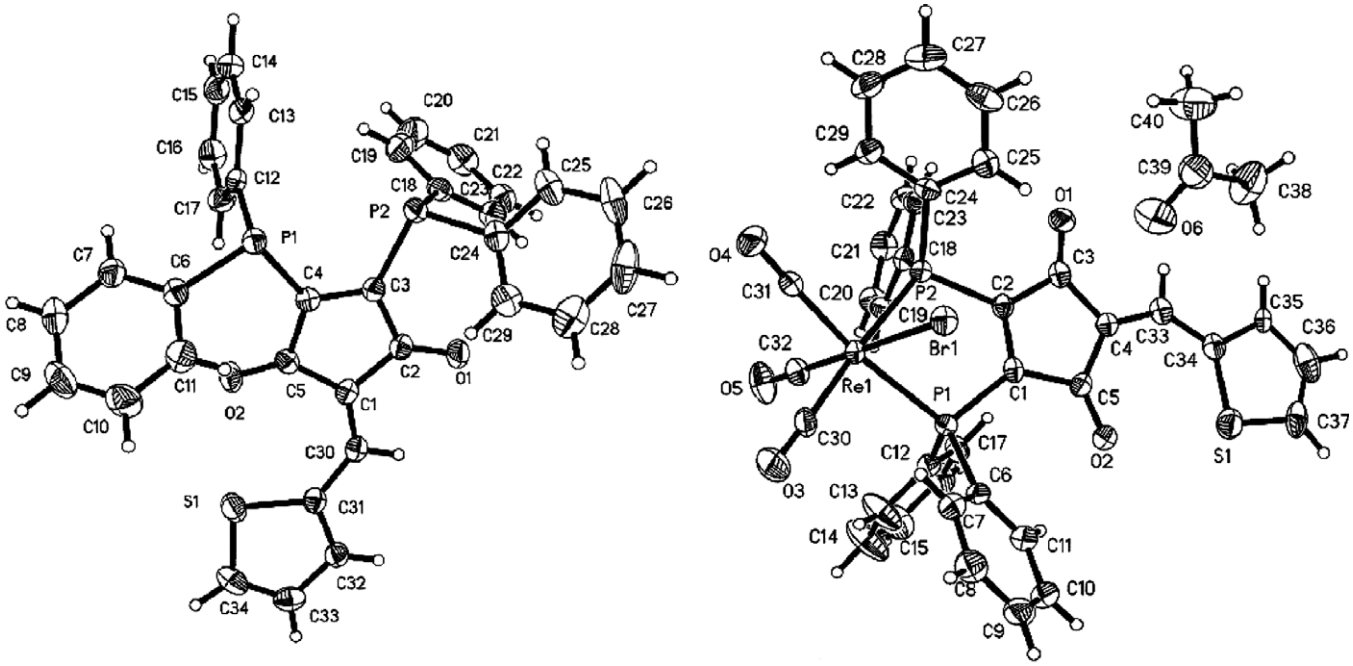

Fig. 2. Thermal ellipsoid plots of the ligand tbpcd (left) and *fac*-BrRe(CO)$_3$(tbpcd) · acetone (right) showing the thermal ellipsoids at the 50% probability level.

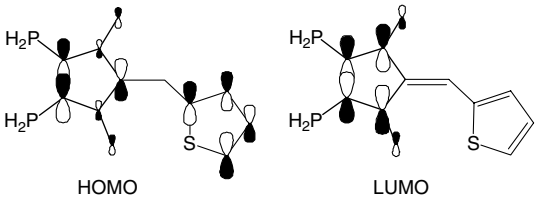
starting materials and unknown material(s) that remained at the origin of the TLC, necessitating a chromatographic separation. Compound **2** is air stable in the solid state, but solutions containing **2** that have been exposed to the atmosphere exhibit signs of decomposition on standing for several hours.

2 was characterized in solution by traditional spectroscopic methods, mass spectrometry (negative-ion mode), and X-ray crystallography. The IR spectrum exhibits three terminal rhenium carbonyl stretching bands at 2039 (s), 1966 (s), and 1912 (s) cm^{-1}, whose frequencies and symmetry closely match the IR data reported by us for the related compounds *fac*-$BrRe(CO)_3$(bma) and *fac*-$ClRe(CO)_3$(bpcd) [4,5]. Coordination of the tbpcd ligand to the $BrRe(CO)_3$ fragment is accompanied by a slight decrease in the electron density associated with tbpcd ligand based on the ca. 10 cm^{-1} shift of the dione ν(CO) bands to higher energy. The symmetric and antisymmetric dione carbonyl stretching bands appear at 1728 and 1684 cm^{-1}, respectively. The ^1H NMR data are fully consistent with the coordination of the tbpcd ligand to the *fac*-$BrRe(CO)_3$ fragment, as is the ^{31}P NMR spectrum, where two down-field singlets at δ 18.09 and 19.18 support the existence of a chelating tbpcd ligand that binds the rhenium atom via the two phosphorus moieties [23]. The UV–Vis spectrum of **2** shown in Fig. 1 exhibits a strong absorbance at 383 nm (ε = 28 000) and a weaker band at 308 (ε = 9500). The UV–vis spectrum recorded in MeCN afforded the same two-band pattern [378 nm (ε = 35 000), 308 (ε = 13 000)] for **2** as found in CH_2Cl_2. The ESI mass spectrum of **2** run in MeOH solvent revealed *m*/*z* peaks at 907.821 and 938.922 for the parent compound $[\mathbf{2}]^-$ and its methoxide adduct $[\mathbf{2} + MeO]^-$, respectively, in agreement with the formulated structure for **2**.

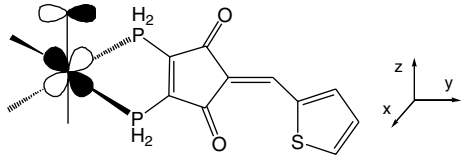
The adopted coordination mode of the tbpcd ligand in **2** was established by X-ray diffraction analysis. Single crystals of **2**, as the acetone solvate, were found to exist as discrete molecules in the unit cell. The thermal ellipsoid plot of **2** is shown in the right-hand side of Fig. 1, where the chelation of the tbpcd ligand to the rhenium center by the two phosphine moieties is confirmed. The rhenium atom is six-coordinate and possesses a distorted octahedral geometry. The Re(1)–P(1) and Re(1)–P(2) distances of 2.468(1) and 2.449(1) Å, respectively, and the observed bond angle of 81.59(3)° for the P(2)–Re(1)–P(1) linkage exhibit acceptable values in comparison to those bond distances and angles in related rhenium compounds structurally characterized by us [24]. The P(1)···P(2) [3.213(2) Å] and S(1)···O(2) [2.912(3) Å] bond distances and the interplanar angle of 5.8(2)° are in agreement with those values of the free tbpcd ligand and confirm that the ancillary ligand does not experience any major structural perturbations upon coordination to the rhenium center. The remaining bond distances and angles are unexceptional and require no comment.



3.3. Cyclic voltammetry, MO calculations, and emission spectroscopy data

The cyclic voltammetric properties of the tbpcd ligand and compound **2** were next probed at a platinum disk electrode in CH_2Cl_2 solvent containing 0.2 M TBAP as the supporting electrolyte. Initially scanning a tbpcd sample at room temperature at a rate of 0.5 V/s over the potential range of 1.2 to −1.8 V revealed the presence of two reduction processes attributed to the $0/1^-$ and $1^-/2^-$ redox couples. The latter reduction exhibits a forward wave at $E_p^c = -1.45$ with no accompanying reverse wave (E_p^a), leading to an irreversible reduction under these conditions. Narrowing the potential window to 0 to −1.3 V and scanning just over the first reduction wave confirmed that $0/1^-$ redox couple, which displays an $E_{1/2} = -1.09$ V, is fully reversible when analyzed by standard electrochemical criteria [15]. The electron stoichiometry for the first reduction process (1e−) was also verified by comparison of the current function of the known one-electron standard ferrocene with that from tbpcd ligand. The recorded $E_{1/2}$ value for the tbpcd ligand closely matches that cyclic voltammetically determined $E_{1/2}$ value for the diphosphine ligand bpcd by Tyler and co-worker and the anthracene-functionalized bpcd ligand ($E_{1/2} = -1.01$ V) prepared by us and depicted in Scheme 1 [7,20,25].

The CV of compound **2** was recorded under identical conditions to those employed for **1**. Here the two reversible one-electron waves found at $E_{1/2} = -0.68$ and −1.39 V are readily assignable to the $0/1^-$ and $1^-/2^-$ redox couples, respectively, and parallel those data reported earlier by us for the related diphosphine complex *fac*-$BrRe(CO)_3$(bma) and the compound *fac*-$BrRe(CO)_3$(bpcd) [4,26]. It is interesting to note that the coordination of the tbpcd ligand to the rhenium center in **2** leads to enhanced stability of the $1^-/2^-$ redox couple.



That the CV data from **1** and **2** are similar and in concert with the UV–vis data for both compounds suggest that the free ligand and its rhenium complex possess common HOMO and LUMO levels. This premise was established by carrying out extended Hückel MO calculations on compounds **1** and **2**. Here the model compound 2-(2-thienylidene) -4,5-bis(diphenylphosphino-H_4)-4-cyclopenten -1, 3-dione (tbpcd-H_4) was employed in our calculations, where the four ancillary phenyl groups were replaced with hydrogen atoms. The HOMO for tbpcd-H_4 occurs at −12.00 eV and is confined to the π system of the dione and thiophene rings, as shown below. The dominant contributions from the C=C π bond of the dione moiety and the carbon framework of the thiophene ring, the latter which displays a strong resemblance to ψ_2 of cyclopentadiene and other four-π-electron systems, are evident. The LUMO occurs at −10.45 eV and is strongly π^* in character and exclusively localized on the four carbon and two oxygen atoms associated with the dione platform. The nodal pattern of the LUMO is consistent with theoretical expec-

tations for a six-π-electron system and the MO results from maleic anhydride [7,27].

HOMO LUMO

The HOMO and LUMO levels in *fac*-BrRe(CO)$_3$(tbpcd-H$_4$) were next determined so that a direct MO comparison with the free tbpcd-H$_4$ ligand could made. The calculated energies and orbital composition of the important HOMO and LUMO levels in *fac*-BrRe(CO)$_3$(tbpcd-H$_4$) were unchanged relative to the free ligand tbpcd-H$_4$. The presence of a low-lying π^* LUMO that is localized on the dione moiety in *fac*-BrRe(CO)$_3$(tbpcd-H$_4$) is expected and has been theoretical and experimentally confirmed in all compounds containing an ancillary bpcd ligand investigated to date [20,28]. The surprising feature here was the composition of the HOMO level in **2** since our earlier report on *fac*-BrRe(CO)$_3$(bma) revealed that the HOMO was associated with an out-of-phase interaction involving the rhenium d_{yz} and bromine p_y orbitals with no contribution from the bma π system. Accordingly, we ran comparative Hückel calculations on *fac*-BrRe(CO)$_3$(bpcd-H$_4$) and confirmed that the LUMO (−10.44 eV) was identical to that calculated for *fac*-BrRe(CO)$_3$(bma-H$_4$) and *fac*BrRe(CO)$_3$(tbpcd-H$_4$). The HOMO in the unfunctionalized diphosphine compound *fac*-BrRe(CO)$_3$(bpcd-H$_4$) occurs at −12.35 eV and exhibits the same antibonding rhenium d_{yz} and bromine p_y interaction as found in *fac*-BrRe(CO)$_3$(bma-H$_4$) [26]. The dichotomy in the HOMO composition between *fac*-BrRe(CO)$_3$(tbpcd-H$_4$) and the corresponding bma and bpcd derivatives is readily traced to π interactions between the dione and thiophene rings in the tbpcd ligand. The extended π conjugation in the functionalized or second-generation tbpcd ligand leads to a high-lying π orbital that has no counterpart in the simple bpcd ligand. Examination of the subjacent highest-occupied molecular orbital (sHOMO) at −12.35 eV in *fac*-BrRe(CO)$_3$(tbpcd-H$_4$), which is depicted below, reveals the presence of the expected metal-based rhenium d_{yz} and bromine p_y antibonding orbital in excellent agreement with the MO data from *fac*-BrRe(CO)$_3$(bma-H$_4$) [4] and *fac*-BrRe(CO)$_3$(bpcd-H$_4$) [26].

sHOMO in *fac*-BrRe(CO)$_3$(tbpcd-H$_4$)

Finally, the photophysics for compounds **1** and **2** were explored through the use of emission spectroscopy as this would allow us to corroborate experimentally the $\pi \rightarrow \pi^*$ HOMO/LUMO transition indicated by the extended Hückel calculations. The emissive properties of compounds **1** and **2** were examined at room temperature in both CH_2Cl_2 and MeCN with excitation into the long wavelength band at ca. 380 nm. However, any emission displayed from either compound was not resolvable from the baseline, indicating very weak emission at best and fully consistent with the proposed intraligand $\pi \rightarrow \pi^*$ transition in the free ligand and its rhenium(I) compound [29].

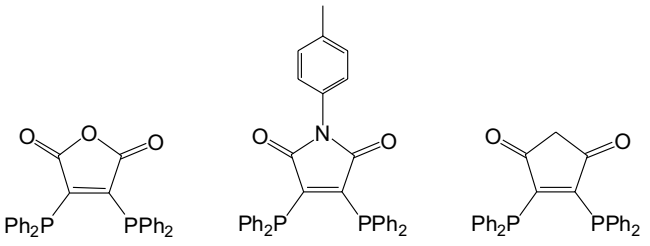
4. Conclusions

The synthesis of the new unsaturated diphosphine ligand 2-(2-thienylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (tbpcd) from 4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (bpcd) and thiophene- 2-carboxaldehyde is described. The ligand substitution chemistry of the tbpcd ligand with the rhenium compounds BrRe(CO)$_5$ and BrRe(CO)$_3$(THF)$_2$ has been examined and found to furnish *fac*-BrRe(CO)$_3$(tbpcd) as the sole observable reaction product. Both new compounds have been fully characterized and their physical properties studied by a combination of methods including cyclic voltammetry, emission spectroscopy, and MO calculations.

5. Supplementary material

CCDC 623341 and 623342 contain the supplementary crystallographic data for tbpcd and *fac*-BrRe(CO)$_3$(tbpcd). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements



Financial support from the Robert A. Welch Foundation (Grants P-0074-WHW and B-1093-MGR) is appreciated. Prof. Andreas H. Franz (University of the Pacific) is thanked for recording the ESI-ACPI mass spectral data for the tbpcd ligand and *fac*-BrRe(CO)$_3$(tbpcd).

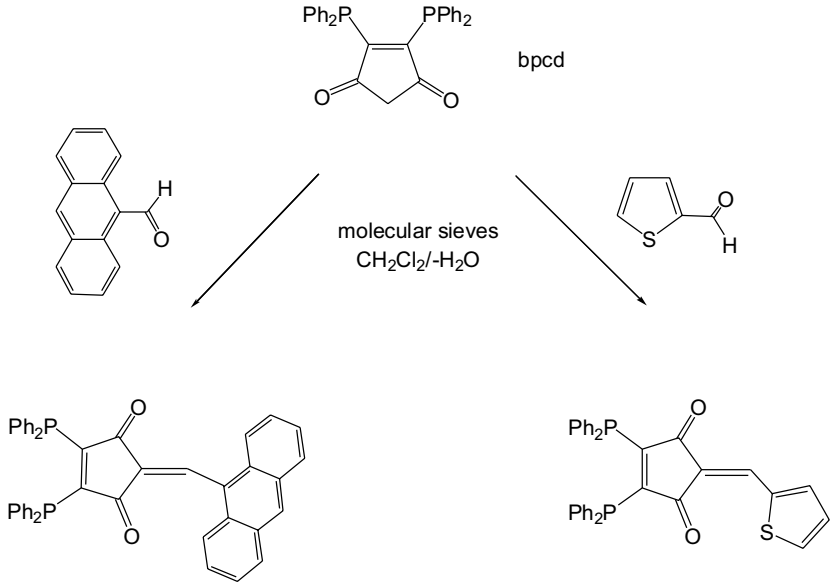
manner analogous to that displayed by CO ligands [4]. The structures of these three diphosphine ligands are shown below.

Wishing to explore further the chemistry of organometallic compounds with structurally more diverse diphosphine ligands that possess highly conjugated π arrays and well-defined redox and photochemically sensitive moieties, we have instituted studies on the modification of the bpcd ligand. The successful synthesis of such second-generation diphosphine ligands would allow us the opportunity to study heretofore novel cluster-ligand systems as redox relays, energy-storage devices, and photochemical and/or redox sensing components [5,6]. Early results using bpcd as a platform for the construction of new diphosphine ligands have been encouraging, and significant structural modifications of the parent diphosphine with the aldehydes 9-anthracenecarboxaldehyde and thiophene-2-carboxaldehyde have produced the new ligands 2-(anthracenyl-9-ylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione and 2-(2-thienylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione, respectively, through a Knoevenagel condensation route [7,8]. Scheme 1 depicts the synthetic protocol and structures of these new diphosphine ligands.



Herein we present our results on the condensation of bpcd with ferrocenecarboxaldehyde to give the new diphosphine ligand 2-(ferrocenylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (fbpcd). The reactivity of the fbpcd ligand with the triosmium cluster 1,2-$Os_3(CO)_{10}(MeCN)_2$ has been examined, and the kinetics for the isomerization of the fbpcd ligand in 1,2-$Os_3(CO)_{10}$(fbpcd) (**2b**) to 1,1-$Os_3(CO)_{10}$(fbpcd) (**2c**) are discussed. Near-UV irradiation of cluster **2c** leads to CO loss and production of the hydride-bridged cluster $HOs_3(CO)_9[\mu\text{-}PhP(C_6H_4)\text{-}C{=}C(PPh_2)C(O)C{=}CH(C_5H_4FeCp)C(O)]$ (**3**). The *ortho*-metalation of one of the aryl groups of the fbpcd ligand in **3** has been structurally confirmed.

2. Experimental

2.1. General

The starting cluster 1,2-$Os_3(CO)_{10}(MeCN)_2$ was prepared from $Os_3(CO)_{12}$ [9], which was in turn was obtained from the carbonylation of OsO_4 using a 450 mL Parr Series 4560 bench-top mini reactor [10]. The bpcd ligand was synthesized from hexachlorocyclopentadiene [11]. The chemicals hexachlorocyclopentadiene, ferrocenecarboxaldehyde, and $Me_3NO \cdot 2H_2O$ were purchased from Aldrich Chemical Co. The latter chemical was dried by azeotropic distillation from benzene and stored under argon when not in use. All reaction and NMR solvents were distilled from an appropriate drying agent using Schlenk techniques and stored under argon in storage vessels equipped with high-vacuum Teflon stopcocks [12]. The combustion analysis was performed by Atlantic Microlab, Norcross, GA.

All IR spectra were recorded on a Nicolet 20 SXB FT-IR spectrometer in sealed 0.1 mm NaCl cells, while the

Scheme 1.

^{1}H spectra were recorded at 200 MHz on a Varian Gemini-200 spectrometer. The ^{31}P NMR spectra were collected in the proton-decoupled mode on a Varian 300-VXR spectrometer at 121 MHz, with the reported chemical shifts referenced to external H_3PO_4 (85%), taken to have $\delta = 0$. The MALDI-TOF mass spectra for the fbpcd ligand and cluster **3** were recorded at the University of the Pacific in the positive ion mode.

2.2. Synthesis of the diphosphine ligand fbpcd

To a Schlenk tube containing 0.20 g (0.43 mmol) of bpcd dissolved in 30 mL of CH_2Cl_2 at room temperature was added 92 mg of ferrocenecarboxaldehyde (0.43 mmol) and ca. 5 g of 4 Å molecular sieves. The introduction of the molecular sieves was accompanied by an immediate color change from the orange–yellow color of the two starting reagents to that of purple, signifying the presence of the desired product. The vessel was sealed and stirring was continued overnight. TLC examination of the reaction solution the following day revealed the complete consumption of the starting materials and the presence of a single purple spot at $R_f = 0.50$ using CH_2Cl_2/hexane (1:1) as a mobile phase. The crude reaction was filtered to remove the molecular sieves and the solvent concentrated down to ca. 0.5 mL, after which the product was run across a short column of silica gel using a 40:60 mixture of CH_2Cl_2/hexane as the eluent. Yield of purple fbpcd: 0.28 g (97%). IR (CH_2Cl_2): ν(CO) 1717 (w, symm dione), 1671 (vs, antisymm dione) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 4.13 (s, 5H, Cp), 4.67 (br, 2H, Cp), 5.16 (br, 2H, Cp), 7.27–7.44 (m, 21H, aryls and alkenyl). ^{31}P NMR ($CDCl_3$): δ −23.49 (AB quartet, $^3J_{P-P} = 60$ Hz). MALDI-TOF MS (m/z): 660.7 [fbpcd]$^+$.

2.3. Preparation of 1,2-$Os_3(CO)_{10}$(fbpcd) (**2b**) from 1,2-$Os_3(CO)_{10}(MeCN)_2$ and fbpcd

To 0.25 g (0.27 mmol) of 1,2-$Os_3(CO)_{10}(MeCN)_2$ in 30 mL of CH_2Cl_2 was added 0.18 g (0.27 mmol) of fbpcd under argon. The solution was stirred at room temperature, and the progress of the reaction was monitored by TLC analysis, which confirmed the consumption of both starting materials after 3 h and the presence of a new dark blue spot corresponding to the clusters **2b**, **2c**, and **3**. The solvent was evaporated under vacuum and the residue passed over a short column of silica gel using a 70:30 mixture of hexane/CH_2Cl_2 to furnish 0.30 g of a dark blue solid. The composition of the isolated cluster mixture was analyzed by using ^{1}H and ^{31}P NMR spectroscopies, which revealed the product distribution: **2b** (80%), **2c** (19%), and **3** (1%).

NMR spectroscopic data for **2b**: ^{1}H NMR (toluene-d_8): δ 3.54 (s, 5H, Cp), 4.20 (br, 2H, Cp), 4.64 (br, 2H, Cp), 6.95–7.25 (m, 12H, aryl), 7.55 (s, 1H, vinyl), 7.70–7.95 (m, 8H, aryl). ^{31}P NMR (toluene-d_8): δ −18.0 (AB quartet, $J_{P-P} = 17$ Hz).

2.4. Thermal isomerization of **2b** to **2c**

To a Schlenk vessel under argon was charged 0.10 g of the previous cluster mixture, followed by 25 mL of toluene via cannula. The solution was next saturated with CO, after which the vessel was sealed and removed from the vacuum line and placed in a thermostated bath at 315 K. The solution was heated for several days and the progress of the reaction was periodically checked by NMR spectroscopy, which revealed the complete consumption of **2b** and a concomitant increase in the amount of cluster **2c** and only a trace amount of cluster **3**. Heating the same sample for an additional 45 days showed only the presence of cluster **2c**. The solvent was removed and cluster **2c** was run across a short column of silica gel and then recrystallized from benzene/CH_2Cl_2. Yield: 95 mg (95%). IR (CH_2Cl_2): ν(CO) 2095 (s), 2046 (s), 2010 (vs), 1975 (s), 1961 (m), 1926 (m), 1719 (w, symm dione), 1675 (m, antisymm dione) cm^{-1}. ^{1}H NMR (toluene-d_8): δ 3.71 (s. 5H, Cp), 4.26 (br, 2H, Cp), 4.95 (br, 2H, Cp), 7.05–7.29 (m, 12H, aryl), 7.63 (s, 1H, vinyl), 7.83–8.00 (m, 8H, aryl). ^{31}P NMR (toluene-d_8): δ 19.8 (AB quartet, $J_{P-P} = 21$ Hz). *Anal.* Calc. for $C_{50}H_{30}FeO_{12}Os_3P_2 \cdot CH_2Cl_2$: C, 38.38; H, 2.02. Found: C, 37.99; H, 1.95%.

2.5. Photochemical preparation of **3** from **2c**

To 50 mg (0.033 mmol) of **2c** in a Schlenk tube was added 20 mL of toluene, after which the vessel was freeze–pump–thaw degassed three times and sealed. The solution was irradiated at room temperature using two GE Blacklights having a maximum output of 366 ± 20 nm for an extended period of time, with periodic removal of the liberated CO through additional freeze–pump–degas cycles. Depending on the thickness of the Schlenk tube, near quantitative conversion to the desired hydride-bridged cluster **3** was typically achieved after two weeks of continuous irradiation. The sample of **3** was passed across a short column of silica gel using CH_2Cl_2 and then recrystallized from benzene/CH_2Cl_2. Yield: 40 mg (82%). IR (CH_2Cl_2): ν(CO) 2085 (vs), 2041 (vs), 2015 (vs), 1986 (vs), 1967 (sh), 1720 (w, symm dione), 1676 (m, antisymm dione) cm^{-1}. ^{1}H NMR (toluene-d_8): δ −15.87 (t, hydride, $J_{P-H} = 14$ Hz), 3.61 and 3.65 (s, 5H each, Cp), 4.19 and 4.32 (br, 2H each, Cp), 4.56 and 4.85 (br, 1H each, Cp), 4.93 and 4.91 (br, 1H each, Cp), 6.90–8.30 (overlapping m, aryls and vinyl). ^{31}P NMR (toluene-d_8): δ 21.40 (d, $J_{P-P} = 13$ Hz), 22.11 (d, $J_{P-P} = 13$ Hz), 30.64 (t, $J_{P-P} = 13$ Hz). MALDI-TOF MS (m/z): 1457.7 [M−CO]$^+$.

2.6. X-ray diffraction data for cluster **3**

Tables 1 and 2 contain the X-ray data and processing parameters and selected bond distances and angles, respectively, for cluster **3**. Single crystals of **3** suitable for X-ray diffraction analysis were grown at room temperature from a CH_2Cl_2 solution containing **3** that had been layered with

pentane. The reported X-ray data were collected on a Bruker SMART™ 1000 CCD-based diffractometer at 211 K. The frames were integrated with the available SAINT software package using a narrow-frame algorithm, [13] and the structure was solved and refined using the SHELXTL program package. [14] The molecular structure was checked by using PLATON [15] and solved by direct methods with all nonhydrogen atoms refined anisotropically. All carbon-bound hydrogen atoms were assigned calculated positions and allowed to ride on the attached heavy atom, unless otherwise noted. The hydride ligand that bridges the Os(1)–Os(2) vector could not be located and the presence of a disordered pentane solvent molecule that resisted refinement was also noted. Convergence for **3** was achieved at $R = 0.0455$ and $R_w = 0.0992$ for 11383 independent reflections with $I > 2\sigma(I)$.

2.7. Kinetic studies

The UV–vis studies were carried out using a mixture of clusters **2b** and **2c** at a concentration of ca. 10^{-4} M using 1.0 cm quartz UV–vis cells that were equipped with a high-vacuum Teflon stopcock to facilitate handling on the vacuum line. Solutions containing the isomeric mixture of clusters **2b** and **2c** were prepared under 1 atm CO and used immediately before each kinetic measurement. The role of CO is to suppress the formation of the hydride-bridged cluster **3** from cluster **2c** at elevated temperature. The Hewlett–Packard 8452A diode array spectrometer employed in our studies was configured with a variable-temperature cell holder and was connected to a VWR constant temperature circulator, allowing for the quoted temperatures to be maintained within ±0.5 K. The UV–vis kinetics for the transformation of **2b** → **2c** were monitored by following the increase of the 360 nm absorbance band as a function of time typically for 4–6 half-lifes. The rate constants quoted in Table 3 were determined by non-linear regression analysis using the single exponential function[1]:

$$A(t) = A_\infty + \Delta A * \ e^{(-kt)}$$

The ^{1}H NMR kinetic experiment was conducted under CO (1 atm) in a 5 mm NMR tube possessing a J. Young valve and was monitored for slightly over 2 half-lifes. The concentration of the initial ca. 70/30 mixture of **2b**/**2c** was ca. 10^{-2} M and the solvent used was toluene-d_8. The extent of the reaction was determined by following the decrease in the intensity of the Cp singlet of **2b** at δ 3.54, as quantified against the methoxy resonance of the internal standard *p*-dimethoxybenzene.

The activation parameters for the isomerization of **2b** to **2c** were calculated from a plot of $\ln(k/T)$ versus T^{-1} [16], with the error limits representing deviation of the data points about the least-squares line of the Eyring plot.

[1] The rate calculations were performed by using the Agilent ChemStation software package configured to the spectrometer or the commercially available program ORIGIN6.0. Here the initial (A_0) and final (A_∞) absorbances and the rate constant (k) were floated to give the quoted least-squares value for first-order rate constant k.

Table 3
Experimental rate constants for the isomerization of **2b** to **2c**[a]

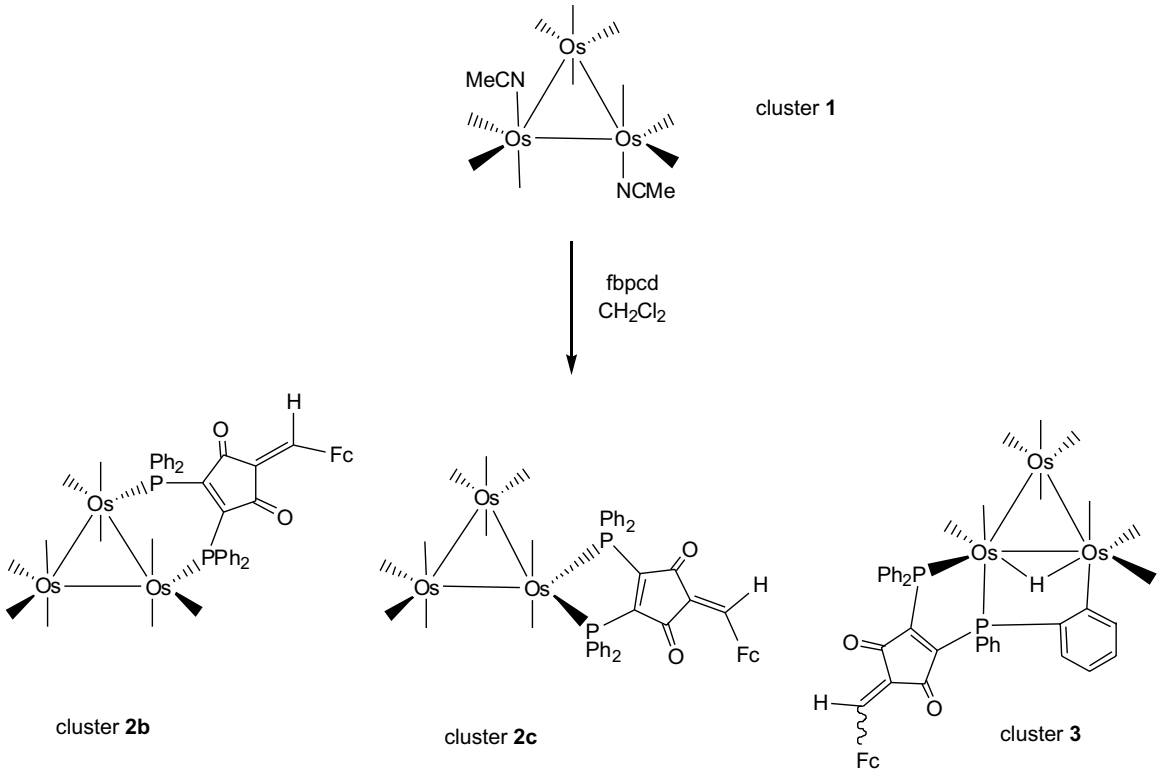
3. Results and discussion

3.1. Synthesis and spectroscopic characterization of the diphosphine ligand fbpcd

Knoevenagel condensation of ferrocenecarboxaldehdye with the diphosphine ligand bpcd proceeds rapidly in CH_2Cl_2 at room temperature in the presence of added molecular sieves (4 Å) to afford the new diphosphine ligand 2-(ferrocenylidene)-4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (fbpcd) in 97% yield. The role of the molecular sieves is to drive the condensation reaction to completion through the removal of the accompanying H_2O. This latter aspect was verified by a control experiment where the ferrocenecarboxaldehdye and bpcd reagents were stirred for a period of several days in the absence of molecular sieves. No fbpcd ligand was observed, as assessed by TLC and IR analyses. However, the addition of the molecular sieves to this solution led to the immediate formation of the desired ligand. The fbpcd ligand was subsequently isolated as an air-sensitive purple solid after chromatographic separation over silica using CH_2Cl_2/petroleum ether (3:2) as the eluent. The following equation illustrates the reaction leading to the fbpcd ligand.



(1)

The fbpcd ligand was fully characterized in solution by IR and NMR spectroscopies, and by MALDI-TOF mass spectrometry. The IR spectrum showed the vibrationally coupled symmetric and antisymmetric ν(CO) bands belonging to the dione moiety at 1717 and 1671 cm^{-1} [17]. These carbonyl stretching bands are 25 and 34 cm^{-1} lower in energy, respectively, relative to the ν(CO) bands of the starting bpcd ligand [11,18], supporting the fact that the fbpcd ligand is more electron rich than the parent diphosphine ligand. The ^{1}H NMR spectrum confirmed the loss of the methylene hydrogens of the bpcd ligand and the formyl hydrogen of the ferrocenecarboxaldehyde substrate. A singlet at δ 4.13 (5H) and two broadened resonances at δ 4.67 and 5.16, each of which integrates for 2H, are readily assigned to the intact ferrocene Cp ring and the functionalized Cp ring that is attached to the dione platform. The vinyl hydrogen associated with the ferrocenylidene moiety and the aromatic hydrogens from the four phenyl groups appear as a multiplet from δ 7.27–7.44. The two inequivalent ^{31}P groups in the fbpcd ligand appear as a classic AB quartet centered at δ −23.49 with a $J/\Delta\nu$ value of 0.30 [19]. The MALDI-TOF mass spectrum of the diphosphine ligand revealed a strong m/z peak at 660.7 for the singly charged parent $[fbpcd]^+$ ion consistent with the proposed formulation of the fbpcd ligand.

3.2. Reaction of 1,2-$Os_3(CO)_{10}(MeCN)_2$ with the ligand fbpcd

Treatment of the activated cluster 1,2-$Os_3(CO)_{10}(MeCN)_2$ (**1**) with an equimolar amount of the fbpcd ligand at 293 K in CH_2Cl_2 leads to the rapid consumption of **1** and the fbpcd ligand (<1 h) and formation of a new dark blue spot ($R_f = 0.60$ using a 1:1 mixture of CH_2Cl_2/hexane as the eluent), as determined by TLC analysis. NMR analysis (^{1}H and ^{31}P) of the reaction solution before a formal work-up revealed the presence of three species assignable to 1,2-$Os_3(CO)_{10}$(fbcpd) (**2b**), 1,1-$Os_3(CO)_{10}$(fbpcd) (**2c**), and $HOs_3(CO)_9[\mu$-$PhP(C_6H_4)C{=}C(PPh_2)C(O)C{=}CH(C_5H_4FeCp)C(O)]$ (**3**). These three products showed no discernable separation on silica gel and neutral alumina when analyzed with sundry different mobile phases. The diphosphine-bridged cluster **2b** is formed as the major product in ca. 80% yield, with cluster **2c** present in ca. 18–19% and the hydride-bridged cluster **3** accounting for the reminder of the ternary mixture. The observed product distribution is reminiscent of that found by us in the reaction between cluster **1** and the related diphosphine ligand bmi [2a]. These data are in accord with cluster **1** serving as an independent platform for the formation of clusters **2b** and **2c** and not a process involving the isomerization of **2b** to **2c** since our extrapolated rate data for such an isomerization at 293 K would occur with a half-life on the order of 42 h (vide infra). The bimodal substitution behavior exhibited in the reaction of cluster **1** and fbpcd is not without precedent, as we have found that the reaction of cluster **1** with the diphosphine ligand 1,2-bis(dimethylphosphino)ethane (dmpe) affords the isomeric clusters 1,2-$Os_3(CO)_{10}$(dmpe) and 1,1-$Os_3(CO)_{10}$(dmpe) as a noninterconverting mixture [20]. Scheme 2 illustrates the course of this substitution reaction using the fbpcd ligand.

Scheme 2.

Given the nature of the product mixture and the fact that both **2b** and **2c** possess overlapping carbonyl bands, the IR spectral data for pure **2b** cannot be reported with certainty.[2] Fortunately, the NMR data for **2b** could be extracted from the crude reaction mixture due to sufficient resolution of the two major components. The ^{1}H NMR spectrum of **2b** recorded in toluene-d_8 exhibits three distinct sets of cyclopentadienyl resonances at δ 3.54 (5H), 4.20 (2H), and 4.64 (2H) that are similar to the pattern displayed by the free fbpcd ligand. The aromatic hydrogens appear as two sets of multiplets from δ 6.95–7.25 (m, 12H, aryl) and 7.70–7.95 (m, 8H, aryl), with a vinyl singlet for the ferrocenylidene moiety appearing at δ 7.55. The ^{31}P NMR spectrum of **2b** reveals the presence of an AB quartet centered at δ −18.0 with $J_{P-P} = 17$ Hz. The high-field location of the bridging fbpcd ligand in **2b** is in keeping with the general trend found in other diphosphine-bridged clusters vis-á-vis the corresponding chelating isomer (vide infra) [21].

3.3. Synthesis of *2c* and isomerization kinetics

The thermally promoted isomerization of the fbpcd ligand about the triosmium frame in **2b** was next explored as part of our interest in the coordinative flexibility exhibited by rigid unsaturated diphosphine ligands [2a,3c,22]. Heating the initially formed cluster mixture under 1 atm CO produced clear spectroscopic changes in the ^{1}H and ^{31}P NMR spectra in concert with the conversion of **2b** and **3** to the chelating cluster **2c**. Provided these reactions were conducted in the dark or under red-light conditions, the formation of **2c** from **2b** was found to be quantitative. Pure **2c** was subsequently isolated via recrystallization and characterized in solution by traditional spectroscopic methods and combustion analysis.

The IR spectrum of **2c** recorded in CH_2Cl_2 revealed terminal Os–CO carbonyl stretching bands at 2095 (s), 2046 (s), 2010 (vs), 1975 (s), 1961 (m), and 1926 (m) cm^{-1}, with the two dione carbonyl bands appearing at 1719 (w) and 1675 (m) cm^{-1}. The symmetry and frequencies of the terminal carbonyl stretching bands closely match those IR data reported by us for the diphosphine-chelated clusters 1,1-$Os_3(CO)_{10}$(bpcd) and 1,1-$Os_3(CO)_{10}$(bmi) [2a,3c]. The chelation of the fbpcd ligand in **2c** is accompanied by a down-field shift of the signature cyclopentadienyl ^{1}H resonances relative to **2b** and appear at δ 3.71 (5H), 4.26 (2H), and 4.95 (2H). The resonances belonging to the aromatic hydrogens [δ 7.05–7.29 (12H) and 7.83–8.00 (8H)] and the lone ferrocenylidene hydrogen (δ 7.63) are relatively unchanged from that of cluster **2b**. Finally, the ^{31}P NMR spectrum displays an AB quartet at δ 19.8 for the diphosphine ligand. The large nuclear deshielding exhibited by

[2] The spectral contributions from the hydride cluster **3** (<1%) did not offer significant interference in comparison to the carbonyl frequencies from cluster **2c**.

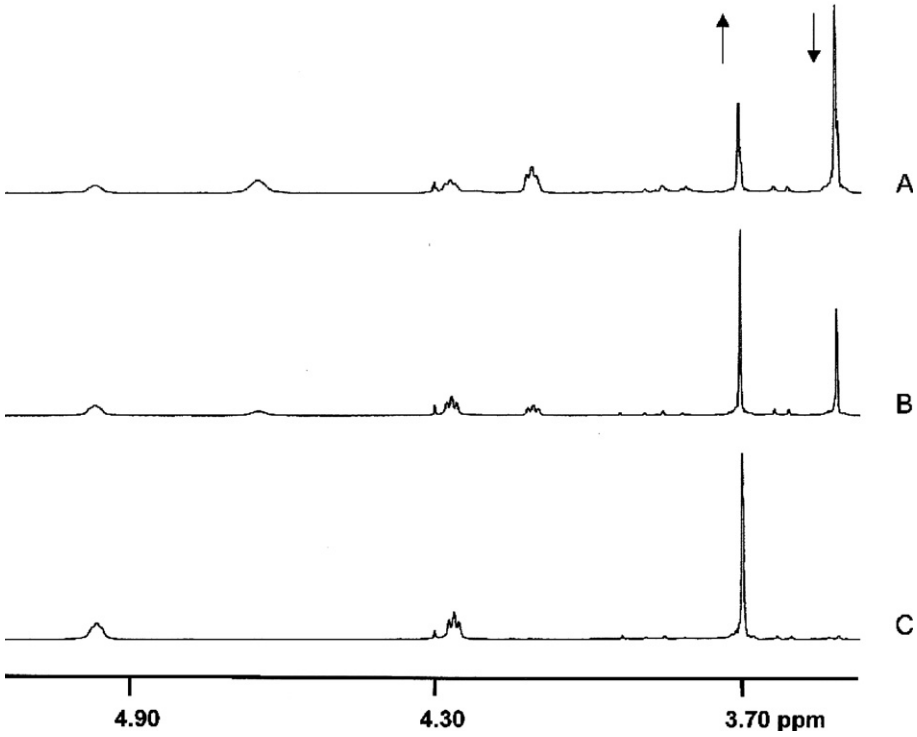


Fig. 1. ^{1}H NMR kinetic data for the isomerization of **2b** → **2c** in toluene-d_8 at 323 K in the cyclopentadienyl region at (A) 0 h, (B) 3 h, and (C) 20 h.

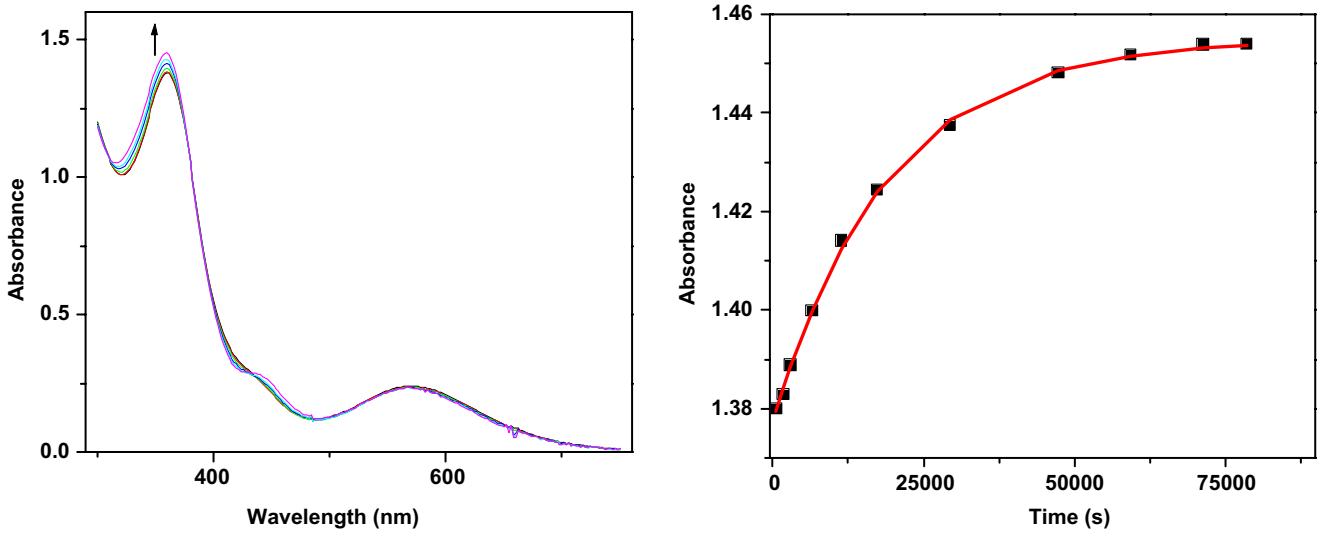
the fbpcd ligand in **2c** relative to the bridging analogue is consistent with the adoption of a chelating coordination mode [21].

The isomerization kinetics for **2b** → **2c** were initially examined by ^{1}H NMR spectroscopy in toluene-d_8 at 323 K. Here a cluster mixture that contained ca. a 70/30 composition of **2b** to **2c** was employed.[3] Representative spectral changes in the cyclopentadienyl region from δ 3.00–5.20 are illustrated in Fig. 1. Here the growth of the three cyclopentadienyl resonances belonging to the chelating isomer was found to be proportional to the rate of consumption of the Cp resonances belonging to **2b**. A traditional plot of ln [**2b**] versus time furnished the first-order rate constant quoted in Table 3 (entry 5), which agrees nicely with the two other rate constants measured by UV–vis spectroscopy at the same temperature (entries 3 and 4). The clean conversion to **2c** found by NMR spectroscopy underscores the fact that the isomerization is not accompanied by the formation of extraneous material(s) and is unidirectional unlike the isomerization reactions in the diphosphine-substituted clusters $Os_3(CO)_{10}$-[(*Z*)$PPh_2CH{=}CHPPh_2$] and $H_4Ru_4(CO)_{10}$(dppe) that give rise to an equilibrium mixture of bridging and chelating isomers [22,23].

[3] The trace amount of cluster **3**, which is initially present and ultimately converted to **2c** under CO, can be ignored as it does not adversely affect the data analysis.

The kinetics for the isomerization of **2b** → **2c** were also investigated by UV–vis spectroscopy in toluene solution over the temperature range 313–343 K. The first-order rate constants for these reactions are reported in Table 3, while Fig. 2a shows the spectral changes that accompany the isomerization at 323 K. The rate of the reaction was easily assessed by following the increase in the absorbance of the 360 nm belonging to **2c**. The isomerization was judged to be free from kinetic complications and negligible material loss based on the isosbestic point at 390 nm that is maintained throughout the course of the reaction. Fig. 2b shows the fit between the absorbance data and the least-squares regression curve that affords the quoted rate constant in Table 3. The effect of added PPh_3 on the reaction at 323 K was also examined (Table 3, entry 4), yielding a rate constant of $5.9 \pm 0.1\ s^{-1}$ that is essentially indistinguishable with the rate constant measured under CO (entry 3). These data argue against a rate-limiting dissociative process that yields a long-lived unsaturated intermediate. The kinetic data for the conversion of **2b** → **2c** strongly support the involvement of a unimolecular process whereby one of the phosphine moieties and two CO groups undergo an equatorial permutation about the cluster polyhedron via a μ-phosphine/μ-CO intermediate. The Eyring plot of ln(k/T) versus T^{-1} shown in Fig. 3 afforded activation parameters ($\Delta H^{\ddagger} = 23.1 \pm 0.3$ kcal/mol and $\Delta S^{\ddagger} = -7 \pm 1$ eu) consistent with the structural rearrangement exemplified by the "merry-go-process" that is depicted in the following equation [2a,3c,22]:



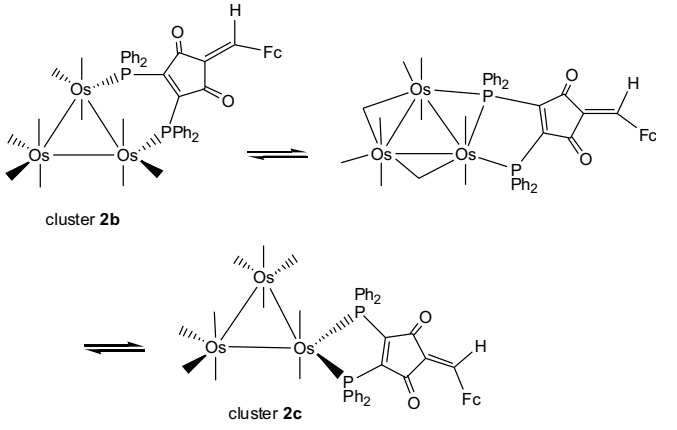


Fig. 2. UV-vis spectral changes for the isomerization of **2b** → **2c** in toluene at 323 K (left) and the absorbance changes at 360 nm versus time curve for the experimental data (■) and the least-squares fit of k (—, right).

(2)

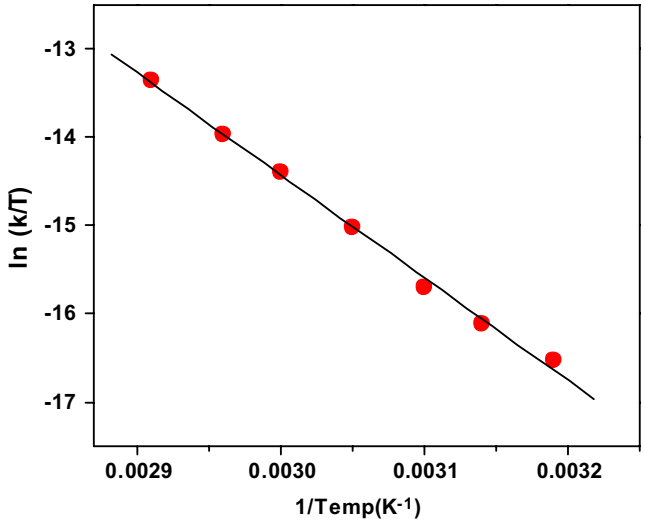

Fig. 3. Eyring plot for the conversion of **2b** → **2c** in toluene over the temperature range of 313–343 K.

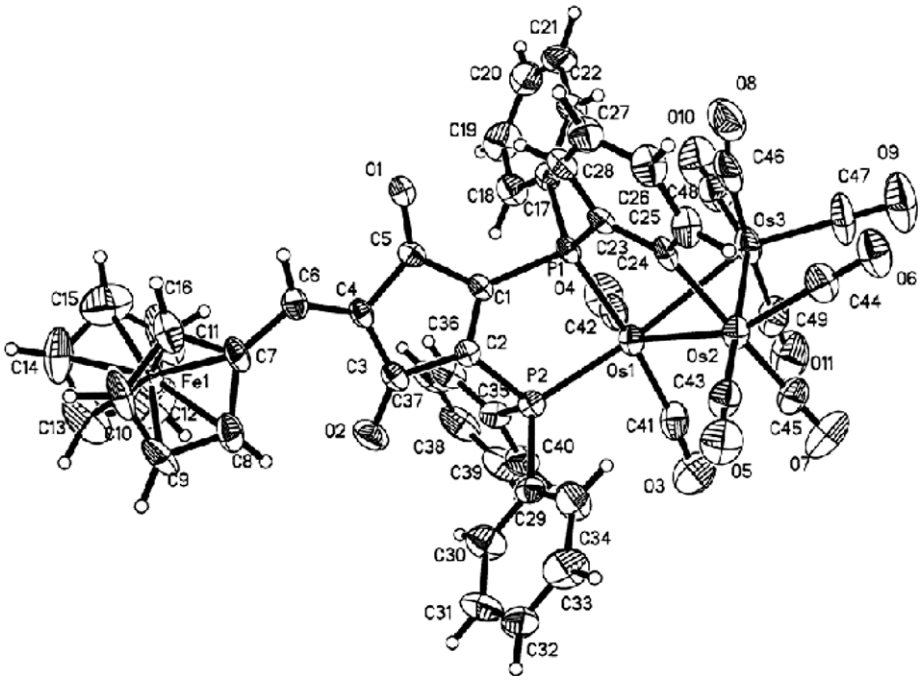
3.4. Synthesis of the hydride-bridged cluster 3 from 2c

The photochemical reactivity of **2c** was examined given our interest in diphosphine ligand activation at metal clusters through *ortho*-metalation [2a,3c,22]. We have previously demonstrated the photoefficient CO loss and C–H bond activation of an ancillary aryl ligand in the diphosphine-chelated clusters $Os_3(CO)_{10}$(bpcd) and $Os_3(CO)_{10}$(bmi) to give the hydride-bridged clusters $HOs_3(CO)_9[\mu\text{-}Ph_2PC{=}C(PhP\{C_6H_4\})C(O)CH_2C(O)]$ and $HOs_3(CO)_9[\mu\text{-}Ph_2PC{=}C(PhP\{C_6H_4\})C(O)N(p\text{-tolyl})C(O)]$, respectively. Irradiation of cluster **2c** using 366 nm light leads to the slow loss of CO and *ortho*-metalation of one of the phenyl ligands to give the cluster $HOs_3(CO)_9[\mu\text{-}PhP(C_6H_4)C{=}C(PPh_2)C(O)C{=}CH(C_5H_4FeCp)C(O)]$ (**3**). In comparison to our earlier studies on $Os_3(CO)_{10}$(bpcd) and $Os_3(CO)_{10}$(bmi), the photochemically promoted *ortho*-metalation of **2c** is exceeding slow, as assessed by NMR analysis. Depending upon the amount of **2c** employed, good yields of **3** could be achieved by prolonged photolysis for several weeks with frequent removal of the liberated CO. Optical excitation of $Os_3(CO)_{10}$(bpcd) has been shown to furnish the unsaturated cluster $Os_3(CO)_9$(bpcd), followed by an intermediate π-aryl complex that precedes the formal *ortho*-metalation step. The π-aryl complex is sensitive to extraneous CO, which upon capture regenerates the starting cluster $Os_3(CO)_{10}$(bpcd) [3c]. The same scenario is assumed to be operative in the case of cluster **2c**, which accounts of the observed sensitivity to CO. Photolysis of a CO-saturated solution of **2c** shows no evidence for the formation of the desired hydride-bridged cluster **3**. Controlled thermolysis of **3** with CO (1 atm) regenerates **2c** in quantitative yield, as determined by NMR spectroscopy. Cluster **3** was isolated by column chromatography, followed by recrystallization, as an air-sensitive, blue solid. Eq. (3) illustrates the reaction of **2c** to **3**:



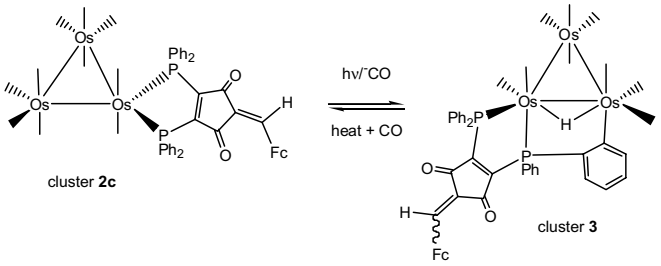


Fig. 4. Thermal ellipsoid plot of cluster **3** showing the thermal ellipsoids at the 50% probability level. The pentane solvent molecule has been omitted for clarity.

(3)

Cluster **3** was characterized in solution by IR and NMR spectroscopies. The *ortho*-metalation attendant on photolysis was confirmed by ^{1}H NMR spectroscopy. The observation of a high-field triplet at δ −15.87 provides unequivocal evidence for the presence of an edge-bridged cluster hydride. Particularly informative were the NMR data that revealed the existence of a 45:55 mixture diastereomers for **3**, whose origin derives from the proximal and distal orientations of the ferrocene moiety relative to the *ortho*-metalated aryl group. The nonfunctionalized Cp ring in the ^{1}H NMR spectrum of **3** appears as two singlets at δ 3.61 and 3.65, while the other Cp ring exhibits three sets of broadened multiplets at δ 4.19 and 4.32 (br, 2H each), 4.56 and 4.85 (br, 1H each), and 4.93 and 4.91 (br, 1H each). The essentially equimolar composition of diastereomers was corroborated by ^{31}P NMR spectroscopy. The presence of two distinct high-field doublets recorded at δ 21.40 and 22.11 and one triplet at δ 30.64, which results from overlapping doublets, is consistent with this formulation. No attempts have been made to assign these resonances to specific phosphine moieties. The MALDI-TOF mass spectrum showed a weak peak centered on *m*/*e* 1457.7 for the loss of one CO group from of **3**, as well as ions for the loss of seven additional CO groups.

The molecular composition of one of the diastereomers of **3** was established by X-ray diffraction analysis. Fig. 4 shows the thermal ellipsoid plot **3** and ascertains the activation of one of the aryl rings via *ortho*-metalation. The Os–Os bond distances range from 2.866(8) Å [Os(2)–Os(3)] to 2.9441(8) Å [Os(1)–Os(2)], with an mean distance of 2.908 Å that parallels those Os–Os single-bond distances reported for other Os_3 clusters. Despite the fact that the bridging hydride was not located during the crystallographic refinement, its location may be confidently assigned to the Os(1)–Os(2) vector [24]. Here the formation of an edge-bridging hydride leads to an elongation of the Os(1)–Os(2) bond length relative to the other two Os–Os bonds in **3**. Both phosphorus atoms of the fbpcd ligand coordinate to the Os(1) center in a chelating fashion and exhibit distinct axial [P(1)] and equatorial [P(2)] dispositions. This represents a change in the phosphine disposition from **2c** where both phosphine moieties were initially situated at equatorial sites. Presumably, the stereochemical change facilitates the ensuing *ortho*-metalation. The P(1)–Os(1)–P(2) angle of 85.95(7)° and the two Os–P distances of 2.305(2) Å [Os(1)–P(2)] and 2.365(2) Å [Os(1)–P(1)] exhibit values unremarkable to those angles and distance found by us in related compounds [1–3]. The Os(2)–C(24) bond distance of 2.165(9) Å is in excellent agreement with those metal-carbon sigma bond distances found in di- and trinuclear osmium compounds containing an *ortho*-metalated aryl ligand [25]. The nine CO groups are

linear and exhibit distances and angles consistent with such linkages. The ferrocene and dione ring moieties are unexceptional and require no comment.

4. Conclusions

The synthesis and properties of the new diphosphine ligand fbpcd are described. The kinetics for the bridge-to-chelate isomerization of the fbpcd ligand in $Os_3(CO)_{10}$(fbpcd) have been measured, with a sequence involving a nondissociative ''merry-go-round'' migration of the ancillary fbpcd ligand and two CO groups supported by a moderately negative entropy of activation. The chelating isomer of $Os_3(CO)_{10}$(fbpcd) losses CO upon 366 nm irradiation, leading to the *ortho*-metalation of the one of the aryl groups and formation of the hydride-bridged cluster $HOs_3(CO)_9[\mu\text{-}PhP(C_6H_4)C{=}C(PPh_2)C(O)C{=}CH(C_5H_4FeCp)C(O)]$, whose molecular structure has been crystallographically determined.

Acknowledgements

Financial support from the Robert A. Welch Foundation (Grants P-0074-WHW and B-1093-MGR) is much appreciated, and Professor. Andreas H. Franz (University of the Pacific) is thanked for recording the MALDI-TOF mass spectra.

Appendix A. Supplementary material

CCDC 628577 contains the supplementary crystallographic data for **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +(44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.03.057.

and spectral characterization of dioxomolybdenum(VI) complexes of N(4)-substituted ONS donor ligands. The single crystal X-ray diffraction studies of three of the synthesized complexes are also described.

2. Experimental

2.1. Materials

$MoO_2(acac)_2$ (Sigma–Aldrich) and pyridine (S.D. Fine Chemicals) were used without further purification. All compounds used for the synthesis of the thiosemicarbazone ligands were purified by standard methods and solvents were purified by distillation. The ligands were recrystallized from ethanol/methanol and dried in vacuo before complexation.

2.2. Synthesis

The ligands H_2L^1 and H_2L^2 were synthesized by the earlier reported methods [5,6].

*[(MoO$_2$L^1)$_2$] (**1**)*. To a hot methanolic solution of the ligand H_2L^1 (2 mmol, 0.582 g), was added a methanolic solution of $MoO_2(acac)_2$ (2 mmol, 0.652 g) with constant stirring. The orange solution obtained was refluxed for about 3 h and allowed to cool. The orange crystals which formed were separated and dried. *Anal*. Calc. for $C_{30}H_{38}N_6O_6S_2Mo_2$: C, 43.17; H, 4.59; N, 10.07. Found: C, 43.05; H, 4.52; N, 10.04%.

*[MoO$_2$L^{1}py] (**2**)*. To a hot methanolic solution of complex **1** (0.5 mmol, 0.417 g), was added 2 mL of pyridine and the mixture was heated until a clear deep yellow solution was produced. The above solution was refluxed for about 3 h and allowed to cool. Slow evaporation of the reaction mixture over 3 days produced yellow crystals. *Anal*. Calc. for $C_{20}H_{24}N_4O_3SMo$: C, 48.39; H, 4.87; N, 11.29. Found: C, 48.16; H, 4.70; N, 11.12%.

*[(MoO$_2$L^2)$_2$] (**3**)*. To a hot ethanolic solution of the ligand H_2L^2 (1.5 mmol, 0.428 g), was added an ethanolic solution of $MoO_2(acac)_2$ (1.5 mmol, 0.489 g) with constant stirring. The orange solution obtained was refluxed for about 3 h and the orange compound formed was filtered, washed with ethanol and ether and dried in vacuo over P_4O_{10}. *Anal*. Calc. for $C_{30}H_{32}N_6O_6S_2Mo_2$: C, 43.80; H, 3.19; N, 10.22. Found: C, 43.69; H, 3.02; N, 10.13%.

*[MoO$_2$L^{2}py] (**4**)*. To a hot ethanolic solution of complex **3** (0.5 mmol, 0.205 g), was added 2 mL of pyridine and the mixture was heated until a clear deep yellow solution was produced. The above solution was refluxed for

2.3. Physical measurements

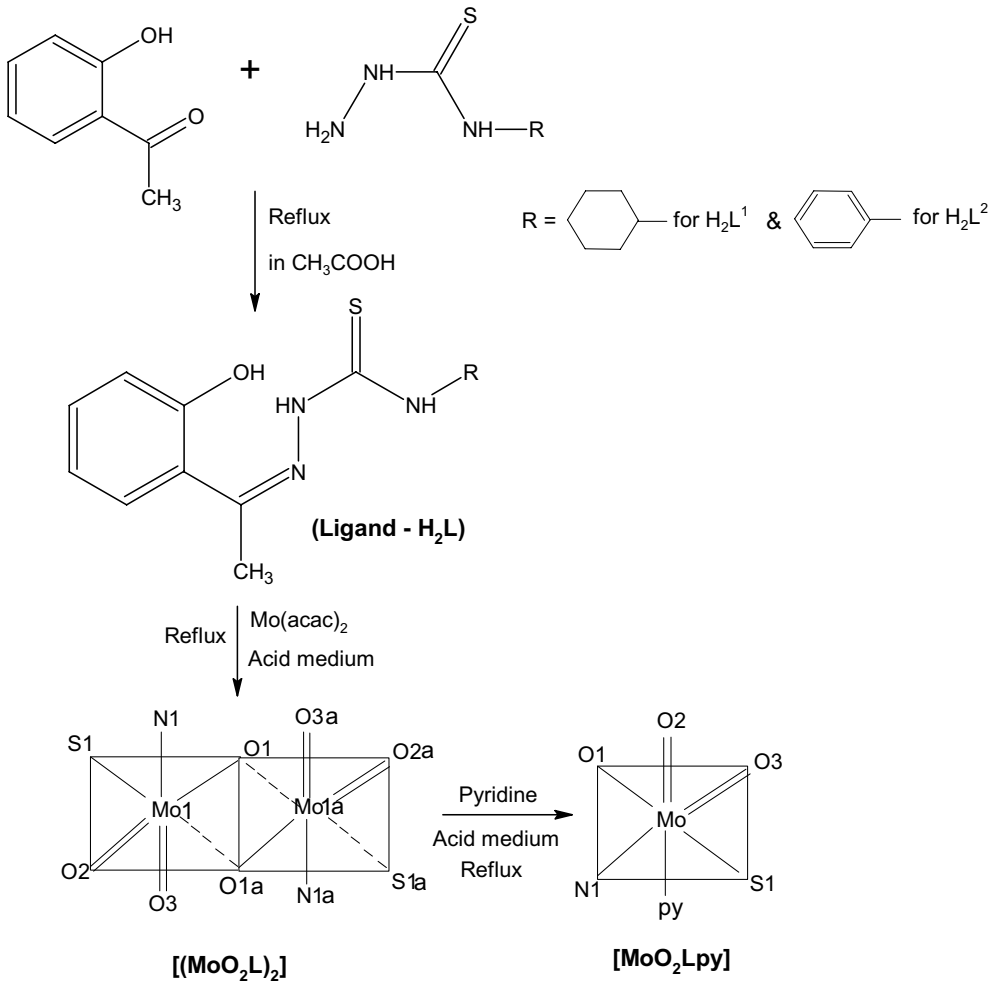
Elemental analyses of C, H and N were done on a Vario EL III elemental analyzer and FT-IR spectra were recorded on a Thermo Nicolet AVATAR 370 DTGS FT-IR spectrophotometer instrument using KBr pellets in the 4000–400 cm^{-1} region at SAIF, Cochin University of Science and Technology, Kochi 22, India. Electronic spectra in solutions were recorded on a Spectro UV–VIS Double Beam UVD-3500 spectrophotometer at the Department of Applied Chemistry, CUSAT, Kochi 22 in the 200–900 nm range. Magnetic susceptibility measurements were carried out at IIT, Roorkee, in the polycrystalline state at room temperature on a Par model 155 Vibrating Sample Magnetometer at 5 kOe field strength. Single crystal X-ray crystallographic analysis of the compounds were carried out using a CrysAlis CCD diffractometer, Oxford Diffraction Ltd., at the Single Crystal X-ray Diffraction Facility, IIT, Bombay.

2.4. Crystallography

The crystallographic data and structure refinement parameters for complexes **1**, **2** and **4** are given in Table 1. An orange block crystal of compound **1**, a golden yellow crystal of **2** and an yellow crystal of **4** were measured at 293(2) K on a CrysAlis CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The program CrysAlis RED was used for data reduction and cell refinement [7]. The structure was solved by direct methods using SHELXS [8] and refined by full-matrix least-squares refinement on F^2 using SHELXL [8]. The N–H hydrogen atoms were located from difference Fourier maps and refined isotropically. The remainder of the H-atoms were included in calculated positions and refined as riding atoms using default SHELXL parameters. For compound **1**, the final refinement cycle was based on all 4891 independent reflections and 217 variables with $R_1 = 0.0229$, $wR_2 = 0.0558$. For compounds **2** and **4**, the final refinement cycles were based on all 3670 and 3511 independent reflections and 266 and 267 variables, respectively, with $R_1 = 0.0388$, $wR_2 = 0.1099$ for **2** and $R_1 = 0.0228$, $wR_2 = 0.0505$ for **4**.

3. Results and discussion

3.1. Synthesis



2-Hydroxyacetophenone N(4)-cyclohexyl and N(4)-phenyl thiosemicarbazones (H_2L^1 and H_2L^2) were used as the ligands. The crystal structures of both ligands were published earlier by us [9,10]. These are found to act as dianionic tridentate ONS donors in this work. The stoichiometric reaction (Scheme 1) of bis(acetylacetonato)dioxomolybdenum(VI) with H_2L in refluxing methanol/ethanol afforded the orange six-coordinated complexes of the type $[(MoO_2L)_2]$ (**1** and **3**). The $[MoO_2L(B)]$ complexes **2** and **4** were prepared by reaction of $[(MoO_2L)_2]$ with a heterocyclic base {B = pyridine (py)} in methanol/ethanol. Magnetic susceptibility and molar conductivity data indicate that these MoO_2^{2+} complexes are diamagnetic and electrically non-conducting in solution. These complexes are soluble in DMF and DMSO.

3.2. Spectral characteristics

Selected spectroscopic data of the complexes are summarized in Tables 2 and 3. Table 2 lists the tentative assignments of the main IR bands of the dioxomolybdenum(VI) complexes for the ligands H_2L^1 and H_2L^2 in 4000–50 cm^{-1} region. The free ligands H_2L^1 and H_2L^2 show bands at ca. 3374 and 3060 cm^{-1}, which are due to the stretching modes of the –OH and –NH groups, respectively. These bands are absent in the complexes which suggests deprotonation of the phenolic group, indicating coordination through the phenolic oxygen, and enolization of the thione sulfur followed by deprotonation. On coordination of the azomethine nitrogen, ν(C=N) shifts to lower wavenumbers by 10–20 cm^{-1} as the band shifts from ca. 1608 to 1592 cm^{-1} in the spectra of the four dioxomolybdenum(VI) complexes. The ν(N–N) of the thiosemicarbazone is found at ca. 1118 cm^{-1}. The increase in the frequency of this band in the spectra of the complexes, due to an increase in the bond strength, again confirms coordination via the azomethine nitrogen [11,12].

The decrease in the stretching frequency of the ν(CS) band from ca. 841 cm^{-1} in the thiosemicarbazones by 80–90 cm^{-1} upon complexation indicates coordination via the thiolato sulfur [13,14]. IR spectra of complexes **1**–**4** show sharp bands at ca. 1540 cm^{-1} due to the newly formed ν(N=C) bond, indicating the coordination of sulfur in the enolate form rather than the keto form [15,16]. In all the complexes, the phenolic oxygen is coordinated to molybdenum by the loss of the OH proton. The ligands have a band at ca. 1279 cm^{-1}, which is due to ν(C–O). This band is shifted to ca. 1244 cm^{-1} in the complexes, indicating the coordination of O^- [17]. It was reported that structurally characterized polymeric dioxomolybdenum(VI)-tridentate complexes have sharp bands in the 810–820 cm^{-1} region [18]. Here, in complexes **1** and **3** a strong band is observed at 821 and 810 cm^{-1}, respectively, suggesting the presence of Mo–O···Mo bridging in their structures [19,20]. All complexes (**1**–**4**) exhibit two bands at ca. 891 and 927 cm^{-1} assigned to symmetric and antisymmetric vibrations, respectively, of the *cis*-MoO_2^{2+} core [21,22].

The electronic absorption bands of the dioxomolybdenum(VI) complexes recorded in DMF solution, are given in Table 3. The thiosemicarbazones (H_2L^1 and H_2L^2) have a ring $\pi \rightarrow \pi^*$ band at ca. 36 690 cm^{-1} and a band at ca. 31 050 cm^{-1} due to $n \rightarrow \pi^*$ transitions associated with the azomethine linkage. These bands suffer marginal shifts on

Scheme 1. Reaction diagram for the isolation of the dioxomolybdenum(VI) complexes.

complexation. The complexes **1**–**4** display a broad band in the 25000–23250 cm^{-1} region and two strong absorptions in the 30300–27020 and 35710–33890 cm^{-1} regions, which are assignable to L → Mo(dπ) LMCT and intraligand transitions, respectively [23–25].

3.3. Description of the crystal structures of the compounds $[(MoO_2L^1)_2]$ (**1**), $[MoO_2L^1py]$ (**2**) and $[MoO_2L^2py]$ (**4**)

The molecular structure and the atom numbering scheme for complexes **1**, **2** and **4** are shown in Figs. 1–3, respectively, and relevant bond distances and angles are presented in Tables 4 and 5. The coordination geometry around molybdenum can be described as distorted octahedral in the three dioxomolybdenum(VI) complexes **1**, **2** and **4**, the ligand $(L)^{2-}$ acting as a tridentate ligand forming a six-membered metallocycle involving the MoO_2^{2+} moiety. In complex **1**, the principal ligand is bonded to *cis*-MoO_2^{2+} in a planar fashion, coordinating through the nitrogen N(1), sulfur S(1) and oxygen O(1) atoms.

Compound **1** is a binuclear dioxomolybdenum(VI) complex, in which structural evidence for the achievement of hexacoordination through Mo–O···Mo bridging is observed. The Mo–O···Mo bridging is effected by one of the carboxylate oxygen atoms with a threefold coordinated oxygen atom C–O–Mo2. Three atoms O(1), N(1) and S(1) of the doubly deprotonated thiosemicarbazone ligand and one terminal oxo atom, O(3), occupy the meridional plane and lie at 0.0599, 0.0983, 0.0105 and 0.0720 Å, respectively,

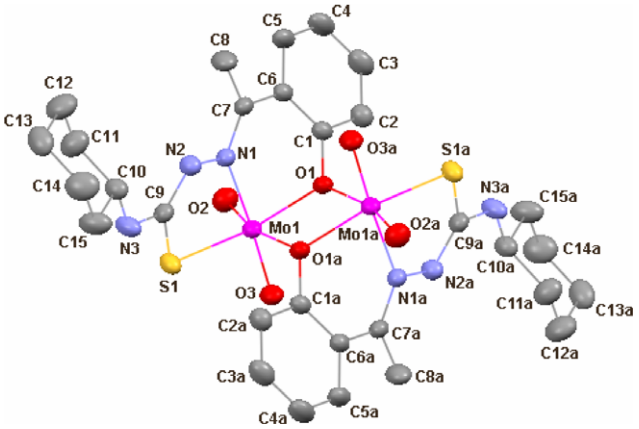

Fig. 1. Ellipsoidal plot of compound **1** (hydrogen atoms are omitted) with the atom labelling scheme.

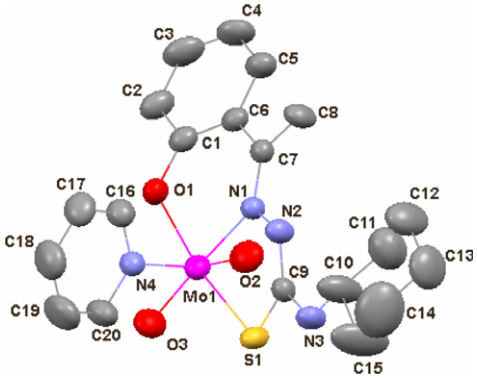

Fig. 2. Ellipsoidal plot of compound **2** (hydrogen atoms are omitted) with the atom labelling scheme.

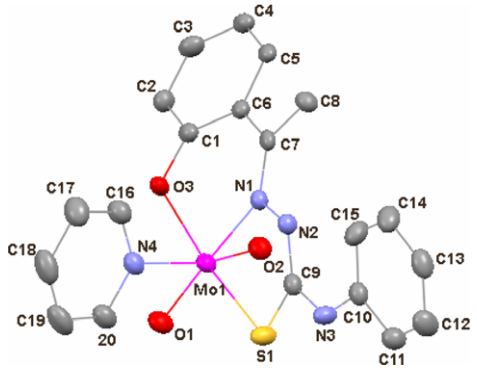

Fig. 3. Ellipsoidal plot of compound **4** (hydrogen atoms are omitted) with the atom labelling scheme.

out of the least squares plane through them, and the Mo atom lies 0.4164 Å out of this plane in the direction of the O(2) atom, the other terminal oxygen. Both oxygen atoms O(2) and O(1a) occupy the axial positions and form an O(2)–Mo(1)–O(1a) angle of 166.97(5)°. The Mo(1)–O(1a) bond [2.4241(12) Å] is significantly longer than the other Mo–O bonds [Mo(1)–O(2), 1.6845(13) Å; Mo(1)–O(3), 1.7075(12) Å; Mo(1)–O(1), 1.9977(11) Å], indicating that O(1a) is weakly bonded to the MoO_2^{2+} moiety. The Mo(1)–O(2) and Mo(1)–O(3) bond distances of the MoO_2^{2+} group are unexceptional and are almost equal [Mo(1)–O(2), 1.6845(13) Å; Mo(1)–O(3), 1.7075(12) Å]. Compound **1** is centrosymmetric, therefore, Mo1 and Mo1a are crystallographically equivalent.

From a comparison of the bond distances and angles of the ligand (H_2L^1) and compound **1**, it is clear that the ligand coordinates to the MoO_2^{2+} core in the deprotonated thiolate form because in compound **1** the C–S bond distance [C(9)–S(1)] exhibits the value 1.7632(16) Å which is nearer to a C–S single bond [1.81 Å] than a C–S double bond distance [1.60 Å] [26]. However, it falls short of the pure C–S single bond distance. The reason for such shortening may be attributed to electron delocalization in the coordinated ligand [27]. The adjacent C(9)–N(2) bond now displays a typical double bond distance [1.299(2) Å] and a N(1)–N(2) bond distance of 1.3851(19) Å is also apparent for compound **1**. In the uncomplexed H_2L^1 ligand, the similar bonds C(8)–N(2) and N(1)–N(2) are 1.351(2) Å and 1.392(2) Å, respectively. The C(7)–N(1) bond distance in compound **1** is close to the usual C=N bond length [C(7)–N(1), 1.3078(19) Å]. The N–N–C bond angle of the ligand (H_2L^1) [N(1)–N(2)–C(8), 119.95(17)°] is reduced by a few degrees [N(1)–N(2)–C(9), 113.28(13)° in **1**] on complex formation. These changes are directly due to coordination of the ligand to the MoO_2^{2+} moiety when it becomes a delocalized system [28–30].

In complexes **2** and **4**, the sixth coordination position is occupied by the heterocyclic base, pyridine coordinating through its nitrogen N(4). The large Mo–N(4) distances [2.433(3) Å in **2**; 2.4380(19) Å in **4**] reveal that the pyridine moiety is rather weakly coordinated to the MoO_2^{2+} core. In complexes **2** and **4**, the Mo–O bond distances of the MoO_2^{2+} core are almost equal [Mo–O(2), 1.688(3) and Mo–O(3), 1.713(3) Å in **2** and Mo–O(2), 1.7070(15) and Mo–O(1), 1.7121(15) Å in **4**]. These observations raise an interesting point about the suspected inherent weakness of the sixth position in the coordination octahedron of the MoO_2^{2+} core, *trans* to the Mo=O(2) bond [31,32].

By comparing the bond distances and angles of ligands (H_2L^1 and H_2L^2) with their respective complexes **2** and **4**, it is clear that the ligands coordinate to the MoO_2^{2+} core in the doubly deprotonated enolate form [C(8)–S(1), 1.688(2) Å in H_2L^1 and 1.6653(17) Å in H_2L^2; C(9)–S(1), 1.746(4) Å in **2** and 1.766(2) Å in **4**; C(8)–N(2), 1.351(2) Å in H_2L^1 and 1.363(2) Å in H_2L^2; C(9)–N(2), 1.299(5) Å in **2** and 1.304(3) Å in **4**; N(1)–N(2)–C(8), 119.95(17)° in H_2L^1 and 118.60(15)° in H_2L^2; N(1)–N(2)–C(9), 113.4(3)° in **2** and 113.35(16)° in **4**].

Ring puckering analyses and least-square plane calculations show that the rings Cg(2) in complex **1** and Cg(1) in complex **2** and Cg(1) in complex **4**, comprising of atoms Mo(1), S(1), C(9), N(2) and N(1), adopt an envelope on Mo(1) and the ring Cg(5) in complexes **1** and **2**, comprising of atoms C(10), C(11), C(12), C(13), C(14) and C(15) adopt chair conformations [33].

In the crystal packing, the molecules of **1** are intermolecularly hydrogen bonded through N(3)–H(3N) and O(3). In molecule **2**, hydrogen bonding interactions are between C(3)–H(3) and O(3) and between C(17)–H(17) and O(2), and the molecules are arranged in an opposite manner and the pyridyl rings are anti-parallel to each other. The molecules of **4** are arranged in an opposite manner and the phenyl rings are parallel to each other. Intermolecular hydrogen bonding interactions are observed between C(13)–H(13) and O(1) and between C(5)–H(5) and O(2).

4. Conclusion

Preparation and characterization of dioxomolybdenum(VI) complexes involving a dianionic tridentate ONS donor in the form of 2-hydroxyacetophenone N(4)-cyclohexyl and N(4)-phenyl thiosemicarbazones are reported. In all these complexes, the main complex MoO_2L is a structurally characterized pentacoordinate species with one vacant position. This vacant position is found to act as a substrate-binding site. Complexes **1** and **3** are binuclear and the vacant position is occupied by an oxygen atom from the second unit, while complexes **2** and **4** are mononuclear and these six coordinate adducts are easily formed by the attachment of pyridine to the sixth position.

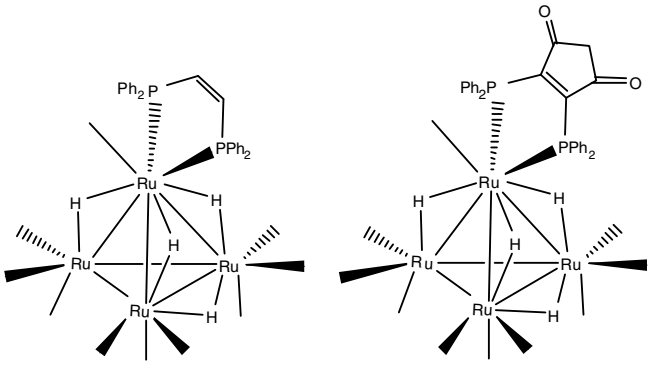
with dppbz. It is believed that the chelation of the dppbz ligand to $Ru_6(\mu_6\text{-}C)(CO)_{17}$ leads to a polyhedral expansion of the ruthenium core, coupled with the scavenging of phosphorus and hydrogen atoms from an additional dppbz ligand to furnish the edge-bridged cluster $HRu_6(\mu_5\text{-}C)(\mu_3\text{-}P)(CO)_{14}$(dppbz) [4]. These novel reactions are depicted in Eqs. (1) and (2).



(1)

(2)

The reaction between the ruthenium cluster $Ru_3(CO)_{12}$ and myriad diphosphine ligands has been thoroughly explored over the last three decades [5]. The formal replacement of two carbonyl groups by the diphosphine ligand affords the corresponding cluster $Ru_3(CO)_{10}$(P–P), where the diphosphine ligand (P–P) may be coordinated to the cluster frame across adjacent ruthenium centers (bridging) or at a single metal center (chelating). Numerous examples exist for both P–P ligand coordination modes. The study of $Ru_3(CO)_{10}$(P–P) clusters has provided valuable insight into the stability of diphosphine ligands (P–P) relative to deleterious ligand decomposition through P–C bond cleavage, C–H bond ortho metalation, and cyclometalation pathways [6]. The observed degradation of phosphine ligands at well-defined metal complexes provides crucial evidence that debunks the innocent or spectator status of such ligands [7]. In comparison, the reactivity of diphosphine ligands with the hydride-bridged cluster $H_4Ru_4(CO)_{12}$ (**1**) has received scant attention vis-a-vis $Ru_3(CO)_{12}$. Other than our recent report on the synthesis and structural characterization of 1,1-$H_4Ru_4(CO)_{10}$[(*Z*)-$Ph_2PCH{=}CHPPh_2$] and 1,1-$H_4Ru_4(CO)_{10}$(bpcd), whose structures are shown below, there exist no other examples for the reaction of $H_4Ru_4(CO)_{12}$ with rigid, unsaturated diphosphine ligands [8,9]. The diphosphine ligands (*Z*)-$Ph_2PCH{=}CHPPh_2$ and bpcd react with cluster **1** to give the diphosphine-chelated clusters without any sign of the corresponding diphosphine-bridged species.

Wishing to establish the generality of ligand chelation at cluster **1** with other unsaturated diphosphine ligands, we have investigated the thermal and Me_3NO oxidative-decarbonylation activation of cluster **1** in the presence of the ligands 1,2-bis(diphenylphosphino)-benzene (dppbz) and 1,8-bis(diphenylphosphino)naphthalene (dppn). The course of these substitution reactions has been established through NMR spectroscopies and X-ray crystallographic analyses of the cluster compounds $H_4Ru_4(CO)_{10}$(dppbz) (**2**) and $H_4Ru_4(CO)_{10}$(dppn) (**3**). The thermal and photochemical stability of both product clusters have been investigated, with the results discussed relative to other diphosphine-substituted ruthenium clusters.

2. Experimental

2.1. General

The starting hydride cluster $H_4Ru_4(CO)_{12}$ (**1**) was prepared from $Ru_3(CO)_{12}$ and H_2 according to the published procedure [10], with the $Ru_3(CO)_{12}$ synthesized from hydrated $RuCl_3$ and CO using a 1l Parr Series 4000 rocking autoclave [11]. The dppn ligand was prepared from 1-bromonaphthalene and Ph_2PCl [12]. The chemicals 1-bromonaphthalene, dppbz, and $Me_3NO \cdot nH_2O$ were purchased from Aldrich Chemical Co. The $Me_3NO \cdot nH_2O$ was dried by azeotropic distillation from benzene and the anhydrous Me_3NO was stored in a Schlenk tube under argon. All reaction, IR, and NMR solvents were of reagent grade and were distilled from a suitable drying agent and stored in Schlenk vessels equipped with Teflon stopcocks [13]. The combustion analyses were performed by Atlantic Microlab, Norcross, GA.

The IR spectral data were recorded on a Nicolet 20 SXB FT-IR spectrometer in sealed 0.1 mm NaCl cells, while the ^1H NMR (200 MHz) and ^{31}P NMR (121 MHz) spectra were recorded on Varian Gemini-200 and 300-VXR spectrometers, respectively. The ^{31}P NMR spectra were collected in the proton-decoupled mode with the reported chemical shifts referenced to external H_3PO_4 (85%), taken to have $\delta = 0$.

2.2. Synthesis of 1,1-$H_4Ru_4(CO)_{10}$(dppbz) (2)

(A) Me_3NO activation: To 0.10 g (0.13 mmol) of cluster **1** and 68 mg (0.14 mmol) of dppbz in a 100-mL Schlenk flask under argon was added 20 mL of CH_2Cl_2, followed by 21 mg (0.28 mmol) of Me_3NO. The solution was stirred at room temperature for 1 h and then examined by TLC analysis using CH_2Cl_2/hexane (1:1) as the eluent, which revealed the presence of a new orange spot at $R_f = 0.55$ corresponding to the desired cluster **2**, in addition to a small amount of unreacted starting cluster **1**. After an initial preparative separation of cluster **2** by column chromatography, the crude product was re-crystallized from CH_2Cl_2/hexane to afford 75 mg of **2** (48%). IR (CH_2Cl_2): ν(CO) 2073 (s), 2043 (vs), 2022 (vs), 1982 (m) cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.80–7.20 (m, 24H, aryl groups), −15.70 (b, 3H), −18.84 (b, 1H). ^{31}P NMR ($CDCl_3$): δ 66.50. *Anal.* Calc. for $C_{40}H_{28}O_{10}P_2Ru_4 \cdot CH_2Cl_2$: C, 40.27; H, 2.47. C, 40.28; H, 2.43%.

(B) Thermolysis reaction: This reaction was carried out in a Schlenk tube containing 50 mg (0.067 mmol) of $H_4Ru_4(CO)_{12}$ and 34 mg (0.070 mmol) of dppbz in 15 mL of 1,2-dichloroethane (DCE). The vessel was heated at ca. 65 °C over night and worked up in a manner similar to that described above. Yield of cluster **2**: 37 mg (48%).

2.3. Synthesis of 1,1-$H_4Ru_4(CO)_{10}$(dppn) (3)

(A) Me_3NO activation: To a Schlenk tube under argon was charged 0.10 g (0.13 mmol) of $H_4Ru_4(CO)_{12}$, 73 mg (0.14 mmol) of dppn, and 21 mg (0.28 mmol) of Me_3NO, after which 25 mL of CH_2Cl_2 was added by syringe. The solution was stirred for 1 h at room temperature and the progress of the reaction was checked by TLC analysis, which confirmed the presence of cluster **3** ($R_f = 0.45$ in 3:2 CH_2Cl_2/hexane) and a trace of unreacted **1**. The desired cluster **3** was isolated by flash-column chromatography employing 3:2 CH_2Cl_2/hexane as the eluent. Crude **3** was re-crystallized from benzene/hexane to afford pure **3** in 38% yield (60 mg). IR (CH_2Cl_2): ν(CO) 2072 (s), 2043 (vs), 2020 (vs), 1998 (s) cm^{-1}. ^1H NMR ($CDCl_3$): δ 7.50–6.50 (m, 26H, aryl groups), −15.70 (b, 3H), −17.20 (b, 1H). ^{31}P NMR ($CDCl_3$): δ 34.90. *Anal.* Calc. for $C_{44}H_{30}O_{10}P_2Ru_4$: C, 44.60; H, 2.55. C, 44.69; H, 3.07%.

(B) Thermolysis reaction: This reaction was conducted in a manner identical to that described for the earlier thermolysis reaction. Here 50 mg (0.067 mmol) of cluster **1** and 37 mg (0.070 mmol) of dppn were heated at ca. 70 °C in DCE solvent overnight. Cluster **3** was isolated by flash-column chromatography in 35% yield (28 mg).

2.4. X-ray diffraction data

Tables 1 and 2 contain the X-ray data and processing parameters and selected bond distances and angles, respectively, for clusters **2** and **3**. Single crystals of clusters **2** and **3** suitable for X-ray crystallography were grown from a CH_2Cl_2 solution containing each cluster that had been layered with hexane. The X-ray data for **2** (TCU) and **3** · 1/2hexane (NMHU) were collected on APEX II CCD-based diffractometers at 213 K and 295 K, respectively. The frames were integrated with the available SAINT [14] and APEX2 [15] software packages using a narrow-frame algorithm, and each structure was solved and refined using the SHELXTL program package [16]. The molecular structures were checked using PLATON [17], and all non-hydrogen atoms were refined anisotropically. All carbon-bound hydrogen atoms were assigned calculated positions and allowed to ride on the attached heavy atom, while the four bridging hydrides associated with the tetraruthenium core of both clusters were located and refined isotropically. The refinement for **2** converged at $R = 0.0374$ and $R_w = 0.0758$ for 9281 independent reflections with $I > 2\sigma(I)$ and for **3** · 1/2hexane at $R = 0.0249$ and $R_w = 0.0563$ for 13172 independent reflections with $I > 2\sigma(I)$.

3. Results and discussion

3.1. Syntheses and spectroscopic data for clusters 2 and 3

The formal replacement of two carbonyl groups in $H_4Ru_4(CO)_{12}$ by the ligands dppbz and dppn is readily achieved by controlled thermolysis of cluster **1** in the presence of the desired ligand in toluene or DCE solution over

Table 2

a temperature range of 65–70 °C. There is no noticeable solvent dependence on the reaction, as both toluene and DCE solvents afford comparable yields of clusters **2** and **3**. The same diphosphine-substituted clusters are also produced when a mixture of **1** and diphosphine ligand is treated with a slight excess of the oxidative-decarbonylation reagent Me_3NO [18]. Scheme 1 illustrates the reactions under consideration. Monitoring these reactions by TLC confirmed the near complete consumption of cluster **1** (>95%) and the presence of the desired product as an orange-yellow spot [**2**: $R_f = 0.55$ using CH_2Cl_2/hexane (1:1); **3**: $R_f = 0.45$ using CH_2Cl_2/hexane (3:2)]. Also accompanying each reaction was the presence of an unknown black material at the origin of the TLC plate that is attributed to decomposed cluster. No attempts were made to characterize this material since it remained irreversibly bound to the chromatographic support. Clusters **2** and **3** were subsequently isolated by column chromatography over silica gel as mildly air-sensitive solids. While clusters **2** and **3** may be handled for short periods of time as solids in the atmosphere, solutions containing these clusters appear to be more oxygen sensitive, exhibiting noticeable decomposition upon exposure to oxygen after only a few hours.

Both **2** and **3** were characterized in solution by IR and NMR spectroscopies. Terminal carbonyl stretching bands observed at 2073 (s), 2043 (vs), 2022 (vs), 1982 (m) cm^{-1} for **2** and 2072 (s), 2043 (vs), 2020 (vs), 1998 (s) cm^{-1} for **3** are in excellent agreement with those data reported by us for the cluster compounds 1,1-$H_4Ru_4(CO)_{10}$[(*Z*)-$Ph_2PCH{=}CHPPh_2$] and 1,1-$H_4Ru_4(CO)_{10}$(bpcd) [8]. The ^1H NMR spectrum of **2** reveals a multiplet for the aromatic hydrogens at δ 7.80–7.20 and two high-field hydrides at δ −15.70 and −18.84 in a 3:1 integral ratio. The ^1H NMR spectrum of **3** mirrors that of cluster **2**, which in turn suggests a common coordination mode of the ancillary diphosphine ligand in both products. The recorded ^{31}P NMR spectra for **2** and **3** exhibit singlets at δ 66.50 and 34.90, respectively, that are consistent with rapid edge-terminal-edge scrambling of the four hydrides, as first put forth by Shapley and Churchill in the chelating isomer of 1,1-$H_4Ru_4(CO)_{10}$(dppe) [19].

3.2. X-ray diffraction data for clusters 2 and 3 · 1/2hexane

The molecular structure of each product was determined by single-crystal X-ray diffraction analysis. Single crystals of both clusters exist as discrete molecules in the unit cell with no unusually short inter- or intramolecular contacts. Fig. 1 shows the thermal ellipsoid plots for clusters **2** and **3**, the latter as a hexane solvate, where the chelation of the dppbz and dppn ligands to their respective cluster core is definitively established. The crystallographically located hydrides in **2** that are associated with the Ru(1)–Ru(4), Ru(1)–Ru(2), Ru(1)–Ru(3), and Ru(2)–Ru(4) vectors range from 3.009(6) Å [Ru(1)–Ru(4)] to 2.9286(6) Å [Ru(2)–Ru(4)] and exhibit a mean distance of 2.9655 Å. The two shorter, non-hydride-bridged Ru–Ru vectors involving the Ru(2)–Ru(3) [2.8029(6) Å] and Ru(3)–Ru(4) [2.7904(6) Å] bonds exhibit a mean distance of 2.7967 Å that is ca. 0.17 Å shorter than the corresponding hydride-bridged Ru–Ru bonds. These bond-length trends are in keeping with those found in related hydride-bridged clusters [19,20,21]. The P(1)···P(2) distance of 3.066(1) Å is slightly smaller compared to the 3.1629(5) Å internuclear P···P distance found by us for the free dppbz ligand.[1] The Ru(1)–P(2) [2.304(1) Å] and Ru(1)–P(1) [2.297(1) Å] bond distances and the bond angle of 83.60(4)° for the P(1)–Ru(1)–P(2) atoms are not unreasonable relative to those values reported for the dppbz-substituted clusters $Ir_4(CO)_7(\mu\text{-}CO)_3$(dppbz) and $HRu_6(\mu_5\text{-}C)(\mu_3\text{-}P)(CO)_{14}$-

[1] Unpublished structural data for the free dppbz ligand.

Scheme 1.

(dppbz) [4,22]. While structurally characterized mononuclear compounds that possess a dppbz ligand are numerous, to our knowledge, the aforementioned Ir_4 and Ru_6 clusters represent the only polynuclear examples containing this diphosphine ligand. The 10 carbonyl groups in **2** are all linear and exhibit a mean Ru–C distance of 1.90 Å. The remaining bond distances and angles are unexceptional and require no comment.

The coordination mode adopted by the dppn ligand and the disposition of the hydrides and carbonyl groups about cluster **3** are similar to that of **2**. The four long Ru–Ru bonds belonging to the Ru(1)–Ru(2), Ru(3)–Ru(4), Ru(1)–Ru(3), and Ru(2)–Ru(3) atoms exhibit a mean distance of 2.9967 Å in excellent agreement with those bond distances found in other hydride-bridged Ru–Ru bonds and the positions associated with the crystallographically located hydrides in **3**. The two shorter bonds defined by the Ru(2)–Ru(4) [2.7707(2) Å] and Ru(1)–Ru(4) [2.7871(2) Å] vectors exhibit an average distance of 2.7789 Å. The chelation of the dppn ligand to the Ru(3) center gives rise to Ru(3)–P(1) and Ru(3)–P(2) distances of 2.3025(5) Å and 2.3150(5) Å, respectively, and an internuclear P(1)···P(2) distance of 3.141(2) Å. The observed angle of 85.74(2)° for the P(1)–Ru(3)–P(2) atoms is slightly smaller than the analogous angle found in the dppn-chelated clusters $Ru_3(CO)_8(\mu\text{-dppm})$(dppn) [89.62(4)°] [23] and $PhCCo_3(CO)_4(\mu\text{-}CO)_3$(dppn) [88.62(3)°] [24], which to date represent the only other structurally characterized clusters containing an intact dppn ligand. Finally, the 10 carbonyl groups in **3** are all linear, with distances and angles consistent with such linkages.

3.3. Thermal and photochemical stability studies of clusters *2* and *3*

Due to our long-term interest in the study of ligand degradation reactions at polynuclear clusters [7], we next examined the temperature and photochemical stability of the new clusters **2** and **3**. Heating sealed NMR tubes containing **2** and **3** in toluene-d_8 at temperatures up to 125 °C for a period of several days showed no evidence for any reaction, as assessed by ^1H and ^{31}P NMR spectroscopies. Noticeable decomposition of both clusters was observed at temperatures above 140 °C, paralleling our earlier stability studies on 1,1-$H_4Ru_4(CO)_{10}$[(*Z*)-$Ph_2PCH{=}CHPPh_2$] and 1,1-$H_4Ru_4(CO)_{10}$(bpcd) [8]. The decomposition of **2** and **3** is accompanied by a broadening of the NMR resonances, which may signal the intervention of radical species, and the deposit of an insoluble dark brown solid. These results stand in contrast to the limited thermal stability of the tetraruthenium cluster $H_4Ru_4(CO)_{10}$-

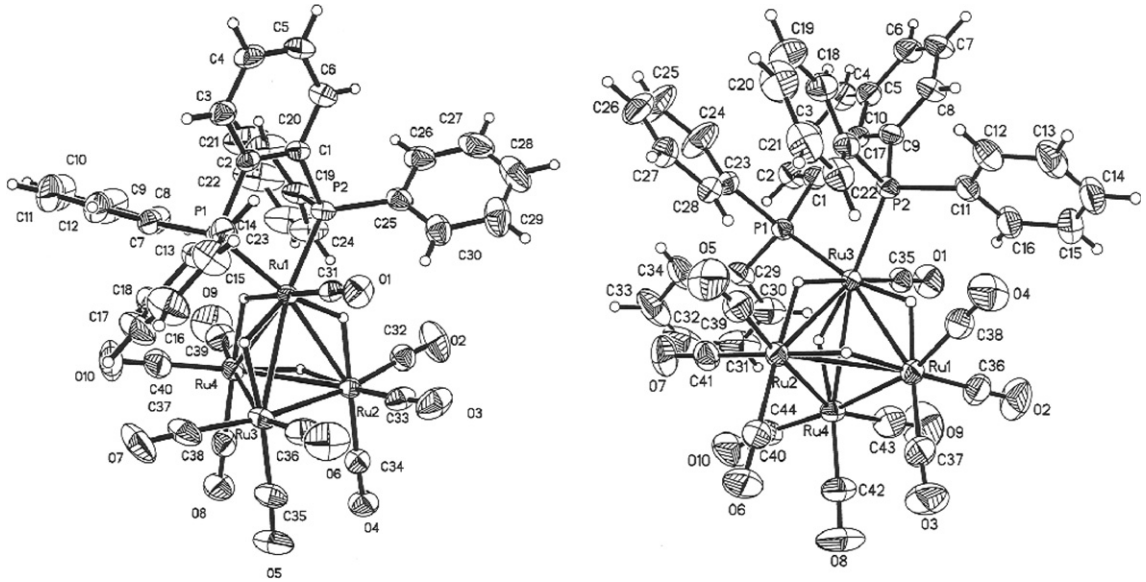

Fig. 1. Thermal ellipsoid plots of clusters **2** (left) and **3** · 1/2hexane (right) showing the thermal ellipsoids at the 50% probability level.

[(*S*)-BINAP], which undergoes facile decarbonylation at 70 °C to afford the face-bridged cluster $H_4Ru_4(CO)_9[\mu_3$-(*S*)-BINAP] [25], as well as the cluster fragmentation exhibited by the trinuclear clusters $Ru_3(CO)_{10}[(Z)$-$Ph_2PCH{=}CHPPh_2]$ (see Eq. (1)) and $Ru_3(CO)_{10}$-(bpcd) to the diruthenium donor–acceptor compounds $Ru_2(CO)_6[(Z)$-$Ph_2PCH{=}CHPPh_2]$ and $Ru_2(CO)_6$-(bpcd) [1a,2].

Whereas the photochemical activation of the parent cluster **1** has been thoroughly examined and shown to undergo CO loss, albeit with low quantum efficiency ($\Phi \approx 10^{-3}$) [26], analogous studies using diphosphine-substituted clusters derived from **1** are scarce [8]. The photochemical reactivity of **2** and **3** was probed in toluene-d_8 and CD_2Cl_2 solvents in sealed NMR tubes. Here the samples were irradiated using 366 nm light for two weeks and periodically monitored by NMR spectroscopy. No reaction was observed under these conditions, signaling the high stability of these particular clusters. The inert behavior of **2** and **3** under these conditions is not surprising since optical excitation of these clusters should be confined to a manifold largely involving the population of ruthenium–ruthenium antibonding σ^* orbitals. Efficient reformation of an optically cleaved ruthenium–ruthenium σ bond is apparently the dominant pathway, accounting for the absence of net photochemical reactivity. Similar results have been found by us for the clusters 1, 1-$H_4Ru_4(CO)_{10}[(Z)$-$Ph_2PCH{=}CHPPh_2]$ and 1,1-H_4Ru_4-$(CO)_{10}$(bpcd) [8].

4. Conclusions

The new cluster compounds 1,1-$H_4Ru_4(CO)_{10}$(dppbz) and 1,1-$H_4Ru_4(CO)_{10}$(dppn) have been synthesized from $H_4Ru_4(CO)_{12}$ and the respective diphosphine ligand. The chelating coordination mode adopted by the ancillary diphosphine ligand in each product has been established by NMR spectroscopy and X-ray crystallography. The thermal and photochemical stability of these clusters parallel related tetraruthenium clusters already prepared by us.

Acknowledgments

Financial support from the Robert A. Welch Foundation (Grants P-0074-WHW and B-1093-MGR) is much appreciated, and the NSF/DMR (Grant 0420863-VNN) is thanked for the purchase of the single-crystal X-ray diffractometer.

Appendix A. Supplementary material

CCDC 627941 and 627940 contain the supplementary crystallographic data for **2** and **3** · 1/2hexane. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.03.034.

dimensionality and control of supramolecular topology. The use of the terephthalate (tp) ligand has frequently been made in the construction of such complexes owing to its diverse binding modes as a linker, and that allows it to assume a variety of structures from discrete molecules to one- (1D), two- (2D), or three-dimensional (3D) networks [18–22]. It is noteworthy that the molecular dimensionality of coordination polymers bridged by tp can be raised by hydrogen bond and other intermolecular contacts, such as face-to-face π–π and edge-to-face CH–π interactions [23,24]. The former is realized when lattice water molecules acting as hydrogen donors and acceptors are present in the crystal structure [25]. A considerable amount of work has been reported in the literature about the binding properties of dicyanamide (dca). It can act as in uni-, bi-, tridentate manner, and both of its homo- and heteroleptic complexes have rich topologies and magnetic properties [26–34]. When co-ligands are introduced, a large number of networks of varied dimensions are obtained and characterized. In short, the principles set forth by organic crystal engineering, especially regarding the reliability of hydrogen bonds, can be applied to the assembly of coordination networks. The controlled synthesis and characterization of different forms has thus become a major issue of solid-state chemistry.

We report herein the syntheses, structures and magnetic properties of three new nickel complexes [Ni(3,2,3-tet)-$\{Ag(CN)_2\}_2$] (**1**), $[Ni(3,2,3\text{-tet})(\mu\text{-tp})]_n \cdot 1.5nH_2O$ (**2**) and $\{[Ni(3,2,3\text{-tet})(\mu_{1,5}\text{-dca})](ClO_4)\}_n$ (**3**). The details of the structural features vary because one is dealing here with intermolecular interactions arising from different hydrogen bonding substituents.

2. Experimental

2.1. Materials

The ligand *N*,*N*′-bis(3-aminopropyl)ethylenediamine was purchased from Aldrich and used as received. Terephthalic acid, and sodium dicyanamide were of analytical reagent grade (Fluka). Ni(II) salts were purchased from commercial sources and used as received. Sodium terephthalate was readily prepared by the reaction of terephthalic acid with a stoichiometric amount of NaOH in water. All other chemicals, e.g. sodium hydroxide, $AgNO_3$ and NaCN were of reagent grade. Methanol and *N*,*N*-dimethylformamide were of reagent grade and were used without further purification. Double distilled water was used throughout.

2.2. Physical measurements

Microanalysis (CHN) was performed in a Perkin–Elmer 240C elemental analyzer. FT-IR spectra were obtained on a Nicolet, MAGNA- IR 750 spectrometer with samples prepared as KBr pellets. Cyclic voltammetry (scan rate of 0.02 V s^{-1}) was performed at a platinum electrode using an EG&G PARC electrochemical analysis system (model 250/5/0) in DMF under dry nitrogen atmosphere in conventional three-electrode configurations. Absorption spectra were carried out on Shimadzu UV2100 UV–Vis recording spectrophotometer. Thermal stability (TG-DTA) studies were carried out on a Mettler Toledo TGA/SDTA 851^e instrument with a heating rate of 10 °C min^{-1} in a nitrogen atmosphere. Magnetic susceptibility measurements of **2** and **3** were carried out with a Quantum Design MPMS XL SQUID magnetometer under an applied magnetic field of 10 000 Oe. The temperature dependence of molar susceptibility, χ_M, for both the complexes was measured on crystalline samples in the temperature range 2–300 K.

2.3. Synthesis of complexes

2.3.1. Synthesis of $[Ni(3,2,3\text{-tet})\{Ag(CN)_2\}_2]$ (*1*)

To an (10 cm^3) aqueous solution of 0.149 g (0.6 mmol) nickel(II) acetate tetrahydrate was added a methanolic solution of 3,2,3-tet (0.6 mmol) to give a pink-violet solution. To this mixture, an aqueous solution of 0.110 g (0.6 mmol) sodium dicyanoargentate(I) (cyano complexes of silver and nickel are toxic!) was added and the solution was stirred for an hour. Upon standing for 8 days at room temperature, pink-violet crystals were separated out. These were filtered off, washed successively with mother liquor and diethyl ether, and dried in vacuo. Yield: 40% (based on nickel). *Anal.* Calc. for **1**: C, 26.00; H, 3.98; N, 20.30. Found: C, 25.80; H, 4.00; N, 20.20%. Selected IR data (cm^{-1}, KBr pellet): 3300 (m), 2163 (s, ν(C≡N)), 2135 (s, ν(C≡N)). UV–Vis (DMF) [λ_{max}, nm]: 350, 555, 806.

2.3.2. Synthesis of $[Ni(3,2,3\text{-tet})(\mu\text{-tp})]_n \cdot 1.5nH_2O$ (*2*)

Nickel(II) perchlorate hexahydrate (0.293 g, 0.8 mmol) was dissolved in 10 cm^3 of water. To this green solution was added a (5 cm^3) DMF solution of 3,2,3-tet (0.8 mmol). The resulting pink-violet solution was stirred for 10 min and filtered off to remove any suspended material. To the filtrate, 5 cm^3 aqueous solution of Na_2-tp (0.168 g, 0.8 mmol) was added and the solution was stirred for 30 min at room temperature. Light pink-violet crystals suitable for X-ray diffraction were obtained after 5 days. Yield: 60% (based on nickel). *Anal.* Calc. for **2**: C, 45.60; H, 6.17; N, 13.30. Found: C, 45.67; H, 6.14; N, 13.40%. Selected IR data (cm^{-1}, KBr pellet): 3300 (m), 2900 (m), 1673 (w, HOH bendings), 1572 (s, $\nu_{asym}(COO^-)$), 1354 (m, $\nu_{sym}(COO^-)$). UV–Vis (H_2O) [λ_{max}, nm]: 275, 350, 555, 806.

2.3.3. Synthesis of $\{[Ni(3,2,3\text{-tet})(\mu_{1,5}\text{-dca})](ClO_4)\}_n$ (*3*)

DMF solution (10 cm^3) containing sodium dicyanamide (0.071 g, 0.8 mmol) and 3,2,3-tet (0.8 mmol) was added to 10 cm^3 of an aqueous solution of nickel(II) perchlorate hexahydrate (0.293 g, 0.8 mmol). The mixture was stirred for 20 min, then filtered off to remove any suspended material. The filtrate was kept at room temperature. Slow evaporation of the resulted purple solution led to purple crystals

of complex **3**. Yield: 65% (based on nickel). *Anal.* Calc. for **3**: C, 30.11; H, 5.52; N, 24.59. Found: C, 30.13; H, 5.55; N, 24.61%. Selected IR data (cm^{-1}, KBr pellet): 3300 (m), 2275 (m, $\nu_{sym}(C{\equiv}N) + \nu_{asym}(C{\equiv}N)$), 2249 (m, $\nu_{asym}(C{\equiv}N) + \nu_{sym}(C{\equiv}N)$), 2161 (s, $\nu_{asym}(C{\equiv}N) + \nu_{sym}(C{\equiv}N)$). UV–Vis (DMF) [$\lambda_{max}$, nm]: 350, 555, 806.

2.4. Crystal structure determination and structural refinement of complexes *1,2* and *3*

Single crystals of compound **1** were grown from an MeOH–H_2O medium whereas those of compound **2** and **3** were grown from a DMF–H_2O medium. The X-ray single crystal data for complexes **1**–**3** were collected on a Siemens P4 4-circle-diffractometer. Crystal size: $0.18 \times 0.37 \times 0.58$, $0.22 \times 0.23 \times 0.38$ and $0.30 \times 0.35 \times 0.36$ mm for complexes **1**, **2** and **3** respectively. Unit cell dimensions and intensity data were measured at 293 K for **1, 2** and **3**. The crystallographic data, conditions used for the intensity data collection and some features of the structure refinement are listed in Table 1. Graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) was used to collect the data sets for **1**–**3**. Unit cell dimensions and intensity data were measured at 293 K for **1** and **2** and 294 K for **3**. For **1**, **2** and **3** the accurate unit cell parameters were determined from automatic centering of 17, 25 and 31 reflections respectively, and refined by least-square methods. 3344 independent reflections were collected for **1** in the range $2.5° < \theta < 25.0°$, 3579 such reflections for **2** in the range $2.1° < \theta < 25.2°$ and 6000 reflections in the range $1.8° < \theta < 25.0°$ for **3**. 2405, 2587 and 2425 reflections were assumed as observed applying the condition $I > 2\sigma(I)$] for complexes **1**, **2** and **3** respectively. All calculations for data reduction, structure solution and refinement were done by standard procedures (SHELXS-97) [35] and (SHELXL-97) [36]. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares techniques on F^2. All the hydrogen atoms of the complexes were constrained to idealized positions and refined using a riding model, with C–H = 0.97 and N–H = 0.90 Å, and with U_{ISO} (H) = 1.2 U_{eq} (C) or 1.2U_{eq} (N). The relatively high values of R_1 (0.086) and wR_2 (0.167) for **3** are due to the low scattering power of the crystal, for which only 2425 of 6000 independent reflections were observed on the basis of the criteria $I > 2\sigma(I)$.

3. Results and discussion

3.1. Description of the crystal structures

3.1.1. Description of the structure of *[Ni(3,2,3-tet){Ag(CN)$_2$}$_2$] (1)*

The molecular structure of the trinuclear complex is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. The nickel atom exhibits a slightly deformed octahedral coordination with one chelate N-bonded 3,2,3-tet molecule placed in the equatorial plane

Table 1

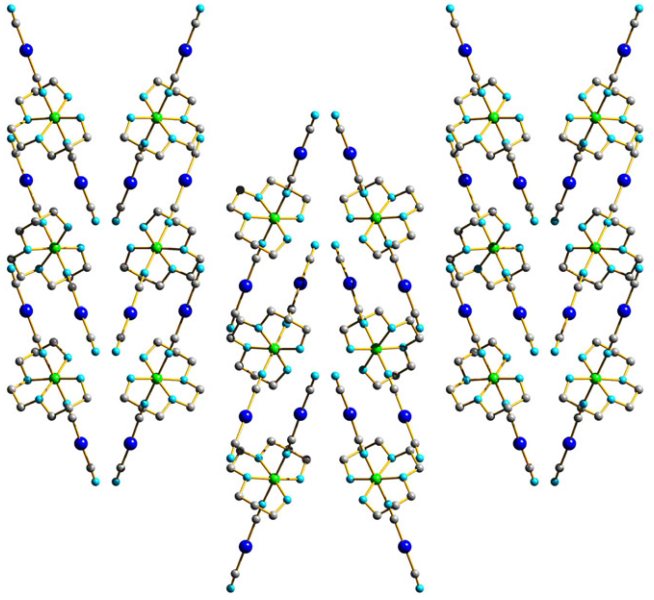

Fig. 2. A view of the packing diagram of complex **1**.

and two N-bonded dicyanoargentate anions as ligands placed in the axial positions. Similar bonding of dicyanoargentate anions has already been observed for other metal complexes, e.g. in the tin complex [N(Ph$_4$)][Cl(Ph$_3$)Sn-(μ-NC)Ag(CN)$_2$] (Ph = phenyl) exhibiting a discrete molecular structure [37] and in the chain-like structure of [Mn^{III}(salen)Ag(CN)$_2$] [38]. The packing diagram (Fig. 2) reveals that the discrete trinuclear heterobimetallic units are packed together with very weak argentophilic interactions as evidenced by the Ag–Ag contact (3.508 Å) that is comparable to the summed van der Waals radii of two silver atoms (3.440 Å). This distance is shorter than the Ag–Ag distances (3.5607(6) and 3.7125(6) Å) found in another Ni complex [Ni(tren)Ag(CN)$_2$][Ag(CN)$_2$] [39] where there are no significant metallophilic interactions. In this compound, [Ag(CN)$_2$]$^-$ building block acts as a monodentate ligand. The bond angles C5–Ag1–C8 (177.8(2)°) and C6–Ag2–C7 (176.3(2)°) deviate slightly from linearity.

3.1.2. Description of the structure of [Ni(3,2,3-tet)-(μ-tp)]$_n$ · 1.5nH$_2$O (2)

A perspective view of complex **2** with the atom-numbering scheme is shown in Fig. 3. Selected bond distances and angles are reported in Table 3. The Ni1 atom shows six coordination, with the four nitrogen atoms of the 3,2,3-tet moiety coordinated in the same equatorial plane while the oxygen atoms O1 and O2 of two bridging terephthalate anions complete the coordination sphere with same Ni–O distances [2.100(3) Å]. The latter distance is slightly longer with respect to those in the basal plane [range 2.075(4)–2.096(3) Å]. Along a chain, the terephthalate anions having the phenyl ring located about a crystallographic symmetry center connect Ni-3,2,3-tet units in a bismonodentate fashion. The bisbidentate fashion of the terephthalate anion has been ruled out due to longer interatomic distance [Ni1–O10 = 3.359 Å] as well as larger Ni1–O1–O10 bond angle (104.16°). The dihedral angle formed by the anion with the equatorial plane is 76.95°; the carboxylate group O1/C10/O10 deviates slightly form coplanarity with the phenyl ring (8.24°) whereas the other carboxylate group O2/C20/O20 deviates from coplanarity with the same phenyl ring by 9.10°. These deviations are uniform throughout the chain. Within a linear chain Ni···Ni is separated by 11.404 Å. This distance is comparable with other terephthalato bridged nickel complexes, 11.446(2) Å in

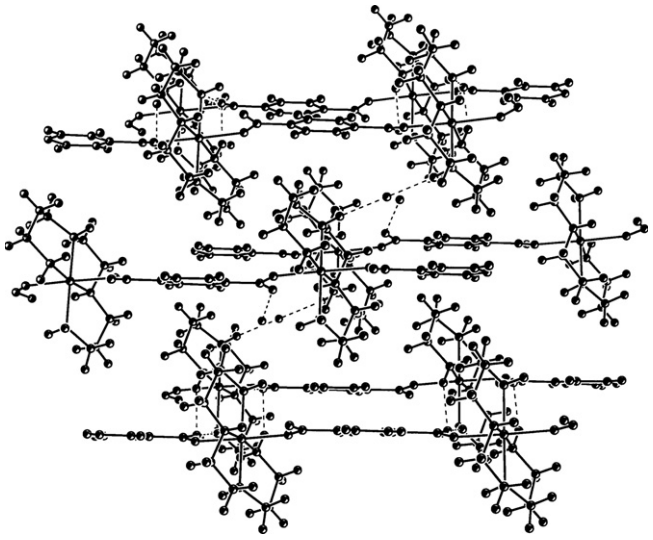

Fig. 4. A view of the packing diagram of **2** showing two-dimension sheet-like network.

[Ni(pyrazole)$_4$(tp)]$_n$ [40], 11.514(1) Å in [Ni($C_{12}H_{30}N_6O_2$)-($C_8H_4O_4$)]$_n \cdot 4nH_2O$ [41] and 11.379(10) Å in (μ-terephthalato)[Ni(dca)(dpt)(H_2O)]$_2$ [34].

The packing diagram of **2** (Fig. 4) consists of 1D polymeric chains formed by Ni-3,2,3-tet moieties bridged by terephthalate units. In addition, hydrogen bonds make the one-dimensional entity extending toward a higher dimensional system. Linkage between the 1D arrays is formed by intermolecular hydrogen bonds. The lattice water molecule OW1 connects two 3,2,3-tet neighboring units via hydrogen bonds (N2···OW1 = 3.042(3) Å). The free carboxylate oxygen atom O10 is additionally hydrogen bonded to another amine group of the 3,2,3-tet moiety (N3···O10 = 2.948(6) Å). Therefore, two C–O bond distances of the carboxylate group have practically no difference although one is coordinated (C10–O1 = 1.223(5) Å) and the other is uncoordinated (C10–O10 = 1.215(6) Å). In general, coordinated C–O bond distances of carboxylate groups range 1.266–1.279 Å which are longer than free carbonyl C–O bond distances of 1.226–1.255 Å when terephthalate coordinates a metal ion in a monodentate fashion [42–46]. As a consequence, these intermolecular hydrogen bonds extend the 1D coordination network into a 2D sheet-like network. No significant π–π interaction between the phenyl rings is observed and hence the formation of any 3D network has been ruled out.

3.1.3. Description of the structure of {[Ni(3,2,3-tet)-($\mu_{1,5}$-dca)](ClO_4)}$_n$ (**3**)

The labeled diagram for complex **3** is shown in Fig. 5 and selected bond lengths and angles are listed in Table 4. The coordination sphere of Ni(II) is defined by four nitrogen atoms of the tetradentate N_4 ligand 3,2,3-tet situated in the equatorial plane and two *trans*-dca nitrogen atoms at the axial positions resulting in a distorted octahedral coordination environment. The Ni(II) is displaced 0.060 Å out of the equatorial plane. The Ni–$N_{3,2,3\text{-tet}}$ and Ni–N_{dca} bond lengths are in the range 2.107(8)–2.118(8) Å and 2.074(8)–2.112(8) Å, respectively. The dca groups are non-linear with C20–N6–C21 and C20′–N6′–C21′ bond angles of 124.6(9) and 120.2(8)° respectively. To achieve internal charge balance there is a perchlorate counter anion outside the coordination sphere. It should be emphasized that the

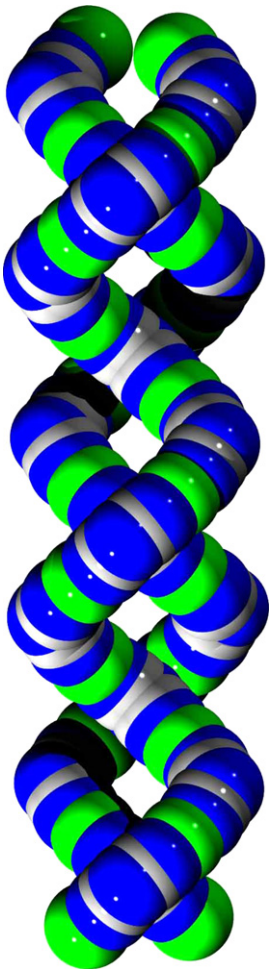

Fig. 7. A perspective view of the double-helical structure.

dca acts as a $\mu_{1,5}$-bridging ligand and links two neighboring Ni^{II}-3,2,3-tet moieties forming an infinite one-dimensional system (Fig. 6). Interestingly, when viewed along the crystallographic *a*-axis, such a 1D chain propagates in a helical fashion. Also, each adjacent chain is composed of an alternating assembly of left-hand (M) and right-hand (P) helices (Fig. 7). A twisting is observed between two successive dca ligands with a dihedral angle of 68.42° which leads to the formation of the helical column in which the repeating period is 13.652 Å. To our knowledge there is no such example of this $\mu_{1,5}$-type of dicyanamide helical bridging in any Ni(II) complexes. An earlier report shows that in the complex [Ni(tmeda)(dca)$_2$] [47], a helical 3D structure is formed but each helical chain is not 'stitched' whereas in complex **3**, the linking mode and structural characteristics are different. The most common 1,5-bridging mode comprises of either a zig-zag or a straight chain-like network [48,49]. No classical hydrogen bond is operative in the packing structure. It may be pointed out that diffraction from the crystal of **3** was apparently rather weak owing to the intrinsic problem of the crystal. Despite the low precision of the structural parameters, the main framework of the 1D chain is clearly revealed. The relevant bond distances and angles are comparable to other reported systems [48,49].

3.2. Cyclic voltammetry

The cyclic voltammogram of complex **1** was recorded in DMF solution with TBAP as supporting electrolyte in the potential range −1.8 to +1.2 V versus SCE. The voltammogram is characterized by a well-defined oxidation wave with $E_{1/2} = 0.86$ V (Fc/Fc$^+$) and $\Delta E = 50$ mV. This anodic response corresponds to the $[Ni^{II}(3,2,3\text{-tet})\{Ag(CN)_2\}_2] - e \rightarrow [Ni^{III}(3,2,3\text{-tet})\{Ag(CN)_2\}_2]^+$ reaction and this is a quasireversible one. In the cathodic region, a quasireversible reduction of Ni^{III} to Ni^{II} for the reaction $[Ni^{III}(3,2,3\text{-tet})\{Ag(CN)_2\}_2]^+ + e \rightarrow [Ni^{II}(3,2,3\text{-tet})\{Ag(CN)_2\}_2]$ with an $E_{1/2}$ value of −0.93 V and $\Delta E = 390$ mV is observed. The quasireversibility of the couples might be due to the instability of the formally Ni^{III} species. In the said potential range no anodic wave for the oxidation of the ligand is observed.

The cyclic voltammogram of complex **3** was recorded in DMF solution with TBAP as supporting electrolyte in the potential range −1.6 to +1.6 V versus SCE. The cyclic voltammogram exhibits two quasireversible waves. The redox couple with the anodic peak $E_{1/2} = 0.79$ V (Fc/Fc$^+$) and $\Delta E = 130$ mV, may be assigned to the reaction

$[Ni^{II}(3,2,3\text{-tet})(\mu_{1,5}\text{-dca})]^{+} - e \rightarrow [Ni^{III}(3,2,3\text{-tet})(\mu_{1,5}\text{-dca})]^{2+}$. In the cathodic wave, a quasireversible reduction with an $E_{1/2}$ value of -0.83 V and $\Delta E = 190$ mV is observed and may be assigned to the reaction $[Ni^{III}(3,2,3\text{-tet})(\mu_{1,5}\text{-dca})]^{2+} + e \rightarrow [Ni^{II}(3,2,3\text{-tet})(\mu_{1,5}\text{-dca})]^{+}$. No anodic wave for the oxidation of the ligands is featured. For both the complexes the chemical environment is not suitable to stabilize the Ni(I) state and hence no Ni^{II}/Ni^{I} couple is observed in the cyclic voltammograms.

3.3. Thermal studies

TG-DTA plots of **1** clearly shows four weight loss steps. The first mass loss in the region 60–130 °C corresponds to the loss of one cyanide unit from one argentocyanide moiety of the complex. The observed weight loss of 5.14% is in agreement with the calculated one (4.70%). The second step (150–300 °C) reveals that rest of the three cyanide moieties are decomposed and the observed mass loss (13.99%) corroborates well with the calculated one (14.11%). The third and fourth steps in the temperature range 300–450 °C are composite in nature and correspond to the complete decomposition of the 3,2,3-tet ligand with the observed weight loss of 32.09%, accompanied by a sharp exothermic peak in the DTA curve. The total weight loss of 51.22% matches fairly with the calculated one (50.29%) if the final product is assumed to be a mixture of metallic nickel and silver.

The TG-DTA curves of complex **2** show two steps corresponding to the decomposition process. The compound is stable up to 80 °C. The weight loss (6.61%) from 80–120 °C corresponds to the loss of all the water molecules (6.37%) from the complex. Meanwhile, in this temperature region, the DTA curve shows an endothermic peak showing energy absorption. The next step (240–440 °C) is attributed to framework decomposition of the 3,2,3-tet and the terephthalate moieties into gaseous products. The observed weight loss (80.01%) matches well with the calculated one (79.78%). The total weight loss of 86.62% is agreeable to the calculated weight loss of 86.15% and the residue is assumed to be metallic nickel.

As complex **3** contains perchlorate as the counter anion, no attempt has been made for the thermal study owing to its possible explosive nature.

3.4. Magnetic properties of 2 and 3

Magnetic susceptibility data for polycrystalline samples were collected in the temperature range 2–300 K and 2–200 K for **2** and **3**, respectively in an applied magnetic field of 1T. The magnetic behavior ($\chi_M T$ versus T) of the complexes **2** and **3** is shown in Fig. 8. Complex **2** displays a temperature-independent $\chi_M T$ value of 1.11 ± 0.01 cm^3 mol^{-1} K in the temperature range 300–15 K. Similarly, complex **3** shows a temperature-independent $\chi_M T$ value of 1.13 ± 0.05 cm^3 mol^{-1} K in the range 200–10 K. The values are expected for magnetically isolated $S = 1$ spin

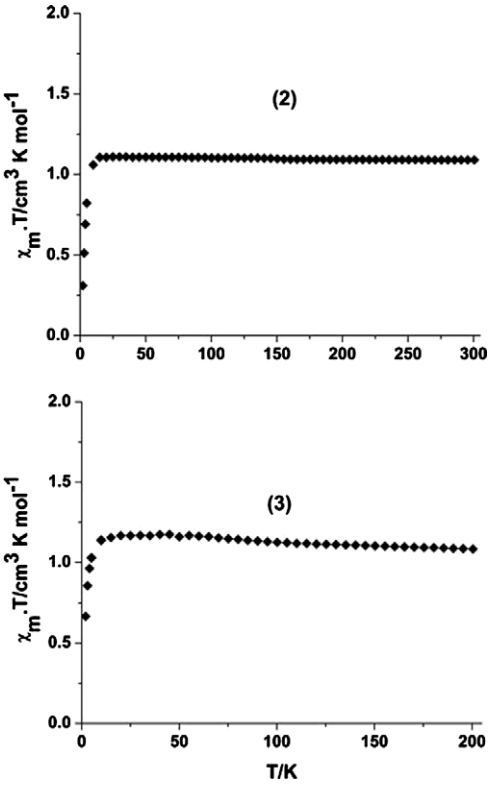

Fig. 8. Plots of $\chi_M T$ vs. T for complexes **2** and **3**.

system with $g = 2.11$ and 2.13 for complexes **2** and **3**, respectively. At lower temperature, they decrease slowly to 0.31 cm^3 mol^{-1} K at 2.0 K for **2** and to 0.66 cm^3 mol^{-1} K at 2.0 K for **3**. This behavior is typical of very weak intermolecular interaction between the magnetic centers. This is expected for a complex where two magnetic centers are quite far from each other for any magnetic exchange. In other Ni(II) complexes reported in literature [50,51], this behavior is also observed. In both cases, the $\chi_M T$ values obey the Curie–Weiss law $\chi = C/(T - \theta)$ giving Weiss constant θ values of -0.51 K and -0.32 K for **2** and **3**, respectively. Several factors that could act simultaneously here are (i) antiferromagnetic intramolecular coupling, (ii) antiferromagnetic intermolecular coupling and (iii) the D (ZFS) parameter intrinsic to the nickel(II) ion. It is difficult to evaluate these parameters since the couplings are small.

4. Conclusion

This paper describes three Ni(II) complexes having 3,2,3-tet as the primary ligand with argentocyanide, terephthalate and dicyanamide as the co-ligands. The complex **1** with argentocyanide is a discrete molecule. This is a rare case where $Ag(CN)_2^-$ does not act as a bridging unit. Complex **2** forms a 2D sheet-like architecture involving the bridging terephthalate and intermolecular hydrogen bonding (N–H···O and O–H···O). A novel 1D helical network with Ni(II) and the dicyanamide is found in the complex **3**.

There are many reports on coordination complexes of Ni(II) with the N_4 donor ligands and dicyanamide as the bridging ligand but our work seems to be the first one where a 1D helical network is characterized. Complex **2** displays a temperature-independent $\chi_M T$ value of $1.11 \pm 0.01\ cm^3\ mol^{-1}\ K$ in the temperature range 300–15 K whereas that of complex **3** is found to be $1.13 \pm 0.05\ cm^3\ mol^{-1}\ K$ in the range 200–10 K. The values are expected for magnetically isolated $S = 1$ spin system with $g = 2.11$ and 2.13 for both the complexes.

Acknowledgements

We thank Dr. A. Ghosh (Department of Chemistry, University of Calcutta) for assistance in getting the measurements of thermal studies. We record our sincere thanks to Dr. T. K. Paine of our Department for useful discussions on magnetic susceptibility results.

and structural properties [9]. Complexes of **1** were screened for their antitumor and antimicrobial activities [10], but their luminescence properties have barely been investigated [11]. In the present investigation we have synthesized a series of novel blue luminescent high-spin ($s = 5/2$) iron(III) complexes using ligand **1** as the blue light emitting species [11a]. Interestingly, the photophysical and chemical properties of the iron(III) complex can be modulated by controlling the degree of protonation of the ligand or by insertion of a nucleophile. Emphasis will be given to understanding the binding phenomenon via the binding constant and thermodynamic calculations for the complexation equilibrium. Other important features scrutinized include absorption, emission, redox and magnetic studies. The X-ray structure of one of the iron(III) complexes authenticates an FeN_4O_2 coordination with interesting Cl···H–O bonding [12].

2. Experimental

2.1. Materials

All starting materials and solvents were purchased from Aldrich Chemical Company and were used without further purification unless otherwise stated.

2.2. Physical measurements

A Perkin–Elmer 2400 C Elemental Analyzer was used to collect microanalytical data (C, H, N). A Sartorius CP64 balance was used for weighing purposes. IR data were collected with the help of a FTIR Perkin–Elmer L 120-000 A. The UV–Vis spectra of the ligand and its complexes were measured on a Shimadzu UV-1601 spectrophotometer and corrected for backgrounds due to solvent absorption. Fluorescence spectra were recorded with a Perkin–Elmer LS 50B Luminescence Spectrometer. For binding constant measurements, solutions were prepared at a fixed concentration of H_2L^1 (1.0×10^{-5} M) and at a concentration of the metal ions ranging from 1.0×10^{-6} M to 10.0×10^{-6} M at room temperature. Electrochemical measurements were performed under a nitrogen atmosphere on a Versastat II PAR Electrochemistry system using solvents and supporting electrolyte (TEAP) prepared and purified as before [13]. The reference electrode was a saturated calomel electrode (SCE). Solution electrical conductivities were measured with the help of a Philips PR 9500 bridge, the solute concentration being 10^{-3} M. For spectroscopic and electrochemical studies HPLC grade solvents were used.

2.3. X–ray crystallography

Single crystals of $[Fe^{III}(HL^1)_2]Cl \cdot H_2O$ (**2**), were grown by slow diffusion of hexane into a dichloromethane solution of the complex, followed by slow evaporation. A rod shaped crystal was mounted on a glass fiber. Intensity data for complex **2** was collected at 173 K (−100 °C) by the ω-scan method over the 2θ range 1.78–29.27° on a Stoe Mark II-Image Plate Diffraction System [14a] equipped with a two-circle goniometer and using Mo Kα graphite monochromated radiation ($\lambda = 0.71073$ Å). Structure solution and refinement were done by direct methods using SHELXS-97 and SHELXL-97 programs [14b,14c]. The structure was successfully solved in the space group $P2_1/c$. Of the 5990 independent reflections, 5006 satisfying $I > 2\sigma(I)$ were used for the structure solution. The NH H atoms were located from Fourier difference maps and refined isotropically. The water H atoms were located from Fourier difference maps. They were refined isotropically with the O–H bond lengths restrained to be 0.82(2) Å. The remainders of the H atoms were included in calculated positions and treated as riding atoms using SHELXL default parameters. All non-hydrogen atoms were refined anisotropically. An absorption correction was applied using MULscanABS in PLATON [14d]. The molecular structure and crystallographic numbering scheme are illustrated in the PLATON drawing [14d].

Molecular formula $C_{24}H_{22}ClFeN_6O_3$, M 533.78, monoclinic, space group $P2_1/c$, $a = 11.9163(6)$ Å, $b = 20.4137(9)$ Å, $c = 9.4770(5)$ Å, $\beta = 106.028(4)°$, $V = 2215.72(19)$ Å^3, $Z = 4$, $D_{calc} = 1.600$ g cm^{-3}, absorption coefficient $\mu = 0.844$ mm^{-1}, crystal dimensions: $0.39 \times 0.36 \times 0.25$ mm, $F(000)$: 1100, θ range for data collection: 1.78–29.27 (°), index ranges: $-16 \leqslant h \leqslant 16$, $-27 \leqslant k \leqslant 27$, $-13 \leqslant l \leqslant 12$, reflections collected/unique: 31 762/5990, significant unique reflections: 5006 with $I > 2\sigma(I)$, refinement method: full-matrix least-squares on F^2, data/parameters/restraints: 5990/332/2, goodness-of-fit on F^2: 1.045, final R indices $[I > 2\sigma(I)]$: $R_1 = 0.0348$, $wR_2 = 0.0797$, R indices (all data): $R_1 = 0.0454$, $wR_2 = 0.0856$, weighting scheme: $w = 1/[(\sigma F_o)^2 + (0.0395P)^2 + 0.9534P]$, where $P = (F_o^2 + 2F_c^2)/3$, largest difference peak and hole (e/Å^3): 0.542 and −0.584.

$R_1 = [\sum||F_o| - |F_c||]/\sum|F_o|$ (based on F), $wR_2 = [[\sum w(|F_o^2 - F_c^2|)^2]/[\sum w(F_o^2)^2]]^{1/2}$ (based on F^2), GOF $= ((\sum(|F_o| - |F_c|)^2)/(N_o - N_v))^{1/2}$ with N_o = number of observed reflections and N_v = number of parameters.

2.4. Syntheses

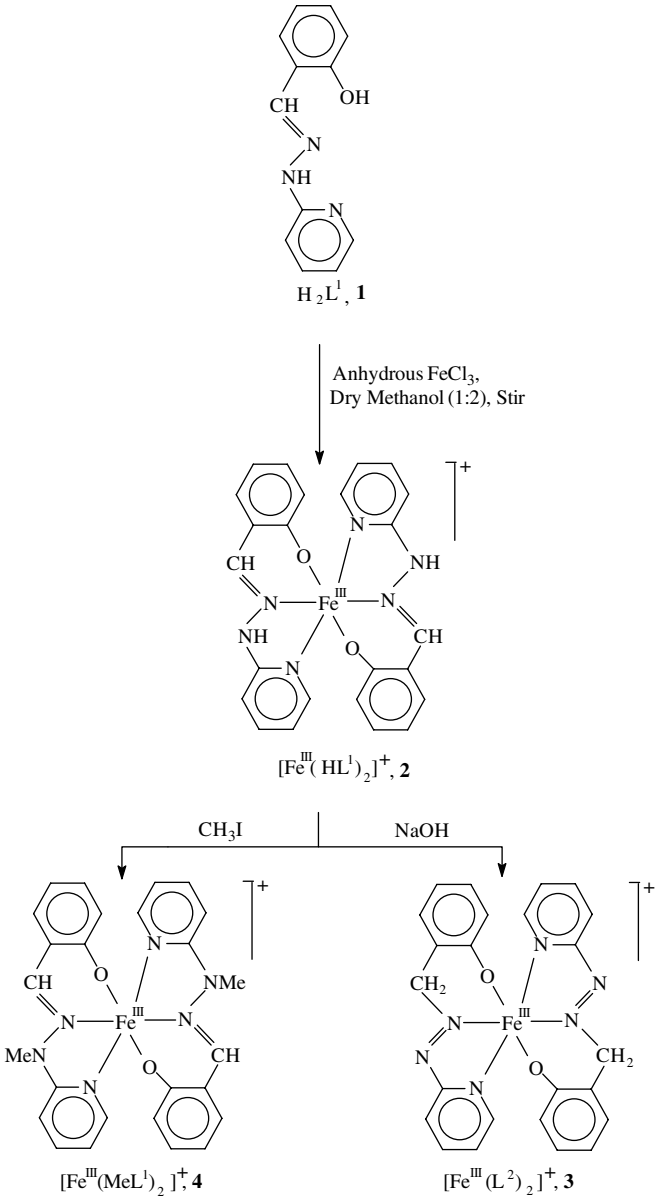
2.4.1. Salicylaldehyde 2-pyridyl hydrazone H_2L^1 (**1**)

The ligand was prepared by the same general procedure as before [15].

2.4.2. Iron complexes

$[Fe^{III}(HL^1)_2]Cl$ (**2**): To a stirred methanolic solution of anhydrous ferric chloride (0.03 g, 0.2 mmol) was added a solution of H_2L^1 (**1**), (0.085 g, 0.4 mmol) in methanol (5 ml) and the resulting brown solution was stirred for 0.5 h. The solvent was evaporated on a rotary evaporator, and on recrystallization from methanol deep brown crystals of $[Fe^{III}(HL^1)_2]Cl$ (**2**), were obtained. Yield 89%. Selected FTIR data, ν (cm^{-1}): 3356, 1623, 1594, 1574,

1537, 1515, 1376, 1355, 1332, 1287, 1250, 1205, 1150, 1139, 1103, 1121, 1030, 1003, 933, 880, 858, 794, 766, 753, 655, 604, 522, 469, 426. *Anal.* Calc. for $C_{24}H_{20}N_6O_2FeCl \cdot H_2O$: C, 54.01; H, 4.12; N, 15.75. Found: C, 54.02; H, 4.14; N, 15.74%.



[$Fe^{III}(L^2)_2$]Cl (**3**): Anhydrous ferric chloride (0.03 g, 0.2 mmol) in methanol (5 ml) was added to a methanolic solution (5 ml) of **1** (0.085 g, 0.4 mmol), previously deprotonated by adding NaOH (0.016 g, 0.4 mmol). A green colored solution was obtained which on evaporation yielded shining greenish brown crystalline solids of $[Fe^{III}(L^2)_2]Cl$ (**3**). Yield 85%. Selected FTIR data, ν (cm^{-1}): 3362, 3011, 2921, 2842, 1614, 1538, 1482, 1469, 1427, 1328, 1285, 1202, 1150, 1100, 1058, 1031, 1008, 931, 881, 848, 753, 604, 429, 469. *Anal.* Calc. for $C_{24}H_{18}N_6O_2FeCl$: C, 56.11; H, 3.50; N, 16.36. Found: C, 55.12; H, 3.56; N 16.38%.

[$Fe^{III}(MeL^1)_2$]Cl (**4**): To a methanolic solution of $[Fe^{III}(HL^1)_2]Cl$ (**2**), (0.1 g, 0.2 mmol) 1 ml methyl iodide was added and stirred for 0.5 h at room temperature resulting in a reddish brown solution. The solvent was evaporated and the complex was recrystallized from methanol and finally dried over fused calcium chloride to obtain $[Fe^{III}(MeL^1)_2]Cl$ (**4**), as reddish brown crystalline solids. Yield 80%. Selected FTIR data, ν (cm^{-1}): 3383, 1621, 1538, 1496, 1358, 1324, 1286, 1148, 1105, 855, 765, 694, 526, 430, 376. *Anal.* Calc. for $C_{26}H_{24}N_6O_2FeCl$: C, 57.43; H, 4.41; N, 15.46. Found: C, 57.42; H, 4.40; N, 15.44%.

3. Results and discussion

3.1. Syntheses and characterization

The ligand system H_2L^1 (**1**), used in the present work is tridentate in nature, incorporating imine, phenolic and pyridyl functions as potential donor sites. The 1:2 reaction of H_2L^1 with anhydrous ferric chloride in methanol at room temperature afforded deep brown colored blue luminescent $[Fe^{III}(HL^1)_2]Cl$ (**2**), in excellent yields, which can subsequently be deprotonated into luminescent green colored $[Fe^{III}(L^2)_2]Cl$ (**3**), followed by methylation leading to another luminescent reddish brown complex, $[Fe^{III}(MeL^1)_2]Cl$ (**4**). The synthetic routes for complexes **2**, **3** and **4** are depicted in Scheme 1. All the complexes are highly soluble in acetonitrile, methanol and ethanol. They are 1:1 electrolytes ($\Lambda = 130$–$134\ \Omega^{-1}\ cm^2\ M^{-1}$) in acetonitrile. The room temperature (298 K) magnetic moments of complexes **2**, **3** and **4** lie in the range 5.56–5.84 μ_B, indicating a high-spin configuration (d^5, $t_{2g}^3e_g^2$, $s = 5/2$) with FeN_4O_2 coordination.

Scheme 1.

3.2. Absorption and Emission Spectra of H_2L^1 and its Iron(III) Complexes

All the spectroscopic measurements were carried out in degassed methanol at room temperature. The bands appearing in the UV region (240–395 nm) are characteristic of the ligand H_2L^1 (**1**) (Fig. 1). In the complexes these

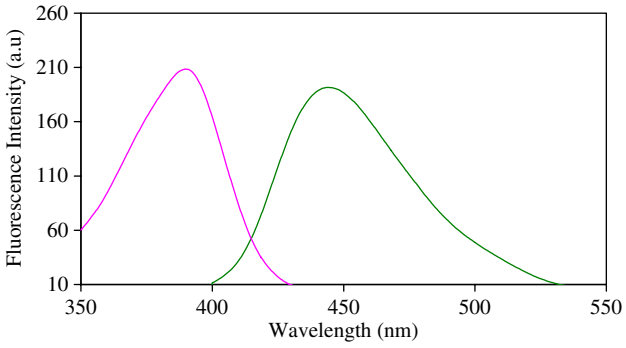


Fig. 1. Excitation (—) and emission (—) spectra of H_2L^1 (**1**), in degassed methanol at 298 K.

ligand centred bands are accompanied by multiple bands extending into the visible region (400–460 nm). The excitation and emission spectra of the ligand and the complexes are listed in Table 1. On excitation at 390 nm, the ligand H_2L^1 (**1**), strongly fluoresces in the blue region (444 nm) due to an intraligand $^1(\pi–\pi^*)$ transition [11a]. Upon complexation with iron(III), the emission peak is slightly red shifted with a significant quenching in emission intensity, as observed in $[Fe^{III}(HL^1)_2]Cl$ (**2**). Subsequent quenching is observed in the deprotonated complex, $[Fe^{III}(L^2)_2]Cl$ (**3**), and the methylated complex, $[Fe^{III}(MeL^1)_2]Cl$ (**4**), with a slight shift in emission wavelength (Table 1). Thus all the complexes **2**, **3** and **4** emit strongly in the blue region (400–460 nm) of the spectrum (Fig. 2). During excitation, the ligand **1** and complex **2** undergo an auto increment in fluorescence intensity at room temperature, without the influence of any external reagent, viz. acid, alkali, excess metal or ligand, possibly due to the internal photo induced azo-imine tautomerism (Scheme 2) [16,17]. The rate of increment is the highest for ligand **1**.

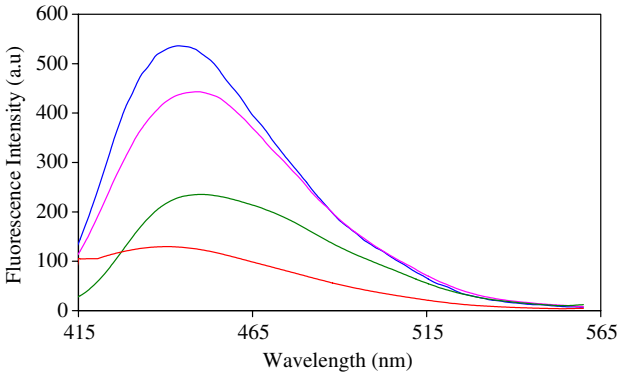
Deprotonation of the imine form, $[Fe^{III}(HL^1)_2]Cl$ (**2**), stabilizes the azo form, $[Fe^{III}(L^2)_2]Cl$ (**3**), with a decreased rate of increment. Complex **3** was isolated and characterized (FTIR $\nu_{N=N} \sim 1450\ cm^{-1}$). Interestingly, the increment is totally stopped in the methyl substituted complex, $[Fe^{III}(MeL^1)_2]Cl]$ (**4**), due to the unavailability of the –NH proton required for the intramolecular tautomerism [16,17].

3.3. Thermodynamics of binding

The association constant (K_{ass}) of complex **2** can be estimated spectrophotometrically (Fig. 3) according to Eq. (1) [18], where X represents the absorption intensity, C_H and C_G are the corresponding concentrations of the ligand and the metal ion.

The K_{ass} (UV–Vis) was found to be 4.6421×10^4 at 298 K. The temperature dependence of the binding constant was studied between 298 and 308 K, and the values of the

$$X = X_0 + (X_{lim} - X_0)/2C_0\{C_H + C_G + 1/K_{ass} - [(C_H + C_G + 1/K_{ass})^2 - 4C_HC_G]^{1/2}\} \quad (1)$$



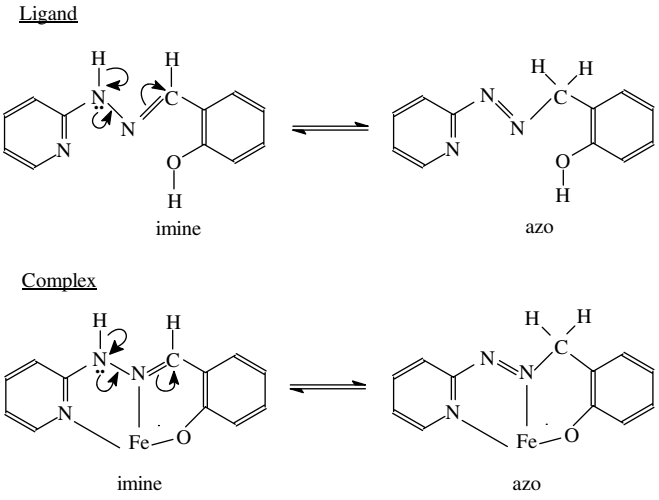


Fig. 2. Emission spectra of ligand **1** (—) and complexes **2** (—), **3** (—), **4** (—), (1×10^{-5} M) in degassed methanol (pH = 7.0), $\lambda_{exc} = 390$ nm, at 298 K.

Scheme 2.

thermodynamic parameters ($\Delta G^0 = -6401.04$ cal/M, $\Delta H^0 = -636.36$ cal/M, $\Delta S^0 = 23.62$ cal/M/deg) were obtained at 298 K in degassed methanol. It is seen that the binding process is favoured by a negative ΔH^0 and positive ΔS^0. A variable temperature UV–Vis titration was performed to monitor the variation of the dissociation constant with temperature, which often gives clues as to the nature of the forces involved in the interaction.

Table 1
Spectral characteristics of iron(III) complexes of H_2L^1

Compounds	Excitation		Emission		F/F_o[a]
	λ_{exc} (nm)	log ε	λ_{em} (nm)	Intensity (a.u)	
H_2L^1 (**1**)	390	5.10	444.49	536.84	
$[Fe^{III}(HL^1)_2]^+$ (**2**)	390	4.58	449.04	438.51	0.81
$[Fe^{III}(L^2)_2]^+$ (**3**)	390	4.32	451.32	235.18	0.47
$[Fe^{III}(MeL^1)_2]^+$ (**4**)	390	4.39	444.11	129.54	0.24

[a] The ratio of fluorescence intensity of the metal complexes of H_2L^1 in the presence of metal (F) and in the absence of metal (F_o). The concentrations of metal and H_2L^1 being 10^{-6} mol/L and 10^{-5} mol/L respectively.

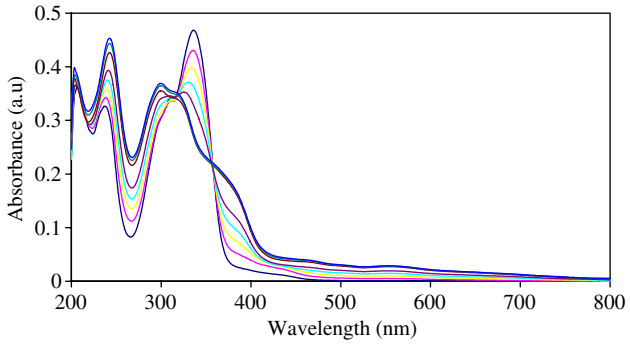

Fig. 3. UV absorbance spectra of H_2L^1 (1.0×10^{-5} M) upon addition of iron(III) (1.0×10^{-6} M – 1.0×10^{-5} M) in degassed methanol (pH = 7.0) at 298 K.

3.4. Electrochemistry

The redox properties of the complexes have been studied in acetonitrile (0.1 M TEAP) solution by cyclic voltammetry (CV) using a platinum-working electrode. $[Fe^{III}(HL^1)_2]Cl$ (**2**), displays a quasi-reversible (ΔE_p = 140 mV) one-electron cyclic response near – 0.15 V versus the saturated calomel electrode (SCE). The response is assigned to the $[Fe^{III}(HL^1)_2]^+/[Fe^{II}(HL^1)_2]$ reduction. Isolation of $[Fe^{II}(HL^1)_2]$ in the pure state is difficult due to rapid air oxidation of the bivalent species. In the deprotonated complex $[Fe^{III}(L^2)_2]Cl$ (**3**), an irreversible couple is observed at a lower potential, possibly due to the predominance of the azo tautomer over the imine form [19].

3.5. X-ray structure of $[Fe^{III}(HL^1)_2]Cl \cdot H_2O$

The molecular structure of complex **2** has been established by single crystal X-ray diffraction. A view of $[Fe^{III}(HL^1)_2]Cl \cdot H_2O$ (**2**), is shown in Fig. 4. The water molecules and chloride ions occur as discrete entities in the lattice and participate in intermolecular hydrogen bonding. The two ligands span meridionally, binding the metal in a hexadentate FeN_4O_2 fashion, utilizing pairs of pyridyl-N, phenolato-O and imine-N, resulting in a *cis* configuration for the FeN_4O_2 sphere. The angles at the metal centre between the *cis* positioned donor pairs span the range 73.27(5)–97.58(5)° and those between *trans* positioned pairs are 154.08(5)–155.30(5)°. The two tridentate ligands have the same gross structures with little conformational change. The five-membered FeN_3C chelate rings are relatively planar. The r.m.s. deviations of the five fitted atoms are 0.0535 for ring [Fe1, N1, C5, N2, N3] and 0.0164 for ring [Fe1, N4, C17, N5, N6]. The six-membered FeC_3NO chelate rings are also relatively planar, with the

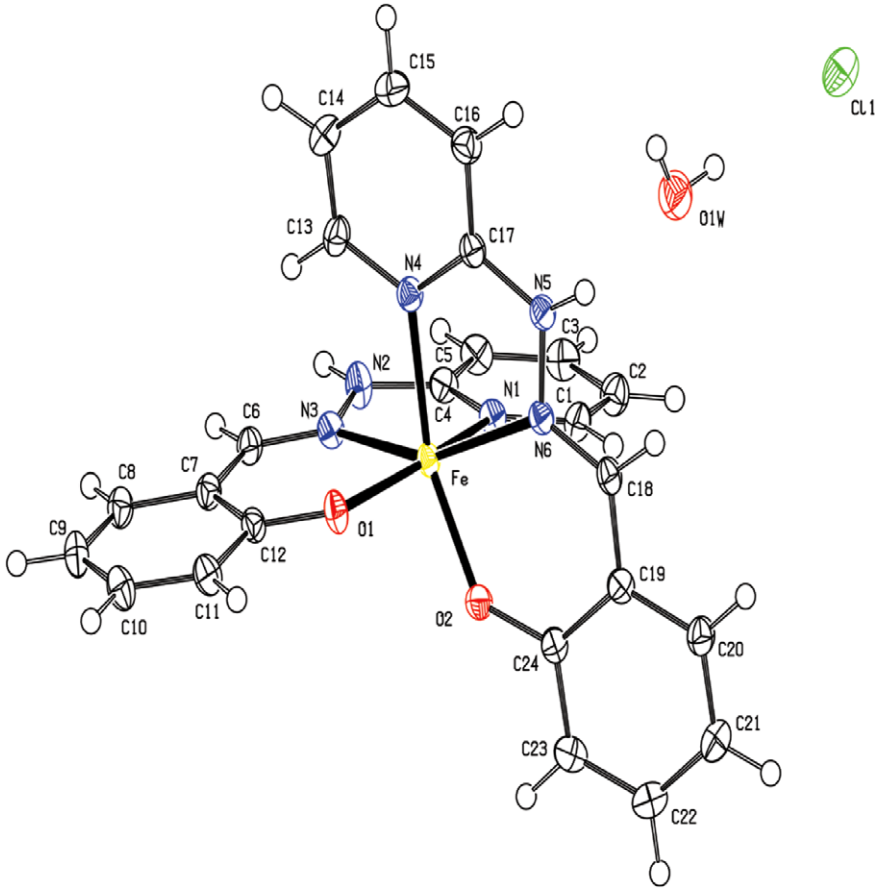

Fig. 4. Perspective view and atom labelling scheme for $[Fe^{III}(HL^1)_2]Cl \cdot H_2O$ (**2**). All atoms are represented by their 50% thermal probability ellipsoids.

r.m.s deviations of the six fitted atoms being 0.0124 for ring [Fe1, O1, C12, C7, C6, N3], and 0.0759 for ring [Fe1, O2, C24, C19, C18, N6]. The four Fe–N lengths are virtually same, the average value being 2.159(1) Å, as expected for high-spin iron(III) complexes (2.1 Å) [20]. The Fe–$O_{phenolate}$, bond length, 1.9041(12) Å, is almost equal to other high-spin iron(III) complexes (~1.89 Å) [21]. The two imine (–NH) bond lengths are almost the same, the average value is 1.373(2) Å, longer than the N=N bond length, 1.28 Å [22]. The bond distance of N(3)–C(6) is 1.295(2) Å and that of N(6)–C(18) is 1.296(2) Å, which is normal for C=N [23] (See Tables 2 and 3).

3.6. Hydrogen bonding

In complex **2**, there is one strong N(5)–H(5A)···O(1w), 2.841(2) Å, and one weak N(2)–H(2A)···Cl(1), 3.111(2) Å intermolecular hydrogen bond, as expected for N–H···O (~2.90 Å) [24] and N–H···Cl (~3.08 Å) [12]. These N–H···O and N–H···Cl hydrogen bonds undergo weak interactions with chloride and water molecules present in the crystal lattice. The crystal packing diagram (Fig. 5) clearly shows this interlayer O–H···Cl bridging (O(1w)–H(1wA)–Cl(1), 3.162(2) Å; O(1w)–H(1wB)–Cl(1), 3.199(2) Å) at the interface of the main molecule [12].

Table 2
Selected bond lengths (Å) and bond angles (°) for $[Fe^{III}(HL^1)_2]Cl \cdot H_2O$ (**2**)

Bond lengths			
Fe–N(1)	2.1583(14)	Fe–O(1)	1.9069(12)

4. Conclusion

A series of blue luminescent high-spin ($s = 5/2$) iron(III) complexes of H_2L^1 have been successfully designed and synthesized. Deprotonation and insertion of a nucleophile into the parent complex significantly modulates the photophysical and chemical properties. Moreover, the ligand and its iron(III) complex undergo photoinduced intramolecular azo-imine tautomerism. The association constant (K_{ass}) and thermodynamic calculations clearly revealed that the binding process is favoured by a negative ΔH^0 and positive ΔS^0. The X-ray structure of complex **2** shows that the acyclic tridentate H_2L^1 (**1**), span meridionally, binding the metal in a hexadentate FeN_4O_2 fashion, utilizing pairs of pyridyl-N, phenolato-O and imine-N, resulting in a *cis* configuration for the FeN_4O_2 coordination sphere. The complex also displays bridging interlayer hydrogen bonding.

(apical) position of this subsite is occupied by a third non-bridging solvent molecule coordinated to the dimanganese cluster. Terminally bound water molecules are easily displaced from the metal complexes and this apical site likely serves as the initial substrate binding site during catalysis. The other subsite (Mn2) has a bidentate (chelating) coordination mode for glutamate, which may prevent exogenous ligands from binding and makes each of the manganese ions six-coordinate in the cluster, with approximately octahedral geometry at each subsite. The Mn–Mn separation in the resting state of the enzyme is 3.03 Å and both manganese centres are in the three oxidation state. The EXAFS analysis of the same protein predicted a Mn–Mn separation of 3.53 Å in the fully reduced state, i.e. 2,2 oxidation state [5]. It is well known that the azide ion acts as an inhibitor of *L. plantarum* catalase forming an active site complex. The crystal structure of the azide coordinated protein is virtually indistinguishable from the native structure except in the vicinity of the active site, where significant differences occur. In the azide complex of the oxidized form of the enzyme, the anion occupies a terminal position on the Mn1 subsite, replacing the solvent present in the native structure. Since azide is an analog of hydrogen peroxide, this mode of bonding is likely to mimic that of the coordinated substrate. The X-ray structure of azide bonded catalase in the oxidized state revealed the terminal bonding mode for the coordinated azide, however the coordination mode of azide in the reduced state of the enzyme is not definitely known.

Carboxylato bridged dinuclear Mn complexes have attracted much attention in recent years because of their potential biological relevance [6] in different manganese containing enzymes [7]. While several dinuclear Mn complexes having (μ-oxo)bis(μ-carboxylato) [8], (μ-hydroxo)-bis(μ-carboxylato) [9], (μ-hydroxo)(μ-acetato) [10], (μ-hydroxo)bis(μ-acetato) [11] bridges are known, no example exist of dinuclear manganese complexes with a (μ-azido)(μ-carboxylato) bridging unit. As a part of our synthetic effort towards modelling the active site of Mn-containing protein by using the hindered tris(pyrazolyl)borate as a supporting ligand, we now report on dinuclear complexes bridged with a single carboxylato and a single azido unit along with other carboxylate complexes of manganese (II), and their catalytic activity.

2. Experimental

2.1. Materials

All solvents used were purified by the literature methods [12]. Reagents of the highest grade commercially available were used without further purification. All manipulations were carried out under a nitrogen atmosphere using standard Schlenk tube techniques unless otherwise stated. 3,5-iPr_2pzH [$Pz^{iPr2}H$] (**1**), KHB(3,5-$iPr_2pz)_3$ [Tp^{iPr2}] (**2**) [13], KHB(3-Ph,5-Mepz)$_3$ [$Tp^{Ph,Me}$] (**3**) [14] and Tp^{iPr2}MnCl (**4**) [15] were synthesized by the literature methods.

2.2. Physical methods

IR spectra were obtained on a Thermo Nikolet Nexus FT-IR spectrometer in KBr discs. Room temperature magnetic susceptibility measurements were done on a Princeton applied research vibrating sample magnetometer Model 155 whereas the magnetic susceptibility measurements at variable temperature (from liquid helium to room temperature) were performed on a Quantum Design Squid Magnetometer Model MPMS. The X-ray data collection and processing for **6** and **9** were performed on a Kappa Apex Bruker CCD detector with Mo Kα radiation ($\lambda = 0.71070$ Å). In the reduction of data, Lorentz and polarization corrections, and empirical absorption corrections were made. All non-hydrogen atoms were refined aniostropically. The structures were solved by Patterson methods and refined anisotropically with the SHELX program suite [16]. Hydrogen atoms were constrained by a rigid model.

2.3. Synthesis of the complexes

2.3.1. [$Tp^{Ph,Me}$MnCl] (**5**)

$MnCl_2 \cdot 4H_2O$ (0.198 g, 1.0 mmol) was stirred with **3** (0.521 g, 1.0 mmol) in 10 mL CH_3OH and 20 mL CH_2Cl_2 for 1 h. The solution was filtered over celite and the solvent was evaporated to dryness under vacuum. Crystallization of complex **5** from acetonitrile yielded a colorless solid in 89% (0.51 g, 0.89 mmol.) yield. *Anal.* Calc. for $C_{30}H_{28}N_6BClMn$: C, 62.79; H, 4.91; N, 14.64; Cl, 6.17. Found: C, 63.00; H, 4.82; N, 14.36; Cl, 6.21%. IR (KBr, cm^{-1}): ν(BH) 2541.

2.3.2. [$Tp^{Ph,Me}$Mn(acac)] (**6**)

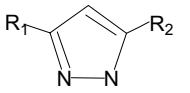
To an acetonitrile (30 mL) solution of complex **5**, one equivalent of sodium acetylacetonate (0.109 g, 0.89 mmol) was added and the resulting solution was stirred for 8 h. The reaction mixture was filtered over celite and the solvent was evaporated to dryness under vacuum. Crystals suitable for X-ray data collection were obtained by slow cooling of the compound in a mixture of CH_2Cl_2 and CH_3CN in 75% (0.43 g, 0.67 mmol.) yield. *Anal.* Calc. for $C_{35}H_{36}N_6O_2BMn$: C, 65.84; H, 5.68; N, 13.16. Found: C, 66.00; H, 5.82; N 13.06%. IR (KBr, cm^{-1}): ν(BH) 2539, ν(CO) 1594. Magnetic moment μ_{eff} (295 K) = 5.78 BM.

2.3.3. [$Tp^{Ph,Me}$Mn(μ-N_3) (μ-acac)Mn $Tp^{Ph,Me}$] (**7**)

The reaction of complex **6** (0.427 g, 0.67 mmol) in dichloromethane (20 mL) and sodium azide (0.043 g, 0.67 mmol) in methanol (10 mL) for 3 h followed by filtration over celite and evaporation to dryness under vacuum resulted in the formation of compound **7** in 77% (0.35 g, 0.52 mmol) yield. *Anal.* Calc. for $C_{65}H_{64}N_{15}O_2B_2Mn_2$: C, 64.05; H, 5.29; N, 17.23. Found: C, 63.90; H, 5.22; N, 17.16%. IR (KBr, cm^{-1}): ν(BH) 2514, ν(CO) 1596, $\nu(N_3)$ 2075. Magnetic moment μ_{eff} (295 K) = 5.57 BM/Mn^{2+}.

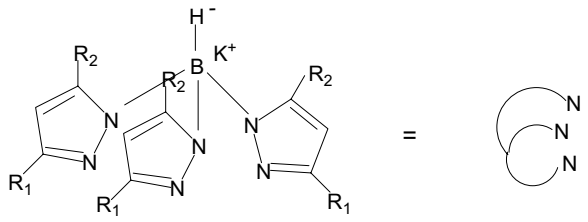
*2.3.4. [Tp^{ipr2}Mn(pic)] (**8**)*

To a dichloromethane (20 mL) solution of **4** (0.556 g, 1.0 mmol) was added a 10 mL methanolic solution of potassium picolinate (0.161 g, 1.0 mmol), and the resulting solution was stirred for 3 h. After this time, the reaction mixture was filtered over celite. The evaporation of solvent under vacuum resulted in a white crystalline compound in 64% (0.41 g, 0.64 mmol) yield. *Anal.* Calc. for $C_{33}H_{50}N_7O_2BMn$: C, 61.68; H, 7.84; N, 15.23. Found: C, 61.59; H, 7.94; N, 15.43%. IR (KBr, cm^{-1}), ν(BH) 2538, ν_{as}(COO) 1592, ν_s(COO) 1470. Magnetic moment μ_{eff} (295 K) = 5.83 BM.



*2.3.5. [Tp^{ipr2}Mn(μ-N$_3$)(μ-pic)Mn(Pz^{ipr2})Tp^{ipr2}] (**9**)*

The reaction of complex **8** (0.411 g, 0.64 mmol), Pz^{ipr2}H (0.097 g, 0.64 mmol) and sodium azide (0.041 g, 0.64 mmol) in 20 mL dichloromethane and 10 mL methanol for 3 h resulted in the formation of complex **9**. The resulting solution was filtered over celite and evaporated to dryness under vacuum. The solid was dissolved in a mixture of dichloromethane and acetonitrile (1:1 ratio) and a crystalline compound was obtained by slow cooling of the solution at 4 °C in 36% (0.310 g, 0.23 mmol) yield. *Anal.* Calc. $C_{69}H_{112}N_{18}O_2B_2Mn_2$: C, 61.06; H, 8.32; N, 18.57. Found: C, 61.39; H, 8.56; N 18.69%. IR (KBr, cm^{-1}), ν(BH) 2545, ν_{as}(COO) 1593, ν_s(COO) 1469, ν(N$_3$) 2077. Magnetic moment μ_{eff} (295 K) = 5.68 BM/Mn^{2+}.



3. Results and discussion

As reported in our previous work [17], the reaction of a binuclear Mn(II) di(μ-hydroxo) complex with one equivalent of benzoic acid results in the replacement of one hydroxide ligand to give the corresponding bimetallic (μ-hydroxo)(μ-benzoato) complex. Further replacement of the bridging hydroxide with azide gave a binuclear Mn(II) complex [18]. Due to the high solubility of this compound in the majority of organic solvents, we could not get a suitable single crystal for X-ray structure determination. However on the basis of IR and other spectroscopic techniques, a (μ-azido)(μ-benzoato) bridged manganese (II) dimer complex was proposed.

In our effort to prepare a model compound for Mn-containing pseudocatalase, first we prepared the starting complexes Tp^{iPr2}MnCl (**4**) and Tp^{Ph,Me}MnCl (**5**). The starting materials were prepared by reacting manganese (II) chloride with both 3-phenyl,5-methyl and 3,5-diisopropyl-substituted pyrazolylborate ligands (Fig. 1). The starting materials viz., **4** and **5** (Fig. 2) when treated with sodium acetylacetonate/sodium picolinate gave 5-coordinated manganese (II) complexes Tp^{Ph,Me}Mn(acac) (**6**) and Tp^{iPr2}Mn(pic) (**8**) (Fig. 3). The IR data suggested that both acac and pic are coordinated in a bidentate manner. The single crystal X-ray study of **6** suggested that the manganese ion is coordinated by three nitrogen atoms of Tp^{Ph,Me} and two oxygen atoms of acetylacetonate (Fig. 4). The Mn–N bond distances range from 2.178(2) to 2.230(2) Å

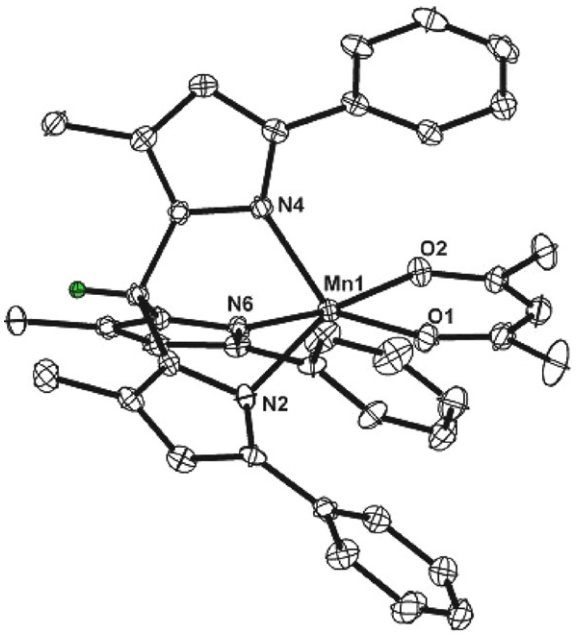
and fall in the range of reported Mn–N bond distances of manganese complexes having other Tp ligands [19]. The Mn–O bond distances of the coordinated acetylacetonate, Mn(1)–O(1), Mn(1)–O(2), are 2.078(2) Å. These Mn–O bond distances are well within the range of other Mn–O bond distances [20]. The IR band at 1592, (ν_{as}(COO)) and 1470, (ν_s(COO)) cm^{-1} in the picolinate complex suggest the bidentate coordination mode of the ligand. Although, a crystal structure is not available for complex **8**, other data suggest the same structure with a 5-coordinated manganese center as is seen for **6**. Both complexes **6** and **8** were used for the synthesis of the corresponding azido complexes. When complexes **6** and **8** in dichloromethane solvent were treated with a methanolic solution of sodium azide for 3 h, **7** and **9** (Fig. 5) were formed, respectively. Although both these reaction were carried out in the presence of an excess amount of azide, no detectable amount of [TpMn(N$_3$)] was formed. Thus, the formation of **7** and **9** is a thermodynamically favorable reaction. Detailed characterization of these



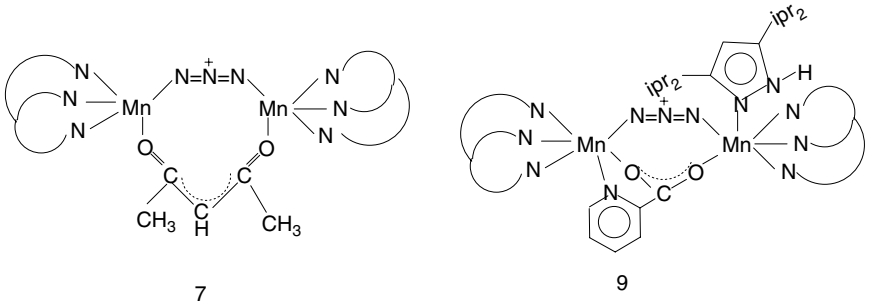


Fig. 4. Thermal ellipsoid view of complex **6** drawn at the 30% probability level. All hydrogen atoms have been omitted for clarity.

complexes revealed that both complexes have azide coordination where each metal center is 6-coordinated in **9** and 5-coordinated in complex **7**. IR data demonstrated that in both **7** and **9**, the azide ligands are coordinated in a μ-1,3-fashion. Complex **7** could not be crystallized as single crystals, but slow recrystallization of **9** from dichloromethane and acetonitrile at 4 °C gave single crystals suitable for X-ray studies. The X-ray data collection for **9** was performed at 100 K (Table 1) and a thermal ellipsoid view is given in Fig. 6. The molecular structure of **9** (Fig. 6) represents a novel (μ-1,3-azido)(μ-picolinato) bridging core. This is the first example of such a structure, while a (μ-hydroxo)(μ-1,3-azido) binuclear copper complex with Tp^{iPr2} was reported previously [21].

As shown in Fig. 6, each manganese is in a 6-coordination sphere as is present in Mn-containing catalase/pseudocatalase. The most interesting feature of this structure is that the picolinate ligand is behaving as a tridentate ligand in this complex, where one nitrogen and one oxygen is coordinated with one manganese center and only one oxygen is coordinated with the other manganese center in an asymmetric manner. The tridentate coordination nature

of picolinate is not uncommon and a few examples have been reported earlier [22], but to the best of our knowledge this is the first report of a (μ-azido)(μ-picolinato) binuclear manganese (II) complex where picolinate is showing tridentate behavior. Mn1 is coordinated with three nitrogen atoms of Tp^{iPr2} and one nitrogen of free pyrazole whereas Mn2 is coordinated with only three nitrogen atoms of Tp^{iPr2} ligand. The azide molecule is coordinated with both manganese centres, bridging in a η-1,3-fashion. The striking feature of the tridentate behaviour of picolinate is that in this complex the coordination sphere of both manganese ions are six, as in native catalase/pseudocatalase enzyme, with a slight difference of the coordinating ligands in the vicinity of the metal ions. In the native enzyme it has been reported that the azide ions act as inhibitors and the crystal structure of the azide bonded catalase demonstrated that the binding of azide is terminal where as in complex **9** the azide is bonded in a bridging mode. Binuclear transition metal complexes with (μ-azido)(μ-carboxylato) are very rare in the literature [23]. The coordination mode of the azide ligand in the oxidized state of catalase is well known, but still there is speculation about the binding mode of this ligand in the reduced state. Also it has been reported in the literature that the metal–metal separation in the reduced state of the enzyme is more than that of the oxidized form and there is strong belief that the binding mode of the azide ligand may also change to bridging in the reduced form, which may be responsible for the large separation of the manganese ions. In fact the Mn–Mn separation in binuclear complexes is very much dependent on the presence of bridging ligands as evident from the Mn–Mn separation in different complexes with the Tp^{iPr2} ligand (Table 3). The Mn–Mn separation in di(μ-hydroxo) dimanganese (II) (3.33 Å), changes to 3.603(2) Å in (μ-hydroxo)(μ-pyrazolato) dimanganese(II) [24], 2.706 Å in di(μ-oxo)(μ-acetato) dimanganese (III,IV) [10] and 2.70 Å in di(μ-oxo) dimanganese (III) [15]. This distance further increases when azide is present in the bridging mode. In complex **9**, the Mn–Mn separation is 5.355 Å. The Mn–Mn separation of 5.355 Å in complex **9** gives us strong support to propose that the terminal mode of azide in the oxidized form of pseudocatalase changes to a bridging mode in the reduced form. The Mn–N bond distances of both coordinated Tp^{iPr2} ligands are in the range 2.208–

Table 3
The distances between Mn–Mn ions in different binuclear complexes of the hydrotris(3,5-diisopropyl-pyrazol-1-yl)borate ligand

Complex	Mn1–Mn2 distance (Å)	Reference
$TpMn^{II}(\mu\text{-}OH)_2Mn^{II}Tp$	3.314(1)	[15]
$TpMn^{III}(\mu\text{-}O)_2Mn^{III}Tp$	2.696(2)	[15]
$TpMn^{II}(\mu\text{-}OH)(\mu\text{-}3,5\text{-}Pr^i_2pz)Mn^{II}Tp$	3.603(2)	[24]
$TpMn^{II}(\mu\text{-}OBz)_3Mn^{II}$ $(3,5\text{-}Pr^i_2pz)_2$	3.753(2)	[19]
$TpMn^{III}(\mu\text{-}O)_2(\mu\text{-}OAc)Mn^{IV}Tp$	2.709(1)	[10]
$TpMn^{II}(\mu\text{-}OBz)_3Mn^{II}$ (Tp^iPr_2)	4.006(1)	[17]

2.281 Å, as reported for other complexes of this ligand. The bond distance of coordinated 3,5-diisopropylpyrazole (Mn1–N7, 2.313 Å) is larger than the Mn–N bond distance of Tp^{iPr2} (Table 2). The Mn–N bond distances of the coordinated azide (Mn1–N16, 2.183; Mn1–N17, 2.207 Å) are very similar to the Cu–N bond distance in the azide bridged dinuclear copper complex (Cu–N4, 2.06 Å) [21].

In complex **9**, both manganese centres (Mn1 and Mn2) are also linked to each other by a μ-1,3-OCO bridge, whereas the nitrogen of picolinate is coordinated to Mn2 only, forming a five coordinate ring as shown in Fig. 6. Fig. 7 shows the interaction between two independent molecules and Fig. 8 shows the packing diagram of the compound. As shown in Fig. 7, a CH_3–π interaction appears

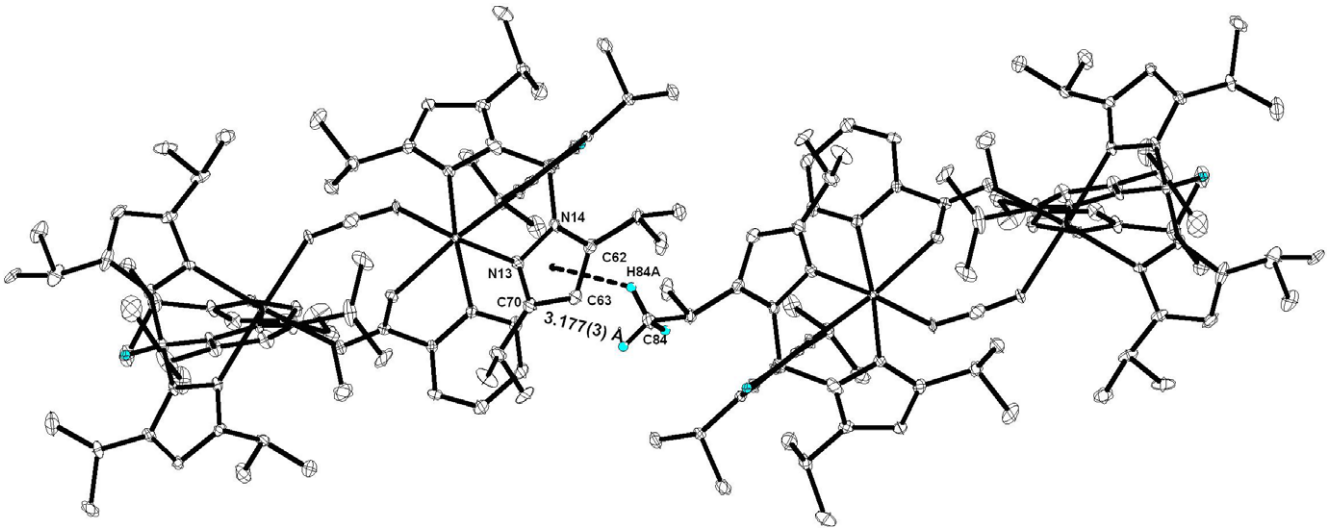

Fig. 7. Molecular structure showing CH_3–π interaction in complex **9**.

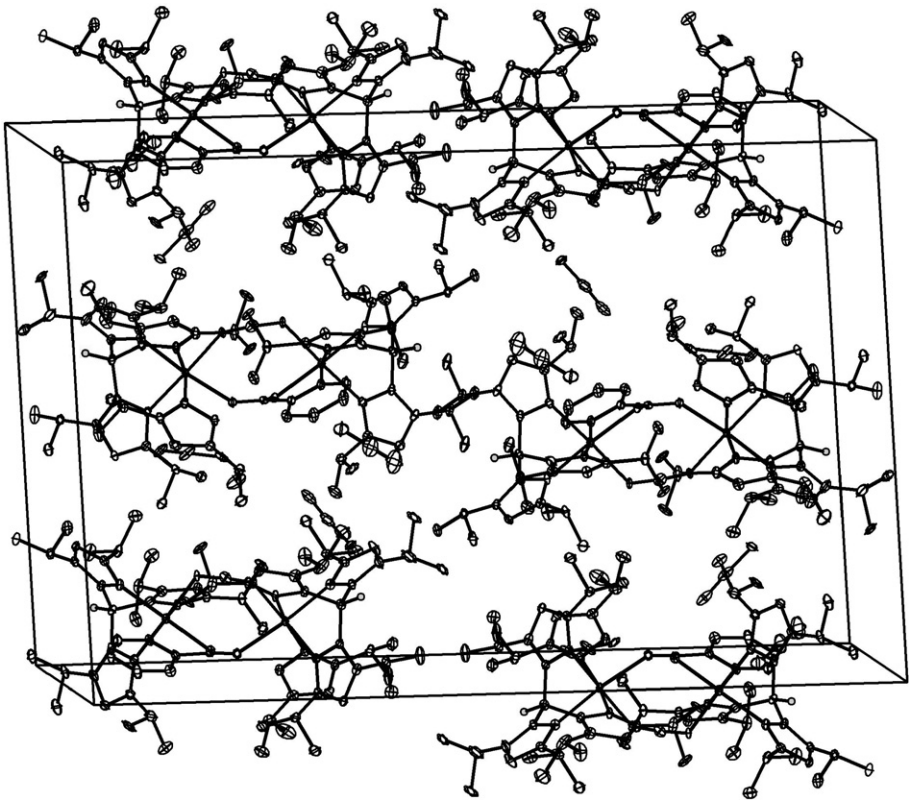

Fig. 8. Packing view of complex **9**.

to exist between the two independent molecules with a separation of 3.177(3) Å.

3.1. Magnetic studies

The room temperature magnetic moment for all the reported complexes are well within the range of magnetic moment reported for manganese (II) complexes [25,26]. Since the coordination structure of complex **9** is very close to the active site structure of manganese containing catalase/pseudocatalase, its magnetic properties has been reported at variable temperatures ranging from helium to room temperature. Fig. 9 shows the temperature dependence plot of μ_{eff} (○) and χ_M (△). The value of μ_{eff} at 300 K amounts to 5.69 μ_B, close to the spin-only value of 5.92 μ_B for $S = 1/2$. The effective magnetic moment smoothly decreases with temperature. The χ_M versus T curve shows maxima at approximately 44 K and then declines rapidly to zero at 6 K, indicating the presence of weak antiferromagnetic coupling between the manganese ions [26].

3.2. Catalytic activity studies

3.2.1. Electronic spectra

Complexes **7** and **9** exhibit no absorption band in the visible region, suggesting that both manganese ions in these complexes are in the two oxidation state. In order to get an insight into the disproportionation of H_2O_2 catalyzed by complexes **7** and **9**, the reaction was monitored by absorption spectroscopy. The UV–vis absorption spectra of these complexes (showing no bands) are very similar to the optical spectrum (lack of visible absorption) of manganese catalase from *T. thermophilus* (TTC) in the reduced (II, II) state [27]. During the reaction of **9** with H_2O_2 in methanol, a new band at 379 nm wavelength appeared and the intensity of this band increases with increasing concentration of hydrogen peroxide until the reaction is completed.

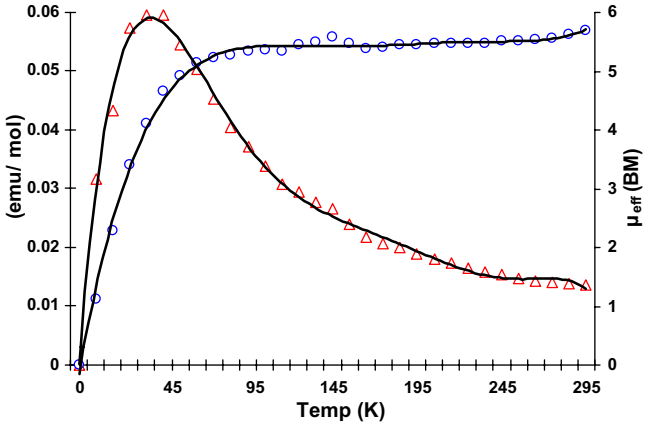

Fig. 9. Plot of μ_{eff} (○) and χ (△) vs. temperature for complex **9**.

3.2.2. Kinetics

Since the coordination geometry of complex **9** is very similar to the active site structure of pseudocatalase, the kinetic experiment of complex **9** with H_2O_2 was performed in detail. An excess concentration of H_2O_2 was used in the reaction to measure the initial rate of oxygen evolution and formation of new manganese species in methanol at room temperature. The order of the reaction with respect to the catalyst was measured by varying the catalyst concentration at a constant concentration of H_2O_2. The initial rate versus catalyst concentration showed a good linear correlation (Fig. 10). The linear dependence of the rate with respect to the catalyst revealed that the reaction is first order. The slope of the line gives a first order rate constant $(k) = 9.725 \times 10^{-4}\ s^{-1}$ for a H_2O_2 concentration of 24.47 mM. The rate constant for complex **9** is slower as compared to other model compounds reported in the literature [28,29]. At a constant concentration, complex **9** exhibits saturation kinetics with H_2O_2 and follows the Michaelis–Menten equation. The catalytic turnover number $(k_{cat}) = 6.676 \times 10^{-3}\ s^{-1}$ and the Michaelis constant (K_M) is 114 mM (Fig. 11). As reported in the literature, some catalases whose activity was not inhibited by CN^- or azide (N_3^-) are called pseudocatalase. The interesting aspect of **9** is that in spite of azide binding, it exhibits catalytic activity and catalyses the disproportionation of hydrogen peroxide.

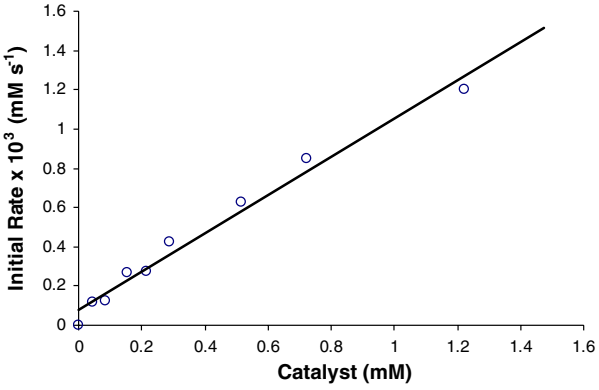

Fig. 10. Effect of the [catalyst] on the initial rate of H_2O_2 disproportionation at 25 °C and $[H_2O_2] = 24.47$ mM in methanol.

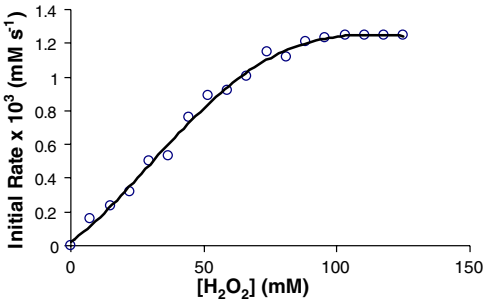

Fig. 11. Effect of the $[H_2O_2]$ on the initial rate of H_2O_2 disproportionation at 25 °C and [catalyst] = 368 μM in methanol.

4. Conclusion

In conclusion, we have reported the synthesis, structural as well as catalytic studies of some manganese compounds as suitable models for manganese-containing pseudocatalase. To the best of our knowledge complex **9** is the first manganese complex that is a μ-1,3-azido bridged dimer having picolinate as a bridging ligand. The most striking feature of this complex is that the picolinate is behaving as tridentate ligand, which is not very common. Due to the tridentate nature of picolinate, each manganese center is 6-coordinated which is very important for the catalytic activity of pseudocatalase. The coordination number of each manganese ion in **7** is five where the acetylacetonate behaves as a bidentate ligand. The interesting observation is that complex **9** has the capability for disproportionation of hydrogen peroxide but complex **7** does not because the coordination geometry of this complex is not very similar to the active site structure of the native enzyme. Thus, complex **9** may be a true model for manganese-containing pseudocatalase both structurally as well as functionally.

Scheme 1. Synthesis of the titanium and zirconium disiloxides **2**–**5**.

the ^{29}Si NMR spectra showed only one signal for the $SiMe_3$ silicon atoms.

In addition, the structure of **2a** was investigated by X-ray crystallography; suitable crystals were grown from *n*-heptane (Fig. 1). Although the quality of the data (*R* value ca. 0.16) was insufficient to make any commentary on the structural parameters in detail, the orientation and connectivity of the located silicon, oxygen and titanium atoms reveals, however, a spirocyclic disilane-1,2-diolate complex with a distorted tetrahedral geometry around the central titanium.

When 3 equiv. of $TiCl_4$ were reacted with **2a**, a ring opening reaction occurs, which results in the formation of the dinuclear complex **4** (Scheme 1). The reaction is almost complete within minutes as indicated by NMR spectroscopy, and the isolated yields were within 80–85% following crystallization from pentane. The composition of the thermally stable but moisture sensitive compound corresponds well to the results of an elemental analysis. An analogous ring opening reaction has been observed previously for the six-membered spirocyclic compound $\{SiMe_2[(Me_3Si)_2SiO]_2\}_2Ti$ [6e]. The formation of **4** can simply be understood as an insertion reaction of $TiCl_4$ into the Ti–O bond sequence of **3a** that is intermediately formed during the course of the reaction. The fact that **2a** rapidly undergoes ring opening to **4** even at low temperatures clearly reflects the constrained nature of these five-membered ring systems relative to larger ring compounds [7]. It should be noted that a similar reaction of the corresponding Zr derivative **2b** with an excess of $ZrCl_4$ did not occur. Besides **4**, small amounts (ca. 5%) of a new species could be detected by NMR spectroscopy. The structural characterization of this compound was accomplished by single-crystal X-ray crystallography; suitable crystals were obtained from pentane solutions in a freezer. The analysis of the X-ray data revealed the compound to be the oxo bridged dinuclear titanium complex **5** (Fig. 2). In the solid state, **5** adopts a dimeric structure in which the two seven-membered ring fragments are linked by Ti–O dative bonds resulting in a planar four-membered ring. Distances from the titanium to the bridging oxygen [Ti1A–O3A 1.9826(18); Ti2–O3 1.9161(19) and Ti1A–O3 1.9529 (19) Å] are strongly elongated compared to the titanium to non-bridging O atom [Ti1A–O2A 1.738(2); Ti2–O1 1.7442(19) Å] within the seven-membered ring, indicating only weak interactions in this dimeric structure. The Ti–O distances of **5** are similar to those found in the closely related six-membered ring compound $SiMe_2[(Me_3Si)_2SiO]_2$-$TiCl_2$ [6e] and the dinuclear species $[(O^tBu_2SiO)TiCl_2]_2$ [8]. The five-coordinated Ti centers of **5** exhibit highly distorted trigonal bipyramidal geometries. Further dative bonds are observed between the non-oxygen bridging Ti2 and the Cl3 that is attached to the oxygen bridging Ti1 [Ti2–Cl3,

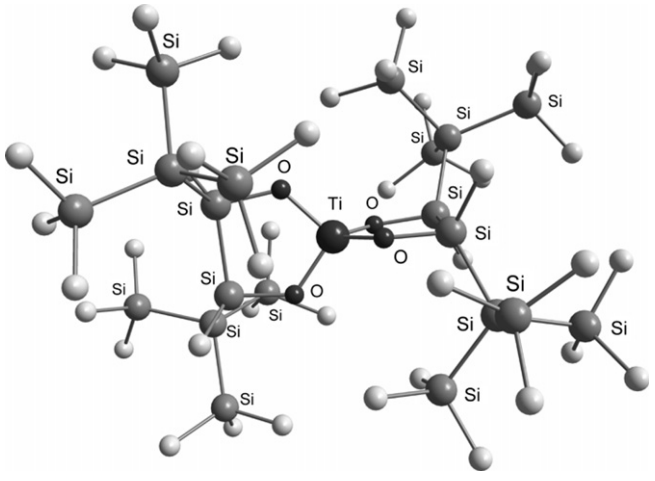

Fig. 1. Structural model of compound **2a**.

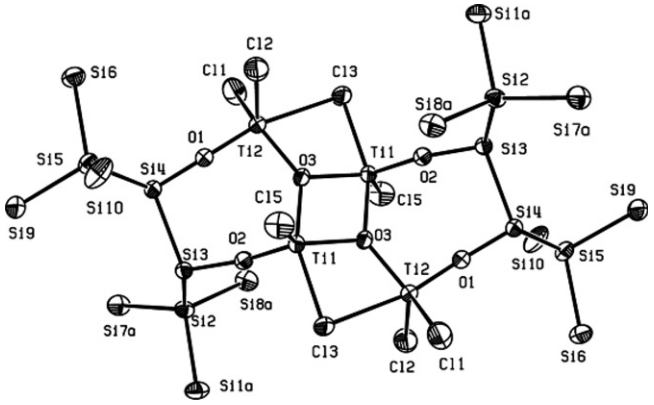

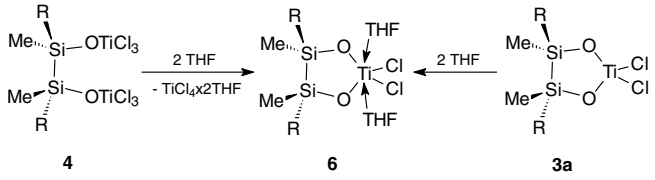

Fig. 2. Molecular structure of **5** in the crystal. The thermal ellipsoids correspond to 50% probability. Methyl groups are omitted for clarity. Selected bond lengths (Å) and angles (°): Si3–Si4 2.3904(10), Si4–O1 1.695(2), Si3–O2A 1.703(2), Ti2–O1 1.7442(19), Ti1A–O2A 1.738(2), Ti2–O3 1.9161(19), Ti1A–O3 1.9529(19), Ti1A–O3A 1.9826(18), Ti2–Cl2 2.1984(10), Ti2–Cl1 2.2356(10), Ti2–Cl3 2.6309(9), Ti1A–Cl5A 2.1918(9), Ti1A–Cl3A 2.3589(9), Si4–O1–Ti2 161.60(14), Si3–O2A–Ti1A 158.11(14), Ti2–O3–Ti1A 134.85(10), Ti2–O3–Ti1 121.39(10), Ti1A–O3–Ti1 103.66(8), O1–Ti2–O3 96.46(8), O2A–Ti1A–O3 97.68(9), O2A–Ti1A–O3A 130.47(9), O3A–Ti1–O3 76.34(8), Cl2–Ti2–Cl1 110.46(4), Cl2–Ti2–Cl3 92.21(4), Cl1–Ti2–Cl3 82.51(3), Cl5A–Ti1A–Cl3A 96.63(4), Ti1–Cl3–Ti2 85.72(3).

2.6309(9); Ti1–Cl3, 2.3589(9) Å]. The unusual formation of this compound can be explained by the fact that $TiCl_4$ stock solutions that have been used for the synthesis of **4** might be contaminated by small amounts of oxo containing titanium species arising from partial hydrolysis. In fact, careful NMR-spectroscopic investigations have shown that also the titanium dichloride **3a** is slightly contaminated by **5**.

Interestingly, upon addition of THF-d_8 the dinuclear titanium disilane-1,2-diolate **4** reacted cleanly within minutes, resulting in the quantitative formation of a new complex. However, the reaction did not yield the expected THF complex of **4**: rather, the quantitative product of $TiCl_4$ elimination, the THF complex **6** was formed as evidenced by multinuclear NMR spectral data (Scheme 2). The structural interpretation has been confirmed by the independent reaction of THF-d_8 with **3a** at room temperature. From the reaction of the dinuclear complex **4** with THF-d_8 single-crystals of $TiCl_4 \cdot 2THF$-d_8, suitable for X-ray crystallography, were obtained. The structure is shown in Fig. 3 and reveals an octahedral titanium center being coordinated by two molecules of THF-d_8.

Scheme 2. Reaction of **3a** and **4** with THF-d_8.

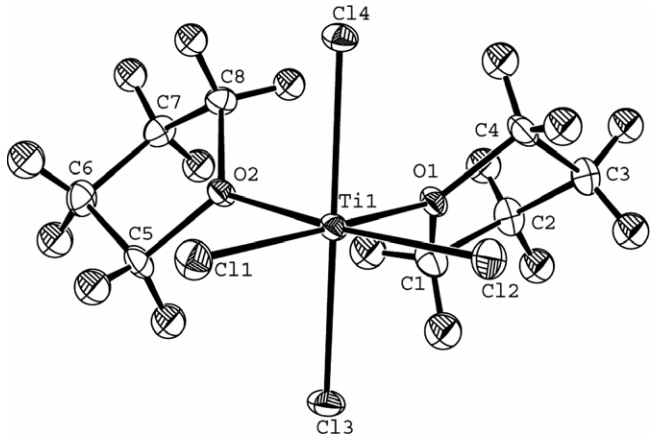

Fig. 3. Molecular structure of $TiCl_4 \cdot 2THF$-d_8 in the crystal. The thermal ellipsoids correspond to 50% probability. 3. Conclusion

The synthesis of the strained five-membered ring compounds $\{(E)$-$[Me(Me_3Si)_3SiSiO]_2\}_2M$ (**2a**,**b**) and (E)-$[Me(Me_3Si)_3SiSiO]_2MCl_2$(**3a**,**b**) derived from the bidentate disilane-1,2-diolate ligand *rac*-$[Me(Me_3Si)_3SiSiO]_2^{2-}$ (**1**)-H_2 has been reported. In the presence of $TiCl_4$, **2a** rapidly undergoes a ring opening reaction to (E)-$[Me(Me_3Si)_3SiSiO]_2Ti_2Cl_6$ (**4**), which clearly reflects the constrained nature of the chelating disilane-1,2-diolate framework.

4. Experimental

4.1. General procedure

All manipulations of air- and/or moisture-sensitive compounds were carried out under an atmosphere of argon using standard Schlenk and Glove Box techniques. THF, *n*-heptane and *n*-pentane were distilled under argon from alkali metals prior to use. Benzene-d_6 and THF-d_8 were dried over activated molecular sieves and stored in the glove box. The racemic ligand **1** was prepared as previously described [6b]. NMR: Bruker AC 250, Bruker ARX 300, Bruker ARX 500 IR: Nicolet 205 FT-IR. MS: Intectra AMD 402, chemical ionization with isobutane as the reactant gas.

4.1.1. $\{(E)$-$[Me(Me_3Si)_3SiSiO]_2\}_2Ti$ (**2a**)

Freshly distilled $Ti(OEt)_4$ (0.45 ml, 2.13 mmol) was added to a stirred solution of rac-**1** (2.5 g, 4.07 mmol) in 20 ml heptane at room temperature. After stirring for 30 min, a yellow microcrystalline material started to precipitate from the solution. After refluxing for 2 h, the resulting solution was concentrated to a volume of ca. 15 ml and slowly cooled to −40 °C for 2 days. The yellow crystals that formed were filtered, washed twice with cold *n*-heptane, and dried under vacuum. Yield 2.34 g (86%). Mp > 230 °C. ^{1}H NMR (C_6D_6, 250 MHz): $\delta = 0.44$ (s, $SiMe_3$, 54H), 1.05 (s, OSiMe, 6H) ppm. ^{13}C NMR (C_6D_6, 62.9 MHz): $\delta = 3.66$ (s, $SiMe_3$), 10.12 (s, OSiMe) ppm. ^{29}Si NMR (C_6D_6, 59.6 MHz): δ −125.59 ($Si(SiMe_3)_3$), −9.42 ($SiMe_3$), 44.90 (SiO). MS: (70 eV, *m*/*z* in %): 1275 (100) [M^+], 1260 (17) [M^+-CH_3]. *Anal.* Calc. for $C_{40}H_{120}O_4Si_{20}Ti$ (1275.02): C, 37.68, H 9.49. Found: C, 36.48, H, 9.34%.

4.1.2. (E)-$[Me(Me_3Si)_3SiSiO]_2TiCl_2$ (**3a**)

To a stirred solution of **2a** (1.0 g, 0.79 mmol) in 30 ml pentane was added a toluene solution of $TiCl_4$ (0.82 ml, 1 M) at room temperature. After stirring for one day, the solution was concentrated to a volume of ca. 15 ml and slowly cooled to −40 °C. The red-orange crystals that formed were filtered, washed twice with cold pentane and dried under vacuum. Yield 0.46 g (40%). Mp 155–157 °C. ^{1}H NMR (THF-d_8, 300 MHz): $\delta = 0.30$ (s, $SiMe_3$, 54H), 1.04 (s, OSiMe, 6H) ppm. ^{1}H NMR (C_6D_6, 250 MHz): $\delta = 0.34$ (s, $Si(SiMe_3)_3$, 54H), 1.09 (s, SiMe, 6 H) ppm.

^{13}C NMR (THF-d_8, MHz): $\delta = 3.75$ ($SiMe_3$), 7.79 (OSiMe) ppm. ^{13}C NMR (C_6D_6, 62.9 MHz): $\delta = 3.5$ ($Si(SiMe_3)_3$), 9.5 (SiMe) ppm. ^{29}Si NMR (THF-d_8, MHz): $\delta = -124.25$ ($Si(SiMe_3)_3$), −9.70 ($SiMe_3$), 65.39 (SiO) ppm. ^{29}Si NMR (C_6D_6, 59.6 MHz): $\delta = -122.3$ ($Si(SiMe_3)_3$), −9.9 ($SiMe_3$), 75.4 (SiO) ppm. MS (70 eV, *m/z* in %): 732 (15) [M^+], 717 (9) [M^+−Me]. *Anal.* Calc. for $C_{20}Cl_2H_{60}O_2Si_{10}Ti$ (732.33): C, 32.80; H, 8.36, Cl, 9.68. Found: C, 32.49; H, 7.96; Cl, 9.75%.

4.1.3. (E)-[Me(Me$_3$Si)$_3$SiSiO]$_2$ZrCl$_2$ · 2THF (3b)

$Zr(NEt_2)_4$ (0.3 ml, 0.85 mmol) was added to a stirred solution of rac-**1** (1.0 g, 1.61 mmol) in *n*-heptane (30 ml) at room temperature. After stirring for 2 h at 95 °C, the solvent and other volatiles were removed under vacuum to leave {(*E*)-[$Me(Me_3Si)_3SiSiO]_2$}$_2$Zr × $HNEt_2$ (**2b**) as a crystalline material (an analytically pure sample can be obtained by recrystallization from *n*-pentane at −40 °C). The residue was dissolved in THF (90 ml) and transferred via cannula into a THF solution of $ZrCl_4$ (0.219 g, 0.94 mmol) at −78 °C. After being stirred for 24 h at room temperature, the solvent was replaced by *n*-pentane and the resulting suspension was filtered and washed twice with *n*-pentane. Then the volume of the combined filtrates was reduced and the solution was kept in a freezer. The colorless crystals that formed were filtered, washed with cold *n*-pentane and dried under vacuum. Yield 0.31 g (40%). Mp > 85 °C (dec.). ^{1}H NMR (C_6D_6, 250 MHz): $\delta = 0.48$ (s, $SiMe_3$, 54H), 1.22 (s, SiMe, 6H), 1.37, 4.07 (2m, THF, 2 × 8H) ppm. ^{13}C NMR (C_6D_6, 62.9 MHz): $\delta = 3.7$ ($SiMe_3$), 9.1 (SiMe), 25.3, 72.9 (THF) ppm. ^{29}Si NMR (C_6D_6, 59.6 MHz): $\delta = -126.2$ ($Si(SiMe_3)_3$), −9.7 ($SiMe_3$), 42.8 (SiO) ppm. *Anal.* Calc. for $C_{20}H_{60}Cl_2O_2Si_{10}Zr \times C_8H_{16}O_2$ (919.58): C 36.57; H, 8.33. Found: C, 34.96; H, 8.29%.

Analytical data of **2b**: Yield 0.41 g (36%); Mp 188–190 °C. ^{1}H NMR (C_6D_6, 250 MHz): $\delta = 0.45$ (s, $Si(SiMe_3)_3$, 108H) 1,02 (s, SiMe, 12H), 1.06 (br, $HNEt_2$, 6H), 2.54 (br, $HNEt_2$, 4H) ppm. ^{13}C NMR (C_6D_6, 75.5 MHz): $\delta = 4.1$ ($SiMe_3$), 10.9 (SiMe), 14.7, 43.2 ($HNEt_2$) ppm. ^{29}Si NMR (C_6D_6, 59.6 MHz): $\delta = -126.9$ ($Si(SiMe_3)_3$), −9.7 ($SiMe_3$), 30.3 (SiO) ppm. MS (70 eV, *m/z* in %): 1316 (100) [M^+−$HNEt_2$], 1244 (14) [M^+−$SiMe_3$], 1072 (20) [M^+−$Si(SiMe_3)_3$]. *Anal.* Calc. for $C_{40}H_{120}O_4Si_{20}Zr \times C_4H_{11}$ N (1391.45): C, 37.98; H, 9.49; N, 1.01. Found: C, 36.69; H, 9.50; N, 0.96%.

4.1.4. Synthesis of (E)-[Me(Me$_3$Si)$_3$SiSiO]$_2$Ti$_2$Cl$_6$ (4) and (E)-[Me(Me$_3$Si)$_3$SiSiO]$_2$Ti$_2$OCl$_4$ (5)

A toluene solution of $TiCl_4$ (2.5 ml, 1 M) was added to a stirred solution of **2a** (0.5 g, 0.79 mmol) in pentane (30 ml) at room temperature. After stirring for 1 day the red solution was concentrated to a volume of ca. 15 ml. Crystallization in a freezer at −40 °C afforded complex **4** as red-orange crystals contaminated by red crystals of **5**. Yield 0.56 g (77%).

Analytical data of (E)-[Me(Me$_3$Si)$_3$SiSiO]$_2$Ti$_2$Cl$_6$ (**4**): ^{1}H NMR (C_6D_6, 250 MHz): $\delta = 0.37$ (s, $SiMe_3$, 54H), 1.13 (s, SiMe, 6H) ppm. ^{13}C NMR (C_6D_6, 62.9 MHz): $\delta = 3.9$ ($SiMe_3$), 9.3 (SiMe) ppm. ^{29}Si NMR (C_6D_6, 59.6 MHz): $\delta = -118.5$ ($Si(SiMe_3)_3$), −9.4 ($SiMe_3$), 56.5 (SiO) ppm. MS (70 eV, *m/z* in %): 732 (24) [M^+−$TiCl_4$], 717 (6) [M^+−$TiCl_4$−Me], 424 (40) [M^+−Me −4 $SiMe_3$], 291 (52) [M^+−Me−4 × $SiMe_3$−$OTiCl_2$], 188 (18) [$TiCl_4$]. *Anal.* Calc. for $C_{20}H_{60}Cl_6O_2Si_{10}Ti_2$ (922.03): C, 26.05; H, 6.56. Found: C, 25.06, H, 6.66%.

Analytical data of (E)-[Me(Me$_3$Si)$_3$SiSiO]$_2$Ti$_2$OCl$_4$ (**5**): ^{1}H NMR (C_6D_6, 250 MHz): $\delta = 0.32$ (s, $SiMe_3$, 54H), 1.09 (s, SiMe, 6H) ppm. *Anal.* Calc. for $C_{20}H_{60}Cl_4O_3Si_{10}Ti_2$ (867.09): C, 27.70; H, 6.97. Found: C, 27.46, H, 6.66%.

4.1.5. Reaction of 3a and 4 with THF-d_8

A J. Young NMR tube was charged in the glove box with **3a** (30 mg) or **4** (30 mg) and dissolved in THF-d_8 (0.5 ml). The progress of the reaction was monitored by ^{1}H NMR spectroscopy and complete conversion of the starting materials into the THF-d_8 adduct **6** was observed immediately. ^{1}H NMR (THF-d_8, 250 MHz): $\delta = 0.30$ (s, $SiMe_3$, 54H), 1.04 (s, SiMe, 6H) ppm. ^{13}C NMR (THF-d_8, 62.9 MHz): $\delta = 3.6$ ($SiMe_3$), 7.7 (SiMe) ppm. ^{29}Si NMR (THF-d_8, 59.6 MHz): $\delta = -124.1$ [$Si(SiMe_3)_3$], −9.6 ($SiMe_3$), 65.6 (SiO) ppm.

5. Crystal structure determination of 5 and $TiCl_4$ · 2THF-d_8

5.1. Crystal data of 5, CCDC 615442

The crystal was fixed with perfluoropolyether on the tip of a thin glass rod. Intensity data of this crystal were then collected at 173(2) K on a Bruker X8 APEX-diffractometer with a CCD camera, Mo Kα-radiation ($\lambda = 0.71073$ Å) and graphite monochromator. Formula $C_{20}H_{60}Cl_4O_3Si_{10}Ti_2$ M = 867.18, monoclinic, $P2_1/n$, $a = 9.6229(2)$ Å, $b = 25.4548(5)$ Å, $c = 19.2748(4)$ Å, $\alpha = \gamma = 90.00°$, $\beta = 98.8450(10)°$, $V = 4665.20(16)$ Å^3, $Z = 4$, $\rho_{calc} = 1.235$ g cm^{-3}, $\mu = 0.849$ m^{-1}, 67 045 measured reflections, 10 684 independent reflections ($R_{int} = 0.0590$), 401 parameters, $R_1(F) = 0.0469$ for 8361 reflections with $I > 2\sigma(I)$ and $wR_2(F^2) = 0.1081$ for all data, residual electron density highest peak 0.528 and deepest hole −0.384 e$^-$/Å^3.

5.2. Crystal data of $TiCl_4$ · 2THF-d_8, CCDC 619743

The crystal was fixed with perfluoropolyether on the tip of a thin glass rod. Intensity data of this crystal were then collected at 173(2) K on a Bruker X8 APEX-diffractometer with a CCD camera, Mo Kα-radiation ($\lambda = 0.71073$ Å) and graphite monochromator. Formula $C_8D_{16}O_2Cl_4Ti$, M = 350.00, orthorhombic, $P2_12_12_1$, $a = 7.7878(3)$ Å, $b = 12.6128(5)$ Å, $c = 13.8568(5)$ Å, $\alpha = \beta = \gamma = 90.00°$, $V = 1361.10(9)$ Å^3, $Z = 4$, $\rho_{calc} = 1.708$ g cm^{-3}, $\mu = 1.393$ mm^{-1}, 8702 measured reflections, 3120 independent reflections ($R_{int} = 0.0252$), 136 parameters, $R_1(F) = 0.0191$ for 3032 reflections with $I > 2\sigma(I)$ and $wR_2(F^2)$

$= 0.0473$ for all data, residual electron density highest peak 0.204 and deepest hole -0.299 e^{-}/Å^{3}.

In this paper, as a part of our continuing study, we would like to report the synthesis and characterization of new cationic cyclopentadienyl (Cp) ruthenium(II), osmium(II) and pentamethylcyclopentadienyl (Cp*) iridium(III) complexes with chelating N ∩ N-donor ligands [L_1 = 2-(2′-pyridyl)imidazole, L_2 = 2-(2′-pyridyl)benzimidazole, L_3 = 2-(2′-pyridyl)-4,5-dimethylimidazole, L_4 = 2-(2′-pyridyl)-4,5-diphenylimidazole (Scheme 1). In order to confirm the nature of bonding, the molecular structures of [CpRu{2-(2′-pyridyl)imidazole}(PPh_3)]PF_6 ([**1**]PF_6), [CpRu{2-(2′-pyridyl)benzimidazole}(PPh_3)]PF_6 ([**2**]PF_6) and [Cp*Ir{2-(2′-pyridyl)imidazole}Cl] PF_6 ([**7**]PF_6) have been solved by X-ray crystallography.

2. Experimental

Elemental analyses were performed on a Perkin–Elmer-2400 CHN/O analyzer. Infrared spectra were recorded on a Perkin–Elmer Model 983 spectrophotometer with the sample prepared as KBr pellets. The ^{1}H NMR spectra were recorded on a Bruker ACF-300 (300 MHz) spectrometer in $CDCl_3$ solvents with TMS as internal reference. All chemicals used were of reagent grade. All reactions were carried out in distilled and dried solvents. Ruthenium trichloride, iridium trichloride and osmium tetraoxide were purchased from Arora Matthey Ltd. and Aldrich. The 2-(2′-pyridyl)imidazole and its derivatives were prepared by following a literature procedure [10]. 2-(2′-Pyridyl)benzimidazole (Aldrich), pyridine-2-aldehyde (Fluka), glyoxal (Aldrich), 2,3-butanedione (Aldrich) and benzyl (Sd Fine) were used as received. The precursor's complexes [$CpRu(PPh_3)_2Cl$], [$CpOs(PPh_3)_2Br$] [11] and [Cp*Ir(μ-Cl)Cl]$_2$ [12] were prepared by following the reported literature methods.

2.1. Synthesis of [CpRu(N ∩ N)(PPh_3)]PF_6

The following general procedure was used for the preparation of complexes [**1**]PF_6 to [**4**]PF_6.

2.1.1. Preparation of [1]PF_6

A mixture of [$CpRu(PPh_3)_2Cl$] (0.1 g, 0.14 mmols), 2-(2′-pyridyl)imidazole (0.04 g, 0.28 mmols) and NH_4PF_6 (0.046 g, 0.28 mmols) was refluxed in dry methanol (20 ml) under a nitrogen atmosphere for 6 h. The yellow suspension turns to a light yellow color. The solvent is evaporated at reduced pressure. Then the residue is dissolved in dichloromethane (5 ml), and the solution filtered to remove ammonium chloride. The yellow solution is concentrated (2 ml) and by addition of an excess of hexane the orange yellow product precipitates. The compound is filtered and dried under vacuum to give [**1**]PF_6.

Complex [CpRu{2-(2′-pyridyl)imidazole}(PPh_3)]PF_6 [**1**]PF_6 (Yield: 63 mg, 64%). Elemental *Anal.* Calc. for $C_{31}H_{27}N_3F_6P_2Ru$: C, 51.81; H, 3.76; N, 5.85. 2.2. Synthesis of [CpM(N ∩ N)(PPh_3)]PF_6

These complexes were prepared by the same method given in Section 2.1 using of [$CpOs(PPh_3)_2(CH_3CN)$]PF_6 instead of [$CpRu(PPh_3)_2Cl$].

Scheme 1. Ligands and numbering scheme used in this study.

Complex [CpOs{2-(2′-pyridyl)imidazole}(PPh_3)]PF_6 [**5**]PF_6 (Yield: 48 mg, 57%). Elemental *Anal.* Calc. for $C_{31}H_{27}N_3P_2F_6Os$: C, 46.09; H, 3.35; N, 5.21. Found: C, 46.36; H, 4.03; N, 5.65%. IR (KBr pellets, cm^{-1}): 1600 ($\nu_{C=C}$), 1480, 1440 (s, $\nu_{C=N}$), 885 (s, br, ν_{PF6}) ^1H NMR ($CDCl_3$, δ): 8.95 (d, $J_{H-H} = 5.7$ Hz, 1H, H_6); 8.78 (d, $J_{H-H} = 6.05$ Hz, 1H, H_3); 8.63 (d, $J_{H-H} = 6.12$ Hz, 1H, H_7); 8.59 (d, $J_{H-H} = 5.52$ Hz, 1H, H_8); 7.89 (m, 15H, Ph); 7.75 (t, 1H, H_4); 7.48 (t, 1H, H_5); 4.59 (s, 5H, C_5H_5).

Complex [CpOs{2-(2′-pyridyl)benzimidazole}(PPh_3)]-PF_6 [**6**]PF_6 (Yield: 46 mg, 52%). Elemental *Anal.* Calc. for $C_{35}H_{29}N_3P_2F_6Os$: C, 49.01; H, 3.38; N, 4.90. Found: C, 49.15; H, 3.56; N, 5.15%. IR (KBr pellets, cm^{-1}): 1613 ($\nu_{C=C}$), 1447 ($\nu_{C=N}$), 885 (s, br, ν_{PF6}). ^1H (NMR, $CDCl_3$, δ): 8.50 (d, $J_{H-H} = 5.2$ Hz, 1H, H_6); 8.10 (d, $J_{H-H} = 5.2$ Hz, 1H, H_3); 7.93 (m, 15H, Ph); 7.78 (t, 1H, H_4); 7.56 (t, 1H, H_5); 7.37 (m, 4H H_{7-10}); 4.65 (s, 5H, C_5H_5).

2.3. Synthesis of [Cp*Ir(N ∩ N)Cl]PF_6

These complexes were prepared by the same method given in Section 2.1 using 0.5 equiv. of [Cp*Ir(μ-Cl)Cl]$_2$ instead of 1 equiv. of [CpM(PPh_3)$_2$Cl].

Complex [Cp*Ir{2-(2′-pyridyl)imidazole}Cl]PF_6 [**7**]PF_6 (Yield: 52 mg, 64%). Elemental *Anal.* Calc. for $C_{18}H_{22}ClN_3F_6PIr$: C, 33.13; H, 3.37; N, 6.44. Found: C, 32.87; H, 3.88; N, 6.23%. IR (KBr pellets, cm^{-1}): 1600 ($\nu_{C=C}$), 1460–1327 ($\nu_{C=N}$), 850 (ν_{P-F}), ^1H NMR ($CDCl_3$, δ): 8.94 (d, $J_{H-H} = 6.4$ Hz, 1H, H_6); 8.50 (d, $J_{H-H} = 6.12$ Hz, 1H, H_3); 8.00 (d, $J_{H-H} = 6.03$ Hz, 1H, H_7); 7.90 (d, $J_{H-H} = 5.23$ Hz, 1H, H_8); 7.73 (t, 1H, H_4); 7.43 (t, 1H, H_5); 1.86 (s, 15H, C_5Me_5).

Complex [Cp*Ir{2-(2′-pyridyl)benzimidazole}Cl]PF_6 [**8**]PF_6 (Yield: 54 mg, 62%). Elemental *Anal.* Calc. for $C_{22}H_{24}ClN_3F_6PIr$: C, 37.61; H, 3.42; N, 5.98. Found: C, 37.52; H, 3.87; N, 6.15%. IR (KBr pellets, cm^{-1}): 1600 ($\nu_{C=C}$), 1474–1407 ($\nu_{C=N}$), 850 (ν_{P-F}), ^1H NMR ($CDCl_3$, δ): 8.97 (d, $J_{H-H} = 5.63$ Hz, 1H, H_6); 8.90 (d, $J_{H-H} = 5.29$ Hz, 1H, H_3); 7.85 (t, 1H, H_4); 7.43 (t, 1H, H_5); 7.24 (m, 4H, H_{7-10}); 1.82 (s, 15H, C_5Me_5).

2.4. Single-crystal X-ray structures analyses

Crystal suitable for X-ray diffraction study for compound [**1**]PF_6, [**2**]PF_6 and [**7**]PF_6 were grown by slow diffusion of diethylether into dichloromethane solution of complexes [**1**]PF_6, [**2**]PF_6 and [**7**]PF_6, respectively. The orange reddish crystals of compound [**1**]PF_6 and [**7**]PF_6 were mounted on a Stoe Image Plate Diffraction system equipped with a ϕ circle goniometer, using Mo Kα graphite monochromated radiation ($\lambda = 0.71073$ Å) with ϕ range 0–200°, increment of 1.2°, D_{max}–$D_{min} = 12.45$–0.81 Å. Whereas crystal of [**2**]PF_6 was mounted on a Bruker Apex CCD diffractometer in a full reciprocal sphere equipped with a CCD detector, X-ray intensity data were collected with Mo Kα graphite monochromated radiation at 120(2) K, with 0.3°ω scan mode and 10 second per frame. The intensity data were corrected for Lorenz and polarization effects. The structures were solved by direct methods using the program SHELXS-97 [13]. Refinement and all further calculations were carried out using SHELXL-97 [14]. The H-atoms were included in calculated positions and treated as riding atoms using the SHELXL default parameters. The non-H-atoms were refined anisotropically, using weighted full-matrix least-square on F^2. In [**2**]$PF_6 \cdot H_2O$, the $-C_5H_4NC_3N_2H-$ fragment of the 2-(2′-pyridyl)benzimidazole was found to be disordered over two positions and the partial occupancy factor was refined at 76:24. Crystallographic details are summarized in Table 1. Figs. 1, 2 and 4 are drawn with ORTEP32 [15] while Figs. 3 and 5 are drawn with MERCURY [16].

3. Results and discussion

The reactions in dry methanol of [CpRu(PPh_3)$_2$Cl] and [CpOs(PPh_3)$_2$Br] (Cp = η^5-C_5H_5) with an excess of chelating N ∩ N-ligands and NH_4PF_6 result, under refluxing conditions, in the dissociation of one triphenylphosphine and the halide ligands to yield the monocationic complexes [CpM(N ∩ N)(PPh_3)]$^+$ (**1**: M = Ru, N ∩ N = 2-(2′-pyridyl) imidazole; **2**: M = Ru, N ∩ N = 2-(2′-pyridyl)benzimidazole; **3**: M = Ru, N ∩ N = 2-(2′-pyridyl)-4,5-dimethylimidazole; **4**: M = Ru, N ∩ N = 2-(2′-pyridyl)-4,5-diphenylimidazole; **5**: M = Os, N ∩ N = 2-(2′-pyridyl)imidazole; **6**: M = Os, N ∩ N = 2-(2′-pyridyl)benzimidazole), see Scheme 2. The compounds are isolated and characterized as hexafluorophosphate salts.

In the case of the reaction of the dinuclear iridium(III) complex [Cp*Ir(μ-Cl)Cl]$_2$ (Cp = η^5-C_5Me_5) with 2 equiv. of chelating N ∩ N-ligands in the presence of NH_4PF_6, cleavage of the chloro-bridge followed by dissociation of one chloride ligand, affords the complexes [Cp*Ir{2-(2′-pyridyl)imidazole}Cl]PF_6([**7**]PF_6) and [Cp*Ir{2-(2′-pyridyl)benzimidazole}Cl]PF_6 ([**8**]PF_6), see Scheme 3.

The complexes **1–8** are pale yellow to orange reddish colored. They are highly soluble in polar solvents such as chloroform, acetone, methanol, dichloromethane *etc.*, but insoluble in non-polar solvents such as hexane, pentane *etc.*, C, H, N analyses, IR, ^1H NMR spectroscopic data were given in the experimental section, which supported the formation of these complexes. The X-ray structures of representative complexes **1**, **2** and **7** were determined to confirm the structure of the complexes (**1–8**). The infrared spectra of complexes **1–6** exhibited very strong bands at 1613–1600 cm^{-1} and 1480–1440 cm^{-1}corresponding to phenyl groups of triphenylphosphine and N-bases, while in complexes **7** and **8** prominent peaks were observed at 1600 cm^{-1} and 1474–1327 cm^{-1}. The counter ion (PF_6) exhibit a strong band around 845 cm^{-1} for ν_{PF6} group.

The protons' corresponding to the cyclopentadienyl ligands appear in the region of 4.6–4.7 ppm while the triphenylphosphine peaks are observed as a multiplet in the aromatic region between 7 and 8 ppm. The chemical shifts of cyclopentadienyl groups appear downfield as compared

[a] Structures were refined on F_o^2: $wR_2 = [\sum[w(F_o^2 - F_c^2)^2]/\sum w(F_o^2)^2]^{1/2}$, where $w^{-1} = [\sum(F_o^2) + (aP)^2 + b]$ and $P = [\max(F_o^2, 0) + 2F_c^2]/3$.

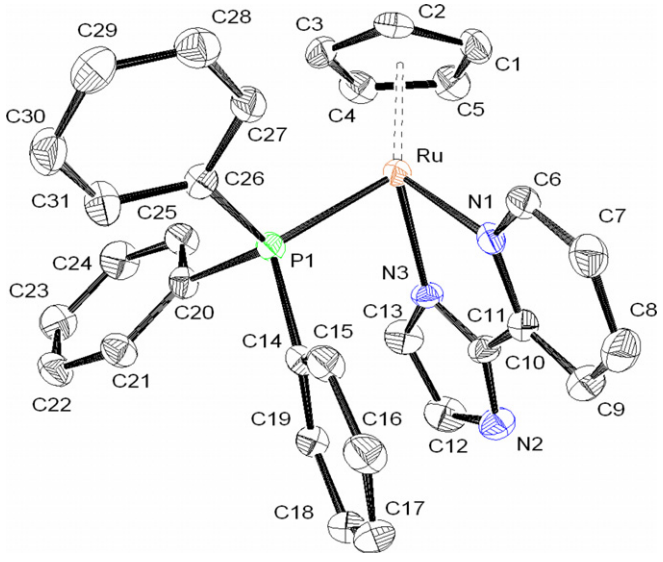

Fig. 1. ORTEP diagram with labelling scheme for [CpRu{2-(2′-pyridyl)imidazole}(PPh_3)]$^+$ ([**1**]PF_6), at 50% probability level, H-atoms and PF_6 anion omitted for clarity.

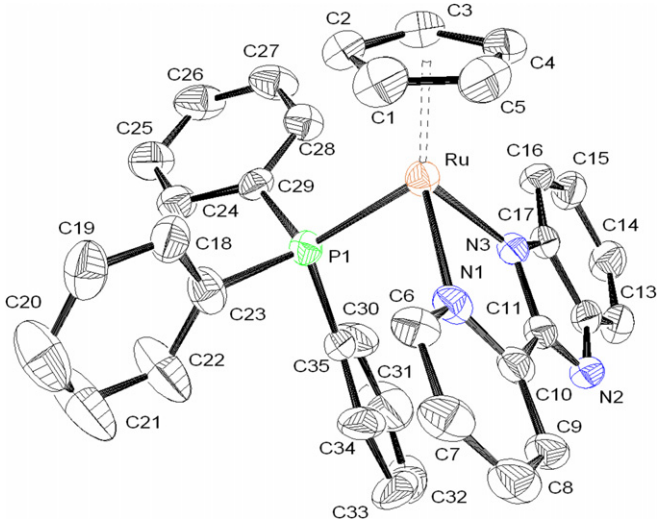

Fig. 2. ORTEP diagram with labelling scheme for [CpRu{2-(2′-pyridyl)benzimidazole}(PPh_3)]$^+$ ([**2**]$PF_6 \cdot H_2O$) at 50% probability level, H-atoms, PF_6 anion and water molecule omitted for clarity.

to the precursor complexes (4.43–4.31 ppm). The downfield shift position of the cyclopentadienyl protons in complexes **1–6**, which might results from the change in electron density on the metal center due to chelation of the nitrogen base ligands through the nitrogen atoms of the 2-(2′-pyridyl)imidazole derivatives ligands. The ^{1}H NMR spectra of complexes **1–6** also showed two pseudo-triplets in the range of 7.85–6.32 ppm due to the pyridine protons (H4 and H5) of the N ∩ N-donor ligands, a singlet at 12.01 ppm corresponds to the NH protons of the ligands. The spectra of the Cp* complexes **7** and **8** showed resonance for the methyl protons of the Cp* ligand as singlets at 1.86 ppm and 1.82 ppm, respectively.

Molecular structure of the representative hexafluorophosphates salts [**1**]PF_6, [**2**]PF_6 and [**7**]PF_6 are presented in Figs. 1, 2 and 4, respectively. Selected bond lengths and angles are recorded in Table 2. The molecular

structures of $[CpRu\{2\text{-}(2'\text{-pyridyl})imidazole\}(PPh_3)]^+$ (**1**) and $[CpRu\{2\text{-}(2'\text{-pyridyl})benzimidazole\}(PPh_3)]^+$ (**2**) have been established by single-crystal X-ray structure analysis of [**1**]PF_6 and [**2**]$PF_6 \cdot \cdot \cdot H_2O$, respectively. Both complexes show typical piano-stool geometry with the metal center coordinated by a cyclopentadienyl ligand, a PPh_3 ligand and a chelating N ∩ N-ligand, see Figs. 1 and 2.

The Ru–N bond distances [2.113(3) and 2.093(3) Å in **1**; 2.117(2) and 2.094(2) in **2**] are comparable to those in $[(\eta^6\text{-}p\text{-}Pr^iC_6H_4Me)RuCl(2,3\text{-bis}(2\text{-pyridyl})pyrazine)]BF_4$[17] and $[(\eta_6\text{-}C_6H_6)RuCl(2\text{-}(1\text{-imidazole-2-yl})pyridine)]PF_6$ [18a]. Accordingly, there is no significant difference in the Ru–P bond length in **1** [2.316(1) Å] or **2** [2.325(1) Å] with reported values [9d,19]. The N(1)–Ru–N(3) bond angle in complexes **1** [76.0(1)°] and **2** [76.1(2)°] are similar to those of compounds $[(\eta^6\text{-}p\text{-}Pr^iC_6H_4Me)RuCl(2,3\text{-bis}(2\text{-pyridyl})pyrazine)]^+$ [N–Ru–N = 76.5(2)°] [17] and $[(\eta^6\text{-}p\text{-}Pr^iC_6H_4Me)RuCl(2,3\text{-bis}(\alpha\text{-pyridyl})quinoxaline)]^+$ [N–Ru–N = 76.2(2)°] [18b]. The angles between the least-square planes of $\eta^5\text{-}C_5H_5$ and that of the N ∩ N-ligand are 57.8(2)° in **1** and 55.3(2)° in **2**.

Complex [**2**]PF_6 crystallizes with one molecule of water per asymmetric unit, which forms a hydrogen-bonded network with two hexafluorophosphate anions and the N–H group of the N ∩ N ligand, see Fig. 3. The N–O and O–F distances of the hydrogen bonds are, respectively, 2.820(3) Å for the N–H of the 2-(2′-pyridyl)benzimidazole

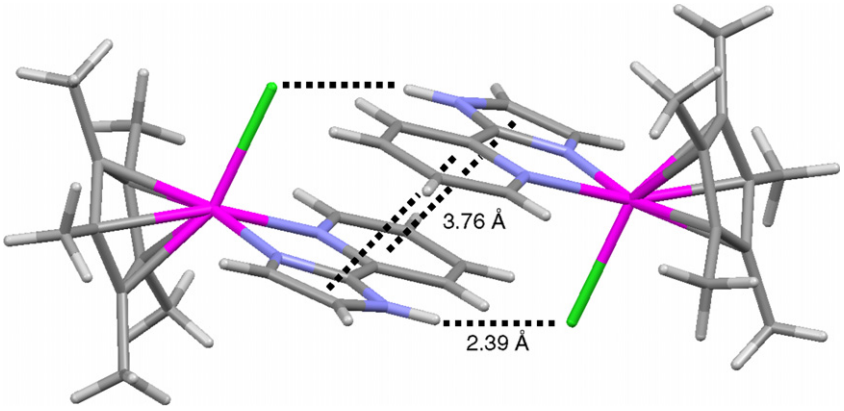

Fig. 5. Dimeric structure of [**7**]PF_6 showing the intermolecular NH···Cl hydrogen contacts and π–π interacting system.

ligand and H_2O, and 2.941(4) and 2.907(4) Å between the hexafluorophosphate anions and the water molecule. The N–H···O angle is 167.1° while the O–H···F angles are 178° and 153°, respectively.

The molecular structure of [Cp*Ir{2-(2′-pyridyl)imidazole}Cl]$^+$ (**7**) has been established by single-crystal X-ray structure analysis of [**7**]PF_6 (see Fig. 4). The complex shows a typical piano-stool geometry with the metal center coordinated by the pentamethylcyclopentadienyl ligand, a terminal chloride and the 2-(2′-pyridyl)imidazole ligand. The Ir–N bond distances [2.106(5) and 2.080(5) Å] are slightly shorter to those in [**1**]PF_6 and [**2**]PF_6. The average distance between the metal atom and the carbon atoms of the η^5-C_5Me_5 ring is 2.16 Å. This average bond length is comparable to that in the related η^5-C_5Me_5 iridium complex [(η^5-C_5Me_5)IrCl((*S*)-1-phenylethylsalicylaldiimine)] [2.17 Å] [20]. The Ir–Cl bond length is 2.4183(14) Å in **7**, which is slightly longer to the reported iridium complex [(η^5-C_5Me_5)IrCl((*S*)-1-phenylethylsalicylaldiimine)] [2.4017(16) Å] [20].

In the crystal packing of [**7**]PF_6, two molecules of **7** form a dimer through N–H···Cl contacts and π-stacking interactions, see Fig. 5. The N–Cl separation is 3.254(5) Å with an N–H···Cl angle of 162.1°. The distance observed between the π-stacking interacting systems (centroid···centroid 3.76 Å) is in good agreement with the theoretical value calculated for this stacking mode [21]. The distance observed between the two iridium centers of the dimer is 7.841(1) Å and excludes any possible metal–metal interactions.

4. Conclusions

The present study describes the synthesis of eight new CpRu, CpOs and Cp*Ir complexes containing 2-(2′-pyridyl)imidazole ligands. Representative complexes have been characterized by single X-ray study. In the crystal packing of [**7**]PF_6, two molecules of **7** form a dimer through N–H···Cl contacts and π-stacking interactions.

Scheme 1. The 5-sulfosalicylic acid species.

$(H_2O)]_n$ [6,7], $[K(H_2SSA)(H_2O)_2]_n$ [8], $[Rb(H_2SSA)(H_2O)]_n$ [9], $[Cs(H_2SSA)]_n$ [10], $[Ca(HSSA)(H_2O)_3]_n$ [8], $\{[Sr(H_2SSA)_2(H_2O)] \cdot H_2O\}_n$ [11], $[Ba(H_2SSA)_2(H_2O)_5]_n$ [12], $\{[La(SSA)(H_2O)_8] \cdot H_2O\}_n$ [13], $[Eu(H_2SSA)_2(H_2O)_5]_n$ [14], $\{[Yb(SSA)_3(H_2O)_8] \cdot H_2O\}_n$ [15], $[Sm(HSSA)_2(H_2O)_6]_n$ [16], and $[Nd(SSA)(H_2O)]_n$ [17]. Also, examples with mixed-metal species are known, e.g. $[NaCu(SSA)(H_2O)_4]_n$ [6], $[Na_3La_2Tb(SSA)_4(H_2O)_{26}]_n$ [18] and $[Na_3La_2Y(SSA)_4(H_2O)_{26}]_n$ [19]. Among the known examples are occasional complexes with mixed mono- and dianionic ligand species, e.g. $\{[Na_3(H_2SSA)(HSSA) \cdot H_2O]\}_n$ [20]. Also, in a number of these complexes the 5-sulfosalicylate species act as counter-anions without participating in coordination, e.g. the Yb^{III} complex which has the actual structural formula $\{[Yb(H_2O)_8(H_2SSA)_3] \cdot H_2O\}_n$ [15], while a series of first-row transition metal(II) complexes have a similar type of constitution, with a general formula $[M(H_2O)_6(H_2SSA)_2 \cdot nH_2O]$ [M = Mn, $n = 2$; M = Co, $n = 4$; M = Ni, $n = 4$; M = Cu, $n = 2$; M = Zn, $n = 4$ [21]. These differ from the polymeric structures shown in the Group 1 complexes and in the silver(I) complexes $[Ag_4(HSSA)_2(H_2O)_2]_n$ and $[Ag_2(HSSA)(H_2O)–Ag_2(H_2SSA)_2(H_2O)_3] \cdot H_2O\}_n$ [22].

In an investigation of the complexes of sulfosalicylic acid with the Group 1 metal ions, it was found that not only were the reported complexes with K^I, Rb^I and Cs^I [8–10] isolated, a second presumably efflorescent form of the Rb complex, $[Rb_3(H_2SSA)(HSSA)(H_2O)_4]_n$ (**1**), was formed and its structure is reported here. This complex also has both H_2SSA^- and $HSSA^{2-}$ ligand species. A parallel determination using 5-sulfosalicylic acid and CsOH similarly gave an unstable compound which when recrystallized from water surprisingly gave the previously reported [10] anhydrous compound $[Cs(H_2SSA)]_n$ (**2**) confirmed by both elemental analysis and a low-temperature single-crystal X-ray diffraction analysis. The structure of the stable hydrated lead(II) complex $[Pb(H_2SSA)_2(H_2O)]_n$ (**3**) is also reported here, the only previous structure of a compound of lead(II) with 5-sulfosalicylic acid being a dimeric mixed-ligand complex with 1,10-phenanthroline, $[Pb_2(HSSA)_2(phen)_2(H_2O)_2]$ [23].

2. Experimental

2.1. Synthesis of compounds

Compound **1** $[Rb_3(H_2SSA)(HSSA)(H_2O)_4]_n$ was synthesized by adding 0.23 g (1 mmol) of 4-carboxy-3-hydroxybenzenesulfonic acid (5-sulfosalicylic acid) to 30 mL of an aqueous solution containing 0.10 g (1 mmol) of rubidium hydroxide. The mixture was heated for ca. 10 min at 90° and the resultant hot-filtered solution was then allowed to evaporate at room temperature. The colourless prisms of **1** which were obtained after several weeks were unstable in air, deteriorating slowly to a white powder, presumably due to loss of water of solvation, prompting the low-temperature X-ray diffraction analysis. No elemental analysis was therefore performed.

Compound **2** $[Cs(H_2SSA)]_n$ was synthesized using a parallel procedure to that in **1**, by adding 0.23 g (1 mmol) of 5-sulfosalicylic acid to 30 mL of an aqueous solution containing 0.15 g (1 mmol) of cesium hydroxide. The crystals obtained after several weeks of room temperature evapora-

tion of the solvent were found to be unstable in air but on recrystallization from water gave stable prismatic crystals of **2**, the previously reported structurally characterized anhydrous complex [10], confirmed here by elemental analysis (*Anal*. Calc. for $C_7H_5CsO_6S$: C, 24.0; H, 1.44. Found: C, 24.2; H, 1.5%) and low-temperature single-crystal X-ray diffraction (see Table 1).

Compound **3** $[Pb(H_2SSA)_2(H_2O)]_n$ was synthesized by mixing together in the solid state, 0.33 g (1 mmol) of lead nitrate and 0.46 g (2 mmol) of 5-sulfosalicylic acid, then extracting with gentle heating for ca. 10 min with 30 mL of 80% water–ethanol. Room-temperature evaporation of the hot-filtered solution gave colourless crystal prisms of **3** (m.p. >281 °C), which darkened on exposure to air. No elemental analysis was performed.

2.2. X-ray structure determinations

X-ray diffraction data for compounds **1**–**3** were collected at 130(2) K on an Bruker CCD-equipped diffractometer by using monochromatized Mo Kα X-radiation ($\lambda = 0.71073$ Å). No significant crystal decomposition in the X-ray beam was in evidence for any compound. Data were corrected for Lorentz and polarization effects (SMART and SAINT [24]), and for absorption (SADABS [24]). The structures were solved by direct methods and refined using full-matrix least-squares (SHELX-97 [25]), with anisotropic thermal parameters for all non-hydrogen atoms. With **1**, three of the water molecules were found to be disordered over similar split sites [O21W, O22W; O31W, O32W; O41W, O42W: site occupancy factors 0.65:0.35] and were refined separately. Hydrogen atoms were either located by difference methods or included in the refinements at calculated positions with coordinates and isotropic thermal parameters fixed or treated as riding models (**1**) or with **2** and **3** the interactive H atom/s were refined isotropically. Cell data and general details of data collection and structure refinement for compounds **1**–**3** are given in Table 1. Bond distances and angles about the metal coordination polyhedra in **1** and **3** are given in Tables 2 and 3, but since there are no significant differences between the 130 K structure of **2** and the previously reported room-temperature structure, details are not considered in any detail here. It should also be noted that in the discussion and the bond distance and angle tables for **1**, only the major-occupancy components of the three split-site water molecules are considered.

3. Results and discussion

3.1. The structural chemistry of *1*–*3*

3.1.1. Compound *1*

The structure of the rubidium complex with 5-sulfosalicylic acid, $[Rb_3(H_2SSA)(HSSA)(H_2O)_4]_n$ (**1**) reported here, represents an unstable hydrate variant of the previously reported polymeric complex, the monohydrate $[Rb(H_2SSA)(H_2O)]_n$ [9]. In **1**, there are two ligand species, one a dianion $(HSSA)^{2-}$ (A), the other a monoanionic $(H_2SSA)^{-}$ (B) and both are involved, along with a bridging water molecule (O1W) in linking the three Rb^{+} centres (Rb1–Rb3) (Fig. 1). The three independent coordination centres are irregular seven-coordinate but differ in their makeup (Table 2). The coordination sphere about Rb1 comprises six sulfonate-O donors and one phenate-O donor [Rb–O range: 2.855(6)–3.152(6) Å]. The coordination sphere about Rb2 consists of four sulfonate-O and one phenolate-O donors and two water molecules, one bridging to Rb3 (O1W), the other monodentate and having split occupancy (O21W, O22W: site occupancy factors 0.65, 0.35) [Rb–O range: 2.796(7)–3.031(7) Å]. The third centre about Rb3 has no sulfonate-O involvement but has four carboxylate-O donors together with three water molecules, the previously mentioned bridging one, and two monodentate ones, both having split sites similar to O2W [O31W, O32W and O41W, O42W, both with site occupancy factors of 0.65, 0.35, respectively] [Rb–O range: 2.889(7)–3.151(13) Å]. The metal coordination as well as the three-dimensional framework polymeric structure generated (Fig. 2) is common in the Group 1 metal complexes of 5-sulfosalicylic acid, including that of $[Rb(H_2SSA)(H_2O)]_n$ [9], which has 7-coordination about the metal [Rb–O, 2.847(5)–3.110(5) Å] but has the single coordinated water non-bridging. In that structure the water acts as an acceptor in a strong hydrogen bond with the carboxylic acid proton of the H_2SSA^{-} ligand whereas in **1**, the acid proton of the B ligand is strongly hydrogen-bonded to a carboxylate-O of the A ligand [O71B···O71A, 2.467(9) Å].

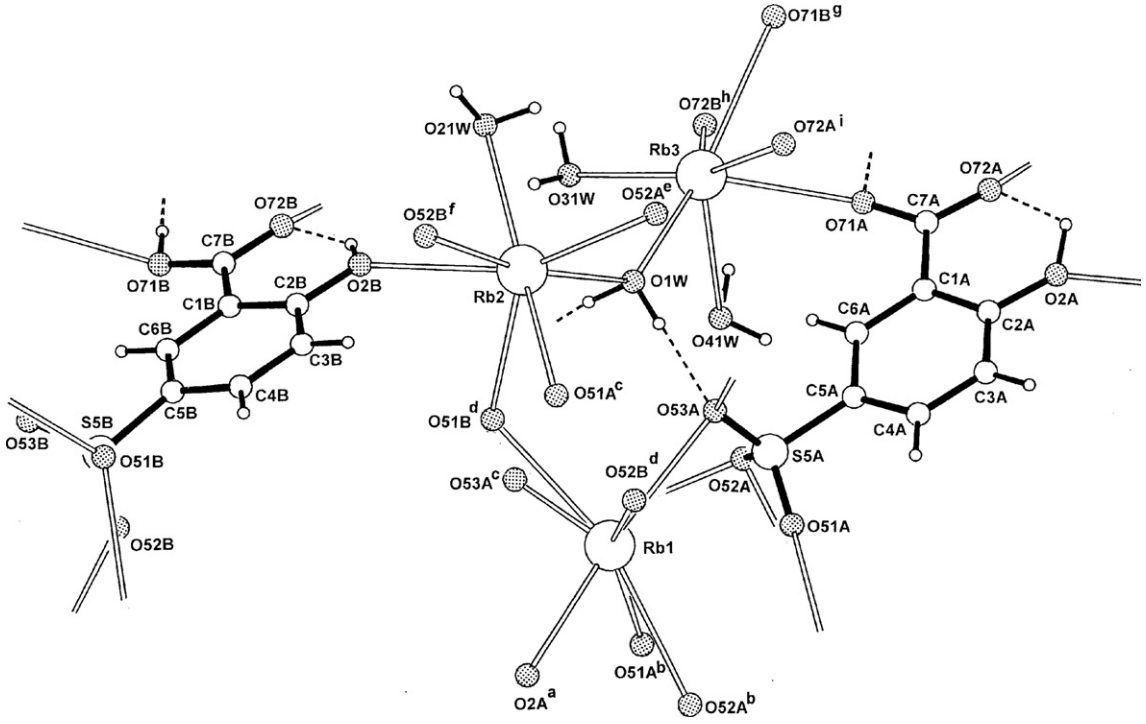

Fig. 1. A general view of the coordination about the three interlinked Rb centres (Rb1–Rb3) in **1** including the atom numbering scheme. Partial hydrogen-bonding interactions are shown as broken lines. The smaller-occupancy components of the split-site water molecules O21W, O31W and O41W (O22W, O32W, O42W) are not shown. For symmetry operators, see Table 2.

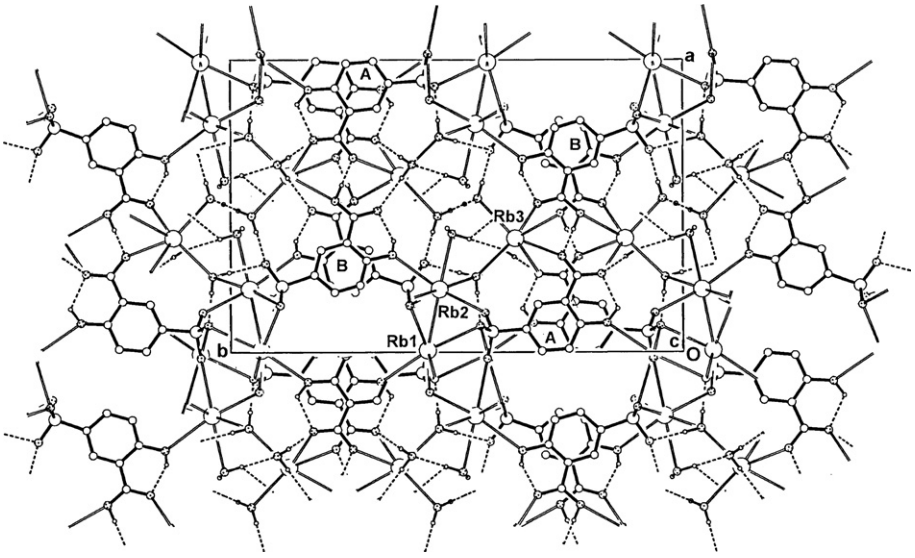

Fig. 2. The three-dimensional framework polymer structure of **1** viewed down the *c* axial direction of the unit cell.

Also present but expected in both ligand species is the intramolecular hydrogen bond linking the phenolic group to the carboxyl-O [O2–H2···O72: 2.552(9) Å (A) and 2.565(10) Å (B)]. This bond is found in the hydrate pseudo-polymorphs of the acid [1–5] as well as in the mono- and dianionic species of the acid found in its salts [26], and in complexes **2** and **3**.

The presence of large number of oxygen acceptor and water hydrogen-donor sites means that there are also a number of hydrogen-bonding associations which stabilize the structure of 1 including an intramolecular water···sulfonate interaction [O1W–H···O53A, 2.792(10) Å]. Although a 1:1 reactant stoichiometry was used in the synthesis of **1**, it would appear that its formation is the result of favoured conditions within the crystallizing product. The presence of water in the crystallization has an obvious influence upon the composition of the crystal in which significant water lability is inherent.

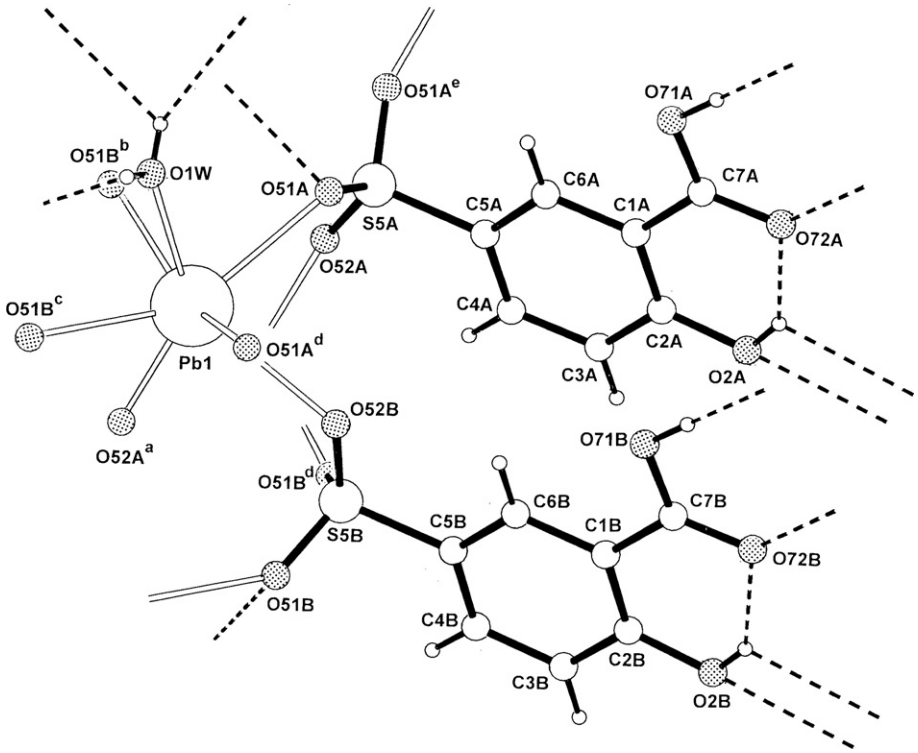

Fig. 3. The stereochemistry about the PbO_7 coordination polyhedron in **3**, including the atom numbering scheme. The atoms O51A^{e} in ligand A and O51B^{d} in ligand B lie across crystallographic mirror planes and are generated by the operators $d = x, 1/2 - y, z$ and $e = x, 11/2 - y, z$. For other operators, see Table 3.

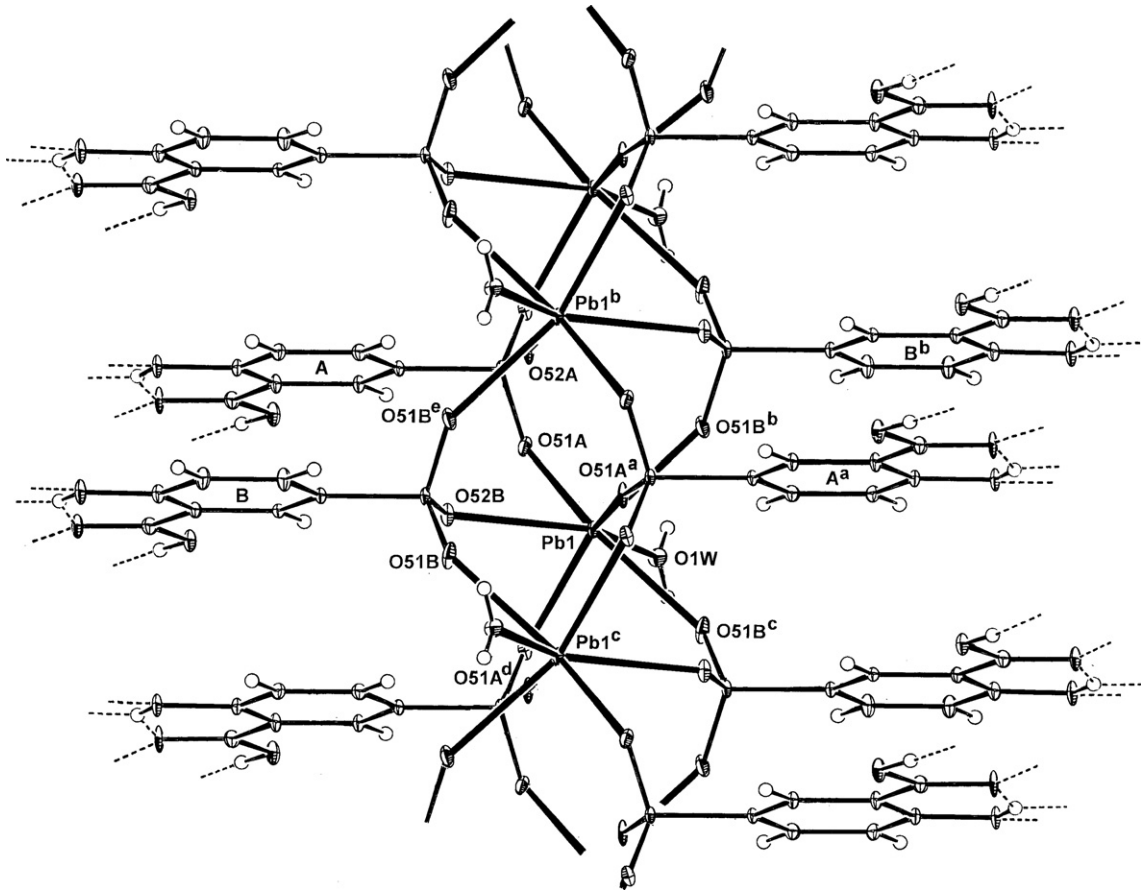

Fig. 4. The helical substructure in **3** extending along the *b* axial direction. The structure is further extended peripherally through head-to-head hydrogen-bonding interactions (shown as broken lines) involving the carboxylic acid and phenolic substituent groups of the SSA ligands. Atoms are shown as 30% probability ellipsoids [33].

3.1.2. Compound *2*

The room-temperature (298 K) structure of the anhydrous caesium complex with 5-sulfosalicylic acid, $[Cs(H_2SSA)]_n$ (**2**), has been previously described [10], and is a three-dimensional framework coordination polymer having an irregular Cs–O9 repeat (the asymmetric unit) which involves all oxygen donor atoms of eight independent H_2SSA^- ligands. Comparative cell parameters for this previous determination are given in Table 1 but the basic structural description remains the same, except for the minor changes in cell dimension-dependent values e.g. Cs–O bond distance range: 2.963(2)–3.434(2) Å (130 K) cf. 3.093(3)–3.449(3) Å (298 K).

3.1.3. Compound *3*

The lead(II) complex with 5-sulfosalicylic acid, $[Pb(H_2SSA)_2(H_2O)]_n$ (**3**), shows a three-dimensional structure based on coordination step-polymer ribbons interlinked by hydrogen-bonding interactions involving the carboxylic acid groups of the H_2SSA^- ligand species. The basic repeat unit (the asymmetric unit) in the helical ribbons is an irregular PbO_7 coordination centre [Pb–O range: 2.407(4)–2.717(4) Å] (Table 3), comprising the single monodentate water and six separate sulfonate oxygen donor atoms (Figs. 3 and 4). Each sulfonate group bridges three lead centres giving Pb···Pb repeats of 4.4747(4) Å down the *b*-axial direction in the unit cell. This is different from the discrete dimer formed in the mixed-ligand [1,10-phenanthroline-($HSSA^{2-}$)] lead complex [23] in which the two six-coordinate lead centres are bridged by the $HSSA^{2-}$ ligands through both the sulfonate and carboxylate groups. However, polymeric $Pb^{(II)}$ carboxylates and sulfonates are very common, as are irregular coordination polyhedra, and although Pb may assume regular octahedral, tetrahedral and square planar stereochemistry [27], irregular systems such as that found in **3** are well documented in the literature [28–32]. In **3**, most atoms including the Pb, the water-O and all atoms of the SSA ligand species, with the exception of two of the sulfonate-O atoms (O51A and O51B and their mirror-related pairs) lie in crystallographic mirror planes in the unit cell at $y = 1/4, 3/4$. The carboxylic acid groups link the coordination chains peripherally in characteristic intermolecular head-to-head cyclic hydrogen-bonding associations [O71A–H···O72B, 2.655(6) Å and O71B–H···O72A, 2.605(5) Å]. In addition, the substituent phenolic groups give a side-to-side interaction [O···O, 2.700(5) Å], closing the steps in the layered framework polymer (Fig. 5). The coordinated water molecule

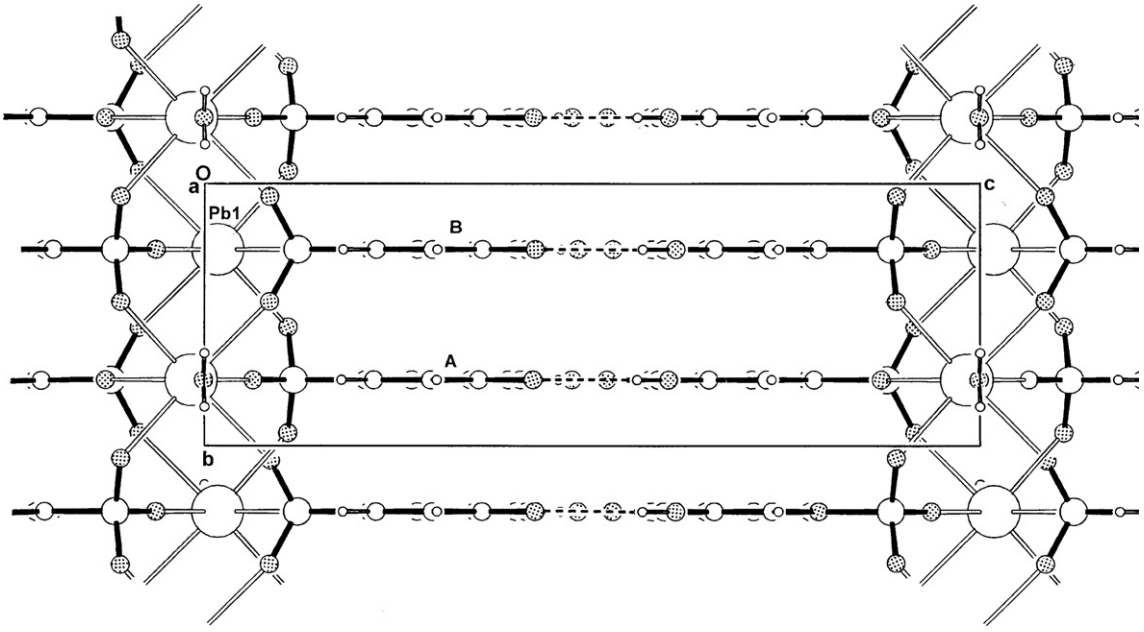

Fig. 5. The step-polymer structure and layering in **3** viewed down the crystallographic mirror planes showing the hydrogen-bonding extensions along the *c* axial direction.

also gives stability to the complex through hydrogen bonding, while within the ligand species the expected [26] intramolecular phenolic O–H···O(carboxylate) hydrogen bond is found [O···O, 2.602, 2.609(6) Å].

3.2. Conclusions

It has been further demonstrated that the 5-sulfosalicylic acid molecule is particularly efficient as a ligand for metal complexation, giving in most compounds (e.g. compounds **2** and **3**) chemically stable polymeric materials. This utility of this compound as a ligand is the result of a number of factors including: (1) The desirable stereochemical features presented by its substituent donor groups providing for multidentate coordination and polymeric structure extension. (2) The inherent selectivity achievable through pH and reactant stoichiometry in the control of ligand speciation (i.e. mono-, di- or trianionic species): mixed-species in complexes such as found in compound **1** are also possible, although uncommon. (3) The proton-acceptor properties of the oxygen atoms of the substituent groups, which allow for secondary hydrogen-bonding associations, commonly with incorporated water molecules (both coordinated and solvated). However, as is demonstrated in the rubidium(I) complex **1** and reinforced by a number of other examples from the crystallographic literature, there is a higher incidence of structures having hydrate lability in complexes of 5-sulfosalicylate with higher atomic number metallic elements.

at least reveal whether intermolecular or intramolecular forces are most important for determining cluster structure.

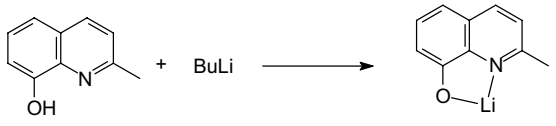
2. Experimental

2.1. Synthesis

2.1.1. Preparation of Liq

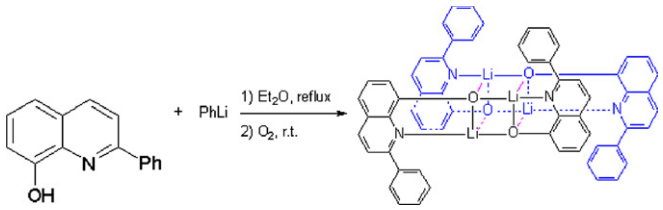
This material is prepared by treating 8-hydroxyquinoline with either *n*-butyllithium [9] or lithium hydroxide [10]; it readily sublimes under reduced pressure to give a pale yellow, highly crystalline material.

2.1.2. Preparation of MeLiq



This compound was prepared by the reaction of 2-methyl-8-hydroxyquinoline with *n*-butyllithium in anhydrous toluene at 0 °C or in hexane at 20 °C [11] as shown in Scheme 1. The MeLiq was formed as a white precipitate and collected by filtration. The crude material was purified by sublimation to give colorless crystals.

2.1.3. Preparation of PhLiq



This compound was prepared by the reaction of 8-hydroxy-2-phenylquinoline with two equivalents of *n*-phenyllithium in anhydrous diethyl ether [12], as shown in Scheme 2. The product was isolated as a green powder, which was then sublimed to purify.

2.2. Crystal structure determination

The crystals suitable for single-crystal X-ray quality were obtained by sublimation. Single-crystal structure determination by X-ray diffraction was performed using a Nonius KappaCCD [13] diffractometer, equipped with a normal focus, sealed-tube X-ray source (Mo Kα radiation, $\lambda = 0.71073$ Å). All data sets were collected at room temperature. The first ten frames were used for indexing reflections using the DENZO package [14] and refined to obtain final cell parameters. Data reductions were performed using DENZO-SMN. The structures were solved by direct methods and refined by full-matrix least squares on F^2 with anisotropic displacement parameters for the non-hydrogen atoms using the Bruker, Shelxtl suite of programs [15]. The hydrogen atoms were incorporated into idealized positions. Details of cell data, data collection, and structure refinement are summarized in Table 1. Structure determination details for Liq are described in detail in Ref. [8]. High R_{merg} values and weak diffraction in the case of the MeLiq and PhLiq indicates that the crystal quality was not good. However, even after several attempts, we were unable to get better quality crystals. Liq and MeLiq both crystallize in the triclinic space group, $P\bar{1}$, whereas PhLiq crystallizes in the monoclinic space group, $P2_1/c$. ORTEP diagrams for asymmetric units are illustrated in Fig. 1. There was slight disorder in PhLiq structure, which was left untreated.

Scheme 1.

Scheme 2.

2.3. Computational methods

Geometry optimizations were performed using the Gaussian 03 [16] and the B3LYP hybrid DFT method

[17]. The DGDZVP DFT-optimized basis set [18] was used on the Li, N, and O atoms because these are directly involved in coordination, while the MIDI! basis set [19] was used for the remaining (C and H) atoms. Use of a smaller basis set of C and H was mostly helpful for some of the relatively large PhLiq calculations, containing many C atoms; but due to the known good performance of MIDI! on hydrocarbon geometries [19], a mixed basis was used throughout in order to maintain a consistent level of theory across all structures. Structures were optimized in C_1 symmetry, although most structures approached idealized symmetry.

In the MeLiq and PhLiq cases, factors such as phenyl torsions and ligand/ligand steric interactions sometimes played a role in the geometry optimizations. Rather than compute multiple trivially different structures using DFT, a prescreening process was done. In these cases, the starting geometry was taken from the corresponding DFT-optimized Liq structure, then the Me or Ph groups were added as appropriate, using the builder in SPARTAN [20]. Any resulting close contacts were relieved if necessary, for example, by permitting some motion of the ligands with respect to the nearby Li–O bonds while maintaining all Li and O atoms at fixed positions. In the case of PhLiq structures, the phenyl torsions were optimized (keeping Li and O atoms still fixed, and N–Li bond distances were constrained to less than 3 Å) using the systematic conformational search algorithm implemented in SPARTAN, using a molecular mechanics force field. If necessary, this step was repeated using HF/PM3 [21], while maintaining the same constraints, in order to identify one or two most favored candidates for subsequent DFT structure and energy refinement.

3. Results and discussion

Liq and MeLiq molecules crystallize as hexamers, whereas PhLiq crystallizes as a tetramer (Fig. 2). For Liq and MeLiq, the asymmetric units are trimers, with each half of the hexamer related to the other half by symmetry, whereas the asymmetric unit of PhLiq is the tetramer itself. In all three cases, in addition to the oxygen of the 8-hydroxyquinolinate, the quinolinate nitrogen is also involved in coordination to the lithium, resulting in a coordination number of four for each lithium atom in the structure. Liq, a hexamer represented by the formula Li_6q_6, can be described as a doubly stacked trimer. Each trimer is composed of a six-membered ring of alternating oxygen and lithium atoms with the second ring rotated 60° relative to the first ring, allowing for alternating oxygen and lithium atoms between the rings. Essentially, each six-membered ring is planar, resulting in a hexagonal prism of alternating lithium and oxygen atoms that represent the base structure. Whereas, the MeLiq structure can best be described as a paddle-wheel structure, with methyl quinolate rings attached edgewise (perpendicular to the plane) onto the hexagonal prism of alternating lithium and oxygen atoms representing base structure. The PhLiq structure

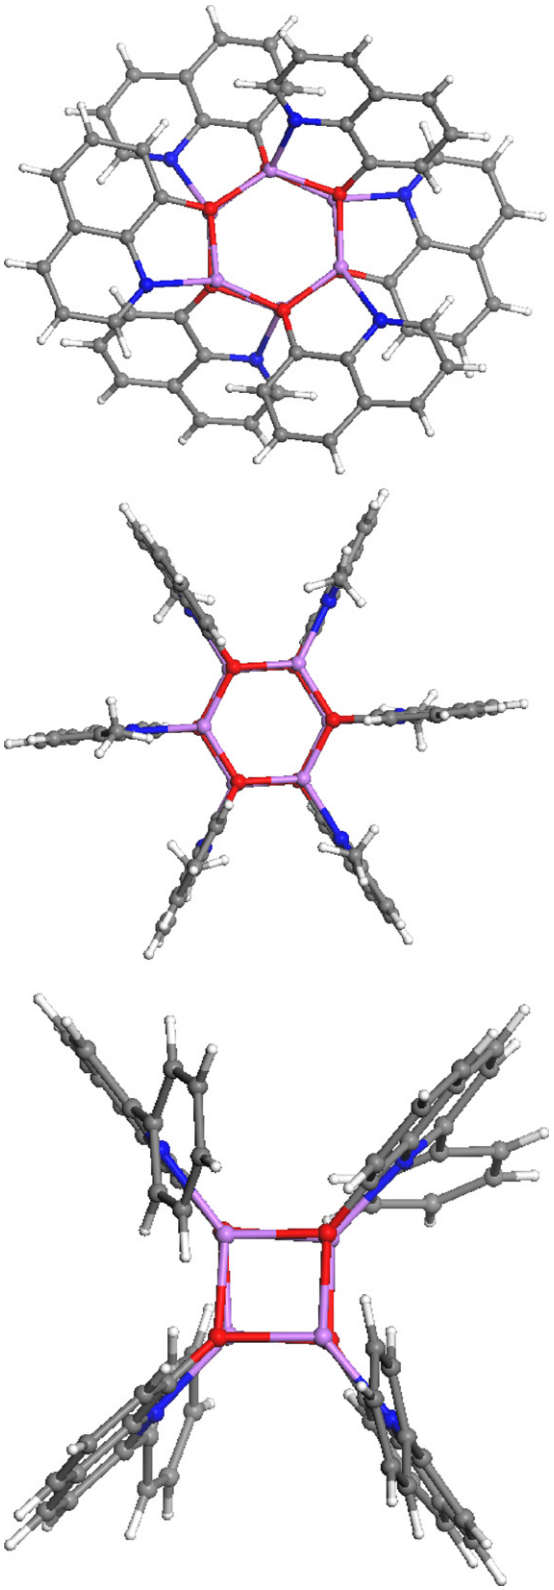

Fig. 2. An illustration of different coordination geometries between hexamers Liq and MeLiq, and tetramer PhLiq.

is described as an eclipsed-form tetramer, with a ring attachment arrangement similar to that for the MeLiq structure. A comparison of the Li–O bond lengths in Table 2 shows a range of 1.892–2.100 Å for the Li–O bond lengths. As expected in case of Liq (and also in MeLiq), the Li–O bond lengths within the trimer are much shorter than those between two stacked trimers in a hexamer. The Li–N bond lengths are in the range of 1.986–2.071 Å (Table 3). The Li–N bond lengths in MeLiq (2.040–2.071) are significantly longer than those in Liq (1.992–2.023). In the Liq and PhLiq crystal packing, intermolecular π–π stacking is evident between the quinoline ring of one molecule and the quinoline ring of the adjacent molecule. In case of MeLiq, there is minimal intramolecular π overlap, instead there seem to be multiple phenyl–phenyl embrace type [22] and C–H···π interactions [23,24].

One of the goals of the computational studies was to evaluate energetic preferences for certain lithium quinolinate structures. Theoretical methods are capable of directly evaluating whether the observed structural variations are due to differences in the inherent stability of various cluster geometries that arise from intracluster steric (and perhaps also electronic) effects from substitution at the quinoline 2-position. If such stability differences are trivial, or poorly match the observations, it would suggest that intercluster factors, such as crystal-packing effects, might better explain the observed structural variations (the observation that these are sublimable compounds seemingly suggests that crystal-packing forces are not unusually strong). The approach we use is similar in principle to the theoretical work previously carried out on oligomeric lithium–oxygen species, [25–29] most notably the studies carried out by Armstrong, Wheatley, and coworkers [26,28] on lithium–oxygen clusters comprising nitrogen-containing ligands. We first geometry-optimize various observed and hypothetical Li_nquinoline$_n$ structures ($n = 1$, 2, 3, 4, and 6) to determine their DFT energy. We are less interested in the total energy of the clusters than the average binding energy (ABE) per monomer. The ABE of a given Li_nquinoline$_n$ structure was obtained by dividing its SCF energy by n and subtracting from that value of the SCF energy for the corresponding monomer ($n = 1$). This was done separately for each case: H, Me, and Ph. The ABE of each Li_1quinoline$_1$ structure is thus by definition 0; and for the clusters ($n = 2$, 3, 4, and 6), relatively negative ABEs imply relatively favored cluster geometries (see Table 4).

The computations were done systematically on Liq, MeLiq, and PhLiq monomers and clusters. The various structures are most easily visualized using the Liq case (Fig. 3), described below, as to their approximate symmetry. One Li_1q_1 (C_s) and one Li_2q_2 (D_{2h}) structure are found (Fig. 3a); the dimer contains a Li_2O_2 four-membered ring core. Two Li_3q_3 structures are found (Fig. 3b): one is a D_{3h} structure with a six-membered ring Li_3O_3 core, and the other is a C_1 structure with a compact polyhedral Li_3O_3 core that could be considered a collapsed or folded ring-ladder structure [30]. While interesting, this polyhedral structure is not conceptually a building block for the $n = 6$ structures, so this structure was not recalculated for the Me and Ph cases. For the Li_4q_4 case, two structures are found (Fig. 3c), each containing similar cubic Li_4O_4 cores. These

Hex. prism, staggered	−2893.213972 (Fig. 3d)[a]	−3127.746714 (Fig. 5)	−4271.456305 (Fig. 5)

[a] Corresponds to an experimentally observed structure (see Ref. [8] for Liq and Fig. 2 for MeLiq and PhLiq).

might be described as two dimers that are stacked such that the quinoline rings are either eclipsed (D_{2d}) or staggered (D_2) with respect to the opposite dimer. Finally, three Li_6q_6 structures were found (Fig. 3d) containing similar hexagonal prism-shaped Li_6O_6 cores and possessing D_3 symmetry. These structures can be considered "paddle wheel", eclipsed, and staggered. Stacking two trimers results in a hexamer that may be either staggered or eclipsed (depending on the directional sense of how they are stacked). Analogous eclipsed hexamers have also been termed "trilobate" [31].

When we compare the ABEs (Fig. 4) of all of the computed clusters, we see that the rough trend of stability is dimer ≪ trimer ≪ tetramers < hexamers. Dimers and trimers seem unlikely as independent lithium quinolinate structures, but it is interesting to note that the polyhedral Li_3q_3 structure is nearly as stable as the isomeric six-membered ring Li_3q_3. For the tetramers, the energy differences between the staggered and eclipsed forms are small, as well as similar in magnitude for the H, Me, and Ph cases. This is because the quinolines splay away from each other on non-adjacent edges of the Li_4O_4 cube, thereby minimizing steric interactions. The energy preferences of the hexagonal-prism hexamers are more complicated. In the absence of Me or Ph steric interactions, the paddle-wheel structure is less favored than the eclipsed or staggered forms. The staggered hexamers are slightly more stable than the isomeric eclipsed forms, but the energy differences are small, again because the three quinolines on one half of the stacked trimer splay away from the three quinolines on the other half of the stack. However, because the MeLiq and PhLiq hexamers do have unfavorable steric interactions between neighboring ligands (i.e., on the same side of the stack) in the eclipsed and staggered forms, the paddle-wheel isomers have the lowest ABEs in the Me and Ph cases. These steric interactions are shown in Fig. 5.

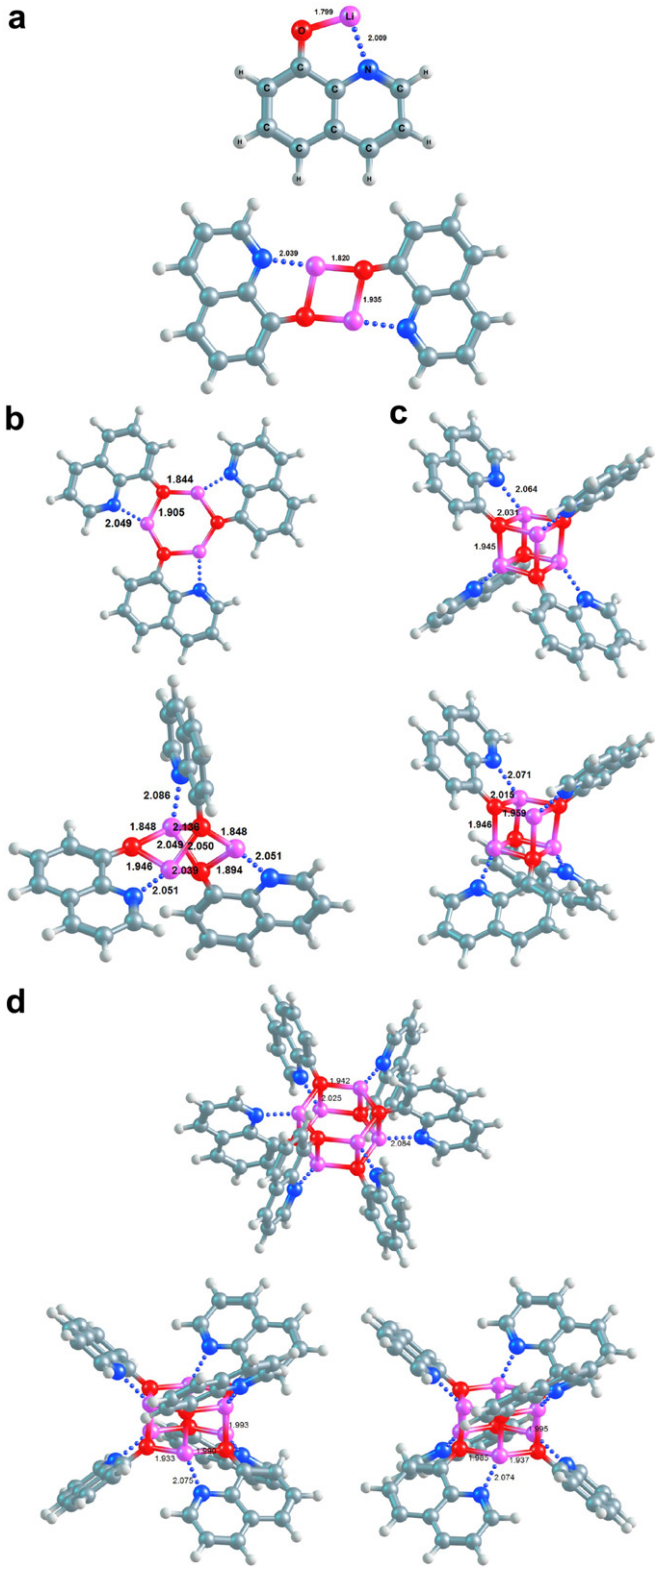

Fig. 3. (a) DFT-computed Liq monomer (top) and dimer (bottom) structures, with unique Li–O and Li–N bond lengths (Å) shown. (b) Isomeric DFT-computed Liq trimer structures. Flat form (top); polyhedral form (bottom), with unique Li–O and Li–N bond lengths (Å) shown. (c) Isomeric DFT-computed Liq tetramer structures. Eclipsed form (top); staggered form (bottom), with unique Li–O and Li–N bond lengths (Å) shown. (d) Isomeric DFT-computed Liq hexamer structures. Paddle-wheel form (top); eclipsed form (bottom left); staggered form (bottom right), with unique Li–O and Li–N bond lengths (Å) shown.

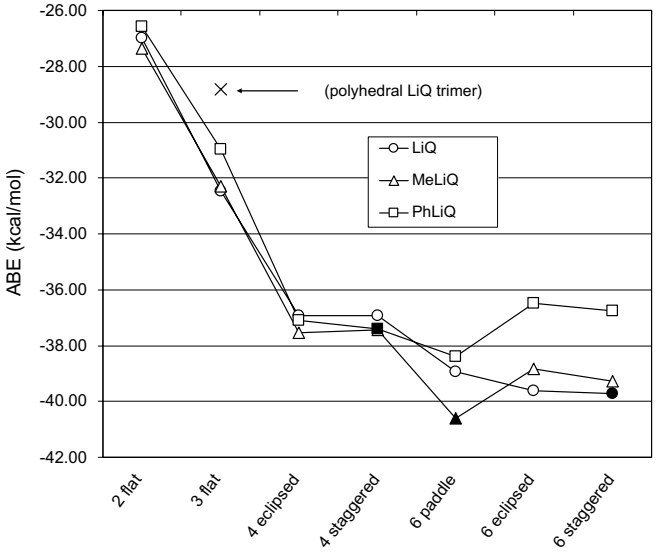

Fig. 4. B3LYP computed average binding energies (ABE, kcal/mol) for Liq, MeLiq, and PhLiq structures, $n = 2$, 3, 4, and 6. Relatively more negative ABEs indicate more stable structures. The "flat", "polyhedral", etc., structures are described in the text and Fig. 3a–c. The filled circle, triangle, and square represent computed models of experimentally observed structures. For Liq and MeLiq, these are also the points with the most favorable ABEs; whereas for PhLiq, the $n = 6$ "paddle" structure has a lower ABE than the observed structure.

The computational results point to crystal-packing effects, rather than inherent favorability of the isolated tetramer, as favoring the observed PhLiq structure. This seems reasonable in as much as the phenyl groups are relatively large substituents that do not directly participate in lithium binding, yet can participate in π-stacking effects (e.g., with neighboring molecules in the crystal lattice, see Fig. 3).

A caveat with respect to the present calculated results is that the level of computed accuracy is unknown, especially because the trustworthiness of computations on lithium alkoxides may be less well established by reference to experimental data than computations of hydrocarbons, for example. Fortunately structural isomers have the same number and type of bonds and lone pairs and therefore benefit from systematic cancellation of errors [32]. Still, errors may be as great as ±2 kcal/mol and perhaps twice that when comparing similar but non-isomeric structures, such as dimer vs. trimer ABEs. This is on the order of the computed ABE differences between the various hexamers and tetramers. Thus we cannot rule out the possibility that it is only coincidental that the calculations point to the observed structures as lowest-energy in both the Liq and MeLiq cases, and in the PhLiq case point to the observed structure as the lowest energy tetramer (and second most stable PhLiq structure overall).

4. Conclusions

A comparison of the solid-state structures of Li complexes, Liq, MeLiq, and PhLiq, illustrates steric effects on the coordination chemistry of lithium. Replacement of

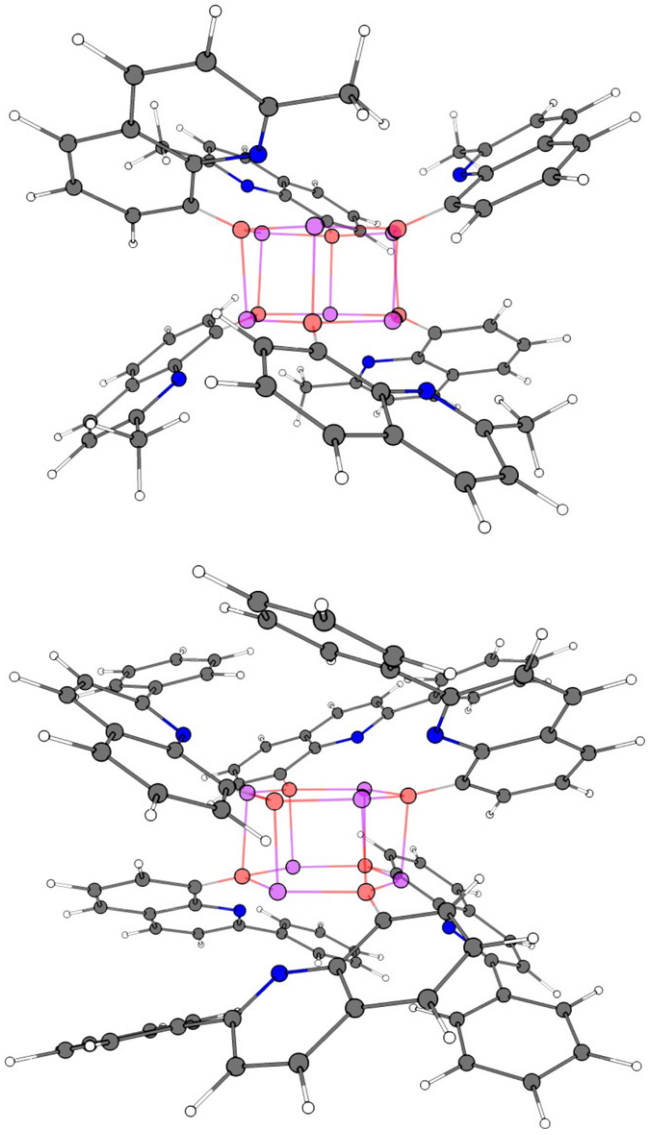

Fig. 5. DFT-computed staggered forms of hexameric MeLiq (top) and PhLiq (bottom), in a perspective view that emphasizes the interligand steric interactions. The N–Li bonds are omitted for clarity. Considering the hexamers as stacked trimers, the important steric interactions between ligands involve methyl or phenyl groups approaching neighboring quinoline rings on the same side of the stack, whereas the steric interactions with ligands on the opposite side of the stack are relatively insignificant.

the 2-hydrogen in 8-hydroxyquinoline with a methyl or phenyl changes the crystal structure from a doubly stacked trimer to a paddle-wheel hexamer to a tetramer. Thus, substitution at the 2-position of the 8-hydroxyquinoline ligand has significant impact on the aggregation of the lithium complex in the crystalline state, indicating different coordination geometries, and coordination numbers may be found when small changes in remote organic substituents are made. The possible influence of crystal-packing forces on the preferred cluster structure was probed using density functional theory calculations on a systematically varied set of Liq, MeLiq, and PhLiq clusters. For all three cases, the order of stabilization energy (per monomer) is dimer < trimer < tetramer ≈ hexamer. For Liq and MeLiq the observed structures match the most stable computed structures. In the PhLiq case, the observed tetrameric structure is computed to be less stable (+1.2 kcal/mol/monomer) than the lowest energy structure, a hexamer. The computational results suggest that crystal-packing effects, rather than the inherent favorability of the isolated tetramer, likely favor the observed PhLiq structure.

ruthenium(III) compound to successfully complete phase I clinical trials [21]. The main feature of the majority of these complexes is the presence of four chlorides, one DMSO, and one N-donor ligand in the coordination sphere. At present, very few examples of such ruthenium(III) complexes exist that have been structurally characterized by X-ray diffraction methods. These include complexes, for example, where the N-donor ligand is ammonia [22], thiazole [23], guaninium [24], imidazole [22], pyridine [25], triazole [26] as well as symmetrical ruthenium dimers with pyrazine, pyrimidine, and bipyridine [27], and the unsymmetrical dimer with bridging pyrazine [28]. Here we report the synthesis and characterization of several ruthenium(III) complexes with dimethylsulfoxide and heterocyclic dinitrogen ligands as well as the crystal structures of the $[Ru(DMSO)(pz)Cl_4]^-$ (pz = pyrazine) monoanion with two different cations, tetraphenylphosphonium (PPh_4) and Na. These cations are quite different and the architectures of the crystal structures were expected to differ considerably. These two compounds are the first two Ru(III) species containing a terminal pyrazine ligand to be characterized structurally.

2. Experimental

Ethanol (100%) was purchased from Pharmaco Products Inc. All other reagents and solvents were purchased from Sigma Aldrich Inc. IR spectra were recorded in the solid state on a Nicolet 4700 FTIR spectrometer between 4000 and 250 cm^{-1}. ^1H NMR spectra were measured in D_2O, acetone-d_6, $CDCl_3$, and CD_3CN on a Varian Gemini 300 MHz spectrometer. The solvent peaks at 4.80 ppm, 2.05 ppm, 7.26 ppm, and 1.94 ppm for D_2O, CD_3COCD_3, $CDCl_3$, and CD_3CN, respectively, were used as internal standards for the ^1H NMR spectra. Spectral abbreviations used below: br (broad), vbr (very broad), s (strong), m (medium), w (weak), sh (shoulder).

2.1. Synthesis

$[(DMSO)_2H]$*trans*-$[Ru(DMSO)_2Cl_4]$, $[Na]$*trans*-$[Ru(DMSO)_2Cl_4]$, and $[NBu_4]$*trans*-$[RuCl_4(DMSO)_2]$ (Bu = *n*-butyl) were synthesized according to the literature methods [27,29].

*[PPh₄]trans-[Ru(DMSO)₂Cl₄] (**1**).* Tetraphenylphosphonium chloride (0.34 g, 0.92 mmol) dissolved in 6 mL of H_2O was added to a solution of $[(DMSO)_2H]$*trans*-$[Ru(DMSO)_2Cl_4]$ (0.34 g, 0.61 mmol) dissolved in 3 mL of H_2O, while stirring. A yellow precipitate formed within minutes. The precipitate was collected by filtration, washed with diethylether and vacuum dried. Yield: 89%. IR (cm^{-1}): 1107s ν(DMSO–S), 416w ν(Ru–S), 339, 319s ν(Ru–Cl). ^1H NMR (CD_3CN/ppm): −13.0 (DMSO–S), 7.95, 7.74 (phenyl protons).

*[PPh₄]trans-[Ru(DMSO)(pz)Cl₄] (**2**).* $[PPh_4]$*trans*-$[Ru(DMSO)_2Cl_4]$ (**1**) (0.30 g, 0.40 mmol) was dissolved in a mixture of 7 mL acetone and 4 mL acetonitrile, while 0.16 g of pyrazine (pyz) (2.0 mmol) was dissolved in 1 mL of acetone. The ruthenium solution was added slowly to the pyrazine solution to form a clear orange mixture. After several hours the product precipitated as orange crystals. The crystals were collected by filtration, washed with cold diethylether and vacuum dried. Yield: 73%. Alternatively, complex **2** can be synthesized from complex **3** by the addition of $[PPh_4]Br$ or $[PPh_4]Cl$ in aqueous solution. IR (cm^{-1}): 1588 (pz), 1108s (DMSO–S), 420m ν(Ru–S), 342, 328s ν(Ru–Cl). ^1H NMR (CD_3CN/ppm): −12.6 (br, DMSO–S), −5.6 (vbr, pz $H^{2,6}$), −1.6 (br, pz $H^{3,5}$), 7.95, 7.74 (phenyl protons). *Anal.* Calc. for $C_{30}H_{30}Cl_4N_2OPSRu$: C, 48.6; H, 4.05; N 3.78. Found: C, 48.4; H, 3.84; N, 3.87%.

*[Na]trans-[Ru(DMSO)(pz)Cl₄] · DMSO (**3**).* The synthesis of this compound was similar to that reported [27] with some changes. Pyrazine (80.2 mg, 1.00 mmol) dissolved in 5 mL of acetone was added to a solution of 82.5 mg (0.198 mmol) of $[Na]$*trans*-$[Ru(DMSO)_2Cl_4]$ dissolved in 2 mL of DMSO. The resulting mixture was filtered and the filtrate was stirred at room temperature for 1.5 h. A 50/50 acetone/diethylether solution (5.0 mL) was added to the reaction mixture followed by an additional 5.0 mL of diethylether. The mixture was then placed at 4 ° C. Orange crystals appeared within 48 h. The mother liquor was decanted and the crystals washed with diethylether. Yield: 67%. ^1H NMR (D_2O/ppm): −13.9 (br), (DMSO–S), −7.5 (vbr, $H^{3,5}$ pyz), −2.1 (br, $H^{2,6}$ pyz). This compound was reported, but the solvate molecules appear different [27].

*[NBu₄]trans-[RuCl₄(DMSO)(bpy)] (bpy = 4,4′-bipyridine) (**4**).* 0.63 g of $[NBu_4]$*trans*-$[RuCl_4(DMSO)_2]$ (0.98 mmol) was dissolved in 15 mL of acetone and 0.60 g of 4,4-bipyridine (3.8 mmol) was dissolved in 4 mL of acetone. The ruthenium solution was added to the 4,4-bipyridine solution to form a clear orange solution. After several hours of stirring, the product was precipitated after the addition of 10 mL of cold diethylether. The yellow precipitate was collected by filtration, washed with cold diethylether and vacuum dried. Yield: 86% (0.60 g). IR (cm^{-1}): 1595, 1612w (bpy), 1109s (DMSO–S), 422m ν(Ru–S), 349, 325s ν(Ru–Cl). ^1H NMR (acetone/ppm): −12.2 (br, DMSO–S), 7.5 (br, bpy $H^{2',6'}$), 6.0 (br, bpy $H^{3',5'}$), −1.2 (br, bpy $H^{3,5}$), −6.0 (vbr, bpy $H^{2,6}$).

*[PPh₄]trans-[RuCl₄(DMSO)(bpy)] (**5**).* 0.50 g of $[PPh_4]$*trans*-$[RuCl_4(DMSO)_2]$ (0.68 mmol) was dissolved in 15 mL of CH_2Cl_2 and 0.40 g of 4,4-bipyridine (2.6 mmol) was dissolved in 6 mL of CH_2Cl_2. The ruthenium solution was added to the 4,4-bipyridine solution to form a clear orange solution. After several hours of stirring, the product was precipitated after the addition of 10 mL of cold diethylether. The yellow precipitate was collected by filtration, washed with cold diethylether, and vacuum dried. Yield: 82% (0.45 g). IR (cm^{-1}): 1595, 1612w (bpy), 1107s (DMSO–S), 422m ν(Ru–S), 331s,br ν(Ru–Cl). ^1H NMR ($CDCl_3$/ppm): −12.8 (br, DMSO–S), 7.5 (br, bpy $H^{2',6'}$), 5.5 (br, bpy $H^{3',5'}$), −1.7 (br, bpy $H^{3,5}$), 8.06 (br, phenyl protons). *Anal.* Calc. for $C_{36}H_{34}Cl_4N_2OPSRu$: C, 52.9; H, 4.17; N 3.43. Found: C, 52.6; H, 3.94; N, 3.23%.

*[PPh4]trans-[RuCl4(DMSO)(pym)] (pym = pyrimidine) (**6**).* 0.20 g of [PPh_4]*trans*-[$RuCl_4(DMSO)_2$] (0.27 mmol) was dissolved in 5 mL of CH_2Cl_2 and 0.15 g of pyrimidine (0.98 mmol) was dissolved in 1 mL of acetone. The ruthenium solution was added to the pyrimidine solution to form a clear orange solution. After several hours of stirring, the product was precipitated with the addition of 10 mL of diethylether. The yellow precipitate was collected by filtration, washed with diethylether, and vacuum dried. Yield: 67% (0.133 g). IR (cm^{-1}): 1585, 1560 (pym), 1107s (DMSO–S), 421m ν(Ru–S), 339, 324sh ν(Ru–Cl). ^1H NMR (CD_3CN/ppm): −13.0 (br, DMSO–S), 6.34 (pym H^4), −0.58 (br, pym H^5), −1.7 (vbr, pym H^6), −6.5 (vbr, pym H^2), 7.96, 7.78 (br, phenyl protons); ($CDCl_3$/ppm): −12.7 (br, DMSO–S), 6.32 (br, bpy H^4), −0.52 (br, H^5), 8.16 (br, phenyl protons). *Anal.* Calc. for $C_{30}H_{30}Cl_4N_2OPSRu$: C, 48.6; H, 4.05; N 3.78. Found: C, 48.4; H, 3.78; N, 3.77%.

2.2. Crystallographic measurements and structure resolution

The crystallographic measurements of crystals **2** and **3** were done on a Bruker P4 diffractometer using graphite-monochromatized Mo Kα ($\lambda = 0.71073$ Å) radiation. The cell dimensions were determined at room temperature, from a least-squares refinement of the angles 2θ, ω and χ obtained for well-centered reflections. The data collection was made by the $2\theta/\omega$ scan technique using the XSCANS program [30]. The background time to scan time ratio was 0.5.

Table 1
Crystallographic data and experimental details

Crystal	**2**	**3**
Name	PPh_4[Ru(DMSO)(pz)Cl_4]	Na[Ru(DMSO)(pz)Cl_4]·DMSO
Chemical formula	$C_{30}H_{30}Cl_4N_2OPRuS$	$C_8H_{16}Cl_4N_2NaO_2RuS_2$
M_w	740.46	502.21
Space group	$P2_1/n$ (No. 14)	$P\bar{1}$ (No. 2)
a (Å)	13.161(3)	7.0972(7)
b (Å)	17.070(4)	10.6838(15)
c (Å)	14.826(4)	12.379(2)
α (°)	90.	91.164(14)
β (°)	104.65(2)	93.48(12)
γ (°)	90.	105.83(11)
Volume (Å^3)	3222.5(14)	900.7(2)
Z	4	2
ρ_{calc} (g cm^{-3})	1.526	1.852
μ(Mo Kα) (mm^{-1})	0.959	1.718
F(000)	1500	498
Reflections collected	12656	10499
Observed Reflections ($I > 2\sigma(I)$)	4778	4284
R_1 ($I > 2\sigma(I)$)	0.0327	0.0307
wR_2 (all data)	0.0748	0.0770
S	1.049	1.023

$R_1 = \sum(|F_o - F_c|)/\sum|F_o|$, $wR_2 = [\sum(w(F_o^2 - F_c^2)^2)/\sum(w(F_o^2)^2)]^{1/2}$.

The coordinates of the Pt atom were determined by direct methods and all the other non-hydrogen atoms were found by the usual Fourier methods. The refinement of the structure was done on F^2 by full matrix least-squares analysis. The hydrogen atom positions were fixed in their calculated positions with $U_{eq} = 1.2\ U_{eq}$ (or 1.5 for methyl groups) of the carbon to which they are bonded. Corrections were made for absorption (semi-empirical from psi-scans for **2** and integration for **3**), Lorentz and polarization effects. The calculations were done using the Bruker SHELXTL system [30]. The crystallographic data and details are shown in Table 1.

3. Results and discussion

3.1. [PPh4]trans-[Ru(DMSO)2Cl4] (1)

This yellow compound was synthesized from the aqueous reaction of [$(DMSO)_2H$]*trans*-[$Ru(DMSO)_2Cl_4$] with tetraphenylphosphonium chloride.

$$[(DMSO)_2H]trans\text{-}[Ru(DMSO)_2Cl_4] + [PPh_4]Cl \xrightarrow[H_2O]{} [PPh_4]trans\text{-}[Ru(DMSO)_2Cl_4]$$

The synthesis and characterization of this ionic complex has not been reported yet in the literature, therefore we give a brief description. The IR spectrum of the compound shows a ν(S–O) vibration at 1107 cm^{-1}. Absorption at 416 cm^{-1} was assigned to the metal stretching vibration ν(Ru–S) while those at 339 and 319 cm^{-1} were attributed to ν(Ru–Cl). The NMR spectrum of **1** and all of the complexes reported here show peaks that are characteristic of complexes containing paramagnetic ruthenium(III). Protons close to the paramagnetic center have large line-width (often some peaks are too wide to be observable) and are shifted greatly upfield [31–33]. The peak at −13.0 ppm is assigned to the coordinated DMSO (through the S atom).

3.2. [PPh4][Ru(DMSO)(pyrazine)Cl4] (2)

This new ionic complex was synthesized from the reaction of the bis-DMSO Ru(III) ionic complex **1** with pyrazine (pz) as shown in the following equation:

$$[PPh_4]trans\text{-}[Ru(DMSO)_2Cl_4] + pz \xrightarrow[\text{acetone/acetonitrile}]{} [PPh_4]trans\text{-}[Ru(DMSO)(pz)Cl_4]$$

Alternatively, compound **2** was also synthesized from the aqueous reaction of compound **3** with tetraphenylphosphonium chloride or tetraphenylphosphonium bromide.

The IR spectrum of **2** shows a ν(S–O) vibration at 1108 cm^{-1}, a ν(Ru–S) band at 420 cm^{-1} and ν(Ru–Cl) vibrations at 342 and 328 cm^{-1}. The NMR spectrum shows a peak at −12.6 ppm integrating to six protons assigned to the coordinated DMSO, while the peak at −1.6 ppm integrating to two protons is assigned to the protons (H^3 and H^5) on the pyrazine ring. The protons on the pyrazine ring

(H^2 and H^6) closest to the paramagnetic ruthenium center are seen in a very broad peak at −5.6 ppm (for labeling see Chart 1).

Compound **2** was recrystallized from acetone/diethylether and the crystals were studied by crystallographic methods. The results have shown that the orange crystals consist of discrete complexed anions, $[Ru(DMSO)(pz)Cl_4]^-$ (Fig. 1) and $[PPh_4]^+$ cations. The complexed anion is the *trans* isomer and the coordination around the Ru(III) center is octahedral. The bond distances and angles are shown in Table 2. The *cis* angles around the metal vary between 87.73(7)° and 92.66(3)°, while the *trans* angles are between 177.32(3)° and 179.07(7)°. The Ru–Cl bond distances range from 2.3425(9) to 2.3589(10) Å, the Ru–S bond is 2.2941(9) Å and the Ru–N distance is 2.118(2) Å. These values are in agreement with published values found in a few related structures [22,24,27,28,34].

The environment around the S atom in the DMSO ligand is approximately tetrahedral but there are small deformations. The O–S–C angles are larger (ave. 107.18(17)°) than the C–S–C angle (98.77(18)°) as expected. The Ru–S–O angle (117.98(10)°) is also larger than the Ru–S–C angles (ave. 111.95(13)°). The average angle Ru–N–C is 121.9(2)°. The N1–C bond lengths (ave. 1.332(4) Å) are not different from those of N4–C (ave. 1.328(5) Å), but the angles C–N–C are different. The internal ring angle at the metal-bonded N1 atom is larger (116.3(3)°) than the angle of the non-bonded N4 atom (114.7(3)°) as observed in Pt(II) compounds of the type *cis*- and *trans*-$Pt(R_2SO)(pz)Cl_2$ where the bonded angle C2–N1–C6 is slightly larger than the C3–N4–C5 angle [35].

In order to minimize the interactions with the rest of the molecule, the pyrazine ligand is at ≈45° to the different Ru square planes. Here, the dihedral angle between the pyrazine and the RuN1S1Cl1Cl3 plane is 47.65(11)°, while it is 42.36(10)° with the RuN1S1Cl2Cl4 plane. In the DMSO ligand, the O atom of DMSO was found almost in the RuS1N1Cl1Cl3 plane, which reduces steric hindrance in the complexed ion, since the larger methyl groups are far from the four *cis* chloro ligands. The torsion angles Cl1–Ru–S–O and Cl3–Ru–S–O are −7.14(15)° and 172.94(15)°, respectively. In this conformation of the DMSO and pyrazine ligands, the energy of the molecular ion is close to a minimum.

The PPh_4 cations are normal. The average P–C bond distance is 1.800(3) Å with an average C–P–C angle of 109.48(13)°. No H-bonds are expected in this crystal. The ions are held together in the crystal by electrostatic forces and by van der Waals interactions.

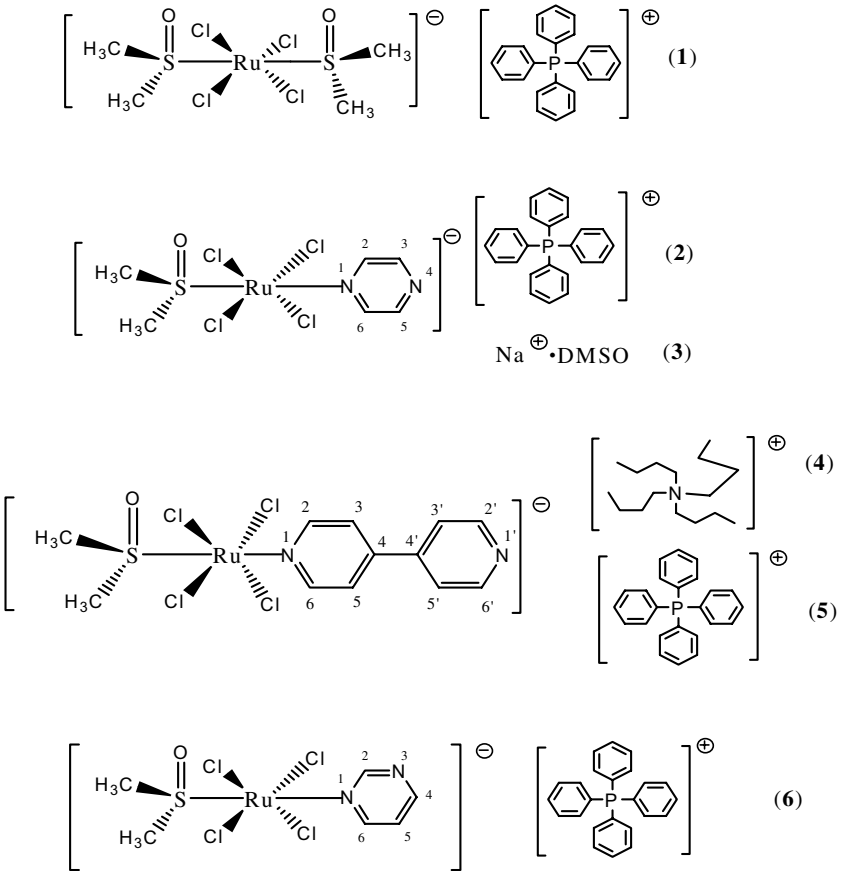

Chart 1. Ruthenium(III) molecular structures.

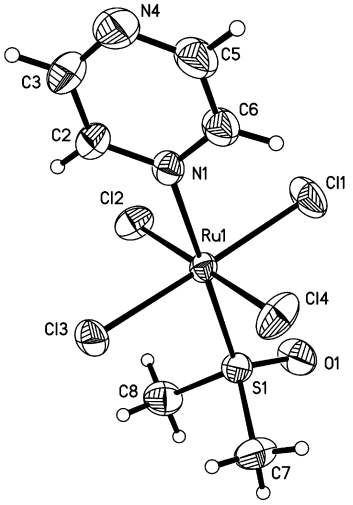

Fig. 1. ORTEP view of the $[Ru(DMSO)(pz)Cl_4]^-$ anion in crystal **2**. Ellipsoids are shown at 40% probability level and the H atoms are of arbitrary size.

3.3. *[Na][Ru(DMSO)(pyrazine)Cl$_4$] · DMSO (**3**)*

This compound was synthesized from the reaction of $[Na][Ru(DMSO)_2Cl_4]$ with pyrazine in acetone and DMSO similar to the procedure already reported.

$$[Na][Ru(DMSO)_2Cl_4] + pz \xrightarrow[DMSO]{acetone} [Na][Ru(DMSO)(pz)Cl_4]\cdot DMSO$$

The orange compound was crystallized in a mixture of acetone and diethylether and the crystals were studied by X-ray diffraction methods. The results have shown that the compound crystallized with a molecule of solvent (DMSO). The reported compound [27], which was not studied by crystallographic methods, contained 1.5 molecule of DMSO and 0.5 molecule of H_2O, although it was crystallized from the same solvents.

Fig. 2 shows the labeling scheme of the asymmetric unit in crystal **3**. The complexed anion is the *trans* isomer and the coordination around the Ru(III) center is octahedral. The bond distances and angles are shown in Table 2. The *cis* angles around the metal vary between 87.95(3)° and 93.96(3)°, while the *trans* angles are between 176.43(2)° and 177.74(2)°. The Ru–Cl bond distances range from 2.3395(8) to 2.3754(7) Å, the Ru–S bond is 2.3027(7) Å and the Ru–N distance is 2.1257(19) Å. These values are very similar to those observed in crystal **2** described above and they are in agreement with published values found in a few related structures [22,24,27,28].

The environment around the bonded S atom in the DMSO ligand is approximately tetrahedral but there are small deformations. The O–S1–C angles are larger (ave. 106.39(17)°) than the C–S1–C angle (100.4(2)°) as expected. The Ru–S–O angle (117.73(8)°) is also larger than the Ru–S–C angles (ave. 112.15(17)°). The average angle Ru–N–C is 121.64(16)°. The N1–C bonds (ave. 1.343(3) Å) are not very different from the N4–C bonds (ave. 1.333(3) Å), but the angles C–N–C are slightly different. The internal ring angle at the metal-bonded N1 atom is slightly larger (116.7(2)°) than the angle of the non-bonded

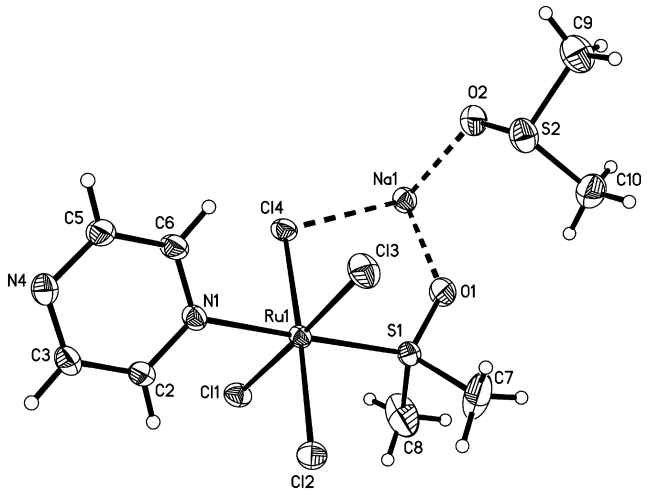

Fig. 2. ORTEP view of [Na][Ru(DMSO)(pz)Cl_4] · DMSO (**3**) showing the labelling scheme of the asymmetric unit. Ellipsoids are shown at 40% probability level and the H atoms are of arbitrary size.

N4 atom (115.2(2)°), as observed in crystal **2**, which also contains a monodentate pyrazine ligand.

Complex **3** crystallized with a molecule of DMSO which is not bonded to the Ru(III) atom. The S2–O2 bond is longer (1.496(2) Å) than the S1–O1 bond distance in crystals **2** and **3** (ave. 1.469(2) Å) as expected when the S atom is not coordinated to a metal. When the binding site of DMSO is the S atom, the order of the S–O bond increases when compared to the free molecule, while it is reduced if the molecule is bonded to the metal atom through its O atom. The NMR and IR spectra are in agreement with the published data. Only one ν(S–O) band was observed at 1104 cm^{-1} [27].

The O atom of the bonded DMSO ligand was found close to the RuS1N1Cl2Cl4 plane, which reduces steric hindrance in the complexed anion, since the larger methyl groups are far for the four *cis* chloro ligands. The torsion angles Cl2–Ru–S1–O1 and Cl4–Ru–S1–O1 are −161.74(11)° and 21.71(11)°, respectively. The plane of pyrazine is located at about ≈45° from the two different Ru(III) square planes. The dihedral angle between the pyrazine and the RuN1S1Cl2Cl4 plane is 41.56(6)°, while it is 48.18(7)° with the RuN1S1Cl1Cl4 plane. This conformation of the molecular ion is similar to the one observed in crystal **2** and corresponds approximately to the one of lowest energy.

The environment around the Na atoms was closely examined. There are six atoms in its close environment. The distances and angles are shown in Table 2. The geometry is a distorted octahedron. Three of the close contacts are shown in Fig. 2. The Na–O1 (from bonded DMSO) and Na–O2 (unbonded DMSO) distances are 2.303(2) and 2.324(2) Å, respectively. The Na–Cl4 distance is 2.9222(12) Å. There are three other short contacts with the following: N4′ (2.519(2) Å), Cl1′ (2.7760(13) Å), and Cl4′ (2.8404(13) Å). The chloro ligand Cl4 forms a bridge between two Na atoms, while Cl1 forms a bridge between a Na and a Ru atom. The two other Cl ligands are not involved with the Na atoms. The DMSO ligand forms a bridge between a Ru (through its S atom) atom and a Na (through its O) atom, while the S atom of the second DMSO molecule is free, but its O atom is in the close environment of the Na atom. There are important distortions from the octahedral structure around the Na atom. The *cis* angles vary between 72.25(3)° (Cl′–Na–Cl4′) and 106.54(7)° (O2–Na–Cl4), while the *trans* angles are between 154.51(7)° and 175.65(8)°.

The Na atom has a very important role in this structure. It bridges the different complexed ions to form infinite polymeric chains or ribbons parallel to the *b* axis. One of these is shown in Fig. 3. The two ligands Cl2 and Cl3, which are not involved with the Na atoms point towards the outside of the chain, along with S2 and the two C atoms of the free DMSO molecule. Several cycles are formed, ranging from four atoms (Ru, Cl1, Na, Cl4) to seven atoms (Ru, Cl1, Na, Cl4, Na, O1, S1). These neutral ribbons are held together by van der Waals forces. There may be weak π–π stacking

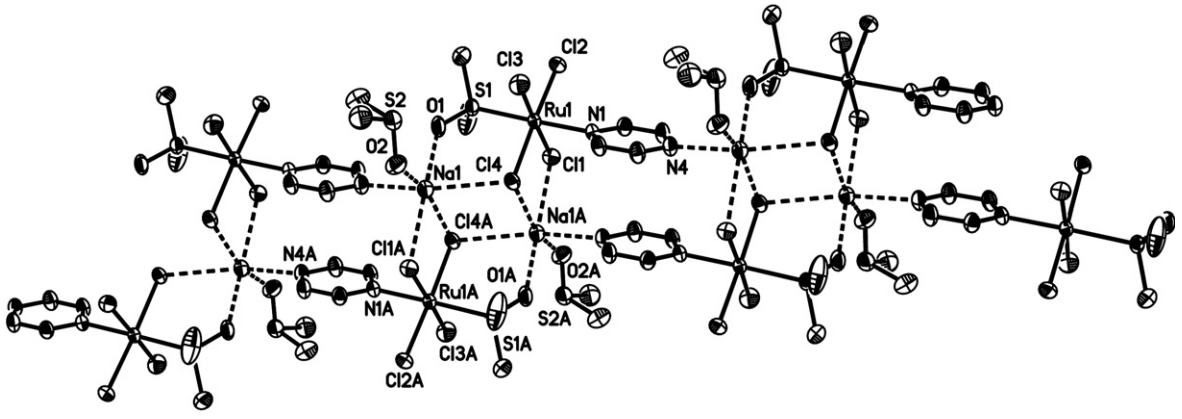

Fig. 3. ORTEP view of a ribbon in compound **3** showing the octahedral environment around the Na atom (---), which bridges the anions [Ru(DMSO)(pz)Cl_4]$^-$.

interactions of the pyrazine ligands, as the distance between pyrazine pairs shown in Fig. 3 is 3.548(16) Å [36].

A few related structures were reported with the sodium cation. In $[Na][Ru(DMSO)(NH_3)Cl_4]\cdot 2DMSO$ and $[Na][Ru(DMSO)(Im)Cl_4]\cdot H_2O$, CH_3COCH_3 [22], the environment around the Na atom is tetrahedral with four Na–O distances between 2.272(4) and 2.489(3) Å. But the long-range arrangement in the crystal was not discussed. A few other related structures containing Na ions were published, but the environment around the Na atom was not considered [27]. In these structures, the role of the Na ions in the architecture, besides its counterion function, was not studied.

In crystal **3**, the unbonded DMSO molecule plays also a very important role in the formation of the chains. In a few reported structures containing the same cation, the chains are not formed, but rather shorter oligomers [22] containing two Ru(III) and two Na atoms were produced. For the latter structures, the tetrahedral environment around the Na atoms is formed with four O atoms from DMSO or H_2O molecules.

3.4. [NBu4]trans-[RuCl4(DMSO)(bpy)] (4) and [PPh4]trans-[RuCl4(DMSO)(bpy)] (5)

$[PPh_4]$*trans*-$[Ru(DMSO)(bpy)Cl_4]$ (**5**) (bpy = 4,4′-bipyridine) was prepared from $[PPh_4]$*trans*-$[Ru(DMSO)_2Cl_4]$ in methylene chloride as shown in the following equation:

$$[PPh_4]\textit{trans}\text{-}[Ru(DMSO)_2Cl_4] + 4,4'\text{-bpy} \xrightarrow[\text{methylene chloride}]{} [PPh_4][Ru(DMSO)(bpy)Cl_4]$$

The NMR spectrum of compound **5** showed, along with signals for the tetraphenyl phosphonium cation, several peaks for the protons of the coordinated ligands. The signal at −12.8 ppm is assigned to the coordinated DMSO while the peak at −1.7 ppm is assigned to the protons (H^3 and H^5) on the coordinated pyridine ring but furthest from the paramagnetic ruthenium(III) center. The protons closest to the ruthenium center (H^2 and H^6, Chart 1) are not observed due to a line-width that is too broad for the peak to be seen. The protons on the second pyridine ring are observed at 5.5 ($H^{3'}$ and $H^{5'}$) and 7.5 ppm ($H^{2'}$ and $H^{6'}$) for the two pairs closer and further from the ruthenium atom, respectively. The IR spectrum of **5** shows a terminal bpy mode at 1595 cm^{-1} along with a ν(S–O) vibration at 1107 cm^{-1}, a ν(Ru–S) band at 422 cm^{-1}, and a ν(Ru–Cl) vibration at 331 cm^{-1}.

$[NBu_4]$*trans*-$[Ru(DMSO)(bpy)Cl_4]$ (**4**) was prepared similarly to complex **5**, however the reaction was done in acetone solution. The NMR and IR spectral characterization and signal assignments were also similar, except in the proton NMR, where all four sets of bpy proton pairs were observed in this case. The protons closest to the ruthenium atom (H^2 and H^6), unobservable for complex **5** are seen as a very broad peak at −6.0 ppm.

3.5. [PPh4]trans-[Ru(DMSO)(pym)Cl4] (6)

$[PPh_4]$*trans*-$[Ru(DMSO)(pym)Cl_4]$ (**6**) was prepared from $[PPh_4]$*trans*-$[Ru(DMSO)_2Cl_4]$ in methylene chloride as shown in the following equation:

$$[PPh_4]\textit{trans}\text{-}[Ru(DMSO)_2Cl_4] + \text{pyrimidine} \xrightarrow[\text{methylene chloride}]{} [PPh_4][Ru(DMSO)(pym)Cl_4]$$

The NMR spectrum of compound **6** in acetonitrile solution showed, along with signals for the tetraphenylphosphonium cation, five peaks for the protons of the coordinated ligands. The signal at −13.0 ppm is assigned to the coordinated DMSO as expected. There are four peaks seen for the pyrimidine ligand as each proton is unique in this case due to the loss of symmetry in the ligand once it has coordinated. The peak at 6.34 ppm has the narrowest line-width and is therefore assigned to the proton furthest from the paramagnetic center, H^4 [31]. The peak at −0.58 ppm is assigned to the H^5 proton similar to complex **3.** Two very broad peaks are observed at −1.7 and −6.5 ppm and are assigned to H^6 and H^2, respectively, those closest to the paramagnetic ruthenium center. In chloroform solution the peaks were observed at 6.32, −0.52, and −12.7 for the H^4, H^5, and DMSO protons, respectively. The H^2 and H^6 protons were too broad to be seen. The IR spectrum of **6** shows a terminal pym mode at 1585 cm^{-1} along with a ν(S–O) vibration at 1107 cm^{-1}, a ν(Ru–S) band at 421 cm^{-1}, and ν(Ru–Cl) vibrations at 339 and 324 cm^{-1}.

4. Conclusion

A library search in the Cambridge data file has revealed no Ru complexes containing both a sulfoxide and a monodentate pyrazine ligand. The two structures are also the first examples of Ru(III) compounds containing a monodentate pyrazine ligand. Three structures containing the pyrazine ligand bridging two Ru(III) atoms were found. These are the symmetric dimers $Na[(DMSO)Cl_4Ru(\mu\text{-}pz)RuCl_4(DMSO)]\cdot H_2O\cdot DMSO$ [27] and $(TMSO)_2H[(TMSO)Cl_4Ru(\mu\text{-}pz)RuCl_4(TMSO)]\cdot CH_3COCH_3$ (where TMSO = tetramethylenesulfoxide) [34], and the unsymmetrical $NH_4[(DMSO)Cl_4Ru(\mu\text{-}pz)RuCl_3(S\text{–}DMSO)(O\text{–}DMSO)]\cdot CH_3OH$ dimer [28]. It seems that pyrazine usually function as a bridging ligand and it is more difficult to prepare complexes containing monodentate pyrazine ligands. In the preparation of these types of complexes, the potential bridging ligand was added in a large excess, in order to reduce the formation of pyrazine-bridged oligomeric species. The same is true for the bipyridine and pyrimidine complexes.

The use of cations like PPh_4^+ or NR_4^+ which do not form H-bonds or other strong electrostatic attractions like alkali metals should prevent the formation of infinite chains or other materials with extended structures. In the few published structures containing Na cations with a tetrahedral environment, small oligomers are formed [22]. In the case of crystal **3**, the Na^+ cations have an octahedral

environment and it can form bridges between the Ru(III) complexed anions to form a ID extended structure. It might be interesting to replace the Na atom by a larger metal like Ba, which could accept a larger environment, for example, a coordination number of 8 and form multidimensional (2D or 3D) materials. The formation of such species is an area of current interest in supramolecular chemistry. The study of multidimensional compounds is important in material science, especially for paramagnetic species.

Scheme 1. Orotic acid.

equally important complexes of the orotate counter anion [36–39]. To our surprise, no reported data were found for either a bis(orotate) complex or a cadmium complex with the orotate ligand. Recently, we have reported some transition metal-orotate complexes with various *N*-donor ligands [19–24,38–41] and the first neutral orotic acid complexes [42]. Polydentate amine ligands generally coordinate to metal ions using all of the available N atoms as donors. Ethylenediamine (en) acts as a bidentate ligand in the majority of its complexes, chelating to one metal ion through both N atoms, and there are a few complexes in which it coordinates as a monodentate ligand [43,44]. Despite the importance of the en ligand in Co(III) chemistry, the first X-ray structure of monodentate en coordinated to Co(III) has been described only recently [45]. The study of Cd-en formation dates back to 1945, when three complexes were shown to form in aqueous solution [46], and only limited structural information is available in the literature [47–50]. Orotic acid complexes with 1,10-phenanthroline are also interesting due to their roles in biological systems such as binding of small molecules to DNA [51].

As a part of our continuing research on the synthesis and characterization of complexes of orotic acid with *N*-donor ligands, we describe in this study, the synthesis, spectroscopic, thermal characterization and crystal structure of the first bis(orotato)cadmium(II) complex with monodentate protonated ethylenediamine ligands, *trans*-$[Cd(HOr)_2(enH)_2]\cdot 2H_2O$ (**1**) and the crystal structure of the diaquabis(1,10-phenanthroline)cadmium(II) complex with two orotate counter ions, *cis*-$[Cd(H_2O)_2(phen)_2]$-$(H_2Or)_2\cdot 2H_2O$ (**2**).

2. Experimental

2.1. Preparation of *1*

A solution of ethylenediamine (0.25 g, 4 mmol) in water (10 mL) was dropped into a stirred solution of $3CdSO_4\cdot 8H_2O$ (1.54 g, 2 mmol) and orotic acid monohydrate (0.70 g, 4 mmol) in water (25 mL). The solution was heated to 60 °C in a temperature-controlled bath and stirred for 10 h at 60 °C. The crystals that formed after cooling to room temperature were filtered off and washed with 10 mL portions of distilled water and ethanol and dried in air. *cis*-$[Cd(H_2O)_2(phen)_2](H_2Or)_2\cdot 2H_2O$ was also prepared according to the method of Yesilel and Ölmez [39].

2.2. Materials and measurements

All used chemicals were analytical reagent products. Elemental analyses for C, H and N were carried out at the TÜBİTAK Marmara Research Centre. The IR spectrum was recorded in the 4000–500 cm^{-1} region with a Mattson 1000 FT-IR spectrometer using KBr pellets. Magnetic susceptibility measurement at room temperature was performed using a Sherwood Scientific MXI model Gouy magnetic balance. Thermal analysis curves (TG, DTG and DTA) were recorded simultaneously in a static air atmosphere with a Rigaku TG8110 thermal analyzer. The heating rate was 10 °C min^{-1} and the DTG sensitivity was 0.05 mg s^{-1}. The conductance value was measured on a 522 CRISON conductimeter.

The intensity data were collected at room temperature using an Enraf-Nonius CAD4 diffractometer [52] with Mo Kα radiation using the $w/2q$ scan mode. The cell parameters were determined from least-squares analysis using 25 centered reflections in the range $2.4° \leqslant \theta \leqslant 26.3°$. Three standard reflections were periodically measured (every 120 min) during data collection and showed no significant intensity variations. The structure was solved by direct methods using the solution program SHELXS97 [53] in the WINGX package [54] and refined on F_0^2 using SHELXL97 [53]. Absorptions corrections were applied using the integration method. All non-hydrogen atoms were refined, first with isotropic and then with anisotropic thermal displacement parameters by full matrix least squares. All H atoms on N and O atoms except C6 and C7 hydrogens were located from a difference Fourier map and freely refined, C6 and C7 hydrogens were treated using a riding model. An ORTEP drawing [55] of the molecule and the atomic numbering scheme is shown in Figs. 1–3. The crystal and experimental data are given in Table 1. Values of

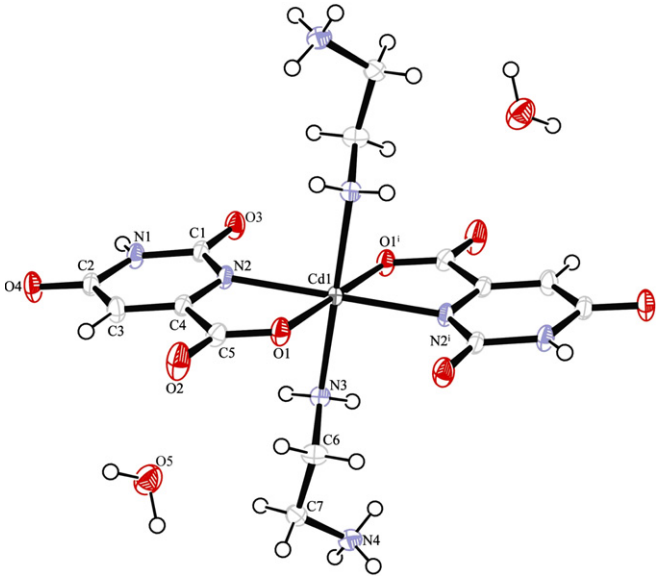

Fig. 1. The molecular structure of **1**.

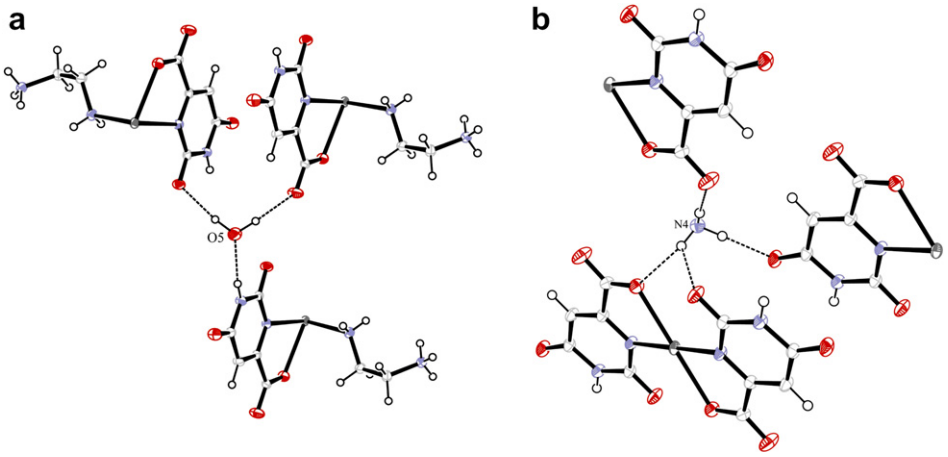

Fig. 2. The hydrogen bonding geometry of **1**.

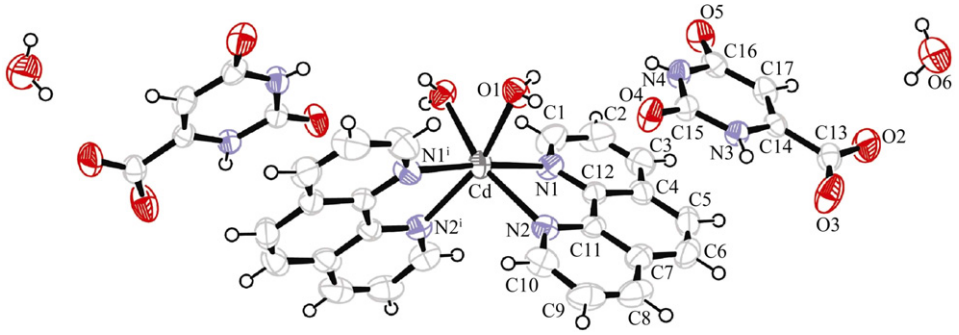

Fig. 3. The molecular structure of **2**.

selected bond lengths and angles, and hydrogen bonding geometries are given in Tables 2 and 3, respectively.

3. Results and discussion

The molar conductance value of the cadmium complex ($\Lambda_M = 40$ ohm^{-1} cm^2 mol^{-1}) indicates that *trans*-[Cd(HOr)$_2$(enH)$_2$]$\cdot$ 2H$_2$O is a non-electrolyte and the magnetic moment measurement shows that complex **1** is diamagnetic as expected.
