The ^1H NMR spectra of both $\mathbf{L}^1$ and $\mathbf{L}^2$ have been found characteristic. On complexation of $\mathbf{L}^1$ with Pd(II) the $-CH_2$ groups in the $-Se-CH_2-CH_2-N$ system show a group of three signals, two correspond to a single proton and one to two protons (one from each $NCH_2 + SeCH_2$). Their assignments are based on the HMQC NMR spectrum of **1**. However in the case of complex **2**, the $-Se-CH_2-CH_2-N$ system shows a group of four signals, each one corresponding to one proton. These assignments are also in agreement with the HMQC NMR spectrum of **1**. On complexation of $\mathbf{L}^1$ with Pd(II)/Pt(II) one signal for the H_6 protons is deshielded by ~0.60–0.70 ppm and the other one is shielded by ~0.14–0.25 ppm. Similarly, of the two signals of H_5, one shows shielding of 0.52–0.67 ppm and the other deshielding of 0.16–0.38 ppm. The CH_3 signal shifts to upfield marginally (up to 0.1 ppm) on complexation. The H_{13} signal shows deshielding of the order of 0.18–0.26 ppm on the formation of **1** and **2**. The deshielding of the H_3 signal was found to be between 0.58 and 0.64 ppm on complexation. In complex **3** the signal of H_6 was observed as a multiplet (upfield ~0.1 ppm). The NCH_2 signal was also found to be a multiplet and deshielded by an amount <0.02 ppm. The pattern of the $-SeCH_2$ signals were found to be similar to those of **1**, but deshielded by up to 0.2 ppm only. The lower deshielding appears to be the effect of one six membered ring formed in the case of **3**. In the proton spectrum of **4**, the OH signal was observed but shielded insignificantly (~0.1 ppm). The signals of H_6 and CH_3 were found to be overlapping but not much shifted with respect to those of the free ligand $\mathbf{L}^2$. The signal of H_7 was found as a multiplet, but unshifted with respect to that of free $\mathbf{L}^2$. The protons of the $SeCH_2$ group give a multiplet deshielded by 0.5 ppm with respect to those of free $\mathbf{L}^2$ and a triplet of doublets at a position similar to that of $\mathbf{L}^2$.

The $^{13}C\{^1H\}$ NMR spectra of both $\mathbf{L}^1$ and $\mathbf{L}^2$ are also characteristic. On formation of **1** and **2** signals of carbon atoms C_2, C_3, C_9, C_{10} and C_{11} exhibit deshielding of up to 12.5 ppm. The signal of C_6 shows maximum deshielding (11.3–12.5 ppm) on complexation. The deshielding of the C_1, C_5, C_8 and C_{13} signals is of the order of 3–6 ppm. The signals of C_4, C_7 and C_{11} have been observed to be shielded by 2–8 ppm with respect to those signals of free $\mathbf{L}^1$. On formation of **3** signals of carbon atoms C_1, C_7, C_9, C_{13}, C_{14} and CH_3 exhibit deshielding between 3.0 and 7.5 ppm. Of them, the signal of C_9 shows maximum deshielding (7.5 ppm) on complexation. The deshielding of signals C_2, C_3, C_5 and C_{10} is of the order of 0.8 –1.0 ppm. The signals of C_4, C_6, C_8, C_{11} and C_{12} have been observed to be shielded (by up to 2.8 ppm) with respect to those of free $\mathbf{L}^2$. On complexation of $\mathbf{L}^2$ with Pt(II), the signals of most of the carbon atoms are shifted marginally (0.1–0.6 ppm), except those of C_1, C_4 and C_5 which are deshielded by 3.3, 3.2 and 3.0 ppm, respectively. These observations suggest that in **1**–**3** the ligands $\mathbf{L}^1$ and $\mathbf{L}^2$ coordinate in a tridentate mono-anionic mode. The bonding of $\mathbf{L}^2$ with Pt(II) appears to be through N and Se only.

In the $^{77}Se\{^1H\}$ NMR spectra, ligands $\mathbf{L}^1$ and $\mathbf{L}^2$ exhibit singlets at 282.3 and 286.6 ppm, respectively, which are deshielded (~25–29 ppm) with respect to those of the precursor selenated amines. On complexation of $\mathbf{L}^1$ with Pd(II) and Pt(II), the signals in the $^{77}Se\{^1H\}$ NMR spectra were found to be shifted downfield by 158 and 105 ppm respectively. In the case of **2**, the signal at 387.4 appears as a triplet because of $^1J(^{195}Pt–Se)$ coupling (2043 Hz). On formation of **3** and **4**, the deshielding of the signals in the ^{77}Se NMR spectra was found only to be 6.9 and 51.3 ppm. This is probably due to formation of one six membered ring in these cases (see Table 1).

Scheme 1.

3.2. Crystal structures

The crystal structures of $\mathbf{L}^1$, $\mathbf{L}^2$, **1** and **2** were solved. The structures of **1** and **2** are isomorphous. The molecular structure of $\mathbf{L}^1$ is shown in Fig. 1 and its selected bond lengths and angles are given in Table 2. The C–Se bond lengths of 1.916(4) and 1.953(4) Å are consistent with the earlier reports (1.939 Å) [20]. The Se–C(Ar) bond distance is somewhat shorter than the Se–C(alkyl) distance, as

expected. Similarly the C–Se–C bond angle of 99.1(2)° was found as expected. Intramolecular hydrogen bonding, O–H···N, exists in the structure of $\mathbf{L}^1$. A perspective view of the structure of $\mathbf{L}^2$ is shown in Fig. 2. It also has intramolecular hydrogen bonding, O–H···N. The Se–C bond

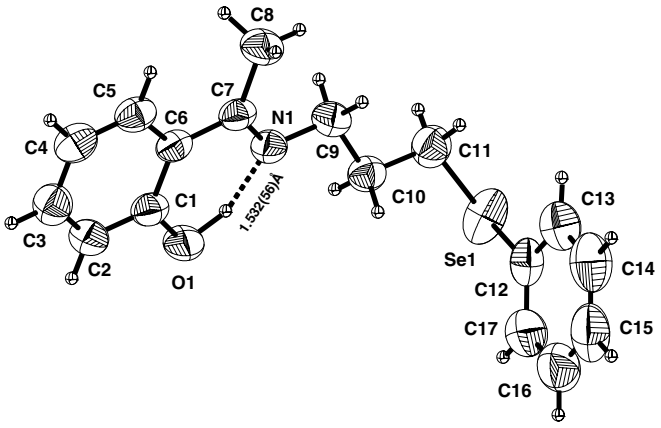

Fig. 2. ORTEP diagram of $\mathbf{L}^2$ with 50% probability ellipsoids.

distances, 1.914(3) and 1.956(3) Å and the C–Se–C bond angle are consistent with those of $\mathbf{L}^1$ and earlier reports [20]. In this case it is also found that the Se–C(Ar) bond distance is shorter than the Se–C(alkyl) bond distance (see Table 3).

The molecular structure of **1** is shown in Fig. 3 and its selected bond distances and angles are given in Table 4. In the asymmetric unit there are two chemically similar but crystallographically independent molecules and two molecules of chloroform solvent. The **1** is the first example of a crystal structure of a Pd complex of a (Se, N, O^-) ligand. The geometry around Pd is square planar. The Pd–Se

bond length, 2.3669(11) Å, is shorter than those reported for $[Pd(PEt_3)_2(SePh)(PO(OPh)_2)]$ (2.518(9) Å) [21] and $[Pd(Me_2PCH_2CH_2PMe_2)(Me)(SeC_6H_4\text{-}4\text{-}Cl)]$ (2.4483(8) Å) [22]. The shorter Pd–Se bond in **1** may be attributed to the tridentate nature of ligand $\mathbf{L}^1$, which makes two chelate rings and forces Se to bind with Pd(II) somewhat strongly in comparison to those complexes in which the selenium ligand is a monodentate one. The Pd–N, Pd–O and Pd–Cl bond distances, 2.003(7), 1.977(6) and 2.305(2) Å, respectively, are consistent with earlier reports [Pd–N = 2.01(1) Å, Pd–O = 2.03(1) Å and Pd–Cl = 2.290 (4) Å] on a Pd(II) complex of a tridentate ligand of the (Te, N, O^-) type [14]. In Fig. 4 the molecular structure of **2** is shown. In Table 4 selected bond lengths and angles are given. In the unit cell of the crystal of **2** also there are two almost similar molecules. One molecule of chloroform per molecule of **2** is also present in the lattice. The structure of **2** is also the first example of a crystal structure of a Pt-complex of a (Se, N, O^-) ligand. The geometry around Pt is nearly square planar. The Pt–Se bond length, 2.3543(16) Å, is consistent with the earlier reported value in the case of $[CH_3SeCH_2CH_2CH(COOMe)NH_2 \cdot PtCl_2]$ (2.3697(8) Å) [23], but is shorter than those reported for *cis*-$[Pt(SePh)_2(PPh_3)_2]$ (2.4970(9), 2.4604(10) Å) [24] and *trans*-$[Pt(SePh)_2$(2,9-dimethyl-1,10-phenanthroline)(MeOOCCH=CHCOOMe)] (2.5197, 2.5142 Å) [25]. The shorter Pt–Se bond in **2** may again be attributed to the tridentate nature of the ligand $\mathbf{L}^1$, as in the case of the Pd(II) complex mentioned above. The absence of the *trans* influence may also contribute, particularly in comparison with *trans*-$[Pt(SePh)_2$(2,9-dimethyl-1,10-phenanthroline)(MeOOCCH=CHCOOMe)]. The Pt–N and Pt–Cl bond distances, 1.988(12) and 2.306(4) Å, respectively, are consistent with the earlier reports [23], 2.043(5) and 2.294(2), 2.322(2) Å, respectively. The Pt–O bond length of 1.976(10) Å is comparable with earlier reports (2.034 Å) [26]. On comparing Pd/Pt–N, Pd/Pt–O, Pd/Pt–Cl and Pd/Pt–Se bond lengths with the sum of their covalent radii 2.03/2.05, 2.01/2.03, 2.27/2.29 and 2.44/2.46 Å. respectively, it appears that the observed bond distances are shorter than this sum, except in the case of Pd/Pt–Cl where the observed values are marginally higher. This indicates that coordination of $\mathbf{L}^1$ is quite strong with Pd as well as with Pt.

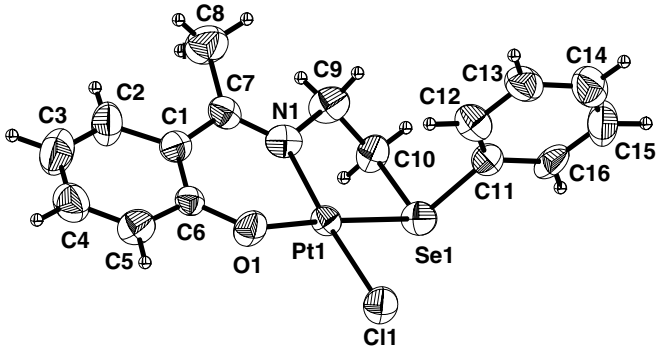

Fig. 4. ORTEP diagram of **2** with 50% probability ellipsoids.

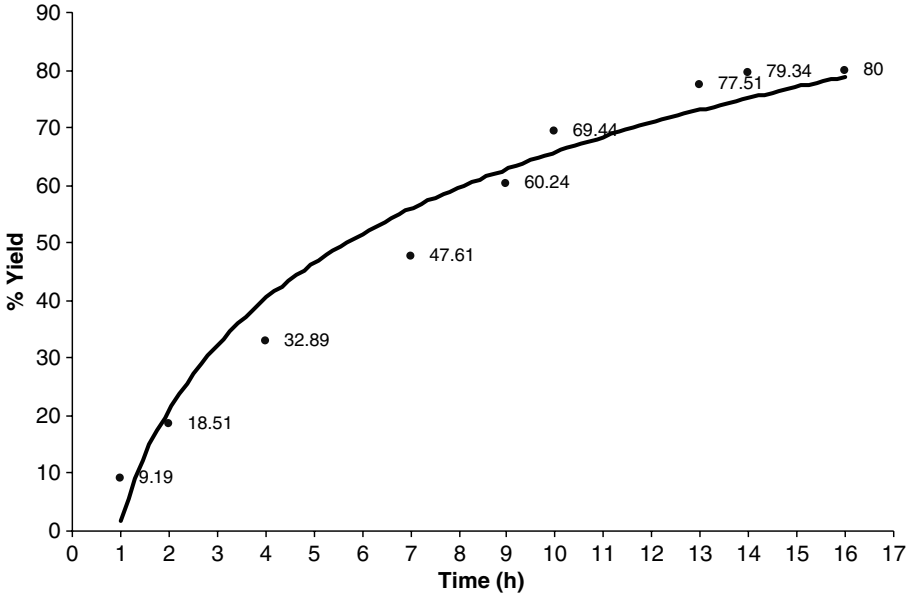

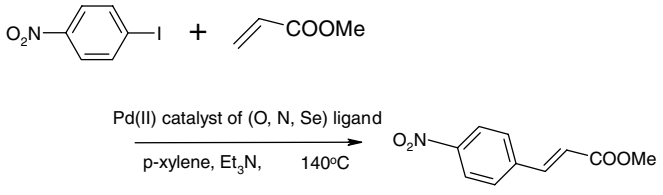

Fig. 5. Kinetic profile of the Heck reaction.

3.3. Application as a homogeneous catalyst for the Heck reaction

1 was found to be suitable to catalyze the Heck coupling reaction, as shown below with ~80% yield.

Using **1**, the time for completion of the reaction is only 14 h, less than that of a recently reported palladium(II) complex of a bidenate Se-ligand (20–90 h at a similar reaction temperature) [17]. The kinetic profile of the above reaction followed by proton NMR is shown in Fig. 5. The temperature cannot be much increased beyond 140 °C as the yield decreases. However at a lower temperature, around 100 °C, the yield goes down to 40–45%. The reaction was carried out in the presence of Na_2CO_3 at 140 °C and the yield was found to be only 20–25%. The trialkylamines (alkyl group = Me, Et, *n*-Bu or *t*-Bu) give the maximum yield.

4. Conclusion

Selenated Schiff bases 2-OH-$C_6H_4C(CH_3)$=$N(CH_2)_n$SePh ($n = 2$, $\mathbf{L^1}$; $n = 3$, $\mathbf{L^2}$) have been designed as such species are scantly known and explored for complexation with Pd(II)/Pt(II). Proton, carbon-13 and selenium-77 NMR spectra of the complexes support the coordination of $\mathbf{L^1}$ and $\mathbf{L^2}$ through Se. In the case of **2**, satellites due to coupling with ^{195}Pt were observed (^1J (^{195}Pt–Se) = 2043 Hz). **1** and **2** are the first examples of crystal structures of Pd and Pt complexes of a (Se, N, O^-) ligand. **1**is explored for the homogeneous catalysis of the Heck reaction between methyl acrylate and *p*-iodonitrobenzene. The yield is ~80% and the reaction time is only 14 h.

The effect of steric hindrance on the Fe(II) complexes of triazine-containing ligands

Abstract

Fe(II) complexes based on ligands containing a 1,3,5-triazine core have been synthesised and characterised and their electrochemical, spectroscopic and magnetic properties have also been investigated. The incorporation of various substituted metal-binding heterocycles into the 2,4-positions of the triazine allows the properties of the complexes to be modified considerably. Whereas the magnetic moments of the pyridyl (**1b**: 2.4 B.M.) and pyrazyl (**1c**: 4.2 B.M.) substituents lead to spin transitions, the 6-picolyl (**1d**: 5.4 B.M.) substituent is a pure Curie paramagnet at 300 K. Interestingly, the Fe(II) complex of bromo-phenyl-2,2′:6″,2‴-terpyridine (**1a**) displays significant anion effects in the solid state, with the ClO_4 salt exhibiting major diamagnetic contributions (2.1 B.M. at 300 K) and the PF_6 salt has more significant paramagnetic contributions (3.5 B.M. at 300 K). The Fe–N bond distances observed in the 6-picolyl complex $[Fe(\mathbf{1d})_2](ClO_4)_2$ for both the central rings 2.084 (5) Å and the distal rings 2.254 (4) and 2.369 (4) Å are significantly longer than those of the pyridyl complex $[Fe(\mathbf{1b})_2](ClO_4)_2$ (centre: 1.869 (4) Å; distal: 1.992 (4) Å; distal: 2.005 (4) Å) due to steric strain, thus generating high-spin $[Fe(\mathbf{1d})_2](ClO_4)_2$.

1. Introduction

The ability to control and fine-tune the magnetic and electronic properties of transition metal complexes is fundamental to the development of efficient molecular electronic devices based on metal ions [1]. Transition metal ions have therefore been included in a wide variety of supramolecular materials [2,3]. Complexes with the potential to undergo a change in spin state are particularly good targets for development of molecular switches as the optical, magnetic and geometric properties may change significantly following a change in spin state [4]. In this regard, complexes with d^6 to d^7 electronic configurations are of great interest as they are able to undergo spin transitions between their low-spin and high-spin states and, consequently, Fe(II) and Co(II) coordination complexes have been intensely studied [5].

In general, Fe(II) complexes incorporating polypyridine ligands are low spin and diamagnetic at room temperature which allows temperature-induced changes in spin state to be monitored by NMR spectroscopy [6]. The spin state of the complexes may also be manipulated by incorporating electron-donating or -accepting groups onto the ligand framework and through the introduction of steric bulk, steric strain or mechanical strain within the ligand [7–10]. These modifications allow both low- and high-spin complexes to be obtained, as well as complexes in which the Fe(II) cations are able to access both states. Another approach to alter the properties of the complexes involves

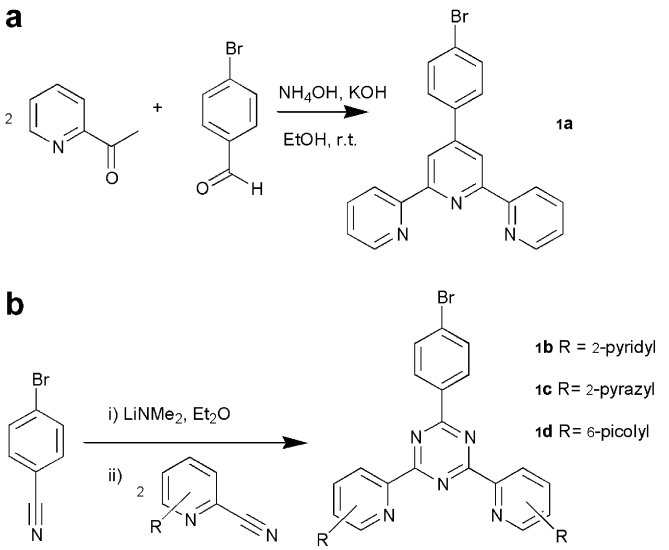
substitution of the pyridyl rings within the tpy-motif with different heterocycles as substitution of distal pyridyl rings in the tpy core is relatively facile [11–19]. There are, however, fewer examples of Fe(II) complexes of tridentate ligands in which the central ring has been substituted [20,21]. One example of such a ligand is 2,4,6-tris(2′-pyridyl)-1,3,5-triazine (tpt), which is readily synthesised and commercially available [22]. The $Fe(tpt)_2^{2+}$ complex is diamagnetic and stable at room temperature [23–26], although due to the nature of the tridentate ligand, further functionalisation is difficult.

We have previously shown that a pendant phenyl ring in triazine ligands of the type 2,4-di(2′-pyridyl)-6-(phenyl)-1,3,5-triazine can be readily functionalised, thus enabling fine tuning of the electronic and redox properties in Ru(II) and Co(II) complexes [27–30]. For example, if a bromophenyl-functionalised triazine ligand is employed, the arrangement of the cations in the solid state is dictated by non-covalent, halogen–halogen interactions (Fig. 1) [28,30]. As such, the weak ligand field strength and facile functionalisation of these ligands make them a perfect platform to investigate the electrochemical, magnetic and spectroscopic properties in their Fe(II) complexes.

Herein, we report the synthesis, electronic and magnetic properties of a series of triazine-based Fe(II) complexes. Whilst functionalisation of the pendant phenyl ring has proved effective in the fine tuning of the electronic properties, functionalisation or substitution of the pyridyl rings provides coarse changes in the electronic, redox and magnetic properties of the assembled complexes.



2. Results and discussion

2.1. Synthesis

In order to develop novel properties in a series of Fe(II) complexes, we required a flexible synthetic strategy to obtain various ligands. Triazine appeared to be the best choice for incorporation into the ligand design as it has a weaker ligand field strength than pyridine, thereby favouring the formation of high-spin complexes. Thus, in a similar fashion to the one-step synthesis of tpy (Scheme 1a) [32], we examined a triazine ring-forming reaction to afford variably substituted ligands (Scheme 1b) [27–29,33].

The synthetic procedure reported for triazine ligands, Fig. 1b, is general for a range of R groups substituted on the phenyl ring. As seen in Fig. 2, we were interested in retaining the bromo-phenyl pendant ring and in examining the versatility of this reaction by methyl substitution on the distal pyridyl rings (Fig. 2, **1c**) or replacing the pyridyl rings with an alternative heterocycle (pyrazine, Fig. 2, **1d**). For the synthesis of **1c** and **1d**, bromobenzonitrile was added to a stirred solution of $LiNMe_2$ in anhydrous diethyl ether. The amidinate intermediate that forms reacts with 2 equiv. of 2-cyanopyrazine or 2-cyano-6-methylpyridine and cyclisation affords ligands **1c** and **1d**, respectively, on work-up.

Fe(II) complexes of ligands **1a** and **1b** could be synthesised as both the PF_6^- and ClO_4^- salts, however, complexes of ligands **1c** and **1d** were only isolated as perchlorate salts due to the instability of the complexes to counter-ion exchange. Complexes $[Fe(\mathbf{1a})_2](PF_6)_2$ and $[Fe(\mathbf{1b})_2](PF_6)_2$

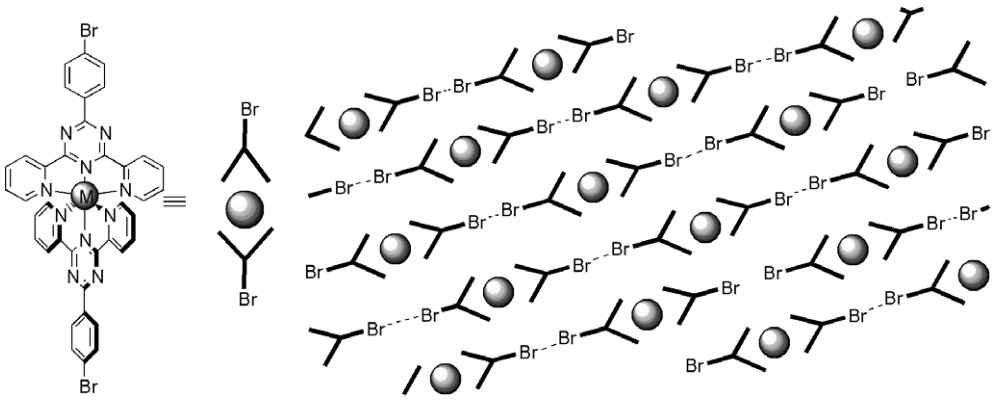

Fig. 1. Halogen–halogen interactions in Ru(II), Fe(II), Co(II) and Cu(II) complexes of bromine-functionalised triazine ligands [31].

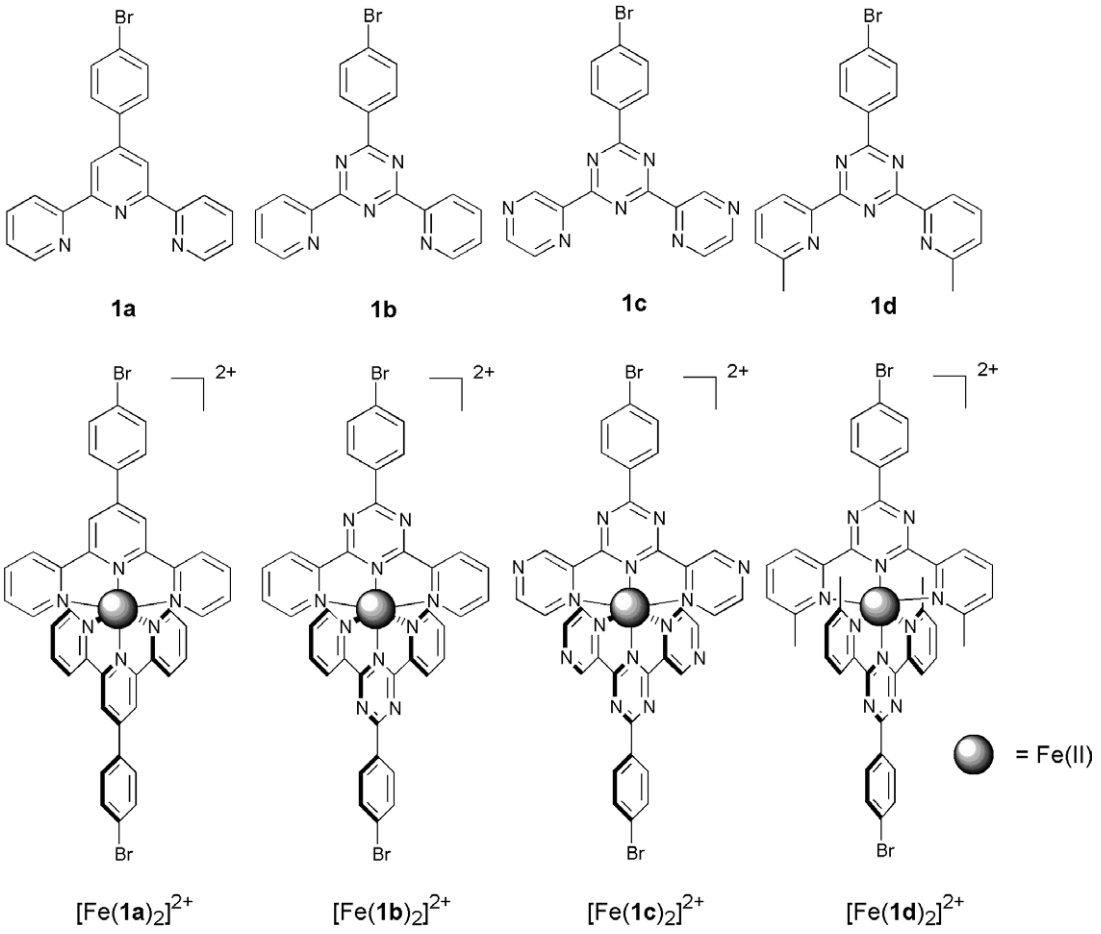

Fig. 2. The brominated terpyridine and triazine ligands and their Fe(II) complexes used in this study.

were synthesised by adapting a reported procedure [31]. Complexes of the type $Fe(L)_2(ClO_4)_2$ were synthesised by addition of $Fe(ClO_4)_2 \ldots 6H_2O$ in acetonitrile to a stirred solution of the ligand in acetonitrile. After 20 min of heating, the solvent was removed under reduced pressure and the mixture was taken up in a small amount of acetonitrile and precipitated in Et_2O. The purple or red product was isolated by filtration and dried.

The ligands and complexes were characterised by ^1H NMR and their chemical shifts are shown in Table 1. The variable temperature spectra of complex $[Fe(\mathbf{1b})_2](PF_6)_2$ are shown in Fig. 3.

Complexes $[Fe(\mathbf{1a})_2]^{2+}$, $[Fe(\mathbf{1b})_2]^{2+}$ and $[Fe(\mathbf{1c})_2]^{2+}$ showed signals in the 7–11 ppm range at room temperature indicating the presence of low-spin complexes. However, less resolution was observed for the ^1H signals closest to the coordinating N-atom in $[Fe(\mathbf{1b})_2]^{2+}$ and $[Fe(\mathbf{1c})_2]^{2+}$ as their PF_6^- and ClO_4^- salts. Increasing the temperature resulted in the loss of signal structure of the next closest signals, H_3 and H_5, followed by H_4, furthest from the coordinating site (Fig. 3). The phenyl protons maintained their doublet character without any broadening as they are furthest from the metal centre.

The shift to low field of H_6 is unexpected as compared to structurally similar paramagnetic complexes based on the $Fe(tpt)_2^{2+}$ motif in which a high-field shift is observed into the negative ppm range [9]. In addition, other complexes showing spin-crossover properties had ^1H NMR spectra

with paramagnetic signals corresponding to the high-spin complex and diamagnetic sub-spectrum as a result of slow exchange of the two states. However, no clear sub-spectrum or paramagnetic spectrum was observed for $[Fe(\mathbf{1b})_2](PF_6)_2$ indicating that the exchange of spin states is occurring faster than the NMR time scale. The room temperature spectrum is more characteristic of a low spin complex despite the broadening observed, suggesting that the diamagnetic contribution is greater in the equilibrium between spin states. $[Fe(\mathbf{1d})_2](ClO_4)_2$ displays paramagnetic shifts in its ^{1}H NMR spectra regardless of temperature and solvent. The signals were assigned by comparison to the previously published paramagnetic spectra of Fe (II) tpy-type complexes [9].

2.2. X-ray crystallography

Purple crystals of $[Fe(\mathbf{1b})_2](ClO_4)_2$ (Fig. 4) and $[Fe(\mathbf{1d})_2](ClO_4)_2$ (Fig. 5) were obtained by slow diffusion of isopropyl ether into acetonitrile solutions of the complexes. Efforts to obtain crystals of $[Fe(\mathbf{1c})_2](ClO_4)_2$ were unsuccessful, however, addition of excess NH_4PF_6 to the acetonitrile solution followed by filtration and crystallisation by slow diffusion yielded purple crystals as the mixed salt (Fig. 5). Attempts to crystallise $[Fe(\mathbf{1a})_2](ClO_4)_2$ were also unsuccessful, but acceptable crystals were obtained as the PF_6^- salt (Fig. 4). A summary of the crystal and structure refinement data for the complexes is gathered in Table 2 and bond length and angle data is in Table 3.

Both complexes $[Fe(\mathbf{1a})_2](PF_6)_2$ and $[Fe(\mathbf{1b})_2](ClO_4)_2$ crystallised in the triclinic space group $P\bar{1}$ with one complete molecule, two counter-ions and two or three acetonitrile solvent molecules in the asymmetric unit (Fig. 4). Complexes $[Fe(\mathbf{1c})_2](ClO_4)(PF_6)$ and $[Fe(\mathbf{1d})_2](ClO_4)_2$ crystallised in the monoclinic space group $C2/c$ (Fig. 5).

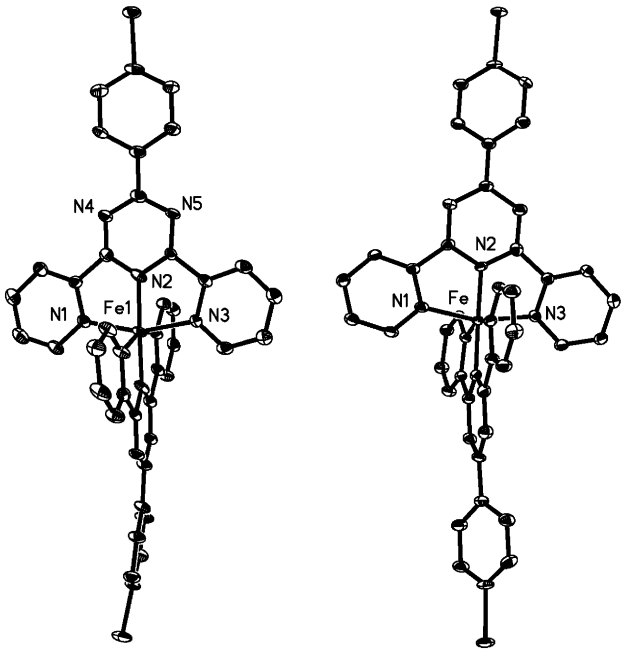

Fig. 4. X-ray crystal structures of complexes $[Fe(\mathbf{1a})_2](PF_6)_2$ and $[Fe(\mathbf{1b})_2](ClO_4)_2$ as ORTEP representations. Thermal ellipsoids are set at 50%. The anions and solvent molecules of crystallisation have been omitted for clarity.

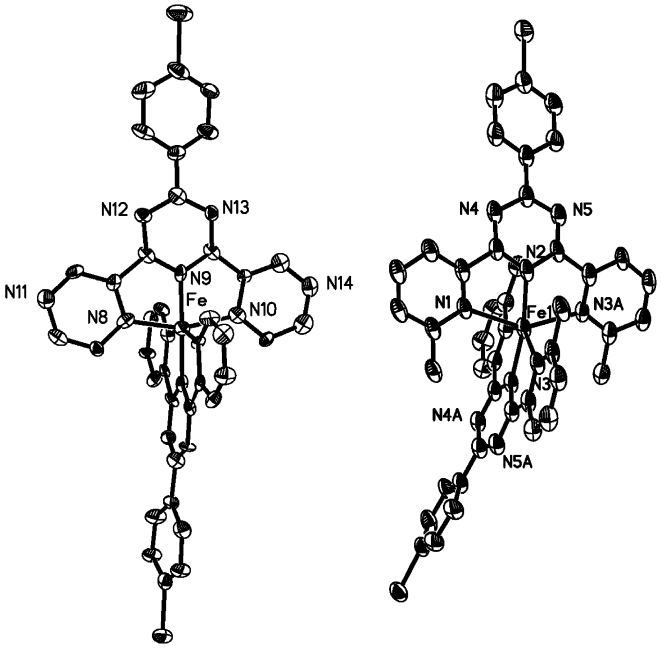

Fig. 5. X-ray crystal structures of complexes $[Fe(\mathbf{1c})_2](ClO_4)(PF_6)$ and $[Fe(\mathbf{1d})_2](ClO_4)_2$ as ORTEP representations. Thermal ellipsoids are set at 50%. The anions and solvent molecules of crystallisation have been omitted for clarity.

The Fe–N (centre) bond distances in all the complexes are shorter than the Fe–N (distal) bond distances (Table 3). The Fe–N bond distances of $[Fe(\mathbf{1a})_2](PF_6)_2$ were unexceptional for Fe(tpy)-type complexes and those for complex $[Fe(\mathbf{1b})_2](ClO_4)_2$ were similar to those found in the

previously reported structure reported as the PF_6^- salt [31]. The Fe–N bond distances in $[Fe(\mathbf{1c})_2](ClO_4)(PF_6)$ were lengthened to the central triazine ring as compared to $[Fe(\mathbf{1b})_2](ClO_4)_2$, but shorter to the peripheral pyrazine rings when compared to the pyridyl rings of $[Fe(\mathbf{1b})_2](ClO_4)_2$.

A significant elongation of Fe–N bond distances is observed in complex $[Fe(\mathbf{1d})_2](ClO_4)_2$ for both the central rings and the distal rings due to a combination of steric strain imposed by the methyl substituents and the consequential occupation of anti-bonding metal-based orbitals in the high-spin complex (Table 3). The bond elongations are consistent with the formation of a high-spin complex [9]. Smaller bite angles (72–73°) are reported for the high-spin complex due to the elongation of the Fe-N bonds consistent with observations made from high-spin tpy-based complexes [9].

Intermolecular Br–Br interactions are observed in all of the complexes in the extended lattice similar to those reported for Co(II) complexes of related ligands [29,31]. Intermolecular Br–Br distances of 3.46, 3.42 and 3.55 Å are observed for $[Fe(\mathbf{1a})_2](PF_6)_2$, $[Fe(\mathbf{1b})_2](ClO_4)_2$ and $[Fe(\mathbf{1d})_2](ClO_4)_2$, respectively, which are all shorter than the sum of the van der Waals radii for Br giving rise to 1-dimensional tapes running throughout the lattice. In complex $[Fe(\mathbf{1c})_2](ClO_4)(PF_6)$, the Br–Br contacts have lengthened to 4.26 Å.

2.3. Electrochemistry and electronic spectroscopy

The redox potentials for the Fe(II) complexes as their ClO_4^- salts are shown in Table 4. The Fe(III)/(II) couples dominate the anodic region and ligand-based reductions dominate the cathodic region of the cyclic voltammograms.

Table 4

$[Fe(tpy)_2]^{2+}$[c]	1.10 (70)	−1.13 (70)	−1.27 (60)	−1.94 (70)	

[a] Potentials are in volts vs SCE for acetonitrile solutions, 0.1 M in TBAP, recorded at 25 ± 1 °C at a sweep rate of 200 mV/s. Unless otherwise stated couples are reversible.
[b] Irreversible; potential is given for the cathodic wave. (ΔE_p in parentheses (mV)).
[c] From Ref. [26].

The Fe(III)/(II) couples of the triazine-based complexes are irreversible as their ClO_4^- salts, although the same couple of $[Fe(\mathbf{1b})_2](PF_6)_2$ is reversible, presumably due to the improved solubility of the PF_6^- salts in acetonitrile solution [31]. The metal-based oxidation of $[Fe(\mathbf{1a})_2](ClO_4)_2$ is observed at +1.11 V, which is in agreement with the parent complex $[Fe(tpy)_2]^{2+}$ (+1.10 V) indicating that bromo-phenyl substitution of the tpy core has a minimal effect on the metal-based orbitals. The same Fe(III)/(II) couple in the triazine-based complexes occurs at a significantly more positive potential (1.38–1.89 V) due the electron-deficient nature of the triazine ligands as compared to the tpy ligand.

Similarly, the triazine-based complexes are easier to reduce than the terpyridine complexes. In complex $[Fe(\mathbf{1a})_2](ClO_4)_2$, a one-electron reduction of one terpyridine is observed followed by a second one-electron reduction of the second terpyridine ligand with a peak separation of 120 mV between the reductions. The separation between the reductions of the first and second triazine-based ligand in $[Fe(\mathbf{1b})_2](ClO_4)_2$ is 150 mV, which indicates greater sensitivity of the triazine ligands to reductive processes. An additional triazine-based reduction is observed on both ligands to give a total of four reductions for the complexes of triazine ligands.

The Fe(II) centres of complexes $[Fe(\mathbf{1c})_2](ClO_4)_2$ and $[Fe(\mathbf{1d})_2](ClO_4)_2$ are more difficult to oxidise and the ligands easier to reduce than triazine complex $[Fe(\mathbf{1b})_2](ClO_4)_2$ (Fig. 6). The pyrazine rings are more electron deficient than the pyridyl rings in $[Fe(\mathbf{1b})_2](ClO_4)_2$, thereby withdrawing more electron-density away from the metal centre. The positive shift, despite the introduction of electron-donating methyl groups in $[Fe(\mathbf{1d})_2](ClO_4)_2$, is a consequence of the high spin-state and weaker ligand field imposed by the elongation of the Fe–N bond distances.

The absorption data for the complexes are gathered in Table 5 and the absorption spectra of $[Fe(\mathbf{1a})_2](ClO_4)_2$, $[Fe(\mathbf{1b})_2](ClO_4)_2$ and $[Fe(\mathbf{1d})_2](ClO_4)_2$ are shown in Fig. 7. The UV regions of the electronic spectra for all of the Fe(II) complexes are dominated by ligand-centred $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions. The visible regions are dominated by MLCT bands, albeit they are much less intense in the high-spin complex $[Fe(\mathbf{1d})_2](ClO_4)_2$ compared to the remaining complexes. The change in intensity may be a result of poor overlap between the ligand and metal orbitals due to the elongated bond distances. The ^{1}MLCT absorption band in complex $[Fe(\mathbf{1a})_2](ClO_4)_2$ is relatively sharp (569 nm) with a high energy shoulder. The transition

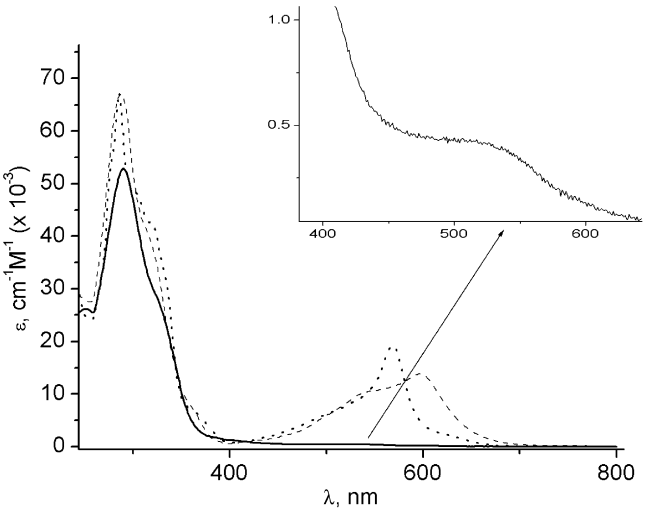

Fig. 7. Electronic spectra in acetonitrile for complexes $[Fe(\mathbf{1a})_2](ClO_4)_2$ (dotted-line), $[Fe(\mathbf{1b})_2](ClO_4)_2$ (dashed-line) and $[Fe(\mathbf{1d})_2](ClO_4)_2$ (solid line). $[Fe(\mathbf{1d})_2](ClO_4)_2$ is expanded in the visible region in the inset.

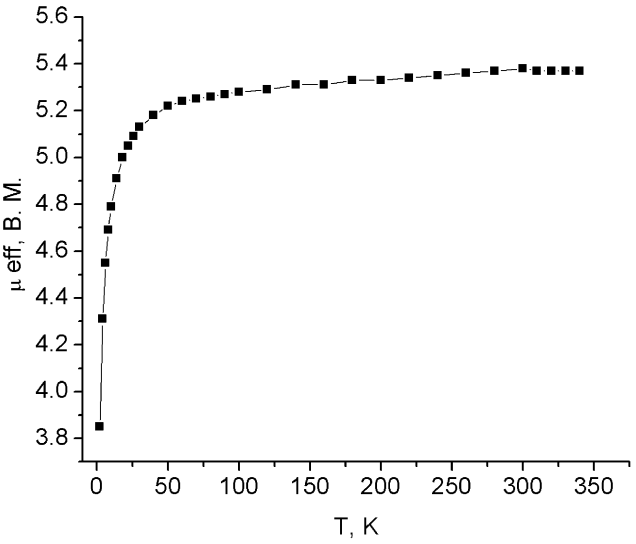

Fig. 8. Plot of the variable temperature magnetic moment of $[Fe(\mathbf{1d})_2](ClO_4)_2$.

is red-shifted compared to the parent complex $[Fe(tpy)_2]^{2+}$ (552 nm) as the bromo-phenyl substituent lowers the energy of the ligand-based LUMO [35]. The triazine complex, $[Fe(\mathbf{1b})_2](ClO_4)_2$, has two resolved MLCT bands at 542 and 597 nm, which may be a consequence of transitions to a triazine-based LUMO and a second, low-lying, triazine-based LUMO + 1 in the ligand. Thus, the two transitions may be considered as MLCT transitions to the ligand-based LUMO and LUMO + 1.

2.4. Magnetic measurements

The magnetism of the complexes was studied in solution at room temperature using the modified Evan's method and in the solid state using a SQUID magnetometer from 2 to 300 K. In solution, it was confirmed that $[Fe(\mathbf{1a})_2]^{2+}$ with both PF_6^- and ClO_4^- cations are diamagnetic at room temperature, consistent with the diamagnetic solution behaviour previously reported for an Fe(II) complex of a tolyl-tpy ligand [7]. The parent complex, $[Fe(tpy)_2]^{2+}$, is considered low spin at room temperature regardless of its counter-anion [34]. In contrast, $[Fe(\mathbf{1a})_2](PF_6)_2$ has significant paramagnetic contributions to the magnetic moment (3.5 B.M.) at 300 K in the solid state, whereas the perchlorate salt remains largely diamagnetic [7]. The magnetic moment of complex $[Fe(\mathbf{1b})_2]^{2+}$ as both the PF_6^- and ClO_4^- salts differ marginally between 2 and 300 K, with the PF_6^- salt having slightly greater paramagnetic contribution (2.5 B.M.) and a more gradual increase in the magnetic moment up to room temperature. Complex $[Fe(\mathbf{1c})_2](ClO_4)_2$ shows behaviour similar to complex $[Fe(\mathbf{1b})_2](ClO_4)_2$ with a magnetic moment of 4.2 B.M. at 300 K, more characteristic of a high-spin complex.

A plot of $1/\chi$ versus temperature for complex $[Fe(\mathbf{1d})_2](ClO_4)_2$ indicates a zero value for the Weiss constant, thereby suggesting that complex $[Fe(\mathbf{1d})_2](ClO_4)_2$ is a pure Curie paramagnet. The magnetic moment measured between 20 and 300 K corresponds to a high-spin Fe(II) complex ($S = 2$), with 5.4 B.M. measured at 340 K (Fig. 8). Below 20 K there is a reduction in the magnetic moment, down to 3.9 B.M. at 4 K, associated with zero-field splitting of the spin quintet state.

3. Conclusions

In solution, $[Fe(\mathbf{1a})_2]^{2+}$ is low spin, with no evidence of a paramagnetic contribution, whereas solid state measurements indicate significant high-spin contributions as the PF_6^- salt but not as the ClO_4^- salt. The solution and solid state magnetic data for complexes $[Fe(\mathbf{1b})_2](ClO_4)_2$ and $[Fe(\mathbf{1c})_2](ClO_4)_2$, on the other hand, indicate a small paramagnetic contribution to a largely diamagnetic ground state, due to the weaker ligand field strength of the triazine-containing ligands. Modification of complex $[Fe(\mathbf{1b})_2](ClO_4)_2$ with methyl substituents in the 6-position of the pyridyl rings induces sufficient steric strain to force a high-spin configuration over the temperature range 20–300 K. As too much steric strain leads to paramagnetic complexes, removing some of the steric strain may lead to spin-crossover complexes. We are currently undertaking further investigations of phenyl-tpy type ligands and the effects of substitution at other positions on the ligands on the magnetic and electrochemical properties of Fe(II) complexes of tridentate ligands.

4. Experimental

4.1. Materials and instrumentation

Nuclear magnetic resonance (NMR) spectra were recorded in CD_3CN at room temperature (r.t.) on a Bruker AV400 spectrometer at 400 MHz for ^1H NMR and at

100 MHz for ^{13}C NMR. Chemical shifts are reported in part per million (ppm) relative to residual solvent protons (1.93 ppm for acetonitrile-d_3) and the carbon resonance of the solvent. Absorption spectra were measured in deaerated acetonitrile at r.t. with a Cary 500i UV–Vis–NIR Spectrophotometer.

Electrochemical measurements were carried out in argon-purged acetonitrile at room temperature with a BAS CV50W potentiostat interfaced to a PC. The working electrode was a Pt electrode. The counter electrode was a Pt wire, and the pseudo-reference electrode was a silver wire. The reference was set using an internal 1 mM ferrocene/ferrocinium sample at 395 mV versus SCE in acetonitrile and 432 mV in DMF. The concentration of the compounds was 1 mM. Tetrabutylammonium hexafluorophosphate (TBAP) was used as supporting electrolyte and its concentration was 0.10 M. Cyclic voltammograms were obtained at scan rates of 50, 100, 200, and 500 mV/s. For irreversible oxidation processes, the cathodic peak was used as E, and the anodic peak was used for irreversible reduction processes. The criteria for reversibility were the separation of 60 mV between cathodic and anodic peaks, the close to unity ratio of the intensities of the cathodic and anodic currents, and the constancy of the peak potential on changing scan rate. The number of exchanged electrons was measured with OSWV, and by taking advantage of the presence of ferrocene used as the internal reference.

Variable temperature magnetic data were obtained with a Quantum Design MPMS5S Squid magnetometer operating in DC mode. Samples were prepared in gelatine capsules or aluminium cups, and measured data were corrected for sample holder response, and underlying sample diamagnetism using Pascal corrections.

Experimental uncertainties are as follows: absorption maxima, ±2 nm; molar absorption coefficient, 10%; redox potentials, ±10 mV.

X-ray crystallographic data for all complexes were collected from a single crystal sample, which as obtained by slow diffusion of isopropyl ether into acetonitrile solutions of the complexes, were mounted on loop fibers. Data were collected using a Bruker Platform diffractometer, equipped with a Bruker SMART 2K Charged-Coupled Device (CCD) Area Detector using the program SMART and normal focus sealed tube source graphite monochromated Cu Kα radiation.

Empirical adsorption corrections were applied using the SADABS program.

The structures were solved by direct method and refined using full-matrix least squares on F^2 using the SHELXTL suite of programs [36]. The H atoms were generated geometrically and were included in the refinement in the riding model approximation.

4.2. Synthetic procedures

Complexes **1a**, **1b** and $Fe(L)_2(PF_6)_2$ were synthesised as previously described [29,31,32].

4.2.1. *1c*

^{n}BuLi (1.6 M in hexanes, 11.0 mL, 0.018 mol) was added dropwise to a stirring solution of $HNMe_2$ (2 M in THF, 8.8 mL, 0.018 mmol) in anhydrous Et_2O (150 mL) under an inert atmosphere. The mixture was stirred until a white suspension formed (20 min) and *p*-bromo-benzonitrile (3.00 g, 0.016 mol) was added to the mixture as a solid. The mixture was stirred for 1 h, followed by addition of 2-cyanopyrazine (3.47 g, 0.033 mol). The reaction was stirred under N_2 for 4 h and in air for a further 30 min. The solid was collected by filtration, recrystallised from ethanol:water 1:2, washed with diethyl ether and dried to afford **1c** as a white powder (1.00 g, 16% yield).

^1H NMR (400 MHz, $CDCl_3$): 9.98, d, 2H, ($J = 1$ Hz), $H_{3,3''}$; 8.94 (t, $J = 2$ Hz, 2H) $H_{5,5''}$; 8.87 (d, $J = 2$ Hz, 2H) $H_{6,6''}$; 8.69 (d, $J = 9$ Hz, 2H) $H_{2''',6'''}$; 7.77 (d, $J = 9$ Hz, 2H) $H_{3''',5'''}$. ^{13}C {^1H} NMR (100 MHz, $CDCl_3$): 128.65, 130.56, 131.97, 133.21, 144.65, 145.87, 147.01, 148.02, 170.37, 172.12. High Res ESMS *m/z* calc. for $C_{17}H_{11}N_7Br$: $[M + H]^+$ 392.02594. Found: 392.02582.

4.2.2. *1d*

^{n}BuLi (1.6 M in hexanes, 1.45 mL, 2.32 mmol) was added dropwise to a stirring solution of $HNMe_2$ (2 M in THF, 1.16 mL, 2.32 mmol) in anhydrous Et_2O (30 mL) under an inert atmosphere. The mixture was stirred until a white suspension formed (20 min) and *p*-bromo-benzonitrile (0.38 g, 2.11 mmol) was added to the mixture as a solid. The mixture was stirred for 1 h, followed by addition of 2-cyano-6-methylpyridine (0.50 g, 4.23 mmol). The reaction was stirred under N_2 overnight and in air for a further 30 min. The solid was collected by filtration, recrystallised from ethanol:water 1:2, washed with diethyl ether and dried to afford **1d** as a white powder (333 mg, 38% yield).

^1H NMR ($CDCl_3$, 400 MHz): 8.67 (d, $J = 9$ Hz, 2H) $H_{2''',6'''}$; 8.63 (d, $J = 8$ Hz, 2H) $H_{3,3''}$; 7.85 (t, $J = 8$ Hz, 2H) $H_{4,4''}$; 7.71 (d, $J = 9$ Hz, 2H) $H_{3''',5'''}$; 7.41 (d, $J = 7$ Hz, 2H) $H_{5,5''}$; 2.80 (s, 6H) $H_{6,6''}$. ^{13}C {^1H} NMR ($CDCl_3$, 100 MHz): 23.90, 121.84, 126.37, 127.71, 130.29, 131.63, 133.95, 137.09, 151.96, 159.14, 171.11, 171.17. *Anal*. Calc. for $C_{21}H_{16}BrN_5$: C, 60.30; H, 3.86; N, 16.74. Found C, 59.87; H, 3.88; N, 16.52%.

4.3. The Fe(II) complexes

$[Fe(\mathbf{1a})_2](ClO_4)_2$: **1a** (198 mg, 0.51 mmol) was dissolved in acetonitrile (30 mL) and heated gently. In a separate flask, the $Fe(ClO_4)_2.6\,H_2O$ (65 mg, 0.26 mmol) was heated in acetonitrile (5 mL) and was then added on stirring to the ligand solution. An intense purple colour was immediately observed and stirring and heating were continued for a further 10 min. The solution was filtered, cooled and the solvent removed. The solid was dissolved in a minimum amount of acetonitrile and added to diethyl ether (200 mL). The solid was collected and dried to afford $[Fe(\mathbf{1a})_2](ClO_4)_2$ as a purple powder (150 mg, 57% yield).

ESMS: $[M]^{2+}$416.4. *Anal.* Calc. for $C_{42}H_{28}N_6Br_2Fe_1(ClO_4)_2 \cdot H_2O$: C, 48.08; H, 2.88; N, 8.01. Found: C, 47.94; H, 2.37; N, 7.89%.

$[Fe(\mathbf{1b})_2](ClO_4)_2$: The same method of preparation was used as $[Fe(\mathbf{1a})_2](ClO_4)_2$, starting with $Fe(ClO_4)_2.6H_2O$ (65 mg, 0.26 mmol) and **1b** (199 mg, 0.51 mmol). $[Fe(\mathbf{1b})_2](ClO_4)_2$ was isolated as a purple powder (115 mg, 44% yield).

ESMS: $[M]^{2+}$418.3. *Anal.* Calc. for: $C_{38}H_{24}N_{10}Br_2Fe_1 \cdot (ClO_4)_2$: C, 44.09; H, 2.34; N, 13.53. Found: C, 43.77; H, 1.86; N, 13.41%.

$[Fe(\mathbf{1c})_2](ClO_4)_2$: The same method of preparation was used as $[Fe(\mathbf{1a})_2](ClO_4)_2$, starting with $Fe(ClO_4)_2.6H_2O$ (65 mg, 0.26 mmol) and **1c** (200 mg, 0.51 mmol). $[Fe(\mathbf{1c})_2](ClO_4)_2$ was isolated as a purple powder (162 mg, 56% yield).

High Res ESMS *m/z* calc. for $C_{34}H_{20}N_{14}Br_2Fe$: $[M]^{2+}$ 419.9845; found: 419.9846. *Anal.* Calc. for $C_{34}H_{20}N_{14}Br_2Fe_1(ClO_4)_2 \cdot 0.5(H_2O)$: C, 38.96; H, 2.02; N, 18.71. Found: C, 39.30; H, 1.94; N, 18.87%.

$[Fe(\mathbf{1d})_2](ClO_4)_2$: The same method of preparation was used as $[Fe(\mathbf{1d})_2](ClO_4)_2$, starting with $Fe(ClO_4)_2.6H_2O$ (30 mg, 0.12 mmol) and **1d** (100 mg, 0.24 mmol). $[Fe(\mathbf{1d})_2](ClO_4)_2$ was isolated as a red solid (80 mg, 61% yield).

High Res ESMS *m/z* calc. for $C_{34}H_{20}N_{14}Br_2Fe$: $[M]^{2+}$ 445.0263; found: 445.0270. *Anal.* Calc. for $C_{42}H_{32}N_{10}Br_2Fe_1(ClO_4)_2 \cdot H_2O$: C, 45.47; H, 3.09; N, 12.63. Found: C, 45.72; H, 2.64; N, 12.81%.

Abstract

The crystal structures of compounds $Na[Cr(dipic)_2]\cdot 2H_2O$ (**1**) and $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$ (**2**), dipic = dipicolinate, phen = 1,10-phenantroline, were determined. In both complexes, Cr(III) is in a distorted octahedral environment. In complex (**1**), the metal is coordinated to two nearly perpendicular dipic anions acting as tridentate ligands through one oxygen of each carboxylate group and the pyridinic nitrogen atom. In complex (**2**), Cr(III) ion is similarly coordinated to a dipic anion, defining a ligand equatorial plane. The phen molecule bridges the remaining equatorial coordination site and one of the axial positions through its N-atoms. The other axial position is occupied by a chloride ion.

The optimized geometries of both compounds and their corresponding harmonic vibrational frequencies were calculated using methods of density functional theory. The infrared, Raman and electronic spectra of the complexes were recorded. Assignments of the most characteristic bands are reported and discussed. Their electrochemical properties were also investigated. Both compounds exhibit similar redox behavior; they undergo two main reduction processes involving the metal center and the dipicolinato ligand. No Cr(III) oxidation processes were found.

1. Introduction

Numerous studies have been developed with the aim of determining the chromium function at molecular level but its biological role is still controversial and not well understood. Some compounds of Cr(VI) are well-established carcinogens [1,2]. Chromium enters mammalian cells in the hexavalent form and it is reduced by intracellular materials to Cr(III), which binds to DNA via guanine N-7 atoms and phosphate groups [3]. The long-term toxicity effects observed in workers exposed to occupational Cr(VI) was proposed to be attributed to reoxidation of accumulated Cr(III), previously reduced within the cell [1].

In contrast, Cr(III) is considered an essential trace element for humans, enhancing the activity of insulin in glucose and fat metabolism and it is recognized as a dietary supplement [4–6]. However, some divergence is found actually with respect to this role [2,7–10]. Studies carried out with the popular dietary supplement $Cr(pic)_3$ (pic = picolinate) show that this compound produces oxidative stress and DNA damage [11–14]. Recently, it was also suggested that the antidiabetic activities of Cr(III)-containing nutritional supplements could involve the formation of

doi:10.1016/j.poly.2007.10.005

genotoxic Cr(V/VI) species, by intra or extra cellular oxidation, which acts similarly to well-known insulin-mimetic V(V) compounds [15].

Mechanistic studies of biologically relevant redox reactions of chromium complexes in different oxidation states have been recently reviewed [16]. The involvement of Cr(III) in intracellular redox reactions, that generate species capable to produce DNA damage and mutation in bacterial and mammalian cells, has been postulated and some mechanisms were proposed [17–19]. Cr(III) compounds containing aromatic imines as ligands have shown mutagenic effects in bacterial assays. Electrochemical studies reveal that, for these compounds, the Cr(III)/Cr(II) redox couple is reversible and exhibits reduction potential within the range of cellular reductant agents. Thus, it was suggested that the mutagenic compounds could be reduced intracelullary and generate DNA damaging hydroxyl radicals via Fenton-like reactions. In contrast, non-mutagenic Cr(III) complexes show irreversible behavior and more negative Cr(III)/Cr(II) reduction potential [19].

As part of our studies on metal complexes of biological interest, containing dipicolinic acid and related ligands [20–22] and in an attempt to contribute to a better understanding of the physicochemical properties of Cr(III) complexes containing organic ligands, $Na[Cr(dipic)_2]\cdot 2H_2O$ (**1**) and $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$ (**2**) were investigated. Dipicolinic acid (H_2dipic, 2,6-pyridinedicarboxylic acid) is a relevant N–O chelating agent, present in many natural compounds, that shows various biological functions and potential pharmacological activity. Even though 1,10-phenantroline has no significant biological role, complexes of this ligand with Cr(III) have been extensively studied as models of metal centers coordinated by aromatic bases [17–19].

In the present paper, the optimized geometries, calculated by means of the density functional theory were compared with crystallographic data and the experimental vibrational modes were assigned with the help of calculated frequencies. The electrochemical study of both complexes was performed in dimethysulfoxide (DMSO) solutions. The results were complemented with electronic spectroscopy and the assignment of experimental bands was accomplished with the aid of calculated electronic transitions obtained through the time dependent density functional theory.

2. Experimental

2.1. Reagents

$CrCl_3\cdot 6H_2O$, dipicolinic acid and 1,10-phenantroline (analytical grade, Sigma) were used without further purification. High purity DMSO (Aldrich) was used for the electrochemical measurements. Tetrabutylammonium hexafluorophosphate ($TBAPF_6$), employed as supporting electrolyte, was purchased from Fluka (electrochemical grade).

2.2. Synthesis of complexes

2.2.1. $Na[Cr(dipic)_2]\cdot 2H_2O$ (1)

Dipicolinic acid (H_2dipic, 0.12 g, 0.72 mmol) was dissolved in ethanol (25 ml) and drop wise added, under continuous stirring, to an ethanolic solution (25 ml) of $CrCl_3\cdot 6H_2O$ (0.14 g, 0.53 mmol). After 60 min stirring, at room temperature, 0.1 M NaOH was drop wise added to the resulting dark green solution until a color change, first to blue and finally to violet, was observed. The reaction mixture was stirred during 60 min more and then left to stand at room temperature. After two weeks, purple crystals suitable for X-ray structural analysis were obtained. The yield was 57%. *Anal.* Calc. for $C_{14}H_{10}CrN_2O_{10}Na$: C, 38.1; H, 2.3; N, 6.3. Found: C, 37.8; H, 2.5; N, 6.1%.

2.2.2. $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$ (2)

Even though the complex was prepared following the reported procedure [23], crystals suitable for X-ray structural analysis were obtained in the present case. To an ethanolic solution (50 ml) of $CrCl_3\cdot 6H_2O$ (0.27 g, 1.0 mmol) was added drop-by-drop an ethanolic solution (50 ml) of dipicolinic acid (0.17 g, 1.0 mmol). The mixture was stirred at room temperature for 60 min, when it turned deep green colored. Afterwards, an ethanolic solution (50 ml) of phenantroline (0.20 g, 1.1 mmol) was dropwise added and the stirring was continued for 60 min, at room temperature, until a violet solution was obtained. The system was kept at room temperature and after two weeks it showed the precipitation of purple single crystals. The yield was 42%. *Anal.* Calc. for $C_{19}H_{12}CrN_3O_{4.5}Cl$: C, 51.6; H, 2.7; N, 9.5. Found: C, 51.2; H, 2.5; N, 9.7%.

2.3. Physicochemical characterization

Elemental analysis (C, H, N) was performed using a Carlo Erba EA 1108 analyzer. FTIR spectra (4000–200 cm^{-1}) were measured using the KBr pellet technique with a Bruker 113v instrument. Raman spectra were obtained with a Bruker IFS 66 FTIR spectrophotometer, using the FRA 106 Raman accessory and the 1064 nm line of a Nd:YAG solid state laser for excitation. The electronic absorption spectra of the complexes and the ligands were measured on freshly prepared DMSO solutions in the 200–800 nm spectral range. They were recorded with a Hewlett–Packard 8452-A diode array spectrometer, using 10 mm quartz cells. Cyclic voltammetry was carried out with a computer controlled Princeton Applied Research (PAR) Potentiostat/Galvanostat model 263A. A standard three-electrode cell was used with a glassy carbon electrode as the working electrode, a platinum wire as the counter electrode and an Ag/(10^{-3} M) $AgNO_3$ in CH_3CN as the reference electrode. This electrode was calibrated against the $[Fe(C_5H_5)_2]/[Fe(C_5H_5)_2]^+$ redox couple, for which a potential of +0.4 V vs NHE was assumed [24,25]. All potentials reported here are referred to NHE in volts. Measurements were performed in oxygen purged 10^{-3} M DMSO solutions

with 0.1 M $TBAPF_6$ as supporting electrolyte. During the measurements, a continuous nitrogen stream was passed over the solutions.

2.4. Theoretical calculations

The GAUSSIAN 03 package [26] was used both for geometry optimizations and vibrational frequencies calculations. Becke's three parameters hybrid density functional [27] with the gradient-corrected correlation functional due to Lee et al. [28], a combination that gives rise to the well-known B3LYP method, was employed. The 6-31G(d,p) basis set was utilized for all atoms.

The ADF package [29–31] was used to calculate the electronic spectra of both complexes. The gradient-corrected exchange-correlation functional due to Perdew et al. [32] was used for the self-consistent field calculations, whereas the adiabatic local density approximation [33] was utilized for the time dependent density functional kernel. The atomic orbitals of all atoms were represented by a basis set of Slater functions having triple-zeta quality in the valence space and including two sets of polarization functions. The frozen core approximation up to the 1s orbital for C, N, and O, and up to the 2p orbital for Cr was used.

2.5. X-ray diffraction data and crystal structure determination

Diffraction data were collected on an Enraf-Nonius CAD4 diffractometer with EXPRESS [34] and reduced with XCAD4 [35]. The data were corrected numerically for absorption with PLATON [36]. The structures were solved by direct and Fourier methods with SHELXS [37] and its non-H atom refined by full-matrix least-squares with SHELXL [38]. The hydrogen atoms of the organic molecules in both substances were positioned stereo-chemically and refined with the riding model. The H-atoms of one crystallization water molecule of $Na[Cr(dipic)_2]\cdot 2H_2O$ were found in a difference Fourier map and refined isotropically with Ow-H and H···H distances restrained to target values of 0.86(1) and 1.36(1) Å, respectively. The H-atoms of the other water molecule could not be positioned reliably and therefore they were not included in the refinement. The crystallization water molecule of the $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$ complex showed positional disorder around a crystal inversion center. It was modeled in term of two sites for the oxygen atom and refined isotropically with occupation factor of 1/2 for each site.

3. Results and discussion

3.1. Theoretical calculations

The geometry of both complexes were optimized in the gas phase using tools from the density functional theory [39–41]. Calculations were carried out without specifying any symmetry for the complexes. A quartet electronic state corresponding to a high-spin electronic configuration for the Cr(III) ion was considered for both compounds, thus unrestricted Kohn–Sham calculations were accomplished throughout. No countercations were taken into account in the calculations for complex (**1**).

A vibrational analysis was performed for the optimized geometries to verify whether they are local minima or saddle points on the potential energy surface of the molecules. No scale factor was used to correct the calculated frequencies.

The electronic excitations of both complexes were calculated using the time dependent density functional theory [42,43].

3.2. Structural results

Crystal data and refinement results for compounds (**1**) and (**2**) are summarized in Table 1. Experimental and calculated bond distances and angles around Cr(III) ion are presented in Tables 2 and 3. Figures 1 and 2 show the ORTEP [44] drawings of the molecules.

$Na[Cr(dipic)_2\cdot 2H_2O$: Cr(III) ion is in a distorted octahedral environment, coordinated to two dipic anions acting as tridentate ligands through its carboxylic oxygen atoms [Cr–O distances in the range from 1.985(5) to 1.998(4) Å] and the nitrogen atoms [d(Cr–N1) = 1.972(5) and d(Cr–N2) = 1.980(5) Å]. The dipic ligands are nearly planar [rms deviation of atoms from the corresponding least-squares planes less than of 0.07 Å] and perpendicular to each other [dihedral angle of 81.73(5)°]. The metal ion lies close onto the intersection of the coordination planes (along the N1···N2 direction).

The sodium ion is in a compact sixfold coordination with four carboxylic oxygen atoms of neighboring dipic groups [Na···O distances in the range from 2.406(6) to 2.651(6) Å] and the two water molecules [d(Na···O1w) = 2.329(6) Å and d(Na···O2w) = 2.412(5) Å].

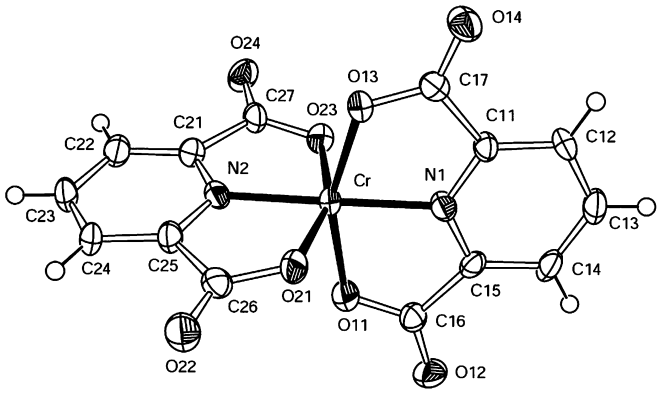

Fig. 1. Molecular plot of the $[Cr(dipic)_2]^-$ anion showing the labeling of the non-H atoms and their displacement ellipsoids at the 50% probability level. Chromium-ligand bonds are indicated by full lines.

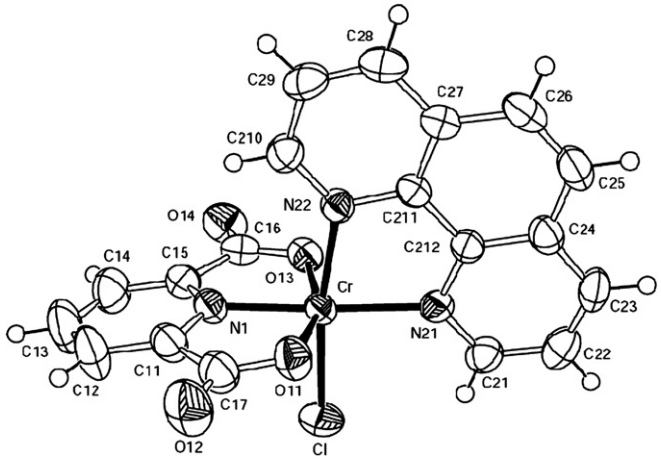

Fig. 2. Molecular diagram showing the [Cr(dipic)(phen)Cl] complex.

As the geometry optimization within the density functional framework was accomplished in the gas phase, that is without any perturbation as the ones arising from crystal packing effects, the two dipic ligands are located symmetrically around the metal ion, as can be seen from Table 2. This fact is in clear contrast with the experimental N1–Cr–N2 bond angle, which amounts to ca. 173°. Moreover, experimental N–Cr–O bond angles, in which N belongs to one of the dipic ligands and O belongs to the other dipic ligand, deviate from the gas phase value of 101.4°. It can also be observed in Table 2 that experimental N2–Cr–O11 and N2–Cr–O13 bond angles differ by about 3° with respect to the gas phase value, whereas N1–Cr–O21 and N1–Cr–O23 bond angles differ by about 6°. These findings seem to indicate that countercations interact differently with the two dipic ligands.

[*Cr(dipic)(phen)Cl*] · *1/2H*$_2$*O*: Cr(III) ion is in a sixfold environment, coordinated to one dipic ion defining a ligand equatorial plane [Cr–O distances of 1.975(3) and 1.999(3) Å and d(Cr–N) = 1.969(4) Å] and to a phen molecule acting as a bidentate ligand that bridges the fourth equatorial coordination site and one axial position through

its nitrogen atoms [Cr–N distances of 2.075(4) and 2.081(3) Å, respectively]. The other axial position is occupied by a chlorine ion [d(Cr–Cl) = 2.290(1) Å]. The dipic and phen molecules are nearly planar [rms deviation of atoms from the corresponding least-squares planes less than of 0.045 Å for both ligands] and close to mutual perpendicularity [angled at 86.60(7)° from each other]. As for the sodium salt, the Cr(III) ion nearly lies on the intersection of the coordination planes (along the N1···N21 direction).

The agreement between theoretical and experimental data is better than for complex (**1**) as can be seen in Table 3. The most relevant differences are observed when the N1–Cr–N21, N1–Cr–N22 and N21–Cr–N22 bond angles are compared. The ideal, gas phase values are 173.8° and 96.2°, respectively, whereas the experimental ones are 177.2° and 97.8°, respectively. These facts suggest that the phen ligand becomes stabilized in the solid state in a rather strained conformation. This can also be confirmed by comparing the experimental and gas phase values of the N21–Cr–N22 bond angle, which amount to 79.4° and 77.6°, respectively, thus differing by about 1.8°.

3.3. Vibrational spectra

Data of some of the most characteristic IR and Raman bands of the compounds are presented in Table 4 along with those of the H_2dipic and phen ligands. Main differences between the spectra of the ligands and the complexes were found below 700 cm^{-1}.

The O–H stretching modes of the crystallization water molecules give rise to two bands of medium intensity at 3475–3200 cm^{-1} in the IR spectrum of (**1**). For compound (**2**), this mode is superimposed with the ν(CH) mode of phen and appears as one broad and weak IR band centered at 3400 cm^{-1}.

In the compounds spectra, all the bands involving O–H motions of the carboxylate group are absent, namely the O–H stretching of the COOH groups, the C–OH in-plane bending and out-of-plane O–H deformation modes, hence showing deprotonation of the –COOH group and coordination to the metal [45], as disclosed by the X-ray structure. The characteristic IR carboxylate bands of the free acid, ν(C=O) and ν(C–O), are transformed into the asymmetric, ν_{as}(COO), and symmetric, ν_s(COO), stretching vibrations of the carboxylate group and as expected they are shifted after complex formation. The frequency difference between these bands is consistent with unidentate coordination of the carboxylate moiety to the metal [46]. Moreover, the δ(COO) mode, which appears in the spectra of the ligand as a strong band at 701 cm^{-1}, is shifted to higher frequency upon complexes formation. This behavior is similar to that observed in some complexes containing the dipic ligand [21, and references therein]. From the calculations, the splitting observed in the ν_{as}(COO) bands is attributed to the presence of in-phase and out-of-phase motions due to vibrational coupling between both terminal groups. Nevertheless, both calculated frequencies for complex (**1**) have almost coincident values (1771 cm^{-1}). In the symmetric mode, coupling with the C–COO stretching is also predicted. The calculated spectra also allow assigning differentially the vibrations for each free ligand, which are usually coupled with other modes. As expected, they undergo changes in intensity and position upon complexation [46,47].

The changes observed in the spectra of the complexes in the 700–200 cm^{-1} region are attributed to the coordination of the ligands to the metal. A new band of medium intensity at 683 cm^{-1} can be assigned to the out-of-plane ring deformation of the dipic, coupled with out-of-plane deformation of the Cr–N–C–C–O rings (Cr–L rings in Table 4).

Furthermore, a band at ca. 450 cm^{-1} with two shoulders, at higher and lower frequencies respectively, is present in both complexes. Calculations allow the assignment of these shoulders to ν(Cr–N) and to ν(Cr–O) stretchings. Some bands in this low-frequency region can be attributed to out-of-plane Cr–L rings deformations. The very weak bands at 395 cm^{-1} and at 226 cm^{-1} can be assigned to the Cr–Cl stretching and to the out-of-plane deformation of Cr–L ring, coupled with a Cr–Cl stretching in complex (**2**), respectively.

3.4. Electrochemical results

Cyclic voltammograms (CV) of the compounds were performed, in the potential range where they are electroactive, at incremental scan rates (v) from 0.05 V/s to 2.5 V/s. They were compared with those obtained with $CrCl_3$ and H_2dipic under similar experimental conditions. Data of the reduction and oxidation peaks at $v = 0.25$ V/s are summarized in Table 5.

The phen ligand was not active within the investigated potential range. The CV of H_2dipic display two overlapping irreversible reduction peaks at −1.36 V and −1.56 V which do not show associated oxidation processes in the reverse scan, even at the highest scan rate. Moreover, at more positive potentials one small couple is observed. The anomalous behavior of this couple and its dependence with electrode pretreatment suggest adsorption on the electrode surface.

Figure 3, curve A, shows the voltammetric behavior of the $Na[Cr(dipic)_2]\cdot 2H_2O$ compound, at $v = 0.25$ V/s. Two redox couples labeled I/I′ and II/II′, are observed.

The reduction current associated with peak II was measured from decaying baseline of peak I. The results indicates that the current ratio I/II is close to one at all scan rates investigated, suggesting that in both reduction the same number of electrons is involved.

On the other hand, although the separations of anodic (E_{pa}) and cathodic (E_{pc}) peak potentials of each process is larger than the value expected for a reversible charge transfer, the separation between the peak and half peak potential ($E_{pc} - E_{p/2}$) is 58 mV. This fact seems to point

Table 4

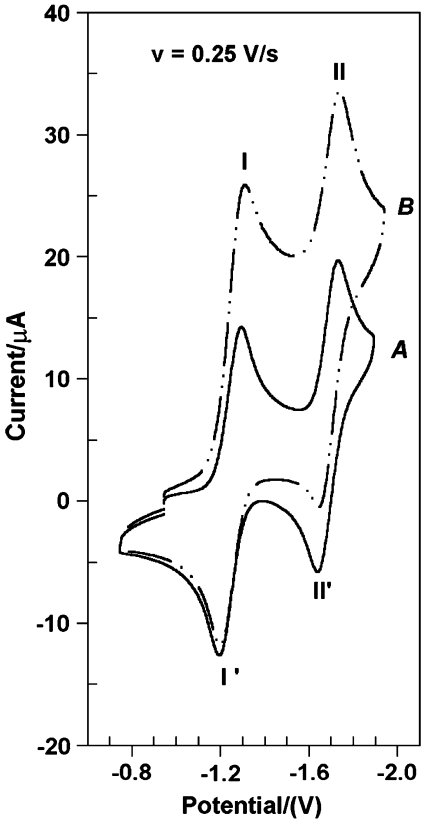

Fig. 3. Cyclic voltammograms of $Na[Cr(dipic)_2] \cdot 2H_2O$ in DMSO solution at $v = 0.25$ V/s (A) and after addition of dipicolinic acid (B).

to a reversible one electron transfer for these processes (a reversible diffusion-controlled process should have $(E_p - E_{p/2})$ values of 56.5/n mV) [48–50]. In addition, the peak current of both reductions increases with the square root of the scan rate ($v^{1/2}$), approaching a single straight-line plot, in accordance with diffusion control, and the ratio of anodic to cathodic peak currents (i_{pa}/i_{pc}) is near unity. These observations are indicative that the products of these reductions are stable during the time of the measurements.

To determine the origin of couples I and II, a complementary set of experiments was performed:

(a) 1 mM solution of $CrCl_3 \cdot 6H_2O$ was first measured in the absence of the ligand (see Table 5). Subsequently, H_2dipic was added to this solution. For ligand to metal concentration ratio L/M = 2 a new species is formed. Two main processes, at similar potential to that found for the complex, and a cathodic shoulder at *ca.* −1.26 V were observed. This last contribution corresponds to the reduction of a fraction of "free" Cr(III), since it appears at similar potential to that found when a solution of $CrCl_3$ in the absence of ligand was measured.

(b) Cyclic voltammograms of 1 mM complex solution were recorded at selected scan rates, and afterwards, an equimolar amount of H_2dipic was added. In Figure 1, curve B, a representative voltammogram at 0.25 V/s, is presented. After ligand addition, the cathodic current of peak I increases while the one related to peak II, measured from decaying baseline of peak I, remains unchanged. In this case, and for all scan rates investigated, the ratio I/II was close to 1.85, in contraposition with the value of 1, found when a solution of the complex alone was measured. The cyclic voltammogram of the free ligand in solution exhibited also one reduction peak at similar potential to that observed for peak I (−1.36 V), which remains irreversible at all scan rates investigated. In a similar way, after addition of the ligand, the oxidation current *I′*, associated with peak I, remains almost unchanged.

Therefore, based upon the discussed results, it can be assumed that the first peak corresponds to a ligand-centered reduction. The coordination with the metal changes the kinetic of this process from an irreversible to a reversible charge transfer [49]

$$\text{Peak I} \quad [Cr^{III}(dipic)_2]^- + e^- \rightleftharpoons [Cr^{III}(dipic)_2]^{2-}$$
$$E_{1/2} = -1.24\ \text{V} \qquad \text{(a)}$$

In addition, process II can be attributed to the reduction and subsequent oxidation of the metal center:

$$\text{Peak II} \quad [Cr^{III}(dipic)_2]^{2-} + e^- \rightleftharpoons [Cr^{II}(dipic)_2]^{3-}$$
$$E_{1/2} = -1.68\ \text{V} \qquad \text{(b)}$$

Figure 4 shows that a compound (**2**) holds a qualitatively similar cyclic voltammetric behavior. In fact, the electrochemical results indicate that $[Cr(dipic)(phen)Cl] \cdot 1/2H_2O$ dissociates in solution generating $[Cr(dipic)_2]^-$, as principal product. The two main couples, which appear at similar potential and display analogous behavior to that observed for complex (**1**), can be also described by means of Eqs. (a) and (b).

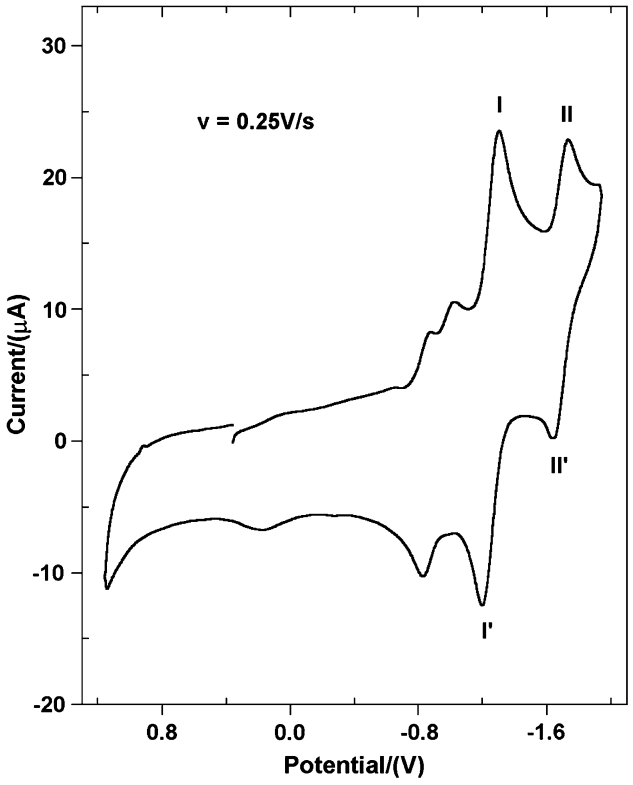

Fig. 4. Cyclic voltammograms of $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$ in DMSO solution at $v = 0.25$ V/s.

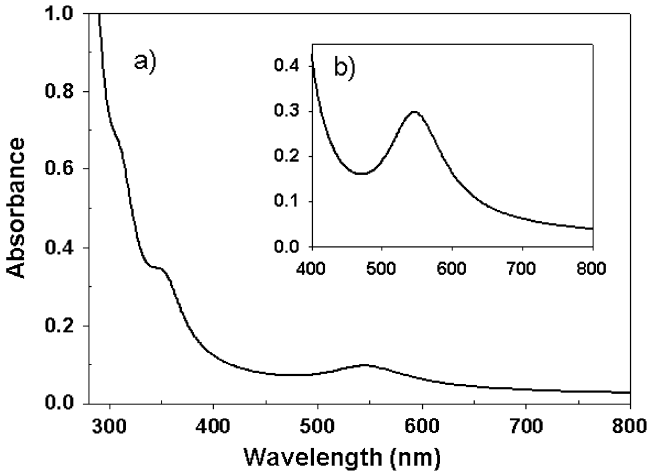

Fig. 5. Electronic spectra of $Na[Cr(dipic)_2]\cdot 2H_2O$ in DMSO solution. (a) 2×10^{-4} M; (b) 1×10^{-3} M, in a restricted wavelength range.

In addition, the small cathodic peaks and their anodic counterpart, that are absent in complex (**1**), can be attributed to new species in solution that contain phen, chloro and probably solvent molecules in their coordination spheres. The characteristic couple $2Cl^-/Cl_2$, which appears at 1.18 V in the $CrCl_3$ solution, is absent in this case, thus denoting that the chloride ligand remains attached to the metal.

3.5. Electronic spectra

The electronic spectra of complex (**1**) in DMSO solution is shown in Figure 5. The positions of the absorption maxima are listed in Table 6, together with the calculated transitions, which are selected according their respective oscillator strengths. The composition of the molecular orbitals, shown in Table 7, is determined in terms of atomic gross populations obtained through a Mulliken population analysis. Atomic percent contributions to molecular orbitals are summed up for each ligand in complex (**1**).

The experimental spectrum of complex (**2**) differs appreciably from the calculated one and, furthermore, it is very similar to the experimental spectrum corresponding to complex (**1**). These facts seem to suggest that complex (**2**) undergoes some reaction in solution in accordance with the electrochemical studies, which predict the same final species in solution for both complexes. Then, the assignments for both experimental spectra are discussed in terms of the calculated transitions for complex (**1**). Theoretical electronic transitions, the corresponding assignments, and the molecular orbital composition of non-dissociated complex (**2**) are available as Supplementary material.

Both ligands show strong absorptions at short wavelengths and up to ca. 300 nm. In addition, the phen spectrum presents a band of lower intensity around 320 nm.

Calculated transitions at ca. 432 nm in complex (**1**), attributed to d–d transitions, are not seen in the experimental spectrum. It can be assumed to be hidden by the more intense charge-transfer bands.

According to the analysis of the orbitals involved in the transitions, the broad band with maximum at 548 nm for complex (**1**) can be assigned to Cr → dipic charge-transfer transitions, mainly involving ligand rings. The strong absorption at the short wavelength end of the spectrum presents two shoulders, located at 353 nm and 312 nm. The first one can be considered as a combination of intraligand and dipic → Cr charge-transfer transitions, involving the oxygen atoms of the ligands. The shoulder at higher energy can be mainly attributed to dipic → Cr charge-transfer transitions, from the oxygen atoms.

Two high-intensity transitions at 656 nm and 604 nm are calculated for complex (**2**). They involve molecular orbitals having large contributions from dipic and phen ligands. Since those absorption bands are not observed in the experimental spectrum, it could be suggested that none species in solution contains simultaneously both ligands. Moreover, the experimental spectrum of complex (**2**) exhibits a small shoulder at 422 nm, which is not observed for complex (**1**) and that can be assigned to a Cr → phen charge-transfer transition, according to the theoretical results.

The above results support the proposal that complex (**2**) undergoes decomposition in DMSO solution, giving rise to new minor species containing phen, but no dipic, in the

Table 6

	309	0.005796	HOMO − 6 → LUMO + 4 (31.32%) HOMO − 9 → LUMO + 3 (13.46%)

Wavelengths are in nm, oscillator strengths in atomic units. Only the dominant one-electron transitions are taken into account for the assignment. The percent contribution of each one-electron transition is given in parenthesis.

[a] The one-electron transitions involve alpha molecular orbitals only, except for those cases in which it is explicitly stated that beta molecular orbitals are implied.

[b] d–d transitions are not observed in the experimental spectrum of complex (**1**). See text.

Contributions from atoms in dipicolinic ligands are summed up to overall ligand contributions named L1 and L2.

coordination sphere. These species could be responsible for the slight differences observed in the spectrum of this solution with respect to that of complex (**1**).

4. Conclusions

The IR and Raman properties of the compounds $Na[Cr(dipic)_2]\cdot 2H_2O$ and $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$, dipic = dipicolinate, phen = 1,10-phenantroline, are in good agreement with the results of X-ray crystallography. Unidentate coordination of the carboxylate moiety to the metal, determined from the difference between $\nu(COO)_{as}$ and $\nu(COO)_s$, is in accordance with the structural and theoretical results. Important changes, that can be attributed to metal coordination, were observed in the IR spectra of the compounds when compared with the ligands, in the 700–200 cm^{-1} region. Out-of-plane deformations involving the five member ring (Cr–N–C–C–O) formed upon coordination of chromium with the dipic ligand, as well as the ν(Cr–N) and ν(Cr–O) vibrations modes, were clearly identified in the low-frequency region of the spectra with the help of harmonic vibrational frequencies, calculated in this work.

Both compounds are stable in air in the crystalline state. Electrochemical and electronic spectroscopy measurements show that the complex $[Cr(dipic)(phen)Cl]\cdot 1/2H_2O$ undergoes decomposition in DMSO solution generating $[Cr(dipic)_2]^-$ as major product.

It was also established by cyclic voltammetry that the Cr(III) center is not oxidized to Cr(VI) or Cr(V) genotoxic species within the potential range investigated. The complexes experienced two main redox processes, corresponding to the ligand and to the metal center reduction, respectively. The Cr(III)/Cr(II) redox couple does not lie within the range of biological reductants. It was found at

more negative potential that than reported for chromium mutagenic compounds.

Acknowledgments

This work has been supported by CONICET and the National University of La Plata, Argentina. The X-ray diffraction data were collected at LANADI (CONICET), Argentina. A.C.G.B., R.P.D, O.E.P, and B.S.P.C. are Research Fellows of CONICET.

Synthesis of ethyl zinc fluoroalkoxide complexes and the crystal structure of $[EtZn(py)\{\mu\text{-}OCH(CF_3)_2\}]_2$

Seigi Suh, Liliana A. Mîinea, Saba Javed, David M. Hoffman *

Abstract

Fluorinated alkoxide complexes of zinc were synthesized for possible use as precursors to fluorine-doped ZnO films. Diethyl zinc reacted with fluorinated alcohols to form $[EtZn(OR_f)]_n$ ($R_f = CH(CF_3)_2$, CMe_2CF_3, $CMe(CF_3)_2$) compounds. The $[EtZn(OR_f)]_n$ compounds reacted with excess pyridine to yield the pyridine adducts $[EtZn(py)(\mu\text{-}OR_f)]_2$. The X-ray structure of $[EtZn(py)\{\mu\text{-}OCH(CF_3)_2\}]_2$ showed that it has virtual C_i symmetry.

Keywords: Zinc; Alkyl; Alkoxide; Fluoroalkoxide; ZnO films

1. Introduction

Jones, O'Beiwn, and co-workers reported using methyl zinc isopropoxide, $[MeZn(\mu_3\text{-}O\text{-}i\text{-}Pr)]_4$, and methyl zinc *tert*-butoxide, $[MeZn(\mu_3\text{-}O\text{-}t\text{-}Bu)]_4$, as single-source metal–organic chemical vapor deposition (MOCVD) precursors to undoped ZnO films with high resistivities (300–900 Ω cm) [1]. In this paper, we describe the synthesis of ethyl zinc fluoroalkoxide complexes that are related to the ZnO precursors employed by Jones, O'Brien, and co-workers. Our motivation for incorporating fluorine in the alkoxide ligands was the possibility that the complexes could be used as MOCVD precursors to conductive fluorine-doped zinc oxide films where the fluorine originates via a "self-doping" process [2,3].

2. Experimental

All manipulations were carried out in a nitrogen-filled glove box or by using standard Schlenk techniques. Diethyl zinc was obtained from Akzo Chemicals Inc. and used as received. The alcohols were purchased from Aldrich and DCR Inc. and were degassed before being used. Standard distillation procedures were used to purify and dry the solvents, which were stored in the glove box over 4-Å molecular sieves after they were collected. Oneida Research Services, Whitesboro, NY, and Midwest Microlab, LLC, Indianapolis, IN, performed the elemental analyses.

2.1. Synthesis of $[EtZn\{OCH(CF_3)_2\}]_n$

$(CF_3)_2CHOH$ (3.23 g, 19.2 mmol) was added slowly to a cold (−78 °C) solution of Et_2Zn (2.50 g, 20.2 mmol) in hexanes (20 ml) over a period of 20 min. A white precipitate formed during the addition. The reaction mixture was warmed slowly to room temperature. During the warming process, the precipitate dissolved. After stirring the reaction mixture for 3 h at room temperature, the volatile components were removed in vacuo to give a colorless liquid, which was distilled in vacuo (b.p. 48 °C, 0.05 mmHg). Some decomposition occurred during distillation (yield 2.6 g, 49%;). *Anal.* Calc. for $C_5H_6OF_6Zn$: C, 22.97; H, 2.31. Found: C, 22.76; H, 2.25%.

^1H NMR (C_6D_6): δ 3.84 (septet, 1, $^3J_{HF} = 6.0$ Hz, $OCH(CF_3)_3$), 1.26 (t, 3, $J_{HH} = 8.1$ Hz, CH_2CH_3), 0.56

(q, 2, $J_{HH} = 8.1$ Hz, CH_2CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): 122.5 (q, 2, $J_{CF} = 285$ Hz, $OCH(CF_3)_2$), 72.6 (septet, 1, $^2J_{CF} = 32$ Hz, $OCH(CF_3)_2$), 11.3 (s, 1, CH_2CH_3), −0.1 (s, 1, CH_2CH_3). IR (Nujol, CsI, cm^{-1}): 1375 m, 1289 s, 1231 s, 1196 s, 1138 s, 1101 s, 984 s, 912 w, 895 m, 860.3 m, 745 m, 689 m, 637 w, 544 w, 525 m, 457 w.

2.2. Synthesis of $[EtZn(py)\{\mu\text{-}OCH(CF_3)_2\}]_2$

Excess pyridine (2.0 g, 25 mmol) was added dropwise to a solution of $[EtZn\{OCH(CF_3)_2\}]_n$ (0.50 g, 1.9 mmol) in ether (10 ml) at room temperature. After stirring the mixture for 15 min, the volatile components were removed in vacuo, leaving a white solid. The solid was dissolved in a minimum amount of toluene. The solution was cooled (−35 °C), which resulted in the formation of large colorless blocks. The mother liquor was decanted and the crystals were dried in vacuo, producing a white solid (yield 0.61 g, 94%). The product could be sublimed in vacuo (80–86 °C, 0.05 mmHg). *Anal.* Calc. for $C_{20}H_{22}N_2O_2F_{12}Zn_2$: C, 35.27; H, 3.26; N 4.11. Found: C, 35.04; H, 3.19; N, 4.38%.

^1H NMR (C_6D_6): δ 8.46 (m, 4, *o*-py), 6.88 (m, 2, *p*-py), 6.64 (m, 4, *m*-py), 4.30 (septet, 2, $^3J_{HF} = 6.6$ Hz, $OCH(CF_3)_2$) 1.76 (t, 6, $J_{HH} = 8.1$ Hz, CH_2CH_3), 0.85 (q, 4, $J_{HH} = 8.1$ Hz, CH_2CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): 148.7 (4, *o*-py), 139.0 (2, *p*-py), 124.6 (4, *m*-py), 123.7 (q, 4, $J_{CF} = 287$ Hz, $OCH(CF_3)_2$), 73.5 (septet, 2, $^2J_{CF} = 31$ Hz, $OCH(CF_3)_2$), 13.5 (s, 2, CH_2CH_3), −3.3 (s, 2, CH_2CH_3). IR (Nujol, KBr, cm^{-1}): 1607 s, 1287 s, 1260 s, 1209 s, 1152 s, 1098 s, 1070 m, 1042 m, 1013 m, 986 w, 957 w, 887 m, 854.5 s, 756 m, 701 s, 685 s, 633 w.

2.3. Synthesis of $[EtZn(OCMe_2CF_3)]_n$

A solution of $(CF_3)Me_2COH$ (1.0 g, 7.7 mmol) in ether (10 mL) was added slowly to a cold (−78 °C) solution of Et_2Zn (1.0 g, 8.1 mmol) in ether (15 ml). The colorless reaction mixture was warmed slowly to room temperature whereupon it was left to stir overnight. The volatile components were removed in vacuo to yield a white solid. The solid was extracted with ether (10 ml), the extract was filtered, and the filtrate was concentrated in vacuo to ca. 4 mL. The clear filtrate was cooled slowly to −35 °C whereupon colorless crystals formed. The mother liquor was decanted and the crystals were dried in vacuo to give a white solid (yield 1.6 g, 89%). *Anal.* Calc. for $C_6H_{11}OF_3Zn$: C, 32.58; H, 5.00. Found: C, 32.26; H, 5.07%.

^1H NMR (C_6D_6): δ 1.38 (t, 3, $J_{HH} = 8.1$ Hz, CH_2CH_3), 1.26 (s, 6, $OCCF_3(CH_3)_2$), 0.59 (q, 2, $J_{HH} = 8.1$ Hz, CH_2CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): 127.0 (q, 1, $J_{CF} = 286$ Hz, $OCCF_3(CH_3)_2$), 75.5 (q, 1, $^2J_{CF} = 28$ Hz, $OCCF_3(CH_3)_2$), 24.9 (s, 2, $OCCF_3(CH_3)_2$), 12.3 (s, 1, CH_2CH_3), 6.1 (s, 1, CH_2CH_3). IR (Nujol, KBr, cm^{-1}): 1395 m, 1321 m, 1224 m, 1161 s, 1125 s, 999 w, 968 s, 939 w, 868 s, 756 m, 619 m, 592 w.

2.4. Synthesis of $[EtZn(py)(\mu\text{-}OCMe_2CF_3)]_2$

Excess pyridine (0.320 g, 4.06 mmol) was added dropwise to a solution of $[EtZn(OCMe_2CF_3)]_n$ (0.300 g, 1.35 mmol) in ether (10 ml) at room temperature. After stirring the solution overnight, the volatile components were removed in vacuo, leaving a white solid. The solid was dissolved in ether, and the solution was cooled (−35 °C). This produced colorless blocks, which were isolated by decanting the mother liquor and drying in vacuo (yield 0.37 g, 91%). The compound could be sublimed in vacuo (80–82 °C, 0.05 mmHg). *Anal.* Calc. for $C_{22}H_{32}N_2O_2F_6Zn_2$: C, 43.95; H, 5.37; N, 4.66. Found: C, 43.96; H, 5.42; N, 4.57%.

^1H NMR (C_6D_6): δ 8.61 (m, 4, *o*-py), 6.90 (m, 2, *p*-py), 6.63 (m, 4, *m*-py), 1.86 (t, 6, $J_{HH} = 8.1$ Hz, CH_2CH_3), 1.24 (s, 12, $OCCF_3(CH_3)_2$), 0.83 (q, 4, $J_{HH} = 8.1$ Hz, CH_2CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): 149.1 (4, *o*-py), 138.2 (2, *p*-py), 128.5 (q, 2, $J_{CF} = 288$ Hz, $OC(CF_3)(CH_3)_2$), 124.3 (4, *m*-py), 72.8 (q, 2, $^2J_{CF} = 27$ Hz, $OCCF_3(CH_3)_2$), 26.2 (s, 4, $OCCF_3(CH_3)_2$), 14.0 (s, 2, CH_2CH_3), −0.3 (s, 2, CH_2CH_3). 2.5. Synthesis of $[EtZn\{OCMe(CF_3)_2\}]_n$

A solution of $(CF_3)_2MeCOH$ (6.60 g, 36.4 mmol) in hexanes (10 ml) was added dropwise to a cold (−78 °C) solution of Et_2Zn (5.00 g, 40.5 mmol) in hexanes (30 ml) over a period of 30 min. The reaction mixture was warmed slowly to room temperature, whereupon it was left to stir for an additional 30 min. The volatile components were removed in vacuo to yield a colorless liquid. The liquid was pure product as judged by an ^1H NMR spectrum. The compound could be distilled under vacuum (b.p. 48–49 °C at 0.05 mm Hg; yield, 8.93 g, 80%). *Anal.* Calc. for $C_6H_8OF_6Zn$: C, 26.16; H, 2.93. Found: C, 26.09; H, 2.89%.

^1H NMR (C_6D_6): δ 1.28 (t, 3, $J_{HH} = 8.1$ Hz, CH_2CH_3), 1.17 (s, 3, $OCCH_3(CF_3)_2$), 0.56 (q, 2, $J_{HH} = 8.1$ Hz, CH_2CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): 124.8 (q, 2, $J_{CF} = 287$ Hz, $OCCH_3(CF_3)_2$), 76.4 (septet, 1, $^2J_{CF} = 29$ Hz, $OCCH_3(CF_3)_2$), 19.1 (s, 1, $OCCH_3(CF_3)_2$), 10.9 (s, 1, CH_2CH_3), 2.0 (s, 1, CH_2CH_3). IR (Nujol, KBr, cm^{-1}): 1310 s, 1265 w, 1215 s, 1161 s, 1127 m, 1082 s, 997 w, 961 s, 870 m, 762 m, 704 s, 652 m, 629 m.

2.6. Synthesis of $[EtZn(py)\{\mu\text{-}OCMe(CF_3)_2\}]_2$

Excess pyridine (0.260 g, 3.27 mmol) was added dropwise to a solution of $[EtZn\{OCMe(CF_3)_2\}]_n$ (0.300 g, 1.09 mmol) in ether (10 ml) at room temperature. After stirring the solution for 15 h, the volatile components were removed in vacuo, leaving a white solid. The solid was dissolved in ether, and the solution was cooled in the freezer (−35 °C). Colorless crystals formed, which were isolated by decanting the mother liquor and drying in

vacuo (yield 0.34 g, 88%). The compound could be sublimed in vacuo (85–90 °C, 0.05 mmHg). *Anal.* Calc. for $C_{22}H_{26}N_2O_2F_{12}Zn_2$: C, 37.26; H, 3.69; N, 3.95. Found: C, 37.29; H, 3.71; N, 3.94%.

^{1}H NMR (C_6D_6): δ 8.54 (m, 4, *o*-py), 6.86 (m, 2, *p*-py), 6.61 (m, 4, *m*-py), 1.84 (t, 6, $J_{HH} = 8.1$ Hz, CH_2CH_3), 1.35 (s, 6, $OCCH_3(CF_3)_2$), 0.89 (q, 4, $J_{HH} = 8.1$ Hz, CH_2CH_3). ^{13}C{^{1}H}NMR (C_6D_6): 149.0 (4, *o*-py), 138.7 (2, *p*-py), 124.4 (4, *m*-py), 125.2 (q, 4, $J_{CF} = 291$ Hz, $OCCH_3(CF_3)_2$), 77.2 (septet, 2, $^2J_{CF} = 28$ Hz, $OCCH_3(CF_3)_2$), 19.8 (s, 2, $OCCH_3(CF_3)_2$), 13.5 (s, 2, CH_2CH_3), −0.5 (s, 2, CH_2CH_3). IR (Nujol, KBr, cm^{-1}): 1607 s, 1460 s, 1304 s, 1215 s, 1165 s, 1117 m, 1074 s, 1040 m, 1013 w, 961 m, 862 w, 756 m, 700 s, 611 w.

2.7. Crystal structure determination of [EtZn(py)-{μ-OCH(CF$_3$)$_2$}]$_2$

The crystals for this study (colorless square columns) were grown from a concentrated toluene solution at −35 °C. All measurements were made with a Siemens SMART platform diffractometer equipped with a CCD area detector. The programs used in the X-ray crystallographic analysis were as follows: Data collection, APEX2 v1.0–27 software (Bruker-Nonius, 2005); cell refinement and data reduction, SAINT v7.12A software (Bruker-Nonius, 2004); and structure solution and refinement, SHELXL v5.10.

Crystal data: $C_{20}H_{22}N_2O_2F_{12}Zn_2$, monoclinic, space group $P2_1/n$, $a = 10.2183(4)$, $b = 17.3567(7)$, $c = 15.0818(6)$ Å, $\beta = 94.494(1)°$, $T = 223(1)$ K, $V = 2666.62(18)$ Å^3, $Z = 4$, $D_{calc} = 1.697$ g/cm^3, $F(000) = 1360$, μ(Mo Kα) = 1.903 mm^{-1}, crystal size: 0.45 × 0.25 × 0.20 mm. There were 12095 reflections measured of which 4132 reflections were unique ($R_{int} = 0.0278$). Final R indices for 2905 reflections with $I > 4\sigma(I)$ were $R_1 = 0.0299$ and $wR_2 = 0.0772$ and for all data $R_1 = 0.0400$ and $wR_2 = 0.0832$.

The ethyl and alkoxide ligands are significantly disordered. The disordered ligands were treated during refinement by using distance constraints. Ideal rigid body models were used for each of the CF_3 groups. Occupancy factors for each disordered group were estimated based on comparison of isotropic displacement parameters.

3. Results and discussion

The fluorinated alcohols $HOCH(CF_3)_2$, $HOCMe_2CF_3$, and $HOCMe(CF_3)_2$ reacted with slightly more than one equivalent of diethyl zinc at room temperature in hexanes to yield hydrocarbon-soluble $[EtZn(OR_f)]_n$ compounds (Eq. (1)). A slight excess of diethyl zinc was required to maximize reaction yields. The $R_f = CH(CF_3)_2$ and $CMe(CF_3)_2$ derivatives were volatile distillable liquids, albeit the hexafluoroisopropoxide complex partially decomposed on distillation. The decomposition product from the distillation of $[EtZn\{OCH(CF_3)_2\}]_n$ was a white solid that was not soluble in benzene but was soluble in acetonitrile. An ^{1}H NMR spectrum of the solid in CD_3CN revealed resonances consistent with one type each of Et and $CH(CF_3)_2$ groups in an approximately 1:3 ratio, respectively. Based on these data, the solid is probably an alkoxide-rich oligomer. The $R_f = CMe_2CF_3$ derivative was a solid that decomposed upon attempted sublimation. An ^{1}H NMR spectrum of the benzene-soluble residue from the attempted sublimation was uninformative.

Attempts to characterize $[EtZn(OCMe_2CF_3)]_n$ by X-ray crystallographic analysis failed because a suitable crystal could not be grown. The structures of all three derivatives are presumably tetrameric cubes analogous to the structurally characterized alkoxide complexes $[MeZn(\mu_3\text{-}OR)]_4$, where R = Me or *t*-Bu. Proton and C-13 NMR spectra had resonances consistent with the presence of only one type of alkoxide ligand. This is in agreement with a cube structure as well as other possible structures.

$$Et_2Zn + R_fOH \xrightarrow{-78\ ^\circ C} [EtZn(OR_f)]_n + EtH$$
$$R_f = CH(CF_3)_2, CMe_2CF_3, CMe(CF_3)_2 \quad (1)$$

In an effort to prepare a derivative of the $[EtZn(OR_f)]_n$ complexes for X-ray characterization, they were reacted with excess pyridine at room temperature to yield hydrocarbon-soluble pyridine adducts, $[EtZn(py)(\mu\text{-}OR_f)]_2$ (Eq. (2)). These results are consistent with the earliest reactivity studies of $[RZn(\mu_3\text{-}OR')]_4$ compounds by Coates and Ridley [4], who found that alkoxide tetramers did not react with pyridine, whereas the phenoxide tetramer $[MeZn(\mu_3\text{-}OPh)]_4$ reacted readily with pyridine to form the dimer $[MeZn(py)(\mu\text{-}OPh)]_2$. Coates and Ridley explained this

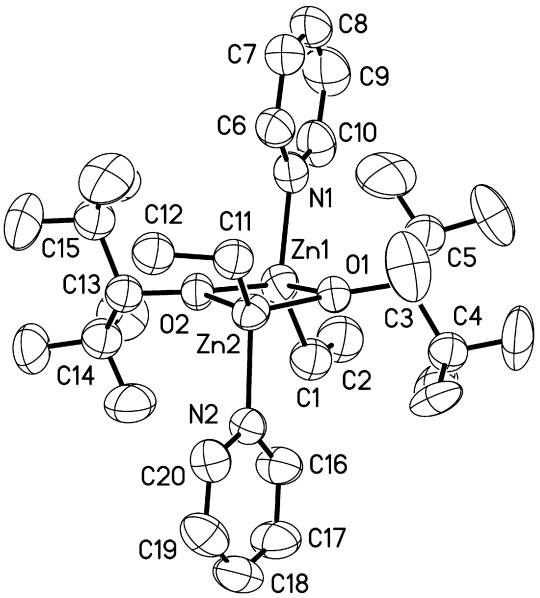

Fig. 1. Plot of the $[EtZn(py)\{\mu\text{-}OCH(CF_3)_2\}]_2$ molecule with hydrogens omitted (40% equiprobability envelopes). Only one orientation of each disordered group is shown. Selected bond lengths (Å) and angles (°): Zn(1)–O(2) 2.019(2); Zn(1)–O(1) 2.061(2); Zn(2)–O(1) 2.014(2); Zn(2)–O(2) 2.036(2); Zn(1)–N(1) 2.093(3); Zn(2)–N(2) 2.111(3); Zn(1)···Zn(2) 3.138(1); O(2)–Zn(1)–O(1) 78.38(8); O(1)–Zn(2)–O(2) 79.04(8); O(2)–Zn(1)–N(1) 101.14(9); O(2)–Zn(2)–N(2) 98.76(9); O(1)–Zn(1)–N(1) 96.03(9); O(1)–Zn(2)–N(2) 99.73(9).

difference in reactivity by pointing out that the phenoxide was a weaker donor than the alkoxides, and therefore the pyridine donor could break the phenoxide cube apart but could not disrupt the alkoxide cubes. In the present instance, the trifluoromethyl substituents make the alkoxide ligands weaker donors than their non-fluorinated counterparts, and thus the tetramers react with pyridine to form the dimeric pyridine adducts.

$$[EtZn(OR_f)]_n + \text{excess pyridine} \rightarrow [EtZn(py)(\mu\text{-}OR_f)]_2$$
$$R_f = CH(CF_3)_2, CMe_2CF_3, CMe(CF_3)_2 \quad (2)$$

An X-ray crystallographic analysis of $[EtZn(py)\{\mu\text{-}OCH(CF_3)_2\}]_2$ revealed a dimer structure in which the pyridine ligands are in an anti configuration (Fig. 1). The ethyl ligands were severely disordered, precluding any discussion of distances or angles with respect to $Zn–C_1$ or $Zn–C_{11}$. The Zn–O distances, 2.014(2)–2.061(2) Å, are within the range of distances found for $[(Me_3SiCH_2)Zn(\mu\text{-}O\text{-}2,6\text{-}i\text{-}Pr_2C_6H_3)]_2$ (1.934(10)–1.975(11) Å), $[(Me_3SiCH_2)Zn(\mu\text{-}O\text{-}2,4,6\text{-}t\text{-}Bu_3C_6H_2)]_2$ (1.948(6)–2.021(4) Å), $[(Me_3SiCH_2)Zn(\mu\text{-}O\text{-}1\text{-adamantyl})]_4$ (2.048(2)–2.121(3) Å), $\{Zn[(\mu\text{-}O\text{-}2,6\text{-}i\text{-}Pr_2C_6H_3)_2Zn(CH_2SiMe_3)]_2\}$ (1.933(3)–1.985(2) Å) [5], $[EtZn(\mu\text{-}O\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3)]_2$ (1.970 (1)–1.990(1) Å) [6], $[MeZn(\mu_3\text{-}O\text{-}t\text{-}Bu)]_4$ (2.06(2) Å) [7], and $[MeZn(\mu_3\text{-}OMe)]_4$ (2.039(14)–2.114(15) Å) [8], while the Zn–N distances (2.093(3) and 2.111(3) Å) are comparable to those in $ZnX_2(py)_2$ (X = C l, 2.046(5) and 2.052(6) Å) and (X = I, 2.05(1) and 2.06(1) Å) [9,10].

The ^1H NMR spectrum of $[EtZn(py)(\mu\text{-}OCMe_2CF_3)]_2$ in toluene-d_8 revealed a quartet and triplet arising from the methylene and methyl groups of the ethyl ligand, respectively, and two closely spaced singlet resonances for the alkoxide methyl protons. These data are consistent with the solid-state structure of $[EtZn(py)\{\mu\text{-}OCH(CF_3)_2\}]_2$. In benzene-$d_6$ the alkoxide methyl resonances are accidentally degenerate.

4. Conclusion

The fluorinated alkoxide complexes $[EtZn(OR_f)]_n$ (R_f = $CH(CF_3)_2$, CMe_2CF_3, $CMe(CF_3)_2$) were synthesized for possible use as CVD precursors to fluorine-doped ZnO films. The compound $[EtZn\{OCMe(CF_3)_2\}]_n$, a volatile liquid that distills without decomposition at low temperature (b.p. 48–49 °C, 0.05 mm Hg), is the most promising precursor candidate because of its physical properties. Pyridine adducts (py/Zn = 1) of the new complexes were prepared, and the X-ray structure of $[EtZn(py)\{OCH(CF_3)_2\}]_2$ was determined.

Abstract

Two ONO donor tridentate Schiff base ligands, two aromatic 1,2-diols and a monomethyl ether derivative of aromatic 1,2-diol are used in this work. The ONO donor ligands are deprotonated forms of *N*-(1-hydroxyphenyl)salicylaldimine (H_2L^1) and *N*-(1-hydroxyphenyl)napthaldimine(H_2L^2) (general abbreviation H_2L). The concerned diols are catechol (H_2cat), its 3, 5-Bu^t_2 derivative (H_2dbcat) and the monomethyl ether derivative of aromatic 1,2-diol is 2-methoxyphenol (HMecat), commonly known as guaiacol. The syntheses of hexa-/penta-coordinated vanadate esters of monoionized aromatic 1,2-diols and 2-methoxyphenolate, with diionized *N*-salicylidene/*N*-napthalidine-α-aminophenol as coligands are described and the reactivities of the compounds are reported. The concerned vanadate esters are [VO(L)(Hcat)], [VO(L)(Hdbcat)] and [VO(L)(Mecat)], where Hcat, Hdbcat and Mecat are monoionised forms of H_2cat, H_2dbcat and HMecat, respectively. The complexes are electroactive in MeCN solution. Molecular oxygen reacts smoothly with the oxovanadium(V) complexes quantitatively, furnishing the corresponding *o*-quinone. In the presence of the aromatic diol or guaiacol the reaction becomes catalytic. The X-ray structure of [VO(L^2)(Mecat)] has also been reported.

Keywords: Oxovanadium(V); Catecholase reaction; Catalytic cycle; Aromatic 1,2-diols, 2-methoxyphenol

1. Introduction

The past few years have seen a rapid development in the chemistry and biochemistry of vanadium(V). It has been documented for a long time that the vanadium, like phosphorous, forms ester mainly in the pentavalent state [1–3]. The functional motif characterizing such species is oxovanadium alkoxides [4,5]. The rich chemistry of vanadate ester is however emerging only in recent years. A sizeable number of compounds representing diverse forms of structure and reactivity are available [6]. Oxovanadium alkoxides have been documented to act as selective redox reagent [7,8], as mimics in studies of phosphorylation [9] and insulin action [10,11]. Vanadium is also found in the haloperoxides of some marine algae and in nitrogen-fixing enzymes in some bacteria [12]. Extensive reviews of these biochemical functions of vanadium have recently been published [13]. The topic that has generated a considerable amount of interest is the chemistry of reaction between vanadate and 1,2-diol functionalities [6]. Herein the synthesis, characterization and reactivity of a family of vanadate esters of monoionised aromatic 1,2-diols and 2-methoxyphenolate, with diionized *N*-salicylidene/*N*-napthalidine-α-aminophenol as coligands, are reported.

The complexes are stable in solid state but undergo spontaneous oxidation in solution in the presence of oxygen affording quinone and an oxovanadium(V) product. In presence of excess free aromatic 1,2-diol or 2-methoxyphenol the oxidation process becomes catalytic [14]. Some aspects of the rate and nature of the reaction have been scrutinized. The spectral and electrochemical features of the complexes along with a X-ray structure of a 2-methoxyphenate complex are reported.

2. Experimental

Commercially available $VOSO_4 \cdot 5H_2O$, salicylaldehyde, 2-hydroxynapthaldehyde, aminophenol, guaiacol, catechol, substituted catechol and dimethyl sulfate were used as received. $[VO(acac)_2]$ [15], $[V_2O_3(ONO)_2]$ [16] and tetraethylammonium perchlorate (TEAP) [17] were prepared as reported. All the other chemicals and solvents were of AR grade and used as obtained.

2.1. Physical methods

UV–Vis spectra were recorded on a Shimadzu UVPC 1601 PC spectrometer fitted with thermostated cell compartments. IR spectra were measured with Nicolet Magna IR 750 series II spectrometer. Proton NMR spectral measurements were carried out with a Brucker FT 300 MHz spectrometer. The atom-numbering scheme used for ^{1}H NMR is the same as that used in crystallography. Spin–spin structures are abbreviated as follows: s, singlet, d, doublet, t, triplet. The electrochemical measurements were performed on a PAR 370-A electrochemical system [18], using a Pt working electrode with reference to saturated calomel electrode (SCE). Perkin–Elmer 2400 is used for elemental analysis.

2.2. Rate measurements

The representative case of the reaction of $[VO(L^1)(Hdbcat)]$ in O_2-saturated Me_2CO (298 K) will be described. The initial O_2 concentration in O_2-saturated Me_2CO, determined by using an O_2 sensitive electrode, was found to be 9.0×10^{-4} M. The concentration of the complex was varied in the range $(4–10) \times 10^{-5}$ M. The spectrum of a solution of $[VO(L^1)(Hdbcat)]$ in O_2-saturated Me_2CO (298 K) was followed spectrophotometrically (quartz cell path length, 1 cm) by measuring the absorbance (A_t) at 610 nm as function time, t. The absorbance A_∞ at the end of 19 h of reaction was also measured. The values of k_{obs} were obtained from the slope of the linear plot of $-\ln(A_t - A_\infty)$ versus t.

2.3. Synthesis of the ligands

Two tridentate Schiff base ligands H_2L^1 and H_2L^2 (general abbreviation H_2L) have been employed in the present work. The ligands were prepared by the same general method.

2.4. Preparation of H_2L^2 ligand

To a MeOH (50 cm^3) solution of 2-hydroxynapthaldehyde (740 mg, 4.6 mmol), 2-aminophenol (500 mg, 4.6 mmol) was added while stirring at room temperature. After 2 h, a canary yellow precipitate appeared which was filtered, washed with cold MeOH, dried over P_4O_{10} for 48 h. Yield: 78%. *Anal.* Calc. for $C_{17}H_{13}NO_2$: C, 77.55; H, 4.98; N, 5.32. Found: C, 77.44; H, 5.09; N, 5.23%. IR (KBr): ν(OH) 3410; ν(C=N) 1598 cm^{-1}. ^{1}H NMR [($CDCl_3$), δ, (J/Hz)]: 9.40 (s, 1H, H(7)), 8.30 (d, 1H, H(2), $J = 8.02$), 7.42 (d, 1H, H(3), $J = 7.80$), 6.97 (d, 1H, H(9), $J = 8.00$), 7.12 (t, 1H, H(10), $J = 8.10$), 6.88 (t, 1H, H(11), $J = 7.90$), 7.89 (d, 1H, H(12), $J = 8.19$), 7.32 (d, 1H, H(14), $J = 7.90$), 7.10 (t, 1H, H(15), $J = 8.04$), 7.16 (t, 1H, H(16), $J = 8.01$), 7.09 (d, 1H, H(17), $J = 8.02$), 9.75 (br, 2H, H(OH)).

2.5. Preparation of H_2L^1 ligand

Salicyaldehyde (1 g, 8.0 mmol) and aminophenol (800 mg, 8.0 mmol) were employed. Yield: 83%. *Anal.* Calc. for $C_{13}H_{11}NO_2$: C, 73.22; H, 5.19; N, 6.56. Found: C, 73.27; H, 5.29; N, 6.47%. IR (KBr): ν(OH) 3405; ν(C=N) 1590 cm^{-1}. ^{1}H NMR [($CDCl_3$), δ, (J/Hz)]: 8.92 (s, 1H, H(7)), 7.28 (d, 1H, H(2), $J = 7.81$), 7.34 (t, 1H, H(3), $J = 7.79$), 7.11 (t, 1H, H(4), $J = 7.09$), 7.41 (d, 1H, H(5), $J = 7.80$), 6.94 (d, 1H, H(9), $J = 7.79$), 7.11 (t, 1H, H(10), $J = 8.00$), 6.81 (t, 1H, H(11), $J = 8.06$), 7.00 (d, 1H, H(12), $J = 8.10$), 9.73 (s, 2H, H(OH)).

2.6. Synthesis of the complexes

[VO(L)(Hcat)] and [VO(L)(Hdbcat)], type (**1**) complexes reported in this work were prepared by the same general method. Details are given for the case of $[VO(L^1)(Hcat)]$.

2.7. Preparation of $[VO(L^1)(Hcat)]$

To a stirred Me_2CO (30 cm^3) solution of $[V_2O_3(L^1)_2]$ (50 mg, 0.09 mmol), H_2cat (29 mg, 0.27 mmol) was added under N_2 atmosphere. After 0.5 h the reaction mixture was concentrated 10 cm^3 and the greenish solution then kept in cold. The precipitate thus obtained was filtered off, washed with hexane and dried in vacuum. Yield: 70%. *Anal.* Calc. for $C_{19}H_{14}NO_5V$: C, 58.92; H, 3.64; N, 3.62. 2.10. [VO(L)(Mecat)], type (**2**)

Two complexes were prepared by the same general procedure based on the reaction of [$V_2O_3L_2$] with HMecat in Me_2CO at room temperature. Details are given for the case of [VO(L^2)(Mecat)].

2.11. Preparation of [VO(L^2)(Mecat)]

To a stirred Me_2CO (30 cm^3) solution of [$V_2O_3(L^2)_2$] (50 mg, 0.07 mmol) was added HMecat (130 mg, 1.10 mmol) at ambient condition. After 1 h the reaction mixture was concentrated 10 cm^3 and the dark solution then kept in slow evaporation. After two days a dark crystalline compound was obtained. The complex was recrystallized from dichloromethane–methanol mixture in presence of excess guaiacol. Yield: 67%. *Anal.* Calc. for $C_{25}H_{20}NO_5VCl_2$: C, 55.99; H, 3.76; N, 2.61. Found: C, 55.90; H, 3.66; N, 2.53%. ^{1}H NMR [$CDCl_3$, δ, (J/Hz)]: 9.97 (s, 1H, H(7)), 8.29 (d, 1H, H(2), $J = 8.4$), 8.02 (d, 1H, H(3), $J = 9.09$), 7.58 (d, 1H, H(9), $J = 8.01$), 7.69 (t, 1H, H(10), $J = 8.00$), 7.98 (t, 1H, H(11), $J = 7.98$), 7.85 (d, 1H, H(12), $J = 8.10$), 7.25 (d, 1H, H(14), $J = 7.70$), 7.00 (t, 1H, H(15), $J = 8.04$), 7.00 (t, 1H, H(16), $J = 8.04$), 7.05 (d, 1H, H(17), $J = 8.00$), 6.96 (d, 1H, H(19), $J = 8.2$), 6.84 (t, 1H, H(20), $J = 6.86$), 6.96 (t, 1H, H(21), $J = 8.20$), 6.92 (d, 1H, H(22). $J = 6.92$), 3.32 (s, 3H, C(24)). VO^{3+}–VO^{2+} couple (CH_2Cl_2–CH_3CN (1:1)): $E_{1/2}$, −1.28 V (100 mV) and E_p,1.33 V.

2.12. Preparation of [VO(L^1)(Mecat)]

[$V_2O_3(L^1)_2$] (50 mg, 0.09 mmol) and HMecat (150 mg, 1.20 mmol) were employed. Yield: 71%. *Anal.* Calc. for $C_{20}H_{16}NO_5V$: C, 59.86; H, 4.02; N, 3.49. 2.13. Crystal structure determination

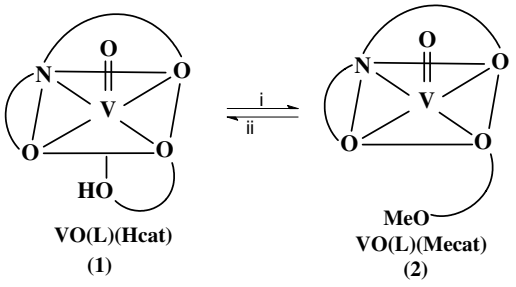
Single crystals of [VO(L^2)(Mecat)] ($0.40 \times 0.35 \times 0.35$) were grown by slow evaporation of a solution in dichloromethane–methanol, in presence of excess HMecat. The cell parameters were determined by least squares fit of 30 machine centred reflections ($14° \leqslant 2\theta \leqslant 28°$). Data were collected by ω-scan method in the range $2\theta = 3$–50° on a Siemens R3m/V diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Two check reflections measured after every 198 reflections showed on significant intensity reduction. Data were collected for Lorentz-polarization effects. An empirical absorption correction was done on the both sets of data on the basis of azimuthal scans [19]. All calculations for the data reductions, structure solution and refinement were done with the programs of SHELXTL Version 5.03 [20]. The structure of [VO(L^2)(Mecat)] was solved by direct methods and was refined by full-matrix least-squares anisotropic. All the H atoms were directly located in difference Fourier maps. Significant crystal data are listed in Table 1.



3. Results and discussion

The structures of the tridentate Schiff base ligands, aromatic diols and 2-methoxyphenol used in the present work are given in Box 1.

Box 1.

The potentially dissociable H atoms belong to the phenol groups. To ensure that only mononuclear configuration is attained we used the strategy of blocking three oxovanadium coordination positions leaving just two/one (assuming hexa-/pentacoordination) position for possible chelation by phenol/phenoxidic or phenoxidic functions [6].

Scheme 1. (i) Me_2SO_4 in alkaline MeOH/H_2O, stir. (ii) O_2 saturated Me_2CO/H_2O, stir.

The reaction of $[V_2O_3L_2]$ with excess aromatic diol (H_2cat/H_2dbcat) or guaiacol in Me_2CO under N_2 conditions afforded a dark colored solution. The complexes precipitated in cold. Monoionised aromatic diol chelation is rare in transition metal chemistry. A notable example, relevant to catechol dioxygens activity [21], occurs in iron chemistry [22]. The type **1** complexes undergo methylation in presence of dimethyl sulfate in alkaline aqueous methanol solution leading to the formation of type **2** complexes. Type **2** complexes readily form type **1** complexes in oxygen saturated aqueous acetone solution. The interconversion is shown in Scheme 1.

The complexes display strong V=O stretch in the region 986–991 cm^{-1} and type (**1**) species display OH stretching and very broad ^1H NMR spectrum. In UV–Vis spectra the complexes display moderately strong absorption band near 560–610 nm in visible region. The absorption and IR spectral data are set out in Table 2. All the reported complexes are electroactive in MeCN solution. The complexes display a quasi-reversible reductive one-electron response of V^V/V^{VI} at negative potentials and a irreversible oxidative response of catecholate/semiquinonate at positive potentials.

3.1. Structure

The X-ray structure of $[VO(L^2)(Mecat)]$ has been determined. Molecular view is shown in Fig. 1 and selected bond parameters are listed in Table 3. The VO^{3+} moiety is coordinated to the phenoxidic O4 atom of guaiacol and O2, N1 and O3 atoms of the meridionally tridentate Schiff base ligand, the N1 atom lying *trans* to O4.

The V=O [1.567(3) Å] and V–O(phenoxiodic) 1.806(3) Å are similar to these in polyol [23] and hexacoordinated mono-/diionised catechol complexes [14]. In monoionised catechol complexes the V–O (phenolic) distance is lengthened by the V=O trans influence so as to lie within 2.34 ± 0.05 Å [14]. A remarkable feature of $[VO(L^2)(Mecat)]$ is the usually long V–O(phenolic) contact 2.502(3) Å signifying the virtual absence of bonding. In effect $[VO(L^2)(Mecat)]$ is a square pyramidal complex.

Since the V=O length in $[VO(L^2)(Mecat)]$ is normal, the state of the V–O(phenolic) contact cannot be ascribed to

[c] In KBr disk.

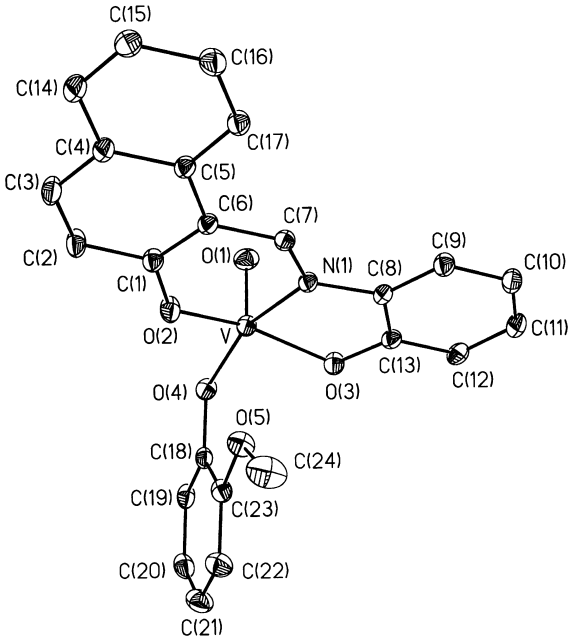

Fig. 1. Molecular view and atom labeling scheme for [VO(L^2)(Mecat)]. All non hydrogen atoms are represented by 30% thermal probability ellipsoids. Hydrogen atoms and solvent molecule have been omitted for clarity.

any augmented trans influence. The V–O2, V–N1 and V–O3 distance within the Schiff base fragment are similar to these observed elsewhere [24]. The atoms O2, O3, O4 and N1 constitute an excellent plane (mean deviation ca. 0.04 Å) from which the metal atom displacement is larger than that observed in monoionised diols [6].

3.2. Reaction with oxygen

The complexes are stable only in solid state. Their dark solutions which are otherwise stable, get progressively bleached in presence of oxygen. The products isolated from the yellowish brown solutions are dimeric $[V_2O_3L_2]$ [14] and the corresponding *o*-quinone (Q) of the used diols and guaiacol. The reaction has been quantitated in the case of [VO(L^1)(Hdbcat)] complex, Eq. (1). The progress of the reaction is scrutinized by both electronic and ^{1}H NMR spectra. Time evolution electronic spectra are characterized by a isosbestic point, and is shown in Fig. 2. In time evolution ^{1}H NMR spectra, the *tertiary*-butyl signals in oxygen saturated acetone-d_6 at δ 1.56 and 1.25 decay with time due to decrease of concentration of coordinated monoionized ditertiarybutylcatechol and those at δ 1.27 and 1.26 grow with time due to increase in concentration of free ditertiarybutylquinone.

$$[VO(L^1)(Hdbcat)] + 1/2\ O_2 \rightarrow 1/2[V_2O_3(L^1)_2] + Q + 1/2H_2O \quad (1)$$

Under pseudo-first-order conditions (saturated), the rates are proportional to the concentration of the VO^{3+} complex and the observed rate constant is k_{obs}. The value of k_{obs} increases with increasing electron withdrawing properties of ONO donor ligands ($H_2L^2 > H_2L^1$) and electron donating properties of momoionized diols ($Hdbcat^- > Hcat^-$). Rate data are listed in Table 4.

Upon adding free H_2dbcat to the solution during the reaction or after its completion the ester is regenerated to the original level and the reaction of Eq. (1) can start over again. A catalytic cycle for the oxidation of H_2dbcat into corresponding quinone (Q) by oxygen is clearly realized by combining two reactions (Eqs. (2) and (3)). It is a rare catecholase reaction in which the active intermediate, [VO(L^1)(Hdbcat)] and the catalyst, $[V_2O_3L_2]$, are vanadium complexes (Fig. 3) [14].

$$[V_2O_3(L)_2] + 2H_2dbcat \rightarrow 2[VO(L)(Hdbcat)] + H_2O \quad (2)$$

$$2H_2dbcat + O_2 \rightarrow 2Q + 2H_2O \quad (3)$$

4. Conclusion

The important aspects of this paper can now be summarized. The oxovanadium(V) complexes synthesized by chelation with catechols and guaiacol have been characterized. The complexes are oxidized spontaneously and quantitatively by O_2 in solution furnishing the corresponding quinone (Q) and $[V_2O_3L_2]$, which is reconverted to the original active complex upon addition of diol or guaiacol. These reactions provided a method for catalytic oxidation (catecholage reaction) of aromatic 1,2-diols and guaiacol to corresponding quinone.

5. Supplementary material

CCDC 288154 contains the supplementary crystallographic data for $[VO(L^2)(Mecat)] \cdot CH_2Cl_2$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Polarised electronic spectra of *trans*-$[Cr(tmd)_2F_2](ClO_4)$, *trans*-$[Cr(en)_2(dma)_2](ClO_4)_3$, *trans*-$[Cr(en)_2(dmf)Cl](ClO_4)_2$ and *trans*-$[Cr(en)_2(dmf)Br](ClO_4)_2$ have been measured at 77 K (tmd = trimethylenediamine; dma = *N*,*N*-dimethylacetamide; dmf = *N*,*N*-dimethylformamide; en = ethylenediamine, pn = propylenediamine). The observed quartet bands have been given definitive quadrate assignments based on polarisation characteristics. The four-component quadrate quartet bands have been uncovered and assigned also in the unpolarised crystal spectrum of *trans*-$[Cr(en)_2(dmf)_2](ClO_4)_3$ at 77 K and the solution spectrum of *trans*-$[Cr(en)(pn)F_2]^+$. The band maxima derived by gaussian analysis in these spectra have been fitted with the theoretical energy equations of d^3 configuration in quadrate ligand fields including full configuration interaction. The ligand field parameters *Dq*, *Dt*, and *Ds* and the election correlation parameter, *B*, extracted by such a fitting, have been compared with those obtained for other similar systems earlier. The significance of the ligand field symmetry parameters and the translated angular overlap model parameters is discussed.

Keywords: Single-crystal electronic spectra; Chromium(III) complexes

1. Introduction

Most of the spectra of quadrate chromium(III) complexes that have been studied and interpreted were obtained either in solution or by diffuse reflectance [1–5]. Spectra of polarised single-crystals of quadrate chromium(III) complexes studied so far are still limited [6–11]. This study extends the list of polarised single-crystal spectra, as well as the list of unpolarised and solution spectra by providing an analysis of the polarised single-crystal spectra of *trans*-$[Cr(tmd)_2F_2]ClO_4$, *trans*-$[Cr(en)_2(dma)_2](ClO_4)_3$, *trans*-$[Cr(en)_2(dmf)Cl](ClO_4)_2$ and *trans*-$[Cr(en)_2(dmf)Br](ClO_4)_2$, unpolarised crystal spectrum of *trans*-$[Cr(en)_2(dmf)_2](ClO_4)_3$, and solution spectrum of *trans*-$[Cr(en)(pn)F_2]^+$.

2. Experimental

The complexes have been prepared as described in the literature [12–15]. Single-crystals of the complexes were grown by one of the following methods: (i) slow evaporation of a saturated solution (*trans*-$[Cr(en)_2(dma)_2](ClO_4)_3$, *trans*-$[Cr(en)_2(dmf)Br](ClO_4)_2$), (ii) slow evaporation of a saturated solution in 3:1 ethanol–water (*trans*-$[Cr(en)_2(dmf)Cl](ClO_4)_2$, *trans*-$[Cr(en)_2(dmf)_2](ClO_4)_3$), and (iii) a 3 mL volume of ice-cold 2 M perchloric acid was saturated with the complex to which acetone was added and the mixture was cooled in a refrigerator for 24 h, yielding single-crystals at the interface of the two layers (*trans*-$[Cr(tmd)_2F_2]ClO_4$). Single-crystals of *trans*-$[Cr(en)_2(dmf)Cl](ClO_4)_2$, *trans*-$[Cr(en)_2(dmf)Br](ClO_4)_2$ and *trans*-$[Cr(en)_2(dmf)_2](ClO_4)_3$ showed pink to green, deep-blue to green and orange to pink dichroism, respectively.

All compounds were analysed for Cr^{3+} content [16] by boiling with alkaline hydrogen peroxide and then measuring absorbance of the resulting CrO_4^{2-} at 372 nm; analysis

Spectral measurements were carried out as described in detail in the literature [6,9,17].

3. Results and discussion

3.1. Spectral data and band assignment

For all the systems studied, bands in each of the spectra were resolved into gaussian components.[2] Values of band maxima for complexes studied are listed in Table 1. The earlier studies [6] of the *dmf* systems only made tentative assignments for the second cubic band components $^4A_{2g}$ and ^4E_g of $^4T_{1g}$ based on shifts of the band maxima in different polarisations. For these systems, the experimental data were reproduced and gaussian analysis was carried out to obtain accurate band maxima for a definitive band assignment.

For complexes with d^3 configuration with octahedral geometry, three spin-allowed bands should be observed as follows: $^4A_2^C \rightarrow {}^4T_2^C$, $^4A_2^C \rightarrow {}^4T_1^C$ and $^4A_2^C \rightarrow {}^4T_1^C$, where $^4A_2$ represents the ground state and $^4T_2$ and $^4T_1$ represent the quartet excited states to which transitions are allowed. The third high-energy transition is usually not seen as it is buried in charge-transfer bands. The lower two transitions are expected to spilt into two components each as the symmetry of the complex is lowered when the axial ligands are different from those on the equatorial plane (D_{4h} to C_{4v}). In the lower symmetry, the ground state is $^4B_1$ and gives rise to the following transitions: $^4B_1^Q \rightarrow {}^4B_2^Q(^4T_2)$, $^4B_1^Q \rightarrow {}^4E^Q(^4T_2)$, $^4B_1^Q \rightarrow {}^4A_2^Q(^4T_1)$ and $^4B_1^Q \rightarrow {}^4E^Q(^4T_1)$.

In the case of D_{4h} complexes, vibronic selection rules predict [7–9] that the ^4E components are both 'z' ($\|$) and 'xy' ($\perp$) polarised whereas the $^4A_2$ and $^4B_2$ components are 'xy' polarised but not 'z' polarised. In the case of strictly C_{4v} complexes, however, the $^4A_2$ component becomes allowed in the 'z' polarisation by vibronic mechanism, although it is orbitally forbidden which means the $^4A_2$ may appear in 'z' polarisation, although with weak intensity. In addition, it is predicted [2,18] that among the two components of the lowest energy cubic band, $^4T_2$, the $^4B_2$ component will be at higher energy than the ^4E component for complexes with negative parameter Dt. This prediction has been verified in all the systems studied by polarised measurements [6–9]. These observations were used in making definitive assignments of the bands in the spectra of the systems studied. Spectra are those of energy (given in kiloKayser, $1\ kK = 1000\ cm^{-1}$) versus optical density (crystals) or extinction coefficient (solution).

3.1.1. *trans*-$[Cr(tmd)_2F_2]ClO_4$

Owing to the well-resolved spectra in each of the polarisations, band assignment for this complex was relatively straight-forward (Fig. 1). Bands in the perpendicular polar-

isation are seen to occur at 18 663 cm^{-1}, 21 578 cm^{-1}, 24 848 cm^{-1} and 29 829 cm^{-1}. Those in the parallel polarisation are seen to occur at 18 776 cm^{-1}, 21 587 cm^{-1}, 24 806 cm^{-1} and 29 882 cm^{-1}. In all cases, band maxima (when comparing the two polarisations) are separated by no more than 100 cm^{-1}, with the lowest separation being 9 cm^{-1}. The lowest energy band in each case (18 663 cm^{-1} and 18 776 cm^{-1}) is assigned to $^4B_1^Q \rightarrow {}^4E^Q(^4T_2)$. The assignment of the second lowest energy band (at 21 578 cm^{-1} and 21 587 cm^{-1}) is made to $^4B_1^Q \rightarrow {}^4B_2^Q$ since its intensity is considerably lower in the parallel polarisation. Looking at the intensities of the next two bands, the marked reduction of the intensity in the highest energy band (at 29 829 cm^{-1} and 29 882 cm^{-1}) allows assignment to $^4B_1^Q \rightarrow {}^4A_2^Q$, which leaves the penultimate band (at 24 806 cm^{-1} and 24 848 cm^{-1}) in both polarisations assigned to $^4B_1^Q \rightarrow {}^4E^Q(^4T_1)$.

3.1.2. *trans*-[Cr(en)$_2$(dma)$_2$](ClO$_4$)$_3$

Single-crystal polarised spectra of the above complex were obtained in the parallel and perpendicular orientations (Fig. 2). Bands in the parallel polarisation are seen to occur at 19 518 cm^{-1}, 21 362 cm^{-1}, 26 608 cm^{-1} and 29 356 cm^{-1}. Those in the perpendicular polarisation are seen to occur at 19 243 cm^{-1}, 21 859 cm^{-1}, 26 400 cm^{-1} and 29 355 cm^{-1}. In looking at the spectra, in both polarisations it appears that the lowest energy band appears as a shoulder. Since the intensity of this band is not reduced significantly, it is assigned to $^4B_1^Q \rightarrow {}^4E^Q(^4T_2)$. The second lowest energy band is then assigned as $^4B_1^Q \rightarrow {}^4B_2^Q$. The last two assignments were somewhat difficult, as the reduction of intensity on one band in one polarisation was accompanied by an increase in intensity of the second band in the next polarisation. With greater weight given to the disappearance of one of the bands in the parallel polarisation, the assignment of $^4B_1^Q \rightarrow {}^4E^Q(^4T_1)$ is given to those bands at 26 608 cm^{-1} and 26 400 cm^{-1} in the two polarisations. The significant reduction in intensity of the band at 29 356 cm^{-1} in the parallel polarisation requires this and the one at 29 355 cm^{-1} in the perpendicular polarisation to be assigned to $^4B_1^Q \rightarrow {}^4A_2^Q$.

3.1.3. *trans*-[Cr(en)$_2$(dmf)Cl](ClO$_4$)$_2$

Bands in the spectrum of this complex in the perpendicular polarisation are seen to occur at 18 293 cm^{-1}, 22 547 cm^{-1}, 25 751 cm^{-1} and 27 600 cm^{-1} (Fig. 3). Those in the parallel polarisation are seen to occur at 18 181 cm^{-1}, 22 536 cm^{-1}, 25 546 cm^{-1} and 27 509 cm^{-1}. Looking at the relative intensities of the peaks, it is evident that the lowest energy band, in both cases, can be assigned to the transition $^4B_1^Q \rightarrow {}^4E^Q(^4T_2)$. The justification for this assignment is the almost-unchanged intensity of the band in both polarisations. The assignment of the second band, done so simultaneously, is made as $^4B_1^Q \rightarrow {}^4B_2^Q$. Here too, justification is made based on the consideration of intensity, in this case, a pronounced reduction in intensity, as expected for this band in the parallel polarisation. Again, using the criterion of intensity, the third transition

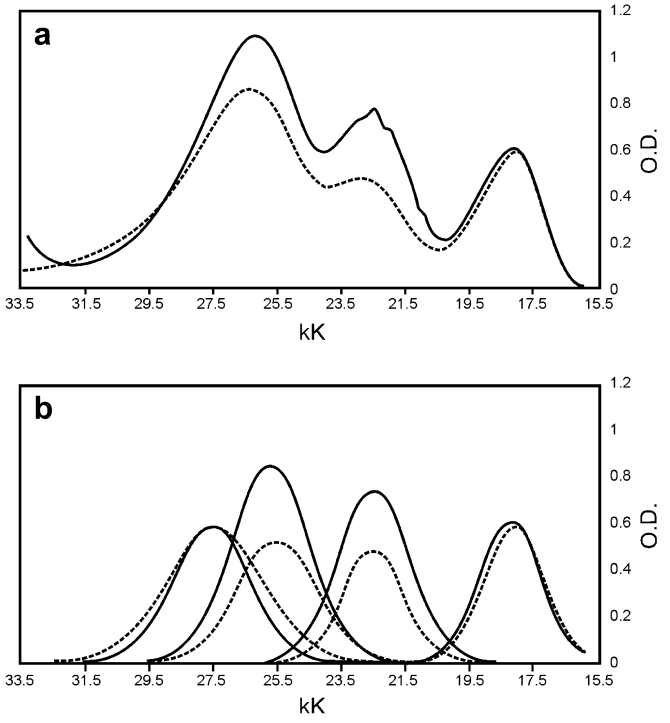

Fig. 3. (a) Polarised single-crystal spectrum of *trans*-[Cr(en)$_2$(dmf)Cl](ClO$_4$)$_2$ at 77 K and (b) gaussian fit. In both graphs, the solid line represents perpendicular polarisation and dashed line that of parallel polarisation.

$^4B_1^Q \rightarrow {}^4A_2^Q$ is characterised by bands at 25 546 cm^{-1} (parallel) and 25 751 cm^{-1} (perpendicular). Bands at 27 509 cm^{-1} and 27 600 cm^{-1} are assigned to the $^4B_1^Q \rightarrow {}^4E^Q(^4T_1)$ transition. A prominent feature of the analysis presented here, different from that given in earlier work, is the increased splitting of the second spin-allowed transition. A spin-forbidden band at 21 950 cm^{-1} is tentatively assigned to $^4B_1^Q \rightarrow {}^2B_2(^2T_{2g})$ transition.

3.1.4. *trans*-[Cr(en)$_2$(dmf)Br](ClO$_4$)$_2$

As was the case with *trans*-[Cr(en)$_2$(dmf)Cl](ClO$_4$)$_2$, an analysis of the spectra with gaussian fitting is made (Fig. 4). Bands in the perpendicular polarisation are seen to occur at 18 119 cm^{-1}, 22 247 cm^{-1}, 24 766 cm^{-1} and 27 172 cm^{-1}. Those in the parallel polarisation are seen to occur at 17 846 cm^{-1}, 22 229 cm^{-1}, 24 708 cm^{-1} and 27 143 cm^{-1}. Again, as was the case with *trans*-[Cr(en)$_2$(dmf)Cl](ClO$_4$)$_2$, by looking at the relative intensities of the peaks, the lowest energy band, in both cases, can be assigned to the transition $^4B_1^Q \rightarrow {}^4E^Q(^4T_2)$. As before, the justification for this assignment is the almost-unchanged intensity of the band in both polarisations while observing that the band at higher energy is lowered, as expected. The assignment of the second band is $^4B_1^Q \rightarrow {}^4B_2^Q$. The band at 24 766 cm^{-1} is assigned to the $^4B_1^Q \rightarrow {}^4A_2^Q$ transition since it is lowered in intensity in the parallel polarisation and the band at 27 369 cm^{-1} which has the same intensity in both polarisations is assigned to the $^4B_1^Q \rightarrow {}^4E^Q(^4T_1)$. A spin-forbidden band at 21 186 cm^{-1} is tentatively assigned to $^4B_1^Q \rightarrow {}^2B_2$, $^2E(^2T_{2g})$ transitions.

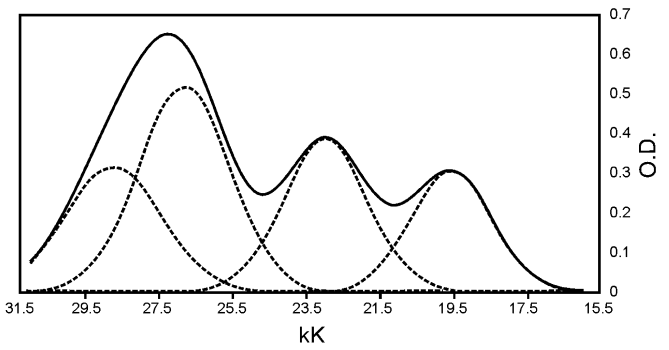

Fig. 5. Unpolarised single-crystal spectrum of *trans*-[Cr(en)$_2$(dmf)$_2$](ClO$_4$)$_3$ at 77 K and gaussian fit. The solid line represents the experimental spectrum and the dashed line represents the gaussian fit.

3.1.5. *trans*-[Cr(en)$_2$(dmf)$_2$](ClO$_4$)$_3$

Attempts to obtain polarised spectra of this complex were unsuccessful. Consequently, an analysis of the unpolarised crystal spectra with gaussian fitting is performed (Fig. 5). Bands are seen to occur at 19 600 cm^{-1}, 23 052 cm^{-1}, 26 950 cm^{-1} and 28 900 cm^{-1}. These bands can be assigned on the basis of a comparison with the corresponding *bis(dma)* and *di-aqua* systems which were studied [8] by the analysis of polarised spectra.[3] In addition to a spin-forbidden band at 22 270 cm^{-1}, two other spin-forbidden bands were uncovered for this system [6] at very high energy, i.e. 32 447 cm^{-1} and 32 658 cm^{-1}. These spin-forbidden bands have been thoroughly interpreted earlier [19].

3.1.6. *trans*-[Cr(en)(pn)F$_2$]$^+$

Even though repeated attempts to grow single-crystals were unsuccessful, this is perhaps one of the very few systems that exhibits all four components clearly in the solution spectrum, hence it has been included in this study (Fig. 6). The four obvious band positions gave a correspondingly similar gaussian fit which resulted in the following band assignments: The lowest energy band is assigned to $^4B_1^Q \rightarrow {}^4E^Q(^4T_2)$ and the next band to $^4B_1^Q \rightarrow {}^4B_2^Q$. Considering the other ligands in the complex, the other two bands are assigned as follows: the band at 25 035 cm^{-1} is assigned to $^4B_1^Q \rightarrow {}^4E^Q(^4T_1)$ and that at 28 630 cm^{-1} is assigned to $^4B_1^Q \rightarrow {}^4A_2^Q$. These assignments are similar to those in the well-known [7] complex *trans*-[Cr(en)$_2$F$_2$]ClO$_4$. These and all other assignments can be found in Table 2.

3.2. Fitting and analysis of parameters

Once the band assignments have been established, ligand field parameters *Dq*, *Dt*, *Ds* and *B* are determined according to the following: The parameter *Dq* is obtained from the band position of $^4B_2$, as this level has an energy of 10*Dq*. The difference in energy between $^4B_2$ and ^4E (i.e. splitting in the first cubic band) is $-\frac{35}{4}Dt$. The difference in energy between the $^4A_2$ and ^4E (i.e. the splitting

[3] This work.

in the second cubic band) is $6Ds - \frac{5}{4}Dt$ and can be rearranged for Ds. The last parameter B, is obtained as $12B$, by taking the difference of the averages of the components of the two cubic bands, $^4T^C_{2g}$ and $^4T^C_{1g}$. These *initial* parameters are then varied until all observed bands in the spectra are fitted *exactly*. The manner in which this was achieved was to assume a linear effect of each of the parameters on the individual energy level and then solve a system of linear equations repeatedly until an exact fitting was obtained. The summary of these calculations are shown below in Table 3 along with the angular overlap model (AOM) parameters (to be discussed) calculated using equations given below.

A discussion of the parameters follows. The parameter Dt, is given by

$$Dt = -\frac{4}{7}(Dq_E - Dq_A),$$

where Dq_E and Dq_A are the Dqs of the equatorial ligands and axial ligands, respectively, of the octahedral complexes. Since *en* is of greater ligand-field strength than any of the ligands used in the axial position here, a negative value of Dt is expected and this is what is seen in the values tabulated (Table 3).

It should be noted that the value of Dq of the quadrate complex is predicted [2,17] to be very similar to the value of Dq_E. Considering the parameter Dq in the complex $Cr(en)_3$, the value reported [18] is 2185 cm^{-1}. Inspection of the values of Dq for all complexes shows a range of 2136–2305 cm^{-1}, indicating that the Dq value of the hexa-coordinated complex is approximately the same as the Dq value of the substituted complex with the ligand

[b] Bonding similarities between *en*-Cr, *pn*-Cr and *dmf*-Cr, *dma*-Cr, allow interchange of Dq values.

occupying the equatorial positions. With the extracted values of Dq and Dt, it is possible, by rearranging the above formula and setting $Dq = Dq_E$, to calculate a value for Dq_A which can be compared to reported values of Dq for the hexa-coordinated complex having the axial ligand in all six coordination sites. This comparison is shown in Table 4.

Since the bonding between the metal and the ligands *dmf* and *dma* is expected to be very similar, the reported value of Dq for *dma* is used for the similar complex with *dmf* in Table 4. For the complexes *trans*-$[Cr(en)_2(dmf)Cl]^{2+}$ and *trans*-$[Cr(en)_2(dmf)Br]^{2+}$, since the axial positions are occupied by two different ligands, the observed Dq_A reported in Table 4 is the average of the values of Dq of the two axial ligands. The additional parameter values of Dq needed for this purpose are of $[CrCl_6]^{3-}$ (1370 cm^{-1}) and $[CrBr_6]^{3-}$ (1300 cm^{-1}).

In the case of $CrBr_6^{3-}$, a value of 1300 cm^{-1} was used after consideration of the Dq values of the other hexa-halo complexes. Inspection of the calculated and observed values of Dq for the axial ligands shows that although a good correlation is observed in the case of dmf(Cl), dmf(Br) complexes, in all the others a deviation of 100 cm^{-1} is observed (except in the case of the *dma* complex, in which the deviation is 200 cm^{-1}). Any large deviation implies that the bonding of the ligands in an octahedral complex does not remain the same when they are the axial ligands in a quadrate complex.

In order to analyse these parameters further, those of the angular overlap model (AOM) are used. This model has been widely used in the analysis of the spectra of transition-metal complexes [21]. The relationships of interest are listed here:

$$e_\sigma(E) = \frac{10}{3}Dq$$

$$e_\sigma(A) = \frac{10}{3}Dq + 2Ds + \frac{5}{2}Dt$$

$$e_\pi(A) = \frac{3}{2}Ds - \frac{5}{2}Dt$$

$$e_\pi(E) = 0.$$

These calculated AOM parameters are also presented in Table 3. Since these parameters are expected to be characteristic of the ligands, the AOM parameters obtained for similar systems in a previous study [7–9] are listed in Table 5. This table also includes, for comparison, parameters obtained for the $[Cr(pn)_2(dmf)_2]^{3+}$ and $[Cr(tmd)_2F_2]^+$ systems in a diffuse-reflectance spectral study [3]. These parameters are very similar to those extracted in the present study.

Table 5
Reported AOM parameters for complexes of Cr^{3+}

Complex	AOM parameters (cm^{-1})			
	$e'_\sigma(E)$	$e'_\pi(E)$	$e'_\sigma(A)$	$e'_\pi(A)$
trans-$[Cr(en)_2F_2]^+$	7267	0	8061	1930
trans-$[Cr(en)_2Cl_2]^+$	7540	0	5755	1103
trans-$[Cr(en)_2Br_2]^+$	7500	0	5155	766
trans-$[Cr(en)_2BrCl]^+$	7540	0	5363	826
trans-$[Cr(en)_2(H_2O)_2]^{3+}$	7787	0	7418	1630
trans-$[Cr(pn)_2(dmf)_2]^{3+}$	7833	0	7380	1402
trans-$[Cr(tmd)_2F_2]^+$	7457	0	8394	1933

4. Conclusions

In this study, the polarised electronic spectra of a number of *trans*-disubstituted bis(ethylenediamine) chromium(III) complexes have been measured at 77 K. The ligand field parameters Dq, Dt, and Ds and the election correlation parameter, B, extracted with the use of theoretical energy equations of d^3 configuration, have been compared with those obtained for similar systems. A favourable comparison of the parameters extracted in this study as well as the relationship to the AOM parameters has been shown. This study contributes to the data available for the growing comparison to results obtained through an analysis using density functional theory [22–25].

Abstract

The synthesis and solid-state IR, ^1H and $^{31}P\{^1H\}$ NMR spectroscopic characterization of complexes of the type $MH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ [M = Ru, Os; R = CH_3, CH_2Cl, C_6H_5 and $CH(CH_3)_2$] are reported in this paper. These compounds were obtained by reaction of the respective cationic complex $[MH(CO)(NCMe)_2(PPh_3)_2]BF_4$ with the sodium salt of the corresponding carboxylic acid in a 1:1 v/v dichloromethane/methanol solution at room temperature. The spectroscopic data of these complexes and some DFT calculations reveal an octahedral geometry with a bidentated carboxylate, two equivalent triphenylphosphines in a mutually *trans* positions, a linear hydride and a linear carbonyl both in the *cis*-positions of the coordination sphere. The catalytic results indicate that these complexes are efficient and regioselective precatalysts for the quinoline hydrogenation and for the hydroformylation of 1-hexene, under mild reaction conditions (130 °C and 4 atm H_2 and 120 °C and 15 atm H_2/CO, respectively). For benzothiophene hydrogenation, the osmium complexes showed low activities whereas the analogous ruthenium complexes were catalytically inactive under somewhat more drastic reaction conditions to those of the quinoline hydrogenation (140 °C and 10 atm H_2).

1. Introduction

The chemistry of ruthenium and osmium complexes containing hydrido, carbonyl and trivalent phosphorus co-ligands has attracted continuous attention because of the wide variety of structures and reactivities exhibited by these compounds [1,2]. Perhaps the Vaska and Diluzio's complex $RuHCl(CO)(PPh_3)_3$ [3] is the most thoroughly studied compound of this series [2]. Interaction of this compound, or alternatively of $RuH_2(CO)(PPh_3)_3$, with carboxylic acids produces $RuCl(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$ and $RuH(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$, where R = CH_3 [4,5], C_2H_5, C_6H_5 [4], $C(CH_3)_3$, C_6H_{11}, CH_2Cl, CF_2Cl, CF_3 [5]. Examples of analogous osmium-complexes are rather scarce in the literature [6] and, to our knowledge, complexes of the type $OsH(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$ have not been synthesized.

Furthermore, interest in hydrido-carboxylate complexes of transition-metals have been further enhanced by their catalytic activity in a number of industrially important chemical reactions [7].

In the present paper, we reported the synthesis and spectroscopic characterization of a group of complexes with general formulae $MH(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$ [M = Ru and Os; R = CH_3, CH_2Cl, C_6H_5 and $CH(CH_3)_2$]; these were tested as precatalysts for the homogeneous hydrogenation of polynuclear heteroaromatic nitrogen and sulfur compounds (quinoline and benzothiophene) and for the olefin hydroformylation (1-hexene).

2. Results and discussion

2.1. Synthesis and characterization of complexes $MH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$

The complexes $MH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ (**III**–**X**) were synthesized in high yields (>70%) by reaction of the respective cationic complex $[MH(NCMe)_2(CO)(PPh_3)_2]BF_4$ (Ru = **I** and Os = **II**) with the sodium salt of the corresponding carboxylic acid in a 1:1 v/v dichloromethane/methanol solution, at room temperature (see Eq. (1)).

M = Ru; R = CH_3 (**III**), CH_2Cl (**IV**), $CH(CH_3)_2$ (**V**) and C_6H_5 (**VI**)
M = Os; R = CH_3 (**VII**), CH_2Cl (**VIII**), $CH(CH_3)_2$ (**IX**) and C_6H_5 (**X**)

(1)

The products **III**–**X** were white unstable solids that had to be manipulated and stored strictly under N_2 atmosphere. Three of the hydrido-carboxylate ruthenium complexes (R = CH_3, CH_2Cl and C_6H_5) were reported early by Dobson and Robinson [4] by the reaction of $RuH_2(CO)(PPh_3)_3$ with the corresponding carboxylic acid and by Sánchez-Delgado et al. [5] by slight modifications of the Robinson's method. However, this method is not of general use for Ru complexes, in the sense that the reaction time, the amount of the carboxylic acid added and the solvent used depend of the carboxylate ligand. On the other hand, the synthetic route that we are reporting in this article is of general application and allowed us to prepare the osmium analogues which, to our knowledge, were unknown to the date. No satisfactory analytical data could be obtained for these complexes, which darken after a few hours even under inert atmosphere at room temperature. Structural characterization of these complexes had to be based on their FT-IR and NMR spectroscopic properties and by comparison of those with the spectra from well-known complexes.

The FT-IR spectra of all complexes **III**–**X** showed medium-to-weak absorptions between 2150 and 2000 cm^{-1}, and very strong and broad bands between 1900 and 1950 cm^{-1}. Comparison with the reported data for $RuH(CO)(\kappa^3\text{-}OCOCMe_3)(PPh_3)_2$[1] and $OsHCl(CO)(PPh_3)_3$ [8][2] allowed us to assign the main bands in these wavenumber regions to the ν(MH) and ν(CO) vibrations of terminal MH and linear MCO groups, respectively [9]. The C–O distance is estimated to be 1.15 ± 0.02 Å for the carbonyls of these complexes [9b]. The wide wavenumber range found for the ν(MH) vibration relative to the ν(CO)-range shows the high sensitivity of the metal–hydrogen bond to changes in electron density around the central metal atom [9b]. This is affected by the type of metal in question [i.e. ν(RuH) = 2010–2070 cm^{-1} whereas ν(OsH) = 2090–2133 cm^{-1}] and by charge donation or withdrawal of the other co-ligands [e.g. ν(RuH) = 2019 or 2036 cm^{-1} for $RuH(CO)(\kappa^3\text{-}OCOCH_3)(PPh_3)_2$ or $RuH(CO)(\kappa^3\text{-}OCOCH_2Cl)(PPh_3)_2$, respectively].

The infrared spectra of the new complexes (with the exception of the Os-complex **VII**) also show the two expected, symmetry-allowed, infrared-active absorptions of the carboxylate group at 1560–1521 [ν_{asym}(OCO)] and 1457–1425 [ν_{sym}(OCO)] cm^{-1}. These values indicate bidentated coordination between the two equivalent oxygen atoms of the OCOR groups and the Ru or Os atom. Indeed when the carboxyl group is monodentated, one of the C–O bonds should have enhanced double bond character and therefore give rise to a high frequency band in the 1590–1650 cm^{-1}-region which is not observed in our spectra [10].

High field ^1H NMR spectra showed triplets between −16.3 and −16.9 ppm with coupling constants close to 20 Hz for the ruthenium complexes, whereas for the corresponding osmium ones the triplets appear between −19.3 and −20.0 ppm ($^2J_{HP}$ close to 16 Hz). These values are consistent with a hydride ligand coupled to two equivalent triphenylphosphines in mutually *trans* positions [5]. This is further supported by the spectra from the $^{31}P\{^1H\}$NMR experiments which show singlets between 41.8 and 46.4 ppm and between 23.3 and 25.2 ppm for the Ru and Os compounds, respectively.

Our results and interpretations are summarized in Table 1. It clearly indicates an octahedral geometry with four monodentated ligands (hydride, carbonyl and two PPh_3) and one bidentated carboxylate group coordinated to the central Ru or Os atom.

A more detailed analysis of the infrared spectra in the 2100–1850 cm^{-1} region (Fig. 1) indicates the presence of two isomers for the above octahedral complexes in solid state, as may be observed by the presence of two hydride bands. For complexes with the general formula $RuH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$, four geometrical isomers could be drawn, which are shown in Fig. 2; for convenience we refer to these below as the *trans*-PPh_3/*trans*-PPh_3 (**A**), *trans*-CO/*trans*-PPh_3 (**B**), *trans*-H/*trans*-PPh_3 (**C**) and *trans*-H/*trans*-CO (**D**) isomers.

[1] For $RuH(CO)(OCO(CH_3)_3)(PPh_3)_2$; IR: ν(Ru–H) = 2000 cm^{-1} and ν(CO) = 1925 cm^{-1}.

[2] For $OsHCl(CO)(PPh_3)_3$. IR: ν(Os–H) = 2097 and ν(CO) = 1912 cm^{-1}.

[a] Negative values are upfield from the signal of external $SiMe_4$.
[b] Positive values are downfield from the signal of external 85% H_3PO_4.
[c] FT-IRS abbreviations: ν = bond-stretching, vs = very strong, s = strong, m = medium, w = weak, vw = very weak, br = broad and sh = shoulder.
[d] NMR abbreviations: s = singlet, d = doublet, t = triplet, sept = septuplet, m = multiplet.
[e] The infrared spectrum also shows bands at 3480 (s, br), 2200 (vw, br), 2050 (vw, br), 1910 (s, br), 1610 (vs), 1490 (m), 1410 (s), 1380 (s), 1325 (m) and 1100 (vs) cm^{-1}. These can be assigned to vibrational modes of water, N≡C M–H, C=O, P–Ph_3 and BF_4^-. They indicate a mixture of small amounts of $[OsH(NCMe)_2(CO)(PPh_3)_2]BF_4$ and $OsH(OCOCH_2Cl)(CO)(PPh_3)_2$ (**VIII**) which probably adsorbed water during the pressing-disc procedure.

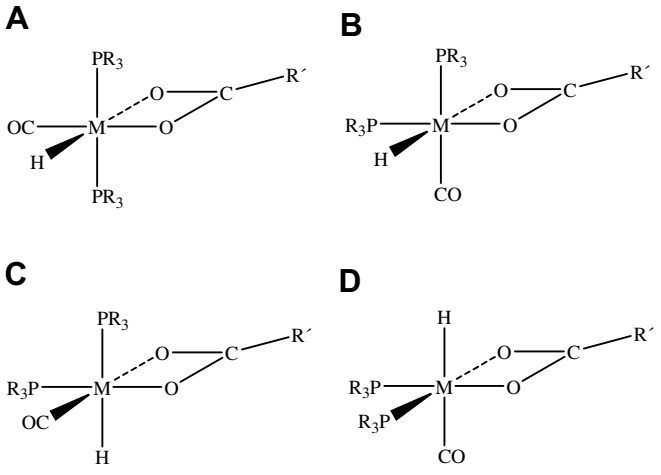

Fig. 1. Possible isomers for complexes $MH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ (M = Ru, Os).

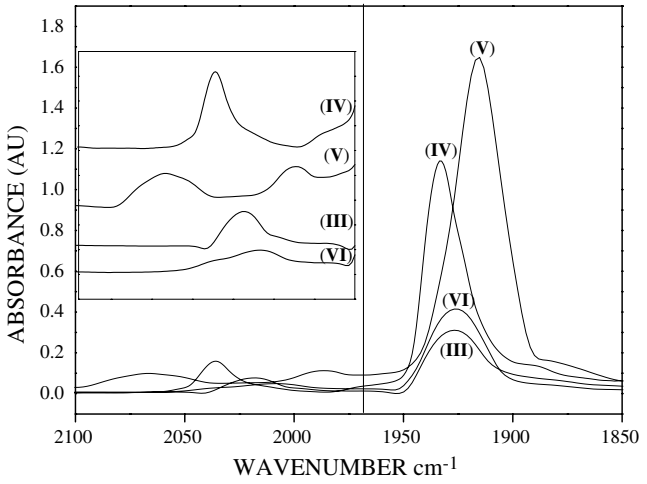

Fig. 2. FTIR for complexes $RuH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ in the 2100–1850 cm^{-1} region.

In other to determine the stability of these isomers, theoretical DFT-calculations were performer for these four isomers with the $FeH(CO)(OOCH)(PH_3)_2$ models using the STO/6-31+G(d,p) extended basis; in Table 2 are listed the calculated energies of these four isomers. As may be observed the isomer **A**, which present the two phosphine ligands in a mutually *trans* position was the more stable isomer, having an energy 20.1, 12.0 and 24.4 kJ mol^{-1} lesser than those of **B**, **C** and **D**, respectively. Isomers **B** and **D** were the least stable of the four isomers. The order of stability was **A** < **C** < **B** < **D**. In view of these results, we proposed that, in solid state, isomer **A** was the major isomer whereas **C** was the minor one. Halide complexes of the type $MX(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ have been found to have similar structure to that of **A** (M = Ru, X = Cl) or **C** (M = Os, X = Br) isomers.

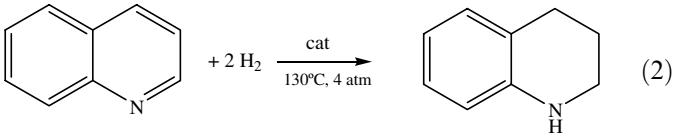

Table 2
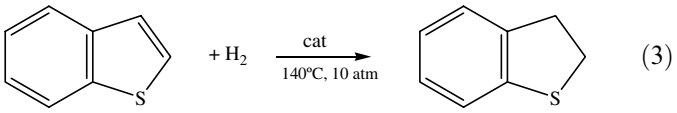
Optimized total energies (hartrees) of the isomers of the model compound $Fe(H)(CO)(OOCH)(PH_3)_2$

Isomer	Energy
A	−2253.089846
B	−2253.082210
C	−2253.085265
D	−2253.080594



Although small amounts of the isomer **C** of complexes **III**–**X** can be presented (less than 10%) in the solid state, the spectroscopic data in solution are in agreement with a stereochemistry in which the two triphenylphosphine are in a mutually *trans* position, the carboxylate ligand is bonded in a bidentated fashion and the hydride and the carbonyl ligand occupy the *cis* positions of the coordination sphere (isomer **A**).

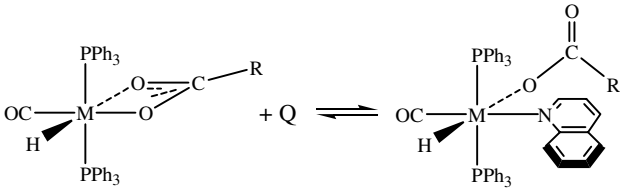
2.2. Catalytic activities of complexes MH(CO)(κ^3-OCOR)(PPh_3)$_2$

The new Rh and Os complexes MH(CO)(κ^3-OCOR)(PPh_3)$_2$ were tested as catalytic homogeneous precursors for the regioselective hydrogenation of quinoline (Q) to 1,2,3,4-tetrahydroquinoline (THQ) and of benzothiophene (BT) to 2,3-dihydrobenzothiophene (DHBT) under mild temperatures and low hydrogen pressures; see Eqs. (2) and (3).

(2)

(3)

The hydrogenation of the heterocyclic ring of polynuclear heteroaromatic nitrogen and sulfur compounds is an area of considerable interest in connection with the industrially important hydrodenitrogenation (HDN) and hydrodesulfurization (HDS) reactions, respectively [11]. Although some Rh- and Ir-complexes have been used for the hydrogenation of the heterocyclic ring of Q and related compounds, the only ruthenium and osmium precatalysts used in this reaction were $RuHCl(PPh_3)_3$ [12], $[MH(CO)(NCMe)_2(PPh_3)_2]^+$ (M = Ru or Os) [13] and $RuCl_2(NCMe)_4$/tris(pyrazolyl)borate [14]. Recently, Borowski et al. [15] reported the regioselective hydrogenation of the non-heterocyclic rings of Q, by using $[RuH_2(\eta^2\text{-}H_2)_2(PCy_3)_2]$ (Cy = cyclohexyl) as the precatalyst. For the BT hydrogenation, the complexes $[Ru(NCMe)_3(triphos)]^{+2}$ [16] and $[RuH_2(\eta^2\text{-}H_2)_2(PCy_3)_2]$ [17] were the only precursors that showed very high activities for this reaction.



The hydrogenation of Q to THQ was achieved by all of the ruthenium and osmium hydrido-carboxylate complexes with high catalytic activities; the results are collected in Table 3 together with the pK_a values of the R groups of the carboxylate ligand of the Ru and Os complexes. As may be observed, the ruthenium complexes were twice more active than the corresponding osmium ones. It is clear that the hydrogenation activities of these compounds (except for the hydrido-isobutyrate cases where steric effects seem to be important) are affected by the electron-releasing character of the carboxylate substituents. Thus, for example, a plot of $\log r_i$ versus pK_a of the acid from which the carboxylate ligand is derived shows an excellent correlation [$\log r_i(\mathrm{Ru}) = -6.48 + 0.09\mathrm{p}K_a$, $r^2 = 0.99$], as may be observed in Fig. 3; for the osmium complexes, a similar tend was observed [$\log r_i(\mathrm{Os}) = -7.17 + 0.17\mathrm{p}K_a$, $r^2 = 0.99$]. Sánchez-Delgado et al. [7] found the contrary effect for the propionaldehyde hydrogenation, which was explained through a mechanism involving equilibrium between species containing the carboxylate ligand coordinated in a bi- and monodentated mode. In our case, we propose that the equilibrium between these two species (Eq. (4)) is very fast and, therefore, is not the rate-determining step of the catalytic reaction. Preliminary kinetic studies indicate that the hydrogenation rate is independent of the amount of quinoline present in the reaction mixture; these results are consistent with the opening of the carboxylate ligand and the coordination of Q molecule being a very fast step.

Table 3
Quinoline hydrogenation catalyzed by MH(CO)(κ^3-OCOR)(PPh_3)$_2$

R	pK_a[a]	$10^7 r_i$ (ms^{-1})	
		Ru	Os

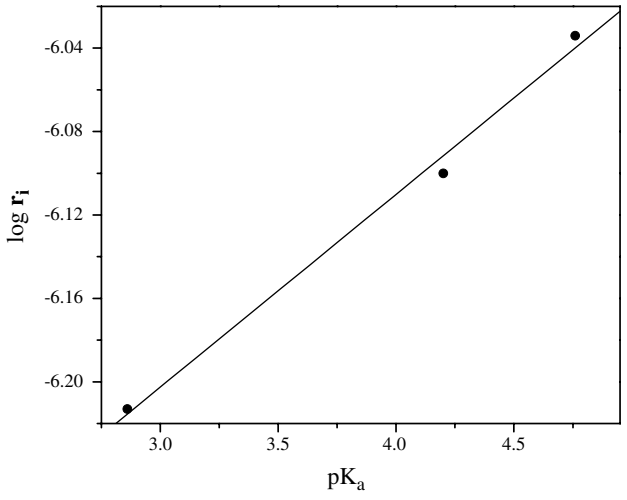
Conditions: $[cat] = 1.0 \times 10^{-3}$ M, $[Q] = 0.17$ M, $p(H_2) = 4$ atm, $T = 130$ °C, solvent = xylene, r_i (initial rate) are expressed in means ± SEM; $P = 0.05$.

[a] pK_a of the acid from which the carboxylate ligand is derived. Yield: 70–80% for Ru complexes and 40–50% for Os ones.

(4)

On the other hand, the hydrogenation of BT to DHBT was observed only with the osmium hydrido-carboxylate complexes (Table 4), the activities being very low (less than 10% conversion); the analogous ruthenium complexes were catalytically inactive for this reaction. Because of the close and very small activities of these osmium systems, no conclusions may be extracted on the relation between activity and the donor character of the carboxylate substituent.



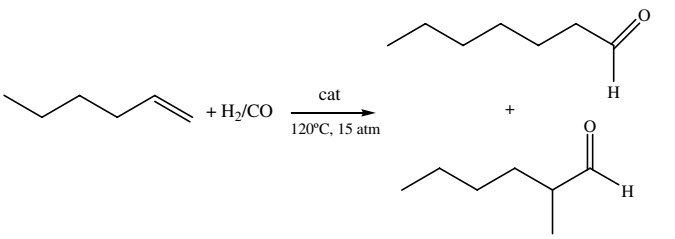


Fig. 3. Hydrogenation of quinoline catalyzed by RuH(CO)(κ^3-OCOR)(PPh_3)$_2$ showing the relation between initial rate (r_i) and the nature of the carboxylate ligand. Conditions as in Table 3.

In order to find new and lesser expensive precatalysts than the rhodium ones for the alkene hydroformylation, in the present work we used the hydrido-carboxylate complexes $MH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ as catalyst precursors for this reaction. This reaction is a well-known synthetic tool for a wide range of organic molecules of commercial value and it is also one of the largest scale applications of homogeneous catalysis in industry. The major capacity is based on the processes using phosphine-modified cobalt [18] and rhodium carbonyl systems [19] but some ruthenium precatalysts have been used for this reaction, such as $RuH_2(CO)_2(PPh_3)_2$ [20], $[RuH(CO)(NCMe)_2(PPh_3)_2]BF_4$ [21], $[Ru(CO)_2(\eta^5\text{-}Cp)]_2$ [22] and $RuH_2(CO)_2(TPPMS)_2$ [23].

The ruthenium and osmium hydrido-carboxylate complexes were efficient and regioselective precatalysts for the hydroformylation of 1-hexene towards heptanal and 2-methyl-hexanal (Eq. (5)), under mild reaction conditions (120 °C and 15 atm H_2/CO) in toluene as the solvent; the results in turnover frequency (TF) are showed in Table 5.

(5)

The ruthenium complexes were more active than the corresponding osmium ones and similar to the Q hydrogenation described before, the complexes with carboxylates presenting donor groups were more active than those containing electron-withdrawing substituents. Again, this effect may be explained through a mechanism which did not involve the opening of the carboxylate ligand as the rate-determining step. For the ruthenium complexes, a plot of log TF versus pK_a of the acid from which the carboxylate ligand is derived shows a very good correlation, $\log TF(Ru) = 0.61 + 0.32pK_a$, $r^2 = 0.96$ (Fig. 4); a similar graph may be constructed for the osmium analogues [$\log TF(Ru) = 0.41 + 0.20pK_a$, $r^2 = 0.92$]. Finally, the regioselectivity find for ruthenium complexes, measured as the linear to branch ratio (l/b), is ranging between 2.5 and 3.5, which is somewhat higher that those found for other ruthenium complexes; the l/b ratio for the osmium analogues varied from 0.8 to 1.6.

Table 4
Benzothiophene hydrogenation catalyzed by $OsH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$

R	Conversion (%)
CH_2Cl	8.9
C_5H_6	6.2
CH_3	8.7
$CH(CH_3)_2$	9.1

Conditions: [cat] = 1.0×10^{-3} M, [BT] = 0.1 M, $p(H_2)$ = 15 atm, T = 140 °C, t = 8 h, solvent = xylene.

Table 5
Hydroformylation of hex-1-ene catalyzed by $MH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ (M = Ru, Os)

R	pK_a[a]	TF (l/b)	
		Ru	Os
CH_2Cl	2.86	38 (2.8)	10 (1.6)
C_5H_6	4.20	80 (3.5)	15 (0.8)
CH_3	4.76	155 (2.5)	22 (1.2)
$CH(CH_3)_2$	4.86	180 (3.0)	27 (0.9)

Conditions: [cat] = 3.3×10^{-3} M, [1-hexene] = 1 M, $p(H_2)$ = 15 atm, T = 120 °C, solvent = toluene, TF = mole of product per mole of catalyst per hour, l/b = linear to isoaldehyde ratio.
[a] pK_a of the acid from which the carboxylate ligand is derived.

The results found both for the Q and BT hydrogenation reactions as for the 1-hexene hydroformylation are promising for two reasons. First, although the Ru precatalysts synthesized in this work are close to one magnitude order less active than Rh ones, ruthenium is a metal less expensive than rhodium and, on the other hand, it is possible through the variation of the electronic properties of the carboxylate and phosphine ligands to increase the catalytic activities of our systems. Finally, it is convenient to mention that Fe complexes have shown to have less catalytic activity for both reactions. For example, $Fe(CO)_5$ is inactive for quinoline hydrogenation and $Fe(CO)_4(PBu_3)$ presented low activity (1% in 5 h) for hydrogenation of 5,6-benzoquinoline under drastic water-gas shift reaction conditions [27], whereas the activities of the Fe systems for olefin hydroformylation are four magnitude order lower than those of the ruthenium ones [18c].

More detailed kinetic and coordination chemistry studies of these catalytic reactions (hydrogenation of Q and BT and olefin hydroformylation) are in progress, aimed at better understanding these systems and at improving even more both the activity as the selectivity properties of the hydroformylation reaction.

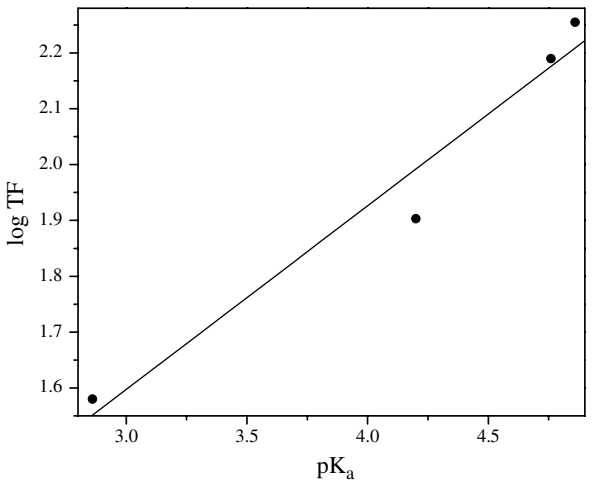

Fig. 4. Hydroformylation of 1-hexene catalyzed by $RuH(CO)(\kappa^3\text{-}OCOR)(PPh_3)_2$ showing the relation between turnover frequency (TF) and the nature of the carboxylate ligand. Conditions as in Table 5.

3. Experimental

3.1. General considerations

All manipulations were performed under argon using standard Schlenck techniques. Solvents, $MCl_3 \cdot 3H_2O$ (M = Ru, Os) for the home-made preparation of $[MH(NCMe)_2(CO)(PPh_3)_2]BF_4$, M = Ru (**I**) [21] and Os (**II**) [13c], quinoline, benzothiophene and 1-hexene were obtained as high purity compounds from Aldrich. Prior to use solvents, quinoline and 1-hexene were distilled over appropriate standard agents under nitrogen. Research grade H_2 and CO gases were obtained from Praxair Venezuela. Before use, these gases were dried by passing them through a column containing $CaSO_4$.

3.2. Analytical procedures

FT-IR spectra of dried discs (i.e. solid samples + KBr) were obtained using a 13-mm-die, 13-mm disk holder, a Caver hydraulic press (>12 ton), a vacuum pump and a Shimadzu FTIR-8300 interferometer. High resolution ^1H and $^{31}P\{^1H\}$ NMR spectra of the samples dissolved in $CDCl_3$were obtained at 300 MHz and 121 MHz, respectively, in a Bruker AC-300 instrument at room temperature; ^1H- and ^{31}P-chemical shifts are expressed in part per million down-field and up-field from $SiMe_4$ and H_3PO_4, respectively.

Gas chromatographic analyses were performed in a 3300 Series VARIAN instrument fitted with a flame ionization detector (FID) and a 2 m 20% SP-2100 on a 0.1% carbowax 100/120 Supelcoport column, using N_2 as carrier gas and naphthalene (for the Q and BT hydrogenation) and *n*-heptane (for hydroformylation of 1-hexene) as internal standards. The results were quantified with a VARIAN 4400 microcomputer.

3.3. Synthesis of complexes

$RuH(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$ [R = CH_3 (**III**), CH_2Cl (**IV**), $CH(CH_3)_2$ (**V**), and Ph (**VI**)] were prepared by the following method. To a solution of $[RuH(NCMe)_2(CO)(PPh_3)_2]BF_4$ (**I**) (0.5 mmol) in a 1:1 v/v mixture of $CHCl_2$ and MeOH (25 mL) was added the corresponding carboxylic Na salt (1.5 mmol). The mixture was stirred vigorously at room temperature for 3–4 h, giving a pale yellow solution which was evaporated under vacuum to about, one-third of its initial volume, obtaining a white precipitate. This solid was washed with methanol and diethylether, and then dried in vacuum. It affords white solids (yields: 70–80%).

The corresponding $OsH(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$ complexes [where R = CH_3 (**VII**), $CH(CH_3)_2$ (**IX**), Ph (**X**)] were synthesized by a similar method but with a reaction time of approximately 7 h. All products were white solids (yields: 70–80%). However, reaction of $[OsH(NCMe)_2(CO)(PPh_3)_2]BF_4$ (**II**) with $Na[OCOCH_2Cl]$ afforded a amourphous, white solid which darken after few minutes even in inert atmosphere. The infrared spectrum of this solid as KBr pellet revealed a solid mixture of small amounts of compound **II** and $OsH(OCOCH_2Cl)(CO)(PPh_3)_2$ (**VIII**) (see footnote e of Table 1). So increasing amounts of the Na salt and a longer period of reaction time (8 h) were needed to obtain white microcrystals of complex **VIII**. ^1H- and proton-decoupled ^{31}P NMR spectra indicated that only compound **VIII** was present in the $CDCl_3$ solutions.

3.4. Computational details

The optimized energy calculations of complexes $MH(\kappa^3\text{-}OCOR)(CO)(PPh_3)_2$ were carried out using Fe as metal, R = H and the simplified PH_3 analogues in order to have a better calculation level. These were performed with the GAUSSIAN-98 computational package by using the B3LYP [24] hybrid method of density functional density theory (DFT); the optimizations were carried out with the 6-31+G(d,p) basis sets [25].

3.5. Details of the catalytic runs

The apparatus and the reaction procedure for the catalytic runs of hydrogenation [13] and hydroformylation reactions [26] have been described in details elsewhere. Briefly, a solution of the precatalyst, substrate, internal standard and solvent were placed in a high pressure reactor which was flushed three times with argon. When this system reached thermal equilibrium, H_2 (or an H_2/CO mixture) was admitted into the reactor at the desired pressure. The reactions were followed by both measuring the gas pressure-drop as a function of time and by gas chromatography. Each reaction was repeated at least twice in order to ensure reproducibility of the results. All straight lines were fitted by conventional linear regression programs to $r^2 > 0.98$.

Acknowledgements

This work was supported from Consejo de Desarrollo Científico y Humanístico through Project (CONDES-0174-02) and for the acquisition of a gas chromatograph. We thank Dr. José Ortega for his valuable help to record the NMR spectra.

Abstract

Purposes of these studies were to synthesize Zn(II) and Co(II) complexes of 3-nitro-4-hydroxybenzoic acid, determine their structures through X-ray crystallography, and obtain their anticonvulsant activities. Thermogravimetric, differential scanning calorimetry, impedance of aqueous solutions and magnetic properties analyses were also determined. Anticonvulsant and related activities of these complexes as well as Zn(II), Co(II), Ni(II) and Mg(II) (5-nitrosalicylato) complexes were determined by the National Institutes of Health, Antiepileptic Development Program. Results of these analyses are presented to document unique bonding features and physical properties of these compounds and their anticonvulsant activities. It is concluded that these compounds have chemical and physical properties that can be used to account for their anticonvulsant activities.

Keywords: Crystal structures; 3-Nitro-4-hydroxybenzoic acid ligand; Zn(II) and Co(II) complexes; Anticonvulsant activity

1. Introduction

Besides their relevance to solid state structure and supramolecular design [1–3], (salicylato)–metal complexes have attracted considerable attention, because of their promising anti-inflammatory and anticonvulsant activities [4–10]. As part of a systematic program devoted to the study of structure–activity relationships of (salicylato)–metal complexes, we recently reported the preparation and crystal structures of (5-nitrosalicylato) complexes of Mg(II), Zn(II), Co(II) and Ni(II). The building units of these complexes self-assemble via π–π stacking and extensive intermolecular hydrogen bonding, resulting in a 3D supramolecular architecture [5]. Although the 5-nitrosalicylate ligand, 5-nsa, has a very versatile coordination behavior, an exciting feature in this series is the possibility of modifying the original structure by moving groups attached to the aromatic nucleus. By shifting the hydroxyl group from C-2 to the C-4 position of the 5-nsa ligand, a

doi:10.1016/j.poly.2007.10.006

suitable set of ligands for intermolecular anchoring through hydrogen bonding was thus obtained for our intended evaluations.

Herein we report the crystal structures of (3-nitro-4-hydroxybenzoato) complexes of Zn(II) and Co(II). A key aspect of these structures is that the individual units self-assemble via extensive hydrogen bonding, leading to an original 3D continuum. Although, in the strict sense, the present complexes are not salicylate derivatives but 4-OH regioisomers, their anticonvulsant properties were determined to examine the effect of this structural change on the structural and physical properties of these complexes in relation to their pharmacological effects. For the sake of comparison, the anticonvulsant activities of related transition metalloelement 5-nsa complexes were also determined [5]. Interestingly, promising pharmacological responses were obtained for these complexes as anticonvulsants. Critical to the knowledge of the mode of action of present anticonvulsant metal complexes was the identification of the actual pharmacologically active entity that crosses the blood–brain barrier. Toward this end, this report presents: (1) the conducting properties of the metal complexes in dilute aqueous solution and (2) water/1-octanol extraction experiments which revealed an unexpected equilibrium between these complexes and the corresponding free ligands.

2. Experimental

2.1. Materials

High purity 3-nitro-4-hydroxybenzoic acid, zinc sulfate heptahydrate and cobalt sulfate heptahydrate were purchased from Acros (USA) and used without further purification.

2.2. Physical measurements

Elemental analyses (C, H and N) were performed with a Perkin–Elmer 2400 analyzer. Infrared spectra were recorded with a Bruker Vector 22 spectrometer. Thermogravimetric analyses (TGA) were performed with a TA Instruments TGA Q500 apparatus. Calibrations were performed at different temperatures using Curie magnetic transitions for the recommended materials: alumel (163 °C) and nickel (354 °C). Mass calibrations were performed using a standard mass of 100 mg. The furnace was calibrated between 100 and 900 °C to verify thermocouple performance. All experiments were performed under dry nitrogen, with a flow rate of 6×10^{-2} l min^{-1}. Analysis of compounds following nitrogen purging was conducted using a heating rate of 20 °C min^{-1} in order to determine percent mass loss with optimal precision. Differential Scanning Calorimetry (DSC) experiments were performed with a TA Instruments Universal V4.2E apparatus under nitrogen. Samples were introduced in aluminum pans and covered with holed caps in view to avoid uncontrolled variation of pressure. Calibration of temperature was performed with 5 N quality indium at 156.6 °C and tin at 231.9 °C and a heating rate of 10 °C min^{-1}. Impedance measurements of aqueous solutions were performed using a VoltaLab 80 (Radiometer Analytical) with a 2-pole cell with two platinum plates. The signal amplitude was 100 mV. A continuous potential of 0 mV was imposed. Solutions, preserved under nitrogen, were placed in a double walled glass cell ensuring thermal stabilization. Measurements were obtained at 20 °C. Magnetic measurements in the 2–300 K temperature range were carried out with a MPMS5 SQUID susceptometer (Quantum Design Inc.).

2.3. Synthesis of complexes

2.3.1. $C_{14}H_{16}N_2O_{14}Zn$ (**1**)

Sodium 3-nitro-4-hydroxybenzoate was prepared by neutralizing 3-nitro-4-hydroxybenzoic acid (0.915 g, 5 mmol) with 5 ml of 1 M NaOH in deionized water. To this solution was added $ZnSO_4 \cdot 7H_2O$ (0.720 g, 2.5 mmol) in 3 ml of water. After a few days **1** was filtered, crystallized from water, and dried over anhydrous magnesium sulfate. Yield: 0.939 g (75%). *Anal.* Calc. for $C_{14}H_{16}N_2O_{14}Zn$ (**1**): C, 33.52; H, 3.21; N, 5.58. Found: C, 33.43; H, 3.18; N, 5.56%. IR (neat, cm^{-1}): 3254 (s), 1621 (s), 1587 (s), 1526 (s), 1420 (s), 1379 (s), 1323 (s), 1264 (s), 1178 (s), 1153 (s), 1118 (s), 1074 (s), 942 (m), 916 (m), 858 (m), 825 (m), 789 (s), 764 (s), 684 (s), 638 (s).

2.3.2. $C_{14}H_{16}N_2O_{14}Co$ (**2**)

Sodium 3-nitro-4-hydroxybenzoate was prepared by neutralizing 3-nitro-4-hydroxybenzoic acid (0.915 g, 5 mmol) with 5 ml of 1 M NaOH in deionized water. To this solution was added $CoSO_4 \cdot 7H_2O$ (0.702 g, 2.5 mmol) in 3 ml of water. After a few days **2** was filtered, crystallized from water, and dried over anhydrous magnesium sulfate. Yield: 0.943 g (76%). *Anal.* Calc. for $C_{14}H_{16}N_2O_{14}Co$ (**2**): C, 33.95; H, 3.25; N, 5.66. Found: C, 34.05; H, 3.18; N, 5.64%. IR (neat, cm^{-1}): 3259 (m), 1621 (s), 1586 (s), 1545 (s), 1524 (s), 1418 (s), 1381 (s), 1323 (s), 1264 (s), 1179 (s), 1153 (s), 1117 (s), 1073 (m), 938 (m), 915 (m), 859 (m), 825 (m), 807 (s), 789 (s), 763 (s), 685 (s), 638 (s).

2.4. X-ray diffraction measurements

Diffraction data were collected with a Bruker-SMART three axis diffractometer equipped with a SMART 1000 CCD area detector using graphite monochromated Mo Kα X-radiation (wavelength $\lambda = 0.71073$ Å) at 100.0(1) K. The low temperature was reached by an evaporated liquid nitrogen stream over the crystal, provided by the Oxford Cryosystem device. Data collection and processing were performed using Bruker SMART programs [11] and empirical absorption correction was applied using SADABS computer program [11]. The structure was solved by direct methods using SIR97 [12], and refined by full-matrix least-

squares based on F^2 using CRYSTALS software [13]. The molecule was drawn using the CAMERON program [14]. All non-hydrogen atoms were anisotropically refined. Hydrogen atoms were located in difference Fourier maps. H atoms were refined isotropically with $U_{iso} = 1.20U_{eq}$ where U_{eq} is the equivalent isotropic atomic displacement parameter of the attached atom. Crystal parameters, data collection and the refinement details of compounds **1** and **2** are reported in Table 1.

2.5. Determination of anticonvulsant activities and Rotorod toxicity

Anticonvulsant activities and Rotorod toxicity of $C_{14}H_{16}N_2O_{14}Zn$ (**1**) and $C_{14}H_{16}N_2O_{14}Co$ (**2**), as well as previously reported related complexes **3**–**6** [5], were determined by the National Institute of Health-National Institute of Neurological Disorders and Stroke-Antiepileptic Drug Development program for the detection and evaluation of compounds as anticonvulsant agents (USA). *Maximal electroshock seizure* were elicited with a 60 cycle alternating current of 50 mA, five to seven times that necessary to elicit minimal electroshock seizures, delivered for 0.2 s via corneal electrodes. *Psychomotor seizures test*: the delivery of a less intense electric stimulation, which produces less intense brain inflammation, via corneal electrodes of 6 Hz, 44 mA or lower, for 3 s is used to produce psychomotor seizures, following instillation of a drop of 0.9% saline prior to this application of electric current. Abolition of the visual stereotypic behavior characterized as minimal clonic automatistic behaviors. *Subcutaneous* (*sc*) *pentylenetetrazol* (*Metrazol*) *seizure threshold test*: a dose of pentylenetetrazol, a potent CNS stimulant (Central Nervous System), which produces seizures in greater than 97% of treated mice, 85 mg/kg of body mass, was administered sc as a 0.5% solution in saline at the posterior neck midline. Animals were observed for 30 min. Failure to observe even a threshold seizure, a single episode of clonic spasms of at least 5 s duration, is defined as anticonvulsant activity. *Rotating rod test*: mice or rats are placed on a 1 inch diameter knurled plastic rod rotating at six revolutions per min. Normal mice and rats can remain on a rod rotating at this speed indefinitely. Neurologic toxicity, either CNS stimulation or depression, is evidenced by a failure of the mouse or rat to remain on the rotating rod for 1 min.

3. Results and discussion

3.1. Description of the $C_{14}H_{16}N_2O_{14}Zn$ (**1**) and $C_{14}H_{16}N_2O_{14}Co$ (**2**) structures based upon X-ray crystallography

Complexes **1** and **2** can be represented by the general formula $(C_7H_4NO_5)_2M(H_2O)_4$, where $M = Zn^{II}$ or Co^{II}. The canonical drawings of these complexes are represented in Fig. 1 and the CAMERON molecular structures in Figs. 2 and 3, with the atom numbering system used in Table 2 which lists the most relevant bond distances and angles.

The formula units of complexes **1** and **2** can be represented by $(C_7H_4NO_5)_2M(H_2O)_4$ where M = Zn or Co. For complex **2**, the asymmetric unit consists of the half of formula unit. In both complexes, the coordination octahedron around the metal atom involves one carboxylato O-atom from each 3-nitro-4-hydroxybenzoate ligand (acting as a monodentate linker) and the O-atoms of the four water molecules harnessed to the metal atom. In $(C_7H_4NO_5)_2Zn(H_2O)_4$ (**1**), the octahedron is slightly distorted. The *cis* angles around the Zn center vary between 85.97(7)° and 92.95(7)° while the *trans* angles vary from 175.70(5)° to 178.68(5)°. The Zn–O(26) and Zn–O(36) distances, 2.074(2) and 2.052(2) Å, respectively, are notably shorter than those for Zn–O(10), Zn–O(11), Zn–O(12), and Zn–O(13); 2.186(2), 2.114(2), 2.092(2), and 2.118(2) Å, respectively.

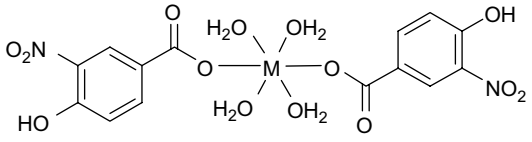

Fig. 1. Canonical representation of $(C_7H_4NO_5)_2M(H_2O)_4$ (**1**, M = Zn; **2**, M = Co).

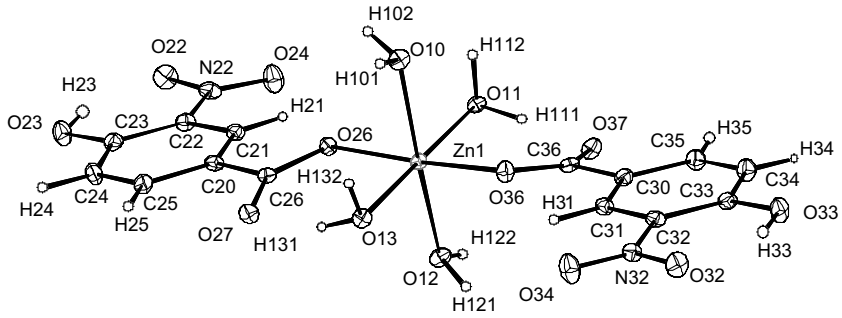

Fig. 2. Labeled CAMERON diagram of $(C_7H_4NO_5)_2Zn(H_2O)_4$ (**1**). Ellipsoids are drawn at a 50% probability level.

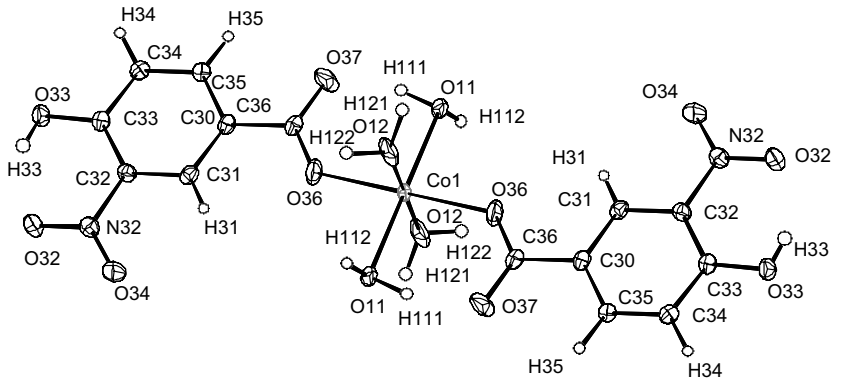

Fig. 3. Labeled CAMERON diagram of $(C_7H_4NO_5)_2Co(H_2O)_4$ (**2**). Ellipsoids are drawn at a 50% probability level.

In contrast, the structure of $(C_7H_4NO_5)_2Co(H_2O)_4$ (**2**) consists of centrosymmetric monomers with the metal atom occupying the inversion center at 0, 1/2, 1/2 of the triclinic unit cell. This symmetry is revealed by two identical metal–carboxylato O-atom lengths of 2.070(2) Å and two pairs of metal–O (water) distances of 2.100(2) and 2.070(2) Å. On the other hand, the *cis* angles around the Co center consist of six centrosymmetrically-related pairs, while identical values were observed for the three *trans* angles, 180.00(8)°. Since complexes **1** and **2** exhibit very close structural features, only details of the packing in **1** were arbitrarily chosen for presentation and discussion in the present paper. The presence of four water molecules around the metal center led to a very extensive and complicated H-bonding network. A list of the most probable atoms involved in H-bonds with their related angles is given in Tables 3 and 4. Fig. 4 shows the H-bonding in **1** around the Zn center. The crystal cohesion is thus ensured by fourteen hydrogen bonds per formula unit.

The individual zero-dimensional units (0D) of **1** are linked together through intermolecular hydrogen bonding implying their *ortho*-nitrophenol groups ends, $O(23)^{iv}$–$H(23)^{iv}\cdots O(32)$ and $O(33)$–$H(33)\cdots O(22)^{iv}$ forming infinite 1D chains (Figs. 5 and 6). The intrachain separation of the Zn centers is 18.82 Å (18.85 Å for Co–Co in complex **2**). It is noteworthy that the *ortho*-nitrophenol groups are also implied in intramolecular hydrogen bonding, $O(23)^{iv}$–$H(23)^{iv}\cdots O(22)^{iv}$ and $O(33)$–$H(33)\cdots O(32)$, which clearly reinforces the cohesion of these chains.

Table 2

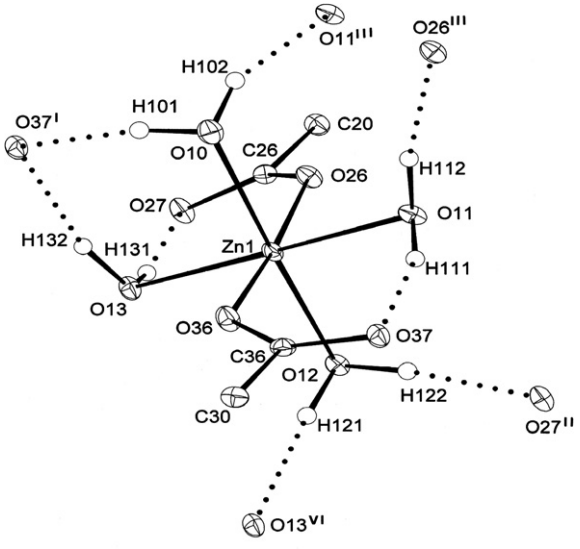

Fig. 4. Labeled diagram of $(C_7H_4NO_5)_2Zn(H_2O)_4$ (**1**) focusing on the hydrogen bonding system around the Zn atom (dashed lines).

plex **2**) resulting in 2D sheets (Fig. 7). These, in turn, self-assemble via hydrogen bonds implying H(122) and H(132) with an interplanar separation of 6.209 Å (7.996 Å for complex **2**) yielding a 3D supramolecular architecture (Fig. 8).

One of the most salient features of this architecture is the compact 3D arrangement of the metal atoms. In complex **1**, the Zn atoms are close to each other, with distances of 4.904, 5.200 and 6.209 Å (Fig. 9a). A centrosymmetric metal arrangement pattern was observed for complex **2** with Co – Co distances of 5.047 and 6.197 Å (Fig. 9b).

3.2. Thermal analysis: TGA and DSC measurements

TGA analysis of **1** revealed a mass loss of 14.8% on heating from 50 to 180 °C, corresponding to a loss of four crystalline water molecules (Calc. 14.4%). TGA analysis of **2** revealed a mass loss of 15.1% on heating from 80 to 180 °C, corresponding to a loss of four crystalline water molecules (Calc. 14.5%). On heating **2** from 80 to 550 °C, an overall mass loss of 85.5% was observed. The non-volatile residue, 14.5% of the starting material, corresponds to one molecule of CoO (Calc. 15.1%). The DSC study of **1** revealed, as the main event, a narrow endotherm centered at 141 °C corresponding to loss of water and a narrow exotherm centered at 342 °C. A similar thermal pattern was observed for complex **2**, with an endotherm centered at 130 °C and exotherm centered at 349 °C.

3.3. Electrochemical impedance measurements

The electrochemical impedance $Z(\omega)$ of the studied sample between the two plates of the conductivity cell is a complex number which can be represented, in polar coordinates by its module $|Z|$ and its phase, in Cartesian representations by its real part Z' and its imaginary part Z'' with $Z(\omega) = Z' + i\,Z''$. At the time of frequency scanning, the experimental points were distributed on a curve having the form of an arc of a circle. The obtained curve is called a Nyquist diagram ($-Z''$ versus Z'). Z'_1 to high frequency, HF, and Z'_2 to low frequency, LF, are the impedance when 'Z' crosses the OZ axis (real axis). The Nyquist curves for 1×10^{-4} M solutions of complexes **1** and **2** (a concentration close to the doses administered in the anticonvulsant and toxicity assays, see Section 3.6) are shown in Fig. 10. The existence of a half circle is typical of the presence of a simple charge transfer. Table 5 gives the electrochemical conductances $(1/Z')$ of complexes **1** and **2** at concentrations of 1×10^{-4} M and 5×10^{-4} M in deionized water. At LF, conductances $(1/Z'_2)$ of solutions of complexes **1** and **2** at identical concentrations are very similar (compare entries 1 and 5 in one hand, and 3 and 7 in the other hand). These values are notably higher than the conductance of deionized water employed in the present experiments (entry 9), that is to say, approximately 25 times for a concentration of 1×10^{-4} M and 130 times for a concentration of 5×10^{-4} M. Note that at LF, the cell capacitance is assumed to be so small that it may be neglected. However, at HF, conductances $(1/Z'_1)$ for solutions of both complexes are of the same order of magnitude, irrespective of

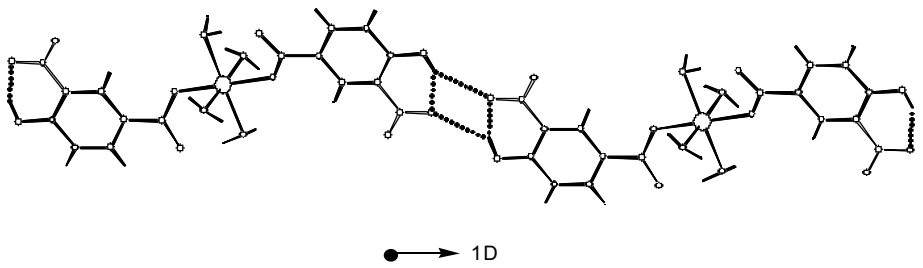

Fig. 5. Part of $[(C_7H_4NO_5)_2Zn(H_2O)_4]_n$ (**1**)$_n$ showing the 1D chain structure with intrachain hydrogen bonds (dashed lines). Zn centers are symbolized by large circles.

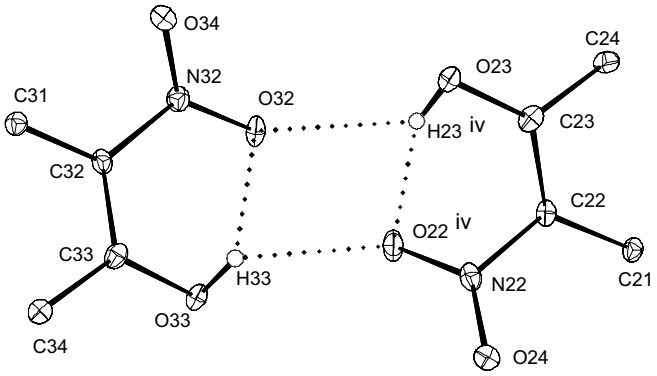

Fig. 6. Labeled diagram of $(C_7H_4NO_5)_2Zn(H_2O)_4$ (**1**) focusing on the hydrogen bonding system around the *ortho*-nitrophenol groups (dashed lines).

concentrations of these complexes (entries 2, 4, 6 and 8), and close to that of deionized water (entry 10). Clearly, at HF, the cell capacitance now markedly competes with the cell resistance, leading to fatal errors in conductance measurements. LF measurements indicate that the conductances of the 1×10^{-4} M and 5×10^{-4} M complex solutions do not differ greatly from those of KCl solutions at these concentrations (entries 11 and 12). Complexes **1** and **2** are therefore strong electrolytes.

3.4. Magnetic measurements

The magnetic properties of Co-complex **2** are shown in Fig. 11. At room temperature, $\chi_M T$ is equal to 3.02 cm^3 K mol^{-1}, value expected for an isolated Co(II) ion. Upon cooling, the $\chi_M T$ values steadily decrease up to 7 K. Below this temperature, the decrease of $\chi_M T$ is steeper to reach a value of 1.62 cm^3 K mol^{-1} at 2 K. In fact, in the 300–30 K temperature range, the experimental curve can be fitted using the theoretical behavior of a distorted octahedral isolated cobalt ion [15]. The best fit of the data by full-matrix diagonalization of the appropriate spin Hamiltonian is obtained with the following parameter $\lambda = -117$, $D = 605$ and $\kappa = 1$ where λ, D and κ stand for spin–orbit constant, axial distortion and orbital reduction factor, respectively. As shown in the inset of Fig. 11, below 30 K the experimental data deviate from the theoretical curve. First, between 30 and 3 K the experimental data are above the theoretical curve indicating that ferromagnetic interaction between Co ions is operative within the

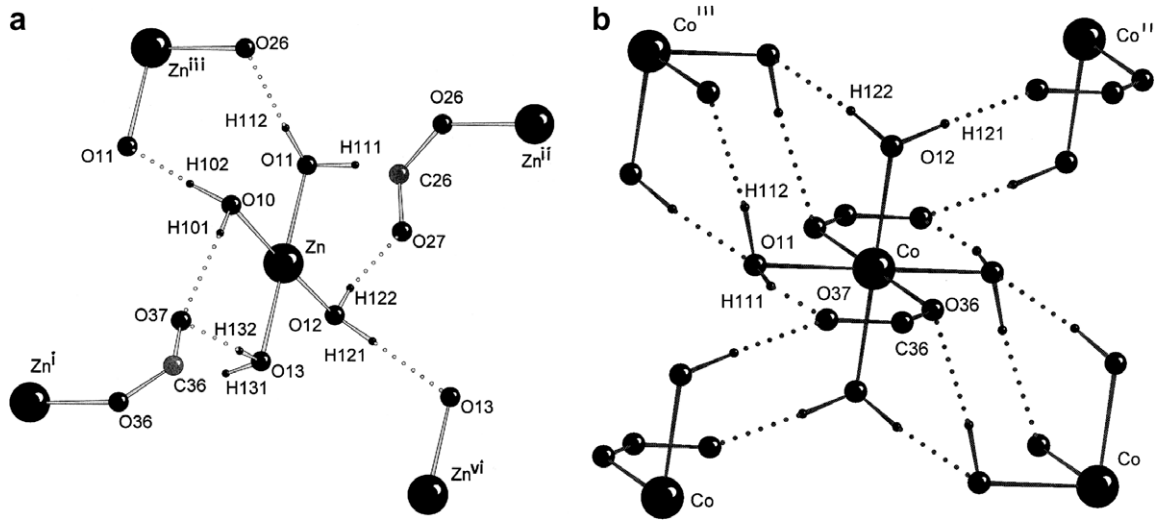

Fig. 9. Packing of $(C_7H_4NO_5)_2Zn(H_2O)_4$ (**1**) (a) and $(C_7H_4NO_5)_2Co(H_2O)_4$ (**2**) (b) concentrating on the 3D arrangement of the metal atoms. Hydrogen bonds are symbolized by dashed lines. Metal–metal distances for Zn–Zn^{iii}: 4.904 Å, Zn–Zn^{vi}, 5.200 Å and Zn–Zn^{i} = Zn–Zn^{ii}, 6.209 Å. Symmetry codes: i: $x+1$, y, z; ii: $x-1$, $y+z$; iii: $-x$, $-y$, $-z+1$; vi: $-x$, $-y+1$, $-z+1$. Metal–metal distances for Co–Co^{iii}: 5.047 Å and Co–Co^{ii}, 6.197 Å. Symmetry codes: iii: $-x+1$, $-y+1$, $-z+1$; ii: x, $y-1$, z.

crystal. Secondly, at very low temperature (3–2 K) the experimental values becomes lower than the theoretical curve showing that a weak antiferromagnetic interaction is also present in **2**. These results are in agreement with the two first levels of hydrogen bonds network in Co-complex **2** (Fig. 9b). On this basis, one can conclude that, magnetically, the cobalt ions are ferromagnetically coupled through the hydrogen bonds network of water molecules (Co^{iii}–O_{11}–O_{10}–Co, Co–Co = 5.047 Å) forming 1D ferromagnetic chains which are antiferromagnetically coupled by the hydrogen bonds developed through the *ortho*-nitrophenol groups of 3-nitro-4-hydroxybenzoate ligand.

3.5. Water/1-octanol extraction experiments

Only the details of the extraction experiment involving Zn-complex **1** are given below. Similar results were obtained with Co-complex **2**. Complex **1** (306 mg, 6.1×10^{-4} mol) was dissolved in deionized water (15 ml).

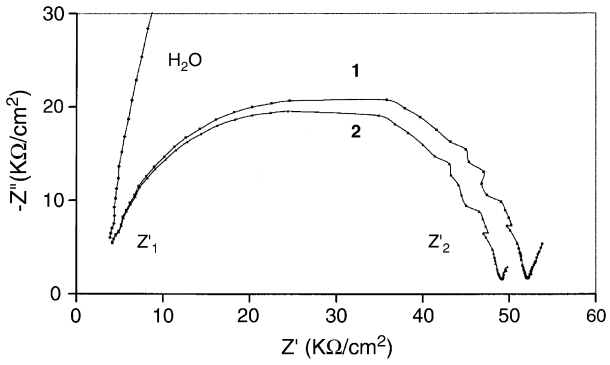

Fig. 10. Nyquist diagrams of complexes **1** and **2** at concentration of 1×10^{-4} M.

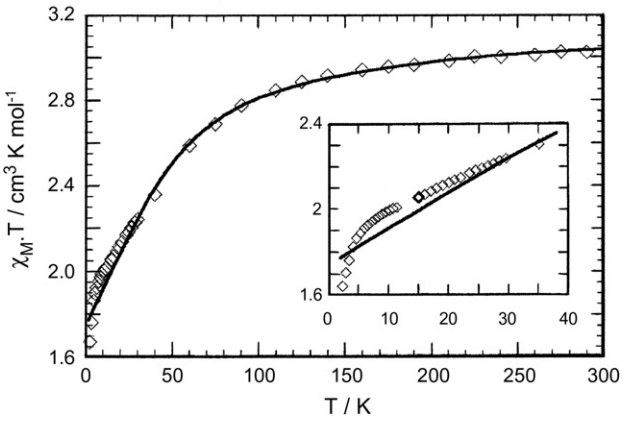

Fig. 11. $\chi_M T$ vs. T plot of Co-complex **2**, experimental (◇) and calculated (——). The inset shows the deviation of the experimental $\chi_M T$ values from the Co monomer behavior.

This solution was extracted with 1-octanol (15 ml) at room temperature. The extraction was repeated four times and the 1-octanol extracts combined. After removal of 1-octanol by vacuum distillation at 1 Torr, 3-nitro-4-hydroxybenzoic acid (111 mg, 6.1×10^{-4} mol), compound **C** in Fig. 12, was obtained as a pale yellow solid, which was unambiguously identified by comparison with an authentic sample using R_f values in thin layer chromatography and IR, UV, and ^{1}H NMR spectra. During this experiment, the color of the aqueous phase changed from pale yellow to bright orange. Evaporation of this solution at room temperature under vacuo gave a microcrystalline orange solid which was successively washed with THF and diethyl ether. Elemental analysis of this solid (Found: C, 30.71; H, 2.41; N, 5.05; Zn, 22.99%) is consistent with the molecular formula $C_7H_3NO_5Zn(H_2O)_2$ (Calc: C, 29.79; H, 2.48; N, 4.96; Zn, 23.14%) corresponding to a salt of type **D** (Fig. 12) in which the ligand **C** and Zn atom components are in the ratio of 1 to 1 (while starting complex **1** comprises two ligands **C** per Zn atom). Two water molecules are linked to each Zn atom of this salt, in order to satisfy the tetrahedral coordination of the metal. The IR spectrum of this salt, (neat, cm^{-1}): 3226 (m, ν O–H), 1596 (s, ν_{as} COO$^-$), 1518 (s), 1391 (s, ν_s COO$^-$), 1324 (s), 1248 (s), 1192 (m), 1153 (s), 1073 (m), 927 (m), 831 (m), 783 (s), 763 (s), 709 (s), 643 (s), is in agreement with the proposed molecular structure. The above outcome can be interpreted on the basis of the putative two-step equilibrium of complexes **1** and **2** in aqueous medium depicted in Fig. 12. The first step of this process involves the dissociation of the complexes into cation **A** and anion **B** [16] (note that similar discrete ionic entities were found in the crystal structures of 5(nsa)-metal complexes **3** and **4**, regioisomers of **1** and **2**, respectively, see Fig. 13). These, in turn, may interconvert through proton transfer into ligand **C** and salt **D** (in which each metal atom is coordinated to two ligand molecules acting as bidendate linkers through their carboxylato and phenoxo groups). Because of its marked lipophilicity (calculated $\log P = 1.78$) [17], ligand **C** is extractable with 1-octanol (an operation that drives the equilibrium towards **C** and **D** partners), while hydrophilic salt **D** remains in the aqueous phase.

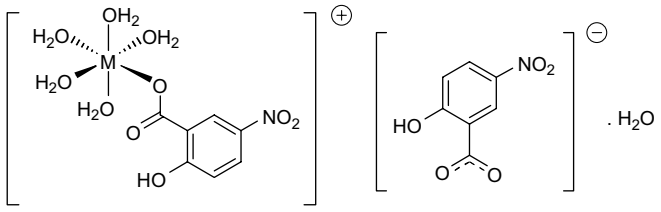

Fig. 13. Crystal structure-based canonical representation of $[M(H_2O)_5(5\text{-nsa})]^+(5\text{-nsa})^- \cdot H_2O$ (**3**, M = Zn; **4**, M = Co; **5**, M = Ni; **6**, M = Mg) [5].

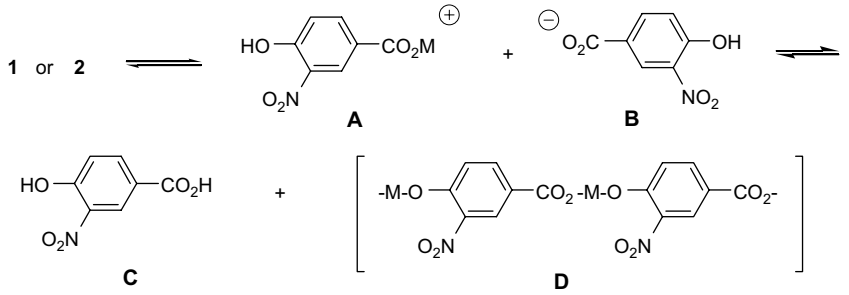

Fig. 12. Putative equilibrium of complexes **1** and **2** in aqueous solution (M = Zn or Co). The water molecules coordinated to the metal atoms have been omitted for clarity.

[a] MES = maximal electroshock seizure test.
[b] Psychomotor seizure or minimal clonic seizures are usually produced with the delivery of 6 Hz (32 mA) or slightly higher current designed to detect compounds that are missed with the MES tests which employs a larger current of 50 mA. It is a much less intense stimulation of the CNS than the MES test.
[c] scMET = subcutaneous Metrazol seizure threshold test, and Rotorod toxicity test.
[d] Rotorod toxicity, an inability to grasp the rotating rod, may be due to CNS depression due to sedative and/or hypnotic activities, or a state of eminent death, due to medullary paralysis at high doses, a common unwanted side effect caused by high doses of all anticonvulsant drugs. A = Activity at indicated dose and time of challenge. I = Inactive, ip = intraperitoneal, o = oral, m = mice, r = rats.

3.6. Anticonvulsant activities

Anticonvulsant activities for compounds **1** and **2**, as well as related (5-nitrosalicylato)–metal complexes [5] (compounds **3**–**6**, Fig. 13), are presented in Table 6.

Only **4** was found to have activity against MES-induced seizures. This modest activity was observed at a relatively low and non-toxic dose given orally to rats. Compounds **1**–**6** had activity in protecting against the less intense minimal clonic seizure with an apparent activity order being $\mathbf{5} > \mathbf{2} \cong \mathbf{1} > \mathbf{3} \cong \mathbf{6}$ and **4**, based upon these preliminary results. Only compounds **1**, **2**and **3** afforded some protection against the MET-induced seizure and the relative order of effectiveness was $\mathbf{1} > \mathbf{2} > \mathbf{3}$.

4. Conclusion

We have shown that the individual subunits of the (3-nitro-4-hydroxybenzoato) complexes of Zn(II) (**1**) and Co(II) (**2**) self-assemble via extensive hydrogen bonding involving water molecules leading to a 3D supramolecular architecture. The electrochemical impedance measurements show that these complexes are strong electrolytes in dilute aqueous solution. On the other hand, magnetic measurement of Co-complex indicates that the Co ions are ferromagnetically coupled thought the hydrogen bonds network of water molecules forming 1D ferromagnetic chains.

The anticonvulsant activities of complexes **1** and **2** as well as related Zn(II), Co(II), Ni(II) and Mg(II) (5-nitrosalicylato) complexes (**3**, **4**, **5** and **6**, respectively) where also determined. The pharmacological responses obtained for these complexes are consistent with those obtained for many related metal complexes [4–10].

The transport of therapeutics across the blood–brain barrier (BBB) is critical for the treatment of disorders of the central nervous system. There is a good correlation between BBB penetration *in vivo* and lipid solubility of a drug, the latter being conventionally expressed as its partition coefficient (*P*), calculated as the ratio of solubilities in 1-octanol and water [18]. Because of their marked hydrophilicity, revealed by their notable water solubility (Section 2.3) and the important conductance of their aqueous solutions (Section 3.3), metal salts **1** and **2** can have direct access to the systemic circulation *via* blood plasma. Lipophilic ligand **C**, which is in equilibrium with complexes **1** and **2** in aqueous medium (Section 3.5), can then penetrate the BBB by diffusion (passive translocation *via* a lipophilic pathway). On this basis, we may hypothesize that the active form of these anticonvulsant metal complexes might be free ligand **C**, the metal salts playing the role of hydrosoluble vectors that release the drug at BBB level. This hypothesis is in full agreement with a previous investigation of (salicylato)–copper complex equilibrium under physiological conditions, which ruled out any implication of the copper complex in the anti-inflammatory activity, since the salicylate anion cannot significantly mobilize plasma copper into tissue–diffusible complexes. Even though the salicylate ligand can effectively promote the gastrointestinal absorption of copper, the reciprocal effect of the metal upon the drug seems to be negligible, except for high metal-to-drug ratios [19–21].

Abstract

The iron(III) complexes $[Fe(2Am4DH)_2]Cl$ (**1**), $[Fe(2Am4Me)_2]Cl$ (**2**) and $[Fe(2Am4Et)_2]Cl$ (**3**) with 2-pyridineformamide thiosemicarbazone (H2Am4DH) and its *N*(4)-methyl (H2Am4Me) and *N*(4)-ethyl (H2Am4Et) derivatives were obtained and characterized by means microanalyses, infrared and EPR spectra. The electrochemical behavior of the complexes was investigated. The thiosemicarbazones and complexes (**1**) and (**2**) presented toxicity against *Artemia salina* at low concentrations. Since this bioassay has a good correlation with cytotoxic activity in human solid tumors, the studied compounds present potential pharmacological applications.

1. Introduction

Thiosemicarbazones and their metal complexes present a wide range of bioactivities [1,2]. The pharmacological profile of a variety of α(N)-heterocyclic thiosemicarbazones derived from pyridine has been extensively investigated, as well as the role of metal coordination in the mechanism of action of these compounds [1,3,4].

It has been shown that the antitumoral action of α(N)-heterocyclic thiosemicarbazones occurs through the inhibition of ribonucleotide diphosphate reductase (RDR), a key enzyme involved in the conversion of ribonucleotides into deoxyribonucleotides during DNA syntheses [5–7]. The active form of the drugs are their iron(II) complexes [8,9]. In the proposed mechanism of action oxidation of the iron(II) complex occurs with release of one electron, which inactivates a tyrosyl free radical present in the structure of the enzyme. Our group suggested that reduction of the iron(III) to the iron(II) complex by cellular thiols could be part of this pathway [10–13]. Hence the preparation of new iron complexes with thiosemicarbazones constitutes an interesting strategy in designing antitumoral drug candidates.

Although the literature reports some structural and spectral studies on 2-pyridineformamide-derived thiosemicarbazones [14–18], to our knowledge their pharmacological applications have not so far been investigated. Our group recently started the study of the possible pharmacological applications of this class of compounds.

In the present work, iron(III) complexes with 2-pyridineformamide thiosemicarbazone (H2Am4DH) and its *N*(4)-methyl (H2Am4Me) and *N*(4)-ethyl (H2Am4Et) derivatives (Fig. 1) were obtained. The toxicity of the

thiosemicarbazones and their metal complexes against *Artemia salina* was assayed as a prescreening of antitumoral action.

2. Experimental

2.1. Apparatus

Partial elemental analyses were performed on a Perkin Elmer CHN 2400 analyzer. Infrared spectra were recorded on a Perkin Elmer FT-IR Spectrum GX spectrometer using KBr pellets; an YSI model 31 conductivity bridge was employed for molar conductivity measurements. Magnetic susceptibility measurements were carried out on a Johnson Matthey MSB/AUTO balance. Electron paramagnetic resonance (EPR) spectra of samples in the solid state and in frozen methanol solution were obtained in quartz tubes of 3 mm of internal diameter at liquid N_2 temperature (77 K) on a Bruker ESP300E equipment with modulation frequency of 100 kHz and modulation amplitude of 1.1 mT. Spectral simulations were performed using EasySpin [19].

The electrochemical experiments were carried out at room temperature in aqueous solution containing 0.1 mol L^{-1} KCl, using an electrochemical analyzer from Bioanalytical Systems Inc. (BAS), model 100BW. The working and auxiliary electrodes were stationary Pt foils, and the reference electrode was Ag/AgCl a medium in which ferrocene is oxidized at 0.48 V (Fc^+/Fc).

2.2. Synthesis of the iron(III) complexes with 2-pyridinoformamide thiosemicarbazone (H2Am4DH) and its N(4)-methyl (H2Am4Me) and N(4)-ethyl (H2Am4Et) derivatives

The thiosemicarbazones were obtained as reported in the literature [14]. The iron(III) complexes were obtained by mixing the desired thiosemicarbazone with $FeCl_3 \cdot 6H_2O$ in acetone at room temperature in 1:2 metal-to-ligand molar ratio. The solids which precipitate were filtered off and washed with diethyl ether.

2.2.1. Bis(2-pyridineformamidethiosemicarbazonato)-iron(III) chloride [Fe(2Am4DH)$_2$]Cl (1)

Brown solid. *Anal.* Calc. for $FeC_{14}H_{16}N_{10}S_2Cl$: C, 35.05; H, 3.36; N, 29.19. Found: C, 35.15; H, 3.29; N, 29.28%; FW: 479.77 g mol^{-1}. IR (KBr, cm^{-1}): ν(C=N)+ ν(C=S) 1509, ν(C=S) 786, ρ(py) 656, ν(Fe–N) 459, ν(Fe–S) 376, ν(Fe–N_{py}) 333. Molar conductivity (1×10^{-3} mol L^{-1} H_2O): 89.8 μS cm^{-1}. Effective magnetic moment = 1.62 (BM). Yield: 82%. Melting point 220–221 °C.

2.2.2. Bis(N(4)-methyl-2-pyridineformamidethiosemicarbazonato)iron(III) chloride [Fe(2Am4Me)$_2$]Cl (2)

Green solid. *Anal.* Calc. for $FeC_{16}H_{20}N_{10}S_2Cl$: C, 37.84; H, 3.97; N, 27.58. Found: C, 37.61; H, 3.94; N, 27.33%; FW: 507.83 g mol^{-1}. IR (KBr, cm^{-1}): ν(C=N)+ ν(C=S) 1551, ν(C=S) 774, ρ(py) 661, ν(Fe–N) 459, ν(Fe–S) 397, ν(Fe–N_{py}) 354. Molar conductivity (1×10^{-3} mol L^{-1} H_2O): 87.9 μS cm^{-1}. Effective magnetic moment = 1.66 (BM). Yield: 70%. Melting point 217–218 °C.

2.2.3. Bis(N(4)-ethyl-2-pyridineformamidethiosemicarbazonato)iron(III) chloride [Fe(2Am4Et)$_2$]Cl (3)

Green solid. *Anal.* Calc. for $FeC_{18}H_{24}N_{10}S_2Cl$: C, 40.34; H, 4.51; N, 26.14. Found: C, 40.48; H, 4.46; N, 26.25%; FW: 535.88 g mol^{-1}. IR (KBr, cm^{-1}): ν(C=N)+ ν(C=S) 1575, ν(C=S) 789, ρ(py) 612, ν(Fe–N) 457, ν(Fe–S) 389, ν(Fe–N_{py}) 349. Molar conductivity (1×10^{-3} mol L^{-1} H_2O): 83.2 μS cm^{-1}. Effective magnetic moment = 1.59 (BM). Yield: 73%. Melting point 205–206 °C.

2.3. Assay of toxicity against Artemia salina

The *Artemia salina* (brine shrimp) lethality test was employed as an antitumor prescreen. Lethality towards brine shrimp was assayed using procedures related in the literature [20,21]. Lethal dose (LD_{50}) is the amount of a substance which causes the death of 50% of a group of test animals. Determination of LD_{50} is an indication of the short-term poisoning potential (acute toxicity) of a compound.

Artemia salina encysted eggs (10 mg) were incubated in 100 mL of seawater under artificial light at 28 °C, pH 7–8. After incubation for 24 h, nauplii were collected with a Pasteur pipette and kept for an additional 24 h under the same conditions to reach the metanauplii stage. The samples to be assayed were dissolved in 1% DMSO (dimethylsulfoxide) and diluted in five different concentrations in seawater. About 10 nauplii were added to each set of tubes containing the samples. Controls containing 1% DMSO in seawater were included in each experiment. Forty-eight hours later, the number of survivors was counted, recorded and the lethal dose 50% (LD_{50} value) and 95% confidence intervals were calculated by Probit analysis [22]. The repeatability of the method was evaluated using at least three replicates of concentration of each sample.

3. Results and discussion

Microanalyses suggest the formation of [Fe(2Am4DH)$_2$]-Cl (**1**), [Fe(2Am4Me)$_2$]Cl (**2**) and [Fe(2Am4Et)$_2$]Cl (**3**) in which the thiosemicarbazones coordinate as anionic ligands. The molar conductivity data reveal that the complexes

are 1:1 electrolytes, in accordance with the proposed formulations.

The values of magnetic moments in the 1.59–1.66 BM range are close to the calculated value of 1.73 BM, characteristic of the presence of one unpaired electron as in low spin iron(III) complexes.

3.1. Infrared spectra

The ν(C=C)+ ν(C=N) composed mode observed in the 1593–1611 cm^{-1} range in the spectra of the thiosemicarbazones shifts to 1551–1575 cm^{-1} in the spectra of the complexes, indicating coordination of the azomethine nitrogen N_2 [14,23].

The ν(C=S) absorption at 850–856 cm^{-1} in the spectra of the uncomplexed thiosemicarbzones is observed at 774–789 cm^{-1} in those of the complexes, in accordance with coordination through a thiolate sulfur. The 61–66 cm^{-1} shift observed upon complexation is compatible with coordination of an anionic thiosemicarbazone in all cases [24–27]. The pyridine in-plane deformation mode at 601–617 cm^{-1} in the spectra of the free bases shifts to 612–661 cm^{-1} in those of the complexes, suggesting coordination of the heteroaromatic nitrogen [14,23]. In addition, new absorptions at 457–459 cm^{-1} and 333–354 cm^{-1} have been attributed to ν(Fe–N) and ν(Fe–N_{py}), respectively, and bands in the 376–397 cm^{-1} range have been assigned to ν(Fe–S) [14,23,28,29].

The infrared data for the complexes indicate coordination of the thiosemicarbazones through the N_{py}–N–S chelating system.

3.2. EPR spectra

The EPR spectra of the frozen methanol solutions in liquid nitrogen (77 K) (Fig. 2a) are very similar and show three different g values (orthorhombic g tensor) characteristic of low-spin Fe^{III} with rhombic distortion. The similarity between the EPR spectra indicates that the iron coordination spheres in the three complexes are similar. The small deviation of the anisotropic g values from 2.0 suggests that the unpaired electron is in the d_{xy} orbital, indicating a $d^2_{xz}d^2_{yz}d^1_{xy}$ ground state configuration for the complexes [23,28,29].

The polycrystalline samples of the three compounds, on the other hand, present different EPR spectra (Fig. 2b). The spectrum of [Fe(2Am4DH)$_2$]Cl (**1**) is mainly isotropic ($g_{iso} = 2.119$), with very small shoulders at $g_1 = 1.990$ and $g_3 = 2.220$. The spectrum of [Fe(2Am4Me)$_2$]Cl (**2**) is anisotropic, with three different g values, and that of [Fe(2AMEt)$_2$]Cl (**3**) has almost axial symmetry.

Spectral simulations were performed for a simple orthorhombic system, a single low-spin Fe^{III} ($S = 1/2$) with given g_1, g_2, and g_3 values (principal values of the g tensor), Lorentzian or Gaussian line-shapes, and magnetic field strain, to account for orientation dependent line-widths. The g values and line-width parameters are presented in Table 1. The simulated spectra are presented in Fig. 2 as dotted lines superimposed to the experimental spectra.

Table 1 shows that the three complexes dissolved in methanol (77 K) have basically the same EPR parameters. The spectral shapes were simulated using a Gaussian uniform broadening ($\Delta B_{FWHM} = 1.5$ mT), and B_{strain}

$[Fe(2Am4DH)_2]Cl$ (**1**)	1.5	0.0, 3.1, 4.1	1.991	2.147	2.221	2.120
$[Fe(2Am4Me)_2]Cl$ (**2**)	1.5	0.0, 3.1, 3.9	1.991	2.147	2.219	2.119
$[Fe(2Am4Et)_2]Cl$ (**3**)	1.7	0.0, 2.9, 4.0	1.990	2.149	2.220	2.119
Polycrystalline complex						
$[Fe(2Am4DH)_2]Cl$ (**1**)	16.0		2.119	2.119	2.119	2.119
$[Fe(2Am4Me)_2]Cl$ (**2**)	13.0	10; 0.0; 0.0	1.991	2.145	2.226	2.120
(2 components)	3.2	0.0; 1.5; 2.0				
$[Fe(2Am4Et)_2]Cl$ (**3**)	4.8	6.5; 0.0; 4.2	2.047	2.132	2.161	2.110

broadening components of about 3 and 4 mT for g_2 and g_3, respectively.

Contrary to the frozen methanol solutions, the spectral shapes of the polycrystalline samples were simulated using a Lorentzian line-shape, which is characteristic of homogeneous broadening. The polycrystalline spectrum of **1** was simulated with an isotropic $g = 2.119$, and $\Delta B_{FWHM} = 16$ mT. Complex **2** on the other hand, presented an anisotropic polycrystalline spectrum ($g_1 \neq g_2 \neq g_3$), with narrow peaks but wide wings. It was not possible to fit this spectrum using a single component, but it was almost completely simulated using two components with equal g values but different line-widths (see Table 1), suggesting the presence of two different populations of iron(III) ions. Polycrystalline **3** has almost axial symmetry ($g_1 \neq g_2 \approx g3$), and the g values differ from those in methanol. It is interesting to note that the average g values for the crystalline complexes **1** and **2**, and for the methanol solutions of the three complexes are the same.

The line-widths of the polycrystalline samples are much larger than in methanol (Table 1), and decrease in the following order: **1** > **2** > **3**. Large line-widths are usually due to spin–spin interactions in concentrated samples. In fact, the distances between the iron atoms are much smaller in the crystals than in the frozen methanol solutions. Among the polycrystalline samples, the distances between the iron atoms are expected to be greater for complexes with thiosemicarbazones containing the bulkier substituents. Indeed, it is observed that the line-width for **3** is the smallest one (Table 1).

3.3. Electrochemical studies

The cyclic voltammograms of complexes **1**–**3** (see Fig. 3) show one quasi-reversible process in the −0.17 to −0.19 V range, attributed to the Fe^{II}/Fe^{III} oxidation, followed by the corresponding reduction at −0.24 to −0.27 V. A second quasi-reversible process is observed at 0.55–0.66 V, attributed to the Fe^{III}/Fe^{IV} oxidation followed by the corresponding reduction at 0.47–0.54 V. The remaining wave in the −0.70 to −0.79 V range was attributed to a reduction process of the thiosemicarbazone (Table 2). The resemblance of electrochemical behaviors of the three complexes suggests that their structures in solution are also very similar.

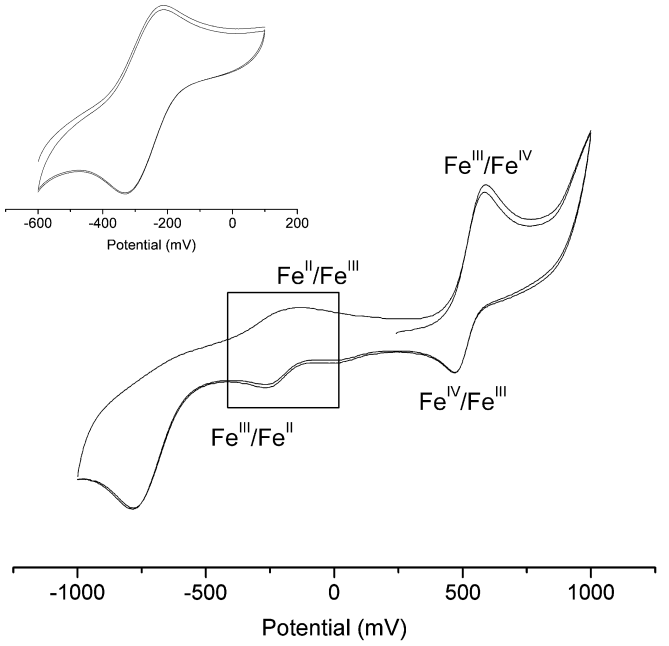

Fig. 3. Cyclic voltammogramm of $[Fe(2Am4Et)_2]Cl$ (**3**) (0.100 V s^{-1}, H_2O, 0.1 mol L^{-1} KCl).

Table 2

[Fe(2Am4DH)$_2$]Cl (**1**)	30.14 ± 1.93
H2Am4Me	26.09 ± 3.96
[Fe(2Am4Me)$_2$]Cl (**2**)	14.12 ± 0.98
H2Am4Et	31.89 ± 3.38
[Fe(2Am4Et)$_2$]Cl (**3**)	> 90

[a] LD_{50}, lethal dose which causes the death of 50% of a group of test animals; SD, standard deviation.

obtained $LD_{50} = 6.88$ mg L^{-1} (35.24 μM); 5.46 mg L^{-1} (26.09 μM) and 7.12 mg L^{-1} (31.89 μM) for H2Am4DH, H2Am4Me and H2Am4Et, respectively. For complexes **1** and **2** we found $LD_{50} = 14.46$ mg L^{-1} (30.14 μM) and 7.17 mg L^{-1} (14.12 μM), respectively. Complex **3** did not show activity up to the concentration of 48 mg L^{-1} (90 μM). The tested compounds were found to be more active than lapachol ($LD_{50} = 68$ μg $mL^{-1} = 281$ μM), which is known as reference compound [30].

Upon complexation with formation of complexes **1** and **2** the values of LD_{50} decrease, indicating higher toxicity. Complex **2** proved to be the most promising ($LD_{50} =$ 14.12 μM). In addition, the complexes are water-soluble, which strongly helps in vivo toxicity assays.

4. Conclusions

The toxicity against *Artemia salina* bioassay has a good correlation with cytotoxic activity in some human tumors [30]. The low values of LD_{50} obtained for the studied compounds in this assay indicate that they could present antineoplastic properties. Moreover, the determined values of Fe^{III}/Fe^{II} redox potentials for **1**–**3** fall in the range of cellular reductants [31]. Therefore, if the complexes present antitumoral activity, their biochemical pathway could involve Fe^{III}/Fe^{II} reduction by cellular thiols, as suggested previously by us for iron complexes of other thiosemicarbazones [10–13].

Abstract

Two novel rhenium(IV) compounds, namely $(NBu_4)[ReCl_5(pym)]$ (**1**) and $(NBu_4)[ReCl_5(pyd)]$ (**2**) (pym = pyrimidine, pyd = pyridazine and NBu_4 = *n*-tetrabutylammonium cation), have been obtained by reaction of $[ReCl_6]^{2-}$ and the diazine in dmf, and their crystal structures determined by single-crystal X-ray diffraction. The structures of **1** and **2** consist of $[ReCl_5(pym)]^-$ or $[ReCl_5(pyd)]^-$ anions and NBu_4^+ cations held together by electrostatic forces and van der Waals interactions. Stacking interactions are present only in **1**. The coordination sphere of the Re^{IV} ion is defined by five chloride anions and one nitrogen atom of a monodentate diazine, resulting in a distorted octahedral environment. Voltammetric profiles in CH_3CN show a one-electron reduction step at ca. −0.5 V vs. NHE for both complexes. Magnetic measurements reveal weak antiferromagnetic interactions among the metal centers in the crystal lattices of **1** and **2**, superimposed to the well-known zero-field splitting of Re(IV) compounds.

1. Introduction

In recent years it has been reported the synthesis of several new coordination compounds of Re^{IV} by ligand substitution onto $[ReX_6]^{2-}$ (X = Cl, Br) [1–6]. Some of these mononuclear complexes can in turn act as ligands towards other transition metal ions, leading to structurally diverse heterometallic compounds with interesting magnetic properties [1a–3,7].

Two aspects related to the use of $[ReX_6]^{2-}$ precursors in synthetic work have required some attention. First, Re(IV) complexes are inert to substitution, and then the full exchange of the halide ligands is commonly hindered. For example, the reaction of $[ReX_6]^{2-}$ with the bidentate O-donor ligands oxalato (ox) or malonato (mal) in refluxing 2-propanol or hot dmf leads to $[ReX_4(O^{\frown}O)]^{2-}$ ($O^{\frown}O$ = ox, mal) and $[ReX_2(O^{\frown}O)_2]^{2-}$ ($O^{\frown}O$ = ox), but never $[Re(O^{\frown}O)_3]^{2-}$ [1,2]. A similar situation is observed with the bidentate N-donor ligand 2,2′-bipyrimidine (bpym), where only the neutral species $[ReX_4(N^{\frown}N)]$ have been isolated [5]. The complete substitution of chloride ligands has been only reported for the synthesis of $[Re(CN)_7]^{3-}$ in dmf with a huge excess of $(NBu_4)CN$ [6] and of $[Re(NCS)_6]^{2-}$ in molten KNCS [8].

Second, the compounds $[ReX_4(N^{\frown}N)]$ can be easily reduced to $[ReX_4(N^{\frown}N)]^-$ in CH_3CN or dmf, but the analogous reduction of $[ReX_4(O^{\frown}O)]^{2-}$ was not evidenced.

pym pyd

Scheme 1.

This fact agrees with a higher affinity of Re^{III} respect to Re^{IV} for bpym, as indicated by the Re–N bond distances in this family of compounds, and reflects the π-accepting ability of the ligand.

In this work, we explore the possibilities of synthesizing new Re(IV) complexes with the ligands pyrimidine (pym) and pyridazine (pyd), which are structurally related to bpym (Scheme 1). These diazines were studied by several authors as potentially bent-bridging ligands and, in many compounds where bridging was observed, their magnetic properties have also been investigated [9,10].

Here, we report the synthesis and crystal structure of the two novel complexes, $(NBu_4)[ReCl_5(pym)]$ (**1**) and $(NBu_4)[ReCl_5(pyd)]$ (**2**). Also, we present the results of our investigations into their electrochemical behaviour and their magnetic properties.

2. Experimental

2.1. General procedure

All reagents were used as received from commercial sources. Potassium hexachlororhenate was prepared from $KReO_4$ following the literature procedure [11]. Solvents were dried by standard methods when necessary. *N*,*N*-dimethylformamide (dmf) was stored with Linde type 4 Å molecular sieves before use.

Infrared spectra were recorded with a Bomen MB 102 FTIR spectrophotometer as KBr pellets in the 4000–200 cm^{-1} region. UV–Vis spectra were recorded with a Shimadzu UV-1603 spectrophotometer in CH_3CN.

The voltammetric profile of the systems were evaluated in CH_3CN with tetraethylammonium perchlorate 0.04 M as supporting electrolyte. The analysed solutions were 1 mM in the Re^{IV} complexes and 1 mM in the ligands. Voltammetric measurements were carried out in a one compartment conic cell, using a polycrystalline (pc) Au disc (3 mm diameter) as working electrode, a Pt sheet as counter electrode and an $Ag/AgNO_3$ 0.1 M in the supporting electrolyte ($E = 0.60$ V vs. NHE) as the reference. Two different electrochemical routines were applied: (a) cyclic voltammetry run at scan rates v varying between $0.005\ V\ s^{-1} \leqslant v \leqslant 0.10\ V\ s^{-1}$ from a cathodic switching potential $E_c = -0.85$ V to an anodic switching potential $E_a = +1.20$ V, and (b) repetitive triangular potential scans at $v = 0.05\ V\ s^{-1}$ with either constant E_c and gradual changes of E_a or constant E_a and gradual changes of E_c.

The magnetic measurements on polycrystalline samples were carried out with a Quantum Design SQUID magnetometer in the temperature range 1.9–300 K and under an applied magnetic field of 1 T ($T > 25$ K) and 250 G ($T < 25$ K) to avoid any problem of magnetic saturation. The device was calibrated with $(NH_4)_2Mn(SO_4)_2 \cdot 6H_2O$. Diamagnetic corrections of the constituent atoms were estimated from Pascal's constants.

2.2. Preparation of $(NBu_4)[ReCl_5(pym)]$ (1)

K_2ReCl_6 (72 mg, 0.15 mmol) and pym (120 mg, 1.5 mmol) were stirred in dmf (1 mL) for 5 h at 125 °C. After cooling the solution was filtered and evaporated at 60 °C until complete elimination of the solvent. The residue was extracted with 10 mL of CH_3CN/MeOH (1:1, v/v) and $(NBu_4)Cl$ (50 mg, 0.18 mmol) was added. Any undissolved material was removed by filtration if necessary. The filtrate was allowed to evaporate slowly, producing bright green crystals of **1** in 80% yield after 3 days. X-ray quality crystals were obtained directly from the mother liquors. Selected IR data [KBr, ν_{max}/cm^{-1}] 3088w, 1647w, 1594s, 1555m, 1407s, 1230m, 1174m, 817m, 699s, 641m, 367w, 349m, 312 vs. UV–Vis [CH_3CN, λ_{max}/nm ($\varepsilon/dm^3\ mol^{-1}\ cm^{-1}$)] 249 (6600), 285 (13 000), 639 (6), 666sh, 680 (7), 719sh, 737 (12). *Anal.* Calc. for $C_{20}H_{40}Cl_5N_3Re$: C, 35.0; H, 5.9; N, 6.1. Found: C, 34.6; H, 6.0; N, 5.9%.

2.3. Preparation of $(NBu_4)[ReCl_5(pyd)]$ (2)

Compound **2** was prepared in 40% yield by a similar procedure, replacing pyd for pym and stirring in dmf for 3 h. Selected IR data [KBr, ν_{max}/cm^{-1}] 3069w, 1641m, 1579w, 1567m, 1419s, 1289w, 964m, 778s, 679w, 641w, 425w, 385w, 344m, 312 vs. UV–Vis [CH_3CN, λ_{max}/nm ($\varepsilon/dm^3\ mol^{-1}\ cm^{-1}$)] 256 (7500), 284 (16 000), 636 (6), 669sh, 683 (7), 719sh, 740 (10). *Anal.* Calc. for $C_{20}H_{40}Cl_5N_3Re$: C, 35.0; H, 5.9; N, 6.1. Found: C, 34.6; H, 5.7; N, 6.0%.

2.4. Crystal structures determination and refinement

Suitable crystals were mounted on a Bruker-Nonius X8-APEXII CCD area detector system and used for data collection. Diffraction data were collected at room temperature, by using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Unfortunately crystals of **2** are too small and not of good quality, diffracting very poorly at higher theta value than 21°. Furthermore, any of our attempt to grow more suitable crystals to perform a better structure determination than the reported one failed. Consequently, the data of **2** were collected with a shorter crystal-to-detector distance (40 mm) and an higher exposure time (30 s) respect to **1** (50 mm and 5 s, respectively). A total of 6317 (**1**) and 5063 (**2**) frames of data were collected using a narrow-frame method with scan widths of 0.3° in ω and ϕ (**1**–**2**). These data were processed through the SAINT [12] reduction and SADABS [13] absorption software to yield a total of 44 083 (**1**) and 33 891 (**2**) reflections. The unit cell

parameters were based upon least-squares refinement of 9588 (**1**) and 7176 (**2**) reflections. Information concerning crystallographic data collection and structure refinements is summarized in Table 1. The structures were solved by standard Patterson methods through the SHELXTL structure determination package [14] and subsequently completed by Fourier recycling. In the structure of compound **2** nitrogen atom N(2) shows large displacements in one direction suggesting that it is affected by thermal disorder. Also carbon atoms of the pyd ring in **2** result very disordered. Consequently, the better model has been found refining them isotropically and with restrains. Both structures show large thermal motion on chains of *n*-tetrabutylammonium as often found in other complexes containing this cation. The refinement was done with terminal carbon atoms of the butyl side chains C13–C16 and C17–C20 treated with restrains on C–C bond distances and C–C–C angles. All non-hydrogen atoms were refined anisotropically except carbon atoms of pyd ligand and C16, C17, C18, C19 and C20 atoms of cation in **2**. The hydrogen atoms were set in calculated positions and refined as riding atoms with a common fixed isotropically thermal parameter. Full-matrix least-squares refinements on F^2, carried out by minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, reached convergence with values of the discrepancy indices given in Table 1. The final geometrical calculations were carried out with the PARST program [15]. The graphical manipulations were performed using the XP utility of the SHELXTL structure determination package. The main interatomic bond distances and angles are listed in Table 2 (**1**–**2**).

3. Results and discussion

3.1. Description of the structures

Compounds **1** and **2** consist of discrete $[ReCl_5(L)]^-$ [where L = pym (**1**) or pyd (**2**)] anions and $[(n\text{-}C_4H_9)_4N]^+$ cations held together by means of electrostatic and van der Waals interactions. Stacking interactions between aromatic rings are observed only in **1**. A perspective drawing of the structures showing the atom numbering is depicted in Fig. 1, while selected bond lengths and angles are listed in Table 2. Each $[ReCl_5(L)]^-$ unit contains a Re(IV) atom in a distorted octahedral geometry, being bonded to a monodentate pym/pyd molecule and five chloride anions. The Re–N and the average Re–Cl bond distances [2.170(2) and 2.338(1) Å in **1** and 2.123(6) and 2.335(3) Å in **2**] are in agreement with those found in the literature [5,16–18]. The Re–Cl bond lengths in *trans* position to the nitrogen donors are slightly shorter than those in *cis* position. The N(1), Cl(2), Cl(3), and Cl(5) set of atoms constitute the best equatorial plane around Re, the largest deviation from planarity being 0.006(1) and 0.023(3) Å at N(1) in **1** and **2**, respectively. The Re atom is 0.0110(4) Å out of this plane in **1** and practically placed in plane in **2**. The pyrimidine/pyridazine ring is planar and the C–C and C–N bond lengths are as expected. The dihedral angle between the pyrimidine/pyridazine mean plane and the equatorial one are 45.5(1)° and 38.5(4)° in **1** and **2**, respectively.

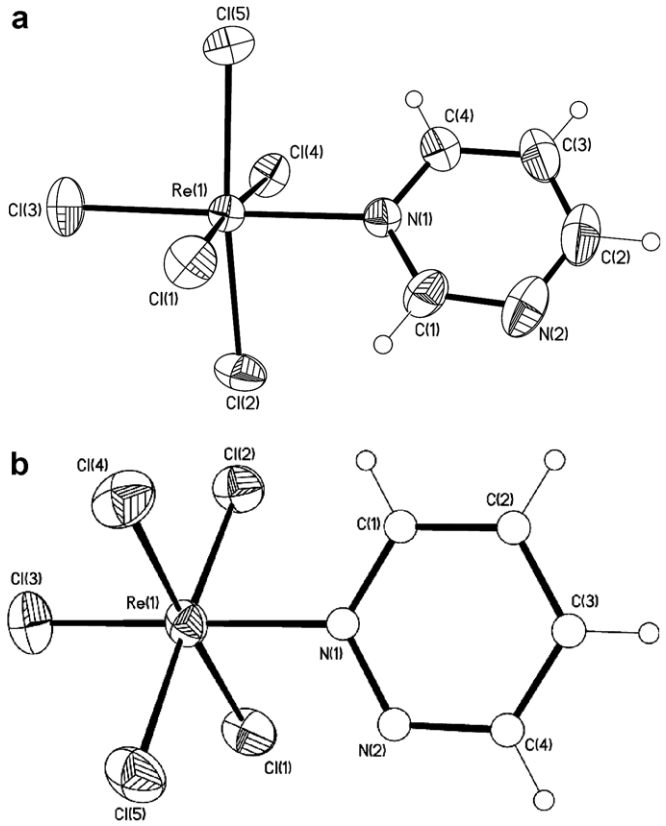

Fig. 1. Perspective drawing of the anionic $[ReCl_5(pym)]^-$ unit in **1** (a) and the $[ReCl_5(pyd)]^-$ unit in **2** (b) showing the atom numbering scheme. Thermal ellipsoids are drawn at 30% of probability level.

In compound **1**, the $[ReCl_5(pym)]^-$ anions show short Cl···Cl distances between them of 4.361(1) Å [Cl(5)···Cl(2a); (a) $= x+1, y, z$] that define chains developing along x axes, with a related Re(1)···Re(1a) distance of 8.863(1) Å. Adjacent chains of anions are packed through π–π interactions which take place between pyrimidine rings with an interplanar distance of 3.63 Å and an efficiency of overlap of about 60% (Fig. 2). The Re···Re distance between these stacked units is 8.517(1) Å [Re(1)···Re(1b); (b) $= -x+1, -y+1, -z+1$], the shortest observed in the structure. The resulting compound could be viewed as pairs of chains intercalating $[(n\text{-}C_4H_9)_4N]^+$ cations.

In compound **2**, even if there are aromatic groups no π–π interactions are present and anions are packed through weak forces. Also in **2** there are short Cl···Cl distances between $[ReCl_5(pyd)]^-$ units of 4.627(1) Å [Cl(1)···Cl(5a); (a) $= -x+1, -y, -z+1$] that lead to *pseudo*-dimers, as shown in Fig. 3, lying on layers intercalated by $[(n\text{-}C_4H_9)_4N]^+$ cations. The value of Re(1)···Re(1a) distance within dimers is 7.206(1) Å and corresponds to the shortest Re···Re distance observed in compound **2**. The pseudo-dimers anions have four nearest complex ions, with rhenium–rhenium distances of 9.020(1) Å.

The distances and angles of each tetrahedral $[(n\text{-}C_4H_9)_4N]^+$ cations in **1** and **2** are as expected. The scatter in the N–C and C–C distances and in the N–C–C and C–C–C angles doubtless arises from the considerable thermal motion, which is quite a common feature observed in most of the crystals containing this organic cation.

3.2. Electrochemical studies

The voltammetric profiles for compounds **1** and **2** in CH_3CN solution are shown in Fig. 4. Both complexes exhibit an electron transfer controlled process for the Re^{IV}/Re^{III} redox couple at practically the same potential peak values. For the pyridazine complex, this couple is located at −0.48 V vs. NHE, showing a slow electron transfer electrochemical reaction with an asymmetry parameter higher than 0.5. The intensity current peak ratio (i_{pc}/i_{pa}) is smaller

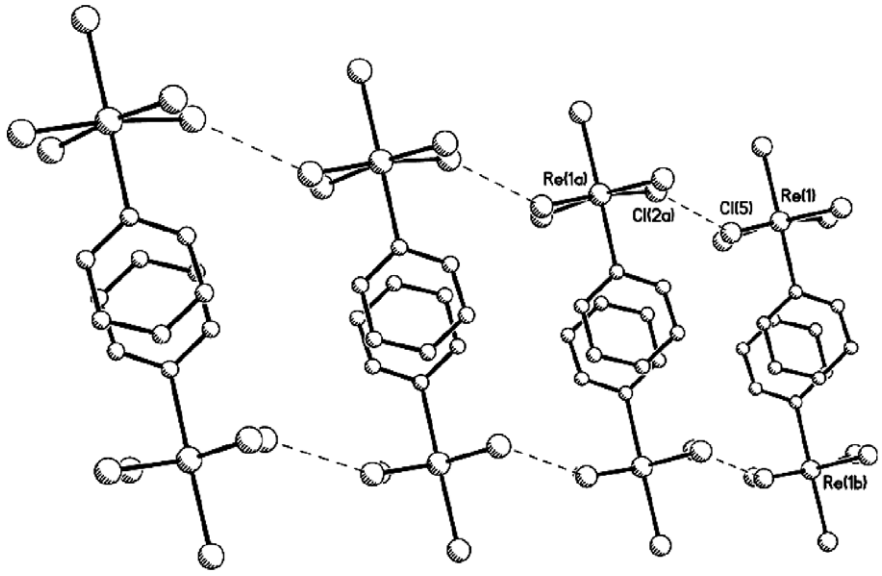

Fig. 2. Perspective view of the short Cl···Cl contacts (dotted lines) between anions and the stacking interactions between adjacent chains in **1**.

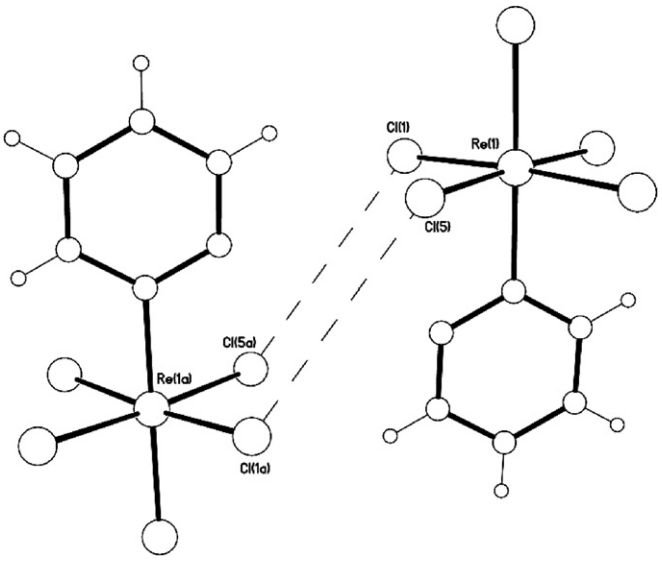

Fig. 3. View of the short Cl···Cl contacts (dotted lines) between anions in **2**.

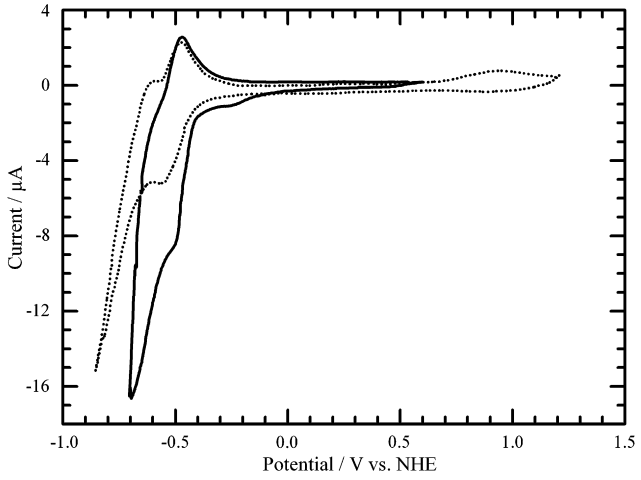

Fig. 4. Voltammetric profile of Au-pc in 1 mM $[ReCl_5(pym)]^-$ (solid line) and $[ReCl_5(pyd)]^-$ (dotted line) in 0.04 M tetraethylammonium perchlorate in acetonitrile at $v = 0.050$ V s^{-1}.

than 1, the potential peak value difference ($E_{pa} - E_{pc}$) is higher than 0.06 V, and the anodic potential peak E_{pa} shifts with ln v (slope = 0.010 V decade^{-1}) with an important overlapping with the contributions coming from the ligand-supporting electrolyte-solvent system. Moreover, the electron transfer is so slow that for $v < 0.010$ V s^{-1} the cathodic contribution is not detected. In addition, the electroactive species diffuses onto the electrode, as assessed by the linear relationship between i_{pa} and $v^{1/2}$.

For the pyrimidine complex, the Re^{IV}/Re^{III} couple is located at –0.50 V vs. NHE, with $\Delta E_p = 0.10$ V. The potential peak values for the anodic and cathodic contributions are the same for all v. The process is electron transfer controlled and involves the diffusion of the electroactive species. In addition, due to the overlapping with the contributions from the ligand-supporting electrolyte-solvent system, it is not possible to quantify the intensity of the related cathodic contribution.

Cyclic voltammetry in the same experimental conditions shows that the compound $(NBu_4)_2[ReCl_6]$ is not reduced to Re^{III} within the applied potentials range. Also, it is worthwhile to recall that for $[ReCl_4(bpym)]$ in CH_3CN, a reversible Re^{IV}/Re^{III} couple was located at more positive potential peak values ($E'^{\circ} = +0.19$ V vs. NHE) [5].

3.3. Magnetic properties

The magnetic properties of both complexes under the form of $\chi_m T$ vs. T plot (χ_m being the molar magnetic susceptibility) are shown in Fig. 5. At room temperature, the values of $\chi_m T$ are 1.51 and 1.55 cm^3 mol^{-1} K for **1** and **2**, respectively, as expected for non-interacting Re^{IV} ions ($S = 3/2$) with $g \approx 1.8$. Upon cooling, the curves remain practically constant down to until $T = 100$ K and then decrease at lower temperatures to reach values of 0.48 (**1**) and 0.72 cm^3 mol^{-1} K (**2**) at 1.9 K. No maximum of susceptibility is observed for **1** or **2** in the temperature range studied.

This behaviour could be attributed to zero-field splitting, that has been previously shown to be very important for Re^{IV} in pseudo-octahedral environments. However, the $\chi_m T$ values at 1.9 K are smaller than the expected for a magnetically diluted mononuclear Re^{IV} complexes (ca. 0.9 cm^3 mol^{-1} K) which would support the occurrence of noticeable antiferromagnetic interaction between the spin carriers.

Thus, we have analysed the magnetic data through the theoretical expressions for the magnetic susceptibility according to Eq. (1b) derived from the Hamiltonian in Eq. (1a) [19]:

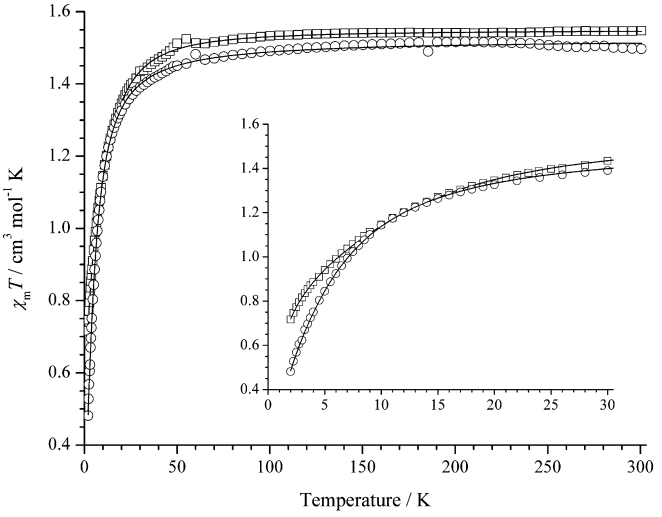

Fig. 5. Thermal dependence of $\chi_m T$ for **1** (circles) and **2** (squares). The solid lines are the calculated curves (see text).

$$\mathbf{H} = D[\mathbf{S}_z^2 - S(S+1)/3] + g_{//}\mu_B H_z \mathbf{S}_z + g_\perp \mu_B (H_x \mathbf{S}_x + H_y \mathbf{S}_y) \quad (1a)$$

$$\chi_{//} = \frac{N\mu_B^2 g_{//}^2}{4k(T-\theta)} \frac{1 + 9\exp(-2D/kT)}{1 + \exp(-2D/kT)}$$
$$\chi_\perp = \frac{N\mu_B^2 g_\perp^2}{k(T-\theta)} \frac{1 + (3kT/4D)[1 - \exp(-2D/kT)]}{1 + \exp(-2D/kT)} \quad (1b)$$
$$\chi_m = \frac{\chi_{//} + 2\chi_\perp}{3}$$

where $2D$ is the energy gap between $\pm 3/2$ and $\pm 1/2$ Kramers doublets, and a θ term has been added to account for magnetic coupling among the mononuclear units.

If θ is set to zero, the calculated curves do not match very well the experimental data, specially in the low temperature range. But when θ is included, and assuming $g_{//} = g_\perp = g$ in order to avoid overparametrization, an excellent agreement between experimental and calculated data is achieved. The best least-squares fit parameters are then $|2D| = 12.4(4)\ \mathrm{cm}^{-1}$, $g = 1.803(1)$, $\theta = -2.33(5)$ K and $R = 2.26 \times 10^{-5}$ for **1** and $|2D| = 28.2(2)\ \mathrm{cm}^{-1}$, $g = 1.818(1)$, $\theta = -0.75(1)$ K and $R = 0.82 \times 10^{-5}$ for **2** (R is the agreement factor defined as $\Sigma_i[(\chi_m T)_{obs}(i) - (\chi_m T)_{calc}(i)]^2 / \Sigma_i[(\chi_m T)_{obs}(i)]^2$).

4. Conclusions

The reaction of $[ReCl_6]^{2-}$ with an excess of pym or pyd in hot dmf leads to the monosubstituted anions $[ReCl_5(pym)]^-$ and $[ReCl_5(pyd)]^-$, respectively, which can be isolated as tetrabutylammonium salts. No further chloride substitution was observed in our studies.

Voltammetric profiles in CH_3CN show that both complexes can be electrochemically reduced, the quasi reversible Re^{IV}/Re^{III} couples being located at -0.50 V (**1**) and -0.48 V (**2**). These results suggest that so long as N-donor π-acceptor ligands contribute to stabilizing Re^{III} with respect to Re^{IV}, the higher the number of Re^{IV}–N bonds, the more oxidant the complex is.

Finally, compounds **1** and **2** have very similar magnetic behaviours. The thermal variation of the product $\chi_m T$ can be mainly attributed to the large zero-field splitting of Re^{IV}. In addition, the separations between the anions in the lattices make possible some weak antiferromagnetic interactions. The magnitude of these interactions given by the θ values can be roughly related to the Cl···Cl intermolecular distances in the crystal.

Abstract

Five copper(II) complexes of formulas [Cu(bpcam)(CN)(H_2O)] (**1**), [Cu(bpcam)(N_3)(H_2O)]$_2$ (**2**), [Cu(bpcam)(NCS)(H_2O)] (**3**), [Cu(bpcam)(dca)(H_2O)]$_2$ (**4**) and [Cu(bpca)(tcm)]$_n$ (**5**) [bpcam = bis(2-pyrimidylcarbonyl)amidate, bpca = bis(2-pyridylcarbonyl)amidate, dca = dicyanamide and tcm = tricyanomethanide] have been prepared and their structures determined by single crystal X-ray diffraction. Compounds **1** and **3** are mononuclear species where each copper atom is five coordinated with a tridentate bpcam and a terminally bound cyanide (**1**)/thiocyanate (**3**) ligands creating a basal plane with a water molecule in the axial position of a distorted square pyramid. Compound **2** is made of neutral di-μ-1,1-azidobis[(aqua)(bpcam)copper(II)] dinuclear and aqua(azido)(bpcam)copper(II) mononuclear units. The copper–copper separation in the dinuclear entity is 3.730(5) Å. The structure of **4** consists of neutral di-μ-1,3-dcabis[(aqua)(bpcam)copper(II)] units, the intramolecular copper–copper distance being 5.701(3) Å. Compound **5** is a uniform copper(II) chain where the [Cu(bpca)]$^+$ units are connected through single μ-1,5-tcm bridges which link one equatorial position of a copper atom with the apical position of the adjacent copper. The intrachain copper–copper separation in **5** is 7.688(3) Å. Magnetic susceptibility measurements of **2**, **4** and **5** in the temperature range 1.9–295 K show the occurrence of weak antiferromagnetic interactions between the copper(II) ions, $J = -1.7$ (**2**), -0.53 (**4**) and -0.64 cm^{-1} (**5**) [the Hamiltonians used being defined as $\hat{H} = -J\hat{S}_1 \cdot \hat{S}_2$ (**2** and **4**) and $\hat{H} = -J\sum_i \hat{S}_i \cdot \hat{S}_{i+1}$ (**5**)].

1. Introduction

Copper(II)-assisted hydrolysis of the substituted triazines 2,4,6-tris(2-pyridyl)-1,3,5-triazine (tpyt) and 2,4,6-tris(2-pyrimidyl)-1,3,5-triazine (tpymt) in mild conditions affords the highly stable [Cu(bpca)]$^+$ and [Cu(bpcam)]$^+$ species (see Scheme 1) where bpca and bpcam are the bis(2-pyridylcarbonyl)amidate and bis(2-pyrimidylcarbonyl)amidate anions, respectively. They were isolated and structurally characterized as the mononuclear complexes of formula [Cu(bpcam)(H_2O)$_n$]X · $p$$H_2O$ [$n = 2$ and $p = 3$ (X = ClO_4^-) and $n = 3$ and $p = 2$ (X = NO_3^-)] [1,2] and [Cu(bpca)(H_2O)$_2$]NO_3 · 2H_2O [3], where the tridentate bpcam and bpca groups and either two or three coordinated water molecules achieve the five- or six-coordination around the copper atoms. The facile replacement of these water molecules by potentially bridging ligands has allowed the preparation of homo- [2,4–8] and heterometallic [9,10]

Scheme 1.

polynuclear species exhibiting interesting magnetic properties. For instance, intramolecular ferromagnetic interactions were observed between the copper(II) ions through oxalate [5a,d,e] and 1,2-dithiosquarate (1,2-dtsq) [7] bridges and also between copper(II) and low-spin iron(III) ions across the cyanide bridge [10].

Additionally, the tridentate bpca ligand can also adopt a bidentate coordination through its two carbonyl-carbon atoms as illustrated for the first time by the copper(II) chain $[Cu(bpca)]ClO_4$ [11]. This result together with the fact that the bpca ligand is able to form mononuclear complexes $[M(bpca)_2]^{0/+}$ with di- [M = Mn^{II}, Fe^{II}, Ni^{II}, Cu^{II}, Zn^{II} and Rh^{II}] [12–16] and trivalent [M = Fe^{III} and Rh^{III}] [13,16,17] transition metal ions have allowed the preparation of variable-dimensionality magnetic compounds: homo- and heterotrimetallic complexes [14,18,19], single-chain magnets [20] and honeycomb layered materials [18b,21].

In the context of our previous magneto-structural studies with the bis(2-arylcarbonyl)amidatecopper(II) complexes as precursors of polynuclear species, we have now prepared five new compounds of formulas $[Cu(bpcam)(CN)(H_2O)]$ (**1**), $[Cu(bpcam)(N_3)(H_2O)]_2$ (**2**), $[Cu(bpcam)(NCS)(H_2O)]$ (**3**), $[Cu(bpcam)(dca)(H_2O)]_2$ (**4**) and $[Cu(bpca)(tcm)]_n$ (**5**), (dca = dicyanamide and tcm = tricyanomethanide). The syntheses and X-ray structures of **1**–**5** together with the investigation of the variable-temperature magnetic behaviour of **2**, **4** and **5** are included herein.

2. Experimental

2.1. Materials

The potassium salts of cyanide, thiocyanate and tricyanomethanide and the sodium salts of azide and dicyanamide were purchased from commercial sources and used as received. $[Cu(bpcam)(H_2O)_3]NO_3 \cdot 2H_2O$ and $[Cu(bpca)(H_2O)_2]NO_3 \cdot 2H_2O$ were prepared by the copper(II)-assisted hydrolysis of the tpymt and tptz ligands, respectively, as previously reported [1,3]. Elemental analysis (C, H, N) was conducted by the Microanalytical Service of the Universidad Autónoma de Madrid.

2.2. Synthesis

2.2.1. $[Cu(bpcam)(CN)(H_2O)]$ (1)

Single crystals of **1** as blue blocks were grown by slow diffusion in an H-shaped tube of aqueous solutions of $[Cu(bpcam)(H_2O)_3]NO_3 \cdot 2H_2O$ (0.094 g, 0.2 mmol) in one arm and KCN (0.013 g, 0.2 mmol) at the other one. The yield is practically quantitative after one month on standing in a hood at room temperature. *Anal.* Calc. for $C_{11}H_8CuN_6O_3$ (**1**): C, 39.36; H, 2.38; N, 25.03. Found: C, 39.19; H, 3.30; N, 29.91%.

2.2.2. $[Cu(bpcam)(N_3)(H_2O)]_2$ (2)

This compound is obtained as a polycrystalline blue solid by the reaction of aqueous solutions containing stoichiometric amounts of $[Cu(bpcam)(H_2O)_3]NO_3 \cdot 2H_2O$ and sodium azide. The yield is quantitative. X-ray quality crystals of **2** as blue blocks were grown by slow diffusion in an H-shaped tube of aqueous solutions of $[Cu(bpcam)(H_2O)_3]NO_3 \cdot 2H_2O$ (0.094 g, 0.2 mmol) in one arm and NaN_3 (0.013 g, 0.2 mmol) at the other arm. The yield is practically quantitative after one month. *Anal.* Calc. for $C_{10}H_8CuN_8O_3$ (**2**): C, 34.15; H, 2.28; N, 31.85. Found: C, 34.08; H, 2.23; N, 31.60%.

2.2.3. $[Cu(bpcam)(NCS)(H_2O)]$ (3)

X-ray quality crystals of **3** as blue plates were grown by slow diffusion in water as done for **1** and **2**, the starting chemicals being $[Cu(bpcam)(H_2O)_3]NO_3 \cdot 2H_2O$ (0.094 g, 0.2 mmol) and KSCN (0.019 g, 0.2 mmol). The yield is practically quantitative after three weeks. *Anal.* Calc. for $C_{11}H_8CuN_6O_3S$ (**3**): C, 35.93; H, 2.18; N, 22.84. Found: C, 35.81; H, 2.11; N, 22.73%.

2.2.4. $[Cu(bpcam)(dca)(H_2O)]_2$ (4)

Single crystals of **4** as blue blocks were grown by slow diffusion of aqueous solutions of $[Cu(bpcam)(H_2O)_3]NO_3 \cdot 2H_2O$ (0.094 g, 0.2 mmol) and Nadca (0.018 g, 0.2 mmol). The yield is practically quantitative after one month. *Anal.* Calc. for $C_{12}H_8CuN_8O_3$ (**4**): C, 38.36; H, 2.13; N, 29.81. Found: C, 38.25; H, 2.08; N, 29.72%.

2.2.5. $[Cu(bpca)(tcm)]_n$ (5)

The reaction of $[Cu(bpcam)]^+$ with tcm^- in water afforded crystals of [Cu(bpam)(tcm)] (**6**) which poorly diffract. Then, the corresponding system with bpca instead of bpcam was investigated and X-ray quality cystals of **5** as blue plates were grown by slow diffusion of aqueous solutions of $[Cu(bpca)(H_2O)_2]NO_3 \cdot 2H_2O$ (0.085 g, 0.200 mmol) and Ktcm (0.026 g, 0.100 mmol). The yield is practically quantitative after six weeks. *Anal.* Calc. for $C_{16}H_8CuN_6O_2$ (**5**): C, 50.61; H, 2.11; N, 22.12. Found: C, 50.53; H, 2.04; N, 22.05%.

2.3. Physical techniques

Infrared spectra of **1**–**5** were recorded with a Bruker IF S55 spectrophotometer as KBr pellets in the 4000–400 cm^{-1} region. The magnetic susceptibility measurements on polycrystalline samples of **2**, **4** and **5** were performed in the temperature range 1.9–295 K with a Quantum Design SQUID susceptometer, using an applied magnetic field of 1000 G. Diamagnetic corrections of the constituent atoms of **2**, **4** and **5** per mol of copper atoms were estimated from Pascal's constants [22] as -150×10^{-6} (**2**), -160×10^{-6} (**4**) and -168×10^{-6} cm^3 mol^{-1} (**5**). A value of 60×10^{-6} cm^3 mol^{-1} was used for the temperature-independent paramagnetism of the copper(II) ion.

2.4. X-ray data collection and structure refinement

Diffraction data for complexes **1**–**5** were collected with a Bruker Smart CCD area detector diffractometer equipped with Oxford Cryosystems low temperature system. Crystal parameters and refinement results are listed in Table 1. The reflections of **1**–**5** were measured from an hemisphere of data collected of frames each covering 0.3° in ω. They were corrected for Lorentz and polarisation effects and for absorption by semiempirical methods based on symmetry-equivalent and repeated reflections [minimum and maximum transmission coefficients 0.5724 and 0.8135 (**1**), 0.5342 and 0.7875 (**2**), 0.5131 and 0.8273 (**3**), 0.5116 and 0.5720 (**4**) and 0.5137 and 0.9411 (**5**)]. All five structures were solved by direct methods and refined by full-matrix least-squares methods on F^2. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed geometrically and refined with a riding model and with U_{iso} constrained to be 1.2 times U_{eq} of the carrier atom. The refinements for all reflections converged at final R/R_w values which are listed in Table 1. The values of the minimum and maximum final electron density peaks are −0.805 and 0.985 (**1**), −0.611 and 0.836 (**2**), −0.459 and 0.546 (**3**), −0.377 and 0.303 (**4**) and −0.923 and 0.909 e $Å^{-3}$ (**5**). A weighting scheme $w = 1/[\sigma(F_o)^2 + (mP)^2 + nP]$, where $P = (F_o + 2F_c^2)/3$ with $m = 0.0603$ (**1**), 0.0452 (**2**), 0.0486 (**3**), 0.0387 (**4**) and 0.0568 (**5**) and $n = 0.0000$ (**1**), 0.4605 (**2**), 0.0272 (**3**), 0.2182 (**4**) and 0.7295 (**5**), was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL [23] as implemented on the Viglen Pentium computer. Selected bond lengths and angles are listed in Table 2 (**1**), Table 3 (**2**), Table 4 (**3**), Table 5 (**4**) and Table 6 (**5**).

3. Results and discussion

3.1. Synthesis and infrared spectra of 1–5

The tridentate coordination of the bpcam ligand to the copper(II) ion through the imido and two pyrimidine nitrogen atoms affords a very robust $[Cu(bpcam)]^+$ scaffold which has been used as a building block in the design of both homo- (**1**–**10**) and heterometallic (**11**) complexes (see

[a] D = donor and A = acceptor.
[b] Symmetry operations used to generate equivalent atoms: #1 = $-x+2$, $-y+1$, $-z$;#2 = $-x+2$, $-y$, $-z$; #3 = x, $y-1$, z; #4 = x, $y+1$, z.

Scheme 2) where the bpcam group acts as a terminal ligand. Its possible coordination modes as a bridge (either through the two carbonyl-carbon atoms and/or through each carbonyl-carbon atom and the adjacent free pyrimidine nitrogen) remain unknown in contrast to the situation for the related bpca ligand where the bridging mode as tridentate/bidentate (through the three nitrogen atoms at one side and through the two carbonyl-carbon atoms at the other side) has been established [11,18–21].

Mono- (**1**–**3** and **9**) and polynuclear (**2**, **4**, **6**–**8**, **10** and **11**) compounds are obtained depending on the coordination properties of the anion used to neutralize the positive charge of the $[Cu(bpcam)]^+$ unit and on the solubility of the neutral species resulting from the charge balance. The synthesis of **9** and **10**, both compounds being obtained as products from the same reaction, deserves a brief comment [2]. The latter is a dinuclear copper(II) complex with a μ-1,2-sulfate as a bridge whereas the former is an ionic salt with a monodentate sulfate in the anionic fragment. So, **9** can be viewed as the precursor of **10**: the removal of a coordinated water molecule from the $[Cu(bpcam)(H_2O)_2]^+$ cation followed by the subsequent coordination of the terminally bound sulfate from the $[Cu(bpcam)(H_2O)(SO_4)]^-$ anion would afford compound **10**. In the present work, the insolubility of the neutral compounds **1** and **3** in water [with cyanide (**1**) and thiocyanate (**3**) acting as terminal ligands] precludes any polymerization. Curiously, the neutral [Cu(bpcam)(N_3)(H_2O)] (mononuclear) and [Cu(bpcam)(N_3)(H_2O)]$_2$ (dinuclear) species coexist in **2** with monodentate azide and di-μ-1,1-azide groups, respectively. Double μ-1,3-dca bridges occur in **4** leading to the neutral [Cu(bpcam)(dca)(H_2O)]$_2$ dinuclear complex. Finally, although the structure of [Cu(bpcam)(tcm)] (**6**) could not be solved, the determination of the crystal structure of the related bpca-containing complex (**5**) strongly supports the occurrence of a copper(II) chain with single μ-1,5-tcm bridges. The variation in the nuclearity of species **1**–**6** constitutes a suitable example to illustrate the difficulties associated with the structural predictions concerning neutral products when using ligands that can adopt both terminal and bridging coordination modes.

The infrared spectra of **1**–**6** all display a strong intensity peak at 1730–1720 (**1**–**4** and **6**) and 1715 (**5**) cm^{-1}; this indicates the presence of coordinated bpcam and bpca ligands [ν_{as}(CO)], respectively [1,2,11]. The high-frequency region of the ir spectra of **1**–**4** is dominated by strong and broad absorptions in the range 3500–3380 cm^{-1} [ν(OH) stretching vibration] which is due to the presence of coordinated

water molecules that are involved in hydrogen bonds. The C–N stretching frequency of 2150 cm^{-1}, which is observed in the ir spectrum of **1** as a weak absorption, agrees with the presence of a terminally bound cyanide. For the sake of comparison, this absorption appears 2136 and 2111 cm^{-1} in the ir spectra of the five-coordinated mononuclear copper(II) complexes $[Cu(phen)_2)(CN)]NO_3 \cdot H_2O$ [24] and $[Cu(tpa)(CN)]ClO_4 \cdot 3\ H_2O$ [25] [phen = 1,10-phenanthroline and tpa = tris(2-pyridylmethyl)amine] where the cyanide group acts as a terminal ligand. A strong peak at 2055 cm^{-1} in the ir spectrum of **2** corresponds to the ν_{as} stretching of the azide ligand. The shift to higher wavenumbers of this vibration when compared to the free azide (2133 cm^{-1} for sodium azide) indicates that it is coordinated to the copper atom [26]. The ν_s stretching of the azide (vibration which is ir active for the terminal or end-on bridging mode) that is predicted to occur near 1300 cm^{-1} could not be observed because this region is obscured for several absorptions of the bpcam or bpca ligands. The pattern of the vibrational modes of the thiocyanate ligand of **3** [2090s (ν_{CN}), 810m (ν_{CS}) and 495m cm^{-1} (δ_{NCS})] is indicative of thiocyanato-N coordination [27], as confirmed by the crystal structure. The ir spectrum of **4** shows three stretch frequencies in the 2300–2170 cm^{-1} region [sharp and strong peaks at 2295s ($\nu_{as} + \nu_s(C{\equiv}N)$), 2237 ($\nu_{as}(C{\equiv}N)$) and 2177 cm^{-1} ($\nu_s(C{\equiv}N)$)] which are close to those of the dca anion in its sodium salt (2286, 2232 and 2179 cm^{-1}, respectively). As the monodentate coordination of dca has been found to exert a minor influence on the values of the stretching vibrations of free dca [28], a monodentate coordination of dca in **4** can be inferred. This is consistent with the X-ray structure of **4** where dca is found

to coordinate to the copper atom through one of its cyano nitrogen atoms. Finally, the presence of three strong intensity peaks at 2180, 2198 and 2251 cm^{-1} in the ir spectrum of **5** (2186, 2204 and 2256 cm^{-1} for **6**), which are asigned to ν_{CN} stretches of the tcm group [to be compared with the strong absorption at 2178 cm^{-1} for the free tricyanomethanide in its potassium salt), suggests the coordination of this ligand to the copper atom. This is confirmed by the structure of **5** where the tcm adopts the μ-1,5-bridging mode. The quasi identical ir pattern of tcm in **5** and **6** strongly supports the same coordination mode of this ligand in both species.

3.2. Description of the structures

3.2.1. [Cu(bpcam)(CN)(H$_2$O)] (1)

The structure of **1** is made up of three neutral and crystallographically independent [Cu(bpcam)(CN)(H_2O)] units (**I**–**III** in Fig. 1) which are interlinked through hydrogen bonds involving the water molecule, the cyanide-nitrogen atom and the two carbonyl-carbon atoms of the bpcam ligand (see end of Table 2). This leads to two types of chains of the copper(II) units through hydrogen bonds: one with regular alternating of **I** and **II** units and the other having only **III** as the repeating unit (Fig. 2).

The three crystallographically independent copper atoms [Cu(1) (**I**), Cu(1A) (**II**) and Cu(1B) (**III**)] exhibit a distorted square pyramidal surrounding, the values of the trigonality parameter τ being 0.01 (**I**), 0.20 (**II**) and 0.08 (**III**) ($\tau = 0$ and 1 for ideal square pyramid and trigonal bipyramid, respectively) [30]. The basal plane is formed by three nitrogen atoms from the tridentate bpcam ligand [Cu–N bonds varying in the range 1.948(3)–2.036(3) Å] and the cyanide-carbon atom [Cu–N = 1.955(4)–1.968(4) Å] whereas the apical position is filled by a water molecule [Cu–O_w = 2.250(2)–2.264(2) Å]. The values of the Cu–N distances agree with those observed in other bpcam-containing copper(II) complexes [1,2,5e,10]. The values of the bond length for the copper to cyanide carbon in **I**–**III** compare well with those observed in other five-coordinated cyano-containing copper(II) complexes: 1.94(1), 1.970(5) and 1.98(1) Å for $[Cu(phen)_2](CN)]NO_3 \cdot H_2O$ [24], $[Cu(phen)_2(CN)]tcm \cdot 2H_2O$ [29] and $[Cu(tpa)(CN)]ClO_4 \cdot 3H_2O$ [25], respectively. The angles in the basal plane are distorted from the ideal square-planar value mainly due to the constrained geometry of the tridentate bpcam ligand. So, the angles subtended at the copper atoms of **I**–**III** by the bpcam ligand vary in the range 80.51(11)–81.18(11)° evidencing the small bite size of the corresponding five-membered chelate rings. The copper atom is shifted by 0.1233 (**I**), 0.1877 (**II**), and 0.1269 Å (**III**) from the mean basal plane toward the axial water molecule. This significant out-of-plane displacement of the copper atom is accompanied by large deviations from the ideal value of 180° in the angles at the copper atom of the trans ligands [values varying in the range 159.38(12)–165.94(14)°].

The bond lengths and angles involving the cyanide ligand are all normal the C–N bond distance and C–N–Cu bond angle varying in the range 1.136(5)–1.140(4) Å and 177.9(3)–179.1(4)°, respectively]. The pyrimidyl rings of the bpcam ligand in **I**–**III** are essentially planar and the dihedral angles *between* these rings within each bpcam moiety are 6.8 [at Cu(1)], 8.7 [at Cu(1A)] and 8.4°

Scheme 2.

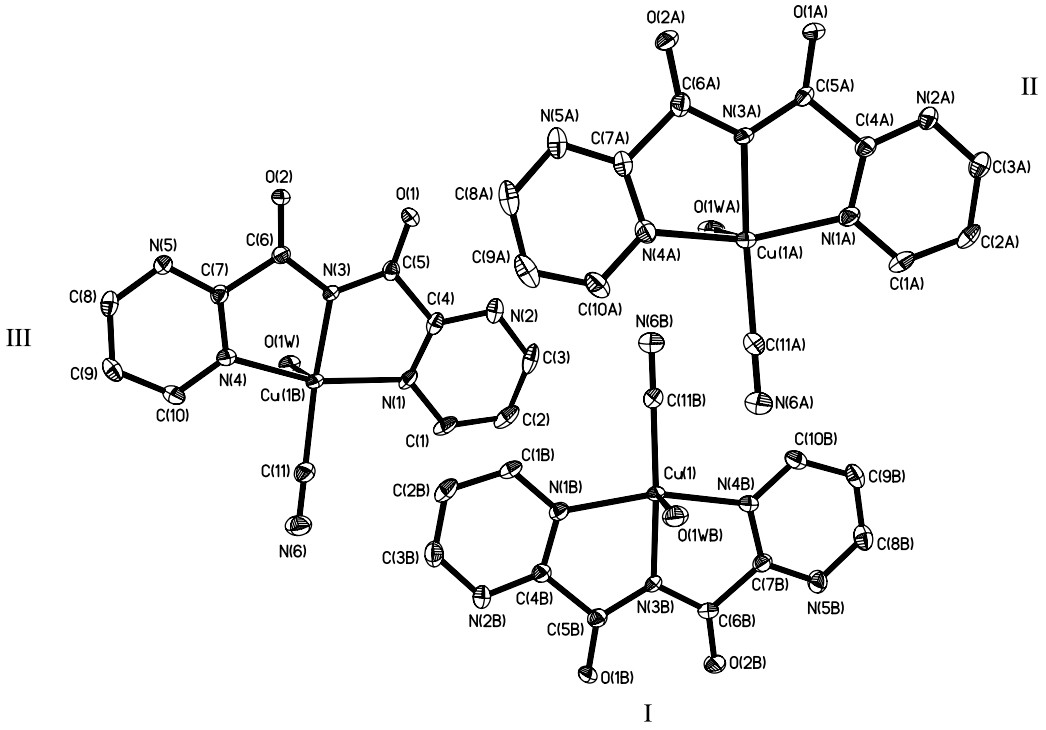

Fig. 1. A perspective view of the three crystallographically independent copper(II) units **I**–**III** in **1** with the atom numbering. Thermal ellipsoids are drawn at the 50% probability level and the hydrogen atoms are omitted by simplicity.

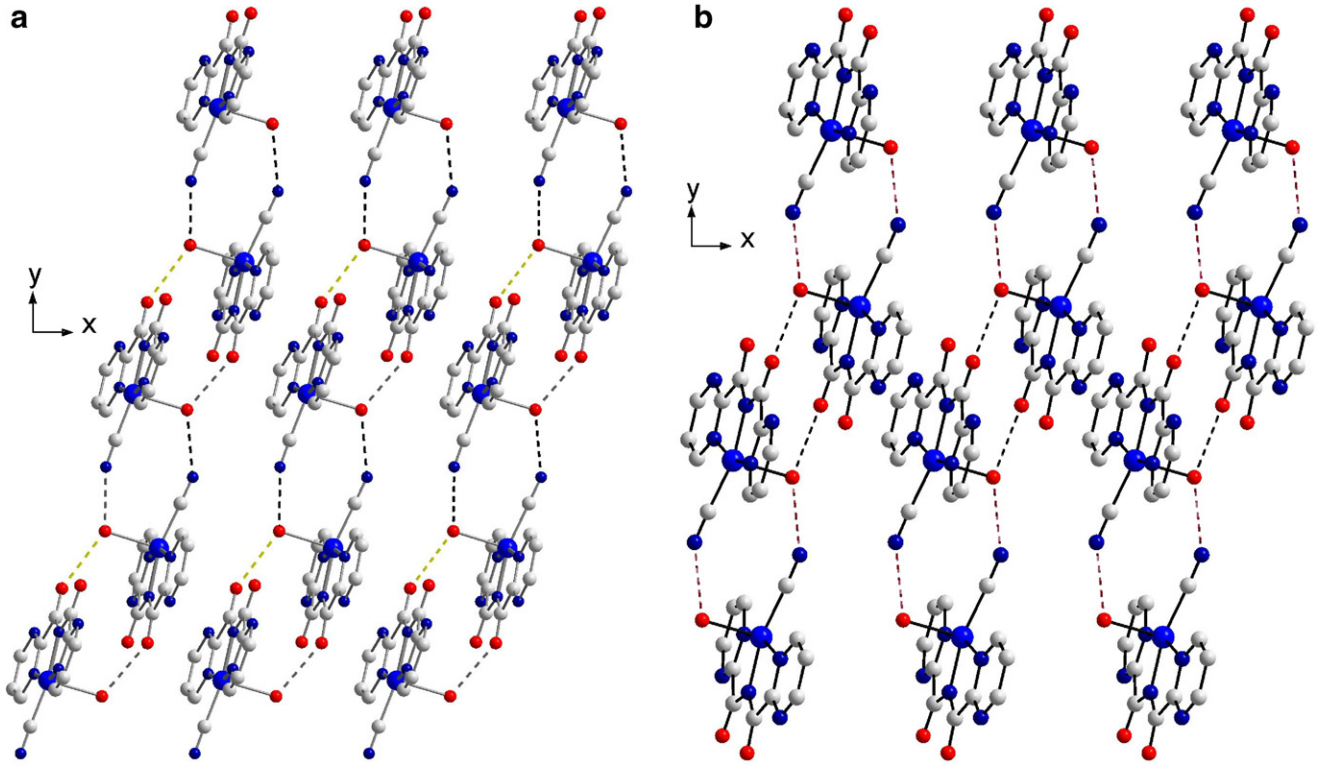

Fig. 2. Views on the *xy* plane showing the hydrogen bonds linking the **I** and **II** (dashed yellow line) and **III** (dashed pink lines) mononuclear units of **1**.

[at Cu(1B)]. Bond lengths and angles of the bpcam group in **I**–**III** agree with those reported for this ligand in previous structurally characterized bpcam-containing copper(II) complexes [1,2,5e,10].

The values of the intermolecular copper–copper separation are all greater than 6.0 Å [6.275 and 6.098 Å for Cu(1)···Cu(1A)#5 and Cu(1B)···Cu(1B)#5, respectively; #5 = 1 − *x*, 1 − *y*, 1 − *z*].

3.2.2. $[Cu(bpcam)(N_3)(H_2O)]_2$ (2)

The structure of **2** consists of two crystallographically independent neutral units of formula $[Cu(bpcam)(N_3)(H_2O)]$ which are noted as A and B (Fig. 3). The azide group in the A unit acts as a terminal monodentate ligand whereas it adopts the asymmetric end-on bridging mode in the B unit leading to mono- and dinuclear copper(II) units, respectively (Fig. 4). Both entities are stacked along the *y* axis through hydrogen bonds involving the carbonyl-oxygen atoms from the bpcam ligand and the coordinated water molecule (see Fig. 4 and the end of Table 3). The value of the copper–copper separation through the

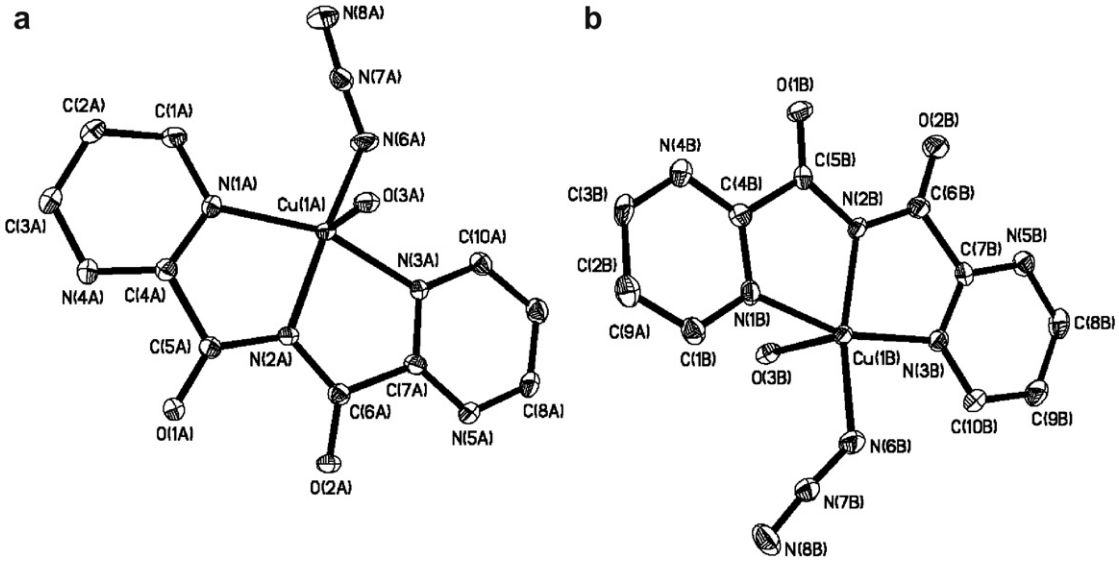

Fig. 3. A perspective view of the crystallographically independent units of **2** with the atom numbering. Thermal ellipsoids are drawn at the 50% probability level and the hydrogen atoms are omitted for simplicity.

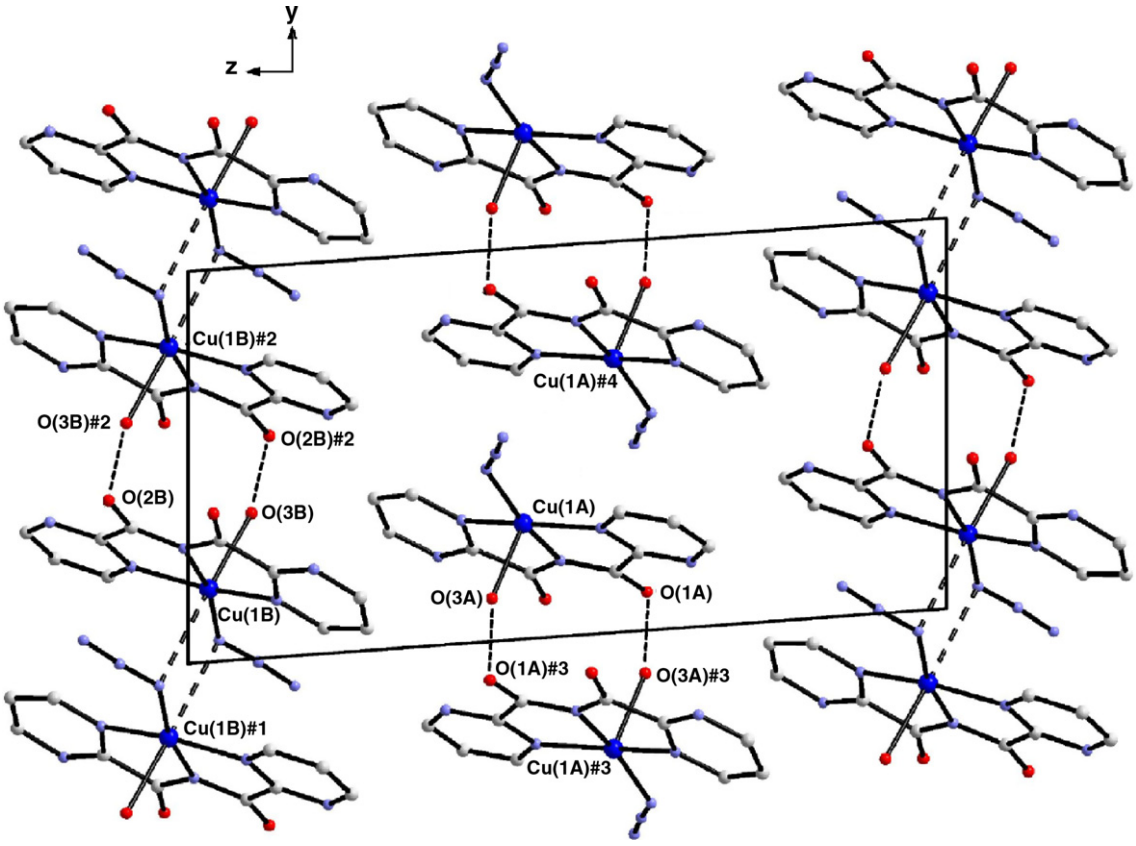

Fig. 4. A projection down the *a* axis of the unit cell contents of **2** showing the relative arrangement of the A (orange) and B (green) units. The double μ-1,1-azido bridge (B) and part of the hydrogen bonds between the coordinated water and carbonyl-carbon atoms (A and B) are shown as broken lines.

di-μ-1,1-azido bridge is 3.730(5) Å [Cu(1B)···Cu(1B)#1; #1 = 1 − x, 2 − y, −z] [to be compared to 4.600(8) Å for Cu(1A)···Cu(1A)#4; #4 = −x, 1 − y, 1 − z]. These values are much shorter than those of the metal–metal separation through the hydrogen bonds, 6.614(16) [Cu(1A)···Cu(1A)#3; #3 = 1 − x, 2 − y, 1 − z] and 6.928(15) Å [Cu(1B)···Cu(1B)#2; #2 = −x, 2 − y, −z].

The copper environment of the A and B units differs. While the A unit can be described as square pyramidal with the basal plane defined by the bpcam and azide nitrogen donors, the B unit is described as distorted octahedral: the equatorial plane being formed by four nitrogen atoms, three from bpcam [N(1B), N(2B) and N(3B)] and one from an azide group [N(6B)], whereas the axial positions are filled by a water molecule [O(3B)] and a nitrogen atom of a symmetry-related azido group [N(6B)#1]. The values of the Cu–N(bpcam) bond lengths vary in the ranges 1.944(5)–2.031(3) [at Cu(1A)] and 1.946(4)–2.040(3) Å [at Cu(1B)] agreeing with those observed in **1** and in other bpcam-containing copper(II) complexes [1,2,5e,10]. As in **1**, the small bite size of the two five-membered chelate rings subtended by the tridentate bpcam at the copper atom causes the deviations from the ideal value of 90° [81.30(9)° and 80.70(9)° for N(1A)–Cu(1A)–N(2A) and N(2A)–Cu(1A)–N(3A); 81.21(9)° and 80.77(9)° for N(1B)–Cu(1B)–N(2B) and N(3B)–Cu(1B)–N(2B)]. As might be expected, in the case of the pseudo-octahedral Cu(B) unit, the equatorial Cu–N(azide) bond distance [1.954(2) Å] is shorter than that of the axial one [2.896(5) Å for Cu(1B)–N(6B))#1]. The copper atom is shifted from the mean basal plane toward the axial water molecule by 0.1735 [Cu(1A)] and 0.0391 Å [Cu(1B)].

The pyrimidyl rings of the bpcam ligand at the two copper atoms are essentially planar and the dihedral angles between these rings within each bpcam moiety are 10.24° [at Cu(1A)] and 8.17° [at Cu(1B)]. The azido groups are quasi linear and two different nitrogen–nitrogen bond distances occur within them. As expected, the longer bond involves the end that is equatorially bound to the copper atom. The value of the angle at the equatorially bound azide nitrogen [130.2(2) and for N(7A)–N(6A)–Cu(1A) and 134.1(2)° for N(7B)–N(6B)–Cu(1B), respectively] is greater than the ideal 120° predicted for a sp^2 hybridization.

3.2.3. [Cu(bpcam)(NCS)(H$_2$O)] (3)

The crystal structure of **3** consists of discrete, neutral units of formula [Cu(bpcam)(NCS)(H$_2$O)] (Fig. 5) which are linked by hydrogen bonds involving the coordinated water molecule and two carbonyl-oxygen atoms from two bpcam ligands (see Fig. 6 and end of Table 4). This compound is isostructural with the complex [Cu(bpca)(NCS)(H$_2$O)] [31] where the bpca ligand substitutes for bpcam.

The coordination sphere of the copper atom in **3** is best described as a distorted square pyramid, the value of the trigonality parameter τ being 0.11. The basal plane is formed by three nitrogen atoms from the tridentate bpcam ligand [N(1), N(3) and N(5)] and the nitrogen atom from the monodentate thiocyanate group [N(6)] whereas the apical position is occupied by a water molecule [O(3)]. The values of Cu–N(bpcam) bond distances ranging from 1.9362(19) to 2.028(2) Å are close to those reported for the previous structures. The Cu(1)–N(6) bond length is 1.926(2) Å, a value which is practically identical to those observed in the structures of the mononuclear complexes [Cu(bpca)(NCS)(H$_2$O)] [31] and [Cu(paphy)(NCS)(SCN)] (paphy = pyridine-2-aldehyde-2′-pyridylhydrazone) [32]. The axial Cu–O$_w$ bond [2.2429(16) Å] is somewhat longer than the basal ones. The coordinated nitrogen atoms are nearly coplanar with deviations from the mean plane of 0.280 Å and the copper atom is displaced from this mean plane by 0.1837 Å toward the apical position. The angles subtended by the bpcam ligand at the copper atom are 81.03(8)° [N(3)–Cu(1)–N(5)] and 81.39(8)° [N(3)–Cu(1)–N(1)].

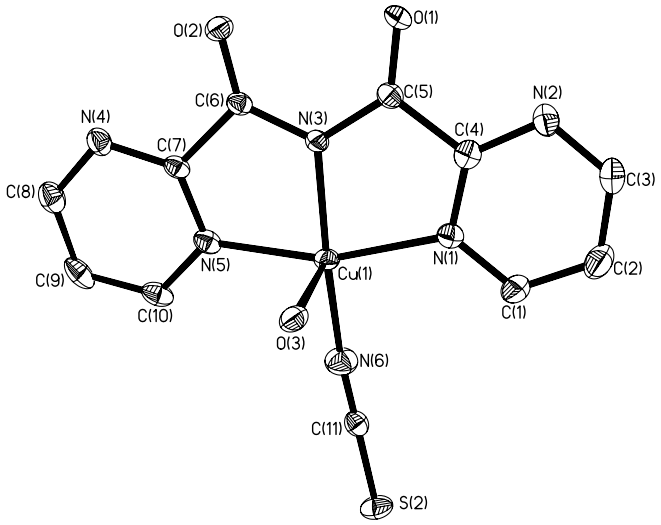

Fig. 5. A perspective view of the structure of **3** with the atom numbering. Thermal ellipsoids are drawn at the 50% probability level and the hydrogen atoms are omitted for simplicity.

The bpcam ligand is nearly planar within 0.0382 Å, although it is subject of a significant angular strain as evidenced by the values of the angles at the carbonyl-carbon atoms [110.74(19)° and 110.35(19)° for N(3)C(5)C(4) and N(3)C(6)C(7), respectively]. The thiocyanate ligand is linear but its coordination to the copper atom *via* the nitrogen atom is achieved in a significant bending mode [169.6(2)° for Cu(1)–N(6)–C(11)]. The values of the intraligand N–C and C–S bond distances have their typical values. The value of the shortest intermolecular copper–copper separation is 5.058(11) Å [Cu(1)···Cu(1)#3; #3 = 1 − x, −y, −z].

3.2.4. [Cu(bpcam)(dca)(H$_2$O)]$_2$ (4)

The structural building block of **4** is the neutral [Cu(bpcam)(dca)(H$_2$O)] complex in which the three bpcam-nitrogen atoms and a nitrile-dca nitrogen bind to copper in equatorial positions, and a water molecule occupies an

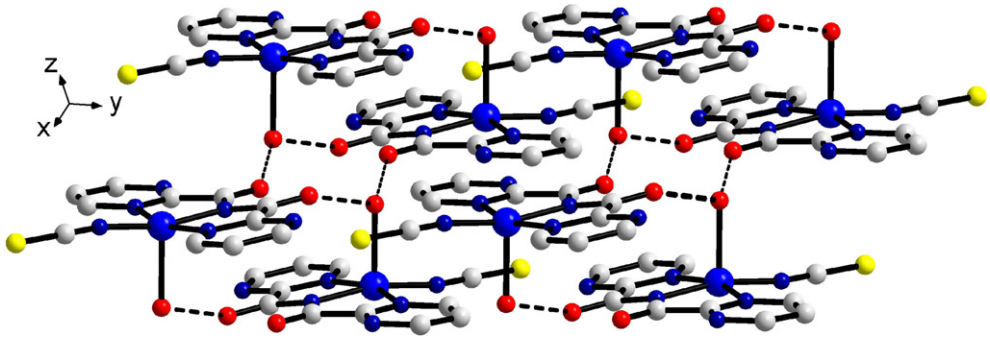

Fig. 6. A view of the packing in **3** showing the hydrogen bonding pattern as broken lines.

apical position. Considering only these interactions, the copper environment may be described as distorted square pyramidal [Cu(1)–N = 1.9412(13) Å–2.0445(14) Å and Cu(1)–O(3) = 2.2655(12) Å] with $\tau = 0.15$. The amide dca nitrogen atom of a centrosymmetrically related unit is semi-coordinated to copper [Cu(1)–N(5)#3 = 2.817(2) Å; #3 = $1-x$, $2-y$, $2-z$], resulting in a dinuclear entity (Fig. 7). These units are interlinked through hydrogen bonds involving the water molecule and the carbonyl-carbon atoms of the bpcam ligand (see Fig. 8 and the end of Table 5). This compound is isostructural with [Cu(bpca)(dca)$(H_2O)]_2$ [8] where the bpca ligand occurs instead of bpcam.

The atoms defining the equatorial plane of copper are approximately coplanar (maximum atomic deviation being 0.0205 Å) and the copper atom is displaced by 0.1448 Å from this plane toward the apical oxygen. The atoms of the dca bridge are also coplanar (maximum atomic deviation 0.0086 Å) and this plane forms an angle of 37.2° with the equatorial plane of the copper atom to which the dca is coordinated. The bpcam group acts as a tridentate ligand through its three nitrogen atoms, the copper to amido-nitrogen bond being significantly shorter than the two copper to pyrimidine–nitrogen ones, as observed in the structures described above. The pyrimidyl rings of bpcam are planar and the dihedral angle between these rings is 6.0°. The values of the nitrile [1.156(2) and 1.149(2) Å] and amide [1.292(2) and 1.321(3) Å] carbon–nitrogen distances in the dca group are consistent with the triple and single carbon–nitrogen bond character.

The copper–copper separation within the dinuclear unit is 5.701(3) Å [Cu(1)···Cu(1)#3], a value which is very close to the distance of 5.732(2) Å in the related bpca-containing complex. The shortest interdimer metal–metal separation in **4** is 6.755 Å [Cu(1)···Cu(1)#4; #4 = $-x$, $2-y$, $1-z$].

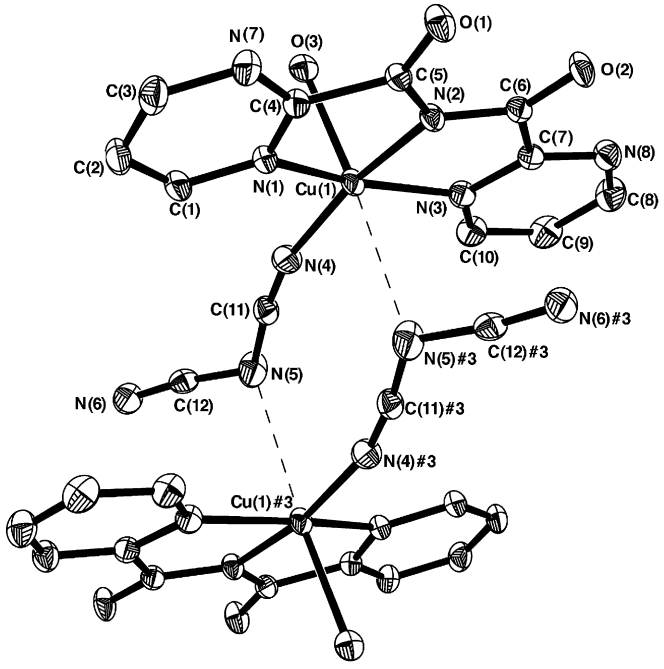

Fig. 7. A perspective view of the dinuclear unit in **4** [Cu(bpcam)(dca)$(H_2O)]_2$. Thermal ellipsoids are drawn at the 50% probability level and the hydrogen atoms are omitted for simplicity.

3.2.5. *[Cu(bpca)(tcm)]$_n$* (**5**)

A chain structure is present in this compound with the tcm group serving as a μ-1,5-bridging ligand between the [Cu(bpca)] units (Fig. 9). The chains extend along the *c* axis in a zigzag fashion and they are stacked in a zipper arrangement (Fig. 10) in the *ac* plane.

The copper atom is five-coordinated in a somewhat distorted square pyramidal surrounding, the value of the trigonality parameter being $\tau = 0.08$. The equatorial positions are defined by the three bpca-nitrogen atoms [N(1), N(2) and N(3)] and a nitrile-nitrogen [N(5)#1; #1 = x, y, $z+1$] from a tcm group whereas the apical position is occupied also by a nitrile-nitrogen [N(4)] from another tcm ligand. The four atoms in the equatorial positions around the copper atom are practically coplanar with the metal atom being displaced by 0.1065 Å from this plane toward the apical nitrile-nitrogen. The values of the dihedral angle between the equatorial plane and the mean planes of the bpca and tcm ligands are 4.0° and 11.4°, respectively. The bpca group acts as a tridentate ligand through its three nitrogen atoms, the copper to amido-nitrogen bond being significantly shorter than the two copper to pyridine–nitrogen ones, as observed in other bpca-containing copper(II) complexes [3–5a,5d–13,31]. Bond lengths and angles within the bpca ligand are in agreement

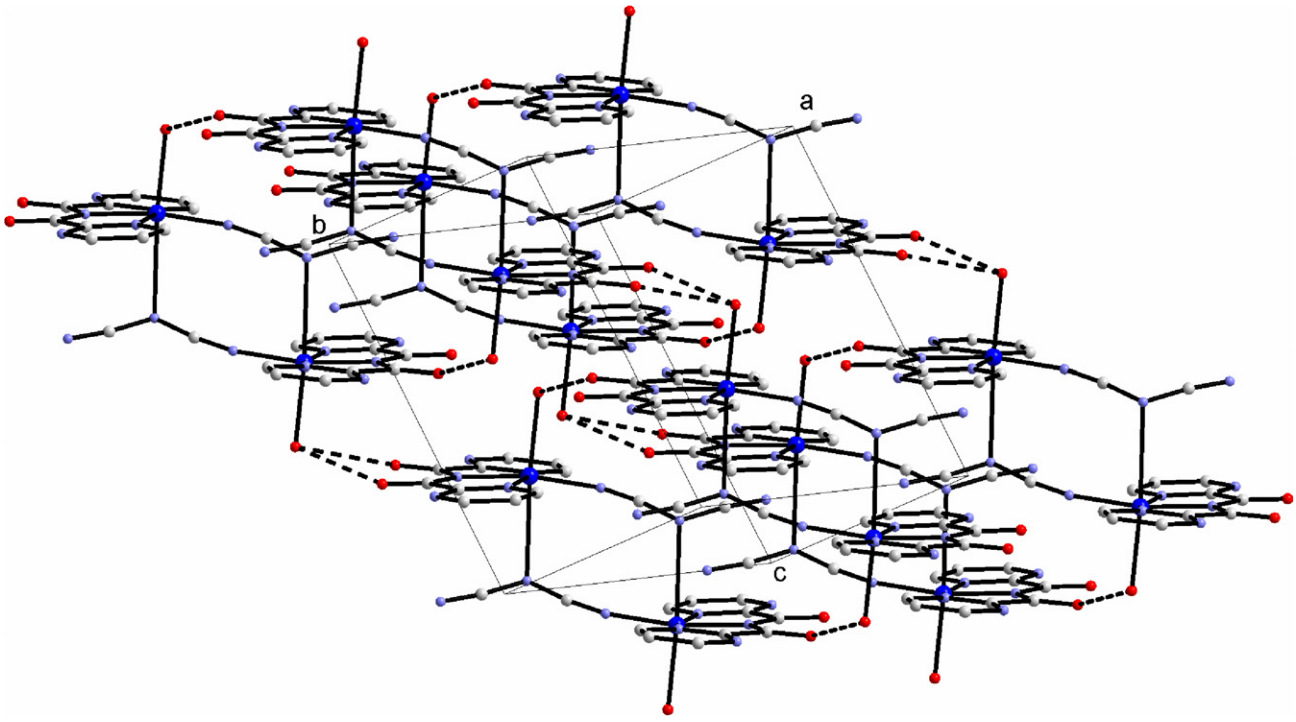

Fig. 8. A view of the packing in **4** showing the hydrogen bonds (broken lines) which link the double dca-bridged dicopper(II) units.

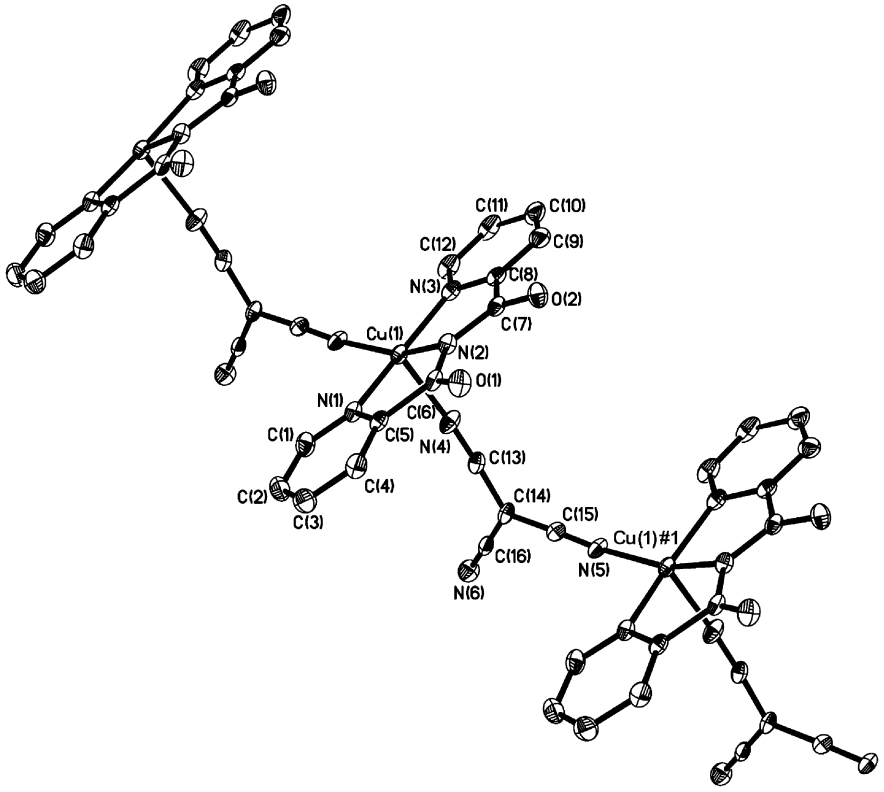

Fig. 9. Section of the $[Cu(bpca)(tcm)]_n$ chain (**5**) showing the atom numbering. Thermal ellipsoids are drawn at the 30% probability level and the hydrogen atoms are omitted for clarity.

with those reported previously [3–5a,d–13,31]. The pyridyl rings of the bpca are planar and the dihedral angle between them is 3.9°.

The values of the C–N and C–C bond lengths and the CCC bond angles of the tcm ligand in **5** remain in rather narrow ranges, 1.148(3)–1.150(4), 1.404(4)–1.419(4) Å and

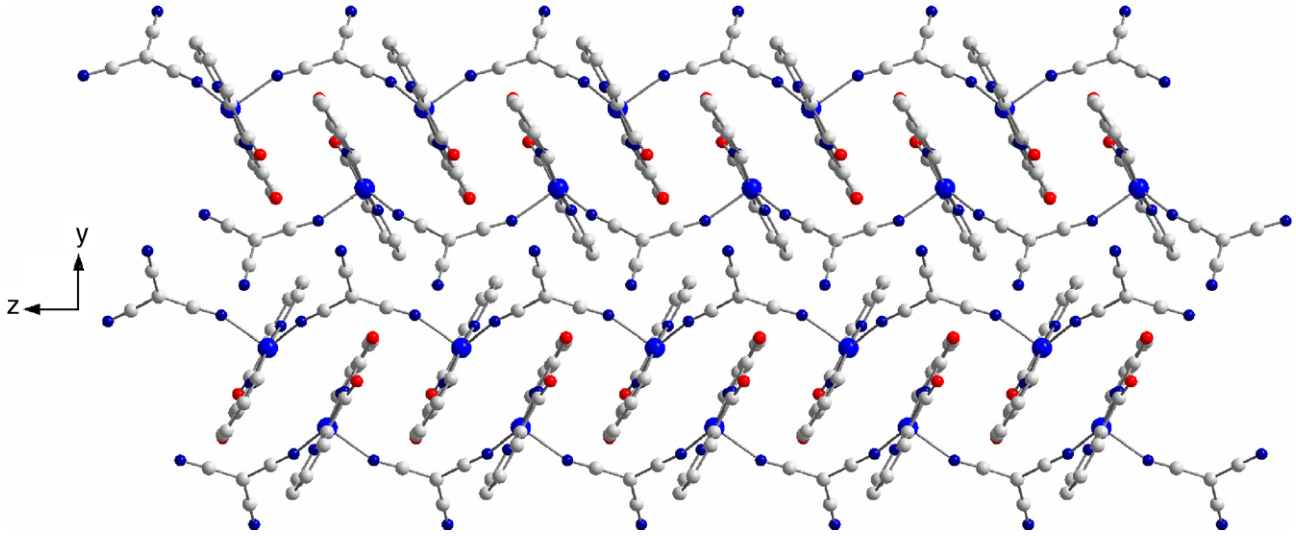

Fig. 10. A view of the stacking of the chains of **5** in the *bc* plane.

119.5(2)–120.5(3)°, respectively. This is in agreement with almost ideal sp^2 hybridisation of the central carbon atom. The asymmetric μ-1,5-bridging mode of the tcm ligand which occurs in **5** was also observed in other compounds [33,34] but as far as we know, **5** is the first structurally characterized example of uniform copper(II) chain with a single μ-1,5 tcm bridge. It is worthy to note that the analogous copper(II) complex with dca of formula $[Cu(bpca)(dca)(H_2O)]_2$ is a dinuclear compound with double μ-1,3-dca bridges [8]. The intrachain copper–copper distances in **5** is 7.688(3) Å [Cu(1)···Cu(1)#1], a value which is much longer than the the shortest interchain metal–metal separation [4.291(9) Å for Cu(1)···Cu(1)#3; #3 = 2 − *x*, −*y*, 1 − *z*].

3.3. Magnetic properties of 2, 4 and 5

The magnetic properties of the complexes **2**, **4** and **5** under the form of $\chi_M T$ versus T plot [χ_M is the magnetic susceptibility per copper(II) ion] are shown in Fig. 11. A Curie law behaviour of a magnetically isolated copper(II) ion, the values of $\chi_M T$ remaining practically constant from room temperature [values at 295 K varying in the range 0.44–0.41 $cm^3\,mol^{-1}$ K] until $T \leqslant 20$ K, and then they decrease to ca. 0.28 (**2**), 0.38 (**4**) and 0.32 $cm^3\,mol^{-1}$ K (**5**) at 1.9 K. No maximum is observed in the corresponding magnetic susceptibility versus T plots. The smooth decrease of $\chi_M T$ in the low temperature range for **2**, **4** and **5** is indicative of the occurrence of a weak antiferromagnetic interactions.

Having in mind the dinuclear structure of **4**, its magnetic data were analyzed through a simple Bleaney-Bowers expression for two interacting spin doublets [Eq. (1)] which is derived from the isotropic Hamiltonian in Eq. (2)

$$\chi_M = (2N\beta^2 g^2/kT)[3 + \exp(-J/kT)]^{-1} \quad (1)$$

$$\hat{H} = -J\hat{S}_A \cdot \hat{S}_B \quad (2)$$

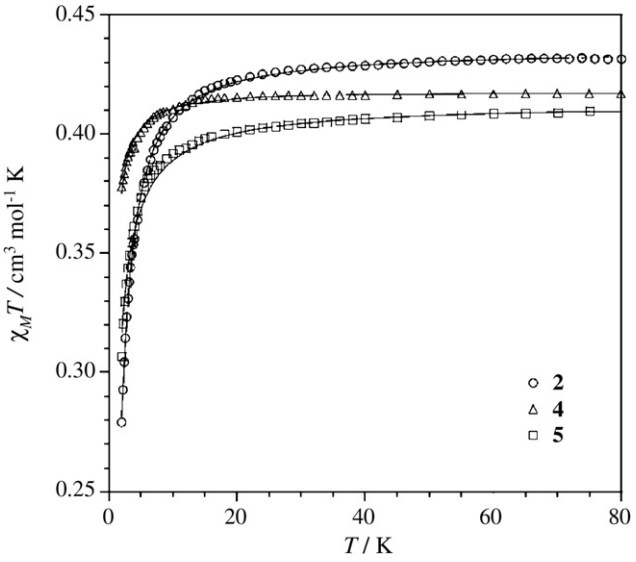

Fig. 11. Thermal dependence of $\chi_M T$ for **2**, **4** and **5** at $T \leqslant 80$ K. The solid lines are the best-fit curves (see text).

where N, g and β have their usual meanings and J is the spin coupling parameter. The best-fit parameters are $J = -0.53$ cm^{-1}, $g = 2.11$ and $R = 5.0 \times 10^{-6}$ (R is the agreement factor defined as $\sum_i[(\chi_M)_{obs(i)} - (\chi_M)_{calc(i)}]^2 / \sum_i[(\chi_M)_{obs(i)}]^2$). In the case of **2**, because of the coexistence of the di-μ-1,1-azido-bridged dicopper(II) unit [Cu(1B)···Cu(1B))#6] and the monuclear copper(II) entity [Cu(1A)], its magnetic data were analyzed through Eq. (3) (per four copper atoms)

$$\chi_M = (2N\beta^2 g^2/kT)[3 + \exp(-J/kT)]^{-1} + N\beta^2 g^2/2kT \quad (3)$$

where the first term is the Bleaney-Bowers expression for a copper(II) dimer and second term is the Curie law for two magnetically isolated copper(II) ions. The same average Landé factor (g) is assumed for the dinuclear and mononuclear copper(II) units. The best-fit parameters for **2** through Eq. (3) (per one copper atom) are $J = -3.3$ cm^{-1}, $g = 2.15$

and $R = 4.5 \times 10^{-6}$. The calculated curves in **2** and **4** match the experimental data very well. Given that **5** is a uniformly spaced chain of copper(II) ions, its magnetic data were analyzed through the theoretical expression proposed by Hall [35] for a uniform chain of local spins S = 1/2 [Eq. (4)] which is derived from the isotropic Hamiltonian in Eq. (5)

$$\chi_M = (N\beta^2 g^2/kT)[0.25 + 0.14995x + 0.30094x^2) / (1 + 1.9862x + 0.68854x^2 + 6.0626x^3) \quad (4)$$

$$\hat{H} = -J \sum_i \hat{S}_i \cdot \hat{S}_{i+1} \quad (5)$$

where $x = |J|/kT$ and J is the exchange coupling constant describing the magnetic interaction between two nearest-neighbour spin doublets. This expression, which derives from the numerical results from Bonner and Fisher [36], has been widely used to treat the magnetic data of uniform copper(II) chains. Least-squares fit of the magnetic data of **5** through Eq. (3) leads to the following parameters: $J = -0.64$ cm^{-1}, $g = 2.10$ and $R = 6.7 \times 10^{-5}$.

The magnetic interactions in **2**, **4** and **5** are all weak and antiferromagnetic. This can be understood by looking at the respective orientation of the magnetic orbitals involved, that is, the molecular orbitals which define the unpaired electron on each copper(II) ion. The unpaired electron on each copper atom in this family of complexes is essentially located in the equatorial plane and it is roughly defined by a $d_{x^2-y^2}$ type orbital [the x and y axes being roughly defined by the Cu–N(imido) (**2**, **4** and **5**) and Cu–N(pyrimidine/pyridine) (**2** and **4**/**5**) bonds, respectively]. Given that the spin density in the apical position is very weak, the overlap between the parallel magnetic orbitals of the adjacent copper(II) ions is very small. Under these conditions, the exchange coupling is expected to be very weak or zero [37]. In all three compounds, the out-of-plane exchange pathway is involved through double end-on azido (**2**)/μ-1,3-dca (**4**) and single μ-1,5-tcm (**5**) bridges. At this respect, a literature survey shows that weak ferro- [38,39] and antiferromagnetic [40,41] interactions occur in asymmetric double end-on azido-bridged copper(II) complexes, their nature and magnitude being dependent on several structural parameters such as the angle at the end-on azide nitrogen, the value of τ, the axial azido-nitrogen to copper bond length and the intramolecular copper–copper separation (see Table 7). The antiferromagnetic coupling in **4** is also very weak ($J = -0.53$ cm^{-1}). This feature together with the lack of magnetic coupling in the related dinuclear complex [Cu(bpca)(dca)(H$_2$O)]$_2$ [8] (isostructural to **4**) demonstrate that the asymmetric μ-1-3-dca bridge between copper(II) ions is a very poor exchange mediator. Finally, the value of the antiferromagnetic coupling in **5** ($J = -0.64$ cm^{-1}) is very close to that reported for the ladder-like compound of formula [Cu(tn)(tcm)$_2$]$_n$ (tn = 1,3-diaminopropane) ($J = -0.7$ cm^{-1}) [34] where the rods and the rungs are asymmetric single- and double μ-1,5 tcm bridges, respectively. The magnetic behaviour of this last compound was modelled through a uniform copper(II) chain model, the single tcm bridge that connects one equatorial position of one copper atom to an axial one of the adjacent copper atom being considered the only operative exchange pathway. These magneto-structural investigations show the low efficiency of the tcm bridge as exchange mediator.

4. Conclusions

The combined use of cyanide (**1**), azide (**2**), thiocyanate (**3**), dicyanamide (**4**) and tricyanomethanide (**5**) as ligands toward the stable building block bis(2-arylcarbonyl)amidatecopper(II) [aryl = pyrimidyl (**1**–**4**) and pyridyl (**5**)] afforded the neutral mononuclear species [Cu(bpcam)(CN)(H$_2$O)] (**1**) and [Cu(bpcam)(NCS)(H$_2$O)] (**3**), the mononuclear (**2**)/dinuclear (**2** and **4**) complexes [Cu(bpcam)(N$_3$)(H$_2$O)]$_2$ (**2**) and [Cu(bpcam)(dca)(H$_2$O)]$_2$ (**4**) and the chain compound [Cu(bpca)(tcm)]$_n$ (**5**). The monodentate coordination of cyanide (**1**) and thiocyanate (**3**) to copper(II) produces neutral mononuclear species which are insoluble in water and this insolubility precludes their polymerization. However, in the case of the azide and dicyanamide coligands, dinuclear compounds result because of

[a] Abbreviations used: L = 7-amino-4-methyl-5-aza-3-hepten-2-onato; bipy = 2,2′-bipyridine; terpy = 2,2′:6′,2″-terpyridine; dpp = 2,3-bis(2-pyridyl)-pyrazine.
[b] Value of the Cu···N$_{(azide)}$···Cu bridging angle.
[c] Axial azide–nitrogen to copper bond distance.
[d] Copper–copper separation across the double end-on azido bridge.
[e] The two compounds with the same formula are uniform and alternating chain compounds, respectively.
[f] These values refer to the Cu(1B)···Cu(1B)#6 dinuclear unit.

the μ-1,1-azido (**2**) and the μ-1,3-dca (**4**) adopted bridging modes. Surprisingly, the mononuclear [Cu(bpcam)(N_3)-(H_2O)] unit containing a terminally bound azide ligand is also present in **2**. Finally, the tcm group in **5** adopts the μ-1,5-bridging mode linking an equatorial position at one copper atom with the apical one at the adjacent metal atom leading to a uniform chain of copper(II) ions. Weak intradimer (**2** and **4**)/intrachain (**5**) antiferromagnetic interactions between the copper(II) ions are observed through the out-of-plane exchange pathway across the double μ-1,1-azido (**2**) and μ-1,5-dca (**4**) bridges and the single μ-1,5-tcm (**5**) group.

Abstract

Four new coordination polymers were obtained by employing polycarboxylato spacers and cationic copper(II) complexes as nodes: $^{\infty}_{2}[Cu_3(trim)_2(NH_3)_6(H_2O)_3]$ (**1**); $^{\infty}_{1}[Cu(tmen)(dhtp)]$ (**2**), $^{\infty}_{1}[Cu(tmen)(hitp)(H_2O)]$ (**3**), $^{\infty}_{1}[Cu(tmen)(nitp)]$ (**4**). (H_3trim = trimesic acid, H_2dhtp = 2,5-dihydroxy-terephthalic acid; H_2hitp = 5-hydroxy-isophthalic acid, H_2nitp = 5-nitro-isophthalic acid; tmen = *N*,*N*,*N*′,*N*′-tetramethyl-ethylenediamine). The crystal structures of the four compounds have been solved. Compound **1** consists of 2D coordination polymers with heart-shaped meshes, while compounds **2**–**4** contain infinite zigzag chains. The role of the hydrogen bond interactions in sustaining the supramolecular solid-state architectures in compounds **1** and **3** is discussed. The cryomagnetic investigation of compounds **1**, **2**, and **4** reveals antiferromagnetic interactions between the copper ions.

1. Introduction

Polycarboxylates are extremely popular as ligands in designing coordination polymers with various dimensionalities and network topologies [1]. The increasing interest in metal–organic frameworks arises not only from their intrinsic beauty, but also from their potential applications in gas storage, catalysis or ion exchange processes [2]. The main factors which influence the rich structural variety of the coordination polymers constructed from polycarboxylato ligands are: (i) the number of the carboxylato groups attached to the organic ligand; (ii) the spatial orientation of the carboxylato groups; (iii) the various coordination modes exhibited by each COO^- group; (iv) the presence of the coligands in the coordination sphere of the metal ions.

Both flexible aliphatic and rigid aromatic carboxylates are extensively used as linkers. From the last category we mention here the trimesic acid, H_3trim, which was found to generate both high-nuclearity clusters [3], and 1D, 2D, and 3D coordination polymers [4]. Most of these polymers are constructed from copper(II) ions. Let us recall some of them, which are relevant to this paper. A one-dimensional coordination polymer, $[Cu(Htma)(H_2O)_3]$ results from a neutral solution containing cupric ions and trimesic

Scheme 1.

acid [4]. In the presence of sodium hydroxide, it results a bimetallic coordination polymer, $[NaCu(trim)(H_2O)_4]\cdot 2H_2O$, with a double-sheet architecture [5]. The reaction between copper(II) nitrate and trimesic acid, under hydrothermal conditions, affords a spectacular nanoporous material, $[Cu_3(trim)_2(H_2O)_3]$ [6]. The porosity, catalytic [7], and the magnetic properties [8] of this material were intensively investigated. The network topology of the coordination polymers constructed from trimesate linkers is strongly influenced by ancillary ligands attached to the copper(II) ions. For example, 2D coordination polymers, $[Cu_3(tmen)_3(trim)_2(H_2O)_2]\cdot 6.5H_2O$ and $[Cu_3(Ph_2SNH)_6(trim)_2]$, were obtained by employing *N*,*N*,*N*′,*N*′-tetramethylethane-1,2-diamine (tmen) [9] or *S*,*S*′-diphenylsulfimide (Ph_2SNH)[10] as coligands.

In this paper we report on four coordination polymers constructed from aromatic polycarboxylato spacers and assembling copper(II) complex cations. The following acids were employed: 1,3,5-benzenetricarboxylic acid (trimesic acid, H_3trim), 2,5-dihydroxy-terephthalic acid (H_2dhtp); 5-hydroxy-isophthalic acid, (H_2hitp), 5-nitro-isophthalic (H_2nitp) – Scheme 1.

2. Experimental

2.1. Materials

All the chemicals were purchased from commercial sources and used without any further purification. The [Cu(acac)(tmen)](ClO$_4$) complex has been previously reported [10]. The tetrafluoroborate derivative, [Cu(acac)(tmen)](BF$_4$), was prepared by an alternative method, as follows: two solutions, one containing acetylacetone (200.2 mg, 2 mmol) and triethylamine (202 mg, 2 mmol) in 10 mL ethanol, and the other one containing *N*,*N*,*N*′,*N*′-tetramethyl-ethylenediamine (232.4 mg, 2 mmol) in 10 mL ethanol, were added rapidly into 20 mL ethanolic solution of $Cu(BF_4)_2\cdot xH_2O$ (474.3 mg, 2 mmol). The slow evaporation of the resulted mixture gives dark blue crystals.

2.2. Syntheses

2.2.1. $^{\infty}_{2}[Cu_3(trim)_2(NH_3)_6(H_2O)_3]$ (**1**)

An ethanolic solution (15 mL) of trimesic acid (84 mg, 0.4 mmol) and triethylamine (121.4 mg, 1.2 mmol) was mixed with a solution of $Cu(CF_3SO_3)_2$ (217 mg, 0.6 mmol) in 10 mL water and stirred for about 30 min. An aqueous ammonia solution was added to the resulted mixture under stirring until the light blue precipitate dissolved. The resulted blue solution was allowed to slowly evaporate at room temperature and the reaction vessel was sealed when the first crystals appeared. Blue single crystals suitable for X-ray diffraction were collected after 1 week. Selected IR data (KBr, cm^{-1}): 3330, 3188, 2925, 1615, 1552, 1438, 1362, 1255, 759, 723.

2.2.2. $^{\infty}_{1}[Cu(tmen)(dhtp)]$ (**2**)

A solution of 2,5-dihydroxy-terephthalic acid (118.9 mg, 0.6 mmol) and triethylamine (121.4 mg, 1.2 mmol) in 10 mL methanol was slowly added to a methanol solution (10 mL) of [Cu(acac)(tmen)](BF$_4$) (219.4 mg, 0.6 mmol). The resulted mixture was filtered and the slow evaporation of the filtrate gave after several days a microcrystalline blue complex. Single crystals suitable for X-ray diffraction were obtained by recrystallisation from methanol. The crystals were collected by filtration and washed with small amounts of water and methanol. Selected IR data (KBr, cm^{-1}): 2985, 2922, 1587, 1479, 1439, 1420, 1383, 1359, 1240, 1020, 870, 815, 792.

2.2.3. $^{\infty}_{1}[Cu(tmen)(hitp)(H_2O)]$ (**3**)

A water/methanol (1:1, v/v) solution (10 mL) of 5-hydroxy-isophthalic acid (36.4 mg, 0.2 mmol) and triethylamine (40.4 mg, 0.4 mmol) was slowly added to a methanol solution (10 mL) of [Cu(acac)(tmen)](BF$_4$) (73.1 mg, 0.2 mmol). After 2 weeks, a microcrystalline blue compound separated from the resulted mixture on evaporation at room temperature. Blue single crystals of X-ray diffraction quality were obtained by recrystallisation from

methanol. Selected IR data (KBr, cm^{-1}): 3071, 2981, 1578, 1471, 1411, 1349, 1298, 1277, 1216, 1022, 919, 783, 714.

2.2.4. $^{\infty}_{1}$[Cu(tmen)(nitp)] (4)

An aqueous solution (10 mL) of 5-nitro-isophthalic acid (63.3 mg, 0.3 mmol) and triethylamine (60.7 mg, 0.6 mmol) was mixed with a solution of *N*,*N*,*N*′,*N*′-tetramethyl-ethylenediamine (34.8 mg, 0.3 mmol) in 5 mL water. The resulted mixture was slowly added to a solution of $Cu(CF_3SO_3)_2$ (108.5 mg, 0.3 mmol) in 10 mL water and allowed to evaporate at room temperature. Small blue crystals suitable for X-ray diffraction were separated after several days. Selected IR data (KBr, cm^{-1}): 2894, 1617, 1586, 1565, 1532, 1460, 1346, 1288, 1020, 808, 733.

2.3. Physical measurements

The IR spectra were recorded as KBr pellets with a Bio-Rad FTS 135 spectrophotometer in the 4000–400 cm^{-1} range. Magnetic data were obtained with a Quantum Design MPMS XL SQUID magnetometer. Magnetic susceptibility measurements were performed in the 1.8–300 K temperature range at 1000 G applied magnetic field. Diamagnetic corrections were applied by using Pascal's constants [11]. Isothermal magnetization measurements as a function of the external magnetic field were performed up to 7 T at 2 K and 4 K.

2.4. X-ray crystallography

X-ray diffraction data on single crystals of **1** and **2**–**4** were collected on a Huber four circle cradle equipped with a BRUKER SMART CCD detector and a Nonius Kappa CCD diffractometer respectively, using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Crystal data and details of the refinement for compounds **1**–**4** are listed in Table 1. All calculations for data reduction, structure solution, and refinement were done by standard procedures (WINGX) [12].

The structures of **1**–**4** were solved by direct methods using the SHELXS97[b] computational program. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares technique on F^2 through the SHELXL97 program [13]. The hydrogen atoms for all compounds were located from difference Fourier maps and refined with isotropic temperature factors. The final geometrical calculations and the graphical manipulations were carried out with PARST97 [14] and DIAMOND [15] programs, respectively.

3. Results and discussion

3.1. Description of the structures

Four new coordination polymers were obtained: $^{\infty}_{2}[Cu_3(trim)_2(NH_3)_6(H_2O)_3]$ (**1**); $^{\infty}_{1}$[Cu(tmen)(dhtp)] (**2**), $^{\infty}_{1}[Cu(tmen)(hitp)(H_2O)]$ (**3**), $^{\infty}_{1}$[Cu(tmen)(nitp)] (**4**), and their crystal structures were solved. Selected bond lengths and angles for the four compounds are listed in Table 2.

The first compound was obtained by reacting copper triflate with trimesic acid in the presence of ammonia. Its structure consists of 2D layers built up by two crystallographically independent copper(II) ions (Fig. 1). The Cu1 ions, located on a C_2-axis, are heptacoordinated by two ammonia, one aqua and two unsymmetrically chelating carboxylato groups from two $trim^{3-}$ ligands (one of the carboxylato oxygens is semicoordinated, Cu1–O4 = 2.825(2) Å). The Cu2 ions show a strongly distorted octahedral

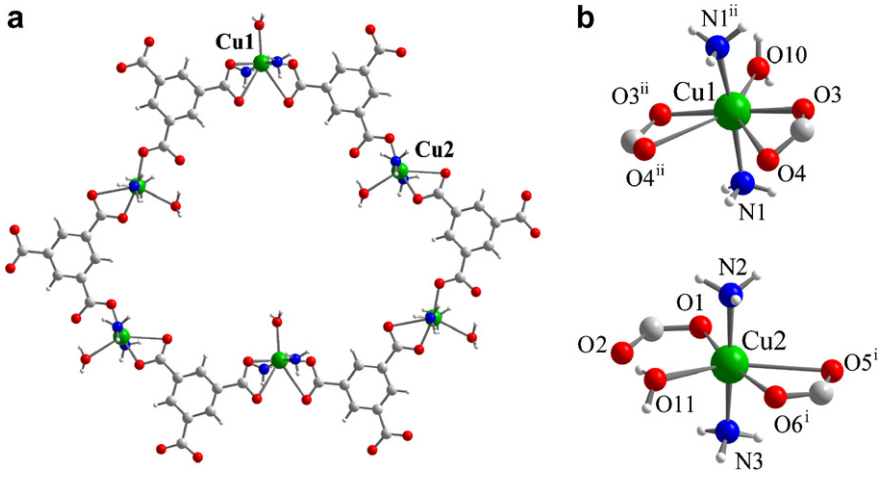

Fig. 1. Coordination environments of the copper ions in crystal **1**.

geometry, being coordinated by one chelating carboxylato group, one oxygen from a monodentate carboxylato arising from another trimesate ion, one aqua and two ammonia ligands. Two out of the *trans* Cu–O oxygen bonds [Cu2–O11 = 2.516(2) and Cu2–O5^{i} = 2.666(2) Å ($^{i} = 0.5 - x$, $-0.5 + y$, $1.5 - z$)] are much longer than the other four bonds [Cu2–O1 = 2.0066(15); Cu2–O6^{i} = 1.9989(15); Cu2–N2 = 1.9821(18); Cu2–N3 = 1.9690(18) Å].

The construction of the coordination polymer in **1** can be described as follows: the $trim^{3-}$ ligands connect with two of the carboxylato groups the Cu2 ions, resulting in zigzag chains. These chains are further interconnected by the Cu1 ions, which are coordinated to the third carboxylato group arising from trimesate ions belonging to two different chains. The coordination fashion of the trimesate ion is chelating bis-bidentate and unidentate. Two-dimensional layers with heart-shaped mashes, which are parallel to the *bc* crystallographic plane, are thus formed. The distance between the copper ions within a mesh are: Cu1···Cu2 = 10.159; Cu2···Cu2′ = 8.726; Cu1′···Cu2′ = 9.285 Å (Fig. 2a). Intralayer hydrogen bonds are established between the aqua ligand coordinated to Cu2 and an oxygen atom from the unidentate carboxylato group (O11–H11···O2 = 1.937 Å – Fig. 3a). It is interesting to recall that within the $3M^{2+}$: $2trim^{3-}$ stoichiometry, the following network topologies have been observed so far (M^{2+} = various transition metal ions): (1) honeycomb layers with the trimesate ion located on a threefold axis with all the metal centres crystallographically equivalent [16–18]; (2) herringbone (parquet flooring) [16]; (3) brick wall network [16]; (4) layers with heart-shaped mashes [19]; (5) double stranded chain [19]; (6) single zigzag chains with both connecting and terminal metal ions [3b,20]; (7) T-shaped bilayer [21].

The view along the *b* crystallographic axis reveals a stair-like conformation of the layers (Fig. 2b). The layers stack in the crystal as follows: ABAB··· The adjacent A and B layers (Fig. 3a) interact through hydrogen bonds established between the aqua ligands coordinated to the Cu1 and Cu2 ions from one layer and the carboxylato oxygen atoms that are semicoordinated to Cu2 and Cu1 from the other layer: (Cu1)O10···$O5^{iii}$(Cu2) = 2.669 Å ($^{iii} = -x$, $2 - y$, $2 - z$); (Cu2)O11···$O4^{iv}$(Cu1) = 2.792 Å ($^{iv} = -x$, $1 - y$, $2 - z$). Hydrogen bonds are also established between the first and the third layer (Fig. 3b), and involve the ammonia ligands: (Cu1)N1···$O11^{v}$(Cu2) = 3.039 Å ($^{v} = -0.5 + x$, $0.5 + y$, z), with O11 from the aqua ligand; (Cu2)N2···$O3^{vi}$(Cu1) = 3.044 Å ($^{vi} = 0.5 + x$, $-0.5 + y$, z); (Cu2)N3···$O2^{vii}$(Cu2) = 2.936 Å ($^{vii} = -x$, y, $1.5 - z$); O2 and O3 arise from carboxylato groups.

During the preparation of this manuscript, Long et al. published the synthesis and crystal structure of another copper complex that contains the same ligands: aqua, ammonia and trimesate. This compound, obtained via hydrothermal synthesis, has a different composition, $[Cu_3(trim)_2(NH_3)_4(H_2O)_3]\cdot 3H_2O$, and a different crystal structure, namely a threefold parallel interpenetration of 2D layers [22].

Compound **2** was obtained by reacting [Cu(tmen)(acac)][BF_4] with 2,5-dihydroxy-terephthalic acid (acac = acetylacetonato). The investigation of its crystal structure reveals the formation of infinite zigzag chains constructed from {Cu(tmen)} nodes and $dhtp^{2-}$ spacers (Fig. 4). The copper ions are hexacoordinated with a distorted octahedral geometry: two nitrogen atoms from the tmen ligand [Cu1–N1 = 2.023(4); Cu1–N2 = 2.012(4) Å], and four oxygens from two chelating carboxylato groups arising from two spacer molecules [Cu1–O1 = 2.473(4); Cu1–O2 = 1.993(3); Cu1–O5 = 1.961(3); Cu1–O6 = 2.562(3) Å]. The hydroxo groups are not involved in the coordination, but form strong intramolecular hydrogen bonds with one oxygen from each carboxylato groups (O1···O3 = 2.579 Å, O4···O6 = 2.581 Å). Each $CuN_2O_2O'_2$ chromophore is chiral, being related through an inversion centre to the neighbouring copper chromophore, so the chains are not chiral.

The third compound, $^{\infty}_{1}$[Cu(tmen)(hitp)(H_2O)] (**3**), consists also of infinite zigzag chains with {Cu(tmen)} nodes connected through 5-hydroxy-isophthalato linkers (Fig. 5). The copper ions are pentacoordinated with a strongly distorted square-pyramidal geometry. The basal plane is formed by two nitrogen atoms from the tmen molecule [Cu1–N1 = 2.015(2); Cu1–N2 = 2.067(2) Å], one aqua ligand [Cu1–O16 = 1.974(2) Å], and one carboxylato oxygen [Cu1–O5 = 1.9719(18) Å]; the apical position is occupied by one carboxylato oxygen from another spacer [Cu1–O2 = 2.2241(17) Å]. A measure of trigonal distortion

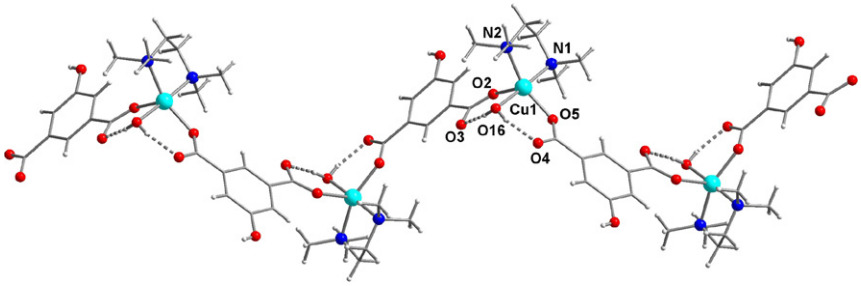

Fig. 5. Perspective view of a zigzag chain in crystal **3**, along with the atom numbering scheme.

for a square-pyramidal geometry can be described using the parameter τ, defined as $[(\theta-\varphi)/60]\times 100$, where θ and φ are the angles between the donor atoms and the Cu(II) ion forming the diagonals of the basal plane in a square-pyramidal geometry [23]. The value of τ for the coordination polyhedron of the Cu(II) ion is $\tau = 40.3$. Strong intrachain hydrogen bond interactions are established between the aqua ligand and the uncoordinated oxygens from two carboxylato groups: O16···O3 = 2.632(2); O16···O4^{i} = 2.573(2) Å ($^{i} = 0.5 - x, -y, 0.5 + z$).

The chains are interconnected through hydrogen bonds involving the OH group, from one chain, and one carboxylato oxygen from another one [O1···O3^{v} = 2.652 Å; ($^{v} = -0.5 + x, y, 0.5 - y$)], resulting in layers paralleling the crystallographic *ac* plane (Fig. 6). The shortest intrachain Cu···Cu distance is 9.919(2) Å.

The relative position of the OH group with respect to the carboxylate influences the coordination and the hydrogen bond abilities of such ligands: the *ortho* OH group favours the chelating behaviour of the hydroxy-carboxylic

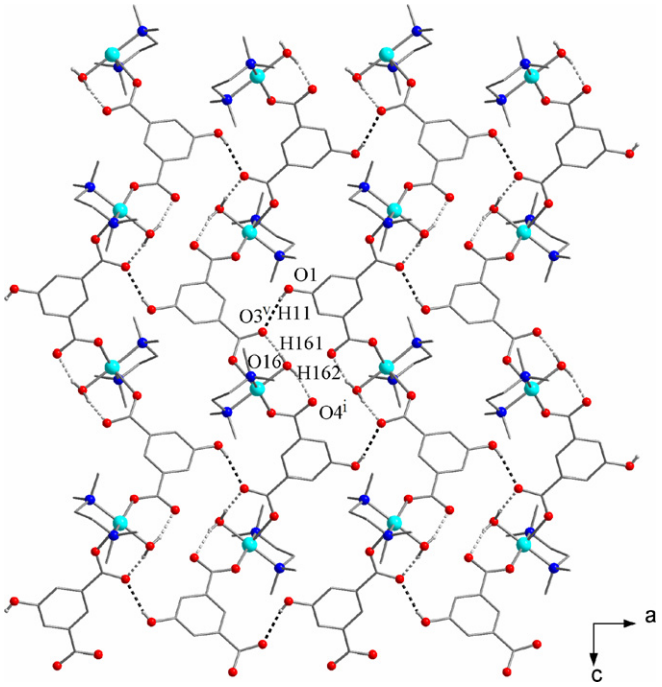

Fig. 6. Packing diagram for crystal **3** showing the hydrogen bonds connecting the chains.

acid or the formation of intramolecular hydrogen bonds (as in the case of compound **2**). The *meta* OH is too far away to coordinate together with the carboxylato group to the same metal ion, but it can be involved in intermolecular hydrogen bonds, as observed with compound **3**. The geometrical parameters associated to the hydrogen bonds in crystals **1**–**3** are listed in Table 3.

Compound **4**, $^{\infty}_{1}$[Cu(tmen)(nitp)], has been constructed by employing the 5-nitro-isophthalate as a spacer. Its structure consists of the zigzag chains similar to those found in crystal **3** (Fig. 7). The copper ions are hexacoordinated by one tmen molecule and two chelating carboxylato groups, with a strongly distorted octahedral geometry. The equatorial plane is described by the nitrogen atoms [Cu1–N2 = 2.022(4); Cu1–N3 = 2.033(4) Å], and by two carboxylato oxygen atoms arising from two spacers [Cu1–O1 = 2.000(3); Cu1-O4^{vi} = 1.939(3) Å with (vi) = $x - 0.5$, $-y + 0.5$, $z - 0.5$]; the apical positions are occupied by the other carboxylato oxygens [Cu1–O2 = 2.464(5); Cu1–O3^{vi} = 2.758(4) Å]. The distance between the neighbouring copper ions within a chain is 9.562(5) Å. Unlike compound **3**, the chains are not connected through hydrogen bonds, since the hydroxo group in the isophthalic acid is replaced by the nitro one.

3.2. Magnetic properties

Compounds **1**, **2**, and **4** have been magnetically characterized by following the temperature dependence of the magnetic susceptibility as well as the field dependence of the magnetization at 2 and 4 K. Let us start with compound **1**. The $\chi_M T$ versus T curve is shown in Fig. 8 (χ_M is the magnetic susceptibility per Cu_3 unit). At room temperature, the value of the $\chi_M T$ product (1.20 cm^3 mol^{-1} K) corresponds to the one expected for three uncoupled copper ions. By decreasing the temperature, $\chi_M T$ remains constant down to 200 K, when it starts to decrease slowly, then more and more, reaching 0.46 cm^3 mol^{-1} K at 2 K. This behaviour indicates an antiferromagnetic interaction between the copper ions within the 2D layers. Antiferromagnetic interactions between the layers, mediated by the hydrogen bonds, may also occur.

The $\chi_M T$ versus T curves for compounds **2** and **4** (Figs. 9 and 10) suggest that the intrachain exchange interactions between the copper ions are very weak (we assume that the absence of the interchain hydrogen bonds prevents the intermolecular exchange interactions). For such chains of equally spaced copper(II) ions, the temperature dependence of the magnetic susceptibility is described by the Bonner and Fisher's equation [24]:

$$\chi_M = \frac{Ng^2\beta^2}{kT}\frac{A}{B}$$
$$A = 0.25 + 0.074975x + 0.075235x^2$$
$$B = 1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3$$
$$\text{with } x = |J|/kT$$

The best fit to the data, by including the temperature independent paramagnetism (TIP), leads to the following values: $J = -0.12$ cm^{-1}, $g = 2.05$, TIP $= 2.0 \times 10^{-5}$ cm^3 mol^{-1} (compound **2**); $J = -0.53$ cm^{-1}, $g = 2.15$, TIP $= 4.1 \times 10^{-5}$ cm^3 mol^{-1} (compound **4**). For compounds **2** and **4** the magnetization saturates by increasing the magnetic field, and reaches the expected value ($\sim 1\ N\beta$ mol^{-1}) at 2 K (see insets to Figs. 9 and 10). In the case of compound **1**, the magnetization does not reach saturation even at 2 K (inset to Fig. 8), indicating stronger Cu(II)–Cu(II)

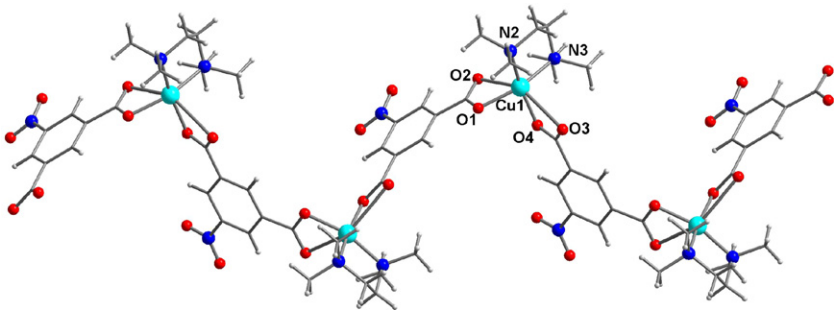

Fig. 7. Perspective view of a chain in crystal **4**, along with the atom numbering scheme.

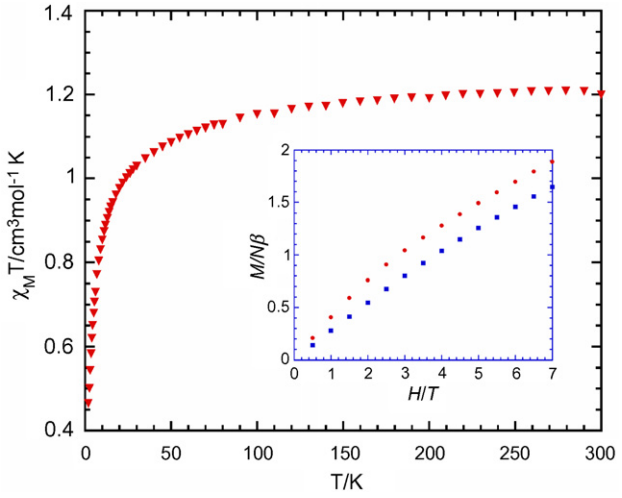

Fig. 8. $\chi_M T$ vs. T curve for compound **1** Inset: the field dependence of the magnetization at $T = 2$ K (circles) and 4 K (squares).

antiferromagnetic interactions than those found in **2** and **4**. The magnitude of the exchange interactions in **1** can not be estimated, lacking the appropriate $\chi_M(T)$ equation for its complicated topology of the spin carriers.

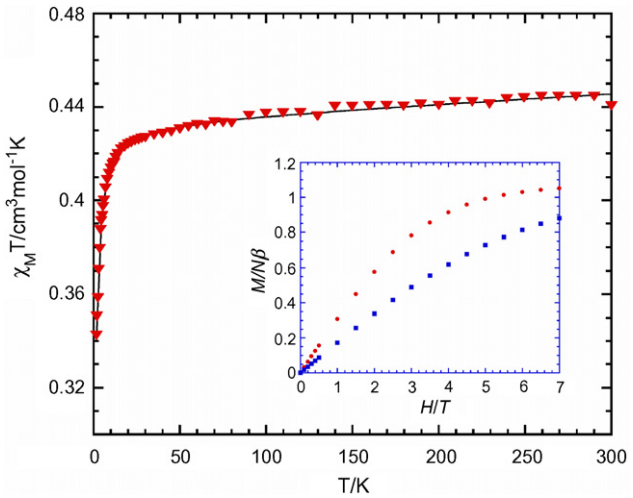

Fig. 10. $\chi_M T$ vs. T curve for compound **4** (the solid line represents the best fit curve). Inset: the field dependence of the magnetization $T = 2$ K (circles) and 4 K (squares).

4. Conclusions

In conclusion, we have illustrated with new examples the richness of the chemistry generated by polycarboxylato ligands acting as bridges. The ancillary ligands attached to the copper ions influence the topology of the metallic centers as well. The case of the trimesato complexes is quite interesting: as mentioned in the Introduction and illustrated by compound **1**, coordination polymers with various dimensionalities and solid-state architectures can be obtained by changing the ancillary ligands.

The values of the exchange parameters were found to be very low, as expected for polycarboxylato bridges, which impose long distance between the paramagnetic centres [3c,9,25,26].

5. Supplementary material

CCDC 658431, 658432, 658433 and 658434 contain the supplementary crystallographic data for compounds **1**, **2**, **3** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road,

Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

A series of metal-organic frameworks, namely $[Ni(PDB)(H_2O)]_n$ (**1**), $[Pb(PDB)(H_2O)]\cdot(H_2O)$ (**2**), $[Co_2(PDB)_2(bpy)_2(H_2O)_4]\cdot 4H_2O$ (**3**) and $[Co_2(PDB)_2(phen)_2]_n$ (**4**) (H_2PDB = pyridine-3,5-dicarboxylic acid, bpy = 2,2′-bipyridine, phen = 1,10-phenanthroline), have been synthesized based on pyridine-3,5-dicarboxylate acid and two neutral chelate ligands, with different metal ions such as Ni^{II}, Co^{II} and Pb^{II}, under hydrothermal conditions. The framework structures of these polymeric complexes have been determined by the X-ray single crystal diffraction technique. In the four complexes, the pyridine-3,5-dicarboxylate acid ligand exhibits diverse coordination modes, which play an important role in the construction of metal-organic frameworks. The thermal analyses of these four complexes have been measured and discussed. In addition, complex **2** shows strong phosphorescent emission at room temperature and the magnetic measurement of the polymer of **4** reveals a typical antiferromagnetic exchange.

1. Introduction

The construction of metal-organic framework (MOF) structures is receiving increasing attention because of the potential applications of novel functional materials such as magnetism, gas storage, molecular sieves, size- and shape-selective catalysis and electric conductivity [1,2]. However, rational design and synthesis of MOFs with unique structures and functions is still hard work. Therefore, the rational exploitation of the knowledge of the coordination geometry of a metal and ligand structure continues to be an important synthetic strategy widely used in the construction of metal-organic framework structures [3]. Organic aromatic polycarboxylate ligands as an important family of multidentate O-donors have been employed in the preparation of such metal-organic compounds [4]. Pyridyl dicarboxylic acids containing N- and O-donors are also particularly attractive as excellent building blocks with charge and multi-connecting ability [5]. In particular, pyridine-2,4-dicarboxylate acid, pyridine-3,4-dicarboxylate acid, pyridine-2,5-dicarboxylate acid and pyridine-2,6-dicarboxylate acid have been widely used by Kitagawa, Wang, Cao, Zhu and their co-workers in the construction of high-dimensional structures with large pores or undulated layers [5–8]. In contrast, pyridine-3,5-dicarboxylic acid [9], as a member of the multicarboxylate ligands containing N-donors, is rarely used. In this context, the majority of this research focuses on the synthesis, structural elements and properties of complexes constructed from different divalent metal ions and pyridine-3,5-dicarboxylic acid as well as two chelate bpy-liked ligands, and the utility of these versatile ligands in the fabrication of functional organic–inorganic hybrid materials is contemplated. In this paper, four new coordination complexes, namely,

[Ni(PDB)(H_2O)] (**1**), [Pb(PDB)(H_2O)]·(H_2O) (**2**), [Co_2(PDB)$_2$(bpy)$_2$(H_2O)$_4$]·4H_2O (**3**) and [Co_2(PDB)$_2$(phen)$_2$] (**4**) (H_2PDB = pyridine-3,5-dicarboxylic acid, bpy = 2,2′-bipyridine, phen = 1,10-phenanthroline), were prepared and investigated to determine the influence of metal ions and chelate ligands on the formation of such metal-organic frameworks. In addition, the photoluminescent property of complex **2** and the magnetic property of complex **4** were measured and discussed.

2. Experimental

2.1. Materials and analyses

All chemicals were commercially purchased and used without further purification. Elemental analyses (C, H and N) were performed on a Perkin–Elmer 2400CHN Elemental Analyzer. FT-IR spectra were recorded in the range 400–4000 cm^{-1} on an Alpha Centaurt FT/IR spectrophotometer as KBr pellets. The emission/excitation spectra were recorded on a Varian Cary Eclipse spectrometer. TG analyses were performed on a Perkin–Elmer TGA7 instrument in flowing N_2 with a heating rate of 10 °C min^{-1}. Variable-temperature magnetic susceptibility data were obtained on a SQUID magnetometer (Quantum Design, MPMS-5) in the temperature range 5–300 K with an applied field of 1000 Oe.

2.2. Syntheses of the complexes

2.2.1. [Ni(PDB)(H_2O)] (*1*)

A mixture of $NiCl_2 \cdot 6H_2O$ (0.072 g, 0.3 mmol), pyridine 3,5-dicarboxylate acid (0.05 g, 0.3 mmol), NaOH (0.024 g, 0.6 mmol) and H_2O (10 ml) was heated at 150 °C for 3 days in a 25 ml Teflon-lined stainless steel vessel under autogenous pressure. After the reaction mixture was slowly cooled down to room temperature, green block crystals were produced in a yield of 60%. Elem. *Anal.* Calc. for complex $C_7H_5NiNO_5$ (**1**) (241.83): C, 34.77; H, 2.07; N, 5.79. Found: C, 34.80; H, 2.11; N, 5.71%. IR (cm^{-1}, KBr): 3398 (br), 1607 (s), 1560 (s), 1432 (m), 1377 (s), 1302 (m), 1124 (m), 1035 (w), 936 (w), 835 (m), 775 (m), 697 (m), 564 (sm), 437 (m).

2.2.2. [Pb(PDB)(H_2O)]·(H_2O) (*2*)

An identical procedure to **1** was followed to prepare **2** except $NiCl_2 \cdot 6\,H_2O$ was replaced by $Pb(NO_3)_2$ (0.099 g, 0.3 mmol), yield 65%. Elem. *Anal.* Calc. for complex $C_7H_7PbNO_6$ (**2**) (408.33): C, 20.59; H, 1.71; N, 3.43. Found: C, 20.50; H, 1.75; N, 3.40%. IR (cm^{-1}, KBr): 3396 (br), 3080 (m), 1603 (s), 1557 (s), 1361 (vs), 1261 (m), 1147 (ms), 1208 (w), 958 (w), 911 (w), 821 (m), 767 (m), 725 (s), 681 (m), 669 (w), 573 (w), 515 (w), 430 (w).

2.2.3. [Co_2(PDB)$_2$(bpy)$_2$(H_2O)$_4$]·4H_2O (*3*)

A mixture of $Co(OAc)_2 \cdot 4H_2O$ (0.075 g, 0.3 mmol), pyridine 3,5-dicarboxylate acid (0.05 g, 0.3 mmol), 2,2′-bipyridine (0.031 g, 0.02 mmol), NaOH (0.024 g, 0.6 mmol) and H_2O (10 ml) was heated at 150 °C for 3 days in a 25 ml Teflon-lined stainless steel vessel under autogenous pressure. After the reaction mixture was slowly cooled down to room temperature, pink block crystals were produced in a yield of 70%. Elem. *Anal.* Calc. for complex $C_{34}H_{38}Co_2N_6O_{16}$ (**3**) (904.56): C, 45.15; H, 4.20; N, 9.29. Found: C, 45.10; H, 4.27; N, 9.31%. IR (cm^{-1}, KBr): 3420 (br), 1608 (vs), 1566 (s), 1489 (w), 1478 (w), 1438 (m), 1397 (m), 1375 (s), 1282 (w), 1151 (w), 1125 (w), 932 (w), 771 (s), 736 (mm), 695 (m), 529 (m), 439 (m).

2.2.4. [Co_2(PDB)$_2$(phen)$_2$] (*4*)

An identical procedure to **3** was followed to prepare **4** except 2,2′-bipyridine was replaced by 1,10-phenanthroline (0.031 g, 0.02 mmol), yield 50%. Elem. *Anal.* Calc. for complex $C_{38}H_{22}Co_2N_6O_8$ (**4**) (808.48): C, 56.45; H, 2.72; N, 10.39. Found: C, 56.38; H, 2.81; N, 10.32%. IR (cm^{-1}, KBr): 3420 (br), 3056 (m), 2359 (w), 1663 (s), 1610 (s), 1576 (s), 1516 (m), 1496 (w), 1442 (m), 1404 (s), 1354 (s), 1311 (s), 1284 (s), 1226 (w), 1144 (w), 1125 (m), 1104 (w), 1047 (w), 1031 (w), 936 (w), 918 (w), 866 (w), 846 (s), 818 (w), 771 (s), 725 (s), 715 (m), 696 (m), 641(w), 610(w), 564 (w), 438 (w).

2.3. X-ray crystallography analysis

Crystal data, data collection and refinement details for **1**–**4** are given in Table 1. X-ray diffraction measurements were performed using a Bruker APXII CCD diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. An empirical absorption correction was applied using the SADABS computer program [10]. The coordinates of the heavy atoms were determined by direct methods with the SHELXS program [11]. The coordinates and anisotropic thermal displacement parameters for all non-hydrogen atoms were refined by the least squares methods based on F^2 using the SHELXL97 program [12]. The H atoms attached to C atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding C atom. The hydrogen atoms from water molecules were directly located from successive Fourier differences syntheses and were included in the calculation with estimated isotropic displacement parameters without refinement, with O–H distances restrained (DFIX) to 0.85(2) Å, in order to ensure a chemically reasonable geometry for these molecules.

3. Results and discussion

3.1. Description of the structures

Crystallographic and structural refinement data for the compounds are given in Table 1. Selected bond distances and angles for **1**, **2**, **3** and **4** are shown in Tables 2–5, respectively.

Symmetry transformations used to generate equivalent atoms: (a) x, $y+1$, z.

3.1.1. [Ni(PDB)(H$_2$O)] (**1**)

Single crystal X-ray diffraction analysis shows that the asymmetric unit of compound **1** contains one Ni^{II} ion, one PDB ligand and one coordinated water molecule. As shown in Fig. 1, each Ni^{II} ion adopts distorted octahedral coordination geometry supplied by one N atom and five O atoms. Three carboxylate oxygen atoms (O1, O2, O4) and the nitrogen atom (N2) (Ni1–N2 2.064(2) Å) comprise the equatorial plane, and the other carboxyl oxygen atom (O5C) and the oxygen atom (O3) from a coordinated water molecule occupy the axial positions (O3–Ni–O5C = 179.64(2)°), the Ni–O (2.005(2)–2.143(2) Å) and Ni–N (2.064(2) Å) bond distances are similar to those found in related Ni(II) complexes [13] (see Figs. 2a and 2b).

The coordination modes of PDB in this work are summarized in Scheme 1. As can be seen in Scheme 1c, one carboxylate bridges two metal atoms in a carboxylate *O,O′* mode, and the other links to the third Ni atom in bidentate–chelate mode. The pyridyl N atom bonds to the fourth Ni center, and thus, each pydc ligand acts as a tetra-connector. Interestingly, one carboxylate group is roughly coplanar with the adjacent pyridine ring and the other is

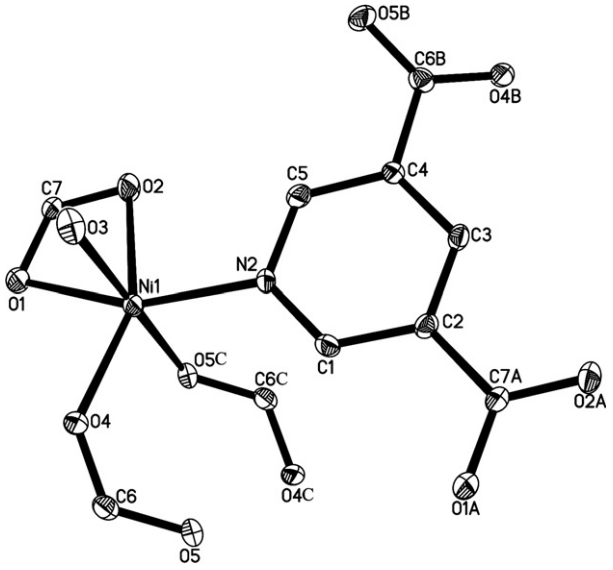

Fig. 1. ORTEP diagram showing the coordination environment for the Ni atoms in **1**. Symmetry code A: $x-1$, y, z; B: x, $-y+1/2$, $z+1/2$; C: $-x$, $-y+1$, $-z$.

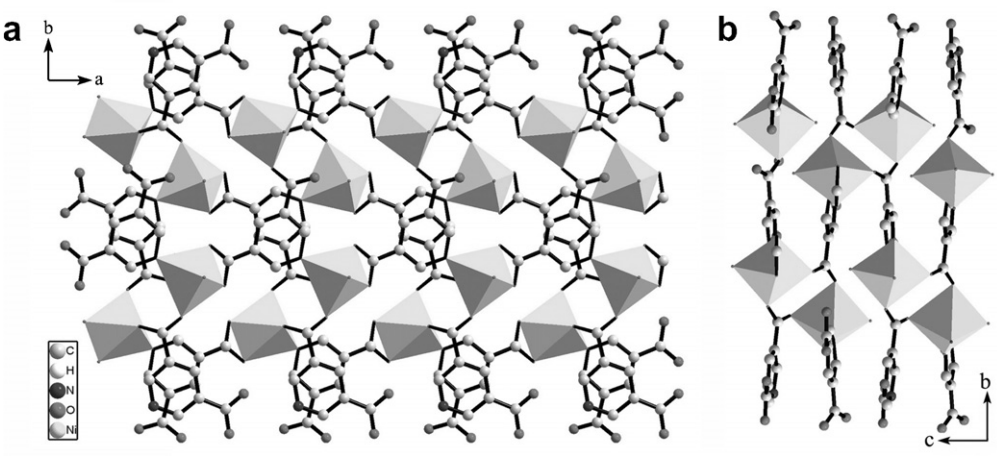
deviated from the plane with a dihedral angle of 21.55°, nipping two Ni atoms located in adjacent single layers. Such a regular crossing-plane coordination fashion is still rare in the system of multi-carboxylates, and it plays an important role in the construction of the 3D metal-organic framework (see Fig. 4b). Moreover, the hydrogen bondings between the water molecule and carboxylic O atoms (O3···O1i = 2.708(3) Å, i: $1-x$, $1-y$, $1-z$; O3···O5ii = 3.143(4) Å, ii: x, y, $1+z$) further stabilize the framework.

3.1.2. *[Pb(PDB)(H$_2$O)]·(H$_2$O) (**2**)*

The structural analysis of complex **2** reveals that it is a 2D layer structure containing (6,3) topology. The Pb atom is in a square-pyramidal coordinated geometry with four O atoms and one N atom from three separated PDB ligands and one aqua ligand (Fig. 3). Three oxygen atoms (Pb1–O2 = 2.463(3) Å, Pb1–O5 = 2.492(3) Å, Pb1–O1 = 2.685(3) Å) from two carboxylic groups of the PDB ligands and one pyridyl N atom (Pb1–N1 = 2.824(3) Å) are ligated to the Pb^{II} ion in the quasi-plane, with another oxygen atom belonging to a water molecule (Pb1–O1W =



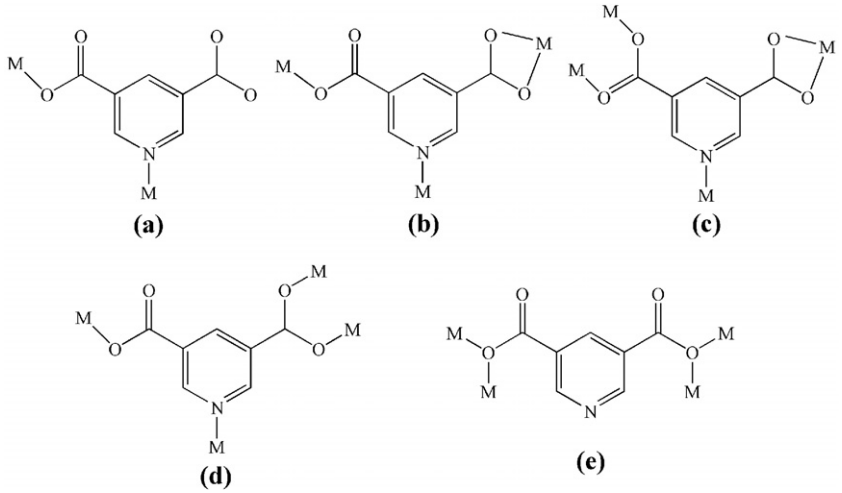


Fig. 2. Views of the 2D layer structure of **1** viewed down along the (a) *c*-axis; (b) *a*-axis.

Scheme 1. Coordination modes of the PDB ligand in compounds **1**–**4**.

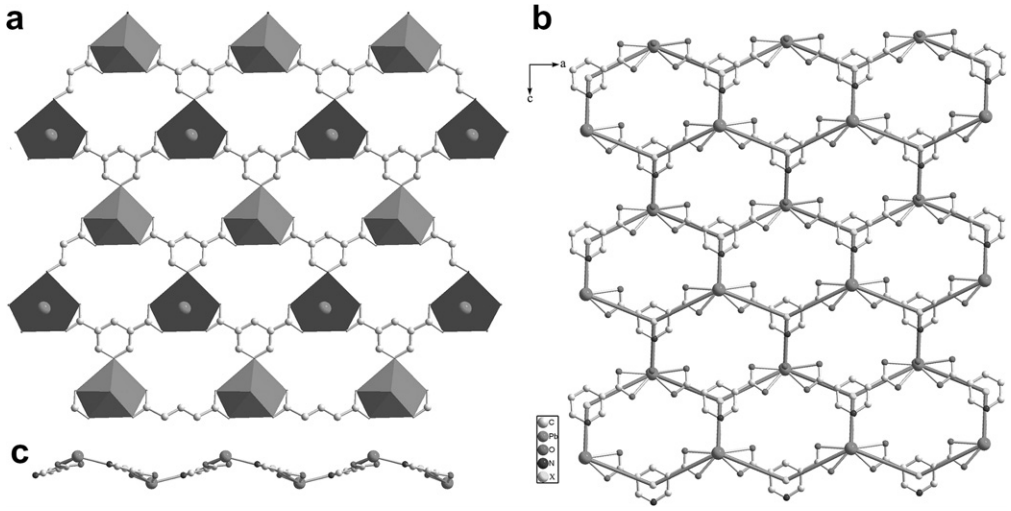

Fig. 4. (a) 2D layer structure of **2** viewed along the *b*-axis; (b) undulated along the *c*-axis; (c) projection of **2** showing the (6, 3) net based on the Pb atoms and PDB ligands.

2.392(4) Å) located in the axial position, as displayed in Fig. 4a. Longer distances are observed between Pb and O4 (2.781(4) Å); some long Pb–O weak bonds have also been reported in other lead complexes [14].

Different from that of complex **1**, each PDB ligand acts as a tri-connector linking three Pb atoms in complex **2** (Scheme 1b), one of carboxylate groups connects with one Pb atom through a mono-dentate O atom, the other bonds with the second Pb atom; the pyridyl N atom binds to the third Pb atom, consequently resulting in the formation of a 2D layer. In compound **2**, two carboxylate groups and the pyridine ring of the ligand are both distorted. The twist angles between the two $-CO_2$ planes and the pyridyl ring plane of PDB are 9.39° (O4, O5) and 14.51° (O1, O2), so the 2D layer is developed in an undulated layer pattern parallel to the *ab*-plane. By treating the Pb atom as a single node and connecting the nodes according to the connectivity defined by the geometrical centers of the benzene rings of the BTC ligands, a distorted 2D (6, 3) network sustained by 3-connected nodes is then yielded, as illustrated in Fig. 4c. The multipoint hydrogen-bonding interactions among free water molecules, coordinated water molecules and carboxylic O atoms extend the 2D layer into a 3D supramolecular net.

3.1.3. $[Co_2(PDB)_2(bpy)_2(H_2O)_4]\cdot 4H_2O$ (**3**)

When the chelate neutral ligand 2,2′-bpy is introduced, and simultaneously replacing the divalent lead salt with a divalent cobalt salt, complex **3** is obtained. Single-crystal X-ray diffraction analysis reveals that complex **3** crystallizes in a triclinic space group $P\bar{1}$ and there are two crystallographically independent cobalt atoms, two PDB, two bpy, four aqua ligands and four free water molecules in the asymmetric unit. The Co atom, in a distorted octahedral geometry (Fig. 5), is bounded by two N atoms from one bpy molecule, two O atoms from coordinated water

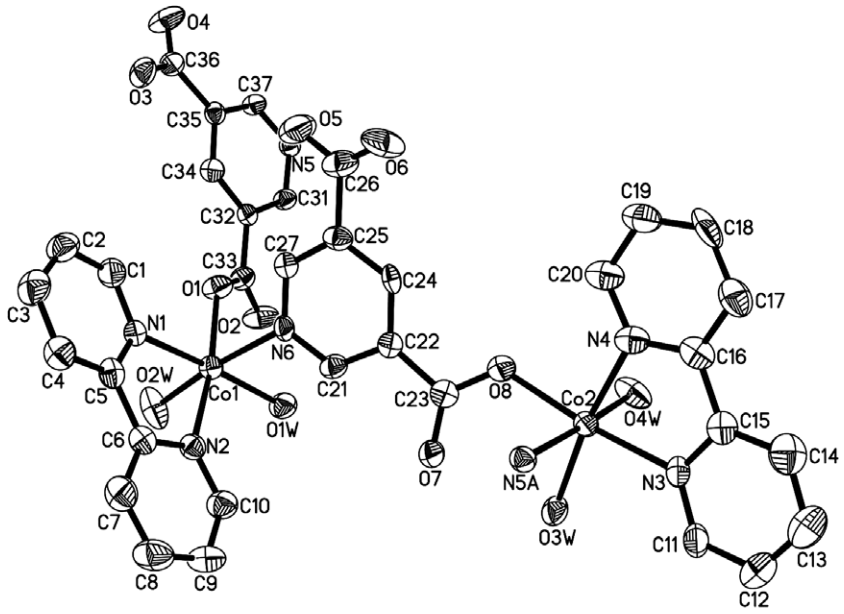

Fig. 5. ORTEP diagram showing the coordination environment of two Co atoms in **3**. Symmetry code A: x, $y+1$, z.

molecules (Co–O(water) 2.075(3)–2.136(3) Å), one pyridyl N atom and one carboxylic O atom from two PDB ligands.

Each PDB ligand acts as a bridge to connect with between Co^{II} centers through one carboxyl O atom and the pyridyl N atom (Scheme 1a), and thus a one-dimensional zig-zag chain is generated, as shown in Fig. 6. Two types of supramolecular interactions, $\pi\cdots\pi$ stacking interactions between bpys of adjacent layer (3.375 Å) and multipoint hydrogen-bonding interactions between lattice water molecules, and coordinated water molecules, as well as uncoordinated carboxylate O atoms, contribute to the formation of the three-dimensional supramolecular architecture.

3.1.4. $[Co_2(PDB)_2(phen)_2]$ (**4**)

When another chelate ligand, phen, is used, we obtained complex **4** under similar reaction conditions. The asymmetry unit of complex **4** contains two Co ions, two phen ligands and two PDB ligands. As shown in Fig. 7, the two crystallographically unique cobalt atoms exhibit two different coordination geometries. The Co1 site shows a distorted-octahedral geometry, being chelated by two N atoms from one phen ligand. The remaining four coordination sites are occupied by one N atom and three oxygen atoms from three pydc ligands. The Co1–O bond lengths are in the range 2.076(2)–2.107(2) Å and the Co1–N bond lengths are 2.141(3) and 2.166(3) Å. The Co2 ion is also six-coordinated in a more distorted octahedral symmetry with a N2O4 donor set. The equatorial plane is occupied by two N-donors from a phen molecule and two O-donors from carboxylate groups of two PDB ligands, and the axial positions are completed by two oxygen atoms from another two PDB ligands. The Co2–O bond lengths are in the range 1.985(2)–2.226(2) Å and Co2–N bond lengths are 2.102(3) and 2.137(3) Å.

In complex **4**, PDB ligands adopt two coordination modes different from those in complexes **1**–**3**: one acts as

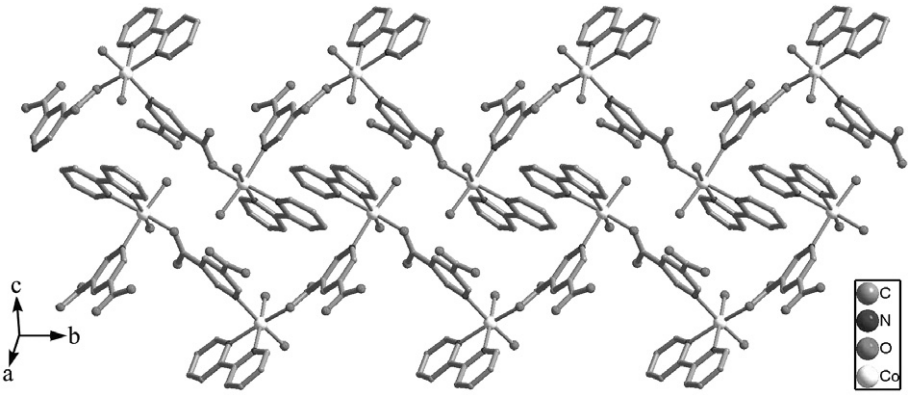

Fig. 6. View of the 1D zigzag chain highlighting the π–π interactions between pyridine rings in adjacent chains in **3**.

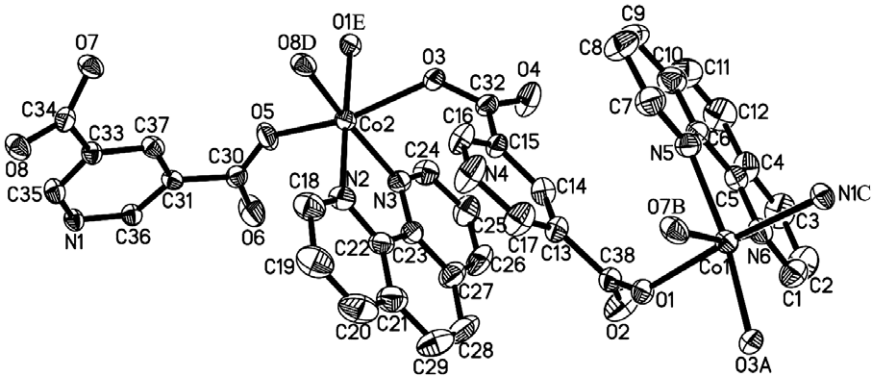

Fig. 7. ORTEP diagram showing the coordination environment for the two Co atoms in **4**. Symmetry code A: $x+1$, y, z; B: $x+1$, $-y+1/2$, $z-1/2$; C: $x+1$, y, $z-1$; D: x, $-y+1/2$, $z-1/2$; E: $x-1$, y, z.

a tetra-connector to link four Co atoms through two monodentate carboxylic O atoms from two carboxylic groups in the μ-O mode, containing an uncoordinated pyridyl N atom; the other, also being a tetra-connector, bonds with four Co atoms through one pyridyl N atom, one monodentate carboxylic O atom from one carboxylate group and two bis-monodentate carboxylic O atom from the other carboxylate group, as depicted in Scheme 1d–e.

A pair of μ-O atoms link to two adjacent Co atoms, generating a $[Co_2O_2]$ unit with a Co1···Co2 separation of 3.202 Å, in which the distances are in the normal range compared with those reported (3.076–3.393 Å) in the literature [15]. As shown in Fig. 8, firstly, one kind of PDB ligand bridges to two $[Co_2O_2]$ units to form a 2D net. Interestingly, when viewed along the *b*-axis, the two-dimensional layer contains rectangular windows with a dimensions of ca. 9.129×10.557 Å^2 that are occupied by phen ligands. Secondly, the other kind of PDB ligand connects with three $[Co_2O_2]$ units in two layers, consequently resulting in the formation of a bilayer structure (see Fig. 9).

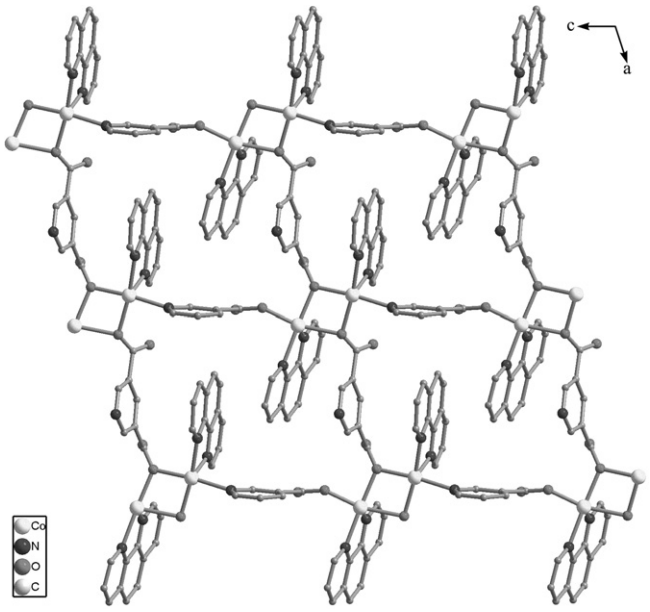

Fig. 8. View of the 2D net showing the rectangular window in **4**.

3.2. Properties

3.2.1. Luminescent properties

Luminescent compounds are of great current interest because of their various applications in chemical sensors, photochemistry and electroluminescent (EL) displays [16]. Recently, the luminescent properties of complexes containing Pb^{II} have been reported [17]. In this work, we investigated the photoluminescent property of compound **2** in the solid-state at room temperature. The free pyridine-3,5-dicarboxylic acid ligand only shows a fluorescent emission band at $\lambda_{max} = 378$ nm under 320 nm excitation (see Fig. 1S), whereas, the complex exhibits an emission peak located at about 475 nm (upon excitation at 330 nm), and undergoes a red shift by 97 nm compared to the acid ligand, as shown in Fig. 10. Hence, the emissions of compound **2** in this work might be assigned to be derived from a ligand to metal charge transition (LMCT). The low-energy emissions associated with large Stokes shifts for complex **2** have been commonly observed for other s^2-metal complexes [18]. The heavy-atom effect of lead(II) increases the spin–orbit coupling and facilitates intersystem crossing, so the phosphorescence is fast enough to successfully compete with radiationless deactivations [18d]. The observation indicates that complex **2** may be an excellent candidate for potential photoactive materials.

3.2.2. Magnetic properties

The magnetic property of polymer **4** has been investigated over the temperature range 5–300 K at 1000 Oe. The temperature dependence of the molar magnetic susceptibility is illustrated in Fig. 11. The $\chi_m T$ value of **4** remains almost constant from 300 to 115 K (5.659 cm^3 K mol^{-1}), and then decreases on further cooling, reaching a value of 0.793 cm^3 K mol^{-1} at 5 K. This behavior indicates a dominant weak antiferromagnetic interaction between the Co^{II} ions in the structure. In **4**, the Co···Co distance

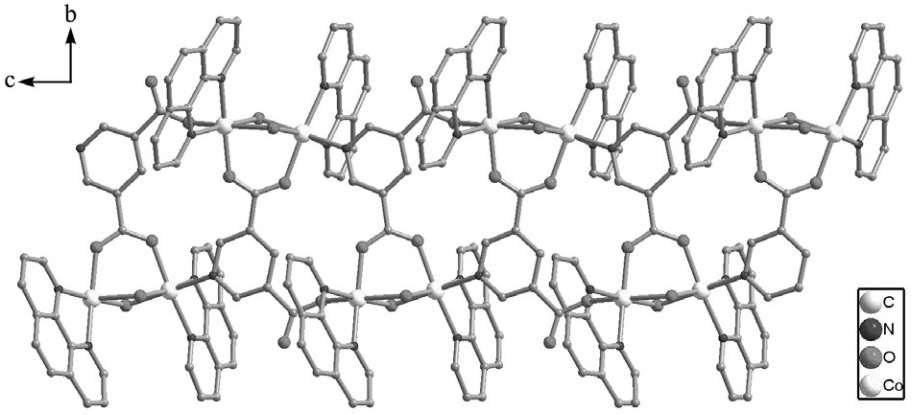

Fig. 9. View of the bilayer structure in **4**.

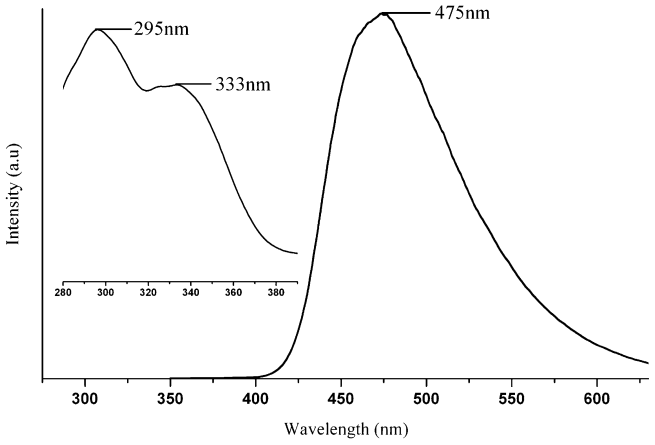

Fig. 10. Absorption (left) and phosphorescence (right) spectra of complex **2** in the solid state.

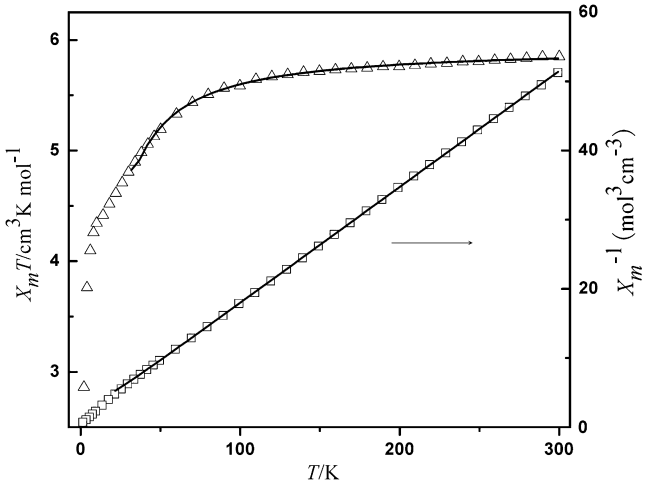

Fig. 11. Thermal variations of $\chi_M T$ and $\chi_M{}^{-1}$ for complex **4**.

through two μ_2-O atoms is 3.202 Å. Even small changes in these parameters could lead to changes in the Co···Co interaction. For polymer **4**, Co–O bridge distances ranging from 2.076(2) to 2.226(2) Å are slightly longer than those in the literature [19], but the lengths of the pathways are about 4.6 Å, which is a very short transmittance distance, helpful for magnetic coupling. The variation of $\chi_M{}^{-1}$ is well described by the Curie–Weiss law in the experimental temperature range 5–300 K with $C = 5.86\ \mathrm{cm^3\ K\ mol^{-1}}$ and $\theta = -3.69$ K.

The experiment data of complex **4** was fitted using the theoretical expression of the magnetic susceptibility, (Eq. (1)) which was deduced from the Heisenberg spin Hamiltonian $H = -JS_1 \cdot S_2$, where J is the intradimer interaction parameter between the Co(II) ions [20].

$$\chi_{\mathrm{dim}} = \frac{2Ng^2\beta^2}{kT} \times \frac{e^{5x} + 5e^{3x} + 14}{7 + e^{6x} + 3e^{5x} + 5e^{3x}} \tag{1}$$

where $x = -J/kT$. Taking into consideration the possibility of an interdimer interaction in the crystal lattice, the following correction of the molecular field is made:

$$\chi_{\mathrm{M}} = \frac{\chi_{\mathrm{dim}}}{1 - \chi_{\mathrm{dim}}(zJ'/N^2\beta^2)} \tag{2}$$

The best fitting of the experimental magnetic data by Eq. (2) gives the following parameters: $g = 2.52$, $J = -4.67\ \mathrm{cm^{-1}}$, $zJ' = 0.878\ \mathrm{cm^{-1}}$ and $R = 9.98 \times 10^{-4}$, where $R = \sum[(\chi_m T)_{\mathrm{obs}} - (\chi_m T)_{\mathrm{calcd}}]^2/\sum[(\chi_m T)_{\mathrm{obs}}]^2$. The results suggest that the interlayer interactions are weak compared with the intralayer interaction. The negative J value suggests the occurrence of an obvious antiferromagnetic Co(II)–Co(II) interactions in **4**, being in good agreement with the $\chi_m T$ versus T curve behavior in the temperature range 300–5 K. It is difficult to estimate the exchange interaction accurately within the Co(II) complexes because of the effect of spin–orbit coupling.

3.2.3. Thermal properties

Thermal gravimetric analyses (TGA) were carried out to examine the thermal stabilities of **1**–**4**. The results show that complexes **1**–**4** are very stable in air at ambient temperature, which make them potential candidates for practical applications. The samples were heated up in air at 1 atm pressure with a heating rate of 10 °C min^{-1}. The TGA curve shows that **1** is stable up to 127 °C. A weight loss of 7.6% occurred in the temperature range 127–226 °C, pre-

sumably due to the removal of a coordinated water molecule per formula unit (calcd. 7.4%). Another weight loss of 60.9% occurred in the temperature range 297–465 °C, corresponding to the removal of two PDB ligands per formula unit (calcd. 61.7%), no weight losses were observed up to 800 °C indicating the complete deposition of the complex with the formation of NiO as the final product. The TGA curve of **2** shows that the first weight loss of 4.2% between 46 and 90 °C corresponds to the loss of the lattice water molecules (calcd. 4.4%). A total weight loss of 41.2% occurred in the temperature range 215–513 °C, mainly corresponding to the removal of the one coordinated water molecule and one PDB ligand per formula unit (calcd. 40.9%), no weight losses were observed up to 800 °C indicating the complete deposition of the complex with the formation of PbO as the final product. The TGA curve of **3** shows that the first weight loss of 16.01% between 40 and 172 °C corresponds to the loss of the lattice water molecules and coordinated water molecules (calcd. 15.92%), and then it is stable up to 280 °C. The framework collapsed in the temperature range 280-800 °C before the final formation of a metal oxide. The TGA curve shows that **4** is stable up to 350 °C. The framework collapsed in the temperature range 350–800 °C, suggesting that the organic ligands decompose slowly over a wide temperature range. The results indicate that a 3D porous framework constrained by the N–H···N self-complementary hydrogen bonds is more stable than 2D sheets.

4. Conclusion

In summary, we have synthesized four novel metal-organic frameworks based on pyridine-3,5-dicarboxylic acid and two chelate ligands by hydrothermal reactions. The successful syntheses of the four compounds indicate that it is promising to build up unusual architectures via combining transition metals or main group elements and pyridine–carboxylate ligands, thus opening up a new field in the preparation of metal coordination polymers with potential magnetic and luminescent properties.

5. Supplementary material

CCDC 625481, 625482, 625483 and 625484 contain the supplementary crystallographic data for **1**, **2**, **3** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Two pyrimidine based NNS tridentate Schiff base ligands *S*-methyl-3-((2-*S*-methyl-6-methyl-4-pyrimidyl)methyl)dithiocarbazate [HL_1] and *S*-benzyl-3-((2-*S*-methyl-6-methyl-4-pyrimidyl)methyl)dithiocarbazate [HL_2] have been synthesised by 1:1 condensation of 2-*S*-methylmercapto-6-methylpyrimidine-4-carbaldehyde and *S*-methyl/*S*-benzyl dithiocarbazate. One Co(III) and one Mn(II) complex of HL_1 and one Mn(II) complex of HL_2 have been prepared and characterized by elemental analyses, molar conductivities, magnetic susceptibilities and spectroscopic studies. All the bis-chelate complexes have a distorted octahedral arrangement with an N_4S_2 chromophore around the central metal ion. Each ligand molecule binds the metal ion using pyrimidyl nitrogen, azomethine nitrogen and the thiolato sulfur atoms. In the free ligand moieties, the pyrimidine nitrogen atoms, azomethine nitrogen atoms and thione sulfur atoms are in EEE orientation to each other. During chelation, all the donor sites of the ligands are reoriented to ZEZ configuration in order to facilitate the chelation process. In all the complexes, the respective ligand molecule functions as the monoanionic tridentate one. All complexes were analyzed by single crystal X-ray diffraction and significant differences concerning the distortion from octahedral geometry of the coordination environment were observed.

Keywords: Cobalt(III) and manganese(II) complexes; Pyrimidine derived dithiocarbazate ligands; X-ray structures; Spectroscopy

1. Introduction

Thiosemicarbazones of *S*-alkyl dithiocarbazate are one of the most important classes of NNS donor ligands, which have considerable pharmacological interest due to their significant antibacterial, antimalarial, antileprotic and anticancer activities [1–14]. Moreover, metal complexes of pyrimidine derived thiosemicarbazones have been extensively studied in recent years because of presence of the pyrimidine ring which is an integral part of the active sites of several enzymes [15–22]. Most of the metal complexes of thiosemicarbazones particularly with copper, cobalt, platinum and palladium show marked and diverse biological activity [23–28]. However, manganese is also an essential trace element, forming the active sites of a number of metalloproteins [29]. In these metalloproteins, manganese does exist in any of the five oxidation states or in mixed valence states. The most important role of manganese is in the oxidation of water in green plant photosynthesis where its presence in photosystem II is essential [30,31]. Manganese complexes exhibit interest due to their catalytic anti-oxidant activity, in blocking oxidant trace in vitro [32]. Synthesis, characterization, structure and reactivity studies of pyrimidine derived NNS donor ligands lead to valuable

doi:10.1016/j.poly.2007.10.012

information toward understanding the functions of different enzymes at the molecular level [15]. Attention has been given towards the chemistry of Co(III) and Mn(II) complexes with pyrimidine derived thiosemicarbazones primarily because of their coordination mode, novel electrochemical and electronic properties as well as their biological importance [33–37]. Although there has been considerable interest in transition metal complexes derived from pyridine and pyrazole containing heterocyclic thiosemicarbazones but a scanty attention has been centered towards the coordinating properties of pyrimidine derived thiosemicarbazones. In continuation of our previous work [38], here we report the synthesis and structural characterization of Co(III) and Mn(II) complexes of *S*-methyl-3-((2-*S*-methyl-6-methyl-4-pyrimidyl)methyl)dithiocarbazate [HL_1] and Mn(II) complex of *S*-benzyl-3-((2-*S*-methyl-6-methyl-4-pyrimidyl)methyl)dithiocarbazate [HL_2]. The crystal and molecular structures, room temperature magnetic properties, electrochemical properties and electronic spectra of $[Co(L_1)_2]ClO_4 \cdot H_2O$, $[Mn(L_1)_2]$ and $[Mn(L_2)_2]$ complexes have been investigated.

2. Experimental

2.1. Materials

Ethyldiethoxyacetate were purchased from Aldrich Chemical Company, USA and were used as received. All other solvents and reagents were obtained from commercial sources and purified by standard procedures [39]. *S*-methy/*S*-benzyl dithiocarbazate and 2-*S*-methylmercapto-6-methylpyrimidine-4-carbaldehyde were synthesized following the reported methods [40,41].

Caution! Since perchlorate compounds in presence of organic ligands are explosive, only a small amount of the material should be prepared and it should be handled with care.

2.2. Physical measurement

Elemental analyses [carbon, hydrogen, nitrogen and sulfur] of **1** and **2** complexes were determined with a Perkin–Elmer CHNS/O analyzer 2400 at the Indian Association for the Cultivation of Science, Kolkata. The molar conductance values of the complexes were measured in purified methanolic solution with a Systronic model 304 digital conductivity meter. The electronic spectra of the complexes in purified acetonitrile solution were recorded on a Hitachi model U-3501 spectrophotometer. IR spectra [KBr pellet, 4000–400 cm^{-1}] were recorded on a Perkin–Elmer model 883 infrared spectrophotometer. Room temperature magnetic susceptibilities were measured with a PAR 155 vibrating sample magnetometer. Cyclic voltammetry was carried out using Sycopel model AEW2 1820 F/S instrument. The measurements were performed at 300 K in acetonitrile solution containing 0.2 (M) TEAP as the supporting electrolyte and 10^{-3}–10^{-4} (M) of the Co(III) and Mn(II) complexes, deoxygenated by bubbling with nitrogen. The working, counter and reference electrodes used were a platinum wire, a platinum coil and an SCE.

2.3. Preparation of the ligands

S-methyl-3-((2-*S*-methyl-6-methyl-4-pyrimidyl)methyl)dithiocarbazate [HL_1] and *S*-benzyl-3-((2-*S*-methyl-6-methyl-4-pyrimidyl)methyl)dithiocarbazate [HL_2] were synthesized following the method as reported earlier [38]. The two ligands HL_1 and HL_2 were synthesized in a similar way by refluxing a methanolic solution (10 cm^3) of 2-*S*-methylmercapto-6-methylpyrimidine-4-carbaldehyde (0.168 g, 1 mmol) with *S*-methyl dithiocarbazate (0.122 g, 1 mmol) and *S*-benzyl dithiocarbazate (0.198 g, 1 mmol), respectively, also taken in methanol (10 cm^3). Reflux was continued for ca. 2 h at water bath temperature during which a solid microcrystalline compound separated. It was filtered off, washed several times with cold methanol and dried in vacuo over fused $CaCl_2$. Single crystals of HL_1 and HL_2, suitable for X-ray diffraction were obtained by slow evaporation of the respective methanolic solution of the ligand.

HL_1: pale yellow; yield, 0.217 g (80%); m.p. (°C) 186, *m*/*z* 272 (M+, 100%). *Anal*. Calc. for $C_9H_{12}N_4S_3$: C, 39.70; H, 4.41; N, 20.58; S, 35.29. Found: C, 39.83; H, 4.72; N, 20.52; S, 35.23%.

HL_2: yellow; yield, 0.278 g (80%); m.p. (°C) 175, *m*/*z* 348 (M+, 100%). *Anal*. Calc. for $C_{15}H_{16}N_4S_3$: C, 51.72; H, 4.59; N, 16.09; S, 27.05. Found: C, 51.84; H, 4.89; N, 16.01; S, 27.51%.

2.4. Preparation of the complexes

In continuation of our previous work which described the preparation and structural studies of Ni(II) complex of HL_1 and Co(III) and Fe(III) complexes of HL_2, here three complexation reactions of these ligands (HL_1 and HL_2) have been investigated with Co(III) and Mn(II) of HL_1 and Mn(II) of HL_2. All the complexes [**1**–**3**] were obtained from suitable reaction mixtures of the respective ligand and the corresponding hydrated metal salts, taken in 2:1 molar proportion in suitable solvent. The oxidation to Co(III) occurs during preparation of the complex. Although the mechanism of this oxidation is not proven we can safely assume that the starting cobalt(II) salt presumably undergoes aerial oxidation in presence of the ligand in methanolic solution.

2.4.1. $[Co(L_1)_2]ClO_4 \cdot H_2O$ (**1**)

A methanolic solution (5 cm^3) of $Co(ClO_4)_2 \cdot 6H_2O$ (0.0915 g, 0.25 mmol) was added dropwise to a solution of HL_1 (0.136 g, 0.5 mmol) in the same solvent (15 cm^3) with constant stirring. The resulting pink coloured solution was further stirred for ca. 15 min and then refluxed at water bath temperature for ca. 2 h. The solution was cooled to room temperature and filtered. The filtrate was kept for slow evaporation. After two days, X-ray quality crystals

of **1** were isolated. Yield, 0.45 g (70%). *Anal.* Calc. for $C_{18}H_{22.5}ClCoN_8O_{4.25}S_6$ (**1**): C, 30.61; H, 3.19; N, 15.87; S, 27.21. Found: C, 30.69; H, 3.25; N, 15.85; S, 27.20%. IR: ν (cm^{-1}) 2925(ν_{NH}); 1596($\nu_{C=Npym}$); 1510($\nu_{CH=N}$); 1267($\nu_{C=S}$); 1079(ν_{N-N}); 741($\nu_{C=S}$); UV–Vis, λ_{max}: 343, 413, 711 nm. DRS, λ_{max}: 436, 517, 703 nm. λ_M (MeOH, Ω^{-1} cm^2 mol^{-1}): 93. μ_{eff} (at 298 K): 0.00 B.M.

2.4.2. [Mn(L_1)$_2$] (2)

HL_1 (0.136 g, 0.5 mmol) was dissolved in chloroform (20 cm^3). Solid $Mn(ClO_4)_2 \cdot 6H_2O$ (0.362 g, 1 mmol) was added to the above solution with constant stirring using a magnetic stirrer and few drops of methanol was added to dissolve $Mn(ClO_4)_2 \cdot 6H_2O$. To it two drops of triethyl amine were added. The resulting red coloured solution was stirred for an additional 2 h. The solution was filtered and the filtrate was kept for slow evaporation. After two days, a red coloured sticky mass was obtained. This was dried over fused $CaCl_2$ and dissolved in purified CH_3CN. It was filtered and the filtrate was kept for slow evaporation. After three days, single crystals, suitable for X-ray diffraction were separated. Yield, 0.16 g (60%). *Anal.* Calc. for $C_{18}H_{22}MnN_8S_6$ (**2**): C, 36.12; H, 3.68; N, 18.74; S, 32.12. Found: C, 36.20; H, 3.72; N, 18.72; S, 32.15%. IR: ν (cm^{-1}) 2920(ν_{NH}); 1582($\nu_{C=Npym}$); 1508($\nu_{CH=N}$); 1268($\nu_{C=S}$); 1074(ν_{N-N}); 749($\nu_{C=S}$). UV–Vis, λ_{max}: 425 nm. λ_M (MeOH, Ω^{-1} cm^2 mol^{-1}): 20. μ_{eff} (at 298 K): 5.82 B.M.

2.4.3. [Mn(L_2)$_2$] (3)

Complex **3** was prepared using the same procedure and reaction stoichiometry as for **2**. The colour of the resulting reaction mixture was red. Yield, 0.16 g (60%). *Anal.* Calc. for $C_{30}H_{30}MnN_8S_6$ (**3**): C, 48.00; H, 4.00; N, 14.93; S, 25.60. Found: C, 48.15; H, 4.12; N, 14.91; S, 25.57%. IR: ν (cm^{-1}) 2929(ν_{NH}); 1575($\nu_{C=Npym}$); 1512($\nu_{CH=N}$); 1334, 1267($\nu_{C=S}$); 1072(ν_{N-N}); 745($\nu_{C=S}$). UV–Vis, λ_{max}: 352, 428 nm. λ_M (MeOH, Ω^{-1} cm^2 mol^{-1}): 25. μ_{eff} (at 298 K): 5.85 B.M.

2.5. Single crystal X-ray crystallography

Relevant crystallographic data are summarized in Table 1. The intensity data for the ligand HL_1 and the complexes **1**, **2** and **3** were collected on a Bruker SMART CCD diffractometer, using graphite monochromated Mo Kα radiation [$\lambda = 0.71073$ Å] in the ω and φ scan mode and ω scan mode at 100(2) K, 296(2) K, 293(2) K and 273(2) K for HL_1, **1**, **2** and **3**, respectively. Accurate unit cell parameters and orientation matrices for data collection were obtained from least-squares refinement using the programs SMART and SAINT [42] and the data were corrected for absorption using SADABS [42]. All structures were solved using SHELXTL and the SHELX-97 packages of programmes [42] i.e. SHELXS-97 for the solution of the structure and refined by full-matrix least-squares technique based on F^2 [SHELXL-97]. Positions of H-atoms were treated as riding on their parent atoms.

3. Results and discussion

3.1. Syntheses

These newly formed three complexes (**1**–**3**) were characterized by elemental analyses, solution electrical conductivity, magnetic susceptibility, IR, UV–Vis spectra and electrochemical property. The results are consistent with the proposed mononuclear formulation. The complexes were found to be fairly soluble in most of the common organic solvents. Molar conductivity value of **1** is in accord with 1:1 electrolyte behavior but the molar conductivity values of **2** and **3** show non-electrolytic behavior in nature. The complex **1** is diamagnetic in nature. The effective magnetic moment values (5.82 B.M. for **2** and 5.85 B.M. for **3**) suggest the high spin nature of the paramagnetic complexes with five unpaired electrons.

3.2. Description of crystal structures

Structural representation of the ligand HL_1 and that of the complexes **1**, **2** and **3** with atom numbering schemes are shown in Figs. 1–4, respectively. Selected metrical parameters are listed in Table 2. The unit cell of both HL_1 and **1** comprises of two molecules and those of both **2** and **3** comprise of eight molecules. A packing diagram of **2** and **3** are shown in Figs. 5 and 6, respectively.

3.2.1. Structural description of HL_1

The structure of HL_1 (Fig. 1) shows that the neutral tridentate ligand has a EEE configuration based on the C(6)–C(7), N(2)–C(7) and N(4)–C(8) bonds for the donor centers nitrogen, nitrogen and sulfur, respectively. But, on coordination to the metal ion, the ligand undergoes structural reorientation about the C(6)–C(7), N(2)–C(7) and N(4)–C(8) changes from EEE to ZEZ configuration. This suggests that a possible rotation about the azomethine double bond on coordination to the metal ion and this ZEZ configuration is necessary for its participation as a tridentate NNS chelate ligand. From the analysis of the bond lengths (Table 2) of HL_1, we may conclude that the ligand exists in thione form in its solid state but in presence of metal ions, the ligand behaves as a monoanionic tridentate one in its thiol tautomer with concomitant deprotonation of the thiol hydrogen. The tridentate ligand is nearly planar which is evident from the analysis of torsion angles of HL_1 (Table 3).

3.2.2. Structural description of 1

The complex **1** contains $[Co(L_1)_2]^+$ cation and a ClO_4^- anion. The single crystal X-ray diffraction studies show a distorted octahedral geometry for the compound. A list of selected bond parameters and angles of **1** is presented in Table 2. The Co(III) center is coordinated in an N_4S_2 meridional manner by two monodeprotonated ligand moieties using pairs of *cis*-pyrimidyl-N, *trans*-azomethine-N and *cis*-thiolate-S atoms and form four five membered

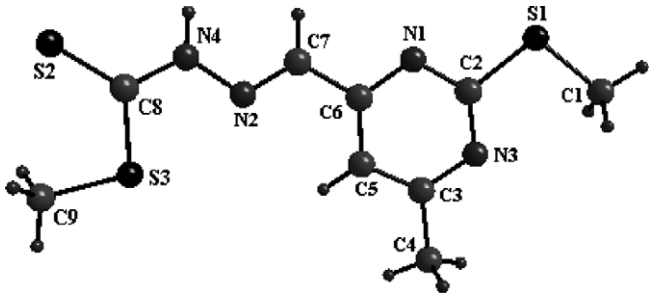

Fig. 1. Structural representation and atom numbering scheme of HL_1.

chelate rings. The meridional configurations of the NNS tridentate thiosemicarbaone ligands around the metal ion have been found in other bis-ligated metal chelates [43,44]. Consequently, the two pyrimidyl nitrogen atoms [N(1A) and N(1B)] and two thiolato sulfur atoms [S(1A) and S(1B)] are positioned in a square plane. In **1**, the atoms defining the equatorial plane lie −0.257, 0.256, −0.236 and 0.236 Å, respectively, are out of the least squares plane through them. The axial positions are occupied by the two remaining azomethine nitrogen atoms [N(2A) and N(2B)] which is evident from the N(2A)–M–N(2B) angle [169.60°]. From the bond angles Table 2, it is observed that the coordination geometry is quite far from a perfect octahedron due to the steric interactions and asymmetric nature of the ligand molecules. The maximum distortions from the ideal octahedral geometry occur for N(1A)–Co–N(2A) [81.43°] and N(1B)–Co–N(2B) [81.36°] angles in Co(III) complex [38]. The dihedral angle formed by the mean planes of the bicyclic chelate systems of each of the ligands is 88.78°. The C(8)–S(1) [A and B] bond distances appear to be longer than those reported for free thiosemicarbazone such as 1.678(2) Å in 4-formylpyridinethio-

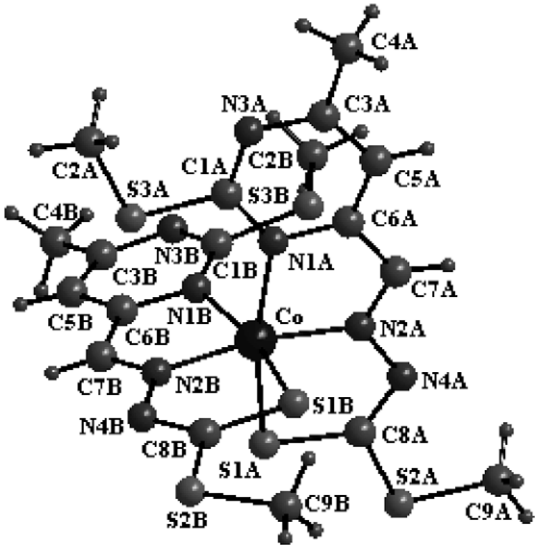

Fig. 2. Structural representation and atom numbering scheme of cationic complex **1**.

semicarbazone [45] and 1.684(4) Å in 2-keto-3-ethoxybutyraldehyde-bis(thiosemicarbazone) [46].

3.2.3. Structural descriptions of *2* and *3*

Structural representations of $[Mn(L_n)_2]$ (where $n = 1$ and 2) with atom numbering schemes are shown in Figs. 3 and 4, respectively. The anionic ligands HL_1 and HL_2 act as tridentate ones which coordinate to manganese(II) through the pyrimidyl nitrogen N(1), azomethine nitrogen N(2) and thiolato sulfur S(1) atoms with ZEZ configuration based on the C(6)–C(7), N(2)–C(7) and N(4)–C(8) bonds for the NNS donor set. Like **1**, the manganese atoms (in **2** and **3**) are also coordinated in a distorted octahedral arrangement in a *trans*-N(2)-*cis*-N(1)-*cis*-S(1) fashion. Of these sulfur involving rings are somewhat planar and slightly puckered, while the other two are almost planar. In complexes **2** and **3**, the atoms defining the equatorial plane [N(1) and S(1)] (A and B) lie −0.796, 0.787, −0.623 and 0.664 Å in **2** and −0.776, 0.776, −0.616 and 0.616 Å in **3** are out of the least squares plane through them. The two thiolato sulfur atoms are observed to be deviated farthest from the central Mn(II) atoms, at

distances of 2.519(3) Å [Mn–S(1A)] and 2.546(2) Å [Mn–S(1B)] for **2** and 2.555(2) Å [Mn–S(1)] (A and B) for **3**, while the Mn–N(1) and Mn–N(2) bonds are observed at an average distances of 2.33 Å and 2.23 Å, respectively. The Mn–$N_{azomethine}$, Mn–N_{pym} and Mn–S bond lengths are comparable well with the previously reported manganese(II) complexes [47,48]. These comparatively larger bond lengths are indicative of weak bonding of the ligand to the metal. The coordination process lengthens the C(8A)–S(1A) bond by 0.068 Å, C(8B)–S(1B) by 0.035 Å for **2** and C(8)–S(1) (A and B) bond by 0.061 Å for **3**. The decrease in bond length of N(4A)–C(8A), N(4B)–C(8B) by 0.045 and 0.027 Å for **2** and N(4)–C(8), N(4)–C(8) (A and B) by 0.036 Å for **3**, respectively, on coordination confirms the deprotonation after enolization [49]. The S–Mn–S angles are much greater than 90° [100.59(8)° for **2** and 104.90(8)° for **3**]; it is closer to the tetrahedral value and demonstrates that the two ligands exert significant steric effects on each other. The –S–CH_2–Ph in **3** exerting greater steric congestion over –S–CH_3 in **2**, registers higher S–Mn–S angle in **3**. The negative charge of the monoanionic ligands is delocalised over the main backbone of the respective ligand and the increased S–C bond distances are consistent with the single bond character, while the imine C–N distances and both thioamide C–N distances (**2** and **3**) indicate considerable double bond character. In both the cases, the tridentate ligands are nearly planar. The displacement from coplanarity is indicated by the dihedral angle between the pyrimidyl ring and the plane defined by the five membered chelate rings Mn–S–C–N–N, 0.94° and 2.34° for **2** and 7.87° for **3**. The pyrimidine ring thus makes an extended coplanar system with the two chelate rings. This extended coplanar ring system of the two ligands (HL_1 and HL_2) face each other orthogonally. This is supported from the analysis of their dihedral angles [88.52° for **2** and 81.66° for **3**].

4. Characterization of the complex species

All the three complexes gave satisfactory C, H, N and S analyses. Spectral properties of these complexes are described below in details.

4.1. IR spectra of the complexes

A comparative study of the IR spectral data of the reported complexes with those of the uncomplexed ligand gives supportive information regarding bonding sites of the ligand molecules. The Schiff base contains a proton adjacent to the thiocarbonyl group and consequently can exhibit thione–thiol tautomerism. The IR spectra of the ligands, however, display no band at ca. 2600 cm^{-1} corresponding to ν_{S-H} [50] indicating that the ligands remain as a thione tautomer. The ligand (HL_1) when dissolved in methanol in presence of Co(II) salts, quickly converts to the corresponding 'thiol' form with the concomitant formation of cobalt(III) complexes of the deprotonated mercaptide form of the ligand.

Some characteristic and recognizable spectral changes have been noticed in the IR spectra of the complexes as compared to that of the free ligands and the data can be

successfully utilized for an additional support of the bonding mode. The corresponding spectral data of the two ligands are described in our earlier report [38]. A red shift of $\nu_{(C=N)}$ from 1511 cm^{-1} (in HL_1) and 1523 cm^{-1} (in HL_2) to 1510 cm^{-1} (in **1**), 1508 cm^{-1} (in **2**), 1512 cm^{-1} (in **3**) is consistent with coordination of azomethine nitrogen [51]. The presence of a band at ca. 550 $cm^{-1}$is also assignable to (ν_{M-N}) [38] (here M stands for the corresponding metal ion). A blue shift of $\nu_{(C=Npym)}$ from 1570 cm^{-1} in the uncomplexed ligand toward ca. 1584 cm^{-1} in all the complexes is also consistent with coordination of pyrimidine nitrogen [51]. For all the complexes, the thioamide band at ca. 775 cm^{-1} in the free ligand owing to $\nu_{(C=S)}$ undergoes a red-shift by ca. 30 cm^{-1}, pointing to the sulfur atom of thiol as a possible coordination site [51]. The low frequency band appearing in the region at ca. 315–320 cm^{-1}, 340–360 cm^{-1} and 490–515 cm^{-1} in all the three complexes are assigned as $\nu_{M-N(pym)}$, ν_{M-S} and $\nu_{M-N(azomethine)}$, respectively [52].

4.2. UV–Vis and DRS of the complexes

The DRS of **1** exhibits a broad band at ca. 436 nm with two distinct shoulders at low energy side (at ca. 517 nm and ca. 703 nm). The broad band is due to the S → Co(III) charge transfer transition as is also evident from the solution spectral study. The other two bands may be assigned as $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^3T_{2g}$ transitions, respectively, [53]. In methanolic solution, it displays S → Co(III) charge transfer transition (LMCT) at 413 nm with one d–d band at 711 nm. The intense band at ca. 343 nm is due to the intraligand CT band.

The UV–Vis spectral data of HL_1 and HL_2 have already been reported in our previous communication. The complex **2** in CH_3CN displays the absorption band at 425 nm, which is assigned as the intraligand CT band ($n \rightarrow \pi^*$ transition of imine portion of the TSC moiety) [54]. The intense band of the complex **3** in CH_3CN are exhibited at 428 and 352 nm which are due to $n \rightarrow \pi^*$ transition of imine portion of the TSC moiety and $\pi \rightarrow \pi^*$ transition of the aromatic ring, respectively [55]. The absorption of the organic ligand tailing into the visible region obscure the very weak d–d absorption bands of the manganese(II) complexes [55].

5. Electrochemistry

Figs. 7 and 8 show the cyclic voltametric profile of the complexes **2** and **3**, respectively. Cyclic voltametric tests on the complexes reveal the presence of an irreversible, anodic process ($E_p = +0.79$ V for **2** and +0.82 V for **3**) and quasi-reversible reduction ($E_{1/2} = -1.06$ V for **2** and −1.04 V for **3**), which regenerates in the reverse scan of the oxidation of the original complexes. On this basis, the oxidation may be attributed to the Mn(II)/Mn(III) couple, where the Mn(III) complex after its formation, being quite unstable in the original geometry, evolves to an unidentified differently coordinated species (fragmentation can not be ruled out), which, however upon reduction regenerates the Mn(II) complex. Similar type of observation was recorded by Godbole et al. [56] in their $[Mn(mesalim)_2Cl]$ complex (Hmesalim is methyl salicylimidate) where manganese being in originally in +III stable oxidation state is electrochemically oxidized to unstable Mn(IV) species. From the comparison of $E_{1/2}$ values of Mn(III)/Mn(II) couple for **2** and **3**, we may state that $E_{1/2}$ for **3** being comparatively of higher value and hence HL_2 stabilizes Mn(II) more than HL_1.

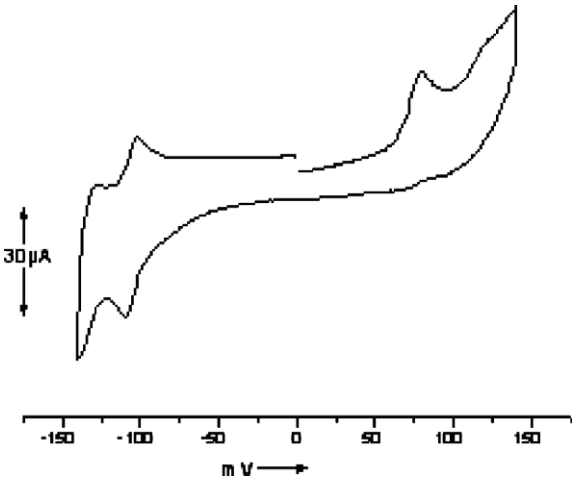

Fig. 7. Cyclic voltammogram of **2**. Scan rate 50 mV/s.

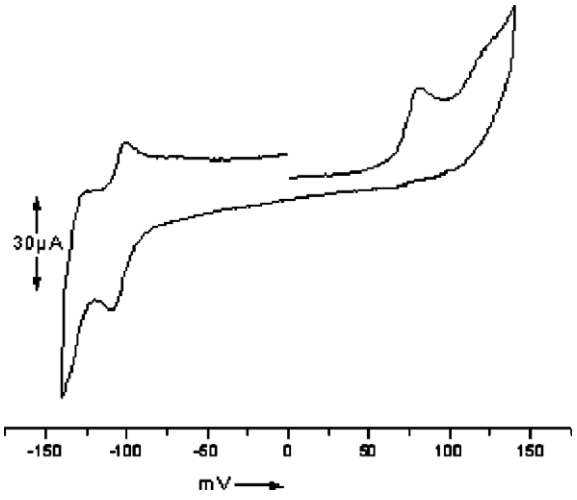

Fig. 8. Cyclic voltammogram of **3**. Scan rate 50 mV/s.

6. Concluding remarks

We have prepared Co(III) and Mn(II) complexes of HL_1 and a Mn(II) complex of HL_2 where HL_1 and HL_2 are pyrimidine derived similar Schiff base ligands. In all the complexes, the ligands HL_1 and HL_2 behave as the monoanionic NNS tridentate one through deprotonation of one proton from their corresponding thiol tautomer. Each of them forms bis-chelate with the metal ions having distorted

octahedral geometry. The deprotonation accompanied with tautomerization produces a delocalised ring system with overall intermediate interatomic bond distances on the ligand network. Cyclic voltametric studies show an irreversible anodic process and a quasi-reversible reduction.

Crystal structure and spectral characterization of hexanuclear oxo titanium(IV) clusters: $[Ti_6O_6(OSi(CH_3)_3)_6(OOCR)_6]$ ($R = Bu^t$, CH_2Bu^t, $C(CH_3)_2Et$)

Abstract

Hexanuclear oxo titanium(IV) siloxo carboxylate complexes with the general formula $[Ti_6O_6(OSi(CH_3)_3)_6(OOCR)_6]$ ($R = Bu^t$ (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**)) were synthesized in quantitative yield, by the reaction of $Ti(OSiMe_3)_4$ with the appropriate organic acid. Crystal structure determination revealed that molecules of **1**–**3** are composed of $[Ti_6\text{-}(\mu_3\text{-}O)_6]$ cores stabilized by six *syn–syn* carboxylato bridges and six terminal siloxide ligands. Each metal atom is surrounded by six oxo atoms, capping the triangular faces of the distorted octahedron. Spectral characterization (IR, NMR) of **1**–**3** revealed a significant non-equivalence of the carboxylate group interactions, resulting from the asymmetry of the Ti-μ-OOC bonds of the *syn–syn* bridges. The thermal stability of the studied compounds was determined from TGA/DTA analysis.

1. Introduction

Multinuclear oxo titanium(IV) carboxylato alkoxide complexes are used as precursors mainly in sol–gel methods for manufacturing titanium oxide ceramics, TiO_2 nanoparticle layers and organic–inorganic hybrid polymers [1,2]. We have recently shown that the thermal properties of selected complexes also enable their application as CVD precursors for the preparation of thin titanium dioxide layers [3,4]. Especially interesting are hexanuclear oxo titanium(IV) alkoxide carboxylates, synthesized in the reaction of titanium(IV) alkoxides with carboxylic acids. X-ray diffraction studies revealed that molecules of these compounds consist of clusters formed by titanium(IV) oxo cores stabilized by carboxylate bridges and terminal alkoxide ligands [5–9]. The type and the thermal properties of Ti(IV) oxo-clusters depend on the $Ti(OR)_4/R'COOH$ stoichiometry, the type of carboxylate ligands and alkoxide groups [5,6]. The sensitivity of titanium carboxylato alkoxides to moisture was significantly lower than the parent alkoxides. However, during longer storage in air (2–4 months) their partial decomposition was observed. Therefore, in order to moderate the reactivity of these complexes, the titanium(IV) alkoxides have been replaced by titanium(IV) siloxides.

The most popular among the Ti(IV) siloxide derivatives is $Ti(OSiPh_3)_4$ [10,11], used in the epoxidation of alkenes. The reaction of $[(Cp)Ti(CHPh)_2]$ or $[Cp_2TiCl]$ with Ph_3SiOH leads to the formation of complexes of the general formula $[(Cp)(Ph_3SiO)Ti(CHPh)_2]$ [12] and $[Cp_2TiCl(OSiPh_3)]$ [13]. The crystal structure of these compounds consists of a regular tetrahedron of $Ti(OSiPh_3)_4$ surrounded by cyclopentadienyl ligands. Polyhedral titansiloxanes containing Si–O–Ti bonds were used as model systems for titanium doped zeolites [14]. The Ti(IV) complexes mentioned above were synthesized from a $Ti(OR)/R'Si(OH)_3$ mixture.

They form a multinuclear ring system, composed of 2–8 titanium atoms. The silicon atoms were four-coordinated, whilst the titanium atoms show coordination numbers from four to six [15–17]. Moreover, cubic titanosiloxanes were obtained in the reaction of titanium(IV) alkoxides with suitable silanotriols in the molar ratio 1:7 or 4:4 [18,19]. The titanium(IV) silanol derivatives of the general formula $[Ti(OSiOBu^t)_4]$ [20] and $[(Bu^tO)_3Si–O–Ti(OBu^t)_3]$ [21] have also been used as precursors in CVD methods. However, there are no data concerning the structure and thermal properties of Ti(IV) complexes formed during the reaction of $Ti(OSi(R)_3)_4$ and organic acids. Therefore, the aim of the reported research was to synthesise and structurally characterise multinuclear Ti(IV) oxo sioloxo carboxylate derivatives formed in the reaction between $Ti(OSi(CH_3)_3)_4$ and branched organic acids (RCOOH; $R = Bu^t$, CH_2Bu^t, $C(CH_3)_2Et$). The structures of the novel group of complexes have been studied by single crystal X-ray diffraction, IR and NMR spectroscopy. The thermal properties of the obtained compounds have been determined using thermogravimetric analysis.

2. Results and discussion

2.1. Synthesis

Hexanuclear oxo Ti(IV) siloxo carboxylate derivatives were synthesized under the conditions described in earlier reports concerning $[Ti_6O_6(OPr^i)_6(OOCBu^t)_6]$ [5–7] (molar ratio titanium siloxide/organic acid = 1:1, Ar atmosphere, room temperature). Yellowish crystals suitable for single crystal X-ray studies or fine-crystalline powders were grown by slow solvent evaporation (glovebox, RT) over one week. The results of the elemental analysis of the powders confirms the formation of complexes of the general formula $[Ti_6O_6(OSi(CH_3)_3)_6(OOCR)_6]$ ($R = Bu^t$ (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**)). The obtained compounds showed stability against moisture higher than that of the corresponding hexanuclear oxo Ti(IV) isopropoxo carboxylate derivatives [7].

2.2. Description of the structures

Analysis of X-ray data, collected at 293 K, shows that **1** and **3** crystallize in the triclinic space group $P\bar{1}$ (no. 2) and **2** in the monoclinic group $C2/c$ (no. 15). Table 1 lists the main X-ray data collection parameters for the synthesized complexes. The X-ray diffraction studies showed the presence of toluene in the crystal lattice of **1**. That is the main reason for the observed differences in the crystal packing between this complex and **2**. The poor quality of crystals obtained for **3** made their crystallographic studies impossible. Selected bond distances and angles of the studied complexes are presented in Table 2.

The structures of the investigated compounds consist of hexanuclear titanium oxo cores ($[Ti_6$-$(\mu_3$-$O)_6]$) surrounded by carboxylate bridges and siloxide ligands (Fig. 1). Six equivalent titanium atoms are arranged in the corners of an octahedron. The average Ti···Ti distances in the $[Ti_6$-$(\mu_3$-$O)_6]$ cores of **1** and **2** vary from 3.141(9) to 4.699(25) Å (Table 2) and are longer than the analogous distances in the structure of $[Ti_6O_6(OPr^i)_6(OOCBu^t)_6]$ (3.098 Å [6,7]). The center of the hexameric cluster is empty, with the internal diameter of the $[Ti$-$(\mu_3$-$O)]_3$ ring being 3.69–3.71 Å. Each titanium atom is surrounded by three oxygen atoms of μ_3-O bridges, two μ-O of a carboxylate bridge, and the oxygen atom of the terminal siloxide ligand capping the triangular faces in a distorted octahedron (μ_3-O–Ti–OSi angles 177.6(1)–178.9(2)° for (**1**) and 177.3(1)–178.0(1)° for (**2**); μ_3-O–Ti–OOC1 – 157.4(1)–160.1(2)° for (**1**) and 158.2(1)–158.8(1)° for (**2**); μ_3-O–Ti–OOC2 – 160.1(1)–162.8(1)° for (**1**) and 160.7(1)–161.1(1)° for (**2**)).

The titanium-oxide bond lengths of the μ_3-O bridges change in the range 1.863(2)–2.220(16) Å. The Ti–O distances of the respective bonds within the $[Ti–(\mu_3$-$O)]_3$ rings (1.863(2)–1.903(6) Å) are significantly shorter than those between planes of $[Ti–(\mu_3$-$O)]_3$ rings (2.200(19)–2.220(16) Å). Simultaneously, the lengths of these bonds are similar to the analogous titanium–(μ_3-O) distances in the $[Ti_6–(\mu_3$-$O)_6]$ cores of $[Ti_6O_6(OPr^i)_6(OOCR)_6]$ (R = H [5] and Bu^t [7]). Values of Ti–(μ_3-O)–Ti angles in the plane of the $[Ti–(\mu_3$-$O)]_3$ rings and between them are 134.9(1)–136.5(1)° and 99.6(1)–100.8(2)°, respectively. The hexanuclear titanium oxide core is stabilized by six asymmetric, carboxylate *syn–syn* bridges (μ-OOCR), with the length of the shorter bonds being 2.032(7)–2.068(6) Å and the longer ones 2.049(4)–2.073(8) Å (Table 2). The length of the Ti–OSi bonds change from 1.771(14) to 1.794(15) Å in the cluster of **1** and 1.776(8)–1.782(10) Å in **2** (Table 2), which is typical for Ti–OSi bonds of titanium(IV) siloxides (1.78–1.80 Å) [22,23].

3. NMR spectroscopy

The structures of **1–3** have also been characterized by multinuclear NMR spectroscopy in the solid phase and in solution ($[D_8]$ toluene). Results of our studies are listed in Table 3. The coordination effects were studied mainly as a result of the chemical shift of resonance signals descended from carbon atoms of the carboxylate ligands. However, changes in the electronic density of carbon atoms in hydrocarbon aliphatic chains remote from the coordination core can also influence the shift of the resonance peaks. The crystallographic similarity of **1** and **3** explains the analogical shifts and the splitting of COO carbon signals in ^{13}C NMR spectra, as well as the shift of the silicon peak in the ^{29}Si NMR spectra (Tables 1 and 3). Three resonance signals at $\delta = 183.95$, 184.15, 184.31 ppm and $\delta = 183.74$, 184.05, 184.24 ppm, attributed to the carbon atoms of the COO group, were found in the ^{13}C NMR spectra of **1** and **3** (crystallizing in the triclinic system), respectively. In the spectrum of **2**, which crystallizes in the monoclinic system, two peaks for the carboxylate

carbon, at $\delta = 178.42$ and 178.70 ppm have been detected. Comparison of these data with chemical shifts of carboxylate carbons in the spectra of the corresponding acids ($\delta = 186.12$ ppm (**1**), 179.85 ppm (**2**)) suggests a significant influence of the type of the carboxylate ligand on the shift of the resonance signals of the COO group. The crystal data reported in this paper show that carboxylate ligands form non-equivalent interactions with titanium ions of [Ti$_6$–(μ_3-O)$_6$] cores (Table 2). It suggests that the asymmetry of the COO bridges causes the splitting of the resonance signals of the carboxylate atoms, observed in the ^{13}C NMR spectra of **1**–**3**.

^{29}Si NMR studies of **1**–**3** revealed the presence of single resonance signals, attributed to coordinated OSi(CH$_3$)$_3$ groups in the spectra of **1** and **2**, and a double signal in the spectrum of **3** (Table 3). The chemical shift of the silicon peaks in the spectra of **1**–**3** have been compared to the spectrum of Ti(OSi(CH$_3$)$_3$)$_4$ ($\delta = 13.24$ ppm). In the spectrum of **1**, a shift of the silicon signal by about 0.28 ppm toward higher values of the magnetic field was found. The corresponding signal was shifted towards lower field by 1.27 ppm in the spectrum of **2**. Analysis of ^{29}Si and ^{13}C NMR spectra of **3** showed a significant splitting of the silicon ($\delta = 13.58$ and 14.43 ppm) and carbon ($\delta = 1.67$, 1.95, 2.18 ppm) resonance signals of the OSi(CH$_3$)$_3$ groups (Table 3). That suggests the presence of significant differences in the strength of the Ti–OSi(CH$_3$)$_3$ interactions in [Ti$_6$O$_6$(OSi(CH$_3$)$_3$)$_6$ (OOC(CH$_3$)$_2$Et)$_6$] clusters in comparison to **1** and **2**.

NMR spectra of [D$_8$] toluene solutions were recorded in order to determine the structural changes caused by ligand dissociation or interactions of the complex molecules with solvent. In the ^{1}H and ^{13}C NMR spectra of **1**–**3** C$_7$D$_8$ solutions, signals assigned to OOCR resonance signals and signals due to the methyl moiety of the OSiMe$_3$ ligand were found. A comparison of ^{13}C NMR spectra of the solid complexes with their solutions revealed single peaks attributed to the carbon of the carboxylate groups. This indicates that symmetrical multinuclear Ti(IV) carboxylato siloxo clusters are also present in solution.

4. Analysis of IR spectra

Differences in the strength of the metal-ligand interactions in the crystalline structures of **1**–**3** have been determined using IR spectroscopy. The frequency of the

fundamental vibrations of Ti–L functional groups (L = OOCR, $OSi(CH_3)_3$, μ_3-O), detected in spectra registered at room temperature (RT), are listed in Table 4.

4.1. Carboxylate bridge vibrations

Bands attributed to symmetric and asymmetric stretching vibrations of the coordinated carboxylate groups were observed between 1528 and 1594 cm^{-1} (ν_{as}(COO)), and 1380–1434 cm^{-1} (ν_s(COO)) (Table 4). Values of the Δ parameter (calculated as the difference between ν_{as}(COO) and ν_s(COO)), being 153–156 and 115–121 cm^{-1}, correspond to a bidentate coordination of the carboxylate groups participating in *syn–syn* bridges stabilizing the $[Ti_6(\mu_3\text{-}O)_6]$ cores. Differences in the mutual orientation of the carboxylate groups linking the $[Ti_3(\mu_3\text{-}O)_3]$ rings and the asymmetry of the carboxylate ligands are factors which cause the splitting of the COO stretching bands.

Analysis of data presented in Table 4 also reveals significant shifts of ν_{as}(COO) and ν_s(COO) bands towards lower wavenumbers in the sequence **2** > **1** > **3**. This effect can be explained by the influence of the type of alkyl group on the strength of the Ti–OOC interactions. According to the crystallographic data, the average metal-oxide distances of the carboxylate groups change from 2.043, 2.058 Å for **2** to 2.049, 2.060 Å for **1**. Two medium intensity bands between 470 and 472 cm^{-1}, and 421–444 cm^{-1} have been attributed to the stretching Ti–(μ-OOC) and bending (COO) modes. The mild splitting of these bands

is caused by the differences in the symmetry of the carboxylic groups interaction in the $[Ti_6O_6(OSiMe_3)_6(OOCR)_6]$ clusters.

4.2. Fundamental frequencies of –OSiMe$_3$ terminal ligands

The bands at 919–923 cm^{-1} and 525–647 cm^{-1} were assigned to vibrations of the trimethylsiloxide ligands. According to previous reports [24], the first band can be assigned to Si–O stretching vibrations of siloxide groups (ν(SiO)), whereas the second one to Ti–OSi modes (ν(Ti–O)). In comparison to $[Ti(OSi(CH_3)_3)_4]$, the frequencies of Si–O (ν(SiO), 918 cm^{-1}) and Ti–OSi (ν(Ti–O), 517 cm^{-1}) vibrations are shifted towards higher wavenumbers by 1–5 cm^{-1} and 8–14 cm^{-1}, respectively (Table 4). That can be explained by stronger Ti–OSi interactions in hexanuclear clusters in comparison with $[Ti(OSi(CH_3)_3)_4]$. Slight differences in the frequencies corresponding to the modes mentioned above indicate the formation of equivalent Ti–OSi interactions in the $[Ti_6O_6(OSi(CH_3)_3)_6(OOCR)_6]$ clusters, independent of the type of carboxylate ligands. The obtained spectral results are consistent with the structural analysis presented in this paper.

4.3. Fundamental frequencies of Ti–O–Ti vibrations of $[Ti_6–(\mu_3\text{-}O)_6]$ clusters

Two bands, which were detected in the spectra of **1**–**3** at 704–710 and ~754 cm^{-1}, can be attributed to vibrations of Ti–O–Ti non-linear bridges of the $[Ti_6–(\mu_3\text{-}O)_6]$ cores. In contrast to the complexes discussed in this paper, in the

spectra of $[Ti_6O_6(OPr^i)_6(OOCR)_6]$ ($R = Bu^t$, CH_2Bu^t, $C(CH_3)_2$- Et) [4,7], single ν_{as}(Ti–O–Ti) bands between 720 and 750 cm^{-1} were detected. Analysis of the crystallographic data suggest that the symmetry of the $[Ti_6–(\mu_3\text{-}O)_6]$ core is the main difference between the $[Ti_6O_6(OSi(CH_3)_3)_6$-$(OOCR)_6]$ and $[Ti_6O_6(OPr^i)_6(OOCR)_6]$ clusters. Differences in the length of the Ti–O bonds in the $[Ti_3–(\mu_3\text{-}O)_3]$ ring and mutual "twisting" of these rings causes the splitting of ν_{as}(Ti–O–Ti) bands, detected in the IR spectra of the compounds reported here.

5. Thermal stability

The thermal properties of the synthesized complexes were studied using thermogravimetric methods (TGA/DTA) over the temperature range 25–600 °C. According to these data, the thermal decomposition of **1** proceeds in five endothermic steps (maxima at 47, 107, 269, 366 and 402 °C). The mass of the decomposition residue (31.9%) was consistent with titanium dioxide, and this was confirmed by XRD measurements. The biggest weight loss (39%), between 134 and 291 °C, suggests the formation of fragments containing titanium oxide species, which are detached at these temperatures. In the case of **2** and **3**, the maxima of the endothermic steps were detected at 125, 247, 346, 411 °C and 181, 276, 398 °C, respectively. The mass of the decomposition residue, 29.3% and 29.1%, indicates that TiO_2 is also the main decomposition product in these cases. The biggest weight losses for **2** and **3** were detected in range 182–286 °C (41.2%) and 208–318 °C (47.4%), respectively. The lowest temperature of conversion with the biggest weight loss was found for compound **1**, which can be assigned to the higher volatility of this compound in comparison with **2** and **3**.

6. Conclusions

Titanium trimethylsiloxide ($Ti(OSiMe_3)_4$) modified by branched organic acids ($HOOCR'$; $R' = Bu^t$, CH_2Bu^t, $C(CH_3)_2Et$) in the molar ratio 1:1 resulted in novel titanium oxo siloxo carboxylate complexes of the general formula $[Ti_6O_6(OSi(CH_3)_3)_6(OOCR')_6]$ ($R' = Bu^t$ (**1**), CH_2Bu^t(**2**), $C(CH_3)_2Et$ (**3**)). The structure of **1** was solved in the triclinic space group $P\bar{1}$ (no. 2) and the structure of **2** in the monoclinic group $C2/c$ (no. 15). The space group determined for **3** was triclinic $P1$ (no. 2). In comparison with known hexanuclear titanium oxo alkoxo carboxylate clusters, the titanium atoms form a similar type of cluster in the crystal lattice of **1**–**3**. Spectral analysis (IR, ^{13}C NMR) of **1**–**3** powders proved that the obtained complexes form a similar type of structure of the general formula $[Ti_6O_6(OSi(CH_3)_3)_6(OOCR')_6]$. Although significant differences in the length of the bonds and angles inside the cluster of **1** have not been found, the results of spectroscopic studies revealed the clear influence of the carboxylate ligand type on the strength of the Ti–OOC interactions with $[Ti_6(\mu_3\text{-}O_6)]$ clusters. The following factors affect the non-equivalence of the carboxylate bridge interactions in complexes **1**–**3**: (a) asymmetry of the carboxylate group interactions, (b) the type of hydrocarbon group of the organic acid, and (c) different orientation of the COO groups in the cluster. Thermogravimetric analysis of the synthesized compounds suggests that the volatile properties of **1** are better than those of **2** and **3**.

7. Experimental

The studied compounds were synthesized under an argon atmosphere using standard Schlenk line and glovebox techniques. $Ti(OSi(CH_3)_3)_4$ and the acids $R'COOH$ ($R' = Bu^t$, CH_2Bu^t, $C(CH_3)_2Et$, Aldrich) were used as received. The synthesized compounds were characterized using IR and NMR spectroscopy. IR spectra were registered on a Perkin–Elmer Spectrum 2000 spectrometer within the range 400–4000 cm^1 with a medium slit width and a peak resolution of 4.0 cm^{-1}. The crystals were studied as a powder dispersed in a KBr pellet (400–4000 cm^{-1}) and as a Nujol suspension between CsI plates (160–700 cm^{-1}). Solution ^1H and ^{13}C NMR spectra (toluene-d_8) were recorded using a 5 mm solution probe on a Varian Gemini 200. Solid state ^{13}C NMR spectra were registered on Bruker AMX 300. Thermogravimetric analysis (TGA) was carried out using SDT 2960 TA Instruments, in nitrogen atmosphere from 25 to 600 °C at a ramp rate of 3° min^{-1}.

7.1. Preparation of $Ti_6O_6(OSi(CH_3)_3)_6(OOCR)_6$

$Ti(OSi(Me)_3)_4$ (1.00 g, 2.47 mmol) was added to a solution of organic acid (0.25 g, 2.47 mmol of Bu^tCOOH, 0.28 g of Bu^tCH_2COOH or 0.28 g of $Et(CH_3)_2CCOOH$) in toluene (3.00 cm^3), and stirred for 12 h. Crystals were grown by slow evaporation of the reaction mixture under an argon atmosphere (glovebox). Yellowish crystals were obtained after 2–3 days. Crystalline powders of the obtained complexes were dried in a vacuum before further analysis.

7.2. $Ti_6O_6(OSi(CH_3)_3)_6(O_2CBu^t)_6$ (**1**)

Crystalline yield: 0.39 g (61.3%). The % Ti was gravimetrically determined as TiO_2, according to the Meth-Cohn et al. method [25] *Anal.* Calc. for $C_{48}H_{96}O_{24}Ti_6Si_6$: C, 37.80; H, 7.09; Ti, 18.86. Found: C, 37.30; H, 7.21; Ti, 18.50%.

7.3. $Ti_6O_6(OSi(CH_3)_3)_6(O_2\ CCH_2Bu^t)_6$ (**2**)

Yield: 0.25 g (42.42%). *Anal.* Calc. for $C_{54}H_{120}O_{24}$-Ti_6Si_6: C, 40.28; H, 7.46; Ti, 17.86. Found: C, 40.78; H, 7.60; Ti, 17.61%.

7.4. $Ti_6O_6(OSi(CH_3)_3)_6(O_2\ C(CH_3)_2Et)_6$ (**3**)

Yield: 0.28 g (45.45%). *Anal.* Calc. for $C_{54}H_{120}O_{24}$-Ti_6Si_6: C, 40.23; H, 7.46; Ti, 17.86. Found: C, 40.51; H, 7.68; Ti, 17.55%.

7.5. X-ray data collection and structure determination

The yellowish single crystals of all the compounds were crystallized by slow evaporation from toluene solution. The X-ray data were collected with an Oxford Sapphire CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å), at 293(2) K, by the $\omega - 2\theta$ method. A shape-based absorption correction was applied for **1**–**3** (RED171 package of programs, Oxford Diffraction, 2000 [26,27]) with maximum and minimum transmissions of 0.8200/0.7905, 0.9138/0.7863 and 0.97047/0.88027 for **1**–**3**, respectively. The structures were solved by direct methods and refined with the full-matrix least-squares method on F^2 using the SHELX-97 program package [28]. No extinction correction was applied. The data collection and refinement processes are summarized in Table 1. Selected bond lengths and angles of **1** and **2** are presented in Table 2.

Abstract

The reinvestigation of the title reaction over the extended pH range, $3.25 \leqslant pH \leqslant 6.3$, has shown that the reaction is first-order in $[Co(III)W]^{5-}$, [SIV] and $[M^+]$ where M^+ is the alkali metal ion, with SO_4^{2-} as the exclusive product. The alkali metal ions form ion-pairs with SO_3^{2-} and $[Co(III)W]^{5-}$ (abbreviation for 12-tungstocobaltate(III)) ions and also act as a bridge between the ion-pairs in the formation of the activated complex, the decomposition of which is rate limiting. A mechanism based on the above fact explains the kinetics results. Because of the nature of the rate dependence on M^+ and H^+, the application of the extended Marcus theory involving work terms could not be applied, but the application in its simple form does support that the reaction is outer-sphere.

Keywords: 12-Tungstocobatate(III); Sulfite: S(IV), kinetics, mechanism, oxidation and redox reaction

1. Introduction

The mechanism of oxidation of S(IV) or SO_2(aq), catalysed by transition metals, relevant to atmospheric processes has been reviewed [1]. The oxidation product could be SO_4^{2-}, $S_2O_6^{2-}$ or a mixture of the two ions [2]. The kinetics with two-electron oxidants such as hypochlorite [3], hypobromite [4], tetrachloroaurate(III) [5], tetrachloroaurate(III), *trans*-dicyanodichloroaurate(III) and *trans*-dicyanodibromoaurate(III) ions [6], tetrahydroxyargentate(III) [7], hexaaquothalium(III) [8], aquopentaammineplatinum(IV) [9], hexachloroplatinum(IV) [10], *trans*-tetracyanohydroxobromoplatinum(IV) [11] and tetracyanodichloroplatinum(IV) [12], and extensively by one-electron oxidants [13] including the studies with tetraamine(phenanthroline)Ru(III) [14], tris-(2,2-bipyridyl)Os(III) [15], Co(III)dipicolinate [16], tris(acetylacetonato)Mn(III) [17] were studied in acidic solutions whereas those by $Mn(cdta)^-$ ions [18,19] were studied in acetic acid–acetate buffer.

The recent studies include metal ion catalysed oxidations by non-metal oxidants such as dioxygen and the $S_2O_8^{2-}$ ion. CdS and Mn(II) [20], and diaminesilver(I) [21] catalysts are used in the dioxygen oxidation; Ag(I) [22] and Cu(II)–tetramine [23] catalysts are used in the $S_2O_8^{2-}$ ion oxidation in acetate and ammonia buffered solutions, respectively.

The oxidation by the one-electron oxidant dodecatungstocobaltate(III) [24], $[CoW_{12}O_{40}]^{5-}$, here after referred to as $Co(III)W^{5-}$, was studied in the pH range $1.5 \leqslant pH \leqslant 3.5$. The ratio of $Co(III)W^{5-}$ and S(IV) decided the exclusive formation of $S_2O_6^{2-}$, or its formation in combination with SO_4^{2-} from the reaction mixtures having an excess of $Co(III)W^{5-}$ or SO_2(aq) in a slight excess. There were mixed first and second orders pathways in S(IV), observed in the oxidation by Cr(VI) [25], $[Fe(phen)_3]^{3+}$ [26] (phen = 1,10-phenanthroline) and $Mn(cdta)^-$ ions [18]. The formation of dithionate is considered to indicate an inner-sphere process whereas the sulfate ion is the exclusive product in the outer-sphere process [15]. An inner-sphere mechanism

doi:10.1016/j.poly.2007.10.013

with $Co(III)W^{5-}$, which is substitution inert, is most unlikely. The use of the Marcus theory [27–29], which has given good correlations for metal complexes oxidising S(IV) by an outer-sphere mechanism [14], is desirable to decide upon the nature of the mechanism.

The reinvestigated reaction over the extended pH range, $3.25 \leqslant pH \leqslant 6.32$, has given altogether different results with a stoichiometry ratio $Co(III)W^{5-}$:S(IV) = 2:1 under the conditions of excess and deficient concentrations of $Co(III)W^{5-}$ over [S(IV)]. SO_4^{2-} is the exclusive oxidation product under any concentration conditions because dithionate was not detected, and there were no parallel first- and second-order paths in S(IV). The application of the Marcus theory [27–29] to the present reaction supports an outer-sphere nature of the mechanism which is consistent with the absence of dithionate as the product of the reaction [15].

2. Experimental

2.1. Material

The solutions of potassium salts of 12-tungstocobaltate(III), $[CoW_{12}O_{40}]^{5-}$ and 12-tungstocobaltate(II), $[CoW_{12}O_{40}]^{6-}$ were prepared, characterised and standardised by the method described in the literature [30,31] ($CoW_{12}O_{40}^{5-}$: $\varepsilon_{390} = 1215 \pm 5$, pH 4.63; ε_{390} [32] = 1207, ε_{390} [33] = 1225 $dm^3\ mol^{-1}\ cm^{-1}$; $CoW_12O_{40}^{6-}$: $\varepsilon_{625} = 214$; ε_{624} [34] = $212 \pm 4\ dm^3\ mol^{-1}\ cm^{-1}$, pH 4.63).

The solutions of sodium sulfite (Fluka, puriss), found stable over a period of a few hours, were freshly prepared in twice distilled water purged with nitrogen for sufficient time and used within 2 h. The solutions were standardised as described earlier [18].

The sodium acetate–acetic acid buffer solutions of different pH were prepared by mixing a 0.2 mol dm^{-3} solution of sodium acetate (Merck, GR) and acetic acid (Qualigen, GR) in volumes as described elsewhere [35]. The pH of the buffer solutions was checked with a Systronics 335 digital pH meter with a glass electrode.

The stock solution of lithium perchlorate, used to adjust the ionic strength, was prepared by neutralising a calculated amount of lithium hydroxide(Sigma, LR) by a calculated volume of the standard perchloric acid (Merck, GR) solution. The solution was standardised gravimetrically [36].

All other chemicals were of highest purity and were used as received. The twice distilled water was used in the preparation of all the solutions. The nitrogen purged reactant solutions were mixed to initiate the reaction.

The spectral studies were made on a HP 8452A UV–Vis spectrometer with a 2 nm band width and an integration time of 1 s.

2.2. Rate measurement

A union Giken RA-401 stopped flow spectrophotometer with a dead time of 0.5 ms for a 2 mm flow-cell was used to study the kinetics of the reaction under pseudo first-order conditions ($[S(IV)] \geqslant 10[Co(III)W^{5-}]$) at constant ionic strength (1.0 mol dm^{-3}, $LiClO_4$) in acetate–acetic acid buffered solutions. The reactant solutions, previously purged with nitrogen to remove the dissolved oxygen, were thermostated in the storage cylinders which along with the reaction cell were maintained at the desired temperature (±0.1 °C) by circulating water from a Haake-D8G refrigerated circulatory water-bath.

The rate in general was measured in terms of disappearance of $[Co(III)W]^{5-}$ at 390 nm, though some identical runs were repeated with the appearance of $[Co(II)W]^{6-}$ at 625 nm with almost the same results. At least 8–10 runs were studied for any given condition. The spectrophotometer is interfaced with a SORD microcomputer for collecting and analysing the data involving averaging the volt time curves of replicate runs, displaying the plots of log absorbance against time, which were linear over the entire range of the reaction studied, and reporting the averaged k_{obs} values. The averaged k_{obs} value was within ±3–5% of the value from the individual runs. The linear log absorbance-time plots are against a simultaneous second-order dependence in $[SO_2(aq)]$ [24].

Finally all the statistical calculations are based on the use of the EXCEL program which is also used to draw the plots given in the paper.

2.3. Stoichiometry

The stoichiometry of the reaction was estimated under two conditions at pH 4.63 and 25 °C. In one set of experiments $[Co(III)W^{5-}]$ was in excess over $[SO_2(aq)]$. After sufficient time the $[Co(III)W^{5-}]$, left unreacted, was generally estimated spectrometrically at 390 nm though in a few cases $[Co(II)W^{6-}]$ was also estimated at 625 nm. In the other set of experiment $[SO_2(aq)]$ was in excess over the $Co(III)W^{5-}$ ion. The unreacted sulfite was estimated titrimetrically using iodine solution. The results from the two sets of experiments, Table 1, indicate that $\Delta[Co(III)W]^{5-}/\Delta[SO_2(aq)] = 1.95 \pm 0.04$, which is the basis of the stoichiometric Eq. (1).

$$2Co(III)W^{5-} + SO_2(aq) + 2H_2O \rightarrow 2Co(II)W^{6-} + SO_4^{2-} + 4H^+ \quad (1)$$

The present stoichiometry result is, therefore, in disagreement with the results of the previous study [24], which reported a 1:1 ($[Co(III)W]^{5-}$:[S(IV)]) stoichiometry from the reaction mixtures having excess of $SO_2(aq)$.

2.4. Oxidation product

The spent reaction mixtures prepared under both the conditions were heated and nitrogen gas was bubbled through the solution over a period of time to remove $SO_2(aq)$. The treatment of these solutions with an excess of $BaClO_4$ solution resulted in the formation of an insoluble white precipitate which was filtered for gravimetric

Table 1
The estimation of stoichiometry ratio at pH 4.63 and 25 °C

S.no.	$10^3[Co(III)W^{5-}]_o$	$10^3[S(IV)]_o$	$10^3[Co(II)W^{6-}]_o$	$\frac{\Delta[Co(II)W^{6-}]}{\Delta[S(IV)]}$
1	1.50	0.272	0.528[a]	1.94

8	6.55	10.1	3.32	1.97
9	8.20	12.5	4.25	1.93

Mean $\frac{\Delta[Co(II)W^{6-}]}{\Delta[S(IV)]} = 1.95 \pm 0.04$.
[a] Based on the estimation of $[Co(II)W^{6-}]$ at 625 nm.
[b] Based on the estimation of $[Co(III)W^{5-}]$ at 390 nm.

estimation. The estimated amount of SO_4^{2-} ion was in fair agreement with the amount expected from Eq. (1).

In a separate experiment the spent reaction mixtures after degasification with nitrogen gas were treated with a dilute strongly acidified dichromate solution in the manner described in the previous study [24]. The back estimated concentration of dichromate at 348 nm was almost the same as that of the added dichromate indicating that $S_2O_6^{2-}$ was not present, if any formed, in the spent reaction mixtures.

These results are also contradictory to the previous study because $S_2O_6^{2-}$ was not detected as the oxidation product, which is exclusively the SO_4^{2-} ion whatever the conditions of $[Co(III)W^{5-}]$, present in excess or in a deficient amount.

The reason for the totally different results with respect to both the stoichiometry and the oxidation product could be the use of more dilute solutions of $Co(III)W^{5-}$ and $SO_2(aq)$ than used in the previous study [24]. The possible bearing of the concentration of the $SO_2(aq)$ solution on the reaction product will be discussed later along with a general discussion.

2.5. Test for free radical

The buffered solutions of $Co(III)W^{5-}$ and $SO_2(aq)$, in separate glass stoppered flasks, were degassed with nitrogen before 2 ml of acrylonitrile was added to each of the flasks. The two solutions, that remained clear even after 5–7 min of adding the monomer, were mixed and swirled, and left for sometime. A cloudiness appeared which changed to a thick white precipitate of polyacrylonitrile, indicating the formation of free radicals. Convincing esr evidence for the formation of a free sulfur radical in the solution has been known for a long time [37,38].

2.6. Distribution of the species of $SO_2(aq)$ different pH

The very soluble SO_2 in aqueous solution has the following speciation [39].

$$SO_2 + nH_2O \rightleftharpoons SO_2 \cdot nH_2O \quad \text{or} \quad SO_2(aq) \tag{2}$$

$$SO_2(aq) \overset{K}{\rightleftharpoons} H_2SO_3 \tag{3}$$

$$SO_2(aq) \overset{K_{a1}}{\rightleftharpoons} HSO_3^- + H^+ \tag{4}$$

$$HSO_3^- \overset{K_{a2}}{\rightleftharpoons} SO_3^{2-} + H^+ \tag{5}$$

The equilibrium constant $K \lll\lll 1$ so much so that H_2SO_3 is either not present or is present in an infinitesimal quantity in the aqueous solution [39]. The fraction distribution of the species $SO_2(aq)$, HSO_3^- and SO_3^{2-}, based on the equilibria (4) and (5), was calculated using the equilibrium constants $K_{a1} = 4.30 \times 10^{-2}$ and $K_{a2} = 4.57 \times 10^{-7}$ mol dm^{-3}, respectively, at 25 °C [40]. The equilibrium (6), $K_d = 8.8 \times 10^{-2}$ dm^3 mol^{-1} at 25 °C [41], was neglected because a second-order dependence in $[S(IV)]_o$, the analytical concentration, was not shown by the reaction and $S_2O_6^{2-}$ was not detected as the reaction product.

Table 2
The calculated fractions (=concentration of the species/$[S(IV)]_o$) of the species $SO_2(aq)$, HSO_3^- and SO_3^{2-} at different pH for $[S(IV)]_o = 0.01$ mol dm^{-3}

pH	$SO_2(aq)$	HSO_3^-	SO_3^{2-}
1	7×10^{-1}	3×10^{-1}	1.37×10^{-6}
1.5	4.2×10^{-1}	5.8×10^{-1}	8.3×10^{-6}

4.15	1.6×10^{-3}	9.9×10^{-1}	6.4×10^{-3}
4.45	8×10^{-4}	9.84×10^{-1}	1.3×10^{-2}
4.63	5×10^{-4}	9.8×10^{-1}	1.9×10^{-2}
4.9	2.8×10^{-4}	9.6×10^{-1}	3.5×10^{-2}
5.65	4×10^{-5}	8.3×10^{-1}	1.7×10^{-1}
6	2×10^{-5}	6.86×10^{-1}	3.1×10^{-1}
6.32	6×10^{-6}	5.1×10^{-1}	4.9×10^{-1}

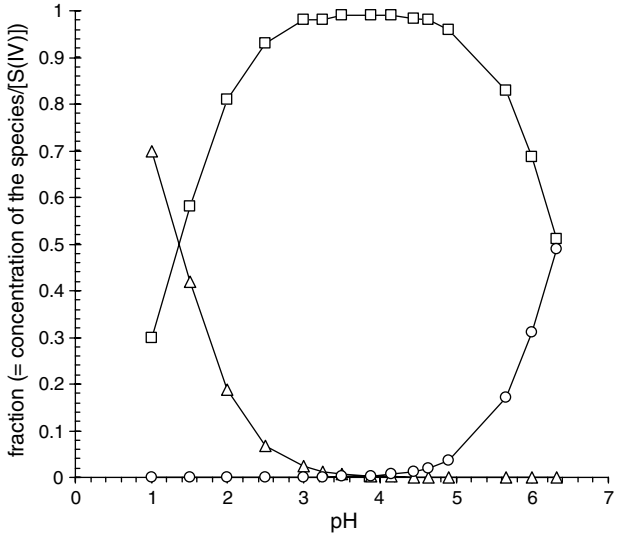

Fig. 1. The distribution of $SO_2(aq)$ (△), HSO_3^- (□) and SO_3^{2-} (○) species as a fraction (=concentration of the species/$[SO_2(aq)]_o$) at different pH at 25 °C for the initial $[SO_2(aq)]_o = 0.1$ mol dm^{-3}.

$$2HSO_3^- \overset{K_d}{\rightleftharpoons} S_2O_5^{2-} + H_2O \quad (6)$$

The fraction distribution (fraction = concentration of the species/[S(IV)]) of SO_2(aq), HSO_3^- and SO_3^{2-} species over different pH values is numerically given in Table 2 and graphically shown in Fig. 1. The SO_2(aq) fraction decreases with increasing pH, becoming negligible around pH 3.6 and beyond. The HSO_3^- fraction increases with pH and attains a plateau around pH 3.1–4.5 and thereafter it decreases and around pH 6.2 its concentration is equal to that of the fraction SO_3^{2-} which is negligible at pH $\leqslant$ 3.1 and thereafter increases continuously until its concentration equals that of HSO_3^-. Hence, the reactive species in the pH range 3.2–6.3 are possibly HSO_3^- and SO_3^{2-} ions since SO_2(aq) is negligible in this range.

3. Results

The $k_{obs} = 0.0663 \pm 0.0018\ s^{-1}$ was obtained when [Co(III)W^{5-}] was varied in the range $(0.25–4.0) \times 10^{-4}$ mol dm^{-3} at constant ionic strength (1 mol dm^{-3}), pH 4.15 and [SO_2(aq)] = 0.025 mol dm^{-3} at 40 °C. The result is, therefore, consistent with Eq. (7).

$$\frac{-d[Co(III)W^{5-}]}{dt} = k_{obs}[Co(III)W^{5-}]_o \quad (7)$$

A proportionate increase in k_{obs}, over a twenty-fivefold variation in [S(IV)] at five temperatures, Table 3, resulted in linear plots of k_{obs} against $[S(IV)]_o$, passing through the origin at all temperatures, Fig. 2, indicating the applicability of Eq. (8).

$$k_{obs} = k[S(IV)]_o \quad (8)$$

Eq. (8) is significant in the sense that it does not have an additional second-order term in $[S(IV)]_o$ [24], despite the fact that relatively high concentrations of S(IV) and higher pH were used.

The results over the pH range 3.25–6.32, Table 4, indicate that k_{obs} increased with the increase in the pH of the reaction. The plots of k_2^{-1} ($k_2 = k_{obs}/[S(IV)]_o$) against [H^+] (10^{-pH}) are linear with the intercept as shown in Fig. 3 for all temperatures.

Table 3
The dependence of k_{obs} on [S^{IV}] at different temperatures 10^4[Co(III)$W]^{5-} = 2.0$; $\mu = 1.0$ mol dm^{-3} and pH 4.15

[S^{IV}] (mol dm^{-3})	k_{obs} (s^{-1})				
	30 °C	36 °C	40 °C	45 °C	50 °C

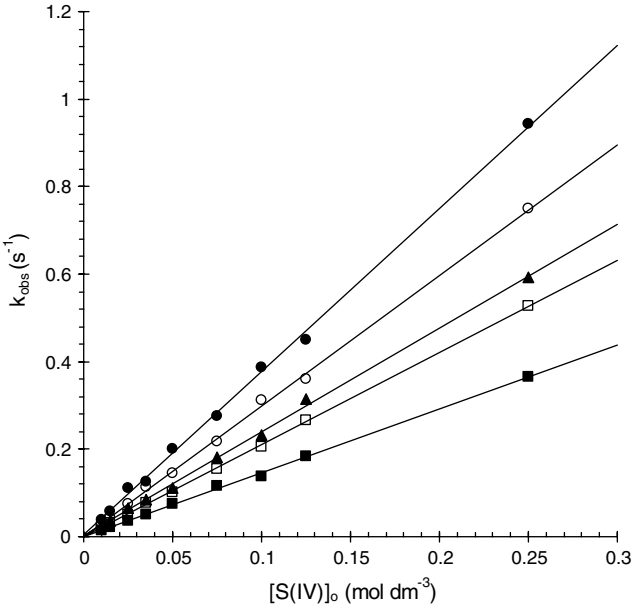

Fig. 2. The plots of k_{obs} against $[S(IV)]_o$ that pass through the origin at 30° (■), 35 °C (□), 40 °C (▲), 45 °C (○) and 50 °C (●).

The data in Table 5 is from an earlier study [24]. It has been analysed for the effect of ionic strength on k_{obs} in terms of Eq. (9), proposed by Davies [42].

$$\log k_{obs} = \log k_o + z_a z_b \left(\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.05\mu \right) \quad (9)$$

where z_a and z_b are the charges on the reacting species. The plot of log k_{obs} against $\left(\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.05\mu\right)$ is shown in Fig. 4. The slope of the plots corresponding to the variation of the ionic strength using salts of Li^+ (4.35), Na^+ (4.13) and K^+ (3.91) are averaged to 4.13 ± 0.22, and are therefore independent of the nature of the salt used. The significance of the average slope value $\cong 4$ in the context of the proposed mechanism is discussed later.

4. Mechanism and discussion

A different mechanism in the extended range of pH is indicated because the order with respect to S(IV) is strictly one against a simultaneous first and second-order dependence in the earlier study [24]. The inverse dependence on [H^+] is indicative of a deprotonation equilibrium prior to the rate limiting step where the deprotonated species, a stronger reducing agent than the protonated one, behaves as the sole reactive entity or is in combination with the protonated one. This equilibrium is likely to involve S(IV) species in aqueous solution because Co(III)W^{5-} species are not affected by H^+ ions [43].

The distribution pattern of the S(IV) species, Fig. 1, indicated that HSO_3^- and SO_3^{2-} are the major species in the pH range 3.25 $\leqslant$ pH $\leqslant$ 6.32 and are singularly or collectively treated as reactive entities in all the reactions [2–26]. A mechanism based on these species was initially

Table 4
The dependence of k ($=k_{obs}/[S^{IV}]$) at different pH and temperatures $10^4[Co(III)W^{5-}] = 2.0$; $[S^{IV}] = 0.10$ and $[\mu] = 1.0$ mol dm^{-3}

6.32	.0479	5.24	9.43	13.91	128.2	205.3	287.3

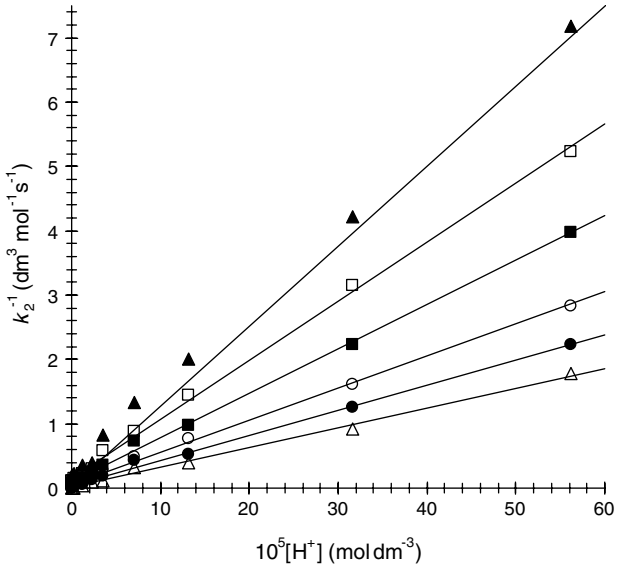

Fig. 3. The plots of k_2^{-1} ($k_2 = k_{obs}/[S(IV)]_o$) against $[H^+]$ ($=10^{-pH}$) with intercepts at 20 °C (▲), 25 °C (□), 30° (■), 35° (○), 40 °C (●) and 45 °C (△).

considered and rejected[1] because the deduced rate equation suggested a different correlation between k_{obs} and $[H^+]$ and a slope value between 5 and 8 for the plot in Fig. 4 (the observed value is 4).

The anionic species are likely to form an ion-pair with the cationic species of the alkali metal ion used to adjust the ionic strength. The following mechanism is based on this consideration and is treated as the most probable mechanism of the reaction.

[1] Only basic steps of the reaction are considered in the following mechanism.

$$HSO_3^- + Co(III)\ W^{5-} \xrightarrow{k_1} HSO_3^{\cdot} + Co(II)W^{6-}$$

$$SO_3^{2-} + Co(III)W^{5-} \xrightarrow{k_1} SO_3^{-\cdot} + Co(II)W^{6-}$$

$$= \frac{-d[Co(III)W^{5-}]_o}{dt} = \frac{(k_1[H^+] + k_2K_{a2})[S(IV)]_o}{K_{a2} + [H^+]}$$

$$SO_2(aq) \overset{K_{a1}}{\rightleftharpoons} HSO_3^- + H^+ \quad (4)$$

$$HSO_3^- \overset{K_{a2}}{\rightleftharpoons} SO_3^{2-} + H^+ \quad (5)$$

$$HSO_3^- + M^+ \overset{K_1}{\rightleftharpoons} MSO_3^- + H^+ \quad (10)$$

$$SO_3^{2-} + M^+ \overset{K_2}{\rightleftharpoons} MSO_3^- \quad (11)$$

$$[Co(III)W]^{5-} + M^+ \overset{K_5}{\rightleftharpoons} [Co(III)W\cdots M]^{4-} \quad (12)$$

$$[Co(III)W\cdots M]^{4-} + M^+ + MSO_3^- \overset{K_M}{\rightleftharpoons} MCo(III)W^{4-}\cdots M^+\cdots{}^-O_3SM \quad (13)$$

$$MCo(III)W^{4-}\cdots M^+\cdots{}^-O_3SM \xrightarrow{k} [Co(II)W\cdots M]^{5-} + MSO_3^{\cdot} + M^+ \quad (14)$$

$$[Co(III)W\cdots M]^{4-} + MSO_3^{\cdot} + H_2O \xrightarrow{fast} [Co(II)W\cdots M]^{5-} + MSO_4^- + 2H^+ \quad (15)$$

The $SO_3^{-\cdot}$ (which is the same as $MSO_3^{\cdot}$) radical had been proposed as an intermediate in the mechanism of transition-metal ion catalysed oxidation [44] of SO_2(aq). Since Eq. (14) is rate limiting, the rate is expressed by Eq. (16)

$$\text{rate} = k[MCo(III)W^{4-}\cdots M^+\cdots{}^-O_3SM] \quad (16)$$

$$= kK_MK_5K_2K_{a2}[Co(III)W^{5-}][HSO_3^-][M^+]^3/[H^+] \quad (17)$$

The derivation of Eq. (19) is based on the correlation expressed in Eq. (18).

$$[Co(III)W^{5-}]_o = [Co(III)W^{5-}] + [MCo(III)W^{4-}] \quad (18)$$

therefore,

$$[Co(III)W^{5-}] = \frac{[Co(III)W^{5-}]_o}{1 + K_5[M^+]} \quad (19)$$

Similarly, Eq. (21), derived with the assumption that $[H^+] + K_1\{M^+\} \gg K_{a2}K_2\{M^+\}$, is based on the mass balance of the S(IV) species given in Eq. (20), neglecting SO_3^{2-} because of its negligible concentration compared to the concentration of the MSO_3^- ion.

$$[S(IV)]_o = [HSO_3^-] + [MSO_3^-] + [MSO_3^-] \quad (20)$$

Table 5
The deduced values of k_{obs} (s^{-1}) from the plot between k_{obs} and $[M^+]$ in Ref. [19] $10^4[Co(III)W]^{5-} = 2.0$, $[S^{IV}] = 0.01$ mol dm^{-3}, pH 3.50 at 25 °C

$[M^+]$ (mol dm^{-3})	μ[a] (mol dm^{-3})	$10^4 k_{obs}$ (Li^+)	$10^4 k_{obs}$ (Na^+)	$10^4 k_{obs}$ (K^+)
0.09	0.103	1.72	5.16	13.8
0.27	0.283	5.16	12.0	31.0
0.48	0.493	6.88	17.2	43.0
0.68	0.693	10.4	26.7	65.4
0.98	0.993	15.5	42.1	99.8

[a] The ionic strength is calculated considering the concentrations of the alkali metal salts and S^{IV}. Since $[CH_3COO^-]$ used in the buffer solution is not reported, its contribution is not included and that of $[Co(III)W]^{5-}$ is neglected.

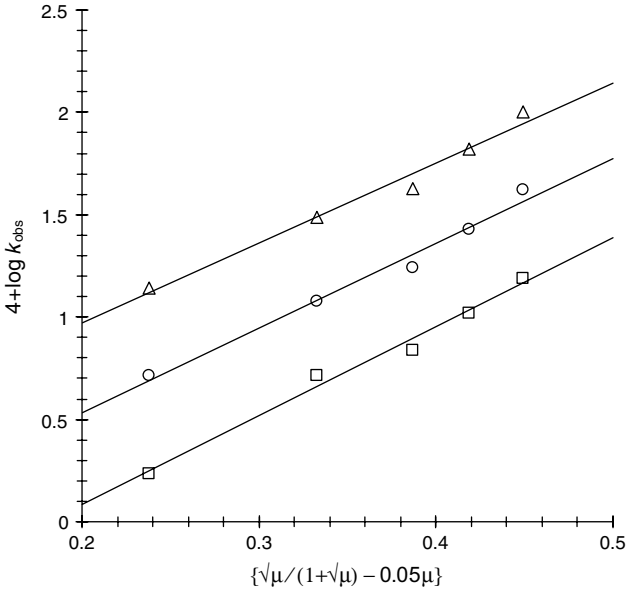

Fig. 4. The plots of log k_{obs} against $\{\sqrt{\mu}/(1+\sqrt{\mu}) - 0.05\mu\}$ where the ionic strength is varied with the salts of Li^+ (□, slope = 4.3), Na^+ (○, slope = 4.1) and K^+ (△, slope 3.9). The data is taken from Ref. [24].

therefore,

$$[HSO_3^-] = \frac{[S(IV)]_o[H^+]}{[H^+] + K_1[M^+]} \quad (21)$$

Eq. (17) is expressed by Eq. (22) on the proper substitution of the values of $[Co(III)W^{5-}]$ and $[MSO_3^-]$ given in Eqs. (19) and (21).

$$k_{obs} = \frac{-d[Co(III)W^{5-}]_o}{dt[Co(III)W^{5-}]_o} = \frac{kK_MK_5K_2K_{a2}[S(IV)]_o[M^+]^3}{[H^+] + K_5[M^+][H^+] + K_1[M^+] + K_5K_1[M^+]^2}. \quad (22)$$

Eq. (22) is simplified to Eq. (23) with the assumption that $K_5[M^+][H^+] + K_5K_1[M^+]^2 \gg [H^+] + K_1[M^+]$

$$k_2 = \frac{k_{obs}}{[S(IV)]_o} = \frac{kK_MK_2K_{a2}[M^+]^2}{[H^+] + K_1[M^+]} \quad (23)$$

$$\frac{1}{k_2} = \frac{[H^+]}{kK_MK_2K_{a2}[M^+]^2} + \frac{K_1}{kK_MK_2K_{a2}[M^+]} \quad (24)$$

Eq. (23) is consistent with the linear plots of k_{obs} against $[S(IV)]_o$, Fig. 2, that pass through the origin. Eq. (24), the inverted form of Eq. (23), is consistent with the linear plots of k_2^{-1} against $[H^+]$ with intercepts (Fig. 3). The values of the intercept and slope from the figure are in Table 5. In view of the excellent agreement between the observed results and the deduced rate Eq. (22), the above mechanism is acceptably very probable.

Eq. (23) could also be expressed as Eq. (25) under the rational assumption that $K_1[M^+] \gg [H^+]$. Eq. (25) is consistent with the linear plot of k_{obs} against $[M^+]$ that pass through the origin [24].

$$k_{obs} = \frac{kK_MK_2K_{a2}}{K_1}[S(IV)]_o[M^+] \quad (25)$$

The alkali metal ions M^+ (=Li^+, Na^+, K^+) either enhance or inhibit the rate of reactions [31,45–47]. Rate enhancement has been reported in several $[Co(III)W]^{5-}$ oxidations [24,48,49]. The data in Table 6 is from the linear plot between k_{obs} and $[M^+]$, shown in the earlier study [24], and an attempt has been made to analyse it in ways discussed below.

The M^+ ions may facilitate the approach of the anionic species. However, retardation rather than acceleration in the rate is expected with increasing size of Li^+ to Cs^+ ion [50]. The presence of M^+ ions could also affect the oxidation–reduction potential which is related to the rate of electron-transfer. The increase in the oxidation–reduction potential for the $Fe(CN)_6^{3-}$–$Fe(CN)_6^{4-}$ system from Li^+ to Cs^+ is in the same direction as the increase in the rate [51].

The possibility of ion pair formation ($[KFe(CN)_6]^{2-}$ and $[KFe(CN)_6]^{3-}$) is well known [52,53]. The formation of an

Table 6
The intercept and slope values of the plots in Fig. 3 at different temperatures

Temperature (°C)	20	25	30	35	40	45
Slope (S) $(kK_MK_2K_a[M^+]^2)^{-1}$	12460	9170	6910	5010	3935	3090
Intercept (I) $(K_1/kK_MK_2K_a[M^+])^{-1}$	0.255	0.157	0.0896	0.0470	0.0285	0.0106
$I/S = K_1[M^+]$	2.05	1.71	1.30	0.94	0.72	0.34

ion pair between M^+ and $[Co(III)W]^{5-}$ is supported by the increase in the optical density of the $[Co(III)W]^{5-}$ solution with increasing $[M^+]$, similar to that reported with $[Co(II)W]^{6-}$ [54]. It is, therefore, assumed that a similar ion pair, MSO_3^-, is formed between the M^+ and SO_3^{2-} ions. Therefore, the likely reactive species are MSO_3^- and $[MCo(III)W]^{4-}$ ions, which are consistent with the slope value 4.13 ± 0.22 obtained in the plot in Fig. 4.

Yet another possibility is the formation of a bridge between two anions [47,50,55,56]. In the bridge model a large sized alkali metal ion associated with a high value of polarisability [57] is likely to be more effective as a bridge between two anions. The greater polarisability of the larger cations [58] and the polarisability of the organic ligand acting as a bridge in the electron-transfer between metal ions are reported [59]. This view is strengthened by the linear plot of $k_{obs}/[M^+]$ against $\propto_{M+}$, as shown in Fig. 5. A similar plot is reported in the oxidation of $Co(III)W^{6-}$ with MnO_4^- [54] and the oxidation of $[Mo(CN)_8]^{4-}$ by $[Mn(cdta)]^-$(cdta = 1,2-diaminocyclohexanetetra-acetic acid) [60].

In view of the above discussion the formation of a bridge by the M^+ ions is very likely. Two types of bridges are possible. In one case the bridge may be $Co(III)W^{5-}\cdots M^+\cdots{}^-O_3SM$, in which one of the M^+ ions, which is part of the ion-pairs, acts as a bridge. The other bridge could be $MCo(III)W^{4-}\cdots M^+\cdots{}^-O_3SM$, in which the ion-pairs are bridged by an additional M^+ ion. The later one seems more likely in view of the linear plot of k_{obs} against $[M^+]$ that passes through the origin. This is consistent with MSO_3^- as the reactive entity.

The earlier study reported that scanning of the reaction mixture (pH not mentioned) gave an isosbestic point at 510 nm, indicating the absence of a complex [24], which is consistent with the substitution inert nature of $[Co(III)W]^{5-}$ and suggestive of an outer-sphere nature of the reaction. The outer-sphere nature of the reaction could have been supported with the application of the Marcus theory [27–29] which in its usual form involving work terms is inapplicable because of the high ionic strength ($\mu = 1$ mol dm^{-3}) adjusted with the alkali metal salt and the M^+ ion which accelerates the rate. As a measure of approximation the theory, under the present experimental conditions when the work terms cancel, the driving force is not too large and the term f approximates to zero, and in its simplest form is given by Eq. (26).

$$k_{12} = (k_{11}k_{22}K_{12})^{0.5} \tag{26}$$

The calculated value of k_{12}, using $E^\circ_{22} = 1.01$ [61], k_{22} (obtained by extrapolation at $\mu = 1$ mol dm^{-3}) = 1.15 dm^3 mol^{-1} s^{-1} [62], $E^\circ_{11} = 0.72$ V and $k_{11} = 4$ dm^3 mol^{-1} s^{-1} [14] at 25 °C where the subscripts 22 and 11 stand for $[Co(III)W]^{5-/6-}$ and SO_3^{2-}/HSO_3^- couples, is 4.75 dm^3 mol^{-1} s^{-1}, which is in fair agreement with the value 3.17 at pH 3.5 at 25 °C (Table 4) from where the fraction of SO_3^{2-} starts increasing with the pH. If the agreement is not too close then it is also not wide enough to conclude against the outer-sphere mechanism.

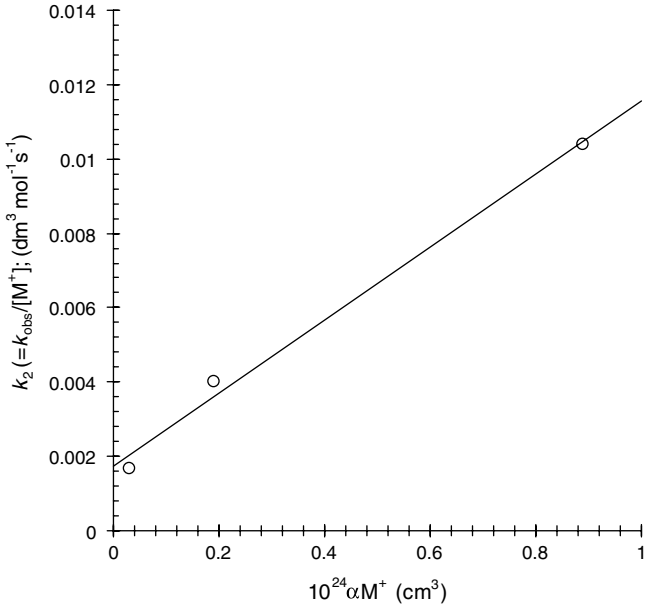

Fig. 5. The plot of k_2 (=k_{obs}/[akali metal ion, M^+]) against α_{M^+}, the polarisability of M^+.

5. Conclusion

In conclusion, the reaction studied at the extended pH range $3.25 \leqslant pH \leqslant 6.3$ has different kinetics results from the previous study [24] carried out at pH $\leqslant 3.5$. In the studied pH range the reaction is first-order in $[Co(III)W]^{5-}$, [SIV] and $[M^+]$ where M^+ is the alkali metal ion, with the SO_4^{2-} ion as the exclusive product. The M^+ ions form ion-pairs with $[Co(III)W]^{5-}$ and the species of [SIV] and also act as a bridge in the formation of the activated complex. The outer-sphere nature of the reaction is supported by the application of the Marcus theory [27–29] in its simple form because the extended theory is inapplicable to rate having dependence on H^+ and M^+ ions.

Abstract

The synthesis, crystal structure, as well as the electronic and magnetic properties, of a new trinuclear-based Cu(II) compound $[Cu_3(\mu\text{-aapm})_2(\mu\text{-dca})_2(Haapm)_2](CF_3SO_3)_2$, containing the ligands *N*-(pyridin-2yl)acetamide (Haapm) and dicyanamide (dca) is reported.

The central Cu1 atom has a distorted elongated octahedral coordination with the basal plane comprised of two nitrogens from two different tetrachelating dehydronated aapm ligands and two nitrogen atoms of two dca anions (Cu–N distances 2.016(2) and 1.988(3) Å). The apical positions are occupied by two nitrogen atoms of the two different tetrachelating aapm ligands (Cu–N distance 2.539(3) Å), with a trans angle of 180°. Also the N–Cu–N angle is extremely small (58.25(9)°), due to the four-membered chelate ring. The outer Cu2 ions have also a distorted octahedral geometry with the basal plane formed of two nitrogens and two oxygen atoms from a tetrachelating dehydronated aapm ligand (which is bridging between Cu1 and Cu2) and from a Haapm ligand (Cu–N/O distances vary from 1.95.4(2) and 2.022(2) Å), with basal angles of 177.29(9)° and 171.12(8)°. The apical positions are occupied by an oxygen atom of a triflate anion (Cu–O distance 2.534(3) Å) and a nitrogen atom of a neighbouring dca anion (Cu–N distance 2.314(3) Å), with an angle of 171.92(8)°. The Cu–Cu distance within the trinuclear unit is 5.23 Å. The dca anions are connected in an end-to-end fashion to a neighbouring Cu(II) ion (Cu–Cu distance 8.54 Å), forming in this way a chain of trinuclear units bridged by two dca anions.

The EPR as a powdered solid revealed a weak $S = 1$ triplet spectrum at RT. The magnetic susceptibility measurements, measured from 5 to 200 K, revealed a weak ferromagnetic interaction between the Cu(II) ions.

1. Introduction

The coordination properties of acid amide ligands are known for several decades, and in all cases coordination of neutral acid amides takes part via the lone pair of the amide oxygen atom. The lone pair at the N atom is conjugated with the amide and therefore not available for metal–ion binding. Only when the N atom is ionized it can bind to metal ions. Pyridine-substituted acetamides were investigated some decades ago for the first time [1–3], Nonoyama et al. [4] synthesized several transition-metal compounds

Scheme 1. *N*-(pyrimidin-2-yl)acetamide (Haapm).

with the ligand *N*-(pyridin-2yl)acetamide (abbreviated as Haap). Also a number of X-ray crystal structures with Haap and aap were published in later years [5].

The ligand Haap might have biological interest, and as a free ligand it was tested as an inducer for some types of Leukemia cells [6]. Very recently the pairwise arrangement of a donor and acceptor H bond group was realized and the molecule was used as a highly effective co-crystallizing agent for carboxylate acids [7].

More recently we investigated Cu(II) compounds with this ligand in more detail and also synthesized the new ligand *N*-(pyrimidin-2-yl)acetamide (abbreviated as Haapm) (see Scheme 1) and synthesized Cu(II) compounds with different anions [8].

On the other hand compounds of transition-metals and the ligand dicyanamide (abbreviated as dca = $N(CN)_2$) have gained much attention the last decade because of their interesting coordination, physical and magnetic properties [9–16], also due to the fact that the dca anion itself is a most interesting bridging ligand with three potential donor sites. As a result the co-ligand can vary from monodentate to even pentadentate [9–23]. The first generation of magnetically interesting compounds of the type Metal$(dca)_2$ compounds were, however, quite limited in structural types. Introducing co-ligands various new and exciting structures in the field of crystal engineering showing one-, two- and three-dimensional compounds have been obtained [9–23].

In this study the synthesis, X-ray crystal structure, characterization and magnetic behavior of a new linear trinuclear Cu(II) compound with the formula [Cu_3-(μ-aapm)$_2$(μ-dca)$_2$(Haapm)$_2$] $(CF_3SO_3)_2$ has been investigated. Linear trinuclear Cu(II) compounds have gained much interest in the field of magnetism [24].

However, linear trinuclear Cu(II) compounds, of which the trinuclear units forming a chain bridged via dca ligands are quite rare, *i.e.* to the best of our knowledge only one such compound, although not completely linear, has been reported [25].

2. Experimental

2.1. General

C, H, N determinations were performed on a Perkin–Elmer 2400 Series II analyzer. Ligand-field spectra were obtained on a Perkin–Elmer Lambda900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. X-band powder EPR spectra were obtained on a Jeol RE2x electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. FTIR spectra were obtained on a Perkin–Elmer Paragon 1000 FTIR spectrophotometer equipped with a Golden Gate ATR device, using the reflectance technique (4000–300 cm^{-1}, resp. 4 cm^{-1}).

Magnetic susceptibility measurement (5–200 K) were carried out (at 0.1 T) using a Quantum Design MPMS-5S SQUID magnetometer. Data were corrected for the magnetization of the sample holder and for diamagnetic contributions, which were estimated from standard Pascal constants.

2.2. Synthesis of the coordination compound

The ligand dipm was prepared by the method reported in the literature [8]. All other chemicals were used as received without further purification.

Synthesis of the compound: 1.2 mmol of Cu(II) triflate and 2.4 mmol of the ligand were each dissolved in 20 ml ethanol. The ligand salt solution was then added slowly to the Cu(II) solution. Then 1.2 mmol of sodium dicyanamide dissolved in about 2 ml of water was added slowly, while stirring, to the solution. The solution was filtered to remove any non-dissolved material. After one week a blue crystalline product separated. This product was isolated by filtration and dried in air. Yield 65%. *Anal.* Calc. for $C_{30}H_{26}Cu_3F_6N_{18}O_{10}S_2$: C, 31.2; H, 2.2; N, 22.4; S, 5.4. Found: C, 30.9; H, 2.2; N, 22.4; S, 5.4%.

[c] Goodness-of-fit $S = [\sum w(F_o^2 - F_c^2)^2/(n-p)]^{1/2}$, where n is the number of reflections and p the number of parameters.

2.3. Crystal structure determination and refinement

A suitable crystal for the title compound was selected from the mother liquid and mounted to a glass fibre using the oil-drop method [26] data were collected on a Nonius KappaCCD diffractometer (graphite-monochromated Mo Kα radiation). The structures were solved by direct methods. The programs COLLECT [27], SHELXS-97 [28], SHELXL-97 [29] were used for data reduction, structure solution and structure refinement, respectively. Refinement of F^2 was done against all reflections. All non-hydrogen atoms were refined anisotropically. The water H atoms were picked from a difference map and refined isotropically. All other H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. Crystallographic data of the compound is summarized in Table 1.

3. Results and discussion

3.1. Description of the crystal structure

A thermal ellipsoid plot, together with the numbering scheme is shown in Fig. 1, with selected bond lengths and bond angles given in Table 2. The unit structure consist of a three Cu atoms, two Haapm ligands, two dehydronated aapm ligands, two triflate anions and two dca anions. A centre of symmetry is located at the Cu1 atom.

The central Cu1 atom has a distorted elongated octahedral coordination with the basal plane comprised of two nitrogens from two different tetrachelating dehydronated aapm ligands and two nitrogen atoms of two dca anions (Cu–N distances 2.016(2) and 1.988(3) Å), with basal angles of 180°. The apical positions are occupied by two nitrogen atoms of the two different tetrachelating aapm ligands (Cu–N distance 2.539(3) Å), with a trans angle of 180°. Another interesting feature is that one N–Cu–N angle is extremely small (N15–Cu1–N17 = 58.25(9)°), as a result of the four-membered chelate ring. The outer Cu2 ions have also a distorted octahedral geometry with the basal plane formed of two nitrogens and two oxygen atoms from a tetrachelating dehydronated aapm ligand (which is bridging between Cu1 and Cu2) and from a Haapm ligand (Cu–N/O distances vary from 1.95.4(2) and 2.022(2) Å), with basal angles of 177.29(9)° and 171.12(8)°. The apical positions are occupied by an oxygen atom of a triflate anion (Cu–O distance 2.534(3) Å) and a nitrogen atom of a neighboring dca anion (Cu–N distance 2.314(3) Å), with an angle of 171.92(8)°.

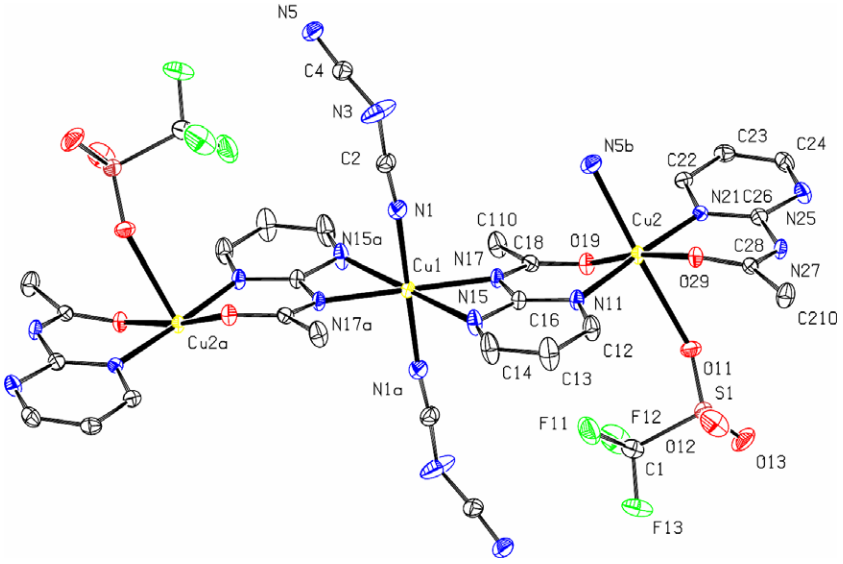

Fig. 1. Atomic displacement plot (50% probability level) of the molecular structure of $[Cu_3(\mu\text{-aapm})_2(\mu\text{-dca})_2(Haapm)_2](CF_3SO_3)_2$. H atoms have been omitted for clarity.

The Cu–Cu distance within the trinuclear unit is 5.23 Å. The dca anions are connected in an end-to-end fashion to a neighboring Cu(II) ion (Cu–Cu distance 8.54 Å), forming in this way a chain of trinuclear units bridged by two dca anions (Fig. 2). The lattice structure is stabilized by stacking between the pyrimidine rings of different units (Shortest Ring–Ring distances of 3.509 Å) and by a strong hydrogen-bonding between the amide N–H of the Haapm ligand and an oxygen atom of a triflate anion (N27···O13 2.847(4) Å), forming in this way a 3D array (see Fig. 3).

3.2. Spectroscopy and EPR

The ligand-field transition measured as a solid with the diffuse reflectance technique is observed as a very broad band with a maximum at about $14.4 \times 10^3\ cm^{-1}$, with a shoulder at around $10.0 \times 10^3\ cm^{-1}$. These are normal ligand-field transitions for (distorted) octahedral geometries [30].

In the IR a clear broad vibration band is observed at 3265 cm^{-1}, which is assigned to the NH of the Haapm molecule. Furthermore strong absorptions are observed in the 2370–2150 cm^{-1} region corresponding to the combination modes of vibration of the dca anion. These bands are characteristic of the $\nu_{s(C-N)} + \nu_{as(C-N)}$ and $\nu_{(C\equiv N)}$ vibrations [9,31]. The bands are observed as strong sharp vibrations at 2306, 2251 and 2183 cm^{-1}. The $\nu_{as(S=O)}$ bands in the compound are observed at 1276, 1249 cm^{-1} and the $\nu_{as(S=O)}$ bands at 1222 and 1032 cm^{-1}. All these bands are in agreement with the literature for monodentate and/or H-bonded triflate absorptions [32,33].

The amide bands of the Haapm ligand are observed at 1646, 1613, 1577 and 1532 cm^{-1}. In the mononuclear compound $Cu(Haapm)_2(CF_3SO_3)_2$ these bands are observed at 1641, 1604 and 1527 cm^{-1} [8], concluding that the extra band in the trinuclear compound originates from the two different Haapm/aapm ligands present in the compound.

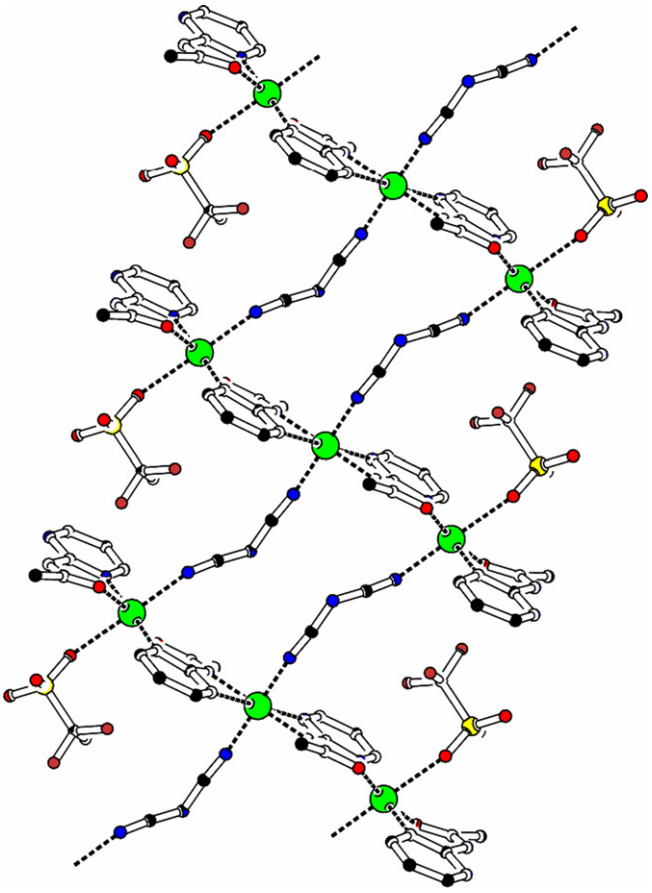

Fig. 3. Packing diagram of the title compound showing the links via the dca anions.

The EPR spectra of the title compound was recorded as a polycrystalline powder at RT and 77 K. At RT a strong isotropic band was observed with $g = 2.11$ and furthermore weak to very weak triplet bands are observed at 160, 230, 265 and 410 mT, indicating a weak zero-field splitting. At 77 K also the isotropic signal was observed at $g = 2.11$, while now only a very weak half-field signal was observed

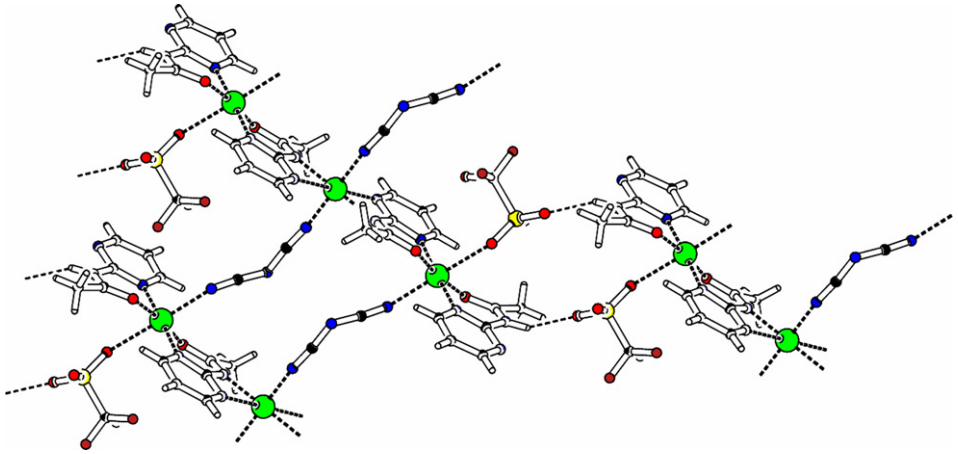

Fig. 2. Illustration of the H-bonding interactions between the triflate anion and the Haapm ligand.

at 160 mT. This signal is consistent with the trinuclear nature of the compound and the magnetic susceptibility measurements (*vide infra*).

3.3. Magnetic susceptibility

The temperature-dependent magnetic susceptibility of the title compound, measured as a powdered sample from 5 to 200 K, is depicted in Fig. 4 in the form $\chi_M T$ *versus* T and χ_M *versus* T. At 200 K, the $\chi_M T$ product is equal to 1.33 $cm^3\,mol^{-1}$ K, *i.e.* a value that is close to the expected value for three non-interacting copper(II) ions with $S = 1/2$($\chi_M T = 1.125\ cm^3\,mol^{-1}$ K). By lowering the temperature, the $\chi_M T$ value remains almost constant until 100 K where after it increases, reaching a value of 1.95 $cm^3\,mol^{-1}$ K at 5 K. This type of behavior arises from dominant ferromagnetic interactions between the three linear copper(II) within the trinuclear unit. The experimental data were fitted with the equation derived from the Hamiltonian $\widehat{H} = J(\widehat{S}_1\widehat{S}_2 + \widehat{S}_2\widehat{S}_3) + J'\widehat{S}_1\widehat{S}_3$ given as follows [24]:

$$\chi_M = \frac{N\beta^2 g^2}{4kT}\cdot\frac{1+\exp((J_1-J_2)/kT)+10\exp(3J_1/2kT)}{1+\exp((J_1-J_2)/kT)+2\exp(3J_1/2kT)} + \mathrm{TIP}$$

where J_1 is the interaction between neighboring copper(II) ions and J_2 represents the exchange parameter between the terminal copper(II) ions. A TIP value of $60\times10^{-6}\ cm^3\,mol^{-1}$ per each copper(II) was considered. The g value is the average of the three Cu(II) ions calculated from the fit of the magnetization *versus* field plot (Fig. 5). The best-fit parameters were found to be $g = 2.13$, $J_1 = 7.84\ cm^{-1}$ and $J_2 = 2.45\ cm^{-1}$, which are obtained from a fit of the experimental data from 5 to 200 K, with $R = 8\times10^{-5}$. Intermolecular interactions (zJ') between the chains formed by trinuclear copper units bridged by dca^- ligand also have been considered [34]. The best fitting parameters were found in this case: $J_1 = 8.98\ cm^{-1}$, $J_2 = 3.36\ cm^{-1}$, $zJ' = -0.019\ cm^{-1}$ and $g = 2.10$, with $R = 2\times10^{-5}$.

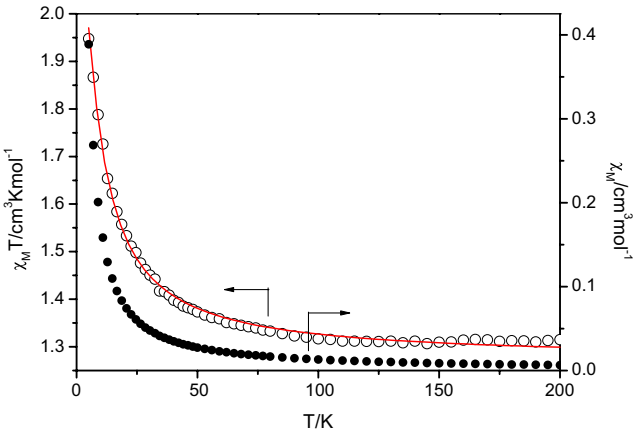

Fig. 4. Plot of $\chi_M T$ *vs* T (○) and χ_M *vs* T (●) for in the range of 5–200 K at 0.1 T applied field. The solid line represents the fit with $J_1 = 7.84\ cm^{-1}$ and $J_2 = 2.45\ cm^{-1}$ (see text).

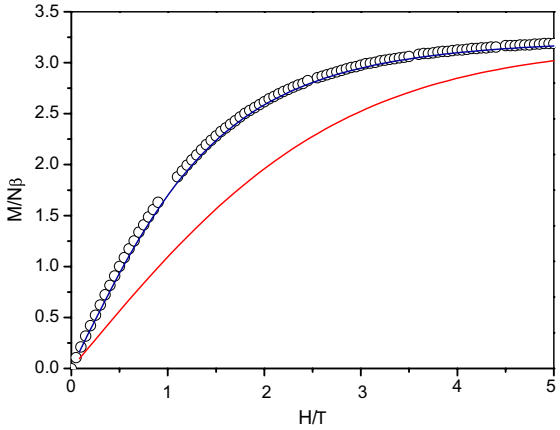

Fig. 5. The field dependence of the magnetization measured at 2 K (the red and the blue solid line represent the theoretical curve calculated with the Brillouin function for three copper(II) ions non-interacting and ferromagnetically coupled, respectively). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

The effective exchange pathway is through the Haapm ligand, while the dca^- bridge can be considered with negligible contribution as this group acts only by linking an equatorial site of one copper(II) ion with an axial position of a copper(II) ion belonging to an adjacent trinuclear unit (Cu···Cu = 8.54 Å) [35,36]. Each copper(II) ion within the trinuclear unit is octahedrally coordinated with $d_{x^2-y^2}$ being the magnetic orbital. As the bridging ligands are coordinated in the xy plane, the non-coplanarity of the coordination plane corresponding to the terminal copper(II) ion and central copper(II) ion could be a possible origin of the observed ferromagnetic interaction. The dihedral angle between the two coordination planes amounts to 19.09°, which is likely to have an effect on the orientation of the magnetic orbitals. More detailed analyses would be required to relate this distortion to the observed ferromagnetism. This is beyond the scope of the present study.

4. Conclusion

In this study a unique linear trinuclear CU compound in which the Cu ions are connected via end-to-end dca molecules forming a 1D chain has been synthesized and fully characterized. Also the magnetic susceptibility has been studied in detail.

In the literature only one trinuclear Cu(II) compound, although not completely linear, has been reported with end-to-end dca molecules bridging trinuclear units and forming a 1D chain, *i.e.* the compound {[Cu_3(dca)$_2$(nicotinato)$_4$(H_2O)$_8$](H_2O)$_2$} [25]. The Cu–Cu distances in this compound are 7.176(4) Å (Cu–Cu in trinuclear species) and 7.235(2) (Cu–Cu via dca bridge), compared to 5.23 and 8.54 Å in the title compound. The magnetic susceptibility revealed a weak ferromagnetic interaction contributed from the Cu–Cu interactions from the trinuclear

units, while the interaction via the dca anions are negligible, similar to the observation for the nicotinato compound [25].

5. Supplementary material

CCDC-653725 contains the supplementary crystallographic data for the title compound. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

The compound *N*-(4-amino-1-methyl-5-nitroso-6-oxo-1,6-dihydropyrimidin-2-yl)-(s)-glutamic acid (H_3L) was synthesised and structurally characterised by analytical methods and ^1H, ^{13}C and ^{15}N NMR spectroscopy. This compound (H_3L) shows the same topology as other model receptors previously used to develop chemical functionalization at the surface of an active carbon when they adsorb on it. Protonation of H_3L and its coordination ability towards Cd^{2+}, Zn^{2+}, Cu^{2+} and Mn^{2+} ions in water solution was also studied by potentiometric methods, UV–Vis and ^1H, ^{13}C NMR spectroscopies. The obtained results allow us to fit the operative conditions for the use of the activated carbon–H_3L adsorbent for the retaining of the above-mentioned metal ions in aqueous solutions. The molecular structure of $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$ was solved by single-crystal X-ray diffraction methods.

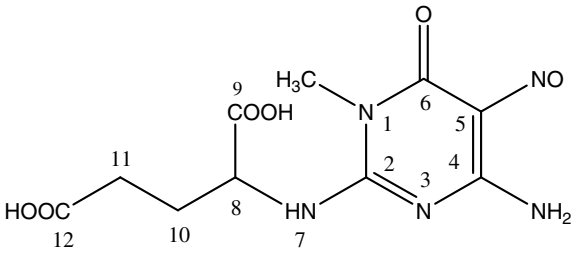
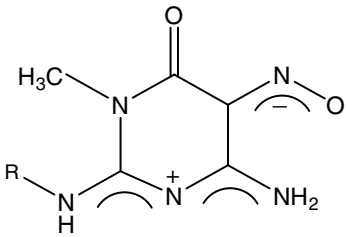
1. Introduction



Environmental contamination from a wide variety of sources has become an increasingly serious problem in recent years. Activated carbons have been extensively used for the purification or recovery of pollutant metals in waste waters [1–3]. In recent works [4,5], we have described a new method to add chemical functionality to the surface of an active carbon based on adsorbing the above-mentioned model compounds on it. That adsorption, which takes place when pyrimidine residues interact with carbon arene centres, favours adsorbed compounds acting as metal–ion receptors. This method provides specific chemical functionalization of the carbon surface provided by the substituent existing at the C2 position of the pyrimidine.

Previous results point out that in the case of analogous molecular compounds derived from single amino acids L-alanine, L-valine, L-methionine, L-serine and L-glycylglycine, the adsorption capacity of adsorbents AC-molecular receptors to different metal ions was improved in relation to AC. It was also proved that this fact is due to the metal-binding capacity of the carboxyl function existing at the C2 substituent [6].



The model compound *N*-2-(4-amino-1,6-dihydro-1-methyl-5-nitroso-6-oxo-pyrimidin,2-yl) L-glutamic acid, H_3L (Scheme 1), shows the metal binding bicarboxylate COO^-–CHR–CH_2–CH_2–COO^- at the C2 position of the pyrimidine moiety. Thus, it is expected that the metal binding ability of the amino acid residue would improve the

single monocarboxyl function existing at the single amino acid derivatives previously studied. In this work, we present the synthetic procedure for the H_3L compound and its structural characterization by thermal analysis, NMR and UV–Vis spectroscopy. The coordinating behaviour of H_3L to Zn(II), Cd(II), Cu(II) and Mn(II) metal ions has been recognized by studying the reactivity of the different H_3L/metal systems. The aim of this recognition was establishing the experimental conditions at which the bi-carboxyl function of the adsorbed ligand on an activated carbon is operative to metal ions, and also providing the thermodynamic properties of such a function for the above-mentioned metal ions. Reactivity studies were carried out using potentiometric, ^{13}C NMR and UV–Vis methods. The structure of the $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$ complex, which was solved by X-ray single crystal methods [7], is also reported.

2. Results and discussion

2.1. Synthesis and characterization of the molecular receptor

H_3L was prepared by a synthetic procedure [8] consisting of condensation of L-glutamic acid and 4-amino-1,6-dihydro-1-methyl-5-nitroso-6-oxo-pyrimidine [8,9]; this reaction takes place by the nucleophilic attack of the α-NH_2 amino group of L-glutamic acid on the C2 atom of the pyrimidine [8,9]. The structure of H_3L was determined by ^1H–^1H, ^1H–^{13}C and ^1H–^{15}N bi-dimensional spectra (see Section 4). Assignments are in accordance with the structural data of the H_3L unit, which were obtained by single X-ray diffraction methods [8].

The pyrimidine moiety shows alike structural and electronic features to a series of analogous compounds obtained by condensation of the above-mentioned pyrimidine derivatives with a series of single amino acids [10]. These data show extensive π-electron delocalization at the cyclic moiety which also involves the C2NH_2, C6O, C5NO and C4NH_2 exocyclic substituents. The somewhat long bond length values in the NH–C2–N3–C4–NH_2 fragment and the short bond distances in the C5NO grouping point out the location of a positive charge at the former fragment, and a negative charge at the latter; for example, the bipolar character of the aromatic moiety. These features have already been observed in the case of analogous amino acid derivatives [10] (Scheme 2).

2.2. Ligand protonation

The Brönsted acid–base behaviour of H_3L in aqueous solution was studied as a previous step on the study of the reactivity of the H_3L/metal ion systems in aqueous solutions. The protonation pattern of the ligand was also determined by following the dependence of the ^{13}C NMR signals of a H_3L solution on pH.

The protonation equilibrium of the ligand in solution (0.1 mol dm^{-3}KCl, 25 °C) within a 2.5–10.5 pH range was determined by a potentiometric method (see Section 4) and results are reported in Table 1.

Distribution plots of the protonated species of the ligand were obtained from the data of Table 1 and are shown in Fig. 1. The tri-anion L^{3-}, which exists at high pH values, binds four protons in the pH range investigated (2.0–10.5).

Table 1
Protonation constants ($\log K$) of the ligand H_3L (0.1 mol dm^{-3} KCl, 298.1 K)

Reaction	$\log K$[a]
	H_3L
$L^{3-} + H^+ = [HL]^{2-}$	12.11 (2)
$[HL]^{2-} + H^+ = [H_2L]^-$	4.43 (3)
$[H_2L]^- + H^+ = [H_3L]$	3.00 (1)
$[H_3L] + H^+ = [H_4L]^+$	1.90 (2)

[a] Values in parentheses are standard deviations in the last significant number.

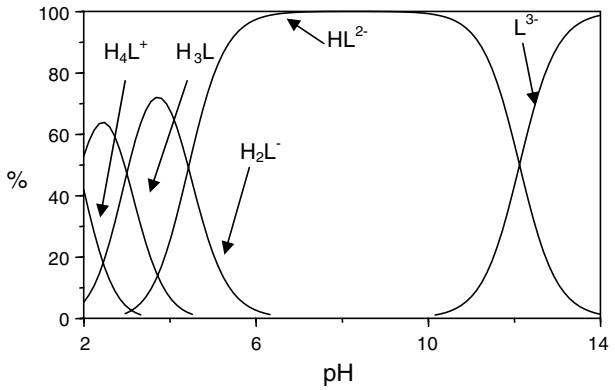

Fig. 1. Distribution species diagram as a function of pH for the ligand H_3L (10^{-3} mol dm^{-3}) in aqueous solution (0.1 mol dm^{-3} KCl) at 298.1 K.

The $\log K_{HL}$ value corresponding to the protonation of the tri-anion, $L^{3-} + H^+ = HL^{2-}$ (12.12), indicates that the corresponding binding site is strongly basic. The two protonation processes corresponding to the neutralization of the resulting bi-anion markedly overlap (see Fig. 1), and their matching constants are found within the expected range for the protonation of the two carboxylate residues existing at the *F* function of the ligand [11] ($\log K_{H_2L} = 4.43$, $\log K_{H_3L} = 3.00$). Bearing in mind the presence of a long spacer between terminal carboxylate groups, their basicities should be analogous; therefore the differences between both $\log K$ values can be attributed to statistical effects [12]. Finally, a protonation step corresponding to the $H_3L + H^+ = H_4L^+$ equilibrium (with $\log K_{H4L} = 1.9$) points out the very weak basic character of the corresponding proton binding site.

The addition of two protons to the HL^{2-} species, which takes place under the pH range 3–7 (see Fig. 1), does not produce any change in the UV–Vis spectrum of the ligand. On the other hand, as shown in Fig. 2, an increasing shielding of the ^{13}C NMR signal corresponding to the CH_2 groups at positions 8, 10 and 11 and of the two C atoms of the carboxyl groups (C(9) and C(12)) is observed in the above pH range as the pH decreases, indicating the protonation of the two COO^- anions.

The onset of H_3L protonation, which takes place at pH 3.5 (Fig. 1), is accompanied by changes in the UV and visible spectra of the compound (Fig. 3). Among these changes, the vanishing of a band at 524 nm stands out, which is assigned to a forbidden $n_N \rightarrow \pi^*$ transition of the C5NO chromophore (see Fig. 3), indicating that the protonation site is the nitrogen atom of the above mentioned group [13,14].

Deprotonation of HL^{2-}, which onsets at pH ca. 10.32, is accompanied by UV and visible spectral changes (see Figs. 1 and 3). Moreover this process is accompanied by significant shifts of the C(2) signal in the ^{13}C NMR spectra of H_3L, suggesting that the group involved in this protonation

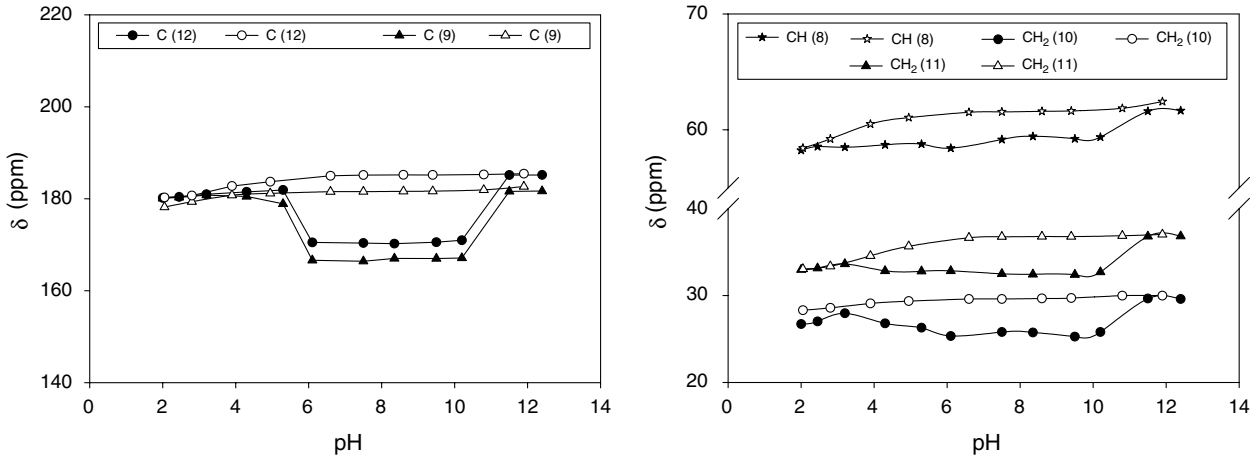

Fig. 2. ^{13}C NMR chemical shifts of C(8), C(10), C(11) and C(12) carbon atoms vs. pH of an H_3L D_2O solution (white points) and an H_3L/Cd^{2+} (1/1 molar ratio) D_2O solution (black points).

step is C2HN, which is conjugated with the pyrimidine moiety.

2.3. Complex formation in aqueous solution

As it has been previously said [4–6], the main adsorption mechanism of ligands analogous to H_3L and also of the H_3L ligand [15] on the activated carbon involves a plane-to-plane interaction between the pyrimidine moiety of the former and the arene centres of the graphite planes of the AC. This kind of interaction blocks the basic functions of the pyrimidine moiety, limiting the reactivity of the ligand (AC–H_3L) anchored with metal–ions to that of the amino acid residue of H_3L. Therefore, the main objectives of the studies of ligand–metal ion complex formation in solution are to obtain the data necessary to fit pH conditions at which the bi-carboxyl function of the anchored H_3L are operative for metal–ion binding, and also determine its coordinating ability to these ions, (i.e., to characterize its coordination patterns and stabilities) which would state the metal adsorption capacities of the AC–H_3L adsorbent.

The complex formation equilibria and the corresponding constants in aqueous solutions for the studied H_3L/metal ion systems were obtained from the potentiometric-titration data of the corresponding ligand/metal ion mixtures ([H_3L]/[metal ion] = 1/1), which were processed with the HYPERQUAD software [16]. The best fit of the experimental data for each of the studied systems corresponds to those summarized in Table 2. The corresponding species distribution plots appear in Fig. 4.

Data displayed in Table 2 and Fig. 4 highlight that the highest reactivities and the most stable complexes are displayed in ligand/Cu^{2+} and ligand/Cd^{2+} systems, whereas the lowest are shown in the ligand/Mn^{2+} system.

In all the studied systems, mononuclear complexes showing 1/1 ligand/metal–ion stoichiometries are formed, even though the ligand can be found in the following forms: neutral (H_3L), monoanionic (H_2L^-), bianionic (HL^{2-}) and trianionic (L^{3-}). Additionally, a mononuclear complex with a 2/1 ligand to metal–ion stoichiometry is formed in the case of the ligand/Cd^{2+} system. Moreover, binuclear complexes (e.g., with 1/2 ligand/metal–ion stoichiometries) which contain the ligand partially deprotonated, as the bi and/or

mono-anion, are also detected. Table 2 shows that the highest reactivity corresponds to the Cu^{2+}/ligand system, whereas a poor speciation is found in the Mn^{2+}/ligand system.

Mononuclear complexes containing the fully protonated ligand H_3L are detected in the cases of Cu^{2+} and Cd^{2+} ions. As is expected, it can be seen in Fig. 4 that these complexes are the main species existing in the pH range under 4. Bearing in mind the poor nature of coordination of carboxyl groups and the N3 atom of the pyrimidine to metal–ions [5,13,14,17,18], single positions of the H_3L ligand available for binding to metal ions are the C5NO and C6O groups of the aromatic residue. Thus, it is expected that in complexes of the $[M(H_3L)]^{2+}$ type detected ($M^{2+} = Cu^{2+}$ and Cd^{2+}), H_3L behaves as a chelating bidentate ligand, using the N atom of C5NO and the O atom of C6O as binding positions to the mentioned metal ions. Otherwise, this behaviour is consistent with analogous pyrimidine derivatives, having the substituents –NO and =O at the C5 and C6 positions, respectively. In fact, the stability constants of $[CuH_3L]^{2+}$ and $[CdH_3L]^{2+}$ ($\log K = 3.75$ and 3.76 respectively, see Table 2) are in a similar range to those found for Cu^{2+} and Cd^{2+} complexes, with analogous C5-nitroso C6-oxo derivatives [18].

Deprotonation of H_3L species in the H_3L/metal ion system takes place at slightly lower pH values than in a water solution of the ligand. This fact produces the formation of binuclear $[M_2H_2L]^{3+}$ and/or mononuclear $[MH_2L]^{+}$ species. The former is only detected in the case of the H_3L/Cd^{2+} system (see Fig. 4). In the remaining three systems, these binuclear species are not detected, but mononuclear complexes $[MH_2L]^{+}$ are formed. Log K_{MH2L} values for the association of Cu^{2+}, Zn^{2+}, Cd^{2+} and Mn^{2+} to the carboxylate group in these complexes are similar to those described in the literature for single carboxylate ligands [5,13,14,17–21]. The onset of the deprotonation of the remaining carboxyl functions of H_2L^{-} occurs at higher pH values than the domain of H_2L^{-} complex species, giving rise to mono- and binuclear [MHL] and $[M_2HL]^{2+}$ complexes, respectively. The former is detected in all systems, excluding the Mn^{2+}/ligand system, whereas the second is detected in all systems. The formation of $[M_2HL]^{2+}$ metal complexes suggests that the anchorage of the H_3L ligand on an activated carbon surface would improve the metal–ion capture capacity showed by similar ligands having a C2-substituent with a mono-carboxyl function [6]. In fact, previous results, obtained in the study of the Cu^{2+} adsorption by an H_3L–AC adsorbent, strengthen this hypothesis [15].

It is noteworthy that the calculated $\log K_{MHL}$ values for a given metal ion are very alike to those corresponding to $[MH_2L]^{+}$ complexes (see Table 2), which demonstrate that the coordination of HL^{2-} to the metal–ions in the detected MHL complexes only takes place through one of the two carboxylate groups, whereas the second probably remains uncoordinated. This fact can be due to the low stability of the seven-membered chelate ring, which would result from a cooperative binding of the two carboxylate functions to the same metal ion. However, more stable $[M_2HL]^{2+}$ complexes containing two metal ions coordinated to each of the two carboxylate groups are formed.

Species distribution plots of the Cu^{2+}/ligand system (Fig. 4a) show the formation of CuL^{-} and $CuLOH^{2-}$ metal complexes in the upper pH range, which holds the fully deprotonated L^{3-} anion as a ligand. It is also noteworthy in this system that the onset of the formation of the CuL^{-} species takes place at pH ca. 4, which is a lot lower than that determined for the deprotonation of HL^{2-} in water, which is ca. 10 (Fig. 1). This fact is due to the electron-withdrawing character of Cu^{2+} which induces early deprotonation of the HL^{-} species. The high Log K_{CuL} and $\log K_{CuLOH}$ values probably point out the role of the $C2_{py}N^{-}$ group as a binding site to the metal ion, together with one of the carboxylate groups.

To get further insight into the coordinating behaviour of H_3L, we carried out a spectrophotometric titration in the visible range of an aqueous 1/1 ligand/Cu^{2+} mixture. Fig. 5 shows the spectra obtained at given pH values by

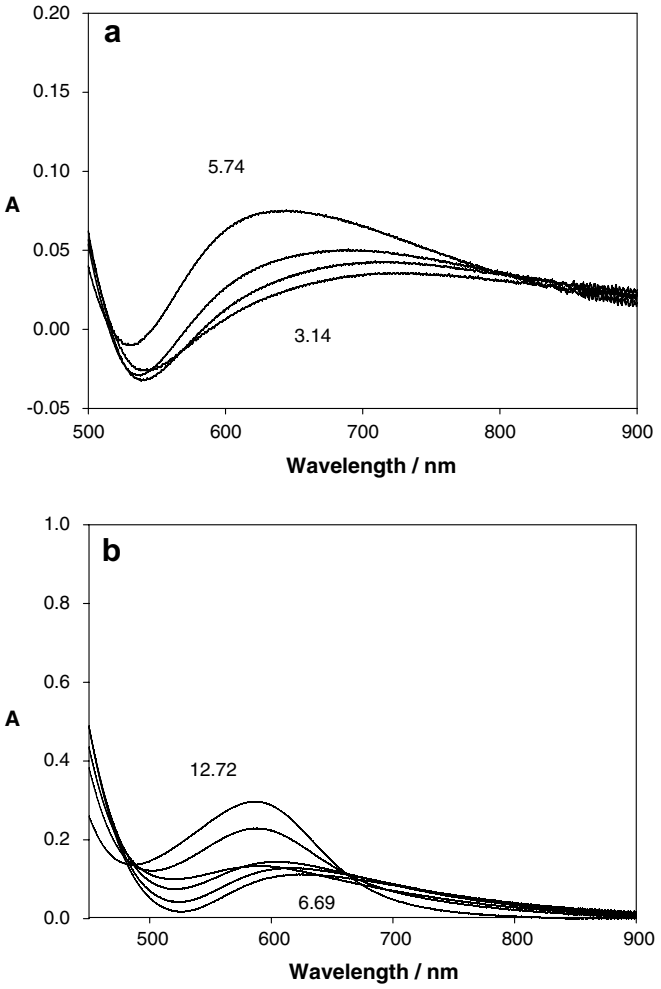

Fig. 5. Spectral curves of the ligand/Cu system in the visible range vs. pH ($[H_3L] = 10^{-3}$ mol dm^{-3}, 0.1 mol dm^{-3} KCl): (a) acidic medium from pH 3.14 to 5.74 (top), (b) basic medium from pH 6.69 to 12.72 (top).

subtracting those of H_3L from the corresponding 1/1 ligand/Cu^{2+} mixtures in aqueous solution.

In the lowest pH range, in which the main complex species existing in solution is $[CuH_3L]^{2+}$, the observed negative absorbance-values at the characteristic wavelength of the forbidden $n_N \rightarrow \pi^*$ transition of the C5NO chromophore ($\lambda_{max} = 524$ nm, see above) point out the blocking of the *n* electron pair of the N atom of such a group. This fact indicates that, in the $[CuH_3L]^{2+}$ complex, the Cu^{2+} ion is coordinated to the nitroso group of the pyrimidine. Moreover, a wide weak band with a λ_{max} value of ca. 700 nm indicates a weak ligand field in this complex.

As the pH increases within the 3–5 range, the concentration of the $[CuH_3L]^{2+}$ complex diminishes until it vanishes at the last pH value, and the $[CuH_2L]^{+}$, $[Cu_2HL]^{2+}$ and CuHL COO^--coordinated complexes increase, becoming the main ones, as Fig. 4 illustrates. The disappearance of the $[CuH_3L]^{2+}$ complex, in which the Cu^{2+} ion is coordinated through the C5NO group, explains the vanishing of the absorbance minimum at 524 nm in the mentioned 3–5 pH range in the spectra of Fig. 5, while the formation of more stable COO^--coordinated complexes explains the shifting of λ_{max} due to the d → d transition to values lower than the above mentioned 700 nm. It can also be seen in Fig. 5 that this shifting continues steadily as pH increases within the 6–12 pH range, reflecting the formation of more stable complexes: $[CuL]^-$ (the only species existing at a pH value of ca. 6.7) and $[CuLOH]^{2-}$, which is the unique complex existing at pH values up to 10.

To get further information on the coordination models of the ligand to the metal ions a series of NMR experiments with various ligand/metal ions mixtures have been performed. As was said above, the metal ions coordination to the N atom of the C5NO group can be enhanced by the disappearance of a characteristic absorption band of this group in the visible range. This weak band, which appears at 525 nm in the H_3L spectrum, is due to a $n \rightarrow \pi$ transition of the σ non-bonding pair of the mentioned N atom [18].

Fig. 6 shows the vanishing of the mentioned 525 nm band with the addition of growing amounts of Cu^{2+} to an H_3L aqueous solution at a constant pH 2.0. This fact proves that the N atom of the C5–NO group act as a binding site in the mononuclear CuH_3L complex formed at this pH value (see Fig. 4a). Due to conjugation of the C5-nitroso group with the pyrimidine moiety, metal coordination to the C5NO group induces electronic changes in the conjugated moiety of the H_3L molecule. These changes explain also the variations observed in the strong intensity bands (which are due to allowed $\pi \rightarrow \pi^*$ transitions) of the UV spectrum of an H_3L water solution (see Fig. 6) under the addition of increasing amounts of Cu^{2+} at a constant pH 2. Thus, it would be expected that the binding of some of the conjugated basic atoms of H_3L to metal ions in the complexes formed in water solution (i.e. in the cases of $[Cu H_3L]^{2+}$, $[Cd H_3L]^{2+}$ and $[CuL]^-$) would be accompanied by clear changes in the UV spectrum. On the contrary the metal ion complexes of H_2L^- and HL^{2-} in which carboxylate anions act as binding sites would not induce such changes in the UV spectrum of the ligand.

Thus, the differences between the UV spectra of a ligand/Cu^{2+} mixture with a 1:1 molar ratio and the ligand alone ($[ligand] = 5 \times 10^{-5}$ mol dm^{-3}) in water solution were obtained at several pH values in the 2.5–10 pH range. The maximum differences in absorbance values are found at a λ value of ca. 338 nm. Insignificant differences in the whole UV range were found in a narrow pH window centred at pH 4. This observation is consistent with the hypothesis established through the potentiometric data, that in the main complex species existing at these pH values ($[CuH_2L]^+$, $[Cu_2HL]^{2+}$ and [CuHL], (see Fig. 4a)) the coordination of the ligands would take place through the carboxylate groups. On the contrary, as the pH values decrease in the 4.0–2.5 pH range, increasing negative differences in the absorbance values at 338 nm are observed in the difference spectra. The last observation is consistent with the fact that the amount of $[CuH_3L]$ (the species in which the H_3L ligand is NO-coordinated) increases with decreasing pH values in that pH range. In the same way the trends of differences in the absorbance values observed in the 4 to 10 pH range, are also consistent with the forma-

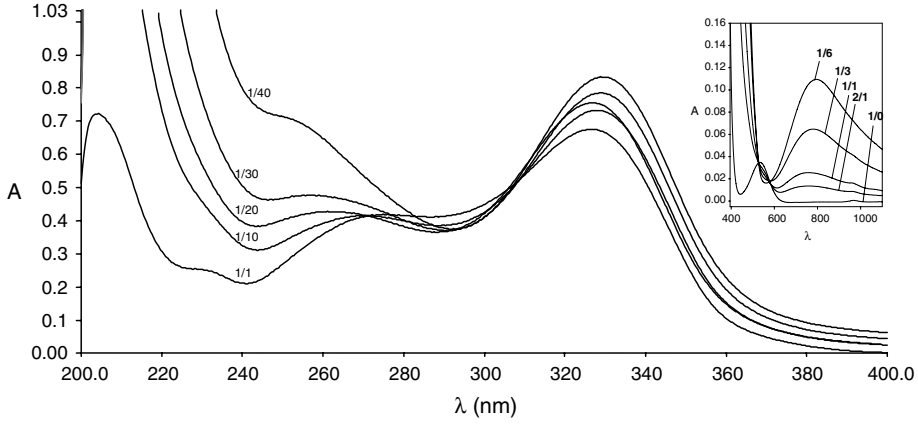

Fig. 6. [Cu] Variations of the visible and UV spectra of an H_3L/Cu^{2+} mixture with variable $H_3L:Cu^{2+}$ molar ratio values at constant pH 2.

tion of $[CuL]^-$ and $[CuLOH]^{2-}$ complexes, which contain the L^{3-} ligand, coordinated through the conjugated N^- atom of the deprotonated amine group attached to $C(2)_{pyr}$.

In the case of the ligand/Cd^{2+} system, the difference spectra shows a negative band at ca. 338 nm in the 2.5–6.0 pH range whereas zero absorbance is obtained in the whole UV region in the 6–10 pH range (see Fig. 6c). The shape of the plot of the absorbance difference values versus pH at the above wavelength is consistent with the potentiometric hypothesis. Thus, the appearance of a band at 338 nm in the UV difference spectra in the low pH range indicates that in the main existing species $[Cd_2(H_2L)]^{3+}$ and $[Cd(H_3L)]^{2+}$the ligand interacts with the metal ion through the N atom of the C(5)NO group. On the contrary, zero absorbance values in the pH range corresponding to values higher than 4 indicate that in [Cd(HL)] and $[Cd(H_2L)]^+$ complexes the ligand is not coordinated to Cd^{2+} through any of the conjugated basic atoms. Fig. 2 shows the plots of the chemical shift values of the carbon signals of the three methylene and the carboxyl groups of the amino acid moiety versus the pH values. These were obtained by the NMR titration of an H_3L/Cd^{2+} mixture as described in the experimental section. Fig. 2 shows that the onset of the formation of [Cd(HL)] and $[Cd(H_2L)]^+$ complexes taking place at a pH value of ca. 3 (see Fig. 4c) is accompanied by the shielding of the methylene carbon atoms and also the carboxyl ones. This indicates the existence of a carboxylate–Cd^{2+} interaction in the above complexes. The observed shielding, which is clearly stronger for the carboxylate groups than for methylene, can be explained by the stronger ionic character of the carboxylate–Cd^{2+} interaction than the carboxylate–proton one.

Very different behaviour is observed in the cases of the H_3L/Zn^{2+} and H_3L/Mn^{2+} systems in aqueous solutions. The difference spectra of both systems, in the 200–400 nm UV region were obtained in the 2.3–10.5 pH range and in the 2.7–10.1 pH range, respectively. The negligible differences in absorbance observed in all of the wavelength range in the two systems prove that complexes having the ligand coordinated through the basic conjugated atoms are not formed in any of the two systems. This proves that complexes detected in the potentiometric studies of these two systems, contains the ligands coordinated through the carboxylate groups (see above).

2.4. Conclusions

The results obtained from the above reactivity studies have provided the needed information (see above) to further interpret the adsorption properties to metal ions of the anchored ligand at the graphitic surface of activated carbon [15]. The whole reactivity data point out that H_3L behaves as a bi-functional ligand. In the low pH range, the only operative function is the C6O–C5NO grouping. This supports the formation of the five-member chelate complexes detected in this pH range with all the studied metal ions, excluding the Mn^{2+} and Zn^{2+} ions. In the last cases, the potentiometric and UV spectroscopic data ruled out the formation of a complex of this type. Nevertheless, the crystal structure of a Mn^{2+} complex with a pyrimidine analogue of H_3L with the methionine residue at the C2 cyclic atom [13], shows a supramolecular assembly in which COO^- coordinated Mn^{2+} ions of each unit interacts with the oxygen atom of the C5NO group of the pyrimidine moiety. All the previous data points out the possibility of the formation of a Mn^{2+} complex in the low pH range (also in the H_3L/Mn^{2+} system), in which the metal ion would be weakly coordinated to the pyrimidine moiety in a similar way. If so, the lack of protic properties of the oxygen atom of the NO group, would be the reason why this complex was not detected with the potentiometric method used in this work.

The deprotonation of the carboxyl functions of the substituent at $C2_{py}$ of the pyrimidine taking place in the intermediate pH range involves the availability of the carboxylate groups as operative basic functions for the binding to metal–ions. This leads to the formation of mono- and binuclear metal complexes within this pH range, in which one or two of the COO^- functions are coordinated to one or two metal ions respectively. Nevertheless, within this pH range, also binuclear complexes of H_2L^- ligand, containing one of the metal ions coordinated to the pyrimidine moiety and the second to a COO^- function, are also formed in the case of the Cd^{2+}/ligand system. Finally, in the highest pH range of all studied systems, the ligand uses one of the two carboxylate groups as a coordinating basic site, although cooperative coordination of both of them to the same metal–ion does not occur. In the case of the Cu^{2+} ion, the ligand also uses the $C2_{py}$-N^- group as a binding site, together with a COO^- group forming chelate complexes. It is noteworthy that the $N3_{py}$ position displays no affinity to any of the studied metal–ions. This fact, which is consistent with previous observations done with other analogous pyrimidine derivatives [5,19], agrees with the typical low electron density existing at the $–NH–(C2–N3–C4)_{py}–NH_2$ moiety [8,10].

In the species distribution diagrams of all the studied systems, it is seen that the deprotonation pH of the most acidic carboxyl groups (those of formation of $[M_2H_2L]^{3+}$ and/or $[M_2HL]^{2+}$ species) takes place at pH values meaningfully lower than those corresponding to the free ligand (see Fig. 1). These results bring up to date the pH values at which the H_3L ligand anchored on the graphite moiety of an AC (the H_3L–AC adsorbent) would be operative for the adsorption of metal ions in aqueous solution, although the expected optimum values would be those corresponding to the maximum of the plots for the metal-complexes with the fully deprotonated carboxyl functions, $[M_2HL]^{2+}$ and [MHL].

3. Crystal structure of $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$

The crystal structure of the complex $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$ was solved by single X-ray diffraction methods. A view of the asymmetric unit and the crystal packing is

depicted in Fig. 7, and selected bond and angles are listed in Table 3.

The compound consists of 2D molecules containing equivalent hepta-coordinated Cd^{2+} centres, each of which is coordinated to one water molecule, to two carboxylate groups of two individual HL^{2-} molecules (acting as bidentate chelating ligands with the two oxygen atoms in binding position), and to a third HL^{2-} molecule (also acting as a chelating ligand), using the N atom of the C5NO group and the O atom of the C6O of the pyrimidine moiety as binding sites. Thus, as shown in Fig. 7, HL^{2-} anions act as bridging ligands to three different Cd^{2+} ions using the pyrimidine moiety and the two carboxylate groups as binding moieties, as it has been previously said. The resulting structure around the Cd^{2+} ions can be described as a strongly distorted bipyramid. The distances of the metal ion to the five atoms (the O1, N4, O6, O5 and O3 atoms) in the equatorial plane are similar, and Cd–O3 bonds are widely deviated from the plane. On the other hand, the distances of atoms placed at the apical positions (O4 and O1W), which are also be very alike, are however shorter than the equatorial distances.

The 2D molecules are extended parallel to the *c* axis and are stacked parallel to one another along the *a* axis. Non-coordinated water molecules are placed in the inter-planar space, contributing to the stabilization of the 3D framework through their involvement in hydrogen bonding between neighbour molecular planes.

Concerning the organic ligand, it is noteworthy that the N3 cyclic atom of the pyrimidine does not act as donor atom, as observed in several structures of metal complexes of analogous ligands [14,18,22–25]. This fact is in agreement with the dipolar character of the pyrimidine moiety of the H_3L ligand [8].

Table 3
Selected bond lengths (Å) and bond angles (°) for $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$

4. Experimental

4.1. Reagents

The anhydrous ligand, H_3L ($C_{10}H_{13}N_5O_6$), was obtained by a synthetic method previously reported [8]. Nanopure water was used as the solvent for potentiometric and spectrophotometric measurements. Standardised KOH, HCl, $ZnCl_2$, $CuCl_2$ and $MnCl_2$ aqueous solutions (Merck) were also used. All the potentiometric measurements were carried out in 0.1 mol dm^{-3} KCl as the background electrolyte.

4.2. Synthesis of $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$

$CdCl_2\cdot 2\cdot 1/2\cdot H_2O$ (114.17 mg, 0.5 mmol) was added to a solution of H_3L (149.5 mg, 0.5 mmol). This solution was left to evaporate over a few days in air until orange crystals suitable for X-ray analysis were formed. *Anal.* Calc. for $C_{10}H_{13}CdN_5O_7$ 3(H_2O): C, 24.94; H, 3.97; N, 14.54. Found: C, 25.20; H, 3.99; N, 14.97%.

4.3. X-ray structure analyses

Details for data collection and structure refinement are summarized in Table 4.

[a] $R = \sum(|F_o| - |F_c|)\sum|F_o|$.
[b] $Rw = [|\sum w(|F_o| - |F_c|)^2|\sum w|F_o|^2]^{1/2}$.

4.4. X-ray structure of $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$

Suitable crystals of $\{[Cd(HL)H_2O]\cdot 3H_2O\}_n$ were obtained as orange block-like crystals by slow evaporation of an aqueous solution. The intensity data were collected at 153 K on a Stoe Image Plate Diffraction System [26] using Mo Kα graphite monochromated radiation. Image plate distance 70 mm, ϕ oscillation scans 0–200°, step $\Delta\phi = 2.0°$, 2θ range 3.27–52.1°, d_{min}–d_{max} = 12.45–0.81 Å. The structure was solved by direct methods using the program SHELXS-97 [7]. The refinement and all further calculations were carried out using SHELXL-97 [7]. The NH and NH_2 H atoms were located from difference Fourier maps and refined isotropically. The water molecule H atoms could be located from difference Fourier maps but in the final cycles of refinement they were constrained to be 0.86 Å and their U_{iso} thermal parameters = $1.5U_{eq}$(O atom). The remainder of the H atoms were included in calculated positions and treated as riding atoms using SHELXL default parameters; CH_3 = 0.98 Å, CH_2 = 0.99 Å, CH = 1.00 Å and $U_{iso} = 1.5(CH_3)$ or $1.2U_{eq}$(parent C atom). The non-H atoms were refined anisotropically, using weighted full-matrix least-squares on F^2.

An empirical absorption correction was applied using the DELrefABS subroutine in PLATON [27]; transmission factors $T_{min}/T_{max} = 0.426/0.808$.

The molecular structure and crystallographic numbering scheme are illustrated in the PLATON [27] drawing (see Fig. 6).

4.5. Potentiometric measurements

All potentiometric measurements ($pH = -\log[H^+]$) were carried out in degassed 0.1 mol dm^{-3} KCl solutions at 298.1 ± 0.1 K, with a 713 Methrom pH-mV meter, equipped with a combined glass electrode and connected to a Methron 765 Dosimat autoburette (1 ± 0.001 mL). The experimental procedure used was the same as that described elsewhere [28]. Typically, (1–1.5) × 10^{-3} mol dm^{-3} ligand concentration and 1:1 ligand/metal molar ratios were employed in the potentiometric measurements. At least four titration experiments (150 data points each) were carried out in the pH range between 2.5 and 10.5. The HYPERQUAD software [16], was used to calculate the equilibrium constants from the emf data.

4.6. Spectrophotometric measurements

Adsorption spectra were recorded on a Perkin–Elmer Lambda-19 spectrophotometer. H_3L spectra were obtained from 5×10^{-5} mol dm^{-3} aqueous solutions in the UV range and from 10^{-3} mol dm^{-3} aqueous solutions in the visible range (μ = 0.1 mol dm^{-3} KCl).

UV difference spectra were obtained using metal ion/H_3L mixtures with 1:1 molar ratios in aqueous solutions ($[H_3L] = 5 \times 10^{-5}$ mol dm^{-3}; μ = 0.1 mol dm^{-3} KCl) as samples, and a 5×10^{-5} mol dm^{-3} (μ = 0.1 mol dm^{-3} KCl) solution of the ligand as a reference.

HCl and KOH were used to adjust the pH values in all cases, which were measured on a Crison 2002 micro-pH meter.

4.7. NMR spectroscopy

^{1}H (300.13 MHz) and ^{13}C (75.48 MHz) spectra of H_3L and H_3L/Cd^{2+} mixtures in 1:1 molar ratios ([H_3L = 0.07 mmol dm^{-3}]) in D_2O solution, at several pH values were recorded at 298 K on a Bruker DPX300 spectrometer. ^{1}H–^{1}H and ^{13}C 2D correlation experiments were performed to assign the signals. Small amounts of 0.001 mol dm^{-3} NaOD or DCl solutions were added to a solution of H_3L to adjust the pD. The pH was calculated from the measured pD values using the following relationship pH = pD − 0.40 [29].

Abstract

Copper(II) complexes of 2-di1*H*-2-imidazolylmethylmalonate (DIMMAL) have been studied by potentiometric methods. The data revealed that the $CuHL_2^-$ and CuL_2^{2-} species are prevalent in the studied pH range. Moreover, this paper reports the synthesis, structure solution and spectroscopic characterization of two new DIMMAL containing complexes, $(NH_4)_2[Cu(DIMMAL)_2]\cdot 4H_2O$ (**1**) and $[Cu(DIMMAL)(en)(H_2O)]\cdot 5H_2O$ (**2**). The structure of compound **1** consists of centrosymmetric mononuclear anionic $[Cu(DIMMAL)_2]^{2-}$ units, NH_4^+ cations and lattice water molecules, in which $DIMMAL^{2-}$ acts as a tridentate ligand through two imidazole nitrogen atoms and one oxygen atom from a carboxylate group. The crystal structure of compound **2** is built up from mononuclear neutral $[Cu(DIMMAL)(en)(H_2O)]$ and water molecules of crystallization. In both cases the MBBs are interconnected into 3D networks by multiple H-bonding paths and aromatic–aromatic interactions, which play a determinant role in the modulation of the crystal packing. EPR spectra are indicative of an essentially $d_{x^2-y^2}$ ground state for the copper(II) ions in both compounds (CuN_4O_2 chromophores).

1. Introduction

Considerable effort has been spent over the last decade to explore the use of coordination compounds as molecular building blocks (MBBs) that, by an appropriate combination of strong coordinative capacity with weak non-covalent interactions (hydrogen bond and π–π stacking), would provide directional motifs leading to the self-assembling of new network structures [1]. In particular, the understanding of all non-covalent interactions has been shown determinant for the development of inorganic supramolecular chemistry [2].

In recent years, our research interest has focused mainly on the coordinating behaviour of several ligands containing bis(imidazolyl) moieties. These kinds of ligands form very stable complexes with 3d ions *via* the coordination of imidazole nitrogen atoms in six-member chelate rings. In earlier works, we reported the results on the coordination chemistry of several bis(imidazolyl) ligands such as HBIP (3,3-bis(2-imidazolyl)propionic acid) [3], BIBM (bis(2-imidazolyl)bis(methoxycarbonyl)methylmethane) [4], DIMMAL (2-di1*H*-2-imidazolylmethylmalonate) [5] and BIMAM (bis(imidazol-2-yl)methylaminomethane) [6]. As part of our continuing studies on metal complexes of

doi:10.1016/j.poly.2007.10.026

imidazole–carboxylate-based ligands, we herein report the results of a solution study on the copper(II) complexes of DIMMAL, as well as the molecular and crystal structure and spectroscopic properties of two new DIMMAL derivatives, $(NH_4)_2[Cu(DIMMAL)_2]\cdot 4H_2O$ (**1**) and $[Cu(DIMMAL)(en)(H_2O)]\cdot 5H_2O$ (**2**). DIMMAL is a versatile polyfunctional ligand combining the donor function of the imidazole groups with that of two carboxylic groups, being therefore a potential *N,N,O,O*-tetradentate ligand. These functional groups can undergo acid–base reactions, having in consequence several donor/acceptors centers. In this sense, its efficiency for the build-up of hydrogen-bonded metal coordination network structures has been previously corroborated [5]. Beside this, the imidazole rings are available to generate aromatic–aromatic interactions that would play an important role in the modulation of the crystal packing [7]. Thus the combination of all these multiple simultaneous modes of interactions (coordinative, H-bonding and π–π, i.e., the three driving forces usually involved in the formation of high-dimensional systems [1d,8]) as the directional motifs guiding the self-assembly process, make DIMMAL a particularly attractive structural support that builds interesting supramolecular networks.

2. Experimental

2.1. Materials

The compounds $Na_2(DIMMAL)\cdot 5H_2O$ and $[Cu_2(DIMMAL)_2(H_2O)_2]\cdot 2H_2O$ were prepared as previously described [5] and characterized by elemental analysis and powder X-ray diffraction. All other reagents were used as supplied. Elemental analyses (C, H, N) were performed by the Servei de Microanalisi, Consell Superior d'Investigacions Científiques, Barcelona, Spain. Copper was determined by atomic absorption using a Perkin–Elmer 4100 ZL spectrophotometer.

2.2. Synthesis of the complexes

2.2.1. Synthesis of $(NH_4)_2[Cu(DIMMAL)_2]\cdot 4H_2O$ (*1*)

Aqueous solutions of $Na_2(DIMMAL)\cdot 5H_2O$ (0.5 mmol, 15 mL) and copper(II) chloride (0.25 mmol, 5 mL) were mixed together, resulting in a purple–blue solution. Solid ammonium chloride (1 mmol) was then added with stirring; the final pH value was 7.6. The solution was allowed to stand at a temperature of 4 °C for several days to produce single rectangular purple crystals of (**1**), which were filtered, washed with cold ethanol and dried. *Anal.* Calc. for $C_{20}H_{32}CuN_{10}O_{12}$: C, 35.95; H, 4.83; N, 20.97; Cu, 9.51. Found: C, 35.78; H, 4.97; N, 20.53; Cu, 9.62%.

2.2.2. Synthesis of $[Cu(DIMMAL)(en)(H_2O)]\cdot 5H_2O$ (*2*)

Single crystals of suitable size for X-ray work of compound **2** were obtained according to the following procedure: 0.5 mmol of $[Cu_2(DIMMAL)_2(H_2O)_2]\cdot 2H_2O$ were suspended in water (25 mL) and then ethylenediamine (1 mmol) was added with stirring, producing the redissolution of the blue powder and leading to a purple solution. The solution was left to stand at room temperature, and violet rectangular crystals of **2** formed overnight. The crystals were filtered, washed with cold ethanol and dried. *Anal.* Calc. for $C_{12}H_{28}CuN_6O_{10}$: C, 30.02; H, 5.89; N, 17.51; Cu, 13.24. Found: C, 29.72; H, 5.62; N, 17.79; Cu, 13.31%.

2.3. Physical measurements

Potentiometric titrations were carried out at 298.1 ± 0.1 K using $NaClO_4$ 0.15 M as a supporting electrolyte. The experimental procedure (burette, potentiometer, cell, stirrer, microcomputer, etc.) has been fully described elsewhere [9]. The acquisition of the emf data was performed with the computer program PASAT [10]. The reference electrode was a Ag/AgCl electrode in saturated KCl solution. The glass electrode was calibrated as a hydrogen-ion concentration probe by titration of previously standardized amounts of HCl with CO_2-free NaOH solutions and the equivalent point determined by the Gran's method [11] which gives the standard potential, $E^{\circ\prime}$, and the ionic product of water ($pK_w = 13.73(1)$).

The computer program HYPERQUAD was used to calculate the protonation and stability constants [12]. The pH range investigated was 2.5–11.0 and the concentration of the metal ion and the ligand ranged from 1×10^{-3} to 5×10^{-3} M with 1:1 and 1:2 M:L molar ratio. However, 1:1 M:L ratios gave rise to a non-soluble product not amenable for analysis. The different titration curves for each system (at least two, number of points *ca.* 50 in every titration) were treated either as a single set or as separated curves without significant variations in the values of the stability constants. Finally, the sets of data were merged together and treated simultaneously to give the final stability constants.

Diffuse reflectance spectra were obtained using a Perkin–Elmer Lambda 9 UV/Vis/IR spectrophotometer. Polycrystalline powder EPR spectra were recorded on a Bruker ESP-300 equipped with a variable temperature device.

2.4. X-ray structure determination

X-Ray data sets for compounds **1** and **2** were collected on a Nonius Kappa CCD diffractometer and intensity measurements were carried out at 293 K using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods using SIR97 [13]. All non-hydrogen atoms were refined anisotropically on F^2 (program SHELXL-97 [14]). Hydrogen atoms from DIMMAL and the ethylenediamine molecule were placed at calculated positions, and hydrogens from water molecules and the ammonium cation were located by difference synthesis. All of them were included using a riding model in

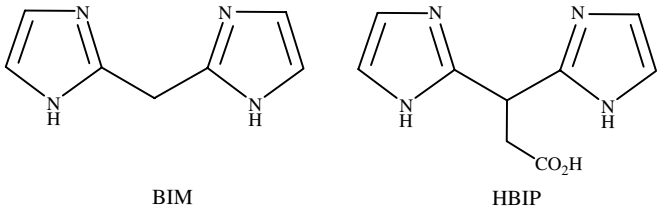
[b] $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_c^2)^2]\}^{1/2}$ for all reflections; $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = [2F_c^2 + F_o^2]/3$ and a and b are constants set by the program.

the final refinement. Molecular representations were produced with ORTEP3 for Windows [15]. Packing figures were produced with Mercury 1.2 [16]. Other relevant data of the crystal structure study are listed in Table 1.

3. Results and discussion

3.1. Potentiometric studies

The stepwise protonation constants of DIMMAL are included in Table 2, along with those previously reported for the related HBIP and BIM (BIM = bis(imidazol-2-yl)methane) ligands [17]. Scheme 1 shows the structure of the H_2DIMMAL molecule in addition to the other two bis(imidazolyl) ligands.



Compared with BIM [17] the two first stepwise constants of DIMMAL and HBIP can be ascribed to the protonation of the imidazole nitrogen atoms while the other two values are associated with the protonation of one (HBIP) or two (DIMMAL) carboxylate groups. The log K values corresponding to the protonation of the imidazole nitrogen atoms are scarcely affected when comparing the HBIP and BIM ligands; on the contrary, when a second carboxylate group is attached to the bis(imidazole) moiety in DIMMAL, although the ionic strength employed is not the same, slight but significant variations are observed: log K shift to higher values by *ca.* 0.6 in HL formation and *ca.* 0.9 in the corresponding H_2L formation.

Stability constants of the copper(II) complexes of all three bis(imidazolyl) ligands are given in Table 3. Speciation studies confirm the presence of 1:2 Cu:DIMMAL species, analogous to those found in the complexes with HBIP and BIM. Early formation of insoluble products in the equilibrium for the Cu:DIMMAL system in a 1:1 molar ratio prevented the acquisition of reliable data.

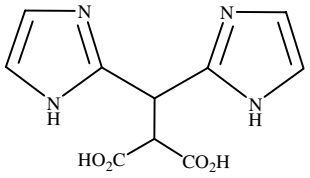


Table 2
Logarithms of the stepwise protonation constants for DIMMAL

Equilibrium[a]	DIMMAL	HBIP[b]	BIM[b]
$L + H \leftrightarrows LH$	7.54(2)[c]	6.90(1)	6.93(1)
$LH + H \leftrightarrows LH_2$	5.54(3)	4.62(1)	4.74(1)
$LH_2 + H \leftrightarrows LH_3$	3.75(4)	2.79(1)	
$LH_3 + H \leftrightarrows LH_4$	2.62(4)		

The corresponding constants for HBIP and BIP have been included for comparison (see text).
[a] Charges omitted.
[b] Taken from Ref. [17].
[c] Values in parentheses are standard deviations in the last significant figure.

Table 3
Logarithms of the stability constants for the formation of Cu(II) complexes by DIMMAL

Equilibrium[a]	DIMMAL	HBIP[b]	BIM[b]
$Cu + 2L \leftrightarrows CuL_2$	14.40(4)	17.29(3)	17.03(1)
$Cu + 2L + H \leftrightarrows CuHL_2$	20.44(3)	21.20(3)	
$CuL_2 + H \leftrightarrows CuHL_2$	6.04(4)	3.91(3)	

The corresponding constants for HBIP and BIM have been included for comparison (see text).
Values in parentheses are standard deviations in the last significant figure.
[a] Charges omitted.
[b] Taken from Ref. [17].

The most interesting feature in Table 3 is the lower stability of the 1:2 complex with the DIMMAL ligand in comparison with HBIP and BIM. On the other hand when the considered ligands contain carboxylate groups (DIMMAL and HBIP), protonated $CuHL_2$ species, which likely correspond to the complexes with a protonated carboxylate group, are observed. In the case of DIMMAL, this species is predominant in the pH range 4–6 and the large value for the protonation constant of CuL_2 suggests that it is occurring on a non-coordinated group. However, above pH 7, the CuL_2 complex predominates. So it seems plausible to isolate the dinegative $[Cu(DIMMAL)_2]^{2-}$ anions from 1:2

Cu:DIMMAL solutions at pH $\geqslant$ 7 (see distribution diagram in Fig. 1).

3.2. Description of the structures

3.2.1. Crystal structure of $(NH_4)_2[Cu(DIMMAL)_2]\cdot 4H_2O$ (1)

Compound **1** was obtained at pH > 7, in agreement with the solution data (see above). The structure of compound **1** consists of centrosymmetric mononuclear anionic $[Cu(DIMMAL)_2]^{2-}$ units, NH_4^+ cations and lattice water molecules. Both ionic species are held by extensive hydrogen bonding interactions that involve the water molecules to furnish a three-dimensional network structure. Fig. 2 shows a perspective view of the anionic unit with the atomic numbering scheme. Selected bond distances and angles are listed in Table 4.

The DIMMAL ligands are centrosymmetrically arranged around the copper atoms through two imidazole nitrogen atoms and one carboxylate oxygen atom. Therefore the coordination around the Cu(II) ions adopts a tetragonally elongated octahedral geometry (4 + 2 coordination mode of CuN_4O_2 chromophores). The basal octahedron plane is made up of four nitrogen atoms from four imidazoles rings, with Cu–N bond distances of 1.978(2) and 2.003(2) Å, which are similar to those observed in other *trans*-CuN_4O_2 chromophores with imidazole nitrogen atoms in equatorial positions [3g,5,18]. The axial sites are occupied by oxygen atoms from two carboxylate groups, with a Cu–O distance of 2.773(2) Å, which exceeds the Cu–N_{eq} ones by *ca.* 0.73 Å. According to Hathaway's criterion [19a], the axial oxygen atoms must be considered as semi-coordinated. In fact, the tetragonality parameter, defined as the mean in-plane Cu–N bond length divided by the mean out-of-plane M–O bond length [19b] is $T = 0.72$, similar to those observed in several *trans*-CuN_4O_2 chromophores of imidazole-containing six-coordinate copper(II) complexes with four imidazole rings as strong donor ligands in the basal plane and weaker oxygen donor ligands in apical positions [3g,5,18a,18c,18d].

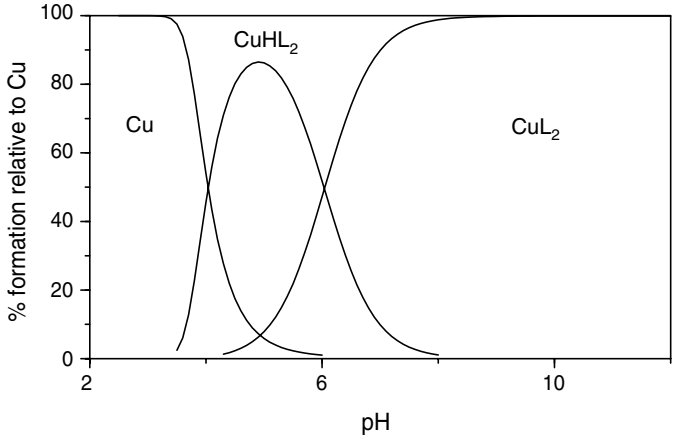

Fig. 1. Distribution diagram for the system Cu(II)–DIMMAL with $[Cu(II)] = 10^{-3}$ M, $[DIMMAL{\equiv}L] = 2\times10^{-3}$ M.

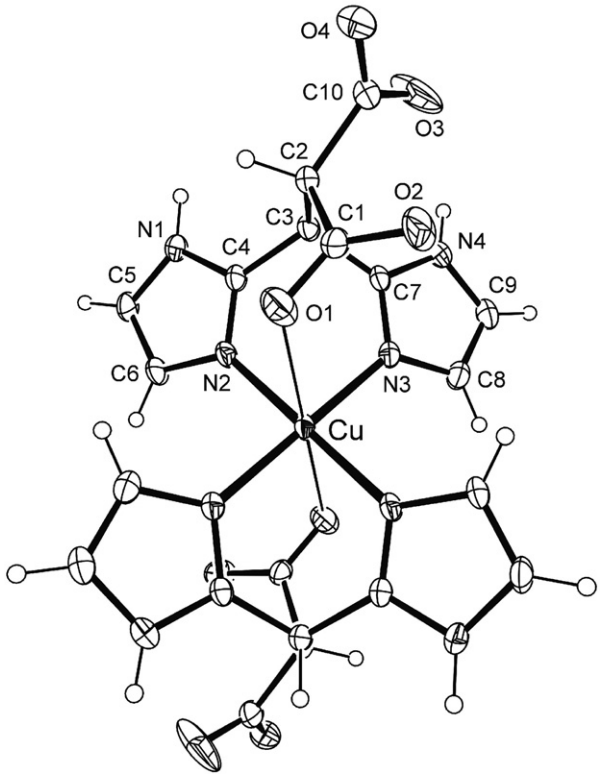

Fig. 2. Structure and atomic numbering scheme of $[Cu(DIMMAL)_2]^{2-}$ units in compound **1**.

Table 4
Selected bond distances (Å) and angles (°) for compound **1**

Cu–N(2)	1.978(2)	N(2)–Cu–N(3)	87.4(1)
Cu–N(3)	2.003(2)	N(2)–Cu–O(1)	81.3(1)
Cu–O(1)	2.773(2)	N(3)–Cu–O(1)	89.6(1)

The interatomic distances and angles within the DIMMAL moieties are similar to those found in the disodium salt as well the two copper(II) complexes previously described [5]. The imidazole rings are planar, with deviations from the mean planes not greater than 0.006(2) Å. The dihedral angle between the two imidazole rings of each ligand is 131.1(1)°.

Both kinds of carboxylate groups (coordinated and non-coordinated) display a similar degree of asymmetry. So the values of the asymmetry parameter [20] δ [$\delta = \{d(C–O_A)–d(C–O_B)\}\times10^3$] are $\delta = 21$ for the coordinated $–CO_2^-$ group and $\delta = 23$ for the uncoordinated one. It must be stressed that in the coordinated $–CO_2^-$ group the $C–O_{uncoord}$ distance is longer than the $C–O_{coord}$ one (1.256(4) and 1.235(4) Å, respectively). The weakness of the interaction Cu–O(1) in addition to the involvement of the uncoordinated O(2) atom in a relatively strong hydrogen bond ($O(6)–H(6B)\cdots O(2^{II})$, $d_{O\cdots O} = 2.596(5)$ Å) may be invoked to explain this behaviour.

Table 5
Hydrogen bonds for compound **1**

X–H···Y (Å)	X–H (Å)	H···Y (Å)	X···Y (Å)	X–H···Y (°)
O(5)–H(5A)···O(1)	0.81	2.828(4)	2.02	178
O(5)–H(5B)···O(4^{I})	0.88	2.707(3)	1.84	168
O(6)–H(6A)···O(5)	0.96	3.229(5)	2.36	151
O(6)–H(6B)···O(2^{II})	0.90	2.596(5)	1.73	159
N(1)–H(1)···O(4^{III})	0.95	2.736(3)	1.79	170
N(4)–H(4)···O(1^{IV})	0.87	3.158(3)	2.36	152
N(5)–H(51)···O(2)	0.92	2.909(4)	2.00	168
N(5)–H(52)···O(3^{V})	0.97	2.666(4)	1.78	150
N(5)–H(53)···O(5^{VI})	0.87	2.829(4)	2.00	158
N(5)–H(54)···O(6^{I})	0.72	2.975(5)	2.32	155

Symmetry operators: I: $-x$, $-y$, $-z+1$; II: x, $y+1$, z; III: $-x-1$, $-y$, $-z+1$; IV: $x-1$, y, z; V: $-x-1$, $-y-1$, $-z+1$; VI: x, $y-1$, z.

Crystal packing is primarily induced by the H-bonds listed in Table 5. As it has been observed in the previously reported DIMMAL derivatives [5] the H-bonding interaction is a determinant force involved in the self-assembly process.

The $[Cu(DIMMAL)_2]^{2-}$ entities, considered as a whole, can behave as hydrogen bond donors (through the protonated imidazole nitrogen atoms) and H-acceptors, by means of the carboxylate groups. The linkage of the $[Cu(DIMMAL)_2]^{2-}$ units by double N(1)–H(1)···O(4^{III}) (d_{O-O} = 2.736(3) Å) hydrogen bonds and aromatic–aromatic interactions generate chains running along the *a* direction with copper–copper distances of 7.4074(3) Å. These chains are linked together into sheets parallel to the *ac* plane by hydrogen bonds of the imidazole N(4) and the crystallization water O(5), both atoms acting as H-donors. Fig. 3 shows the 2D framework originated by these interactions between the chains. The water molecules O(5), which are located between the chains, play a relevant role by taking part in H-bonds with the $[Cu(DIMMAL)_2]^{2-}$ entities. They act as H-donors towards two oxygen atoms, O(1) and O(4^{I}), from two different $[Cu(DIMMAL)_2]^{2-}$ units belonging to neighboring chains. Both interactions should be relatively strong since the O–H···O bridges are nearly linear (angles of 178° for O(1) and 168° for O(4^{I})) and the O···O separations are not far from the range (2.4–2.7 Å) of strong hydrogen-bonded O···O distances [21].

Apart from the hydrogen-bonding set, aromatic–aromatic interactions between the imidazole rings constitute an additional factor in the 2D self-assembly process. The rings containing N(3) and N(4) atoms (in short, [N(3)N(4)] rings) belonging to two neighboring $[Cu(DIMMAL)_2]^{2-}$ units in the same chain interact in a offset face-to-face mode, as usual in observed π–π stacking interactions between imidazole rings [7g]. The geometrical parameters of these interactions are d_c = 3.58 Å, d_p = 3.55 Å and $\gamma = 7.0°$ (d_c being the centroid-to-centroid distance, d_p the plane-to-plane distance and γ the angle between the centroid–centroid vector and the perpendicular to the imidazole nucleus least-square plane [2a,7e]). The key parameters d_c and γ are significantly lower that those observed in other DIMMAL derivatives (mean values of d_c = 3.84 Å and $\gamma = 21.5°$ [5]).

The ammonium cations participate in hydrogen bonds as H-donors towards two carboxylate oxygen atoms and both crystallization water molecules (see Table 5). Every cation is surrounded by four oxygen atoms with N···O distances in the range 2.67–2.98 Å.These set of H-bond contacts, in combination with the π–π interaction between the imidazole rings (the [N(1)N(2)] and [N(3)N(4)] rings are involved in edge-to-edge interactions with d_c = 4.84 Å and a dihedral angle between the imidazole rings of 48.9°), link the above described *ac* layers into an infinite three-dimensional array. Fig. 4 shows the H-bond interactions between adjacent layers along the *b*-axis.

3.2.2. Crystal structure of $[Cu(DIMMAL)(H_2O)(en)]\cdot 5H_2O$ (2)

Compound **2** is the first characterized ternary copper (II) complex containing DIMMAL as a primary ligand. The crystal structure of compound **2** is built up from mononuclear neutral [Cu(DIMMAL)(H_2O)(en)] units (MBBs)

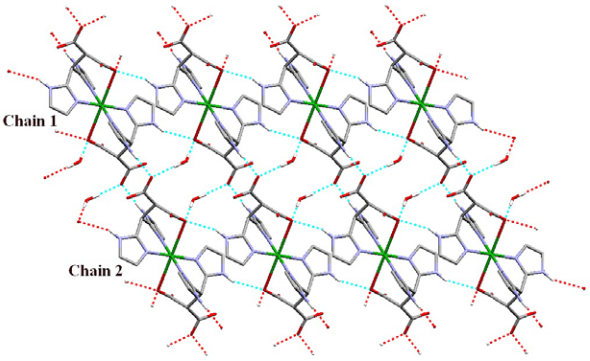

Fig. 3. The two-dimensional network of compound **1** as viewed down the crystallographic *b*-axis, showing the extensive hydrogen bonding in the *ac*-plane.

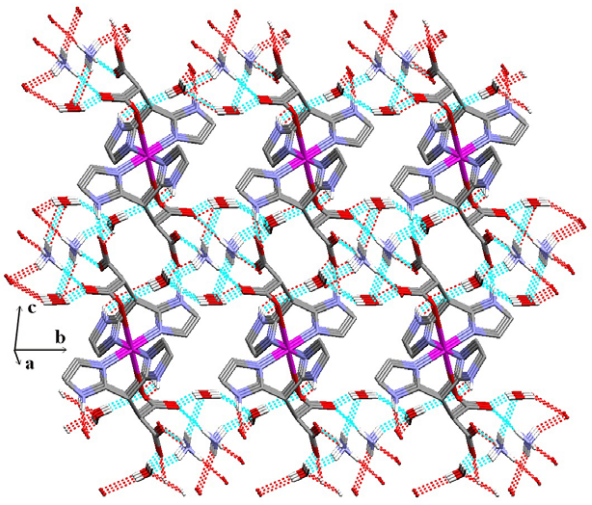

Fig. 4. 3D framework of compound **1**.

which are held by extensive hydrogen bonding interactions that involve the water molecules of crystallization to furnish a three-dimensional network structure. Fig. 5 shows a perspective view of the molecular unit with the atomic numbering scheme. Selected bond distances and angles are listed in Table 6.

The coordination geometry around the metal ion can be described as an elongated distorted octahedron. The equatorial plane comprises four nitrogen atoms, two belonging to the bis(imidazolyl) moiety (N(2) and N(3)) and two from an ethylenediamine molecule (N(5) and N(6)). The hexacoordination is achieved with the participation of two oxygen atoms, O(1) (from a propionate arm of DIMMAL) and O(5) (a water molecule) which occupy the axial positions (O(1)–Cu–O(5) 174.7(1)°), with Cu–O distances near to the borderline to be considered semi-coordinated (see Table 6). Therefore, the coordination mode for the copper atom can thus be viewed as $4+1+1$ (CuN_4OO' chromophore).

Ethylenediamine acts as a chelating ligand, forming five-membered rings with usual Cu–N bond distances. The torsion angle N(5)–C(11)–C(12)–N(6) is 50.7(3)° and the dihedral angle between the C(11)–C(12)–Cu and N(5)–N(6)–Cu planes is 26.5(2)°. Both conformational parameters are similar to those reported for other ethylenediamine–copper(II) complexes [22].

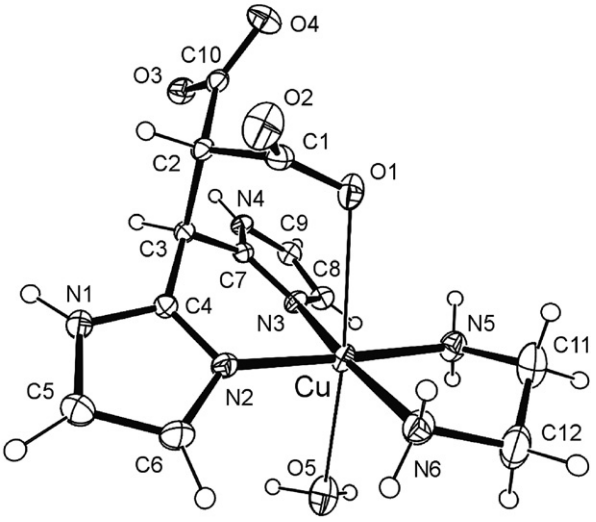

Fig. 5. Molecular structure and atomic numbering scheme of [Cu(DIMMAL)(H_2O)(en)] · $5H_2O$ compound.

Table 6
Selected bond distances (Å) and angles (°) for compound **2**

Cu–N(2)	1.988(2)	Cu–N(6)	2.012(2)
Cu–N(3)	1.980(2)	Cu–O(1)	2.677(2)
Cu–N(5)	2.030(2)	Cu–O(5)	2.596(2)
N(2)–Cu–N(3)	88.9(1)	N(3)–Cu–O(5)	95.7(1)
N(2)–Cu–N(5)	176.1(1)	N(5)–Cu–N(6)	83.6(1)
N(2)–Cu–N(6)	94.7(1)	N(5)–Cu–O(1)	92.0(1)
N(2)–Cu–O(1)	84.7(1)	N(5)–Cu–O(5)	92.8(1)
N(2)–Cu–O(5)	90.6(1)	N(6)–Cu–O(1)	95.5(1)
N(3)–Cu–N(5)	92.5(1)	N(6)–Cu–O(5)	87.4(1)
N(3)–Cu–N(6)	175.2(1)	O(1)–Cu–O(5)	174.7(1)
N(3)–Cu–O(1)	81.8(1)		

The interatomic distances and angles within the DIMMAL moieties are similar to those found in compound **1**. The imidazole rings are planar, with deviations from the mean planes not greater than 0.004(2) Å. The dihedral angle between the two imidazole rings of each ligand is 148.0(1)°. The carboxylate groups (coordinated and non-coordinated) display different degrees of asymmetry. In fact the values of the asymmetry parameter are $\delta = 21$ for the coordinated $-CO_2^-$ group and $\delta = 2$ for the uncoordinated one. Like in compound **1**, in the coordinated $-CO_2^-$ group the C–$O_{uncoord}$ distance is longer than the C–O_{coord} one (1.266(3) and 1.245(3) Å, respectively). Similar arguments (the weakness of the interaction Cu–O(1) together to the greater implication in the hydrogen bonds of the uncoordinated O(2) atom) may be used to explain this similar behaviour.

The existence of several H-donor (NH from the imidazole rings and NH_2 from the ethylenediamine molecule) and H-acceptor (carboxylates) groups confers interesting properties to the [Cu(DIMMAL)(H_2O)(en)] units as potential MBBs for building supramolecular frameworks.

As in compound **1**, the crystal packing is primarily induced by the H-bonds (see Table 7). The [Cu(DIMMAL)(H_2O)(en)] units are linked into a 1D chain structure running along the direction of the *a*-axis by means of O(5)–H(5A)···O(2^{I}) and N(5)–H(5C)···O(2^{I}) hydrogen bonds. In addition, the chains further extend into a double-strand structure based on double N(1)–H(1)···O(3^{VI}) hydrogen-bonds and π–π interactions (see Fig. 6). The latter involve the [N(3)N(4)] imidazole rings of neighboring MBBs in an offset face-to-face mode. The geometrical parameters of such interactions are $d_c = 3.86$ Å, $d_p = 3.44$ Å and $\gamma = 27.1°$. Such a parallel displaced structure agrees with those

Table 7
Hydrogen bonds for compound **2**

reported for π–π interactions between aromatic nitrogen heterocycles and suggest a significant σ,π-contribution to this interaction [2a].

The five water molecules of crystallization (W6–W10) complete an extensive and intricate hydrogen-bond framework through W···W and W···[MBB] interactions (see Table 7), expanding the supramolecular aggregation to a three-dimensional network. In addition, aromatic–aromatic interactions between the imidazole [N(1)N(2)] rings (edge-to-face mode, $d_c = 5.74$ Å) belonging to adjacent double-chains contribute to stabilize the crystal structure.

3.3. Electronic and EPR spectroscopy

The diffuse reflectance spectra of compounds **1** and **2** exhibit very broad absorptions in the visible region with maxima centered at 17400 and 17800 cm^{-1}, respectively. The position of these absorptions, which is consistent with the presence of CuN_4O_2 chromophores with a tetragonally distorted octahedral geometry, is similar to those reported for other imidazole-containing copper(II) complexes exhibiting elongate octahedral *trans*-CuN_4O_2 chromophores [3,5,18].

The room-temperature Q-band EPR spectra of polycrystalline samples of compounds **1** and **2** are very similar (see Fig. 7), showing an axial type signal ($g_{\|} = 2.23_1$, $g_{\perp} = 2.05_1$ for compound **1** and $g_{\|} = 2.24_2$, $g_{\perp} = 2.05_2$ for compound **2**) with resolved hyperfine coupling in the parallel part of the spectrum ($A_{\|} = 186 \times 10^{-4}$ cm^{-1} for compound **1** and $A_{\|} = 184 \times 10^{-4}$ for compound **2**). When the temperature is lowered to 120 K, the signals narrow but the *g* values remain practically unchanged; no half-field signal was detected. These results are consistent with a predominantly $d_{x^2-y^2}$ ground state for the Cu(II) ions in a statically distorted CuN_4O_2 polyhedron in both compounds [23]. On the other hand, the observed set of EPR parameters are similar to those reported for related imidazole-containing copper(II) complexes [3f,5,18].

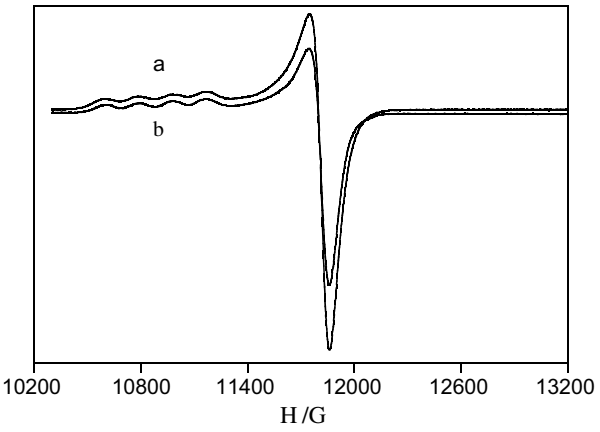

Fig. 7. EPR powder spectra (Q-band) of compounds **1** (a) and **2** (b) at room temperature.

Abstract

The compounds $[\{VO(O_2)_2(NH_3)\}_2\{\mu\text{-}Cu(NH_3)_4\}]$ (**1**) and $[Zn(NH_3)_4][VO(O_2)_2(NH_3)]_2$ (**2**) were prepared and characterized by elemental analysis and infrared spectra. The single crystal X-ray study revealed that the structure of **1** consists of trinuclear complex molecules $[(NH_3)OV(O_2)_2\{\mu\text{-}Cu(NH_3)_4\}(O_2)_2VO(NH_3)]$ with a rare heterobimetalic peroxo bridge: copper(II)–peroxo ligand–vanadium(V). The structure of **2** is composed of tetraamminezinc(II) cations and ammineoxodiperoxovanadate(V) anions. In course of thermal decomposition of **1** performed up to 620 °C, the following intermediate products: $[Cu(NH_3)_2(VO_3)_2]$, and subsequently a mixture of V_2O_5 with monoclinic $\beta\text{-}Cu_2V_2O_7$, were gradually formed. The final product of decomposition is $Cu(VO_3)_2$. The thermal decomposition of **2** is a two-step process. In the first stage, $[Zn(NH_3)_3(VO_3)_2]$ as supposed intermediate was formed, which transformed at higher temperatures by release of ammonia molecules to the monoclinic modification of $Zn(VO_3)_2$.

Keywords: Peroxovanadium complexes; Ammine complexes; X-ray structure; IR spectra; Thermal decomposition

1. Introduction

The study of interactions of the $[VO(O_2)_2(NH_3)]^-$ ions with transition metal ammine complexes is attractive from several points of view.

First, the pentagonal pyramidal diperoxovanadium(V) complexes exhibit a certain tendency towards completion of the coordination sphere to pentagonal bipyramidal. This completion proceeds in several stereochemically interesting ways, due to the different bonding interaction between the central atom and a donor atom coordinated in the axial position *trans* to the oxo ligand. These interactions range from normal covalent bonds, as it was observed in the $[VO(O_2)_2F_2]^{3-}$ ion [1], to very weak interactions of non-covalent character, e.g. of the V···O=V type [2]. These different interactions also have an influence on the spectral properties of complexes [3]. The presence of a complex cation in the structure of peroxovanadates provides further possibilities for the completion of the coordination sphere of vanadium. A similar tendency of weakly bonded atoms to occupy the axial positions is obvious for square planar complexes of Cu(II),

doi:10.1016/j.poly.2007.10.016

and complexes with 4 + 1 or 4 + 2 coordinations are thus formed. In complexes with the 4 + 2 coordination, the axial Cu–O bonds are typically longer by several tenths of angström when compared with the equatorial bond lengths [4].

Second, the interactions between the $[VO(O_2)_2NH_3]^-$ ion and transition metal complexes provide a possibility for formation of a peroxo bridge between the vanadium atom and the other transition metal atom. The reactions based on the formation of peroxo bridges are "responsible" for catalytic properties of many important catalysts for oxygen transfer reactions [5]. Moreover, heterobimetallic peroxo-bridged complexes are extremely rare: to the best of our knowledge, only one such example is known for copper(II) (Fe(III)–O_2–Cu(II), Chart 1g).

Third, increasing attention has been recently paid to vanadium based oxide materials due to their impressive structural variability and potential applications in areas of catalysis, sorption, electrochemistry and photochemistry [7]. These oxide materials are often prepared by solid state reactions of the oxides (carbonates, sulfates and hydroxides). Thus, $Cu(VO_3)_2$ obtained by Mocala et al. [8] is a very promising material for lithium batteries [9]. The second way for preparation of these materials is the thermal decomposition of precursors. As suitable precursors, coordination compounds with molecular or anionic ligands which are easily released or decomposed on heating (e.g. H_2O, NH_3, O_2^{2-} and $C_2O_4^{2-}$) can be used. The peroxo complexes of transition metals are often used for such purposes [10,11].

In this paper, we present the results of the study of the $CuSO_4$–NH_4VO_3–NH_3–H_2O_2–H_2O and $ZnSO_4$–NH_4VO_3–NH_3–H_2O_2–H_2O–ethanol reaction systems. Two new ammine complexes were prepared and characterized, including the X-ray structure. For $[\{VO(O_2)_2(NH_3)\}_2\{\mu\text{-}Cu(NH_3)_4\}]$, the unique Cu-μ-$\eta^1$:$\eta^2$-($O_2$)–V bridge was observed.

2. Experimental

2.1. Materials, analyses and measurements

All chemicals were of analytical grade and used as received, except for V_2O_5, which was prepared by thermal decomposition (at 500 °C) of previously purified NH_4VO_3. Vanadium(V) was determined by titration with aqueous solution of $FeSO_4$ in presence of H_3PO_4 and diphenylamine as indicator in a sample previously heated to decompose the peroxidic oxygen. The peroxide content was determined by potentiometric titration with an aqueous solution of $KMnO_4$ in presence of H_2SO_4. Nitrogen was determined on a CHN analyzer 1106 (Carlo Erba).

The IR spectra in nujol mulls were recorded on a FT IR Nicolet Magna 750 spectrometer. The thermal analysis and interrupted thermal treatment were accomplished on a Derivatograph Q 1500 D (MOM, Hungary). The experimental parameters: air atmosphere, sample mass 100 mg, heating rate 10 °C min^{-1}, Pt crucible. The temperature intervals were 20–450 °C for **1** and 20–550 °C for **2**. The mixture of β-$Cu_2V_2O_7$ and V_2O_5, obtained as decomposition product of **1** at 450 °C was annealed at 620 °C for 2 h to induce the mutual reaction of the components. The X-ray powder diffraction patterns were obtained on a Philips PW 1050 diffractometer using Cu Kα radiation.

The single crystal diffraction data were collected with a KM4 CCD four-circle diffractometer with an area-detector (KUMA Diffraction, Poland), and equipped with an Oxford Cryostream Cooler (Oxford Cryosystems, UK). Mo Kα radiation ($\lambda = 0.71073$ Å, monochromator Enhance, Oxford Diffraction, UK) was used in all measurements. The ω scan technique with different κ and φ offsets for covering a whole independent part of reflections in the 2–25° θ range was performed. The cell parameters were refined from all strong reflections. The data reductions were carried out using the CRYSALIS RED (Oxford Diffraction, UK) program. The structures were determined by SHELXS-97 [12] and refined by SHELXL-97, [13] the data for publication were prepared by SHELXL and PARST [14] and the figures by DIAMOND [15]. All H atoms were located in a difference map and refined as riding, with d(N–H) = 0.91 Å, and with U_{iso}(H) = 1.5U_{eq}(N). The crystal data and refinement details are given in Table 1.

2.2. Syntheses

2.2.1. Preparation of $[\{VO(O_2)_2(NH_3)\}_2\{\mu\text{-}Cu(NH_3)_4\}]$ (1)

$CuSO_4$ (0.200 g; 1.25 mmol) was dissolved in aqueous solution of NH_3 (15.0 ml; $w = 25\%$; 200 mmol) and the solution of H_2O_2 (0.50 ml; $w = 30\%$; 5.0 mmol) was added. In the obtained solution, NH_4VO_3 (0.290 g; 2.48 mmol) was dissolved. The resulting solution was cooled in an ice bath, and H_2O_2 (2.0 ml; $w = 30\%$; 20 mmol) was dropwise added. The obtained blue solution was stored at −5 °C. The dark blue crystals formed were isolated after 24 h,

2.2.3. Hydrothermal synthesis of $[Cu(NH_3)_2(VO_3)_2]$ (3)

The compound $[Cu(NH_3)_2(VO_3)_2]$ (**3**) was previously prepared by heating of a mixture of NH_4VO_3–Cu–H_2O at 50 °C for six weeks, and also structurally characterized [16]. We describe here its synthesis by hydrothermal method.

NH_4VO_3 (0.190 g; 1.62 mmol), $CuSO_4$ (0.130 g; 0.814 mmol) and a solution of NH_3 (5.0 ml; w = 25%; 66 mmol) were mixed, placed to a teflon container and heated at 120 °C under autogeneous pressure for 3 days. After cooling to the room temperature, dark green crystals were isolated, washed and dried at room temperature. *Anal.* Calc. for $CuH_6N_2O_6V_2$: N, 9.5. Found: N, 9.4%. IR: 3332 s, 3253 s, 3163 s ($\nu_{as} + \nu_s(NH_3)$); 1597 s ($\delta_{as}(NH_3)$); 1226 vs ($\delta_s(NH_3)$); 969 vs, 937 s (ν(V=O)); 897 vs, 853 vs, 684 b (ν(V–O–V)); 554 s, 469 m ($\nu(M–N)$, M = V, Cu). The X-ray diffraction pattern of **3** corresponds to the pattern calculated from the structure [16].

3. Results and discussion

3.1. Synthesis

Compounds **1** and **2** were prepared by crystallization from the NH_4VO_3–MSO_4–NH_3–H_2O_2–H_2O–(ethanol) systems (M = Cu, Zn). It is recommended to follow exactly the given preparation procedure as under changed conditions, different products, mainly $NH_4[VO(O_2)_2(NH_3)]$, can crystallize out.

Compound **3** was obtained by hydrothermal reaction and also by interrupted thermal decomposition (*vide infra*). While compounds **2** and **3** are stable at room temperature, the crystals of **1** undergo weathering accompanied by their destruction.

3.2. Crystal structures

Despite the similar composition, compounds **1** and **2** possess significantly different structures.

The crystal structure of **1** consists of trinuclear [(NH_3)O-$V(O_2)_2${μ-$Cu(NH_3)_4$}$(O_2)_2VO(NH_3)$] complex molecules with a C_i symmetry. The copper(II) atom is octahedrally coordinated by four ammonia molecules in the equatorial positions and two peroxo oxygen atoms originating from the $[VO(O_2)_2(NH_3)]^-$ anions in axial positions (Fig. 1): the Cu1–O5 bond length (2.484 Å) can be considered as a normal one for the 4 + 2 coordination of the copper atom [4,17]. All other bond lengths are within the expected intervals. The geometry of the $[VO(O_2)_2(NH_3)]^-$ ion is pentagonal pyramidal: the four peroxo oxygen atoms and the nitrogen atom form the base of the distorted pyramid and the oxygen atom of the V=O moiety occupies the apical position. The structure of this ion is similar to the structure of the $[VO(O_2)_2(NH_3)]^-$ ion in $NH_4[VO(O_2)_2(NH_3)]$

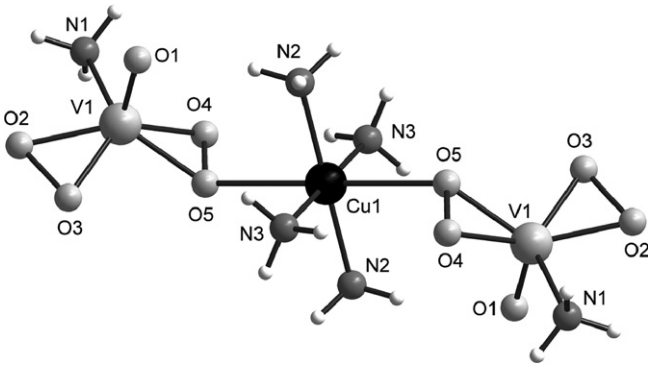

Fig. 1. Molecular structure of **1**. Selected interatomic distances (Å) and angles (°): Cu(1)–N(2) 2.0255(19), Cu(1)–N(3) 2.0269(19), Cu(1)–O(5) 2.4839(14), V(1)–O(1) 1.6227(17), V(1)–O(3) 1.8798(16), V(1)–O(4) 1.8937(17), V(1)–O(5) 1.8948(17), V(1)–O(2) 1.8950(18), V(1)–N(1) 2.1017(19), O(2)–O(3) 1.483(2), O(4)–O(5) 1.476(2), N(2)–Cu(1)–N(3) 90.26(8), O(1)–V(1)–O(3) 107.35(8), O(1)–V(1)–O(4) 107.30(8), O(1)–V(1)–O(5) 103.22(8), O(1)–V(1)–O(2) 105.83(9), O(1)–V(1)–N(1) 94.17(8).

[18]. The vanadium atom is considerably displaced by 0.4475(4) Å from the pentagonal plane towards the oxo ligand. The supramolecular 3D structure of **1** is formed by four types of hydrogen bonds formed between the molecules of $[\{VO(O_2)_2(NH_3)\}_2\{\mu\text{-}Cu(NH_3)_4\}]$: N1–H···O2*, N1–H···O5*, N2–H···O3*, N3–H···O3*; *d*(N···O): 2.789–3.034 Å (* denotes symmetry equivalent atoms).

The crystal structure of **2** consists of slightly distorted tetrahedral $[Zn(NH_3)_4]^{2+}$ cations and two crystallographically independent $[VO(O_2)_2(NH_3)]^-$ anions with an approximate C_s symmetry (Fig. 2).

The structure of the $[VO(O_2)_2(NH_3)]^-$ ion is similar to that found in the structure of **1**; the deviations of the vanadium atoms from the pentagonal plane are: 0.5077(5) (for V1) and 0.5218(4) (for V2) Å. The anions are arranged into chains of two types, A and B, oriented along the *a*-axis (Fig. 3).

The chain A is constructed by anions of the first crystallographic type (V1) and consists of pairs of antiparallely oriented anions. These anions form hydrogen bonds between the atoms N1 and O2* ($d(N1\cdots O2^*) = 2.896$ Å) and a weak contacts between the atoms V1 and O3* in axial position ($d(V1\cdots O3^*) = 3.245$ Å) (Fig. 4). Though very weak, they give an evidence for a tendency of the vanadium atom to complete its coordination sphere [19]. The pairs of anions are mutually connected into chains by hydrogen bonds between the N1 and O5* (peroxo) atoms ($d(N1\cdots O5^*) = 3.079$ Å) (Fig. 4).

In the chain B, the anions of the second type (V2) have an antiparallel orientation too. A very weak axial interaction in which the oxo ligands from the anions of the first type are involved, ($d(V2\cdots O1(V1)) = 3.565$ Å), can be recognized. The hydrogen bonds between the O9 and N6* atoms ($d(O9\cdots N6^*) = 2.972$ Å), respectively, O11 and N6* ($d(O11\cdots N6^*) = 2.931$ Å) connect the anions into a zig-zag chain (Fig. 5). The whole crystal structure is also stabilized by numerous hydrogen bonds between the chains and $[Zn(NH_3)_4]^{2+}$ cations.

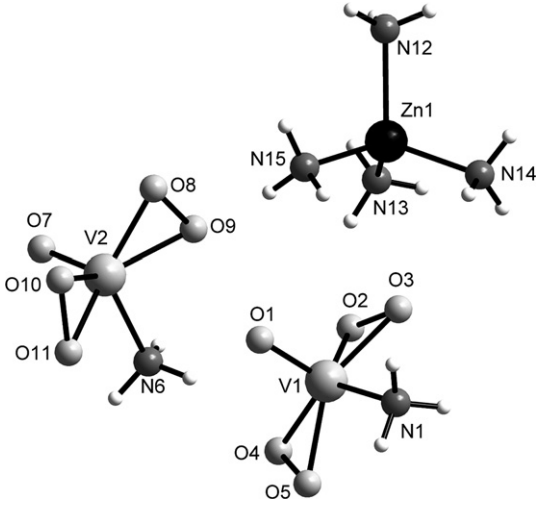

Fig. 2. Part of the crystal structure of **2**. Selected interatomic distances (Å) and angles (°): V(1)–O(1) 1.6003(19), V(1)–O(2) 1.8698(19), V(1)–O(3) 1.8847(18), V(1)–O(5) 1.8995(18), V(1)–O(4) 1.9079(19), V(1)–N(1) 2.102(2), V(2)–O(7) 1.5993(19), V(2)–O(9) 1.8698(19), V(2)–O(11) 1.8748(19), V(2)–O(8) 1.875(2), V(2)–O(10) 1.8947(19), V(2)–N(6) 2.094(2), O(2)–O(3) 1.473(3), O(4)–O(5) 1.478(2), O(8)–O(9) 1.457(3), O(10)–O(11) 1.472(3), Zn(1)–N(13) 1.996(2), Zn(1)–N(15) 2.024(2), O(1)–V(1)–O(2) 108.37(9), O(1)–V(1)–O(3) 106.90(10), O(1)–V(1)–O(5) 107.20(9), O(1)–V(1)–O(4) 104.22(9), O(1)–V(1)–N(1) 99.90(10), O(7)–V(2)–O(9) 108.53(10), O(7)–V(2)–O(11) 109.32(10), O(7)–V(2)–O(8) 106.04(10), O(7)–V(2)–O(10) 106.53(10), O(7)–V(2)–N(6) 98.24(10), N(13)–Zn(1)–N(15) 117.24(10).

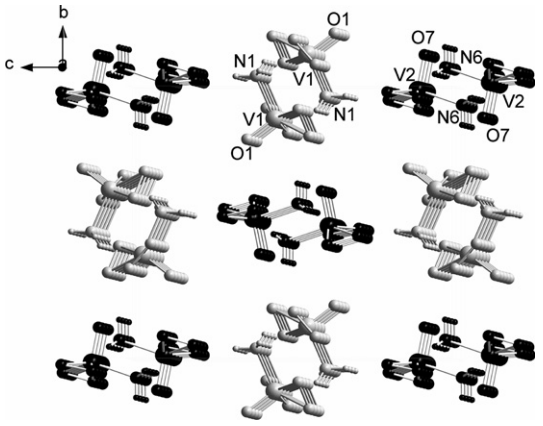

Fig. 3. Packing of the anionic chains along the *a*-axis in the crystal structure of **2** (in grey or black two crystallographically different types of anions).

3.3. IR spectra and thermal analysis

The IR spectrum of compound **1** (see Section 2 and Fig. 6a) exhibits the characteristic bands of coordinated ammonia molecules but the vibrations corresponding to the Cu–NH_3 or to the V–NH_3 groups cannot be distinguished [20]. The intensive splitting of these bands is in accordance with the three different *M*–NH_3 bond lengths in the unit cell (Fig. 1). The bands assigned to the $VO(O_2)_2$ group are similar to those observed for $NH_4[VO(O_2)_2(NH_3)]$ [21].

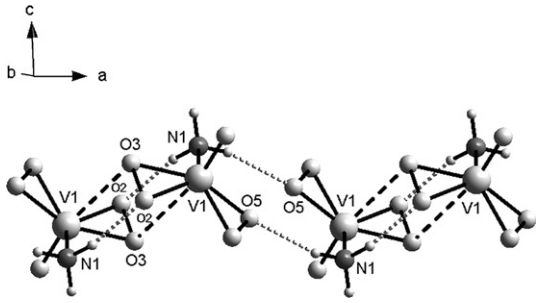

Fig. 4. Representations of pairs of anions in the chain A in the crystal structure of **2**.

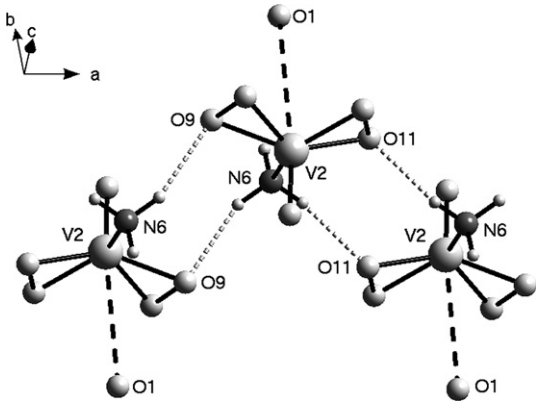

Fig. 5. The chain B in the crystal structure of **2**.

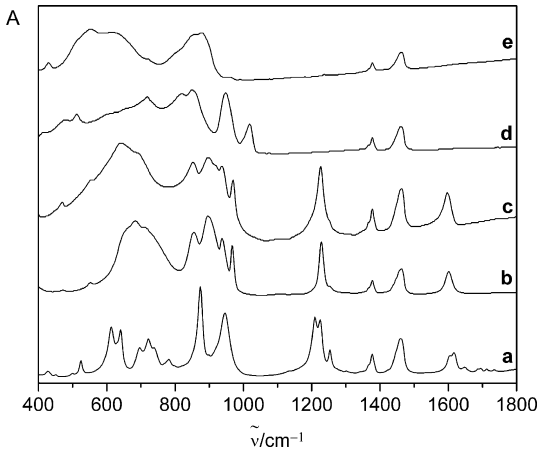

Fig. 6. IR spectra of: (a) **1**; (b) intermediate product obtained by interruption of thermal decomposition of **1** at 150 °C; (c) **3**; (d) intermediate product obtained by interruption of thermal decomposition of **1** at 450 °C and (e) final product of thermal decomposition of **1** at 625 °C.

The thermal decomposition of compound **1** is a two-step process: the individual steps are separated by distinct plateau (Fig. 7).

The first step on the TG curve (20–200 °C) can be described by Eq. (I) (calc. mass loss 30.9, found 30.0%):

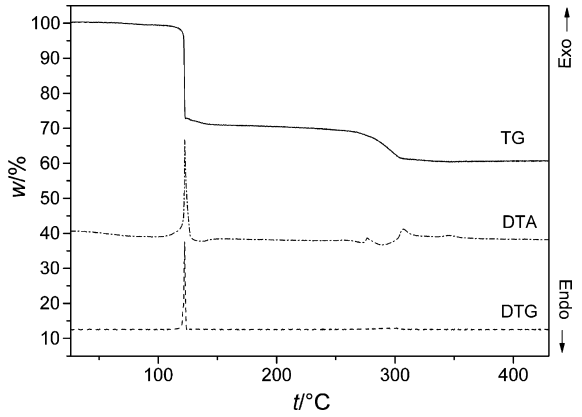

Fig. 7. Thermoanalytical curves of **1**.

$$[\{VO(O_2)_2(NH_3)\}_2\{\mu\text{-}Cu(NH_3)_4\}] \xrightarrow{\Delta t} [Cu(NH_3)_2(VO_3)_2] + 4NH_3 + 2O_2 \quad (I)$$

This reaction is expressed on the DTA curve by the strong exothermic peak at 126 °C. The X-ray powder pattern (Fig. 8c) and the IR spectrum of the product obtained by interruption of thermal decomposition at 150 °C (Fig. 6b) fully correspond to the X-ray powder pattern (Fig. 8b), and the IR spectrum of the hydrothermally prepared compound **3** (Fig. 6c). The IR spectrum of **3** exhibits all characteristic bands of the coordinated ammonia molecule. The broad band at 684 cm^{-1}, which can be assigned to ν_{as}(VOV), gives evidence of a polymeric character of compound **3** [22].

In the second step of decomposition (200–450 °C) accompanied by two exothermic effects on the DTA curve at 269 and 300 °C, the ammonia molecules are released (Eq. II).

$$2[Cu(NH_3)_2(VO_3)_2] \xrightarrow{\Delta t} Cu_2V_2O_7 + V_2O_5 + 4NH_3 \quad (II)$$

This process is manifested by disappearance of IR bands corresponding to the vibrations of the M–NH_3 groups (Fig. 6d). As can be seen from the X-ray powder diffraction

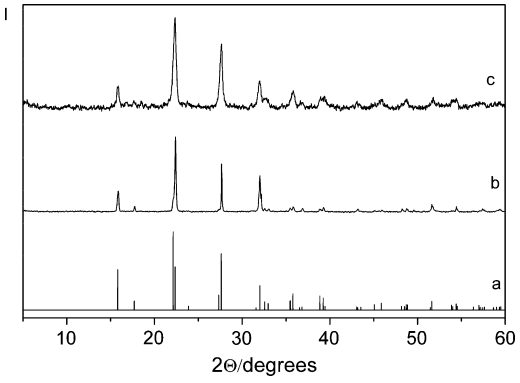

Fig. 8. X-ray powder diffraction patterns: (a) $[Cu(NH_3)_2(VO_3)_2]$ – pattern according the data in Ref. [16]; (b) **3**; (c) intermediate product obtained by interruption of thermal decomposition of **1** at 150 °C.

patterns, the product obtained at 450 °C is a mixture of V_2O_5 and monoclinic β-$Cu_2V_2O_7$ (Fig. 9a–c).

This mixture was annealed for two hours at 620 °C to prepare pure triclinic $Cu(VO_3)_2$ as the only product (Eq. III):

$$Cu_2V_2O_7 + V_2O_5 \xrightarrow{\Delta t} 2Cu(VO_3)_2 \quad \text{(III)}$$

The X-ray diffraction pattern of the annealed product (Fig. 9d) is fully in accordance with the published data on $Cu(VO_3)_2$ [8,9,23].

The IR spectrum of compound **2** exhibits bands which can be assigned to the vibrations of the M–NH_3 (M = Zn, V) and $VO(O_2)_2$ groups (Section 2 and Fig. 10a).

In the first step of thermal decomposition of compound **2** (20–170 °C, Fig. 11), three molecules of ammonia and two molecules of oxygen are released (calc. mass loss 26.8, found 27.2%) and an intermediate with proposed composition $[Zn(NH_3)_3(VO_3)_2]$ is formed (Eq. IV):

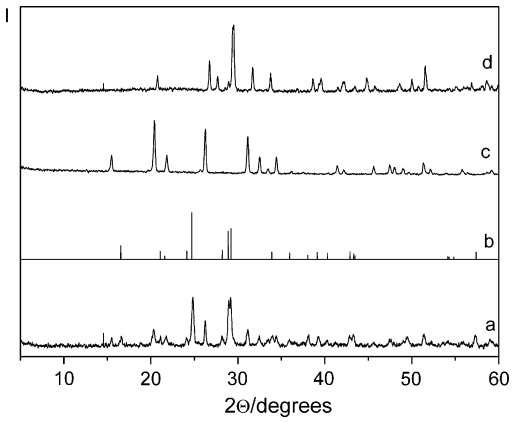

Fig. 9. X-ray powder diffraction patterns: (a) intermediate product obtained by interruption of thermal decomposition of **1** at 450 °C; (b) β-$Cu_2V_2O_7$ – pattern according the data in Ref. [24]; (c) V_2O_5; (d) $Cu(VO_3)_2$ obtained by annealing the mixture of β-$Cu_2V_2O_7$ and V_2O_5 at 620 °C.

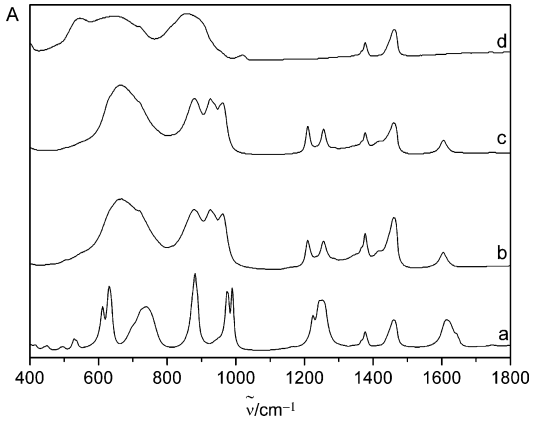

Fig. 10. IR spectra of: (a) **2**; (b) intermediate product obtained by interruption of thermal decomposition of **2** at 130 °C; (c) at 170 °C and (d) at 550 °C.

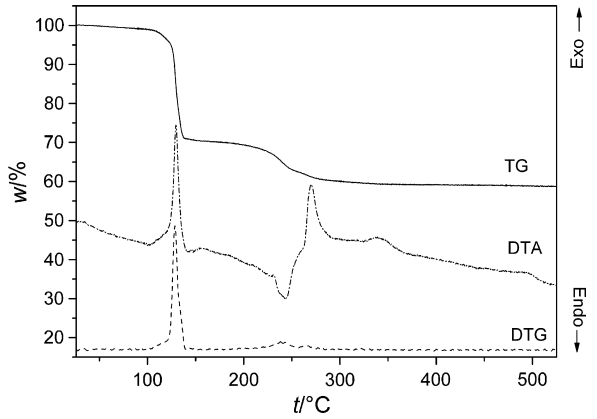

Fig. 11. Thermoanalytical curves of **2**.

$$[Zn(NH_3)_4][VO(O_2)_2(NH_3)]_2 \xrightarrow{\Delta t} [Zn(NH_3)_3(VO_3)_2] + 3NH_3 + 2O_2 \quad \text{(IV)}$$

This process is manifested on the DTA curve by the strong exothermic peak at 126 °C. The X-ray powder diffraction patterns of the decomposition products obtained at 130 and 170 °C and their IR spectra are identical (Figs. 12a and b and 10b and c). The IR spectra exhibit bands corresponding to vibrations of two differently bonded ammine ligands (see e.g. bands corresponding to $\delta_s(NH_3)$ at 1256 and 1210 cm^{-1}). The broad band at 665 cm^{-1}, which can be assigned to ν_{as}(VOV) and which is typical for the $(VO_3)_n^{n-}$ chains [22], may be considered as an evidence for a polymeric structure of the intermediate.

The unusual stoichiometry of $[Zn(NH_3)_3(VO_3)_2]$ raises questions about the structure of this compound. Unfortunately, our attempts to prepare crystals of this compound under hydrothermal conditions were unsuccessful.

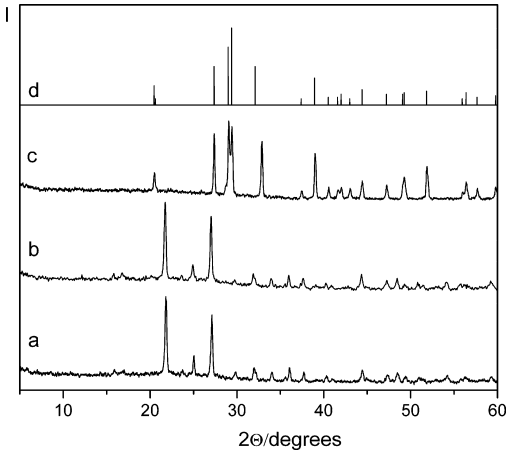

Fig. 12. X-ray powder diffraction patterns: (a) intermediate product obtained by interruption of thermal decomposition of **2** at 130 °C; (b) at 170 °C; (c) at 550 °C; (d) monoclinic $Zn(VO_3)_2$ – pattern according the data in Ref. [25].

The second step of thermal decomposition of **2** (170–550 °C) is described by Eq. (V) (calc. mass loss 11.9, found 10.9%):

$$[Zn(NH_3)_3(VO_3)_2] \xrightarrow{\Delta t} Zn(VO_3)_2 + 3NH_3 \quad (V)$$

On the DTA curve, this process is expressed by the endothermic effect at 236 °C and ensuing exothermic peak at 262 °C. The exothermic peak at 350 °C is not accompanied by any mass loss and corresponds probably to a phase transition. The X-ray diffraction pattern of the final product obtained at 550 °C (Fig. 12c) corresponds to the diffraction pattern of monoclinic modification of $Zn(VO_3)_2$ (Fig. 12d). The IR spectrum of this compound (Fig. 10d) exhibits characteristic bands of polymeric metavanadate chain [22].

Abstract

Three polyamine ligands of N1-(2-nitrobenzyl)-N1-(2-aminoethyl)ethane-1,2-diamine (L_1), N1-(2-nitrobenzyl)-N1-(2-aminoethyl)-propane-1,3-diamine (L_2) and N1-(2-nitrobenzyl)-N1-(3-aminopropyl)propane-1,3-diamine (L_3) were synthesized and their cyclocondensation with 2-[2-(2-formyl phenoxy)ethoxy]benzaldehyde (L_4) in the presence of various metal(II) ions was examined. These reactions only in the presence of a stoichiometric amount of cadmium(II) nitrate gave the related cadmium(II) macrocyclic Schiff-base complexes. In all the other cases no cyclic complexes have been obtained and metal(II) polyamines were the only products. The complexes have been studied with IR, ^{1}H NMR, ^{13}C NMR, DEPT, COSY, HMQC and microanalysis. The crystal structures of $[Cd(NO_3)(L_5)$-$(\mu$-$NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$ (**1**) and $[CdL_5(NO_3)(CH_3OH)]ClO_4$ (**2**) have been also determined.

Keywords: Macrocyclic complexes; Schiff-base; Crystal structure; NMR spectroscopy

1. Introduction

Macrocyclic Schiff-base complexes have attracted much attention since the early 1980s, and several reviews covering this area of research have appeared [1–7]. Template Schiff-base condensations between dicarbonyl compounds and diamines are among the simplest and most popular methods for macrocycle synthesis. The size and preferred coordination geometry of the metal ion control the structure of the condensation products [8,9]. We have been interested during the last three decades in the design and synthesis of a range of amines, both for their own intrinsic interest and also because of the possibilities of extending them by the formation of open-chain and macrocyclic Schiff-bases complexes [10]. We have developed a general method for synthesis of [1 + 1] macrocyclic complexes with a single or double alkylamine pendant arm via cyclocondensation of 2,6-diacetalpyridine with appropriate polyamines in the presence of the required metal ions. This allows the preparation of new macrocyclic complexes having one or two 2-aminoethyl pendant arms [11,13–15]. As an extension of this idea, in this work we have synthesized three new Cd(II) macrocyclic complexes by the metal ion templated [1 + 1] cyclocondensation of 2-[2-(2-formyl phenoxy)ethoxy]benzaldehyde (L_4) instead of 2,6-diacetylpyridine and different newly prepared polyamines (L_1, L_2 and L_3). The main purpose of the present work is to study the effect of addition of the 2-nitrobenzyl arm on the formation of macrocycles and their corresponding metal complexes. However, in the presence of the 2-nitrobenzyl arm and in the absence of metal ion, ring closure does not occur. In the presence of metal ions only Cd(II) was effective as a template and attempts for synthesizing the macrocycle using some other metal ions such as Mn(II), Cu(II), Ni(II), Zn(II) and Hg(II) were unsuccessful.

2. Experimental

2.1. Starting materials

All solvents were of reagent grade quality and purchased commercially. N-(2-aminoethyl)ethane-1,2-diamine, N-(2-aminoethyl)propane-1,3-diamine, N-(3-aminopropyl)propane-1,3-diamine and 2-nitrobenzylcholoride were obtained from Merck and were used without further purification.

2.2. Instrumentation

NMR spectra were obtained using a Bruker A V 300 MHz spectrometer. Infrared spectra were recorded in KBr pellets using a BIO-RAD FTS-40A spectrophotometer (4000–400 cm^{-1}).

2.3. X-ray crystal structure determination

Vapour diffusion of ether into a solution of $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$ in acetonitrile and $[CdL_5(NO_3)(CH_3OH)]ClO_4$ in methanol afforded pale yellow crystalline needles. X-ray data were measured on a STOE IPDS-II two circle diffractometer, using graphite-monochromated Mo Kα X-ray radiation ($\lambda = 0.7107$ nm). Other crystallographic data are summarized in Table 1.

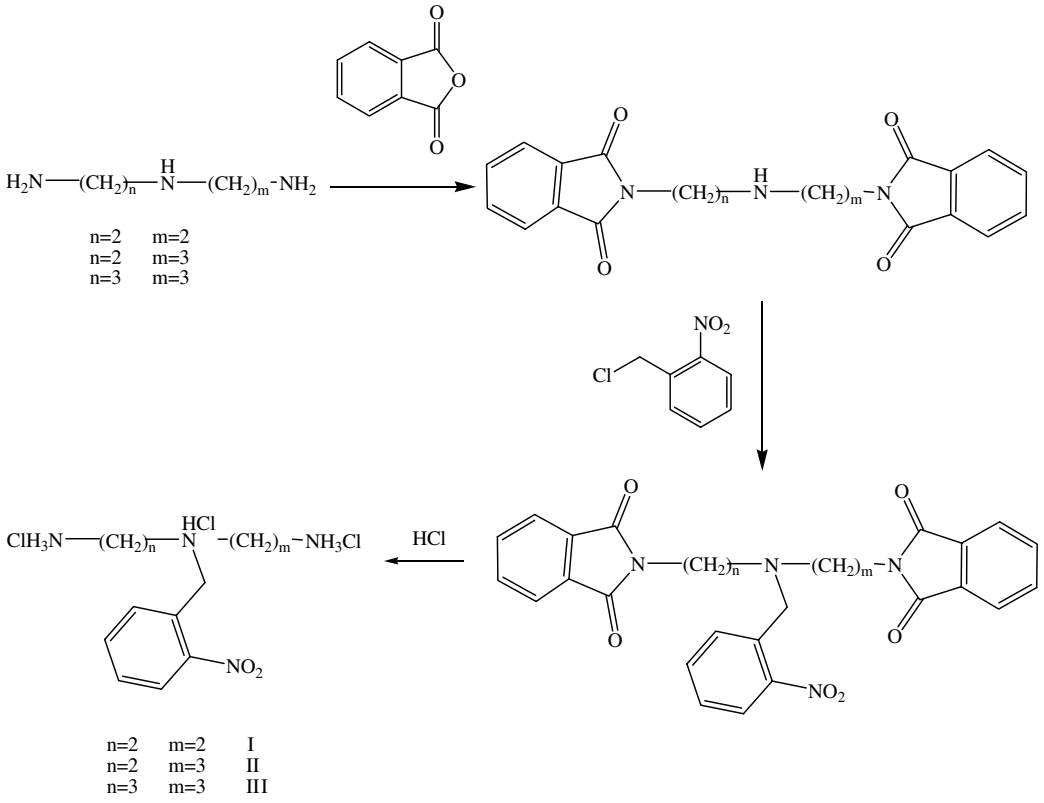
2.4. Synthesis

2.4.1. Ligand synthesis

*2.4.1.1. N1-(2-nitrobenzyl)-N1-(2-aminoethyl)ethane-1,2-diamine threehydrochloride (**I**).* 2,2′-Diphthalimidodiethylamine (3.63 g, 10 mmol) [12] and 2-nitrobenzylcholoride (2 g, 12 mmol) and potassium carbonate (1.38, 10 mmole) were fused together at 160 °C with constant stirring for 1 h. The resulting solid was pulverized and stirred in boiling 1:3 ethanol–water for about 20 min. The insoluble materials were filtered off and then heated under reflux with HCl (200 cm^3, 25%w/w) for 12 h. The phthalic acid which formed on cooling was removed by filtration, and the filtrate was evaporated to small bulk and poured into absolute EtOH. The residue was washed several times with small amounts of cooled absolute EtOH, and dried in vacuo; Yield (70%) [16], Scheme 1.

Anal. Calc. for $C_{11}H_{21}Cl_3N_4O_2$: C, 38.00; H, 6.09; N, 16.11. Found: C, 38.22; H, 6.23; N, 16.31%. IR (KBr, cm^{-1}) 1343, 1527 $\nu(NO_2)$, 2710–3428 $\nu(NH_3Cl)$; ^1H NMR δ_H (D_2O, ppm) 3.57 (m, 8H), 4.48 (s, 2H), 7.84 (m, 3H), 8.26 (d, 1H); ^{13}C NMR δ_C (D_2O, ppm) 33.82, 50.13, 56.76, 123.67, 126.50, 132.32, 135.03, 135.51, 147.91.

*2.4.1.2. N1-(2-nitrobenzyl)-N1-(2-aminoethyl)propane-1,3-diamine threehydrochloride (**II**) and N1-(2-nitrobenzyl)-N1-(3-aminopropyl)propane-1,3-diamine threehydrochloride (**III**).* The compounds (**II**) and (**III**) can be readily prepared by the above procedure except using 2,3′-diphthalimidoethylpropylamine (3.77 g, 10 mmol) and/or 3,3′-diphthalimidodipropylamine (3.91 g, 10 mmol) instead of 2,2′-diphthalimidodiethylamine (3.63 g, 10 mmol).



(**II**): Yield (65%). *Anal.* Calc. for $C_{12}H_{23}Cl_3N_4O_2$: C, 39.85; H, 6.41; N, 15.49. Found: C, 40.01; H, 6.32; N, 15.40%. 2.5. Preparation of the complexes

2.5.1. General synthesis

A solution of NaOH (1.5 mmol) in methanol (10 cm^3) was added to a suspension of the appropriate triamine trihydrochloride (0.5 mmol) in methanol (10 cm^3). The mixture was stirred at room temperature for a few minutes then filtered, and the precipitate was washed well with methanol (10 cm^3). The washings and the filtrate were combined and this solution was added dropwise to a hot solution of $Cd(NO_3)_2 \cdot 6H_2O$ (0.5 mmol) and L_4 (0.5 mmol) in methanol (20 cm^3) over a period of 2 h. After refluxing the solution for 24 h on cooling the product was recovered as a white powder, which was recrystallized from methanol/ethanol [17].

2.5.2. $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$ or $[Cd(L_5)]^{2+}$ (1)

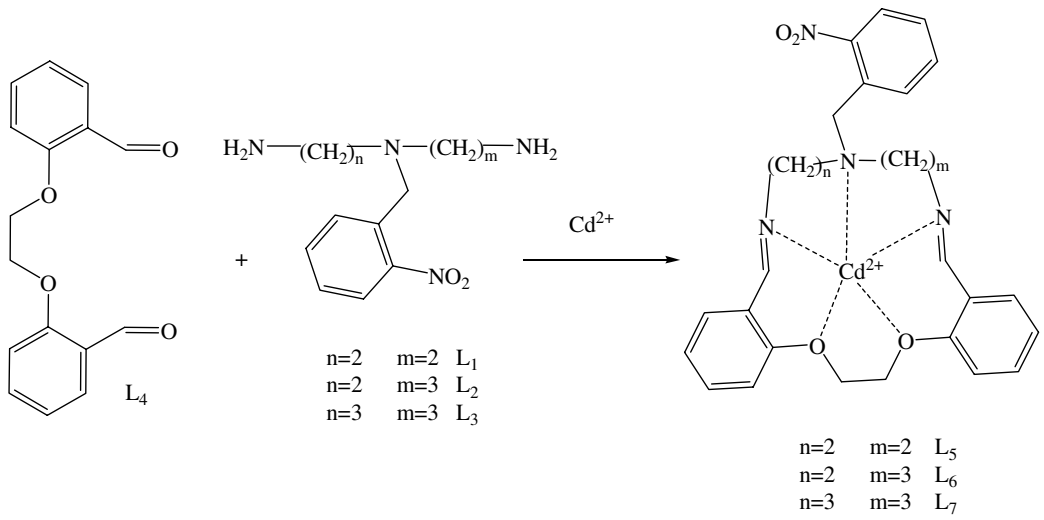
Yield 66%. *Anal.* Calc. for $C_{108}H_{112}Cd_5N_{26}O_{46}$: C, 44.94; H, 3.91; N, 11.16. Found: C, 44.51; H, 4.01; N, 11.31%. IR (KBr) 3060, 2923, 1644, 1360, 1601, 1527 cm^{-1}.

2.5.3. $[Cd(NO_3)(CH_3OH)L_5]ClO_4 \cdot C_2H_6O$ (2)

0.122 g (1 mmol) of $NaClO_4$ was added to a solution of $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$ (0.5 mmol) in methanol and was stirred for 15 min. The solution volume was then reduced to 10 ml by roto-evaporation and a yellow precipitate was formed. This was filtered off, washed with ether and dried in vacuo. Vapour diffusion of ether into a solution of the powder in methanol afforded pale yellow crystalline needles. Yield 55%. *Anal.* Calc. for $C_{30}H_{38}CdClN_5O_{13}$: C, 43.70; H, 4.65; N, 8.49. Found: C, 43.61; H, 4.57; N, 8.52%. IR (KBr) 3060, 2923, 1644, 1360, 1601, 1527, 1090, 624 cm^{-1}.

2.5.4. $[CdL_6](NO_3)_2$ (3)

Yield 55%. *Anal.* Calc. for $C_{28}H_{30}CdN_6O_{10}$: C, 46.52; H, 4.18; N, 11.62. Found: C, 46.61; H, 4.32; N, 11.72%. IR (KBr) 3070, 2871, 2918, 1636, 1523, 1356 cm^{-1}.



2.5.5. $[CdL_7](NO_3)_2$ (4)

Yield 53%. *Anal.* Calc. for $C_{29}H_{32}CdN_6O_{10}$: C, 47.26; H, 4.38; N, 11.40. Found: C, 47.31; H, 4.44; N, 11.45%. IR (KBr) 3088, 2900, 1645, 1523, 1352 cm^{-1}.

3. Results and discussion

3.1. Synthesis and characterization

The Schiff-base condensation of L_4 and (L_1, L_2 or L_3) in methanol in the presence of the appropriate hydrated Cd(II) salt and in a 1:1:1 mole ratio gave good yields of the analytically pure products $[CdL_5]^{2+}$, $[CdL_6]^{2+}$ and $[CdL_7]^{2+}$, respectively (Scheme 2). All of the complexes

Scheme 2.

were characterized by spectroscopic methods and furthermore by using different counter ions two types of crystalline $[CdL_5]^{2+}$ were isolated and characterized by X-ray crystallography. All the complexes are pale yellow, air-stable solids, moderately soluble in CH_3CN and DMSO. Our attempt to synthesize macrocyclic ligands in the absence of various metal ions were unsuccessful and cyclocondensation reactions did not occur, therefore we tried different metal ions in order to examine the effect of the template reaction on the occurrence of ring closure. Our results clearly demonstrate that the nature of the metal template determines the outcome of the Schiff-base condensation between the difunctional carbonyl component 2-[2-(2-formyl phenoxy)ethoxy]benzaldehyde (L_4) and a difunctional amine component.

Cd(II) facilitates the formation of macrocyclic products in 50-60% yield, attempts to obtain these macrocyclic compounds in the presence of Zn(II), Ni(II), Ag(II) and Cu(II) metal ions were unsuccessful and metal(II) polyamine complexes were the only final products (in high yield). The infrared spectra of the complexes confirm the formation of the macrocyclic compounds by the absence of bands characteristic of carbonyl and primary amine groups of the starting materials. The complexes exhibit a Schiff-base ν(C=N) vibration in the range 1636–1644 cm^{-1} and also bands at approximately 1524–1527 and 1353–1360 cm^{-1} associated with nitro groups. The shift of the imine band to higher wavenumbers upon complexation suggests coordination through the imine nitrogen atoms [21,22].

The NMR study of the cadmium nitrate complexes also provides strong evidence for the formation of the macrocyclic complexes. In order to obtain a suitable crystal for crystal structure determination we simply added $NaClO_4$ to the solution of $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)\ Cd(NO_3)(L_5)]\text{-}0.5Cd(NO_3)_4$ and we observed the replacement of the counter ion by the perchlorate ion and the disappearance of the nitrate bridge.

3.2. X-ray crystal structure

The molecular structures of $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$ (**1**) and $[Cd(NO_3)(CH_3OH)L_5]ClO_4$ (**2**) are shown in Figs. 1 and 2. Selected bond lengths and angles of **2** are given in Table 2. Although the crystal structure of $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$ (**1**) could not be refined to publication standard, the general features of the molecule were obvious from the direct methods solution (Fig. 1). However, the situation for the cadmium complex (**1**) is not straightforward owing to the presence of a $[Cd(NO_3)_4]^{2-}$ ion for each four complex cations in the solid state. Similar structures have been observed for other cadmium complexes [19,20]. The geometry of the complex is best considered as a slightly distorted triangular face dodecahedron structure. In complex **2** (Fig. 2), the Cd^{2+} ion is eight coordinate, being bonded to three nitrogen and two oxygen atoms, lying in an approximately pentagonal plane (N_3O_2), in addition the oxygen atom of methanol and two oxygen atoms of a terminal nitrate ion are also coordinated. The coordination of the nitrate group is asymmetric, with metal to oxygen distances of 2.322(3) and 2.776(3) Å. The only nearest structure to the L_5 complex which has been reported so far is a diamine macrocycle having no side chain [21]. The structure of this complex shows a distorted pentagonal bi-pyramidal coordination geometry with a N_3O_2pentagonal plane (**5**). Comparing the bond lengths for complexes **2** and **5** reveals a small (but significant) increase in bond lengths of the latter complex. Inspection of molecular models suggested that this increase may reflect a slightly poorer fit of the Cd(II) ion for the donor cavity of this larger ring size of macrocycle **5** (two C–N instead of two C=N). This contention is supported by X-ray structure analysis: bond lengths Cd(1)–O(3) and Cd(1)–O(4) of complex **2** are 0.291 and 0.057 Å shorter than those of complex **5**, respectively [21]. Charge balance for complex **2** is provided by a

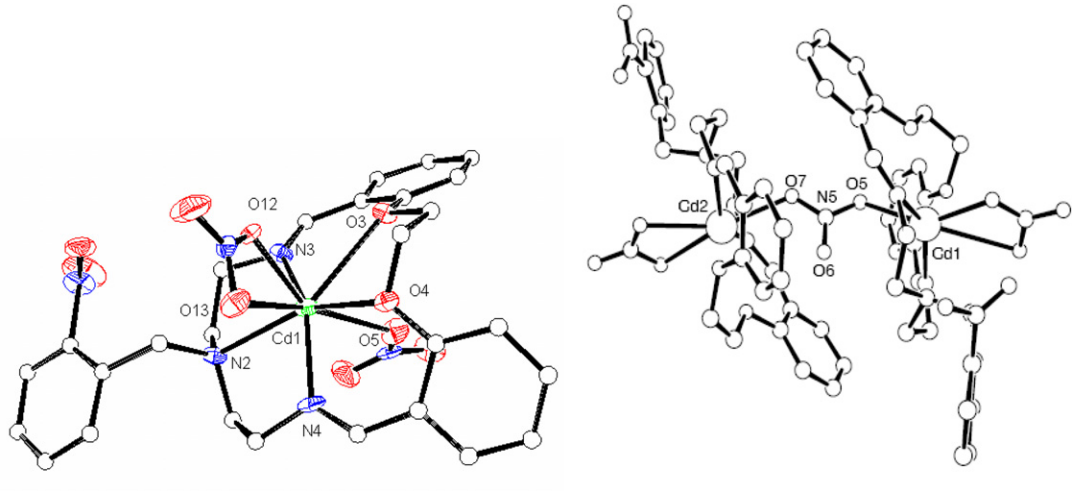


Fig. 1. Structure of the cation $[Cd(NO_3)(L_5)(\mu\text{-}NO_3)Cd(NO_3)(L_5)]0.5Cd(NO_3)_4$.

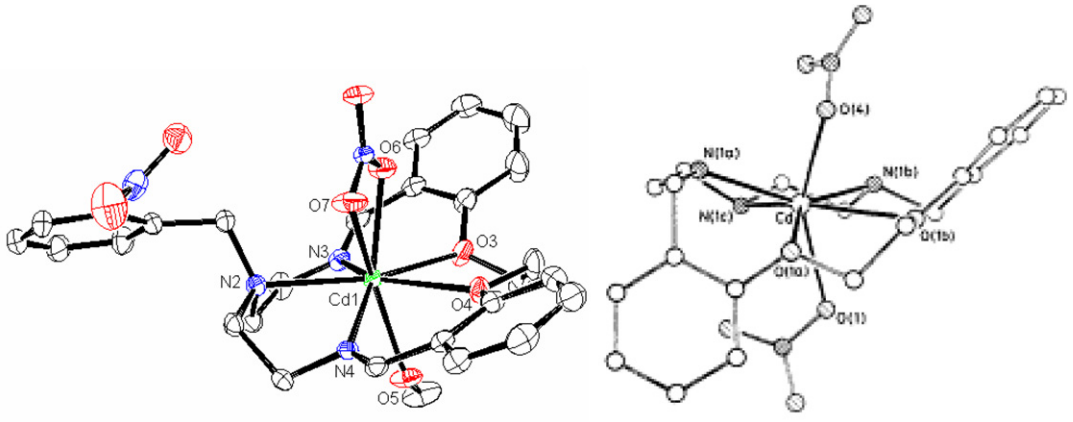

Fig. 2. ORTEP depiction of $[Cd(NO_3)(CH_3OH)\ L_5]^+$ (**2**) and a similar complex (**5**) [21].

Table 2
Important bond lengths (Å) and bond angles (°) for $[Cd(NO_3)(CH_3OH)\ L_5]ClO_4$

Bond	Bond length (Å)	Bond	Bond length (Å)
Cd(1)–N(2)	2.440(3)	Cd(1)–O(4)	2.557(2)

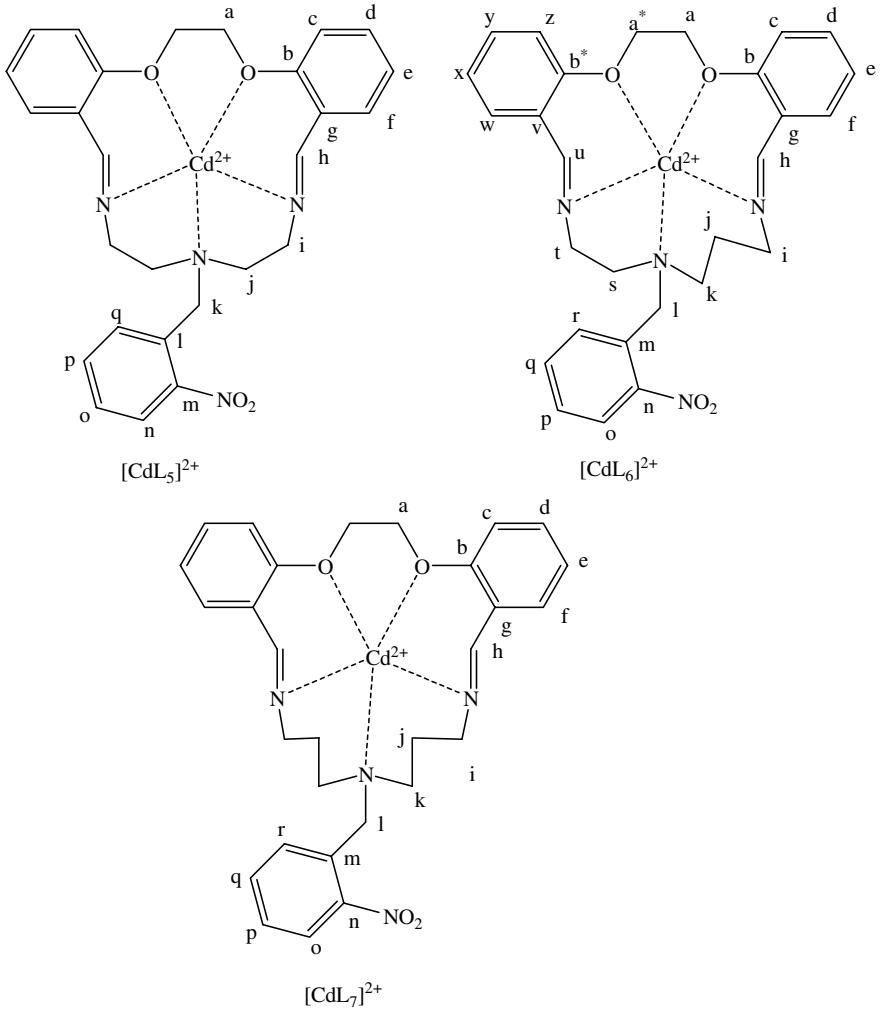
coordinated nitrate ion and a ClO_4^- ion. Bond lengths and angles are shown in Table 2. The sum of the angles subtended by the donor atoms at Cd is 362.76° and the plane containing N(4), N(2), N(3), O(3) and O(4) has a r.m.s. of 0.2684 and the metal atom is displaced from this towards the nitrate oxygen atoms, O(8) and O(7), by 0.204 Å. The r.m.s. values of the aromatic rings are 0.0079 and 0.0023 and the angle between their planes is 33.58°.



3.3. NMR studies

The ^1H as well as $^{13}C\{1H\}$ NMR data for $[CdL_n]^{2+}$ ($n = 5$, 6 and 7) dissolved in DMSO-d_6 are surveyed, using the lettering scheme shown in Scheme 3. The ^1H and ^{13}C signals were assigned using one- and two-dimensional ^1H–^1H COSY, ^1H–^{13}C HMQC and DEPT spectra.

The ^1H NMR spectrum of the complex $[CdL_6]^{2+}(C_1)$ shows a signal due to the H_j resonance at ca. 1.75 ppm, a signal due to the H_k resonance at ca. 2.38 ppm, a signal due to the H_s resonance at ca. 2.59 ppm, a signal due to the H_l resonance at ca. 3.77 ppm and a signal due to the H_a and $H_a{}^*$ resonances at ca. 4.43 ppm, also the related signals due to H_t and H_i are under the DMSO signal, identified using the HMQC spectrum. Two signals due to the ^1H imine resonance at ca. 8.63 and 8.76 ppm demonstrate the non-equivalence of the two imine (H_h and Hu) environments [18]. In the region characteristic of aromatic protons (6.99–7.83 ppm) five signals were found. Unfortunately, since the protons do not show scalar-coupling, we were not able to assign explicitly the signals to each of the aromatic systems present in the molecule. The ^{13}C NMR spectrum shows that the imine carbon atoms C_h and C_u (156.47, 156.76 ppm) and C_a and C_{a^*} (156.48, 156.76 ppm) are chemically non-equivalent. In the region corresponding to the signals of aromatic ring carbons (113.92–158.09 ppm), 17 peaks are observed, and two aromatic carbon atoms are equivalent, also in the region corresponding to the signals of aliphatic carbons (28.36 – 67.61 ppm), eight peaks are observed.

The ^1H NMR spectrum of the complex $[CdL_5]^{2+}(C_{2v})$ shows a signal due to the H_j resonance at ca. 2.66 ppm, a signal due to the H_i resonance at ca. 3.56, a signal due to the H_k resonance at ca. 3.83 ppm, a signal due to the H_a resonance at ca. 4.43 pm, and also only a single ^1H imine resonance at ca. 8.72 ppm, demonstrating the equivalence of the two imine environments. In the aromatic region (6.98–7.82 ppm) five signals were found, and since the protons do not show scalar-coupling we were not able to assign explicitly the signals to each of the aromatic systems present in the molecule.

The ^{13}C NMR spectrum shows that the imine carbon atoms, C_h (159.0 ppm) are equivalent. Also twelve lines are observed for the carbon atoms of the aromatic rings

Scheme 3.

(114.08–158.05 ppm). The ^{1}H NMR and ^{13}C NMR spectra of the complex $[CdL_7]^{2+}$ resemble those of complex $[CdL_5]^{2+}$.

Abstract

The reactions of 1 mol equiv. each of $[Ru(PPh_3)_3Cl_2]$ and *N*-(acetyl)-*N*′-(5-*R*-salicylidene)hydrazines (H_2ahsR, R = H, OCH_3, Cl, Br and NO_2) in alcoholic media afford simultaneously two types of complexes having the general formulae $[Ru(HahsR)(PPh_3)_2Cl_2]$ and $[Ru(ahsR)(PPh_3)_2Cl]$. The complexes have been characterized by elemental analysis, magnetic, spectroscopic and electrochemical measurements. Molecular structures of $[Ru(HahsH)(PPh_3)_2Cl_2]$ and $[Ru(ahsH)(PPh_3)_2Cl]$ have been confirmed by X-ray crystallography. In both species, the PPh_3 ligands are *trans* to each other. The bidentate $HahsH^-$ coordinates to the metal ion via the O atom of the deprotonated amide and the imine–N atom in $[Ru(HahsH)(PPh_3)_2Cl_2]$. In $HahsH^-$, the phenolic OH is involved in a strong intramolecular hydrogen bond with the uncoordinated amide N atom forming a seven-membered ring. In $[Ru(ahsH)(PPh_3)_2Cl]$, the tridentate $ahsH^{2-}$ binds to the metal ion via the deprotonated amide O, the imine N and the phenolate O atoms. In the electronic spectra, the green $[Ru(HahsR)(PPh_3)_2Cl_2]$ and brown $[Ru(ahsR)(PPh_3)_2Cl]$ complexes display several absorptions in the ranges 385–283 and 457–269 nm, respectively. Both complexes are low-spin and display rhombic EPR spectra in frozen solutions. Both types of complexes are redox active and display a quasi-reversible ruthenium(III) to ruthenium(II) reduction which is sensitive to the polar effect of the substituent on the chelating ligand. The reduction potentials are in the ranges −0.21 to −0.12 and −0.42 to −0.21 V (versus Ag/AgCl) for $[Ru(HahsR)(PPh_3)_2Cl_2]$ and $[Ru(ahsR)(PPh_3)_2Cl]$, respectively.

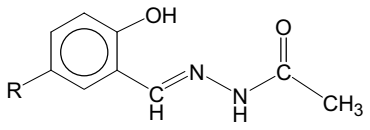
Keywords: Ruthenium(III) complexes; Acetylhydrazones; Crystal structures; Intramolecular hydrogen bond; Redox properties



1. Introduction

Coordination complexes of ruthenium are well known for their versatile electron-transfer and energy-transfer properties [1–21]. These characteristics enable ruthenium complexes to exhibit a wide range of reactivities. As a result a large variety of ruthenium complexes have found applications in various research areas, such as artificial photosynthesis, photomolecular devices, probes for biological macromolecules, oxidation catalysts and organic synthesis [8–21]. The continuing quest for new complexes of ruthenium is primarily due to their efficacy in such a broad range of applications. We have been working on organometallic and coordination complexes of ruthenium with amide–O coordinating acid hydrazide based Schiff bases [22–26]. Recently we have reported a diruthenium(III) complex $[Ru_2(\mu\text{-}OCH_3)_2(bhsH)_2(PPh_3)_2]$ and some mononuclear mixed-ligand ruthenium(III) complexes $[Ru(bhsR)(PPh_3)_2Cl]$ with *N*-(benzoyl)-*N*′-(5-*R*-salicylidene)hydrazines (H_2bhsR) [25]. The diruthenium(III) species could be isolated only for the unsubstituted ligand (R = H) due to its poor solubility in the methanolic reaction mixture. The cryomagnetic measurements revealed the antiferromagnetic nature of this diruthenium(III) complex. Scrutiny of the magnetic data and EPR features

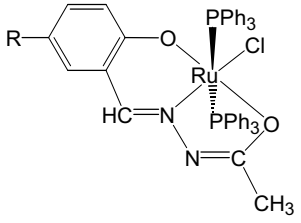
doi:10.1016/j.poly.2007.10.027



indicate that intermolecular rather than intramolecular metal ion spin-exchange is responsible for the antiferromagnetic behaviour of this complex. In search of similar unusual diruthenium(III) species, we have examined the ruthenium chemistry with *N*-(acetyl)-*N*′-(5-*R*-salicylidene) hydrazines (H_2ahsR), which are sterically less bulky analogues of H_2bhsR. However, instead of dinuclear species, two types of mononuclear ruthenium(III) complexes [Ru(HahsR)$(PPh_3)_2Cl_2$] and [Ru(ahsR)$(PPh_3)_2$Cl] have been obtained. Interestingly in the first type of species, the phenolic OH of $HahsR^-$ remains protonated and the ligand acts as a bidentate imine–N and deprotonated amide–O donor. In the second type of complex, $ahsR^{2-}$ is a typical tridentate phenolate–O, imine–N and deprotonated amide–O donor ligand. In the following account, we have described the syntheses, characterization and physical properties of these complexes. Molecular structures of representative complexes determined by X-ray crystallography have been reported.

H_2ahsR (R = H, Cl, Br, OCH_3, NO_2)

[Ru(HahsR)$(PPh_3)_2Cl_2$]

[Ru(ahsR)$(PPh_3)_2$Cl]

2. Experimental

2.1. Materials

The Schiff bases were synthesized in ~80% yield by condensation of 1 mol equiv. of acetylhydrazine and 1 mol. equiv. of the corresponding 5-substituted salicylaldehyde by following a reported procedure [27]. [Ru$(PPh_3)_3Cl_2$] was prepared using the method reported before [28]. All other chemicals and solvents were of analytical grade available commercially and were used as received.

2.2. Physical measurements

A Thermo Finnigon Flash EA1112 series elemental analyzer was used for the elemental (C, H, N) analysis data. Infrared spectra were recorded by using KBr pellets on a Jasco-5300 FT-IR spectrophotometer. A Cary 100 Bio UV/Vis spectrophotometer was used to record the electronic spectra. The X-band EPR spectra of the complexes in frozen (110 K) dichloromethane–toluene (1:1) solutions were recorded on a Jeol JES-FA200 spectrometer. Room temperature (300 K) magnetic susceptibilities were measured using a Sherwood Scientific balance. Diamagnetic corrections calculated from Pascal's constants [29] were used to obtain the molar paramagnetic susceptibilities. A Digisun DI-909 conductivity meter was used to measure the solution electrical conductivities. Cyclic voltammetric experiments with dichloromethane solutions of the complexes containing tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte were performed using a CH-Instruments model 620A electrochemical analyzer. The three electrode measurements were carried out at 298 K under a dinitrogen atmosphere with a platinum disk working electrode, a platinum wire auxiliary electrode and an Ag/AgCl reference electrode. The potentials reported in this work are uncorrected for junction contributions.

2.3. Synthesis of [Ru(HahsH)$(PPh_3)_2Cl_2$] (1) and [Ru(ahsH)$(PPh_3)_2$Cl] (6)

Solid [Ru$(PPh_3)_3Cl_2$] (260 mg, 0.28 mmol) was added to an ethanol solution (30 ml) of H_2ahsH (50 mg, 0.28 mmol) and stirred in air at room temperature for 8 h. The green solid that precipitated was collected by filtration, washed with *n*-hexane and dried in air. This solid was dissolved in a minimum amount of dichloromethane and transferred to a neutral aluminium oxide column (15 cm length). Elution with dichloromethane–*n*-hexane mixture (2:1) provided complex **1**. It was recrystallized from the same solvent mixture. Yield: 90 mg (37%).

The brown filtrate containing complex **6** was evaporated to dryness on a rotary evaporator. The solid obtained was dissolved in a minimum amount of dichloromethane, transferred to a neutral aluminium oxide column, eluted with dichloromethane and finally recrystallized from dichloromethane–*n*-hexane mixture (1:1). Yield: 115 mg (49%).

These complexes can also be synthesized in methanol instead of ethanol. However, the yields vary significantly due to the change of the solvent. In methanol the yield of **1** was 57% and that of **6** was 22%.

The other complexes [Ru(HahsR)$(PPh_3)_2Cl_2$] (R = OCH_3 (**2**), R = Cl (**3**), R = Br (**4**) and R = NO_2 (**5**)) and [Ru(ahsR)$(PPh_3)_2$Cl] (R = OCH_3 (**7**), R = Cl (**8**), R = Br (**9**) and R = NO_2 (**10**)) reported in this work were synthesized from [Ru$(PPh_3)_3Cl_2$] and the corresponding H_2ahsR (1:1 mol ratio) by following similar procedures as described above. In ethanol, the yields of **2**–**5** and **7**–**10** were in the ranges 24–35% and 44–50%, respectively. On the other hand, the yields of **2**–**5** and **7**–**10** in methanol were in the ranges 44–58% and 16–21%, respectively.

2.4. X-ray crystallography

Single crystals of **1** and **6** were grown by slow evaporation of their solutions in dichloromethane–acetonitrile–

n-hexane (1:1:1) mixture. In each case, unit cell parameters and the intensity data were obtained on a Bruker-Nonius SMART APEX CCD single crystal diffractometer, equipped with a graphite monochromator and a Mo Kα fine-focus sealed tube ($\lambda = 0.71073$ Å) operated at 2.0 kW. The detector was placed at a distance of 6.0 cm from the crystal. Data were collected at 298 K with a scan width of 0.3° in ω and an exposure time of 15 s/frame. SMART software was used for data acquisition and SAINT-PLUS software was used for data extraction [30]. The absorption corrections were performed with the help of the SADABS program [31]. Complex **1** crystallizes as **1**·$2CH_2Cl_2$ in the space group $P2_1/m$, while complex **6** crystallizes as **6**·CH_3CN in the space group $P2_1/n$. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures. All non-hydrogen atoms in both structures were refined using anisotropic thermal parameters. The positional parameters of the methyl group hydrogen atoms in **1**·$2CH_2Cl_2$ located in a difference Fourier map were refined with geometric restraints and $U_{iso}(H) = 1.5U_{eq}(C)$. The remaining hydrogen atoms in **1**·$2CH_2Cl_2$ and all the hydrogen atoms in **6**·CH_3CN were included in the structure factor calculations at idealized positions by using a riding model. The SHELX-97 programs [32] were used for structure solution and refinement. The ORTEX6A package [33] was used for molecular graphics. Selected crystallographic data are listed in Table 1.

3. Results and discussion

3.1. Synthesis and characterization

Two types of complexes are produced in the reactions of [Ru(PPh_3)$_3Cl_2$] with *N*-(acetyl)-*N*′-(5-*R*-salicylidene) hydrazines (H_2ahsR, R = H, OCH_3, Cl, Br and NO_2) in ethanol or methanol. Elemental analysis data (Table 2) for these two varieties of complexes are consistent with the general formulae [Ru(HahsR)(PPh_3)$_2Cl_2$] and [Ru(ahsR)(PPh_3)$_2$Cl]. Each of the complexes having the formula [Ru(HahsR)(PPh_3)$_2Cl_2$] precipitates from the reaction mixture as a green solid due to its poor solubility, while the brown species of formula [Ru(ahsR)-(PPh_3)$_2$Cl] remain in solution. In ethanol, the yields (24–37%) of [Ru(HahsR)(PPh_3)$_2Cl_2$] were less than the yields (44–50%) of [Ru(ahsR)(PPh_3)$_2$Cl]. In contrast, [Ru(HahsR)(PPh_3)$_2Cl_2$] were obtained in significantly larger yields (44–58%) compared to the yields (16–22%) of [Ru(ahsR)(PPh_3)$_2$Cl] in methanol. All the complexes are electrically non-conducting in solution. The room temperature (298 K) magnetic moments of the complexes are within 1.80–2.01 μ_B (Table 2). Thus the oxidation state of the metal ion in each complex is +3 and it is low-spin. In all likelihood atmospheric oxygen is responsible for the oxidation of the metal ion during the synthesis of all these complexes.

3.2. Spectroscopic features

None of the infrared spectra of the complexes display the characteristic bands associated with the C=O and N–H stretches of the amide functionality, indicating the enolate form of it in the metal coordinated Schiff base [34,35]. All the spectra are also devoid of any band assignable to the phenolic OH stretch. Although deprotonation of phenolic OH is expected for [Ru(ahsR)(PPh_3)$_2$Cl] (**6**–**10**), it should be protonated in [Ru(HahsR)(PPh_3)$_2Cl_2$] (**1**–**5**) as the amide functionality in $HahsR^-$ is in the enolate form. Perhaps involvement of the phenolic OH in strong intramolecular hydrogen bonding (vide infra) is the primary reason for the absence of the OH stretch in the spectra of **1**–**5**. All the complexes display a medium to strong band in the range 1578–1595 cm^{-1}. This band is assigned to the conjugated –C=N–N=C– fragment of the tridentate ligand [22–26]. The presence of ruthenium bound PPh_3 is indicated by three strong bands at ~745, ~694 and ~516 cm^{-1}. [Ru(PPh_3)$_3Cl_2$] and complexes containing {Ru(PPh_3)$_2$} are known to display similar bands [24–26,36].

Dichloromethane solutions of the complexes were used to record the electronic spectra. The spectral data are listed in Table 2. The spectra of the green complexes (**1**–**5**) display primarily three strong absorptions in the wavelength ranges 385–358, 340–300 and 288–283 nm. The spectral profiles of the brown complexes (**6**–**10**) are also very similar. Four strong absorptions are observed in the wavelength ranges 457–413, 375–354, 329–213 and

[b] At 298 K.
[c] Shoulder.

269–276 nm. In both cases, the low-energy absorptions are likely to be due to the ligand-to-metal charge transfer transitions and the high-energy absorptions are possibly due to ligand centred transitions [23,25,26,36].

The EPR spectral profiles of **1**–**10** in frozen (110 K) dichloromethane–toluene (1:1) solutions are very similar. The EPR data are listed in Table 3 and representative spectra are shown in Fig. 1. The complexes display three distinct signals indicating the distortion of the $NOCl_2P_2$ (in **1**–**5**) and the NO_2ClP_2 (in **6**–**10**) coordination spheres around the metal centres from octahedral symmetry. These distortions can be calculated in terms of axial (Δ) and rhombic (V) components. The axial distortion splits the t_2 level into "a" and "e" and the rhombic component again splits "e" into non-degenerate components (Fig. 1). In addition to Δ and V, spin–orbit coupling also affects the energies of these levels. Thus two ligand-field transitions of energies ΔE_1 and ΔE_2 ($\Delta E_1 < \Delta E_2$) are possible within these three levels. The distortion parameters and the transition energies have been calculated with the help of the EPR g-values and the g tensor theory for low-spin d^5 metal ion complexes [37]. In all the complexes, the axial distortion is larger than the rhombic distortion (Table 3). Thus

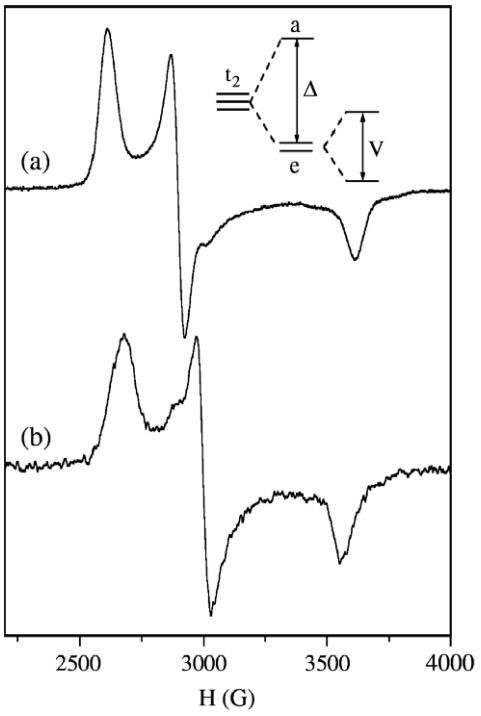

Fig. 1. EPR spectra of: (a) [Ru(HahsNO$_2$)(PPh$_3$)$_2$Cl$_2$] (**5**) and (b) [Ru(ahsNO$_2$)(PPh$_3$)$_2$Cl] (**10**) in frozen (110 K) dichloromethane–toluene (1:1) solutions and the t_2 splitting pattern.

7	2.37	2.13	1.87	5.578	−3.787	3.812	7.670
8	2.39	2.15	1.86	5.310	−3.369	3.752	7.206
9	2.39	2.15	1.85	5.091	−3.158	3.643	6.891
10	2.43	2.18	1.83	4.756	−2.758	3.511	6.374

[a] In 1:1 dichloromethane–toluene at 110 K.
[b] The calculations are based on the spin–orbit coupling constant (λ) = 1000 cm^{-1}.

the energy-level order is $d_{xy} > d_{xz}$, d_{yz} with the unpaired electron in d_{xy}. Presumably the *trans* binding of the two PPh_3 ligands is primarily responsible for the large and positive axial distortion [24–26,36,38] in these complexes. Such axial distortion is clearly evident in the X-ray structures of **1** and **6** (vide infra). Interestingly there are small but definite differences in the g-values and hence in the Δ, V, ΔE_1 and ΔE_2 values (Fig. 1 and Table 3) for each pair of [Ru(HahsR)(PPh$_3$)$_2$Cl$_2$] and [Ru(ahsR)(PPh$_3$)$_2$Cl] complexes. In general, these values suggest that the extent of distortion is less in **1**–**5** in comparison with that in **6**–**10**. The ΔE_1 and ΔE_2 transitions for [Ru(HahsR)(PPh$_3$)$_2$Cl$_2$]

(**1**–**5**) are expected to occur in the ranges 3324–3470 cm^{-1} (3008–2882 nm) and 5554–5749 cm^{-1} (1800–1739 nm), respectively. On the other hand, for $[Ru(ahsR)(PPh_3)_2Cl]$ (**6**–**10**) the ΔE_1 transition is predicted within 3511–3812 cm^{-1} (2848–2623 nm) and the ΔE_2 transition should appear in the range 6374–7670 cm^{-1} (1568–1304 nm). Further scrutiny of the Δ/V ratios (1.97–2.24 for **1**–**5** and 1.47–1.72 for **6**–**10**) reveals that the rhombic component (V) of the distortion is less in **1**–**5** when compared with that in **6**–**10**. It is very likely that the larger constraint imposed by the rigid tridentate [39] $ahsR^{2-}$ in **6**–**10** compared to the constraint imposed by the bidentate $HahsR^-$ in **1**–**5** is the main reason for the observed differences in the extent of distortions and its rhombic components in these two types of complexes.

3.3. Description of the molecular structures

The molecular structures of **1** and **6** determined by X-ray crystallography are depicted in Figs. 2 and 3, respectively. The bond parameters associated with the metal centres are listed in Table 4. In **1**, the metal centre is in a distorted octahedral $NOCl_2P_2$ coordination sphere assembled by the bidentate deprotonated amide–O and the imine–N donor $HahsH^-$, two mutually *cis* oriented chlorides and two bulky PPh_3 molecules which are *trans* to each other. The asymmetric unit of **1**·$2CH_2Cl_2$ contains half of the complex molecule and a CH_2Cl_2 molecule. Both halves of **1** are related by a crystallographic mirror plane. The *cis*-$\{Ru(HahsH)Cl_2\}$ moiety is perfectly planar as it resides on the mirror plane. There is a strong intramolecular hydrogen bond involving the phenolic-OH and the uncoordinated amide–N atom of $HahsH^-$ (Fig. 2). The O2···N1 distance and the O2–H2···N1 angle are 2.502(6) Å and 171°, respectively. In the case of **6**, the asymmetric unit contains a full complex molecule and a CH_3CN molecule. The meridionally

spanning tridentate phenolate–O, imine–N and deprotonated amide–O donor $ahsH^{2-}$ and the chloride form an NO_2Cl square-plane around the metal centre in **6**. The bulky PPh_3 molecules occupy the remaining two axial positions. The *trans* P–Ru–P bond angles (Table 4) in **1** and **6** are very close to the ideal value of 180°. All other *trans* bond angles in **1** and **6** are in the range 167.28(11)–171.92(12)°. In both complexes, the chelate bite angles for the five-membered ring formed by the amide–O and the imine–N centres are unexceptional and very similar (76.92(14)° for **1** and 77.56(16)° for **6**). The chelate bite angle (90.87(16)°) for the six-membered ring formed by the phenolate–O and the imine–N centres in **6** is very close to the ideal value for a *cis* bond angle. The remaining *cis* bond angles in **1** and **6** are within 89.2(3)–99.18(4)°. As expected, the two *trans* Ru–P bond lengths are significantly longer than the four equatorial bond lengths, indicating a large axial distortion in both complexes (Table 4). The Ru–O(amide) bond lengths in **1** (2.023(3) Å) and **6** (2.028(4) Å) are essentially identical. However, the Ru–N(imine) bond, which is *trans* to the chloride in both **1** and **6**, is significantly longer (2.072(4) Å) in **1**, containing the bidentate $HahsH^-$, than that (2.005(4) Å) in **6**, containing the tridentate $ahsH^{2-}$. Most likely the rigid tridentate binding mode of $ahsH^{2-}$ and hence the constraint imposed on the imine–N is the main factor for shortening of the Ru–N(imine) bond in **6**. The more effective *trans* influence of the chloride due to the less rigid bidentate binding mode of $HahsH^-$ and the participation of the adjacent amide–N in a strong intramolecular O–H···N hydrogen bond in **1** may also contribute to the observed difference in the Ru–N(imine) bond lengths. Both Ru–Cl bond lengths (2.3289(13) and 2.3282(13) Å) in **1** are very similar but shorter than the Ru–Cl bond length (2.3630(16) Å) in **6**. This is perhaps due to the stronger binding of the imine–N *trans* to the chloride in **6** in comparison with that in **1**. In general, all the bond lengths in both complexes are comparable with the bond lengths reported for ruthenium(III) complexes having the same coordinating atoms [23,25,26,36,38,40,41].

3.4. Electrochemical properties

Cyclic voltammetric measurements with dichloromethane solutions of **1**–**10** have been used to study the electron transfer properties. The potential data are listed in Table 5. Representative cyclic voltammograms are shown in Fig. 4. All the complexes display a quasi-reversible ruthenium(III) to ruthenium(II) reduction in the potential range −0.42 to −0.12 V. In each case, the one-electron stoichiometry of the observed response is confirmed by comparing the current heights with known one-electron redox processes under identical experimental conditions [22–26,36]. The ruthenium(III) to ruthenium(II) reduction potential for $[Ru(HahsR)(PPh_3)_2Cl_2]$ is higher than that for the corresponding $[Ru(ahsR)(PPh_3)_2Cl]$. The potentials for complexes **1**–**5** are in the range −0.21 to −0.12 V, while those for complexes **6**–**10** are within −0.42 to −0.21 V (Table 5). Most likely the more basic phenolate–O coordination in **6**–**10** (NO_2ClP_2 coordination sphere) instead of the less basic chloride coordination in **1**–**5** ($NOCl_2P_2$ coordination sphere) is the primary reason for the observed differences in potentials for these two types of complexes.

In both types of complexes, the trend in the ruthenium(III) to ruthenium(II) reduction potentials reflects the effect of the electronic nature of the substituents (R) on the salicylidene moieties of $HahsR^-$ and $ahsR^{2-}$. In the case of $[Ru(HahsR)(PPh_3)_2Cl_2]$ (**1**–**5**), the $E_{1/2}$ values

Table 5

[a] In dichloromethane solution (298 K) at a scan rate of 50 mV s^{-1}.
[b] $E_{1/2} = (E_{pa} + E_{pc})/2$, where E_{pa} and E_{pc} are anodic and cathodic peak potentials, respectively; $\Delta E_p = E_{pa} - E_{pc}$.

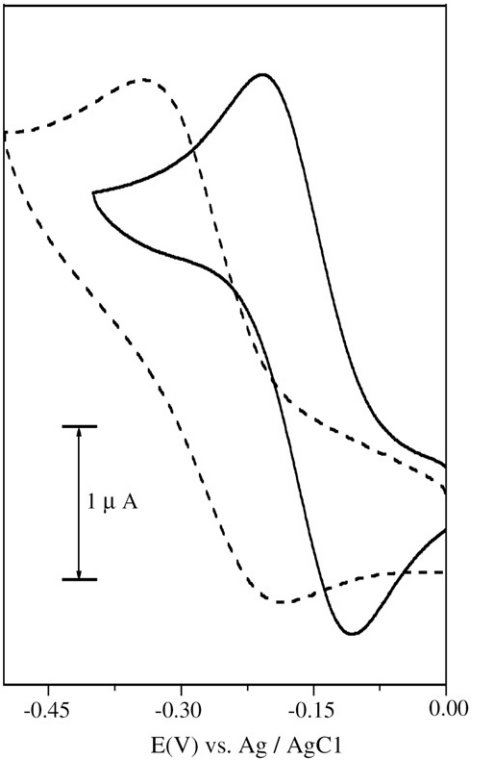

Fig. 4. Cyclic voltammograms (scan rate 50 mV s^{-1}) of $[Ru(HahsBr)(PPh_3)_2Cl_2]$ (**4**) (—) and $[Ru(ahsBr)(PPh_3)_2Cl]$ (**9**) (---). In each case, the solvent is dichloromethane (0.1 M TBAP) and the electrode is platinum.

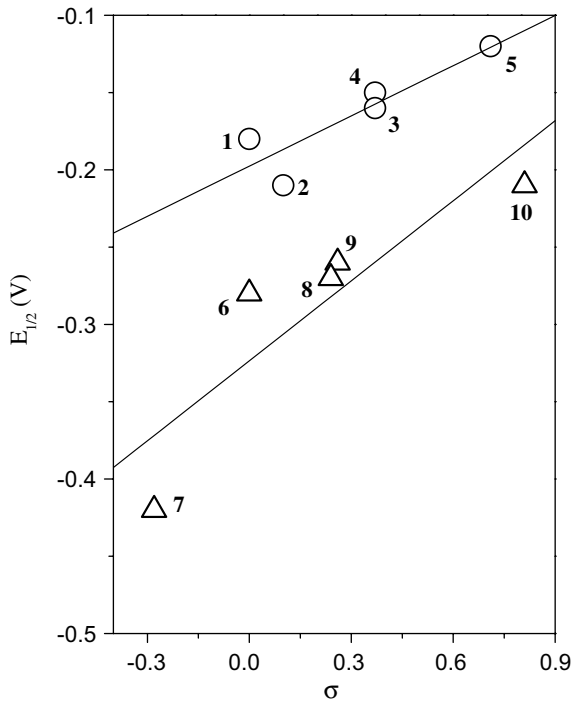

Fig. 5. Correlations between the $E_{1/2}$ values for the ruthenium(III) to ruthenium(II) reductions and the Hammett substituent constants for [Ru(HahsR)$(PPh_3)_2Cl_2$] (○) and [Ru(ahsR)$(PPh_3)_2Cl$] (△). The straight lines represent the linear least-squares fits.

are plotted against the Hammett constants (σ_m) [42] for the substituents (R) which are at the *meta*-position with respect to the metal coordinated azomethine (–CH=N–) group. On the other hand, the $E_{1/2}$ values of [Ru(ahsR)$(PPh_3)_2Cl$] (**6**–**10**) are plotted against the Hammett constants (σ_p) [42] for the substituents (R) which are *para* to the metal coordinated phenolate–O. In both cases, reasonable linear relationships ($R = 0.89$ and 0.88) are observed (Fig. 5). We have also plotted the $E_{1/2}$ values of **6**–**10** against the σ_m values as the substituent is *meta* to the coordinated azomethine–N. However, the linear least-squares fit of this plot is poor ($R = 0.68$) in comparison with that of the $E_{1/2}$ against σ_p plot. It may be noted that the two lines in Fig. 5 are not parallel. This indicates that there is a difference in the reaction constants (ρ). To calculate the values of ρ, we have used the relation $\Delta E_{1/2} = \rho\sigma$ where $\Delta E_{1/2}$ is the shift of $E_{1/2}$ of a particular complex from the $E_{1/2}$ of the complex having R = H [43]. The ρ values are 0.14(3) and 0.19(5) V for [Ru(HahsR)$(PPh_3)_2Cl_2$] and [Ru(ahsR)$(PPh_3)_2Cl$], respectively. Thus the ruthenium(III) to ruthenium(II) reduction in [Ru(ahsR)$(PPh_3)_2Cl$] is slightly more susceptible to the polar effects of the substituents compared to that in [Ru(HahsR)$(PPh_3)_2Cl_2$].

4. Conclusion

Formation of two types of ruthenium(III) complexes [Ru(HahsR)$(PPh_3)_2Cl_2$] ($HahsR^-$ is N,O-donor) and [Ru(ahsR)$(PPh_3)_2Cl$] ($ahsR^{2-}$ is O,N,O-donor) in the reactions of [Ru$(PPh_3)_3Cl_2$] with *N*-(acetyl)-*N*′-(5-*R*-salicylidene)hydrazines (H_2ahsR) in alcohol has been demonstrated. It is very likely that [Ru(HahsR)$(PPh_3)_2Cl_2$] is the intermediate during the formation of [Ru(ahsR)-$(PPh_3)_2Cl$]. Interestingly in [Ru(HahsR)$(PPh_3)_2Cl_2$] the less acidic amide functionality is deprotonated and coordinated through the O-atom while the more acidic phenol remains protonated. Earlier we have observed that in complexes of monoanionic tridentate acid hydrazide based Schiff bases, the more acidic functionality such as phenol or enol is deprotonated and bonded to the metal ion while the protonated amide functionality binds the metal ion through its O-atom [23,44,45]. It may be noted that these complexes do not contain bulky ancillary ligands. Perhaps during the formation of [Ru(HahsR)$(PPh_3)_2Cl_2$] from [Ru$(PPh_3)_3Cl_2$] the ligand first binds the metal centre through the acetyl end instead of the salicylaldimine end due to the steric constraints imposed by the bulky phosphine ligands of the starting material. The strong intramolecular phenolic-OH···N(deprotonated amide) hydrogen bond may also have a partial role in the observed binding mode of $HahsR^-$ in [Ru(HahsR)$(PPh_3)_2Cl_2$].

The one-electron paramagnetic complexes in frozen (110 K) dichloromethane–toluene (1:1) solutions display rhombic EPR spectra. Analysis of the EPR data shows that the rhombic component of the distortion in [Ru-(HahsR)$(PPh_3)_2Cl_2$] is significantly less than that in [Ru(ahsR)$(PPh_3)_2Cl$]. In the cyclic voltammetry, all the complexes display a ruthenium(III) to ruthenium(II) reduction response. The reduction potentials indicate that the reduction of the metal centre in [Ru(ahsR)$(PPh_3)_2Cl$] is difficult and more susceptible to the polar effects of the substituents (R) in comparison with that in [Ru(HahsR)$(PPh_3)_2Cl_2$].

5. Supplementary material

CCDC 661515 and 661516 contain the supplementary crystallographic data for **1**·$2CH_2Cl_2$ and **6**·CH_3CN. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Available online 3 December 2007

Abstract

Eight new antimony (III) complexes containing dithiocarbamate ligands $(R_2NCS_2)_2SbBr$ [$R_2NCS_2 = OC_4H_8NCS_2$ (**1**), $C_2H_5NC_4H_8NCS_2$ (**2**), Me_2NCS_2 (**3**), $C_4H_8NCS_2$ (**4**)] and $(R_2NCS_2)_3Sb$[$R_2NCS_2 = C_5H_{10}NCS_2$ (**5**), Bz_2NCS_2 (**6**), Et_2NCS_2 (**7**), $(HOCH_2CH_2)_2NCS_2$ (**8**)] have been synthesized by the reactions of antimony (III) halides with dithiocarbamate ligands in 1:2 or 1:3 stoichiometries. All the complexes have been characterized by elemental analysis, melting point as well as spectral [IR and NMR (^1H and ^{13}C)] studies. The crystal structures of complexes **1**, **5** and **8** have been determined by X-ray single crystal diffraction, and their electrochemical character has also been studied.

The structure of complex **1** shows that the five-coordinated antimony (III) atom adopts a distorted trigonal bipyramidal geometry. Furthermore, the supramolecular structure of **1** consists of a one-dimensional linear molecular chain which is built up by intermolecular Sb···S and S···S weak interactions. In complex **5**, the central antimony atom is six-coordinated with a distorted octahedral geometry and the supramolecular structure is constructed by C–H···S weak hydrogen bonds. The structure of complex **8** is stabilized by strong intermolecular hydrogen bonds between the ethanolic hydrogens (O–H).

1. Introduction

Dialkyl-substituted dithiocarbamate anions have been proved to be highly versatile chelating agents for the separation of metals as metal chelates using gas chromatography [1]. Their performance in liquid–liquid extraction and other analytical procedures [2] make them attractive for the determination of metals using gas chromatography [3]. Some dialkyl-substituted dithiocarbamate salts have also shown interesting biological effects which include anti-alkylation [4,5] or anti-HIV properties [6,7]. With regard to structural studies, dithiocarbamate ligands often display unsymmetrical bidentate coordination patterns. Besides that, the ability of dithiocarbamate ligands to bind to metals has been known for many years [8], forming chelates with virtually all transition elements [9]. However, the chemistry of 1,1,-dithiochelates of main group elements is less widely explored than that of transition metals [8], especially the synthesis and structures of antimony (III) complexes with dithiocarbamate.

On the other hand, antimony complexes have been reported with good cytotoxicity and antitumor activities [10], especially Takahashi et al. have reported some antimony complexes can affect the repair of a DNA-double strand break [10c]. As a continuation of our interest in sulfur-containing ligands, we have synthesized eight new antimony (III) complexes with dithiocarbamates. All the complexes have been characterized by elemental analyses, IR spectra and NMR (^1H and ^{13}C). The crystal structures of complexes **1**, **5** and **8** have been determined by X-ray diffraction and their electrochemical character has also been studied.

2. Experimental

2.1. Materials and instrumentation

Solvents were dried and distilled before use. The elemental analyses were performed on a PE-2400-II elemental analyzer. IR spectra were recorded on a Nicolet-460 spectrophotometer as KBr discs. X-ray measurements were made on a Bruker Smart-1000 CCD diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury Plus-400 NMR spectrometer and the chemical shifts were reported in ppm relative to tetramethylsilane (TMS) in $CDCl_3$. The electrochemical characterisation was carried out on CHI900B.

2.2. Syntheses of dithiocarbamate

To a stirred solution of dialkyl-secondary amine (0.05 mol) in ethanol or methanol (5 ml) was added, at less than 4 °C, carbon disulfide (3.1 ml, 0.052 mol) and sodium hydroxide (50% aqueous solution, 4 ml). After stirring for 4–5 h, evaporation of volatiles was performed without heating. Pure [Na(R_2dtc)] was obtained by recrystallization from ethanol (or methanol). Yield: 80–90%:

$$CS_2 + R_2NH + NaOH \xrightarrow[\text{or } CH_3OH]{CH_3CH_2OH} R_2NCS_2Na + H_2O$$

where $R_2NCS_2Na = OC_4H_8NCS_2Na$, $C_2H_5NC_4H_8NCS_2Na$, Me_2NCS_2Na, $C_4H_8NCS_2Na$, $C_5H_{10}NCS_2Na$, Bz_2NCS_2Na, Et_2NCS_2Na $(HOCH_2CH_2)_2NCS_2K$.

2.3. Syntheses of complexes *1–8*

2.3.1. Preparation of $(OC_4H_8NCS_2)_2SbBr$ (*1*)

Morpholinyldithiocarbamate (74.2 mg, 0.4 mmol) was added to a stirring solution containing $SbBr_3$ (72.3 mg, 0.2 mmol) in acetone (25 ml). After stirring for 5 h at room temperature a yellow solution was obtained and then filtered. The solvent was gradually removed by evaporation under vacuum until a yellow solid was obtained. The solid was recrystallized from ethanol/dichloromethane (1:1) to give yellow crystals, yield 80%, m.p. 235 °C. *Anal.* Calc. for $C_{10}H_{16}BrN_2O_2S_4Sb$ (Mw = 526.15): C, 22.83; H, 3.06; N, 5.32. Found: C, 22.67; H, 3.17; N, 5.43%. IR (KBr) ν(cm^{-1}): 3431, 2973, 2927, 1634, 1569, 1495, 1383, 1353, 1295, 1266, 1203, 1140, 1091, 987, 880, 776, 564, 412. ^{1}H NMR ($CDCl_3$) δ: 4.08 (8H, t, OCH_2), 3.68 (8H, s, NCH_2). ^{13}C NMR ($CDCl_3$) δ: 198.43 (CS_2), 61.01 (CH_2N), 45.21 (CH_2O).

2.3.2. Preparation of $(C_2H_5NC_4H_8NCS_2)_2SbBr$ (*2*)

Complex **2** was prepared in the same way as **1**. The yellow solid was recrystallized from chloroform to give yellow crystals, yield 85%, m.p. 240 °C. *Anal.* Calc. for $C_{14}H_{26}BrN_6S_4Sb$ (Mw = 608.32): C, 27.64; H, 4.31; N, 13.82; S, 21.08. Found: C, 27.51; H, 4.50; N, 13.96; S, 21.25%. IR (KBr) ν(cm^{-1}): 3415, 2961, 2930, 1645, 1548, 1479, 1375, 1310, 1132, 1071, 994, 839, 619, 545, 419. ^{1}H NMR ($CDCl_3$) δ: 3.76 (16H, t, NCH_2CH_2N), 2.52 (4H, m, NCH_2), 2.76 (6H, t, CH_3). ^{13}C NMR ($CDCl_3$) δ: 197.13 (CS_2), 51.96, 51.62 (NCH_2CH_2N), 43.59, 11.92 (NCH_2CH_3).

2.3.3. Preparation of $(Me_2NCS_2)_2SbBr$ (*3*)

Complex **3** was prepared in the same way as **1**. The yellow solid was recrystallized from ethanol to give yellow crystals, yield 85%, m.p. 258 °C. *Anal.* Calc. for $C_6H_{12}BrN_2S_4$ Sb (Mw = 442.10): C, 16.30; H, 2.74; N, 6.34; S, 29.01. Found: C, 16.42; H, 2.63; N, 6.26; S, 29.12%. IR (KBr) ν(cm^{-1}): 3420, 2968, 2920, 1630, 1562, 1485, 1379, 1342, 1135, 985, 850, 530, 415. ^{1}H NMR ($CDCl_3$) δ: 3.02 (12H, s, NCH_3). ^{13}C NMR ($CDCl_3$) δ: 196.70 (CS_2), 46.45 (NCH_3).

2.3.4. Preparation of $(CH_3NC_4H_8NCS_2)_2SbBr$ (*4*)

Complex **4** was prepared in the same way as **1**. The yellow solid was recrystallized from ethanol to give yellow crystals, yield 85%, m.p. 250 °C. *Anal.* Calc. for $C_{12}H_{22}BrN_6S_4Sb$ (Mw = 580.27): C, 24.84; H, 3.82; N, 14.48; S, 22.10. Found: C, 24.70; H, 3.69; N, 14.59; S, 21.95%. IR (KBr) ν(cm^{-1}): 3426, 2964, 2923, 1640, 1546, 1481, 1385, 1329, 1141, 991, 842, 560, 416. ^{1}H NMR ($CDCl_3$) δ: 2.72 (6H, s, NCH_3), 4.08, 4.22 (16H, t, NCH_2CH_2N). ^{13}C NMR ($CDCl_3$) δ: 198.61 (CS_2), 53.52, 50.64, 47.60 (NCH_2, NCH_3).

2.3.5. Preparation of $[(C_5H_{10}NCS_2)_3Sb]_2 \cdot CH_2Cl_2$ (*5*)

Dithiopiperidylcarbamate (109 mg, 0.6 mmol) was dissolved in 10 ml of acetone. $SbCl_3$(45.6 mg, 0.2 mmol) dissolved in acetone (5 ml) was added dropwise to the complex in solution with continuous stirring. The reaction mixture was stirred for 5 h at room temperature. Then the solvent was gradually removed by evaporation under vacuum until a yellow solid was obtained. Single crystals suitable for X-ray diffraction analysis were obtained from ethanol/dichloromethane (1:1) solution, yield 90%, m.p. 258 °C. *Anal.* Calc. for $C_{37}H_{62}C_{l2}N_6S_{12}Sb_2$ (Mw = 1290.05): C, 34.44; H, 4.84; N, 6.51; S, 29.82. Found: C, 34.59; H, 4.68; N, 6.70; S, 29.67%. IR (KBr) ν(cm^{-1}): 3423, 2970, 2918, 1635, 1543, 1495, 1468, 1380, 1334, 1137, 1058, 992, 975, 846, 546, 423. ^{1}H NMR ($CDCl_3$) δ: 1.69, 1.56 (18H, t, CH_2), 3.63 (12H, m, NCH_2). ^{13}C NMR ($CDCl_3$) δ: 198.06 (CS_2), 51.93 (NCH_2), 29.71, 24.82 (CH_2).

2.3.6. Preparation of $(Bz_2NCS_2)_3Sb$ (*6*)

Complex **6** was prepared in the same way as **5**. The yellow solid was recrystallized from acetonitrile to give yellow crystals, yield 85%, m.p. 285 °C. *Anal.* Calc. for $C_{45}H_{42}N_3S_6$ Sb (Mw = 938.98): C, 57.56; H, 4.51; N, 4.48; S, 20.49. Found: C, 57.41; H, 4.68; N, 4.56; S, 20.63%. IR (KBr) ν(cm^{-1}): 3424, 2965, 2925, 1630, 1556, 1483, 1372, 1325, 1136, 996, 871, 556, 420. ^{1}H NMR

2.3.7. Preparation of $(Et_2NCS_2)_3Sb$ (7)

Complex **7** was prepared in the same way as **5**. The yellow solid was recrystallized from acetonitrile to give yellow crystals, yield 85%, m.p. 270 °C. *Anal.* Calc. for $C_{15}H_{30}N_3S_6Sb$ (Mw = 566.57): C, 31.80; H, 5.34; N, 7.42; S, 33.96. Found: C, 31.97; H, 5.18; N, 7.56; S, 34.12%. IR (KBr) ν(cm^{-1}): 3428, 2967, 2923, 1632, 1558, 1492, 1379, 1346, 1269, 1148, 983, 884, 845, 562, 425. ^{1}H NMR ($CDCl_3$) δ: 1.23 (18H, t, CH_3), 3.68 (12H, m, NCH_2). ^{13}C NMR ($CDCl_3$) δ: 197.19 (CS_2), 49.69, 43.61 (NCH_2CH_3).

2.3.8. Preparation of $[(HOCH_2CH_2)_2NCS_2]_3Sb$ (8)

N,*N*′-Iminodiethanoldithiocarbamate (133 mg, 0.6 mmol) was dissolved in 10 ml of THF. $SbBr_3$ (72.3 mg, 0.2 mmol) dissolved in tetrahydrofuran (5 ml) was added dropwise to the complex in solution with continuous stirring. The reaction mixture was stirred for 5 h at room temperature. Then the solvent was gradually removed by evaporation under vacuum until a yellow solid was obtained. Single crystals suitable for X-ray diffraction analysis were grown by recrystallization from ethanol/dichloromethane (1:1) solution, yield 80%, m.p. 260 °C. *Anal.* Calc. for $C_{15}H_{36}N_3O_6S_6Sb$ (Mw = 662.53): C, 26.94; H, 5.43; N, 6.28; S, 28.77. Found: C, 27.05; H, 5.31; N, 6.38; S, 38.62%. IR (KBr) ν(cm^{-1}): 3429, 2975, 2931, 1615, 1572, 1486, 1378, 1352, 1271, 1134, 1086, 995, 876, 775, 558, 416. ^{1} NMR ($CDCl_3$) δ: 3.72 (12H, t, NCH_2), 4.06 (12H, m, OCH_2), 4.5 (OH). ^{13}C NMR ($CDCl_3$) δ: 197.86 (CS_2), 54.36 (NCH_2), 46.32 (OCH_2).

2.4. Crystal structure determination and refinement

Single crystals suitable for X-ray analysis were mounted on a fiber. All measurements were made on a Bruker Smart-1000 CCD diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation at 298(2) K using the Φ/ω scan technique. The structures were solved by the direct method and different Fourier syntheses using the SHELXL-97 program, and refined by full-matrix least-squares on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed at calculated positions with C–H distances of 0.96 Å and riding on carrier atoms. In the refinement of compound **5**, the restraint we used was delu 0.001 0.0005 Sb2 S10. Crystallographic data and experimental details of the structure determinations are listed in Table 1.

3. Results and discussion

3.1. IR spectra

The explicit feature in the IR spectra compared with sodium dithiocarbamate is the new absorption at around 420 cm^{-1}, which may be assigned to the Sb–S stretching

mode of the vibration. The strong bands at about 1480–1500 cm^{-1} are attributed to the ν(C–N) stretching vibration, which shift to higher frequencies than the free ligands (1450–1476 cm^{-1}). It is suggested that the coordination mode of the dithiocarbamate ligands with antimony ions is bidentate by the sulfur atom. In addition, it is worthy to note that besides the absorption at 1495 cm^{-1}, belonging to C–N, there is another strong band at 1468 cm^{-1} in complex **5**. The shift to higher frequency is only 10–20 cm^{-1}, which is smaller than the shift above. It is shown that there is another coordination mode of dithiopiperidylcarbamate, a unidentate form, which is consistent with the crystal structure of complex **5**.

Furthermore, $\Delta\nu[\nu(CS_2)_{asym}-\nu(CS_2)_{sym}]$ can also illuminate the coordination fashion of these complexes. $\nu(CS_2)_{asym}$ and $\nu(CS_2)_{sym}$ appear at 1132–1152 cm^{-1} and 980–998 cm^{-1}, respectively. The $\Delta\nu$ values $[\nu(CS_2)_{asym}-\nu(CS_2)_{sym}]$ are 110–153 cm^{-1}, which are much smaller than the $\Delta\nu$ values for R_2NCS_2R' [11], but are much larger than the corresponding sodium dithiocarbamate values [12]. All of the above show that the dithiocarbamate groups are coordinated to the Sb atom in an anisobidentate fashion. In complex **5**, however, the C–S stretching vibration also appears at 1058 cm^{-1} and 975 cm^{-1}. The $\Delta\nu$ value is 83 cm^{-1}, almost the same as the corresponding sodium dithiocarbamate value ($\Delta\nu = 90$ cm^{-1}), which suggests that some of the dithiocarbamate ligands adopt a unidentate coordination mode in this complex.

3.2. ^1H and ^{13}C NMR

The ^1H NMR chemical shifts at 2.9 and 3.6 ppm are ascribed to methyl and methylene linked directly with N atoms contained in dithiocarbamate, respectively. They shift downfield by δ 0.4–0.9 ppm as compared to the salts of the appropriate acid. It is shown that the coordinated dithiocarbamate group is more electronegative than in the case of no coordination [13]. The multiple signals observed in the region δ 6.72–7.41 ppm are attributed to the protons of phenyl rings. The methylene protons connected with the O atom in complexes **1** and **8** appear at around 4.10 ppm.

The ^{13}C NMR spectra of these complexes show one sharp singlet signal in the region about δ 196 ppm which may be attributed to the carbon of CS_2. In addition, the signals for the carbons of methyl and methylene groups connected directly to the N atoms appear at about 50 ppm. Additionally, these derivatives also exhibit the expected signals due to the carbons of aryl groups at 120–150 ppm and the carbons of methylene linked directly with the O atoms appear at about 46 ppm.

3.3. Electrochemical properties

The cyclic voltammetric studies were carried out with a glassy carbon electrode as the working electrode, a saturated calomel electrode (SCE) as the reference electrode, and a platinum slice as the counter electrode. Typical voltamograms of complexes **1**, **5** and **8** are shown in Fig. 1. All three complexes show two completely irreversible oxidation responses around −0.6 V and −0.2 V, which are attributed to Sb^{3+}/Sb^{4+} and Sb^{4+}/Sb^{5+}, respectively. That is to say, all the oxidation processes for the complexes involve the transfer of one electron. Compared with complexes **5** and **8**, there is also an irreversible oxidation response at about +0.85 V in complex **1**, which may be due to Br^-/Br_2. Owing to the insolubility of the complexes, the peak current is very weak.

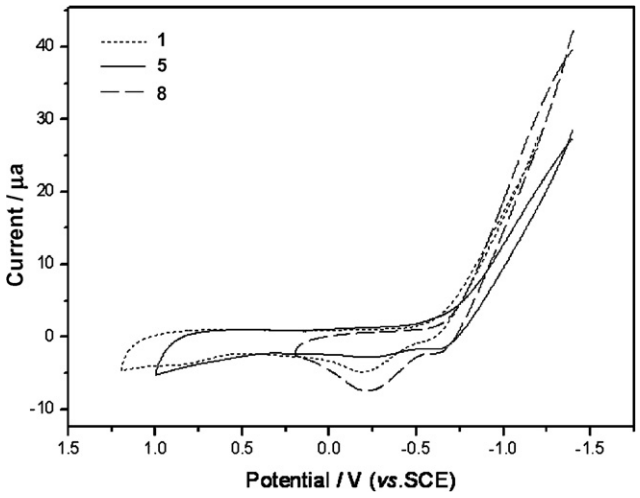

Fig. 1. Voltammograms of complexes **1**, **5** and **8**.

3.4. Crystal structure of complex *1*

Selected bond distances and angles of complex **1** are given in Table 2 and the molecular structure is shown in Fig. 2. The two-dimensional network is displayed in Fig. 3.

As is shown in Fig. 2, the coordination environment of the central antimony atom is five-coordinated with a dis-

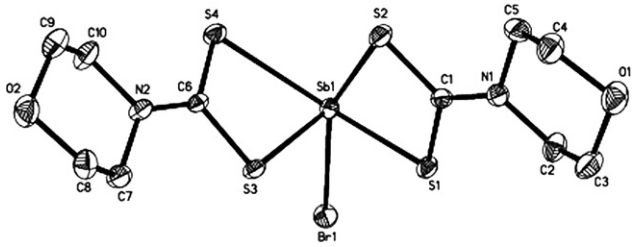

Fig. 2. The molecular structure of complex **1**.

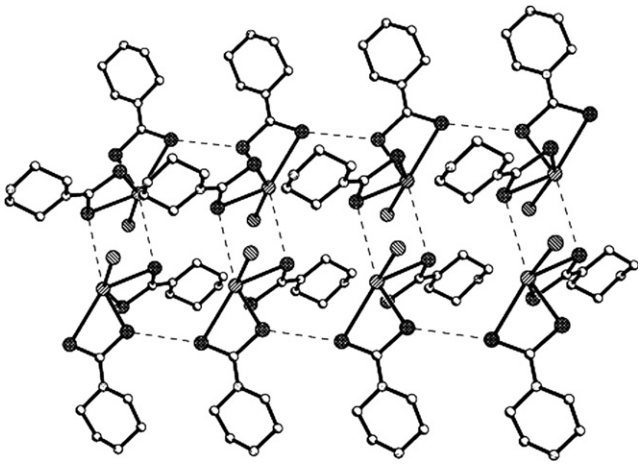

Fig. 3. The supramolecular structure of complex **1**, showing a 2D network linked by intermolecular Sb···S and S···S contacts.

torted trigonal bipyramidal geometry. Around the central Sb atom, S(1), S(3) and S(4) occupy the equatorial plane, while Br(1) and S(2) lie in axial sites. The sum of the equatorial angles is 295.24° ((S(3)–Sb(1)–S(1) 89.32(8)°, S(3)–Sb(1)–S(4) 66.17(7)°, S(1)–Sb(1) –S(4) 139.75(7)°) and the corresponding axial–Sb–axial angle is 150.27(6)°, which suggests that it has large deviations from an ideal trigonal bipyramidal geometry. Among the four Sb–S bond lengths, two of them are short (Sb1–S3 2.469(2) Å, Sb1–S1 2.542(2) Å), which form strong bonds. While the other two are long (Sb1–S2 2.621(2) Å, Sb1–S4 2.909(2) Å), forming weak bonds.

The C–S bonds associated with the strong Sb–S bonds are significantly longer (mean = 1.744(9) Å) than those associated with the weak Sb–S bonds (mean = 1.709(9) Å) [14,15], suggesting some delocation in the system. The N–C bond distances in this complex (mean = 1.33(1)) are manifestations of the presence of a partial double bond. The IR spectrum of the above complex shows a ν(C–N) value of 1490 cm^{-1}, which lies between the single and double bond values, indicating contribution of the thioureide form to the dithiocarbamate [8].

In this complex, the N–C═S angles (mean 123.1(6)°) are considerably larger than the N–C–S angles (mean 119.5(6)°), as expected due to the mutual repulsion between the double bond and the adjacent electronegative atom.

Interestingly, there is a two-dimensional network in the crystal lattice of the complex, which is linked by intermolecular weak Sb···S and S···S contacts of 3.647(2) and 3.564(3) Å, respectively.

3.5. Crystal structure of complex 5

Selected bond distances and angles of complex **5** are given in Table 3. The molecular structure and two-dimensional network are shown in Figs. 4 and 5.

As shown in Fig. 4, the asymmetric unit contains two crystallographically independent molecules A and B, together with a dichloromethane solvent molecule. Between the independent molecules, there is an intramolecular weak hydrogen bond C26–H26A···S4 (C26···S4 3.737(8) Å, H26A···S4 2.79 Å, C26–H26A···S4 166.3°), which links them together. Conformations of the two independent molecules are almost the same, with only a few differences in bond lengths and angles. From Table 3 we can see that around the Sb atom there are three short Sb–S bonds and three long ones, indicating strong coordinations and weak interactions, for Sb(1) as well as for Sb(2). The distances of the long Sb–S bonds are much shorter than the sum of the van der Waals radii of the Sb and S atom, 3.92 Å[16]. Obviously, there are apparent weak intramolecular Sb···S interactions in this complex. Therefore, the Sb atom could be described as six-coordinated with a distorted octahedral geometry, if the weak Sb···S interactions are also taken into consideration.

The central Sb1 atom is surrounded axially by S2 and S5 atoms and equatorially by S1, S3, S4 and S6. The sum of the equatorial angles are 355.97(5)° (S(1)–Sb(1)–S(3) 86.68(5)°, S(1)–Sb(1)–S(6) 86.82(5)°, S(3)–Sb(1)–S(4) 64.47(4)°, S(6)–Sb(1)–S(4) 118.0(5)°), which show that these atoms are not coplanar. Furthermore, the angle of

axial S2–Sb1–S5 is 153.53(5)°, deviating from 180°. The conformation of Sb2 is almost the same as Sb1, with only a few differences in bond lengths and bond angles.

The supramolecular structure of complex **5** is dominated by a two-dimensional network connected by intramolecular C–H···S (C26···S4 3.737(8) Å, H26A···S4, 2.79 Å, C26–H26A···S4 166.3°) and intermolecular C–H···S (C3···S6 3.710(6) Å, H3B···S6 2.83 Å, C3–H3B···S6 152.1°, C36···S6 3.821(7) Å , H36B···S6 2.94 Å, C36–H36B···S6 151.5°) weak hydrogen bonds.

3.6. Crystal structure of complex *8*

Selected bond distances and angles of complex **8** are given in Table 4 and hydrogen bonds in Table 5. The molecular structure, projections of the unit cell and the 3D framework are depicted in Figs. 6–8, respectively.

A similar molecular structure of this complex has been reported, which was prepared by the reaction of $SbCl_3$ with the corresponding dithiocarbamate ligand [17].

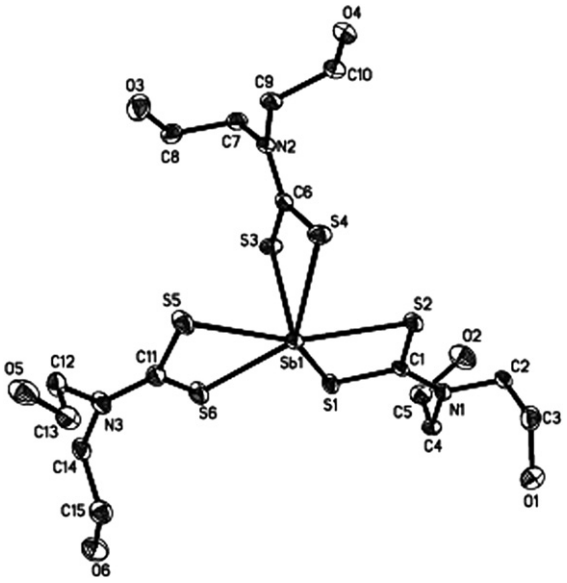

Fig. 6. The molecular structure of complex **8**.

In this complex the Sb atom is coordinated by six S atoms belonging to three *N*,*N*′-iminodiethanoldithiocarbamate ligands. The resulting SbS_6 coordination polyhedron approximates a pentagonal pyramid with S3 in the apical position and the other five atoms (Sb1, S1, S2, S4, S5, S6) occupying the equatorial position, which is similar to the structure reported earlier, with only some differences in bond lengths and bond angles.

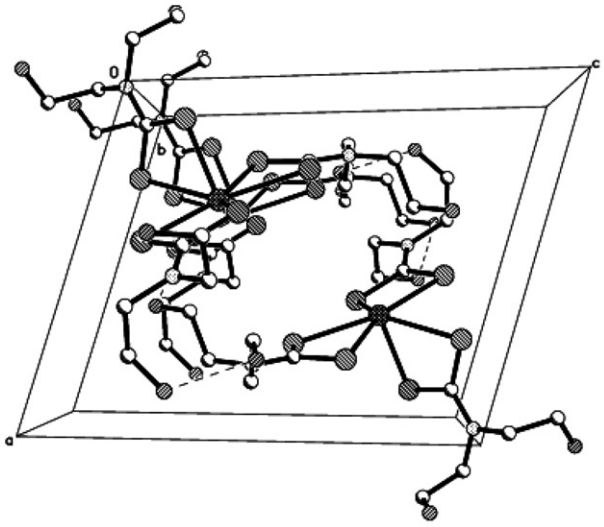

Fig. 7. Projection of the unit cell of complex **8**.

The molecules are held together by strong intermolecular hydrogen bonds between the ethanolic hydrogens (O–H). As a result, the supermolecular structure of this complex can be described as 3D network structure, which is shown in Fig. 8, built up by intermolecular O–H···O hydrogen bonds.

Abstract

Pyridine-2,6-dicarboxylic acid reacts as the first ligand under hydrothermal conditions with divalent cobalt ions to form three 1D polymeric complexes in the presence of 2,4′-bipyridine as well as its derivatives 5-phenyl-2,4′-bipyridine or 5-(4-bromophenyl)-2,4′-bipyridine as the second ligands. The structures and properties of these complexes are characterized by X-ray crystallography, variable temperature magnetic measurements, infrared and thermal gravimetric analyses. It was found that the antiferromagnetic interactions between the Co^{II} ions can be tuned by the substituent on the second ligand.

1. Introduction

Coordination metal complexes have been the subject of intensive investigation because of their potential applications to material science as catalytic, conductive, luminescent, magnetic, porous, chiral or non-linear optical materials [1–4]. The chemistry of coordination polymers containing paramagnetic metal ions and exhibiting extended structures is at the forefront of modern research, due to these compounds' potential applications in molecular magnetism [3–8]. The most useful strategy to construct such one dimensionally extended systems is to employ appropriate bridging ligands, carboxylate for example, capable of binding metal centers through direct bond formation, promoting magnetic interactions. Pyridine-2,6-dicarboxylate (pdc^{2-}), which has been used as a ligand in homoleptic coordination polymers and coordination complexes, is a suitable building block for two-dimensional arrays [9–14]. Previous studies showed that the magnetic behaviors of a carboxylate bridging complex relate to the planarity of the M–O–C–O–M skeleton, characterized by the dihedral angles between the two adjacent metal center planes [15,16]. It is known that at 180° the interaction is antiferromagnetic, but it is ferromagnetic when this angle is close to 90° [17]. Therefore, we are interested in the design of a 1D magnetic coordination polymeric complex containing transition metals with a twisted skeleton for tuning the magnetic property by crystal engineering of the second ligand. Our studies here aimed at constructing such a 1D cobalt polymeric chain using pdc^{2-} as the first ligand and 2,4′-bipyridine (2,4′-bpy) as well as its derivatives 5-phenyl-2,4′-bipyridine (5-ph-2,4′-bpy) or 5-(4-bromophenyl)-2,4′-bipyridine (5-(4-Br-ph)-2,4′-bpy) as the second ligands (see Scheme 1). The 2,4′-bpy ligand has been employed for the construction of organic solid materials [18,19]. The 5-ph-2,4′-bpy and 5-(4-Br-ph)-2,4′-bpy molecules, with very good π-electron conjugated systems, have been extensively used for functionalized polyoxometallates [20]. The incorporation of paramagnetic cobalt centers with strong anisotropy in extended systems has the potential to afford important new magnetic materials. While, there are only a few reports of 1D coordination polymeric

Scheme 1.

cobalt complexes [21–24], we have isolated three families of 1D polymeric cobalt complexes successfully. In this article we will report the structural and magnetic characterization of $[Co(pdc)L_2 \cdot H_2O]_n$ (L = 2,4′-bpy (**1**), 5-ph-2,4′-bpy (**2**), 5-(4-Br-ph)-2,4′-bpy (**3**)) polymeric complexes which were obtained in the reaction of pyridine-2,6-dicarboxylic acid (H_2pdc) with divalent cobalt ions under hydrothermal conditions in the presence of the second bipyridyl ligands. Antiferromagnetic coupling between the Co^{II} ions in these complexes has been observed.

2. Experimental

2.1. Reagents and physical measurements

All chemicals purchased were of reagent grade and were used without further purification. 2,4′-Bpy, 5-phenyl-2,4′-bipyridine, and 5-(4-bromophenyl)-2,4′-bipyridine were synthesized in the laboratory and were characterized by their NMR spectra. The IR spectra were obtained on a Nicolet, Magana 560 spectrometer with the samples prepared as KBr pellets. A PE TGA thermogravimetric analyzer was used to obtain TGA curves at a heating rate of 10 °C min^{-1}. Elemental analyses were carried out using a Perkin–Elmer elemental analyzer 2400CHN. The magnetic susceptibilities of **1**–**3** were measured in the temperature range 2–300 K with an applied field of 1000 Oe on a SQUID magnetometer by using polycrystalline samples. Experimental data were corrected for diamagnetic contributions employing both subtraction of the sample holder and Pascal's constants [25]. The temperature-independent paramagnetism (TIP) of the sample was taken into account as well.

2.2. Synthesis

2.2.1. $[Co(pdc)(2,4'\text{-bpy})_2 \cdot H_2O]_n$ (**1**)

Standard hydrothermal conditions used for the synthesis of **1** did not afforded solids suitable for X-ray crystallography. H_2pdc (0.084 g, 0.5 mmol) in an aqueous solution (3 mL) of NaOH (0.080 g, 2 mmol) was mixed with 2,4′-bpy (0.0156 g, 0.1 mmol) in EtOH (2 mL). The mixture was then added to an aqueous solution (2 mL) of $Co(NO_3)_2 \cdot 6H_2O$ (0.145 g, 0.5 mmol). The new mixture was placed in a 15 mL Teflon-lined autoclave and heated at 150 °C for 4 d and then left to cool to room temperature (RT). On allowing the filtrate from the reaction to evaporate at RT, red blocks of **1** could be isolated in ~41% yield. *Anal.* Calc. for $C_{27}H_{21}N_5O_5Co$ (**1**): C, 58.36; H, 3.21; N, 12.41. *2.2.2. [Co(pdc)(5-ph-2,4′-bpy)$_2$ · H_2O]$_n$ (**2**)*

In a typical experiment, H_2pdc (0.042 g, 0.25 mmol) in an aqueous solution (3 mL) of NaOH (0.040 g, 1 mmol) was mixed with 5-ph-2,4′-bpy (0.0231 g, 0.1 mmol) in EtOH (2 mL). The mixture was then added to an aqueous solution (2 mL) of $Co(NO_3)_2 \cdot 6H_2O$ (0.145 g, 0.5 mmol). The new mixture was placed in a 15 mL Teflon-lined autoclave and heated at 150 °C for 4 d. The autoclave was then cooled over a period of 12 h at a rate of 4 K h^{-1}. Red block crystals of **2** that were deposited on the wall of the container were collected and air-dried. Yield: ~40%. *Anal.* Calc. for $C_{39}H_{29}N_5O_5Co$ (**2**): C, 66.30; H, 3.81; N, 9.76. Found: C, 66.29; H, 4.14; N, 9.91%. IR (KBr, cm^{-1}): 3426 s, 3062 vs, 1649 s, 1608 s, 1567 m, 1465 m.

*2.2.3. [Co_2(pdc)$_2$(5-(4-Br-ph)-2,4′-bpy)$_4$ · 2H_2O]$_n$ (**3**)*

H_2pdc (0.042 g, 0.25 mmol) in an aqueous solution (3 mL) of NaOH (0.040 g, 1 mmol) was mixed with 5-(4-Br-ph)-2,4′-bpy (0.0331 g, 0.1 mmol) in EtOH (2 mL). The mixture was then added to an aqueous solution (2 mL) of $CoSO_4 \cdot 7H_2O$ (0.140 g, 0.5 mmol). The new mixture was placed in a 15 mL Teflon-lined autoclave and heated at 150 °C for 4 d. The autoclave was then cooled over a period of 12 h at a rate of 4 K h^{-1}. Red block crystals of **3** that were deposited on the wall of the container were collected and air-dried. Yield: ~43%. *Anal.* Calc. for $C_{78}H_{54}Br_4N_{10}O_{10}Co_2$ (**3**): C, 54.19; H, 3.15; N, 8.10. Found: C, 54.01; H, 2.98; N, 7.89%. IR (KBr, cm^{-1}): 3525 s, 3305 vs, 1677 s, 1648 s, 1538 m, 1464 m.

2.3. X-ray crystallography

All diffraction data were collected at room temperature on a Siemens SMART APEX CCD area detector diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) [26]. Intensity data were collected by the

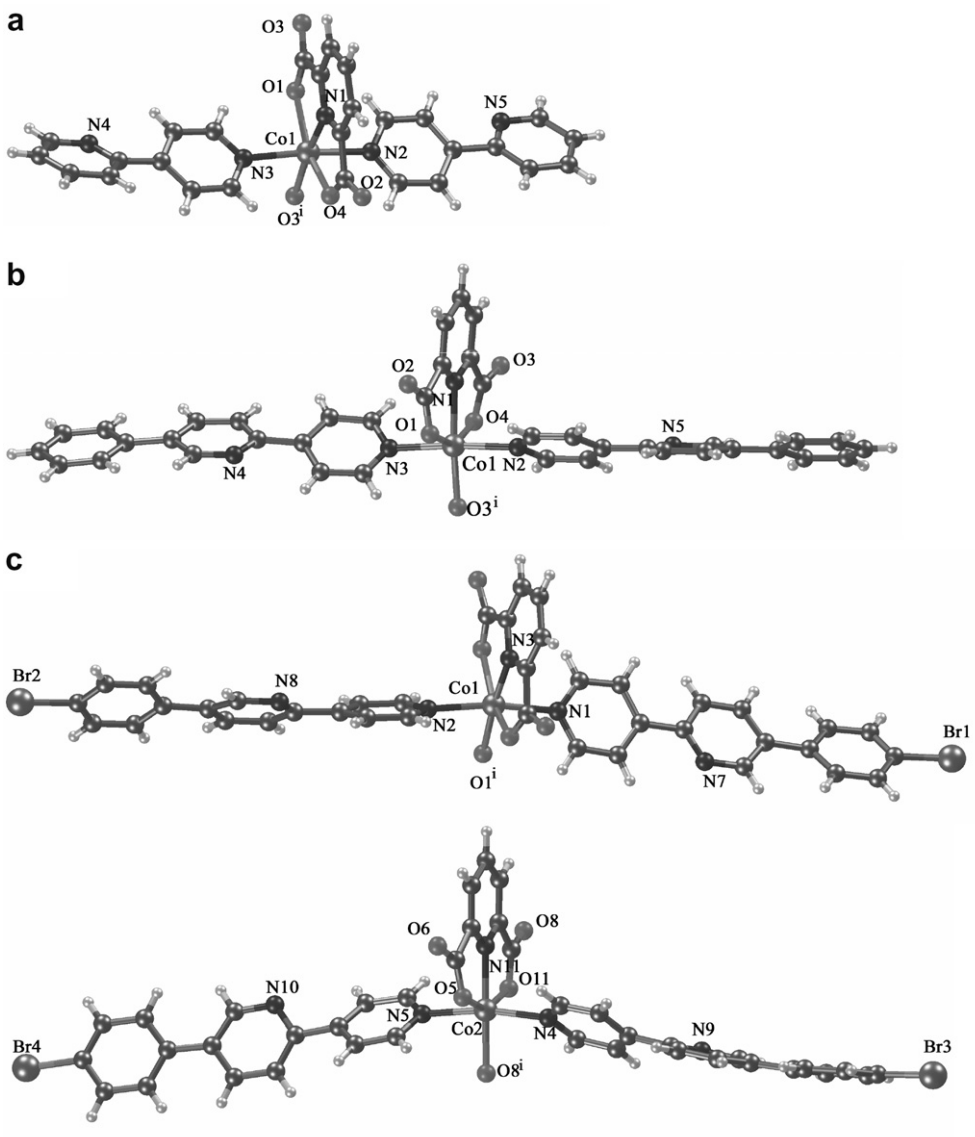

Fig. 1. View illustrating the coordination geometry around the metal ions in complexes **1** (a), **2** (b) and **3** (c) (left: Co1 chain; right: Co2 chain).

ω scan technique. Data were corrected for Lorentz polarization effects [27]. The structures were solved by the direct method using SHELXS-97 [28] and were refined on F^2 by full-matrix least-squares using the SHELXL-97 [28] program package. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms on the water molecule of complex **1** were found in electron-density difference Fourier maps and were refined freely. In **2** and **3**, it was not practical to assign hydrogen atoms on the disordered water molecules. The other H atoms were added in ideal positions (C–H = 0.93 Å, $U_{iso}(H) = 1.2U_{eq}(C)$) and were not refined. The main crystallographic data of these compounds are listed in Table 1.

3. Results and discussion

3.1. Crystal structure

In complex **1**, the Co^{II} ions are bridged by pdc^{2-} anions to form 1D coordination zigzag polymeric chains along the *b*-axis. The metal atoms exist in distorted octahedral coordination environments. The equatorial sites are occupied by one N and two O atoms offered by one pdc^{2-} and one O atom from a neighboring pdc^{2-} in the trans position of the N atom (Figs. 1a and 2a), with normal Co–N (2.071(2) Å) and Co–O (2.019(2)–2.227(2) Å) bond distances (Table 2) [29]. The two axial sites are occupied by two N atoms of the second ligand, 2,4′-bpy. Furthermore, the two Co–N bonds are almost the same length (2.172 (2) and 2.177(2) Å), which are longer than those of other reported cobalt complexes containing 4-pyridyl ligands (2.12–2.15 Å) [21–24,30,31].

In complex **2**, a 1D coordination polymer could be engineered with the same first ligand as in **1** along the *b*-axis, in the presence of the second ligand 5-ph-2,4′-bpy (Figs. 1b and 2b). The two axial sites are occupied by two 5-ph-2,4′-bpy molecules. The equatorial Co–N (2.075(1) Å) and Co–O (2.043(1)–2.201 (1) Å) bond distances are similar to those found in related structures [29]. The two axial Co–N distances are unequal (2.155(2) and 2.175 (2) Å), which is different from that of **1**.

Complex **3** can be engineered with the same first ligand as in **1** or **2** along the *b*-axis, in the presence of the second ligand 5-(4-Br-ph)-2,4′-bpy (Figs. 1c and 2c). Interestingly, there are two crystallographically independent cobalt ions in complex **3**, which is different from complexes **1** and **2**. Each cobalt atom exists in a distorted octahedral coordination environment. The Co^{II} ions are bridged by pdc^{2-} anions to form 1D coordination zigzag polymeric chains along the *b*-axis. Thus, two kinds of 1D coordination zigzag polymeric chains (the Co1 chain and the Co2 chain) occur in complex **3**. In the Co1 chain, the equatorial Co–N (2.062(6) Å) and Co–O (2.039(6)–2.218(5) Å) bond distances are slightly different (±0.03 Å) from those of complexes **1** and **2**, although they are within the range of normal distances as found in related literature [29], the two axial Co–N distances (2.146(6) and 2.152(6) Å) are shorter than those in the former complexes. For the Co2 chain, the equatorial Co–N bond distance is 2.069(6) Å, and the equatorial Co–O bond distances are in the range

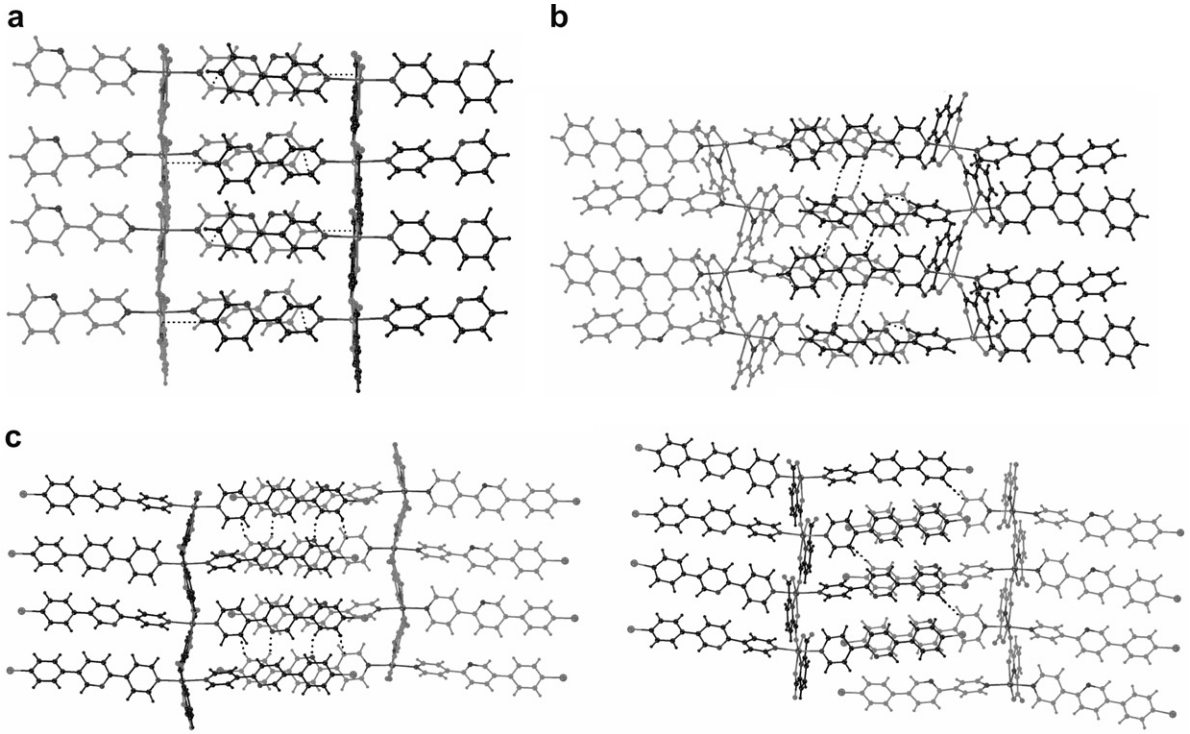

Fig. 2. The crystal packing along the *c*-axis for complex **1** (a), complex **2** (b) and complex **3** (c) (left: Co1 chain; right: Co2 chain). Hydrogen bonds are shown as black dashed lines.

Symmetry codes for complex **1**: (i) $1-x, -0.5+y, 0.5-z$. For complex **2**: (i) $1-x, -0.5+y, 0.5-z$. For complex **3**: (i) $-x, -0.5+y, 0.5-z$; (ii) $1-x, 0.5+y, 0.5-z$.

2.055(6)–2.194(4) Å. The two axial Co–N distances are 2.147(6) and 2.158(7) Å, which are similar to those of the Co1 chain.

The crystal packing patterns along the *c*-axes of the three complexes are shown in Fig. 2. For complexes **1** and **2**, the neighboring zigzag chains are assembled into two-dimensional layers *via* interdigitation involving C–H···π hydrogen bonds [32]. The C–H groups form structural hydrogen bonds in **1** (H···π, *ca.* 2.84 Å, C–H···π, *ca.* 151.1°), both C–H groups and uncoordinated nitrogen atoms contribute to the hydrogen bond formation in **2** (H···π, *ca.* 2.71 Å, C–H···π, *ca.* 140.4°). While for complex **3**, each Co1 or Co2 neighboring chains associate into a 2D layer by hydrogen bond interactions, and the Co1 and Co2 layers are alternately arranged. Interestingly, in the Co1 layer of complex **3**, C–H groups and uncoordinated nitrogen atoms contribute to the hydrogen bond formation (H···π, *ca.* 2.78 Å, C–H···π, *ca.* 151.4°), which is similar to the feature of complex **2**, whereas in the Co2 layer only C–H groups form hydrogen bonds (H···π, *ca.* 2.86 Å, C–H···π, *ca.* 166.8°), which is similar to that of complex **1**. The intra-chain metal–metal distances are 5.64 and 5.43 Å for **1** and **2**, respectively. For complex **3**, the intra-chain Co1–Co1 and Co2–Co2 distances are 5.62 and 5.57 Å, respectively. The neighboring polymer backbones can superpose by a shift in **1**, whereas the backbones of **2** and **3** in neighboring sheets cannot superpose (Fig. 3) with each other. In complex **1**, the torsion angles Co1–O1–C24–O3 and O1–C24–O3–Co1^{ii} are 173.3° and 7.2°, respectively, while the torsion angles Co1–O4–C1–O3 and O4–C1–O3–Co1^{ii} are 168.3° and 12.1° for **2**, respectively. Therefore, the polymeric cobalt chains of **2** are severely twisted compared to those of **1** by the introduction of a phenyl substituent on the second ligand in **2**. In complex **3** the torsion angles Co1–O4–C4–O1, O4–C4–O1–Co1^{iii}, Co2–O5–C8–O8 and O5–C8–O8–Co2^{iv} are 166.9°, 9.7°, 179.5° and −3.9°, respectively. Similarly, the Co1 chains of **3** are more twisted compared to those of **1** by the introduction of the bromophenyl substituent on the second ligand, though the Co2 chains are less twisted in **3**.

3.2. Thermal properties

Thermal gravimetric analysis shows that the coordination polymers **1**–**3** normally begin to lose their uncoordinated water molecules at a low temperature, ranging from 100 to 170 °C (Fig. 4). Complex **1** is the least stable and decomposes at 175 °C, and the weight loss of 52.5% (calc. ~56%) corresponds to the loss of the 2,4′-bpy ligand in the temperature range 175–225 °C. The pdc^{2-} anion begins to decompose at 250 °C. The molecular structure of **2** begins to collapse at 250 °C, and the weight loss of 63.9% in the range 250–325 °C corresponds to the loss of 5-ph-2,4′-bpy (calc. ~65%), and another weight loss of 22.5% (calc. ~23%) corresponds to the loss of one pdc^{2-} anion in the range 325–580 °C. Complex **3** begins its decomposition at 210 °C. The weight loss between 210 and 380 °C is attributed to the loss of the 5-(4-Br)-ph-2,4′-bpy ligand (obsd. 73.7%, calc. ~72%), and another weight loss between 380 and 600 °C is attributed to the loss of pdc^{2-}(obsd. 21.2%, calc. ~19%). The above data clearly demonstrate that the introduction of a substituent on the second ligand is responsible for the increase of the stability of the coordination complexes.

3.3. Magnetic properties

The magnetic behaviors for complexes **1**–**3** are shown in Figs. 5–7. The global feature of the $\chi_M T$ versus T curve of **1** is a weak intramolecular antiferromagnetic interaction between the Co(II) ions, as shown in Fig. 5. The value of $\chi_M T$ at 300 K is 2.734 $cm^3\ mol^{-1}$ K and thus is higher than the spin-only value of 1.875 $cm^3\ mol^{-1}$ K expected for an uncoupled high-spin Co^{II} ion ($S = 3/2$, $g = 2$), in accordance with the well-documented orbital contribution of the octahedral Co^{II} ion [33,34].As the sample is cooled from room temperature, the $\chi_M T$ value smoothly decreases from 2.734 $cm^3\ mol^{-1}$ K to 2.530 $cm^3\ mol^{-1}$ K at 120 K and then decreases more rapidly at low temperatures, reaching a value of 0.953 $cm^3\ mol^{-1}$ K at 2 K. Fig. 6 shows the temperature dependence of the $\chi_M T$ product for complex **2**. The $\chi_M T$ value at 300 K for **2** is 2.616 $cm^3\ mol^{-1}$ K, and the global feature of the $\chi_M T$ versus T curve for **2** suggests a weak intramolecular antiferromagnetic interaction, the same as that of **1**. Similarly, the global feature of the $\chi_M T$ versus T curve of **3** is a weak intramolecular antiferromagnetic interaction between the Co(II) ions (Fig. 7). As the sample is cooled from room temperature, the $\chi_M T$ value smoothly decreases from 3.214 $cm^3\ mol^{-1}$ K to 2.701 $cm^3\ mol^{-1}$ K at 50 K and then decreases more rapidly at low temperatures, reaching a value of

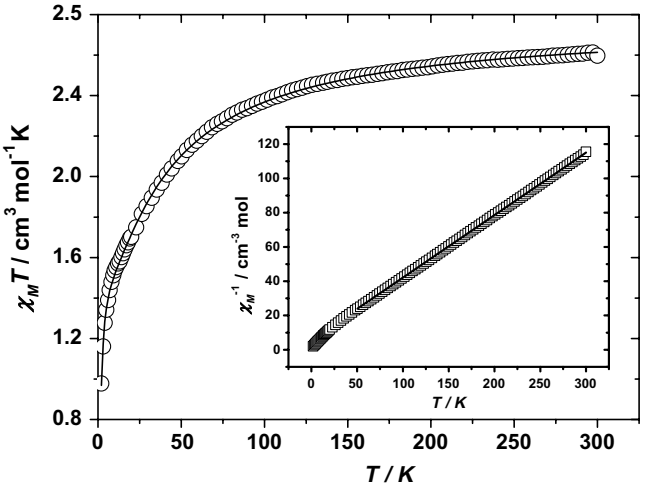

Fig. 6. Plots of $\chi_M T$ vs. T and $\chi_M{}^{-1}$ vs. T (insert) for complex **2**. Solid lines show the best fits to the model (see text).

1.405 $cm^3\ mol^{-1}$ K at 2 K. The high-temperature data (above 50 K) for **1**–**3** can be fitted to the Curie–Weiss law with $C = 2.82$, 2.74 and 3.35 $cm^3\ mol^{-1}$ K, $\theta = -12.85$, −11.06 and −11.79 K, respectively. These values are typical of uncoupled high-spin Co^{II} ions [33]. The high value of C (for a spin-only system with $S = 3/2$ and $g = 2$, the calculated Curie constant is $C = 1.88$ $cm^3\ mol^{-1}$ K) emphasizes a significant orbital contribution to the susceptibility. The θ values of complexes **2** and **3** are less negative than that for complex **1**. This indicates that the antiferromagnetic interactions between the Co^{II} ions can be decreased by the substituent on the second ligand, introducing a larger twisting for the 1 D chain.

To obtain an estimate of the strength of the antiferromagnetic coupling, we used a simple phenomenological equation, which is proposed by Masciocchi and his coworkers [35], $\chi T = A\exp(-E_1/kT) + B\exp(-E_2/kT)$, to fit the magnetic data. Here, $A + B$ equals the Curie constant, E_1 and E_2 represent the "activation energy" corresponding to the spin–orbit coupling and the antiferromagnetic exchange interaction, respectively. This equation adequately describes the spin–orbit coupling, which results in a splitting between discrete levels, and the exponential low-temperature divergence of the susceptibility [$\chi T \propto \exp(\alpha J/2kT)$]. The fitted parameters for complexes **1**, **2** and **3** are $A + B = 2.83$, 2.76 and 3.38 $cm^3\ mol^{-1}$ K, $E_1/k = 46.4$, 42.5 and 42.9 K, $E_2/k = -1.40$, −1.09 and −1.12 K, $R = 1.3 \times 10^{-4}$, 5×10^{-5} and 6.8×10^{-4}, respectively, where $R = \sum[(\chi_M T)_{obs} - (\chi_M T)_{calcd}]^2 / \sum[(\chi_M T)_{obs}]^2$. The $A + B$ and E_1/k values of complexes **1**–**3** are consistent with those reported in the literature for the Curie constant and the effect of spin–orbit coupling [35,24]. E_2/k values of −1.40, −1.09 and −1.12 correspond to $J = -2.80$, −2.18 and −2.24 K according to the Ising chain approximation [$\chi T \propto \exp(J/2kT)$]. The J value of complex **1** is more negative than the values for complexes **2** and **3**. This also demonstrates that the antiferromagnetic interactions between the Co^{II} ions can be decreased by the substituent on the second ligand, introducing a larger twisting for the 1D chain.

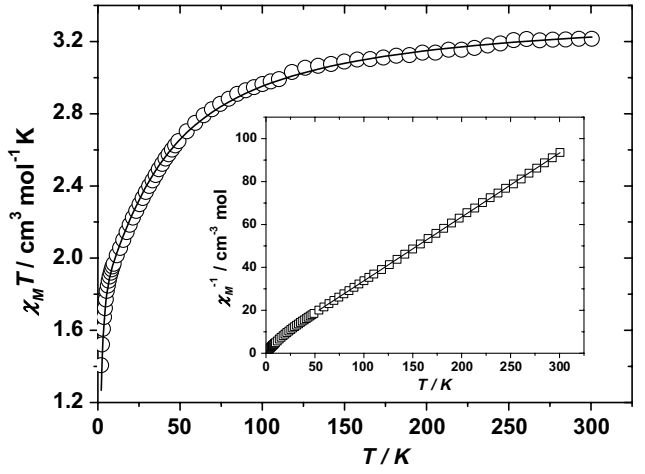

Fig. 7. Plots of $\chi_M T$ vs. T and $\chi_M{}^{-1}$ vs. T (insert) for complex **3**. Solid lines show the best fits to the model (see text).

4. Conclusions

In summary, we have synthesized three new complexes $[Co(pdc)(2,4'\text{-bpy})_2 \cdot H_2O]_n$ (**1**), $[Co(pdc)(5\text{-ph-}2,4'\text{-bpy})_2 \cdot H_2O]_n$ (**2**) and $[Co_2(pdc)_2(5\text{-(4-Br-ph)-}2,4'\text{-bpy})_4 \cdot 2H_2O]_n$ (**3**). Complexes **1**–**3** show antiferromagnetic interactions between the Co^{II} centers bridged by the O–C–O bridge in a trans mode. The polymeric cobalt chains of **2** are severely twisted compared to those of **1** by the introduction of a phenyl substituent on the second ligand, while for **3** half severely and half less twisted polymeric cobalt chains are ascribed to the bromophenyl substituent of the second ligand. As a result, the steric hindrance of the substituent groups from neighboring chains results in the distorted structure of the polymeric chains. The antiferromagnetic interactions between Co^{II} ions are decreased in the order of **1** > **3** > **2**, corresponding to the increasing distorted structure for the polymeric chains. Furthermore, the thermal stability of the coordination complexes is increased by the introduction of substituent groups on the second ligand. This report may provide a promising strategy for the design and exploitation of new polymeric coordination compounds for useful applications.

Abstract

The dibenzodioxatetraazamacrocycle [26]*p*$bz_2N_4O_2$ was characterised by single crystal X-ray diffraction and the protonation constants of this compound and the stability constants of its copper(II) and lead(II) complexes were determined by potentiometry in water at 298.2 K in 0.10 mol dm^{-3} in KNO_3. Mono- and dinuclear complexes were found for both metal ions, the dinuclear complexes being the main species in the 5–7.5 pH range for copper(II) and 7.5–8.5 for lead(II). As expected the values of the stability constants for the copper(II) complexes are lower than those for related macrocycles containing only nitrogen atoms. The presence of mono- and dinuclear copper complexes was also confirmed by electrospray ionization mass spectrometry. These results suggest that the symmetric macrocyclic cavity of [26]*p*$bz_2N_4O_2$ has enough space for the coordination of two metal ions. Additionally, NMR spectroscopy showed that the dinuclear complex of lead(II) has high symmetry. The equilibrium constants of the dinuclear copper(II) complexes and dicarboxylate anions (oxalate, malonate and succinate) were also determined in 0.10 mol dm^{-3} aqueous KNO_3 solution. Only species containing one anion, $Cu_2H_hLA^{(2+h)}$, were found, strongly suggesting that the anion bridges the two copper(II) ions. The binding constants of the cascade species formed by $[Cu_2[26]pbz_2N_4O_2(H_2O)_x]^{4+}$ with dicarboxylate anions decrease with the increase in length of the alkyl chain of the anion, a fact which was attributed to a higher conformational energy necessary for the rearrangement of the macrocycle to accommodate the larger anions bridging the two copper(II) centres. The variation of the magnetic susceptibility with temperature of $[Cu_2(H_2[26]pbz_2N_4O_2)(oxa)_3]\cdot 4H_2O$ and $[Cu_2([26]pbz_2N_4O_2)(suc)Cl_2]$ were measured and the two complexes showed different behaviour.

1. Introduction

The growing interest in symmetrical and large polyazamacrocycles mainly results from their ability to form stable dinuclear metal complexes. The capacity of these complexes to interact with additional species can also be used to modulate their physical, chemical and magnetic properties giving rise to new species that can be of great significance as models for interacting paramagnetic centres, catalysts and new molecular materials [1,2]. On the other hand, carboxylate groups as the interacting moieties of a guest can assume many types of bridging conformations, leading to different magnetic properties and making them interesting to be studied from a chemical point of view [2].

The ability of copper complexes of related macrocycles, [24]*m*bz_2N_6 and [24]fu_2N_6 (see Scheme 1 for the abbreviations), to interact with different anions, such as oxalate

Scheme 1.

[3], malonate [3], phosphate [4], acetate [5] and various amino acids [6] has been reported. The stability of the formed supramolecular species was explained by cooperative electrostatic forces and hydrogen bonds [3,4]. Following these achievements, in the present work we investigated the ability of a 26-membered macrocycle containing *p*-xylyl and oxodiamine motifs to form homodinuclear copper(II) and lead(II) complexes in aqueous solution. Additionally, the ability of the dicopper complex to form cascade species with dicarboxylate anions with alkyl chains of different sizes (oxalate, malonate and succinate) was also evaluated under the same experimental conditions. The variation of the magnetic moment with temperature was also measured in order to study the modulation effect of the magnetic properties by the guests in the dicopper complex. In a study reported before a similar investigation was carried out, but using DMSO as solvent and UV–Vis and EPR spectroscopic techniques to characterise the dicopper interaction mediated by the different anions [7]. The present study complements the former one because in aqueous solution more information can be obtained by potentiometric techniques.

2. Results and discussion

2.1. Acid–base behaviour

The acid–base reactions of [26]*p*$bz_2N_4O_2$ were studied by potentiometric methods in water at 298.2 K, in 0.10 mol dm^{-3} KNO_3. The protonation constants determined are collected in Table 1, together with the values for the related compounds [26]*p*bz_2N_6, and [24]*m*bz_2N_6 for comparison (see Scheme 1).

The protonation constants of all the basic centres of [26]*p*$bz_2N_4O_2$ could be determined by potentiometric techniques. The four protonation constants are of comparable magnitude, because they correspond to amine centres at alternating positions in the macrocycle, far from each other, and therefore the values are only affected by statistical factors, and are of the same order as those found for linear amines [13]. The formation of intramolecular hydrogen bonds between protonated nitrogen and ether oxygen atoms eventually stabilise the first two protonated species, contributing also for their high basicity.

A lower overall basicity would be expected for [26]*p*$bz_2N_4O_2$ when compared to that of [26]*p*bz_2N_6 or [24]*m*bz_2N_6, however only slightly differences were observed for the three compounds, see Table 1. This indicates that the inductive effect of the ether oxygen in close proximity to the basic centres of [26]*p*$bz_2N_4O_2$ is probably compensated by the contribution of intramolecular N–H···O hydrogen bonds, which is in agreement with the X-ray structure of [26]*p*$bz_2N_4O_2$ presented in Fig. 1.

The macrocycle presents a ladder type conformation with an inversion crystallographic centre. This conformation is stabilised by four N–H···O short intermolecular bonding contacts with H···O distances of 2.58(4) and 2.53(3) Å and corresponding N–H···O angles of 106(3)° and 105(2)°. Bond lengths and angles found for [26]*p*$bz_2N_4O_2$ are within the expected values.

The effect of the electrostatic repulsion between contiguous protonated amine centres, resulting in very low protonation constant values, is only observed for the last two values of [26]*p*bz_2N_6 and [24]*m*bz_2N_6.

2.2. Metal complexes studies

The stability constants of the complexes of [26]*p*$bz_2N_4O_2$ with Cu^{2+} and Pb^{2+} were also determined and the results are collected in Table 2, together with the values of the Cu^{2+} complexes of [26]*p*bz_2N_6 for comparison.

Mono- and dinuclear complexes were found for both metal ions. The dinuclear complexes are the main species in the pH range 7.5–8.5 for lead(II) and 5–7.5 for copper(II), see Figs. 2 and 3. These results suggest that the symmetric macrocyclic cavity of [26]*p*$bz_2N_4O_2$ has enough space for the coordination of two metal ions and that the coordination of the second metal centre should lead to a lower energy conformation of the macrocycle. This tendency to form dinuclear complexes was also verified for the related macrocycle [26]*p*bz_2N_6 [8].

The protonated Cu_2HL complex is the main species in the 5–7.5 pH range, and at pH $\geqslant$ 8 the hydrolysis of water molecules directly coordinated to the metal centre gives rise to hydroxocomplexes. The stability of the Cu_2HL complex and the easy formation of hydrolysed species leave the dinuclear complex Cu_2L as the main species in a short pH range around pH 8, see Fig. 3.

The intriguing stability of the asymmetric Cu_2HL species, particularly from a symmetric ligand, requires that one of the amine centres remains protonated before the final rearrangement of the macrocycle in the dinuclear

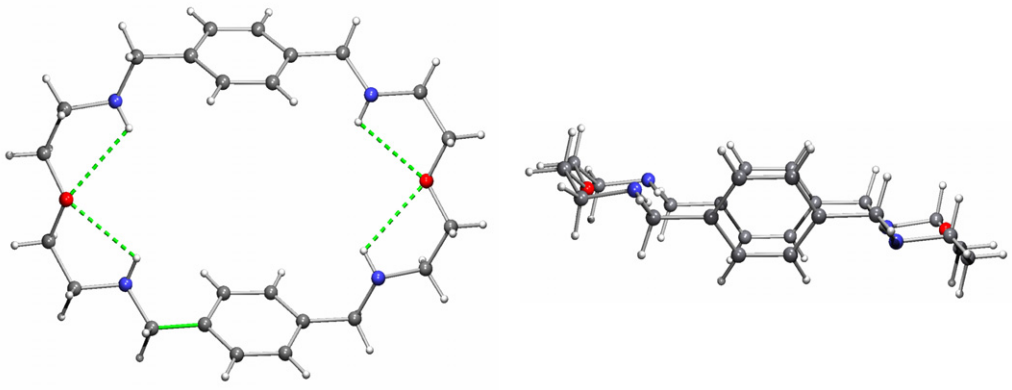

Fig. 1. Molecular structure of [26]*p*bz$_2$N$_4$O$_2$ in two different views, showing the N–H···O intramolecular hydrogen bonding interactions (left) and macrocyclic conformation (right).

complex. This implies that the second copper centre has a NO coordination sphere from donors of the macrocycle, with the remaining positions occupied by solvent molecules or nitrate anions, and the amine not involved in the coordination being still protonated. The proximity of this second copper centre to the positive ammonium cation implies a conformation of the macrocycle minimizing electrostatic repulsion, and a further macrocyclic rearrangement upon deprotonation of the last ammonium group.

The stability constants of the complexes of [26]*p*bz$_2$N$_6$ with Cu^{2+} are about ten log units larger than those of [26]*p*bz$_2$N$_4$O$_2$. This implies that the replacement of the middle nitrogen atom of the diethylenetriamine chain by an oxygen atom has chemical and structural implications. Indeed, the log K_{CuL} corresponding to the replacement of L = diethylenetriamine by 1,5-diamino-3-oxapentane is about 8 units [13], and can reach 10 log units for macrocycles [14]. Therefore the drop found for the constants of the copper(II) complexes of [26]*p*bz$_2$N$_4$O$_2$ when compared with those of [26]*p*bz$_2$N$_6$ is the expected one.

On the other hand, the stability constant obtained for the formation of Pb_2L is relatively high when compared to that of Cu_2L, which can be explained by a better accommodation of lead into the cage formed by the three donor atoms of the macrocycle. However at higher pH values (pH > 7.5), the dinuclear complex gives rise to the mononuclear one in spite of the fact that the large ionic radii of this metal ion does not make good use of all the donor atoms of the macrocycle, giving a small stability constant.

2.3. Cascade species formed by the dinuclear copper(II) complex as the receptor for dicarboxylate substrates

Taking advantage of the tendency of the macrocycle [26]*p*bz$_2$N$_4$O$_2$ to form dinuclear complexes with copper(II), this complex was used as the receptor for anion recognition. Dicarboxylate anions were chosen as the substrates, as indicated in Scheme 1.

The association constants of the cascade species were also determined in aqueous solution by potentiometric

measurements at 298.2 K and 0.10 mol dm^{-3} KNO_3. For solubility reasons the association constants with glutarate could not be determined by this technique. The results are compiled in Table 3 and the distribution curves for the system with oxa^{2-} is shown in Fig. 4.

The values of the protonation constants of the anions were previously determined [15] and the stability constants of their copper(II) complexes are presented in Table 4.

Only species containing one anion, $Cu_2H_hLA^{(2+h)}$, were found, strongly suggesting that the anion bridges the two copper(II) ions. Supporting this suggestion, cascade species with bridging oxa^{2-} and suc^{2-} were found in the solid state by X-ray determination [7].

The $Cu_2H_2LA^{4+}$ species, which can be formed by the reaction of Cu_2HL^{5+} with HA^- or by Cu_2L^{4+} with H_2A, is the main species at low pH (5–7.5). All these species

(Cu_2HL^{5+}, Cu_2L^{4+}, HA^- and A^{2-}) exist in this pH range, therefore the $Cu_2H_2LA^{4+}$ species is the result of both reactions. However for practical reasons, in Table 3, the stepwise constant was determined considering only the first reaction. The remaining species are formed from the reaction of the corresponding copper(II) complex with A^{2-}. At pH 9.5, $Cu_2L(OH)_2A$ is the main species, formed by the hydrolysis of two water molecules directly bound to copper(II), indicating that at this pH the anion bridges the two metal centres and in addition to the coordination of donor atoms of the ligand, one OH^- anion is also in the coordination sphere of each metal centre.

Table 4
Stability constants (log units) of the copper(II) complexes with oxa^{2-}, mal^{2-} and suc^{2-}[a]

Reaction equilibrium	oxa^{2-}[a,b]	mal^{2-}[a,b]	suc^{2-}[a,b]

$T = 298.2 \pm 0.1$ K and $I = 0.10$ mol dm^{-3} in KNO_3.
[a] In parentheses are indicated the standard deviations on the last significant figure. A denotes the anion.
[b] The protonation constants of the anions determined before [15].

$Cu_2HL(suc)^{3+}$ was the only species found at low pH for this system, which is probably formed by the reaction of Cu_2L^{4+} and $Hsuc^-$ or Cu_2HL^{5+} and suc^{2-}, due to the highest basicity of this anion (Table 4).

A decrease of the association constant with an increase of the alkyl chain of the anion is verified (see Table 3). The basicity of the anion does not seem to be responsible for the strength of the association, as the increase of basicity is opposite to the strength of the association. These results indicate that the energy required to adjust the

macrocycle in the complex to the size and geometry of the bridging substrate is larger for suc^{2-} than for oxa^{2-}. Additionally the methylene groups of mal^{2-} and suc^{2-} are considerably hydrophobic and are poorly accommodated in the aqueous environment [3].

The related macrocycle [24]fu_2N_6 (see Scheme 1) presents a slightly higher value of the binding constant with oxa^{2-}, and a similar one for mal^{2-} [2,3]. The crystal X-ray structure of the cascade species confirms that the oxa^{2-} anion bridges both metal centres [3]. This can be an indication that the oxa^{2-} anion adjusts better to the Cu···Cu distance of the [24]fu_2N_6 complex than to the one of [26]*p*$bz_2N_4O_2$.

2.4. Electrospray ionization mass spectrometry (ESI-MS)

The ESI-MS of methanol solutions of the copper(II) complex gives the cations $[Cu_2LCl_3]^+$ at $m/z = 644.9$ and $[Cu_2LCl]^+$ at $m/z = 573.1$. Peaks corresponding to the free ligand $m/z = 413.3$ $[LH]^+$ and $m/z = 429.3$ $[L(H_2O)H]^+$ could also be found, confirming the low stability constant of the complex of this ligand with copper(II). Additionally, the mononuclear species $[CuL]^+$ at $m/z = 473.4$ and 509.2 and $[CuLCl]^+$ at $m/z = 509.2$ could also be found.

2.5. ^1H NMR spectroscopic data of the lead(II) complexes in D_2O

The ^1H NMR spectra of the lead(II) complexes show four resonances (Table 5): a singlet for H_a protons of the benzene ring, one singlet for the H_b protons and two triplets for the H_c and H_d protons (for labelling see Scheme 1), confirming the high symmetry of the dinuclear complexes. The exchange of NH for ND in D_2O is complete and the N–H resonances could not be seen. Lead satellites could not be observed (^{207}Pb, $I = 1/2$, natural abundance 22.6%). All the geminal protons show chemical and magnetic equivalence that can be explained by considering a dynamic process between two energetically favoured conformations.

The spectra performed at 0.5:1, 1:1 and 2:1 Pb^{2+}:[26]*p*$bz_2N_4O_2$ ratios present the resonances downfield shifted in comparison with those of the free ligand, at the same pD values. At the pD values used and even at a low Pb^{2+} ratio there is a significant amount of the dinuclear complex, and the amount of free ligand is high in comparison with the mononuclear complexes formed. This is the reason why the chemical shifts observed for the 0.5:1 ratio are close to those for the free ligand. Unfortunately due to solubility reasons it was not possible to reach high pD values.

Table 5
^1H NMR data for [26]*p*$bz_2N_4O_2$ and its Pb^{2+} complexes in D_2O (δ, ppm) at 300 K

Compound or complex	pD	**a** (s)	**b** (s)	**c** (t)	**d** (t)

[a] For numbering of the atoms see Scheme 1.

2.6. Variation of the magnetic moments with temperature

The temperature dependence of the effective magnetic moment, obtained from molar paramagnetic susceptibility measurements of $[Cu_2(H_2[26]pbz_2N_4O_2)(oxa)_3]\cdot 4H_2O$ and $[Cu_2([26]pbz_2N_4O_2)(suc)Cl_2]$, is presented in Fig. 5.

The behaviour of the two compounds is significantly different, clearly putting into evidence much stronger antiferromagnetic interactions in the succinate compound. In fact, the oxalate-bridged dicopper complex behaviour can be fairly described by a Curie–Weiss law with $\theta = -12.8$ K and the effective magnetic moment in the high temperature range is *ca.* 2.5 μ_B, close to the theoretical value for non-interacting species. On the other hand, for the succinate compound the μ_{eff} at room temperature is *ca.* 1 μ_B and is already temperature dependent. We attempted to fit the susceptibility by the Bleany–Bowers formula [16] for antiferromagnetic coupled copper ions in a dimer, yielding $2J/k = -576$ K, plus a Curie tail to account for impurities and defects. This fraction is unrealistically high (0.17 for $S = 1/2$ impurities), meaning that probably this is not the best model, but it must be stressed that the magnetic moments are significantly damped in this compound from the non-interacting case. At first sight it may appear strange to find a much stronger antiferromagnetic coupling for the succinate compound where the Cu···Cu distances are larger than for the oxalate one, 6.442 Å and 5.484 Å, respectively [7]. However, as pointed out by Carlin [17], the Cu···Cu interaction depends on the superexchange mechanism rather than the distance between the two metal

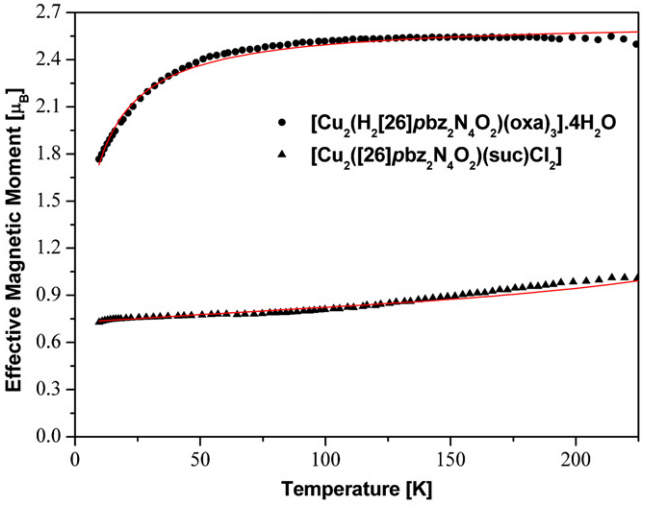

Fig. 5. Thermal dependence of the effective magnetic moment for $[Cu_2(H_2[26]pbz_2N_4O_2)(oxa)_3]\cdot 4H_2O$ and $[Cu_2([26]pbz_2N_4O_2)(suc)Cl_2]$. Solid lines represent fits as described in the text.

ions. This mechanism is provided by the coordinated, highly polarizable, chlorine atoms which are present in the succinate adduct but not in the oxalate one.

3. Conclusions

The presence of mono- and dinuclear copper(II) and lead(II) complexes were confirmed by different techniques (potentiometry, mass spectra and NMR). The presence of oxygen atoms in the macrocyclic backbone lead to a decrease in the stability constants of the copper(II) complex when compared to related macrocycles containing only nitrogen donor atoms.

The high stability constant values of the Pb^{2+} complexes of [26]*p*$bz_2N_4O_2$ when compared with that of the Cu^{2+} one suggest a good fit of lead(II) into the macrocyclic cavity. Even though mononuclear complexes were found, dinuclear ones are the main species even at low metal:ligand ratios, confirming the high tendency of this macrocycle to form dinuclear complexes.

The binding constants of the cascade species formed by $[Cu_2[26]pbz_2N_4O_2(H_2O)_x]^{4+}$ with dicarboxylate anions decrease with the increase in length of the alkyl chain of the anion, a fact that was attributed to a higher conformational energy necessary for the rearrangement of the macrocycle to accommodate the larger anions bridging the two copper(II) centres. The fact that only species with one anion ($Cu_2H_hLA^{(2+h)}$) were found suggest the bridging position for the anion.

In the solid state, the role of the dicarboxylate anions appears to be not very important to mediate the Cu···Cu interaction. In fact the highly polarizable chlorine atoms, when present, provide a superexchange mechanism that couples metallic ions antiferromagnetically, even when the distance between the ions is larger, as was observed in the cases of oxa^{2-} and suc^{2-} for which the crystalline structures were determined [7].

3.1. Experimental

Terephthaldialdehyde and 1,5-diamino-3-oxapentane were obtained from Aldrich, and from Acros Organics, respectively. Oxalic acid (99.5%), malonic acid (>99%) and succinic acid (99%) were purchased from Merck. All the chemicals were of reagent grade and were used as supplied without further purification. The reference used for the ^1H NMR measurements in D_2O was 3-(trimethylsilyl)propanoic acid-d_4 sodium salt, and for ^{13}C NMR spectra dioxane was used as an internal reference. The compound [26]*p*$bz_2N_4O_2$ was synthesised according to the literature [7]. Crystals of quality suitable for X-ray analysis were obtained in four days at room temperature from an ethanol/acetonitrile (1:1 v/v) solution. ^1H NMR (D_2O, ppm): δ 7.26 (8H, s), 3.77 (8H, s), 3.70 (8H, t), 2.91 (8H, t). ^{13}C NMR (D_2O, ppm) δ 138.8, 129.1, 113.3, 79.9, 52.6, 48.0. *Anal.* Calc. for $C_{24}H_{36}N_4O_2$: C 69.87; H, 8.80; N, 13.58. Found: C 69.38; H, 9.25; N, 13.20%.

3.2. Potentiometric measurements

3.2.1. Reagents and solutions

Metal ion solutions were prepared from the nitrate salts, and were standardised as described [18]. A carbonate-free solution of the titrant, KOH, was freshly prepared, maintained in a closed bottle, and discarded when the percentage of carbonate was about 0.5% of the total amount of base (tested by the Gran method) [19,20]. The demineralised water used was obtained from a Millipore/Milli-Q system.

3.2.2. Equipment and working conditions

The equipment used has been described before [15]. The temperature was kept at 298.0 ± 0.1 K; atmospheric CO_2 was excluded from the cell during the titration by passing purified argon across the top of the solution in the reaction cell. The ionic strength of the solutions was kept at 0.10 mol dm^{-3} KNO_3.

3.2.3. Measurements

The $[H^+]$ of the solutions was determined by the measurement of the electromotive force of the cell, $E = E'^{\circ} + Q\log[H^+] + E_j$. E'°, Q, E_j and $K_w = ([H^+][OH^-])$ were obtained as described previously [15]. The term pH is defined as $-\log [H^+]$. The value of K_w was found to be equal to $10^{-13.76}$ mol^2 dm^{-6}.

The potentiometric equilibrium measurements were carried out using 15.00 cm^3 of 2.69×10^{-3} mol dm^{-3} [26]*p*$bz_2N_4O_2$ solutions diluted to a final volume of 32.00 cm^3, in the absence of copper(II) or lead(II), in the presence of metal ions, and in the simultaneous presence of copper(II) and dicarboxylate anions for 1:1:1 and 1:1:2 C_{Cu}:C_L:C_A ratios. A minimum of two replicates was undertaken. All the anions were independently titrated, alone and in the presence of copper(II) ion at 1:1 and 2:1 C_M:C_A ratios.

Only 0.5:1, 1:1 and 1.5:1 Cu^{2+}:L molar ratios were used to determine the stability constants of the complexes, due to precipitation for higher metal ratios. For lead, 1:1 and 2:1 Pb^{2+}:L ratios were used, but for the latter ratio precipitation occurred at pH 8.5.

3.3. Calculation of equilibrium constants

The overall protonation constants, β_i^H, were calculated by fitting the potentiometric data obtained for all the performed titrations with the HYPERQUAD program [21]. The protonation constants of the studied anions (oxa^{2-}, mal^{2-} and suc^{2-}) were also determined from the experimental data under the same experimental conditions, also using the HYPERQUAD program. The stability constants with the copper(II) ion were determined for the ligand and also for the studied anions. All these constants were taken as fixed values to obtain the equilibrium constants of the new species from the experimental data corresponding to all the titrations in different Cu:L:A stoichiometries, also using the HYPERQUAD program. The initial computations

were obtained in the form of overall stability constants, $\beta_{M_mH_hL_lA_a}$ values, $\beta_{M_mH_hLA} = [M_mH_hLA]/([M]^m[H]^h[L][A])$. The species considered in a particular model were those that could be justified by the principles of coordination and supramolecular chemistry. The errors quoted are the standard deviations of the overall stability constants given directly by the program for the input data, which include all the experimental points of all titration curves.

The protonation constants of [26]*p*bz$_2$N$_4$O$_2$ were determined from a minimum of 276 points and the stability constants were determined from a minimum of 138 points. The association constants between the dicopper complex and the different anions were determined from a minimum of 89, 84 and 88 experimental points for oxa^{2-}, mal^{2-} and suc^{2-}, respectively, and a minimum of two titration curves.

3.4. Magnetic susceptibility measurements

The magnetic susceptibility measurements were carried out with a Faraday-type magnetometer (Oxford Instruments) in the range 9–225 K. A magnetic field of 5 T was applied to the polycrystalline powder samples and a gradient of 1 T m^{-1} alternatively in the forward and reverse directions. The force was measured with a Sartorius S3D-V microbalance with powdered samples weighting 10–15 mg placed inside a previous calibrated Teflon bucket. The molar susceptibilities were corrected for the diamagnetism of the constituent atoms by using Pascal constants to give molar paramagnetic susceptibilities.

3.4.1. Preparation of complexes

The dinuclear copper(II) complexes were prepared as described before [7]. The cascade complexes were prepared by addition of 6 equiv. of oxalate or 1 equiv. of succinate potassium salt, dissolved in water, to the dicopper complex dissolved in a mixture of water/ethanol. The mixtures were left stirring overnight and the solvent was removed to dryness. The solid obtained was recrystallised from ethanol to obtain crystals. Yield: 90 % for the copper(II) complexes and 30% for the cascade complexes. [Cu$_2$(H$_2$L)(oxa)$_3$]: C, 41.33; H, 5.43; N, 6.17. *Anal.* Calc. for C$_{30}$H$_{46}$Cu$_2$N$_4$O$_{18}$: C, 41.05; H, 5.28; N, 6.38. [Cu$_2$LCl$_2$(suc)]: C, 43.17; H, 6.11; N, 7.45. *Anal.* Calc. for C$_{28}$H$_{46}$Cl$_2$Cu$_2$N$_4$O$_9$: C, 43.08; H, 5.94; N, 7.18.

3.5. X-ray determination of [26]*pbz*$_2$*N*$_4$*O*$_2$

Crystal data: C$_{12}$H$_{18}$N$_2$O, $M = 206.28$; triclinic $P2_1/a$, $a = 9.300(11)$ Å, $b = 10.590(11)$ Å, $c = 12.270(14)$ Å, $\beta = 97.22(1)$ $V = 1199(2)$ Å^3, $Z = 4$, $D_{calc} = 1.143$ Mg/m^3, $\mu = 0.074$ mm^{-1}, 6494 reflections collected were merged to 2258 independent reflections giving $R_{int} = 0.0747$. The refinement of 143 parameters converged to R indices$R_1 = 0.0980$, $wR_2 = 0.1770$ for all data and $R_1 = 0.1301$, $wR_2 = 0.1908$ for 1672 reflections with $I > 2\sigma(I)$. The X-ray data were collected with a MAR research image plate system with Mo Kα radiation, ($\lambda = 0.71073$ Å) at room temperature. Data analysis was performed with the XDS program [22]. The structure was solved by direct methods and subsequently refined by full-matrix least squares methods on F^2 using the SHELX-97 suite of programs [23]. Anisotropic thermal parameters were used for all non-hydrogen atoms. C–H hydrogen atoms were placed at calculated positions with $U_{iso} = 1.2\ U_{eq}$ of the parent atom refined with individual isotropic thermal parameters. The atomic positions of the hydrogen atoms of the water solvent were not apparent from final difference Fourier maps and they were not included in the refinement of the structure. Molecular diagrams were drawn with PLATON [24].

Abstract

This paper reports on the electrochemical study of Dawson-type polyoxometalates (POMs) disubstituted with phenyl-phosphonate, phenyl silyl or tertbutylsilyl moieties. The polyanions were studied by cyclic voltammetry and on rotating disk electrode in acetonitrile with tetraphenylphosphonium chloride as supporting electrolyte. We found that these hybrid polyoxometalates can accept up to five electrons and that the organic substituents modify the first and second reduction potential of the POM compared to the unsubstituted POM $[P_2W_{18}O_{62}]^{6-}$. Phenyl-phosphonate lowers the reduction potential, whereas the phenyl silyl or tertbutylsilyl moieties shift them cathodically. We also recorded by spectroelectrochemistry the spectrum of the monoreduced and the bisreduced species of the polyoxometalate disubstituted with phenyl-phosphonate.

1. Introduction

Polyoxometalates (POMs) are large inorganic polyanions generally based on oxides of molybdenum or tungsten. Each metal is located at the center of an octahedron, MO_6, and these octahedra are all bonded together through their corners or their edges and are assembled around an internal tetrahedrally coordinated heteroatom, typically PO_4^{3-} or SiO_4^{4-}. Polyoxometalates are a valuable class of compounds because they span a wide range of potential applications in material science, medicine, catalysis and pigments owing to their rich electrochemical, photochemical and catalytic properties [1–4]. One appealing characteristic of POMs is their capacity to accept several electrons [3,5], which makes them particularly well-suited to act as electron reservoirs. As a result, POMs are attractive candidates to be used as multielectron acceptors for the development of photochemical devices aiming at photocumulative electron transfer and as electrocatalysts for multielectron reduction processes such as the reduction of water into hydrogen gas. Indeed, there are several reports showing that some POMs can act as homogenous catalysts for the reduction of water into dihydrogen from aqueous solution [3,6–9].

The possibility to covalently connect POMs to organic molecules *via* phosphonates [10–13], silanes [14–16], imido [17–21] or other binding units [22,23] opens up the possibil-

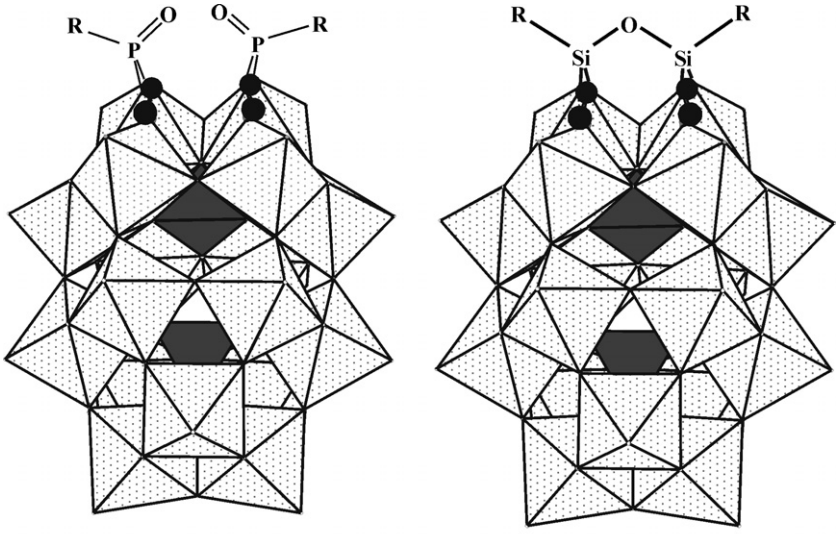
doi:10.1016/j.poly.2007.10.022

ity to prepare inorganic/organic hybrid devices and consequently to merge the intrinsic properties of each fragment. In this context, we are interested to use POMs as electron reservoirs for the construction of photochemical molecular devices in view of water splitting. More precisely, we wish to use the POM as an electron sink that would eventually accept several electrons coming from several multi-component photochemical systems featuring photoinduced electron transfers. Towards this end, we were interested to explore the redox potentials of Dawson type POMs substituted with organic moieties. It was indeed anticipated that the electrochemical properties of the substituted POMs may differ from the unsubstituted parent POM. There is a large amount of information about the electrochemical properties of unsubstituted POMs [3,24–27], but there is almost no report about POMs substituted by an organic group [28] and particularly with Dawson type POMs functionalized with organo-silyl or organo-phosphoryl moieties. The knowledge of the redox potentials of these covalently functionalized POMs is however of a crucial importance to predict the feasibility of a photoinduced electron transfer process with a given sensitizer and therefore for the rational design of a photochemical device relying on POM as terminal electron acceptor, but also in view of other applications since the POMs are often used for their electrochemical properties. The aim of the present paper is therefore to fill this gap by investigating the electrochemical properties of the three functionalized polyoxometalates, α_2-$[P_2W_{17}O_{61}(RPO)_2]^{6-}$ (R = Ph, **1**) and α_2-$[P_2W_{17}O_{61}(RSi)_2O]^{6-}$ (R = Ph, **2** and *ter*-But, **3**) (Fig. 1). More precisely, we have determined the impact of organo-silyl or organo-phosphonate substituents on the reduction potentials of the monovacant Dawson polyoxometalate $[P_2W_{17}O_{61}]^{10-}$ framework and compared to saturated Dawson POM $[P_2W_{18}O_{62}]^{6-}$. We found that the functionalized polyoxometalates **1**–**3** can still receive up to 4 or 5 electrons and that the position of their reduction potentials can be tuned by the nature of the anchoring groups (phosphonate or silyl) used to connect the organic moiety to the POM.



2. Experimental

The polyoxometalates **1**–**3** were prepared as described in the literature [14,29]. The electrochemical measurements were performed with a potentiostat–galvanostat MacLab model ML160 controlled by resident software (Echem v1.5.2 for Windows) using a conventional single-compartment three-electrode cell. The working electrode was a glassy carbon disk of 4 mm^2 area, the auxiliary was a Pt wire and the reference electrode was the saturated potassium chloride calomel electrode (SCE). The solvents used in these studies were distilled prior use following usual drying procedures; however the presence of traces of water in the electrolyte can not be excluded since the POMs themselves are certainly hydrated compounds. All potentials are quoted relative to SCE. In all the experiments the scan rate was 100 mV/s for the cyclic voltammetry and 15 Hz for pulse voltammetry. Spectroelectrochemical spectra were recorded in a thin quartz UV–Vis cell (0.5 mm) surmounted with a reference electrode (SCE) and a platinum wire as counter electrode. The working electrode was a platinum grid inserted within the quartz cell and the other conditions are the same as those for the cyclic voltammetry. UV–Vis absorption spectra were recorded on a UV-2401PC Shimadzu spectrophotometer.

3. Result and discussion

3.1. Electrochemical study

The cyclic voltammograms of the polyoxometalates **1**–**3** are shown in Figs. 2–5 and the half-wave potentials are gathered in Table 1. Since, we were interested to study

1 **2** or **3**

The process in the anodic region is due to ferrocene internal reference.

the influence of the organic substituent on the redox potential values of the polyoxometalates, we therefore started by examining the electrochemical behaviour of the unsubtituted and saturated polyoxometalate $[P_2W_{18}O_{62}]^{6-}$. The latter can take as a reference and could be considered as the parent compound from which the polyanions **1**–**3** are derived, in which the lacunar surface was saturated by both electrophilic groups. The electrochemistry of $[P_2W_{18}O_{62}]^{6-}$ has already been reported several times in the literature, but it was essentially investigated in buffered aqueous solution [3,24–27] and more rarely in an organic solvent [30]. As expected, our results showed both the solubility and the electrochemical behaviour of the reference $[P_2W_{18}O_{62}]^{6-}$ were found poor in acetonitrile compared with the other substituted polyoxometalates **1**–**3**. Herein, DMSO with Bu_4NPF_6 was used as supporting electrolyte solution and showed a good compromise between the solubility and the electrochemical behaviour of $[P_2W_{18}O_{62}]^{6-}$.

The cyclic voltammogram of $[P_2W_{18}O_{62}]^{6-}$ shows four successive reduction waves up to −1.5 V versus SCE, but only the first process displays a well-resolved voltammogram with the peak-to-peak separation ΔE of 70 mV (Fig. 2). This latter process is consistent with the addition of one electron on the polyoxometalate that resides most probably in a tungsten empty d^0 orbital [3–5,26]. The other reduction waves are relatively well-defined but their intensities decreases steadily with a significant increase in the ΔE values. Such electrochemical behaviour could be attributed to the precipitation of the reduced species generated at the electrode surface due to their low solubility in DMSO + Bu_4NPF_6 electrolyte,

Fig. 3 shows the cyclic voltammogram of the polyoxometalate **1** disubstituted by two phenyl phosphonic acid units that displays four quasi-reversible reduction processes. The comparison of the magnitude of the three first processes to the known Fc^+/Fc one-electron process using the rotating electrode reflects a similar height characteristic

Table 1
Redox potentials of the polyoxometalates **1**–**3** along with those of the parent $P_2W_{18}O_{62}(Bu_4N)_6$

	E_{Red1}/V (ΔE/mV)	E_{Red2}/V (ΔE/mV)	E_{Red3}/V (ΔE/mV)	E_{Red4}/V (ΔE/mV)
$[P_2W_{18}O_{62}]^{6-}$[a]	−0.50 (70)	− 0.68 (86)	−1.03 (112)	1.37 (144)
$[P_2W_{17}O_{61}(PhPO)_2]^{6-}$ (**1**)[b]	−0.20 (66)	−0.58 (66)	−1.20 (68)	−1.54 (90)
$[P_2W_{17}O_{62}(PhSi)_2]^{6-}$ (**2**)[b]	−0.62 (70)	−0.92 (90)	−1.17 (134)	−1.17 (134)
$[P_2W_{17}O_{62}(tBuSi)_2]^{6-}$ (**3**)[b]	−0.70 (70)	−0.91 (90)	−1.19[c]	−1.24[c]

All potentials are referred vs. SCE. In these conditions $E_{1/2}(Fc^{+/0}) = 0.37$ V. Working electrode: glassy carbon.

of one-electron process. In contrast, the last wave seems ill-defined with a height value probably less than one electron. It is interesting to note that, the first reduction potential of the compound **1** is anodically shifted by 300 mV compared to that of the parent $[P_2W_{18}O_{62}]^{6-}$ whereas the second potential is shifted by 110 mV (Table 1). This reflects the known electron-withdrawing property of the phosphonate group that pumps up a certain amount of the electronic density on the negatively charged polyoxometalate. However, this effect becomes less pronounced as the number of injected electrons on the polyoxometalate increases, this is probably due to the fact that the first injected electron is trapped close to the metals directly bound to the phosphonate. The other reduction processes involve electrons that reside on the other metals, that are further away and therefore less influence by phosphonate group.

When, the organic moiety is grafted through a silyl anchoring group a different electrochemical behaviour can be observed. The cyclic voltammogram of **2** and **3** exhibits four distinct waves (Figs. 4 and 5). Both the first and second waves can be considered as a monoelectronic and reversible electrochemical process, but the third corresponds to the exchange of about two electrons as determined with the rotating disk electrode and the last process accounts for less than one electron probably due to the precipitation of the preceding reduced species (Figs. 4 and 5). In compound **3**, the potentials of third and fourth reduction process are sufficiently different to be determined by differential pulse voltammetry, but in POM **2** they merge to give a single bielectronic wave. The comparison of the redox potentials of both polyoxometalate **2** and polyoxometalate **3** with those of the reference and of the polyoxometalate **1**, indicates that the silyl group exhibits an opposite effect compared to that observed with the phosphonate group. With the silyl anchoring group, the first reduction process becomes more difficult than that of **1** and that of the unsubstituted polyoxometalate $[P_2W_{18}O_{62}]^{6-}$ (Table 1). Besides, the inspection of the values of the first reduction potential between **2** and **3** shows that the *tert*butyl group renders the silyl moiety more electron rich than the phenyl one and hence destabilizes greater the reduced polyoxometalate. This is perfectly consistent with the known electron releasing property of alkyl chains compare to the weak electron accepting character of phenyl. As a consequence, the first reduction potential of **3** is cathodically shifted with respect of that of **2** (Table 1). Overall, the nature of the anchoring moiety (silyl or phosphonate) and the organic substituent modify the reduction potentials of the substituted Dawson type polyoxometalates.

3.2. Spectroelectrochemical study

The limited number of spectroelectrochemical studies with organo-functionalized POMs[28] prompted us to determine the spectrum of the monoreduced and the bireduced species of POM **1**. The utilization of POMs as electron acceptors in a photochemical molecular device will inevitably requires the knowledge of the spectroscopic signature of the reduced species in order to be able to monitor their formations by time-resolved transient absorption spectroscopy. We chose to study POM **1** by spectroelectrochemistry because it exhibits the most reversible and the most distinct reduction processes within the series. The spectra of the POM **1** were recorded during the course of the electrolysis of a thin layer of a solution of **1** (Fig. 6).

Before reduction, the spectrum of POM **1** exhibits an intense absorbance in the UV region (below 290 nm). It is attributed to a ligand-to-metal-charge-transfer transition (LMCT) and corresponds to a shift of the electronic density from the oxygen to the tungsten atoms [3,4]. Upon

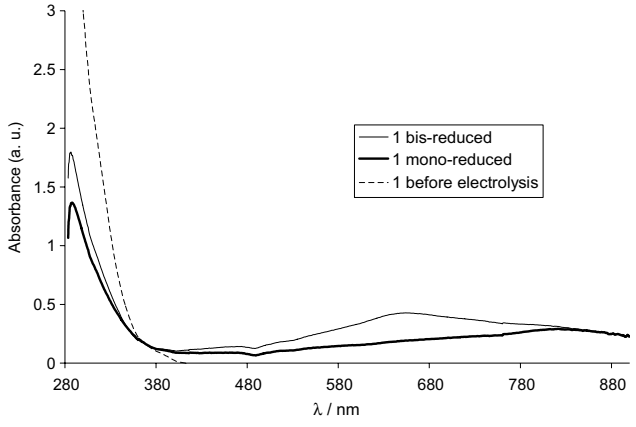

Fig. 6. Electronic absorption spectra of POM **1** (0.3 mM) recorded in CH_3CN with Ph_4PCl (0.1 M) as supporting electrolyte; before electrolysis (dashed line); after one-electron reduction (bold solid line); after two-electron reduction (thin solid line).

one-electron reduction, the colorless solution turned blue evidencing the formation of the expected so-called "heteropoly blue" well-characterized with unsubstituted POMs that were reduced by electrochemical or photochemical means [3–5,30,31]. The one-electron reduction of POM **1** induces a decrease of the absorbance in the far UV region and the formation of a new broad absorption band in the visible region between 500 and 900 nm with a maximum absorption located at 822 nm (Fig. 6). This new band is assigned to an intervalence charge transfer transition between the d^1 reduced-tungsten metal and one of the other d^0 tungsten metals or a metal centered d–d transition [5,30]. Further electrolysis of the solution induces a drop of the absorbance at 822 nm and the formation of a new band localized at 655 nm (Fig. 6). This latter band most probably also corresponds to an intervalence charge-transfer and a tungsten-centered d–d transition, but whose energies has been increased due to the modification of the energy levels of the HOMO and LUMO frontier molecular orbitals of the doubly reduced POM. The spectroscopic features measured here upon reduction of POM **1** are in good agreement with the results of Pope and coworkers on the spectroelectrochemical study of $[P_2W_{18}O_{62}]^{6-}$ [5]. It is worthy of noticing that the application of a positive bias to the grid electrode, after the formation of the doubly reduced species, allows for the retrieval of the initial spectrum recorded before electrolysis. This result clearly demonstrates the chemical stability of the reduced species and the electrochemical reversibility of the two first reduction processes. Overall, we can observe that the monoreduced and bisreduced species exhibit clear and distinct spectroscopic signature that will make the formation of these species easily detected by transient absorption spectroscopy.

4. Conclusions

The electrochemical characterizations of three Dawson POMs substituted by organic phosphonate or silyl moieties are reported for the first time. We demonstrated the influence of organo-phosphonate and organo-silyl groups on the reduction potentials on substituted Dawson type POMs. Compared to the parent unsubstituted $[P_2W_{18}O_{62}]^{6-}$, the phosphonate induces an anodic shift of the first and the second half-wave reduction potential, whereas the silyl group has an inverse effect. The ability to tune the reduction potential of POMs, through the choice of the organic substituent, can be used to alter the electrochemical properties of a specific POM and to engineer new molecular function. Finally, we determined by spectroelectrochemistry the specific fingerprint of the monoreduced and bisreduced species of POM **1** functionalized by two phenyl phosphonic acid groups.

In conclusion, the functionalization of a Dawson type-POM with a phosphonate or silyl groups appears to be an effective mean to prepare electrochemically active hybrid POMs, because the functionalized systems can still undergo several electron reductions at low potentials and they also lead to stable reduced species that can be easily identified by absorption spectroscopy. Therefore, the as-functionalized POMs represent suitable compounds to be used as electron reservoirs for cumulative electron transfers or for other applications such as covalent functionalization of electrodes with POMs for catalysis.

Abstract

Three new copper(II) complexes $[CuL^1]_2(ClO_4)_2$ (**1**), $[CuL^2]ClO_4$ (**2**) and $[CuL^3]$ (**3**) with three Schiff base ligands [HL^1 = 1-phenyl-3-{3-[(pyridin-2-ylmethylene)-amino]-propylimino}-butan-1-one, HL^2 = 1-phenyl-3-[3-(1-pyridin-2-yl-ethylideneamino)-propylimino]-butan-1-one and H_2L^3 = 3-[3-(1-methyl-3-oxo-3-phenyl-propylideneamino)-propylimino]-1-phenyl-butan-1-one] have been synthesized and structurally characterized by X-ray crystallography. The mono-negative tetradentate asymmetric Schiff base ligands $(L^1)^-$ and $(L^2)^-$ are chelated in complexes **1** and **2** to form square planar copper(II) complexes. In complex **1**, the two units are associated weakly through ketonic oxygen of benzoylacetone fragment to form the dimeric entity. The square planar geometry of complex **3** is unusually distorted towards tetrahedral one. All three complexes exhibit reversible cyclic voltammetric responses in acetonitrile solution corresponding to the Cu^{II}/Cu^{I} redox process. The $E_{1/2}$ (−0.47 V versus SCE) of **3** shows significant anodic shift due to the tetrahedral distortion around Cu(II) compare to that of **1** and **2** (−0.82 and −0.87 V versus SCE, respectively).

Keywords: Copper(II); Unsymmetrical Schiff base; 1-Benzoylacetone; Crystal structure; Electrochemical behavior

1. Introduction

The interest in the design, synthesis and characterization of the transition metal complexes of unsymmetrical Schiff base ligands has come from the realization that coordinated ligands around central metal ions in natural systems are unsymmetrical [1]. Recently, this class of compounds has also attracted much attention in the field of optoelectronic technologies for their large nonlinear responses [2]. Compare to their symmetrical counterpart, syntheses of such ligands are rather difficult because simple condensation methodology with three components is no longer applied. However, since the first reports on the synthesis of 7-amino-4-methyl-5-azahept-3-en-2-one (AMAH) [3] and 8-amino-4-methyl-5-azaoct-3-en-2-one (AMAO) [4], the monocondensation products of 2,4-pentanedione with 1,2-ethanediamine and or 1,3-propanediamine, respectively, these 'half units' have been used extensively as precursors for the preparation of unsymmetrical quadridentate Schiff base ligands [2,5]. In most of the ligands reported so far, the acetylacetoneiminato side is usually kept unchanged and the other side of the diamine is condensed with various aromatic carbonyl compounds to study the variation and fine tuning of stability, reactivity and electronic properties of such complexes [5,6]. The apparent reason for keeping the acetylacetoneiminato fixed, seems to be the facile synthesis of the 'half unit' by high dilution method [3,4]. Recently, we successfully synthesized the analogous tridentate Schiff base by monocondensation of 1-benzoylacetone

Scheme 1.

with 1,2-ethanediamine or 1,2-propanediamine under the similar conditions and used those ligands to synthesize trinuclear Cu(II) complexes with a μ_3-OH core [7]. On the contrary, the corresponding 'half unit' of 1,3-propanediamine did not result the similar trinuclear complex, instead underwent hydrolysis during complex formation indicating its lower stability [7]. This encourages us to synthesize tetradentate Schiff base using the precursor 7-amino-3-methyl-1-phenyl-4-azahept-1,3-dien-1-ol (HAMPA, the monocondensation product of 1,3-diaminopropane and 1-benzoylacetone) and to explore if the double condensed ligands are stable enough to result in the formation of complexes with copper(II).

In this paper, we report synthesis, spectral characterization, crystal structures and electrochemical behavior of three Cu(II) complexes. Two of them are derived from the unsymmetrical tetradentate Schiff bases HL^1 and HL^2 formed by the condensation of free amine group of HAMPA with pyridine-2-carboxaldehyde and 2-acetylpyridine, respectively, and the other one from symmetrical Schiff base H_2L^3 containing 1-benzoylacetone at the both ends of 1,3-diaminopropane (Scheme 1). The significant structural differences of these complexes from their acetylacetone analogs are also discussed here.

2. Experimental

All chemicals were of reagent grade and used without further purification.

2.1. Synthesis of the precursor tridentate ligand, HAMPA

The precursor mono-condensed Schiff base, HAMPA was synthesized by high dilution technique [7,8]. 1-Benzoylacetone (10 mmol, 1.6 g) in chloroform (50 cm^3) was added drop wise to a solution of 1,3-propanediamine (10 mmol, 0.76 cm^3) in chloroform (50 cm^3). After completion of the addition, the solution was stirred for an additional 3 h and then chloroform was evaporated under reduced pressure, yielding HAMPA as a viscous liquid.

2.2. Synthesis of the ligands, 1-phenyl-3-{3-[(pyridin-2-ylmethylene)-amino]-propylimino}-butan-1-one (HL^1) and 1-phenyl-3-[3-(1-pyridin-2-yl-ethylideneamino)-propylimino]-butan-1-one (HL^2)

To synthesize HL^1, a methanolic solution (15 cm^3) of pyridine-2-carboxaldehyde (10 mmol, 0.95 cm^3) was added to a methanolic solution (25 cm^3) of HAMPA (10 mmol). The mixture was warmed at 50 °C for 1 h and cooled to room temperature. HL^2 was prepared in the same way as HL^1 using 2-acetyl pyridine (10 mmol, 1.12 cm^3) instead of pyridine-2-carboxaldehyde. The tetradentate ligands HL^1 and HL^2 were not isolated and the methanol solutions were used for the synthesis of the complexes.

2.3. Synthesis of complex $[CuL^1ClO_4]_2$ (1), $[CuL^2ClO_4]$ (2)

A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (10 mmol, 3.7 g) in methanol (20 cm^3) was added to the resulting methanol solution of each tetradentate ligands HL^1 and HL^2 with continuous stirring. Brown colored solid of complex **1** separated immediately. The dark brown single crystal of **1**, suitable for X- ray diffraction was obtained on dissolving it in acetonitrile. In case of complex **2**, separation of brown mass took place on keeping the mixture overnight in a refrigerator. The reddish-brown single crystal for suitable for X- ray diffraction was obtained on dissolving the mass in a mixture of acetonitrile and methanol (1:2).

Complex **1**: Yield: 1.9 g (57%). *Anal.* Calc. for $C_{38}H_{40}Cl_2Cu_2N_6O_{10}$: C, 48.62; H, 4.29; N, 8.95; Cu, 13.54. Found: C, 48.74; H, 4.12; N, 8.87; Cu, 13.46%. λ_{max}/nm (ε_{max}/$dm^3\ mol^{-1}\ cm^{-1}$) (acetonitrile), 631 (144); IR: ν(C=N), 1525, 1572 cm^{-1}, $\nu(ClO_4^-)$, 1086 cm^{-1}.

Complex **2**: Yield: 2.0 g (55%). *Anal.* Calc. for $C_{20}H_{22}ClCuN_3O_5$: C, 49.69; H, 4.59; N, 8.69; Cu, 13.15. Found: C, 49.86; H, 4.61; N, 8.53; Cu, 13.19%. λ_{max}/nm (ε_{max}/$dm^3\ mol^{-1}\ cm^{-1}$) (methanol), 607 (152); IR: ν(C=N), 1522 and 1557 cm^{-1}, $\nu(ClO_4^-)$, 1091 cm^{-1}.

2.4. Synthesis of complex $[CuL^3]$ (3)

The symmetrical Schiff base in complex **3** was formed by the condensation of 1-benzoylacetone at both end of 1,3-propanediamine. To synthesize H_2L^3, a methanolic solution (15 cm^3) of 1-benzoylacetone (10 mmol, 1.6 g) was added to a methanolic solution (20 cm^3) of HAMPA (10 mmol). The mixture was warmed at 50 °C for 1 h and cooled to room temperature. A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (10 mmol, 3.7 g) in methanol (20 cm^3) was added to the resulting solution of the tetradentate ligand with continuous stirring. The resulting solution was left overnight when greenish blue crystalline compound suitable for X-ray analysis were separated out.

Complex **3**: Yield: 1.7 g (45%). *Anal.* Calc. for $C_{12}H_{15}CuN_3O_3$: C, 65.15; H, 5.71; N, 6.61; Cu, 14.99. Found: C, 65.32; H, 5.66; N, 6.57; Cu, 14.87%. λ_{max}/nm (ε_{max}/$dm^3\ mol^{-1}\ cm^{-1}$) (methanol), 568(159); IR: ν(C=N), 1520 cm^{-1}.

2.5. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 240C elemental ana-

lyzer and the copper contents in all the complexes were estimated spectrophotometrically. The IR spectra in KBr (4500–500 cm^{-1}) were recorded using a Perkin–Elmer RXI FT-IR spectrophotometer. The electronic spectra in methanol (1200–350 nm) were recorded in a Hitachi U-3501 spectrophotometer. Cyclic voltammetry was carried out using Sycopel model AEW2 1820F/S instrument. The measurements were performed at 300 K in acetonitrile solutions containing 0.2 M TEAP and 10^{-3} M Cu(II) complex deoxygenated by bubbling with nitrogen. The working, counter, and reference electrodes used were a platinum wire, a platinum coil, and an SCE.

2.6. Crystallographic studies

The data for complex **1** were collected at room temperature with Mo Kα radiation on Bruker AXS Smart single crystal diffractometer with CCD (area detector).The absorption correction was performed with the method inserted in SHELXTL-NT V5.1 [9]. The structure was solved by direct methods with the software SHELXTL-NT V5.1 inserted in the Bruker AXS software [9].

The data for complexes **2** and **3** were collected at room temperature with Cu Kα radiation on Siemens AED single crystal diffractometer with a local program [10]. The preliminary cell parameters were obtained from least squares of the (θ, χ, ϕ) angular values of 3897 and 1948 reflections (θ range = 4–70° and 5.5–70°) respectively for complexes **2** and **3**, accurately well centered on the diffractometer. The intensity of one standard reflection, recorded for every 100 reflections, showed no significant changes. The recorded data were corrected for polarization and Lorentz effects. The absorption correction was performed with the method of Walker and Stuart [11] with a program written by Gluzinski [12].

The crystal structures of the three complexes were solved by direct methods using SHELXS-97 [13] program and refined by using SHELXL-97 [13]. The nonhydrogen atoms were refined anisotropically while the hydrogen atoms were located from difference Fourier map. The positional and thermal parameters were kept fixed during refinement. Neutral atom scattering factors were taken from Cromer and Weber [14] and anomalous dispersion effects were included in F_{calc} [15]. In complex **2** there are disordered carbon atoms in the diamine fragments. The site occupation factors of the disordered pairs of atoms (C3A and C3B; C4A and C4B) were constrained to be unity and were tied to FVAR. The crystallographic illustrations were prepared using ORTEP-3 [16]. Significant crystallographic data are summarized in Table 1.

3. Results and discussion

3.1. IR and electronic spectra

All these compounds contain no significant peak in the region of 3100–3250 cm^{-1}, which clearly indicates that there is no free $-NH_2$ group i.e. all are the quadridentate ligands that form the complexes. The bands corresponding to azomethylene group (C=N) are distinct in all three complexes and appear within 1572–1520 cm^{-1}. The sharp, strong, single peak at 1086 and 1091 cm^{-1} for complexes **1** and **2** clearly indicates the presence of anionic perchlorate group. As expected, complex **3** does not show any such peak.

The electronic spectral data in acetonitrile solution suggest basically square planar geometry for **1** and **2**. In general square-planar complexes are known to exhibit one or two bands [17]. Complexes **1** and **2** show a broad band at 631 and 607 nm, respectively, as was also observed for

the complexes of similar asymmetric ligands [5,18,19]. The appearance of similar d-d transition in both **1** and **2** confirms the semi-coordinated character of the ketonic oxygen of the ligand in **1**, which does not significantly affect the square planar geometry around the Cu(II) ions of the complex. At the higher energy region, the ligand to metal charge transfer bands were located for both the complexes (319 and 281 nm for complex **1** and 345 and 284 nm for complex **2**). Complex **3** also shows a broad band centering at 568 nm for the d-d transition and 341 and 301 nm for ligand to metal charge transfer transitions.

3.2. Description of structures of complexes *1*, *2* and *3*

3.2.1. Complexes *1* and *2*

The structures of the complexes **1** and **2** are shown in Figs. 1 and 2, respectively, with common atom numbering scheme. For both compounds, the structures consist of $[CuL]^+$ cation together with perchlorate anion. In complex **1**, two symmetry related $(1-x, -y, 1-z)$ cations are joined together through very weak interaction from the oxygen atom of the benzoylacetone moiety to the axial position of copper atom at a distance of 2.767(3) (Fig. 3). Although the distance is very long but is less than the sum of the van der Waals radii for copper(II) and oxygen (2.92 Å) [20]. Therefore, a weak bond is considered to be formed between the two. Comparable distances have been regarded as bond in several other reported systems [21]. In **2**, the complex cations are discrete; the closest copper–oxygen distance between the two neighboring units is 3.029 Å. In both complexes, the deprotonated ligands L^1 and L^2 are quadridentate forming two adjacent six-membered and one five-membered chelate rings (6-6-5). The copper(II) ions have square-planar co-ordination with a slight tetrahedral distortion in both the complexes.

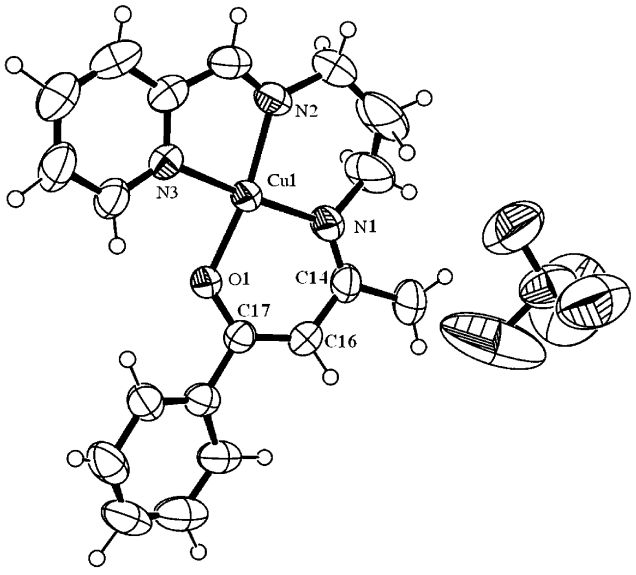

Fig. 1. ORTEP plot of **1** with atom-numbering scheme; ellipsoids at 50% probability.

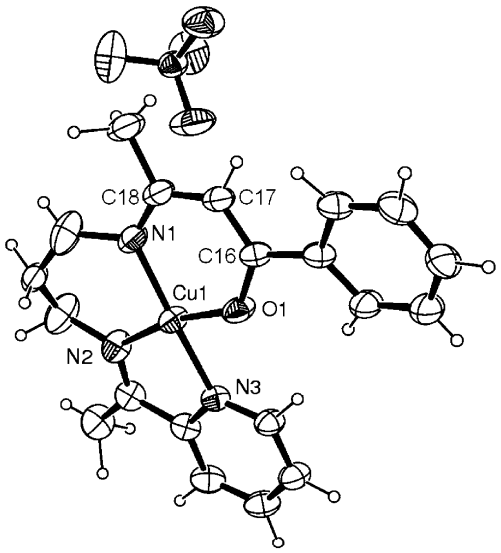

Fig. 2. ORTEP plot of **2** with atom-numbering scheme; ellipsoids at 50% probability.

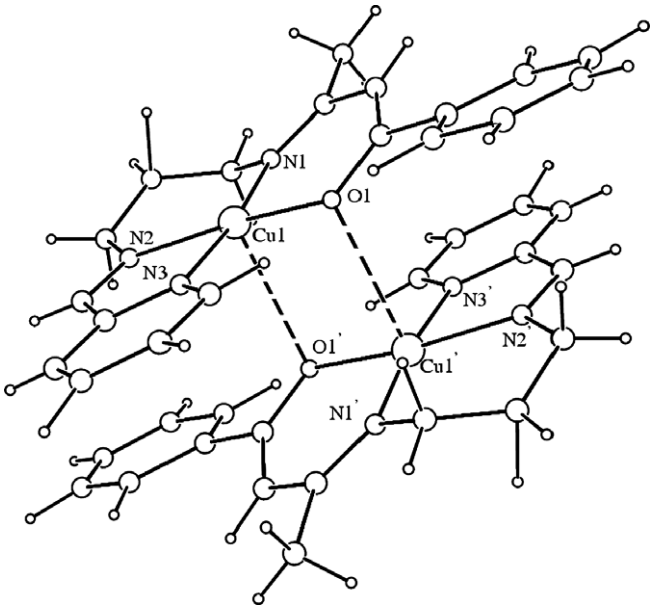

Fig. 3. A view (PLUTO) of the dimer of **1**. Perchlorate ions are not shown for clarity. Symmetry transformation: $' = (1-x, -y, 1-z)$. Dashed bonds represent the weak axial bond.

Deviations of donor atoms O(1), N(1), N(2) and N(3) from the mean plane passing through them are −0.057(2), 0.054(4), −0.059(3) and 0.062(3) Å, respectively, for **1** and −0.047(2), 0.043(3), −0.047(3) and 0.051(2) Å, respectively, for **2**. The central Cu(II) atom deviates negligibly (0.0037(3) Å) in complex **1** and slightly more (0.0274(4) Å) in complex **2** from the same plane. The tetrahedral distortion is apparent since one pair of diagonal donor atoms clearly lies below the plane while the other pair is above the plane with the metal ion in the mean plane. The dihedral angles between the two planes [N(l)–Cu–O(1) and N(2)–Cu–N(3)] is 6.09° for complex **1** and 4.82° for complex **2**

compares with 0° for a perfectly square-planar arrangement and 90° for a perfect tetrahedral arrangement. The two diagonal N–Cu–O and N–Cu–N angles of complex **1** [169.3(1) and 172.8(1)°] and **2** [168.0(1) and 174.7(1)°] are less than 180° as a result of this tetrahedral distortion. The metal ion is not perfectly centered, and the four bond distances between donor atoms to metal ion are significantly different as shown in Table 2. In both the complexes, the mean Cu–N distances (1.999 and 1.988 Å for **1** and **2**, respectively) are slightly longer than that of Cu-O (1.916 and 1.906 Å for **1** and **2**, respectively). This elongated Cu–N bond than the Cu–O is also observed for similar Schiff bases [5,19]. It is worth mentioning that, the Cu–O(1) bonds in complexes **1** and **2** are slightly greater than the similar known copper systems having acetylacetone residue [5].

The six-membered chelate ring incorporating the benzoylacetone moiety is delocalized by the influence of coordination to the metal. In complex **1**, this ring containing Cu(1), N(1), C(14), C(16), C(17) and O(1); the C(16)–C(17) distance of 1.379 Å is much shorter than the normal sp^2–sp^2 C–C single bond (1.51 Å), the C(14)–N(1) distance of 1.288 Å is a little longer than normal imine C=N double bond (1.28 Å) and the C(17)–O(1) bond length of 1.299 Å is shorter than normal sp^2 C–O single bond (1.34 Å). All these changes in bond length indicate delocalization of the chelating ring containing the benzoylacetone fragment. The same trend in bond lengths is also found in the ring of the benzoylacetone fragment in complex **2** with the C(16)–C(17), C(18)–N(1) and C(16)–O(1) distances of 1.370, 1.301 and 1.302 Å, respectively. It is clear that the replacement of acetylacetone residue by a benzoylacetone, slightly increases the C–O (ketonic) and C(16)–C(17) bond distances (1.280 and 1.342 Å, respectively, in the acetylacetone derived complex [5]). However, other bond distances (C–C and C=N) do not show significant changes.

The chelating ring tends to remain planar as a result of this delocalization to form a stable conjugation structure with no atoms deviating from the least square plane by 0.021 and 0.026 Å for complexes **1** and **2**, respectively. It is interesting to note that the mean plane of this ring is not coplanar with the benzene plane, the angles between the two planes are 17.27° and 17.91° for complexes **1** and **2**, respectively. The other six-membered ring incorporating the diamine fragment is not planar as all the carbon atoms are sp^3 hybridized. Two of the carbon atoms (C3 and C4) in **2** are disordered (occupancy of C3b is 0.59(7) and that for C4b is 0.60(1)). Therefore, we perform the conformational analysis with C3b and C4b. The conformation of the chelate ring is intermediate between chair and half-chair conformation for both complexes **1** ($Q = 0.258$ Å, $\theta = 47.7°$ and $\phi = 147.1°$) and **2** ($Q = 0.273$ Å, $\theta = 36.7°$ and $\phi = 17°$) [22]. The bond distances and bond angles of this part of Schiff base are comparable with those of related Cu(II) complexes with other nonsymmetrical Schiff base ligands [5].

The dimerization of **1** through the ketonic oxygen bridge seems to be a noteworthy phenomenon for this type of complexes as the acetylacetone analogue of complex **1** is a discrete monomer [5]. The similar bridging property of phenoxo group is well documented in the literature [23] but the ketonic oxygen of acetylacetone or its derivatives is considered as nonbridging in asymmetrical or symmetrical tetradentate ligands. Till date, the bridging property of such ketonic oxygen is illustrated only in conjunction with other stronger bridging group e.g. hydroxo, oximato, etc. [7,8a,8d,24]. Therefore, to our knowledge, complex **1** is the first example of dimerization in Cu(II) complexes containing tetradentate Schiff base ligand via solely ketonic oxygen bridges.

In both complexes the intermolecular packing is controlled by π-stacking interaction between the aromatic rings. In **1**, there is a strong π–π interaction between the phenyl ring and the pyridyl ring of a neighboring ($2 - x$, $-y$, $1 - z$) dimer with a slip angle of 28.87°, dihedral angle of 5.93° and centroids separation of 3.863(3) Å to form a one-dimensional chain along the a axis as illustrated in Fig. 4. In **2** also there is similar π–π interaction between the phenyl ring and the pyridyl ring of a neighboring ($2 - x$, $-y$, $1 - z$) units (slip angle = 31.71°, dihedral angle = 4.65° and centroid separation = 4.145(2) Å) resulting the stack of molecule along the *a*-axis (Fig S1).

3.2.2. Complex 3

The structure of complex **3** with atomic numbering scheme is shown in Fig. 5. The structure consists of discrete four coordinate copper(II) complex having quadridentate symmetrical Schiff base ligand. Selected bond distances and bond angles given in Table 3. The chelated deprotonated ligand, $(L^3)^{2-}$ forms three adjacent six-membered rings (6-6-6); the two terminal rings are consist of benzoylacetone fragments and the one at the middle by the starting diamine. The central Cu(II) atom has a distorted square planer coordination with a significant tetrahedral distortion. The coordinating atoms N1, N2, O1 and O2 deviates

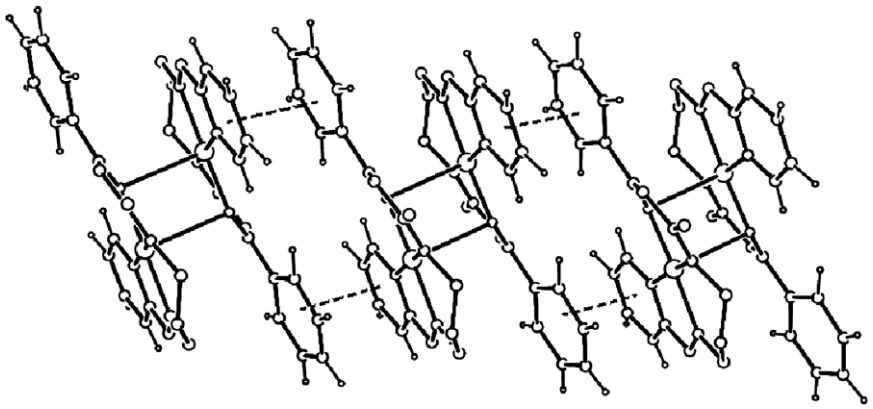

Fig. 4. One-dimensional π–π interactions shown in the dotted lines in complex **1**. Hydrogen atoms of the diamine fragments are not shown for clarity.

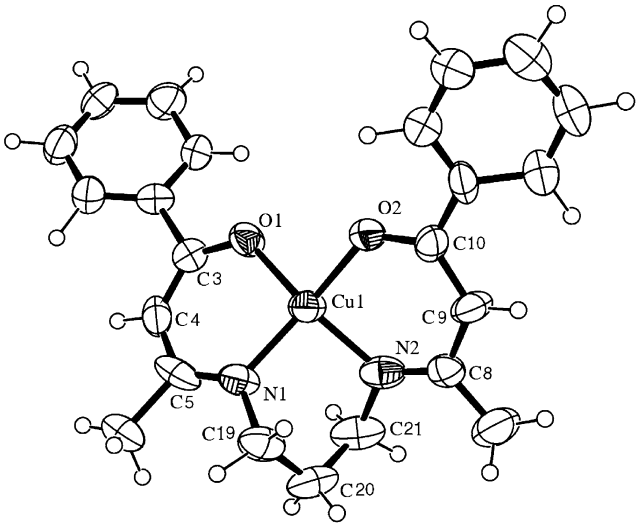

Fig. 5. ORTEP plot of **3** with atom-numbering scheme; ellipsoids at 50% probability.

Table 3

Cu(1)–O(1)	1.898(9)
Cu(1)–O(2)	1.924(9)
Cu(1)–N(1)	1.928(11)
Cu(1)–N(2)	1.955(12)
O(1)–Cu(1)–O(2)	90.7(4)
O(1)–Cu(1)–N(1)	95.4(4)
O(1)–Cu(1)–N(2)	151.5(4)
O(2)–Cu(1)–N(1)	156.3(4)
O(2)–Cu(1)–N(2)	93.5(5)
N(1)–Cu(1)–N(2)	92.0(5)

from the least-square mean plane through them by – 0.442(3), 0.427(3), −0.427(3), 0.442(3) Å. The Cu atom is located 0.039 Å from the same plane. The dihedral angles between the two planes [N(l)–Cu–O(1) and N(2)–Cu–O(2)] is 35.98°, which is much greater than that in the similar tetracoordinated copper(II) complexes like bis-(benzoylacetone)-ethylenediiminato-*N*,*N*′copper(II) complex (3.73°) [25], $[Cu(acactn)H_2O]_2$ (7.77°) and $[Cu_2(acactn)2KClO_4]_2$ (10.85° and 4.6°) where H_2acactn is bis(acetylacetone)-trimethylenediimine [6a] and also than the two asymmetric complexes **1** (6.09°) and **2** (4.82°) reported here. The only known tetradentate copper(II) complex having much distorted system is Cu(sa$l_2$tmput) [26] (H_2sa$l_2$tmput is 2,5-bis(salicylaldimino)-2,5-dimethylhexane (48.5°)) where the diamine (2,5-dimethylhexane-2,5-diamine) fragment produces a more flexible seven membered chelate ring.

These six-membered chelate rings derived from benzoylacetone are not identical with respect to bond distances and bond angles though both the chelating rings are delocalized by the influence of the metal, which is comparable to complexes **1** and **2**. In complex **3**, the first ring containing Cu(1), O(1), C(3), C(4), C(5) and N(1), the C(3)–C(4) distance of 1.379 Å, the C(5)–N(1) distance of 1.294 Å and the C (17)-O(1) bond length of 1.283 Å. Whereas in the second, the chelate ring containing Cu(1), O(2), C(10), C(9), C(8) and N(2), the C(9)–C(10), C(8)–N(2) and C(10)–O(2) distances are 1.427, 1.294 and 1.291 Å, respectively. The angles between the mean plane of these rings with the benzene plane are 24.57° and 24.77° indicating greater nonplanarity compare to that in complexes **1** and **2**. The conformation of six-membered chelate ring incorporating the diamine is an intermediate between boat and twist-boat confirmation [22] ($Q = 0.858$ Å, $\theta = 88.7°$ and $\phi = 265.4°$). Unlike **1** and **2** there is no significant π–π interaction between the molecules in complex **3**. A comparison of the structure of **3** with its acetylacetone analogue [6a] reveal that although the bond angles and distances do not show any significant change, the geometry around the copper atom shows unusually high tetrahedral distortion in **3**.

3.3. Electrochemical study

The cyclic voltammograms of the complexes are recorded in acetonitrile solvent and the diagrams are shown in Fig. 6. As is evident from Fig. 6, all three complexes show reversible reductive responses. The reduction potentials for **1** and **2** are observed at −0.86 and −0.90 V

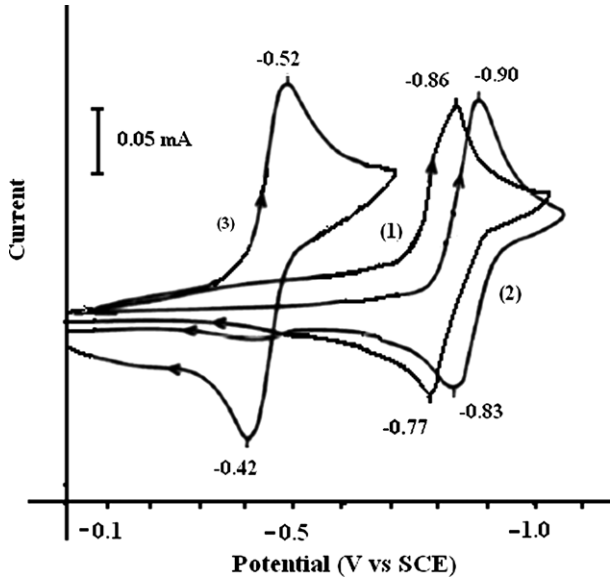

Fig. 6. The cyclic voltammogram of **1**, **2** and **3** in acetonitrile solution (scan rate 100 mV/s).

(E_{pc}). The corresponding E_{pa} values are observed at −0.77 and −0.83 V. The $E_{1/2}$ values of **1** and **2** are −0.82 and −0.87 V (versus SCE), respectively. Under identical experimental conditions the potential values for **3** are −0.52 V (E_{pc}), −0.42 V (E_{pa}) and −0.47 V ($E_{1/2}$) (versus SCE). It is well known that in four-coordinate systems, Cu(II) and Cu(I) have very distinct preference for square-based and tetrahedral geometry, respectively [27]. This preference is well reflected in the redox behavior of these systems. More is the distortion in the coordination geometry around the metal towards tetrahedral arrangement, higher is the anodic shift of the Cu^{II}/Cu^{I} redox potentials [27]. Thus the anodic shift of the potential of **3** compared to **1** and **2** and also to other similar systems corroborates the severe tetrahedral distortion of the copper atom from square planar geometry as observed in the X-ray structural analysis. A similar shift of the potential value and distortion were also observed earlier [26,28].

4. Conclusion

The inability of complex formation of 7-amino-3-methyl-1-phenyl-4-azahept-1,3-dien-1-ol (HAMPA) with Cu(II) but facile synthesis of Cu(II) complexes with three tetradentate ligands, HL^1, HL^2, and HL^3 derived from HAMPA reveals that the singly condensed Schiff bases are more prone to hydrolysis. The successful syntheses of complexes **1** and **2** are significant as they prove that 1-benzoylacetone can also be used like acetylacetone for the synthesis of complexes with unsymmetrical ligands. The crystal structure determination of the complexes shows for the first time that dimerization can occur in this type of systems only through ketonic oxygen bridges. The remarkably different molecular structures of the complexes from their acetylacetone analogues opens up a scope for their potential use in understanding the intricate differences that occur in NLO responses or in natural systems with slight variations in the ligand fragments.

Ruthenium(III) complexes of amine-bis(phenolate) ligands as catalysts for transfer hydrogenation of ketones

Sethuraman Kannan, K. Naresh Kumar, Rengan Ramesh *

School of Chemistry, Bharathidasan University, Tiruchirappalli 620 024, India

Received 15 October 2007; accepted 30 October 2007
Available online 3 December 2007

Abstract

Twelve ruthenium(III) complexes bearing amine-bis(phenolate) tripodal ligands of general formula $[Ru(L^1–L^3)(X)(EPh_3)_2]$ (where $L^1–L^3$ are dianionic tridentate chelator) have been synthesized by the reaction of ruthenium(III) precursors $[RuX_3(EPh_3)_3]$ (where E = P, X = Cl; E = As, X = Cl or Br) and $[RuBr_3(PPh_3)_2(CH_3OH)]$ with the tripodal tridentate ligands H_2L^1, H_2L^2 and H_2L^3 in benzene in 1:1 molar ratio. The newly synthesized complexes have been characterized by analytical (elemental and magnetic susceptibility) and spectral methods. The complexes are one electron paramagnetic (low-spin, d^5) in nature. The EPR spectra of the powdered samples at RT and the liquid samples at LNT shows the presence of three different '*g*' values ($g_x \neq g_y \neq g_z$) indicate a rhombic distortion around the ruthenium ion. The redox potentials indicate that all the complexes undergo one electron transfer process. The catalytic activity of one of the complexes $[Ru(pcr\text{-}chx)Br(AsPh_3)_2]$ was examined in the transfer hydrogenation of ketones and was found to be efficient with conversion up to 99% in the presence of isopropanol/KOH.

Keywords: Synthesis; Ruthenium(III); Symmetrical tripodal chelator; Characterization; Catalytic transfer hydrogenation

1. Introduction

Even though highly efficient catalytic systems for selective transformations are known [1–3], the design of efficient catalysts for large-scale applications is still a challenging problem. Noteworthy, a prerequisite for achieving high activity and selectivity is the fine tuning of the metal by introduction of ligands. With the high activity, ruthenium complexes play a central role in many organic transformations as versatile catalyst due to its reversible and accessible oxidation states [4]. Many research groups are developing the synthetic chemistry related to ruthenium complexes because of their multiple applications in many different scientific fields [5]. Ruthenium complexes have been used as catalysts or catalyst precursors for a variety of purposes including hydrogenation, oxidation, isomerisation, polymerization, nucleophilic addition to multiple bonds and carbon–carbon bond formation [6]. The ability of transition metal catalysts to add or remove hydrogen from organic substrates by either direct or transfer hydrogenation process is a valuable synthetic tool [7]. Ruthenium complexes have a long pedigree as catalysts for transfer hydrogenation reactions in the presence of 2-propanol as hydrogen source [8,9]. Several recent examples of ruthenium N-heterocyclic carbene complexes [10–12], Ru(arene)-(diamine) [13] and Ru(BINAP)(diamine) [14] catalysts have become the most prominent members for the reduction of ketones in high yields. Pincer-type arylruthenium(II) complexes containing the monoanionic terdentate NCN and PCP ligands have been reported by van Koten as active catalysts for the transfer hydrogenation of ketones in the presence of *i*-PrOH and KOH [15]. A number of other groups have followed Noyori's work using XylBinap [16] and have demonstrated the use of other diphosphines that give rise to high activities and selectivities when used in this catalyst system [17]. Ruthenium(II) complex bearing the

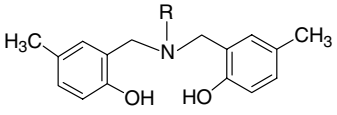
doi:10.1016/j.poly.2007.10.024

ligand 2,6-bis(3,5-dimethylpyrazol-1-yl)pyridine in isopropanol [18] has been proved to be an efficient catalyst for the transfer hydrogenation of ketones. The diversity of tertiary phosphines in terms of their Lewis basicity and bulkiness render them excellent candidates to tune the reactivity of octahedral complexes towards a variety of chemical processes, such as oxidative addition and substitution reactions [19]. Even though there are number of reports available on the transfer hydrogenation of ketones, to the best of our knowledge, there are no reports available for catalytic transfer hydrogenation of ketones by ruthenium tripodal complexes.



Tripodal ligands are in general facially coordinating tridentate chelate ligands which have received considerable attention in both coordination and organometallic chemistry. Over the past 20 years, there have been hundreds of published reports concerning various aspects of metal complexes which contain tripod ligands. Although the coordination properties of tripodal ligand have been extensively investigated using first row transition metals [20], few second and third row transition metals have been the target of studies with this kind of ligand. Tripodal complexes are of considerable interest as they find application in catalytic processes such as polymerization [21], epoxidation [22], enantioselective hydrogenation of olefins [23], Diels–Alder reaction [24], addition of TMS-CN to carbonyl compounds [25].

In view of the growing interest in the catalytic activity of ruthenium complexes to act as an efficient catalyst in transfer hydrogenation of ketones, we herein report the synthesis of a series of hexacoordinated ruthenium(III) tripodal complexes containing PPh_3/$AsPh_3$. The characterization of the complexes were accomplished by analytical and spectral (FT-IR, UV–Vis and EPR) methods. The redox properties of the complexes have been studied by cyclic voltammetric technique. Further, one of the synthesized complexes has been effectively used as catalyst in transfer hydrogenation of ketones in the presence of isopropanol and KOH as base. The following symmetrical amine-bis(phenolate) tripodal ligands have been used to synthesis the ruthenium(III) complexes (Scheme 1).

2. Experimental

2.1. Reagents and materials

All the reagents used were chemically pure and AR grade. Solvents were purified and dried according to standard procedures [26]. $RuCl_3 \cdot 3H_2O$ was purchased from Loba Chemie Pvt. Ltd. and was used without further purification. The primary amines and *p*-cresol were purchased from Aldrich. The supporting electrolyte tetrabutyl ammonium perchlorate (TBAP) was dried in vacuum prior to use. The ketones and their corresponding alcohols, which were used in the catalytic studies, were purchased from Merck and Aldrich.

Scheme 1. Structure of tripodal ligands.

2.2. Physical measurements

The analysis of carbon, hydrogen and nitrogen were performed by analytic function testing VarioEL III CHNS elemental analyzer at STIC, Cochin University of Science and Technology, Cochin, India. FT-IR spectra were recorded in KBr pellets with a JASCO 460 plus spectrophotometer in the range 4000–400 cm^{-1}. A Cary 300 Bio UV–Vis Varian spectrophotometer was used to record the electronic spectra. Room temperature solid-state magnetic susceptibility measurements were carried out by EG and G model 155 vibrating sample magnetometer at IIT, Chennai. EPR spectra were recorded on JEOL JES-FA 200 EPR spectrometer at X-band frequencies for powder samples at 278 K and solution at 77 K (liquid nitrogen) with microwave power 1.00 mW, modulation amplitude 125 and the field being calibrated with diphenylpicryl hydrazyl (DPPH, $g = 2.0037$) at Pondicherry University, India. Electrochemical studies were performed using a Princeton EG and G-PARC model potentiostat with 0.05 M dichloromethane solutions of $[(n\text{-}C_4H_9)_4N]ClO_4$ (TBAP) as supporting electrolyte under a nitrogen atmosphere. A three-electrode cell was employed with glassy carbon working electrode, a platinum wire auxiliary electrode and an Ag/AgCl reference electrode. Melting points were recorded with a Boetius micro-heating table and are uncorrected. The conversion of products from the catalytic reactions was determined using HP 6890 series GC-FID with a DP-5 column of 30 m length, 0.32 mm diameter and 0.25 μm film thickness. The ruthenium(III) complexes $[RuCl_3(PPh_3)_3]$, $[RuCl_3(AsPh_3)_3]$, $[RuBr_3(AsPh_3)_3]$, $[RuBr_3(PPh_3)_2(CH_3OH)]$ [27–30] were prepared according to the literature reports.

2.3. Preparation of amine-bis(phenolate) tripodal ligands

A solution of *p*-cresol (20.0 mmol, 2.16 g), primary amines such as methylamine, cyclohexylamine and 2-aminopyridine (10.0 mmol, 0.31–0.99 g) and aqueous formaldehyde (1.15 g, 38.4 mmol) in methanol (5 mL) was stirred and refluxed for 18 h. The mixture was cooled in freezer overnight and the supernatant solution was decanted. The solid residue was washed with ice cold methanol, filtered, and washed thoroughly with cold methanol. The solid residue was then again washed with acetonitrile for recrystallization to give a colorless product [31].

Spectral and analytical data for ligands: H_2L1 (pcr-me) (white solid): M.p.: 58 °C. IR (KBr, cm^{-1}): 3442, 1260. ^1H NMR (400 MHz, $CDCl_3$): δ 10.6(s, 2H, OH), δ 6.9–8.0 (m, 6H, Ar–H), δ 3.3 (s, 4H, benzylic protons), δ 2.3 (s, 9H,

CH_3). *Anal.* Calc. for $C_{17}H_{21}NO_2$: C, 75.24; H, 7.80; N, 5.16. Found: C, 74.95; H, 7.68; N, 4.98%.

H_2L2 (pcr-chx) (white solid): M.p.: 157 °C. IR (KBr, cm^{-1}): 3440, 1274. ^1H NMR (400 MHz, $CDCl_3$): δ 10.5 (s, 2H, OH), δ 7.0–7.8 (m, 6H, Ar–H), δ 3.6 (s, 4H, benzylic protons), δ 2.2 (s, 6H, CH_3), δ 1.0–2.0 (br multiplets, 11 H). *Anal.* Calc. for $C_{22}H_{29}NO_2$: C, 77.83; H, 8.61; N, 4.12. H_2L3 (pcr-ampy) (white solid): M.p.: 150 °C. IR (KBr, cm^{-1}): 3445, 1251. ^1H NMR (400 MHz, $CDCl_3$): δ 9.8 (s, 2H, OH), δ 6.9–7.5 (m, 10H, Ar–H), δ 3.7 (s, 4H, benzylic protons), δ 2.2 (s, 6H, Ar–CH_3). *Anal.* Calc. for $C_{21}H_{22}N_2O_2$: C, 75.42; H, 6.53; N, 8.37. Found: C, 75.20; H, 6.34; N, 8.04%.

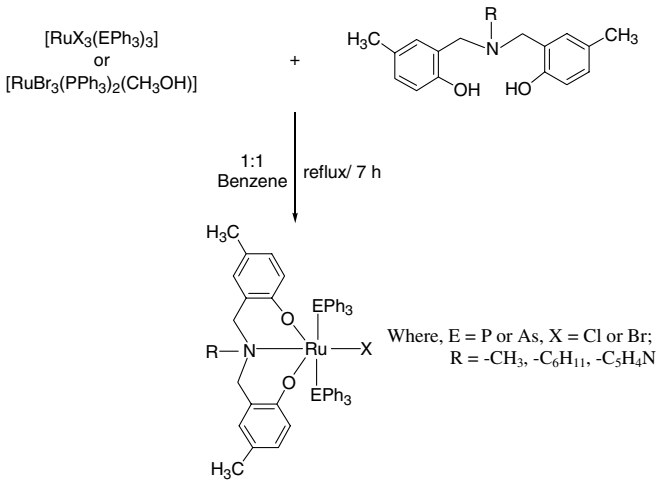
2.4. Synthesis of ruthenium(III) tripodal complexes



All the reactions were carried out under anhydrous conditions and were prepared by the following general procedure. To a benzene (20 cm^3) solution of the ruthenium(III) precursors $[RuX_3(EPh_3)_3]$ (0.120–0.157 g; 0.125 mmol) (E = P, X = Cl; E = As, X = Cl or Br) or $[RuBr_3(PPh_3)_2(CH_3OH)]$ (0.112 g; 0.125 mmol) was added the appropriate tripodal ligands (0.030–0.032 g; 0.125 mmol) (H_2L1–H_2L3). The solution was allowed to heat under reflux for 7–8 h. The reactions were monitored by TLC. The reaction mixture gradually changed to deep color and the solvent was removed under reduced pressure. The residue was precipitated by addition of light petroleum ether (60–80 °C) and recrystallized from CH_2Cl_2/pet. ether (60–80 °C). The compounds were dried under vacuum (yield: 58–72%).

2.5. Procedure for catalytic transfer hydrogenation

Under an inert atmosphere a mixture containing ketones (3.75 mmol), the ruthenium catalyst (0.0125 mmol) and (0.0625 mmol) KOH was heated to reflux in 10 ml of *i*-PrOH for appropriate period of time as mentioned. The catalyst was removed as precipitate from the reaction mixture by the addition of diethyl ether followed by filtration and subsequent neutralization with 5 ml of 1 M HCl. Then the ether layer was passed through a short path of silica gel and the filtrate was subjected to GC analysis. The hydrogenated product was identified and was determined with authentic sample.

3. Results and discussions

Ruthenium(III) precursors of the type $[RuX_3(EPh_3)_3]$ (E = P, X = Cl; E = As, X = Cl or Br) or $[RuBr_3(PPh_3)_2(CH_3OH)]$ were allowed to react with the tripodal ligands (L1–L3) in 1:1 molar ratio in dry benzene resulting in the formation of low-spin ruthenium(III) complexes (Scheme 2). In all the reactions, the ligands replace two chlorides/bromides, one triphenylphosphine or triphenylarsine and a methanol molecule from the precursor complexes (see Table 1).

Scheme 2. Structure of Ru(III) tripodal complexes.

3.1. Spectroscopic characterization

Infrared spectra of the complexes show many sharp and strong vibrations within 400–1600 cm^{-1} and the assignment of all these vibrations has not been attempted. However, the ligands exhibit bands in the region 1251–1274 cm^{-1} corresponding to phenolic ν_{C-O} stretching vibration. The coordination through phenolic oxygen is confirmed by the increase of ν_{C-O} stretching at higher frequencies in the region 1258–1304 cm^{-1} in all the complexes (Table 2). This was further supported by the disappearance of ν_{OH} band in the range 3440–3445 cm^{-1} in all the complexes. Further, the complexes show a strong band near 530, 690, 740 and 1556 cm^{-1}, which are due to PPh_3/$AsPh_3$ ligands. Besides, all the complexes show strong bands corresponding to ν_{M-N} and ν_{M-O} in the region 400–450 cm^{-1} and 500–550 cm^{-1}, respectively [32,33].

The electronic spectra of all the complexes were recorded in dichloromethane solution in the range 800–200 nm. All the complexes exhibit three to four absorption bands in the region 754–231 nm and are listed in Table 2. The ground state of ruthenium(III) is $^2T_{2g}$ and the first excited doublet levels in the order of increasing energy are $^2A_{2g}$ and $^2A_{1g}$, both arise from $t_{2g}^4e_g^1$ configuration. The bands observed in the region of 754–600 nm are attributable to d–d transitions and the absorptions observed in the region of 575–403 nm are probably due to charge transfer transitions taking place from the filled ligand (HOMO) orbital to the singly-occupied ruthenium t_2 orbital (LUMO). In most of the ruthenium(III) complexes the charge transfer bands of the type $L_{\pi y} \rightarrow T_{2g}$ are prominent in the low energy region, which obscures the weaker bands due to d–d transitions [34]. It is therefore difficult to assign conclusively the bands of ruthenium(III) complexes that appear in the visible region. However, the extinction

co-efficient for the bands in the 754–600 nm region are found to be very low as compared to that of charge transfer bands. Hence, the band around 754–600 nm have been assigned to $^2T_{2g} \rightarrow {}^2A_{2g}$ transition. The absorptions in the ultraviolet region below 400 nm are due to the intraligand transitions (n–π^*, π–π^*). The pattern of the electronic spectra of all the complexes indicate the presence of an octahedral environment around ruthenium(III) ion similar to that of other ruthenium(III) octahedral complexes [35–37].

3.2. Magnetic moments and EPR spectra

The complexes are uniformly paramagnetic with magnetic moments in the range of 1.81–1.93 BM, corresponds to one unpaired electron at 298 K (low-spin Ru^{III}, $t_{2g}{}^5$) in an octahedral environment. In a low-spin d^5 system the $^2T_{2g}$ (octahedral) ground state is orbitally degenerate and will be affected by spin–orbit coupling and low-symmetry ligand-field effects, both of which will remove this degeneracy and influence the temperature dependence of the moment. The theory appropriate to such a situation has been described [38,39]. From powder susceptibility data alone it is not possible to accurately determine the symmetry or the magnitude of the low-symmetry ligand-field component.

However, epr measurements clearly demonstrate, at least in frozen solution, the presence of a rhombic ligand-field component, as one might expect from the nature of the ligands around the metal ion. The distortion of the pseudooctahedral complexes can be expressed as the sum of axial (Δ) and rhombic (V) components. The theory of EPR spectra of distorted octahedral low-spin d^5 (idealized $t_{2g}{}^5$ ground term from $^2T_{2g}$) complexes is documented in the literature [40]. The gyromagnetic tensor 'g' values are given in Table 3. The low-spin d^5 configuration is a good probe of molecular structure and bonding since the observed g values are very sensitive to small changes in the structure and to metal-ligand covalency. The EPR spectra of the powdered ruthenium(III) complexes have been recorded at room temperature which shows the presence of three different 'g' ($g_x = 2.29$–2.43, $g_y = 2.00$–2.16, $g_z = 1.84$–1.92) values indicate a rhombic distortion [41,42] in the complexes and the trans position are assigned for triphenylphosphine/arsine. A similar pattern has been observed in the solution spectra of the complexes [Ru(pcr-me)Br($AsPh_3$)$_2$] (**3**) and [Ru(pcr-ampy)Br(PPh_3)$_2$]

12	2.35	2.10	1.90	2.11

[a] $[1/3g_x^2 + 1/3g_y^2 + 1/3g_z^2]^{1/2}$.

(**12**) at LNT and the '*g*' values $g_x = 2.47$, $g_y = 2.30$, $g_z = 1.99$ and $g_x = 2.40$, $g_y = 2.06$, $g_z = 1.92$ for the complexes (**3**) and (**12**), respectively. These values fit very well with the values obtained for other similar ruthenium(III) complexes [42–44]. Further, we have simulated the EPR spectra of both powder (Fig. 1a) and liquid (Fig. 1b) samples. It has been observed that both the experimental and the simulated '*g*' values are very close to each other.

3.3. Redox properties

The electrochemical properties of all the complexes have been examined cyclic voltametrically under N_2 atmosphere at glassy carbon working electrode in dichloromethane solution (0.05 M: NBu_4ClO_4) and the redox potentials are expressed with reference to Ag/AgCl. All the complexes (1×10^{-3} M) are electroactive with respect to the metal centers and exhibited two redox processes in the potential range +1.5 V to −1.5 V. The complexes display a reversible oxidative (Ru^{IV}/Ru^{III}) and an irreversible reductive responses (Ru^{III}/Ru^{II}) at the scan rate of 100 mV s^{-1}. The potentials are summarized in Table 4 and a representative voltamogram of a complex **6** is shown in Fig. 2. All the complexes showed well defined waves in the range 0.60–1.12 V (Ru^{IV}/Ru^{III}) and −0.67 to −0.77 V (Ru^{III}/Ru^{II}). The oxidation potentials are reversible with peak-to-peak separation (ΔE_p) values ranging from 60 to 80 mV corresponding to one electron process. The one electron process of the oxidation has been verified by comparing its current height (i_{pa}) with that of ferrocene/ferrocenium couple under identical experimental conditions [45]. The irreversibility observed for the reductive response may be due to the short live reduced state of the metal ion [46] or probably due to the fast dissociation of chloride or bromide ligand from the ruthenium(III) complexes [47]. There is not much variation in the potentials due to replacement of chlorides by bromides and triphenylphosphine by triphenylarsine.

Table 4
Electrochemical data of ruthenium(III) tripodal complexes

Complexes	Ru^{IV}/Ru^{III}				Ru^{III}/Ru^{II}
	E_{pa}	E_{pa}	ΔE_P (mV)	$E_{1/2}$ (V)	E_{pc}
1	0.60	0.67	70	0.63	−0.77
2	0.64	0.72	80	0.68	−0.70
3	0.56	0.64	80	0.60	−0.72
4	0.75	0.83	80	0.79	−0.73
5	1.14	1.06	80	1.10	−0.76
6	0.98	0.90	80	0.94	−0.72
7	0.86	0.80	60	0.83	−0.75
8	0.90	0.98	80	0.94	−0.67
9	1.08	1.16	80	1.12	−0.72
10	0.63	0.71	80	0.67	−0.74
11	0.93	0.87	60	0.90	−0.75
12	0.91	0.84	70	0.87	−0.77

Supporting electrolyte: NBu_4ClO_4 (0.05 M); complex: 0.001 M; solvent: CH_2Cl_2 where E_{pa} and E_{pc} are anodic and cathodic potentials, respectively; scan rate: 100 mV s^{-1}.

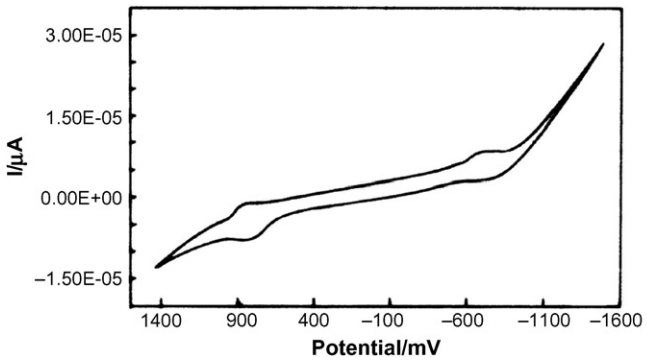
3.4. Catalytic transfer hydrogenation of ketones

Ruthenium mediated transfer hydrogenation reactions are found to be effective catalytic systems in which hydrogen is transferred from one organic molecule to another and this made us to carry out this type of reactions. One



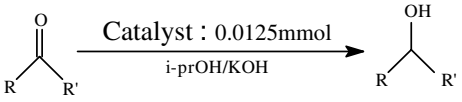


Fig. 2. Cyclic voltammogram of [Ru(pcr-chx)Cl($AsPh_3$)$_2$].

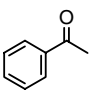
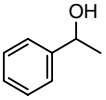
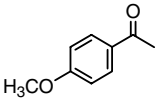
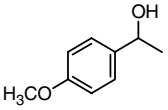
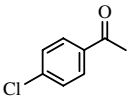
of the complexes [Ru(pcr-chx)Br($AsPh_3$)$_2$] (**7**) is taken as model catalyst and the catalytic activity in the transfer hydrogenation of various aliphatic and aromatic ketones in the presence of isopropanol and KOH as promoter has been explored. The complex catalyzes the reduction of ketones to corresponding alcohols with >90% conversions in all cases and the results are listed in Table 5.

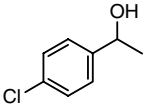


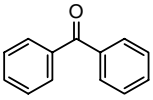


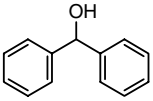


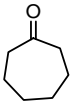


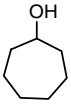


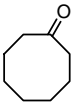


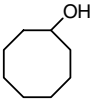


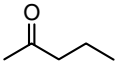


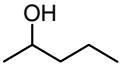


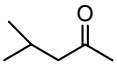


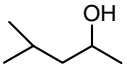


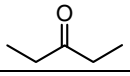


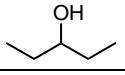












R, R' = alkyl (or) aryl

The necessity of the ruthenium complex to observe the ensuing transfer hydrogenation was ascertained by carrying out a series of blank or control experiments suggest that none of $RuCl_3 \cdot 3H_2O$, Ru(III) precursors or tripodal ligands alone or as a mixture causes these transformations under identical reaction conditions. The alcohols formed after the reflux was determined by GC with authentic samples. In this method, the base facilitates the formation of a ruthenium alkoxide by abstracting the proton of the alcohol, which then undergoes β-elimination to give a ruthenium-hydride which is the active catalyst (Scheme 3). This classical mechanism is proposed by several workers on the studies of ruthenium complexes catalyzed transfer hydrogenation reaction by metal hydrides [48,49].

Excellent conversions are obtained for both aliphatic and aromatic ketones. Benzophenone was converted to benzhydrol in >98%. The complex efficiently catalyzed the reduction of aliphatic ketones such as methyl ethyl ketone, methyl propyl ketone, isobutyl methyl ketone and diethyl ketone to their corresponding alcohols with 99.6%, 98.8%, 97.8% and 90.5% conversions, respectively. The conversion in case of acetophenone is 90.8%. The presence of electron donating (OCH_3) and electron withdrawing (Cl) substituents on the substrates (entries 2 and 3) has marginal effect on the catalytic transfer hydrogenation of ketones. 4-Chloro acetophenone is converted to corresponding alcohol in 93.9% and in case of 4-methoxy acetophenone the conversion is 90.7%. Though the effect is minimal, the greater conversion in case of **3** compared to **2** may be due to the fact that reduction involves the substrate gaining electrons and this would be more facile at an electron deficient center [50]. Moreover, this catalyst efficiently catalyzes the reduction of cyclopentanone and cyclohexanone to corresponding alcohols cyclopentanol and cyclohexanol with 99.3% and 90.8% conversions, respectively. The complex showed also good catalytic activity for seven and eight membered cyclic ketones cycloheptanone and cyclooctanone with 99.3% and 97.9% conversions, respectively. The presence of a catalytic amount of base is necessary for the transfer hydrogenation of ketones. Though no mechanistic study has been carried out, the catalytic transformation is supposed to follow the classical pathway in which the ketone coordinates to hydride-ruthenium intermediates, the observed effects seem to indicate that the hydride transfer from the metal to the coordinated ketone is the turnover-limiting step (rather than the ketone complexation) in the catalytic cycle [51].

Table 5
Catalytic transfer hydrogenation of ketones by [Ru(pcr-chx)Br($AsPh_3$)$_2$]/*i*-PrOH/KOH[a]

Entry	Substrates	Products	Time (h)	Conversion[b]	TON[c]
1			1	90.8	272

11			1	97.8	293
12			1	90.5	271

[a] Conditions: reactions were carried out at 80 °C using 3.75 mmol of ketone (5 ml isopropanol); catalyst/ketone/KOH ratio 1:300:2.5.
[b] Yield of product was determined using a HP 6890 series GC-FID with DP-5 column of 30 m length, 0.32 mm diameter and 0.25 μm film thickness and by comparison with authentic samples.
[c] Ratio of moles of product obtained to the moles of catalyst used.

Scheme 3. The role of base (L = arylazo ligand).

The only byproduct acetone was identified in all the cases. As the catalyst is stable in all organic solvents and it can be recovered and the work up process is also very simple for this catalytic system. Although several catalytic systems have been reported to support transfer hydrogenation reactions of ketones, ruthenium(III) tripodal complexes have been exploited for first time towards the catalytic transfer hydrogenation reactions.

4. Conclusions

In conclusion, we have synthesized and characterized a series of ruthenium(III) tripodal complexes. One of the complexes (**7**) has been found to be an efficient catalyst in transfer hydrogenation of both aliphatic as well as aromatic ketones in the presence of isopropanol/KOH. We are currently perusing development of some new chiral ruthenium complexes for asymmetric catalysis.

Acknowledgements

We express our sincere thanks to Professor P. Sambasiva Rao, Department of Chemistry, Pondicherry University for providing the EPR facility. We express sincere thanks to Prof. P.R. Athappan, School of Chemistry, Madurai Kamaraj University, for cyclic voltammetric facility.

Abstract

A tridentate [*N*,*N*,*O*] Schiff base [3,5-Bu^t_2-2-(OH)-C_6H_2CH=N-8-C_9H_6N(LH)] was prepared, and the corresponding sodium and ytterbium complexes were synthesized and characterized. Reaction of LH with NaH in THF at room temperature afforded the sodium salt of the Schiff base as a dimer [{LNa(THF)}$_2$] (**1**). Complex **1** reacted with anhydrous $YbCl_3$ in THF, after workup, to give the monomeric ytterbium Schiff base dichloride complex, [$LYbCl_2$(DME)] (**2**). Complex **2** is a good precursor for the synthesis of the corresponding ytterbium derivatives. Reaction of complex **2** with 1 equiv. of $NaCH_3C_5H_4$ in THF gave the expected product [Yb($CH_3C_5H_4$)Cl(THF)] (**3**) in a good isolated yield. Similar reaction of complex **2** with 2 equiv. of ArONa (ArO=OC_6H_3-Bu^t_2-2,6) in THF afforded the desired solvent-free ytterbium aryloxide [Yb(OAr)$_2$] (**4**). Complex **4** can also be prepared by the protolytic exchange reaction of LH with $(ArO)_3Yb$ in a 1:1 molar ratio. All of these complexes were well characterized including X-ray structure determination.

1. Introduction

Over the past decade, significant efforts to explore ligands other than traditional ancillary ligand cyclopentadienyl set in organolanthanide chemistry have led to the fruitful design of new non-lanthanocene complexes [1–4]. Of these alternatives, Schiff base ligands, that have hard donor-atom frameworks, are attractive due to their stability and the ease by which modified variations can be obtained. Moreover, these lanthanide complexes are known to serve as precatalysts in homogeneous catalysis, such as asymmetric ring opening reaction of epoxide, ring opening polymerization of lactide and related cyclic esters [5–7], as the materials for the potential applications in biology, medicine as well as high-technology fields [8–12]. Generally, the tridentate Schiff base ligands with a flexible donor atom, in comparison with the bidentate ligands, can provide the protective shields for catalytically active metal centers leading to a ''more stable'' active species via the coordination of the additional donor atom. As a result, the activity of the complex with a tridentate Schiff base ligand is much higher than that of the complex with a bidentate ligand [13,14]. However, anhydrous preparation and reactivity of lanthanide complexes with a tridentate Schiff base ligand still remains poorly explored. Recently, monomeric lanthanocene aryloxide complexes with a tridentate Schiff base ligand *N*-1-(*ortho*-methoxyphenyl) salicylideneamine was synthesized and structurally characterized [15].

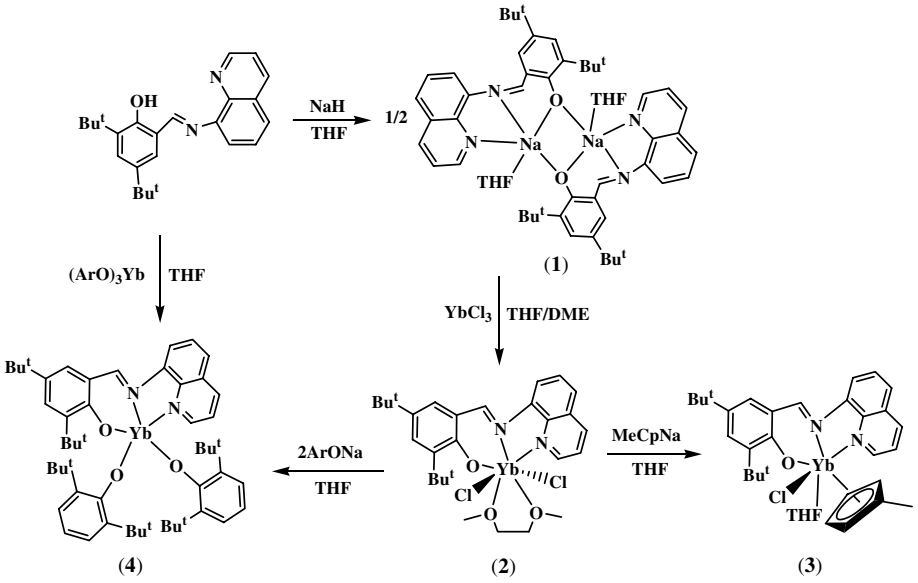
Herein, we report the synthesis and molecular structure of a series of sodium and ytterbium complexes supported by a tridentate Schiff base ligand including the complexes of formulae $[\{LNa(THF)\}_2]$, $[LYbCl_2(DME)]$, $[LYb(CH_3C_5H_4)Cl(THF)]$ and $[LYb(OAr)_2]$, where L = [3,5-Bc_2^t-2-(O)C_6H_2CH=N-8-C_9H_6N]; ArO=$OC_6H_3Bu_2^t$-2,6. To our best knowledge, $[LYbCl_2(DME)]$ is the first structurally characterized lanthanide dichloride complex stabilized by Schiff base ligand.

2. Results and discussion

2.1. Synthesis and characterization of $[\{LNa(THF)\}_2]$ (1)



Alkali metal salts of Schiff base are known to be the starting reagents for the anhydrous preparation of lanthanide Schiff base complexes. It may be very informative to know the structure of these starting reagents. However, few structurally characterized Schiff base sodium complexes were reported in the literatures [16,17]. Thus, the sodium salt of the tridentate Schiff base HL, which was synthesized by the condensation reaction of 8-aminoquinoline with 3,5-di-*tert*-butyl-2-hydroxylbenzaldehyde [13], was synthesized and characterized. Reaction of NaH with HL in THF, after workup, afforded $[\{LNa(THF)\}_2]$ (**1**) as yellow crystals as shown in Scheme 1. Complex **1** gave satisfactory elemental analysis results, and its IR spectrum shows the characteristic absorption bands of aromatic rings in the region 1400–1600 cm^{-1} (skeletal vibrations), and of the C=N stretching vibration at 1613 cm^{-1} and of the phenolic C–O bond at 1242 cm^{-1}. The definitive molecular structure was determined by single-crystal X-ray diffraction.

The molecular structure of complex **1** is shown in Fig. 1, and its selected bond lengths and angles are listed in Table 1. Complex **1** has a dimeric structure, and two molecules are connected together by two bridged oxygen atoms. The molecules have approximate C_2 symmetry. Each sodium atom is five-coordinated with one oxygen atom, two nitrogen atoms from one Schiff base ligand, one oxygen atom from another ligand and one oxygen atom from a THF molecule. The coordination geometry at sodium atom can be described as a distorted trigonal bipyramid, in which O(2), O(3) and N(1) can be considered to occupy the equatorial positions, and O(1) and N(2) to occupy the apical positions.

The average Na–O(Ar) bond lengths of 2.279(4) Å falls in the range of Na–O(Ar) bond lengths in $[Na_4(salphen)_2(DME)_2]$ (salphen = *N*,*N*′-*o*-phenylenebis(salicylideneimine), 2.252(9)–2.291(9) Å) [16] and $[Na(18\text{-crown-}6)(THF)_2]_2[Na_2(OC_6H_4\text{-}2\text{-}C{=}NCH_2CH_2OH)]_4$ (2.221(3)–2.235(4) Å) [17]. The Na–N(imine) bond lengths of 2.407(3) (Na(1)–N(1)) and 2.388(3) Å (Na(2)–N(3)) are comparable with those found in $[Na_4(salphen)_2(DME)_2]$ (2.38(1) and 2.37(1) Å) [16], but are smaller than those in $[Na(18\text{-crown-}6)(THF)_2]_2[Na_2(OC_6H_4\text{-}2\text{-}C{=}NCH_2CH_2OH)]_4$ (2.492(4) and 2.570(4) Å) [17]. The bond lengths of Na–N(quinoline) are 2.550(3) (Na(1)–N(2)) and 2.403(3) Å (Na(2)–N(4)), respectively, which are larger than the Na–N(imine) bond lengths.

2.2. Synthesis and characterization of ytterbium complexes

Although lanthanide dichloride complex supported by a Schiff base ligand might be an important precursor for the synthesis of the corresponding lanthanide derivatives via metathesis reactions, no example of such lanthanide dichloride was reported up to date. Thus, we intend to synthesize the ytterbium dichloride complex with the bulky tridentate Schiff base group L as an ancillary ligand. Reaction of

anhydrous $YbCl_3$ with complex **1** in THF, after workup, gave the first Schiff base lanthanide dichloride complex [$LYbCl_2$(DME)] (**2**) in high isolated yield from toluene/DME mixed solvent as shown in Scheme 1. Complex **2** was characterized by elemental analysis and IR spectrum, and its definitive molecular structure was provided by single-crystal X-ray diffraction. Complex **2** is soluble in THF and DME, and slightly soluble in toluene.

The molecular structure of complex **2** is shown in Fig. 2, and the selected bond lengths and angles are provided in Table 1. Complex **2** has a solvated monomeric structure, and the central metal ytterbium atom is seven-coordinated by one oxygen atom and two nitrogen atoms from one Schiff base ligand, and two chlorine atoms and two oxygen atoms from one DME molecule. The coordination geometry around ytterbium atom can be described as a distorted pentagonal bipyramid, in which O(1), N(1), N(2) (from Schiff base ligand), O(2) and O(3) (from DME) can be considered to occupy the equatorial positions with the sum of the bond angles of 366° and Cl(1) and Cl(2) to occupy the axis positions. The bond angle of Cl(1)–Yb–Cl(2) is slightly distorted away from the ideal value of 180° to 162.29(3)°. The Yb–O(Ar) bond distance is 2.115(2) Å, which is very close to those observed in related ytterbium Schiff base complexes [{2-OC_6H_4CH=(2,6-$^iPr_2C_6H_3$)}$_2$YbCl(THF)] (2.110(7) and 2.10(1) Å) [6], [{(η^5-C_5H_5)Yb(μ-$OC_{20}H_{20}N_2$-O)}$_2$(μ-THF)(THF)] (2.15(2) Å) [18]. The Yb–N(imine) bond distance is 2.386(3) Å, which is slightly smaller than those found in the ytterbium Schiff base complexes mentioned above. The Yb–N(quinoline) bond distance of 2.470(3) Å is apparently larger than the Yb–N(imine) bond distance, indicating the bond strength being somewhat weaker than that of the Yb–N(imine) bond.

Generally, organolanthanide or organolanthanoid chlorides are useful precursors for the synthesis of lanthanide derivatives. Thus, the chloride substitution reactions of complex **2** with other reagents were studied. The reaction of complex **2** with 1 equiv. of $NaCH_3C_5H_4$ in THF went smoothly and, after workup, afforded the desired lanthanide complex [$LYb(CH_3C_5H_4)Cl$(THF)] (**3**) in good

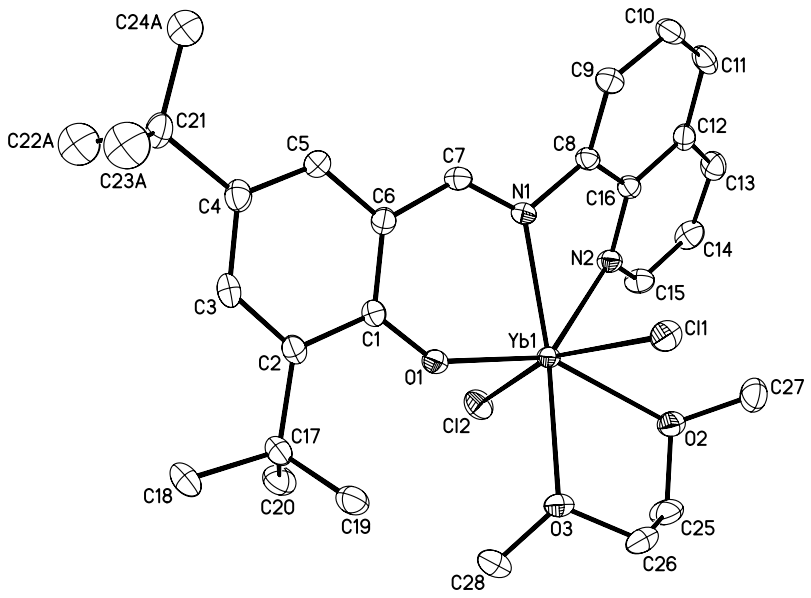

Fig. 2. ORTEP diagram of complex **2** showing atom-numbering scheme. Thermal ellipsoids are drawn at the 40% probability level. Hydrogen atoms are omitted for clarity.

isolated yield (Scheme 1). Similar reaction of complex **2** with 2 equiv. of ArONa in THF, after workup, gave the solvent-free ytterbium aryloxide [$LYb(ArO)_2$] (**4**) as orange-yellow crystals in high yield. Further study revealed that complex **4** can also be conveniently prepared by the direct protolytic exchange reaction of Schiff base LH with $Yb(ArO)_3$ in a 1:1 molar ratio in THF. The compositions of complexes **3** and **4** were confirmed with elemental analysis, and there are characteristic absorption bands of the aryloxo group in their IR spectra. The definitive molecular structures of complexes **3** and **4** were determined by single-crystal structure analysis. Complexes **3** and **4** are well soluble in THF and diethyl ether, and soluble in toluene.

Crystals of complex **3** suitable for an X-ray diffraction study were obtained from THF/Et_2O solution at low temperature. An ORTEP diagram of the molecular structure of complex **3** is shown in Fig. 3, and the selected bond lengths and angles are listed in Table 1. Complex **3** has a monomeric structure. The ytterbium atom is coordinated by two nitrogen atoms and one oxygen atom from the Schiff base ligand, one Cp ring, one chlorine atom and another oxygen atom from THF molecule to form a distorted octahedral geometry, when the Cp ring was considered to occupy one coordination site. Two nitrogen atoms, one oxygen atom of the Schiff base ligand and one chlorine atom can be considered to occupy the equatorial positions with the sum of the bond angles of 359.4°, and the centroid

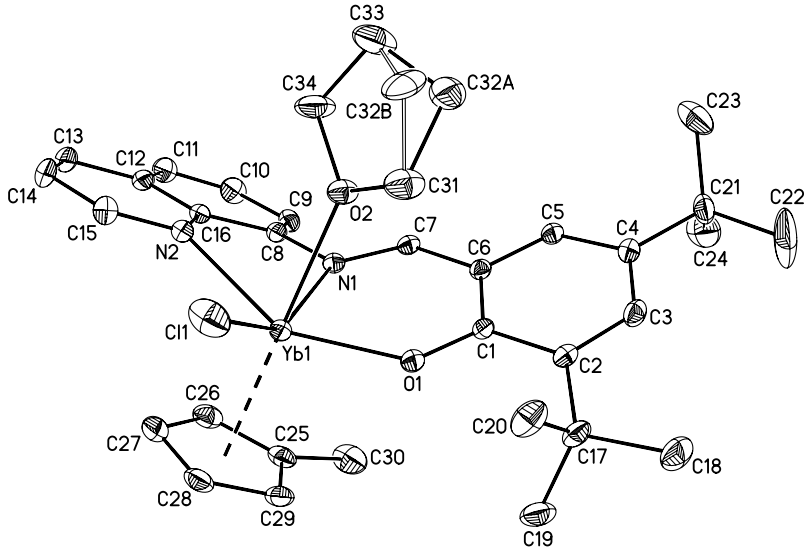

Fig. 3. ORTEP diagram of complex **3** showing atom-numbering scheme. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms are omitted for clarity. Disordered THF molecule is shown in two possible orientations.

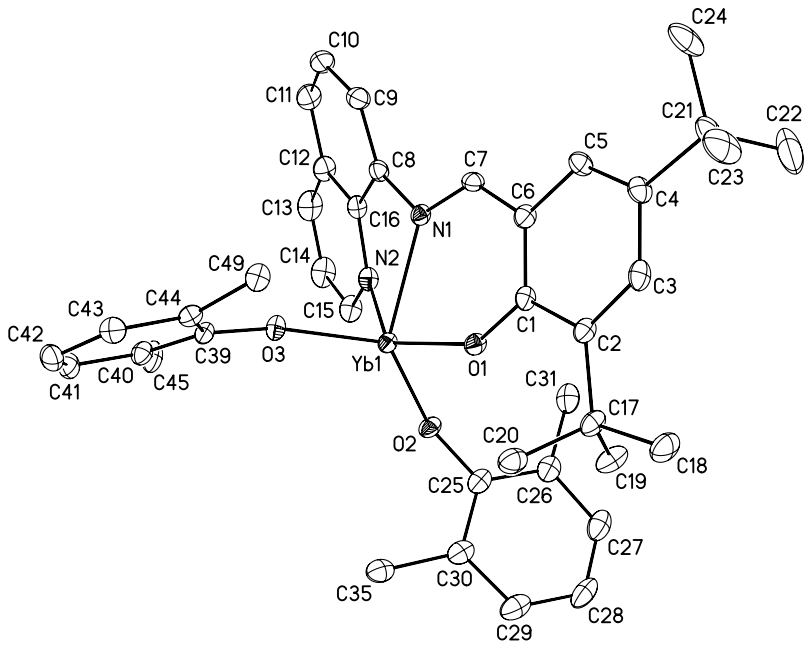

Fig. 4. ORTEP diagram of complex **4** showing atom-numbering scheme. Thermal ellipsoids are drawn at the 30% probability level. Methyl groups of the *tert*-butyl groups of aryloxides and hydrogen atoms are omitted for clarity.

of the Cp ring and the oxygen atom of the THF molecule occupy the apical positions.

The Ln–C(Cp) bond distances range from 2.636(5) to 2.675(5) Å, giving the average 2.648(5) Å, which is slightly smaller than that in lanthanide cyclopentadienyl Schiff base complexes $[\{(\eta^5\text{-}C_5H_5)Ln(\mu\text{-}OC_{20}H_{20}N_2O)\}_2(\mu\text{-THF})(THF)]$ (Ln = Yb, 2.70(3) Å [18]; Ln = Sm, 2.778 Å [19]), and $[(\eta^5\text{-}C_5H_5)_2Sm(OC_{14}H_{13}ON)]$ (2.723 Å) [15], when the difference in ionic radius is considered. The Yb–O(Ar) bond distance of 2.116(3) Å is well comparable with those values in $[\{2\text{-}OC_6H_4CH{=}NC_6H_3\text{-}^iPr_2\text{-}2,6\}_2YbCl(THF)]$ (2.107(7) Å) [6], and other lanthanide Schiff base complexes mentioned above. The Yb–N(imine) bond distance of 2.400(3) Å is comparable with the Yb–N(quinoline) bond distance (2.436(4) Å), which is different from that in complex **2**. The Yb–Cl bond distance of 2.594(1) Å is apparently larger than the corresponding value in $[\{2\text{-}OC_6H_4CH{=}N(2,6\text{-}^iPr_2C_6H_3)\}_2YbCl(THF)]$ (2.497(2) Å) [6], whereas this bond distance is comparable with that in complex **2**.

Crystals of complex **4** suitable for X-ray diffraction were obtained by recrystallization from toluene. The molecular structure diagram with atom-numbering scheme is presented in Fig. 4, and its selected bond lengths and angles are listed in Table 1. The ytterbium atom is coordinated by one oxygen atom, two nitrogen atoms from the Schiff base ligand and two oxygen atoms from two aryloxo groups to form a five-coordinated highly distorted trigonal bipyramidal geometry. O(2), O(3) and N(1) can be considered to occupy the equatorial positions with the sum of the angles of 355.47°, and O(1) and N(2) to occupy the apical positions. Usually, lanthanide Schiff base complexes have high coordination numbers (>6) via oligomerisation or solvent stabilization, these is few structurally characterized five-coordinated mononuclear lanthanide complexes bearing Schiff base ligands in the literatures [20–23].

The Yb–O(Schiff base), Yb–N(imine) and Yb–N(quinoline) bond distances in complex **4** are 2.104(2), 2.359(3) and 2.410(3) Å, respectively, which are in accordance with the corresponding values in complexes **2** and **3**. The bond distances of Yb–O(Ar) of 2.082(2) and 2.089(2) Å, respectively, compare well with the corresponding value in $[(ArO)_2YbCl(THF)_2]$ (2.080(1) Å) [24], but are slightly larger than that in $[\{(DIPPh)_2nacnac\}Yb(ArO)Cl(THF)]$ [2.024(2) Å, $(DIPPh)_2$nacnac=*N*,*N*-diisopropylphenyl-2,4-pentanediimine anion] [25]. In addition, remote π interaction of C(8) with Yb(1) was observed in complex **4**. The bond distance of Yb(1)–C(8) is 3.197(3) Å, which is comparable to those of 3.207(9) and 3.179(10) Å for imidazolidine-bridged bis(phenolate) ytterbium dichloride [26], and 2.814(4) to 3.148(6) Å for chelating η^6-,η^1-Ph–Yb bonding in $[\{Yb(Odpp)_3\}_2]$ (Odpp=2,6-diphenylphenolate) [27].

3. Conclusion

A bulky tridentate Schiff base was prepared, and this compound can be used as an ancillary ligand for a series of sodium and ytterbium complexes. The Schiff base reacted with NaH to give the corresponding sodium salt as a dimeric complex, which reacted with anhydrous $YbCl_3$ to produce the first structurally characterized soluble ytterbium dichloride bearing Schiff base ligand. It was found that this ytterbium dichloride can be used as a useful precursor for the synthesis of the corresponding ytterbium derivatives by direct salt metathesis reactions. All of these complexes were well characterized, and their molecular structures were determined by X-ray diffraction.

4. Experimental

4.1. Materials and methods

All of the manipulations described below were performed under an argon atmosphere, using the standard Schlenk techniques. Solvents were dried and freed of oxygen by refluxing over sodium or sodium benzophenone ketyl and distilled under argon prior to use. Schiff base ligand HL [3,5-Bu^t_2-2-(OH)C_6H_2CH=N-8-C_9H_6N] [13], anhydrous $YbCl_3$ [28] and $Yb(OAr)_3$ [29] were prepared according to the literature methods. $NaCH_3C_5H_4$ was prepared by the reaction of $CH_3C_5H_5$ with sodium in THF. The other reagents were purchased from Acros and used as received without further purification. Metal analyses were carried out using complexometric titration. Carbon, hydrogen, and nitrogen analyses were performed by direct combustion on a Carlo Erba-1110 instrument; Quoted data are the average of at least two independent determinations. IR spectra were recorded on a Nicolet-550 FTIR spectrometer as KBr pellets. ^{1}H NMR spectrum was obtained on an INOVA-400 MHz apparatus. The uncorrected melting points of crystalline samples in sealed capillaries (under argon) are reported as ranges.

4.2. Synthesis of [{NaL(THF)}$_2$] (1)

A solution of HL (1.80 g, 5.0 mmol) in THF (20 mL) was added dropwise to a NaH suspension (1.5 equiv.) in THF at room temperature. The mixture was stirred for 14 h, and then was filtered. The resulting dark red solution was concentrated. Yellow crystals were obtained from the mixture of THF and toluene (6:1) at room temperature in a few days (3.87 g, 85%), m.p.: 279–281 °C (dec). *Anal.* Calc. for $C_{56}H_{70}N_4Na_2O_4$: C, 73.97; H, 7.76; N, 6.16. Found: C, 73.58; H, 7.95; N, 5.76%. IR (KBr pellet, cm^{-1}): 2956(vs), 2909(m), 2871(m), 1613(vs), 1458(vs), 1389(m), 1366(m), 1242(s), 1157(s), 1088(w), 1057(w), 1026(w), 980(w), 880(m), 826(m), 795(m), 640(w), 502(m). ^{1}H NMR (400 MHz, C_6H_6): 8.50–8.48 (m, 1H, C_9H_6N), 8.43 (s, 1H, CH=N), 7.43–7.40 (m, 1H, C_9H_6N), 7.30–7.25 (m, 3H, C_9H_6N), 6.98 (d, 2H, J = 2.6 Hz, C_6H_2), 6.65–6.60 (m, 1H, C_9H_6N), 4.06 (m, 4H, THF), 2.09 (m, 4H, THF), 1.79 (s, 9H, $C(CH_3)_3$), 1.33 (s, 9H, $C(CH_3)_3$).

4.3. Synthesis of [LYbCl$_2$(DME)] (2)

A THF solution (10 mL) of complex **1** (0.91 g, 1.0 mmol) was added to a suspension of anhydrous $YbCl_3$ (0.56 mg, 2.0 mmol) in THF (20 mL) at room temperature. After the solution was stirred overnight, the precipitate was separated from the reaction mixture by centrifugation. The solution was concentrated, and then DME (0.5 mL) was added. Yellow crystals were obtained at room temperature in a few days (1.10 g, 80%), m.p.: 266–268 °C (dec). *Anal.* Calc. for $C_{28}H_{37}Cl_2N_2O_3Yb$: C, 48.49; H, 5.38; N, 4.04; Yb, 24.95. Found: C, 48.87; H, 5.67; N, 3.98; Yb, 24.87%. IR (KBr, cm^{-1}): 2956(m), 2928(m), 1613(s), 1535(m), 1498(m), 1427(m),1319(m), 1234(vs), 1158(vs), 833(m),787(m), 633(m), 556(m), 509(s). The crystals suitable for an X-ray crystal structure determination were obtained by recrystallization from THF–DME solution at room temperature.

4.4. Synthesis of [(CH$_3$C$_5$H$_4$)YbLCl(THF) · THF] (3 · THF)

A Schlenk flask was charged with complex **2** (0.69 g, 1.0 mmol) and THF (20 mL). A THF solution of $NaCH_3C_5H_4$ (1.0 mL, 1.0 mmol) was added by syringe. The reaction mixture was stirred overnight at room temperature. After removed the volatiles in vacuum, the yellow residue was extracted with Et_2O, and NaCl was removed by centrifugation. Orange-yellow crystals were obtained at room temperature, (0.47 g, 60%), m.p.: 158–160 °C (dec). *Anal.* Calc. for $C_{38}H_{50}ClN_2O_3Yb$ (**3** · THF): C, 57.68; H, 6.37; N, 3.54; Yb, 21.87. Found: C, 57.45; H, 6.63; N, 3.57; Yb, 21.51%. IR (KBr, cm^{-1}): 2956(s), 2905(m), 1608 (s), 1534(m), 1503(m), 1463(m), 1425(m), 1330(m), 1223(vs), 1159(vs), 1086(m), 835(m), 792(m), 506(s).

4.5. Synthesis of [LYb(OAr)$_2$] (4)

4.5.1. Method A

A Schlenk flask was charged with complex **2** (0.69 g, 1.0 mmol) and THF (20 mL). A THF solution of NaOAr (2.0 mL, 2.00 mmol) was added by syringe. The reaction mixture was stirred overnight at room temperature. After removed the volatiles in vacuum, the yellow residue was extracted with toluene, and the precipitate was removed by centrifugation. Complex **4** was obtained as yellow crystals at room temperature (0.56 g. 60%), m.p.: 189–191 °C (dec). *Anal.* Calc. for $C_{52}H_{69}N_2O_3Yb$: C, 66.22; H, 7.37; N, 2.97; Yb, 18.35. Found: C, 66.38; H, 7.53; N, 2.91; Yb, 18.27%. IR (KBr, cm^{-1}): 2956(vs), 2909(s), 2871(s), 1613(s), 1528(s), 1505(s), 1466(s), 1428(vs), 1235(s), 1196(s), 1165(s), 1088(m), 1065(m), 833(m), 795(m), 748(m), 656(w), 594(w), 509(w).

4.5.2. Method B

$Yb(OAr)_3$ (0.81 g, 1.0 mmol) in toluene was added dropwise to a THF solution of HL (0.36 g, 1.0 mmol) (30 mL). The reaction mixture was stirred at room temperature for 12 h, and then concentrated in vacuum. Orange-yellow crystals obtained after 4 days at room temperature, (0.66 g. 70%).

4.6. X-ray structures determination

Suitable single crystals of complexes **1**–**4** were sealed in a thin-walled glass capillary for determining the single-crystal structure. Intensity data were collected with a Rigaku Mercury CCD area detector in ω scan mode using Mo

Kα radiation ($\lambda = 0.71070$ Å). The diffracted intensities were corrected for Lorentz polarization effects and empirical absorption corrections. Details of the intensity data collection and crystal data are given in Table 2.

The structures were solved by direct methods and refined by full-matrix least-squares procedures based on $|F|^2$. All of the non-hydrogen atoms were refined anisotropically. All of the hydrogen atoms were held stationary and included in the structure factor calculation in the final stage of full-matrix least-squares refinement. The structures were solved and refined using SHELEXL-97 programs.

Abstract

Six new complexes: $[Ln_2(pzda)_3(H_2O)_2]\cdot 2.5H_2O$ (Ln = Nd, (**1**); Eu, (**2**)), $[Co(pzda)(bpe)]\cdot 0.125(bpe)\cdot 1.75H_2O$ (**3**), $[Mn(pzda)(H_2O)_{1.5}]$ (**4**), $[Co_2(pzda)_2(bpe)(H_2O)_4]\cdot 0.5(CH_3OH)\cdot H_2O$ (**5**) and $[Co(pzda)(2,2'\text{-bpy})(H_2O)]\cdot 0.5H_2O$ (**6**) (H_2pzda = pyrazine-2,6-dicarboxylic acid, bpe = 1,2-bis(4-pyridyl)ethane, 2,2′-bpy = 2,2′-bipyridine) were obtained from metal salts and H_2pzda under hydro(solvo)thermal conditions. The single crystal X-ray structural analysis reveals that the title complexes have different structures, ranging from zero- to three- dimensions, which are mainly due to the different metal ions, and especially the coordination modes of the pzda ligands. Complexes **1** and **2** have 3D metal-organic frameworks containing a 1D tri-strand array, in which the pzda ligand adopts a pentadentate mode to link lanthanide ions. Complex **3** has a 2D metal-organic framework, in which the pzda ligand acts in a tetradentate mode to connect Co(II) ions into 1D chains, which are further connected by bpe spacers into a 2D framework. While in **4**, both of the two carboxylate groups of the pzda ligand adopt μ_2-O bridging modes to link Mn(II) ions into a 1D coordination polymer, which is further assembled into a 2D supramolecular network containing double-stranded hydrogen-bonded helical chains. In both **5** and **6**, the pzda ligand binds metal ions as a tridentate ligand (ONO mode) to form zero dimensional structures. Complex **5** is a binuclear molecule, while **6** is a mononuclear complex, which can be attributed to the bridging ligand bpe for **5** and the terminal auxiliary ligand 2,2′-bpy for **6**.

1. Introduction

Over the past few decades, the design and synthesis of metal-organic frameworks (MOFs) have received much attention not only because of the fascinating structural diversities but also for their useful properties and potential applications as functional materials in molecular adsorption, separation and magnetism [1–3]. From the viewpoint of crystal engineering, one of the most effective approaches to synthesize MOFs is hydro(solvo)thermal controlled assembly of the organic ligands and metal ions. The construction of multidimensional architectures depends mainly on the combination of several factors, including the metal ions, the type of organic ligand and the coordination modes, the auxiliary ligands and the pH value, etc. [4]. Among these factors, the selection or design of a suitable ligand containing appropriate coordination sites is crucial for the construction of coordination polymers or supramolecular architectures [5].

Multidentate N- and O-donor ligands, such as pyridine- [6] or imidazole- [7] carboxylic acids have drawn extensive attention in the construction of coordination polymers or metal-organic frameworks. Among them, pyridine-2,6-dicarboxylic acid has been proved to be effective for the construction of 3d, 4f or 3d–4f MOFs and multidimensional supramolecular networks because it has many coordination modes. Compared with pyridine-2,6-dicarboxylic

acid, pyrazine-2,6-dicarboxylic acid has a similar geometry configuration but one more nitrogen atom in the 4-position of the pyrazine ring, and thus is of particular interest because: (a) it has two carboxylate groups and two nitrogen atoms which can coordinate to metal ions in a variety of coordination modes leading to different topologies for the structures of the complexes, and its diversity of coordination modes in the complexes is depicted in Scheme 1, in which a and c are first reported in this paper; (b) the COOH groups and nitrogen atoms can act as hydrogen bond donors and/or hydrogen bond acceptors, favoring the formation of supramolecular structures; and (c) the COOH groups can be tilted from the pyrazine ring plane and coordinate to metal ions in a different direction, allowing for formation of desirable frameworks. However, the construction of MOFs from the pzda ligand has been rarely reported [8]. Further study is still necessary to understand the coordination chemistry of H_2pzda. In addition, auxiliary ligands such as 2,2′-bpy and bpe often have a significant effect on the formation and structure of metal N-containing polycarboxylate complexes [9].

On the basis of above mentioned points, we synthesized six metal complexes with H_2pzda and auxiliary ligands. Herein, we report the syntheses and crystal structures of six new complexes: $[Ln_2(pzda)_3(H_2O)_2]\cdot 2.5H_2O$ (Ln = Nd, (**1**); Eu, (**2**)), $[Co(pzda)(bpe)]\cdot 0.125(bpe)\cdot 1.75H_2O$ (**3**), $[Mn(pzda)(H_2O)_{1.5}]$ (**4**), $[Co_2(pzda)_2(bpe)(H_2O)_4]\cdot 0.5(CH_3OH)\cdot H_2O$ (**5**) and $[Co(pzda)(2,2'\text{-bpy})\ (H_2O)]\cdot 0.5H_2O$ (**6**). In these complexes, the pzda ligands are able to link metal ions in various modes giving rise to zero-, one-, two- and three-dimensional complexes.

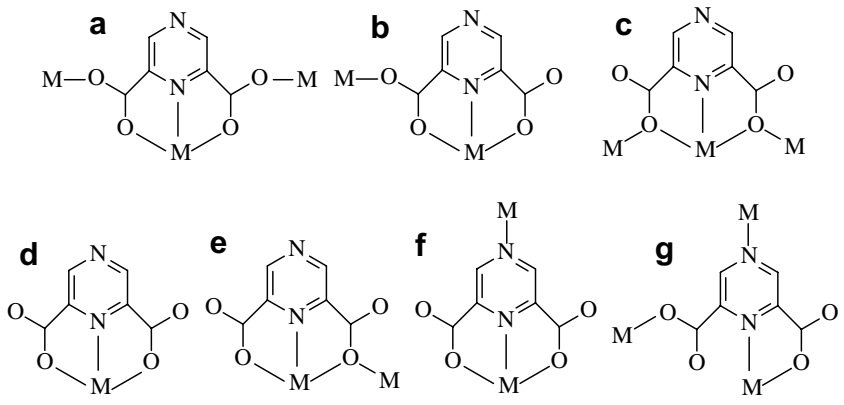
2. Experimental

2.1. Materials and apparatus

Pyrazine-2,6-dicarboxylic acid dihydrate was synthesized according to the literature [10]. All the other reagents were used as received without further purification. The C, H, N microanalyses were carried out with a Vario EL elemental analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer using the KBr pellet technique. The TG experiments for the complexes **1**, **2** and **5** were performed using a Perkin–Elmer TGA7 thermogravimetric analyzer under atmosphere. The heating rate used was 5 °C min^{-1} from ambient temperature to 900 °C.

2.2. Synthesis

2.2.1. Synthesis of $[Nd_2(pzda)_3(H_2O)_2]\cdot 2.5H_2O$ (*1*)



Nd_2O_3 (0.0168 g, 0.05 mmol), H_2pzda (0.0306 g, 0.15 mmol), 4,4′-bpy · $2H_2O$ (0.0192 g, 0.1 mmol), water (3 mL) and isopropyl alcohol (3 mL) were sealed in a Teflon-lined stainless steel vessel (25 mL) and heated at 180 °C for 5 days under autogenous pressure and then cooled slowly to room temperature. Purple plate-like crystals were obtained. Yield: 45%. *Anal.* Calc. for $C_{18}H_{15}Nd_2N_6O_{16.5}$: C, 24.91; H, 1.74; N, 9.69. Found: C, 25.05; H, 1.75; N, 9.60%. IR (KBr pellet, cm^{-1}): 3422br, 1618vs, 1458s, 1406w, 1191m, 1129w,1044m, 946w, 820w, 795m, 746m.

2.2.2. Synthesis of $[Eu_2(pzda)_3(H_2O)_2]\cdot 2.5H_2O$ (*2*)

Eu_2O_3 (0.0176 g, 0.05 mmol), H_2pzda (0.0306 g, 0.15 mmol), 4,4′-bpy · $2H_2O$ (0.0192 g, 0.1 mmol), water (3 mL) and ethanol (3 mL) were sealed in a Teflon-lined stainless steel vessel (25 mL) and heated at 180 °C for 5 days under autogenous pressure and then cooled slowly to room temperature. Colorless crystals were obtained. Yield: 43%. *Anal.* Calc. for $C_{18}H_{15}Eu_2N_6O_{16.5}$: C, 24.47; H, 1.71; N, 9.52. Found: C, 24.61; H, 1.81; N, 9.50%. IR (KBr pellet, cm^{-1}): 3421br, 1617vs, 1459s, 1406w, 1193m, 1130w, 1046m, 796m, 746m.

2.2.3. Synthesis of $[Co(pzda)(bpe)]\cdot 0.125(bpe)\cdot 1.75H_2O$ (*3*)

A mixture of H_2pzda (0.0204 g, 0.1 mmol), $Co(OAc)_2\cdot 4H_2O$ (0.0249 g, 0.1 mmol), 1,2-bis(4-pyridyl)ethane (0.0184 g, 0.1 mmol), NaOH aqueous solution (0.15 mL, 0.65 mol/L) and deionized water (5 mL) was sealed in a Teflon-lined stainless steel vessel (25 mL) and heated at 100 °C for 4 days under autogeneous pressure and then cooled slowly to room temperature. The solution

Scheme 1. The coordination modes of the pzda ligand in the metal complexes.

was filtered and allowed to stand for two months at room temperature. Orange-yellow block crystals were obtained. Yield: 31%. *Anal.* Calc. for $C_{19.5}H_{19}CoN_{4.25}O_{5.75}$: C, 50.45; H, 4.09; N, 12.82. Found: C, 50.58; H, 3.25; N, 13.11%. IR (KBr pellet, cm^{-1}): 3423br, 1646vs, 1613vs, 1559w, 1428m, 1384s, 1364m, 1225m, 1195m, 1116w, 1057m, 814m, 745w.

2.2.4. Synthesis of [Mn(pzda)(H$_2$O)$_{1.5}$] (**4**)

A mixture of $MnCO_3 \cdot H_2O$(0.004 g, 0.03 mmol), H_2pzda (0.0224 g, 0.11 mmol), $Yb(NO_3)_3 \cdot 6H_2O$ (0.009 g, 0.02 mmol), H_2O (1 mL), a drop of NaOH (0.65 mol/L) was sealed in a 25 mL stainless steel reactor with a Teflon liner and heated at 160 °C for 96 h, then cooled to room temperature. Light-yellow crystals were obtained, washed with deionized water and dried in air. Yield: 26%. *Anal.* Calc. for $C_6H_5MnN_2O_{5.5}$: C, 29.02; H, 2.02; N, 11.28. Found: C, 28.94; H, 2.27; N, 11.20%. IR data (KBr pellet cm^{-1}): 3444br, 1621vs, 1454m, 1402s, 1384s 1348m, 1213m, 1188m, 1043 w, 810w, 735w.

2.2.5. Synthesis of [Co$_2$(pzda)$_2$(bpe)(H$_2$O)$_4$] · 0.5(CH$_3$OH) · H$_2$O (**5**)

A mixture of H_2pzda (0.0204 g, 0.1 mmol), $Co(OAc)_2 \cdot 4H_2O$ (0.0249 g, 0.1 mmol), 1,2-bis(4-pyridyl)ethane (0.0184 g, 0.1 mmol), NaOH aqueous solution, (0.3 mL, 0.65 mol/L), deionized water (5 mL) and 0.5 mL methanol was sealed in a Teflon-lined stainless steel vessel (25 mL) and heated at 100 °C for 4 days under autogeneous pressure and then cooled slowly to room temperature. The solution was filtered and allowed to stand for two months at room temperature. Orange-yellow needle crystals were obtained. Yield: 37%. *Anal.* Calc. for $C_{24.5}H_{28}Co_2N_6O_{13.5}$: C, 39.70; H, 3.78; N, 11.34. Found: C, 38.87; H, 4.23; N, 11.21%. IR (KBr pellet, cm^{-1}): 3446br, 1635vs, 1616vs, 1558m, 1541m, 1507w, 1448m, 1335s, 1195m, 1124m, 1062m, 935w, 788w.

2.2.6. Synthesis of [Co(pzda)(2,2′-bpy)(H$_2$O)] · 0.5H$_2$O (**6**)

A mixture of H_2pzda (0.0204 g, 0.1 mmol), $Co(OAc)_2 \cdot 4H_2O$ (0.0249 g, 0.1 mmol), 2,2′-bpy (0.0156 g, 0.1 mmol), deionized water (5 mL) and isopropyl alcohol (1 mL) was sealed in a Teflon-lined stainless steel vessel (25 mL) and heated at 140 °C for 4 days under autogenous pressure and then cooled slowly to room temperature. The solution was filtered and allowed to stand for four weeks at room temperature. Orange-red block crystals were obtained. Yield: 39%. *Anal.* Calc. for $C_{16}H_{13}CoN_4O_{5.50}$: C, 47.07; H, 3.21; N, 13.73. Found: C, 47.03; H, 3.24; N, 13.64%. IR (KBr pellet, cm^{-1}): 3425br, 1613vs, 1474m, 1442s, 1383s, 1193w, 1121m, 1058m, 1024w, 769m.

2.3. X-ray crystallography

Single-crystal X-ray diffraction measurements for the title complexes were carried out on a Bruker Smart 1000 CCD diffractometer, using graphite-monochromatized

Mo Kα radiation ($\lambda = 0.7107$ Å). Semi-empirical absorption corrections were applied using the SADABS program [11]. All the structures were solved by direct methods and refined by full-matrix least squares on F^2 using the SHELXL-97 program [12]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were generated geometrically and treated by a mixture of independent and or constrained refinement. The crystallographic data for **1**–**6** are listed in Table 1, and selected bond lengths (Å) are listed in Table 2.

3. Results and discussion

3.1. Description of the structures

3.1.1. Structural description of $[Nd_2(pzda)_3(H_2O)_2] \cdot 2.5H_2O$ (**1**) and $[Eu_2(pzda)_3(H_2O)_2] \cdot 2.5H_2O$ (**2**)

The single crystal X-ray diffraction determinations show that complexes **1** and **2** are isostructural. So only the structure of complex **2** will be discussed in detail. Complex **2** has a novel 3D metal-organic framework built up from a 1D tri-strand array which is a novel structural motif. In the asymmetric unit of **2**, there are two crystallographically independent Eu(III) ions, three pzda ligands and four and half water molecules. The extended asymmetric unit of Eu(III) ions is shown in Fig. 1. Eu1 is nine-coordinated with a N_2O_7 donor set; six oxygen atoms coming from the carboxylate groups of four different pzda ligands, the remaining oxygen atom from one coordinated water molecule, and two nitrogen atoms from two pzda ligands. The coordination environment of Eu1 can be described as distorted monocapped square-antiprismatic geometry. The Eu1–O bond lengths are in the range 2.362(5)–2.527(4) Å, and the Eu1–N bond lengths are 2.561(5) and 2.566(6) Å. Eu2 displays a distorted dodecahedral geometry with a NO_7 donor set; six oxygen atoms from five pzda ligands, one oxygen atom from one coordinated water molecule, and one nitrogen atom from a pzda ligand. The Eu2–O distances range from 2.333(4) to 2.463(5) Å, and the Eu2–N distance is 2.525(5) Å.

In complex **2**, each pzda ligand adopts a pentadentate mode to connect three Eu(III) ions (see Scheme 1a). One pyrazine nitrogen atom together with two adjacent carboxylate oxygen atoms are coordinated to one Eu(III) ion in a tridentate chelating mode (ONO), forming two five-membered rings. The remaining two oxygen atoms of the pzda ligand coordinate with other two Eu(III) ions, this kind of coordination mode has not been reported before.

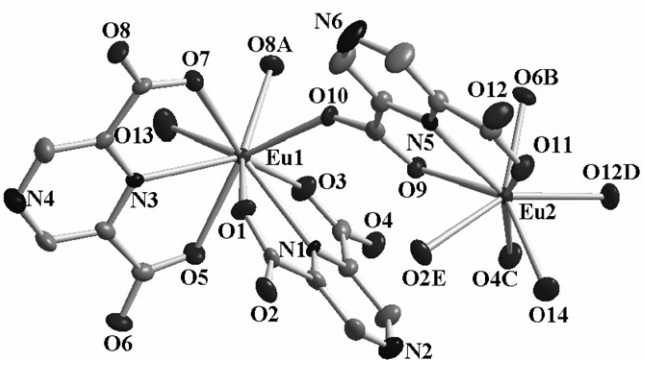

Fig. 1. Extended asymmetric unit of Eu(III) ions in **2** with 30% probability thermal ellipsoids. All the hydrogen atoms are omitted for clarity.

Based on this connection mode, each pzda ligand links three Eu(III) ions, and along the $[10\bar{1}]$ direction, the Eu(III) ions are bridged by pzda ligands to form a Eu–pzda–Eu chain. It is worth noticing that such single chains are interwoven to form a 1D tri-strand array in which the Eu(III) ions are the nodes. This may be contributed to the symmetric coordination mode of the pzda ligand coordinating to the lanthanide ion (see Fig. 2a). Such 1D tri-strand arrays are further connected by bridging carboxylates of the pzda ligands to generate a 3D coordination polymer (see Fig. 2b). To the best of our knowledge, this is the first example of a lanthanide-organic framework constructed from such a unique structural motif.

In complex **2**, there are various hydrogen bonds between the coordinated water and the free water molecules, between the water molecules and the carboxylate oxygen atoms, and between the water molecules and the pyrazine nitrogen atoms, further stabilizing the lanthanide-organic framework of **2**.

*3.1.2. Structural description of [Co(pzda)(bpe)] · 0.125(bpe) · 1.75H_2O (**3**)*

X-ray diffraction analysis shows that complex **3** crystallizes in the monoclinic $P2_1/c$ space group and has a 2D metal-organic framework. There is only one kind of metal

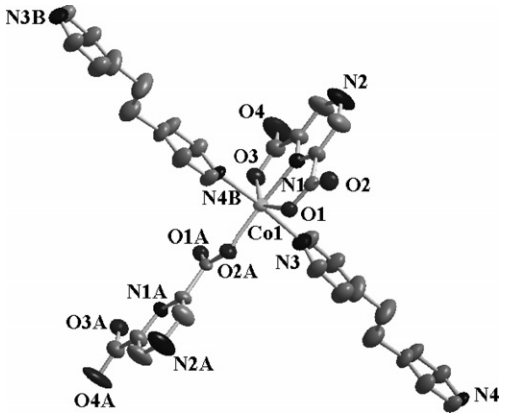

Fig. 3. The coordination environment of the Co(II) ion in complex **3** with 30% probability thermal ellipsoids. All hydrogen atoms are omitted for clarity.

environment in the complex. Each Co(II) ion is coordinated by three oxygen atoms and one nitrogen atom from two pzda ligands, and two nitrogen atoms from two bpe molecules. The coordination environment of the Co(II) ion is shown in Fig. 3.

In complex **3**, each pzda ligand adopts a tetradentate mode to connect two Co(II) ions, as shown in Scheme 1b. In this way, the pzda ligands bridge Co(II) metal centers to form an extended 1D Co–pzda polymeric chain along the *b*-axis. In the crystal of **3**, most bpe molecules are coordinated to Co(II) ions. Also two unit cells share one free bpe molecule. The coordinated bpe molecules are in the *trans*-mode and act as bridging ligands to join these 1D polymeric chains into a 2D rectangular grid-like layer structure with (4,4) topology and the dimension of the rectangular voids is about 5.520×13.598 Å^2, based on Co–Co distances (see Fig. 4a). In the same layer, the Co–pzda chains are arranged in the same fashion, while in the adjacent layers the Co–pzda chains are arranged in another fashion. Such 2D layers are arranged in an alternative sequence along the *c*-axis. The lattice water molecules link free bpe molecules via hydrogen bonds to form hydrogen-bonded chains and these are located between the layers

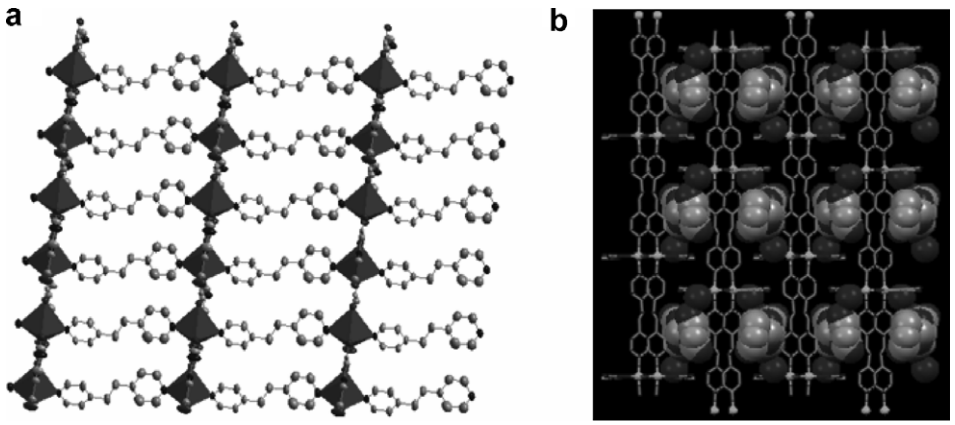

Fig. 4. (a) The 2D rectangular grid-like layer framework of **3** viewed along the *b*-axis; (b) 3D stacking diagram of **3** viewed along the *c*-axis. The space-filling models represent free water and free bpe molecules.

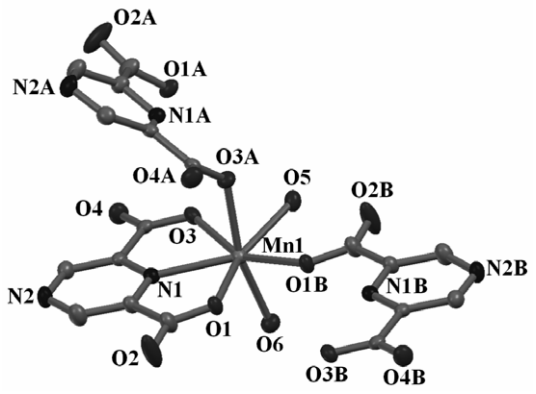

Fig. 5. The coordination environment of the Mn(II) ion in **4** with 30% probability thermal ellipsoids. All hydrogen atoms are omitted for clarity.

(see Fig. 4b). The lattice water molecules are also connected to the 2D metal-organic framework through hydrogen bonds with the coordinated or uncoordinated carboxylate oxygen atoms, and thus a 3D supramolecular network is formed.

3.1.3. Structural description of $[Mn(pzda)(H_2O)_{1.5}]$ (**4**)

The crystal structure of **4** reveals that the complex crystallizes in the monoclinic $C2/c$ space group and consists of 1D Mn–pzda chains. The Mn(II) ion is seven-coordinated to four oxygen atoms and one nitrogen atom from three pzda ligands, and two oxygen atoms from two water molecules (see Fig. 5), displaying a distorted pentagonal bipyramidal geometry. The equatorial plane is occupied by four oxygen atoms and one nitrogen atom, with a maximum deviation of 0.0085 Å. The axial sites are occupied by two oxygen atoms (O3A, O6), the angle O3A–Mn1–O6 being 164.04(9)°.

In **4**, the pzda ligand adopts another pentadentate mode (see Scheme 1c) to link three Mn(II) ions. One pyrazine nitrogen atom together with two adjacent carboxylate oxygen atoms coordinate one Mn(II) ion in the ONO mode. Simultaneously, both the two oxygen atoms act as μ_2-O bridges to connect the other two Mn(II) ions, the other oxygen atom of each carboxylate group of the pzda ligand remains uncoordinated. This is the first example of this kind of coordination mode for the pzda ligand. In this way, Mn(II) ions are linked to form a 1D polymeric $(–Mn–O–)_n$ zigzag chain via oxygen bridges (see Fig. 6a), which is different from the reported 1D coordination polymer featuring a head-to-tail arrangement of the pzda ligand bound to Zn(II) or Cu(II) ions, reported by Leciejewic [8f] and MacDonald. [8i] In these chains of **4**, apart from the carboxylate μ_2-O bridge (the Mn···Mn distance is 3.718 Å), there is a water μ_2-O bridge (the Mn···Mn distance is 3.340 Å), which locates the pzda ligands in different planes.

It is worth noting that in **4** the N atom in the 4-position of the pyrazine ring of the pzda ligand is not coordinated to the Mn(II) ion, which leads to the formation of hydrogen bonds with water molecules. The hydrogen bonds present strong intermolecular interactions to link these 1D polymeric chains into a 2D supramolecular layer structure, which consists of hydrogen-bonded double-stranded helical chains, as shown in Fig. 6b.

3.1.4. Structural description of $[Co_2(pzda)_2(bpe)(H_2O)_4] \cdot 0.5(CH_3OH) \cdot H_2O$ (**5**)

Under similar reaction conditions to complex **3**, except that the amount of NaOH added was different, complex **5** was obtained, but the structures of **3** and **5** are different. Complex **5** crystallizes in the monoclinic $P2_1/c$ space group and is a 0D binuclear molecule. There are two crystallographically independent Co(II) ions in the asymmetric unit and the two Co(II) ions are bridged by the bpe spacer and blocked by the pzda ligand, forming a dimeric unit. The coordination environments of the Co(II) ions are shown in Fig. 7. The two Co(II) ions are both six-coordinated and each Co(II) ion links one pzda ligand, two water molecules and one bpe molecule. The average Co–O distance is 2.134(5) Å for Co1 and 2.138(5) Å for Co2. The average Co–N distance is 2.061(6) Å for Co1 and 2.073(6) Å for Co2. The O(11)–Co(1)–O(12) angle is 177.3(2)°, and the

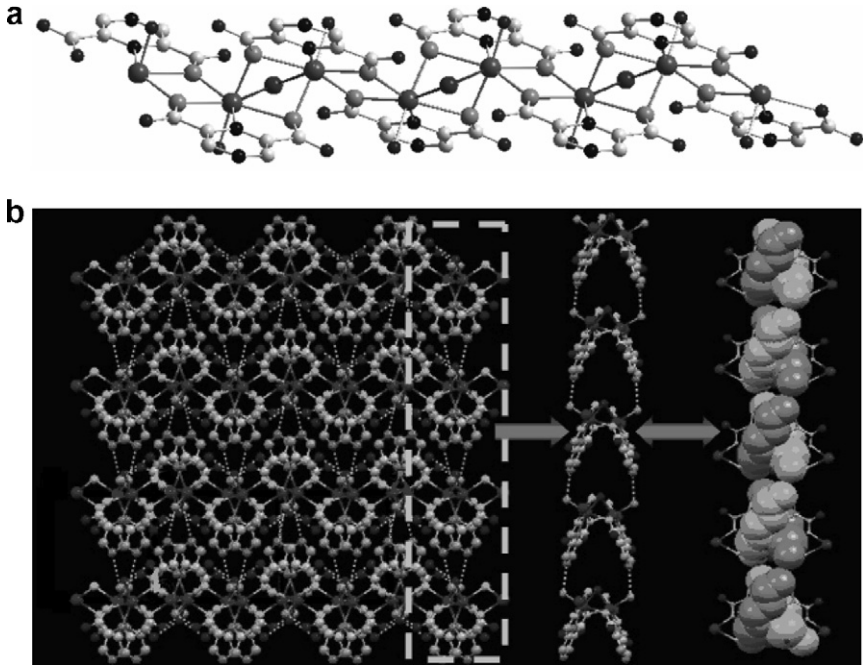

Fig. 6. (a) 1D chain structure of **4** viewed along the *b*-axis; (b) 2D supramolecular layer network of **4** and the hydrogen-bonded double-stranded helical chain.

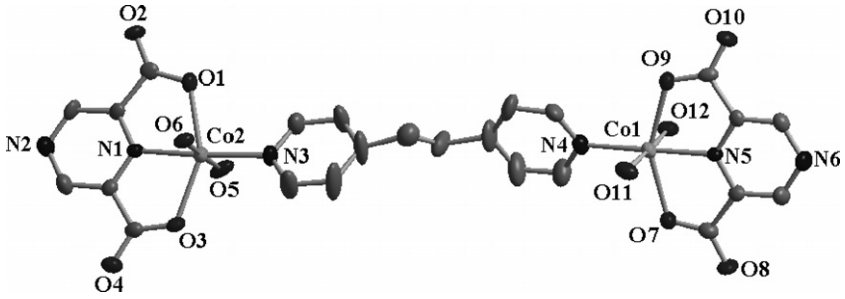

Fig. 7. The coordination environment of Co(II) ions in **5** with 30% probability thermal ellipsoids. All hydrogen atoms are omitted for clarity.

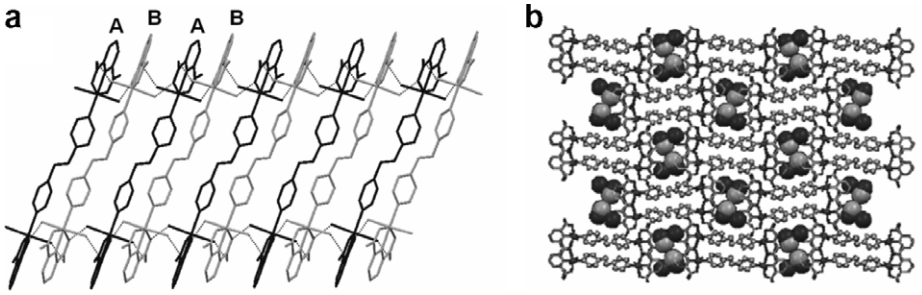

Fig. 8. (a) 1D supramolecular chain of **5** formed via hydrogen bonding along the *b*-axis; (b) 3D supramolecular structure viewed along the *a*-axis. The space-filling models represent free water and methanol molecules.

O(5)–Co(2)–O(6) angle is 177.1(2)°. So the coordination environments of the two Co(II) ions are slightly different.

In the dimer of **5**, two pzda ligands both adopt a tridentate mode (ONO) to coordinate Co(II) ions (see Scheme 1d), the bpe molecule adopts a trans configuration to bridge the two Co(II) ions and the dihedral angle of the two pyridine rings is 74.1°. Each dimer unit is linked with two neighbors by hydrogen bonds between the coordinated water molecules and the carboxylate oxygen atoms of the pzda ligand to afford a 1D hydrogen-bonded chain along the *b*-axis (see Fig. 8a). In these chains, two adjacent binuclear units are in two different layers which are labelled as A and B. These chains are packed alternatively by the hydrogen bonds between the coordinated water molecules

and the coordinated carboxylate oxygen atoms or the uncoordinated carboxylate oxygen atoms of the pzda ligand to afford a 3D supramolecular architecture, as shown in Fig. 8b. Free water and methanol molecules reside in the lattices and form hydrogen bonds with the uncoordinated carboxylate oxygen atoms or uncoordinated nitrogen atoms of the pyrazine ring, which stabilizes the structure of **5**.

3.1.5. Structural description of $[Co(pzda)(2,2'\text{-bpy})(H_2O)]\cdot 0.5H_2O$ (6)

To compare with the binuclear structure of **5**, we replaced the bridging ligand bpe by the terminal ligand 2,2′-bpy, and the mononuclear molecule **6** was obtained. Complex **6** crystallizes in the triclinic $P\bar{1}$ space group and consists of one crystallographically independent Co(II) ion, which is bonded to two oxygen atoms and one nitrogen atom from one pzda ligand, two nitrogen atoms of one 2,2′-bpy molecule, and one oxygen atom from one water molecule. The coordination environment of Co(II) ion is shown in Fig. 9a. The Co–O distances range from 2.150(16) to 2.215(17) Å, and the Co–N distances range from 2.056(18) to 2.103(19) Å.

In complex **6**, the pzda ligand adopts a tridentate mode (ONO) (see Scheme 1d), which is coordinated to one Co(II) ion to form a mononuclear unit. There are two different kinds of interactions that lead to the formation of a 3D supramolecular architecture: hydrogen bonds and π–π stacking interactions. The water molecules form three kinds of hydrogen bonds. The first involves hydrogen bonds between the coordinated water molecules and the uncoordinated carboxylate oxygen atoms such as (O5–H5···O2). The second involves hydrogen bonds between the coordinated water molecules and the uncoordinated pyrazine nitrogen atoms such as (O5–H5···N2). Finally, the lattice water molecules form hydrogen bonds with the uncoordinated carboxylate oxygen atoms such as (O6–H6···O4), which act as hydrogen-bonded bridges together with the former two kinds of hydrogen bonds. Together with the π–π stacking interactions between the 2,2′-bpy molecules, with distances of 3.405 and 3.463 Å, these make the mononuclear units form a 3D supramolecular structure (see Fig. 9b). Free water molecules reside in the voids and connect the network via hydrogen bonds.

3.2. Thermal stability of the complexes

The thermal stability of complexes **1**, **2** and **5** was investigated by thermogravimetric analysis. As observed from the TG curves, the thermal decomposition processes of **1** and **2** are similar. Taking **1** as an example, a weight loss of 9.76% occurred between 53 and 183 °C, corresponding to the release of four and half water molecules (calculated: 9.19%). Then no weight loss occurred until ca. 426 °C, showing a plateau, which indicates that the metal-organic framework is thermally stable. The framework collapsed above the temperature 426 °C. The TG curve of **5** revealed a weight loss of 14.31% between 48 and 149 °C, corresponding to the loss of five water molecules and half a methanol molecule (calculated: 13.28%). A plateau was observed from 149 to 258 °C, indicating no further weight loss, and above 258 °C the complex started to decompose rapidly.

4. Comparison of structures

Six new metal complexes with the pzda ligand were obtained by the hydro(solvo)thermal method. The X-ray crystallographic analyses indicate that these complexes have different structures. They span zero-, one-, two- and three-dimensions. In a comparison of the structures of **1**–**6**, it is found that because of the versatile coordination sites, there are several coordination modes for the pzda ligand to bind the metal ions. Also the coordination modes of the pzda ligand have a very significant effect on the formation and structure of the complexes. In complexes **1** and **2**, in order to meet the requirements of larger radii and higher coordination number of the lanthanide ions, the

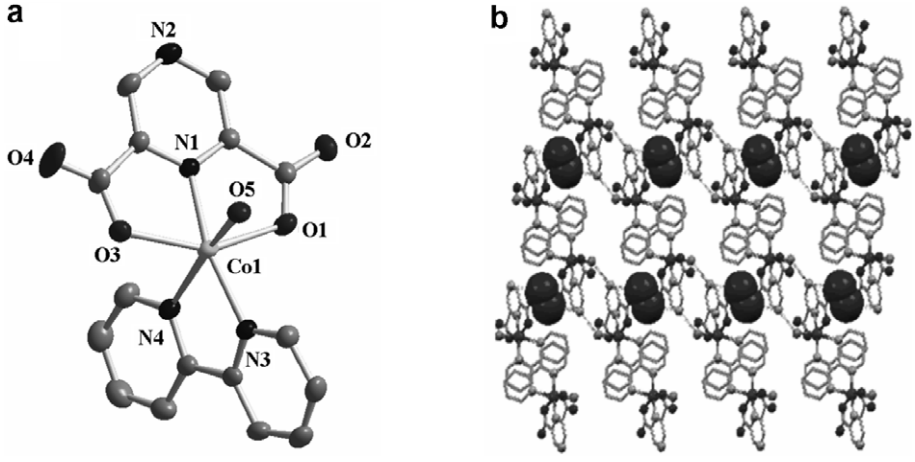

Fig. 9. (a) The coordination environment of the Co(II) ion in **6** with 30% probability thermal ellipsoids. All hydrogen atoms are omitted for clarity; (b) 3D supramolecular network of **6** viewed along the *a*-axis. The space-filling models represent free water molecules.

pzda ligand adopts a pentadentate mode to link the Nd(III) ion (or Eu(III) ion) into a 3D metal-organic framework containing a 1D tri-strand array. In complex **3**, the pzda ligand adopts a tetradentate mode to bind the Co(II) ion cooperatively with a bpe ligand to form a 2D metal-organic framework with (4,4) topology. In complex **4**, the pzda ligand adopts another pentadentate mode to link a Mn(II) ion, which is different from that of **1** and **2**, as shown in Scheme 1c. Two μ_2-O atoms of the carboxylate groups of pzda together with water μ_2-O link three Mn(II) ions into a 1D coordination polymer. It is different from the previously reported Mn–pzda complex ($[Mn(pzda)(H_2O)_2]$),[8b] in which the coordination mode is shown in Scheme 1g. In complexes **5** and **6**, the pzda ligand adopts a tridentate chelating (ONO) mode to coordinate metal ions, forming 0D structures in which the pzda ligand acts as a terminal ligand, but because of the existence of different auxiliary ligands, the structures of **5** and **6** are also different. For complex **5**, bpe is a bridging ligand, connecting Co–pzda units into a binuclear structure. While in **6**, 2,2′-bpy is a terminal ligand, which results in the formation of a mononuclear molecule.

The pH of the reaction mixture also plays an important role in the architectures of complexes **3** and **5**. **3** has a 2D metal-organic framework with (4, 4) topology in which the pzda ligand adopts a tetradentate mode. While **5** is a binuclear molecule, which is further assembled by hydrogen bonds to form a 3D supramolecular structure. This may be attributed to the different pH value, resulting in the different roles for water molecules in **3** and **5**, and thus different coordination modes of pzda, making the coordination number for the Co(II) ions the same. From the above discussion, we can conclude that the higher multidentate modes of the pzda ligand benefit the formation of higher dimensional metal-organic frameworks, while the single tridentate chelating ONO mode of the pzda ligand favors the formation of the 0D structure.

5. Conclusions

Six new complexes with 0D, 1D, 2D and 3D structures using the pzda ligand were obtained under hydro(solvo)thermal conditions. The assembly of structural versatility for the title complexes reveals that the metal ions and the coordination modes of the pzda ligand have a significant effect on the formation and dimensionality of the resulting complexes. The single ONO mode benefits the formation of a 0D structure and the uncoordinated oxygen and nitrogen atoms of the pzda ligand tend to form hydrogen bonds, resulting in a higher dimensional supramolecular structure. The higher multiple dentate mode of pzda together with a larger radius and high coordination number of metal ions, such as the lanthanide (III) ions in complexes **1** and **2**, is available to form 3D MOFs.

Compared with metal pyridine-2,6-dicarboxylate complexes, which show interesting structures and unique properties [6a,6b,6c], metal complexes of pyrazine-2,6-dicarboxylic acid are underdeveloped. Also, the latter ligand has more coordination sites than the former due to the nitrogen atom at the 4-position of the pyrazine ring. Therefore the chemistry of metal pyrazine-2,6-dicarboxylate complexes is a challenge and thus is promising.

Abstract

Three new complexes of the general formula: [Ni($RSO_2N{=}CS_2$)(dppe)], where R = CH_3 (**1**), CH_3CH_2 (**2**), 2-$CH_3C_6H_4$ (**3**) and dppe = 1,2-bis(diphenylphosphine)ethane, were obtained in crystalline form by the one-pot reaction of the appropriate potassium *N*-R-sulfonyldithiocarbimate: $RSO_2N{=}CS_2K_2 \cdot 2H_2O$ and 1,2-bis(diphenylphosphine)ethane with nickel(II) chloride hexahydrate in ethanol/water mixture. The complex **1** forms monoclinic crystals ($P2_1/c$) with two molecules in the asymmetric unit ($Z = 8$), while the crystals of the complexes **2** and **3** are orthorhombic, *Pbca* ($Z = 8$) and $P2_12_12_1$ ($Z = 4$) respectively, with one molecule in the asymmetric unit. All complexes present a distorted square-planar environment around the Ni atom. The elemental analyses and the IR, ^{1}H NMR, ^{13}C NMR and ^{31}P NMR spectra are consistent with the formation of the nickel(II) complexes with mixed ligands.

Keywords: Dithiocarbimates; 1,2-bis(Diphenylphosphine)ethane; Nickel complexes; Crystal structure

1. Introduction

Dithiocarbamate derivatives show a wide range of applications. For example, they are very active accelerators in vulcanization [1–3] and many dithiocarbamates, anions and complexes, show biological activity and are used as fungicides [1,4].

Many authors have investigated complexes of nickel(II) with diphosphines. These systems are quite attractive in view of their importance as precursors in catalytic reactions [5]. Complexes containing the $NiXS_2P$ chromophore (X = halide, S_2 = dithiocarbamate, P = phosphine) are usually obtained by reacting NiX_2 with dithiocarbamates and PR_3 (R = alkyl/aryl) [6]. Nickel(II) dithiocarbamates normally react with phosphines to form complexes with the NiS_2P_2 chromophore [7–12].

Some nickel complexes with dithiocarbimates and phosphines with general formulae [Ni(R′N=CS_2)(PR_3)$_2$] (R and R′ = alkyl/aryl) have been obtained [13]. However, only the nickel complexes with general formulae [Ni($RSO_2N{=}CS_2$)(PPh_3)$_2$] with R = 2-$CH_3C_6H_4$, 4-$CH_3C_6H_4$ and 4-BrC_6H_4 [14] and with R = 2,5-$Cl_2C_6H_3$ [15] have had their structures determined by X-ray diffraction techniques.

We decided to study dithiocarbimato complexes due to their similarities with the dithiocarbamate compounds. As part of these studies three new nickel(II)-dithiocarbimato-diphosphine complexes of the general formula: [Ni($RSO_2N{=}CS_2$)(dppe)], where R = CH_3 (**1**), CH_3CH_2

(**2**), 2-$CH_3C_6H_4$(**3**) and dppe = 1,2-bis(diphenylphosphine)-ethane, were obtained in crystalline form by the reaction of $NiCl_2 \cdot 6H_2O$ with the diphosphine and dithiocarbimate anions derived from sulfonamides. The complexes here studied are the first examples of nickel(II)–sulfonyldithiocarbimato–diphosphine complexes prepared and characterized by single crystal X-ray diffraction techniques. The compounds were also characterized by IR, ^1H, ^{13}C and ^{31}P NMR and elemental analyses for C, H, N and Ni.

2. Experimental

2.1. Methods and materials

The solvents were purchased from Merck and used without further purification. The sulfonamides, nickel(II) chloride hexahydrate and 1,2-bis(diphenylphosphine)ethane were purchased from Aldrich. Carbon disulfide and potassium hydroxide were purchased from Vetec. The *N*-R-sulfonyldithiocarbimate potassium salts dihydrate were prepared in dimethylformamide from sulfonamides analogously as described in the literature [16]. Melting points were determined with a Mettler FP5 equipment. Microanalyses for C, H and N were obtained from a Perkin–Elmer 2400 CHN. Nickel was analysed by atomic absorption with a Hitachi Z-8200 Atomic Absorption Spectrophotometer. The IR spectra were recorded with a Perkin–Elmer 283 B infrared spectrophotometer using KBr pellets and nujol mulls between CsI plates. The ^1H (400 MHz), ^{13}C (100 MHz) and ^{31}P (162 MHz) NMR spectra of the complexes were recorded at 300 K on a Bruker Advance RX-400 spectrophotometer in $CDCl_3$ with TMS (H_3PO_4 for ^{31}P NMR spectra) as internal standard. Additionally, the ^{31}P (162 MHz) NMR spectra were recorded at 240 K.

2.2. Syntheses

The compounds were prepared according to the methodology applied for the syntheses of similar compounds with triphenylphosphine [14] (Scheme 1).

A solution of potassium *N*-R-sulfonyldithiocarbimate dihydrate (1.0 mmol) in water (10 mL) was added to a solution of 1,2-bis(diphenylphosphine)ethane (1.0 mmol) in ethanol (40 mL). Nickel(II) chloride hexahydrate (1.0 mmol) was added to the suspension and the reaction mixture was stirred for 5 h at room temperature. The colour of the suspension changed from green to orange/red. The solid product of the reaction was filtered, washed with distilled water and ethanol, and dried under reduced pressure for one day yielding [Ni($RSO_2N{=}CS_2$)(dppe)] (ca. 70%). Suitable crystals for X-ray structure analysis were obtained after slow evaporation of solutions of the compounds in dichloromethane/ethanol and few drops of water.

H5 of the aromatic rings of dppe); 7.36–7.28 (m, 1H, H5 of the aromatic ring of the dithiocarbimato); 7.20–7.13 (m, 2H, H3 and H4 of the aromatic ring of the dithiocarbimato); 2.68 (s, 3H, CH_3); 2.33 (d, 4H $J_{HP} = 17$, CH_2CH_2). $^{13}C\{^1H\}$ NMR (δ), J (Hz): 198.26 (N=CS_2); 140.80 (C1); 137.98 (C2); 131.69 (C4); 128.55 (C5); 125.19 (C6). dppe signals: 132.90 (t, $J_{CP} = 5.4$, C2 and C6); 131.78 (s, C4); 129.36 (t, $J_{CP} = 5.2$, C3 and C5); 128.35 (t, $J_{CP} = 23$, C1); 25.89 (t, $J_{CP} = 23$, CH_2CH_2). ^{31}P NMR (300 k) (δ): 56.80 (s). ^{31}P NMR (240 k) (δ), J (Hz): 58.10 (d, $J_{PP} = 40.5$, P1); 57.43 (d, $J_{PP} = 40.5$, P2).

2.3. X-ray crystallography

X-ray diffraction data collections for all crystals were performed on an Enraf-Nonius Kappa-CCD diffractometer (95 mm CCD camera on κ-goniostat) using graphite monochromated Mo Kα radiation (0.71073 Å), at room temperature for the complex **2** and at lower temperature for the complexes **1** and **3**. Data collections were carried out using the COLLECT software [17] up to 50° in 2θ with a redundancy of four. Final unit cell parameters were based on all reflections. Integration and scaling of the reflections, correction for Lorentz and polarization effects were performed with the *HKL* DENZO-SCALEPACK system of programs [18]. Numerical absorption correction (GAUSSIAN) were applied using the program SORTAV [19].

The structures were solved by direct methods with SHELXS-97 [20]. The models were refined by full-matrix least squares on F^2 using SHELXL-97 [21]. All the hydrogen atoms were stereochemically positioned and refined with the riding model [21]. Data collections and experimental details for the compounds are summarized in Table 1. The program ORTEP-3 [22] was used for graphic representation and the program WINGX [23] to prepare materials for publication. Selected bond and angles are presented in Table 2.

3. Results and discussion

The complexes are quite stable at ambient conditions. They are soluble in acetonitrile, dimethylformamide, dimethylsulfoxide, chloroform and dichloromethane, and insoluble in water, methanol and ethanol. There are no strong or medium bands in the 1400–1600 cm^{-1} region in the IR spectra of the potassium dithiocarbimates related to the complexes **1**–**3**, their $\nu_{C=N}$ band being observed in the 1300–1260 cm^{-1} region [24,25]. These low values point to a great contribution of the canonical forms (a) and (b) for the resonance hybrid of the dithiocarbimate anions (Scheme 2). In the spectra of the bis(dithiocarbimato)

complexes $[Ni(RSO_2N{=}CS_2)_2]^{2-}$ (R = CH_3, CH_3CH_2 and 2-$CH_3C_6H_4$) this band is observed in the 1400–1360 cm^{-1} region [25–27]. A strong band observed in the 1470–1450 cm^{-1} region in the spectra of the complexes **1**–**3** was assigned to the $\nu_{C=N}$. The mesomeric drift of electrons from the dithiocarbimate moiety towards the metal centre increases the contribution of the canonical form (c) (Scheme 2). This is reflected in the shift in $\nu_{C=N}$ values to higher wavenumbers when compared with those observed in the free ligands and in the analogous bis(dithiocarbimato) complexes spectra. This effect is also observed, for example, when the spectrum of the complex $[Ni(dpdtc)_2]$ (dpdtc = *N*,*N*-propyldithiocarbamato) ($\nu_{C=N}$ band is observed in 1508 cm^{-1}) is compared with the spectrum of $[Ni(dpdtc)(dppe)]^+$ ($\nu_{C=N}$ band is observed in 1526 cm^{-1}) [11]. The ν_{C-S} band were observed at higher frequency in the spectra of the potassium salts of dithiocarbimates (960–940 cm^{-1}) [24,25] than in the spectra of the complexes here studied (925–915 cm^{-1}), and in the spectra of analogous bis(dithiocarbimato) complexes (940–925 cm^{-1}) [25–27]. This band appears without any splitting, confirming the bidentate coordination of the dithiocarbimate moiety. The shifts observed in the ν_{C-S} in the spectra of the complexes are also consistent with the increased importance of the canonical form (c) after complexation (Scheme 2). The spectra of the complexes also show the expected medium band in the 300–400 cm^{-1} range assigned to the NiS vibrations [28]. The *v*NiP bands was not observed above 200 cm^{-1}.

The NMR spectra of **1**–**3** were typical for diamagnetic species supporting the assumption of a square planar geometry around the nickel atom. The ^1H NMR spectra of the complexes showed the signals for the hydrogen atoms of the dppe and the dithiocarbimate moiety. The integration curves on the ^1H NMR spectra were consistent with a 1:1 proportion between the dppe and the dithiocarbimate anion. The signals in the spectra of the free dithiocarbimates [24,25] and in the spectra of the complexes show approximately the same chemical shifts. Nevertheless, the $N{=}CS_2$ (C1) signal is shifted in the spectra of the complexes to higher field if compared to the spectra of the free ligands [24,25] and the correspondent bis(dithiocarbimato) complexes $[Ni(RSO_2N{=}CS_2)_2]^{2-}$ [25–27]. If the canonical form (c) (Scheme 2) is more important for the complexes than for the ligands, then the C1 carbon atom is expected to be more shielded in the complexes here studied.

Most of the diphosphine signals in the ^{13}C NMR spectra appeared as pseudo triplets or doublets. This is consistent with square planar geometry for the complexes. Doublets or pseudo triplets are commonly observed in the ^{13}C NMR spectra of bis(phosphine) transition metal *cis*-complexes [14,29]. The ^{31}P NMR spectra exhibited only one signal (*ca.* 58 δ) at 300 K, but the signal split into two doublets due P–P coupling at 240 K confirming that the phosphorus atoms in the molecules are not magnetically equivalent. Significant changes in the phosphorus chemical shifts in the spectra of the complexes when compared to

Scheme 2. Three canonical forms for *N*-R-sulfonyldithiocarbimate anion.

that of the free diphosphine (*ca.* −12 δ) [5] are caused by the nickel atom that deshields the phosphorus atoms considerably. Similar chemical shifts are also observed in the spectra of many complexes with NiX_2(P–P) chromophores (P–P = 1,2-bis(diphenylphosphine)ethane; X = Cl, Br, I, S) [5,8–12].

The ORTEP-3 view [22] of the solid-state molecular structures of the complexes **1**, **2** and **3** are illustrated in Figs. 1–3. Compound **1** crystallizes in the monoclinic system, space group $P2_1/c$, with two independent molecules in asymmetric unit ($Z = 8$), while the complexes **2** and **3** crystallize in the orthorhombic system, space groups *Pbca* ($Z = 8$) and $P2_12_12_1$ ($Z = 4$), respectively.

In all complexes, the nickel cation is coordinated by the two sulfur atoms of the dithiocarbimato ligand and by two phosphorus atoms of the 1,2-bis(diphenylphosphine)ethane into a distorted square-planar geometry. The P1–Ni–S1 and P2–Ni–S2 angles are more distorted from 90° than the P1–Ni–P2 angles. The S1–Ni–S2 angle is considerably smaller than 90° due to the chelation of the *N*-R-sulfonyldithiocarbimato ligand forming a four membered ring (NiS_2C). When the complex [Ni(2-$CH_3C_6H_4SO_2N{=}CS_2$)-(PPh_3)$_2$] [14] is compared with **3**, some interesting differences can be observed due to the chelation of dppe and its smaller steric effect. The P–Ni–P angle in **3** (86.69°) is smaller than in [Ni(2-$CH_3C_6H_4SO_2N{=}CS_2$)(PPh_3)$_2$] (98.48°). The S–Ni–S angle in **3** (79.21°) is greater than in the bis(triphenylphosphine) complex (77.87°) and the Ni–P bond length in **3** (*ca.* 2.17 Å) is smaller than Ni–P bonding in the bis(triphenylphosphine) complex (*ca.* 2.21 Å).

The Ni–S bonds, in complexes **1** and **2** are symmetric. In **3**, this bond exhibits a small asymmetry, probably due to the repulsive interaction between the S1 atom and the large RSO_2 group. This group, in all complexes, is in *cis* position in relation to the S1 atom. The orientation of the RSO_2 group is also responsible for the difference between the angles S1–C1–N and S2–C1–N.

The C–S bond lengths in complexes **1**–**3** (*ca.* 1.74) are characteristic of partial double bonds (typical bond lengths: 1.81 Å for C–S and 1.69 Å for C=S). The C–N bond distances (*ca.* 1.285) are similar to that of the double bond C=N (1.275–1.300 Å) [30,31]. This behavior indicates that the π electron density is delocalized over S_2CN moiety. The CN bonds in these neutral complexes are shorter than in the bis(dithiocarbimato) complexes (Table 3) [25–27].

The crystallographic data are in accord with the spectroscopic data (Table 3). Both point to an increase on the contribution of the canonical form (c) (Scheme 2) in this sequence: free ligands < bis(dithiocarbimato) complexes < complexes **1**–**3** complexes.

The R-group in complex **3** lies in a significantly different conformation from that observed for the other complexes. The C1–N–S3–C2 torsion angle is 41.8(3)° for the complex **3**, 164.2(2)° for the molecule 1 and −172.0(2)° for the molecule 2 of the complex **1** and 157.0(3)° for the complex **2.**

The P–C_{sp3} and C_{sp3}–C_{sp3} distances in the dppe ligand, in all complexes, are similar to Ni(II) complexes with Ni(S–S)(P–P) chromophores [9,32–34]. The bond lengths and angles in the phenyl rings are in good agreement,

within experimental accuracy, with the values found in the literature [30].

The angles between the planes of the phenyl rings on each phosphorus, P1 and P2 are, respectively: 82.9(1)° and 52.19(8)° (molecule 1) and 63.4(1)° and 61.50(9)° (molecule 2) in complex **1**, 69.7(1)° and 76.4(1) in complex **2** and 87.3(1)° and 68.5(1)° in complex **3**. In all complexes there are weak intermolecular interactions among C33 atom of the ethane group and oxygen, with donor-acceptor distances ranged from 3.209 to 3.405 Å. The complex **2** have another weak interaction [C18–H18...O2 $(-x, -y+1, -z)$] with C...O of 3.409 Å and the complex **1** have two more intermolecular interactions C–H...O involving the carbon atom of the CH_3SO_2 group.

4. Conclusion

Three novel 1,2-bis(diphenylphosphino)ethane(*N*-R-sulfonyldithiocarbimato)nickel(II) complexes were prepared

and characterized by IR, ^{1}H, ^{13}C and ^{31}P NMR, elemental analyses for C, H, N, Ni and by single crystal X-ray diffraction techniques. They are the first examples of nickel(II) complexes with the mixed ligands *N*-R-sulfonyldithiocarbimate and diphosphine.

When the analogous bis(dithiocarbimato) complexes [25–27] are compared with the compounds here studied, the spectroscopic and X-ray data show that the substitution of a dithiocarbimate group by a diphosphine ligand causes a drift of electrons from the dithiocarbimate to the metallic center, increasing the contribution of the canonical form (c) (Scheme 2) to the resonance hybrid, with a consequent increase of the CN double bond character. Therefore, the wavenumbers for the $\nu_{C=N}$ in the IR spectra of **1**–**3** are greater than those in the spectra of the related bis(dithiocarbimato) complexes and this band is observed in smaller wavenumbers in the spectra of the free ligands. Accordingly, the NMR spectra show that the carbon atom of the dithiocarbimate group of **1**–**3** is more shielded than that of the bis(dithiocarbimato) complex and in the parent ligand (see Table 3). Similar behavior is observed for complexes with general formulae $[Ni(RSO_2N{=}CS_2)(PPh_3)_2]$ with R = 2-$CH_3C_6H_4$, 4-$CH_3C_6H_4$ and 4-BrC_6H_4 [14] and with R = 2,5-$Cl_2C_6H_3$ [15].

The comparison between bis(triphenylphosphine)-*N*-R-sulfonyldithiocarbimato-nickel(II) complexes [14,15] and **1**–**3** show that the substitution of two bulky triphenylphosphine ligands by a diphosphine chelating ligand leads to an increase on the S1–C1–S2 angle, and a decrease on the P–Ni–P angle and on the P–Ni bond length.

Abstract

Two new half sandwich ruthenium complexes with 2-*N*-phenylamino-4-*N*-phenylimino-2-pentene (Ph_2nacnac) ligands have been synthesized and characterized. Single crystal X-ray diffraction analysis reveals the monomeric, highly air sensitive complex $Cp^*Ru(Ph_2nacnac)$ (**4**) has a coordinatively unsaturated structure and the coordination environment around Ru(II) is effectively a triangle made up of Ct(Cp^*)–N(1)–N(2). An air stable complex $Cp^*Ru(Ph_2nacnac)(CO)$ (**5**) is prepared by reaction of **4** with CO, and has a *pseudo*-tetrahedral geometry around the Ru(II) center, made up of Ct(Cp^*)–N(1)–N(2)–C(28).

1. Introduction

Half sandwich ruthenium complexes are of considerable interest to coordination chemists since they have been widely used in organometallic synthesis and enantioselective catalysis [1–3]. Clearly it is important to understand any correlations between structure and reactivity of these compounds in order to better understand their behavior as structural templates and catalysts. Coordinatively unsaturated ruthenium complexes of general formula $RuCp^*(X)(PR_3)$ have been obtained previously using bulky phosphine ligands (R = cyclohexyl, *iso*-propyl) [4,5], and analogues of general formula $RuCp(L)^+$ (L = bulky chelating diimine) have also been reported [6–8]. To the best of our knowledge, there are few precedents for neutral, coordinatively unsaturated half sandwich ruthenium complexes stabilized by chelating ligands. One example, **1** reported by Kölle, contains a chiral ligand methyl(bis-5-methyl-tetrahydrooxazol) ligand, but was only characterized by NMR spectroscopy [9]. Yamaguchi et al. reported Cp^*Ru-(amidinate) (**2**) as the first example in which amidinate ligands play an important role in effectively stabilizing a coordinatively unsaturated metal center [10]. An example with a less bulky chelate $Cp^*Ru(acac)$ (**3**), initially reported as a neutral unsaturated monomer [11], was subsequently shown to be a dimer [12].

1 **2** **3**

In recent years, transition metal complexes with β-diketiminate (nacnac) ligands have been the subject of considerable interest [13–18]. Here, we report on a brief

investigation on the synthesis, characterization, and the crystal structure analysis of two half sandwich ruthenium complexes with the "Ph_2nacnac" ligand.

2. Experimental

2.1. General

Air-sensitive reactions were performed in oven-dried glassware, using standard SCHLENK techniques, under an atmosphere of nitrogen, which was deoxygenated over BASF catalyst and dried over Aquasorb, or in a Braun dry-box. Methylene chloride and hexane were dried over an alumina column under nitrogen [19]. Methanol was distilled from Linde type 4 Å molecular sieves. NMR spectra were recorded on a Varian Unity Plus 300 or 500 FT spectrometer. ^{1}H NMR spectra were referenced to the protio impurity in the solvent: C_6D_6 δ (7.16 ppm), CD_2Cl_2 δ (5.32 ppm). Coupling constants are reported as absolute values in units of Hertz. IR spectra were recorded on a Perkin–Elmer FTIR 1600 Series spectrophotometer. Elemental analyses were performed by Schwartzkopf (Woodside, NY).

$RuCl_3 \cdot 3H_2O$ (Johnson Matthey Ltd.) and pentamethylcyclopentadiene (Cp^*H) (Acros) were used without further purification. $[Cp^*RuCl_2]_2$ [20] and Ph_2nacnac [21] were prepared according to published methods.

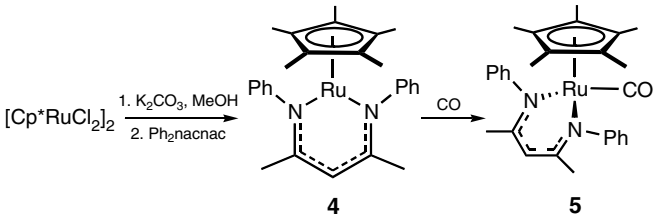
2.1.1. Synthesis of $Cp^*Ru(Ph_2nacnac)$ (4)

$[Cp^*RuCl_2]_2$ (50 mg, 0.17 mmol) and dry K_2CO_3 (150 mg, 1.15 mmol) were suspended in dry N_2 saturated MeOH (10 mL) and allowed to stir for 6 h to give an intensely red solution with some solid. Ph_2nacnac (41 mg, 0.17 mmol) was added to the solution, which was allowed to react for a half hour to give a red solution. The solvent was removed *in vacuo* to give a dark red solid, which was extracted with hexane (50 mL) and filtered. The solvent was removed from the filtrate to give the product as a dark red solid; 50 mg, 81%. Recrystallization by slow evaporation from hexane gave dark red crystals suitable for X-ray diffraction. *Anal.* Calc. for $C_{27}H_{32}N_2Ru$: C, 66.77; H, 6.64; N, 5.77. Found: C, 66.39; H, 6.94; N, 5.78%. ^{1}H NMR (C_6D_6, 300 MHz, 25 °C) δ 1.08 (15H, s, $C_5(CH_3)_5$); 1.90 (6H, s, CH_3); 5.39 (1H, s, HC); 7.00–7.26 (10H, m, H-Ph).

2.1.2. Synthesis of $Cp^*Ru(Ph_2nacnac)(CO)$ (5)

$Cp^*Ru(Ph_2nacnac)$ (23 mg, 0.047 mmol) was dissolved in hexane (10 mL) to give a red solution. CO (1.0 mL, 0.047 mmol) was added by syringe. The color lightened. CO (3 mL/time × 17 times) was added by syringe and the solution was allowed to react overnight to give a brown yellow solution. The solvent was removed *in vacuo* to give the adduct as yellow solid, with a little brown red tint; 24 mg, 99%. Recrystallization by slow evaporation from hexane gave yellow crystals suitable for X-ray diffraction. *Anal.* Calc. For $C_{28}H_{32}N_2ORu$: C, 65.47; H, 6.28; N, 5.46. Found: C, 65.82; H, 6.81; N, 5.46%. ^{1}H NMR (CD_2Cl_2, 300 MHz, 25 °C) δ 1.23 (1;H, s, $C_5(CH_3)_5$); 1.72 (6H, s, CH_3); 4.50 (1H, s, HC); 6.97 (2H, t, $^3J_{HH} = 7.5$ Hz, *p*-H-Ph); 7.05 (4H, d, $^3J_{HH} = 8.7$ Hz, *o*-H-Ph); 7.26 (4H, t, $^3J_{HH} = 7.5$ Hz, *m*-H-Ph). IR (hexane, cm^{-1}): υ_{CO} 1910 (vs).

2.1.3. X-ray crystallography



Crystal data and other parameters for complexes **4** and **5** are given in Table 1. Intensity data were collected at 213(2) K, on Bruker Smart CCD diffractometers using graphite-monochromated Mo Kα radiation (k = 0.71073 Å). Of the 17,362 and 7558 reflections that were collected, 5488 ($R_{int} = 0.0413$) and 4186 ($R_{int} = 0.0249$) were unique for complexes **4** and **5**, respectively. Empirical absorption corrections were employed. The structures were solved by direct methods. The final refinement was done by full-matrix least squares based on F^2 with anisotropic thermal parameters for all non-hydrogen atoms, and the hydrogen atoms were generated geometrically.

3. Results and discussion

Complex **4** was obtained via two steps in a one pot reaction with an overall yield of 81%. $[Cp^*RuCl_2]_2$ was stirred with K_2CO_3 in MeOH to give $[Cp^*Ru(OMe)]_2$, which reacted with the Ph_2nacnac ligand to give **4** as a red air-sensitive solid. Reaction of **4** with CO in hexane afforded **5** as a yellow solid in high yield as shown in Scheme 1. This yellow complex is moderately stable in air, unlike its acac analogue [11]. The CO stretching frequency in the IR of **5** is at 1910 cm^{-1} in hexane, while that for the acac analogue $Cp^*Ru(acac)(CO)$ is 1915 cm^{-1} (KBr) [11]. There

Scheme 1.

was no reaction when complex **4** was treated with H_2 or ethylene.

The principal structural features of complex **4** are given in Fig. 1, while crystallographic data are summarized in Table 1 and selected bond lengths and angles appear in Table 2. In this complex, the plane of the nacnac ligand (N(2)–Ru(1)–N(1)) is perpendicular to the Cp^* plane, which differs from the dimeric acac analogue **3**, in which the ligand plane is tilted with respect to the Ru–Cp^* by 37.5° [11]. The angle involving the metal center and the bis(ketenimine) ligand deviates significantly from 90°, N(1)–Ru(1)–N(2) = 87.70(9)° and the bond distances Ru(1)–N(1) and Ru(1)–N(2) are 2.053(2) and 2.046(2) Å, respectively. The distance between Ru(1) and the center of the Cp^* ring is 1.800 Å. The five atoms in the bis(ketenimine) ligand and Ru(1) are coplanar. For example, the biggest deviation of C(11) to the least square plane (Ru(1)–N(2)–C(13)–C(12)–C(11)–N(1)) is 0.009 Å. The two C–C distances of 1.388(4) and 1.397(4) Å and the two C–N distances of 1.341(3) and 1.349(4) Å suggest significant delocalization within the π-system of the nacnac ligand. There are no intermolecular interactions in the solid state, consistent with the observation that the red color of **4** observed in the solid state is maintained in hexane solution.

During preparation of this manuscript, two similar complexes were reported. In nickel analogue **6**, reported by Bai et al. [22] the Ni–N distances were found to be 1.937(3) and 1.948(3) Å with a N–Ni–N angle of 94.19(11)°. The angle between the plane of the cyclopentadienyl ligand and NiN_2 plane was 90.8°. When **6** was treated with $[PhMe_2NH][B(C_6F_5)_4]$ a cationic complex **7** was formed by protonation at the CH carbon of the nacnac ligand (Scheme 2). In that structure, the Ni–N distances were found to be 1.928(3) and 1.942(3) Å, a little longer than those reported for **6**, consistent with the poorer donor ability of the protonated nacnac ligand. However, the N–Ni–N bite angle in **7** is 95.50(12)°, similar to that in **6**. Similarly,

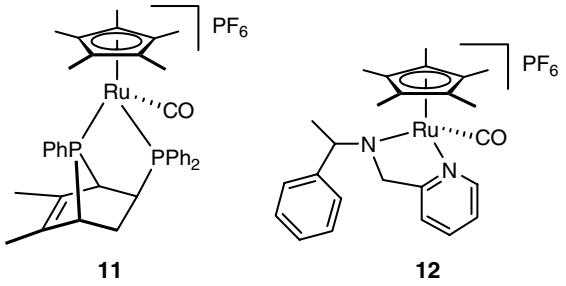

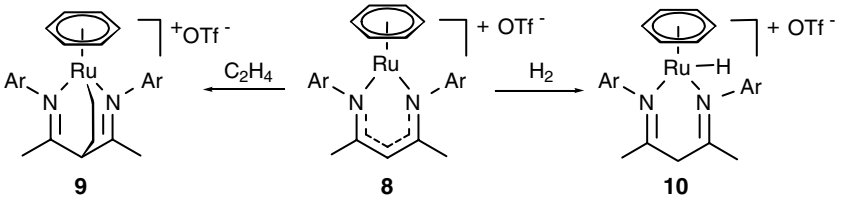

Scheme 2.

the angle between the NiN_2 and Cp^* planes in **7** is 90.5° (see Scheme 3).

A similar 16-electron Ru cationic complex **8** was reported by Phillips et al. [23] The Ru–N bond distances are 1.997(5) and 1.994(5) Å, shorter than those in **4** (2.053(2) and 2.046(2) Å), and the arene centroid to Ru distance is 1.670 Å, also shorter than the Cp^*–Ru distance in **4** (1.800 Å). These differences can perhaps be attributed to the effect of the cationic Ru atom in **8**. The bite angle N–Ru–N is 88.5(2)°, similar to that of **4**. Though neutral complex **4** has no reaction with H_2 and ethylene, **8** can react with H_2 and ethylene in THF to give **9** and **10**, respectively by incorporation of the CH carbon of the nacnac ligand in the reaction chemistry.

In contrast to the lack of reactivity of **4** towards H_2 or ethylene, reaction with CO occurred cleanly to afford adduct **5**, the principal structural features of which are given in Fig. 2. Crystallographic data are summarized in Table 1, and selected bond lengths and angles appear in Table 2. The coordination environment around Ru(1) is *pseudo*-tetrahedral. The angle involving the metal center and the bis(ketenimine) ligand deviates from 90° (N(1)–Ru(1)–N(2) = 88.30(7)°) with bond distances Ru(1)–N(1) and Ru(1)–N(2) of 2.1363(19) and 2.1309(19) Å, respectively. The distance between Ru(1) and the center of the Cp^* ring is 1.885 Å. In this complex, the least squares plane of the nacnac ligand and Ru(1) (Ru(1)–N(2)–C(7)–C(9)–C(10)–N(1)) is tilted toward the Cp^* plane with an interplanar angle of 45.6°. There is still significant delocalization within the π-system of the nacnac ligand, suggested by the two similar C–C distances of 1.399(2) and 1.403(3) Å and the two similar C–N distances of 1.331(3) and 1.325(3) Å. The Ru–nacnac ring itself is, however, less planar than that in **4**, with the largest deviation from the least squares plane of (Ru(1)–N(2)–C(7)–C(9)–C(10)–N(1)) being the Ru atom, which is displaced from the plane by 0.100 Å. The Ru–carbonyl bond distance Ru(1)–C(28) (1.837(2) Å) is shorter than those in two cationic analogues, **11** (1.865(8) Å) [24], and **12**, 1.880(3) Å [25]. The Ru–C(O) bond distance in the analogue Cp^*Ru(amidinate)(CO) is 1.828(7) Å [10] that is identical within experimental error to that of **5**.

Scheme 3.

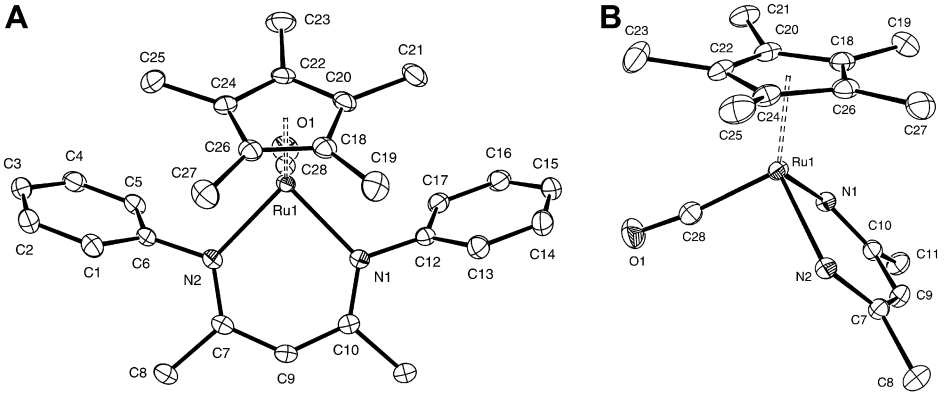

Fig. 2. ORTEP diagram of complex **5** showing atom numbering scheme. (A) Full view; (B) side view (2 Ph groups omitted for clarity).

4. Conclusions

It is evident that the Ru–nacnac complex **4** is disappointingly unreactive with small molecules, unlike some of its cationic analogues. This likely due to decreased Lewis acidity of the metal center in a neutral complex, coupled with the steric effects of the phenyl groups on the α-*N*-atoms.

Received 31 August 2007; accepted 2 November 2007

Abstract

It was established that the reactions of pyrazol-3-yl-substituted nitronyl nitroxide ($\mathbf{HL}^1$) and pyrazol-3-yl-substituted imino nitroxide ($\mathbf{HL}^3$) with Cu(II) acetate lead to self-assembly of the $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ tetranuclear and $Cu_2(OAc)_2(H_2O)_2(L^3)_2$ dinuclear complexes, respectively. The reaction of Cu(II) acetate with 5-ethoxycarbonyl-pyrazol-3-yl-substituted nitronyl nitroxide ($\mathbf{HL}^2$) gave unexpected solid $Cu_2(H_2O)_2(L^6)_2 \cdot 2DMF$, in which $\mathbf{L}^6$ is a deprotonated 5-carboxy-pyrazol-3-yl-substituted nitronyl nitroxide, formed as a result of cleavage of an ester bond in the starting $\mathbf{HL}^2$. A similar transformation of the paramagnetic ligand was observed in the reaction of Cu(II) acetate with 5-ethoxycarbonyl-pyrazol-3-yl-substituted imino nitroxide ($\mathbf{HL}^4$). It led to the formation of $Cu_2(DMF)_2(L^7)_2$, where $\mathbf{L}^7$ is deprotonated 2-(5-carboxy-1*H*-pyrazol-3-yl)-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazole 3-oxide. An X-ray diffraction study indicated that in $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ and $Cu_2(OAc)_2(H_2O)_2(L^3)_2$, the $\mathbf{L}^1$ and $\mathbf{L}^3$ paramagnetic ligands perform the bridging cyclic tridentate function, while in $Cu_2(H_2O)_2(L^6)_2 \cdot 2DMF$ and $Cu_2(DMF)_2(L^7)_2$, the paramagnetic $\mathbf{L}^6$ and diamagnetic $\mathbf{L}^7$ are bridging bicyclic tetradentate ligands. The magnetic behavior of complexes with coordinated nitronyl nitroxide – $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ and $Cu_2(H_2O)_2(L^6)_2 \cdot 2DMF$ is dictated by the dominant antiferromagnetic exchange interactions, which is confirmed by quantum-chemical data. The magnetic susceptibility of $Cu_2(OAc)_2(H_2O)_2(L^3)_2$ reflects the competition between the antiferromagnetic and ferromagnetic components, of which the latter is due to electron coupling in the Cu(II) ← N=C–N ÷ O exchange channels. EPR data confirm the results received from static magnetic measurements for multi-spin solids.

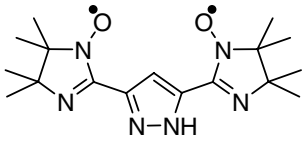
Keywords: Nitronyl nitroxides; Imino nitroxides; Pyrazoles; Copper complexes



1. Introduction

Pyrazolyl-substituted nitronyl (NN-Pz) and imino nitroxides (IN-Pz) are of particular interest as stable paramagnetic ligands useful in the design of magnetic structures, which stimulates the development of methods for their selective synthesis. A wide range of spin-labeled pyrazoles are now accessible [1], with which mixed-ligand complexes of hexafluoroacetylacetonates [1a,2] and polynuclear metal pivalates [3] have been obtained. At the same time, there are few examples of chelate compounds with deprotonated spin-labeled derivatives NN-Pz and IN-Pz and include only two silver complexes: $[Ag(\mathbf{L}^3)]_6$ and $[Ag(\mathbf{L}^5)]_n$ [1d] and two nickel complexes: $[Ni_3(\mathbf{L}^1)_6]$ and $[Ni_3(\mathbf{L}^3)_6]$ [4]. We have attempted to expand this series of complexes by adding to them Cu(II) compounds with $\mathbf{HL}^1$, $\mathbf{HL}^2$, $\mathbf{HL}^3$, and $\mathbf{HL}^4$. Indeed, we have succeeded in isolating new complexes with spin-labeled pyrazoles and defined their structure. The magnetic properties of these compounds were analyzed using DFT calculations. It has been found that the copper ions are capable of promoting unusual transformations of the paramagnetic ligand.

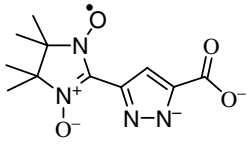
2. Experimental

2.1. Materials and methods

IR spectra were recorded in the 400–4000 cm^{-1} region on a VECTOR 22 Bruker spectrophotometer (KBr pellets). Microanalyses were performed on a Carlo Erba 1106 instrument. The nitroxides **HL**[1], **HL**[2], **HL**[3], and **HL**[4] were prepared by the procedures described in the literature [1e]. All reagents and organic solvents were analytical quality and used as purchased.



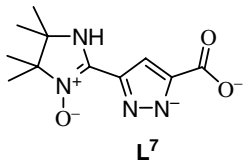
2.2. Syntheses of the complexes

2.2.1. $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ (1)

A solution of $Cu(OAc)_2 \cdot H_2O$ (180 mg, 0.9 mmol) in water (1.5 ml) was added to a solution of nitronyl nitroxides **HL**[1] (100 mg, 0.45 mmol) in a mixture of water (1.5 ml) and MeOH (1.5 ml). The resulting solution was kept for 12 h, whereupon the solvent was distilled off in vacuum at room temperature. The residue was dissolved in a minimal amount of DMF (~4 ml). The solution was filtered into a conical flask, which was then connected via a U-tube with a flask containing Et_2O (20 ml). Single crystals of good quality were grown due to gradual dilution of the DMF solution of the complex with diethyl ether that took place under these conditions. After 7 days, the greenish blue crystals were separated by filtration and washed with ether. Yield 200 mg (80%). IR: $\tilde{\nu}_{max} = 415, 485, 546, 614, 672, 699, 790, 872, 972, 1020, 1080, 1103, 1136, 1171, 1211, 1252, 1328, 1382, 1428, 1477, 1576, 1613, 1667, 2928, 2998, 3129, 3436$ cm^{-1}. Elemental *Anal.* Calc. for $C_{34}H_{56}Cu_4N_{10}O_{16}$: C, 36.6; H, 5.1; N, 12.6. Found: C, 36.8; H, 5.3; N, 12.4%. Compound **1** also formed in ~80% yield when the reaction of $Cu(OAc)_2 \cdot H_2O$ (180 mg, 0.9 mmol) with **HL**[1] (100 mg, 0.45 mmol) was conducted in DMF.

2.2.2. $Cu_2(H_2O)_2(L^6)_2 \cdot 2DMF$ (2)

A solution of $Cu(OAc)_2 \cdot H_2O$ (130 mg, 0.66 mmol) in water (2 ml) was added to a solution of nitronyl nitroxide **HL**[2] (100 mg, 0.33 mmol) in MeOH (3 ml). The resulting solution was stored for 12 h; then the solvent was distilled off in vacuum at room temperature. The residue was crystallized as described for **1**. Compound **2** was obtained as greenish blue crystals suitable for an X-ray analysis. Yield 110 mg (77%). IR: $\tilde{\nu}_{max} = 481, 548, 607, 662, 798, 848, 875, 1026, 1074, 1101, 1138, 1170, 1298, 1324, 1351, 1379, 1403, 1467, 1510, 1627, 1666, 2993, 3393$ cm^{-1}. Elemental *Anal.* Calc. for $C_{28}H_{44}Cu_2N_{10}O_{12}$: C, 40.1; H, 5.3; N, 16.7. Found: C, 39.9; H, 5.3; N, 16.7%. When conducted in DMF, the reaction also gave compound **2** in ~85% yield.



L[6]

2.2.3. $Cu_2(OAc)_2(H_2O)_2(L^3)_2$ (3)

A solution of $Cu(OAc)_2 \cdot H_2O$ (80 mg, 0.39 mmol) in water (1.5 ml) was added to a solution of imino nitroxides **HL**[3] (80 mg, 0.39 mmol) in a mixture of water (1.5 ml), MeOH (1 ml), and EtOH (1.5 ml). The resulting solution was stored for 12 h; then the solvent was distilled off in vacuum at room temperature. The residue was processed as described for **1**. Complex **3** was obtained as dark green crystals suitable for an X-ray analysis. Yield 40 mg (30%). IR: $\tilde{\nu}_{max} = 422, 468, 567, 611, 633, 684, 723, 795, 891, 935, 968, 1020, 1077, 1137, 1188, 1260, 1340, 1369, 1400, 1482, 1593, 1676, 2928, 2972, 3248, 3454$ cm^{-1}. Elemental *Anal.* Calc. for $C_{24}H_{40}Cu_2N_8O_8$: C, 41.4; H, 5.8; N, 16.1. Found: C, 41.6; H, 5.7; N, 16.1%.

2.2.4. $Cu_2(DMF)_2(L^7)_2$ (4)

A solution of $Cu(OAc)_2 \cdot H_2O$ (131 mg, 0.72 mmol) in water (2 ml) was added to a solution of imino nitroxides **HL**[4] (100 mg, 0.36 mmol) in MeOH (1 ml); this immediately resulted in the formation of a brown fine precipitate. Then MeOH (2 ml) was added until the precipitate dissolved. The resulting solution was kept for 15 min; then the solvent was distilled off in vacuum at room temperature. The residue was treated as described for **1**. After 2 days, the solution became greenish blue, and green needles gradually crystallized. After 5 days, the crystals were separated by filtration and washed with ether. Yield 50 mg (36%). IR: $\tilde{\nu}_{max} = 480, 570, 607, 714, 774, 800, 858, 898, 1026, 1074, 1113, 1142, 1202, 1246, 1331, 1348, 1391, 1447, 1544, 1625, 2812, 2885, 2990, 3199, 3454$ cm^{-1}. Elemental *Anal.* Calc. for $C_{28}H_{42}Cu_2N_{10}O_8$: C, 43.5; H, 5.5; N, 18.1. Found: C, 42.5; H, 5.6; N, 16.8%.

2.3. X-ray measurement and structure determination

Diffraction reflections were obtained on a SMART APEX CCD (Bruker AXS) diffractometer (Mo Kα, $\lambda = 0.71073$ Å, $T = 295$ K; an absorption correction was applied using the Bruker SADABS program, version 2.10). The structures were solved by direct methods and refined by the full-matrix least-squares method in an anisotropic approximation for all non-hydrogen atoms. Some of the H atoms were located in a difference electron density map, while others were located at calculated positions. The methyl H atoms were refined as a rigid group in an isotropic approximation. All calculations on structure solution and refinement were carried out with a Bruker SHELXTL Version 6.14 program complex. The crystal data for the complexes, details of experiment, and selected bond lengths and angles are given in Tables 1 and 2.

2.4. Magnetic measurements

The magnetic susceptibility of the polycrystalline complexes was measured with a Quantum Design MPMS-5S SQUID magnetometer in the temperature range 2–300 K with magnetic fields of up to 5 kOe. None of the complexes exhibited any field dependence of molar susceptibility at low temperatures. Diamagnetic corrections were made using the Pascal constants. The effective magnetic moment was calculated as $\mu_{\text{eff}}(T) = [(3k/N_A\mu_B{}^2)\ \chi'_M T]^{1/2}$, where χ'_M is corrected molar susceptibility.

2.5. EPR measurements

The experiments have been carried out at commercial X-band (9 GHz) continuous wave EPR spectrometer (Bruker EMX) equipped with the homemade cryogenic system. For all studied compounds (**1**–**4**) the powder CW EPR spectra have been recorded within a temperature range 20–300 K in a standard way and then analyzed.

2.6. Computational details

All DFT calculations reported in this paper were performed with the ORCA program package [5]. The exchange correlation was treated in Perdew–Burke–Ernzerhof's (PBE) generalized gradient approximation [6]. An accurate all-electron Gaussian basis set of triple-zeta quality with two sets of polarization functions Wachters + f = (14s11p6d3f)/ [8s6p4d2f] [7] was used for the copper atom. All other (carbon, nitrogen, and hydrogen) atoms were described using the polarized 6-31G(d) basis set [8] of double-zeta quality.

Since our quantum-chemical study aimed at the interpretation of the experimentally observed magnetic properties that were obtained for polycrystalline samples, it dictated the use of X-ray data for electronic structure investigations of the complexes without further geometry optimization.

Molecular orbitals and spin density distributions were plotted using the MOLEKEL program [9]. The broken symmetry (BS) approach [10] was employed to elucidate the magnetic properties of multispin systems under study. The exchange coupling constants were calculated by the generalized spin projection method suggested by Yamaguchi et al. [11].

3. Results and discussion

3.1. Syntheses and structures of the complexes

Interaction of Cu(II) acetate with $\mathbf{HL}^1$ forms a heterospin complex, which crystallizes into perfect single crystals after the DMF solution of the complex has been gradually saturated with diethyl ether. The compound is formed at any ratio of the starting reagents. The optimal ratio, $Cu_2(OAc)_4(H_2O)_2/\mathbf{HL}^1 = 2/1$, leads to at least 80% yield of the product. The yield is drastically reduced when the initial reagent ratio is decreased under the same conditions; for example, the product yield is less than 8% when the ratio is 1/1. An X-ray diffraction study showed that the compound is a tetranuclear complex $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ (**1**).

The complex has a centrosymmetric molecule (Fig. 1). The square environment of Cu1, formed by the N3 atom of the pyrazole fragment and by the O atoms of the >N–O and OH groups and bridging bidentate acetate anion, is completed to the elongated bipyramid by the O_{OAc} and O_{DMF} atoms. The O_{OH} atom lies at the apex of the Cu2 square pyramid, while the N4 and O_{OH} atoms and two O_{OAc} atoms lie at its base. The paramagnetic ligand performs the cyclic tridentate bridging function, connecting the two Cu atoms. The planes of the pyrazole ring and the CN_2 fragment of the imidazole ring are

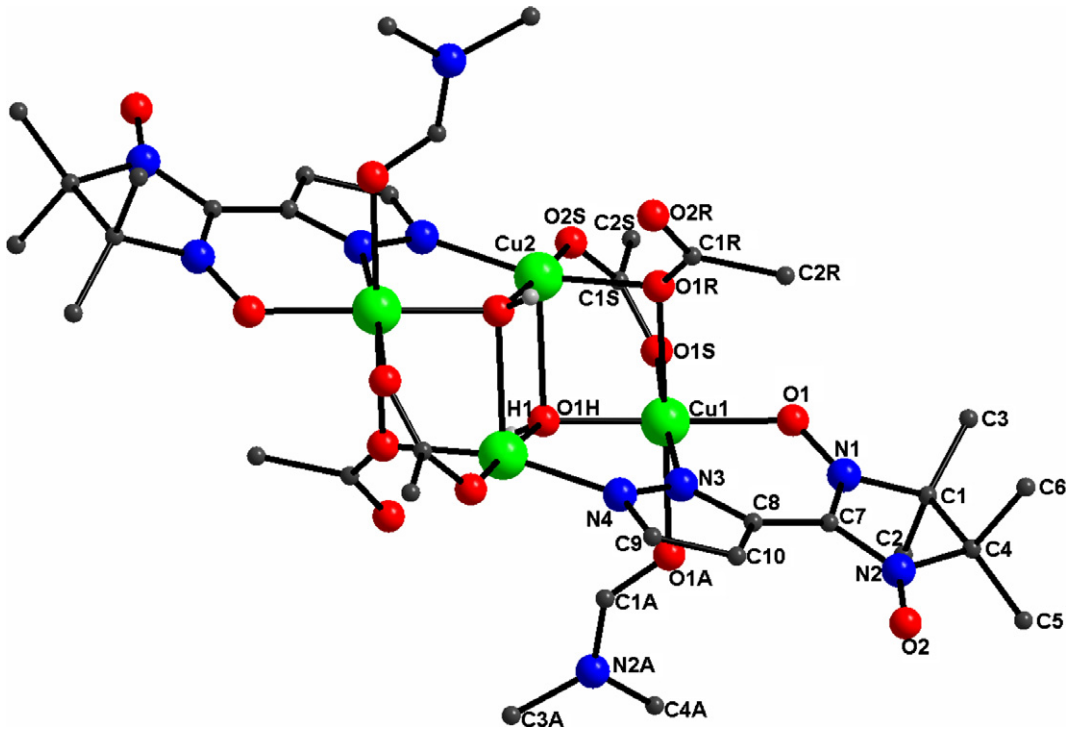

Fig. 1. Structure of molecule **1**.

non-coplanar ($\angle CN_2$-Pz, Table 2). The OH group is coordinated simultaneously by three Cu atoms. The O_{OH} atom lies in the $\{HCu_3\}$ trigonal pyramid. One of the two AcO^- anions is coordinated as a monodentate ligand, while the other, as (μ_2-O,O′), which affects the C–O bond lengths. In the first ligand, these bond lengths are appreciably different (1.272(5) and 1.221(5) Å), while in the second, they are almost the same (1.255(4) and 1.260(4) Å). The N–O distances in the paramagnetic $\mathbf{L}^1$ ligand are non-equivalent: 1.301(4) for the coordinated

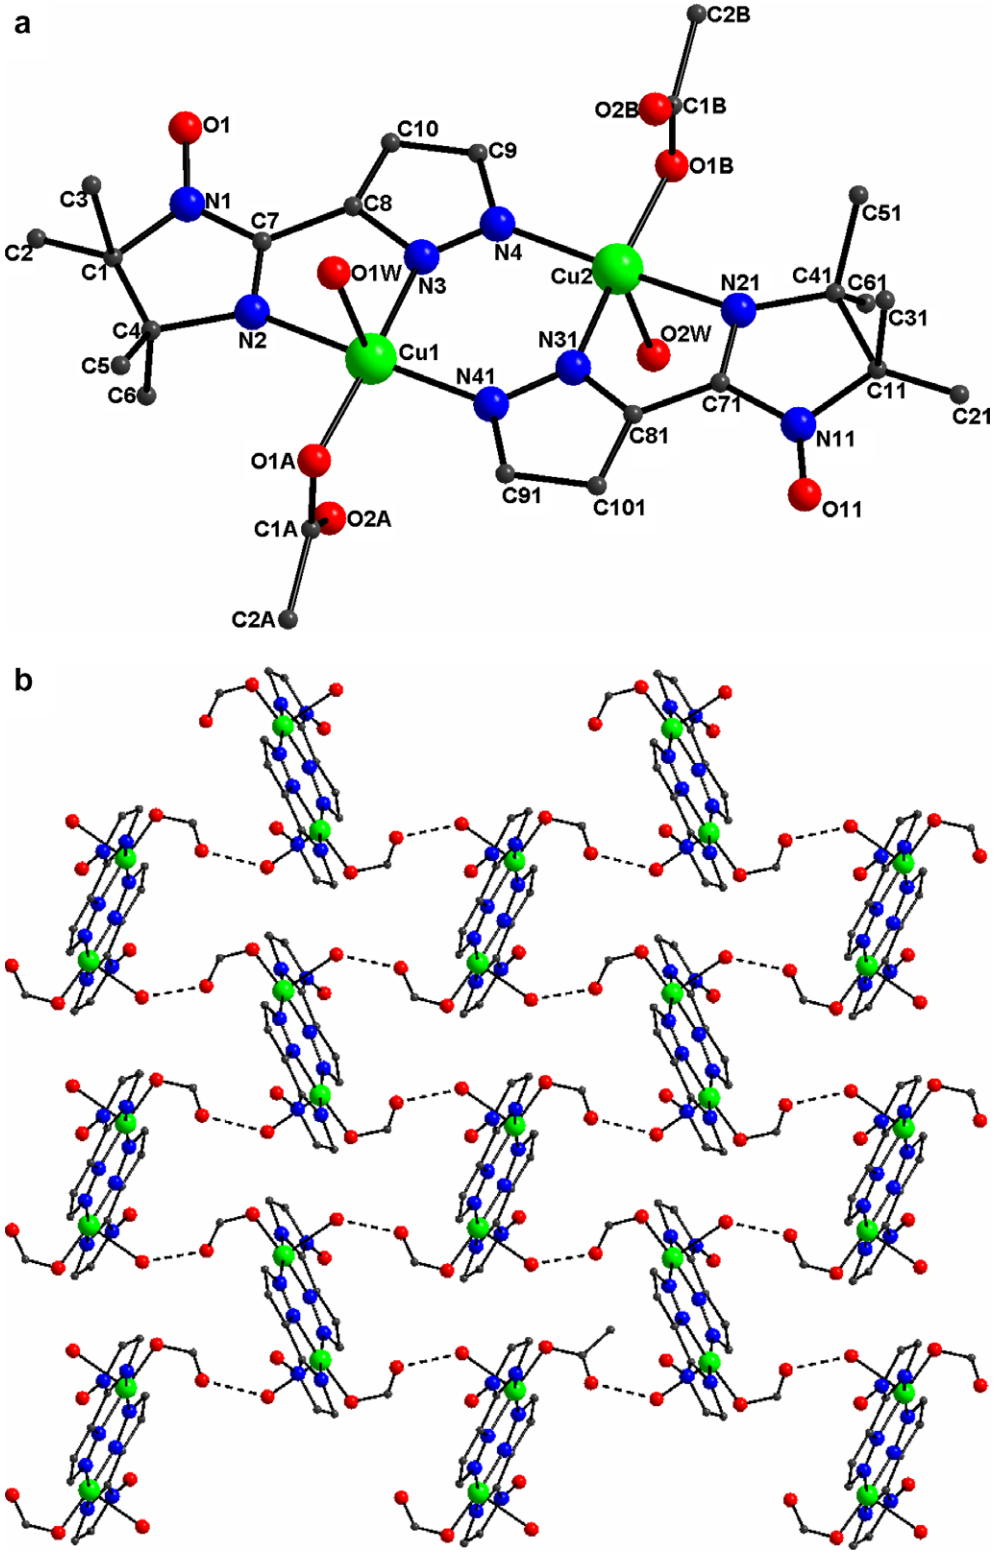

Fig. 2. Structure of the molecule (a) and layer (b, Me groups and H atoms omitted for clarity) in **2**.

NO group versus 1.267(4) Å for the uncoordinated group.

Structure analysis of complex **2**, formed by interaction of Cu(II) acetate with $\mathbf{HL}^3$ (an imine analog of $\mathbf{HL}^1$), showed that this is a dinuclear complex (Fig. 2a). The radical retains its cyclic tridentate bridging function on passing from nitronyl nitroxides to imino nitroxide. In molecule **2**, each of the two Cu atoms is surrounded by a square pyramid with the O atom of the water molecule at the apex. The base of the pyramid is formed by three N atoms of the paramagnetic ligands and the O atom of the acetate anion. The uncoordinated O atoms of the acetate anions form H-bonds with the coordinated water molecules of the neighboring chelates, which leads to the formation of layers in structure **2** (Fig. 2b).

The coordination mode of $\mathbf{L}^3$ was quite predictable; according to the data of the Cambridge Structural Database, this is just the way 3-(2-pyridyl)pyrazole is coordinated to Cu(II) [12,13] to give various products including dinuclear complexes [14]. For $\mathbf{L}^1$, however, the coordination mode cannot be compared with the available data because the database has no structural information for Cu(II) complexes with ligands containing a combination of donor functional groups similar to $\mathbf{L}^1$ [15]. Therefore, one can only assume that the size of the chelate ring that increased from **2** to **1**, as well as the lower donor ability of the O atom of the nitroxyl fragment compared to the imine N atom, enhance dissociation of coordinated water, provoking the condensation of two dinuclear fragments into a tetranuclear fragment in **1** via two μ_3-OH groups.

Based on the data obtained it might be assumed that similar complexes would also be produced from the ester derivatives $\mathbf{HL}^2$ and $\mathbf{HL}^4$. However, the reaction of Cu(II) acetate with $\mathbf{HL}^2$ under conditions similar to the conditions of synthesis of **1** gave the $[CuL^6(H_2O)]_2 \cdot 2DMF$ complex (**3**) as a solid product in a high yield, in which $\mathbf{L}^6$ is the

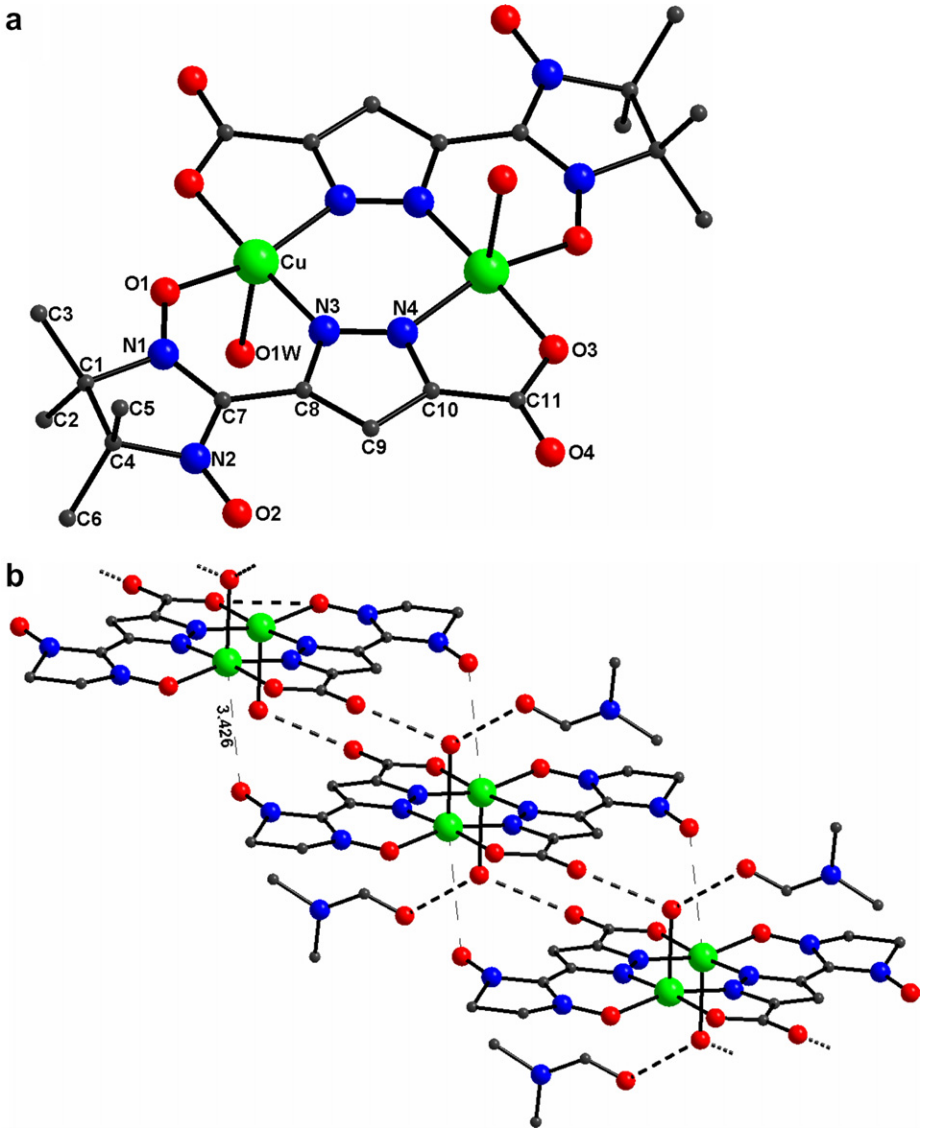

Fig. 3. Structure of the molecule (a) and ribbon (b) in **3**.

product of transformation of the starting nitronyl nitroxide. The complex is the major reaction product that may be reproduced at any starting ratio of reagents. As indicated by the results of X-ray diffraction investigation of **3**, transformation of $\mathbf{L}^2$ into $\mathbf{L}^6$ occurs without affecting the free valence. The structure of the dinuclear compound **3** (Fig. 3a) suggests that the reaction is a cascade process involving the splitting of the O–Et bond in the ester group of $\mathbf{HL}^2$ and further formation of a five-membered metallocycle due to coordination of the O atom of the deprotonated carboxyl group and the N atom of the pyrazole fragment. The structure of the six-membered chelate fragment in **3** is similar to that in **1**. As a result, the $\mathbf{L}^6$ dianion in the dinuclear compound **3** performs the bridging bicyclic tetradentate function.

In the centrosymmetric molecule **3**, the square environment of each Cu atom is completed to pyramidal by the O atoms of the water molecule Å (Fig. 3a), flanking the sides of the chelate plane. The water molecules of the two chelates, in turn, form a couple of contradirectional intermolecular H-bonds with the carboxyl O atoms. This leads to the formation of polymer ribbons in the solid state with short contacts (3.426(4) Å) between the Cu atoms and the N–O groups of the neighboring chelates arising within

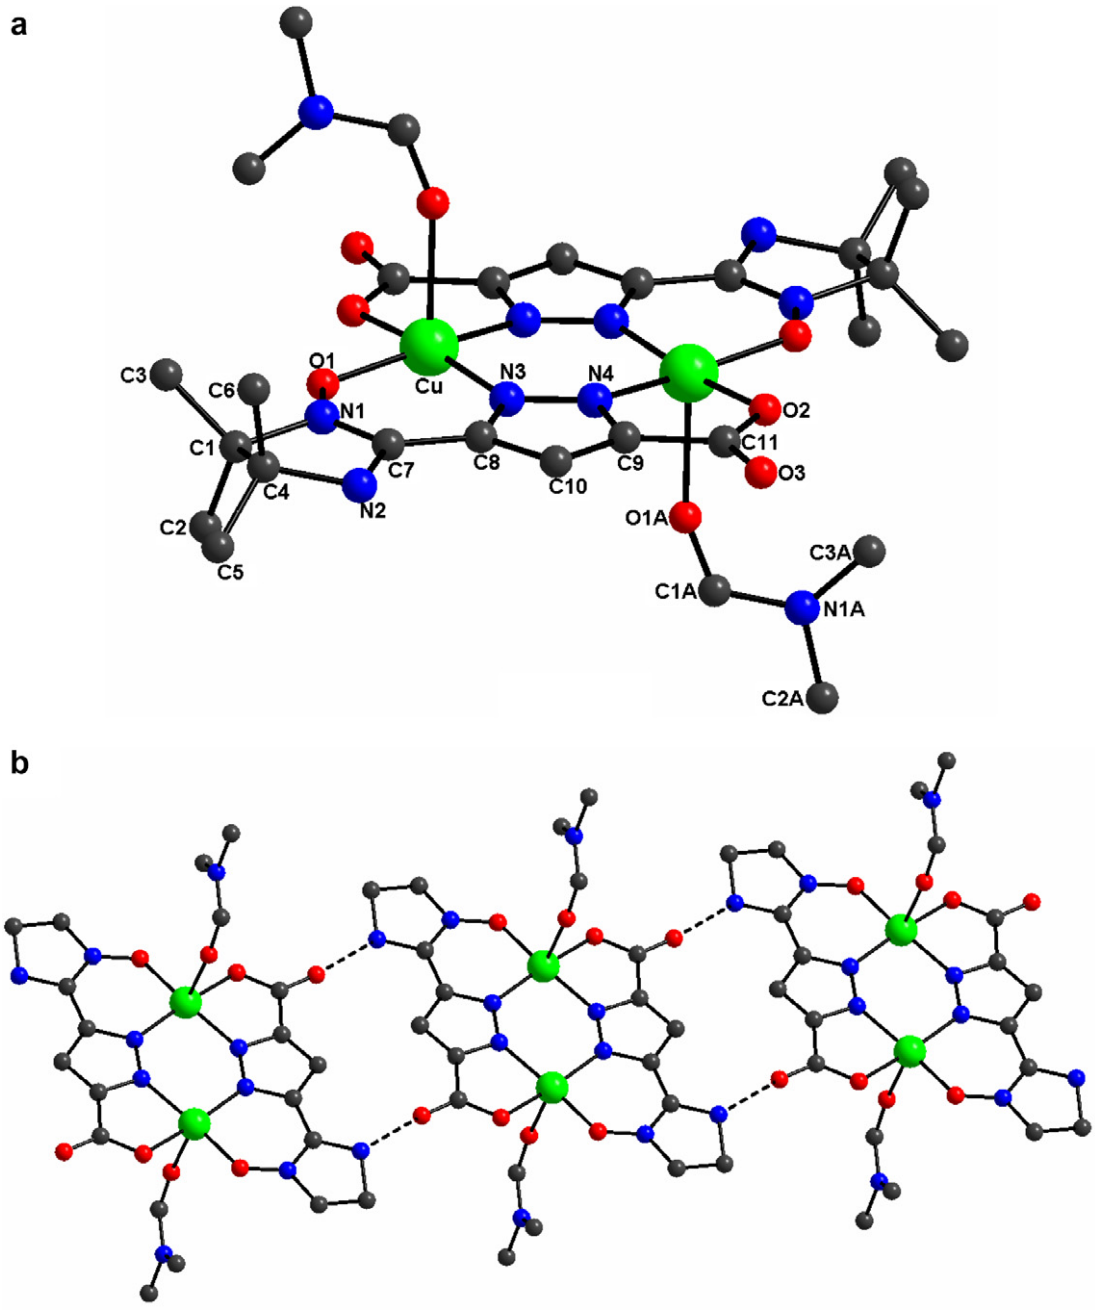

Fig. 4. Structure of the molecule (a) and ribbon (b) in **4**.

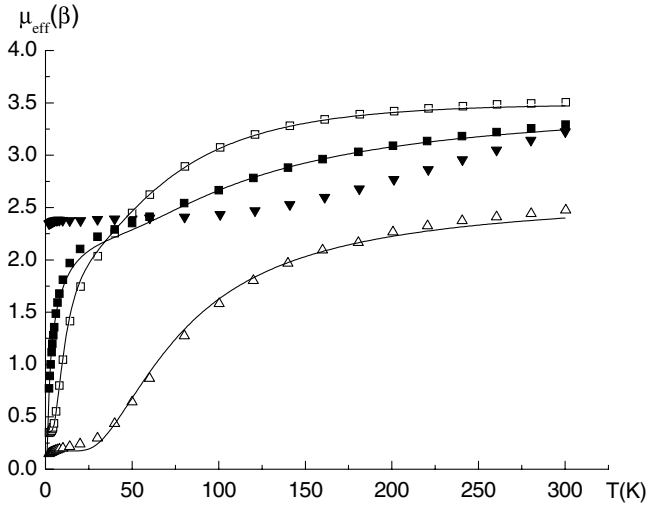
the ribbons. The DMF molecules H-bonded with the water molecules lie on the "periphery" of the ribbons (Fig. 3b).

The interaction of the ester derivative of imino nitroxide **HL**[4] with Cu(II) acetate confirmed that a cascade process is the general tendency for the given compounds. The reaction occurred with deprotonation of **HL**[4], cleavage of the C–O ester bond, and reduction of the imino nitroxide fragment to the oxoamidine fragment. The reaction ultimately formed the $Cu_2(DMF)_2(L^7)_2$ complex (**4**) whose structure is similar to that of $Cu_2(H_2O)_2(L^6)_2 \cdot 2DMF$ except that the axial position in the square pyramidal environment of each copper atom is occupied by the O atoms of the DMF molecule (Fig. 4a). In structure **4**, as well as in structure **3**, polymer ribbons are formed, but here they are formed in a different way – via the O···H–N bonds between the uncoordinated O atoms of the carboxyl groups and the NH groups of the neighboring molecules.

3.2. Magnetic properties of the compounds

The temperature dependences of the effective magnetic moment (μ_{eff}) for complexes **1**–**4** are presented in Fig. 5.

It is reasonable to start this section by discussing the magnetic behavior of compound **4**. This will enable us to evaluate the efficiency of the pyrazolate bridges in exchange interactions between the odd electrons of the Cu(II) ions, which are also present in more complex exchange clusters in **1**–**3**. For complex **4**, the high-temperature value of the magnetic moment is about 2.50 β, which is close to the value expected for the non-interacting spins of two copper(II) atoms (spin-only value is 2.45 β). The reduced magnetic moment at lower temperatures points to the antiferromagnetic exchange interactions. To evaluate the optimal parameters for **4** (J_{CuCu}, g_{Cu}) we employed the exchange-coupled dimer model [16]. The resulting parameters are listed in Table 3. Quantum-chemical calculation of the parameter of the exchange interaction gave



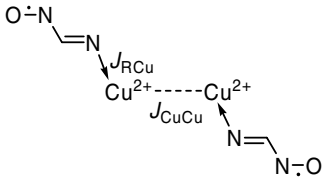


Fig. 5. Dependences $\mu_{eff}(T)$ for **1** (▼), **2** (□), **3** (■), and **4** (Δ). Solid lines – theoretical curves.

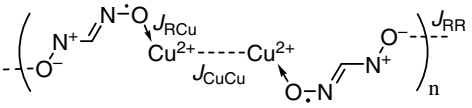
Table 3
Experimental and calculated (in parentheses) effective values of exchange interactions (in cm^{-1}) for **2**–**4**

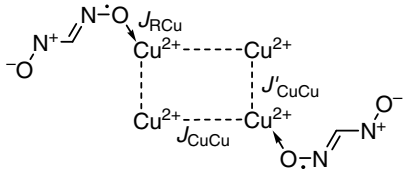
Compound	**2**	**3**	**4**
J_{CuCu}	−72 (−316)	−74 (−120)	−72 (−186)
J_{RCu}	+101 (+174)	−16 (−92)	
g_{Cu}	1.93	2.12	2.19

$J_{CuCu} = -186\ cm^{-1}$ (the calculated values are given in parentheses in Table 3). The calculated value of J coincides (in the order of magnitude and sign) with the experimental value. The slightly overestimated value of J_{CuCu} is explained by the well-known tendency for DFT methods to overstabilize the low-spin states, which generally leads to the parameters of antiferromagnetic exchange exaggerated by a factor of 1.5–2 [17].



For complex **2**, the μ_{eff} increases at elevated temperatures and approaches 3.46 β, which is the theoretical value for four practically uncoupled spins with $S = 1/2$. From X-ray data for **2** it follows that interaction between the odd electrons of the Cu(II) ion and the N ÷ O group in the molecule occurs via the Cu(II) ← N=C–N ÷ O channel, due to which the interaction is ferromagnetic [18]. As in **4**, the intramolecular interaction between the odd electrons of the two Cu(II) ions occurs via the pyrazolate bridges, owing to which this is a strong antiferromagnetic interaction. Since the intermolecular distances between the paramagnetic centers exceed 4.379 Å in solid **2**, other interactions may be neglected in analysis of the experimental dependence $\mu_{eff}(T)$. Therefore, the exchange structure **2** may be regarded as a system of isolated four-center clusters:

Approximation of the experimental dependence $\mu_{eff}(T)$ by the isotropic spin-Hamiltonian of the cluster [19] allowed us to obtain the optimal values of the parameters g_{Cu} and exchange coupling energies J_{CuCu} and J_{RCu} (Table 3). They show that in solid **2** the antiferromagnetic exchange prevails over the ferromagnetic exchange, which was also confirmed by our quantum-chemical data (Table 3).



The high-temperature asymptotics of μ_{eff} for **3**, as well as for **2**, tends to reach the value 3.46 β, which is the theoretical value for a system of four spins with $S = 1/2$ provided that $J \ll kT$. Spin coupling gradually takes place at lower temperatures. In molecule **3**, the exchange interaction of the odd electrons of the Cu(II) ions via the pyrazolate bridges should be antiferromagnetic, as in the case of **2** and **4**. Moreover, each of the Cu(II) ions coordinates the O atom

of the nitronyl nitroxyl fragment in the equatorial position, which is known [18] to predetermine the antiferromagnetic character of exchange in the Cu(II)–O ÷ N< cluster. Another possible channel of exchange interactions may be dictated by the short distances (3.426(4) Å) between the O atoms of the >N ÷ O groups of the neighboring molecules. To substantiate the model of dominant exchange interactions, we performed quantum-chemical calculations of J_{CuCu} and J_{RCu} based on the real geometry of molecule **3**. These calculations showed that the intramolecular exchange interactions are antiferromagnetic (Table 3). The efficiency of intermolecular interaction was evaluated based on the calculated data for the cluster that includes two neighboring molecules **3**. According to this estimation, $|J_{RR}|$ is of the order of 1 cm^{-1}. Therefore, exchange structure **3** may be regarded as a system of intramolecular four-center clusters weakly interacting with one another:

The optimal values of the parameters g_{Cu}, J_{CuCu}, and J_{RCu} obtained by approximation of the experimental dependence $\mu_{eff}(T)$ within the framework of the isotropic spin-Hamiltonian are listed in Table 3.

For complex **1**, μ_{eff} decreases at reduced temperatures, and around 100 K the dependence $\mu_{eff}(T)$ becomes a plateau with $\mu_{eff} \approx 2.41$ β, which is close to the theoretical value 2.45 β for two weakly interacting spins $S = 1/2$ with $g = 2$. This behavior of the dependence $\mu_{eff}(T)$ suggests that at $T \leqslant 100$ K the four spins are completely coupled in **1**. Since the X-ray study showed that in solid compound **1** the intermolecular distances between the paramagnetic centers exceed 6 Å, the strong antiferromagnetic interactions are evidently concentrated in the tetranuclear molecules of the complex. In the centrosymmetric molecule **1**, four Cu(II) ions are linked with one another by pairs of various channels, forming an exchange triangle. Moreover, each of the two Cu(II) ions lying at the opposite vertices of an imaginary exchange triangle interacts with the paramagnetic ligand coordinated to it. Thus, exchange structure **1** may be viewed as a system of isolated six-centered clusters:

The optimal values of the parameters g_{Cu}, J_{CuCu}, J'_{CuCu}, and J_{RCu} could not be determined because of the character of the experimental dependence $\mu_{eff}(T)$ for **1**. Our quantum-chemical calculation indicated that the exchange interaction channels J_{CuCu} via the pyrazolate complex and the coordinated OH group and J'_{CuCu} via the acetate bridge differ considerably in intensity. Interaction via the acetate bridge is weak antiferromagnetic; $J'_{CuCu} \sim -11$ cm^{-1}. At the same time, the exchange interaction channel between the Cu(II) ions linked by the pyrazolate bridge and the OH group is characterized as having an unusually high exchange coupling parameter $J_{CuCu} = -938$ cm^{-1}. This may be assumed to be exactly the channel that is responsible for the effective spin coupling in the exchange rectangle. An antiferromagnetic interaction as strong as this is a consequence of direct overlapping of the copper-centered magnetic orbitals on the oxygen atom of the coordinated OH group (Fig. 6). As would be expected for this type of coordination of the nitronyl nitroxyl fragment, the copper–radical interaction is antiferromagnetic with $J_{RCu} = -60$ cm^{-1}.

3.3. EPR characterization of the compounds

The EPR spectrum of complex **4** and its temperature dependence are typical for the two-spin system coupled antiferromagnetically (Fig. 7a). At high temperatures the spectrum consists of the strong absorption band at $g \approx 2.15$ and weaker line at the half-field region of the spectrum ($g \approx 4.2$), characteristic for spin dimers [20,21]. On lowering the temperature, an absolute intensity of the spectrum decreases and spectrum completely disappears below ca. 30 K. At $T = 20$ K only a weak and narrow signal with $g \approx 2.013$ is observed, which is most likely to be assigned to the small admixture of nitroxide radical. Double integration of spectra at $T = 296$ and 20 K allows for the estimate that the concentration of admixture does not exceed 0.4% and thus its influence on the magnetic properties of **4** can be safely neglected.

The room temperature (296 K) EPR spectrum of the compound **1** consists of the single broad line (peak-to-peak width ca. 90 mT) at $g \approx 2.054$ (Fig. 7b). The line shape is close to Lorentzian, implying an assignment to the strongly-coupled exchange cluster. On lowering the temperature, this line gradually transforms into a narrow line with $g \approx 2.008$ observed at $T = 20$ K. The value of the g-

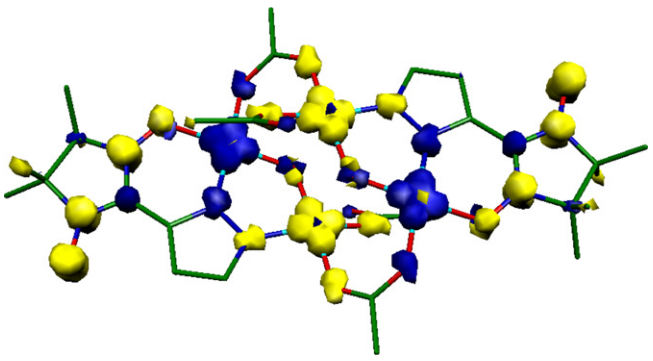


Fig. 6. Spin density in complex **1** for the minimal-energy BS state (H atoms omitted for clarity).

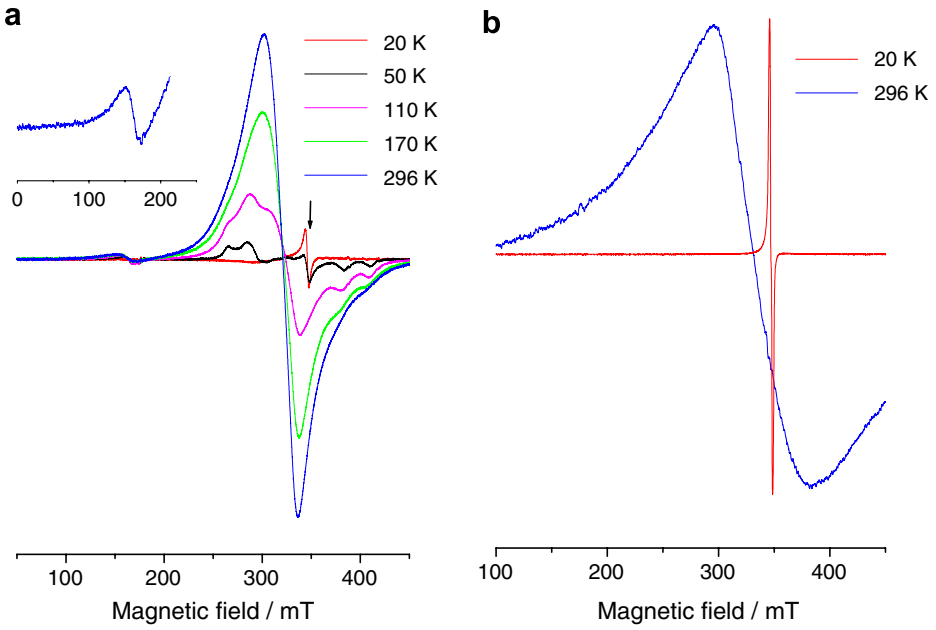

Fig. 7. EPR spectra of **4** at $T = 20$-296 K. The arrow marks the signal of nitroxide admixture. Inset: magnified signal of $\Delta m_s = 2$ transition at $T = 296$ K (a). EPR spectra of **1** at $T = 20$ and 296 K. The intensities are normalized (b).

factor, as well as the width of the line at $T = 20$ K, indicate that at low temperatures the spectrum is dominated by nitroxides and the contribution of copper spins is negligible. This is consistent with the magnetic behavior and the above conclusions, that 4 spins of coppers are strongly-coupled antiferromagnetically and thus virtually do not influence the magnetism below ca. 100 K.

The EPR behavior of the compounds **2** and **3** is rather similar to each other. The spectrum consists of the single broad Lorentzian line (peak-to-peak width ca. 150 mT at room temperature) with no any additional signals. For both compounds, the positions of these lines are temperature dependent. The value $g = 1.969$ is measured for complex **2** at room temperature (296 K), whereas at $T = 20$ K much higher value $g = 2.025$ is observed. For complex **3** the value $g = 1.963$ is found at $T = 296$ K, the value $g = 2.037$ at $T = 120$ K, and at $T = 20$ K the spectrum intensity is too small to be safely detected. The unusual g-values <2 at room temperatures, as well as their temperature dependence, might result from the antiferromagnetic coupling within a four-spin system. Similar effects have been recently observed by us and interpreted for the case of spin triads nitroxide–copper(II)–nitroxide [22–24]. Therefore, these peculiarities are very interesting and will be the future subject of separate investigation beyond this work.

4. Conclusions

Thus our study has shown that the reactions of $\mathbf{HL}^1$ and $\mathbf{HL}^3$ with Cu(II) acetate lead to self-assembly of the $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ tetranuclear and $Cu_2(OAc)_2(H_2O)_2(L^3)_2$ dinuclear complexes, respectively, in which $\mathbf{L}^1$ and $\mathbf{L}^3$ perform the bridging cyclic tridentate function by linking the two Cu atoms. The greatest differences between these complexes are due to the character of the intramolecular exchange interactions. The magnetic behavior of $Cu_4(OH)_2(OAc)_4(DMF)_2(L^1)_2$ is dictated by the dominant antiferromagnetic exchange interactions, as confirmed by the results of quantum-chemical analysis of the exchange coupling channels. The magnetic properties of $Cu_2(OAc)_2(H_2O)_2(L^3)_2$ reflect the competition between the antiferromagnetic and ferromagnetic contributions, of which the latter is due to the interaction of electrons in the Cu(II) ← N=C–N ÷ O exchange channels.

It has been found that the reaction of Cu(II) acetate with $\mathbf{HL}^2$ or $\mathbf{HL}^4$ occurs with cleavage of the ester group, resulting in the formation of $Cu_2(H_2O)_2(L^6)_2 \cdot 2DMF$ and $Cu_2(DMF)_2(L^7)_2$ solid dinuclear complexes, where $\mathbf{L}^6$ and $\mathbf{L}^7$ are the products of transformation of the starting nitroxides, which in the case of $\mathbf{HL}^2$ occurs without affecting the free valence. This possibility should be taken into account in designing heterospin systems based on transition metal complexes with polyfunctional nitroxides.

Abstract

12-Tungstophosphoric acid (TPA) supported on silica, activated carbon and poly(4-styrylmethyl)pyridinium chloride (PMP) were found to be highly efficient catalysts for the synthesis of oxazolines, imidazolines and thiazolines from the condensation of various nitriles with aminoalcohols, ethylenediamine and cisteamine, respectively. In the case of oxazolines, dicyanobenzenes were selectively converted to mono- and bis-oxazolines in the presence of these catalysts. In the reaction of dicyanobenzenes with ethylenediamine, only mono-imidazolines were produced and the remaining cyano group did not react even with long reaction times. In the case of thiazolines, only bis-thiazolines were produced in the reaction of dicyanobenzenes with cysteamine. Furthermore, these catalysts could be recovered and reused without significant loss of their activities.

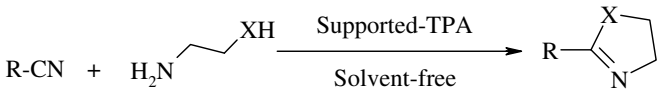
1. Introduction



Reusable heterogeneous catalysts have attracted a great deal of interest in recent years [1]. Since most of the catalysts are expensive and contaminate the environment, the development of efficient methods for recovery and reuse of the catalysts is a very important aspect in this chemistry. An easy solution to this problem is to heterogenize the homogeneous catalysts by supporting them on solid materials. The major advantages of solid-supported catalysts are the facile recovery from the reaction mixture and the possibility of reusing them. Furthermore, supporting of the catalysts efficiently increases the surface area and subsequently the reactivity of the catalysts.

Heteropoly acids (HPAs) are an important class of catalysts having both redox and acid properties [2]. Among the heteropoly acids, polytungstic acids are the most widely used catalysts due to their high acid strengths, thermal stability and low reducibility. Heteropoly acid catalysts have many advantages over liquid acid catalysts, being are harmless to the environment with respect to corrosiveness, safety and quantity of waste. Supported heteropoly acids and specially supported 12-tungstophosphoric acid have been known as important classes of supported catalysts that have received much attention in recent publications [3,4]. These catalysts offer several advantages such as high mechanical and thermal stabilities, easy handling, non-toxicity, high reactivity and recyclability.

2-Oxazolines, 2-imidazolines and 2-thiazolines are very important moieties due to their extensive applications in chemistry, biochemistry and pharmacology [5–9]. These heterocycles are found in the structures of many

biologically active natural products [10,11]. They also exhibit several pharmaceutical activities such as antidiabetic [12], antihypertensive [13], antidepressive [14], anticancer [15], anti HIV-1 [16], antitumor [17] and antialzimer [18] activities. They are also known as important intermediates in organic transformations [19,20]. Optically active mono- and bis-derivatives of these heterocycles have been widely used as both auxiliaries and ligands in asymmetric synthesis [21–23].

Several publications have been reported for the preparation of 2-substituted oxazolines, imidazolines and thiazolines from different precursors such as carboxylic acids [24], esters [25], nitriles [26,27], amides [28], aziridines [29], hydroxymoyl chlorides [30] and aldehydes [31]. Many of these procedures have several drawbacks such as strong acidic conditions, long reaction times, low yields of the products, use of complex reagents and toxic solvents. Therefore, there is still a need to search for a better catalyst with regards to toxicity, selectivity, availability, reusability and easy work-up conditions for these transformations. Herein we wish to report the use of supported-TPAs as highly efficient catalysts for the clean, suitable and chemoselective synthesis of 2-substituted oxazolines, imidazolines and thiazolines (Scheme 1).

2. Experimental

All materials were commercial reagent grades and were prepared from Merck or Fluka. ^{1}H NMR spectra were recorded on a Bruker-Arance AQS 300 MHz. FT-IR spectra were obtained as potassium bromide pellets in the range 400–4000 cm^{-1} with a Nicolet-Impact 400D instrument. All melting points were obtained by a Stuart Scientific apparatus. All the reactions were monitored by TLC and all yields refer to isolated products. The PMP was prepared by the reaction of chloromethylatedpolystyrene with refluxing pyridine [32]. The silica support was Cab-oSil® M5 and was prepared from Riedel-deHaen. The carbon used was activated carbon, purchased from Merck.

2.1. Preparation of the supported 12-tungstophosphoric acid

The supported TPAs catalysts were prepared by the method of incipient wetness. In a typical process, a 400 mg portion of TPA was dissolved in deionized water (50 mL) and impregnated drop-wise onto 1600 mg poly(4-styrylmethyl)pyridinium chloride (PMP), high surface area SiO_2 (Cabosil 20) and activated carbon supports under constant agitation. The resulting pastes were dried at 110 °C for 4 h and then calcined at 250 °C for 4 h (except for PMP) [33]. The PMP catalyst was dried at 100 °C because the polymer is degraded at 250 °C.

FT-IR spectra have been proven to be a powerful technique for the study of the surface interaction between HPA and organic and inorganic supports. Pure TPA compounds display a characteristic infrared fingerprint in the region of ca. 1100–700 cm^{-1}, attributed to ν_{as}(P=O_a) 1090–1060 cm^{-1}, ν(W=O_d) 1010–930 cm^{-1}, ν_{as}(W–O_b–W) 900–870 cm^{-1} and ν_{as}(W–O_c–W) 850–700 cm^{-1} [34,35] For example, the infrared spectrum of TPA–C exhibited strong vibrations at 1080 (P=O), 973 (W=O), 901 and 814 cm^{-1} (W–O–W). The result suggests that the structure of the 12-tungstophosphoric acid of unit TPA–C was similar to that of TPA. The IR spectrum of PMP–TPA exhibited strong vibrations at 1080 (P=O), 973 (W=O), 900 and 819 cm^{-1}, which confirms that the structure of the 12-tungstophosphoric acid of unit PMP–POM was also similar to that of TPA. In the case of TPA–SiO_2 the IR spectrum shows vibrations at 982 (W=O), 899 and 819 cm^{-1} (W–O–W) and the band assigned to P=O vibrations is masked by SiO_2 broad vibrations. To obtain further information on the structure of the catalysts, we analyzed supported-TPAs by neutron activation analysis (NAA). The content of TPA on all supports, which were calculated from the W content in the supported-TPA catalysts, was determined by neutron activation analysis. The amounts of W loading on the supported catalysts were 29.75 ± 0.9, 28.65 ± 0.9 and 29.53 ± 0.8 for SiO_2–TPA, C–TPA and PMP–TPA, respectively.

The specific surface area for silica was 180 m^2/g. After supporting of TPA, this value reduced to 121 m^2/g, which indicated that HPA has been supported successfully on the silica surface. In the case of carbon the specific surface area was 800 m^2/g which reduced to 720 m^2/g after supporting of TPA on it.

2.2. General procedure for the synthesis of mono- and bis-oxazolines and mono-imidazolines

A mixture of nitrile (1 mmol), aminoalcohols or ethylenediamine (4 mmol per each nitrile group) and supported-tungstophosphoric acids (SiO_2–TPA, C–TPA, PMP–TPA) (30 mg, 0.2 mol% for mononitriles and 45 mg, 0.3 mol% of TPA for dinitriles) was placed in a round bottomed flask and heated at 100 °C (in the case of imidazolines the reactions were performed at 110 °C) for the appropriate time according to Tables 2 and 3. After completion of the reaction, as indicated by TLC, the mixture was cooled to room temperature, diluted with cold ethanol (10 mL) and filtered. The solid material was washed with cold ethanol (10 mL). The solvent was evaporated and the residue was purified by recrystallization in *n*-hexane or by column chromatography (neutral alumina) to afford the pure product.

2.3. General procedure for the conversion of nitriles to thiazolines

Nitrile (1 mmol), 2-aminoethanethiol (1.5 mmol per each nitrile group) and supported catalysts (15 mg, 0.1 mol%) were mixed and heated at 110 °C for the appropriate time (Table 4). At the end of the reaction, as indicated by TLC, the mixture was cooled to room temperature, diluted with cold ethanol (10 mL) and filtered. The solid material was washed with cold ethanol (10 mL). Evaporation of the solvent and purification of the crude product by recrystallization in *n*-hexane or by column chromatography on neutral alumina afforded the desired thiazoline.

2.3.1. Spectroscopic data

2.3.1.1. 3-(4′,5′-Dihydro-1H-imidazol-2′-yl)benzonitrile (Table 3, entry 9). Mp: 133–134 °C, ^{1}H NMR (500 MHz, $CDCl_3$): δ 3.81 (s, 4H, $2CH_2$), 4.2 (br s, 1H, NH), 7.51 (t, $J = 7.8$ Hz, 1H, ArH), 7.71 (d, $J = 7.7$ Hz, 1H, ArH), 8.01 (d, $J = 7.9$ Hz, 1H, ArH), 8.05 (s, 1H, ArH). 2.3.1.3. 2-(4′-Pyridyl)-4,5-dihydro-1,3-thiazole (Table 4, entry 7). Mp: 74–76 °C, ^{1}H NMR (300 MHz, $CDCl_3$): δ 3.48 (t, $J = 8.5$ Hz, 2H, CH_2–S), 4.51 (t, $J = 8.5$ Hz, 2H, CH_2–N), 7.68 (dd, $J = 1.5$ and 4.5 Hz, 2H, ArH), 8.71 (dd, $J = 1.5$ and 4.5 Hz, 2H, ArH). MS; $m/z = 164$ (M^+, 93.15%), 162 (4.67%), 136 (17.12%).

2.3.1.4. 2-[3′-(4″,5″-Dihydro-1″,3″-thiazol-2″-yl)phenyl]-4,5-dihydro-1,3-thiazole (Table 4, entry 9). Mp: 111–113 °C, ^{1}H NMR (300 MHz, $CDCl_3$): δ 3.46 (t, $J = 8.4$ Hz, 4H, $2CH_2$–S), 4.49 (t, $J = 8.4$ Hz, 4H, $2CH_2$–N), 7.48 (t, $J = 7.8$ Hz, 1H, ArH), 7.95 (dd, $J = 1.5$ and 7.8 Hz, 2H, ArH), 8.27 (s, 1H, ArH). MS; $m/z = 248$ (M^+, 100%), 246 (11.44%), 244 (2.74%), 220 (32.19%), 192 (11.44%).

3. Results and discussion

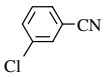
3.1. Optimization of reaction conditions

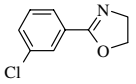
First, the ability of the TPA supported on inorganic (high surface area silica-gel and active carbon) and organic (poly-(4-styrylmethyl)pyridinium chloride) supports was investigated with regard to the synthesis of 2-substituted oxazolines. For this aim, the reaction of benzonitrile with 2-aminoethanol in the presence of 0.15–0.25 mol% of supported catalysts was investigated. The reactions were performed in different solvents such as chloroform, dichloromethane, 1,2-dichloroethane and methanol, and in the absence of solvent at room temperature and under reflux conditions. The best results were obtained with molar ratios of benzonitrile/2-aminoethanol/supported catalysts; 1:4:0.002 at 100 °C under solvent-free conditions (Table 1, entries 1–9). 2-Phenyloxazoline was obtained in 90%, 92% and 90% yields using SiO_2–TPA, C–TPA and PMP–TPA as the catalyst, respectively. When the above mentioned reaction was performed with 1, 2 and 3 mol of 2-aminoethanol in the presence of SiO_2–TPA, the product was obtained in 35%, 55% and 72% yields, respectively.

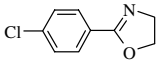
To show the effect of supporting on the catalytic activities of TPA, the reaction of benzonitrile (1 mmol) and 2-aminoethanol (4 mmol) in the presence of the same amounts of non-supported TPA (0.2 mol%) was carried out under the same reaction conditions. The results showed that the catalytic activity of TPA has been increased by supporting on high surface area SiO_2, active carbon and PMP. On the other hand, in the absence of TPA, the supports were less efficient to catalyze the reaction of benzonitrile with 2-aminoethanol. The results are summarized in Table 1.

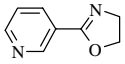
3.2. Synthesis of 2-oxazolines and bis-oxazolines catalyzed by supported TPA

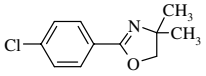
The chosen reaction conditions have been used for the successful preparation of a series of 2-substituted oxazolines. Various aromatic and heteroaromatic nitriles reacted with 2-aminoethanol and 2-amino-2-methylpropanol to produce the corresponding 2-oxazolines in high to excellent yields (Table 2).

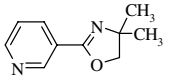


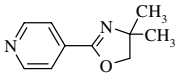


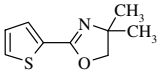


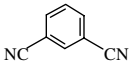


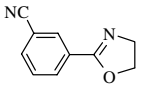


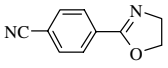












Due to the extensive applications of bis-oxazolines as ligands in chemistry [21–23,34], the reaction of dinitriles with 2-aminoethanol was performed in the presence of

[c] Isolated yields.

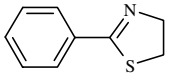
supported-TPAs. Surprisingly, it was observed that both mono- and bis-oxazolines can be obtained by this catalytic system. As shown in Table 2, mono-oxazolines were produced from dinitriles in 90–95% yields with shorter reaction times (0.25–0.5 h). Increasing the reaction times to 6 h, produced bis-oxazolines in 75–80% yields. The preparation of mono-oxazolines from dinitrile compounds is of great interest because the remaining nitrile group can be converted to other functional groups [35].

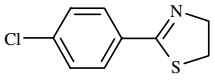
3.3. Synthesis of 2-imidazolines catalyzed by supported TPA

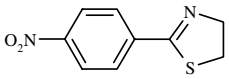
The scope and generality of this catalytic system was shown in the reaction of various types of nitriles with ethylenediamine. Different types of arylnitriles reacted with ethylenediamine under the same reaction conditions used in the synthesis of 2-oxazolines to give the corresponding imidazoline derivatives in good to excellent yields (Table 3). The progress of the reaction was monitored by TLC (eluent: EtOAc/MeOH, 4:1). Work-up of the reaction was very easy. After completion of the reaction, simple filtration of the reaction mixture provided the crude product. Evaporation of the solvent under reduced pressure and recrystallization or chromatography on a neutral alumina column gave the pure product.

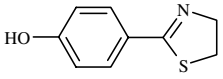
Synthesis of bis-imidazolines from the reaction of dinitriles with ethylenediamine catalyzed by supported TPAs failed. Thus, the reaction of 1,3-dicyanobenzene and 1,4-dicyanobenzene with ethylenediamine in the presence of these catalysts afforded 3-(4′,5′-dihydro-1*H*-imidazol-2′-yl)benzonitrile and 4-(4′,5′-dihydro-1*H*-imidazol-2′-yl)benzonitrile in high yields, respectively (Table 3, entries 9 and 10).

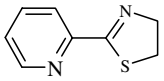
3.4. Synthesis of 2-thiazolines and bis-thiazolines catalyzed by supported TPA

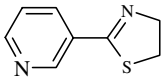


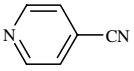


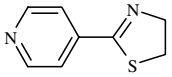


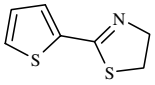


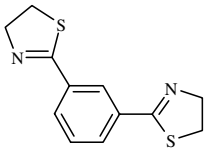


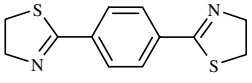












To show the applicability of this catalytic system further, the synthesis of 2-thiazolines was also investigated in the presence of supported TPAs. The reaction of nitriles with 2-aminoethanethiol in the presence of catalytic amounts of supported TPAs (0.1 mol%) produced the corresponding 2-thiazolines in good to excellent yields. The treatment of dinitriles with 2-aminoethanethiol produced bis-thiazolines exclusively (Table 4, entries 9 and 10).

Synthesis of 2-alkyloxazolines, 2-alkylimidazolines and 2-alkylthiazolines with this catalytic system failed. Therefore the chemoselective conversion of arylnitriles to their corresponding 2-aryloxazolines, 2-arylimidazolines and 2-arylthiazolines can be achieved in the presence of alkylnitriles. In this manner, the reaction of an equimolar mixture of some alkyl- and arylnitriles with an excess amount of 2-aminoethanol, ethylenediamine or cysteamine were performed. The results showed that only arylnitriles reacted and the alkylnitriles remained intact in the reaction mixture (Scheme 2).

3.5. Catalyst reuse and stability

The reusability of the catalyst is important for large-scale operation and an industrial point of view. Therefore, the reusability of the catalysts were examined in

the reaction of benzonitrile with 2-aminoethanol. Since the reaction medium is heterogeneous (solid–liquid), the catalysts can be recovered by simple filtration after dilution of the reaction mixture with EtOH. The recovered catalysts were dried at 100 °C and weighed. Afterwards, according to the catalyst amount, the required amount

[b] Reaction time: 2 h.

of fresh nitrile and aminoalcohol were added. The results showed that the catalyst could be reused five consecutive times (Table 5). The amount of catalyst loading after each run was determined by neutron activation analysis (NAA). Addition of fresh nitrile to the filtrates and continuation of the reaction under the same conditions showed that the amounts of 2-phenyloxazoline was about 7–10%, which indicates the catalyst leaching. These data are in agreement with the NAA data about the amount of catalyst loading.

4. Conclusion

In summary, we have demonstrated a simple, efficient and chemoselective catalytic method for the preparation of 2-oxazolines, 2-imidazolines and 2-thiazolines. The use of supported-TPAs as non-toxic, recoverable and reusable heterogeneous catalysts makes this procedure environmentally friendly and economically acceptable. Furthermore, simple work-up, short reaction times, high yields of the products and easy handling of the catalysts are other noteworthy advantages of this catalytic system.

Abstract

The synthesis and characterization of the amine–oxime complex [Ni(*meso*-HMPAO)–H] · ClO_4 (**1**) and its oxidized Schiff-base product [Ni(*meso*-HMPAO)-5H] · ClO_4 (**2**), where HMPAO is hexamethyl propylene amine oxime, are presented. Complex **2** results from the oxidation of **1** by molecular oxygen in basic aqueous solution. The structural change of the amine complex **1** to the Schiff-base complex **2** was investigated by the means of NMR spectroscopy and X-ray crystallography.

Keywords: *meso*-HMPAO; Nickel(II) complex; Oxidation; Schiff-base complex

1. Introduction

The coordination chemistry of oxime compounds has been increasingly interesting and has been studied from a variety of perspectives by many different research groups [1]. Because of the potential applications of metal oxime complexes, they have been shown to be useful in many research areas such as radiopharmaceutical [2], catalysis [3] and analytical chemistry [4]. It was established that the formation of an intramolecular hydrogen bond between the two oxime oxygen atoms is the most favourable characteristic.

It has long been known that bis(dimethylglyoximato)nickel(II) can be oxidized by molecular oxygen and other oxidizing agents. Moreover, it was found that other amine–oxime complexes exhibit the same oxidation behaviour as well. For example, Schlemper has reported that the [Ni(PnAO)–H]$^+$ complex ion can be easily oxidized to a quasi-aromatic system [Ni(PnAO)–6H] in basic solution [5–7].

In the present paper we report the synthesis, spectroscopic and crystallographic characterization of the new complex [Ni(*meso*-HMPAO)–H] · ClO_4 and its oxidized product [Ni(*meso*-HMPAO)–5H] · ClO_4, where HMPAO is hexamethyl propylene amine oxime.

2. Experimental

2.1. Materials and methods

All reagents were of reagent grade and were used without further purification unless stated otherwise. The ligand *meso*-HMPAO was synthesized according to the method described in the literature [8]. The FT-IR spectra were obtained on a Perkin–Elmer FT-IR spectrophotometer using KBr pellets. The UV–Vis spectra were measured in water solution on a Varian Cary 500 UV–Vis spectrophotometer. ^{1}H NMR, ^{13}C NMR and 2D NMR spectra were record in DMSO-d_6 on a Bruker Avance 400 NMR spec-

trometer. Elemental analyses for C, H and N were performed on a Perkin–Elmer 2400 CHN elemental analyzer.

2.2. Syntheses of the complexes

2.2.1. [Ni(meso-HMPAO)-H] · ClO_4 (1)

A solution of $Ni(NO_3)_2 \cdot 6H_2O$ (0.535 g, 1.84 mmol) 2 mL was added to an acidic solution of the ligand *meso*-HMPAO (0.500 g, 1.84 mmol) 10 mL at room temperature. The reaction mixture was adjusted to pH 7.5 by addition of 1 M KOH and the mixture was stirred for 30 min at room temperature under nitrogen atmosphere. Subsequently, 2 M $NaClO_4$ solution was added to the solution, and the obtained amorphous yellow solid was filtered, washed with cold water and dried in vacuo. Yield 0.434 g, (55%). Good quality crystals for X-ray diffraction studies were obtained by recrystallization from methanol. *Anal.* Calc. for $C_{13}H_{27}NiN_4O_6Cl$: C, 36.35; H, 6.34; N, 13.04. Found: C, 36.36; H, 6.37; N, 13.04%. ^{1}H NMR (ppm, DMSO-d_6): δ 0.84 (s, 3H, –C(CH_3)), 0.87 (s, 3H, –C(CH_3)), 1.27 (d, $J = 6.0$, 6H, –CH–(CH_3)$_2$), 1.83 (s, 6H, –N=C–(CH_3)$_2$), 2.22 (m, 4H, –CH_2–), 3.49 (m, 2H, –CH–), 4.43 (s, 2H, *NH*); ^{13}C NMR (DMSO-d_6) δ 13.17, 14.34, 21.52, 26.73, 34.45, 55.95, 62.93, 159.75. ESI: m/z 329.15 $[M]^+$.

Caution! Perchlorate salts are potentially explosive and should be handled with care.

2.2.2. [Ni(meso-HMPAO)–5H] · ClO_4 (2)

The filtrate of compound **1** was kept at room temperature for about one month, giving a solid of orange needles, yield 0.196 g (25%). Recrystallization from ethanol gives intense orange rod crystals suitable for X-ray diffraction studies. *Anal.* Calc. for $C_{13}H_{23}NiN_4O_6Cl$: C, 36.70; H, 5.45; N, 13.17. 2.3. X-ray crystallographic data collection and refinement details

Crystallographic data of **1** and **2** were collected on a BRUKER APEX CCD diffractrometer (graphite-monochromated Mo Kα radiation with $\lambda = 0.71073$ Å). All the structures were solved by direct methods using the program SHLEXS-97 [9] and refined by full-matrix least squares techniques against F^2 using the SHELXL-97 [9] crystallographic software package. Non-hydrogen atoms were refined with anisotropic thermal parameters. During the last stages of refinement some disorder on the perchlorate oxygen atoms of **1** and **2** were evident. Disorder of the oxygen atoms of the perchlorate ion was modelled with two equally weighted sets of oxygen atoms. Detailed crystallographic data and structure refinement parameters for **1** and **2** are summarized in Table 1.

3. Results and discussion

Compounds **1** and **2** are quite stable in the solid state under ambient conditions. They are soluble in water, methanol and ethanol. In the electronic spectra of both complexes in water, weak absorption bands at 435 and 475 nm for complexes **1** and **2** respectively were observed, which are attributed to d–d transitions of square planar nickel(II) complexes [10].

3.1. IR Study

In the IR spectra of the nickel(II) complexes **1** and **2**, displacements of the absorption bands to lower frequencies compare to the free ligand were observed, indicating the coordination of the ligand to the metal ion. In general, the IR spectra of complexes **1** and **2** show the ν(C=N) bands shift to lower frequencies, at 1626 and 1635 cm^{-1} for **1** and **2**, respectively, compared to that of the free ligand at 1690 cm^{-1}, indicating the involvement of the oxime nitrogen atoms in coordination. The oxime hydroxyl stretching of the free ligand is absence, while new vibrational bands of an intermolecular hydrogen bond ν (O–

H–O) between the two oxime groups were observed in the region 1770–1790 cm^{-1} [11,12]. The secondary amine stretching in the region 3151–3269 cm^{-1} for **1**, which are uniquely characteristic and shifted relative to the free ligand (3298 cm^{-1}), suggest the coordination of this group to the metal ion. In contrast, this peak disappears in the spectrum of complex **2**, indicating the deprotonation of the NH group upon coordination. Concerning the ClO_4^- anion, the v_3 mode is around 1121 cm^{-1} for both complexes, but the v_4 band, at 624.01 and 623.76 cm^{-1} respectively, is devoid of any splitting and is consistent with the IR active normal modes for Td symmetry, suggesting that these anions are not coordinated to the nickel ions as is substantiated by the crystal structures of **1** and **2** [13] (see Fig. 1).

3.2. NMR study

The NMR evidence is very useful in distinguishing the two Ni(II) complexes. The sharp NMR peaks in DMSO-d_6 are consistent with planar structures of diamagnetic Ni(II) d^8 complexes. The ^1H NMR and ^{13}C NMR peak assignments are clearly in accordance with the molecular structures determined by X-ray crystal structure analysis, vide infra. The assignments in the 1D spectra were based on additional HMQC and DEPT experiments. The downfield shift of coordinated protons relative to the free ligand can be attributed to the deshielding effect resulting from the coordination of the ligands. However, there are several points of the NMR spectra that merit comment, for example in the ^1H NMR spectrum of compound **2** only four sharp signals appeared, indicating the exclusive formation of a symmetrical complex, which is different from **1**, Fig. 2. In compound **1** the $–CH_2–C–CH_2–$ group must be out of plane of the metal, resulting in the different environments of C7 and C8 atoms and consequently the completely unequivalent positions of their corresponding NMR peaks. In contrast, for compound **2**, these methyl groups are identical, giving a singlet peak, suggesting that the C5 and C9 carbons are essentially in the plane of the rest of the complex, Figs. 2 and 3.

The vic-dioxime carbons peaks appear at 159 and 160 ppm for **1** and **2**, respectively. Interestingly, it is apparent from Fig. 2 that the methane and amine protons of free ligand have moved to downfield positions in complex **1**, whereas these two peaks have disappeared in complex **2**.

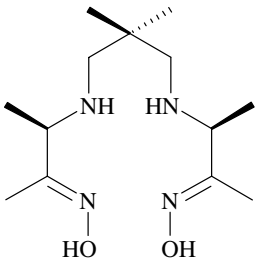

Fig. 1. Structure of *meso*-HMPAO (HL_2).

Moreover, the methine carbons C(3) and C(10) of complex **2** have also disappeared, and simultaneously there is an unexpected signal at 176.6 ppm, Fig. 3. In order to determine the structure of compound **2**, we have used 2D NMR techniques to help analyze the spectrum. It was found that this new peak corresponds to C(3) and C(10) of the double bond –C=N– imine groups, which is in agreement with the conclusion derived from the X-ray crystal structure. It is noteworthy that the NMR data suggests the amine complex can be oxidized to the Schiff-base complex in solution.

3.3. Crystal structures of complexes *1* and *2*

The molecular structures of **1** and **2** are shown in Figs. 4 and 5, respectively and selected bond distances and angles are given in Table 2. The structures consist of discrete $[NiL]^+$ cations together with perchlorate anions. The central Ni(II) atoms in both compounds have a square planar coordination in which the ligand *meso*-HMPAO is coordinated to the nickel atom by four nitrogen atoms. The oxygen atoms O(1) and O(2) of the oximato groups in both complexes are linked by a short hydrogen bond, as in common with oxime–oximate compounds, forming pseudo-macrocyclic complexes.

In compound **1** the deviation of the nickel atom from the basal plane is 0.0198 Å. The six member ring that includes the propylene bridge adopts a chair conformation, which is in agreement with other metal complexes of this ligand type [7,14,15], Fig. 4. The average $Ni–N_{amine}$ distance of 1.882 Å is quite short compared to that found in the $[Ni(PnAO)]^+$ cation (1.937 Å). The N–H group of the *meso*-HMPAO ligand provides no steric hindrance to coordination, and furthermore provides a weak N–H–O hydrogen bond to the perchlorate anion, Table 3. Moreover, the ligand loses one oxime proton on coordinating to nickel(II), forming strong intramolecular hydrogen bonding between the oxime oxygen atoms, in which the O(1)—O(2) distance was found to be 2.413(4) Å, having an asymmetrically disposed hydrogen bond, 1.229(4) Å from O(1) and 1.186(4) Å from O(2).

For compound **2**, the ligand *meso*-HMPAO is coordinated to the nickel atom by four nitrogen atoms, like **1**. The nickel(II) ion sits approximately 0.0481 Å above the plane of the nitrogen atoms. Interestingly, the conformation of the six membered saturated ring of compound **2** present in the asymmetric unit is intermediate between boat and twist boat, Fig. 5. According to the NMR results, not only are the two amine protons are lost by the ligand on coordination, but also the methine protons disappear as well, resulting in the multiple-bond character. Therefore, the average bond length of C(3)–N(1) and C(10)–N(2) is 1.296(4) Å, shorter than the average single bond 1.465(5) Å in complex **1**, but it is in the same range for other Schiff-base complexes (1.27–1.33 Å) [16,17]. The short bond lengths indicate $C(sp^2)–N(sp^2)$ double-bond character and correspondingly the bond angles in the

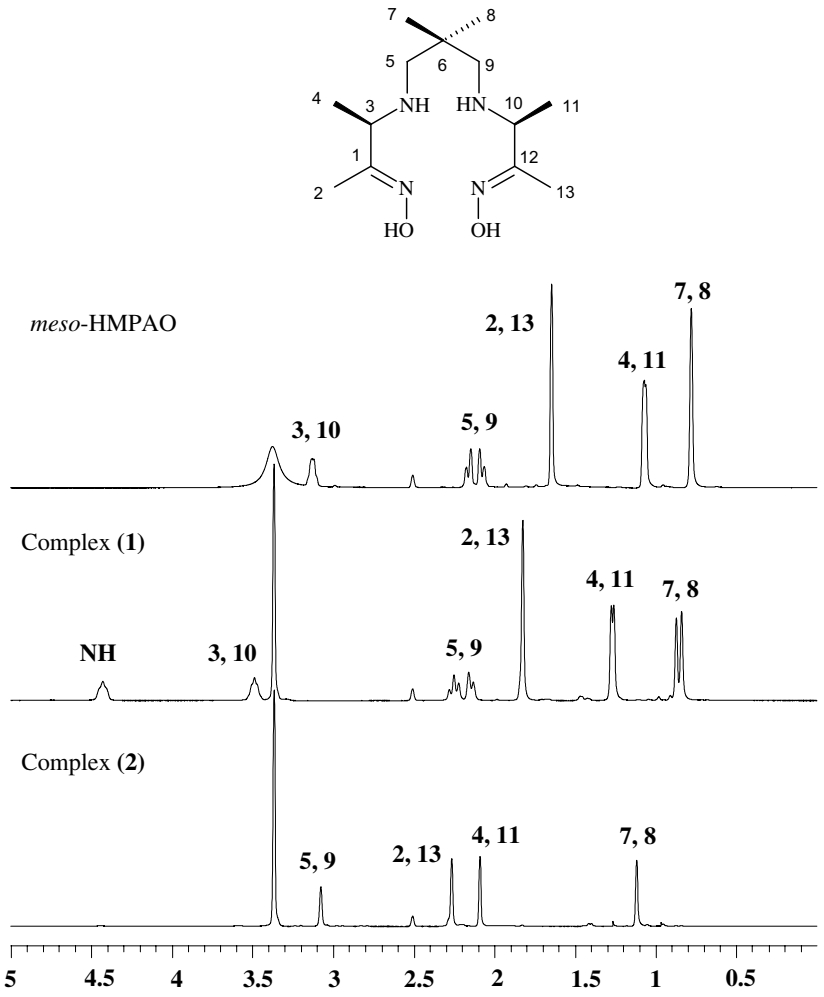

Fig. 2. ^{1}H NMR spectra of the ligand *meso*-HMPAO, and complexes **1** and **2** in DMSO-d_6.

five-membered ring of complex **2** are very close to coplanar, being of the order of 120° rather than 109°. Moreover, the Ni–N(1) and Ni–N(2) bond distances are considerably shorter than those observed in compound **1**, the average bond distance for the complex reported here is 1.879 Å while in complex **1** the average bond distance of Ni–N(1) and Ni–N(2) is 1.904 Å. The ligand is deprotonated at one of the hydroxyl groups, thereby affording an intramo-

4. Conclusion

We have reported that the amine nickel(II) complex [Ni(*meso*-HMPAO)–H]$^{+}$ can be oxidized to the Schiff-base nickel(II) complex [Ni(*meso*-HMPAO)–5H]$^{+}$ in basic

(1) (2)

Fig. 6. Structural formula of complex **1** and its oxidized product **2**.

aqueous solution. This reaction can be rationalized by the oxidation of the amine to the Schiff-base complex by molecular oxygen (Fig. 6), which has been reported previously by Schlemper and co-workers.

X-ray crystal structure and nuclear Overhauser effect studies of cerium(IV) complexes with Schiff bases obtained from *N*,*N*′-(1*R*,2*R*)(−)-1,2-cyclohexanediamine and benzaldehyde derivatives

E. Szłyk *, A. Wojtczak, L. Dobrzańska, M. Barwiołek

Faculty of Chemistry, Nicolaus Copernicus University, 87 100 Toruń, Poland

Received 29 August 2007; received in revised form 5 November 2007; accepted 6 November 2007

Abstract

Schiff bases, obtained by condensation of *N*,*N*′-(1*R*,2*R*)-cyclohexanediamine with 2-hydroxy-5-chlorobenzaldehyde or 2-hydroxy-3,5-dichlorobenzaldehyde and of (±)cyclohexanediamine and salicylaldehyde, have been used as ligands for cerium(IV). The complexes were characterized by circular dichroism (CD), ^{1}H NMR,^{13}C NMR and nuclear Overhauser effect (NOE) studies. X-ray crystal structures determined for: [Ce(IV)((1*R*,2*R*)(−)chxn(3,5-diClba)$_2$)$_2$] and [Ce(IV)(±)(chxn(salal)$_2$)$_2$] revealed different orientation of a pair of Schiff base ligands in the coordination sphere. In [Ce(IV)((1*R*,2*R*)(−)chxn(3,5-diClba)$_2$)$_2$] two ligands form a sandwich with the cerium(IV) ion positioned between two layers of dichlorophenolic moieties. CD spectra in acetonitrile solution revealed exciton coupled $\pi \rightarrow \pi^*$ and LMCT transitions. CD data are characteristic for distortion of the chelate ring from planarity and λ conformation of the cyclohexane bridge. NOE difference spectroscopy for the Schiff bases (saturated –**H**C=N–) demonstrate correlations of the azomethine protons with the protons of the phenyl ring and the cyclohexane's CH protons, and a weak correlation with the hydroxyl group. In the case of the cerium(IV) complexes, the strongest NOE (saturated **H**–C=N) was observed with the phenyl ring's hydrogen atoms, a slightly weaker correlation to the cyclohexane's CH_2 protons, and a much weaker NOE to the cyclohexyl's CH_2 protons. Results of spectral analyses suggest central ions in a distorted square antiprism geometry with the two basal N_2O_2 chromophore group. The X-ray crystallography study also confirmed antiprismatic distortion from planarity in obtained complexes.

Keywords: Cerium(IV); Schiff base; Noe NMR; X-ray; Circular dichroism

1. Introduction

There are several reports on cerium(IV) complexes with Schiff bases derived from salicylaldehyde (salalH), ethylenediamine (salen) and 1,2-phenyldiamine (salophen) [1–3]. In the latter case, two salophen ligands have perpendicular orientation and cerium(IV) is eight coordinated by four nitrogen and four oxygen atoms. The presence of methoxy groups or fluoride atoms causes the ligand to wrap around the metal ions [1]. Cerium(IV) can also coordinate with Schiff bases to form polymers and has been used as a precursor in MOCVD [4–11]. Transition metal complexes of Schiff bases can be used as catalyst [12–14]. In these systems, stereochemical and electronic effects imposed by the Schiff bases, play an important role. Generally, electron-donating or bulky substituents improve the selectivity of the catalyst, whereas the presence of an electron withdrawing group on the phenyl ring enhances the catalyst's efficiency [15,16]. When benzaldehyde is substituted in position 3, the corresponding Schiff base catalysts are more effective, than those with phenyl ring substituted in position 5.

The electronic structure of a benzylaldimine is less suited for stereochemical studies by means of CD, due to the ligand's low effective symmetry, hence the internal $\pi \rightarrow \pi^*$ transition moments are found to have directions far from the N–O vector. Therefore, in this study, we used

doi:10.1016/j.poly.2007.11.004

cyclohexanediamine and benzaldehyde derivatives which can cause deformation of the Ce(IV) coordination sphere.

To the best of our knowledge, Ce(IV) coordination compounds with Schiff bases, derived from *N*,*N*′-(1*R*,2*R*)-cyclohexanediamine [(1*R*,2*R*)(−)chxn] and salicylaldehyde, 5-chlorobenzaldehyde (5-Clba) or 3,5-dichlorobenzaldehyde (3,5-diClba) have not been studied to date, and it is not possible to predict how the ligands orient themselves around the metal ion. In this work, these new Ce(IV) complexes and their structural features are described. Information, about the stereochemistry of the Schiff base complexes in solution, can be deduced from the analysis of NOE difference ^{1}H NMR spectra.

2. Experimental

2.1. Materials

$Ce(NO)_3 \cdot {}^{\cdot}6H_2O$ (analytical grade) was purchased from POCh (Gliwice, Poland); whereas 2-hydroxy-5-chlorobenzaldehyde (5-ClbaH) (98%), 2-hydroxy-3,5-dichlorobenzaldehyde (3,5-diClbaH) (97%) and salicylaldehyde (salalH) (99%) were purchased from Aldrich. *trans*-(−)-1,2-cyclohexanediammonium $(+)_D$-tartrate [(−)-chxn(+)tart], was prepared according to Galsbol [17], from cyclohexanediamine (Aldrich 96%) and used to isolate (1*R*,2*R*)(−)-cyclohexanediamine, which was used for the synthesis of the Schiff bases.

2.2. Instrumentation

IR spectra were taken on a Spectrum 2000 Perkin–Elmer FT-IR, using KBr pellets in the range 400–4000 cm^{-1} and PE discs in 400–200 cm^{-1}. CD spectra were measured on a JASCO 715 spectropolarimeter in 800–180 nm range in acetonitrile concentration 10^{-4} mol/dm^3. The ^{1}H, ^{13}C NMR, DEPT, HETCOR, and NOE difference spectra were measured with an Avance Bruker 300 MHz, in $CDCl_3$, against TMS, at 297 K. NOE difference spectra were measured, at concentration 0.01 M, using NOE mul sequence. X-ray diffraction data were collected on an Oxford Sapphire CCD diffractometer.

2.3. Synthesis of Schiff bases

A solution of (1*R*,2*R*)(−)chxn (1.14 g, 10 mmol) and 2-hydroxy-5-chlorobenzaldehyde (3.15 g, 20 mmol), 2-hydroxy-3,5-dichlorobenzaldehyde (3.82 g, 20 mmol) or salicylaldehyde (2.44 g, 20 mmol) in EtOH was stirred under reflux for 2 h. The yellow solutions of Schiff bases were evaporated on a rotary evaporator and recrystallized from methanol. In the case of (±)chxn(salalH)$_2$ (±)cyclohexanediamine was used for synthesis. (1*R*,2*R*)(−)chxn(5-ClbaH)$_2$ (**1**): IR: 1624 cm^{-1} (*ν* CN), 3445 (*ν* OH); (1*R*,2*R*)(−)chxn(3,5-diClbaH)$_2$ (**2**), IR: 1631 cm^{-1} (*ν* CN), 3440 cm^{-1} (*ν* OH), (±)chxn(salalH)$_2$ (**3**) IR: 1628 (*ν* CN), 3433 cm^{-1} (*ν* OH).

2.4. Synthesis of complexes

Cerium(IV) complexes were obtained according to the following general procedure: $Ce(NO)_3 \cdot {}^{\cdot}6H_2O$ (0.43 g, 10 mmol) was dissolved in ethanol and stirred for 10 min, followed by the addition of the Schiff base (0.78 g, 20 mmol) **1** or (0.93 g, 20 mmol) **2** or (0.65 g, 20 mmol) **3** in ethanol and the reaction mixture was stirred upon heating for 2 h. The obtained precipitates were filtered, washed with methanol and dried in air. Results of elemental analyses:

Anal. Calc. for [Ce(IV)((1*R*,2*R*)(−)chxn(5-Clba)$_2$)$_2$] (**1a**) ($C_{40}H_{36}N_4O_4Cl_4Ce$): Ce, 15.25; C, 52.29; N, 6.09; H, 3.94. Found: Ce, 15.17; C, 51.96; N, 6.13; H, 3.41%. IR: $\tilde{\nu}_{max}$/cm^{-1} 1616 (CN), 287 (Ce–O), 310 (Ce–O), 428 (Ce–N), 467 (Ce–N).

Anal. Calc. for [Ce(IV)((1*R*,2*R*)(−)chxn(3,5-diClba)$_2$)$_2$] (**2a**) ($C_{40}H_{32}N_4O_4Cl_8Ce$): Ce, 13.26; C, 45.47; N, 5.30; H, 3.05. Found: Ce, 13.42; C, 45.15; N, 5.85; H, 3.15%. IR: $\tilde{\nu}_{max}$/cm^{-1} 1626 (CN), 333 (Ce–O), 312 (Ce–O), 420 (Ce–N), 450 (Ce–N).

2.5. Crystal structure determination

The brown crystals of [Ce(IV)((1*R*,2*R*)(−)chxn(3,5-diClba)$_2$)$_2$] (**2a**) crystallized (ethanol) in the tetragonal space group $P4_3$, whereas dark red crystals of [Ce(IV)(±)(chxn(salal)$_2$)$_2$] (**3a**) crystallized (ethanol) in the monoclinic space group $P2_1$. The crystals of **2a** revealed a tendency for twinning. The relatively small crystal selected for the diffraction experiment was also twinned. The diffraction pattern from the main component was isolated and analyzed with the CrysAlis CCD version 1.71 software by Oxford Diffraction. The diffraction data for the studied complexes were measured with an Oxford Sapphire CCD diffractometer and Mo Kα radiation. Structures were solved by the Patterson method and refined to $R_1 = 0.0518$ for **2a** and $R_1 = 0.0821$ for **3a**, using the SHELX-97 program package [23]. The absolute structure was determined by the Flack method [24], with the Flack parameter being 0.02(2) for **2a**, proving the correct enantiomorph, while the value 0.53(4) for **3a** indicated optical twinning (Table 1). Attempts to solve that structure in centrosymmetric space groups were not successful.

3. Results and discussion

3.1. CD absorption spectra

The free ligand absorption spectra in acetonitrile revealed bands below 235 nm, which can be assigned to $\pi \rightarrow \pi^*$ type transitions of the benzene ring. This band in

the CD spectra was observed as a maximum at 231 nm (+1421.66) and a minimum at 263 nm (−355.04) for (1*R*,2*R*)(−)chxn(5-ClbaH), and at 234 nm (+552.06) and at 262 nm (−334.41) for (1*R*,2*R*)(−)chxn(3,5-diClbaH)$_2$ (Fig. 1) [25].

The band from the $\pi \rightarrow \pi^*$ transition, which involves a molecular orbital of –C=N– chromophore, was detected for **1** at 335 nm (−198.96) and for **2** at 338 nm (−123.93) [18,19] (Fig. 1). CD spectra of Ce(IV) complexes exhibit bands (below 320 nm), which can be assigned to $\pi \rightarrow \pi^*$ and ligand to metal charge transfer transitions (LMCT). In the spectrum of [Ce(IV)((1*R*,2*R*)(−)chxn(5-Clba)$_2$)$_2$] (**1a**) bands derived from coupled $\pi \rightarrow \pi^*$ type transitions

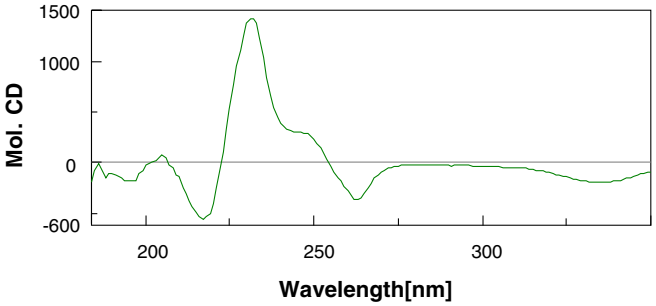

Fig. 1. CD spectrum of (1*R*,2*R*)(−)chxn(5-ClbaH)$_2$.

are splitted: 327 nm (+4.97) and 354 nm (−3.00). The spectrum of [Ce(IV)((1*R*,2*R*)(−)chxn(3,5-diClba)$_2$)$_2$] (**2a**) reveals the band splitted in two components: 320 nm (−24.19) and 343 nm (−37.63), which arise from the exciton coupled $\pi \rightarrow \pi^*$ type transitions. The exciton interaction can be related to the molecular geometry of the complex, where azomethene groups are not planar but produce the square antiprismatic distortion. This band is shifted about 27 nm towards higher energies in comparison to the CD spectrum of the ligand. Besides, the azomethene groups are not planar and 9 nm shift indicates greater distortion of **2a** geometry, than for **1a**. The above results imply, that in Ce(IV) chelates with (1*R*,2*R*)(−)chxn Schiff bases, the cyclohexane ring is *trans* fused to the central chelate ring, forming a rigid structure, in which the metallated ring is locked stereospecifically in λ conformation, as observed previously [26–29].

3.2. NMR spectra

The assignments of hydrogen signals for **1**, **2**, **3**, **1a**, **2a** and **3a** were based on chemical shifts and HETCOR spectra analysis (Table 2).

In the ^{1}H NMR spectra of **1a** and **2a** the OH signals disappeared; indicating Ce–O bond formation. The multiplets from H(1′) in the cyclohexyl ring, centered at 4.38 ppm **1a** and 4.77 ppm **2a**, revealed downfield coordination shifts ($\Delta_{coord} = \delta_{complex} - \delta_{ligand}$) +1.06 ppm for **1a** and +1.2 ppm for **2a**. However, the coordination shift in the case of **2a** is slightly bigger than for **1a**, due to electron withdrawal by 3,5-diCl-benzaldehyde. As the methine hydrogen atoms are three bonds away from the metal center (Ce–N=C(1′)), the coordination shifts are not significant. Then again, the observed coordination shifts are slightly stronger (0.1–0.3 ppm), when compared to those reported for Ni(II) complexes with (1*R*,2*R*)(−)chxn(3-methoxbaH)$_2$] and (1*R*,2*R*)(−)chxn(5-methoxbaH)$_2$] [31]. The latter can be related to the stronger deshielding of the cyclohexyl methine hydrogen, in the presence of chlorine atoms, than in the case of methoxy substituents.

The chemical shifts of H(4′) were detected at 8.44 ppm **1a** and at 8.49 ppm (**2a**), resulting in downfield coordination shifts $\Delta_{coord} = \delta_{complex} - \delta_{ligand} = +0.26$ ppm for **1a**,

Table 2
The ^{1}H NMR chemical shifts (δ, ppm) of the ligands and Ce(IV) complexes

[a] Δ_{coord} for [Ce(IV)(1*R*,2R)(−)chxn(salal)$_2$].
[b] Δ_{coord} for [Ce(IV)(1*S*,2S)(−)chxn(salal)$_2$].

and +0.32 ppm for (**2a**). The magnitude of the H(4′) coordination shift in this case (three bonds distance) can be related to a less effective impact of the dichloro substituted phenyl ring on this hydrogen deshielding. Moreover, the chemical shift of this hydrogen atom is determined mostly by magnetic anisotropy of H–C=N– system, not by electronic effects, explaining why the coordination shift is smaller, than for H(1′). The above can be generalized, that the planarity of the double bond is not changed upon coordination, leaving the hydrogen in the negative sphere of the magnetic anisotropy cone. These coordination shifts are even smaller (*ca.* 0.6 ppm), than those found in the spectra of [Ni(II)(1*R*,2*R*)(−)chxn(3-methoxba)$_2$] and [Ni(II)-(1*R*,2*R*)(−)chxn(5-methoxba)$_2$] complexes [32].

The spectrum of [Ce(IV)((±)chxn(salal)$_2$)$_2$] (**3a**) revealed H(4′) resonances as two singlets at: 8.48 ppm and 8.57 ppm, whereas H(1′) appears as a pair of multiplets centered at 4.54 ppm and 4.74 ppm. When compared to the ^{1}H NMR signals of [Ni(II)(1*R*,2*R*)(−)chxn(salal)$_2$]: (H–C=N′ at 8.15 ppm, H(1′) at 3.16 ppm), the signals found at lower frequencies in **3a**, can be assigned to (1*R*,2*R*)(−)chxn(salal)$_2$ hydrogen atoms. In the case of **3a** the coordination shifts $\Delta_{coord} = \delta_{complex} - \delta_{ligand}$ were: +1.14 ppm and +1.07 ppm for H(1′) and 0.01 ppm and −0.01 ppm for H(4′) for [Ce(IV)(1*R*,2*R*)(−)chxn(salal)$_2$] and [Ce(IV)(1*S*,2*S*)(−)chxn(salal)$_2$] isomers, respectively. The magnitudes of the coordination shifts of both ligand isomers in **3a** are similar or identical, indicating minor distortion of the coordination plane in the chromophore N_2O_2.

^{13}C NMR spectra of **1** and **2** exhibited signals from C(4′) at 163.55 ppm and 163.43 ppm, whereas from C(1′) at 72.65 ppm and 72.23 ppm, respectively. Resonances of the phenyl ring's *ipso* carbons were observed at 159.46 ppm and 156.35 ppm for **1** and **2**. In the spectrum of (±)chxn(salalH)$_2$ (**3**) the doubled number of carbon signals is noted *i.e.*: 72.50 ppm and 69.32 ppm from C(1′), 164.60; 164.03 ppm from C(4′), 118.50; 116.90 ppm from C(1), 161.13 and 160.85 ppm from C(2). In the case of the cyclohexane ring's carbon atoms, resonances were detected in the range 22.38–32.97 ppm. The latter reflects the magnetic unequivalence of two optically active cyclohexane carbons.

^{13}C NMR spectra of [Ce(IV)(1*R*,2*R*)(−)chxn(5-Clba)$_2$] (**1a**) and [Ce(IV)(1*R*,2*R*)(−)chxn(3,5-diClba)$_2$] (**2a**) exhibit signals from C(4′) at 164.64 ppm and 164.40 ppm, shifted downfield $\Delta_{coord} = \delta_{complex} - \delta_{ligand}$ (+0.85 ppm for **1a** and +1.21 ppm for **2a**) in relation to the free bases. These coordination shifts are stronger, than those noted in the proton spectrum, but not distinct enough to be used as unambiguous proof of the coordination sites in the Schiff base.

Resonances of methine C(1′) in the cyclohexyl ring were detected at: 72.66 ppm **1a** and 72.74 ppm **2a**. This carbon atom is two bonds separated from the metal center, same as C(4′), and shifted slightly downfield Δ_{coord}: +0.4 ppm for **1a** and +0.51 ppm **2a**. Surprisingly, *ipso* carbon C(1) in the phenyl ring, which is three bonds apart from Ce(IV), exhibits a stronger coordination shift: −4.43 ppm **1a** (154.97 ppm) and +2.33 ppm **2a** (158.68 ppm). The latter case can be rationalized, as a result of effective deshielding of the *ipso* carbon atom, due to the diamagnetic effect of the deprotonated oxygen atoms involved in M–O σ bond and simultaneous impact of two electron withdrawing chlorine atoms at C(3) and C(5). Another interesting feature is the opposite sign of the C(1) coordination shift in the case of **1a**, when compared to 3,5-dichloro **2a**. The upfield coordination shift of the *ipso* carbon atom in **1a** is in favor of the *para* effect of C(5) chlorine atom. The latter can be generalized, that carbon atom resonances are more sensitive to Ce–O bond formation, than hydrogen atom resonances. The downfield coordination shifts of the *ipso* carbon atom in the 3,5-dichloro derivative can be related to the chlorine atom's strong electron withdrawing properties at C(3). The second interesting feature of the ^{13}C coordination shifts is the bigger magnitude of this effect in three bonds distance from the central ion, than in two bonds. For C(1), the latter can be the result of added effects such as: σ bonds (Ce–O) formation, diamagnetic induction due to the phenyl ring's electrons and deshielding, *via* unsaturated –C=N bond. The stronger coordination shift of C(1) in the discussed complexes, when compared to analogous nickel(II) Schiff base complexes [31–33], can be related to the distance to the central ion, shorter than in the Ni(II) compounds.

3.3. NOE difference measurements

The determination of the structure of the Ce(IV) complex by NMR spectroscopy in solution involves resonance assignment and interpretation of NOE data. The CD exciton chirality method is reliable for determination of the absolute configuration of chiral cyclohexanediamine as was discussed above. The impact of ligand coordination on distances between hydrogen atoms in the nearest proximity to the chelate ring can be evaluated by NOE difference experiment. These NOEs can reveal the whole relative configuration of Schiff bases in solution. In NOE difference experiments, the following protons were saturated: **H**–C=N at 8.18 ppm in **1**; 8.17 ppm in **2**; 8.44 ppm **1a** and 8.49 ppm **2a** and relative enhancements are listed in Table 3 and presented in Fig. 3.

In the spectra of **1** and **2** the strongest enhancements were observed to the methine hydrogen atoms in the cyclohexane ring H(1′) (8.1; 8.50%) and the phenyl ring H(6) (5.1%; 8.54%) respectively. In the case of **2** the enhancements of H(6) are stronger NOE (8.54) than for **1** indicating displacement of H(6) towards the N=C–H plane. Minor enhancements were noted for OH (0.4 in **1** and 1.57% in **2**) and phenyl H(4) in **1** (2.1%). Small but significant difference in NOE of OH signals (**1** and **2**) can be related to deformation of the HOC(1) angle in **2** and a closer distance to the azomethine hydrogen atom. The latter can be caused by the stronger impact of two electronegative chlorine atoms at C(3) and C(5) in **2**, *than in* **1**. The chlorine atoms *can induce* stronger polarization of O–H–N hydrogen bond in **2**, which has further impact on the OH chemical shift (larger for **2**) and displacement of H–O bond from N=C(4′)–H plane. Cyclohexyl CH_2 (C2′, $\delta = 1.9$ ppm) in **1** exhibits low NOE (1.0%) (Figs. 2 and 3), what is in favor of a long distance between the azomethine hydrogen atom and location of CH_2 below azomethine bond plane. In the case of **2**, NOE was not observed for the cyclohexyl CH_2, suggesting even larger distance, than in the case of the monochloro substituted phenyl ring.

The observed NOE enhancements suggest the closest proximity between azomethine hydrogen atom and the cyclohexyl ring H(1′), while the magnitude of the effect in **2** is slightly larger, than in **1** (Table 1). The latter effect can arise from the inclination of N=C–H bond towards C(1′)–H. Moreover, H(1′) in **1** is closer to the azomethine hydrogen, than H(6) due to stronger NOE. From the

Table 3
The results of NOE difference spectra of Schiff bases and cerium(IV) complexes (*H*(4′) saturated)

Compound	*H*(1′)–	(4′)*H*=N (100%)	O*H*	Ar–H	chxn
(1*R*,2*R*)(−)chxn(5-ClbaH)$_2$ (**1**)	3.32(m) (8.1)	8.18(s)	13.20(s) (0.4)	7.21 (2.06)H(4) 7.12 (5.1)H(6)	1.89(m), (1.0)
Ce(IV)(1*R*,2*R*)(−)chxn(5-Clba)$_2$ (**1a**)	4.38(m) (2.49)	8.44(s)		7.07(d) (10.96)H(6)	2.43(d), (6.71)
(1*R*,2*R*)(−)chxn(3,5-diClbaH)$_2$ (**2**)	3.57(m) (8.50)	8.17(s)	14.19(s) (1.57)	7.07(d)H(6) (8.54)	
Ce(IV)(1*R*,2*R*)(−)chxn(3,5-diClba)$_2$ (**2a**)	4.77(m) (2.80)	8.49(s)		7.05(d) (12.79) H(6)	2.39, 2.44 (6.27) 1.85(m), (4.84) 1.54(m)

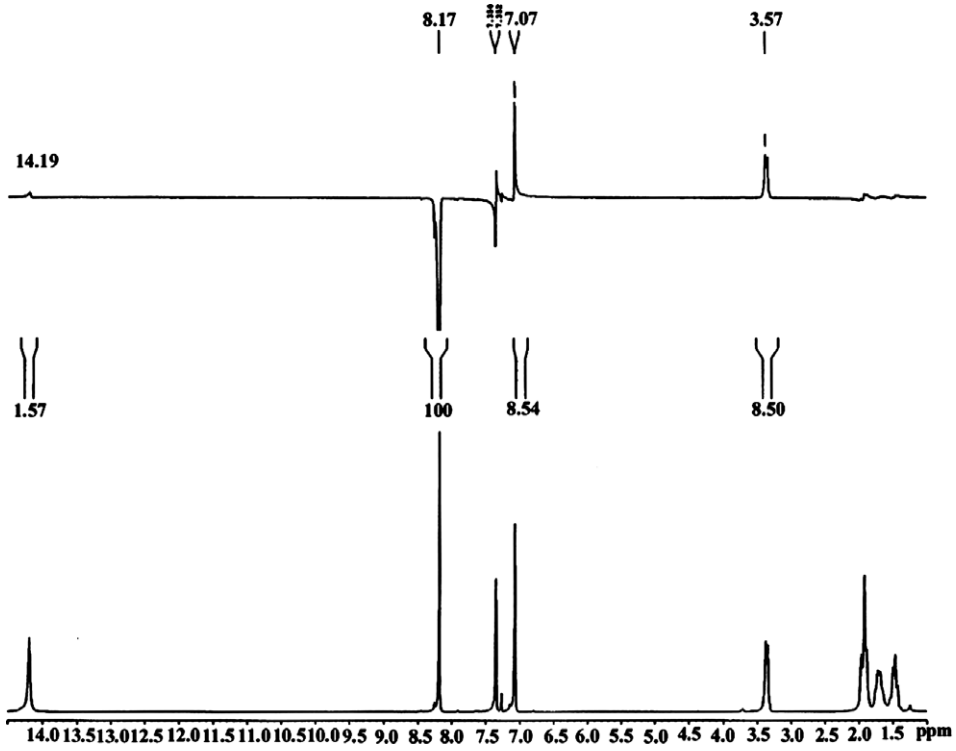

Fig. 2. The NOE spectrum of the ((1*R*,2*R*)(−)chxn(3,5-diClbaH)$_2$) (**2**) – (*H*(4′) saturated).

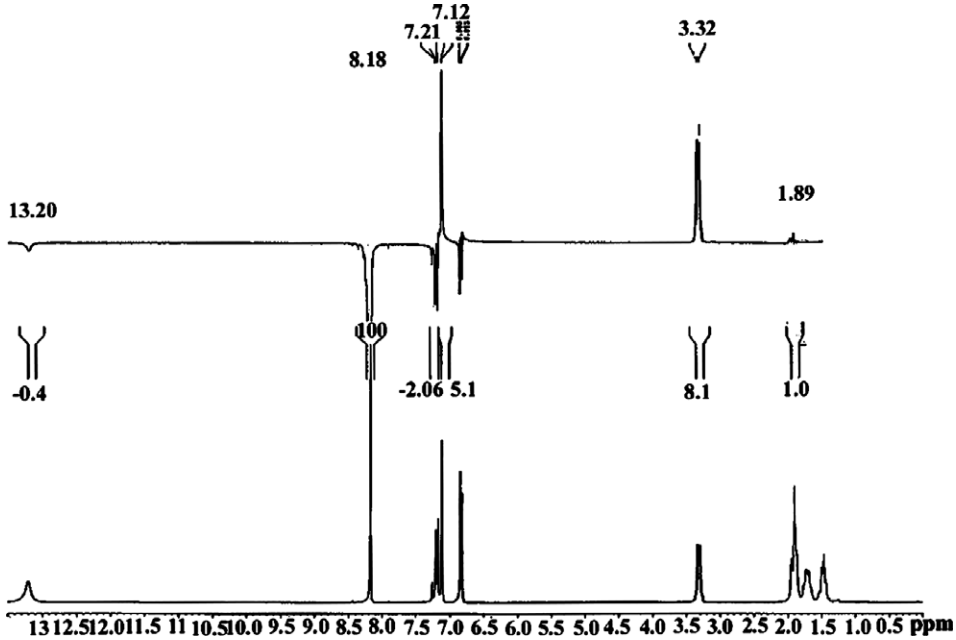

Fig. 3. The NOE spectrum of the ((1*R*,2*R*)(−)chxn(5-ClbaH)$_2$) (**1**) – (*H*(4′) saturated).

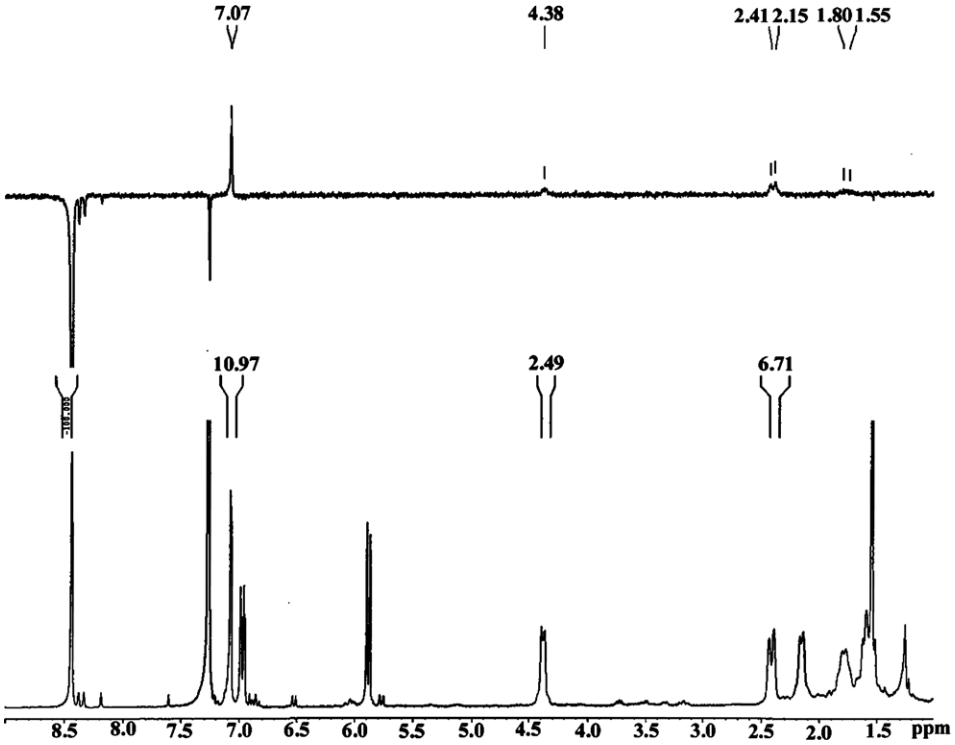
discussion above can be concluded, that in solution the cyclohexane ring retains the chair conformation, while there are some changes in position of the benzaldehyde ring. The phenyl ring can rotate along C(4′)–C(1), what may cause the *strongest NOE enhancement of H(6) signal*.

Saturation of **H**C=N in complex **1a** resulted in the following enhancements: H(6) (10.96% – stronger than in **1**), CH_2(2′) (6.71% in **1**) and H(1′) (2.49% *decrease in relation to* **1**) (Fig. 4). The NOE increase observed for H(6) and CH_2(2′), along with the decrease of H(1′) NOE, suggests deformation of the H-C=N bond plane into the direction opposite to H(1′) (Scheme 1). On the other hand, the methine H(1′) is located far from the H–C=N plane. Surprisingly, the enhancement of CH_2(2′) signals observed for **1a**, suggests cyclohexyl ring deformation and/or simultaneous H–C=N– inclination from the coordination plane



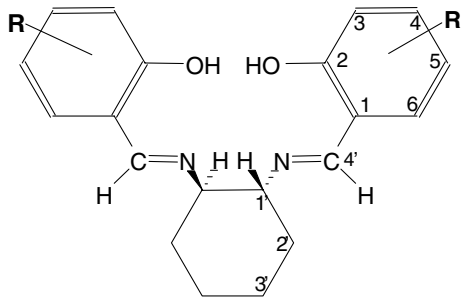


Fig. 4. The NOE spectrum of the [Ce(IV)((1*R*,2*R*)(−)chxn(5-Clba)$_2$)] (**1a**) – (*H*(4′) saturated).

Scheme 1. A schematic representation of (1*R*,2*R*)(−)chxn(**R**-salH)$_2$], **R** = H, or 5-Cl or 3,5-diCl.

towards the cyclohexyl ring. Such effect can be related to deformation of the chelate ring (–Ce–N=C–C(1)–C(2)–O–Ce–), due to molecular packing of two Schiff bases forced by eight coordinated Ce(IV). The electron withdrawing effect of Cl(C5), five bonds away from the donor N atoms, is much less significant.

In the case of **2a** the NOE enhancements were: 12.79% for phenyl H(6), 2.80% for H(1′) and 6.27% for CH_2(2′). The observed NOE correlations suggest stronger interaction between the H(6) hydrogen atom and almost the same for H(1′) (2.49%) and CH_2(C2′) (6.71%) as in the spectrum of **1a**. (Figs. 4 and 5).

The NOEs of **2a** suggest closer distance between H–C=N– and phenyl H(6), due to the influence of the second chlorine atom on conformational changes of the metalloorganic ring. One can assume, that the dihedral angle between the coordination plane and the phenyl ring appears to be smaller, than in the free base and in **1a**. Simultaneous reduction of the C(1)–C(4′)–H angle can be also postulated due to the strongest NOE (12.79%) between H(6) and H(4′). Similar NOE was noted for cyclohexyl –CH_2– (6.27%) in **2a** due to the above mentioned deformations of the coordination ring. These results prompted us to perform a second NOE experiment by saturating the cyclohexane ring's methine H(1′) signals at: 3.32 ppm for (**1**), 3.57 ppm for **2**, 4.38 ppm for **1a** and 4.77 ppm for **2a** (Fig. 6).

The following enhancements were detected for H(4′): (8.65%) in **1**, (2.66%) in **1a**, whereas for **2** and **2a** (8.50%) (2.98%), respectively (Fig. 6). For both complexes, the NOE to azomethine hydrogen is smaller, than in the free bases, what is in accordance with the previous NOE experiment and illustrated at Figs. 7 and 8. There is a small NOE what is in favor of the cyclohexyl chair deformation.

In the Ni(II) complexes with (1*R*,2*R*)(−)chxn(3-methoxbaH)$_2$ and (1*R*,2*R*)(−)chxn(5-methoxbaH)$_2$ when the **H**–C=N protons were saturated, the reported enhancements were as follows: to phenyl ring H(6) (10.68%, 12.28%) and cyclohexyl CH_2 (8.25%, 11.72%) in [Ni(II)(1*R*,2*R*)(−)-chxn(3-methoxba)$_2$] and [Ni(II)(1*R*,2*R*)(−)chxn(5-methoxba)$_2$], respectively [30–33]. However, in these complexes the NOE effect at the H(1′) hydrogen atom was not detected, suggesting different conformational changes due to coordination. Therefore, larger distance between hydrogen atom in the studied cerium(IV), than in nickel(II) complexes can be postulated [30]. In order to correlate

In the crystal structure of complex **2a** positions of the hydrogen and carbon atoms from the two different Schiff bases coordinated to cerium(IV) can be noted, whereas in solution their position in complex molecule is averaged (*vide* numeration). The biggest NOE effect (12.79%) was observed for the phenyl H(6) atoms (Table 4), what can be related to the short distance between hydrogen atoms (H7a–H5a – 2.2958, H14a–H16a – 2.4967) in the solid state. The latter is in favor of the same ligand orientation around metal ion in both states. Second in order NOE effect (6.27) was noted between cyclohexane H(C3′) and azomethine H(4′) atoms (Fig. 8), while in the solid state these two atoms revealed longer distance (about 4 Å) (Table 4). This effect can be related to more pronounced deformation of the cyclohexane ring in solution than in the solid state. NOE effect for other hydrogen atoms in the phenyl ring and cyclohexane ring and corresponding distances in the crystal structure of complex **2a** are comparable.

3.4. Crystal structure description

The details of the diffraction experiment, structure refinement, selected bond distances and angles for the [Ce(IV)((1*R*,2*R*)(−)chxn(3,5-diClba)$_2$)$_2$] are presented in Tables 1 and 5.

Structure **2a** is formed by the molecules of Ce(IV) complex with two Schiff base ligands. The structure revealed the tilt of both dichlorophenolic rings of the Schiff base relative to the coordination plane (Fig. 9).

The aromatic rings are almost parallel to each other, the dihedral angles between their best planes being 6.1(4) and 5.7(5)° for two ligands. The dihedral angles between the CeN_2O_2 coordination plane and the ring planes are 39.3(3) and 33.9(3)° for C1–C6 and C15–C20 rings for the first ligand, and 37.0(4) and 34.0(4)° for C21–C26 and C35–C40 rings of the second ligand. The dihedral angle between the best planes of two ligands, with the cyclohexane's C atoms excluded, is 47.1(2)° In such an arrangement, the aromatic rings forming the double layer are surrounding the central Ce(IV) ion, and the dichlorophenolic moieties of each ligand belong to the different layers (Fig. 9). This is the first report of such an architecture for Schiff base complexes of Ce(IV). This kind of coordination sphere is unique, since in previously reported crystal structures, the Schiff base ligands are always positioned perpendicular to each other [1–3]. The dihedral angle between the best planes of the coordination spheres formed by two ligands is 85.3(3)° and is similar to that of 87.7(3) observed in the complex **3a**.

Each ligand forms four coordination bonds to the central ion. The Ce–O and Ce–N distances vary between 2.212(5) and 2.241(5) Å and between 2.550(7) and 2.570(6) Å, respectively, and are similar to those found in the investigated Ce(IV) complexes of the unsubstituted Schiff ligand **3a**. The angles within the coordination sphere, formed by the atoms of the same Schiff base are similar for both ligands. The O–Ce–O angles are the largest, being 149.7(2) and 149.4(2)° for O(2)–Ce(1)–O(1) and O(3)–Ce(1)–O(4), respectively. The angles formed by the adjacent donor atoms vary between 65.8(2) and 72.7(2)°, while others are between 137.4(2) and 138.5(2)°. Due to the special arrangement of two Schiff base ligands in the sphere, the angles between the coordination bonds formed by the atoms of different ligands vary from 73.0(2) for O(2)–Ce(1)–N(3) to 137.7(2)° for N(1)–Ce(1)–N(3), respectively.

The structure contains two Schiff base ligands, with the absolute configuration of the chiral centers *R*,*R*-(C8,C13) and *R*,*R*-(C28,C29). The torsion angles in the diaminocyclohexane moiety are N(1)–C(8)–C(13)–N(2) −57.0(8)° and N(3)–C(28)–C(33)–N(4) −55.9(8)°.

The cyclohexane ring of the ligand is in the chair conformation. Both the C–N bonds are equatorial. Therefore, the dihedral angle between the plane defined by the central fragment of the cyclohexyl moiety chair and the CeN_2O_2 coordination plane of the ligand are 13.1(9) and 16.6(9)° for C8–C13 and C28–C33 rings, respectively. These values

Table 5
Selected bond lengths and angles (Å) in [(Ce(IV) ((1*R*,2*R*)(−)chxn-(3,5-diClba)$_2$)$_2$)] (**2a**)

Bond	Length	Angle	
Ce(1)–O(3)	2.212(5)	O(3)–Ce(1)–O(2)	90.5(2)
Ce(1)–O(2)	2.241(5)	O(3)–Ce(1)–O(1)	93.9(2)
Ce(1)–O(1)	2.217(5)	O(2)–Ce(1)–O(1)	149.7(2)
Ce(1)–O(4)	2.212(5)	O(3)–Ce(1)–O(4)	149.4(2)
Ce(1)–N(1)	2.570(6)	O(2)–Ce(1)–O(4)	101.8(2)
Ce(1)–N(4)	2.563(5)	O(1)–Ce(1)–O(4)	89.3(2)
Ce(1)–N(2)	2.562(6)	O(3)–Ce(1)–N(1)	78.0(2)
Ce(1)–N(3)	2.550(7)	O(2)–Ce(1)–N(1)	137.4(2)
O(1)–C(1)	1.310(9)	O(1)–Ce(1)–N(1)	72.7(2)
		O(4)–Ce(1)–N(1)	74.0(2)

are similar to those observed for Ni(II) and Zn(II) complexes of Schiff base ligands with (*R*,*R*) configuration of the chiral centers in the analogous ligands [3–5], but are much smaller than the values of almost 90° observed in the Ce complex of the investigated unsubstituted ligand with the (*R*,*S*) chiral centers.

The details of the experiment and structure refinement for **3a** are listed in Table 1. Selected bond lengths and angles are listed in Table 6.

Structure **3a** is formed by complexation of Ce(IV) with two Schiff base ligands. Each ligand forms four coordinate bonds to the central ion. The Ce–O and Ce–N distances vary between 2.148(7) and 2.241(9) Å and between 2.525(11) and 2.619(9) Å, respectively (Fig. 10).

The structure of **3a** contains the Schiff base ligand with the absolute configuration of the chiral centers determined as *R*,*S*-(C8,C13) and *R*,*S*-(C28,C33). However, due to the optical twinning (see Section 2), the *S*,*R*-(C8,C13) and its equivalent also exist in the crystal lattice. This is as a result of the racemic substrate used for the ligand synthesis. The torsion angles in the diaminocyclohexane moiety are N(1)–

O(1)–Ce(1)–N(4)	73.6(4)		
O(2)–Ce(1)–N(3)	85.8(3)		
O(3)–Ce(1)–N(3)	68.9(4)		
O(4)–Ce(1)–N(3)	138.7(4)		
O(1)–Ce(1)–N(3)	75.7(4)		
N(4)–Ce(1)–N(3)	67.6(4)		
O(2)–Ce(1)–N(2)	73.4(3)		

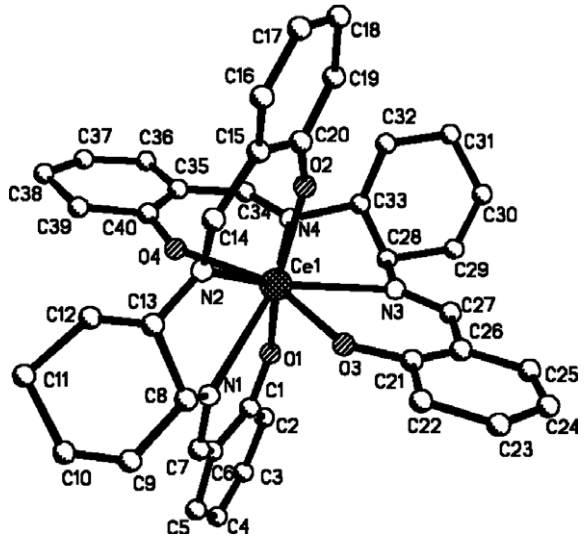

Fig. 10. Molecular diagram with atomic labelling scheme for $[Ce(IV)((\pm)chxn(salal)_2)_2]$ (**3a**).

C(8)–C(13)–N(2) −52.6(14)° and N(3)–C(28)–C(33)–N(4) −64(2)° (Table 6).

The cyclohexane ring of the ligand is in the chair conformation. Since one of the C–N bonds is axial and the other equatorial, the plane defined by the central fragment of the cyclohexyl moiety is almost perpendicular to the coordination plane of the ligand.

This is in contrast to the complexes with the ligands in the (*R*,*R*) configuration of the chiral centers in the Ni(II) complexes of the analogous ligands [31–35] or **2a**, where that angle was below 20°.

Each Schiff base ligand is slightly bent, with the dihedral angles between the phenyl ring planes and the coordination CeN_2O_2 plane being 7.1(8) and 3.8(7)° for the C1–C20 ligand and 5.6(4) and 3.7(5)° for C21–C40 ligand, respectively. In the coordination sphere, two ligands are almost perpendicular to one another, with the dihedral angle between the best CeN_2O_2 planes formed by the two ligands being 87.7(3)°.

4. Conclusions

The present study describes new cerium(IV) complexes with Schiff bases obtained by condensation of *N*,*N*′-(1*R*,2*R*)-cyclohexanediamine with 2-hydroxy-5-chlorobenzaldehyde or 2-hydroxy-3,5-dichlorobenzaldehyde and of (±)cyclohexanediamine with salicylaldehyde.

NOE experiments revealed interactions of the azomethine hydrogen atom with the protons from the cyclohexane ring, phenyl ring and with the hydroxyl group in the case of the Schiff bases, while in the cerium(IV) complexes this proton is in proximity of the phenyl ring hydrogen atom and the cyclohexane CH_2. Results of spectral analyses suggest central ions in a distorted planarity of N_2O_2 chromophore group. The X-ray crystallography study confirmed antiprismatic distortion from planarity in the reported complexes. Different architecture of the coordination sphere is found for **2a** and **3a**. In **2a** the ligand reveals a bent of the chlorophenolic ring relative to the N_2O_2Ce chelate ring. The pair of ligands forms a two-layer environment around the central ion with two phenolic rings of each ligand belonging to a different layer. This type of architecture of the Ce(IV) coordination sphere in Schiff base complexes is reported for the first time. In contrast, in the complex of the unsubstituted ligand **3a**, the coordination N_2O_2 planes of the two ligands are almost perpendicular to each other.

Supplementary material

CCDC 612705 and 612706 contain the supplementary crystallographic data for **2a** and **3a**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

Reaction of $(NH_4)_2[WOS_3]$ or $(NH_4)_2[MoO_2S_2]$, n-Bu_4NBr, CuCl and Imt in acetone solvent afforded air- and moisture-stable clusters (n-Bu_4N)[$MOS_3Cu_3(Imt)_2Br_2$] (M = W or Mo, Imt = imidazolidine-2-thione). These compounds have been characterized by IR, UV–Vis, ^1H and ^{13}C NMR spectra and single-crystal X-ray diffraction. They are crystallographically isostructural, with Imt and $[MOS_3]^{2-}$ acting as monodentate and bidentate S-donor ligands, respectively. In the anions, the three Cu atoms have different coordination environments, one being distorted tetrahedral with Imt and Br as terminal ligands, the other two being approximately trigonal planar with Imt as a terminal ligand for one and Br as a terminal ligand for the other. W and Mo have approximately tetrahedral coordination geometry, with a terminal O and three triply-bridging S atoms. The NH groups of the Imt ligands serve as donors in intramolecular N–H···Br and in intermolecular N–H···Br and N–H···O hydrogen bonds, linking the anions to form layers with the cations in cavities.

1. Introduction

Heterocyclic thiones have attracted considerable interest as ligands in metal complexes because of their relevance in biological systems [1,2]. The chemical interest of heterocyclic thiones is due to the fact that they are potentially ambidentate or multifunctional donors with either the exocyclic sulfur or heterocyclic nitrogen atom available for coordination [3–7]. They are often used for studying binding properties with a soft Lewis acid such as Cu(I) [8–11]. The formation of hydrogen bonds, including both intra- and intermolecular hydrogen bonds, in many thione complexes and biological macromolecules such as azurin and rubredoxin, has been confirmed by X-ray crystallography, vibrational and NMR spectroscopic studies [8]. Tetrathiometallate and oxotrithiometallate anions of molybdenum(VI) and tungsten(VI) have been extensively used as metalloligands for other metal centres, particularly in mixed-metal complexes with copper(I) [12]. We present here two isostructural copper(I) complexes involving the $[MOS_3]^{2-}$ core (M = W, Mo), which display intramolecular and intermolecular N–H···Br and intermolecular N–H···O hydrogen bonds. There are only a few previous examples of crystallographically characterized (oxo)thiometallate–copper complexes with heterocyclic thiones as ligands [13–17]. (Oxo)thiometallate–copper complexes have been investigated in the past because of their biological relevance, including copper–molybdenum antagonism in ruminant animals [18–21].

2. Experimental

2.1. Materials and physical measurements

Starting materials were purchased from commercial sources and used without further purification. Imidazolidine-2-thione (Imt) [22,23], $(NH_4)_2[WOS_3]$ and $(NH_4)_2[MoO_2S_2]$ [24] were prepared from them by published methods. In the case of the thione ligand, a pure sample was obtained by recrystallization from methanol. Infrared spectra (4000–400 cm^{-1}) were recorded from KBr discs with a BOMEN MB102 FT-IR spectrometer. UV–Vis spectra were recorded on a JASCO model 7850 spectrophotometer. ^1H and ^{13}C NMR spectra were obtained using a Bruker DRX 400 AVANCE spectrometer. Microanalysis was carried out by the chemical analysis services of Shiraz University (Iran) and Newcastle University. Melting points could not be determined, as the complexes decomposed on heating.

2.2. Preparation of (n-Bu_4N)[$WOS_3Cu_3(Imt)_2Br_2$] (1)

$(NH_4)_2[WOS_3]$ (0.2 g, 0.60 mmol) was partially dissolved in acetone (50 ml). Solid *n*-Bu_4NBr (0.408 g, 1.27 mmol) was added and the mixture was stirred for ca 10 min, CuCl (0.179 g, 1.8 mmol) was then added and the reaction mixture was stirred for 4 h. The resulting orange solution was filtered to remove the precipitate. After addition of Imt (0.129 g, 1.26 mmol) to the filtrate, the mixture was stirred for another 4 h, the solution was filtered, and the filtrate was evaporated with a vacuum pump. The residue was washed with distilled water (2 × 2 ml), ethanol (2 × 2 ml) and diethyl ether (2 × 5 ml) and dried *in vacuo* to give a yellow powder (0.398 g, 60% based on W). Single crystals were obtained by slow diffusion of diethyl ether into a saturated solution in acetone. On leaving the solution to stand at room temperature overnight, air-stable orange crystals were deposited, which are soluble in common organic solvents. *Anal.* Calc.: C, 24.2; H, 4.4; N, 6.4. Found: C, 23.3; H, 4.0; N, 6.1%.

2.3. Preparation of (n-Bu_4N) [$MoOS_3Cu_3(Imt)_2Br_2$] (2)

The same procedure was employed to synthesize and crystallize the complex (*n*-Bu_4N)[$MoOS_3Cu_3(Imt)_2Br_2$], but using $(NH_4)_2[MoO_2S_2]$ (0.114 g, 0.50 mmol) instead of $(NH_4)_2[WOS_3]$. A red powder was initially obtained (0.217 g, 43% based on Mo), giving red crystals from acetone and diethyl ether. *Anal.* Calc.: C, 26.7; H, 4.8; N, 7.0. Found: C 26.7, H 5.0, N 6.3%. The reaction involves redistribution of O and S atoms at the Mo centre [25].

2.4. X-ray crystallography

Crystal data together with other relevant information on the structure determinations for compounds **1** and **2** are listed in Table 1. All measurements were made on a Nonius KappaCCD diffractometer, with Mo Kα radiation ($\lambda = 0.71073$ Å) at 150 K. Absorption corrections were based on the high redundancy of symmetry-equivalent and repeated reflections. The structures were solved by direct methods and refined by full-matrix least-squares on all F^2 values. Non-hydrogen atoms were refined with anisotropic displacement parameters. Carbon-bound hydrogen atoms were included in calculated positions and refined with isotropic displacement parameters, riding on their parent atoms, while nitrogen-bound hydrogen atoms were refined with a bond-length restraint of 0.88 (1) Å. Programs were standard Nonius control software [26], EvalCCD for data integration [27], SADABS [28] and SHELXTL [29].

3. Results and discussion

3.1. Infrared spectra

The most significant FT-IR bands of the ligands and complexes are summarized in Table 2. The bands appearing at 439 and 900 cm^{-1} for complex **1** and 447.7 and 882 cm^{-1} for complex **2** are assigned to the M-μ_3-S and M = O (M = W or Mo) stretching vibrational frequencies of the WOS_3 and $MoOS_3$ groups respectively. The M-μ_3-S stretching vibrational frequencies of $[MOS_3]^{2-}$ are shifted to a lower frequency, while the M = O stretching vibrational frequencies are shifted to a higher frequency relative

Table 2
Selected IR bands (ν, cm^{-1}) of the ligands and complexes

Compounds	C=S	$\Delta\nu_{CS}$	N–H	$\Delta\nu_{NH}$	W–S_t	W-μ_3-S	W=O
$(NH_4)_2[WOS_3]$					459(vs.)		855
$(NH_4)_2[MoO_2S_2]$					483(vs.)		797, 831
Imt	510		3200				
(n-Bu_4N)$[WOS_3Cu_3(Imt)_2Br_2]$ (**1**)	500.9	9.1	3174	26		439	900
(n-Bu_4N)$[MoOS_3Cu_3(Imt)_2Br_2]$ (**2**)	500.6	9.4	3180	20		447.7	882

Abbreviation: vs., very strong; t, terminal.

to those for uncoordinated $[MOS_3]^{2-}$ ligands (see Table 2). This indicates that the $[MOS_3]^{2-}$ metalloligands are coordinated to Cu(I) through sulfur atoms, as is usually the case. The infrared spectra of the complexes display all of the bands due to the presence of the heterocyclic thione ligand. It can be seen from Table 2 that there is a shift of the ν(NH) vibrational frequencies to lower values upon coordination of the Imt ligand to the Cu(I) metal centre. The shift of the ν(NH) vibration to lower frequencies is indicative of the involvement of the H atom in hydrogen-bond formation with the halide ligand and reflects the relative strength of the N–H···X bond formed. The shifts observed for ν(NH) bands due to coordination, in conjunction with the lack of ν(SH) bands at ca. 2500–2600 cm^{-1} indicate the exclusive S-coordination mode of the thione ligand. Upon coordination of the thione ligand to the Cu(I) metal centre in the (n-Bu_4N)$[MOS_3Cu_3(Imt)_2Br_2]$ complexes, no significant structural changes are observed in the heterocycle ring of the thione. However, in both complexes, the coordination of the thione through the S donor atom of the C=S group results in an elongation of the C=S bond (see Table 4). As a consequence, the ν(C=S) band of the free Imt ligand, which appears at 510 cm^{-1}, is shifted to a lower frequency in the complexes (see Table 2).

3.2. Electronic spectra

The electronic absorption spectra of the complexes in DMF solutions appear to be mainly of intraligand character, presenting three broad bands with maxima at 425, 345 and 273 nm for complex **1**, 504, 406 and 271 nm for complex **2**. The first two bands in each complex are derived from sulfur to metal charge-transfer transitions of the MOS_3 (M = W or Mo) group [30]. These bands are red-shifted compared to the free $[MOS_3]^{2-}$ anions (375 nm for W and 457 nm for Mo) [24]. The third band for each complex lies in the region where the free thione absorbs, with a small red shift as a consequence of the coordination to Cu(I), and should, therefore, be considered as a thione intraligand transition which possesses some MLCT character [31,32].

3.3. NMR spectra

The ^1H and ^{13}C NMR spectra of Imt and the complexes in DMSO-d_6 are summarized in Table 3. In the ^1H NMR spectra of the complexes N–H protons of Imt shift downfield with respect to the uncoordinated thione ligand. The deshielding of the N–H proton is related to an increase of the π-electron density in the C–N bond upon coordination of the thione to Cu(I). The absence of a weak S–H signal for the thiol form of Imt and the presence of the N–H proton signal in the ^1H NMR spectra of the complexes indicates that Imt does not bind to Cu(I) via nitrogen, as confirmed by infrared spectroscopy and X-ray crystallography in the solid state. In the ^{13}C NMR spectra of the complexes the main effect observed is the shift in the C_1 signal (using the crystallographic numbering scheme), which is at a higher field than for free Imt. This observation can be rationalized as the reduction of the C=S bond order upon coordination and a shift of electron density, producing partial double-bond character in the C–N bond [33,34].

Table 3
^1H and ^{13}C NMR chemical shifts (δ in ppm referred to TMS) of Imt and the complexes; atoms are numbered as in the crystallographic result

Compounds	NH(1/2)	$\Delta\delta_{NH}$	CH_2(2/3)	C1	$\Delta\delta_{C1}$	C(2/3)
Imt	7.98		3.50	183.35		44.07
Complex **1**	8.56	0.58	3.63	180.01	3.34	44.99
Complex **2**	8.45	0.47	3.61	180.65	2.7	45.01

3.4. Crystal structures

The two complexes **1** and **2** are crystallographically isostructural, with only minor differences in the details of their structures, so the more precise structure of **2** is described here. Selected bond lengths and angles for both complexes are given in Table 4, and hydrogen-bond geometry in Table 5. Fig. 1 shows the structure of the anion of **2**, including intramolecular hydrogen bonds, and Fig. 2 shows the crystal packing with intermolecular hydrogen bonding for the anions.

The asymmetric unit of the crystal structure consists of a discrete monomeric anion and a cation, interacting through normal coulombic forces. The geometry of the cation is unexceptional, with three fully extended alkyl substituents and only one gauche terminal segment for the fourth (this can be seen in Fig. 2).

The anion has a central MoS_3Cu_3 core with an incomplete cubane (or nest-shaped) structure, the cube vertex opposite Mo being unoccupied. This core has a gross structure typical of OMS_3Cu_3 clusters, with acute angles

Symmetry operators: a, $1/2 - x$, $y - 1/2$, $3/2 - z$; b, $-x$, $2 - y$, $1 - z$.

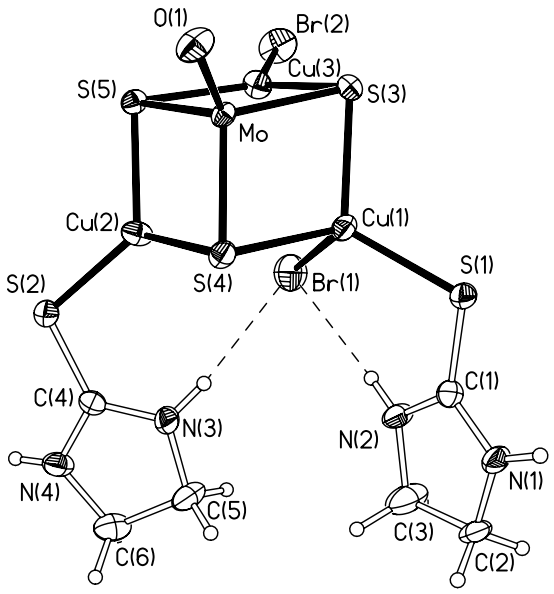

Fig. 1. The structure of the anion of complex **1**, with 50% probability displacement ellipsoids and the numbering scheme for non-hydrogen atoms. Intramolecular hydrogen bonds are shown as dashed lines.

at the S atoms and obtuse angles at the metal atoms. Mo retains the approximate tetrahedral coordination geometry of the parent $[MoOS_3]^{2-}$ anion and deviates only slightly from local C_{3v} symmetry. Each of the Cu atoms has a different coordination environment in this anion. Cu(1), with both thione and bromo substituents, has a distorted tetrahedral geometry; Cu(2) and Cu(3) are both approximately trigonal planar, but Cu(2) has a terminal thione ligand while Cu(3) has a bromo ligand. The source of the bromo ligands is the bromide counterion of (n-Bu_4N)Br used in the synthesis. Bonds to Cu(1) are longer than those to Cu(2) and Cu(3), as expected for the different coordination numbers. The Cu···Mo distances follow the same pattern, with Mo···Cu(2) = 2.6538(1) and Mo···Cu(3) = 2.6600(9) Å, while Mo···Cu(1) = 2.7139(10). Similar trends have been found, for example, for the three- and four-coordinate Cu atoms in polymeric cyano-bridged WS_4Cu_n ($n = 2$, 3) cluster complexes [35] and in $(NEt_4)_3[MoOS_3Cu_3Br_4]\cdot Me_2CO$, which has only halo ligands [36], and is the most similar previously reported structure overall to **1** and **2**. These short Mo···Cu distances do not imply a direct metal–metal bonding interaction, but are a consequence of the incomplete pseudo-cubane cluster structure.

The C–S bond lengths of the coordinated thione ligands are similar to values observed previously for coordinated Imt [13] (the mean for 124 terminally coordinated Imt ligands in the Cambridge Structural Database, Version 5.28 with two updates, is 1.712 Å), and are longer than the distance in the uncoordinated thione (1.688 and 1.692 Å in two independent studies [37,38]). This and the other bond lengths and angles of the ligands are consistent with the thione tautomer having a somewhat weakened C═S double bond on coordination to Cu.

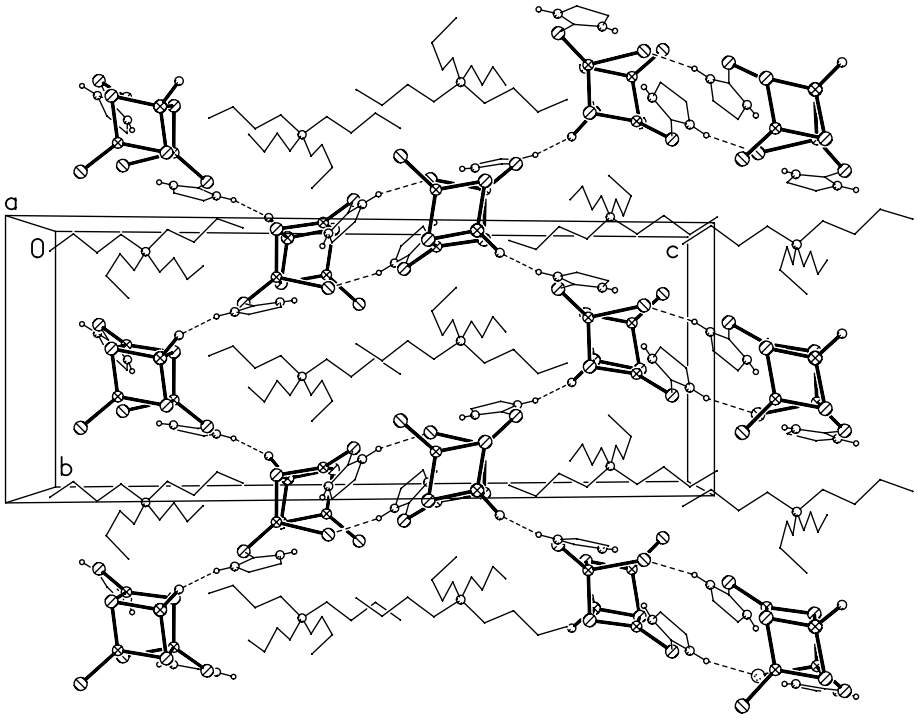

Fig. 2. A packing diagram showing the formation of a layer of anions through intermolecular hydrogen bonds (dashed lines), with cations in the cavities. H atoms bonded to C atoms have been omitted for clarity, and the cations are shown in stick representation.

As shown in Fig. 1, the orientations of the two thione ligands are such that each forms an intramolecular N–H···Br hydrogen bond with Br(1), the bromo ligand attached to Cu(1). The second NH group of each ligand serves as a donor in an intermolecular hydrogen bond to another anion, the two acceptors being O(1) and the same Br atom, which thus acts as a triple acceptor; Br(2) does not take part in hydrogen bonding. The intermolecular hydrogen bonds link anions together in sheets, as shown in Fig. 2, with the cations located in cavities within the sheets. The cavities in successive sheets are aligned above each other to form channels parallel to the *a*-axis, which are occupied by the cations. These channels amount to approximately 50% of the volume of the structure, and it is possible that the particular cations used in this work have a templating effect on the formation of the crystal structure with its hydrogen-bonded network of anions, as a result of their specific size and shape.

Abstract

A series of bimetallic ($[\{M(NO)(Tp^{Me2})X\}_2(Q)]$ [Tp^{Me2} = tris(3,5-dimethylpyrazolyl)borate; M = Mo, X = Cl, Q = $O(CH_2)_nO$, $n = 3$, 5, 6, or $OCH_2(CF_2)_3CH_2O$; M = Mo, X = I, $n = 3$ or 4; M = W, X = Cl, $n = 3$–6, or $OCH_2(CF_2)_3CH_2O$; M = W, X = Br, $n = 2$]), and a number of monometallic complexes ($[M(NO)(Tp^{Me2})X(QH)]$ [M = Mo, X = Cl, Q = $O(CH_2)_nO$, $n = 3$, or $OCH_2(CF_2)_3CH_2O$; M = W, X = Br, $n = 2$]) were prepared. The heterobimetallic complex $[\{Mo(NO)(Tp^{Me2})Br\}O(CH_2)_2O\{W(NO)(Tp^{Me2})Br\}]$ was also obtained. All compounds were characterised by elemental and mass analyses, ^1H NMR and IR spectroscopy. Electrochemical studies (CV and DPV) of the bimetallic species reveal that the metal–metal interactions decrease by *ca.* 100 mV per CH_2 group with increased length for C_2 to C_4 bridges and become undetectable for complexes with bridges longer than C_4. The substitution of fluorine into the C_5 bridge causes the effect to become measurable due to easier polarisation of the σ-bond framework. The crystal structures of $[Mo(NO)(Tp^{Me2})I\{O(CH_2)_2OCOCH_3\}]$ and $[W(NO)(Tp^{Me2})I_2]\cdot 0.5I_2\cdot 0.5C_6H_5CH_3$ were determined.

Keywords: Molybdenum nitrosyl complex; Tungsten nitrosyl complex; Bimetallic complexes; Tris(pyrazolyl)borato complexes; Saturated bridging systems; Electrochemical interactions

1. Introduction

The design and synthesis of redox active binuclear complexes in which metal centres are linked *via* bridging ligands enabling electronic interactions between them are of major interest in the development of models for intramolecular electron transfer over long distances, important for understanding key processes in both chemistry and biology [1–3]. A significant obvious indication of metal–metal interactions is the separation between redox potentials of two redox centres, $\Delta E_{1/2}$, which depends on the metal, its environment, the length and the geometry of the bridge and its electronic properties. The above interactions may be coulombic through-space and through-bond (π-mesomeric effect, σ-inductive effect) in character.

Numerous examples of bimetallic complexes $\{M(NO)(Tp^{Me2})X\}^{+/0}$ [Tp^{Me2} = $HB(3,5\text{-}Me_2C_3HN_2)_3$, X = halide]

doi:10.1016/j.poly.2007.11.008

with π-acceptor ligands (e.g. aromatic heterocycles, polyenes) that make the delocalisation of the unpaired electron possible have been reported in the literature. The highest values of $\Delta E_{1/2}$ were obtained for complexes in which Q = pyrazine (1440 mV, $K_c = 2.2 \times 10^{24}$) [4], Q = 1,4-HNC_6H_4NH (920 mV) [5], Q = 4,4′-bipy (765 mV) [6], Q = $OC_6H_4(2,5\text{-}C_4H_2S)_2C_6H_4O$ (670 mV) [7], and Q = pyC≡Cpy (560 mV) [8]. In all these examples, electrochemical interactions were apparently much greater than in the Creutz-Taube ion (390 mV) [9], although the latter measurements were obtained in aqueous conditions, whereas the former were measured in dichloromethane, solvent effects often having a significant influence on $\Delta E_{1/2}$. It is worth mentioning that observable electrochemical interactions and significant magnetic interactions were detected in the complex [{Mo(NO)(Tp^{Me2})Cl}$_2${4,4′-NC_5H_4-$(CH{=}CH)_4C_5H_4N$}], in which the Mo···Mo distance is *ca.* 2 nm [10]. The introduction of a saturated section into the bridge, as, e.g. in Q = 1,2-bi(4-pyridyl)ethane (105 mV) [6], considerably decreases $\Delta E_{1/2}$, but does not exclude electronic and magnetic through-bridge interactions. Electron tunnelling was shown as possible for $\{Ru(NH_3)_5\}^{n+}$ complexes having fully saturated bridging ligands based on a rigid spirane system with the Ru···Ru distance as long as 17.5 Å [11]. Self-arranged monolayers of alkanethiols adsorbed on gold electrodes are also used in the study of electron transfer through the saturated hydrocarbon chains [12]. Merely a few examples of $\{M(NO)(Tp^{Me2})X\}^+$ complexes containing completely saturated bridges have been described in the literature, among them with Q = $NH(CH_2)_nNH$ ($n = 2, 3$) [13], Q = NC_4H_8N (560 mV) [14] and Q = $O(CH_2)_4O$ (100 mV) [15]. The first one shows irreversible reduction processes, because of the presence of N–H protons, which excludes a detailed discussion of metal–metal interactions in these systems, whereas for the species with a cyclic piperazine bridge, the $\Delta E_{1/2}$ value should be treated with caution because of the irreversibility of the second reduction potential.

We showed in our previous paper [16] that despite the presence of a saturated bridge the complexes [{Mo(NO)(Tp^{Me2})X}$_2${$O(CH_2)_2O$}] (X = Cl or Br) exhibit two chemically reversible one-electron reduction processes separated by a potential difference, $\Delta E_{1/2}$, of *ca.* 310 mV, demonstrating thus significant electrochemical interactions comparable to their analogue with the 1,2-$O_2C_6H_{10}$ cyclic bridge ($\Delta E_{1/2}$ 300 mV) [17], and $\{Mo(NO)(Tp^{Me2})Cl\}^{+/0}$ complexes with aromatic bridges, in which mesomeric effects are not possible, e.g. 1,3-$O_2C_6H_4$ ($\Delta E_{1/2}$ 260 mV) [18], 1,3-$(HN)_2C_6H_4$ ($\Delta E_{1/2}$ 370 mV) [19].

In order to determine the magnitude and the range of electrochemical interactions in the molybdenum and tungsten nitrosyls containing *n*-alkanediolate bridging ligands we synthesised a series of complexes with increasing alkyl chain length. The effect of modifying the electronic properties of the alkyl bridge by introducing fluorine atoms into it was also investigated.

2. Results and discussion

2.1. Synthetic and spectroscopic studies

The reactions between [M(NO)(Tp^{Me2})X_2] and the appropriate α,ω-diol afforded mixtures of mono- and bimetallic complexes which are air-stable and the majority of which may be separated by column chromatography on silica gel using CH_2Cl_2 as eluant. When passing the monometallic complexes through the chromatographic column repeatedly, bimetallic complexes were always formed. Bimetallic species were also formed as a result of heating [Mo(NO)(Tp^{Me2})Cl{$O(CH_2)_nOH$}] with acetic acid (*ca.* 0.1 M) in dichloromethane.

The monometallic complex, [Mo(NO)(Tp^{Me2})Cl-{$O(CH_2)_3OH$}] (**18**), could not be isolated in its pure form. Every attempt to isolate it resulted in a mixture of the monometallic in a great excess and corresponding bimetallic complex.[1] A minor product isolated as green crystals from the reaction between [Mo(NO)(Tp^{Me2})I_2] and ethane-1,2-diol in dichloromethane in the presence of silver acetate, was confirmed by X-ray crystallography to be 2-acetoxyethanolate complex **6**. Despite the large number of syntheses of this type of complex described in the literature such a by-product has never been reported. Generally, acetoxy complexes are intermediate products, that easily undergo substitution by alkoxy ligands because of the labile character of acetoxy group [22]. The compounds obtained from the reaction between **17** and ethane-1,2-diol decomposed during column chromatography.

The reaction between [Mo(NO)(Tp^{Me2})Br(OCH_2-CH_2OH)] and [W(NO)(Tp^{Me2})Br_2] afforded the heterobimetallic complex. The ^{1}H NMR spectrum of this compound indicated it to be a mixture of two different diastereoisomers which could not be separated by column chromatography.

As can be seen from Table 1, all new compounds gave satisfactory elemental analyses, and mass spectrometry usually provided parent molecular ions (M^+) in addition to fragment ions consistent with the loss of halide and/or NO.

The infrared spectra of all the complexes exhibited bands typical for $HB(Me_2pz)_3^-$: ν(BH) at *ca.* 2550 cm^{-1}, ν(C–Me) in the range of 1366–1451 cm^{-1} and ν(C=C) at *ca.* 1540 cm^{-1}. The stretching frequency of the nitrosyl group appeared as the most intense, sharp peak, which reflected the fact that the force constant is related to the effective nuclear charge on the metal centre, which in turn depends on the electron properties of co-ligands X, Y. Mono- and bimetallics showed a single ν(N=O) in the

[1] The ^{1}H NMR spectrum of **18** was deducted from the data of the mixture by subtracting the data of the bimetallic in purity: δ_H($CHCl_3$) 5.91, 5.86, 5.76 (1H, s; 1H, s; 1H, s; $Me_2C_3HN_2$); 2.51, 2.45, 2.38, 2.37, 2.35, 2.34 (3H, s; 3H, s; 3H, s; 3H, s; 3H, s; 3H, s; $(CH_3)_2C_3HN_2$); 6.10, 5.96 (1H, m; 1H, m; $OCH_2CH_2CH_2OH$); 3.88 (2H, m; OCH_2CH_2-CH_2OH); 2.20 (2H, m; $OCH_2CH_2CH_2OH$).

[k] Not measured; its X-ray structure was determined.
[l] From the ^{1}H NMR spectrum this complex appears to be a mixture of two different diastereoisomers which are inseparable by column chromatography.
[m] WI_2 = [W(NO)(Tp^{Me2})I_2]. Compound was synthesised previously [21], but not fully characterised. The isolated complex contained 1/4 mol $C_6H_5CH_3$ which was also detected in its ^{1}H NMR spectrum.

region 1685–1673 cm^{-1} for molybdenum species and 1630–1641 cm^{-1} for their tungsten counterparts. The IR spectra of **4** and **14**, and their monometallic analogues shows ν(N=O) hypochromically shifted by *ca.* 10 cm^{-1}, relative to the species derived from pentane-1,5-diol, which is consistent with the inductive effect of the fluorine substituents. The heterobimetallic complex exhibited two NO stretching frequencies, at 1673 and 1635 cm^{-1} which are assigned to Mo and W centres, respectively. The ν(OH) could be observed in the range 3350–3450 cm^{-1}. For the 2-acetoxyethanolate complex **6** ν(C=O) occurred at 1736 cm^{-1}.

The bimetallic species can occur as two diastereoisomers (*R*–*R*/*S*–*S* and *R*–*S*/*S*–*R*), which could be seen in the ^{1}H NMR spectra of complexes incorporating shorter bridges ($n = 2$ or 3) exhibiting steric interactions between bulky Tp^{Me2} ligands; for longer bridges they were not observed. It reflects the presence of a lower rotational barrier for longer bridges. The species with short bridges differ in thermodynamic stability and, thus, the mixture of them could be brought to an equilibrium state containing most of the more stable isomer following a thermal treatment of the mixture. For some bimetallics, ^{1}H NMR spectra were recorded both in $CDCl_3$ and C_6D_6. The application of the latter solvent enabled the overlapped signals to be separated. It was also observed that the signals due to protons attached to C^4 of pyrazolyl and methylene bridge protons were shifted significantly to stronger and weaker fields, respectively. This indicates specific orientation of the benzene solvent molecules with respect to those particular parts of the complex molecule; C^4 pyrazolyl protons perhaps being placed somewhere above the centre of the benzene molecule plane and methylene protons outside the edge of it. The ^{1}H NMR spectral pattern observed for most bimetallic complexes, namely of three aromatic proton signals of 2:2:2 integrated intensity ratio, and the presence of a single ν(NO) indicates the equivalence of the metallic centres. A certain differentiation in geometry was noticed in [{Mo(NO)(Tp^{Me2})X}$_2$(μ-O)] (X = Cl, I) [23] and [{Mo(NO)(Tp^{Me2})X}$_2$(μ-NHNH)] (not equal lengths of the Mo-bridge bonds) [24].

2.2. Electrochemical studies

The electrochemical behaviour of both mono- and bimetallic complexes was studied using cyclic voltammetry and differential pulse voltammetry and the results are presented in Table 2.

Table 2
Electrochemical data for the complexes

[a] Formal potentials *vs.* ferrocene–ferrocenium couple measured in CH_2Cl_2 with scan rate of 0.1 V s^{-1}; *ca.* 10^{-3} mol dm^{-3} of complex.
[b] Difference between anodic and cathodic peak potentials (for Fc/Fc^+ couple $\Delta E_p = 60$–80 mV).
[c] Separation between two one-electron reduction potentials determined by cyclic voltammetry.
[d] Difference between first and second reduction potentials determined by differential pulse voltammetry; pulse amplitude 50 mV; estimated error 10 mV.
[e] Data from [16].
[f] Practically irreversible ($i_c \gg i_a$).
[g] Quasi-reversible reduction potential of the monoanion degradation product (most probably $[Mo(NO)(Tp^{Me2})Q(solv)]$).
[h] A new anodic wave observed at −0.85 V.
[i] Potential of the quasi-reversible oxidation corresponding to the monocation formation.
[j] A new anodic wave observed at −0.88 V.
[k] Difference between cathodic peaks; only one (or none) anodic wave observed.
[l] Data from [15]; obtained most probably under not exactly the same conditions.
[m] Reexamined.
[n] From deconvoluted voltammogram.
[o] Potential of the irreversible oxidation.
[q] The magnitude of electrochemical interaction was estimated from equation: $\Delta E_{dpv}^{\{Mo-W\}} - (E_{dpv}^{\{Mo\}} - E_{dpv}^{\{W\}}) = 210$ mV.

The monometallic complexes examined, $[M(NO)(Tp^{Me2})X(Y)]$ (M = Mo or W; X = halide, Y = OR; X = Y = OR), underwent one-electron reductions at potentials which were strongly influenced by the nature of M, X and Y (and by the substituents attached to them). Thus, for the Mo complexes the $E_{1/2}$-values become more cathodic in the following order: X = Cl, $Y = OCH_2(CF_2)_3CH_2OH$ < X = I, $Y = O(CH_2)_2OH \approx O(CH_2)_2OCOCH_3$ < X = Cl, $Y = O(CH_2)_2OH$ < X = Cl, $O(CH_2)_3OH$ < X = I, Y = OEt < X = Cl, $Y = O(CH_2)_4OH$ < X = Cl, Y = OEt ≈ X = Cl, $O(CH_2)_2OCH_3$ < X = Cl, $Y = O(CH_2)_5OH \approx$ X = Cl, $O(CH_2)_6OH$ < X = Y = $O(CH_2)_2OH$ < X = Y = OEt, over the range of −0.854 V for the first to −1.90 V for the last complex, which reflects electron

withdrawing/donating capability of the ligands and the inductive effect of their substituents. As expected, the tungsten complexes exhibited reduction potentials of *ca.* 500 mV more cathodic than those of their molybdenum analogues [25]. The complexes in which X is Cl or Br show quasi-reversible behaviour, whereas for [Mo(NO)-(Tp^{Me2})I(Y)] electrochemical reduction is followed by a coupled chemical reaction involving I^- dissociation. Additionally, we observed a quasi-reversible reduction of the degradation product of $[Mo(NO)(Tp^{Me2})I(Y)]^-$ (Y = $O(CH_2)_2OH$, $O(CH_2)_2OCOCH_3$ or OEt), most probably $[Mo(NO)(Tp^{Me2})Y(solv)_n]$, in the region from −1.57 V to −1.83 V. The electronegativity of the halogen is not a determining factor of the redox potentials of [M(NO)-(Tp^{Me2})X(OR)] (X = Cl, Br or I) because the $E_{1/2}$-values for mono- (and the first potential of bi-metallic) complexes become more negative in the sequence I < Br < Cl, which can be explained in terms of $p(\pi) \rightarrow d(\pi)$ donation from X to Mo. At this point it is worth mentioning that for the coordinatively unsaturated boron halides (BX_3) a similar effect is observed, the π character of B–X bond becoming weaker in the sequence $BF_3 > BCl_3 > BBr_3 > BI_3$ [26–28]. The deciding factors of the π-bond strength in these systems are the energy and size of π-donor and π-acceptor orbitals. As the alkyl chain grows, the $E_{1/2}$-values of the complexes $[M(NO)(Tp^{Me2})Cl\{O(CH_2)_nOH\}]$ become more negative and for $n = 5, 6$ assume practically the same value. This is due to a fading induction effect of the hydroxyl group, but other effects like, e.g. torsion angles, could also play a role. In the case of [Mo(NO)-(Tp^{Me2})$(OEt)_2$], quasi-reversible oxidation corresponding to the monocation formation was also observed. Such process is very rarely observed for these type of complexes with anionic X, Y ligands. Correlation analysis of the reduction potentials, which reflects the energy of the LUMO and the nitrosyl stretching frequencies, ν(N=O), has been performed, using the data reported here for the Mo monometallics (Fig. 1).

The linear regression equation obtained reads $\nu(NO) = 1721 + 43E_{1/2}$ with correlation coefficient, R^2, of 0.9779. The inclusion of the point for X = Y = $O(CH_2)_2OH$ reduced the value of R^2 to 0.9563 (perhaps there is some bonding between the two glycol units which forms a chelate). A similar linear dependence has been earlier proposed for the complexes containing aromatic ligands $[M(NO)(Tp^{Me2})X(Y)]$ (M = Mo or W; X = Cl, Y = OPh, NHPh or SPh; X = Y = NC_4H_4, OPh, NHPh or SPh) [29].

The bimetallic {16:16} species exhibited two one-electron reduction processes that lead sequentially to mixed-valence $\{16{:}17\}^-$ and isovalent $\{17{:}17\}^{2-}$ species. The change in the electron density in one of the centres could be sensed by the other centre and, consequently, two signals are observed in the CV. In case of no or negligible interaction, both processes occur as one-electron reductions at virtually the same potential and $\Delta E_{1/2}$ (electrochemical interaction) and corresponding K_c (comproportionation constant) can be calculated from the statistical distribution of products of equal stability with $K_c = 4$ and $\Delta E_{1/2} =$ 35.6 mV consequently.

As can be seen from Fig. 2, the electrochemical interactions decrease by *ca.* 100 mV per CH_2 group with increased length for C_2 to C_4 bridges. Starting with C_5 bridge the electrochemical interactions could not be detected and hence are assumed to be equal to the statistically based value of 35.6 mV. Stabilisation of $\{16{:}17\}^-$ species (K_c range 10 to 10^5) results mainly from through-space coulombic interactions but some polar effects transmitted through σ-bond framework could not be excluded. The replacement of pentane-1,5-diolate bridge by its fluorinated

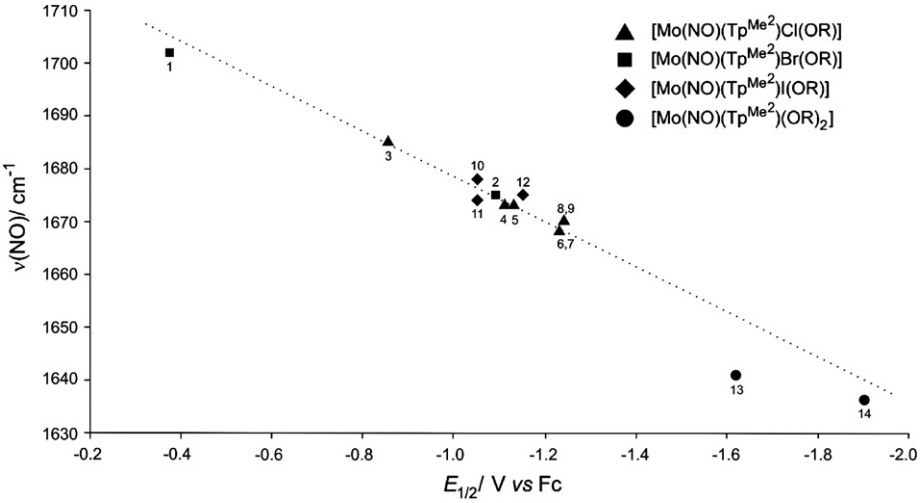

Fig. 1. A plot of ν(N=O) against reduction potentials for $[Mo(NO)(Tp^{Me2})X(Y)]$. Points are labelled as follows: 1 (X = Y = Br), 2 (X = Br, Y = $O(CH_2)_2OH$), 3 (X = Cl, Y = $OCH_2(CF_2)_3CH_2OH$), 4 (X = Cl, Y = $O(CH_2)_2OH$), 5 (X = Cl, Y = $O(CH_2)_3OH$), 6,7 (X = Cl, Y = OEt or $O(CH_2)_2OCH_3$), 8,9 (X = Cl, Y = $O(CH_2)_5OH$ or $O(CH_2)_6OH$), 10 (X = I, Y = $O(CH_2)_2OAc$), 11 (X = I, Y = $O(CH_2)_2OH$), 12 (X = I, Y = OEt), 13 (X = Y = $O(CH_2)_2OH$), and 14 (X = Y = OEt).

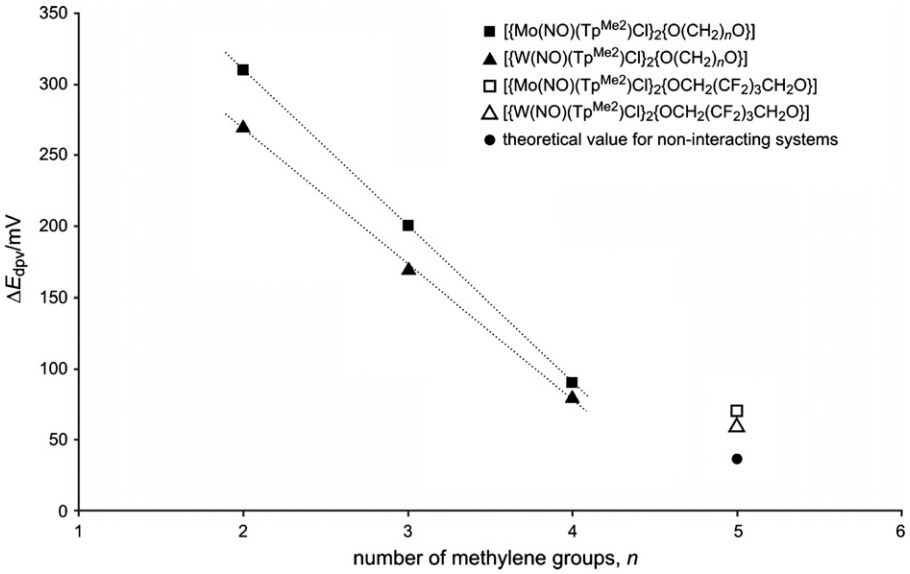

Fig. 2. Dependence of electrochemical interactions, ΔE_{dpv}, on the number of methylene groups in bimetallic Mo and W species. Additionally, for comparison, fluorinated analogues of pentane-1,5-diolate complexes and statistical value for non-interacting systems were included.

analogue causes the appearance of noticeable interactions. As it has been previously noted, interactions between tungsten centres are generally weaker. The heterobimetallic system demonstrates interactions of *ca.* 210 mV that are similar to those observed in the tungsten homobimetallic analogue, which points to mainly through-space coulombic interactions. Bimetallic complexes with C_2 to C_5 bridges undergo the first reduction process at potentials more cathodic by *ca.* 20–70 mV compared with the related monometallic complexes, which seems to be a general rule for the systems with saturated bridges without any significant delocalisation of the unpaired electron [17].

Bimetallic complexes $[\{Mo(NO)(Tp^{Me2})I\}_2\{O(CH_2)_nO\}]$ ($n = 2$–4) show two irreversible reduction waves. The intensity of the cathodic peak for the second reduction process appreciably increases with the scan rate (50–200 mV/s). As was noted above for the monometallic compounds $[Mo(NO)(Tp^{Me2})IQ]$, the signals corresponding to the oxidation of I^-/I_3^- ions were observed. An additional anodic process corresponding to the oxidation of a product of the reaction following the reduction of the complex could also be observed in the range −0.85 V to −0.88 V. It cannot be excluded that the additional wave is associated with the oxidation of the system, in which the I^- ion remains in the proximity of the {17e} centre, and the whole entity is stabilised in the solvent cavity, similar to ion-radical pair in dissociative reduction processes of halogen organic compounds [30,31]. Because of the irreversibility, the $\Delta E_{1/2}$ for these complexes should be taken only as an approximation.

2.3. Crystal and molecular structure of **6**

The molecular structure of **6** is shown in Fig. 3, and selected geometric parameters are listed in Table 3. The asymmetric unit contains two enantiomeric forms (*R* and *S*). The coordination geometry at the molybdenum atoms is distorted octahedral, by a reason of rigid framework of the Tp^{Me2} ligand, which occupies three *fac* sites of the octahedron. The short Mo–O bond lengths (av. 1.88 Å) as well as Mo–O–C angles (130.1°), which reflect a significant degree of $p(\pi) \rightarrow d(\pi)$ donation from O to coordinatively unsaturated Mo, are comparable with those found in $[Mo(NO)(Tp^{Me2})I\{O(CH_2)_3Br\}]$ [32] and $[Mo(NO)(Tp^{*Cl})Cl(OPr^i)]$ (1.86 Å) [33]. For a pure Mo^{II}–O σ bond *ca.* 2.11 Å is expected, as found in $[Mo_2(O_2CCF_3)_4(C_5H_5N)_2]$ [34]. As usually found in this class of complexes, the molybdenum-nitrosyl system is slightly bent from linearity (173.5°, 176.9°), with short Mo–N distance of 1.76 Å. One of the three Mo–N(pyrazolyl) bonds, that lying *trans* to the NO ligand (2.26 Å) is significantly longer than the other two (2.20 Å, 2.22 Å). This has been assigned to the trans influence of the strongly π-accepting nitrosyl group [35]. The Mo–I bond length (2.75 Å) suggests some small degree of π-donor bonding. The pyrazolyl rings of Tp^{Me2} are virtually planar and the N–B–N angles (107.4–109.8°) are close to the tetrahedral value. The boron atom cannot interact with the metal for steric reasons (Mo···B distance 3.29 Å) (see Fig. 4).

2.4. Crystal and molecular structure of ***17*** · $0.5I_2$ · $0.5C_6H_5CH_3$

The complex unit of **17** · $0.5I_2$ · $0.5C_6H_5CH_3$ together with atom numbering is shown in Fig. 5, and its crystal structure is shown in Fig. 6. It contains a molecule of iodine shared between two complex molecules and, as we know from residual electron density and crystallisation conditions, disordered toluene solvates held together by

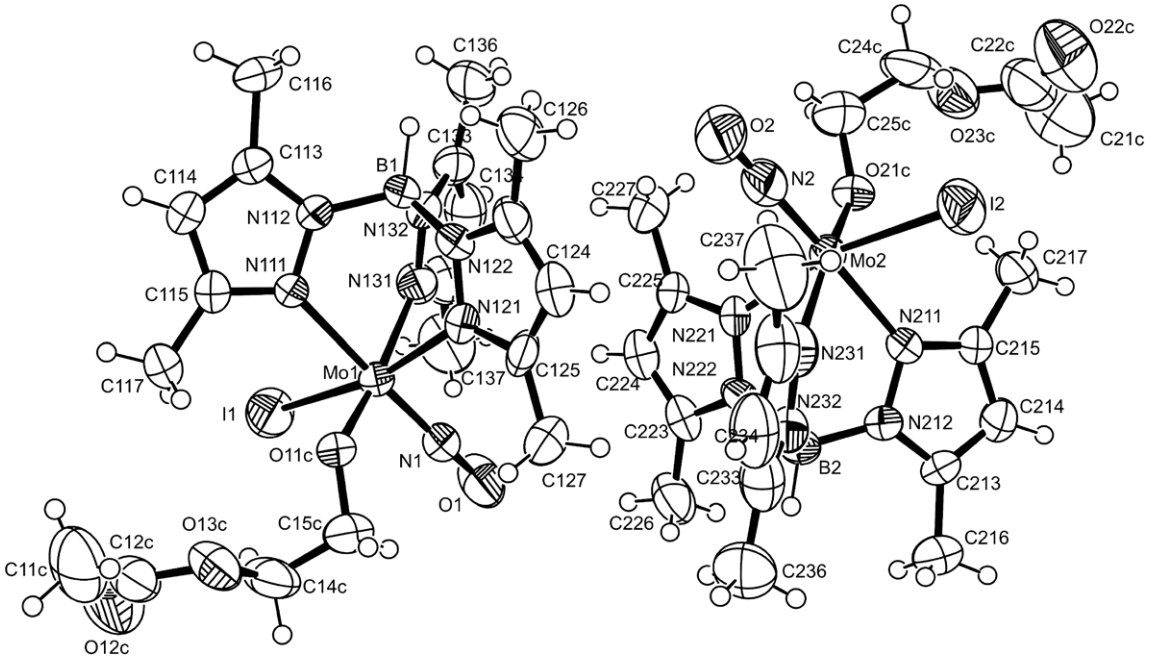

Fig. 3. ORTEP plot of the asymmetric unit of **6** showing thermal ellipsoids at the 50% probability level.

[a] Values in parentheses are estimated standard deviations.

van der Waals forces. The asymmetric unit consists of the complex and half of the iodine molecule (no short contact to the complex). The complex contains a pseudo mirror plane of symmetry passing through W, NO, B and the N(31), N(32), C(33)–C(35) pyrazolyl ring (approximate C_s symmetry which is reflected in ^{1}H NMR spectrum). The co-ordination geometry about tungsten is essentially octahedral. The bond *trans* to the NO group is the longest of the three Mo–N(pyrazolyl) bonds. The tungsten-nitrosyl moiety is slightly bent from linearity (174.8°) with

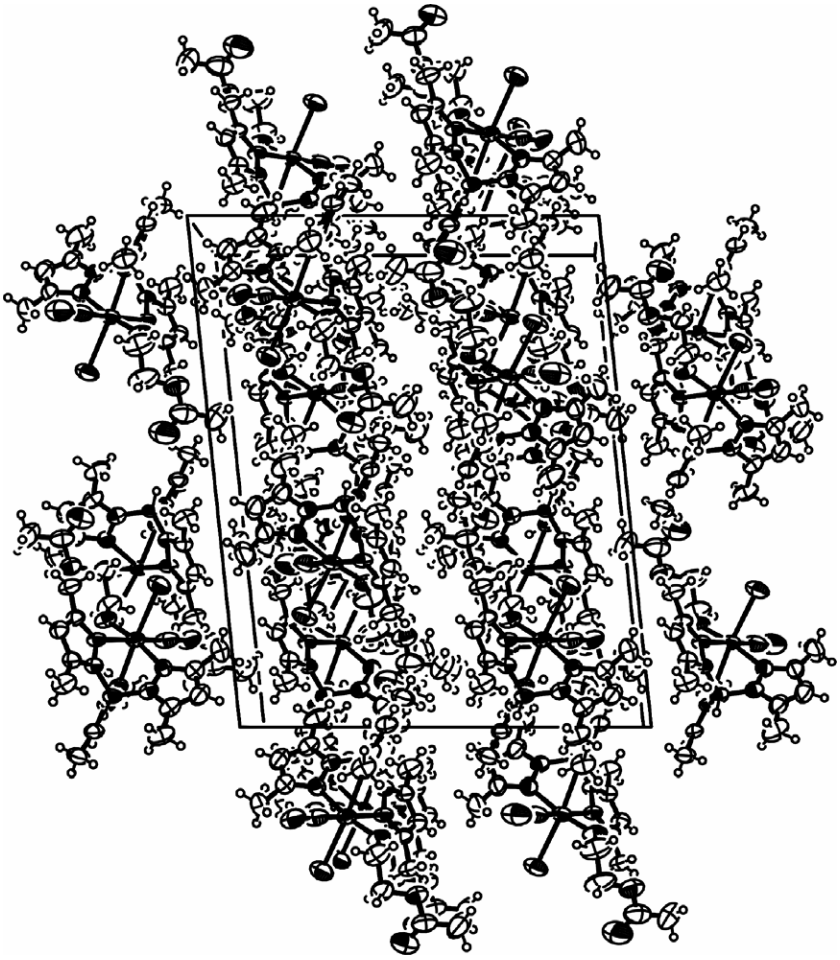

Fig. 4. Packing of molecules in the unit cell of **6** along direct [0 1 0].

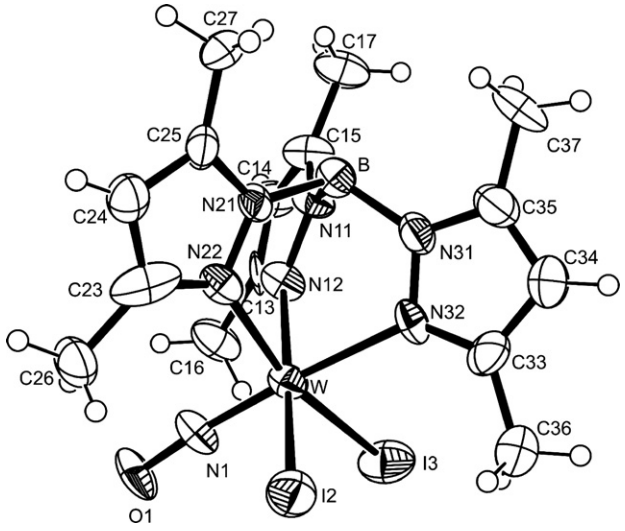

Fig. 5. ORTEP plot of the complex unit of $17 \cdot 0.5I_2 \cdot 0.5\,C_6H_5CH_3$ showing thermal ellipsoids at the 50% probability level.

short W–N distance of 1.75 Å. The W–I distances (2.71, 2.74 Å) are shorter relative to complexes in which formally W^{II} attains normal 18-electron configuration, e.g. $[WI_2(CO)_3(PEt_3)_2]$ (2.85, 2.86 Å) [36], $[Tp^{iPr}WI(CO)_3]$ (2.85 Å) [37]. These distances suggest some degree of $p(\pi) \rightarrow d(\pi)$ donation from I to coordinatively unsaturated W (formally 16-electron). The dimensions of the Tp^{Me2} ligand are as expected with virtually planar pyrazolyl rings and N–B–N angles (106.5–109.8°) close to the tetrahedral value. The boron atom cannot interact with the metal for steric reasons (W···B distance 3.26 Å). The crystal study confirms that iodination of the pyrazolyl rings did not occur.

Selected bond lengths and angles are given in Table 4.

3. Experimental

3.1. Materials and instrumentation

All reactions were carried out under pure argon (BOC, N5.0) using Schlenk techniques and a high-vacuum/gas double line manifold. Commercial solvents and triethylamine were purified by distillation under argon; dichloromethane from calcium hydride, toluene and benzene from sodium-benzophenone and triethylamine from sodium. Anhydrous, 99.8% α,ω-diols were supplied by Aldrich and used directly. The complexes $[M(NO)(Tp^{Me2})X_2]$

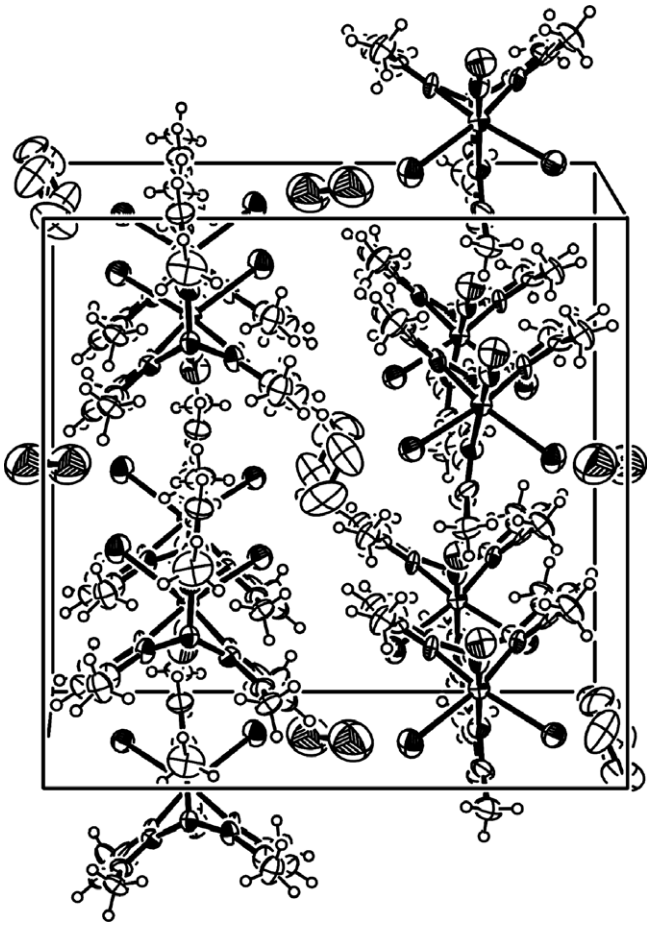

Fig. 6. Packing of molecules in the unit cell of $17 \cdot 0.5I_2 \cdot 0.5C_6H_5CH_3$ along direct [1 0 0].

(M = Mo, X = Cl or I; M = W, X = Cl) were prepared by iodination of $[M(CO)_2(NO)(Tp^{Me2})]$ with (X = Cl) or without (X = I) subsequent addition of benzyl chloride [23]. The monometallic species $[M(NO)(Tp^{Me2})Cl(OR)]$ [M = Mo, $R = (CH_2)_nOH$, $n = 5$, 6; M = W, $R = (CH_2)_nOH$, $n = 2$, 3; M = Mo, $R = (CH_2)_2OMe$] [38], $[Mo(NO)(Tp^{Me2})X(OEt)]$ (X = Cl or I) [33] and $[Mo(NO)(Tp^{Me2})(OEt)_2]$ [21] were prepared according to the literature. Complex **6** was previously obtained as a by-product from the reaction between $[Mo(NO)(Tp^{Me2})I_2]$ and $HOCH_2CH_2OH$ in dichloromethane in the presence of silver acetate [16]. Column chromatography was carried out in glass columns with Merck silica gel 60 (70–230 mesh) as the stationary phase and dichloromethane (to remove bimetallic complexes) or dichloromethane-thf mixtures (to remove monometallic complexes) as elutants. If necessary, fractions were further purified on a second short silica column. The reaction's progress and purity of compounds were monitored by thin-layer chromatography using Merck silica gel (60) F_{254} plates. All yields are based on the starting metal-containing compound. Elemental analyses were performed by the Microanalytical Laboratory of the Faculty of Chemistry at Jagiellonian University or of the Department of Chemistry at the University of Birmingham.

Table 4

[a] Values in parentheses are estimated standard deviations.

The infrared spectra were recorded using a Bio-Rad FTS 175C spectrophotometer in KBr pellets and ^1H NMR spectra from solutions in $CDCl_3$ or C_6D_6 using a Varian Mercury-Vx 300 MHz spectrometer. Chemical shifts were referenced to residual $CHCl_3$ or C_6H_6. Mass analyses were performed on a Bruker-Daltonics Esquire 3000 (ESI) spectrometer, VG-Autospec with 3-nitrobenzyl alcohol as matrix (FAB) and Kratos MS80 (EI). Cyclic and differential pulse voltammetry measurements were carried out using a BAS 100B/W electrochemical workstation (Bioanalytical Systems, USA), under argon in *ca.* 10^{-3} M solution of complex in dry dichloromethane containing 0.1 M $[(n\text{-}C_4H_9)_4N][PF_6]$ as base electrolyte at scan rate of 0.1 V s^{-1}. A standard three-electrode cell was used with a platinum disc working electrode, a platinum wire secondary electrode, and a silver–silver chloride reference electrode that was immersed in supporting electrolyte solution and separated from the test solution by a dense ceramic frit. Ferrocene was added at the end of each experiment as an internal standard; all potentials are quoted versus the ferrocene–ferrocenium couple. The data obtained were reproducible, the measurement error in $E_{1/2}$ was estimated at 5 mV. The number of electrons in each transfer was estimated by comparison with $[\{Mo(NO)(Tp^{Me2})Cl\}_2(\mu\text{-}O)]$, for which a one electron process has been shown [23].

3.2. Synthetic procedures

3.2.1. Synthesis of $[\{Mo(NO)(Tp^{Me2})Cl\}_2\{O(CH_2)_3O\}]$ and $[Mo(NO)(Tp^{Me2})Cl\{O(CH_2)_3OH\}]$ (**1**) and (**18**)

To a solution of $[Mo(NO)(Tp^{Me2})Cl_2]$ (0.50 g, 1.0 mmol) in dry dichloromethane (50 cm^3) AgOCOMe (0.19 g, 1.1 mmol) and propane-1,3-diol (0.30 g, 3.9 mmol) were added. The mixture was stirred and refluxed for 8 h, during which time the colour of the solution changed through green to deep blue. The reaction mixture was cooled to r.t., *n*-hexane was added and further cooled to −10 °C. The precipitate of inorganic salts was filtered off. The solvent was then removed *in vacuo* and the solid was dissolved in the minimum volume of dichloromethane and chromatographed on silica

gel using dichloromethane as eluant. The first and the second blue fractions were collected (bi- and monometallic species), partially evaporated *in vacuo* and precipitated from CH_2Cl_2/*n*-hexane. The resulting blue complexes were filtered off, washed with *n*-hexane, dried at *ca.* 80 °C for 1 h and then *in vacuo* for a few hours (0.1 g, 19.9%, mixture of bimetallic diastereoisomers; 0.05 g, 9.3%, monometallic).

*3.2.2. Synthesis of [{Mo(NO)(Tp^{Me2})Cl}$_2${O(CH$_2$)$_5$O}] (**2**)*

This compound was prepared as a blue-green powder according to the procedure described above using [Mo(NO)(Tp^{Me2})Cl$_2$] (0.50 g, 1.0 mmol), pentane-1,5-diol (0.42 g, 4.0 mmol) and AgOCOMe (0.18 g, 1.1 mmol) in dichloromethane (50 cm^3). The first main fraction was collected and precipitated from CH_2Cl_2/*n*-hexane (0.12 g, 23.3%).

*3.2.3. Synthesis of [{Mo(NO)(Tp^{Me2})Cl}$_2${OCH$_2$(CF$_2$)$_3$CH$_2$O}] and Mo(NO)(Tp^{Me2})Cl{OCH$_2$(CF$_2$)$_3$CH$_2$OH}] (**3**) and (**4**)*

A mixture of [Mo(NO)(Tp^{Me2})Cl$_2$] (0.50 g, 1.0 mmol), 2,2,3,3,4,4-hexafluoro-1,5-pentanediol (0.48 g, 2.2 mmol) and hexamethylenetetramine (0.14 g, 1.0 mmol) in dichloromethane (50 cm^3) was stirred and refluxed for 8 h. The solution was then cooled, filtered, evaporated *in vacuo* and the solid so obtained redissolved in CH_2Cl_2 and purified by column chromatography. Two turquoise fractions were separated and precipitated from CH_2Cl_2/*n*-hexane (0.09 g, 15.8%, bimetallic; 0.07 g, 10.3%, monometallic).

*3.2.4. Synthesis of [{Mo(NO)(Tp^{Me2})Cl}$_2${O(CH$_2$)$_6$O}] (**5**)*

[Mo(NO)(Tp^{Me2})Cl$_2$] (0.50 g, 1.0 mmol) together with hexane-1,6-diol (0.39 g, 3.3 mmol) and hexamethylenetetramine (0.22 g, 1.6 mmol) in dichloromethane (50 cm^3) was stirred and refluxed for 7 h. The resulting blue solution was cooled, filtered and evaporated to dryness. The residue was chromatographed on silica gel using dichloromethane as eluant to give a main blue fraction which was collected (0.1 g, 19.1%).

*3.2.5. Synthesis of [{W(NO)(Tp^{Me2})Cl}$_2${O(CH$_2$)$_3$O}] (**11**)*

The complex [W(NO)(Tp^{Me2})Cl$_2$] (0.59 g, 1.0 mmol) was dissolved in warm toluene (100 cm^3) and propane-1,3-diol (1.1 g, 14.5 mmol) were added. The mixture was stirred and refluxed for 8 h, during which time the solution became purple. After cooling to r.t., *n*-hexane was added and the reaction mixture was refrigerated overnight. The supernatant liquid was decanted from an oily deposit and the unreacted [W(NO)(Tp^{Me2})Cl$_2$], and the filtrate evaporated *in vacuo*. The solid obtained was chromatographed on silica gel using dichloromethane as eluant. The first fraction was collected and precipitated from CH_2Cl_2/*n*-hexane as a purple powder (0.09 g, 15.2%).

*3.2.6. Synthesis of [{W(NO)(Tp^{Me2})Cl}$_2${O(CH$_2$)$_n$O}] (n = 4–6) and [{W(NO)(Tp^{Me2})Cl}$_2${OCH$_2$(CF$_2$)$_3$CH$_2$O}] (**12**)–(**15**)*

These complexes were prepared similarly to **11**, which is described immediately above, with yields 15–25%.

*3.2.7. Synthesis of [{Mo(NO)(Tp^{Me2})I}$_2${O(CH$_2$)$_n$O}] (n = 3, 4) (**7**) and (**8**)*

To a solution of [Mo(NO)(Tp^{Me2})I$_2$] (0.50 g, 0.74 mmol) in dichloromethane (50 cm^3) the appropriate *n*-alkanediol (0.1 cm^3) and hexamethylenetetramine (0.12 g, 0.86 mmol) were added. The mixture was stirred and refluxed for 4 h affording a green solution which was cooled to r.t., then *n*-hexane was added and the mixture further was cooled to −10 °C. A precipitate and oily deposit were discarded and the supernatant solution was evaporated to dryness. The residue was purified by chromatography using dichloromethane as eluant. The first fraction was collected and precipitated from CH_2Cl_2/*n*-hexane as a green powder (yields *ca.* 25%).

*3.2.8. Synthesis of [{Mo(NO)(Tp^{Me2})Br}O(CH$_2$)$_2$O-{W(NO)(Tp^{Me2})Br}] (**16**)*

A mixture of [Mo(NO)(Tp^{Me2})Br(OCH$_2$CH$_2$OH)] (0.08 g, 0.14 mmol), [W(NO)(Tp^{Me2})Br$_2$] (0.11 g, 0.16 mmol) and hexamethylenetetramine (0.02 g, 0.14 mmol) was stirred and refluxed in benzene (20 cm^3) for 5 h and then stirred overnight at r.t. The resulting solution was filtered and the filtrate evaporated *in vacuo*. The residue was chromatographed on silica gel using dichloromethane as eluant. The second navy blue fraction was collected and precipitated from CH_2Cl_2/*n*-hexane (mixture of bimetallic diastereoisomers, 0.03 g, 18.3%).

*3.2.9. Synthesis of [{W(NO)(Tp^{Me2})Br}$_2${O(CH$_2$)$_2$O}] and [W(NO)(Tp^{Me2})Br{O(CH$_2$)$_2$OH}] (**9**) and (**10**)*

To a solution of [W(NO)(Tp^{Me2})Br$_2$] (0.50 g, 0.75 mmol) in dry dichloromethane (60 cm^3) ethane-1,2-diol (0.18 g, 2.9 mmol) and hexamethylenetetramine (0.11 g, 0.78 mmol) were added. The mixture was stirred and refluxed for 7 h. The solution was then cooled, filtered, evaporated *in vacuo* and the solid redissolved in CH_2Cl_2 and purified by column chromatography. Two purple fractions were separated and precipitated from CH_2Cl_2/*n*-hexane (0.11 g, 23.8%, mixture bimetallic of diastereoisomers; 0.06 g, 12.4%, monometallic).

*3.3. Crystal structure determination of **6***

The green crystals were obtained from CH_2Cl_2/*n*-hexane mixture. Selected crystal had dimensions 0.18 × 0.08 × 0.03 mm^3. X-ray data were collected on a Nonius Kappa CCD with graphite monochromated Mo Kα radiation

($\lambda = 0.71069$ Å). 11 984 reflections were measured ($2\theta_{max} = 54.9°$) at 293 K. Corrections for Lorentz and polarization were applied. The structure was solved by direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97 suite of programs [39]. The model, accepted as the 'correct' structure, gave final R $[= \Sigma(F_o - F_c)/\Sigma(F_o)]$ and $wR[= \Sigma\{w(F_o^2 - F_c^2)^2\}/\Sigma\{w(F_o^2)^2\}]^{1/2}$ values of 0.1300 and 0.2087, respectively for 618 parameters and all 11 984 data. The corresponding R values for 8012 data with $I > 2\sigma(I)$ were 0.0872 and 0.1899. The weighting scheme used was $w = 1/[\sigma^2(F_o^2) + (0.0520P)^2 + 39.1869P]$, where $P = (F_o^2 + 2F_c^2)/3$. All non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in calculated positions and refined isotropically.

3.3.1. Crystal data

$C_{19}H_{29}BIMoN_7O_4$, $M = 653.14$, monoclinic, space group $P2_1/n$, $a = 17.233(5)$ Å, $b = 14.213(5)$ Å, $c = 21.583(5)$ Å, $\beta = 95.882(5)°$, V=5259(3) Å^3, $Z = 4$, $D_c = 1.650$ g cm^{-3}, $F(0\,0\,0) = 2592$, μ(Mo Kα) = 1.710 mm^{-1}.

3.4. Crystal structure determination of *17 · 0.5I$_2$ · 0.5C$_6$H$_5$CH$_3$*

The dark brown crystals were grown from toluene and then recrystallised from a $CDCl_3$ solution used for the NMR measurement. A crystal ($0.11 \times 0.09 \times 0.08$ mm^3) was mounted on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71069$ Å). 20 433 reflections were scanned ($2\theta_{max} = 55.0°$) at 293 K. Lorentz and polarization corrections were applied. The structure was determined by direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97 suite of programs [39]. The model, accepted as the 'correct' structure, gave final R $[=\Sigma(F_o - F_c)/\Sigma(F_o)]$ and wR $[=\Sigma\{w(F_o^2 - F_c^2)^2\}/\Sigma\{w(F_o^2)^2\}]^{1/2}$ values of 0.1400 and 0.2940, respectively for 287 parameters and all 6080 data. The corresponding R values for 4295 data with $I > 2\sigma(I)$ were 0.1084 and 0.2768. Weighting scheme, $w = 1/[\sigma^2(F_o^2) + (0.0887P)^2 + 175.9498P]$, where $P = (F_o^2 + 2F_c^2)/3$. All non-hydrogen atoms were refined with anisotropic thermal parameters; hydrogen atoms were included in calculated positions and refined isotropically.

3.4.1. Crystal data

$C_{15}H_{22}BI_2WN_7O \cdot 0.5I_2 \cdot 0.5C_6H_5CH_3$, $M = 937.82$, monoclinic, space group $P2_1/c$, $a = 9.336(5)$ Å, $b = 17.409(5)$ Å, $c = 16.989(5)$ Å, $\beta = 105.843(5)°$, $V = 2656.3(18)$ Å^3, $Z = 4$, $D_c = 2.317$ g cm^{-3}, $F(0\,0\,0) = 1696$, μ(Mo Kα) = 7.858 mm^{-1}.

4. Conclusions

A series of bimetallic molybdenum and tungsten complexes with saturated *n*-alkanediolate bridging ligands and their monometallic analogues was synthesised and characterised. The monometallic complexes, [M(NO)(Tp^{Me2})X(Y)] (M = Mo or W; X = halide, Y = OR; X = Y = OR), underwent one-electron reductions at potentials which were strongly influenced by the nature of M, X and Y and substituents attached to them. The redox potentials ($E_{1/2}$-values) of the studied complexes [M(NO)(Tp^{Me2})X(OR)] (X = Cl, Br or I) decrease in the order I > Br > Cl, which can be explained in terms of $p(\pi) \rightarrow d(\pi)$ donation from X to Mo and not the electronegativity of the halogen. The $E_{1/2}$-values of the complexes [M(NO)(Tp^{Me2})Cl{O(CH$_2$)$_n$OH}] become more negative with increasing the length of the alkyl chain, and levelling off for $n = 5, 6$.

The electrochemical interactions in bimetallic complexes, measured as the separation between redox potentials of two redox centres, $\Delta E_{1/2}$, being large for the complex with a C_2 bridge (310 mV, Mo···Mo distance > 6 Å) decrease by *ca.* 100 mV per CH_2 group with increased length for C_2 to C_4 bridges. Starting with C_5 bridge the electrochemical interactions could not be detected and hence are assumed to be equal to the statistically based value of 35.6 mV. Stabilisation of $\{16{:}17\}^-$ species (K_c range 10 to 10^5) results mainly from through-space coulombic interactions but some polar effects transmitted through σ-bond framework could not be excluded.

The occurrence of a measurable separation between the redox potentials in [{M(NO)(Tp^{Me2})Cl}$_2${OCH$_2$(CF$_2$)$_3$CH$_2$O}] (M = Mo or W, $\Delta E_{1/2}$ respectively 70 and 60 mV) can be explained partly by through-bond interactions that may be assumed to occur in these compounds due to easier polarisation of the σ-bond framework containing fluorine.

Spectroscopic studies (UV–Vis–NIR) of the mixed-valence complexes and DFT calculations carried out at present should make it possible to fully explain the mechanism of the electronic interactions.

Abstract

The reactions of $[ReOBr_3(PPh_3)_2]$ and $[ReOBr_3(AsPh_3)_2]$ with bis(3,5-dimethypyrazol-1-yl)methane (bdmpzm) have been examined and novel dioxorhenium(V) complex $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$ has been obtained. The compound has been studied by IR, UV–Vis, ^1H NMR spectroscopy, magnetization measurements and X-ray crystallography. The electronic structure of the $[ReO_2(bdmpzm)_2]^+$ cation has been calculated with the density functional theory (DFT) method. The spin-allowed electronic transitions of $[ReO_2(bdmpzm)_2]^+$ have been calculated with the TDDFT/PCM method, and the UV–Vis spectrum of $[ReO_2(bdmpzm)_2]Br$ has been discussed on this basis.

1. Introduction

For many years, much attention has been focused on the synthesis and study of oxo transition metal complexes. Such compounds can transfer an oxygen atom to reductants such as phosphines, sulfides, and alkenes. Oxygen atom transfer chemistry has been implicated in various reactions of industrial and biological importance [1–3].

Especially interesting properties are observed for $[ReO_2L_4]^+$ complexes with pyridyl-type ligands. These compounds have attracted interest on account of both their electrochemical properties and their photophysical and photochemical reactivity characteristics [4,5].

Recently, related complexes have attracted attention in connection with the utilization of the ^{186}Re and ^{188}Re nuclides for therapeutic purposes in radiopharmacy [6,7]. Consequently, the inorganic chemistry studies with the naturally occurring non-radioactive rhenium isotopes are very attractive in order to clearly establish the molecular structure of ^{99m}Tc- and $^{186/188}Re$-based radiopharmaceuticals. In this context, the design, synthesis and reactivity of the rhenium oxocomplexes has become the aim of several laboratories, including ours.

This work forms part of a program on the synthesis and characterization of new families of oxorhenium compounds with N-donor ligands. In this report we focus on the examinations of the reactions of $[ReOBr_3(AsPh_3)_2]$

doi:10.1016/j.poly.2007.11.013

and $[ReOBr_3(PPh_3)_2]$ with bis(3,5-dimethypyrazol-1-yl) methane (bdmpzm).

Bis(pyrazol-1-yl)alkane and its derivatives constitute a family of stable and flexible bidentate ligands, isoelectronic and isosteric with the well-known bis(pyrazolyl)borates. The coordination properties of bis(pyrazol-1-yl)alkanes may be varied in a rather wide range by introducing substituents into the pyrazole rings. Hence, the donor ability of the ligands is determined by the presence of electron-withdrawing or electron-donating functional groups, and steric factors altered by the introduction of bulky alkyl groups into the rings and the alkane bridge between them [8].

These molecules form a variety of coordination compounds with main group and transition metals [9–14], but the rhenium complexes with these ligands have been studied relatively little [15–18].

Here we present synthesis, spectroscopic data and crystal, molecular and electronic structures of $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$. The electronic structure of the $[ReO_2(bdmpzm)_2]^+$ cation has been calculated with the density functional theory (DFT) method. The UV–Vis spectrum of the $[ReO_2(bdmpzm)_2]Br$ has been discussed on the basis of time-dependent DFT (TDDFT) calculations.

Recently, some theoretical investigations have been carried out on rhenium compounds. The electronic structures of nitrido, oxo, carbonyl, nitrosyl and nitrile rhenium complexes, as well as their spectroscopic properties, bonding and reactivity have been theoretically studied at the HF, MP2, EHT and DFT levels of theory using various basis sets [19–27]. Gancheff et al. [21] have performed extended tests of the ability of the B3LYP method in LANL2DZ basis set for rhenium compounds in a geometry optimization and calculation of spectral properties. Although this is not a very extended basis set, its use with DFT has shown to be sufficient for the geometry optimization and calculation of spectral properties. It gives good agreement with the experimental data and its use is justified in the case of large molecules.

2. Experimental

2.1. General procedure

All the reagents used to the synthesis were commercially available and were used without further purification. The $[ReOBr_3(PPh_3)_2]$ and $[ReOBr_3(AsPh_3)_2]$ complexes were prepared as reported previously [28], and bis(3,5-dimethypyrazol-1-yl)methane was synthesized according to the modified literature method [29].

IR spectrum was recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectrum was measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 1000–200 nm in dichloromethane solution. The ^1H NMR spectrum was recorded with a Bruker AM 400 spectrometer at room temperature using DMSO-d_6 as a solvent. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 Analyzer.

2.2. Preparation of $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$

$[ReOBr_3(PPh_3)_2]$ (0.5 g, 0.52 mmol) and bdmpzm (0.25 g, 1.22 mmol) were refluxed in ethanol (80 ml) for 5 h. The orange–brown solution was cooled and left to slow evaporation. The orange–brown crystals that formed were filtered and recrystallized from slow evaporation of an acetonitrile solution. Yield 60%.

IR (KBr, cm^{-1}) 3454 (m), 3423 (m), 3190 (m), 3118 (m) 3076 (m) 2993 (w), 1643 (w) 1557 (s) 1468 (s) 1425 (s), 1385 (s), 1373 (s), 1276 (s), 1228 (w), 1060 (s), 845 (s) 741 (w), 725 (w), 686 (s), 661 (w), 625 (w), 557 (w), 507 (w).

Anal. Calc. for $C_{22}H_{37}Br_2N_8O_4Re$: C, 32.08; H, 4.53; N, 13.61. Found: C, 32.25; H, 4.50; N, 13.43%.

^1H NMR (400 MHz, DMSO): $\delta = 2.30$ (s, 12H, $-CH_3$), 2.63 (s, 12H, $-CH_3$), 6.37 (s, 4H, $-CH_2-$), 6.58 (s, 1H, H^aC), 6.60 (s, 1H, H^bC), 7.60 (s, 1H, H^cC), 7.64 (s, 1H, H^dC).

2.3. Crystal structures determination and refinement

An orange–brown crystal of $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$ was mounted on a KM-4-CCD automatic diffractometer equipped with a CCD detector, and used for data collection. X-ray intensity data were collected with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at temperature of 293(2) K. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and empirical absorption correction using spherical harmonics implemented in SCALE3 ABSPACK scaling algorithm [30] were applied. The structure was solved by the Patterson method and subsequently completed by the difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. All the hydrogen atoms were found from difference Fourier synthesis after four cycles of anisotropic refinement, and refined as "riding" on the adjacent carbon atom with individual isotropic temperature factor equal 1.2 times the value of equivalent temperature factor of the endocyclic parent atom and equal 1.5 times the value of equivalent temperature factor of the methyl parent carbon atom. During refinement the methyl groups were allowed to rotate about theirs local threefold axes. The HBr hydrogen atom is symmetry disordered over two positions. SHELXS97 [31], SHELXL97 [32] and SHELXTL [33] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.4. Magnetic measurements

Magnetic measurements in the temperature range 1.8–300 K were performed using a Quantum Design SQUID-

based MPMSXL-5-type magnetometer. The SQUID magnetometer was calibrated with the palladium rod sample (Materials Research Corporation, measured purity 99.9985%). The superconducting magnet was generally operated at a filed strength ranging from 0 to 5 T. Measurements were made at a magnetic field of 0.5 T.

Corrections are based on subtracting the sample – holder signal and contribution χ_D estimated from the Pascal constants [34] and equal -408×10^{-6} cm^3 mol^{-1} for complex $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$. The effective magnetic moment was calculated from equation, $\mu_{eff} = 2.83\ (\chi_M T)^{1/2}$ (B.M.).

2.5. Computational details

The gas phase geometry of $[ReO_2(bdmpzm)_2]^+$ was optimized without any symmetry restrictions in the singlet ground-state using the hybrid B3LYP functional of GAUSSIAN-03 [35–37]. The LANL2DZ with additional *d* function with exponent $\alpha = 0.3811$ and *f* function with exponent $\alpha = 2.033$ ECP basis set [38,39] was chosen for the rhenium atom and the standard 6-31G basis set for all the other atoms. For oxygen and nitrogen atoms, diffuse and polarization functions were added [40,41]. The vibrational spectrum was calculated starting from the ground-state geometry optimized in the gas phase. All vibrations were real thus the geometry structure was a true energy minimum. TDDFT/PCM [42] calculations were employed to produce a number (90) of singlet excited-states starting from the ground-state geometry optimized in the gas phase.

3. Results and discussion

3.1. Preparation

Previously, we investigated the reactions of bis(pyrazol-1-yl)methane with $[ReOCl_3(AsPh_3)(OAsPh_3)]$ and $[ReOCl_3(PPh_3)_2]$ in acetone at ambient temperature. In both cases, only neutral turquoise blue $[ReOCl_3(bpzm)]$ complex has been precipitated from the reaction system [18]. The same compound was obtained in the reaction of $[ReOCl_3(PPh_3)_2]$ with bpzm under reflux in THF [17] and in the reaction of $[NBu_4][ReOCl_4]$ with bpzm [16]. Dilworth and co-workers reported also the formation of dimeric $[Re_2O_3Cl_4(bpzm)_2]$ species. The last one was formed slowly on standing the acetonitrile solution of $[ReOCl_3(bpzm)]$ in air [17].

A different course of the reaction is observed for bis(3,5-dimethypyrazol-1-yl)methane with $[ReOBr_3(PPh_3)_2]$ or $[ReOBr_3(AsPh_3)_2]$. The reactions of $[ReOBr_3(PPh_3)_2]$ or $[ReOBr_3(AsPh_3)_2]$ with bdmpzm were carried out in various conditions: at room temperature, under reflux, in acetone, acetonitrile or ethanol. In all the experiments, the orange–brown crystals of $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$ complex were formed after a few days from the reaction solutions. Refluxing of $[ReOBr_3(PPh_3)_2]$ with an excess of bis(3,5-dimethypyrazol-1-yl)methane (bdmpzm) in ethanol allows to obtain the title complex with the highest yield. Polar solvents favour the high lability of the bromo and phosphine ligands of the starting material [43].

The new complex has been characterized by IR, UV–Vis and ^{1}H NMR spectroscopy, elemental analysis, magnetic studies and X-ray crystallography, and its formulation $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$ is in good accordance with these results.

3.2. IR spectroscopy

The IR spectrum of the title complex displays a single O=Re=O asymmetrical stretching mode at 845 cm^{-1}, consistent with a *trans*-dioxo geometry and within the range accepted for dioxorhenium complexes with pyridyl-type ligands [4]. The characteristic band corresponding to the *ν*(CN), *ν*(C=C) mode of the bdmpzm ligand appears at 1557 cm^{-1} [44].

3.3. ^{1}H NMR spectroscopy

The methyl groups of two bdmpzm ligands appear as two singlets at, respectively, 2.30 and 2.63 ppm. Four singlets corresponding to the pyrazolyl CH protons appear at, respectively, 6.60, 6.58, 7.64 and 7.60 ppm. The singlet at 6.37 ppm is assigned to the protons of the methylene bridge of bdmpzm ligands. Lack of paramagnetic broadening or

shifts of resonances in the ^{1}H NMR spectrum of the title complex confirms its diamagnetism.

3.4. Magnetic properties

Magnetic data of the rhenium complex in the range 1.8–300 K indicated diamagnetism typical for the sample with $5d^2$ electron configuration of the rhenium(V) centers. Relation of the gram magnetic susceptibility in the whole range of measuring temperature characterized the complex as high purity. Also the relation of the magnetization of the sample at 2 K strongly supports this suggestion (0.02 B.M. at $H = 5$ T) (Fig. 2).

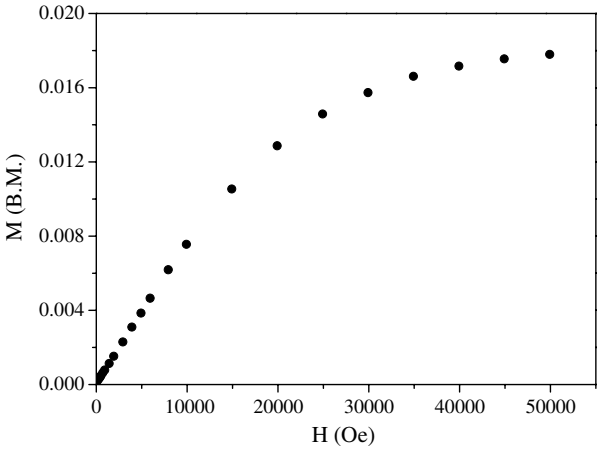

Fig. 2. Field dependence of the magnetization for complex $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$ at 2 K.

3.5. Crystal structure

The compound $[ReO_2(bdmpzm)_2]Br$ (Fig. 1) has been obtained in crystalline form as a solvate with two H_2O and one HBr molecules per Re-containing cation. The Br^- ions and HBr molecules occupy alternatively the same crystallographic position. The rhenium atom occupies the special position *a* of *C*2/*m* space group with site symmetry 2/*m* and site multiplicity 2. In consequence the complex cation $[ReO_2(bdmpzm)_2]^+$ occupy four asymmetric units and the O(1)–Re(1)–O(1)#1, N(2)–Re(1)–N(2)#1 and N(2)#2–Re(1)–N(2)#3 bonds angles (symmetry operators used to generate equivalent atoms: #1 $-x$, $-y$, $-z$; #2 x, $-y$, z; #3 $-x$, y, $-z$) are linear by symmetry. The Br(1), C(6), O(1), O(99) atoms also occupy special positions *h* (Br atom) and *i* (C, O atoms) with site symmetry, respectively, 2 and *m* and multiplicity 4. The molecules are linked *via* one medium strength O(99)—H(99P) $\cdots$ Br(1) (D $\cdots$ A distance 3.276(3) Å and D–H $\cdots$ A angle 168.8) and 1 weak C(2)–H(2) $\cdots$ Br(1)#($1/2 - x$, $1/2 - y$, $1 - z$) (D $\cdots$ A distance 3.785(3) Å and D–H $\cdots$ A angle 156.5°) intermolecular hydrogen bonds to the double chain along crystallographic *b*-axis. The weak intramolecular hydrogen bond linking C(6)–H(6A) $\cdots$ O1(1) atoms (D $\cdots$ A distance 2.956(4) Å and D–H $\cdots$ A angle 124.2) provides additional stabilization to the molecule of title compound [45,46]. The crystallographic data for $[ReO_2(bdmpzm)_2]Br \cdot HBr \cdot 2H_2O$ are given in Table 1, and molecular structure of the $[ReO_2(bdmpzm)_2]Br$ complex is presented in Fig. 1. The dioxo complex shows approximately octahedral coordination geometry with the oxo ligands in the axial positions. The equatorial plane of the Re center is occupied by two bidentate bdmpzm molecules. Upon coordination of bis(3,5-dimethypyrazol-1-yl)methane to the rhenium, a

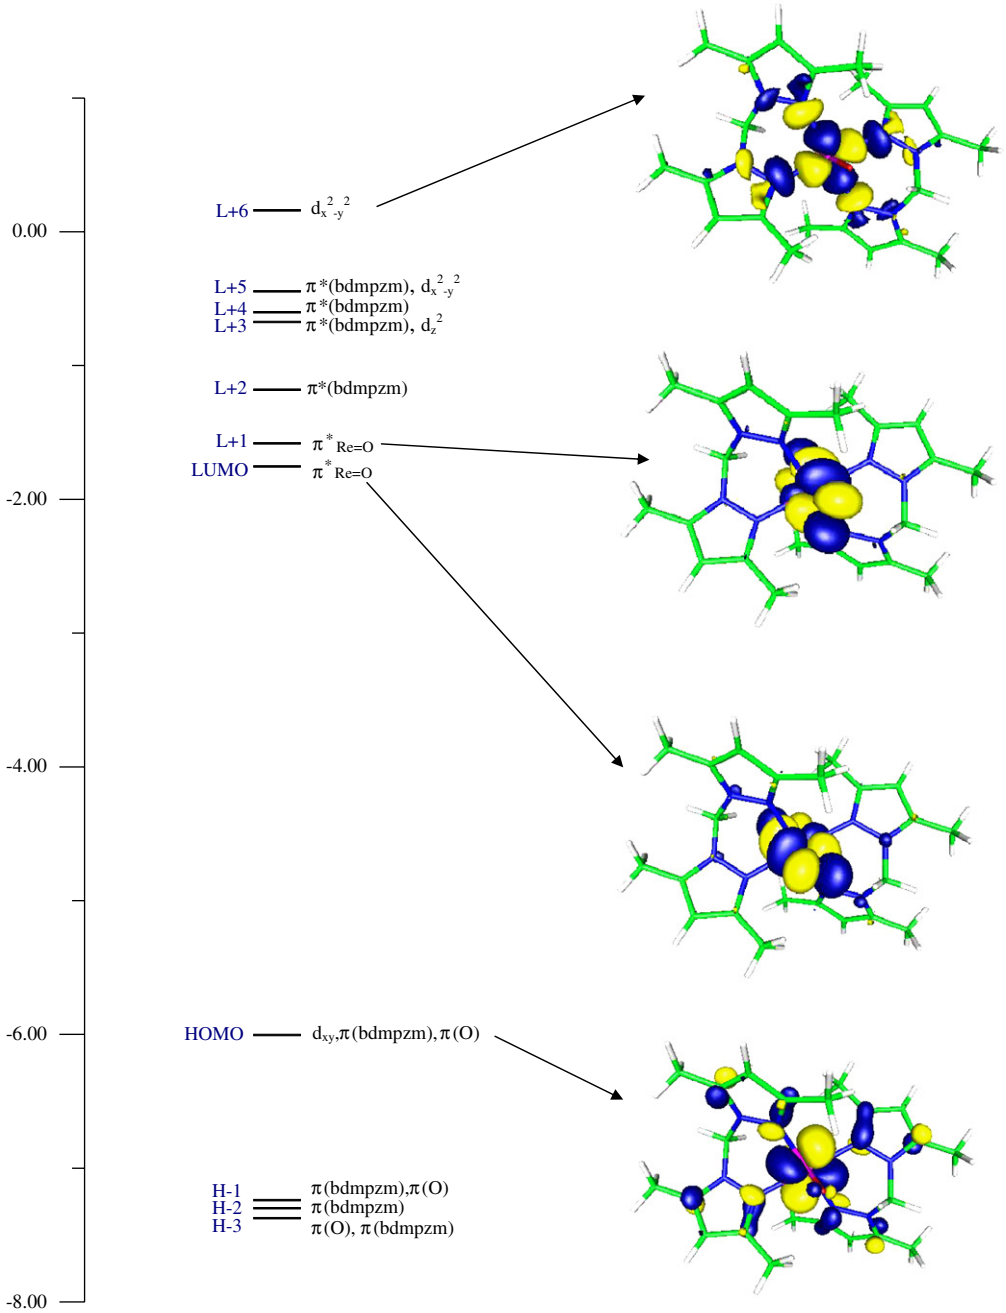

Fig. 3. The energy (eV), character and some contours of the occupied molecular orbitals of the $[ReO_2(bdmpzm)_2]^+$ cation. Positive values of the orbital contour are represented in yellow (0.04 a.u.) and negative values – in blue (−0.04 a.u.). (For interpretation of the references to colour in this figure legend, the reader is referred to see the web version of this article.)

six-membered cycle (made by the four nitrogen atoms, the rhenium atom and the carbon atom) is formed, and the formed ring shows a *boat* conformation with the rhenium and the carbon atoms off the plane defined by the four nitrogen atoms (deviations of 0.809(4) and 0.632(4) Å, respectively, from symmetry planar N_4 moiety). The flapping ReN_2 and CN_2 triangles are inclined to N_4 plane at 30.9(1)° and 49.9(3)°, respectively. The planar in the range of experimental error pyrazole rings are inclined at 63.13(9)°.

The selected bond lengths and angles of the $[ReO_2(bdmpzm)_2]^+$ cation are given in Table 2. The Re–O bond length (1.779(2) Å) falls in the range typical of mononuclear complexes of rhenium(V) having $[ReO_2]^+$ core, but it is one of the longest [47,48].

The Re–N distance, equal 2.1221(19) Å, is also similar to those found in complexes with other N-heterocycles. For $[ReO_2(2\text{-MeImH})_4]^+$, $[ReO_2(py)_4]^+$ and $[ReO_2(en)_2]^+$ cations, average rhenium-oxo distances are 1.766, 1.764 and 1.765 Å, and average Re–N bond lengths are 2.121, 2.148 and 2.162 Å, respectively [5].

3.6. Geometry optimization

The gas phase geometry of $[ReO_2(bdmpzm)_2]^+$ cation was optimized in a singlet state by the DFT method with the hybrid B3LYP functional. The optimized geometric parameters of $[ReO_2(bdmpzm)_2]^+$ are gathered in Table 2. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

3.7. Electronic structure

The molecular orbital diagram of the $[ReO_2(bdmpzm)_2]^+$ cation with several highest HOMO and lowest LUMO contours is presented in Fig. 3. The HOMO–LUMO gap equals to 4.25 eV. The highest occupied MO of $[ReO_2(bdmpzm)_2]^+$ is predominantly of d_{xy} type with some contributions from bdmpzm orbitals and p_π oxygen orbitals. The remaining four d-type orbitals of rhenium are found among unoccupied MOs. It confirms d^2 configuration of the rhenium atom.

The rhenium atom uses its six valence orbitals, $5d_{x^2-y^2}$, $5d_{z^2}$, 6s, $6p_x$, $6p_y$ and $6p_z$ to form σ-bonds with the six ligands, empty $5d_{xz}$ and $5d_{yz}$ orbitals are available to overlap with $2p_x$ and $2p_y$ orbitals on the oxygen atoms to form two double bonds in the $[O{=}Re{=}O]^+$ core. The LUMO and LUMO+1 orbitals can be ascribed as π-antibonding rhenium–oxygen interactions (Fig. 3).

3.8. Electronic spectrum

The experimental and calculated electronic spectrum of $[ReO_2(bdmpzm)_2]Br$ are presented in Fig. 4. Each calculated transition is represented by a gaussian function

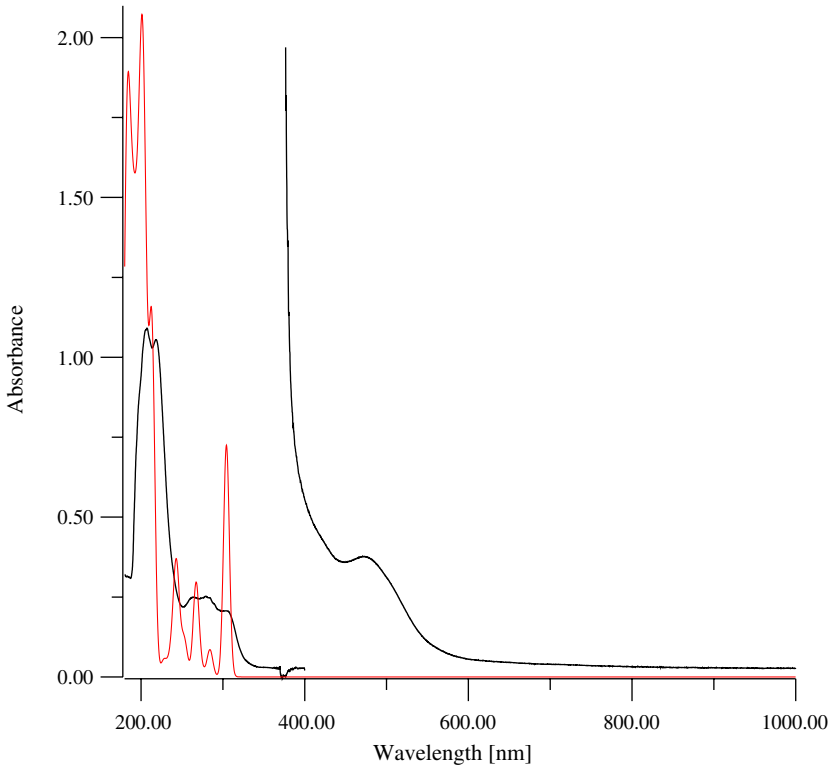

Fig. 4. The experimental (black) and calculated (red) electronic absorption spectrum of $[ReO_2(bdmpzm)_2]Br$. (For interpretation of the references to colour in this figure legend, the reader is referred to see the web version of this article.

ε: molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$); f: oscillator strength; H: highest occupied molecular orbital; L: lowest unoccupied molecular orbital.

$y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}.

The spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method for $[ReO_2(bdmpzm)_2]^+$ are gathered in Table 3. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.020 are listed in Table 3.

The lowest energy electronic transition in the *trans*-dioxo complex (at 478.7 nm) corresponds to $d_{xy} \rightarrow d_{xz/yz}$ orbital excitation and occurs between the $^1A_{1g}$ ground-state and the ^3E_g leading to a spin-forbidden d–d band. The spin-forbidden d–d bands are often observed in the absorption spectra of many dioxo Re(V) complexes, and they indicate that the structural deviations from the expected D_{4h} symmetry have only a minor effect on the energy of electronic states and on the spectra [5].

The intense absorption bands at 305.5, 283.6 and 262.0 nm are assigned to the *Metal–Ligand Charge Transfer* (occurring from the rhenium ion to the π-antibonding orbitals of the bdmpzm ligands) and *Ligand–Metal Charge Transfer* ($\pi_{bdmpzm}/\pi_O \rightarrow d$) transitions. In the experimental spectrum the intensities of the abovementioned bands are very similar, whereas the oscillator strength of the calculated band at 304.4 nm is significantly higher in comparison with the oscillator strengths of the other bands calculated in the region 320–240. These differences between experimental and calculated spectrum can be assigned to intensity borrowing effect or may come from the basis sets which are approximated to a certain extent.

The highest energy experimental absorption bands of $[ReO_2(bdmpzm)_2]Br$ at 218.5 and 208.3 nm result from *Ligand–Ligand Charge Transfer* and interligand (IL) transitions.

4. Supplementary material

CCDC 658076 contains the supplementary crystallographic data for $C_{22}H_{37}Br_2N_8O_4Re$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2. 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Abstract

The bivalent zinc and cadmium complexes of two Schiff bases N-(2-pyridylmethyl)pyridine-2-carbaldimine (**L1**), N-(2-pyridylmethyl)pyridine-2-methylketimine (**L2**), tridentate ligands with an N_3 chromophore and coordinating with two five-membered chelate rings, were synthesized. Complexes $[Zn(\mathbf{L1})(NO_3)_2]$ (**1**), $[Zn(\mathbf{L2})(NO_3)_2]$ (**2**), $[Cd(\mathbf{L1})(NO_3)_2(H_2O)]$ (**3**) and $[Cd(\mathbf{L2})(NO_3)_2(CH_3OH)]$ (**4**) were characterized by X-ray crystallography. In **1** and **2**, Zn(II) has a distorted square-pyramidal geometry where as in **3** and **4**, Cd(II) possesses a pseudo-pentagonal-bipyramidal geometry. The following trends in the bond lengths are observed: $M–N_{im} < M–N_{py}$; Zn–N > Zn–O; Cd–N < Cd–O. The final residues from the thermogravimetric analysis are ZnO and CdO, the SEM studies revealed, respectively, their porous and spherical natures. The average activation energy (E) for the loss of pyridine rings obtained from the Friedman fitting of the DSC data, for **1**, **2**, **3**, and **4** are 193.8(2), 114.5(3), 127.1(4), and 63.7(3) kJ mol^{-1} and their logarithmic pre-exponential factor (A) are 11.22, 5.31, 6.88, and 2.09, respectively.

1. Introduction

Self-assembly of coordination compounds to 1D, 2D, and 3D supramolecules is of much interest [1]. Use of $M(NO_3)_2$ fragment in developing supramolecularly assembled materials, which find application in storing small molecules or ions, as chemical sensors, and the use of the channels or cavities as templates for catalysis, is reviewed [1d]. The combination of nitrate anions and pyridyl donor ligands leads to a subtle balance of nitrate *versus* pyridyl coordination resulting in interesting anion effects. Complexes containing aromatic moieties usually exhibit interactions like π–π stacking, C–H···π, D–H···A, and these are important packing forces in the solid state.

Zinc and cadmium oxides have been the subject of intense interest due to their wide ranging applications [2,3]. Synthesis of nano-structured sheets, belts, rods, tubes and wires are being investigated [4]. The controlled growth of ZnO nanobelts exhibiting piezoelectric and ferroelectric properties is reviewed [5a]. One-dimensional ZnO and CdO nanobelts act as semiconductors, which are used for fabrication of field-effect transistors and gas sensors [5]. The preparations of ZnO and CdO nanostructures by thermolysis, their Raman and photoluminescence properties are also reported [5,6].

As a part of our research programme, we have been investigating the coordination chemistry of tridentate Schiff base ligands containing pyridine rings [7]. With Cu^{2+} salts, N-(2-pyridylmethyl)pyridine-2-carbaldimine (**L1**) and N-(2-pyridylmethyl)pyridine-2-methylketimine (**L2**) behave differently: **L1** is oxidized to bis(2-pyridylcarbonyl)amide (bpca), in which both the imine and the methylene groups

doi:10.1016/j.poly.2007.11.011

are oxidized; **L2** is converted to 4′-(2-pyridyl)-2,2′:6′,2″-terpyridine, during which the methylene group is oxidized and the methylketimine function involving in a double condensation with 2-acetylpyridine [7a]. As continuation, the complexation behavior of **L1** and **L2** towards d^{10} systems *viz.* Zn(II) and Cd(II) were studied and the nature of the final oxide product of the thermal decomposition are reported in this paper.

2. Experimental

2.1. Instrumentation and materials

FT-IR spectrum in the range 4000–400 cm^{-1} was recorded using Perkin–Elmer Spectrum One. Elemental analysis was performed by Perkin–Elmer Series II CHNS/O Analyzer 2400. $Cd(NO_3)_2 \cdot 4H_2O$, $Zn(NO_3)_2 \cdot 6H_2O$ were

purchased from Merck India Ltd. and pyridine-2-carbaldehyde, 2-acetylpyridine and 2-picolylamine from M/S Aldrich, USA. N-(2-pyridylmethyl)pyridine-2-carbaldimine (**L1**) and N-(2-pyridylmethyl)pyridine-2-methylketimine (**L2**) were prepared as reported earlier [7a]. All the chemical and solvents were of reagent grade and used as received without further purifications.

2.2. X-ray crystallography

Single crystals X-ray crystallographic data were collected using Bruker SMART APEX-CCD diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å). The intensity data were corrected for Lorentz and polarization effects and empirical absorption corrections was applied using SAINT program [8,9]. All the structures were solved by direct methods using SHELXS-97 [9]. Non-hydrogen atoms located from the difference Fourier maps were refined anisotropically by full-matrix least-squares on F^2, using SHELXL-97 [9]. The hydrogen atoms were included in the calculated positions and refined isotropically using a riding model. Crystal data and bond parameters are listed in Tables 1 and 2, respectively.

2.3. Thermal measurements

Thermogravimetry were studied by a computer controlled METTLER TOLEDO STAR^e system of module TGA/SDTA851^e under static nitrogen atmosphere using platinum pan at a heating rate of 10 °C/min in the temperature range 25–700 °C. The instrument was calibrated using RTypSDTA sensor. Onset temperature obtained from DTG curve is used to evaluate the onset decomposition temperature of the samples. DSC profiles were recorded by a computer controlled METTLER TOLEDO STAR^e system of module DSC821^e under static nitrogen atmosphere. Temperature and energy of the instrument were calibrated by standard indium using the FRS5 ceramic sensor. A 70 μL aluminium pan was used for the temperature range 25–600 °C, for recording the profiles at heating rates of 10, 15, 20, 25, 28, and 30 °C min^{-1}.

2.4. Syntheses

[Zn(**L1**)$(NO_3)_2$] (**1**): To 258 mg (1.31 mmol) of **L1**, dissolved in 25 cm^3 of methanol was added 390 mg (1.31 mmol) of $Zn(NO_3)_2 \cdot 6H_2O$ solid with stirring. A transient violet color disappeared and the solution was left undisturbed after 10 min. Colorless crystals obtained after 3 days were collected after washing with ice-cold methanol. Yield: 0.22 g (43%). IR (KBr, cm^{-1}): 1665 (C=N_{im}), 1602 (C=N_{py}). *Anal.* Calc. for $C_{12}H_{11}N_5O_6Zn$: C, 37.24; H, 2.85; N, 18.11. Found: C, 37.48; H, 2.91; N, 18.35%.

[Zn(**L2**)$(NO_3)_2$] (**2**), [Cd(**L1**)$(H_2O)(NO_3)_2$] (**3**) and [Cd(**L2**)$(CH_3OH)(NO_3)_2$] (**4**) were prepared as described above using 1.31 mmol of respective ligand and metal nitrates.

[Zn(**L2**)$(NO_3)_2$] (**2**): Yield: 0.23 g (43%). IR (KBr, cm^{-1}): 1673 (C=N_{im}), 1610 (C=N_{py}). *Anal.* Calc. for $C_{13}H_{13}N_5O_6Zn$: C, 38.93; H, 3.24; N, 17.47. Found: C, 39.09; H, 3.31; N, 17.55%.

[Cd(**L1**)$(H_2O)(NO_3)_2$] (**3**): Yield: 0.35 g (59%). IR (KBr, cm^{-1}): 1653 (C=N_{im}), 1595 (C=N_{py}). *Anal.* Calc. for $C_{12}H_{13}N_5O_7Cd$: C, 31.88; H, 2.88; N, 15.50. Found: C, 31.99; H, 2.96; N, 15.68%.

[Cd(**L2**)$(CH_3OH)(NO_3)_2$] (**4**): Yield: 0.33 g (40%). IR (KBr, cm^{-1}): 1651 (C=N_{im}), 1590 (C=N_{py}). *Anal.* Calc. for $C_{14}H_{17}N_5O_7Cd$: C, 35.02; H, 3.54; N, 14.59. Found: C, 35.11; H, 3.62; N, 14.70%.

3. Results and discussion

3.1. Molecular structures

Compound **1** crystallized in the space group $P2_1/n$, belong to 2/m Laue symmetry and the asymmetric unit contained one molecule of [Zn(**L1**)$(NO_3)_2$]. Bivalent zinc is pentacoordianted by N_3O_2 chromophore and has a distorted square-pyramidal geometry, as inferred from the τ value of 0.19 [10]. The N1N2N3O1 forms the basal plane with the O4 atom of the monocoordinated NO_3^-, occupying the axial position. A perspective view of **1** is shown in Fig. 1. The Zn–N_{im} distance is shorter than the Zn–N_{py} distances by an average of 0.027(3) Å and the Zn–N bond lengths are longer than the Zn–O distances by 0.066(3) Å. The longer Zn1···O2, 2.626(2) Å and Zn1···O5, 2.723(2) Å contacts are present. The chelate rings, Zn1N2C7C8N3 and Zn1N2C6C5N1 are planar and the inter-plane angle of these two is 4.78(1)°. The plane formed by the chelate and the pyridine rings intercept at ~1.55(1)°. The inner angles at C7 and C6 are, respectively, are 115.22(1)° and 113.44(1)° and are deviating from the ideal values for a sp^2 and sp^3 carbon. The packing diagram of **1** on viewing down the *a*-axis (shown in Fig. 2) reveals the

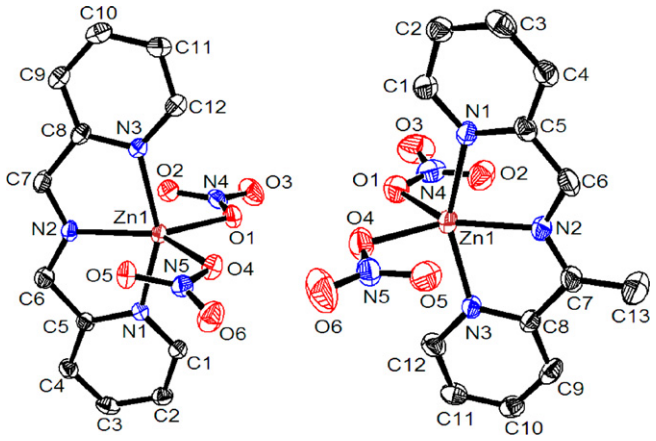

Fig. 1. ORTEP (30% probability) diagram of **1** and **2** (hydrogens are omitted for clarity).

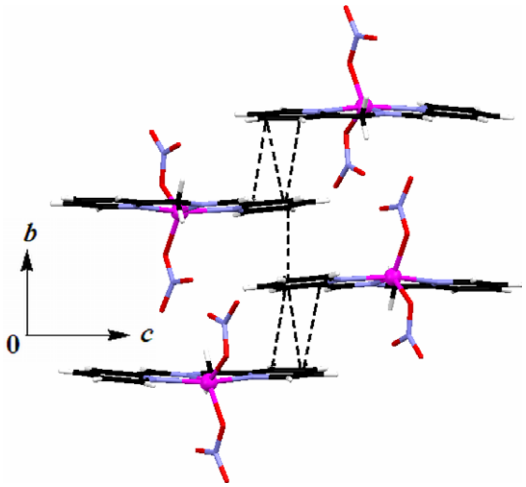

Fig. 2. Packing diagram of **1**.

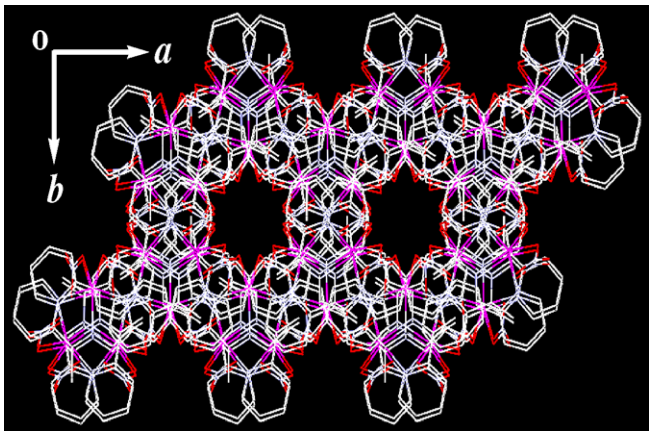

Fig. 3. Packing diagram of **2**.

presence of π–π and C–H···O interactions. The intermolecular π–π contacts are C4···C9 3.287(3) Å, C3···C9 3.348(3) Å, C9···C9 3.361(3) Å and C3···C8 3.379(3) Å.

Compound **2** crystallized in the hexagonal space group $P6_5$, belongs to 6/m Laue symmetry and one molecule of $[Zn(\mathbf{L2})(NO_3)_2]$ is present in the asymmetric unit. The Zn(II) ion has a distorted square-pyramidal geometry with a τ value of 0.26 and has a N_3O_2 coordination environment. In this case also the N1N2N3O1 atoms form the distorted square plane along with O4 at the apical position. A perspective view of **2** is shown in Fig. 1. The following trends are observed: $Zn–N_{im} < Zn–N_{py}$ by an average of 0.057(2) Å and the Zn–N > Zn–O by 0.054(3) Å. The longer Zn1···O2, 2.578(3) Å and Zn1···O5, 2.602(3) Å contacts are present. The chelate rings, Zn1N2C7C8N3 and Zn1N2C6C5N1 are nearly planar and are twisted with respect to each other with the twist angle being 3.37(1)°. The inner angles at sp^2 C7 and sp^3 C6 are, respectively, 113.44(1)° and 114.59(1)°. The packing diagram of **2** on viewing down the *c*-axis is shown in Fig. 3. The predominantly hydrophilic channels of hexagonal cavity of dimension ~4.763 Å containing the O1, O3, O4, and O6 align along *c*-axis. The π–π interactions having intermolecular contacts, C4···C9 3.310(11) Å, C3···C9 3.323(12) Å, C4···C10 3.321(11) Å are dominant in the packing.

The X-ray crystal structure of **3** shows the presence of a discrete mononuclear complex. The Cd(II) is hepta-coordinated by **L1** in a tridentate fashion, one NO_3^- in monodentate and the other in bidentate fashions, and a water molecule. The overall coordination is pseudo-pentagonal-bipyramidal geometry and a perspective view is shown in Fig. 4. The $Cd–N_{im}$ is shorter than the $Cd–N_{py}$ by 0.051(4) Å and the Cd–N bond lengths are shorter than the Cd–O distances by 0.073(5) Å. The chelate rings, Cd1N2C7C8N3 and Cd1N2C6C5N1 are planar and both intercept at an angle 2.21(1)°. The bidentate nitrate ion occupies the pentagonal base and deviates from the plane formed by the two chelate rings by an angle 15.11(1)°. The O2···O7, 2.923(6) Å hydrogen bond and Cd···O6, 2.650(7) Å contact are present.

A discrete mononuclear species of **4** crystallized in an orthorhombic space group *Pbca*, belongs to mmm Laue

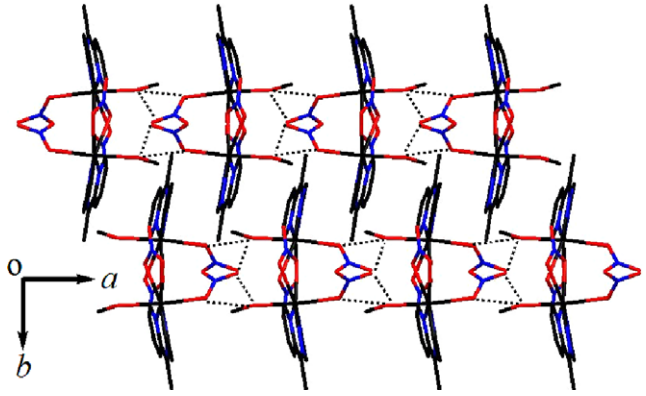

Fig. 5. Packing diagram of **4** viewing down the *c*-axis.

symmetry. The pseudo-pentagonal-bipyramidal geometry around Cd(II) consists of, tridentate **L2**, a monodentate and a bidentate NO_3^- ions, as well as a methanol. A perspective view of **4** is shown in Fig. 4. The Cd–N bond lengths are shorter than the Cd–O distances by 0.050(7) Å. The chelate rings, Cd1N2C7C8N3 and Cd1N2C6C5N1 are planar and both intercept at an angle 7.64(1)°. The plane formed by the chelate and the pyridine rings intercept at ~3.22(1)°. The bidentate nitrate ion occupies the pentagonal base and is twisted with respect to the two chelate rings by an angle 20.50(1)°. The hydrogen bonds, O7···O4, 3.001(10) Å and O7···O5, 2.933(14) Å between the methanol and monodentate nitrate ion dominate the packing diagram, is shown in Fig. 5.

3.2. Thermal decomposition

The thermal decomposition of **1**–**4** was observed using TGA. In **1** and **2** the first step is the loss of $NO_{(g)}$, while in **3** and **4**, coordinated solvent is lost in addition. The volatile components released in step II could not be analyzed and the residue obtained after calcination at respective end-temperatures showed the absence of imine function and the presence of pyridine ring. Loss of two moles of pyridine occur in step III, leaving behind the corresponding metal oxide (ZnO and CdO) as the final residual part. The temperature ranges for the three steps are listed in Table 3.

Table 3
TGA temperature (°C)

Complex	Step I	Step II	Step III
1	35–115	115–280	280–570
2	35–125	125–285	280–580
3	35–120	120–320	320–590
4	35–140	140–280	280–595

The morphology of crystalline samples of **1**–**4** after calcinations at 600 °C, were evaluated by SEM and that from **1** and **4** is shown in Fig. 6. The ZnO obtained from **1** and **2**, are porous in nature having the minimum pore size range of 600–900 nm. Spherical CdO crystalline particles from **3** and **4** are of the size 115–330 nm.

3.3. Kinetics of thermal elimination of pyridine

Thermokinetics of the loss of two moles of pyridine (step III) were analyzed utilizing the DSC data for **1**–**4**. Good analysis was possible with differential iso-conversional method *viz.* Friedman method, which utilizes the differential equation

$$\ln(\mathrm{d}\alpha/\mathrm{d}t)|_{\alpha-\alpha_j} = \ln A - \frac{E}{RT_{kj}} + \ln f(\alpha_j)$$

where α is small ranges of reaction progress, E is the activation energy, A is the pre-exponential factor, R is the universal gas constant [11]. In all the cases, the activation energy remain constant in the region $\alpha = 0.2$–0.9, which is suggestive of a single step reaction. A representative analysis plot of **1** and **3** are displayed in Fig. 7. The average activation energy (E) for **1**, **2**, **3**, and **4** are 193.8(2), 114.5(3), 127.1(4), and 63.7(3) kJ mol^{-1} and their

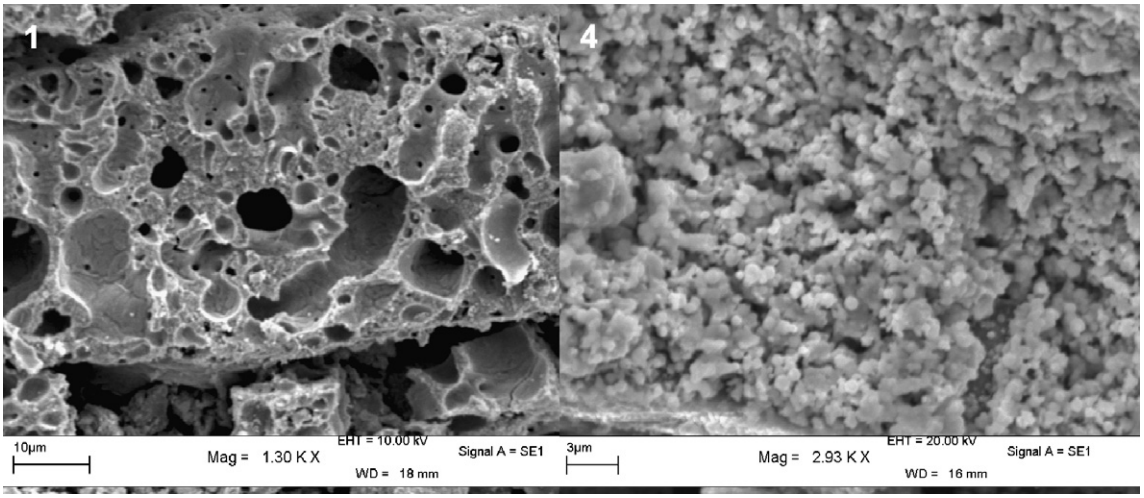

Fig. 6. SEM picture of **1** and **4** calcined at 600 °C.

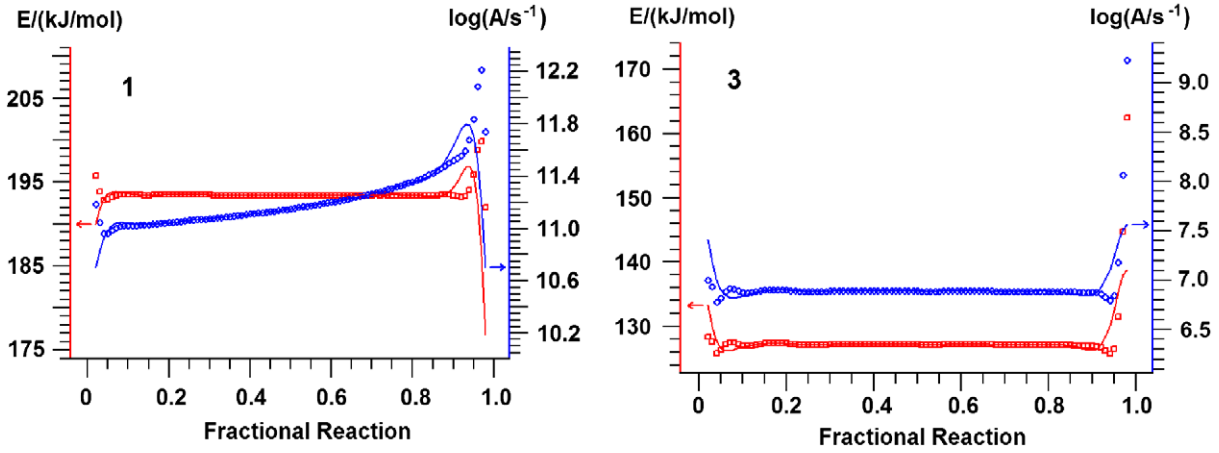

Fig. 7. Friedman plot of **1** and **3** (symbols are the experimental values and lines are simulated).

logarithmic pre-exponential factor (A) are 11.22, 5.31, 6.88, and 2.09, respectively.

4. Conclusion

Four complexes of bivalent zinc and cadmium based on a tridentate-N_3 ligand were synthesized and structurally characterized. Zinc and cadmium complexes, respectively, have pseudo square-pyramidal and pentagonal-bipyramidal geometries. The following trends in the bond lengths are observed: $M–N_{im} < M–N_{py}$; $Zn–N > Zn–O$; $Cd–N < Cd–O$. The final residual part of thermal decompositions are ZnO and CdO, the SEM studies revealed, respectively, their porous and spherical natures. The activation parameters obtained from the Friedman fitting of the DSC profiles for the loss of pyridine rings are reported.

Abstract

Self-assembly of a new carboxylate containing ligand, *N*-(3-carboxyphenyl)iminodiacetic acid (H_3L), with Cd(II) and Co(II) salts under different reaction pH results in the formation of four new coordination polymers, namely $[Cd(HL)(H_2O)]$ (**1**), $[Co(HL)(H_2O)]$ (**2**), $[Cd(HL)(H_2O)_4]$ (**3**) and $[Cd_3(L)_2(H_2O)_9]\cdot 7H_2O$ (**4**). Single crystal X-ray diffraction analysis indicates that **1** and **2** are isomorphous and isostructural with a 2D wave-like network structure, while **3** has a 1D zigzag chain structure. The complexes **1**–**3** were obtained at low pH (<7) which makes the ligands only partly deprotonated. However, complex **4**, obtained at pH 7 with all the carboxylate groups deprotonated, exhibits a 2D network structure. The results suggest that the reaction pH is one of the key factors in the formation of the coordination architectures. In addition, the photoluminescence properties of the free ligand (H_3L) and complexes **1**, **3** and **4** were studied in the solid state at room temperature. Moreover, the magnetic property of complex **2** was investigated.

1. Introduction

In recent years, much attention has been focused on metal–organic frameworks (MOFs) due to their fascinating structures such as zero-dimensional (0D) cages, one-dimensional (1D) helical chains, two-dimensional (2D) grids and three-dimensional (3D) frameworks [1], as well as their attractive properties which can be further utilized in the fields of magnetism, catalysis, absorption, optics, etc. [2]. Among them, MOFs with carboxylate containing ligands are especially of great interest in recent years because the carboxylate groups can adopt varied coordination modes such as monodentate, bis-monodentate, chelating, and as a result diverse structures can be obtained [3]. However, it is still a labyrinth because not all of the structures could be generated as predicted, which might be attributed to the factors that influence the formation of the architectures [4]. Particularly, the pH value of the reaction solution and crystallization conditions are crucial parameters, for example, Stock and co-workers have demonstrated the role of the acid/base ratio, temperature, etc., in determining the structure of the complexes [5].

Taking in account of the factors mentioned above, we have focused our attention on the reactions of various metal salts with multi-carboxylate ligands and the influence of reaction pH on the structure of the resultant complexes was investigated. Recently, a new carboxylate containing

Scheme 1. Schematic drawing structure of the H_3L ligand.

ligand, *N*-(3-carboxyphenyl)iminodiacetic acid (H_3L) (Scheme 1), was obtained, which has remarkable features as follows: (a) it contains three carboxylate groups, therefore quite a lot of bridging modes could be adopted in the formation of MOFs; (b) the three carboxylate groups would be partially or completely deprotonated by tuning the reaction pH; (c) it is a semi-rigid ligand with a carboxyphenyl group fixed and an iminodiacetic moiety which is somewhat flexible, whereby different conformations of the ligand could be achieved which would further generate various architectures; (d) the introduced aromatic and the carboxylate groups could offer additional π–π and hydrogen bonding interactions, respectively, to further consolidate the structure [6].

Herein, we report the synthesis, crystal structure and properties of four new coordination polymers, namely $[Cd(HL)(H_2O)]$ (**1**), $[Co(HL)(H_2O)]$ (**2**), $[Cd(HL)(H_2O)_4]$ (**3**) and $[Cd_3(L)_2(H_2O)_9]\cdot 7H_2O$ (**4**), obtained by the reactions of H_3L with $Cd(NO_3)_2\cdot 4H_2O$ or $CoCl_2\cdot 4H_2O$ under different reaction pH.

2. Experimental

2.1. Materials and methods

All commercially available chemicals and solvents are of reagent grade and were used as received without further purification. Elemental analyses for C, H and N were performed on a Perkin–Elmer 240C Elemental Analyzer at the Analysis Center of Nanjing University. FT-IR spectra were recorded in the range 400–4000 cm^{-1} on a Bruker Vector22 FT-IR spectrophotometer as KBr pellets. ^1H NMR spectra were measured on a Bruker DRX 500 MHz NMR spectrometer at room temperature. Magnetic measurements for complex **2** in the range 1.8–300 K were performed on a MPMS-SQUID magnetometer at a field of 2 kOe on crystalline samples in the temperature settle mode. The diamagnetic contributions of the samples were corrected by using Pascal's constants. The luminescent spectra for the powdered solid samples were recorded at room temperature on an Aminco Bowman Series 2 spectrofluorometer with a Xenon arc lamp as the light source. In the measurements of emission and excitation spectra the pass width was 5.0 nm. All the measurements were carried out under the same experimental conditions.

2.2. Synthesis of the ligand N-(3-carboxyphenyl)iminodiacetic acid (H_3L)

A solution of KOH (33.6 g, 0.6 mol) in water (100 ml) was added dropwise to a solution of monochloroacetic acid (28.4 g, 0.3 mol) in water (100 ml). To the resulting alkaline solution, 3-aminobenzoic acid (13.7 g, 0.1 mol) was added and the mixture was refluxed for 30 h. Then the reaction mixture was cooled to room temperature and a pale brown precipitate appeared, which was collected by filtration, washed by water and recrystallized from water (yield: 52% based on 3-aminobenzoic acid). ^1H NMR (500 MHz, in K_2CO_3, D_2O): δ 7.18 (t, 1H), 7.03 (d, 1H), 6.89 (s, 1H), 6.55 (d, 1H), 3.83 (s, 4H). IR (KBr pellet, cm^{-1}): 3446 (w), 2926 (w), 2552 (w), 1723 (m), 1682 (s), 1603 (m), 1580 (m), 1494 (w), 1465 (m), 1423 (w), 1376 (m), 1361 (m), 1299 (m), 1230 (w), 1183 (w), 1130 (w), 992 (w), 975 (w), 864 (w), 757 (m), 679 (w), 661 (w), 608 (w).

2.3. Synthesis of the complexes

2.3.1. Synthesis of $[Cd(HL)(H_2O)]$ (**1**)

A mixture containing $Cd(NO_3)_2\cdot 4H_2O$ (30.8 mg, 0.1 mmol), H_3L (25.3 mg, 0.1 mmol), KOH (2.8 mg, 0.05 mmol), 6 ml H_2O and 3 ml CH_3OH was sealed in a 16 ml Teflon lined stainless steel container and heated at 140 °C for 3 days. After cooling to room temperature for 12 h, colorless block crystals of **1** suitable for X-ray diffraction analysis were obtained in 68% yield. *Anal.* Calc. for $C_{11}H_{11}CdNO_7$: C, 34.62; H, 2.90; N, 3.67. Found: C, 34.65; H, 2.90; N, 3.70%. IR (KBr pellet, cm^{-1}): 3493 (m), 2917 (w), 1699 (m), 1583 (s), 1439 (m), 1416 (m), 1341 (w), 1313 (m), 1294 (m), 1197 (w), 1135 (w), 992 (w), 971 (w), 931 (w), 878 (w), 809 (w), 774 (w), 756 (w), 720 (w), 690 (w), 664 (w), 620 (w).

2.3.2. Synthesis of $[Co(HL)(H_2O)]$ (**2**)

The preparation of **2** is similar to that of **1** except that $CoCl_2\cdot 4H_2O$ (30.8 mg, 0.1 mmol) was used and that the Teflon container was heated at 120 °C for 3 days. After cooling to room temperature for 12 h, purple block crystals of **2** were collected in 63% yield. *Anal.* Calc. for $C_{11}H_{11}CoNO_7$: C, 40.26; H, 3.38; N, 4.27. Found: C, 40.16; H, 3.27; N, 4.38%. IR (KBr pellet, cm^{-1}): 3474 (m), 2921 (w), 1698 (m), 1586 (s), 1492 (w), 1445 (m), 1419 (m), 1340 (w), 1315 (m), 1295 (m), 1248 (w), 1193 (w), 1175 (w), 1123 (w), 1048 (w), 990 (w), 968 (w), 936 (w), 925 (w), 907 (w), 879 (w), 808 (w), 777 (w), 756 (w), 729 (w), 690 (w), 666 (w), 632 (w).

2.3.3. Synthesis of $[Cd(HL)(H_2O)_4]$ (**3**)

Complex **3** was prepared by a layering method. An aqueous solution (5 ml) of H_3L (25.3 mg, 0.1 mmol) was carefully adjusted to pH 6 by tetrabutylammonium hydroxide (10%) solution and placed at the bottom of a test tube. Then a buffer layer of a solution (5 ml) of

methanol/H_2O 1:1 was layered over it, and afterward, a solution of $Cd(NO_3)_2 \cdot 4H_2O$ (30.8 mg, 0.1 mmol) in methanol (5 ml) was layered over the buffer layer. Colorless block crystals of **3** were collected in 61% yield after several days. *Anal*. Calc. for $C_{11}H_{17}CdNO_{10}$: C, 30.32; H, 3.93; N, 3.22. Found: C, 30.21; H, 3.91; N, 3.29%. IR (KBr pellet, cm^{-1}): 3408 (m), 2930 (w), 1720 (m), 1572 (s), 1535 (s), 1455 (m), 1434 (m), 1413 (m), 1374 (m), 1357 (m), 1317 (m), 1295 (m), 1268 (w), 1234 (w), 1183 (w), 994 (w), 979 (w), 800 (w), 762 (w), 679 (w).

2.3.4. Synthesis of $[Cd_3(L)_2(H_2O)_9] \cdot 7H_2O$ (4)

The preparation of **4** was similar to that described for **3** except that the pH of the bottom solution of H_3L was adjusted to 7 rather than 6. Yield: 53%. *Anal*. Calc. for $C_{22}H_{48}Cd_3N_2O_{28}$: C, 23.47; H, 4.30; N, 2.49. Found: C, 23.59; H, 4.12; N, 2.45%. IR (KBr pellet, cm^{-1}): 3474 (m), 2908 (w), 1597 (s), 1574 (s), 1452 (w), 1402 (s), 1379 (m), 1329 (w), 1297 (m), 1215 (w), 1180 (w), 1135 (w), 987 (w), 933 (w), 891 (w), 800 (w), 762 (w), 681 (w).

2.4. X-ray crystallography

The crystallographic data collections for complexes **1**–**3** were carried out on a Bruker Smart Apex CCD with graphite-monochromated Mo Kα radiation ($\lambda = 0.7107$ Å) at 293(2) K using the ω-scan technique. The data were integrated by using the SAINT program [7], which also used for intensity corrections for Lorentz and polarization effects. An empirical absorption correction was applied using the SADABS program [8]. The structures were solved by direct methods using the program SHELXS-97 [9] and all non-hydrogen atoms were refined anisotropically on F^2 by the full-matrix least-squares technique using the SHELXL-97 crystallographic software package [10]. The hydrogen atoms H2, H3, H5, H6, H7, H7A and H7B in **1**, H7A, H7B and H16 in **2** and all of the hydrogen atoms in **3** were located from difference Fourier maps, and the other hydrogen atoms were generated geometrically. All calculations were performed on a personal computer with the SHELXL-97crystallographic software package. The X-ray diffraction measurement for **4** was carried out on a Rigaku RAXIS-RAPID imaging plate diffractometer at 200 K using graphite-monochromated Mo Kα radiation ($\lambda = 0.7107$ Å). A symmetry-related absorption correction using the program ABSCOR [11] was applied and the data were corrected for Lorentz and polarization effects. The structure was solved by direct methods [11] and expanded using Fourier techniques [12]. The non-hydrogen atoms were refined anisotropically. All calculations for **4** were performed using the TEXSAN crystallographic software package of the Molecular Structure Corporation [13]. Atoms Cd2 and Cd3 in complex **4** are disordered Cd(II) with an occupancy of 0.5, and atoms O3, O4, O10, C13 and C14 in **4** have two positions with site occupancy factors of 0.53(2) and 0.47(2). Atom O17 in **4** is also

disordered into two positions with site occupancy factors of 0.63(5) and 0.37(5). The hydrogen atoms of the uncoordinated water molecules O14, O15 and O16 could not be found from the difference Fourier maps. The details of the crystal parameters, data collection and refinements for the complexes are summarized in Table 1, and selected bond lengths and angles with their estimated standard deviations are listed in Table 2.

3. Results and discussion

3.1. Crystal structure of complexes 1–4

3.1.1. [Cd(HL)(H$_2$O)] (1) and [Co(HL)(H$_2$O)] (2)

The result of X-ray crystallographic analysis revealed that complexes **1** and **2** crystallize in the same monoclinic *C*2/*c* space group with similar cell parameters (Table 1), which indicate that they are isomorphous and isostructural. Thus, as a typical example, only the structure of **1** is described here in detail. The asymmetric unit of **1** consists of one Cd(II) atom, one HL^{2-} ligand and one coordinated water molecule. Each Cd(II) atom is six-coordinated with a distorted octahedral geometry, by one nitrogen atom (N1) from the HL^{2-} ligand and five oxygen atoms from one coordinated H_2O molecule (O7) and three different HL^{2-} ligands (O3 and O5, O4A and O6B), as shown in Fig. 1a. The coordination bond lengths and angles around the Cd(II) centre are in the range 2.234(3)–2.556(3) Å and 68.59(10)–159.67(11)°, respectively as listed in Table 2. On the other hand, each HL^{2-} ligand adopts a μ_3 bridging mode to connect three Cd(II) atoms using its iminodiacetate moiety, in which each carboxylate group links two Cd(II) atoms in a *syn–anti* fashion and the central Cd(II) atom is coordinated by two oxygen atoms from two carboxylate groups and the central nitrogen atom (Scheme 2a). In addition, it is noteworthy that the carboxyphenyl group of the ligand, without deprotonation, is free of coordination. The non-deprotonation of the H_3L ligand in **1** and **2** was further confirmed by IR spectral measurements. The IR spectra of complexes **1** and **2** indicate the incomplete deprotonation of the H_3L ligand since vibration bands at 1699 cm^{-1} for **1** and 1698 cm^{-1} for **2** were

Scheme 2. Coordination modes of the ligand in complexes **1**–**4**.

observed. Such coordination mode makes a 2D network structure of **1**, as illustrated in Fig. 1b in which the carboxyphenyl groups and coordinated water molecules are omitted for clarity.

It can be seen clearly from Fig. 1b that there are two different macrocyclic rings in the 2D sheet of **1**, namely M_4L_4 and M_4L_2 (Fig. 1c), respectively. In the M_4L_4 ring, each iminodiacetate group of the HL^{2-} ligand coordinates with two Cd(II) atoms using three of its four oxygen atoms and this affords one oxygen atom to link to another Cd(II) atom from a neighbouring ring. While in the case of the M_4L_2 ring, four Cd(II) centers are linked by two HL^{2-} ligands and in turn each HL^{2-} ligand connects three Cd(II) atoms using its four oxygen atoms. These two kinds of macrocyclic rings are arranged alternately to generate a 2D wave-like network. Furthermore, as shown in Fig. 1b, the M_4L_4 and M_4L_2 rings adopt entirely different motifs, i.e. the iminodiacetate moiety of the ligand occupies the space of the M_4L_2 ring whilst there is relatively large cavity in the M_4L_4 ring which is filled by the coordinated water molecules (Fig. S1).

The non-deprotonated carboxyphenyl groups point out of the 2D sheet, up and down alternately, and further connect the 2D network to give a 3D framework through the formation of O–H···O hydrogen bonds between the uncoordinated O atoms of the carboxyphenyl groups from two adjacent layers, with an O···O distance of 2.607(6) Å (Fig. 1d). The hydrogen bonding data are summarized in Table S1. There are other O–H···O and C–H···O hydrogen bonds within the 2D network, which further consolidate the structure [14].

3.1.2. [*Cd*(*HL*)(*H*$_2$*O*)$_4$] (***3***)

When the reaction of ligand H_3L with $Cd(NO_3)_2 \cdot 4H_2O$ was carried out by the layering method instead of a hydrothermal reaction as used for the preparation of **1** and **2**, the new complex **3** was obtained. The crystallographic data showed that complex **3** crystallizes the in monoclinic $P2_1/n$ space group and the Cd(II) atom has a pentagonal bipyramid coordination geometry with an O_7 donor set, as illustrated in Fig. 2a. Two oxygen atoms (O1 and O2) from the carboxyphenyl group of the ligand and three other oxygen atoms (O8, O9 and O10) from coordinated water molecules occupy planar positions with Cd–O bond lengths ranging from 2.301(2) to 2.435(2) Å (Table 2). The axial positions are occupied by one oxygen atom (O3A) from the iminodiacetate group of another ligand and O7 from another coordinated water molecule, with Cd–O bond lengths of 2.282(2) and 2.237(2) Å (Table 2), respectively. As illustrated in Scheme 2b, each HL^{2-} ligand links two Cd(II) atoms in **3**, in which the carboxyphenyl group is in a μ_1–η^1:η^1 chelating mode, and one carboxylate of the iminodiacetate group takes a μ_1–η^1:η^0 monodentate fashion and the other one does not take part in the coordination. It is noteworthy that the coordination mode of the ligand in **3** is quite different from that in **1** and **2**, as discussed above. Firstly, one carboxylate unit from the iminodiacetate group of the ligand remains protonated and is free of coordination in **3**, which was confirmed by the observation of a vibration band at 1720 cm^{-1} in the IR spectrum, however, the one in **1** and **2** non-deprotonated and free of

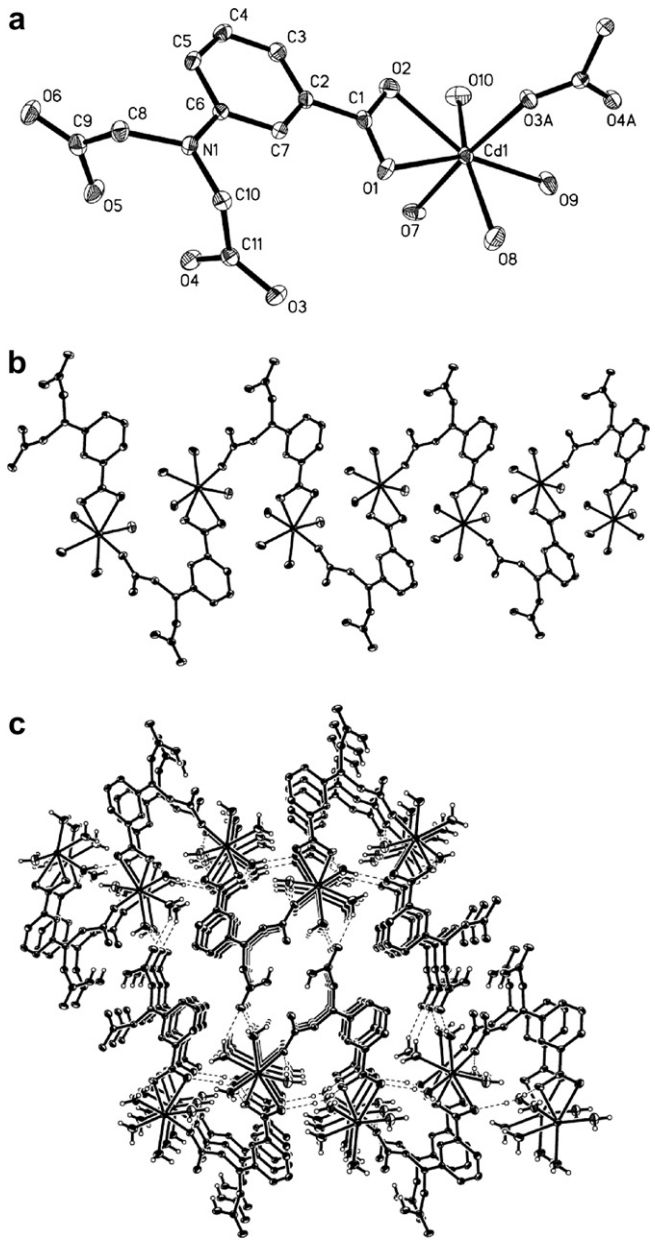

Fig. 2. (a) Coordination environment of the Cd(II) atom in **3** with the ellipsoids drawn at the 30% probability level, hydrogen atoms are omitted for clarity. (b) 1D zigzag chain structure of **3** with hydrogen atoms omitted for clarity. (c) 3D packing structure of **3** with hydrogen bonds indicated by dashed lines.

coordination is the carboxyphenyl group. Moreover, the nitrogen atom of the ligand also does not take part in coordination, and four water molecules participate in coordination to satisfy the coordination need of the Cd(II) atom in **3**. As a result of such differences, a 1D chain-like structure for complex **3** is generated, in which the ligand, utilizing its carboxyphenyl group and one of the iminodiacetate groups, acts as bridge to link the Cd(II) atoms into a zigzag chain structure (Fig. 2b).

In the packing structure of **3**, as shown in Fig. 3c, the 1D chains are firstly linked into a 2D layer by O–H···O hydrogen bonds between the oxygen atoms of the coordinated water molecules (O7 and O10) and carboxyphenyl group from adjacent chains, with O···O distances ranging from 2.707(3) to 3.192(4) Å (Table S1). Then the 2D layers are further connected through O–H···O hydrogen bonds between the oxygen atoms of the coordinated water molecules (O8 and O9) and the free arm of iminodiacetate group from an adjacent layer with O···O distances of 2.814(3) and 2.946(3) Å (Table S1).

3.1.3. $[Cd_3(L)_2(H_2O)_9] \cdot 7H_2O$ (**4**)

In order to further investigate the pH influence on the formation and structure of the complex, the pH value of the ligand solution was carefully adjusted to 7.0, while the other experiment conditions remained the same as those used for the preparation of **3**. As a result, complex **4**, with an entirely different structure, was obtained and the result of crystallographic analysis confirmed that all the carboxylate groups of the ligand are deprotonated and coordinated with the metal atoms in **4**. The complete deprotonation of all three carboxylate groups in **4** was also confirmed by IR spectroscopy since no vibration band around 1700 cm^{-1} for a protonated carboxylate group was observed in the IR spectrum of **4**. The complex crystallizes in the monoclinic *C*2/*m* space group, and in the repeat unit there are two Cd(II) atoms (Cd2 and Cd3) sitting on a symmetry plane with a separation of 2.44 Å and one disordered carboxylate group of the iminodiacetate of the L^{3-} ligand was found near these two Cd(II) atoms. Thus Cd2 and Cd3 are disordered Cd(II) with an occupancy of 0.5. As shown in Fig. 3a, Cd1 is six coordinated by four oxygen atoms (O2, O3, O2A and O6A) from three different L^{3-} ligands, and two oxygen atoms (O7, O8) from two coordinated water molecules, with Cd–O bond lengths ranging from 2.261(7) to 2.446(6) Å (Table 2). While Cd2 and Cd3 are also six coordinated, it is with four oxygen atoms (O3, O4, O3A and O4A) from two L^{3-} ligands and two oxygen atoms (O9, O10) from two coordinated water molecules for Cd2, and two oxygen atoms (O4B and O4BA) from two L^{3-} ligands, and four oxygen atoms (O10B, O11, O13 and O13A) from four coordinated water molecules for Cd3. In addition, two Cd1 atoms (e.g. Cd1 and Cd1A in Fig. 3a) are bridged by two carboxylate oxygen atoms (O2 and O2A) to form a Cd_2O_2 rhombic ring. Therefore, each L^{3-} ligand connects four Cd(II) atoms in two different forms (Scheme 2c and d) in **4** using its three carboxylate groups, and the central nitrogen atom (N1) does not take part in the coordination since the Cd1–N1 distance is 2.70 Å.

The most striking feature of complex **4** is that the Cd(II) centers are connected by the L^{3-} ligand to furnish a 2D network with two different types of cavities filled with water molecules. Firstly, as illustrated in Fig. 3b, six Cd(II) atoms are linked by four L^{3-} ligands to generate a near rectangular ring, and four Cd1 atoms are located at the four corners. Then further connection of the rectangular rings through the Cd_2O_2 rhombic rings results in the formation of an infinite 2D network as

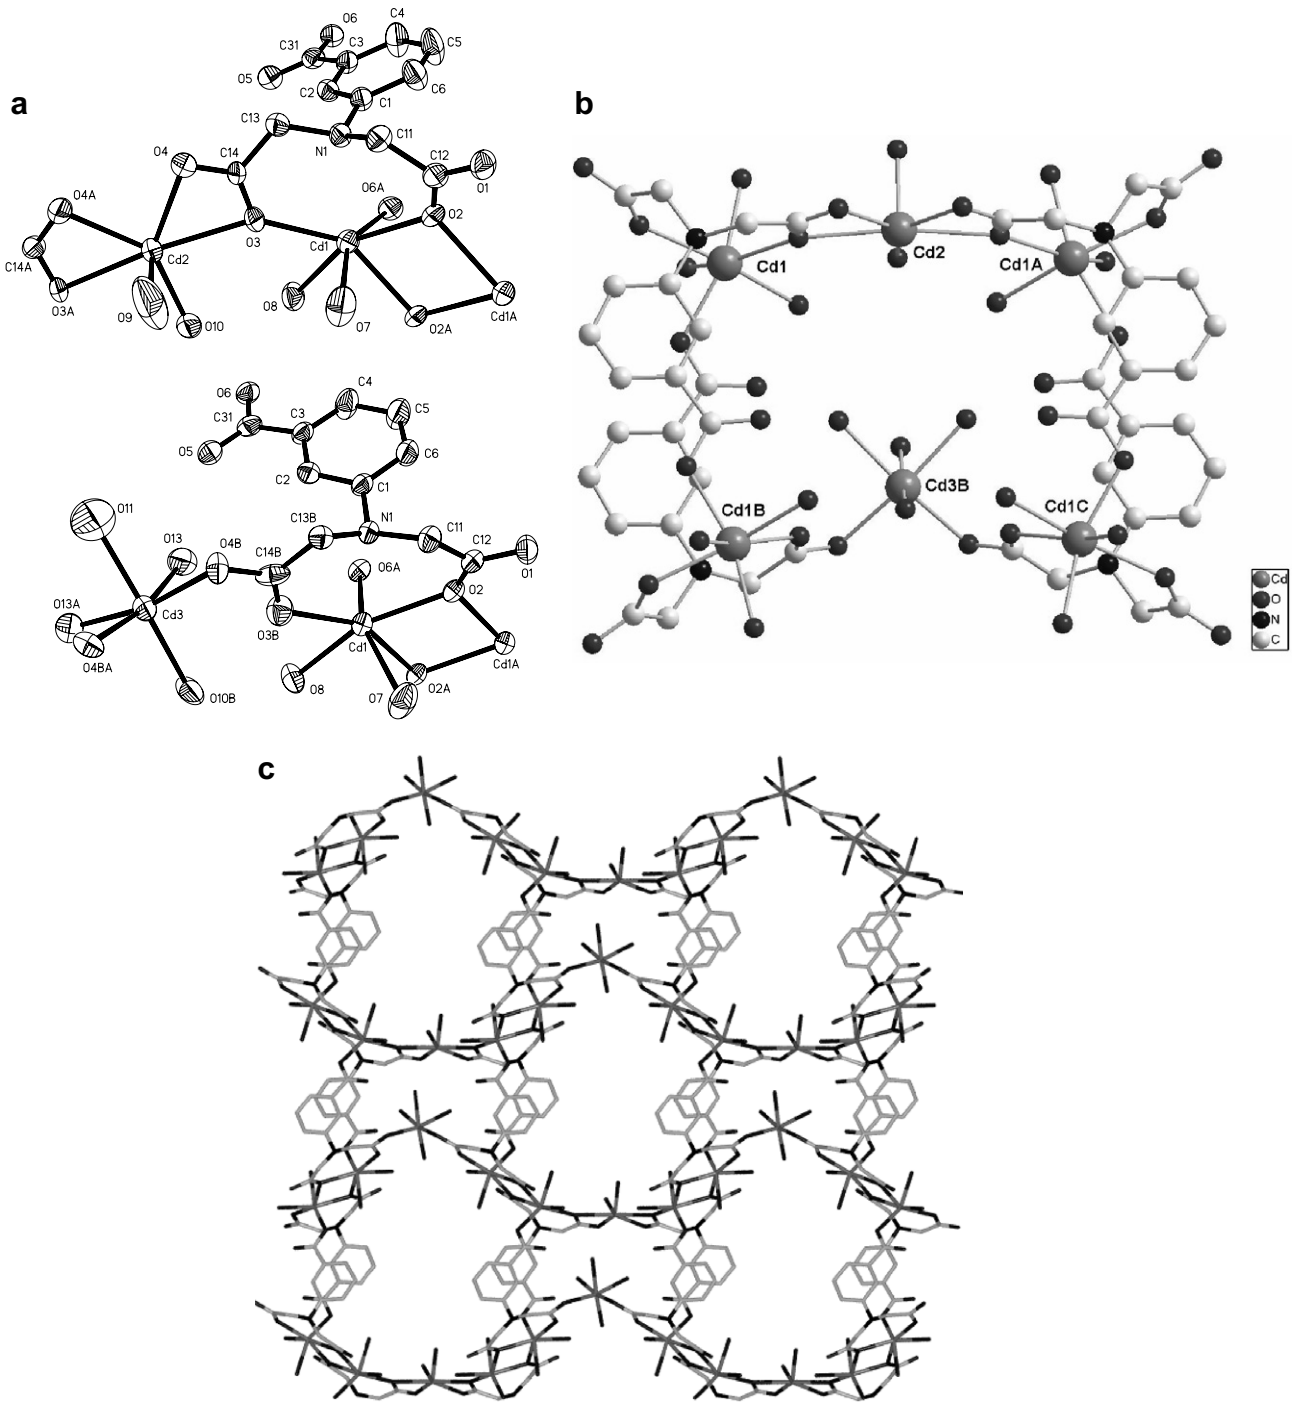

Fig. 3. (a) Coordination environments of the Cd(II) atoms in **4** with the ellipsoids drawn at the 30% probability level, hydrogen atoms and uncoordinated water molecules are omitted for clarity. Top: disordered part with Cd2; bottom: disordered part with Cd3. (b) A near rectangular ring with six Cd(II) atoms linked by four L^{3-} ligands. (c) 2D network structure of **4**. The hydrogen atoms and uncoordinated water molecules are omitted for clarity.

depicted in Fig. 3c. In the crystal packing mode, the 2D sheets are further linked into a 3D structure by C–H···O hydrogen bonds between the C11 atom of an iminodiacetate group and the O1 atom from an adjacent layer, with a C···O distance of 3.552(13) Å, and C–H···O hydrogen bonds also exist in the crystal packing diagram, which further consolidate the structure (Fig. S2, Table S1).

3.2. Effect of synthetic conditions on the structure of the complexes

It has been reported that synthetic conditions, such as pH value, reaction temperature, solvent, etc., are the key factors in assembling MOFs [15,16]. As to the synthesis of **3** and **4**, all the reaction conditions are the same except for the difference of the reaction pH. As a result, complex

3, obtained at a relatively low pH value, is a 1D zigzag chain structure with each Cd(II) center bonded by four water molecules. However in **4**, obtained at a high pH, a more complicated 2D network was generated. Therefore, a rough conclusion could be made that an increase of the pH value in the synthetic process would generate higher dimensionality of the final structure, which is in agreement with the previous reports [17].

In addition, complex **1** was synthesized at a lower pH value and a 2D sheet was obtained rather than a 1D zigzag chain, as in **3**. It might be ascribed to the fact that complex **1** was formed at a high reaction temperature, namely 140 °C under a hydrothermal process, which is considered to be in favor of generating high dimensional structures [18].

From the points discussed above, it is suggested that the increase of reaction pH and temperature may result in a higher connectivity of the carboxylate ligand and further feature a more complicated high dimensional structure.

3.3. Photoluminescence properties of complexes *1*, *3* and *4*

Inorganic–organic hybrid coordination compounds, especially with d^{10} metal centers, have been investigated for fluorescence properties owing to their potential applications as luminescent materials, such as light-emitting diodes (LEDs) [19]. Therefore, in the present study, the photoluminescence properties of **1**, **3** and **4** as well as the free H_3L ligand were investigated in the solid state at room temperature. As shown in Fig. 4, intense emission bands were observed at 407 nm ($\lambda_{ex} = 360$ nm) for the H_3L ligand, 422 nm ($\lambda_{ex} = 350$ nm) for **1**, 414 nm ($\lambda_{ex} = 360$ nm) for **3** and 392 nm ($\lambda_{ex} = 342$ nm) for **4**, respectively. These emissions cannot be attributed to either a metal-to-ligand charge transfer (MLCT) or a ligand-to-metal charge transfer (LMCT) because the Cd(II) ions are in a d^{10} configuration and are difficult to oxidize or to reduce. Therefore,

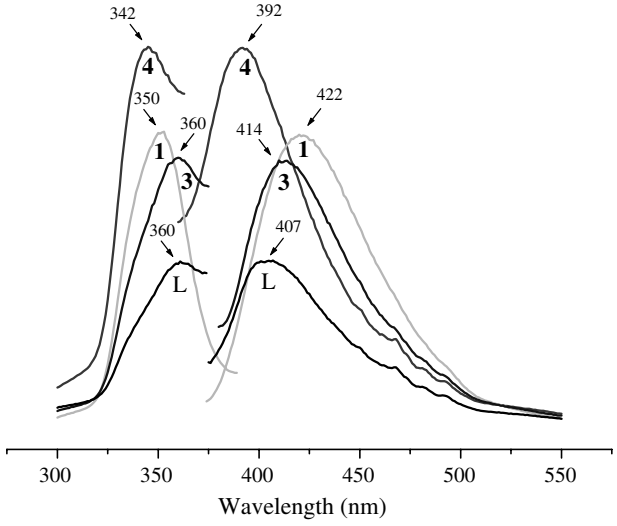

Fig. 4. Excitation and emission spectra of the H_3L ligand and **1**, **3** and **4** in the solid state at room temperature.

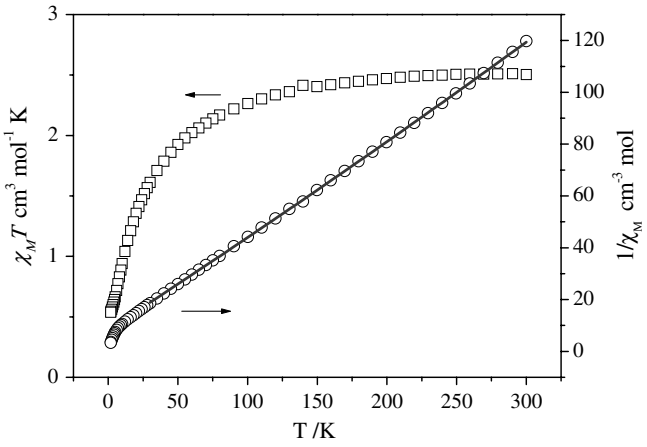

Fig. 5. Temperature dependence of $\chi_M T$ and $1/\chi_M$ for **2**. The solid line shows the Curie–Weiss fitting.

they could be assigned to the π–π^* intraligand fluorescence due to their resemblance to the emission of the H_3L ligand. The enhancement and slight shift of the emissions for **1**, **3** and **4** compared to that of the free ligand probably result from the fact that the coordination of Cd(II) ions increases the ligand conformational rigidity and thus reduces the loss of energy by thermal vibrational decay [20].

3.4. Magnetic properties of complex *2*

The magnetic susceptibility of **2** versus temperature at a field of 2 kOe is shown in Fig. 5, where χ_M is the susceptibility per Co(II) ion. The $\chi_M T$ value is 2.50 cm^3 mol^{-1} K at 300 K, which is significantly larger than the spin-only value of 1.875 cm^3 mol^{-1} K and decreases upon cooling to 0.54 cm^3 mol^{-1} K at 2 K. The magnetic susceptibility above 30 K obeys the Curie–Weiss law with a Weiss constant, $\theta = -24.11$ K, and a Curie constant, $C = 2.88$ cm^3 mol^{-1} K. The high value of C (1.875 cm^3 mol^{-1} K for spin-only Co^{2+}) and negative θ value may be due to the spin–orbit coupling, which is remarkable for the $^4T_{1g}$ state of Co^{2+} in an octahedral ligand field [21].

4. Conclusion

In conclusion, we have successfully synthesized a new carboxylate containing ligand and four new coordination polymers were isolated accordingly under different pH conditions. The results revealed that the reaction pH plays an important role in modulating the architecture of coordination compounds. In addition, complexes **1**, **3** and **4** showed π–π^* intraligand fluorescence in the solid state at room temperature, and the magnetic property of complex **2** was also investigated.

Abstract

Hydrothermal synthesis has afforded a series of 2-D coordination polymers incorporating the flexible α,ω-dicarboxylate pimelate ligand (pim) and either the kinked organodiimine 4,4′-dipyridylamine (dpa) or its conformationally flexible congener 1,3-di-4-pyridylpropane (dpp).

$[M(pim)(dpa)(H_2O)]_n$ (M = Co, **1-Co**; M = Ni, **1-Ni**) both display puckered (4,4) rhomboid grid-like 2-D layers that aggregate into 3-D through O–H···O hydrogen bonding. $\{[Cu_2(pim)_2(dpa)_2]\cdot 5H_2O\}_n$ (**2**) possesses 2-D slab motifs constructed from the linkage of $[Cu_2(pimelate)_2]_n$ ribbons and $[Cu(pimelate)]_n$ double chains through dpa tethers, entraining discrete water molecule chains with D(8) classification. Employing the longer dpp tether resulted in $[Ni(pim)(dpp)]_n$ (**3**), which manifested a doubly interpenetrated 2-D (4,4) grid layer morphology. Analysis of the variable temperature magnetic susceptibility of **1-Ni** indicated the presence of zero-field splitting as well as possible weak antiferromagnetic coupling between Ni atoms in adjacent layer subunits. In contrast, **2** manifested apparent intra-dimer ferromagnetic interactions with underlying interdimer antiferromagnetic coupling.

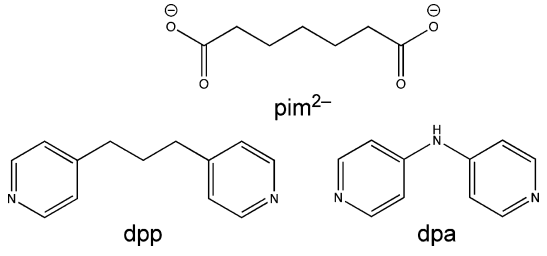
1. Introduction

Over the past decade many researchers have undertaken significant effort towards the synthesis and characterization of metal dicarboxylate and tricarboxylate coordination polymers because of the capability of these materials in diverse applications such as gas storage [1], small molecule shape-selectivity [2], ion-exchange [3], catalysis [4], and optical devices [5]. In these phases dianionic dicarboxylate ligands not only serve to link metal cations into higher dimensionalities but also provide necessary charge balance, thereby permitting formation of a large number of neutral coordination polymer frameworks that exclude porosity-curtailing smaller anions. A wide range of structural patterns occurs in these systems, based on the disposition of the donor groups within the dicarboxylate moieties, coordination geometry preferences, and an array of available binding carboxylate modes. While the predominant focus has rested on aromatic dicarboxylates, aliphatic α,ω-dicarboxylate ligands have also shown their utility in the construction of novel coordination polymers due to their ability to undergo facile conformational interconversions [6].



More recently, elaboration of dicarboxylate-containing inorganic/organic hybrid materials has been achieved through the incorporation of neutral organodiimine tethering ligands such as the rigid-rod 4,4′-bipyridine (4,4′-bpy), which can connect metal cations through its distal pyridyl nitrogen donor atoms into a host of structurally interesting

doi:10.1016/j.poly.2007.11.006

solids with intriguing physicochemical properties [7–10]. For example, the 2-D layered phase {[Zn(isophthalate)(4,4′-bpy)(H_2O)] · 1.5H_2O} manifested intense blue luminescence [8], [Co(thiophene-2,5-dicarboxylate)(4,4′-bipy)] displayed field-dependent spin-flop magnetic behavior at low temperatures [9], and the interpenetrated 3-D material [Zn(terephthalate)(4,4′-bpy)$_{0.5}$] exhibited a remarkable ability to chromatographically separate linear and branched alkanes [10]. This work has been extended to aliphatic α,ω-dicarboxylates, with some divalent metal adipate coordination polymers incorporating 4,4′-bpy or 1,2-di-4-pyridylethane (bpe). In many of these cases doubly interpenetrated 3-D networks were observed [11].

For some time, we have been interested in the synthesis and characterization of coordination polymer materials containing the organodiimine 4,4′-dipyridylamine (dpa, see Scheme 1). Unlike 4,4′-bpy, dpa possesses a kinked disposition of its terminal nitrogen donor atoms as well as a hydrogen bonding locus at its central secondary amine subunit that can assist in the formation of novel structural patterns. Neighboring dpa entities can also interact with each other or with other aromatic subunits through supramolecular π–π stacking interactions. Prior results from our laboratory have shown that coordination polymers with novel structural motifs can result from the hydrothermal combination of metal salts with aliphatic dicarboxylates and dpa [12,13]. Five different divalent metal coordination polymers were prepared utilizing succinate and dpa tethering ligands. Among these, {[Zn(succinate)(dpa)] · H_2O} displayed a rarely seen fourfold interpenetrated $SrAl_2$-type lattice, and {[Ni(dpa)$_2$(succinate)$_{0.5}$]Cl} manifested an unprecedented 5-connected self-penetrated network with 6^{10} topology [12]. [Ni(adipate)(dpa)(H_2O)] exhibited the first-ever example of triple interpenetration within the PtS structure type [13]. In the present study, we have investigated dpa-containing coordination polymers based on pimelate (pim^{2-}), an even longer α,ω-dicarboxylate tethering ligand with enhanced conformational flexibility. Significant differences in their two-dimensional structures were promoted by changes in metal coordination geometry. As the chemistry of dual pimelate/tethering organodiimine coordination polymers remains largely unexplored, we have also investigated the effect of utilizing the more flexible 1,3-dipyridylpropane (dpp) ligand. This change results in interpenetration absent in the dpa cases. Thermal and magnetic properties of these new coordination polymers are also reported herein.

Scheme 1.

2. Experimental

2.1. General considerations

$CoCl_2 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$ (Fisher) and pimelic acid (Aldrich) were obtained commercially. The organodiimine 4,4′-dipyridylamine (dpa) was prepared via a published procedure [14]. Water was deionized above 3 MΩ in-house. Thermogravimetric analysis was performed on a TA Instruments TGA 2050 Thermogravimetric Analyzer with a heating rate of 10 °C/min up to 900 °C. Elemental Analysis was carried out using a Perkin–Elmer 2400 Series II CHNS/O Analyzer. IR spectra were recorded on powdered samples on a Perkin–Elmer Spectrum One instrument.

Powder X-ray diffraction patterns were obtained via Θ–2Θ scans performed on a Rigaku Rotaflex instrument. Variable temperature magnetic susceptibility data (2–300 K) was collected on a Quantum Design MPMS SQUID magnetometer at an applied field of 0.1 T. After each temperature change the sample was kept at the new temperature for 5 min before magnetization measurement to ensure thermal equilibrium. The susceptibility data were corrected for diamagnetism using Pascal's constants.

2.2. Preparation of [Ni(pim)(dpa)(H_2O)]$_n$ (**1-Ni**)

$NiCl_2 \cdot 6\,H_2O$ (0.088 g, 0.37 mmol), dpa (0.063 g, 0.37 mmol) and H_2pim (0.059 g, 0.37 mmol) were added to 10 mL of distilled H_2O in a 23 mL Teflon lined Parr acid digestion bomb. The pH was adjusted to 5.7 with 0.7 mL of a 1.0 M NaOH solution. The bomb was sealed, heated to 120 °C for 53 h, and then gradually cooled to ambient temperature. Green plates of **1-Ni** (0.109 g, 73% yield based on Ni) were obtained after filtration, washing with distilled water and acetone, and drying in air. Crystals of **1-Ni** were stable indefinitely in air. *Anal.* Calc. for $C_{17}H_{21}NiN_3O_5$ **1-Ni**: C, 50.28; H, 5.21; N, 10.35. Found: C, 50.30; H, 5.27; N, 10.41%. IR (cm^{-1}): 3250 w br, 2929 w, 1593 s, 1542 m, 1513 s, 1476 m, 1453 w, 1437 m, 1421 m, 1386 s, 1334 s, 1291 w, 1202 m, 1083 w, 1060 m, 1024 m, 904 w, 873 w, 827 s, 764 w, 731 s, 661 m.

2.3. Preparation of [Co(pim)(dpa)(H_2O)]$_n$ (**1-Co**)

The procedure for the synthesis of **1-Ni** was followed with the use of $CoCl_2 \cdot 6H_2O$ (0.088 g, 0.37 mmol) as the metal source. Magenta plates of **1-Co** (0.031 g, 21% yield based on Co) were obtained after filtration, washing with distilled water and acetone, and drying in air. Crystals of **1-Co** were stable indefinitely in air. *Anal.* Calc. for $C_{17}H_{21}CoN_3O_5$ **1-Co**: C, 50.26; H, 5.21; N, 10.34. Found: C, 50.46; H, 4.82; N, 10.36%. IR (cm^{-1}): 3250 w br, 2927 w, 1591 s, 1513 s, 1476 w, 1454 w, 1437 m, 1420 w, 1383

m, 1336 s, 1310 w, 1292 w, 1233 w, 1082 m, 1058 m, 1020 s, 904 m, 873 w, 827 s, 801 w, 732 s, 717 m, 660 s.

2.4. Preparation of $\{[Cu_2(pim)_2(dpa)_2]\cdot 5H_2O\}_n$ (2)

$CuCl_2\cdot 2H_2O$ (0.063 g, 0.37 mmol), H_2pim (0.059 g, 0.37 mmol) and dpa (0.127 g, 0.74 mmol) were placed into 10 g (555 mmol) distilled H_2O in a 23 mL Teflon-lined Parr acid digestion bomb (1:2:1500 mol ratio). The mixture was acidified to pH 4.5 with 0.5 mL of a 1.0 M HCl solution. The bomb was sealed and heated at 150 °C for 24 h, whereupon it was cooled slowly in air to 25 °C. Small blue crystals of **2** (0.089 g, 55% yield based on Cu) were isolated after washing with distilled water. Because the material effuses its waters of crystallization slowly upon standing, it was kept for long-term storage in its mother liquor. *Anal.* Calc. for $C_{34}H_{48}Cu_2N_6O_{13}$ (**2**): C, 46.62; H, 5.52; N, 9.60. Found: C, 43.36; H, 4.92; N, 9.03%. Elemental analyses showed lower than expected values on multiple samples, ascribed to either incomplete combustion or the presence of an amorphous inorganic impurity, as the powder XRD spectrum of freshly prepared **2** coincides exactly with that predicted from the single-crystal X-ray structure. IR (cm^{-1}): 3250 w br, 2927 w, 1593 s, 1526 s, 1445 m, 1394 s, 1358 s, 1291 m, 1256 w, 1205 s, 1062 m, 1026 s, 907 w, 816 s, 760 w, 729 w, 664 w.

2.5. Preparation of $[Ni(pim)(dpp)]_n$ (3)

$NiCl_2\cdot 6H_2O$ (0.088 g, 0.37 mmol), dpp (0.147 g, 0.74 mmol) and H_2pim (0.059 g, 0.37 mmol) were added to 10 mL of distilled H_2O in a 23 mL Teflon lined Parr acid digestion bomb. The bomb was sealed, heated to 150 °C for 44 h, and then gradually cooled to ambient temperature. Green blocks of **3** (0.050 g, 33% yield based on Ni) were obtained after filtration, washing with distilled water and acetone, and drying in air. Crystals of **3** were stable indefinitely in air. *Anal.* Calc. for $C_{20}H_{24}NiN_2O_4$ **3**: C, 57.87; H, 5.83; N, 6.75. Found: C, 57.65; H, 5.74; N, 6.87%. IR (cm^{-1}): 2921 w, 1614 m, 1560 m, 1537 s, 1510 m, 1432 s, 1410 s, 1314 m, 1213 w, 1140 w, 1069 w, 1023 m, 920 w, 894 m, 862 m, 817 m, 808 m, 723 m, 660 m.

3. X-ray crystallography

Single crystals of all materials were subjected to single crystal X-ray diffraction using a Bruker-AXS SMART 1k CCD instrument. Reflection data was acquired using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The data were integrated via SAINT [15]. Lorentz and polarization effect and empirical absorption corrections were applied with SADABS [16]. The structures were solved using direct methods and refined on F^2 using SHELXTL [17]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms bound to carbon atoms were placed in calculated positions and refined isotropically with a riding model. The hydrogen atoms bound to the central nitrogen of the dpa moieties and all aquo ligands were found via Fourier difference maps, restrained at fixed positions, and then refined isotropically with thermal parameters 1.2 times the average U_{ij} values of the atoms to which they are bound. Distended thermal ellipsoids for some of the pimelate carbon atoms in **2** are indicative of some amount of positional or thermal disorder; however, this could not be successfully modeled. Relevant crystallographic data is listed in Table 1.

4. Results and discussion

4.1. Synthesis and spectral characterization

The coordination polymers **1**–**3** were prepared cleanly under hydrothermal conditions via combination of the appropriate metal chloride, H_2pim, and either dpa (**1**, **2**) or dpp (**3**). The infrared spectra of **1**–**3** were consistent with their formulations. Sharp, medium intensity bands in the range of ~1600 cm^{-1} to ~1200 cm^{-1} were ascribed to stretching modes of the pyridyl rings of the dpa moieties [18]. Features corresponding to pyridyl ring puckering mechanisms were evident in the region between 820 cm^{-1} and 600 cm^{-1}. Asymmetric and symmetric C–O stretching modes of the carboxylate moieties were evidenced by very strong, slightly broadened bands at ~1590 cm^{-1} and ~1340 cm^{-1}. Broad bands in the region of ~3400 cm^{-1} to ~3200 cm^{-1} in all cases represent N–H stretching modes within the dpa ligands and O–H stretching modes within water molecules of crystallization. The broadness of these latter spectral features is caused by significant hydrogen bonding pathways within **1**–**3**. Phase purity was verified with powder XRD by comparison with powder patterns predicted from the single crystal structures.

4.2. Structural description of $[M(pim)(dpa)(H_2O)]_n$ (1-Ni, M = Ni; 1-Co, M = Co)

1-Ni and **1-Co** are isomorphous, both crystallizing in the monoclinic space group $P2_1/c$ and possessing an asymmetric unit consisting of a metal atom, one doubly deprotonated pim^{2-} (pim) moiety, one dpa ligand, and one bound water molecule. The asymmetric unit of **1-Ni** is displayed in Fig. 1; that of **1-Co** is virtually identical. The coordination spheres about the divalent metal ions in these materials are slightly distorted $[MO_4N_2]$ octahedra, with the two nitrogen donors from two different dpa molecules oriented in a *cis* fashion with respect to each other. Two of the oxygen donors (O1, O2) belong to the chelating terminus of a pim^{2-} ligand. The aquo ligand (O5) is disposed in a *cis* manner with respect to the remaining oxygen donor (O3), part of a monodentate carboxylate group of another (but crystallographically identical) pim^{2-} ligand. Bond lengths and angles (Table 2) about the metal ions are standard for distorted octahedral coordination complexes with one chelating ligand. The bond lengths for **1-Ni** are slightly

shorter than those for **1-Co**, consistent with well-established ionic radius trends [19].

The pim^{2-} ligands adopt a *gauche–anti–anti–anti* conformation (four C-atom torsion angles = 69.19°, 173.08°, 178.17° and 170.39° for **1-Ni**) and bridge neighboring metal atoms in an exobidentate chelating/monodentate fashion to form undulating [M(pim)]$_n$ chain motifs that course parallel to the *b* crystal axis (Fig. 2). While the chelating carboxylates in **1-M** display symmetric binding to the metal, the C–O bond lengths of the monodentate carboxylate termini vary by ~0.40 Å, reflective of enhanced π-type character in the between the carboxylate C atom and the unligated oxygen atoms. The [M(pim)]$_n$ chains in turn are connected through tethering dpa ligands to generate a ruffled [M(pim)(dpa)(H$_2$O)]$_n$ two-dimensional (4,4) layer motif parallel to the *ab* crystal plane (Fig. 3). Each metal ion is covalently connected to four others, with two connections each via pim^{2-} and dpa ligands. The metal–metal contact distances through the pim^{2-} ligands measure 8.988 Å and 9.056 Å for **1-Ni** and **1-Co**, respectively; the corresponding contact distances through the dpa tethers are 11.350 Å and 11.465 Å. In order to accommodate the necessary orientation for appropriate covalent bonding, the dpa molecule undergoes a significant inter-ring torsion (47.1° in **1-Ni** and 46.7° in **1-Co**). The incipient void spaces within the resulting puckered rhomboid circuits in **1-Ni** measure 8.673 and 16.176 Å (via through-space Ni–Ni distances), with Ni–Ni–Ni angles of 48.8°, 48.8°, 90.9° and 128.3°. The corresponding through-space Co–Co distances in **1-Co** are slightly longer at 8.736 and 16.295 Å with virtually identical Co–Co–Co angles.

The covalent connectivity within the layer is supplemented by supramolecular hydrogen bonding donation from the amine functional group of dpa to the oxygen atom O3 within the chelating carboxylate moiety. In addition, the aquo ligand provides a hydrogen bonding point of contact to the unligated oxygen atom of type O4 within the monodentate carboxylate group, possibly preventing a bis-monodentate bis-monodentate binding mode for the pim^{2-} ligand. The puckering of the individual 2-D layers causes an alternation of the position of the pim^{2-} ligands above and below the layer, allowing interlayer hydrogen bonding between the aqua ligands and oxygen atoms of type O1 within the chelating carboxylate groups. These supramolecular interactions result in stacking of the [M(pim)(dpa)(H$_2$O)]$_n$ layers along the *c* crystal direction to establish the pseudo 3-D crystal structures of **1-M** (Fig. 4). The interlayer metal–metal contact distances are 5.113 Å and 5.095 Å in **1-Ni** and **1-Co**, respectively, significantly closer than the intralayer metal–metal distances. Metrical parameters for the classical hydrogen bonding interactions in **1-M** are given in Table 3.

*4.3. Structural description of $\{[Cu_2(pim)_2(dpa)_2]\cdot 5H_2O\}_n$ (**2**)*

The asymmetric unit of **2** (Fig. 5) was found to contain two crystallographically distinct divalent copper atoms, two fully deprotonated pim^{2-} dianions (C21–C27/O1–O4, *pim-A*; C31–C37/O5–O8, *pim-B*), two dpa ligands (C1–C10/N1–N3, *dpa-A*; C11–C20/N4–N6, *dpa-B*), and five water molecules of crystallization, one of which (O5W) is disordered equally over two positions. One of the copper atoms (Cu1) adopts a virtually perfect $\{CuN_2O_3\}$ square pyramidal coordination geometry ($\tau = 0.01$) [20], with one nitrogen donor from a *dpa-A* ligand, one nitrogen donor from a *dpa-B* ligand, and oxygen donors from two different *pim-B* ligands situated within the basal plane. The nitrogen donors are oriented in a *trans*-fashion within the basal plane, as are the oxygen donors. The coordination sphere about Cu1 is completed by an oxygen donor from a third *pim-B* ligand lying in the axial position. The bond lengths and angles about Cu1 (Table 4) are consistent with the well-known Jahn-Teller distortion for Cu^{2+}. The other crystallographically distinct Cu atom (Cu2) exhibits

a {*trans*-CuN_2O_2} square planar coordination environment, with the nitrogen donors belonging to two crystallographically distinct dpa ligands and the oxygen donors provided by two different *pim-A* ligands. The O1–Cu2–O3 bond angle (Table 3) is ~20° narrower than the corresponding trans N1–Cu2–N4 bond angle, a deviation from idealized square planar geometry likely provoked by long range Cu···O interactions and other supramolecular effects (*vide infra*).

Extension of the structure about Cu1 reveals {Cu_2O_2} bimetallic kernels formed by the junction of two adjacent Cu1 atoms by two μ_2-bridging oxygen atoms of type O8 belonging to two different *pim-B* units. Each O8 oxygen atom lies in the basal plane of one Cu1 square pyramid, and is in the axial position of another, resulting in an asymmetric rhomboid four-membered ring. The through-space Cu1–Cu1 and O8–O8 distances are 3.391 Å and 2.796 Å, respectively; the Cu–O–Cu and O–Cu–O angles within the rhomboid {Cu_2O_2} unit subtend 101.2(5)° and 78.8(5)°. Adjacent {Cu_2O_2} units are linked to two others along the *b* crystal direction by means of tethering *pim-B* dianions in an *anti–gauche–anti–anti* conformation (C–C–C–C torsion angles: 177.0°, 25.7°, 175.6°, 174.6°), thereby forming 1-D $[Cu_2(pim)_2]_n$ ribbon motifs (Fig. 6A). The Cu–Cu distance through the kinked *pim-B* ligand is 8.888 Å. The pim^{2-} moieties in this chain are exotridentate,

binding to Cu in a monodentate fashion at O5, and bridging two Cu atoms via their O8 termini. An interaction between Cu1 and the unligated carboxylate oxygen atom O7 is evident, with a Cu···O distance of 2.783 Å. Such "secondary bonding" interactions are common in Cu^{2+} coordination complexes [21].

In turn, Cu2 atoms are connected into 1-D $[Cu(pim)]_n$ single chains via tethering *pim-A* dianionic units (Fig. 6B), which adopt a spread out *gauche–anti–anti–gauche* conformation (torsion angles = 77.2°, 177.3°, 173.0°, 68.7°) with a bis-monodentate bis-monodentate binding mode. Due to the more open conformation, the Cu2–Cu2 distance through *pim-A* is 10.352 Å, almost 1.5 Å longer than the *pim-B*-bridged corresponding Cu1–Cu1 distance. Abutting $[Cu(pim)]_n$ single chains are weakly conjoined through long "4+1" type Cu2···O1 secondary interactions (2.700 Å, drawn as dashed lines in Fig. 6B). If these interactions are considered "bonds", $\{Cu_2O_2\}$ bimetallic units similar to those within the Cu1-based ribbons can be invoked. However, the Cu2–Cu2 distances within these units are ~0.25 Å longer, at 3.647 Å, with a Cu2–O1···Cu2 angle of 100.99°. It is likely that the conformational flexibility of the pim^{2-} tethers assists in the formation of two different 1-D copper dicarboxylate motifs in **1**.

Alternating $[Cu_2(pim)_2]_n$ ribbons (based on Cu1) and $[Cu(pim)]_n$ double chain subunits (based on Cu2) are subsequently bridged together by tethering dpa ligands to establish a 2-D $[Cu_2(pim)_2(dpa)_2]$ neutral coordination polymer slab that lies parallel to the $(10\bar{1})$ crystal plane (Fig. 7). The Cu1–Cu2 distances measure 11.485 Å (through *dpa-A* with an inter-ring torsion angle of 28.7°) and 11.527 Å (through *dpa-B* with an inter-ring torsion angle of 29.6°). The covalent connectivity within the slab motif is augmented by π–π stacking between *dpa-A* and *dpa-B* ligands (centroid-to-centroid distances 3.647(1) Å and 3.631(1) Å), imposed by the presence of the $\{Cu_2O_2\}$ bimetallic units with similar metal–metal contact distances.

$[Cu_2(pim)_2(dpa)_2]$ slabs stack along the *a* crystal direction via N–H···O hydrogen bonding interactions between the central amine functional groups of *dpa-B* ligands and unligated carboxylate oxygen atoms of type O5 within the *pim-B* dianions, which project into the interlamellar regions (Fig. 8). The closest interlayer Cu–Cu contact distance is 8.549 Å.

Sequestered within and between the coordination polymer layers are discrete hydrogen bonded aqueous chains of eight water molecules each (O3W···O2W···O4W···O5W···O5W···O4W···O2W···O3W), decorated at each

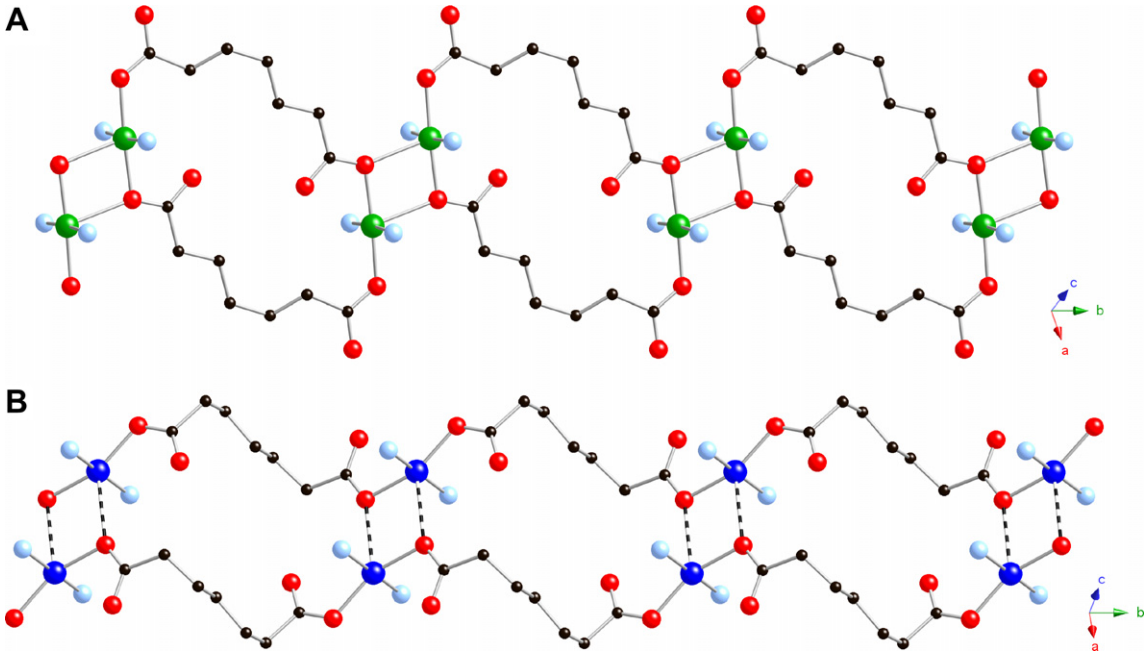

Fig. 6. $[Cu_2(pim)_2]$ ribbons (A) and [Cu(pim)] double chains with long range interactions shown as dashed lines (B) in **2**.

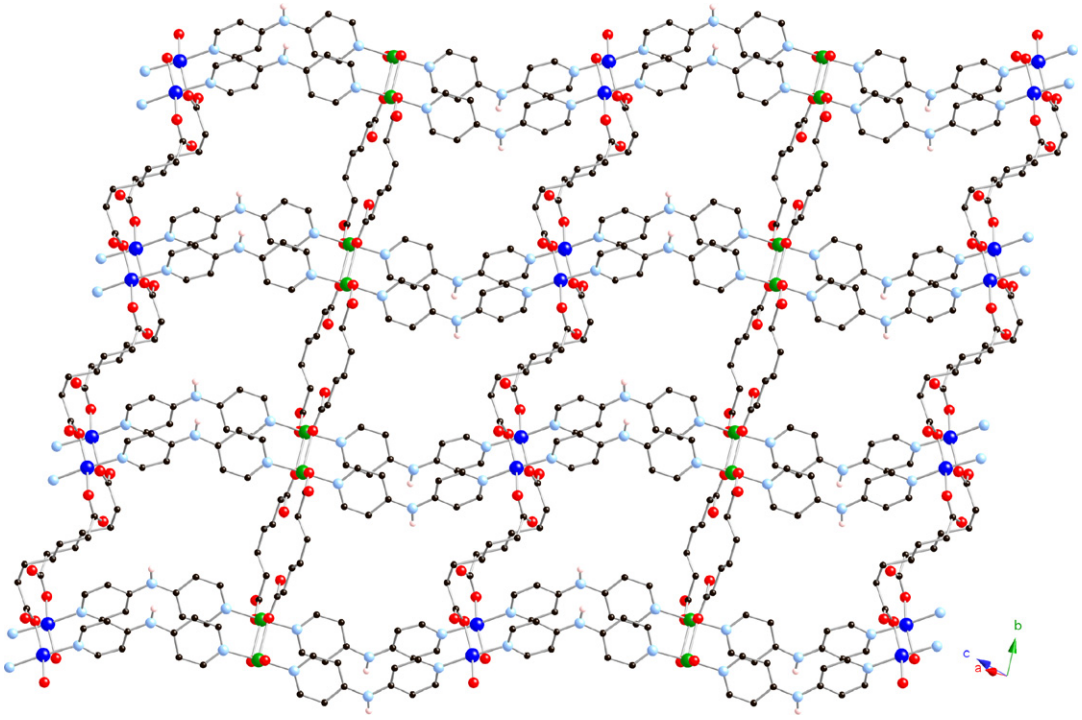

Fig. 7. A 2-D slab motif in **2**, formed from the junction of parallel 1-D $[Cu_2(pim)_2]$ ribbons and [Cu(pim)] double chains through dpa tethers.

O2W position by additional pendant water molecules (type O1W). Therefore the unligated water molecule substructure falls into the uncommonly encountered D(8) morphological classification [22], with a connectivity pattern resembling that of 2,7-dimethyloctane. The uncoordinated water molecules are anchored to the coordination polymer matrix by extensive hydrogen bonding pathways. The water molecules at the chain termini (O3W) engage in hydrogen bonding donation to the ligated and unligated carboxylate oxygen atoms O3 and O2, belonging to two separate *pim-A* ligands. Water molecules of type O1W, serving as "substituents" on the aqueous chain, link to the coordination polymer framework by accepting hydrogen bonds from the amine units of *dpa-A* and donating hydrogen bonds to unligated carboxylate oxygen atoms O4 and O6, belonging to *pim-A* and *pim-B*, respectively. Finally, water molecules of type O4W are held by hydrogen bonding donation to unligated carboxylate oxygen atoms O7, part of *pim-B*. Metrical parameters for the supramolecular hydrogen bonding interactions in **2** are listed in Table 3. According to a calculation performed with PLATON [23], the incipient void spaces occupied by the water molecules of crystallization represent 17.6% of the unit cell volume of **2**.

4.4. Structural description of [Ni(pim)(dpp)] (3)

The asymmetric unit of **3** (Fig. 9) contains one divalent nickel atom, one dpp ligand, and a doubly deprotonated pim^{2-} dianion. Due to the chelation of the pim^{2-} carboxylate termini, the coordination environment about Ni is best described as a distorted $[NiO_4N_2]$ octahedron; bond lengths and angles about Ni are consistent with this description (Table 5). The two nitrogen donors, which belong to two different dpp ligands, are arranged in a *cis* orientation.

Extension of the structure reveals that each Ni atom is linked to four others, two through dpp linkers and two through pim^{2-} dianions, to form a 2-D rhomboid grid coordination polymer morphology. The torsion angles across the trimethylene bridge of the dpp ligand (179.4° and 176.1°) show that the dpp subunit has adopted a splayed-open *anti* conformation, providing a through-ligand Ni–Ni contact distance of 13.42 Å. The bis-bridging bischelating pim^{2-} tethers display a *gauche–anti–anti–anti* conformation (torsion angles 71.6°, 171.2°, 173.6°, and 176.2°), providing a Ni–Ni distance of 10.28 Å, ~3.1 Å shorter than the corresponding through-dpp distance.

The grid apertures in **3**, 17.10 × 15.14 Å as measured by through space Ni–Ni distances, are large enough to accommodate interpenetration of a second identical $[Ni(pim)(dpp)]_n$ 2-D layer (Fig. 10). This stands in marked contrast to **1**, which does not display any interpenetration due to the shorter dpa tethers and resulting smaller grid mesh size. Within a single grid, the Ni–Ni–Ni angles subtend 78.2°, 78.2°, 79.15° and 112.48°. The closest Ni–Ni separation between two independent interpenetrated layers is 7.57 Å. Layer motifs subsequently stack along the *c* crystal direction primarily by means of π–π supramolecular interactions (3.892(2) Å) between dpp pyridyl rings within adjacent layers, thus constructing the pseudo 3-D crystal structure of **3**. The closest interlayer Ni–Ni contact distance is 7.92 Å. Unfortunately, attempts to prepare a copper coordination polymer containing both pim^{2-} and dpp resulted either in amorphous products or the known 1-D chain phase $[CuCl(dpp)]_n$ [24].

4.5. Variable temperature magnetism

To probe possible spin communication, samples of **1** and **2** were subjected to variable temperature magnetic study. For **1**, the $\chi_m T$ value at 300 K was 1.23 cm^3 K mol^{-1}. This is slightly higher than predicted for a spin-only uncoupled Ni^{2+} d^8 $S=1$ ion, indicative of anisotropy. The $\chi_m T$ value remained largely constant to 60 K, whereupon it began to decrease, reaching a value of 1.08 cm^3 K mol^{-1} at 12 K. At lower temperatures the $\chi_m T$ product dropped precipitously, a sign of possible antiferromagnetic coupling, zero field splitting, or a cooperative effect of the two phenomena. The magnetic susceptibility of **1** was modeled using Eq. (1) [25], which accounts for both magnetic coupling between Ni centers (Θ) and zero field splitting (D).

$$\chi_m T = \left(\frac{2Ng^2\beta^2}{3k(T-\Theta)}\left(\frac{(2kT/D)-(2kT\exp(x)/D)+\exp(x)}{1+2\exp(x)}\right)T\right) \quad (1)$$

where $x=-D/kT$.

The best fit to the data (Fig. 11) occurred with $g=2.241(2)$, $\Theta=-1.62(4)$ K and $D=4.9(1)$ cm^{-1} with $R=9.55\times10^{-3}=\{\sum[(\chi_m T)_{obs}-(\chi_m T)_{calc}]^2/\sum(\chi_m T)_{obs}]^2\}$. Within the layer structure of **1**, the pimelate and dpa

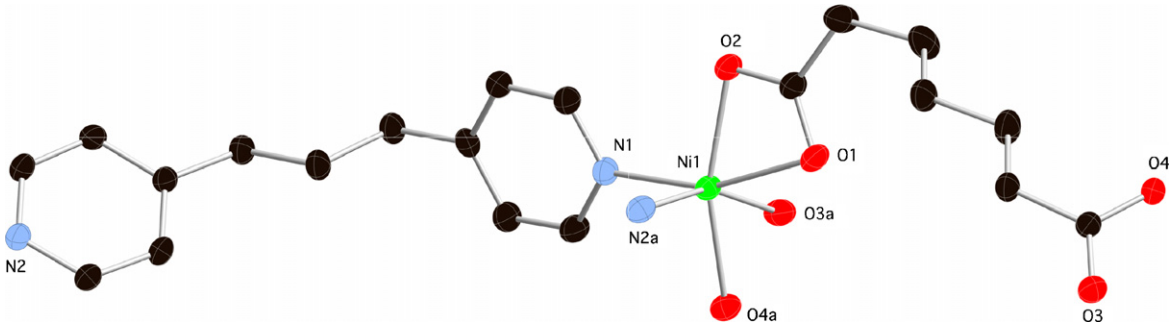

Fig. 9. Asymmetric unit of **3** with thermal ellipsoids shown at 50% probability and partial atom numbering scheme. Most hydrogen atoms have been omitted for clarity.

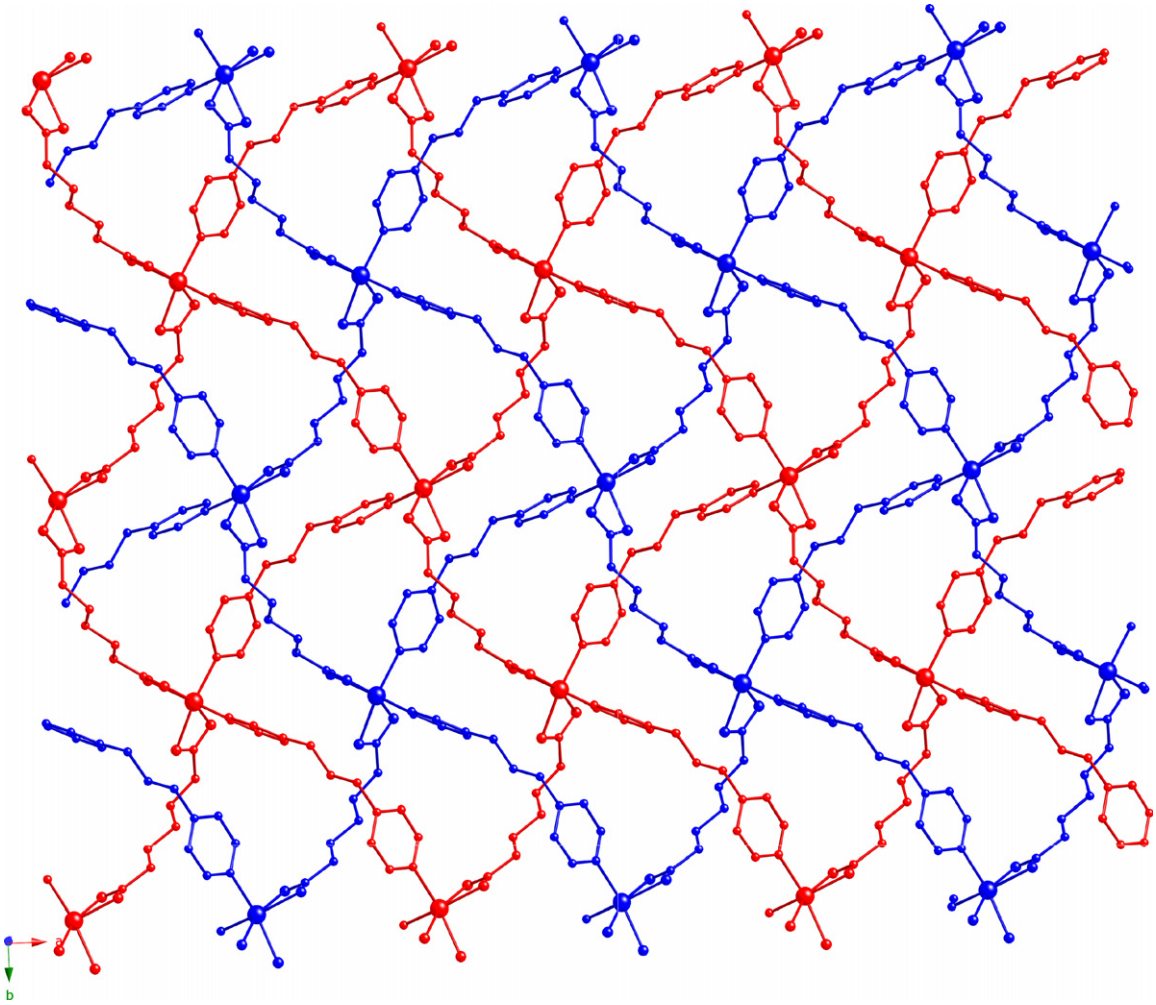

Fig. 10. A view down *c* of doubly interpenetrated (4,4) layers in **3**.

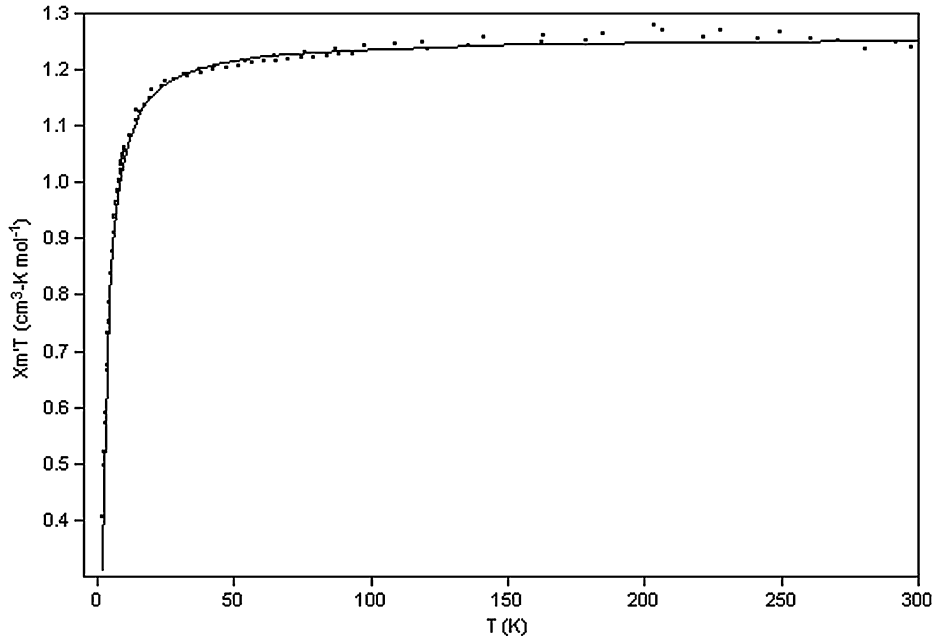

Fig. 11. Plot of $\chi_m T$ vs T for **1-Ni**. The calculated fit to Eq. (1) is indicated as a solid black line.

ligands cause Ni–Ni distances that are likely too long for any significant magnetic communication. Closer Ni–Ni interactions (~5.1 Å), mediated by hydrogen bonding between the aquo ligands and chelating carboxylate moieties in adjacent layers, could be the origin of the observed weak interlayer antiferromagnetic coupling. Attempted fits using models that accounted for either interlayer antiferromagnetic coupling or zero field splitting alone were much less successful. Hydrogen-bonding promoted magnetic communication between paramagnetic metal ions has been reported in other coordination polymer materials [26].

The plot of the $\chi_m T$ product versus T for **2** (Fig. 12) showed an increase in $\chi_m T$ as temperature decreased, a sign of ferromagnetic interactions within one or both types of oxygen bridged dimeric Cu units within the coordination polymer structure. The $\chi_m T$ value reached a maximum of 1.52 cm^3 K mol^{-1} at 5.2 K, below which temperature it began to decrease (see inset of Fig. 12). This low-temperature behavior can be ascribed to weaker antiferromagnetic interactions between adjacent $\{Cu_2O_2\}$ dimeric units through either the pimelate or dpa tethering ligands. Unfortunately no Curie–Weiss regime was found in the variable temperature susceptibility data for **2**, even at higher temperatures. Neither could the data be fit acceptably to the Bleaney–Bowers equation [27] for magnetically interacting Cu(II) dimers, even incorporating an interdimer parameter (Θ). It is possible that the presence of two different types of $\{Cu_2O_2\}$ dimeric units in **2**, with varying Cu···Cu contact distances, results in significant differences in the nature and magnitude of their respective magnetic interactions [28]. Thus, the overall magnetic susceptibility behavior can be ascribed to the simultaneous action of the spin communication within both types of $\{Cu_2O_2\}$ dimer, thereby greatly complicating any attempts at modeling. Nevertheless, it is probable that net intradimer ferromagnetic interactions occur in **2**, with an underlying weak interdimer antiferromagnetic superexchange mechanism.

4.6. Thermal analysis of *1–3*

Compound **1-Ni** underwent loss of its ligated water molecule between 250 °C and 320 °C (4.9% mass loss, 4.4% predicted). Combustion of the organic components ensued, with a series of mass losses between 350 °C and 600 °C. The mass remnant of 21% corresponds roughly with the deposition of NiO (18% calcd.). Compound **2**, which had apparently lost 2 equiv. of unbound water molecules on standing, continued to dehydrate between 45 °C and 115 °C (5.5% mass loss, 6.1% calcd. for 3 equiv. of water). Combustion of organics commenced at ~250 °C, resulting in likely deposition of $CuCO_3$ at 700 °C (29% mass remnant, 30% theoretical). Compound **3** remains stable until ~320 °C at which point rapid expulsion of the organic components occurs. The 22% mass remnant at 600 °C corresponds loosely to NiO (18% calcd.). TGA traces for **1–3** are depicted in Figs. S1–S3.

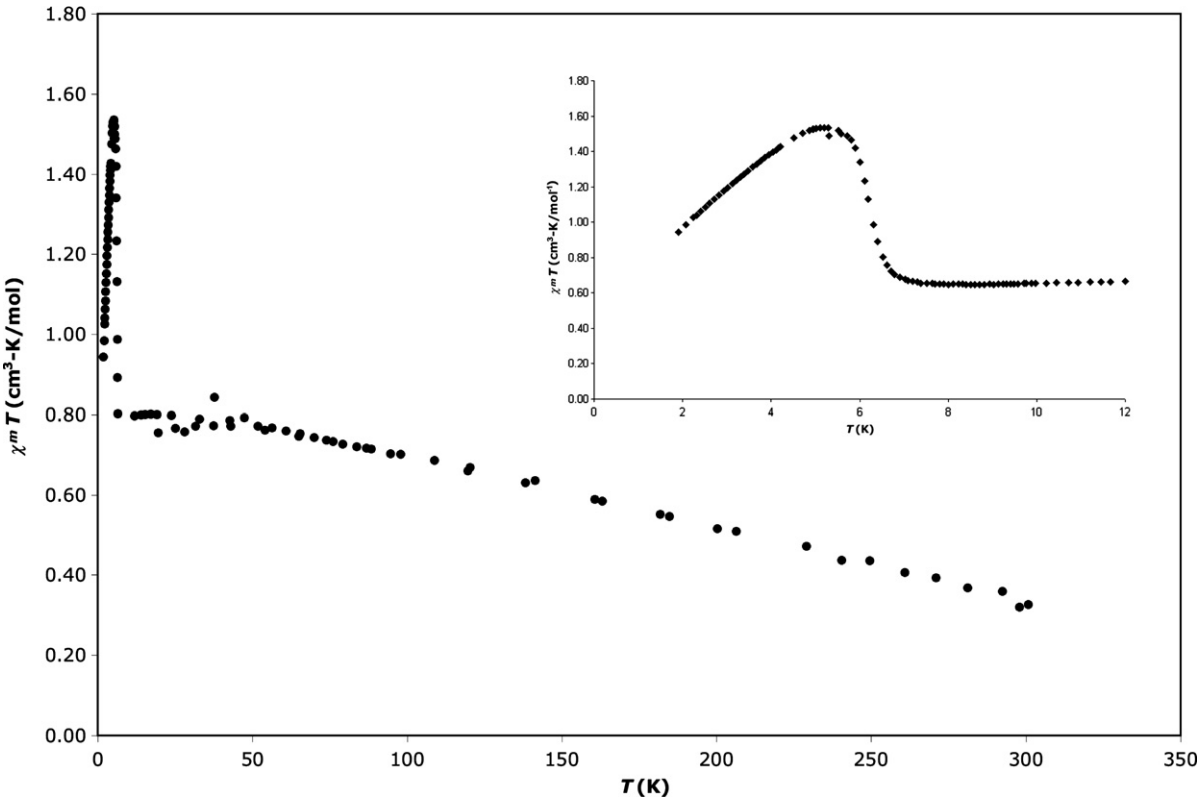

Fig. 12. Plot of $\chi_m T$ vs T for **2** (inset shows low temperature data only).

5. Conclusions

Taking advantage of the conformational flexibility of the α,ω-dicarboxylate pimelate ligand, four two-dimensional organodiimine-containing coordination polymers have been prepared. Both the pimelate conformation and the tether length and hydrogen-bonding capability of the organodiimine component appear to play a significant structure-directing role, in synergy with coordination geometry preferences. Use of a longer tethering organodiimine promotes the formation of rhomboid grids with larger apertures, resulting in an interpenetrated structure. The lowered coordination number at the copper centers in **2**, as opposed to **1** and **3**, promotes a double slab structure with $\{Cu_2O_2\}$ dimers that exhibit apparent ferromagnetic coupling. The differing pimelate conformations observed in these materials reflect this ligand's ability to adjust to the requirements imposed by the metal coordination geometry and the supramolecular environment. Investigation of long-chain α,ω-dicarboxylate coordination polymers incorporating kinked or flexible organodiimines remains a fruitful area of synthetic exploration in our laboratory, and further results will be reported in due course.

Abstract

The reaction of organo(heterocyclic)tellurium(IV) derivative: $C_8H_8TeI_2$(1,3-dihydro-2λ^4-benzotellurole-2,2-diyl diiodide) with $NH_4S_2CNC_5H_{10}$ (ammonium piperidine dithiocarbamate) gives $C_8H_8Te(S_2CNC_5H_{10})_2$ (**1**) and $Te(S_2CNC_5H_{10})_2$ (**2**) or $C_8H_8TeI(S_2CNC_5H_{10})$ (**5**) according to the reaction conditions. In such type of metathetical reactions, the formation of **2** is unprecedented and it corresponds to the first Te–C cleaved product. The reaction of **2** with CH_3I, yields the oxidative addition product, $CH_3TeI(S_2CNC_5H_{10})_2$ (**8**). The formation of **2** is also supported through Quantum Chemical calculations. Another Te–C bond cleaved product $TeI_2[(C_{13}H_{10}N_2S)_2]\cdot 4C_4H_8TeI_2$ (**9**) is obtained in the reaction of $C_4H_8TeI_2$ (1,1,2,3,4,5-hexahydro-1,1-diiodotellurophene) with $NH_4S_2CNHC_6H_5$ (ammonium aniline dithiocarbamate). The reaction of 1,1,2,3,4,5,6-heptahydro-1-iodo-1-(morpholine dithiocarbamato) tellurane $[C_5H_{10}TeI(S_2CNC_4H_8O)]$ (**10**) with 1,10-phenanthroline gives an unusual product $C_{12}H_8N_2\cdot C_4H_{10}INO$ (**11**). The structures of the new complexes **2**, **8**, **9**, **10** and **11** have been determined by the X-ray analysis.

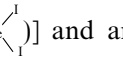
Keywords: Organotellurium; Dithiocarbamates; Cleavage; Quantum Chemical calculations

1. Introduction



Tellurium organic complexes/organotelluriums have received considerable attention because of (i) the inherent unique tendency of tellurium to be retained in myocardium. Hence tellurium fatty acids have been used as heart imaging agents in nuclear medicine [1] (ii) telluroxanes for tellurite glasses because of their potential applications in non-linear optics and as ionic conductive materials [2] (iii) organotelluriums in organic synthesis [3] and as precursors for (a) semiconductors [4] and (b) optoelectronic materials [5]. On the other hand dithiocarbamate complexes can be used to construct sensors for guest molecules [6]. Further, the chemotherapeutic use of *cis*-diamino dichloro platinum(II) and related drugs often results in some negative side effects including nephrotoxicity which is thought to be caused by the inactivation of enzymes due to the coordination of Pt(II) by thiol groups [7a]. The protection of these thiols is achieved by the use of competitive "rescue agents" such as diethyl dithiocarbamate (Et_2NCS_2) ions [7b,7c,7d] containing soft sulfur atoms. A variety of reactions of organotellurium compounds are known [8a] and organotellurium(IV) dithiocarbamate complexes are generally, prepared by the substitution reactions of organotellurium

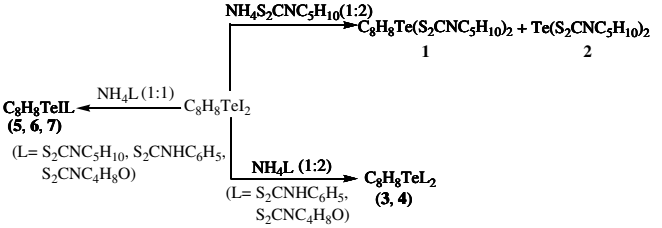
(IV) complexes with sodium or ammonium salts of dithiocarbamates [8].

The reactions of organotelluriums involving cleavage of Te–C bonds are known but they are restricted to organotellurium(II) complexes. McWhinnie et al. [9] described the lability of organic groups from tellurium on reaction of organotellurium(II) with a series of metal compounds. Uemura et al. [10] reported a palladium catalysed cross coupling reaction between organic tellurides and alkenes involving cleavage of Te–C bonds. Recently Singh et al. [11] reported Te–C bond cleavage in the reactions of organotellurium(II) compounds with $HgCl_2$ and $Pt(COD)Cl_2$.

So far, we have not come across any metathetical reaction where organo(heterocyclic)tellurium(IV) compounds have undergone cleavage of Te–C bonds along with the substitution reaction. We report in the following unusual Te–C scissions in the reaction between organotellurium(IV) compound: 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl diiodide [$C_8H_8TeI_2$()] and ammonium piperidine dithiocarbamate ($NH_4S_2CNC_5H_{10}$) (1:2 molar ratio) resulting in the cleavage of Te–C bonds to give the $Te(S_2CNC_5H_{10})_2$ (**2**) along with the expected product $C_8H_8Te(S_2CNC_5H_{10})_2$ (**1**). Reaction of $C_8H_8TeI_2$ with $NH_4S_2CNC_5H_{10}$ (1:1 molar ratio) gives $C_8H_8TeI(S_2CNC_5H_{10})$ (**5**). The reaction of $Te(S_2CNC_5H_{10})_2$ (**2**) with CH_3I gives oxidative addition product $CH_3TeI(S_2CNC_5H_{10})_2$ (**8**). Recent studies [12] show that Quantum Chemical calculations are remarkably successful in predicting/justifying a wide range of problems in organometallic chemistry. We have therefore performed Quantum Chemical calculations on a model system to support the formation of **2**. Other reactions of $C_8H_8TeI_2$ with ammonium salts of aniline- and morpholine-dithiocarbamates in (1:1) and (1:2) molar ratio yield the expected $C_8H_8TeL_2$ and C_8H_8TeIL (L = $S_2CNHC_6H_5$, $S_2CNC_4H_8O$) (**3**, **4**, **6**, **7**).

Another Te–C bond cleaved product $TeI_2[(C_{13}H_{10}N_2S_2)_2]\cdot 4C_4H_8TeI_2$ (**9**) is obtained in the reaction of 1,1,2,3,4,5-hexahydro-1,1-diiodotellurophene [$C_4H_8TeI_2$()] with ammonium aniline dithiocarbamate ($NH_4S_2CNHC_6H_5$) (1:2 molar ratio). The reaction of 1,1,2,3,4,5,6-heptahydro-1-iodo-1-(morpholine dithiocarbamato) tellurane [$C_5H_{10}TeI(S_2CNC_4H_8O)$] (**10**) with 1,10-phenanthroline gives an unusual product $C_{12}H_8N_2\cdot C_4H_{10}INO$ (**11**). The structures of the complexes **2**, **8**, **9**, **10** and **11** have been determined by the X-ray analysis.



2. Experimental

1,3-Dihydro-2λ^4-benzotellurole-2,2-diyl diiodide ($C_8H_8TeI_2$) was prepared by a modified method (developed in our laboratory) and recrystallized from hot 2-methoxyethanol [13a,13b,13c] to obtain yellow–orange crystals. Te metal, α,α′-dibromoxylene, sodium iodide, iodomethane, 1,4-diiodobutane, 1,5-diiodopentane were obtained from Aldrich and used as received. Piperidine, morpholine, aniline and carbon disulphide (Aldrich) were distilled before use. 2-Methoxy ethanol, solvent ether, petroleum ether, dichloromethane and ethanol were dried by usual methods and distilled before use. Ammonium salts of piperidine-, aniline- and morpholine-dithiocarbamates were freshly prepared. Melting points were recorded in capillary tubes and are uncorrected. Elemental analyses for C, H and N were carried on an Elemental Analyser Heraeus Carlo Erba 1108. Tellurium content was determined volumetrically in the laboratory. IR spectra were recorded using a Shimadzu 8210 PC FTIR spectrometer in the frequency range 4000–350 cm^{-1} with the samples in KBr discs. ^1H and ^{13}C NMR spectra were recorded at 300.13 MHz in $CDCl_3$ solutions containing tetramethyl silane as internal standard on a Varian DRX 300 spectrometer.

2.1. Synthesis of $C_8H_8TeL_2$, C_8H_8TeIL and $Te(S_2CNC_5H_{10})_2$ (L = $S_2CNC_5H_{10}$, $S_2CNC_4H_8O$ and $S_2CNHC_6H_5$)

1,3-Dihydro-2λ^4-benzotellurole-2,2-diyl bis (piperidine dithiocarbamate) $C_8H_8Te(S_2CN\ C_5H_{10})_2$ (**1**), bis(piperidine dithiocarbamato) tellurium(II) $Te(S_2CNC_5H_{10})_2$ (**2**), 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl bis(aniline dithiocarbamate) $C_8H_8Te(S_2CNHC_6H_5)_2$ (**3**), 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl bis(morpholine dithiocarbamate) $C_8H_8Te(S_2CN\text{-}C_4H_8O)_2$ (**4**), 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl-1-iodo-1-piperidine dithiocarbamate $C_8H_8TeI(S_2CNC_5H_{10})$ (**5**), 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl-1-iodo-1-aniline dithiocarbamate $C_8H_8TeI(S_2CNHC_6H_5)$ (**6**), 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl-1-iodo-1-morpholine dithiocarbamate $C_8H_8TeI(S_2CNC_4H_8O)$ (**7**) were prepared by stirring 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl diiodide with freshly prepared ammonium salts of piperidine-, aniline- and morpholine-dithiocarbamates in 1:2 and 1:1 molar ratio in CH_2Cl_2 (Scheme 1).

Complex **1** was prepared by stirring 1,3-dihydro-2λ^4-benzotellurole-2,2-diyl diiodide (2.00 g, 4.12 mmol) in dichloromethane (~25 ml) with freshly prepared ammonium salt of piperidine dithiocarbamate (1.466 g, 8.24 mmol) in 1:2 molar ratio at room temperature (25 °C). After ~6 h the orange colour of the reaction mix-

Scheme 1.

ture changed to a brown colour. The reaction mixture was filtered to eliminate the unidentified material. The filtrate was concentrated to ~10 ml under reduced pressure and kept overnight. A few red crystals were obtained along with an orange solid. The red crystals were separated manually, washed with solvent ether and they were analysed through elemental analysis, FT-IR and single crystal X-ray diffraction studies. These red crystals corresponded to $Te(S_2CNC_5H_{10})_2$ (**2**) (Fig. 1) (Table 2). The orange solid was washed with solvent ether and dried. It was characterized through elemental analysis, FT-IR and (^1H, ^{13}C) NMR spectral data and it corresponded to $C_8H_8Te(S_2CNC_5H_{10})_2$ (**1**). Complexes **3**–**7** were obtained following the same procedure as in **1**. Complex **1** yield: 1.05 g (46%),

2.1.1. Synthesis of $CH_3TeI(S_2CNC_5H_{10})_2$ (**8**)

To the stirred solution of $Te(S_2CNC_5H_{10})$ (**2**) (0.11 g, 0.326 mmol) in dichloromethane (~10 ml) was added (0.10 ml, 1.579 mmol) of CH_3I. It was stirred for 24 h. The solution was filtered and reduced to ~5 ml and then poured in a petri dish. A solid was obtained which on recrystallization with CS_2/ether gave yellow needle shaped crystals of **8** (Fig. 3) (Table 3). Complex **8** yield: 0.10 g (34%), m.p. 120 °C. *Anal.* Calc. for $C_{13}H_{23}IN_2S_4Te$: C, 26.46; H, 3.90; N, 4.75; Te, 21.64. Found: C, 26.44; H, 3.88; N, 4.74; Te, 21.62%. ^{1}H NMR ($CDCl_3$) δ: 3.30 [s, 3H, CH_3], 4.03 [s, 8H, (–CH_2)$_2$N], 1.77[m, 12H, –$C(CH_2)_2$ & –$CC(CH_2)$].

2.2. X-ray measurements

A summary of the crystal data and refinement parameters for $Te(S_2CNC_5H_{10})_2$ (**2**), $CH_3ITe(S_2CNC_5H_{10})_2$ (**8**), $TeI_2[(C_{13}H_{10}N_2S_2)_2]\cdot 4C_4H_8TeI_2$ (**9**), $C_5H_{10}TeI(S_2CNC_4H_8O)$ (**10**) and $C_{12}H_8N_2\cdot C_4H_{10}INO$ (**11**) are given in Table 1. The crystals of **2** were mounted on a Bruker P4 and of **9** on an Oxford Diffraction Gemini while those of **8**, **10** and **11** were mounted on a SMART CCD diffractometer using graphite-monochromated MoKα radiation ($\lambda = 0.71073$ Å). The structure of **2** was solved in space group $P2_1/n$, **8** in space group $P\bar{1}$, **9** in space group $P\bar{1}$, **10** in space group $P2_1/n$ and **11** in space group $P2_1/n$. The data were corrected for Lorentz, polarization and absorption effects. Since, we have been able to grow only large size crystals of complex **9**, hence the crystal placed for single crystal diffraction studies was an irregular chunk cut from the large crystal. As such it did not have faces that could be indexed to allow for a numerical absorption correction. Instead, an absorption correction based on equivalent reflections was applied.

The structures of **2**, **8**, **9**, **10** and **11** were solved by routine heavy atom and Fourier methods (SHELXS-97 [14]). Non-hydrogen atoms were refined anisotropically by full-matrix least squares using the SHELXL-97 program [14] for **2**, **8**, **9**, **10** and **11** with hydrogen atoms in idealized positions (Table 1). Selected bond lengths and bond angles for **2** and **8** are listed in Tables 2 and 3, respec-

Table 3

tively, whereas the data for **9**, **11**, **10** are listed in Tables 5–7.

2.3. Quantum Chemical calculations

The core potential basis sets (LANL2DZ) of GAUSSIAN 98 program [15] were employed for the QC calculations, equipped with the extra basis sets of the d-type polarization functions and the sp-type diffusion functions for C, N, S, Te, and I, together with Br and Se. The calculations were performed at the Möller–Plesset second order energy correlation (MP2) level.

3. Results and discussion

The reaction of $C_8H_8TeI_2$ (1,3-dihydro-2λ^4-benzotellurole-2,2-diyl diiodide) with $NH_4S_2CNC_5H_{10}$ (ammonium piperidine dithiocarbamate) in 1:2 molar ratio in CH_2Cl_2 gives the expected product $C_8H_8Te(S_2CNC_5H_{10})_2$ (**1**) as well as the Te–C bond cleaved product $Te(S_2CNC_5H_{10})_2$ (**2**). A detailed investigation of the Te–C bond cleavage processes resulting in formation of **2** has been explained through Quantum Chemical calculations. The complexes (**1**–**8**) are thermally stable and unaffected by atmospheric oxygen and moisture. Spectroscopic data of (**1**–**8**) are given in the experimental section. In the IR spectra of the complexes (**1**–**8**) except **2**, the presence of doublets for ν(CN) and ν(CS) indicates the unidentate nature of the dithiocarbamate ligands. In **2**, single absorptions appear for ν(CN) and ν(CS) indicating the chelating nature of the piperidine dithiocarbamate ligand [16] and [17]. The solution (^{1}H, ^{13}C) NMR data exhibit characteristic signals at their expected positions with expected multiplicity [8d,8f].

When $C_4H_8TeI_2$ is reacted with ammonium aniline dithiocarbamate, one of the products is the Te–C bond cleaved complex $TeI_2[(C_{13}H_{10}N_2S)_2]\cdot 4C_4H_8TeI_2$ (**9**) which results from the cleavage of Te–C bonds from $C_4H_8TeI_2$.

The reaction of $C_5H_{10}TeI(S_2CNC_4H_8O)$ (**10**) with 1,10-phenanthroline yields the unusual product $C_{12}H_8N_2 \cdot C_4H_{10}INO$ (**11**). The X-ray structures and the supramolecular associations of **2**, **8**, **9**, **10** and **11** are described in the following pages.

3.1. Description of the structure of $Te(S_2CNC_5H_{10})_2$ (2)

In bis(piperidine dithiocarbamato) tellurium(II) $[Te(S_2CNC_5H_{10})_2]$ (**2**), the tellurium atom is bonded to two piperidine dithiocarbamate ($S_2CNC_5H_{10}$) groups through two sulfur atoms from each $S_2CNC_5H_{10}$ group (Fig. 1) with the bond distances and angles; Te–S(1A) = 2.505(1) Å, Te–S(2A) = 2.855(2) Å, Te–S(1B) = 2.523(1) Å, Te–S(2B) = 2.858(2) Å; ∠ S(1A)–Te–S(1B) = 80.91(5)°, ∠S(1A)–Te–S(2A) = 66.28(4)°, ∠S(1B)–Te–S(2A) = 147.17(4)°, ∠S(1A)–Te–S(2B) = 146.87(4)°, ∠S(1B)–Te–S(2B) = 66.02(4)°, ∠S(2A)–Te–S(2B) = 146.71(4)° (Table 2). Thus tellurium is tetra coordinated and a stereochemically active electron lone pair, apparently, occupies the fifth coordination position.

The $S_2CNC_5H_{10}$ ligands chelate the tellurium atom with asymmetric Te–S bonds (approximately 2.5 and 2.8 Å) and this asymmetry is reflected in the associated C–S bonds. The two sulfur atoms of both $S_2CNC_5H_{10}$ groups are bonded to the carbon atom with the bond length and bond angles, S(2A)–C(1A) = 1.685(5) Å, S(1A)–C(1A) = 1.734 (5) Å, S(1B)–C(1B) = 1.740(5) Å, S(2B)–C(1B) = 1.693 (5) Å; ∠S(2B)–C(1B)–S(1B) = 118.2(3)°, ∠ S(2A)–C(1A)–S(1A) = 118.9(3)°. The C(1A) and C(1B) carbon atoms are bonded to N(1A) and N(1B) with the bond distances 1.338(6) and 1.317(6) Å, respectively. The average C–N and C–C bond length in both $C_5H_{10}N$ rings are 1.422 Å and 1.506 Å, respectively.

The molecule of $Te(S_2CNC_5H_{10})_2$ is connected to an adjacent molecule by Te···S secondary bonds [Te···S(2-BA) = S(2B)···TeA = 3.548(1) Å, ∠C–S···Te = 142.4°] resulting in a dimer (the sum of covalent radii and van der Waal radii of Te–S are 2.38 Å and 3.86 Å, respectively [8c] and [18] hence Te···S corresponds to a secondary bond). In this dimer each tellurium is surrounded by four sulfur atoms and one stereochemically active electron lone pair and a secondary bond (Te···S). This results in hexa-coordination around each tellurium atom resulting in distorted octahedral geometry. The structure of **2** is similar to the structure of $Te(S_2CNC_4H_8O)_2$ by Husebye [19]. These dimeric units of $Te(S_2CNC_5H_{10})_2$ are interlinked with each other by S···S intermolecular secondary bonds (3.607 Å) [8c] (∠C–S···S = 128.7 Å) resulting in decameric supramolecular association (Fig. 2). Such type of inorganic–organic hybrid polymeric supramolecular associations have attracted considerable attention in recent years because of their interesting molecular topologies and crystal packing motifs along with their potential applications in many areas including catalysis, transport, optics as well as electrical conductivity [20–24].

3.1.1. Description of the structure of $CH_3TeI(S_2CNC_5H_{10})_2$ (**8**)

An ORTEP diagram of iodomethyl bis(piperidine dithiocarbamato) tellurium(IV) $[CH_3TeI(S_2CNC_5H_{10})_2]$ (**8**) is shown in Fig. 3. The selected bond lengths and angles are listed in Table 3. Coordination to the tellurium atom in **8** is from four sulfur atoms, one methyl carbon and an iodine atom. The four sulfur atoms [Te–S(1A) = 2.681(8) Å, Te–S(2A) = 2.672(7) Å, Te–S(1B) = 2.711(7) Å, Te–S(2B) = 2.722(8) Å] and the iodine atom [Te–I = 2.973(4) Å, ∠S(2A)–Te–I = 143.68(17)°, ∠S(1A)–Te–I = 77.32(17)°, ∠S(1B)–Te–I = 77.08(17)°, ∠S(2B)–Te–I =

142.53(16)°] are arranged in a pentagonal plane about the tellurium atom. The methyl group is perpendicular to the

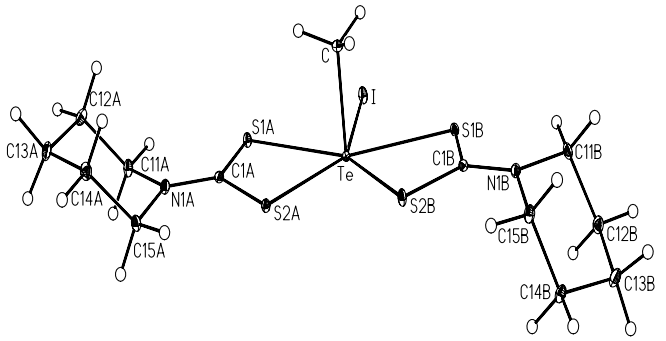

Fig. 3. Crystal structure of $CH_3TeI(S_2CNC_5H_{10})_2$ (**8**).

plane [Te–C = 2.122(3) Å, ∠C–Te–S(1A) = 86.51(8)°, ∠C–Te–S(2A) = 88.62(8)°, ∠C–Te–S(1B) = 86.46(8)°, ∠C–Te–S(2B) = 87.48(8)°] and a sterically active electron lone pair in the opposite side of the plane impart an overall seven coordinated pseudo-pentagonal bipyramidal environment about tellurium atom. The Te–S bond angles are ∠S(1A)–Te–S(IB) = 153.41(2)°, ∠S(2A)–Te–S(2B) = 73.66 (2)°, ∠S(1A)–Te–S(2A) = 66.38(2)° and ∠S(1B)–Te–S(2B) = 65.45(2)°.

The two sulfur atoms of each $S_2CNC_5H_{10}$ group are bonded to the carbon atoms with the bond lengths and bond angles; S(1A)–C(1A) = 1.723(3) Å, S(2A)–C(1A) = 1.727(3) Å, ∠S(1A)–C(1A)–S(2A) = 116.26(2)°, S(1B)–C(1B) = 1.725(3) Å, S(2B)–C(1B) = 1.717(3) Å, ∠S(1B)–C(1B)–S(2B) = 117.16(2)°. The C(1A) and C(1B) carbon

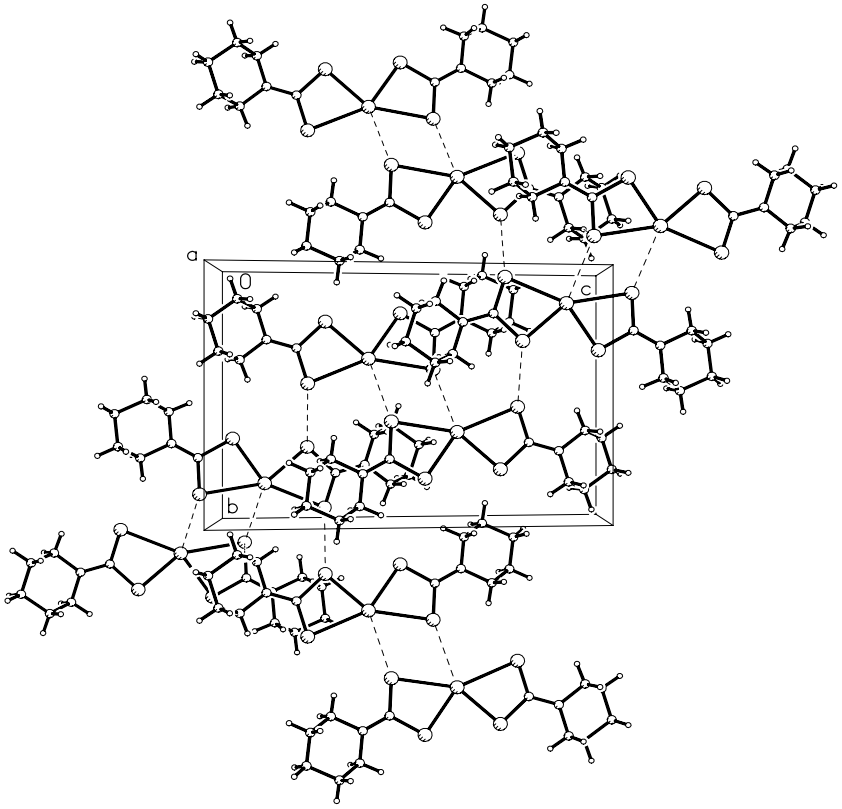

Fig. 2. Decameric supramolecular associations of **2** linked through Te···S and S···S intermolecular secondary bonds.

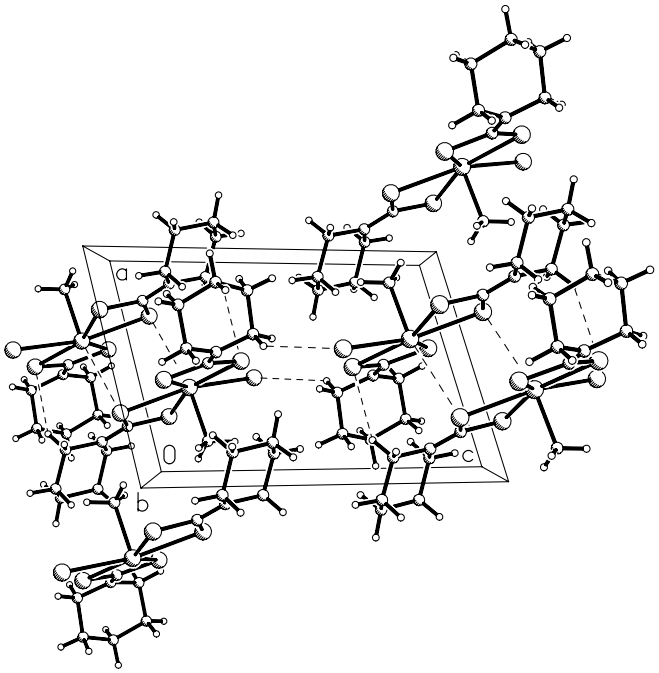

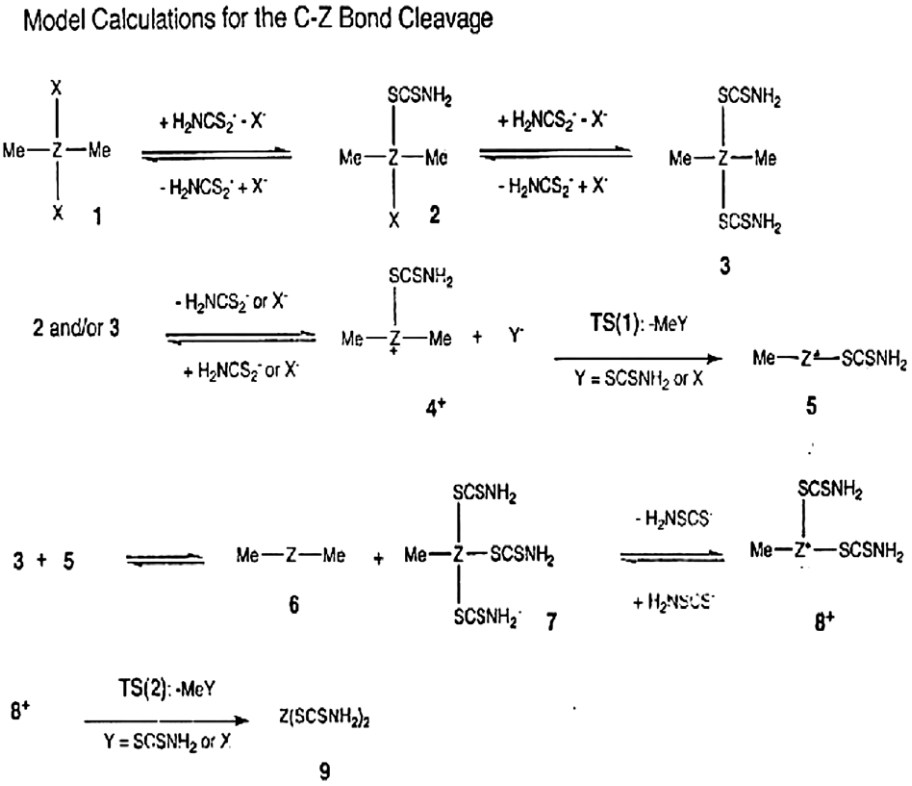

Fig. 4. Tetrameric supramolecular associations of **8** linked through Te···S secondary bonds C–H···I and C–H···S hydrogen bonds.

atoms are bonded to N(1A) and N(1B) with the bond distances 1.321(4) Å, 1.325(4) Å, respectively. The average C–N and C–C bond lengths in both $C_5H_{10}N$ rings are 1.421 Å and 1.523 Å, respectively.

The structure of **8** differs significantly from that of $Te(S_2CNC_5H_{10})_2$ (**2**) where pentacoordination environment about tellurium atom is present. Furthermore, the dithiocarbamate ligands are anisobidentically chelated in $Te(S_2CNC_5H_{10})_2$ (**2**) whereas in $CH_3ITe(S_2CNC_5H_{10})_2$ (**8**) all the tellurium sulfur bonds are close to equivalent and thus dithiocarbamate ligand is symmetrically chelated in the latter case.

It is interesting to note that changing the donor set about the tellurium atom from S_4 in $Te(S_2CNC_5H_{10})_2$ to S_4CI in $CH_3TeI(S_2CNC_5H_{10})_2$ causes the dithiocarbamate ligands to coordinate symmetrically in the latter case. This in turn, implies that the asymmetry observed in the former complex **2** is not a result of steric strain within the four membered (TeS_2C).

In the unit cell (Fig. 4) the molecules of $CH_3TeI(S_2CNC_5H_{10})_2$ are symmetrically connected through Te···S secondary bonds [Te–S(2A) #1 = 3.549 Å] to form dimers. These dimers are connected through C–H···I hydrogen bonds [C(12A)···I#1 = 4.098(3) Å, H(12D)···I#1 = 3.24 Å, ∠C(12A)–H (12D)···I#1 = 146.5°; C(11B)···I#2 = 4.015(3) Å, H(11A)···I#2 = 3.20 Å, ∠C(11B)–H (11A)···I#2 = 140.9°, C(15B)···I#3 = 4.353(3) Å, H(15D)···I#3 = 3.40 Å, ∠C(15B)–H(15D) ···I#3 = 162.9°] to form tetrameric supramolecular association where octa- and heptacoordinated telluriums are present. Apart from these hydrogen bonds, intermolecular C–H···S hydrogen bonds [C(15A)···S(1B)#4 = 3.808(3) Å, H (15B)···S(IB)#4 = 2.93 Å, ∠C(15A)–

Scheme 2.

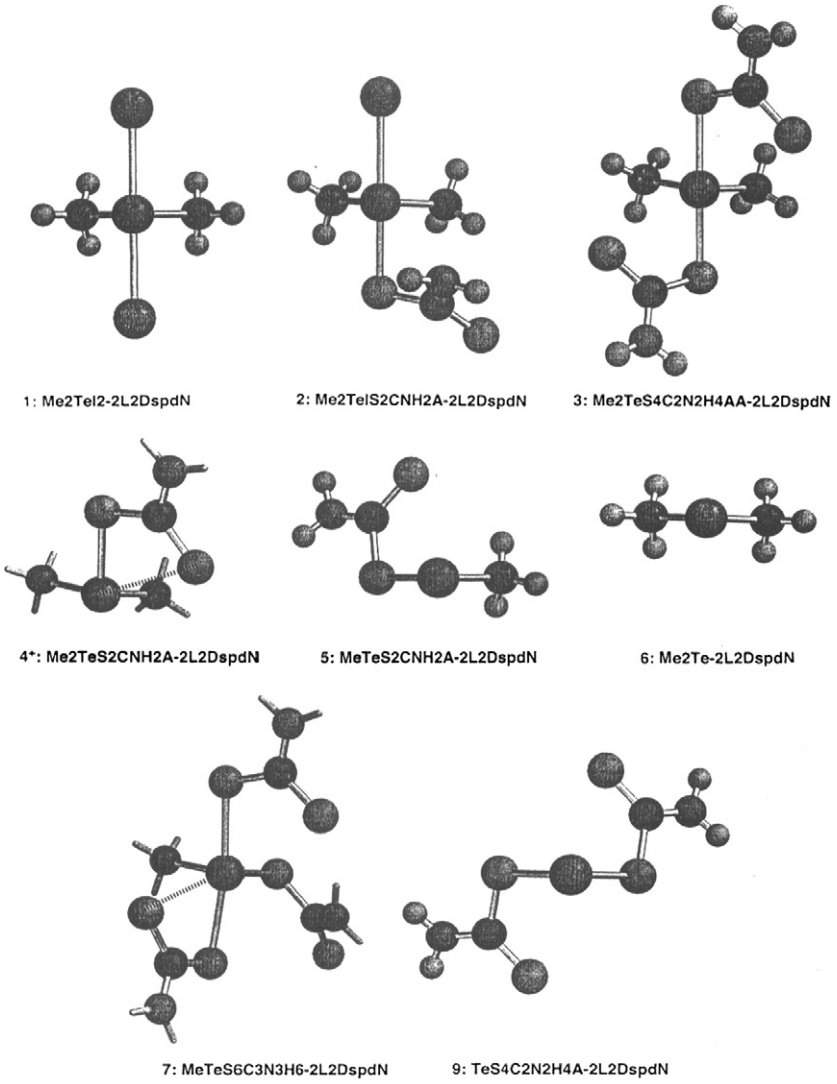

Fig. 5. Optimized structures of substrates, intermediates, products, and transition states of the reaction involved in the formation of $Te(S_2CNC_5H_{10})_2$ (**2**).

H(15B)···S(1B)#4 = 147.6°, C(14B)···S(2A)#5 = 3.719 (3) Å, H (14A)···S(I2A)#5 = 2.80 Å, ∠C(14B)–H(14A) ···S(2A)#5 = 155.3°] are also present.

3.2. Quantum Chemical calculations

The reaction of $C_8H_8TeI_2$ with $NH_4S_2CNC_5H_{10}$ gives $C_8H_8Te(S_2CNC_5H_{10})_2$ (**1**) and $Te(S_2CNC_5H_{10})_2$ (**2**) and/or $C_8H_8TeI(S_2CNC_5H_{10})$ (**5**), according to the reaction conditions. QC calculations were performed on the processes of the reaction, modeled by the reaction Me_2TeI_2 with $H_2NCS_2^-$. The MP2/LANL2 method of the GAUSSIAN 98 program [15] was employed for the calculations, with the extra basis sets of the d-type polarization functions and the sp-type diffusion functions for C, N, S, Te, and I. Scheme 2 shows the postulated processes of the reaction, together with the species produced or intervened in the reaction.

Fig. 5 draws optimized structures of substrates, intermediates, products, and transition states of the reaction.

Table 4 collects the optimized energies of the species. Fig. 6 shows the energy profiles of the reaction, which clarifies the mechanism.

The results strongly support the mechanism shown in Scheme 2. The Te–C bond cleaves by the nucleophilic substitution at C_{Me} of the substrate after ligand exchange with the reagent followed by the partial dissociation, which gives the key substrates ($\mathbf{4}^+$ and $\mathbf{8}^+$) in the reaction. The transition states are also well optimized. However, they are more stable than $\mathbf{4}^+ + I^-$ or $\mathbf{4}^+ + Y^-$, since ionic species are evaluated to be at higher energy.

4. Another Te–C bond cleavage reaction

The reaction of another organo(heterocyclic)tellurium(IV) derivative: 1,1,2,3,4,5-hexahydro-1,1-diiodotel-

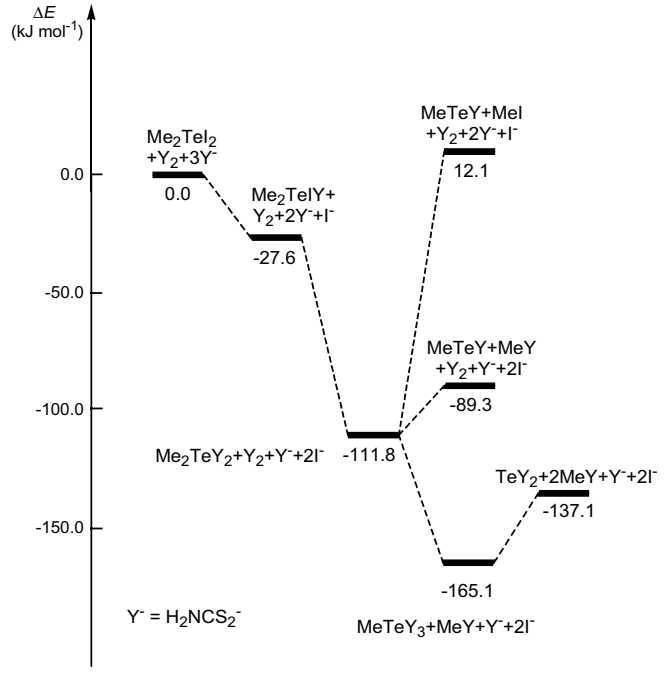

Fig. 6. Calculation on the reaction of Me_2TeI_2 and $H_2NCS_2^-$ (Y^-) with the MP2/LANL2DZ method, containing polarization of d-type and diffusion of sp type functions for non-H atoms.

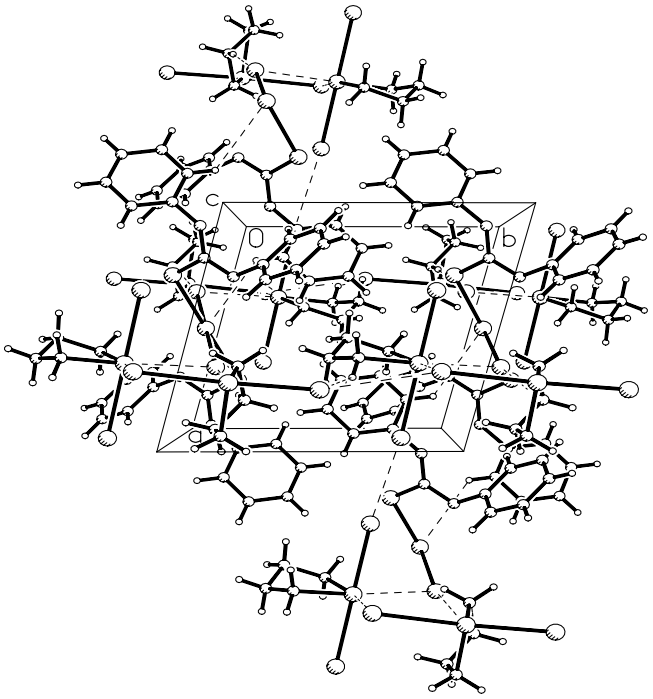

Fig. 8. Crystal structure of $TeI_2[(C_{13}H_{10}N_2S)_2] \cdot 4C_4H_8TeI_2$ (**9**).

lurophene ($C_4H_8TeI_2$) [25] (1.00 g, 2.285 mmol), containing the Te(C_4H_8Te) heterocycle with ammonium aniline dithiocarbamate ($NH_4S_2CNHC_6H_5$) (0.85 g, 4.570 mmol) in 1:2 molar ratio in chloroform gave Te–C bond cleaved product $TeI_2[(C_{13}H_{10}N_2S)_2] \cdot 4C_4H_8TeI_2$ (**9**) with four complete ($C_4H_8TeI_2$) moieties. This has been characterized by single crystal X-ray diffraction studies only (Table 5). A cursory glance at the structure of **9** (Fig. 7) indicates rearrangement of aniline dithiocarbamate groups bound to tellurium of TeI_2 through their S atoms and such system is connected to parent $C_4H_8TeI_2$ moieties through Te···I interactions (Fig. 8).

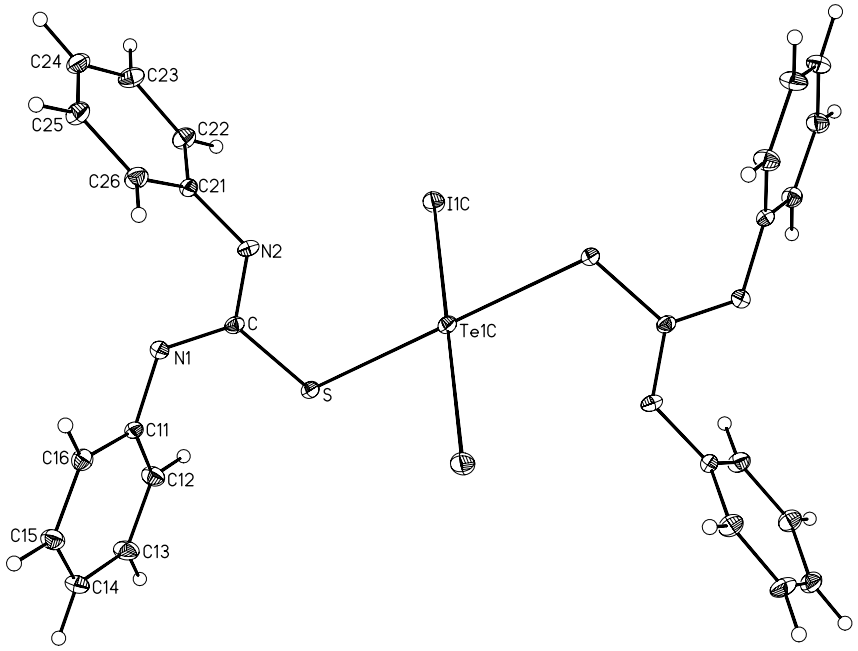

Fig. 7. Crystal structure of $TeI_2[(C_{13}H_{10}N_2S)_2]$.

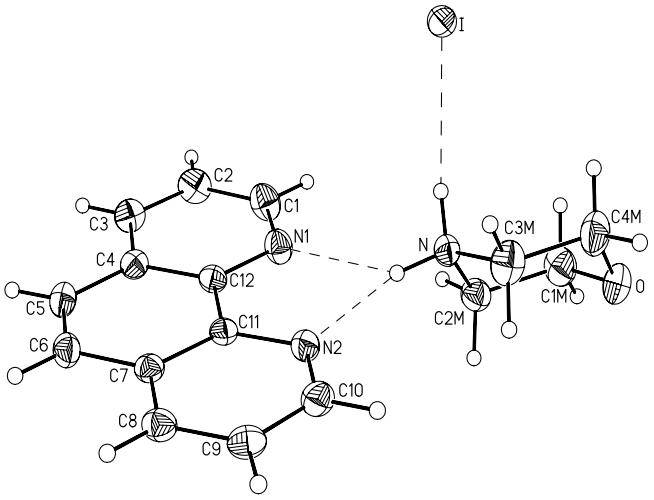

Fig. 9. Crystal structure of $C_{12}H_8N_2 \cdot C_4H_{10}INO$ (**11**).

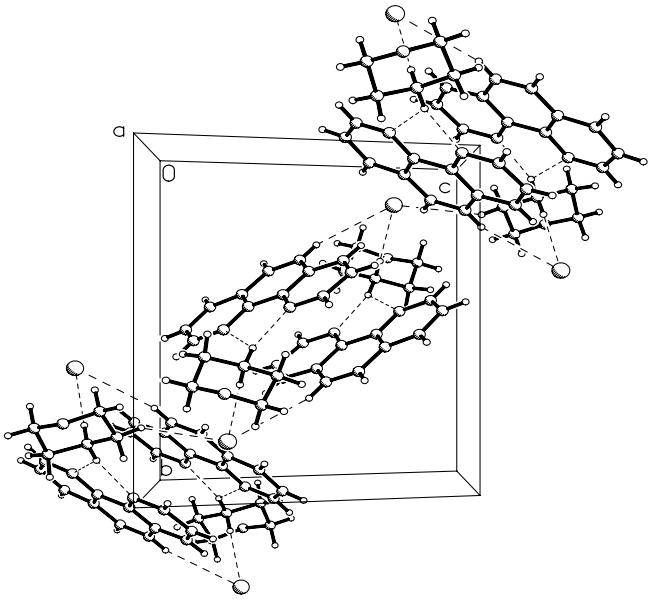

Fig. 10. Hexameric supramolecular associations of **11** linked through N···H and I···H secondary interactions.

4.1. Related reaction

The reaction of 1,1,2,3,4,5,6-heptahydro-1-iodo-1-(morpholine dithiocarbamato) tellurane $[C_5H_{10}TeI(S_2CNC_4H_8O)]$[1] (**10**) (0.50 g, 1.028 mmol) with 1,10-phenanthroline ($C_{12}H_8N_2 \cdot H_2O$) (0.204 g, 1.030 mmol) in 1: 1 molar ratio in dry acetone yielded $C_{12}H_8N_2 \cdot C_4H_{10}INO$ (**11**). The structure of **11** reveals it to contain morpholine connected to 1, 10-phenanthroline through N···H and I···H secondary interactions (Fig. 9) (Table 6).

The dimer of **11** is formed by the association of molecules of **11** connected through I···H (1,10-phenanthroline) secondary interactions and these dimeric units are connected to each other through I···H (morpholine) secondary interactions yielding hexameric supramolecular assembly (Fig. 10).

5. Conclusions

Reaction of $C_8H_8TeI_2$ with $NH_4S_2CNC_5H_{10}$ gives the usual product $C_8H_8Te(S_2CNC_5H_{10})_2$ (**1**) and the Te–C bond cleaved product $Te(S_2CNC_5H_{10})_2$ (**2**). The formation of **2** in such type of metathetical reaction is unprecedented. The reaction of **2** with CH_3I yields the oxidative addition product $CH_3TeI(S_2CNC_5H_{10})$ (**8**). Quantum Chemical calculations also support the formation of **2** (Fig. 11).

The other Te–C cleaved product, **9**, is obtained from the reaction of $C_4H_8TeI_2$ with ammonium aniline dithiocarbamate. The reaction of $C_5H_{10}TeI(S_2CNC_4H_8O)$ (**10**) with 1,10-phenanthroline yields the unusual product **11**.

[1] Yellow crystals of **10** were obtained by the reaction of $C_5H_{10}TeI_2$ [26] (2.00 g, 4.42 mmol) with ammonium salt of morpholine dithiocarbamate (0.79 g, 4.42 mmol) in 1:1 molar ratio in acetone (Yield 1.20 g, 56%, m.p. 186 °C). The X-ray structure determination of $C_5H_{10}TeI(S_2CNC_4H_8O)$ (**10**) reveals it to contain the telluracyclohexane ring which is present in chair conformation in which part of the ring is flattened and a part is considerably puckered. The tellurium atom of this tellurium heterocycle is bonded to one of the sulfur atoms of the morpholine dithiocarbamate group and one I atom by two axial bonds approximately perpendicular to C–Te–C plane with the bond distances Te–I = 3.042(1) Å, Te–S(1)=2.520(10) Å forming bond angle I–Te–S(1) = 171.92(2)° which deviates from linearity with the sulfur and iodine atoms pushed away from the equatorial electron lone pair. This type of geometry has been observed previously in a variety of acyclic- and cyclic-organotellurium complexes [8e,8j,27–36]. The S of morpholine dithiocarbamate is connected to carbon through single bond and the other S of C=S (of CS_2 group) remains free [the bond distances and bond angles are C(1)–S(1) = 1.751(3) Å, C(1)–S(2) = 1.685(3) Å, C(1)–N = 1.316(4) Å, C(2)–N = 1.471(5) Å, ∠S(1)–C(1)–S(2) = 120.7(2)°, ∠S(1)–C(1)–N = 115.5(2)° and ∠N–C(1)–S(2) = 123.7(3)° (Fig. 11) (Table 7)].

X = Me, OMe, Cl, Br, H

Fig. 1. *meso*-Tetraarylporphyrins (H_2t(X)pp).

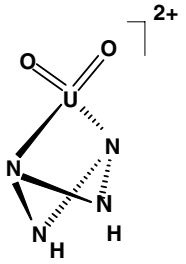

Fig. 2. In the scheme only the tetrahedrally tilted pyrrolenine nitrogens of a porphyrin core are shown. Two nitrogen atoms of pyrrolenine in one side of the porphyrin plane act as the electron donors to the uranium atom of the uranyl.

In this study we present the sitting-atop complex formation of *meso*-tetraarylporphyrins (Fig. 1) with uranyl nitrate hexahydrate. The ionic radius of the uranyl cation is too large so that it is not able to fit into the hole in the center of the macrocycle and it is located out of the ligand plane, distorting it (Fig. 2). Also, the selection of uranyl with a high oxidation number for uranium and using just a small amount of chloroform as a solvent with very weak basicity could be the cause that we successfully prepared the stable sitting-atop complexes as a solid. These conditions determined that the reactions did not progress until the deprotonation of the *meso*-tetraarylporphyrins and they remained at the intermediate step. The similarity of the results of UV–Vis and ^{1}H spectroscopy between the produced complexes and the molecular complexes obtained from the reaction of *meso*-tetraarylporphyrins with 2,3-dichloro-5,6-dicyano-benzoquinone (DDQ) [17], tetracyanoethylene (TCNE) [18], BF_3 [19], SiR_3Cl [20], $BiCl_3$ [21] and $SbCl_3$ [22], suggested saddled porphyrin core structures with one uranyl bonded to only two pyrrolenine nitrogens of the porphyrin, with the pyrrole protons not being released.

2. Experimental

2.1. Material and measurements

Benzaldehyde, various substituted benzaldehydes and uranyl nitrate hexahydrate were obtained from Merck and were used without further purification. Pyrrole, purchased from Merck, was distilled and chloroform (Merck) was dried over anhydrous calcium chloride for 3 days before use. Other solvents that were employed for the synthesis of the porphyrins and sitting-atop complexes were obtained from Merck and Fluka, and were used as received. *meso*-Tetraphenylporphyrin and its substituted derivatives were prepared and purified by the usual methods [23,24]. Alumina and trifluroacetic acid (TFA) were purchased from Merck and were used as received.

The ^{1}H NMR spectra were recorded on a Bruker 400 MHz spectrometer in $CDCl_3$. The residual $CHCl_3$ in the conventional 99.8% atom $CDCl_3$ gives a signal at $\delta = 7.26$ ppm, which was used for calibration of the chemical shift scale. The electronic absorption spectra were obtained in chloroform on an ATI UNICAM-UV\VIS Vision SOFTWARE V-2011 spectrophotometer. The molar conductance of the complexes was measured in acetone on a METROHM 644 conductometer. The FT-IR spectra were recorded on a Magna 550 Nicolet spectrometer using KBr pellets in the range 400–4000 cm^{-1}.

2.2. Preparation of $[(UO_2)H_2t(4\text{-}Me)pp](NO_3)_2$

To an equimolar mixture of *meso*-tetra(4-methylphenyl)porphyrin (0.5 mmol) and $UO_2(NO_3)_2 \cdot 6H_2O$ (0.5 mmol) in a mortar, chloroform (1 ml) was added dropwise, with grinding at ambient temperature for 30 min, until complexation was complete, which was determined by the disappearance of the Soret band of the porphyrin in the UV–Vis spectrum. The sitting-atop complex was obtained as a green solid and dried under vacuum at 50 °C and identified by elemental analysis, molar conductivity and spectroscopic data. *Anal.* Calc. for $C_{48}H_{38}N_6O_8U$: C, 54.1; H, 3.6; N, 7.9. Found: C, 53.5; H, 3.4; N, 7.6%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.5 (br, 2H, NH), 2.77 (s, 12H, CH_3), 8.58 (s, 8H, β), 8.50 (d, 8H, o, o′), 7.81 (d, 8H, m, m′). IR (KBr, cm^{-1}): $\upsilon_{NH} \sim 3320$.

2.3. Preparation of $[(UO_2)H_2t(4\text{-}OMe)pp](NO_3)_2$

This complex was synthesized by the method described for $[(UO_2)H_2t(4\text{-}Me)pp](NO_3)_2$. *Anal.* Calc. for $C_{48}H_{38}N_6O_{12}U$: C, 51.1; H, 3.4; N, 7.4. Found: C, 50.5; H, 3.1; N, 7.1%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.3 (br, 2H, NH), 4.17 (s, 12H, OCH_3), 8.55 (s, 8H, β), 8.24 (d, 8H, o, o′), 7.55 (d, 8H, m, m′). IR (KBr, cm^{-1}): $\upsilon_{NH} \sim 3320$.

2.4. Preparation of $[(UO_2)H_2t(3\text{-}Me)pp](NO_3)_2$

To a mixture of *meso*-tetra(3-methylphenyl)porphyrin (0.5 mmol) and $UO_2(NO_3)_2 \cdot 6H_2O$ (0.6 mmol) in a mortar, chloroform (1 ml) was added dropwise, with grinding at ambient temperature for 30 min, until complexation was complete, which was determined by the disappearance of the Soret band of the porphyrin in the UV–Vis spectrum. The crude product was washed with diethylether for purification and dried under vacuum at 50 °C. The sitting-atop

complex was obtained as a green solid and identified by elemental analysis, molar conductivity and spectroscopic data. *Anal*. Calc. for $C_{48}H_{38}N_6O_8U$: C, 54.1; H, 3.6; N, 7.9. Found: C, 55.0; H, 3.5; N, 7.7%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.5 (br, 2H, NH), 2.87 (s, 12H, CH_3), 8.77 (s, 8H, β), 8.46 (s, 4H, o), 8.46 (d, 4H, o′), 7.95 (t, 4H, m), 7.85 (d, 4H, p). IR (KBr, cm^{-1}): υ_{NH} ~ 3320.

2.5. Preparation of [(UO$_2$)H$_2$t(3-OMe)pp](NO$_3$)$_2$

The procedure was similar to that for [(UO$_2$)H$_2$t(3-Me)pp](NO$_3$)$_2$. *Anal*. Calc. for $C_{48}H_{38}N_6O_{12}U$: C, 51.1; H, 3.4; N, 7.4. Found: C, 50.3; H, 3.3; N, 7.1%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.5 (br, 2H, NH), 3.99 (s, 12H, OCH_3), 8.84 (s, 8H, β), 7.87 (s, 4H, o), 7.87 (d, 4H, o′), 7.73 (t, 4H, m), 7.40 (d, 4H, p). IR (KBr, cm^{-1}): υ_{NH} ~ 3320.

2.6. Preparation of [(UO$_2$)H$_2$t(4-Cl)pp](NO$_3$)$_2$

This synthesis was carried out using the above method. *Anal*. Calc. for $C_{44}H_{26}Cl_4N_6O_8U$: C, 46.1; H, 2.3; N, 7.3. Found: C, 45.5; H, 2.0; N, 7.5%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.5 (br, 2H, NH), 8.53 (s, 8H, β), 8.37 (d, 8H, o, o′), 7.85 (d, 8H, m, m′). IR (KBr, cm^{-1}): υ_{NH} ~ 3320.

2.7. Preparation of [(UO$_2$)H$_2$t(4-Br)pp](NO$_3$)$_2$

The same procedure was adopted. *Anal*. Calc. for $C_{44}H_{26}Br_4N_6O_8U$: C, 39.9; H, 2.0; N, 6.3. Found: C, 39.5; H, 2.2; N, 6.6%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.5 (br, 2H, NH), 8.79 (s, 8H, β), 8.50 (d, 8H, o, o′), 8.24 (d, 8H, m, m′). IR (KBr, cm^{-1}): υ_{NH} ~ 3320.

2.8. Preparation of [(UO$_2$)H$_2$tpp](NO$_3$)$_2$

This complex was synthesized by the method described above. *Anal*. Calc. for $C_{44}H_{30}N_6O_8U$: C, 52.4; H, 3.0; N, 8.3. Found: C, 53.0; H, 3.1; N, 8.1%. ^{1}H NMR ($CDCl_3$, δ ppm): ~−0.5 (br, 2H, NH), 8.64 (s, 8H, β), 8.25 (d, 8H, o, o′), 8.02 (t, 8H, m, m′), 7.71 (d, 4H, p). IR (KBr, cm^{-1}): υ_{NH} ~ 3320.

3. Results and discussion

The ^{1}H NMR spectra obtained for the reactions of different ratios of uranyl nitrate hexahydrate (0.25, 0.5, 0.75, 1.0, 1.5 and 2.0) with *meso*-tetraarylporphyrins (H$_2$t-(4-Me)pp and H$_2$t(4-OMe)pp) showed when the amount of $UO_2(NO_3)_2 \cdot 6H_2O$ was less than a 1:1 mole ratio, we produced a mixture of the porphyrin and the related sitting-atop complex. In presence of excess $UO_2(NO_3)_2 \cdot 6H_2O$ no changes in the spectrum of the 1:1 mixture were observed. Consequently, the sitting-atop complexation between $UO_2(NO_3)_2 \cdot 6H_2O$ and the porphyrins occurred with a 1:1 mole ratio. This was also confirmed by the elemental analysis data.

It is observed that in the free bases H$_2$t(X)pp, the N–H protons are upfield (−2.75 to −2.86 ppm, singlet), and the β-protons appear in the range 8.85–8.90 ppm (singlet). The formation of sitting-atop complexes of *meso*-tetraarylporphyrins with uranyl, similar to the molecular complexation of *meso*-tetraarylporphyrins with various acceptors [17–22], cause downfield shifts for the proton signals of N–H (to a broad peak at about −0.5 ppm for all of the porphyrins in Fig. 1) and aryl rings, and an upfield shift of the β-hydrogens, Table 1. The shifts of the internal N–H (~2.3 ppm downfield) and β-protons (0.06–0.31 upfield) are related to the difference in the ring current between the *meso*-tetraarylporphyrins and the related sitting-atop complexes. The effect of the ring current is lost in the sitting-atop complex. This is because of geometric distortion of the porphyrin macrocycle and the produced positive electric charge in the porphyrin core. The downfield shifts of the aryl ring hydrogens can be related to a direct increase in the ring current of the aryl groups produced by the extension of the aryl π-system. These changes are in the same direction as for molecular complexation of the corresponding *meso*-tetraarylporphyrins with various acceptors [17–22]. The direction of the NH and β-protons shifts of the sitting-atop complexes is similar to the related diprotonated porphyrin species [25], for example, the

Table 1
^{1}H NMR spectral data of different *meso*-tetraarylporphyrins and sitting-atop complexes

Compounds	N–H	H_β
H$_2$t(4-Me)pp	−2.77	8.85

[a] $\Delta\delta_1$: chemical shifts of the proton signals for the porphyrins upon sitting-atop complexation.
[b] $\Delta\delta_2$: chemical shifts of the proton signals for the H$_2$t(4-Me)pp upon diprotonation with excess TFA.

chemical shifts of the proton signals for $H_2t(4\text{-}CH_3)pp$ upon diprotonation with excess TFA are −0.65 and 8.67 ppm, respectively (Table 1). On the other hand, an excess of uranyl had no effect on the ^1H NMR spectra of the sitting-atop complexes, whereas the ^1H NMR spectrum of $H_4t(4\text{-}CH_3)pp^{2+}$ is quite sensitive to the concentration of trifluoroacetic acid [20,21]. Also, our sitting-atop complexes are rapidly decomposed by alumina or solvents such as DMSO, but their diprotonated porphyrins were quite stable under these conditions. Therefore, the remarkable spectral correspondence between the sitting-atop complexes and the diprotonated species is due to analogous tilted porphyrin core structures in these species, and is not related to the formation of diprotonated porphyrins in our reaction system [20,21].

The results of the UV–Vis spectra for the *meso*-tetraarylporphyrins and related sitting-atop complexes and the diprotonated species are listed in Table 2. The spectra of the porphyrins have five absorption bands (one Soret and four Q bands), whereas the sitting-atop species show two new absorption bands. The observed red shifts for the sitting-atop complexation of *meso*-tetraarylporphyrins with uranyl are similar to the diprotonation of the porphyrins or the molecular complexation with various acceptors [17–22]. The UV–Vis spectra of the diprotonated porphyrins is very like to the related sitting-atop complexes, but, as in the case of NMR spectra, the spectra of the diprotonated species are sensitive to the additional amount of acid added [20,21]. These similarities suggest analogous porphyrin core structures in all of the species (sitting-atop complex, diprotonated porphyrin and molecular complex).

Upon the sitting-atop complexation with uranyl, the UV–Vis spectra of the free base *meso*-tetraarylporphyrins are shifted 24–34 nm to the red. This is interpreted as an evidence for an increased resonance interaction of the aryl ring with the porphyrin nucleus in going from the free base to the sitting-atop complex, which would be allowed by the tilting of the pyrrole groups.

The spectral correspondence (^1H NMR and UV–Vis) between the sitting-atop complexes and the molecular complexes of σ- or π-acceptors with *meso*-tetraarylporphyrins [17–22] proposes a similar structure for the porphyrin core in the two species. Consequently, the non-coplanar pyrrole rings tilted alternatively up and down and the lone pairs of two pyrrolenine nitrogens act as electron donors to the uranium center of the uranyl on one side of the mean plane of the porphyrin, Fig. 2.

The ^1H NMR and UV–Vis spectral shifts for the sitting-atop complexation of various *meso*-tetraarylporphyrins with uranyl showed that the greater steric hindrance of the *meta*-substituents of the aryl rings in the porphyrins decrease the electron donation of those in compare to *para*-substituent (Tables 1 and 2). For *ortho*-substituents this factor make the inconsiderable yield in the reaction of $UO_2(NO_3)_2 \cdot 6H_2O$ with *meso*-tetraarylporphyrins.

Table 2
UV–Vis spectral results of the various *meso*-tetraarylporphyrins, sitting-atop complexes and their diprotonated species in $CHCl_3$

[b] $\Delta\lambda_2$: red shifts for the bands of the porphyrins upon diprotonation.
[c] The data obtained by the diprotonation with excess of TFA.

The measurements of molar conductivity in methanol solutions indicate the new complexes behave as 1:2 electrolytes [26], completely in accordance with the proposed formula for the sitting-atop complexes, $[(UO_2)H_2t(X)pp](NO_3)_2$. On the other hand, the IR spectra show three bands for NO_3^- anions (for example at 746, 900 and 1476 cm^{-1} for $[(UO_2)H_2t(4\text{-OMe})pp](NO_3)_2$, Fig. 3) that demonstrate these act as counter ions [27]. Also the N–H stretching band, observed at 3320 cm^{-1} for the free base porphyrins [28], does not change upon sitting-atop complexation with uranyl. Furthermore, as mentioned above, the ^1H NMR spectra of the sitting-atop complexes showed that the two protons on the pyrrole nitrogens still remained. Therefore, in our procedure sitting-atop complexation occurred, not metallation.

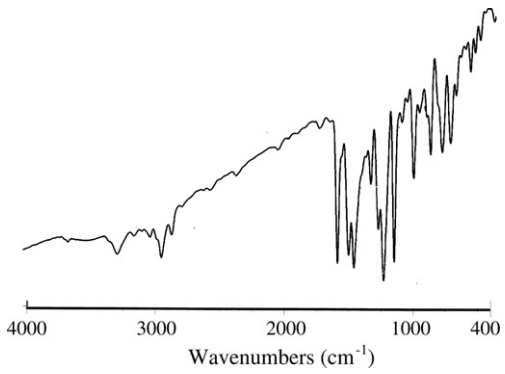

Fig. 3. Infrared spectrum of $[(UO_2)H_2t(4\text{-OMe})pp](NO_3)_2$.

4. Conclusion

Funahashi et al. postulated that in the reaction of copper(II) with H_2tpp in acetonitrile, an intermediate complex species forms, $[Cu(H_2tpp)]^{2+}$, in which the metal stays above the tetraaza plane. We have successfully prepared similar structures from the reaction of uranyl with *meso*-tetraarylporphyrins as a solid, using a little chloroform and grinding. These mild conditions are the reason that the reactions do not progress to the metallation of the porphyrins and remain in the intermediate step (sitting-atop complexes).

Bruker AVANCE 400 spectrometer (400, 100 and 162 MHz, respectively). ^{13}C and ^{31}P NMR resonances were obtained with broad-band proton decoupling. Melting points were measured in capillaries sealed under argon and are uncorrected.

2.2. Synthesis of the complexes

2.2.1. trans-[(1-Carbonyl-2-oxo-cyclohexenediyl)-(2-diphenylphosphanyl)thiophenyl(S,P)]bis-(trimethylphosphine)cobalt(III) (6)

To a suspension of *mer*-hydrido(1-carbonyl-2-oxo-cyclohexenediyl)tris(trimethylphosphine)cobalt(III) (**1**) (1.27 g, 3.07 mmol) in 60 ml of diethyl ether (2-diphenylphosphanyl)thiophenol (0.92 g, 3.12 mmol) dissolved in 20 ml of diethyl ether was added slowly at −80 °C. When the mixture was stirred at ambient temperature for 18 h, the solution changed from yellow to dark-red. After evaporating the volatiles under vacuum, the residue was extracted with pentane and diethyl ether. Both filtrates were crystallized at −27 °C. From pentane solution complex **6** was obtained as dark-red cubic crystals which turned to effloresce under vacuum. Yield: 0.17 g of **6** (9% based on **1**). **17** was also obtained from pentane as brown-yellow cubic crystals suitable for X-ray diffraction analysis. Yield: 0.09 g of **17** (8% based on (2-diphenylphosphanyl)thiophenol). From THF **11** could be obtained as red microcrystals: 0.18 g (yield 25%, based on **1**). From diethyl ether **16** was isolated as brown crystals: 0.61 g (yield 33% based on (2-diphenylphosphanyl)thiophenol). **6**: m.p. (dec.) > 142 °C. *Anal.* Calc. for $C_{31}H_{40}CoO_2P_3S$ (628.57 g/mol): C, 59.23; H, 6.41. Found: C, 59.31; H, 6.38%. thiophenol (0.94 g, 3.20 mmol) in 20 ml of diethyl ether after stirring for 18 h at 20 °C gave a red-brown suspension. After evaporating the volatiles in vacuo a red-brown residue was obtained. Pentane, diethyl ether and THF were used in turn to extract the residue, and the three filtrates were crystallized at −27 °C. From diethyl ether **16** was obtained (0.72 g, yield 40%). From THF **15** was obtained as orange crystals of (0.35 g yield 43% based on **5**). **15**: m.p. (dec.) > 202 °C. *Anal.* Calc. for $C_{22}H_{31}CoO_6P_2$ (512.36 g/mol): C, 51.57; H, 6.10. 2.3. X-ray diffraction

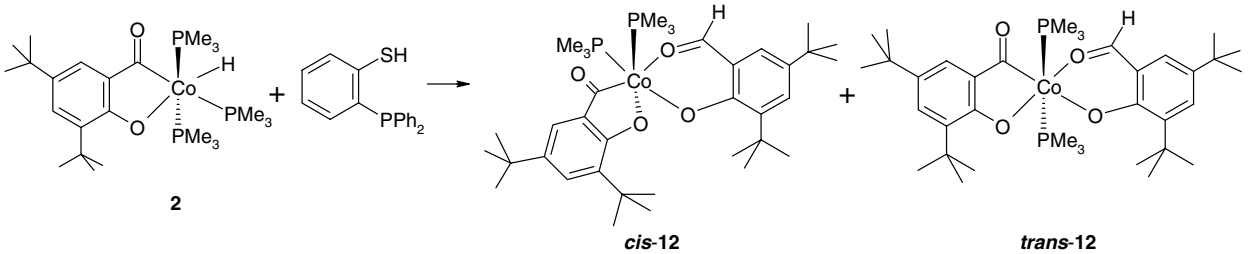
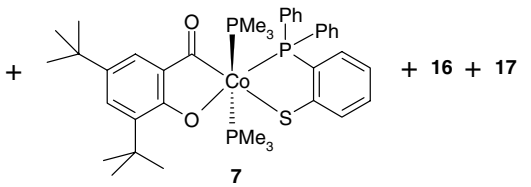
Crystals of complexes **15** and **17** suitable for X-ray diffraction analysis were grown from THF and pentane at 6 °C. The molecular structures are shown in Fig. 1 and Fig. 2, respectively, and related crystallographic data are included in Table 1. The structures were solved by direct methods and refined with full-matrix least-squares on all F^2 (SHELXL-97) with non-hydrogen atoms anisotropically.

3. Results and discussion

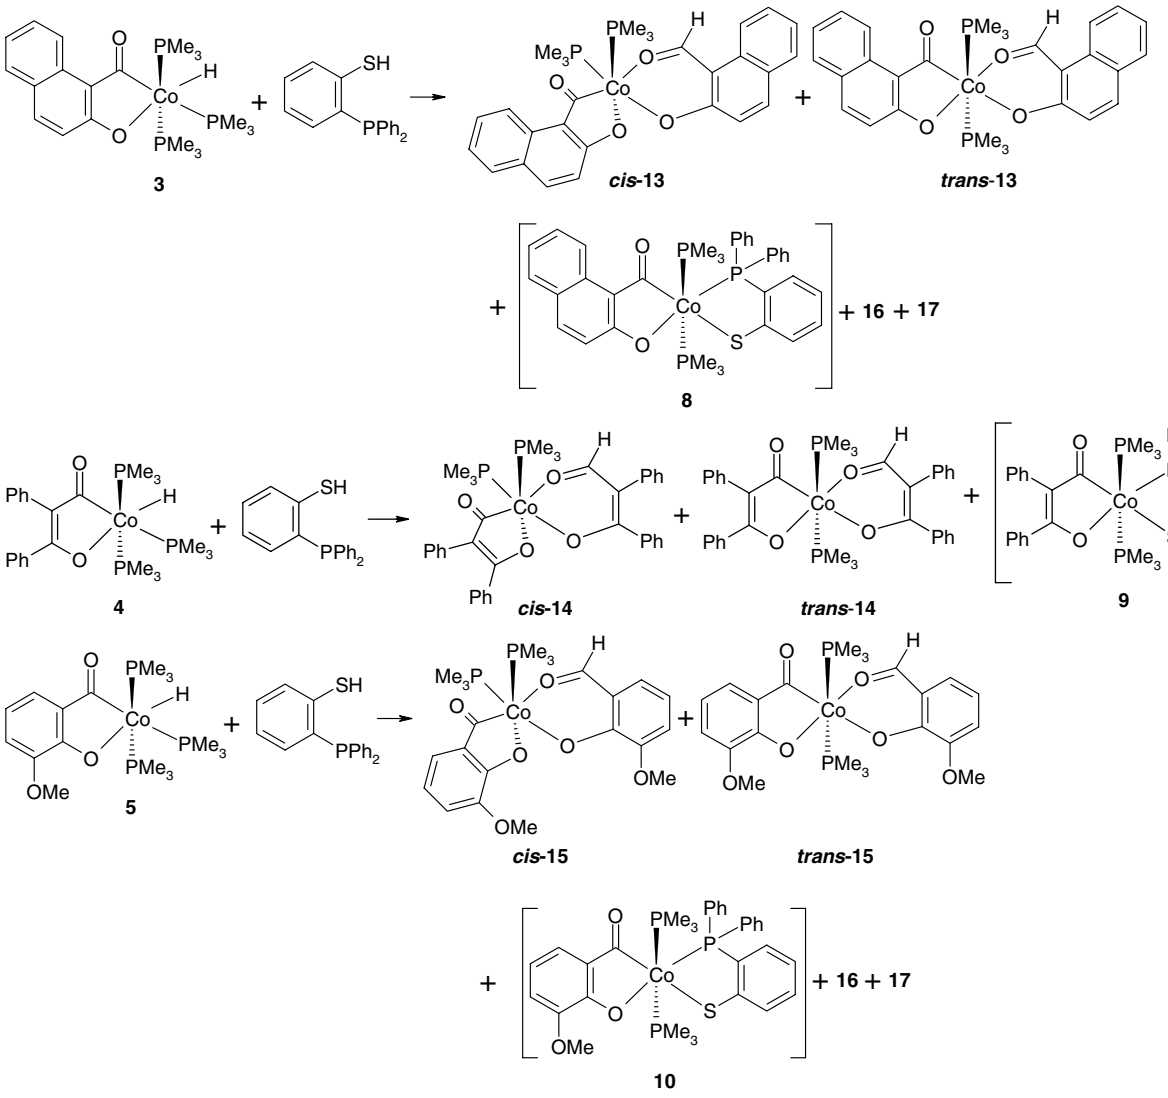


The acyl(hydrido)cobalt complexes **1** and **2** were reacted with (2-diphenylphosphanyl)thiophenol in diethyl ether. After careful work-up, apart from the expected novel cobalt complexes **6** and **7** containing one 2-acylphenolato ligand and one (2-diphenylphosphanyl)thiophenolato ligand, three additional types of cobalt complexes, **11**, **12**, **16**, and **17** were successfully isolated and shown to exist in different formal oxidation states (Eqs. (1) and (2)).

Complexes **6** and **7** are stable below 142 °C and 132 °C under inert atmosphere. In the IR spectra the conspicuous ν(Co–H) absorption of the acyl(hydrido)cobalt complexes (complex **1** and **2**) are absent.



The ^{1}H and ^{31}P NMR spectra of complexes **6** and **7** are well resolved. The pattern of PCH_3 signals as pseudotriplets are is consistent with an octahedral coordination geometry and two *trans*-trimethylphosphine ligands. Two ^{31}P NMR singlets represent one diphenylphosphanyl group and two isochronic trimethylphosphine ligands. Due to

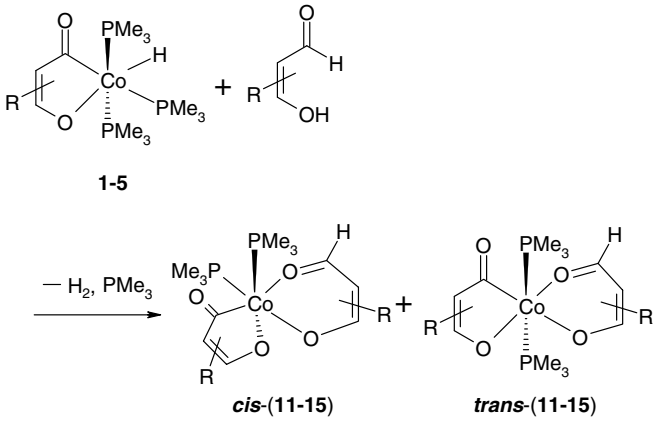


(1)

(2)

(3)

(4)

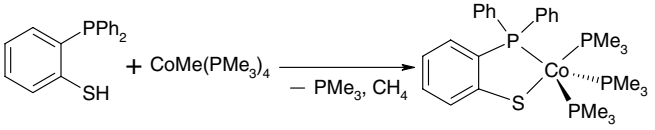


(5)

efflorescence of crystals the crystal structure of complex **6** could not be determined by X-ray diffraction.

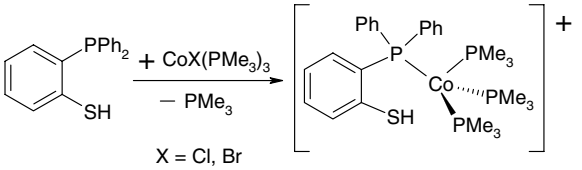
In the case of complexes **3**–**5**, the analogous reactions according to Eqs. (3)–(5) have been carried out without successfully isolating the expected complexes **8**, **9**, and **10** due to very low yields of these compounds.

As by-products, the bis-chelate complexes **11**–**15** were obtained from the reactions (Eqs. (1)–(5)) as yellow to orange crystals. In the ^{1}H NMR spectra the aldehyde protons appear between 9 and 10 ppm. X-ray diffraction indicates that complex **15** attains an octahedral configuration with two trimethylphosphine groups in *cis*-positions, while the two 2-acylphenolato ligands are arranged perpendicular to each other (Fig. 1). Complexes **11**–**15** could be isolated as *cis* and *trans* isomers. The ratio of the isomers was determined from ^{1}H NMR and ^{13}P NMR data. Crystalline materials of all these complexes are stable in the air at room temperature.



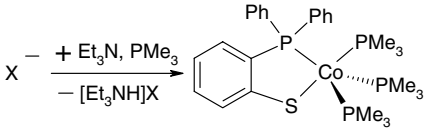
Complexes **11**–**15** can be directly prepared by the reaction of acyl(hydrido)cobalt **1**–**5** with the corresponding β-hydroxy aldehyde (Eq. (6)) [5].

(6)



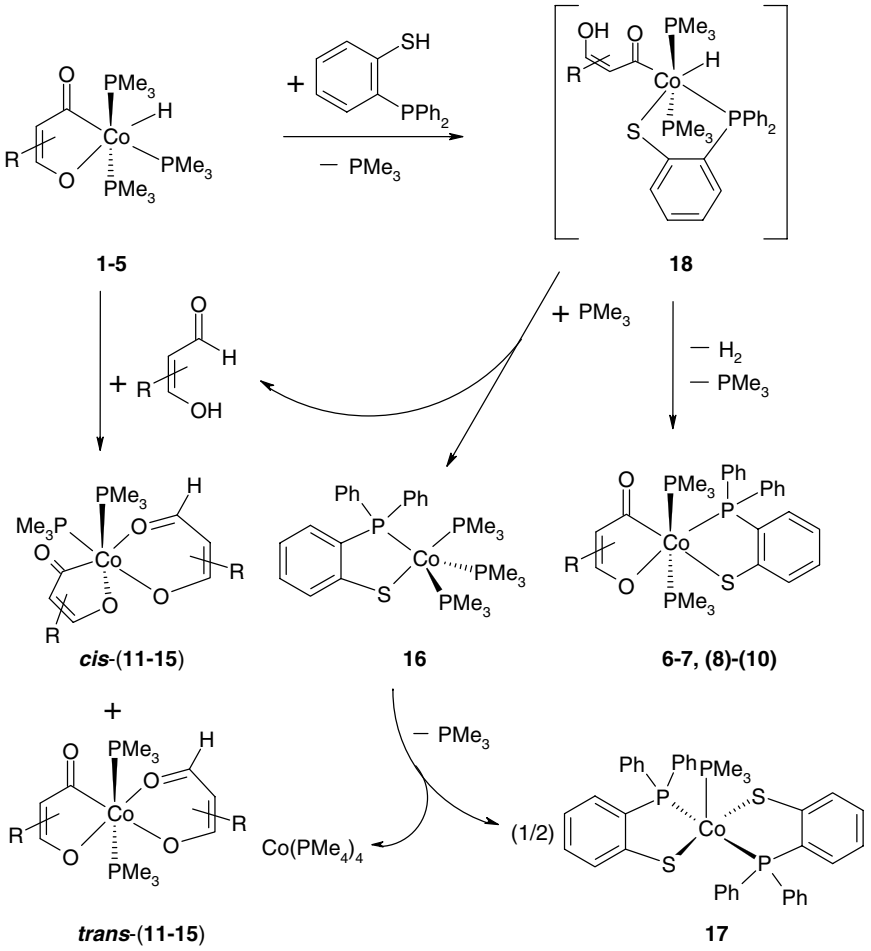
From each reaction in Eqs. (1)–(5) cobalt(I) complex **16** with one [P,S]-chelating ligand was obtained in good yield (>30%). The direct synthesis of complex **16** can be achieved by reaction of (2-diphenylphosphanyl)thiophenol with methyl tetrakis(trimethylphosphine)cobalt(I), $CoMe(PMe_3)_4$, or by reaction of (2-diphenylphosphanyl)thiophenol with

tris(trimethylphosphine)cobalt(I), $CoX(PMe_3)_3$, (Eqs. (7) and (8)) [7].

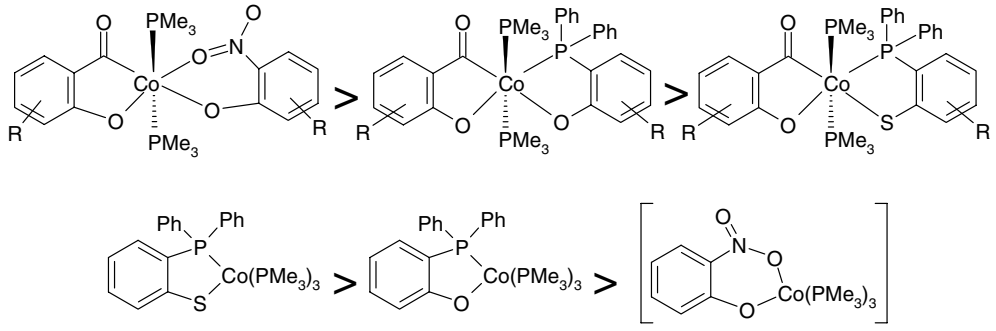


16

(7)



(8)



16

At the same time a penta-coordinate cobalt(II) complex with two [P,S]-chelating ligands (**17**) was also isolated from the mother liquor in small amount as tiny brown-yellow cubic crystals. The molecular structure (Fig. 2) shows the expected square-pyramidal geometry of complex **17**. The cobalt atom is located above the center of a plane containing two P-donor and two S-donor atoms of the diphenylphosphanylthiophenolato ligands arranged in mutual *trans*-positions. The P-donor atom of trimethylphosphine is located at the apical point of the pyramid.

Regarding all information obtained from this complicated reaction system (Eqs. (1) and (2)) a mechanism is proposed as given in Scheme 1. In the first step the phenoxy O-donor of the 2-acylphenolato chelating ligand in complexes **1**–**5** is substituted by a (2-diphenylphosphanyl)thiophenolato chelating ligand leading to an intermediate hydridocobalt complex **18**. In the presence of trimethylphosphine, **18** undergoes a reductive elimination to generate the [P,S]-chelate cobalt(I) complex **16** with liberation of a β-hydroxy aldehyde. Subsequently, hydrogen is evolved from the acyl(hydrido)cobalt(III) complexes **1**–**5** and the β-hydroxy aldehyde to afford the bis-chelate cobalt(III) complexes **11**–**15**. Disproportionation of complex **16** gives rise to the bis-chelate complex **17** and tetrakis(trimethylphosphine)cobalt(0). In a parallel reaction of complexes **1**–**5** with 2-diphenylphosphanylthiophenol the bis-chelate complexes **6**–**7** are formed with evolution of hydrogen.

Scheme 1. A proposed mechanism of reaction of acyl(hydrido)cobalt(III) complexes with (2-diphenylphosphanyl)thiophenol.

Scheme 2. Influence of chelating ligands containing hard/soft donor atoms on the stability of cobalt complexes.

According to the earlier work of Klein [1–5] and Sun [8], when reacting an acyl(hydrido)cobalt(III) complex with 2-nitrophenol and (2-diphenylphosphanyl)phenol, respectively, to form cobalt(III) complexes with chelating 2-nitrophenolato ligands, in the light of the HSAB rule, the hard/hard product is expected to be more stable than the hard/soft product with (2-diphenylphosphanyl)phenolato ligands. In combination with our present work, the influence of chelating ligands containing hard/soft donor atoms on the relative stabilities of cobalt complexes can be described as in Scheme 2. In the reaction system with 2-nitrophenol the stable 2-acylphenolato cobalt(III) complex was obtained, while a corresponding cobalt(I) complex could not be experimentally verified [8]. In the present work, the cobalt(I) complex **16** was isolated in high yield, while relatively low yields were attained for complexes **6**–**7** and **8**–**10**. Derivatives of salicylaldehyde released in situ react with starting materials to generate bis-chelate cobalt(III) complexes **11**–**15**, and no formation of salicylalcohol was observed, while salicylalcohol was identified in the reaction system with (2-diphenyl)phosphanylphenol [8]. This result confirms the key role of (2-diphenylphosphanyl)phenol in the formation of salicylalcohol.

4. Conclusions

The reaction of acyl(hydrido)cobalt(III) complexes **1**–**5** with (2-diphenylphosphanyl)thiophenol generated two types of chelate cobalt(III) complexes (**6**–**7**, **8**–**10** and **11**–**15**), one chelate cobalt(I) complex (**16**) and one chelate cobalt(II) complex (**17**). Complex **16** bearing a soft/soft [P,S]-chelate ligand and a soft low-valent cobalt(I) central atom was obtained in the highest yield of about 30–40%, while the expected products with a soft/soft [P,S]-chelate ligand and a hard high-valent cobalt(III) central atom (**6**, **7** and **8**–**10**) show low yields (less than 10%). The by-products **11**–**15** with a hard/hard [O,O]-chelating ligand and a hard cobalt(III) center are very stable. Cobalt(II) complex **17** could be separated as a result of a disproportionation reaction of complex **16**. A possible mechanism is proposed. Coordination of chelating ligands at Co(III) decreases as [N,O] > [P,O] > [P,S], while at Co(I) this order is reversed, which is in accord with the HSAB rule.

behavior of the compounds in various solvents was also investigated.

2. Experimental

2.1. Materials

9-Anthraldehyde (abbreviated as AnthAl; TCI), acetylferrocene (ActFc; Aldrich), ferrocenecarboxaldehyde (FcAl; FC Chiral) and 9-acetylanthracene (ActAnth; Aldrich) were commercially purchased and used as received. The HPLC-grade organic solvents (Aldrich) utilized for column chromatography and crystal growth were used without further purification.

2.2. Measurements

The melting point was measured using an IA 9100 digital melting point apparatus. The high-resolution FAB mass spectra were obtained on a JMS-AX 505 WA mass spectrometer (JEOL). The infrared spectra were recorded by the KBr pellet method on a MIDAC FT-IR spectrophotometer in the range of 4000–400 cm^{-1}. The UV–Vis spectra were obtained at ambient temperature on an HP 8452A diode array spectrophotometer in methanol, ethanol, chloroform, and *n*-hexane. The ^1H NMR measurements were performed at room temperature using an Avance 500 (Bruker, 500 MHz) with the samples dissolved in $CDCl_3$. Tetramethylsilane (TMS) was used as an internal standard. Cyclic voltammetry and differential pulse voltammetry were performed at room temperature with a CHI 620A Electrochemical Analyzer (CHI Instrument Inc.) in 10 mL of acetonitrile solution containing 1.0 mM of the sample, using 0.1 M n-$Bu_4N \cdot BF_4$ as a supporting electrolyte, a Pt-button working electrode ($r = 0.8$ mm), Ag/Ag^+ in CH_3CN as the reference electrode, a Pt wire as the counter electrode and with a scan rate of 50 mV s^{-1}. All redox potentials were referenced against the standard ferrocene/ferrocenium redox couple ($E_{1/2} = +0.136$ V). The fluorescence spectra were measured by a Cary Eclipse fluorescence spectrophotometer (Varian) in methanol, ethanol, chloroform and *n*-hexane. Approximately 3 mL of solutions of the samples at a concentration of 10^{-5}–10^{-6} M in a quartz cell were used to measure the spectra.

2.3. X-ray structure determination

The orange-colored single crystals of Fc–Anth and Anth–Fc suitable for the X-ray structure analysis were obtained by the recrystallization of the purified compounds from CH_2Cl_2/*n*-hexane (needle-shaped Fc–Anth) or CH_2Cl_2/diethyl ether (diamond-shaped Anth–Fc). The X-ray crystallographic data for these compounds were collected on a SMART APEX CCD SYSTEM (Bruker) equipped with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were solved by the direct method and refined by full-matrix least-squares analysis using anisotropic thermal parameters for non-hydrogen atoms with the SHELXL-97 program [24]. The crystallographic data and the details of the data collection are listed in Table 1, and the selected bond distances and angles are summarized in Table 2.

2.4. Synthesis

A mixture of 9-anthraldehyde (5.0 mmol, 1.14 g) and acetylferrocene (5.0 mmol, 1.03 g) or ferrocenecarboxaldehyde(2.0 mmol, 0.43 g) and 9-acetylanthracene(2.0 mmol, 0.44 g) was ground homogeneously in the presence of solid NaOH (at a mole ratio of the mixture to NaOH of 1:5) with a mortar and pestle. The mixture was then allowed to stand in a water bath at 60–70 °C for 24 h, during which time the color of the mixture consistently turned deep red. The product was extracted with CH_2Cl_2 and dried with $MgSO_4$. After filtration, the product was separated by column chromatography (SiO_2, petroleum ether:diethyl ether = 1:1 for Fc–Anth and CH_2Cl_2 for Anth–Fc).

Fc–Anth: yield 57.4% (1.19 g); m.p. 187–188 °C, HR-FABMS Calc. for $C_{27}H_{20}FeO$ 416.0864. Found: 416.0853 (M^+); FT-IR(KBr, cm^{-1}) 3096, 3081, 3050, 3033 (Ar C–H), 1650 (C=O), 1597, 1458 (C=C), 1271, 1088 (Cp C=C), 999, 984 (=C–H), 726 (Ar C–H), 525, 502, 485 (Fe–Cp); ^1H NMR ($CDCl_3$, ppm) 4.30 (5H, CH, s), 4.63 (2H, CH, s), 4.94 (2H, CH, s), 7.18 (1H, CH, s), 7.52 (4H, CH, m), 8.05 (2H, CH, d, $J = 9.4$ Hz), 8.35 (2H, CH, d, $J = 7.7$ Hz), 8.48 (1H, CH, s), 8.76 (1H, CH, s).

Anth–Fc: yield 68.6% (0.57 g); HR-FABMS Calc. for $C_{27}H_{20}FeO$ 416.0864. Found 416.0869 (M^+); m.p. 221–222°C; FT-IR(KBr, cm^{-1}) 3081, 3057 (Ar C–H), 1607 (C=O), 1459 (Ar C=C), 1359, 1224, 1171, 1149 (Cp C=C), 967 (=C–H), 889, 819, 735 (Ar C–H), 488 (Fe–Cp); ^1H NMR ($CDCl_3$, ppm) 4.10 (5H, CH, s), 4.44 (4H, CH, d, $J = 12.4$ Hz), 6.89 (1H, CH, d, $J = 16.0$ Hz), 7.03 (1H, CH, d, $J = 16.0$ Hz), 7.49 (4H, CH, m), 7.93 (2H, CH, d, $J = 8.2$ Hz), 8.06 (2H, CH, d, $J = 8.2$ Hz), 8.54 (1H, CH, s).

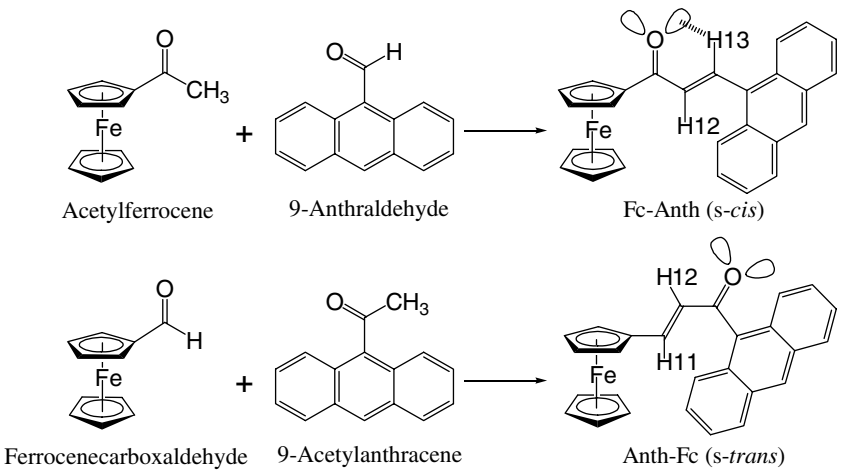
3. Results and discussion



3.1. Synthesis and characterization

The two ferrocenyl chalcones, Fc–Anth and Anth–Fc, were prepared by base-catalyzed solvent-free aldol condensation in 57.4% and 68.6% yields, respectively. These compounds can also be prepared by the reaction method under reflux in CH_2Cl_2 and obtained in yields similar to those of the solvent-free method. However, the solvent-free method is faster, easier and more environmentally friendly than that using an organic solvent. In the high-resolution FAB-MS analysis of Fc–Anth ($m/z = 416$), two main fragments, viz. $[M-Fc]^+$ ($m/z = 231$) and $[FcCO]^+$ ($m/z = 213$), are observed. Also, in the analysis of Anth–Fc ($m/z = 416$), $[M-Anth]^+$ ($m/z = 239$) and $[AnthCO]^+$ ($m/z = 205$) are observed as the two main fragments. These findings indicate that the C–C bonds connected to the C=O bond are susceptible to bond cleavage, resulting in the above fragmentations. The NMR spectrum of Anth–Fc measured at room temperature shows two doublets at 6.89 ppm ($J_{ab} = 16.0$ Hz) and 7.03 ppm ($J_{ab} = 16.0$ Hz), suggesting that the ethylene moiety in the enone linkage is in the *trans*-conformation [25], possibly with an s-*trans* conformation around the C–C bond, as illustrated in Scheme 1. On the other hand, the NMR spectrum of Fc–Anth gives no corresponding peaks in this region, but broad ones at 8.76 ppm and 7.18 ppm. These findings led us to postulate that the ethylene and carbonyl groups are in an s-*cis* conformation and that they cause a significant intramolecular interaction between the lone-pair electrons of the oxygen atom and H13 atom in the solution state, resulting in the up-field shift of the ethylenic protons. This was also supported by the X-ray structural analysis described below.

The UV–Vis spectra of the ferrocenyl chalcones were measured in several solvents of different polarity and compared with those of the AnthAl and FcAl reactants in order to investigate the solvent effect on the electronic transition, or so-called solvatochromic shift, as shown in Table 3. The $\pi \rightarrow \pi^*$ (246–252 nm) and $n \rightarrow \pi^*$ (308–318 nm) transitions of the enone linkage were not significantly influenced by the solvent polarity. However, this was not the case for the d–d transition of the ferrocenyl group which varied from 450 nm (*n*-Hx) to 464 nm (MeOH and EtOH) for FcAl, from 486 nm (*n*-Hx) to 502 nm (EtOH) for Fc–Anth and from 468 nm (*n*-Hx) to 512 nm (EtOH and MeOH) for Anth–Fc. The extent of the solvatochromic shift is only 16 nm for Fc–Anth and 14 nm for FcAl. On the other hand, Anth–Fc shows a strong solvatochromic shift of 44 nm in a lower energy region. Given that a strong solvatochromic shift is a good indication of the potential of a compound to be used as a non-linear optical (NLO) material, Fc–Anth could be a good candidate NLO material, as many chalcones have such properties [6,7].

3.2. X-ray structure analyses

The X-ray structural analyses of the Fc–Anth and Anth–Fc single crystals show that they crystallize in the monoclinic and orthorhombic systems, respectively, with the cell parameters shown in Table 1. The selected bond lengths, bond angles and torsion angles of the compounds are listed in Table 2. The molecular structures of Fc–Anth and Anth–Fc (Fig. 1) and their torsion angles (Table 2) reveal that the Cp ring and enone linkage are almost co-planar with a dihedral angle of less than 9.0(3)°. The planar anthracenyl groups, however, deviate significantly from the plane made by the enone linkage: the dihedral angle between the anthracenyl group and the plane of the enone linkage is

Scheme 1. Solvent-free syntheses of Fc–Anth and Anth–Fc.

Table 3
UV–Vis spectroscopic data for Fc–Anth, Anth–Fc, AnthAl and FcAl dissolved in various solvents

Compound	MeOH	EtOH	$CHCl_3$	*n*-Hx
AnthAl	372 sh, 400 s	372 sh, 400 s	374 sh, 406 s	372 sh, 396 s
Fc–Anth	246 s, 404 m, 500 w	246 s, 404 m, 502 w	252 s, 406 m, 494 w	248 s, 394 m, 486 w
FcAl	244 s, 342 m, 464 w	246 s, 342 m, 464 w	266 s, 342 m, 460 w	238 s, 268 m, 450 w
Anth–Fc	316 s, 364 sh, 512 w	318 s, 364 sh, 512 w	316 s, 366 sh, 506 w	308 s, 346 sh, 468 w

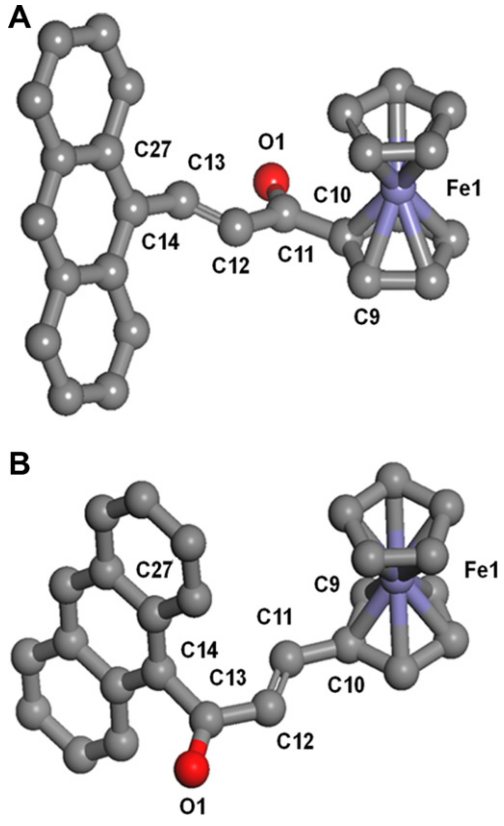


Fig. 1. Molecular structures of Fc–Anth (A) and Anth–Fc (B) with the selected atomic numbering scheme. Hydrogen atoms are omitted for the sake of clarity.

74.9(4)° for Anth–Fc and 55.7(4)° for Fc–Anth. These large dihedral angles indicate that the possibility for electronic communications between the anthracenyl and ferrocenyl groups through the enone linkage is reduced. This is comparable to the case of the ferrocenyl chalcone with naphthalenyl group (Fc–COCH=CH–Naph), in which the naphthalenyl group and the enone linkage are almost coplanar with a dihedral angle of less than 4.4(3)° [23]. It is also noteworthy that the spatial arrangement of the enone part is different in the two compounds. The two double bonds (C=O and C=C) about the intervening C–C single bond are in the s-*cis* conformation for Fc–Anth, while they are in the s-*trans* conformation for Anth–Fc, as clearly shown in Fig. 1. This conformational difference is likely responsible for the significant chemical shift of H13 of up to 8.76 ppm in Fc–Anth due to the intramolecular interaction with the lone-pair electrons of the oxygen atom (Scheme 1), based on the assumption that the solid state X-ray crystal structure is accepted in the solution state. On the other hand, the C=O ⋯ H12–C=C interaction is not probable in Anth–Fc, due to its long distance, as evidenced by the NMR data resulting in the two doublets at 6.89 and 7.03 ppm. This conformational difference together with the positions of the C=O and C=C bonds also influences the oxidation potentials of the ferrocenyl and anthracenyl groups, as will be discussed below.

In the molecular packing of both Fc–Anth (Fig. 2) and Anth–Fc (Fig. 3), the two enantiomers are found to form a racemic mixture: the Fc–Anth enantiomers

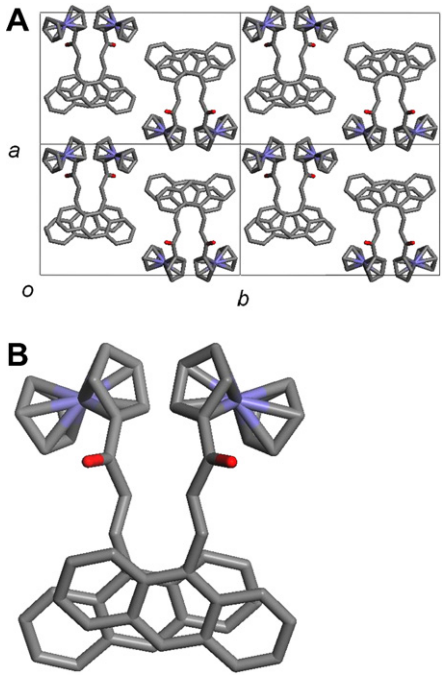

Fig. 2. (A) Crystal structure of Fc–Anth viewed along the *c*-axis. (B) The two enantiomeric molecules are partially overlapped by the anthracene groups. Hydrogen atoms are omitted for the sake of clarity.

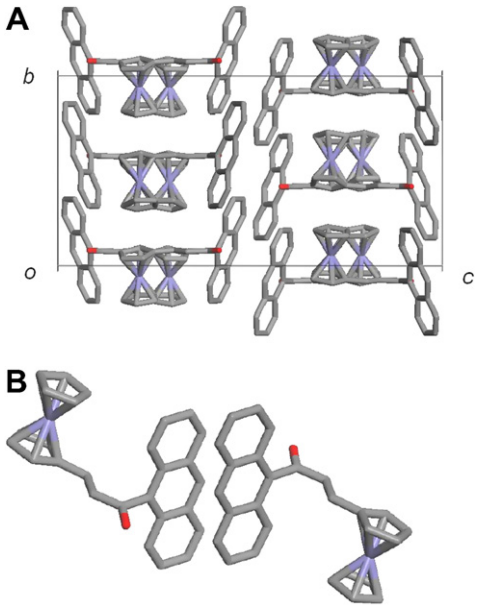

Fig. 3. Crystal structure of Anth–Fc viewed along the *a*-axis (A), and those of the two enantiomeric Anth–Fc molecules (B). Hydrogen atoms are omitted for clarity.

are stacked along the *c*-axis through the partial overlapping of the anthracenyl groups with a long enough separation (3.993(1) Å) for the intermolecular interaction to be ignored. The separation of the anthracenyl groups is longer than the sum of the van der Waals radii of the carbons (3.4 Å). The Anth–Fc crystal is also a racemic mixture, which consists of alternative ferrocene and anthracene layers perpendicular to the *c*-axis. No close intermolecular contacts such as Fe(II)···Fe(II) or anthracene···anthracene interactions are observed in these crystal structures.

3.3. Electrochemical properties

The electrochemical properties of Fc–Anth and Anth–Fc were measured and compared with those of the reactants, as summarized in Table 4. In the cyclic voltammograms (CV) and differential pulse voltammograms (DPV) scanned from 0.0 to +2.0 V and then back to 0.0 V, both compounds exhibit one reversible redox wave in the lower potential region ($E_{1/2} = +0.402$ V for Fc–Anth and +0.277 V for Anth–Fc) and one irreversible oxidation peak in the higher potential region ($E_{pa}{}^2 = +1.073$ V and +1.153 V, respectively), as shown in Fig. 4. These reversible redox peaks can be attributed, without doubt, to the Fc/Fc^+ process. The reversibility of these peaks is more clearly observed in the inset, where the reversible cycles were obtained by scanning within the redox potential region of the ferrocenyl group. The irreversible peaks therefore correspond to the oxidation of the anthracenyl group. The half-wave potential ($E_{1/2}$) for the reversible peak of Fc–Anth (+0.402 V) is slightly higher than that of ActFc (+0.379 V), both of which have a carbonyl group directly connected to a ferrocenyl group. On the other hand, the $E_{1/2}$ value for Anth–Fc (+0.277 V) is much lower than those of the above two compounds. This is ascribed to the functional groups being directly connected to the ferrocenyl group, as can be seen in the comparison of the oxidation potentials of ActFc ($E_{pa}{}^1 = +0.413$ V), vinylferrocene ($E_{pa} = +0.24$ V) [26] and ferrocene ($E_{pa}{}^1 = +0.169$ V). For the same reasons, the second oxidation potential of Anth–Fc ($E_{pa}{}^2 = +1.153$ V) is higher than that of Fc–Anth ($E_{pa}{}^2 = +1.073$ V). Consequently, the potential separation of Fc–Anth ($\Delta E = E_{pa}{}^2 - E_{pa}{}^1 = +0.631$ V) is much smaller than that of Anth–Fc (+0.839 V), suggesting that the magnitude of the on-site Coulomb repulsion in Fc–Anth is smaller than that in Anth–Fc. These results can be explained by the positional difference of the C=O and C=C bonds in the enone linkage.

Table 4
Electrochemical parameters for Fc–Anth and Anth–Fc compared with the reactants[a]

Compounds[b]	E^1_{pa}	E^2_{pa}	E^1_{pc}	E^2_{pc}	$E^c_{1/2}$
Fc	0.169		0.102		0.136
ActFc	0.413		0.345		0.379
ActAnth		1.144		−1.287	
Fc–Anth	0.442	1.073	0.361		0.402
Anth–Fc	0.314	1.153	0.239		0.277

[a] Samples are dissolved in acetonitrile solution containing 0.1 M n-$Bu_4N \cdot BF_4$ electrolyte and measured with a scan rate of 50 mV s^{-1} (ferrocene/ferrocenium: $E_{1/2} = +0.136$ V).
[b] Full names are found in Section 2.
[c] $E_{1/2} = (E_{pa}{}^1 + E_{pc}{}^1)/2$.

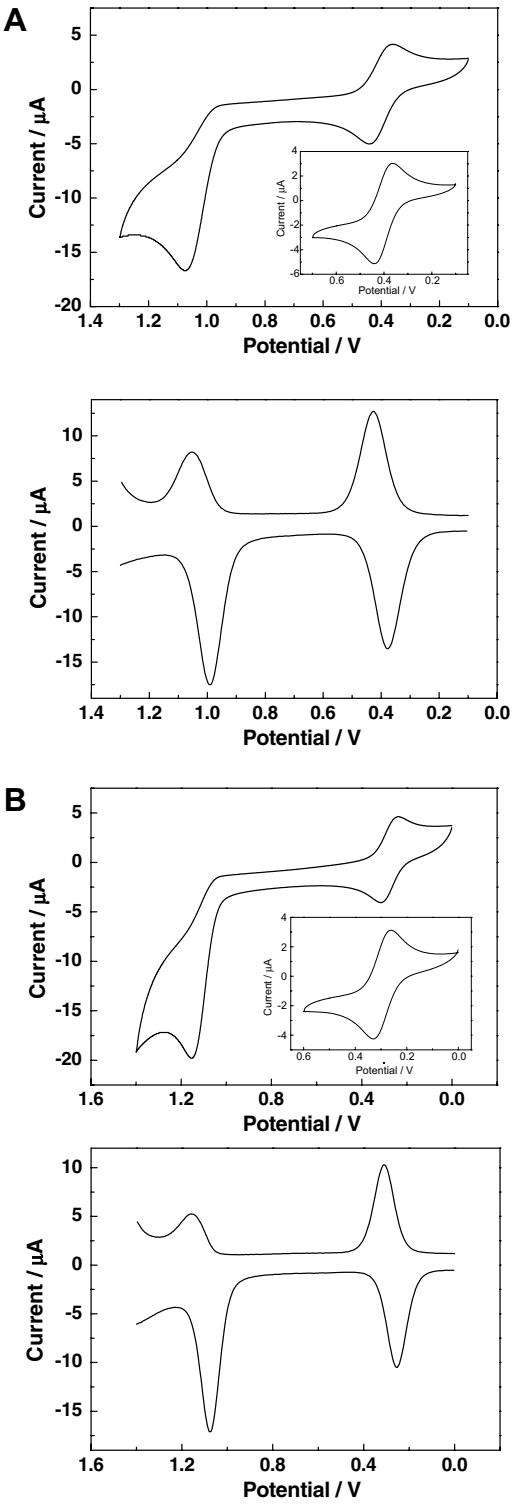

Fig. 4. Cyclic voltammograms (above) and differential pulse voltammograms (below) of Fc–Anth (A) and Anth–Fc (B). The insets show the reversible cycles for the ferrocenyl group in each compound.

3.4. Fluorescence spectroscopy

The fluorescence spectra of the two ferrocenyl chalcones were measured in methanol, ethanol, chloroform, and *n*-hexane with the maximum excitation wavelength. Irrespective of the solvent polarity, the fluorescent properties of Fc–Anth and Anth–Fc are quenched, while those of AnthAl and ActAnth are clearly observed. This is surely due to the quenching of the fluorescence of anthracene by the ferrocenyl group, because ferrocene and its derivatives are known to be effective quenchers of excited states [27,28]. Based on these observations together with the significant deviation of the co-planarity of the ferrocenyl and anthracenyl groups, it can be suggested that the intramolecular fluorescence quenching occurred *via* a through-space process rather than a through-bond process.

4. Conclusion

Two ferrocenyl chalcones with the anthracenyl group, Fc–COCH=CH–Anth (Fc–Anth) and Anth–COCH=CH–Fc (Anth–Fc), synthesized by base-catalyzed solvent-free aldol condensation, were analyzed by X-ray structure determinations. The planar anthracenyl group and the enone linkage are severely distorted from co-planarity with torsion angles of 55.7(4)° for Fc–Anth and 74.9(4)° for Anth–Fc. Also the enone linkages are in the s-*cis* conformation for Fc–Anth, but in the s-*trans* conformation for Anth–Fc. The cyclic voltammetry and differential pulse voltammetry measurements for the compounds exhibit one reversible cycle at $E_{1/2} = +0.402$ V for Fc–Anth and at $E_{1/2} = +0.277$ V for Anth–Fc, corresponding to the Fc/Fc^{+} process, and one irreversible peak attributed to the oxidation of the anthracenyl group at $E_{pa}{}^{2} = +1.073$ V for Fc–Anth and at $E_{pa}{}^{2} = +1.153$ V for Anth–Fc. The potential separations ($\Delta E = E_{pa}{}^{2} - E_{pa}{}^{1}$) of Fc–Anth (+0.631 V) and Anth–Fc (+0.839 V) are closely related to the magnitude of the on-site Coulomb repulsion, and caused by the positional difference of the C=O and C=C bonds in the enone linkage. The fluorescent properties of the anthracenyl group are quenched by the ferrocenyl group.

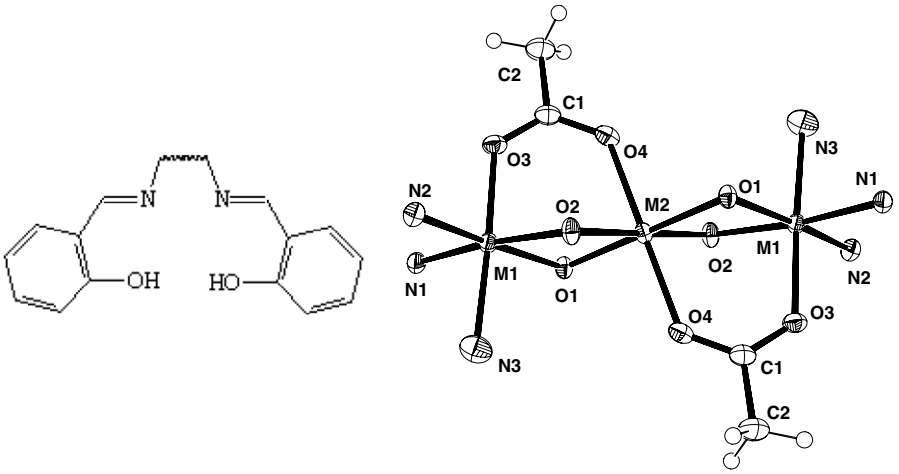

Fig. 1. The common trimetallic motif adopted by tetradentate Schiff base complexes of divalent transition metal acetates. Typically the polymethylene chain (▬▬) between the salicylidene units is either a propane or butane moiety. The sixth coordination site here is filled by a coordinated pyridine (N3) [6].

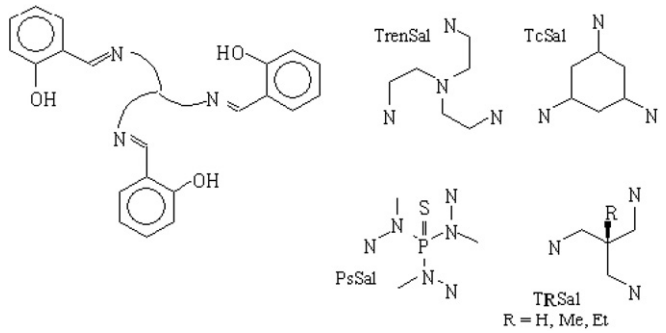

Fig. 2. Commonly used hexadentate and heptadentate Schiff base systems. TrenSal: tris-((2-hydroxybenzylidene)aminoethyl)amine, TcSal: tris(2-oxybenzylidene)-1,3,5-triaminocyclohexane, PsSal: tris-(methyl-(2-hydroxybenzylidene)hydrazono)phosphine sulfide, TRSal (e.g TMeSal and TEtSal, where R = Me and Et respectively): tris-((2-hydroxybenzylidene)-aminomethyl)ethane.

[18–27] and that this combination facilitates the encapsulation of the cation and the formation of simple discrete complexes (Fig. 3). Divalent metals make additional demands on these tri-anionic ligands and an inspection of the small number of complexes derived from these combinations suggest that the trimetallic motif (Fig. 1) will re-establish itself with metals such as nickel and zinc [1,28–30].

As a result of our studies on ligand flexibility [6,12,30,31] we have begun to study the series of multidentate Schiff base species derived from tris-(2-aminoethyl)amine (Fig. 2, Tren) and salicylaldehyde, which potentially offers seven donor atoms [17]. Significantly this motif allows flexibility around the aminoethyl regions in conjunction with the rigidity of the salicylidene units. In our formative study of this ligand system we have elected to revisit the chemistry of nickel and zinc in the expectation that we will expand the catalogue of trimetallic complexes. A comparison is made with the hexadentate ligand system, tris-((2-hydroxybenzylidene)-aminomethyl)propane (TEtSal) which is expected behave in an identical manner to the previously reported TMeSal system [29].

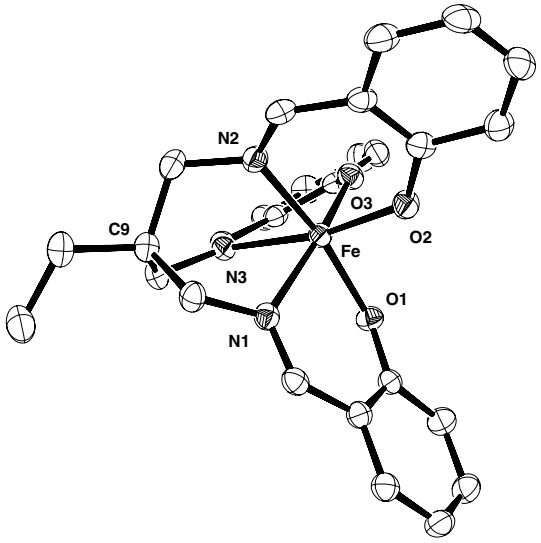

Fig. 3. A typical hexadentate complex of a trivalent metal, [(TEtSal)Fe] (R = Et, Fig. 2), demonstrating how the metal can be fully encapsulated [20].

2. Experimental

All experiments were carried out using standard apparatus and commercially available chemicals apart from 1,1,1-tris(methylamino)propane which was prepared by the combined methods Fleischer [32] and Hellmann [33]. NMR analysis was carried out on either a JEOL EX 270 operating at 270 MHz for ^{1}H and 67.5 MHz for ^{13}C or a Bruker AMX 400 operating at 400 MHz for ^{1}H and 100 MHz for ^{13}C. Solution (solvent) and reflectance (solid, between 350 and 900 nm) spectra were recorded on a Photonics CCD array UV–Vis spectrophotometer. Mass spectra were recorded in house on a Thermo Finnigan LCQDuo by electrospray ion trap apart from $[(TrenSal)_2Ni_3]$ which was recorded at the EPSRC facilities at the University of Wales, Swansea, UK, using a Finnegan MAT95. Infra

red spectra were recorded as potassium bromide discs using a Nicolet Avatar 360 FTIR spectrometer. Magnetic measurements were determined at room temperature in the solid state using an MSB1 magnetic susceptibility balance. Single crystal diffraction data were recorded by Nonius Kappa CCD diffractometers ($\lambda = 0.71073$ Å) except for compound [(Tren5BrSal)$_2$Zn$_3$] where data were obtained at Station 16.2smx of the Daresbury Synchrotron Radiation Source ($\lambda = 0.82520$ Å). All structures were solved and then refined to convergence against F^2 using the SHELXS-97 and SHELXL-97 programs and the WinGX interface [34,35]. Specific crystallographic data and refinement parameters are given in Table 1.

2.1. Preparation of tris-((2-hydroxybenzylidene)-aminoethyl)amine (TrenSal) and tris-((2-hydroxy-5-bromobenzylidene)aminoethyl)amine (Tren5BrSal)

Briefly: 3 mol equiv. of the relevant salicylaldehyde were mixed with 1 mol equivalent of tris(2-aminoethyl)amine (0.9 g; 6.2 mmol) in ethanol (100 ml). The resulting solution was refluxed for 1 h, filtered when hot and allowed to cool whereupon copious amounts of yellow crystals began to form. These were collected and allowed to air dry.

2.2. N,N′,N″-Tris-((2-hydroxybenzylidene)-aminoethyl)amine

Yield 55%. *Anal.* Calc. for $C_{27}H_{30}N_4O_3$: C, 70.72; H, 6.59; N, 12.22. Found: C, 70.64; H, 6.74; N, 12.10%. ^{1}H NMR (400 MHz, $CDCl_3$; δ): 13.7 (br s, 1H, –OH); 7.8 (s, 1H, –HC=N); 7.3 (t, 1H, arom); 6.9 (d, 1H, arom); 6.6 (t, 1H, arom); 6.1 (d, 1H, arom); 3.5 (t, 2H, –CH_2–); 2.8 (t, 2H, –CH_2–). ^{13}C-{^{1}H} NMR (100 MHz $CDCl_3$; δ): 166, 161, 132, 131, 119, 118, 116, 58, 56. FTIR [ν/cm^{-1} (KBr)]: 1634 (C=N); 1500 (C=C); 1275 (C–O); 753, 778 (arom), m.p. 83 °C.

2.3. N,N′,N″-Tris-((2-hydroxy-5-bromobenzylidene)-aminoethyl)amine

Yield 85% *Anal.* Calc. for $C_{27}H_{27}N_4Br_3O_3$: C, 46.64; H, 3.91; N, 8.06. Found: C, 46.65; H, 4.06; N, 7.92%. ^{1}H NMR (400 MHz, $CDCl_3$; δ): 7.9 (s, 1H, –HC=N); 7.4 (dd, 1H, arom); 6.8 (d, 1H, arom); 6.5 (d, 1H, arom); 6.1 (d, 1H, arom); 3.6 (t, 2H, –CH_2–); 2.8 (t, 2H, –CH_2–); 1.6 (br s, 1H, –OH). ^{13}C-{^{1}H} NMR (100 MHz $CDCl_3$; δ): 165, 160, 135, 133, 120, 119, 110, 57, 55. FTIR [ν/cm^{-1} (KBr)]: 1645 (C=N), 1470 (C=C), 1280 (C–O), 819 (arom), m.p. 139 °C.

2.4. Preparation of bis-(tris-((2-hydroxybenzylidene)-aminoethyl)amine nickel)nickel

A methanol solution (100 ml) of TrenSal (0.46 g, 1 mmol) and nickel actetate (0.375 g, 1.5 mmol) was refluxed for 90 min. The solution was allowed to cool and the resulting yellow-green powder collected, washed with water, methanol, dichloromethane and diethyl ether. The product was found to be insoluble in all common solvents. Yield 75%. *Anal.* Calc. for $C_{54}H_{54}N_8Ni_3O_6 \cdot H_2O$[2]C, 58.69; H, 5.65; N, 9.80%. Found: C, 58.78; H, 5.77; N, 9.80%. FTIR [ν/cm^{-1} (KBr)]: 1635 (C=N), 1475 (C=C), 1340, 1321 (C–O), 760 (arom). Mass Spec. (EI) m/z 1084, 1086 $[M]^+/[M-H]^+/[M-2H]^+$. λ_{max} (solid reflectance): 382 nm. μ_{eff}: 4.9 BM (300 K).

2.5. Preparation of bis-(tris-((2-hydroxy-5-bromobenzylidene)aminoethyl)amine nickel)nickel

A methanol solution (100 ml) of Tren5BrSal (0.695 g, 1 mmol) and nickel acetate (0.375, 1.5 mmol) was refluxed for 90 min. The solution was allowed to cool and the resulting green powder collected and recrystallised from dichloromethane: diethyl ether by vapour diffusion. Yield 94%. *Anal.* Calc. for $C_{54}H_{48}N_8Br_6Ni_3O_6 \cdot 2CH_2Cl_2$: C, 38.87; H, 3.03; N, 6.47. Found: C, 38.54; H, 3.17; N, 6.12%. FTIR [ν/cm^{-1} (KBr)]: 1625 (C=N), 1465 (C=C), 1305 (C–O), 820 (arom). Mass Spec. (ESI) m/z 1560 [M+]. λ_{max} (dichloromethane): 382 nm (ε/dm^{3}mol^{-1} cm^{-1}, 1361). μ_{eff}: 6.0 BM (300 K).

2.6. Attempted direct crystallisation of [(TrenSal)$_2$Ni$_3$]

A methanol (20 ml) solution TrenSal (0.131 g, 0.29 mmol) was added to a methanolic solution (30 ml) of nickel bromide trihydrate (0.117 g, 0.43 mmol). The mixture was heated for 90 min and the resulting red solution allowed to cool before being filtered. Excess TMEDA (6 ml, 40 mmol) was introduced into the solution and the mixture allowed to stand, open to the air, for a week during which time the solution slowly changed colour from red to yellow-green. A portion (approx. 50%) of the methanol was allowed to evaporate. Two sets of crystals suitable for X-ray analysis form in the solution which could be manually separated with ease.

Orange crystals: *Anal.* Calc. for $C_{46}H_{64}N_{10}Br_2Ni_3O_4 \cdot MeOH \cdot 3\,H_2O$: C, 45.41; H, 6.00; N, 11.27. Found: C, 45.15; H, 5.76; N, 11.06%. FTIR [ν/cm^{-1} (KBr)]: 1620 (C=N), 1445 (C=C), 775 (arom). Mass Spec. (ESI) m/z 1075 [MBr+].

Green crystals: *Anal.* Calc. for $C_{40}H_{120}N_{12}Br_4Ni_6O_{24} \cdot 2H_2O$: C, 25.81; H, 6.71; N, 9.03. Found: C, 26.20; H,

[2] This compound was obdurately insoluble and could not be recrystallised. Purification was restricted to washing the material with a range of solvents in an attempt to remove the obvious impurities. However, the spectroscopic information obtained from the solid in conjunction with the successful characterisation of the Tren5BrSal below clearly support the formation of the desired compound. The microanalysis consistently returned values somewhat lower than required for an anhydrous product and we resorted to scaling the analysis by adding one or two water molecules to gain agreement. The analysis reported is thus a faithful record of the values one might expect to obtain for this material.

2.7. Preparation of bis-(tris-((2-hydroxybenzylidene)-aminoethyl)amine zinc)zinc

A methanolic solution (30 ml) of zinc acetate (0.33 g, 1.5 mmol) was added dropwise to a stirred methanolic (30 ml) solution of TrenSal (0.46 g, 1 mmol). The resulting solution was refluxed for 90 min. The solution was filtered hot and the solvent removed to reveal a gelatinous yellow material. This was recrystallised from pyridine: diethyl ether by vapour diffusion. Yield 75%. *Anal.* Calc. for $C_{54}H_{54}N_8Zn_3O_6$ C, 58.57; H, 4.91; N, 10.12. Found: C, 57.85; H, 4.85; N, 10.71%. ^{1}H NMR (400 MHz, $CDCl_3$; δ): 8.2–8.4 (br m, 3H, –HC=N); 7.1 (br s, 6H, arom); 6.5 (br d, 6H, arom); 3.6–3.8 (m, 6H, –CH_2–); 2.7–2.9 (m, 6H, –CH_2–). 2.9. Preparation of bis-(μ-chloro(tris-((2-hydroxy-benzylidene)aminoethyl)amine nickel)pyridino lead)

[(TrenSal)$_2$Ni$_3$] (0.25 g, 0.20 mmol) and lead chloride (0.25 g, 0.9 mmol) were suspended in pyridine (10 ml). The solution was allowed to reflux for 72 h whereupon the colour of the solution darkened. The solution was allowed to cool and then filtered to remove the remaining [(TrenSal)$_2$Ni$_3$] and $PbCl_2$. The solution was re-filtered through celite to leave a dark brown solution which was vapour diffused with diethyl ether to produce a dark brown crystals suitable for X-ray crystallography. Yield 10%. *Anal.* Calc. for $C_{64}H_{64}Cl_2N_{10}Ni_2O_6Pb_2$: C, 45.97; H, 3.86; N, 8.38. Found: C, 45.51; H, 3.58; N, 8.04%. FTIR [ν/cm^{-1} (KBr)]: 1630 (C=N), 1450 (C=C), 1095 (Pb–Cl).

2.10. Preparation of bis-(μ-chloro(tris-((2-hydroxy-5-bromobenzylidene)aminoethyl)amine nickel)pyridino lead)

[(Tren5BrSal)$_2$Ni$_3$] (0.25 g, 0.16 mmol) and lead chloride (0.25 g, 0.9 mmol) were suspended in pyridine (10 ml). The solution was allowed to reflux for 72 h whereupon the colour of the solution darkened. The solution was allowed to cool and then filtered to remove the remaining [(TrenSal)$_2$Ni$_3$] and $PbCl_2$. The solution was taken to dryness and extracted with THF. The resulting brown solution was filtered through celite and taken to dryness again. The resulting gum was re-dissolved in pyridine to form a brown solution, which was filtered through celite. The mixture was crystallised by vapour diffusion with diethyl ether producing a dark brown powder. Yield 20%. *Anal.* Calc. for $C_{64}H_{58}Br_6Cl_2N_{10}Ni_2O_6Pb_2 \cdot$ pyridine: C, 38.58; H, 2.98; N, 7.30. Found: C, 38.88; H, 2.52; N, 6.86%. FTIR [ν/cm^{-1} (KBr)]: 1630 (C=N), 1460 (C=C), 1100 (Pb–Cl).

2.11. Preparation of 1,1,1-tris-((2-hydroxybenzylidene)-aminomethyl)propane (TEtSal)

Briefly: 3 mol equivalents of salicylaldehyde was mixed with 1 mol equivalent of 1,1,1-tris(methylamino)propane [32,33] in chloroform (50 ml). The resulting solution was refluxed for 4 h. The solvent was removed and the resulting dark orange oil recrystallised from chloroform/hexane. Yield 55% *Anal.* Calc. for $C_{27}H_{29}N_3O_3$: C, 73.11; H, 6.59; N, 9.47. Found: C, 72.97; H, 6.55; N, 9.42%. ^{1}H NMR (400 MHz, $CDCl_3$; δ): 13.2 (br s, 3H, –OH); 8.3 (s, 3H, –HC=N); 7.2 (t, 3H, arom); 7.1 (d, 3H, arom); 6.8 (d, 3H, arom); 6.7 (t, 3H, arom); 3.55 (s, 6H, –CH_2–); 1.55 (q, 2H, –CH_2–); 0.95 (t, 3H, –CH_3). ^{13}C-{^{1}H} NMR (100 MHz $CDCl_3$; δ): 166.7, 161.3, 132.8, 131.7, 119.0, 118.9, 117.1, 62.5, 42.6, 25.6, 7.6. FTIR [ν/cm^{-1} (KBr)]: 1635 (C=N); 1490 (C=C); 1275 (C–O); 755 (arom). m.p. 100 °C. Mass Spec (ESI) m/z 444 [M+H$^+$].

2.12. Preparation of bis-((tris-(2-hydroxybenzylidene)-aminomethyl)propane nickel)-μO_6-nickel

TEtSal (0.5 g, 1.1 mmol) and nickel acetate (0.42 g, 1.7 mmol) were mixed in ethanol (50 ml). The resulting solution was refluxed for 4 h. The solvent was removed and the solid recrystallised from chloroform–diethyl ether by vapour diffusion. Yield 60% *Anal.* Calc. for $C_{54}H_{52}N_6Ni_3O_6$ C, 61.35; H, 4.96; N, 7.95. Found: C, 61.57; H, 5.44; N, 7.45%. FTIR [ν/cm^{-1} (KBr)]: 1635 (C=N), 1450 (C=C), 1326 (C–O), 750 (arom). Mass Spec (ESI) m/z 1057 [M+H$^+$]. λ_{max} (solid reflectance): 540 nm. λ_{max} (dichloromethane): 370 nm ($\varepsilon = 97.5$ M^{-1} cm^{-1}). μ_{eff}: 3.6 BM (300 K).

2.13. Preparation of bis-(tris-((2-hydroxybenzylidene)-aminomethyl)propane nickel)lead

$[(TEtSal)_2Ni_3]$ (0.25 g 0.20 mmol) and lead chloride (0.25 g, 0.9 mmol) were suspended in pyridine (10 ml). The solution was allowed to reflux for 72 h whereupon the colour of the solution darkened. The solution was allowed to cool and then filtered to remove the remaining $[(TEtSal)_2Ni_3]$ and $PbCl_2$. The solution was re-filtered through celite to leave a deep orange solution. Vapour diffusion with diethyl ether produced a small number of dark brown crystals suitable for X-ray crystallography distributed amongst the impure powder. These were isolated by Pasteur separation. Yield 5%. *Anal.* Calc. for $C_{64}H_{64}Cl_2N_{10}Ni_2O_6Pb_2$: C, 45.97; H, 3.86; N, 8.38. Found: C, 45.51; H, 3.58; N, 8.04%.

3. Results and discussion

The potentially heptadentate Schiff base ligands, TrenSal and Tren5BrSal can be prepared with ease from tris-(2-aminoethyl)amine and salicylaldehyde and 5-bromo-salicylaldehyde respectively. The reaction of these species with nickel acetate or zinc acetate gives rise to the formation of a homologous series of L_2M_3 complexes (L = TrenSal, Tren5BrSal: M = Ni, Zn). Although the series of complexes $[(TrenSal)_2M_3]$ have proved difficult to properly structurally characterise, the analogous $[(Tren5BrSal)_2M_3]$ species were easily crystallised (Fig. 4). The structures obtained reveal the expected trimetallic motif in which the three metals adopt two different environments. Two metals are fully encapsulated within the Schiff base ligands in an almost symmetric N_3O_3 environment creating two moieties which can be considered as a mono-anionic ligands. Thus the central unique metal (Fig. 4, Ni2) can be described as being effectively coordinated to two facially capping tripodal ligands in an O_6 octahedral motif. This elegant MO_6 core has been observed previously in a limited number of related ligands (Table 2). Consistent with these structures the central metal cations (e.g. nickel, Fig. 4) are found to lie a few degrees off the major axis creating a slight expansion and compression of the metrical parameters about the central O_6–M units (M = Ni, Zn, Table 2). The room temperature magnetic moments of the two nickel complexes are in good agreement with those obtained by Chandrasekar et al. [28] for the phosphotrihydrazone (PsSal, Fig. 2) complex of nickel and Ohta et al. [29] for their tris-((salicylidene)aminomethyl)ethane (TMeSal, Fig. 2) nickel complex both of which contains an iso-struc-

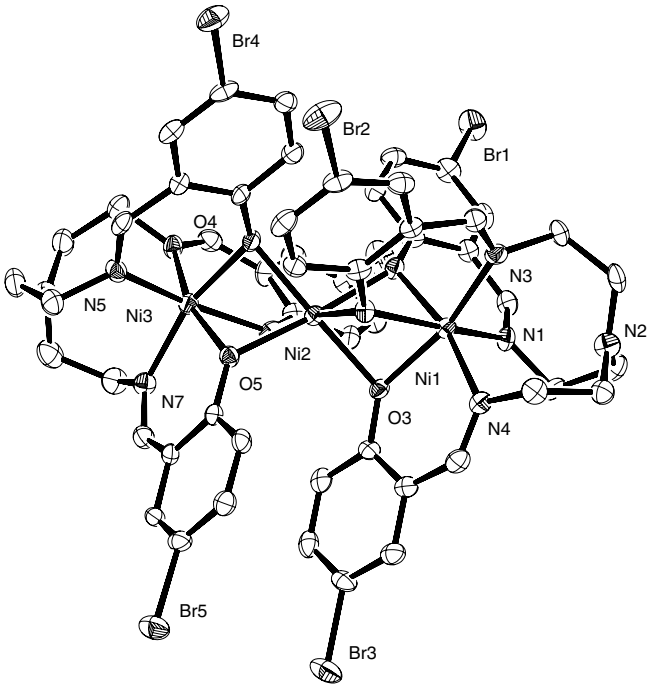

Fig. 4. The X-ray crystal structure of $[(Tren5BrSal)_2Ni_3]$. The thermal ellipsoids are drawn at 50%. The structure of the iso-structural $[(Tren5BrSal)_2Zn_3]$ is not shown. However its metrical parameters are given in Table 2.

tural M_3O_6 motif. These studies suggest that, in the compounds reported here, the two adjacent metal centres (Ni1, Ni2) are ferromagnetic and the two terminal nickels (Ni1, Ni1) antiferromagnetic. As such it was decided that the system was not worthy of deeper study at this time.

There can be some confusion regarding the nature of these species. Although Ohta et al. have produced a trimetallic species similar to $[(TrenSal)_2Ni_3]$ (Table 2) a dimeric species (L_2M_2) and monomeric species have also been isolated [29]. Thus although our data supported the formation of trimetallic motifs from the outset, throughout the study we were driven to conclusively demonstrate this by the isolation of crystals suitable for X-ray analysis. The insolubility of $[(TrenSal)_2Ni_3]$ once formed forced us to investigate more robust crystallisation methods. Within this series of experiments we reluctantly opted to use TMEDA as a chelating agent and base (typically Et_3N is used) in an attempt to slow the rate of complex formation. These reaction mixtures slowly produced two sets of crystals one orange and the other green both of which were identified by X-ray crystallography as TMEDA adducts of nickel.

The orange product was identified as two partially hydrolysed NiTrenSal units coordinated to a Ni(TMEDA) unit (Fig. 5). Imine hydrolysis is not an uncommon consequence of a prolonged "crystallisation" process. Indeed we have previously reported on the X-ray structure of a related partially hydrolysed Schiff base complex [30]. The environment around the three nickels in the compound obtained is unremarkable being comprised of a simple N_4O_2 octahedral motif at TMEDA (Ni1) and two square planar N_3O motifs within the residue of the Schiff base species (Ni2). In contrast to the metal environments the behaviour of the ligand is of more interest. Hydrolysis of the ligand removes one of the phenoxide units and in its absence its function as a donor in the hexadentate motif (c.f. Fig. 4) is replaced by the apical nitrogen of Tren (N2). This modification makes it more difficult for both the remaining salicylidene units to chelate to the same nickel and one of the donor sites is forced to rotate away from nickel (Ni2) and bind to a Ni(TMEDA) moiety which is also present in the solution.

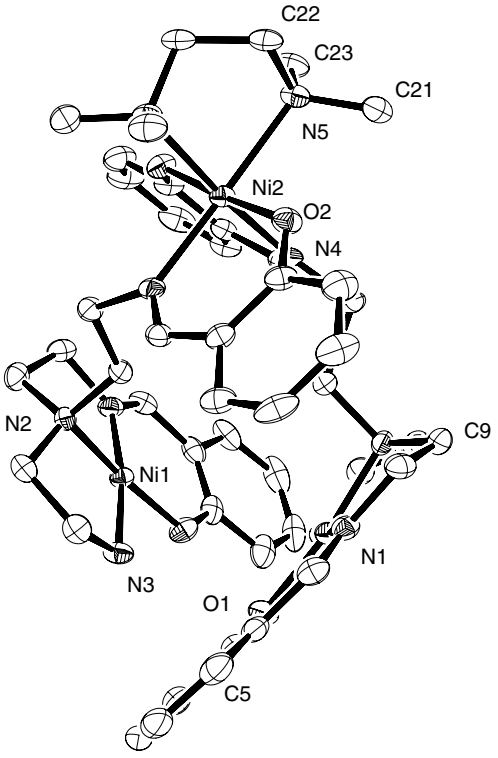

Fig. 5. The X-ray crystal structures of the orange product obtained from the mixture containing TMEDA, nickel bromide and TrenSal: Bis-((bis (2-hydroxybenzylidene)aminoethyl)amine nickel) tetramethylethylenediamine nickel. The thermal ellipsoids are drawn at 50%.

More intriguing was the second green product. These are devoid of the Schiff base ligand and are instead composed of Ni(TMEDA), carbonate and bromide (Fig. 6). There are six Ni(TMEDA) units connected to each other via a carbonate scaffold. Each of the carbonates (e.g. C14) bridge three nickels thus creating a cyclic motif. Water and not bromide fill the remaining coordination sites at nickel. The cyclic Ni(TMEDA) carbonate units stack to form columns. Although the bromides remain in close attention to balance the charge they do not fill the interstitial volumes and the resulting pores are remarkably large −4781 $Å^3$ pore space per unit cell which represents

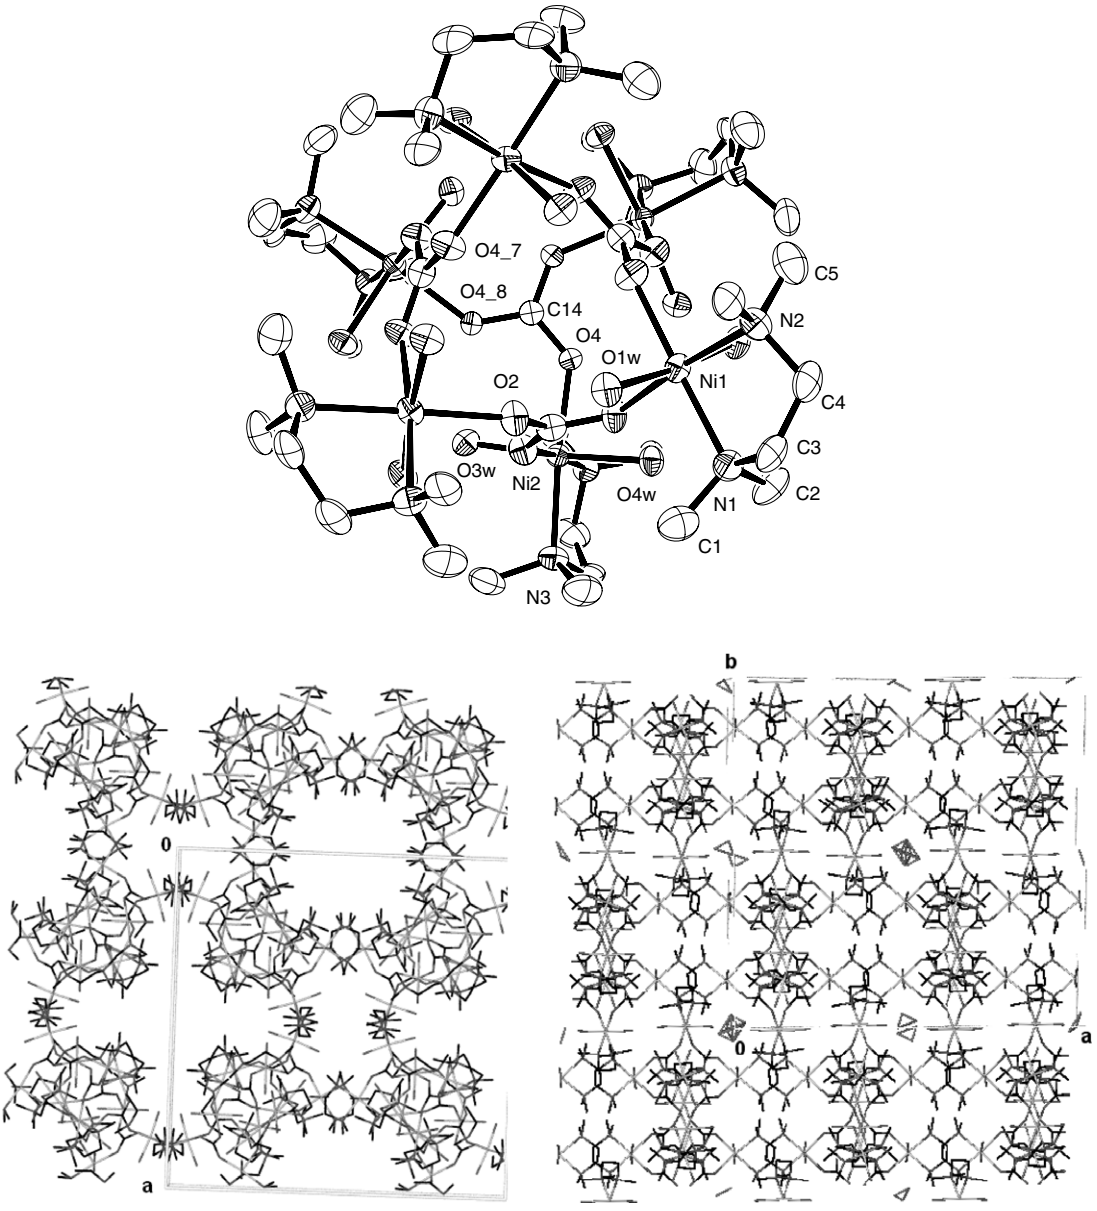

Fig. 6. The X-ray crystal structures of the green product obtained from the mixture containing TMEDA, nickel bromide and TrenSal: TMEDA nickel carbonate bromide. The supramolecular structure of the two crystallographically characterised isoforms of this species are shown which demonstrate the changes in gross structure which were observed. The thermal ellipsoids are drawn at 50%.

25.6% of the structure but contains only small traces of disordered water (Fig. 6 left). Our attempts to synthesis this compound from nickel bromide, TMEDA and sources of carbonate failed. In the absence of TrenSal we only obtained TMEDA · HBr and solvated nickel adducts of TMEDA. The synthesis of the complex from TrenSal is however, highly reproducible including the formation of the crystals. A second sample of these were also crystallographically analysed. Although the coordination environments of the metals and ligands were found to be essentially iso-structural with the species above (Fig. 6, top) with only minor variation in the water balance (Table 1), the supramolecular structures were found to be completely different (Fig. 6, right). The pore network in the second sample would seem to have completely collapsed now only occupying 564 $Å^3$ of space per unit cell which represents only 3.5% of the structure. The variable behaviour of these carbonate structures is in retrospect not surprising. The complex forms slowly under the influence of two rate determining factors *viz* CO_2 diffusion and ligand hydrolysis, which we did not attempt to control. The conditions would seem to allow the reproducible formation of the nickel μ^3-carbonate moiety, in the face of widely variable packing forces.

Our previous studies on trimetallic nickel complexes of tetradentate Schiff base species [6] (Fig. 1) demonstrated that it was possible to replace the central nickel by lead thus generating an interesting heterobimetallic complex.

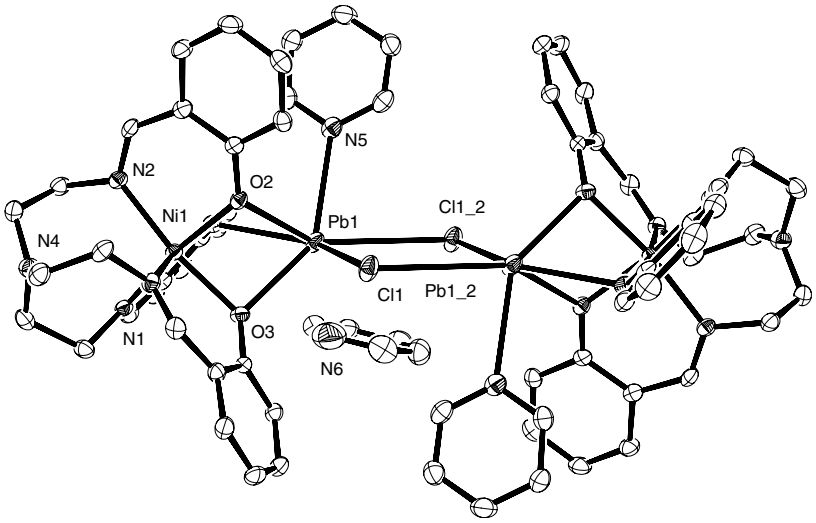

Fig. 7. The X-ray crystal structure of $[\{(TrenSal)Ni\}Pb(NC_5H_5)Cl]_2$ pyridine. Selected bond lengths and angles: Distances (Å): Ni–N1, 2.053(3); Ni–N2, 2.079(3); Ni–O3, 2.075(3); Ni–O1, 2.060(2); Ni–O2, 2.049(2); Ni–O3, 2.078(2); Pb–O1, 2.711(2); Pb–O2, 2.3615(19); Pb–O3, 2.415(2); Pb–Cl, 2.7070(9); Pb–Cl1 3.2719(10): Angles(°): O1–Ni–O2, 81.45(8) O1–Ni–O3, 83.23(8) O2–Ni–O3, 83.93(8) N1–Ni–O2, 168.89(9) N2–Ni–O3, 170.86(9) N3–Ni–O1, 167.91(10); O1–Pb–O2, 63.37(7) O1–Pb–O3, 64.54(7) O2–Pb–O3, 70.58(7). The thermal ellipsoids are drawn at 50%.

A similar reaction was carried out here whereby $[(TrenSal)_2Ni_3]$ and $[(Tren5BrSal)_2Ni_3]$ were refluxed with lead chloride in pyridine. From this mixture containing $[(TrenSal)_2Ni_3]$ we retrieved some X-ray quality crystals that confirm that the replacement reaction proceeds as predicted (Fig. 7). The complex is dimeric containing two bridging chlorides which are not equidistant from the lead centres. The bridge between the two [{(TrenSal)Ni}Pb] units is achieved via a somewhat longer Pb–Cl interaction (3.2719(10) Å). The TrenSal moiety again fully encapsulates the nickel atom holding it in an almost regular octahedral environment. This arrangement again collects the three phenoxide donors such that they generate an O_3 tripodal motif. Thus the [(TrenSal)Ni] moiety can be considered to be a uninegative ligand in its own right. The lead binds at the O_3 cleft in a more asymmetric manner showing a wider variation in bond lengths and angles to that of nickel. The presence of a lone pair on the lead atom can be inferred from the compression of the angles between lead and its six donor atoms.

The manner in which this elegant tetrametallic species forms is in line with the studies of Ohta et al. [29] which suggest that in solution trimetallic species such as TMeSal can also be encouraged to heterometallic species in a similar manner [36,37]. To further investigate this we prepared the related TEtSal ligand which differs from that reported by Ohta et al. [29] only in that it has an ethyl group on the apical carbon. The synthesis of the TEtSal and the respective nickel complex presented no problems. Indeed the nickel complex was isolated in a form that allowed it to be structurally analysed by X-ray crystallography. As expected it is iso-structural with the trimetallic complex previously reported by Ohta et al. (Table 2) where the three nickels lie in octahedral environments two encapsulated within the hexadentate frameworks with the third nickel sandwiched between the O_3 anionic clefts of the folded metallo-ligand ([(TEtSal)Ni], Fig. 8).

The reaction of $[(TEtSal)_2Ni_3]$ with lead chloride was only a partial success in that we only obtained a small number of crystals suitable for X-ray crystallography. However, these revealed that the replacement reaction reported above does proceed and that the nickel Schiff base moiety can be considered to be a ligand capable of being transferred intact. The structure obtained is trimetallic consistent with the studies of Kojima et al. who have recently reported mixed nickel-lanthanide [36] (gadolinium) and nickel-transition metal [37] (iron, manganese) TMeSal complexes. Thus the complex reported here completes the series of trimetallic (Ni–M–Ni) complexes derived from metals located in different parts of the periodic table (f-, d- and p-block). The transition metal complexes form

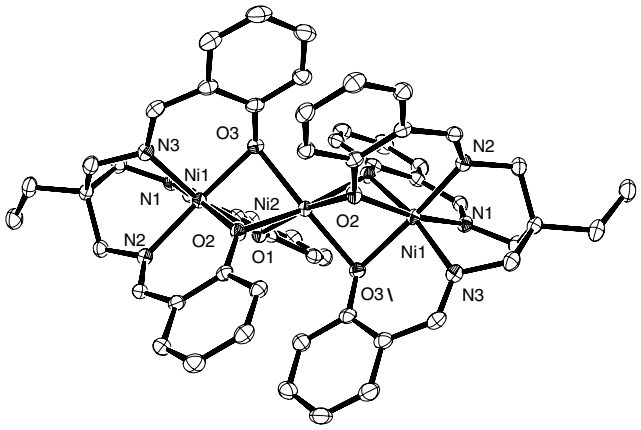

Fig. 8. The X-ray crystal structure of Bis-((tris-(2-hydroxybenzylidene)-aminomethyl)-propane nickel)-μO_6-nickel $[(TEtSal)_2Ni_3]$. The structural homology of $[(TEtSal)_2Ni_3]$ with the previously published structure $[(TMeSal)_2Ni_3]$ should be noted [29]. The key metrical parameters are given in Table 2. The thermal ellipsoids are drawn at 50%.

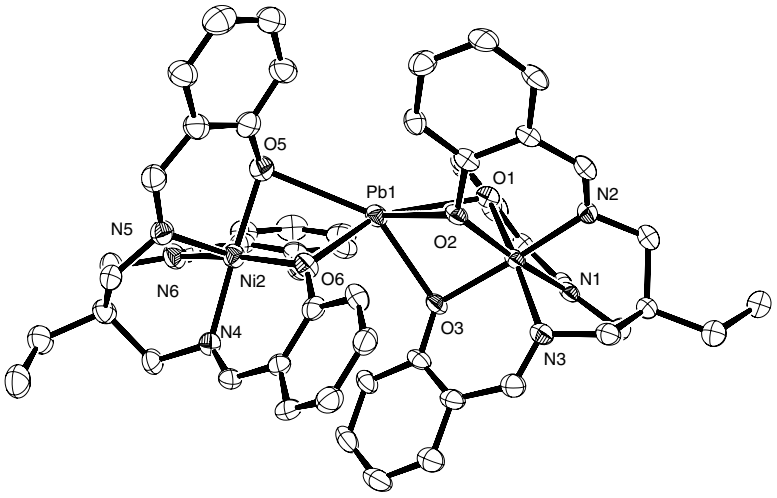

Fig. 9. The X-ray crystal structure of Bis-((tris-(2-hydroxybenzylidene)-aminomethyl)-propane nickel)lead [{(TEtSal)Ni}$_2$Pb]. The key metrical parameters are given in Table 3. The thermal ellipsoids are drawn at 50%.

species that provide an almost regular octahedral environment for the central atom (Fe, Mn, Ni, Table 2) with the three metals adopting a liner arrangement. The lead complex shown here is similar to that of gadolinium in that a significant angle is created between the three metal ions. For gadolinium this angle is created by the presence of the didentate nitrate ligand whereas for lead it arises from the influence of the lone pair on the divalent lead centre (Table 2) Fig. 9.

Of the two NiPb structures reported here that of [{(TEtSal)Ni}$_2$Pb] is consistent with an emerging catalogue of trimetallic complexes where a heteroatom (M = Mn, Fe, Ni, Gd, Pb) is sandwiched between two metallo-ligands. The complex formed from TrenSal [{(TrenSal)Ni}-Pb(NC_5H_5)Cl]$_2$ is in contrast more unique. Kojima et al. have reported a tetrametallic nickel–gadolinium complex that is held together by acetate bridges [36]. However, our ability to produce complexes such as [{(TrenSal)Ni}Pb(NC_5H_5)Cl]$_2$ which contain good leaving groups suggest that even more complex systems can be constructed.

Supplementary material

CCDC 657463, 657464, 657465, 657466, 660524, 661264, 661265, 661266 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

AM would like to express his gratitude to Kano University of Science and Technology, Wudil for financial assistance. Thanks are due to the EPSRC National Mass Spectrometry service at the University of Swansea and X-ray Crystallography Service at the University of Southampton for data collection on samples [(TrenSal)$_2$Ni$_3$] and ((TrenSal-1)Ni)$_2$ · (TMEDA)Ni respectively and to the CCLRC for award of beamtime at the Daresbury SRS which allowed us to collect data on [(Tren5BrSal)$_2$-Zn$_3$].

hydrazone (ATH). The Ni(II) and Cu(II) complexes have also been characterized through single crystal X-ray diffraction, as well as electronic paramagnetic resonance (EPR) of the latter.

2. Experimental

2.1. General procedures

All reagents were commercial grade materials and were used without further purification. The ligand 2-acetyl-2-thiazoline hydrazone (ATH) was synthesized according to a reported procedure [17].

ATH

Chemical analyses of carbon, hydrogen, nitrogen and sulphur were performed by means of microanalytical methods using a Perkin–Elmer 240C microanalyser. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, from a KBr pellet in the 4000–370 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from a polyethylene pellet in the 500–150 cm^{-1} range. The UV–Vis–NIR reflectance spectra for complexes in the 200–1500 nm range were registered from a pellet of the sample, using a Shimadzu UV-3101 PC spectrophotometer and $BaSO_4$ as reference. Magnetic susceptibility measurements were performed on polycrystalline samples using a magnetometer with pendulum MANICS DSM8, equipped with helium continuous-flow cryostat and an electromagnetometer DRUSCH EAF 16 UE. Data were corrected for temperature-independent paramagnetism and diamagnetic contributions, which were estimated from the Pascal constants. EPR spectra were recorded at room temperature in solid state and at 77 K in methanol solution employing a BRUKER ESP-300E spectrometer using the X band of microwave.

2.2. Synthesis of $[CoCl_2(ATH)_2]$ (1)

This complex was isolated from an ethanol solution (3 mL) of $CoCl_2 \cdot 6H_2O$ (166 mg, 0.7 mmol) that was added to an ethanol solution (25 mL) of ATH (200 mg, 1.4 mmol). After an hour, pink crystalline solid was isolated from the solution at room temperature (104 mg, 36%). Solid was filtered and washed with cold ether and air-dried. *Anal.* Calc. for $C_{10}H_{18}Cl_2CoN_6S_2$: C, 28.85; H, 4.35; N, 20.18; S, 15.40. Found: C, 29.23; H, 3.98; N, 20.45; S, 15.15%. IR(KBr): ν(NH_2) 3367, 3247, 3167; δ(NH_2) 1616; (ring vibration) 1603; ν(C=N) 1546; (ring vibrations) 1000, 950, 734, 682; 653, 602, 564, 448 cm^{-1}.

[a] $R = \sum \| F_o \| - \| F_c \| / \sum | F_o |$.
[b] $R = \{\sum[w(F_o^2 - F_c^2)^2] / \sum[w(F_o^2)^2]\}^{1/2}$.
[c] The Goodness-of-fit (GOF) equals $\{\sum[w(F_o^2 - F_c^2)^2]/(N_{rf\,ln\,s} - N_{params})\}^{1/2}$.

2.3. Synthesis of $[NiCl_2(ATH)_2]$ (2)

This complex was isolated from an ethanol solution (2 mL) of $NiCl_2 \cdot 6H_2O$ (83 mg, 0.35 mmol) that was added to an ethanol solution (15 mL) of ATH (100 mg, 0.7 mmol). After several hours, 103 mg (71% yield) of a green solid was recovered filtering. This solid was recrystallized from a ethanol/acetonitrile (1:1 v/v) solution, yielding plate dark green crystals, of considerable size, suitable for X-ray diffraction. Anal. Calc. for $C_{10}H_{18}Cl_2NiN_6S_2$: C, 29.01; H, 4.38; N, 20.30; S, 15.49. Found: C, 28.99; H, 4.45; N, 20.35; S, 15.21%. IR(KBr): ν(NH_2) 3335, 3245, 3142; δ(NH_2) 1619; (ring vibration) 1601; ν(C=N) 1546; (ring vibrations) 1001, 954, 741, 683, 642, 602, 562, 435 cm^{-1}.

2.4. Synthesis of $[\{CuCl(ATH)\}_2(\mu\text{-}Cl)_2]$ (3)

This complex was isolated from a methanol solution (2 mL) of $CuCl_2 \cdot 2H_2O$ (119 mg, 0.7 mmol) that was

added to a methanol solution (15 mL) of ATH (100 mg, 0.7 mmol). Green crystals were isolated after a slow evaporation of the solution at room temperature (176 mg, 91%). The crystals were filtered and washed with cold ether and air-dried. *Anal.* Calc. for $C_5H_9Cl_2CuN_3S$: C, 21.63; H, 3.27; N, 15.13; S, 11.55. Found: C, 21.61; H, 3.37; N, 15.11; S, 11.35%. IR(KBr): ν(NH_2) 3364, 3255; δ(NH_2) 1614; (ring vibration) 1581; ν(C=N) 1550; (ring vibrations) 1002, 949, 751, 684, 657, 621, 566, 440 cm^{-1}.

2.5. X-ray determination structure

X-ray diffraction data of **2** and **3** were collected on a Bruker SMART CCD diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å, graphite monochromator). The first fifty frames were measured at the end of data collection to monitor instrument and crystal stability. The data were empirically corrected for absorption and other effects using the SADABS [19] program. The structures were solved by direct methods and subsequent Fourier differences using the SHELXS-97 [20] program and refined by full-matrix least-squares on F^2 with SHELXL-97 [21], included in WINGX [22] package assuming anisotropic displacement parameters for non-hydrogen atoms. All hydrogen atoms attached to carbon and nitrogen atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding carbon and nitrogen atoms. Diagrams were generated using ORTEP3 for Windows [23]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

3. Results and discussion

3.1. Description of the crystal structures

The X-ray study of the complex **2** reveals that the crystals are made up of monoclinic unit cells, each containing four $[NiCl_2(ATH)_2]$ molecules. The overall view and labelling of the atoms of complex are displayed in Fig. 1.

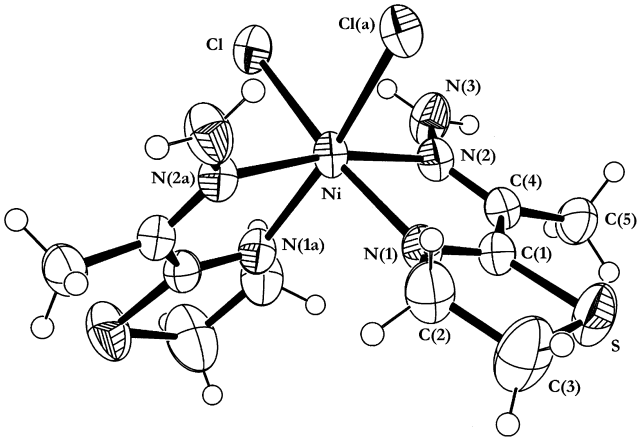

Fig. 1. Molecular structure of **2**, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 50% probability level.

N(3)–H(3C)···Cl	$x, -y, z + 1/2$	3.280(2)	146.70(14)

Table 2 lists selected bond lengths, angles and hydrogen-bond parameters.

The complex cation possesses a C_2 symmetry, with the twofold axis placed at the bisector of the Cl–Ni–Cl(a) angle.

The environment around the nickel(II) atom may be described as a slightly distorted octahedral geometry with the ligand-metal-ligand bite angles varying between 77.61(7)° [N(1)–Ni–N(2)] and 95.26(11)° [N(1)–Ni–N(1a)]. The metallic atom is coordinated by two chlorine ligands [Ni–Cl = 2.4403(6) Å], two thiazolinic nitrogen atoms [Ni–N(1) = 2.075(2) Å] and two iminic nitrogen atoms [Ni–N(2) = 2.089(2) Å].

The Ni–Cl bond distance is similar to the average value [2.449(60) Å] calculated using the data of 52 six-coordinated nickel(II) complexes with a chromophore group $NiCl_2N_4$ obtained with CONQUEST software [24] from the Cambridge Structural Database (CSD, Version v5.28, May 2007) [25]. Likewise, the Ni–N_{imine} bond length is comparable to the mean value 2.073(41) Å found for 10 six-coordinated nickel(II) complexes with a Cl_2N_4 environment in CSD. Finally, the Ni–$N_{thiazoline}$ bond length is similar to that found in $[Ni(ATsc)_2](NO_3)_2 \cdot H_2O$ (av. 2.073 Å) [18], $[Ni(PyTT)_2(H_2O)_2]Cl_2 \cdot 3H_2O$ (2.061 Å) [26], $[Ni(L)(H_2O)_2]ClO_4 \cdot H_2O$ (2.057 Å) [27] and $[Ni_4(OH)_4(tzdt)_4(py)_4] \cdot 2py$ (2.106 Å) [28], but somewhat longer to than that observed in $[Ni(TzHy)_2(H_2O)_2]Cl_2 \cdot 2H_2O$ (2.027 Å) [29].

The five-membered chelate ring is essentially planar. The maximum deviation in relation to the corresponding mean plane is produced for C(1) [0.055 Å].

The thiazoline ring shows an intermediate conformation between envelope and half-chair, with C(2) and C(3) deviating 0.095 and 0.116 Å above and below, respectively, the plane formed by S, C(1) and N(1). This geometry is proved by the puckering parameters $q = 0.160$ Å and $\phi = 134.5°$, calculated according to Cremer and Pople [30].

The crystal structure is stabilized by hydrogen-bonds Cl···H(3C)–N(3) of intermolecular type. This hydrogen bonding (Fig. 2) produces an one dimensional chain parallel to the *c*-direction.

The molecular structure of the complex **3** is shown in Fig. 3. Selected interatomic distances and angles are listed

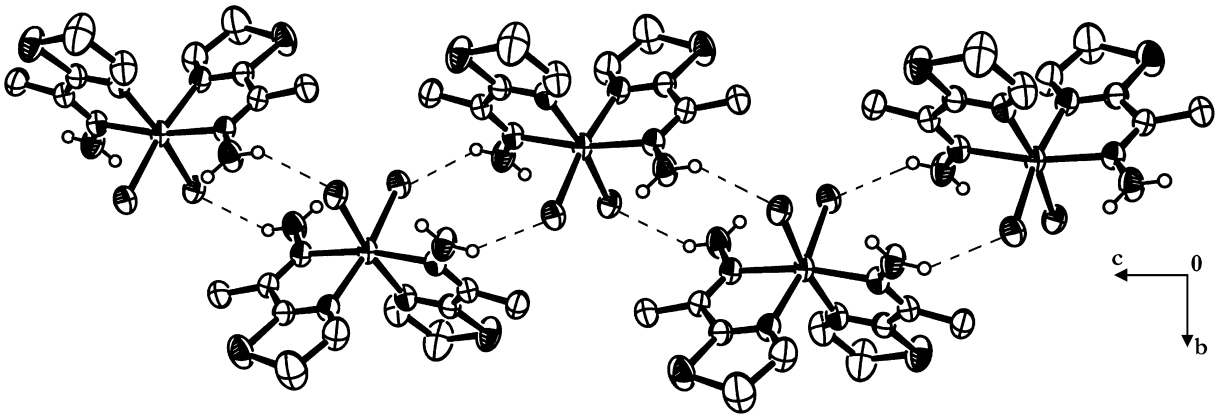

Fig. 2. View of the hydrogen bonds of **2**.

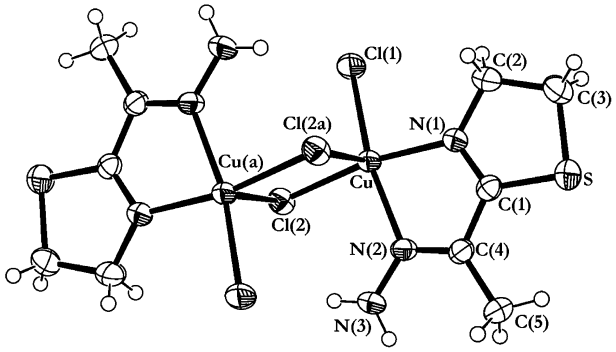

Fig. 3. Molecular structure of **3**, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 40% probability level.

Table 3
Selected bond lengths (Å) and angles (°) for **3**

Cu–N(1)	1.984(2)	Cu–N(2)	2.077(2)
Cu–Cl(1)	2.2554(9)	Cu–Cl(2)	2.2725(8)
Cu–Cl(2a)	2.6598(8)	C(1)–N(1)	1.280(3)
C(1)–C(4)	1.456(3)	N(2)–C(4)	1.287(3)
N(1)–Cu–N(2)	79.04(8)	N(1)–Cu–Cl(1)	93.35(6)
N(1)–Cu–Cl(2)	169.49(6)	N(1)–Cu–Cl(2a)	94.85(7)
N(2)–Cu–Cl(1)	166.88(6)	N(2)–Cu–Cl(2)	91.46(6)
N(2)–Cu–Cl(2a)	91.22(6)	Cl(1)–Cu–Cl(2)	95.12(3)
Cl(1)–Cu–Cl(2a)	100.13(3)	Cl(2)–Cu–Cl(2a)	89.78(3)
Cu–Cl(2)–Cu(a)	90.22(3)	C(1)–N(1)–Cu	113.90(17)
C(4)–N(2)–Cu	114.78(17)	C(4)–C(1)–N(1)	120.0(2)
N(2)–C(4)–C(1)	112.3(2)		

in Table 3. The structure consists of centrosymmetric dimeric $[\{CuCl(ATH)\}_2(\mu\text{-}Cl)_2]$ units, in which two chlorine ligands bridge the copper atoms forming a four-membered ring; a terminal chlorine ligand and a bidentate chelating molecule of ATH completing five-coordination at each metal. The bridging Cu_2Cl_2 unit is strictly planar by the presence of the crystallographic inversion centre in the middle of the dimer.

The geometry around the copper centres can be described as a slightly distorted tetragonal pyramid with a τ value of 0.04 [31] and a Δ value of 0.86 [32]. The basal plane is made up of one thiazoline nitrogen atom N(1), one imine nitrogen atom N(2), the bridging chlorine ligand Cl(2) and the terminal chlorine ligand Cl(1), while the apical site is occupied by the other bridging chlorine ligand Cl(2a). The Cl(2a)–metal–basal ligand angles differ from the ideal value for a square pyramid, ranging between 100.13(3)° [for Cl(1)–Cu–Cl(2a)] and 89.78(3)° [Cl(2)–Cu–Cl(2a)]. Likewise, the basal ligand–metal–basal ligand angles differ from the ideal value, ranging between 95.12(3)° [Cl(1)–Cu–Cl(2)] and 79.04(8)° [N(1)–Cu–N(2)].

The Cu–Cl and Cu···Cu bond lengths have been compared with the mean value calculated using the data of 65 dichlorine-bridged dimers of copper(II) with a Cl_3N_2 environment obtained from CSD [25]. The $Cu–Cl_{terminal}$ [Cu–Cl(1) = 2.2554(9) Å], the short $Cu–Cl_{bridging}$ [Cu–Cl(2) = 2.2725(8) Å], the long $Cu–Cl_{bridging}$ [Cu–Cl(2a) = 2.6598(8) Å] and the Cu···Cu [Cu···Cu(a) = 3.505(1) Å] distances are similar than the calculated average values [2.257(24) Å], [2.286(33) Å], [2.74(10) Å] and [3.53(14) Å], respectively. The $Cu–N_{imino}$ bond distance is slightly larger than the calculated average value [1.996(33) Å] for 21 copper(II) dimers with this type of unions containing two chlorine bridging ligands and a chromophore group $CuCl_3N_2$ in CSD [25]. Finally, the $Cu–N_{thiazoline}$ bond distance is comparable to the calculated average value [1.960(38) Å] for 16 copper(II) complexes with the 2-thiazoline ligand collected in CSD [25].

The five-membered chelate ring is essentially planar with maximum mean-plane deviation for N(2) [0.059 Å]. The geometry of 2-thiazoline ring is similar to that found in **2**.

Finally, it should be pointed out that the main difference in complexes **2** and **3** with respect to the structure of free ATH [17] is due to the different degree of rotation of the thiazoline ring around the C(1)–C(4) bond, which permits the coordination through thiazoline nitrogen atom [torsion angle S–C(1)–C(4)–N(2) = −169.4° in **2**; 178.0° in **3**; 9.6° in ATH].

3.2. Magnetic susceptibility

The observed molar magnetic susceptibility for complex **1** were corrected for diamagnetism and temperature-inde-

pendent paramagnetism to provide the fully corrected magnetic moment at room temperature, 4.89 BM. This value can be considered in the range 4.7–5.2 BM characteristic of complexes with an high-spin octahedral environment around cobalt(II) [33]. The corrected magnetic moment measured for complex **2** was 3.18 BM, which can be related to an octahedral environment in nickel(II) complexes [34].

The temperature dependence of the molar magnetic susceptibility, χ_M, for complex **3** was measured in 2–300 K temperature range and the plot of χ_M and $\chi_M T$ versus T is shown in Fig. 4. The χ_M value is equal to 2.98×10^{-3} $cm^3\,mol^{-1}\,K$ ($\mu = 1.89$ BM) at room temperature, which is the expected value for two uncoupled copper(II) ions. Upon cooling, the χ_M value for copper(II) firstly increases to a maximum around 10 K, whereupon it decreases. This behaviour is typical for antiferromagnetic interaction between the two Cu(II) centres of the dimer. The fitting of $1/\chi_M$ versus T above 10 K with the Curie–Weiss equation yields $C = 0.95\ cm^3\,mol^{-1}\,K$ and $\theta = -17.2$ K, which clearly indicates that magnetic interaction between copper(II) ions is antiferromagnetic [35].

To estimate the magnitude of the antiferromagnetic coupling the magnetic susceptibility data were fitted to the modified Bleaney–Bowers equation for two interacting copper(II) ions ($S = 1/2$) with the Hamiltonian in the form $H = -2JS_1 \cdot S_2$. The susceptibility equation for such a dimeric system can be written as follows [36]:

$$\chi_M = \frac{2Ng^2\mu_B^2}{K_B T[3 + \exp(-2J/K_B T)]} \quad (1)$$

where χ_M represents the susceptibility per mole of dimer, corrected for diamagnetism and temperature independent paramagnetism, J is the exchange coupling and the other symbols have their usual meaning. The average value got from EPR spectrum (2.14) has been taken as g value.

An attempt to fit the data to the last expression gave a poor fit in the region around the maximum of χ_M.

In a second approach, the possible presence of paramagnetic impurities was considered. These impurities modify extraordinarily the temperature dependence of χ_M at low temperature in complexes with antiferromagnetic coupling, stretching χ_M to infinity at 0 K [37]. The plateau of our experimental data at low temperature (see Fig. 4) confirms this fact. Thus, Bleaney–Bowers expression was modified taking into account the paramagnetic impurities [38]

$$\chi_M = \frac{2Ng^2\mu_B^2}{K_B T[3 + \exp(-2J/K_B T)]}(1 - \rho) + \frac{Ng^2\mu_B^2}{2K_B T}\rho \quad (2)$$

where ρ is the amount of paramagnetic impurities.

The parameters J and ρ were determined as adjustable parameters, in a least-squares fitting procedure that led to the values $J = -7.52(22)\ cm^{-1}$ and $\rho = 0.085(5)$. The agreement factor R, defined as

$$R = \sum \left[\left(\chi_{MJ}^{obs} - \chi_{MJ}^{calc}\right)^2 / \chi_{MJ}^{obs} \right]^2$$

is then equal to 5.58×10^{-4}. The value of J parameter implies weak antiferromagnetic interaction.

Detailed magneto-structural correlations have been carried out on dinuclear copper(II) complexes with a $Cu(\mu\text{-}Cl)_2Cu$

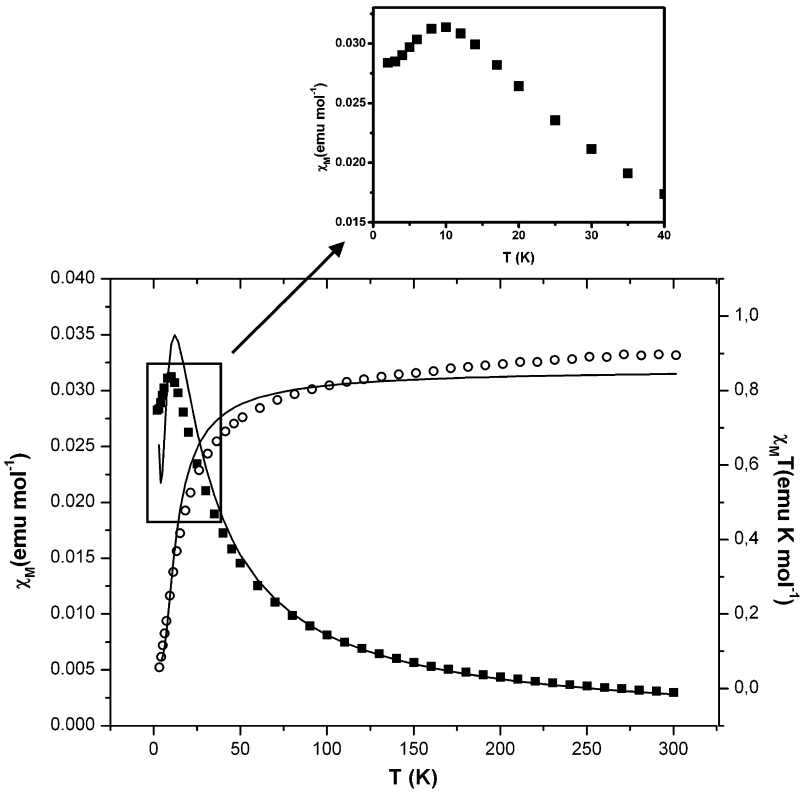

Fig. 4. χ_M vs. T (■) and $\chi_M T$ vs. T (O) plot for **3**. Solid lines represent the best fit of the data with the model described in the text.

motif containing chlorine bridging ligands. In these complexes, the local geometry around the two metal centre is usually a square pyramid with a different degree of distortion towards a trigonal bipyramid. The global arrangement for the square-pyramidal polyhedra can be defined as coplanar, parallel and perpendicular [39]. The extended Hückel calculations performed by Rodríguez et al. [39,40] show that the super exchange pathway with the metal centres will take place mainly through a π^* type interaction between the $d_{x^2-y^2}$ orbitals of Cu(II) ions and the p orbitals of chlorine bridging ligands for square pyramids with parallel basal planes sharing one base-to-apex edge, as it is the case of **3**. For an ideal geometry with a square core, the overlap integral between the former orbitals would be zero. As above, these complexes with parallel arrangement for square pyramids present very small J values, which are due to structural deviations from the ideal square Cu_2Cl_2 core. The small calculated J value for **3** is therefore consistent with the calculations performed by the aforementioned authors.

3.3. Spectroscopic studies

Cobalt(II) complex **1** exhibits a typical electronic spectrum for octahedral species in the solid state [41]. Two main bands are observed in the 7000–25 000 cm^{-1} range, which are assigned to the ν_1 [$^4T_{1g}(F) \rightarrow {}^4T_{2g}(F)$] (9295 cm^{-1}) and ν_3 [$^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$] (20 160 cm^{-1}) transitions. Moreover, the spectrum shows one intense band at 31 055 cm^{-1} with a shoulder at 34 965 cm^{-1} which are assigned to a charge-transfer band and the $\pi \rightarrow \pi^*$ transition of the organic ligand, respectively. Ligand field parameters, 10Dq and B, were calculated using the following known Konig's equations [42]:

$$\nu_1 = \frac{1}{2}(10Dq - 15B) + \frac{1}{2}[(10Dq + 15B)^2 - 12B \cdot 10Dq]^{\frac{1}{2}}$$

$$\nu_3 = [(10Dq + 15B)^2 - 12B \cdot 10Dq]^{\frac{1}{2}}$$

The calculated values of the ligand field parameters $10Dq = 10\,478\ cm^{-1}$ and $B = 803\ cm^{-1}$ are in good agreement with the predicted values for octahedral complexes of Co(II) [43–45].

Electronic spectrum of the nickel(II) complex **2** shows one intense band at 33 557 cm^{-1}, which is assigned to charger transfer band. Moreover, the spectrum exhibits bands at 10 331 and 16 474 cm^{-1}, all of which were of low intensity. These bands may be assigned as: $\nu_1[{}^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)]$ (10 331 cm^{-1}) and $\nu_2[{}^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)]$ (16 474 cm^{-1}) transitions, in an idealized O_h symmetry. The position of the observed d–d transitions permits to calculate the ligand field parameters, 10Dq and B, using the following known relationships [42]:

$$\nu_1[{}^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)] = 10Dq$$

$$\nu_2[{}^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)] = (1/2)(15B + 30Dq) - (1/2)[(15B - 10Dq)^2 + 12B \cdot 10Dq]^{1/2}$$

The calculated values of the ligand field parameters $10Dq = 10\,331\ cm^{-1}$ and $B = 834\ cm^{-1}$ are consistent with the presence of a chromophore group $[Ni^{II}N_4Cl_2]$ [46,47].

Electronic reflectance spectrum of the copper(II) complex **3** displays one strong band at 26 738 cm^{-1} which can be assigned to Cl → Cu charge transfer transition [48,49]. Moreover, the reflectance spectrum exhibits a broad band centred at 13 850 cm^{-1} with a shoulder at 12 315 cm^{-1}, assigned to the $^2B_1 \rightarrow {}^2A_1$ and $^2B_1 \rightarrow {}^2B_2$, ^2E transitions, respectively, in agreement with the square-pyramidal stereochemistry [50] that presents this complex.

EPR spectra of a polycrystalline sample at 298 K (Fig. 5) and at 77 K (Fig. 6) of complex **3** were recorded in the X-band, using the 100 kHz field modulation. The EPR parameters are presented in Table 4. The spectrum of **3** at 298 K is typically elongated axial with well defined $g_\perp$ and $g_\parallel$ values. The geometric parameter

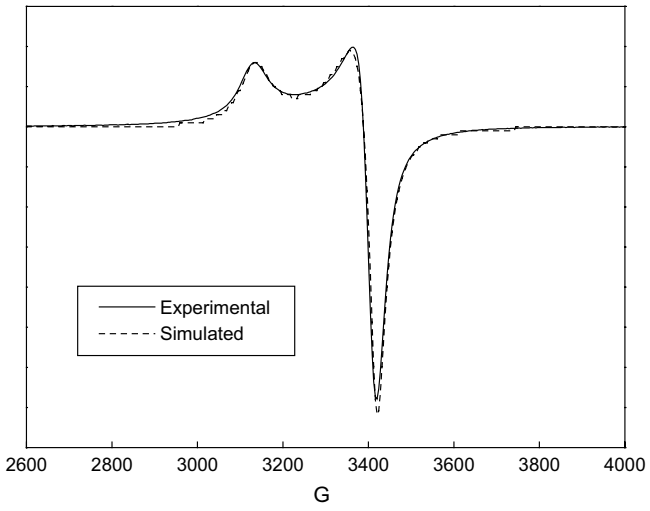

Fig. 5. EPR spectrum of **3** in the polycrystalline state at 298 K.

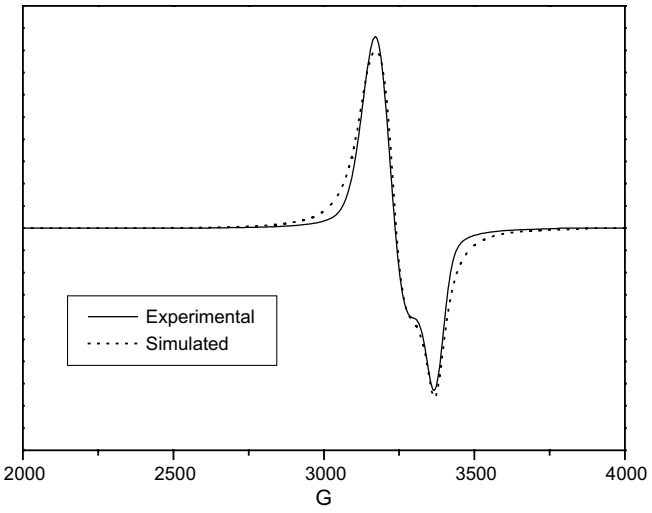

Fig. 6. EPR spectrum of **3** in methanol solution at 77 K.

Table 4
EPR parameters of **3**

Solid (298 K)			Methanol (77 K)			
$g_\perp$	$g_\parallel$	G	g_3	g_2	g_1	R
2.05	2.23	3.80	2.22	2.15	2.08	1.0

Table 5
Far IR bands (cm^{-1}) with tentative assignments

Compound	ν(M–N_{imino})	ν(M–$N_{thiazoline}$)	ν(M–$Cl_{terminal}$)	ν(M–$Cl_{terminal}$), ν(M–Cl_{bridge})
1	325	255	213	
	312			
2	333	271	214	
3	325	253		304
				292

$G = (g_\parallel - 2)/(g_\perp - 2)$ value is found to be in the range 3.5–5.0 and $g_\parallel > g_\perp > 2.0023$, which is consistent with a distorted square-pyramidal geometry with a $(d_{x^2-y^2})^1$ ground state [51,52]. These results are in good accord with the X-ray structural determination data.

With regard to the EPR spectrum in frozen methanol (77 K) is typically compressed rhombic. The geometric parameter $R = (g_2 - g_1)/(g_3 - g_2)$ value is 1, which gives no information indicative to ground state in solution [50–53].

In the low frequency region, the IR spectra of these complexes show bands assignable to metal-ligand stretching vibrations. Tentative assignments are listed in Table 5. Thus, the ν(M–N_{imino}) vibrations [54–56] are registered at 312–333 cm^{-1}, the bands in the region 253–271 cm^{-1} can be attributed to ν(M–$N_{thiazoline}$) vibration [26,44,45,57] and the bands due to ν(M–$Cl_{terminal}$) vibrations [58–63] are found in the range 213–304 cm^{-1}. Finally the bands at 292 and 304 cm^{-1} in the spectrum of Cu(II) complex can also include the ν(M–Cl_{bridge}) vibration according to Refs. [58,59,61].

4. Conclusion

In summary we have synthesized and structurally characterized Co(II), Ni(II) and Cu(II) complexes with 2-acetyl-2-thiazoline hydrazone (ATH). In the same way as that in the cadmium(II) complex preliminary reported [17], it should be pointed out that ATH acts as bidentate ligand coordinating to the metal ion through the imine and thiazoline nitrogen atoms. A study of all the characterization methods applied for complex **1** suggests that cobalt(II) ion presents an octahedral environment. Thus, complex **1** could be formulated as $[CoCl_2(ATH)_2]$. Crystallographic study of **2** shows a distorted octahedral geometry around the nickel(II), meanwhile the structure of complex **3** is consistent with a dimer copper(II) complex doubly bridged by chlorine ligands. The copper centres are penta-coordinated with a slight distortion from square-pyramidal geometry and present a weak ferromagnetic through chlorine-bridge.

[1] The unpaired electron is located in $d_{x^2-y^2}$.

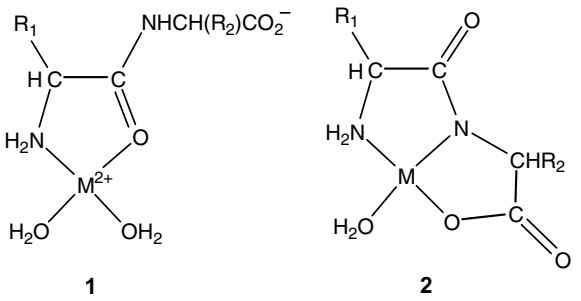

Fig. 1. Structure of dipeptide complexes ML^+ (**1**) and MLH_{-1} (**2**). Central atom (Cu or Ni) is denoted with M.

is denoted as K_a. Ovarall stability constant of the complex MLH_{-1} is β_1 ($=K_1K_a$).

In the Eqs. (1) and (2), L stays for the ionized form of the dipeptide, e.g. $NH_2CH(R_1)CONHCH(R_2)COO^-$. General structure of the ML^+ (**1**) and MLH_{-1} (**2**) complex [26] is given in Fig. 1.

By regarding the formation of the complex MLH_{-1} as a two-step process, enabled us to model Reactions (1) and (2) separately, and to estimate the overall stability constant β_1 from estimates of the K_1 and K_a.

2. Methods

2.1. Calculation of topological indices

The calculations of topological indices were performed with a program system DRAGON 2.1, written by Todeschini and coworkers [28], which is capable to yield 262 topological indices in a single run, along with many other molecular descriptors. The connectivity matrix was constructed with the aid of *Online SMILES Translator and Structure File Generator* [29].

All calculations were done with the Randić index ${}^3\chi^v$ (the valence molecular connectivity index of the 3rd order):

$$ {}^3\chi^v = \sum_{\text{path}} [\delta(i)\delta(j)\delta(k)\delta(l)]^{-0.5} \quad (3)$$

where $\delta(i)$, $\delta(j)$, $\delta(k)$, and $\delta(l)$ are weights (valence-delta values) of vertices (atoms) i, j, k, and l making up the path of length 3 (three consecutive chemical bonds) in a vertex-weighted molecular graph [23,24]. Valence-delta value, $\delta(i)$, of a vertex i is defined by:

$$ \delta(i) = [Z^v(i) - H(i)]/[Z(i) - Z^v(i) - 1] \quad (4)$$

where $Z^v(i)$ is the number of valence electrons belonging to the atom corresponding to vertex i, $Z(i)$ is its atomic number, and $H(i)$ is the number of hydrogen atoms attached to it. For instance, delta values for primary, secondary, tertiary and quaternary carbon atoms are 1, 2, 3, and 4, respectively; for oxygen in OH group is equal to 5, and for NH_2 group $\delta(N) = 3$. (It has to be pointed out that ${}^3\chi^v$ is only a member of the family of valence connectivity indices, ${}^n\chi^v$, which differ each other by path length, i.e. the number of δ's in the summation term, Eq. (3).) The value of ${}^3\chi^v$ index rise with the size (number of atoms) and drops with the branching of molecule.

All the calculations were done on the valence connectivity graph derived from formula of MLH_{-1} complex (**2**, Fig. 1). Application of formula **1** (ML^+) altered results insignificantly.

2.2. Regression calculations

Regression calculations, including the leave-one-out procedure of cross validation, *cv*, were done by CROMRsel program [30]. The standard error of cross validation estimates is defined as:

$$ SE_{cv} = (1/N\Sigma\Delta X^2)^{0.5} \quad (5)$$

where ΔX and N denotes *cv* residuals and number of reference points, respectively.

3. Results

3.1. Estimation of formation constant K_1 (Eq. (1))

The first step in the developing of our model for the estimation of stability constants of copper(II) and nickel(II) complexes with dipeptides is to estimate the formation constant of the ML^+ complex (K_1, Eq. (1), see Table 1). We chose altogether 15 copper(II) and eight nickel(II) complexes (Table 2). All the constants were measured at the same temperature ($T = 25$ °C) and two ionic strengths ($I = 0.1$, 0.16 mol L^{-1}). If more constants for a complex were referred to in the literature, their arithmetic mean is presented in Table 2. The discrepancy between experimental values goes up to 0.86 (for Cu(GG).

Table 1
Linear regressions of $\log K_1$ on the connectivity index ${}^3\chi^v$ of MLH_{-1} complexes (c.f. Table 2)

Model no.	N	Independent variable(s)[a]	Var1 slope (*SE*)	Var2 slope (*SE*)	Intercept (*SE*)	r	*SE*	SE_{cv}

[a] Arithmetic mean of N values [26,33–43].

The plot of $\log K_1$ versus connectivity index $^3\chi^v$ (Fig. 2), indicates three subsets of complexes, consisting of YG, GY, and YY type of peptides, where G stays for glycyl and Y for any amino-acid residue. Regression on the subsets (Table 1) gave estimates for copper(II) complexes with SE_{cv} ranging from 0.05 to 0.21 (Models 2–4, Table 2).

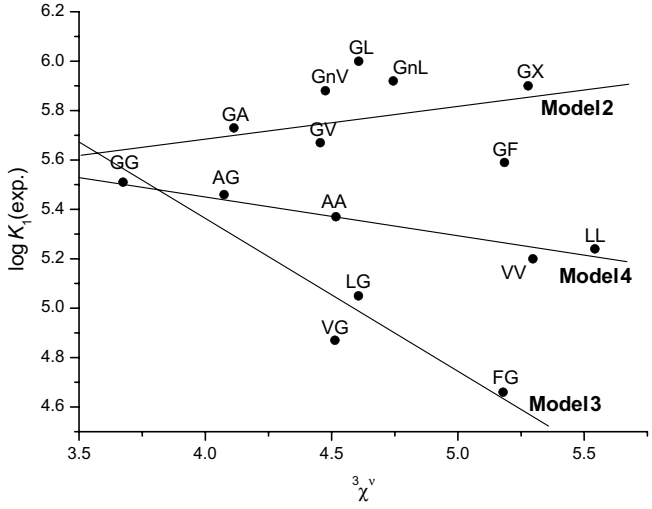

Fig. 2. Regression models for $\log K_1$ of copper(II) complexes with three classes of dipeptides, GY (Model 2), YG (Model 3), and YY (Model 4), Table 1. Dipeptides are denoted by the standard one-letter code, with an exception for norvaline (nV) and norleucine (nL).

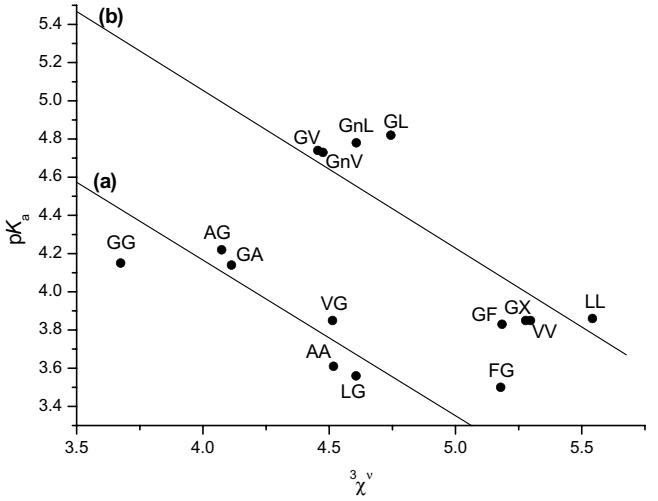

Fig. 3. Regression model for pK_a of copper(II) complexes with two classes of dipeptides, differing in type of the second amino-acid residue (Model 7, Table 3): (a) the second residue is G or A ($In_2 = 0$), (b) the second residue is any other amino-acid residue ($In_2 = 1$). Dipeptides are denoted by the standard one-letter code, with an exception for norvaline (nV) and norleucine (nL).

Unfortunately, paucity of data enabled such kind of estimation only for Ni(GY) complexes, yielding $SE_{cv} = 0.12$.

Other models gave similar results. Model 1 with two variables, where $^3\chi^v(r_1)$ and $^3\chi^v(r_2)$ corresponds to the $^3\chi^v$ index of the first and second chelate ring, respectively, in complex **2** (Fig. 1), yielded $SE_{cv} = 0.16$, and the maximum error of 0.37, for Cu(GF). Introduction of an indicator variable ($In_1 = 0$ for Cu, $In_1 = 1$ for Ni) enabled us to apply the same model along with nickel(II) complexes (Model 6). In this way the results of the same quality were obtained for copper(II) complexes, and $\log K_1$ values for nickel(II) chelates were reproduced with $SE_{cv} = 0.23$. The model with indicator variable was also checked on YG type ligands (Model 5), which enabled estimation of $\log K_1$ for nickel(II) complexes. Averaging all the estimates, as we used to do [21,22], did not alter substantially the results.

3.2. Estimation of dissociation constant K_a (Eq. (2))

For the estimation of deprotonation constant of the complex ML^+ (K_a, Eq. (2)) data from the same papers are subtracted as for the constant K_1. Unfortunately, data for nickel(II) chelates with glycylleucine (GL), and leucylglycine (LG) were missing. Values of constant K_a were determined with lesser accuracy than the values of constant K_1; differences of pK_a for the same chelate span the range from 0.04, for Cu(GL), to 0.5, for Cu(LG), and even 1.0, for Ni(GV).

Table 5
The *rms* values for the estimates of the $\log\beta_1$ (=$\log K_1 - pK_a$) for copper(II) complexes with dipeptides from the estimates given in Tables 2 and 4

pK_a	$\log K_1$			
	Model 1	Model 6	Mean (Models 1–6)	Mean (Models 1–4,6)
Model 7	0.21	0.22	0.20	0.21
Model 8	0.20	0.21	0.19	0.20
Model 12	0.25	0.27	0.26	0.25
Mean (Models 7–12)	0.21	0.23	0.21	0.21

The plot of pK_a versus $^3\chi^v$ (Fig. 3) shows two sets of copper(II) chelates of dipeptides. In the first set the second amino-acid residue belongs to an amino acid with a very short side chain, glycyl (–H) or alanyl (–CH_3). The second set consists of all other amino acids. By dividing copper(II) chelates into two subsets, it was possible to apply the regression with an indicator variable In_2 ($In_2 = 0$ for G or A, $In_2 = 1$ for any other amino acid as the second residue, Regr. 7, Table 3). The model yielded very good agreement with experimental data (Table 4), yielding $SE_{cv} = 0.25$ and maximal error = 0.46 (for complex with FG). Unfortunately, such an estimate for nickel(II) complexes was not possible due to paucity of data ($N = 6$), but regression supports general validity of the model (intercept = 12.7(19), slope($^3\chi^v$) = −0.87(45), slope(In_2) = 0.94(51), $r = 0.757$, $SE = 0.28$).

By introduction of indicator variable In_1 (Regr. 8, Table 3) it was possible to obtain even better estimates for copper(II) complexes ($SE_{cv} = 0.23$), and also estimates for nickel(II) complexes, but of lesser quality ($SE_{cv} = 0.37$, max. error = 0.62, for the complex Ni(GF).

Another kind of model checked on copper(II) as well as on nickel(II) chelates were models with hydrophobicity parameters (Regr. 9–12, Table 3). Hydrophobicity parameter of the complex was calculated as the difference of the hydrophobicity parameters (KD [31] or C [32]) of the first and second amino-acid residue with an assumption that this difference reflects dipol momentum of the complex and, accordingly, pK_a of NH group. These models were not shown in any way superior to the previously discussed models (7 and 8, Table 3). Due to lack of data, it was not possible to estimate pK_a of dipeptides with norvaline and norleucine by using such models.

Averaging the results obtained by the all six models for copper(II) and three models for nickel(II) no general improvement was obtained in terms of SE_{cv}. Model 8 proved best in all respects, for both metals.

3.3. Estimation of overall stability constant β_1

The *rms* (root-mean-square) error of estimates of overall stability constant of complex MLH_{-1} (**2**, Fig. 1), $\log\beta_1 = \log K_1 - pK_a$, calculated from the data in Tables 2 and 4 are presented in Table 5. By combining estimates of $\log K_1$ with the estimates of pK_a, *rms* values in the range 0.19–0.27 units were obtained, indicating consistency of all models used.

Close inspection of the results presented in Table 5 reveals, however, that the worst results were obtained with Model 12 ($SE_{cv} = 0.25$–0.27), and the best with model 8 ($SE_{cv} = 0.19$–0.21). The best result ($SE_{cv} = 0.19$) was obtained by the mean value of all models for estimation of $\log K_1$, but the difference to the other estimates with Model 8 is insignificant. By the best model errors of estimates lay in the range from 0.00, for Cu(GL), to 0.34, for Cu(VG).

4. Conclusion

The application of model with the valence connectivity index $^3\chi^v$ on copper(II) and nickel(II) chelates with dipeptides shows its ability to estimate stability of such a complex system (1) if overall stability constant is calculated from the estimations of their constituting constants, and if, subsequently, (2) the set of chelates is divided into subsets or (3) the molecule is divided into constituting parts (chelate rings). (Straight-forward regression of $\log\beta_1$(Cu) versus $^3\chi^v$ yielded $r = 0.26$, $N = 15$.) Consistency of the models (c.f. Table 1) is reflected in fact that the SE_{cv}/SE ratio (1.18–2.00) approaches one for models with higher number of points (N).

Our results are also consistent with the fact that the influence of the first chelate ring is predominant, and the influence of the second one is more dependent on the type of amino-acid residue, than on the specific residue itself. It is noteworthy the separation of pK_a's into two subsets differing in the size of the side chain of the second residue (see Fig. 3 and Section 3.2). Obviously, in the dissociation process $ML^+ \rightarrow MLH_{-1}$ complex ML^+ (**1**, Fig. 1) goes through conformational changes, which are dependent on the size of the side chain of the second residue. Possibly, ML^+ species in two subsets do not exist in the same conformational states – but to discuss this point is beyond the scope of the paper.

site. Thus with the sterically more hindered site, higher branching frequencies are observed [18].

The cationic methallyl complexes with symmetrical β-diimine ($R_1 = R_2 = CH_3$) are excellent catalysts for the oligomerization of the styrene, they yield 1,3-diphenylbut-1-ene with selectivity ⩾98%. However cationic methallyl complexes with α-diimine ligand produce polymer. This reflects the effect of change of rigidity of the ligand toward the catalytic activity of the complex [19]. Different chemistry can be carried out with subtle changes of steric demand in the R_1 and R_2 positions.

The present work is a continuation of our study in β-diimine allylic complexes. In this paper we describe a one-pot synthesis of new η^3-allyl cationic complexes of palladium (II) supported by new ligands, the unsymmetrical β-diimine [20].

2. Results and discussion

These compounds $[(PhCNAr)CH_2(CH_3CNAr)Pd(allyl)]PF_6$ which are isolated as stable salts, can be easily obtained in high yields by an oxidative addition of methallyloxyphosphonium salt **6** to the zerovalent compound $Pd(dba)_2$ **5** in methylene chloride in the presence of a β-iminoamine ligand (Scheme 1).

The new complexes **7**–**10** which are soluble in methylene chloride and sparingly soluble in diethyl ether gave satisfactory analysis and were characterized by ^1H, ^{13}C $\{^1H\}$ NMR and IR spectroscopy.

The NMR data of ligands **1**–**4** are consistent with the hydrogen-bridged β-iminoamine structure [20], although complexes **7**–**10** incorporating these ligands as a β-diimine tautomer.

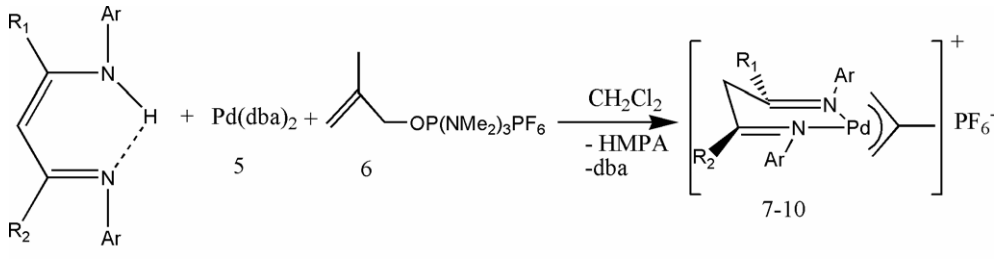
The ^1H NMR spectra of these compounds show two resonance signals for the allyl protons (H_{syn} and H_{anti}) which appear as a multiplet in contrast with the complexes of the symmetrical β-diimine ($R_1 = R_2 = CH_3$) which appear as a singlet [16]. The multiplicity of these signals is explained by the unsymmetrical diimine backbone and the *syn*/*syn* and *anti*/*anti* interconversion due to the dynamic behaviour of the allyl protons [21].

Thus the two resonances are located, respectively, at 2.19, 2.09, 2.58, 2.54 ppm for H_{anti} and at 2.59, 2.39, 2.88, 2.63 ppm for H_{syn} for complexes **7**–**10**.

In ^{13}C NMR spectra, the allylic carbon C(11) and C(13) appears at (62.51 and 64.54); (63.57 and 64.26); (64.41 and 64.94) and (62.33 and 65.72 ppm), respectively, for complexes **7**–**10**.

The imine carbons show two signals between 172 and 177 ppm.

The IR spectrum of compounds **7**–**10** indicated a shift in the C=N stretching frequency (1645; 1603, 1641; 1623, 1660 and 1616, 1647 cm^{-1}) relative to the respectively corresponding stretching frequency in the free ligands **1**–**4** (1622; 1622; 1610, 1649 and 1615 cm^{-1}). Moreover, the C=N stretching frequency appears at low frequency compared with their value for the compounds with the symmetrical β-diimine.



Complexes **7**–**10** exhibit the frequencies of the counter-ion PF_6^- at 838, 846, 832 and 837 cm^{-1}.

X-ray single-crystal analysis reveals that compound **10** exhibits some interesting features compared with the symmetrical β-diimine complexes. Suitable prismatic and colourless single crystals of **10** were obtained by crystallization from CH_2Cl_2/*n*-hexane. Complex **10** crystallizes in the monoclinic unit cell $P2_1/n$ group (Table 1).

An ORTEP-plot shown in Fig. 1 confirms the identity of complex **10**.

The $[(\eta^3\text{-}C_4H_7)Pd(NN)]^+$ cation of **10** adopts the usual slightly distorted square planar arrangement and this distortion is illustrated by the N(1)–Pd–N(2) bond angle equal to 90.9° (Fig. 1b). We note that this distortion is more attenuated than in the complex with the symmetrical β-diimine (N(1)–Pd–N(2) = 90.6°).

Selected bond lengths and angles are listed in Tables 2 and 3.

If we define a plane containing the Pd and the two nitrogen atoms, then the terminal carbons are 0.24 (C11) and 0.25 Å (C13) below the plane, whereas the central allyl carbon is 0.44 Å above.

The allyl ligand is bonded almost symmetrically to the palladium centre Pd–C(11) = 2.09 Å and Pd–C(13) = 2.11 Å.

The N1–Pd–N2 plane is tilted by 63.74° with regard to the C11–C12–C13 plane. The methyl on the allyl group is slightly tilted out of the allyl plane by about 9.1° as indicated by the torsion angle of 170.1° of C(11)–C(12)–C(13)–C(14). The allyl plane (C(11), C(12), C(13)) makes an angle of 67.65° with the palladium coordinative least-square plane (N(1), N(2), C(11), C(13))

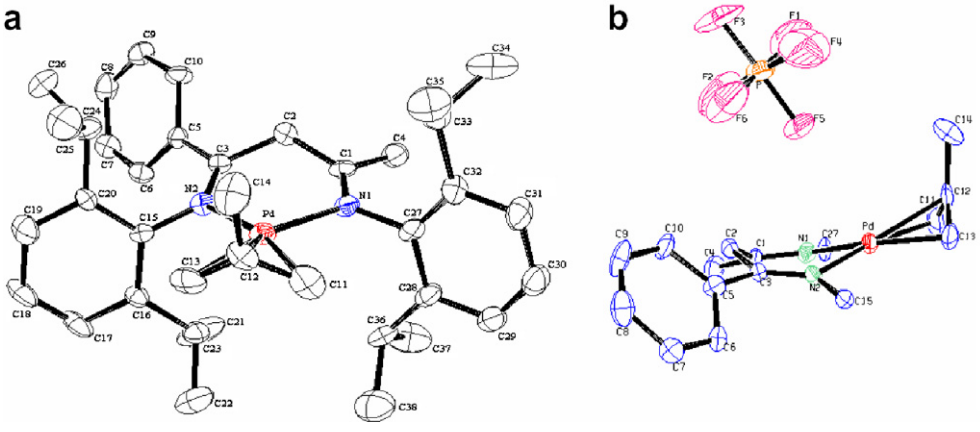

Fig. 1. (a) Perspective ORTEP diagram of the cation of **10**. Thermal ellipsoids are at 30% probability. Hydrogen atoms and anion are omitted for clarity. (b) View of the chelate ring in **10**. Hydrogen atoms and aryl ring are omitted for clarity.

The β-iminoamine ligand is bounded in a unsymmetrical fashion as the β-diimine tautomer, the C(1)–N(1) and C(3)–N(2) distances are 1.29 Å and 1.263 Å, respectively.

This ligand forms a six-membered ring with the palladium atom with Pd–N (sp^2) bond length of 2.10 Å and 2.13 Å in agreement with known values in the literature for related complexes [15,22–24]. Bond distances within the six-member chelate ring are consistent with the localized β-diimine structure drawn in Fig. 1, while the ring itself adopts a boat conformation as indicated in Fig. 1b. The aryl rings C(15–20) and C(27–32) are tilted out of the (N(1), C(1), C(3), N(2)) least-square plane by 70° and 69.49°, respectively.

3. Conclusion

New cationic methallyl palladium complexes supported by unsymmetrical β-diimine have been described. The application of these compounds in catalytic reactions such as dimerization and polymerization of alkenes and functional alkenes is in current study in order to compare them with the symmetric ones.

4. Experimental

4.1. General

All manipulations were carried out under an atmosphere of dry argon using standard Schlenk techniques.

Diethyl ether was distilled from sodium benzophenone; methylene chloride and hexane were distilled over P_2O_5. 2-Methylaniline, 2,6-dimethylaniline, 2-methoxyaniline and 2,6-diisopropylaniline were distilled from potassium hydroxide prior to use. $Pd(dba)_2$ [25,26] methallyloxyphosphonium salt [27] and β-iminoamine ligands [20] were prepared according to literature methods. All other reagents were obtained from standard commercial vendors and used as received. NMR spectra were recorded on a Bruker AC-300 spectrometer. H and C chemical shifts are given in ppm and referenced to the residual solvent resonance relative to TMS. Infrared spectra were recorded on a Bruker Victor 22 (Golden Gate Technique).

4.2. General procedure for the preparation of [(β-diimine)Pd(η^3-C_4H_7)]$^+PF_6^-$ complexes

In an inert atmosphere, $Pd(dba)_2$ complex (1 equiv.) was dissolved in 20 cm^3 anhydrous CH_2Cl_2. Methallyloxyphosphonium salt $C_4H_7OP^+(NMe_2)_3PF_6^-$ and β-iminoamine ligands were added (1 equiv.). The black-red solution was stirred at room temperature for 24 h. The supernatant was separated by filtration through a celite filter, and the solvent was removed under vacuum to afford the oil compound. This was washed with diethyl ether (3×15 cm^3) and dried in vacuum. The solid was crystallized from methylene chloride/*n*-hexane solution. Yields and spectral data of compounds **7**–**10** are reported below.

4.2.1. [(2-CH_3-C_6H_4NC(Ph)CH_2C(Me)NC_6H_4-2-CH_3)Pd(η^3-C_4H_7)]$^+PF_6^-$ (7)

Following the general procedure, from [2-CH_3-C_6H_4-NC(Ph)CHC(Me)NHC_6H_4-2-CH_3] (0.059 g, 0.173 mmol), $Pd(dba)_2$ (0.1 g, 0.173 mmol) and 2-methylallyloxyphosphonium (0.173 mmol, 0.065 g) was obtained 0.097 g of **7** as a pale yellow solid after crystallization from a mixture (CH_2Cl_2/*n*-hexane: 1/1).

Yield 87%. IR (Golden Gate): $\nu_{C=N} = 1645$ cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 1.62$ (s, 3H, Me (allyl)); 1.79 (s, 3H Me on ligand); 1.98 (s, 3H, Me–C_6H_4); 2.11 (s, 3H, Me–C_6H_4); 2.19 (m, 2H, H_{11anti} and H_{13anti}); 2.59 (m, 2H, H_{11syn} and H_{13syn}); 3.83 (m, 2H, ligand–CH_2); 6.97–7.42 (m, 13H, ArH). ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 14.25$ (Me (allyl));18.85 (Me on C_6H_4); 19.48 (Me on C_6H_4); 22.31 (Me on ligand); 49.71 (CH_2 on ligand); 62.51 and 64.52 (C(11) and C(13)); 121.37–133.24 (C(ar) and C(12)); 138.13 (C–C on C_6H_5); 148.13 and 150.61 (C–N on C_6H_4); 172.45 and 176.25 (C=N on ligand).

4.2.2. [(2-CH_3O-C_6H_4NC(Ph)CH_2C(Me)NC_6H_4-2-CH_3O)-Pd(η^3-C_4H_7)]$^+PF_6^-$ (8)

Following the general procedure, from [2-CH_3O-C_6H_4NC(Ph)CHC(Me)NHC_6H_4-2-CH_3O] (0.064 g, 0.173 mmol), $Pd(dba)_2$ (0.1 g, 0.173 mmol) and 2-methylallyloxyphosphonium (0.173 mmol, 0.065 g) was obtained 0.104 g of **8** as a pale yellow solid after crystallization from a mixture (CH_2Cl_2/*n*-hexane: 1/1).

Yield = 89%. IR (Golden Gate): $\nu_{C=N} = 1603$ and 1641 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 1.81$ (s, 3H, Me (allyl)); 2.00 (s, 3H, Me on ligand); 2.09 (m, 2H, H_{11anti} and H_{13anti}); 2.39 (m, 2H, H_{11syn} and H_{13syn}); 3.65–3.80 (m, 2H, ligand–CH_2); 3.85–3.91(m, 6H, H_3CO); 6.77–7.60 (m, 13H, ArH). ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 14.18$ (Me (allyl)); 22.75 (Me on ligand); 55.88 (CH_3O); 49.95 (CH_2 on ligand); 62.33 and 65.72 (C(11) and C(13)); 111.52–130.64 (C(ar) and C(12)-allyl); 134.44 (C–C on C_6H_5) 139.58 and 144.42 (C–N on C_6H_4); 177.07 and 177.21 (C=N on ligand).

4.2.3. [2,6-$(CH_3)_2$-C_6H_3NC(Ph)CH_2C(Me)NC_6H_3-2,6-$(CH_3)_2$Pd(η^3-C_4H_7)]$^+PF_6^-$ (9)

Following the general procedure, from [2,6-$(CH_3)_2$-C_6H_3NC(Ph)CHC(Me)NHC_6H_3-2,6-$(CH_3)_2$] (0.063 g, 0.173 mmol), $Pd(dba)_2$ (0.1 g, 0.173 mmol) and 2-methylallyloxyphosphonium (0.173 mmol, 0.065 g) was obtained 0.107 g of **9** as a pale yellow solid after crystallization from a mixture (CH_2Cl_2/*n*-hexane: 1/1).

Yield 92%. IR (Golden Gate): $\nu_{C=N} = 1623$ and 1660 cm^{-1}. ^1H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 0.87$ (s, 3H, Me (allyl)); 1.56 (s, 3H, Me on ligand); 1.95 (s, 3H, Me on C_6H_3); 2.02 (s, 3H, Me on C_6H_3); 2.19 (s, 3H, Me on C_6H_3); 2.25 (s, 3H, Me on C_6H_3); 2.58 (m, 2H, H_{11anti} and H_{13anti}); 2.88 (m, 2H, H_{11syn} and H_{13syn}); 4.72 (m, 2H, ligand CH_2); 6.92–7.26 (m, 11H, Har). ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]):

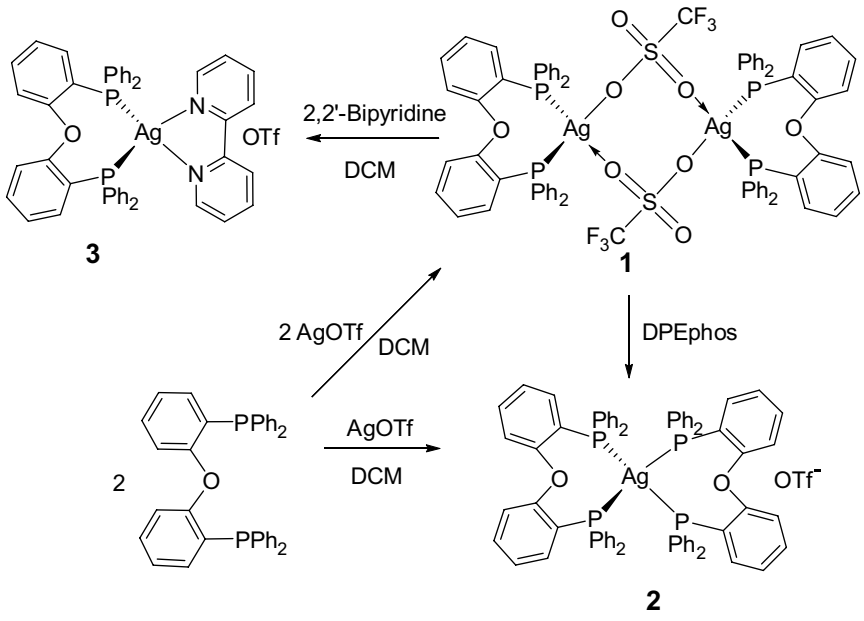
$\delta = 14.20$ (Me (allyl)); 22.72 (Me on ligand); 18.16, 18.37, 18.82 and 19.19(Me on C_6H_3); 49.46 (CH_2 on ligand); 63.57 and 64.26 (C(11) and C(13)); 126.24–135.68 (C(ar) and C(12)); 137.21 (C–C on C_6H_5); 149.84 and 150.51(C–N on C_6H_3); 173.73 and 176.54 (C=N on ligand).

4.2.4. [2,6-(iPr)$_2$-C$_6$H$_3$NC(Ph)CH$_2$C(Me)NC$_6$H$_3$-2,6-(iPr)$_2$Pd(η^3-C$_4$H$_7$)]$^+$PF$_6^-$ (**10**)

Following the general procedure, from [2,6-(iPr)$_2$-$C_6H_3NC(Ph)CHC(Me)NHC_6H_3$-2,6-(iPr)$_2$] (0.083 g, 0.173 mmol), Pd(dba)$_2$ (0.1 g, 0.173 mmol) and 2-methylallyloxyphosphonium (0.173 mmol, 0.065 g) was obtained 0.129 g of **10** as a pale yellow solid after crystallization from a mixture (CH_2Cl_2/*n*-hexane: 1/1).

Yield = 95%. IR (Golden Gate): $\nu_{C=N} = 1616$ and 1647 cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 0.88$–1.40 (m, 21 H, Me-iPr and Me on allyl); 1.99 (s, 3H, Me on ligand); 2.17 (d, 6H, $J = 16.8$ Hz, Me-iPr); 2.54 (m, 2H, H_{11anti} and H_{13anti}); 2.63 (m, 2H, H_{11syn} and H_{13syn}); 3.02 (sept, 2H, $J = 7.5$ Hz, H-C-iPr); 3.39 (sept, 1H, $J = 6.9$ Hz, H-C-iPr); 3.76 (sept, 1H, $J = 7.2$ Hz, H-C-iPr); 4.66–5.06 (m, 2H, CH_2 on ligand); 7.02–7.26 (m, 11H, H_{ar}); ^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): $\delta = 15.87$ (Me-allyl); 22.84 (Me on ligand); 23.84, 23.88, 24.00, 24.21, 24.34, 24.38, 24.71 and 25.66 (Me on iPr group); 28.68, 28.76, 29.20 and 29.43 (CH on iPr group); 49.91 (CH_2 on ligand); 64.41 and 64.9 (C(11) and C(13)); 124.25–138.08 (C(ar) and C(12)); 138.23 (C–C on C_6H_5); 147.26 and 148.14 (C–N on C_6H_3); 172.77 and 177.45 (C=N on ligand).

4.3. X-ray crystallographic study



The X-ray crystallographic study of complex **10** was carried out on a CAD4 Enraf-Nonius diffractometer (Mo Kα). Data were collected at 283 K in the range 1–27° and this gave a total of 9354 reflections, yielding 8271 independent values ($R_{int} = 0.1933$). The structure was solved by direct method and difference Fourier techniques and were refined by full-matrix least-squares analysis. Refinements were based on F^2 and were carried out using all the data (SHELXL-97). All of the non-hydrogen atoms were re-fined anisotropically. The hydrogen atoms were fixed geometrically in their idealized positions. The set of physical and crystallographic characteristics as well as the experimental conditions are listed in Table 1.

Appendix A. Supplementary material

CCDC 272962 contains the supplementary crystallographic data for **10**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033, or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.11.026.

Scheme 1.

molecular ion peak corresponding to the cationic complex part at m/z 1185.46 $[M]^+$ with the appropriate isotopic pattern. This evidences that the Ag^I metal center is bis-chelated by DPEphos ligands to form a spirocyclic compound (Fig. 2). The microanalysis supports the structural composition of complex **2**, which is further confirmed by single crystal X-ray data.

The solid state structure of complex **1** shows the presence of a Ag^I complex as a dimer, in which DPEphos binds in a chelating mode whereas the two triflate ions are bridging the two silver atoms *via* O═S–O^- units, thus making a three eight-membered spirocyclic ring structure as shown in Fig. 1. The counter ion plays an important role in coordination with silver atoms, providing stability to complex **1**. Similarly, counter ions such as nitrate, acetate and perchlorate are also known to bridge silver atoms [9–11]. Although the triflate units anchor the silver(I) centers to stabilize complex **1**, they are labile and can be easily substituted with P- and N-donors. The mixed-ligand complex [Ag(κ^2-*P*,*P*′-DPEphos)(2,2′-bpy)][OTf] (**3**) was synthesized in good yield by the reaction of **1** with 2,2′-bipyridine in a 1:2 molar ratio at room temperature. The $^{31}P\{^1H\}$ NMR spectrum of complex **3** at room temperature exhibits a pair of doublets centered at −8.8 ppm with J^{109}_{AgP} and J^{107}_{AgP} values of 426 and 374 Hz, respectively. The ^1H NMR spectrum confirms the presence of 2,2′-bipyridine, which presents peaks at 8.04 and 8.35 ppm. The J_{AgP} values are in the range 370–430 Hz, which is in agreement with those values reported for analogous complexes [10,12].

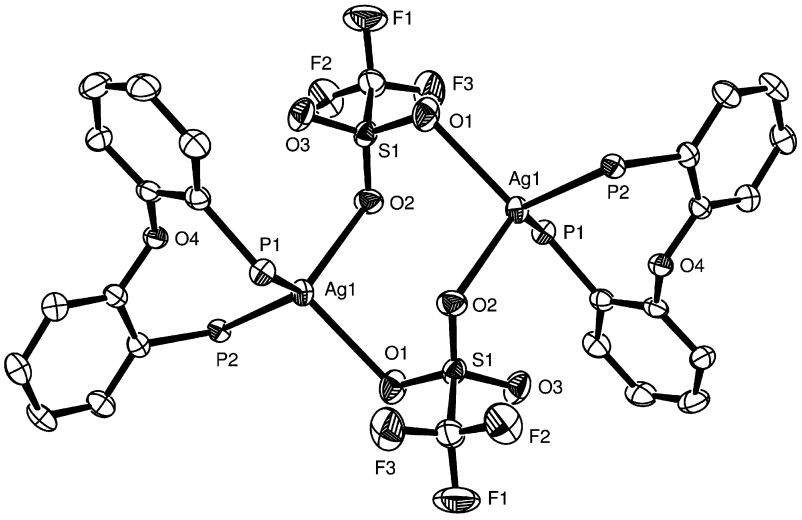

Fig. 1. Molecular structure of complex **1**. Thermal ellipsoids are drawn at the 50% probability level. Hydrogen atoms, phenyl rings attached to phosphorus and uncoordinated solvent molecules have been omitted for clarity.

2.1. Crystal structures of complexes *1–3*

Complexes **1** and **2** were recrystallized from a mixture of CH_2Cl_2/Et_2O, and complex **3** was recrystallized from a $CHCl_3/Et_2O$ mixture. The molecular structures of complexes **1–3** are shown in Figs. 1–3, respectively, and selected bond parameters are displayed in Tables 1 and 2. The crystallographic information is given in Table 3.

Complex **1** crystallizes in the monoclinic crystal system with a center of symmetry and it is dimeric in nature. The Ag^I center possesses a distorted tetrahedral geometry, whose edges are shared by two phosphorus atoms of a DPEphos ligand and two oxygen atoms of triflate ions. Each silver atom is anchored to a chelating DPEphos and bridged by triflate units. The Ag1–O1, Ag1–O2, Ag1–P1 and Ag1–P2 bond distances are 2.553(2),

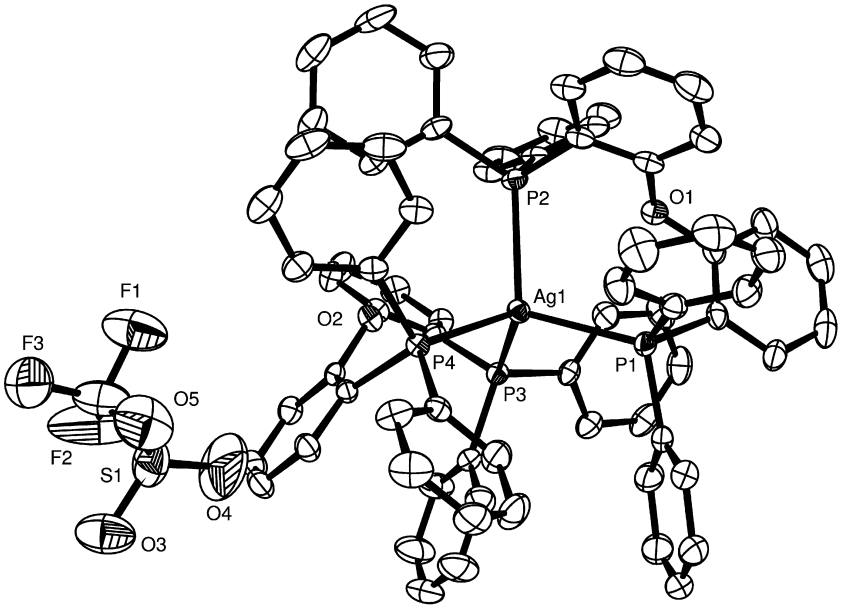

Fig. 2. Molecular structure of complex **2**. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms have been omitted for clarity.

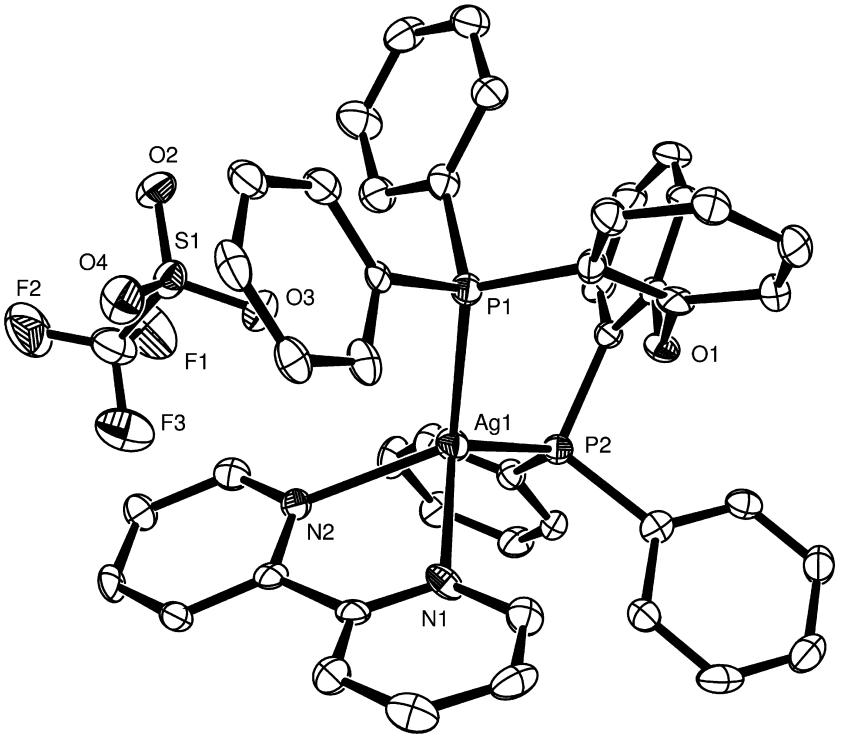

Fig. 3. Molecular structure of complex **3**. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms and uncoordinated solvent molecules have been omitted for clarity.

Table 1
Selected bond distances and bond angles for complexes **1** and **2**

Complex **1**				Complex **2**			
Bond distances (Å)		Bond angles (°)		Bond distances (Å)		Bond angles (°)	
Ag1–O2	2.411(2)	O2–Ag1–P2	111.52(6)	Ag1–P3	2.5385(7)	P3–Ag1–P4	106.37(2)
Ag1–P2	2.4383(9)	O2–Ag1–P1	113.49(6)	Ag1–P4	2.5461(7)	P3–Ag1–P1	107.47(2)
Ag1–P1	2.4521(8)	P2–Ag1–P1	117.40(3)	Ag1–P1	2.6119(7)	P4–Ag1–P1	115.38(2)
Ag1–O1	2.553(2)	O2–Ag1–O1	99.12(8)	Ag1–P2	2.6232(7)	P3–Ag1–P2	107.77(2)
S1–O3	1.426(2)	P2–Ag1–O1	104.07(6)	S1–O3	1.450(3)	P4–Ag1–P2	110.56(2)
S1–O1	1.436(3)	P1–Ag1–O1	109.13(6)	S1–C73	1.786(5)	P1–Ag1–P2	108.96(2)
S1–C1	1.815(3)	O3–S1–O1	115.41(15)	F1–C73	1.338(5)		
F1–C1	1.327(4)	S1–O1–Ag1	112.58(13)				

Table 2
Selected bond distances and bond angles for complex **3**

Complex **3**			
Bond distances (Å)		Bond angles (°)	
Ag1–N2	2.305(6)	N2–Ag1–N1	70.4(2)
Ag1–N1	2.355(6)	N2–Ag1–P2	126.98(16)
Ag1–P2	2.405(2)	N1–Ag1–P2	119.60(17)
Ag1–P1	2.488(2)	N2–Ag1–P1	110.69(15)
S1–O2	1.439(6)	N1–Ag1–P1	107.77(15)
F3–C47	1.317(11)	P2–Ag1–P1	113.51(7)
S1–C49	1.853(11)		

2.411(2), 2.453(3) and 2.438(2) Å, respectively. The Ag1–O2 bond distances of 0.142(2) Å is shorter than Ag1–O1, which indicates that the former one is an ionic bond and the latter one is a covalent bond. The bite angle of the DPEphos ligand is 117.40(3)°, which is 15.4° larger than its natural bite angle (β_n). Complex **2** crystallizes in the monoclinic crystal system and Ag^I exists in a distorted tetrahedral geometry. The silver(I) atom is attached to four phosphorus atoms of two DPEphos ligands. The Ag–P bond distances are 2.5385(7), 2.5460(7), 2.6118(7) and 2.6232(7) Å and are approximately 0.1–0.19 Å longer than the same distances in complex **1**. The bite angles of the two DPEphos ligands are 106.37(2)° and 108.96(2)°, which are 10.73° and 8.44° less when compared with the same angles in complex **1**.

In complex **3**, the Ag^I atom possesses a distorted tetrahedral geometry containing two phosphorus and two nitrogen atoms. The pyridyl units of the 2,2′-bipyridine ligand are not in a plane and are twisted by an angle of 14.50°. The Ag1–P1 bond (2.488(2) Å) is considerably longer than the Ag1–P2 bond (2.405(2) Å). The Ag1–N1 and Ag1–N2 bond distances are 2.305(6) and 2.355(6) Å, respectively. One set of diagonally opposite Ag–N and Ag–P bonds are longer than the other set of Ag–N and Ag–P bonds.

[a] $R = \sum||F_o| - |F_c||/\sum|F_o|$.
[b] $R_w = \{[\sum w(F_o^2 - F_c^2)/\sum w(F_o^2)^2]\}^{1/2}$ $w = 1/[\sigma^2(F_o^2) + (xP)^2]$ where $P = (F_o^2 + 2F_c^2)/3$.

A similar trend was observed in the analogous copper complex $[Cu(\kappa^2\text{-}P,P'\text{-DPEphos})(\mu\text{-}4,4'\text{-bpy})]_n[BF_4]_n$, but to a lesser extent [5].

3. Conclusion

The silver(I) complexes $[Ag_2(\kappa^2\text{-}P,P'\text{-DPEphos})_2(\mu\text{-}OTf)_2]$ (**1**), $[Ag(\kappa^2\text{-}P,P'\text{-DPEphos})_2][OTf]$ (**2**) and $[Ag(\kappa^2\text{-}P,P'\text{-DPEphos})(2,2'\text{-bpy})][OTf]$ (**3**) have been synthesized and structurally characterized. In all the complexes, the silver(I) atoms exist in a distorted tetrahedral environment and the DPEphos ligand binds in a chelating fashion. The solid state structure of complex **1** evidences the presence of three adjacent eight-membered spirocyclic rings. The triflate ions in complex **1** act as bridging units between the two silver atoms to form a dinuclear complex.

4. Experimental

4.1. General methods

All manipulations were performed under an atmosphere of dry nitrogen using standard Schlenk techniques. All the solvents were purified by conventional procedures and distilled under nitrogen prior to use [13]. The ligand DPEphos was prepared according to the published procedure [14].

4.2. Instrumentation

The ^1H and $^{31}P\{^1H\}$ NMR (δ in ppm) spectra were recorded using a Varian 400 Mercury Plus spectrometer operating at the appropriate frequencies using TMS and 85% H_3PO_4 as internal and external references, respectively. Microanalyses were performed on a Carlo Erba Model 1112 elemental analyzer. Electro-spray ionization (EI) mass spectrometry experiments were carried out using a Waters Q-Tof micro-YA-105.

4.2.1. Synthesis of $[Ag_2(\kappa^2\text{-}P,P'\text{-DPEphos})_2(\mu\text{-}OTf)_2]$ (*1*)

A mixture of DPEphos (0.252 g, 0.467 mmol) and AgOTf (0.120 g, 0.467 mmol) in CH_2Cl_2 (20 mL) was stirred for 4 h at room temperature. All the solvents were dried under vacuum to obtain a white solid, which was recrystallized from CH_2Cl_2/Et_2O as colorless crystals of **1**. Yield: 83% (0.309 g), m.p.: 256–258 °C. ^1H NMR (400 MHz, $CDCl_3$): 6.75–7.46 ppm (m, 56H, Ph). ^{31}P NMR (162 MHz, $CDCl_3$): −10.0 ppm (d, $J_{AgP} = 486.8$ Hz). ^{31}P NMR (162 MHz, 223 K, $CDCl_3$): −10.4 ppm (2d, $J^{109}_{AgP} = 526.8$, $J^{107}_{AgP} = 456.7$). *Anal.* Calc. for $C_{74}H_{56}O_8P_4Ag_2F_6S_2$: C, 55.86; H, 3.55; S, 4.03. Found: C, 55.90; H, 3.56; S, 3.92%.

4.2.2. Synthesis of $[Ag(\kappa^2\text{-}P,P'\text{-DPEphos})_2][OTf]$ (*2*)

The procedure was similar to that of **1**, but using AgOTf (0.025 g, 0.097 mmol) and DPEphos (0.105 g, 0.194 mmol). Yield: 98% (0.127 g), m.p.: >260 °C. ^1H NMR (400 MHz, $CDCl_3$): 6.68–7.21 (m, 56H, Ph). ^{31}P NMR (162 MHz, $CDCl_3$): −10.5 ppm (2d, $J^{109}_{AgP} = 269.7$, $J^{107}_{AgP} = 233.8$). MS (EI): m/z 1185.46 $[M-OTf]^+$. *Anal.* Calc. for $C_{73}H_{56}O_5P_4AgF_3S$: C, 65.72; H, 4.23; S, 2.40. Found: C, 65.74; H, 4.20; S, 2.44%.

4.2.3. Synthesis of $[Ag(\kappa^2\text{-}P,P'\text{-DPEphos})(2,2'\text{-bpy})][OTf]$ (*3*)

A solution of 2,2′-bipyridine (0.010 g, 0.063 mmol) in CH_2Cl_2 (5 mL) was added dropwise to a stirring solution of **1** (0.050 g, 0.031 mmol) also in CH_2Cl_2 (10 mL) at room temperature. After 4 h all the solvents were removed under vacuum and the remaining white solid was recrystallized from a $CHCl_3/Et_2O$ mixture as colorless crystals of **3**. Yield: 88% (0.053 g), m.p.: >260 °C. ^1H NMR (400 MHz, $CDCl_3$): 6.79–7.38 (m, 28H, Ph), 7.00 (t, 2H, bpy), 8.04 (dt, 2H, bpy), 8.35 ppm (m, 4H, bpy). ^{31}P NMR (162 MHz, $CDCl_3$): −8.8 ppm (2d, $J^{109}_{AgP} = 425.6$, $J^{107}_{AgP} = 374.3$). *Anal.* Calc. for $C_{47}H_{36}O_4P_2AgF_3SN_2$: C, 59.32; H, 3.81; N, 2.94; S, 3.37. Found: C, 59.25; H, 3.85; N, 2.86; S, 3.32%.

4.3. X-ray crystallography

A single crystal of each compound **1**–**3** suitable for X-ray crystal analysis was mounted on a glass fiber with epoxy resin. Unit cell determination and data collection of all the compounds were collected on an Oxford Diffraction XCALIBUR-S CCD system using Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were solved and refined by full-matrix least-squares techniques on F^2 using SHELX-97 (SHELXL program package) [15]. The absorption corrections were done by multi-scan and all the data were corrected for Lorentz and polarization effects. The non-hydrogen atoms were refined with anisotropic thermal parameters. All the hydrogen atoms were geometrically fixed and allowed to refine using a riding model.

saccharinate through the *N* atom. The *O*-coordination mode of the saccharinate ligand was found for the complexes $[Cu(sac)_2(pypr)_2]$ [6], $[Ni(sac)_2(dmen)_2]$ [12], $[Cu(sac)(H_2O)(mpy)_4]$ (mpy = 4-methylpyridine) [13], $[Cu(sac)_2(iqn)_4]$ (iqn = isoquinoline) [13] and $[Cu(sac)_2(prz)_4]$ (prz = pyrazole) [14]. Although the literature lists many reports on the coordinating presence of the sac moiety in copper(II) complexes, from an X-ray crystal structure point of view only a limited number of structures with dinuclear copper saccharinate complexes have been obtained to date, $[Cu_2(bipym)_3(sac)_2(H_2O)_2]$ $(sac)_2(H_2O)_4$(bipym = 2,2′-bipyrimidine) [15], $[Cu_2(sac)_2(\mu\text{-}\ dmea)_2(\mu\text{-}\ H_2O)]_n$ (Hdmea = 2-dimethylaminoethanol) [15], $[Cu_2(sac)_2(\mu\text{-}dea)_2]$ (dea = diethanolamine) [16] and $[Cu_2(pypr)_2(sac)_2]$ (pypr = 2-pyridinepropanoxy anion) [17]. An hydroxo-bridged saccharinate complex has not yet been reported.

Square-pyramidal Cu(II)-complexes of the saccharinate ligand with pyridine [18], benzimidazole [19], nicotinamide [20], triethanolaminate [21], *S*-methyl-*N*-(6-methylpyrid-2-yl)methylenedithiocarbazate [22], the pyridine-2-carboxaldehyde Schiff base of the *S*-methyldithiocarbazate anion [23] and 2-formylpyridinethiosemicarbazonate [24] have been reported.

In hydroxo-bridged complexes of transition metals, there is often the possibility of a metal–metal interaction due to the rather small bridging ligands, and these complexes have received much attention because of their interesting magnetic properties [25]. These complexes make interesting model compounds for spin-coupling phenomena.

$[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ showed a certain inhibitory effect over carbonic anhydrose [26]. $[M(sac)_2(H_2O)_4]\cdot 2H_2O$ (M = Mn(II), Fe(II), Co(II), Ni(II), Cu(II) and Zn(II)) possess the ability to dismutate the O^{2-} anion. The copper(II) complex presents the most important activity [27]. It has also been commented that copper-saccharinate complexes $[Cu(NNS')(sac)(H_2O)]$, $[Cu(NNS'')(sac)(H_2O)]$ and $[Cu(NNS''')(sac)(H_2O)]$ have potent antimicrobial activity against bacteria and yeast [22].

In this paper we describe the syntheses, spectral, thermal, antimicrobial effect and structural characterization of the novel dinuclear di-μ-hydroxo-bis[(*N*,*N*-diethylethylenediamine)(saccharinato-*N*)copper(II)] dihydrate and di-μ-hydroxo-bis[(*N*,*N*,*N*′,*N*′-tetramethylethylenediamine)-(saccharinato- *O*)copper(II)] complexes.

2. Experimental

2.1. Materials and measurements

All chemicals used were analytical reagents and were commercially purchased. IR spectra were obtained with a Bruker Tensor 27 FT-IR spectrometer using KBr pellets in the 4000–400 cm^{-1} range. Elemental analysis for C, H and N were performed using a Carlo Erba 1106 microanalyser. Magnetic susceptibility measurement at room temperature was performed using a Sherwood Scientific MXI model Gouy magnetic balance. The UV–Vis spectra were obtained for aqueous solutions of the complexes (10^{-3} M) with a Unicam UV2 spectrometer in the range 900–190 nm. A Diamond TG/DTA thermal analyzer was used to record simultaneous TG, DTG and DTA curves in static air atmosphere at a heating rate of 10 K min^{-1} in the temperature range 20–600 °C using platinum crucibles.

2.2. Antimicrobial activity studies

The antimicrobial activities were tested against standard strains of Gram-positive (*Stapylococcus aureus* ATCC 6535, *Bacillus cereus* ATCC 7064) and Gram-negative (*Escherichia coli* W3110, *Citrobacter freundii* NRRLB 2643) bacteria and one yeast (*Candida albicans* ATCC 10231) and mould (*Aspergillus niger*) using the disc diffusion method. Antimicrobial studies were performed according to broth microdilution (1 gram + and 1 gram −) and agar diffusion methods.

The agar diffusion experiments were based on the obtained MIC values by broth dilution methods. Stock solutions of the ligand and the new complexes were prepared both in dimethylsulfoxide (DMSO, Merck) and in ultra pure water according to the needed concentrations for the experiments. Nutrient Agar (Merck) plates were prepared and dried for 5 days at room temperature. All the test cultures were grown in 5 ml nutrient broth at 37 °C in a shaker incubator. Then 200 μl cultures were inoculated into 5 ml fresh nutrient broth and the incubation period was 24 h for bacterial strains and 48 h for fungal strains at 37 °C. Test strains were spread on solid nutrient agar surfaces using a sterile glass rod. The final inoculation (inoculums) was approximately 10^5 cfu ml^{-1}. Absorbent paper discs of 6 mm were placed on the agar surface and impregnated with known concentrations (200, 500 and 1000 μg for each disc) determined previously by MIC tests. Antibiotic discs were placed on the same agar plate. Sulfamethoxazole, chloramphenical, streptomycin, tetracyline, neomycin, sulfafurazole, oflaxacin, ceftriaxone were used for antibacterial control while nystatin was used as the antifungal control for test microorganisms. To ensure that the solvent had no effect on bacterial growth, a control test was performed with a test medium supplemented with DMSO following the same procedures as used in the experiments. Incubations were done at 37 °C for 24 h for bacteri and 48 h for fungi after inoculums. The antimicrobial activity was indicated by the presence of clear inhibition zones and cloudiness around the discs, and was measured as diameters in millimeters. All tests were repeated three times and average data were taken as the final result.

2.3. Crystallographic analyses

For the crystal structure determination, single crystals of the compounds $[Cu(\mu\text{-}OH)(sac\text{-}N)(deten)]_2\cdot 2H_2O$ (**1**) and

$[Cu(\mu\text{-}OH)(sac\text{-}O)(tmen)]_2$ **(2)** were used for data collection on a four-circle Rigaku R-AXIS RAPID-S diffractometer equipped with a two-dimensional area IP detector. The cylindrically shaped imaging plate covered the two-theta angular range between −60 and 140° with a crystal-film distance of 127.4 mm. Graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å) and the oscillation scans technique with $\Delta\omega = 5°$ for one image were used for data collection. Images were taken successfully by varying ω with three sets of different χ and ϕ values. One hundred and seven images for three different runs covering about 99.8% of the Ewald spheres were performed. The lattice parameters were determined by least-squares methods on the basis of all reflections with $F^2 > 2\,\sigma\,(F^2)$. Integration of the intensities, correction for Lorentz and polarization effects and cell refinement were performed using CRYSTALCLEAR (Rigaku/MSC Inc., 2005) software [28]. The structures were solved by the direct method using SHELXS [29]. The positional and atomic displacement parameters (ADPs) were refined by the full-matrix least-squares method using SHELXL [29]. The positional and isotropic atomic displacement parameters of hydrogen atoms were refined together with other structural parameters by the full-matrix least-squares procedure based on the squared value of the structure factors. Except for water molecules, hydrogen atomic positions were calculated from assumed geometries. Hydrogen atoms were included in structure factor calculations but they were not refined. The isotropic displacement parameters of the hydrogen atoms were approximated from the *U* (equiv.) value of the atom to which they were bonded. The final difference Fourier maps showed no peaks of chemical significance. Details of the data collection and final refinement parameters are listed in Table 2.

2.4. Preparation of the complexes

A solution of *N*,*N*-diethylethylenediamine (2 mmol, 0.23 g) or *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (2 mmol, 0.23 g) in water (10 mL) was added dropwise to an aqueous solution of $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ [30] (1 mmol, 0.54 g) and stirred for 4 h at 50 °C. The reaction mixture was then slowly cooled to room temperature. The violet crystals that formed were filtered and washed with 5 mL of ethanol and dried in air. $[Cu(\mu\text{-}OH)(sac\text{-}N)(deten)]_2\cdot 2H_2O$. Yield *ca.* 76%. *Anal.* Calc. for $C_{26}H_{46}N_6O_{10}S_2Cu_2$(%): C, 39.34; H, 5.84; N, 10.59; S, 8.08. Found: C, 39.57; H, 5.74; N, 10.70; S, 8.32%. $[Cu(\mu\text{-}OH)(sac\text{-}O)(tmen)]_2$ *Anal.* Calc. for $C_{26}H_{42}N_6O_8S_2Cu_2$(%): C, 41.21; H, 5.59; N, 11.09; S, 8.46. Found: C, 40.70; H, 5.07; N, 10.80; S, 8.93%.

3. Results and discussion

3.1. Spectral and magnetic properties

The UV–Vis spectra of the complexes in H_2O display a broad absorption band at 546 nm for **1** ($\varepsilon = 60$ L mol^{-1} cm^{-1}) and 648 nm for **2** ($\varepsilon = 64$ L mol^{-1} cm^{-1}). These observed single broad peaks are consistent with the square pyramidal stereochemistry and are assigned to the $d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$ transition.

Hydroxo-bridged dinuclear complexes have received a lot of attention due to their different magnetic properties [25]. Di-μ-hydroxo-bridged copper(II) complexes display an antiferromagnetic effect for a Cu–O–Cu angle more than 97.5° [31]. The complexes exhibit magnetic moment values of 2.20 and 2.24 BM which corresponds to two unpaired electrons. However, these magnetic moment values are lower than the spin only value for two unpaired electrons in Cu(II) complexes, indicating an antiferromagnetic effect. These results are surprising because the Cu–O–Cu angles are less than 97.5° in the complexes.

The most important and characteristic absorption bands of both complexes are compared with those of the respective bands of sodium saccharinate [32] in Table 1. The IR spectra of the copper(II) complexes exhibit the characteristic features of OH (hydroxyl), C=O (ketone), symmetric SO_2 and asymmetric SO_2.

The infrared spectra of the copper(II) complexes show a strong and broad band at 3536 cm^{-1}, (water), 3330 cm^{-1} for **1** and 3324 cm^{-1} for **2** due to the bridging hydrogen-bonded OH group [33]. The strong bands in the 3241–3130 cm^{-1} range are attributed to the $\nu(NH_2)$ stretching vibrations of the deten ligand in **1**. The splitting of the CH/CH_2 stretching absorption bands occurs in the 2981–2892 cm^{-1} range as medium bands in the IR spectra of the complexes. The carbonyl (C=O) stretching band of sodium saccharinate (Nasac) appears as one main peak at 1642 cm^{-1} [32], and a comparison between the infrared spectra of Nasac and **1** shows this band is shifted to 1623 cm^{-1}. This shift indicates that the involvement of the *N* atom of the sac ligand in coordination to the metal reduces the electron density in the C=O bond, leading to a downward shift of the related frequencies, whereas the lower band at 1615 cm^{-1} in the IR spectrum of **2** is assigned to the *O*-coordinated sac ligand, *via* the carbonyl group. The very strong bands at 1585 cm^{-1} for **1** and 1582 cm^{-1} for **2** correspond to the ν(CC) vibrations of the sac ligand. The $\nu_{asym}(SO_2)$ and $\nu_{sym}(SO_2)$ modes of sac appear as strong bands at 1275 and 1155 cm^{-1} for **1**

$R_1 = \sum ||F_o| - |F_c|| / \sum |F_o|$, $wR_2 = \left\{ \sum [w(F_o^2 - F_c^2)^2] / \sum [w(F_o^2)^2] \right\}^{1/2}$.

and 1284 and 1153 cm^{-1} for **2**, respectively. Additional peaks at *ca.* 1338 cm^{-1} and 944 cm^{-1} may be assigned to the symmetric and asymmetric modes of the CNS moiety of the sac ligand, respectively [34]. The weak bands below 600 cm^{-1} may be attributed to both Cu–N and Cu–O vibrations.

3.2. Thermal analyses

The thermal decomposition behavior of the complexes was followed up to 600 °C in static air atmosphere.

3.2.1. [Cu(μ-OH)(sac-N)(deten)]$_2$ · 2H$_2$O

The first stage in the 99–138 °C range corresponds to the endothermic elimination of crystal water molecules (Found: 4.01, Calc. 4.54%). The second stage between 139 and 175 °C corresponds to the loss of two OH ligands. In the temperature range 176–408 °C, the third and fourth stages of the Cu(II) complex are related to the successively decomposition of the neutral deten and sac ligands, by giving initially an exothermic and then an endothermic contribution ($DTG_{max} = 224$, 386 °C). The following stage involves the extreme burning of organic residue, leading finally to CuO (Found: 79.66, Calc. 79.96%).

3.2.2. [Cu(μ-OH)(sac-O)(tmen)]$_2$

Complex **2** starts to decompose at 106 °C and the endothermic DTA peaks at 171 and 205 °C correspond to removal of the one tmen and two OH ligands (Found: 20.42, Calc. 19.82%). In the second stage, the endothermic elimination of tmen and exothermic decomposition of sac ligands occurs simultaneously between 260 and 386 °C, with a mass loss of 40.34%. In the last stage, the solid residue decomposes in the 385–514 °C range with an extremely exothermic peak at 481 °C. The decomposition product is CuO. The experimental mass loss value of 79.00% is consistent with the calculated value 79.01%. The decomposition product was identified by IR spectroscopy. On the basis of the first DTG_{max}, the thermal stability of the anhydrous complexes follows the order: **1** (224 °C) > **2** (171 °C).

3.3. Crystal structures

The molecular view of [Cu(μ-OH)(sac-*N*)(deten)]$_2$ · 2H$_2$O (**1**) and [Cu(μ-OH)(sac-*O*)(tmen)]$_2$ (**2**) with the atomic numbering scheme are shown in Figs. 1 and 2, respectively. Selected bond lengths and angles together with the hydrogen bonding geometry are given in Tables 3 and 4, respectively. Compound **1** crystallizes in the monoclinic $P21/c$ space group, while **2** crystallizes in the triclinic $P\bar{1}$ space group. Although a lot of saccharinato complexes are well known, quite surprisingly, up until

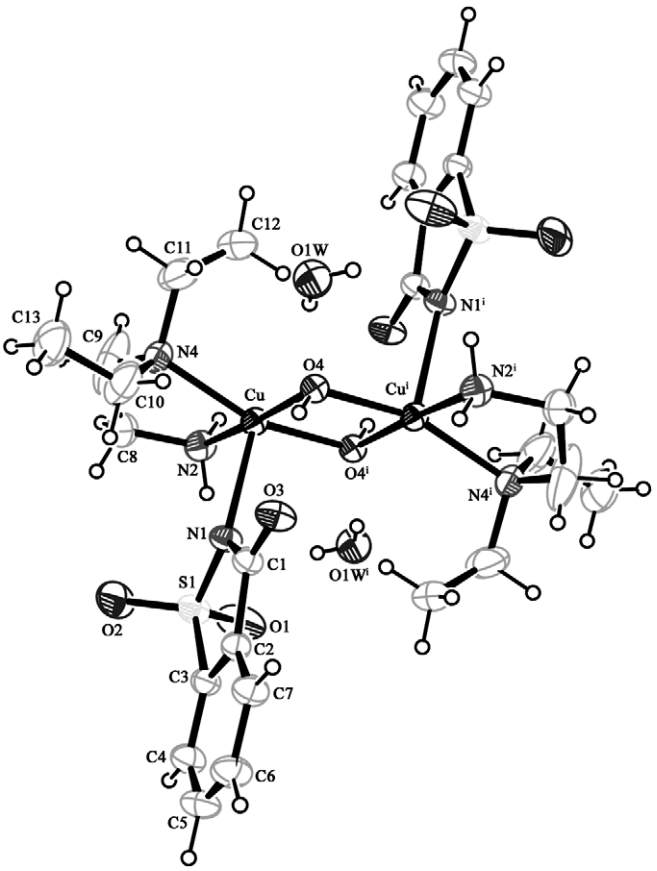

Fig. 1. The molecular structure of [Cu(μ-OH)(sac-*N*)(deten)]$_2$ · 2H$_2$O (**1**) showing the atom numbering scheme. The thermal ellipsoids are plotted at the 50% probability level.

now hydroxo-bridged dimeric metal complexes of saccharinate have not been reported. In the complexes, the sac ligands exhibit different coordination modes: in **1**, the sac ligand is *N*-bonded, while in the other complex it is *O*-coordinated. Both dinuclear units have a centre of symmetry located in the Cu_2O_2 planes and the copper(II) atoms have a square pyramidal coordination, with the basal plane comprising of two nitrogens atoms from deten or tmen ligands [Cu–N(2) = 2.004(3), Cu–N(4) = 2.098(3) Å] and the oxygen atoms of two hydroxo ligands [Cu–O(4) = 1.951(3), Cu^i–O(4) = 1.972(3) Å, (i) $-x, -y, -z$] for **1** and [Cu–N(2) = 2.076(2), Cu–N(3) = 2.032(2) Å] and [Cu–O(4) 1.951(2), Cu^i–O(4) 1.944(2) Å, (i) $-x+1, -y+2, -z+1$] for **2**. The apical position is occupied by the nitrogen atom of the sac ligand [Cu–N(1) = 2.395(3) Å] for **1** and by the oxygen atom of the sac ligand [Cu–

[a] pmdeta = 1,1,4,7,7-pentamethyldiethylenetriamine, dmtac = 1,4-dimethyl-1,4,7-triazacyclononane, dmbtac = 1,4-dimethyl-7-benzyl-1,4,7-triazacyclononane, tcbtac = 1,4,7-tris(3-cyanobenzyl)-1,4,7-triazacyclononane, phen = 1,10-phenanthroline, tpa = terephthalic acid, aprm = 2-aminopyrimidine, bmpma = di-benzyl(6-methyl-2-pyridylmethyl)-amine, 3-pyOH = /3-hydroxypyridine.

O(1) = 2.336(2) Å] for **2**. The Cu···Cu distance within the dinuclear unit is 2.924(1) Å for **1** and 2.888(1) Å for **2**, while the O–Cu–O angle is 83.60(11)° for **1** and 84.30(7)° for **2**. The Cu ··· Cu distances are shorter than that found in $[Cu_2(OH)_2(pmdeta)_2]Br_2 \cdot 2CH_3CN$ [3.0022(7) Å] [35]. Comparison of values of the Cu ··· Cu, Cu–O_{OH} distances and the O_{OH}–Cu–O_{OH} and Cu–O_{OH}-Cu angles for similar hydroxo-bridged complexes can be found in Table 5. The *sac* ligands are essentially planar with a r.m.s. deviation 0.0197 Å for **1** and 0.0204 Å for 2, and the largest deviation from the mean plane is −0.0224 Å for the C2 atom for **1** and −0.0108 Å for the N1 atom for **2**.

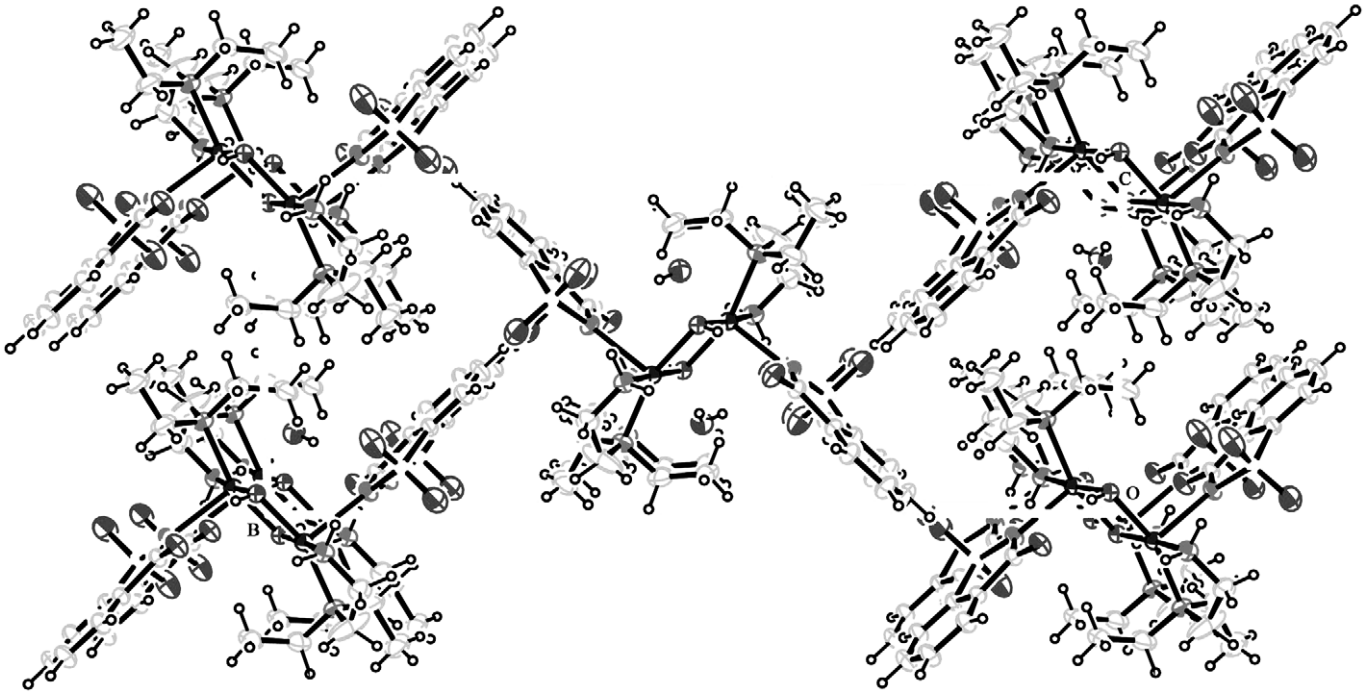

Fig. 3. Packing diagram of **1** viewed along the *a*-axis.

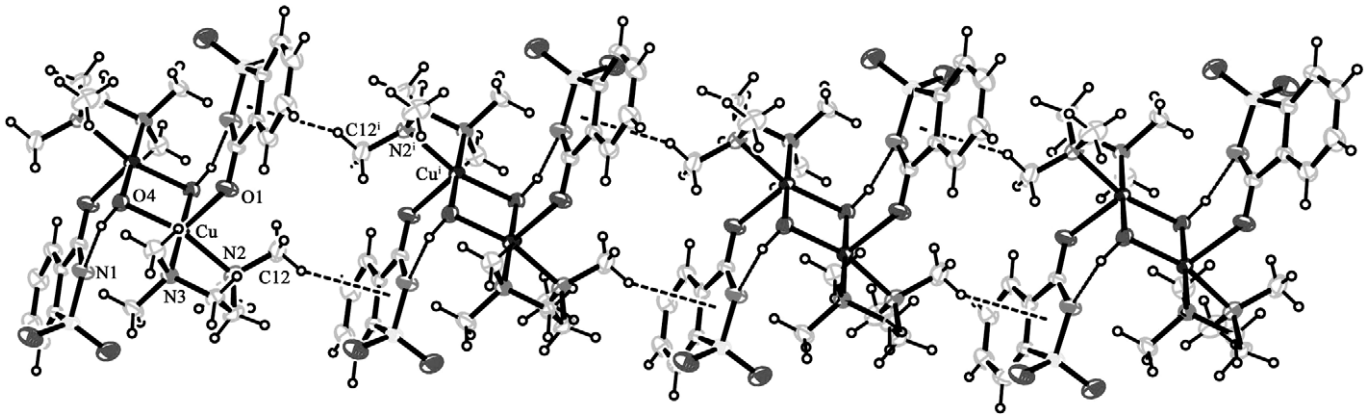

Fig. 4. Intramolecular hydrogen-bonding geometry and C–H···π interactions along the *b*-axis for the complex **2** (i = 1 − *x*, 1 − *y*, 1 − *z*).

The crystal packing is mainly stabilized by hydrogen bonds and van der Waals interactions (Fig. 3). There are also C–H···π interactions between the C(12)–CgA^{i} ring (Cg*A*: Cu, O(4), Cu^{i}, $O(4)^{i}$ for **1** and S(1), N(1), C(7), C(6), C(1) for **2**) (Fig. 4). The nitrogen atom N1 of the sac ligand is also involved in an intramolecular hydrogen bond with the OH group in **2**, N1–H···O4 = 2.9876(6) Å.

3.4. Antimicrobial activity studies

The in vitro antimicrobial activity of saccharin (main matter), $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$, $[Cu(\mu\text{-}OH)(sac)(deten)]_2\cdot 2H_2O$ and $[Cu(\mu\text{-}OH)(sac)(tmen)]_2$ were tested according to the disc diffusion method, and the results are given in Tables 6 and 7. The compounds were dissolved in DMSO or water. Antimicrobial activity was measured for 200, 500 and 1000 μg concentrations against Gram-positive *Staphylococcus aureus* ATCC 6535, *Bacillus cereus* ATCC 7064, Gram-negative *Escherichia coli* W3110, *Citrobacter freundii* NRRLB 2643 and the yeast *Candida albicans* ATCC 10231 and the mould *Aspergillius niger*. Sulfamethoxazole, chloramphenical, streptomycin, tetracycline, neomycin, sulfafurazole, ceftriaxone, oflaxacin and nystatin antibiotics were also used for comparison. The inhibition zones formed by standard antibiotic discs are shown in Table 8.

The saccharinate complexes (**1** and **2**) showed different antimicrobial activities against test strains. As can clearly be seen from Tables 6 and 7, to dissolve of saccharin and the complexes with different solvents (DMSO or water) did not affect the antimicrobial activity on the tested microorganisms. Furthermore, it appears that the activity of the tested complexes increases as the concentration increases, with the exception of *A. niger*, but it is a well-known fact that the concentration plays a vital role in increasing the degree of inhibition. Saccharin did not show any activity on the bacteria, the fungi or the yeast. Whilst there was no antimicrobial activity of $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$,

SXT: sulfamethoxazole/trimethoprim; C: chloramphenical; S: streptomycin; TE: tetracyline; N: neomycin; SF: sulfafurazole; OFX: oflaxacin; CRO: ceftriaxone; N: nystatin.

$[Cu(\mu\text{-}OH)(sac)(deten)]_2\cdot 2H_2O$ and $[Cu(\mu\text{-}OH)(sac)(tmen)]_2$ on the mould *A. niger*, $[Cu(\mu\text{-}OH)(sac)(tmen)]_2$ and $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ show weak antimicrobial activity at 1000 μg concentration against the yeast *C. albicans* used in this study. $[Cu(\mu\text{-}OH)(sac)(deten)]_2\cdot 2H_2O$, dissolved in DMSO, had weak antimicrobial activity on *C. albicans* (inhibitory zone <15 mm), but, this complex is more effective than saccharin and $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ on *C. albicans*. Tables 6 and 7 show there is an unclear zone for *S. aureus* and *B. cereus*. This could be due to the relationship with the gram-positive state. It seems that the cloudiness decreases with concentration increases. The compounds are more active against gram-negative than gram-positive bacteria, according to the clear zone. In classifying the antibacterial activity as gram-positive or gram-negative, it would generally be expected that compounds would be more active against gram-positive than gram-negative bacteria, due to the outer membrane layer of these bacteria, which do not allow compounds to enter the cell. According to the clear zone diameter, **1** and **2** at 1000 mg concentration have an antimicrobial activity on only *E. coli* (inhibitory zone ⩾15 mm). Against the other bacteria, they have weak antimicrobial activity (inhibitory zone <15 mm).

It could be said that the Cu(II) complexes **1** and **2** have a lower effect compared to standard antibiotics and they display activity at higher concentrations than antibiotics (Tables 6 and 8). Saccharin metal complexes have been demonstrated to possess antibacterial and antifungal properties [22,27,36,37].

Finally, there are no differences, from the point of view of antimicrobial activity, between $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ and the new compounds $[Cu(\mu\text{-}OH)(sac)(deten)]_2\cdot 2H_2O$ and $[Cu(\mu\text{-}OH)(sac)(tmen)]_2$on gram (+), gram (−) bacteria and a mould *A. niger*, but the $[Cu(\mu\text{-}OH)(sac)(deten)]_2\cdot 2H_2O$ complex is more effective than saccharin and $[Cu(sac)_2(H_2O)_4]\cdot 2H_2O$ on *C. albicans*.

4. Supplementary material

CCDC 655440 and 655441 contain the supplementary crystallographic data for $[Cu(\mu\text{-}OH)(sac)(deten)]_2\cdot 2H_2O$ and $[Cu(\mu\text{-}OH)(sac)(tmen)]_2$, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

describe the syntheses and characterization of dinuclear platinum(IV) complexes with bridging pyrazolato ligands starting from tris(acetone) complex $[PtMe_3(OCMe_2)_3]^+$ and the pyrazole complexes $[PtMe_3(pzH)_3]^+$ and $[PtMe_3I(pzH)_2]$, respectively, as precursor complexes. Due to the advantages of platinum(IV) complexes can have over platinum(II) complexes in chemotherapy, these complexes were investigated with respect to their antitumoral activity.

2. Experimental

2.1. General considerations

Syntheses of complexes were carried out under argon using standard Schlenk techniques whereas the work-up procedures were performed on air. Methylene chloride, acetone, *n*-pentane, benzene and diethyl ether were dried (CH_2Cl_2 over CaH_2, Me_2CO over molecular sieve 3A, *n*-pentane, benzene and Et_2O over Na-benzophenone) and distilled prior to use. $[(PtMe_3I)_4]$ and $[PtMe_3(OCMe_2)_3](BF_4)$ were obtained according to the literature [11,8]. Microanalyses (C, H, N, S) were performed by the microanalytical laboratory of the University of Halle using CHNS-932 (LECO) and Vario EL (elementar Analysensysteme) elemental analyzers. ^1H and ^{13}C NMR spectra were recorded on Varian Gemini 200, VXR 400 and Unity 500 NMR spectrometers. Solvent signals and residual protons of solvent signals were used as internal standard.

2.1.1. Preparation of $[PtMe_3(pzH)_3](BF_4)$ (**1**)

A solution of $[PtMe_3(OCMe_2)_3](BF_4)$ (100 mg, 0.200 mmol) in acetone (10 ml) was added to a solution of pyrazole (40.9 mg, 0.600 mmol) in acetone (10 ml). The solution was evaporated to dryness under vacuum and the residue was extracted with CH_2Cl_2 (10 ml). The colourless product, which was precipitated within 12 h after adding of *n*-pentane (10 ml), was washed with *n*-pentane/CH_2Cl_2 (1:1, 3 × 2 ml) and dried under vacuum. Yield 96 mg, 90%.

Anal. Calc. for $C_{12}H_{21}BF_4N_6Pt$: C, 27.13; H, 3.98; N, 15.82. Found: C, 27.07; H, 4.85; N, 15.77%. ^1H NMR (200 MHz, $(CD_3)_2CO$) δ 1.12 (s + d, $^2J_{Pt,H} = 70.1$ Hz, 9H, PtCH_3), 6.56 (m, 3H, *H*4), 7.70 (m, 3H, *H*5), 8.00 (m, 3H, *H*3), 12.35 (br, 3H, N*H*). ^{13}C NMR (50 MHz, $(CD_3)_2CO$) δ −7.7 (s + d, $^1J_{Pt,C} = 695.8$ Hz, Pt*C*H_3), 107.4 (s + d, $^3J_{Pt,C} = 8.6$ Hz, *C*4), 132.9 (s + d, $^2J_{Pt,C} = 5.3$ Hz, *C*5), 140.4 (s + d, $^3J_{Pt,C} = 8.4$ Hz, *C*3).

2.1.2. Preparation of $[PtMe_3I(pzH)_2]$ (**2**)

A solution of pyrazole (37.7 mg, 0.554 mmol) in acetone (5 ml) was added to a suspension of $[(PtMe_3I)_4]$ (100 mg, 69.2 μmol) in acetone (10 ml). After dissolving the solid (4 h) the solution was evaporated to dryness under vacuum and the solid was extracted with CH_2Cl_2 (10 ml). The product was precipitated within 12 h on addition of *n*-pentane (10 ml) and filtered off. The solid was washed with *n*-pentane/CH_2Cl_2 (1/1, 3 × 2 ml) and dried under vacuum. Yield 41 mg, 90%.

Anal. Calc. for $C_9H_{17}IN_4Pt$: C, 21.48; H, 3.40; N, 11.13. Found: C, 22.00; H, 3.49; N, 11.14%. ^1H NMR (500 MHz, $(CD_3)_2CO$): δ 1.29 (s + d, $^2J_{Pt,H} = 72.9$ Hz, 6H, PtCH_3 *trans* to pzH), 1.33 (s + d, $^2J_{Pt,H} = 71.6$ Hz, 3H, PtCH_3 *trans* to I), 6.43 (m, 2H, *H*4), 7.74 (m, 2H, *H*5), 7.88 (m, 2H, *H*3), 12.09 (br, 2H, N*H*); ^{13}C NMR (126 MHz, $(CD_3)_2CO$): δ −10.5 (s + d, $^1J_{Pt,C} = 682.3$ Hz, Pt*C*H_3 *trans* to pzH), 8.4 (s + d, $^1J_{Pt,C} = 715.9$ Hz, Pt*C*H_3 *trans* to I), 106.4 (s + d, $^3J_{Pt,C} = 8.6$ Hz, *C*4), 131.1 (s + d, $^2J_{Pt,C} = 5.3$ Hz, *C*3), 138.5 (s + d, $^3J_{Pt,C} = 11.5$ Hz, *C*5).

2.1.3. Preparation of $(PPN)[(PtMe_3)_2(\mu\text{-}pz)_3]$ (**3**)

KOAc (118 mg, 1.20 mmol) was added to a solution of $[PtMe_3(OCMe_2)_3](BF_4)$ (100 mg, 0.200 mmol) in acetone (10 ml). A solution of $[PtMe_3(pzH)_3](BF_4)$ (**1**) (106 mg, 0.200 mmol) in acetone (10 ml) was added dropwise to this suspension. After 30 min the suspension was filtered and the filtrate evaporated to dryness under vacuum. The solid was extracted with CH_2Cl_2 (10 ml) and the extract was added to a solution of (PPN)Cl (115 mg, 0.200 mmol) in CH_2Cl_2 (10 ml). After evaporation to 10 ml the KCl was filtered off and the product was precipitated within 12 h by adding of Et_2O (10 ml). The resulting solid was filtered off, washed with *n*-pentane/CH_2Cl_2 (1/1, 3 × 2 ml) and dried under vacuum. Yield 146 mg, 60%.

Anal. Calc. for $C_{51}H_{57}N_7P_2Pt_2$: C, 50.20; H, 4.71; N, 8.04. Found: C, 49.67; H, 5.01; N, 7.77%. ^1H NMR (200 MHz, $(CD_3)_2CO$): δ 0.85 (s + d, $^2J_{Pt,H} = 66.2$ Hz, 18H, PtCH_3), 6.00 (m, 3H, *H*4), 7.31 (m, 6H, *H*3/*H*5), 7.50–7.77 (m, 30H, PPN^+); ^{13}C NMR (126 MHz, $(CD_3)_2CO$): δ −6.7 (s + d, $^1J_{Pt,C} = 675.2$ Hz, Pt*C*H_3), 103.9 (s + d + t, $^3J_{Pt,C} = 15.4$ Hz, *C*4), 127.9/130.2/132.7/134.3 (PPN^+), 134.8 (s + d + d + d · d, $^{2/4}J_{Pt,C} = 25.9/10.6$ Hz, *C*3/*C*5).

2.1.4. Preparation of $(PPN)[(PtMe_3)_2(\mu\text{-}I)(\mu\text{-}pz)_2] \cdot 1/2Et_2O$ (**4**)

The reaction was carried out according to the above procedure. Instead of $[PtMe_3(pzH)_3](BF_4)$ (**1**), $[PtMe_3I(pzH)_2]$ (**2**) (101 mg, 0.200 mmol) was used. Yield 163 mg, 60%.

Anal. Calc. for $C_{100}H_{118}I_2N_{10}OP_4Pt_4$: C, 45.60; H, 4.52; N, 5.32. Found: C, 45.89; H, 4.59; N, 5.75%. ^1H NMR (500 MHz, $(CD_3)_2CO$): δ 1.08 (s + d, $^2J_{Pt,H} = 67.6$ Hz, 12H, PtCH_3 *trans* to pz), 1.10 (t, $^3J_{H,H} = 7.0$ Hz, 3H, OCH_2CH_3), 1.31 (s + d, $^2J_{Pt,H} = 75.7$ Hz, 6H, PtCH_3 *trans* to I), 3.39 (q, $^3J_{H,H} = 7.0$ Hz, 2H, OCH_2CH_3), 5.96 (m, 2H, *H*4), 7.27 (m, 4H, *H*3/*H*5), 7.50–7.77 (m, 30H, PPN); ^{13}C NMR (126 MHz, $(CD_3)_2CO$): δ −11.1 (s + d, $^1J_{Pt,C} = 646.3$ Hz, Pt*C*H_3 *trans* to pz), 7.6 (s + d, $^1J_{Pt,C} = 740.4$ Hz, Pt*C*H_3 *trans* to I), 14.9 (s, OCH_2CH_3), 104.7 (s + d, $^3J_{Pt,C} = 13.6$ Hz, *C*4), 129.1/131.2/134.1/135.4 (PPN^+), 135.8 (s + d + d + d · d, $^{2/4}J_{Pt,C} = 28.2/11.8$ Hz, *C*3/*C*5).

2.1.5. Preparation of [K(18C6)][(PtMe$_3$)$_2$(μ-I)(μ-pz)$_2$] (5)

The reaction was carried out analogously to **4**, but instead of working with a solution of (PPN)Cl in CH_2Cl_2, a solution of 18C6 (52.9 mg, 0.200 mmol) in CH_2Cl_2 (10 ml) was used. Yield 105 mg, 50%.

Anal. Calc for $C_{24}H_{48}IKN_4O_6Pt_2$: C, 27.59; H, 4.63; N, 5.36. Found: C, 27.74; H, 5.08; N, 5.34%. ^{1}H NMR (500 MHz, $(CD_3)_2CO$): δ 1.08 (s + d, $^2J_{Pt,H} = 67.6$ Hz, 12H, PtC*H*$_3$ *trans* to pz), 1.31 (s + d, $^2J_{Pt,H} = 75.7$ Hz, 6H, PtC*H*$_3$ *trans* to I), 3.65 (s, 24H, C*H*$_2$O), 5.96 (m, 2H, *H*4), 7.27 (m, 4H, *H*3/*H*5).

2.1.6. Preparation of [(PtMe$_3$)$_2$(μ-pz)$_2$(μ-Me$_2$S)] (6)

AgO_2CCF_3 (15.5 mg, 70 μmol) was added to a solution of (PPN)[(PtMe$_3$)$_2$(μ-I)(μ-pz)$_2$] · 1/2Et$_2$O (**4**) (92.2 mg, 70 μmol) in acetone (10 ml). After complete precipitation of AgI (12 h) the reaction mixture was filtered. Me_2S (4.9 mg, 78 μmol) was added to the solution and the reaction mixture was evaporated to dryness under vacuum. The residue was extracted in benzene (10 ml) and washed with H_2O (10 ml). The combined organic phases were dried (Na_2SO_4) and concentrated to 5 ml. Then the product was precipitated by adding of *n*-pentane (10 ml), filtered of, washed with *n*-pentane (3 × 2 ml) and dried under vacuum. Yield 28.4 mg, 60%.

Anal. Calc. for $C_{14}H_{30}N_4Pt_2S$: C, 24.85; H, 4.47; N, 8.28; S, 4.74. Found: C, 25.37; H, 4.76; N, 8.38; S, 4.40%. ^{1}H NMR (200 MHz, $(CD_3)_2CO$): δ 0.76 (s + d, $^2J_{Pt,H} = 66.8$ Hz, 12H, PtC*H*$_3$ *trans* to pz), 1.40 (s + d, $^2J_{Pt,H} = 73.0$ Hz, 6H, PtC*H*$_3$ *trans* to S), 2.38 (s + d + t, $^3J_{Pt,H} = 8.7$ Hz, 6H, S(C*H*$_3$)$_2$), 6.18 (m, 2H, *H4*), 7.39 (m, 4H, *H3*/*H5*); ^{13}C NMR (126 MHz, $(CD_3)_2CO$): δ −9.8 (s + d, $^1J_{Pt,C} = 642.1$ Hz, Pt*C*H$_3$ *trans* to pz), 5.2 (s + d, $^1J_{Pt,C} = 694.9$ Hz, Pt*C*H$_3$ *trans* to S), 15.2 (s, S*C*H$_3$, pz), 105.5 (s + d + t, $^3J_{Pt,C} = 14.9$ Hz, *C*4) 136.3 (s + d + d + d · d, $^{2/4}J_{Pt,C} = 27.7/10.3$ Hz, *C*3/*C*5).

2.1.7. Preparation of [(PtMe$_3$)$_2$(μ-pz)$_2$(μ-MeSPh)] (7)

The reaction was carried out according to the above procedure. Instead of Me_2S, MeSPh (9.7 mg, 78 μmol) was used. Yield 31.0 mg, 60%.

2.2. X-ray crystallography

Single-crystal X-ray diffraction analyses of suitable crystals of complexes **3** and **4** were performed at 220(2) K on a STOE-IPDS diffractometer using Mo Kα radiation (λ = 0.71073 Å, graphite monochromator). A summary of the crystallographic data, the data collection parameters and the refinement parameters is given in Table 1. Absorption correction for **3** was applied numerically ($T_{min}/T_{max} = 0.49/0.60$). The structures were solved by direct methods with SHELXS-97 [12]. The structure refinements were carried out by full-matrix least-square procedures against F^2 (SHELXL-97 [12]) for all reflections. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were refined isotropically. In complex **3** all H atoms except those of the methyl ligands were found in the difference Fourier map. The H atoms of the methyl ligands and those of complex **4** were added to the models in their calculated positions using the "riding model". The thermal ellipsoids of the C atoms of the ether molecule in **4** point to a disorder, but refinement in split positions did not succeed.

2.3. Computational details

DFT calculations of compounds **3c**,[1] **4c**, **8c**, **8c′**, pz$^-$ and I$^-$ were carried out by the GAUSSIAN 03 program package [13] using the modified Perdew–Wang 1991 exchange functional

[1] The index "c" denotes calculated equilibrium structures.

by Adamo and Barone [14] plus the Perdew–Wang 1991 correlation functional [15] (MPWPW91). The 6-311G(d,p) [16] basis set as implemented in GAUSSIAN 03 was employed for C, H and N atoms, while the relativistic pseudopotentials of the Ahlrichs group and related basis functions of TZVPP quality [17] were employed for Pt and I atoms. All systems were fully optimized without any symmetry restrictions. The resulting geometries were characterized as equilibrium structures by the analysis of the force constants of normal vibrations. The interaction energies were corrected for basis set superposition errors (BSSE), that were estimated with counterpoise type calculations [18].

2.4. In vitro studies

Stock solutions of investigated platinum complexes and reference compound cisplatin were made in dimethyl sulfoxide (DMSO) at a concentration of 20 mM and diluted by nutrient medium to various working concentrations. Nutrient medium was RPMI-1640 (PAA Laboratories) supplemented with 10% fetal bovine serum (Biochrom AG) and penicillin/streptomycin (PAA Laboratories).

2.4.1. Cell cultures

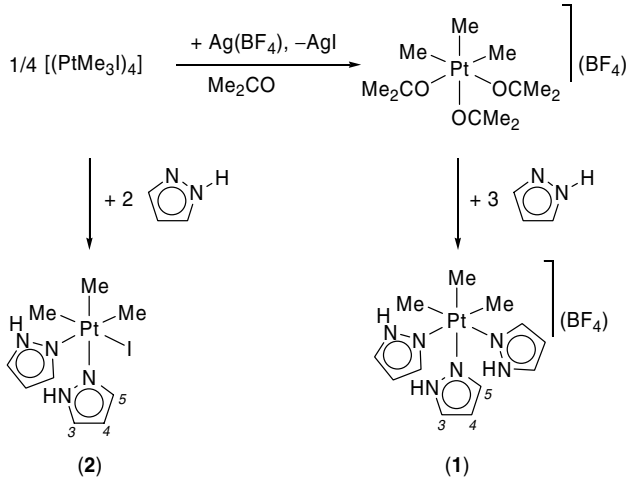
The human tumor cell lines anaplastic thyroid cancer 8505C, head and neck tumors A253 and FaDu, cervical cancer A431, lung carcinoma A549, ovarian cancer A2780, colon carcinoma DLD-1, HCT-8 and HT-29 were cultivated in the Biocentrum, Martin Luther University Halle-Wittenberg. All cells were maintained as monolayers in nutrient medium in a humidified atmosphere with 5% CO_2.

2.4.2. Cytotoxicity assay

The cytotoxic activity of the platinum compounds was measured by the sulforhodamine-B (SRB) assay [19]. In brief, exponentially growing cells were seeded into 96-well plates and 24 h later, after the cell adherence, nine different concentrations of investigated compounds were added to the wells. The final concentrations were in the range from 0.1 to 100 μM. All experiments were done in triplicate. Nutrient medium with corresponding concentrations of compounds, but void of cells was used as blank. Five days after seeding the cells were fixed with 10% trichloroacetic acid and processed according to the published SRB assay protocol. Absorbance was measured at 570 nm using a 96-well plate reader (SpectraFluor Plus Tecan, Germany) and the percentages of surviving cells relative to untreated controls were determined. The concentration IC_{50}, was defined as the concentration of a drug that inhibited cell survival by 50%, compared with vehicle-treated control.

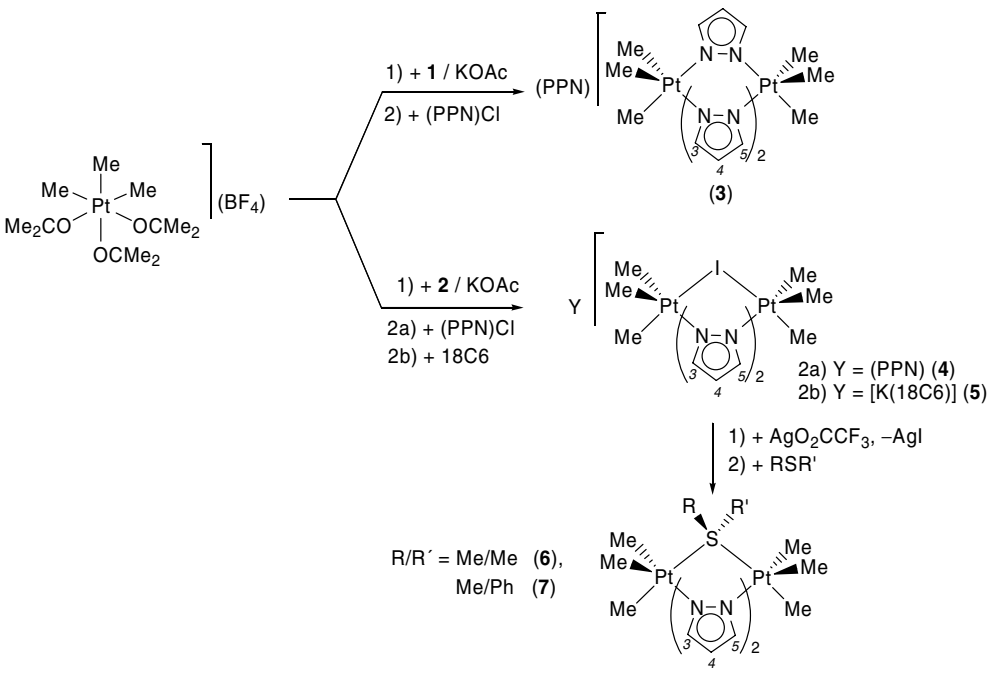
3. Results and discussion

3.1. Syntheses



The complex $[PtMe_3(OCMe_2)_3](BF_4)$, obtained by the reaction of $[(PtMe_3I)_4]$ with $Ag(BF_4)$ in acetone [8], was found to react rapidly in acetone with three equivalents of pyrazole yielding the cationic tris(pyrazole) complex **1** (Scheme 1). Furthermore, the tetranuclear platinum complex $[(PtMe_3I)_4]$ was also found to react with pyrazole yielding the neutral bis(pyrazole) complex **2**, but this reaction took one day at room temperature (Scheme 1). Both mononuclear complexes were isolated as airstable colourless (**1**) and pale yellow (**2**) crystals in high yields (ca. 90%). The constitution of both complexes was determined unambiguously by microanalysis and NMR spectroscopy (^1H, ^{13}C).

Deprotonation of the coordinated pyrazole ligand in **1** and **2** afforded μ-pyrazolato complexes. Thus, complexes **1** and **2** reacted with $[PtMe_3(OCMe_2)_3](BF_4)$ in the presence of KOAc yielding dinuclear tris(μ-pyrazolato) and (μ-iodo)bis(μ-pyrazolato) complexes, respectively (Scheme 2). To yield crystalline complexes, the primarily obtained potassium salts were converted in a methatetical reaction to the PPN salts **3** and **4**, respectively. Addition of the crown ether 18C6 to the potassium salt of the (μ-iodo)-bis(μ-pyrazolato) complex resulted in the formation of the [K(18C6)] salt **5**. The colourless, airstable complexes (**3**, **4**, **5**) were obtained in moderate yields (ca. 50–60%) and characterized by microanalysis, NMR spectroscopy (^1H, ^{13}C) and single-crystal X-ray diffraction analyses.



Substitution of the μ-iodo ligand in complex **4** could be achieved by reaction with silver trifluoroacetate followed by addition of thioethers (Scheme 2). Thus, the thioether bridged complexes **6** and **7** were obtained as colourless, airstable crystals in moderate yields (ca. 60%). Their identities have been confirmed by microanalysis and NMR spectroscopy (^1H, ^{13}C).

3.2. Spectral properties

^1H and ^{13}C NMR spectra gave proof that complexes **1** and **2** exhibit (mean) C_{3v} and C_s symmetry, respectively. Thus, in complex **1** all three pyrazole and methyl ligands are chemically equivalent. In complex **2** the two pyrazole

Scheme 1.

Scheme 2.

ligands were found to be equivalent, whereas two different methyl signals were observed. ^{1}H and ^{13}C NMR spectroscopic measurements established the identities of complexes **3**–**7**. In all these complexes the chemical equivalence $\delta(C^3) = \delta(C^5)$ and $\delta(H^3) = \delta(H^5)$[2] indicated a mirror plane perpendicular to the pyrazolato ligands. Furthermore, in accordance with a (mean) D_{3h} symmetry, the anion in **3** showed six and three chemically equivalent methyl and pyrazolato ligands, respectively. In accordance with a (mean) C_{2v} symmetry, in complexes **4**, **5** and **6** two equivalent pyrazolato ligands and two groups of chemically inequivalent methyl ligands (*trans* to pz^- and *trans* to I^-/Me_2S) were observed. On the other hand, in complex **7** (mean C_s symmetry) two inequivalent pyrazolato ligands and three inequivalent methyl ligands were found.

In *fac*-trimethylplatinum(IV) complexes the $^{1}J_{Pt,C}$ and $^{2}J_{Pt,H}$ coupling constants are indicative of the *trans* influence of ligands *trans* to the methyl ligands [20]. The values for dinuclear complexes **3**, **4**, **6** and **7** are given in Table 2. On the basis of the $^{1}J_{Pt,C}$ coupling constants the expected sequence of the *trans* influence was found: 642.0–675.2 Hz (pz^- in **3**–**7**) >694.9 Hz (Me_2S in **6**) ≈ 704.4 Hz (MeSPh in **7**) >740.4 Hz (I^- in **4**). The unusually low *trans* influence of the pyrazolato ligand in complex **3** compared with that in complexes **4**–**7** (675.2 Hz versus 642.0–646.3 Hz) might be reasoned to be due to a different angle strain in the tris- and bis(μ-pyrazolato) complexes as well as a different *cis* influence of the pz^- ligand compared to I^-/MeSR ligands. Principally, the same order of the *trans* influence can be derived from the $^{2}J_{Pt,H}$ coupling constants

Table 2
Selected coupling constants (in Hz) of complexes (PPN)[$(PtMe_3)_2$(μ-pz)$_2$(μ-X)] (**3**, **4**) and [$(PtMe_3)_2$(μ-pz)$_2$(μ-L)] (**6**, **7**)

Compound	X/ L = ligand	$^{1}J_{Pt,C}$ (*trans* N)	$^{1}J_{Pt,C}$ (*trans* X/L)	$^{2}J_{Pt,H}$ (*trans* N)	$^{2}J_{Pt,H}$ (*trans* X/L)
3	$X = pz^-$	675.2		66.2	
4	$X = I^-$	646.3	740.4	67.6	75.7
6	$L = Me_2S$	642.1	694.9	66.8	73.0
7	L = MeSPh	643.9/642.0	704.4	66.0/66.0	74.7

but, as known [21], these are not so sensitive as the $^{1}J_{Pt,C}$ coupling constants are.

In the neutral mononuclear complex [$PtMe_3I(pzH)_2$] (**2**) the magnitude of the $^{1}J_{Pt,C}$ coupling constant *trans* to N (682.3 Hz) demonstrated that, in comparison with the requisite coupling constants in **3**–**7** (642.0–675.2 Hz), pyrazole has a smaller *trans* influence than that of the μ-pyrazolato ligand. Furthermore, the comparison to the $^{1}J_{Pt,C}$ coupling constants in complexes **2** and **4** *trans* to the iodo ligand (715.9 versus 740.4 Hz) showed a *trans* influence $I_{terminal} > I_{bridging}$ as expected.

3.3. Structures

Crystals of complexes **3** and **4** suitable for X-ray diffraction analyses were obtained by recrystallization from CH_2Cl_2/Et_2O. The complexes crystallized as isolated cations and anions without unusual intermolecular interactions. The shortest distances of non-hydrogen atoms between cations and anions are 3.52 Å (C13···C12, **3**) and 3.43 Å (C1···C18, **4**). At distances <3.8 Å from the anion, in complex **3** seven PPN cations are found whereas

[2] Numbering scheme of pzH/pz^- ligands see Schemes 1 and 2.

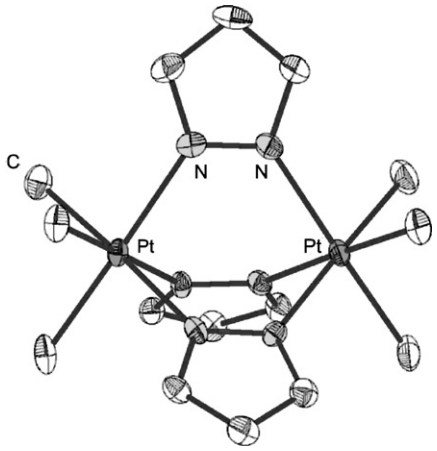


Fig. 1. Molecular structure of $[(PtMe_3)_2(\mu\text{-}pz)_3]^-$ in crystals of **3** (H atoms are omitted for clarity, 30% probability ellipsoids).

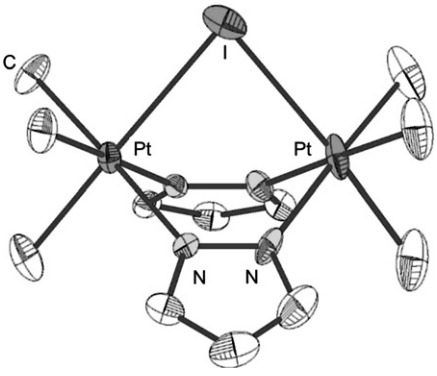

Fig. 2. Molecular structure of $[(PtMe_3)_2(\mu\text{-}I)(\mu\text{-}pz)_2]^-$ in crystals **4** (H atoms are omitted for clarity, 30% probability ellipsoids).

in complex **4** six PPN cations and another anion are found. The molecular structures of the anions are shown in Figs. 1 and 2, selected geometrical parameters are given in Table 3.

The structure of the tris(μ-pyrazolato) bridged dinuclear anion in crystals of **3** is approximately of D_{3h} symmetry (Fig. 1). The platinum atoms exhibit an octahedral coordination (angles between neighbouring ligands: 88.1(3)–91.8(3)°). The Pt···Pt distance amounts to 3.7827(8) Å excluding any direct interaction. The structure of the (μ-iodo)bis(μ-pyrazolato) bridged dinuclear anion $[(PtMe_3)_2(\mu\text{-}I)(\mu\text{-}pz)_2]^-$ in crystals of **4** is very nearly of C_{2v} symmetry (Fig. 2). The platinum atoms are octahedrally coordinated exhibiting a PtC_3N_2I coordination (angles between neighbouring ligands: 87.3(6)–91.4(4)°). The Pt–C bond lengths did not prove to be dependent on the ligand in the *trans* position (Pt–C (*trans* to N): 2.05(2)–2.08(1) Å; Pt–C (*trans* to I): 2.06(2)/2.07(1) Å). The Pt···Pt distance in **4** is significantly shorter than in **3** (3.706(1) versus 3.7827(8) Å).

3.4. DFT calculations

To gain further insight into the strength of the platinum–μ-ligand bonds in the dinuclear platinum(IV) complexes **3** and **4**, quantum chemical calculations were performed on the DFT level. The calculated equilibrium structures of the dinuclear anions $[(PtMe_3)_2(\mu\text{-}pz)_3]^-$ (**3c**) and $[(PtMe_3)_2(\mu\text{-}I)(\mu\text{-}pz)_2]^-$ (**4c**) contained in complexes **3** and **4/5** are illustrated in Fig. 3. Two different diastereoisomers of fragments $[(PtMe_3)_2(\mu\text{-}pz)_2]$ (**8c/8c′**, Fig. 3), with similar energies, were observed in these calculations. Only fragment **8c** is discussed here, because it exhibits a structure close to complexes **3c** and **4c**. Thus, **8c** is expected to be an intermediate in the substitution processes of complex **4**. Selected structural parameters of the equilibrium structures of **3c**, **4c** and **8c** are listed in Table 4. The calculated structures **3c** and **4c** show a good agreement with the experimentally found values. Interestingly, both in the calculated and experimental structures the Pt···Pt distance of the (μ-iodo)-bis(μ-pyrazolato) complex (**4c/4**) was found to be shorter than in the tris(μ-pyrazolato) complex (**3c/3**). An even shorter Pt···Pt distance was found in the complex fragment **8c**. Thus, addition of the μ-pyrazolato (**8c→3c**) and μ-iodo ligand (**8c→4c**) results in a lengthening of the Pt···Pt distance, indicating that the "coordination pocket" of this fragment is too small for both the μ-iodo and the μ-pyrazolato ligand.

Table 3

On the basis of an energetic approach the strength of metal–ligand interactions can be expressed either as the dissociation energy E_{diss} of the complex into the free fragments in their equilibrium structures or as the interaction energy E_{int} of the "prepared" fragments (isolated fragments having the same geometry as in the complex). For an explanation of these fundamental steps, see Ref. [22]. Thus, the equation

$$-E_{diss} = E_{int} + E_{prep}$$

holds whereas the preparation energy E_{prep} of a bond formation A + B→AB is the energy which is necessary to promote fragments A and B from their equilibrium geometries

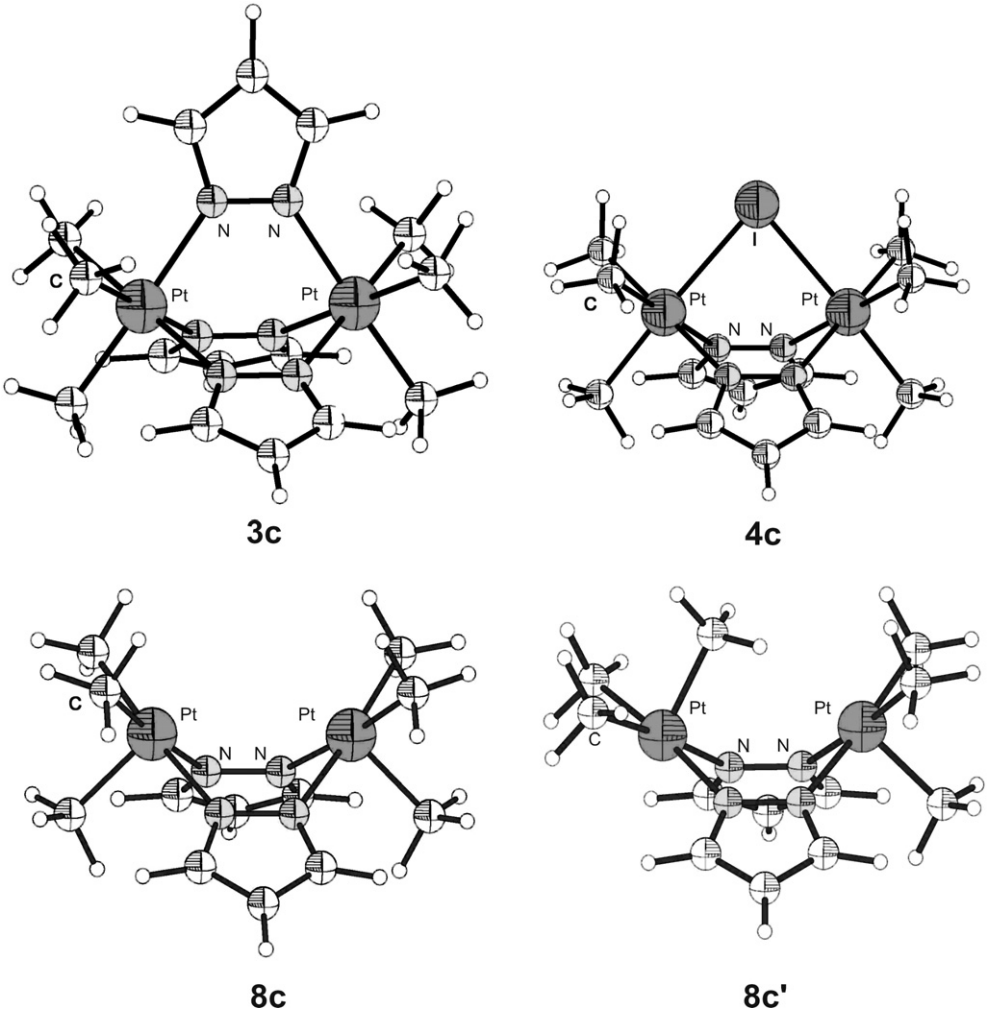

Fig. 3. Calculated equilibrium structures of $[(PtMe_3)_2(\mu\text{-}pz)_3]^-$ (**3c**), $[(PtMe_3)_2(\mu\text{-}I)(\mu\text{-}pz)_2]^-$ (**4c**) and $[(PtMe_3)_2(\mu\text{-}pz)_2]$ (**8c**/**8c′**).

Table 4
Selected interatomic distances (in Å) and angles (in °) of calculated equilibrium structures $[(PtMe_3)_2(\mu\text{-}X)(\mu\text{-}pz)_2]^-$ (μ-X = pz^-, **3c**; I^-, **4c**) and $[(PtMe_3)_2(\mu\text{-}pz)_2]$ (**8c**)

	3c	4c	8c
Pt–$C_{trans\,L}$		2.071	2.043[a]

C–Pt–N_{cis}	88.9–91.3	89.9–92.5	90.6–92.6
C–Pt–N_{trans}	178.1–179.3	178.9–179.8	175.8–179.8

[a] *trans* to the free coordination site.

to the geometries which they acquire in the complex AB. As shown in Fig. 4, for both processes the μ-pyrazolato ligand in **3c** is more strongly bound ($E_{int} = -80.5$ kcal/mol, $-E_{diss} = -73.7$ kcal/mol) than the μ-iodo ligand in **4c** ($E_{int} = -50.8$ kcal/mol, $-E_{diss} = -46.2$ kcal/mol), which is in accord with the differences in the *trans* influence of the bridging ligands measured by the $^1J_{Pt,C}$ coupling constants. The preparation energy of the platinum fragment in **3c** was found to be larger than that in **4c** (6.3 versus 4.6 kcal/mol) as expected by inspection of the Pt···Pt distances (3.636 Å (**8c**) <3.780 Å (**4c**) <3.830 Å (**3c**)).

3.5. Antitumoral activities

Since the discovery of cisplatin (*cis*-$[PtCl_2(NH_3)_2]$) by Rosenberg [23] the anticancer activity of platinum complexes is well known. In contrast to the large number of platinum(II) complexes, substantially fewer platinum(IV) complexes have been investigated with respect to their cancerostatic properties [24,25]. However, a number of platinum(IV) complexes have been tested in clinical trials. These include iproplatin (*cis*, *trans*, *cis*-$[PtCl_2(OH)_2(NH_2iPr)_2]$) [24] tetraplatin ($[PtCl_4$(D,L-dach)]; dach = 1,2-diaminocyclohexane) [24] and satraplatin (*cis*, *trans*-$[PtCl_2(OAc)_2(NH_3)(NH_2cy)]$) [24,26]. As reported in the literature [27], dinuclear platinum(II) complexes should be able to coordination to DNA in a fashion differing from that observed for mononuclear complexes and thus might show activity against tumor cell lines resistant to cisplatin.

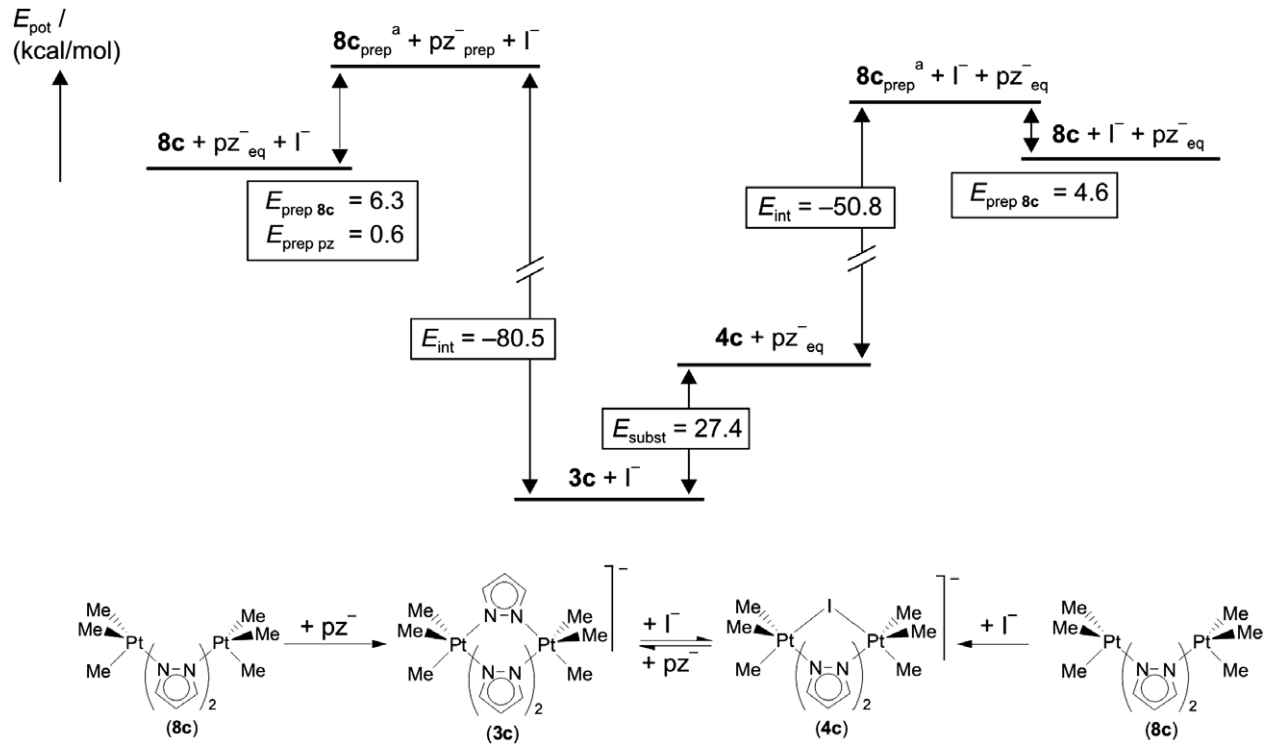

Fig. 4. Energy decomposition analyses of bond formation between fragment **8c** and pz^- and I^-, respectively. Interaction energies include BSSE corrections. (a) $\mathbf{8c}_{prep}$ denotes the fragment **8c** having the geometry as in complex **3c** and **4c**, respectively.

In contrast to the investigation of the anticancer activities of dinuclear platinum(II) complexes, investigations with dinuclear platinum(IV) complexes are lacking. To study the activity of the synthesized trimethylplatinum(IV) complexes two different compounds were chosen (**2**, **5**), exhibiting mono- and dinuclear arrangement, but containing similar (iodo, pyrazole/pyrazolato) ligands.

To investigate the activities of complexes **2** and **5** against various human tumor cell lines, in vitro experiments were carried out. The antitumoral activities of compounds **2** and **5** in comparison to the respective activity of cisplatin are presented in Table 5. The anti-proliferative activity of complex **2** was found to be about one order of magnitude lower than that of cisplatin (IC_{50}(**2**)/IC_{50}(cisplatin) = 7.0–58.4). In contrast, the activity of complex **5** proved to be in the same order than the corresponding activity of cisplatin (IC_{50}(**5**)/IC_{50}(cisplatin) = 0.4–2.7). Two cell lines (8505C, DLD-1), which exhibit low sensitivities against cisplatin, were included in these investigations. On these particular cell lines, complex **5** was found to be more active than cisplatin (IC_{50}(**5**)/IC_{50}(cisplatin) = 0.4–0.5). However, taking into consideration that **5** is a dinuclear complex, roughly the same anti-proliferative activity per Pt atom was observed. The reason for the significantly higher anti-proliferative activity of the dinuclear complex **5** in comparison with the mononuclear complex **2** is not yet clear. It can be speculated that the dinuclear fragment [$(PtMe_3)_2(\mu\text{-pz})_2$] allows a bridging coordination of the nucleobases.

Table 5
IC_{50} values of complexes **2** and **5** against different human tumor cell lines

Cell line	IC_{50} [μM]		
	Complex **2**[a]	Complex **5**[a]	Cisplatin[b]
8505C	35.03 ± 0.86	1.96 ± 0.15	5

[a] Mean value ± SD from experiments.
[b] Mean value without SD.

To summarize, the investigations showed that dinuclear pyrazolato bridged platinum(IV) complexes can be built up by the synthesis of mononuclear pyrazole precursor complexes followed by controlled deprotonation of the pyrazole ligands. Due to the highly stable *fac*-$PtMe_3$ moiety, threefold bridged dinuclear platinum(IV) complexes were obtained. The substitution lability of the μ-iodo ligand in complex **4**/**5** opened up a way to synthesize and to characterize further complexes having a relatively rigid $Me_3Pt(\mu\text{-pz})_2PtMe_3$ fragment in which to metal centers in high oxidation state are in the vicinity of one another. Furthermore it could be demonstrated that the investigated dinuclear complex **5** exhibited a quite high proliferative activities against a series of human tumor cell lines.

and $[ReOX_3(AsPh_3)(OAsPh_3)]$ (X = Cl or Br) – towards pyrazole, 3,5-dimethylopyrazole, benzotriazole and pyrazine [8]. As an extension of this work, we were keen to examine the reactivity of $[ReOX_3(PPh_3)_2]$ and $[ReOX_3(AsPh_3)_2]$ towards pyrazole ligands containing additional hydrogen-bonding functionality, in addition to the N–H group of the pyrazole ring. 2-(1-H-pyrazol-3-yl)phenol is one such ligand, and is readily available. Furthermore, no other rhenium complexes containing 2-(1-H-pyrazol-3-yl)phenolato ligand have been previously characterized [9].

Here we present synthesis and spectroscopic data for $[ReOCl_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$ (**1** · MeCN), $[ReOBr_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$ (**2** · MeCN), $[ReOCl_2(C_9H_7N_2O)(AsPh_3)]\cdot MeCN$ (**3** · MeCN) and $[ReOBr_2(C_9H_7N_2O)(AsPh_3)]\cdot MeCN$ (**4** · MeCN) complexes. X-ray studies have been performed for **1** · MeCN, **3** · MeCN and **4** · MeCN, and electronic structure of **1** has been calculated with the density functional theory (DFT). TD-DFT/PCM calculations have been employed to produce a hundred of singlet excited-states starting from the ground-state geometry optimized in the gas phase, and the UV–Vis spectrum of the complex has been discussed on this basis.

Currently density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [10]. Recent calculations with TD-DFT method for open- and closed-shell of 5d-metal complexes (including rhenium complexes) have also supported the TD-DFT method to be applicable for such systems giving good assignment of experimental spectra [11,12].

Some theoretical investigations have been carried out on rhenium compounds. The electronic structures of nitrido, oxo, carbonyl, nitrosyl and nitrile rhenium complexes, as well as their spectroscopic properties, bonding and reactivity have been theoretically studied at the HF, MP2, EHT and DFT levels of theory using various basis sets [13–22]. Gancheff and co-workers [15] have performed extended tests of the ability of the B3LYP method in LANL2DZ basis set for rhenium compounds in a geometry optimization and calculation of spectral properties. Although this is not a very extended basis set, its use with DFT has shown to be sufficient for the geometry optimization and calculation of spectral properties. It gives good agreement with the experimental data and its use is justified in the case of large molecules.

2. Experimental

2.1. General procedure

The reagents used to the synthesis were commercially available and were used without further purification. The $[ReOX_3(AsPh_3)_2]$ and $[ReOX_3(PPh_3)_2]$ complexes were prepared according to the literature methods [23].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 1000–180 nm in acetonitrile solution. ^1H NMR spectrum was obtained in $CDCl_3$ using Bruker Avance 400 spectrometer. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of $[ReOCl_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$

A mixture of $[ReOCl_3(PPh_3)_2]$ (0.50 g, 0.6 mmol), 2-(1-H-pyrazol-3-yl)phenol (0.12 g, 0.75 mmol) and acetone (50 ml) was stirred at room temperature for 3 h. Half of the solvent was removed and diethyl ether (50 ml) was added to precipitate the product as a green solid, which was filtered off, dried and recrystallized from acetonitrile. Yield 85%.

Anal. Calc. for $C_{29}H_{25}Cl_2N_3O_2PRe$: C, 47.35; H, 3.43; N, 5.71. Found: C, 47.60; H, 3.46; N, 5.59%.

IR (KBr; ν/cm^{-1}): 1606 (m), 1581 (w), 1531 (m), 1506 (s) ν_{CN} and $\nu_{C=C}$; 960 (vs) $\nu_{Re=O}$.

^1H NMR (400 MHz; $CDCl_3$) $\delta = 10.61$ (br, 1H, N–H), 7.45-7.36 (m, 10H), 7.34 (dd, 1H, $J = 2.6$ Hz, $J = 1.6$ Hz, H26-pz), 7.29-7.24 (m, 5H), 7.21 (dd, 1H, $J = 7.7$ Hz, $J = 1.6$ Hz, H20–Ar), 6.94 (td, 1H, $J = 7.7$ Hz, $J = 1.6$ Hz, H22–Ar), 6.86 (td, 1H, $^3J = 7.7$ Hz, $J = 1.0$ Hz, H21–Ar), 6.63 (t, 1H, $J = 2.6$ Hz, H27-pz), 6.61 (dd, 1H, $J = 7.7$ Hz, $J = 1.0$ Hz, H23–Ar).

2.3. Preparation of $[ReOBr_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$

A procedure similar to that for $[ReOCl_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$ was used with $[ReOBr_3(PPh_3)_2]$ (0.50 g, 0.52 mmol and 2-(1-H-pyrazol-3-yl)phenol (0.11 g, 0.69 mmol). Crystalline precipitate of $[ReOBr_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$ was collected in 80% yield.

Anal. Calc. for $C_{29}H_{25}Br_2N_3O_2PRe$: C, 42.24; H, 3.06; N, 5.10. Found: C, 42.50; H, 3.16; N, 5.05%.

IR (KBr; ν/cm^{-1}): 1603 (m), 1582 (w), 1531 (m), 1504 (s) ν_{CN} and $\nu_{C=C}$; 963 (vs) $\nu_{Re=O}$.

2.4. Preparation of $[ReOCl_2(C_9H_7N_2O)(AsPh_3)]\cdot MeCN$

A procedure similar to that for $[ReOCl_2(C_9H_7N_2O)(PPh_3)]\cdot MeCN$ was used with $[ReOCl_3(AsPh_3)_2]$ (0.50 g, 0.54 mmol) and 2-(1-H-pyrazol-3-yl)phenol (0.11 g, 0.69 mmol). Crystalline precipitate of $[ReOCl_2(C_9H_7N_2O)(AsPh_3)]\cdot MeCN$ was collected in 85% yield.

Anal. Calc. for $C_{29}H_{25}Cl_2N_3O_2AsRe$: C, 44.68; H, 3.23; N, 5.39. Found: C, 44.77; H, 3.18; N, 5.35%.

IR (KBr; ν/cm^{-1}): 1607 (m), 1581 (w), 1534 (m), 1504 (s) ν_{CN} and $\nu_{C=C}$; 965 (vs) $\nu_{Re=O}$.

2.5. Preparation of $[ReOBr_2(C_9H_7N_2O)(AsPh_3)]\cdot MeCN$

A procedure similar to that for $[ReOCl_2(C_9H_7N_2O)(PPh_3)]$ was used with $[ReOBr_3(AsPh_3)_2]$ (0.50 g,

2.6. Crystal structure determination and refinement

The X-ray intensity data of **1** · MeCN, **3** · MeCN and **4** · MeCN were collected on a KM-4-CCD automatic diffractometer equipped with CCD detector and graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at room temperature. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and absorption correction [24] were applied. The structures were solved by the Patterson method and subsequently completed by the difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. The hydrogen atoms were treated as "riding" on their parent carbon atoms and assigned isotropic temperature factors equal 1.2 times the value of equivalent temperature factor of the parent atom.

For structure **4**, a final difference electron density residual peak of 1.701 e Å^{-3} was observed at 0.90 Å of the Re(1) atom, and a hole of −2.142 e Å^{-3} at 0.90 Å of the Br(2) atom. SHELXS97 [25], SHELXL97 [26] and SHELXTL [27] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

Table 2
Hydrogen bonds for **1** · MeCN, **3** · MeCN and **4** · MeCN complexes

D	A	H···A	D···A	D–H···A
***1** · MeCN*

The Cg(1), Cg(2), Cg(3), Cg(4) indicates the centroids of aromatic rings containing N(1), C(1), C(7), C(19) atoms respectively; α is a dihedral angle between planes I and J; β is an angle between Cg(I)–Cg(J) vector and normal to plane I and d_p is a perpendicular distance of Cg(I) on ring J plane.

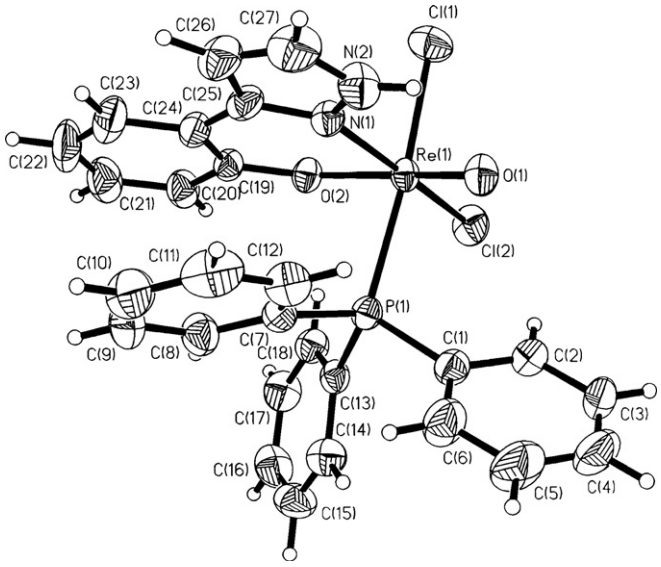

Fig. 2. The molecular structure of **1**. Displacement ellipsoids are drawn at 50% probability.

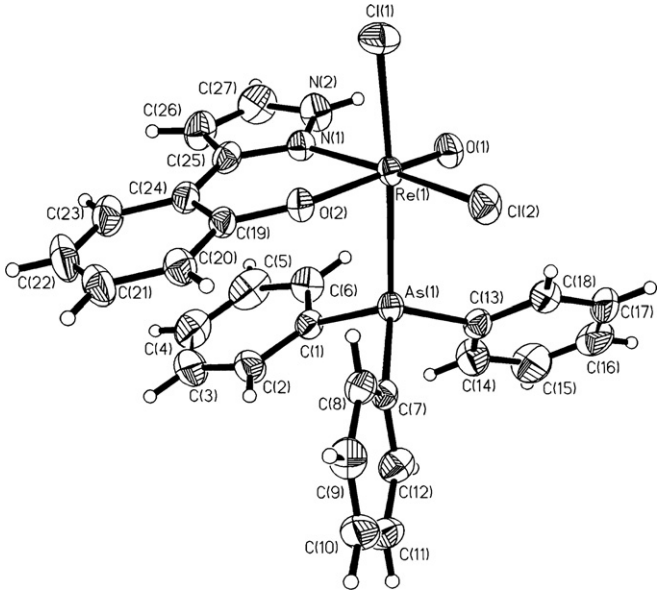

Fig. 3. The molecular structure of **3**. Displacement ellipsoids are drawn at 50% probability.

3. Computational details

The gas phase geometry of **1** was optimized in the singlet ground-state with the DFT method using the hybrid B3LYP [28,29] functional of GAUSSIAN-03 [30]. The LANL2DZ with additional *d* function with exponent $\alpha = 0.3811$ and *f* function with exponent $\alpha = 2.033$ basis set [31,32] was chosen for the rhenium atom and the standard 6-31G basis set for all the other atoms [33,34]. TD-DFT/PCM [35] calculations were employed to produce a hundred singlet excited-states starting from the ground-state geometry optimized in the gas phase.

Natural bond orbital (NBO) calculations were performed with the NBO code [36] included in GAUSSIAN03.

4. Results and discussion

4.1. Preparation and infrared data

The $[ReOX_2(C_9H_7N_2O)(EPh_3)]$ (X = Cl, Br; E = As, P) complexes were prepared in good yields by ligand exchange reactions starting from $[ReOX_3(EPh_3)_2]$ complexes and 2-(1-H-pyrazol-3-yl)phenol in acetone:

$[ReOX_3(EPh_3)_2] + C_9H_8N_2O \rightarrow [ReOX_2(C_9H_7N_2O)(EPh_3)] + HX + EPh_3$ X = Cl, Br; E = As, P.

They were isolated as green microcrystalline solids, soluble in common organic solvents.

The strong ν(Re=O) stretching bands of the $[ReOX_2(C_9H_7N_2O)(EPh_3)]$ compounds are found in the narrow range 960–965 cm^{-1}. They are in the higher end of the range observed for $\{ReO\}^{3+}$ core complexes. It suggests that the Re-hydoxy bond *trans* to the oxo ligand does not compete effectively for the d_{Re} orbitals and indicates the presence of the {O=Re–O} structural subunit in the examined structures. A similar trend is observed for the related Re(V)-oxo complexes with an monoanionic oxygen (RO^- and $R–COO^-$,) *trans* to the oxo group [37].

The H21 and H22 protons (Fig. 2) appear as two doublet of triplets at 6.86 and 6.94 ppm, respectively. Three doublet of doublets at 7.34, 7.21 and 6.61 correspond to H26, H20 and H23, respectively. The H27 proton appears as triplet at 6.63 ppm. The broad singlet at 10.61 ppm is assigned to

4.2. Crystal structures

All the complexes crystallise as acetonitrile solvates in the monoclinic space group $P2_1/c$. The cell packing of **1** is shown in Fig. 1. The intra- and intermolecular contacts, which can be considered as weak hydrogen bonds [38,39] are gathered in Table 2. Table 3 presents a short analysis of the π···π stacking interactions between the rings of the 2-(1-H-pyrazol-3-yl)phenolato ligand and one of the triphenyl phospine rings detected in the examined structures [40].

The molecular structures of **1** and **3** are presented in Figs. 2 and 3, and the selected bond distances and angles of **1**, **3** and **4** are collected in Tables 4 and 5.

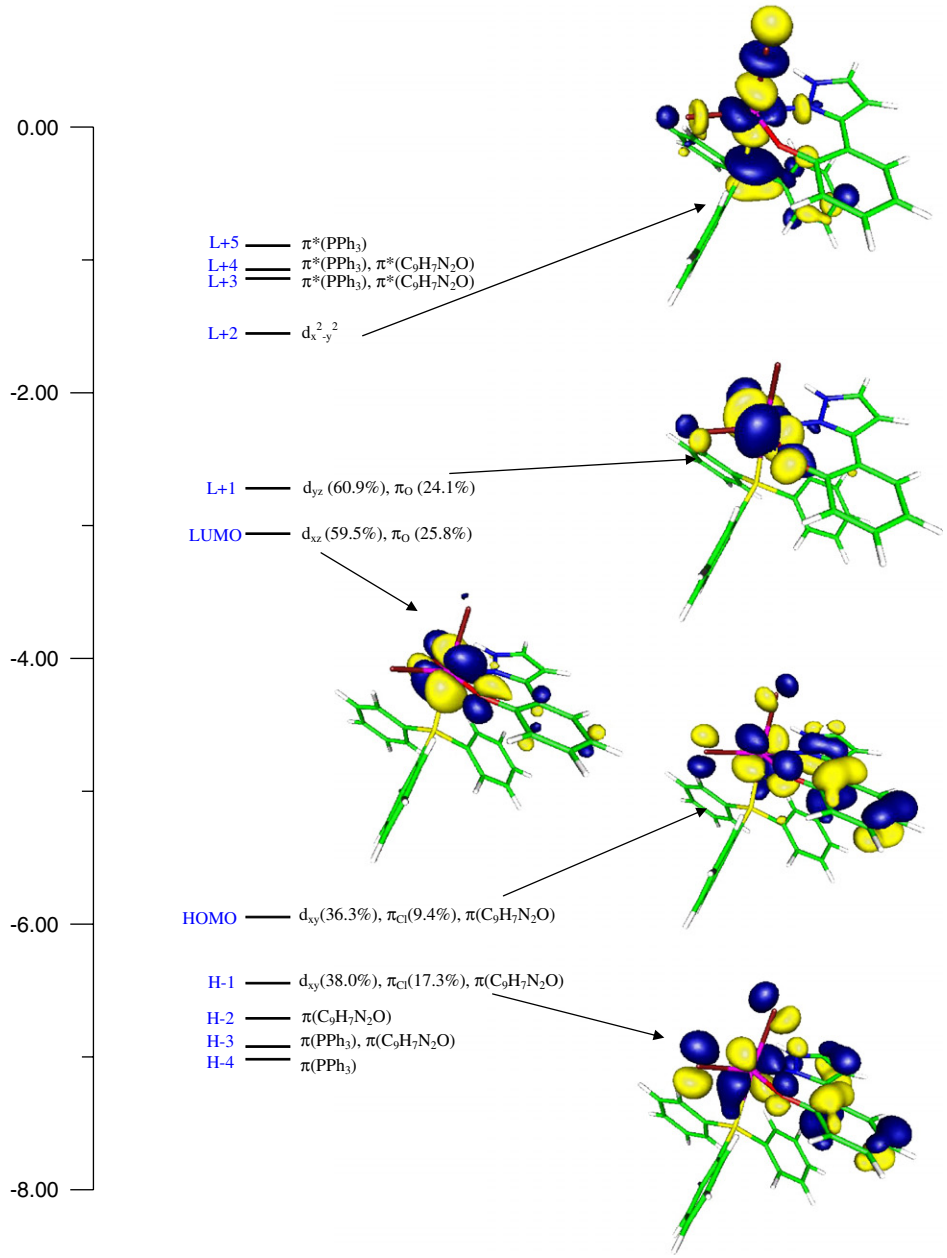

Fig. 4. The energy (eV), character and some contours of the unoccupied molecular orbitals of **1**. Positive values of the orbital contour are represented in blue (0.04 au) and negative values – in yellow (−0.04 au). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 7
The occupancy of the calculated natural bond orbitals (NBOs) between the rhenium and the oxo ligand for **1**

BD	Occupancy	BD	BD*	Occupancy
Re–O_t	1.988	$0.559(d)_{Re} + 0.829(p)_O$	$0.829(d)_{Re} - 0.559(p)_O$	0.285
Re–O_t	1.990	$0.565(d)_{Re} + 0.825(p)_O$	$0.825(d)_{Re} - 0.565(p)_O$	0.305

BD denotes 2-center bond, * denotes antibond NBO.

The geometry of $[ReOX_2(C_9H_7N_2O)(EPh_3)]$ compounds reveals typical features of quasi-octahedral oxorhenium-(V)complexes with oxygenated bidentate ligands. In each complex, the rhenium atom is coordinated by a terminal oxygen atom (O_t), two halide ions in *cis* arrangement, the phosphorus or arsine atom from EPh_3 molecule, and the bidentate N,O donors of the 2-(1-H-pyrazol-3-yl)phenolato ligand. The oxygen atom of 2-(1-H-pyrazol-3-yl)phenolato ligand occupies *trans* position to the terminal oxo ion. The deformation of the octahedron is caused by the presence multiple bonding ligand (terminal oxo) and narrow bite angle of the chelating ligand. The high concentration of electronic density along the Re–O_t axis strongly influences the positions of the adjacent halogen atoms, which are pushed away.

The Re–O_t bond lengths of $[ReOX_2(C_9H_7N_2O)(EPh_3)]$ complexes fall in the range 1.639–1.76 Å, typical of mononuclear complexes of rhenium(V) having $[ReO]^{3+}$ core, and indicate the presence of a triple bond Re≡O [41]. The interatomic distances between the rhenium atom and the oxygen atom of 2-(1-H-pyrazol-3-yl)phenolato ligand are somewhat shorter than an ideal single Re–O bond length (ca. 2.04 Å) [42], It indicates small delocalization in the O(2)–Re(1)–O(1) moiety. The similar trend is observed for many Re(V)-oxo complexes with an monoanionic oxygen *trans* to the oxo group [43].

The Re1–X(1) distances *trans* to the phosphorus or arsine atom of EPh_3 molecule are slightly longer than the Re1–X(2) bonds *trans* to the nitrogen atom of the 2-(1-H-pyrazol-3-yl)phenolato ligand. It is a consequence of *structural trans* effect of the EPh_3 ligands.

4.3. Geometry optimisation, charge distribution, electronic structure and NBO analysis

The geometry of **1** was optimised in a singlet state by the DFT method with the B3LYP functional. The energy of the triplet state is of 15.9 kcal/mol higher. The optimized geometric parameters of **1** are gathered in Table 4. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data (discussed above) are well reproduced in the calculations.

Table 6 presents the atomic charges from the Natural Population Analysis (NPA) for **1**. The calculated charge on the rhenium atom in **1** is considerable lower than the formal charge +5, corresponding d^2 configuration of the central ion. It results from charge donation from the oxo ligands, halide ions and phosphine molecule. ligands. The P atom is positively charged, and the charges on the terminal oxo, chloride and oxygen atom of 2-(1-H-pyrazol-3-yl)phenolato are significantly smaller than −2, −1 and −1, respectively. The terminal oxo ions are less negative in comparison with the oxygen atoms of 2-(1-H-pyrazol-3-yl)phenolato ligand. It indicates the higher electron density delocalization from the terminal ligand towards the rhenium center and corresponds to differences in the Re–O(1) and Re–O(2) bond lengths.

The energies and characters of several highest occupied and lowest unoccupied molecular orbitals of **1** are presented in Fig. 4. The local symmetry of the rhenium centre

has been considered in the discussion: z axis goes along the O–Re–O linkage, and x axis – through the P–Re–Cl bonds. The HOMO–LUMO gap of **1** equals to 2.89 eV. Two highest occupied MOs are delocalized among d_{xy} rhenium orbital, chloride and 2-(1-H-pyrazol-3-yl)phenolato orbitals. The LUMO and LUMO + 1 are predominately localized on the rhenium atom (d_{xz} and d_{yz} orbitals) with some contribution of p_π oxygen orbitals. They can be ascribed as π-antibonding rhenium–oxygen molecular orbitals. The LUMO + 2 is of $d_{x^2-y^2}$ character, and d_{z^2} rhenium orbital contributes to the LUMO + 11.

Since the rhenium atom has d^2 electronic configuration, the empty $5d_{xz}$ and $5d_{yz}$ orbitals are available to overlap with $2p_x$ and $2p_y$ orbitals of the terminal oxygen to form an effective triple bond.

The nature of rhenium–terminal oxygen interaction in **1** has been studied by NBO analysis. The occupancy and composition of the calculated Re–O_t natural bond orbitals (NBOs) are given in Table 7.

Each natural bond orbital (NBO) σ_{AB} can be written in terms of two directed valence hybrids (HHOs) h_A and h_B on atoms A and B:

ε – molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$); f – oscillator strength; H – highest occupied molecular orbital; L – lowest unoccupied molecular orbital.

$$\sigma_{AB} = c_A h_A + c_B h_B$$

where c_A and c_B are polarization coefficients. Each valence bonding NBO must in turn be paired with a corresponding valence *anti*-bonding NBO:

$$\sigma^*_{AB} = c_B h_A - c_A h_B$$

to complete the span of the valence space. The Lewis-type (donor) NBOs are thereby complemented by the non-Lewis-type (acceptor) NBOs that are formally empty in an idealized Lewis picture. The interactions between 'filled' Lewis-type NBOs and 'empty' non-Lewis NBOs lead to loss of occupancy from the localized NBOs of the idealized Lewis structure into the empty non-Lewis orbitals, and they are referred to as 'delocalization' corrections to the zeroth-order natural Lewis structure [36].

Two detected natural Re–O_t bond orbitals of **1** are π orbitals – the p_x and p_y oxygen orbitals and d_{xz} and d_{yz} rhenium orbitals are involved in their formation. Not detected σ_{Re-O_t} bond has character of predominant Coulomb-type interactions between the central ion and ligands [44]. The terminal oxo ligand of **1** has two lone pair orbitals, and electron density from one of them is strongly delocalized into non-Lewis rhenium orbital. Accordingly, NBO analysis confirms a triple bond between the rhenium and the terminal oxygen ligand.

4.4. Electronic spectra

The electronic spectra of $[ReOX_2(C_9H_7N_2O)(EPh_3)]$ complexes are very similar in terms of the position, intensity and shape of the bands in the whole region 1000–180 nm. The positions and molar absorption coefficients of electronic bands for $[ReOX_2(C_9H_7N_2O)(EPh_3)]$ complexes are given in Table 8.

The experimental and calculated electronic spectra of **1** are presented in Fig. 5. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}. Table 9 presents the calculated singlet–singlet electronic transitions of **1** and their assignments to the experimental bands. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.020 are listed in Table 9.

The assignment of the calculated transitions to the experimental bands is based on the criterion of the energy and oscillator strength of the calculated transitions. In the description of the electronic transitions the HOMO orbital is described as d_{Re} orbital, whereas the participation of d_{Re} in the H − 1 orbital is omitted.

The longest wavelength experimental bands of **1** at 814.2 and 686.8 nm are attributed to the transitions of d → d character. The *Ligand–Metal Charge Transfer* ($\pi(PPh_3)/\pi(Cl)/\pi(C_9H_7N_2O)$ → d) transitions make the largest contribution into the experimental band at 401.4 nm. The absorption band at 283.4 nm is mainly assigned to *Metal–Ligand Charge Transfer* excitations, whereas the experimental bands at 224.2 and 208.0 nm result mainly from the *Ligand–Ligand Charge Transfer* and interligand (IL) transitions.

5. Supplementary material

CCDC 659177, 659178, and 659179 contain the supplementary crystallographic data for $C_{29}H_{25}Cl_2N_3O_2Pre$, $C_{29}H_{25}Cl_2N_3O_2AsRe$ and $C_{29}H_{25}Br_2N_3O_2AsRe$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgement

The GAUSSIAN03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland.

property via chelating ability of hydrophilic carboxylate group. Such pronounced effects have already resulted in good dispersibility of CuO nanoparticles in variety of organic solvents such as *n*-octane, *n*-dodecane and *n*-hexadecane [15].

However, we have explored somewhat different approach where in the precursor is devised utilizing the coordination tendency of carboxylate group of oleic acid and the resultant precursor possesses chelated iron center surrounded by hydroxide-gel. This may lead to the generation well segregated iron nuclei in the matrix of oleate groups which upon appropriate chemical treatment may result in small sized, well-dispersed and structurally defined nanoparticles. The present communication describes the nonaqueous synthesis of iron oxide nanoparticles using iron hydroxy-oleate precursor in different organic solvents such as hexadecane, 2-pyrrolidinone and 1-methylnaphthalene generating high-purity iron oxide nanocrystals.

2. Experimental

2.1. Materials

In the present exercise, iron(III) nitrate nonahydrate (99.5%) ammonia (30% v/v) were obtained from Samchun Chemicals while oleic acid, hexadecane, 2-pyrrolidinone and 2-methyl naphthalene were purchased from Aldrich Chemical Co. and were used as received.

2.2. Synthesis of iron hydroxy-oleate precursor

The iron hydroxy-oleate precursor was prepared from iron(III) nitrate and oleic acid. In 200 ml of commercial ethanol, 20.0 g of $Fe(NO_3)_3 \cdot 9H_2O$ was dissolved. To this solution, 7.06 g of oleic acid in 10 ml of ethanol was added with constant stirring followed by a rapid addition of 20 ml of concentrated NH_3 (30%) under vigorous stirring. After the addition of ammonia, the brown colored solution was stirred for 30 min and the as-formed precipitate was filtered, washed well with hot ethanol (5–6 times). The washed precipitate was dried at room temperature overnight.

2.3. Synthesis of iron oxide nanoparticles

In a typical preparation of iron oxide nanocrystal, 2.0 g of iron hydroxy-oleate precursor was suspended in 50 ml of hexadecane and 2.7 g of oleic acid was added at room temperature. The reaction mixture was heated to 250 °C with constant stirring in an oil bath and then kept at that temperature for 2 h. The resulting solution containing nanocrystals was then cooled to room temperature and the excess of ethanol (100 ml) was added to it. A brown precipitate formed immediately, which was isolated by centrifugation at 3000 rpm for 30 min and finally purified with ethanol (3–4 times).

The synthesis was also carried out in two other solvents viz. 2-methylnaphthalene and 2-pyrrolidinone under the similar conditions. The nanoparticles prepared in different solvents are abbreviated as Fe_1 (hexadecane), Fe_2 (2-methylnaphthalene) and Fe_3 (2-pyrrolidinone).

2.4. Characterization

The XRD patterns of as-prepared iron-oxy precursor and iron oxide particles were examined by Rigaku D/MAX IIIB X-ray diffractometer with Cu Kα radiations while FT–IR spectra were recorded on BIO-RAD FT–IR spectrometer (FTS165). The TG/DTA analysis of precursor under N_2 was carried out on Setaram TG 92–12 from 20 to 700 °C at a heating rate of 10 °C/min. The morphological analyses of iron oxide nanomaterial were performed on SEM (Phillips XL30S FEG microscope) and TEM (Model-EM 912Ω, Leo Zeiss Germany). Photoluminescence (PL) emission and excitation spectra of powder sample as well as dispersed solution in $CHCl_3$ were obtained using a Perkin–Elmer LS50B luminescence spectrometer. XPS were recorded with nine channeltron CLAM4 analyzer under vacuum better than 1×10^{-8} Torr using Mg Kα radiation and a constant energy of 50 eV.

3. Results and discussion

The objective of the present work is focused on the nonaqueous synthesis of iron oxide nanoparticles and for this purpose different organic solvents are used. The precursor molecule is designed in such a way that the surfactant molecule will not only function as capping agent but also its coordination tendency will also be effectively utilized for the generation of small sized hydroxide gel. These precursor molecules shall then be decomposed in appropriate organic solvent at elevated temperatures without the loss of capping agent during the synthesis. Being a long chain carboxylic acid, oleic acid is found to possess both these tendencies and its effectiveness has already been explored for CuO nanoparticles [15]. Thus, in the present case, the iron oxide nanoparticles are prepared using oleic acid, which is used both as coordinating and capping agent.

3.1. Thermal studies

In order to determine the decomposition temperature for the formation of iron oxide nanoparticles, the iron hydroxy-oleate precursor was subjected for thermogravimetric studies under N_2 atmosphere at heating rate of 10 °C/min. The thermal pattern exhibits (Fig. 1) two distinct stages of thermal decomposition; the first peak around 100 °C corresponds to desorption of water molecules from the grain surfaces while the other peak centered around 250 °C is probably originating form the onset of thermal decomposition of oleate molecules. Afterwards, there is gradual weight loss with the formation of oxide phase. Similar behavior is also noted for DTA curve with

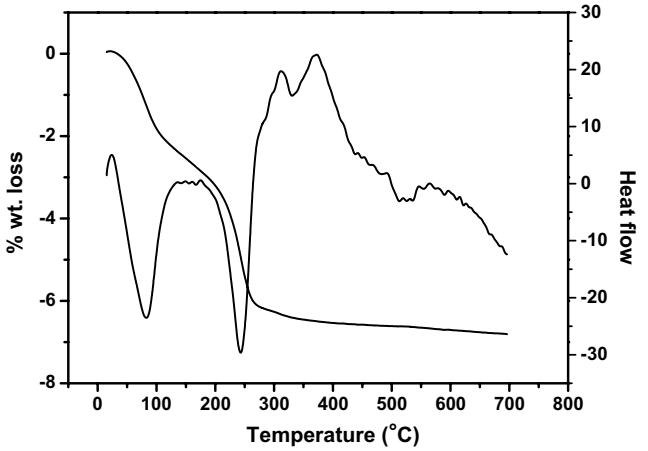

Fig. 1. Thermogravmetric profile of iron hydroxy-oleate precursor.

two endothermic peaks suggesting that the decarboxylation proceeds thorough liberation of oleate fragment from the precursor molecule. From such decomposition patters, it is significant to note that the formation of stable iron oxide phase can be achieved during the thermal decomposition of the iron hydroxy-oleate precursor around 250 °C in various organic solvents thus generating oleate capped iron oxide nanoparticles.

3.2. FT-IR characterization

It is observed that the carboxylate absorption in free oleic acid (1711 cm^{-1}) is considerably shifted towards lower energy side which appears as a doublet for precursor molecule (Fig. 2). Since these two bands are not symmetric in nature as well as they are well separated by almost 150 cm^{-1}, the oleate group is functioning as a bridge (Fig. 2a) between precursor molecules indicating the strong associations through electrostatic interactions [16]. After the thermal treatment of precursor, the presence of splitted absorption at 1534 and 1431 cm^{-1} for Fe_1 (Fig. 2b) reveals the anchoring of the oleate molecules on the surfaces of iron oxide nanoparticles while the bands at 2925 and 2856 cm^{-1} due to $–CH_2$ and $–CH_3$ signify that oleate group still remains as a part of iron oxide nanoparticles. In addition to these changes, the spectrum of capped iron oxide nanoparticles exhibit characteristic Fe–O stretches at 594 and 459 cm^{-1} from iron oxide network.

3.3. XRD analysis

Fig. 3 presents the XRD patterns of iron hydroxy–oleate precursor before (as received) and after thermal treatment in different solvents. It is observed that the precursor material exhibits very broad reflections due to formation small-sized particles (30–40 nm) as evaluated using Scherrer equation showing partial crystallinity. Upon thermal treatment in organic solvents at 250 °C for 2 h, the initial broad signals are replaced with sharp and intense reflections in the 2θ regions 20–80° pointing to the formation of nanocrystalline iron oxide particles. Inspection of these features reveals that iron hydroxy-oleate precursor undergoes structural changes during the thermal decomposition process resulting in the formation of hematite nanoparticles. The characteristic d-spacing values obtained for the reflections due to different planes are in agreement with the reported values (JCPDS No. 33-663) suggesting the presence of α-phase [17,18] of iron oxide (α-Fe_2O_3). The average crystallite sizes evaluated from Scherrer equation for Fe_1–Fe_3 are found to be 32.6, 31.5 and 22.6 nm respectively. However, it is observed that there exists an effect of organic solvent on the morphologies of nanocrystals formed during their synthesis as evidenced from the peak intensities as well as shape of the characteristic oxide phase. For example, the smaller particle size is observed for α-Fe_2O_3 prepared in hexadecane (Fe_1) while for Fe_2 and Fe_3, there seems to be not much of difference in their sizes. Such a size and structural features dependency with the solvent used for synthesis may be originating from the fact that the oleate capping is less effective in hexadecane due to its

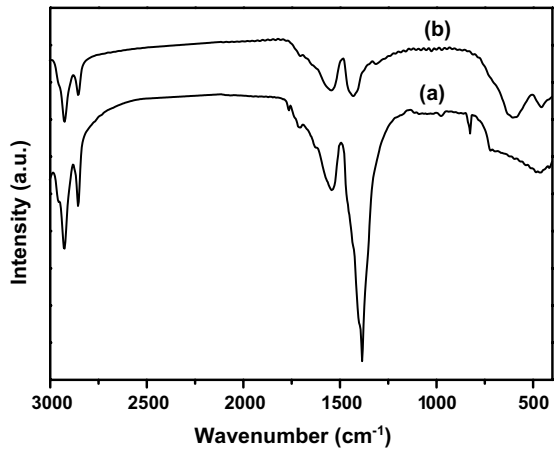

Fig. 2. FT-IR spectra of: (a) iron hydroxy-oleate precursor and (b) Fe_1.

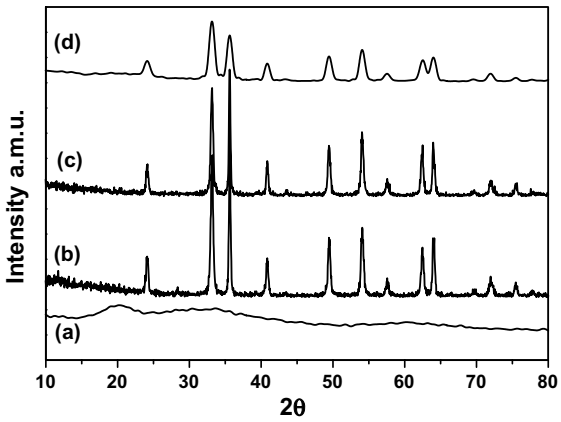

Fig. 3. XRD patterns of: (a) iron hydroxy oleate precursor; (b) Fe_1; (c) Fe_2 and (d) Fe_3.

higher solubility while remaining two solvents have pronounced effect on the crystal growth during the synthesis of iron oxide nanoparticles.

3.4. SEM and TEM analysis

The SEM image of precursor indicates the presence of agglomeration for precursor particles having diameters ranging from 30 to 40 nm. However, the SEM pictures of Fe_2 and Fe_3 (Fig. 4b, c) reveal the spherical-globular clusters with acicular shapes of α-Fe_2O_3 indicating that these particles are agglomerated. On the other hand, TEM photograph of Fe_1 (Fig. 4a) exhibits a cubic shape having particle size of about 30 nm with almost monodisperse phase while Fe_2 and Fe_3 display spherical morphology (Fig. 4b and c) with particle size of about 20 nm. It is evident form this analysis that the morphologies from irregular shape (Fe_2 and Fe_3) transforms into a regular cubic geometry with increase in the particle size (Fe_1). Also, the particle size of Fe_1 observed from TEM measurements is comparable with the one calculated by XRD revealing that the particles are polycrystalline in nature having almost monodisperse phase while Fe_3 consists of a large number of smaller subparticles of tens of nanometers; a feature already been noted by other coworkers [19].

3.5. Photoluminescence studies

It has been reported earlier that bulk hematite exhibits an absorption band around 400 nm attributed to d–d transition [20] while high-energy bands are originating from charge transfer process [21]. However, the criterias are quite different for nanoparticles where the large surface-to-volume ratios induce defects on the surface of particles and bonding of these molecules may result in changes of electronic structures of the particle. It is suggested that localized d–d transition near band-edge as well as other states like 4s or 4p may be involved in the band-edge transition as result of organosol formation between iron oxide nanoparticles and carboxylate groups resulting in a photoluminescent properties for capped iron oxide. Fig. 5 depicts photoluminescence spectra of Fe_1 in solid as well as its dispersion in toluene which are excited at 400 nm. Inspection of this figure reveals that bulk iron oxide (Fe_1) exhibit emission band at lower energy (592 nm) as compared to dispersed organosol (446 nm) indicating that the bulk nanoparticles are agglomerated while they are well dispersed in solution. Red shift of about 55 nm with peak broadening for the bulk is indicative of band-edge emission with decrease in the band-gap. Considering the large Stokes shift of emission peak compared with excitation line, it is attributable to bound-exciton emission, as usually

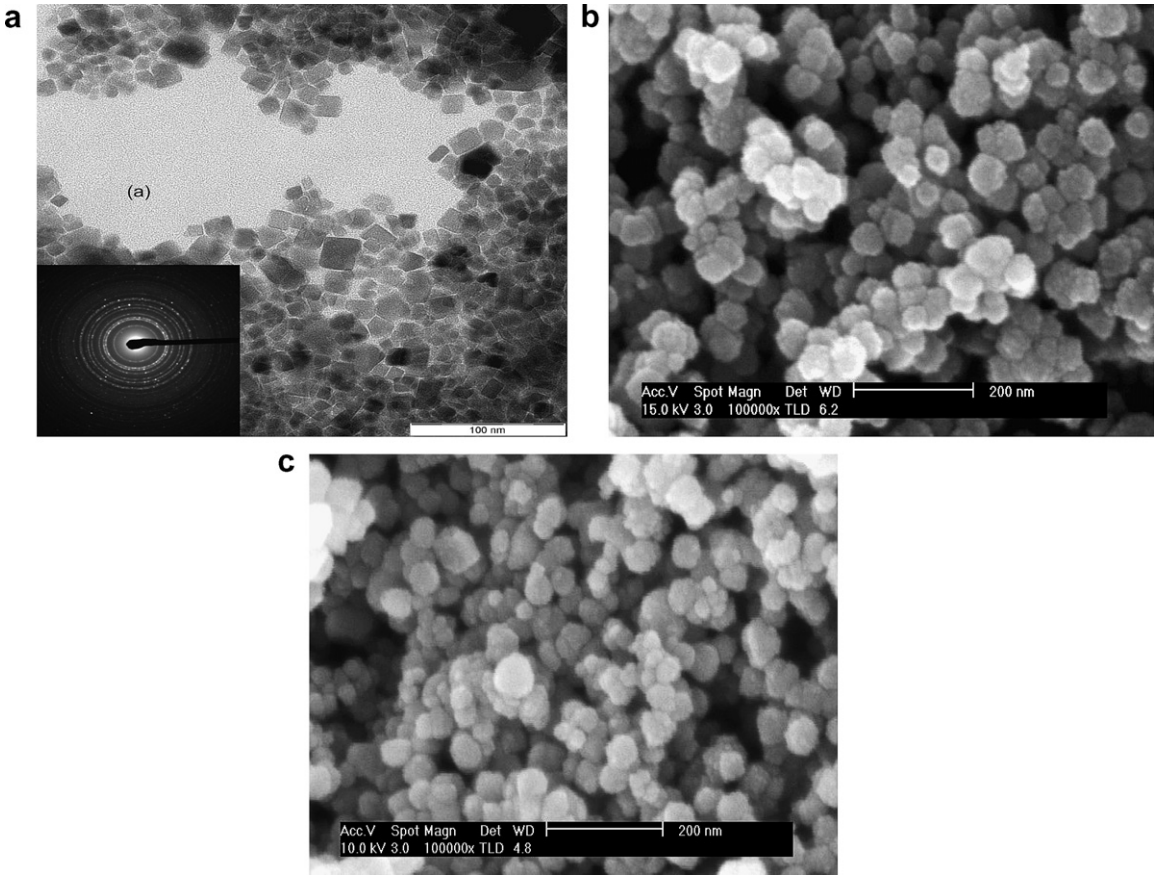

Fig. 4. Morphology of iron oxide nanoparticles: (a) TEM image with SAED pattern of Fe_1, SEM images of Fe_2 (b) and Fe_3 (c).

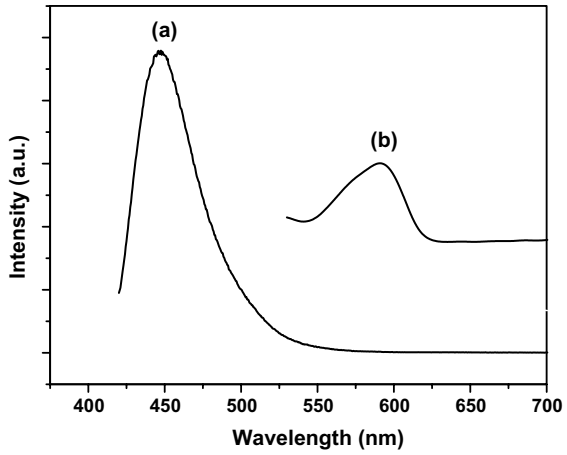

Fig. 5. The photoluminescence spectra of: (a) dispersed solution of Fe_1 in toluene and (b) solid Fe_1 nanocrystals at 400 nm excitation wavelength.

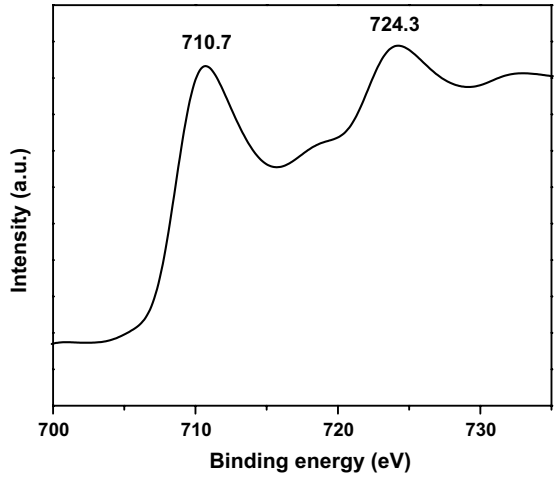

Fig. 6. XPS spectrum for Fe_1.

observed for typical semiconductor nanoparticles. Therefore, it can be argued that the photoluminescence is essentially observed due to the surface modifications of nanoparticles, as observed for hematite nanocrystals with dodecyl benzene sulfonate [22] and pyrene carboxylic acid [23] surfactants.

3.6. XPS measurements

XPS measurements have provided valuable information about the oxidation state as well as surface state of the nanoparticles. The binding energies at 710.7 and 724.3 eV are the characteristic doublet from Fe $2p_{3/2}$ and Fe $2p_{1/2}$ core electrons, respectively (Fig. 6). The spectra of nanoparticles not only matched with the peak positions but also the shapes of the curves reported for α-Fe_2O_3. Moreover, the intensity ratio of the doublet suggests that nanoparticles exclusively exists in the α-form of iron oxide as γ-iron oxide possess difference in the intensity of the doublet with the former peak having about twice the intensity as compared to later peak [24].

4. Conclusion

Solvothermal decomposition of iron hydroxy-oleate precursor in organic solvents in presence of oleic acid can be an effective method for synthesizing iron oxide nanoparticles exhibiting organophilic character. It is observed that these nanocrystals possess cubical as well as spherical morphologies depending upon the solvent employed for synthesis having size of 20–30 nm. Present investigation also highlights an effective way to synthesize surfactant-modified nanoparticles via pre-dispersed precursor molecule thus inferring that dispersibility may be achieved via surface modification technique. The morphology is found to be strongly influenced by the solvents used for the synthesis while the band-edge emission of dispersed nanoparticles is indicative of surface modifications as revealed from the PL measurements. Such modifications bearing the structural network incorporated in functional groups of capping agent possess high technological and biological importance and certainly are the subject of future work in the field of colloidal chemistry.

A meticulous search on the literature discloses numerous studies on many transition metal complexes with hydroxypyrones but little or no work on Ru thus far [14–17]. Hence, the present work aims at the synthesis and characterization of Ru(II) and Ru(III) complexes of a hydroxypyrone ligand, namely dehydroacetic acid (DHA), in order to explore their biological activities such as DNA-binding and antibacterial activity.

2. Experimental

2.1. Materials and methods

All chemicals were of reagent grade and were used without further purification. Dehydroacetic acid was obtained from Acros organics and solvents were purified following the literature procedures [18]. Protein free Herring Sperm ds DNA obtained from SRL chemicals was stored at 0–4 °C and its purity was checked by measuring the optical density before use. The Tris-buffer solution was prepared with double-distilled water and its pH was adjusted to 7.1 using 0.1 M NaOH solution. DNA stock solutions were freshly prepared with this buffer solution before use. Distilled DMSO (dimethylsulfoxide) was used for the preparation of solutions of the complexes for DNA-binding studies. Commercially available TBAP was properly dried and used as a supporting electrolyte for recording cyclic voltammograms of the complexes (except for DNA-binding studies). The starting complexes $[RuCl_3(PPh_3)_3]$, $[RuCl_3(AsPh_3)_3]$, $[RuBr_3(AsPh_3)_3]$, $[RuHCl(CO)(PPh_3)_3]$, $[RuH_2(CO)(PPh_3)_3]$ and $[RuHCl(CO)(AsPh_3)_3]$ were prepared as described in the literature [19–23].

FT-IR spectra (4000–400 cm^{-1}) of the complexes and the free ligand were recorded as KBr pellets with a Nicolet Avatar Model FT-IR spectrophotometer. Electronic spectra (800–250 nm) of the complexes were obtained on a Systronics 119 UV–Vis spectrophotometer. Room temperature EPR spectra of powdered samples were recorded on an E-112 Varian model instrument in X-band frequencies using DPPH as an internal standard. Magnetic moments were measured on an EG&G-PARC vibrating sample magnetometer at 25 °C. ^1H NMR spectra of the complexes were recorded using a Varian-Australia AMX-400 instrument. Micro analyses (C, H, N and S) were performed on a Vario EL III Elementar analyzer. Cyclic voltammograms were recorded on a CHI 1120A Electrochemical analyzer with a three electrode compartment consisting of a platinum disc working electrode, platinum wire counter electrode and Ag/Ag^+ reference electrode.

2.2. Synthesis of $[RuCl(CO)(PPh_3)_2(L)]$ (1)

$[RuHCl(CO)(PPh_3)_3]$ (0.996 g, 0.1 mmol) was suspended in a mixture of dry ethanol (15 mL) and benzene (10 mL). To this the ligand dehydroacetic acid (0.0168 g, 0.1 mmol) was added. After refluxing the mixture for 10 h, it was cooled and filtered. On evaporation of the solvent to a small volume, the complex separated out. It was filtered and recrystallized from $CHCl_3$/petroleum ether (1:1) mixture. The other Ru(II) complexes, namely $[RuCl(CO)(AsPh_3)_2(L)]$ (**2**) and $[RuH(CO)(PPh_3)_2(L)]$ (**3**), were prepared by the same procedure starting from $[RuHCl(CO)(AsPh_3)_3]$ and $[RuH_2(CO)(PPh_3)_3]$, respectively.

2.3. Synthesis of $[RuCl_2(AsPh_3)_2L]$ (4)

$[RuCl_3(AsPh_3)_3]$ (0.113 g, 0.1 mmol) was suspended in a mixture of dry ethanol (15 mL) and benzene (10 mL). To this the ligand dehydroacetic acid (0.0168 g, 0.1 mmol) was added. The mixture was then refluxed for 10 h, then the solution was filtered and allowed to stand for 3 days whereby a microcrystalline product appeared. Addition of 20 ml of DMF to the solution yielded single crystals suitable for X-ray diffraction. The product was washed with cold methanol and dried.

The other Ru(III) complexes, namely $[RuCl_2(PPh_3)_2L]$(**5**) and $[RuBr_2(AsPh_3)_2L]$(**6**), were synthesized by a similar procedure starting from $[RuCl_3(PPh_3)_3]$ and $[RuBr_3(AsPh_3)_3]$, respectively. However no single crystals could be grown for the products even after several attempts.

2.4. X-ray structure determination

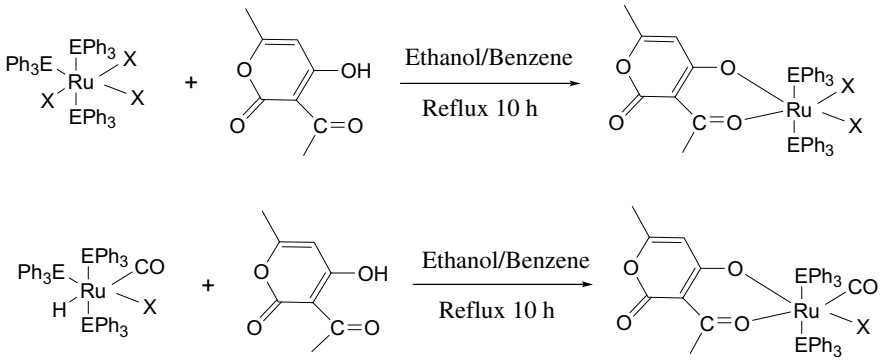
X-ray diffraction measurements were performed on a Bruker AXS SMART APEX CCD diffractometer with graphite monochromatised Mo Kα radiation. The unit cell was determined using SMART [24a] and SAINT+ [24b], and the data were corrected for absorption using SADABS [24c]. The structure was solved by direct methods and refinements were carried out by full-matrix least-square techniques. The hydrogen atoms were treated by a mixture of independent and constrained refinement. The computer program SHELXTL 6.14 [24d] was used for structure solution, refinement and molecular graphics. Refinement of an extinction coefficient was found to be insignificant. All non-hydrogen atoms were refined anisotropically. The chelating DHA ligand is flip disordered. The occupancy ratio for both moieties refined to 0.732(7) to 0.268(7). For the minor component the following restraints have been applied. The whole ligand was restraint to have the same shape as its major component counterpart (SAME instruction, standard deviation = 0.02). The atoms C5b, C6b, O2b and O3b were restraint to be flat (standard deviation = 0.1), and the atoms C3b, C4b, O2b and C2b were restraint to have similar anisotropic displacement parameters. The following pairs of atoms were restraint to each have identical anisotropic displacement parameters: O1 and O4b, O1b and O4, C6 and C6b, C5 and C5b, C2 and C2b, C8 and C8b, O2 and O3b, C1 and C7b, and C1b and C7. Hydrogen atoms were placed in calculated positions and were refined with an isotropic displacement parameter 1.2 (C–H and CH_2) or 1.5 (CH_3) times that of the adjacent carbon atom.

2.5. Antimicrobial screening and determination of minimum inhibitory concentration

The agar well diffusion method was employed for the determination of antimicrobial activities. MICs (minimum inhibitory concentration) of the compounds against test organisms were determined using the broth micro dilution method [25]. All the tests were performed in duplicate and repeated twice. Modal values were selected. The compounds were weighed and dissolved in DMSO and were filter sterilized using a 0.45 μm membrane filter. Each microorganism was suspended in sterile saline and diluted to ca. 106 colony forming units (cfu/ml). They were flood inoculated on to the surface of Mueller–Hinton Agar (MHA). The wells (8 mm in diameter) were cut from the agar and 0.1 mL of solution was delivered into them. After incubation for 24 h at 37 °C, all plates were examined for any zones of growth inhibition, and the diameter of these zones were measured in millimeters.

A broth microdilution broth susceptibility assay was used as recommended [26] by NCCLS for determination of the MIC. All the tests were performed in Mueller–Hinton Broth (MHB) supplemented with Tween-80 detergent (final concentration of 0.5% (v/v)). Bacterial strains were cultured overnight at 37 °C in MHA. Test strains were suspended in MHB to give a final density of 5×10^5 cfu/ml and these were confirmed by viable counts. Geometric dilutions of the compounds were prepared in a 96-well microtiter plate, including one growth control (MHB + Tween 80) and one sterility control (MHB + Tween 80 + Compound). The plates were incubated under normal atmospheric conditions at 37 °C for 24 h. The MIC of kanamycin and oxytetracycline was individually determined in parallel experiments in order to control the sensitivity of the test organisms. The bacterial growth was indicated by the presence of a white "pellet" on the well bottom.

3. Results and discussion



Complexes of the general formulae $[RuX(CO)(EPh_3)_2(L)]$ and $[RuX_2(EPh_3)_2(L)]$ (E = P or As, X = H, Cl or Br and L = monoanion of DHA) were obtained by the reaction of the precursors $[RuX_3(EPh_3)_3]$ and $[RuHX(CO)(EPh_3)_3]$ with the ligand. All the new complexes are stable to air and light and are soluble in most common organic solvents. The analytical data of the metal complexes fit well with the molecular formulae suggested above. The method of synthesis of the complexes is displayed in Scheme 1.

3.1. IR spectra

The new ruthenium complexes were also studied by IR spectroscopy. In the free ligand, three bands at 1713, 1642 and 1252 cm^{-1} have been ascribed to the stretching vibrations of $\nu_{C=O}$(lactone), $\nu_{C=O}$(carbonyl) and ν_{C-O} (phenolic), respectively [27]. In all the complexes $\nu_{C=O}$(lactone) remains unaltered while the other two peaks shift to 1648–1658 cm^{-1} and 1272–1276 cm^{-1}, respectively. The absence of ν_{OH} at 3400 cm^{-1} suggests the deprotonation of the phenolic oxygen prior to coordination [28]. This is further substantiated by the absence of a ^1H NMR signal for the OH group around δ 11.3 ppm for all the complexes. The strong absorption around 1960 cm^{-1} has been assigned to the coordinated terminal carbonyl group and in the hydrido complex ν_{Ru-H} appears at 2010 cm^{-1}. From the IR spectral data, it has been concluded that DHA behaves as a monobasic bidentate ligand coordinating through the deprotonated phenolic oxygen and the carbonyl oxygen.

3.2. Electronic spectra

The electronic spectra of the complexes were recorded in $CHCl_3$ in the 250–800 nm region. For a low-spin d^5 system in an octahedral environment, the ground state is $^2T_{2g}$ arising from a t_{2g}^5 configuration. The next higher energy configuration $t_{2g}^4e_g^1$ gives rise to four states, namely $^2A_{2g}$, $^2A_{1g}$, $^2T_{1g}$ and $^2T_{2g}$, and so four bands are expected. In most Ru(III) complexes, the absorption spectra show only charge transfer bands [29]. In a d^5 system, and especially in Ru(III) which is a relatively good oxidizing agent, the

Scheme 1. Synthesis procedure for the complexes.

charge transfer bands of the type $L_{\pi y} \rightarrow t_{2g}$ are prominent in the low energy region and obscure the weaker bands due to d–d transitions. It, therefore, becomes difficult to conclusively assign bands of Ru(III) complexes which appear in the visible region [30]. The new Ru(III) complexes synthesized in this study showed two to four bands in the region 268–456 nm. The assortment of intense bands exhibited by the complexes in the region 268–359 nm are believed to be ligand centered transitions. In addition, the other bands at 400 and 456 nm have been assigned to charge transfer bands. This is in conformity with the assignments made for other similar Ru(III) octahedral complexes [29]. All the Ru(II) complexes display one intraligand transfer band in the region 309–359 nm, as displayed by other analogous octahedral Ru(II) complexes [29,31].

3.3. ^1H NMR spectra

The ^1H NMR spectra of the Ru(II) complexes were recorded in d_6-DMSO to confirm the binding of DHA to the ruthenium ion. All the complexes showed a sharp peak in the range δ 2.0–2.1 ppm due to the methyl group attached to the pyrone ring. The other peak observed in the range δ 2.4–2.5 ppm is due to the methyl protons of the CH_3–C═O group. A singlet around δ 5.7 ppm was assigned to the vinylic proton. The characteristic multiplets of the PPh_3 or $AsPh_3$ ring protons appear in the range δ 7.2–7.6 ppm. No peak was observed for the OH proton, supporting the assumption that the phenolic group is deprotonated, suggesting coordination through the phenylato oxygen of DHA to the ruthenium.

3.4. Magnetic susceptibility and EPR spectra

Magnetic susceptibility measurements of the Ru(III) complexes showed that they are paramagnetic ($\mu_{eff} = 1.82$–1.93 BM), which corresponds to the +3 state of ruthenium (low-spin d^5, $S = 1/2$) in the complexes. The room temperature EPR spectra of the powdered samples were also recorded at the X-band frequencies. A selected spectrum is shown in Fig. 1. The complexes **5** ($g_\perp = 2.03$, $g_\parallel = 1.95$) and **4** ($g_\perp = 2.38$, $g_\parallel = 2.30$) exhibit two lines indicating a tetragonal distortion and axial symmetry in the complexes. Hence, *trans* positions are assigned for the PPh_3 or $AsPh_3$ groups [32]. On the other hand, complex **6** exhibits a single isotropic line ($g = 2.10$). Such isotropic lines are usually observed either due to intramolecular spin exchange, which can broaden the lines, or due to occupancy of the unpaired electron in a degenerate orbital [33]. The distortion in complex **4** is also supported by its crystal structure.

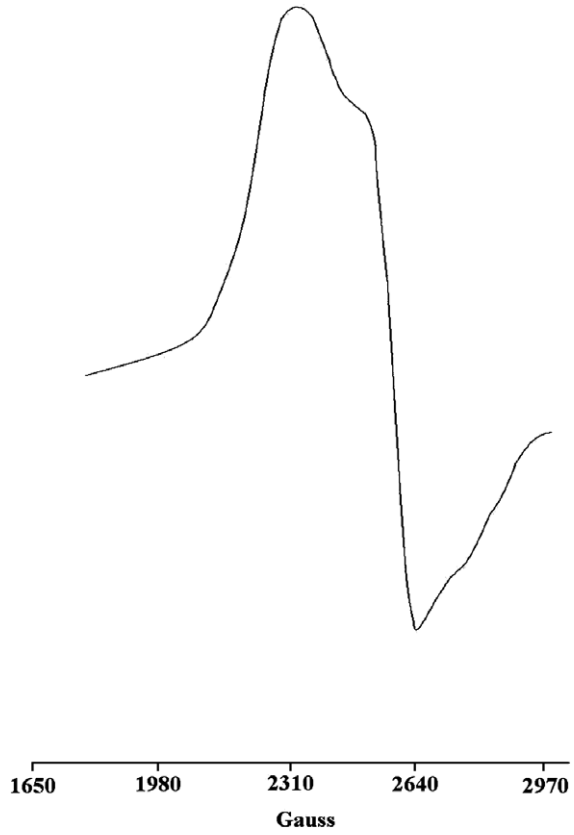


Fig. 1. Powder EPR spectra of **4**.

3.5. Cyclic voltammetry

Cyclic voltammetric experiments were performed with acetonitrile solutions of the complexes. Complexes **4** and

6 showed a quasi-reversible reduction wave (Ru^{III}–Ru^{II}) at −0.71 and −0.69 V, respectively. A close examination of the reduction potentials of the complexes show that the bromo complex is reduced more readily than the corresponding chloro complexes, which is in accordance with a previous study [34]. Similarly the Ru(II) complexes **2** and **3** present a quasi-reversible reduction wave (Ru^{II}–Ru^{I}) at −0.54 V ($\Delta E_p = 910$ mV) and −0.53 V ($\Delta E_p = 830$ mV), respectively. The presence of a π-acidic carbonyl ligand in the Ru(II) complexes helps to stabilize the lower oxidation state of the metal ion. Also, an irreversible oxidation wave ($E_{pa} = 0.64$–0.83 V) is displayed invariably by all the complexes. This may be due to the short lived reduced state of the metal ion [35].

3.6. X-ray crystallography

The molecular structure of complex **4** is shown in Fig. 2. The crystal data are supplied in Table 1 and selected geometrical parameters are listed in Table 2. The coordination sphere around the ruthenium atom consists of two mutually *cis* chloride ligands, an OO chelate of the dehydroacetic acid ligand and two *trans* triphenylarsine ligands. The chelating DHA ligand is flip disordered with a refined occupancy ratio of 0.732(7)–0.268(7). The coordination environment around the ruthenium centre is distorted octahedral in nature. The ligand (DHA) is coordinated to ruthenium as a bidentate OO donor forming a six membered chelate ring with a bite angle (O1–Ru1–O4) of 86.77°. The Ru–As distances (Ru1–As1 = 2.479 and Ru1–As2 = 2.489 Å) are comparable with those of other ruthenium complexes [36,37]. Similarly the two *cis* Ru–Cl distances are almost equal and comparable to those in other Ru(III) complexes [38,39]. However the Ru–Cl distances are shorter than those found in some six coordinated Ru(III) complexes [4,40]. The Ru1–O4(oxy) bond distance of 1.977 Å is significantly shorter than the distance observed in a ruthenium(III)-orthometallated azophenol system [41] (Ru–O = 2.2112 Å), but comparable to Ru–O distances of 1.981 and 1.982 Å found in a ruthenium(III)-salicylaldehydato complex [42] and [Ru(trpy)(L^3)Cl] ClO_4 (L^3 = *o*-$^-OC_6H_3(NO_2)CH{=}NCH_2C_6H_5$) [43], respectively. The Ru–O (keto) bond distance of 2.045 Å agrees well with that reported for other ruthenium(III) complexes [44,45]. From the data, it is obvious that the Ru1–O4 distance is shorter than the Ru1–O1 distance, indicating the stronger preference of the Ru(III) ion for the hydroxyl oxygen than the ketonic oxygen atom. The two chloride ligands bind to ruthenium in a *cis* arrangement (Cl1–Ru1–Cl2 = 95.63), and the Cl anions are opposite to the two oxygen atoms of the chelating ligand. The two axial triphenylarsine ligands are slightly bent towards the *cis* chloride ligands due to the steric bulk of the chelating ligand, causing a slight deviation from a linear *trans* arrangement.

3.7. Antibacterial study

The ligand DHA and its complexes were found to possess antibacterial activity against both the Gram positive (*S. aureus* and *S. epidermidis*) and Gram negative (*S. sonnei*, *E. coli* and *K. pneumoniae*) strains of bacteria. The zone of inhibition in mm and MIC values in μg/ml are given in Table 3. DHA exhibited an inhibition zone ranging from 13 to 16 mm against the test organisms. Complexes **6** and **1** alone were resistive to all the microorganisms with inhibition zones ranging from 12 to 21 mm. The resistivity of **5** against *E. coli* was fairly comparable with that of the standards used in the study and the activity of the other complexes was only to a lesser extent. The Gram negative bacteria *K. pneumoniae* is sensitive only to complexes **1** and **6**. Another Gram negative bacteria *S. sonnei* is sensitive to all the complexes except **4**. The complexes **5** and **3** were non-resistive to the Gram positive bacteria *S. aureus*. Similarly, **4** and **1** show null activity against another Gram positive bacteria, *S. epidermidis*. In some cases the complexes exhibit better activity than the ligand DHA, which can be explained by the faster diffusion of the metal complexes as a whole through the cell membrane or due to the synergistic effect of the ligand and the metal.

3.8. DNA-binding studies

3.8.1. Absorption spectroscopic studies

The experiments were carried out in Tris–HCl buffer (50 mM, pH 7.2) using a solution of Herring sperm DNA which gave a ratio of UV absorbance at 260 and 280 nm of 1.8:1, indicating that the DNA is sufficiently free from protein. So, no further effort was made to purify the commercially obtained DNA. The concentration of DNA was determined by absorption spectroscopy using the ε value of 6600 mol^{-1} cm^{-1} L^{-1} at 260 nm. Absorption titrations were performed using a fixed ruthenium concentration to which increments of the DNA stock solutions were added in different ratios ranging from 0 to 5 [DNA]/[Ru]. Complex-DNA solutions were allowed to stand for 5 min before recording their absorption. The intrinsic binding constants of the complexes could not be evaluated using the equation valid for perfect intercalators like phenanthroline complexes, due to the random changes in the absorption on the addition of DNA.

The binding of the ruthenium complexes to DNA helices was characterized by following the changes in the absorbance and shift in wavelength on each addition of DNA solution to the complex. A representative absorption spectrum is given in the Fig. 3. The ruthenium(II) complexes in DMSO-buffer mixture exhibit an intense transition in the region around 370–310 nm, which is attributed to a $\pi \rightarrow \pi^*$ intraligand transition. On the titration of Herring sperm DNA with the complexes, a considerable increase or decrease in the absorption along with small red or blue shift was observed. The titration process was repeated until no further change was observed in the spectrum. With increasing concentration of DNA, the absorption bands of the complexes were affected to a considerable extent. There was no appreciable change in the absorption bands of complexes **2** and **3** when they were titrated with DNA. Complexes **1** and **5** exhibit 49% and 42% hypochromicity and 21 and 3 nm bathochromism, respectively in the presence of DNA at saturation. These results indicate the interaction between the complexes and DNA is through the intercalation mode [46]. Based on the percentage of the hypochromism, **1** is thought to bind DNA more strongly than **5**. During the titration the extent of hypochromicity and bathochromism varied. This implies binding of the complexes to DNA through different modes to different extents [47]. As the concentration of the DNA was increased, the absorption bands of **4** showed hyperchromism of 12% initially and on further increment, hypochromism of 21% with a blue shift (20 nm) was observed. This behavior reveals an electrostatic association of the complex with the helix surface [46,48]. The existence of different binding modes between **6** and DNA can be realized by analyzing the spectral data.

3.8.2. Cyclic voltammetry

Since all the new complexes are electroactive, electrochemical methods such as cyclic voltammetry can be used

Table 3
Antibacterial activity of DHA and its ruthenium complexes

[b] MIC, minimum inhibitory concentration. Values given as μg/ml for both compounds and antibiotics. NA – not active; NT – not tested.

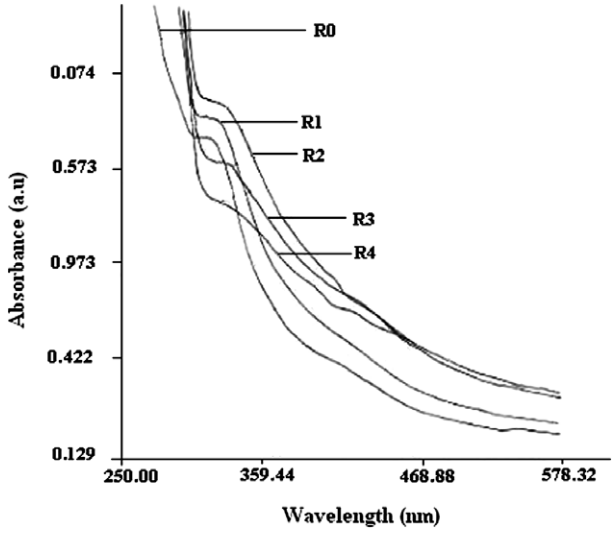

Fig. 3. Change in the absorption of **6** on titration with DNA at different [Ru]/[DNA] ratios (R). R0 = 0, R1 = 1, R2 = 2, R3 = 3, R4 = 4.

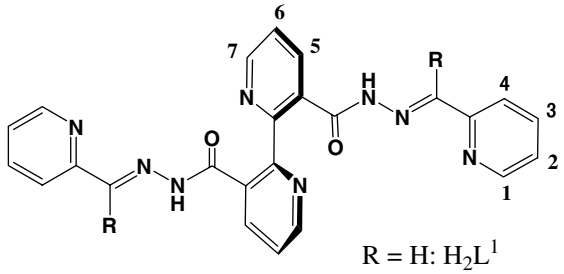
effectively to monitor their binding to DNA as a complement to absorption spectroscopic techniques. In a typical cyclic voltammetric titration a fixed concentration of the complex was taken and DNA solution in buffer was added in different ratios as done in the absorption titration, and the voltammetric response was recorded. As observed in the UV experiments, an increase and decrease of the peak current was observed for all the complexes.

Cyclic voltammetric curves were obtained in the absence and in the presence of DNA. The separation of anodic and cathodic peak potentials suggests a quasi-reversible one electron transfer process. The peak-to-peak separation value differed appreciably when DNA was added to the complex in buffer in comparison with that of the solution containing the complex alone. Reversibility of the electron transfer was maintained in the presence of DNA. The positive shift in reduction potential with increase in concentration of DNA suggests a difference in binding properties of the Ru(III), Ru(II) and Ru(I) species [49]. For **1** and **5**, the addition of DNA causes a decrease in the peak current with a slight shift in E_f to less positive potentials. These behaviors are reflective of intercalation of the metal complexes to the DNA double helix. The initial increase in the peak current for **4** and **6** is due to the electrostatic interaction between these complexes and DNA. The intercalation mode of binding is also observed to a small extent in these complexes.

4. Conclusion

A series of Ru(II) and Ru(III) complexes of dehydroacetic acid were prepared and characterized by analytical, magnetic and spectral techniques. The molecular structure of one of the complexes, studied by single crystal X-ray diffraction, shows that the DHA ligand has coordinated to the metal centre as an OO chelate in the equatorial plane. From the data, the geometry around the ruthenium centre is found to be a distorted octahedron. The same observation has also been evidenced by EPR spectroscopy. The redox properties of the complexes studied by cyclic voltammetry show that the presence of the π-acidic carbonyl ligand in the Ru(II) complexes helps to stabilize the lower oxidation state of the metal ion. All of the complexes along with the ligand DHA were tested for their antimicrobial property against five pathogenic bacteria. Since the compounds could interact with DNA they can be used for probing DNA structures.



Appendix A. Supplementary material

CCDC 608059 contains the supplementary crystallographic data for complex **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2007.11.039.

Scheme 1. The chemical structures of ligand $\mathbf{H_2L^{1-3}}$.

the side chain position can strongly influence the supramolecular structure and the properties of the complexes.

2. Experimental

2.1. Materials and instrumentations

All chemicals were of reagent grade quality obtained from commercial sources and used without further purification. Dicarboxylic acid hydrazide-2,2′-bipyridine is prepared according to the previous work [8]. Elemental analyses (C, H and N) were carried out with a Perkin–Elmer 2400 Analyzer. IR spectra were recorded on a VECTOR 22 Bruker spectrophotometer with KBr pellets in the range of 4000–400 cm^{-1}. ^1H NMR spectra were performed on DRX500 Bruker spectrometer at 298 K with TMS as an internal reference. Electrospray mass spectra were carried out on a LCQ system (Finnigan MAT, USA) with methanol as mobile phase. Solid photoluminescent spectra were performed on AB Series-2 fluorescence spectrometer. Thermogravimetric analyses were carried out with a TA2000/2960 unit at a heating rate of 10 °C/min under nitrogen atmosphere.

Safety note. Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only a small amount of material should be prepared and handled with care.

2.2. Synthesis of the ligand H_2L^{1-3} and cobalt(II) complexes 1–3

2.2.1. Di(2-pyridylcarbaldehyde)-6,6′-dicarboxylic acid hydrazone-2,2′-bipyridine (H_2L^1) and di(2-acetylpyridyl)-6,6′-dicarboxylic acid hydrazone-2,2′-bipyridine (H_2L^2)

Di(2-pyridylcarbaldehyde)-6,6′-dicarboxylic acid hydrazone-2,2′-bipyridine ($\mathbf{H_2L^1}$) and di(2-acetylpyridyl)-6,6′-dicarboxylic acid hydrazone-2,2′-bipyridine ($\mathbf{H_2L^2}$) are prepared and characterized according to the literature method.[9,10] The ligands, $\mathbf{H_2L^1}$ and $\mathbf{H_2L^2}$, are obtained by refluxing a mixed methanol solution of dicarboxylic acid hydrazide-2,2′-bipyridine with pyridyl-2-carbaldehyde and 2-acetylpyridine, respectively, in presence of several drops of acetic acid.

2.2.2. Di(di-2-pyridylketone)-6,6′-dicarboxylic acid hydrazone-2,2′-bipyridine (H_2L^3)

A solution of dicarboxylic acid hydrazide-2,2′-bipyridine (2 mmol, 0.54 g) in methanol (15 mL) was added to a methanol solution (10 mL) containing di-2-pyridylketone (4 mmol, 0.736 g). After 5 drops of acetic acid was added, the yellow mixture was heated at reflux under magnetic stirring for 2 h. During the reaction, a pale yellow precipitate was formed, which was collected by filtration, washed with methanol–ether, and dried in vacuo. Yield: 0.75 g, 62%. ^1H NMR (DMSO-d_6): δ 14.243 (1H, s, NH), 8.624 (1H_7, d, $J = 11.6$ Hz), 8.570 (2H_1, d, $J = 17.6$ Hz), 8.376 (1H_5, d, $J = 32.8$ Hz), 8.126(2H_4, m, $J = 26.4$ Hz), 7.826 (2H_3, t, $J = 12.8$ Hz), 7.743 (2H_2, m, $J = 24.0$ Hz,), 7.641 (1H_6, t, 15.6 Hz). *Anal.* Calc. for $C_{34}H_{24}N_{10}O_2$: H, 4.00; C, 67.54; N, 23.17. Found: H, 4.12; C, 67.34; N, 23.65%. IR (solid KBr pellet, cm^{-1}): 3453.98(m), 1665.27 (s), 1581.78(m), 1432.67(m), 1365.01(m), 1146.87(m), 785.14(m), 674.45(m), 545.45(w). ESI-MS: *m*/*z* 605.58 for $[\mathbf{H_2L^3} + H]^+$, calc. for $[\mathbf{H_2L^3}+H]^+$, 605.21.

2.2.3. Preparation of complex $Co_2(L^1)_2(ClO_4)_2(C_2H_5OH)_2(H_2O)_2$ (1)

$Co(ClO_4)_2 \cdot 6H_2O$ (0.1 mmol, 0.037 g) dissolved in 15 mL ethanol/H_2O (v: v, 95: 5) was added dropwise to a suspension of $\mathbf{H_2L^1}$ (0.1 mmol, 0.045 g) in 10 mL ethanol. The solution was stirred at reflux for 20 min to get dark-red solution. Dark-red block crystals suitable for X-ray diffraction were obtained by evaporating the filtrate after several days (0.051 g, 78.9%). *Anal.* Calc. for $Co_2(C_{24}H_{16}N_8O_2)_2(ClO_4)_2(C_2H_5OH)_2(H_2O)_2$: H, 3.61; C, 46.56; N, 16.72. Found: H, 3.68; C, 46.19; N, 16.41%. ESI-MS: *m*/*z* 1014.3 (calc. for $[Co_2(\mathbf{L^1})_2]^+$, 1014.1) and 507.3 (calc. for $[Co_2(\mathbf{L^1})_2]^{2+}$, 507.1). IR (solid KBr pellet, cm^{-1}): 3425.5 (m), 2442.21(m), 1648.39(m), 1570.89(m), 1502.85(m), 1154.74(s), 1121.06(s), 1094.12(s), 759.13(w), 628.85(w), 576.78(w).

2.2.4. Preparation of compound $Co_2(L^2)(HL^2)(ClO_4)_3(C_2H_5OH)_2(H_2O)_2$ (2)

$Co(ClO_4)_2 \cdot 6H_2O$ (0.1 mmol, 0.037 g) dissolved in 15 mL methanol was added to a suspension of $\mathbf{H_2L^2}$ (0.1 mmol, 0.048 g) in 10 mL methanol. The solution was stirred at reflux for 20 min to obtain a clear solution and allowed to stand at room temperature. After several days, pale-red block microcrystals were obtained (0.042 g, 56.0%). *Anal.* Calc. for $Co_2(C_{26}H_{20}N_8O_2)(C_{26}H_{21}N_8O_2)(ClO_4)_3(C_2H_5OH)_2(H_2O)_2$: H, 3.84; C, 44.91; N, 14.97. Found: H, 3.95; C, 44.79; N, 15.91%. ESI-MS: *m*/*z* 535.4 (calc. for $[Co_2(\mathbf{L^2})_2]^{2+}$, 535.11). IR (solid KBr pellet, cm^{-1}): 3422.42(m), 2443.67(m), 1647.34(m), 1571.76(m), 1507.34(m), 1151.65(s), 1120.43(s), 1090.34(s), 758.67(w), 627.34(w).

2.2.5. Preparation of complex $Co_2(L^3)(HL^3)(ClO_4)_3(H_2O)_4$ (3)

$Co(ClO_4)_2 \cdot 6H_2O$ (0.1 mmol, 0.037 g) dissolved in 15 mL methanol was added to a suspension of H_2L^3 (0.1 mmol, 0.048 g) in 10 mL methanol. The solution was stirred at reflux for 20 min to obtain a clear solution and allowed to stand at room temperature. After several days, dark-red block crystals suitable for X-ray diffraction were obtained (0.064 g, 75.4%). *Anal.* Calc. for $Co_2(C_{34}H_{22}N_{10}O_2)(C_{34}H_{23}N_{10}O_2)(ClO_4)_3(H_2O)_4$: H, 3.27; C, 48.14; N, 16.51. Found: H, 3.35; C, 48.29; N, 16.45%. ESI-MS: *m/z* 1421.69 (calc. for $[Co_2(L^3)_2(ClO_4)]^+$, 1421.20), 660.9 (calc. for $[Co_2(L^3)_2]^{2+}$, 661.1). IR (solid KBr pellet, cm^{-1}): 3423.45(m), 2442.68(m), 1648.24(m), 1571.58(m), 1508.12(m), 1161.25(s), 1125.23(s), 1091.34(s), 757.45(w), 628.04(w).

2.3. X-ray crystallography

Suitable crystals were selected for single-crystal X-ray diffraction structural analysis and the data were collected on a Siemens SMART-CCD diffractometer with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å), using the SMART and SAINT programs [11]. Forty-five frames of data were collected at 298 K with an oscillation range of 1°/frame and an exposure time of 10 s/frame. Indexing and unit cell refinement were based on all observed reflections from those 45 frames. The structures were solved by direct method and refined on F^2 by full-matrix least-squares methods with SHELXTL version 5.1 [12]. Anisotropic thermal parameters were refined for non-hydrogen atoms. Hydrogen atoms were localized in their calculated positions and refined by using the riding model. Crystallographic data and parameters for data collection and refinement of the complexes are summarized in Table 1.

3. Results and discussion

The ligands H_2L^{1-3} are prepared with a moderate yield and synthesized according to the method in the previous work. [8–10] It should be noted that the construction of metal helicates requires the elaborately designed ligand to transmit the chirality from one metal center to another one. As expected, the designed ligand H_2L^{1-3} can wrap around two metal ions, chiral helices will result only when the two metal centers display the same absolute configurations.

3.1. Crystal structure of complex 1

Interaction of the $Co(ClO_4)_2 \cdot 6H_2O$ with H_2L^1 at reflux gave a dark-red complex whose elemental analysis data for the complex is in good agreement with the general molecular formula $[Co(HL^1)]_n$ as would be expected for a complex consisting of two ligands with two-armed tridentate donor sites and two six-coordination metal ions. As shown in Fig. 1, ESI-MS in acetonitrile/methanol combined solution shows two distinct peaks at 1014.3 and 507.3, corresponding to the species $[Co^{II}Co^{III}(L^1)_2]^+$, calc. 1014.8) and $[Co_2^{III}(L^1)_2]^{2+}$, calc. 507.4), respectively, consistent with formation of a double helical structure. The strongest peak at *m/z* 507.3 corresponds to the most abundant ion $[Co_2(L^1)_2]^{2+}$ with isotopic peaks separated by 0.5, which confirmed the 2+ charge borne by the cation [13]. The presence of one strong $[Co_2(L^1)_2]^{2+}$ peak indicates that this double helical species has high stability even under the electronic spray conditions, which corresponds to the predominant existence of Co(III) species in solution. Considering the easier deprotonation nature and the labile oxidation state of cobalt ion, it is expected that Co(II) is readily oxidised to Co(III) which would account for the intense color and the similarity of the two ends of the ligand. A magnetic susceptibility measurement on the crystal samples showed the room temperature χT value is close to zero, corresponding to the low spin Co(III) species. Figs. 2 and 3 show the molecular structure of metal complex $Co_2(L^1)_2(ClO_4)_2(C_2H_5OH)_2(H_2O)_2$ (**1**). The bis-tridentate ligand H_2L^1 exhibits a *trans* configuration and acts as bridging ligand installed with the pocket-like coordination sites at the terminal. The complex is best described as a double-stranded helicate, and two metal centers occupy the helical axis with the center-to-center separation of 6.077 Å. The complex **1** possesses a crystallographic C_2 axis perpendicular to the helical Co···Co axis. The Co(1) center occupies a six-coordinated pseudooctahedral environment surrounded by two different ligands, each ligand provides a set of N_2O pocket-like coordination sites. Angles O–Co–O, O–Co–N, N–Co–N are all in the range of 82.06(22)–101.69(23)° and 165.09(20)–171.60(0.22)°, respectively, which show a distorted octahedral geometry around two crystallographically equivalent cobalt centers. The Co–O distances of 1.8714–1.8773 Å and Co–N lengths of 1.8467–1.9171 Å agree well with those of the related

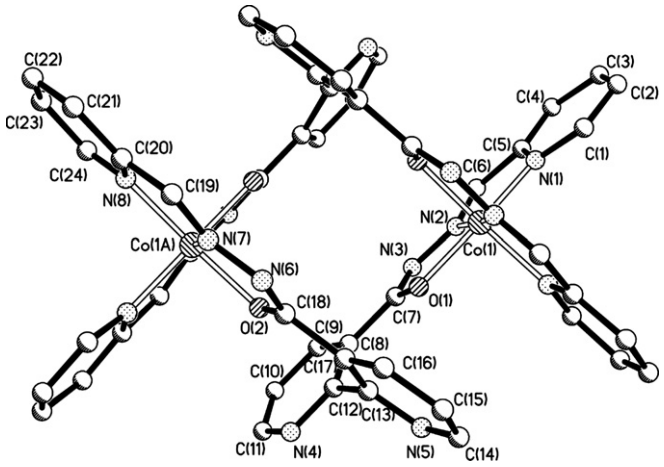

Fig. 3. The helicate structure of complex **1** with the selected atom labels. The hydrogen atoms, anions and solvent molecules are omitted for clarity.

complexes [14]. The presence of two counteranions per helicate suggests the ligand herein lost protons in virtue of coordination to metal ions. As a result, all the bond distances within two arms are intermediate between the normal single bond and double bond, further indicating extensive delocalization over the entire molecular skeleton (Table 2). The coordination to the metal ions also induces the configuration changes within the ligand $\mathbf{H_2L^1}$. The two arms are strongly twisted by the coordination to the metal centers, subsequently resulting in pseudo-perpendicularity each other with the torsion angle of substituted bipyridyl groups being ca. 88.0°.

Since helicate **1** is the molecule possessing true 2-fold symmetry, it is not surprising that the most-frequent space group $C2/c$, a group of maximum density for packing such the molecules, occurs for the complex **1** [15]. The crystal packing structure of helicate **1** can nearly be described as deformed hexagonal unit cells, in fact, the helicates form layers of hexagonal close packed cyclindrical molecules, this leads to pseudohexagonal AB close-packed arrangements [4b]. As in most cases for the helicate structures in monoclinic system, the pseudohexagonal direction is to be found in the *ac* plane. Parallel to the principal axis (H_a) the molecules tend to align themselves to give the densest packing, leaving sufficient space in cavities for the counteranions and solvent molecules (Fig. 4). The observation exactly fit those previously reported by other workers [16]. No obvious weak intermolecular interactions were found in the crystal packing.

3.2. Crystal structure of complex *3*

In acetonitrile-methanol combined solution, ESI-MS studies revealed only one main peak at *m/z* 660.9 corresponds to the species $[\ Co_2^{III}\ (\mathbf{L^3})_2]^{2+}$ (calc. $m/z = 661.5$),

Symmetric code for complex **1**: # $-x+2$, y, $-z+5/2$.

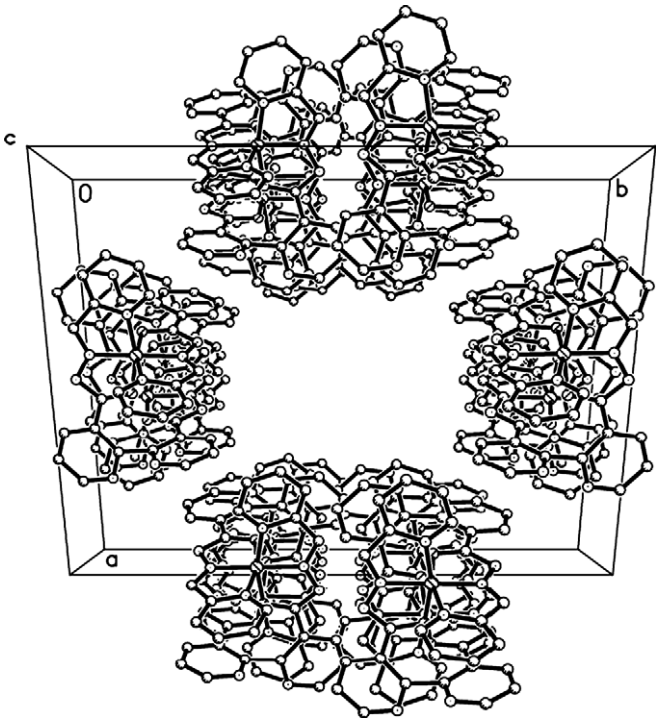

Fig. 4. The crystal packing of complex **1** along the crystallographic *c* axis showing the pore structure, the solvent molecules and anions in the channel are omitted for clarity.

suggesting the helical structure of complex **3** dominantly persists in solution. (Fig. 5) The crystal structure of complex **3** is shown in Fig. 6. The complex **3** crystallizes in the monoclinic crystal system as previously found for the analogous complex **1** but the space group changes from $C2/c$ to $P2(1)/n$. The asymmetric unit contains a dinuclear helicate cation, three anions ClO_4^- and some solvent molecules. The presence of three ClO_4^- anions per helicate indicates that the helicate **3** has trivalent oxidation state. Each Co center adopts pseudo-octahedral configuration and is coordinated by two sets of N_2O unit from the different ligands. The average distances of Co–O and Co–N are consistent with those of complex **1**. The distance between two cobalt centers is 6.156 Å, somewhat longer than that of complex **1**. Two bipyridyl groups are almost perpendicular and the dihedral angles between the substituted pyridyl block is 90.9°. As shown in the complex **1**, the coordination pockets rotate in the opposite direction to assemble as a helicate and the metal center has the homochiral configuration. Based on the fact that the complex **3** crystallized in the achiral space group, the individual helicate, which is inherently chiral, aggregates as a racemate of *P* for right-hand and *M* for left-hand in the solid [17,18].

3.3. Thermogravimetric studies

The TGA curve of the complex **1** showed that the desolvation process takes places beginning at ca. 70 °C. The weight loss is 10.02% in total above 110 °C and slightly greater than the theoretical value (9.54%), corresponding to the loss of all the water and ethanol molecules. As shown in Fig. 7, the desolvated products, $Co_2(C_{24}H_{17}N_8O_2)_2(ClO_4)_2$ are stable enough to ca. 340 °C, on further heating, the complex **1** abruptly begin to decompose. The decomposing curves of complexes **2** and **3** are similar to that of complex **1**.

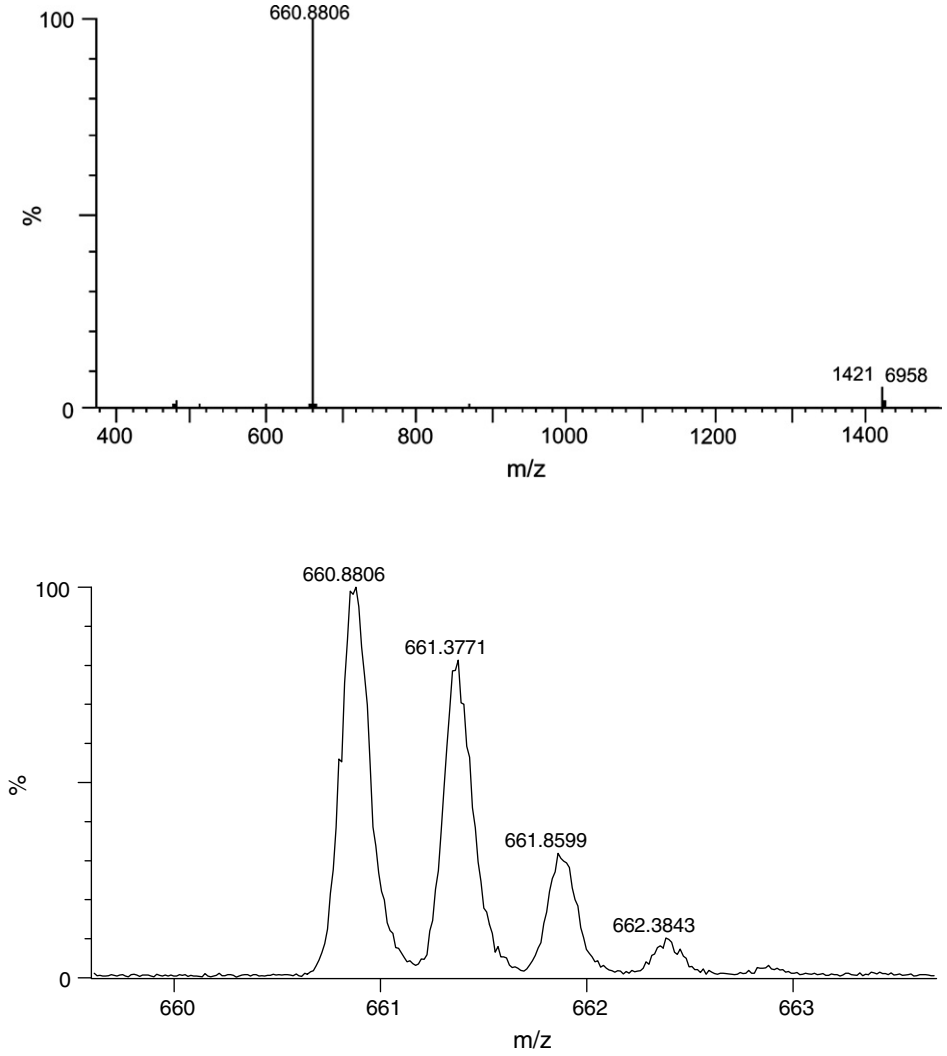

Fig. 5. (a) The ESI-MS of compound **3** in CH_3CN/CH_3OH mixed solution. (b) Isotropic pattern of ESI-MS for compound **3**.

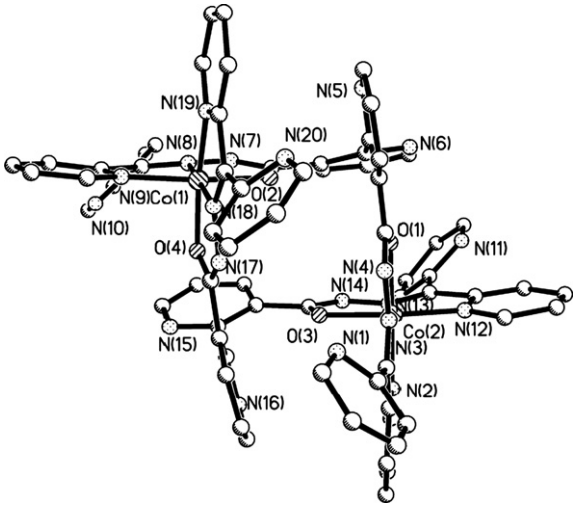

Fig. 6. The crystal structure of complex **3** with the selected atom labels. Hydrogen atoms, anions and solvent molecules are omitted for clarity. Ellipsoids are represented with 50% probability.

3.4. Photoluminescence property

In the solid state, the complex **1** shows photoluminescence at room temperature. Complex **1** exhibits one obvious emission at ca. 530 nm with the excitation at 400 nm at room temperature (Fig. 8). To understand the nature of the emission bands, we analyzed the photoluminescence property of the free $\mathbf{H_2L^1}$ ligand and found that it does not display any emission bands. As well known, cobalt ion is not an excellent metal source for photoluminescence, whereas complex **1** exhibits obvious emission spectrum, which indicates that the photoluminescence property is closely related with the ligand structure in complex **1**. The intense emission at 530 nm of complex **1**, which is different from those of the free $\mathbf{H_2L^1}$ ligand, might be assigned to the intraligand emission excited state [19–21]. It is presumed that the deprotonization of the ligand due to the coordination to metal ion might promote charge delocalization within the whole structure compared to the free ligand,

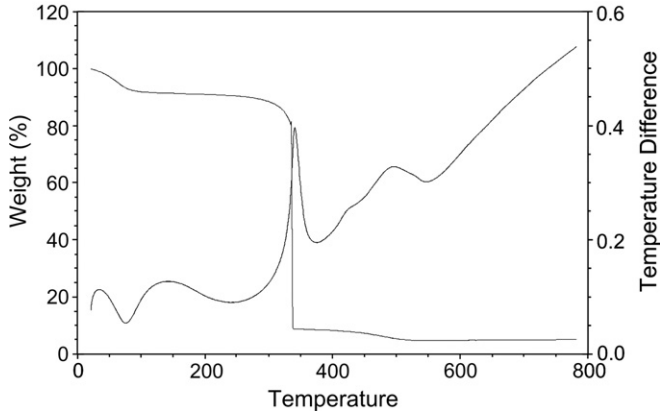

Fig. 7. The TG-DTA curve of complex **1** (T in °C).

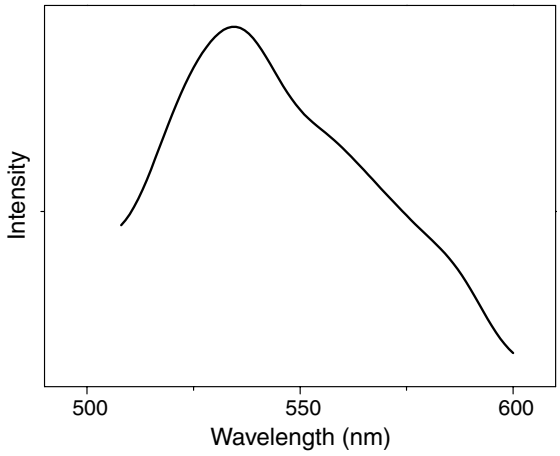

Fig. 8. The emission spectrum of complex **1**. $\lambda_{ex} = 400$ nm.

and thus enhance the photoluminescence of complex **1**. Whereas for the ligand $\mathbf{H_2L^3}$ in complex **3**, in which the ligand can not easily be deprotonated, charge delocalization cannot happen and complex **3** does not exhibit photoluminescence property. This work shows photoluminescence property is closely related with the structure of complex in addition to metal ions.

3.5. Conclusions

In summary, three ligands $\mathbf{H_2L^{1-3}}$ equipped with bipyridine-bridged bis-multidentate coordination pockets have been designed to construct cobalt-containing metallohelicate complexes. Due to the flexible nature and suitable coordination pocket of ligand, the assembly process can produce helicate structure, which can intrinsically transfer the chirality from one metal center to another one. This crystal packing of complex **1** exhibits an interesting pore structure and helicate complex **1** shows photoluminescence at room temperature in the solid state.

ligands were synthesized using metal carbonyls and aziridine by Singh and Angelici [32,33] and also in our group [34] whereas isocyanide complexes were employed by Michelin and co-workers [35]. Beck and co-workers observed the metal-mediated dimerisation of two aziridine ligands forming the chelate *N*-(2-aminoethyl)aziridine ligand [8], and in 1997, Kojima et al. reported the first X-ray structure of a *N*-(2-amino-2-methylethyl)-2-methylaziridine cobalt(III) complex [36].

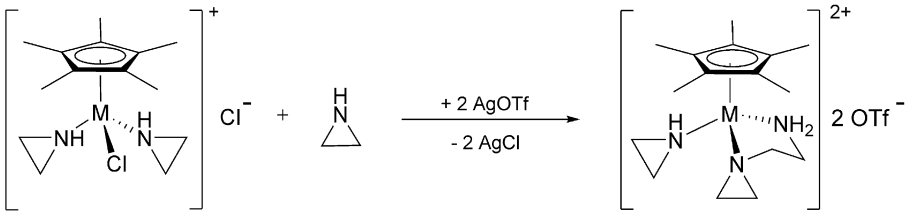
The tendency towards ring opening of aziridine is mainly a result of Baeyer and Pitzer ring strain [37], especially after NH protonation has occurred and can easily lead to nucleophilic attack. The versatility of the aziridine motif has resulted in widespread interest in this heterocycle [38–40]. Particularly in organic chemistry, aziridine compounds have a variety of synthetic applications, for example, as catalysts in asymmetric synthesis [41–44], synthones in natural product synthesis [45–48], monomers in macromolecular chemistry, [49,50] or target molecules in organic synthesis [51–53]. Another important reason for the increased interest in aziridine chemistry is its biological role, whereby *in vivo* effects of aziridine derivatives are mostly the result of ring opening and alkylation reactions. This results in the carcinogenic activity of natural and synthetic aziridine compounds [54–57]. In this context, the promising cytotoxic and anticancerogenic activities of chelating amine ligands in the coordination sphere of the platinum group metals is also worth mentioning [58]. Biological studies concerning this issue are currently being undertaken, and will be reported in future work. In this communication, the transition metal lewis acid mediated ring opening reaction of aziridine yielding the chelating ligand *N*-(2-aminoethyl)aziridine-*N*,*N*′ is reported.

2. Results and discussion

2.1. Synthesis

Scheme 1 illustrates the reactions of the bis-aziridine complexes $[MCl(Cp^*)(az)_2]Cl$ (M = Rh: **1**, M = Ir: **2**) with first 2.2 equiv. silvertriflate and then with an excess (1:2.5) of aziridine C_2H_4HN (**3**), which leads to the formation of the *N*-(2-aminoethyl)aziridine complexes $[M(Cp^*)(aeaz)(az)](OTf)_2$ (M = Rh: **4**, M = Ir: **5**; aeaz = *N*-(2-aminoethyl)aziridine). Monitoring the first step of this reaction using IR spectroscopy shows that a triflato-*O* ligand is weakly coordinated to the metal centres forming the $[M(Cp^*)(OTf)(az)_2]$ intermediate. For related complexes, we have succeeded in the isolation and structural characterization of triflato-*O* complexes [59].

The same reaction as that described above with the analogous complex $[RuCl(C_6Me_6)(az)_2]Cl$ (**6**) and aziridine **3** did not result in the formation of the analogous complex $[Ru(C_6Me_6)(aeaz)(az)](OTf)_2$ (**7**). Obviously under the reaction conditions applied, **6** appears to be not electrophilic enough to induce the desired ring opening reaction and therefore, an anion exchange reaction occurs yielding the $[RuCl(C_6Me_6)(az)_2]OTf$ (**8**) complex. Nevertheless, even although the preparation of the desired Ru complex was unsuccessful using the mild reaction conditions applied in this work, the synthesis of this complex should be possible.



All products were obtained as colourless (**4**) or yellow (**5**, **8**) powders in acceptable yields (60–74%) and are soluble in polar solvents such as acetone, but insoluble in non-polar solvents such as *n*-pentane. Compounds **4**, **5** and **8** can be stored infinitely under an atmosphere of argon.

2.2. X-ray crystal structure analysis

The molecular structures of compounds **4**, **5** and **8** were determined using single crystal X-ray diffraction. Isothermic diffusion of *n*-pentane into solutions of **4** and **5** in acetone or of **8** in dichloromethane resulted in the formation of X-ray quality single crystals. Details of the relevant data collection and refinement are summarised in Table 1. The molecular structures of **4**, **5** and **8** are illustrated in Figs. 1–3. Bond lengths and angles within the coordination sphere of Rh(III), Ir(III) and Ru(II) are listed in Figs. 1–3, respectively.

All three complexes show similar structures with a distorted octahedral geometry as is expected for Rh(III), Ir(III) or Ru(II) transition metal centres. The aromatic ligand L (C_6Me_6 or C_5Me_5) constitutes one octahedral face, while the other three coordinating atoms (Cl or N) form the opposite one.

All of M–N bond lengths (213–218 pm) observed for **4** and **5** lie within a small range and are only slightly elongated in comparison to the M–N bond lengths of the analogous bis-aziridine complexes **1** and **2** [60]. It is worthwhile

to note that in both cases the M–NH bonds (213/214 pm) are significantly shorter than the M–NH_2 bonds (218 pm). The N–C bond lengths within the aziridine ring as well as in the ethane bridge lie in the expected range between 144 and 148 pm, whereas the C–C bond lengths (154/151 pm) within the five-membered ring of the *N*,*N*′-chelate ligand are longer than those in the three-membered aziridine ring (141–147 pm). All of the angles of the intact aziridine rings (58.5–61.5°) are approximately 60° and similar to those observed in free aziridine [61,62]. The N–M–NH_2 angles (78.4°/77.3°) within the five-membered rings are much smaller in comparison with the other N–M–N angles, e.g. the NH–M–NH_2 angles are 91.3° or 90.0° in **4** and **5**, respectively and are larger than the NH–M–N angles (87.0° (**4**)/86.0° (**5**)). This may be constraint due to the five-membered ring that does not allow the opening up to 90°. However, all of the bond lengths and angles mentioned above are found in the expected range and are comparable to those in similar complexes [63–66]. Compound **8** shows Ru–N, Ru–C and Ru–Cl bond lengths in the 213 pm, 216–223 pm ranges and 242 pm range respectively, which are consistent with the corresponding values observed for the analogous bis-aziridine–ruthenium(II) complexes [60]. It is worth mentioning that the angles of the intact aziridine rings (59.5–60.6°) are approximately 60° and similar to those in the uncoordinated aziridine [61,62]. The N–M–N angle is 81.2° and is smaller in comparison with the N–M–Cl angles (88.4° and 88.1°) due to steric reasons. All of the bond lengths and angles mentioned above are within the expected ranges and are comparable to those in similar complexes [60].

2.3. Spectroscopy

The IR, ^{1}H, ^{13}C NMR and mass spectra of compounds **4**, **5** and **8** have been obtained and are consistent with the spectroscopic data expected based on the molecular structures obtained by single crystal X-ray diffraction. The complexes **4** and **5** show two chiral centres at the metal centre and the aziridine–nitrogen atom of the aeaz ligand. Inspite of the potential existence of two diastereomers which should arise a double number of signals in the NMR spectra, only one set of signals for one diastereomer has been observed. In general, the ^{1}H and ^{13}C NMR spectra of **4**, **5** and **8** show signals shifted to lower field in comparison to the signals observed for the free ligand due to deshielding caused by coordination to the transition metal. In particular, in the case of the NH and NH_2 ^{1}H NMR signals for coordinated az and aeaz at 3.55 ppm (NH, **4**), 4.06 ppm (NH, **5**), 3.29–3.39 ppm (NH, **8**), 4.65/5.03 ppm (NH_2, **4**)

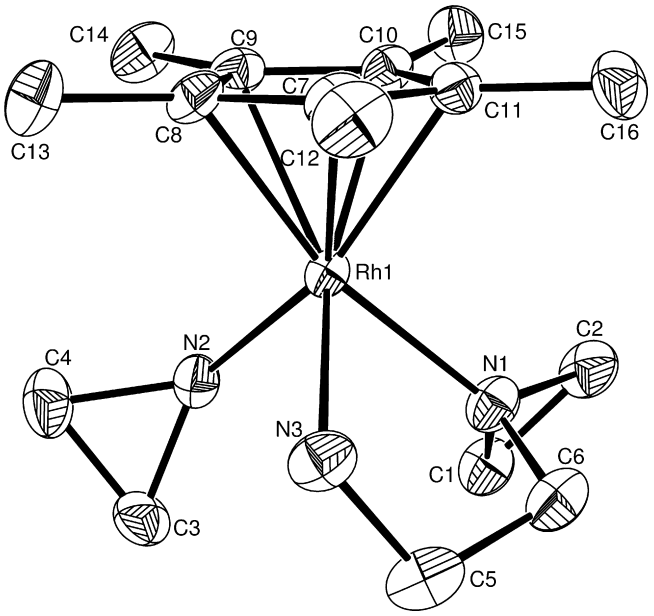

Fig. 1. Molecular structure of 4 with thermal ellipsoids drawn at the 30% probability level. Hydrogen atoms and the two triflate anions are omitted for clarity. Selected bond lengths (Å) and angles (°): Ir(1)–N(1) 2.152(6), Ir(1)–N(2) 2.180(7), Ir(1)–N(3) 2.136(7), N(1)–C(1) 1.473(11), N(1)–C(2) 1.457(10), C(1)–C(2) 1.438(14), N(1)–C(4) 1.460(11), C(3)–C(4) 1.513(15), N(2)–C(3) 1.459(11), N(3)–C(5) 1.435(11), N(3)–C(6) 1.457(11), C(5)–C(6) 1.413(15), N(1)–Ir(1)–N(2) 77.3(3), N(1)–Ir(1)–N(3) 86.0(3), N(2)–Ir(1)–N(3) 90.0(3), N(1)–C(1)–C(2) 60.1(6), N(1)–C(2)–C(1) 61.1(6), C(1)–N(1)–C(2) 58.8(6), N(3)–C(5)–C(6) 60.0(6), N(3)–C(6)–C(5) 61.5(6), C(5)–N(3)–C(6) 58.5(7).

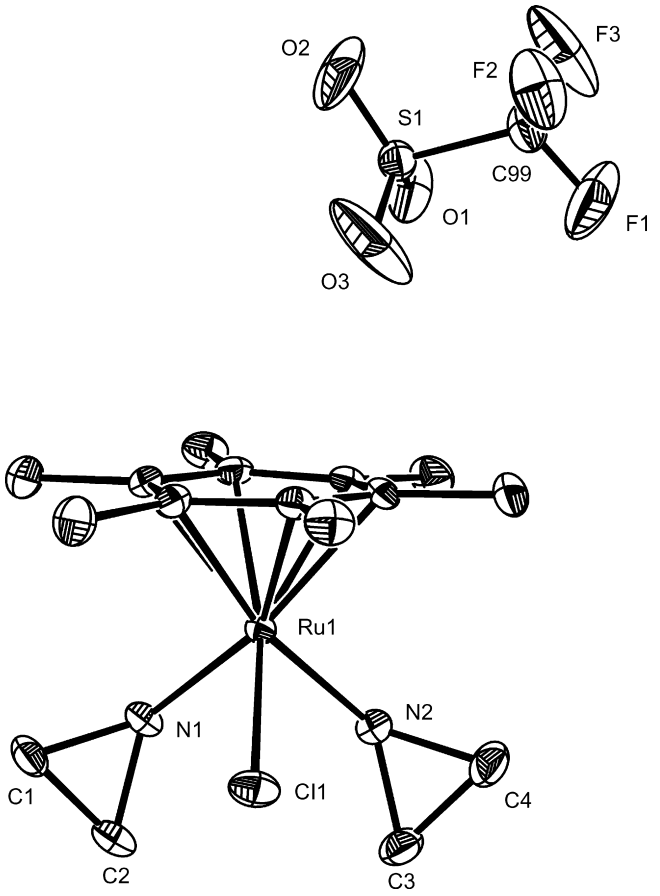

Fig. 3. Molecular structure of **8** with thermal ellipsoids drawn at the 30% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Ru(1)–N(1) 2.125(3), Ru(1)–N(2) 2.133(4), Ru(1)–C(8) 2.162(4), Ru(1)–C(10) 2.226(4), Ru(1)–Cl(1) 2.417(12), N(1)–C(2) 1.471(5), N(1)–C(1) 1.484(5), C(1)–C(2) 1.467(7), N(2)–C(3) 1.470(6), N(2)–C(4) 1.479(6), C(3)–C(4) 1.469(7), N(1)–Ru(1)–N(2) 81.16(14), N(1)–Ru(1)–Cl(1) 88.40(10), N(2)–Ru(1)–Cl(1) 88.12(11), C(2)–N(1)–C(1) 59.54(3), C(1)–C(2)–N(1) 60.66(3), C(2)–C(1)–N(1) 59.80(3), C(3)–N(2)–C(4) 59.75(3), C(3)–C(4)–N(2) 59.81(3), C(4)–C(3)–N(2) 60.43(3).

and 5.22/5.68 ppm (NH_2, **5**), a strong shift to lower field is observed compared to the free ligand with NH (az) and NH_2 (aeaz) ^1H NMR signals at −0.02 ppm (az, $CDCl_3$) and 1.60 ppm (aeaz, CD_3OD). As was noted above, the CH_2 signals for az and aeaz in the ^{13}C NMR spectra are shifted to lower field, for example, whereas the CH_2 groups of the uncoordinated az show a signal at 17.8 ppm, in the coordinated az (**8**) CH_2 signals are detected at 19.6 ppm and 23.8 ppm.

Mass spectrometry was used to investigate the fragmentation of the cationic complexes using positive FAB mode in a nitrobenzylalcohol (NBA) matrix. Compounds **4** and **5** exhibit similar fragmentation patterns with m/z peaks at 516, 266 (**4**) and 607, 457 (**5**) corresponding to M^+ and M^{2+}, respectively. In addition, the fragmentation pattern for complexes **4** and **5** shows the successive loss of the az, aeaz and both ligands for M^+ and az and aeaz for M^{2+}. Compound **8** shows a peak at $m/z = 499$ corresponding to the $M^+ + OTF^- - Cl$ fragment and at $m/z = 385$ for the

M^+ peak. In the fragmentation pattern of M^+ (**8**), the successive loss of one and two az ligands could be identified.

The IR spectra of complexes **4**, **5** and **8** show similar values for the vibrational modes of the transition metal coordinated az and aeaz ligands with those reported for related aziridine complexes [60]. Compounds **4**, **5** and **8** show sharp absorption bands for the aziridine N–H stretching vibrations in the range 3251–3245 cm^{-1} as expected for secondary amines coordinated to transition metals [67]. In addition, typical σ- and δ-ring vibrations in the fingerprint region of az and aeaz were observed [68].

3. Experimental

3.1. Materials and methods

All experiments were performed under a dry argon atmosphere using Schlenk line techniques. Aziridine [69], [RhCl(Cp*)(az)$_2$]Cl, [IrCl(Cp*)(az)$_2$]Cl and [RuCl(Cp*)(az)$_2$]Cl were prepared according to the literature methods [60]. Acetone was distilled from calcium chloride, dichloromethane was distilled from calcium hydride, and *n*-pentane and *n*-hexane were distilled from sodium. All solvents were stored under a dry argon atmosphere over 3 Å molecular sieves. The ^1H and ^{13}C NMR spectra were recorded using a Jeol Eclipse 270 and a Jeol Eclipse 400 instrument operating at 270 MHz (^1H), 400 MHz (^1H) and 68 MHz (^{13}C), 100 MHz (^{13}C). The ^1H and ^{13}C chemical shifts were determined relative to TMS as external standard. IR spectra (KBr) were recorded using a Nicolet 520 FT-IR and Perkin Elmer Spectrum One FT-IR spectrometer. Mass spectra were obtained using a Joel MStation JMS 700, NBA matrix (FAB). Multi-isotope containing fragments refer to the isotope with the highest abundance. Single crystal X-ray diffraction data were collected using a Nonius Kappa CCD diffractometer using graphite-monochromated Mo Kα radiation. Single crystal X-ray structure analyses were performed using direct methods using the SHELXS software and refined by full-matrix least squares with SHELXL-97 [70]. Table 1 contains the crystallographic data and details of the structural refinement of **4**, **5** and **8**. The hydrogen atoms of the C_6Me_6 methyl groups in **8** were found to be disordered in the difference map and were fixed geometrically. Elemental analysis were performed by the Microanalytical Laboratory of the Department of Chemistry and Biochemistry, LMU Munich using a Heraeus Elementar Vario El.

3.2. Synthesis of the aziridine-N-(2-aminoethyl)aziridine complexes *4* and *5*

The bis-aziridine complex (**1** or **2**) was dissolved in 20 mL dichloromethane, together with 2.2 equiv. of AgOTf. After stirring for 1 h and removal of the precipitated AgCl by centrifugation, an excess of 2.5 equiv. of the aziridine **3** was added. The solution was stirred overnight and the precipitate was filtrated through a frit (por. 4). For purification, the powder was stirred in 10 mL *n*-hexane for 12 h. After decantation of the *n*-hexane phase, the product was dried in vacuo.

3.2.1. [Rh(Cp*)(C$_2$H$_4$NC$_2$H$_4$NH$_2$)(C$_2$H$_4$NH)](OTf)$_2$ (*4*)

Reagents: 49.8 mg (0.126 mmol) **1**, 71.2 mg (0.277 mmol) AgOTf, 17.0 μL (0.315 mmol) **3**; Yield: 50.0 mg (0.075 mmol, 60 %) pale yellow powder; decomposition >204 °C. *Anal.* Calc. for $C_{18}H_{30}F_6N_3O_6RhS_2$ (665.48 g/mol): C, 32.49; H, 4.54; N, 6.31. Found: C, 32.23; H, 4.15; N, 6.38%. 3.3. Synthesis of [bis(aziridine)-chloro-ruthenium(II)]trifluoromethanesulfonate (8)

The bis-aziridine ruthenium(II) complex **8** was dissolved in 20 mL dichloromethane together with 2.2 equiv. of AgOTf. After stirring for 1.5 h and removal of the precipitated AgCl by centrifugation, an excess of 2.0 equiv. of aziridine (**3**) was added. The solution was stirred over night and the solvent was removed in vacuo. The residue was purified by stirring in 10 mL *n*-hexane for 12 h. After decantation of the *n*-hexane phase, the product was dried in vacuo.

3.3.1. $[RuCl(C_6Me_6)(C_2H_4NH)_2]OTf$ (8)

Reagents: 71 mg (0.169 mmol) **6**, 91 mg (0.354 mmol) AgOTf, 18.2 μL (0.338 mmol) **3**; Yield: 64 mg (0.119 mmol, 70%) yellow powder; decomposition >172 °C. *Anal.* Calc. for $C_{17}H_{28}ClF_3N_2O_3RuS$ (534.00 g/mol): C, 38.24; H, 5.29; N, 5.25. Found: C, 38.65; H, 5.84; N, 4.89. IR (KBr) [cm^{-1}] 3251 (m), 3021 (w), 1437 (w), 1394 (w), 1290 (vs), 1259 (s), 1225 (s), 1157 (s), 1092 (w), 1071 (w), 1032 (vs), 935 (w), 891 (m), 885 (m), 805 (w), 757 (w), 638 (vs), 575 (w), 518 (w), 426 (w). [16,17]. This work is the continuation of our studies on steric repulsion between ligands controlling the formation of group 13 complexes. We report the syntheses and X-ray structure determination of aluminium and gallium alkyl complexes supported by 2,3-dimethylbutane-2,3-diolato (pinacolato) ligands.

2. Results and discussion

Pinacol reacted with Me_3Al in a 2:3 molar ratio to produce the trinuclear aluminium complex $Me_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ (**1**), containing two diolate units (Scheme 1).

Compound **1** was sublimed from the post-reaction mixture in 52% yield. The molecular structure of **1** was determined on the basis of an X-ray diffraction study and is shown in Fig. 1. Data collection and structure analysis are listed in Table 1. Crystals of compound **1** contain three kinds of molecules (**A**, **B** and **C**) in a cell differing in bond lengths and angles. The two terminal aluminium atoms, Al(2) and Al(3), are 4-coordinate, residing in the distorted tetrahedrons. The angles O(2A)–Al(1A)–O(4A) 128.5(1)° [O(2B)–Al(1B)–O(4B) 129.2(1)°, O(1C)–Al(1C)–O(3C) 128.4(1)°] and O(1A)–Al(1A)–O(3A) 144.3(1)° [O(1B)–Al(1B)–O(3B) 143.1(1)°, O(2C)–Al(1C)–O(4C) 143.7(1)°] indicate that the coordination sphere geometry of the central aluminium atom Al(1) can be regarded both as a distorted square pyramidal structure with the basal plane consisting of four oxygen atoms and C(5) situated in an apical position and as a distorted trigonal bipyramidal geometry. In **1A** and **1B** molecules, the O(1) and O(3) atoms occupy the axial positions and the C(5), O(2) and O(4) atoms define the equatorial sites of the trigonal bipyramid. In **1C** molecules, the O(2) and O(4) atoms are situated in the axial positions and the O(1), O(2) and C(5) atoms lie in the equatorial sites. The sums of the angles about the oxygen atoms {∑[O(1A)]356.3°; ∑[O(2A)] 351.6°; ∑[O(3 A)]355.4°; ∑[O(4A)351.7°}, {∑[O(1B)] 355.9°; ∑[O(2B)]351.8°; ∑[O(3B)]356.3°; ∑[O(4B)351.7°} and {∑[O(1C)]351.7°; ∑[O(2C)]355.2°; ∑[O(3C)]351.0°; ∑[O(4C)355.8°} are slightly less than 360°, which indicates a small steric strain in the molecule. Bond lengths between the central aluminium atom Al(1) and the oxygen atoms and those between the terminal aluminium atoms Al(2) and Al(3) and the oxygen atoms are very similar. They are situated in the region of 1.84 to 1.86 Å.

Scheme 1.

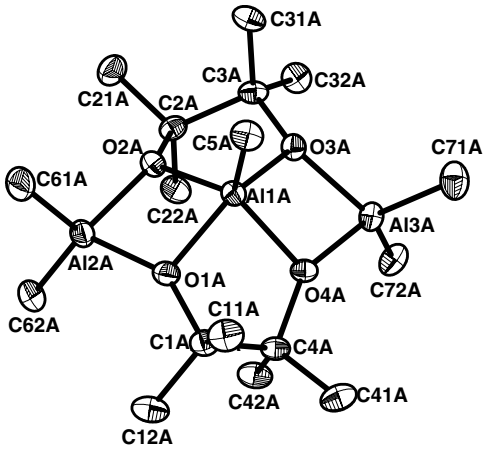

Fig. 1. Molecular structure of $Me_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ (**1**). Thermal ellipsoids are shown at the 50% level. Hydrogen atoms are omitted for clarity. The picture shows a molecule of kind A. Selected bond lengths (Å) and bond angles (°) for molecules of **1** of kind A, B and C: Al(1A)–O(2A) 1.866(2) [Al(1B)–O(2B) 1.871(3), Al(1C)–O(2C) 1.876(2)], Al(1A)–O(4A) 1.870(2) [Al(1B)–O(4B) 1.874(2), Al(1C)–O(4C) 1.867(2)], Al(1A)–O(1A) 1.875(2) [Al(1B)–O(1B) 1.875(2), Al(1C)–O(1C) 1.865(2)], Al(1A)–O(3A) 1.876(2) [Al(1B)–O(3B) 1.868(2), Al(1C)–O(3C) 1.877(2)], Al(1A)–C(5A) 1.961(3) [Al(1B)–C(5B) 1.958(4), Al(1C)–C(5C) 1.958(4)], Al(2A)–O(1A) 1.834(2) [Al(2B)–O(1B) 1.833(2), Al(2C)–O(1C) 1.853(3)], Al(2A)–O(2A) 1.858(2) [Al(2B)–O(2B) 1.856(2), Al(2C)–O(2C) 1.835(2)], Al(3A)–O(3A) 1.840(2) [Al(3B)–O(3B) 1.839(2), Al(3C)–O(3C) 1.862(2)], Al(3A)–O(4A) 1.855(2) [Al(3B)–O(4B) 1.855(2), Al(3C)–O(4C) 1.837(2)], O(2A)–Al(1A)–O(4A) 128.5(1) [O(2B)–Al(1B)–O(4B) 129.2(1), O(2C)–Al(1C)–O(4C) 143.7(1)], O(2A)–Al(1A)–O(1A) 80.5(1) [O(2B)–Al(1B)–O(1B) 80.2(1), O(2C)–Al(1C)–O(1C) 80.4(1)], O(4A)–Al(1A)–O(1A) 84.2(1) [O(4B)–Al(1B)–O(1B) 84.2(1), O(4C)–Al(1C)–O(1C) 83.8(1)], O(2A)–Al(1A)–O(3A) 84.1(1) [O(2B)–Al(1B)–O(3B) 84.1(1), O(2C)–Al(1C)–O(3C) 84.2(1)], O(4A)–Al(1A)–O(3A) 80.5(1) [O(4B)–Al(1B)–O(3B) 80.3(1), O(4C)–Al(1C)–O(3C) 80.4(1)], O(1A)–Al(1A)–O(3A) 144.3(1) [O(1B)–Al(1B)–O(3B) 143.1(1), O(1C)–Al(1C)–O(3C) 128.4(1)].

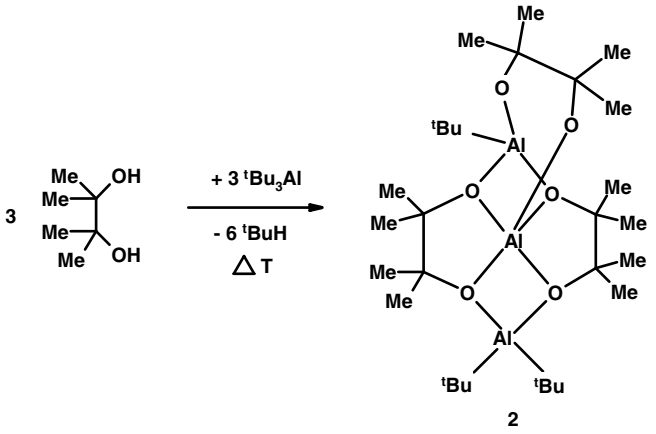

The ^{1}H NMR spectrum of **1** in solution revealed three singlets of CH_3Al group protons (at −0.63, −0.79 and −0.87 ppm) in a 2:1:2 relative intensity ratio. The integration ratio of the signals indicated that protons of the methyl group attached to the central aluminium atom exhibited a singlet at −0.79 ppm. The singlets at −0.63 and −0.87 ppm were assigned to protons of the four CH_3 groups bonded to the terminal aluminium atoms. The presence of these two singlets indicated the equivalence of the two CH_3Al groups positioned *syn* to $CH_3Al_{central}$. The two *anti* CH_3Al groups were also equivalent. Signals of the CCH_3 pinacolate unit protons appeared as two singlets at 1.31 and 1.24 ppm. It indicated that the protons of the four CCH_3 pinacolate units, positioned *anti* to the $CH_3Al_{central}$ group, were magnetically equivalent in solution. Similarly, the protons of *syn* CCH_3 groups were also equivalent. It contrasts with the solid-state structure, in which the CCH_3 groups were inequivalent. The differences between the solid-state structure and the NMR observations are a result of fluxionality phenomena involving transitions between the two non-equivalent antisymmetric structures falling in the fast exchange regime.

The ^{13}C NMR spectrum of **1** revealed one signal of *C*O carbons at 80.44 ppm. In comparison with the *C*O signals of methyl aluminium benzopinacolate $Me_5Al_3[OC(C_6H_5)_2C(C_6H_5)_2\ O]_2$ (93.31 ppm) [1], the *C*O signal of **1** was shifted upfield. It is the result of the lack of aromatic rings in compound **1**. In the case of benzopinacolates, the electron withdrawing effect of aromatic rings caused a downfield shift of *C*O carbon signals. The presence of one signal of *C*O carbons in the ^{13}C NMR spectrum indicates the equivalence of the four *C*O carbons of the pinacolate units.

The reaction of $^tBu_3Al$ with one equivalent of pinacol in refluxing toluene followed by the removal of the solvent resulted in the pure compound $^tBu_3Al_3[OC(CH_3)_2C(CH_3)_2O]_3$ (**2**) as the only product (Scheme 2). Compound **2** is soluble in most common organic solvents such as pentane, hexane, and toluene. X-ray quality crystals were crystallised from a pentane solution. The molecular structure was determined on the basis of an X-ray diffraction study and is shown in Fig. 2. Data collection and structure analysis are presented in Table 1. The molecule of **2** consists of three aluminium atoms, three diolate units and three *tert*-butyl groups. ^{t}Bu groups are bonded to the terminal 4-coordinate Al(1) and Al(2) metal atoms. The central Al(3) atom is 5-coordinate, residing in a highly distorted square pyramidal geometry with the basal plane consisting

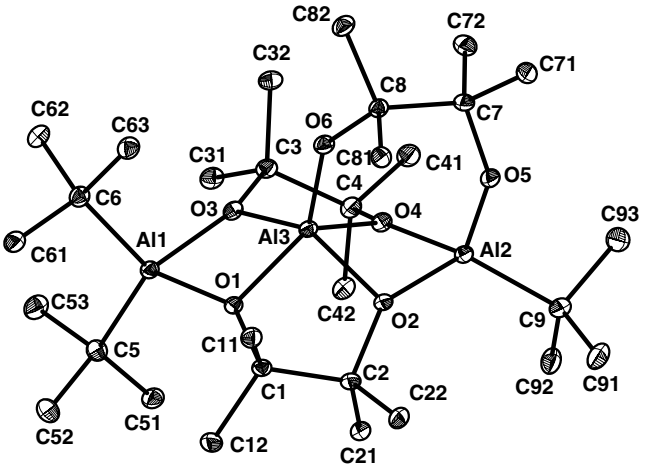

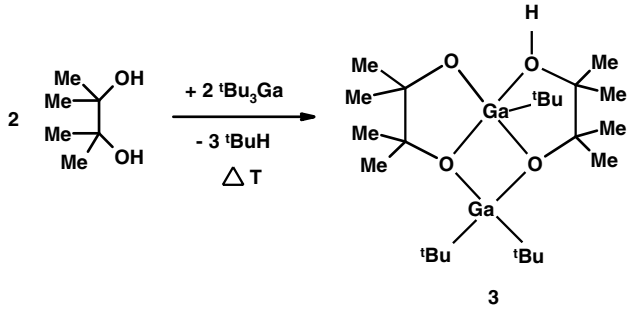

Fig. 2. Molecular structure of $^{t}Bu_3Al_3[OC(CH_3)_2C(CH_3)_2O]_3$ (**2**). Thermal ellipsoids are shown at the 20% level. Hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and bond angles (°): Al(3)–O(6) 1.712(3), Al(3)–O(1) 1.857(3), Al(3)–O(4) 1.861(3), Al(3)–O(3) 1.871(3), Al(3)–O(2) 1.896(3), Al(2)–O(5) 1.708(3), Al(2)–O(4) 1.844(3), Al(2)–O(2) 1.850(3), Al(2)–C(9) 1.993(4), Al(1)–O(3) 1.856(3), Al(1)–O(1) 1.884(3), O(6)–Al(3)–O(1) 124.0(1), O(6)–Al(3)–O(4) 104.0(1), O(1)–Al(3)–O(4) 131.9(1), O(6)–Al(3)–O(3) 110.6(1), O(1)–Al(3)–O(3) 79.6(1), O(4)–Al(3)–O(3) 85.0(1), O(6)–Al(3)–O(2) 104.4(1), O(1)–Al(3)–O(2) 85.3(1), O(4)–Al(3)–O(2) 81.7(1), O(3)–Al(3)–O(2) 144.6(1), C(6)–Al(1)–C(5) 117.8(2), O(5)–Al(2)–C(9) 110.3(2).

They are very similar to the corresponding Al–$O_{3\text{-coord.}}$ bond lengths of compound **1** and longer than the Al(2)–O(5) and Al(3)–O(6) bonds [Al(3)–O(6) 1.712(3) and Al(2)–O(5) 1.708(3) Å].

The ^{1}H NMR spectrum of **2** in solution shows three singlets (at 1.07, 1.03 and 1.02 ppm in a 9:9:9 relative integration ratio) belonging to the hydrogen atoms of the $^{t}BuAl$ groups and five singlets (at 1.59, 1.42, 1.34, 1.28 and 1.14 ppm in a 6:6:6:6:12 integration ratio) of the diolate unit CH_3 protons. The integration ratio of the signals indicates that three $^{t}BuAl$ groups and twelve CH_3 groups of the diolate units are present in the molecule of **2**. The ^{13}C NMR spectrum of **2** exhibits four resonances of *C*O carbons (at 81.20, 80.79, 77.84 and 76.15 ppm). One of them was assigned to the *C*(1) and *C*(3) carbons. The carbons *C*(2) and *C*(4) also gave one signal. The *C*(5) and *C*(6) atoms are magnetically inequivalent and exhibit two signals (numeration of carbons, see Fig. 2).

It is worth noting that compound **2** is the first group 13 diolate with the general formula $R_3M_3[diol\text{-}(2H)]_3$. The presence of three diolate units in the molecule of **2** suggests the formation of the $^{t}Bu_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ complex as an intermediate product followed by the reaction of this product with one molecule of pinacol. Unfortunately, the synthesis of $^{t}Bu_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ failed. In order to obtain the compound with two pinacolate units, $^{t}Bu_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$, $^{t}Bu_3Al$ and pinacol were employed in different ratios, ranging from 3:2 to 2:1, under the same reaction conditions. However, compound **2** was the only product of all the reactions, which indicates a reaction course without the intermediate aluminium dipinacolate. On the other hand, the formation of $^{t}Bu_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ as a product in the reaction of $^{t}Bu_3Al$ with pinacol cannot be excluded. It is very likely that this compound is formed as an unstable product due to the high steric repulsion of bulky ^{t}Bu and pinacolate ligands, and then it reacts immediately with pinacol, yielding the less sterically crowded compound **2**.

In contrast to the reaction of pinacol with $^{t}Bu_3Al$, a reaction of pinacol with $^{t}Bu_3Ga$ (in a 1:1 molar ratio and with an excess of $^{t}Bu_3Ga$) in refluxing toluene for 3 hours afforded the dinuclear compound $^{t}Bu_3Ga_2[OC(CH_3)_3C(CH_3)_2O][OC(CH_3)_3C(CH_3)_2OH]$ (**3**) (Scheme 3). The compound was isolated as $\mathbf{3}\cdot 0.5C_6H_{14}O_2$ in 40% yield after crystallisation from the post-reaction solution. The molecular structure of **3** is shown in Fig. 3 and selected bond lengths and angles are given in Table 1. One molecule of pinacol per two molecules of **3** is present in the formula unit. The molecule of **3** consists of a tricyclic structure formed from two GaO_2C_2 five-membered rings and one Ga_2O_2 four-membered ring. The two metal atoms are chelated and bridged by mono- and di-deprotonated pinaco-

Scheme 3.

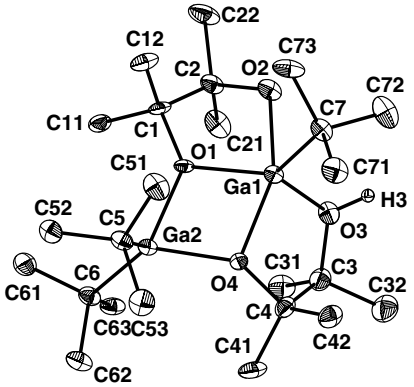

Fig. 3. Molecular structure of $^{t}Bu_3Ga_2[OC(CH_3)_3C(CH_3)_2O][OC(CH_3)_3C(CH_3)_2OH]\cdot 0.5C_6H_{14}O_2$ ($\mathbf{3}\cdot 0.5C_6H_{14}O_2$). Thermal ellipsoids are shown at the 40% level. Hydrogen atoms and a molecule of $C_6H_{14}O_2$ (pinacol) are omitted for clarity. Selected bond lengths (Å) and bond angles (°): Ga(1)–O(3) 1.859(3), Ga(1)–O(1) 1.973(3), Ga(1)–O(4) 2.011(3), Ga(1)–C(7) 2.035(4), Ga(1)–O(2) 2.180(3), Ga(2)–O(4) 1.963(3), Ga(2)–O(1) 1.975(3), O(3)–Ga(1)–O(1) 119.5(1), O(3)–Ga(1)–O(4) 84.7(1), O(1)–Ga(1)–O(4) 75.9(1), O(3)–Ga(1)–C(7) 111.1(2), O(1)–Ga(1)–C(7) 128.1(2), O(4)–Ga(1)–C(7) 121.0(2), O(3)–Ga(1)–O(2) 91.6(1), O(1)–Ga(1)–O(2) 75.6(1), O(4)–Ga(1)–O(2) 144.7(1), C(7)–Ga(1)–O(2) 93.1(2).

late ligands. The molecule adopts a highly distorted trigonal bipyramidal geometry around the Ga(1) atom with the O(2) and O(4) atoms situated in the axial positions and the O(1), C(7) and O(3) atoms placed in the equatorial sites [O(4)–Ga(1)–O(2) 144.7(1)° and O(3)–Ga(1)–O(1) 119.5(1)°].

Potentially possible, intermolecular O–H···O hydrogen bonds between pinacol and **3** or between molecules of **3** were not observed in the crystal structure. Moreover, the signal of O*H* protons at about 4 ppm in the ^{1}H NMR spectrum shows the absence of hydrogen bonds in the solutions. The signals of hydrogen bond protons in complexes of group 13 metals are reported to be shifted downfield (at 14–17 ppm) [15,16,18].

In the ^{1}H NMR spectrum in solution, compound **3** shows three signals (at 1.17, 1.11 and 1.10 ppm) of equal intensity assigned to the protons of the ^{t}Bu groups attached to the gallium atoms. Signals of the CCH_3 protons of the pinacolate units appear as four singlets (at 1.37, 1.29, 1.27 and 1.18 ppm). An integration ratio of the ^{t}Bu and CCH_3 proton signals indicates the presence of three ^{t}Bu and eight CH_3 groups in the molecule. Besides the signals of the CCH_3 protons of **3**, the ^{1}H NMR spectrum reveals a singlet at 1.25 ppm, assigned to the CCH_3 protons of pinacol present in the crystalline compound.

The *C*O carbons of the diolate units of **3** exhibit ^{13}C resonances at 76.49 and 76.39 ppm, indicating two kinds of CO groups. The presence of three inequivalent ^{t}Bu groups attached to the metal atoms is confirmed by three singlets (at 32.69, 31.80 and 31.71 ppm) of GaC(CH_3)$_3$ carbons.

In the literature, a similar structure has been found for the aluminium glycolate ^{t}Bu$_3$Al$_2$(OCH$_2$CH$_2$O)(OCH$_2$CH$_2$OH) [19]. Recently, we have reported that compounds with the formula R_3M_2[diol-(2H)][diol-(H)] (R = alkyl group, M = Al, Ga, In) are intermediate products in reactions of 1,2-diols with group 13 metal trialkyls. These dinuclear intermediate complexes react subsequently with R_3M forming final trinuclear products R_5M_3[diol-(2H)]$_2$ [15]. Presumably, the reaction of ^{t}Bu$_3$Ga with pinacol stopped at the stage of the digallium compound **3** due to the lower reactivity of ^{t}Bu$_3$Ga in comparison with ^{t}Bu$_3$Al. Very recently, ^{t}Bu$_3$Ga has been found unreactive towards benzopinacol, whilst ^{t}Bu$_3$Al reacted with benzopinacol yielding the monomeric compound ^{t}BuAl[OC(C$_6$H$_5$)$_2$C(C$_6$H$_5$)$_2$O](C$_4$H$_8$O) [20].

In summary, we found that the structure of the products of reactions of sterically overcrowded 1,2-diol (pinacol) with aluminium and gallium trialkyls depends on the kind of alkyl group bonded to the metal atoms and on the kind of metal. The reaction of Me_3Al with pinacol afforded the trinuclear complex **1**. We found earlier that Me_3M (M = Al, Ga, In) reacts with sterically overcrowded 1,3-diols resulting in the formation of similar trinuclear diolates. Numerous compounds with structures similar to **1** have been published previously [2].

As was mentioned in Section 1, the interaction of sterically demanding 1,3-diols with aluminium and gallium trialkyls substituted by bulky alkyl groups (i.e., ^{t}Bu) leads to the dimeric complexes ^{t}Bu$_2$M$_2$[OC(CH)$_3$CH$_2$C(CH$_3$)$_2$O]$_2$. In contrast, a sterically overcrowded 1,2-diol (i.e., pinacol) forms the trinuclear complex **2** in reaction with ^{t}Bu$_3$Al. On the other hand, the reaction of pinacol with ^{t}Bu$_3$Ga stopped at the stage of the formation of compound **3**, which is an intermediate product of the reaction of 1,2-diols with group 13 trialkyls. It was presumably caused by the lower reactivity of ^{t}Bu$_3$Ga in comparison with ^{t}Bu$_3$Al.

3. Experimental

All manipulations were carried out using standard Schlenk techniques under an inert gas atmosphere. The solvents were distilled over a blue benzophenone–K complex. Me_3Al and pinacol were purchased from Aldrich. ^{t}Bu$_3$Al and ^{t}Bu$_3$Ga were synthesised as described in the literature [21,22] ^{1}H, ^{13}C and ^{27}Al NMR spectra were obtained on a Mercury-400BB spectrometer. ^{1}H NMR spectra were recorded at 400.09 MHz. Chemical shifts were referenced to the residual proton signals of $CDCl_3$ (7.26 ppm). ^{13}C NMR spectra were acquired at 100.60 MHz (standard: chloroform $^{13}CDCl_3$, 77.20 ppm). Chemical shifts of aluminium signals in ^{27}Al NMR spectra were referenced to the standard Al(acac)$_3$.

Elemental analysis of $\mathbf{3}\cdot 0.5C_6H_{14}O_2$ was obtained on a Perkin–Elmer 2400 analyser. Generally, alkylaluminium complexes are more sensitive to a moisture and oxygen than alkylgallium complexes. Therefore the complexes **1** and **2** were analysed by determination of hydrolysable Me groups and aluminium. The content of carbon and hydrogen in alkylaluminium compounds determined by the analyser was not proper due to a partial decomposition of the compounds during the preparation of samples under air atmosphere. Hydrolysable Me groups for compounds **1** and **2** were determined by hydrolysis of the compound (0.2–0.3 g) under argon using HNO_3 solution (10% concentrated, 5 cm^3) and measurement of the volume of CH_4. Subsequently the sample was transformed into Al_2O_3 by mineralization and the obtained white solid was dissolved in a diluted water solution of HNO_3. The content of aluminium was determined by complexation of Al^{3+} kations with versenate anions using an excess of the titrated solution of calcium disodium versenate. Then the excess of calcium disodium versenate was titrated by $FeCl_3$ according to the procedure described in [23].

Molecular weight of the complexes **1** and **2** was determined by the cryoscopy in benzene. The observed values of the molecular weight are lower than the calculated due to a presence of a small amount of solvents in the solid compounds.

3.1. Synthesis of $Me_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ (1)

A solution of pinacol (1.180 g, 10 mmol) in Et_2O (20 cm^3) was added to a stirred solution of Me_3Al

(1.224 g, 17 mmol) in Et_2O (30 cm^3) at −76 °C. A reaction mixture was allowed to warm to room temperature and then filtered. Volatiles were removed *in vacuo* from the filtrate. Compound **1** was sublimed off *in vacuo* from the residue as a white solid (yield 1.009 g, 2.6 mmol, 52%).

^{1}H NMR ($CDCl_3$): δ 1.31 (12H, s, CCH_3), 1.24 (12H, s, CCH_3), −0.63 (6H, s, AlCH_3), −0.79 (3H, s, AlCH_3), −0.87 (6H, s, AlCH_3). ^{13}C NMR ($CDCl_3$): δ 80.44 (*C*O), 26.08 (*C*H_3), 25.97 (*C*H_3), −6,01 (Al*C*H_3, broad), −9.18 (Al*C*H_3, broad). ^{27}Al NMR ($CDCl_3$) δ 148 (Al 4-coord.), 83 (Al 5-coord.) ppm.

Elemental *Anal.* Found: Al, 20.40; hydrolysable methyl groups, 19.92; Calc. for $Me_5Al_3[OC(CH_3)_2C(CH_3)_2O]_2$ Al, 20.85; Me, 19.31 wt.%. Molecular weight: found: 375, calc.: 388.

A solution of **1** in *n*-C_5H_{12} upon cooling to −25 °C furnished X-ray quality crystals. M.p.: 186–190 °C.

3.2. Synthesis of $^tBu_3Al_3[OC(CH_3)_2C(CH_3)_2O]_3$ (2)

A solution of pinacol (1.180 g, 10 mmol) in $C_6H_5CH_3$ (10 cm^3) was added to a stirred solution of $^tBu_3Al \cdot OEt_2$ (2.720 g, 10 mmol) in $C_6H_5CH_3$ (10 cm^3) at room temperature. The reaction mixture was refluxed for 0.5 h. Then volatiles were removed *in vacuo* from the post-reaction mixture resulting in a pure compound **2** as a white solid (yield 1.982 g, 3.3 mmol, 99%).

^{1}H NMR ($CDCl_3$): δ 1.59 (6H, s, CCH_3), 1.42 (6H, s, CCH_3), 1.34 (6H, s, CCH_3), 1.28 (6H, s, CCH_3), 1.14 (12H, s, CCH_3), 1.07 (9H, s, AlCCH_3), 1.03 (9H, s, AlCCH_3), 1.02 (9H, s, AlCCH_3). ^{13}C NMR ($CDCl_3$): δ 81.20, 80.79, 77.84, 76.15 (*C*O), 31.27, 31.16, 30.48 (AlC(*C*H_3)), 29.20, 28.72, 27.92, 27.88, 26.25, 25.65 (C*C*H_3) ppm.

Elemental *Anal.* Found: Al, 13.02; hydrolysable ^{t}Bu groups, 27.98; Calc. for $^tBu_3Al_3[OC(CH_3)_2C(CH_3)_2O]_3$ Al, 13.48; ^{t}Bu, 28.45 wt.%. Molecular weight: found: 570, calc.: 601.

A solution of **2** in *n*-C_5H_{12} upon cooling to −25 °C furnished X-ray quality crystals. M.p.: 213 °C.

3.3. Synthesis of $^tBu_3Ga_2[OC(CH_3)_3C(CH_3)_2O][OC(CH_3)_3C(CH_3)_2OH] \cdot 0.5C_6H_{14}O_2$ (**3** · $0.5C_6H_{14}O_2$)

A solution of pinacol (1.180 g, 10 mmol) in $C_6H_5CH_3$ (10 cm^3) was added to a stirred solution of $^tBu_3Ga$ (2.410 g, 10 mmol) in $C_6H_5CH_3$ (10 cm^3) at room temperature. The reaction mixture was refluxed for 3 h, then filtered. After the filtrate was stored at 5 °C for several days, colourless crystalline **3** · $0.5C_6H_{14}O_2$ was isolated (yield 0.965 g, 1.6 mmol, 40% based on pinacol). M.p.: 150–152 °C.

^{1}H NMR ($CDCl_3$): δ 3.90, [(2H, s, broad, O*H*), The chemical shift of the O*H* group signal depends on the conditions of NMR measurements. In the spectra of different samples we also observed the O*H* signal at 4.24, 3.60 and 3.85 ppm.], 1.37 (6H, s, CCH_3), 1.29 (6H, s, CCH_3), 1.27 (6H, s, CCH_3), 1.25 (6H, s, CCH_3, 0.5 mol of $HOC(CH_3)_2C(CH_3)_3COH$ per 1 mol of **3**), 1.18 (6H, s, CCH_3) 1.17 (9H, s, GaC(CH_3)$_3$) 1.11 (9H, s, GaC(CH_3)$_3$), 1.10 (9H, s, GaC(CH_3)$_3$). ^{13}C NMR ($CDCl_3$): δ 76.49, 76.39 (*C*O), 32.69, 31.80, 31.71 (GaC(*C*H_3)$_3$), 31.70, 31.48, 31.31 (Ga*C*)$(CH_3)_3$ 28.96, 27.74, 27,44, 26.93 (C*C*H_3), 24.88 (C*C*H_3, 0.5 mol of $HOC(CH_3)_2C(CH_3)_3$-COH per 1 mol of **3**).

Anal. Found (Calc.) for $C_{27}H_{59}Ga_2O_5$: C, 53.40 (53.73); H, 9.80 (9.78)%.

3.4. X-ray crystal structure analyses

Crystals of compounds **1**, **2** and **3** · $0.5C_6H_{14}O_2$ were mounted in inert oil and sealed in glass capillaries under argon. Determination of the crystal structures of **1**, **2** and **3** · $0.5C_6H_{14}O_2$ was performed on a KUMA KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation. The crystal of **1** was positioned at 62.25 mm from the KM4CCD camera and 600 frames were measured at 1.0° intervals with a counting time of 25 s. The crystal of **2** was positioned at 62.25 mm from the KM4CCD camera and 500 frames were measured at 1.2° intervals with a counting time of 35 s. The crystal of **3** · $0.5C_6H_{14}O_2$ was positioned at 62.25 mm from the KM4CCD camera and 900 frames were measured at 1.0° intervals with a counting time of 30 s. All of the data were corrected for Lorentz and polarisation effects. The numeric absorption correction was applied. Data collection, cell refinement and data reduction were carried out with the KUMA diffraction programs [24]. The structure was solved by direct methods [25] and refined using SHELXL [26]. All hydrogen atoms were placed in the calculated positions and their thermal parameters were refined isotropically. Scattering factors were taken from the literature [27, Tables 6.1.1.4 and 4.2.4.2].

The X-ray structures were measured in the Crystallography Unit of the Physical Chemistry Laboratory at the Chemistry Department of the University of Warsaw.

4. Supplementary material

CCDC 662821, 662822, 662821 contain the supplementary crystallographic data for **1**, **2** and **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

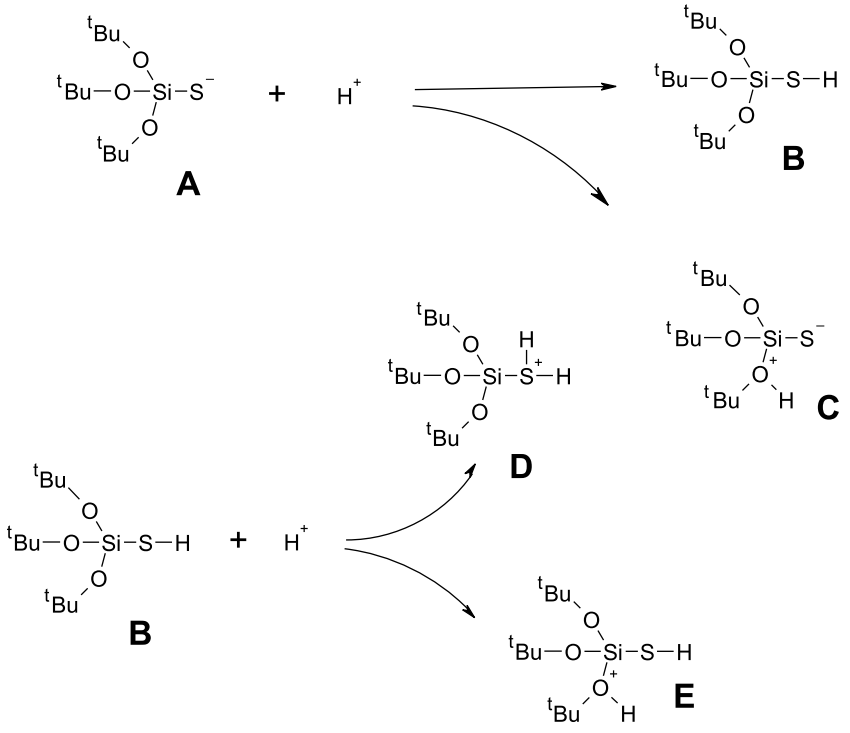
level were made only for the simplest H_3SiSH/H_3SiS^- case. We decided to asses again the problem of geometry changes using the currently available quantum chemistry tools that focus on the search for anomeric effects.

This work describes a systematic examination of tri-*tert*-butoxysilanethiol and its derivatives by analyzing protonation on the sulfur as well as the oxygen atoms. The study involves density functional theory (DFT) studies on the equilibrium geometry of the species, and the subsequent analysis of the structures by the natural bond orbital (NBO) method. The latter has a unique feature of analyzing the electron density by using sophisticated basis sets and methods in terms that are familiar to a chemist, such as: Lewis structure, lone pairs, bonds, anti-bonds and Rydberg electrons. It also allows the analysis of intramolecular donor–acceptor orbital interactions. Such (anomeric) interactions have successfully explained some of the kinetic characteristics of alcoholysis in silanethiols [6,7].

The results of the study should be applicable for describing and better understanding the chemical reactivity of silicon–sulfur compounds in vacuum and in condensed phases. In addition, the aim of this study was to provide a theoretical basis for rationalizing the geometry changeability found in many metal and ammonium silanethiolates [8] that have been characterized by the X-ray method.

2. Results and discussion



Basic mechanisms of the protonation and deprotonation of tri-*tert*-butoxysilanethiol, and the characterization of the described species are presented in Scheme 1.

Only the processes of proton exchange on the sulfur and oxygen atoms were analyzed as they are presumed to be the most important.

The structure of compounds **A**, **B**, **C**, **D** and **E** (**A**–**E**) were optimized at the B3LYP/6-31+G(d) level. Vibrational frequencies were calculated for all species to determine whether they were minima, transition structures or higher order saddle points. No imaginary frequency mode was found, which is equivalent to classifying all the species as stable compounds, being at the minimum of their potential energy surface. The computed electronic and vibrational energy values for the analyzed species are shown in Table 1.

2.1. Energetics of proton exchange processes

(a) *Reactivity in vacuum.* Protonation of the $(^tBuO)_3SiS^-$ anion **A** on the sulfur atom leads to silanethiol **B**, while its protonation on the oxygen atom gives "zwitterion" **C** with a negative charge on sulfur and a positive charge at the $-OH^+-$ oxonium group. Ground state energy calculations indicate that **B** is the preferred product, and it is *ca.* 100 kJ mol^{-1} more stable than **C**. Further protonation of tri-*tert*-butoxysilanethiol **B** on the sulfur atom yields the $-SH_2^+$ group in compound **D**; when the oxygen atom is attacked, the oxonium group is formed (preserving the –SH residue) in compound **E**. In this case, energy considerations point to compound **E** as being more stable than **D** by *ca.* 17 kJ mol^{-1}. Every protonation decreases the energy. The abovementioned results describe (more or less accurately) acceptance of a

Scheme 1.

Table 1
Overview of electronic DFT (RB + HF–LYP) energies, thermal corrections (zero point energy, ZPE) obtained from geometry optimization, and the results of single point calculations for compounds **A**–**E**

	A	**B**	**C**	**D**	**E**
	Geometry optimization B3LYP/6-31+G(d)				
DFT (a.u.)	−1387.17383	−1387.708633	−1387.671416	−1388.044723	−1388.049933

IPCM B3LYP/6−311++G(d,p) (a.u.)	−1387.49249265	−1387.95053269	−1387.92716924	not converged	−1388.36029228

The last but one row lists the differences in the corrected (by subtraction of ZPE scaled by 0.9804) DFT energies in relation to tri-*tert*-butoxysilanethiol **B**. The single point methods included DFT and isodensity polarized continuum model, IPCM [9] computation.

free proton by a single molecule placed in a vacuum. Such an energy gain is usually termed the "proton affinity".

(b) *Protonation in solution.* Considering a real life chemical experiment, the proton source is most often either the hydrated proton $H^+(H_2O)_n$ (from $n = 1$ up to $n \geqslant 6$) from the bulk aqueous phase or the solvated non-ionized acid molecule (or acid oligomer) from an organic phase. Therefore, instead of a simple reaction:

(a) $(^t\mathrm{BuO})_3\mathrm{SiSH} + \mathrm{H}^+ = (^t\mathrm{BuO})_3\mathrm{SiSH_2}^+$

one must regard another reaction scheme:

(b) $(^t\mathrm{BuO})_3\mathrm{SiSH} + \mathrm{H}^+(\mathrm{H_2O})_n = (^t\mathrm{BuO})_3\mathrm{SiSH_2}^+ + (\mathrm{H_2O})_n$

which can be decomposed into the following algebraic sum: (b) = (a)–(c), where

(c) $\mathrm{H}^+ + (\mathrm{H_2O})_n = \mathrm{H}^+(\mathrm{H_2O})_n$.

Heat balance for the aqueous phase was estimated based on this decomposition. The formation energy for water clusters and protonated water clusters (Reaction c) has been the subject of many studies [10,11] as it is important for calorimetric measurements of enthalpy and the Gibbs energy of ion solvation. The absolute hydration enthalpy for a proton was determined with good accuracy [12] to be −1150.1(9) kJ mol^{-1}.

In order to calculate the energy gain in the type (a) reaction, we applied Tomasi's Isodensity Polarized Continuum Model energy values instead of the previously computed energies of molecules in a vacuum. In this approach, we regarded water only as a polarized medium of dielectric constant $\varepsilon = 78.38$, *i.e.* the formation of all additional hydrogen bonds was neglected. The pertinent results have been collated in Table 2. The hydration enthalpy value turned out to be lower than the energy gain for protonation on the sulfur atom in anion **A**, but bigger than the energetic stabilization for protonation on the oxygen atom or any protonation of silanethiol **B**.

Thus, we arrived at the qualitatively correct conclusion about protonation in silanethiol-related systems. Protonation of the anion derived from silanethiol in the aqueous solution of acids is energetically feasible, while further protonation of silanethiol in such medium does not take place (see Table 2). The single point energy calculation using the ICPM method for $(^t\mathrm{BuO})_3\mathrm{SiSH_2}^+$ failed to converge. This might indicate that the compound ionizes in solvents with a higher dielectric constant. Products **C**, **D** or **E** are not stable in the presence of the water phase, however they can be found in the gas phase, *e.g.* during mass spectroscopy experiments.

Table 2
Model of protonation in the aqueous phase

Compound	Protonation site	Protonation energy ICPM (kJ mol^{-1})	Energy gain (a)–(c) (kJ mol^{-1})
A: $(^t\mathrm{BuO})_3\mathrm{SiS}^-$	S	−1177.904	−27.804
	O	−1107.657	42.443
B: $(^t\mathrm{BuO})_3\mathrm{SiSH}$	S	not converged	>104
	O	−1045.831	104.269

The third column lists the energy difference between the protonated and non-protonated species obtained by the IPCM B3LYP/6-311++G(d,p)// B3LYP/6-31+G(d) model, and is corrected for vibrational zero point energy, scaled by 0.9804.

2.2. Geometry of the species

A search of the Cambridge Structural Database (CSD version 5.28, with May 2007 updates [13]) revealed that X-ray structural data are currently available for 61 metal and 7 ammonium tri-*tert*-butoxysilanethiolates. Unfortunately, there are no such data for the species analyzed in this study, except for anion **A** present in ionic compounds, *e.g.* $\{[\mathrm{Co}\{\mathrm{SSi}(\mathrm{OBu}^t)_3\}_2(\mathrm{NH_3})_4]^{(+)}$ and $(\mathrm{Bu}^t\mathrm{O})_3\mathrm{SiS}^{(-)}\}$ [14]. The lack of crystal structures is perhaps due to the limited stability of compounds **C**, **D** and **E**, or, in the case of **B**, due to a low melting point of *ca.* −28 °C which is, of course, only a technical obstacle. The starting geometries were derived from the X-ray structure of **A** by cutting-out from the abovementioned structure. Because the geometries of all the other compounds were optimized by quantum-chemical

* Group with protonated oxygen.

methods [22], *i.e.* by assuming a no-neighbors environment, the same optimization procedure was also applied to the anionic species. Optimization by the B3LYP/6-31+G(d) method gave satisfactory results, especially with regards to the reproduction of the Si–S bond length.

Let us first consider changes in geometry due to protonation on sulfur only, *i.e.* along the pathway from anion **A** through silanethiol **B** to *S*-protonated silanethiol **D**. There is quite a regular trend in the Si–S bond length, namely the more the positive charge on the sulfur atom, the longer the bond. This observation is consistent with the previous findings [5] based on the Si–S bond elongation during transformation from the anion form into silanethiol. It is commonly recognized that the role of the Si d-electrons is marginal in explaining the strength and consequently the length of the Si–S bond. This question will be addressed once more in the section dedicated to NBO analysis.

It is noteworthy that the Si–S–H valence angle is close to a right angle, indicating that the hybridization of the orbitals plays a minor role in the case of sulfur. This is also true for the $-SH_2^+$ groups (see Table 3).

The average Si–O bond length decreases in the series of species arranged according to increasing protonation, *i.e.* **A** → **B** → **D**. Changes in the Si–O bond length can be explained by taking into account the second order perturbation effects, also called the anomeric effect or hyperconjugation. This phenomenon has the character of energetic stabilization due to the donation of electrons from the sulfur lone pair(s) to the anti-bonding σ^*(Si–O) orbitals. Obviously, the donation is more significant for anion **A**, where nominally 3 lone pairs are available (actually, only 2 lone pairs of higher energy are interacting.). In compound **B** only one high energy pair on sulfur is available, while in **D** there are none. As the anti-bonding orbitals become more populated, the Si–O bonds get weaker (and longer too). A detailed discussion on the effects in natural bond orbital (NBO) terms will be presented in a later part of this work.

One more feature can be considered now. The coordination mode of the silicon atom changes from pseudo tetrahedral to pseudo trigonal pyramidal. Changes in the S–Si–O angles are quite substantial, namely from on average *ca.* 116° for **A** to 98° for **D**. On one hand, this indicates that the *S*-protonated silanethiol is ready for cleavage of the Si–S bond with the accompanying release of H_2S and the creation of a flat silicenium cation. On the other hand, such a deformation facilitates nucleophilic attack on the silicon atom from the direction opposite to the SH_2^+ group.

Moreover, a backward shift of the *tert*-butoxy groups in the case of anion **A** leads to greater steric hindrance at the reaction side of the Si atom. This can provide another explanation for the smaller hydrolytic reactivity of **A** in comparison to the respective silanethiol. The described difference has been observed for long time in experimental studies, *e.g.* by Sommer et al. [15,16]. So, the lower reactivity of **A** in nucleophilic attack can be explained in three ways:

(a) The negative charge of the anion slows the reaction down because of electrostatic repulsion.
(b) The Si–S bond to be cleaved is shorter (and stronger) in the anion form than in silanethiol.
(c) For anions, the steric hindrance of the butoxy groups is greater if we assume axial attack of a nucleophile, *e.g.* amongst the three O^{t}Bu groups. Such a geometry facilitates vertical attack of a nucleophile, *e.g.* between the sulfur atom and the O^{t}Bu group which are at a wider angle.

Now, let us turn to the *O*-protonated species. First of all, protonation of anion **A** is preferred on the *S* atom leading to silanethiol **B**. The *O*-protonated species **C** is of higher energy. Nevertheless, the optimal geometry of **C** has some interesting features. Most striking is the shortening of the Si–S bond length. It is even shorter than the corresponding bond in anion **A**. This resembles bond lengths (*ca.* 1.95–2.01 Å) found in silathione [17,18] compounds of the $R_2Si{=}S$ type with the R residues being bulky 2,4,6-substituted (with –*i*Pr or $-CH(SiMe_3)_2$) phenyl groups, or silathiones [19] with additional coordination of nitrogen by silicon. Short Si–S bond can also be found in zwitterions: silatiolato-phosphonic [20] Ph_3P^+–CMe_2–

$SiMe_2S^-$, or silatiolato-arsonic [21] Et_3As^+–$CHSiMe_3$–$SiMe_2$–S^-, or Et_3As^+–CHPh–$SiMe_2$–S^-.

Compound **C** can be regarded as a kind of adduct of $^tBuOH...(^tBuO)_2Si{=}S$ with a separated charge (and ^tBuOH with a long C–O bond) which explains the shortening of the Si–S bond. Additional DFT computations using the same B3LYP/6-31+G(d) method were carried out to calculate the optimized geometry for the molecule of $(^tBuO)_2Si{=}S$ (**F**). The obtained Si–S bond length of 1.963 Å has confirmed the expected shortening for the double bonding. Species **C** can decompose into *tert*-butanol + silathion or into buten+"zwitterionic" di-*tert*-butoxysilanethiolate anion with the OH_2^+ group bound to silicon. Both decompositions are more likely to occur in vacuum at elevated temperatures.

Let us examine the geometry of the *O*-protonated silanethiol **E**. The reason for the shortening of the Si–S bond in **E** in relation to **D** cannot be directly inferred from the above discussion, but the changes are of similar character. In this case, the structure can be regarded as a loose adduct of *tert*-butanol with the silicenium cation: $^tBuOH...(^tBuO)_2Si(+)SH$. The Si–S bond length in the cation is also short. DFT-based geometry optimization carried out for $(^tBuO)_2Si(+)SH$ (**G**) yielded a bond length of 2.077 Å. A qualitative explanation for this effect might be the shrinking of the silicon orbitals resulting in better matching for the size of sulfur, which leads to the higher value of the Si–S bond overlap integral and the consequent shortening of the bond.

Both cases, *i.e.* bond shortening for *O*-protonation and bond elongation for *S*-protonation, show some similarities to the shortening of Si–S bonds found in metal silanethiolates where the ligand acts as a chelating *O,S*-donor for the metal centers. Of course it is not obvious how to separate the shortening of the Si–S bond related to the greater ionic character of the $(^tBuO)_3SiS$ group from shortening due to chelation (which is similar to *O*-protonation).

The Si–O bonds are substantially longer (1.636 and 1.623 Å) in **F** as compared to the respective bonds in **G** (1.577 and 1.579 Å). This phenomenon can be explained in many possible ways. First of all, a positive charge on silicon can result in stronger interactions with the oxygen atoms. It can also be a manifestation of electron donation from the sulfur lone pairs to the anti-bonding Si–O orbitals, which is stronger in the case of silathion **F** than the silicenium cation **G**.

For a more quantitative discussion, we will analyze the NBO orbitals and the second order perturbation energy stabilization due to internal donor–acceptor orbital interactions (principal delocalizations).

2.3. NBO analysis

2.3.1. Anion $(^tBuO)_3SiS^-$ (**A**)

Selected results from the natural population analysis for the compound are presented in Tables 4 and 5. Let us analyze both the occupation and hybridization of the S and O lone pairs. One lone pair on sulfur lp(1) S has mainly s character and it is practically occupied by two electrons. The second and third lone pairs are mainly of p character and their occupation is lower, suggesting the interaction with other, possibly anti-bonding, orbitals. Interestingly, the silicon d orbitals (here RY*(1) Si2) are by far less occupied than the anti-bonding Si–O orbitals. The lone pairs on oxygen are not uniform. Each oxygen atom possesses one pair of p character and one hybrid orbital approximately described as $sp^{2.65}$. Less populated and used as donors in the stabilization of the molecule are mainly the p character lone pairs lp(2) O3, etc. (see Table 5).

Second-order perturbation stabilization (Table 5) is dominated by the donation of electrons from lone pairs (from the sulfur as well as oxygen atoms) to the anti-bonding Si–O orbitals. In turn, the populated, anti-bonding Si–O orbitals behave as electron donors to the Rydberg silicon orbitals, which also results in a stabilizing effect. It is worth noting that in a polarized bond such as Si–O, the anti-bonding σ^*(Si–O) orbital has a greater wavefunction coefficient at the silicon atom as compared to oxygen, so the overlap with the sulfur p-electrons is relatively strong. This σ–π overlap is also effective because the σ^*(Si–O) orbital has three nodal planes so the symmetry of the orbitals is compatible (see Fig. 1). When the aforementioned interaction is analyzed as delocalization, we arrive at the following situation. Two three-centered orbitals are produced from a lone pair and an anti-bond. The lower energy 3c–2e orbital

Table 4
Characteristics of selected orbitals in **A** based on the natural population analysis

Orbital	Occupation	Composition %			
		s	p	d	Contributions of atoms to the orbital
LP(1)S1	1.97102	76.17	23.82	0.01	
LP(2)S1	1.87979	0.12	99.82	0.47	
LP(3)S1	1.85530	0.04	99.89	1.94	
LP(1)O3	1.93702	27.31	72.64	0.05	
LP(2)O3	1.91047	0.03	99.93	0.04	
RY*(1)Si2	0.02935	0.53	11.88	87.59	
BD*(1)S1–Si2	0.06831				32.4%S, 67.6%Si
BD*(1)Si2–O3	0.13495				87.79%Si, 12.21%O
BD*(1)Si2–O4	0.15554				88.04%Si, 11.96%O
BD*(1)Si2–O5	0.14056				87.89%Si, 12.11%O

Abbreviations: LP – lone pair; RY*, BD, BD* – Rydberg, bonding and anti-bonding orbital, respectively.

Table 5
Second order perturbation theory analysis of the Fock matrix for [**A**] based on the NBO method

Donor NBO (*i*)	Acceptor NBO (*j*)	$E^{(2)}$ (kcal/mol)	$E(j) - E(i)$ (a.u.)	$F_{i,j}$ (a.u.)
LP(3)S1	BD*(1)Si2–O5	13.98	0.44	0.070
LP(2)S1	BD*(1)Si2–O4	11.11	0.44	0.063
LP(2)O3	BD*(1)Si2–O4	9.08	0.59	0.067
LP(2)S1	BD*(1)Si2–O3	8.84	0.45	0.056
LP(2)O4	BD*(1)Si2–O3	8.70	0.61	0.066

Items with the highest energy gain were selected.

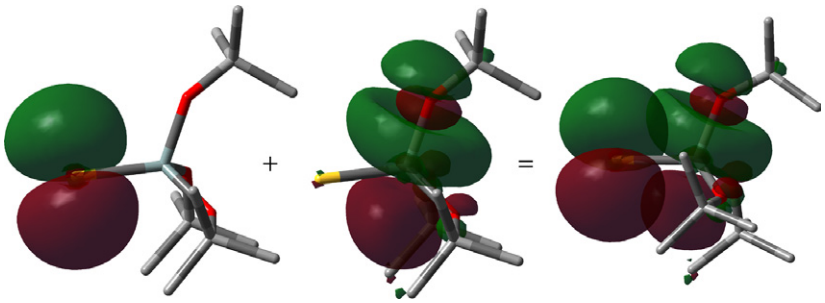

Fig. 1. Geometry of sulfur lone pair overlap with the anti-bonding Si–O orbital generated by GaussView 4.1 (Gaussian, Inc., Pittsburg, PA). Hydrogen atoms are not shown.

increases electron density between the Si and S atoms and decreases electron density between Si and O. This serves as a good explanation for the geometry changeability in **A**, **B** and **D**.

It should be emphasized that the sulfur lone pairs do not act as donors for empty d silicon orbitals (here described as RY* Si), as was initially believed at the earlier developmental stages of silicon chemistry. The energy difference between the two levels is too high to result in important interactions (*e.g.* for lp(2) S1 and RY*(2) Si2, $E(j) - E(i) = 1.03$ a.u.).

2.3.2. Tri-tert-butoxysilanethiol (*B*)

The detailed results of the NBO analysis are given in the Supplementary Materials. This time, the stabilization effects were not reinforcing the Si–S bond so much. As stated previously in qualitative terms, only one lone pair of sulfur gives the second order perturbational stabilization. Lone pairs on oxygen O3 and O4 mutually populate their anti-bonding Si–O orbitals. The third oxygen lone pair lp(2) O5 populates the anti-bonding Si–S orbital, which obviously weakens the bond.

2.3.3. O-protonated anion "zwitterion" (*C*)

The NBO algorithm search for the best Lewis structure returned the structure split into silathion and butanol. Because of that one can find two Si–S bonds, *i.e.* BD(1) S1–Si2 and BD(2) S1–Si2 of σ and π character, respectively, and their anti-bonding partners. Electron density is transferred from one pair LP(2) S1 to the anti-bonding Si2–O5 and Si2–O4 orbitals which, in turn, interact with the anti-bonding C–O orbitals in silathion. The occupation values of the Si–O anti-bonds are quite high. It seems that the orbitals in the vicinity of the silicon atom are indeed highly delocalized.

2.3.4. S-protonated silanethiol (*D*)

Inertness of the lone pair on sulfur is again apparent (see Tables 9 and 10 in the Supplementary Materials); it does not participate in the donation of electrons. This has been confirmed by the high occupancy of the orbital and the pair's absence on the donors list. A relatively high occupation of the anti-bonding Si–S orbital is noteworthy. In this specific compound, the most important second order perturbation effects are generated by lone pairs on the oxygen atoms. In this case, the oxygen pairs that are essentially of p character destabilize the Si–S bond, which results in the greatest energy gain for the system. The process is facilitated by the symmetry of the Si–S anti-bond, namely, sigma symmetry with three nodal planes (Fig. 2). The anti-bonding orbital fits well to the p-type lone pairs on oxygen because SiO_3 is almost a flat system. Again, the lone pairs on oxygen additionally and mutually populate the Si–O anti-bonding orbitals. However, this interaction is not very strong because the energy difference between the levels is high (*ca.* 0.7 a.u.).

2.3.5. O-protonated silanethiol (*E*)

The assignment of double bonds to the two Si–O groups in the best Lewis structure is noteworthy. Inertness of the lone pair on sulfur can be easily seen in Tables 11 and 12 (Supplementary Material). The pair's contribution to donating electrons is not significant. The analysis of the donors and acceptors list points to the high delocalization of the Si–O bonds as being the main stabilizing effect.

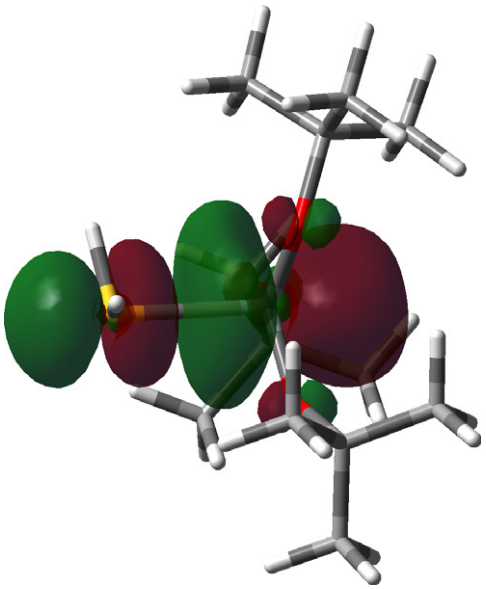

Fig. 2. Shape of the anti-bonding σ*(Si–S) orbital in **D**.

3. Experimental

The quantum mechanical calculations were made using the GAUSSIAN03W [22] package, including NBO [23,24] analysis. Geometry optimizations were performed using the B3LYP/6-31+G(d) method. The starting geometry for **A** was taken from a fragment of the X-ray structure of $[Co(RS)_3(NH_3)_4]^{(+)} \cdot {}^{(-)}SSi(OBu^t)_3$ [14] and later optimized by applying DFT analysis to cancel the effects of packing and hydrogen bonds present in the solid state. This procedure also removed the differences of the C–H bond lengths measured by the X-ray crystallography [25] and set by quantum mechanics. All the other starting geometries were derived from **A** by adding hydrogen atoms and by modifying the total charge of the species. The optimized structures of compounds **A**–**E** are available in PDB format as supplementary material.

Single point ground state energy calculations were carried out on the B3LYP/6-311++G(d,p) and MP2/6-311++G(d,p) level (see Supplementary Materials). The inclusion of solvent effects was performed with a Tomasi IPCM – B3LYP model using the same basis set.

4. Summary

Theoretical considerations of protonation and deprotonation of tri-*tert*-butoxysilanethiol led to the following conclusions:

1. Protonation of the $({}^t BuO)_3SiS^-$ anion is energetically preferred on the sulfur atom and yields tri-*tert*-butoxysilanethiol. Protonation on the oxygen atom also yields a relatively stable product.
2. Protonation of tri-*tert*-butoxysilanethiol can be accomplished by proton acceptance in the gas phase, which yields relatively stable products. Energetically preferred is protonation on the oxygen atom although protonation on the sulfur atom is almost equal in lowering the total energy. These processes do not proceed by transfer of a proton solvated in the aqueous phase or bound in $H^+(H_2O)_n$ clusters with a solvation energy greater than *ca.* 870 kJ mol^{-1} in vacuum.
3. Protonation of both tri-*tert*-butoxysilanethiol and its anion on the sulfur atom results in the elongation of the Si–S bond.
4. Protonation of both tri-*tert*-butoxysilanethiol and its anion on the oxygen atom results in the shortening of the Si–S bond.
5. Delocalization of lone pairs from sulfur proceeds mainly by the interaction with the anti-bonding σ^*_{Si-O} orbitals. It is noteworthy that due to polarization effects these orbitals have greater lobes on the silicon side, which is critical for effective interactions.
6. The numerous values of bond lengths and their changes during transformation can be explained by the intermolecular donor–acceptor orbital interactions. The NBO analysis provides a satisfactory description of the geometry changes in the analyzed class of substances.

The obtained results provide a good basis for a more detailed analysis of geometry changes that have been observed in the structure of metal (or ammonium) silanethiolates.

Although a large amount of work on the synthesis and characterization of transition metal complexes of Schiff bases of *S*-alkyl esters of dithiocarbazic acid have been reported [1–15] very little work has been reported on organometallic complexes of these ligands. In view of very little information available on organotin(IV) complexes of dithiocarbazates and as part of our ongoing work on metal complexes of dithiocarbazic acid and its derivatives, we report here the synthesis, characterization and X-ray crystal and molecular structures of the acetone Schiff bases of *S*-methyl- and *S*-benzyldithiocarbazate together with the structures of their chlorodiphenyltin(IV) complexes.

2. Experimental

2.1. Reagents

Chemicals and solvents used were of analytical reagent grade and used without any further purification. Dichlorodiphenyltin(IV) was purchased from the Aldrich Chemical Company.

2.2. Physical measurements

Microanalyses for C, H & N were performed by the Elemental Analysis Laboratory, National University of Singapore, Singapore. Molar conductivity of *ca.* 10^{-3} M solutions of the complexes in DMSO were measured by means of a Jenway 4310 conductivity meter. The IR spectra were measured as KBr discs on a Perkin–Elmer 2000 FT-IR spectrometer and the electronic spectra were measured as Nujol mulls on a Shimadzu MPC-3100 spectrophotometer. The ^{1}H NMR spectra of the tin(IV) complexes were run in $CDCl_3$ on a Bruker DPX 300 MHz spectrometer using TMS as an internal standard. The Mössbauer spectra were recorded using a Model MS-900 (Ranger Scientific Co., Burleson, TX) spectrometer in the acceleration mode with moving source geometry. A 5-mCi $Ca^{119m}SnO_3$ source was used. The spectra were measured at 80 K using a liquid–nitrogen cryostat (CYRO Industries of America Inc.). The velocity was calibrated at ambient temperature using a composition of $BaSnO_3$ and tin foil (splitting 2.52 mm s^{-1}). The resultant spectra were analyzed by a least-square fit to Lorentzian shaped lines.

2.3. Preparation of the ligands

The Schiff bases were prepared by following procedures reported previously [14,16]. The compounds as isolated from the reaction were suitable for X-ray crystallography.

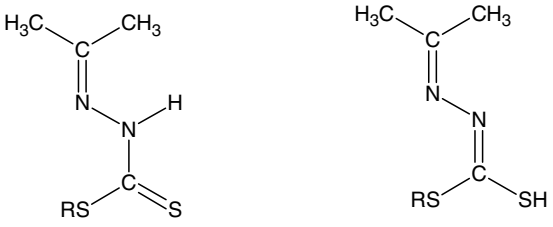
2.4. General method of preparation of the complexes

To a solution of $SnPh_2Cl_2$ (1 mmol) in boiling abs. ethanol (70 ml) was added a solution of the appropriate Schiff base (1 mmol) in the same solvent (70 ml) and the mixture heated under reflux for 48 h and then left to stand overnight. The product that had formed was filtered off, washed with abs. ethanol and dried in a vacuum desiccator over anhydrous silica gel. These compounds as isolated were suitable for X-ray work. Yield: 50–60%. *Compound* **3** Sn(acsme)Ph_2Cl: *Anal.* Calc. for $C_{17}H_{19}N_2S_2ClSn$: C, 43.48; H, 4.08; N, 5.96. Found: C, 43.40; H, 4.03; N, 5.85%. *Compound* **4** Sn(acsbz)Ph_2Cl: *Anal.* Calc. for $C_{23}H_{23}N_2S_2ClSn$: C, 50.62; H, 4.25; N, 5.13. Found: C, 50.52; H, 4.15; N, 5.46%.

2.5. Crystallography

Cell constants were determined by a least-squares fit to the setting parameters of 25 independent reflections, measured on an Enraf-Nonius CAD 4 four-circle diffractometer using graphite monochromated Mo Kα radiation (0.71073 Å) and operating in the $\omega - 2\theta$ mode within the range $2 < 2\theta < 50°$. Empirical absorption correction (ψ scans) and data reduction were performed with the WINGX [17] suite of programmes. The structures were solved by direct methods with SHELX86 and refined by full-matrix least-squares analysis with SHELXL97 [18]. Non-hydrogen atoms were refined with anisotropic thermal parameters whereas H-atoms were included at estimated positions using a riding model. Drawings of each molecule were produced with ORTEP3 [19]. A summary of the crystal data, structure solution and refinement parameters are given in Table 1 and selected bond lengths appear in Table 6.

3. Results and discussion



The acetone Schiff bases of *S*-methyldithiocarbazate and *S*-benzyldithiocarbazate have a thioamide (–NH–CS–) functional group and consequently, in principle, they are capable of existing either as the thione form (1a) or the thiol form (1b) or as a mixture of both thione and thiol tautomeric forms (Fig. 1). In the solid state it has been shown that they exist in their thione forms since their IR spectra exhibit the *ν*NH band at *ca.* 3300 cm^{-1} and no *ν*SH band at *ca.* 2600 cm^{-1} [14]. However, in solution they might exist as an equilibrium mixture of both the thione and thiol tautomeric forms. The ^{1}H NMR spectra of the Schiff bases in $CDCl_3$ exhibit a signal at *ca.* 10.15 ppm which is characteristic of an NH as opposed to an SH resonance. No signal at *ca.* 4.00 ppm attributable to the SH proton was detected indicating that even in solution they remain predominantly as the thione tautomer.

3.1. Characterization of the Sn(IV) complexes

In a boiling ethanolic solution the Schiff bases react with $SnPh_2Cl_2$ in their thiol tautomeric forms, deprotonate and coordinate to the tin(IV)ion forming charge neutral complexes of formula, $SnPh_2(NS)Cl$ (NS = deprotonated form of the Schiff bases). The analogous acetone thiosemicarbazone which exhibits a structural backbone very similar to the present compounds, has been shown to react with

$SnPh_2Cl_2$ yielding a diphenyltin(IV) complex containing the neutral form of the ligand [20]. This example illustrates the diversity of reactivity found in these Schiff base ligands in their coordination chemistry with Sn(IV).

The complexes are stable at room temperature and may be kept in a desiccator over anhydrous silica gel for extended periods without any sign of decomposition. The molar conductivities of Sn(acsme)Ph_2Cl and Sn(acsbz)Ph_2Cl in DMF are 11.7 and 11.8 Ω^{-1} cm^2 mol^{-1}, respectively, indicating that even in a polar coordinating solvent like DMF, they behave essentially as non-electrolytes. The conductance data confirm that the Schiff bases coordinate to the tin atom in their monodeprotonated forms.

The IR spectra of the $SnPh_2$(*NS*)Cl complexes when compared with those of the free Schiff bases (Table 2) show that the νNH bands of the free ligands at *ca.* 3300 cm^{-1} are absent in the spectra of the complexes indicating that the ligands are coordinated to the tin atom in their deprotonated mercaptide forms. The shift of the azomethine $\nu_{C=N}$ band in the IR spectra of the free ligands (1634–1628 cm^{-1}) to lower wavenumber (1612–1608 cm^{-1}) in the spectra of complexes support coordination of the azomethine nitrogen atom to the tin atom. This is further supported by the shift of the ν_{N-N} band of the free ligands to higher wavenumbers in the spectra of the complexes.The electronic spectra of the complexes show the intraligand $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions in the ranges 363 and 311–258 nm, respectively. The $n \rightarrow \pi^*$ band of the free ligands is not affected in the electronic spectra of the complexes but there is a hypsochromic shift of the $\pi \rightarrow \pi^*$ band upon coordination to Sn(IV).

The ^{1}H NMR spectra of the complexes do not contain the signal due to the NH proton of the free ligands at 10.15 ppm supporting further the IR evidence presented earlier that the ligands are coordinated to the tin atom in

their deprotonated thiolate forms. The ^{1}H NMR spectra of $SnPh_2(NS)Cl$ show two signals due to two acetone-derived methyl groups due to restricted rotation about the C=N bond. The methyl group, *syn* to the N–N bond resonates at a higher field than the *anti* methyl group [21] (see Table 3).

The Mössbauer spectra of the $Sn(NS)Ph_2Cl$ complexes are shown in Figs. 2 and 3 and the isomer shift (δ), quadrupole splitting (Δ) and ρ values are given in Table 4. The parameters (δ and Δ) are within the range found with Sn (IV) and organotin compounds [22]. The Mössbauer spectra of the tin complexes exhibit identical δ indicating that the substituents (methyl or phenyl) on one of the sulfur atoms of the dithiocarbazate moiety do not have any effect at all on the s-electron density at the tin nucleus. The spectra of the two compounds also exhibit the same values of Δ indicating that they have the same structure. X-ray crystallographic structure determination (see later) confirms this fact. The Mössbauer spectra of the present tin(IV) complexes have lower δ values than the starting tin compound, $SnPh_2Cl_2$ (1.34 mm s^{-1}) [23]. A re-hybridization in the [Sn(NS)Ph_2Cl] complexes (due to higher coordination number of the tin atom in the complexes relative to that in $SnPh_2Cl_2$) accounts for the smaller isomer shift δ value. A greater involvement of the d orbitals in the tin complexes, which take part in the re-hybridization scheme causes a reduction in the s-electron contribution in the complexes relative to that of the starting tin compound [23], thus decreasing the value of the isomer shift. The ρ values, which are used to predict coordination numbers of tin complexes, are found to be 2.02, supporting a coordination number greater than four for the tin ion in the tin complexes [24].

The angle, θ between the axial carbon atoms and tin atom can be obtained from the Mössbauer spectrum using the relationship, $|\Delta| = -4[R](1–0.75\sin^2\theta)^{1/2}$ where Δ is the observed quadrupole splitting, θ is the R–Sn–R angle in the complex and $[R]$ is the partial quadrupole splitting (PQS) of the axial groups [25]. The calculated angle for Sn(acsme)Ph_2Cl is 122.9° using $[R]$ of −0.94 [26] and for Sn(acsbz)Ph_2Cl, 127.3° using $[R]$ of −0.89 [26]. This compares favorably with the values of the angles found by X-ray crystallography; 122.9° and 127.1°, respectively.

3.2. Crystal structures of the free ligands

The structures of Hacsme and Hacsbz are shown in Figs. 4 and 5, respectively, and relevant bond lengths and bond angles are given in Table 5. The asymmetric unit of Hacsme has four crystallographically independent molecules (referred to here as molecules A, B, C and D) which have very similar bond lengths and bond angles. Molecule

cally related molecule in the same manner as molecules A and D in the structure of Hacsme. The crystal structures of the Schiff bases also confirm that both ligands crystallize in their thione tautomeric forms as previously predicted by spectroscopic techniques with the thione sulfur atom *trans* to the azomethine nitrogen atoms. In this conformation these ligands are unable to bind the tin atom as bidentate *NS* chelating ligands but, in solution, a 180° rotation about the C1–N1 bond enables them to act as bidentate chelating agents. The C1–S1 bond lengths (~1.65 Å) indicate that they are essentially double bonds but the length of the C3–N2 bond is intermediate of a single and double bond indicating electron delocalization in the –N–C–S (thioamide) group.

3.3. Crystal structures of the Sn(IV) complexes

The crystal structures of the two Sn complexes are shown in Figs. 6 and 7 and important bond lengths and bond angles are given in Table 5.

The structures show that the tin atom in each compound is five-coordinated with the deprotonated Schiff base chelates the metal ion *via* the azomethine nitrogen atom and the thiolate sulfur atom. The phenyl and chloro ligands occupy the remaining three coordination positions of the coordination polyhedron. The stereochemistry adopted by the metal is intermediate between a trigonal-bipyramid (TBPY) and a square-pyramid (SPY). This may be illustrated by considering distortion from an ideal TBPY geometry. Thus, taking the azomethine nitrogen atom (N2) and the chloro ligand as the axial donor atoms, angles of 163.2(6)° and 163.97(7) are subtended in **3** and **4**, respectively, which are much smaller than the ideal value of 180°. The coordinate angles between the equatorial donors (C6, C12 and S1) also show marked differences from their ideal 120° values. A similar comparison can also be made for an ideal SPY geometry taking S1 as the apical donor and Cl(1), C(6), C(12) and N(2) as donors defining the basal plane.

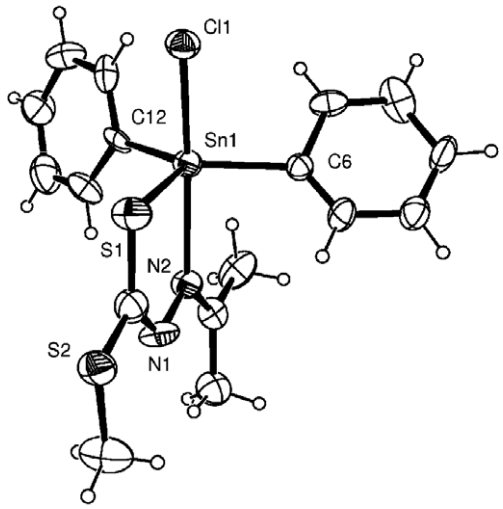

Fig. 6. ORTEP3 view of **3** Sn(acsme)Ph_2Cl (30% probability ellipsoids).

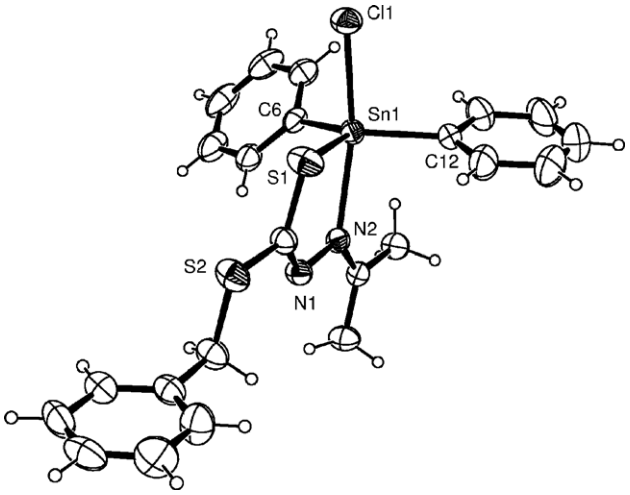

Fig. 7. ORTEP3 view of **4** Sn(acsbz)Ph_2Cl (30% probability ellipsoids).

An angular structural parameter, τ (index of trigonality) has been proposed previously [27] for distinguishing, quantitatively, between a distorted trigonal-bipyramid and a distorted square-pyramid in five-coordinate complexes. The parameter $\tau = \beta - \alpha/60°$ where α and β are the two largest angles; $\tau = 0$ for an ideal SPY geometry (α and $\beta = 180°$) and $\tau = 1$ for an ideal TBPY geometry. Using this criteria the τ values of the present complexes are found to be 0.6 indicating distortion that is somewhere between both extrema, but tending slightly toward TBPY. The largest deviations from ideal geometry are attributable to the restricted bite size of the chelating Schiff base.

The Sn–S distances in both complexes are close to the sum of the covalent radii (2.42 Å) but much shorter than the sum of their van der Waal's radii [4.0 Å] indicating the formation of a genuine Sn–S bond. The Sn–N distances in **3** and **4** are only slightly larger than the sum of the non-polar covalent radius (2.15 Å) again indicating strong Sn–N interactions. A comparison of Sn-donor atom distances in the present diphenyltin(IV) complexes with those of related tin(IV) complexes is presented in Table 6 where the influence of coordination number and ligands is illustrated.

The five-membered chelate ring in **4** adopts an envelope conformation with the atoms C1 and N1 each lying *ca.* 0.3 Å out of the plane defined by Sn1, N2 and S1, while the same chelate ring in **3** is essentially planar within experimental uncertainty. A comparison of the bond distances in the dithiocarbazate chain shows that in both tin complexes the C–S bonds are longer than observed in the respective free ligands but intermediate between those characteristic of single C–S (~1.85 Å) and double bonds (~1.56 Å). Coordination of the ligands to the tin atom in their iminothiolate forms raises the C1–N1 bond order at the expense of the C1–S1 bonds.

3.4. Conclusions

In the solid state, the acetone Schiff bases of *S*-methyl and *S*-benzyldithiocarbazate, like all other Schiff bases derived from *S*-alkyl esters of dithiocarbazic acid, remain in their thione tautomeric forms with the thione sulfur atom *trans* to the azomethine nitrogen atom but in solution they convert to the thiol form accompanied by an inversion of N2 with the concomitant formation of diphenyltin(IV)chloride complexes of the deprotonated Schiff bases. Spectroscopic and X-ray diffraction studies show that the substituents on one of the sulfur atoms of the dithiocarbazate moiety virtually have no effect on the s-electron density at the tin nucleus and on the stereochemistry adopted by the tin complexes.

4. Supplementary material

CCDC 653521, 653522, 653523 and 653524 contain the supplementary crystallographic data for **1**, **2**, **3** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

hindered *o*-aminophenols may be assumed to have great potential as ligands in synthesis of new bioactive metal complexes. As for the coordination chemistry of transition metal complexes formed by *O*,*N*-coordinated ligands of this sort, it is quite possible that synthetic difficulties have inhibited the study of metal complexes of sterically hindered *o*-aminophenols, since the attempts to isolate complexes of this type were often unsuccessful and resulted in the ligand being recovered without coordination [21,22]. This has prompted us to investigate the peculiarities of complexation of some di-*tert*-butylated *o*-aminophenolate ligands with transition metal ions [23,24]. Selecting Co(II) and Cu(II) complexes as the main subjects for this study, we had in mind that the antifungal effect of copper(II) and cobalt(II) ions had been known, their complexes still being under study in order to find effective antifungal agents [25–29]. The effect of some transition metal complexes on the structure of fungal and mammalian cell organelles has been studied [25,30–35]. In particular, when administered to some fungal strains, both metal-free 1,10-phenantroline derivatives and the their metal complexes inhibited respiration, reduced the levels of ergosterol in the membrane and altered cytochrome content [25,32–35]. In this connection it may be expected that metal complexes capable of participating in redox processes and of affecting electron-transport cell systems will be promising in the search for antifungal agents. Other papers should be also mentioned, their authors having shown that the bioactivity of metal complexes may be due to their redox effect on electron-transport cell systems, and that a correlation between *in vitro* potency and reduction potential is possible [36,37]. This encouraged us to investigate redox properties of the synthesized *o*-aminophenol derivatives and their Co(II) and Cu(II) complexes by cyclic voltammetry. In so doing we took into account that Co(II) and Cu(II) ions were able to take part in redox processes, thus affecting the properties of the ligands of the phenolic or quinoid types [38]. It was also interesting to find out whether there is any correlation between the antifungal activity of the compounds under study and their redox properties.

Since our earlier work had revealed that Ag(I) and Cu(II) complexation led to an enhancement of the antimicrobial activity of some sterically hindered phenolic derivatives [24,39–41], we were motivated to explore whether there was a similar trend in the case of other transition metal(II) complexes of these organic compounds. We report here the complexation of Co(II) ion with two sterically hindered *o*-aminophenols, namely, 4,6-di(*tert*-butyl)-2-aminophenol (HL^{I}, see the scheme below, R = H) and 2-anilino-4,6-di(*tert*-butyl)phenol (HL^{II}, R = Ph), in order to compare their coordinative behaviour in relation to Co(II) ion with the data obtained previously for their Cu(II) complexes [24] and to assess the influence of complexation on antifungal activities and redox properties of *o*-aminophenols. We have examined the possibility of the formation of *tert*-butyl-substituted *o*-aminophenolates of Cu(II) and Co(II), which may be less toxic than the oxidized (radical) forms of respective ligands [42,43].

HL^{I} – R=H

HL^{II} – R=Ph

2. Experimental

2.1. Materials and methods

Chemicals were purchased from commercial sources and were used without further purification. The two sterically hindered *o*-aminophenols and their Cu(II) complexes were prepared as described elsewhere [24,44,45]. The preparation of Co(II) complexes is described later.

Infrared spectra of solids were recorded with a Spectrum 1000 spectrophotometer in the wavelength range 4000–400 cm^{-1} at room temperature, using nujol mulls of the ligands and their complexes, and polyethylene windows. Thermal analysis was performed with a derivatograph OD-103 MOM. TG/DTA measurements were run in the air between 20 and 450 °C (5 °C min^{-1}). Elemental analyses were carried out according to the standard methods by Microanalytical Laboratory, Bioorganic Chemistry Institute, National Academy of Sciences, Belarus. Metal determination was carried out using an atomic emission spectrometer with an inductively coupled plasma excitation source (Spectroflame Modula). A sample of the Co(II) complex was decomposed on treatment with $HNO_3 + H_2O_2$ using Milestone mls 1200 mega microwave digestion system. After the complex had been decomposed, the content of the metal in the resulting solution was determined. XRD studies were made with an HZG 4 A diffractometer. The UV–Vis absorption spectra were measured in the 220–900 nm range with a Specord M500 spectrophotometer, using acetonitrile solutions of the compounds. Magnetic susceptibility was determined with the use of a Gouy balance at room temperature using $Hg[Co(SCN)_4]$ as a calibrant. ESR spectra of polycrystalline samples were measured with ERS-220 X-band spectrometer (9,45 GHz) at room temperature and at 77 K, using 100-kHz field modulation; *g* factors were quoted relative to the standard marker DPPH ($g = 2.0036$). The molar conductance of 10^{-3} mol L^{-1} solution of the metal(II) complex in acetonitrile was measured at 20 °C using a TESLA BMS91 conductometer (cell constant 1, 0). Electrochemical measurements were performed under dry nitrogen in a three-electrode two-compartment electrochemical cell using a glassy-carbon (GC) working electrode, Pt auxiliary electrode and Ag|AgCl|0.1 mol L^{-1} $(C_2H_5)_4NCl$ reference electrode. The supporting electrolyte was 0.1 mol L^{-1} $(C_2H_5)_4NClO_4$. The Ag|AgCl|0.1 mol L^{-1} $(C_2H_5)_4NCl$ ref-

erence electrode was calibrated with ferricinium|ferrocene redox couple located at $E_{1/2} = +0.52$ V. Acetonitrile was used as a solvent.

2.2. Synthesis of the Co (II) complexes with sterically hindered o-aminophenol derivatives

Based on our previous findings [23], the conditions were created to purposefully provide the preferential formation of the Co(II) complexes, with the composition corresponding to the general formula CoL_2: a solution of Co(II) salt was added in small portions to the ligand solution under continuous stirring, so that the complexation always took place with the excess ligand present. A solution of 0.050 mmol $Co(CH_3COO)_2 \cdot 4H_2O$ in 10 mL of water was added dropwise to a colorless solution of 0.100 mmol of HL^I or HL^{II} dissolved in 10 mL of ethanol (molar ratio Co(II):HL = 1:2). As these ligands can be readily oxidized by oxygen, it is to be taken into account when producing their complexes in order to guard against formation of oxidized ligands (in particular, *o*-iminosemiquinones, as it was shown in some papers [15–21]). To this end, argon was bubbled through the solutions (pH $\leqslant$ 6) during the synthesis. Colored precipitates formed instantaneously. After 1.5–2 h stirring, they were collected on membrane filters (JG 0.2 μm), washed with ethanol and water, and dried *in vacuo* (yield > 70%). It should be specially emphasized that to separate individual $Co(L^I)_2$ complex, the precipitate must be more thoroughly washed with ethanol (5 × 50 mL) in order to eliminate uncoordinated ligand molecules which otherwise could be able to form adducts with the metal complex through hydrogen bonding.

$Co(L^I)_2$ complex. Grey-brown. *Anal.* Calc. for $C_{28}H_{44}N_2O_2Co$: C, 67.29; H, 8.88; N, 5.61; Co, 11.80. Found: C, 67.25; H, 8.83; N, 5.58; Co, 11.75%.

$Co(L^{II})_2$ complex. Blue. *Anal.* Calc. for $C_{40}H_{52}N_2O_2Co$: C, 73.69; H, 8.04; N, 4.30; Co, 9.05. Found: C, 73.61; H, 7.95; N, 4.23; Co, 8.96%.

2.3. Antifungal activities

Antifungal activities of the compounds were tested against the following fungal species (the collection of the Department of Microbiology, The Belarusian State University): *Aspergillus niger*, *Fusarium* spp., *Mucor* spp., *Penicillium lividum*, *Botrytis cinerea*, *Alternaria alternata*, *Sclerotinia sclerotiorum*, *Monilia* spp. Compounds were dissolved in DMSO and diluted in potato dextrose agar medium to yield working solutions of the test compounds with the concentration of 100 μg mL^{-1}. The amount of DMSO in the medium was 1% and did not affect the growth of the tested microorganisms. Antifungal activities of the compounds against moulds and common plant pathogens were checked by the agar plate technique as described elsewhere [41]. The degree of inhibition of radial growth (RI) was calculated as follows [46]: $RI = 100(C - T)/C$ (%), where T is the mean value of the diameter of the fungal colonies in the presence of a given concentration of the compound tested, and C is the mean value of the diameter of the fungal colonies in the absence of the compound, measured under the same conditions.

3. Results and discussion

3.1. Physico-chemical characterization

The stoichiometry of the solid complexes was confirmed by elemental analyses of the isolated chelates. The data show satisfactory agreement with the proposed formulae CoL_2. The complexes demonstrated X-ray patterns of their own, which were significantly different from those of the respective ligands. However, a full structural analysis could not be performed, no crystals suitable for single-crystal X-ray analysis having been obtained, which is not uncommon for compounds with sterically hindered ligands [22]. It is noteworthy that a similar problem when carrying out crystallization of metal complexes of aminophenol derivatives is described in [21,47]. Because of the well-known difficulties in direct X-ray investigations of these complexes, the geometrical arrangement of the ligating atoms in the Co(II) complex has been investigated by several spectroscopic and magnetochemical methods.

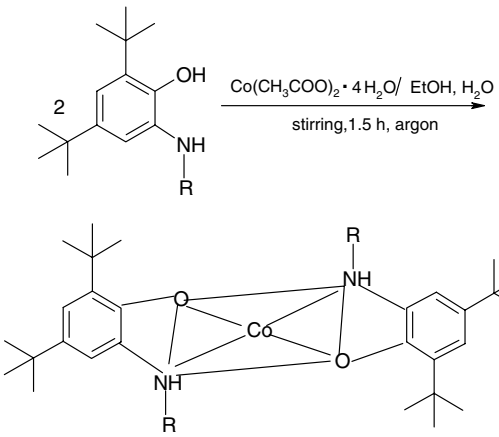
Thermal analysis in air flow with identification of the final products by X-ray powder diffraction has shown $Co(L^I)_2$ and $Co(L^{II})_2$ complexes to be anhydrous and unsolvated. No weight loss was observed until decomposition which began about 185 °C (for $Co(L^I)_2$) or 200 °C (for $Co(L^{II})_2$), with exothermic peaks at 190 °C (for $Co(L^I)_2$) or 210 °C (for $Co(L^{II})_2$) without any noticeable weight loss, and at 360 °C (for both complexes), ultimately leaving CoO as the residue. The maximal weight loss (83.72% and 84.1%, respectively, for $Co(L^I)_2$ and $Co(L^{II})_2$) corresponds to the loss of two ligand molecules (Calc. 84.99% and 85.2%, respectively, for $Co(L^I)_2$ and $Co(L^{II})_2$). The agreement between the experimental and theoretical weight losses for the above processes confirms the above-mentioned general formula CoL_2.

The Co(II) complexes are soluble in acetonitrile, acetone, dimethyl formamide, dimethyl sulfoxide, insoluble in nitromethane and ethanol. The conductivity data for the complexes $Co(L^I)_2$ ($\Lambda_{mol} = 11.4\ \Omega^{-1}\ cm^2\ mol^{-1}$) and $Co(L^{II})_2$ ($\Lambda_{mol} = 5.8\ \Omega^{-1}\ cm^2\ mol^{-1}$) indicate their being essentially non-electrolytes in acetonitrile [48], and suggest that the bidentate ligands HL^I and HL^{II} may be coordinated to Co(II) ion as uninegatively charged ligands.

To specify the coordination modes in the Co(II) complexes, we used IR spectroscopy (Table 1).

The IR spectra of the Co(II) complexes as against those of the free ligands are distinguished by the following features: (i) the bands corresponding to ν(OH) vibrations in the free ligands disappear, suggesting the participation of the *o*-OH in complex formation through proton displacement; (ii) the bands at 1230–1140 cm^{-1} assigned to C–I stretching vibrations are shifted towards lower wave num-

Table 1
IR spectral assignments (cm^{-1}) of the ligands and Co(II) complexes



Compound	ν(OH)	ν(C–O)	ν(C–N)	ν(C=C)	ν(N–H)	ν(Co–N)	ν(Co–O)
HL^I	3290m	1235s	1292w	1593m	3366m		
		1204m					
		1142w					
$Co(L^I)_2$		1180s	1300m	1556m	3340w	469w	570w
		1091m				435w	539m
		1044m					514m
		1021m					
HL^{II}	3585m	1202m	1311s	1599s	3352m		
		1150w		1495s			
$Co(L^{II})_2$		1144s	1302m	1537m	3334w	469w	571w
		1106s				424w	545w
		1074w					513m

bers as compared to their positions in the spectra of the ligands; (iii) the positions of the bands assigned to N–H (3352 and 3366 cm^{-1}) and C–N (1292 and 1311 cm^{-1}) stretching vibrations are changed, the presence of the weak bands 3340 and 3334 cm^{-1} in the spectra of the complexes indicating the participation of NH group in coordination without deprotonation; and (iv) bands of moderate intensity appear at 571–424 cm^{-1}, which can be assigned to ν(Co–N) and ν(Co–O). The above-listed facts suggest that NH-groups and deprotonated hydroxyls take part in forming the CoN_2O_2 coordination cores in the Co(II) complexes [49].

The electronic absorption spectra of the free ligands in acetonitrile show characteristic intraligand transition bands at 225 and 280 nm [21,50]. The spectra of the Co(II) complexes in acetonitrile solution exhibit absorption bands in the high-energy region, which can be assigned to intraligand transitions: 230–240 nm ($\log\varepsilon = 4.3$–4.4) and 280–282 nm ($\log\varepsilon = 4.1$–4.2). The bands located in the 305–430 nm region can be attributed to the ligand-to-cobalt(II) charge transfer transitions $N(\sigma) \rightarrow Co^{II}$ and $O_{phenolate} \rightarrow Co^{II}$: respectively, 305 nm ($\log\varepsilon = 4.1$) and 395 ($\log\varepsilon = 3.9$), 430 nm ($\log\varepsilon = 3.7$) [50,51]. The new absorption bands that appeared upwards of 500 nm can be imputed to the d–d transitions of the $Co(L^I)_2$ and $Co(L^{II})_2$ complexes: respectively, 520 nm ($\log\varepsilon = 3.65$) and 640 nm ($\log\varepsilon = 3.69$), characteristic of the low-spin, square planar Co(II) complexes [47,50–58]. This is also corroborated by the effective magnetic moment values: $\mu_{eff} = 2.38$ BM for the $Co(L^I)_2$ complex and $\mu_{eff} = 2.58$ BM $Co(L^{II})_2$ complex, expected for the low-spin square planar geometry around Co(II) ions [47,51–56].

The ESR spectra of Co(II) complexes were obtained in the solid (polycrystalline) state at 77 K and room temperature in order to confirm the geometry of the coordination cores. These spectra are typical axial ones with $g_{\|} = 1.96$ and $g_{\perp} = 2.01$ (for the $Co(L^I)_2$ complex) and $g_{\|} = 1.98$ and $g_{\perp} = 2.07$ (for the $Co(L^{II})_2$ complex), characteristic of low-spin, square-planar Co(II) complexes [47,51,54,55,59–61]. No signal of stabilized radicals present in the ESR spectrum at 77 K, as well as the ν(C=O) and ν(C=N) stretching vibrations lacking in the IR spectrum of Co(II) complex, respectively, in the ranges of 1400–1500 and 1690–1640 cm^{-1}, confirm the phenolate character of the ligand.

In the light of the physico-chemical data and elemental analysis results the mode of bonding in the Co(II) complex can be represented schematically as shown below:

This coordination core agrees with the data obtained by physico-chemical methods for the Cu(II) complex investigated previously [24], where the copper site has the square planar stereochemistry. It should be particularly emphasized that any departure from the specified conditions of the synthesis makes the possibility of separating the individual complex problematic, the free ligands in their oxidized forms being generally obtained in abundance along with it.

3.2. Cyclic voltammetry

Redox properties of the compounds were examined by cyclic voltammetry. Cyclic voltammogram of the ligand HL^I at positive potential shows two anodic peaks at 0.58, 1.72 V, and only one cathodic peak at 0.495 V on the reverse scan (Fig. 1a, solid line). For the ligand HL^{II} a dou-

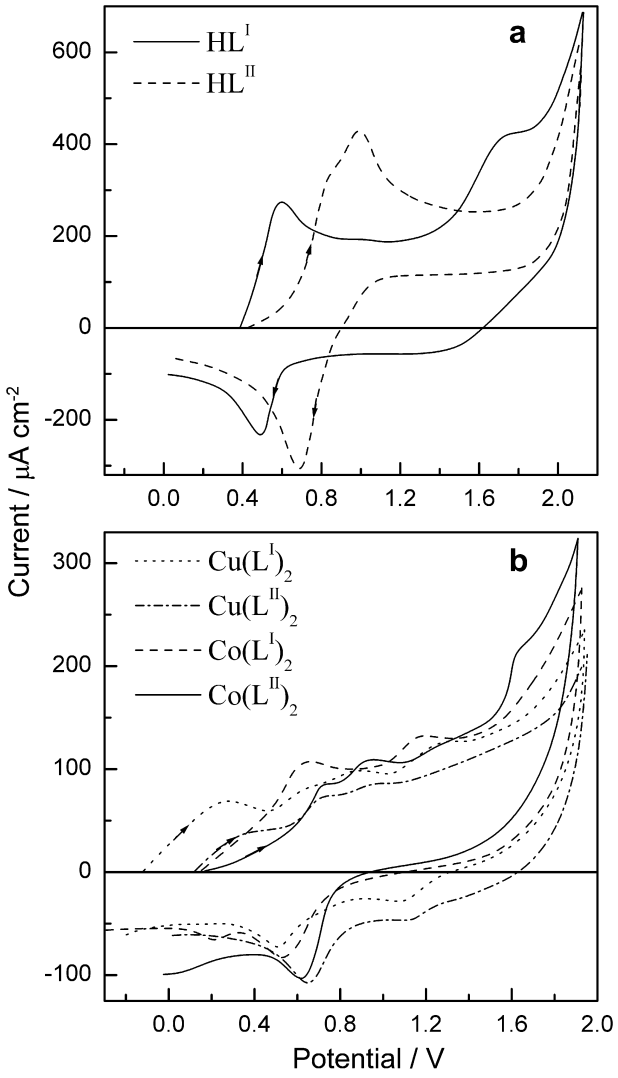


Fig. 1. Cyclic voltammograms (50 mV/s) of the ligands (1.36 mmol L^{-1}) HL^I (solid line), HL^{II} (dashed line) (a) and metal complexes (0.68 mmol L^{-1}) $Cu(L^I)_2$ (dotted line), $Cu(L^{II})_2$ (dashed-dotted line), $Co(L^I)_2$ (dashed line), $Co(L^{II})_2$ (solid line) (b) in 0.1 mol L^{-1} $(C_2H_5)_4NClO_4$ acetonitrile solution on glassy-carbon electrode. (The potentials were measured against Ag|AgCl|0.1 mol dot L^{-1} $(C_2H_5)_4NCl$ reference electrode.)

ble anodic peak is observed at 0.85–0.98 V (is not two overlapping peaks), and a cathodic peak (0.70 V) on the reverse scan (Fig. 1a, dashed line). On cathodic polarization (down to −1.8 V) for HL^I and HL^{II} no peaks are observed. Controlled potential electrolysis carried out for HL^{II} at 1.2 V consumed two electron per molecule. The UV–Vis spectra of the oxidized HL^{II} solution show two broad absorption bands at 400 and 500 nm. These findings agree with the results of electrochemical investigation of HL^{II} compound [16,21], according to which HL^{II} undergoes 2 e-oxidative transformation to give iminobenzoquinone. Controlled potential coulometry for HL^I shows two 1 e-oxidative processes corresponding to anodic peaks at 0.58 and 1.72 V. On the basis of the data on oxidation of *o*-aminophenols [15–19,21] it may be suggested that HL^I is successively oxidized to iminosemiquinone and iminobenzoquinone.

The difficulty of interpreting the electrochemical data for metal complexes of sterically hindered *o*-aminophenol derivatives is caused by the fact that, as noted above, in coordination compounds ligands of this kind can exist in different protonation and redox forms (*o*-aminophenol or *o*-iminosemiquinone). It should be emphasized that the electrochemical properties of the ligands and metal complexes have been studied mainly to compare their reducing power rather than to monitor spectral and structural changes accompanying an electron transfer. The assignment of the redox processes was facilitated by comparison with the literature [16,21,62].

On voltammograms of Cu(II) complexes in the range from −0.1 to +2.1 V anodic peaks are observed: at 0.27, 0.61, 0.89, 1.27 V for $Cu(L^I)_2$ (Fig. 1b, dotted line) and 0.4, 0.7, 0.96 V for $Cu(L^{II})_2$ (Fig. 1b, dashed-dotted line). Cathodic peaks are registered on the reverse scan: at 0.14, 0.51, 1.07 V for $Cu(L^I)_2$ and 0.25, 0.65, 1.12 V for $Cu(L^{II})_2$. Two peaks, at 0.14 and 0.25 V, for Cu(II) complexes are observed in voltammograms on polarization to about 0.6–1.0 V; upon more anodic polarization on the reverse scan they are obscured by the peaks at 0.51 and 0.65 V. On anodic polarization two peaks are observed at 0.65 and 1.19 V for $Co(L^I)_2$ complex, and three peaks are observed at 0.71, 0.94 and 1.63 V for $Co(L^{II})_2$, with cathodic ones on the reverse scan at 0.54, 0.21 V for $Co(L^I)_2$ and 0.62 V for $Co(L^{II})_2$) (Fig. 1b, dashed and solid lines). No prominent cathodic processes are observed on cathodic polarization from the open circuit potential down to −1.8 V.

The cyclic voltammograms of $Cu(L^I)_2$ and $Cu(L^{II})_2$ complexes are more or less similar in their shape, voltammogram of $Cu(L^{II})_2$ being shifted by 0.15–0.20 V into cathodic region because of the influence of phenyl substitute in aminogroup (Fig. 1b). A similar regularity can be observed also for voltammograms of $Co(L^I)_2$ and $Co(L^{II})_2$ complexes. A comparison between cyclic voltammograms of $Cu(L^I)_2$ and $Co(L^I)_2$ complexes shows that common peaks are present at ~0.65 V, and a comparison between voltammograms of $Cu(L^{II})_2$ and $Co(L^{II})_2$ complexes shows that there are common peaks at 0.9 V, corresponding to oxidation of the ligands L^I and L^{II}, as well as cathodic peaks at ~0.5 V (for the complexes of the ligand L^I) and at ~0.65 V (for those of the ligand L^{II}), relating, respectively, to the reduction of the products of L^I and L^{II} oxidation on the reverse scan.

On the basis of the above findings obtained by cyclic voltammetry, and taking into account the data of [62], it may be suggested that Cu(II) and Co(II) ions take part in a sequence of electron transfers; otherwise, whatever the metal (II) ion nature, the redox potentials of the complexes would have differed only slightly in a series of ligands. A comparison between the redox properties of the ligands and those of their metal(II) complexes shows that their reducing ability decreases in the following order: $Cu(L^I)_2 > Cu(L^{II})_2 \geqslant Co(L^I)_2 > Co(L^{II})_2 > HL^I > HL^{II}$ (Fig. 1).

Table 2
Antifungal activities of the compounds tested as evaluated by radial inhibition of mycelial growth (RI, %)

Compound	RI (%)							
	Alternaria alternata	*Sclerotinia sclerotiorum*	*Monilia* spp.	*Aspergillus niger*	*Fusarium* spp.	*Mucor* spp.	*Penicillium lividum*	*Botrytis cinerea*

Terbinafine	50	50	50	100	80	50	60	60
Questiomycin B	40	50	50	30	40	50	40	30

3.3. Antifungal activities

The test microorganisms (the collection of the Department of Microbiology, the Belarusian State University) are listed in Table 1. Inhibition values of the free ligands and their Co(II) and Cu(II) complexes are listed in Table 1. Commonly used antifungal drugs Nystatin, Terbinafine and Questiomycin B were tested as positive controls. The effect of the starting metal(II) acetates is also reported. It should be emphasized that the antifungal tests of these ligands and their Co(II) and Cu(II) complexes were first performed here.

It was found that the inhibitory effects of HL^{I} and HL^{II} ligands and their metal(II) complexes differed with the species of fungi. All of them demonstrate the highest inhibitory properties against *S. sclerotiorum*. A like high activity against *Fusarium* spp., *A. alternata* and *B. cinerea* is characteristic of Co(II) and Cu(II) complexes (Table 1). And it was only $Cu(L^{I})_2$ that showed the highest antifungal activity against *Mucor* spp. and *Monilia* spp. Both the free ligands and Co(II) and Cu(II) complexes exhibit pronounced antifungal activities against some strains, which in a number of cases were comparable with those of Nystatin and Terbinafine or even higher (Table 2).

Antifungal screening *in vitro* indicated that in the cases mentioned above a synergistic effect is present, the antifungal activities of the metal(II) complexes being higher than those of both the ligand and the starting metal salts. This provides reason to believe that antifungal activities of the metal(II) complexes synthesized do not correlate with the toxicity of the metal(II) ions against the fungi tested. It is noteworthy that the two sterically hindered derivatives of *o*-aminophenol synthesized and their metal(II) complexes were more active than Questiomycin B antibiotic tested. In this connection, when estimating the effect of modification of the molecule of *o*-aminophenol by introducing substitutes (two *tert*-butyl ones into the ring and a phenyl one into aminogroup) and complexation with Cu(II) and Co(II) ions on the antifungal activities of the compounds tested, we may suggest that one of the likely reasons for their different activities is related to the nature of the substitute in the ring and to a substitute being present at the nitrogen atom of the amino group. Moreover, the antifungal activities of the complexes exhibit some metal-ion-dependency. By and large the inhibitory effects of the compounds examined decrease in the order: $Cu(L^{I})_2 > Cu(L^{II})_2 \geqslant Co(L^{I})_2 > Co(L^{II})_2 > HL^{I} > HL^{II}$ (Table 1), and their reducing ability declines in the same order, as it was shown above. These data are in accordance with the results of the studies [32–35], where the influence of redox properties of the metal complexes on their antifungal effect was found, and it was shown that this effect appears to be mediated through the disruption of mitochondrial function and uncoupling respiration. These facts may be of interest in designing new antifungal drugs, since this effect is different to the mode of action of the conventional azole and polyene drugs.

Acknowledgement

We are grateful to Dr. R. Zheldakova (The Belarusian State University) for the antifungal testing.

In this paper we report upon the first example of an 'empty' dithiophosph(in)ate Cu^{I}_{8} cube, thus showing that so-called templating anions are not prerequisite for Cu^{I}_{8} cube formation with dithio-phosphorus ligands. In addition, the analogous dithiophosphinate Cu^{I}_{8} cube with an encapsulated chloride anion is reported, hence allowing for the first time a direct structural and bonding comparison between a dicationic vacant cube, a mono-cationic chloride centered cube and a neutral sulfide centered cube all with the same ligand system.

2. Experimental

2.1. General procedure

All reactions and manipulations were carried out under an inert atmosphere of dry nitrogen or argon using standard double manifold and glove-box techniques. Purification and drying of the solvents were done using standard methods. Ph_2PH was purchased from Strem and all other chemicals from Sigma–Aldrich. $[Cu(CH_3CN)_4][PF_6]$ was prepared according to known literature procedures [9]. NMR spectra were recorded on a Bruker AV-400 spectrometer. External standards used were TMS (^{1}H) or 85% H_3PO_4 (^{31}P). Mass spectra were recorded on Micromass AutoSpec Premier. Microanalytical data were obtained from the Science Technical Support Unit, London Metropolitan University.

2.2. Preparation of $[Cu_8(S_2PPh_2)_6][PF_6]_2 \cdot 5CH_2Cl_2$ (1)

A solution of Ph_2PH (0.35 mL, 2 mmol) and NEt_3 (0.28 mL, 2 mmol) in CH_3CN (5 mL) was added to a suspension of yellow S_8 (0.128 g, 4 mmol) in CH_3CN (10 mL) and stirred to give a clear solution. $[Cu(CH_3CN)_4][PF_6]$ (0.746 g, 2 mmol) in CH_3CN (10 mL) was then added to yield a yellow precipitate. Ten mL of deoxygenated water were added, the precipitate filtered off and washed with copious amounts of deoxygenated water to give the product **1** in 44% yield (1.01 g). Colorless crystals of $[Cu_8(S_2PPh_2)_6][PF_6]_2 \cdot 5CH_2Cl_2$ suitable for analysis using single crystal X-ray diffraction were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **1**. M.p. 211–214 °C. *Anal.* Calc. for $C_{72}H_{60}Cu_8P_6S_{12} \cdot 2PF_6$: C, 37.77; H, 2.64. Found: C, 37.83; H, 2.60%. FAB MS [m/z (m/z_{calc})]: 2148.8 (2149.2), $(M-PF_6)^+$; 2003.2 (2004.2), $(M-2PF_6)^+$. ^{1}H NMR (270 MHz, $CDCl_3$): $\delta = 7.3$–7.9 (m, 60H, Ph_2P–). $^{31}P\{^1H\}$ NMR (109 MHz, $CDCl_3$) 59.28 (s), −143.91 (sept, $^1J_{PF} = 763$ Hz, PF_6).

2.3. Preparation of $[Cu_8(\mu_8\text{-}Cl)(S_2PPh_2)_6][PF_6] \cdot 6CH_2Cl_2$ (2)

A solution of Ph_2PH (0.35 mL, 2 mmol) and NEt_3 (0.28 mL, 2 mmol) in CH_3CN (5 mL) was added to a suspension of yellow S_8 (0.128 g, 4 mmol) in CH_3CN (10 mL) and stirred to give a clear solution. $[Cu(CH_3CN)_4][PF_6]$ (0.746 g, 2 mmol) in CH_3CN (10 mL) was then added to yield a yellow precipitate. Ten mL of deoxygenated water were added, the precipitate filtered off and washed with copious amounts of deoxygenated water. The resulting solid was refluxed in CH_2Cl_2 for 30 min to give a pale yellow solution. Slow evaporation of the CH_2Cl_2 solvent from this solution over a period of 8 weeks gave a low yield (0.09 g, 17%) of colorless crystals of $[Cu_8(\mu_8\text{-}Cl)(S_2PPh_2)_6][PF_6] \cdot 6CH_2Cl_2$ (**2**) suitable for analysis using single crystal X-ray diffraction. M.p. 203–206 °C. *Anal.* Calc. for $C_{72}H_{60}Cu_8P_6S_{12}ClPF_6 \cdot 2CH_2Cl_2$: C, 37.86; H, 2.75. Found: C, 37.83; H, 2.60%. ^{1}H NMR (270 MHz, d_6-DMSO): $\delta = 7.5$–7.9 (m, 60H, Ph_2P–). $^{31}P\{^1H\}$ NMR (109 MHz, d_6-DMSO) 58.68 (s, Ph_2P–), −143.56 (sept, $^1J_{PF} = 763$ Hz, PF_6).

2.4. X-ray diffraction studies

Table 1 provides a summary of the crystallographic data for compounds **1** and **2**. Data were collected using a Bruker P4 diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å), and the structures were refined based on F^2 using the SHELXTL and SHELX-97 program systems [10,11]. All atoms were refined with anisotropic displacement parameters unless stated below and hydrogen atoms were placed in idealized positions and allowed to ride on the relevant carbon atom.

In the structure of **1** the C(31) phenyl ring of the dicationic cluster was found to be disordered. Two orientations were identified of ca. 60% and 40% occupancy, and refined as optimized rigid bodies with only the non-hydrogen atoms of the major occupancy orientation being refined anisotropically. The unique PF_6 anion was found to be disordered and

Table 1
Summary of crystal structure data for **1** and **2**

Data	1	2
Formula	$[C_{72}H_{60}Cu_8P_6S_{12}][PF_6]_2 \cdot 5CH_2Cl_2$	$[C_{72}H_{60}Cu_8P_6S_{12}Cl][PF_6] \cdot 6CH_2Cl_2$
Formula weight	2718.63	2694.04
Crystal size (mm)	0.67 × 0.33 × 0.23	0.67 × 0.53 × 0.47

R_{int}	0.0417	0.0286
Reflections observed, $\lvert F_o\rvert > 4\sigma(\lvert F_o\rvert)$	5161	2213
Number of parameters	603	232
R_1, wR_2 ($I > 2\sigma I$)[a]	0.0590, 0.1241	0.0369, 0.0742
Residuals (e Å^{-3})	0.776, −0.690	0.388, −0.326

[a] $R_1 = \sum\lvert\lvert F_o\rvert - \lvert F_c\rvert\rvert / \sum\lvert F_o\rvert$; $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2] / \sum[w(F_o^2)^2]\}^{1/2}$; $w^{-1} = \sigma^2(F_o^2) + (aP)^2 + bP$.

two orientations sharing a common phosphorus site were identified of ca. 66% and 34% occupancy. The phosphorus, and the fluorine atoms of the major occupancy orientation, were refined anisotropically, the fluorine atoms of the minor occupancy orientation being refined isotropically. The five included dichloromethane solvent molecules per complex (i.e. 2.5 in the asymmetric unit) were located across three separate sites. At one site the molecule was found to be ordered and so the non-hydrogen atoms were refined anisotropically. At the second site three orientations were identified of ca. 65%, 22% and 13% occupancy; only the chlorine atoms of the two highest occupancy orientations were refined anisotropically, all the other atoms being refined isotropically. At the third site, which is adjacent to a 2-fold axis and so has a maximum occupancy of 50%, two orientations were identified of ca. 29% and 21% occupancy; the chlorine atoms of both orientations were refined anisotropically whilst the carbon atoms were refined isotropically.

In the structure of **2** the C(1) phenyl ring of the cationic cluster was found to be disordered. Two orientations were identified of ca. 81% and 19% occupancy, and refined as optimized rigid bodies with only the non-hydrogen atoms of the major occupancy orientation being refined anisotropically. The unique PF_6 anion, which sits at a $\bar{3}$ position, was found to be disordered and two complete orientations sharing a common phosphorus site (at the $\bar{3}$ position) were identified of ca. 11% and 5% occupancy (totalling the 1/6 occupancy required by the $\bar{3}$ symmetry). The phosphorus atom was refined anisotropically, and all of the fluorine atoms were refined isotropically. Just one unique site was found for the included dichloromethane solvent molecule, and this site was found to be disordered; two orientations were identified of ca. 86% and 14% occupancy with the non-hydrogen atoms of the major occupancy orientation being refined anisotropically, and those of the minor occupancy orientation being refined isotropically.

2.5. Computational details

All calculations were carried out with a GAUSSIAN 03 package [12]. The density functional theory method was employed using the B3LYP hybrid functional [13]. Structures were optimized using a effective core potential with a LanL2DZ basis set for copper and 6-31G(d) for the other atoms. Natural charges were calculated by natural population analysis at the same level used for geometry optimization [14]. Frequency analysis was carried out after geometry optimization to confirm the models were true energy minima with no imaginary frequencies.

3. Results and discussion
