Analyzing the results obtained for the uncoordinated ligands, it is to note that the substitution of one hydrogen atom linked to N(4) in the thiosemicarbazone moiety for bulky entities (phenyl or methyl group) causes an improvement on their activities. Considering the N(4)-substituted ligands and their complexes studied, it can be seen that the complexes **2**, **5** and **6** have slightly better and similar activities when compared with the free ligands. On the other hand, the vanadium(IV) complex **3** presented a very small value of MIC (1.56 μg/mL), which represents a 10-fold higher activity than its free ligand and is comparable or better than some commonly used anti-*M. tuberculosis* agents like ciprofloxacin (MIC = 2.00 μg/mL), *p*-aminosalicylic acid (MIC = 0.5–>2.0 μg/mL), ethionamide (MIC = 0.63–1.25 μg/mL), cycloserine (MIC = 12.5–50 μg/mL), gentamicin (MIC = 2.0–4.0 μg/mL), ethambutol (MIC = 0.94–1.88 μg/mL), kanamycin (MIC = 1.25–5.0 μg/mL), tobramycin (MIC = 4.0–8.0 μg/mL), clarithromycin (MIC = 8.0–16 μg/mL) and thiacetazone (MIC = 0.125–>2.0 μg/mL) [2,43].

The variation in the oxidation state of the vanadium center between IV and V seems not to play an important role in the activity of the complexes, since no systematic behavior could be observed by varying between V(IV) and V(V), maintaining the thiosemicarbazone ligand, by the studied complexes. Acetylacetone, $[VO(acac)_2]$ and the inorganic vanadium salts $VOSO_4$ and NH_4VO_3 have not shown any inhibition at the concentration of 50 μg/mL, implying that the thiossemicarbazone ligands are the active species and that their activity may be improved upon complexation to vanadium. The reduction of the polarity of a complex as a whole, when compared with the free ions or ligands, by partial sharing of their charges within the coordination compounds, which include the bioactive thiosemicarbazones, may favor their permeation through the lipid layer of the cell membrane, resulting possibly in a better cell uptake of the active species, as suggested former for similar findings [41,44].

4. Conclusions

Neutral oxovanadium(IV) and dioxovanadium(V) complexes having *N,N,S*-donor ligands have been synthesized in satisfactory yields and were characterized by several methods. One of the complexes exhibited *in vitro* antitubercular activity towards *M. tuberculosis* $H_{37}Rv$ better than observed for some medications commonly used in the treatment of tuberculosis. The coordination of thiosemicarbazones to some vanadium (IV) and (V) centers may result in an enhancement of their anti-*M. tuberculosis* activities. The presence of bulky groups (methyl or phenyl units) attached to the N(4) atom of the substituted thiosemicarbazone moiety in the complexes **2**, **3**, **5** and **6** or in the free Hapmtsc and Happtsc ligands increases their inhibitory activity by comparison with the non-substituted Haptsc ligand and its complexes **1** and **4**, which presented the lowest activities in this study. Considering the present results and especially that obtained for the complex **3**, the coordination of a thiosemicarbazone to vanadium may represent a novel strategy to prepare new antitubercular agents. New investigations must be done to know exactly the participation of the vanadium in the bacterial inhibitory effect observed.

ABSTRACT

Described are the reaction of the silver(I) salts of trifluoroacetate (tfa^-) and trifluoromethanesulfonate (Otf^-) with the bidentate ligands 4,4′-dimethyl-2,2′-bipyridine (L1), 5,5′-dimethyl-2,2′-bipyridine (L2) and 2,2′-bipyridine (L3), to afford the formation of five structures. A systematic study was conducted to obtain the different coordination moieties possible by changing the ligand to metal ratio and the solvent of crystallization. In total, six discrete molecules (Agtfa)(L1), **1**, (Agtfa)(L2), **2A** and **2B**, $(AgOtf)_2(L2)_3$, **3A** and **3B**, $(AgOtf)_2(L3)_3$, **5,** and one polymeric structure $(AgOtf)(L3)_n$, **4** were obtained. Compounds **2** and **3** form two crystal structures each, where differences in connectivity of the corresponding anion to the metal center are observed, as directed by solvent of crystallization. The varying degree of interaction of the two anions, combined with the functionality of the ligand used in the reaction, gave rise to coordination numbers from 4 to 6, representing capped-trigonal, distorted tetrahedral, trigonal bipyramidal and distorted octahedral environments, which illustrate the range of coordination moieties that can be adopted in silver(I) complexes, and the possibility of systematic control of the coordination framework topology of a compound. This study complements the already reported silver coordinated structures associated with the bipyridine ligands mentioned herein.

1. Introduction

Design and construction of self-assembled coordination structures is one of the most active areas of materials research due to their intriguing structural motifs and functional properties such as molecular adsorption, magnetism and luminescence [1–10]. During the past few decades, metal–organic frameworks, coordination polymers and numerous examples of discrete macromolecules have been built based upon the functionality or geometry of the corresponding ligand, ratio of reactants or solvent system [11–14]. Designed coordination architectures can be tuned by predicting supramolecular interactions such as hydrogen bonds, π–π stacking, and host–guest ionic interactions, which are also responsible for unique structural features in multidimensional coordination networks [15–22]. In particular, coordinative structures involving the silver(I) ion have made contributions to this field due to the capability of Ag(I) to vary its geometry and coordination number. This ability has produced an extensive library of silver(I) compounds, and has contributed to the determination of reaction conditions that can deliberately induce structural changes in the topology of the metal complex [23–27]. Accordingly, many self-assembled compounds of silver(I) can be readily obtained with slight variations in ligand and/or anion that directs the formation of both small discrete molecules and polymeric arrays. In this paper several coordinative environments are seen which depend on the solvent of crystallization and the interacting ability of the anion.

The employ of symmetrically methyl-substituted 4,4′-dimethyl-2,2′-bipyridine, L1 and 5,5′-dimethyl-2,2′-bipyridine, L2 and the unsubstituted 2,2′-bipyridine, L3 ligands is determinant in the formation of distinct structural motifs mainly due to the free rotation along the central C–C bond. Therefore, bipy cannot only be regarded as a chelating ligand [28–36], but also as a potential connector between metal centers by acting as a bridging ligand [37–41]. As observed in this series of compounds, the most common mode of binding of these bipy ligands is the chelating fashion by virtue of the proximity of the pyridine rings, forming with the metal center a stable five-member ring. Only with L2 and L3, were both coordination modes observed in a single compound.

Overall, the compounds reported herein illustrate the range of coordination environments that can be adopted in silver(I) complexes, and the possibility of systematic control the coordination framework topology of a compound by aim of the geometry and functionality of the ligand. This report provides an extension of a previous work to encompass silver(I) complexes associated with bipyridine type ligands [28,30,34,35,41]. In conjunction they offer

a compilation of the structural and coordinative factors on which the formation of discrete molecules and polymeric arrays depend.

2. Experimental

2.1. General methods

All experiments were carried out under an argon atmosphere using a Schlenk line and standard Schlenk techniques. Silver(I) trifluoroacetate and silver(I) trifluoromethanesulfonate were purchased from Strem Chemicals Inc. and stored in an inert-atmosphere glovebox; solvents were distilled under nitrogen from the appropriate drying agent immediately before use. 5,5′-dimethyl-2,2′-bipyridine, 4,4′-dimethyl-2,2′-bipyridine, and 2,2′-bipyridine were purchased from Aldrich and used as received. Celite was also purchased from Aldrich and dried at 120 °C prior to use. All flasks were shielded from light with aluminum foil to prevent the photodecomposition of the silver compounds. Percent yields are based upon the amount of silver salt used. ^{1}H NMR spectra were recorded at 202.31 MHz on a Varian 500 MHz NMR spectrometer. Elemental analyses were performed by Atlantic Microlabs Inc., Norcross, GA. High resolution mass spectra (HRMS) were obtained in the Baylor University Mass Spectrometry Core Facility on a Thermo Scientific LTQ Orbitrap Discovery using +ESI.

2.2. Synthesis of Agtfa(L1) (**1**)

The reaction was done in a 1:1 ratio of 4,4′-dimethyl-2,2′-bipyridine (0.073 g, 0.396 mmol) and Agtfa (0.089 g, 0.398 mmol) in CH_3CN. The resulting solution remained clear and colorless, and after stirring for 5 min, the solution was dried in vacuo to obtain a white powder in 69% isolated yield (0.111 g, 0.274 mmol). Colorless blocks were formed by layering hexane over a CH_2Cl_2 solution of **1** at 5 °C. ^{1}H NMR (CD_3CN, 298 K) δ: 2.52 (s, 6H, CH_3), 7.46 (d, 2H, J = 4.5 Hz, aromatic), 8.14 (s, 2H, aromatic), 8.60 (d, 2H, J = 4.9 Hz, aromatic). $C_{14}H_{12}AgF_3N_2O_2$ (405.12): *Anal.* Calc. for C, 41.51; H, 2.99; N, 6.91. Found: C, 41.52; H, 3.02; N, 6.94%. +ESI-HRMS for $[Ag(L1)]^+$ calc. 291.0051 m/z; found: 291.0039 m/z; $[Ag(L1)(CH_3CN)]^+$ calc. 332.0317 m/z; found: 332.0303 m/z; $[Ag(L1)_2]^+$ calc. 475.1052 m/z; found: 475.1034 m/z.

2.3. Synthesis of $[Agtfa(L2)]_2$ (**2A** and **2B**)

This reaction used 1 equiv. of 5,5′-dimethyl-2,2′-bipyridine (0.074 g, 0.404 mmol) in CH_3CN (5 mL) added to a stirred solution of Agtfa (0.089 g, 0.398 mmol) in CH_3CN (5 mL). This was stirred for 5 min and the solvent was removed in vacuo to leave a white powder in 47% isolated yield (0.075 g, 0.093 mmol). Colorless blocks were formed by slow diffusion of hexane into a CH_2Cl_2 solution of the compound at 5 °C, which afforded crystal structure **2A**. A slightly different conformation of the same compound was obtained as colorless blocks formed by slow diffusion of hexane into a THF solution of the resulting product at 5 °C, giving crystal structure **2B**. ^{1}H NMR (CD_3CN, 298 K) δ: 2.45 (s, 6H, CH_3), 7.89 (d, 2H, J = 7.5 Hz, aromatic), 8.14 (d, 2H, J = 7.9 Hz, aromatic), 8.58 (s, 2H, aromatic). $C_{28}H_{24}Ag_2F_6N_4O_4$ (810.25): *Anal.* Calc. for C, 41.51; H, 2.99; N, 6.91. Found: C, 41.64; H, 3.04; N, 6.98. +ESI-HRMS for $[Ag(L2)]^+$ calc. 291.0051 m/z; found: 291.0041 m/z; $[Ag(L2)(CH_3CN)]^+$ calc. 332.0317 m/z; found: 332.0306 m/z; $[Ag(L2)_2]^+$ calc. 475.1052 m/z; found: 475.1040 m/z.

2.4. Synthesis of $(AgOtf)_2(L2)_3$ (**3A**) and $(AgOtf)_2(L2)_3$·MeOH (**3B**)

A solution of 5,5′-dimethyl-2,2′-bipyridine (0.170 g, 0.923 mmol) in CH_3CN (5 mL) was added to AgOtf (0.166 g, 0.602 mmol) in CH_3CN (5 mL) to leave a brownish solid upon evaporation of the solvent. This was then re-dissolved in 10 mL of CH_3CN and filtered through celite to obtain a yellow-white powder in 61% isolated yield (0.195 g, 0.183 mmol). Colorless blocks were formed by layering hexane over a CH_2Cl_2 solution of the compound at 5 °C, which afforded crystal structure **3A**. A slightly different conformation (crystal structure **3B**) of the same compound was obtained as colorless blocks formed by layering ether over a CH_3OH solution of the product at 5 °C, this resulted in the incorporation of a solvent MeOH molecule. ^{1}H NMR (CD_3CN, 298 K) δ: 2.38 (s, 6H, CH_3), 7.90 (d, 2H, J = 7.9 Hz, aromatic), 8.15 (d, 2H, J = 8.5 Hz, aromatic), 8.55 (s, 2H, aromatic). *Anal.* Calc. for $C_{38}H_{36}Ag_2F_6N_6O_6S_2$ (1066.59): C, 39.52; H, 2.56; N, 9.08. Found: C, 40.02; H, 2.49; N, 8.86%. +ESI-HRMS for $[Ag(L2)]^+$ calc. 291.0051 m/z; found: 291.0042 m/z; $[Ag(L2)(CH_3CN)]^+$ calc. 332.0317 m/z; found: 332.0306 m/z; $[Ag(L2)_2]^+$ calc. 475.1052 m/z; found: 475.1041 m/z.

2.5. Synthesis of $[AgOtf(L3)]_n$ (**4**)

To a stirred solution of AgOtf (0.109 g, 0.398 mmol) in CH_3CN (5 mL) was added 2,2′-bipyridine (0.061 g, 0.396 mmol) in CH_3CN (5 mL). The resulting solution was allowed to stir for 5 min and then dried in vacuo to leave a yellow-white solid upon evaporation of the solvent. The resulting product was obtained in 70% isolated yield (0.115 g, 0.278 mmol). Colorless blocks were obtained by slow diffusion of hexane into a CH_2Cl_2 solution of **4** at 5 °C. ^{1}H NMR (CD_3CN, 298 K) δ: 7.63 (t, 2H, J = 5.9 Hz, aromatic), 8.10 (t, 2H, J = 7.9 Hz, aromatic), 8.32 (d, 2H, J = 7.9 Hz, aromatic), 8.70 (d, 2H, J = 4.9 Hz, aromatic). *Anal.* Calc. for $C_{11}H_8AgF_3N_2O_3S$ (413.12): C, 31.98; H, 1.95; N, 6.78; found C, 32.24; H, 2.05; N, 7.05%. +ESI-HRMS for $[Ag(L3)]^+$ calc. 262.9738 m/z; found: 262.9727 m/z; $[Ag(L3)(CH_3CN)]^+$ calc. 304.0004 m/z; found: 303.9993 m/z; $[Ag(L3)_2]^+$ calc. 419.0426 m/z; found: 419.0411 m/z.

2.6. Synthesis of $(AgOtf)_2(L3)_3$ (**5**)

The reaction was done in a 3:2 ratio of 2,2′-bipyridine (0.142 g, 0.923 mmol) and AgOtf (0.164 g, 0.602 mmol) in CH_3CN to leave a off-white solid upon evaporation of the solvent. This was re-dissolved in 10 mL of CH_3CN and filtered through celite. Upon evaporation, the product was obtained in 52% isolated yield (0.153 g, 0.156 mmol). Colorless blocks were formed by layering hexane over a CH_2Cl_2 solution of **5** at 5 °C. ^{1}H NMR (CD_3CN, 298 K) δ: 7.60 (t, 2H, J = 6.9 Hz, aromatic), 8.10 (t, 2H, J = 7.5 Hz, aromatic), 8.33 (d, 2H, J = 7.9 Hz, aromatic), 8.67 (d, 2H, J = 4.9 Hz, aromatic). *Anal.* Calc. for $C_{96}H_{72}Ag_6F_{18}N_{18}O_{18}S_6$ (982.43): C, 39.12; H, 2.46; N, 8.55. Found: C, 39.33; H, 2.31; N, 8.52%. +ESI-HRMS for $[Ag(L3)]^+$ calc. 262.9738 m/z; found: 262.9726 m/z; $[Ag(L3)(CH_3CN)]^+$ calc. 304.0004 m/z; found: 303.9992 m/z; $[Ag(L3)_2]^+$ calc. 419.0426 m/z; found: 419.0411 m/z.

2.7. Crystallographic analyses

Single X-ray diffraction data of compounds **1–5** were collected at 110 K on a Bruker X8 Apex using Mo Kα radiation (λ = 0.71073 Å). All structures were solved by direct methods after correction of the data using SADABS [42,43]. Crystallographic data were collected on crystals with approximate dimensions of 0.285 × 0.245 × 0.084 mm for **1**, 0.120 × 0.290 × 0.364 mm for **2A**, 0.170 × 0.201 × 0.300 mm for **2B**, 0.100 × 0.181 × 0.370 mm for **3A**, 0.130 × 0.190 × 0.390 mm for **3B**, 0.190 × 0.230 × 0.300 mm for **4**, and 0.130 × 0.170 × 0.242 mm for **5**. Details of the crystal parameters, data collection, and refinement are summarized in Table 1. The molecular structure of the compounds is displayed in Figs. 1–6. Summary of selected bond lengths, angles, and interatomic distances are given in Table 2. All data were processed using the Bruker AXS SHELXTL software,

version 6.10 [44]. Hydrogen atoms were placed in calculated positions and all non-hydrogen atoms were refined anisotropically, unless specified. The triflate ions for structure **3A** were restrained to have similar bond lengths and angles. The structure of **5** contained one disordered triflate which was modeled over two positions. Corresponding bonds and anisotropic displacement parameters were restrained to be similar.

3. Results and discussion

3.1. Synthesis and NMR spectroscopy

The silver compounds **1–5** were synthesized by reaction of substituted and un-substituted bipy ligands with simple silver salts under ambient conditions. All of the compounds synthesized herein can be isolated as white or off-white powders that appear to be indefinitely stable in solution if kept shielded from light in a sealed container. The powders of each compound have proven themselves to be quite robust, withstanding long exposure to air and room temperatures. Photodecomposition of the white solid is observed to be faster in the Otf compounds when compared to the tfa metal complexes, which result in the formation of a gray-black solid. Purification of the compounds from decomposition products can be achieved by dissolving the solid in CH_3CN and inducing precipitation of the product with ether.

Reaction of Agtfa with each of the bipy ligands only affords metal complexes in a 1:1 ligand to metal ratio; no higher ratios have been isolated for tfa. On the other hand, the use of the moderately interacting triflate yielded compounds that display a 3:2 ligand to metal ratio for 5,5′-dimethyl-2,2′-bipyridine and 4,4′-dimethyl-2,2′-bipyridine. The 3:2 ratio X-ray crystal structure of 4,4′-dimethyl-2,2′-bipyridine to AgOtf was obtained, although it is not reported in this work due to unsatisfactory refinement of the crystallographic data. The unsubstituted L3, which lacks any hindered effects from methyl groups substituted in the pyridine rings, allows the formation of coordinative structures in the different ratios possible, only when the AgOtf salt is used in the reaction. Compounds **2** and **3** each present two different structural conformations from crystals obtained by using distinct crystallization solvent systems. The variations observed in the two conformations for compounds **2A** and **2B** stem solely from slight differences in the interaction of the counterion with the corresponding metal centers, while there is the additional interaction of MeOH in going from **3A** to **3B**. It should be noted that the structural variation that is observed in **2A** and **2B** is repeatable. Several crystal tubes of each were grown and several crystals from each batch were checked by determining the unit cell. In each case the structural motif was preserved by crystallization procedure. Overall, the crystal structures of compounds **1–5** exhibit the silver(I) cation in a variety of settings and coordinative environments which is demonstrative of the effects of two variables: anion and ligand/ratio dependence of structural features. This variability in structure and bonding is enhanced on silver(I) complexes due to the facility with which it varies its coordination sphere to accept the number of donors

present, and the functionality of the bipy ligands to either chelate or bridge in the metal complex. A feature that is seen to occur with the noninteracting BF_4^- ion but was not observed here is the temperature dependence of morphology caused by differences in the rate of crystallization. In the present case, interaction of the metal center with the corresponding anion appears to overwhelm any temperature effects that would be had on the structures.

The ^{1}H NMR spectra of compounds **1–5** are, as expected, generally similar, observing the corresponding shifting of the aromatic signals of the bipyridines when compared to the spectra of the free ligands. However, the aromatic protons of a bipy ligand that is terminally bound to a metal center are not distinguishable to those from a bipy that displays a bridging coordination mode in the same compound, thus resulting in equivalent signals as observed in compounds **2**, **3**, and **5**. High Resolution Mass Spectrometry was used in an attempt to determine the nuclearity of the species in solution. The only peaks observed were for $Ag(L)^+$ and $Ag(L)_2^+$ species, confirming that the crystallized compounds dissociate in solution. None of the compounds discussed here exhibited any fluorescence, even at liquid nitrogen temperatures. This agrees with the previous observation that 2,2′-bipy tends to quench luminescence [18,20–22].

3.2. X-ray structure of Agtfa(L1) *1*

The crystal structure of compound **1** consists of two silver atoms, each bonded to a tfa anion and one 4,4′-dimethyl-2,2′-bipyridine ligand displaying a chelating coordination mode (Fig. 1). The center of the Ag–Ag axis is on a crystallographic C2 axis. The metal centers are in capped trigonal planar environments with angles ranging between 72.21(19) and 156.40(18)° (Table 2). The Ag–Ag interaction exhibits a distance of 3.0249(12) Å, and the Ag–N distances fall in the range of reported values. The pyridyl rings of the 4,4′-dimethyl-2,2′-bipyridine ligand are nearly coplanar with a twist angle of 7.7(8)° (Table 3). Adjacent molecules of **1** display π–π interactions between the aromatic rings of the bipy ligands; the distance from a plane drawn through the N2 ring of L1 yields a distance to the facing ring ranging from 3.355 to 3.396 Å (Fig. S1). Addition of another equivalent of 4,4′-dimethyl-2,2′-bipyridine to a 1:1 ligand to metal ratio reaction yielded only compound **1** upon crystallization, likely due to the electronically and sterically crowded silver centers by coordination of the strong interacting tfa anions.

3.3. X-ray structure of [Agtfa(L2)]$_2$ *2A* and *2B*

Due to the same factors that cause the stoichiometric limitations on compound **1**, compound **2** has only been obtainable in a 1:1 ligand/metal ratio. More interesting is the conformation of the bipy ligands in this structure which completely differs from that observed in compound **1**, even though the only difference that exists between the ligands used is the position of the methyl groups on the pyridine rings. Compound **2** is the first example of the series of Ag:bipy structures reported in this work that presents two different conformations arising from the change of the crystallization solvent system. Crystal structure **2A** shown in Fig. 2a was obtained by layering hexane into a solution of the product in CH_2Cl_2 at low temperature, while crystal structure **2B** (Fig. 2b) is formed by using THF/hexane as crystallization solvents. The two structures differ in the bidentate interaction of one of the tfa anions with Ag2 in structure **2B**, while in **2A** both counteranions are bound to silver through a single oxygen. In both structures one 5,5′-dimethyl-2,2′-bipyridine ligand is chelating Ag1, and the other bipy bridges the two silvers, which allows the observed metallophilic interaction. A distinctive characteristic of these poly-

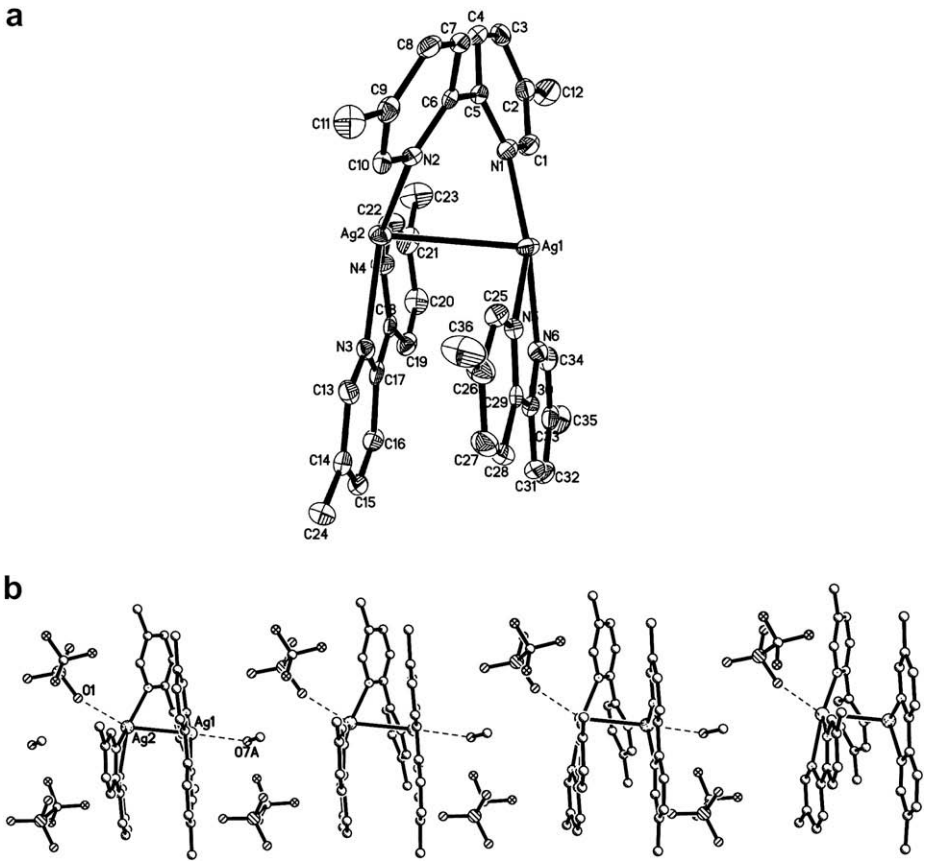

Fig. 4. (a) Thermal ellipsoid plot of **3B** with an atomic numbering scheme. Ellipsoids are shown at the 50% level. Hydrogen atoms, Otf anions and a solvent molecules have been removed for clarity. (b) Ball-and-stick view of the packing structure of **3B**. H atoms have been removed from clarity.

morphs is that both tfa anions are linked to a same silver atom. Relevant literature and CCDC searches reveal this structural feature to be previously unseen. It is then suggested that the functionality of the bipy to chelate and to act as a bridging ligand in the molecule, accounts for Ag1 to be coordinatively saturated, thus aiding the coordination of both tfa anions to Ag2.

The Ag1–Ag2 distance presents values of 2.9833(3) and 2.8921(5) Å for **2A** and **2B** respectively. Despite the similarities between the two structures, the notable difference of about 0.1 Å in the Ag–Ag distances possibly arises from the extra Ag2–O2 interaction in conformation **2B**, that provides extra electron density to the Ag1–Ag2 bond, thus resulting in a contraction of the bond. Angles around the metal centers in **2A** indicate a distorted trigonal pyramidal geometry for both silver atoms, where the sum of the angles of the trigonal base approaches 360° (354.82 and 345.18° for Ag1 and Ag2 respectively). Ag1 also displays a distorted trigonal pyramidal geometry in **2B**, while Ag2 is five coordinate with a wide range of angles between 51.78(6) and 140.02(7)°. The Ag–O distances in **2A** are comparable with values of 2.2953(14) and 2.3733(15) Å for Ag2–O1 and Ag2–O4 respectively. In **2B** the bidentate tfa anion is symmetrically coordinated to Ag2 with equivalent distances of 2.513(2) and 2.518(3) Å for Ag2–O1 and Ag2–O2 respectively. The Ag2–O3 interaction exhibits a shorter contact of 2.3309(16) Å by comparison. The two pyridyl rings of the chelating bipy ligand are nearly coplanar with a twist angle of 7.7(9)° and 6.9(9)° for **2A** and **2B** respectively. As expected, a more pronounced twist is observed for the bridging ligand with angles of 29.1(6)° and 33.6(6)° in **2A** and **2B** respectively. According to Fig. S2, the packing structure of **2B** shows a weak interaction between the only unbound oxygen atom of the monodentate tfa anion and a metal center of the next adjacent molecule (2.662 Å), which consists of a difference of only 0.15 Å when compared to the Ag2–O3 bond distance.

3.4. X-ray structure of $(AgOtf)_2(L3)_3$ **3A** and $(AgOtf)_2(L3)_3 \cdot MeOH$ **3B**

Reaction of AgOtf with 5,5′-dimethyl-2,2′-bipyridine in different ligand to metal ratios (1:1, 2:1, and 3:2), resulted only in the formation of a discrete molecule where two 5,5′-dimethyl-2,2′-bipyridines are chelating two silver atoms, and a third bipy is bridging the metal centers. By using two different crystallization solvent systems, formation of two distinct crystal structures was observed, in which one of the Otf anions is bound to Ag1 in **3A** (layered in CH_2Cl_2/hexane), while in **3B** (layered in CH_3OH/ether) a molecule of Otf^- and CH_3OH exhibit weak interactions of 2.6832(2) and 2.6483(3) Å with Ag2 and Ag1 respectively (Fig. 4). In this case the Ag–Ag distances of both structures are minimally affected by the difference in connectivity, with similar values of 2.8921(5) and 2.9223(4) Å for **3A** and **3B** respectively. Angles around Ag1 in **3A** describe a distorted trigonal bipyramidal geometry in which the axial angle is 170.9(2)° corresponding to the O1–Ag1–Ag2 angle (Fig. 3). Ag2 displays a capped trigonal planar geometry where the angles range between 72.73(14) and 146.02(14)°. In **3B** both silver atoms also present a common capped trigonal planar geometry, regardless of the weak interactions that Ag2 and Ag1 present with a molecule of Otf^- and CH_3OH respectively. The rings of the bridging bipy ligands are twisted from planarity at an angle of 47.0(2)° and 41.8(2)° in **3A** and **3B** respectively.

3.5. X-ray structure of [AgOtf(L3)]$_n$ **4**

The 1:1 ratio reaction of 2,2′-bipyridine to AgOtf produces a one-dimensional Ag polymer as shown in Fig. 5. The ball-and-stick view of the molecular growth of **4** is generated by a 3-fold screw axis and a 2-fold rotation as shown in Fig. 5b. The crystal structure of compound **4** reveals the Otf anion playing an integral part in the polymeric chain, and in deciding the geometry of the silver ions. In this molecule the 2,2′-bipyridine is acting solely as a bridging ligand, displaying a twist angle of 35.91(9)°. The Otf is acting as a

coordinating anion, with the characteristic that for every two silver atoms, the two corresponding anions are bound to the same metal center. This structural feature has been reported earlier for compound **2** when the corresponding bipy ligand is also displaying a bridging coordination mode. Therefore, the molecular structure of **4** contains two distinct silver environments which is representative of the coordination extremes mentioned herein. Ag1 is four coordinated to two half of 2,2′-bipyridine ligands and to two silver atoms, which describes a distorted tetrahedral geometry with angles ranging between 70.92(8) and 170.62(19)°. Ag2 exhibits the same bonding as Ag1 in addition to two Otf anions, which makes it a 6 coordinated metal center. The Ag–Ag interactions are typical lengths at 3.0437(3) Å [36,45–48], and are supported by the bridging ligand to form a infinite chain which deviates from linearity with angles of 171.733(16) and 163.451(18)° for Ag(1)#2–Ag(2)–Ag(1) and Ag(2)#4–Ag(1)–Ag(2) respectively. In this molecule the Otf anions are highly disordered about the C–S axis; due to the disorder, they were refined isotropically, and each group was restrained to have the same C–F and S–O bond lengths, angles, and thermal parameters.

3.6. X-ray structure of $(AgOtf)_2(L3)_3$ **5**

Changing the stoichiometry of the reaction between 2,2′-bipyridine and AgOtf to a 3:2 ligand/metal ratio produced compound **5** shown in Fig. 6. It consists of two discrete molecules, each one

containing four silver atoms lying in nearly a straight line, and six 2,2′-bipyridine groups, of which four are chelating and two are bridging. One of these discrete molecules is oriented on an inversion center which gives a Z of 6 for the structure. For each four silver chain, two Otf anions are capping the terminal silver atoms through a single sulfonate oxygen, and the remaining anions show no interaction with the chain. The interacting Otf anions truncate the formation of a polymeric chain as observed in compound **4**. This linear silver chain structure can be described as two molecules of compound **3** linked together through Ag2, to form the same core structure as observed for compound **5**. This observation can be used to suppose possible hindered effects provided by the methyl groups of the 5,5′-dimethyl-2,2′-bipyridine ligand, that encumber the formation of a elongated chain composed of metallophilic interactions. The thermal ellipsoid plot of compound **5** shows distinct silver environments encompassed in one structure, and defined by the functionality of the bipy ligand. The terminal silver atoms (Ag1, Ag4, Ag5, and Ag5#1) display a distorted capped tetrahedral geometry, while the central silver atoms exhibit a distorted trigonal bipyramidal conformation. The Ag–Ag distances fall in the range of reported values, ranging between 2.9347(4) Å for Ag5–Ag6 and 3.0867(4) Å for Ag2–Ag3. The angle between the planes of the π-systems describes a considerable twist of the bipyridine ligands that exhibit either a chelating or a bridging coordination mode. The twist angle for the 2,2′-bipyridines that are chelating range between 19.79(2) and 29.32(1)°, and for the ligands bridging a range between 36.85(1) and 40.58(1)°. It is also noted that the chelating bipy ligands bound to Ag1 and Ag4 respectively, present smaller twist angles when compared to those coordinated to Ag2 and Ag3 where more steric effects can be found in the molecular structure of the compound. One of the noncoordinating Otf anions in the crystal structure is disordered about the position of the sulfur and carbon; therefore it was refined isotropically, and the two sulfur and carbon positions restrained to have the same thermal parameters.

4. Conclusion

Herein we have demonstrated the versatility and functionality of bipy type ligands associated with silver(I) salts of two different anions that exhibit varying degree of interaction. The crystal structures are seen to be highly dependent not only on the coordinating ability of the anion but also on the ratio of ligand/metal. In particular, the simplicity of these ligands made it an appealing candidate for use to study the structural and coordinative factors that produce molecular structures that span from simple discrete molecules to one or two-dimension polymeric conformations. This report complements other studies of coordinative silver structures associated with bipy ligands, where several factors are involved in the construction of such coordinative arrays.

ABSTRACT

Peripherally and non-peripherally 2-diethylaminoethanethiol tetra-substituted zinc phthalocyanine (**5a** and **6a**) and their quaternized derivatives (**5b** and **6b**) have been synthesized and characterized. The quaternized derivatives (**5b** and **6b**) show excellent solubility in aqueous medium. The photophysical and photochemical properties of the 2-diethylaminoethanethiol appended zinc phthalocyanine in dimethylsulfoxide (DMSO) for the non-ionic (**5a** and **6a**) and in both DMSO and aqueous medium (phosphate buffered saline solution PBS, pH 7.4) (in the presence and absence of cremophore EL (CEL)) for the quaternized (**5b** and **6b**) derivatives were studied and compared with that of the peripherally octa-substituted derivatives (**7a** and **7b**). The complexes have intense absorption in the visible/near-IR region though the quaternized forms (**5b**, **6b** and **7b**) were slightly blue shifted and highly aggregate in aqueous solution. The triplet state quantum yields (Φ_T) and the triplet lifetimes (τ_T) were found to be higher in DMSO (Φ_T values ranged from 0.57 to 0.75 while τ_T values ranged from 190 to 220 μs in DMSO for all complexes) compared to aqueous medium (Φ_T values ranged from 0.15 to 0.17 while τ_T values ranged from 20 to 70 μs in pH 7.4 buffer). Addition of cremophore EL in aqueous solution resulted in induced disaggregation leading to increased Φ_T and τ_T.

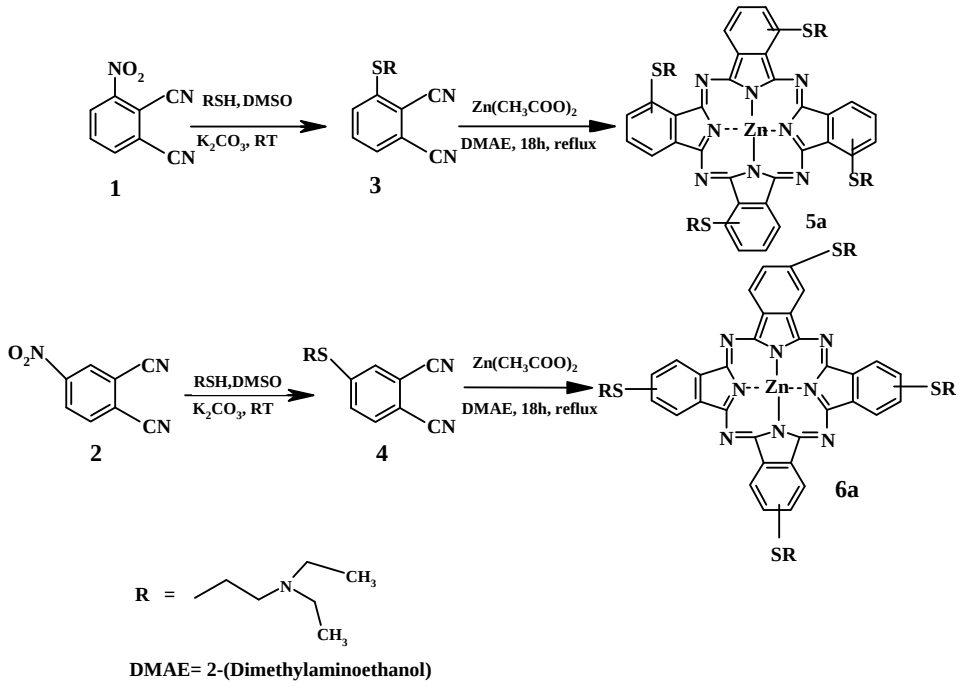
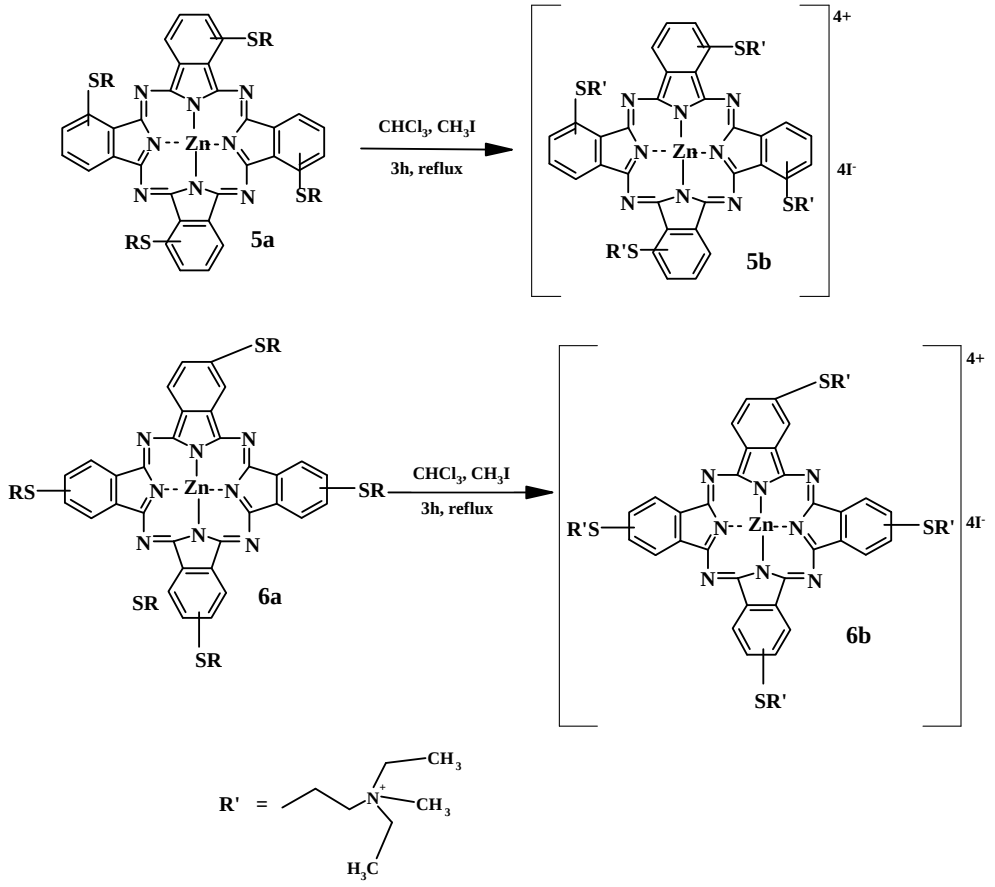
1. Introduction

Metallophthalocyanines (MPcs), a family of aromatic macrocycles based on an extensive delocalized 18π electron system, have been extensively studied due to their unique optical, electronic, catalytic and structural properties [1]. There has been growing interest in the use of phthalocyanines in a variety of new technological fields such as semiconductor devices [2], electrochromic display devices [3], liquid crystals [4], Langmuir–Blodgett films [5], and as photosensitizers in photodynamic therapy of cancer (PDT) [6].



PDT is a prominent application of phthalocyanine derivatives. It is based on a noninvasive treatment of superficial tumors. The concept is that a photosensitizer can be preferentially localized in malignant tissues, followed by activation of the photosensitizer with the light of the appropriate wavelength to generate cytotoxic radical and non-radical species of oxygen that lead to tumor destruction [6–10].

MPcs can be modified in a number of ways by incorporation of substituents in their peripheral (β) and non-peripheral (α) positions. This incorporation increases the π-electron density and makes solvation easier [11]. Tetra-substituted phthalocyanines (Pcs) are usually more soluble than the corresponding octa-substituted Pcs due to the formation of constitutional isomers and the high dipole moment that results from the unsymmetrical arrangement of the substituents at the periphery [12,13]. Incorporation of non-transition metals like zinc in the centre of the phthalocyanine (Pc) ring results in complexes with high triplet state quantum yields and long triplet lifetimes, which are required for efficient photosensitization [14]. MPcs are particularly interesting since anionic or cationic groups such as sulfonic, carboxylic, phosphonic or quaternized amino groups render them water soluble [15–18]. Some cationic phthalocyanines have been reported [19–22] and it has been discovered that they target vulnerable sites in cells [23], showing their importance in tumor necrosis and photoinactivation of bacteria.



We report herein on the synthesis, of ZnPc tetra-substituted at the (β) peripheral and (α) non-peripheral position with 2-diethylaminoethanethiol (complexes **5a** and **6a**) and their quaternized derivatives (complexes **5b** and **6b**) (Scheme 1). It is expected that substitution at the more sterically crowded α position will result in reduced aggregation tendencies compared to the β position [24]. The spectroscopic, photophysical and photochemical properties of **5a** and **6a** (in DMSO) and **5b** and **6b** (in both DMSO and aqueous medium, phosphate buffered saline solution PBS, pH 7.4) in comparison with the (β) peripherally octa-substituted counterparts (**7a** and **7b**, respectively) has also been investigated to give

Scheme 1b. Synthesis route of quaternized 2-diethylaminoethanethiol substituted zinc(II) phthalocyanine.

an indication of the potential of the complexes as photosensitizers. Peripherally (β) octa-substituted complexes **7a** and **7b** (Fig. 1) have been reported before [22]. As stated above, tetra-substituted MPc complexes are more soluble than octa-substituted ones, hence the are studied in this work. Substitution at the α position results in red shifting of spectra which is useful for PDT applications.

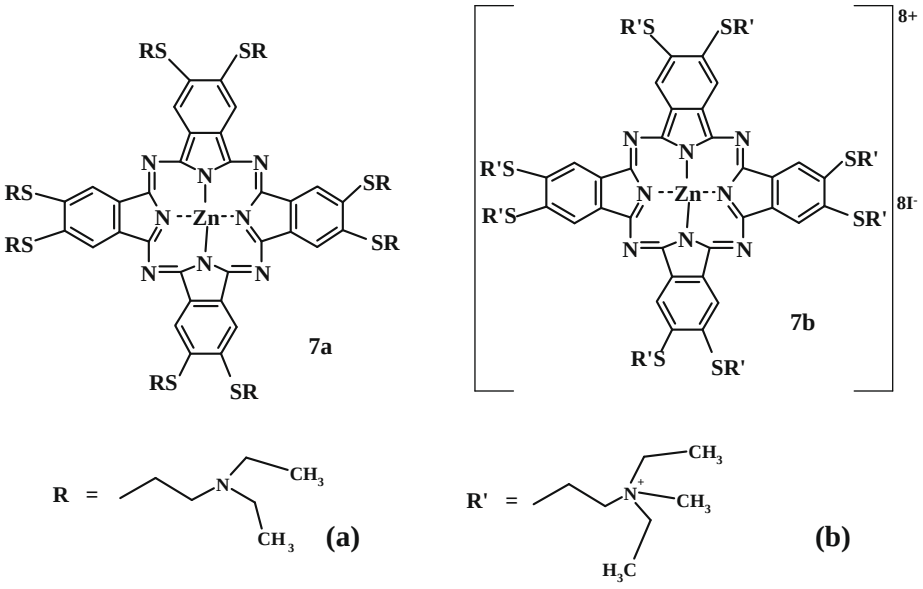

Fig. 1. Molecular structures of complexes **7a** and **7b**.

Lipophilic phthalocyanine derivatives have been reported to have a higher tumor affinity, but they are associated with cutaneous phototoxicity [25], water soluble phthalocyanines are therefore still considered the best targets of photosensitizers [26] since they can be injected directly into the bloodstream, despite their aggregation tendency in aqueous medium [27,28]. However, aggregation can be hindered by addition of surfactants [29,30]. Thus in this work, the quaternized MPcs (**5b**, **6b** and **7b**) are also studied in aqueous medium in the presence of cremophore EL (CEL), a non-ionic surfactant which is an excipient to drugs and can provide a more selective accumulation of the drugs in tissues. The association of the MPc complexes with bovine serum albumin (BSA) has also been investigated since hydrophilic dyes bind preferentially to serum proteins, such as BSA [31] and serum albumin is one of the key components in the body that influences drug delivery [32].

2. Experimental and method

2.1. Materials

Methanol, tetrahydrofuran (THF) and dimethylsulfoxide (DMSO) were dried as described by Perrin and Armarego [33] before use. Deuterated DMSO (d_6-DMSO), 2-diethylaminoethanethiol hydrochloride, cremophore EL (CEL), 3-diphenylisobenzofuran (DPBF), anthracene-9,10-bis-methylmalonate (ADMA), 2-dimethylaminoethanol and zinc acetate were purchased from Sigma–Aldrich. BSA was obtained from Fluka. Chromatography was performed on neutral alumina. Phosphate-buffered saline (PBS) solution (0.01 M, pH 7.4) was prepared using appropriate amounts of Na_2HPO_4, KH_2PO_4 and chloride salts, dissolved in ultra pure water, from a Milli-Q Water System (Millipore Corp., Bedford, MA, USA). Zinc tetrasulfophthalocyanine ($ZnPcS_4$), zinc phthalocyanine (ZnPc) and $ZnPcS_{mix}$ were synthesized, purified and characterized according to literature methods [29,34,35]. 3-Nitrophthalonitrile (**1**), 4-nitrophthalonitrile (**2**), 1,2-dichlorophthalonitrile, [36–38], 3-diethylaminoethylsulfanyl phthalonitrile (**3**), 4-diethylaminoethylsulfanyl phthalonitrile (**4**), and 1,2-bis-(diethylaminoethylsulfanyl)-4,5-dicyanobenzene were all synthesized and purified according to the literature [19,22]. Complexes **7a** and **7b** were synthesized and characterized as reported in literature [22].

2.2. Equipment

UV/Vis spectra were recorded on a Cary 500 UV/Vis/NIR spectrophotometer. IR spectra (KBr pellets) were recorded on a Perkin–Elmer spectrum 2000 FTIR spectrometer. ^{1}H NMR spectra were recorded using a Bruker EMX 400 MHz NMR spectrometer. Low resolution atmospheric pressure chemical ionisation (APCI) mass spectra were recorded on a Finnigan MAT LCQ ion trap mass spectrometer equipped with XCALIBUR software.

Fluorescence excitation and emission spectra were recorded on a Varian Eclipse spectrofluoremeter using a 1 cm pathlength cuvette at room temperature. Laser flash photolysis experiments were performed with light pulses produced by a Quanta-Ray Nd:YAG laser providing 400 mJ, 90 ns pulses of laser light at 10 Hz, pumping a Lambda-Physik FL3002 dye (Pyridin 1 dye in methanol). Single pulse energy was 7 mJ. The analyzing beam source was from a Thermo Oriel xenon arc lamp, and a photomultiplier tube was used as detector. Signals were recorded with a digital real-time oscilloscope (Tektronix TDS 360); the kinetic curves were averaged over 256 laser pulses. The triplet life times were determined by exponential fitting of the kinetic curves using the program ORIGINPRO 7.5. Solutions for triplet yield and lifetime determinations were purged of oxygen (by bubbling with Argon) before laser irradiations. Photo-irradiations for photodegradation or singlet oxygen determination were performed using a General electric Quartz line lamp (300 W). A 600 nm glass cut off filter (Schott) and water were used to filter off ultraviolet and infrared radiations, respectively. An interference filter (Intor, 700 nm with a band width of 40 nm) was additionally placed in the light path before the sample. Light intensity was measured with a POWER MAX5100 (Molelectron detector incorporated) power meter and was found to be 5.14×10^{16} photons s^{-1} cm^{-2} for photobleaching and to be 1.78×10^{16} photons s^{-1} cm^{-2} for singlet oxygen studies.

2.3. Determination of percentage aggregation, equilibrium constant

Percentage aggregation (% Agg) was calculated using Eq. (1) [30,39]

$$\%\ \mathrm{Agg} = \frac{\mathrm{Abs}_{\mathrm{MeOH}} - \mathrm{Abs}}{\mathrm{Abs}_{\mathrm{MeOH}}} \times 100\% \qquad (1)$$

where Abs_{MeOH} and Abs are the absorbances at the *Q-band* monomer maxima in the presence and absence of methanol.

The equilibrium constant of the monomer/dimer equilibrium for $2M \leftrightarrow D$ is defined by Eq. (2)

$$K_D = [D]/[M]^2 \tag{2}$$

where [M] and [D] are the concentrations of the monomer and the dimer, respectively. The total concentration of the MPcs is given by Eq. (3)

$$C = [M] + 2[D] \tag{3}$$

The absorbance of a solution containing both the monomer and the dimer is given by Eq. (4) [40]

$$Abs = \frac{[1 - \sqrt{(1 + 8K_DC)}][\varepsilon_D/2 - \varepsilon_M] + 2\varepsilon_D K_D C]}{4lK_D} \tag{4}$$

where C is the total concentration of the MPcs (monomer and dimer), ε_M and ε_D are the extinction coefficients of the monomer and dimer, respectively, and l the path length.

An estimated value of ε_M obtained from the measurements in aqueous solution within the concentration range at which the Beer–Lambert's law holds for each MPc was substituted in Eq. (4) and the absorbance data were fitted to obtain ε_D and K_D by a non-linear least square procedure using MATLAB 6.1 software.

2.4. Photophysical and photochemical studies

Fluorescence quantum yields (Φ_F) were determined by comparative method using Eq. (5) [41],

$$\Phi_F = \Phi_{F(Std)} \cdot \frac{F \cdot A_{Std} \cdot n^2}{F_{Std} \cdot A \cdot n_{Std}^2} \tag{5}$$

where F and F_{Std} are the areas under the fluorescence curves of the MPc derivatives and the reference, respectively. A and A_{Std} are the absorbances of the sample and reference at the excitation wavelength, and n and n_{Std} are the refractive indices of solvents used for the sample and standard, respectively. ZnPc in DMSO was used as a standard, $\Phi_F = 0.2$ [42]. At least three independent experiments were performed for the quantum yield determinations. Both the sample and the standard were excited at the same relevant wavelength.

Triplet quantum yields were determined using a comparative method based on triplet decay, using Eq. (6)

$$\Phi_T^{Sample} = \Phi_T^{Std} \frac{\Delta A^{Sample} \varepsilon^{Std}}{\Delta A^{Std} \varepsilon^{Sample}} \tag{6}$$

where A_T^{Sample} and A_T^{Std} are the changes in the triplet state absorbance of the sample derivative and the standard, respectively. ε_T^{Sample} and ε_T^{Std} are the triplet state extinction coefficients for the sample and standard, respectively. Φ_T^{Std} is the triplet state quantum yield for the standard. $ZnPcS_4$ in aqueous solution, $\Phi_T^{Std} = 0.56$ [43] and ZnPc ($\Phi_T^{Std} = 0.65$ in DMSO [44]) were used as standards. Quantum yields of internal conversion were obtained from Eq. (7) which assumes that only three processes (fluorescence, intersystem crossing and internal conversion); jointly deactivate the excited singlet states of the complexes.

$$\Phi_{IC} = 1 - (\Phi_F + \Phi_T) \tag{7}$$

The values of photobleaching quantum yields (Φ_P) were determined using Eq. (8)

$$\Phi_{Pd} = \frac{(C_0 - C_t)VN_A}{I_{abs}S \cdot t} \tag{8}$$

where C_t and C_0 are the MPc concentration in mol dm^{-3} after and prior to irradiation, respectively. V is the reaction volume, S is the irradiation area of the cell, t the irradiation time, N_A is the Avogadro's number and I_{abs} the overlap integral of the radiation light source intensity and the absorption of the MPc in the region of the interference filter transmittance [45,46]. Eq. (9) was employed for calculating singlet oxygen quantum yields

$$\Phi_\Delta = \Phi_\Delta^{Std} \cdot \frac{RI_{abs}^{Std}}{R^{Std}I_{abs}} \tag{9}$$

where Φ_Δ^{Std} is the singlet oxygen quantum yield for the standard ($ZnPcS_{mix}$, $\Phi_\Delta^{Std} = 0.45$ in aqueous solution) [47] and ZnPc ($\Phi_\Delta^{Std} = 0.67$ in DMSO [46]). R and R^{Std} are the ADMA or DPBF photobleaching rates in the presence of the respective MPcs under investigation and the standard, respectively. I_{abs} and I_{abs}^{Std} are the rates of light absorption by the MPcs and the standard, respectively. To avoid chain reactions, the concentration of ADMA was kept at $\sim 6 \times 10^{-5}$ mol l^{-1} while that of DPBF was kept at $\sim 3 \times 10^{-5}$ mol l^{-1}.

Solutions of the MPcs with an absorbance of 0.2 at the irradiation wavelength were prepared in the dark and irradiated at the *Q-band* region, monitoring the ADMA and DPBF degradation at 380 nm and 417 nm, respectively. The error was ~10% from several values of Φ_Δ.

2.5. Binding of MPcs to BSA

The binding of the MPcs to BSA was studied by spectrofluorometry at room temperature. An aqueous solution of BSA (fixed concentration) was titrated with varying concentrations of the respective MPc solution. BSA was excited at 280 nm and fluorescence recorded between 290 and 500 nm. The steady decrease in BSA fluorescence with increase in MPc concentration was noted and used in the determination of the binding constants and the number of binding sites on BSA, according to Eq. (10) [40,48,49]

$$\log\left[\frac{(F_0 - F)}{(F - F_\infty)}\right] = \log k_b + n \log[MPc] \tag{10}$$

where F_0 and F are the fluorescence intensities of BSA in the absence and presence of MPc, respectively; F_∞, the fluorescence intensity of BSA saturated with MPc; k_b, the binding constant; n, the number of binding sites on a BSA molecule; and [MPc] the concentration of the different MPc complexes. Plots of $\log\left[\frac{(F_0-F)}{(F-F_\infty)}\right]$ against log [MPc] would provide the values of n (from slope) and k_b (from the intercept). The changes in BSA fluorescence intensity were related to MPc concentrations by the Stern–Volmer relationship, Eqs. (11) and (12) [50]

$$\frac{F_0^{BSA}}{F^{BSA}} = 1 + K_{SV}^{BSA}[MPc] \tag{11}$$

and K_{SV}^{BSA} is given by

$$K_{SV}^{BSA} = k_q \tau_F^{BSA} \tag{12}$$

where F_0^{BSA} and F^{BSA} are the fluorescence intensities of BSA in the absence and presence of MPcs, respectively; K_{SV}^{BSA}, the Stern–Volmer quenching constant; k_q, the bimolecular quenching constant; and τ_F^{BSA}, the fluorescence lifetime of BSA. τ_F^{BSA} is known to be 10 ns, [51–53]. Thus, from the values K_{SV}^{BSA} obtained from the plots of $\frac{F_0^{BSA}}{F^{BSA}}$ versus [MPc], the value of k_q may be determined (Eqs. (11) and (12)).

2.6. Synthesis

2.6.1. 1(4)-Tetra-(2-diethylaminoethylsulfanyl)-phthalocyaninato zinc(II) (**5a**, Scheme 1a) [22]

A mixture of 3-diethylaminoethylsulfanyl phthalonitrile (**3a**) (0.26 g, 1 mmol), 2-(dimethylaminoethanol) (1 ml) and anhydrous

$Zn(CH_3COO)_2$ (0.064 g, 0.35 mmol) was refluxed under N_2 for 18 h. After cooling to room temperature, MeOH:H_2O (1:1) was added to precipitate the product. The dark green product was filtered off and washed with water. It was isolated on a neutral alumina column with THF:MeOH (30:1) as eluent. Yield: 0.11 g (42%). UV–Vis (DMSO): λ_{max} nm (log ε) 339 (4.78), 643 (4.57), 717 (5.30). IR [(KBr) ν_{max}/cm^{-1}]: 3015 (Ar–CH), 2968–2797 (C–H), 1591 (C=C), 737 (C–S–C). ^{1}H NMR (DMSO-d_6) δ = 8.99 (m, 8H, Ar–H), 8.05 (m, 4H, Ar–H), 3.14 (m, 8H, SCH_2), 2.77 (br, 8H, NCH_2), 2.59 (m, 16H, CH_2C), 1.21 (m, 24H, CH_3). LRAPCI-MS *m/z*: Calc. for $C_{56}H_{68}N_{12}S_4Zn$: 1102.85; found $[M+2H]^{2+}$ 1104.4.

2.6.2. 1(4)-Tetra-(2-diethylmethylaminoethylsulfanyl)-phthalocyaninato zinc(II) tetraiodide (**5b**, Scheme 1b)

Compound **5a** (0.03 g, 0.027 mmol) was dissolved in $CHCl_3$ (5 ml), and methyl iodide (0.15 g, 1.059 mmol) was added to this solution. The mixture was refluxed for 3 h. After cooling to room temperature, the green precipitate was filtered off, washed with $CHCl_3$ and dried. Yield: 0.032 g (87%). UV–Vis (DMSO): λ_{max} nm (log ε) 336 (4.81), 636 (4.66), 707 (5.41). IR [(KBr) ν_{max}/cm^{-1}]: 2927 (C–H), 1589–1565 (C=C) ^{1}H NMR (DMSO-d_6) δ = 9.36 (quin, 4H, Ar–H), 8.35 (m, 8H, Ar–H), 4.09 (br, 8H, SCH_2), 3.98 (br, 8H, NCH_2), 3.65 (m, 16H, CH_2C), 3.28 (d, 12H, CH_3), 1.4 (m, 24H, CCH_3). LRAPCI-MS *m/z*: Calc. for $C_{60}H_{80}N_{12}S_4I_4Zn$: 1670.63; found $[M-I+2H]^{2+}$ 1546.

2.6.3. 2(3)-Tetra-(2-diethylaminoethylsulfanyl)-phthalocyaninato zinc(II) (**6a**, Scheme 1a)

Synthesis and purification was as outlined for **5a** except **4a** (0.26 g, 1 mmol) was employed instead of **3a** in the presence of 2-(dimethylaminoethanol) (1 ml) and anhydrous $Zn(CH_3COO)_2$ (0.064 g, 0.35 mmol). Yield: 0.12 g (45%). UV–Vis (DMSO): λ_{max} nm (log ε) 363 (4.83), 627 (4.46), 694 (5.19). IR [(KBr) ν_{max}/cm^{-1}]: 3007 (Ar–CH), 2967–2803 (C–H), 1600 (C=C), 743 (C–S–C). ^{1}H NMR (DMSO-d_6) δ = 8.78 (t, 4H, Ar–H), 8.02 (m, 4H, Ar–H), 7.87 (s, 4H, Ar–H), 3.37 (br, 8H, SCH_2), 3.05 (br, 8H, NCH_2), 2.76 (quin, 16H, CH_2C), 1.16 (t, 24H, CH_3). LRAPCI-MS *m/z*: Calc. for $C_{56}H_{68}N_{12}S_4Zn$: 1102.85; found $[M+3H]^{3+}$ 1106.1.

2.6.4. 2(3)-Tetra-(2-diethylmethylaminoethylsulfanyl)-phthalocyaninato zinc(II) tetraiodine (**6b**, Scheme 1b)

Synthesis and purification was as outlined for **5b** except **6a** (0.03 g, 0.027 mmol) was employed instead of **5a** in the presence of $CHCl_3$ (5 ml) and methyl iodide (0.15 g, 1.059 mmol). Yield: 0.035 g (95%). UV–Vis (DMSO): λ_{max} nm (log ε) 368 (4.85), 621 (4.54), 691 (5.34). IR [(KBr) ν_{max}/cm^{-1}]: 2974 (C–H), 1599 (C=C), 743 (C–S–C). ^{1}H NMR (DMSO-d_6) δ = 9.48 (m, 8H, Ar–H), 8.38 (quin, 4H, Ar–H), 3.95 (br, 8H, SCH_2), 3.74 (br, 8H, NCH_2), 3.56 (t, 16H, CH_2C), 3.15 (d, 12H, CH_3), 1.33 (m, 24H). LRAPCI-MS *m/z*: Calc. for $C_{60}H_{80}N_{12}S_4I_4Zn$: 1670.63; found $[M-I+2H]^{2+}$ 1546.

3. Results and discussion

3.1. Synthesis and characterization

Scheme 1 shows the synthetic pathways for the compounds used in this work. Substituted phthalocyanines are prepared by cyclotetramerization of substituted phthalonitriles. 3-Tetra-substituted phthalocyanines can be synthesized from 3-substituted phthalonitriles while 4-tetra-substituted phthalocyanines are obtained from 4-substituted phthalonitriles [54]. As stated above, the syntheses of complexes **7a** and **7b** (Fig. 1) have been reported before, and gave satisfactory spectroscopic analyses.

The 2-diethylaminoethanethiol substituents on the complex are suitable for conversion into quaternary ammonium groups and this can increase the products' solubility in water. Metal phthalocyanines were obtained in the presence of metal salts and the substituted phthalonitriles. Compounds **5b** and **6b** were obtained by methylation of **5a** or **6a** in $CHCl_3$ in good yield.

The non-ionic complexes (**5a**, **6a** and **7a**) in this study were soluble in organic solvents such as THF, toluene, and DMSO and the ionic complexes (**5b**, **6b** and **7b**) were highly soluble in polar solvents like water, methanol and DMSO. The 2-diethylaminoethanethiol group was tetra-substituted at the α and β positions and octa-substituted at the β position of the ring for comparative purposes.

The complexes were characterized by various spectroscopic methods: IR, UV–Vis, ^{1}H NMR and mass spectra and are consistent with predicted structures. The characteristic nitrile (C≡N) stretch at ~2225 cm^{-1} of **3** and **4** disappears upon formation of the phthalocyanine. The ^{1}H NMR spectra of the complexes showed ring protons between 8.99 and 9.36 ppm with the substituent protons observed between 1.21 and 4.09 ppm for the complexes (see Section 2). Integration of the peaks correctly corresponded to the expected total number of protons for each complex, confirming the relative purity of the complexes, 68 protons for complex **5a** and **6a** and 80 protons for **5b** and **6b**. Although the presence of isomers as well as phthalocyanine aggregation at the concentrations used for the NMR measurements may lead to broadening of the aromatic signals [55], the observed spectra of the complexes were relatively well resolved except for the peaks corresponding to protons attached to the sulfur or nitrogen groups and this is consistent with literature [19].

3.2. Spectrophotometric studies

The ground state electronic absorption spectra of the complexes showed monomeric behaviour evidenced by a single *Q-band,* typical of metallated phthalocyanine complexes (Fig. 2a and b) [56]. The *Q*-bands were observed in the near infrared region between 691 and 717 nm (Table 1) with the B-bands between 340 and 380 nm in DMSO.

The *Q*-bands of the α-tetra-substituted complexes (**5a** and **5b**) are red-shifted by 16 and 21 nm, when compared to the corresponding β-tetra-substituted (**6a** and **6b**) complexes in DMSO. Bathochromic shifts are known to occur into the near infrared region with electron-donating groups with a greater effect when the substitution is at the non-peripheral α positions [57,58] due to a greater destabilization effect of the HOMO level at the α position compared to the β position since linear combinations of the atomic orbitals (LCAO) coefficients at the α positions of the HOMO level are greater than those at the β positions. Therefore, a decreased energy gap between the HOMO and LUMO levels and a subsequent bathochromic shift is observed. Octa β substituted complexes **7a** and **7b**, showed red-shifted spectra compared to the tetra β substituted complexes **6a** and **6b**. The complexes showed monomeric behaviour up to $\sim 1 \times 10^{-5}$ mol dm^{-3} in DMSO.

On quaternization, blue shifts of about 2–10 nm was observed in complexes **5b**, **6b** and **7b** when compared to their corresponding non-ionic forms **5a**, **6a** and **7a** in DMSO (Table 1). This is due to the reduced electron-donating ability of the nitrogen groups when quaternized. The quaternized **5b**, **6b** and **7b** complexes are highly soluble in aqueous medium but were aggregated (Fig. 2c) with the formation of two main bands at ~680–700 nm (not well resolved for the β substituted complexes **6b** and **7b**) due to the monomeric species and ~640–660 nm due to the aggregated species, respectively. Aggregation in MPc complexes is due to a coplanar association of rings, resulting in splitting and broadening of spectra, with a blue shifted peak due to the aggregate. The presence of the bulky quaternized 2-diethylaminoethanethiol substituent at the periphery of the Zn(II)Pc significantly increases its solubility in aqueous medium, but is not so efficient in preventing

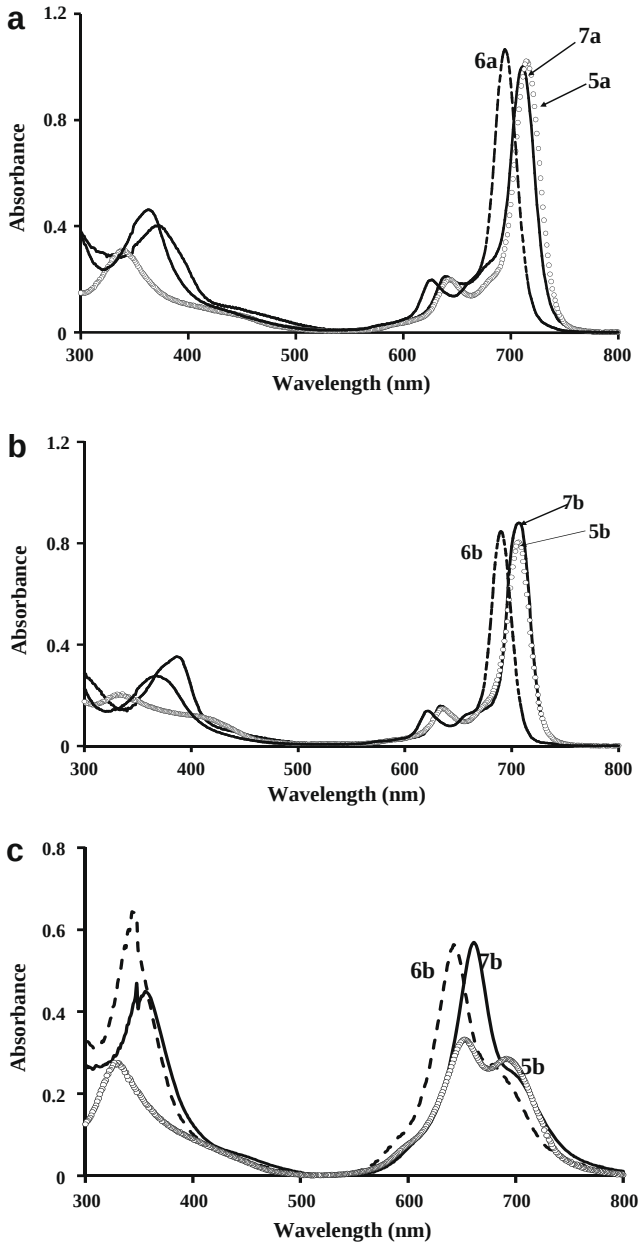

Fig. 2. Ground state electronic absorption spectra of: (a) **5a**, **6a** and **7a**; (b) **5b**, **6b** and **7b** in DMSO (concentration ~5×10^{-6} mol dm^{-3}); (c) **5b**, **6b** and **7b** in aqueous medium (concentration ~4×10^{-6} mol dm^{-3}).

aggregation of the Pc macrocycle. Metal ions like gallium and silicon, containing axial ligands in association with bulky substituents have been found to be more efficient in preventing aggregation of the Pc macrocycles [20,59]; buttressing the fact that aggregation can be dependent on the complexed metal ion. The addition of a surfactant cremophore EL (CEL), to the aqueous solution of **5b**, **6b** or **7b** resulted in a decrease in the intensity of the band due to the aggregates with an increase in the intensity of the band due to the monomeric species as shown for **5b** in Fig. 3, which confirms that the complexes are aggregated in aqueous solution with *Q-band* maxima given in Table 1. The addition of CEL caused ~11 nm red shift for the monomer peak in **5b** due to the disaggregation in water (this shift may have occurred in **6b** and **7b** also but it is not quite evident since their monomer peaks were not well resolved; Table 1). This shift may be due to the difference in media or existence of two or more different types of dimers in solution resulting in different positions and shapes of the absorption bands as has been observed before in sulfonated AlPc complexes [60]. It is also known that the electronic structure of phthalocyanines is perturbed when they are aggregated, therefore leading to an alteration of the ground and excited state properties [24]. The disappearance of the peak due to the aggregates was however not complete for all the complexes as seen in Fig. 3, by the persistent dimeric peak in the ~640–660 nm region. This suggests that strong forces are responsible for the aggregation. Aggregated MPcs are expected to disaggregate and exhibit monomeric behaviour in organic solvents [29], and this was observed in Fig. 2b, with the complexes in dimethylsulfoxide (DMSO).

Percentage aggregation (% Agg) was calculated using (Eq. (1)) for the quaternized complexes, they all exhibit high values as shown in Table 2 with the α substituted complex having the lowest % Agg which may be due to reduced aggregation tendencies when substitution is at the non-peripheral positions [24]. This high % Agg may lead to low photoactivity of the complexes in aqueous solution since aggregation diminishes the photosensitizing ability of MPc complexes. The values of equilibrium constant (K_D) for the monomer/dimer equilibrium are high for the complexes (Table 2) indicating a strong association between the aggregates. These values are within the range for some MPc complexes [30,39]. The values of ε_D (Table 2) and ε_M (Table 1) are within the range reported for some MPc complexes [39,56].

Absorption and fluorescence excitation spectra of MPcs are expected to be similar and mirror images of their emission spectrum. There is however a lack of agreement between these spectra for the complexes (**5b**, **6b** and **7b**) in aqueous medium, as shown in Fig. 4a for complex **6b**. The band around 640 nm, associated with the dimer is not seen in the fluorescence excitation spectra suggesting that only the monomer fluoresces. It has been documented that

dimers are non-photoactive [43]. In DMSO, the absorption and fluorescence excitation spectra of the complexes (ionic and non-ionic) are similar and are mirror images of their respective emission spectrum (Fig. 4b for complex **7b**). Fig. 4c shows the fluorescence excitation and emission spectra for complex **5b** in aqueous medium in the presence of CEL, they are both mirror images of each other. Stokes' shifts ($\lambda_{ems} - \lambda_{exc}$) were ~10–14 nm, typical of MPc complexes.

In DMSO, excitation spectra were the same as absorption spectra for all the complexes. In PBS in the presence of CEL, the excitation spectra maxima were significantly different from the absorption spectra, suggesting differences in the nuclear configuration of the ground and excited states.

3.3. Photophysical studies

The complexes have relatively low quantum yields of fluorescence (Φ_F) as listed in Table 1. The highest values are exhibited in DMSO for all complexes. It is also interesting to note that the Φ_F values for ionic complexes (**5b**, **6b** and **7b**) were higher than for the non-ionic complexes (**5a**, **6a** and **7a**) in DMSO, where full disaggregation of the complexes has occurred. Aggregation is known to dissipate the electronic energy of the excited singlet state, thereby lowering fluorescence, so the low Φ_F values for (**5b**, **6b** and **7b**) in PBS are expected. Monomerization of aggregates leads to enhanced fluorescence and this is noticed in the Φ_F of (**5b**, **6b** and **7b**) in the presence of CEL in aqueous medium and in DMSO compared to that in aqueous medium alone. The Φ_F values followed the trend PBS 7.4 < PBS 7.4 + CEL < DMSO for complexes **5b**, **6b** and **7b**.

Fig. 5 shows the transient absorption spectrum of **5a** in DMSO. The absorption of the triplet state is at ~540–560 nm. The triplet absorption maxima were also obtained at ~540 nm for all the other complexes. The triplet absorption curve of **5a** in DMSO is shown in Fig. 5 (inset), and it obeyed second order kinetics. This is typical of MPc complexes at high concentrations [61] due to triplet–triplet recombination. The concentrations employed in this work were in this range hence triplet–triplet recombination is expected [61].

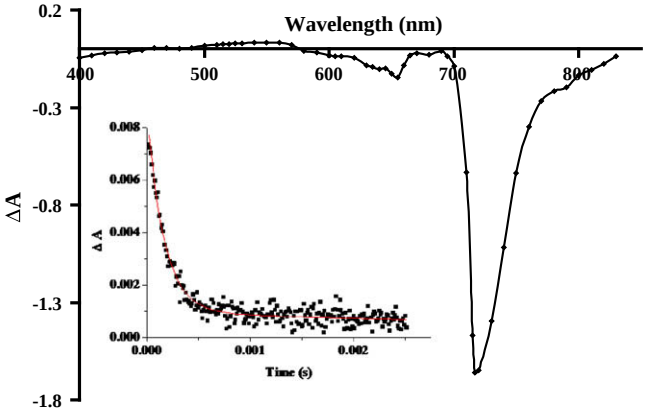

Fig. 5. Transient absorption spectrum for **5a** in DMSO (inset: triplet decay curve of **5a** in DMSO). [**5a**] = ~7.5 × 10^{-6} mol dm^{-3}. λ_{exc} = 717 nm.

Φ_T values were highest for **5a**, **6a** and **7a** in DMSO (Table 1), compared to their quaternized counterparts **5b**, **6b** and **7b**. Φ_T values for the latter were however relatively lower than for the former. The higher Φ_T values of complexes **5a**, **6a** and **7a** correspond to the lower values of Φ_F values for these complexes compared to **5b**, **6b** and **7b** since low values of the later suggest efficient intersystem crossing, hence increased values of the former. As expected, the presence of CEL gave increased Φ_T values for (**5b**, **6b** and **7b**) compared to PBS alone since the MPc complexes experience some disaggregation in this case, monomers have greater tendencies to undergo intersystem crossing because less energy is lost through internal conversion [29].

Φ_{IC} values in DMSO for all the complexes were relatively low, but quite high for (**5b**, **6b** and **7b**) in aqueous medium, due to the dissipation of electronic energy by the aggregates. Φ_{IC} values decreases in the order, PBS 7.4 > PBS 7.4 + CEL > DMSO for (**5b**, **6b** and **7b**) which suggests that molecules are more photoactive in DMSO than in aqueous solution. The decrease in Φ_{IC} values in the presence of CEL is due to its monomerizing effect on the MPc complexes.

An increase in triplet lifetimes (τ_T) in the order, PBS 7.4 < PBS 7.4 + CEL < DMSO is observed with the complexes. The lowest τ_T values exhibited in PBS 7.4 are likely due to the fact that the triplet state of MPcs can be quenched by water [42]. The slight increase in the presence of CEL may be due to less exposure of the phthalocyanine to the aqueous medium.

3.4. Photochemical studies

Energy transfer between the triplet state of photosensitizers and ground state molecular oxygen leads to the production of singlet oxygen, Φ_Δ. Therefore, singlet oxygen quantum yield which is the efficiency of singlet oxygen generation, should depend on the triplet state quantum yield and lifetime, the efficiency of energy transfer, which depends on the energy of the triplet state and the ability of the substituents to quench the triplet state amongst other factors. An efficient production of Φ_Δ in DMSO was observed with values of S_Δ which represents the efficiency of quenching of the triplet excited state by singlet oxygen, near unity for the complexes. The low values of Φ_Δ for **5b**, **6b** and **7b** in PBS (Table 1) are due to low Φ_T values discussed above. There is a slight improvement in Φ_Δ values in CEL.

Oxidative attack on the excited triplet state of MPcs by singlet oxygen brings about photodegradation, since the triplet state is sufficiently long lived to participate in photochemical reactions. Photodegradation quantum yields were highest in DMSO for all the MPc complexes with higher values exhibited in **5a**, **6a** and **7a** compared to their quaternized derivatives **5b**, **6b** and **7b**. The lowest values of photodegradation were exhibited in PBS pH 7.4. Thus, the trend shows that photodegradation is dependent on singlet oxygen. It is believed that singlet oxygen has the ability to react with macrocyclic metal complexes [62].

3.5. Interaction of MPcs (*5b*, *6b* and *7b*) with BSA

3.5.1. Binding constants and fluorescence quenching

Fig. 6a shows quenching of BSA fluorescence by **6b**. This quenching in fluorescence of BSA suggests that the complexes readily bind to BSA. The binding constants (k_b) and binding stoichiometry (n) was therefore estimated using this quenching of fluorescence and Eq. (10). The values of k_b and n shown in Table 2 were estimated from the binding plot (Fig. 6b). The k_b values increased in the order **5b** < **6b** < **7b**. This suggests that the peripherally substituted derivatives **6b** and **7b** bind more strongly to BSA than the non-peripherally substituted derivative, **5b**, probably due to steric hindrance that the substituents of **5b** may be experiencing in binding to BSA. It is also evident that the k_b value for **7b** is the highest in the set, which may be due to the presence of eight substituents on the periphery that are available for binding compared to four in the other derivatives. n values of ~1 are obtained for the complexes suggesting a 1:1 stoichiometry which is characteristic for MPc–BSA interactions in aqueous medium [30,40].

The inset in Fig. 6a shows the Stern–Volmer plot which indicates that within the investigated range of concentrations, Stern–Volmer equation (Eq. (11)) is obeyed. The K_{SV}^{BSA} values were determined from the slopes of plots in Fig. 6a (inset). Table 2 shows that complex **7b** has the highest K_{SV} values, suggesting that the BSA fluorescence quenching is most effective in this complex in this

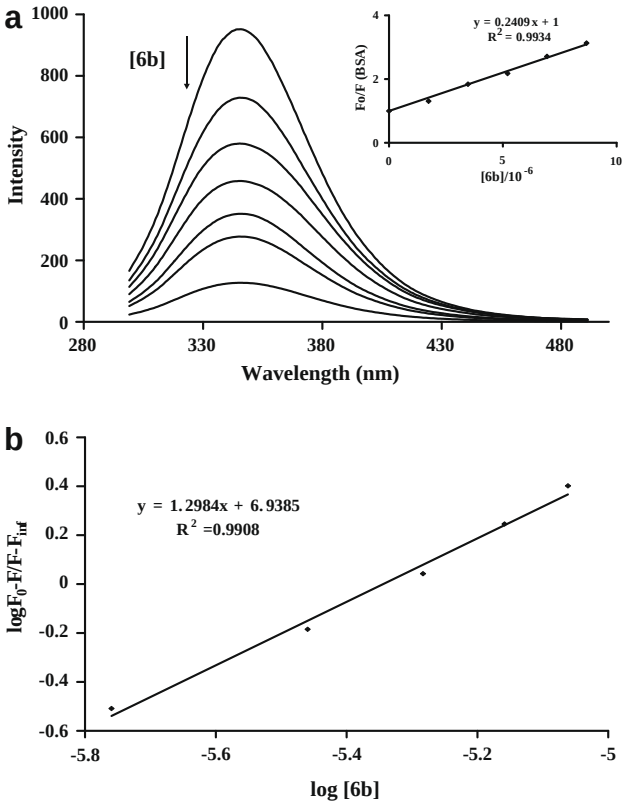

Fig. 6. (a) Spectral changes of BSA (3×10^{-5} mol dm^{-3}) on addition of **6b** (0–8.68×10^{-6} mol dm^{-3}) in aqueous medium. Inset is the Stern–Volmer's plot and (b) binding plot of BSA to **6b**.

particular set. This shows some agreement between k_b and K_{SV} values. The bimolecular quenching constants (k_q) were determined for the individual MPcs using Eq. (12) and the approximate values of fluorescence lifetime of BSA (10 ns) [51–53]. As shown in Table 2, the k_q values are higher (being in the order of 10^{13} dm^3 mol^{-1} s^{-1}) than the proposed value for dynamic quenching (10^{10} dm^3 mol^{-1} s^{-1}) [63] indicating that quenching mechanism in this case is static.

4. Conclusion

Peripherally and non-peripherally 2-diethylaminoethanethiol tetra-substituted zinc phthalocyanine (**5a** and **6a**) and their quaternized derivatives (**5b** and **6b**) have been synthesized and characterized. Their photophysical and photochemical properties and that of their peripherally octa-substituted counterpart have been studied and compared with each other in both aqueous and non-aqueous media. The complexes exhibited similar characteristics dependent on the solvent media. The quaternized complexes were aggregated in aqueous solution, but the addition of cremophore EL hindered aggregation resulting in increased photoactivity and improved photosensitizing ability. Strong binding to BSA occurred in the order **7b** > **6b** > **5b** due to steric effect at the non-peripheral position.

ABSTRACT

Electrochemical reactions of manganese(III) complexes, $Mn^{III}(L)X$ (L; salen, salpn, 5-NO_2–salen or 5-NO_2–salpn, X; Cl, Br or NO_2) and $Mn^{III}(L')_2X$ (L'; *N*-Bu-sal, *N*-Oct–sal, *N*-Oct–5-Br–sal or *N*-Oct–5-NO_2–sal, X; Cl or Br), were investigated by voltammetry at a glassy carbon electrode in the absence/presence of Cl^- in acetonitrile solution. By the addition of Cl^-, oxidation processes of $Mn^{III}(L)X$ and $Mn^{III}(L')_2X$ have been found to be improved from quasi-reversible to reversible, and their oxidation products, $[Mn^{IV}(L)X]^+$ and $[Mn^{IV}(L')_2X]^+$, were stabilized by the combination with Cl^- resulting in $[Mn^{IV}(L)Cl_2]$ and $[Mn^{IV}(L')_2Cl_2]$, respectively. On the other hand, the reduction processes of $Mn^{III}(L)X$ and $Mn^{III}(L')_2Cl$ were not so significantly affected by Cl^- as those observed for their oxidation. Other types of manganese(III) complexes and iron(III) complex were also investigated. The present study may clarify the role of Cl^- being involved in OEC (oxygen-evolving center) in photosystem II.

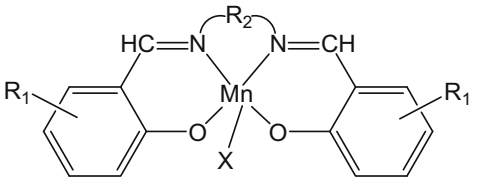
1. Introduction

Redox reactions of manganese(II), (III) and/or (IV) complex are essential in relation to biological redox systems involving manganese ions, such as oxygen-evolving center (OEC) of photosystem II (PS II) in green plants, manganese-containing catalases and manganese superoxide dismutases. In particular, the reaction center of OEC has been proposed to consist of a cluster $CaMn_4O_4$ and chloride ions in appropriate concentration [1–4]. Moreover, studies of higher oxidation state manganese complexes are of special importance because their potential is employed practically for the oxidation of water to dioxygen in the OEC of PSII. In order to stabilize higher oxidation states of manganese ions, chloride ions have been considered to play an important role as well as preventing to form peroxide, acting to provide charge balance, and helping to shuttle protons to manganese center [5,6]. The role of chloride ions in the OEC, however, is still remained and less well established than that of a calcium ion, and there is no firm evidence that chloride ions are bound to the manganese cluster in OEC [5,6]. The recent study suggests that chloride ions are not absolutely required for the oxidation of water but that reaction rate (possibly at the $S_2 \rightarrow S_3$ step) only slow in the absence of chloride ions [7–9], and therefore it would be considered that chloride ions effect on the oxidation reaction process of manganese cluster in OEC.

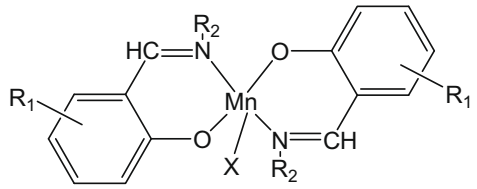
There are many reports for syntheses of OEC model complexes binding with Cl^- and electrochemical analyses for redox reactions between Mn(II) and Mn(IV) of the complexes [10–14]. Hureau et al. synthesized the new mononuclear manganese(II) complex and reported that the electrochemical irreversible oxidation process of Mn(II) to Mn(III) complex changed to be reversible by the addition of Cl^- [14]. Chloride-manganese bonds in mononuclear manganese complexes were measured with the chlorine K-edge X-ray absorption spectra by Rompel et al. and then chloride ion in mononuclear compound was found out to bind covalently to manganese ions and the bond strength increased in the order Mn(II) < Mn(III) < Mn(IV) [15]. Previously, we have synthesized a series of dichloromanganese(IV) complexes with bidentate and tetradentate Schiff base ligands and determined their molecular structures, and moreover, pointed out that higher oxidation states of manganese complexes can be stabilized by chloride ions [16–18].

In the present work, effects of chloride ions on redox reactions of manganese(III) complexes have been investigated by voltammetry at a glassy carbon electrode. Manganese(III) complexes used in this work are summarized in Fig. 1. In order to compare an iron(III) complex, Fe^{III}(salen)Cl was also used. Here, H_2salen, H_2salpn, H_2salhexn and Hacac are abbreviation for *N,N′*-disalicylidene-1,2-diaminoethane, *N,N′*-disalicylidene-1,3-diaminopropane, *N,N′*-disalicylidene-1,6-diaminohexane and acetylacetone, respectively.



2. Experimental

2.1. Preparation of manganese complexes



Tetradentate Schiff bases, H_2salen, H_2salpn and H_2salhexn were synthesized by standard methods (Schiff base condensation of 2 mole of the salicylaldehyde with 1 mole of appropriate diamines) [17]. Mn^{III}(salen)Cl, Mn^{III}(salpn)Cl and Mn^{III}(salhexn)Cl complexes were obtained by reacting the respective ligand (1 mmol) with $Mn^{III}(OAc)_3 \cdot H_2O$ (1 mmol) and LiCl (1.5 mmol) in methanol

solution and the resulting precipitates were collected, washed, and then dried *in vacuo*. They were recrystallized from methanol or dichloromethane [17,19,20]. Although Mn^{III}(salhexn)Cl was also synthesized in a similar manner, of which solubility is very poor in acetonitrile (MeCN) probably due to the formation of a polymeric complex, $[Mn^{III}(salhexn)Cl]_n$, and thus was not adopted in the present work. Mn^{III}(salen)Br or Mn^{III}(salen)NO_2 was prepared in the similar manner with LiBr or $LiNO_2$, respectively, instead of LiCl. Mn^{III}(5-NO_2–salen)Cl and Mn^{III}(5-NO_2–salpn)Cl were obtained in a similar manner as reported previously [19]. Fe^{III}(salen)Cl was also prepared in the similar manner to that of Mn^{III}(salen)Cl but with $FeCl_3$ instead of $Mn(OAc)_3$ and LiCl [21].

Bidentate Schiff base ligands, *N*-alkyl-substituted-salicylideneamine [*N*-R–X–salH where R can be *n*-C_4H_9 (Bu) or *n*-C_8H_{17} (Oct) and X can be H, Br or NO_2] were prepared by a condensation of the salicylaldehydes with butylamine or octylamine [19]. Mn^{III}(*N*-R–X–sal)$_2$Cl or Mn^{III}(*N*-R–X–sal)$_2$Br was synthesized by the reaction of the respective ligand (2 mmol) with $Mn^{III}(OAc)_3 \cdot H_2O$ (1 mmol) and LiCl or LiBr (1.5 mmol) in methanol solution, and the resulting precipitates were collected, washed, and then dried *in vacuo*. They were recrystallized from methanol or dichloromethane [19].

$Mn^{III}(acac)_3$ was prepared by conventional method [22].

2.2. Reagents

MeCN was purified by distillation over P_4O_{10} twice and then distilled further before use. Other solvents were purified by usual methods. Reagent grade tetra-*n*-butylammonium hexafluorophosphate ($TBAPF_6$) and tetraethylammonium chloride (TEACl) were purchased from Wako Pure Chemicals Co., Ltd., and used without further purification.

All other chemicals used were of reagent grade quality.

2.3. Electrochemical measurements

All electrochemical measurements were performed using a single compartment cell containing a three-electrode configuration with ALS 822A Electrochemical Analyzer (CH Instruments, Inc., Austin, TX). The working electrode was a glassy carbon disk with a diameter of 3 mm. Before each measurement, it was polished with 0.05 μm alumina slurry, and then sonicated in a distilled water and dried. An Ag/AgCl (in 3.3 M KCl) electrode (SSE) was used as the reference electrode. All potentials were referred to SSE, which correspond to a potential difference from that of Fc^+/Fc (Fc = ferrocene) couple of 0.43 V in MeCN. The counter electrode was a platinum wire. The solution was deaerated by passing argon gas before measurements, and an atmosphere of argon gas was then maintained over the solution throughout measurements. The supporting electrolyte and the scan rate (v) were $TBAPF_6$ (0.1 M) and 100 mV s^{-1}, respectively. The stock solution of TEACl was adjusted to 0.2 M with MeCN, and the appropriate amount was added to MeCN containing the manganese complex.

The controlled-potential electrolysis was performed at a column electrode [23] by forcing a sample solution deaerated by argon gas to flow through carbon fiber electrodes with the aid of a pump (Cole-Parmer Instrument Co., Model 7518-10) at a flow rate of 0.5 ml min^{-1}. The pretreatment of working electrode was carried out according to the literature [24] by scanning the applying potential between +1.2 and −0.7 V at v of 10 mV s^{-1}. During the pretreatment, 1 M HNO_3 solution was pumped through the carbon fibers.

All the electrochemical measurements were carried out at 25 ± 1 °C.

2.4. Other physicochemical measurements

All complexes used in this study were confirmed by the elemental analysis, IR and UV–Vis spectroscopies and magnetic susceptibilities. Results have been reported previously [17,19–21].

3. Results and discussion

3.1. Redox behavior of Mn^{III}(salen)Cl and Mn^{III}(salpn)Cl in the absence/presence of chloride ion in MeCN

This study has been done to clarify the role of chloride ions (Cl^-) involved in OEC using manganese complexes as models for PSII. We have found that the presence of Cl^- can stabilize the higher oxidation states of manganese ions in terms of electrochemical measurements.

Curve 1 in Fig. 2 is the cyclic voltammogram of 1.0 mM Mn^{III}(salen)Cl in MeCN. Curve 1′ is the background current in the absence of Mn^{III}(salen)Cl. One positive current wave due to the oxidation of Mn^{III}(salen)Cl to $[Mn^{IV}(salen)Cl]^+$ appeared with a half peak potential ($E_{1/2}$) at 0.94 V (versus SSE) in the voltammogram. A peak to peak separation (ΔE_p) is about 0.13 V, which indicates that the electrochemical process for the oxidation of Mn^{III}(salen)Cl is quasi-reversible. The positive peak current (I_{pa}) was proportional to the square root of v in the range between 10 and 200 mV s^{-1} and to the concentration of Mn^{III}(salen)Cl in the range between 0.05 to 1.0 mM, and hence the electrochemical oxidation of Mn^{III}(salen)Cl is considered to be controlled by the diffusion of Mn^{III}(salen)Cl to the surface of the working electrode. One negative current wave due to the reduction of Mn^{III}(salen)Cl to $[Mn^{II}(salen)Cl]^-$ was also obtained with $E_{1/2}$ at −0.20 V as shown in curve 1, which is found to be reversible process and controlled by the diffusion of Mn^{III}(salen)Cl since ΔE_p was about 0.07 V and the negative current peak

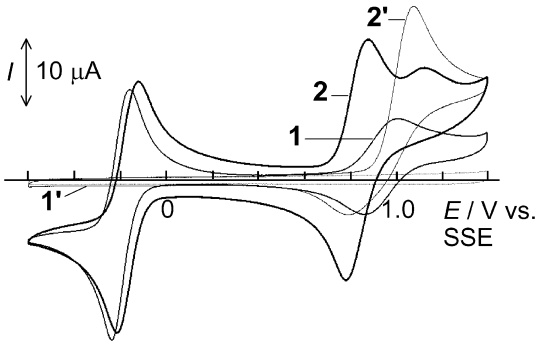

Fig. 2. Cyclic voltammogram of 1.0 mM Mn^{III}(salen)Cl in the absence (curve 1) or presence of 1.0 mM Cl^- (curve 2) in MeCN containing 0.1 M $TBAPF_6$. Curves 1′ and 2′: residual currents of curves 1 and 2 in the absence of Mn^{III}(salen)Cl in MeCN. Scan rate: 0.1 V s^{-1}.

(I_{pc}) was proportional to the v and the concentration of Mn^{III}(salen)Cl. These values are similar to those reported previously [25,26].

The addition of 1.0 equiv. of TEACl per Mn^{III}(salen)Cl dramatically changed its cyclic voltammogram: the $E_{1/2}$ for the redox couple of Mn^{III}(salen)Cl/$[Mn^{IV}$(salen)Cl$]^+$ shifts from 0.94 to 0.83 V as shown in curve 2 in Fig. 2. Curve 2′ is the voltammogram of 1.0 mM TEACl in MeCN. The positive current wave due to the oxidation of Cl^- appeared at the more positive peak potential (E_{pa}) of 1.08 V. Therefore, the voltammogram at $E_{1/2}$ of 0.83 V in curve 2 can be safely assigned to the oxidation of Mn^{III}(salen)Cl and not Cl^-. The I_{pa} at 0.87 V in curve 2 increased upon addition of Cl^- up to maximum of the ratio of Cl^- to Mn^{III}(salen)Cl to be unity, and no significant increase was observed on further addition of Cl^- as shown in Fig. 3. The ΔE_p for the redox potential of Mn^{III}(salen)Cl/$[Mn^{IV}$(salen)Cl$]^+$ changed from 0.13 to 0.09 V upon addition of Cl^- and the ratio of peak heights (I_{pa}/I_{pc}) in curve 2 was almost 1.0, which suggests in the view of uncompensated *IR*-drop that the oxidation of Mn^{III}(salen)Cl become a reversible process rather than quasi-reversible process by the addition of Cl^-. The oxidation product of Mn^{III}(salen)Cl is considered to be stabilized by the combination of the oxidation product of Mn^{III}(salen)Cl with Cl^- resulting in Mn^{IV}(salen)Cl_2 [19]. The reaction stoichiometry is 1.0 equiv. of Cl^- per Mn^{III}(salen)Cl as

$$Mn^{III}(salen)Cl + Cl^- \rightleftarrows [Mn^{IV}(salen)Cl]^+ + e^- + Cl^- \rightleftarrows Mn^{IV}(salen)Cl_2 \quad (1)$$

Here, the irreversible oxidation of Mn^{II} complex was also reported to become reversible upon addition of Cl^- to MeCN by the similar reason [14]. It can therefore be presumed that Cl^- has a role of the stabilization of Mn^{III} and Mn^{IV} complexes in organic solution.

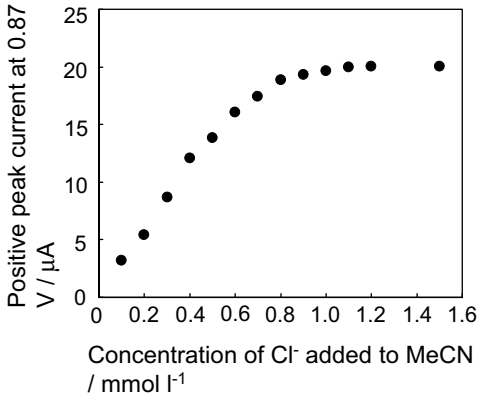

Fig. 3. A plot of positive peak current, I_{pa}, at 0.87 V against the concentration of Cl^- added to MeCN containing 1 mM Mn^{III}(salen)Cl.

The $E_{1/2}$ for the redox couple of $[Mn^{II}$(salen)Cl$]^-$/Mn^{III}(salen)Cl was also shifted from −0.20 to −0.16 V by the addition of Cl^-. It is thought that Cl^- in MeCN prevents the dissociation of $[Mn^{II}$(salen)Cl$]^-$ to Mn^{II}(salen) and Cl^- and makes $[Mn^{II}$(salen)Cl$]^-$ stable

$$Mn^{III}(salen)Cl + e^- \rightleftarrows [Mn^{II}(salen)Cl]^- \quad (2)$$

Similar stabilization of Mn^{III}(salpn)Cl over $[Mn^{IV}$(salpn)Cl$]^+$ by Cl^- in MeCN is also observed, and $E_{1/2}$ and ΔE_p for the redox couples of Mn^{III}(salpn)Cl/$[Mn^{IV}$(salpn)Cl$]^+$ and $[Mn^{II}$(salpn)Cl$]^-$/Mn^{III}(salpn)Cl in the absence/presence of Cl^- are summarized in Tables 1 and 2. The $E_{1/2}$ for the redox couple of Mn^{III}(salpn)Cl/$[Mn^{IV}$(salpn)Cl$]^+$ shifted from 0.95 to 0.85 V by adding Cl^- to MeCN, and ΔE_p decreased from 0.14 to 0.09 V. The I_{pa} at 0.89 V increased upon addition of Cl^- and no longer increased by the addition of Cl^- at the ratio of Cl^- to Mn^{III}(salpn)Cl more than unity as well as the case of those for Mn^{III}(salen)Cl. The $E_{1/2}$ for the redox couple of $[Mn^{II}$(salpn)Cl$]^-$/Mn^{III}(salpn)Cl shifted from −0.08 to 0.05 due to the stabilization of $[Mn^{II}$(salpn)Cl$]^-$ by Cl^-. The ΔE_p, however, increases from 0.07 to 0.10 V, which indicates that the reduction

[c] irreversible reduction process.

process of Mn^{III}(salpn)Cl becomes quasi-reversible even under the presence of Cl^-. The reaction mechanisms for the oxidation and reduction of Mn^{III}(salpn)Cl in the presence of Cl^- can be expressed as Eqs. (3) and (4) as well as those of Mn^{III}(salen)Cl

$$Mn^{III}(salpn)Cl + Cl^- \rightleftarrows [Mn^{IV}(salpn)Cl]^+ + e^- + Cl^- \rightleftarrows Mn^{IV}(salpn)Cl_2 \quad (3)$$

$$Mn^{III}(salpn)Cl + e^- \rightleftarrows [Mn^{II}(salpn)Cl]^- \quad (4)$$

Here, it can be seen by comparing the $E_{1/2}$ for the redox couples of $[Mn^{II}(salen)Cl]^-/Mn^{III}(salen)Cl$ and $[Mn^{II}(salpn)Cl]^-/Mn^{III}(salpn)Cl$ in Table 2 that the stabilization of Mn^{III} complex increases with a decrease of chain length in Schiff base ligand. This is probably due to the general argument that a five-membered chelate ring in Mn^{III}(salen)Cl is more stable compared to a six-membered chelate ring for Mn^{III}(salpn)Cl [27]. The similar effect has been found in the case of copper(II) complexes having different ring size [28].

3.2. Redox behavior of Mn^{III}(salen)Br and Mn^{III}(salen)NO_2 in the absence/presence of chloride ion in MeCN

Curve 1 in Fig. 4 is the cyclic voltammogram of 1.0 mM Mn^{III}(salen)Br in MeCN. The voltammogram exhibits the irreversible positive current wave and the reversible negative current wave ($E_{1/2}$ = −0.15, ΔE_p = 0.08 V). This may be caused by the difference in electron density between Br^- and Cl^- [27,29]. Therefore, the $E_{1/2}$ for the couple of $[Mn^{II}(salen)Br]^-/Mn^{III}(salen)Br$ is 0.05 V to more positive than that of $[Mn^{II}(salen)Cl]^-/Mn^{III}(salen)Cl$ (Table 2).

The cyclic voltammogram of curve 2 in Fig. 4 is recorded under the conditions with the same as that for curve 1 but by adding 2.0 mM TEACl. The clear positive current wave appeared in the voltammogram at I_{pa} of 0.86 V in curve 2 increased upon addition of Cl^- up to maximum of the ratio of Cl^- to Mn^{III}(salen)Br to be twice, and no significant increase was observed on further addition of Cl^-. Here, the value of positive current at 0.86 V is about twice as large as that of negative current at −0.22 V, which would be caused by the oxidation reaction of Br^- dissociated from Mn^{III}(salen)Br. The $E_{1/2}$ for the redox couple of $[Mn^{II}(salen)Br]^-/Mn^{III}(salen)Br$ shifted from −0.15 to −0.17 V but the ΔE_p was independent of the Cl^- added to MeCN. The $E_{1/2}$ and ΔE_p of curve 2 in Fig. 4 are almost identical with those of curve 2 in Fig. 2 recorded with Mn^{III}(salen)Cl and Cl^-. Therefore, it can be concluded that Br^- in Mn^{III}(salen)Br is replaced by two Cl^- ions via the oxidation of Mn^{III}(salen)Br as

$$Mn^{III}(salen)Br + 2Cl^- \rightleftarrows [Mn^{IV}(salen)Br]^+ + e^- + 2Cl^- \rightleftarrows Mn^{IV}(salen)Cl_2 + Br^- \quad (5)$$

The reduction of Mn^{III}(salen)Br may be expected to proceed by substitution of Br^- for Cl^- as

$$Mn^{III}(salen)Br + e^- + Cl^- \rightleftarrows [Mn^{II}(salen)Cl]^- + Br^- \quad (6)$$

The effect of Cl^- on the oxidation and reduction of Mn^{III}(salen)-NO_2 was almost identical with that of Mn(salen)Br as summarized in Tables 1 and 2. The NO_2^- in Mn^{III}(salen)NO_2 can be replaced by two Cl^- molecules via the oxidation of Mn^{III}(salen)NO_2, so that the reaction stoichiometry is 2.0 equiv. of Cl^- per Mn^{III}(salen)NO_2 as

$$Mn^{III}(salen)NO_2 + 2Cl^- \rightleftarrows [Mn^{IV}(salen)NO_2]^+ + e^- + 2Cl^- \rightleftarrows Mn^{IV}(salen)Cl_2 + NO_2^- \quad (7)$$

Since the $E_{1/2}$ for the redox couple of $[Mn^{II}(salen)NO_2]^-/Mn^{III}$(-salen)$NO_2$ in the presence of Cl^- exhibits almost the same potential with that of Mn^{III}(salen)Cl, the reduction process of Mn^{III}(salen)-NO_2 in the presence of Cl^- could be also expressed as

$$Mn^{III}(salen)NO_2 + e^- + Cl^- \rightleftarrows [Mn^{II}(salen)Cl]^- + NO_2^- \quad (8)$$

3.3. Redox behavior of Mn^{III}(5-NO_2–salen)Cl and Mn^{III}(5-NO_2–salpn)Cl in the absence/presence of chloride ion in MeCN

Since the solubility of Mn^{III}(5-NO_2–salen)Cl or Mn^{III}(5-NO_2–salpn)Cl was not so good, 0.5 mM Mn^{III}(5-NO_2–salen)Cl or Mn^{III}(5-NO_2–salpn)Cl in MeCN solution was adopted in this section. The cyclic voltammogram of Mn^{III}(5-NO_2–salen)Cl in MeCN is illustrated in curve 1 of Fig. 5. The quasi-reversible positive current wave corresponding to the redox couple of Mn^{III}(5-NO_2–salen)Cl/$[Mn^{IV}$(5-NO_2–salen)Cl$]^+$ and the reversible negative current wave corresponding to the redox couple of $[Mn^{II}$(5-NO_2–salen)Cl$]^-$/Mn^{III}(5-NO_2–salen)Cl appeared in the voltammogram with $E_{1/2}$ at 1.09 and 0.16 V, respectively. When equivalent amounts of TEACl were added to Mn^{III}(5-NO_2-salen)Cl in MeCN, the $E_{1/2}$ for the positive current wave shifted from 1.09 to 0.95 V and the $E_{1/2}$ for the negative current wave, however, was independent of Cl^- as shown in curve 2. The I_{pa} at 1.00 V in curve 2 increased upon addition of Cl^- up to maximum of the ratio of Cl^- to Mn^{III}(5-NO_2–salen)Cl to be unity, and no significant increase was observed on further addition of Cl^-. The ΔE_p for the redox couple of Mn^{III}(5-NO_2–salen)Cl/$[Mn^{IV}$(5-NO_2–salen)Cl$]^+$ decreased from 0.12 to 0.09 V, which indicates that the oxidation of Mn^{III}(5-NO_2–salen)Cl becomes near to the reversible process. ΔE_p and I_{pc} for the negative current wave were not influenced by Cl^- added to MeCN.

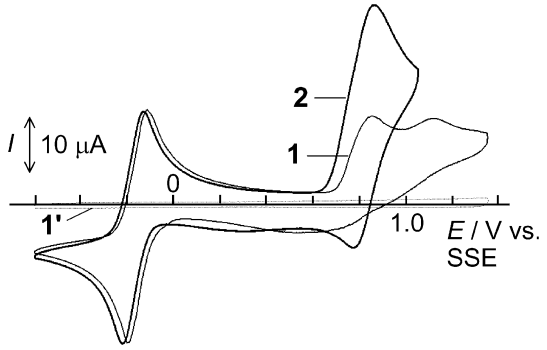

Fig. 4. Cyclic voltammogram of 1.0 mM Mn^{III}(salen)Br in the absence (curve 1) or presence of 2.0 mM Cl^- (curve 2) in MeCN containing 0.1 M $TBAPF_6$. Curve 1′: residual current of curve 1 in the absence of Mn^{III}(salen)Br in MeCN. Scan rate: 0.1 V s^{-1}.

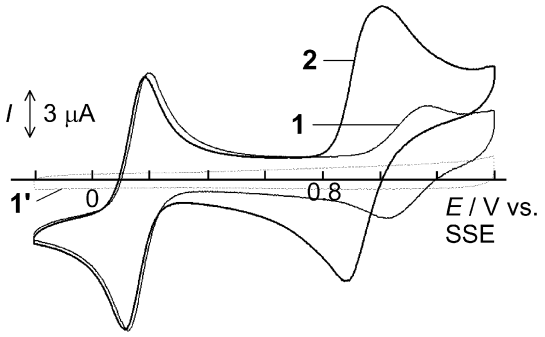

Fig. 5. Cyclic voltammogram of 0.5 mM Mn^{III}(5-NO_2–salen)Cl in the absence (curve 1) or presence of 0.5 mM Cl^- (curve 2) in MeCN containing 0.1 M $TBAPF_6$. Curve 1′: residual current of curve 1 in the absence of Mn^{III}(5-NO_2–salen)Cl in MeCN. Scan rate: 0.1 V s^{-1}.

$E_{1/2}$ and ΔE_p for redox reactions of Mn^{III}(5-NO_2–salpn)Cl in the absence/presence of 0.5 mM Cl^- are summarized in Tables 1 and 2. The effect of Cl^- on the redox reaction of Mn^{III}(5-NO_2–salpn)Cl is similar to that of Mn^{III}(5-NO_2–salen)Cl.

The oxidation reaction stoichiometry for the addition of 1.0 equiv. of Cl^- per Mn^{III}(5-NO_2–salen)Cl or Mn^{III}(5-NO_2–salpn)Cl is shown in Eqs. (9) and (10), respectively

$$Mn^{III}(5\text{-}NO_2\text{-salen})Cl + Cl^- \rightleftarrows [Mn^{III}(5\text{-}NO_2\text{-salen})Cl]^+ + e^- + Cl^- \rightleftarrows Mn^{IV}(5\text{-}NO_2\text{-salen})Cl_2 \quad (9)$$

$$Mn^{III}(5\text{-}NO_2\text{-salpn})Cl + Cl^- \rightleftarrows [Mn^{III}(5\text{-}NO_2\text{-salpn})Cl]^+ + e^- + Cl^- \rightleftarrows Mn^{IV}(5\text{-}NO_2\text{-salpn})Cl_2 \quad (10)$$

The reduction processes of Mn^{III}(5-NO_2–salen)Cl and Mn^{III}(5-NO_2–salpn)Cl are independent of Cl^- as Eqs. (11) and (12)

$$Mn^{III}(5\text{-}NO_2\text{-salen})Cl + e^- \rightleftarrows [Mn^{II}(5\text{-}NO_2\text{-salen})Cl]^- \quad (11)$$

$$Mn^{III}(5\text{-}NO_2\text{-salpn})Cl + e^- \rightleftarrows [Mn^{II}(5\text{-}NO_2\text{-salen})Cl]^- \quad (12)$$

The $E_{1/2}$ potentials for the redox reaction of Mn^{III}(5-NO_2–salen)Cl and Mn^{III}(5-NO_2–salpn)Cl were shifted 0.16 (oxidation) or 0.35 (reduction) V on the average to more positively regardless of the existence of Cl^-. These results can be explained by the introduction of an electron withdrawing substituent of 5-NO_2 group in Mn^{III}(5-NO_2–salen)Cl and Mn^{III}(5-NO_2–salpn)Cl [19,30,31]. This means that Mn–Cl bonds in these cases could not be dissociated after reductions of Mn(III) complexes.

3.4. Redox behavior of Mn^{III}(*N*-Bu–sal)$_2$Cl, Mn^{III}(*N*-Oct–sal)$_2$Cl, Mn^{III}(*N*-Oct–5-NO_2–sal)$_2$Cl and Mn^{III}(*N*-Oct–5-Br–sal)$_2$Cl in the absence/presence of chloride ion in MeCN

Curve 1 in Fig. 6 is the cyclic voltammogram for 1.0 mM Mn^{III}(*N*-Bu–sal)$_2$Cl in MeCN. One quasi-reversible positive current wave and two irreversible negative current waves were observed in the voltammogram. Since two negative current waves due to the reduction of Mn^{III}(*N*-Bu–sal)$_2$Cl appeared in the voltammogram, a part of Cl^- in Mn^{III}(*N*-Bu–sal)$_2$Cl would seem to be dissociated from Mn^{III}(*N*-Bu-sal)$_2$Cl resulting in $[Mn^{III}$(*N*-Bu–sal)$_2]^+$ and Cl^-. The positive current wave at 0.50 V appeared by reverse scan at −0.35 V, and therefore this positive current wave is confirmed to be re-oxidation of the reduction products formed at the potential of the first negative current wave.

When 1.0 mM TEACl was added to MeCN containing 1.0 mM Mn^{III}(*N*-Bu–sal)$_2$Cl, $E_{1/2}$ for the redox couple of Mn^{III}(*N*-Bu–sal)$_2$Cl/$[Mn^{IV}$(*N*-Bu–sal)$_2$Cl$]^+$ shifted from 0.99 to 0.86 V and ΔE_p decreased from 0.23 to 0.11 V (curve 2 in Fig. 6). Therefore, the electrochemical oxidation of Mn^{III}(*N*-Bu–sal)$_2$Cl occurs more easily and attains near to the reversible process in the presence of Cl^-. The I_{pa} at 0.92 V increased with an increase of Cl^- added to MeCN up to maximum of the ratio of Cl^- to Mn^{III}(*N*-Bu–sal)$_2$Cl to be unity, and no significant increase was observed on further addition of Cl^-. The oxidation reaction of Mn^{III}(*N*-Bu–sal)$_2$Cl could be expressed as Eq. (13) as well as Mn^{III}(salen)Cl

$$Mn^{III}(N\text{-Bu-sal})_2Cl + Cl^- \rightleftarrows [Mn^{III}(N\text{-Bu-sal})_2Cl]^+ + e^- + Cl^- \rightleftarrows Mn^{IV}(N\text{-Bu-sal})_2Cl_2 \quad (13)$$

Peak potentials of first and second negative current waves shifted from −0.06 to −0.09 V and from −0.56 to −0.60 V, respectively, and I_{pc} for the second negative current wave increased by the addition of Cl^-. Two negative current waves in curve 1 are thought to be attributable to reductions of Mn^{III}(*N*-Bu–sal)$_2$Cl and $[Mn^{III}$(*N*-Bu–sal)$_2]^+$, but it would be the possibility of the presence of another species, and therefore further discussion about the effect of Cl^- on the reduction reaction is considered to be difficult.

When Mn^{III}(*N*-Oct–sal)$_2$Cl was adopted in MeCN instead of Mn^{III}(*N*-Bu–sal)$_2$Cl, $E_{1/2}$ and ΔE_p for the redox couple of Mn^{III}(*N*-Oct–sal)$_2$Cl/$[Mn^{IV}$(*N*-Oct–sal)$_2$Cl$]^+$ in the absence/presence of 1.0 mM Cl^- are almost identical with those for Mn^{III}(*N*-Bu–sal)$_2$Cl as summarized in Table 1. This result suggests that the redox reactions of Mn^{III}(*N*-Bu–sal)$_2$Cl and Mn^{III}(*N*-Oct–sal)$_2$Cl are not much affected by the alkyl groups of the Schiff base ligands [16]. Mn^{III}(*N*-Oct-5-NO_2–sal)$_2$Cl and Mn^{III}(*N*-Oct–5-Br–sal)$_2$Cl also gave one quasi-reversible positive current wave and two irreversible negative current wave. The coexisting Cl^- in MeCN makes these positive current waves reversible. The $E_{1/2}$ for the redox couple of Mn^{III}(*N*-R–X–sal)$_2$Cl/$[Mn^{IV}$(*N*-R–X–sal)$_2$Cl$]^+$ wave shifted to more positively in the order Mn^{III}(*N*-Oct–sal)$_2$Cl (1.01 V) < Mn^{III}(*N*-Oct–5-Br–sal)$_2$Cl (1.05 V) < Mn^{III}(*N*-Oct–5-NO_2–sal)$_2$Cl (1.13 V) because of electron withdrawing substituent effects such as 5-NO_2 and 5-Br groups in these complexes [19,30,31].

3.5. Redox behavior of Mn^{III}(acac)$_3$ in the absence/presence of chloride ion in MeCN

Curve 1 in Fig. 7 is the cyclic voltammogram of 1.0 mM Mn^{III}(acac)$_3$ in MeCN, which exhibits one quasi-reversible positive current wave corresponding to the redox couple of Mn^{III}(acac)$_3$/$[Mn^{IV}$(acac)$_3]^+$ with $E_{1/2}$ at 0.99 V and one irreversible negative current wave corresponding to the reduction of Mn^{III}(acac)$_3$ to $[Mn^{II}$(acac)$_3]^-$ appeared in the voltammogram with negative current peak potential at −0.25, respectively [32]. When 1.0 mM

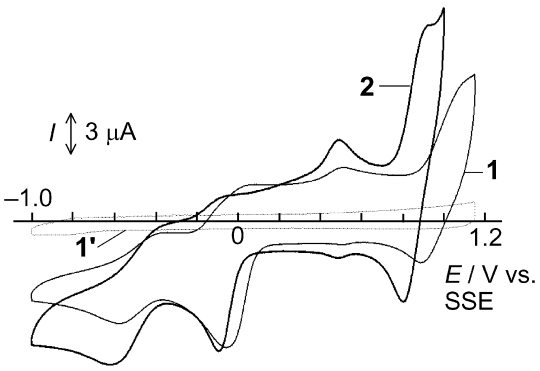

Fig. 6. Cyclic voltammogram of 1.0 mM Mn^{III}(*N*-Bu–sal)$_2$Cl in the absence (curve 1) or presence of 1.0 mM Cl^- (curve 2) in MeCN containing 0.1 M $TBAPF_6$. Curve 1′: residual current of curve 1 in the absence of Mn^{III}(*N*-Bu–sal)$_2$Cl in MeCN. Scan rate: 0.1 V s^{-1}.

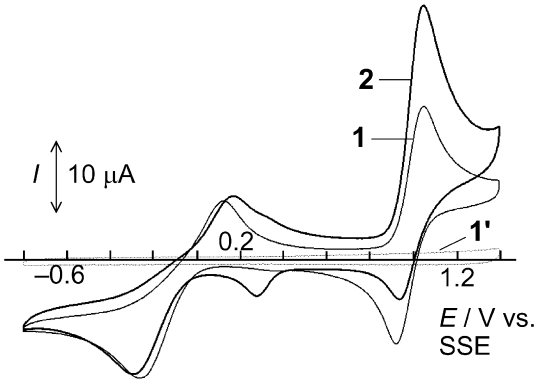

Fig. 7. Cyclic voltammogram of 1.0 mM Mn^{III}(acac)$_3$ in the absence (curve 1) or presence of 1.0 mM Cl^- (curve 2) in MeCN containing 0.1 M $TBAPF_6$. Curve 1′: residual current of curve 1 in the absence of Mn^{III}(acac)$_3$ in MeCN. Scan rate: 0.1 V s^{-1}.

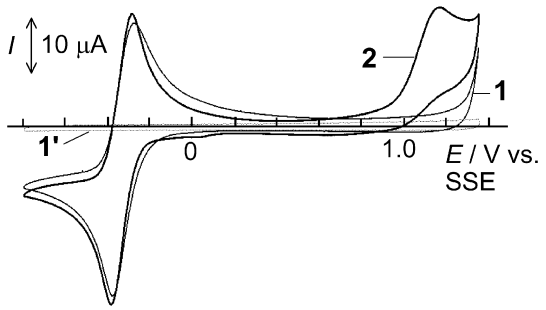

Fig. 8. Cyclic voltammogram of 1.0 mM Fe^{III}(salen)Cl in the absence (curve 1) or presence of 1.0 mM Cl^- (curve 2) in MeCN containing 0.1 M $TBAPF_6$. Curve 1′: residual current of curve 1 in the absence of Fe^{III}(salen)Cl in MeCN. Scan rate: 0.1 V s^{-1}.

TEACl was added to MeCN containing 1.0 mM $Mn^{III}(acac)_3$, the I_{pa} for the oxidation of $Mn^{III}(acac)_3$ increased even though the oxidation process varied to be irreversible. The new negative peak current at 0.28 V appeared by the reverse scan at 1.4 V, which indicates that the new species such as $Mn^{III}(acac)_2Cl$ may be produced by addition of Cl^-. While the negative current peak potential shifted from −0.25 to −0.29, I_{pc} for the reduction of $Mn^{III}(acac)_3$ was independent of Cl^-. $Mn^{III}(acac)_3$ is a six-coordinate complex of which structure is a distorted octahedron, and therefore the oxidation product of $Mn^{III}(acac)_3$ would be hardly stabilized via the combination with Cl^-.

3.6. Redox behavior of Fe^{III}(salen)Cl in the absence/presence of chloride ion in MeCN

Curve 1 in Fig. 8 is the cyclic voltammogram of 1.0 mM Fe^{III}(salen)Cl in MeCN. One negative current wave due to the redox couple of $[Fe^{II}(salen)Cl]^-/Fe^{III}(salen)Cl$ appeared with $E_{1/2}$ at −0.34 V in the voltammogram, and the positive current wave due to the oxidation of $Fe^{III}(salen)Cl$ to $[Fe^{IV}(salen)Cl]^+$ was not observed within the sweep range from −0.80 to 1.40 V. The ΔE_p for the redox couple of $[Fe^{II}(salen)Cl]^-/Fe^{III}(salen)Cl$ is about 0.10 V, which indicates that the electrochemical process for the reduction of $Fe^{III}(salen)Cl$ is almost reversible. The voltammogram of curve 1 was unchanged except for the appearance of the positive current wave at around 1.15 V due to the oxidation of Cl^- even though 1.0 mM TEACl was added to MeCN containing 1.0 mM $Fe^{III}(salen)Cl$ as shown in curve 2 in Fig. 8. This result indicates that the reduction of $Fe^{III}(salen)Cl$ is little affected by the presence of Cl^-, which is strongly contrast to the cases of manganese(III) complexes discussed in the above sections. This is ascribed by the difference in the spin configuration between Mn(III) ($3d^4$ high-spin) and Fe(III) ($3d^5$ high-spin) [25,33]. This means that the oxidation of a half-filled shell of Fe(III) may need more energy compared to the case of Mn(III).

4. Conclusions

Effects of Cl^- on redox reactions of manganese(III) complexes have been ascertained in the present work. The oxidation process of manganese(III) complexes, $Mn^{III}(L)X$ and $Mn^{III}(L')_2X$, became reversible by the addition of Cl^-, and the oxidation products were found to be stabilized by Cl^- resulting in $Mn^{IV}(L)Cl_2$ and $Mn^{IV}(L')_2Cl_2$. The reduction of $Mn^{III}(L)X$ or $Mn^{III}(L')_2Cl$ was affected not so significantly as the oxidation of $Mn^{III}(L)X$ or $Mn^{III}(L')_2Cl$. In OEC, the generation rate of dioxygen from water has reported to be slow when Cl^- is substituted by another anions such as Br^-, F^- and SO_4^{2-} [6]. Results obtained in the present work would support the idea that Cl^- in OEC makes the redox process of manganese cluster reversible and higher valent manganese ions stable.

Aromaticity

ABSTRACT

The nature of the molecule $C_{60}CrC_{60}$ was studied from a theoretical point of view. Calculations on this molecule were carried out at the BPW91 level. The results are compared with those from another two molecules, dibenzenechromium that is a known and stable species, and η^6-fullerene chromium(0) η^6-benzene, a nonexisting molecule. This analysis has been carried out in order to study the stability of the target compound and provide useful information for its synthesis. The aromaticity of the rings in the three compounds was analyzed by means of HOMA and NICS methods whereas their intrinsic stability was estimated by means of homodesmotic reactions. The electronic structure of the three molecules was also studied. The results show fullerenocene should be a moderately stable species and should display semiconductor behaviour and some of the interesting properties of fullerene itself.

1. Introduction

Dibenzenechromium is a well known organometallic molecule that has been object of several studies [1]. The large symmetry (D_6h) of this species has its origin in the uniform electronic distribution on both decks arising from the aromaticity that gives place to a π bond with perfect hexahapticity [2]. The aromaticity of both benzene fragments does not seem to be affected by the coordination to the metal centre [3]. This system is analogous to ferrocene except that it contains benzene instead of cyclopentadienyl ions.

All the research groups that have studied this structure experimentally as well as theoretically [1,4], are in agreement about the relatively low energy value of the rotational barrier (≈0.9 kcal/mol) between the eclipsed and the staggered isomers, the former being the more stable one. This compound is very interesting because its strong donor capability can lead to a material with one-dimensional conductivity [1d].

Fullerenes [5] are a set of interesting molecules that have been object of many different studies [6]. Their metallic complexes, endohedral as well as exohedral, have also been studied experimentally and theoretically [7]. In this paper, we focused on compounds where the interaction between the fullerene fragment and a phenyl part occurs through a metal centre [8].

The most interesting experimental results are those obtained by Nakamura and co-workers [9]. In these works, Nakamura reported the first ferrocenoid complexes, including a ferrocene fragment molecule. The main characteristics of these complexes are that the π bond on one side of the metal centre is focused on a pentagonal face of the fullerene fragment, the other side forms another π bond with a Cp fragment and in the majority of cases the metal atom has an intrinsic positive charge, as in the case of ferrocene, calculations on this species and analogous have been reported. Additionally, there are some very interesting theoretical reports [8], in which the capability of the fullerene fragments to generate this kind of bonds was studied.

The present study is different because the initial proposition is that the molecules have, in all cases, hexahapto π bonds. This feature was proposed and studied by Jemmis et al. and by Stankevich et al. [8]. The formed complexes should be analogous to the dibenzenechromium. Therefore, the π bond on one side of the metal centre is localised on a six-membered face of the fullerene fragment, whereas on the other side the π bond of the metal atom is associated with a benzene molecule or another hexagonal face of a new fullerene fragment. Furthermore, the metal atom has been considered to have not a formal oxidation state, i.e., in all cases Cr(0). Particularly Stankevich and his group carried out a very interesting work [8d] in which they analysed from a theoretical point of view the same systems considered in the present work. They focused in the capability of the fullerene to generate η^6 bonds and suggested that the large size of the fullerene may be the cause of inhibition of the formation of such molecules, and a perturbation of the symmetry of fullerene by substituents is necessary in order to stabilise the complex.

The aim of this work was to perform theoretical studies of two non existing new molecules. $C_{60}CrC_{60}$ is the fullerene analogue to dibenzenechromium; this molecule has been named fullerenocene, there is only one previous experimental report about the possibility of having a sandwich molecule with fullerene decks. It was isolated as a film and the authors claimed that the structure is possibly a

☆ The author is aware that this name is not correct, but the temptation of the comparison with ferrocene is so strong, that the author decided to introduce this name for the main compound under study in this work.

doi:10.1016/j.poly.2008.11.015

polymer with alternate Pd atoms and fullerene units [10a,b]. However, the nature of the bonding in this species is not totally clear. Besides a polymer which contains C_{60}–Co has been studied in a theoretical fashion [10c], the authors suggest these polymers favours ferromagnetic ground states, these results are important for our research because of the emphasis on the electronic mobility in these complexes. Additionally, Stankevich [8d] has studied this molecule ($C_{60}CrC_{60}$) in a theoretical way, analyzing its stability and found moderately stability for fullerenocene although he suggests the substituted derivatives should be more stable.

Dibenzenechromium is a very well known molecule [1]. It has been calculated in the present work in the same conditions that the others in order to validate the method of calculation by comparison with published results [1] and for the internal comparisons with the molecules under study.

Finally, the third molecule is a hybrid molecule similar to that studied by Nakamura [9] and Chystiakov [11] that arose for the interaction among a fullerene fragment, a benzene molecule and a Cr(0) atom. This case has been previously studied by Jemmis and Stankevich [8] by using an energy criterium and semiempirical methods in the first case and DFT methods in the second case.

In this work fullerenocene is studied from a theoretical point of view. The present analysis extended the cited works mainly performed by the comparison of the aromaticity results obtained by means of the ASE factor [12] estimated by homodesmotic reactions, HOMA [13] and NICS [14] routines employing other DFT method. The electronic structure of the three molecules was also studied. Furthermore the most relevant features derived from the study are addressed. The results are analysed on the basis of possible preparation and electronic application of these substances.

2. Methods

All structures were optimised in the gas phase using the JAGUAR 4.0 package [15]. A pure DFT method containing Becke's gradient correction [16] for exchange and Perdew–Wang's for correlation [17] was used for the energy evaluations. All calculations were performed using the 6-31G** basis set. The quality of this combination of method and basis set was validated by comparing the result of total energy of dibenzenechromium (−550.675 au) and the heat of formation of $C_6H_6CrC_{60}$ (947.5 kcal/mol) obtained in this work with the same values obtained by Jemmis (−550.706 au and 977.2 kcal/mol, respectively) [8b]. The frequency calculations were carried out at the same level of theory in order to confirm that the optimised structures were at the minimum of the potential surface. These frequencies were then used to evaluate the zero-point vibrational energy, the thermal vibrational corrections to the enthalpy, and the total enthalpy values. The bond lengths of the optimised structures were used for the HOMA (Harmonic Oscillator Model of Aromaticity) method [13] to study the aromaticity. The NICS (Nucleus Independent Chemical Shifts) [14] is a technique that was proposed by Schleyer as a new aromaticity index. The authors named it 'absolute magnetic shielding' and computed the value at the ring centres, which were determined by the non-weighted mean of the heavy atom coordinates. In this work, NICS calculations were performed following this technique, carried out with GAUSSIAN03 [18] at the BPW91/6-31G** level.

3. Results and discussion

3.1. Energy and aromaticity comparisons

The results of the energy and aromaticity of the molecules under study are shown in this section Fig. 1.

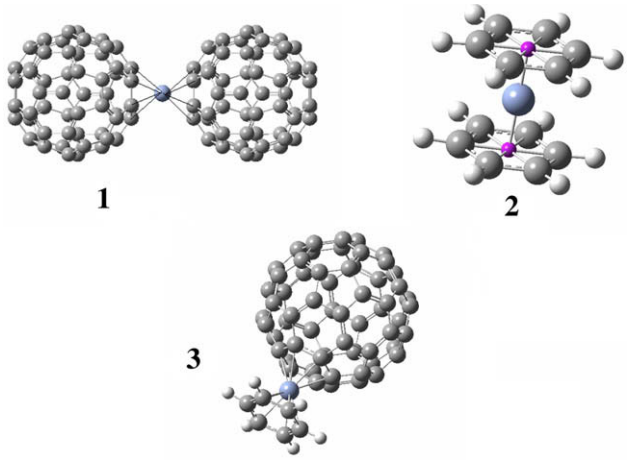

Fig. 1. Molecules under study.

Homodesmotic reactions were developed in order to calculate the ASE (aromatic stabilization energy) [12] in the three cases. In order to develop similar reactions for all cases, a set of two parent molecules were selected for all the species. The first parent molecule is similar to the bis(2,4-dimethylpentadienyl)chromium molecule prepared by Ernst and his group [19], but in our case it is bis(dibutadienyl)chromium. This molecule was chosen because it contains a delocalised electronic system without a clear aromatic scheme, but it has a framework of π bonds and this characteristic makes it suitable for analysing the stabilisation scheme produced by the appearance of aromaticity. The methyl substituents originally found in the compound by Ernst were removed, because these fragments would have been a source of carbon atoms with sp^3 hybridisation, that would be a problem in the definition of homodesmotic reactions. Therefore, the parent molecule is only bis(butadienyl)chromium ($C_8H_{12}Cr$) and its geometry is shown in Fig. 2.

The other parent molecule was 3-ethylene–butadiene (C_6H_8), which is an excellent source of carbon atoms containing only sp^2 hybridization. These species are shown in Fig. 3.

These last two compounds were calculated to find their optimised structures, followed by frequency calculations that were carried out in order to obtain their enthalpy values. In these cases, exactly the same methods and level of theory were used. The developed reactions for each case are shown in the next subsections together with the enthalpy analysis.

3.1.1. Homodesmotic reaction for $C_{60}CrC_{60}$

The homodesmotic reaction for the fullerenocene complexes is:

$$C_8H_{12}Cr + 59\ C_6H_8 \rightarrow C_{120}Cr + 121\ C_2H_2$$

The result is excellent; the ASE value obtained was 7026.698 kJ/mol, which is very large compared with results obtained for fuller-

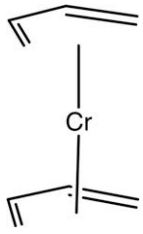

Fig. 2. Bis(butadienyl)chomium.

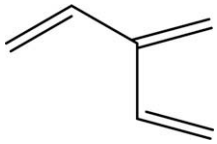

Fig. 3. 3-Ethylene–butadiene (parent molecule).

ene as 2345.88 kJ/mol [20] or 2509 kJ/mol ± 55 kJ/mol (from seven reports) [12]. Indeed the result should be 3521.349 kJ/mol for each fullerene unit with its respective bonds to the metal atom. This feature suggests the extra electronic flux due to the organometallic bonds help to stabilize the complex.

3.1.2. Homodesmotic reaction for dibenzenechromium

In the case of dibenzenechromium ($C_{12}H_{12}Cr$), the reaction was easy and the ASE result was very representative. The corresponding scheme is as follows:

$$C_8H_{12}Cr + 2\ C_6H_8 \rightarrow C_{12}H_{12}Cr + 4\ C_2H_4$$

The homodesmotic reaction yielded a value of ASE of 564.49 kJ/mol. Such a value denotes a highly aromatic behaviour and can be compared with coronene, a known aromatic molecule, with a reported value ~418 kJ/mol [12]. The proposition of Phillips et al. [3] is therefore correct, and hence the coordination on this molecule does not affect the aromaticity of the phenyl ring.

3.1.3. Homodesmotic reaction for $C_6H_6CrC_{60}$

The last homodesmotic reaction is remarkable. The corresponding scheme is

$$C_8H_{12}Cr + 30.5\ C_6H_8 \rightarrow C_{66}H_6Cr + 62.5\ C_2H_4$$

The result is even better than that found for the fullerenocene. The ASE value is 3964.5 kJ/mol.

A direct comparison of these results is not obvious. A valid comparison can be carried out by means of the ASE/π index proposed by Liebman [12]. This index indicates a stabilisation energy per carbon atom that contributes to the resonance framework. The ASE/π is 58.55 kJ/mol for fullerenocene, 47.04 kJ/mol for dibenzencrhomium and 60.07 kJ/mol for $C_6H_6CrC_{60}$. The best value is that for the hybrid molecule $C_6H_6CrC_{60}$ but very near to the fullerenocene. It has been proposed that the fullerene molecule is deficient in electrons [21], and present low polarizability [8c,d]. Indeed the nature of Cp and C_{60} is different since the first one is an electron donor whereas de second one is a weak electron acceptor. This feature changes the behaviour of the bond as it is shown in these results. It is important to note that the ASE is a global criterium of aromaticity, therefore it evaluates the whole system but not a specific zone of the molecules. Therefore, the application of some local criteria is important to reach a conclusion.

4. Aromaticity indices

The global aromaticity of the proposed molecules seems to be large on the basis of the results outlined in the last section; however, an energy criterium is not conclusive because global and local aromaticities can show a different behaviour as outlined by Solà and his co-workers [6g], and Chen and King [21]. Therefore, two popular methods to measure local aromaticity were applied; HOMA [13] and NICS [14].

The HOMA and NICS results for the six-membered face joined to the metal atom and in the centre of the fullerene ligands are shown in Table 1 for the three molecules under study.

The results of HOMA show that the dibenzenechromium is the most aromatic system; however the value is very close to that of fullerenocene and only in the hybrid molecule there is a notable decrease for the fullerene fragment. It is important to note that the large value of aromaticity of the benzene ring joint to the Cr atom is associated with the hybrid molecule. This feature should lead to the full planarity of this ring as compared with the same section in the fullerene fragment, where the phenomenon of pyramidalisation is present. Since HOMA is a geometric criterium, the difference between both kinds of aromatic fragments is emphasised.

Table 1
HOMA and NICS results for the molecules under study.

Molecule	$C_{60}CrC_{60}$	$C_6H_6CrC_6H_6$	$C_6H_6CrC_{60}$
HOMA	0.915	0.918	0.874 (ful) 0.957 (ben)
NICS	−10.08 (centre) −61.99 (η^6-face)	−47.07	−7.95 (ful) −57.90 (ben) −47.08 (η^6-face)

The NICS results follow a slightly different trend but are striking. First, the value of the aromatic rings joined to a metal are very large; this feature has been studied previously and discussed on the basis of paratropic and diatropic σ and π contributions [22]. However, in the present case the results are so high for dibenzenechromium that they indicate a large contribution of C–C(π) orbitals from two decks. The result grows significantly in the case of fullerene. There are two computed values, one for the centre of the sphere and the other for the six-membered face joined to the metal atom. The first one depicts the spherical aromaticity and the value is in the normal gap of NICS. This shows that the fullerene fragments of $C_{60}CrC_{60}$ are more aromatic than the same fragment in the hybrid molecule suggesting a larger current in the first. But the large difference appears for the surface where the trend is the same but the values are much higher, showing that there is a large contribution from the C–C(π) orbitals, which are donating electronic charge to the Cr atom.

The hybrid compound shows a peculiar behaviour similar to that found in the HOMA analysis. The NICS of the benzene ring is almost the same than that of the fullerene six-membered face (although this last one value is in itself very high). This feature means it can be expected a similar behaviour of the bonds from the metal centres with single aromatic fragments as well as for fullerenes, although the nature of this bonding is a little different as it will be discussed in the last section.

A conclusion about aromaticity can be reached with these results: based on the global criterium, the trend can be written as $C_6H_6CrC_{60} \approx C_{60}CrC_{60} > C_6H_6CrC_6H_6$. The HOMA and the NICS results show discrepancies mainly due to the pyramidalisation phenomenon present in the aromatic rings belonging to the fullerene fragments. However, in both cases the fullerenocene exhibited values that suggest a good aromatic behaviour on the faces directly joint to the chromium atom, and this result matches well with the global criterium.

5. Electronic structure

The electronic structure of fullerene has been extensively studied [23]. The scheme of molecular orbitals has been the object of particular attention due the I_h point group symmetry, which is not common in other kinds of molecules. The particular characteristic of this molecule is the nature of the frontier orbitals having a five-fold degenerated set for the HOMO which belongs to the irreducible representation h_u (with a very near HOMO-1 being a four-fold degenerated molecular orbital belonging to the g_g irreducible representation) and a triple degenerated set for the LUMO which belongs to the irreducible representation t_{1u}. Such a richness of electron states leads to a very narrow HOMO–LUMO gap. An

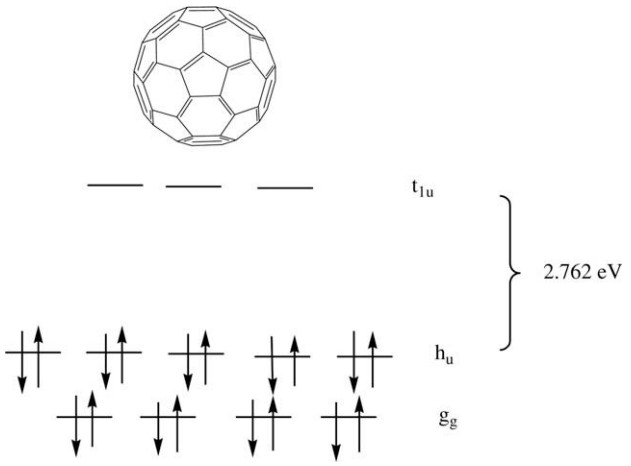

Fig. 4. Frontier molecular orbital scheme for fullerene (results obtained in this work).

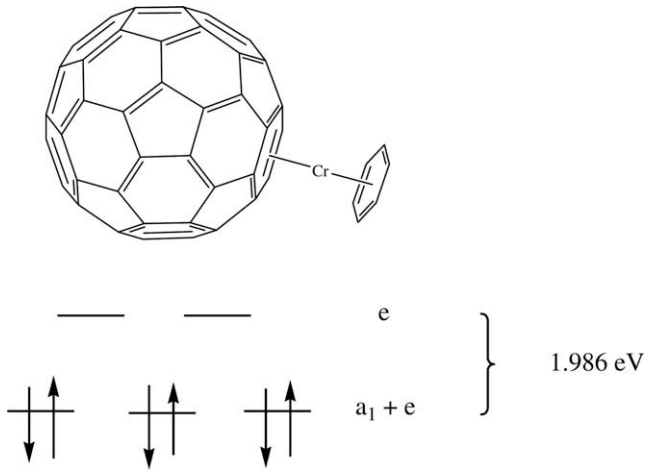

Fig. 6. Frontier molecular orbital for fullerene–benzene–chromium, the HOMO presents accidental degeneracy between irreducible representations a1 and the set e.

anomalous pyramidalisation of the hybridisation of the sp^2 carbon atoms [24] appears as well. The same scheme was used in the present study through the BPW91/6-31G** method in order to compare the energy values on the same scale; the ordering is the same as well as the separation of levels, which yields a gap of 2.762 eV between the Frontier orbitals (see Fig. 4).

The molecular orbital distribution of dibenzenechromium has also been studied [25]. It belongs to the D_6h point group and its main characteristic is a HOMO-1 double degenerated, which belongs to the irreducible representation e_{2g} that is very near the a_{1g} HOMO. The set of frontier orbitals is shown in Fig. 5; again the system was studied at the same level of theory for comparison purposes and in this case the gap between HOMO–LUMO is 3.946 eV.

The hybrid compound presents a peculiar ordering of its molecular orbitals with the molecule belonging to the C_3v point group. It has been seen that in the case of this point group it is possible to find an accidental degeneracy [26], since the C_3v group does not have triple-folded degenerated irreducible representations. However, the molecular orbital scheme for the hybrid molecule shows, at first sight, a triple degenerated set for the HOMO. This set does not correspond to an irreducible representation but to a mixing of a totally symmetric a_1 and a double e irreducible representation. This is a curious example of accidental degeneracy. It is important to note that this set results from the combination of HOMO (a_{1g}) and HOMO-1 (e_{2g}) of the D_6h *dibenzenechromium,* that are two irreducible representations which lie very close together, as pointed out above.

There is no contribution of the fullerene fragment to this last set of molecular orbitals, as the contribution of the fragment is totally concentrated in the LUMO and this feature confirms the weak electron acceptor nature of fullerene. The HOMO–LUMO gap is 1.986 and this result is interesting because such a value suggests that this molecule should have semiconductor behaviour. The large value of aromaticity found by the HOMA and NICS methods for this species

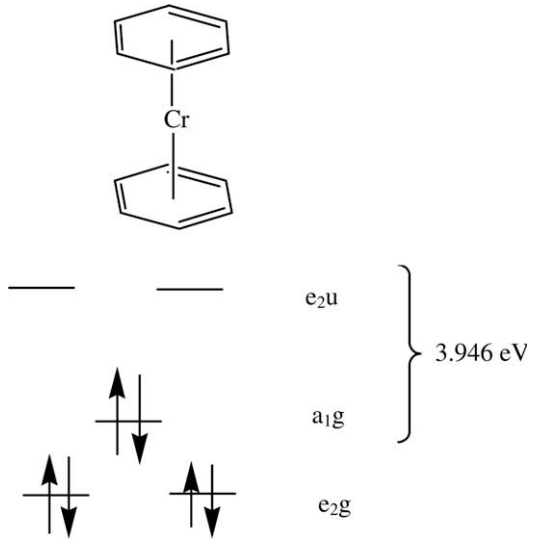

Fig. 5. Frontier orbitals for dibenzenechromium.

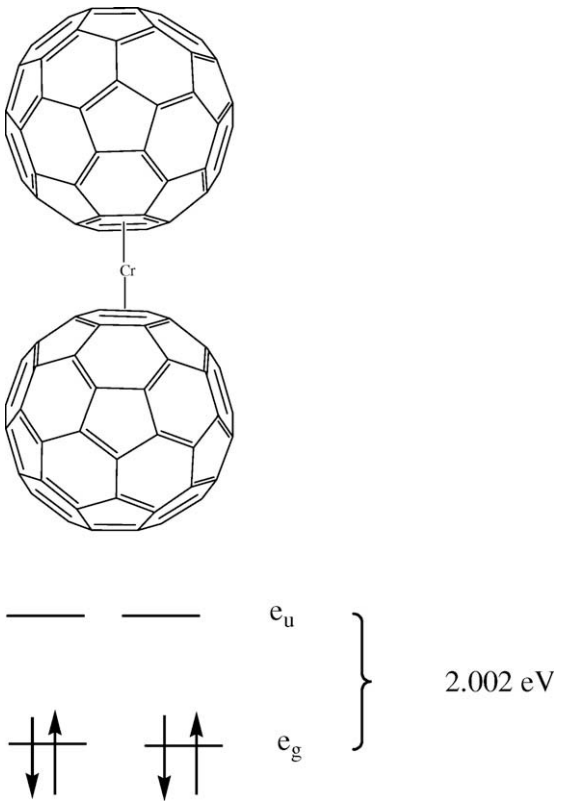

Fig. 7. Frontier molecular orbitals from fullerenocene.

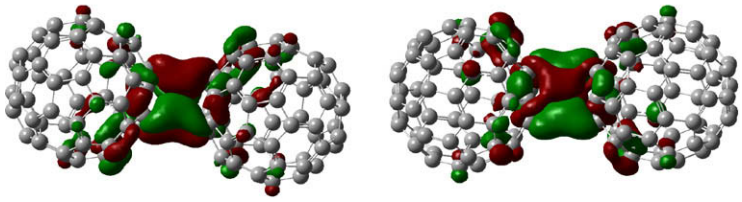

Fig. 8. Degenerated set for the HOMO of fullerenocene 1.

arise from this phenomenon because the *pseudo* triple degenerated set corresponding to the HOMO contributes with six electrons of the same energy to the aromaticity instead of the same six of dibenzenechromium but at different energy levels. The corresponding molecular orbital interaction is shown in Fig. 6.

Concerning the fullerenocene there are also interesting results. The molecule belongs to the D_3d symmetry group and the large symmetry of fullerene changes dramatically. The HOMO, as well as the LUMO are only two-fold degenerated sets. The HOMO belongs to the e_g irreducible representation, whereas the LUMO belongs to the e_u irreducible representation. The interesting point is that the HOMO–LUMO gap is even smaller than that of free fullerene, at 2.002 eV. This again suggests a semiconductor behaviour and all the known electronic characteristics of fullerene [27] must be found in this molecule. The molecular orbital interaction diagram is shown in Fig. 7.

Rayón and Frenking carried out a very interesting analysis by comparing the nature of the bond in ferrocene and that in dibenzenechromium [28]. In this work the authors showed, by means theoretical calculations, that the largest contribution to the orbital interactions in ferrocene comes from the π electronic donation from Cp to Fe. In a different pathway, the main contribution to the orbital interaction in dibenzenechromium is δ back-donation considering the symmetry of the corresponding irreducible representations. A similar analysis in the present case show that the irreducible representations e_g for fullerenocene, corresponding to the degenerated set of the HOMO (into the scheme of D_3d point group) have π symmetry and it contains only the electron donation from fullerene fragments to the d_{xz} and d_{yz} atomic orbitals of the Cr atom (see Fig. 8). On the other hand, the LUMO is again a degenerated set which belongs to the irreducible representation e_u, and this MO has only a contribution from the fullerene fragments without the presence of atomic orbitals coming from the metal atom. The behaviour in this sense is therefore very different than in dibenzenechromium.

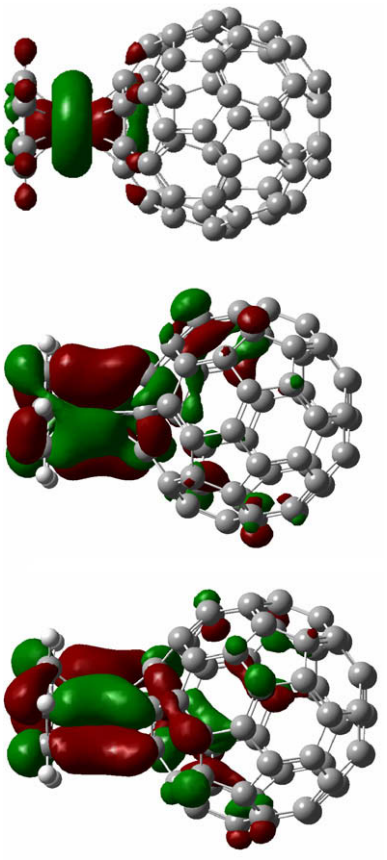

Fig. 9. Degenerated set for the HOMO of molecule 3.

Concerning the hybrid molecule, the behaviour is different but not completely defined. The 'actual' HOMO is a MO which corresponds to the irreducible representation a_1. This orbital has a clear symmetry δ where the main contribution to the d_z^2 atomic orbital arises from the Cr atom. However, the accidental degeneracy produces the pseudo triple-folded set, joining to this single orbital the next degenerated set. This set corresponds to the e irreducible representation with π symmetry (see Fig. 9). Besides, the LUMO that should act as the receptor of the back-donation do not participate in the bonding between the metal atom and the ligands. Therefore, this compound should be again a π-bonded molecule.

It is important to note that the latter results for fullerenocene correspond to an eclipsed isomer, therefore the staggered isomer was also calculated leading to a slightly less stable species. The difference in total energy between both isomers is 3.4132 kJ/mol in favour of the eclipsed structure. The staggered isomer belongs to the D_3 point group and its HOMO as well as its LUMO belong to the a_1 and a_2 irreducible representations respectively. Here again there is a curious phenomenon: the lack of symmetry causes the gap between HOMO and LUMO to be much more open than the corresponding value of the eclipsed one (5.898 eV), therefore this species seems less interesting than its isomer.

6. Conclusions

The aromaticity and relative stability of the fullerene analogue of dibenzenechromium was studied as well as a hybrid species which contains a deck of benzene and a deck of fullerene. The energy study carried out by means of homodesmotic reactions showed that the new structures have both large values of ASE as compared with dibenzenechromium itself, suggesting that these fullerene complexes should be as stable as the classically known π bonded organometallic compounds. Besides, the HOMA and NICS analysis suggested a strong aromatic character in both compounds and a reinforcement of the spherical aromaticity. This last condition is more marked in the case of fullerenocene, which showed a very large value of NICS in the face of the sphere joint to the

metal atom. The analysis of the electronic structure showed that both molecules have narrow HOMO–LUMO gaps suggesting that these molecules might have a semiconductor character. In particular, the molecular orbital analysis results of the hybrid compound were significant because they showed a triple degenerated set corresponding to the HOMO. However, the corresponding point group does not possess an irreducible representation yielding a triplet; therefore, this is a peculiar example of accidental degeneracy. The phenomenon does account for the size of the energy gap which is even narrower than in the free fullerene itself.

Acknowledgements

The author wish to express his gratitude to Prof. Stephen Muhl and Prof. Raul Valenzuela for very useful discussions, Ms. Maria Teresa Vázquez, Ms. Oralia Jimenez, Ms. Sara Jimenez and Mr. Victor Gomez for technical help. The author is also indebted to DGSCA-UNAM and Sun Enterprise for invaluable help in computation work. This research was supported by projects PUNTA-UNAM and CONACYT-57432.

Copper(II) complexes

ABSTRACT

Three novel Cu(II)-pyrazine-2,3-dicarboxylate complexes with 1,3-propanediamine (pen), $[Cu_2(\mu\text{-pzdc})_2(pen)_2]\cdot 2H_2O$ **(1)**, *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmen), $\{[Cu(\mu\text{-pzdc})(tmen)]\cdot H_2O\}_n$ **(2)**, and 2,2′-bipyridine (bipy), $\{[Cu(\mu\text{-pzdc})(bipy)]\cdot H_2O\}_n$ **(3)** have been synthesized and characterized by means of elemental and thermal analyses, magnetic susceptibilities, IR and UV/vis spectroscopic studies. The molecular structures of dinuclear **(1)** and polynuclear **(2** and **3)** complexes have been determined by the single crystal X-ray diffraction technique. The pyrazine-2,3-dicarboxylate acts as a bridging ligand through oxygen atom of carboxylate group and N atom of pyrazine ring and one oxygen atom of neighboring carboxylate. It links the Cu(II) ions to generate a distorted square pyramidal geometry forming a one-dimensional (1D) chain. Adjacent chains of 1 and 2 are then mutually linked via hydrogen bonding interactions, which are further assembled to form a two and three-dimensional network, respectively. The chains of complex **3** are further constructed to form three-dimensional framework by hydrogen bonding, C–H···π and ring···ring stacking interactions. In the complexes, Cu(II) ions have distorted square pyramidal geometry. Thermal analyses properties and thermal decomposition mechanism of complexes have been investigated by using thermal analyses techniques (TG, DTG and DTA).

1. Introduction

The rational design and synthesis of metal-directed the supramolecular framework have received much attention in coordination chemistry in recent years owing to their novel and diverse topologies and potential applications in host–guest chemistry, catalysis, electrical conductivity, magnetism, nonlinear optics and gases sensors [1–8]. In crystal engineering the cyclic dicarboxylates [4–36], oxocarbons [37–39] and pyrimidine bases have been used as building blocks [40–42] and many coordination polymers. Pyrazine-2,3-dicarboxylic acid (H_2pzdca, Scheme 1a) generally tends toward react with metal salts to yield insoluble polynuclear materials and it behaves as a polyfunctional ligand in metal complexes and coordinates to metal ions by means of its four carboxylate oxygens and two nitrogen atoms forming monodentate [14], bidentate [15–19], bis(bidentate) bridging [20–23], tridentate bridging [24–29], tetradentate bridging [30–35] and mixed chelating-bridging ligand [36]. The Pyrazine-2,3-dicarboxylate coordinated to the Cu(II) ion for the first time as a monodentate ligand in the $[Cu(pdca)(H_2O)(en)_2]$ and $[Cu(pdca)(H_2O)(dmpen)_2]$ [14], pzdca behaved as a bidentate ligand *via* O atom of carboxylate and N atom of pyrazine ring in the $K_2[Cu(pzdca)_2(H_2O)]\cdot 6H_2O$ [18] complexes, as a bis(bidentate) bridge ligands coordinated to metal ions through two carboxylate oxygen atoms and two nitrogen atoms of pyrazine ring in the [Cu(pzdca)(HCl)] [20] and $\{[Cu(pzdca)(H_2O)_2]\cdot 2H_2O\}_n$ [35]. The pzdca acts as a tridentate and tetradentate bridge between the metal ions forming one-dimensional polymeric chains, its coordination sites being the O atom of carboxylate and N atom of ring and one O atom (for tridentate) or two O atoms (for tetradentate) of neighboring carboxylate group in the $\{[Cu(pzdca)(H_2O)_2]\cdot H_2O\}_n$ [26], $\{[Cu(pzdc)_2]\cdot 3(H_2O)\cdot 2(idzc)\}_n$ [29], $[Cu_2(pzdca)_2(L)]_n$ [35].

In the present study, we describe the syntheses, spectroscopic, thermal studies (TG, DTG and DTA) and crystal structures of novel three supramolecular Cu(II)-pyrazine-2,3-dicarboxylate complexes with 1,3-propanediamine (pen), *N*,*N*,*N*′,*N*′-tetramethylethylenediamine (tmen) and 2,2′-bipyridine (bipy) (Scheme 1b–d); $\{[Cu(\mu\text{-pzdc})(pen)]\cdot H_2O\}_2$ **(1)**, $\{[Cu(\mu\text{-pzdc})(tmen)]\cdot H_2O\}_n$ **(2)** $\{[Cu(\mu\text{-pzdc})(bipy)]\cdot H_2O\}_n$ **(3)**.

Scheme 1. (a) Pyrazine-2,3-dicarboxylic acid, (b) 1,3-propanediamine, (c) N,N,N′,N′-tetramethylethylenediamine, (d)2,2′-Bipyridine.

2. Experimental

2.1. Preparation of the complexes

2.1.1. Complexes *1* and *3*

A solution of pyrazine-2,3-dicarboxylic acid (0.840 g, 5 mmol) in water (25 mL) was neutralized with NaOH (0.4 g, 10 mmol) and added dropwise with stirring at 50 °C to a solution of $CuCl_2 \cdot 2H_2O$ (0.852 g, 5 mmol) in water (25 mL). The solution immediately became precipitate and was stirred for 4 h at 50 °C. The addition of the pen ligand (0.372 g, 5 mmol) or 2,2'-bipyridine (0.781 g, 5 mmol) in ethanol (10 mL) to the precipitate mixture resulted in a clear solution. The mixture was stirred for 2 h at 50 °C and then cooled to room temperature. The crystals formed were filtered and washed with 10 mL of water and were dried in air. Elemental *Anal.* Calc. (%). Found: C, 34.11; H, 3.88; N, 17.67%. Calc. for $C_{18}H_{28}N_8O_{10}Cu_2$: C, 33.59; H, 4.39; N, 17.41% for **1**. Found: C, 47.99; H, 2.39; N, 14.13%. Calc. for $C_{16}H_{12}N_4O_5Cu$: C, 47.59; H, 3.00; N, 13.87% for **3**.

2.1.2. Complex *2*

A solution of pyrazine-2,3-dicarboxylic acid (0.840 g, 5 mmol) in water (25 mL) was added dropwise with stirring at 50 °C to a solution of $Cu(CH_3COO)_2 \cdot H_2O$ (1 g, 5 mmol) in distilled water (25 mL). The solution immediately became suspension and was stirred for 4 h at 50 °C. Then the tmen ligand (0.581 g, 5 mmol) in water (10 mL) was added dropwise to this suspension. The clear solution was stirred for 2 h at 50 °C and then cooled to room temperature. The crystals formed were filtered and washed with 10 mL of water and were dried in air. Elemental *Anal.* Calc. (%). Found: C, 40.13; H, 5.33; N, 15.68%. Calc. for $C_{12}H_{20}N_4O_5Cu$: C, 39.61; H, 5.54; N, 15.40% for **2**.

2.2. Materials and measurements

All chemicals used were analytical reagent and were commercially purchased. IR spectra were obtained with a Perkin–Elmer 100 FT-IR Spectrometer using KBr pellets in the 4000–400 cm^{-1} range. The UV–Vis. spectra were obtained for the aqueous solution of the complex (10^{-3} M) with a Shimadzu UV-3150 spectrometer in the range 900–190 nm. Magnetic susceptibilities measurements at room temperature were performed using a Sherwood Scientific MXI model Gouy magnetic balance. Elemental analysis for C, H and N were performed using a Carlo Erba 1106 microanalyser. Perkin–Elmer Diamond TG/DTA Thermal Analyser was used to record simultaneous TG, DTG and DTA curves in the static air atmosphere at a heating rate of 10 K min^{-1} in the temperature range 60–550 °C using platinum crucibles.

2.3. Crystallographic analyses

Diffraction experiments were carried out at 296 K on a Stoe IPDS diffractometer. The structures were solved by direct methods and refined using the programs SHELXS97 and SHELXL97 [43]. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares methods [43]. In complex **2**, the tmen ligand shows three-positioned orientational disorder, the final site-occupancy factors for C(7)a–C(7)b/C(8)a–C(8)b/C(9)–C(9)b. The hydrogen atoms were placed in geometrically idealized positions and refined as riding atoms. Data collection: X-Area, cell refinement: X-Area, data reduction: X-RED [44]; program(s) used for molecular graphics: ORTEP-3 for Windows [45]; software used to prepare material for publication: WINGX [46].

3. Results and discussion

3.1. UV–Vis spectra and magnetic properties

The electronic spectra of water solutions of the complexes **1**–**3** display broad absorption bands at 617 (ϵ = 159 L mol^{-1} cm^{-1}), 647

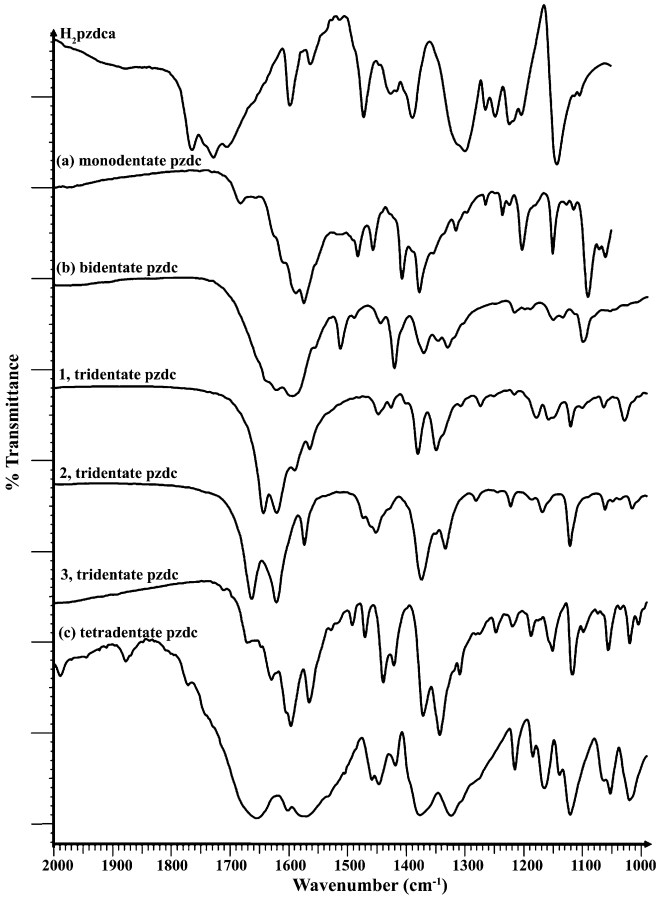

Fig. 1. A comparison of IR spectra of pyrazine-2,3-dicarboxylic acid and Cu(II)-pzdca complexes: (a) $[Cu(pzdca)(H_2O)(en)_2] \cdot H_2O$ [14], (b) $[Cu(pzdca)(phen)_2] \cdot 5.5H_2O$ [15], [Cu(pzdca) (mea)], (mea = monoethanoleamine, in prepare) and complexes 1-3.

(ϵ = 88 L mol^{-1} cm^{-1}) and 700 (ϵ= 127 L mol^{-1} cm^{-1}), respectively, which are assigned to the d_{xz}, $d_{yz} \rightarrow d_{x2-y2}$ ($a_1 \rightarrow b_1$) transition. The strong absorption bands below 300 nm are due to $n \rightarrow \Pi^*$ and $\Pi \rightarrow \Pi^*$ transitions of pen, tmen, bipy and pzdca ligands.

The complexes exhibit magnetic moment value of 1.57 for **2** and 1.58 for **3** which corresponds to one unpaired electron, while the dimeric complex **1** exhibits 2.46 BM, which lower than the spin only value for two unpaired electrons in Cu(II) complexes, indicates to antiferromagnetic effect.

3.2. IR spectra

The most characteristic FT-IR bands of the complexes correspond to the stretching vibrations of carboxyl group in the expected regions. For the coordination modes of carboxylate group, the difference between the asymmetric (ν_{asym}) and symmetric (ν_{sym}) carboxylate stretches ($\Delta = \nu_{asym} - \nu_{sym}$) are often used [47]. The C=N, C=C and OCO stretching band of the free pyrazine-2,3-dicarboxylic acid observed at 1753, 1715 and 1690 cm^{-1} were appear as three strong bands in the frequency range 1667–1568 cm^{-1} in the IR spectra of the complexes. The ν_{asym}(OCO) values were observed at 1568 for **1**, 1576 for **2** and 1569 for **3** and ν_{sym}(OCO) values were also observed at 1355 for **1**, 1339 for **2** and 1349 for **3**. The corresponding $\Delta\nu$ data are 213 for **1**, 237 for **2** and 220 for **3**. The separation between ν_{asym}(OCO) and ν_{sym}(OCO) indicate that the presence of monodentate coordination mode for the pzdca [47]. These conclusions are also supported from the results obtained from X-ray diffraction measurements.

The IR spectra of the complexes shows broad bands at 3507 and 3387 for **1** and 3476 and 3428 cm^{-1} for **2**, 3410 cm^{-1} for **3** the characteristic stretching of crystal water molecule. The bands at 3292 and 3244 cm^{-1} for **1** are attributed to the NH_2 stretching vibration in pen ligand. The weak bands between 3074 and 2893 cm^{-1} are attributed to the ν(CH) and $\nu(CH_2)$ vibrations in the IR spectra of the complexes. The weak bands observed in the 445–553 cm^{-1} region are due to Cu–O and Cu–N stretching vibrations [47]. A comparison between IR spectra of pyrazine-2,3-dicarboxylic acid and the IR spectra of the Cu(II)-pzdca complexes, in which pzdca ligand exhibits monodentate [14], bidentate [15], tridentate bridge and tetradentate bridge coordination modes are shown in Fig. 1.

3.3. Thermal analyses

Thermal decomposition behaviors of the complexes were performed in static atmosphere of air in the temperature range 60–550 °C. Thermoanalytical results (TG, DTG and DTA) on the complexes are summarized in Table 1.

Table 1
Thermoanalytical results (TG, DTG and DTA) on the complexes (1–4).[a]

Complexes	Decomposition		$DTG_{max.}$ (°C)	Remove Group	Mass loss (%)		Total Mass loss(%)		Decomposition product
	Stage	Temp. range			Calc.	Found	Calc.	Found

[a] (+) endothermic, (−) exothermic effect.

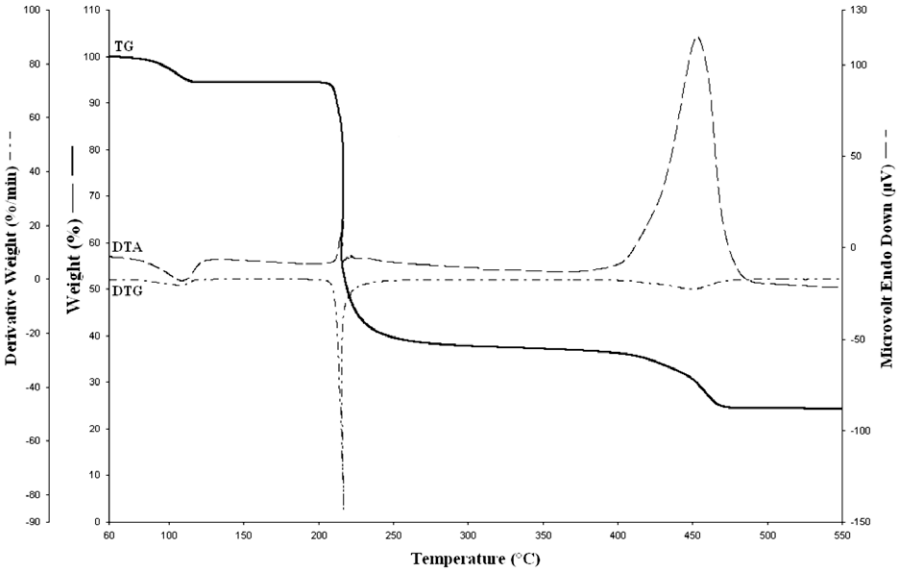

Fig. 2. TG, DTG and DTA curves of 1.

*3.3.1. $[Cu_2(\mu\text{-pzdc})_2(pen)_2] \cdot 2H_2O$ (**1**)*

Complex **1** shows a three stage decomposition process (Fig. 2) and it starts to the lose crystal water molecules between 104 and 134 °C with an experimental mass loss of 5.57% (calc. mass loss 5.59%). Anhydrous complex is stable up to 203 °C and in the second stage, it begins to decompose between 203 and 245 °C and to calculate mass loss value for the release of both pen and pzdca ligands is impossible due to overlapping decomposition processes. In the last exothermic stage, remaining organic part is abruptly burnt (DTA = 478 °C). The total mass loss of all decomposition process is 77.44% (calc. 75.28%) suggest that CuO is the end product at 518 °C.

*3.3.2. $\{[Cu(\mu\text{-pzdc})(tmen)] \cdot H_2O\}_n$ (**2**)*

The complex **2** exhibits four decomposition stages (Fig. 3). In the first stage, endothermic removal of crystal water molecule occurs between 89 and 142 °C (found 4.47, calc. 4.95%, DTA_{max} = 126 °C). In the temperature range of 186–228 °C, the anhydrous Cu(II) complex involves the consecutive decomposition stages of neutral tmen ligand by the endothermic effects (DTA_{max} = 228 °C). The endothermic effects between 228 and 250 °C is likely due to the release of CO_2 from pzdca ligand. The IR spectrum of the complex heated just to the end of this weight loss show no evidence of CO_2 bands. The following stage involves the burning of pyrazine ligand by the exothermic effect (DTG_{max} = 344 °C), leading finally to CuO. The overall mass loss of 78.94% (calc. 78.14%) agrees with the propose structure well.

3.3.3. $\{[Cu(\mu\text{-pzdc})(bipy)] \cdot H_2O\}_n$ (3)

In the stages of range of 28–81 °C, the complex **3** involves endothermic decomposition, corresponding to the loss of crystal water molecule as indicated by TG mass loss (found 5.34, calc. 4.46%). The

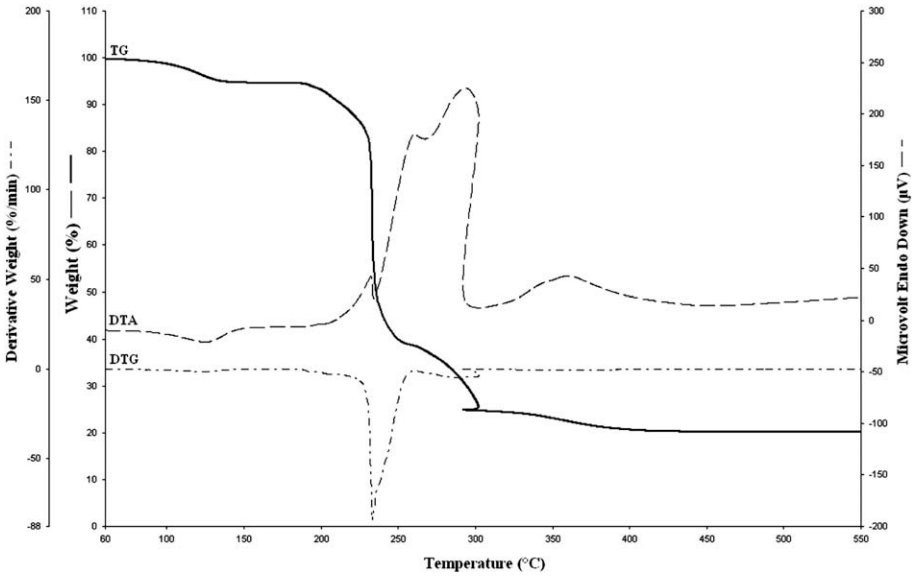

Fig. 3. TG, DTG and DTA curves of 2.

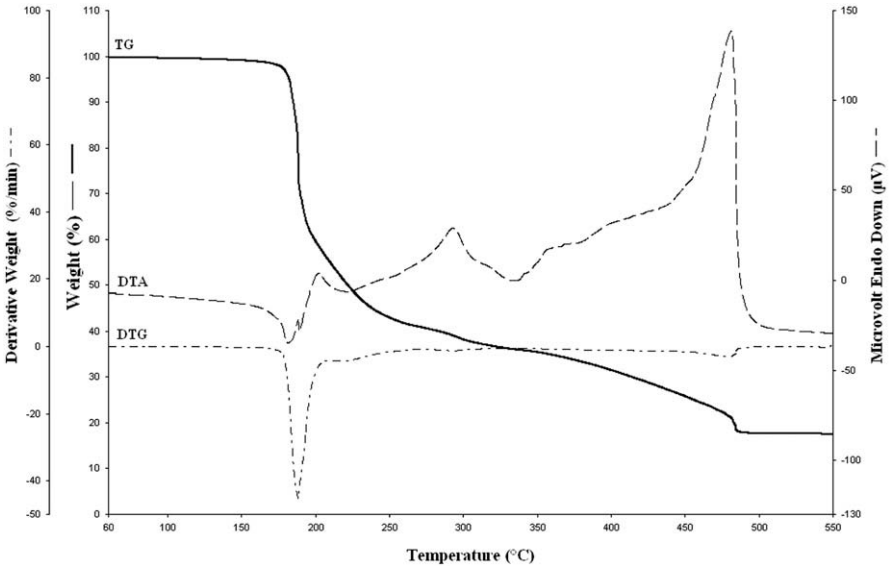

Fig. 4. TG, DTG and DTA curves of 3.

anhydrous complex is thermally stable up to 171 °C. In the third stage between 171 and 208 °C, the complex involves the decomposition of the bipy ligand by giving exothermic effect (found 38.44, cal. 38.67%). The fourth stage is related to the release of CO_2 + CO from the pzdca (found 16.85, calc. 17.80%). The last strong exothermic stage can be assigned to the combustion of the residual organic matter. The final solid product of thermal decomposition was identified as CuO (found 79.90, calc. 80.44%) (Fig. 4).

The final decomposition products were identified by IR spectroscopy and also confirmed by mass loss calculations. On the basis of the first decomposition temperature, the thermal stability of the anhydrous complexes follows the order: **1**, (203 °C) > **2**, (185 °C) > **3**, (171 °C) in static air atmosphere.

3.4. Crystal structures

The relevant crystal data and experimental conditions along with the final parameters are summarized in Table 2. The selected bond lengths and angles together with the hydrogen bonding geometry are given in Tables 3 and 4, respectively. The comparison of the Cu–N_{pzdc}, Cu–O_{pzdc} distances and O_{pzdca}–Cu–N_{pzdca} angle for the similar 2,3-pyrazinedicarboxylic acid complexes are given in Table 5.

3.4.1. $[Cu_2(\mu\text{-pzdc})_2(pen)_2] \cdot 2H_2O$ (1)

The molecular structure of $[Cu_2(\mu\text{-pzdc})_2(pen)_2] \cdot 2H_2O$ with the atom labeling is shown Fig. 5. The selected bond lengths and angles are collected in Table 3. The structure consists of a complex $[Cu_2(\mu\text{-pzdc})_2(pen)_2]$ and two crystal water molecules. Although there are many metal complexes of pzdc forming polymeric structure, dinuclear pzdc complex has been reported only one by our group [15]. In the title dinuclear Cu(II) complex **1**, pzdc dianion acts as a tridentate bridging ligand with the nitrogen atom and oxygen atom of one carboxylate group, chelating the copper atom whereas another oxygen atom of the second carboxylate group binds the symmetry-related Cu atom. Distorted square pyramidal geometry is completed with two nitrogen atoms of bidentate pen ligand. One carboxylate oxygen atom (O1) and three nitrogen atoms (N1, N3, N4) from the pzdc and pen ligands comprise the equatorial plane, while one oxygen atom of carboxylate group ($O3^i$, (i) –x + 1, –y + 1, –z + 1) from the neighboring complex molecule occupy the axial position. The Cu1–N1 and Cu1–O1 bond distances are comparable to those reported for $[Cu_2(pzdc)_2(L)]_n$ [1.99(1) and 1.947(9) Å] [48], $[Cu(pzdc)_2] \cdot 2H_2O$ (1.994(3) and 1.941(3) Å) [49], $[Cu(Hpzdc)_2]_n$ (1.973(3), 1.934(3) Å) and $\{[Cu_4(\mu\text{-pzdc})_4(phen)_2(H_2O)_4] \cdot 10H_2O\}_n$ (1.983(3), 1.998(3) and 1.942(3), 1.947(3) Å) [25]. The Cu–$O3^i$

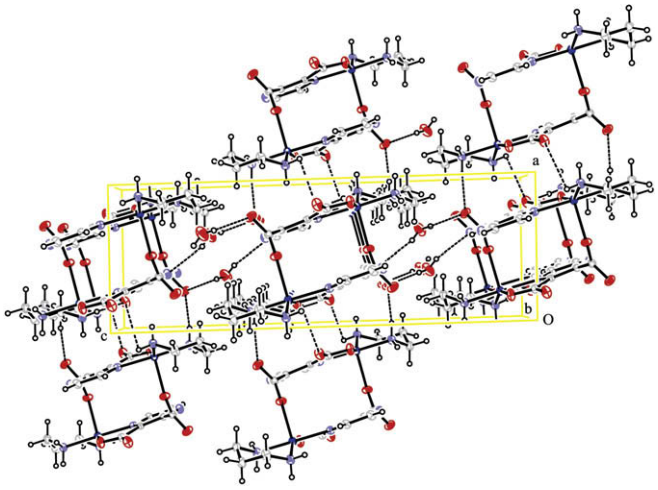

Fig. 6. Packing diagram of 1.

bond distance of 2.212(2) Å are different from the values observed in $\{[Cu_4(\mu\text{-pzdc})_4(phen)_2(H_2O)_4]\cdot 10H_2O\}_n$ (1.937(3) Å) [25], $[Cu_2(pzdc)_2(L)]_n$ [1.973(8) Å] [48] and $[Cu(Hpzdc)_2]_n$ (2.616(3) Å), while the Cu1–$O3^i$ bond distance is in agreement with the corresponding values in $\{(H_2bpe)[Cu(\mu\text{-pzdc})_2]\cdot 2H_2O\}_n$ (2.469(2) Å) [33], $[Cu(pzdc)_2]\cdot 2H_2O$ (2.401(3) Å) [49], $\{[Cu(pzdc)_2]\cdot 3H_2O{\cdot}2idzc\}_n$ (2.420(4) Å) [26], and $\{[Cu(\mu\text{-pzdc})(H_2O)_2]\cdot H_2O\}_n$ (2.306(3) Å) [29].

The complex 1 exhibits a number of intermolecular N–H···O, O–H···O and O–H···N hydrogen bonds as given Table 4. The amine hydrogen atoms of pen participate in hydrogen bonding with the oxygen atoms of pzdc and crystal water molecules. These hydrogen bonding interactions give 3D framework (Fig. 6).

3.4.2. $\{[Cu(\mu\text{-pzdc})(tmen)]\cdot H_2O\}_n$ (2)

The crystal structure of **2** with the atom labeling is shown in Fig. 7. The selected bond lengths and angles and hydrogen bonding geometry are given in Tables 3 and 4, respectively. The Cu(II) ion is bridged by the tridentate pzdc ligand through the oxygen atom of carboxylate group and nitrogen atom of pyrazine ring as a bidentate manner and oxygen atom of carboxylate group of neighboring molecule. Each Cu(II) ion is also coordinated bidentate tmen ligand forming distorted square pyramid geometry. The structure contains of an helicoidal chains devolopping paralel to *b*-axis. The Cu1–O1 and Cu1–N1 bond distances are similar that found in the $\{(H_2bpe)[Cu(\mu\text{-pzdc})_2]\cdot 2H_2O\}_n$ (1.954(1) and 1.978(2) Å) [33], $\{[Cu_4(\mu\text{-pzdc})_4(phen)_2(H_2O)_4]\cdot 10H_2O\}_n$ (1.942(3), 1.947(3) and 1.983(3), 1.998(3) Å) [25] and $\{[Cu(\mu\text{-pzdc})(H_2O)_2]\cdot H_2O\}_n$ (1.978(3) and 2.061(3) Å) [29]. The Cu1–$O3^i$ bond distance is significantly shorter that found in the $\{[Cu(\mu\text{-pzdc})(H_2O)_2]\cdot H_2O\}_n$ (2.306(3)Å) [29] and $\{(H_2bpe)[Cu(\mu\text{-pzdc})_2]\cdot 2H_2O\}_n$ (2.469(2) Å) [33], but is much longer than 1.938(3) Å reported for $\{[Cu_4(\mu\text{-pzdc})_4(phen)_2(H_2O)_4]\cdot 10H_2O\}_n$ [25].

The pzdc ligand is essentially planar with r.m.s. deviation −0.0021 Å and the largest deviation from the mean plane is 0.0080 Å for C4 atom. The carboxylate C–O distances in the pzdc anion also display some variability, depending on their environment. The C–O distances are practically equal in the pzdc anion in pzdca ligand [50].

The crystal water molecule is involved in intermolecular hydrogen bonding with the carboxyl oxygen atoms (O2 and O4) of pzdca ligand. The intermolecular O5–H5A···$O2^{ii}$ and O5–H5B···$O4^{iii}$ hydrogen bonds have the H···O distances of 2.10(3) and 2.10(2) Å,

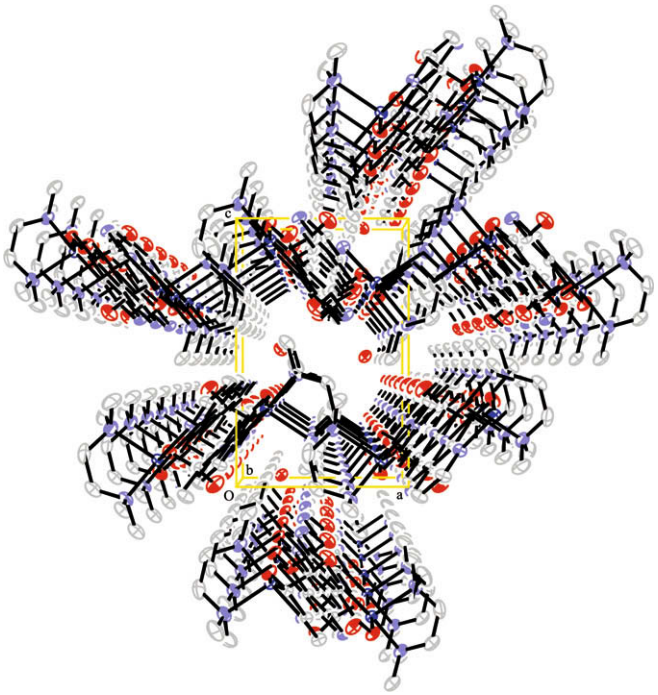

Fig. 8. Packing diagram of 2.

respectively [(ii) −x + 1, y − 1/2, −z + 1/2; (iii) x − 1/2, −y + 3/2, −z]. These hydrogen bonding interactions give three dimensional networks (Fig. 8).

3.4.3. {[Cu(μ-pzdc)(bipy)] · H_2O}$_n$ (**3**)

Crystal structure of polymeric complex **3** with the atom labeling is shown in Fig. 9. Cu(II) ion is coordinated by two N atoms of bipy ligand, O atom of carboxylate group and N atom of pyrazine ring and O atom of symmetry related carboxylate group, forming a distorted square pyramid geometry. Atoms N1, N3, N4 and O3 comprise basal plane, while atom O1 occupy the axial positions. The

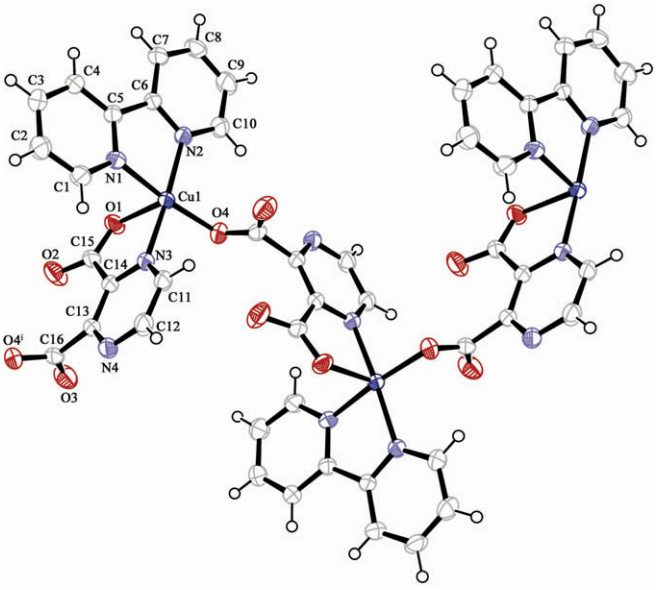

Fig. 9. The molecular structure of 3 showing the atom numbering scheme. The thermal ellipsoids are plotted at the 50% probability level.

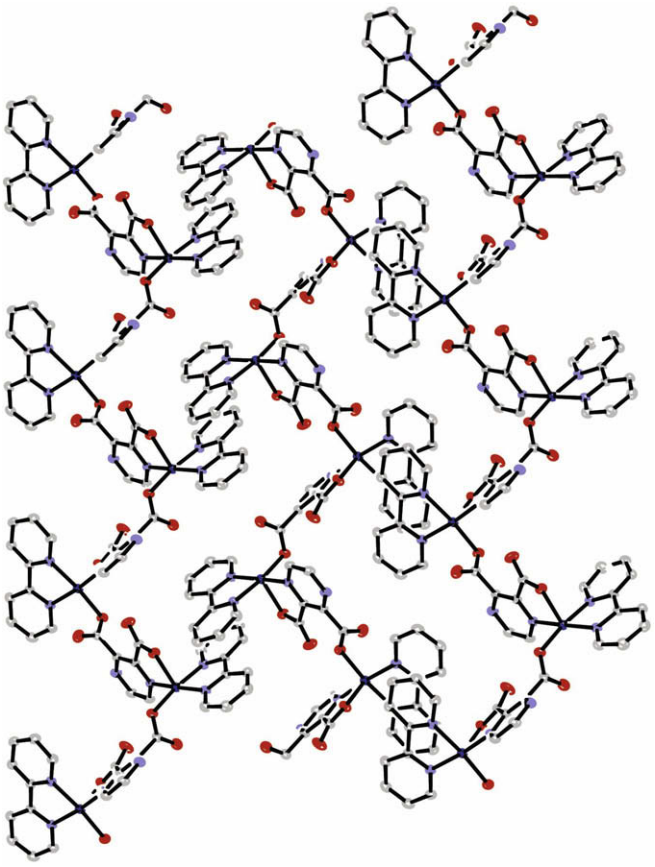

Fig. 10. The two-dimensional structure of 3.

Cu1–O1 and Cu1–N1 bond distances are similar that reported for the related Cu(II) complexes [29]. The Cu1–O3^{i} bond distance is significantly shorter that found Cu(II)-pzdc complexes [29,33]. Pzdc moiety is planar with slightly more rotated carboxylate group in the coordinated one [C1/C5/O1/O2 10.41, C2/C6/O3/O4 71.05°]. The dihedral angle between two carboxylate groups is 72.04°.

The crystal packing of complex is a composite of intermolecular hydrogen bonding, ring···ring and C–H···π interactions. The crystal structure is stabilized through strong intermolecular hydrogen bonding between O atom of crystal water molecule and uncoordinated O atom of carboxylate groups. The distances O5···O2^{i} and O5···O2^{ii} are 2.922(5) and 2.833(5) Å, respectively and the hydrogen bonds are nearly linear (173(6)° and 176(7)°). An intermolecular ring···ring interaction contact occurs between the two symmetry-related bipy ligand [Cg5=N(1), C(1), C(2), N(2), C(3), C(4) and Cg6=N(3), C(7), C(8), C(9), C(10), C(11); Cg5···Cg6^{i} 3.7345 Å, (i): −x,−y,−z], while C–H···π interaction take place between C(2)–H(2) ···Cg(6) [2.91 Å], C(9) –H(9) ···Cg(5) [2.89 Å], C(8) –H(8) ···Cg(7)^{ii} [2.91 Å, (i): −x,−1/2 + y,1/2 − z] and C(15) –H(15) ···Cg(6)^{iii} [2.83 Å, (iii): x,1/2 − y,−1/2 + z] (Fig. 10). From all of these intermolecular interactions give a two-dimensional network results (Fig. 11).

4. Conclusion

We have successfully synthesized and characterized the three novel dimeric and polymeric Cu(II)-pyrazine-2,3-dicarboxylate complexes. The molecular structures of dinuclear **(1)** and polynuclear **(2** and **3)** complexes have also been determined by the single crystal X-ray diffraction technique. The pyrazine-2,3-dicarboxylate behaves as a tridentate bridging ligand.

ABSTRACT

The synthesis and structural chemistry of four new divalent transition metal complexes of the fluorene ligands 4,5-diazaspirobifluorene (L1) and bis-9-biphenyl-4,5-diazafluorenyl peroxide (L2), $[Cu_3(L1)_4(NO_3)_6(H_2O)_2]\cdot 2CH_3CN$ (**1**), $[Cu(L1)(CH_3CO_2)_2(H_2O)]\cdot 2H_2O$ (**2**), $[Cd(L1)_2(NO_3)_2]\cdot DMF$ (**3**) (DMF = N,N-dimethylformamide) and $[Zn_2(L2)(\mu\text{-}Cl)_2Cl_2]_\infty$ (**4**) are described. Single-crystal X-ray diffraction analysis reveal that the four complexes exhibit various frameworks due to diverse coordination modes and different conformations of ligands L1 or L2, as well as nitrate, acetate or chloro counterions. L1 in complexes **1**, **2** and **3** present an asymmetric rigid bidentate ligand with two nitrogen atoms as the donor sites. Novel complex **4** was formed through complexation between conformationally bent shaped peroxide ligands and zinc(II) dichlorides that adopt a linear coordination geometry, which can also give rise to extended polymeric chains with a zigzag secondary structure.

1. Introduction

Organocopper, cadmium and zinc complexes have been widely explored due to their rich structural chemistry [1] and importance in organic synthesis [2], and in polymerization chemistry [3], e.g., as well-defined catalysts for the copolymerization of CO_2 and epoxides [4]. The applications of these complexes must be based on the fundamental understanding of their components and structure chemistry. Hence it is of interest to study the coordination modes and structural features of the complexes. Several rigid multidentate oxygen-donor ligands have been used to design and synthesize the metal–organic complexes [5,6]. At the same time, many rigid bidentate nitrogen-donor ligands, such as 2,2′-bipyridine and its derivatives have also been used to prepare the metal organic materials [7]. However, the nitrogen-donor ligands with larger volumes are not easy to coordinate with the metal ions because of the large steric hindrance, and larger crystals suitable for single-crystal XRD analysis are difficult to obtain due to the low coordination strength of the nitrogen-donor organic ligands caused by the less negative charge on the nitrogen compared with the oxygen [8]. The coordination chemistry of the rigid ligand 4,5-diazaspirobifluorene has rarely been reported, except for a complex with silver ion [9]. In order to study the structure feature of the transition metal complex with the rigid and bulky ligands and the coordination code of the nitrogen-donor ligands, herein, we report the synthesis, characterization, and crystal structure of copper(II), cadmium(II) and zinc(II) complexes bearing bipyridine-based N,N-chelate fluorene ligands, 4,5-diazaspirobifluorene (L1) and bis-9-biphenyl-4,5-diazafluorenyl peroxide (L2). Remarkably, we have obtained the first zinc complex with peroxide so far, which may have potential applications in catalysis chemistry in the future.

2. Experimental

2.1. General

All of the reagents were commercially available and used as purchased. 9-Biphenyl-4,5-diazafluorenol and 4,5-diazaspirobifluorene was prepared according to the literature [10]. Interestingly, along with the expected 4,5-diazaspirobifluorene, bis-9-biphenyl-4,5-diazafluorenyl peroxide was unexpectedly formed as a by-product by the oxidation of 9-biphenyl-4,5-diazafluorenol with H_2SO_4/HOAc.

The elemental analysis was carried out with a Perkin–Elmer 240C elemental analyzer. ^1H NMR spectra were performed on a Bruker model Advance DRX 500 spectrometer in DMSO-d_6 and were referenced to TMS. The FT-IR spectra were recorded from KBr pellets over the range 4000–400 cm^{-1} with a Vector 22 spectrometer. The emission/excitation spectra were recorded with a

Hitachi 850 fluorescence spectrophotometer by using 1×10^{-4} M CH_3CN solution. Optical absorption spectra were collected on a Shimadzu 3100 spectrophotometer at room temperature. The absorbance was directly proportional to the concentration of complexes in the range from 1×10^{-4} M to 1×10^{-3} M.

2.2. Preparation of $[Cu_3(L)_4(NO_3)_6(H_2O)_2] \cdot 2CH_3CN$ (**1**)

Equimolar amounts of 4,5-diazaspirobifluorene (0.079 g, 0.25 mmol) and $Cu(NO_3)_2 \cdot 3H_2O$ (0.061 g, 0.25 mmol) were stirred together in CH_3CN (30 ml) at room temperature for 2 h. The resulting glaucous solution was filtered and concentrated to 10 ml. Blue block crystals of complex **1** suitable for X-ray diffraction were obtained in 69% yield by slow diffusion of diethyl ether into the filtrate for several days. At room temperature, crystals of complex **1** are unstable and decompose slowly into blue powder over the course of several days. *Anal.* Calc. for $C_{96}H_{62}Cu_3N_{16}O_{20}$ (1950.24): C, 59.12; H, 3.21; N, 11.49. Found: C, 59.36; H, 3.44; N, 11.23%. ^{1}H NMR (DMSO-d_6): δ = 8.09 (s, 4H, $H_{1,7}$), 7.44 (s, 4H, $H_{3,4}$), 7.17 (s, 4H, $H_{5,6}$), 6.68 (s, 2H, H_2), 2.07 (s, 3H, CH_3CN) (see Table 4 for the atom numbering arrangement). IR data (KBr, cm^{-1}): 3447 (s), 3053 (vw), 1578 (w), 1473 (m), 1447 (m), 1406 (s), 1384 (s), 1279 (s), 1169 (w), 1013 (w), 797 (w), 765 (m), 737 (m) cm^{-1}.

2.3. Preparation of $[Cu(L)(CH_3CO_2)_2(H_2O)] \cdot 2H_2O$ (**2**)

Similar procedures were performed to obtain blue crystals of complex **2**, except that $Cu(CH_3CO_2)_2 \cdot 4H_2O$ was used instead of $Cu(NO_3)_2 \cdot 4H_2O$, yield 55%. *Anal.* Calc. for $C_{27}H_{26}CuN_2O_7$ (554.04): C, 58.53; H, 4.73; N, 5.06. Found: C, 58.33; H, 4.77; N, 5.21%. ^{1}H NMR (DMSO-d_6): δ = 8.84 (s, 2H, H_1), 8.07 = (d, 2H, H_7, J = 7.31), 7.46 (t, 2H, H_3, J = 14.11), 7.33 (s, 2H, H_4), 7.18 (s, 4H, $H_{5,6}$), 6.70 (d, 2H, H_2, J = 7.00), 2.45 (s, 6H, CH_3CO_2) (see Table 4 for the atom numbering arrangement). IR data (KBr, cm^{-1}): 3423 (s), 2927 (w), 1606 (s), 1404 (s), 1339 (w), 1163 (w), 807 (w), 762 (m), 737 (m), 676 (w) cm^{-1}.

2.4. Preparation of $[Cd(L)_2(NO_3)_2] \cdot DMF$ (**3**)

A mixture with a stoichiometric 2:1 solution of ligand L1 (0.079 g, 0.50 mmol) and $Cd(NO_3)_2 \cdot 4H_2O$ (0.077 g, 0.25 mmol) in CH_3CN (30 ml) were stirred together for 2 h at room temperature. The clear solution thus obtained was evaporated under vacuum to form a white solid and recrystallized from CH_2Cl_2–DMF to give colorless crystals, yield 70%. *Anal.* Calc. for $C_{52}H_{42}CdN_8O_8$ (1019.34): C, 61.27; H, 4.15; N, 10.99. Found: C, 61.09; H, 3.99; N, 10.46%. ^{1}H NMR (DMSO-d_6): δ = 8.71 (d, 2H, H_1, J = 3.34), 8.07 = (d, 2H, H_7, J = 7.61), 7.96 (s, 1H, DMF–H), 7.45 (d, 2H, H_3, J = 7.49), 7.26 (t, 2H, H_4, J = 6.88), 7.16 (d, 4H, $H_{5,6}$, J = 7.08), 6.70 (d, 2H, H_2, J = 7.64), 2.89, 2.73 (s, 6H, DMF–CH_3) (see Table 4 for the atom numbering arrangement). IR data (KBr, cm^{-1}): 3449 (w), 3074 (w), 2922 (w), 1661 (s), 1582 (m), 1432 (s), 1408 (s), 1383 (s), 1298 (s), 1166 (w), 1089 (w), 1028 (w), 954 (w), 803 (w), 762 (m), 738 (m), 652 (w) cm^{-1}.

2.5. Preparation of $[Zn_2(L2)(\mu\text{-}Cl)_2Cl_2]_\infty$ (**4**)

A solution containing anhydrous zinc dichloride (0.071 g, 0.50 mmol) and bis-9-biphenyl-4,5-diazafluorenyl peroxide (0.168 g, 0.25 mmol) in CH_3CN (30 ml) was stirred for 2 h at room temperature. The resulting light brown solution was filtered, and then it was left open for slow evaporation of the solvent at room temperature. After standing for two weeks, small needle-like crystals of complex **4** were obtained, yield 50%. Because the growing rate of crystal is too fast, the structure quality of complex **4** is not high. Calc. for $C_{23}H_{15}Cl_2N_2OZn$ (471.64): C 58.57, H 3.21, N 5.94. Found: C, 58.44, H, 3.60, N, 5.99%. ^{1}H NMR (DMSO-d_6): δ = 8.35 (d, 2H, H_1, J = 4.00), 8.13 (d, 1H, H_7, J = 8.00), 7.57 (m, 1H, H_{10}, J = 30.00), 7.37 (t, 1H, H_6, J = 14.50), 7.19 (d, 2H, H_3, J = 7.50), 6.97 (t, 1H, H_4, J = 12.00), 6.85 (d, 1H, H_9, J = 7.00), 6.77 (t, 1H, H_8, J = 14.50), 6.54 (t, 2H, H_5, J = 15.00), 5.86 (d, 2H, H_2, J = 7.00) (see Table 4 for the atom numbering arrangement). IR (KBr pellet): ν = 3435 (s), 1600 (m), 1586 (m), 1473 (w), 1438 (w), 1411 (s), 1161 (m), 1008 (m), 814 (w), 769 (m), 707 (m), 557 (w) cm^{-1}.

2.6. Crystal structure determination and refinement

Suitable single crystals were selected for indexing and intensity data were measured with a Bruker Smart Apex CCD diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) at 298 K. The raw data frames were integrated into SHELX-format reflection files and corrected using the SAINT program. Absorption corrections based on multiscans were obtained from the SADABS program. The structures were solved with direct methods and refined with full-matrix least-squares techniques using the SHELXS-97 and SHELXL-97 programs, respectively. Metal atoms in each complex were located from the *E*-maps, and other non-hydrogen atoms were located in successive difference Fourier syntheses, where they were refined with anisotropic thermal parameters on F^2. The hydrogen atoms of the ligands were generated theoretically onto the specific atoms and refined isotropically with fixed thermal factors. The hydrogen atoms of the water molecules were located using the different Fourier method and refined freely. Further details for structural analysis are summarized in Tables 1 and 2.

3. Results and discussion

3.1. Synthesis of metal complexes

Complexes **1**–**4** have been prepared in moderate to good yields (50–70%) by mixing acetonitrile solutions of ligand L1 or L2 with a salt of a divalent metal, M^{II} = Cu, Cd, Zn (Scheme 1). Crystal of **1** or **2** can be obtained through slow diffusion of diethyl ether into the reaction mixture. Otherwise, crystals for cadmium and zinc complex have grown tardily from the solution along with the volatilization of the solvent acetonitrile, respectively. From the crystal structure of complex **1**, we could deduce that ligand L forms a

4:3 complex with copper(II) nitrate (Fig. 1), although the reaction was processed in a 1:1 ratio.

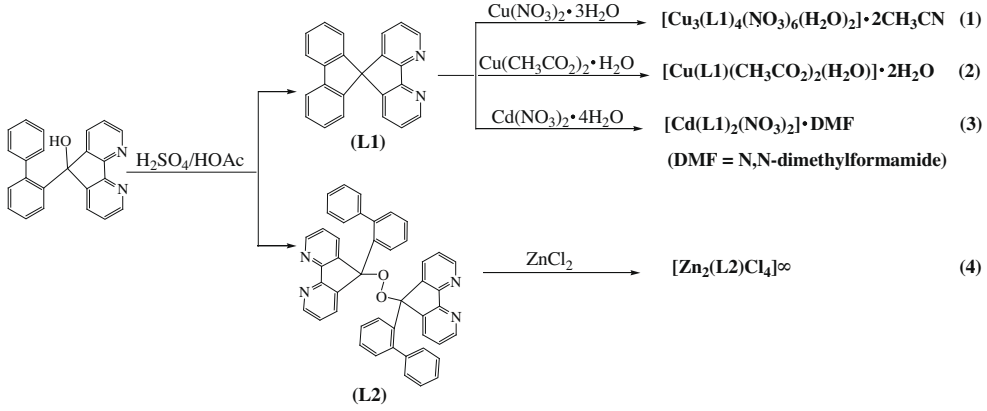
Reactions of ligand L1 with one equivalent of copper(II) acetate yielded complex **2** whose chemical analysis suggested a 1:1 ratio of ligand to metal salt. This result parallels the reaction of substituted 2,2′-bipyridine with copper(II) acetate which forms a simple four-coordinate 1:1 complex [11]. In contrast, crystals from a mixture of ligand L1 and cadmium(II) nitrate with a 2:1 ratio in DMF/CH_2Cl_2 were shown by X-ray crystallography to be a DMF solvate.

The addition of ligand L2 in a 1:2 ratio to a acetonitrile solution of $ZnCl_2$ after two weeks, accompanied with slow evaporation of the solvent at room temperature, results in small needle-like crystals of complex **4**.

3.2. X-ray crystallography

Single crystals suitable for X-ray analysis could be obtained for all five compounds in this study. The solved crystal structures are shown in Figs. 1, 3, 5, 6 and 9, and the selected bond lengths and angles are collected in Table 3.

3.2.1. $[Cu_3(L1)_4(NO_3)_6(H_2O)_2]\cdot 2CH_3CN$ (**1**)



Single-crystal X-ray study reveals that the asymmetric unit of complex **1** consists of three crystallographically independent molecules. Thus, the structure of $[Cu_3(L1)_4(NO_3)_6(H_2O)_2]\cdot 2CH_3CN$ is best represented by the formula $[Cu(L1)_2(H_2O)_2]\cdot[Cu(L1)(NO_3)_3]_2\cdot 2CH_3CN$, and for clarity, of two molecules with identical structures only one is shown in Fig. 1. From crystal structure of complex **1** we can see that the coordination geometry of Cu1 center is unusual in that the elongated Jahn–Teller axis of the molecule lies along the N–Cu–N vector [Cu1–N2 = 2.631(2) Å] and not in the O–Cu–O axis [Cu1–O1 = 2.002(3) Å], which is occupied by water molecules. To our knowledge, this is one of only two examples of $N_2O_2N'_2$ coordination to a Cu(II) center with two water molecules bound *trans* in the equatorial plane and the nitrogen atoms of the chelates directed along the *J–T* axis. [12] This $N_2X_2N'_2$ geometry has been observed in other Cu(II) complexes with the 4,5-diazafluorene template and other anions such as Cl^-, Br^- or NO_3^- [12,13], while complexes with transition metals other than Cu(II) (e.g., Re(I), [14] Co(II) [15]) typically exhibit a more symmetrical coordination.

On the other hand, the environment of Cu2 center is square pyramidal. The basal plane is built by a nitrogen atom from the ligand L1 and three oxygen atoms of three nitrate groups, whereas the apical position is occupied by the other nitrogen atom of the bidentate ligand L1. Main bond distances and angles for non-hydrogen atoms are listed in Table 3. Meanwhile, the structure analysis indicates that biphenyl and 2,2′-bipyridine units in two kinds of coordinated ligand L1 are both perpendicularly cross-linked by a carbon atom. The dihedral angles between the mean planes of the two units are 88.6° (L1 coordinated to Cu1) and 91.5° (L1 coordinated to Cu2), which are very similar to that in the crystal structure of the free ligand L1 we have reported previously [16].

Interestingly, as can be seen from Fig. 2, a one-dimensional supramolecular chain is formed by intermolecular hydrogen bonding involving the water molecules coordinated to the copper center which chelated by two bidentate ligands L1 and the nitrate oxygen atoms coordinated to the other copper center (Table 4). Undoubtedly, these hydrogen bonds contribute to the stability of the whole crystal structure.

3.2.2. $[Cu(L1)(CH_3CO_2)_2(H_2O)]\cdot 2H_2O$ (**2**)

Copper(II) acetate forms a variety of structures with unsubstituted 2,2′-bipyridine. The formation of multinuclear systems containing two or three copper ions [17–19], polymers [20] and a mononuclear cation [21] $[Cu(bipy)_2(acetate)]^+$ are facilitated by the possibility of acetate either acting as a bidentate ligand, or using one oxygen atom to bridge two metal centers. To determine the structure feature of the complex formed by 2,2′-bipyridine-based ligand L1 and copper(II) acetate, complex **2** was synthesized

Scheme 1. Synthetic routes of the ligands L1, L2 and complexes **1**–**4**.

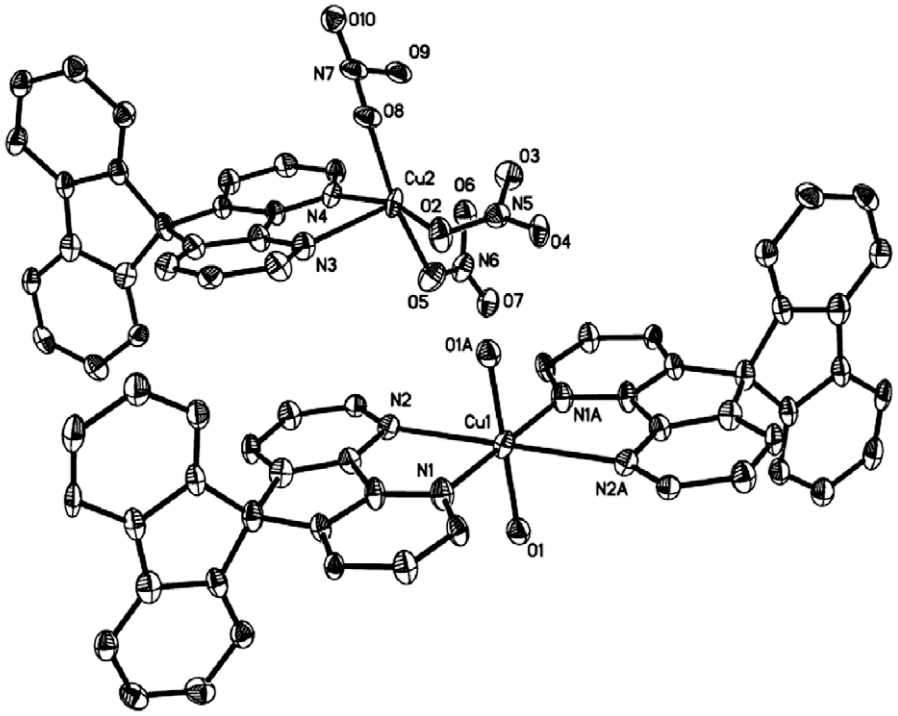


Fig. 1. X-ray single crystal structure of complex **1** (thermal ellipsoids at 30% probability).

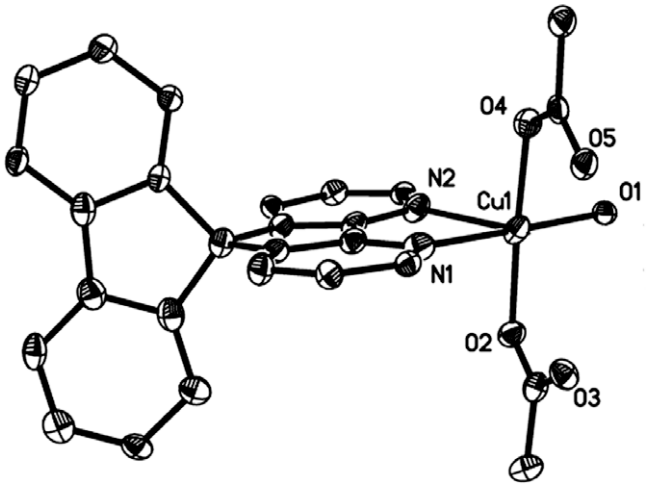

Fig. 3. X-ray single crystal structure of complex **2** (thermal ellipsoids at 30% probability).

in our case, which was characterized by X-ray crystallography. The molecular structure is shown in Fig. 3, which is different from the mononuclear copper(II) complexes mentioned above. The crystal structure of **2** consists of mononuclear units in which the copper(II) center surrounding is square pyramidal. A nitrogen atom (N2) from the bidentate ligand L1 is in the apical position. Two oxygen atoms (O2 and O4) from the monodentate acetate groups, one oxygen atoms (O1) from a water molecule and the other nitrogen atom of ligand L1 (N1) build the basal plane. The Cu–N bond distances are similar to those observed in the foregoing mononuclear five-coordinate molecular structure of complex **1**. However, the Cu–O (water oxygen atom) [1.961(3) Å] is slight shorter than the one [2.002(3) Å] observed in the foregoing another six-coordinate molecular structure of complex **1**. N1, O1, O2, and O4 atoms fall on a plane: the largest deviation from the mean plane is −0.0273 Å for O1. The copper(II) ion is 0.032(3) Å out of this plane. The value of the axial copper-nitrogen distance is 2.489(3) Å, which is much longer than the observed one [2.037(3) Å] in the quadrilateral plane.

In **2** there are no π–π aromatic interactions between the biphenyl or bipyridyl rings, Fig. 4, but there are several sets of intermo-

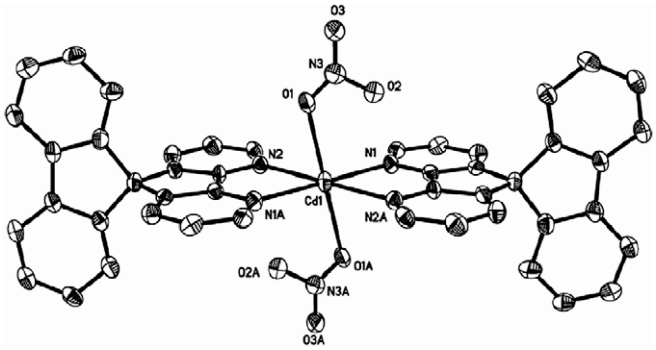

Fig. 5. Molecular structure of complex **3**. Thermal ellipsoids are at the 30% probability level.

lecular hydrogen bonding (see Table 4) between the waters of crystallization and the coordinated acetic groups which link the adjacent molecules into an infinite one-dimensional supramolecular chain (Fig. 4).

3.2.3. $[Cd(L1)_2(NO_3)_2] \cdot DMF$ (**3**)

The crystal structure of complex **3** unambiguously confirms the $[Cd(L1)_2]$ stoichiometry as well as the bidentate nature of the ligand L1 (Fig. 5). The cadmium atom lies on a crystallographic inversion center. N_4O_2 coordination polyhedron around the Cd(II) center is Jahn–Teller distorted octahedron. Four N atoms from the two ligands L1 coordinate to the Cd(II) center in the equatorial plane, wherein, for each ligand moiety, one Cd–N distance is slightly longer than the other [2.447(4) and 2.329(3) Å]. Two nitrate counterions occupy the apical position, d(Cd–O) = 2.411(5) Å. The bite angle of the ligand L1 [77.14°] indicates that there is a certain strain in the six-membered chelate ring. According to the literatures, this is the first example of $N_2O_2N'_2$ coordination to a Cd(II) center with four nitrogens of the chelates bound in the equatorial plane and two *trans* nitrates directed along the *J–T* axis. [22,23] Similar $N_2O_2N'_2$ geometry has been observed in other Cd(II) complex with the 4,5-diazafluorene template and anions NO_3^-, while it typically exhibit a more symmetrical coordination by adopting *cis* structures for two nitrate anions and two bidentate ligands (e.g., 4′,5′-diaza-9′-(4,5-bis(ethylthio)-1,3-dithiole-2-ylidene)-fluorene) [23].

3.2.4. $[Zn_2(L2)(\mu\text{-}Cl)_2Cl_2]_\infty$ (**4**)

A section of the one-dimensional polymer $[Zn_2(L2)(\mu\text{-}Cl)_2Cl_2]_\infty$ is illustrated in Fig. 6; selected intramolecular distances and angles are presented in Table 3. The asymmetric unit contains only one-half of the molecules, the remainder being generated by a center of symmetry located on the O–O bond. The structure features of the peroxide group in **4** are similar to those of ap-9-(*o*-isopropylphenyl)-9-fluorenyl peroxide. [24] They include a C–O–O–C dihedral angle of 180°, and C–O and O–O distances of 1.433(4) and 1.473(5) Å, respectively. One phenyl ring of the biphenyl group is nearly perpendicular to their respective fluorenyl rings [79.7°], and the other is parallel to the fluorenyl ring [21.3°]. Meanwhile, the symmetry requires the two fluorene-ring planes connected by the O–O bond to be anti-parallel, which is also the case for the corresponding four phenyl-ring planes. In the similar fluorene

peroxide mentioned above [24], there only exists the perpendicular phenyl ring.

In complex **4**, zinc(II) centers are linked by bis-9-biphenyl-4,5-diazafluorenyl peroxide ligands to form an infinite zigzag chain. Terminal and bridged chloro groups complete the distorted trigonal–bipyramidal coordination around each metal ion. The coordination geometry of **4** is novel, in which one nitrogen atoms (N2, from the ligand L2) and two chloride ions (Cl1, Cl2) are in the basal plane, another nitrogen atom of the ligand (N1) and a chloride ion Cl2^{i} from the neighboring molecular unit occupy the axial position [symmetry code i: $1-x$, $2-y$, $-z$]. The distortion of the trigonal-bipyramid is indicated by the fact that the basal donor atoms not planar but deviate by as much as 0.0176 Å from their least-squares plane, and by the angle of N1–Zn1–Cl2^{i} [162.3(1)°]. As usual in the case of zinc(II) compounds, the axial Zn–Cl distance [2.718(1) Å] is much longer than the ones in the basal plane [2.233(1) and 2.185(1) Å].

An additional structural feature of interest is the involvement of four-membered Zn_2Cl_2 ring. The four-membered ring is coplanar completely with four atoms Zn1, Cl2, Zn1^{i} and Cl2^{i}. The Zn–Zn distance in the coordination dimmer is 3.630 Å, which is comparable with the Zn–Zn distance of 3.620 Å in the reported $[ZnCl_2(\mu\text{-bipy})]_\infty$ (bipy = 4,4′-bipyridine) polymer [1a].

Because of the flexibility of the ligand L2, the geometry arrangement between the biphenyl and 2,2′-bipyridine units in complex **4** differentiates markedly from that of the ligand L1. The most interesting characteristic is that one of the phenyl ring is approximately paralleled to the 2,2′-bipyridyl ring.

The role of π–π stacking interaction in the stability of structures in metal–organic coordination compounds has been a topic of much interest. [25,26] In the present complex, π–π interaction involving the 9-biphenyl-4,5-diazafluorenyl peroxide is also observed (Fig. 7). The centroid–centroid distance (d) between the phenyl and the bipyridyl rings is 3.495 Å and their interplanar angle (θ) is 20.9°. It should be noted that the intramolecular π–π interactions play an important role for the structural stability.

All efforts to obtain the crystal structure of the ligand L2 were not successful so far. However, we have determined the structure of the precursor of the ligands L1 and L2, 9-biphenyl-4,5-diazafluorenol. As it is shown from Fig. 8, in each independent fluorenol molecule there is an intramolecular π–π interaction which is extremely identical with the π-π interaction observed in complex **4.** So

Table 5
^{1}H NMR spectroscopic data for complexes containing L1 or L2.

L1 L2

	Hydrogen					
1	8.09 (1,7-H)		7.44 (3,4-H)	7.17 (5,6-H)		6.68 (2-H)
2	8.84 (1-H)	8.07 (7-H)	7.46 (3-H)	7.33 (4-H)	7.18 (5,6-H)	6.70 (2-H)
3	8.71 (1-H)	8.07 (7-H)	7.45 (3-H)	7.26 (4-H)	7.16 (5,6-H)	6.70 (2-H)
4	8.35 (1-H)		8.13 (7-H)	7.57 (10-H)	7.37 (6-H)	7.19 (3-H)
	6.97 (4-H)		6.85 (9-H)	6.77 (8-H)	6.54 (5-H)	5.86 (2-H)

it can be concluded that, when the biphenyl group is not fully fixed to the 9-position carbon atom appeared in the ligand L1, the conformation of one phenyl ring perpendicular to the fluorenyl ring and the other parallel is the most stable. Meanwhile, there also exists intermolecular π–π interaction for the fluorenyl rings between two adjacent 9-biphenyl-4,5-diazafluorenol in the unit cell, which contributes to the stability of the whole crystal structure.

3.3. ^{1}H NMR spectroscopy

All ^{1}H NMR spectra were measured in DMSO-d_6 for consistency. The ^{1}H NMR chemical shifts for complexes **1**–**4** are shown in Table 5.

From the ^{1}H NMR spectra of complexes **1**–**4** we can see that, different metal ions or coordination geometry have less affect on the chemical shift of the ligands in the complex except complex **1**. Both complex **2** and **3** exhibit six sets of aromatic hydrogen between 6.70 and 8.84 ppm. Only obvious difference for the protons at the 1 ortho-position of nitrogen-donor atoms can be found. But for complex **1**, due to the existence of two kinds of coordination geometry between ligand L1 and copper center, and the environment of some aromatic hydrogen have mixed a lot and shown only four

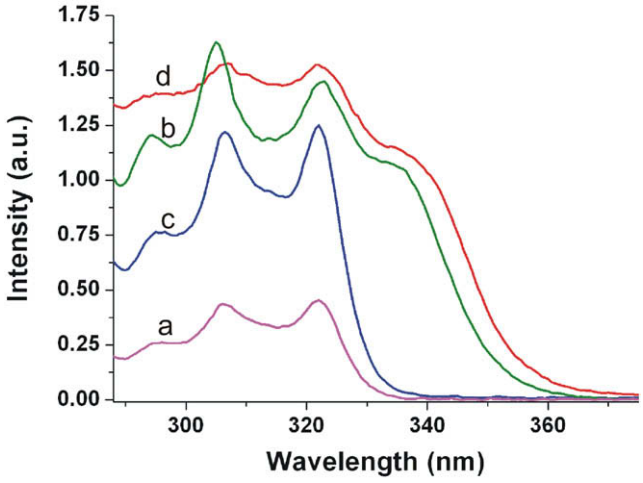

Fig. 10. Absorption spectra of L1 (a) and complex**1** (b), **2** (c), **3** (d) at 298 K in CH_3CN.

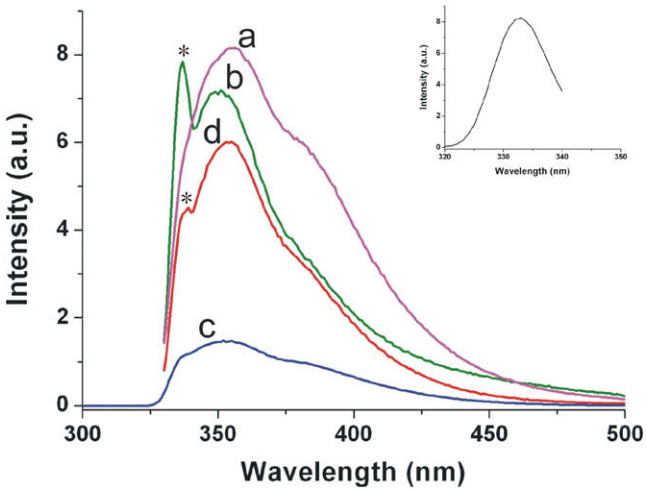

Fig. 11. Emission spectra of the free ligand L1 (a) and complex **1** (b), **2** (c), **3** (d) in CH_3CN solution at room temperature, excited at 333 nm (the peaks with a star are assigned to the scattering of the excitation; *inset:* excitation spectrum of the fluorescent species).

types of chemical shifts in the ^1H NMR spectra. Just like the proton environment of ligand L2 themselves, the ^1H NMR spectra of complex **4** shows ten sets of different types of aromatic hydrogen.

3.4. UV–Vis and fluorescent spectra of complexes *1*–*3*

The UV–Vis spectral data of the ligand L1 and the three complexes in acetonitrile were measured. The dominant vibronic absorption peaks in complexes **1**–**3** at ~294, ~305, and ~322 nm can be ascribed to the ligand-centered (LC) π–π^* transitions. These spectral assignments were made on the basis of their spectral similarities with those of free ligand L1 (see Fig. 10) and a silver(I) complex with L1 [9]. Furthermore, for complex **1** and **3**, the Cu(II) and Cd(II) d–d transitions are observed as a single broad feature centered at 334 nm, consistent with a 6-coordinate mixed N, O coordination environment. [27]

In acetonitrile (CH_3CN), both the ligand L1 and corresponding metal complexes are emissive; fluorescent emission at UV wavelength (354 nm) of the free ligand L1 can be attributed to the ligand-centered π^*–π relaxation (Fig. 11). Ligand-based emission bands (~354 nm) are preserved in the corresponding Cu or Cd complexes, but the Ag complex reported previously is intrinsically nonluminescent throughout 350–800 nm in any organic solvent [9].

Crystal structure

ABSTRACT

The structures of two forms of a mixed anionic one-dimensional coordination polymers of lead(II) nitrate derived from benzoate and 2,2'-bipyridyl N-oxide are reported. The X-ray crystal structures show subtle differences in the two binding modes of nitrate in the coordination polymers obtained from two independent solvents. The solid state UV–Vis spectra show differences in the absorption pattern of the crystalline solids obtained from different solvents. The solid state UV–Vis spectra as well as the solution spectra are compared.

1. Introduction

With the recent advancement in the area of inorganic supramolecular chemistry, there has been increasing interest in the studies on the sub-areas like supramolecular isomerism [1,2], topological isomerism [3], and structural isomerism [4]. Occurrence of such isomerism is dependent on various factors viz. reaction condition, temperature, solvents, etc. [5]. However only few reports are there that exemplify the effect of solvents on the formation of supramolecular isomers [6]. Although, a good number of reports are there regarding coordination polymers of lead [7–12] to our best of knowledge only a limited number of lead complexes show supramolecular isomerism [13]. Recently our group has shown that the nitro group orientation around a binuclear structure of cobalt (II) complex can lead to different supramolecular isomers [14]. With the objective of understanding the effect of different solvents on the orientation of the molecules in a superstructure we have studied the possibility of coordination isomerism in polymeric mixed anionic lead complex containing nitrate group as one of the ligands. Herein, we report the structures of two mixed anionic one-dimensional coordination polymers of lead(II) having composition $[Pb(Ben)(BPNO)(NO_3)]_n$; in which we have observed interesting solid state and solution properties occurring from slightly different orientation of the coordinating nitrate group.

2. Experimental

Solid state UV–Vis spectra were recorded with KBr pellets in a Perkin Elmer Lambda 750 UV–Vis spectrometer (UV–Vis resolution $\leqslant 0.17$ nm). Infrared spectra were recorded with a Perkin–Elmer FT-IR spectrometer in the range 4000–400 cm^{-1} (FT-IR resolution $\leqslant 0.5$ cm^{-1}). The X-ray crystallographic data were collected at 296 K with Mo Kα radiation ($\lambda = 0.71073$ A°) using a Bruker Nonius SMART CCD diffractometer equipped with graphite monochromator. The SMART software was used for data collection and also for indexing the reflections and determining the unit cell parameters; the collected data were integrated using SAINT software. The structures were solved by direct methods and refined by full-matrix least-squares calculations using SHELXTL software. All the non-H atoms were refined in the anisotropic approximation against F^2 of all reflections. The H-atoms, except those attached to N and O were placed at their calculated positions and refined in the isotropic approximation; those attached to heteroatoms (N, O) were located in the difference Fourier maps, and refined with isotropic displacement coefficients. The crystallographic parameters are given in Table 1.

2.1. Synthesis of bidentate-nitrato-$[Pb(Ben)(BPNO)(NO_3)]_n$ (**1**) and monodentate-nitrato-$[Pb(Ben)(BPNO)(NO_3)]_n$ (**2**)

For the synthesis of **1** sodium benzoate (2 mmol, 0.288 g) was dissolved in methanol (10 mL). After stirring for about 30 min lead(II) nitrate (1 mmol, 0.331 g) and 2,2'-bipyridyl N-oxide (1 mmol, 0.188 g) was added and stirred for another 30 min. A white precipitate appeared. The precipitate was dissolved in a methanol:toluene mixture (2:1) (20 mL) by warming. The clear solution was

Found: C, 34.76; H, 2.02%.

From another identical reaction in dimethylformamide (10 mL), the white precipitate formed was dissolved in a mixed solvent of dimethylformamide (10 mL) and methanol (5 mL) followed by warming. Yellow colored crystals of **2** were obtained after a week. Isolated yield, 77%. IR (KBr, cm^{-1}): 1593 (m), 1537 (m), 1424 (m), 1384 (s), 1319 (m), 1208 (m), 847 (m). *Anal.* Calc.: C, 35.29; H, 2.26. Found C, 34.66; H, 2.11%. UV (methanol, λ_{max}) 230 nm, 265 nm (sh).

3. Results and discussion

The reaction between lead(II) nitrate with sodium benzoate in the presence of 2,2′-bipyridyl N-oxide (BPNO) leads to two forms of a mixed anionic coordination polymers (Scheme 1). The two forms of the polymer have differences in their physical properties but they have very closely related structures.

Scheme 1.

The reaction of lead(II) nitrate with sodium benzoate and BPNO in a mixed solvent containing methanol and toluene (2:1) leads to the coordination polymer **1** having composition [Pb(Ben)(BPNO)(-NO_3)]$_n$. Unlike this, the synthesis of **2** was performed using lead(II) nitrate with benzoate and BPNO in dimethylformamide. During both the syntheses the reaction mixtures were refluxed for few minutes, to dissolve the precipitate that appeared after addition of the BPNO ligand. The crystals of **1** were obtained as colorless thin needles whereas **2** crystallize as pale yellow blocks. Good quality crystals of both the forms were obtained within a week or so, which were analyzed by using single crystal X-ray diffraction technique, powder X-ray diffraction technique and also with other spectral analysis viz. UV–Vis spectroscopy and FT-IR spectroscopy.

The X-ray structural analysis of **1** reveals the formation of a mixed anionic one-dimensional coordination polymer. It is a well known fact that the lead complexes can have different co-ordination numbers varying from 2 to 10 [7–10]. Each of the lead(II) centers in coordination polymer **1** is nine coordinated. Four of these coordination are provided by the bridging N-oxide ligands, three by carboxylate and rest two are by a chelating nitrate anion. It crystallizes in the space group *P*2(1)/*c*. In the structure **1** Pb1–O5 distance is 2.721(9) Å and the Pb1–O6 distance is 2.923(4) Å. Some of the important bond angles are Pb1–O5–N3, 101.2(5)°; Pb1–O6–N3, 92.4(3)°; O5–N3–O6, 119.0(6)°. Structure of the coordination polymer is shown in Fig. 1b along with its asymmetric unit in Fig. 1a.

As shown in Fig. 2a, all the lead(II) centers in **2** are eight coordinated. Unlike **1** the nitrate group in **2** coordinates to the lead(II) center in a monodentate fashion. All other coordination remaining identical to **1**, the monodentate nitrate offers the metal node an eight coordinated geometry. However, the bond parameters of the nitrate group in the complexes are so similar that it is difficult to distinguish them with authority. In the coordination polymer 2 the Pb1–O5 distance is 2.683(7) Å and there is no coordinating bond between Pb1 and O6 (distance of separation is 2.935(3) Å) as shown by the software Mercury 1.4.2. The bond angles around the nitrate group of this form are also slightly different from those of **1**: Pb1–O5–N3, 102.7(4)°; Pb1–O6–N3, 92.0(2)°; O5–N3–O6,

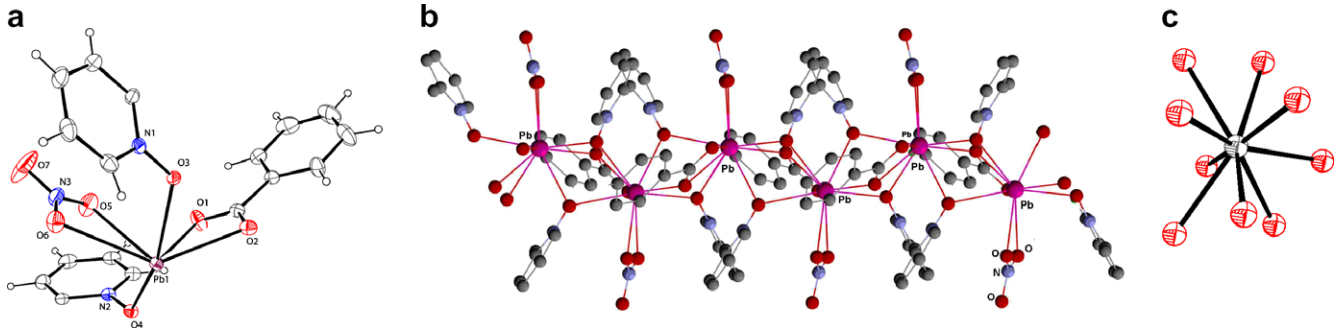

Fig. 1. (a) Smallest building block of **1;** (b) the polymeric structure of **1** showing chelating nitrates; and (c) the nine coordinated environment around lead.

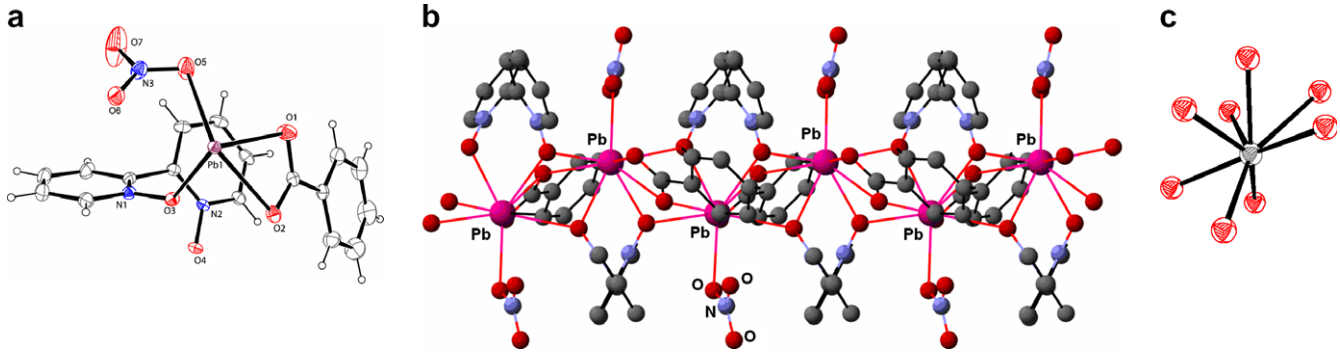

Fig. 2. (a) Smallest building block of **2;** (b) the polymeric structure of **2** showing mono-dentate nitrates; and (c) the eight coordinate geometry around lead.

118.0(4)°. The differences in the bond angles around the nitrate groups of two compounds namely O5–N3–O6 discern the difference in the co-ordination geometry.

To differentiate the coordination environment around the lead various lead-oxygen bond distances in the complexes are listed in Table 2.

The structure of the coordination polymer **2** is shown in Fig. 2b along with its asymmetric unit in Fig. 2a. The compounds have their characteristic IR absorptions at 1421–1424 cm^{-1} and 1316–1319 cm^{-1} due to the metal bound nitrate groups and at 1208–1210 cm^{-1} due to the N-oxide functionality of BPNO. The carbonyl frequency appears at 1591–1593 cm^{-1}. Benzoate ligand can have different binding modes, such as monodentate, bidentate, bridging while binding to lead ions [14,15,11,12,16], however in the present cases, each lead ion is associated with one chelating benzoate, which acts as bridge to anchor another lead ion to make a polymeric chain like structures. The polymeric chains have also two other bipyridine N-oxide bridges. The overall binding mode of benzoates in the complexes can be represented as oxo-bridged chelated carboxylate. Unfortunately, it is very difficult to differentiate the two forms of the polymers **1** and **2** from their FT-IR spectra.

Both the forms are found to crystallize in the same space group *P*2(1)/*c*. The unit cell differs slightly which is obvious as the two complexes differ slightly only in the binding mode of the nitrate ion and have identical composition. To check the bulk property of these forms, we have checked the powder X-ray diffraction pattern, which matches to the simulated one quite well (see Supplementary data). However, the powder X-ray diffraction patterns are also not found to be very informative as it also could not distinguish the two forms.

The colors of the crystals obtained for the two forms differ from one another to a considerable extent. The solid state UV–Vis spectra of both the isomers are shown in Fig. 3. It is clear from the spectra obtained that they are almost identical throughout the region of study except in the range 200–250 nm. Interestingly this region is known to be the region for $\pi \rightarrow \pi^*$ transition of the nitrate group [17]. The compound **1** absorbs at 221 nm while the compound **2** absorbs at 211 nm. This difference in the position of absorbance

Table 2
The lead–oxygen bond distances in the complexes.

Bonds	Bond length for **1** (Å)	Bond length for **2** (Å)
Pb1–O1	2.542(4)	2.545(3)
Pb1–O2	2.622(3)	2.623(2)
Pb1–O3	2.529(3)	2.545(19)
Pb1–O4	2.537(3)	2.534(18)
Pb1–O5	2.721(9)	2.683(7)
Pb1–O6	2.923(4)	2.935(3)

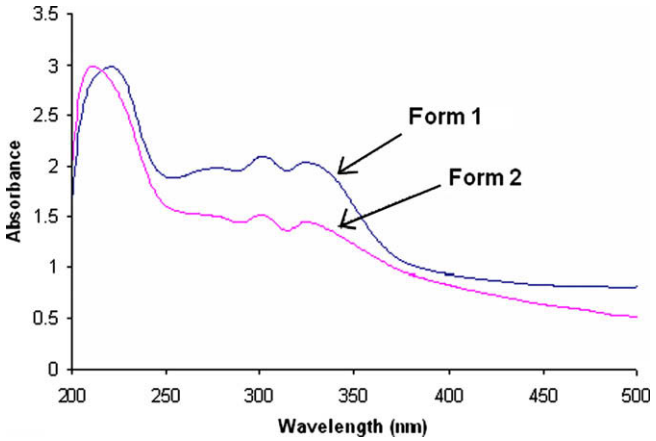

Fig. 3. Solid state UV–Vis spectra (KBr pallet) of **1** and **2**.

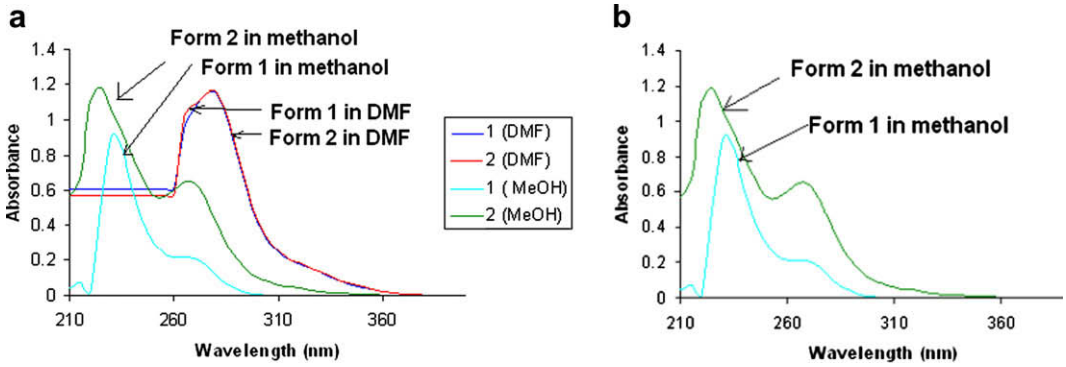

Fig. 4. UV spectra of **1** and **2** in two different solvents: (a) methanol and dimethylformamide and (b) UV–Vis spectra of the **1** and **2** in methanol.

for **1** and **2** in the solid state is significant enough to distinguish them as different forms.

We have also checked the UV–Vis spectral behaviors of the two forms in solution. Interesting solvent dependence of the UV–Vis spectra of the forms is observed as shown in Fig. 4. It is clear from the spectra that the two forms have distinct absorptions in two different solvents. In dimethylformamide both the forms of the compound absorb at 275 nm. However, in methanol the two forms of the compound absorb at different wavelengths, form **1** has absorption at 230 nm with a shoulder at 265 nm and the form **2** has absorption at 225 nm with the shoulder at 265 nm. The bands at 230 nm in the case of **1** and 225 nm in the case of **2** arises due to the $\pi \rightarrow \pi^*$ transition of the nitrate group [18]. The bands at 265 nm are due to the ligand to metal charge transfer transitions, evident from the high values of the molar extinction coefficients (13 000 L mol^{-1} cm^{-1}–19 000 L mol^{-1} cm^{-1}). From these observations, it can be inferred that the two forms adopts two different solvated forms in methanol; whereas in dimethylformamide it preferentially transforms to one state. The spectrum in methanol (Fig. 4b) clearly shows that the two independent solvated intermediates species may be formed from the two forms on solvation with methanol. It is important to note that the two solvents differ in their properties to significant extent as also their H-bonding ability. Methanol being a mono-protic solvent may remain associated to the nitrate ion in solution through only one H-bond, thereby leaving the other two oxygen atoms capable of ligation to the metal node as shown as proposed intermediate species I in Fig. 5. This can stabilize either chelating or monodenate nitrate leading to distinction of the two forms. However in the case of dimethylformamide the possible weak interactions viz. C–H···O interactions along with O–H···O interactions may lead to solvated intermediate having resemblance to a proposed solvated intermediate II shown in Fig. 5. This type of possible interactions of the nitrate ligand with solvent leaves only one oxygen of the ligand capable of ligation to the metal center. So, it can be supposed that the two different solvent imparts different twist to the nitrate ligand that leads to the formation of the two forms. Unfortunately, we are unable to get any pseudo polymorph in this study which could have supported this solvent induced isomerism with a far more logical justification. Recently our group has reported a work on solvent dependence of the conformation of carboxylic acid moieties where the different weak interactions are possible for different solvents and their effect can be seen [19]. From the solution study it is clear that the solvent modifies the structures and the two crystalline forms can thus be obtained from two different solutions which have subtle differences in solid state structures and absorption spectra.

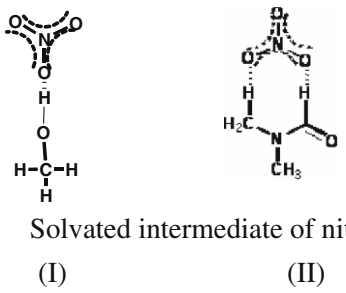

Fig. 5. Two possible ways of interactions of metal bound nitrate ligand with methanol and dimethyl formamide.

4. Conclusions

In conclusion, crystallization of a mixed anionic lead(II) 2,2′-bipyridyl N-oxide coordination polymer from two different solvents showed subtle differences in structures arising from two different nitrate binding modes leading to two different co-ordination numbers. The subtle differences are observed in different response towards UV–Vis spectroscopy in both solid state and solution state arising from mono dentate or bidentate mode of nitrate ligand.

ABSTRACT

New mononuclear compounds of the ligand 1-(2-hydroxyphenyl)-3-phenylpropane-1,3-dione (H_2L) with Cu(II) and several lanthanoid(III) ions, where Ln(III) = Pr, Nd, Eu, Gd, have been synthesized and characterized by spectroscopic methods and X-ray crystal structure determinations. In all compounds, the ligand coordinates in a bidentate chelating manner, using the diketone function. In the $[Cu(HL)_2]$, the coordination geometry of Cu(II) ion is slightly distorted square-planar; two strong intramolecular (OH···O) hydrogen-bonding interactions are established between the phenolate group and the neighboring ketone function. The lanthanoid(III) compounds have the general formula $[Ln(HL)_3(CH_3OH)_2] \cdot CH_3OH \cdot 2H_2O$; the lanthanoid(III) ion (Ln) is eight-coordinated and the coordination geometry is based on a distorted square-antiprism. In addition to the intramolecular hydrogen bonding (OH···O), intermolecular hydrogen-bonding interactions are also present between the coordinated methanol molecule and the non-coordinated methanol molecule giving rise to a three-dimensional network.

1. Introduction

The construction of molecular assemblies through the coordination of a metal ion with polydentate organic ligands has become a fascinating area of interest in inorganic chemistry. Particularly, coordination compounds of β-diketone ligands have attracted considerable attention due to their often supramolecular architectures and their peculiar optical or magnetic properties [1]. Transition-metal complexes based on various analogues of acetylacetone have been largely studied and most of the examples reported so far belong to the category of cluster compounds [1]. Considerably fewer examples of compounds with extended networks have been isolated [1–5]. The coordination ability of β-diketone ligands towards lanthanoid(III) ions has been studied and representative examples of the formation of highly coordinated complexes are the lanthanoid(III) tris-(β-diketonates) containing several nitrogen ligands such as 2,2′-bipyridine, and 1,10-phenanthroline or their derivatives [6–8]. In this work, we report the synthesis, spectroscopic characterization and X-ray crystal structure determination of new Cu(II) and lanthanoid(III) complexes with the ligand 1-(2-hydroxyphenyl)-3-phenylpropane-1,3-dione (H_2L). The ligand was selected because of its potential dual binding modes, namely coordination and hydrogen-bond donor, or bridging coordination.

2. Experimental

2.1. General remarks

Starting materials were purchased from Aldrich and all manipulations were performed using materials as received. The ligand 1-(2-hydroxyphenyl)-3-phenylpropane-1,3-dione (H_2L) was synthesized according to the procedure reported previously for similar ligands [9].

2.2. Synthesis

$[Cu(HL)_2]$ (**1**). A solution of $Cu(NO_3)_3 \cdot 3H_2O$ (0.3 mmol) in 10 ml methanol was added to a solution of the ligand H_2L (0.6 mmol) and triethylamine (0.6 mmol) in 10 ml methanol. Slow evaporation of the resulting solution afforded green single crystals within one day. After filtration, the crystalline material was washed with diethyl ether and dried in air. $C_{30}H_{22}CuO_6$, **1** (M = 542.04 g/mol). Yield: 52% (85 mg). El. Anal. (%): calc. 66.48 C, 4.45 H; exp. 66.98 C, 4.41 H. IR (ν_{max}/cm^{-1}): 2992 (w), 1616 (m), 1584 (m), 1536 (s), 1517 (s), 1481 (s), 1455 (s), 1430 (m), 1389 (s), 1343 (m), 1309 (s), 1243 (m), 1201 (m), 1160 (w), 1137 (m), 1104 (w), 1056 (m), 1020 (m), 941 (m), 845 (m), 806 (w), 787(m), 764 (m), 749 (m), 728 (s), 702 (s), 686 (s), 580 (m), 563 (s), 526 (m) UV–Vis (λ/nm): 270, 365, 415, 620.

2.2.1. Synthesis of the compounds $[Ln(HL)_3(CH_3OH)_2] \cdot CH_3OH \cdot 2H_2O$

A solution of $Ln(NO_3)_3 \cdot 6H_2O$ (0.24 mmol) in 10 ml methanol was added to a solution of the ligand H_2L (0.72 mmol) and trieth-

UV–Vis (λ/nm): 270, 346, 409, 520, 537, 586, 752, 810, 900.

$C_{48}H_{49}O_{12}Eu$, **4** (M = 1001.86 g/mol). Yield: 85% (210 mg). El. Anal. (%): calc. 57.55 C, 4.93 H; exp. 57.25 C, 4.17 H. IR (ν_{max}/cm^{-1}): 3360 (br), 2988 (m), 2858 (m), 1589 (m), 1542 (m), 1508 (s), 1457 (m), 1394 (m), 1339 (m), 1286 (s), 1198 (m), 1137 (m), 1066 (m), 1023 (m), 937 (m), 841 (m), 753 (m), 710 (m), 676 (w), 622 (s), 516 (m). UV–Vis (λ/nm): 270, 348, 408.

$C_{48}H_{49}O_{12}Gd$, **5** (M = 1007.15 g/mol). Yield: 72% (175 mg). El. Anal. (%): calc. 57.24 C, 4.90 H; exp. 57.07 C, 4.51 H. IR (ν_{max}/cm^{-1}): 3360 (br), 2988 (m), 2858 (m), 1590 (m), 1547 (m), 1510 (s), 1461 (m), 1398 (m), 1334 (m), 1286 (s), 1198 (m), 1137 (m), 1066 (m), 1023 (m), 937 (m), 842 (m), 753 (m), 711 (m), 677 (w), 623 (s), 514 (m). UV–Vis (λ/nm): 270, 350, 405.

2.3. Physical measurements

C, H, and N analyses were performed with a Perkin–Elmer 2400 series II analyzer. Infrared spectra (4000–300 cm^{-1}, resol. 4 cm^{-1}) were recorded on a Perkin–Elmer Paragon 1000 FTIR spectrometer equipped with a Golden Gate ATR device, using the reflectance technique. Diffuse reflectance spectra were obtained on a Perkin–Elmer Lambda 900 spectrophotometer using MgO as a reference. X-band powder EPR spectra were obtained on a Bruker-EMX*plus* electron spin resonance spectrometer (Field calibrated with DPPH (g = 2.0036)).

2.4. X-ray crystallography

Intensity data for a single crystal of **1** and **4a** were collected using Mo Kα radiation (λ = 0.71073 Å) on a Nonius Kappa CCD diffractometer. Crystal data for **1** and **4a** are collected in Table 1. The intensity data were corrected for Lorentz and polarization effects, for absorption (multiscan absorption correction) and extinction. The structures were solved by Patterson methods. The programs SABABS [10], DIRDIF96 [11] and SHELXL-97 [12] were used for data reduction, structure solution and structure refinement, respectively. Refinement of F^2 was done against all reflections. The weighted R factor, wR, and goodness of fit S are based on F^2. Conventional R factors are based on F, with F set to zero for negative F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed at calculated positions and were refined riding on the parent atoms. Geometric calculations and molecular graphics were performed with the PLATON package [13].

3. Results and discussions

3.1. Synthesis and characterization of the complex [Cu(HL)$_2$]

Complex **1** is easily obtained by the reaction of hydrated Cu(II) nitrate with triethylamine and the β-diketone ligand H_2L (1:2:2 ratio) using methanol as solvent. The infrared spectrum of **1** shows the vibration characteristic of the organic ligand; the most important feature that indicates the coordination of the β-diketone ligand to the Cu(II) ion, is the shift of the $\nu_{C=O}$ stretching vibration of the carbonyl group to lower energy, *ca.* 1616 cm^{-1} as compared with the free ligand (at 1657 cm^{-1}). The ligand field spectrum, measured as a solid with the diffuse reflectance technique, shows a broad band at 620 nm which is ascribed to the d-d transitions of the Cu(II) ion and a Cu–O charge transfer band at 415 nm.

The molecular structure of **1** consists of a centrosymmetric mononuclear unit in which the Cu(II) ion is coordinated by two bidentate chelating HL^- ligands that use the diketonate function for coordination to the metal center (Fig. 1). Schematic geometric information is given in Table 2. The coordination geometry of Cu(II) ion is slightly distorted square–planar. The Cu–O bond lengths of 1.889(3) Å and 1.896(4) Å, respectively are normal and comparable with the similar distances in other Cu(II) complexes with β-diketonate ligands [14–18]. The in-plane O–Cu–O angle differs slightly from 90°, being 87.03(15)°. As shown in Fig. 1, the molecular structure is stabilized by two strong intramolecular hydrogen-bonding interactions established between the phenol group and the neighboring coordinating ketonate function (O5···O1 = 2.5038 Å; O5–H5···O1 = 144°). A view of the crystal packing of **1** is shown in Fig. 2; the shortest intermolecular Cu···Cu distance is 5.838 Å.

The X-band spectrum of the complex **1** as a powder, recorded at room temperature (Fig. 3), is slightly anisotropic with a g value of 2.05 and a $g_{||}$ value of 2.25. No hyperfine splitting is resolved. This might be due to some exchange interactions leading to exchange narrowing, in view of the rather short intermolecular Cu···Cu distance indicated by the X-ray crystal structure.

3.2. Synthesis and characterization of the compounds of formula

3.2.1. [Ln(HL)$_3$(CH$_3$OH)$_2$] · CH$_3$OH · 2H$_2$O

The reaction of the hydrated lanthanoid(III) nitrates with the ligand H_2L in the presence of triethylamine as base (1:3:3 molar ratio) and using methanol as solvent afforded yellow crystalline materials. The analytical studies have shown that these compounds have the general formula [Ln(HL)$_3$(CH$_3$OH)$_2$] · CH$_3$OH. An X-ray crystallographic study has been performed for the complex [Ln(HL)$_3$(CH$_3$OH)$_2$] · CH$_3$OH (**4a**) and its crystal structure is described below. The crystallinity of the complexes

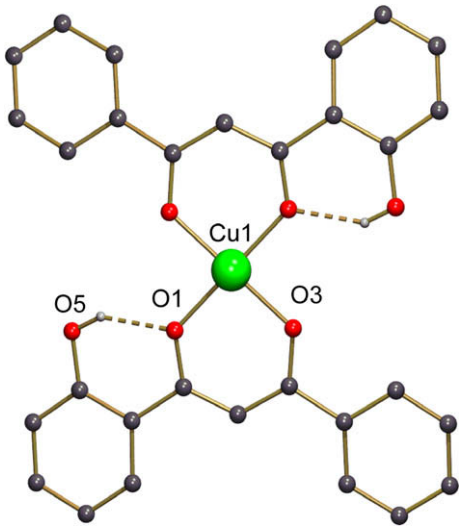

Fig. 1. View of the molecular structure of **1** showing the intramolecular hydrogen bonds. Hydrogen atoms not involved in hydrogen bonding were omitted for clarity.

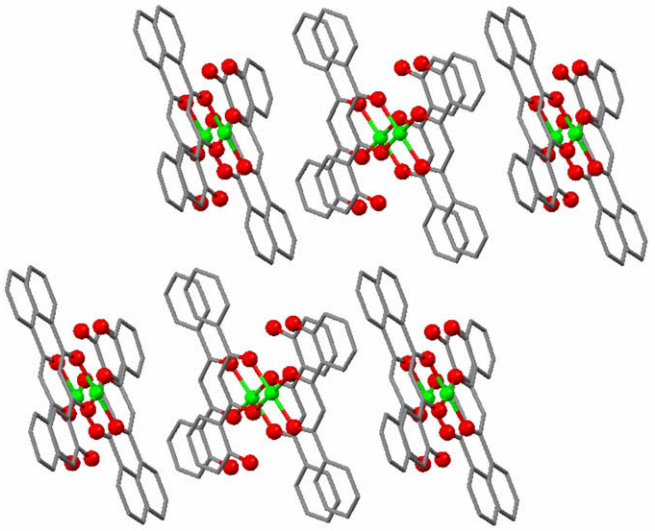

Fig. 2. View of the crystal packing of **1** in the *ac* plane. Hydrogen atoms were omitted for clarity. Cu···Cu contacts are 5.838 Å.

		O1b–Eu1–O21	121.30(9)

$[Ln(HL)_3(CH_3OH)_2] \cdot CH_3OH$ is partly lost upon removing the crystals from the mother liquid and the elemental analysis and spectroscopic studies suggest that these compounds all have the general formula $[Ln(HL)_3(CH_3OH)_2] \cdot CH_3OH \cdot 2H_2O$ (Ln = Pr **2**, Nd **3**, Eu **4**, Gd **5**).

The IR spectra of compounds **2**–**5** are nearly identical, in agreement with the fact that these compounds are isostructural. The binding of the β-diketone ligand to the lanthanoid(III) ions is indicated by the shift of the $\nu_{C=O}$ stretching vibration of the carbonyl group to lower energy, *ca.* 1590 cm^{-1} as compared with the free ligand at 1657 cm^{-1}. The broad band in the range 3200–3400 cm^{-1} is characteristic to the ν_{O-H} stretching vibrations of the lattice water molecules.

The UV–Vis absorption spectrum of the ligand shows characteristic bands at 267, 345 and 425 nm. In the UV range, the spectral features observed for compounds **2**–**5** are similar to those observed for the corresponding ligand. In the visible range, compounds **2** and **3** display the characteristic bands due to the f–f transitions. Room-temperature excitation in the UV absorption bands ($\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$) of the free ligand does not result in lanthanoid emission in these complexes. This result points to the presence of efficient non-radiative deactivation pathways in all compounds, which is due to the presence of lattice water molecules. Nevertheless, a weak ligand emission was observed at λ_{em} = 545 nm (λ_{exc} = 275 nm).

The crystal structure of **4a** consists of a mononuclear Eu(III)-containing molecule, $[Eu(HL)_3(CH_3OH)_2]$ and a lattice methanol molecule. As shown in Fig. 4, the Eu(III) ion is eight-coordinated by three monodeprotonated ligands (HL^-) and two methanol molecules. The coordination geometry of Eu(III) is based on distorted square-antiprism; the two bases are identical and they are formed by two oxygen atoms of the same bidentate ligand, an oxygen atom of a second HL^- ligand and an oxygen atom from a methanol molecule. Selected bond lengths and angles are listed in Table 2. The Eu–O bond lengths are in the range 2.320(4)–2.479(3) Å, with the Eu–O bond lengths involving the methanol molecules being the longest. The average of the C–O bond length of the β-diketone group is *ca.* 1.269 Å, much shorter than the corresponding bond in other lanthanoid(III) complexes with β-diketone ligands. This short distance suggests a lower π-electron delocalization of the C=O bond [19].

The molecular structure is stabilized by multiple intra- and intermolecular O–H···O hydrogen-bonding interactions (Fig. 5, Table 3). Three intramolecular hydrogen bonds are established between the phenolic group and the neighboring oxygen of the diketonate function. Additionally, the phenolic group of the ligand is also involved in a hydrogen bond with one of the coordinated

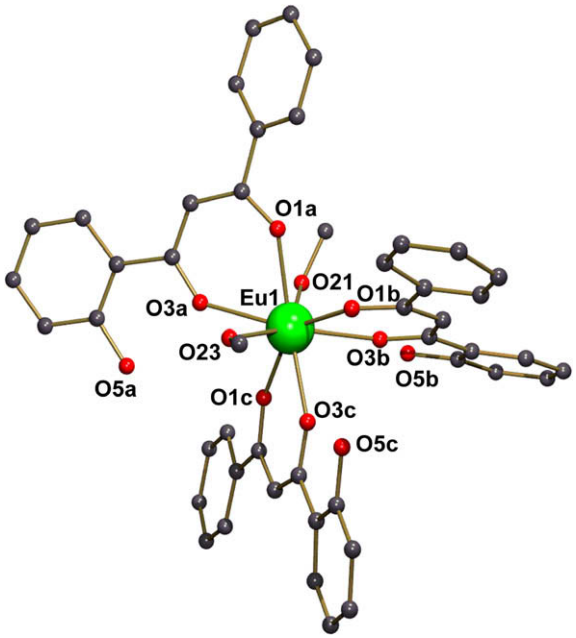

Fig. 4. View of the molecular structure of **2**. The non-coordinated methanol molecule and hydrogen atoms were omitted for clarity.

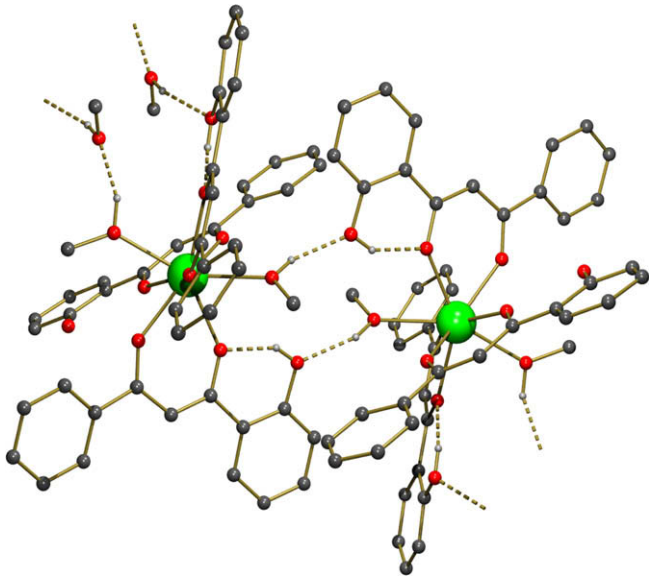

Fig. 5. View of the hydrogen bonding interactions in **2**.

Table 3
Details of the hydrogen bonding interactions in **4a**.

	D–H	H···A	D···A	D–H···A

methanol molecule of a neighboring mononuclear unit. The second coordinated methanol molecule establishes a hydrogen bonding interaction with the non-coordinated methanol molecule. All these interactions give rise to a complicated three-dimensional crystal structure. The shortest intermolecular Eu···Eu distance is 13.920 Å along the *b*-axis.

4. Conclusions

The reaction of a new β-diketonate ligand, 1-(2-hydroxyphenyl)-3-phenylpropane-1,3-dione, with Cu(II) and Ln(III) ions does result in the formation of mononuclear complexes. In all compounds, the ligand is coordinated in a bidentate chelating manner, using the diketone function for coordination to the metal center, and stabilization of the chromophore by strong intramolecular hydrogen bonding (OH···O). The preparation of the compounds reported in this paper offers promising prospects in the direction of heterobimetallic polynuclear compounds. We are currently exploring the coordination chemistry of the 1-(2-hydroxyphenyl)-3-phenylpropane-1,3-dione ligand with other metals.

Supplementary data

CCDC 705139 - 705140 contains the supplementary crystallographic data for the compounds **1** and **4a**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

en complexes

ABSTRACT

Two novel Ni(II) complexes {[Ni(en)$_2$(pot)$_2$]0.5CHCl$_3$} (**3**) {pot = 5-phenyl-1,3,4-oxadiazole-2-thione} (**1**) and [Ni(en)$_2$](3-pytol)$_2$ (**4**) {3-pytol = 5-(3-pyridyl)-1,3,4-oxadiazole-2-thiol} (**2**) have been synthesized using en as coligand. The metal complexes have been characterized by physical and analytical techniques and also by single crystal X-ray studies. The complexes **3** and **4** crystallize in monoclinic system with space group *P*21/*a* and *P*121/*c*, respectively. The complex **3** has a slightly distorted octahedral geometry with *trans* (pot)$^-$ ligands while **4** has a square planar geometry around the centrosymmetric Ni(II) center with ionically linked *trans* (3-pytol)$^-$ ligands. The π···π (face to face) interaction plays an important role along with hydrogen bondings to form supramolecular architecture in both complexes.

1. Introduction

The transition metal complexes of dithiocarbazates have attracted considerable attention for their interesting biological applications [1–3]. They behave as versatile ligands and act as monodentate (S or N2), bidentate anionic (via N3–S or S,S) [4–6] and polydentate chelating ligands [7–11]. The conversion of potassium salt of *N*-aroyldithocarbazates and 3-acyldithiocarbazic acid esters to the corresponding 1,3,4-oxadiazoles are reported in the literature [12–16]. A few papers are available on the metal complexes of 5-phenyl-1,3,4-oxadiazole-2-thiol/thione [17–19], 5-(4-pyridyl)-1,3,4-oxadiazole-2-thione [20–25] and 5-(2-pyridyl)-1,3,4-oxadiazole-2-thione [26]. These oxadiazoles have attracted attention in the field of coordination chemistry because of the presence of potential multifunctional donor sites viz. exocyclic sulfur, endocyclic nitrogen and pyridyl nitrogen. The pyridyl containing oxadiazoles are known to show three types of binding modes involving monodentate (N_{oxa}/N_{py}/S)/bidentate (N_{py},N_{oxa}/N_{py},S)/tridentate (N_{py}, N_{oxa}, S) donor sites [21]. Recently, we have reported the X-ray structure of [Ni(en)$_2$(3-pyt)$_2$] {3-pyt = 5-(3-pyridyl)-1,3,4-oxadiazole)-2-thione} where the ligand is covalently bonded through the endocyclic nitrogen [27]. Following our interest in the study of the metal complexes of 1,3,4-oxadiazoles-2-thione/thiol, we report herein the syntheses, spectroscopic and X-ray structural studies of two new Ni(II) complexes viz. {[Ni(en)$_2$(pot)$_2$]0.5CHCl$_3$} (**3**) and [Ni(en)$_2$](3-pytol)$_2$ (**4**).

2. Experimental

2.1. Materials and methods

All starting materials of analytical grade were obtained commercially and used as received. Nicotinamide was purchased from Sigma Aldrich Chemicals (USA) and used as such. Nicotinic acid hydrazide [28], [Ni(en)$_2$(NCS)$_2$] [29], potassium *N*-benzoyldithiocarbazate (**1**) [30] and potassium[pyridine-3-carbonyl)]-hydrazinecarbodithioate (**2**) [21] were synthesized according to the reported methods.

2.2. Synthesis of {[Ni(en)$_2$(pot)$_2$]0.5CHCl$_3$} (3)

A methanol–water (9:1 v/v) solution (20 ml) of [Ni(en)$_2$(NCS)$_2$] (1 mmol) was mixed with the aqueous-methanolic solution (50:50 v/v) (10 ml) of potassium *N*-benzoyldithiocarbazate (**1**) (2 mmol) to which 2 ml of chloroform was added. The resulting solution was filtered off and kept for crystallization. After 12 days, light pink crystals of **3** suitable for an X-ray crystallographic study were obtained.

{[Ni(en)$_2$(pot)$_2$]0.5CHCl$_3$} (**3**): Pink crystals, Yield 67%, *Anal. calc.* (%) for $C_{41}H_{53}Cl_3N_{16}Ni_2O_4S_4$ (1186.00): C, 41.52; H, 4.50; N, 18.90; S, 10.81; Ni, 9.90. Found: C, 40.96; H, 4.30; N, 18.77; S, 10.75; Ni, 9.27%. μ_B = 2.90 BM per Ni(II). M.p. 200 °C (dec.). IR data (*ν*, KBr, cm^{-1}): *ν*(NH of en) 3255m; *ν*(C=N) 1604s; ν_s(C–O–C) 1276w;

2.3. Synthesis of $[Ni(en)_2](3\text{-pytol})_2$ (**4**)

A methanol solution (10 ml) of $Ni(OAc)_2 \cdot 2H_2O$ (1 mmol) was stirred with the aqueous-methanolic solution (50:50 v/v) (10 ml) of potassium[*N*′-(pyridine-3-carbonyl)-hydrazinecarbodithioate] (**1**) (2 mmol), the precipitated green product was filtered off and washed twice with cold water. The above precipitate was added to a MeOH solution of en and shaken for a few minutes, the resulting solution of **4** was filtered off and kept for crystallization and after 25 days, red-pink crystals of **4** suitable for an X-ray crystallography study were obtained.

$[Ni(en)_2](3\text{-pytol})_2$ (2): Red pink, Yield 58%, Anal. Calc. for $C_{18}H_{24}N_{10}O_2S_2Ni$ (535.30) C, 40.39; H, 4.52; N, 26.17; S; 11.98; Ni, 10.96. 3. Analyses and physical measurements

Carbon, hydrogen, nitrogen and sulfur contents were estimated on a CHN Model CE-440 Analyser and on an Elementar Vario EL III. Magnetic susceptibility measurements were performed at room temperature on a Cahn Faraday balance using $Hg[Co(NCS)_4]$ as the calibrant and the electronic spectra were recorded on an UV-1700 Pharmaspec spectrophotometer. By following standard procedure, the complexes were analyzed for their nickel content, after decomposition with a mixture of conc. HNO_3 and HCl, followed by conc. H_2SO_4 [31]. I.R. spectra were recorded in the 4000–400 cm^{-1} region as KBr pellets on a Varian 3100 FT-IR Excalibur series.

4. Crystal structure determination

Data for the complex **3** was obtained at 173(2) K on a Bruker three-circle diffractometer equipped with a SMART 6000 CCD diffractometer and for **4**, X-ray single crystal refinement, diffraction data collection and data reduction were performed at 200(2) K with a graphite monochromated Mo Kα (λ = 0.71073 Å) radiation source using standard methods [32]. Intensity measurements were performed on a rapidly cooled crystal. The structure was solved by direct methods (SHELX-97) and refined against all data by full-matrix least-squares on F^2 using anisotropic displacement parameters for all non-hydrogen atoms. All hydrogen atoms were included in the refinement at geometrically ideal positions and refined with a riding model [33,34]. MERCURY was used for molecular graphics [35]. Crystal structure diagrams were generated by use of the ORTEP-3 for Windows program [36]. The crystallographic data and structural refinement details of complex **3** and **4** are given in Table 1 whereas the important bond distances and bond angles of complex **3** and **4** are given in Tables 2 and 4. The details of hydrogen bonds are given in Tables 4 and 5.

5. Results and discussion

As a part of our study on metal complexes of 1,3,4-oxadiazole-2-thione/thiol [17,27], we report herein the preparation, spectroscopic and X-ray studies of two new Ni(II) complexes based on 5-phenyl-1,3,4-oxadiazole-2-thione $(pot)^-$ and 5-(3-pyridyl)-1,3,4-oxadiazole-2-thiol $(3\text{-pytol})^-$. The potassium salt of *N*-acyldithiocarbazates lead to ring closure by desulphurization into the corresponding 1,3,4-oxadiazole during complexation [17,27]. Recently, the crystal structure of $[Ni(en)_2(3\text{-pyt})_2]$ based on 5-(3-pyridyl)-1,3,4-oxdiazole-2-thione has been reported [27]. The present work reports the complex $[Ni(en)_2](3\text{-pytol})_2$ of the same ligand in the thiol form. The 5-(3-pyridyl)-1,3,4-oxdiazole-2-thiol can exist in two forms viz. [H(3-pytone)] (thione) and [H(3-pytol)] (thiol). These two forms of the ligand yielded octahedral and square planar complexes, respectively, with Ni(II). It is observed that the reaction of an aqueous-methanol solution of $[K^+(H_2L)^-]$ and methanol solution of $Ni(OAc)_2 \cdot 4H_2O$ formed a green precipitate which dissolved in the methanol solution of en (ethylenediamine) resulting in a red-pink solution which crystallized to give red-pink crystals of $[Ni(en)_2](3\text{-pytol})_2$. However, the reaction of methanol–water solution of $[K^+(H_2L)^-]$ and methanol solution of $[Ni(en)_2(NCS)_2]$ gave a reddish solution which crystallized to form dark red crystals of $[Ni(en)_2(3\text{-pyt})_2]$.

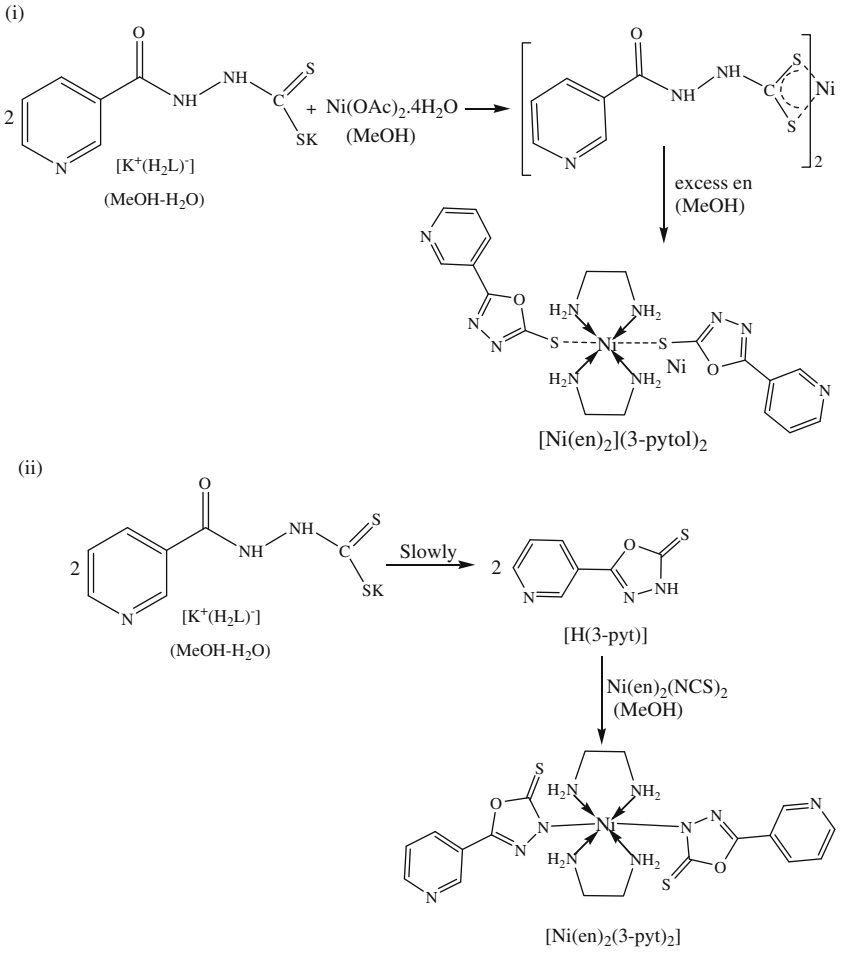
Symmetry transformations used to generate equivalent atoms: #1 $-x+1,-y+1,-z+1$ #2 $x-1,y,z$ #3 $x-1,y,z-1$

The possible pathways followed for the formation of two types of complexes are shown in scheme 1. The ligand $[K^+(H_2L)^-]$ reacts with $Ni(OAc)_2\cdot 4H_2O$ to give a green precipitate (Scheme 1) in which Ni(II) is bonded through both thiolato sulfur in a square planar form. It is believed that this green product on reaction with a strong chelating ligand en replaced $(H_2L)^-$ and formed $[Ni(en)_2]^{2+}$, maintaining the earlier square planar geometry. During this process $(H_2L)^-$ got cyclized into 5-(3-pyridyl)-1,3,4-oxadizole-2-thiol in the presence of en. The positive charge of the complex cation $[Ni(en)_2]^{2+}$ is balanced by two thiolato (3-pytol)$^-$ ligands resulting in the formation of the complex $[Ni(en)_2](3\text{-pytol})_2$.

The route followed for the formation of $[Ni(en)_2(3\text{-pyt})_2]$ from $[Ni(en)_2(NCS)_2]$ and $[K^+(H_2L)^-]$ is shown in scheme 1(ii) where $[K^+(H_2L)^-]$ is slowly cyclized to 5-(3-pyridyl)-1,3,4-oxadiazole-2-thione in aqueous-methanol which then exchanges N-bonded thiocyanato from $[Ni(en)_2(NCS)_2]$ and finally yields $[Ni(en)_2(3\text{-pyt})_2]$ maintaining the octahedral geometry around Ni(II).

5.1. I.R. spectra



The I.R. spectra of potassium *N*-benzoyldithiocarbazate [17] and potassium[*N*′-(3-pyridine-carbonyl)hydrazinecarbodithioate $[K^+(H_2L)^-]$ [27] are compared with the I.R. spectra of their respective Ni(II) complexes which indicate that bands due to –C(O)NHNHC(S)– moiety i.e. ν(C=O), thioamide I, thioamide II and ν(C=S) are absent [37]. In addition, the I.R. spectra of both complexes are devoid of any peak due to ν(NH) which are present in the ligands **1** and **2**. Appearance of new bands at 1604–1610 cm^{-1} (endocyclic C=N), 1276–1275 [ν_{as}(C–O–C)] and 1182–1198 [ν_s(C–O–C)] cm^{-1}, suggest cyclization of the acyclic dithiocarbazate moiety. The I.R. data are thus consistent with the presence of 1,3,4-oxadiazole moiety [38]. The absorption in the region of 3255–3229 cm^{-1} is due to NH stretching vibrations of en.

5.2. Electronic spectra and magnetic moments

The magnetic moment of 2.90 B.M. for $\{[Ni(en)_2(pot)_2]0.5CHCl_3\}$ and the presence of two d–d bands at 15001 and 22345 cm^{-1} assigned to the $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ and $^3T_{1g}(P)$ transitions, respectively, suggest an octahedral geometry around Ni(II) in the complex **3** [39]. The diamagnetism of $[Ni(en)_2](3\text{-pytol})_2$ and occurrence of two bands at 16500 and 20350 cm^{-1} assigned to the $^1A_{1g} \rightarrow {}^1B_{2g}$ and $^1B_{1g}$ transitions, respectively suggest it to be square planar. Other band at 32035–31645 cm^{-1} in **3** and **4,** respectively, may be due to charge transfer/intraligand transition [39].

6. Crystal structure description of $\{[Ni(en)_2(pot)_2]0.5CHCl_3\}$ (3)

As depicted in Fig. 1, the basic building unit consists of one Ni cation, two (pot)$^-$ ligands and two neutral ethylenediamine (en) molecules resulting in a distorted octahedral geometry with NiN_6 core. One unit of $\{[Ni(en)_2(pot)_2]0.5CHCl_3\}$ possesses the centrosymmetric nickel at inversion center. There are interstitial $CHCl_3$ molecules in the structure of **3** (Fig. 1). The two axial (pot)$^-$ anions around each Ni(II) at *trans* positions are bonded through nitrogen atoms at a distance of Ni1–N(3A), Ni1–N(3A)#1 = 2.117(5) (#1 = $-x+1,-y+1,-z+1$) , Ni2–N(3B), Ni2–N(3B)#1 = 2.121(5) (#1 = $-x+1,-y+1,-z+1$) and Ni3–N(5C) = 2.109(4), Ni3–N(7C) = 2.110(4) Å, respectively and the four equatorial sites are occupied by two bidentate *N,Ń*-ethylenediamine. The bonding of en to Ni(II) through Ni1–N1A = Ni1–N1A#1 and Ni1–N2A = Ni1–N2A#1 with a bond distances of 2.113(4) and 2.125(4) Å form two five membered chelate rings $NiN2AC_2N1A$ and $NiN2BC_2N1B$ with bite angles of 82.28(13)° and 82.03(13)°, respectively. All N1A, N1A#1, N1B and N1B#1 atoms of en involved in bonding with Ni1 lie in the same plane. Similar arrangement of other two units of $[Ni2(en)_2]^{2+}$ and $[Ni3(en)_2]^{2+}$ core are also observed. The geometry and bonding parameters within en molecules are in good agreement with those of related compounds eg $[Ni(en)_2(3\text{-pyt})_2]$ {(3-pyt)$^-$ = 5-(3-pyridyl)-1,3,4-oxadiazole-2-thione [27], [Ni{*trans*-(L)$_2$(en)$_2$]{L = N-(5-chlorouracilato) [40], isothiocyanato [41] and salicylato [42]}. Almost planar (pot)$^-$ ligands in complex **3** bonded to Ni(II) and designated as Ni1–N(3A) = Ni1–N(3A)#1 = 2.117(5), Ni2–N(3B) =

Scheme 1.

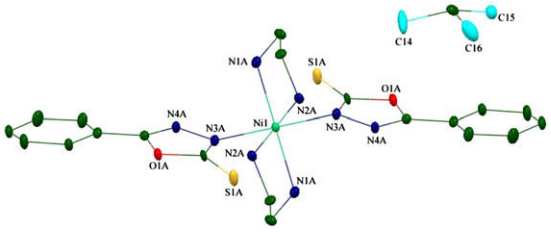


Fig. 1. Molecular structure of {[Ni(en)$_2$(pot)$_2$]0.5CHCl$_3$} with heteroatom labeling scheme. The hydrogen atoms are omitted for clarity.

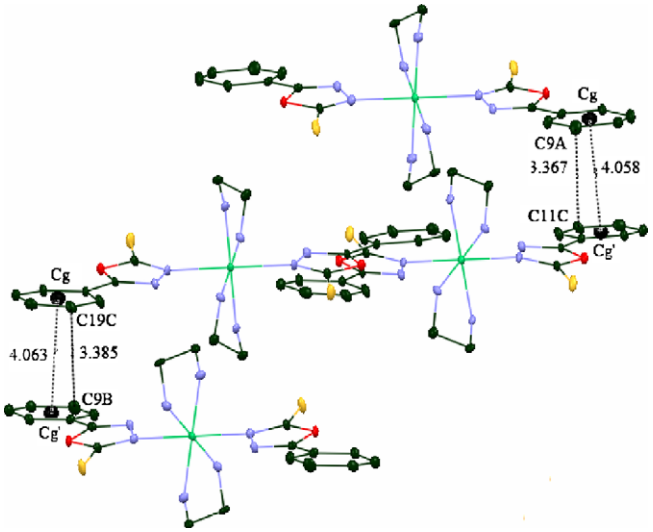

Fig. 2. Mercury view of the crystal packing of {[Ni(en)$_2$(pot)$_2$]0.5CHCl$_3$} showing face to face (π···π) interactions between two phenyl rings.

Ni2–N(3B)#1 = 2.121(5) and Ni3–N(5C) = 2.109(4), Ni3–N(7C) = 2.110(4) Å are almost equal but significantly lengthened in comparison to the corresponding bond lengths of 1.907(3) and 1.895(4) Å reported for [Ni{η^5-(2-dimethylaminoethyl)cyclopentadienyl}(pti)]0.5(C_7H_8) [43], [Ni{η^5-(1-methy-lindene)(pti)(PPh_3)] [44], {pti = phthalimidate} respectively, but comparable to those of ca. 2.1090(14), 2.1150 Å encountered in the related [Ni(en)$_2$(3-pyt)$_2$] {(3-pyt)$^-$ = 5-(3-pyridyl)-1,3,4-oxadiazole-2-thione} [27] and ca. 2.102 Å for *N*-succinimido compound [Ni(succinimido(H_2O)$_4$] · 2H_2O [45]. All hydrogens of NH_2 groups are involved in H-bonding to the thione sulfur and oxadiazole nitrogen of (pot)$^-$, thus providing intramolecuar hydrogen bonding in all three units of the complex **3**. These hydrogen bondings have stabilized **3** in the solid state (Table 3). The shortest intra and interchain Ni···Ni separations are 12.208 and 8.203 Å, respectively. The intermolecular hydrogen bonding between the thione sulfur of one (pot)$^-$ anion of one asymmetric unit with the hydrogen atom of the phenyl ring (S···H = 2.954 Å) extended the chain in one dimension along a axis. Further two π···π interactions between carbon atoms of adjacent phenyl rings have distances of 3.367 (C9A...C11C) and 3.385 (C9B...C19C) Å while centroid (Cg_1)–centroid (Cg_2) separation be-

tween two phenyl rings is 4.058 and 4.063 Å which cause the chain to grow in one dimension (Fig. 2). This one dimensional framework is extended into two dimensional network due to the presence of $[Ni(en)_2]^{2+}$ unit perpendicular to *trans* $(pot)^-$ ligands. The whole arrangement provides one dimensional open channel enclosing the $CHCl_3$ molecules and gives 2D dimensional supramolecular architecture (Fig. 3). The $CHCl_3$ molecules are stable in the open channels due to the presence of weak intermolecular interactions between phenyl ring of $(pot)^-$ and hydrogen atom of the $CHCl_3$.

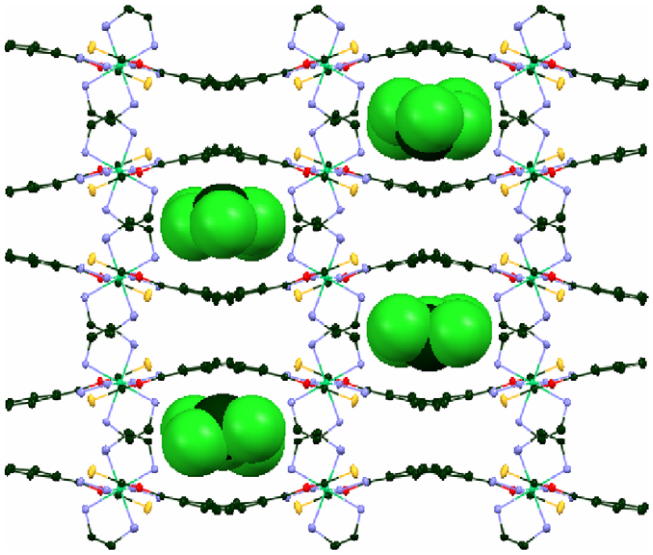

Fig. 3. The molecular packing of $\{[Ni(en)_2(pot)_2]0.5CHCl_3\}$ (**3**), view along *a* axis. The $CHCl_3$ molecules are represented as space filling form.

7. Crystal structure of $[Ni(en)_2](3\text{-pytol})_2$ (4)

The X-ray crystal structure analysis of **4** shows that $[Ni(en)_2]^{2+}$ cation is surrounded by two $(3\text{-pytol})^-$ anions. In the centrosymmetric unit of $[Ni(en)_2](3\text{-pytol})_2$, the metal ion has a square planar geometry where Ni(II) is bonded with four symmetry related N-atoms of two en molecules and is ionically linked with thiolato sulfur of two $(3\text{-pytol})^-$ anions. The two en molecules chelate Ni(II) at equatorial positions and two $(3\text{-pyt})^-$ occupy apical positions in *trans* manner (Fig. 4). The Ni–N distances in complex **4** are in the range of 2.0138(13)–2.0235(12) Å which is almost normal for Ni–N (amine) bonds [21,30]. The bite angle for NiN_4 core is 84.83(5) indicating a substantial distortion in the molecule with two five membered NiC_2N_2 chelate rings around Ni(II). In the $[Ni(en)_2]^{2+}$ the nickel(II) and the donor atoms of ethylenediamine lie in the same plane. Each $[Ni(en)_2]^{2+}$ forms a pair of weak intermolecular Ni···S interactions at a distance of 2.997 Å. The Ni(II) present in a D_{2h} symmetry is bonded to four N atoms of NH_2 group of en which offer interesting hydrogen bonding packing. The elements of the structure are joined to each other in the crystal packing by means of extended system of hydrogen bonding. The π···π interaction is observed between two adjacent pyridine rings as shown in Fig. 5.

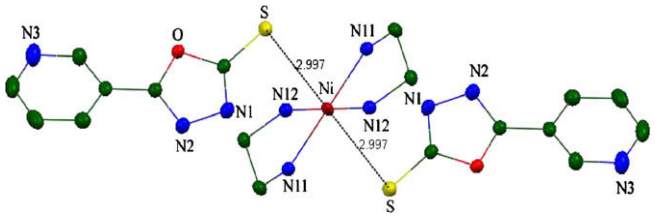

Fig. 4. Molecular structure of $\{[Ni(en)_2](3\text{-pytol})_2$ (**4**) with heteroatom labeling scheme.

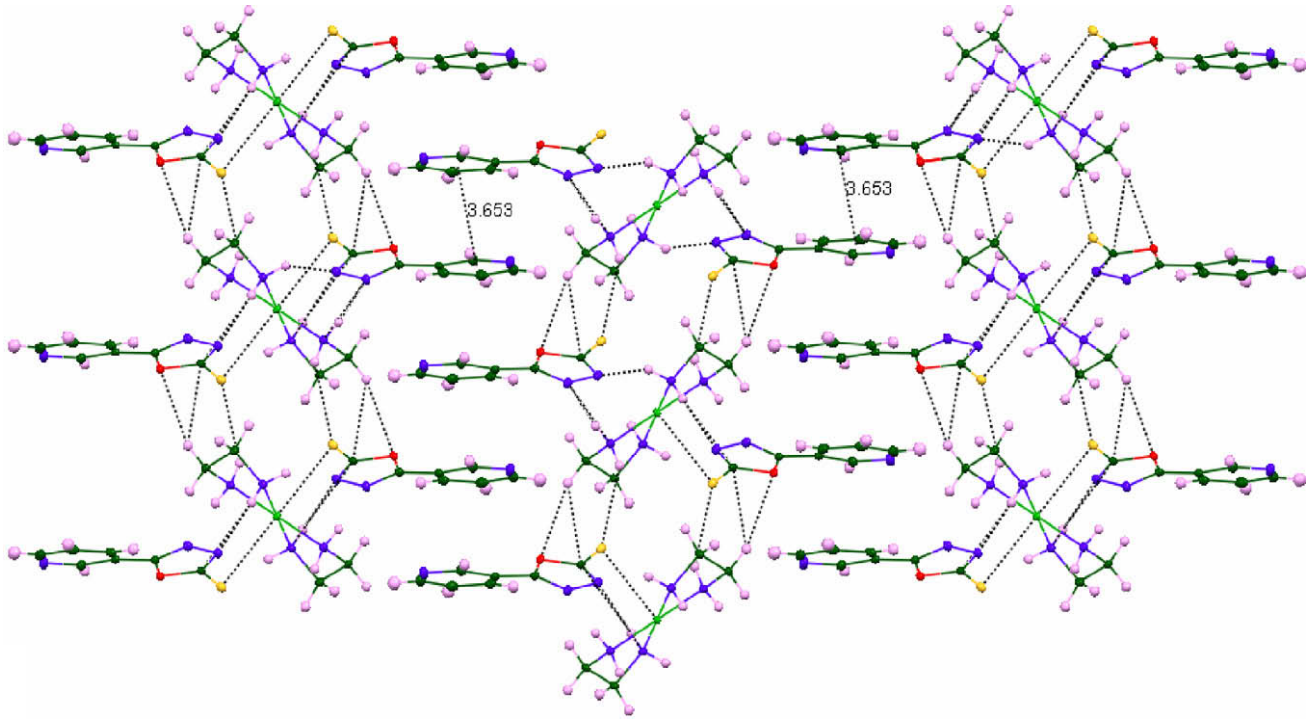

Fig. 5. Mercury view of the crystal packing of $[Ni(en)_2](3\text{-pytol})_2$ showing face to face (π···π) interaction, weak Ni···S and weak C···S interactions along with hydrogen bonding.

The centroid ($C_g$pyridine) to centroid ($C_g$pyridine) separation is of 3.653 Å. The hydrogen bonding parameters are listed in Table 5. The X-ray analysis reveals that in the solid state the molecules are self assembled via. N–H···N, N–H···O and N–H···S intermolecular hydrogen bonding and weak C···S interactions (4.274 Å) between the thioalto sulfur and carbon of phenyl ring. This hydrogen bonding together with π···π interaction form metal organic framework of three dimensional network (Fig. 5).

8. Conclusion

Two new complexes $[Ni(en)_2(pot)_2]0.5CHCl_3$ and $[Ni(en)_2](3\text{-pytol})_2$ containing en and 1,3,4-oxadiazole have been synthesized and fully characterized by X-ray techniques. The desulphurization of the *N*-acylhydrazinecarbodithioate {–C(O)–NHNH–C(S)–} moiety was observed during complexation. The $[Ni(en)_2](3\text{-pytol})_2$ is a rare example of Ni(II) complex containing two en molecules in a square planar geometry.

ABSTRACT

Treatment of Ph_2PbCl_2 with $O(C_6H_4SH)_2$ (**1**a), $S(C_6H_4SH)_2$ (**2**a) and $S(C_6H_3SH)_2O$ (**3**a) afforded the stable organolead compounds [{$O(C_6H_4S)_2$}$PbPh_2$] (**1**b), [{$S(C_6H_4S)_2$}$PbPh_2$] (**2**b) and [{$S(C_6H_3S)_2O$}$PbPh_2$] (**3**b). X-ray structure determinations of dithiolate-diphenyl lead compounds **1**b–**3**b revealed that the trichalcogenated ligands are tridentate in **1**b and **2**b, and bidentate in **3**b. The lead atom acts as an acceptor atom exhibiting weak intramolecular transannular interactions with the donor D atom, with tetrahedral distortions of 48% for **1**b, 51% for **2**b and 45% for **3**b. The local geometry at the lead atom is described as monocapped tetrahedral. The crystal packing of title compounds is stabilized by several non-bonded interactions.

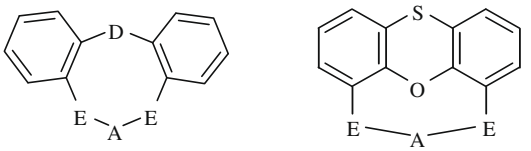
1. Introduction

Hypercoordination through non-bonded intramolecular as well as intermolecular interactions is well documented in compounds containing group 14 elements [1,2]. So far lead, the heaviest atom in the group with environmental and toxicological relevance, show the broadest possibilities for coordination numbers and coordination geometries. The higher coordination numbers are usually achieved by intra- or intermolecular bonding with ligands potentially polydentate bearing several soft and/or hard donors [3–7].

On the other hand, we are interested in the synthesis and design of ligands capable to promote the expansion of the coordination number of heavy p-block elements; such ligands are $D(C_6H_4SH)_2$ [D = O, S] and $S(C_6H_4SH)_2O$ and they yield hypercoordinated compounds of type **I** and **II**, respectively [8–12]. In these compounds, hypercoordination is achieved by a transannular D···A interaction (Scheme 1). In general, has been observed that the coordination ability of the ligands can be tuned by the appropriate choice of the exocyclic ligands attached to A, prompting a bidentate or, in most of the cases, tridentate coordination pattern.

Following with the study of hypercoordination in group 14 elements, herein we report the synthesis and characterization of three diphenyl lead organometallic compounds containing a transannular interaction D···Pb, where the flexibility of the ligands is crucial in order to achieve hypercoordination at the lead atom. The choice of the $PbPh_2$ moiety is widely supported due is less toxic than their aliphatic counterparts. The molecular and crystal structures of compounds **1**b, **2**b and **3**b were obtained by X-ray diffraction studies. The detailed description of the synthesis, spectroscopic characterization and crystallographic data are presented and discussed below.



2. Experimental

2.1. Materials and methods

All manipulations were performed under a dry, oxygen-free argon atmosphere using standard Schlenk techniques unless noted otherwise. Solvents were dried by standard methods and distilled prior to use. $S(C_6H_4SH)_2$, [13] $O(C_6H_4SH)_2$ [8] and $S(C_6H_3SH)_2O$ [12] were synthesized according to literature methods. Ph_2PbCl_2 and *n*-BuLi (1.6 M, in hexanes) were purchased from Alfa Aesar and Aldrich respectively and were used as supplied. Melting points were determined with a Mel-Temp II instrument and are uncorrected. Spectra were recorded with the following instruments. Mass spectra: EI, 70 eV, Hewlett Packard MS-598 mass spectrometer. The elemental analyses were recorded with a Perkin–Elmer Series II CHNS/O Analyzer. The IR spectra were recorded in the 4000–400 cm^{-1} range with a Perkin–Elmer System 2000 FT-IR spectrometer, as KBr pellets. The NMR spectra were recorded with a Jeol Eclipse 400 spectrometer at 25 °C, with the residual

protio-solvent signal used as referenced for ^{1}H NMR spectra. ^{13}C{^{1}H} NMR spectra were referred through the solvent peaks. Chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane (^{1}H, 13C{1H} NMR spectra). Spectra were recorded at 25 °C. ^{1}H NMR spectra; 399.78 MHz, ^{13}C{1H} NMR spectra; 100.53 MHz.

2.2. Synthesis of diphenyl lead organometallic compounds

2.2.1. Synthesis of [{O(C$_6$H$_4$S)$_2$}PbPh$_2$] (**1**b)

n-BuLi in hexanes (1.6 M, 1.6 mL, 2.6 mmol) was added to a solution containing O(C$_6$H$_4$SH)$_2$ (**1**a, 0.27 g, 1.15 mmol) in THF (40 mL) at 0 °C. After the solution was stirred for 30 min, was slowly added a suspension of Ph_2PbCl_2 (0.50 g, 1.15 mmol) in THF (30 mL). The suspension was dissolved, and the yellow solution obtained was stirred for 24 h at room temperature. The white solid formed was filtered out and the solution dried by means of a column of Celite and Na_2SO_4. The solvent was removed in vacuum. The resulting yellow solid was dissolved in chloroform. By slow evaporation **1**b was obtained as yellow crystals. Yield: 66% (0.45 g, 0.76 mmol). Mass spectra (EI-MS, 70 eV) *m*/*z* (rel int) = 594 (5) [M$^+$], 517(3) [M$^+$−Ph], 439(8) [M$^+$−2Ph−H], 397(10) [Ph_2PbSH_2+1], 285(8) [PhPb$^+$], 200(10) [O(C$_6$H$_4$)$_2$S$^+$]. M.p. 115–119 °C. *Anal. Calc.* for $C_{24}H_{18}OPbS_2$ C, 48.55; H, 3.06. Found: C, 48.75; H, 3.12%. ^{1}H NMR ($CDCl_3$): δ = 7.62 [d, 4H, $^3J_H{}^5{-}_H{}^6$ = 7.52 Hz, $^3J(^1H{-}^{207}Pb)$ = 107 Hz, H^5), 7.57 (m, 2H, H^1), 7.40 (t, 4H, $^3J_H{}^6{-}_H{}^5 = {}^3J_H{}^6{-}_H{}^7$ = 7.52 Hz, 4H H^6), 7.29 (m, 2H, H^7), 7.02 (m, 4H, H^2 and H^3), 6.82 (m, 2H, H^4) ppm. 2.2.3. Synthesis of [{S(C$_6$H$_4$S)$_2$O}PbPh$_2$] (**3**b)

Ph_2PbCl_2, (0.13 g, 0.30 mmol) was added to a solution of S(C$_6$H$_3$SH)$_2$O (**3**a, 0.08 g, 0.30 mmol) in 15 mL of dry methanol at room temperature. The solution was refluxed overnight. The yellow solid obtained was filtered and dissolved in chloroform (30 mL). By slow evaporation, **3**b was obtained as yellow crystals. Mass spectra (EI-MS, 70 eV) *m*/*z* (rel int) = 624 (25) [M$^+$], 547(100) [M$^+$−Ph], 470(10) [M$^+$−2Ph−H], 438(50) [M$^+$−2Ph−H], 396(6) [Ph_2PbSH_2], 285(8) [PhPb$^+$], 208(38) [Pb$^+$]. Yield: 54% (0.10 g, 0.16 mmol). M.p. 135–137 °C. *Anal. Calc.* for $C_{24}H_{16}OPbS_3$, C 46.21, H 2.59. Found: C 47.28, H 2.79%. ^{1}H NMR ($CDCl_3$): δ = 7.39 (dd, $^3J_H{}^1{-}_H{}^2$ = 8.00 Hz, $^4J_H{}^1{-}_H{}^3$ = 2.00 Hz, 2H, H^1), 7.26 (m, 6H, H^5, H^6, H^7), 6.93 (dd, $^3J_H{}^2{-}_H{}^1 = {}^3J_H{}^2{-}_H{}^3$ = 8.00 Hz, 2H, H^2), 6.77 (dd, $^3J_H{}^3{-}_H{}^1$ = 8.00 Hz, $^4J_H{}^3{-}_H{}^2$ = 2.00 Hz, 2H, H^3) ppm. ^{13}C{^{1}H} NMR ($CDCl_3$): δ = 155.7 [$^1J(^{13}C{-}^{207}Pb)$ = 560 Hz, C^{5a}], 150.0 [$^3J(^{13}C{-}^{207}Pb)$ = 39.2 Hz, C^{1a}], 135.4 [$^2J(^{13}C{-}^{207}Pb)$ = 90.7 Hz, C^5], 132.9 [$^3J(^{13}C{-}^{207}Pb)$ = 20.0 Hz, C^2], 130.4 [$^3J(^{13}C{-}^{207}Pb)$ = 116.1 Hz, C^6], 130.0 [$^4J(^{13}C{-}^{207}Pb)$ = 26.1 Hz, C^7], 126.3 [$^2J(^{13}C{-}^{207}Pb)$ = 26.1 Hz, C^1], 124.7 [C^3], 124.3 [C^4], 120.7 [C^{4a}] ppm. IR (KBr pellet, cm^{-1}): 3059, 3037, 1566, 1469, 1431, 1401, 1223, 1197, 1055, 1011, 904, 872, 831, 770, 723, 686.

2.3. X-ray crystallography

Suitable single crystals of the compounds **1**b, **2**b (thin plates) and **3**b were grown by slow evaporation from a chloroform solution. X-ray diffraction data were collected at room temperature on a CCD Smart 6000 diffractometer through the use of Mo Kα radiation (λ = 0.71073 Å, graphite monochromator). Data were integrated, scaled, sorted, and averaged using the SMART software package. The primary structure of **2**b was solved by heavy atom method using SHELXS86 [14] and the structures of **1**b and **3**b were

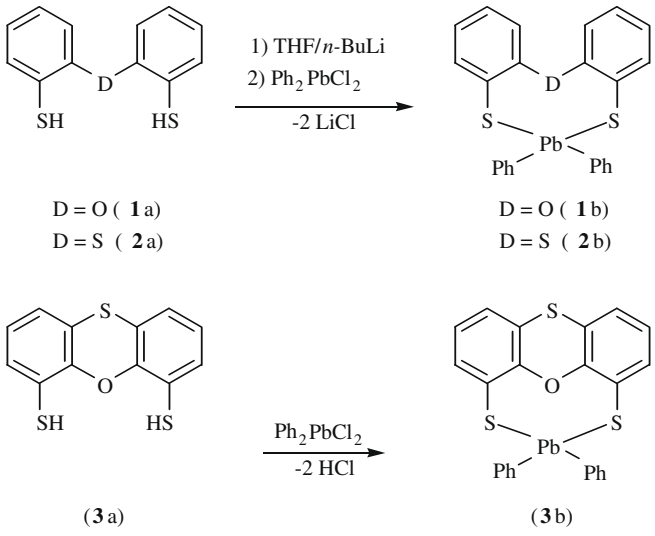
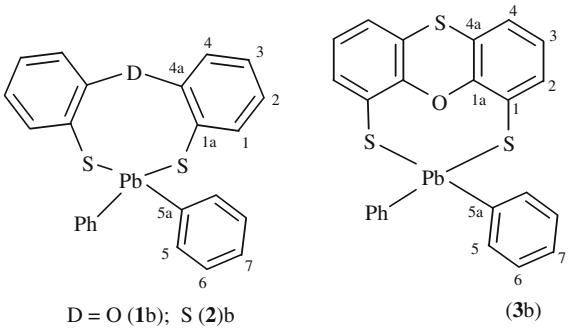
solved by direct methods using SHELXTL NT Version 5.10 and refined by full-matrix least squares against F^2 [15]. An empirical absorption correction based on the multiple measurement of equivalent reflections was applied by using the program SADABS [16]. The displacement parameters of non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were kept fixed with a common isotropic displacement parameter. Selected crystallographic data are given in Table 1.



3. Results and discussion

3.1. Synthesis



The ligands $O(C_6H_4SH)_2$ (**1**a), $S(C_6H_4SH)_2$ (**2**a) and $S(C_6H_3SH)_2O$ (**3**a) were prepared following the reported method [8,13,12]. The compounds **1**b and **2**b were obtained from the reaction of Ph_2PbCl_2 in THF at 0 °C with the dilithium salt of **1**a and **2**a generated *in situ*, yielding the corresponding Pb(IV) compounds as yellow crystals. **3**b was obtained from the reaction of **3**a with Ph_2PbCl_2 in hot methanol (see Scheme 2). All compounds are air-stable, soluble in chloroform, methylene chloride and benzene, and insoluble in *n*-hexane, pentane, methanol and 2-propanol.

3.2. NMR spectra

NMR spectra of all the complexes were recorded in $CDCl_3$ solutions at room temperature and the chemical shifts are relatives to TMS. The assignments of these compounds were performed by 2D

Scheme 2.

Scheme 3.

experiments (COSY, HETCOR and COLOC). In solution the two DC_6H_4SPbPh [D = O (**1**b); S (**2**b)] and $S(C_6H_3S)OPbPh$ (**3**b) halves are equivalents.

3.2.1. ^1H NMR spectra

In the spectra of title compounds, besides to the disappearance of the signal of the SH protons of the free ligands $O(C_6H_4SH)_2$ (δ = 3.90 ppm), $S(C_6H_4SH)_2$ (δ = 4.10 ppm) and $S(C_6H_3SH)_2O$ (δ = 4.05 ppm), is observed that the $PbPh_2$ moiety deshields the ortho protons to the thiolate sulfurs. Moreover, the protons 5-H in **1**b and **2**b show coupling with the ^{207}Pb isotope [$^3J(^1H-^{207}Pb)$ = 120 and 107 Hz for **1**b and **2**b, respectively]; in **3**b the coupling constant was not observed because the protons of the phenyl groups are displayed as a multiplet.

3.2.2. $^{13}C\{^1H\}$ NMR spectra

In the $^{13}C\{^1H\}$ spectra of title compounds is observed $^{13}C-^{207}Pb$ coupling, with one to four-bond coupling constants. Comparison of ^{13}C data and coupling constants with other related compounds is listed in Table 2, Scheme 3. The $^nJ(^{13}C-^{207}Pb)$ coupling constant diminishes in the order of C5a > C6 > C5 > C7 for the phenyl groups in all compounds. The magnitude of the $^1J(^{13}C-^{207}Pb)$ for the 5a *ipso*-carbon is similar to some thiolate lead compounds with coordination number four [6]. An increase in the coordination number of Pb(IV) is observed when the one-bond $^{13}C-^{207}Pb$ coupling constant and the chemical shift for the 5a *ipso*-carbon are increased; in our compounds we conclude that the O···Pb (**1**b and **3**b) and S···Pb (**2**b) transannular interactions are very weak or completely lacking in solution.

3.3. X-ray crystallographic studies

The crystal structures in crystalline solid state of the title compounds were determined by single crystal X-ray diffraction analy-

3.3.1. Molecular structures

All lead–carbon bond distances agree very well with the corresponding covalent radii sum [18]. The lead–sulfur distances also agree with those reported in compounds containing the kernel S_2PbPh_2 into a cyclic system [19–22]. The bond angles around the central lead atom are quite different from the tetrahedral angles. In particular, the S1–Pb1–S2 and C13–Pb1–C19 bond angles in **2**b are the smallest. This difference in angles causes a distortion in the tetrahedron formed by the S1, S2, C13 and C19 vertices enclosing the coordination sphere of the lead atom.

In addition to the four covalent bonds expected for a lead (IV) compound, a relatively short distance involving the transannular D and Pb atoms is observed in the three compounds. The O···Pb lengths in **1**b [3.053(4) Å] and **3**b [3.113(4) Å] are shorter than the van der Waals radii sum [Σr_{vdW}(O,Pb) = 3.54 Å] [23], but 39 and 42% longer than the covalent radii sum [Σr_{cov}(O,Pb) = 2.20 Å] [24]. These distances are longer than those reported for the more flexible plumbocane $[\{O(CH_2CH_2S)_2\}PbPh_2]$ contained in two polymorphs [O···Pb = 2.855(5) and 2.888(6) Å in the orthorhombic system; 2.92(1) and 3.08(1) Å in the triclinic system] [18] and in $Ph_3PbSOCC_6H_4Me$ [2.990(4) Å] [7]. Likewise, the distance S···Pb in **2**b [3.280(3) Å] is also less than the corresponding van der Waals radii sum [Σr_{vdW}(S,Pb) = 4.1 Å] [23] and comparable to distances reported for compounds containing anisobidentate ligands [2.941 and 2.958 Å in $\{(PhCH_2O)_2PS_2\}_2PbPh_2$] [25]; 3.017 Å in $(Ph_2PS_2)_2$-$PbPh_2$ [26]. The magnitude of these intramolecular D···Pb interactions are consistent with a secondary bonding.

The molecular structures of the **1**b and **2**b compounds are similar, despite the presence of different donors atoms (O versus S). On the other hand, there are marked differences between the structures of the **1**b and **3**b compounds with oxygen as a donor atom; in **1**b the eight-membered ring conformation can be described as a twist boat (C_1 symmetry), while in **3**b the ring conformation can be described as boat–chair (*Cs* symmetry), according to the torsion angles listed in the Table 3. In regard to these conformations, it is normally accepted that just the first conformation is consistent with a transannular interaction. These results show the flexibility of the $D(C_6H_4S)_2^{2-}$ [D = S and O] and $S(C_6H_3S)_2O^{2-}$ O potentially tridentate ligands in order to adopt different arrangements.

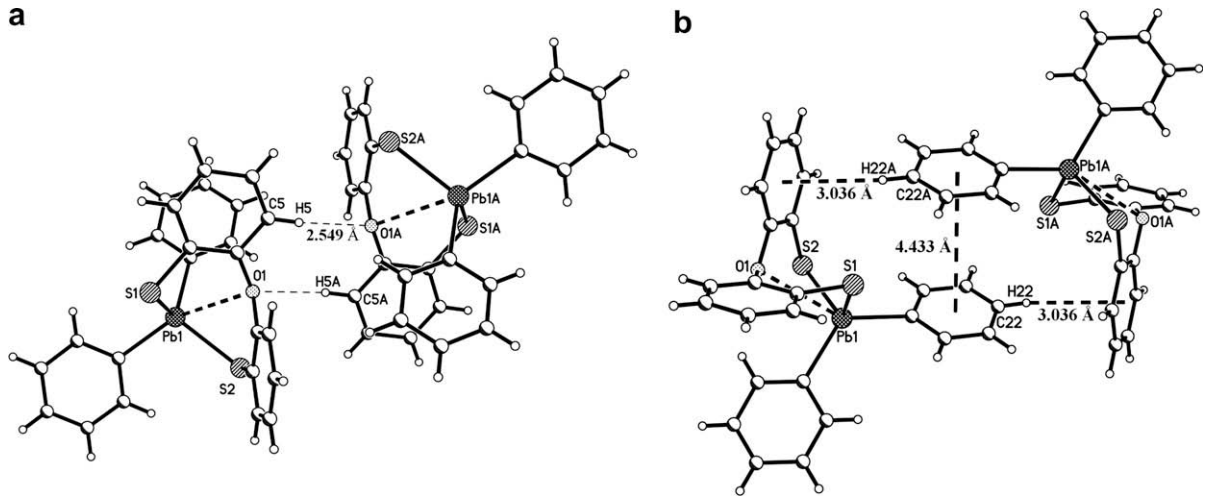

Fig. 2. The crystal packing of compound **1**b. (a) Intermolecular hydrogen bonds (C–H···O) showing the dimeric associations. (b) Arrangement of the π-stacking interactions type offset-stacked and face-tilted-T.

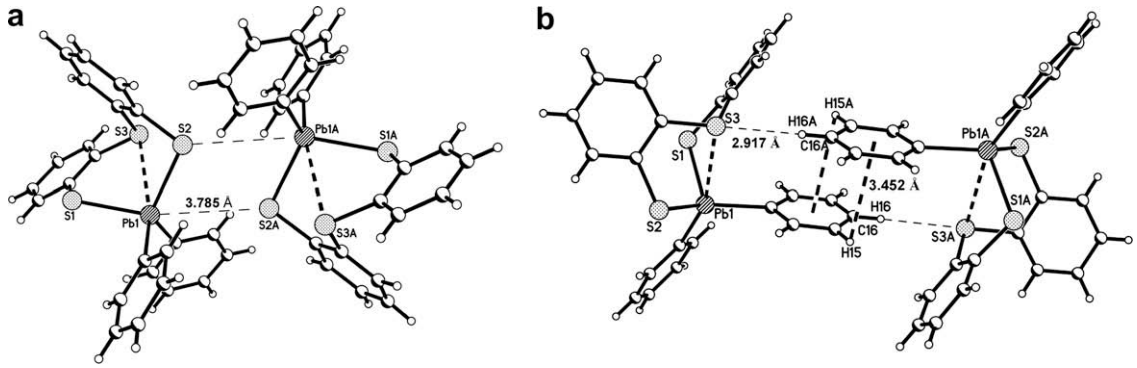

Fig. 3. The crystal packing of compound **2**b. (a) The intra and intermolecular interactions S···Pb, showing the hexacoordinated lead atom. (b) Arrangement of the intermolecular hydrogen bonds in (C–H···S) and the π-stacking interactions.

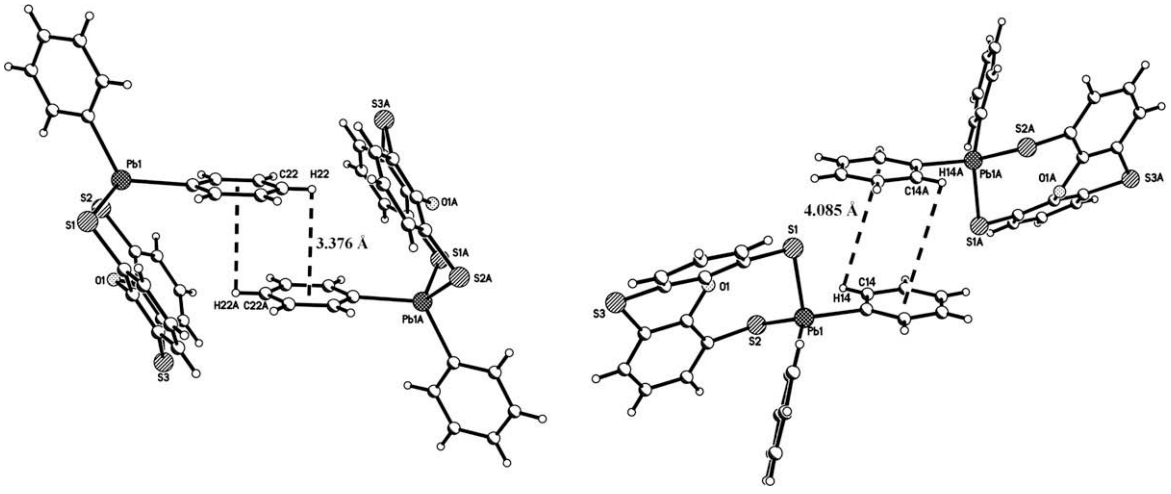

Fig. 4. The crystal packing of compound **3**b. Arrangements of the different π-stacking interactions type offset-stacked.

In order to compare the magnitude of the transannular interaction in all compounds, the Pauling-type bond order (BO) [27,28] has been calculated, according to the formula $BO = 10^{-[1.41(d_{exp}-\sum r_{cov})]}$, where d_{exp} is the D···Pb transannular distance. The BO are 0.063 for **1**b, 0.077 for **2**b and 0.052 for **3**b, respectively. The BO calculated indicates that sulfur is a better donor than the oxygen atom towards lead, however, in all cases the D···Pb transannular interaction is weak.

Considering the four covalent bonds and the secondary interactions D···Pb, the Pb atom in all compounds is penta-coordinated with a coordination sphere geometry described as monocapped tetrahedral, where the D donor atom (O for **1**b and **3**b; S for **2**b) is capping the tetrahedron. This proposal is supported by the short displacement percent from tetrahedral to trigonal bipyramidal geometry calculated for the compounds according to the procedure of Holmes based upon donor-acceptor atom bond length [29–31]. The tetrahedral distortion calculated is 48% for **1**b, 51% for **2**b and 45% for **3**b.

3.3.2. Crystal structures

The crystal packing of title compounds is stabilized by several non-bonded interactions.

In **1**b the molecules are associated by weak hydrogen bonding C–H···O as well as offset-stacked parallel – displaced and face-tilted-T aromatic interactions [32]. In this compound, the lead atom is not involved in intermolecular interactions (Fig. 2).

In the crystal structure of **2**b is observed the presence of molecules associated by S···Pb interactions (3.782 Å, a distance slightly shorter than the corresponding van der Waals radii sum [23]), by weak hydrogen bonding C–H···S and by offset π-stacking interactions (Fig. 3).

If both transannular and intermolecular S···Pb interactions are considered, then the lead atom is hexacoordinated, and its geometry can be described as bicapped tetrahedral.

In the crystal structure of **3**b, only are present dimeric building blocks self-assemble into chains *via* π-stacking interactions between the phenyl groups (see Fig. 4).

4. Conclusions

In order to study the phenomena of hypercoordination in organolead compounds we have synthesized and structurally characterized three new diphenyllead(IV) compounds by employing efficient tridentate ligands. In the solid state, the compounds display a distorted tetrahedral local geometry at Pb(IV) center. In view of the above findings and previous results, we conclude that, for a given $PbPh_2^{2+}$ fragment, the more flexible ligand $D(C_6H_4S)_2^{2-}$ (D = O, S) is able to show a weak interaction, leaving without change the conformation of the eight-membered ring, and displaying a tridentate coordination mode. On the other hand, the more rigid ligand $S(C_6H_3S)_2O^{2-}$ displays a bidentate coordination mode, with a totally different conformation that avoids any transannular interaction.

ABSTRACT

In the reaction of $K_4[W(CN)_8] \cdot 2H_2O$ and $Co^{2+}(aq)$ cations on the polycrystalline or monocrystalline [3 1 1] copper using layer-by-layer deposition, a thin film of the coordination polymer $\{[\{Co(H_2O)_2(\mu\text{-}CN)_4\}_2W] \cdot 4H_2O\}_n$ was formed. The work function of copper and deposited on it bi-layers depended on a number of layers and the concentrations of the deposited precursors. At high complex concentrations work function reached the plateau after several deposition processes, while at low concentrations oscillations in the work function were observed when K^+ or Co^{2+} cations were present in the outside layer. The changes of the work function were also dependent on Co^{2+} salt used ($CoCl_2 \cdot 6H_2O$ or $Co(NO_3)_2 \cdot 6H_2O$). This was interpreted in terms of a layer structure resulting from various coordination of external anions to cobalt cations.

1. Introduction

The new class of materials based on cyano-bridged metallic centers (framework materials) is of high interests for the contemporary materials science, due to their vastly unexplored physical properties. The cyano-based bridging (–CN–) provides stable and regular framework connecting metallic centers of different *d*-block elements (possibly at various oxidation levels). For a metallic center of a given coordination number, the certain symmetry of the crystalline network is provided. For a low symmetry coordination surrounding (*e.g.* coordination numbers 5, 7 and 8) an anisotropy in the physical properties can be present. The –CN– network enables interaction of the metallic centers along the $–M_1–CN–M_2–$ chain. Thus, charge transfer, magnetic coupling, colossal positive and negative thermal expansion and other effects may occur, leading to new optical, magnetic or mechanical properties [1].

For the practical applications, positioning of the cyano-bridged network in the form of thin films at the interfaces is essential. The series of interesting experiments in the subject was performed by Culp et al. [2]. The deposition was performed on the air/water interface (in the next stage transferred to a solid polymeric support). A formation of the two dimensional self-assembled square grid was observed in the system of the Langmuir monolayer based on amphiphilic pentacyanoferrate(III) complex and metal ions (Ni^{2+}) in the sub-phase [3,4]. In the further experiments the multilayer was obtained by a step-wise deposition process, in which the monolayer (transferred to a solid support) acted as a substrate, whereas the consequent layers were formed in the iterative process of deposition of Fe^{3+} ions (the first precursor) and hexacyanoferrate(II) complex ion (the second precursor). As a result, a three dimensional network of a Prussian blue was formed. For the Prussian blue Fe^{3+}/Co^{2+} analogs an anisotropic photo-magnetic effect was observed.

The thin layers modify and tailor the electronic properties of the substrate, which is especially important if one is a conductor or a semi-conductor (*e.g.* like the titanium oxide used as a material for the photovoltaic cells). The change of the electronic parameters of the substrate might be associated, among others, with a band gap change or the work function change. Such investigations have not been conducted for the cyanide frameworks. However, a very similar research concerning layer-by-layer deposition involving sequential deposition of polyelectrolytes (alternately, polyanions and polycations) can be found in the literature [5–8]. The properties of the film can be changed in the regime of a single molecular layer. The surface potential is alternately driven by the consequent polyanions or polycations and exhibit oscillations: the reversely varying properties with the surface potential of the terminating layer [9,10].

The formation of a monolayer in a liquid phase (Langmuir) allows the surface morphology adapt to the structure of polymer formed. Thus, the layers deposited have the same structure as of monocrystal of material deposited. Similar problems arise when nanoparticles are precipitated in solution. Other techniques

doi:10.1016/j.poly.2008.11.036

involving electrodeposition, CVD methods, etc. can give layers which are much stronger connected with the support, however, the main limit of these methods is the number of substrates available, relative simplicity of layers formed and structures accessible. Recently, it became clear, that less symmetric particles or layers can give rise to more complex and more interesting superstructures. For example it was possible to prepare nanowires of gold isolated along their length, but reactive at their ends [11]. Thus, we decided to develop the method of iterative deposition of the cyanide coordination compounds from aqueous solution, onto the pure metallic substrate, that leads to a layer-by-layer growth of a thin layer of the coordination polymer. The cyano-complexes of transition metals, (for example Fe(II,III), Mo(IV,V), W(IV,V), Mn(II,III,IV), etc.) easily form polymetallic compounds with d-metal cations, insoluble in all solvents studied. This type of reaction is of great importance in contemporary studies of molecular magnets and formation of low dimensional, molecular structures [11,12]. In this study the $K_4[W(CN)_8] \cdot 2H_2O$ salt was used as a starting compound for the monolayer deposition. The tungstate(IV) complex anion is thermally as well as kinetically stable, thus the side reactions (as ligand exchange, metal oxidation or reduction) can be eliminated [13]. High coordination number and the reliability of cyano-ligand to rearrange (from C_s to D_{4d} symmetry) in order to accommodate the structure of the anion to the local surrounding is also important for a high symmetry of the formed polymer [14]. As a cation Co^{2+}(aq) (in the form of $CoCl_2 \cdot 6H_2O$ or $Co(NO_3)_2 \cdot 6H_2O$ solution) was used. The lability of aqua ligands in Co^{2+} cation, enable the formation of insoluble $\{[\{Co(H_2O)_2(\mu\text{-}CN)_4\}_2W] \cdot 4H_2O\}_n$ salt and the possibility of Co^{2+} cation to form up to six cyano-bridges which is essential for desired layer composition [15].

2. Experimental

2.1. Materials and methods

The $K_4[W(CN)_8] \cdot 2H_2O$ was synthesized according to the published procedure [16], whereas $CoCl_2 \cdot 6H_2O$ and $Co(NO_3)_2 \cdot 6H_2O$ were used as received from Aldrich. The elemental analyses were performed using elemental analyzer, Euro EA 3000 (Euro Vector) and the presence of other elements was excluded by the EDXS spectrometry (EDS EDAX Genesis 4000). The thermogravimetric measurements were performed on a TDA/SDTA microanalyser (Mettler Toledo) combined with a Termostar GSD 300T Balzers quadruple mass spectrometer in the 30–1000 °C range, scan speed 5°/min, argon atmosphere. IR spectrum was measured in KBr pallets on a Bruker EQIUNOX 55 spectrometer. The reflectance UV–Vis spectrum was measured on a Shimadzu UV-2101PC spectrophotometer equipped with ISR-260 integrating sphere.

The work function measurements were performed on the vacuum setup equipped with Kelvin probe head (McAllister KP6500). Two plates of copper of required dimensions were cut from polycrystalline and/or monocrystalline copper (the parallel bases were the only requirement; the surface of bases was 1.35 cm^2). The bases (one of each plate) were mechanically polished to the mirror-like surface. The monocrystalline plate was then placed inside the vacuum chamber equipped with sample manipulator and evacuated. The commercial McAllister reference electrode plate, of diameter of 5 mm, was made of stainless steel. The Kelvin probe measurements were carried out at the vacuum level of 5×10^{-2} mbar. The sample was being moved parallel towards the reference electrode (vibrating at 200 Hz) until the contact potential difference (V_{CPD}) values, as well as, the gradient of the electric field values were stable (distance between the electrodes *ca.* 1 mm) at ambient conditions. The accuracy of the measurement was of 2.5 mV. The data were collected by the data acquisition system for further processing. The same parameters of the setup were used in all experiments.

2.2. Synthesis of $\{[\{Co(H_2O)_2(\mu\text{-}CN)_4\}_2W] \cdot 4H_2O\}_n$ (1)

The salt **1** was synthesized using modified method described in literature [15]. The 0.584 g (1 mmol) of $K_4[W(CN)_8] \cdot 2H_2O$ in 10 ml of water and 0.476 g (2 mmol) of $CoCl_2 \cdot 6H_2O$ in 10 ml of water were mixed together under continuous steering. After mixing the steering was continued for 1 h and the resulting precipitate was filtered off on a Büchner funnel, washed with distilled water, ethanol and dried on air at 35 °C for 3 h. Yield: 0.650 g (99%). Calc. for $C_8H_{16}N_8O_8Co_2W$: C, 14.7; N, 17.1; H, 2.47%. Found: C, 14.8; N, 16.7; H, 2.71%. The EDXS analysis of the precipitate excluded presence of potassium and chlorine ions. IR (KBr): 2138 cm^{-1} (ν_{CN}), 1614 cm^{-1} (H_2O), 3416 cm^{-1} (H_2O and hydrogen bonds).

2.3. The layer preparation

(a) The deposition process at high complex concentrations - double deposition manner. Two different aqueous solutions were prepared: 3.42×10^{-3} M $K_4[W(CN)_8] \cdot 2H_2O$ and 6.84×10^{-3} M $CoCl_2 \cdot 6H_2O$ (1:2 molar ratio). The potassium octacyanotungstate(IV) solution had been deposited on the copper monocrystalline plate (of measured V_{CPD}) by dip-coating and left for 60 s, the plate was then rinsed with a distilled water. The cobalt(II) chloride solution was then deposited on the sample in the same manner and left for 60 s. Finally, the plate was rinsed with distilled water again and dried on air. The contact potential difference of the monocrystalline plate, with such a deposited bimetallic bi-layer, was measured by means of Kelvin probe (experimental procedure analogical to the pure copper sample). The procedure was repeated for a number of double deposition processes resulting in a multilayer system (Fig. 1A). The entire procedure was conducted for the polycrystalline copper plate.

(b) The deposition process at high complex concentrations - single deposition manner. The procedure was analogous to (a) but the measurements were taken after each deposition of a monolayer (anionic or cationic) not the bi-layer (Fig. 1 B), (for a polycrystalline copper substrate only).

(c) The deposition process at low complex concentrations - single deposition manner. The procedure was analogous to (b) but 3.42×10^{-6} M $K_4[W(CN)_8] \cdot 2H_2O$ and 6.84×10^{-6} M $CoCl_2 \cdot 6H_2O$ (1:2 molar ratio) were used in each deposition step (Fig. 1 B).

(d) The deposition process at low complex concentrations - single deposition manner. The secondary anion effect. The procedure was analogous to (c) but 3.42×10^{-6} M $K_4[W(CN)_8] \cdot 2H_2O$ and 6.84×10^{-6} M $Co(NO_3)_2 \cdot 6H_2O$ (1:2 molar ratio) were used in each deposition step (Fig. 1 B).

3. Results

3.1. Characterisation of 1

The method of single crystal synthesis of **1** was described earlier in literature [15]. The modified method was used to check if rapid crystallization and formation of a colloidal phase of **1** will give the same product. The synthesized colloidal $Co_2[W(CN)_8] \cdot 8H_2O$ salt is insoluble both in polar and non polar solvents and is stable on air. It is formulated as $[W\{(\mu\text{-}CN)_4Co(H_2O)_2\}_2 \cdot 4H_2O]_n$, but basing on the structure presented it should be rather written as $\{[\{Co(H_2O)_2(\mu\text{-}CN)_4\}_2W] \cdot 4H_2O\}_n$. Both analysis and the IR spectrum of **1** are in agreement with the literature data indicating that

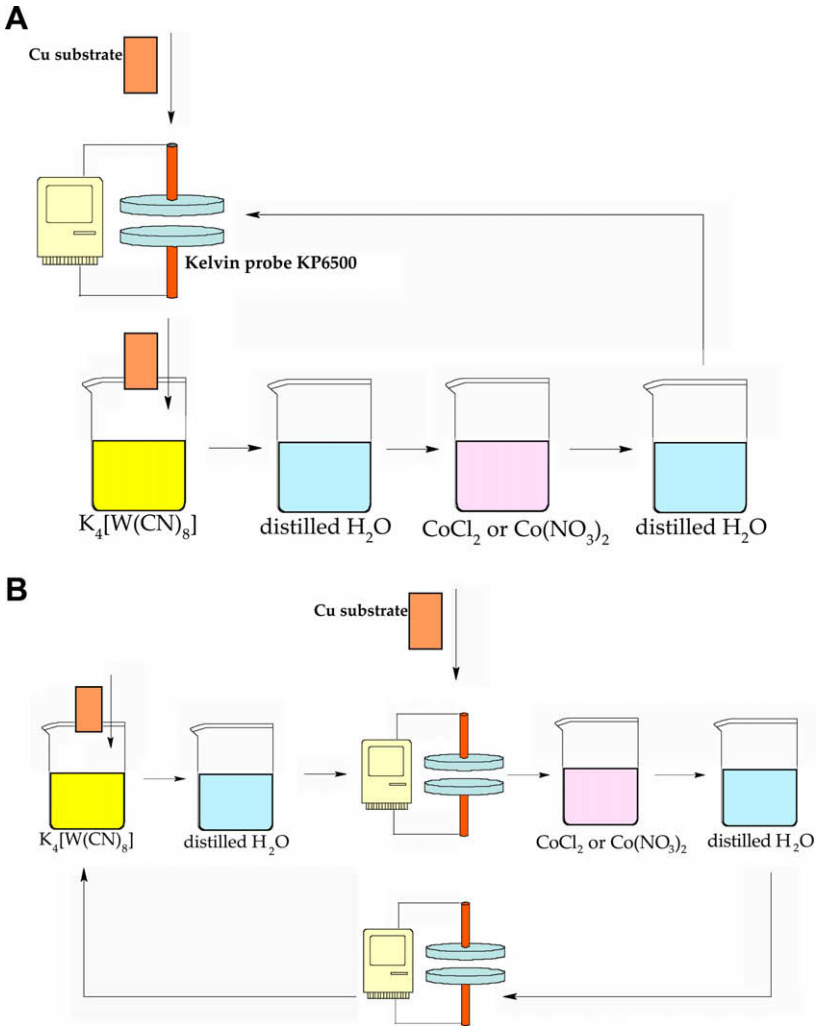

Fig. 1. The double (**A**) and single **(B)** deposition process and work function measurements

the salt composition is independent on the synthetic method used and is identical for single crystals and for colloidal form [15].

The reflectance spectrum of **1** is shown in Fig. 2. The spectrum of **1** differs significantly from that of $K_4[W(CN)_8] \cdot 2H_2O$. The new, low energy transitions at *ca.* 470 and 590 nm, can be observed. The difference can be interpreted as a formation of a low energy band attributed to the ion pair (anion–cation) charge transfer (CT) transition. Similar CT bands were observed for a numerous compounds with $[W(CN)_8]^{4-}$ ion and different cations, including organic ones [17]. According to the literature data, it can be found that formation of Co–NC–W bridges result in close W–Co distance (5.40 Å) and the charge transfer from tungsten to Co^{2+} becomes a relatively low energy process [15]. The formation of cyano-bridges with Co^{2+} is additionally confirmed by the drastic change at the intensity of the band at 240 nm attributed to W–CN CT transition, and shift of that band to lower energy (charge withdrawing effect caused by coordination of Co^{2+} to negatively charged CN^- ligands).

The thermogravimetric analysis of **1** shown in Fig. 3 indicates a complicated decomposition process. Combining with the quadruple mass spectrometer results it can be concluded that in the first step only four water molecules are released. The mass loss after first decomposition process (up to 300 °C) is 10.9% (calculated for four H_2O molecules, 11.0%). The release of four water molecules per tungstate is in agreement with the salt **1** formula and indicates that the net of cyano-bridges bonds remains unaltered at this stage

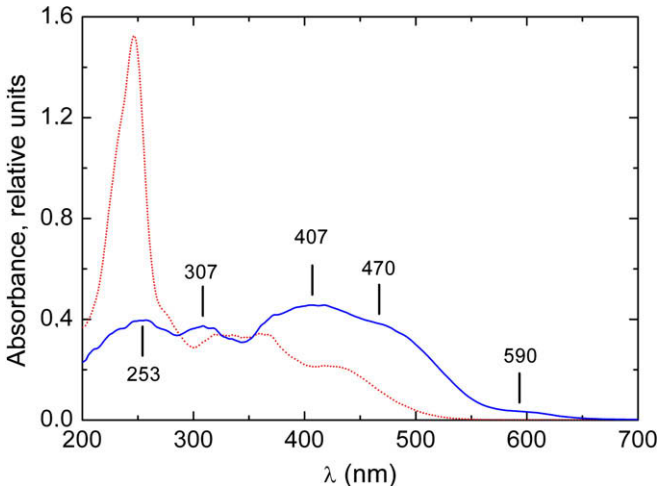

Fig. 2. The reflectance spectrum of **1** (blue line), for comparison spectrum of $K_4[W(CN)_8] \cdot 2H_2O$ is also included (dotted red line). Spectra in absorbance mode, after Kubelka-Munk transformation (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.).

of dehydration. In the next steps total decomposition of **1** with all water molecules and cyano ligands release is observed. The final mass loss is 43.7% (at 650 °C), whereas calculated for eight H_2O

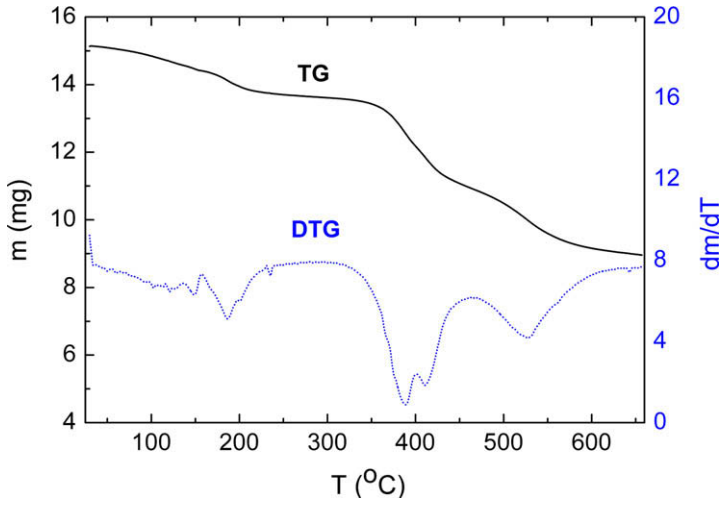

Fig. 3. TG and DTG curves of decomposition of **1**.

and eight CN^- molecules is 46.2%. The observed difference can be caused by still going decomposition at 650 °C (see Fig. 3) and/or presence of small amounts of oxygen in apparatus which can cause formation of oxides of molybdenum and cobalt.

3.2. The deposition process at high complex concentrations

An immersion of the copper substrate in an aqueous $K_4[W(CN)_8] \cdot 2H_2O$ solution for a couple of seconds was the first step of a nanolayer formation, as described in the experimental section. To protect such a formed film on a copper surface, it was necessary to fix it. It is known, that $[W(CN)_8]^{4-}$ ion forms insoluble salts with d-electron metals. We decided to use Co^{2+} cations, as cobalt complexes are one of the best known, with the well-defined coordination number 6 (with aqua ligands) and which form insoluble **1**. Also lability of $[Co(H_2O)_6]^{2+}$ ion was crucial for the fast fixation of tungsten layer [18]. Since copper does not exhibit a well-defined coordination number (4–6) in aqueous solution it cannot be used for this purpose. After $[W(CN)_8]^{4-}$ ions deposition on a copper substrate, it was washed with water (to prevent precipitation of colloidal **1** over the copper surface and its deposition on a solid substrate) and immersed in a solution of Co^{2+} ions (for 60 s) and again washed with water. Such a double deposition process was repeated for a required number of times (up to 50 layers formed) both for monocrystalline [3 1 1] and polycrystalline copper substrate.

The Kelvin probe was used to measure the work function changes of a pure copper substrate and the substrate covered with different numbers of bi-layers. The results are presented in Fig. 4.

As, at the concentration and volume used, number of the $[W(CN)_8]^{4-}$ ions exceeded the number of copper atoms at the surface (*ca.* 8×10^{15} atoms/cm^2) by several orders of magnitude it was assumed that the copper substrate was totally covered with anions in a single deposition process. For the pure metallic substrates, when there was no thin film deposited, the difference between the work functions values of the monocrystalline and polycrystalline copper was of 0.4 eV. As the work function depends on the surface potential, χ which reflects any asymmetric surface charge distribution, therefore oriented monocrystal surfaces and polycrystalline substrates exhibit different work function values [19]. In both cases, the deposition of the first several bi-layers (as low as one for polycrystalline sample but less than five in general; for the monocrystalline copper there was only first and fifth measured) led to the V_{CPD} values reaching the minimum, therefore, the work function of the substrates increased (reaching maximum).

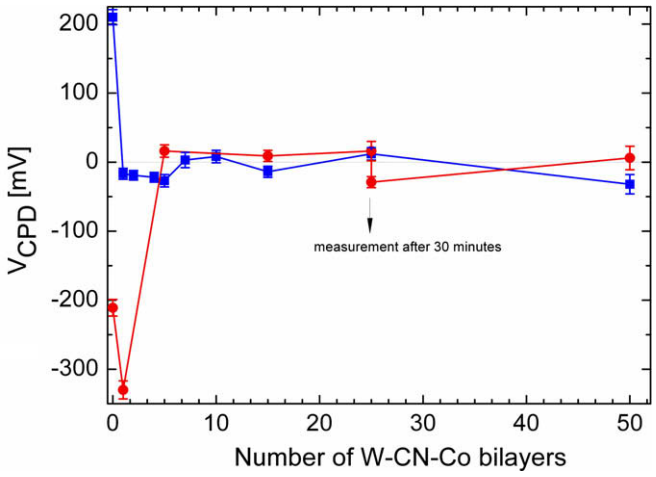

Fig. 4. Contact potential difference values (V_{CPD}) vs. total number of deposited bimetallic W-CN-Co bi-layers for the monocrystalline and polycrystalline copper substrate. High concentrations of the precursors: ■, polycrystalline Cu; ○, monocrystalline [3 1 1] Cu.

For the subsequent bi-layers the work function reached the constant value, equal for both types of copper substrates. The work function changes, for the number of deposition processes larger than five, are practically independent of the number of the bi-layers and/or type of copper substrate. Thus, the formation of the thin film on copper is independent of the crystalline form of the copper. Because after the initial monolayers are deposited and chemically bonded, the work function is permanently changed, reaching the constant value characteristic for the deposited material. The increase in the work function values is caused by the dominant coordination bond formation between octacyanotungstate(IV) anion, charge of which is compensated by the cobalt cations. Two main contributions to the work function value φ come form the band bending part (V) and electron affinity part (X). Thus, the total change of work function is given by the equation:

$$\Delta\varphi = \Delta V + \Delta X$$

The band banding change contribution is connected with strong interaction between the substrate and the absorbed molecule (*e.g.* strong covalent bond formation), whereas the electron affinity change contribution results from weaker interactions with the substrate (*e.g.* charge bindings).

The electron affinity of the deposited complex ion, is larger than the work function of the metal, and the electron density from the substrate is moved towards the ion. In this process a new acceptor level is formed and the band is bent upwards. Both band banding (Fermi level modification) contribution and electron affinity change contribution are taken under the consideration. The extreme in the work function value, observed only for the first several bi-layers, indicates that the dipole layer interacts strongly with the copper substrate. The conclusion is supported by the investigation in which the contact potential difference is measured after each single deposition process, as presented in Fig. 5.

In this case the large change of the work function for the first $[W(CN)_8]^{4-}$ monolayer with a charge compensated by the K^+, indicates that this layer is formed by bonding the complex ion to the Cu by the strong cyano-bridges. The maximum of the work function values is reached for one and a half of the bi-layer as presented in Fig. 5. After the deposition of the first three double layers the constant value of the work function is being reached similarly as in Fig. 4. This result confirms that the initial layer forms Cu–NC–W bridges with the substrate, therefore interacts chemically, not by weak charge bindings (like in the case of polyelectrolyte-based films deposited layer-by-layer, to which the investigated system is in analogy) [20,21].

After the first layer deposition, fixation with Co^{2+} resulted in the potassium cation exchange leading to further work function modification. As it is shown in Fig. 5, after three double deposition processes work function reaches plateau indicating that at this point metal is separated from the surface and only layer properties are important for the work function. Up to this value, work function is not a simple sum of metal and layer properties. It can be seen also, that exchange of K^+ cations into Co^{2+} (points at 1, 2, 3, 4 number of bi-layers) result in decrease of work function (probably as a result of CN bridge formation and easier electron transfer from coppers to the surface).

3.3. The deposition process at low complexes concentrations

In order to study in detail the coverage of the copper surface with the initial first layers of complexes deposited, the method (b) was introduced (see Section 2). The depositions were performed for relatively low concentrations of the precursors, assuming the structure of copper surface. The total number of copper atoms on the surface is of *ca.* 8×10^{15} atom/cm^2. The $[W(CN)_8]^{4-}$ ion radius (*ca.* 7.2 Å) and the Cu–Cu distance in the metal corresponds to less than *ca.* 10^{-8} mol of the anion in solution necessary to bond to each copper available. The applied amount of $[W(CN)_8]^{4-}$ ions in method (b) is close to that minimum, the diffusion of anions from the solution to the surface must be also taken under the consideration, additionally decreasing number of $[W(CN)_8]^{4-}$ ions available for copper atoms. All these factors cause that in method (b) surface of copper was not totally filled with the tungsten complex. The work function measurements were performed after each single deposition process and the results are presented in Fig. 6.

For the low concentrations of the precursors of the order of 10^{-9} mol/cm^3 comparable to the surface concentration of copper, the oscillating pattern of the work function changes is observed. After the first deposition of the complex anion, work function of the substrate increases. The deposition of the charge compensating and cyano-bridge-forming co-cation (one bi-layer deposited, see Fig. 6) resulted in the decrease of work function of copper to the initial value (within the experimental error). Such oscillations repeated on three consecutive deposition processes, after which

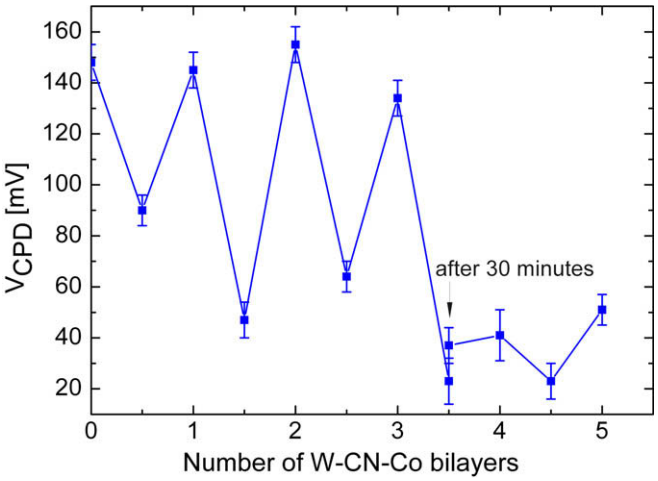

Fig. 6. Contact potential difference values in the function of total number of deposited monolayers ($[W(CN)_8]^{4-}$ or Co^{2+}) for the polycrystalline copper substrate. Low concentrations of the precursors.

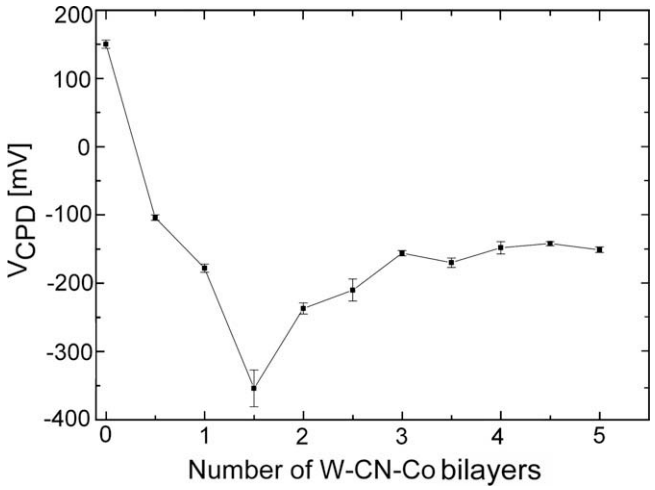

Fig. 5. Contact potential difference values in the function of total number of deposited monolayers ($[W(CN)_8]^{4-}$ or Co^{2+}) for the polycrystalline copper substrate. High concentrations of the precursors.

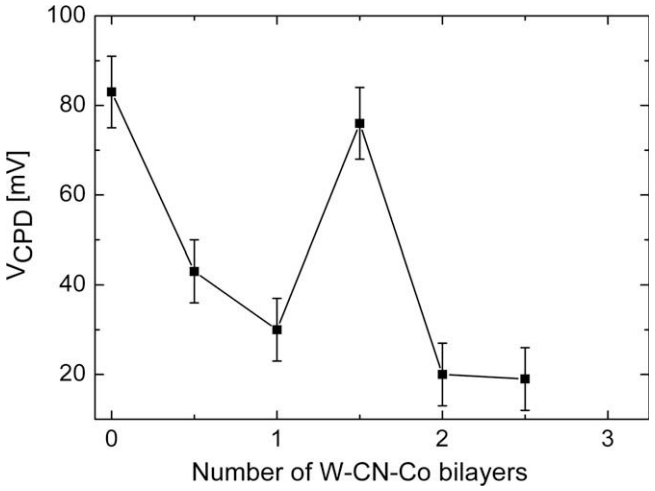

Fig. 7. Contact potential difference values in the function of total number of deposited monolayers ($[W(CN)_8]^{4-}$ or Co^{2+}) for the polycrystalline copper substrate. Low concentration of the precursors, cobalt(II) nitrate(V) instead of cobalt(II) chloride.

the new work function value established, constant for the consequent depositions (in the regime of 30 meV), and higher of 120 meV than the initial work function of copper. If the oscillations had been permanent for a large number of deposited layers their presence would be explained on the basis of the work function modification by the electron affinity part alone (no band banding contribution). Hence, the interaction of the dipole layer with a substrate would be rather weak. In the case investigated in this work, initial several deposition processes leading to the oscillations can be also explained in this way. The deposited precursors, as are of low concentrations, cannot be bonded to all copper atoms. For a Kelvin probe measurements such a deposition can be treated as a formation of a weak interaction between cooper substrate and complex anion from the point of view of the system in general, as the coordination bonds are still formed, but due to the low concentration of $[W(CN)_8]^{4-}$ they have local, not global impact on the work function values. The deposition of the precursors of high concentrations suggest that the layer is interacting with the substrate after the first bi-layer is deposited, as the minimum of the work function is reached after the very first several layers and no oscillations are present (see Fig. 5). Therefore, in the case of low concentrations of ions, the thick layer is obtained after several deposition processes and then the band bending contribution to the work function values starts to be considerable. Such a result is somehow expectable, because the concentration of the precursors is of the surface concentration of copper, the kinetics of the reaction and transport phenomena cause that only a fraction of copper atoms, that can bind the complex anion, actually forms the cyano-bridges (not mentioning that due to the symmetry of the bond and steric interactions this number of bonding places is limited anyway).

The chloride ions are very important in such an interpretation. At high distances between anions cobalt atoms cannot form required numbers of cyano-bridges, the coordination sphere and charge of Co^{2+} cations must be in part compensated by other than $[W(CN)_8]^{4-}$ ions. When (in the third deposition process) anions are again supplied to the system, they can be bonded neither to cobalt cations nor to copper surface. External anions, such as Cl^- are expected to play a role at the very beginning of the deposition process. To study this effect cobalt(II) nitrate(V) was applied instead of $CoCl_2 \cdot 6H_2O$ (method (c), Section 2.3). The results are shown in Fig. 7.

Both secondary anions (Cl^- or NO_3^-) should have the same contribution for the charge compensation, but they differ in sterical interactions. The deposition of the complex anion (0.5 numbers of bi-layers) led to the increase in the work function values, similarly as in Fig. 6, where Cl^- external anions were present. However, the deposition of Co^{2+} precursor with a NO_3^- anion caused further work function increase and also the decrease after the second complex anion deposition process (points at 1 and 2 bi-layers). Then, after 2.5 deposition steps again new constant value of the work function was established. The chaotic, pattern-less behavior of values of work function may be interpreted by the competition between the complex anion forming cyano-bridges with copper and the NO_3^- acting as the ligand to copper. This is possible due to the low concentration of the precursors and, as mentioned before, the kinetics of the reaction and transport phenomena, when the coverage of the substrate by the complex anions is less than 1 ($\Theta < 1$). It is also possible, that bigger NO_3^- ion give additional steric problems for $[W(CN)_8]^{4-}$ ions to reach copper surface, and the separation of metal from deposited layer starts much faster (after 3.5 depositions in case of Cl^- anions, see Fig. 6). Therefore, the appropriate choice of the seemingly unimportant secondary anion is essential for the thin layer deposition process.

4. Conclusion

The bimetallic cobalt–tungsten cyano-bridged layer were interactively deposited in up to 50 double deposition processes from aqueous solutions of potassium octacyanotungstate(IV) and cobalt(II) chloride on the mono and polycrystalline copper surfaces. The work function values were very sensitive to the number of bi-layers deposited as well as to the concentrations of the deposited precursors. When the surface coverage was high (at least one complete monolayer of the deposited precursors was present), then after *ca.* 3 deposited bi-layers the work function was independent of the initial surface work function and was driven only the outer layer properties. As a single bi-layer is *ca.* 0.8 nm thick, then 3 nm complex coating is sufficient to reach the maximum modification of the metallic substrate work function value. When the surface coverage with the first layer is not complete (below one monolayer), the work function values started to oscillate. The characteristic of the oscillations and the number of peaks depended also on a counter anion type, probably due to its coordination to the copper surface. The results presented indicate possibility of an easy fine-tuning of the work function of a metallic substrate (the dependence of its change and the complex anions and cations used is in progress). The strong cyano-bonds between deposited layers and copper substrate can be utilized for the deposition of insulating layer on a metallic substrate providing a precise tool for tuning the work function value which is essential for catalysis on metallic centers.

Photodegradation quantum yield

ABSTRACT

This work reports on the synthesis and photophysicochemical parameters of unsubstituted $[Sb^{III}Pc]^{+}I_3^{-}$ and octa-phenoxy ($[Sb^{III}OPPc]^{+}I_3^{-}$) and -4-*t*-butylphenoxy ($[Sb^{III}OTBPPc]^{+}I_3^{-}$) substituted antimony phthalocyanines. Photophysical and photochemical properties were studied for these complexes in dimethylsulfoxide, dimethylformamide and toluene. The excitation spectra of oxidized antimony (Sb(V)Pc) derivates were similar to absorption spectra. Low fluorescence quantum yields, high triplet quantum yields and low triplet lifetimes were observed as the result of heavy atom (antimony ion).

1. Introduction

Since their accidental discovery in the early 1900s, metallophthalocyanines (MPcs) have attracted much interest [1] due to their high chemical and thermal stability, high degree of aromaticity, synthetic flexibility and ability to adapt to a wide range of applications, including in non-linear optics [2,3] and photodynamic therapy [4].

MPcs exhibit intense absorption towards the red end of the visible spectrum, and the wavelength varies depending on the central metal and the type, number and position of substituents attached to the phthalocyanine macrocycle [5]. The presence of substituents on the Pc ring increases the solubility and also reduces molecular aggregation. Some central metal ions can allow axial ligation, which increases solubility, reduces molecular aggregation and brings about changes to the electronic structure of the molecule due to the dipole moment of the central metal-axial ligand bond [6]. MPcs containing heavy atoms such as antimony are expected to show enhanced intersystem crossing [7], resulting in improved photophysical and photochemical properties.

There has been less attention paid to MPc derivatives of group-15 elements except for a few reports on antimony and bismuth complexes of phthalocyanine [8–14]. Some properties of SbPc derivatives show distinct differences compared to the majority of MPc complexes. For example, the Sb tetra-*tert*-butyl phthalocyanine $[SbTBPc]I_3$ has shown the formation of J aggregates (red-shifted) in non-aqueous solutions [12]. J aggregates are rare in non-aqueous media for MPc complexes. The $[SbTBPc]I_3$ complex was found to be stable in the dark in chloroform and dichloromethane, but readily demetalated in donor solvents such as dimethylformamide (DMF) and tetrahydrofuran (THF) [15]. Photobleaching of this complex occurred under visible light irradiation in chloroform. Attempts to determine singlet oxygen producing ability of $[SbTBPc]I_3$ using 1,3-diphenylisobenzofuran (DPBF) as a quencher resulted in oxidation of Sb(III) to Sb(V) [15]. It has also been reported that some SbPc complexes do not show fluorescence in the Q-band region [12,15]. However, the behaviour of the triplet state of SbPc complexes has not been explored. Hence, in this work we report on the synthesis of new SbPc complexes: octa-phenoxy ($[Sb^{III}OPPc]^{+}I_3^{-}$) and -4-*t*-butylphenoxy ($[Sb^{III}OTBPPc]^{+}I_3^{-}$) substituted antimony phthalocyanines and on their photophysical and photochemical behaviour.

2. Experimental

2.1. Materials

Acetone, ethanol, chloroform ($CHCl_3$), methanol (MeOH), 1-chloronaphthalene (1-CNP), 1-octanol, tetrahydrofuran (THF), dimethylformamide (DMF), hexane and deuterated chloroform ($CDCl_3$) were obtained commercially and dried before use. Potassium carbonate (K_2CO_3), urea, phenol, 4-*tert*-butylphenol and phthalonitrile were purchased from Aldrich and used as received. Dimethylsulphoxide (DMSO) was purchased from SAARCHEM, and dried in alumina before use. 4,5-Dichlorophthalonitrile (**3**) [16] was synthesized and purified according to literature procedure.

2.2. Equipment

Ground state electronic absorption spectra were performed on a Varian Cary 500 UV–Vis–NIR spectrophotometer; infrared spectra (KBr pellets) on Perkin–Elmer Spectrum 2000 FT-IR Spectrometer and ^{1}H nuclear magnetic resonance (^{1}H NMR) signals on a Bruker EMX 600 NMR spectrometer. Triplet lifetimes (τ_T) and yields were obtained (at 22 °C) using an Nd-YAG laser providing 400 mJ, 90 ns of laser light at 10 Hz, pumping a Lambda-Physik FL 3002 dye laser. A 300-W xenon arc lamp (Thermo Oriel) provided the analysing light. Kinetic curves were averaged over 256 laser pulses using a Tektronix TDS 360 digital oscilloscope. The τ_T values were obtained by fitting an exponential curve to the kinetic data using ORIGIN Pro 6.0.

Photo-irradiations for photodegradation quantum yield terminations were performed using a General electric Quartz line lamp (300 W), as has been reported before [17]. A 600 nm glass cut off filter (Schott) and water were used to filter off ultraviolet and infrared radiations, respectively. An interference filter (Intor, 700 nm with a band width of 40 nm) was additionally placed in the light path before the sample. Light intensity was measured with a POWER MAX5100 (Molelectron detector incorporated) power meter and was found to be 5.14×10^{16} photons s^{-1} cm^{-2} for photobleaching studies. Elemental analysis was performed at the University of Cape Town, South Africa, using a Thermo Flash EA 1112 series elemental analyzer.

2.3. Photophysical and photochemical properties

Fluorescence quantum yields (Φ_F) were determined by the comparative method, using Eq. (1) [17,18]:

$$\Phi_F = \Phi_F^{std} \frac{F \cdot A_{std} \cdot n^2}{F_{std} \cdot A \cdot n_{std}^2} \quad (1)$$

where F and F_{std} are the areas under the fluorescence curves of the MPc derivatives and the standard, respectively. A and A_{std} are the respective absorbances (which was ~0.05 in all solvents used), of the sample and standard at the excitation wavelengths and n and n_{std} are the refractive indices of the solvents used for sample and standard, respectively. ZnPc was employed as a standard in DMSO (Φ_F = 0.20) [17].

The triplet quantum yields were determined using Eq. (2) [19]:

$$\Phi_T = \Phi_T^{std} \frac{\Delta A_T \cdot \varepsilon_T^{std}}{\Delta A_T^{std} \cdot \varepsilon_T} \quad (2)$$

where ΔA_T and ΔA_T^{std} are the changes in triplet state absorbance of MPc derivatives and the standard, respectively. Φ_T^{std} is the triplet quantum yield for the standard, ZnPc (Φ_T = 0.65 in DMSO [20], 0.58 in DMF [21] and 0.65 in toluene [22]). ε_T and ε_T^{std} are the triplet state molar extinction coefficients for the MPc derivatives and the standard, respectively.

ε_T^{Sample} and ε_T^{std} were determined from the molar extinction coefficients of their respective ground singlet state (ε_S^{Sample} and ε_S^{std}), the changes in absorbances of the ground singlet states (ΔA_S^{Sample} and ΔA_S^{std}) and changes in the triplet state absorptions, (ΔA_T^{Sample} and ΔA_T^{std}) according to Eqs. (2a) and (2b):

$$\varepsilon_T^{Sample} = \varepsilon_T^{Sample} \frac{\Delta A_T^{Sample}}{\Delta A_S^{Sample}} \quad (2a)$$

$$\varepsilon_T^{std} = \varepsilon_T^{std} \frac{\Delta A_T^{std}}{\Delta A_S^{std}} \quad (2b)$$

2.4. Photodegradation quantum yields

To determine the stability of SbPc derivatives, photodegradation quantum yields were calculated using Eq. (3):

$$\Phi_{Pd} = \frac{(c_0 - c_t)VN_A}{I_{abs}St} \quad (3)$$

where C_0 and C_t in mol dm^{-3} are concentrations before and after irradiation, respectively, V the reaction volume, S is the irradiated cell area (2.0 cm^2), t is the irradiation time, N_A is the Avogadro's number and I_{abs} is the overlap integral of the radiation source intensity and the absorption of the Pc (the action spectrum) in the region of the interference filter transmittance.

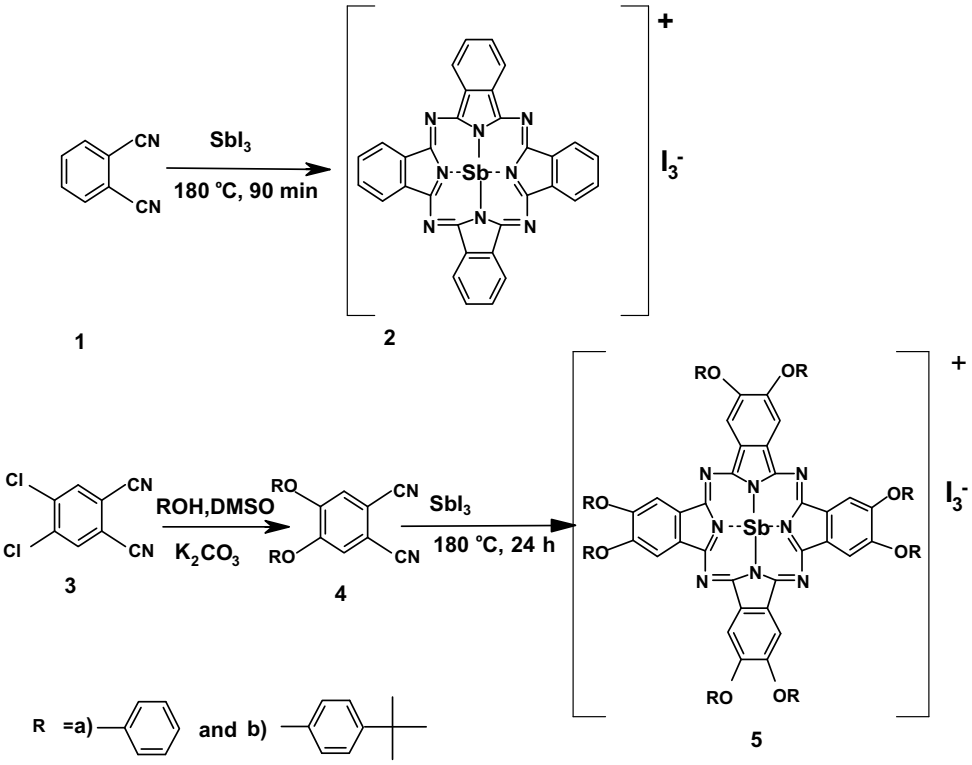
2.5. Synthesis

4,5-Diphenoxyphthalonitrile (**4a**), and 4,5-bis(4-*t*-butylphenoxy)phthalonitrile (**4b**) were synthesized and characterized according to reported procedures [23–25].

2.5.1. 2,3-Octaphenoxyphthalocyaninatoantimony triiodide ([Sb^{III}OPPc]$^+I_3^-$) (**5a**)

4,5-Diphenoxyphthalonitrile **4a** (0.62 g, 1.99 mmol) was heated to 180 ^{0}C until it completely melted. Then, antimony iodide (0.25 g, 0.50 mmol) was added in small portions to the completely molten solution. The reaction mixture was maintained at 180 ^{0}C for 24 h with constant stirring. The solid product was dissolved in CH_2Cl_2 and precipitated from the solution by addition of methanol. The product was washed with methanol three times, ethanol and then with acetone, respectively, until the washings turned essentially colourless. The solid product was further purified by washing with methanol, ethanol and then with acetone in a Soxhlet apparatus. Yield: 50.0 mg (18%). UV–Vis (DMSO): $\lambda_{max.}$ nm (log ε) 740 (5.03), 667 (4.62), 349 (4.78), 345 (4.78). IR [(KBr) $\nu_{max.}$/cm^{-1}]: 1271 (C–O–C), 1000, 883, 856, 749, 732 (Pc skeletal). ^{1}H NMR (DMSO): δ, ppm 8.72–8.79 (8H, s, Pc–H), 7.35–7.76 (40H, m, phenyl–H). *Anal.* Calc. for $C_{80}H_{48}N_8O_8SbI_3 \cdot 2H_2O$: C, 53.75; H, 2.71; N, 6.27. Found: C, 53.80; H, 3.17; N, 6.60%.

2.5.2. 2,3-[Octakis(4-t-butylphenoxyphthalocyaninato)] antinomy triiodide ([Sb^{III}OTBPPc]$^+I_3^-$) (**5b**)



Synthesis and purification of **5b** was as outlined for **5a** except **4b** instead of **4a** was employed. The amounts of the reagents employed were: **4b** (0.84 g, 1.99 mmol) and antimony iodide (0.25g, 0.50 mmol). Yield: 10.0 mg (2.7%). UV–Vis (DMSO): $\lambda_{max.}$ nm (log ε) 740 (5.02), 667 (4.44), 349 (4.73), 345 (4.64). IR [(KBr) $\nu_{max.}$/cm^{-1}]: 1270 (C–O–C), 883, 827, 769, 751,749 (Pc skeletal), 2965 (*t*-butyl-H). ^{1}H NMR (DMSO): δ, ppm 8.70 (8H, s, Pc–H), 7.01–7.40 (32H, m, phenyl–H), 1.11–1.40 (72H, s, ^{t}Bu). *Anal.* Calc. for $C_{112}H_{112}N_8O_8SbI_3 \cdot 2H_2O$: C, 60.15; H, 5.05; N, 5.01. Found: C, 60.57; H, 5.61; N, 5.09%.

The synthesis of phthalocyaninatoantimony triiodide (**2**) has been reported before [26].

3. Results and discussion

3.1. Syntheses and characterization

Scheme 1 gives the synthetic pathways for the SbPc complexes discussed in this work. The general procedure for synthesis of substituted phthalonitrile derivatives has been well documented [27,28] and the preparation of the substituted phenoxy derivatives was carried out as reported before [23–25]. Unsubstituted phthalocyanine (**2**) was prepared according to literature [26] by cyclotetramerization of 1,2-dicyanobenzene in the presence of metal salt. The syntheses of octa-substituted metallophthalocyanine complexes (**5a** and **5b**) were achieved by treatment of 4,5-disubstitutedphthalonitrile with metal salt. Soxhlet extraction was employed to obtain pure products.

Scheme 1. Synthesis of phenoxy ($[Sb^{III}OPPc]^+I_3^-$) and -4-*t*-butylphenoxy ($[Sb^{III}OTBPPc]^+I_3$) octa-substituted and unsubstituted SbPcs.

The MPc derivatives were characterized by UV–Vis, NMR (Fig. S1) and IR (Fig. S2) spectroscopies and elemental analyses. The analyses were consistent with the predicted structures as shown in Section 2. It has been reported before that for large Pc molecules, elemental analyses often gives unsatisfactory results [29]. However, the elemental analyses for complexes **5a** and **5b** gave satisfactory results that were close to calculated values. The sharp peak for the C≡N vibrations in the IR spectra of phthalonitriles **4a** and **4b** at ~2237 and 2224 cm^{-1}, respectively, disappeared after conversion into metallophthalocyanines. All MPc derivatives showed vibrational peaks between 700 and 1000 cm^{-1} which may be assigned to phthalocyanine skeletal vibrations [30]. The characteristic vibrations corresponding to ether groups (C–O–C) at ca. 1265–1275 cm^{-1} and aliphatic CH stretching at ca. 2900–3000 cm^{-1} were observed for the substituted MPc derivatives, Fig. S2.

The antimony phthalocyanines were found to be pure by ^1H NMR with all the substituents and ring protons observed in their respective regions. The phenoxy substituted complex **5a** showed the resonances belonging to ring protons as a singlet at 8.72–8.79 ppm, and a multiplet between 7.35 and 7.76 ppm, integrating for 8 and 40 protons, respectively, Fig. S2. The *tert*-butylphenoxy substituted complex **5b** showed the resonances belonging to ring protons as a singlet at 8.70 ppm and a multiplet between 7.01 and 7.40 ppm for aromatic protons integrating for 8 and 32 protons each, respectively, making a total of 40 protons as expected. The methyl protons appear as multiplets between 1.11 and 1.40 ppm integrating for 72 protons.

The ground state electronic absorption spectra of $[Sb^{III}OPPc]^+I_3^-$ and $[Sb^{III}OTBPPc]^+I_3^-$ show relatively sharp Q-bands typical of unaggregated MPc complexes, as has been reported before for other antimony derivatives [8–14], Fig. 1. It has been reported that the spectra of SbPc complexes are slightly broadened compared to other MPc complexes [12]. Sb(III) is larger than the equilibrium cavity size of the ring and cannot be accommodated without ring expansion; so the metal prutrudes out of the cavity, forming a domed shape. Under this situation, the symmetry of the complex becomes lower than D_{4h} [31]. The symmetry lowering allows some hitherto forbidden transitions; and consequently, spectral splitting and broadening is observed (Figs. 1 and 2). The Q-bands were observed at 730 (log = 5.23), 740 (log = 5.03) and 740 (log = 5.02) nm in DMSO (Fig. 1) for $[Sb^{III}Pc]^+I_3^-$ (**2**), $[Sb^{III}OPPc]^+I_3^-$ (**5a**) and $[Sb^{III}OTBPPc]^+I_3^-$ (**5b**), respectively. The Q-bands are slightly red-shifted in the latter two complexes, suggesting a small electron donating ability of the substituents. As reported before [12], the triiodide ion does not contribute to the Q-band absorption but contributes to the absorption near 360 nm in Fig. 1. Thus, the B band spectra will be affected by absorption from the triiodide ions. A

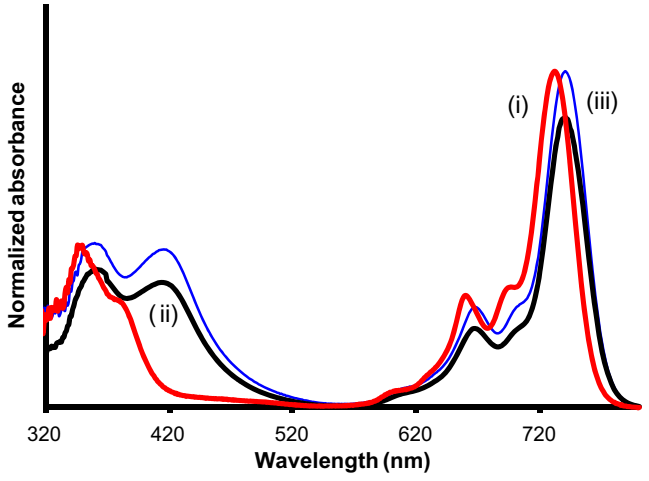


Fig. 1. Absorption spectra of complex (i) **2**, (ii) **5a** and (iii) **5b** in DMSO (~4×10^{-6} M).

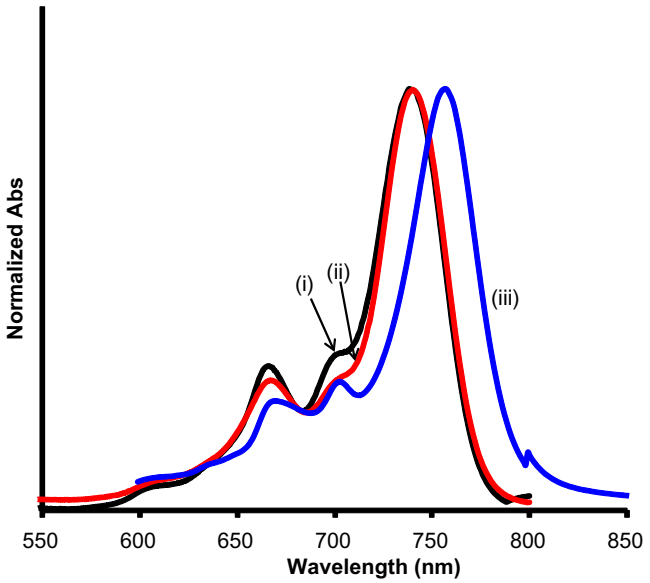

Fig. 2. Absorption spectra of complex **5b** in (i) DMSO, (ii) DMF and (iii) Toluene ($\sim 4 \times 10^{-6}$ M).

large red-shift has been reported in aromatic solvents [32], hence the red-shift of the SbPc derivatives in toluene is not surprising.

Phthalocyanines readily aggregate. The formation of aggregates was explored in this work by recording the spectra on increasing the concentrations of the $[Sb^{III}OPPc]^{+}I_3^{-}$ (**5a**) and $[Sb^{III}OTBPPc]^{+}I_3^{-}$ (**5b**), Fig. 3. At the concentrations employed in Fig. 3 (2×10^{-5}–3×10^{-6} M in DMSO), the intensity of the Q-bands decreased with concentration and no red (or blue) shifting due to aggregated species was observed at high concentration.

Even though some SbPc complexes are known to demetalate in donor solvents such as DMF and THF [15], there was no evidence of demetalation for complexes **2**, **5a** and **5b** in DMSO, DMF and toluene.

Since $Sb^{III}Pc$ derivatives do not fluoresce, we oxidized complexes **2**, **5a** and **5b** to $Sb^{V}Pc$ derivatives in order to study their fluorescence behaviour. The oxidation of antimony complexes has been reported using H_2O_2 as an oxidant [26]. It was found that antimony(III) phthalocyanine complexes can be readily converted to the corresponding antimony(V) derivates through oxidative addition process [26]. Even though H_2O_2 is a readily available oxidant, it is known not to give clean spectra of the resulting $Sb^{V}Pc$

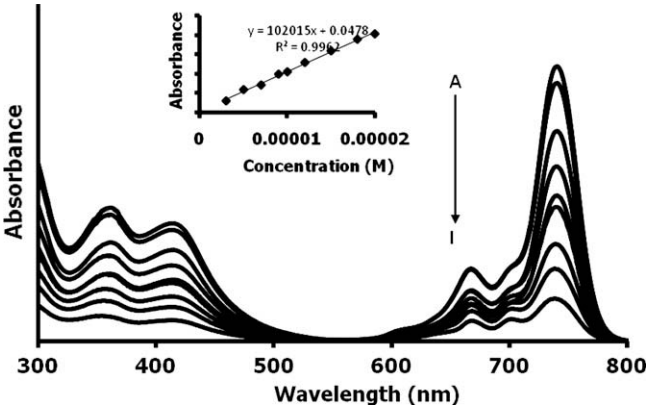

Fig. 3. Absorption spectra of compound **5a** in DMSO at different concentrations: (A) 2×10^{-5}, (B) 1.8×10^{-5}, (C) 1.5×10^{-5}, (D) 1.2×10^{-5}, (E) 1×10^{-5}, (F) 9×10^{-6}, (G) 7×10^{-6}, (H) 5×10^{-6} and (I) 3×10^{-6} M.

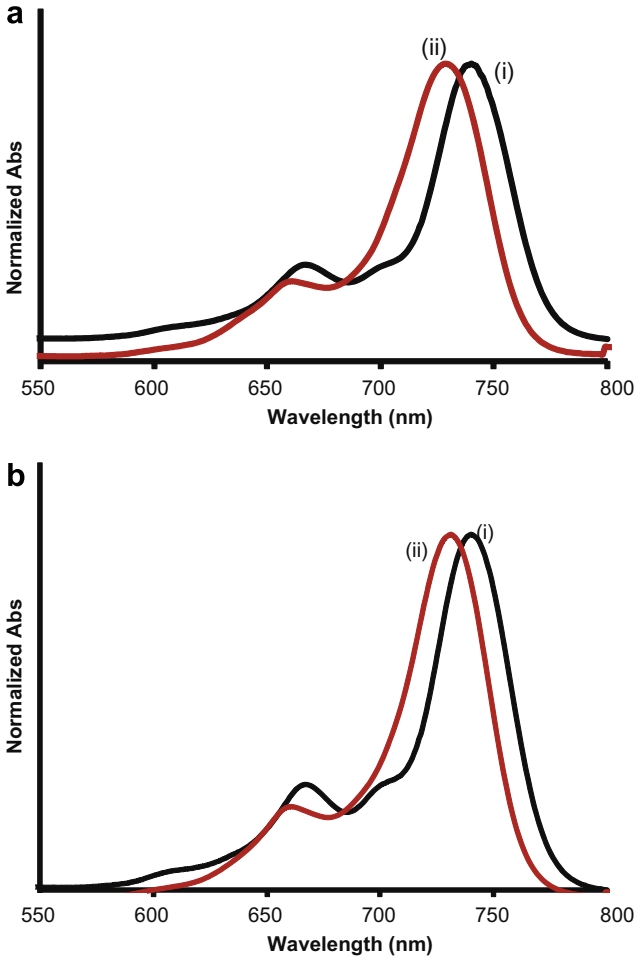

Fig. 4. Absorption spectra before (i) and after (ii) oxidation of complex (a) **5a** and (b) **5b** using TBHP in DMSO as an oxidant. Concentration $\sim 1 \times 10^{-5}$ M.

[33], hence in this work we employed an organic oxidant *t*-butylhydroperoxide (TBHP). The oxidation of $Sb^{III}Pc$ derivatives is known to proceed more cleanly if organic peroxides such as *tert*-butyl perbenzoate are employed as oxidants [33].

After addition of TBHP to $Sb^{III}Pc$ complexes (**2**, **5a** and **5b**), Q-band absorptions were blue-shifted as indicative of oxidized $Sb^{III}Pc$

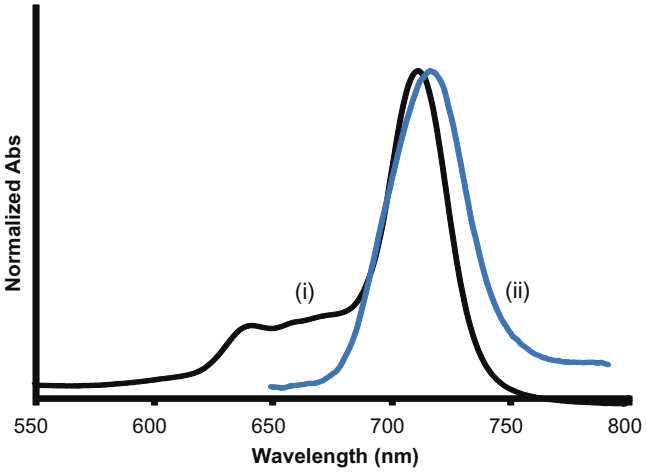

Fig. 5. Absorption (i) and emission (ii) spectra of oxidized compound **2** in DMSO using TBHP as oxidant ($\sim 8 \times 10^{-6}$ M).

Table 1
Spectral, photophysical parameters of $Sb^{III}Pc$ derivatives in DMSO, DMF and toluene.

MPc	Solvent	$\lambda_{max.}$ (nm) absorption	Φ_T	Φ_{Pd} ($\times 10^{-5}$)	τ_T (μs)
[a](I)SbPc (**2**)	DMSO	730	0.75	0.31	30
	DMF	728	0.76	0.52	7
(I)SbOPPc (**5a**)	DMSO	740	0.79	0.42	20
	DMF	735	0.78	0.61	5
	Toluene	758	0.77	0.57	7
(I)SbOTBPPc (**5b**)	DMSO	740	0.80	0.48	30
	DMF	735	0.82	0.53	5
	Toluene	753	0.78	0.81	6

derivates, Fig. 4a and b. The Q-bands were observed at 710, 735 and 731 nm in DMSO for oxidized forms of complexes **2**, **5a** and **5b**, respectively. Sb(V) is smaller than Sb(III) (ionic radii are 0.62 Å and 0.89 Å, respectively), and also more electronegative. The smaller size and higher electronegativity increase the conjugation of the Pc's HOMO with the metal $5p_z$ orbital [34], which results in lower charge density and energy of the Pc's HOMO. The effect of this is the observed blue-shifting of spectral band positions (Fig. 4).

3.2. Photophysical and photochemical properties

3.2.1. Fluorescence spectra and quantum yields

It is known that low valent main group porphyrin and phthalocyanine complexes (such as $Sb^{III}Pc$ derivatives) do not show emission around the Q-band [12]. The $[Sb^{III}Pc]^+I_3^-$ (**2**), $[Sb^{III}OPPc]^+I_3^-$ (**5a**) and $[Sb^{III}OTBPPc]^+I_3^-$ (**5b**) complexes were oxidized to the corresponding $[X_2Sb^{V}Pc]^+I_3$, $[X_2Sb^{V}OPPc]^+I_3^-$ and $[X_2Sb^{V}OTBPPc]^+I_3^-$ (where X represents monoanionic axial ligands containing oxygen donors OR) using TBHP. Fig. 5 shows the absorption and fluorescence spectra of oxidized complex **2** in DMSO. Similar spectra were observed for complexes **5a** and **5b**. The observed emission spectra are red-shifted when compared to their corresponding excitation and absorption spectra. The fluorescence excitation spectral maxima agree very well with absorption of the compounds, Tables 1 and 2, suggesting that there are no differences in the nuclear configuration of the ground and excited states, Fig. 5. The fluorescence emission peaks were observed: 716, 741 and 736 nm for oxidized compound **2**, **5a** and **5b** (in DMSO), respectively.

The fluorescence quantum yield (Φ_F) is the fraction of molecules in the excited state that do return to ground state via fluorescence. It is a parameter that is affected by molecular properties as well as the solvent and environment surrounding the molecule. The Φ_F values for the oxidized **2**, **5a**, **5b** are very low as reported before ($\Phi_F < 0.01$) for Sb(V)Pc complexes [33]. The Φ_F yields were relatively low compared to MPc in general [17] due to the presence of heavy atom effect (antimony ion) which enhances intersystem crossing to populate the triplet state.

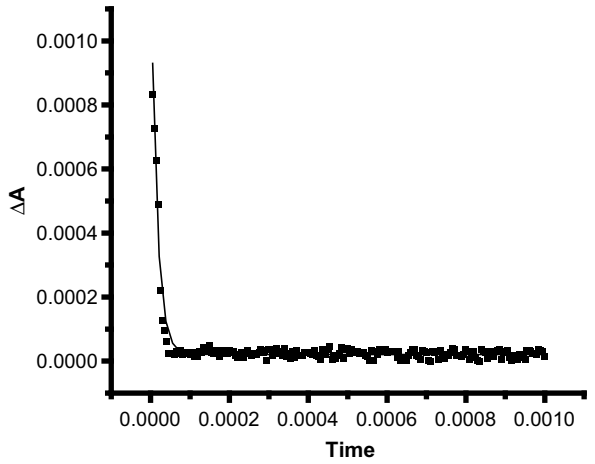

Fig. 6. Triplet decay curve of complex **5a** in DMSO. Excitation wavelength = 510 nm.

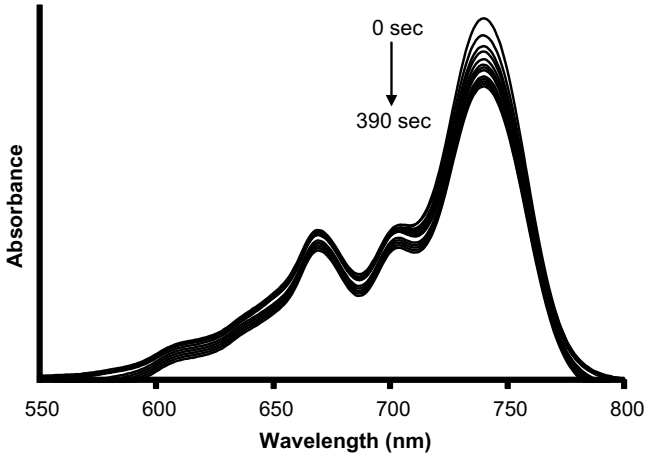

Fig. 7. Photobleaching of complex **5a** in DMSO.

3.2.2. Triplet quantum yields and lifetimes

Both the triplet quantum yields and lifetimes were determined by laser flash photolysis. Fig. 6 shows representative triplet decay curves for the $Sb^{III}Pc$ derivatives, which is similar to those of their oxidized counterparts ($Sb^{V}Pc$). Fig. 6 shows the triplet decay curve for the complexes obeyed second order kinetics. This is typical of MPc complexes at high concentrations (>1×10^{-5} M) [35] due to the triplet–triplet recombination. The concentrations employed in this work were in this range, hence triplet–triplet recombination is expected.

Table 2
Spectral, photophysical parameters of $Sb^{V}Pc$ derivatives in DMSO, DMF and toluene.

MPc	Solvent	$\lambda_{max.}$ (nm)			Φ_T	Φ_{Pd} ($\times 10^{-5}$)	τ_T (μs)
		Absorption	Emission	Excitation			
[a]Oxidized **2**	DMSO	710	716	711	0.71	1.23	70
	DMF	706	710	705	0.72	2.42	8
Oxidized **5a**	DMSO	735	741	736	0.74	1.51	60
	DMF	728	733	727	0.74	2.23	9
	toluene	743	750	742	0.73	3.42	10
Oxidized **5b**	DMSO	731	736	730	0.76	2.01	50
	DMF	730	734	729	0.77	3.22	8
	toluene	742	748	740	0.78	2.42	9

[a] (I)SbPc (**2**) is insoluble in toluene.

Tables 1 and 2 gives the triplet state parameters, Φ_T and τ_T. The triplet quantum yield which are a measure of molecules that undergo intersystem crossing to occupy the triplet state, were calculated using Eq. (2). Table 1 shows high Φ_T values (0.75–0.82, for complexes **2**, **5a** and **5b**) in DMSO, DMF and toluene, due to the presence of antimony. It seems that the introduction of substituents onto the ring had only a small effect on the Φ_T, the values increased from 0.75 for complex **2**, to 0.79 for **5a** and 0.80 for **5b** in DMSO. The Φ_T values (0.71–0.78) for oxidized $Sb^{V}Pc$ complexes were a bit lower than for the $Sb^{III}Pc$ complexes. The values are in general high due to the heavy atom effect of Sb, Table 2.

The triplet lifetime (τ_T) values were found to be low for SbPc complexes compared to ZnPc or AlPc [36] derivatives but are similar to the corresponding InPc [37,38] derivatives, containing a heavy metal. The τ_T values in DMSO (Tables 1 and 2) ranged from 20 to 30 μs for $Sb^{III}Pc$ complexes while in DMF and toluene the τ_T values were less than 10. τ_T Values are lower in DMF than in DMSO because of the greater absorption by DMF (than DMSO) in the region of the complexes' triplet energy [17]. The τ_T values for oxidized complexes $Sb^{V}Pc$ complexes were longer than for corresponding $Sb^{III}Pc$ compounds.

Photodegradation or photobleaching (Φ_{Pd}) is used to determine the photostability of MPc molecules and is identified by a decrease in the intensity of the absorption spectra without the appearance of new peaks. Photodegradation is a function of the nature of the substituents attached to the phthalocyanines periphery, the solvent and the central metal. SbPc derivatives have been shown to photodegrade without transformation to other visible absorbing species [15]. The spectral changes observed during photobleaching were similar for all the complexes (**2**, **5a** and **5b**) during irradiation. The collapse of the absorption spectra without any distortion of the shape confirms clean photodegradation not associated with phototransformation, Fig. 7. All the complexes showed same stability as compared to InPc and GaPc [25,36,37] with Φ_{Pd} of the order of 10^{-5}.

4. Conclusion

In this study, we synthesized and characterized new peripherally (phenoxy and 4-*t*-butylphenoxy) octa-substituted antimony phthalocyanine complexes. For the oxidized $[X_2Sb^{V}Pc]^{+}I_3$, $[X_2Sb^{V}OPPc]^{+}I_3^{-}$ and $[X_2Sb^{V}OTBPPc]^{+}I_3^{-}$ complexes, the excitation spectra were the same as absorption spectra and both are mirror images of the emission spectra. The low fluorescence quantum yields, high triplet quantum yields and low triplet lifetimes were observed as the result of heavy atom (antimony ion).

4-aminopyroglutamate motif

ABSTRACT

Spectroscopic data, including electronic absorption, CD and EPR results, as well as theoretical calculations have shown that the insertion of 4-aminopyroglutamate, a novel *cis*-peptide bond mimic, in the insect kinin peptide leads to an effective ligand towards Cu(II) ions at basic pH ranges. The 4-aminopyroglutamate motif induces a specific peptide conformation which favors the formation of one or two five-membered chelating rings stabilizing a bent structure, with the coordination of 3N-type or 4N-type in the metallopeptide molecule involving in metal bonding C-terminal of modified peptide. It is worth noting that the copper(II) bonding does not undergo hydrolysis even at a very high pH range.

1. Introduction

Insect kinins share a highly conserved C-terminal pentapeptide sequence Phe–Xaa–Xbb–Trp–Gly–NH_2, where Xaa can be Tyr, His, Ser or Asn and Xbb can be Ala but is generally Ser or Pro. Insect kinins, and/or analogues, have been reported to inhibit the growth of serious agricultural pests, e.g. the tobacco budworm (*Heliothis virescens*) or corn earworm (*Helicoverpa zea*) [1]. The insect kinins preferentially form a *cis*-Pro, type VI β-turn. An insect kinin analog containing (2S,4S)-4-aminopyroglutamate, a novel *cis*-peptide bond, type VI β-turn motif has demonstrated significant activity in the physiological range in a cricket diuretic assay. This is the first instance of a 4-aminopyroglutamate analog of a peptide with a preference for a type VI β-turn that demonstrates significant bioactivity [2].

Their chelating properties have not been studied yet. Many essential metal ions act as important factors that influence the structure of natural and synthetic oligopeptides and, as a consequence, they may affect their biological activity.

In this work the interaction of copper(II) ions with the peptidomimetic insect kinin analogs, containing 4-aminopyroglutamate (apy or aPy), has been studied. The aim was to identify coordination sites for the metal ion. In peptides and proteins copper ions usually interact with the peptide bond most easily via an amino terminal amine nitrogen anchor then the coordination followed by the sequential deprotonation of neighboring peptide nitrogens. In our case such an anchoring site does not occur because the amine terminal is protected. However, the other anchoring donor atom could be the oxygen of the carbonyl group of the apy/aPy motif. To determine the coordination mode of the metal ion in the formation of the peptide-metal complex, potentiometric, spectroscopic (UV–Vis, CD, EPR) studies, in conjunction with computer modelling optimisation, have been performed on several ligand systems: AcRFapyWG-OH, AcRFFPWG-NH_2 and AcRFaPyWG-NH_2 (Fig. 1). The results reveal that the peptides containing the apy or aPy motif form complexes with 3N or 4N coordination modes above pH 8. One of nitrogen donor atoms is very likely from the pyrrolidine group of the apy/aPy motif. The Cu(II) ion coordination to the AcRFFPWG-NH_2 ligand is not observed until above pH 10.

reported procedures [2]. The purity of these ligands was verified by HPLC (high performance liquid chromatography) and mass spectrometry to be >99%. The $Cu(NO_3)_2$, KNO_3, HNO_3 and NaOH were Merck products and used without any further purification.

2.2. Spectroscopic studies

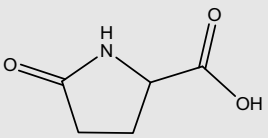
Electronic absorption spectra (UV–Vis) were recorded with a Perkin–Elmer Lambda 11 spectrophotometer. Circular dichroism (CD) spectra were obtained with a Jobin-Yvon CD-6 dichrograph over the range 200–750 nm, using 1 and 0.05 cm cuvettes. The spectra are expressed as $\Delta\varepsilon = \varepsilon_l - \varepsilon_r$, where ε_l and ε_r are the molar absorption coefficients for left and right circularly polarized light, respectively. Electron paramagnetic resonance (EPR) measurements were carried out with a Varian E-9 instrument at the X-band frequency (9.1 GHz) at 120 K; about 10% of ethanediol was added to the samples in order to obtain glasses with the proper viscosity. The EPR parameters were read from the spectra (estimated uncertainties for A_{II} and g_{II} values are 1×10^{-4} cm^{-1} and 0.002, respectively). All measurements were made over the pH 6–11 range, at

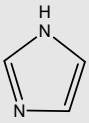
a constant ionic strength using 0.1 M KNO_3, a temperature of 298 K, a Cu(II)/L ratio of 1:1, and a metal concentration 1×10^{-3} M. The pH was changed using NaOH.

2.3. Potentiometric studies

The protonation constants (pK_a) of the ligand AcRFapyWG-OH and the stability constants of Cu^{II} complexes (log β) were determined by pH-potentiometric titrations of 2.0 mL samples. The ligand:metal molar ratio was 1,1:1 and the concentration of Cu^{II} was 0.001 M. Measurements were carried out at 298 K and at a constant ionic strength of 0.1 M KNO_3 with a MOLSPIN pH meter (Molspin Ltd., Newcastle-upon-Tyne, UK) equipped with a digitally operated syringe (the Molspin DSI 0.250 mL) controlled by computer. The titrations were performed with a carbonate-free NaOH solution of known concentration (ca. 0.1 M) using a Russel CMAWL/S7 semi-micro combined electrode, calibrated for hydrogen ion concentration by the method of Irving et al. [3]. The number of experimental points was 100–150 for each titration curve. The reproducibility of the titration points included in the evaluation was within 0.005 pH units in the whole pH range examined (2–11). The stability constants of the complexes, reported as the logarithm of the overall formation constants $\beta_{pqr} = [Cu_pL_qH_r]/[Cu]_p[L]_q[H]_r$, where Cu is the copper ion, L is the ligand with the deprotonated carboxylate group of C-terminal, and H is the proton, were calculated with the aid of the SUPERQUAD program [4].

2.4. Computational studies





All calculations were carried out using the MOPAC 2007 program [5]. The geometries of ligand and all complexes were fully optimized using the semi-empirical molecular orbital method PM6 [6]. In the case of the copper ion complexes all calculations were carried out using Unrestricted Hartree-Fock (UHF) approximation, assuming the open shell electronic state of the molecule as a doublet, and the solvent (water) environment was simulated by employing the COSMO method [7]. In the first step of our calculations a conformational search of the free ligand was performed to find the lowest energy conformations. The conformational search was performed by random perturbation of torsion angles following by energy minimization. For every investigated ligand about 6000 conformations were energy minimized. The lowest energy conformations of free ligand were used as a starting point for calculations of the copper complexes. For the AcRFapyWG-OH, the copper ion initially bound to the C-terminal carboxyl group. For this complex, a conformational search was performed to determine the most favorable position for the copper ion. To determine the lowest energy conformations we identified structures for which the amide proton is close to the hydration shell of the copper ion. For a given conformation any amide proton closer than 2.5 Å from the copper ion is removed from the system, which corresponds to the deprotonation reaction observed in the potentiometric experiment. Conformational search and deprotonation cycles were repeated until the coordination sphere of the metal ion was occupied by at least four ligand atoms. In the case of the AcRFFPWG-NH_2 and AcRFaPyWG-NH_2 peptides, we do not have a favorable initial coordination site. So in the first step the copper ion was placed close to one of seven oxygen carbonyl atoms. The initial complex conformational search was then performed and structures for which any amide proton is closer than 2.5 Å from the copper ion the proton is removed from the system and the structure is energy minimized. For all ligands the conformational search is terminated if after the generation of a 1000 consecutive new conformations we are not able to find another amide proton close to the central ion.

3. Results and discussion

3.1. The AcRFapyWG-OH peptide

The protonation constant of the studied ligand and several others for comparison are given in Table 1.

Table 1
The protonation constants of AcRFapyWG-OH and several other ligands and the complex formation constants of AcRFapyWG-OH with Cu(II) at 25 °C, I = 0.1 mol dm^{-3} (KNO_3).

Ligand	Species	Logβ	Stepwise protonation constants	Ref.
AcRF**apy**WG-OH	HL	3.47(1)	$pK_{HL} = 3.47$	This work
Copper(II) complexes	$CuH_{-2}L$	−9.35(4)		
	$CuH_{-3}L$	−16.95(3)	$pK_{CuH_{-3}L} = 7.60$	
	$CuH_{-4}L$	−26.05(2)	$pK_{CuH_{-4}L} = 9.10$	
3-Amino-2-Oxopyrrolidine-5-Carboxylic acid (APy) 	HL	~12.39(5)	$\sim pK_{HL} = 12.39$	From [8]
	H_2L	19.54(1)	$pK_{H_2L} = 7.15$	
	H_3L	21.89(2)	$pK_{H_3L} = 2.35$	
Pyroglutamyl-histidyl-prolinamide (TRH)	HL	~13.99	$\sim pK_{HL} = 13.99$	From [9]
	H_2L	20.22	$pK_{H_2L} = 6.23$	
L-Pyroglutamic acid 	HL	3.10	$pK_{HL} = 3.10$	From [9]
Imidazole 	HL	~14.44	$\sim pK_{HL} = 14.44$	From [10,11]
	H_2L	21.56	$pK_{H_2L} = 7.12$	

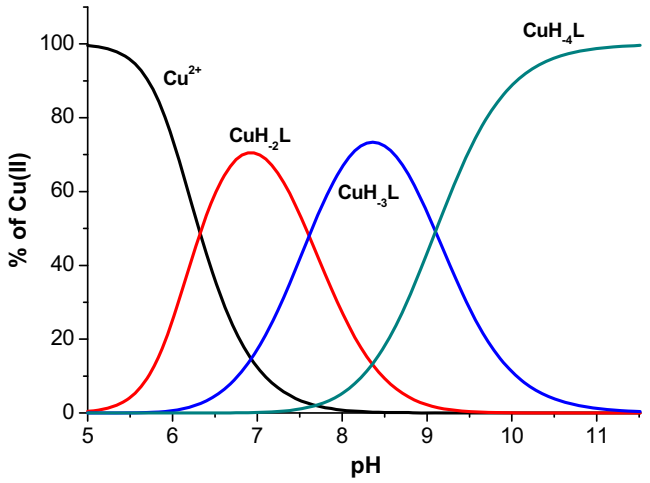


Fig. 2. Species distribution curves for complexes of AcRF**apy**WG at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3). Metal concentration 1×10^{-3} M. Ligand to metal ion 1, 1:1.

All modified peptides contain an Arg residue (Fig. 1) at the first position of the peptide backbone. The arginine residue contains a very basic terminal nitrogen atom as a result of resonance stabilization of the protonated guanidine group (log $K \approx 12$) [12]. Under the experimental conditions used, the pH is ≈11 and, at this value, the degree of deprotonation of the guanidine group is insignificant. Therefore the proton was considered as unionisable under the conditions used and its protonation constant ignored. Therefore we studied potentiometrically only AcRFapyWG-OH containing a protonation site located on the C-terminus. The pK of the carboxylic group is similar to that of other peptides like tetraGly [13] or tetraAla [14]. The next protonation constant might be assigned to the pyrrolidine nitrogen, but due to its high basicity that determination is problematic. We can only assume that the value could be similar to that found for 3-amino-2-oxopyrrolidine-5-carboxylic acid and the other ligands (see Table 1 and Ref. [8]. The potential electron donor atoms for Cu(II) ion are the oxygen or nitrogen of 4-aminopyroglutamate (apy), the peptide backbone amide groups and the C-terminal carboxyl oxygen. This unusual coordination can be deduced from our previous study of the Pyr–WG–NH_2–Cu(II) system [15]. The best fit of the titration curves indicates the presence of the species $CuH_{-2}L$, $CuH_{-3}L$ and $CuH_{-4}L$ (charges omitted for simplicity, Fig. 2) in pH 5–11 range.

The first detectable complex $CuH_{-2}L$ with the 2N coordination mode, exists around pH 7. It appears as a main species without the coexistence of the 1N complex due to the 2N coordination proceeds in a cooperative manner after Cu(II) ion anchoring at the oxygen of the C-terminal carboxylate. Then coordination follows by sequential deprotonation of NH apy motif group and the neighboring peptide nitrogen $\{N^-_{apy}, N^-_{amide}\}$. The $CuH_{-2}L$ species is supported by spectroscopic data with the d–d transition at 673 nm in absorption and at 640 nm in the CD spectra (Table 2), characteristic for the 2N coordination [16].

Evidence for this species arises from the CD in the 200–240 nm region which is different from that of the "free" ligand (Fig. 3a) and suggests that the chiral chelate conformation prevails over the vicinal contribution of the asymmetric carbon [17]. The EPR parameters with $A_{II} = 176 \times 10^{-4}$ cm^{-1} and $g_{II} = 2.270$ (Table 2) are also in a good agreement with binding of two nitrogen atoms to the Cu(II) ion [18]. The charge transfer band seen in CD spectra at 309 nm, corresponding to a $N^- \rightarrow$ Cu(II) transition, indicates the presence of at least one amide nitrogen donor atom in the copper coordination sphere. The next complex species with the stoichiometry $CuH_{-3}L$ becomes dominant at about pH 8.5 (Fig. 2). Its formation is a result of the CuH_{-2} L deprotonation according to the equilibrium reaction: $CuH_{-2}L \rightleftarrows CuH_{-3}L + H^+$. The deprotonation constant pK = 7.60 (Table 1) indicates the deprotonation and coordination of the second amide nitrogen atom to Cu(II) ion [19,20]. The hypsochromic shift of the d–d absorption maximum to 555 nm in UV–vis and 546 nm in CD spectra and the EPR parameters: $A_{II} = 186 \times 10^{-4}$ cm^{-1}, $g_{II} = 2.207$ support additional amide nitrogen atom binding [16] and a $\{N^-_{apy}, N^-, N^-\}$ coordination (Table 2). The next species $CuH_{-4}L$ was detected by potentiometry above pH 11. The spectrum (Fig. 3a) registered at this pH range indicates

Table 2

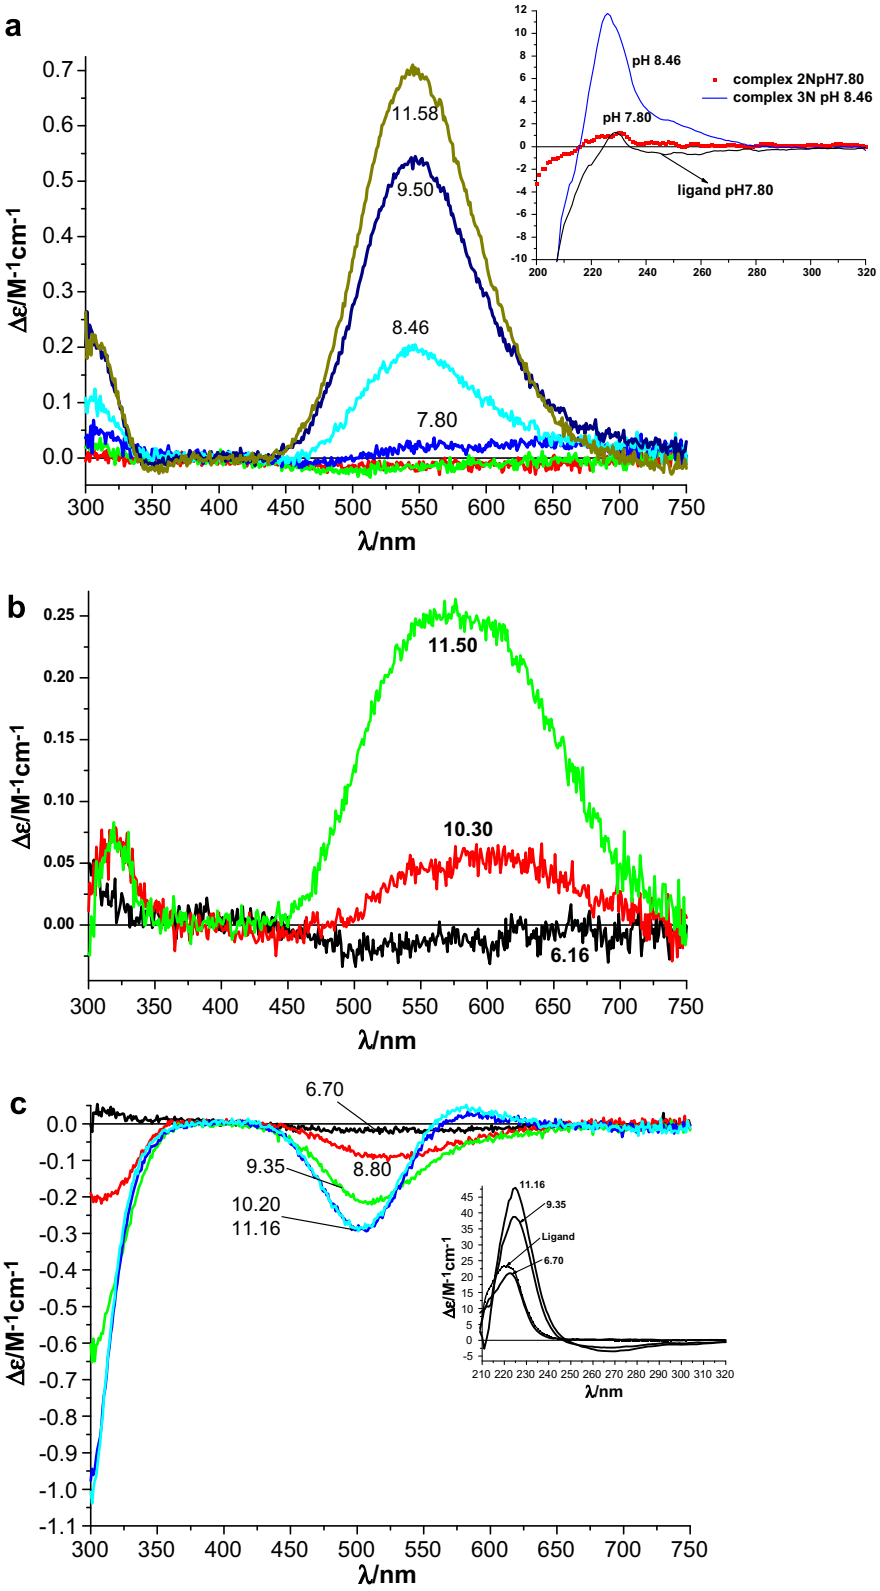

Fig. 3. CD spectra as function of pH for the systems: (a) Cu(II)-AcRF**apy**WG-OH, (b) Cu(II)-AcRF**FP**WG-NH_2 and (c) Cu(II)-AcRF**aPy**WG-NH_2.

that $CuH_{-4}L$ still has the 3N coordination but with very likely deprotonated guanidine group of the Arg residue. This conclusion can be derived from the theoretical calculations. In Fig. 4a the lowest energy conformation of complex of AcRFapyWG-OH with the copper ion deduced from theoretical calculations is presented. The central metal ion is surrounded by three deprotonated amide nitrogens and the C-terminal carboxyl oxygen. Cu–N distances vary from 1.87 to 1.91 Å and the distance Cu–O is 2.01 Å, clearly showing that the typical square planar geometry of coordination is a little bit distorted for this complex. From one side of the

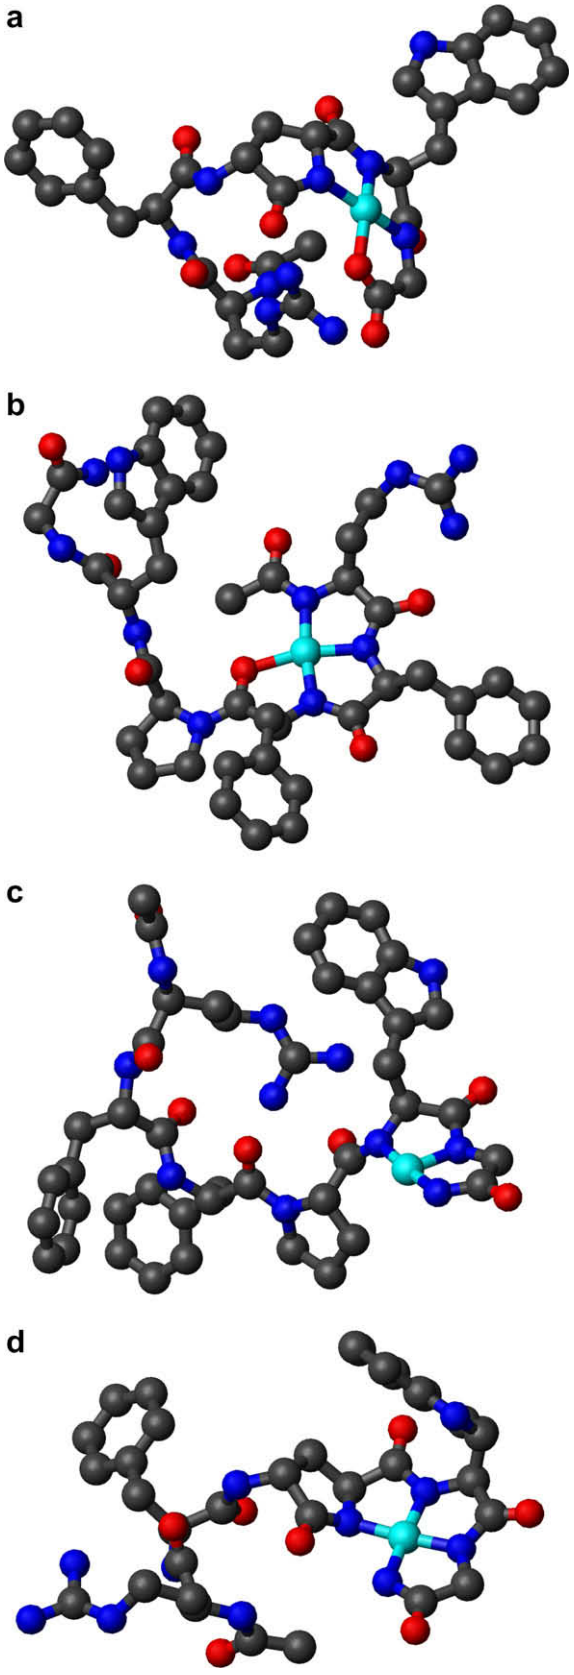

Fig. 4. The structure of complexes obtained from theoretical calculations: (a) *AcRF**apy**WG*; (b) *AcRF**FP**WG-NH*$_2$ N-terminus coordination mode, (c) *AcRF**FP**WG-NH*$_2$ C-terminus coordination mode, (d) *AcRF**aPy**WG-NH*$_2$. All hydrogen atoms are removed for clarity. The copper(II) ion is shown in magenta, oxygen, carbon and nitrogen atoms are shown in red, black and blue respectively.

coordination plane we have located the tryptophane side chain and from another side we have the N-terminus of the peptide. The presence of such large flexible elements can rule out the possibility of the stable location of water molecules to fill the fifth and the sixth coordination sites of the central ion. Interestingly, we find that the protonated guanidine group of the arginine residue is always located very close to the coordination plane and always very close to the C-terminal carboxyl group. The close spatial orientation of both of these groups could suggest an increase in the acidity of the protonated guanidine. This observation could lead to the hypothesis that species $CuH_{-4}L$ is formed due to the deprotonation of guanidine at an unusually low pH ($pK_a = 9.10$) because of favorable electrostatic interactions.

3.2. The AcRFFPWG-NH$_2$ peptide

In the AcRFFPWG-NH$_2$ ligand both N-and C-termini are blocked. The formation of a metallopeptide molecule starts after the anchoring of the copper(II) ion at a carbonyl group. The coordination pattern may continue in a part of any terminus of the peptide, as our calculations suggest. Potential nitrogen donors in this ligand molecule arise from the peptide bonds and from an amidated C-terminus. Following that, the peptide amide bonds undergo deprotonation to form stable fused ring structures. The oxygen donor could be one of the carbonyls, a water or a hydroxide. The Pro residue acts as a breakpoint in the consecutive nitrogen peptide bond coordination because the tertiary amide is a weak donor and not a metal binding site [21]. The detectable CD and electronic absorption spectra are not distinguishable in the Cu(II)-AcRFFPWG-NH$_2$ system before pH 10 (Table 2, Fig. 3b). At this pH the visible absorption spectra exhibit a broad, single absorption band around 630 nm (Table 2) which is in agreement with the presence of two nitrogen donor atoms coordinated to the copper ion [18,19]. The presence in the CD spectra of an $N^- \rightarrow Cu^{2+}$ charge transfer transition at *ca.* 300 nm (Fig. 3b) is consistent with 2N coordination {N^-, N^-} of the peptide to copper(II) ions [22]. At pH 11 the metallopeptide molecule may lose the next amide proton to give a species with three nitrogen donors{N^-, N^-, N^-} or, alternatively, via binding of the Cu(II) ion to a third nitrogen arising from the C-terminal amide without involvement of further deprotonation. The shift of d-d transitions to 545 nm in the electronic absorption and to 576 nm in the CD spectra support the involvement of a third nitrogen donor atom (Table 2). An increase in pH does not affect the band of a $N^- \rightarrow Cu^{2+}$ charge transfer transition (Table 2, Fig. 3b). It may suggest the localization of the third nitrogen at the blocked C-terminus.

In Fig. 4b and c the lowest energy conformations of the complex of AcRFFPWG-NH$_2$ with copper ion from theoretical calculations are presented. Following a conformational search we identified two distinct families of complexes arising from the presence of the proline residue in the middle of the sequence. In both families three deprotonated amide nitrogen atoms are bound to the central metal ion. In Fig. 4b a complex with the metal ion bound to three consecutive amide nitrogens starting from the N-terminus of the peptide is presented. The fourth coordination site is occupied by a carbonyl oxygen from the Phe^3 residue. The geometry of the coordination sphere is square planar with Cu–N distances in the range of 1.88–1.85 Å and a Cu–O distance of 2.02 Å. It is interesting to note that all amino acid side-chains and the C-terminal part of the peptide are located on one side of coordination plane of this complex and thus are not able to isolate the central ion from solvation, which can destabilize the complex. The second complex presented in Fig. 4c is formed with the C-terminal part of the peptide. In this case the coordination plane is composed of three deprotonated amide nitrogens, whereas the fourth coordination site

cannot be filled by any atom from the ligand molecule and is probably occupied by a water molecule. All three nitrogens are located at a distance of 1.84 Å from the central ion and all four atoms (three nitrogens and central ion) are ideally coplanar. We can observe two very interesting interactions, which stabilize the structure of the complex. We can see strong interactions between the protonated arginine side chain and the tryptophane aromatic ring [23]; as well as the formation of a hydrophobic cluster between the aromatic rings of the two phenylalanines. Both of these interactions should decrease the conformational flexibility of the ligand, which usually leads to an increase in complex stability [23]. Based on the computed heat of formation and solvation energies we can conclude that the complex presented in Fig. 4c is more thermodynamically stable and is better solvated. Thus, theoretical calculations support the experimental observation that the C-terminal part of the peptide is involved in coordination with the metal ion. (Table 2, Fig. 3b)

3.3. AcRFaPyWG-NH_2 peptides

The AcRFaPyWG-NH_2 peptide has no protonation constant detectable potentiometrically. Hence, we could not make calculations to find a stoichiometry of complex species. Therefore spectroscopic parameters were only used to support copper coordination. They are, however, good indications of the importance of a particular coordination mode in complex species formation. As deprotonation is a crucial step in the binding of Cu(II) with a peptide, the pH of the solution is expected to significantly affect the formation of a complex. It is evident that three detectable species with different coordination modes are forming in the 7–11 pH range. These complexes have significantly different chiroptical properties (Fig. 3c) and spectral parameters (Table 2). The coordination binding starts very likely after anchoring Cu(II) ion at the oxygen of the aPy motif and then proceeds via the sequential deprotonation of N pyrrolidine and neighboring peptide nitrogens. Evidence for the formation of the first complex is seen at pH 7. The binding mode involves the 2N {N^-_{apy}, N^-} donor set as in other similar peptide analogs [15]. The 2N coordination is clearly confirmed by EPR parameters with $A_{II} = 177 \times 10^{-4}\,cm^{-1}$ and $g_{II} = 2.270$ (Table 2). The charge transfer transition at 310 nm (Fig. 3c) in the CD spectrum corresponds to the involvement of the peptide amide $N^- \rightarrow Cu(II)$. When the pH increases to 8.80 the deprotonation of the next amide nitrogen occurs and the formation of a 3N complex species can be observed. It is accompanied by a change of the Cotton effect in the 300–310 nm range assigned to $N^- \rightarrow Cu(II)$ transition and the band shift of d–d transition observed both in CD and electronic absorption spectra (Fig. 3c, Table 2). Following an increase of the pH to 10–11 the all spectral parameters clearly support the binding of four nitrogen donor atoms to Cu(II) ion in a metallopeptide molecule. The donor set is confirmed by EPR parameters ($A_{II} = 209 \times 10^{-4}\,cm^{-1}$ and $g_{II} = 2.170$). In the electronic absorption spectra, the λ_{max} of the d–d band shifts to 518 nm and its intensity reaches 160 $dm^3\,mol^{-1}\,cm^{-1}$ (Table 2), which is typical for copper(II) oligopeptide complexes [16,18,19]. The amidated C-terminus (NH_2) can deliver the fourth nitrogen donor atom as was reported for Pyr-WG-NH_2 and AcRFapyWG-NH_2 peptides [15]. A modification of the AcRFaPyWG-NH_2 conformation therefore accompanies the formation of a 4N species. It may reflect a specific conformational constraint arising within the peptide backbone as it is induced to wrap around the copper ion. In addition, a negative effect appears at 270 nm (Fig. 3c), which is characteristic of charge transfer (c.t.) transitions due to the nitrogen atom from the amide group [24]. The band is distinctly broad, indicative of the overlap of the NH_2 and N^- c.t. transitions. In the AcRFapyWG-OH and AcRFFPWG-NH_2 spectra this band is not observed (Table 2). It is likely due to a strong tendency of the first amide group in this kinin analogue to undergo deprotonation in a cooperative manner, as a result of a bent structure imposed by the aPy(R,S) motif, leading to the simultaneous coordination of amide nitrogens of the 4N complex that exists at high pH range. The distinct effect of the aPy(R,S) motif is also demonstrated in the visible part of CD spectra. The spectra observed above pH 9 assigned to the 4N species [16,22] exhibits two d-d bands. This splitting is an effect of the (R,S) configuration at the carbons 4 and 2, respectively. The aPy(R,S) motif constrains the conformational freedom of the peptide backbone around the Cu(II) ion. The presence of a split in the d-d bands indicates a deviation from square-planar geometry around the metal ion, as has been observed in other oligopeptides [25,26]. In Fig. 4d the structure of the AcRFaPyWG-NH_2 complex deduced from theoretical calculations is shown. As was the case for the AcRFFPWG-NH_2 peptide, we are not able to identify an initial metal ion binding site. However during a conformational search, we are able to find out that the stereochemistry of the aPy moiety induces the metal ion to bind with the carbonyl oxygen, which immediately brings the amide proton into the coordination sphere and facilitates its dissociation. Such a situation does not exist in the case of regular peptides because peptide bonds are usually present in a *trans* orientation. In a regular peptide, if the metal ion is coordinating to the carbonyl oxygen then the closest amide proton is either located at the opposite side of the peptide chain or at a distance of three of four chemical bonds away. Therefore it is generally kinetically unfavorable to bring the amide proton of a normal peptide into the coordination sphere of a metal ion. Based on this information we can conclude that the initial coordination site is the aPy moiety, which is supported by the likely-low pK_a value associated with this type of molecule [8]. Hence, we assume that the metal ion initially binds to aPy deprotonated moiety for both steric reasons and a low pK_a value. For stereochemical reasons, the metal ion binds simultaneously to the carbonyl oxygen and the amide nitrogen of the aPy motif, which is isolated from the amide bond preceding the motif in the peptide sequence and has an easy access to the peptide bond in the direction of the C-terminus of the peptide. As shown in Fig. 4d, in our complex model structure the metal ion is bound by four deprotonated amide nitrogens from the C-terminal part of the AcRFaPyWG-NH_2 peptide. The central ion and four nitrogen donor atoms form a very regular planar square as would be expected from this type of complex. Cu–N distances demonstrate very little variance in the range from 1.79 to 1.81 Å. Spectroscopy measurements suggest that the square planar coordination geometry can be distorted, although our calculations suggest that the complex is very regular. We presented only one conformation from this family of complexes in which the aPy ring is almost flat. In other structures we observed that the aPy moiety can form a chair conformation (data not shown) and the stability difference between the flat-chair conformation is very small, leading to the conclusion that both of these types of conformations exist in a rapid equilibrium. It is very likely that the fast equilibrium between the two conformations of the aPy ring can lead to the split in the d-d bands observed in CD spectra (Fig. 3c). For the most part, one side of coordination plane is shielded by side chain of tryptophan residue and another side remains open to solvent in low energy structures. The conformationally restricted aPy moiety keeps the N-terminal part of molecule far away from the coordination site.

4. Conclusions

In conclusion, our study has demonstrated the coordination potentiality of oligopeptides containing a novel *cis*-peptide bond.

Incorporation of the apy/aPy motif into the peptide backbone results in the considerable acidification of the neighboring amide hydrogen, making it easier to deprotonate than in an unmodified peptide. This motif does not occur in AcRFFPWG-NH_2 therefore the formation of the first complex cannot be observed before pH 10 (Fig. 3b). One can suppose that the motif could be an anchoring site for copper(II) ion in the pH 7–8 range, providing that the N- or C-terminals are blocked or other possible coordinating anchors, *e.g.* carboxylate or histidine side chains, are not present.

ABSTRACT

Novel [ReOBr(hmquin-7-COOH)$_2$] (**1**) and [ReOCl(hmquin-7-COOH)$_2$] · MeCN (**2** · MeCN) complexes have been prepared by treatment of [ReOX$_3$(AsPh$_3$)$_2$] with an excess of 8-hydroxy-2-methylquinoline-7-carboxylic acid in acetonitrile. The compounds were characterized structurally and spectroscopically. The electronic structure of **1** has been calculated with the density functional theory (DFT) method, and additional information about binding has been obtained by NBO analysis. The UV–Vis spectrum of **1** has been discussed on the basis of TDDFT calculations.

1. Introduction

There is considerable interest in the chemistry of inorganic compounds containing an oxygen atom that is multiply bonding to a transition metal in a high oxidation state. These compounds can transfer an oxygen atom to reductants such as phosphines, sulfides, and alkenes. For many years they have been in the centre of interest to those scientists engaged in basic research and to those trying to employ these complexes in catalytic processes. Oxygen atom transfer chemistry has been implicated in various reactions of industrial and biological importance, including olefin epoxidation and catalysis by cytochrome P-450 [1–3].

The chemistry of oxo rhenium complexes arouses particular interest among these compounds. Methyltrioxorhenium and its derivatives are among the most versatile oxidation catalysts known to date [4]. The oxorhenium(V) chelates [ReOCl$_2$(O–N)(PPh$_3$)] with pyridinecarboxylate ligands exhibit a remarkable catalytic activity for the conversion of ethane, under relatively mild conditions, to a mixture of propionic and acetic acids in a single-pot process with various advantages over the industrial ones [5]. The [CH$_3$ReO(pic)$_2$] complex is an active precursor in olefin oxidation and forms epoxides in a two-phase H$_2$O$_2$–H$_2$O/CH$_2$Cl$_2$ system [6].

Furthermore, favourable nuclear properties of ^{186}Re and ^{188}Re nuclides make the compounds with these radioisotopes useful for applications in radioimmunotherapy [7,8].

In this context, the design, synthesis and reactivity of novel rhenium oxocomplexes has become the aim of several laboratories, including ours.

Previously, we investigated structural and spectroscopic properties of [ReOX(hqn)$_2$] and [ReOX(quin-2-c)$_2$] (Hhqn = 8-hydroxyquinoline, quin-2-cH = quinoline-2-carboxylic acid) [9,10]. As an extension of this work, we chose 8-hydroxy-2-methylquinoline-7-carboxylic acid (Hhmquin-7-COOH) as a ligand. Potentially, Hhmquin-7-COOH can act as a bidentate, tridentate or bridging ligand. As a chelate 8-hydroxy-2-methylquinoline-7-carboxylic acid can bind to the metal centre through the pyridine nitrogen and the deprotonated hydroxyl group (N,O-chelation) or through the carboxylate group and the deprotonated hydroxyl group (O,O-chelation).

X-Ray and spectroscopic studies for [ReOBr(hmquin-7-COOH)$_2$] (**1**) and [ReOCl(hmquin-7-COOH)$_2$]·MeCN (**2** · MeCN) confirm N,O-chelation of the hydroxy-2-methylquinoline-7-carboxylic acid. The COOH group of the Hhmquin-7-COOH in the examined complexes is available for further conjugation.

For complex **1** the nature of the frontier orbitals and the electronic transitions involved in the absorption spectrum have been

doi:10.1016/j.poly.2008.11.053

studied by means of density functional and time-dependent density functional calculations. Gancheff and co-workers [11] have performed extended tests of the ability of the B3LYP method in LANL2DZ basis set for rhenium compounds in a geometry optimization and calculation of spectral properties. Although this is not a very extended basis set, its use with DFT has shown to be sufficient for the geometry optimization and calculation of spectral properties. The correctness of B3LYP method with LANL2DZ basis set for rhenium complexes has been also proven in this paper. The experimental geometry of [ReOBr(hmquin-7-COOH)$_2$] is well reproduced and the calculated electronic spectrum is in good accordance with the experimental one.

2. Experimental

2.1. General procedure

The [ReOX$_3$(AsPh$_3$)$_2$] (X = Cl, Br) complexes were synthesised according to the literature methods [12]. 8-hydroxy-2-methylquinoline-7-carboxylic acid was prepared as reported previously [13].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 1000–180 nm in acetonirile solution. Elemental analyses (C H N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of [ReOBr(hmquin-7-COOH)$_2$](**1**)

[ReOBr$_3$(AsPh$_3$)$_2$] (0.5 g, 0.47 mmol) was added to 8-hydroxy-2-methylquinoline-7-carboxylic acid (0.28 g, 1.38 mmol) in acetonitrile (50 ml) and the reaction mixture was refluxed for 6 h. The resulting solution was allowed to cool to room temperature and reduced in volume to ~10 ml. A greenish-brown crystalline precipitate of **1** was filtered off and dried in the air. Yield 75%.

Single crystals of **1** were obtained by recrystallization from acetonitrile.

Anal. Calc. for C$_{22}$H$_{16}$N$_2$O$_7$BrRe: C, 38.49; H, 2.35; N, 4.08. Found: C, 38.35; H, 2.43; N, 4.37%.

2.3. Preparation of [ReOCl(hmquin-7-COOH)$_2$] · MeCN (**2** · MeCN)

A procedure similar to that for **1** was used with [ReOCl$_3$(AsPh$_3$)$_2$] (0.5 g, 0.54 mmol) and 8-hydroxy-2-methylquinoline-7-carboxylic acid (0.28 g, 1.38 mmol). Crystalline precipitate of **2** · MeCN was collected in 70% yield.

Anal. Calc. for C$_{24}$H$_{19}$N$_3$O$_7$ClRe: C, 42.20; H, 2.80; N, 6.15. Found: C, 42.98; H, 2.68; N, 6.81%.

2.4. Crystal structures determination and refinement

The X-ray intensity data of **1** and **2** · MeCN were collected on a KM-4-CCD automatic diffractometer equipped with CCD detector and graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at temperature of 293(2) K. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and empirical absorption correction using spherical harmonics implemented in SCALE3 ABSPACK scaling algorithm [14] were applied. The structures were solved by the Patterson method and subsequently completed by the difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. The hydrogen atoms were treated as 'riding' on their adjacent atoms and assigned isotropic temperature factors equal 1.2 times the value of equivalent temperature factor of the aromatic parent atoms and equal 1.5 times the value of equivalent temperature factor of the methyl parent carbon atom and oxygen atom (OH). SHELXS97 [15], SHELXL97 [16] and SHELXTL [17] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.5. Computational details

GAUSSIAN 03 program [18] was used in the calculations. The geometry optimization of [ReOBr(hmquin-7-COOH)$_2$] in a singlet state was carried out with the DFT method with the use of B3LYP functional [19,20]. The electronic spectrum of [ReOBr(hmquin-7-COOH)$_2$] was calculated with the TDDFT method [21], and the solvent effect was simulated using the polarizable continuum model with the integral equation formalism (IEF-PCM). The calculations were performed by using ECP basis set on the rhenium atom, the standard 6-31+G** basis for bromine, oxygen and nitrogen, 6-31G* for carbon and 6-31G for hydrogen atoms [22,23]. The Xe core electrons of Re were replaced by an effective core potential and DZ quality Hay and Wadt Los Alamos ECP basis set (LANL2DZ) [24] was used for the valence electrons. Additional d function with exponent α = 0.3811 and f function with exponent α = 2.033 on the rhenium atom were added [25]. The optimized geometry of **1** was verified by performing a frequency calculation. The vibrations in the calculated vibrational spectrum of **1** were real, thus the optimized geometry corresponds to true energy minimum.

Natural bond orbital (NBO) calculations were performed with the NBO code [26] included in GAUSSIAN 03.

3. Results and discussion

3.1. Preparation and infrared data

The [ReOX(hmquin-7-COOH)$_2$] (X = Cl, Br) complexes were prepared in high yields by a route analogous to that used for the

Table 2

They were isolated as greenish-brown microcrystalline solids, soluble in common organic solvents.

The selected frequencies observed in the IR spectra of [ReOX(hmquin-7-COOH)$_2$] complexes are collected in Table 2. The assignments are based on those found in the literature for related species [27,28]. Similar to the [ReOX(hqn)$_2$] complexes, the strong ν(Re=O) stretching bands of [ReOX(hmquin-7-COOH)$_2$] appear at ~975 cm^{-1}, in the range typical of six-co-ordinate complexes with a phenolic oxygen *trans* to Re=O [29]. A significant difference between complexes **1** and **2** can be noticed for ν(C=O)$_{COOH}$ stretching frequency. The ν(C=O)$_{COOH}$ stretching vibration of **1** is downshifted in comparison with ν(C=O)$_{COOH}$ for complex **2**. It is a result of delocalisation of CO bonds of the carboxylic group, observed for complex **1** and discussed in detail in crystal structure part (Table 3).

3.2. Crystal structures

The crystallographic data for **1** and **2** · MeCN are given in Table 1. The intermolecular interactions found in the examined structures are shown in the Table 2 [30,31] and Figs. 1 and 2.

The packing of molecules in crystal and in consequence hydrogen bonding scheme of compound **1** distinctly differ from these of compound **2** · MeCN. In compound **1** the medium strength intermolecular O—H···O bond create typical $N_1R_2^2(8)$ motif, but in **2** · MeCN $N_1R_2^2(24)$ motif is created. The intermolecular bonding scheme in both compound is identical (S(6) motif of O—H···O interactions) due to similarity of inner coordination spheres.

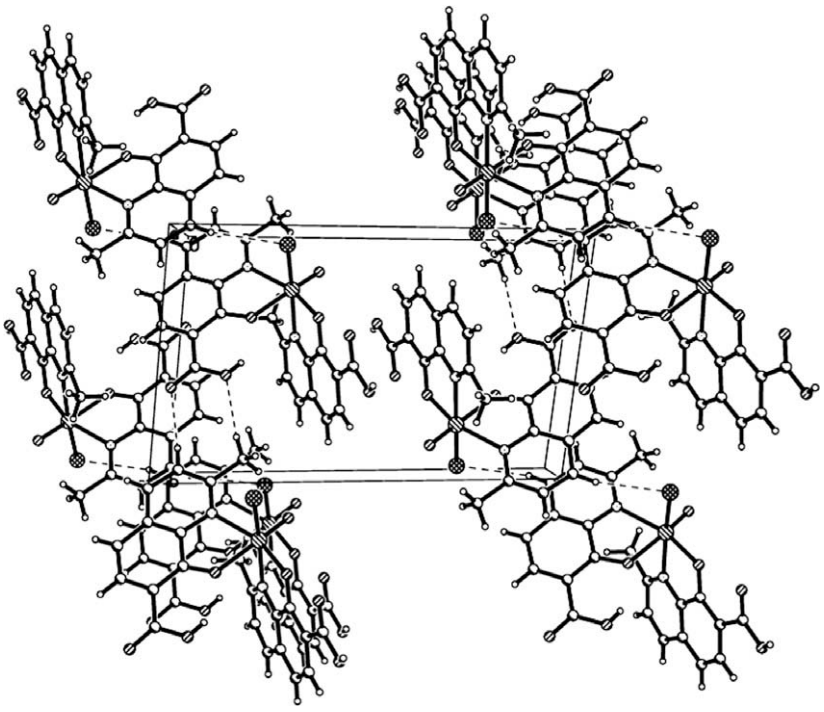

Fig. 1. Packing diagram of **1** showing the shortest intermolecular interactions.

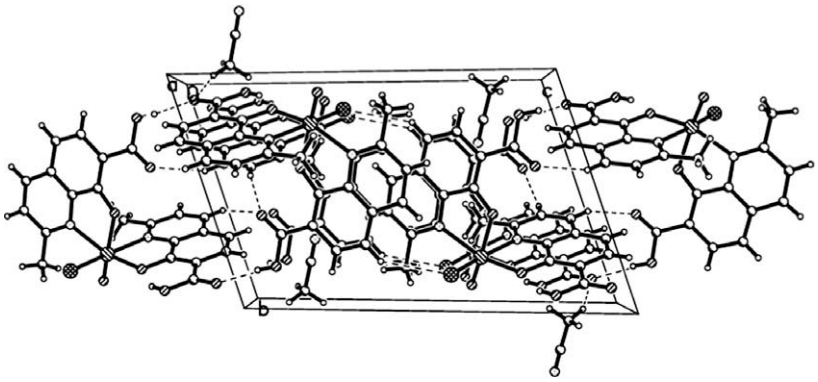

Fig. 2. Packing diagram of **2** · MeCN showing the shortest intermolecular interactions.

The molecular structure of [ReOBr(hmquin-7-COOH)$_2$] is presented in Fig. 3, and the selected bond distances and angles of [ReOX(hmquin-7-COOH)$_2$] complexes are collected in Tables 4 and 5, respectively.

The geometry of [ReOX(hmquin-7-COOH)$_2$] compounds reveals typical features of quasi-octahedral oxorhenium(V)complexes with oxygenated bidentate ligands. For complex **1** the rhenium atom is displaced 0.3240 (28) Å from the equatorial plane formed by the two nitrogens, one oxygen and one bromide atoms (plane A) and 0.0730(30) and 0.0249(25) Å from the axial planes formed respectively by the three oxygen, one nitrogen atoms (plane B) and two oxygens, one bromide and one nitrogen atoms (plane C). Least squares plane A is inclined at 88.90(13)° to the plane B and at 89.81(12)° to the plane C. The planes B and C are inclined at 85.50(14)°. These values for chloride analogue are respectively 0.2916 (13), 0.0773 (13), and 0.0292(12) Å, 89.92(7) 89.25(5) and 83.92(7)°. Clear distortions of the pseudooctahedral environment of Re center in [ReOX(hmquin-7-COOH)$_2$] is induced by the multiple bonding ligand (terminal oxo ligand –O$_t$) and narrow bite angles of the chelating ligands. The last ones are similar to those observed for [ReOX(hqn)$_2$] (75.9(3)° and 80.1(3)°) [9].

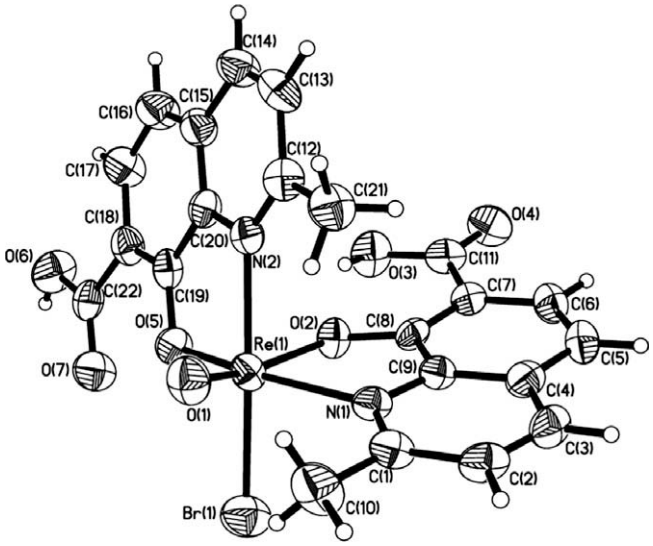

Fig. 3. The molecular structure of [ReOBr(hmquin-7-COOH)$_2$]. Displacement ellipsoids are drawn at 50% probability.

The Re–O$_t$ bond lengths fall in the range typical of mononuclear complexes of rhenium(V) having $[ReO]^{3+}$ core, and indicates the presence of a triple bond Re≡O [32]. The interatomic distance between the rhenium atom and the oxygen atom of hmquin-7-COOH in *trans* position to the terminal oxo ion is somewhat longer than the corresponding Re–O bond in the equatorial plane. This structural *trans* influence is common in mononuclear six-coordinate oxo Re(V) complexes with an monoanionic oxygen *trans* to the oxo group [33]. Noteworthy is fact that CO bonds of indicated by C(22) atom –COOH group of **1** are delocalised and they have can be considered as bonds with multiplicity of 1.5 (all other –COOH groups have localised double C=O and single C–O–H bonds). Such effect should be explained by O–H.O hydrogen bond creating symmetric 8-membered rings ($N_1R_2^2(8)$ motifs).

3.3. Geometry optimization, charge distribution, electronic structure and NBO analysis

The geometry of **1** was optimized in a singlet state by the DFT method with the B3LYP functional. The optimized geometric parameters of **1** are gathered in Table 4. In general, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

Table 6 presents the atomic charges from the Natural Population Analysis (NPA) for **1**. The calculated charge on the rhenium atom is considerable lower than the formal charge +5, corresponding d^2 configuration of the central ion. It results from significant charge donation from the ligands. The charges on the terminal oxo, bromide and oxygen donor atoms of hmquin-7-COOH are significantly smaller than –2, –1 and –1, respectively. The terminal oxo ion is less negative in comparison with the oxygen atom of hmquin-7-COOH ligand. It indicates the higher electron density delocalization from the O_t ligand towards the central ion and corresponds to differences in the Re–$O_{hydroxy}$ and Re–$O_{terminal}$ bond lengths. Similarly, the oxygen atom of hmquin-7-COOH in *trans* position to the bromide ion is less negative in comparison with the corresponding Re–O bond opposite the terminal oxo ligand.

A comparison of the NPA analysis for [ReOBr(hqn)$_2$] and [ReOBr(hmquin-7-COOH)$_2$] allows to notice less efficient ligand-to-metal donation from the bromide ion in the case [ReOBr(hqn)$_2$], resulting in a significantly elongation of the Re–Br bond length in this complex.

The complex [ReOBr(hmquin-7-COOH)$_2$] is a closed-shell structure. Its partial molecular orbital diagram with several highest occupied and lowest unoccupied molecular orbital contours is presented in Fig. 4. In discussion of the orbital character the local symmetry of the rhenium centre has been considered: *z* axis goes along the O–Re–O linkage, and *x* axis – through the N(1)–Re–O(5) bonds.

Table 6
Atomic charges from the natural population analysis (NPA) for [ReOBr(hmquin-7-COOH)$_2$].

Atom	Charge
Re(1)	1.441
O(1)	−0.498
O(2)	−0.722
O(5)	−0.619
N(1)	−0.487
N(2)	−0.486
Br(1)	−0.349

The value of the energy separation between the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) equals to 2.80 eV. This value is somewhat higher in comparison with the HOMO–LUMO gap calculated for [ReOBr(hqn)$_2$] [9]. The bigger absolute value of the gap energies means better stability of the title complex.

The highest occupied MO of **1** is of d_{xy} type with some contributions from p_π bromide and π-bonding of hmquin-7-COOH. Four lowest virtual orbitals are delocalized among Re, O_t and π-antibonding orbitals of hmquin-7-COOH. As d_{xz} and d_{yz} rhenium orbitals take main part in the LUMO and LUMO+1 orbitals, they are indicated in Table 8 by d_{Re} orbitals, whereas LUMO+1 and LUMO+2 were treated as π-antibonding orbitals of hmquin-7-COOH. The LUMO+6 is of $d_{x^2-y^2}$ character, and d_z^2 rhenium orbital contributes to the LUMO+12.

The nature of rhenium–terminal oxygen interaction in **1** has been studied by NBO analysis. The occupancy and composition of the calculated Re–O_t natural bond orbitals (NBOs) are given in Table 7. Each natural bond orbital (NBO) σ_{AB} can be written in terms of two directed valence hybrids (NHOs) h_A and h_B on atoms A and B:

$$\sigma_{AB} = c_A h_A + c_B h_B$$

where c_A and c_B are polarization coefficients. Each valence bonding NBO must in turn be paired with a corresponding valence *anti*-bonding NBO:

$$\sigma^*_{AB} = c_B h_A - c_A h_B$$

to complete the span of the valence space. The Lewis-type (donor) NBOs are thereby complemented by the non-Lewis-type (acceptor) NBOs that are formally empty in an idealized Lewis picture. The interactions between 'filled' Lewis-type NBOs and 'empty' non-Lewis NBOs lead to loss of occupancy from the localized NBOs of the idealized Lewis structure into the empty non-Lewis orbitals, and they are referred to as 'delocalization' corrections to the zeroth-order natural Lewis structure [26].

The detected natural Re–O_t bond orbitals of **1** are π orbitals – the p_x and p_y oxygen orbitals and d_{xz} and d_{yz} rhenium orbitals are involved in their formation. Not detected σ_{Re-Ot} bond has character of predominant Coulomb-type interactions between the central ion and ligands [34]. The terminal oxo ligand of **1** has two lone pair orbitals, and electron density from one of them is strongly delocalized into non-Lewis rhenium orbital. Accordingly, NBO analysis confirms a triple bond between the rhenium and the terminal oxygen ligand.

3.4. Electronic spectra

The experimental and calculated electronic spectra of **1** are presented in Fig. 5. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}. In order to examine the effect of adding additional basis functions on the heavy atoms, the TDDFT/PCM calculations were performed by using LANL2DZ basis set on the rhenium atom (blue curve) and by using LANL2DZ basis set with additional d function with exponent $\alpha = 0.3811$ and f function with exponent $\alpha = 2.033$ (red curve). As seen in the Fig. 5, the effect of additional d functions for TDDFT calculations is very small. The B3LYP method in LANL2DZ basis set is sufficient for calculation of spectral properties of rhenium compounds.

The spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method for **1** are gathered in Table 8. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.030 are listed in Table 8.

The TDDFT/PCM calculations show that the two longest wavelength experimental bands of **1** originate in the HOMO → LUMO

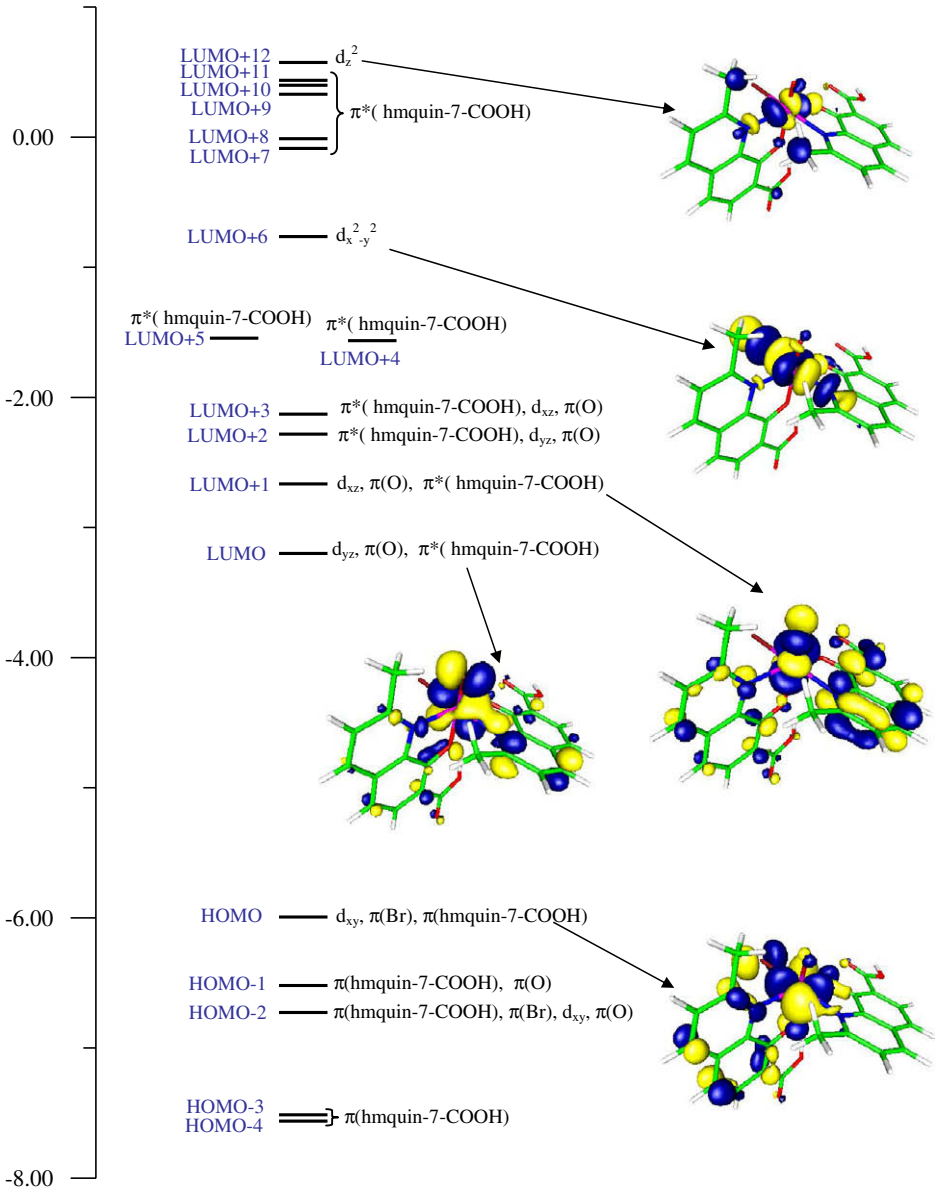

Fig. 4. The energy (eV), character and some contours of the occupied and unoccupied molecular orbitals of [ReOBr(hmquin-7-COOH)$_2$]. Positive values of the orbital contour are represented in blue (0.04 au) and negative values – in yellow (−0.04 au). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 7
The occupancy of the calculated natural bond orbitals (NBOs) between the rhenium and the oxo ligand for [ReOBr(hmquin-7-COOH)$_2$].

BD	Occupancy	Composition of NBO	BD*	Occupancy
Re–O_t	1.993	$0.552(d)_{Re} + 0.834(p)_O$	$0.834(d)_{Re} - 0.552(p)_O$	0.274
Re–O_t	1.983	$0.568(d)_{Re} + 0.823(p)_O$	$0.823(d)_{Re} - 0.568(p)_O$	0.301

BD denotes 2-center bond; * denotes antibond NBO.

and HOMO → LUMO+1 transitions, respectively. As d_{Re} orbitals take main part in the HOMO, LUMO and LUMO+1 orbitals, the HOMO → LUMO and HOMO → LUMO+1 transitions may be attributed to the transitions of d → d character. However, as it can be seen from the Fig. 4, the HOMO, LUMO and LUMO+1 orbitals are delocalized among rhenium ion, bromide, oxo and hmquin-7-COOH ligands so a delocalized *MLLCT* (metal-ligand-to-ligand CT) description can also be used.

The broad absorption band with maximum at 397.8 nm results from the *ligand-metal charge transfer* and *metal-ligand charge transfer* transitions.

The experimental bands below 300 nm nm result mainly from *ligand-ligand charge transfer* and interligand (*IL*) transitions.

The shape of the UV–Vis spectrum of **2** is the same as for the bromo analogue; the absorption bands of the chloro complex were recorded at 802.1, 678.9, 575.9, 398.5, 263.4 and 203.7 nm.

Table 8

ABSTRACT

Two *N*-thiophosphorylated thiosemicarbazides of the common formula RC(S)NHP(S)(O*i*Pr)$_2$ [R = PhNHNH- (**1**); EtN(NH_2)- (**2**)] have been synthesized and characterized by IR, ^{1}H and ^{31}P spectroscopy, and the single crystal X-ray diffraction method. Single crystal X-ray diffraction studies showed the thiosemicarbazides form both intra- and intermolecular hydrogen bonds, which in turn lead to polymeric chain formation. Moreover, according to the X-ray data of the phenylsubstituted thiosemicarbazide, the formation of intermolecular H···η^6-phenyl interactions were established.

1. Introduction

N-(Thio)phosphorylated (thio)amides RC(X)NHP(Y)R′$_2$ and (thio)ureas RR′NC(X)NHP(Y)R″$_2$ (X = O, S) have been intensively studied [1,2]. The interest is caused not only from the fact that these compounds show a wide variety of complexes with various metal cations but also from the potential of these amidophosphates as agents for extraction and transporting different cations, anions and organic molecules [3], and as ligands in metal complexes used as single source precursors for thin films, nanocrystals and semiconductors [4].

On the other hand, thiosemicarbazides and their derivatives are very attractive compounds among NS donor compounds because of the large number useful biological properties, particularly their antitumor activity [5,6]. Since 4,4′,4″-phosphinylidynetrisemicarbazide showed the confirmed activity in Walker carcinosarcoma [7] the preparation of additional hydrazine compounds as potential antitumor agents, particularly (thio)phosphorylated derivatives, was encouraged [8–10]. Both compounds reported, herein, are structurally related to agents possessing antimicrobial and anticancer activities [8,10].

Herein, we report two *N*-thiophosphorylated thiosemicarbazides PhNHNHC(S)NHP(S)(O*i*Pr)$_2$ (**1**) and EtN(NH_2)C(S)NHP(S)(O*i*Pr)$_2$ (**2**). Compound **1** was described by us earlier [11] and in this work we present the X-ray structure investigation of it in comparison with **2**.

2. Experimental

2.1. Synthesis

Thiosemicarbazide **1** was synthesized according to the previously described method [9]. Compound **2** was synthesized similarly to **1**: a solution of ethylhydrazine (5 mmol, 0.30 g) in anhydrous CH_2Cl_2 (15 mL) was treated under vigorous stirring with a solution of (*i*PrO)$_2$P(S)NCS (5.5 mmol, 1.31 g) in the same solvent. The mixture was stirred for 2 h. The solvent was removed in a vacuum, and the product was purified by recrystallization from a 1:5 (v/v) mixture of methylene chloride and *n*-hexane.

Compound **1**: ^{1}H NMR ($CDCl_3$): δ = 1.35–1.40 (m, 12H, CH_3), 4.92 (d. sept, $^3J_{POCH}$ = 10.6 Hz, $^3J_{H,H}$ = 6.2 Hz, 2H, OCH), 6.34 (s, 1H, PhNH), 6.84–6.92 (m, 2H, *o*-H, Ph), 6.96–7.05 (m, 1H, *p*-H, Ph), 7.24–7.32 (m, overlapped with the solvent signal, *m*-H, Ph), 8.00 (s, 1H, C(S)NHN), 8.23 (d, 1H, $^2J_{PNH}$ = 13.9 Hz, P(S)NH), 9.44 (d, $^4J_{PNH}$ = 5.6 Hz, C(S)NHN, minor form) ppm. ^{31}P NMR ($CDCl_3$): δ = 53.5 (br t, $^3J_{POCH}$ = 9.8 Hz, 1P), 58.5 (q, $^2J_{PNH}$ = $^3J_{POCH}$ = 12.2 Hz, 1.9P) ppm. IR: ν = 624 (P=S), 1000, 1010 (POC), 1528 (S=C–N), 3224, 3288 (NH) cm^{-1}.

Compound **2**: Yield: 1.27 g (85%). M.p. 97 °C. ^{1}H NMR ($CDCl_3$): δ = 1.25 (t, $^3J_{H,H}$ = 7.2 Hz, 3H, CH_3, Et), 1.37 (d, $^3J_{H,H}$ = 6.2 Hz, 12H, CH_3, O*i*Pr), 3.91 (br s, 2H, NH_2), 4.16 (q, $^3J_{H,H}$ = 7.1 Hz, 2H, CH_2, Et), 4.94 (d. sept, $^3J_{POCH}$ = $^3J_{H,H}$ = 6.2 Hz, 2H, OCH), 8.98 (br s, 1H, P(S)NH) ppm. ^{31}P{^{1}H} NMR ($CDCl_3$): δ = 54.1 (1P), 59.3 (3.5P) ppm. IR: ν = 653 (P=S), 981, 998, 1020 (POC), 1488 (S=C–N), 1627, 3106, 3173, 3208, 3247, 3323 (NH + NH_2) cm^{-1}. *Anal.* Calc. for $C_9H_{22}N_3O_2PS_2$ (299.39): C, 36.11; H, 7.41; N, 14.04. Found: C, 36.18; H, 7.34; N, 14.10%.

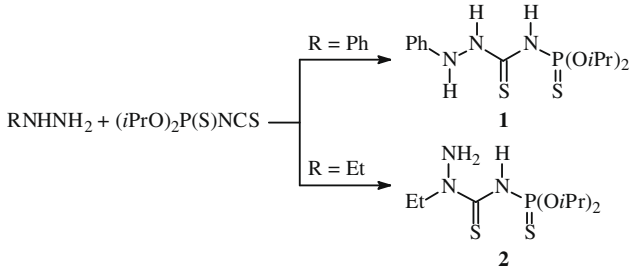
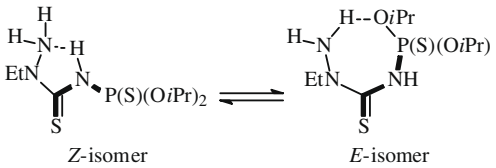
2.2. Physical measurements

Infrared spectra (Nujol) were recorded with a Specord M-80 spectrometer in the range 400–3600 cm^{-1}. NMR spectra were obtained on a Varian Unity-300 NMR spectrometer at 25 °C. ^1H and ^{31}P NMR spectra were recorded at 299.948 and 121.420 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ (^1H) and H_3PO_4 (^{31}P). Elemental analyses were performed on a Perkin–Elmer 2400 CHN microanalyser.



2.3. Crystal structure determination and refinement

The X-ray data were collected on a STOE IPDS-II diffractometer with graphite-monochromatized Mo Kα radiation generated by a fine-focus X-ray tube operated at 50 kV and 40 mA. The images were indexed, integrated and scaled using the X-Area data reduction package [12]. Data were corrected for absorption using the PLATON program [13]. The structure was solved by direct methods using the SHELXS-97 program [14] and refined first isotropically and then anisotropically using SHELXL-97 [14]. Hydrogen atoms were revealed from $\Delta\rho$ maps and those bonded to C were refined using a riding model. H atoms bonded to N were freely refined.



3. Results and discussion

Thiosemicarbazide **1** was synthesized according to the previously described method [9]. Compound **2** was synthesized similar to **1** by treatment of ethylhydrazine isothiocyanate (iPrO)$_2$P(S)NCS (Scheme 1). Their compositions were successfully proved by microanalysis data. Condensations of isocyanates with arylsubstituted hydrazines are reported to yield 1-substituted semicarbazides [15]. The reaction between monoalkylhydrazines and isocyanates, however, gives 2-substituted alkyl semicarbazides [16] due to the greater nucleophilic character of the secondary amine groups.

There are absorption bands for the NH_2 group in the IR spectrum of **2**. This confirms the isothiocyanate addition to the substituted nitrogen atom of the parent hydrazine. The $^{31}P\{^1H\}$ NMR spectrum of **2** contains two signals at 54.1 and 59.3 ppm. The ratio of the integrated intensities at 25 °C is ~1:3.5. When the crystalline material is dissolved in $CDCl_3$ two lines in the $^{31}P\{^1H\}$ NMR spectrum indicate that the equilibrium reaction shown in Scheme 2 is slow on the NMR timescale. We suppose that in a solution of **2** both

Z- and *E*-forms are present, as was previously observed for **1** [9], which are stabilized by intramolecular hydrogen bonds (Scheme 2). The chemical shifts of phosphorus are in the area, which is characteristic for the *Z*- and *E*-isomers of *N*-thiophosphorylthioureas related by structure to the investigated compounds [1]. The ^{1}H NMR spectrum of **2** contains all the characteristic signals.

Crystals of **1** and **2** were obtained by recrystallization from a 1:5 (v/v) mixture of methylene chloride and *n*-hexane (Table 1). The NMR probes and the crystals for the X-ray determination were taken from the same samples. The parameters of the C=S, C–N, P–N and P=S bonds observed for both compounds (Tables 2–4) are in the typical range for *N*-thiophosphorylated thiourea and dithiobiurea derivatives [1,9,17].

Table 4

[b] Symmetry transformations used to generate equivalent atoms: #1 $-x+1, -y+1, -z+1$; #2 $-x+1, y, -z+3/2$.

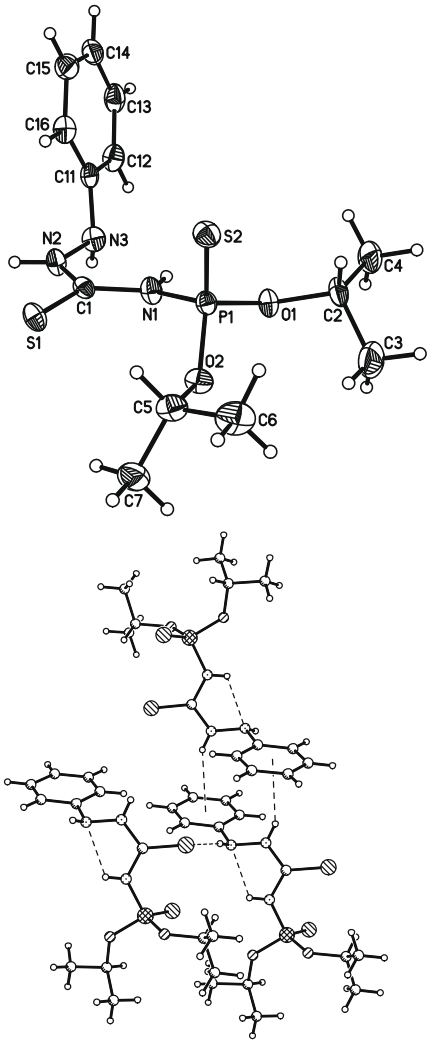

Fig. 1. Molecular structure and crystal packing of **1**.

The molecular conformation of the thiosemicarbazide **1** is shown in Fig. 1, and geometric parameters are given in Table 2. The N1–C1(S1)–N2–N3 moiety is significantly flattened and placed practically orthogonal to the phenyl and P=S groups. The S1–C1–N1–P1 backbone in the crystal phase has a *Z* conformation. The crystal structure of **1** is stabilized by an intramolecular hydrogen bond in the crystal lattice with a N(1)–H(1)···N(3) hydrogen bond. Molecules of **1** in the crystal structure form polymeric chains due to the N(3)–H(3)···S(1)#1 H-bonds (Table 4). Yet another mode of aggregation is found for this thiosemicarbazide. Two neighboring polymeric chains form interactions between the H atoms and the phenyl rings of an adjacent molecule (Fig. 1). For **1** the distance between H and the centroid of the closest phenyl ring measures 2.598 Å.

The molecular conformation of compound **2** in the crystal is shown in Fig. 2, and geometric parameters are given in Table 3. The O2–P1–N1–C1(S2)–N2–N3 moiety is flattened. The S2–C1–N1–P1 backbone, as in **1**, in the crystal phase has a *Z* conformation (Scheme 2). The conformation is supported by an intramolecular N(1)–H(1)···N(3) hydrogen bond in the solid state of **2** (Table 4).

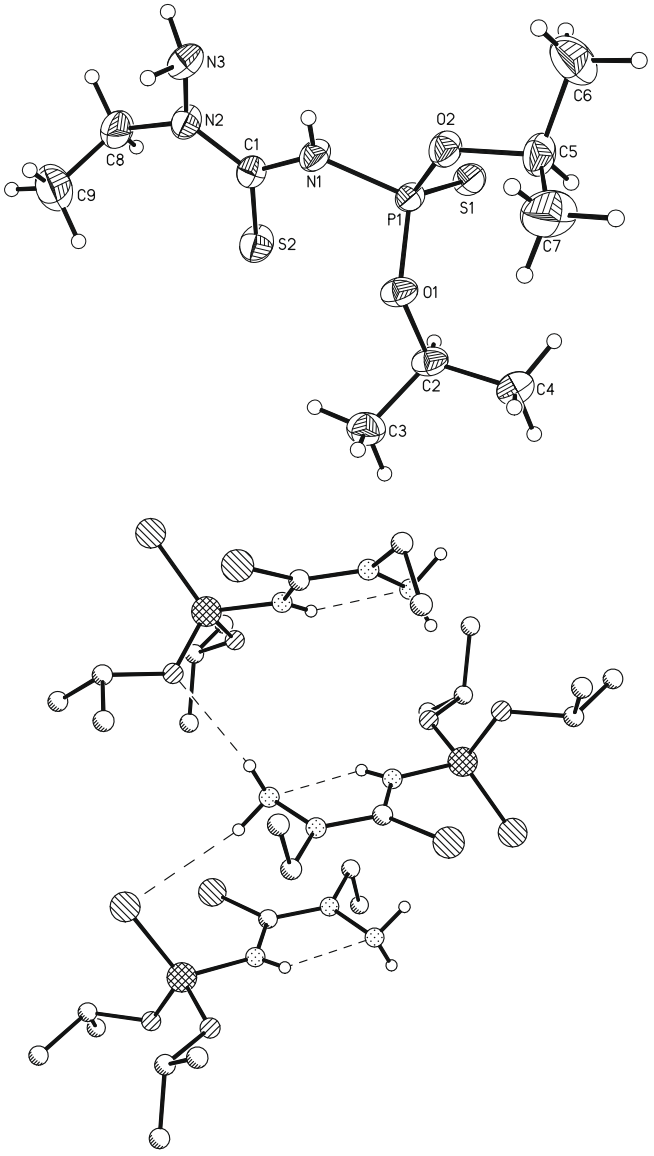

Fig. 2. Molecular structure and crystal packing of **2** (H atoms not involved in hydrogen bonds are omitted for clarity).

Two types of intermolecular H-bonds were found in the structure of the thiosemicarbazide **2**: N(3)–H(3A)···S(1)#1=P(1) and N(3)–H(3B)···O(1)#2–P(1) (Table 4). Due to this, the formation of polymeric chains is also observed for **2** (Fig. 2).

4. Conclusions

In summary, we have demonstrated the syntheses of two *N*-thiophosphorylated thiosemicarbazides by addition of thiophosphorylisothiocyanate to the corresponding phenyl- or ethylhydrazine. It was established that the phenylsubstituted hydrazine yields a 1-substituted thiosemicarbazide, whereas the reaction between ethylhydrazine and isocyanate, under the same conditions, gives a 2-substituted alkyl semicarbazide.

Single crystal X-ray diffraction studies showed the thiosemicarbazides to form both intra- and intermolecular hydrogen bonds which in turn lead to polymeric chain formation. Moreover, according to the X-ray data of the phenylsubstituted thiosemicarbazide, the formation of the intermolecular H···η^6-phenyl interactions were established.

ABSTRACT

Reaction of tetrabromoterephthalic acid (H_2TBTA) with $Co(OAc)_2$, $AgNO_3$, or $Pb(OAc)_2$ under similar conditions affords three new coordination polymers $\{[Co(TBTA)(DMF)_2(H_2O)_2](DMF)_2\}_n$ (**1**), $[Ag(TBTA)_{0.5}]_n$ (**2**), and $[Pb_2(TBTA)_{1.5}(OH)(DMF)]_n$ (**3**). All these complexes have been characterized by elemental analysis, IR, powder X-ray diffraction, and TG-DTA techniques. Single-crystal X-ray diffraction reveals that complex **1** has a 1-D neutral coordination array in which the adjacent Co^{II} centers are bridged by the TBTA spacers, whereas **2** displays a binodal $CdCl_2$-type coordination layer in which the Ag^{I} ions and TBTA ligands function as 3- and 6-connected nodes, respectively. In the structure of **3**, two types of Pb^{II} ions are interconnected via the μ_4- and μ_5-TBTA ligands as well as the μ_3-hydroxyl ions to generate a complicated 3-D penta-nodal coordination framework with (3,4,5)-connectivity. These results clearly suggest that the metal centers with distinct binding tendencies are responsible for the remarkable structural diversity of such crystalline materials.

1. Introduction

During the past decade, the design and synthesis of coordination polymers by using crystal engineering strategy has attracted ever-increasing research interests for the sake of inosculating the aesthetic features of intriguing crystalline materials [1–11] with their potential applications in optics, magnetism, adsorption, ion exchange, and catalysis, etc. [12–33]. In principle, the most effective approach for the construction of the coordination framework solids is based upon the sophisticated design and selection of the organic bridging ligand with desired connectivity and the metal ion with certain coordination preference [34,35]. To date, aromatic polycarboxylate compounds have been extensively used to prepare a variety of coordination polymers in virtue of the robust and versatile coordination capability of carboxylate [36–40], especially the rigid dicarboxylate building blocks such as terephthalate and isophthalate [41–49]. However, the related ligands bearing coordination-unfavored substituents on the phenyl group have received less attention at this stage [50]. In this context, tetrabromoterephthalate (TBTA) may serve as a suitable building block to construct novel coordination polymers, which has almost not been explored so far [51]. In this paper, we will present three novel coordination polymers $\{[Co(TBTA)(DMF)_2(H_2O)_2](DMF)_2\}_n$ (**1**), $[Ag(TBTA)_{0.5}]_n$ (**2**), and $[Pb_2(TBTA)_{1.5}(OH)(DMF)]_n$ (**3**) assembled from H_2TBTA with the corresponding metal salts under similar conditions. Interestingly, these complexes display distinct network structures such as the 1-D coordination chain for **1**, 2-D $CdCl_2$-type layer for **2**, and 3-D penta-nodal coordination framework for **3**, revealing the significant metal-directed effect on the structural assembly of such network solids.

2. Experimental

2.1. Materials and general methods

All the reagents were commercially available and used without further purification. Distilled water was used throughout. Fourier transform (FT) IR spectra (KBr pellets) were taken on an AVATAR-370 (Nicolet) spectrometer. Elemental (C, H, and N) analyses were performed on a CE-440 (Leemanlabs) analyzer. Thermal analyses were carried out on a simultaneous TG-DTA system (Rigaku) in the temperature range of 25–600 °C at a heating rate of 10 °C/min under nitrogen atmosphere. An empty Al_2O_3 crucible was used as the reference. Powder X-ray diffraction (PXRD) data were recorded on a Rigaku D/Max-2500 diffractometer at 40 kV and 100 mA for a Cu-target tube. The calculated PXRD patterns were produced from the single-crystal diffraction data using the PLATON software.

2.2. Synthesis of complexes **1**–**3**

2.2.1. {[Co(TBTA)(DMF)$_2$(H$_2$O)$_2$](DMF)$_2$}$_n$ (**1**)

The pH value a DMF/H$_2$O solution (5 mL, v/v = 1/4) of H$_2$TBTA (48 mg, 0.1 mmol) was adjusted to *ca.* 6 by dropwise adding a dilute aqueous solution of NaOH, which was placed at the bottom of a straight glass tube. Then, a solution of Co(OAc)$_2 \cdot 4$H$_2$O (25 mg, 0.1 mmol) in methanol (5 mL) was carefully layered onto it. Upon slow evaporation of the solvents, red block single crystals suitable for X-ray diffraction were obtained after 5 days in 67% yield (58 mg). IR (cm^{-1}): 3547s, 3148b, 2935s, 1646vs, 1588s, 1397s, 1324s, 1249w, 1112m, 1075w, 841m, 676m, 608w, 565m, 523w. *Anal.* Calc. for $C_{20}H_{32}CoN_4O_{10}Br_4$: C, 27.71; H, 3.72; N, 6.46. Found: C, 27.72; H, 3.74; N, 6.44%.

2.2.2. [Ag(TBTA)$_{0.5}$]$_n$ (**2**)

The same synthetic procedure as that for **1** was used except that the metal salt was replaced by AgNO$_3$ (17 mg, 0.1 mmol), producing colorless block crystals after a period of one week in 46% yield (16 mg, based on silver nitrate). IR (cm^{-1}): 1618vs, 1563vs, 1401s, 1316s, 1077w, 825m, 574m, 515w. *Anal.* Calc. for $C_4AgO_2Br_2$: C, 13.82. Found: C, 13.87%.

2.2.3. [Pb$_2$(TBTA)$_{1.5}$(OH)(DMF)]$_n$ (**3**)

The same synthetic procedure as that for **1** was used except that the metal salt was replaced by Pb(OAc)$_2 \cdot 3$H$_2$O (38 mg, 0.1 mmol), producing colorless block crystals after a period of one week in 45% yield (28 mg, based on lead acetate). IR (cm^{-1}): 3511s, 1642s, 1585vs, 1404s, 1323s, 1078m, 830m, 726w, 694w, 663w, 565s, 525m. *Anal.* Calc. for $C_{15}H_8Pb_2NO_8Br_6$: C, 14.72; H, 0.66; N, 1.14. Found: C, 14.75; H, 0.62; N, 1.12%.

2.3. X-ray crystallography

Single-crystal X-ray diffraction data for **1**–**3** were collected on a Bruker Apex II CCD diffractometer at room temperature with Mo Kα radiation (λ = 0.71073 Å) by ω scan mode. There was no evidence of crystal decay during data collection. Semi-empirical absorption corrections were applied using SADABS and the program SAINT was used for integration of the diffraction profiles [52]. All structures were solved by direct methods using the SHELXS program of the SHELXTL package and refined with SHELXL [53]. The final refinement was performed by full-matrix least-squares methods on F^2 with anisotropic thermal parameters for all non-H atoms. C-bound hydrogen atoms of the DMF molecules in **1** and **3** were generated geometrically, and the hydrogen atoms of water in **1** and hydroxyl in **3** were first located in difference Fourier syntheses and then treated as riding. Isotropic displacement parameters of the hydrogen atoms were derived from the parent atoms. Further details for crystallographic data of complexes **1**–**3** are listed in Table 1.

Table 1
Crystallographic data and structural refinement summary for complexes **1**–**3**.

3. Results and discussion

3.1. Preparation and general characterization

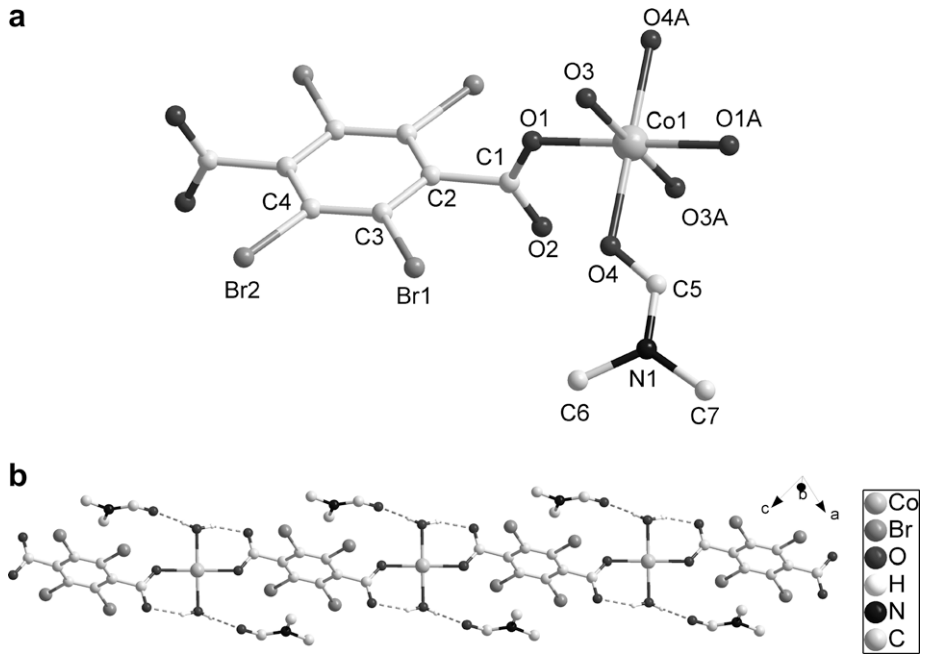
All complexes were prepared by layer-separation diffusion of the DMF/H$_2$O solution of ligand and the corresponding CH$_3$OH solution of metal salt at the ambient conditions, which will facilitate the slow crystallization of X-ray quality single crystals of **1**–**3**. In each synthetic case, the equivalent metal/ligand ratio was utilized for the starting materials. However, the resultant complexes are found to have the metal/TBTA stoichiometric compositions of 1:1, 2:1, and 4:3, respectively for complexes **1**–**3**, which were identified by single-crystal X-ray diffraction and elemental analysis. The phase purities of the bulk samples were confirmed by powder X-ray diffraction (PXRD) patterns, which agree well with the calculated ones (see Fig. S1 in Supporting Information).

The IR spectrum of H$_2$TBTA suggests that the characteristic absorption bands of −COOH occur in 1734/1655 and 1344 cm^{-1}, which can be assigned to the antisymmetric and symmetric stretching vibrations, respectively. In the IR spectra of complexes **1**–**3**, the corresponding peaks appear in 1588 and 1324 cm^{-1} for **1**, 1618/1563 and 1316 cm^{-1} for **2**, and 1585 and 1323 cm^{-1} for **3**, respectively, which indicate the complete deprotonation of carboxyl in these complexes [54]. In addition, the observation of strong absorption peaks at 1646 and 1642 cm^{-1} in the IR spectra of **1** and **3** indicates the presence of DMF molecule.

3.2. Structural analysis of **1**–**3**

3.2.1. {[Co(TBTA)(DMF)$_2$(H$_2$O)$_2$](DMF)$_2$}$_n$ (**1**)

As shown in Fig. 1a, the Co^{II} center is located at an inversion center and coordinated by six oxygen atoms coming from a pair of carboxylate groups of different TBTA, two DMF and two aqua ligands. Thus, the local coordination environment around the Co^{II} ion (CoO$_6$) can be properly portrayed as a nearly ideal octahedron, and the Co–O bonds are in range of 2.065(2)–2.130(2) Å (see Fig. 1a caption for details). As for the ligand, the carboxylate groups deviate from the Br$_4$-substituted phenyl ring with a dihedral angle of 85.2° due to the steric effect, which adopt the unidentate coordination modes. Notably, in this series of coordination polymers, the carboxylate groups of TBTA exhibit a variety of binding modes due to the distinct coordination tendencies of the metal ions (see Scheme 1). As a result, the Co^{II} centers are connected by the TBTA dianionic bridges to produce a 1-D linear chain motif along [1 0 $\bar{1}$], as shown in Fig. 1b, in which the adjacent Co···Co separation is 11.396(1) Å. Furthermore, each coordinated aqua molecule forms an intrachain O3–H3B···O2^{i} (i = 2 − x, 1 − y, 1 − z) interaction with the adjacent carboxylate (H···O/O···O distances: 1.914/2.721 Å; O–H···O angle: 158°) as well as an O3–H3A···O5^{ii} (ii = 1 − x, 1 − y, 1 − z) interaction with the lattice DMF (H···O/O···O distances: 1.914/2.763 Å; O–H···mO angle: 176°). These secondary contacts may further stabilize this structure and no significant interchain interaction is found.



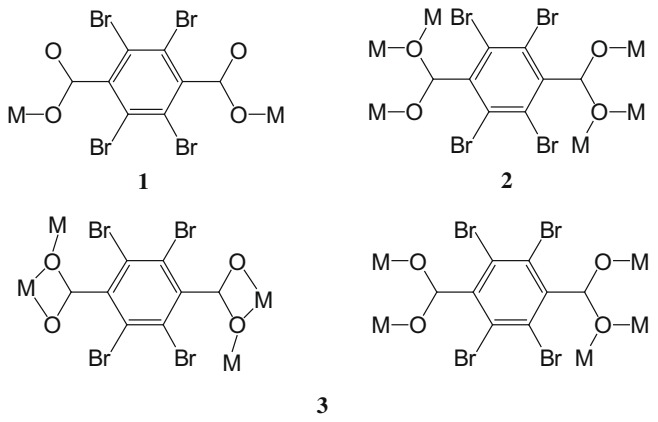


Fig. 1. (a) A portion view of **1** with atom labeling of the asymmetric unit and Co^{II} coordination sphere (symmetry operation A: $-x+2$, $-y+1$, $-z+1$). All H atoms were omitted for clarity. Selected bond parameters: Co1–O1 2.065(2), Co1–O3 2.106(2), Co1–O4 2.130(2) Å; O1–Co1–O3 88.71(7), O1–Co1–O4 90.27(7), O3–Co1–O4 90.39(8)°. (b) 1–D polymeric chain of **1** showing O–H···O hydrogen bonds. Irrelevant H atoms and the terminal DMF ligands were omitted for clarity.

Scheme 1.

3.2.2. $[Ag(TBTA)_{0.5}]_n$ (**2**)

When the close-shell d^{10} Ag^{I} ion with larger radius is applied instead of Co^{II}, a novel 2-D coordination polymer **2** is achieved. Notably, it is of rare occurrence that there exists none H or N atom in this complex. As shown in Fig. 2a, each Ag^{I} center adopts a distorted trigonal coordination geometry (see Fig. 2a caption for detailed bond geometries) which consists of three oxygen atoms from different TBTA ligands. In this case, each carboxylate group of TBTA takes the μ-O, O'_{syn}-μ-O, O coordination fashion (see Scheme 1) and acts as a μ_3-bridge to link three silver ions, which is inclined to the Br_4-substituted phenyl by 72.1°. As a result, each Ag^{I} center is linked to three TBTA ligands and each TBTA is connected to six Ag^{I} ions to afford a 2-D coordination layer along the *ab* plane (see Fig. 2b). This extended structure can be topologically recognized as a binodal (3,6)-connected network (see Fig. 2c) with the Schläfli symbol of $(4^3)_2(4^6.6^6.8^3)$, which is equivalent to that of the $CdCl_2$ lattice [35]. Furthermore, the familiar dimeric $[Ag_2(\mu\text{-}COO)_2]$ subunits are found in this 2-D pattern with the Ag···Ag separation of 2.934(1) Å. This distance is significantly shorter than that of the van der Waals Ag···Ag contact (3.40 Å) and only slightly longer than that in metallic silver (2.89 Å) [55], suggesting the existence of weak argentophilic interaction [7,56–65]. Additionally, these 2-D layers take a parallel stacking mode along [001] in *ABAB* sequence and none significant interlayer interaction is detected.

3.2.3. $[Pb_2(TBTA)_{1.5}(OH)(DMF)]_n$ (**3**)

Divalent lead, as one of the post-transition metal elements, bears larger cation radius with an identifiable void for the disposition of ligands, which can be termed as "inert-pair effect" [66]. Previous study has revealed that the stable and relatively inert outer lone pair of electrons around Pb^{II} causes a nonspherical charge distribution, and thus results in the unusual and rich coordination chemistry with a wide range of coordination numbers and irregular geometries [67]. In the structure of **3**, the fundamental building unit (see Fig 3a) contains two independent Pb^{II} centers, one and a half TBTA ligands, one OH^- ion for the charge-balance requirement, and a DMF molecule. Both Pb^{II} ions adopt the distorted octahedral coordination geometries of $[PbO_6]$ but different surroundings (see Fig. 3a caption for detailed bond geometries). Pb1 is coordinated by five carboxylate oxygen atoms from four TBTA and a hydroxyl ion, whereas the coordination environment around Pb2 is provided by three carboxylate oxygen atoms from different TBTA, two hydroxyl ions and a DMF molecule. Of particular interest is that the coordination geometries of both Pb^{II} ions can be regarded as *hemi-directed*, in which the Pb–O bonds are directed throughout only part of an encompassing globe, implying the presence of a stereochemically active lone pair of electrons [68]. Each carboxylate of the TBTA ligand with centrosymmetry takes the μ-O, O–η–O, O' coordination mode (see Scheme 1) and forms the dihedral angle of 83.5° with the Br_4-substituted phenyl. As for the other TBTA ligand, the two carboxylate groups adopt the μ–O, O'_{syn} and μ–O,

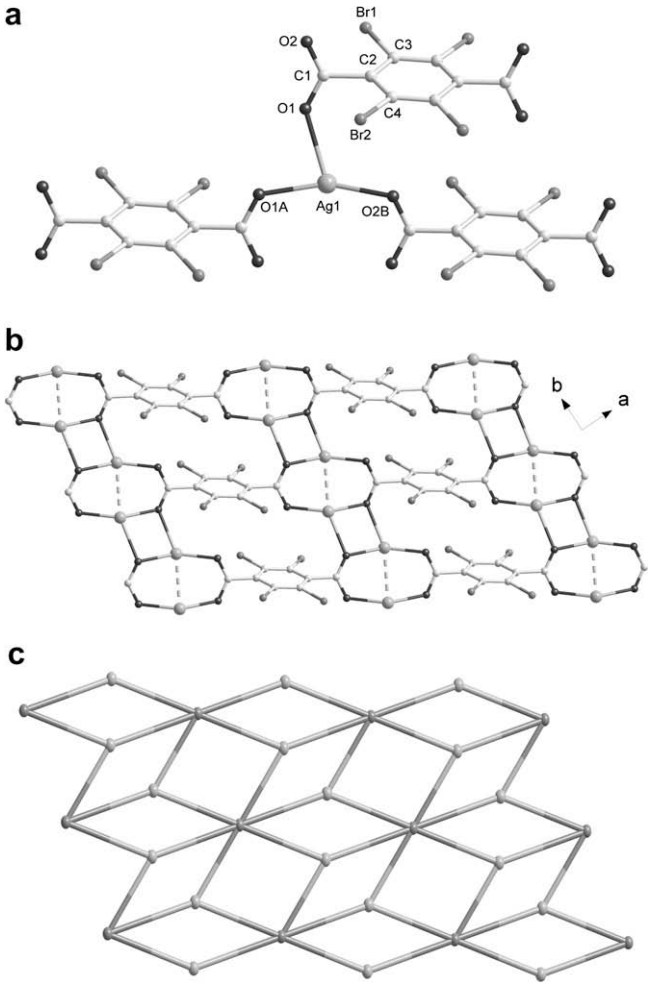

Fig. 2. (a) A portion view of **2** with atom labeling of the asymmetric unit and Ag^{I} coordination sphere (symmetry operations A: $-x, -y+1, -z+1$, B: $x, y-1, z$). Selected bond parameters: Ag1–O1 2.523(3), Ag1–O1A 2.230(3), Ag1–O2B 2.183(3) Å; O1–Ag1–O1A 84.0(1), O1–Ag1–O2B 117.4(1), O1A–Ag1–O2B 153.8(1)°. (b) 2-D coordination layer of **2** showing Ag···Ag interactions as dashed lines. (c) A schematic representation of the layered structure with $(4^3)_2(4^6.6^6.8^3)$ topology.

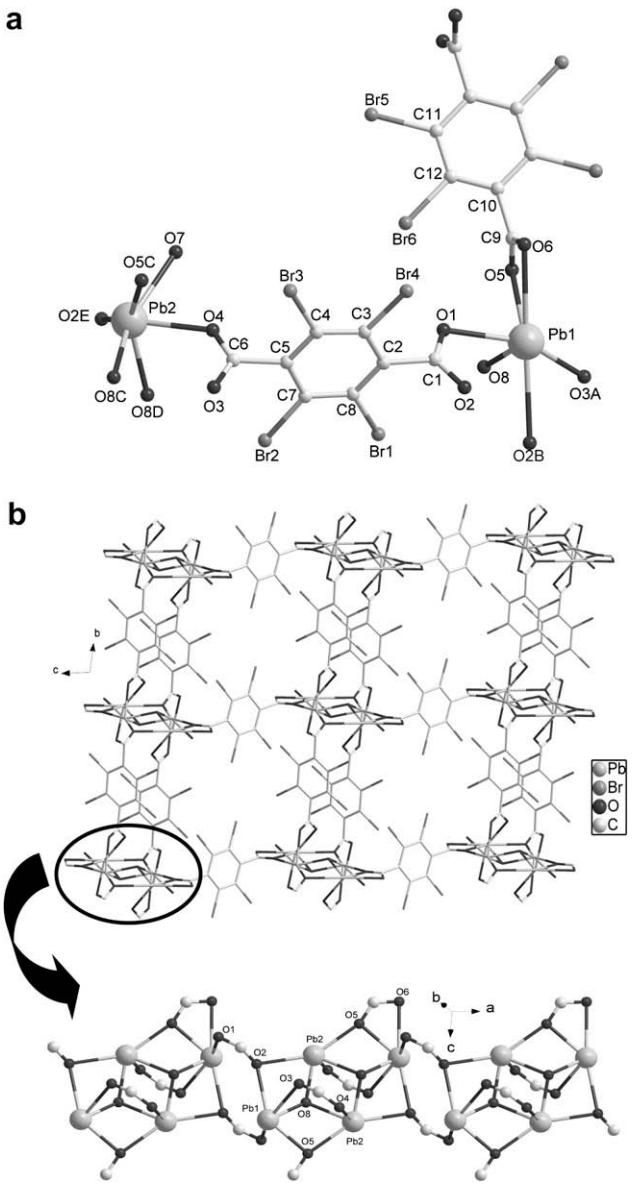

Fig. 3. (a) A portion view of **3** with atom labeling of the asymmetric unit and Pb^{II} coordination spheres (symmetry operations A: $x-1, y-1, z$, B: $-x+1, -y+1, -z+1$, C: $x+1, y+1, z$, D: $-x+1, -y+2, -z+1$, E: $x, y+1, z$). Selected bond parameters: Pb1–O1 2.432(6), Pb1–O2B 2.871(6), Pb1–O3A 2.666(8), Pb1–O5 2.491(7), Pb1–O6 2.833(7), Pb1–O8 2.336(6), Pb2–O2E 2.776(6), Pb2–O4 2.403(6), Pb2–O5C 2.687(8), Pb2–O7 2.67(1), Pb2–O8D 2.354(6), Pb2–O8E 2.545(6) Å; O1–Pb1–O3A 144.4(3), O2B–Pb1–O6 169.1(2), O2E–Pb2–O5C 153.0(2), O7–Pb2–O8C 155.3(3)°. (b) (top) A perspective view of the 3-D coordination framework of **3**. (bottom) 1-D polymeric Pb^{II} chain bridged by carboxylate and hydroxyl. All H atoms were omitted for clarity in Fig. 3.

O'_{syn}–μ–O, O binding modes (see Scheme 1), respectively, which are inclined to the central Br_4-substituted phenyl by 86.83 and 85.6°. With regard to the hydroxyl ion, it plays the trifurcated role to connect two Pb2 and one Pb1 centers. In this way, the Pb^{II} centers are interconnected by the μ_4- and μ_5-bridging TBTA ligands as well as the μ_3-hydroxyl ions to generate a very complicated 3-D coordination framework, in which the 1-D $[Pb_2(COO)_3(OH)]_n$ arrays are shaped along the [100] direction (see Fig. 3b). Examination of this structure with PLATON program [69] reveals that there exists no solvent accessible void.

In order to fully understand this intricate structure, the approach of topological reduction is properly used to simplify the 3-D network by using the TOPOS package [70]. In this instance, both Pb^{II} centers can be viewed as 5-connected nodes ($3\mu_5$-TBTA + μ_4-TBTA + OH^- for Pb1 and $2\mu_5$-TBTA + μ_4-TBTA + $2OH^-$ for Pb2) with the vertex symbols of $(4.4.4.4.4.4.6.6.6_3.8_9)$ for Pb1 and $(4.4.4.4.4.6_2.6_3.6_4.8_{14}.8_{22})$ for Pb2, respectively. In addition, OH^-, μ_4-TBTA, and μ_5-TBTA serve as 3-, 4-, and 5-connected nodes (1Pb1 + 2Pb2 for OH^-, 2Pb1 + 2Pb2 for μ_4-TBTA, and 3Pb1 + 2Pb2 for μ_5-TBTA) with the vertex symbols of $(4.4.4_2)$, $(4_2.4_2.8_4.8_4.8_5.8_5)$, and $(4.4.4.4_2.6.6.6_3.6_4.8_{14}.8_{15})$, respectively. Thus, this 3-D coordination framework can be considered as 5-nodal (3,4,5)-connected network with the Schläfli symbol of $(4^2.8^4)(4^3)_2(4^4.6^4.8^2)_2(4^5.6^3.8^2)_2(4^6.6^3.8)_2$ which represents a new topology type.

3.3. Structural comparison of *1*–*3* with related metal terephthalates

As for Co^{II} terephthalates, four types of 3-D polymeric networks and a 1-D chain motif have been reported hitherto, which were prepared under different conditions [71–77]. In the 3-D coordination complexes $[Co(tp)(H_2O)]_n$ [71,72], $[Co(tp)(DMF)]_n$ [73,74], and $[Co_2(tp)(OH)_2]_n$ [71,75], the secondary co-ligands water, DMF, and hydroxyl thereof play the bridging role, and in $\{[Co_3(tp)_4](NH_2^+(Et)_2)_2(DEF)_3\}_n$ [76], the DEF (diethylformamide) and $NH_2(Et)_2^+$ components are incorporated within the crystalline lattice as templates. Notably, the similar 1-D chain coordination array to that of

1 is observed in complex $\{[Co(tp)(DMF)_2(H_2O)_2](DMF)(H_2O)\}_n$ [77], in the structure of which the dihedral angle between the carboxylate and phenyl is only 20.2°, and the adjacent chains are hydrogen-bonded to the lattice aqua molecules and thus extended to afford a 2-D supramolecular layered structure.

In contrast to **2**, $[Ag_2(tp)]_n$ displays a 3-D polymeric framework [78], in which the similar 2-D coordination layers consisting of dimeric $[Ag_2(\mu\text{-}COO)_2]$ motifs are further interlinked by additional Ag–O bonds. Besides the different coordination modes of carboxylate, other structural difference such as the torsion angle between carboxylate and Ag^I center (154.4° for **2** and 0.3° for $[Ag_2(tp)]_n$) as well as the dihedral angle between carboxylate and phenyl (72.1° for **2** and 23.3° for $[Ag_2(tp)]_n$) is also found for the two structures.

Comparatively, a variety of coordination polymers constructed from Pb^{II} and tp in the presence of different solvents or hydroxyl have been documented [74,79–81]. For instance, complex $[Pb(tp)(H_2O)]_n$ demonstrates a unique binodal (4,7)-connected 3-D network with the Schläfli symbol of $(3^2.4.5^3)(3^4.4^2.5^5.6^9.7)$ [79]. However, in the case of $\{[Pb(tp)(EtOH)](EtOH)\}_n$, each Pb(II) ion is 8-coordinated and bound to the carboxylate groups of four tp connectors to result in a 3-D **sra** framework based on rod-type SBUs [74]. In addition, when dimethylacetamide (DMA) is used instead of the small solvent molecules of H_2O and EtOH, a unique 3-D coordination polymer $[Pb(tp)(DMA)]_n$ is generated, in which the distorted octahedral Pb^{II} centers are linked via μ_2- and μ_4-tp ligands to feature a (3,4)-connected **fsh** network with the topology notation of $(8^3)_2(8^5.10)$ [80]. In a more related example of $[Pb_2(tp)(OH)_2]_n$ [81], the hydroxyl group plays a μ_3-bridging role to interconnect the Pb^{2+} ions into 1-D polymeric chains, which are further linked by the bridging tp ligands to result in a new 3-D (3,6)-connected framework with the Schläfli symbol of $(4^3)_2(4^7.6^7.8)_2(4^8.6^6.8)$.

With regard to the more related halogen-substituted ligand tetrafluoroterephthalate (TFTA), a series of Mn [82], Fe [83], Cu [84,85], Zn [86], Mo [87–91], W [90,91], Rh [92], and Er [93] coordination complexes have been reported, which show diverse discrete or infinite coordination motifs. In the structure of $[Mn(TFTA)_2(C_5H_4N\text{-}2\text{-}CH_2\text{-}OH)_2]_n$ [82], the adjacent Mn^{II} centers are bridged by the TFTA spacers to afford a 1-D polymeric chain that is similar to that in **1**, and the C_5H_4N-2-CH_2-OH co-ligand is chelated to Mn^{II}. Significantly, a mixed-valent iron isoreticular crystalline material $\{Fe_3O[Fe_4(TFTA)_3(H_2O)_3](DMF)_{3.5}\}_n$ [83] is constructed from the trigonal prismatic $[Fe_3(\mu_3\text{-}O)(O_2C\text{–})_6]$ clusters and the TFTA linkers, which has the **acs** network topology and large channels. For the Cu^{II} complexes, $\{[Cu_4(TFTA)_3(ttc)_4](ClO_4)_2(H_2O)_6\}_n$ consists of $[Cu_4(TFTA)_2(ttc)_4]$ tetranuclear units (ttc = 1,4,7-trimethyl-1,4,7-triazacyclononane), which are further bridged by TFTA to feature a 1-D polymeric array [84]. While the 3-D jungle-gym-like microporous framework $[Cu(TFTA)(dacbo)_{0.5}]_n$ can be obtained by a heterogeneous reaction of 1,4-diazabicyclo[2,2,2]octane (dacbo) with the 2-D coordination species $[Cu(TFTA)(CH_3OH)]_n$ based on paddle-wheel-like dinuclear nodes [85], being similar to that of $[Zn_2(TFTA)_2(dabco)]_n$ [86]. Fascinatingly, two structurally related Mo-TFTA coordination polygons, including a molecular square $[cis\text{-}Mo_2(DAniF)_2]_4(TFTA)_4$ and a triangle $[cis\text{-}Mo_2(DAniF)_2]_3(TFTA)_3$ (DAniF = the anion of *N*,*N*′-di-*p*-anisylformamidine), have been found under the dynamic equilibrium in $CDCl_3$ [87]. Similarly, another molecular square $\{[Rh_2(DAniF)_2(CH_3CN)_2]_4(TFTA)_4$ is also obtained [92]. Moreover, in $[Mo_2(DAniF)_3]_2(TFTA)$, two quadruply bonded $Mo_2(DAniF)_3$ units are linked by TFTA, which displays the controllable electrochemical behavior [88,89]. As for $[(^tBuCO_2)_3M_2(TFTA)M_2(O_2C^tBu)_3]_n$ (M = Mo and W) [90,91], the metal ions are interlinked by TFTA to generate a 1-D polymeric chain. Notably, in $\{[Er_2(TFTA)_3(DMF)(H_2O)](DMF)\}_n$ [93], a 3-D rod-packing coordination framework with tiny 1-D pore is observed.

3.4. Thermal stability of *1*–*3*

All complexes are air stable and their thermal stabilities were investigated by thermogravimetric (TG) and differential thermal analysis (DTA) experiments (see *Fig.* S2 Supporting Information for TG curves). The TG curve of **1** shows the first weight loss of 22.37% from 68 to 261 °C, corresponding to the loss of two lattice DMF and two coordinated water molecules (calc.: 21.01%). Accordingly, an endothermic peak is observed at 112 °C in the DTA curve. With that, the residual coordination framework starts to decompose with a sharp weight loss that ends at 448 °C (two exothermic peaks at 360 and 404 °C in the DTA curve). Upon further heating to 600 °C, no weight loss is observed and the final species holds a weight of 20.9% of the total sample. Complex **2** retains intact until heating to 163 °C and then suffers a series of continuous weight loss, which does not end until heating to 600 °C. Only one obvious exothermic peak at 296 °C is observed in the DTA curve. As for **3**, the TG curve indicates that the 3-D coordination framework remains stable upon heating to 204 °C, followed by a series of weight loss that does not end until heating to 600 °C (one endothermic peak at 300 °C and one exothermic peak at 343 °C in the DTA curve).

4. Conclusion

The present work demonstrates that the Br_4-substituted terephthalate ligand TBTA is a reliable and versatile building block to construct novel coordination polymers. The resultant Co^{II}, Ag^I, and Pb^{II} coordination frameworks with TBTA exhibit significant structural diversity from the 1-D chain, 2-D $CdCl_2$-type layer, to 3-D network, which can be ascribed to the metal-directed assembly. In addition, the TBTA ligand displays various coordination modes with these metal ions due to their distinct ion radii, extranuclear electron distributions, and thus coordination preferences. From the results presented in this work and previous research, we can also clearly conclude that the coordination-unfavored –Br substituent attached to the phenyl backbone of terephthalate may display the critical effect on the structural assemblies of coordination architectures. Anyway, these opinions may provide a possible strategy for the rational design and construction of novel metal-organic coordination frameworks, and further useful information for understanding the crystal engineering of such network solids.

ABSTRACT

A new tridentate N_2O donor Schiff base ligand [$(C_6H_5C(OH)$═$CHC(CH_3)$═$NCH_2C_5H_4N)$═**LH**] was obtained by 1:1 condensation of benzoylacetone with 2-picolylamine and has been used to synthesise a mononuclear [CuLCl] (**1**) and an *end-to-end* dicyanamide bridged polynuclear $\{[Cu_2(\mu\text{-}L)_2(\mu_2\text{-}1,5\text{-}(CN)_2N)]ClO_4\}_n$ (**2**) copper(II) complexes. The ligand, **1** and **2** were clearly characterised by elemental analysis, FT-IR, ^{1}H NMR, UV–Vis spectral studies, electrochemical studies and in addition single crystal X-ray diffraction studies were performed for **1** and **2**. The Schiff base ligand [**LH**] shows a significant variation in its coordination behaviour with copper(II) ion in absence and in presence of dicyanamide ion in **1** and **2** respectively. In absence of dicyanamide the deprotonated enolato oxygen of the tridentate Schiff base ligand $[\mathbf{L}]^-$ coordinates the copper(II) ion in a monodentate fashion generating a mononuclear species (**1**) whereas in presence of the dicyanamide ion, the deprotonated enolato oxygen of $[\mathbf{L}]^-$ bridges two adjacent $[CuL(CN)_2N]$ units through μ-OL bridges, forming dimers. The dimeric units are further linked to adjacent dimeric units through μ_2-1,5-dicyanamide bridges to produce 1D polymeric chains in **2**. Variable temperature magnetic susceptibility measurements for **2** in the temperature range 2-300 K reveal the presence of weak antiferromagnetic exchange interactions in the polymeric chain.

1. Introduction

Inorganic chemists have shown interest in synthesising coordination complexes derived from a Schiff base ligand since such complexes have wide applicability in catalysis, in designing molecular ferromagnets, in biological modeling as liquid crystals and as heterogeneous catalysts [1–7]. Several authors and our research team have successfully reported a large number of metal complexes derived from Schiff bases containing two, three, four, five and six donor atoms [8–17]. Tridentate Schiff bases with N_2O donor sets have been preferred by authors as such ligands effectively act as a chelate and can block the coordination sites of metal ions leaving the metal ion coordinatively unsaturated. In order to saturate the coordination number of metal ions preferring square planar, square pyramidal and octahedral geometry, different bridging ligands (N_3^-, NCO^-, NCS^-, acetates, carboxylates) have been used, giving rise to dinuclear and multinuclear complexes [11,14,15,18–27]. One such bridging ligand which is gaining interest among many researchers is dicyanamide (dca = $(CN)_2N^-$). Many authors have shown that this ligand may induce a large variety of topologies and magnetic properties due to its versatile coordination modes [28–31]. In comparison to the aforementioned bridging ligands, dca can coordinate metal ions through its eight different kinds of coordination modes (shown in Fig. 1). The *end-to-end* μ_2-1,5 bridging mode of dca with metal ions give rise to a weak antiferromagnetic coupling whereas μ_3-1,3,5 bridging mode is able to produce weak or strong ferromagnetic interactions between the metal centers. Dicyanamide can construct extended architectures by utilising its different bridging modes along with its unusual μ_4-1,1,3,5 and μ_5-1,1,3,5,5 coordination modes [32,33]. Until now our research group has reported four dicyanamide bridged metallo organic polymeric architectures derived from a N_2O donor Schiff base ligand [34–37].

There have been considerable interests for synthesising new N_2O donor tridentate Schiff bases which can effectively coordinate metal ions. To explore the chemistry of the metal complexes derived from N_2O donor tridentate Schiff bases, many authors including our research group have shown that 1:1 condensation of acetylacetone or benzoylacetone and diamines (e.g. 1,2-diaminoethane, 1,2-diaminopropane and 1,3-diaminopropane) under high dilution condition can produce mono-condensed N_2O donor

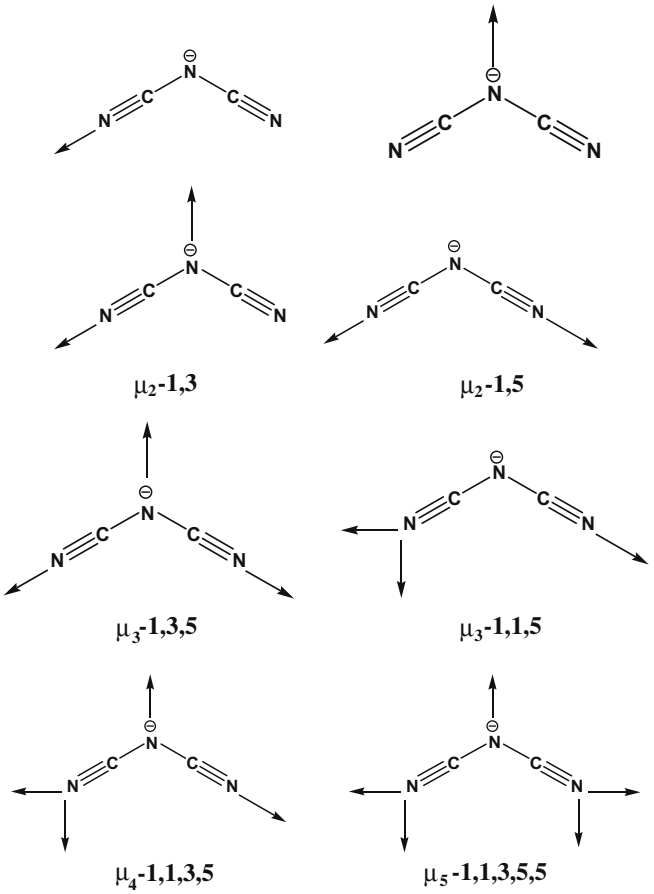

Fig. 1. Bridging modes of dca.

tridentate Schiff bases [32–42]. This group of tridentate ligands have been exhaustively used for the synthesis of mono-, di- and tri-nuclear complexes with first row transition elements [38–49] and are also used as precursor for the synthesis of unsymmetrical tetradentate Schiff bases [38–41,46]. To further explore the coordination behaviour of the N_2O donor tridentate Schiff bases obtained by condensation of benzoylacetone and diamine, some of us have used bridging ligands (N_3^-, NCO^-, SCN^-) and tried to find whether any variation in the coordination behaviour of such tridentate ligand is induced by such bridging ligands. Thus, we have reported mononuclear and polynuclear nickel and copper complexes [50–52] but no significant variation in the coordination behaviour of the N_2O donor ligand was observed in the mononuclear and polynuclear complexes.

As an extension of our earlier work, in this paper we report the synthesis of a new tridentate N_2O donor Schiff base ligand **LH** [(1Z,3E)-3-((pyridin-2-yl)methylimino)-1-phenylbut-1-en-1-ol] obtained by 1:1 condensation of benzoylacetone with 2-picolylamine and we have used it to synthesise a mononuclear and a μ_2-1,5-dicyanamide bridged polynuclear copper(II) complexes, **1** and **2** respectively. From literature survey we found that our group is the first one to characterise the new Schiff base ligand [**LH**] and its metal complexes. Earlier in the year 2002 McNeill with his research group proposed the reaction mechanism to synthesise 3,5-disubstituted and 3,4,5-trisubstituted-2-(2-pyridyl)pyrroles where they showed that **LH** was the precursor of the desired ligand system [53]. The ligand **LH** and the complexes **1** and **2** were clearly characterised by elemental analysis, FT-IR, ^{1}H NMR, UV–Vis spectral studies, and electrochemical studies. Single crystal X-Ray diffraction study of **1** and **2** were performed to investigate the structural aspects of the complexes. It is really interesting to note that unlike the earlier reported complexes derived from benzoylacetone and diamine [11], the ligand **LH** showed significant variation in its coordination behaviour with copper(II) ion in absence and in presence of the dca anion. In absence of dicyanamide the deprotonated enolato oxygen of $[\mathbf{L}]^-$, coordinates the copper(II) ion in its monodentate mode and produces a mononuclear complex (**1**), whereas in presence of dicyanamide the same deprotonated enolato oxygen of $[\mathbf{L}]^-$ bridges two adjacent $[CuL(CN)_2N]$ units through μ-OL bridges forming copper(II) dimers. The dimeric units are further linked to the adjacent dimeric units through μ_2-1,5-dicyanamide bridges to produce a 1D polymeric chain (**2**). The temperature dependence of the magnetic susceptibility has been investigated for **2**.

2. Experimental

2.1. Materials

All solvents were of reagent grade and used without further purification. Benzoylacetone and 2-picolylamine were purchased form Aldrich Chemical Company. Copper chloride dihydrate and sodium dicyanamide were purchased form Fluka and were used as received. Copper perchlorate hexahydrate was prepared by treatment of copper carbonate (E. Merck, India) with 60% perchloric acid (E. Merck, India) followed by the slow evaporation on a steam bath. It was then filtered through a fine glass-frit and preserved in a $CaCl_2$ desiccator for further use.

2.2. Syntheses

Caution! Perchlorate salts are potentially explosive and should be used in small quantity with much care.

2.2.1. Synthesis of the Schiff base ligand

*2.2.1.1. $[C_6H_5C(OH)=CHC(CH_3)=NCH_2C_5H_4N]$ (**LH**).* The Schiff base ligand (**LH**) was prepared by the reflux condensation of a 25 mL methanolic solution of 2-picolylamine (5 mmol, 0.51 mL) with an equivolume methanolic solution of benzoylacetone (5 mmol, 0.18 g). The mixture was refluxed for 2 h until a yellow coloured solution resulted. The colour indicated the formation of the Schiff base (**LH**) which was used without further purification. The scheme of synthesis and the keto-enol tautomerisation of the ligand **LH** is shown in Fig. 2. *Anal.* Calc. for $[C_{16}H_{16}N_2O]$: C, 76.19%; H, 6.35%; N, 11.11%. Found: C, 76.21; H, 6.38; N, 11.14%.

2.2.2. Syntheses of the complexes

*2.2.2.1. [CuLCl] (**1**).* Copper chloride dihydrate (0.170 g, 1 mmol) was dissolved in 5 mL methanol. 20 mL of a yellow methanolic solution of the Schiff base (**LH**) (0.252 g, 1 mmol), was added to the metal solution and stirred. The mixture was allowed to stir for 2 h at 30 °C. The resulting dark green solution was kept in the refrigerator at 16 °C to yield brown needle shaped crystals suitable for X-ray diffraction after a week. Crystals were isolated by filtration and were air-dried. *Anal.* Calc. for $[C_{16}H_{15}Cl_1Cu_1N_2O_1]$: C, 54.81%; H, 4.28%; N, 7.99%. Found: C, 54.85; H, 4.29; N, 8.01%.

*2.2.2.2. $\{[Cu_2(\mu\text{-}L)_2(\mu_2\text{-}1,5\text{-}(CN)_2N)]ClO_4\}_n$ (**2**).* Copper perchlorate hexahydrate (1 mmol, 0.37 g) was added to the brown needle shaped crystals of **1** (2 mmol, 0.70 g) and were dissolved together in 20 mL of methanol with stirring, resulting in a clear green solution. The solution was maintained at 40 °C with continuous stirring and 5 mL methanolic solution of sodium dicyanamide (2 mmol, 0.178 g) was added dropwise, resulting in a dark green solution. The mixture was then further stirred for 3 h at 30–35 °C and then filtered. The dark green solution was kept in the refrigerator at

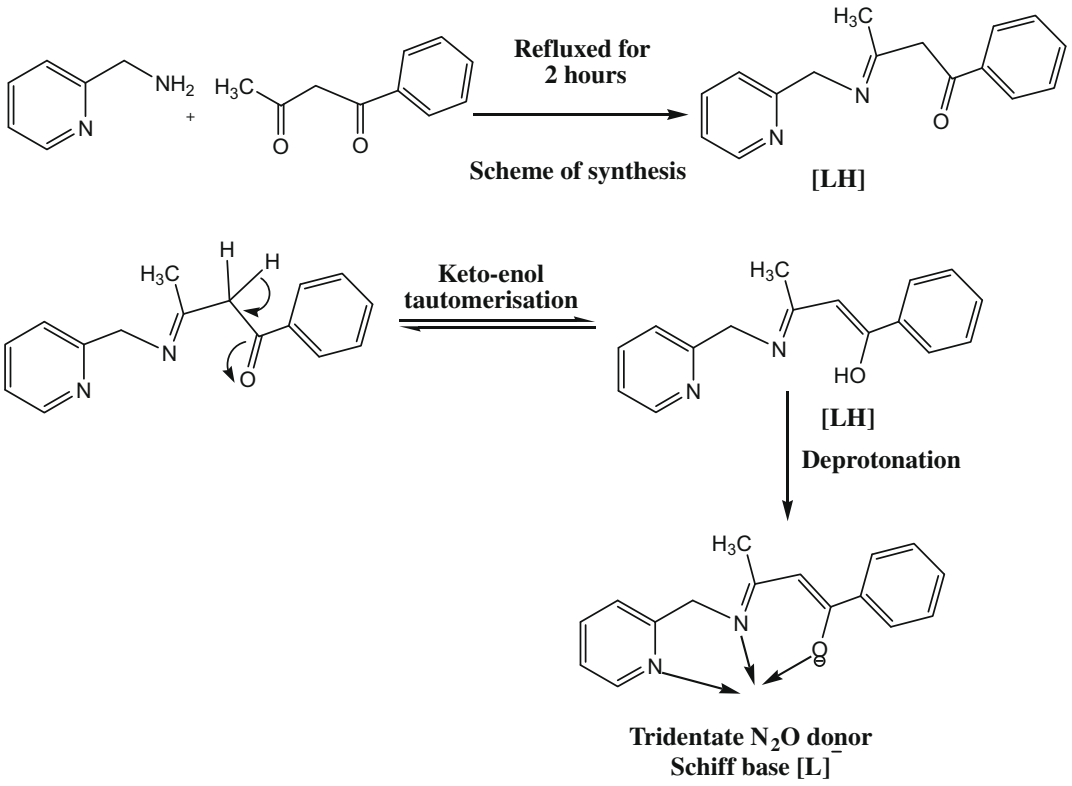

Fig. 2. Scheme of the synthesis and keto-enol tautomerisation of **LH**.

16 °C yielding light brown cubic shaped crystals suitable for X-ray diffraction after two weeks. Crystals were isolated by filtration and were air-dried. *Anal.* Calc. for $[C_{34}H_{30}Cl_1Cu_2N_7O_6]$: C, 51.31%; H, 3.77%; N, 12.32%. Found: C, 51.33; H, 3.78; N, 12.36%.

2.3. Physical measurements

The Fourier transform infrared spectra (4000–300 cm^{-1}) of **LH**, **1** and **2** were recorded on a Perkin–Elmer Spectrum RX I FT-IR system as solid KBr pellets. The electronic spectra of the complexes were recorded at 300 K on a Perkin–Elmer λ-40 UV/Vis-spectrometer using HPLC grade acetonitrile as solvent with a 1 cm quartz cuvette in the range 200–800 nm. C, H, N microanalyses of the ligand and the complexes were carried out with a Perkin–Elmer 2400 II elemental analyser. Electrochemical measurements of the complexes were performed on a VersaStat-PotentioStat II cyclic voltammeter, using HPLC grade acetonitrile as solvent with tetrabutylammonium perchlorate as supporting electrolyte, at a scan rate of 0.05 V/s. Platinum and saturated calomel electrode (SCE) were the working and the reference electrodes in the process, respectively. ^{1}H NMR spectra of the ligand and the complexes were recorded on a BRUKER 300 MHz FT-NMR spectrometer using trimethylsilane as an internal standard in $CDCl_3$. Mass spectra of the ligand (**LH**) was recorded by Qtof Micro YA mass spectrophotometer. Variable temperature susceptibility measurements were carried out in the temperature range 2-300 K with an applied magnetic field of 0.1 T on a polycrystalline sample (40.14 mg) of 2 with a Quantum Design MPMSXL-5 SQUID magnetometer. The isothermal magnetization was performed in the same sample at 2 K with applied magnetic fields of up to 5 T. The susceptibility data were corrected for the sample holder previously measured using the same conditions and for the diamagnetic contributions of the salt as deduced by using Pascal's constant tables ($\chi_{dia} = -454.6 \times 10^{-6}$ emu mol^{-1}).

2.4. X-ray crystallography

Single-crystals X-ray studies of **1** and **2** were carried out using a Nonius Kappa CCD and the related analysis softwares [54]. Crystallographic data and the refinement results are given in Table 1. For **1** absorption correction called *Analytical* [55] (based on the shape of the single crystal used for the X-ray diffraction analyses performed at 150 K) has been applied whereas for **2** a semi-empirical absorption correction MULTISCAN program [56] has been applied to the data sets. Both structures have been solved by direct methods using the SIR97 program [57] combined to Fourier difference syntheses and refined against F using reflections with $[I/\sigma(I) > 3]$ with CRYSTALS program [58]. All atomic displacements parameters for non-hydrogen atoms have been refined with anisotropic terms. The hydrogen atoms were theoretically located on the basis of the conformation of the supporting atom and also found by Fourier Difference. Then they have been refined (positions and isotropic terms) to find their real position keeping some constraints belonging to the supporting atoms.

3. Results and discussion

The formation of the new Schiff base ligand **LH** has been supported by infrared, ^{1}H NMR and mass spectroscopy. IR bands obtained at 1654 cm^{-1} clearly indicate the presence of an imine bond which must have resulted by condensation of 2-picolyl amine with benzoylacetone. IR bands at 3339 and 3302 cm^{-1} for the asymmetric and symmetric $-NH_2$ stretching are not observed which also indicate that the $-NH_2$ functionality of 2-picolyl amine has successfully condensed with one of the carbonyl functionality of benzoylacetone. Moreover, a well defined band due to the enolic O–H stretching frequency at 3406 cm^{-1} is observed in the spectrum of the free ligand which not only support the formation of **LH** but also ensures that the free ligand have undergone tautomerisation

Table 1

and exists in the enolic form. In the ^{1}H NMR spectrum of the free ligand **LH** no signal at 5–8 ppm is observed, indicating the absence of free –NH_2 functionality, supporting the formation of the ligand **LH**. The mass spectrum also ensures the formation of the Schiff base ligand **LH**. The mass spectrum of the ligand **LH** shows a peak at m/e 275, which is attributed to the molecular ion peak $[C_{16}H_{16}N_2ONa]^+$. In the mass spectrum the highest intensity peak was obtained at m/e 275 (100%) and may be assigned to the neutral **LH** bound to one sodium ion to generate a molecular ion. Hence, we can state from the mass spectrum that proper condensation of the 2-picolyl amine with benzoylacetone has resulted in the formation of the Schiff base ligand **LH**. The most conclusive evidence which supports the condensation of 2-picolyl amine with benzoylacetone is the single crystal X-ray study of **1** and **2** which clearly indicate the coordination of the deprotonated tridentate ligand $[\mathbf{L}]^-$ to the copper(II) centers.

3.1. Infrared spectra

The IR spectra of **1** and **2** have been analysed in comparison with that of the free ligand **LH** in the region 4000–250 cm^{-1}. The IR spectra of **1** and **2** are very similar to each other except in the regions 2150–2400 cm^{-1} and 1090–1129 cm^{-1}. In **1** none of the three sharp characteristic peaks for the dicyanamide ligand are observed in the region 2290–2170 cm^{-1} clearly indicating the absence of dca. In **2** the three characteristic bands of the free dca ligand [$\nu_{\mathbf{as}} + \nu_{\mathbf{s}}$(C≡N) combination modes (2286 cm^{-1}), $\nu_{\mathbf{as}}$(C≡N) (2232 cm^{-1}) and $\nu_{\mathbf{s}}$(C≡N) (2179 cm^{-1})] are further splitted and are shifted towards higher frequencies: 2292 (m, with shoulder on the high frequency side), 2290 (s) cm^{-1} ($\nu_{\mathbf{as}} + \nu_{\mathbf{s}}$(C≡N)), 2234 (s) cm^{-1} ($\nu_{\mathbf{as}}$(C≡N)) and 2160 (s/m) cm^{-1} ($\nu_{\mathbf{s}}$(C≡N)) (s, strong; m, medium). The splitting of the bands and the displacements observed are consistent with the presence of bridging (bidentate) dca in **2**, as revealed by the X-ray structure determinations [59]. Moreover bands corresponding to the $\nu_{\mathbf{as}}$(C–N) stretching frequencies (1406–1302 cm^{-1} region), and the $\nu_{\mathbf{s}}$(C–N) stretching (930–900 cm^{-1} region), also support the coordination of dca in **2**. The characteristic bifurcated absorbtion band in the region 1059–1121 cm^{-1} for perchlorate anion is observed in **2** but is absent in **1**. A strong sharp absorption band around 1624 cm^{-1} in the spectrum of the Schiff base ligand can be assigned to the C=N group. In **1** and **2** this band is shifted to lower frequencies 1612 and 1611 cm^{-1} upon complexation with the respective metal centers, which can be attributed to the coordination of the nitrogen atom of the imino group to the metal centers [60]. The ligand shows a well defined band at 3412 cm^{-1} due to the enolic O–H stretching frequency which disappears in **1** and **2** and a C–O absorption band that appears at 1056–1095 cm^{-1}, indicating that the deprotonated ligand $[\mathbf{L}]^-$ is coordinated to the copper(II) center. The low energy pyridine ring in-plane and out-of-plane vibrations are observed in the spectrum of the **LH** molecule at 621 and 412 cm^{-1}, respectively, whereas the corresponding bands for **1** and **2** are shifted to higher frequencies at 623, 677 and 419, 422 cm^{-1}, respectively, which are good indications of the coordination of the heterocyclic nitrogen atom to the metal centers [61]. Sharp bands corresponding to ν_{Cu-N} appear in the complexes **1** and **2** at 412 and 408 cm^{-1} respectively indicating the coordination of the nitrogen atom to the metal center.

3.2. NMR spectra

^{1}H NMR spectroscopy has been used to extract information regarding the formation of the Schiff base ligand **LH** and its mode of coordination with the copper(II) centers in **1** and **2**. The NMR spectra of **1** and **2** are almost superimposable but differ significantly from that of the free ligand **LH**. The NMR proton numbering scheme of **LH** along with the NMR spectra of the ligand and the complexes are represented in Fig. 3a and b. The NMR data are summarised in Table 2. In the NMR spectra of the free ligand **LH** a signal at 5–8 ppm is not observed, indicating the absence of free –NH_2 functionality, supporting the formation of the ligand **LH** [62]. In **1** and **2** the signal due to the enolic hydrogen (H8) of the free ligand (11.3 ppm) is absent and the phenyl protons are shifted more downfield (H9 ~0.02 ppm and H10 ~0.02 ppm and H11 ~0.02 ppm) in both the complexes, indicating the coordination of a deprotonated enolic oxygen of $[\mathbf{L}]^-$ in the complexes. The methylene and methyl protons (H5 and H6 respectively) of **LH** attached to the imine nitrogen are shifted downfield (~0.06 ppm and

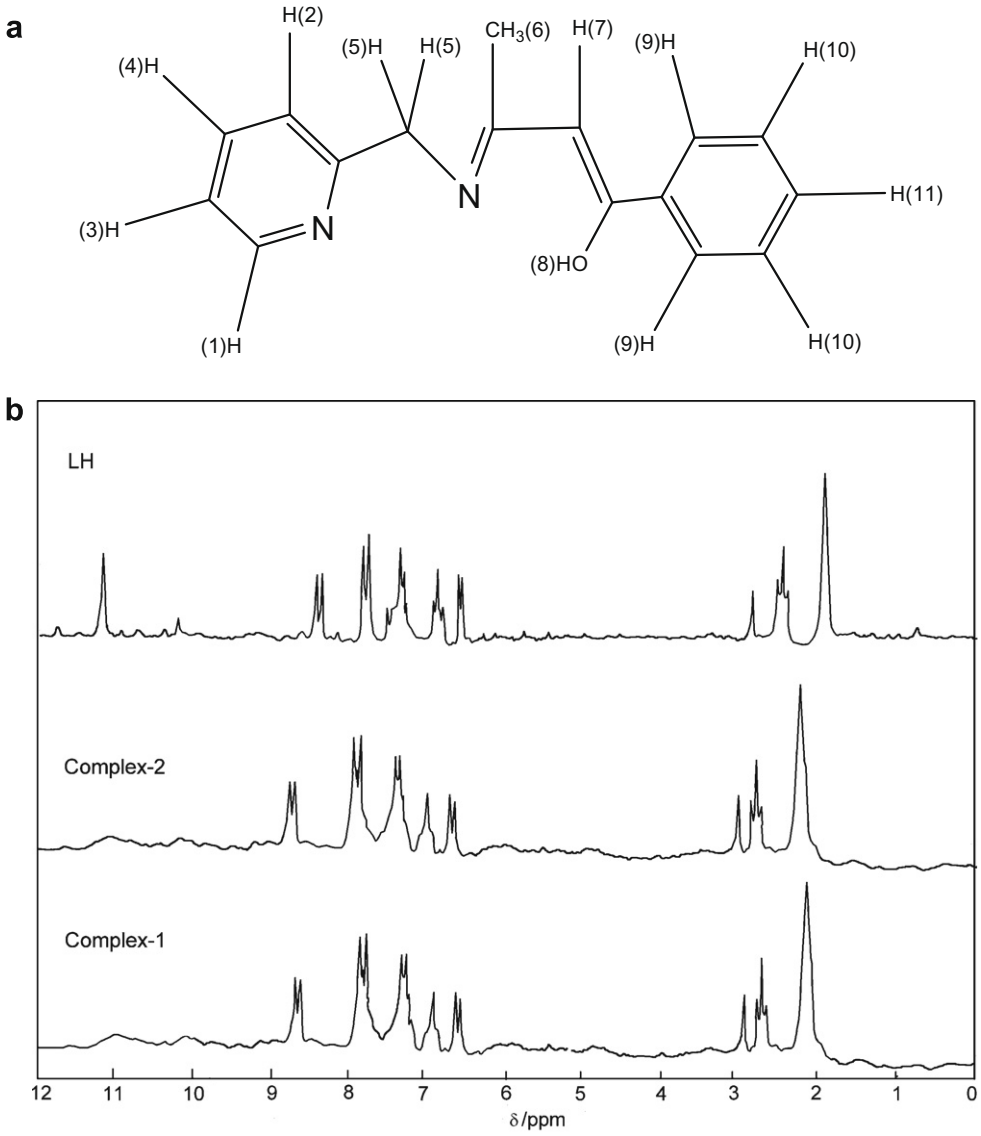

Fig. 3. (a) NMR proton numbering scheme of **LH**. (b) NMR spectra of the Schiff base ligand [**LH**] and the complexes **1**, **2**.

~0.04 ppm, in **1** and **2**, respectively), indicating the coordination of the imine N to the metal center. In the free ligand, the hydrogen atoms of the pyridine ring are deshielded due to the presence of the nitrogen atom in the ring. The ortho and para hydrogen atoms (H1 and H4 respectively) undergo –I and –M effect owing to the nitrogen atom. The –I effect on H1 is greater than that on H4 so H1 is more deshielded than H4 and appears downfield than H4. The meta hydrogen atoms (H2 and H3) undergo only –I effect and –M effect of nitrogen atom is absent hence H2 and H3 appear upfield than H1 and H4. H1 and H4 are shifted significantly downfield (~0.13 ppm and ~0.09 ppm in **1** and **2**, respectively), indicating the coordination of the pyridinium nitrogen to the metal centers [62].

Table 2
NMR data for the ligand **LH** and for complexes **1** and **2**.

Schiff base/ complex	δ (in ppm)
LH	2.0 (3H,s, H6); 2.5 (2H,t, H5); 2.8 (1H,s, H7); 6.85 (1H,d, H2); 7.0 (1H,t, H3); 7.4 (1H,dd, H4); 7.57 (2H,dd, H10); 7.57(1H,t, H11); 7.87 (2H,d, H9); 8.5 (1H,d, H1); 11.3 (1H,s, H8)
1	2.03 (3H,s,H6); 2.54 (2H,t, H5); 2.84 (1H, s, H7); 6.86(1H,d, H2); 7.02 (1H,t, H3); 7.48 (1H,dd, H4); 7.58 (2H,dd, H10); 7.58 (1H,t, H11); 7.88 (2H,d, H9); 8.62 (1H,d, H1)
2	2.04 (3H,s,H6); 2.56 (2H,t, H5); 2.85 (1H, s, H7); 6.87(1H,d, H2); 7.04 (1H,t, H3); 7.49 (1H,dd, H4); 7.59 (2H,dd, H10); 7.59 (1H,t, H11); 7.89 (2H,d, H9); 8.63 (1H,d, H1)

3.3. Electronic spectra

UV–Vis spectra of the ligand and the complexes have been recorded at 300 K in HPLC grade acetonitrile solution. The electronic spectra of the free ligand [**LH**] shows two intraligand charge transfer (CT) bands at 331 nm and 248 nm but for **1** and **2** three different CT bands at 407, 307, 276 nm and 412, 322, 255 nm are observed respectively. In **1** and **2** the bands obtained at 307, 276 nm and 322, 255 nm are assigned to L → L charge transfer transitions but since the spectrum of the free ligand lacks CT bands in the region 407–422 nm hence it can be concluded that in **1** and **2** the CT bands obtained at 407 and 422 nm are associated with the L → M charge transfer transitions. In comparison to the spectrum of the

free ligand, much weaker and less well defined broad bands are found at 602 and 650 nm in the respective complexes and are assigned to d–d transitions. The d–d transition at 602 nm for **1** is attributed to structurally well characterised square planar copper(II) complex, whereas the d–d bands near 650 nm for **2** are more consistent with copper(II) complex with square pyramidal geometry [63].

3.4. Cyclic voltammetry

Electrochemical properties of **1** and **2** have been studied in HPLC grade acetonitrile medium with tetrabutylammonium perchlorate as supporting electrolyte at a scan rate of 50 mVs^{-1}. During the cathodic scan **1** shows a reductive response at −0.283 V versus SCE, which is assigned to the Cu(II) → Cu(I) reduction and during the anodic scan it shows an oxidative response at +0.587 V versus SCE assigned to the Cu(I) → Cu(II) oxidation. These reduction and oxidation are irreversible, characterised by a peak to peak separation (ΔE_p) of 294 mV, which remains unchanged upon changing the scan rate. For **2** two irreversible reductive responses at −0.06 V versus SCE and −0.751 V versus SCE are observed during the cathodic scan which are assigned to the Cu(II) → Cu(I) reductions. The first reductive response at −0.06 V may be assigned to the reduction of one copper(II) center which is followed by a successive reduction (−0.751 V) of the adjacent copper(II) center via the bridging ligands. Similarly during the anodic scan, two metal centered irreversible oxidative responses at +0.21 V and +0.52 V versus SCE are observed which are assigned to the Cu(I) → Cu(II) oxidations of the adjacent copper centers.

3.5. Description of the crystal structure

3.5.1. [CuLCl] (*1*)

The structure of **1** consists of a neutral copper(II) monomer with the metal center residing in a distorted square planar environment surrounded by two nitrogen atoms, one deprotonated oxgyen atom of the tridentate N_2O donor Schiff base ligand and a terminal chloride ion of the precursor metal salt (Fig. 4). In **1** the pyridine nitrogen atom is located in *trans* to the deprotonated enolato oxygen of the Schiff base ligand whereas the imine nitrogen atom of $[\mathbf{L}]^-$ and the chlorine atom occupy the other trans pair. The distortion from the square planar geometry of the copper(II) center is evident from the bond lengths and bond angles (Table 3). The Cu-Cl bond length (2.258(1) Å) is significantly longer than the Cu–N and Cu–O ones (in the range 1.908(3)-2.000(3) Å) and the bond angles

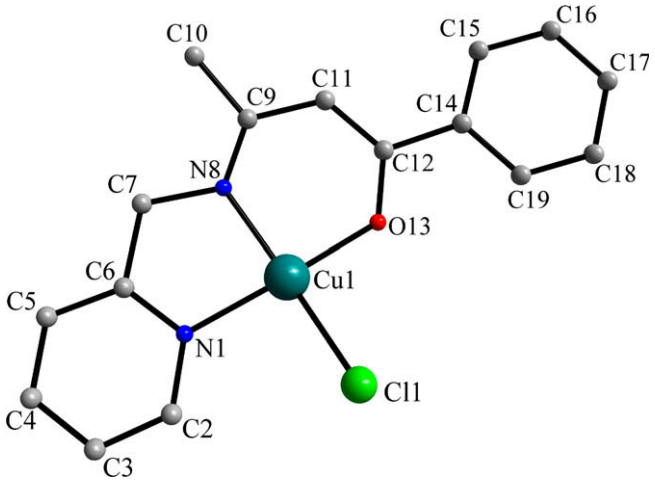

Fig. 4. Mononuclear unit of **1** with the atom labelling scheme.

Table 3
Bond lengths (Å) and angles (°) around the copper centres in **1** and **2**.

1		**2**	
Bond lengths (Å)

Cu1–O13	1.908 (3)	Cu1–O28	1.912 (2)
Cu1–N1	2.000 (3)	Cu1–N32	1.935 (3)
–	–	Cu1–N39	1.988 (3)
–	–		
Bond angles (°)			
Cl1–Cu1–N1	94.6 (1)	O28–Cu1–N11	82.2 (2)
Cl1–Cu1–N8	166.4 (1)	O28–Cu1–O28	84.4 (1)
N1–Cu1–N8	83.3 (1)	N11–Cu1–O28	87.7 (2)
Cl1–Cu1–O13	90.84 (9)	O28–Cu1–N32	106.5 (1)
N1–Cu1–O13	170.1 (1)	N11–Cu1–N32	171.3 (1)
N8–Cu1–O13	93.3 (1)	O28–Cu1–N32	93.4 (1)
–	–	O28–Cu1–N39	94.9 (1)
–	–	N11–Cu1–N39	95.2 (2)
–	–	O28–Cu1–N39	176.9 (1)
–	–	N32–Cu1–N39	83.8 (1)

deviate from the ideal values (the *trans* angles are in the range 166.4(1)–170.1(1)° and the *cis* angles are in the range 83.3–94.6°). As a consequence of the distortion the copper(II) center, the pyridine nitrogen and the enolato oxygen lie 0.045, 0.195 and 0.192 Å, respectively, below the average plane whereas the imine nitrogen and the terminal chlorine atom lie 0.216 and 0.171 Å above the mean plane. The most significant distortion is associated with the chlorine atom, which is 0.524(1) Å away from the (Cu1, N1, N8, O13) plane. Complex **1** does not show any intramolecular nor intermolecular hydrogen bonding interactions. The chelate bite angles in the five-membered and the six-membered rings formed by the coordination of pyridine-N and the imine-N, and enolato-O and imine-N of the tridentate Schiff base $[\mathbf{L}]^-$ are 83.27° and 93.31° respectively. Both of these five and the six-membered chelate rings formed due to the coordination of the N1, N8 and O13 atoms of the tridentate Schiff base to the copper(II) center lie in the same plane and are almost parallel to the two aromatic rings of $[\mathbf{L}]^-$ with a dihedral angle of 2.76°. The structure packing can be described as monomer columns running along the *a*-axis (Fig. 5). Inside the columns, the monomeric complexes are shifted with an angle of 180° whereas between two neighbour columns, the complexes are shifted with an angle of 43.0(2)° in the *c*-direction (Fig. 6) and are parallel along the *b*-direction.

3.5.2. $\{[Cu_2(\mu\text{-}L)_2(\mu_2\text{-}1,5\text{-}(CN)_2N)]ClO_4\}_n$ (*2*)

The asymmetric unit constructing 1D polymeric architecture of **2** is shown in Fig. 7. The bond lengths and bond angles around the copper (II) centres are given in Table 3. The asymmetric unit of **2** consists of a crystallographic independent copper(II) center, one unit of deprotonated Schiff base ligand $[\mathbf{L}]^-$, one dca $[N(CN)_2]^-$ and one perchlorate counter anion. The asymmetric unit indicates the presence of two different bridging moieties in **2**. Compared to **1**, the deprotonated enolato oxygen of $[\mathbf{L}]^-$ shows a different coordinating behaviour since now it bridges two adjacent asymmetric units in **2** to generate a centrosymmetric dimeric structure. These dimers are further connected to adjacent dimers by *end-to-end* dicyanamide bridges to generate a 1D polymeric chain in **2** (Figs. 8 and 9). The copper(II) centers in the centrosymmetric dimeric units are located in a five-coordinated environment bonded to three coordinating N_2O donor atoms of the tridentate Schiff base ligand $[\mathbf{L}]^-$, one enolato oxygen of the other unit of $[\mathbf{L}]^-$ and a nitrile nitrogen atom of the μ_2-1,5 bridging dicyanamide anion. The charge balance is achieved by the insertion of perchlorate anions in the [(101); *b*] planes, between the cationic chains of **2** (Fig. 10). The chelate bite angles in the five- and six-membered

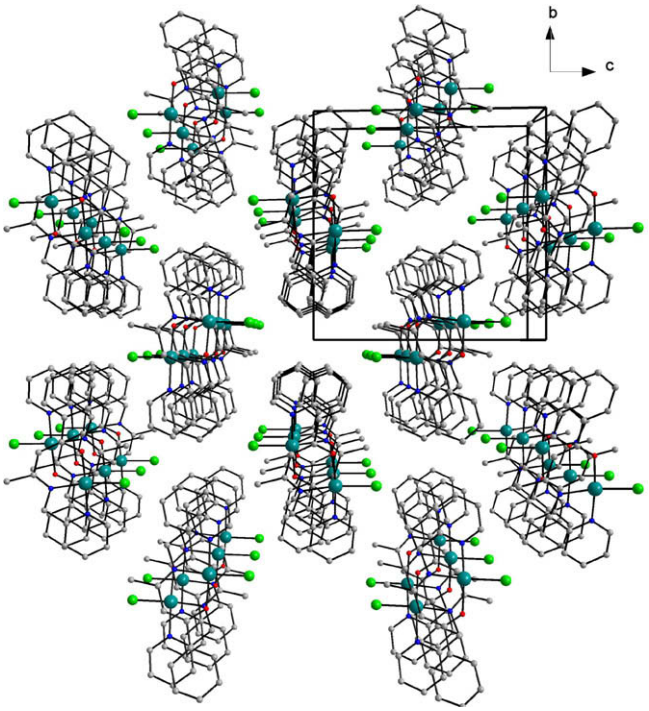

Fig. 5. Packing diagram of **1** showing the monomer columns running along the *a*-axis.

rings formed by the coordination of the pyridine-N and the imine-N, the enolato-O and the imine-N of the tridentate Schiff base $[\mathbf{L}]^-$ are 83.82° and 93.42° respectively and are very close to that of **1**. The geometry of the each copper(II) center is very close to square pyramidal with $\tau = 0.094$, $[\tau = |\beta - \alpha|/60°]$, where β and α are the two largest angles around the central atom; $\tau = 0$ and 1 for the perfect square pyramidal and trigonal bipyramidal geometries, respectively [64]. The square base of each copper(II) center is formed by the pyridyl and imine nitrogen atoms, an enolate oxygen of the tridentate Schiff base ligand $[\mathbf{L}]^-$ and a nitrile nitrogen of the μ_2-1,5 bridging dicyanamide anion. All the equatorial bond lengths are similar (in the range 1.912(2)–1.988(3) Å, Table 3) and much shorter than the axial Cu–O bond distance

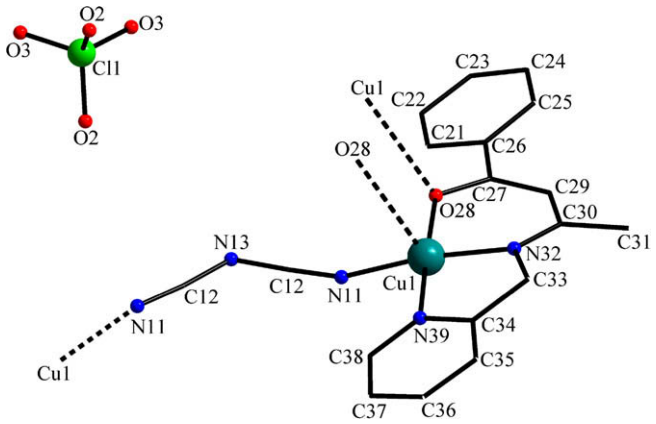

Fig. 7. Asymmetric unit of **2** with the atom labelling scheme.

(2.790(4) Å), in good agreement with those previously reported in the literature. The bridging enolato oxygen atom connects the copper(II) centers of two adjacent $[CuL(CN)_2N]$ independent units in an asymmetric (basal-apical) fashion with two very different bond distances (1.912(2) and 2.790(4) Å, $\Delta d = 0.878$ Å). The Cu1–O28–Cu1 bridging angle in **2** is 95.63° and the Cu1···Cu1 separation inside a dimer is equal to 3.533(3) Å. The other Cu···Cu distances inside the cationic chains are equal to 7.942(9) Å and 8.422(8) Å and are in the same range as those observed between chains (8.374(3) Å and 8.604 (6) Å). The copper(II) atoms in **2** show a displacement of 0.063 Å from the basal plane towards the axially coordinated enolato oxygen constituting the apex of the pyramid. There are no interchain H-bonding interactions in **2**.

3.6. Magnetic study

Room temperature magnetic moment of the mononuclear copper(II) Schiff base precursor complex was recorded for a polycrystalline sample at 30 °C. The $\mu_{effective}$ value was found to be equal to 1.76 BM, which is in excellent agreement with the theoretical value (1.797 BM) for one unpaired electron in magnetically dilute copper(II) complexes. Variable temperature magnetic susceptibility studies of **1** have not been measured as its structural characterisation shows that it is a well isolated copper(II) mononuclear

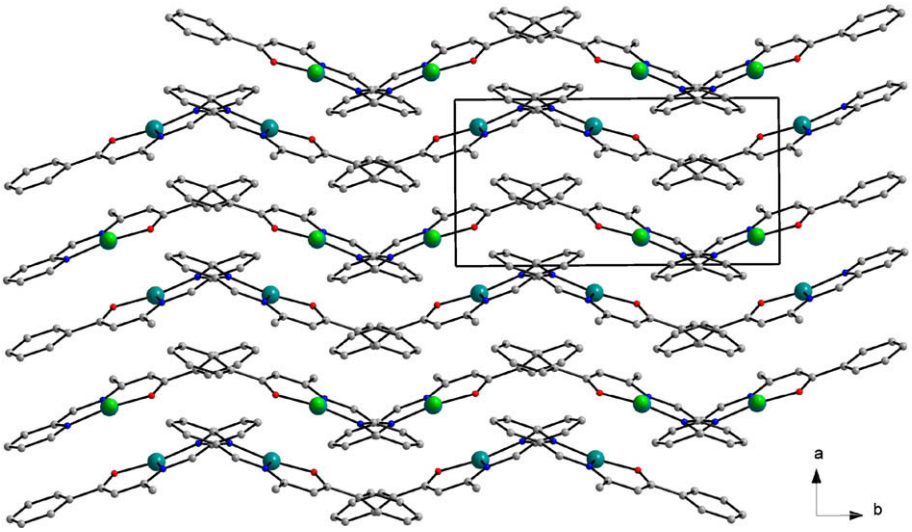

Fig. 6. Packing diagram of **1** showing the orientation of the neighbouring mononuclear units along *c*-axis.

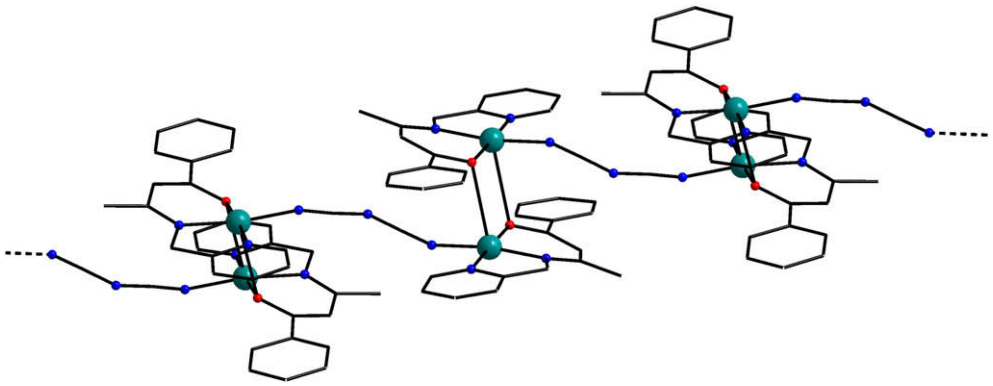

Fig. 8. 1D polymeric chain structure of **2**.

species and therefore, it is expected to show a paramagnetic behavior.

The product of the molar susceptibility times the temperature ($\chi_m T$) for compound **2** shows a room temperature value of ca. 0.80 emu K mol^{-1} (per two copper(II) ions), in agreement with the expected value for two non interacting copper(II) ions ($S = 1/2$). When the temperature is decreased, the $\chi_m T$ product remains constant down to ca. 50 K. Below this temperature the $\chi_m T$ product shows a progressive rounded decrease to reach a value of ca. 0.54 emu K mol^{-1} at 2 K. This behavior indicates that **2** presents a weak, although noticeable, antiferromagnetic coupling.

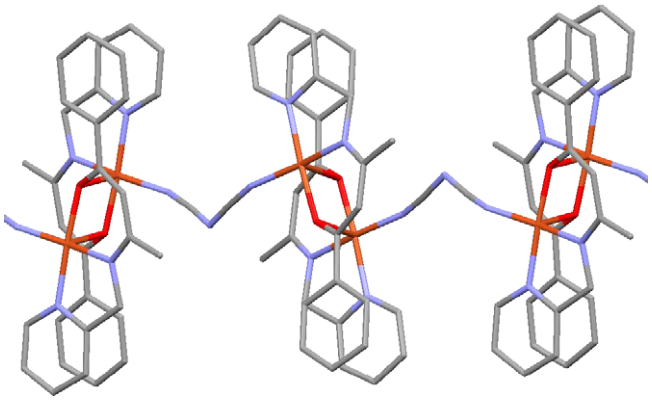

Fig. 9. Projection of the 1D polymeric chain structure of **2** along the *a*-axis.

Since the structure of compound **2** shows the presence of two alternating types of bridges: a dicyanamide bridge and a double (although long) oxo bridge, there are three possible magnetic exchange schemes: (1) A dicyanamide-bridged copper(II) dimmer, if the double long oxo bridges do not contribute to the magnetic exchange, (2) a doubly oxo-bridged copper(II) dimer, if the contribution of the dicyanamide bridge is negligible and (3) an alternating S = 1/2 chain, if both bridges contribute to the magnetic exchange. Accordingly, we have fit the magnetic behavior to the two possible different models: (i) the simple Bleaney–Bowers dimer model for $S = 1/2$ ions (cases 1 and 2) [65] and the alternating $S = 1/2$ chain model of Hatfield et al. (case 3) [66].

The dimer model reproduces quite satisfactorily the magnetic behavior of **2** in the whole temperature range with the following parameters (dotted line in Fig. 11): $g = 2.0532(5)$ and $J = -1.53(1)\,\mathrm{cm}^{-1}$ (the Hamiltonian is written as $H = -JS_1S_2$). Nevertheless, a closer look at the low temperature region (inset in Fig. 11), shows that the low temperature rounded decrease at low temperatures is not perfectly reproduced. The second model used (the alternating $S = 1/2$ chain) reproduces very satisfactorily the magnetic properties of **2** in the whole temperature range (solid line in Fig. 11) with the following parameters: $g = 2.0701(8)$, $J = -1.12(1)\,\mathrm{cm}^{-1}$ and $J' = -1.62(1)\,\mathrm{cm}^{-1}$ ($\alpha = J'/J = 1.43(1)$) (the Hamiltonian is written as $H = -JS_1S_2$). As can be seen in the inset in Fig. 11, this model reproduces much better the rounded decrease at low temperatures, as well as the high temperatures region, sug-

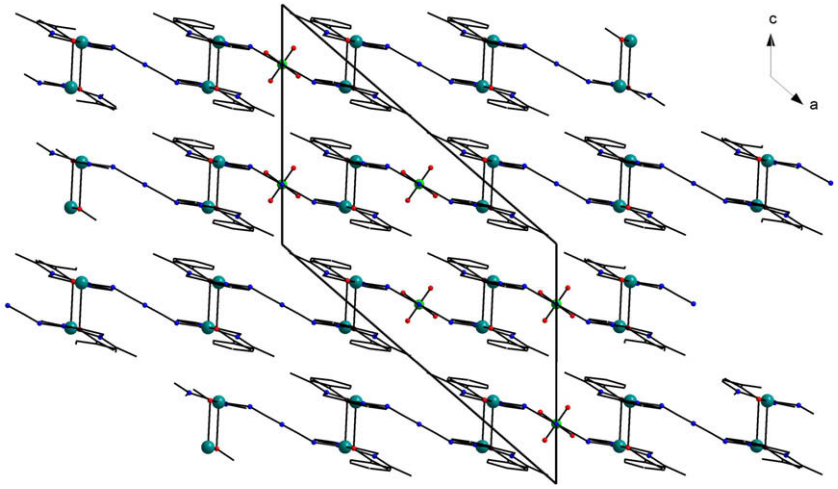

Fig. 10. Projection of **2** along the *b*-axis of the unit-cell showing the 1D parallel cationic chains and the perchlorate counter-ions.

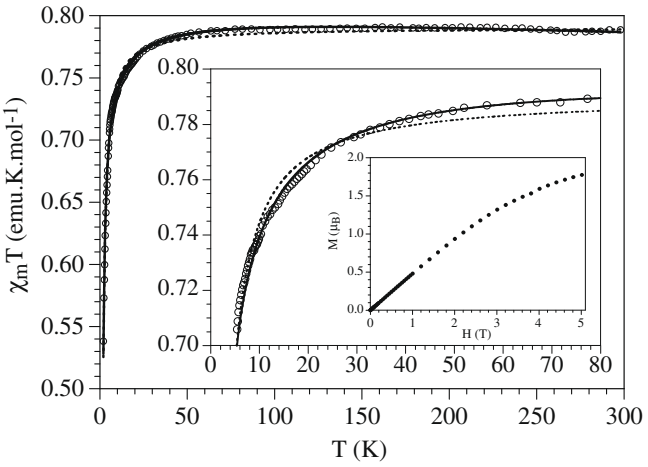

Fig. 11. Thermal variation of the $\chi_m T$ product for 2. Dotted and solid lines are the best fit to the dimer and alternating chain models (see text). Insets show the low temperature region and the isothermal magnetization at 2 K.

gesting that both bridges are operative in the magnetic exchange scheme. Although the assignment of the obtained J values to the two different bridges is not straightforward, the very weak exchanges usually found in dicyanamide bridges (in the range -0.44 to $0.20\ cm^{-1}$ [59,67–73]), suggests that the lower J value ($J = -1.12\ cm^{-1}$) might correspond to the dicyanamide bridge, whereas the higher J value ($J' = -1.62\ cm^{-1}$) would correspond to the double oxo bridge.

Even with this assignment, the dicyanamide exchange coupling found in **2** is slightly higher than those found in other dicyanamide-bridged copper(II) complexes. This fact may be explained from two main structural features: (1) the dicyanamide ligand occupies equatorial positions in both copper(II) ions and (2) the equatorial planes of the copper(II) ions connected through the dicyanamide bridge are almost parallel and also parallel to the dicyanamide plane. Thus, the angles between the dicyanamide plane and the average copper(II) equatorial planes are 16.69 and 16.71°. These two features enable a bigger overlap of the magnetic $d_{x^2-y^2}$ orbitals (that are parallel to the equatorial planes), giving rise to a stronger antiferromagnetic coupling. In fact, the dca-bridged examples with higher magnetic coupling are those where the dca ligand links two equatorial positions [73].

A further confirmation of this weak antiferromagnetic coupling comes from the isothermal magnetization at 2 K which is not saturated at 5 T and shows a value below the expected one (ca. 2 μ_B) (inset in Fig. 11).

4. Conclusions

A novel Schiff base ligand (**LH**) has been prepared by the 1:1 condensation of benzoylacetone with 2-picolylamine. This Schiff base ligand shows a different coordinating behavior towards the copper(II) ions when it is used alone or in presence of dicyanamide ligand. Thus, a mononuclear [CuLCl] (**1**) and an *end-to-end* dicyanamide bridged polynuclear $\{[Cu_2(\mu\text{-}L)_2(\mu_2\text{-}1,5\text{-}(CN)_2N)]ClO_4\}_n$ (**2**) complexes have been prepared and structurally characterised. The magnetic properties of compound **2** have been very well reproduced with an alternating antiferromagnetic $S = 1/2$ chain model that confirm the presence of weak antiferromagnetic exchange interactions in the chain. A comparative study of the dca bridges in **2** and in other dca bridged copper(II) complexes has allowed an assignation of the exchange constants. This assignment shows that the exchange constant in **2** is higher than in other dca bridged copper(II) complexes. This relatively high antiferromagnetic coupling observed in the dca bridges is due to the occupancy of the equatorial positions by the dca ligand in both copper(II) environments and the almost parallel disposition of the equatorial copper(II) and the dca planes.

ABSTRACT

The metal–ligand bonds in $[(ZnCl_2)_2L]$, $[NiLCl]^+$ and two isomers of $[NiLCl_2]$ complexes with multimodal ligand L = hexakis(2-pyridyloxy)cyclotriphosphazene, cyclo-$[NP(NC_5H_4O)_2]_3$, are investigated at DFT level of theory using hybrid B3LYP functional. Electron density is evaluated in terms of QTAIM (quantum theory of atoms-in-molecule) topological analysis of electron density. The bonds of central transition metal atoms with phosphazene nitrogens are shorter, stronger and more polar than with the aromatic pyridine nitrogens. The atomic charges of phosphazene nitrogens are ca twice more negative than at the pyridine ones. The higher mechanical strain in the five-coordinate metal complexes than in the six-coordinate ones may be concluded.

1. Introduction

Cyclophosphazenes, cyclo-$(NPX_2)_n$, are an important family of inorganic ring systems. Their heterocyclic rings are particularly well-suited for being used as scaffolds or platforms for the construction of multisite coordination ligands [1]. The phosphazene backbone consists of alternating phosphorus and nitrogen atoms with formally alternating single and double P–N bonds. X-ray crystal structure analysis of cyclic phosphazenes imply that all P–N distances in the cyclophosphazene ring are equal [2–4].

The old "island model" [5,6] describes the bonding between the phosphorus and nitrogen atoms in terms of σ bonding and additional (out-of-plane and in-plane) π bonding arising from the overlap of 3d orbitals of the phosphorus with nitrogen 2p orbitals being combined into sets of three-centre π molecular orbitals ('islands' of electron density over P–N–P units with nodes at the phosphorus centres). Each nitrogen is attached by equally strong π bonds to both neighboring phosphorus atoms. However, the group-theoretical analysis of molecular orbitals in planar cyclophosphazenes of D_{nh} symmetry with odd n [7,8] excludes any d(P)–p(N) bonding and it makes this bonding scheme doubtful in other phosphazenes as well.

More recent bonding models [9–11] are based on prevailingly ionic P–N bonding (involving substantial charge transfer from phosphorus to nitrogen) with negative hyperconjugation contributions resulting from the donor-acceptor interactions of (out-of-plane and in-plane) nitrogen lone pairs into strongly polarized antibonding σ^*_{PN} and σ^*_{PX} orbitals. The extent of this negative hyperconjugation depends significantly on the nature of the X substituents on phosphorus atoms. Unequal negative hyperconjugation contributions provide a previously lacking and compelling explanation for the P–N bond length alternation observed in some linear polyphosphazenes.

The ring nitrogen atoms of cyclophosphazenes have sufficient basicity and can interact with Lewis acids [1]. The Lewis basicity of these ring nitrogen atoms can be modulated by the proper choice of substituents on phosphorus atoms. Relying on the ring nitrogen basicity of cyclophosphazenes as the sole ingredient of ligand design severely restricts the utility of these ring systems as ligands. On the other hand, additional coordination sites may be provided on the cyclophosphazene phosphorus substituents which facilitate binding of the metal ion to the less basic phosphazene ring nitrogen atoms.

Pyridyloxycyclophosphazenes are multisite coordination ligands [1], where the coordinating pyridine ligand is attached to the phosphorus atom of the cyclophosphazene ring by means of a "spacer" oxygen atom. Almost in all cases, the cyclophosphazene ring remains planar. This is in contrast to the situation found for other cyclophosphazene ligands such as pyrazolylcyclophosphazenes, where the ring undergoes puckering upon coordination. The planar cyclophosphazene geometry found in the metal complexes of pyridyloxycyclophosphazenes is probably due to the flexible oxygen spacer that separates the pyridyl group from the cyclophosphazene ring and allows a *strainfree* coordination to the metal ions.

The reactions of hexakis(2-pyridyloxy)cyclotriphosphazene, cyclo-$[NP(NC_5H_4O)_2]_3$, (L) with zinc(II), copper(II), nickel(II) and cobalt(II) halides form a diverse range of five- or six-coordinated

doi:10.1016/j.poly.2008.11.043

transition metal complexes which exhibit κ^3N to κ^5N coordination modes where a single cyclophosphazene ring nitrogen atom and two to four pyridyloxy nitrogen atoms are involved [12–15]. Such compounds are very suitable for the comparative studies of the different bonding of these ligands with transition metal ions. The aim of our study is not to describe the bonding in cyclotriphosphazenes which has been published elsewhere [9–11,16]. We will rather focus on the quantum–chemical description of the metal–nitrogen bonding for the nitrogen atoms of aromatic pyridine and non-aromatic phosphazene rings within the same coordination centre. Our results might be important for the utility of cyclophosphazene-based metal complexes in catalytic reactions which remains largely unexplored [1].

2. Method

In the first step, the hydrogen atoms positions in the experimental geometries of the complex compounds under study are optimized by molecular mechanics (MM+ method) [17]. Then, the electronic structure of the complexes is evaluated at DFT level of theory using hybrid B3LYP functional with 6–311G bases for Ni and Zn, 6–31G* bases for P and Cl and 6–31G bases from Gaussian library [18] for the remaining atoms. GAUSSIAN03 software [18] is used for single-point calculations.

The electronic structure of the species under study is investigated using QTAIM (Quantum theory of atoms-in-molecule) topological analysis of electron density [19]. The results are evaluated in terms of atomic volumes V and atomic charges q obtained using the electron density integrated over atomic basins (up to 0.001 e/Bohr^3 level). Bond characteristics are evaluated in terms of electron density ρ, its Laplacian $\nabla^2\rho$

$$\nabla^2\rho = \lambda_1 + \lambda_2 + \lambda_3 \quad (1)$$

and bond ellipticity ε

$$\epsilon = \lambda_1/\lambda_2 - 1 \quad (2)$$

at bond critical points (BCP), where $\lambda_1 < \lambda_2 < 0 < \lambda_3$ are the eigenvalues of the Hessian of the BCP electron density.

d Electron populations on central M atoms, d^x(M), are evaluated in terms of Mulliken population analysis.

AIM200 [20] software packages are utilized for QTAIM analysis of GAUSSIAN03 results. MOLDRAW 2.0 software [21] is used for visualization and geometry manipulation purposes.

3. Results

Using the above mentioned treatment, we have investigated the following transition metal M(II) complexes with hexakis(2-pyridyloxy)cyclotriphosphazene, cyclo-[NP(NC$_5$H$_4$O)$_2$]$_3$, (L) [14]:

(i) The dimetallic neutral complex [(ZnCl$_2$)$_2$L] (model A, see Fig. 1) with five- (κ^3N non-geminal *trans* binding mode of L with the equatorial nitrogen of the phosphazene ring) and four-coordinate (κ^2N geminal binding mode of L without any bond to the phosphazene ring) Zn(II) sites;
(ii) The cationic complex [NiLCl]$^+$ (model B, see Fig. 2) of [NiLCl]PF$_6$ compound with a six-coordinate Ni(II) site (κ^5N tetrapodal binding mode of L);
(iii) The green neutral complex [NiLCl$_2$] (model C, see Fig. 3) with a six-coordinate Ni(II) site (κ^4N tripodal donor binding mode of L);
(iv) The red neutral complex [NiLCl$_2$] (model D, see Fig. 4) with a five-coordinate Ni(II) site (κ^3N non-geminal *trans* binding mode of L with the equatorial nitrogen of the phosphazene ring).

If we denote the metal-bonded nitrogen atoms in cyclotriphosphazene as N' and in pyridine as N, the coordination spheres of individual metal central atoms in the systems under study are summarized in Table 1.

Nickel(II) complexes may be either diamagnetic (singlet spin state) or paramagnetic (triplet spin state). The comparison of total energy data of the systems under study (Table 1) indicate that unlike the expected higher stability of Zn(II) complex A in singlet state (spin multiplicity $M_S = 1$), the triplet state ($M_S = 3$) seems to be more stable for the studied Ni(II) complexes. Due to high sin-

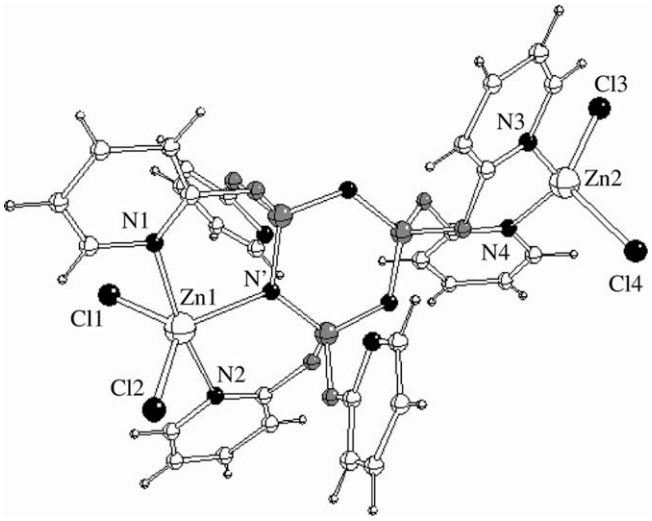

Fig. 1. Structure of [(ZnCl$_2$)$_2$L] complex, L = hexakis(2-pyridyloxy)cyclotriphosphazene cyclo-[NP(NC$_5$H$_4$O)$_2$]$_3$ (model A) [14] with atoms notation (Zn – large white, C – white, H – small white, N – black, Cl – large black, P – large grey and O – grey spheres).

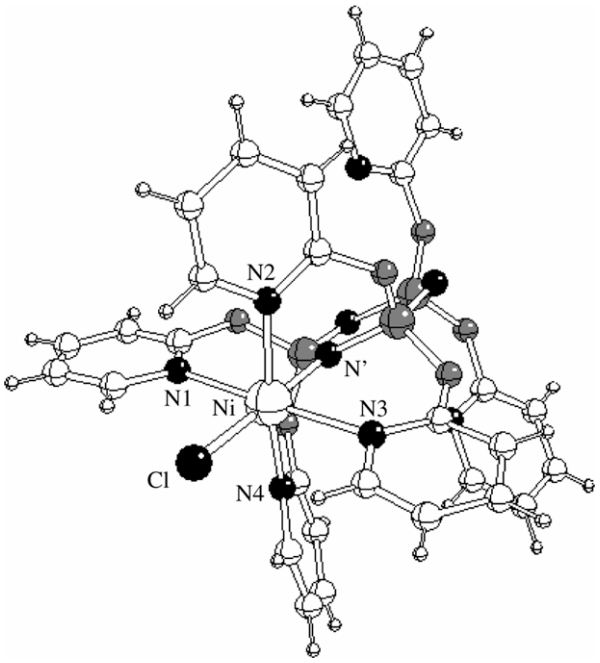

Fig. 2. Structure of [NiLCl]$^+$ complex cation, L = hexakis(2-pyridyloxy) cyclotriphosphazene cyclo-[NP(NC$_5$H$_4$O)$_2$]$_3$ (model B) [14] with atoms notation (Ni – large white, C – white, H – small white, N – black, Cl – large black, P – large grey and O – grey spheres).

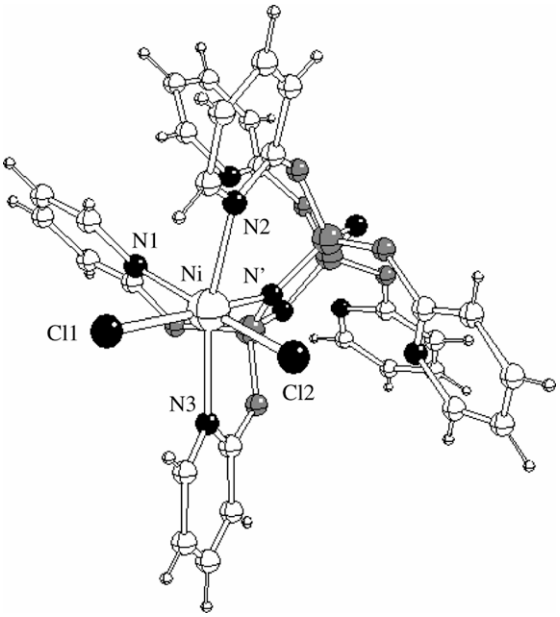

Fig. 3. Structure of green [$NiLCl_2$] complex, L = hexakis(2-pyridyloxy) cyclotriphosphazene cyclo-[$NP(NC_5H_4O)_2]_3$ (model C) [14] with atoms notation (Ni – large white, C – white, H – small white, N – black, Cl – large black, P – large grey and O – grey spheres).

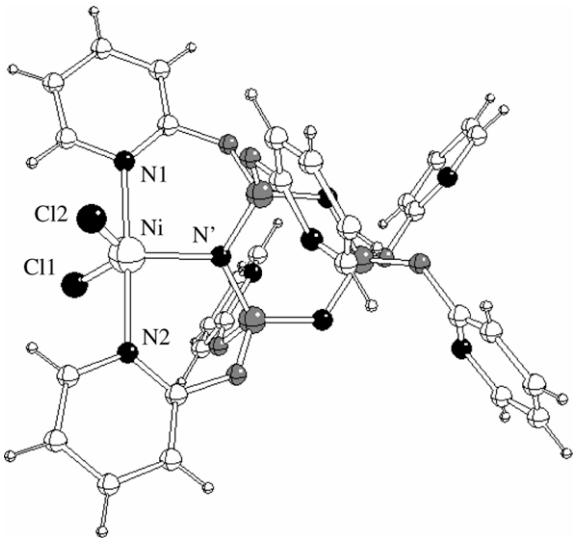

Fig. 4. Structure of red [$NiLCl_2$] complex, L = hexakis(2-pyridyloxy)cyclotriphosphazene cyclo-[$NP(NC_5H_4O)_2]_3$ (model D) [14] with atoms notation (Ni – large white, C – white, H – small white, N – black, Cl – large black, P – large grey and O – grey spheres).

glet–triplet energy separation (over 120 kJ/mol) we will restrict our electronic structure studies to the more stable spin states only.

Our results (Tables 2 and 3) indicate that M–N' bonds with cyclophosphazene nitrogens in all the systems under study are significantly shorter and stronger (higher electron density ρ at BCP) than the M–N ones with pyridine nitrogens at the same M central atom. M–Cl bond strengths decrease much less with bond strengths than the M–N ones. The BCP Laplacians of all metal–ligands bonds are positive as expected, for non-sharing coordination bonding [19]. The higher BCP $\nabla^2\rho$ values of M–N' bonds in comparison with the M–N ones might be explained by their higher polarity (see the atomic charges in Table 3). The shorter metal–nitrogen bonds have higher BCP Laplacians. Except D model, the BCP ellipticity values correspond to σ metal–ligand bonding with small π contribution only. The BCP ε values of M–N' bonds are in most cases higher than the M–N ones and are lower for shorter bonds.

The atomic volumes of central metal atoms decrease with their coordination numbers (Table 3). Phosphazene N' atoms are significantly bigger then the pyridine N atoms. Chlorine atoms taking part in six-coordinate M sites are smaller than in the five-coordinate ones. The phosphazene N' atomic charges are negative and ca twice higher than the pyridine N ones. Chlorine atoms are much less negative. The higher atomic volumes and nearly equal or more positive M charges in five-coordinate A and D complexes than in the six-coordinate B and C ones indicate higher mechanical strain in the five-coordinate systems under study. The bigger phosphazene N' atomic volumes in five-coordinate A and D complexes than in the six-coordinate B and C ones with the nearly equal N' atomic charges imply the same conclusion. Similarly, the higher mechanical strain of more distant N(1) and N(3) atoms (compared to the N(2) and N(4) ones) in model B as well as of the N(2) atom (compared to the N(1) and N(3) ones) in model C may be concluded.

Unfortunately, no data on the magnetic state of the compounds studied are presented in the structural study [14]. Their frontier molecular orbitals are not located at central metal atoms (except D complex with up to 10% location at Ni) which are connected with very small energy differences between the corresponding α and β spinorbitals (maybe except D complex, see Table 4). Any trends in HOMO–LUMO energy separation cannot be extracted because compound A is dinuclear Zn complex and model compound B is a cation. The relation between the color and HOMO–LUMO energy separation in the green C compound (with a hexacoordinated Ni(II)) and in the red D compound (with a pentacoordinated Ni(II)) need not be so straightforward. QTAIM atomic charges of central metal atoms indicate their oxidation states between M(I) and M(II). For this purpose their d electron populations of Mulliken population analysis $d^x(M)$ are more reliable and confirm Zn(II) with $d^x(Zn) = 10.0$ in A compound and Ni(II) with $d^x(Ni) = 8.2$ for the remaining ones (see Table 4).

Our results show that the bonds of central transition metal atoms with phosphazene nitrogens are stronger and more polar than with the aromatic pyridine nitrogens. Increased mechanical strain and thus higher reactivity in five-coordinate metal sites is predicted. Despite the high flexibility of the pyridyloxycyclophos-

Table 1
The model systems under study, their total (E_{tot}) and relative (ΔE) energies in singlet ($M_S = 1$) and triplet ($M_S = 3$) spin states (L = hexakis(2-pyridyloxy) cyclotriphosphazene, cyclo-[$NP(NC_5H_4O)_2]_3$, $\Delta E = E(M_S = 1) - E(M_S = 3)$, the higher stability in bold).

ABSTRACT

The reaction of $W(CO)_6$ with 1-alkyl-2-(naphthyl-α-azo)imidazole (α-NaiR) has synthesized $[W(CO)_5$(α-NaiR-N)] (α-NaiR-N refers to the monodentate imidazole-N donor ligand) at room temperature. The structure of $[W(CO)_5$(α-NaiMe-N)] shows a monodentate imidazole-N coordination of 1-methyl-2-(naphthyl-α-azo)imidazole (α-NaiMe). The complexes are characterized by elemental, mass and other spectroscopic data (IR, UV–Vis, NMR). On refluxing in THF at 323 K, $[W(CO)_5$(α-NaiR-N)] undergoes decarbonylation to give $[W(CO)_4$(α-NaiR-N,N′)] (α-NaiR-N,N′ refers to the imidazole-N(N), azo-N(N′) bidentate chelator). Cyclic voltammetry shows metal oxidation (W^0/W^I) and ligand reductions (azo/azo$^-$, azo$^-$/azo$^{=}$). The redox and electronic properties are explained by theoretical calculations using an optimized geometry. DFT computation of $[W(CO)_5$(α-NaiMe-N)] suggests that the major contribution to the HOMO/HOMO − 1 come from W d-orbitals and the orbitals of CO. The LUMOs are occupied by α-NaiMe functions. The back bonding interaction thus originates from the $W(CO)_n$ moiety to the LUMO of α-NaiR. A TD-DFT calculation has ascribed that HOMO/HOMO − 1 → LUMO is a mixture of metal-to-ligand and ligand-to-ligand charge transfer underlying the CO → azoimine contribution. The complexes show emission spectra at room temperature. $[W(CO)_4$(α-NaiR-N,N′)] shows a higher fluorescence quantum yield (ϕ = 0.05–0.07) than $[W(CO)_5$(α-NaiR-N)] (ϕ = 0.01–0.02).

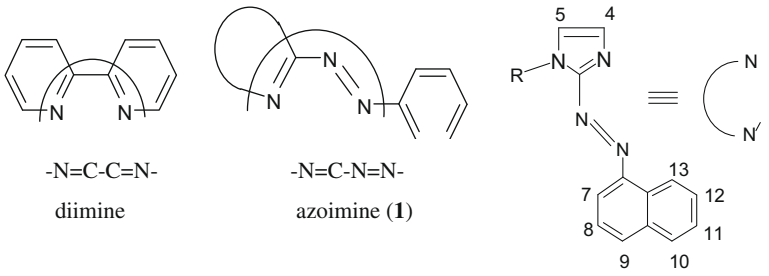
1. Introduction

Transition metal–polypyridine complexes are attractive due to their crucial role in catalyses, photophysics and photochemistry, electrochemistry, supramolecular properties, medicinal activity etc. [1–3]. Recent years have witnessed a great deal of interest in the synthesis of new ligands with a diimine group (–N=C–C=N–) [4,5] (in the framework of pyridine derivatives) or the design of isolectronic groups to the diimine function, such as the azoimine function, (–N=N–C=N–) [6–29] (Scheme 1). The azoimine function is capable of stabilizing low valent metal oxidation states [22–25]. Zero valent Group 6 metal carbonyls are also stabilized by the azoimine (–N=N–C=N–) function [30–40]. The *N*-heterocyclic azo molecules belong to the azoimine family and have been used to explore the chemistry of transition [6–25] and non-transition metals [26–29]. We have designed 1-alkyl-2-(naphthylazo)imidazole (**2**) a potential member of the azoimine family [41–43]. The present work is concerned with W(0)–carbonyl complexes of 1-alkyl-2-(naphthyl-α-azo)imidazoles (α-NaiR). The reaction of α-NaiR, with $W(CO)_6$ under ambient conditions (298 K) in the presence of Me_3NO has synthesized the penta-carbonyl complexes, $[W(CO)_5$(α-NaiR-N)] (**3**) (imidazole-N coordinated α-NaiR is abbreviated as α-NaiR-N). Penta-carbonyl Group 6 transition metal complexes are a source of Fischer carbene precursors in the studies of organic transformations [44–46], and are even used as diagnostic probes in the determination of nucleosides by measuring ν_{CO} of the coordinated CO [47].

$[W(CO)_4$(α-NaiR-N,N′)] exhibit high intense fluorescence emissions while $[W(CO)_5$(α-NaiR-N)] are weak emitters. The free ligand is non-fluorescent. The complexes were characterized by different spectroscopic studies (IR, UV–Vis, Mass, NMR, fluorescence), and the electrochemical properties have been studied with cyclic voltammetry. One of the penta-carbonyl complexes, $[W(CO)_5$(α-NaiMe-N)], has been structurally confirmed by a single crystal X-ray diffraction study. Theoretical calculations (DFT and TD-DFT) using an optimized molecular system have been carried out to predict the electronic structure, the spectral, redox and photophysical properties.



2. Experimental

2.1. Materials and measurements

The 1-alkyl-2-(naphthyl-α-azo)imidazoles (α-NaiR, **2**; R = CH_3 (**a**), CH_2–CH_3 (**b**), CH_2Ph (**c**)) were prepared by the reported procedure [42]. $W(CO)_6$ and $Me_3NO \cdot 2H_2O$ were Sigma–Aldrich reagents. The reactions were carried out under an extremely dry oxygen free atmosphere under atmos bags (Sigma–Aldrich).

Scheme 1.

$Me_3NO \cdot 2H_2O$ was dehydrated at a controlled temperature under reduced pressure before use. THF and *n*-heptane were dried before use [48]. The solution spectral studies were carried out using spectroscopic grade solvents from Lancester, UK. Microanalyses (C, H and N) were performed using a Perkin Elmer 2400 CHN elemental analyzer. Spectroscopic measurements were carried out using the following instruments: UV–Vis spectra, Lambda 25 Perkin Elmer; IR spectra (KBr disk, 4000–450 cm^{-1}), RX-1 Perkin Elmer; ^1H NMR and ^{13}C NMR spectra in $CDCl_3$, Bruker 300 MHz FT-NMR spectrometers in the presence of TMS as an internal standard. The emission was examined on a LS 55 Perkin Elmer spectrofluorimeter at room temperature (298 K) in benzene under degassed conditions. The FAB-MS was collected from a JEOL-AX 500. Electrochemical measurements were carried out with a computer controlled EG & G PARC VersaStat model 250 Electrochemical instrument using a Pt-disk working electrode, a Pt-wire auxiliary electrode and [*n*-Bu_4N][ClO_4] supporting electrolyte under inert (dry N_2) environment at scan rate of 50 mV S^{-1}. The solution was IR compensated and the results were collected at 298 K. The reported results were referenced to SCE in CH_2Cl_2 and were uncorrected for junction potentials.

The fluorescence quantum yield of the complexes was determined using carbazole as a reference for [$W(CO)_5$(α-NaiR-N)] (**3**) with a known ϕ_R value of 0.42 in C_6H_6 [49] and anthracene (ϕ_R of 0.62 in C_6H_6 [50]) as a reference for [$W(CO)_4$(α-NaiR-N,N′)] (**4**). The complex and the reference dye were excited at the same wavelength, maintaining nearly equal absorbance (~0.1), and the emission spectra were recorded. The areas of the emission spectra were integrated using the software available in the instrument and the quantum yield was calculated according to the following equation:

$$\phi_S/\phi_R = [A_S/A_R] \times [(Abs)_R/(Abs)_S] \times [\eta_S^2/\eta_R^2]$$

here, ϕ_S and ϕ_R are the fluorescence quantum yields of the sample and reference, respectively. A_S and A_R are the areas under the fluorescence spectra of the sample and the reference respectively, $(Abs)_S$ and $(Abs)_R$ are the respective optical densities of the sample and the reference solution at the wavelength of excitation, and η_S and η_R are the values of refractive index for the respective solvents used for the sample and reference.

2.1.1. Preparation of $W(CO)_5$(α-NaiMe-N) (**3a**)

To $W(CO)_6$ (50 mg, 0.142 mmol) dissolved in dry THF (10 ml) was added Me_3NO (11 mg, 0.145 mmol), and the solution was stirred for 1 h. To the resulting yellow solution, α-NaiMe (34 mg, 0.144 mmol) was added and the solution was stirred for 6 h. The color of the solution changed to brown-red. The solvent was evaporated under reduced pressure and the crude product was passed down a neutral Al_2O_3 column. A brown-red solution was eluted with benzene:pet-ether (60–80 °C) (1:1 v/v), followed by a small volume of a violet solution in the same solvent as a tailing band and this was rejected due to the negligibly small amount of the compound. Removal of the solvent of the brown-red solution afforded the analytically pure product (**3a**) in 45% yield.

Microanalytical data are as follows: *Anal.* Calc. for [$W(CO)_5$(α-NaiMe-N)] (**3a**), $C_{19}H_{12}N_4O_5W$: C, 40.71; H, 2.44; N, 10.00. Found: C, 40.66; H, 2.50; N, 10.10%. FAB-MS, M^+ 560, $(M–5CO)^+$ 420; IR (KBr, cm^{-1}) ν_{CO}: 2068, 2015, 1916, 1881; IR in DCM ν_{CO}: 2071, 2023, 1922, 1885; UV (λ_{max}, nm (ε, 10^3 M^{-1} cm^{-1}), benzene): 546 (2.045), 401 (4.696), 343 (3.768) (shoulder). *Anal.* Calc. for [$W(CO)_5$(α-NaiEt-N)] (**3b**), $C_{20}H_{14}N_4O_5W$: C, 41.81; H, 2.44; N, 9.76. Found: C, 42.00; H, 2.50; N, 9.64%. FAB-MS, M^+ 574, $(M–5CO)^+$ 434; IR (KBr, cm^{-1}) ν_{CO}: 2068, 2015, 1907, 1853; IR in DCM ν_{CO}: 2070, 2020, 1925, 1860; UV (λ_{max}, nm (ε, 10^3 M^{-1} cm^{-1}), benzene) 547 (3.822), 403 (15.328), 341 (8.547) (shoulder). *Anal.* Calc. for [$W(CO)_5$(α-NaiBz-N)] (**3c**), $C_{25}H_{16}N_4O_5W$: C, 40.17; H, 2.52; N, 8.81. Found: C, 40.08; H, 2.48; N, 9.00%. FAB-MS, M^+ 636, $(M–5CO)^+$ 496; IR (KBr, cm^{-1}) ν_{CO}: 2068, 2016, 1974, 1918; IR in DCM ν_{CO}: 2075, 2022, 1985, 1924; UV (λ_{max}, nm (ε, 10^3 M^{-1} cm^{-1}), benzene) 548 (4.3), 402 (12.733), 341 (7.342) (shoulder).

2.1.2. Preparation of $W(CO)_4$(α-NaiMe-N,N′) (**4a**)

To $W(CO)_6$ (50 mg, 0.142 mmol) dissolved in dry THF (10 ml) was added Me_3NO (11 mg, 0.145 mmol), and the solution was stirred and refluxed for 0.5 h. To the resulting solution, α-NaiMe (34 mg, 0.144 mmol) was added and the solution was stirred and refluxed for an additional 4 h. The color of the solution changed to brown-violet. Then the solvent was evaporated under reduced pressure and the crude product was passed down a neutral Al_2O_3 column. A small volume of a brown-red band was eluted by benzene:pet ether (60–80 °C) (1:1 v/v), and this was rejected due to the very small amount of the compound. A violet solution was then collected using benzene:pet-ether (60–80 °C) (3:1 v/v) as eluent. Removal of the solvent afforded the analytically pure product (**4a**) in 60% yield.

Microanalytical data are as follows: *Anal.* Calc. for [$W(CO)_4$(α-NaiMe-N,N′)] (**4a**), $C_{18}H_{12}N_4O_4W$: C, 40.60; H, 2.26; N, 10.53. Found: C, 40.54; H, 2.35; N, 10.46%. FAB-MS, M^+ 532, $(M–4CO)^+$ 420; IR (KBr, cm^{-1}) ν_{CO}: 2011, 1913, 1866; IR in DCM ν_{CO}: 2019, 1919, 1872; UV (λ_{max}, nm (ε, 10^3 M^{-1} cm^{-1}), benzene) 551 (7.226), 401 (4.381), 337 (6.121). *Anal.* Calc. for [$W(CO)_4$(α-NaiEt-N,N′)] (**4b**), $C_{19}H_{14}N_4O_4W$: C, 41.76; H, 2.56; N, 10.25. Found: C, 41.68; H, 2.60; N, 10.34%. FAB-MS, M^+ 546, $(M–4CO)^+$ 434; IR (KBr, cm^{-1}) ν_{CO}: 2014, 1915, 1868; IR in DCM ν_{CO}: 2021, 1922, 1871; UV (λ_{max}, nm (ε, 10^3 M^{-1} cm^{-1}), benzene) 552 (4.767), 420 (1.908), 337 (3.808). *Anal.* Calc. for [$W(CO)_4$(α-NaiBz-N,N′)] (**4c**), $C_{24}H_{16}N_4O_4W$: C, 47.37; H, 2.63; N, 9.21. Found: C, 47.43; H,

2.68; N, 9.18%. FAB-MS, M^+ 608, $(M–4CO)^+$ 496; IR (KBr, cm^{-1}) ν_{CO}: 2010, 1907, 1850; IR in DCM ν_{CO}: 2017, 1917, 1861; UV (λ_{max}, nm (ε, 10^3 M^{-1} cm^{-1}), benzene) 552 (8.851), 420 (6.376), 337 (8.289).

2.2. Transformation of [W(CO)$_5$(α-NaiR-N)] (**3**) to [W(CO)$_4$(α-NaiR-N,N′)] (**4**)

Preparation of [W(CO)$_4$(α-NaiMe-N,N′)] (**4a**) from [W(CO)$_5$(α-NaiMe-N)] (**3a**) is detailed below. A THF solution of [W(CO)$_5$(α-NaiMe-N)] (100 mg in 15 ml THF) was heated at 60 °C for 2.5 h, which leads to the preparation of [W(CO)$_4$(α-NaiMe-N,N′)]. The solution is evaporated to dryness and violet crystalline compounds were then isolated by chromatographic purification, as stated before, and dried in a $CaCl_2$ (fused) desiccator. Yield: 73%. Microanalytical data support the chemical formula [W(CO)$_4$(α-NaiR-N,N′)]

2.3. Crystallographic data collection and refinement of [W(CO)$_5$(α-NaiMe-N)] (**3a**)

Crystals were grown by slow evaporation of a benzene solution of [W(CO)$_5$(α-NaiMe-N)] (**3a**). Crystal parameters and refined data are summarized in Table 1. The data of **3a** (0.80 × 0.15 × 0.10 mm) were collected by a fine focus sealed tube at 293(2) K using a fine focus graphite monochromator Bruker Smart CCD Area Detector (Mo Kα radiation, λ = 0.71073 Å). Unit cell parameters were determined from least-squares refinement of setting angles with 2θ in the range $3.86° \le \theta \le 49.42°$. Of 9331 collected data, 3368 with $I > 2\sigma$ (I) were used for the structure solution. The *hkl* range was $-9 \le h \le 9$, $-12 \le k \le 12$, $-14 \le l \le 14$. Reflection data were recorded using the ω-scan technique. Data were corrected for Lorentz polarization effects and for linear decay. Semi-empirical absorption corrections based on ψ-scans were applied. Data reduction was carried out using the Bruker SAINT program. The structure was solved by the direct method using SHELXS-97 [51] and successive difference Fourier syntheses. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed geometrically and refined using the riding model. In the final difference Fourier map the residual minima and maxima (−0.735, 0.308 e/Å^3) were evaluated using SHELXL-97 [52].

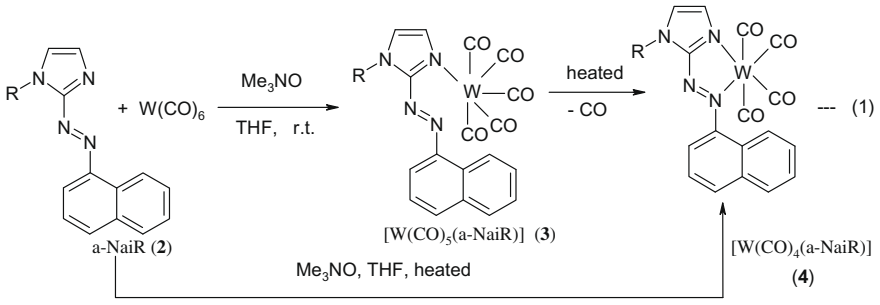
[a] $R = \sum||F_o| - |F_c||/\sum|F_o|$.
[b] $wR = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$; $w = [\sigma^2(F_o)^2 + (0.0235P)^2 + 0.1361P]^{-1}$, where $P = (F_o^2 + 2F_c^2)/3$.



2.4. Computational details

All computations were performed using GAUSSIAN03 (G03) software [53]. The Becke's three-parameter hybrid exchange functional and the Lee–Yang–Parr non-local correlation function [54] (B3LYP) was used throughout the calculations. A LanL2DZ basis set [55] for W, 6–31G(d, p) for C, H, N and O atoms were used for all types of calculations. In all cases, vibrational frequencies were calculated to ensure that the optimized geometries represented local minima. We performed TD-DFT calculations of the low-lying excitation at the singlet optimized geometry. The excitation energies were calculated by the TD-DFT approach.

3. Results and discussion

3.1. Synthesis

1-Alkyl-2-(naphthyl-α-azo)imidazole (Scheme 1: α-NaiR, **2**; R = CH_3 (**a**), CH_2–CH_3 (**b**), CH_2Ph (**c**)), may serve as a monodentate imidazole-N ligand (abbreviated: α-NaiR-N) and as a bidentate chelating agent (abbreviated: α-NaiR-N,N; where N and N′ refer to N(imidazole) and N(azo) donor centers, respectively). The reaction of α-NaiR with W(CO)$_6$ in the presence of Me_3NO resulted in the isolation of the penta-carbonyl [W(CO)$_5$(α-NaiR-N)] (**3**) at room temperature (298 K). The reaction between α-NaiR and W(CO)$_6$ at a higher temperature (323 K) yielded the tetra-carbonyl complex [W(CO)$_4$(α-NaiR-N,N′)] (**4**). The complexes **3** may be converted into **4** by refluxing in a high boiling solvent like acetonitrile, THF and 2-methoxyethanol (Scheme 2). The composition of the complexes is supported by microanalytical and spectroscopic data. The structure of the penta-carbonyl complex has been confirmed by single crystal X-ray structure determination of [W(CO)$_5$(α-

Scheme 2. Preparation of penta-carbonyl and tetra-carbonyl azo-imidazole.

NaiMe-N)] (**3a**) (Fig. 1). We have attempted to crystallize [W(CO)$_4$(α-NaiR-N,N′)] (**4**), but failed to get good quality diffracting crystals.

3.2. Molecular structure of [W(CO)$_5$(α-NaiMe-N)] (*3a*)

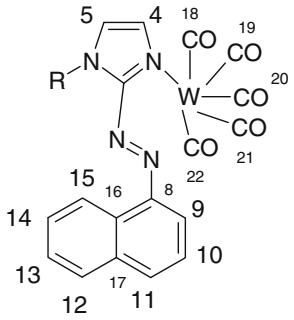
The X-ray structure of [W(CO)$_5$(α-NaiMe-N)] (**3a**) is shown in Fig. 1 and selected bond parameters are listed in Table 2. The molecule consists of a central W atom surrounded by six coordination centers and the arrangement is distorted octahedral [56–59]. The atomic arrangement involves the coordination of five CO ligands and the imidazole-N of a 1-methyl-2-(naphthyl-α-azo)imidazole ligand. The coordinated imidazole is inclined at an angle of 7.95° to the pendant naphthyl group. The W–N (imidazole) distance is 2.268(3) Å and the W–C(O) distances lie I the range 1.954–2.035 Å. The W–C(17) displays the shortest distance (1.954(4) Å) and this is due to the trans influence of the imidazole-N coordination to the central W atom. The four equatorial W–C(O) distances are within the range 2.028–2.035 Å. The *trans* C–W–C angles are slightly deviated from the ideal value (180°): C(18)–W(1)–C(15), 174.93(14)° and C(19)–W(1)–C(16), 178.63(14)°, while the other C–W–C angles are *cis*-angles and lie in the range 87.8 to 92.5° (see Table 3).

3.3. Spectroscopic characterization

3.3.1. FT-IR and mass spectra

FT-IR spectra were taken in both in solution (CH_2Cl_2) and in the solid phase (solid KBr). The spectra (Fig. 2) show three or four bands [60]. The solution spectra (CH_2Cl_2) show ν(CO) at 5–15 cm^{-1} higher frequency than that of the KBr-phase data. The mean value of the CO frequencies, ν(CO), in these cases is lower ($\Delta\nu$(CO) = 15–25 cm^{-1}) than that of M(CO)$_4$(2-PAP) (2-PAP = 2-(phenylazo)pyridine) [30–37]. This supports weaker π-acidity of the naphthylazoimidazoles than that of phenylazopyridine. On comparing with the spectral pattern and frequency of the CO stretching of [W(CO)$_5$(PQ)] [56–57] (PQ = 2-(2′-pyridyl)quinoxaline) the present complexes are assigned to a penta-carbonyl complex with octahedral coordination where the ligand α-NaiR binds as a monodentate imidazole-N donor agent (α-NaiR-N). The ν(N=N) and ν(C=N) bands appear at 1360–1390 and 1660–1620 cm^{-1}, respectively. The mass fragmentation by FAB-MS of the complexes support the expected fragmentation pattern of M$^+$, (M–CO)$^+$, (M–2CO)$^+$, (M–3CO)$^+$ etc. for both types of complexes.

3.3.2. UV–Vis spectra and emission properties



Benzene solutions of [W(CO)$_5$(α-NaiR-N)] (**3**) are brown-red and those of [W(CO)$_4$(α-NaiR-N,N′)] (**4**) are brown-violet. The absorption spectra show three intense ($\varepsilon \sim 10^4$) bands within the region 330–600 nm (Fig. 3). The complexes do not show significant solvatochromism, unlike their Schiff base analogs [43]. In d^6-octahedral complexes of the M(0)-state, the lowest energy electronic transition arises from a filled metal d-orbital to the unoccupied lowest energy π* orbital of the ligand (MLCT). The transition at

545–555 nm of [W(CO)$_5$(α-NaiR-N)] (**3**) is assigned to a metal-to-ligand charge transfer transition [30–37,61,62]. In [W(CO)$_4$(α-NaiR-N,N′)] (**4**) the bands in the visible region are shifted by ~10 nm to a longer wavelength region, which suggests a decrease in the energy gap between the d π(W)–π*(L) state. Other transitions at ~400 nm and ~340 nm may be attributed to intraligand (n–π*/π–π*) transitions (LLCT or lLCT). DFT and TD-DFT calculations of these complexes have undertaken to verify the electronic structure of the molecules, and they are discussed below.

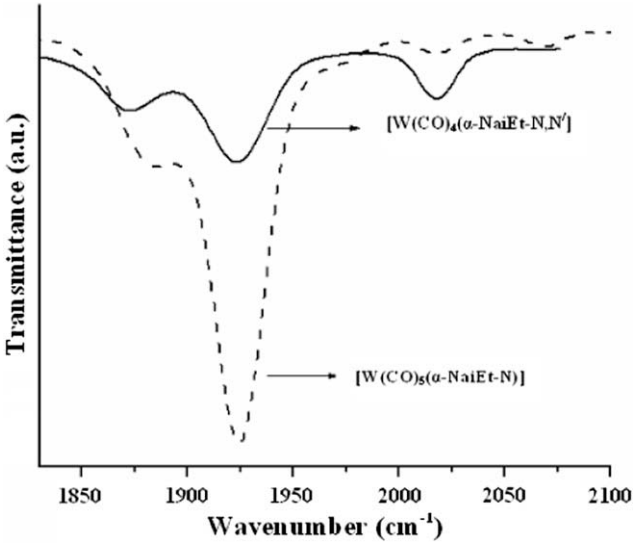

Fig. 2. Solution FT-IR spectra in CH_2Cl_2.

The photoluminescence properties of the complexes (**3** and **4**) were studied at room temperature (298 K) in benzene (Fig. 3). The ligands are photo-inactive. The lowest singlet $S_0 \rightarrow S_1$ transition in the UV region (<400 nm) is in good agreement with the $\pi \cdot \pi^*$ transition. Longer wavelength excitation shows very weak emission. The excitation spectra are perfectly matched with the absorption spectra, which indicate sufficient stability of the excited state upon irradiation and this being structurally rigid against any chemical deformation at least on the spectroscopic timescale. The photophysics of these complexes shows high energy (HE) and low energy (LE) transitions. The low energy emission appears at 615–647 nm and its quantum yield has not been evaluated because of very low intensity. The quantum yields (ϕ) of the excitation at 331–341 nm (Table 4) show a better prospect for [W(CO)$_4$(α-NaiR-N,N′)] (**4**) (ϕ = 0.05–0.07) than [W(CO)$_5$(α-NaiR-N)] (**3**) (ϕ = 0.01–0.02). In the absence of a metal ion, the fluorescence of the ligand is probably deactivated through n–π* states rather than by PET (photoinduced electron transfer) [63].

Lifetime data of the complexes were taken in benzene solution when excited at 370 nm. The fluorescence decay curve was deconvoluted with respect to the lamp profile. The observed florescence decay fits with the bi-exponential nature of the complexes (Fig. 4). We have used the mean fluorescence lifetime ($\tau_f = a_1\tau_1 + a_2\tau_2$ where a_1 and a_2 are the relative amplitudes of the decay process) to compare the excited state (population at S_1 and S_2 states) stability of the complexes. The radiative and non-radiative rate constants (k_r and k_{nr}) are calculated and data show the usual higher k_{nr} value than the k_r value. The excited state is appreciably stable for [W(CO)$_4$(α-NaiR-N,N′)] (**4**). We could not evaluate quantitative

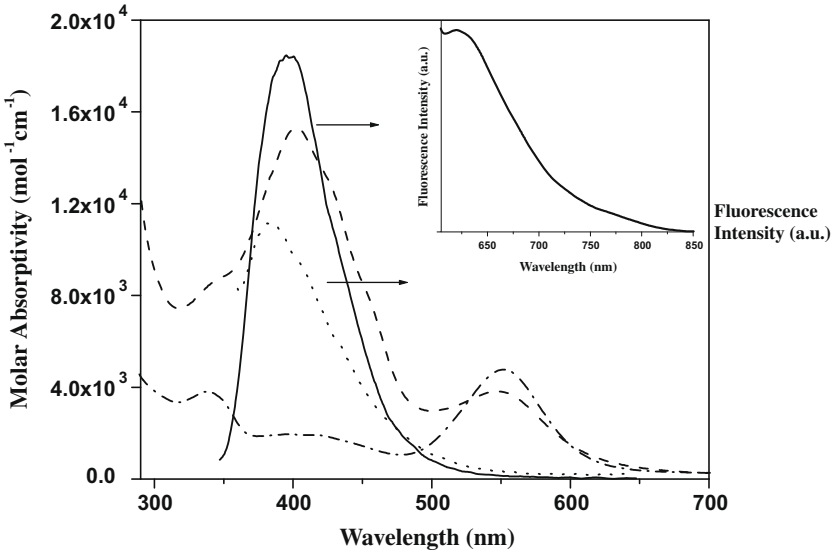

Fig. 3. Absorption spectra of $[W(CO)_5(\alpha\text{-NaiEt-N})]$ (– – –), $[W(CO)_4(\alpha\text{-NaiEt-N,N}')]$ (–·–·–) and fluorescence spectra of $[W(CO)_5(\alpha\text{-NaiEt-N})]$ (. . . . .), $[W(CO)_4(\alpha\text{-NaiEt-N,N}')]$ (—) in benzene. Higher energy emissions are recorded at 341 and 337 nm for **3b** and **4b**, respectively, and the lower energy emission is recorded at 552 nm wavelength for **4b**, shown in the inset figure.

emission parameters of $[W(CO)_5(\alpha\text{-NaiR-N})]$ (**3**). The presence of a dangling non-coordinated naphthylazo motive may be responsible for vibrational relaxation and energy transfer from the excited state that quenches the respective excited state. The emission features of these complexes may arise from the participation of π-acidic, strong field ancillary CO [64,65] with the third-row metal, which also increases the metal–ligand bonding [66–68]. The bi-exponential feature of the fluorescence decay may be due to population of the S_2 state in addition to the usual S_1 population.

3.4. Electrochemistry

The cyclic voltammetry of the compounds show one oxidation and two reductions. By analogy with similar types of α-diimine complexes, $[M(CO)_n(L)]$ (L = diimine or azoimine) [30–40] we advocate that the oxidation is primarily metal-centered. In the case of the tetra-carbonyl complexes (**4**), the oxidation on scan reversal shows a cathodic peak at a potential difference >100 mV to that of the anodic peak and supports quasireversibility (Fig. 5) of the voltammogram, while the penta-carbonyls (**3**) show irreversible oxidation. The results are collected in Table 4. Significantly $[W(CO)_5(\alpha\text{-NaiR-N})]$ shows a higher potential than $[W(CO)_4(\alpha\text{-NaiR-N,N}')]$ by 0.2–0.3 V. This is obviously due to the presence of the strongly π-acidic additional CO group in complexes **3** compared to **4**. The reduction is referred to azo/azo$^-$ and azo$^-$/azo$^{=}$, which appear at a more negative potential than those of the analogous 2-(phenylazo) pyridine complexes [30–37]. This is due to higher π-acidity of pyridine rather than imidazole and the electronic influx of the naphthyl rather than the phenyl group to the azo function.

3.5. DFT and TD-DFT calculations of $[W(CO)_5(\alpha\text{-NaiMe-N})]$ and $[W(CO)_4(\alpha\text{-NaiMe-N,N}')]$

DFT and TD-DFT computations of optimized structures of $[W(CO)_5(\alpha\text{-NaiMe-N})]$ (**3a**) and $[W(CO)_4(\alpha\text{-NaiMe-N,N}')]$ (**4a**) were performed to establish their electronic structure, spectral transitions and redox properties. The calculation has overthrown the earlier concept of MLCT transitions [66–70]. The structural agreement between theory and experiment is satisfactory (Table 2) for $[W(CO)_5(\alpha\text{-NaiMe-N})]$. The theoretical W–N(1) length is 0.01 Å shorter than the observed one, while the W–C(17) bond *trans* to W–N(1) is elongated by ~0.03 Å compared to the experimental results. Other W–C distances are comparable, as are the angles (Table

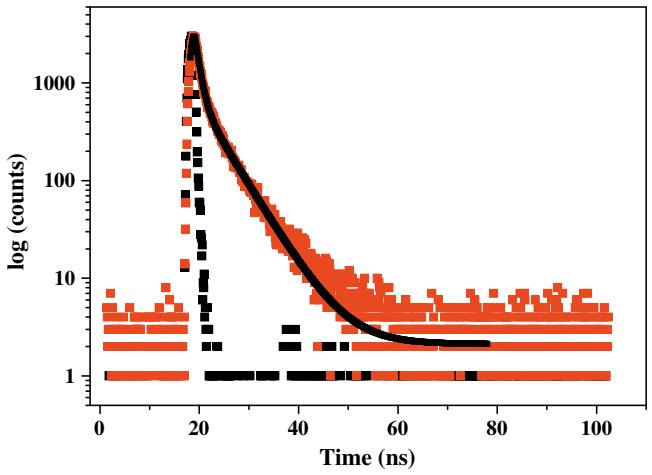

Fig. 4. Bi-exponential decay profile (●) and fitting curve (—) of [W(CO)$_4$(α-NaiBz-N,N′)] (**4c**) in benzene. Excitation is carried out at 370 nm.

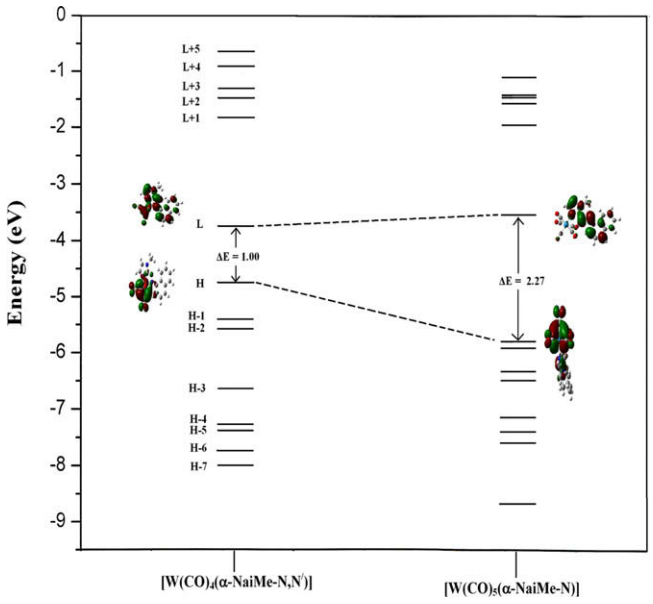

Fig. 6. Energy level correlation diagram in the gas phase.

2). The orbital energies, along with contributions from the ligands and metal, are given in the Supplementary Table. A correlation of MOs is given in Fig. 6. An interesting feature of the valence orbitals in [W(CO)$_5$(α-NaiMe-N)] is that the two highest occupied MOs (HOMO, abbreviated as H; HOMO − 1, abbreviated as H-1) are very close in energy (the difference is only 0.11 eV), with a significant contribution from the metal d-orbitals and the π* orbital of the carbonyls. The contribution from COs is 30–40% while W contributes 50–60%. The two occupied MOs in [W(CO)$_4$(α-NaiMe-N,N′)] (**4a**) H and H-1 are separated by 0.7 eV, while H-1 and H-2 are closely associated (the energy difference is only 0.17 eV). The LUMOs (L + n) are primarily π* of the COs and α-NaiMe. The L (LUMO) and L + 2 (LUMO + 2) are mainly composed of α-NaiMe (L 99% α-NaiMe; L + 2 78% α-NaiMe) while L + 1, L + 3, L + 5 have >70% π* of the COs. Although there is a substantial energy difference (∼ 1.6 eV) between L and L + 1, higher unoccupied MOs (L + 2, L + 3, etc.) are closely spaced. The energy separation between the HOMO and LUMO is lower (ΔE = 1 eV) in [W(CO)$_4$(α-NaiMe-N,N′)] (**4a**) than [W(CO)$_5$(α-NaiMe-N)] (**3a**) (ΔE = 2.27 eV). The bonding scheme has unequivocally suggested the existence of two fragments in the complexes, namely the electron donor group W(CO)$_n$ and the electron acceptor group α-NaiMe.

To gain detailed insight into the electronic transitions, the TD-DFT calculations were performed on two series of complexes, namely [W(CO)$_5$(α-NaiMe-N)] and [W(CO)$_4$(α-NaiMe-N,N′)]. H and H-1 are localized on parts of the metal (55–60%) and CO (30–40%), and L carries 99% ligand character (Supplementary Tables). The transition 545–555 nm may be assigned to H/H-1 → L because of the very small energy difference (0.11 eV) between H and H-1. Thus the transition may be defined as an admixture of MLCT and LLCT transitions, as suggested by Vlcek [70], contradicting the widely accepted MLCT concept. The H-2 → L transition may be responsible for the broadening of the MLCT and LLCT bands. The transitions H/H-1/H-2 → L + 2 may also contribute in part to the MLCT and LLCT transitions. The back-bonding, W → CO transitions may be assigned to H/H-1/H-2 → L + 1/L + 3 transitions, and those may be obstructed by the intraligand π → π* transitions localized on the napthylazoimidazole ligand at 400–420 nm (Table 5). This is indeed observed. The electronic spectra of the complexes ([W(CO)$_5$(α-NaiMe-N)] and [W(CO)$_4$(α-NaiMe-N,N′)]) show three main transition regions: 545–555, 400–420 and 320–345 nm. The intensity of these transitions has been assessed from the oscillator strength (*f*). From the calculations, the longest wavelength band appears at 691.5 (*f*, 0.095) which is assigned to H → L, while other bands around the main transition of low oscillator strength, such as H-1 → L, H-2 → L, and H-4 → L, are a combination of MLCT and LLCT transitions. A second band of high oscillator strength (*f*, 0.321) appears at 460.0 nm, which is also of MLCT origin and the transitions around this band come from H/H-1/H-2 → L + 1, H-2 → L + 4, and are of MLCT and LLCT origin. The third recognized band is located at 334.9 nm (*f*, 0.164) which is a ligand centered

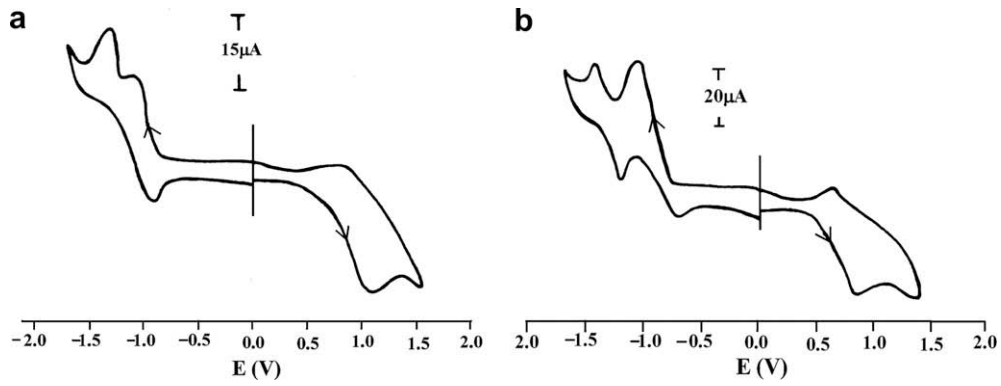

Fig. 5. Cyclic voltammograms of (a) [W(CO)$_5$(α-NaiEt-N)] (**3b**) and (b) [W(CO)$_4$(α-NaiEt-N,N′)] (**4b**) in CH_2Cl_2 using a Pt-disk working electrode, SCE reference and [*n*-Bu_4N][ClO_4] as the supporting electrolyte.

32	252.8 (0.0178)	[(28%) H-2 → L + 5, (10%) H-1 → L + 7](MLCT), (24%) H-8 → LUMO (IL)

MLCT: metal-to-ligand charge transfer; LLCT: ligand-to-ligand charge transfer; IL: intraligand charge transfer; H = HOMO; L = LUMO.

transition (H-6 → L), and associated transitions are H → L + 2/L + 5, H-2 → L + 3 which are intra ligand charge transfer and MLCT transitions. High energy transitions appear at 250–280 nm, and those mainly are of intra-ligand charge transfer origin.

4. Conclusion

Tungsten(0)–carbonyl complexes of 1-alkyl-2-(naphthyl-α-azo)imidazoles (α-NaiR) are described. The complexes [W(CO)$_5$(α-NaiR-N)] are obtained at room temperature (298 K), which on heating lose one CO ligand to synthesize [W(CO)$_4$(α-NaiR-N,N′)]. In [W(CO)$_4$(α-NaiR-N,N′)], α-NaiR-N,N′ serve as a bidentate chelating agent and in [W(CO)$_5$(α-NaiR-N)] α-NaiR-N act as a monodentate imidazole-N donor ligand. The structure of [W(CO)$_5$(α-NaiMe-N)] has been confirmed by a single crystal X-ray diffraction study, where α-NaiMe exhibits a monodentate nature. The complexes show emission spectra at room temperature; [W(CO)$_4$(α-NaiR-N,N′)] shows a higher quantum yield (ϕ = 0.05–0.07) than [W(CO)$_5$(α-NaiR-N)] (ϕ = 0.01–0.02). Cyclic voltammetry shows metal oxidation and ligand reductions. DFT calculations of [W(CO)$_5$(α-NaiMe-N)] and [W(CO)$_4$(α-NaiR-N,N′)] explain the origin of the electronic spectra and redox activities. The HOMO/HOMO − 1 → LUMO transition is assigned as a mixture of MLCT and LLCT transitions, underlying the CO → azoimine contribution as calculated by the TD-DFT method.

ABSTRACT

The solid state reaction of $[Ca(H_2O)_4(\eta^1\text{-4-nba})(\eta^2\text{-4-nba})]$ **1** (4-nba = 4-nitrobenzoate) with 2-methylimidazole (L^2) at 100 °C results in the formation of a Ca(II) coordination polymer $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$ **2**. Compound **2** was characterized by elemental analysis, spectral and thermal methods, and its structure determined. The coordination polymer **2** crystallizes in the centrosymmetric monoclinic space group $P2_1/n$ with all atoms situated in general positions and its structure consists of a central Ca(II), a monodentate 2-methylimidazole, a bridging water ligand (μ_2-H_2O), a bidentate bridging (μ_2-η^1:η^1) 4-nba ligand and a monoatomic bridging (μ_2-η^2) 4-nba ligand. Each seven-fold coordinated Ca(II) in the title compound is bonded to a nitrogen atom of a terminal 2-methylimidazole (L^2) ligand, two symmetry related water molecules and four symmetry related 4-nba ligands, resulting in a distorted pentagonal bipyramidal $\{CaO_6N\}$ polyhedron. Due to the bridging nature of the aqua and 4-nba ligands [(2-methylimidazole)calcium(II)] units in **2** are linked into a one-dimensional coordination polymer consisting of three chains, all of which propagate along *b*-axis. In the triple chain coordination polymer a Ca···Ca separation of 3.8432(3) Å is observed between neighbouring Ca(II) ions. The oxygen atoms of the carboxylate and nitro functionalities of the 4-nba ligand and the coordinated water are involved in O–H···O, N–H···O and C–H···O interactions. A comparative study of nine alkaline-earth 4-nitrobenzoate compounds is described.

1. Introduction

In recent years metal-organic frameworks (MOFs) or coordination polymers have attracted much attention because of their topology and potential applications in catalysis, adsorption (gas storage), separation, luminescence, magnetism, drug delivery etc [1–9]. Ligands containing carboxylic acid functional groups are attractive candidates for the construction of coordination polymers as metals can be linked into an extended chain with the aid of bridging binding modes of the carboxylate ligand [10,11]. Depending on the electronic and steric requirements of the central metal, the flexibility, binding modes and hydrogen bonding characteristics of the carboxylate ligand, the presence of additional bridging or terminal ligands, coordination polymers of differing dimensionalities (D) namely one (1D)-, two (2D)- and three (3D)-dimensional can be constructed.

Compared to the extensive chemistry of coordination polymers based on transition metals, the coordination chemistry of group 1 and 2 metal compounds with organic ligands is a relatively less explored area. Recently there is a growing interest in the chemistry of the coordination compounds of s-block elements as alkali and/or alkaline-earth metal cations are preferred to transition or lanthanide metal ions because most of the s-block cations have the advantage of being non-toxic, cheap and soluble in aqueous media. The recent work of Fromm [12] provides an overview on different ligand and polymer types of the s-block compounds. In the past decade several MOFs of alkaline earth metals have been synthesized, structurally characterized and their properties investigated [13–48].

For the preparation of coordination polymers different synthetic methodologies have been reported. These include the aqueous reaction of basic metal sources like metal carbonate or hydroxide with the carboxylic acid under ambient conditions [13–26], reaction of aqueous metal chloride or nitrate with the carboxylic acid in the presence of a mild base [27–41], the hydrothermal reaction of metal sources with carboxylic acids in autoclaves under autogeneous pressures [42–48]. Based on a review of the synthetic methods of s-block coordination compounds, it has been noted that microwave and solid state synthesis are scarce for the preparation of alkaline-earth metal-organic frameworks unlike the solution or hydrothermal methods of synthesis, which have been more widely used [12].

doi:10.1016/j.poly.2008.11.022

Recently we reported [49] that the zero-dimensional compound $[Ca(H_2O)_4(\eta^1\text{-4-nba})(\eta^2\text{-4-nba})]$ (4-nba = 4-nitrobenzoate) **1** can be readily transformed into a one-dimensional Ca(II) coordination polymer $[Ca(L^1)(4\text{-nba})_2]_n$ by heating it in the presence of *N*-methylimidazole (L^1) (Scheme 1) demonstrating that thermal reactions can be employed as an useful alternative method for the preparation of new coordination polymers. The loss of coordinated water molecules during the thermal reaction leads to a reorganization of the coordination sphere around Ca(II) resulting in the formation of a polymeric chain compound. In the present work, we have investigated the solid state reaction of compound **1** with 2-methylimidazole (L^2) which is an isomer of L^1 (Scheme 1). It is interesting to note that the reaction of **1** with L^2 at 100 °C results in the formation of a new mixed ligand one-dimensional Ca(II) coordination polymer **2** consisting of three chains.

2. Experimental

2.1. Materials and methods

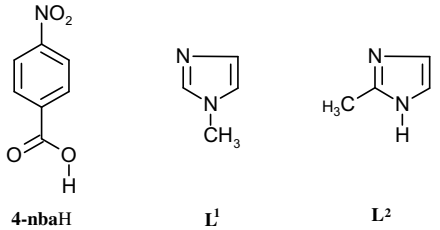
All the chemicals used in this study were of reagent grade and were used as received. The starting materials and reaction products are air stable and hence were prepared under normal laboratory conditions. The compounds $[Ca(H_2O)_4(\eta^1\text{-4-nba})(\eta^2\text{-4-nba})]$ **1** [50] and $[Ca(H_2O)(4\text{-nba})_2]$ **1a** [49] were prepared as described earlier. Infrared (IR) spectra were recorded on a Shimadzu (IR Prestige-21) FT-IR spectrometer in the range 4000–400 cm^{-1}. The samples for the IR spectra were diluted with KBr in the solid state and the signals referenced to polystyrene bands. UV–Vis diffuse-reflectance spectra were obtained using a Shimadzu UV-2450 double beam spectrophotometer. $BaSO_4$ powder was used as reference (100% reflectance). Absorption data were calculated from the reflectance data using the Kubelka–Munk function $(a/S = (1-R)^2/2R$ where a is the absorption coefficient, R the reflectance and S the scattering coefficient). ^{1}H NMR spectrum was recorded in DMSO-d_6 on a Bruker 400 MHz FT-NMR spectrometer. Luminescence spectra were recorded at RT using a Perkin–Elmer LS 55 Luminescence spectrophotometer. TG-DSC measurements were performed in flowing air, in Al_2O_3 crucibles on a STA-409PC simultaneous thermal analyzer from Netzsch. A heating rate of 10 K min^{-1} was employed for all measurements. The insoluble 4-nbaH obtained on acid treatment of the complexes was weighed as described earlier [51] and metal analysis was performed titrimetrically following a standard procedure. Isothermal weight loss studies were performed in an electric furnace.

2.2. Preparation of $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$ **2**

A powdered sample of compound **1** (0.444 g, 1 mmol) was mixed well with 2-methylimidazole (L^2) (0.082 g, 1 mmol) and the solid mixture was heated on a steam bath for ~30 min. The hot reaction mixture was cooled, washed well with ether and dried in air to obtain compound **2** as a yellow powder in quantitative yield. Crystals suitable for structure determination were prepared by recrystallizing the powdered sample from hot water (~10 ml) containing L^2 (0.246 g, 3 mmol). The crystalline needles of **2** were washed with cold water followed by alcohol and then dried in air. The infrared spectrum and the DSC thermogram of the crystalline product are identical with that of the yellow powder. **2** can also be prepared by first heating a powdered sample of **1** on a steam bath for ~20 min to obtain the monohydrate $[Ca(H_2O)(4\text{-nba})_2]$. The N-donor ligand ($L^2$) was mixed with this freshly prepared monohydrate and left at 100 °C for 15 min to obtain **2**.

Anal. Calc. for $CaC_{18}H_{16}N_4O_9$ (**2**): Ca 8.48; 4-nbaH 70.75; CaO 11.87; C 45.76; H 3.41; N 11.86. Found: Ca, 8.45; 4-nbaH, 70.30, CaO, 11.81; C, 45.73; H, 3.63; N, 11.8%.

IR data: 3536 (υ_{O-H}), 3264 (υ_{N-H}), 3117, 2204, 1944, 1622, 1591, 1570, 1514, 1487, 1412, 1346, 1323, 1280, 1169, 1148, 1103, 1011, 997, 876, 854, 827, 795, 787, 752, 721, 673, 600, 517, 440 cm^{-1}.



^{1}H NMR (DMSO-d_6) δ (in ppm): 2.25 (s, 3H); 6.83 (d, 2H); 7.14 (d, 2H); 8.14 (q, 2H); 11.52 (s, H).

DSC data (in °C): 172 (*endo*) 410 (*exo*) 559 (*exo*).

UV–Vis (diffuse reflectance): 251, 330 nm.

2.3. X-ray crystal structure determination

Intensity data for **2** was collected on a STOE Image Plate Diffraction System using graphite-monochromated Mo Kα radiation. The structure was solved with direct methods using SHELXS-97 [52] and refinement was done against F2 using SHELXL-97 [52]. All non-hydrogen atoms were refined anisotropically. Aromatic hydrogens were introduced at their calculated positions and included in the refinement riding on their respective parent atoms. The H atoms of the coordinated water molecule were located in the difference Fourier map and refined with fixed isotropic displacement parameters. The technical details of data acquisition and some selected refinement results are summarized in Table 1.

Extinction coefficient	0.027(3)
Largest differences in peak and hole	0.337 and −0.386 e Å^{-3}

3. Results and discussion

3.1. Synthesis and spectroscopy

The solid state reaction of an intimate mixture of the tetraaqua compound $[Ca(H_2O)_4(4\text{-nba})_2]$ **1** and 2-methylimidazole (L^2) at 100 °C resulted in the formation of the mixed ligand Ca(II) compound $[Ca(L^2)(H_2O)(4\text{-nba})_2]$ **2** in quantitative yield (Scheme 2). Compound **2** was formulated based on the elemental analysis and the mass loss leading to the formation of CaO on pyrolysis. The use of excess L^2 in the thermal reaction did not result in the formation of new products containing additional N-donor ligands. The mixed ligand compound **2** can also be synthesized in a two step process. The first step involves the synthesis of a monohydrate compound $[Ca(H_2O)(4\text{-nba})_2]$ **1a** by heating **1** at 100 °C. The reaction of L^2 with **1a** at 100 °C afforded the new compound **2**, which is insoluble in all common solvents like water, CH_3CN, CH_2Cl_2, DMF etc. The solid is partially soluble in DMSO and this property was used to study its NMR spectrum, which exhibits the characteristic signals of the organic moieties 4-nba and L^2.

The thermal reaction of **1** was investigated with other N-donor ligands like pyridine (pKa 5.1), benzimidazole (pKa 5.4) and 4-picoline (pKa 6.02). However from these reactions no new product containing N-donor ligand could be obtained. In all these cases the product obtained consisted of a mixture of $[Ca(H_2O)(4\text{-nba})_2]$ and unreacted N-donor ligand. The unreacted ligand could be quantitatively recovered by washing the mixture with ether. The non-incorporation of N-donor ligand can be attributed to the less basic nature of benzimidazole and the pyridine ligands as compared to L^1 (pKa 7.1) or L^2 (pKa 7.75). The N-donor ligands L^1 and L^2 are isomers and differ in terms of the positioning of the methyl substituent. The ligand L^2 employed in this work resulted in the formation of a final product containing a mole of water for each mole of Ca, unlike imidazole or N-methylimidazole (L^1) which yielded anhydrous compounds having molar composition of Ca:4-nba:L^1 1:2:1 [49]. Crystals of **2** suitable for structure determination were prepared by recrystallising compound **1** from an aqueous solution containing L^2. The crystalline nature of **2** (Fig. 1) can be evidenced from the sharp signals in its powder diffractogram. A comparison of the powder pattern of the bulk sample with that of the theoretically calculated pattern from the single crystal data (*vide infra*) reveals the phase purity of the mixed ligand product **2**. The presence of water in **2** is inferred from the strong signal in its infrared spectrum at 3536 cm^{-1}. The signal at 3264 cm^{-1} can be assigned to the υ_{N-H} (L^2) vibration (Supplementary Fig. 1) of the N-donor ligand. It is to be noted that the profile of the infrared spectra in the region 3500–2800 cm^{-1} of compound **2** is quite different as compared to that of the tetraaqua compound **1** or the monohydrate $[Ca(H_2O)(4\text{-nba})_2]$ **1a**. Compound **2** exhibits several signals in the mid IR region indicating the presence of the organic moieties. The strong signals at 1514 and 1346 cm^{-1} can be assigned to the asymmetric and symmetric stretching vibrations of the $-NO_2$ group of 4-nba while the bands at 1591 and 1570 cm^{-1} are assignable to the asymmetric vibration of the carboxylate group. The signal at 1411 cm^{-1} is assigned for the symmetric vibration of the –COO group. However based only on the infrared data, the exact nature of the binding of the 4-nba ligand cannot be unambiguously determined. In view of the insolubility of **2** in all common solvents the diffuse reflectance spectrum was recorded in the UV–Vis region. The observed signals at 251 and 330 nm in the spectrum can be attributed to the intraligand charge transfer bands of the 4-nba ligand based on a comparison of the reflectance spectra of compounds **2** and **1** (Fig. 2). The luminescence studies of alkaline-earth metal complexes are of considerable importance since the divalent cations Mg and Ca are the most abundant in living cells and play vital roles in many cellular processes [1]. Two emission maxima are observed at around 450 and 490 nm for compound **2**. Interestingly both 4-nbaH and L^2 exhibit emission signals around 450 nm. A scrutiny of the emission spectra reveals that the emission of the Ca(II) compound **2** is reduced as compared to that of the free ligands (Fig. 3). A reduction in the emission intensity has

been recently reported for the 1D coordination polymer $[Ca(SA)_2(phen)]_n$ (SA = salicylate; phen = 1,10-phenanthroline) [53].

3.2. Crystal structure description of **2**

Compound **2** crystallizes in the centrosymmetric monoclinic space group $P2_1/n$ with all atoms situated in general positions. The structure reveals that **2** is a coordination polymer and can be formulated as $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$. The structure of *catena*-poly[[(2-methylimidazole)calcium(II)](μ_2-aqua)(μ_2-η^1:η^1-4-nitrobenzoato)(μ_2-η^2-4-nitrobenzoato)] **2** consists of a central Ca(II) ion, a terminal 2-MeIm ligand, a bridging aqua ligand and two crystallographically independent bridging 4-nba ligands

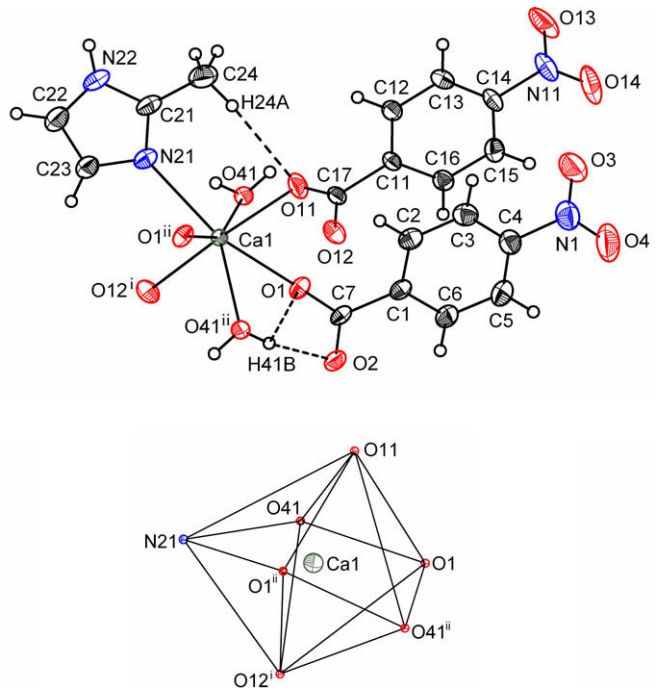

Fig. 4. A view of the coordination sphere of Ca(II) in $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$ **2**, showing the atom-labeling scheme. Displacement ellipsoids are drawn at the 50% probability level excepting for the H atoms, which are shown as circles of arbitrary radius (top). Intramolecular H-bonding is shown by the broken lines. The distorted pentagonal bipyramidal coordination polyhedron around Ca(II) in **2** (bottom). Symmetry code: (i) $-x+1/2, y-1/2, -z+3/2$; (ii) $-x+1/2, y+1/2, -z+3/2$.

(Fig. 4). In the crystal structure, each Ca(II) is bonded to a nitrogen atom of a terminal 2-methylimidazole ligand, two oxygen atoms from two symmetry related aqua ligands and four oxygen atoms from four symmetry related 4-nba ligands resulting in a distorted $\{CaO_6N\}$ pentagonal bipyramidal polyhedron around Ca (Fig. 4). The geometric parameters of the 4-nba anions and 2-MeIm are in the normal range. The O–Ca–O and O–Ca–N angles range from 65.73(3) to 172.63(5)°, The Ca–O distances in **2** range from 2.3100(11)–2.5654(11) Å (Table 2) and are in agreement with literature values [49,50,53]. A Ca–N bond distance of 2.5024(13) Å is observed. The oxidation state of the central metal in compound **2** based on the bond valence sum was found to be 2.139 [54]. The bond valence sum for the precursor calcium compound $[Ca(H_2O)_4(4\text{-nba})_2]$ **1**, the mixed ligand compound $[Ca(H_2O)_3(Im)(4\text{-nba})_2]\cdot Im$ and the 1-D ladder polymer $[Ca(L^1)(4\text{-nba})_2]_n$ are 2.187, 2.27 and 2.177, respectively. It is interesting to note that the bond valence sums are very close to the expected value of 2 for the bivalent metal and the estimated bond valence sums for the coordination polymers **2** and $[Ca(L^1)(4\text{-nba})_2]_n$ are slightly less than those observed for the zero-dimensional calcium compounds.

The coordinated water (O41) functions as a μ_2-bridging ligand with the O41 atom linked to two symmetry related Ca(II) ions resulting in the formation of an infinite chain extending along *b*-axis (Supplementary Fig. 2). It is interesting to note that both 4-nitrobenzoates in each formula unit are coordinated to the central Ca(II) in different bridging modes. One of the two unique 4-nba anions in each formula unit is coordinated to two different Ca(II) ions through one of the carboxylate oxygen atoms (O1), which functions as a monoatomic bridge (μ_2-η^2) resulting in an extended chain along *b*-axis (Supplementary Fig. 3). The second independent 4-nba ligand functions as a bridging bidentate ligand (μ_2-η^1:η^1) and is linked to two symmetry related Ca(II) ions via O11 and O12 oxygen atoms. An infinite chain extending along *b*-axis is formed due to this binding mode of 4-nba. Due to the bridging nature of the aqua and 4-nba ligands, [(2-methylimidazole)calcium(II)] units in **2** are linked into a one-dimensional coordination polymer consisting of three chains, all of which propagate along *b*-axis (Fig. 5). In the triple chain coordination polymer a Ca···Ca separation of 3.8432(3) Å is observed between neighbouring Ca(II) ions. This value is comparable with the Ca···Ca distance of 3.8585(7) Å reported for the related compound $[Ca(L^1)(4\text{-nba})_2]_n$ [49] and in several other Ca(II) coordination polymers.

A scrutiny of the structure reveals that the oxygen atoms of the carboxylate and nitro functionalities of the 4-nba ligand and the coordinated water are involved in O–H···O, N–H···O and C–H···O interactions. A total of six H-bonding interactions with H···O dis-

$[Ba(H_2O)_5(4\text{-nba})_2]_n$	9	$P2_1/c$	Polymer	η^2, μ_2-η^1:η^1	O–H···O, C–H···O	[58]

Abbreviations: C.N. = coordination number; 4-nba = 4-nitrobenzoate; Im = imidazole; L^1 = *N*-methylimidazole; L^2 = 2-methylimidazole.

3.3. Comparative study of alkaline-earth 4-nitrobenzoates

The coordination polymer $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$ **2** described in this work and the reported compounds $[Ca(H_2O)_4(\eta^1\text{-4-nba})(\eta^2\text{-4-nba})]$ **1** [50], $[Ca(H_2O)_3(Im)(\eta^1\text{-4-nba})_2] \cdot Im$ [55], and $[Ca(L^1)(4\text{-nba})_2]_n$ [49] constitute a group of Ca(II) compounds with a 1:2 mol ratio of Ca:4-nba and exhibit different binding modes of the 4-nba ligand. In addition to these 4-nitrobenzoates of Ca(II), five other 4-nba compounds containing Mg, Sr and Ba have been structurally characterized [55–58]. The availability of structural features of several compounds (Table 4) permits a comparative study of the structural chemistry of alkaline-earth 4-nitrobenzoates, the details of which are described below. All the structurally characterized alkaline-earth 4-nitrobenzoates listed in Table 4, exhibit a metal:4-nba ratio of 1:2 and crystallize in centrosymmetric space groups. The nuclearity of the compounds ranges from monomer (five compounds) to dimer (one compound) and polymer (three compounds). The coordination number of the central metal varies from 6 to 9, with the Mg(II) compounds showing hexacoordination. The Sr and Ba compounds exhibit nine coordination while both hexa and hepta coordination are observed in the Ca(II) compounds. In addition to functioning as charge balancing anions for the bivalent metal in all the compounds, 4-nba is bonded to the central metal as a monodentate (η^1) or bidentate or (η^2) or as a bridging (μ-) ligand (Scheme 3). In $[Mg(H_2O)_6](4\text{-nba})_2 \cdot 2H_2O$ the 4-nba anions are not coordinated to the central metal, while in $[Sr(H_2O)_7(4\text{-nba})](4\text{-nba}) \cdot 2H_2O$ one unique 4-nba remains uncoordinated with the other 4-nba functioning as a chelating bidentate ligand. The bridging bidentate binding mode (μ_2-η^1:η^1) is observed in the mixed ligand dimeric Mg(II) compound as well as in the three coordination polymers. The monoatomic bridging binding mode (μ_2-η^2) and the tridentate bridging coordination modes (μ_3-η^2:η^1) are observed in the Ca(II) coordination polymers. Interestingly in the four different Ca(II)-4-nitrobenzoates a total of five different coordination modes of the 4-nba ligand are observed. All the compounds exhibit several H-bonding interactions resulting in different H-bonded networks.

Scheme 3. Structurally characterized binding modes of 4-nba ligand in alkaline-earth 4-nitrobenzoates.

3.4. Thermal studies

The TG–DSC thermogram of compound **2** is depicted in Fig. 6. The DSC curve of compound **2** exhibits three thermal events. The first endothermic process at 172 °C can be assigned to the loss of a neutral water ligand. The observed mass loss of 10.52% is much more than the loss expected for the loss of a mole of water. The drop in the TG curve indicates that the loss of water results in the loss of the neutral N-donor ligand. The isothermal weight loss studies at this temperature showed a mass loss of 13% which is much more than the loss expected for a mole of water and much less than loss due to either L^2 or a combination of two neutral ligands in **2**. The exothermic events at 410 and 559 °C correspond to the degradation of the 4-nba ligand as evidenced by the rapid drop in the TG curve. The assignment of the endothermic signal at 410 °C for the decomposition of 4-nba gains more credence as a similar behaviour has been observed for the related Ca(II) com-

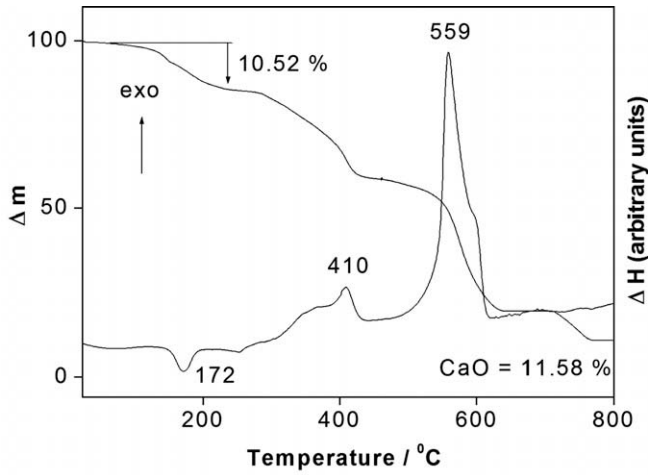

Fig. 6. TG–DSC thermogram of compound **2**.

pounds **1** and **1a** [49]. The TG curve above 750 °C is parallel to the temperature axis and observed residue of 11.58% is in very good agreement with the expected value of 11.87% for the formation of CaO. The formation of CaO as the final residue has been confirmed based on the X-ray powder pattern of the residue (Supplementary Fig. 4) as well as isothermal weight loss studies.

4. Conclusions

In summary, we have shown that the zero-dimensional mononuclear tetraaqua Ca(II) compound **1** can be transformed into a phase pure Ca(II) coordination polymer $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$ **2** by heating it in the presence of 2-methylimidazole (L^2). The key step in this solid state transformation is the formation of an intermediate monohydrate compound followed by incorporation of the N-donor ligand into the coordination sphere of Ca(II) resulting in the formation of a triple stranded coordination polymer. A comparative study of the structural features of nine 4-nitrobenzoate compounds of alkaline-earth metals reveals five different binding modes of the 4-nba ligand all of which are observed in the structurally characterized compounds $[Ca(H_2O)_4(4\text{-nba})_2]_n$ **1** $[Ca(H_2O)_3(Im)(4\text{-nba})_2]\cdot Im$, $[Ca(L^1)(4\text{-nba})_2]_n$ and $[Ca(H_2O)(L^2)(4\text{-nba})_2]_n$ **2**.

Biological activity prediction

ABSTRACT

The preparation of two new 1,3,2-diazaphospholidine-2,4,5-triones is reported. Thus, 2-chloro-1,3,2-diazaphospholidine-2,4,5-trione [ClP(O)(NHC(O)C(O)NH) (**I**)] and 2-benzylamino-1,3,2-diazaphospholidine-2,4,5-trione [$C_6H_5CH_2NHP(O)(NHC(O)C(O)NH)$ (**II**)] have been synthesized by the reaction of $POCl_3$ with the corresponding carboxylic diamide salts. The characterization of the compound **I** was performed by multinuclear (^1H, ^{13}C, ^{31}P) NMR and FTIR spectroscopies, elemental analysis and also mass spectrometry. Both compounds show two signals at room temperature in the low field region of the ^1H NMR spectrum, which collapsed to a single peak when the temperature is increased. Dynamic NMR (^1H DNMR) and quantum chemical studies were performed to gain insight from this conversion process. The free activation energies, calculated at the coalescence temperatures are 18.51 and 17.45 kcal/mol for compounds (**I**) and (**II**), respectively, which are associated with a tautomeric interconversion process, most likely between the lactam and lactim forms. The relative energy, molecular geometry and vibrational properties of several plausible tautomers were analyzed by using quantum chemical calculations at the HF/6-311G** and B3LYP/6-311++G** levels of the theory. The nuclear magnetic shielding tensors have been calculated for both tautomeric forms using the gauge independent atomic orbital (GIAO) method at the B3LYP/6-311++G(3df,2p) level of approximation. A biological activity prediction using the PASS software shows that compound (**I**) can be characterized by a superb anti-HIV activity whereas compound (**II**) is a very good antineoplastic.

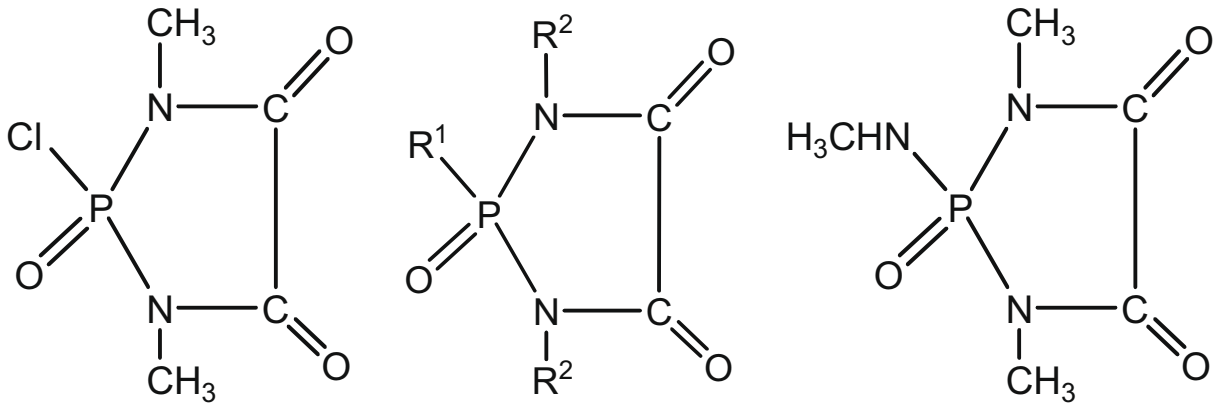
1. Introduction



N-heterocycles formed by oxo group(s) constitute a family of polar ligands with peculiar properties since they may change either their hydrogen-bond donating or accepting sites through the protonation/deprotonation process or by a tautomeric transformation. Pyrimidine and purine derivatives are the best-known examples for such oxo-hydroxy (lactam-lactim) tautomerism [1,2]. 3-OH and 5-OH isooxazoles also show this proton relocation mechanism [3–5]. Another important class of molecules with this versatility consists of five-membered heterocycles with at least two more N atoms in the ring. In the neutral form, N-atom is bounded to a mobile H-atom (pyrrolic N–H) whereas the remaining N-atoms posses a basic character being their lone pairs formally situated in the ring plane. Imidazole is the most well-known representative of this family [6–8].

The syntheses of heterocycles containing N- and pentavalent P-atoms (phospholidines) as well as carbonyl groups (Scheme 1) were conducted by Becke-Goehring and Wolf [9] reacting oxamide with PCl_5. In such a five-membered ring heterocycles, the reactivity of the heteroatom towards nucleophiles is greatly enhanced in comparison with the acyclic analogues. The reactivity of phospholidines towards amines and alcohols, as well as the mechanism and the influence of steric hindrance have been reported [10]. Moreover, the molecular structure for the 1,3-dimethyl-2-methylamino-1,3,2-diazaphospholidine-2,4,5-trione (Scheme 1) has been studied from an X-ray diffraction analysis [11].

Carbacylamidophosphate compounds with general formula $R'C(O)NHP(O)R_2$ have a decisive role in catalytic and metabolism processes [12–14], and many applications in agricultural and pharmacological industries [15–19]. Their rich biological activity is related with the presence of a peptide group in these compounds. Some *N*-ethyleneimine derivatives at the phosphoryl group have been proposed as anti-cancer drugs [20–22]. Furthermore, carbacylamidophosphate compounds are also potential O,O′-donor

Scheme 1. Five membered heterocycles (phospholidines) related with the species studied in this work. *Left:* 1,3-Dimethyl-2-chloro-1,3,2-diazaphospholidine-2,4,5-trione [9]. *Centre:* 1,3-(R^2)-2-R^1-1,3,2-diazaphospholidine-2,4,5-trione, with (R_1 = Alk, OAlk, OAr, R_2 = Me, CH_2Ph) [10]. *Right:* 1,3-dimethyl-2-methylamino-1,3,2-diazaphospholidine-2,4,5-trione [11].

ligands for metal ions and play a dominant role as ligands in the development of transition metal-catalyzed asymmetric synthesis specially as powerful chelating systems, closely related to β-diketonates [23–25]. Carboxylamides have a very low nucleophilic reactivity on their nitrogen moieties due to the interaction between N-atom and the C=O π-system [26,27]. In addition, reactions of phosphorus halides with amides lead to products in which the contribution of the P–O linkage is more evident than the corresponding P–N linkages [12,26,27]. This wide range of applications has stimulated a great research effort involving preparations and characterizations of compounds possessing the –C(O)NHP(O)– moiety [22,23,28–36].

In the present study, two new cyclic diazaphospholidine species have been synthesized by the reaction of $POCl_3$ with the carboxylic diamide (oxamide) salt. The characterization of the products was carried out by IR, ^1H, ^{13}C, ^{31}P NMR spectroscopy, elemental analysis and also mass spectrometry for compound (**I**). Both compounds show two signals at room temperature in the low field region of the ^1H NMR spectrum, which collapsed to a single peak when the temperature is increased. Dynamic NMR (DNMR) and quantum chemical studies were performed to clarify this process. Moreover, a prediction of the biological activity for these compounds was performed using the PASS (prediction of activity spectra for substances) software [37–43].

2. Results

2.1. Synthesis

The synthesis of the compound **I** was carried out according to Eq. (1)

$$Na_2(H_2N_2C_2O_2) + POCl_3 \rightarrow ClP(O)(NHC(O)C(O)NH) + 2NaCl \quad (1)$$

A mixture of oxamide ($H_2NC(O)C(O)NH_2$) and NaH dissolved in toluene was stirred at ca. 110 °C. After 3.5 h, the mixture was filtered and the solvent was distilled off in vacuum. To the formed oxamide natrium salt in benzene was added a large excess of $POCl_3$ under stirring. After 6 h refluxing, the mixture was filtered and **I** was obtained in a yield of 83 %. All reactions were done under inert (dry gas N_2) atmosphere.

Compound **II** was subsequently prepared by reaction of **I** with benzyl amine according to Eq. (2)

$$ClP(O)(NHC(O)C(O)NH) + C_6H_5CH_2NH_2 \rightarrow C_6H_5CH_2NHP(O)(NHC(O)C(O)NH) + HCl \quad (2)$$

Compound **I** and benzyl amine were dissolved in chloroform at 0 °C and stirred for 5 h. The mixture was then filtered and the remaining solid was purified by washing with DMF and Et_2O. Compound **II** was obtained in a yield of 90%.

2.2. Mass spectrometry

Mass spectrum of **I** reveals the presence of the molecular ion at *m*/*z* 168. Its fragmentation shows two peaks at *m*/*z* 133 and 105, corresponding to the loss of Cl and ClC=O groups and three intense peaks at *m*/*z* 89, 59, 42 due to the P(O)NC=O, NPN and NC=O fragments, respectively.

2.3. NMR spectroscopy

^1H NMR spectra of the products show two signals corresponding to amidic H-atom at 7.68 ppm and 7.97 ppm for **I** and at 7.66 ppm and 7.92 ppm for **II**. In addition **II** shows typical signals corresponding to the aromatic ring and to the methylene group. As expected for compound **I**, the ^{13}C NMR spectrum shows only one single peak in the carbonylic region at 163.4 ppm assigned to the C=O group. For compound **II**, the ^{13}C NMR shows in addition peaks from the aromatic ring and the methylene moiety. In the ^{31}P NMR spectra both compounds present a signal near −0.8 ppm.

The peaks near 7.8 ppm in the ^1H NMR spectra disappear when compounds **I** and **II** are dissolved in D_2O. Whereas no changes are observed by decreasing the temperature of the aqueous solutions, both peaks collapse at higher temperatures. The coalescence temperatures (T_c) are 90 °C for (**I**), and 70 °C for (**II**) (Fig. 1).

2.4. Vibrational spectra

To our knowledge, no vibrational spectra for phospholidinones have been reported. The analysis of calculated harmonic vibrational frequencies can be useful in the present circumstances for both purposes, the assignment of the experimental vibrational data and the search for the occurrence of tautomeric forms (See Fig. 2). A tentative assignment of the observed bands was carried out by comparison with theoretical wavenumbers, as well as with relevant data reported in the literature for related molecules [45–47]. The main features in the vibrational spectra can be satisfactorily interpreted on the basis of the presence of one most stable oxo tautomer. Characteristic fundamental modes assigned to the vibrations of cyclic N-carbonyl phosphordiamidates moiety in compounds **I** and **II** are shown on Table 1.

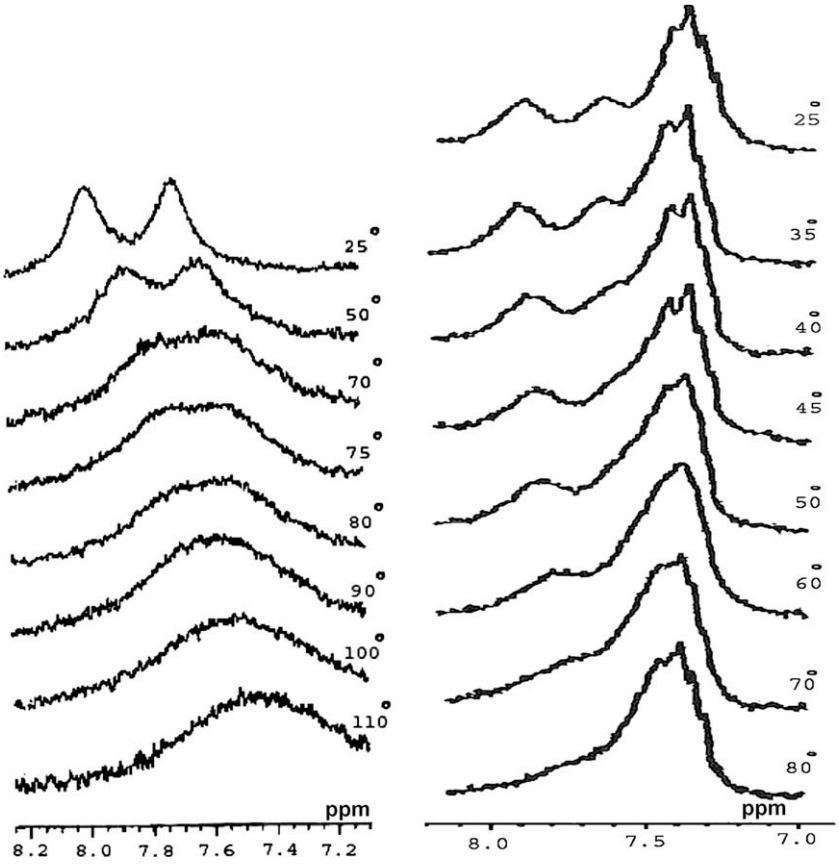

Fig. 1. Dynamic ^{1}H NMR spectra in the 7-8.2 ppm region of compounds **I** (left) and **II** (right).

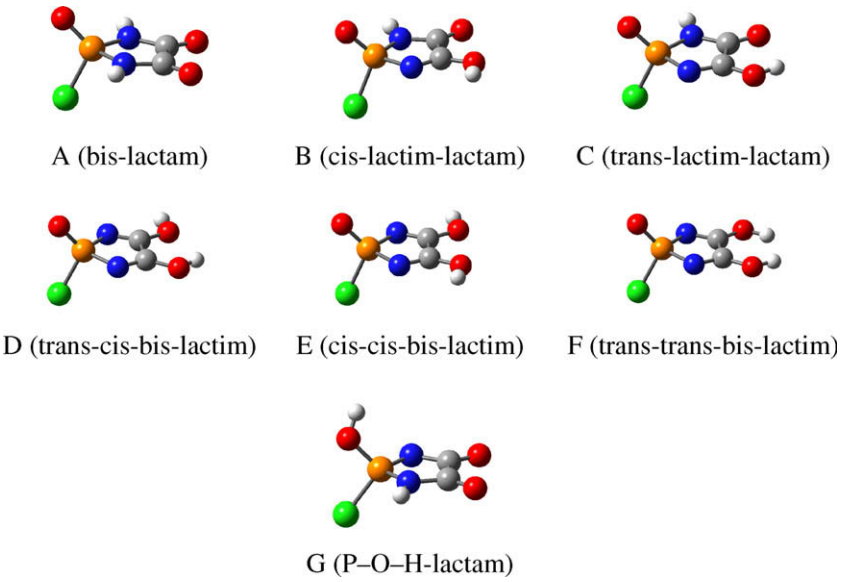

Fig. 2. Molecular models for tauromeric forms (A–G) of compound **I**.

The infrared spectra for the title compounds are dominated by strong absorptions in the high frequency range near 3360 cm^{-1} and 3150 cm^{-1}. These bands are assigned to the antisymmetric and symmetric N–H stretching mode, respectively. A third ν(N–H) mode is expected for compound **II**, due to the $-CH_2-NH-$ moiety, which was observed as an intense band in the infrared spectrum at 2975 cm^{-1}. The strong integrated intensity displayed for these bands, as well as the difference in the frequency values observed between these modes, can serve as an evidence of the presence of hydrogen bond interactions in the solid state. These interactions are obviously absent in the free molecule. Therefore, the theoretical calculations predict quite similar values for the antisymmetric and symmetric N–H stretching mode. The strong intensity band near 1650 cm^{-1} for compounds **I** and **II** can be as-

signed to the C=O stretching vibrations. This relatively low frequency value could be related again with the presence of hydrogen bond interaction in the solid phase. Calculated values for the υ(C=O) mode are 1849 and 1831 cm^{-1} for compounds **I** and **II**, respectively. The bands observed near 1280 cm^{-1} in the infrared spectra of both compounds **I** and **II**, can be assigned with confidence to the P=O stretching mode. The computed values are in good agreement with this assignment (1287 and 1281 cm^{-1}, respectively). Other characteristic fundamental modes of vibration for these molecules are the N–C and N–P symmetric and antisymmetric stretching modes, observed in the 1100–800 cm^{-1} region as bands of medium intensity.

2.5. Ab initio calculations

The species studied in the present work can exist as different lactam-lactim tautomers [19]. Moreover different conformations are plausible for each lactim tautomer, depending on the relative mutual orientation of the C=N double bond and the O–H single bond. The P–O–H-lactam tautomer has been also considered. Accordingly, seven structures of **I**, whose molecular models are shown in Fig. 2, have been taken into consideration. Full geometry optimizations and frequency calculations were performed for each of these structures by using quantum chemical calculations at the HF and B3LYP methods with the 6-311G** and 6-311++G** basis sets, respectively. Relative ΔE° energy values (corrected by zero point energy) are listed in Table 2.

All computational methods predict the bis-lactam structure (form A in Fig. 2) as the most stable form of compound **I** and a molecular structure with C_S symmetry. The second and third stable forms correspond to the lactim-lactam tautomers represented as structures B and C in Fig. 2, respectively. HF and B3LYP approximations predict a slightly different order for the energy difference of these conformers. The HF/6-311G** level of the theory computes the structure B and C 9.67 and 10.10 kcal mol^{-1} higher in energy than the lactam form, respectively. Similar values are computed with the B3LYP/6-311++G** (9.74 and 9.00 kcal mol^{-1}, respectively). The bis-lactim tautomers (forms D–F in Fig. 2) result also in minima of the potential hypersurface. They are located ca. 20 kcal mol^{-1} higher in energy than the global minimum. The P–O–H-lactam tautomer (form G) also results to be a high energy minimum (ΔE^0 > 24 kcal/mol).

Table 2
Calculated relative energies (corrected by zero-point energy) in kcal mol^{-1} for the different tautomers and conformers of compound **I**.

Tautomer	HF/6-311G**	B3LYP/6-311++G**	PCM/B3LYP /6-311++G**[a]
A	0.00	0.00	0.00

G	26.04	24.65	21.08

[a] DMSO dielectric constant was used in the PCM calculations.
[b] Converges to structure D.

The influence of the solvent on the tautomeric equilibrium is well known. Changes in the difference of polarity among tautomers can induce significant variations of their relative energies in solution. As the very first approximation, we decided the use of the PCM/B3LYP approximation to compute the influence of solvent effects on tautomerism. Because DMSO is the solvent used in our NMR experiments, its dielectric constant was used for these calculations. It is important to mention, however, that the PCM model does not consider the presence of explicit solvent molecules; hence specific solute–solvent interactions are not described and the calculated solvation effects arise only from mutual solute–solvent electrostatic polarization. Results obtained at the PCM/B3LYP/6-311++G** level of approximation are also given in Table 2. It is observed that the inclusion of electrostatic polarization has minor influence on the calculated relative energy values. Thus, the order of stability for DMSO solvated (ε = 46.7) molecules of **I** affords the following trend: A > B > C > E > G > D > F.

The optimized geometrical parameters for the gas phase and DMSO-solvated species for the main tautomers are summarized in Table SM1 given as Supplementary data. For comparison, the geometrical parameters determined from X-ray diffraction analysis for the closely related 1,3-dimethyl-2-methylamino-1,3,2-diazaphospholidine-2,4,5-trione [11] (see Scheme 1) are also listed in Table SM1.

The similarity between the computed and experimental [11] structural parameters for molecule **I** is remarkable. The 1,3,2-diazaphospholidine ring together with the C=O groups tend to adopt a planar system. The planarity of the ring promotes further stereoelectronic interactions of the P- and the N-atoms of the ring. The P–N distance in the compound **I** **(ca.** 1.68 Å) is significantly shorter than that reported for single P–N bond (1.78 Å). A similar range (1.60–1.66 Å) was observed for this bond length for a variety of carbacylamidophosphates [22,23,28–31]. By comparison of the acyclic moiety, dramatic changes in the geometry of the oxamide skeleton result from its incorporation into a five-membered phospholidine ring. The formation of a ring from the acyclic moiety constrains the N–C–C angles to near 108°, which represents an unusually low value for a sp^2 hybridized C-atom. As suggested previously, the trigonal geometry around the N-atoms and the small N–P–N angle caused by the cyclic structure (91°) enable stabilizing interactions between the vacant d orbitals on phosphorus and the two 2p non-bonding orbitals of the ring nitrogen atoms, suggesting the presence of a delocalized π system, which could play a important role in the chemical properties of this species [10].

As expected, the main differences in the geometrical structure of lactam/lactim tautomers are related with the N–C and C=O bonds. In the most stable oxo form, the N–C and C=O bond length values are 1.688 and 1.196 Å (B3LYP/6-311++G**), which can be considered as typical values for N-carbonyl phosphoramidate compounds. These values are 0.12 Å shorter and longer in the tautomeric hidroxo structure, respectively, denoting a strengthening of the N=C bond order and the concomitant diminution of the C–

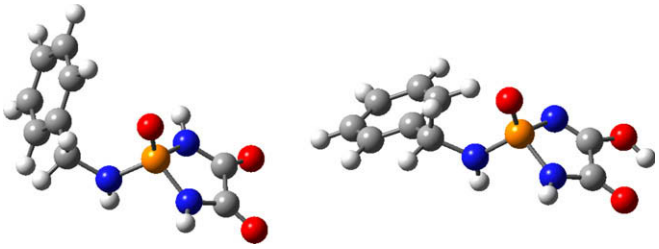

Fig. 3. Molecular models for the most stable tautomeric forms of compound **II**.

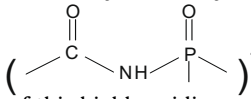
O(H) bond order. The influence of solvent effects on the geometrical parameters can be clearly seen through the changes of bond lengths and bond angles, as shown in Table SM1 given as Supplementary data. In general, the changes are more significant in the oxo- than in the hydroxy-form tautomer. The N–C bond parameter is mostly affected by the solvation. In the oxo tautomer, both bonds become shorter in solution than in the gas phase by 0.018 Å. In the hydroxy-form, the most affected parameters correspond to the C–O(H) and N=C bond lengths, which increase their lengths by ca. 0.011 and 0.014 Å, respectively, when the structure B (Fig. 2) is formally transferred from the gas phase to DMSO solution. As expected, the oxo form tautomers have slightly larger dipole moments than their hydroxy-form counterparts. In DMSO, this difference is 0.66 D.

Taking into consideration the results obtained for compound **I**, the two main tautomers were calculated for compound **II**. Molecular models for these forms are shown in Fig. 3. At the HF/6-311G** level of calculations, the lactam tautomer is more stable than the lactim form by 11.9 kcal/mol. The gas phase optimized geometrical parameters for these structures are summarized in Table SM2 in the Supplementary data section.

2.6. PASS results (biological activity prediction)



The title compounds were considered by the software PASS (prediction of activity spectra for substances) [37–43]. The current version of PASS predicts simultaneously 900 biological activity types for 45 000 compounds with a mean accuracy of 85% [48,49]. The results of the PASS for a certain compound are presented to be either active (Pa) or inactive (Pi). The total PASS list is reported on the web-site [45]. The Pa values should be considered in the following way. In the case that Pa > 0.7 the expectation of activity is high. By the contrary, if Pa < 0.7 the activity should be considered less probable. Selected biological activity spectra for compound (**I**) and (**II**) are given in Table 3 (The whole spectra are given as Supplementary data). According to this table, the prediction of the activity as HIV-1 protease inhibitor and antiviral (HIV) activities in compound (**I**) and antineoplastic activity in compound (**II**) are remarkably high.

Table 3
Biological activity spectra for compound (**I**) and (**II**) evaluated by the PASS 1.913 program.

Compound **I**			Compound **II**		
Biological activity	Pa	Pi	Biological activity	Pa	Pi
HIV-1 protease inhibitor	0.997	0.000	Antineoplastic	0.957	0.006

Pa = predictive activity, Pi = predictive inactivity.

3. Discussion

Intramolecular interactions of the N–H group could occur either with the P=O or with the C=O moiety in carbacylamidophosphate compounds with structure  . Therefore, the spectroscopic consequence of this highly acidic proton is a shift to low field in the ^{1}H NMR spectra. Moreover, carbacylamidophosphates generally show values of $^2J_{PNH}$ coupling constants between the phosphorus and the amino proton [23,29,50,51]. Unexpectedly, no evidence of coupling between the phosphorus and the amidic protons ($^2J_{PNH}$) was observed in the ^{1}H NMR spectra for both synthesized molecules. ^{1}H NMR spectra of compounds **I** and **II** show two singlet peaks with roughly equal intensities at 7.97 and 7.68 ppm for compound (**I**) and 7.92 and 7.66 ppm for compound (**II**), respectively.

Dynamic NMR study of both compounds **I** and **II** shows that by increasing the temperature, the two amine proton single peaks collapse into one single resonance with a coalescence temperature of ca. 90 °C for **I**, and 70 °C for **II**. The rate constant and the activation free energy for this process calculated *via Eyring* equation [44] for compounds **I** and **II** are 18.5 and 17.5 kcal/mol, respectively.

To understand the exchange process, the following points should be considered:

(a) Since the P–N amidic bonds in **I** and **II** are restricted, there are no rotations around these bonds and the calculated energies could not be considered as rotational barrier.
(b) According to the quantum chemical calculations both molecules present planar N-atoms with sp^2 hybridization in their ground states. The planarity of the N-atoms was also determined by X-ray crystallography for phospholidines [11] and similar carbacylamidophosphates [22,23,29,30]. Thus, the calculated activation free energies ($\Delta G^{\#}$) could not be due to an inversion barrier.
(c) The tautomeric equilibrium of hydroxypyridines has been studied theoretically owing to their relevance in the oxoamino ↔ hydroxyamino tautomerism of nucleic acids [52]. The 2-pyridone/2-hydroxypyridine system has also been subject of several studies [53–55], the estimated activation energies for the tautomeric conversion has been recently determined by IR spectroscopy [56]. On the other hand, the lactam/lactim equilibrium in parabanic acid has been studied by NMR techniques. No lactim form has been found at room temperature, the activation energy for the formation of the lactim form appear to be extremely high for this compound [57].

The activation free energy values $\Delta G^{\#}$ derived from D NMR for compounds **I** and **II** in DMSO solution can be associated with a tautomeric interconversion process, most likely between the main bis-lactam (A) and the *cis*-lactim-lactam (B) forms. Molecular orbital calculations at the B3LYP/6-311++G** level of approximation for compound **I** in vacuum and DMSO-solvated show that A is more stable than B by 9.74 and 9.32 kcal mol^{-1}, respectively.

Further calculations of the NMR properties of compounds **I** and **II** support this assumption. For compound **I**, the computed B3LYP/6-311++G(3df,2p) magnetic isotropic shielding tensors for both N–H protons in the main form (A) is 6.45 ppm (referred to TMS). The calculated values for the N–H and O–H protons in the cis-lactam-lactim (B) tautomer are 5.48 and 5.40 ppm, respectively. These results are in a qualitative agreement with the ^{1}H-NMR spectrum (Fig. 1), and allow tentatively assigning the corresponding N–H and O–H shift to the signals at 7.97 and 7.68 ppm, respectively.

The chemical shifts for N–H and O–H protons present in the lactam and lactim tautomers of compound **II** were also computed. Due to the C_1 molecular symmetry, both N–H protons in the most stable form of compound **II** are expected to occur at slightly different values. Calculated [B3LYP/6-311++G(3df,2p)] chemical shifts are 5.73 and 5.42 ppm. In the lactim tautomers the N–H proton suffers a little shift to 5.82 ppm and the O–H proton is predicted to appear at lower fields (8.21 ppm). These features are in qualitative good agreement with the experimental spectra taken below the coalescence temperature, where two signals appear at 7.92 and 7.66 ppm.

Thus, quantum chemical calculations suggest that both species exists in DMSO solution in the dynamic equilibrium of the lactam and lactim forms. The extreme low solubility showed by compounds **I** and **II** precludes the study of the solvent effect for these equilibria.

4. Experimental

4.1. Materials and methods

^{1}H, ^{13}C, ^{31}P NMR spectra were recorded on a Bruker (Avance 500, DRY) spectrometer. ^{1}H NMR spectra at high temperatures were recorded on a Jeol–Ex90A spectometer. ^{1}H-, ^{13}C-, ^{31}P-chemical shifts were determined relative to TMS and 85% H_3PO_4, respectively.

Infrared (IR) spectra were recorded on a Shimadzu IR 460 spectrometer. The elemental analysis was performed using a Foss Heraeus model CHN–O-Rapid chemical analysis.

Mass spectroscopy was performed with an 8430 magnetic sector Finnigan-Mat mass spectrometer using 70 eV as ionization energy.

Benzene and chloroform were distilled, other chemicals were used without any further purification and were purchased from the following companies: phosphoryl chloride supra pure (Merck), Toluene 99% (Fluka), Diethylether >9% (Merck), *N*,*N*-dimethylformamide 99% (Merck), phosphorylchloride >99% (Merck), Oxamid 99% (Merck), Benzylamine 99% (Merck), sodium hydride 85% (Merck).

4.2. Synthesis

4.2.1. 2–Chloro–1,3,2.–diazaphospholidine–2,4,5–trione (*I*)

A mixture of 1.1 g (12.5 mmol) oxamide, 0.9 g (37.5 mmol) NaH in 40 ml toluene was stirred at reflux temperature. After 3.5 h, the mixture was filtered and the solvent was distilled off in the vacuum and a salt of oxamide was obtained. Then, 7.67 g (50 mmol) $POCl_3$ was gradually added to a stirred mixture of 25 ml benzene and 0.66 g (5 mmol) salt of oxamide ($Na^+H^-NC(O)C(O)NH^-Na^+$). After 6 h refluxing, the mixture was filtered. The compound (**I**) was obtained in 83 % yield.

Anal. Calc. for (NHC(O)C(O)NH)P(O)Cl: C , 14.2 ; H , 1.2 ; N , 16.6 . Found: C, 14.1; H, 1.3; N, 16.8%; IR Spectrum (KBr, cm^{-1}) : 3365 (s), 3125 (s), 1653 (vs), 1339 (ms), 1278 (m), 1090 (m), 965 (w), 882 (w), 791 (m), 681 (w), 528 (w), 489 (w); ^{1}H NMR (DMSO):$\delta_{(ppm)}$ = 7.68 (s), 7.97 (s); ^{13}C-NMR (DMSO) $\delta_{(ppm)}$ = 163.4 (s); ^{31}P NMR (DMSO): $\delta_{(ppm)} = -0.89$ (s); MS: m/e 168: [(NHC(O)C(O)NH)-P(O)Cl]$^+$ (molecular ion), 133: [(NHC(O)C(O)NH)P(O)]$^+$, 105: [(NHC(O) NH)P(O)]$^+$, 89: [P(O)NC(O)]$^+$, 59: [NPN]$^+$ and 42: [NC(O)]$^+$.

4.2.2. 2-Benzylamino–1,3,2–diazaphospholidine–2,4,5–trione (*II*)

0.428 g (4 mmol) of benzyl amine was added to a stirred mixture of 0.337 g (2 mmol) of compound (**I**) and 25 ml chloroform at 0 °C. After 5 h, the mixture was filtered, the remaining residue was purified by washing with *N*,*N*-dimetyl formamide and diethyl ether, respectively. Then, compound (**II**) was obtained with a yield of 90%.

Anal. Calc. for (NHC(O)C(O)NH)P(O)($NHCH_2Ph$): C, 45.2; H, 4.2, N, 17.6. Found: C, 45.0; H, 4.4; N, 17.9%. IR spectrum (KBr, cm^{-1}): 3365 (s), 3165 (ms), 2975 (vs), 1654 (vs), 1372 (m), 1330 (m), 1280 (m), 1106 (m), 965 (m), 876 (m), 787 (w), 691 (m), 571 (m), 493 (w); ^{1}H NMR (DMSO): $\delta_{(ppm)}$ = 2.07 (s), 3.98 (s), 7.33–7.50 (m), 7.66 (s), 7.92 (s); ^{13}C NMR (DMSO) : $\delta_{(ppm)}$ = 161.1 (s), 40.7 (s), 132.8 (s), 127.6 (s), 127.2 (s), 126.8 (s); ^{31}P NMR (DMSO): $\delta_{(ppm)} = -0.87$ (s).

4.3. Computational methods

All quantum chemical calculations were performed with the GAUSSIAN 98 program package [58]. HF and B3LYP methods were employed with standard basis sets up to the extended valence triple-ζ basis sets augmented with polarization and diffuse functions for both hydrogen and non-hydrogen atoms (6-311++G** basis sets). Gradient techniques were used for the geometry optimizations and vibrational calculations. The stationary structures are confirmed by ascertaining that all ground states have only real frequencies. The tautomeric forms were also optimized in solvents according to the polarisable continuum method, which exploits the generating polyhedra procedure to build the cavity in the polarisable continuum medium, where the solute is accommodated [59–61]. The magnetic isotropic shielding tensors were calculated within the gauge independent atomic orbital (GIAO) method [62] at the B3LYP method with the extended 6-311++G(3df,2p) basis set, using the lowest energy optimized structures calculated at the B3LYP/6-31G(d) level of approximation. Chemical shifts were derived with respect to the NMR isotropic magnetic shielding tensors (in ppm) from the corresponding standard tensor (TMS = 31.62 ppm for ^{1}H [B3LYP/6-311++G(3df,2p)]).

Appendix A. Supplementary data

Supporting material for this article is available from the web or from the authors. Computed (B3LYP/6-311++G**) geometrical parameters for the most stable lactam and lactim-lactam tautomers for **I** and **II** in the gas as well as in solution phases are given in Tables SM1 and SM2, respectively. The whole biological activity spectra for compound **I** and **II** evaluated by the PASS program are given in Table SM3. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2008.11.024.

ABSTRACT

The title compounds $Ph_3PbSPbPh_3$ (**1**) and $Ph_3SnSSnPh_3$ (**2**) were prepared in high yields by a reaction of Na_2S, respectively, with $Ph_3Pb(SOCMe)$ and $Ph_3Sn(SOCMe)$. X-ray crystallographic and density functional studies were made to understand the structure and bonding in these molecules. Though the Pb–Pb distance in **1** is only marginally shorter than the sum of the corresponding van der Waals' radii, a smaller Pb–S–Pb angle suggests for a Pb···Pb interaction. DFT calculations were performed to analyse the nature of M···M interaction in **1** and **2**. Strong intramolecular π–π interactions subsist between the different phenyl rings of the molecules.

1. Introduction

The synthesis of compounds with bonds between heavier main group elements have attracted attention of chemists over the last decade due to their structures, bonding and in some cases, unusual properties [1]. A large number of bi/polynuclear compounds of group 14 metals have been prepared and many of them contain M–M bonds. Though distannane [2] and diplumbane [3] with M–M covalent bonds are known for a long time, a large number of compounds containing various types of tin–tin [4] and lead–lead bonds [5] have been synthesized during past few years. On the other hand, compounds with Sn–Sn or Pb–Pb weak interactions in bi/polynuclear M(II) or M(IV) complexes are rare. Recently, Magyar et al. [6] have reexamined the structures of some Pb(II) compounds and have found the existence of a weak intramolecular interaction in tetraphenylarsonium Pb(II) *iso*-maleonitriledithiolate, $[AsPh_4]_4[Pb_2(i\text{-mnt})_4]$. Importance of such interactions though unrevealed yet, should be viewed in light of enzyme binding with the heavy metal (poisoning). Here, we report a new route of synthesis of Ph_3MSMPh_3 [M = Pb(**1**), Sn(**2**)] and their X-ray structures along with the results of quantum chemical studies to critically analyse the possibility of a weak metal–metal interaction of significance.

2. Experimental

2.1. Starting materials

All solvents were of reagent grade quality and purchased commercially. These were purified by standard methods [7]. Anhydrous sodium sulfide (E. Merck), triphenyltin chloride (Aldrich) and triphenyllead chloride were used as received. Thioacetic acid (96%, Aldrich) was distilled before its use.

2.2. Instrumentation

Elemental analyses were performed using an Exter Model E-440 CHN analyser. NMR spectra were obtained using a JEOL AL 300 FTNMR spectrometer.

2.3. X-ray crystal structure determination

Single-crystal X-ray data on **1** and **2** were collected on a Bruker SMART APEX CCD diffractometer using graphite monochromated Mo Kα radiation (λ = 0.71073 Å). The data integration and reduction were processed with SAINT+ [8] software. The structures were solved by the direct method and then refined on F^2 by the full-matrix least-squares technique with the SHELXL-97 software [9] using the WinGX (version 1.70.01) program package [10]. All non-hydrogen atoms were refined anisotropically. All hydrogen atoms were treated as riding atoms using SHELX default parameters. Other crystallographic data are summarized in Table 1. Since the data collections were done at room temperature the thermal ellipsoids on the carbon atoms are large leading to large esds on the C–C distances.

2.4. Theoretical calculations

All theoretical calculations were performed with the GAUSSIAN 03W set of programs [11]. The effective core potential (ECP) standard basis set LanL2DZ [12] was utilized for all the atoms. Polarization functions (*d,p*) were included in the basis set for calculation of

[b] $wR_2 = \{\sum[w(F_0^2 - F_c^2)]/\sum[w(F_0^2)^2]\}^{1/2}$.

bond order. Attempts to use LanL2DZ for Sn/Pb and 6–31V + G** [13] for all other atoms were unsuccessful as convergence criteria [14] could not be met in single point energy calculations using X-ray atomic coordinates.

2.5. Synthesis

2.5.1. Improved preparation of complexes

In a typical synthesis of **1**, THF solutions of triethylamine (0.025 g, 0.25 mmol) (10 ml) and thioacetic acid (0.019 g, 0.25 mmol) were mixed and added to a stirred solution of triphenyllead chloride (0.120 g, 0.25 mmol) in the same solvent (25 ml). After stirring for 4 h the solvent was removed under reduced pressure and the residue was extracted in benzene (25 ml). The filtered solution was then added to a stirred suspension of anhydrous sodium sulfide (0.019 g, 0.25 mmol). After stirring for 3 h the precipitate was filtered off and the solvent was evaporated from the filtrate. The residue was recrystallized from its benzene solution by slow evaporation of the solvent. Yield (0.183 g) 80%. *Anal.* Calc. for $C_{36}H_{30}Pb_2S$: C, 47.56; H, 3.33. Found: C, 47.05; H, 3.30%. **2** was also prepared following a similar procedure. Yield (85%), *Anal.* Calc. for $C_{36}H_{30}S$: C, 59.06; H, 4.13. Found: C, 58.71; H, 4.19%.

3. Results and discussion

3.1. Syntheses

Bahr and Boudjouk have reported the synthesis of **1** in 58% yields by a reaction of Ph_3PbCl with Na_2S (generated in situ by a reaction of elemental sulfur and sodium metal in presence of a catalytic amount of naphthalene) [15]. In a similar reaction, when triphenyllead chloride was treated with thioacetic acid in presence of triethylamine followed by a reaction with anhydrous sodium sulfide **1** was isolated in more than 80% yields. In an analogous reaction when Ph_3PbCl was replaced with its tin analogue **2** was obtained:

$$Ph_3MCl + MeCOSH + Et_3N \xrightarrow{M=Pb,\,Sn} Ph_3M(SOCMe) + Et_3NHCl$$

$$2Ph_3M(SOCMe) + Na_2S \rightarrow (Ph_3M)S + 2Na(OSCMe)$$

3.2. X-ray crystallography

Single crystals suitable for X-ray diffraction analyses were grown from its benzene solution. **1** crystallizes in orthorhombic crystal system ($P2_12_12_1$). Molecular structure and numbering scheme are given in Fig. 1 and important bond dimensions are given in Table 2. The discrete molecular unit contains two Ph_3Pb groups bonded to the sulfur asymmetrically. The two S–Pb distances are different and so are the alignments of the two Ph_3Pb groups with respect to each other. As can be seen in Fig. 1 there are two phenyl rings bonded to Pb1 atom which are sufficiently close to other two phenyl rings bonded to Pb2 to allow π–π interactions. Both the phenyl ring pairs are arranged in a displaced T-shape with centroid–centroid distances of 4.86 and 5.24 Å.

An interesting feature in the molecular structure is the Pb···Pb distance of 3.989 Å which is little shorter than the sum of their van der Waals' radii (4.04 Å) [16]. On the other hand the Pb–Pb distance in $[AsPh_4]_4[Pb_2(i\text{-mnt})_4]$ is much shorter being 3.70 Å. Similarly, in a binary intermetallic compound $Ti_6Pb_{4.8}$ the Pb–Pb distance is 3.74 Å [17]. In these compounds the existence of a Pb···Pb bond though weak is unquestionable. Structures of a few β-diketonates of lead have been reported recently. The Pb···Pb distance in these dimeric compounds varies from 3.80 to 4.14 Å [18–20] and existence of any Pb···Pb bonding is ambiguous in these complexes.

It is sometimes vexing to interpret the nature of Pb–Pb bonding based on just bond distance measurements [21–22] The PbPb double bond is known to be longer than the single bond [23]. Similar inconsistencies are apparent in weak interactions too. Although the sum of van der Waals' radii is 4.04 Å [16], Pb–Pb distances in $Pb_6O(OH)_6^{4+}$ ranges between 3.44 and 4.09 Å.[24]. The chains and layers in both α- and β-PbO are held together by real Pb–Pb bonds (not just van der Waals' forces) but the Pb–Pb distances are quite long (up to 3.97 Å) [25].

To gain further insight in the bonding we have reexamined the molecular structure of the analogous tin compound **2**. An ORTEP drawing of the molecular structure of **2** is given in Fig. 2. Results of our study are not much different from the earlier report [26]. However, we could refine the structure much better. The Sn–Sn

Table 2
Selected geometric parameters of **1** and **2**.

Distances (Å)	M = Pb	M = Sn
M–M	3.989	3.879
S–M1	2.491	2.402
S–M2	2.484	2.397
C1–M1	2.214	2.120
C7–M1	2.200	2.148
C13–M1	2.202	2.142
C19–M2	2.179	2.126
C25–M2	2.196	2.138
C31–M3	2.199	2.145
Angles (°)		
M_1–S–M_2	106.61	107.86
Dihedral angles (°)		
M1–S–M2–C19	−24.8	−27.7
M1–S–M2–C25	97.7	94.76
M1–S–M2–C31	145.1	−147.0
M2–S–M1–C13	−166.9	−46.97
M2–S–M1–C7	76.4	−163.92
M2–S–M1–C1	−49.7	78.8

distance in this molecule being 3.879 Å (Table 2) is quite shorter than the sum of their van der Waals' radii (4.34 Å) which is indicative of a weak Sn···Sn bonding.

The M–S–M angle in **1** is smaller than that in **2** which may apparently be attributed to the higher electronegativity of **1** (VSEPR theory). Glidewell and Liles have rationalized the geometrical properties of $(R_3M)_2S$ molecules on the basis of second order Jahn–Teller effect. They have concluded that the angular geometry of S will be anomalous in the context of the VSEPR [26]. Since the electronegativity decreases from Ge to Sn (2.01 and 1.96, respectively) the M–S–M angle also decrease in the same fashion (Ge–S–Ge = 111.0°; Sn–S–Sn = 107.86°). Since electronegativity of Pb is higher (2.33) than both Sn and Ge the Pb–S–Pb angle should be still larger. Thus a smaller Pb–S–Pb angle in **1** indicates the existence of a Pb–Pb bond.

3.3. Theoretical studies

Since in the present case the Pb–Pb distance is almost at the edge we performed theoretical calculations using density functional theory (DFT) method [27] to understand the electronic structure of the compound and nature of the Pb···Pb bond. The atomic coordinates for the calculations were obtained from the X-ray data. Single point energy calculation and bond order calculations were performed using LanL2DZ (*d*,*p*) basis set at B3LYP level. Pb···Pb bond order (Wiberg) is only 0.0085 which is too small to be of any significance.

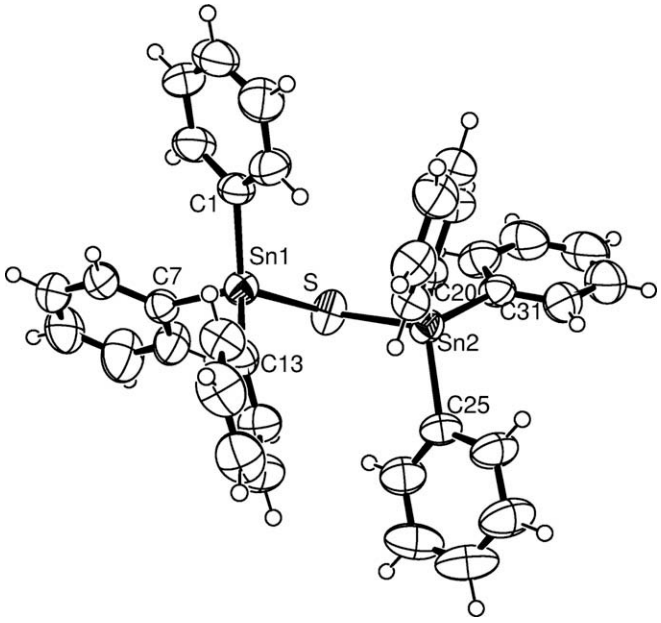

Fig. 2. ORTEP drawing of **2**.

Recently, Inagaki and co-workers have reported the structures of $RC(O)SMR'_3$ (M = Ge, Sn, Pb) [28]. On the basis of NBO analyses they have concluded intramolecular $n_O \rightarrow \sigma_{MS}$ interactions to be responsible for short M–O distances in these molecules. Results of second order perturbation theory analysis of Fock matrix (NBO) using LanL2DZ basis set reveal that similar bonding interactions are present both in **1** and **2** due to electron transfers from σ_{SM} to $\sigma^*_{M'C}$ orbitals. The contour diagram showing the overlap of

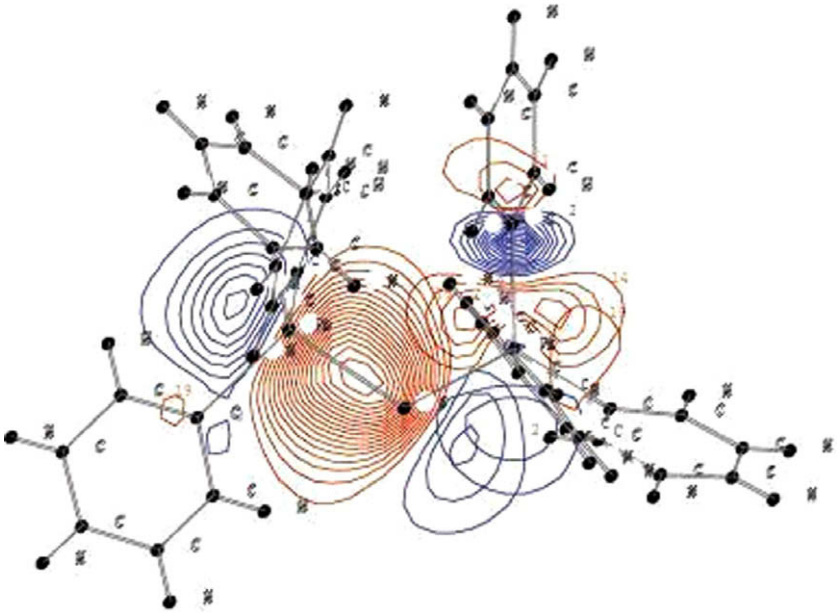

Fig. 3. Contour diagram showing natural bond orbital overlap.

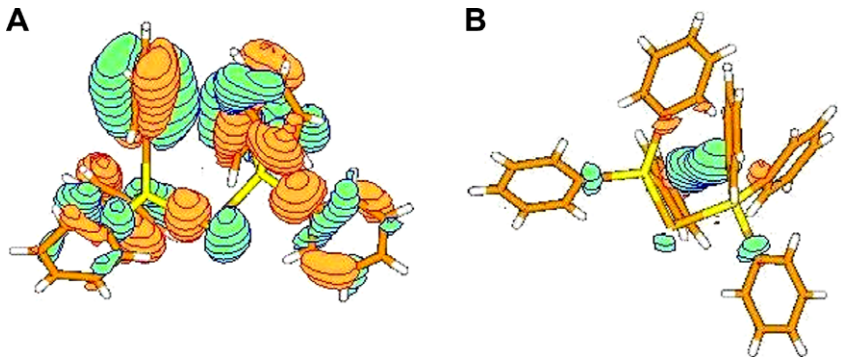

Fig. 4. π–π interactions in **1**.

orbitals is given in Fig. 3. It is clear from the figure that the extent of overlap is small and the nature of bond is essentially very weak. The stabilization energies associated with the delocalization are only 1.62 and 1.24 kcal/mol for **1** and **2**, respectively. The stabilization energies reported for $RC(O)SMR'_3$ molecules are also of the same order (0.64–2.25 kcal/mol). Similar weak bonding by overlap of molecular orbitals has also been reported in case of some thioacylsulfanylarsines [29]. However, to our understanding it is not logical to draw any conclusion on the basis of such small stabilization energies. Moreover, the lowering in energy does not corroborate to the M–M distance shortening: Sn···Sn distance is shorter than Pb···Pb distance but the stabilization energy is greater in the later case. It should be kept in mind that the crystal packing and even π-stacking energies [30,31] are often higher than the above mentioned delocalization energies. As described already, π–π interactions exist among the phenyl rings in both **1** and **2** (Fig. 4). To evaluate the extent of π–π interactions calculations on benzene dimers have been performed. Single point energies of the benzene dimers have been calculated after constructing them using the atomic coordinates of the carbon atoms of phenyl ring pairs from the X-ray data of **1** while the positions of the hydrogen atoms were optimized. The energies of same benzene dimers without any π–π interactions were then calculated by replacing the C and H atoms of one ring in each turn by ghost atoms. All the calculations were carried out at B3LYP level using 6–31 + G* basis set. Interaction energies were found to be −0.44 and −0.83 kcal/mol for the benzene pairs with centroid–centroid distances of 4.86 and 5.24 Å, respectively.

4. Conclusion

Ph_3MSMPh_3 (M = Sn, Pb) have been prepared using $Ph_3M(SOCMe)$ in high yields. X-ray structures of the compounds showed short M–M distances (compared to the sum of the corresponding van der Waals' radii) which are indicative of weak M···M interactions. DFT studies though revealed electron transfers from σ_{SM} to $\sigma^*_{M'C}$ orbitals but the corresponding stabilizations are too small to contribute to the structure of the molecules. The short MM distances are due to crystal packing effects and π–π interactions.

ABSTRACT

Four new coordination polymers formed by zinc-benzoate with the 1,2-bis(4-pyridyl)ethane (bpe) bridging ligand have been prepared and characterized. Zinc-benzoates can be rationally tuned to form four different structures with a bridging bpe ligand by controlling ligand-to-zinc-benzoate molar ratios and by using different solvent systems, and reveal three coordination polymers having similar one-dimensional characteristics but having different mono-, di-, trinuclear nodes (**1**–**3**), and a dinuclear ring type molecule (**4**). This work reveals that the ligand-to-metal ratio and solvent play very important roles in the formation of different coordination structures. We have also shown that the compounds **1**–**4** catalyzed efficiently the transesterification of a variety of esters. The complex **3** showed the most efficient reactivity and is the best among the catalytic efficiencies reported previously with zinc-containing coordination and polymeric compounds. The substrates with the electron-withdrawing substituents have undergone faster transesterification than those with the electron-donating ones. In addition, the scope of the application of **1**–**4** as transesterification catalysts has been expanded to now include ethanol and propanol, suggesting that this catalytic system can be potentially useful for preparing various esters by transesterification. Moreover, the transesterification reaction mechanism was discussed by ^{1}H NMR study.

1. Introduction

The design and construction of metal-organic coordination polymers has recently attracted much attention not only due to their structural and topological novelty [1–8], but also for their potential applications as functional materials such as gas storage [9–15], ion-exchange [16,17], catalysis [18–27], magnetism [28–30], and molecular sensing [31]. The rational design of these coordination polymers is highly affected by several factors such as the coordination geometry of metal ions [32,33], the structure of organic ligands [34–36], the solvent system [37,38], pH value [39–41], temperature [42,43], the counteranion [44,45], and the ligand-to-metal ratio [46,47]. Therefore, an investigation for understanding the relationships between the structures of complexes and those factors is at the center of controlling coordination network assembly.

Though numerous coordination polymers and macrocycles have been generated from transition metal nodes with a variety of organic spacers over the past few years, there is still little understanding of how ligand-to-metal stoichiometry and solvent system among several factors can be used to control the type of polymeric structures. While these two factors are relatively notable in copper- and silver-containing coordination polymers [48–53], their influence on the formation of coordination polymers, especially, with zinc ion is much less well understood and systematic studies of their role are very scarce [54–56].

Quite recently, we have reacted zinc-benzoate with pyrazine and its derivatives, 2,3-dimethylpyrazine, 2,5-dimethylpyrazine, 2,6-dimethylpyrazine, and quinoxaline, and characterized five new Zn(II)-benzoate coordination architectures, from dinuclear, trinuclear and pentanuclear complexes to one-dimensional and two-dimensional coordination polymers [57]. These results have shown that the substituents of pyrazine are very important roles for construction of various zinc-benzoate complexes. Interestingly, the compounds catalyzed efficiently the transesterification of a variety of esters.

As an extension of our previous work, in this study, we have investigated the complex formation of zinc-benzoate with another bridging ligand 1,2-bis(4-pyridyl)ethane (bpe) in order to further

doi:10.1016/j.poly.2008.11.048

prepare functional supramolecular complexes with intriguing structures and potential applications especially in catalysis and to systematically investigate the influence of the concentration and solvent effects less studied on the assembly processes of the structure of zinc-carboxylate containing coordination polymers. Here, we report the syntheses, characterization and crystal structures of four zinc coordination complexes $[Zn_2(O_2CPh)_4(H_2O)_2][Zn(O_2CPh)_2\text{-}(bpe)]_n$ (**1**), $[Zn_3(O_2CPh)_6(bpe)]_n$ (**2**), $[(Zn_3(O_2CPh)_6)(\mu\text{-}bpe)(Zn_2(O_2CPh)_4)]_n$ (**3**), and $[Zn_2(O_2CPh)_4(bpe)_2]$ (**4**) from the reaction of zinc-benzoate and bpe which were obtained by tuning solvent mixtures and ligand-to-zinc-benzoate ratios. These complexes contain mononuclear nodes **1**, trinuclear nodes **2**, and trinuclear alternating with dinuclear nodes **3** and a discrete dinuclear complex **4**, respectively. These results illustrate how both stoichiometry and solvent play a vital role in affecting the product formation, their structures and topology. We have also reported that the compounds **1**–**4** catalyzed efficiently the transesterification of a variety of esters with different alcohols, and discussed about the reaction mechanism of the transesterification reaction based on ^{1}H NMR study.

2. Experimental

Materials: Acetone, methanol, ethanol, methylene chloride, propanol, 2-propanol, *para*-substituted phenyl acetate, *para*-substituted phenyl benzoate, methylacetate, methylbenzoate, 1,2-bis(4-pyridyl)ethane (bpe), ammonium benzoate, and zinc nitrate hexahydrate were purchased from Aldrich and were used as received. 4-Fluorophenyl acetate and 4-nitrophenyl benzoate were obtained from Lancaster.

Instrumentation: Elemental analysis for carbon, nitrogen, and hydrogen was carried out by using an EA1108 (Carlo Erba Instrument, Italy) in the Organic Chemistry Research Center of Sogang University, Korea. IR spectra were measured on a BIO RAD FTS 135 spectrometer as KBr pellets. Product analysis for the transesterification reaction was performed on either a Hewlett–Packard 5890 II Plus gas chromatograph interfaced with Hewlett–Packard Model 5989B mass spectrometer or a Donam Systems 6200 gas chromatograph equipped with a FID detector using 30-m capillary column (Hewlett–Packard, HP-1, HP-5, and Ultra 2). ^{1}H NMR spectra were recorded on a Varian Mercury 400 spectrometer. Chemical shifts (δ) are reported in ppm, relative to TMS (0.00).

*Synthesis of $[Zn_2(O_2CPh)_4(H_2O)_2][Zn(O_2CPh)_2(bpe)]_n$ (**1**):* 38.0 mg (0.125 mmol) of $Zn(NO_3)_2 \cdot 6H_2O$ and 36.0 mg (0.25 mmol) of $C_6H_5COONH_4$ were dissolved in 4 ml water and carefully layered by 4 ml acetone solution of 1,2-bis(4-pyridyl)ethane (11.6 mg, 0.0625 mmol). The yield was 34.5 mg (21.2%) for compound **1**. Suitable crystals of compound **1** for X-ray analysis were obtained in a week. The structure **1** was also obtained with the same ratio of bpe to zinc-benzoate in methylene chloride (4 ml) /methanol (4 ml) system. *Anal.* Calc. for $C_{66}H_{56}N_4O_{13}Zn_3$ (1309.26), **1**: C, 60.54; H, 4.32; N, 4.28. Found: C, 60.45; H, 4.30; N, 4.55%. IR (KBr): ν (cm^{-1}) = 3422(br), 3064(w), 2362(m), 1619(s), 1572(m), 1364(s), 1229(w), 1070(w), 1030(w), 940(w), 720(s), 684(w), 550(m).

*Synthesis of $[Zn_3(O_2CPh)_6(bpe)]_n$ (**2**):* 38.0 mg (0.125 mmol) of $Zn(NO_3)_2 \cdot 6H_2O$ and 36.0 mg (0.25 mmol) of $C_6H_5COONH_4$ were dissolved in 4 ml methanol and carefully layered by 4 ml methylene chloride solution of 1,2-bis(4-pyridyl)ethane (23.3 mg, 0.125 mmol). The yield was 53.7 mg (38.9%) for compound **2**. Suitable crystals of compound **2** for X-ray analysis were obtained in 5 days. The structure **2** was also obtained with the ratio of bpe to zinc-benzoate (0.5:1) in ethanol/water system. *Anal.* Calc. for $C_{54}H_{42}N_2O_{12}Zn_3$ (1107.01), **2**: C, 58.58; H, 3.83; N, 2.53. Found: C, 58.64; H, 3.93; N, 2.65%. IR (KBr): ν (cm^{-1}) = 3078(w), 2958(w), 2362(w), 1613(s), 1572(m), 1445(m), 1367(s), 1227(m), 1066(m), 1032(m), 939(w), 842(w), 812(m), 715(s), 683(m), 558(w), 524(m), 431(w).

*Synthesis of $[(Zn_3(O_2CPh)_6)(\mu\text{-}bpe)(Zn_2(O_2CPh)_4)]_n$ (**3**):* 38.0 mg (0.125 mmol) of $Zn(NO_3)_2 \cdot 6H_2O$ and 36.0 mg (0.25 mmol) of $C_6H_5COONH_4$ were dissolved in 4 ml water and carefully layered by 4 ml acetone solution of 1,2-bis(4-pyridyl)ethane (26.6 mg, 0.25 mmol). The yield was 58.3 mg (24.5%) for compound **3**. Suitable crystals of compound **3** for X-ray analysis were obtained in a week. *Anal.* Calc. for $C_{94}H_{74}N_4O_{20}Zn_5$ (1906.42), **3**: C, 59.22; H, 3.92; N, 2.94. Found: C, 59.51; H, 3.81; N, 2.72%. IR (KBr): ν (cm^{-1}) = 3077(brm), 1619(s), 1573(s), 1438(m), 1364(s), 1229(m), 1173(m), 1069(m), 1032(m), 940(w), 841(m), 811(m), 719(s), 684(m), 558(w), 524(m), 439(w).

*Synthesis of $[Zn_2(O_2CPh)_4(bpe)_2]$ (**4**):* 38.0 mg (0.125 mmol) of $Zn(NO_3)_2 \cdot 6H_2O$ and 36.0 mg (0.25 mmol) of $C_6H_5COONH_4$ were dissolved in 4 ml water and carefully layered by 4 ml methanol solution of 1,2-bis(4-pyridyl)ethane (23.3 mg, 0.125 mmol). The yield was 78.0 mg (63.4%) for compound **4**. Suitable crystals of compound **4** for X-ray analysis were obtained in five days. The structure **4** was also obtained with the ratios of bpe to zinc-benzoate (2:1 and 4:1) in methanol/water and (3:1 and 4:1) in ethanol/water system, respectively. *Anal.* Calc. for $C_{52}H_{44}N_4O_8Zn_2$ (983.65), **4**: C, 63.49; H, 4.52; N, 5.70. Found: C, 63.70; H, 4.49; N, 5.47%. IR(KBr): ν (cm^{-1}) = 3078(m), 2958(w), 1612(s), 1572(s), 1429(m), 1367(s), 1227(m), 1171(w), 1066(m), 1032(m), 939(w), 842(m), 812(m), 715(s), 683(m), 558(m), 524(m), 431(m).

*Catalytic activity of compounds **1**–**4**:* Catalytic homogeneous reaction conditions: Ester (0.05 mmol) was dissolved in an appropriate solvent (1 ml), methanol or propanol, and the catalyst (1.3 mg, 1.10×10^{-3} mmol for **1**, 1.9 mg, 1.01×10^{-3} mmol for **2**, 1.0 mg, 1.00×10^{-3} mmol for **3**, and 0.986 mg, 1.00×10^{-3} mmol for **4**, respectively) were added and shaken in an incubator at 50 °C (450 rpm). Reaction conversion was monitored by GC/Mass analysis of 20 μl aliquots withdrawn periodically from the reaction mixture. All reactions were run at least three times and the average conversion yields are presented.

*NMR experiments for the structural determination of the complex **4** before and after the transesterification reaction:* ^{1}H NMR spectra of ammonium benzoate and bpe were obtained in CD_3OD at room temperature. For ammonium benzoate, ^{1}H NMR (CD_3OD, 400 MHz): δ 7.91–7.94 (m, 2H, aromatic-*ortho*-H), *δ 7.30–7.44* (m, 3H, aromatic-*meta*-H and aromatic-*para*-H). For bpe, ^{1}H NMR (CD_3OD, 400 MHz): δ 8.38–8.40 (d, 2H, aromatic-*meta*-H), *δ 7.27–7.29* (d, 2H, aromatic-*ortho*-H), *δ* 3.032 (s, 4H, CH_2). ^{1}H NMR spectrum of the complex **4** was obtained in CD_3OD; ^{1}H NMR (CD_3OD, 400 MHz): δ 8.02–8.05 (m, 2H, aromatic-*ortho*-H for benzoate), *δ 7.45–7.50* (q, 1H, aromatic-*para*-H for benzoate), *δ 7.37–7.42* (q, 2H, aromatic-*meta*-H for benzoate), *δ 8.40–8.43* (d, 2H, aromatic-*meta*-H for bpe), *δ 7.29–7.32* (d, 2H, aromatic-*ortho*-H for bpe), *δ* 3.045 (s, 4H, CH_2 for bpe). ^{1}H NMR spectrum of the complex **4** was again obtained after the reaction mixture of **4** and phenyl acetate in CD_3OD was incubated for 1 day at 50 °C. The transesterification reaction of phenyl acetate was found to be complete by GC and ^{1}H NMR. ^{1}H NMR (CD_3OD, 400 MHz): 8.02–8.05 (m, 2H, aromatic-*ortho*-H for benzoate), *δ 7.45–7.50* (q, 1H, aromatic-*para*-H for benzoate), *δ 7.37–7.41* (q, 2H, aromatic-*meta*-H for benzoate), *δ 8.41–8.43* (d, 2H, aromatic-*meta*-H for bpe), *δ 7.29–7.31* (d, 2H, aromatic-*ortho*-H for bpe), *δ* 3.045 (s, 4H, CH_2 for bpe).

X-ray crystallography: The X-ray diffraction data for all four compounds were collected on a Bruker SMART AXS diffractometer equipped with a monochromater n the Mo Kα (λ = 0.71073 Å) incident beam. Each crystal was mounted on a glass iber. The CCD data were integrated and scaled using the Bruker-SAINT software package, and the structure was solved and refined using SHEXTL V6.12 [58]. All hydrogen atoms were placed in the calculated positions. The crystallographic data for compounds **1**–**4** are listed in Table 1.

3. Results and discussion

To investigate the effect of solvent and ligand-to-metal ratio on the structures of zinc-containing coordination polymers, we have reacted Zn(II)-benzoate with 1,2-bis(4-pyridyl)ethane (bpe) by changing the solvent systems and ligand-to-zinc-benzoate ratios. The coordination complexes **1**–**4** were prepared cleanly as single phase crystalline products, respectively. The infrared spectra of **1**–**4** were fully consistent with their formulations. Asymmetric and symmetric C=O stretching modes of the ligated benzoate moieties were evidenced by very strong, slightly broadened bands at ~1600 cm^{-1} and ~1400 cm^{-1} [59–61]. The absence of any bands in the area of ~1710 cm^{-1} indicates full deprotonation of all carboxylate groups in **1**–**4** [59–61].

The reaction of zinc-benzoate with the bpe ligand revealed four different structures as a function of ligand concentration in the different solvent systems. The relationship between the molar ratio of bpe-to-zinc-benzoate and the solvent system is shown in Table 2. Compound **1** was obtained with the molar ratio of bpe-to-zinc-benzoate of 0.5:1 both in the acetone/H_2O system and in the methylene chloride/methanol system. Compound **2** was obtained with the molar ratios of bpe-to-zinc-benzoate of 0.5:1 in the ethanol/H_2O system and of 1:1 in the methylene chloride/methanol system, respectively, and compound **3** was obtained with the molar ratio of 2:1 in the acetone/H_2O system. When we use the methanol/H_2O system, only compound **4** was obtained with any molar ratios of bpe-to-zinc-benzoate (1:1, 2:1, and 4:1). **4** was also obtained with the molar ratios of both 3:1 and 4:1 in the ethanol/H_2O system, and **4** could not be obtained from the acetone/H_2O system. These results indicate that the formation of compounds **1**–**4** depends primarily on both the bpe ligand-to-zinc-benzoate ratios and the solvent systems.

*The structure of compound (**1**):* An X-ray structural analysis revealed that compound **1** consists of mononuclear $Zn(O_2CC_6H_5)_2$ units bridged by bpe (bpe = 1,2-bis(4-pyridyl)ethane) ligand to form a one-dimensional zigzag chain (Fig. 1a). Zn(II) ion is coordinated by two monodentate benzoate ligands, two bridging bpe ligands with a tetrahedral geometry. The Zn–$O_{benzoate}$ bond distances are 1.932(2) and 1.964(1) Å that are similar to those found in $[Zn(O_2CCH_3)_2(\mu\text{-bpe})]\cdot 2H_2O$ (1.922(3) and 1.949(3) Å) [62] and $[Zn(O_2CCH_3)_2(py)_2]$ (1.941(4) and 1.945(2) Å, py = pyridine)[63] and the Zn–N_{bpe} bond distances range from 2.036(2) to 2.075(2) Å which are typical in Zn complexes (ranging from 2.010(3) to 2.044(3) Å) [62,63]. The packing diagram of the one-

[a] Zinc-benzoate ($Zn(NO_3)_2\cdot 6H_2O + C_6H_5COONH_4$) was dissolved in water and layered by an acetone solution of bpe.
[b] Zinc-benzoate ($Zn(NO_3)_2\cdot 6H_2O + C_6H_5COONH_4$) was dissolved in water and layered by an ethanol solution of bpe.
[c] Zinc-benzoate ($Zn(NO_3)_2\cdot 6H_2O + C_6H_5COONH_4$) was dissolved in water and layered by a methanol solution of bpe.
[d] Zinc-benzoate ($Zn(NO_3)_2\cdot 6H_2O + C_6H_5COONH_4$) was dissolved in methanol and layered by a methylene chloride solution of bpe.
[e] A one-dimensional zigzag chain containing $Zn(O_2CPh)_2$ units bridged by bpe ligands with dinuclear paddle-wheel $Zn_2(O_2CPh)_4(H_2O)_2$, $[Zn_2(O_2CPh)_4(H_2O)_2]$-$[Zn(O_2CPh)_2(bpe)]_n$.
[f] A one-dimensional chain containing trinuclear $Zn_3(O_2CPh)_6$ units bridged by bpe ligands, $[Zn_3(O_2CPh)_6(bpe)]_n$.
[g] A one-dimensional chain containing trinuclear $Zn_3(O_2CPh)_6$ units and dinuclear $Zn_2(O_2CPh)_4$ units bridged by bpe ligands alternatively, $[(Zn_3(O_2CPh)_6)(\mu\text{-bpe})(Zn_2(O_2CPh)_4)]_n$.
[h] A dinuclear ring molecule containing two $Zn(O_2CPh)_2$ bridged by two bpe ligands, $[Zn_2(O_2CPh)_4(bpe)_2]$.
[i] We could not obtain any crystals suitable for X-ray analysis under these conditions.

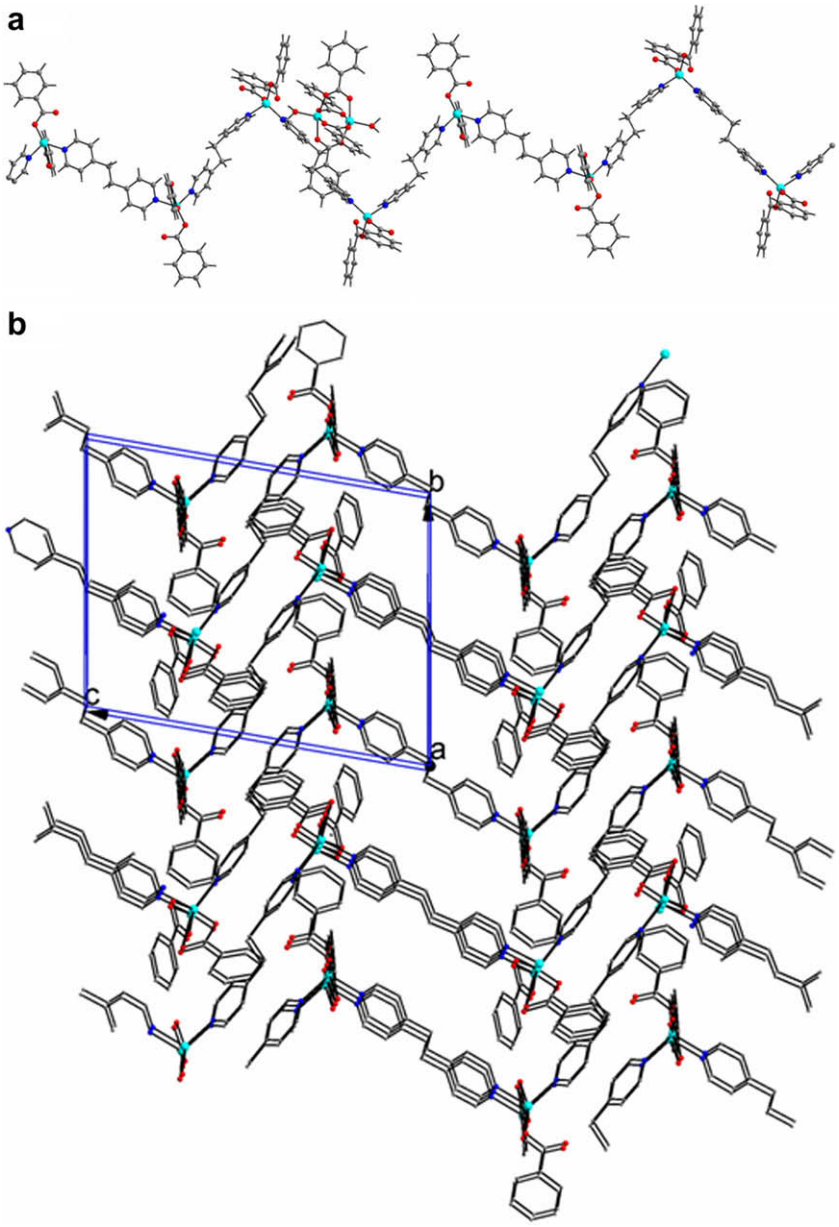

Fig. 1. (a) Structure of one-dimensional zigzag chain coexisting with dinuclear paddle-wheel Zn complex, **1**. (b) The packing diagram of the one-dimensional zigzag chains along an axis. All hydrogen atoms were omitted for clarity.

dimensional zigzag chains is shown in Fig 1b. There coexist dinuclear paddle-wheel type $Zn_2(O_2CC_6H_5)_4$ molecules with water axial ligands (Fig. 1a). Each Zn atom in this unit has distorted square-pyramidal environment, with four oxygen atoms from benzoates, which form the equatorial plane, and one water oxygen atom. The $Zn–O_{benzoate}$ bond distances range from 2.042(2) to 2.062(2) Å longer than those of the 1-D zigzag chain, but similar to those of the paddle-wheel type complexes [64–67], and the $Zn–O_{water}$ bond distance is 1.986(1) Å (Table 3). The Zn···Zn distance is 2.983(2) Å similar to those found in $Zn_2(MeCH{=}CHCO_2)_4(quinoline)_2]$ (2.976 Å) [64], $[Zn_2(O_2CPh)_4(py)_2]$ (2.927(4) Å) [65], [Zn(bdc)·(DMF)(H_2O)] (2.940(3) Å) [66], and $[Zn_2(bdc)_2(dabco)]$ (2.909(1) Å, bdc = 1,4-benzenedicaboxylate and dabco = 1,4-diazabicyclo[2.2.2]octane) [67]. There is a hydrogen bond interaction between oxygen atom of a benzoate ligand in a zigzag chain and the axial water hydrogen atom of a dinuclear unit ($O22_{benzoate}$···$H15A–O15_{water}$ 1.657(2) Å). Importantly, this is the first example of coexistence of 1-D and Zn dinuclear paddle-wheel type, to our best knowledge.

*The structure of compound (**2**):* An X-ray structural analysis revealed that compound **2** consists of trinuclear $Zn_3(O_2CC_6H_5)_6$ units bridged by bpe ligand to form a one-dimensional chain (Fig. 2a). A trinuclear Zn(II)-benzoate unit is constructed by six bridging benzoate ligands and similar to the previously described trinuclear zinc-carboxylate with axial N- or O-donor ligands [57,65,68–70]. There is an inversion center on the central Zn atom. Out of three Zn centers the central Zn is all O-donor hexa-coordinated from six benzoate groups to form a distorted octahedral geometry. The other two Zn centers are symmetric to each other, and each has a bridging bpe ligand and four oxygen atoms from benzoate ligands. Thus each Zn1 center has NO4 coordination environment with distorted trigonal bipyramid geometry. The coordination modes of benzoate ligands show two kinds of bridging modes [71–73]: one mode is a typical bridging mode, and the other is

Table 3
Selected bond distances for compounds **1**, **2**, **3**, and **4**.

	1	2	3	4
Zn–O (Å)	1.932(2)–2.062(2)	1.9628(16)–2.2640(19)	1.9607(19)–2.373(2)	1.950(3), 1.951(3)
Zn–N (Å)	2.036(2)–2.075(2)	2.0384(18)	2.035(2)	2.039(3), 2.064(3)
Zn–Zn (Å)	2.9827(7) (paddle-wheel type unit)	3.370(2)	2.9541(5) (paddle-wheel type unit), 3.347(2) (trinuclear unit)	8.502(14)

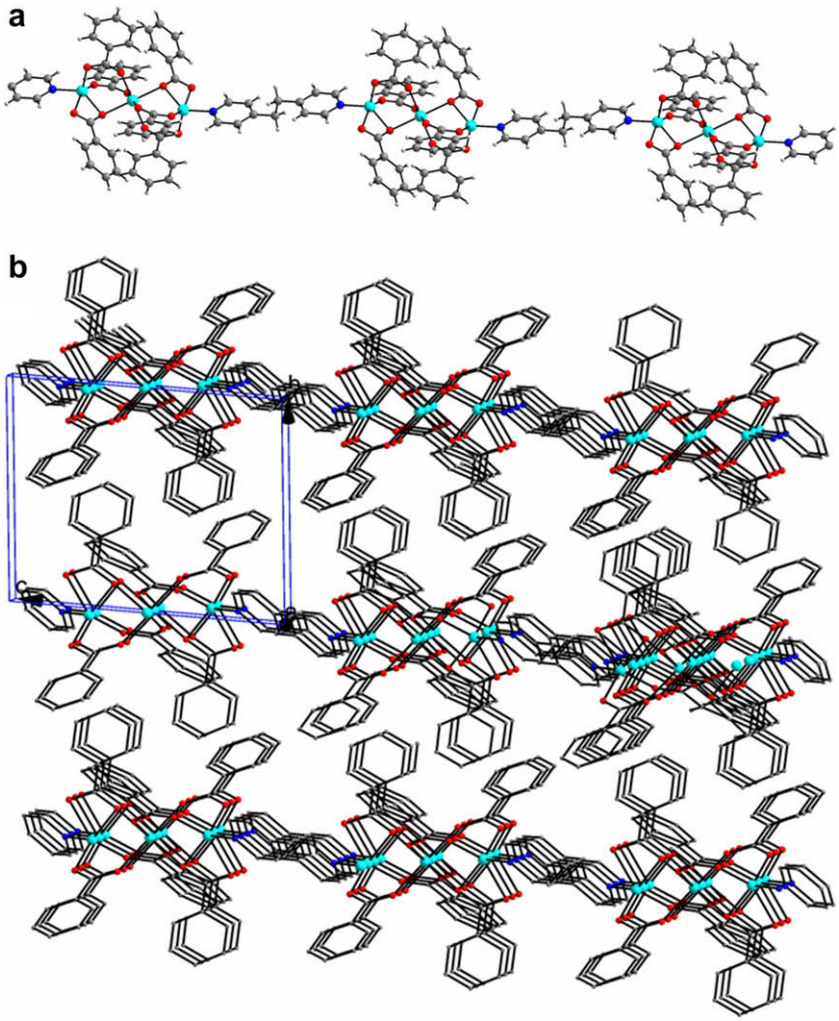

Fig. 2. (a) Structure of one-dimensional chain **2** containing trinuclear Zn units bridged by bpe ligands. (b) The packing diagram of the one-dimensional zigzag chains along an axis. All hydrogen atoms were omitted for clarity.

the unusual coordination mode, a monatomic coordination mode, that chelates to one Zn2 atom and, at the same time, bridges the other Zn1 atom as shown in Fig. 2a. This unusual coordination mode of carboxylate group provides a big distortion around Zn1. The packing diagram is shown in Fig. 2b. In the typical bridging carboxylate coordination mode, Zn1–$O_{bridging}$ distances are 1.963(1) and 1.968(1) Å, and Zn2–$O_{bridging}$ distances are 2.014(1) and 2.098(1) Å. In the unusual coordination mode, Zn2–$O_{bridging}$ distance is 2.207(2) Å which is a little longer than typical one, and Zn1–$O_{chelating}$ distances are 2.103(1) and 2.264(1) Å. Zn–N bond distance is 2.038(1) Å which is typical in Zn complexes (Table 3) [68–70]. The Zn···Zn distance is 3.370(2) Å that is much longer than that of dinuclear one in the compound **1**, and that can be comparable to those found in $[Zn_3(MeCH{=}CHCO_2)_6(quinoline)_2]$ (3.26 Å) [68], $[Zn_3(O_2CPh)_6(2,3\text{-diMepz})_2]$ (3.362(4) Å, 2,3-diMepz = 2,3-dimethylpyrazine) [57], $\{[Zn_3(1,4\text{-BDC})_3(DEF)_2]\cdot DEF\}_\infty$ (3.228(4) and 3.528(4) Å, 1,4-BDC = 1,4-benzene dicarboxylate and DEF = diethylformamide) [70].

*The structure of compound (**3**):* An X-ray structural analysis revealed that compound **3** consists of dinuclear paddle-wheel type $Zn_2(O_2CC_6H_5)_4$ units and trinuclear $Zn_3(O_2CC_6H_5)_6$ units bridged by bpe ligands alternatively to form a one-dimensional chain (Fig. 3a). Trinuclear $Zn_3(O_2CC_6H_5)_6$ units are similar to that of compound **2**, and dinuclear paddle-wheel type $Zn_2(O_2CC_6H_5)_4$ units are similar to that of the dinuclear one in compound **1**. While the trinuclear zinc-carboxylate units and the dinuclear paddle-wheel zinc-carboxylate units of structures from zinc-carboxylates have been often reported in literature [63,64–70], this arrangement in which bipyridyl ligands bridge dinuclear units and trinuclear units alternatively is unprecedented, to our best knowledge. On the other hand, it is worthwhile to mention that in $Cu_2(maa)_4$/bpp systems (Hmaa = 2-methylacrylic acid, bpp = 1,3-bis(4-pyridyl)pro-

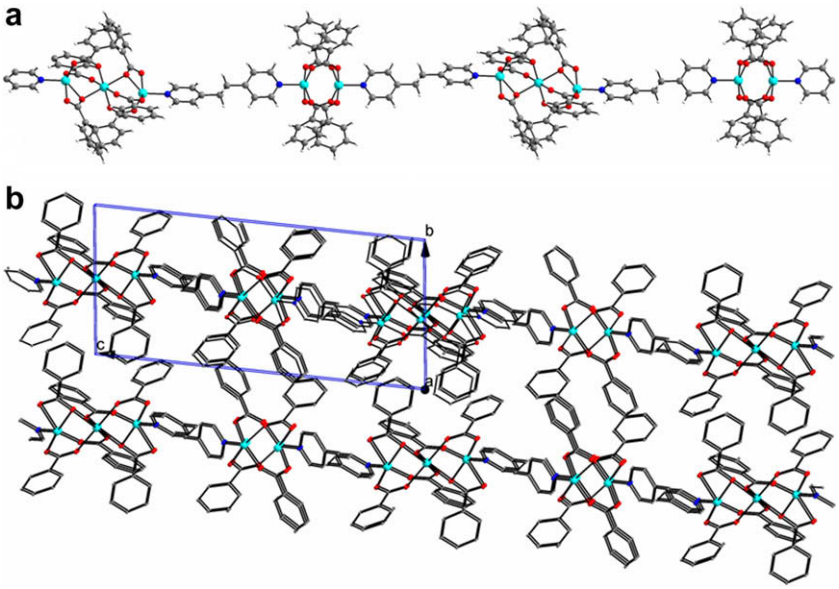

Fig. 3. (a) Structure of one-dimensional chain **3** containing dinuclear and trinuclear units bridged by bpe ligands alternatively. (b) The packing diagram of the one-dimensional zigzag chains along an axis. All hydrogen atoms were omitted for clarity.

pane), dinuclear and mononuclear alternating paddle-wheel 1-D instead of trinuclear and dinuclear alternating 1-D has been observed [48]. However, we could not obtain the dinuclear and mononuclear alternating polymer systems in our Zn systems. The packing diagram is shown in Fig. 3b. In the dinuclear unit, the Zn–$O_{bridging}$ bond distances range from 2.0240(19) to 2.054(2) Å similar to those of the dinuclear unit in the compound **1**, and the Zn–N bond distance is 2.035(2) Å which is typical in Zn complexes [64–67]. In the trinucelar unit, the Zn–$O_{bridging}$ bond distances of the typical bridging mode range from 1.9607(19) to 2.0903(19) Å, the Zn2–$O_{chelating}$ bond distances of the unusual coordination mode are 2.0491(17) and 2.373(2) Å, and the Zn1–$O_{bridging}$ bond distance of the unusual mode is 2.2428(17) Å which is a little longer than that of compound **2**. The Zn–N bond distance of the unusual mode is 2.035(2) Å which is typical in Zn complexes (Table 3) [68–70]. The Zn···Zn distances of dinuclear and trinuclear units are 2.9541(5) and 3.347(2) Å, respectively, which are shortened from dinuclear unit of **1** and trinuclear unit of **2**.

*The structure of compound (**4**):* An X-ray structural analysis revealed that compound **4** consists of two $Zn(O_2CC_6H_5)_2$ bridged by two bpe ligands to form a dinuclear molecule (Fig. 4). The Zn(II) ion has a distorted tetrahedral environment with two monodentate benzoate ligands and two bridging bpe ligands. The bpe ligand adopts a gauche conformation to form a ring type molecule. The Zn–O bond distances are 1.950(1) and 1.951(1) Å which are a little shorter than those of compounds **1**, **2**, and **3**, and the Zn–N bond distances are 2.039(2) and 2.064(6) Å which are typical in Zn complexes (Table 3). The Zn···Zn distance is 8.502(14) Å.

Structural diversity of zinc polymeric compounds by tuning ligand-to-metal ratio and solvent system: Zinc-benzoates can be rationally tuned to form four different structures with a bridging bpe ligand by controlling ligand-to-zinc-benzoate molar ratios and by using different solvent systems, and reveal three coordination polymers having similar one-dimensional characteristics but having different mono-, di-, trinuclear nodes, and a dinuclear ring type molecule. In case of the low concentration of the bpe ligand such as the bpe-to-zinc-benzoate molar ratio of 0.5:1 in both acetone/H_2O and CH_2Cl_2/MeOH solvent systems, compound **1** was obtained and revealed unprecedented one-dimensional zigzag chains coexisting with the paddle-wheel type dinuclear Zn_2 units which would not participate to form an one-dimensional chain. If the concentration of bpe ligand increases such as 1:1 molar ratio in acetone/MeOH solvent system, compound **2** was obtained and revealed trinuclear units connected by bpe ligands to form one-dimensional chains without the paddle-wheel type Zn_2 units. In ethanol/H_2O solvent system, **2** was also obtained in 0.5:1 bpe-to-zinc-benzoate molar ratio. If the concentration of bpe ligands increases more such as 2:1 molar ratio in acetone/H_2O system, compound **3** was obtained and revealed trinuclear and dinuclear units connected by bpe ligands alternatively, that is the first example in zinc-carboxylate systems. If the concentration of bpe ligands increases much more such as 4:1 molar ratio in EtOH/H_2O system, compound **4** was obtained and revealed the dinuclear ring type molecule which is a totally different structure from the previous structures. In MeOH/H_2O solvent system, importantly, only **4** was obtained without respect to the molar ratio of bpe-to-zinc-benzoate.

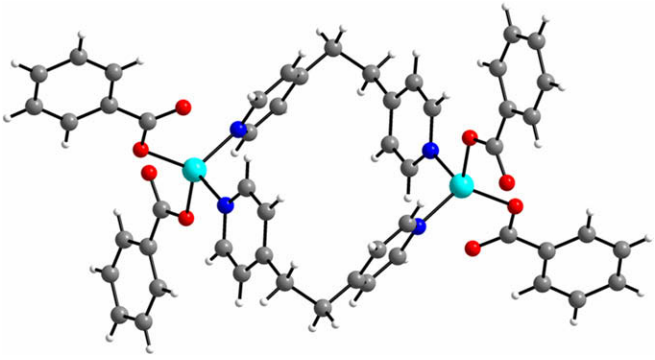

Fig. 4. Structure of dinuclear molecule **4**.

This result indicates that the solvent and the ligand-to-metal ratio are simultaneously playing a controlling role over the structure. Further, solvent seems to have more effect than the ligand-to-metal ratio, because in a certain case only one class of complexes was obtained (e.g., only **4** in MeOH/H_2O system), although the ratios of bpe-to-zinc-benzoate increase from 1 to 2 to 4. Interestingly, the solvents used in this work were not involved in the structures of

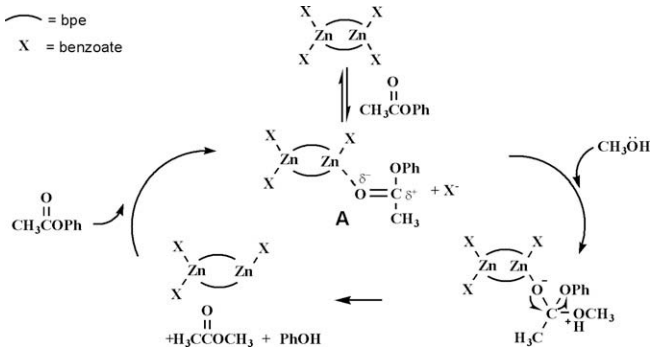
[a] All esters were completely converted to the corresponding products, methyl acetate and methyl benzoate. Reaction conditions: esters; 0.05 mmol, catalyst; 1.10×10^{-3} mmol for **1**, 1.01×10^{-3} mmol for **2**, 1.00×10^{-3} mmol for **3**, 1.00×10^{-3} mmol for **4**, solvent; methanol or propanol (1 ml). See Section 2 for the detailed reaction conditions.
[b] Time necessary for the complete conversion of substrate to product.
[c] Transesterification of esters was carried out in methanol (MeOH).
[d] Transesterification of esters was carried out in propanol (PrOH).
[e] The solvent was a mixture of $MeOH/CH_2Cl_2$ or $PrOH/CH_2Cl_2$ (1/1) because of low solubility of substrate in MeOH or PrOH.

1–4 which means that the coordinating solvents such as H_2O, methanol, and ethanol, act as the "templating" role rather than the "coordination" one [38]. Therefore, the solvent used in this preparation should be considered as an innocent one instead of a potential participant in any coordination polymer formation.

In addition, the structural diversity of compounds **1–4** shows that the dinuclear paddle-wheel Zn(II) units can be rationally controlled and can serve as mono-, di-, and trinuclear nodes towards a dipyridyl ligand, respectively, and that four classes of mixed-ligand complexes can be obtained simply by manipulating the ligand-to-zinc-benzoate molar ratio and the solvent. This result led us to suggest that the ligand concentration as well as the solvent system can tune topology in the system of zinc-benzoate with a variety of bipyridyl bridging ligands.

*Catalytic transesterification reactions by the compounds **1–4**:* Transesterifications are important transformations in organic synthesis in industrial as well as in academic laboratories [74–76]. As part of our efforts to design transesterification catalysts based on metal ions that are not redox active, therefore, we have recently synthesized several discrete complexes and coordination polymers and reported that some of them could carry out efficiently the catalytic transesterification of a range of esters with methanol under the mild conditions [77–79]. While these catalyst systems constitute a promising class of catalysts that appears to be an efficient, mild, and easily recyclable method for the alcoholysis of esters, there is still more demand to develop new types of catalysts that show better efficiency. With our previous experience, therefore, compounds **1–4** have been also employed as a catalyst for transesterification reaction in methanol under a homogeneous condition. The ester, *p*-nitrophenyl acetate, was initially used as a substrate (Eq. (1)):



(1)

We observed that compounds **1–4** catalyzed the reaction of *p*-nitrophenyl acetate with methanol, with quantitative conversion to methyl acetate in 0.3–0.9 day (see the entry 1 of Table 4) at 50 °C under the neutral conditions. Among them, the complex **3** shows the most efficient reactivity. Importantly, this result is the second best among the catalytic efficiencies reported previously with zinc-containing coordination and polymeric compounds, to our best knowledge [77–84]. Since we have established that **1–4** represent excellent catalysts for the tansesterification reaction of *p*-nitrophenyl acetate with methanol, we have investigated the transesterification of various *p*-substituted phenyl acetates and benzoates. As shown in Table 4, the substrates with the electron-withdrawing substituents have undergone faster transesterification (entries 1 and 5) than those with the electron-donating ones (entries 4 and 8). In addition, vinyl acetate as a precursor widely used for ester synthesis [85–87] was converted efficiently to the product methyl acetate by **1–4** within 0.3–1.5 day (entry 9). This result suggests that this catalytic system can be useful for preparing various esters by transesterification. Moreover, it is worthwhile that 4-nitrophenyl acetate and 4-nitrophenyl benzoate with nitro substituents at the *para*-position, which are known to be problematic substrates for the transesterification reaction due to undesirable side reactions such as isomerization or polymerization [88], were also converted quantitatively to the corresponding products.

Furthermore, this promising result led us to test the transesterification with more challenging nucloephiles such as ethanol, 2-propanol, and propanol, in the presence of the catalysts **1–4**. Phenyl acetate reacted very slowly with either ethanol (70 days) or 2-propanol (90 days), respectively, whereas with propanol the transesterification reaction was complete within 2–7 days in the presence of **1–4**, respectively (entry 3). The complex **3** again shows the most efficient reactivity. This result is the best among the catalytic efficiencies reported previously with zinc-containing coordination and polymeric compounds, to our best knowledge [77–84]. Various esters were also examined with propanol as a nucleophile in the presence of **1–4**. The substrates with the electron-withdrawing substituents have undergone faster conversion to the corresponding products (entries 1 and 5), while those with the electron-donating ones have shown slow transesterification reaction (entries 4 and 8).

Though we do not know, at this moment, about the exact reactive species and the reaction mechanism for the transesterification reaction by the catalysts, it has been proposed that the mechanism of metal ion catalyzed transesterification probably involves electrophilic activation of the carbon center of the carbonyl moiety by binding of the metal to the carbonyl oxygen [89–93]. Therefore, Lewis acidity of the metal center may be important in catalytic transesterification. Based on this idea and our previous proposal on the transesterification reactions [79,94,95], a possible transesterification mechanism in these catalyst systems can be proposed with the catalyst **4** as shown in Scheme 1. The complex **4** could

Scheme 1. Plausable transesterification mechanism.

possibly be a catalytic species because only **4** has been obtained in methanol/H_2O without respect to the ligand-to-metal ratios and because the transesterification reactions were carried out in methanol. At the first step, the substrate phenyl acetate substitutes a labile ligand benzoate to give the adduct **A** (Scheme 1). Then, the nucleophile methanol would attack the carbon atom of carbonyl moiety of the adduct to produce the product methyl acetate. After the catalytic reaction, the structure of **4** was proved to be kept, based on ^{1}H NMR experiments. ^{1}H NMR data of benzoate and bpe of **4** appear at different positions from those of free benzoate and free bpe (see Section 2). ^{1}H NMR data of benzoate and bpe of the complex **4** taken after the transesterification reaction were exactly identical to those of benzoate and bpe of the starting complex **4** and we were not able to observe any free benzoate and bpe separated from **4** (see Section 2). This result indicates that there is no structural change of **4** after the transesterification reaction. This investigation was consistent with the proposed transesterification mechanism. Further detailed mechanistic studies are currently under investigation.

4. Conclusion

We have shown here how the structures of the coordination compounds of the bpe ligand with zinc-benzoate are able to be varied not only by the traditional method such as solvent control but also by changes in the ratio of ligand-to-zinc-benzoate. This work reveals that both the ligand-to-metal ratio and the solvent play very important roles in the formation of different coordination structures, and this offers the possibility to control the formation of such structures by varying those factors. Furthermore, these results led us to suggest that many of zinc-containing coordination polymers previously reported on specific solvents and ligand-to-metal ratios may be converted to yet unknown new structures according to the change of the reaction conditions such as solvent and ligand-to-metal ratio.

We have also shown that the compounds **1**–**4** catalyzed efficiently the transesterification of a variety of esters. Importantly, the overall transesterification reactivity shown by the catalyst **3** is the best among the catalytic efficiencies reported previously with zinc-containing coordination and polymeric compounds, to our best knowledge. In addition, the scope of the application of **1**–**4** as transesterification catalysts has been expanded to now include ethanol and propanol. Further explorations into the uses of this catalyst family in organic transformations as well as mechanistic investigations are ongoing.

Taken all together, this observation is very significant since it encourages us to construct new polymeric compounds that might be efficiently used as homogeneous or heterogeneous catalysts friendly to the environment simply by altering the ratio of ligand-to-metal and solvent system in the reaction mixtures.

ABSTRACT

The molybdenum(VI) complexes $[Mo_2O_4(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}ONH_2)_2]$ (**1**), $[MoO_2(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)]$ (**3**) and $[MoO_2(C_{19}H_{19}N_2O_5)(CH_3OH)]Cl \cdot CH_3OH$ (**4**), of salicylaldehyde amino acid derivatives (DL-asparagine or L-ornithine hydrochloride) have been synthesized and characterized. The Schiff base containing a saturated heterocyclic ring (in complex **4**) is the first example of such a molecule derived from salicylaldehyde and the amino acid, L-ornithine hydrochloride. We proposed that the formation of a molybdenum(VI) complex coordinated by a Schiff base containing a saturated heterocyclic ring depends upon the nature of the solvent and upon the presence of molybdenum(VI). In the absence of molybdenum(VI), the condensation product obtained from the reaction of L-ornithine hydrochloride and salicylaldehyde was the Schiff base *N*-salicylidene-L-ornithine (**5**). In the dinuclear complex **1** and the mononuclear complexes **3** and **4**, the molybdenum atoms are octahedrally coordinated with two *cis* oxo-oxygen atoms (in **3** and **4**), oxo-bridging atoms (in **1**) and the Schiff base ligand. In **3** the *N*-salicylidene-DL-asparaginato ligand coordinates molybdenum tetradentately while in **1** and **4** the Schiff base ligand acts as a tridentate ligand.

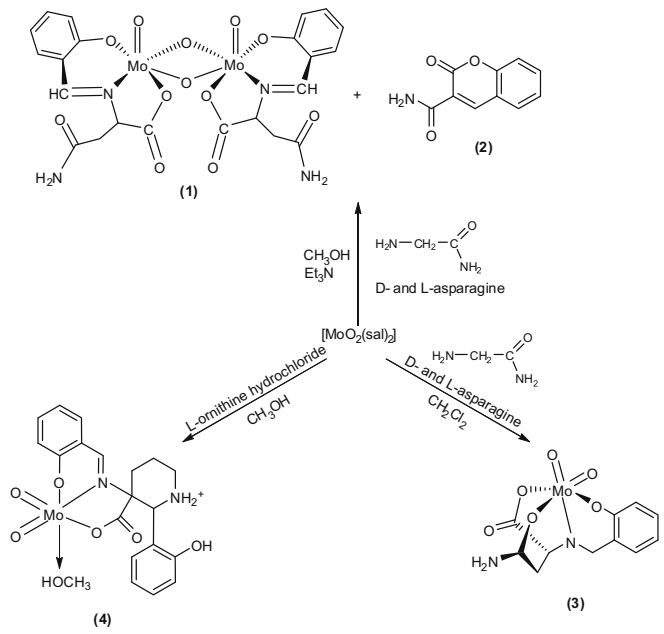
1. Introduction

During the last decade, intensive studies have been carried out on the biochemical, pharmacological and physicochemical functions of molybdenum. In particular, many kinds of dioxomolybdenum(VI) compounds have been synthesized as models of molybdoenzymes in order to study and elucidate catalytic oxygen atom transfer reactions [1–7]. For example, dioxomolybdenum(VI) complexes have been studied as models for oxidized forms of molybdoenzymes, e.g. aldehyde oxidase and sulfite oxidase which are supposed to contain *cis*-$MoOX_2$ units (X = O, S) coordinated to sulfur, nitrogen and oxygen donor atoms in the protein structure [4–7]. During the enzymatic turnover, the mononuclear molybdenum center is proposed to cycle between the IV and VI oxidation states, with the paramagnetic V state being the obligatory catalytic intermediate in the oxidative half-reaction of the enzyme. In the context of model systems for this type of reaction, a few studies have been concerned with the preparation and reactivity of molybdenum(VI) complexes of *N*-salicylidene-L-amino acids and their derivatives [8].



In the present work we describe products of the template synthesis of potentially tridentate and tetradentate Schiff base ligands, derived from salicylaldehyde (salH) and the amino acids DL-asparagine and L-ornithine hydrochloride, with the dioxomolybdenum(VI) core (Scheme 1).

Complex formation of $[MoO_2(sal)_2]$ with DL-asparagine and L-ornithine hydrochloride was studied in methanolic and dichloromethane solutions. The presence of mononuclear dioxomolybdenum(VI) centers in the complexes $[MoO_2(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)]$ (**3**) and $[MoO_2(C_{19}H_{19}N_2O_4)(CH_3OH)]Cl \cdot CH_3OH$ (**4**) was confirmed by the crystal structure determinations, while the chemical structure of the complex $[Mo_2O_4(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)_2]$ (**1**) was determined by NMR spectroscopy.

Computational studies were proved and were concerned with the role of the molybdenum atom in the cyclization of the Schiff base derived from L-ornithine hydrochloride and salicylaldehyde.

Scheme 1. Reactions of $[MoO_2(sal)_2]$ with D- and L-asparagine and L-ornithine hydrochloride.

2. Experimental

Materials and methods: L-Ornithine hydrochloride, DL-asparagine and triethylamine were of reagent grade and were used as purchased. Methanol was dried using magnesium turnings and iodine, and then distilled. Dichloromethane was dried over P_2O_5. The starting complex $[MoO_2(sal)_2]$ was prepared as described in the literature [9].

IR spectra: Infrared spectra were recorded in KBr with a Spectrum RX I spectrophotometer in the 4500–450 cm^{-1} region.

Elemental analyses: The Analytical Services Laboratory of the Rudjer Bošković Institute provided C, H and N analyses. Molybdenum was determined according to the method described in the literature [10].

2.1. Syntheses of the molybdenum(VI) complexes

2.1.1. Synthesis of di-μ-oxo-di(N-salicylidene-DL-asparaginato) dioxodimolybdenum(VI), $[Mo_2O_4(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)_2]$ (**1**)

$[MoO_2(sal)_2]$ (0.63 g, 1.7 mmol) was dissolved in dry methanol (35 ml) and the solution was refluxed under an argon atmosphere for 15 min before addition of DL-asparagine (0.45 g, 3.4 mmol) and a few drops of triethylamine. The reaction mixture was refluxed under an argon atmosphere for 7 h. The color of the solution changed from pale yellow to red. The yellow crystalline product, (**1**), that formed after 7 h was filtered off, washed with cold methanol and dried in vacuo. Yield: 0.08 g (13%). After six weeks needle-like transparent crystals of coumarin-3-carboxamide (**2**) were obtained from the mother liquor at room temperature. Yield: 0.06 g (10%).

2.1.2. Synthesis of cis-dioxo(N-salicylidene-DL-asparaginato) molybdenum(VI), $[MoO_2(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)]$ (3)

$[MoO_2(sal)_2]$ (0.63 g, 1.7 mmol) was dissolved in dry dichloromethane (35 ml) and the solution was refluxed under an argon atmosphere for 15 min before addition of DL-asparagine (0.45 g, 3.4 mmol). The reaction mixture was refluxed under an argon atmosphere for 5 h. The color of the solution changed to yellow. The yellow crystalline product, (**3**), that formed after 5 h was filtered off, washed with cold dichloromethane and dried *in vacuo*. Yield: 0.1 g (16%).

Anal. Calc. for $C_{11}H_{10}MoN_2O_6$: C, 36.48; H, 2.78; N, 7.74; Mo, 26.49. Found: C, 36.59; H, 2.75; N, 7.52; Mo, 26.30%. IR (KBr) ν/cm^{-1}: 3372, 1730, 1665, 1600, 1576, 1422, 1410, 928, 944.

2.1.3. Synthesis of 3-[(2,5-salicylideneiminato)-2-(2-hydroxyphenyl) (piperidinum)-3-carboxylato)methanol dioxomolybdenum(VI)] chloride methanol, (1/1) $[MoO_2(C_{19}H_{19}N_2O_4)(CH_3OH)]Cl \cdot CH_3OH$ (**4**)

$[MoO_2(sal)_2]$ (0.15 g, 0.41 mmol) and L-ornithine hydrochloride (0.14 g, 0.83 mmol) were dissolved in dry methanol (35 ml). The mixture was refluxed for 5 h under an argon atmosphere. After a few days an unstable yellow-green crystalline product (**4**) was obtained. The product was filtered off, washed with cold methanol and dried *in vacuo* under an argon atmosphere. Yield: 0.1 g (42%).

Anal. Calc. for $C_{21}H_{27}ClMoN_2O_8$: C, 44.49; H, 4.80; N, 4.94; Cl, 6.25; Mo, 16.92. Found: C, 43.96; H, 4.56; N, 5.01; Cl, 6.20; Mo, 16.63%. IR (KBr) ν/cm^{-1}: 3172, 3028, 2938, 1668, 1624, 1600, 1454, 1428, 934, 909.

2.1.4. Synthesis of N-salicylidene-L-ornithine hydrochloride, $C_6H_4(OH)CH_2NHCH(COOH)(CH_2)_3NH_2{\cdot}HCl$ (**5**)

L-Ornithine hydrochloride (0.84 g, 5 mmol) was dissolved in potassium hydroxide solution (0.289 g KOH in 10 ml water) and added to salicylaldehyde (1.22 g, 10 mmol in 10 ml EtOH). The mixture was stirred under reflux for 1 h with the almost immediate appearance of a yellow product. It was filtered off, washed with cold ethanol and dried in vacuo. Yield: 0.84 g (61.83%).

(**5**) *Anal.* Calc. for $C_{12}H_{17}ClN_2O_3$: C, 52.85; H, 6.28; N, 10.27; Cl, 13.00. Found: C, 53.01; H, 6.10; N, 9.87; Cl, 12.65%. IR (KBr) ν/cm^{-1}: 3050, 2948, 1638, 1582, 1514, 1410, 1338, 1284, 846, 750.

2.2. X-ray crystallography

Crystal parameters, data collection details and refinement results for compounds **3** and **4** are summarized in Table 1. Diffraction data for **3** were collected on an Oxford Diffraction Xcalibur 3 CCD diffractometer at 295 K, and those for **4** on an Enraf-Nonius Mach 2000 diffractometer at 110 K. Graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) was used for both data collections. The data were corrected for Lorentz and polarization effects by CRYSALIS [11] and DENZO programs [12] for **3** and **4**, respectively. Both structures were solved by direct and Fourier methods using SHELXS-97 [13] and SHELXL-97 [14], respectively. They were refined by the full-matrix least-squares method based on F^2 values against all reflections assuming anisotropic temperature factors for all non-H atoms using the SHELXL-97 program integrated in the WINGX package [15]. All hydrogen atoms were found, however due to the somewhat poor geometry, those on carbon atoms were generated and left to ride on their parent atoms. The two amino-hydrogen atoms in **3** were refined isotropically. The positional parameters of the hydrogen atoms attached to the nitrogen and oxygen atoms in **4** were left as found in the difference Fourier map and only their isotropic thermal parameter was refined. Figures were made with the programs ORTEP [16] and PLATON [17].

2.3. NMR measurements

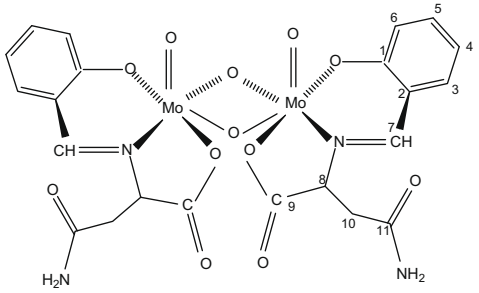
One and two-dimensional NMR spectra were recorded on Bruker Avance DRX500 and Bruker Avance DPX 300 spectrometers equipped with a 5 mm diameter inverse detection probe and a 5 mm $^1H/^{13}C$ dual probe, respectively, and z-gradient accessory. TMS was used as the internal standard. Standard spectral conditions were used for the ^1H and ^{13}C (PENDANT) NMR experiments. The sample concentration was 20 mg ml^{-1} in [D_6]DMSO solutions. The digital resolution was 0.1 and 0.3 Hz per point for ^1H and ^{13}C spectra, respectively. COSY spectra were recorded with spectral width of 4000 Hz in each domain and with 1024 points in the f2 dimension. A 2s relaxation delay was used to acquire 512 increments for each data set. Free induction decays were processed using a 2K × 1K matrix with appropriate zero filling and sine weighting. The digital resolution was 3.9 and 15.6 Hz per point in the f2 and f1 dimensions, respectively. The HSQC and HMBC spectra were recorded with a relaxation delay of 1.5 s and 32 scans per increment. The spectral width was 31 000 Hz in acquisition domain f2 and 4000 Hz in time domain f1. Data were collected into a 2048 × 512 acquisition matrix and processed using a 2K × 1K transformed matrix with zero filling in the f1 domain. Sine multiplication was performed before Fourier transformations. In HMBC spectra the delay for long-range couplings was set to 60 ms.

2.4. Computational details

In all calculations we consistently used the same generalized gradient (GGA) corrections in determining the self-consistent charge density and the exchange-correlation (XC) part of the energy corresponding to the charge density. The used functional was the recently proposed OPBE [18], which combines the OPTX exchange devised by Handy and Cohen [19] with the correlation term proposed by Perdew et al. [20]. The local density approximation (LDA) part was based upon the Vosko–Wilk–Nusair (VWN) [21] parameterization of electron gas. The relativistic effects were accounted for via the scalar zeroth order regular approximation (ZORA) formalism [22], which was employed throughout. We made use of a basis set built from Slater type functions (STOs) and tailored especially for the ZORA approach, as reflected by the use of much steeper functions in the core region. The basis set consisted of a TZP quality set on the Mo atom with all the orbitals up to, and including 3d treated as a frozen core, DZP sets on the C, N and O atoms with the 1s orbital frozen, and a DZP set on the H atoms. In [$MoO_2(C_{19}H_{19}N_2O_4)$] (the complex cation of **4** without coordinated and solvated methanol molecules) there thus resulted a total of 473 symmetrized fragment orbitals. The recommended sets of auxiliary fit functions to facilitate computations of the Coulomb potential were employed unchanged. All the DFT calculations were performed using the ADF program system [23].

3. Results and discussion

3.1. Synthesis of the complexes



The yellow dinuclear molybdenum(VI) complex [Mo_2O_4-(C_6H_4(O)CH=NCH(COO)CH_2C=(O)NH_2)$_2$] (**1**) and coumarin-3-carboxamide $C_{10}H_7NO_3$ (**2**) were obtained by the reaction of [MoO_2(sal)$_2$] and DL-asparagine in dry methanol under an argon atmosphere. Cavaco et al. isolated coumarin 3-carboxamide and the vanadium(IV) complex [VO(sal-L-asn)(py)(H_2O)] in the reaction of $VOSO_4$, salicylaldehyde and L-asparagine, and they proposed a mechanism of oxidative decarboxylation of L-asparagine [24]. These reactions of biochemical and chemical decarboxylation of α-amino acids activated by metal ions are well documented [25–27].

The compounds **1** and **2** were characterized by IR spectra and the chemical structure of compound **1** was determined by the combined use of one- and two-dimensional NMR spectroscopy. The NMR results for compound **2** were in accordance with the literature data [24]. The proton and carbon chemical shifts of **1** are displayed in Table 2.

The two amide protons in **1** were readily assigned in the proton spectrum since their signals disappeared after the addition of D_2O owing to a rapid proton/deuterium exchange. Also the HMBC spectrum revealed connectivities from these protons to the C(11) carbonyl carbon. The HMBC correlation peak between one of the amide protons and C(10) was further established. In addition, the imino proton H(7) showed connectivities to C(2), C(3) and C(1) in the aromatic ring and to C(8) which was further correlated to

H(10). HMBC correlation peaks between H(8) and C(9) and C(11) were also observed corroborating the structure depicted in Scheme 2.

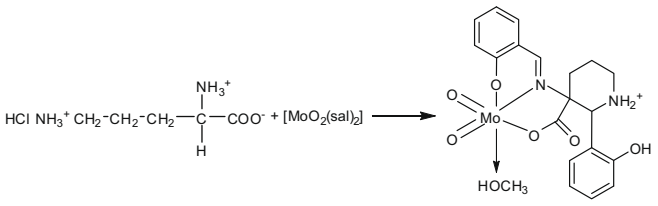
In the IR spectrum of compound **1**, the strong absorption bands at 820 cm^{-1} and in the region 908–944 cm^{-1} were assigned to the bridging and terminal Mo–O groups of the $Mo_2O_4^{4+}$ core and are in accordance to the literature data for the same type of complexes [28].

The mononuclear molybdenum(VI) complex, $[MoO_2(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)]$ (**3**) was obtained by the reaction of $[MoO_2(sal)_2]$ and DL-asparagine in dry dichloromethane under an argon atmosphere. In the dinuclear **1** and mononuclear **3** complexes, molybdenum is coordinated by the deprotonated tridentate ONO (in **1**) and tetradentate OONO (in **3**) *N*-salicylidene-DL-asparaginato ligand. The coordination sphere in **1** is completed by one oxo-oxygen and two oxo-bridging atoms, and in **3** by two *cis* oxo-oxygen atoms.

The mononuclear molybdenum(VI) complex $[MoO_2(C_6H_4(O)CH{=}NC_5H_7(COO)NH_2C_6H_4(O)(CH_3OH)]Cl \cdot CH_3OH$ (**4**) was obtained in the reaction of $[MoO_2(sal)_2]$ and L-ornithine hydrochloride in dry methanol under an argon atmosphere (Scheme 3). We were able to isolate complex **4** from the methanolic solution, however the same reaction in dichloromethane (with or without addition of triethylamine) was unsuccessful.

Since L-ornithine contains an additional side-chain amino group we expected the formation of a molybdenum(VI) complex coordinated by a *bis*-Schiff base such as $[MoO_2C_6H_4(O)CH{=}NCH(COOH)(CH_2)_3N{=}CH(O)C_6H_4]$. However, X-ray investigations showed that in the obtained molybdenum(VI) complex, the molybdenum atom is coordinated by a Schiff base containing a saturated heterocyclic ring. According to the literature data [29] such Schiff base ligands are formed from the condensation reaction of 2-pyridinecarboxaldehyde derivatives with certain polyamines. Different metal salts (e.g. Fe(II), Ni(II), Zn(II)) have been reported to yield complexes of the corresponding Schiff base obtained in the condensation reaction of 2-pyridinecarboxaldehyde and α,ω-triamines [30].

In absence of molybdenum(VI) the condensation product obtained from the reaction of L-ornithine hydrochloride and salicylaldehyde in a 1:2 molar ratio was the Schiff base *N*-salicylidene-L-ornithine hydrochloride, $C_6H_4(OH)CH_2NHCH(COOH)(CH_2)_3NH_2 \cdot HCl$.



The IR spectra of all the described molybdenum(VI) complexes showed characteristic vibrations for this type of compound and the data are in accordance with that in the literature [28]. Complexes **3** and **4** underwent a rapid decomposition when dissolved in DMSO–d_6 and they were found to be insoluble in other solvents.

3.2. Structural studies

3.2.1. Structures of $[MoO_2(C_6H_4(O)CH{=}NCH(COO)CH_2C{=}(O)NH_2)]$ (3) and $[MoO_2(C_{19}H_{19}N_2O_5)(CH_3OH)]Cl \cdot CH_3OH$ (4)

In both structures the main feature is the mononuclear, octahedrally coordinated molybdenum atom with two *cis* oxo-oxygen atoms and a bound Schiff base ligand. In **3** the *N*-salicylidene-DL-asparaginato ligand coordinates molybdenum tetradentately (Fig. 1), while in **4** (2,5-salicylideneiminato)-2-(2-hydroxophenyl)(piperidinum)-3-carboxylate acts as a tridentate ligand. The coordination sphere in **4** is completed by a methanol molecule (Fig. 2). Selected bond distances and angles are presented in Table 3 for both structures.

Distortion from an ideal octahedral geometry is more pronounced in **3** with the acute angle N(1)–Mo–O(6) of 70.40(8)°, obtuse angle O(1)–Mo–O(2) of 105.96(15)° closed by two *cis* oxo-oxygen atoms, and the *trans* chelating angle O(2)–Mo–N(1) of 150.92(11)°. This is caused by more strain imposed by the rigid geometry of the tetradentate Schiff base ligand in **3**. The greatest distortion from the octahedral geometry in **4** is that of the *trans* chelating angle O(3)–Mo–O(4) of 151.07(5)°. An analysis was carried out on structures deposited with the Cambridge Structural Database [31] by defining an octahedrally coordinated mononuclear molybdenum atom, a Schiff base *N*-donor, three single bonded oxygen atoms and two *cis* oxo-oxygen atoms. The search gave 55 hits. The Mo=O bond is the shortest, with a mean value of 1.701(1) Å. The mean Mo–O bond that is *trans* to the Mo–O single bond is 1.945(4) Å (Mo–O range 1.887–2.025 Å, O–Mo–O range 147.4–158°), whereas the one *trans* to the oxo-oxygen atom is lengthened due to the *trans*-influence and amounts to 2.334(6) Å (Mo–O range 2.171–2.416 Å, O=Mo–O range 160.7–175.6°). The lengths of the Mo–O(1) and Mo–O(2) bonds in both structures are within the normal range for typical *cis*-MoO_2 structures. The coordinating oxygen atoms O(3) and O(5) of the Schiff base ligand are *trans* to each other and their distance to Mo is close to the mean value from the CSD. The Mo–O(6) bond in **3** exhibits a *trans*-influence and is significantly longer than the two unaffected bonds mentioned above. This bond length is comparable to those found in the complexes $[MoO_2L(ROH)]$ (L = tridentate Schiff bases derived

from salicylaldehyde or 2-hydroxy-1-naphthaldehyde and 2-(hydroxymethyl)aniline or 2-aminoethanol; R = CH_3 or C_2H_5) [32] and [MoO_2LD] (L = tridentate Schiff bases derived from 2-hydroxy-1-naphthaldehyde or 2-hydroxy-3-methoxybenzaldehyde and 2-amino-*p*-cresol; D = methanol, ethanol, DMSO, imidazole or 4,4′-bipyridine) [33]. A CSD search similar to the one described above was carried out, this time defining that the single bonded oxygen atom in the *trans* position to the oxo-oxygen is from methanol. This search gave 20 hits with a Mo–O mean distance of 2.357(7) Å (range 2.311–2.414 Å, O=Mo–O range 165.8–173.2°). The methanol oxygen atom O(7) is *trans* to the terminal oxo-group in **4** and is at 2.2925(14) Å from Mo. It is the shortest bond of that kind found so far. Only one Mo–OCH_3 bond is shorter but it is from a binuclear complex in which the methoxo group bridges two molybdenum atoms [34]. In the 55 structures from the CSD, the imine nitrogen is always *trans* to the terminal oxo-oxygen with a mean value of the Mo–N distance of 2.272(5) Å (range 2.202–2.413 Å, N–Mo=O 156.1–168.6°). The Mo–N(1) distance is similar in **3** and **4** (2.253(3) and 2.2510(14) Å, respectively) and slightly shorter than the mean value. It is similar to that in [MoO_2(L)(D)] (L = tridentate Schiff baze, D = azole ligand) [35]. The C(3)–N(1) bond distance is close to the usual C=N bond length [33,36]. The

Table 4
Hydrogen bond geometry (distances (Å), angles (°)) in **3**.

C(3)–H(3)···O(2)[iii]	0.93	2.51	3.396(2)	159

Symmetry transformations used to generate equivalent atoms: (i) $-1/2-x$, $1/2+y$, $-z$; (ii) $-x$, $1-y$, $-z$; (iii) x, $1+y$, z.

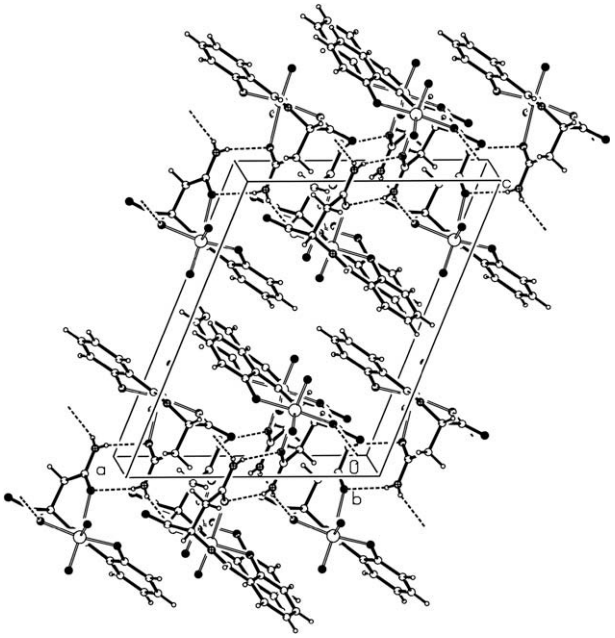

Fig. 3. Packing of **3** in the unit cell. Hydrogen bonds are shown by dashed lines.

angle between the planes of the two chelate rings Mo–O(3)–C(1)–C(2)–N(1) and Mo–O(5)–C(9)–C(4)–C(3)–N(1) is 11.28(6) and 17.72(14)° in **3** and **4**, respectively. Two centrosymmetrical hydrogen bonds of the type N–H···O (Table 4, Fig. 3) interconnect each molecule of **3** to two neighboring ones, thus forming infinite chains along [1 0 0].

In **4** a network of hydrogen bonds interconnects the complex cation, chloride anion and the methanol solvent molecule (Fig. 4, Table 5). One hydrogen atom of the non-coordinating N(2) atom in the piperidinium ring is linked by intra- and intermolecular hydrogen bonds to the carboxylic oxygen atom O(6) at 2.880(2) and 2.871(2) Å, respectively, while the other hydrogen atom forms an intermolecular hydrogen bond to the chloride ion at 3.0389(17) Å. The oxygen atom of the methanol molecule O(8) is linked by two hydrogen bonds, as an acceptor from the hydroxo group of the 2-hydroxophenolic ring O(5) at 2.647(2) Å, and as a donor toward the oxo-oxygen atom O(1) at 2.858(2) Å. The coordinating methanol ligand forms a hydrogen bond with the chloride ion. The crystal structure is additionally stabilized by weak C–H···O hydrogen bonds in the range 3.288(2)–3.670(2) Å.

3.3. Computational studies

Computational studies were primarily concerned with the role of the molybdenum atom in the cyclization step, which connects the reactant **R** with product **P** (Figs. 2 and 5). The latter is essentially equivalent to complex **4**, apart from the omission of the solvent CH_3OH molecule from the Mo coordination sphere. As the

most demanding test of accuracy of the current theoretical approach, the calculated distances of the Mo–ligand bonds in **P**, as well as the torsional angles within the MoO_2 containing ring, are compared to the experimental ones in Table 6.

The **P** complex is 2.8 kcal mol^{-1} less stable than **R**, which is not much considering the unfavorable steric interactions arising in **P**, where the 6-membered heterocyclic ring has to accommodate the two very large substituents in a vicinal position (Fig. 5).

To get a better understanding of the role of the Mo atom in the cyclization process, reference test compounds were devised by substituting MoO_2 with a CH_2 group. These are labelled as P(CH_2) and R(CH_2) in analogy with the parent compounds. The energy difference between P(CH_2) and R(CH_2) now increases to 6.7 kcal mol^{-1}. More importantly, substantial differences are observed between the MoO_2 and CH_2 containing rings. The former is much less puckered owing to the additional Mo binding to the imine N(1), which makes the ring more rigid, thus restricting its conformational mobility. As a result, the steric repulsions are less pronounced in P than in P(CH_2). Still, it seems that the reaction involving the CH_2 substituted compounds would proceed as well, albeit with much more difficulty.

The basic assumptions about the mechanism include the activation of C(2) as a nucleophile, which is achievable either *via* abstraction of the attached H atom by a base (whereby a carbanion is formed), or via a keto-enol tautomerism. With regards to the tautomerism, the energy difference between the keto and enol form in R is 16.3 kcal mol^{-1}, being in favor of the former form. This however is much less than that for R(CH_2), where the difference equals 26.4 kcal mol^{-1}. The calculated Hirshfeld charges [37] concerned the trends in the charge re-distribution on going from the keto to the enol tautomeric form in R and R(CH_2). The main differences may be summarized in the O(4) atom, which upon enolization passes considerably more (by ca. 0.05e) of its negative charge in R than in R(CH_2). One small part of it (ca. 0.01e) is received by the Mo atom, however, most importantly the C(3) atom (Fig. 2) receives a major part (0.06e) of the charge in R, whereas in R(CH_2) the equivalent atom receives effectively none. In the enol forms, C(1) of R(CH_2) gets notably richer (by ca. 0.05e) than in R, while negligible differences between R and R(CH_2) upon the charge redistribution are found only for the C(2) and N(1) atoms. The near flatness of the MoO_2 containing ring (Table 6) brings about a much more effective delocalization of the charge via resonance effects, all the way to C(3). Thus, R is much better adapted to the emergence of the double C(1)=C(2) bond of the enol form than R(CH_2). An alternative route of activating the C(2) atom via H transfer to the vicinal imine N(1) is highly unlikely. In this case, upon protonation, N(1) rapidly escapes the Mo coordination sphere, which severely distorts the MoO_2 containing ring and destabilizes the structure by several 10s of kcal mol^{-1}. Similarly, the N(2) Schiff base is itself far too weak to directly deprotonate the C(2) atom. Indicative of this are the very high energies (around 60 kcal mol^{-1} above **R**) when the proton is moved away from C(2) toward N(2). According to our calculations, yet another prerequisite for the cyclization to occur involves H transfer from O(6) to the imine N(2), whereby the electrophilicity of the vicinal C(13) is enhanced, making it much more prone to attack by the nucleophilic C(2), which completes the cyclization. The structures with the H atom on O(6) and N(2) are effectively isoenergetic, the energy difference being only 2.9 kcal mol^{-1} in favor of the structure with the protonated O(6). The corresponding H bond is a very strong one, around 15 kcal mol^{-1}. Similar activation steps involving H transfer from

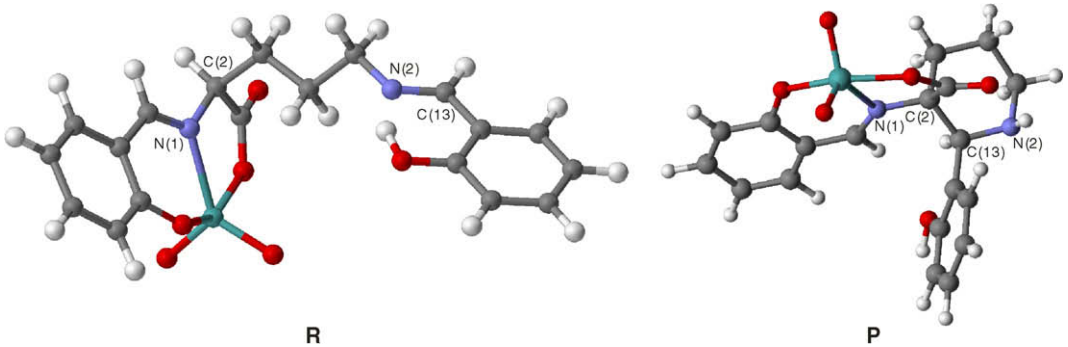

Fig. 5. Optimized structures of reactant **R** and product **P**.

an OH group to a nearby Schiff base have been discovered several times in the past [38].

Finally, the mutual approach of the C(2) and C(13) reaction centers is easily achieved owing to the mobility of the aliphatic $–(CH_2)_3–$ chain, e.g. the conformations of **R** likely to precede the cyclization are less than 10 kcal mol^{-1} above the most stable conformer of **R**. In the Supplementary movie it is seen that the reaction proceeds without a barrier once the C(2) and C(13) are separated by ca. 2.5 Å, and the enol and N(2) protonated forms are realized. Simultaneously as the C(2)–C(13) bond is formed, the proton attached to O(4) is smoothly abstracted by the N(2) atom, thus restoring the carbonyl bond. At the end a zwitterionic species is formed with the positive ammonium and negative phenolate parts. Additional calculations confirmed this zwitterionic form as unstable, with the proton eventually returning from N(2) to the O(6) atom. In conclusion, the formation of the tautomeric enol form (nucleophilic activation of C(2)) accompanied by the H transfer from O(6) to N(2) (electrophilic activation of C(13)) are the most probable initiation steps under the experimental conditions (CH_3OH as the solvent). By far the largest barrier is expected for the keto-enol tautomerism, which is therefore the most likely candidate for the rate-determining step.

4. Conclusions

In this study it was shown that the *N*-salicylidene-DL-asparaginato anion coordinates to molybdenum(VI) as a tridentate OON (in **1**) or a tetradentate OONO (in **4**) ligand, depending on the reaction conditions (solvent). The coumarine-3-carboxamide (**2**) was obtained as a product of decarboxylation of DL-asparagine in methanolic solution and in the presence of molybdenum(VI). The reaction of L-ornithine hydrochloride and the salicylaldehydato molybdenum(VI) complex in methanol resulted in a mononuclear molybdenum(VI) complex (**4**) coordinated by a Schiff base containing a saturated heterocyclic ring. The presence of molybdenum(VI) and methanol as the solvent were important for obtaining this type of complex.

ABSTRACT

Cationic complexes $[Mo(\eta^3\text{–}C_3H_4\text{–}Me\text{–}2)(N\text{–}N)(CO)_3]^+PF_6^-$, {N–N = bipy **(2)**; DAD (Ar–N=C(Me)–C(Me)=N–Ar: Ar = o-Me–C_6H_4 **(3)**, 2,6-Me_2–C_6H_3 **(4)**; Ar–BIAN (Ar = o-Me–C_6H_4 **(5)**, Ar = iPr_2–C_6H_3 **(6)**}; were synthesized by treating the compound $Mo(CO)_3$(p-xylene) with the allyloxyphosphonium salt in situ in presence of diimine ligand. Complex **4** was characterized by single crystal X-ray diffraction. The solid state structure of the complexes revealed a preference for the more unsymmetrical axial isomer.

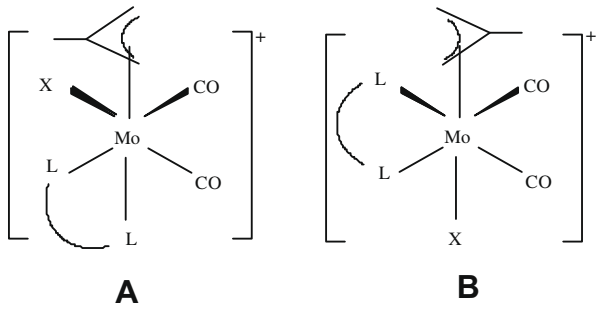
1. Introduction

Molybdenum(II) complexes of the type $[Mo(\eta^3\text{-}C_3H_4)(CO)_2(NCMe)_2X]$ (X = halide or pseudohalide) have been used extensively over several decades as synthetic precursors for a wide variety of Mo(II)-allyl derivatives containing the 12e-$[Mo(CO)_2\text{-}(\eta^3\text{-allyl})]^+$ fragment which are formed by substitution of the labile nitrile ligands and/or the anion X [1]. It has been recently found that the pseudooctahedral $[MoX(CO)_2(\eta^3\text{-allyl})(N\text{–}N)]$ (N–N = 2,2′-bipyridine, bipy; 1,10-phenanthroline, phen) complexes react with organolithium or organomagnesium reagents and with sodium alkoxides to afford new alkyl [2], alkynyl [3] and alkoxo [4] complexes by selective halide substitution. The same reaction with NaCN has provided access to the complexes $[Mo(CN)(\eta^3\text{-allyl})(CO)_2(N\text{–}N)]$ [5].

The well known allyl complex $[Mo(\eta^3\text{-}C_3H_4)(CO)_2(NCMe)_2X]$ has been shown as a useful precursor to prepare mononuclear derivatives, used both as catalysts for polymerisation of certain dienes [6] and in organic synthesis for allylic alkylations [7]. Their cationic anologues, having the two nitriles replaced by a L–L ligand, for instance, always show a fac arrangement of the $\eta^3\text{-}C_3H_4$ and the two CO ligands and exhibit two isomers, B (equatorial) with C_s symmetry and A (axial) without symmetry (Scheme 1).

An increased interest in the chemistry of α-diimine ligands and their complexes [8–12] was stimulated by the recent discovery by Brookhart and co-workers of Ni(II) and Pd(II) α-olefin polymerization catalyst containing bulky α-diimine ligands [13–16].

In the last few years, several new cationic allyl complexes of palladium and nickel with α-diimine ligands have been synthesized by our group [17]. We wish therefore to report new cationic Mo(II) allyl complexes of general formula $[Mo(\eta^3\text{-}C_3H_4\text{–}Me\text{-}2)(CO)_3(N\text{–}N)]^+PF_6^-$ with N–N as an α-diimine ligands. The solid state structure of the cation **4** (N–N = 2,6-Me_2–C_6H_3–N=C(Me)–C(Me)=N–C_6H_3–2,6-Me_2) was determined at room temperature, allowing the observation of the allyl geometry in great detail.



2. Results and discussion

Allyl complexes of the type $[Mo(\eta^3\text{-}C_3H_4\text{–}Me\text{-}2)(CO)_3(N\text{–}N)]^+PF_6^-$ **(2–6)** (N–N = bipy, Ar-BIAN [18], DAD [19]) can be obtained successfully in high yields by an oxidative addition of methallyloxyphosphonium [20] to the zerovalent compound $Mo(CO)_3$(p-xylene) in tetrahydrofuran to produce the axial isomer $[Mo(\eta^3\text{-}C_3H_4\text{–}Me\text{-}2)(CO)_3(THF)_2]^+PF_6^-$ **(1)** whereas "equatorial" isomers are found for halide analogues [21]. The reaction in situ of compound **1** with the α-diimine ligand in methylene chloride at room temperature offered the cationic η^3-methallyl molybdenum complexes **(2–6)** supported by the α-diimine ligands (Scheme 2).

Compounds **2–6**, crystallized as red crystals for complex **2**, blue-purple for complexes **3–4** and green for complexes **5–6** from CH_2Cl_2/n-hexane, and are soluble in methylene chloride, chloroform and acetonitrile but only sparingly soluble in diethylether. They are stable at room temperature under an inert atmosphere; however, significant decomposition can be observed at high temperature. These compounds have been characterized by various techniques including ^1H, ^{13}C, IR spectroscopy and the single crystal X-ray structure determinations of the complex **4**.

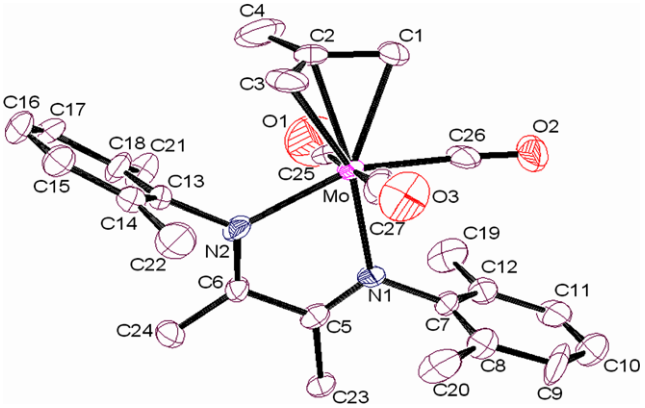
Scheme 1.

The variation of the steric and electronic proprieties of α-diimine ligands is possible by changing the aromatic substituent on the imine N atom. The new complexes exhibit spectroscopic data in accord with the proposed structures. The formation of the allyl complexes **2–6** is clear from the observed syn and anti allylic proton signals in the ^{1}H NMR. These signals were attributed considering that in allyl complexes, the syn protons resonate at higher frequencies than the anti protons [21,22]. Thus, the two resonances are located, respectively, at 1.07, 1.72 and 1.97, 0.92 and 1.43 ppm for H_{anti} and 1.23, 2.98, 2.58, 2.19 and 3.22 ppm for H_{syn} for complexes **2–6**. In ^{13}C NMR spectroscopy, the two terminal allylic carbons C1 and C3 appear at 61.6, 67.0, 69.0, 63.2 and 70.6 ppm, respectively, for complexes **2–6**. The C=N functions are shifted to high frequency when compared to free ligands and appear at 172.1, 171.0, 176.0 and 168.6, for complexes **3–6**, respectively. Two carbonyl carbon signals are shown in the ^{13}C NMR spectra.

The IR spectra are also instructive. The complexes **2–6** show in IR spectroscopy a C=N stretching frequency in the region 1606–1690 cm^{-1}, which is in agreement with those reported for other α-diimine complexes coordinated as an s-cis conformation [18,23]. Moreover, complexes **2–6** exhibit the frequency of the corresponding counteranion. The $\nu(PF_6^-)$ value is evident (843 cm^{-1}). The IR data for **2–6** show two strong carbonyl bands of equal intensity, consistent with cis-carbonyl groups in the [Mo(CO)$_2$(η^3-allyl] moiety.

A single crystal X-ray diffraction study confirms the identity of complex **4.** The molecular structure of **4** with the adopted numbering Scheme is shown in Fig. 1 with details of the structure determination, including unit-cell data, summarized in Table 1 and relevant bond distances and angles in Table 2. The coordination environment of the molybdenum center is pseudooctahedral with two carbon atoms from the carbonyl groups and the centroid of the allyl ligand determining a fac stereochemistry. The structure of complex **4** consists of loosely associated [(η^3-C$_3$H$_4$–Me-2)Mo(CO)$_3$(N–N)]$^+$ cation and octahedral PF_6^- counteranion without direct interactions as appears from the large distance between the metal and the nearest fluorine atom (Mo–F4 = 4.369 Å) which is close to other cationic allyl complexes [17].



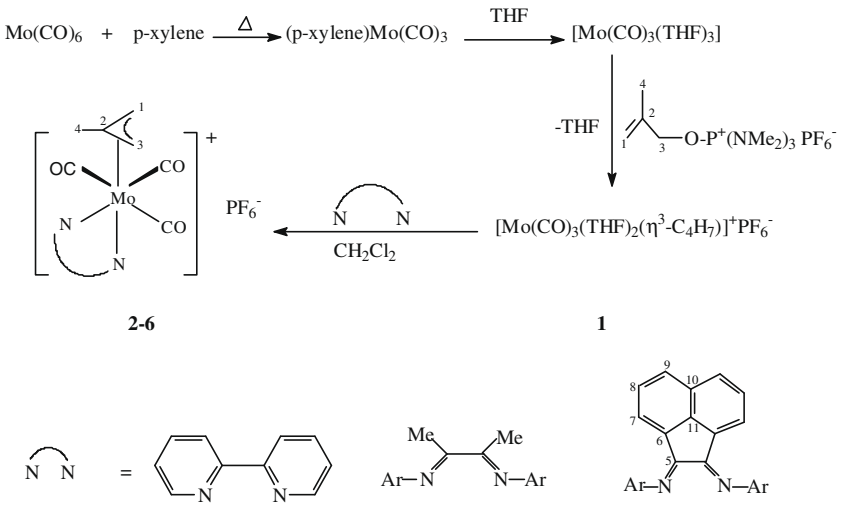


Fig. 1. ORTEP diagram of **4**.Thermal ellipsoids are drawn at the 50% probability level. PF_6^- anion and hydrogen atoms have been omitted for the sake of clarity.

In complex **4** structure, the allyl ligand adopts the usual endo conformation in the solid or in the solution state, with the open side eclipsing the two carbonyls C26O2 and C27O3. The two nitrogen donors from the (N–N) fragment occupy an equatorial and an axial coordination position (B in Scheme 2) which is in agreement with those reported for other diimine complexes [21,22].

In all complexes, the remaining equatorial position is taken by a carbonyl ligand. The α-diimine ligand is coordinated in a symmetric fashion as seen in Fig. 1, with Mo–N bond lengths of 2.213(7) and 2.267(9) Å which are very close to those reported for other related complexes [21,22]. The N1–Mo–N2 angle of 70.8(3)° reflects a

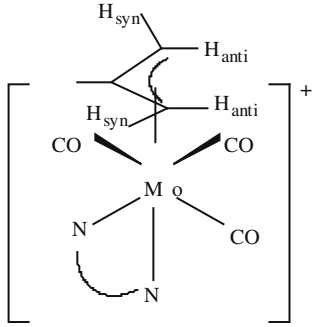
slightly distorted pseudo-octahedral coordination sphere which is identical to known values in the literature for other molybdenum allyl complexes [21,22]. The metal chelate ring (Mo–N1–C5–C6–N2) in complex **4** is almost flat as indicated by the torsion angles of −2.7(16), 7.0(13) and −3.0(13)° for N1–C5–C6–N2, Mo–N2–C6–C5 and Mo–N1–C5–C6, respectively. The allyl ligand is bonded symmetrically to the molybdenum center (Mo–C1 = 2.344(10) Å and Mo–C3 = 2.369(10) Å). We note that the Mo–C(allyl) distances are reasonable for an allyl trans to a ligand of moderate trans influences. The methyl on the allyl group is in the same plane of the allyl ligand as indicated by the torsion angle of 178.1° for C4–C2–C3–C1. The geometric arrangement found for the studied complex can be easily characterized by ϕ, which is the angle between the Mo–C25 with the line defined by the centroid of the allyl moiety and the molybdenum with Mo–C25. This ϕ parameter gives the orientation of the allyl fragment relative to the monodentate ligand and determines unequivocally the position of the bidentate ligand in the metal coordination sphere. Thus, in complex **4**, the ϕ angle takes an approximate value of 90° and the chelating of the α-diimine ligand occur via equatorial and axial sites.

The N1–C5, N2–C6 and C5–C6 bond distances of 1.289(13), 1.289(11) and 1.502(13) Å, respectively, confirm the conjugated nature of this ligand [24]. The o,o′-dimethylphenyl groups make an angle of approximately 90° to the plane of the C=N bonds, due to the presence of the o-methyl substituents, as appears from the torsion angles of −82.5(13), 98.5(11), 100.2(12) and −80.4(13) for C6–N2–C13–C18, C6–N2–C13–C14, C5–N1–C7–C12 and C5–N1–C7–C8, respectively.

3. Conclusion

π-Allyldicarbonyl complexes of molybdenum and tungsten formulated as [M(η^3-allyl)X(CO)$_2$L$_2$] (M = Mo, W; X = halogen; L = 2-electron donating molecule) have been extensively explored [25], since [M(η^3-allyl)(CO)$_2$] fragment often plays a role of the key in the catalytic organic transformations [26]. From this point of view, much effort has been made on the synthesis and reaction of these compounds bearing various monodendate (2-electron donor) and bidentate (4-electron donor) ligands [27].The nitrile complexes [Mo(η^3-C$_3$H$_5$)X(CO)$_2$(NCMe)$_2$] (X = halide) have been shown to act as precursors in the ring-opening metathesis polymerization of norbornene [28] and polymerization of terminal acetylenes as well as catalyze the oligomerization of *n*Ph(CC)*n*Ph, (*n* = 1, 2) [29]. Following these results, we prepared and characterized new complexes of the type [Mo(η^3-C$_3$H$_4$–Me-2)-(N–N)(CO)$_3$]$^+$PF$_6^-$ (N–N = α-diimine).



The X-ray structure of the complexes studied showed the presence of the equatorial-axial isomer, B in Scheme 1.

The synthetic procedure for preparing **2–6** complexes offers great versatility for the generation of other α-diimine allyl complexes of possible catalytic interest. The application of these compounds in catalytic reaction such as polymerisation of alkenes (ethylene, styrene, etc.), functional alkenes (methyl acrylate) and ring opening metathesis polymerisation of norbornene is currently under study.

4. Experimental

4.1. General

All manipulations were carried out under an atmosphere of dry argon using standard schlenk techniques. Diethyl ether was distilled from sodium benzopheneone; methylene chloride and hexane was distilled over P_2O_5. 2-Methylaniline, 2,6-diisopropylaniline were distilled from potassium hydroxide prior to use. Bipyridine (Bipy) and acenaphtenquinone were used as received from commercial sources. p-xylene was purified via column on alumna. α-diimine ligands were prepared according to literature methods [18,19]. NMR spectra were recorded on a Bruker AMX 300 spectrometer. H and C chemical shifts were given in ppm and referenced to the residual solvent resonance relative to TMS; H_{syn} and H_{anti} designate the syn- and the anti-H atoms, respectively, of the allyl ligand. The atom labelling scheme for the allyl complexes was shown below.

4.2. General procedure for the preparation of [(α-diimine)Mo(CO)$_3$ (η^3-C_3H_4–Me-2)]$^+PF_6^-$ complexes

In an inert atmosphere, $Mo(CO)_6$ compound (1 equiv.) was dissolved in small amount of p-xylene and refluxed for 2 h. Methallyloxyphosphonium [$C_4H_7OP^+(NMe_2)_3PF_6^-$] was added to the cold solution previously prepared in tetrahydrofuran. The yellow solution was stirred at room temperature for 24 h. The solvent was removed under vacuum to afford an oil compound which was dissolved in anhydrous CH_2Cl_2 and a α-diimine ligand was added. The solution was stirred at room temperature for 24 h. The supernatant was separated by filtration through a Celite filter, and the solvent was removed under vacuum to afford the oil complex. This was washed with n-hexane (3 × 15 ml) and dried in vacuum. The solid was crystallized from methylene chloride/ n-hexane solution at room temperature. Yields ranged from 83% to 94%.

4.2.1. Synthesis of [(Bipy)Mo(CO)$_3$(η^3-C_3H_4–Me-2)]$^+PF_6^-$ (**2**)

Following the general procedure, from $Mo(CO)_6$ (0.080 g, 0.3 mmol), p-xylene (5 ml), THF (15 ml), 2-methylallyloxyphosphonium (0.1 g, 0.26 mmol) and Bipy. (0.049 mg, 0.31 mmol) was obtained 0.188 g of **2** as a red solid after crystallization from a mixture (n-hexane/CH_2Cl_2: 9/1).

Yield 91%: IR [ν cm^{-1}] (KBr): 1606 (C=N); 1937, 1840 (CO); 848 (PF_6^-).

^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): 1.02 (s, 3H, H_4); 1.05–1.07 (d, 2H, H_{anti}, J_{HH} = 6 Hz), 1,23 (s, 2H, H_{syn}); 7.50–8.80 (m, 8H, bipy).

^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): 19.7 (C_4); 61.6 ($C_{1,3}$), 81.9 (C_2); 124.7, 126.9, 141.4, 151.3, 154.3 (bipy); 205, 208 (CO).

4.2.2. Synthesis of [(o-CH_3–C_6H_4N=C(Me)–C(Me)=N–C_6H_4–o-CH_3) Mo(CO)$_3$ (η^3-C_3H_4–Me-2)]$^+PF_6^-$ (**3**)

Following the general procedure, from $Mo(CO)_6$ (0.080 g, 0.3 mmol), p-xylene (5 ml), THF (15 ml), 2-methylallyloxyphosphonium (0.1 g, 0.26 mmol) and (*o-CH_3–C_6H_4N=C(Me)–C(Me)=N–C_6H_4–o-CH_3*) (0.079 mg, 0.3 mmol) was obtained 0.180 g of **3** as a blue-purple solid after crystallization from a mixture (n-hexane/CH_2Cl_2: 8/2).

Yield 93%. IR [ν cm^{-1}] (KBr): 1608 (C=N); 1949, 1860 (CO); 846 (PF_6^-).

^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): 1.18 (s, 6H, o-CH_3); 1.57 (s, 3H, H_4); 1.72 (s, 2H, H_{anti}); 2.14 (s, 3H, CH_3–C=N); 2.31 (s, 3H, CH_3–C=N); 2.98 (s, 2H, H_{syn}); 7.01–7.38 (m, 8H, H_{ar}).

^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): 18.1 (o,o-CH_3), 20.4 (o′,o′-CH_3); 21.5, 26.9 (CH_3–C=N); 30.1 (C_4); 67.0 ($C_{1,3}$); 71.0 (C_2); 104 ($C_{ortho'}$); 121.1 (C_{para}); 127.9 (C_{ortho}); 128.1 ($C_{meta'}$); 131.8 (C_{meta}); 149.8 (C_{ipso}); 172.1 (C=N); 204, 205 (CO).

4.2.3. Synthesis of [(2,6-(CH_3)$_2$–C_6H_3N=C(Me)–C(Me)=N–C_6H_3–2,6-(CH_3)$_2$)Mo(CO)$_3$ (η^3-C_3H_4–Me-2)]$^+PF_6^-$ (**4**)

Following the general procedure, from $Mo(CO)_6$ (0.080 g, 0.3 mmol), p-xylene (5 ml), THF (15 ml), 2-methylallyloxyphosphonium (0.1 g, 0.26 mmol) and (*2,6-(CH_3)$_2$–C_6H_3N=C(Me)–C(Me)=N–C_6H_3–2,6-(CH_3)$_2$*) (0.087 mg, 0.3 mmol) was obtained 0.190 g of **4** as a blue-purple solid after crystallization from a mixture (n-hexane/CH_2Cl_2: 8/2).

Yield 94%. IR [ν cm^{-1}] (KBr): 1622 (C=N); 1940, 1857 (CO); 843 (PF_6^-).

^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): 1.25 (s, 6H, o,o′-CH_3); 1.73 (s, 3H, H_4); 1.97 (s, 2H, H_{anti}); 2.18 (s, 6H, o,o′-CH_3); 2.24 (s, 6H, CH_3–C=N); 2.58 (s, 2H, H_{syn}); 7.00–7.26 (m, 6H, H_{ar}).

^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): 17.5 (o,o-CH_3), 18.6 (o′,o′-CH_3); 20.2, 23.4 (CH_3–C=N); 24.1 (C_4); 69.0 ($C_{1,3}$); 86.0 (C_2); 127.2 ($C_{ortho,ortho'}$); 128.7 (C_{para}); 129.0 (C_{meta}); 149.8 (C_{ipso}); 171 (C=N); 200, 207 (CO).

4.2.4. Synthesis of [(o-CH_3–C_6H_4–BIAN)Mo(CO)$_3$ (η^3-C_3H_4–Me-2)]$^+PF_6^-$ (**5**)

Following the general procedure, from $Mo(CO)_6$ (0.080 g, 0.3 mmol), p-xylene (5 ml), THF (15 ml), 2-methylallyloxyphosphonium (0.1 g, 0.26 mmol) and (*o-CH_3–C_6H_4–BIAN*) (0.108 g, 0.3 mmol) was obtained 0.185 g of **5** as a green solid after crystallization from a mixture (n-hexane/CH_2Cl_2: 8/2).

Yield 91%. IR [ν cm^{-1}] (KBr): 1638, 1690 (C=N); 1948, 1854 (CO); 840 (PF_6^-).

^{1}H NMR (300 MHz, MeOD, 25 °C, δ [ppm]): 0.92 (s, 2H, H_{anti}); 1.29 (s, 3H, H_4); 2.19 (s, 2H, H_{syn}); 2.39(s, 3H, o,o′-CH_3); 2.69 (s, 3H, o,o′-CH_3); 7.15–7.29 (m, 14H, 8H_{ar} + 6 $H_{7,8,9}$).

^{13}C NMR (75.5 MHz, MeOD, 25 °C, δ [ppm]): 14.2 (o,o′-CH_3); 22.7 (C_4); 63.2 ($C_{1,3}$); 71.6 (C_2); 113.1 ($C_{ortho'}$); 123.6 (C_7); 127.1 (C_{para}); 127.2 (C_{ortho}); 127.6 ($C_{meta'}$); 128.9 (C_8); 129.7(C_9); 129.9 (C_{10}); 130.3 (C_{meta}); 131.5 (C_6); 139.2 (C_{11}); 148.1 (C_{ipso}); 176 (C=N); 203, 205 (CO).

4.2.5. Synthesis of [(2,6-(iPr)$_2$–C_6H_3–BIAN)Mo(CO)$_3$ (η^3-C_3H_4–Me-2)]$^+PF_6^-$ (**6**)

Following the general procedure, from $Mo(CO)_6$ (0.080 g, 0.3 mmol), p-xylene (5 ml), THF (15 ml), 2-methylallyloxyphosphonium (0.1 g, 0.26 mmol) and (*2,6-(iPr)$_2$–C_6H_3–BIAN*) (0.142 g, 0.3 mmol) was obtained 0.226 g of **6** as a green solid after crystallization from a mixture (n-hexane/CH_2Cl_2:8/2).

Yield 88%. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C, δ [ppm]): 0.77–0.79 (d, 12 H, J_{HH} = 6.6 Hz, CH_3–iPr); 1.05–1.03 (d, 12H, J_{HH} = 6.9 Hz, CH_3–iPr); 1.25 (s, 3H, H_4); 1.43 (s, 2H, H_{anti}); 2.81–2.86 (sept, 4H, J_{HH} = 6,6 Hz, CH–iPr); 3.22 (s, 2H, H_{syn}); 6.43–6.45 (d, 2H, J_{HH} = 7.2 Hz, H_7); 7.07–7.37 (m, 6H, H_{ar}), 7.67–7.70 (d, 2H, H_9, J = 8.1 Hz).

^{13}C NMR (75.5 MHz, $CDCl_3$, 25 °C, δ [ppm]): 14.1 (C_4); 23.7, 24.3, 25.0, 25.3, 25.7, 26.5 (CH_3–iPr); 28.0, 28.5, 29.4, 29.7 (CH–iPr); 70.6 ($C_{1,3}$); 75.1 (C2); 125.0 (C_7); 125.3 (C_{meta}); 125.7 (C_{para}); 127.5 (C_8); 128.1(C_9); 128.6 (C_6); 130.3 (C_{10}); 139.5 (C_{ortho}); 141.0(C_{11}); 147.7 (C_{ipso}); 168.6 (C=N); 203, 205 (CO).

4.3. X-ray crystallographic study

The X-ray crystallographic study of complex **4** is carried out on a MACH3 Enraf Nonius diffractometer using monochromated Mo Kα radiation (λ = 0.71073 Å) at 293 K. Accurate unit cell parameters and orientation matrix are determined from 25 reflections in the range 13–15°. Intensity data are collected by using the ω–2θ scan mode with a range of 2 < θ < 27°. All the intensity data are corrected for Lorentz and polarization effects. The crystal structure solution carried out with direct methods from the SHELXS-97 permitted the location of all non-hydrogen atoms. After anisotropic least-squares refinement, hydrogen atoms are placed at their geometrically calculated positions and refined riding on the corresponding atoms with isotropic thermal parameters. Final refinement based on the reflections [$I > 2\sigma(I)$] converged at R_1 = 0.0880, wR_2 = 0.2175 and GoF = 0.960. The experimental conditions of data collection, strategy followed for the structure determination, and final results are given in Table 1.

Appendix A. Supplementary data

CCDC 276931 contains the supplementary crystallographic data for this article. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ,

UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2008.11.050.

ABSTRACT

The synthesis of lanthanide hydroxo complexes stabilized by a carbon-bridged bis(phenolate) ligand 2,2'-methylene-bis(6-*tert*-butyl-4-methylphenoxo) ($MBMP^{2-}$) was described, and their reactivity toward phenyl isocyanate was explored. Reactions of $(MBMP)Ln(C_5H_5)(THF)_2$ with a molar equiv. of water in THF at −78 °C afforded the bis(phenolate) lanthanide hydroxides as dimers $[\{(MBMP)Ln(\mu\text{-}OH)(THF)_2\}_2]$ [Ln = Nd (**1**), Yb (**2**)] in high yields. Complexes **1** and **2** reacted with phenyl isocyanate in THF, after workup, to give the desired O−H addition products, $[(MBMP)Ln(\mu\text{-}\eta^1\text{:}\eta^2\text{-}O_2CNHPh)(THF)_2]_2$ [Ln = Nd (**3**), Yb (**4**)] in excellent isolated yields. These complexes were well characterized, and the molecular structures of complexes **2** to **4** were determined by X-ray crystallography. The ytterbium atom in complex **2** is coordinated to six oxygen atoms to form a distorted octahedral geometry, whereas each metal center in complexes **3** and **4** is seven-coordinated, and the coordination geometry can be best described as a distorted pentagonal bipyramid.

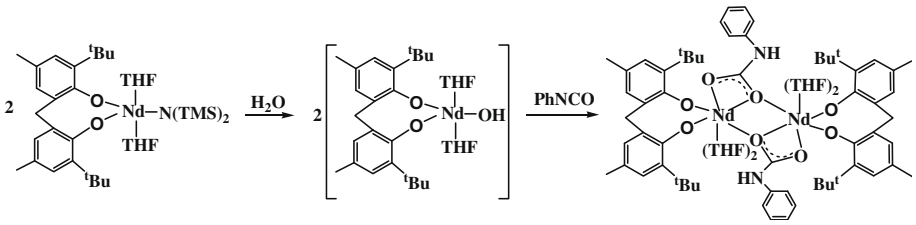
1. Introduction

Carbon-bridged bis(phenol)s, such as 2,2'-methylene-bis(6-*tert*-butyl-4-methylphenol) ($MBMPH_2$) and 2,2'-ethylidene-bis(4,6-di-*tert*-butylphenol) ($EDBPH_2$), have been used in transition and main group metal coordination chemistry for a long time. These ligands have been found to be able to act as dianionic ligands, which have the advantage of providing a stereochemically rigid framework for the metal center that could affect stereospecific transformations. Meanwhile, some of these transition and main group metal complexes have shown great potential application in homogeneous catalysis [1–13]. In contrast, the synthesis and reactivity of lanthanide complexes stabilized by carbon-bridged bis(phenolate) groups has seldom been studied.

Our recent studies have demonstrated that the carbon-bridged bis(phenolate) lanthanide complexes also have interesting reactivity [14–19]. For example, the neutral trivalent lanthanide alkoxo complexes based on these ligand systems can initiate efficiently the ring-opening polymerization of ε-caprolactone in a controlled manner [15,17]; the neutral and anionic lanthanide amides stabilized by the $MBMP^{2-}$ group can be synthesized in a controlled manner using $[(MBMP)Ln(\mu\text{-}Cl)(THF)_2]_2$ as the precursors by tuning of the molar ratio of the reagents, and the neutral bis(phenolate) lanthanide amides $[(MBMP)Ln\{N(SiMe_3)_2\}(THF)_2]$ cannot only initiate efficiently ε-caprolactone polymerization, but also activate carbodiimide to give lanthanide guanidinate complexes [18]. During our further study of the reactivity of $[(MBMP)Nd\{N(SiMe_3)_2\}(THF)_2]$ with phenyl isocyanate, an unexpected by-product $[\{(MBMP)Nd(\mu\text{-}\eta^1\text{:}\eta^2\text{-}O_2CNHPh)(THF)_2\}_2]$ was isolated. The proposed formation mechanism of this complex is that the partial hydrolysis of bis(phenolate) neodymium amide forms the corresponding neodymium hydroxide first, and then phenyl isocyanate inserts to the O−H bond to form the final product as shown in Scheme 1. Although the lanthanide hydroxides have been known for a long time, to our best knowledge, there is only one paper which reported the regioselective transformation of the hydroxo group of the organolanthanide hydroxides. Zhou et al. recently reported the reactivity of the lanthanocene hydroxides toward some small molecules [20]. This promoted us to study the synthesis and reactivity of bis(phenolate) lanthanide hydroxides. Here we report the results.



2. Results and discussion

2.1. Synthesis and characterization of bis(phenolate) lanthanide hydroxides

In order to confirm the above postulation, we intend to synthesize the bis(phenolate) lanthanide hydroxides and explore their reactivity toward phenyl isocyanate. Our previous work has demonstrated that carbon-bridged bis(phenolate) lanthanide

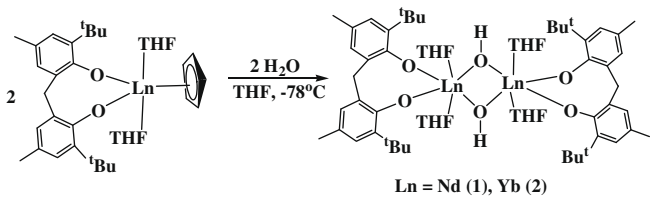

Scheme 1.

cyclopentadienyl complexes, $[(MBMP)Ln(C_5H_5)(THF)_n]$, are good precursors for the synthesis of the corresponding lanthanide derivatives via protic exchange reactions and a partial hydrolysis product was isolated [15,19]. Thus, $[(MBMP)Ln(C_5H_5)(THF)_n]$ were used as starting materials to synthesize the bis(phenolate) lanthanide hydroxides by controlled hydrolysis reaction. $[(MBMP)Ln(C_5H_5)(THF)_2]$ (Ln = Nd, Yb) reacted with distilled water in THF in a 1:1 molar ratio at −78 °C, the color of the solution changed gradually from blue to pale blue (for neodymium) or yellow to pale yellow (for ytterbium). After workup, pale blue (complex **1**) or pale yellow (complex **2**) microcrystals were obtained in good isolated yields. Elemental analysis results revealed that these complexes consist of one dianionic bis(phenolate) group ($MBMP^{2-}$), one hydroxide, and two coordinated THF molecules at the metal center. Their IR spectra show the characteristic absorption bands of hydroxo group at about 3605 cm^{-1}, and aromatic rings in the region 1400–1600 cm^{-1} (skeletal vibrations). Further molecular structure determination of complex **2** confirmed that they have solvated dimeric structures $[\{(MBMP)Ln(\mu\text{-}OH)(THF)_2\}_2]$ [Ln = Nd (**1**), Yb (**2**)] as shown in Scheme 2.

The molecular structure of complex **2** is shown in Fig. 1, and its selected bond lengths and angles are listed in Table 1. Complex **1** has a dimeric structure, and two molecules are connected together by two bridged hydroxo groups. The molecule has approximate C_2 symmetry. Each ytterbium atom is six-coordinated with two oxygen atoms from one bridged bis(phenolate) group, two oxygen atoms from two bridged hydroxo groups and two oxygen atoms from two THF molecules. The coordination geometry at ytterbium atom can be described as a distorted octahedron, in which O(1), O(2), O(5) and O(6) can be considered to occupy the equatorial positions, and O(7) and O(8) to occupy the apical positions, and the angle of O(7)–Yb–O(8) is distorted away from the idealized 180° to 171.9(2)°.

The average Yb–O(Ar) bond length of 2.085(6) Å falls in the range of Yb–O(Ar) bond lengths in other carbon-bridged bis(phenolate) ytterbium complexes, such as $[\{(MBMP)_2Yb(\mu\text{-}OPr^i)(THF)_2\}_2]$ [15], $[Li(THF)_4][(MBMP)Yb\{N(SiMe_3)_2\}_2]$, and $[\{(MBMP)Yb(\mu\text{-}Cl)(THF)_2\}_2]$ [18] [2.059(2)–2.120(3) Å]. The Yb–O(H) bond lengths range from 2.211(4) to 2.241(4) Å, giving the average of 2.227(5) Å, which is comparable well with the corresponding bond lengths in $[\{(MBMP)_2Yb(THF)_2\}_2(\mu\text{-}OCH_2Ph)(\mu\text{-}OH)]$ [2.211(4) Å] [15], $[\{Yb(OC_6H_3\text{-}2,4,6\text{-}Bu^t_3)_2(\mu\text{-}OH)(THF)\}_2]$ [2.208(6) Å] [21], $[\{Yb(OC_6H_3\text{-}2,6\text{-}Bu^t_2)_2(\mu\text{-}OH)(THF)\}_2]$ [2.217(7) Å] [22] and $[(Me_3SiC_5H_4)_2Yb(\mu\text{-}OH)_2]$ [2.29(2) Å] [23]. The most remarkable feature of the structure of complex **2** is that there is remote O–H···Yb interaction involving the hydroxide hydrogen atom. The Yb(2)–H(5A) bond length of 2.75(4) Å is significantly longer than the Ln–H bond lengths in most of the organolanthanide hydrides [24,25], but it accords with the Lu(1)–H(2) of 2.70(5) Å in $[\{(C_5Me_4SiMe_3)LuH_2\}_4]$ [25], and Y(1)–H(16e) of 2.935(6) Å in $[(C_5Me_5)Y(OC_6H_3{}^tBu_2)CH(SiMe_3)_2]$ [26].

Scheme 2.

2.2. Reactivity with phenyl isocyanate

Reactions of complexes **1** and **2** with phenyl isocyanate in THF, after workup, gave the desired O–H addition products, $[\{(MBMP)Ln(\mu\text{-}\eta^1\text{:}\eta^2\text{-}O_2CNHPh)(THF)_2\}_2]$ [Ln = Nd (**3**), Yb (**4**)] in excellent isolated yields as shown in Scheme 3. Complexes **3** and **4** were characterized by elemental analysis and IR spectroscopy, and their definitive molecular structures were provided by single-crystal X-ray diffraction. These reactions are quite different from those of lanthanocene hydroxides with phenyl isocyanate reported by Zhou et al. and complexes **3** and **4** can be considered as the proposed intermediate species (II) in the latter [20]. Attempts to eliminate the N–H proton with $[(C_5H_5)_3Ln(THF)]$ as that reported by Zhou were unsuccessful, and the isolated compound is the starting material. These results revealed that the ancillary ligands have a profound effect on the reactivity of the corresponding lanthanide complexes.

Complexes **3** and **4** are isostructural, and only the molecular structure of complex **3** is shown in Fig. 2, and their selected bond lengths and angles are provided in Table 2. Both complexes have solvated C_2 symmetric dimeric structures. Two molecules are connected together by two bridged oxygen atoms from carbaminate groups $PhNHCO_2$, and the eight atoms Nd(1), O(3), C(24), O(4), Nd(1A), O(3A), C(24A), and O(4A) form an interlinked tricyclic structure via the two bridged Nd–O bonds [Nd(1)–O(3A) and Nd(1A)–O(3)]. The corn structure is similar to those of $[\{(CH_3C_5H_4)_2Y(\mu\text{-}\eta^1\text{:}\eta^2\text{-}S_2CNPh_2)\}_2]$ [27], and $[\{Cp_2Ln(\mu\text{-}\eta^1\text{:}\eta^2\text{-}O_2CCHEtPh)\}_2]$ (Ln = Yb, Er, Y) [20], but different from that of $[\{(C_5Me_5)_2Sm(\mu\text{-}O_2CEPh)\}_2]$ [28]. Each central metal atom is seven-coordinated by two oxygen atoms from one bridged bis(phenolate) ligand, and one oxygen atom from a $PhNHCO_2$ group, and two oxygen atoms from another $PhNHCO_2$ group, and two oxygen atoms from two THF molecules. The coordination geometry around the central metal atom can be described as a distorted pentagonal bipyramid, in which O(1), O(5), O(4A), O(3A) and O(3) can be considered to occupy the equatorial positions with the sum of the bond angles of 360.2° in complex **3**, and 359.7° in complex **4**, respectively, and O(2) and O(6) to occupy the axis positions. The bond angles of O(2)–Ln–O(6) are slightly distorted away from the ideal value of 180° to 164.6(1)° in complex **3**, and 162.8(1)° in complex **4**, respectively.

The Nd–O(Ar) bond distances are 2.267(3) and 2.154(4) Å, giving the average of 2.210(4) Å, which is very close to those observed in related neodymium complexes $[\{(MBMP)_2Nd(\mu\text{-}OPr^i)(THF)_2\}_2]$ [2.215(6) Å] [15], $[\{(EDBP)Nd(\mu\text{-}O^iPr)(THF)\}_2]$ [2.225(5) Å] [17], $[(MBMP)Nd\{N(TMS)_2\}(THF)_2]$ [2.200(2) Å], and $[Li(THF)_4][(MBMP)Nd\{N(TMS)_2\}_2]$ [2.195(3) Å] [18]. The carbaminate group is asymmetrically coordinated to the neodymium atom with the var-

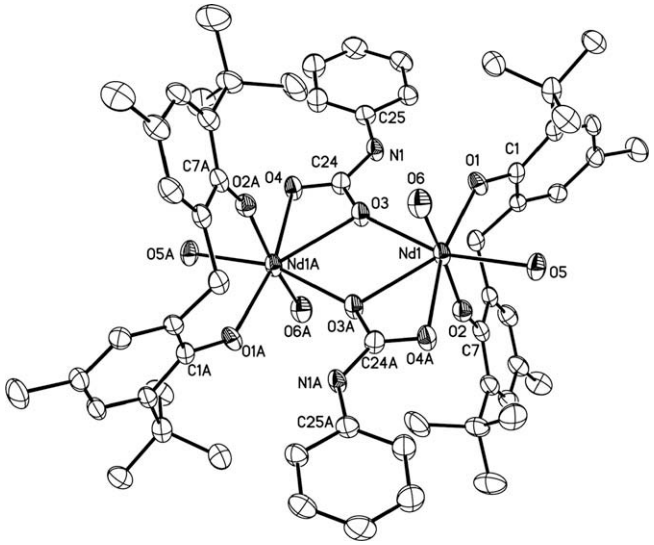
Yb(1)–O(6)	2.237(4)	Yb(2)–O(6)	2.211(4)
O(1)–C(1)	1.344(6)	O(3)–C(24)	1.338(6)
O(2)–C(7)	1.351(6)	O(4)–C(30)	1.340(6)
Bond angle			
O(1)–Yb(1)–O(2)	97.4(2)	O(3)–Yb(2)–O(4)	97.8(2)
O(2)–Yb(1)–O(6)	88.8(2)	O(4)–Yb(2)–O(5)	90.6(2)
O(5)–Yb(1)–O(6)	71.7(1)	O(5)–Yb(2)–O(6)	71.9(1)
O(1)–Yb(1)–O(5)	102.9(1)	O(6)–Yb(2)–O(3)	100.8(2)
O(8)–Yb(1)–O(7)	171.9 (2)	O(9)–Yb(2)–O(10)	172.7(1)

iation in Nd–O bond lengths of about 0.07 Å [2.493(3) and 2.563(3) Å, respectively], which is similar to those found in [{$Cp_2Ln(\mu\text{-}\eta^1{:}\eta^2\text{-}O_2CCHEtPh)$}$_2$] (Ln = Yb, Er, Y) [20]. The Nd–O(3) bond length of 2.395(3) Å is comparable with the averaged bridged Nd–O(Ar) bond length in neodymium bis(phenolate) guanidinate complex [{(μ-O-MBMP)Nd[(^{i}PrN)$_2$CN(TMS)$_2$]}$_2$] (2.401 Å) [18], but is apparently smaller than the bond lengths of Nd–O(3A) [2.493(3) Å] and Nd–O(4A) [2.563(3) Å]. The latter compare well with the bond lengths of Nd–O(THF) [2.458(3) and 2.567(4) Å], which revealed that these bonds are donating bond of neutral oxygen-donor ligands. It is worthy to note that the bridged Nd–O(3A) bond is shorter than the terminal Nd–O(4A) bond, which is quite different from those in [{$Cp_2Ln(\mu\text{-}\eta^1{:}\eta^2\text{-}O_2CCHEtPh)$}$_2$] (Ln = Yb, Er, Y) [20]. Generally, the bridged bond is longer than the terminal one. The shorter bridged Nd–O bond length in our case might be attributed to the relatively weak electron delocalization within the carbaminate group. Because the C(24)–O(4) bond length of 1.249(6) Å falls in the range



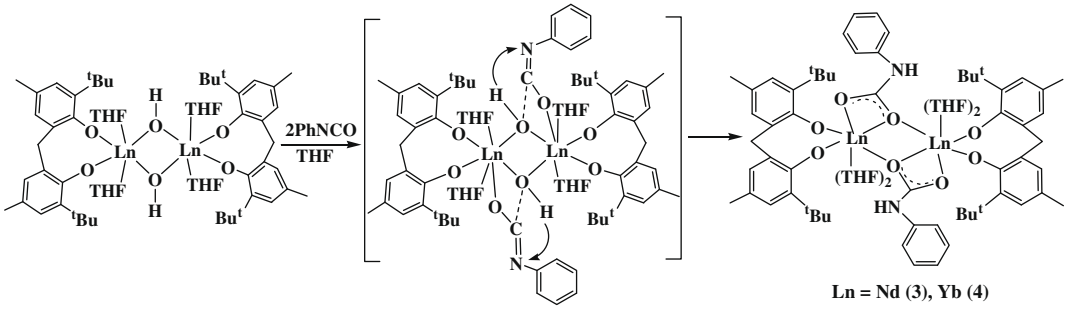


Fig. 2. ORTEP diagram of complex **3** showing atom-numbering scheme. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms and carbon atoms of THF molecules are omitted for clarity. Complex **4** is isostructural with complex **3**.

Scheme 3.

Ln(1)–O(3)	2.395(3)	2.285(3)	Ln(1)–O(3A)	2.493(3)	2.368(3)
Ln(1)–O(4A)	2.565(3)	2.421(3)	Ln(1)–O(5)	2.458(3)	2.326(3)
Ln(1)–O(6)	2.567(4)	2.407(4)	Ln(1)–C(24A)	2.924(5)	2.780(5)
O(3)–C(24)	1.307(5)	1.308(6)	O(4)–C(24)	1.249(6)	1.240(6)
Bond angle					
O(2)–Ln(1)–O(6)	164.6(1)	162.8(1)	O(1)–Ln(1)–O(5)	87.7(1)	84.9(1)
O(5)–Ln(1)–O(4A)	76.1(1)	76.3(1)	O(4A)–Ln(1)–O(3A)	51.7(1)	54.4(1)
O(3A)–Ln(1)–O(3)	64.9(1)	64.5(1)	O(3)–Ln(1)–O(1)	79.8(1)	79.6(1)
Ln(1)–O(3)–Ln(1A)	115.2(1)	115.6(1)			

of C=O double bond and the C(24)–O(3) bond length of 1.307(5) Å falls in the range of C–O single bond, and the deviation of their bond distances is apparently larger than the corresponding values found in [{$Cp_2Ln(\mu\text{-}\eta^1{:}\eta^2\text{-}O_2CCHEtPh)$}$_2$] (Ln = Yb, Er, Y) [20]. There is a strong π interaction of the carbon atom of the carbaminate group with the neodymium atom. The Nd–C(24A) bond length of 2.924(5) Å is apparently lower than the Nd–C contact observed in [{(MBMP)Nd(μ-O^{i}Pr)(THF)$_2$}$_2$] [3.101(7) Å] [15] and compares well with those observed in the neutral arene neodymium complexes [Nd(η^6-C_6H_6)($AlCl_4$)$_3$] [2.933(18) Å] [29], [Nd(η^6-C_6H_5Me)($AlCl_4$)$_3$] [2.926(5) Å] [30], and [Nd(η^6-1,3,5-$C_6H_3Me_3$)($AlCl_4$)$_3$] [2.916(9) Å] [31], in which the Nd–C π interaction was considered to exist unambiguously.

In complex **4**, the average Yb–O(Ar) bond length is 2.112(3) Å, which accords with those found in the carbon-bridged bis(phenolate) lanthanide complexes mentioned above when the difference in ionic radii is considered. The Yb–O(3) bond distance of 2.285(3) Å is also apparently smaller than the Yb–O(3A) and Yb–O(4A) bond distances, which revealed the Yb–O(3A) and Yb–O(4A) bond are donating bond. The Yb–C(24A) bond length of 2.780(5) Å compares well with that in complex **3**, when the difference in ionic radii is considered, but apparently lower than that found in the neutral arene ytterbium complex [Yb(η^6-1,3,5-C_6Me_6)($AlCl_4$)$_3$] [2.87(4) Å] [32], which indicating the presence of strong π interaction. Similar to that in complex **3**, the terminal Yb–O(4A) bond is longer than the bridged Yb–O(3A) bond.

3. Conclusion

In summary, the lanthanide hydroxides stabilized by a carbon-bridged bis(phenolate) ligand were prepared, and their reactivity toward phenyl isocyanate was explored. The structural properties of some of these complexes were provided by X-ray diffraction. Controlled hydrolysis of bis(phenolate) lanthanide cyclopentadienyl complexes in THF at low temperature gave the corresponding lanthanide hydroxides as dimers. These lanthanide hydroxo complexes reacted with phenyl isocyanate in THF to give the desired O–H addition products, which provided an alternative route to synthesize lanthanide carbaminate complexes. In comparison with the final products of the reactions of lanthanocene hydroxides with phenyl isocyanate, theses results revealed that the ancillary ligands have a profound effect on the reactivity of the corresponding lanthanide complexes.

4. Experimental

4.1. Materials and methods

All of the manipulations described below were performed under an argon atmosphere, using the standard Schlenk techniques. Solvents were dried and freed of oxygen by refluxing over sodium or sodium benzophenone ketyl and distilled under argon prior to use. [(MBMP)Ln(C_5H_5)(THF)$_2$] were prepared according to the literature methods [15,19]. The other reagents were purchased from Acros and used as received without further purification. Metal analyses were carried out using complexometric titration. Carbon, hydrogen, and nitrogen analyses were performed by direct combustion on a Carlo Erba-1110 instrument; Quoted data are the average of at least two independent determinations. IR spectra were recorded on a Nicolet-550 FTIR spectrometer as KBr pellets. The uncorrected melting points of crystalline samples in sealed capillaries (under argon) are reported as ranges.

4.2. Synthesis of [{(MBMP)Nd(μ-OH)(THF)$_2$}$_2$] (**1**)

A solution of [(MBMP)Nd(C_5H_5)(THF)$_2$] (1.47 g, 2.13 mmol) in THF (30 mL) was cooled to −78 °C. The solution was stirred half an hour, and then a THF solution (30 mL) containing distilled water (38 mg, 2.13 mmol) was added dropwise. The color of the solution was changed gradually from blue to pale blue. The mixture was stirred for 2 h, and then warmed to room temperature and stirred overnight. Little precipitate was separated by centrifugation, and the resulting pale blue solution was concentrated to about

18 mL. Pale blue microcrystals were obtained at room temperature in a few days (0.97 g, 71%), m.p.: 176–178 °C (dec). *Anal. Calc.* for $C_{62}H_{94}Nd_2O_{10}$: C, 57.82; H, 7.36; Nd, 22.40. Found: C, 57.58; H, 7.81; Nd, 22.66%. IR (KBr pellet, cm^{-1}): 3607(m), 3385(m), 2955(s), 2913(m), 1605(m), 1461(s), 1433(s), 1350(m), 1212(s), 1158(s), 867(w), 729(w).

4.3. Synthesis of [{(MBMP)Yb(μ-OH)(THF)$_2$}$_2$] (**2**)

The synthesis of complex **2** was carried out in the same way as that described for complex **1**, but [(MBMP)Yb(C_5H_5)(THF)$_2$] (1.34 g, 1.86 mmol) was used instead of [(MBMP)Nd(C_5H_5)(THF)$_2$]. Pale yellow microcrystals were obtained at room temperature in a few days (0.75 g, 60%), m.p.: 180–182 °C (dec). *Anal. Calc.* for $C_{62}H_{94}O_{10}Yb_2$: C, 55.35; H, 7.04; Yb, 25.72. The crystals suitable for an X-ray crystal structure determination were obtained in THF solution at room temperature.

4.4. Synthesis of [{(MBMP)Nd(μ-η^1:η^2-O$_2$CNHPh)(THF)$_2$}$_2$] (**3**)

A Schlenk flask was charged with complex **1** (0.77 g, 0.60 mmol) and THF (30 mL). Phenyl isocyanate (PhNCO) (0.65 mL, 1.20 mmol) was added by syringe. The reaction mixture was stirred overnight at room temperature. After removed the volatiles under reduced pressure, the pale blue residue was washed with cooled THF twice. The pale blue powder was dried at room temperature (0.77 g, 84%), m.p.: 218–220 °C (dec). *Anal. Calc.* for $C_{76}H_{104}N_2Nd_2O_{12}$: C, 59.81; H, 6.87; N, 1.83; Nd, 18.90. Found: C, 59.41; H, 6.42; N, 1.95; Nd, 19.11%. IR (KBr, cm^{-1}): 3346(w), 2953(m), 2904(m), 1616(s), 1590(s), 1538(vs), 1445(s), 1337(m), 1298(s), 1239(m), 1024(m), 864(m), 779(m). The crystals suitable for an X-ray crystal structure determination were obtained by recrystallization from THF-toluene solution at room temperature.

4.5. Synthesis of [{(MBMP)Yb(μ-η^1:η^2-O$_2$CNHPh)(THF)$_2$}$_2$] (**4**)

The synthesis of complex **4** was carried out in the same way as that described for complex **3**, but complex **2** (0.67 g, 0.50 mmol) was used instead of complex **1**. Pale yellow powder was obtained at room temperature (0.64 g, 81%), m.p.: 198–200 °C (dec). *Anal.* Calc. for $C_{76}H_{104}N_2O_{12}Yb_2$: C, 57.64; H, 6.62; N, 1.77; Yb, 21.85. Found: C, 57.39; H, 6.50; N, 1.91; Yb, 21.54%. IR (KBr, cm^{-1}): 3347(w), 2953(m), 2905(m), 1617(s), 1591(s), 1538(vs), 1446(s), 1338(m), 1298(s), 1239(m), 1025(m), 864(m), 780(m). The crystals suitable for an X-ray crystal structure determination were obtained by recrystallization from THF-toluene solution at room temperature.

4.6. X-ray structures determination

Suitable single-crystals of complexes **2**–**4** were sealed in a thin-walled glass capillary for determination the single-crystal structure. Intensity data were collected with a Rigaku Mercury CCD area detector in ω scan mode using Mo Kα radiation (λ = 0.71070 Å). The diffracted intensities were corrected for Lorentz polarization effects and empirical absorption corrections. Details of the intensity data collection and crystal data are given in Table 3.

The structures were solved by direct methods and refined by full-matrix least-squares procedures based on $|F|^2$. All of the non-hydrogen atoms were refined anisotropically. All of the hydrogen atoms were held stationary and included in the structure factor calculation in the final stage of full-matrix least-squares refinement. The structures were solved and refined using SHELXL-97 programs.

Stoichiometry and homogeneity

ABSTRACT

When divalent metal chloride solutions of Mn, Fe, Co, Ni and Cd were mixed with potassium titanyl oxalate solution, mixed metal oxalates were obtained in the case of Fe, Co and Ni at room temperature in the pH range 1.5–3. In the case of manganese, heating was found to be necessary to induce precipitation and complete precipitation occurred at 80 °C. Mixed cadmium and titanyl oxalate precipitation was complete at a pH of 3 at room temperature. Various physico-chemical techniques were employed to characterize the as-dried oxalate precursors and the final $MTiO_3$ oxide powders (M = Mn, Fe, Co, Ni and Cd) obtained on thermal decomposition. All these experimental results relating to the synthesis and characterizations of $MTiO_3$ oxides are presented in this paper. The results suggest that the reaction of potassium titanyl oxalate and metal chloride solutions may not lead to the formation of a single molecular precursor by direct salt elimination reaction in the pH range 1.5–3.

1. Introduction

The chemical synthesis of solid inorganic materials is making an increasingly important contribution to the development and manufacture of ceramic materials [1,2]. It also plays a vital role in the development of fabrication techniques for the successful exploitation of various useful properties of ceramics [3]. There is a growing realization that a single source precursor with different metals assembled in one molecule in the desired metal ratios can lead to nanometer level defined morphology and interesting physical properties [4,5]. The metal titanates of the general formula $MTiO_3$ (M = Ba, Pb, Cd, Mn, Fe, Co, Ni, Cu and Zn), possessing perovskite or ilmenite structures, have been studied extensively as inorganic functional materials [6–9]. Of these, $BaTiO_3$, a well-known component of high dielectric constant ceramics for manufacturing capacitors, has been the subject of intense investigation by various research groups ([6] and the references cited therein). The microstructure and consequently the dielectric properties of $BaTiO_3$ are very much dependent on the stoichiometry with regard to the Ba/Ti ratio. The single source or molecular precursor, such as barium titanyl oxalate which is isostructural to potassium titanyl oxalate, has been used to control the final stoichiometry of $BaTiO_3$ [10].

The titanates of other divalent cations, such as Pb, Cd or transition metals Mn, Fe, Co, Ni, Cu and Zn, have wide applications ranging from solid oxide gas sensors to fuel cells [11–16]. In general, a solid state reaction of the respective oxides and/or carbonates of the respective metals is usually employed in industrial processes because of cost effectiveness. However, the ceramic method suffers from several disadvantages such as non-uniform distribution of grains, longer schedule of heating cycles etc. There have been many chemical methods such as co-precipitation, polymerized complexes and sol–gel that have been reported as alternate strategies to synthesize these titanates [17–36]. The sol–gel method of synthesis is not an ideal alternative route since it is not very cost effective. Among the other wet chemical methods, co-precipitation is a simple and convenient method of obtaining solids containing two or more metals.

Balyaev et al. [37] reported the preparation and thermal decomposition of cobalt titanyl oxalate, a molecular precursor for $CoTiO_3$. The authors have claimed that a molecular precursor was obtained when $CoCl_2 \cdot H_2O$ was reacted with potassium titanyl oxalate solution; however there was no clear structural characterization of the precursor and the final product. The authors have also reported that crystallization of $CoTiO_3$ occurred at temperatures as low as 650 °C. Prasad Rao and Suresh [32] studied the pH dependence of the formation of a stoichiometric precursor of the type $M[TiO(C_2O_4)_2] \cdot xH_2O$ (M = Ca, Cd and Pb), but it did not yield conclusive results. Dhage et al. [38] carried out a detailed work on the preparation of $PbTiO_3$ using potassium titanyl oxalate and concluded that the anionic species $TiO(C_2O_4)_2^{2-}$, obtained by dissolving potassium titanyl oxalate in water, is stable over a narrow range of pH and is destabilized by the addition of $PbCl_2$ solution to

doi:10.1016/j.poly.2008.11.056

produce the mixed metal oxalates, PbC_2O_4 and $TiO(C_2O_4)$. Lopes et al. [28] prepared $NiTiO_3$ and $CoTiO_3$ by a modified Pechini method in which they proposed the formation of ilmenite phases from $MTi(C_6H_5O_7)_2$ through an intermediate of the type $MTiO(C_2O_4)_2$ (M = Ni and Co).

With this background, the present investigation was carried out to examine whether a single source precursor of the type $MTiO(C_2O_4)_2$ can be obtained by a simple salt elimination reaction between divalent transition metal chlorides and potassium titanyl oxalate in an aqueous medium. This study has clearly shown that the stability of $TiO(C_2O_4)_2^{2-}$ could not be retained in aqueous solutions by the addition of divalent transition metal chlorides to yield a molecular precursor; instead a very fine mixture of transition metal oxalate and titanyl oxalate was obtained. The potassium titanyl oxalate played the dual role of the precipitating agent as well as the titanium source. The thermal decomposition of these mixed metal oxalates yielded a pure ilmenite structure in case of $MnTiO_3$ at significantly lower temperatures as compared to the standard ceramic method [19]. However, in the cases of Fe, Co, Ni and Cd, few impurities were present along with the ilmenite phase after decomposition. In all these cases, the ilmenite phase appeared after an initial firing at low temperatures.

2. Experimental

2.1. Synthesis

A solution of $MCl_2 \cdot xH_2O$ (M = Mn, Fe, Co, Ni and Cd) was prepared in 100 ml (0.2 M) of double distilled water. The starting metal salts were AnalaR Grade from CDH, India. Potassium titanyl oxalate (A.R. Grade, Specpure, India) solution was also prepared in double distilled water (0.1 M in 100 ml). To 100 ml of the potassium titanyl oxalate solution in a 500 ml beaker, 50 ml of $MCl_2 \cdot xH_2O$ solution was added dropwise under constant stirring. After complete addition, the pH of the mixture was measured. A pale pink colored precipitate was obtained by mixing the cobalt(II) chloride solution and potassium titanyl oxalate solution at room temperature. The pH of the solution containing the precipitate was found to be between 2 and 2.5. A sky blue colored precipitate was the product when the nickel(II) chloride solution was added. The pH of the solution containing the precipitate was found to be 1.5–2.0. A yellow colored precursor was obtained by the addition of iron(II) chloride solution to potassium titanyl oxalate solution. The pH of the solution containing the precipitate was between 2 and 3. In the case of $MnCl_2$, a precipitate did not appear at room temperature even though the pH of the mixed solution was in the range between 2 and 2.5. However, on heating to around 80 °C for nearly an hour, a white colored solid separated out. Also the addition of $CdCl_2$ solution to the potassium titanyl oxalate solution did not yield any solid product. However, when the pH of the solution was adjusted from 2 to 3, by the addition of ammonia solution, a white colored precipitate was obtained. The precipitates obtained in all the above cases were digested and filtered. The air dried powders were then subjected to various analyses.

2.2. Characterization

The thermal analysis studies in air and flowing nitrogen were carried out on a combined TG/DTA instrument Shimadzu model DTG-60 employing a heating rate of 10 °C/min. The FT-IR spectra were recorded in KBr medium using a Perkin–Elmer 2000 spectrometer. The powder X-ray diffraction patterns were recorded using a Philips X'Pert diffractometer as well as a Bruker D8 high resolution diffractometer employing Cu Kα radiation at a scan rate of 1°/min. The FT-Raman spectra of the samples were recorded on a Ranishaw spectrometer equipped with a CCD camera detector and an Ar ion laser operating at 514.5 nm at a power level of 10 mW. The Brunauer, Emmett and Teller (BET) method has been used to determine the specific surface area by means of a nitrogen adsorption isotherm on a Micromeritics, ASAP 2000. The SEM micrograph of the sample was recorded on a JEOL 200 keV instrument and a Zeiss EVO 50 machine. The EDX analysis of the samples was carried out using a Cambridge scanning electron microscope with an EDX attachment.

3. Results and discussion

Since there is a report on the formation of a molecular precursor in the case of cobalt in the literature by Balyaev et al. [37], the very first reaction that we carried out was between cobalt(II) chloride and potassium titanyl oxalate solutions. The EDX spectrum of the pale pink precipitate, obtained from this reaction, showed the ratio between Co and Ti to be 1:1 (Fig. 1a). The thermal analysis of the precursor in air showed that the mass loss took place in two major steps. This behavior is typical of metal oxalates and the total mass loss of 61% might correspond to $CoTiO_3$ or a physical mixture of

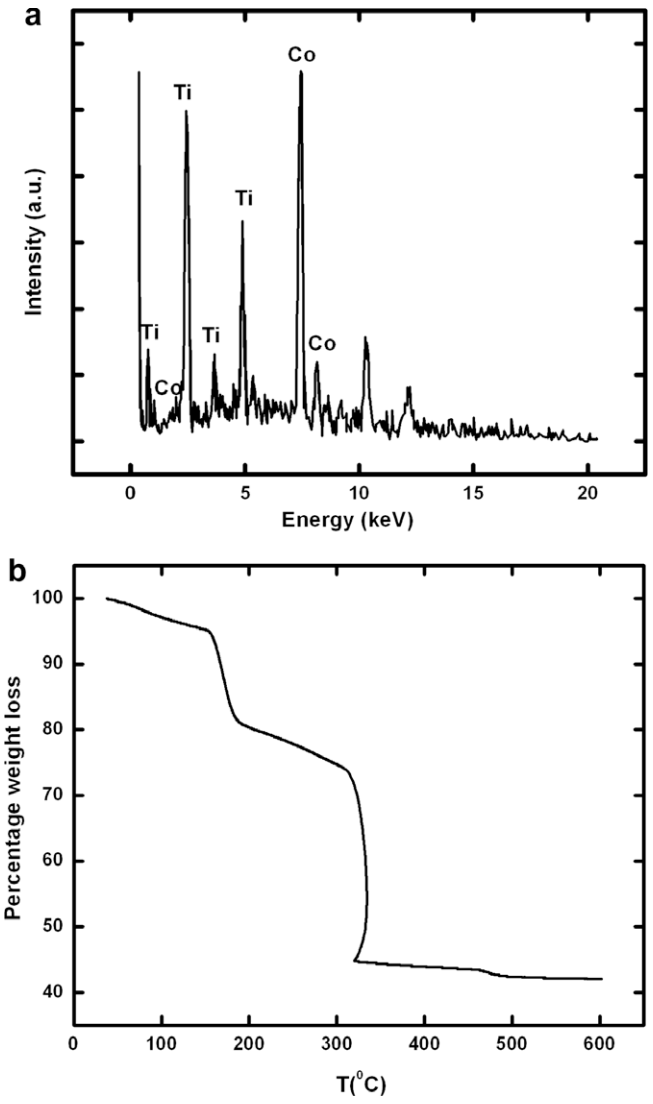

Fig. 1. (a) EDX spectrum of the precursor containing cobalt and titanium oxalates. (b) Thermogravimetric analysis of the precursor obtained from the reaction between solutions of $CoCl_2 \cdot 2H_2O$ and potassium titanyl oxalate in air.

CoO and TiO_2 as decomposition products (Fig. 1b). Two thermal events, one endothermic and one exothermic, were observed accompanying the mass loss in the DTA experiments. However, Balyaev et al. [37] reported three thermal events, two endotherms and one exotherm, during the thermal decomposition in air. The small exotherm around 650 °C, which the authors ascribed to the crystallization of $CoTiO_3$, was not observed in our preparation.

The powder X-ray diffraction pattern of the precursor showed that the product was poorly crystalline, while the major reflections corresponded to cobalt(II) oxalate as per the JCPDS File No. 48-1069 (Fig. 2a). The precursor was decomposed in air as well as in nitrogen at different temperatures. Peaks due to Co_3O_4 and TiO_2 (anatase) were observed in the powder X-ray diffraction pattern of the product decomposed at 500 °C in nitrogen (Fig. 2b). $CoTiO_3$ was the major phase formed along with the Co_2TiO_4 phase when the precursor was decomposed at 1100 °C in air over 12 h (Fig. 2c) (JCPDS File No. 15-0866). The spinel structured Co_2TiO_4

was reported to be a highly competitive phase with the ilmenite structured $CoTiO_3$ in the solid state reaction leading to $CoTiO_3$ [39]. Also, it was reported that repeated grinding and heating at 1200 °C between Co_3O_4 with TiO_2 was necessary to obtain pure $CoTiO_3$ [40]. However, in the present study, the precursor contained oxalates of cobalt and titanium, and therefore the in situ generation of the respective oxides might have taken place during the decomposition, leading to a diffusion controlled solid state reaction [38].

The FT-IR and FT-Raman spectra confirmed the formation of the ilmenite structure of $CoTiO_3$. The FT-IR spectrum exhibited two bands at 640 and 450 cm^{-1} due to O–Ti–O and Co–Ti–O bond formation, and showed the absence of metal carbonates. The Raman spectrum showed nine bands at 693, 603, 521, 480, 459, 383, 335, 267 and 246 cm^{-1} (Fig. 3). As per the theoretical analysis, 10 Raman modes ($5A_g + 5E_g$) were expected for the ilmenite structure of $CoTiO_3$ [41].

The surface morphology and surface area of the precursor, from mixing nickel(II) chloride and potassium titanyl oxalate solutions, were examined by the SEM and BET methods, respectively. An agglomeration of the particles was observed in the SEM and the observed BET surface area value of 4 m^2/g also suggested agglomeration. The EDX analysis of the precursor showed the ratio between Ni and Ti to be 1:1 (Fig. 4a). The thermal analysis of the product in air is shown in Fig. 4b. The total mass loss of 56% at 600 °C suggested that $NiTiO_3$ or a mixture of NiO and TiO_2 might be the decomposition products. The powder X-ray diffraction pattern of the precursor was highly crystalline as shown in Fig. 5a. The precursor contained peaks from nickel(II) oxalate (JCPDS File No. 47-0798) showing no indication of the presence of titanyl oxalate. This may be due to the higher scattering power of nickel (26) compared with titanium (18) [42]. The powder X-ray diffraction pattern of the precursor decomposed at 500 °C showed peaks due to NiO and the anatase form of TiO_2 (Fig. 5b). When this product was heated at 950 °C for 12 h in air, evolution of ilmenite $NiTiO_3$ was observed. The major peaks matched with JCPDS File No. 89-7131. Further heat treatment at 1100 °C for 12 h in air resulted in yellow colored $NiTiO_3$ (JCPDS File No. 33-0960) with a few peaks from Ni_2TiO_4 and one unidentified impurity (Fig. 5c).

The strong bands at 643 and 473 cm^{-1} in the FT-IR spectrum could be assigned to O–Ti–O and Ni–O–Ti bond formation. Ilmenite $NiTiO_3$ exhibited ten sharp bands in FT-Raman spectrum at 187, 224, 242, 289, 340, 391, 456, 498, 610 and 703 cm^{-1}, as reported earlier (Fig. 6) [41]. In our preparation, the anatase form of TiO_2 was generated in situ and the phase pure product was obtained at 1100 °C. In the standard ceramic method for the preparation

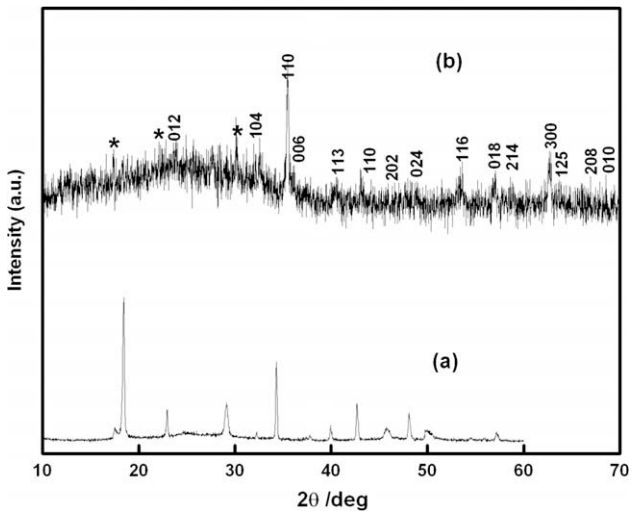

Fig. 8. Powder X-ray diffraction pattern of (a) the precursor containing the (Fe + Ti) oxalates, (b) heated at 600 °C. The peaks marked with * are due to Fe_3O_4.

of $NiTiO_3$, repeated heating at a high temperature of 1475 °C was required [40]. In the present method, the pure product can be obtained at 1100 °C.

The SEM micrograph of the yellow colored solid, obtained from the reaction of iron(II) chloride and potassium titanyl oxalate solution, showed agglomeration of particles (Fig. 7a). The thermal analysis was performed in nitrogen atmosphere to prevent the oxidation of Fe^{2+} during decomposition. The decomposition showed a total weight loss of 48.6% in two steps in nitrogen as shown in Fig. 7b. The decomposition was complete before 400 °C. The powder X-ray diffraction pattern of the precursor corresponded to iron(II) oxalate (Fig. 8a) (JCPDS File No. 14-0762). A brown black colored solid was obtained when the precursor was heated at 600 °C in flowing nitrogen for 12 h. The powder X-ray diffraction showed that the major phase was ilmenite $FeTiO_3$ (JCPDS File No. 29-0733) with a few peaks due to Fe_3O_4 (Fig. 8b).

Evidence for the presence of Fe–O–Ti and O–Ti–O bonds was obtained from the FT-IR spectrum of $FeTiO_3$ which showed strong bands at 480 and 570 cm^{-1}. The FT-Raman spectrum of $FeTiO_3$ showed nine bands at 233, 260, 301, 356, 404, 453, 480, 624 and 719 cm^{-1}, as shown in Fig. 9. Among the co-precipitation methods used for preparing $FeTiO_3$, hydroxide precipitation was found to be very sensitive to the amount of precipitant, and carbonate co-precipitation required higher decomposition temperatures to yield the final oxide [22]. However, in the present method the amount of precipitant did not pose a problem because no extra precipitating agent was used. In addition to this, the formation of ilmenite $FeTiO_3$ was observed at temperatures as low as 600 °C.

The thermal analysis of the white solid, obtained in case of manganese, was carried out in flowing nitrogen to prevent oxidation similar to iron containing titanates. The thermal decomposition of the precursor exhibited a total mass loss of 46% in two steps (Fig. 10). The powder X-ray diffraction pattern of the precursor matched that of manganese(II) oxalate (Fig. 11a) (JCPDS File No. 14-0713). Decomposing the precursor at 500 °C in nitrogen for 10 h resulted in the ilmenite form of $MnTiO_3$ (Fig. 11b), the peaks matching well with JCPDS File No. 29-0902 with a broad hump around $2\theta \sim 25°$. When the precursor was decomposed at 600 °C for 10 h this resulted in the muddy brown colored ilmenite $MnTiO_3$ with the removal of the hump (Fig. 11c).

In the FT-IR spectrum strong bands at 533 and 620 cm^{-1} were present, which can be assigned to Mn–O–Ti and O–Ti–O vibrational modes, respectively. The FT-Raman spectrum showed seven bands at 234, 273, 335, 452, 527 and 695 cm^{-1}, with the most intense one at 695 cm^{-1} (Fig. 12) as observed by others [18]. The synthesis of $MnTiO_3$ by the ceramic method required temperatures as high as 1200 °C [19]. Therefore the present mode of synthesis has significant advantages over the ceramic method.

The white colored solid, obtained from the reaction between cadmium(II) chloride and potassium titanyl oxalate solutions, was subjected to thermal analysis in air. The plot of the percentage mass loss with temperature is shown in Fig. 13. The mass loss took place in three steps, the first one was attributed to the removal of water molecules followed by the release of gaseous products such as CO and CO_2. The total mass loss of 48% suggested $CdTiO_3$ might be the end product. The powder X-ray diffraction of the precursor was highly crystalline, showing the presence of cadmium(II) oxalate (JCPDS File No. 14-0712) (Fig. 14a). When the precursor was decomposed at 600 °C in air for 6 h, it resulted in ilmenite $CdTiO_3$, which was dirty white in color (Fig. 14b) (JCPDS File No. 29-0277), along with peaks of CdO. Further heating at 750 °C for 12 h in air improved the reduction in the intensity of the CdO peaks (Fig. 14c).

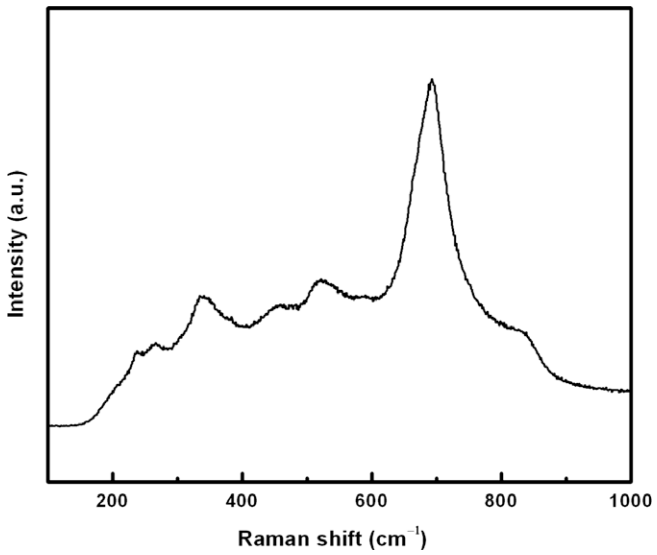

Fig. 12. Raman spectrum of $MnTiO_3$.

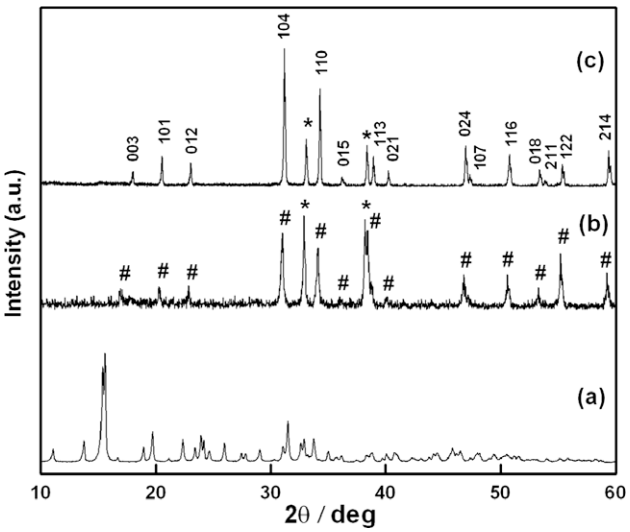

Fig. 14. Powder X-ray diffraction pattern of (a) the precursor containing the (Cd + Ti) oxalates (b) heated at 600 °C (c) heated at 750 °C. The peaks marked with # are due to $CdTiO_3$ and the peaks marked with ∗ are due to CdO.

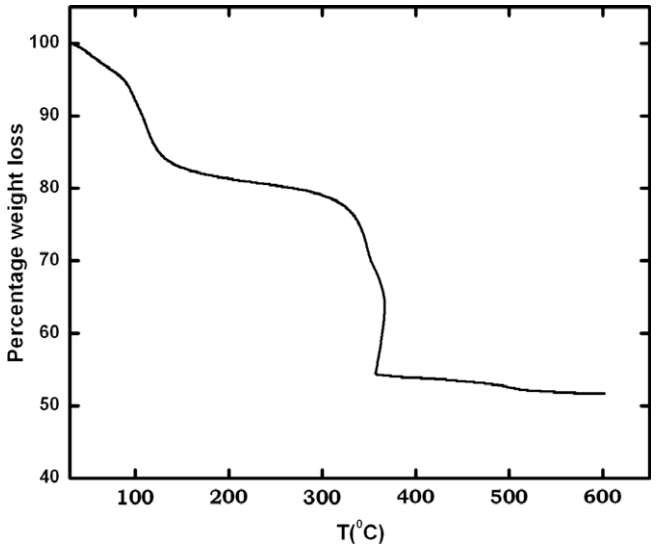

Fig. 13. Thermogravimetric analysis of the product obtained from the reaction between solutions of $CdCl_2 \cdot 2H_2O$ and potassium titanyl oxalate in air.

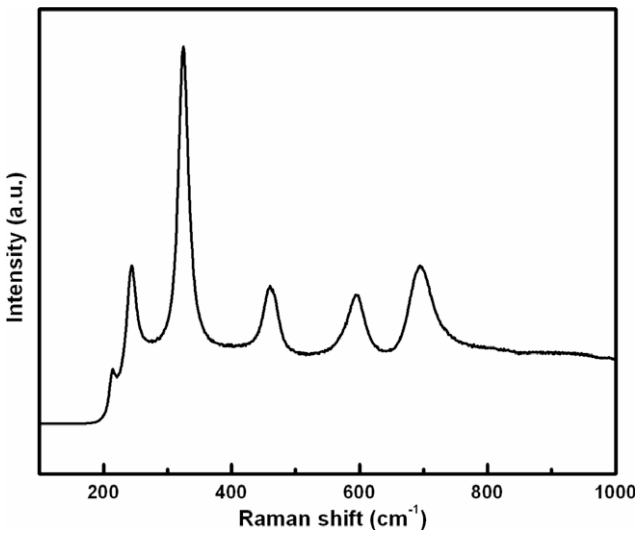

Fig. 15. Raman spectrum of $CdTiO_3$.

The FT-IR spectrum of the decomposed powder residue showed bands at 436 and 586 cm^{-1} and the FT-Raman spectrum exhibited seven bands at 213, 242, 324, 460, 593 and 694 cm^{-1}, as shown in Fig. 15. These bands were assigned to the ilmenite structure of $CdTiO_3$ [33]. The synthesis of the phase pure bulk $CdTiO_3$ possessing the ilmenite structure was reported to be difficult [32,33]. The volatile and toxic natures of CdO as well as the phase transition from the ilmenite to perovskite structure were cited to be some of the reasons for the difficulty. Bersani et al. [33] synthesized $CdTiO_3$, both in the ilmenite and perovskite forms, employing the sol–gel method in nitric acid. However, they observed the presence of rutile TiO_2 as an impurity together with the ilmenite phase even after heating at the higher temperature of 800 °C [33]. A modified sol–gel method using ethylene glycol and a hydrothermal method were found to be very effective in obtaining phase pure ilmenite $CdTiO_3$ [34,35]. In the present study, $CdTiO_3$ possessing the ilmenite structure was obtained from the very fine mixture of oxalates of cadmium and titanium by adjusting the pH to 3. Earlier, Prasad Rao and Suresh [32] attempted to prepare $CdTiO_3$ by oxalate co-precipitation by adjusting the pH to 7, which yielded a mixture of $CdTiO_3$, CdO and TiO_2.

4. Conclusions

The present study suggests that a molecular precursor of the formula M $[TiO(C_2O_4)] \cdot xH_2O$ may not be possible for M = Mn, Fe, Co, Ni and Cd by the reaction of their chlorides with potassium titanyl oxalate solution in the pH range 2–3. The addition of transition metal chlorides solution did not facilitate to stabilize the $TiO(C_2O_4)_2^{2-}$ species so as to result in the molecular precursor. The narrow pH range of the stability of the titanyl species may be one of the reasons for the unsuccessful attempt towards the molecular precursor preparation, but this may also arise from structural considerations. In the reported single crystal structure of $BaTiO(C_2O_4)$, the Ba^{2+} ion is both nine and ten coordinated by oxygen. The ionic radius of Ba^{2+} (1.50 Å) is comparable to the potassium ion under similar coordination environments. However, the ionic radii of the metal ions, Co^{2+}, Ni^{2+}, Fe^{2+}, Mn^{2+} and Cd^{2+} are

much smaller compared with either the Ba^{2+} or K^{+} ion. The smaller size of these ions might be destabilizing the molecules and consequently might prevent the molecular precursor formation. This chemical co-precipitation as oxalates has many advantages in synthesizing transition metal containing titanates. They can be obtained in the pure form at relatively low temperatures with very few heating cycles. The dual role of potassium titanyl oxalate as a precipitating agent as well as the titanium source avoids excess precipitant, thereby improving the purity of the final oxides as compared to the standard ceramic method.

Acknowledgements

The authors would like to thank UGC-DAE Consortium, Indore and Dr.C.Shivakumara, SSCU, IISC, Bangalore for their help in recording powder X-ray diffraction spectra and the University of Delhi for financial assistance under the "Scheme to strengthen R&D Doctoral program in Universities". Also thanks are due to Mr. Raman Malhotra of USIC, University of Delhi for recording the Raman spectra.

Nuclease activity

ABSTRACT

Two new copper(II) complexes with aminothioether ligands, $[Cu(L^1)(ClO_4)](ClO_4)\cdot 0.5H_2O$ (**1**) and $[Cu(L^2)(H_2O)](ClO_4)_2\cdot H_2O$ (**2**) (L^1 = 2-benzyl-1,3-bis(aminoethylthio)propane and L^2 = 2-(4-butylbenzyl)-1,3-bis(aminoethylthio)propane), have been synthesized and characterized. The single crystal X-ray diffraction analysis reveals that both **1** and **2** adopt distorted square pyramidal geometries. The binding modes of both complexes with calf thymus DNA were investigated by UV–Vis and CD spectroscopies. The results show that both complexes mainly adopt an electrostatic attraction binding mode with DNA and the binding constants are $(1.62 \pm 0.02) \times 10^3$ and $(2.02 \pm 0.02) \times 10^3$ M^{-1}, respectively. Both complexes are able to cleave pBR322 plasmid DNA efficiently in the presence of ascorbic acid and the activity of **2** is higher than that of **1**. The DNA cleavage by **1** and **2** were inhibited strongly in the presence of DMSO and tert-butyl alcohol, which suggests that hydroxyl radicals are the reactive oxygen species for the cleavage.

1. Introduction

DNA cleavage can occur by hydrolytic or oxidative pathways. Hydrolytic cleavage directly breaks the phosphodiester bond, but does not result in sugar damage [1,2]. Oxidative cleavage involves either oxidation of the deoxyribose moiety by abstraction of sugar hydrogen or oxidation of nucleobases [3]. Copper complexes have been widely used as nuclease mimics. Since $[Cu(OP)_2]^{2+}$ was reported to break the DNA chain in the presence of H_2O_2 (OP = 1,10-phenanthroline) [4–6], many mononuclear [7–18] and multi-nuclear copper(II) complexes [19–22] have been widely synthesized and some of them show efficient oxidative cleavage activities. Especially, many mononuclear copper(II) complexes of N_3 tridentate [23–25] and N_4 tetradentate ligands [26] have been recently investigated and are revealed to show efficient DNA cleavage activities in the presence of reducing agents.

However, studies involving aminothioether tetradentate ligand complexes are very limited [27]. Further, no investigations of DNA cleavage involving aminothioether S_2N_2 complexes with different hydrophobic groups on the backbone of the ligands have been reported. We have designed two new aminothioether ligands: 2-benzyl-1,3-bis(aminoethylthio)propane (L^1) and 2-(4-tert-butylbenzyl)-1,3-bis(aminoethylthio)propane (L^2), and have successfully synthesized two copper(II) complexes with these ligands, $[Cu(L^1)(ClO_4)](ClO_4)\cdot 0.5H_2O$ (**1**) and $[Cu(L^2)(H_2O)](ClO_4)_2\cdot H_2O$ (**2**). Because of the different hydrophobicity of the ligands, different DNA binding abilities and 'chemical nuclease' activities in the presence of ascorbic acid are expected for these two complexes.

2. Experimental

2.1. Materials and general information

2-Aminoethanethiol hydrochloride and ascorbic acid were purchased from Alfa Aesar Co. Ltd. $LiAlH_4$, distamycin and SOD were purchased from Sigma–Aldrich Chemical Co., pBR 322 DNA was purchased from MBI, tris(hydroxymethyl)aminomethane (Tris) and catalase were purchased from BBI, CT-DNA and ethidium bromide were purchased from Sino-American Biotechnology, 2,2,6,6-tetramethyl-4-piperidone monohydrate (TEMP) was purchased from Acros organic. Other reagents of analytical grades were obtained from domestic chemical corporations and were used without further purification except that thionyl chloride was purified by distillation. Milli-Q water was used in all physical measurement experiments.

Microanalyses (C, H and N) were carried out on an Elementar Vario EL elemental analyzer. ESI-mass spectra were recorded using a LCMS-2010A Liquid Chromatograph Mass Spectrometer. ^{1}HNMR spectra were collected on a Varian Mercury-plus 300 NMR spectrometer.

2.2. Synthesis

2.2.1. 2-Benzyl-1,3-propanediol

$LiAlH_4$ (2.26 g, 59.6 mmol) was suspended in dry THF (150 mL) under N_2 at 0 °C. 2-Benzyldiethylmalonate [28] (5.37 g, 21.5 mmol) in dry THF (40 mL) was carefully added dropwise during constant stirring. The reaction was allowed to warm to room temperature and stirred for 12 h. Quenching was performed at 0 °C with constant stirring by careful dropwise addition of 2.26 mL H_2O, 2.26 mL 15% NaOH and 6.78 mL H_2O in sequence. The resulting precipitate was filtered off and washed with ethyl acetate (150 mL). The filtrate was dried with anhydrous Na_2SO_4, filtered and evaporated to afford a solid crude product, which was crystallized from petroleum/hexane (1:1) to give 2.84 g (79.8%) of 2-benzyl-1,3-propanediol as a white solid mp 66.9–67.5 °C (Ref. [29]. Mp 66–68 °C); ^1H NMR ($CDCl_3$, 300 MHz): δ 2.01–2.11 (m, 1H), 2.14 (brs, 2H), 2.64 (d, J = 7.5 Hz, 2H), 3.65–3.71 (m, 2H), 3.79–3.84 (m, 2H), 7.25 (m, 5H).

2.2.2. 2-(4-Tert-butylbenzyl)-1,3-propanediol

2-(4-Tert-butylbenzyl)-1,3-propanediol was synthesized from 2-(4-butylbenzyl)diethylmalonate [30], as described for 2-benzyl-1,3-propanediol, in 75.7% yield. ^1H NMR ($CDCl_3$, 300 MHz) δ 1.32 (s, 9H), 1.97 (brs, 2H), 2.03–2.14 (m, 1H), 2.60 (d, J = 7.5 Hz, 2H), 3.70–3.72 (m, 2H), 3.80–3.81 (m, 2H), 7.11 (d, J = 8.1 Hz, 2H), 7.30 (d, J = 8.4 Hz, 2H).

2.2.3. 2-Benzyl-1,3-dichloropropane

$SOCl_2$ (10 mL) was carefully added to a mixture of 2-benzyl-1,3-propanediol (2.00 g, 12.1 mmol) and pyridine (0.1 mL) at 0 °C in an ice-water bath with constant stirring. After the addition, the mixture was permitted to warm to room temperature and then refluxed at 70 °C for 12 h. The reaction mixture was then cooled to room temperature and the excess $SOCl_2$ was evaporated. The residue was treated with 40 mL H_2O and the mixture was extracted with ethyl acetate (50 mL × 3). The ethyl acetate extracts were combined, washed with 100 mL saturated $NaHCO_3$ solution and H_2O (100 mL × 2), then dried over anhydrous Na_2SO_4. The ethyl acetate was removed on a rotary evaporator to give 2-benzyl-1,3-dichloropropane as a pale yellow oil, yield 2.29 g (93.8%). ^1H NMR ($CDCl_3$, 300 MHz) δ 2.29–2.41 (m, 1H), 2.79 (d, J = 7.2 Hz, 2H), 3.54–3.60 (m, 2H), 3.66–3.71 (m, 2H), 7.19–7.34 (m, 5H).

2.2.4. 2-(4-Tert-butylbenzyl)-1,3-dichloropropane

2-(4-Tert-butylbenzyl)-1,3-dichloropropane was prepared from 2-(4-tert-butylbenzyl)-1,3-propanediol in 95.0% yield. The synthetic method was similar to that of 2-benzyl-1,3-dichloropropane. ^1H NMR ($CDCl_3$, 300 MHz) δ 1.32 (s, 9H), 2.31–2.35 (m, 1H), 2.75 (d, J = 7.2 Hz, 2H), 3.56–3.71 (m, 4H), 7.13 (d, J = 7.8 Hz, 2 H), 7.33 (d, J = 6.9 Hz, 2H).

2.2.5. 2-Benzyl-1,3-bis(aminoethylthio)propane (L^1)

L^1 was prepared by a modified procedure [31,32]. 2-Aminoethanethiol hydrochloride (4.42 g, 38.9 mmol) was added to a solution of sodium (1.79 g, 77.80 mmol) in absolute ethanol (25 mL) with stirring under N_2. The mixture was refluxed at 70 °C for 1 h and cooled to room temperature, and then KI (2.66 g, 16.00 mmol) was added. A solution of 2-benzyl-1,3-dichloropropane (1.63 g, 8.01 mmol) in 12 mL of absolute ethanol was added dropwise to the above mixture at 0 °C in an ice-water bath with constant stirring. After the addition, the mixture was again refluxed with stirring at 70 °C for 20 h under N_2, cooled and filtrated to remove the precipitate of sodium and potassium salts. The filtrate was concentrated to remove almost all of the solvent and H_2O (100 mL) was added to the residue. The strongly basic solution was extracted three times with 300 mL dichloromethane. The dichloromethane extracts were combined, washed three times with 300 mL H_2O, dried over anhydrous Na_2SO_4 and then the dichloromethane was removed on a rotary evaporator to give 2-benzyl-1,3-bis(aminoethylthio)propane (L^1) as a pale yellow oil, yield 2.15 g (94.3%). ESI-MS, m/z: 285.4 ($[M+H]^+$). This crude material was quite satisfactory for the preparation of the copper(II) complex.

2.2.6. 2-(4-Tert-butylbenzyl)-1,3-bis(aminoethylthio)propane (L^2)

L^2 was prepared in a similar procedure to that of L^1 from 2-(4-tert-butylbenzyl)-1,3-dichloropropane and 2-aminoethanethiol hydrochloride, in 96.1% yield. ESI-MS, m/z: 341.3 ($[M+H]^+$), 379.3 ($[M+K]^+$). This crude material was quite satisfactory for the preparation of the copper(II) complex.

2.2.7. $[Cu(L^1)(ClO_4)](ClO_4) \cdot 0.5H_2O$ (**1**)

L^1 (0.29 g, 1.02 mmol), dissolved in 2 mL ethanol, was added to 2 mL ethanol solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.51 g, 1.37 mmol) with stirring. A purple precipitate appeared immediately, which was filtrated and washed with ethanol several times, and a purple powder was obtained. The powder was recrystallized from MeOH, filtrated and dried in a vacuum desiccator, and 0.20 g purple microcrystals were obtained (34.9%). *Anal.* Calc. for $C_{14}H_{25}Cl_2CuN_2O_{8.5}S_2$: C, 30.25; H, 4.53; N, 5.04. Found: C, 30.69; H, 3.92; N, 5.17%. Single crystals suitable for X-ray analysis were obtained by slow evaporation of a methanol solution of complex **1**.

2.2.8. $[Cu(L^2)(H_2O)](ClO_4)_2 \cdot H_2O$ (**2**)

Complex **2** was prepared in a similar way to that of **1**, 0.34 g (1.0 mmol) L^2 gave 0.15 g complex **2** as purple microcrystals (23.5%). *Anal.* Calc. for $C_{18}H_{36}Cl_2CuN_2O_{10}S_2$: C, 33.83; H, 5.68; N, 4.38. Found: C, 34.18; H, 5.60; N, 4.49%. Evaporating a methanol solution of **2** gave single crystals for X-ray analysis.

Caution: Copper(II) perchlorates are potentially explosive chemicals, and they should be prepared in small quantities and handled with care.

2.3. X-ray crystallography

Single crystals, sized $0.49 \times 0.43 \times 0.10$ mm and $0.46 \times 0.28 \times 0.10$ mm for **1** and **2**, respectively, were used for X-ray diffraction analyses. Data collections of **1** and **2** were performed with Mo Kα ($\lambda = 0.71073$ Å) radiation on a Bruker AXS SMART CCD area detector diffractometer at 293(2) K. An absorption correction by multi-scan was applied to the intensity data. The structures were solved by direct methods and the heavy atoms were located from the E-map. The remaining non-hydrogen atoms were determined from the successive difference Fourier syntheses. The non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms were generated geometrically with isotropic thermal parameters. The structures were refined on F^2 by full-matrix least-squares methods using the SHELXTL-97 program package [33]. Crystallographic details, and selected bond lengths and angels for **1** and **2** are given in Tables 1 and 2, respectively.

2.4. CD spectroscopy

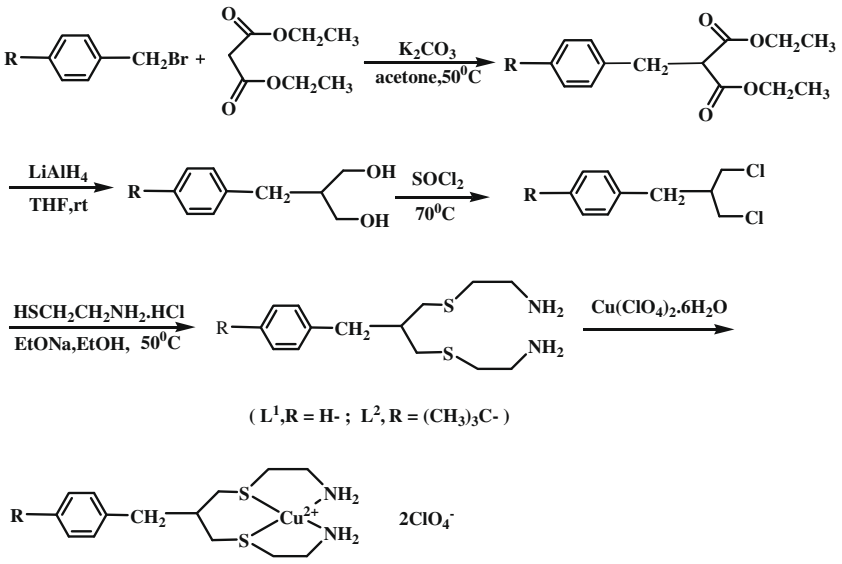
CD spectra of CT-DNA were recorded on a Jasco J-810 spectropolarimeter at room temperature in the absence or the presence of 20 μM and 40 μM complexes **1** or **2** ($r = 0.2$, 0.4. r = [complex]/[DNA]). The concentration of DNA was 100 μM and 5 mM Tris–50 mM NaCl solution (pH 7.5) was the buffer solution. Each test solution was scanned at a speed of 50 nm min^{-1} for four repetitions and the average spectra were used. The buffer background was subtracted automatically.

2.5. UV–Vis spectroscopy

UV–Vis spectra were recorded on a Varian Cary 300 UV–Vis spectrophotometer attached to a Cary Peltier temperature controller. The concentration of the complexes was 60 μM and the buffer solution was the same as that of CD spectroscopy.

2.6. DNA cleavage

The cleavage of pBR322 plasmid DNA (38 μM bp) was performed in 20 mM Tris buffer (pH 7.2) by treating DNA with a certain concentration of the complex in the presence of 20-fold ascorbic acid. The total volume of 10 μL sample solution was incubated in a sealed plastic vessel and the cleavage was carried out at 37 °C for 1 h, then 4 μL loading buffer (0.05% bromophenol blue, 50% glycerol and 2 mM EDTA) was added. The sample was stored at −20 °C for preservation, and then it was loaded onto a 0.9% agarose gel and electrophoresed at a constant voltage of 120 V for 100 min in TBE buffer (100 mM Tris–2 mM EDTA–HBO_3, pH 8.3). DNA bands were visualized in an electrophoresis documentation and analysis system 120.



3. Results and discussion

3.1. Preparation of the Cu(II) complexes

The synthesis route for ligands L^1 and L^2, and their complexes **1** and **2**, is shown in Scheme 1. **1** and **2** are stable in air and are soluble in water and common polar organic solvents. The electronic absorption of **1** is similar to that of **2** (Fig. S2 in the Supporting data). Both complexes display an absorption band at 244 nm (**1** ε 4950 M^{-1} cm^{-1}, **2** ε 5290 M^{-1} cm^{-1}) which was assigned as the π-π^* transition of benzene of the ligands. The strong absorption peaks of 322 nm (**1** ε 9230 M^{-1} cm^{-1}) and 323 nm (**2** ε 9620 M^{-1} cm^{-1}) were assigned as metal-to-thioether transfer transitions. At 567 nm, both **1** and **2** showed a weak electronic absorption band (**1**, ε 674 M^{-1} cm^{-1}; **2**, ε 723 M^{-1} cm^{-1}), typical for d–d transitions of Cu(II) [34,35].

3.2. Crystal structure of complexes *1* and *2*

The molecular structure of complex **1** consists of one $[CuL^1(ClO_4)]^+$ unit, one free ClO_4^- anion and half of one water molecule, as shown in Fig. 1. In **1**, the Cu(II) ion has a geometric parameter of $\tau = 0.05$ and suggests a distorted square pyramidal geometry [36], with two N and two S atoms of L^1 located in the basal plane and one O atom from one of ClO_4^- anions in the apical position with a Cu–O distance of 2.428(3) Å (Table 2). The Cu–S and Cu–N distances are within the range 2.303(1)–2.314(1) Å and 1.993(3)–2.004(3) Å, respectively, comparable with the distances in complexes containing 14-member S_4^- [2.303(1) Å] [37] or N_4-donor [1.976(1) Å] ligands [38]. Each L^1 ligates one metal ion with two N and two S atoms to form a 12-member macrometallocycle, moreover, L^1 in **1** is significantly non-planar with the terminal phenyl ring pointing to the C3 atom [C4–C8–C9 113.4(4)°] due to intramolecular C–H···π interactions between them (H···π 2.608 Å), which also leads to the obvious slant between the terminal phenyl ring and the CuN_2S_2 plane with a dihedral angle of 48.5°. In the solid state, the molecules of **1** are stabilized by intermolecular hydrogen bond interactions (Fig. S3 in the Supporting data). Each water O1w atom acts as hydrogen acceptors to bond two –NH groups

Scheme 1. Synthetic route for the ligands and their copper(II) complexes.

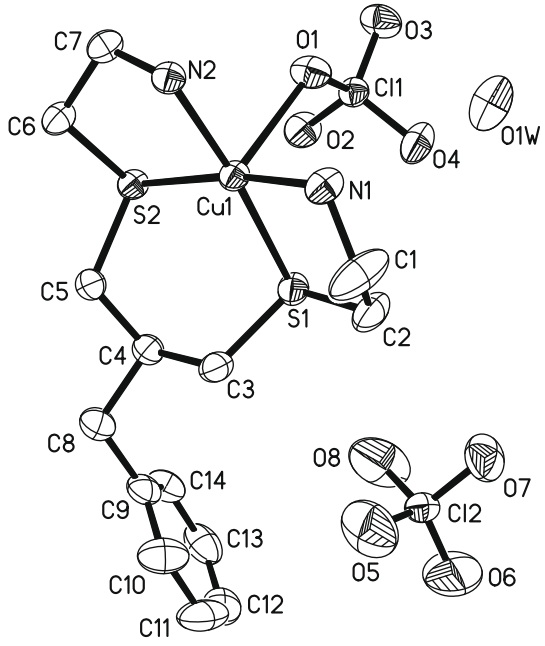


Fig. 1. View of the molecular structure of **1** with displacement ellipsoids drawn at the 30% probability level. The H atoms are omitted for clarity.

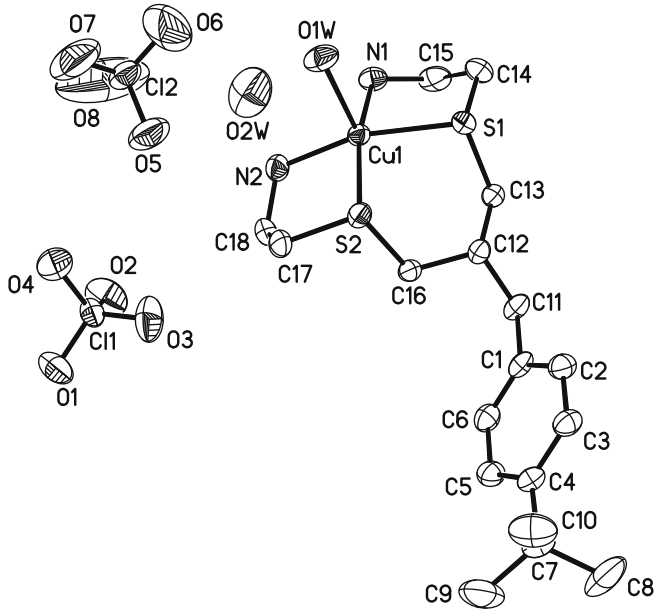

Fig. 2. View of the molecular structure of **2** with displacement ellipsoids drawn at the 30% probability level. The H atoms are omitted for clarity.

[N1···O1w 2.933 Å] from two different L^1 ligands. Meanwhile, O1w also serves as a donor to hydrogen bond to two coordinated ClO_4^- anions, and thus each water molecule can be viewed as a four-connected node to connect four $[CuL^1(ClO_4)]^+$ units to generate a two-dimensional supramolecular structure [O1w···O2 2.832 Å].

The crystal structure of complex **2** is similar to that of **1**, as shown in Fig. 2, it contains one $[CuL^2(H_2O)]^{2+}$ cation, two ClO_4^- anions and one water solvate. The Cu(II) ion in **2** also has a distorted square pyramidal geometry ($\tau = 0.06$) with two N and two S atoms of L^2 forming the basal plane, however the apical position is occupied by one water ligand with a Cu–O distance of 2.243(3) Å (Table 2). The Cu–S and Cu–N distances are in the regions 2.309(1)–2.329(9) and 2.013(3)–2.021(3) Å, respectively, similar to those of **1**. Just as for L^1 in **1**, L^2 is also non-planar in **2** owing to intramolecular C–H···π interactions (H···π 2.673 Å) between the terminal phenyl ring and the H16A atom of the –CH group [C1–C11–C12 113.9(3)°]. The terminal phenyl ring is tilted about the CuN_2S_2 plane with a dihedral angle of 33.4°, smaller than that of L^1 in **1**. In the crystal packing of **2**, a strong hydrogen bond is formed between the coordinated water O1w as a hydrogen donor and a solvent water molecule [O1w···O2w 2.652 Å] to give a $(H_2O)_2$ dimer, which is further hydrogen-bonded to two different ClO_4^- anions [O1w···O8 3.008 Å and O2w···O2 2.794 Å]. Additionally, the ClO_4^- anions are involved in intermolecular hydrogen bonding interactions with two –NH groups (N1···O4 3.049 Å and N1···O7 3.029 Å)

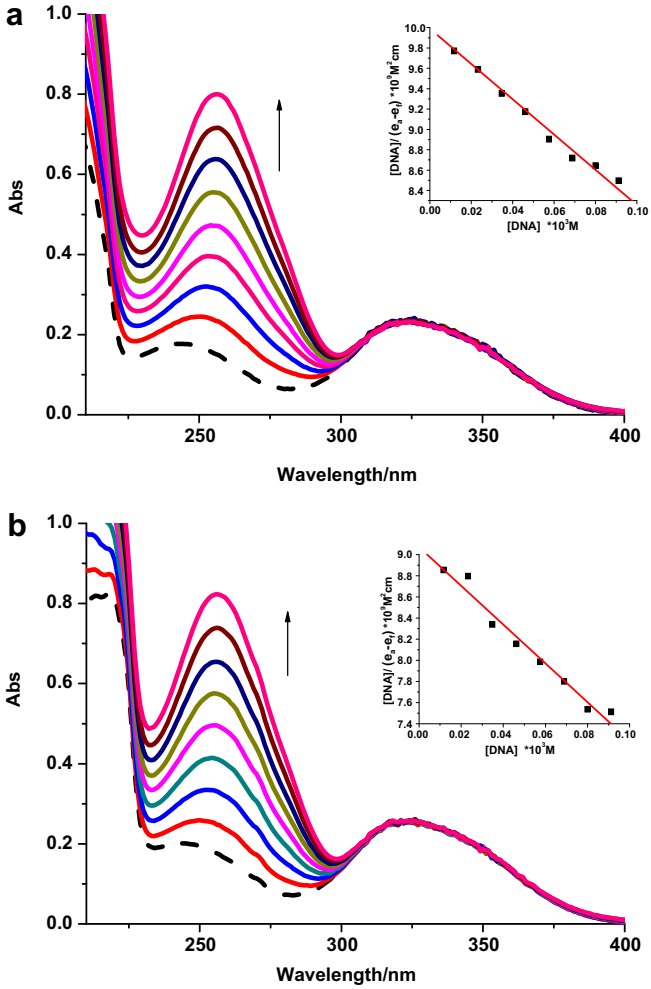

Fig. 3. Absorption spectra of 6.0×10^{-5} M **1** (a) and **2** (b) in the absence (dot line) and the presence (solid line) of increasing amounts of CT-DNA ($0–8 \times 10^{-5}$ M) in 5 mM Tris–50 mM NaCl aqueous buffer solution (pH 7.5) at 25 ± 0.1 °C.

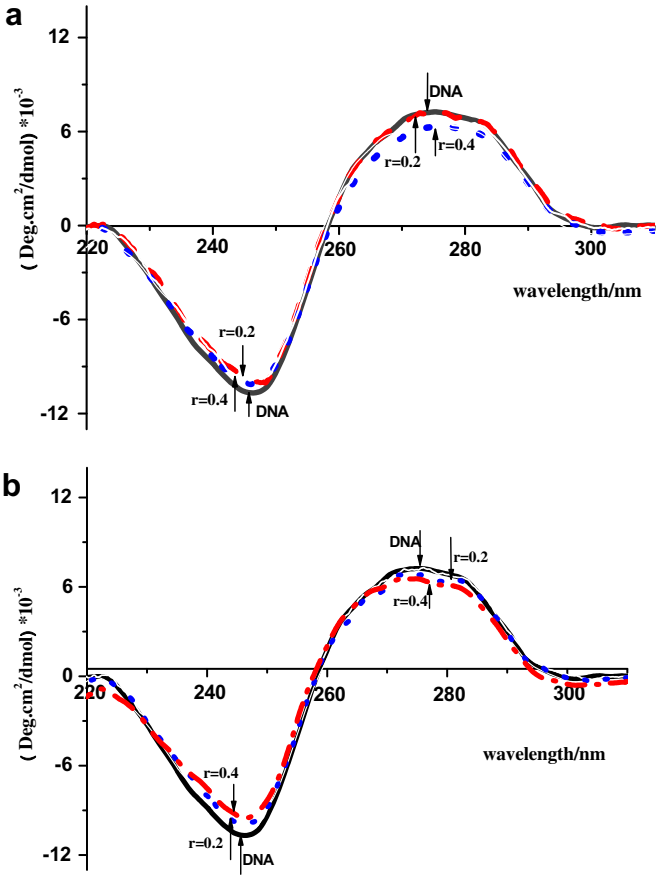

Fig. 4. CD spectra of CT-DNA (1.0×10^{-4} M) in the absence and the presence of **1** (a) and **2** (b) at ratio [complex]/[DNA] = 0.2, 0.4 in 5 mM Tris–50 mM NaCl aqueous buffer solution (pH 7.5).

of L^2 from a neighboring $[CuL^2(H_2O)]^{2+}$ unit to generate a one-dimensional zig-zag chain (Fig. S4 in the Supporting data).

3.3. Interaction with CT-DNA

The interactions between both complexes and CT-DNA were evaluated by UV–Vis spectroscopy titration and CD spectroscopy. The UV–Vis spectra are shown in Fig. 3. In both spectra of complexes **1** and **2**, hyperchromicity was observed on the addition of CT-DNA ($0–8 \times 10^{-5}$ M). The hyperchromicity argued that the binding mode of these two complexes as 6.0×10^{-5} M solutions towards CT-DNA should not be intercalation, since intercalation would bring on hypochromicity as a result of the stacking effect of π electrons [39], which leads to a decrease of the transition probability of π electrons, and ultimately results in a decrease of absorption. The intrinsic binding constants (K_b) of **1** and **2** were calculated as $(1.62 \pm 0.02) \times 10^3$ and $(2.02 \pm 0.02) \times 10^3$ M^{-1}, respectively, which are much smaller than those reported for typical intercalators (e.g. EB-DNA, $\sim 10^6$ M^{-1}) [40,41], but are comparable with some reported non-intercalators [22,42]. The quite low K_b values do not favor intercalation binding. Furthermore, the higher K_b value of **2** indicates the interaction of **2** with DNA is stronger than that of **1**.

The interaction between the two complexes and CT-DNA was further studied by CD spectroscopy (Fig. 4). The CD spectrum of CT-DNA consists of a positive band at 277 nm due to base stacking and a negative band at 245 nm because of helicity, which is characteristic of DNA in the right-handed B form [26]. Intercalation of small molecules with DNA enhances the intensities of both bands, while groove binding and electrostatic interactions show little or no perturbations to the base stacking and helicity bands. With increasing concentrations of **1** and **2**, both positive and negative bands show little change, which implies a non-intercalative mode between DNA and complexes again. The cationic core of **1** and **2** could exert a strong electrostatic attraction to the anionic phosphate backbone of DNA, thus, the electrostatic binding mode is highly possible. This inference was further demonstrated in the following section.

3.4. DNA cleavage studies

The oxidative DNA cleavage activities of complexes **1** and **2** were studied in the presence of ascorbic acid. Fig. 5 exhibits the concentration dependence of the cleavage reactions after 60 min incubation (pH 7.2, 37 °C). Comparing the ligands with **1** and **2**, both ligands L^1 and L^2 showed very low nuclease activity even at a concentration of 100 μM. For complex **1**, the amount of form II DNA increased with the increase of complex concentration, form I DNA disappeared completely and form III started to appear when the complex concentration reached 50 μM. Complex **2** behaved similarly to **1** except that the appearance of form III DNA occurred at a lower concentration (40 μM), and at 40 μM form I DNA was converted to form II and form III completely. This suggests that **2** exhibits slightly higher nuclease activity than **1**. The difference of

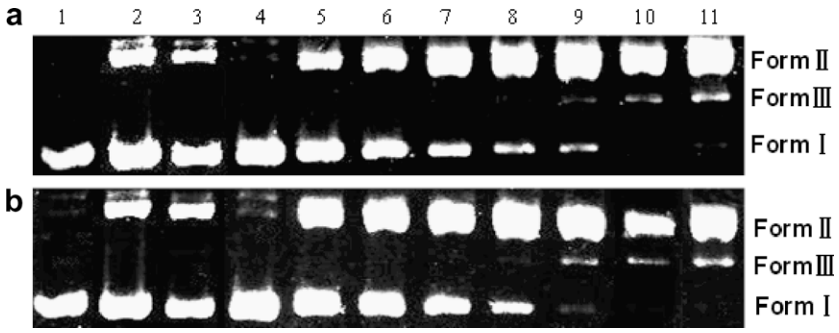

Fig. 5. Cleavage of pBR322 DNA by **1** (a) and **2** (b) in the presence of ascorbic acid. DNA (38 μM bp) was incubated with **1**, **2** for 60 min in 20 mM Tris–$HClO_4$/0.1 M $NaClO_4$ aqueous buffer solution (pH 7.2) at 37 °C. Lane 1, DNA control; lane 2, DNA + ascorbic acid (2 mM); lane 3, DNA + 100 μM ligand + ascorbic acid (2 mM); lane 4, DNA + complex (100 μM); lane 5–11, DNA + complex (5, 10, 20, 30, 40, 50 and 70 μM) + ascorbic acid (20-fold of complex).

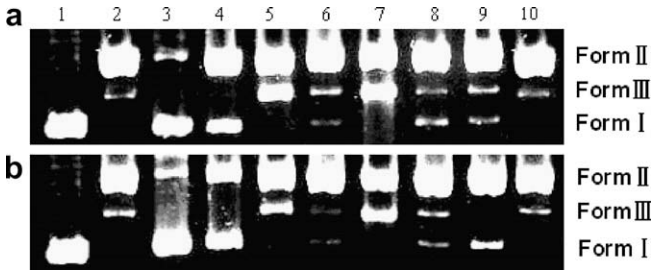

Fig. 6. Cleavage of pBR322 DNA by 50 μM **1** (a) and **2** (b) in the presence of different inhibitors with a 20-fold excess of ascorbic acid. DNA (38 μM bp) was incubated with **1** and **2** for 60 min in 20 mM Tris–$HClO_4$/0.1 M $NaClO_4$ aqueous buffer solution (pH 7.2) at 37 °C. Lane 1, DNA control; lane 2, no inhibitor; lane 3, 0.5 M DMSO; lane 4, 0.5 M t-BuOH; lane 5, 1.2 mM His; lane 6, 0.5 mM TEMP; lane 7, 500 U/mL catalase; lane 8, 500 U/mL SOD; lane 9, 10 μM distamycin; lane 10, 10 μM methyl green.

the nuclease activities of both complexes may be ascribed to the influence of the substituted groups in L^1 and L^2. Compared with the structure of **1**, complex **2** has a hydrophobic t-butyl group on the backbone of L^2, which makes **2** interact with DNA more effectively. This suggestion has been supported by their K_b values.

The reactive oxygen species were also investigated, as shown in Fig. 6. The strong inhibitions of DNA cleavage to complexes **1** and **2** were observed in the presence of the hydroxyl radical scavengers DMSO and tert-butyl alcohol, indicating that hydroxyl radicals are responsible for the cleavage. The singlet oxygen scavengers histidine and 2,2,6,6-tetramethyl-4-piperidone monohydrate, and the hydrogen peroxide scavenger catalase failed to inhibit cleavage, suggesting that singlet oxygen and hydrogen peroxide are not likely to be the reactive oxygen species. A weak inhibition was observed by the addition of the superoxide anion radical scavenger SOD, arguing that the superoxide anion radical may play a role in the cleavage, but is not a major active species.

The minor groove binding agent distamycin and major groove binding agent methyl green were used to probe the potential interacting site of the small molecular complexes **1** and **2** with DNA, which are shown in Fig. 6. The major groove binding agent methyl green did not affect the cleavage activity of **1** and **2** at all (lane 10), and the minor groove binder distamycin displayed different degrees of inhibition in the DNA cleavage (lane 9): for **1**, form I appeared but form III was not changed at all. However, for **2**, form III disappeared completely, and form I was present to a much greater extent than for **1**, which suggests that distamycin shows a certain cleavage but not complete inhibition for both complexes and displays a stronger inhibition ability for **2**. The conclusion can then be drawn that the groove binding mode exists but it is not the major binding mode for both complexes. So, together with the results of the UV–Vis and CD spectroscopies, electrostatic attraction should be the major binding mode.

4. Conclusion

The present work describes the synthesis, characterization and DNA binding studies of two new CuS_2N_2 complexes. Both complexes have similar structures and adopt distorted square pyramidal geometries, having plentiful N–H···Ow, Ow–H···O (**1**) and Ow–H···Ow, Ow–H···O and Ow–H···N (**2**) intermolecular hydrogen bonds linking the mononuclear molecules into stable supramolecular structures. The complexes interacted with CT-DNA mainly by electrostatic attraction. Both **1** and **2** exhibit efficient nuclease activities in the presence of ascorbic acid, especially, complex **2** whose higher nuclease activity was attributed to the hydrophobic t-butyl group on the backbone of the ligand L^2. Hydroxyl radicals are mainly the reactive oxygen species.

Kinetics

ABSTRACT

The kinetics of the reaction between the tetrachloroaurate(III) ion and L-methionine (L-Met) (0.1 M $HClO_4$, pH 1.0–2.5) have been studied spectrophotometrically using a stopped-flow technique at different temperatures. Initially, the fast substitution reaction was ascribed to the formation of the short-lived square-planar Au(III)–(L-Met) that was followed by the replacement of a Cl^- ligand and a subsequent, slower reduction to Au(I)–(L-Met). This is an intermolecular process, involving attack on the $[AuCl_4]^-$ complex by an outer-sphere L-methionine. The activation parameters ($\Delta H^{\neq}$ and $\Delta S^{\neq}$) for substitution and reduction were determined. IR spectroscopy indicates that L-methionine acts as a bidentate ligand, most likely coordinating *via* the S and N atoms, while ^1H and ^{13}C NMR data indicate methionine sulfoxide as the final product. Finally, the components of the reaction were treated thermally in order to investigate the solid phase synthesis of the resulting complex.

1. Introduction

Interest in Au(III) reactions with amino acids, peptides and proteins arises from the proposal that these compounds may be involved in the reactions of potential antitumor agents [1,2]. However, the clinical application of gold complexes is limited since they are extremely unstable under physiological conditions [3]. Similar to Pt(II) compounds, Au(III) species are capable of binding DNA, and this is the reason for their cytotoxicity. The molecular basis of these toxic effects are still poorly understood, but the coordination of a thioether group to gold(III) by sulfur-donor ligands in the side-chains of amino acids, peptides and proteins, accompanied by the reduction of Au(III) to Au(I), could be responsible for the observed cytotoxicity [3,4]. It has been suggested that the reduction of Au(III) could take place by interactions with basic amino acids from the cell wall, since Au(III) compounds are able to oxidize several biomolecules such as L-methionine, L-cysteine, histidine and glycine [5–9]. Surprisingly, there are only a few reports of reactions of Au(III) with sulfur containing amino acids, and these have focused on stereo-specific oxidation, where the identity of the intermediates was not clarified [10,11].

The naturally occurring L-methionine amino acid, containing a thioether group, is an important molecule in living organisms that provides the metal binding sites in many enzymes. It forms chelates with metal ions mostly by coordinative binding to amino and carboxyl groups of α-amino acid residues [12]. Kinetic studies of the reduction of Au(III) by L-methionine and dialkyl sulfides have been reported [10,11], but there is a lack of data concerning the ligand substitution steps in the overall reaction mechanism. The interest in the speciation of Au(III) and L-methionine complexes arises from their relevance to the fundamental aspects of environmental and medical science, since the coordinated Au(III) ion may serve as an electron acceptor in biochemical processes within the cell [13–16]. Reactions between L-methionine derivatives and Au(III) have shown that the oxido-reduction process that occurs induces the production of sulfoxide and a Au(I)–L-methionine species [12,13]. The Au(III)-induced oxidation of L-methionine and related amino acids may be important in relation to the severe toxicity of gold-based drugs [17]. To our knowledge, a stable complex between Au(III) and L-methionine has not been isolated, but recently, Au(III) mononuclear complexes with some L-methionine containing peptides were synthesized and structurally characterized [18]. Au(III) was coordinated through the S atom from a L-methionine fragment and a N atom from an amino group residue, forming a macrochelate ring.

The elucidation of a stepwise Au(III) reduction mechanism, including the ligand substitution, provides the basis for obtaining further insights into the mechanism of drug toxicity. In this view, it is necessary to understand the chemistry of gold–biomolecule interactions. In this paper, special attention was paid to the detailed investigation of the equilibrium and kinetics of the reaction between $[AuCl_4]^-$ and L-methionine, as it may have a significant impact on the further exploration of Au(III) reactions with similar nucleophiles.

2. Experimental

2.1. Chemicals

Tetrachloroaurate(III) acid ($HAuCl_4 \cdot 3H_2O$, Merck), L-methionine, potassium hydroxide (Zorka, Šabac) and potassium chloride (Merck) and all other reagents were commercial products of the highest purity available. Stock solutions of 1×10^{-2} M $HAuCl_4 \cdot 3H_2O$ and L-methionine were prepared directly before use in 0.1 M $HClO_4$ to suppress formation of the aqua and hydroxo complexes. More dilute solutions were obtained by appropriate dilution with double distilled water. The acidities were obtained by addition of HCl or NaOH. To control the Cl^- concentration, KCl was used.

2.2. Physical methods

Absorption spectra were recorded using a Perkin–Elmer Lambda 35 UV–Vis spectrophotometer. For the stopped-flow experiments, the universal rapid kinetic accessory HI-TECH model SFA 12, with a dead time of 20 ms, was fitted to the spectrophotometer. The pH of the solutions was measured by a Beckman Expandometric pH meter.

NMR spectra were obtained on a Bruker ADVANCE III 500 spectrometer (500.26 MHz for ^1H, 125.8 MHz for ^{13}C) at 298 K, using a BBO multinuclear probehead and 5 mm tubes. The solvent was D_2O, pD 1 adjusted by D_2SO_4. The chemical shift reference was sodium 3-(trimethylsilyl)-propanesulfonate. The ^1H NMR spectra of L-methionine and $HAuCl_4 \cdot 3H_2O$ equimolar mixtures (66 mM) were measured 12, 25 and 50 min after mixing. The ^{13}C NMR spectra were obtained 1 h after mixing. The chemical shifts are reported in ppm, and the coupling constants (J) in Hz.

Thermal analysis was carried out using an SDT Q600 thermal analyzer from TA Instruments in a flowing nitrogen gas carrier with heating rates of 20, 5 and 2 °C min^{-1}. The pans were made of aluminium with an empty pan as a reference cell.

IR spectra were recorded at room temperature using KBr pellets in the range of 4000–400 cm^{-1} on a ThermoNicolett NEXUS 670 FT-IR spectrometer. The spectra were obtained with a resolution of 4 cm^{-1} after 32 scans.

FT-IR spectra were recorded with a ZnSe crystal on the Excalibur™ FT-IR Spectrometer (Varian, Darmstadt, Germany). All spectra were analyzed with Digilab Resolutions Pro Software. The solution of L-methionine was applied on the crystal as a thin film to cover the entire surface. After drying in the nitrogen stream, a solution of $HAuCl_4$ was applied on the L-methionine film and spectra were recorded 5 and 30 min after beginning the reaction.

2.3. Kinetic measurements

The kinetic experiments were performed by mixing equal volumes of $[AuCl_4]^-$ and L-methionine solutions. The temperature was controlled to ±0.1 °C in the interval from 282 to 303 K. The kinetic curves were monitored at 225 and 280 nm. The experimental points in the pseudo first-order experiments were fitted by a single exponential function. All kinetic measurements were reproducible within limits of error of ±5%. The values reported are averages of at least five runs under identical experimental conditions.

3. Results and discussion

3.1. Complex formation between $[AuCl_4]^-$ and L-methionine

The absorption spectra of solution containing 2.5×10^{-5} M $[AuCl_4]^-$ and L-methionine in 0.1 M $HClO_4$ in the presence of 0.1 M KCl were recorded on the dependence of time and are presented in Fig. 1. Two reaction steps can be deduced from the change of the absorbance vs. time at 280 and 225 nm. The faster one, accompanied by the absorbance increase at 280 nm, followed by two well-defined isosbestic points at 245 and 295 nm, indicated the short-lived complex formation between $AuCl_4^-$ and L-methionine. The slower reaction step, accompanied by the decrease in absorbance, can be ascribed to the reduction of Au(III). The second-order complex formation (fast) and first-order (slow) Au(III) reduction (Fig. 2, inset) are confirmed by analyzing the kinetic curves at 225 and 280 nm (Fig. 2) for two equimolar solutions containing 2.5×10^{-5} M or 5×10^{-5} M $[AuCl_4]^-$ and L-methionine in 0.1 M $HClO_4$. The 1:1 stoichiometry of the complex formed in the fast reaction step was determined from the absorbance vs. time curves at 280 nm by using Jobb's and molar ratio methods at 280 nm. It is of note, that the maximum of the kinetic traces was independent of L-methionine concentration. The molar absorptivity of the complex ($a = 3.64 \times 10^3$ M^{-1} dm^3) was determined as the average value on the plateau of the kinetic traces at 280 nm.

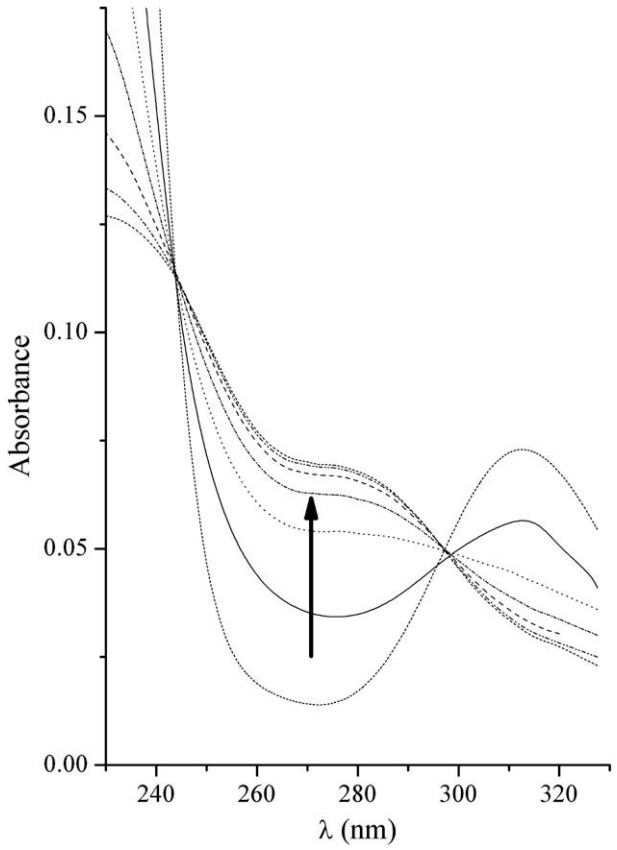

Fig. 1. Time dependence of UV–Vis spectra of solution containing 2.5×10^{-5} M $[AuCl_4]^-$ and L-methionine in 0.1 M $HClO_4$ at 10 °C. The time interval between two consecutive spectra was 2 s.

In the ^1H NMR spectrum measured 12 min after mixing the components, one could observe traces of some intermediary species, with approximately 10% of the product probably originating from the Au(III)–(L-methionine) complex (data not shown). The ^1H NMR spectrum measured 25 min after mixing, and the ^{13}C NMR data, show only the presence of methionine sulfoxide as a diastereomeric mixture (Table 1) [19,19a].

Regarding the NMR data, free ligand and complex mostly differ in the chemical shifts of the nuclei adjacent to the S atom (Table 1). In both the ^1H and ^{13}C NMR spectra of the complex, the signals of the γCH_2 and CH_3 groups are significantly shifted downfield, while the ^1H NMR signal of the γCH_2 showed a typical, diastereotopic

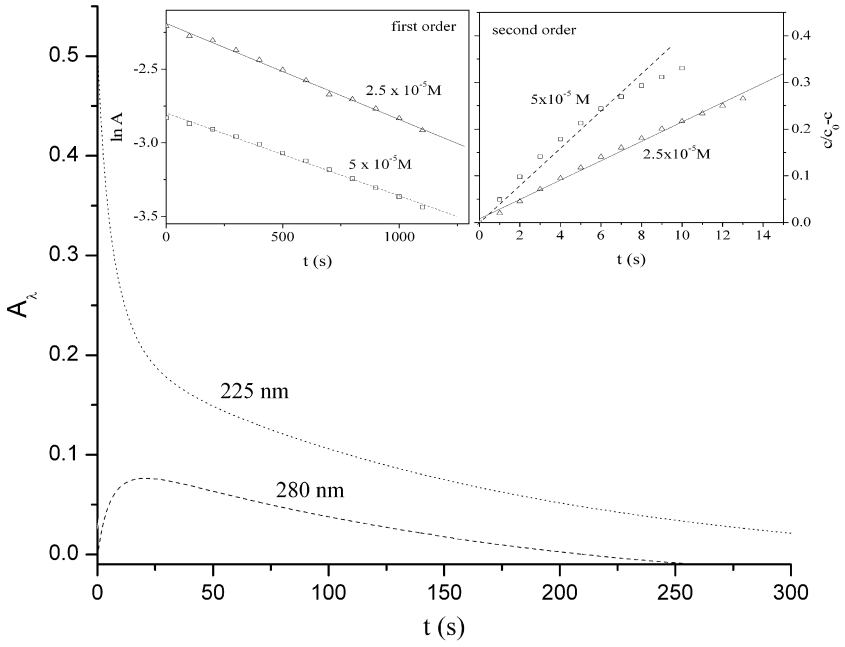

Fig. 2. Kinetic curves of solution containing 2.5×10^{-5} M $[AuCl_4]^-$ and L-methionine in 0.1 M $HClO_4$ at 280 nm and 225 nm at 20 °C. *Inset:* The kinetic analysis of the ascending (second-order) and descending (first-order) branch of the kinetic curve at 280 nm for 2.5×10^{-5} M and 5×10^{-5} M equimolar solutions.

Table 1
The ^1H and ^{13}C NMR chemical shifts (ppm) of L-methionine and methionine sulfoxide at pD 1.

	Position	L-Methionine δ (multiplicity, J)	Methionine sulfoxide [a] δ (multiplicity, J)
^1H	α	4.22 (1H, dd, 6, 6.8)	4.29, 4.28 (1H, 2xdd, 6.1, 6.9; 6.4, 6.7)[b]
	β	2.16–2.35 (2H, m)	2.34–2.52 (2H, m)[c]
	γ	2.7 (2H, t, 7.4)	2.96–3.26 (2H, m)[c]
	CH_3	2.13 (3H, s)	2.75, 2.76 (3H, 2xs)[d]
^{13}C [e]	α	54.49	54.18, 54.32[f]
	β	31.57	25.76, 26.01[f]
	γ	31.19	50.50, 50.64[f]
	CH_3	16.54	39.19, 39.27[f]
	C=O	174.49	173.40

[a] The 1H δ values are from the spectrum measured after 25 min.
[b] The signals are overlapped, but distinguishable.
[c] Signals overlapped.
[d] Signals are not fully overlapped, enabling separate integration major/minor = 2/1.
[e] The assignation of ^{13}C signals was proven by H–C correlations in HSQC spectra of both, ligand and its sulfoxide (data not shown).
[f] First and second value are for the major and minor diastereoisomer, respectively; the same is valid for αH and CH_3 in ^1H NMR spectrum.

pattern. This clearly indicates S-coordination in the Au(I)–(L-methionine) complex.

The NMR findings were further confirmed with FT-IR analysis of 1×10^{-1} M L-methionine (lines are indicated in Fig. 3) and a solution containing 1×10^{-1} M Au(III) and L-methionine (Fig. 3). These results also imply S,N-coordination. The spectrum recorded 5 min after starting the reaction represents the spectrum of the Au(III)–(L-methionine) complex in solution. After 30 min of the reaction the band located approximately at 1650 cm^{-1} disappeared.

Shifts of the NH_2 scissoring vibrations in the IR spectrum of L-methionine (shifted from 1650 to 1700 cm^{-1}) and the suppression of the –C–S stretching vibration in the region of 790–830 cm^{-1} after the addition of $HAuCl_4$ indicate that both N- and S-atoms from the L-Met are involved in the formation of coordinative bonds in the complex.

In order to check if there was a complex formation between the components and to isolate the final product, the reaction was carried out as a solid-state thermal reaction. TA measurements of a solution containing 2.5×10^{-5} M $AuCl_4^-$ and 1.0×10^{-3} M L-methionine in an inert (N_2) atmosphere did not suggest the reduction of Au(III). In order to follow the complex formation in the solid-state, the components were mixed in a mortar. However, the reduction of Au(III) to Au(0) was observed when mixing $HAuCl_4 \cdot 3H_2O$ and L-methionine. To avoid the reduction of Au(III), the components were put directly into the crucible without mechanical mixing in a molar ratio of about 1:1, with L-methionine being in excess (~10 m/m%). The mixture was equilibrated at 50 °C and then heated at a heating rate of 5 °C min^{-1} up to 140 °C. At about 90 °C, almost all of the water content of the mixture was removed. However, before the evaporation of water had finished, another processes began. The extruded gases were bubbled through a $AgNO_3$ solution. In the temperature range of 90–130 °C, a white precipitate indicated HCl evaporation, which was most likely followed by organic fragments of the uncoordinated L-methionine.

Additionally, a stepwise (SWI), or quasi-isothermal method [20], was applied to a similar mixture of $HAuCl_4 \cdot 3H_2O$ and L-methionine. In this experiment, an intermediate with low stability was isolated at 118 °C (Fig. 4). The mass loss of 24.4% was much higher compared to dehydration (66 °C) and a loss of HCl (calcd. 10.71%). It might be a consequence of the sublimation of L-methionine. However, its sublimation temperature, according to literature data [21], should be higher by about 50 °C. It is more likely that the higher mass loss is a consequence of the reduction of Au(III) to Au(I) and the departure of the corresponding oxidation product – sulfoxide.

The IR spectrum of the intermediate was compared to the spectrum of L-methionine. There is a change in the position and intensity of the νCS bands [22,23] in the range of about 800–600 cm^{-1} (data not shown). The most significant shift of the corresponding bands is in the range of 1730–1500 cm^{-1}. Namely, bands at 1612 and 1511 cm^{-1} assigned to $\nu_{as}NH_3^+$ and $\nu_{as}COO^-$, respectively [22,23], suffered a blue shift to 1723 and 1687 cm^{-1}. The spectrum of the intermediate may support complex formation of Au(III) with

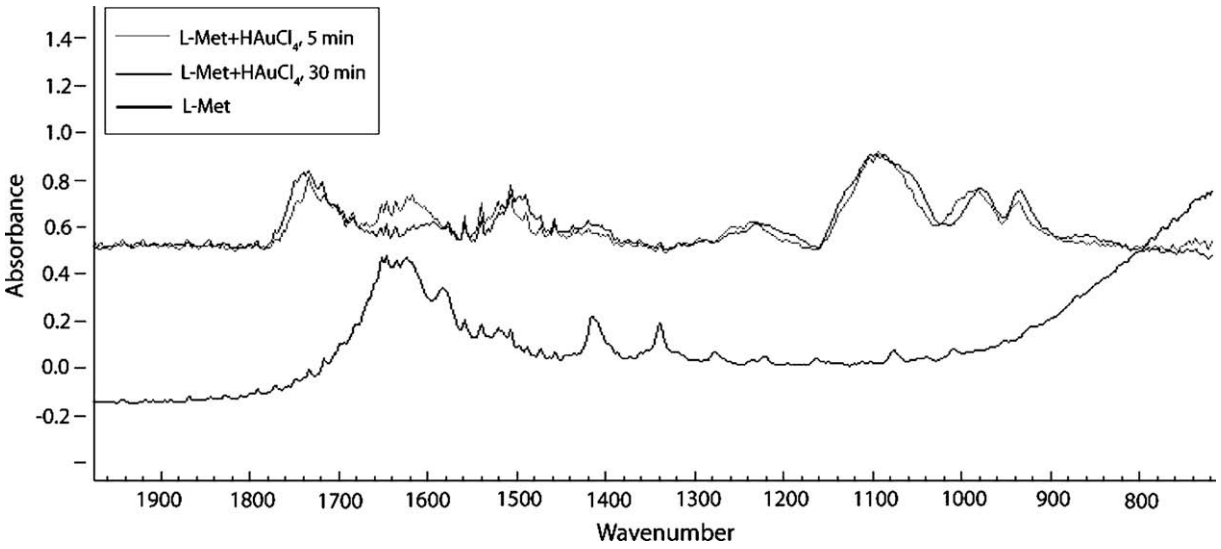

Fig. 3. FT-IR spectra of solution containing 1×10^{-1} M L-methionine and $[AuCl_4]^-$ in 0.1 M $HClO_4$ after 5 and 30 min after starting the reaction.

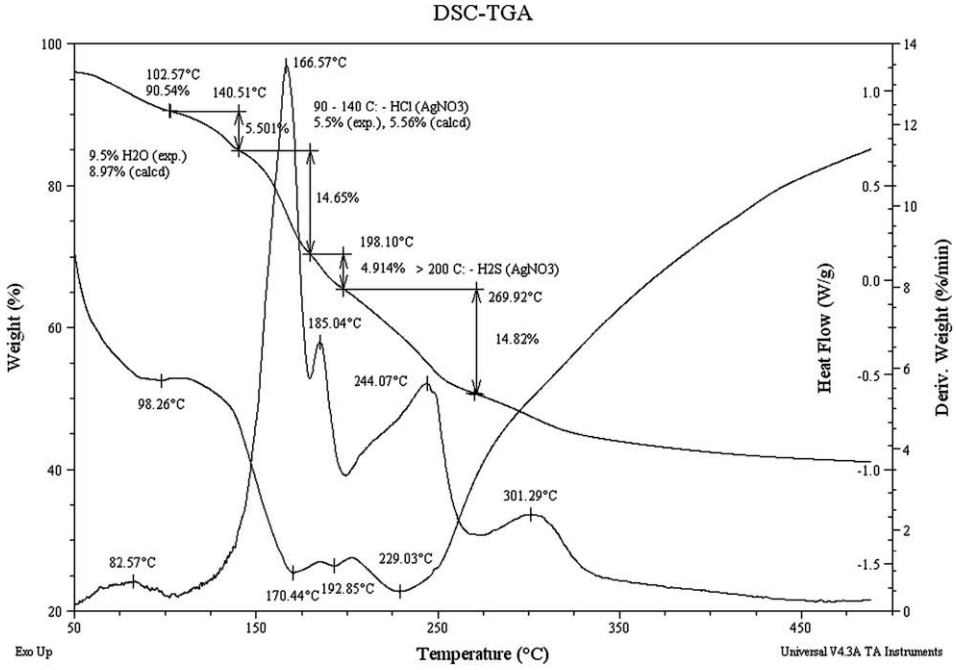

Fig. 4. Thermal curves of the mixture of $HAuCl_4 \cdot 3H_2O$ and L-methionine solids.

L-methionine as a bidentate ligand with S,N-coordination. Also, the lower intensity of the bands in the 800–600 cm^{-1} range of the intermediate may support the partial oxidation of the ligand into the corresponding sulfoxide. The bands of the uncoordinated ligand did not change position.

An additional solid-state reaction was carried out by heating the reaction mixture up to 70 °C at a heating rate of 2 °C min^{-1} in cycles. At the third cycle, the mass loss was less than 0.4%. The complete mass loss of 11.0% compared to the calculated one (12.73%) corresponds most likely to the loss of three H_2O molecules and one HCl molecule (Fig. 4). The solid-state reaction is endothermic up to 300 °C, suggesting an endothermic reduction of the central atom, which means that the increase in entropy is the determining stabilizing factor in the complex formation.

The IR spectrum of the end product of this reaction shows the unchanged bands of the uncoordinated ligand, similar to the spectrum of the intermediate obtained using the SWI method.

3.2. Kinetics of ligand substitution and oxido-reduction

The kinetics were investigated at pH 1.0 in the presence 0.1 M KCl under pseudo first-order conditions, keeping the concentration of $[AuCl_4^-]$ constant (2.5×10^{-5} M) and varying [L-methionine] from 2×10^{-4} M to 1×10^{-3} M. The rise and fall of the absorbance at 280 nm as a function of time is characteristic for a reaction that involves an intermediate B in the overall process during which A is transformed into P, as shown in Eq. (1), and the time dependence for B is given by Eq. (2):

$$A \overset{k_{obs1}}{\rightarrow} B \overset{k_{obs2}}{\rightarrow} P \quad (1)$$

$$[B] = \frac{k_{obs1}}{k_{obs2} - k_{obs1}} [B]_{\infty} (e^{-k_{obs1}t} - e^{-k_{obs2}t}) \quad (2)$$

In Eq. (1) B represents the 1:1 complex resulting from nucleophilic attack of the sulfur donor of the thioether group in L-methionine and Cl^- substitution. In Eq. (2), [B] and $[B]_\infty$ are the concentrations of the complex at t and when equilibrium is reached, and k_{obs1} and k_{obs2} are pseudo first-order rate constants for the reactions (1). Fig. 5 represents the change of complex concentration as a function of time obtained from the kinetic curve (A_{280} *versus* t, Fig. 5, inset) for the solution containing 2.5×10^{-5} M $[AuCl_4]^-$ and 1×10^{-4} M L-methionine. The first-order rate constants $k_{obs1} = (0.46 \pm 0.03)\ s^{-1}$ and $k_{obs2} = (1.08 \pm 0.02) \times 10^{-2}\ s^{-1}$ were determined from the separate treatment of the ascending and descending branch of the kinetic curve and were used to recalculate the dependence of [B] *versus* t. The results are presented in Fig. 5 as a solid line, since the points represent the experimentally obtained data. As can be seen, the calculated results are in good agreement with the experimental results.

The rising parts of the kinetic curves were single exponentials in all cases. The observed rate constant (k_{obs1}) as a function of the total concentration of L-methionine can be described by the well known two-term rate law common for substitution reactions of square-planar complexes [23]:

$$k_{obs1} = k_I + k_{II}\ [\text{L-methionine}] \quad (3)$$

where k_I is the solvent-dependent rate constant and k_{II} is the second-order rate constant, which is characteristic for direct nucleophilic attack and formation of a Au(III)–L-methionine complex. The rate constants k_I and k_{II} were determined from the intercept and the slope of the linear plots of k_{obs1} *versus* [L-methionine].

The slow reaction path leads to the reduction of gold by forming a linear two-coordinated Au(I)–(L-methionine) complex [10,11]. It is apparent that a second L-methionine is required in order to promote the reduction of Au(III)–(L-methionine) since the pseudo first-order rate constants for the reduction are a function of the L-methionine concentration and obey the relationship:

$$k_{obs2} = k_2\ [\text{L-methionine}] \quad (4)$$

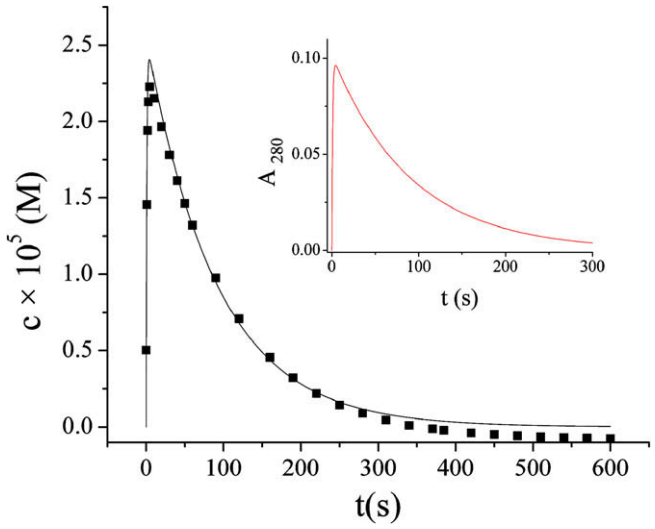

Fig. 5. Dependence of complex concentration on time for the reaction between 2.5×10^{-5} M $[AuCl_4]^-$ and 1×10^{-4} M L-methionine at pH 1.0 and 0.1 M KCl. Solid curve represents Eq. (2) fitted to the experimental values (points). Inset: dependence of absorbance at 280 nm on time.

In this reaction step, the L-methionine was oxidized in the presence of water to the corresponding sulfoxide [11,14]:

$$[Au^{III}Cl_3(HMet)]^+ \overset{k}{\rightarrow} Au^{I}Cl(HMet)^+ + 2Cl^- + 2H^+ \quad (5)$$

$$[Au^{III}Cl_3(HMet)]^+ + HMet^+ + H_2O \rightarrow [Au^{I}Cl(HMet)]^+ + SOCH_3CH_2CH_2CH(-COOH)(-H_2N) + H^+ \quad (6)$$

The rate constants k_{obs1} and k_{obs2}, as a function of ligand concentration at various temperatures and pH 1.0 are summarized in Tables 2 and 3, along with the determined values for k_I, k_{II} and k_2.

3.3. Reaction mechanism

The pH dependence of the pseudo first-order rate constants (pH profile) for solutions containing 2.5×10^{-5} M $[AuCl_4]^-$, 10-fold excess L-methionine and 0.1 M KCl, obtained by analysis of the ascending branch of the kinetic curves at 280 nm, is presented in Fig. 6. The results show the significant increase of k_{obs1} with the decrease of acidity in the pH range of 1–2.5. This behavior indicates that different reacting species of Au(III) ($AuCl_4^-$, $AuCl_3OH^-$) are involved in the forward reaction [24]. Also, two acid–base forms of the ligand are present ($pK_{COOH} = 2.28$) [25]. The appearance of species containing OH^- groups may be interpreted using the HSAB principle [26]: a hard OH^- base has a preferences for hard Au(III) acids, even in an acidic solutions, which is also promoted by steric hindrance. A reaction scheme for ligand substitution compatible with the pH dependence of k_{obs} is given by reactions (7)–(10). However, it is more probable that reactions (9) and (10) are faster compared to (7) and (8) [27]. The assumption was made that the protolytic equilibria (reactions (12) and (13)) are faster compared to substitution of the ligand, and consequently that the equilibrium between Au(III) species was maintained throughout the kinetic run [24]. This is in accordance with the observations at low temperature, and the solid-state reactions up to 70 °C. In addition,

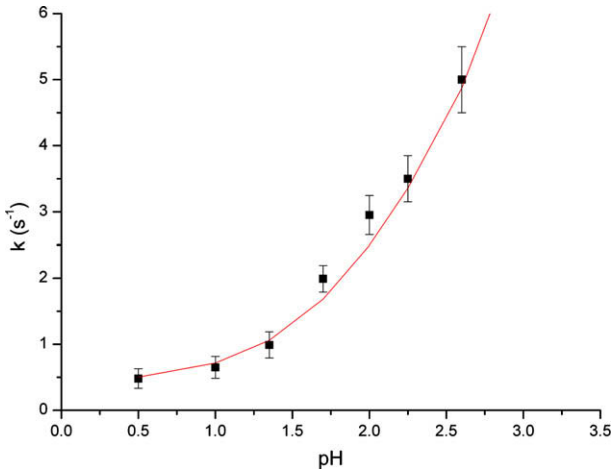

Fig. 6. Dependence of k_{obs1} on pH in solution containing 2.5×10^{-5} M $[AuCl_4]^-$, 2.5×10^{-4} M L-methionine and 0.1 m KCl at 20 °C.

both Au(III)–(H^+L-methionine) and Au(III)–(L-methionine) are formed under these experimental conditions, as found previously in reactions between Pd(II) and –SH containing amino acids and peptides [28–31]:

$$AuCl_4^- + HMet^+ \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} AuCl_3(HMet)^+ + Cl^- \quad (7)$$

$$AuCl_4^- + Met \underset{k_2'}{\overset{k_2}{\rightleftharpoons}} AuCl_3Met + Cl^- \quad (8)$$

$$AuCl_3OH^- + HMet^+ \underset{k_3'}{\overset{k_3}{\rightleftharpoons}} AuCl_3(HMet)^+ + OH^- \quad (9)$$

$$AuCl_3OH^- + Met \underset{k_4'}{\overset{k_4}{\rightleftharpoons}} AuCl_3Met + OH^- \quad (10)$$

$AuCl_3(HMet)^+$ + Cl^- → (fast) → $[AuCl_2HMet]^{+2}$ ⇌ $[AuCl_2Met]^{+1}$

$HMet^+$ and Met represent L-methionine with and without a protonated $-NH_2$ group, respectively. It can be easily shown that under the above mentioned experimental conditions, a pH dependence of k_{obs} can be described as follows:

$$k_{obs} = \frac{k_I[H^+]^2 + k_{II}[H^+] + k_{III}}{\alpha \cdot \beta} \quad (11)$$

where $\alpha = [H^+] \cdot [Cl^-] + K_1$, $\beta = [H^+] + K_a$, $k_I = k_1 \cdot [Cl^-]$, $k_{II} = k_2 \cdot K_a \cdot [Cl^-] + k_3 \cdot K_1$ and $k_{III} = k_4 \cdot K_1 \cdot K_a$.

In addition, the following equilibrium must be taken into account:

$$HMet^+ \overset{K_a}{\rightleftharpoons} H^+ + Met \quad (12)$$

$$AuCl_4^- + H_2O \overset{K_1}{\rightleftharpoons} AuCl_3OH^- + H^+ + Cl^- \quad (13)$$

The experimentally determined pH dependence of k_{obs} is shown by the points in Fig. 6. The best fit to Eq. (11) was obtained using $k_{I–III}$ as variable parameters. The agreement between the experimentally determined and calculated values of k_{obs} was obtained for the following set of $k_{I–III}$:$k_I = 3.98 \times 10^{-2}$ M^{-1} s^{-1}, $k_{II} = 3.68 \times 10^{-3}$ s^{-1} and $k_{III} = 2.68 \times 10^{-6}$ M^{-1} s^{-1}.

The individual rate constants $k_{1–4}$ were easily determined knowing values of $k_{I–III}$, and are presented in Table 4. The parameter k_{II} gives the sum of the contributions of paths 2 and 3 (Eqs. (8) and (9)). The individual rate constants k_2 and k_3 were estimated

Table 4
Individual rate constants for different reaction paths in the system Au(III)–L-methionine.

Reaction path	Metal ion	Ligand	$k_{1–4}$ (M^{-1} s^{-1})

3	$AuCl_3OH^-$	$HMet^+$	5.25×10^4
4	$AuCl_3OH^-$	Met	$(5.18 \pm 0.20) \times 10^2$

assuming that one of the two rate constants is equal to zero, and vice versa. The obtained values are the upper limits of the individual rate constants. Taking into account the experimental conditions (Cl^- concentration and pH range), the contribution of path 3 could be considered negligible, since the concentration of protonated L-methionine significantly decreased with a pH > 2.

3.4. Activation parameters

The temperature dependencies of the rate constants (k_{II} and k_2, Table 2) obtained for complex formation between $AuCl_4^-$ and L-methionine allowed the calculation of the enthalpies and entropies of activation by using Eyring's equation [26]:

$$\text{Rate constant} = kT/h \exp(\Delta S^{\neq}/R) \exp(-\Delta H^{\neq}/RT) \quad (14)$$

It is important to point out that under the stated experimental conditions (pH 1, 0.1 M KCl), the ligand was protonated and Au(III) was in the form of $AuCl_4^-$, so the reaction pathways described by reactions (8)–(10) can be neglected. The same equation was applied for the reduction process under the same experimental conditions. The values of enthalpy ($\Delta H^{\neq}$ = 19.19 kJ mol^{-1}) and entropy ($\Delta S^{\neq}$ = −121.66 J mol^{-1} K^{-1}) for the forward reaction in ligand replace-

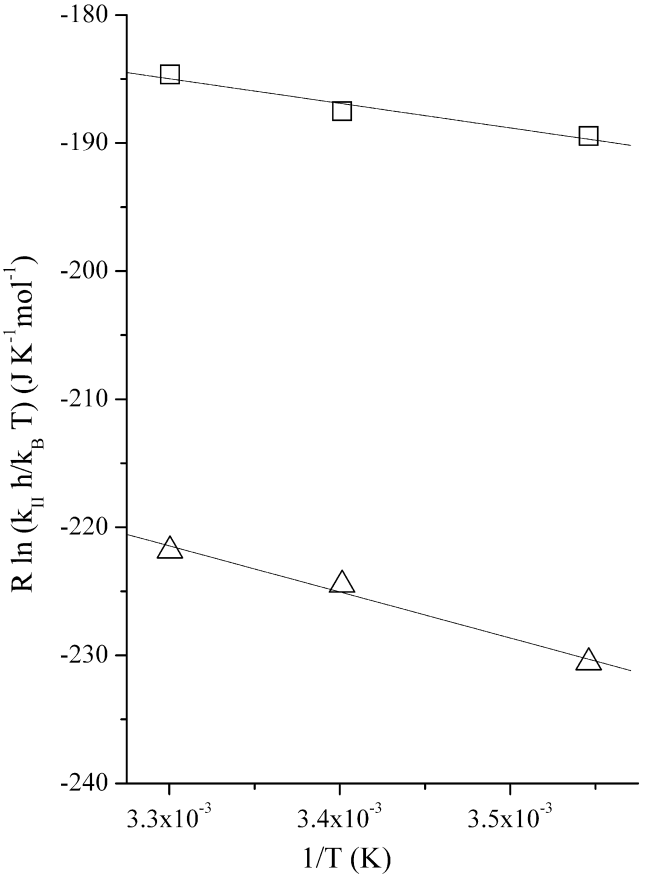

Fig. 7. Dependence of $R \ln(k_f h/k_b T)$ (J K^{-1} mol^{-1}) on $1/T$ for ligand substitution and reduction.

ment were obtained from the intercept and the slope of the plot (Fig. 7). Values of $\Delta H^{\neq} = 35.97$ kJ mol^{-1} and $\Delta S^{\neq} = -102.75$ J mol^{-1} K^{-1} for Au(III) reduction were also obtained.

4. Conclusion

Based on the experimental results presented in this work and other literature data concerning the reaction between $[AuCl_4]^-$ and some amino acids and dialkyl sulfides, which were obtained using multi-instrumental techniques [5,6,14], the conclusion was made that the reaction mechanism takes place in a few steps. The first one is the second-order coordination of the ligand with chloroaurate(III), displacing the chloride anion.

In addition, our point of interest was to investigate how L-methionine acts towards gold under the conditions of the experiment. The hypothesis that L-methionine acts as bidentate S- and N-donor ligand forming $[Au^{III}Cl_2(HMet)]^{+2}$ was confirmed in the solid-state as well in solution, since the ring-closing process is favored by the large chelate effect, even though the amino group is almost totally protonated due to the acidity of the reaction medium [23]. This is also supported by the pH profile. By keeping the Cl^- concentration at 0.1 M, Au(III) is predominantly in the $AuCl_4^-$ form [24]. Above pH 2, the dissociation of the –COOH group occurs, and consequently L-methionine is in its zwitterionic form. However, the –COOH group is not responsible for complex formation, but these results indicate that in a less acidic medium, the zwitterionic ligand enhanced the participation of the unprotonated amino group of L-methionine in the reaction process.

The inequality in enthalpic contribution appears to reflect a variance in structural transformations to break old bonds and form new ones in the transition state, depending on the type of processes (substitution/reduction reaction), thus producing the corresponding difference in the nature of the bonds between metal ions and their respective ligand. It should be noted that the negative value of the entropy term, exhibiting the change in the order of the system, is indeed expected for the substitution reaction followed by reduction [23]. However, a large negative value of the entropy of activation is compatible with an associative mode of activation (Ia or A mechanism) in the first reaction step. This finding indicates that bond-making with the entering ligand is important in the activation processes, and that the leaving ligand is still tightly bound to the metal center in the transition state.

ABSTRACT

Metal–organic frameworks with the compositions $[Zn(bpy)(bdc)(H_2O)]_n$ **1**, $[Zn(bpy)(btec)_{1/2}(H_2O)]_n$ **2**, $[Cd(bpy)(bdc)(H_2O)]_n$ **3** and $Cd(bpy)(btec)_{1/2}(H_2O)]_n$ **4** (H_2bdc = 1,4-benzenedicarboxylic acid = terephthalic acid, H_4btec = 1,2,4,5-benzenetetracarboxylic acid and bpy = 2,2′-bipyridine) have been synthesized and characterized using spectroscopic and single-crystal X-ray diffraction techniques. In these complexes, Zn^{II}/Cd^{II}-2,2′-bipyridine units and carboxylate anions exists as nodes and spacers respectively. An infinite 1D zig-zag chain structure is observed for both complexes **1** and **3**, whereas complexes **2** and **4** display a 3D supramolecular architecture. The complexes are found to be photoluminescent, porous and show significant thermal stability.

1. Introduction

Recent years have witnessed rapid progress made in the construction of metal–organic frameworks (MOFs) owing to their intriguing molecular topologies [1–7] and potential applications in porosity [8–10], catalysis [11–15], ion exchange [16], chirality [17–21], luminescence [22–26], non-linear optics (NLO) [27–31], conductivity [32–35], optoelectronics [36,37], magnetism [38–42], spin-transition behavior [43–46], gas storage [47–49] and selective binding of molecules through absorption [13,50]. Most of the current studies in this area involve d^{10} transition metal ions with functional ligands. However, it is still considered a challenge to explore successful synthetic routes for the preparation of MOFs that could be exploited for targeted applications.

In this context, polycarboxylates are widely used in the development of supramolecular networks organized through coordination bonds, hydrogen bonds and π–π stacking interactions. Among these anionic polycarboxylates, 1,4-benzenedicarboxylic (H_2bdc) acid and 1,2,4,5-benzenetetracarboxylic acid (H_4btec) are extensively exploited as ligands in the construction of supramolecular architectures through their self-assembly [51–53].

In recent years, functional coordination polymers caught the attention of researchers owing to their potential applications in technology. Di-anionic dicarboxylate ligands are commonly used as molecular tethers for this work. These ligands can link metal cations into coordination polymer chains, layers or networks, in the process providing the charge balance necessary to avoid the inclusion of porosity-inhibiting smaller anions. The disposition of the donor groups within the dicarboxylate moieties, the coordination geometry preferences at the metal ions and the array of accessible carboxylate binding modes have been shown to act synergistically in the structure directed self-assembly of coordination polymers in solution. On the other hand, auxiliary ligands like 2,2′-bipyridine also impact on the conformations of the flexible carboxylic ligand (*trans*- or *cis*-), and play an important role in the formation of the final structure of the complex [54]. The terminal ligand 2,2′-bpy tends to construct low-dimension structures which can be extended into high-dimensional supramolecular networks through hydrogen bonds and π–π stacking interactions.

Thus, the present article is thought to be of worth as it deals with the synthesis and characterization of the structures obtained on the skeleton of d^{10} divalent metal (Zn^{II},Cd^{II})2,2′-bipyridines together with 1,2-benzenedicarboxylic acid and 1,2,4,5-tetracarboxylic acid. Since such types of metal–organic frameworks show the formation of porous structures [5], micro structural studies have also been carried out on these synthesized complexes.

2. Experimental

2.1. Materials and methods

Reagents of A.R. purity were purchased from standard commercial sources (Sigma–Aldrich, Merck) and were used without further

purification. Elemental analyses have been carried on a Carbo-Erba elemental analyzer 1108, and IR spectra were recorded as KBr pellets on a Varian 3100 FT-IR spectrometer. TGA measurements were performed on a Perkin Elmer Pyris diamond TG-DTA instrument at a heating rate of 5 °C/min in a nitrogen atmosphere with a flow rate of 200 ml/min in the temperature range 50–800 °C. Photoluminescence (PL) was measured using a Hitachi F-4500 spectrofluorometer. $M(bpy)(NO_3)_2 \cdot H_2O$ ($M = Zn^{II}/Cd^{II}$) were prepared using the procedure as reported by Sen et al. [55] for analogous complexes.

2.2. X-ray crystallographic studies

Suitable X-ray quality crystals of the complexes were grown directly from their corresponding reaction mixtures in DMF/EtOH/H_2O (6:2:0.4 by volume) at room temperature and X-ray crystallographic data were collected by mounting a single-crystal of the sample on a glass fiber. An Oxford diffraction XCALIBUR-S and Bruker SMART CCD area detector diffractometer equipped with an LN-2 low-temperature attachment was used for the determination of cell parameters and intensity data collection. Appropriate empirical absorption corrections using the programs multi-scan were applied. Monochromated Mo Kα radiation (λ = 0.71073 Å) was used for the measurements. The crystal structures were solved by direct methods [56] and refined by full matrix least squares SHELXL-97 [57]. Drawings were carried out using MERCURY [58] and DIAMOND [59], and special computations were carried out with PLATON [60].

2.3. Synthesis of the complexes

The complexes were synthesised by general procedures as reported by Guo et al. [61]. In a typical synthetic procedure, Zn^{II}(2,2′-bipyridyl)$(NO_3)_2 \cdot H_2O$ (0.363 g, 1 mmol) and Cd^{II}(2,2′-bipyridyl)$(NO_3)_2 \cdot H_2O$ (0.410 g, 1 mmol) were added separately to the corresponding solutions of H_2bdc (0.166 g, 1.0 mmol) and H_4btec (0.127 g, 0.5 mmol) dissolved in DMF (6 ml) and ethanol (2 ml) at room temperature, containing an equimolar amount of triethylamine. Few drops of 5N-HNO_3 (pH 4–5) was added until the mixture become clear. The mixture was heated at 120 °C for 6–8 h to give the corresponding complexes in 65–90% yield. The complexes thus isolated were found to be insoluble in water and common organic solvents.

2.3.1. Synthesis of [Zn(2,2′-bpy)(bdc)(H_2O)] **1**

Using the above procedure, after heating the components together at 120 °C for 6 h then cooling to room temperature, tiny round shaped crystals were obtained after two weeks, which were washed several times with diethylether. Yield: ~77%. *Anal.* Calc. for $C_{18}H_{14}N_2O_5Zn$ (**1**): C, 53.55; H, 3.50; N, 6.94. Found: C, 53.99; H, 3.68; N, 7.52%. IR (KBr, cm^{-1}): 3207 (w), 1590 (vs), 1474 (m), 1439 (s), 1376 (vs), 1313 (s) 1152 (w), 1020 (w), 840 (w), 753 (vs), 658 (m), 549 (m).

2.3.2. Synthesis of [Zn(2,2′-bpy)(btec)$_{1/2}$(H_2O)] **2**

Complex **2** was also synthesized using a similar method as used for the synthesis of complex **1** except that H_4btec was used instead of H_2bdc. After heating at 120 °C for 8 h and then cooling to room temperature colorless block shaped crystals were obtained after 10 days, which were washed with diethylether and dried. Yield: ~93%. *Anal.* Calc. for $C_{15}H_{11}N_2O_5Zn$ (**2**): C, 49.41; H, 3.04; N, 7.68. Found: C, 49.72; H, 3.38; N, 7.79%. IR (KBr, cm^{-1}): 3409 (w), 3071 (m), 1634 (vs), 1580 (s), 1483 (m), 1381 (vs), 1129 (vs), 1020 (s), 817 (m), 763 (vs), 654 (m), 540 (m), 458 (m).

2.3.3. Synthesis of [Cd(2,2′-bpy)(bdc)(H_2O)] **3**

Complex **3** was also synthesized using a similar procedure as used for the synthesis of complex **1** but $Cd(bpy)(NO_3)_2 \cdot H_2O$ was used instead of $Zn(bpy)(NO_3)_2 \cdot H_2O$. Colorless block shaped crystals of **3** were recovered after one week, which were washed several times with methanol followed by diethylether. Yield: ~66%. *Anal.* Calc. for $C_{18}H_{14}N_2O_5Cd$ (**3**): C, 47.97; H, 3.13; N, 6.22. Found: C, 48.22; H, 3.34; N, 5.92%. IR (KBr, cm^{-1}): 3368 (w), 3199 (w), 1571 (vs), 1434 (m), 1380 (vs), 1310 (m) 1153 (s), 1014 (s), 820 (s), 74 (vs), 651 (m), 534 (m).

2.3.4. Synthesis of [Cd(2,2′-bpy)(btec)$_{1/2}$(H_2O)] **4**

Using the above procedure, complex **4** resulted in colorless tiny round shaped crystals after three weeks, which were washed with methanol followed by diethylether. Yield: ~69%. *Anal.* Calc. for

3. Result and discussion

3.1. IR spectra

Major peaks observed between ~1600 and ~1200 cm^{-1} are assigned to υ(bpy) and υ(phenyl) of the benzenecarboxylate ligands. The $\upsilon_{as}(COO^-)$ and $\upsilon_s(COO^-)$ bands are observed at ~1570 and ~1380 cm^{-1} respectively [62]. The peaks lying in the region ~3400 to ~3200 cm^{-1} are assigned to υH_2O(coordinated) whereas $\rho r H_2O$(coordinated) and $\rho w H_2O$(coordinated) appear at ~655 and ~540 cm^{-1} respectively.

3.2. Structural description of the complexes

Crystallographic data and refinement details for the structural analyses of all the complexes are summarized in Table 1. Selected bond lengths and bond angles with their estimated standard deviations are presented in Table 2 while selected parameters for weak interactions are listed in Table 3. Molecular structures (ORTEP diagrams) of the complexes **1**–**4** are shown in Fig. 1.

3.2.1. Complex *1* and *2*

The X-ray single-crystal structure determination reveals that complex **1** exists as a neutral one-dimensional infinite zig-zag coordination chain. Each Zn^{II} center is surrounded by two N donors from the 2,2′-bipyridine ring, two oxygen atoms from two carboxylate groups of two different terephthalic acid molecules together with one water molecule, in a distorted pentacoordinated geometry, as depicted in Fig. 1a. The neighboring Zn^{II} centers are connected by a terephthalate dianionic moiety which acts as a bridge through its benzene ring, as shown in Fig. 2a. The two terephthalate units are almost orthogonal to each other with a dihedral angle of 88.87° and the two Zn^{II} centres are separated at a distance of 11.10 Å. In this structure, the 2,2′-bipyridine molecule acts as a

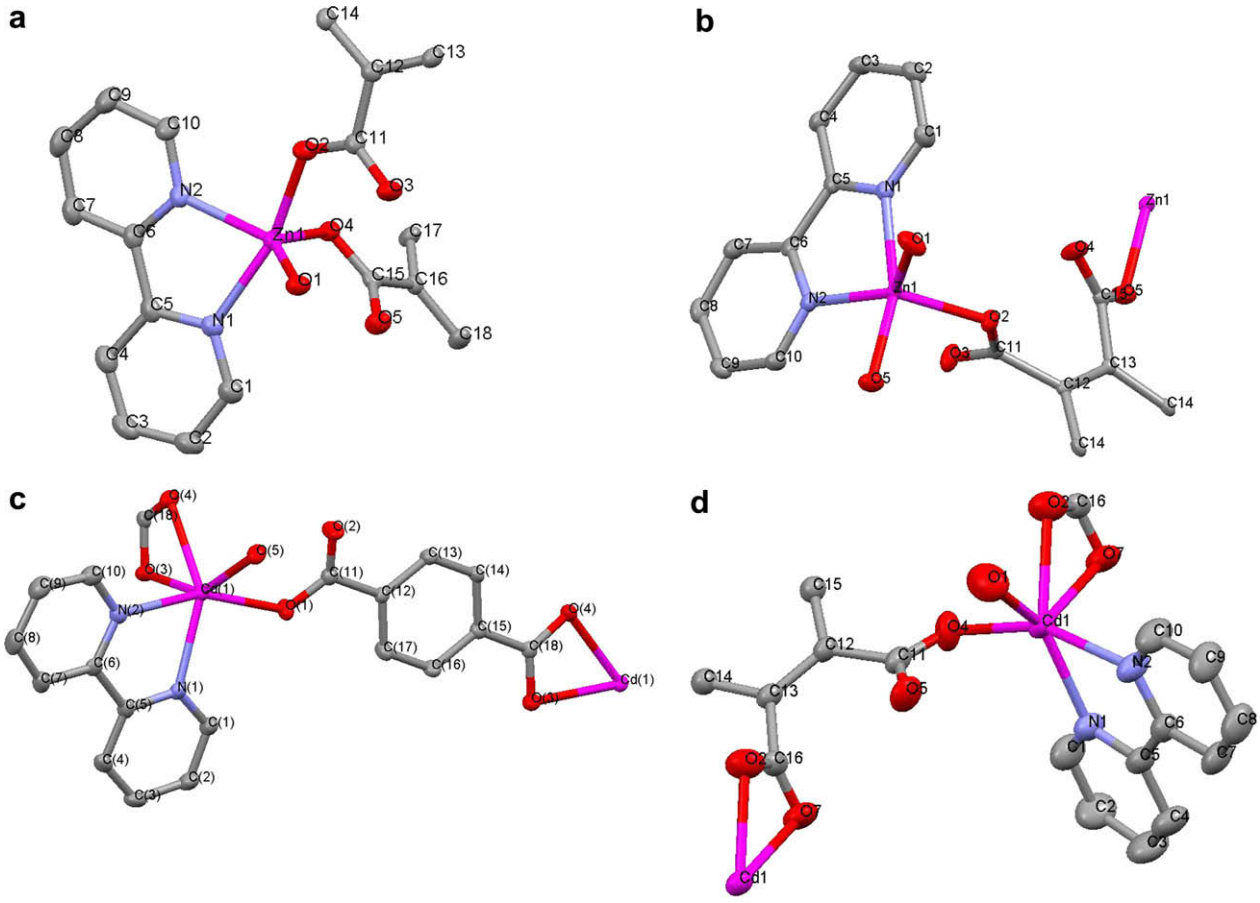

Fig. 1. Molecular structures of complexes **1**(a), **2**(b), **3**(c) and **4**(d).

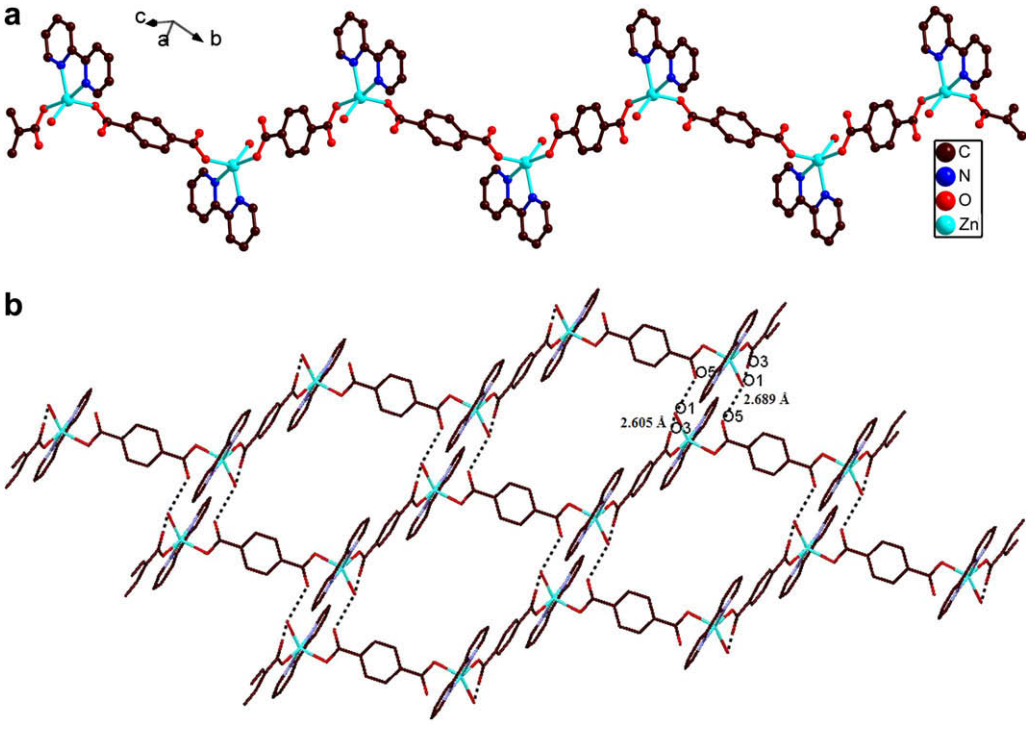

Fig. 2. ID zig-zag chain (a) and supramolecular 2D sheet network of complex **1** containing hydrogen bonds and π–π stacking (b).

peripheral ligand. It prevents the chain growth in a straight forward direction; hence a zigzag chain is formed.

It is very interesting to note that two independent chains are linked through hydrogen bonds formed between coordinated

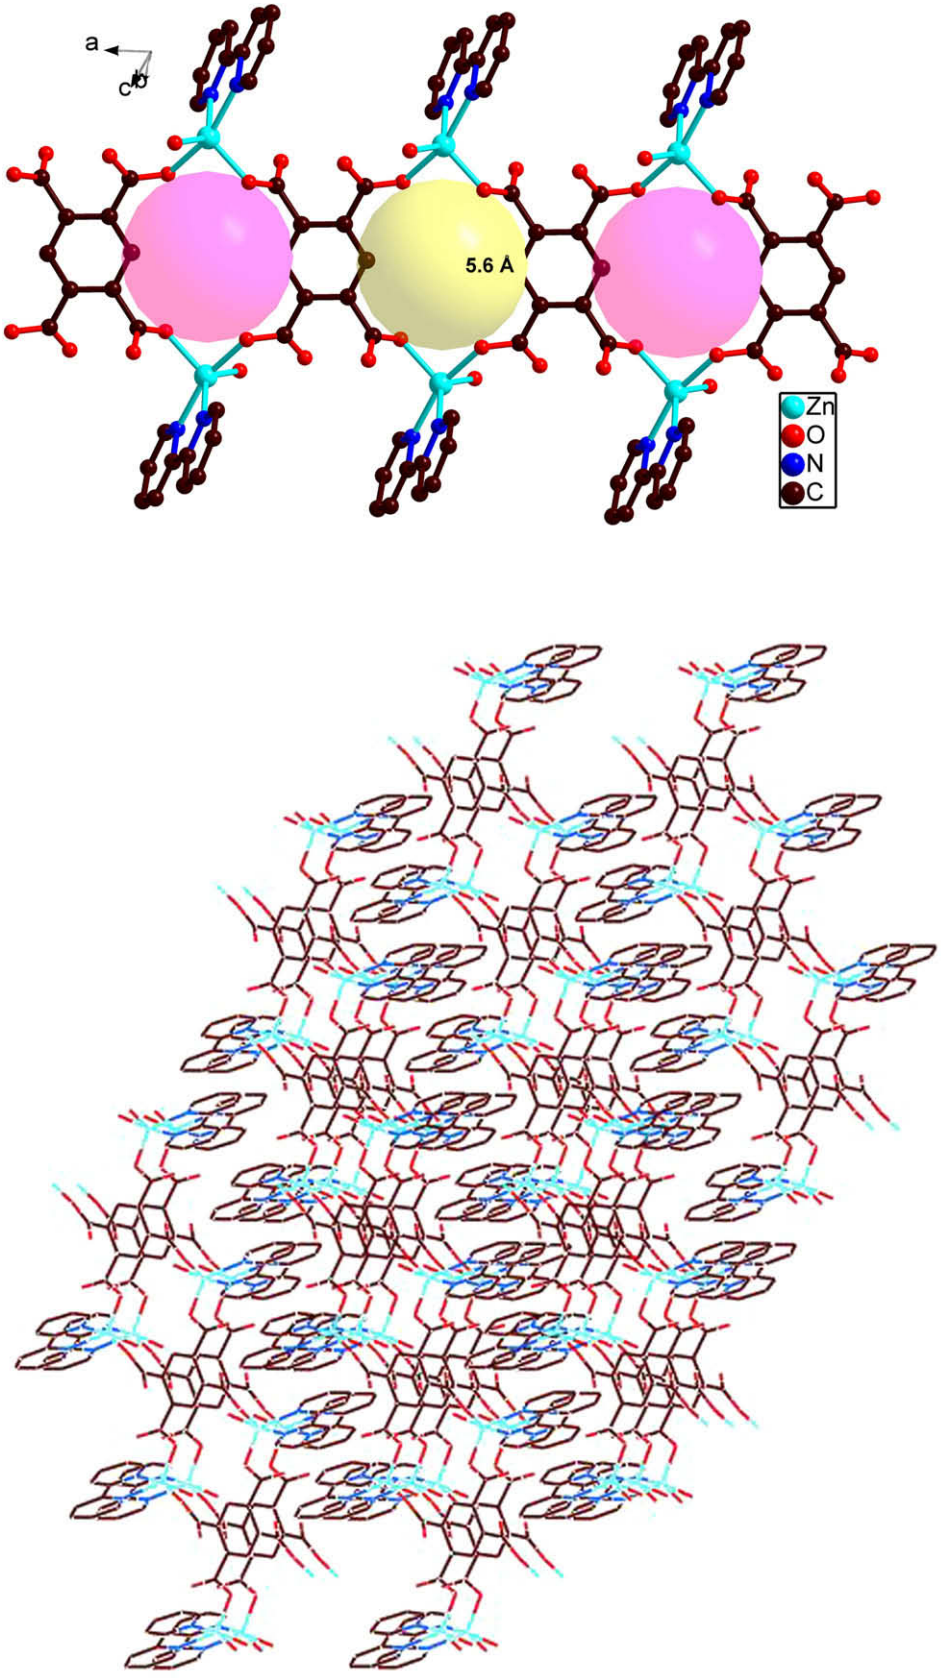

Fig. 3. 1D linear chain with the continuous cavity of diameter ~5.6 Å (a), crystal packing in complex **2** through inter- and intra-molecular H-bonding and π–π stacking (b).

water molecules and the carbonyl oxygen atoms of theterephthalate dianion, in addition to π–π stacking interactions between the 2,2′-bpy rings at a distance of 3.80 Å. It results in the formation of a 2D sheet-like supramolecular structure (Fig. 2c).

Crystal packing analysis of complex **1** shows the formation of independent intra-chain (O–H···O) as well as inter-chain (O–H···O) hydrogen bonds (Table 3). The intra-chain hydrogen bond is formed between the O–H group of the coordinated water molecule and an uncoordinated carboxylate oxygen at a D···A distance of 2.6056 Å and an O–H–O angle of 158°. However, in the formation of the inter-chain O–H···O hydrogen bonds, the O–H group of the coordinated water molecule of one chain is linked through the uncoordinated oxygen atoms of the terephthalate dianion of the adjacent chain at a D···A distance of 2.6895 Å and an O–H–O angle of 177°. The KPI for this complex, found to be 71.8%, indicates compact packing in its crystal lattice.

The molecular structure of the Zn^{II} complex with benzenetetracarboxylic acid (H_4btec), **2**, is depicted in Fig. 1b. This complex is also pentacoordinated, but the two carboxylate oxygen atoms (O2 and O5) come from two different carboxylate groups, acting in a monodentate fashion, together with one oxygen atom (O1W) of the coordinating water molecule and in addition to two nitrogen atoms (N1 and N2) from the 2,2′-bipyridine ring. As shown in Table 2, one Zn–O (carboxylate) distance, Zn(1)–O(2) 1.9843(14) Å, is found to be shorter than the Zn–O (carboxylate) distance Zn(1)–O(2) = 2.0423(12) Å as found in complex **1**. Other distances in this complex are comparable with the bond distances observed in complex **1**.

It is quite interesting to observe from Fig. 3a, that each carboxylate group is acting as a linker between four Zn(bpy) units, out of these four units, two units are common in the formation of a 16-membered macrocyclic ring of diameter ~5.6 Å. This 16-membered macrocyclic ring extends along the molecular axis in a linear fashion and provides a chain structure. The distance between two Zn^{II} centres across the cavity is found to be 8.144 Å, whereas adjacent Zn^{II} centres are separated by a distance of 7.709 Å (Fig. 3b).

Weak force studies reveal that six hydrogen bonds are formed in the molecular packing of complex **2**. Three hydrogen bonds are conventional hydrogen bonds whereas the remaining three

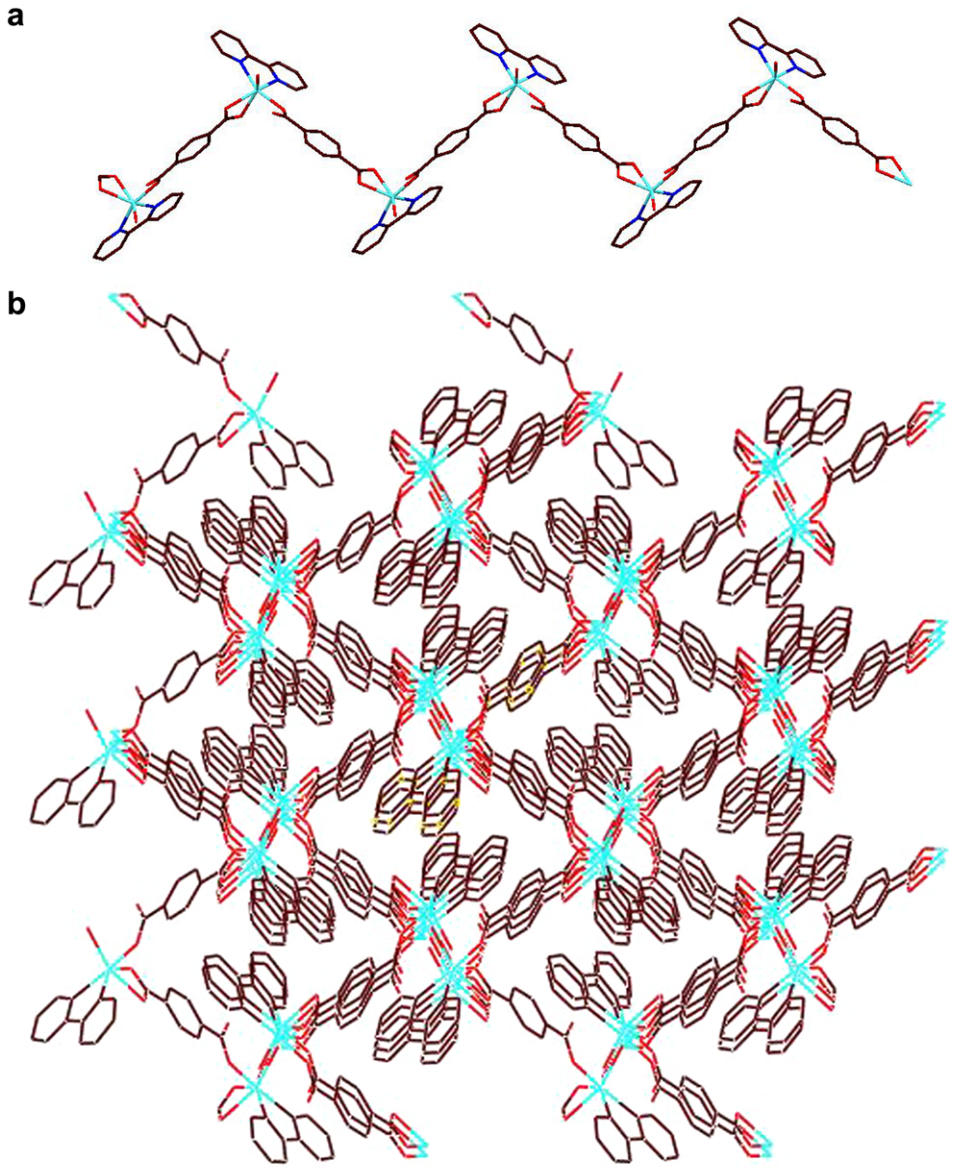

Fig. 4. 1D zig-zag chain (a), view of the crystal packing along the *a*-axis, the packing is stabilized through π–π stacking between bipyridyl rings and H-bonding in complex **3**.

bonds are non-conventional hydrogen bonds. The non-conventional hydrogen bonds involve C–H units as donor groups, whereas the acceptors are oxygen atoms in each case (Table 3). This complex has a Kitagorodskii Packing Index (KPI) of 76.6%, indicating a compact packing with no solvent accessible voids. In complex **1** the KPI value is found to be 71.8%. Thus the Zn(bpy)-benzenetetracarboxylate complex **2** possess more compact packing as compared to the Zn(bpy)-dicarboxylate complex **1**.

Both inter and intra molecular hydrogen bonds, in addition to π–π stacking interactions, provide a 3D supramolecular architecture (Fig. 3b) in complex **2**.

3.2.2. Complex *3* and *4*

Complex **3** is a Cd^{II} analogue of complex **1**. It also possesses an infinite zig-zag one-dimensional chain structure, but each Cd^{II} ion is hexa-coordinated in a highly distorted octahedral geometry (Fig. 4a). The formation of a seven coordinated CdN_2O_5 core has been reported [63] for a complex of Cd^{II} with the terephthalate dianion, but it contains 1,10-phenanthroline as one of the components instead of 2,2′-bipyridine as used in the present complex.

In the present complex **3**, the CdN_2O_4 coordinated core consists of two nitrogen atoms (N1 and N2) from 2,2′-bpy, one oxygen atom [O(5)] from a water molecule together with one oxygen atom (O1) from one terephthalate dianion and other two oxygen donors atoms [O(3) and O(4)] from another terephthalate unit which lies nearly orthogonal to the first terephthalate unit (dihedral angle: 80.16 °). It is interesting to note that each terephthalate unit serves as a bridging ligand between two cadmium atoms, forming a one-dimensional zig-zag polymeric chain (Fig. 4a). However, the bridging terephthalate dianion linked to two Cd^{II} ion, acts as monodentate at one coordination end and bidentate to another coordination end. Thus, one bridging terephthalate unit overall acts as a tridentate ligand and links two Cd^{II} ions at a distance of 11.341 Å. This distance is a little larger than the distance of 11.10 Å observed between the two Zn^{II} ions in complex **1**. This difference may be explained by the larger size and higher coordination mode of the Cd^{II} ion as compared to the Zn^{II} ion.

The cell packing analysis, as depicted in Fig. 4b, shows that both coordinated planes, as well as the bridging ligand plane, are more tilted from the crystallographic plane as compared to that

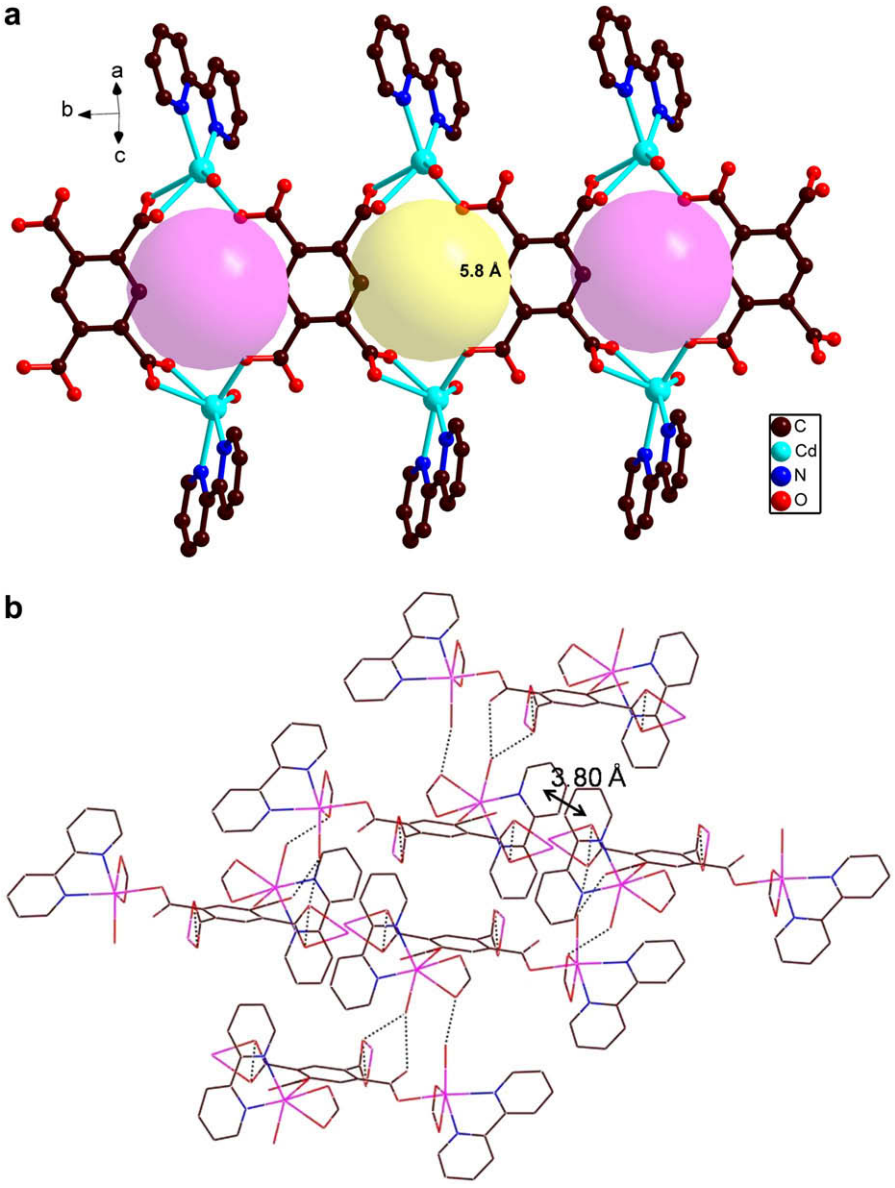

Fig. 5. 1D linear chain containing the continuous cavity of diameter of ~5.8 Å (a), packing of molecules in the crystal lattice; H-bonding and π–π stacking in complex **4**.

observed in the analogous Zn^{II} complex **1**. This may be understood due to the different modes of coordination (monodentate and bidentate) of the same ligand.

The crystal packing of complex **3** consists of two conventional and four non-conventional hydrogen bonds. In all cases, oxygen atoms acts as the acceptor atoms. The intra-molecular hydrogen bonding is formed between O(5)–H(13) and O(2) at a H···A distance of 1.75 Å with an O–H–O angle of 162°, whereas inter-molecular hydrogen bonding between O(5)–H(14) is formed at a H···A distance of 1.79 Å with an O–H–O angle of 178°. It indicates that two structural units are attached closely through hydrogen bonding. Out of the four non-conventional hydrogen bonds, two intra-molecular hydrogen bonds are formed at H···A distances of 2.35 (C4–H4···O3) and 2.59 Å (C7–H5···O3), whereas inter-molecular non-conventional hydrogen bonds are formed at the larger distances of 2.49 and 2.56 Å.

Complex **4** also possesses a distorted octahedral coordination geometry with a CdN_2O_4 coordination core around the Cd^{II} ion. In the construction of this structure, btec acts as hexadentate ligand, bis (bidentate + monodentate). However, again in a recently reported Cd^{II} complex containing 1,10-phenanthroline as a terminal ligand, btec acted in a tetrakis(bidentate) fashion [63]. Thus, the presence of the 2,2′-bipyridine ring as a terminal ligand alters the mode of coordination of the btec ligand. Additionally, one btec ligand links four Cd^{II} ions in the present complex **4** whereas the same btec ligand linked six Cd^{II} ions in the earlier reported complex [63]. Thus, the effect of the terminal ligand on the coordinating mode of the tetradentate ligand is quite evident.

The unit cell packing mode of complex **4**, depicted in Fig. 5a, again shows the formation of a 16-membered ring, but a little change in the ring size is observed (5.8 Å diameter in complex **4** as compared to 5.6 Å in complex **2**). Six hydrogen bonds (two conventional and four non-conventional) are found in the weak force studies of complex **4**.

3.3. Photoluminescent properties

The photoluminescent properties of complexes **1–4** are examined at room temperature and the corresponding spectral features are shown in Fig. 6. Upon excitation at λex = 340 nm, complex **1** emits at 365 nm with a shoulder at 430 nm, while in complex **2** the corresponding peaks are red shifted and appear at 370 and 435(sh) nm. Since solid-state emissions from the free 2,2′-bpy group are also observed in a similar region at λem = 360 and 385 nm due to the π–π^* transition, the strong emissions arising from complexes **1** and **2** are assigned to intra-ligand fluorescence of the coordinated 2,2′-bpy ligand. However, weak emissions from complexes **1** and **2** observed at 430 (sh) and 435 (sh) nm respectively are considered to arise from a charge-transfer transition, consistent with earlier reports [64–66]. Additionally, multiple emissions arising at 400, 462(sh) and 520(sh) nm for complex **3**, and 401, 465(sh) and 523(sh) nm for complex **4** are assigned to a combination of strong π–π^* transitions of the coordinated 2,2′-bpy ligand along with weak π–π^* transition from both bdc and btec ligands.

3.4. Thermogravimetric (TG) analysis

Thermogravimetric analyses (TGA) performed on crystalline samples under a nitrogen atmosphere are depicted in S1. In complex **1**, a weight loss of 4.40% at 100–220 °C is assigned to the loss of coordinated water molecules (calculated per formula unit weight loss = 4.45%). This loss is further followed by a second weight loss of 38.60% in the temperature range 241–270 °C, corresponding to the loss of the terminal 2,2′-bpy group. The final decomposition starts at 280 °C and continues up to 800 °C, at which only 45% residue remains, which may be due to carbon residues as well as metal oxides. Complex **2** shows a weight loss (47.9%) only after 230 °C, corresponding to the removal of the coordinated water molecule together with the 2,2′-bpy ligand (calculated 47.71%) from the structural framework. At 800 °C complex **2** also shows 41.25% residue remains. Multiple steps of weight loss occur upon heating complexes **3** and **4**.

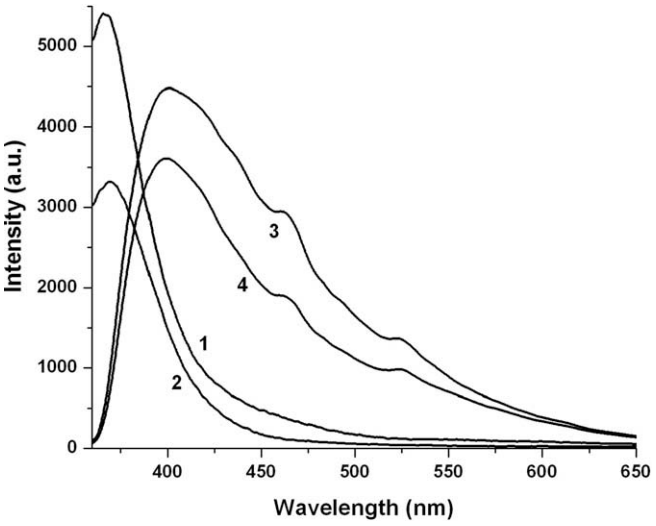

Fig. 6. Photoluminescence spectra of complexes **1**–**4** in the solid-state at room temperature.

3.5. Microstructural studies

Since such structural frameworks of complexes are constructed from hetero components, the formation of porosity in their bulk structure may be looked upon. Therefore, their SEM images were recorded. The SEM images of the complexes show the formation of micro-sized grains varying from 10–30 μm in complex **1** to 15–70 μm in complex **2**. In between these grains, pores can be seen which are dispersed throughout the structure (marked as 'P') (S2). The SEM micrograph of complex **3** shows the presence of parallelepipeds crystals with an average size of $25 \times 5 \times 4\ \mu m^3$ whereas in complex **4**, the grain size varies in the 15–30 μm range.

4. Conclusion

In summary, the reactions of Zn^{II}/Cd^{II}-2,2′-bipyridine with di and tetra carboxylates under mild conditions (pH 4–5) provide a series of photoluminescent polymeric complexes with diverse architectures from zig-zag chains (complexes **1** and **3**) to straight chains (complexes **2** and **4**). The weak forces of inter-molecular and intra-molecular hydrogen bonding interactions together with π–π aromatic stacking interactions provide a two-dimensional layer for complex **1**, whereas for complexes **2**, **3** and **4**, three-dimensional supramolecular networks result as a secondary structure. The complexes with the tetracarboxylate ligand provide a 16-membered metallomacrocyclic cavity of diameter 5.6 Å in **2** and 5.8 Å in **4**. Additionally, the presence of 2,2′-bipyridine rings is found to alter the coordination behavior of the carboxylates.

ABSTRACT

The kinetics of complex formation between palladium(II) acetate, and 1,1'-bis(diphenylphosphino)ferrocene, dppf, in two different deuterated solvents $CDCl_3$ and DMSO-d_6 were investigated using ^{31}P NMR spectroscopy. The mole ratio and the ^{31}P-chemical shifts in DMSO-d_6 solution revealed the formation of an intermediate, which is gradually converted into the more stable [Pd(dppf)$OAc)_2$] species with a dppf acting as a chelate ligand. In the chloroform solution however, the interaction of metal ion and the ligand resulted directly in the formation of [Pd(dppf)$OAc)_2$] species with a chelating dppf. The rate constant for the complexation reaction was evaluated from computer fitting of the corresponding integration-time data.

1. Introduction

Since the time of the synthesis of 1,1'-bis(diphenylphosphino) ferrocene [1], dppf, this ligand is probably the most intensively studied ferrocenyl phosphines compounds to date and a variety of transition-metal complexes stabilized by dppf have been characterized [2–12]. Among them, the Pd-dppf complexes have richer chemistry and have been widely used as catalysts especially for carbon-carbon bond forming reactions [13–27]. It is well known that the bidentate dppf shows a versatile coordination ability adapting its steric bite angle as well as electronic properties to the geometric and electronic requirements of the metal through the appropriate coordination [28–30]. Although the chelating coordination mode is the predominant character of dppf, multinuclear complexes containing bridging dppf are also known [31–60].

While very high efficiency of Pd-dppf catalysts is due to a combination of electronic and steric parameters of these precursors, no comprehensive study on the rate of the formation of dppf complexes has been carried out, albeit to the best of our knowledge. We have recently reported the application of Pd-phosphine catalysts in the Suzuki cross coupling reactions [61]. Our interest in the physicochemical properties of the dppf [62], encouraged us to determine the rate constants for formation of the Pd-dppf complexes and to gain some useful information about the mechanism of complex formation.

2. Experimental

$CDCl_3$ and DMSO-d_6 were commercially available from the Aldrich and used as received. The ligand dppf was prepared as previously described [62]. An authentic sample of Pd(dppf)$(OAc)_2$ was synthesized by the reaction of equimolar amounts of palladium(II) acetate and dppf according to literature procedure for preparation of Pd(dppf)Cl_2 [63] and characterized by multi-nuclear NMR spectroscopy as well as ICP elemental analysis. *Anal. calc.* for $C_{38}H_{34}FeO_4P_2Pd$, C, 58.29%, H, 4.92%, Fe, 7.13%, P, 7.91%, Pd, 13.59%. Found C, 58.87, H, 4.65, Fe, 7.52, P, 7.75, Pd, 13.91%. ^1H NMR (200 MHz, $CDCl_3$): δ 2.15 (s, 6, CH_3 of acetate ions), 4.00–4.45 (m, 8), 7.15–7.90 (m, 20); $^{31}P\{^1H\}$ NMR (81.014 MHz, $CDCl_3$): δ 28.05 (s). $^{31}P\{^1H\}$ NMR (81.014 MHz, DMSO-d_6): δ 24.58 (s).

All NMR measurements were made on a Bruker Avance (DPX) 200FT- NMR spectrometer with a field strength of 4.7 T (47 KG) equipped with a temperature controller, (±0.1 °C). At this field, ^{31}P resonates at 81.014 MHz. In ^{31}P NMR experiments, the standard was %85 H_3PO_4. All chemical shift measurements were carried out at a temperature of 25.0 ± 0.1 °C.

One milliliter of stock solution of the ligand (0.0554 g in 1 mL, 0.1 M) in each solvent was placed in a NMR tube and then, 50 μL of the stock metal solution of Pd$(OAc)_2$ dissolved in the same solvent (0.0673 g in 0.3 mL, 1 M, calculated for monomeric form)

was added. The ^{31}P NMR spectrum of the resulting solution was measured at different times.

3. Results and discussion

In the solid state, palladium(II) acetate exists as a trimer and has a maximum at 370–450 nm in its UV–Vis spectrum [64,65]. In contrast, the UV–Vis spectra of this salt in both solvents $CDCl_3$ and DMSO-d_6 do not have such typical signal (Fig. 1). In addition, the trimer–monomer equilibrium strongly depends on the addition of ligand; led to formation of monomeric form of palladium(II) acetate in solution. Therefore, it could be possible to consider it as monomer in kinetic calculations.

NMR spectroscopy has been widely used for the investigation of the kinetics and mechanisms of inorganic reactions. The chemical shifts, line broadening, and the integral of the signals are quantitative factors used for this purposes. In the cases where the changes in the chemical shifts and line broadening are negligible, the integral of the signals could be used as a very sensitive measure of the concentration of a particular species. This tool has been particularly used for consecutive reactions.

The kinetics of the complexation between palladium(II) acetate and dppf were sufficiently slow to lead us monitor all species formed during the complexation.

Initial investigation of reaction rates was carried out using different metal to ligand mole ratio. It was observed that the concentration of the product as a measure of the rate of reaction, increases with increasing the concentration of palladium(II) acetate linearly. This evidence led us to conclude that the reaction is first-order with respect to the palladium source (Fig. 2).

The best intensity changes in the ^{31}P NMR lines were observed at 0.5 metals to ligand mole ratio. In addition, many reports have been published in where, the catalytic reactions were carried out using this mole ratio [66]. Therefore, the kinetic studies were investigated using this mole ratio.

3.1. Investigation of the species involved in the $CDCl_3$ solution

In $CDCl_3$ solution, 1,1'-bis(diphenylphosphino)ferrocene, dppf, has two chemically and magnetically equivalent phosphorus atoms, which appear as a singlet at −18.90 ppm, with respectto an internal standard solution of H_3PO_4 (Fig. 3). During the complexation at 25 °C, the intensity of this signal is gradually decreased and simultaneously, a signal at 28.05 ppm downfield-shifted from the ligand appears which corresponds to $[Pd(dppf)(OAc)_2]$ [67].

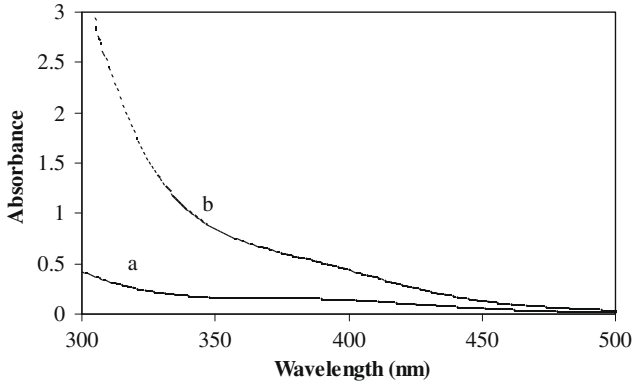

Fig. 1. Spectra of Pd(II) acetate (4.5×10^{-4} M, calculated for the monomeric form) at 25 °C in $CDCl_3$ (a) and DMSO-d_6 (b).

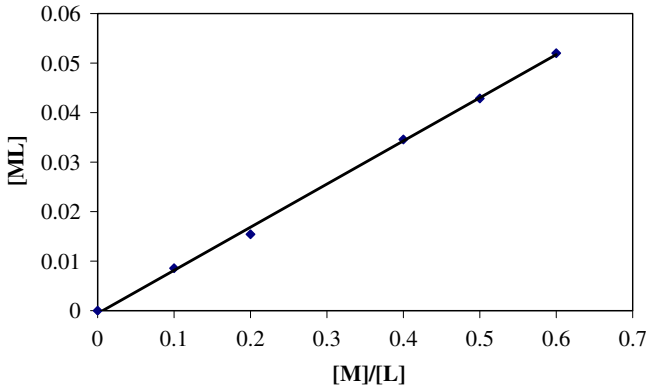

Fig. 2. The product formation as a measure of the rate of reaction vs. the metal to ligand mole ratio. All concentrations were determined by the integration of their ^{31}P NMR signals at the same times.

The ICP elemental analysis confirms the formation of $[Pd(OAc)_2(dppf)]$ (Scheme 1).

Therefore, the reaction may be considered as a simple second-order reaction either reversible Eq. (1) or irreversible reactions Eq. (2)

$$[Pd] + dppf \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Pd(dppf)] \quad (1)$$

$$[Pd] + dppf \xrightarrow{k_1} [Pd(dppf)] \quad (2)$$

where [Pd] represents the starting palladium(II) acetate.

3.2. Kinetic studies in chloroform solution

The concentration of the free dppf and its Pd complex are determined by the integration of their ^{31}P NMR signals. The stack diagram for the ^{31}P NMR spectra is shown in Fig. 4.

At the first stage, calculations were carried out using the second-order reversible Eq. (1). The resulted rate constants show that the forward rate constant is much greater than the backward rate constant (Table 1). In addition, careful monitoring of the ^{31}P NMR spectra rules out any dissociation of dppf and reaction reversibility. Therefore, the overall reaction may be considered as irreversible Eq. (2) which involves the following rate law Eq. (3):

$$\frac{1}{[dppf]_0 - [Pd]_0} \mathrm{Ln} \frac{[Pd]_0[dppf]_t}{[dppf]_0[Pd]_t} = k_1 t \quad (3)$$

with subscripts t and 0 representing time t and 0, respectively. A plot of the left term of Eq. (3) versus time should be a straight line with a positive slope equal to k (Fig. 5). The overall rate constant of the reaction is listed in Table 1.

It is reported that even if one reagent (here [Pd]) be maintained in only a two-fold excess over another reagent (here [dppf]), the error in the computed second-order rate constant is $\leqslant$2% for 60% conversion and as the reaction proceeds toward the end of the reaction, pseudo first-order conditions certain hold [68,69]. Similar re-computation of our kinetics data for pseudo first-order irreversible reaction was carried out and the resulted rate constant confirmed this hypothesis (Table 1, entry 3). Other re-computations of the kinetic data for other kinetic models such as third-order resulted poor regressions.

3.3. Investigation of the species involved in the DMSO-d_6 solution

In the DMSO-d_6 solution, the free ligand appears at −19.27 ppm. This signal is gradually decreased during the complexation and a

Entry	Type of reaction	k_1 (s^{-1} M^{-1})	k_{-1}(s^{-1}) × 10^4	K_e (M^{-1})
1	Reversible second-order	0.52 ± 0.03	5.2× ± 0.2	1000 ± 90
2	Irreversible second-order	0.50 ± 0.02		
3	Pseudo first-order	0.53 ± 0.03		

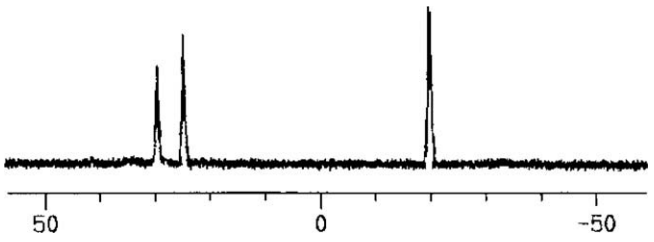

Fig. 6. ^{31}P NMR spectrum of Pd(II) acetate/dppf in DMSO-d_6 and at 25 °C.

signal appears at 29.70 ppm, which may be due to the formation of a M_2L_2 di-palladium intermediate (Fig. 6) [70–72]. The observation of this intermediate is probably due to the coordinating ability of DMSO, which probably makes the coordination of dppf slower and allows the formation of the intermediate.

The relative intensities of both signals are decreased on going to continue the reaction and an additional signal appears at 24.58 ppm corresponding to the ML species involved chelating dppf [67]. The ICP elemental analysis confirms the formation of $[Pd(OAc)_2(dppf)]$. The pattern of relative intensity changes indicates that the ML is produced possibly from two paths; directly from the starting reactants via a consecutive reaction as a main path [73,74] together with a simple second-order reaction Eq. (4)

$$\begin{cases} Pd + dppf \xrightarrow{k_1} \frac{1}{2}[Pd_2(\mu - dppf)_2] \xrightarrow{k_2} [Pd(dppf)] \\ Pd + dppf \xrightarrow{k_3} [Pd(dppf)] \end{cases} \quad (4)$$

3.4. Kinetic studies in DMSO-d_6 solution

The concentration of the free dppf and its Pd complexes are determined by the integration of their characteristic ^{31}P NMR signals. Distribution of all species versus time is shown in Fig. 7. It should be noticed that the concentration of the free ligand could not exponentially decay to zero since it is used in two-fold excess.

Initial calculation based on Eq. (5) was carried out by simultaneously solving of three equations for the change of concentration

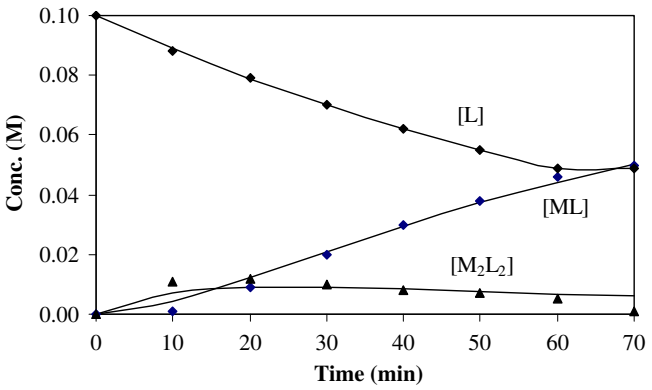

Fig. 7. Distribution diagram for involving species in the reaction of Pd(II) acetate and dppf in DMSO-d_6 at 25 °C. The solid lines are the best trendlines obtained by Excel program.

Table 2
Rate constants of the reaction of Pd(II) acetate:dppf (1:2) in DMSO-d_6 at 25 °C.

Entry	Type of reaction	k_{obs} $(s^{-1}\,M^{-1}) \times 10^2$	k_2 $(s^{-1}) \times 10$
	Parallel consecutive and irreversible reactions	1.0 ± 0.1	1.0 ± 0.1

of the ligand, [L]; the intermediate, $[M_2L_2]$; and the final chelating complex; [ML], with time Eq. (5)

$$\begin{cases} [L] = [L_0]e^{-k_{obs}t} \\ [M_2L_2] = \frac{k_{obs}[L]}{k_2 - k_{obs}}\{e^{-k_{obs}t} - e^{-k_2 t}\} \\ [ML] = [L]\left\{1 - \frac{1}{k_2 - k_{obs}}(k_2 e^{-k_{obs}t} - k_{obs}e^{-k_2 t}\right\} \end{cases} \quad (5)$$

The corresponding rate constants are calculated by Excel-fitting of the experimental points (Fig. 7) and are given in Table 2.

As Eq. (5) shows, determination of individual amounts of k_1 and k_3 is impossible and a summation of them as k_{obs} could be obtained in this way. An approximate value for these rate constants could be easily calculated by considering two extremes of Eq. (5)

$$\begin{cases} a) k_1 >> k_3 \Rightarrow\ k_{obs} \approx k_1 \\ b) k_1 << k_3 \Rightarrow k_{obs} \approx\ k_3 \end{cases}$$

The first extreme was arisen if the consecutive reaction is the major contributor of the overall rate constant while the second extreme could be obtained if the second-order path is the major contributor.

The relative magnitude of the k_{obs} [Pd] (s^{-1}) and k_2 (s^{-1}) rate constants shows that the consecutive reaction is the major contributor of the overall reaction rate. Therefore, the first extreme is more logic.

Interestingly, the intermediate was observed only in metal to ligand mole ratios near 0.5. This may be because both rate of formation (k_1) and consumption (k_2) of the intermediate depend on the concentrations of metal and ligand as a same way (steady state approximation).

4. Conclusion

In comparison, the complex formation is faster in $CDCl_3$ than DMSO, which may be due to the coordinating ability of DMSO. This coordination probably makes the coordination of dppf slower and allows the formation of the intermediate. It also decreases the electrophilicity of metal as well as the steric crowding at the metal center [75]. The better solubility of the reactants in $CDCl_3$ also plays an important role. The difference in the reaction rates make such kinetic studies very important in the catalytic reactions in where, a mixture of metal and ligand are used as catalyst. For example, it is reported that using methanol as solvent, no methoxycarbonylation of 2-bromoaniline was observed. Changing to a solvent mixture of toluene-methanol increased remarkable the conversion [76]. This feature is of greater importance particularly whenever the complex formation between metal and ligand is the rate determining step and/or one of previous catalytic cycle.

Another noteworthy of such kinetics studies outcome on comparing the rate of catalytic reactions using a ML catalyst with *in situ* prepared catalyst by addition of metal and ligand. The similarity between the rates of both reactions may be an excellent evidence for the presence of a similar mechanism.

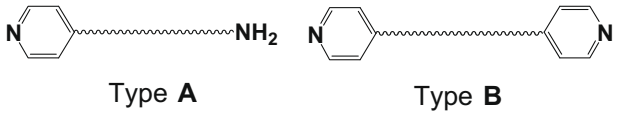
ABSTRACT



We have prepared four potential linking ligands, [(3-py)–CH=N–C_6H_4–O–C_6H_4–NH_2, **L^1**], [(4-py)–CH=N–C_6H_4–O–C_6H_4–NH_2, **L^2**], [(3-py)–CH=N–C_6H_4–O–C_6H_4–N=CH–(3-py), **L^3**] and [(4-py)–CH=N–C_6H_4–O–C_6H_4–N=CH–(4-py), **L^4**], all of which contain an intervening oxydianiline fragment. Whereas ligands **L^1** and **L^2** have two types of terminal groups (pyridyl and amine groups), ligands **L^3** and **L^4** have a single type of terminal group (pyridyl groups at both terminals). Ligands **L^1**–**L^3** reacted with cadmium nitrate ($Cd(NO_3)_2\cdot 6H_2O$) to produce $[CdL^1_2(NO_3)_2]$ (**1**), $[CdL^2_2(NO_3)_2]$ (**2**) and $[Cd_2L^3_2(NO_3)_4(H_2O)_4]\cdot(C_4H_8O)_2$ (**3**), respectively. Compound **1** is a 2-D brick-wall coordination polymer and compound **2** is a 1-D double-strand-chain polymer. On the other hand, compound **3** is a discrete dinuclear macrocycle (molecule) with a double-helical structure, which contains THF (C_4H_8O) guest molecules.

1. Introduction

Much attention has been continually paid to the design and synthesis of coordination polymers, due to their useful zeolite-like properties applicable to various fields such as size-selective sorption, gas storage, host–guest recognition and catalysis [1–13]. In preparing these polymers, experimental parameters such as a metal ion with a proper coordination sphere, a proper linking ligand set, reaction temperature, pH, concentration and synthetic methods (hydrothermal, solvothermal, hydro(solvo)thermal, and layer methods) are crucial in determining the ultimate structures of the resulting polymers.

Relatively long linking ligands containing terminal pyridyls were recently employed for the preparation of coordination polymers with various topologies [14–21]. We also reported several long bis-pyridine-type ligands **L1**–**L8** (Chart 1) and their coordination polymers [22–28]. All these ligands commonly contain pyridyls at their ends. During our ongoing research, we have become interested in the comparison of the linking patterns between ligands containing two types of terminal groups (pyridyl and amine groups) and those containing a single type of terminal groups (pyridyl groups at both terminals). In this context, we have prepared four potential linking ligands possessing an intervening 4,4′-oxydianiline fragment (a flexible spacer group), two of which contain pyridyl–amine terminals (Type **A**) and another two of which contain two pyridyl terminals (Type **B**): 4-(4-aminophenoxy)-*N*-(pyridin-3-ylmethylene)aniline (**L^1**), 4-(4-aminophenoxy)-*N*-(pyridin-4-ylmethylene)aniline (**L^2**), *N*,*N*′-4,4′-oxybis(*N*-(pyridin-3-ylmethylene)aniline) (**L^3**) and *N*,*N*′-4,4′-oxybis(*N*-(pyridin-4-ylmethylene)aniline) (**L^4**). Herein, we report the preparation of these ligands and their cadmium compounds, $[CdL^1_2(NO_3)_2]$ (**1**), $[CdL^2_2(NO_3)_2]$ (**2**) and $[CdL^3(NO_3)_2(H_2O)_2]\cdot(C_4H_8O)_2$ (**3**).

Type **A** Type **B**

2. Experimental

All the solid chemicals were purified by recrystallization, and all solvents were distilled and stored over molecular sieves. ^1H and

$^{13}C\{^1H\}$ NMR data were collected on a 500 MHz Varian Inova spectrometer at the Cooperative Center for Research Facilities (CCRF), Sungkyunkwan University. Infrared (IR) samples were prepared as KBr pellets, and their spectra were obtained in the range 400–4000 cm^{-1} on a Nicolet 320 FTIR spectrophotometer. Elemental analyses were performed with an EA1110 (CE instrument, Italy) at the Korea Basic Science Institute. Thermogravimetric analysis (TGA) was conducted on a TA4000/SDT 2960 instrument (CCRF). X-ray powder diffraction (XRPD) spectra were obtained with a Rigaku D/Max-RC diffractometer.

2.1. Preparation of the ligands

All the ligands were prepared in the same way. To 3-pyridinecarboxaldehyde (0.53 g, 4.9 mmol) in ethanol (50 ml) was added 4,4-oxydianiline (1.00 g, 4.9 mmol) at room temperature. After the addition of dichloromethane (30 ml) and then two drops of formic acid, the mixture was stirred at room temperature for 24 h and filtered. The resulting yellow crystalline solid was washed with ethanol (3 × 10 ml) and hexane (3 × 10 ml), and crystallized from CH_2Cl_2–hexane to give ligand **L**^{1}.

Data for ligand **L**^{1}: Yield 85%. ^1H NMR (500 MHz, $CDCl_3$) δ: 9.01 (m, 1H), 8.71 (m, 1H), 8.53 (d, 1H), 8.29 (m, 1H), 7.42–6.63 (9 H), 3.58 (br, NH_2). $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$) δ: 158.2, 156.4, 152.0, 151.0, 148.7, 147.0, 145.7, 143.2, 142.0, 135.0, 132.1, 124.0, 122.7, 122.5, 121.3, 119.8, 118.1, 116.4. 2.2. Preparation of the polymers $[Cd\mathbf{L}^1{}_2(NO_3)_2]$ (**1**) and $[Cd_2\mathbf{L}^2{}_4(NO_3)_4]$ (**2**)

Polymers **1** and **2** were prepared in the same way. At room temperature, a methanol (2 ml) solution containing $Cd(NO_3)_2 \cdot 6H_2O$ (30 mg, 0.097 mmol) was layered onto the top of a dichloromethane solution (2 ml) containing ligand **L**^{1} (57 mg, 0.195 mmol). After 5 days, the resulting crystals were filtered, washed with ethanol (3 × 5 ml), and air-dried to give $[Cd\mathbf{L}^1{}_2(NO_3)_2]_\infty$ (78 mg, 0.096 mmol, 98%). Anal. *Calc.* for $C_{36}H_{30}N_8O_8Cd_1$ (M_r = 815.08): C, 53.05; H, 3.71; N, 13.75. Found: C, 53.38; H, 3.89; N, 13.59%. Mp: 258–260 °C (decomp.). IR (KBr, cm^{-1}): 3315 (m), 1630 (m), 1499 (s), 1421 (m), 1229 (m), 1037 (m), 832 (m), 698 (s), 520 (m).

Data for polymer **2**. Yield 99%. Anal. *Calc.* for $C_{36}H_{30}CdN_8O_8$ (M_r = 815.08): C, 53.05; H, 3.71; N, 13.75. Found: C, 53.24; H, 3.97; N, 13.71%. Mp: 208–210 °C (decomp.). IR (KBr, cm^{-1}): 3378 (w), 1685 (m), 1577 (s), 1528 (s), 1503 (s), 1412 (s) 838 (m), 770 (m).

2.3. Preparation of $[Cd_2\mathbf{L}^3{}_2(NO_3)_4(H_2O)_4] \cdot (C_4H_8O)_2$ (**3**)

At room temperature, a methanol (2 ml) solution containing $Cd(NO_3)_2 \cdot 6H_2O$ (30 mg, 0.097 mmol) was layered onto the top of a tetrahydrofuran solution (2 ml) containing ligand **L**^{3} (37 mg, 0.097 mmol). After 5 days, the resulting crystals were filtered, washed with ethanol (3 × 5 ml), and air-dried to give compound **3** $\cdot (C_4H_8O)_2$ (68 mg, 0.094 mmol, 97%). Anal. *Calc.* for $C_{56}H_{60}Cd_2N_{12}O_{20}$ (M_r = 1445.96): C, 46.52; H, 4.18; N, 11.62. Found: C, 45.98; H, 4.02; N, 11.50%. Mp: 266–268 °C (decomp.). IR (KBr, cm^{-1}): 1630 (m), 1500(s), 1392 (m), 1244 (m), 1044 (m), 834 (m), 696 (m), 535 (m).

2.4. X-ray structure determination

All X-ray data were collected on a Bruker Smart APEX2 diffractometer (CCRF) equipped with a Mo X-ray tube. Absorption corrections were made by SADABS based upon the Laue symmetry of equivalent reflections [29]. All calculations were carried out with SHELXTL programs [30]. All structures were solved by direct methods. All non-hydrogen atoms were refined anisotropically.

A colorless crystal of polymer **1**, shaped as a block of approximate dimensions 0.22 × 0.18 × 0.06 mm, was used for crystal and intensity data collection. The NH_2 hydrogen atoms were located and refined isotropically, and the remaining hydrogen atoms were generated in ideal positions and refined in a riding mode. A yellow crystal of polymer **2** (a block, 0.14 × 0.10 × 0.08 mm) was used, and the NH_2 hydrogen atoms were located and refined isotropically. A colorless crystal of compound **3** (a block, 0.24 × 0.20 × 0.04 mm) was used, and the hydrogen atoms in the aqua ligands were located. The nitrato ligands in polymer **1** and compound **3** are slightly disordered, but the disorder was not resolved and anisotropic refinements applying several possible site occupation factors were unstable. Site occupancy refinements of the nitrato atoms all yielded values close to unity. Details of the crystal data, intensity collection and refinement are given in Table 1. Selected bond lengths and angles for compounds **1**–**3** are given in Tables 2–4, respectively.

3. Results and discussion

3.1. Preparation of the ligands

Four potential linking ligands **L¹**–**L⁴**, all of which contain an intervening 4,4′-oxydianiline fragment, were prepared in high yields by a simple and straightforward Schiff-base condensation. At room temperature, 4,4′-oxydianiline reacted with 1 equiv. of 3-pyridine-carboxaldehyde and 1 equiv. of 4-pyridine-carboxaldehyde to give pyridyl–amine-type ligands **L¹** and **L²**, respectively. In the same way, bis-pyridine-type ligands **L³** and **L⁴** were obtained by treating 4,4′-oxydianiline with 2 equiv. of pyridine-carboxaldehyde (Scheme 1). Ligands **L¹** and **L²** are structural isomers due to the difference in the nitrogen positions in the terminal pyridyl groups. Ligands **L³** and **L⁴** are also structural isomers.

The IR spectra of all the ligands display a common absorption band at 1623–1627 cm^{-1}, assignable to the C=N bond, consistent with the fact that C=N stretching frequencies of Schiff bases appear in the range 1680–1603 cm^{-1} [31–33]. In particular, the IR spectra of ligands **L¹** and **L²** display two characteristic N–H absorption bands (3300 and 3204 cm^{-1} for ligand **L¹**; 3308 and 3202 cm^{-1} for ligand **L²**), which strongly support the presence of the terminal NH_2 group in both ligands.

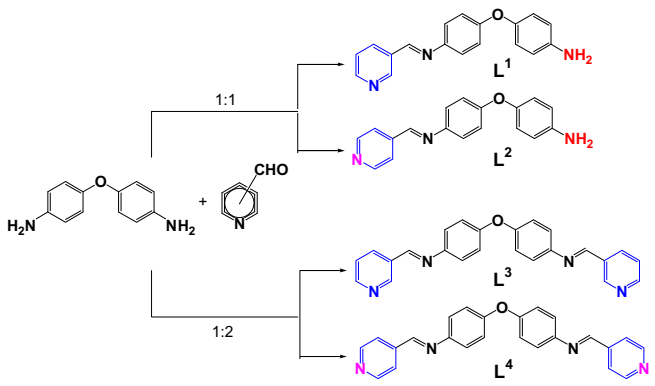
3.2. Coordination polymers *1* and *2*

Two coordination polymers $[CdL^1_2(NO_3)_2]$ (**1**) and $[CdL^2_2(NO_3)_2]$ (**2**) were prepared by layering a methanol solution containing $Cd(NO_3)_2 \cdot 6H_2O$ onto the top of a dichloromethane solution containing the corresponding ligand (Eqs. (1) and (2)). Reactions involving benzene or tetrahydrofuran in place of dichloromethane produced very poor crystalline products:



$$Cd(NO_3)_2 + \mathbf{L^1} \xrightarrow{MeOH/CH_2Cl_2} [CdL^1_2(NO_3)_2] \quad (1)$$

$$Cd(NO_3)_2 + \mathbf{L^2} \xrightarrow{MeOH/CH_2Cl_2} [CdL^2_2(NO_3)_2] \quad (2)$$

A monomer unit of polymer **1** with the atom-numbering scheme is presented in Fig. 1, which shows an asymmetric unit consisting of one half Cd metal, one **L¹** ligand and one nitrato ligand. The Cd metal is six-coordinate with a $[CdN_4O_2]$ core and is coordinated by two pyridyl N atoms and two amine N atoms from four ligands as well as two O atoms from two η^1-NO_3 ligands (Table 2). The Cd metal is located on a crystallographic twofold axis. The NH_2 hydrogen atoms participate in N–H···O (O4) hydrogen bonds. The N(pyridyl)···N(amino) separation N1···N3 is 14.161(5) Å. Fig. 2 shows a packing diagram of polymer **1**, which displays a 2-D brick-wall structure extending approximately in the [1 0 1] direction. This structure consists of quasi-parallelogram units, each of which contain four Cd metals and four **L¹** ligands to form a large 64-membered (60 ligand atoms and four Cd metals) ring with a Cd···Cd separation of 17.337(1) Å. However, the Cd···Cd···Cd angles are far from 90°, and therefore the size of the quasi-parallelogram is rather small. Fig. 3 shows small channels approximately along the *b*-axis.

An asymmetric monomer unit of polymer **2** is given in Fig. 4, which is composed of one Cd metal, two **L²** ligands and two nitrato ligands. As is the case for polymer **1**, the pseudo-octahedral Cd metal in polymer **2** is coordinated by two pyridyl N, two amino N and two O atoms (Table 3). The NH_2 hydrogen atoms participate in N–H···O (O5, O7, O8) hydrogen bonds. The two N(pyridyl)···N(amino) separations are practically the same: N1···N3 = 14.628(7) Å and N4···N6 = 14.599(6) Å, and are somewhat longer than that

Scheme 1.

(14.161(5) Å) in polymer **1**, consistent with the expectation based on the different nitrogen positions in the terminal pyridyl rings. A packing diagram of polymer **2** is given in Fig. 5, which illustrates a 1-D wave-like chain structure. The ligands link the $Cd(NO_3)_2$ fragments approximately along the *b*-axis, and the overall structure can be described as a chain of double strands. The Cd···Cd separation is 16.732(1) Å and the Cd···Cd···Cd angle is 113.59(1)°.

Several coordination polymers with interesting topologies, $[M(NCS)_2(4,4'\text{-oda})_2]$ (M = Ni, Co), $[M(N)_3(4,4'\text{-oda})_2](NO_3)$ (M = Cd, Co) and $[Cd(SCN)_2(4,4'\text{-oda})_2]$, which are related to polymers **1** and **2**, were prepared previously by employing 4,4′-oxydianiline (4,4′-oda) as a linking ligand [34,35]. For example, in the local coordination of Co in the polymer $[Co(NCS)_2(4,4'\text{-oda})_2]$, four amine (aniline) N atoms form an equatorial plane and two thiocyanate N atoms occupy axial positions. This polymer has a two-dimesional sheet structure, which resembles the brick-wall structure found for polymer **1**, and has a 48-memebered ring unit (44 ligand atoms and four Co atoms) [34].

To examine the thermal behavior of polymers **1** and **2**, thermogravimetric analyses (TGA) were performed by heating them up to 800 °C. The framework of polymer **1** is stable up to 250 °C, above which an abrupt weight loss occurs at 280–310 °C, corresponding to the loss one NO_3 and the pyridine aldehyde fragment of the ligand $\mathbf{L^1}$ (calculated: 20%; observed: 18%). Above this temperature range a gradual weight loss continues. Polymer **2** is stable up to 200 °C, and a steady weight follows from 200 to 540 °C. These data indicate that the thermal stability of the framework of polymer **1** is somewhat higher than that of polymer **2**.

3.3. Molecular compound *3*

A macrocyclic dinuclear cadmium compound $[Cd_2\mathbf{L^3}_2(NO_3)_4(H_2O)_4]\cdot(C_4H_8O)_2$ (**3**) was obtained by layering a methanol solution containing $Cd(NO_3)_2\cdot 6H_2O$ onto the top of a tetrahydrofuran solution containing ligand $\mathbf{L^3}$ (Eq. (3)). Unlike compounds **1** and **2**, compound **3** is a molecular species with a double-helical structure, not a coordination polymer:

$$2Cd(NO_3)_2 + 2\mathbf{L^3} \xrightarrow{MeOH/THF} [Cd_2\mathbf{L^3_2}(NO_3)_4(H_2O)_4](THF)_2 \quad (3)$$

The molecular structure of compound **3** is presented in Fig. 6, which shows an asymmetric unit consisting of one Cd metal, one $\mathbf{L^3}$ ligand, two nitrato ligands, two aqua ligands and one C_4H_8O (THF) guest molecule. The Cd metal is eight-coordinated by two pyridyl N atoms, two aqua O atoms and four nitrate (η^2-NO_3) O atoms (Table 4). All the aqua H atoms are involved in O–H···O hydrogen bonds. In paricular, the THF guest molecule interacts with the aqua ligands by a hydrogen bond (O9–H = 0.955 Å; H···O10 = 1.778 Å; O9···O10 = 2.730 Å; O9–H···O10 = 174°). The N1···N4 and Cd···Cd separations are 17.0801(3) and 17.1837(5) Å, respectively, and the Cd···O1···Cd angle is 101.61(1)°. A space filling model of compound **3** (Fig. 7) demonstrates its double-helical structure.

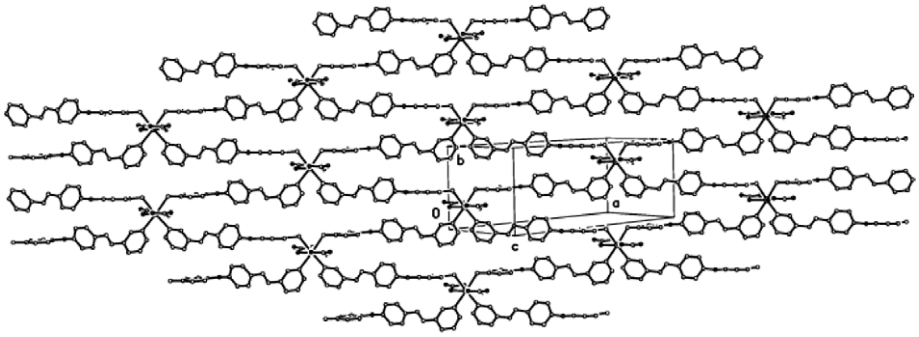

Fig. 2. Packing diagram of polymer **1**, showing a 2-D brick-wall structure.

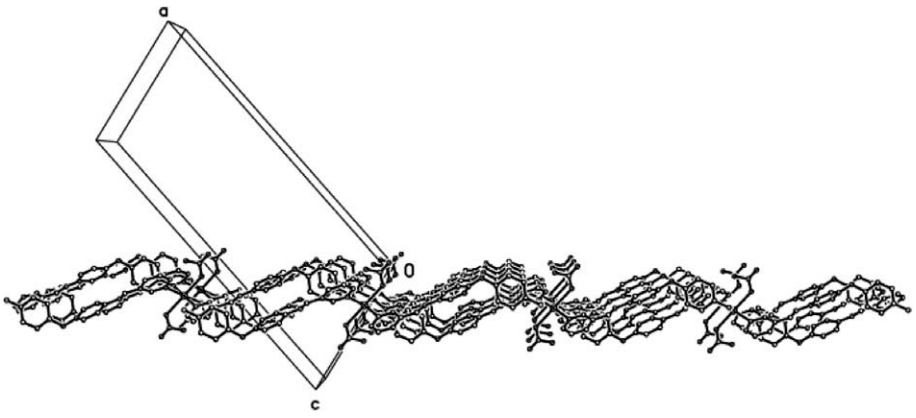

Fig. 3. Projection of compound **1**, showing a channel approximately along the *b*-axis.

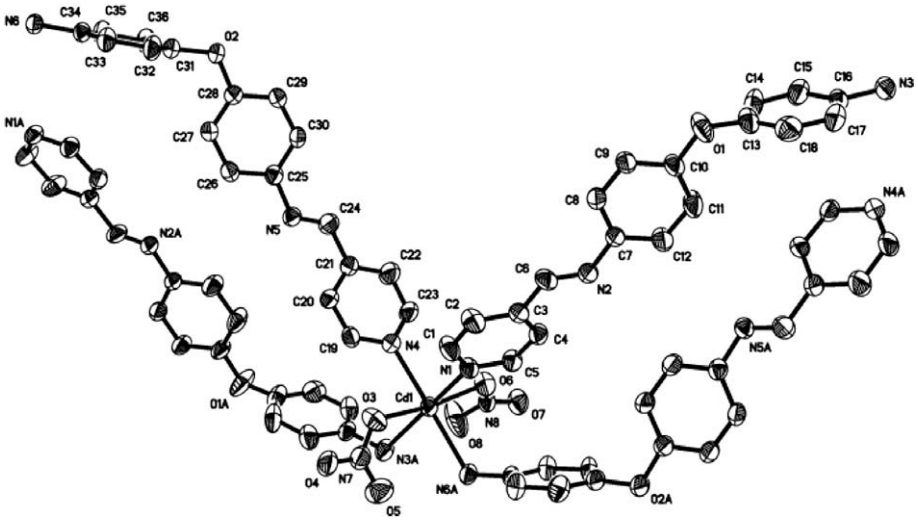

Fig. 4. Local coordination environment of cadmium in compound **2**.

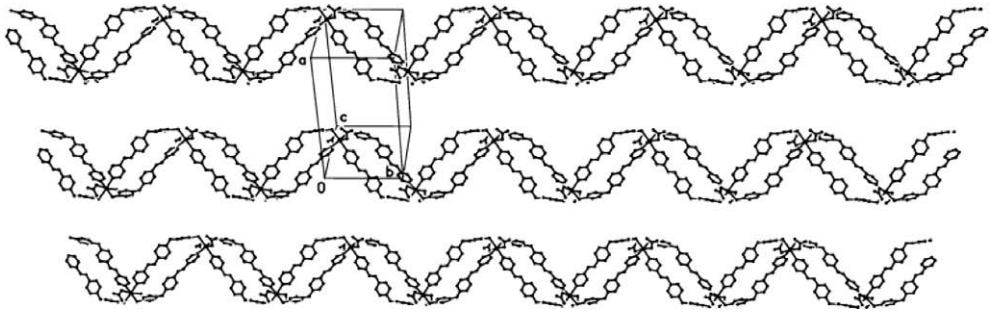

Fig. 5. Packing diagram of compound **2**, showing a 1-D wave-like chain of double strands.

Several flexible Schiff-base-type ligands, **L9**–**L11** (Chart 2), have been prepared recently and have been employed to prepare intriguing compounds. Examples are the cage-like $[Ag_2(\mathbf{L9})_2][BF_4]_4$, the triple-helical $[Co_2(\mathbf{L9})_3](BF_4)_4$, the triple-helical $[Ni_2(\mathbf{L9})_3](BF_4)_4$ [36], the triple-helical $[Ni_2(\mathbf{L10})_3](BF_4)_4$-$(MeOH)_2$ [37], the triple-helical $[Zn_2(\mathbf{L10})_3](ClO_4)_4(DMF)(CH_3CN)_2$ [38], the double-helical $[Cu_2(\mathbf{L10})_2](BF_4)_2$ [39], the triple-helical $[Fe_2(\mathbf{L10})_3]Cl_4$ [40] and the double-helical $[Ag_2(\mathbf{L11})_2](PF_6)_2$ complexes [41]. In these compounds the central imine N atoms (–CH=N–) as well as the 2-pyridyl N atoms in ligands **L9**–**L11** are bound to the metal, indicating that these ligands act as typical Schiff-base-type ligands. Furthermore, all the compounds containing these ligands are molecular species rather than polymeric species (coordination polymers). It is worth noting that ligands $\mathbf{L^3}$ and $\mathbf{L^4}$ have 3-pyridyl and 4-pyridyl terminal groups, respectively, and the imine nitrogen of $\mathbf{L^3}$ in polymer **3** does not coordinate to the Cd metal (Fig. 6). The difference in the binding pattern between the ligands **L9**–**L11** and ligand $\mathbf{L^3}$ is presumably due to the different nitrogen positions in the terminal pyridyl groups (2,2′ versus 3,3′). Although we failed to prepare a compound containing ligand $\mathbf{L^4}$, we speculate the resulting complex to be a molecular species.

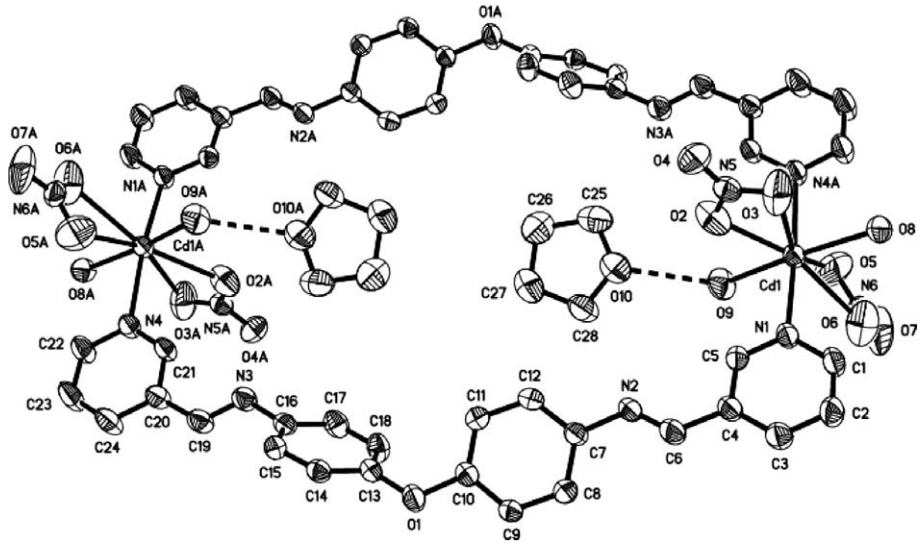

Fig. 6. ORTEP drawing of compound 3.

TGA of compound **3** shows that the first weight loss occurs at 120–150 °C, which corresponds to the loss of the THF guest (calculated: 10%; observed: 10%). Between 150 and 270 °C, the compound framework appears to be stable. Above this temperature range, the second weight loss occurs abruptly and then continues steadily up to 480 °C. At the second phase, ligand $\mathbf{L^3}$, one NO_3 ligand and two aqua ligands seem to be lost (calculated: 64%; observed: 64%), and the framework breaks down.

On the basis of the TGA analysis, the guest-free form of compound **3** was obtained by heating it at 150 °C for 24 h. The XRPD patterns of the original compound (Fig. 8a) and its guest-free form (Fig. 8b) show some discrepancies in the *d*-spacing and peak shape (the peaks with asterisks in Fig. 8a and b). To examine the reversibility of the desorption–resorption of the THF guest molecules, we took the XRPD spectrum of a sample that was prepared by immersing the guest-free form in THF in a capped vial at 50 °C for 24 h. The XRPD spectrum of this sample (Fig. 8c) clearly shows that compound **3** is restored. These XRPD data indicate a roughly reversible desorption–resorption behavior of the guest THF molecules. By contrast, the sorption of benzene, dichloromethane, acetone or 1,4-dioxane for the guest-free form is not observed. Moreover, pyridine and DMSO dissolve compound **3**.

In summary, we have prepared four ligands, [(3-py)–CH=N–C_6H_4–O–C_6H_4–NH_2, $\mathbf{L^1}$], [(4-py)–CH=N–C_6H_4–O–C_6H_4–NH_2, $\mathbf{L^2}$],

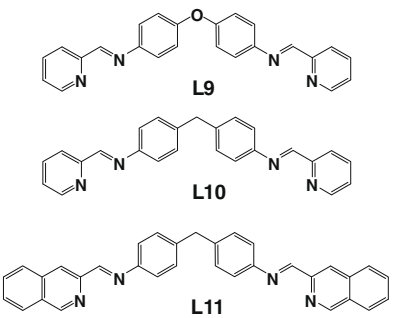

Chart 2.

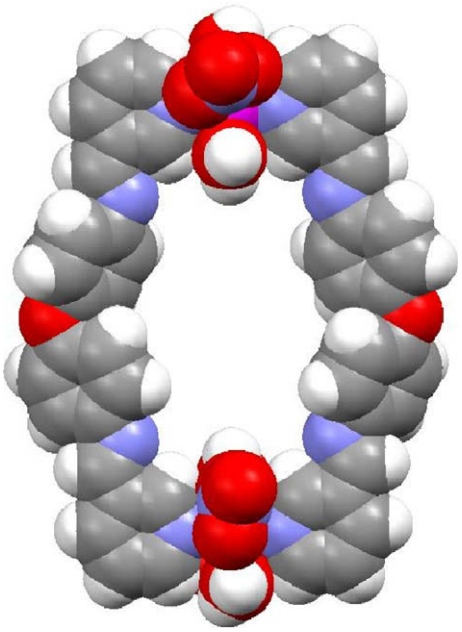

Fig. 7. A space filling model of compound 3 showing its double-helical structure: purple, Cd; red, O; blue, N; grey, C; white, H. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

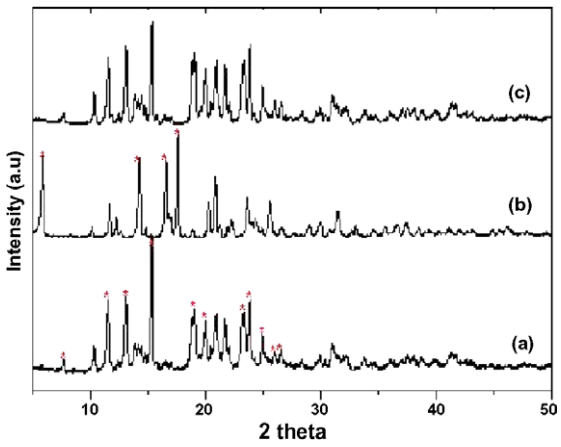

Fig. 8. XRD patterns of compound **3**: (a) original form; (b) guest-free form and (c) THF-resorbed form.

[(3-py)–CH=N–C_6H_4–O–C_6H_4–N=CH–(3-py), $\mathbf{L^3}$] and [(4-py)–CH=N–C_6H_4–O–C_6H_4–N=CH–(4-py), $\mathbf{L^4}$], all of which contain an intervening oxydianiline fragment. Whereas ligands $\mathbf{L^1}$ and $\mathbf{L^2}$ have two types of terminal groups (pyridyl and amine groups), ligands $\mathbf{L^3}$ and $\mathbf{L^4}$ have a single type of terminal group (pyridyl groups at both terminals). Ligands $\mathbf{L^1}$–$\mathbf{L^3}$ reacted with $Cd(NO_3)_2 \cdot 6H_2O$ to produce [Cd$\mathbf{L^1}_2(NO_3)_2$] (**1**), [Cd$\mathbf{L^2}_2(NO_3)_2$] (**2**) and [Cd$\mathbf{L^3}_1(NO_3)_2$-$(H_2O)_2$] $\cdot (C_4H_8O)_2$ (**3**), respectively. Compounds **1**–**3** were structurally characterized by X-ray diffraction. Compound **1** is a 2-D brick-wall coordination polymer and compound **2** is a 1-D double-strand-chain polymer. On the other hand, compound **3** is a discrete dinuclear molecule with a double-helical structure, which contains THF (C_4H_8O) guest molecules. Compound **3** exhibited a roughly reversible desorption–sorption behavior toward THF. The above results revealed that the ligands containing one pyridyl and one amine terminal group created coordination polymers, whereas those containing only the terminal pyridyl groups gave a molecular species.

Supplementary data

CCDC 705524–705526 contain the supplementary crystallographic data for compounds **1**–**3**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

A series of organometallic complexes possessing new tetrathia-[7]-helicene nitrile derivative ligands [**TH-7**] as chromophores, of general formula [MCp(P–P)(NC{TH-[7]-Y}Z)][PF_6] (M = Ru, Fe, P–P = DPPE, Y = H, NO_2, Z = H, C≡N; M = Ru, L–L = $2PPh_3$, Y = H, Z = H) has been synthesized and fully characterized. ^{1}H NMR, FT-IR and UV–Vis. spectroscopic data were analyzed with in order to evaluate the existence of electronic delocalization from the metal centre to the coordinated ligand to have some insight on the potentialities of these new compounds as non-linear optical molecular materials. Slow crystallization of compound [$RuCp(PPh_3)_2$(NC{TH-[7]-H}H)][PF_6] **2Ru** revealed an interesting isomerization of the helical ligand with formation of two carbon-carbon bonds between the two terminal thiophenes, leading to the total closure of the helix (**2**∗**Ru**).

1. Introduction

The search for new organic and organometallic materials with significant non-linear optical (NLO) properties has been an area of considerable interest due to their relevance to optical device technology [1–6]. Nevertheless, the observation of even-order non-linearity is limited to the asymmetric crystallization of the bulk materials. Thus, chiral structures appear as ideal systems to investigate second-order NLO effects due to their intrinsic non-centrosymmetry, which allows these effects to be observed even in symmetric media such as chiral isotropic liquids [7]. Large chiral effects have been demonstrated in surface NLO responses of films of chiral molecules adsorbed at the air/water interface [8] and of Langmuir–Blodgett films of chiral polymers [9].

In this context, the intrinsically chiral structures of helicenes [10] make these compounds very attractive to be investigated, leading to several theoretical and experimental studies of carbohelicenes [11] and heterohelicenes [12]. The easier functionalization of thiaheterohelicenes, compared to carbohelicenes, allows the introduction of several different functional groups, either in the terminal thiophene rings (formyl, alkoxycarbonyl, trifluoromethyl, amide, trialkylsilyl, cyanoacrylic and acrylates) or in the central benzene rings (alkyl and electron-withdrawing groups such as alkoxycarbonyl and trifluoromethyl) [13]. The reported optimized synthesis of tetrathia-[7]-helicene (TH[7]) and the convenient preparation of the formyl derivative 2-CHO-TH[7] [13a] paved the way for the synthesis of a variety of substituted heterohelicenes.

The present work reports the synthesis of three new TH[7] derivatives, through the functionalization of one terminal thiophene ring with a nitrile group (**L1**), two terminal thiophene rings with two nitrile groups (**L2**) and one terminal thiophene group with one nitrile group followed by nitration in the benzene rings (**L3**). These new TH[7] derivatives were used as ligands for the synthesis of a new family of η^5-monocyclopentadienyl ruthenium(II) and iron(II) organometallic complexes represented by the general formulation [MCp(PP)(NC{TH-[7]-Y} Z)] [PF_6] (M = Ru(II), Fe(II), P–P = DPPE, Y = H, NO_2, Z = H, C≡N; M = Ru(II), L–L = $2PPh_3$, Y = H, Z = H).

The new compounds have been characterized by the usual FT-IR, UV–Vis, ^{1}H and ^{31}P NMR spectroscopic techniques. Nevertheless, the poor solubility of the compounds in common deuterated solvents did not allow the characterization by ^{13}C NMR. The crystallization of compound [$RuCp(PPh_3)_2$(NC{TH-[7]-H}H)] [PF_6] **2Ru**, by slow diffusion of *n*-hexane into an acetone solution of the compound, afforded single crystals suitable for X-ray diffraction studies. This revealed isomerization of the helical ligand, due to the formation of two new carbon–carbon bonds between the terminal thiophene rings, giving the new complex **2**∗**Ru**.

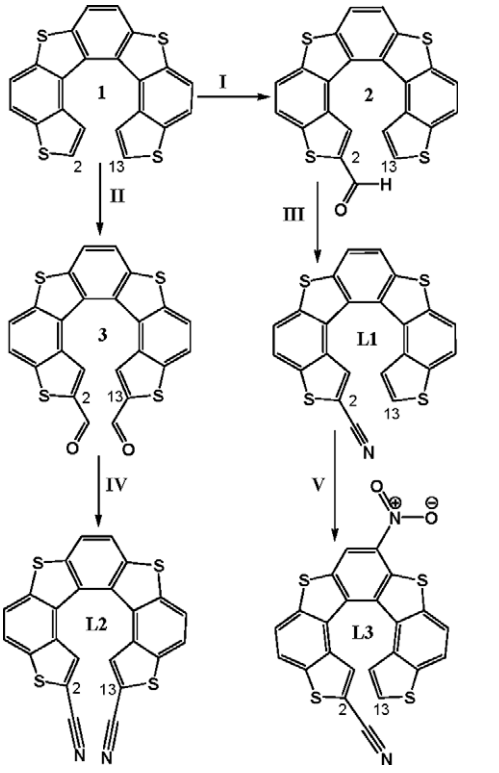
2. Results and discussion

2.1. Synthesis of the tetrathia-[7]-helicene ligands *L1*, *L2* and *L3*

The synthesis of the TH[7] derived nitrile ligands, tetrathia-[7]-helicene-2-carbonitrile (**L1**), tetrathia-[7]-helicene-2,13-dicarbonitrile (**L2**) and tetrathia-[7]-helicene-2-carbonitrile (**L3**), bearing the nitro group in an unidentified position of the helix, is summarized in Scheme 1.

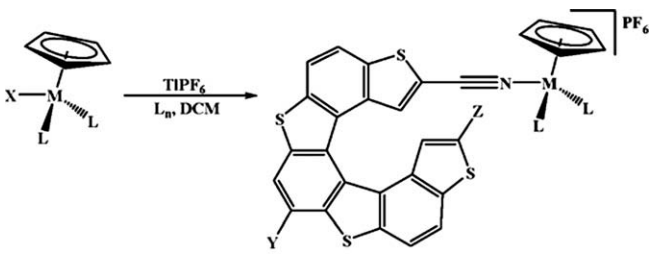
Tetrathia-[7]-helicene-2-carbaldehyde (**2**) was synthesized in good yield by electrophilic formylation of the α-anion of tetrathia-[7]-helicene, generated with *n*-BuLi at −78 °C in DMF, following Ref. [13a]. The ligand tetrathia-[7]-helicene-2-carbonitrile (**L1**) was synthesized from compound **2** and hydroxyl ammonium chloride in pyridine, with *in situ* dehydration by acetic anhydride.

The reaction of **L1** with nitric acid in acetic anhydride was carried out with the purpose of synthesizing tetrathia-[7]-helicene-13-nitro-2-carbonitrile, nitrated at the opposite end of the helix relatively to the nitrile group, as would be expected following our previous experience with benzo[1,2-b;4,3-b′]dithiophene derivative complexes [14]. However the analysis of the ^{1}H NMR spectrum of the obtained compound showed the presence of two doublets at 6.65 and 7.57 ppm (J_{HH} = 5.6 Hz), attributed to the thiophene ring protons, revealing that the nitration had occurred in one of the benzene rings. Nevertheless, substitution of the H on the two terminal thiophene rings was possible with two nitrile groups (**L2**), whilst the introduction of NO_2 in position 13 through an electrophilic substitution failed, thus demonstrating that the only way to functionalize the helical system in a regioselective manner is through the generation of anions in the positions 2 and 13 and the reaction with electrophilic reagents. ^{13}C NMR studies were not carried out due to the low solubility of the organic ligands in common deuterated solvents (acetone-d_6, chloroform-*d*, acetonitrile-d_3 and DMSO-d_6) even at high temperatures and, consequently, further characterization by *HMQC* and *HMBC* NMR techniques could not be applied to identify the position of the NO_2 group; therefore, the structure proposed for **L3** in Scheme 1 is simply one out of six possible structures.



Tetrathia-[7]-helicene-2,13-dicarbonitrile (**L2**) was synthesized by the reaction of tetrathia-[7]-helicene (**1**) with two equivalents of *n*-BuLi at −78 °C in DMF, affording tetrathia-[7]-helicene-2,13-dicarbaldehyde (**3**), which was used, without purification, in the reaction with hydroxylammonium chloride in pyridine, and dehydration *in situ* with acetic anhydride.

2.2. Synthesis of complexes [M(η^5-C$_5$H$_5$)(PP)(L)][PF$_6$]



Complexes of the general formula [M(η^5-C$_5$H$_5$)(PP)(L)][PF$_6$] (M = Ru and Fe, PP = DPPE, L = **L1**, **L2** and **L3**; M = Ru(II), (PP) = 2PPh$_3$, L = **L1**) were prepared by halide abstraction with TlPF$_6$ from the parent neutral complexes [M(η^5-C$_5$H$_5$)(PP)X] (M = Fe, X = I; M = Ru, X = Cl) in dichloromethane, in the presence of an adequate excess of the corresponding nitrile (Scheme 2).

The reactions were carried out at reflux, stirring overnight under inert atmosphere. The compounds were recrystallized by slow diffusion of n-hexane in acetone or dichloromethane, affording microcrystalline products with colours ranging from orange to dark red. The compounds were fairly stable in air and moisture, both in the solid state and in solution, and were obtained in fair yields of 27–56%. The formulation of the new compounds is supported by analytical data, FT-IR and ^{1}H, ^{31}P NMR spectroscopic data, with the exception of compounds **L3** and **2Ru**, for which the elemental analysis always gave a significant error. Nevertheless, the elemental percentages for **L3** containing complexes are in good agreement with the proposed formulations. An effort is currently being made at our laboratory to obtain suitable crystals for X-ray diffraction studies of any of the compounds **L3**, **4Ru** and **4Fe**, so that the structure of **L3** can be unequivocally determined.

The solid state FT-IR spectra (KBr pellets) of the complexes presented the characteristic bands of the cyclopentadienyl ligand (≈ 3060 cm^{-1}), the PF_6^- anion (840 and 560 cm^{-1}) and the coordinated nitrile (ν_{CN} from 2214 to 2191 cm^{-1}) in all of the studied complexes. As observed for other ruthenium and iron related compounds,[14,15] negative shifts were found for ν_{CN}, compared to the corresponding values of the uncoordinated nitrile, in particular for the iron compound containing the coordinated TH-[7] functionalized with the strong acceptor NO_2 group (**L3**), where a shift of −24 cm^{-1} was found. Negative shifts in the nitrile and acetylide

Scheme 2. Reaction scheme for the synthesis and numbering of the tetrathia-[7]-helicene Ru/Fe derived complexes.

coordinated ligands have been attributed to π-back donation, due to π bonding between the d orbitals of the metal and the π^* orbital of the nitrile group, leading to a decreased C≡N bond order [14,15]. The magnitude of the ν_{CN} negative shift has been clearly related to the electron-donor capacity of the organometallic fragment $[MCp(P–P)]^+$ and the electron-attractor capacity of the substituent group on the chromophore.

^{1}H NMR resonances of the cyclopentadienyl ring are in the characteristic range of monocationic ruthenium(II) and iron(II) complexes. The coordination of TH-[7] derived nitriles leads to a shielding of most of the protons, especially the one in the thiophene ring adjacent to the nitrile group coordinated to the metal. The upfield shift of this proton was more significant for compounds with DPPE as a coligand, up to −1.57 ppm for compound **3Fe**. The unexpected higher shielding (∼0.2 ppm) found for compounds **3Ru** and **3Fe** (with **L2**) than for the analogues **4Ru** and **4Fe** with the better acceptor **L3** might be explained by the spatial effect of the neighbouring uncoordinated C≡N group of **L2**.

^{31}P NMR spectra of the complexes showed a resonance at −144.1 ppm, characteristic of PF_6^-, and resonances of the coordinated phosphines. For compounds **2Ru**, **4Ru** and **4Fe**, the phosphine resonance signals are singlets, but for compounds **1Ru**, **1Fe**, **3Ru** and **3Fe**, the phosphine resonances appear as two doublets with coupling constants ranging from 23.1 to 33.5 Hz, characteristic of phosphorus–phosphorus coupling. This effect may be due to interactions of the phosphines with the opposite end of the helical ligand, causing the unequivalency of the phosphorus atoms. For compounds **4Ru** and **4Fe**, the higher planarity predicted for the helical ligand **L3**, due to the resonant structures originating from the donor (organometallic moiety)-acceptor (NO_2) conjugation, should minimize the referred interactions, while for compound **2Ru**, the less rigid PPh_3 coligands, relatively to DPPE, must allow the phosphorus equivalency.

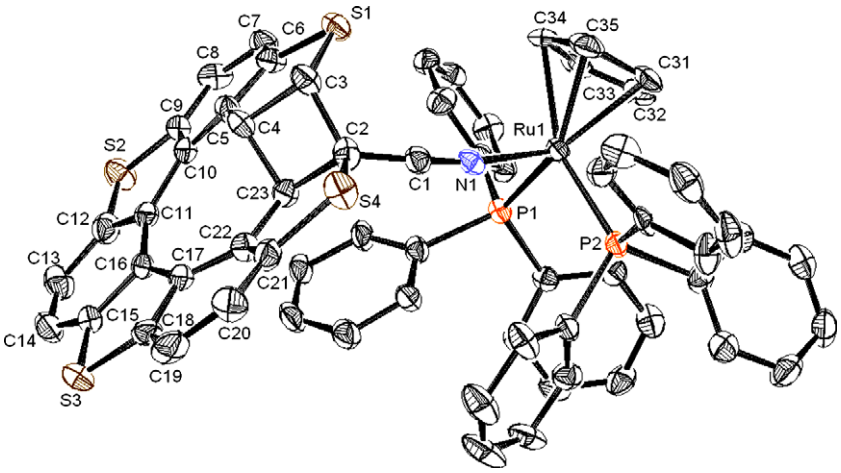

Fig. 3. ORTEP of the cation of compound **2∗Ru**.

2.3. Electronic spectra

Optical absorption spectra of all the complexes $[M(\eta^5\text{-}C_5H_5)(P\text{–}P)(L)][PF_6]$ were recorded in 10^{-4} M dichloromethane and methanol solutions (Table 1), in order to identify the M → L charge transfer and $\pi\text{–}\pi^*$ absorption bands expected for these complexes.

The electronic spectra of the helical ligands show several bands in the UV region due to their extensive π conjugated systems. As would be expected, the introduction of acceptor groups, either CN or NO_2, leads to a bathochromic shift of these bands.

The electronic spectra of the organometallic compounds are characterized by an intense absorption in the range 230–280 nm, attributed to the organometallic fragments $[MCp(P\text{–}P)]^+$, and in the range 280–430 nm, attributed to internal transitions in the TH-[7] derived ligands, by comparison to the free ligand spectra. For compounds **1Fe** and **3Fe**, an additional band is found, as a shoulder, in the ligands lower energy band, attributed to a metal to ligand charge transfer, $d(M^{II}) \rightarrow \pi^*(L)$. For compound **4Fe** no additional band was verified, although enlargement of the lower energy band of the ligand can obscure the existence of any superimposed MLCT band, as was observed before for other compounds with NO_2 substituted nitrile ligands [15e].

In the ruthenium compounds there is no evidence for any MLCT band, although it might be superimposed with the lower energy ligand internal transitions bands. Fig. 1 shows the electronic spectra of compounds $[MCp(DPPE)(NC\{TH\text{-}[7]\}CN)][PF_6]$, **3Ru** and **3Fe**, and of the free ligand **L2**. The existence of a CT band at lower energy is very obvious in compound **3Fe**, in accordance with the spectroscopic data discussed above.

Superimposition of the electronic spectra of compounds **3Fe** and **4Fe**, pictured in Fig. 2, shows that the ~500 nm CT band found in **3Fe** seems also occur in **4Fe**, although in this case it might be obscured by the enlargement of the band at a lower energy.

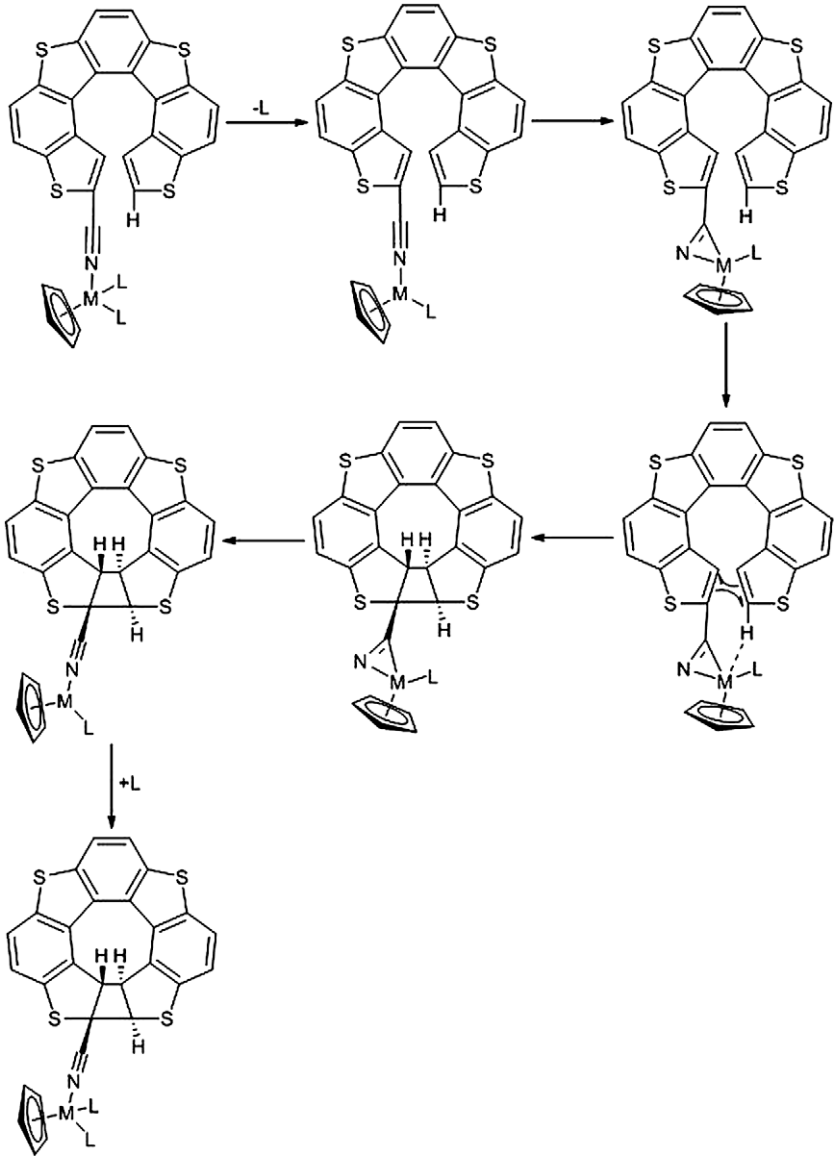
In the ruthenium compounds there is no evidence for any MLCT band, although it might be superimposed with the lower energy ligand internal transitions bands. Fig. 1 shows the electronic spectra of compounds $[MCp(DPPE)(NC\{TH\text{-}[7]\}CN)][PF_6]$, **3Ru** and **3Fe**, and of the free ligand **L2**. The existence of a CT band at lower energy is very obvious in compound **3Fe**, in accordance with the spectroscopic data discussed above.

Superimposition of the electronic spectra of compounds **3Fe** and **4Fe**, pictured in Fig. 2, shows that the ~500 nm CT band found in **3Fe** seems also occur in **4Fe**, although in this case it might be obscured by the enlargement of the band at a lower energy.

2.4. X-ray crystallographic studies

Crystals of compound $[RuCp(PPH_3)_2(NC\{TH\text{-}[7]\})][PF_6] \cdot (CH_3)_2CO$ were obtained by slow diffusion of *n*-hexane in an acetone solution. The results obtained by X-ray diffraction studies showed that the molecular structure of the cation does not correspond to the one expected and confirmed by ^{1}H NMR spectroscopy, due to isomerization of the coordinated ligand **L1**. As can be seen in Fig. 3, the opposite ends of the helical structure of **L1** are bonded (C(2)–C(3) and C(4)–C(23)) in a four-member ring arrangement, with a change in the hybridization of the carbon atoms involved in these bonds from sp^2 to sp^3. A similar phenomenon was reported for another TH[7] derivative [13a], although only one new bond is formed between the helix end rings in that case. Selected bond distances and angles are presented in Table 2. For isomer distinction, the isomer identified by X-ray diffraction is designated as **2∗Ru**.

The referred isomerization was only detected when X-ray diffraction studies were performed, since the initial ^{1}H NMR spectrum of compound **2Ru** is consistent with the predicted structure, with the chemical shifts of the thiophene rings protons and the coupling constant J_{3-4} (5.6 Hz) in the normal ranges for these structures. The isomerization must happen during the slow recrystallization and the **2∗Ru** isomer crystallized preferentially to **2Ru**. The ^{1}H NMR spectrum of **2∗Ru**, described in Section 4, is in accordance with the structure determined by X-ray, showing a significant shielding of protons H(4), H(23) and H(3), compared with **2Ru**, due to the hybridization change in the correspondent carbon atoms. Moreover, H(4) appears as a double doublet, due to coupling with H(3) and H(23), with coupling constants of 6.3 and 8.6 Hz, respectively. The chemical shifts of H(23) and H(3) were attributed based on the coupling constant magnitudes, since J_{23-4} is expected to be higher than J_{3-4} due to the larger H–C–C–H dihedral angle.



Compound **2∗Ru** crystallizes in the centrosymmetric space group $P\bar{1}$. The coordination geometry around the metal centre shows the typical structure of cyclopentadienyl complexes in pseudo-octahedral three-legged piano stool geometry, on the assumption that the cyclopentadienyl ring takes up three coordination sites, with the two PPh_3 phosphorus atoms and the nitrile nitrogen atom occupying the other three sites. The angles P–Ru–P and (C≡)N–Ru–P, close to 90°, and the angles Cp(centroid)–Ru–N(≡C) and Cp(centroide)–Ru–P (121.79(14)–124.15(5)°), along with the distances of the coordinated ligands to the metal centre, are within the range found for η^5-monocyclopentadienylruthenium nitrile derivatives with coordinated phosphines [14,15c,16]. The bond lengths of the cycle formed by atoms C(2), C(3), C(4) and C(23) are in the range 1.519(9)–1.598(9) Å, with bond lengths C(3)–C(4) (1.535(9) Å) and C(2)–C(23) (1.565(9) Å) clearly superior to the analogous ones verified in compounds [MCp(L-L)(NC{BDT}Z)][Y] [14], showing loss of the double bond character. Angles C(5)–C(4)–C(23) (106.9(6) Å) and C(4)–C(23)–C(22) (107.7(5) Å) show the almost superposition of the helix ends.

A possible mechanism to explain the isomerization of **2Ru** to **2∗Ru** is depicted in Scheme 3. It can be assumed that the metal center is involved in the isomerization of the helical ligand. The decoordination of a PPh_3 ligand, followed by the sliding of the nitrile to side-on (four-electron-donor) coordination allow the interaction of the metal centre with H(3). Nucleophilic attack at C(3)

Scheme 3. Proposed mechanism for formation of **2∗Ru**.

Table 4
Intermolecular contacts for compound **2∗Ru**.

2∗Ru	
C(35)–H(35)···F(1)	2.568
C(124)–H(124)···F(4)	2.647
C(3)–H(3)···F(4)	2.619
C(13)–H(13)···O(100)	2.491

and subsequent rearrangement results in bonding between the helix ends. Return of the nitrile to end-on coordination and coordination of PPh_3 affords **2∗Ru**. This mechanism is supported by the fact that isomerization was only detected in one complex, and not in the free ligand, and this being the complex with coordinated monodentate phosphines.

The dihedral angles between adjacent rings and terminal rings of the helicene ligand of compound **2∗Ru,** as well as the mean-square atom deviations Δ from the ring least-squares planes, are listed in Table 3. The planarity of the aromatic rings in the molecules is apparent from the mean deviations of the atoms from the least-squares plane of the ring (Table 3). The terminal rings 1 and 7 have an almost flat configuration, but the planarity is poorer towards the middle thiophene rings and is poorest in the benzene rings. Also, a decrease of the dihedral angle towards the middle part of the helix can be noticed, although the deformation of the rings from planarity does not follow the same correlation. This behavior is opposite to that observed in free TH[7] [17]. A possible explanation for this different structural arrangement is the isomerization of the helical ligand that forces a smaller aperture in the two terminal thiophene rings, as reflected by the dihedral angle between the rings 1 and 7 (4.43° vs. 45.9° for free TH[7]).

The pitch of the helix in **2∗Ru** compound is very similar to the free TH[7] ligand (14.30 Å vs. 14.03 Å), since the two thiahelicenes have the same number of rings [18].

The evaluation of the crystal packing of **2∗Ru** revealed the formation of pseudo dimeric units, with parallel alignment of the chromophores of distinct cations, via intermolecular interactions with the PF_6 anion and one acetone molecule (Table 4), reinforced through π–π interactions of the helical ligand.

This pseudo dimeric arrangement is illustrated in Fig. 4, where it can also be seen that these units are constituted by two enantiomers, (+) and (−), relative to the helix orientation.

Analysis of the crystal packing disclosed an interesting supramolecular array for this compound, which displays holes in the *c* direction, as illustrated in Fig. 5, suggesting that this network can possibly be used for selectively storing guests material [19]. These holes, that have an almost square shape, have the smaller dimensions between two fluorine atoms of the counter-ion PF_6, 4.851 Å, and two of the carbons of the acetone solvent molecule, 4.750 Å. The holes are created by two of the parallel lines produced via intermolecular interactions involving the helicene–PF_6–acetone. A similar array with a significant degree of porosity was verified for the compound $[RuCp(PPh_3)_2(NC(BDT))][PF_6]$ (BDT = benzo[1,2-b;4,3-b′]dithiophene) [14], although the holes aperture is larger in this compound.

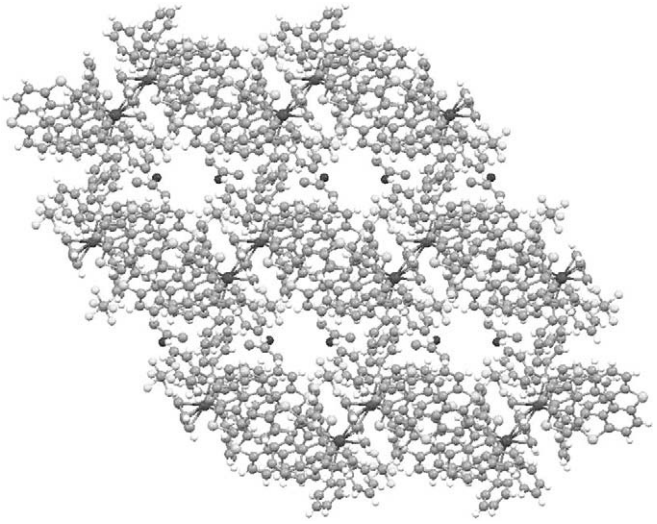

Fig. 5. Supramolecular arrangement of the compound **2∗Ru**, displaying holes along direction *c*.

3. Conclusion

We have described here the synthesis of the new organometallic complexes $[MCp(P–P)(NC\{TH\text{-}[7]\text{-}Y\}Z)][PF_6]$ (M = Ru, Fe, P–P = DPPE, Y = H, NO_2, Z = H, C≡N; M = Ru, L-L = $2PPh_3$, Y = H, Z = H), with coordinated helical ligands derived from tetrathia-[7]-helicene. Spectroscopic data revealed the electron-donor effect of the organometallic fragments $[MCp(P–P)]^+$. The magnitude of this effect depends on the metal and on the presence and/or position of the acceptor group (C≡N, NO_2), showing a good conjugation between the metal centre and the acceptor group on the chromophore.

The three new substituted tetrathia-[7]-helicene derivatives, synthesized in this work and used as ligands in the presented organometallic complexes, may also be interesting as organic materials for NLO purposes, according to the significant β values predicted by theoretical studies for other tetrathia-[7]-helicene derivatives [20].

The major interest in this family of compounds is the intrinsic chirality for NLO purposes, which has not yet been exploited, since the TH[7] ligands were prepared as a racemic mixture. Nevertheless, the synthetic procedure developed in the present work is valid for the synthesis of the pure isomers complexes, starting from the respective isomerically pure TH[7], bearing in mind that isomer inter-conversion is not possible.

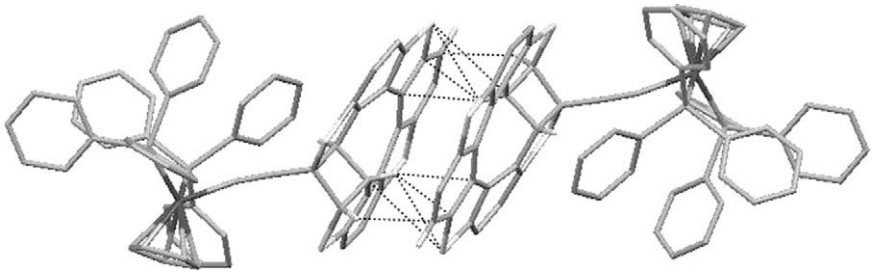

Fig. 4. Dimeric units of compound **2∗Ru**, showing intermolecular π–π interactions of the helical ligand.

4. Experimental

4.1. General procedures

All experiments were carried out under nitrogen atmosphere using standard Schlenk techniques. All of the solvents used were dried using standard methods [21]. The starting materials were prepared following the methods described in the literature: [Ru(η^5-C_5H_5)(DPPE)Cl] and [Ru(η^5-C_5H_5)(PPh_3)$_2$Cl] [22]; [Fe(η^5-C_5H_5)(DPPE)I] [15c]; tetrathia-[7]-helicene and tetrathia-[7]-helicene-2-carbox aldehyde [16a]. FT-IR spectra were recorded in a Mattson Satelite FTIR spectrophotometer with KBr; only significant bands are quoted in the text. ^{1}H and ^{31}P NMR spectra were recorded on a Brüker Avance 400 spectrometer at the probe temperature. ^{1}H (DMSO-d_6) chemical shifts are reported in parts per million (ppm) downfield from internal Me_4Si and coupling constants are reported in Hertz; ^{31}P (DMSO-d_6) NMR spectra are reported in ppm downfield from the external standard, 85% H_3PO_4. Elemental analyses were obtained at the Laboratório de Análises, Instituto Superior Técnico, using a Fisons Instruments EA1108 system. Data acquisition, integration and handling were performed using a PC with software package EAGER-200 (Carlo Erba Instruments). Electronic spectra were recorded at room temperature on a Jasco V-560 spectrometer in the range 200–900 nm.

4.2. Synthesis of the organic ligands

4.2.1. Tetrathia-[7]-helicene-2-carbonitrile (**L1**)

An $H_2NOH \cdot HCl$ (0.14 g, 2 mmol) solution in pyridine (4 mL) was added to a stirred solution of tetrathia-[7]-helicene-2-carbaldehyde (0.22 g, 0.5 mmol) in pyridine (5 mL), cooled to 5 °C. After stirring for 1 h at 5 °C, acetic anhydride (1 mL) was added, and the mixture was refluxed for 2 h. After cooling, the mixture was poured onto ice and the resulting precipitate was dissolved in CH_2Cl_2 (30 mL), washed with a saturated solution of $NaHCO_3$ and water, and dried over $MgSO_4$. The solvent was removed under reduced pressure and the product was purified by flash column chromatography (eluent:*n*-hexane/CH_2Cl_2 1:1), affording 0.10 g (47%) of pure tetrathia-[7]-helicene-2-carbonitrile as a yellow solid. *Anal.* (%) Calc. for $C_{23}H_9NS_4 \cdot 0.1C_6H_{14}$: C, 64.99; H, 2.40; N, 3.21. Found: C, 65.72; H, 2.13; N, 3.23. IR (KBr, cm^{-1}): ν(CN) 2206. ^{1}H NMR (DMSO-d_6): 6.49 (d, 1H, J_{HH} = 5.6), 7.23 (s, 1H) 7.40 (d, 1H, J_{HH} = 5.6), 8.28 (d, 1H, J_{HH} = 8.4), 8.29 (m, 4H), 8.51 (d, 1H, 8.8).

4.2.2. Tetrathia-[7]-helicene-2,13-dicarbonitrile (**L2**)

A *n*-BuLi 2.0 M pentane solution (0.55 mL, 1.1 mmol) was added dropwise to a stirred solution of tetrathia-[7]-helicene (0.20 g, 0.5 mmol) in dry THF (20 mL) at −78 °C. The solution was stirred for 40 min at −78 °C, and the resulting dark orange solution was treated with dry DMF (0.11 mL, 1.2 mmol). After 4 h at −78 °C, the solution was warmed up to room temperature and quenched with a saturated aqueous solution of NH_4Cl (5 mL). The THF was removed under reduced pressure, and the crude was taken up with CH_2Cl_2 (20 mL) and washed with water and a saturated solution of NH_4Cl. The solvent was removed under reduced pressure, affording tetrathia-[7]-heliceno-2,2′-dicarbaldehyde, as a dark oil, used without further purification. The product was dissolved in pyridine, cooled to 5 °C, and an $H_2NOH \cdot HCl$ (0.14 g, 2.0 mmol) solution in pyridine (4 mL) was added. After stirring for 5 min at 5 °C, acetic anhydride (1 mL) was added and the mixture was refluxed for 2 h. After cooling, the mixture was poured onto ice and the resulting precipitate was dissolved in CH_2Cl_2 (20 mL), washed with water and dried over $MgSO_4$. The product was purified by flash column chromatography (eluent:*n*-hexane/CH_2Cl_2 2:3), affording 0.05 g (25%) of pure tetrathia-[7]-helicene-2,13-dicarbonitrile as a yellow solid. *Anal.* (%) Calc. for $C_{24}H_8N_2S_4$: C, 63.69; H, 1.78; N, 6.19. Found: C, 64.02; H, 1.86; N, 5.99. IR (KBr, cm^{-1}): ν(CN) 2209. ^{1}H NMR (DMSO-d_6): 7.21 (s, 2H), 8.46 (s, 2H), 8.49 (d, 2H, J_{HH} = 8.8), 8.58 (d, 2H, J_{HH} = 8.8).

4.2.3. Tetrathia-[7]-helicene-?-nitro-2-carbonitrile (**L3**)

Nitric acid (0.02 mL, 0.35 mmol) was added to a stirred solution of tetrathia-[7]-helicene-2-carbonitrile (0.11 g, 0.26 mmol) in acetic anhydride (8 mL), cooled to 5 °C. After 1 h, the solution was poured onto ice and the resultant precipitate was dissolved in CH_2Cl_2 (15 mL). The solution was washed with a saturated solution of $NaHCO_3$, water, dried over $MgSO_4$ and the solvent removed under reduced pressure. The product was purified by flash column chromatography (eluent:*n*-hexane/CH_2Cl_2 2:3), affording 0.05 g (41%) of tetrathia-[7]-helicene-?-nitro-2-carbonitrile as an orange solid. IR (KBr, cm^{-1}): ν(CN) 2215, ν(NO_2) 1507 and 1316, δ (NO_2) 731. ^{1}H NMR (DMSO-d_6): 6.65 (d, 1H, J_{HH} = 5.6), 7.29 (s, 1H), 7.57 (d, 1H, J_{HH} = 5.6), 8.45 (d, 1H, J_{HH} = 8.8), 8.54 (m, 3H), 9.60 (s, 1H).

4.3. Synthesis of the complexes [M(η^5-C_5H_5)(P–P)(NC{TH-[7]-Y}Z)][PF_6]

Complexes of the general formula [M(η^5-C_5H_5)(P–P)(NC{TH-[7]-Y}Z)][PF_6] were prepared by halide abstraction from the parent neutral complexes [M(η^5-C_5H_5)(LL)X] (1 mmol) with $TlPF_6$ (1 mmol) in dichloromethane, in the presence of a slight excess (1.1 mmol) of the ligands tetrathia-[7]-helicene-2-carbonitrile (**L1**), tetrathia-[7]-helicene-2,2′-carbonitrile (**L2**) or tetrathia-[7]-helicene-?-nitro-2-carbonitrile (**L3**), at reflux for 48 h under an inert atmosphere. After cooling to room temperature, filtering and removing the solvent, the complexes were washed with *n*-hexane (3 × 15 mL) and recrystallized from dichloromethane/*n*-hexane or acetone/*n*-hexane, giving crystalline products.

4.3.1. [Ru(η^5-C_5H_5)(DPPE)(NC{TH-[7]})][PF_6] (**1Ru**)

Orange. Yield: 48%. Recrystallized from dichloromethane/*n*-hexane. *Anal.* (%) Calc. for: $C_{54}H_{38}NS_4P_3F_6Ru$: C, 57.04; H, 3.37; N, 1.23. Found: C, 57.30; H, 3.56; N, 1.60. IR (KBr, cm^{-1}): ν(C–H, η^5-C_5H_5) 3051, ν(CN) 2210, ν(PF_6^-) 839; ^{1}H NMR ($(CD_3)_2SO$): 2.65 (m, 4H, –CH_2–), 4.91 (s, 5H, η^5-C_5H_5), 6.06 (s, 1H), 6.22 (d, 1H, J_{HH} = 5.6), 7.04 (d, 1H, J_{HH} = 5.6), 7.24 (m, 4H, C_6H_5, DPPE), 7.36 (m, 6H, C_6H_5, DPPE), 7.51 (m, 6H, C_6H_5, DPPE), 7.78 (m, 4H, C_6H_5, DPPE), 8.28 (d, 1H, J_{HH} = 8.8), 8.41 (d, 1H, J_{HH} = 8.4), 8.47 (m, 4H). ^{31}P NMR ($(CD_3)_2SO$): −144.1 (qt, PF_6^-, J_{PF} = 711.0), 78.3 (d, DPPE, J_{PP} = 24.5), 79.5 (d, DPPE, J_{PP} = 24.5).

4.3.2. [Fe(η^5-C_5H_5)(DPPE)(NC{TH-[7]})][PF_6] (**1Fe**)

Red. Yield: 46%. Recrystallized from dichloromethane/*n*-hexane. *Anal.* (%) Calc. for $C_{54}H_{38}NS_4P_3F_6Fe \cdot 0.3CH_2Cl_2$: C, 58.54; H, 3.48; N, 1.25. Found: C, 58.29; H, 3.78; N, 1.26. IR (KBr, cm^{-1}): ν(C–H, η^5-C_5H_5) 3052, ν(CN) 2193, ν(PF_6^-) 840. ^{1}H NMR ($(CD_3)_2SO$): 2.46 (m, 2H, –CH_2–), 2.62 (m, 2H, –CH_2–), 4.53 (s, 5H, η^5-C_5H_5), 5.97 (s, 1H), 6.22 (d, 1H, J_{HH} = 5.6), 7.04 (d, 1H, J_{HH} = 5.6), 7.06 (m, 4H, C_6H_5, DPPE), 7.56 (m, 12H, C_6H_5, DPPE), 7.81 (m, 4H, C_6H_5, DPPE), 8.25 (d, 1H, J_{HH} = 8.8), 8.43 (m, 5H). ^{31}P NMR ($(CD_3)_2SO$): −144.1 (qt, PF_6^-, J_{PF} = 710.2), 96.4 (d, DPPE, J_{PP} = 33.2), 96.8 (d, DPPE, J_{PP} = 33.5).

4.3.3. [Ru(η^5-C_5H_5)(PPh_3)$_2$(NC{TH-[7]})][PF_6] (**2Ru**)

Orange. Yield: 27%. Recrystallized from acetone/*n*-hexane. IR (KBr, cm^{-1}): ν(C–H, η^5-C_5H_5) 3053, ν(CN) 2210, ν(PF_6^-) 840. ^{1}H NMR ($(CD_3)_2SO$): 4.61 (s, 5H, η^5-C_5H_5), 6.45 (d, 1H, J_{HH} = 5.6), 6.90 (s, 1H), 7.21 (m, 12H, C_6H_5, PPh_3), 7.31 (m, 12H, C_6H_5, PPh_3), 7.40 (d, 1H, J_{HH} = 5.6), 7.44 (m, 6H, C_6H_5, PPh_3), 8.14 (d, 1H, J_{HH} = 8.8), 8.24 (d, 1H, J_{HH} = 8.8), 8.40 (d, 1H, J_{HH} = 8.8), 8.43 (d,

1H, J_{HH} = 8.4), 8.47 (d, 1H, J_{HH} = 8.4), 8.55 (d, 1H, J_{HH} = 8.8). ^{31}P NMR ($(CD_3)_2SO$): −144.1 (qt, PF_6^-, J_{PF} = 711.1), 41.31 (s, PPh_3).

(***2*Ru***): Orange. ^{1}H NMR ($(CD_3)_2SO$): 3.29 (d, 1H, H(3), J_{3-4} = 6.4), 4.41 (dd, 1H, H(4), J_{4-3} = 6.3, J_{4-23} = 8.6), 5.27 (d, 1H, H(23), J_{23-4} = 8.8), 6.76 (m, 5H, C_6H_5, PPh_3), 6.96 (m, 6H, C_6H_5, PPh_3), 7.07 (m, 6H, C_6H_5, PPh_3), 7.17 (m, 5H, C_6H_5, PPh_3), 7.26 (m, 3H, C_6H_5, PPh_3), 7.35 (m, 3H, C_6H_5, PPh_3), 7.48 (m, 2H, C_6H_5, PPh_3), 7.62 (d, 1H, J_{HH} = 8.3), 7.69 (d, 1H, J_{HH} = 8.4), 7.99 (d, 1H, J_{HH} = 8.3), 8.07 (d, 1H, J_{HH} = 8.3), 8.39 (d, 1H, J_{HH} = 8.6), 8.42 (d, 1H, J_{HH} = 8.4).

4.3.4. [Ru(η^5-C_5H_5)(DPPE)(NC{TH-[7]}CN)][PF_6] (***3Ru***)

Dark red. Yield: 56%. Recrystallized from dichloromethane/*n*-hexane. *Anal.* (%) Calc. for $C_{55}H_{37}N_2S_4P_3F_6Ru$: C, 56.84; H, 3.21; N, 2.41. Found: C, 56.40; H, 3.38; N, 2.41. 4.3.5. [Fe(η^5-C_5H_5)(DPPE)(NC{TH-[7]}CN)][PF_6] (***3Fe***)

Dark red. Yield: 59%. Recrystallized from dichloromethane/*n*-hexane. *Anal.* (%) Calc. for $C_{55}H_{37}N_2S_4P_3F_6Fe$: C, 59.15; H, 3.34; N, 2.51. Found: C, 59.01; H, 3.70; N, 2.14. IR (KBr, cm^{-1}): ν(C–H, η^5-C_5H_5) 3052, ν(CN) 2191, $\nu(PF_6^-)$ 839. ^{1}H NMR ($(CD_3)_2SO$): 2.37 (m, 2H, –CH_2–), 2.70 (m, 2H, –CH_2–), 4.52 (s, 5H, η^5-C_5H_5), 5.64 (s, 1H), 6.85 (s, 1H), 7.26 (m, 4H, C_6H_5, DPPE), 7.56 (m, 12H, C_6H_5, DPPE), 7.93 (m, 4H, C_6H_5, DPPE), 8.35 (d, 2H, J_{HH} = 8.8), 8.67 (d, 2H, H_6, J_{HH} = 8.8). ^{31}P NMR ($(CD_3)_2SO$): −144.1 (qt, PF_6^-, J_{PF} = 710.6), 96.8 (d, DPPE, J_{PP} = 33.4), 97.4 (d, DPPE, J_{PP} = 32.7).

4.3.6. [Ru(η^5-C_5H_5)(DPPE)(NC{TH-[7]-NO_2})][PF_6] (***4Ru***)

Dark red. Yield 40%. Recrystallized from dichloromethane/*n*-hexane. *Anal.* (%) Calc. for $C_{54}H_{37}N_2O_2S_4P_3F_6Ru$: C, 54.87; H, 3.15; N, 2.37. Found: C, 54.52; H, 3.56; N, 2.63. IR (KBr, cm^{-1}): ν(C–H, η^5-C_5H_5) 3054, ν(CN) 2214, $\nu(NO_2)$ 1507 and 1314, $\delta(NO_2)$ 730, $\nu(PF_6^-)$ 839. ^{1}H NMR ($(CD_3)_2SO$): 2.34 (m, 2H, –CH_2–), 2.67 (m, 2H, –CH_2–), 4.84 (s, 5H, η^5-C_5H_5), 5.98 (s, 1H), 6.40 (d, 1H, J_{HH} = 5.6), 7.29 (d, 1H, J_{HH} = 5.6), 7.35 (m, 6H, C_6H_5, DPPE), 7.51 (m, 6H, C_6H_5, DPPE), 7.72 (m, 8H, C_6H_5, DPPE), 8.33 (d, 1H, J_{HH} = 8.8), 8.52 (d, 1H, J_{HH} = 8.8), 8.59 (s, 2H), 9.75 (s, 1H). ^{31}P NMR ($(CD_3)_2SO$): −144.1 (qt, PF_6^-, J_{PF} = 712.7), 78.7 (s, DPPE).

4.3.7. [Fe(η^5-C_5H_5)(DPPE)(NC{TH-[7]-NO_2})][PF_6] (***4Fe***)

Dark red. Yield 44%. Recrystallized from dichloromethane/*n*-hexane. *Anal.* (%) Calc. for $C_{54}H_{37}N_2O_2S_4P_3F_6Fe \cdot 0.3CH_2Cl_2$: C, 56.11; H, 3.26; N, 2.41. Found: C, 55.91; H, 3.39; N, 3.08. IR (KBr, cm^{-1}): ν(C–H, η^5-C_5H_5) 3052, ν(CN) 2191, $\nu(NO_2)$ 1507 and 1313, $\nu(PF_6^-)$ 839. ^{1}H NMR ($(CD_3)_2SO$): 2.12 (m, 2H, –CH_2–), 2.35 (m, 2H, –CH_2–), 4.57 (s, 5H, η^5-C_5H_5), 5.90 (s, 1H), 6.39 (d, 1H, J_{HH} = 5.6), 7.32 (d, 1H, J_{HH} = 5.6), 7.35 (m, 8H, C_6H_5, DPPE), 7.55 (m, 8H, C_6H_5, DPPE), 7.74 (m, 4H, C_6H_5, DPPE), 8.30 (d, 1H, J_{HH} = 8.8), 8.49 (d, 1H, J_{HH} = 8.8), 8.57 (s, 2H), 9.72 (s, 1H). ^{31}P NMR ($(CD_3)_2SO$): −144.1 (qt, PF_6^-, J_{PF} = 710.2), 97.0 (s, DPPE).

4.4. X-ray crystallography

X-ray data for compound **2*Ru** was collected on a Bruker AXS APEX CCD area detector diffractometer at 293(2) K using graphite-monochromated Mo Kα (λ = 0.71073 Å) radiation. Intensity data were corrected for Lorentz polarization effects. Empirical absorption corrections, using SADABS [23], were applied and the data reduction was done with SMART and SAINT programs [24]. All structures were solved by direct methods with SIR97 [25] and refined by full-matrix least-squares on F^2 with SHELXL97 [26], both included in the package of programs WINGX-Version 1.70.01 [27].[7] Non-hydrogen atoms were refined with anisotropic thermal parameters, whereas H-atoms were placed in idealised positions and allowed to refine riding on the parent C atom. Graphical representations were prepared using ORTEP [28] and Mercury 1.1.2 [29]. Crystallographic data: crystal colour orange, crystal habit plate, crystal dimensions 0.10 × 0.09 × 0.02 mm, empirical formula $C_{67}H_{44}F_6NO_3P_3S_3Ru$, M = 1315.25, crystal system triclinic, space group $\bar{P}$, a = 14.038(3), b = 14.992(3), c = 16.937(3) Å, α = 110.185(7), β = 103.719(6), γ = 102.132(6)°, V = 3079.0(10) Å^3, Z = 2, $D_{calc.}$ = 1.765 g cm^{-3}, T = 150(2) K, reflections collected/unique 23 172/13 568, parameters 748, final R indices [$I > 2\sigma(I)$]: R_1 = 0.0687; wR_2 = 0.1422.

Supplementary data

CCDC 688367 contains the supplementary crystallographic data for **2*Ru**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Two new chiral dinuclear Cu(II) complexes $[Cu_2(\mu\text{-}Cl)_2(HL^1)_2]\cdot C_2H_5OH$ (**1**) and $[Cu_2(\mu\text{-}Cl)_2(HL^2)_2]\cdot CH_3OH$ (**2**), have been synthesized and structurally characterized, where the chiral ligands H_2L^1 and H_2L^2 are derived from the chiral amino alcohols (S)-(−)-2-amino-3-phenyl-1-propanol and (S)-(+)-2-phenylglycinol. Single-crystal X-ray crystallographic analyses revealed that in these complexes, the dominant hydrogen bonding property of metal bound chloride anion directs the self assembly of complex molecules through C–H···Cl hydrogen bonding interactions leading to the formation of intriguing hydrogen bonded metallo-supramolecular architectures in their respective crystal lattices. The supramolecular systems described here belong to the rare class of metal-organic architectures that are formed as a result of metal directed hydrogen bonding interactions among chiral complex molecules. Complexes **1** and **2** are further characterized by IR, ESR, UV–Vis and CD spectroscopy.

1. Introduction

The influence of transition metals on hydrogen bonding (H-bonding) is a current topic of fundamental relevance [1]. Transition metals and their primary coordination sphere can exert considerable control over H-bonds, affecting the nature of intermolecular interactions in synthetic as well as natural systems [2–4]. In nature, the active sites of metalloenzymes exhibit many H-bonding interactions which are influential in deciding their properties [5]. Many interesting synthetic supramolecular systems are being developed in recent years having relevance to host–guest [6–8], bio-inorganic [9], medicinal [10,11], organometallic [12,13] and solid state [14,15] chemistry, by strategically combining the properties of transition metals with that of H-bonding ligands. Nevertheless, the design and synthesis of metallo-supramolecular systems is still a daunting task, as it involves a number of variables such as properties of ligands, metal ions, solvents and counterions. Incorporation of a powerful H-bonding functionality into the molecular building unit, capable of directing its supramolecular self-assembly is vital in the design of such systems [16–20]. In this respect, metal bound chlorine (M–Cl) is recognized as a strong H-bond functionality in metallo-supramolecular chemistry [21–27].

Meanwhile, chiral metallo-supramolecular systems are in demand for specific applications such as non-linear optics, chiral catalysis, sensing and enantioselective inclusion studies [28–31]. One strategy to ensure the chirality of supramolecular architectures is to employ chiral building units [32–36]. Chiral amino alcohols are a promising class of chiral sources employed for the synthesis of chiral coordination compounds [37–42]. Eventhough chiral amino alcohol based coordination compounds are well known for their applications in asymmetric catalysis [43–46], the number of structurally characterized coordination complexes derived from chiral amino alcohol based ligands are limited in the literature [37–42]. Structural studies of such complexes will help to design new systems with improved functionalities.

Herein we report the synthesis, structural characterization and properties of two chiral dinuclear copper complexes containing Cu–Cl as the dominant H-bond acceptor, which self assemble through C–H···Cl–Cu, C–H···O, etc. interactions leading to the formation of fascinating H-bonded metal-organic architectures in the solid state.

2. Experimental

2.1. Materials and measurements

Microanalytical (C, H, N) data were obtained with a FLASH EA 1112 Series CHNS Analyzer. A Shimadzu 3101-PC UV–Vis–NIR spectrophotometer was used to record the electronic spectra. Infrared spectra were recorded by using KBr pellets on a Jasco-5300 FT-IR spectrophotometer. ^1H NMR spectra in $CDCl_3$ solutions were recorded with a Bruker DRX-400 spectrometer, using $Si(CH_3)_4$ as an internal standard. Room temperature solid state magnetic susceptibilities were measured by using a Sherwood Scientific

magnetic susceptibility balance. The CD spectra were measured in solution phase with a JASCO J-810 spectropolarimeter. EPR spectra were recorded on a Jeol JES-FA200 spectrometer. Solvents used for UV and CD analyses were of HPLC grade and procured from E. Merck (India). The metal salts used were of analytical grade and purchased from S.D. Fine Chem. Ltd. (India). All other chemicals used were of analytical grade.

2.2. Synthesis of chiral ligands H_2L^1 and H_2L^2

The chiral ligands employed in this study are prepared by the Schiff base condensation reactions of 5-H- and 5-Br-substituted salicylaldehydes with (S)-(+)-2-phenylglycinol and/or (S)-(−)-2-amino-3-phenyl-1-propanol. A schematic representation of ligand synthesis is given in Scheme 1. Synthesis and characterization data for the chiral ligand $C_{16}H_{17}NO_2$ (H_2L^1) are reported elsewhere [47].

2.2.1. Synthesis of H_2L^2

(S)-(+)-2-phenylglycinol (0.137 g, 1 mmol) and 5-bromosalicylaldehyde [5-bromo-2-hydroxybenzaldehyde] (0.201 g, 1 mmol) were stirred together in methanol (15 ml) for 1 h at room temperature. The resulting yellow solution was filtered and the filtrate was kept for 2 days in an open beaker for slow evaporation. Yellow solid of H_2L^2 thus obtained was washed with hexane and dried at room temperature.

MF: $C_{15}H_{14}BrNO_2$, MW: 320.18 Yield: 0.278 g, 87%. *Anal.* Calc. for $C_{15}H_{14}BrNO_2$: C, 56.27; H, 4.41; N, 4.37. Found: C, 56.33; H, 4.35; N, 4.44%. 2.3. Synthesis of chiral copper complexes **1** and **2**

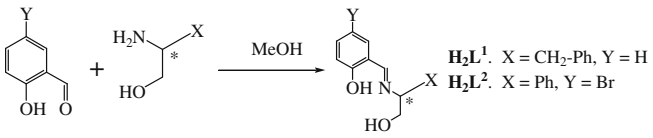
2.3.1. Synthesis of $[Cu_2(\mu\text{-}Cl)_2(HL^1)_2]\cdot C_2H_5OH$ (**1**)



To a methanolic solution of the ligand H_2L^1 (0.25 g, 1 mmol) was added $CuCl_2\cdot 2H_2O$ (0.179 g, 1 mmol). The mixture was allowed to stir at room temperature in air overnight. The resultant green solution was evaporated to dryness using rotavapor and vacuum pump. The green solid, thus obtained, was recrystallized from ethanol.

MF: $[Cu_2(\mu\text{-}Cl)_2(HL^1)_2]\cdot C_2H_5OH$, MW: 752.67, Yield: 0.210 g, 56%. *Anal.* Calc. for $C_{34}H_{38}N_2O_5Cl_2Cu_2$: C, 54.26; H, 5.09; N, 3.72. Found: C, 53.94; H, 5.11; N, 3.66%. Scheme 1. Synthesis scheme for chiral ligands H_2L^1 and H_2L^2.

2.4. Single-crystal structure determination of $[Cu_2(\mu\text{-}Cl)_2(HL^1)_2]\cdot C_2H_5OH$ (**1**) and $[Cu_2(\mu\text{-}Cl)_2(HL^2)_2]\cdot CH_3OH$ (**2**)

A summary of the crystallographic data for complexes **1** and **2** is given in Table 1. Suitable green crystals of **1** and **2** were grown from ethanol and methanol solutions, respectively, by slow evaporation method. The X-ray data were collected at room temperature with a Bruker–Nonius SMART APEX CCD single-crystal diffractometer using graphite monochromated Mo Kα radiation (0.71073 Å). The SMART software [48] was used for intensity data acquisition and the SAINTPLUS software [48] was used for data extraction. In each case, absorption correction was performed with the help of SADABS program [48]. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures using programs of SHELX-97 [49]. All the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included in the structure factor calculation by using a riding model. The absolute configurations for the enantiopure complex molecules were successfully determined by refining the Flack parameters [50].

For complex **1**, hydrogen atoms were not located in association with alcoholic oxygens of the ligands. The highest residual electron density of 1.99 (e/Å^3) is observed near Cu3 atom at a distance of 1.156 Å for this complex.

3. Results and discussion

3.1. Syntheses and characterization of complexes **1** and **2**

Complexes **1** and **2** were synthesized in moderate yields by 1:1 molar reactions of the respective chiral ligand (H_2L^1 or H_2L^2) with $CuCl_2\cdot 2H_2O$ in methanol at room temperature. The reaction mix-

tures on evaporation gave green solids which on recrystallization from ethanol/methanol provide analytically pure crystalline samples of dinuclear copper complexes **1** and **2**. Elemental analyses revealed 1:1 ligand to metal ratio in these complexes.

The IR peaks observed for these complexes in the range of 2800–3000 cm^{-1} are most likely due to the aliphatic and aromatic C–H stretches.These complexes show a strong peak around 1635 cm^{-1} due to υ(C=N). The strong peak observed around 1550 cm^{-1} is characteristic of the phenolic C–O stretch acquiring partial double bond character through conjugation with the imine system in the chelate ring. The peaks observed in the range 1570–1600 cm^{-1} can be assigned to C=C stretch. Alcoholic C–O stretch for these complexes appears in the range 1055–1082 cm^{-1}.

The electronic spectra for the complexes **1** and **2** were recorded in methanol solutions. The absorption spectra of these complexes show a weak d–d band in the visible region around 700 nm. The strong band observed around 380 nm is assigned to phenolate to copper charge transfer transition (LMCT). The sharp peaks in the 200–290 nm range of the electronic spectrum are due to intra-ligand charge transfer (ILCT) transitions, judging from their molar extinction coefficient values. The optical activity of the complexes **1** and **2** is induced by the enantiopure ligands. The circular dichroism (CD) spectra of the complexes recorded in methanol solutions show bands corresponding to their d–d, LMCT and ILCT transitions. The d–d bands of these complexes are observed as a negative Cotton effect at high concentrations.

The X-band EPR measurements for the complexes **1** and **2** were performed at liquid nitrogen temperature in methanol solutions. The EPR spectra of the complexes **1** and **2** are similar and typical of a mononuclear square planar/square-pyramidal Cu(II) complex with a $d_{x^2-y^2}$ ground-state doublet, see Fig. 1. The data suggest that the bis(μ-halo)-bridged structures [(HL)Cu(μ-Cl)$_2$Cu(HL)] get dissociated in solution presumably due to interaction with the solvent molecules. This observation is also consistent with the fact that the chloride bridges in the dinuclear complexes **1** and **2** are rather weak as shown by the large Cu–Cl distances (2.8802(16), 2.6872(15) Å, etc., *vide infra*) in their crystal structures. Similar behavior has also been observed for some analogous chlorobridged dimeric copper complexes [51,52]. The *g*-values observed for complexes ($g_{||}$ = 2.28–2.29, $g_{\perp}$ = 2.06–2.07, $A_{||}$ = 160–168 G) are comparable to those of other similar dinuclear Cu(II) complexes [51,52]. The detailed EPR parameters as well as the room temperature magnetic susceptibility data for the powdered samples of the complexes **1** and **2** are given in Table 2. The magnetic moments for dinuclear complexes **1** and **2** are in the range 2.63–2.90μ_B which are less than the spin only values expected for two non-interacting Cu(II) centers.

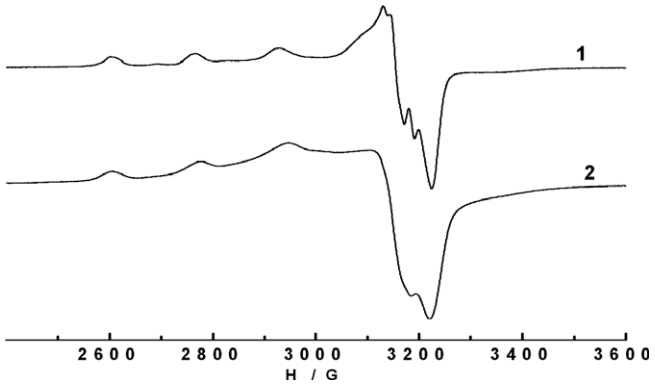

Fig. 1. X-band EPR spectra of complexes **1** and **2** in methanol at liquid nitrogen temperature.

Table 2
EPR data and magnetic moments for complexes **1** and **2**.

Complex	$g_{||}$	$g_{\perp}$	$A_{||}$	μ_{eff}/μ_B
1	2.29	2.06	160	2.63
2	2.28	2.07	168	2.90

*3.2. Crystal structure and supramolecular chemistry of the complex $[Cu_2(\mu\text{-}Cl)_2(HL^1)_2]\cdot C_2H_5OH$ (**1**)*

The complex **1** crystallizes in the non-centrosymmetric space group triclinic *P*1. Interestingly, the asymmetric unit contains four molecules of complex **1** (i.e., $Z' = 4$). Such complexes having $Z' > 1$ are of interest crystallographically [53] and are less common in the literature. In each of these four dichlorobridged dinulcear copper complexes present in the asymmetric unit, the copper centers are penta-coordinated with the Schiff base ligand coordinating to the metal ion *via* the phenolate oxygen, alcohol oxygen and imine nitrogen. The fourth and fifth coordination sites of these copper centers are satisfied by bridging chloro ligands. The thermal ellipsoid plot of a representative dinuclear complex of **1** is presented in Fig. 2.

For convenience, the four dinuclear complexes present in the asymmetric unit of complex **1** are labeled as CuA (containing copper centers Cu1 and Cu2), CuB (containing Cu3 and Cu4), CuC (containing Cu5 and Cu6) and CuD (containing Cu7 and Cu8). These four dinuclear complexes show slight variations in their respective bond lengths and angles. The asymmetric bridging of two copper centers through two chloro ligands leads to the formation of a central non-planar Cu_2Cl_2 ring in all of these complex structures. The dihedral angle between the planes defined by Cu1, Cl1, Cl2 and Cu2, Cl1, Cl2 for the representative dinuclear complex given in Fig. 2 (CuA) is 28.69°. The corresponding dihedral angles for other three dinuclear complexes are 23.11° (CuB), 23.46° (CuC) and 22.57° (CuD). Selected bond lengths and angles for a representative dinuclear complex (CuA) are listed in Table 3. Analysis of the shape-determining angles of the copper centers present in the asymmetric unit of complex **1,** using the approach of Reedijk and co-workers [54], yielded τ values in the range 0.05–0.38 (ideally, $\tau = 0$ for a square pyramidal and $\tau = 1$ for a trigonal bipyramidal

Cu1–Cl1–Cu2	84.25(10)	Cu2–Cl2–Cu1	88.03(10)

complex). Hence the structural distortions of the copper centers in complex **1** are more towards square pyramidal rather than trigonal bipyramidal geometry.

The geometry of the copper centers present in complex **1** is therefore distorted square pyramidal with four short bonds in the basal plane formed by two trans oxygen atoms and one nitrogen atom of the tridentate ligand and a bridge chloride ion. The fifth axial long bond is formed by a chloride ion which is in the basal plane of the neighbouring copper center. As expected, the basal Cu–Cl bonds are found to be considerably shorter than the axial Cu–Cl bonds for each copper center [for the four dinuclear complexes present in the asymmetric unit of **1**, the average basal Cu–Cl bond length = 2.257(4) Å and average axial Cu–Cl bond length = 2.808(4) Å]. The average Cu–Cl–Cu bond angle and Cu···Cu distance for these complexes are 86.10(10)° and 3.605(2) Å, respectively. These observed geometrical features of Cu centers in **1** are quite comparable to those of the similar dinuclear complexes reported in the literature [55–62].

Supramolecular analysis of the crystal structure of complex **1** revealed the presence of dominant intermolecular C–H···Cl H-bonding interactions among the four dinuclear complexes present in the asymmetric unit. In the crystal lattice, the dinuclear units CuA and CuB are interconnected through two intermolecular C–H···Cl interactions [C23–H23···Cl4 and C55–H55···Cl2] resulting in the formation of an infinite one-dimensional chain (1-D chain) structure as shown in Fig. 3a. At the same time, the dinuclear complexes CuC and CuD are interconnected through another C–H···Cl interaction [C119–H119···Cl5] forming a discrete H-bonded dimer (Fig. 3b). Interestingly, these discrete dimers are 'hooked' to the 1-D chains formed by CuA and CuB through yet another C–H···Cl interaction [C69–H69···Cl2]. The final supramolecular structure of complex **1** appears, as if, the discrete H-bonded dimers are 'hanging' from the infinite 1-D chain as shown in Fig. 3c. The relevant H-bonding parameters are given in Table 4, which are comparable to those of the previously reported similar systems [21–27]. This kind of supramolecular structures are not known in metal complexes, and it can be assumed that the dominant H-bonding nature of Cu–Cl moiety plays an important role in forming such an intriguing metal-organic architecture. Also these extensive H-bonding interactions might be having a stabilizing effect in the formation of such a large asymmetric unit containing four dinuclear copper complexes.

In addition to these C–H···Cl interactions, there are also some intra- and intermolecular O–H···O H-bonding interaction, present in the crystal structure of complex **1**. These interactions involve the intramolecular H-bonding between one pair of metal bound alcoholic and a phenolic oxygens in each dinuclear complexes. Although the relevant hydrogen atoms are not located, it appears that, in these interactions, the protonated alcoholic oxygens act as donors while the deprotonated phenolic oxygens act as acceptors. The relevant parameters are O2···O3 2.638(12) Å (CuA), O8···O5 2.588(13) Å (CuB), O10···O11 2.612(11) Å (CuC) and O16···O13 2.688(12) Å. The other pair of metal bound alcoholic and phenolic oxygens, present in each complex molecule, is H-bonded to one solvent ethanol molecule through intermolecular O–H···O (in CuA, CuB and CuD) and C–H···O (in CuC) interactions. The relevant parameters are O19···O1 2.887(14) Å and O19···O4 2.552(14) Å for CuA, O6···O17 2.576(12) Å and O17···O7 2.866(12) Å for CuB and O14···O20 2.601(12) Å and O20···O15 2.794(12) Å for CuD. The relevant C–H···O H-bonding parameters for CuC are presented in Table 4. These intra- and intermolecular O–H···O and C–H···O interactions do not affect the Cu–Cl directed supramolecular assembly of complex **1**, nevertheless, these interactions help to stabilize the overall crystal packing.

3.3. Crystal structure and supramolecular chemistry of $[Cu_2(\mu\text{-}Cl)_2(HL^2)_2] \cdot CH_3OH$ (**2**)

Single crystals of complex **2**, suitable for X-ray analysis, were grown from methanol solutions by slow evaporation method. The complex crystallizes in chiral tetragonal space group $P4_3$. The asymmetric unit contains one molecule of complex **2** and one solvent methanol molecule. Complex **2** has a dichlorobridged dinuclear geometry containing two penta-coordinate copper(II) centers bridged by two chloro ligands, similar to the structure of complex **1**, see Fig. 4. Each Cu center has a distorted square pyramidal geometry as ascertained by Reedijk and co-workers' τ factor [54] of 0.1588 for Cu2 and 0.255 for Cu1. The central Cu_2Cl_2 ring is non-planar with a dihedral angle of 25.59° between the planes de-

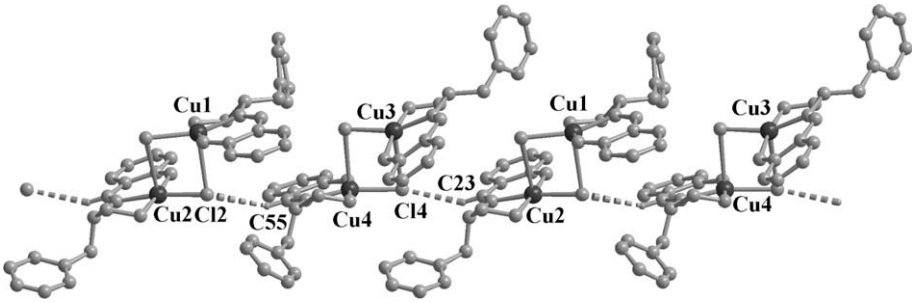

Fig. 3a. 1-D chain structure formed by C–H···Cl–Cu interaction in the crystal lattice of complex **1**. H-bonding interactions are represented by dotted lines.

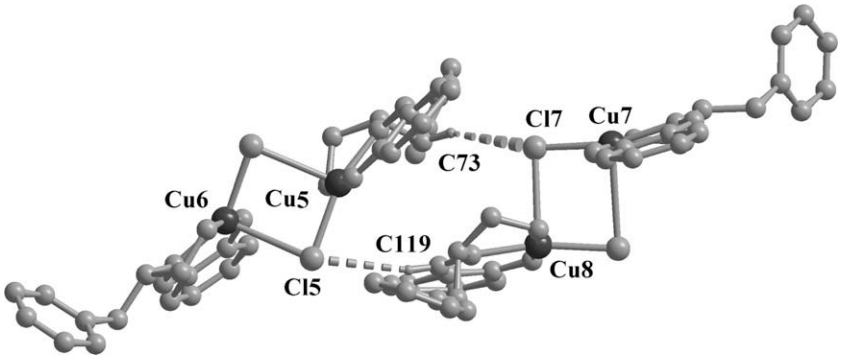

Fig. 3b. Discrete dimer formed by C–H···Cl–Cu interaction in the crystal lattice of complex **1**. H-bonding interactions are represented by dotted lines.

fined by Cu1, Cl1, Cl2 and Cu2, Cl1, Cl2. Selected bond distances and angles for complex **2** are tabulated in Table 5.

The geometry of the copper centers present in complex **2** are quite similar to that of complex **1**, viz. distorted square pyramidal with four short bonds in the basal plane formed by two trans oxygen atoms and one nitrogen atom of the tridentate ligand and a bridge chloride ion. The fifth axial long bond is formed by a chloride ion which is in the basal plane of the neighbouring copper center. The basal Cu–Cl bond lengths are 2.2600(14) and 2.2753(14) Å while the axial Cu–Cl bond lengths are 2.7327(15) and 2.7263(15) Å. The average Cu–Cl–Cu bond angle and Cu···Cu distance for this complex are 84.44(5)° and 3.3752(8) Å, respectively. These geometrical features are comparable to those reported in the literature for similar dinuclear copper complexes [55–62].

This complex also exhibits dominant C–H···Cl interactions through which adjacent molecules are interconnected leading to the formation of 1-D homochiral helices in the crystal lattice. In these interactions, the metal bound chlorine Cl1 acts as the H-bond acceptor while the aromatic carbon C29 of the ligand acts as the H-bond donor. The C–H···Cl H-bonding parameters are quite comparable to those of the reported C–H···Cl systems [21–27], see Table 6 for details. The helix propagates through crystallographic *c* axis. One full turn of the helix has a pitch distance of 13.24 Å and contains four molecules of the dinuclear copper complex. The path of the helix can be traced by following the H-bonds counter-clockwise around the fourfold screw axis of the helix. Here, the local chirality of the enantiopure ligand H_2L^2 ensures the supramolecular chirality, leading to the formation of only left handed helices at the supramolecular level (Fig. 5).

The solvent methanol molecule is H-bonded to the complex through two intermolecular O–H···O interactions. In addition, there is also an intramolecular H-bonding between the metal coordinated alcoholic and phenolic oxygens of the complex. The details of these H-bonding interactions are summarized in Table 6.

4. Concluding remarks

The synthesis, structural characterization and supramolecular chemistry of two new chiral dinuclear copper complexes containing Cu–Cl as the main H-bond acceptor has been discussed in this paper. The basic coordination sites of the ligands in these complexes are kept the same, minor structural changes have been introduced onto the ligand periphery. These small structural changes are found to have pronounced role in determining the supramolecular outcome of these dinuclear complexes. The chirality of the starting complexes ensures supramolecular chirality of the resulting metal-organic architectures, especially in the case of complexes **2**, which gave homochiral helices in its crystal lattice.

In the complexes described here, the metal bound chloride is found to act as strong H-bond acceptor and is pivotal in directing the supramolecular assembly. It was found that these complexes exhibit C–H···Cl–Cu, C–H···O and O–H···O H-bonding interactions in their crystal lattices resulting in quite different supramolecular architectures. It is interesting to note here that the main supramolecular structures in complexes **1** and **2** are formed solely through the interactions between the complex molecules, and no solvent molecules are involved in their formation. Such molecular building blocks are very important in terms of supramolecular chemistry, since they can be reliably employed in the synthesis of predictable supramolecular systems [2]. Finally, it has been shown that the tridentate chiral Schiff bases H_2L^1 and H_2L^2 derived from substituted salicylaldehydes and chiral amino alcohols are versatile ligands forming interesting H-bonded metallo-supramolecular architectures with copper.

Supplementary data

CCDC 681491 and 681492 contain the supplementary crystallographic data for compounds **1** and **2**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgments

We thank the Department of Science and Technology, Government of India, for financial support (Project No. SR/SI/IC-23/2007). The National X-ray Diffractometer facility at the University of Hyderabad by the Department of Science and Technology, Government of India, is gratefully acknowledged. We are grateful to University Grants Commission (UGC), New Delhi, for providing the infrastructure facility at the University of Hyderabad under University with Potential for Excellence (UPE) Grant. C.P.P. thanks University Grants Commission (UGC), New Delhi, for a fellowship.

ABSTRACT

The new pyrazole ligand 5-(2-hydroxyphenyl)-3-methyl-1-(2-pyridylo)-1*H*-pyrazole-4-phosphonic acid dimethyl ester (**2a**) has been used to obtain a series of platinum(II), palladium(II) and copper(II) complexes (**3a**–**7a**) as potential anticancer compounds. The molecular structures of the platinum(II) and copper(II) complexes **3a** and **6a** have been determined by X-ray crystallography. The cytotoxicity of the phosphonic ligand **2a** and its carboxylic analog **2b** as well as their complexes has been evaluated on leukemia and melanoma cell lines. Copper(II) complexes were found to be more efficient in the induction of melanoma cell death than the platinum(II) or palladium(II) complexes. Cytotoxic effectiveness of compound **7b** against melanoma WM-115 cells was two times better than that of cisplatin. The reaction of compound **5b** with 9-methylguanine has been studied.

1. Introduction

New, efficient therapy for cancer is the challenge for medicine of the XXI century. The clinical success of cisplatin and carboplatin as antitumor agents constitutes the most impressive contribution to the use of metals in medicine [1]. The severe problems associated with these anticancer metal-based drugs include serious toxicity and side-effects, and major difficulties concerning tumor cells resistance. New potent and selective antitumor drugs are urgently needed.

A new series of antitumor *cis*- and *trans*-platinum(II) complexes that have nonplanar heterocyclic amine ligands such as piperidine, piperazine and 4-picoline have been described [2,3]. Some of these complexes, especially the *trans* analogs, could overcome multifactorial cisplatin resistance in human ovarian cell lines. The possibility to overcome cisplatin resistance could be related to the ability of these compounds to form DNA lesions that are different from those formed by cisplatin. While cisplatin interacts with double-helical DNA forming preferentially 1,2-GG or AG intrastrand cross-links, the trans complexes cannot form in double-helical DNA intrastrand cross-links between adjacent purines. Trans complexes can cross-link two bases on the same strand only if they are separated by at least one intervening base, forming mostly 1,3-GNG cross-links, where N is adenine, cytosine or thymine. Importantly, these cross-links are stable in single-stranded DNA, while in double-stranded DNA some of these cross-links readily isomerize to the interstrand cross-links [4–7].

Novel metal-based complexes containing metal such as palladium, copper, ruthenium, gold and rhodium have been reported with promising chemotherapeutic potential and different mechanisms of action in comparison with the platinum based drugs [8–10].

Synthesis and structures of palladium(II) complexes containing pyrazole and thiocyanate ligands have been documented in the literature [11]. Thiocyanate complexes of palladium(II) have been applied in analytical determinations [12] and in chemotherapy [13].

Copper(II) plays an important biological role in all living systems as an essential trace element [14]. The copper(II) complexes with organic ligands have been used as analgesic, antipyretic, antiinflammatory and platelet antiaggregating agents. Recently, several reports have appeared in the literature describing the anticancer activity of copper(II) derivatives of many classes of nitrogen donors including thiosemicarbazone and imidazole [15]. There are also examples of copper complexes of ligands containing

doi:10.1016/j.poly.2008.12.013

α-diimino (N=C–C=N) moiety such as phenanthroline that can induce apoptosis [16] and 2-(4′-thiazolyl)benzimidazole that have antimicrobial activity [17]. Various anticancer copper(II) complexes occurred to alter the cell cycle and decrease the telomerase activity [18–21]. A wide variety of biological activities of copper(II) complexes can also be exemplified by recent finding of their antiamoebic activity against *Entamoeba histolytica* [22].

The interest in dinuclear copper(II) complexes with nitrogen-containing ligands is caused by their resemblance to the active sites of several copper-containing proteins. Besides that, the investigation of the magnetic properties of such complexes provides more insight into the relationship between their structural features and the strength of magnetic exchange interactions between the metal ions [23–29].

The introduction of the aromatic *N*-containing ligands as pyrazole, pyridine, imidazole and 1,10-phenanthroline and their derivatives whose donor properties are similar to the purine and pyrimidine bases to antitumor agents is drawing attention [30]. Complexes of pyrazole-type ligands have been used in catalysis [31,32], chemotherapy [33,34], electrochemical reduction of carbon dioxide [35], as metallomesogens [36,37] and as models of active sites in metalloenzymes [38].

In our previous papers we described the synthesis of 5-(2-hydroxybenzoyl)-3-methyl-1-(2-pyridinyl)pyrazol-4-carboxylic acid methyl ester **2b** and its complexes with platinum(II) (**3b**), palladium(II) (**4b**) and copper(II) (**5b** and **6b**) [39,40]. The cytotoxicity assay of the ligand **2b** and its complexes **3b**–**5b** were performed on L1210 and K562 leukemia cell lines. The complexes showed lower cytotoxicity than cisplatin and the platinum(II) (**3b**) and copper(II) (**5b**) complexes were found to be more efficient in the induction of leukemia cell death than the palladium(II) complex **4b**. Our investigation indicated that the antiproliferating activity of the platinum(II) (**3b**) and copper(II) (**5b**) complexes was partly due to the modulation of cellular differentiation. However, all these complexes **3b**–**5b** were not strong cellular differentiation inducers in comparison to cisplatin [40].

Here, we present the synthesis of new chelating ligand 5-(2-hydroxybenzoyl)-3-methyl-1-(2-pyridinyl)pyrazol-4-phosphonic acid dimethyl ester **2a** and its solid complexes with platinum(II), palladium (II) and copper(II) (**3a**–**7a**), the new copper(II) complex **7b** with carboxylic ligand **2b** as well as X-ray structures of the phosphonic platinum(II) and copper(II) complexes **3a** and **6a**, cytotoxic studies of both ligands **2a** and **2b** and their complexes performed on leukemia and melanoma cell lines and the reaction of copper(II) complex **5b** with 9-methylguanine (9MeG).

Synthesis of dimethyl 2-methyl-4-oxo-4*H*-chromen-3-yl-phosphonate (**1a**) [41], 2-methyl-4-oxo-4*H*-chromene-3-carboxylic acid methyl ester (**1b**) [42], 5-(2-hydroxyphenyl)-3-methyl-1-(2-pyridylo)-1*H*-pyrazole-4-carboxylic acid methyl ester (**2b**) [39] and its platinum(II) (**3b**), palladium(II) (**4b**) [40] and copper(II) (**5b** and **6b**) [39,40] complexes were described elsewhere.

2. Experimental

2.1. Materials

All substances were used without further purification. Potassium tetrachloridoplatinate(II), potassium tetrachloridopalladate(II), copper(II) chloride dihydrate and copper(II) perchlorate hexahydrate were purchased from Aldrich. Chloroform-d and DMSO–d_6 solvents for NMR spectroscopy were obtained from Dr. Glaser AG, Basel. Solvents for synthesis (acetone, diethyl ether, dimethylformamide, ethanol, ethyl acetate and methanol) were reagent grade or better and were dried according to standard protocols [43]. The melting points were determined using an Electrothermal 1A9100 apparatus and they are uncorrected. The IR spectra were recorded on a Pye-Unicam 200G Spectrophotometer in KBr and CsI. The ^{1}H NMR spectra were registered at 300 MHz on a Varian Mercury spectrometer. The MS data were obtained on a LKB 2091 mass spectrometer (70 eV ionisation energy). The MS-FAB data were determined on Finnigan Matt 95 mass spectrometer (NBA, Cs^+ gun operating at 13 keV). For the new compounds satisfactory elemental analyses were obtained using a Perkin–Elmer PE 2400 CHNS analyser.

Dimethyl 2-methyl-4-oxo-4*H*-chromen-3-yl-phosphonate (**1a**) [41], 2-methyl-4-oxo-4*H*-chromene-3-carboxylic acid methyl ester (**1b**) [42], 5-(2-hydroxyphenyl)-3-methyl-1-(2-pyridylo)-1*H*-pyrazole-4-carboxylic acid methyl ester (**2b**) [39] and its platinum(II) (**3b**), palladium(II) (**4b**) [40] and copper(II) (**5b** and **6b**) [39,40] complexes were prepared as described elsewhere.

2.2. Synthesis of the ligand

2.2.1. 5-(2-Hydroxybenzoyl)-3-methyl-1-(2-pyridinyl)-1H-pyrazol-4-phosphonic acid dimethyl ester (*2a*)

2-Hydrazinopyridin (109.1 mg, 1 mmol) in EtOH (5 ml) was added at room temperature to a solution of dimethyl 2-methyl-4-oxo-4*H*-chromen-3-yl-phosphonate **1a** (268.0 mg, 1 mmol) in EtOH (5 ml). The mixture was stirred for 24 h in room temperature. EtOH was evaporated under reduced pressure. Ethyl acetate was added to the oil product and it was left in 4 °C for 24 h. The solid white product was filtered off and dried. Yield: 179.0 mg (49.72%), mp: 101–105 °C. IR: ν_{max}/cm^{-1} 3170 (OH); 2940 (C–CH_3); 1607 (C=C, phenyl); 1228 (P=O); 1031 (O–CH_3); 807 (P–O) cm^{-1}. ^{1}H NMR ($CDCl_3$): δ = 6.88–7.53 (m, 8H, aromat.); 2.56 (s, 3H, CH_3); 3.52–3.63 (dd, 6H, O–CH_3). ^{13}C NMR ($CDCl_3$): δ = 14 (C–CH_3); 52.5 (O–CH_3); 107.3 (C–P); 154 (C–CH_3); 146 (C=C, pyrazole); 147.5 (C=N, pyridin); 151 (C–N); 155.5 (C–OH). ^{31}P NMR ($CDCl_3$): δ = 17.0. MS *m/z*: 358.0. *Anal.* Calc. for $C_{17}H_{18}N_3O_4P$ (359.322): C, 56.82; H, 5.05; N, 11.69. Found: C, 56.59; H, 4.95; N, 11.32%.

2.3. Synthesis of the complexes

2.3.1. Pt complex *3a*

The aqueous solution of $K_2[PtCl_4]$ (41.5 mg, 0.1 mmol, in 1 ml) was slowly added drop-wise to the methanolic solution of the ligand **2a** (36 mg, 0.1 mmol, in 5 ml). The mixture was stirred at room temperature for 1 h. The yellow solid that precipitated after 24 h was filtered off, washed with water and diethyl ether and dried to yield complex **3a**. Yield: 24.0 mg (38.4%), td: 120 °C. IR: ν_{max}/cm^{-1} 3401 (OH); 2955 (C–CH_3); 1612 (C=C, phenyl); 1226 (P=O); 808 (P–O); 1028 (O–CH_3); 493 (Pt–N) cm^{-1}. ^{1}H NMR (DMSO–d_6): δ = 6.67–7.53 (m, 8H, aromat.); 2.56 (s, 3H, CH_3); 3.38–3.50 (dd, 6H, O–CH_3). ESI MS(−): 624.1. *Anal.* Calc. for $C_{17}H_{18}N_3O_4PPtCl_2$ (625.306): C, 32.65; H, 2.90; N, 6.72. Found: C, 32.01; H, 2.43; N, 6.48%.

2.3.2. Pd complex *4a*

An aqueous solution of $K_2[PdCl_4]$ (33.0 mg, 0.1 mmol, in 1 ml) was slowly added drop-wise to a methanolic solution of ligand **2a** (36.0 mg, 0.1 mmol, in 5 ml). The mixture was left with stirring at room temperature for 1 h. After 24 h the resulting yellow crystals were filtered off, washed with water, diethyl ether and dried. Yield: 41.0 mg (77.6%), td: 345 °C. IR: ν_{max}/cm^{-1} 3399 (OH); 2955 (C–CH_3); 1611 (C=C, phenyl); 1226 (P=O); 1028 (O–CH_3); 811 (P–O); 495 (Pd–N) cm^{-1}. ^{1}H NMR (DMSO–d_6): δ = 6.60–7.60 (m, 8H, aromat.); 2.82 (s, 3H, CH_3); 3.44–3.53 (dd, 6H, O–CH_3). ESI MS(−): 535.9. *Anal.* Calc. for $C_{17}H_{18}N_3O_4PPdCl_2$ (536.648): C, 38.05; H, 3.38; N, 7.83. Found: C, 37.39; H, 3.57; N, 7.56%.

*2.3.3. Cu complex **5a***

A methanolic solution of $CuCl_2 \times 2H_2O$ (18.0 mg, 0.1 mmol, in 1 ml) was slowly added drop-wise to a solution of ligand **2a** in ethyl acetate (36.0 mg, 0.1 mmol, in 5 ml). The mixture was left with stirring at room temperature for 0.5 h. After 24 h the resulting green crystals were filtered off, washed with diethyl ether and dried. Yield: 39.0 mg (79.6%), td: 163.8 °C. IR: ν_{max}/cm^{-1} 3482 (OH); 2959 (C–CH_3); 1605 (C=C, phenyl); 1546 (C=N); 1239 (P=O); 1038 (O–CH_3); 799 (P–O); 508 (Cu–N) cm^{-1}. ESI MS(+): 457.0. *Anal.* Calc. for $C_{17}H_{18}N_3O_4PCuCl_2$ (493.774): C, 37.14; H, 3.42; N, 7.50; Cl, 15.99. Found: C, 40.75; H, 3.59; N, 8.09; Cl, 14.36%.

*2.3.4. Cu complex **6a***

Recrystallization done by the diffusion of diethyl ether (5 ml) into a DMF solution of **5a** (20.0 mg, 0.04 mmol, in 1 ml) gave a complex **6a**. Yield: 21.0 mg (91.3%), mp: 185 °C. IR: ν_{max}/cm^{-1} 3410, 3061 (OH); 2953 (C–CH_3); 1644 (C=O); 1600 (C=C, phenyl); 1233 (P=O); 1045 (O–CH_3); 797 (P–O); 419 (Cu–N) cm^{-1}. *Anal.* Calc. for $C_{20}H_{25}N_4O_5PCuCl_2$ (566.869): C, 42.38; H, 4.95; N, 9.88. Found: C, 41.59; H, 4.61; N, 9.74%.

*2.3.5. Cu complex **7a***

A methanolic solution of $Cu(ClO_4)_2 \times 6H_2O$ (26.5 mg, 0.07 mmol, in 2 ml) was slowly added drop-wise to a solution of ligand **2a** in ethyl acetate (51.3 mg, 0.14 mmol, in 5 ml). The mixture was refluxed 24 h. The resulting green crystals were filtered off, washed with diethyl ether and dried. Yield: 59.4 mg (84.9%), td: 285.4 °C. IR: ν_{max}/cm^{-1} 3371 (OH); 2956 (C–CH_3); 1614 (C=C, phenyl); 1230 (P=O); 1102 (ClO_4^-); 1033 (O–CH_3); 800 (P–O); 622 (ClO_4^-); 569 (Cu–N) cm^{-1}. ESI MS(+): 781.2. *Anal.* Calc. for $C_{34}H_{36}N_6O_{16}P_2CuCl_2$ (981.088): C, 41.62; H, 3.70; N, 8.57; P, 6.31; Cl, 7.23. Found: C, 41.32; H, 3.48; N, 8.24; P, 6.19; Cl, 7.21%.

*2.3.6. Cu complex **7b***

A methanolic solution of $Cu(ClO_4)_2 \times 6H_2O$ (30.9 mg, 0.08 mmol, in 2 ml) was slowly added drop-wise to a solution of ligand **2a** in ethyl acetate (51.5 mg, 0.16 mmol, in 5 ml). The mixture was refluxed 24 h. The resulting green crystals were filtered off, washed with diethyl ether and dried. Yield: 41.2 mg (56.1%), td: 268.8 °C. IR: ν_{max}/cm^{-1} 3383 (OH); 2951 (C–CH_3); 1723 (C=O); 1617 (C=C, phenyl); 1109 (ClO_4^-); 1048 (O–CH_3); 622 (ClO_4^-); 569 (Cu–N) cm^{-1}. ESI MS(+): 681.2. *Anal.* Calc. for $C_{34}H_{30}N_6O_{14}CuCl_2$ (881.094): C, 46.34; H, 3.43; N, 9.54; Cl, 8.05. Found: C, 46.01; H, 3.32; N, 8.88; Cl, 6.65%.

*2.3.7. Cu complex **8b***

A methanolic solution of 9-methylguanine (11.6 mg, 0.07 mmol, in 10 ml) was added to a methanolic solution of **5b** (31.0 mg, 0.07 mmol, in 5 ml). The mixture was refluxed 24 h. The resulting green solid was filtered off, washed with diethyl ether and dried. Yield: 19.9 mg (46.1%), mp: 202.9–203.4 °C. IR: ν_{max}/cm^{-1} 3493 (C–NH_2); 3125 (OH); 2924 (C–CH_3); 2849 (N–CH_3); 1713 (C=O); 1601 (C=C, phenyl); 1547 (C=N); 1011 (O–CH_3); 695 (Cu–N) cm^{-1}. UV–Vis: λ_{max} = 285.5 nm. MS-FAB (*m*/*z*): 686 (20%), $[LCu9MeGCl_2+DMSO+H]^+$; 681 (100%), $[LCu9MeGCl_2+4H_2O]$; 644 (10%) $[LCu9MeGCl_2+2H_2O]$; 623 (5%), $[LCu9MeGCl_2+H_2O]$; 537 (10%), $[LCu9MeG]^{2+}$; 443 (10%), $[LCuCl_2]$; 408 (10%), $[LCuCl]^+$; 372 (40%), $[LCu]^{2+}$. *Anal.* Calc. for $C_{23}H_{22}N_8O_4CuCl_2 \times H_2O$ (626.93): C, 44.06; H, 3.53; N, 17.87. Found: C, 44.29; H, 3.84; N, 17.36%.

2.4. Cell and cytotoxicity assay

2.4.1. Cell cultures

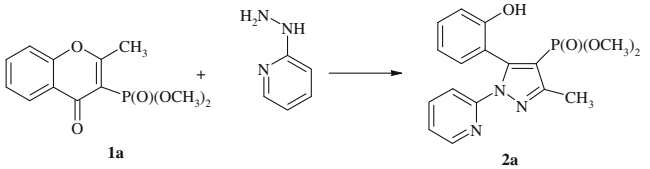
Human skin melanoma WM-115 cells as well as human leukemia promyelocytic HL-60 and lymphoblastic NALM-6 cell lines were used. Leukemia cells were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum and antibiotics (100 μg/ml streptomycin and 100 U/ml penicillin). For melanoma WM-115 cells Dulbecco's minimal essential medium (DMEM) instead of RPMI 1640 was used. Cells were grown in 37 °C in a humidified atmosphere of 5% CO_2 in air.

2.4.2. Cytotoxicity assay by MTT

Cytotoxicity of ligands **2a**, **b**, their complexes **3a**, **b**–**7a**, **b**, carboplatin and cisplatin was determined by the MTT [3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide, Sigma, St. Louis, MO] assay as described [44]. Briefly, after 46 h of incubation with drugs, the cells were treated with the MTT reagent and incubation was continued for 2 h. MTT-formazan crystals were dissolved in 20% SDS and 50% DMF at pH 4.7 and absorbance was read at 562 and 630 nm on an ELISA-plate reader (ELX 800, Bio-Tek, USA). The values of IC_{50} (the concentration of test compound required to reduce the cells survival fraction to 50% of the control) were calculated from concentration–response curves and used as a measure of cellular sensitivity to a given treatment. Ligands, complexes, carboplatin and cisplatin were tested for their cytotoxicity in a final concentration 10^{-7}–10^{-3} M. As a control, cultured cells were grown in the absence of drugs. Data points represent means of at least 12 repeats ± S.D.

2.5. X-ray measurements

A crystal of **3a** suitable for X-ray crystallography was selected by means of a polarization microscope, mounted on the tip of a glass fiber, and investigated on a Nonius KappaCCD diffractometer (Mo Kα radiation, λ = 0.71073 Å). A multi-scan absorption correction of the reflection intensities was performed with SADABS [45]. The structure was solved by direct methods with SHELXS-97 [46] and refined by full-matrix least-squares calculations based on F^2 (SHELXL-97) [47]. All non-hydrogen atoms are refined anisotropically. The C-bound hydrogen atoms are riding on their parent atoms while the O-bound hydrogen atoms were located from the electron density map.



A crystal of **6a** suitable for X-ray crystallography was selected by means of a polarization microscope, mounted on the tip of a glass fiber, and investigated on a Nonius KappaCCD diffractometer (Mo Kα radiation, λ = 0.71073 Å). The structure was solved by direct methods with SIR-97 [48] and refined by full-matrix least-squares calculations based on F^2 (SHELXL-97) [47]. All non-hydrogen atoms are refined anisotropically. The hydrogen atoms are riding on their parent atoms.

3. Results and discussion

3.1. Preparation of the ligands and their complexes

In the reaction of dimethyl 2-methyl-4-oxo-4*H*-chromen-3-ylphosphonate [41] with 2-hydrazinopyridine in methanolic solution we have obtained the new ligand **2a** (Scheme 1).

First we have investigated this reaction with the phosphonic derivative **1a** in an NMR tube. The progress of the conversion of **1a** to **2a** was monitored by ^{31}P NMR spectroscopy and by thin layer

Scheme 1. The synthesis of new highly substituted pyrazole ligand **2a**.

chromatography. In the ^{31}P NMR spectrum (Fig. 1) obtained within one hour after starting the reaction, the signal of one new product at 17.20 ppm was observed, in addition to the signal of the substrate **1a** at 17.91 ppm. The intensity of this signal at 17.20 ppm gradually increased until only traces of substrate were left and we observed only one signal in the reaction mixture, what corresponds to only one product formed during this reaction. According to literature data hydrazinopyridine has only one dissociation constant $K_1 = 7.24$ for N2 and this nitrogen atom is responsible for nucleophilic attack [49]. The N1 does not have nucleophilic activity. Therefore, the first step of reaction is nucleophilic attack of hydrazinopyridine N2 atom at the chromone derivative **1a** C2 atom. The second step of the reaction is the opening of the γ-pyrone ring and cyclization to pyrazole derivative (Scheme 2). This reaction proceeds according to the general mechanism described for the reaction of chromones with nitrogen nucleophiles [50,51] such as hydrazines [52–54]. A multimilligram reaction of **1a** and **1b** with one equivalent of 2-hydrazinopyridine gave the same products as in the NMR tube.

The substituted pyrazoles **2a** and **2b** (Fig. 2) were used as the ligands L in the formation of the $MLCl_2$ complexes with platinum(II), palladium(II) and copper(II) ions (M) (Scheme 3 and 4). Complexes **3b**, **4b** and **5b** were obtained to compare the influence of the functional group on cytotoxic activity. The synthesis of the carboxylic ligand **2b** and its complexes **3b**, **4b**, **5b** and **6b** are described elsewhere [39,40].

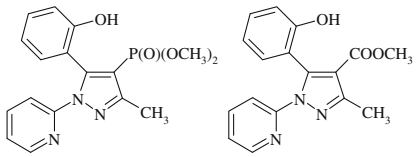


Fig. 2. Structures of ligands **2a** and **2b**.

Complexes **3a** and **4a** were obtained by adding aqueous solution of K_2PtCl_4 or K_2PdCl_4, respectively, to the methanolic solution of the ligand **2a** (Scheme 3). The copper(II) complexes were obtained in molar ratio L:Cu 1:1 (**5a** and **5b**) by adding methanolic solution of $CuCl_2 \times 2H_2O$ or 2:1 (**7a** and **7b**) by adding methanolic solution of $Cu(ClO_4)_2 \times 6H_2O$ to the solution of ligands **2a** or **2b** in

Scheme 4. Synthesis of copper(II) complexes.

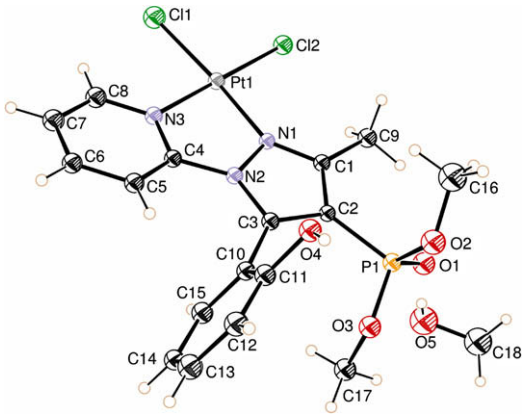

Fig. 3. The molecular structure of platinum(II) complex **3a**.

ethyl acetate (for complex **5a**) or methanol (for complexes **5b**, **7a** and **7b**). In one of our earlier works [39] we postulated that the interaction of ligand **2b** with copper(II) ions in solution might be related to interaction of the phenol 2-hydroxy group with metal ion. The ionisation of this group introduces an additional negative charge and enhances the donor properties of the potential nitrogen functions. As a result copper(II) complexes in two different L:Cu molar ratios, 1:1 or 2:1, could be formed (Scheme 4). Complexes **5a** and **5b** (L:Cu molar ratio: 1:1) occured to be neutral and complexes **7a** and **7b** (L:Cu molar ratio: 2:1) occured to be ionic.

Recrystallization of compounds **5a** and **5b** by dissolving in DMF and the diffusion of diethyl ether into the solution gave complexes **6a** and **6b**, respectively. All complexes were recrystallized but, unfortunately only compound **3a**, **6a** and **6b** yielded crystals suitable for X-ray diffraction. **6b** structure was described in our recent paper [40]. The structures **3a** and **6a** are presented here.

Knowledge of the type of interactions and the structural environment of metal complexes in relation to potential targets and other biomolecules has helped to establish binding patterns and can assist in the rational design of drugs. In this respect, interactions with DNA bases in particular have been investigated in detail resulting in a growing body of structural data on metal-nucleobase adducts [55]. Here, we have studied the reaction of complex **5b** with 9-methylguanine model DNA bases and we have obtained a complex **8b**. The compound **5b** was chosen basing on the fact that it was one of the most active among studied compounds. In this reaction we have observed the change of colors from yellow (complex **5b**) to green (complex **8b**), what can suggest occurring the pentacoordinated compound. Scheme 5 shows a probable structure of complex **8b** that has been proposed on the basis of complex **6a** structure (Fig. 4). It is possible that 9-methylguanine could coordinate to complex **5b** similar to DMF molecule.

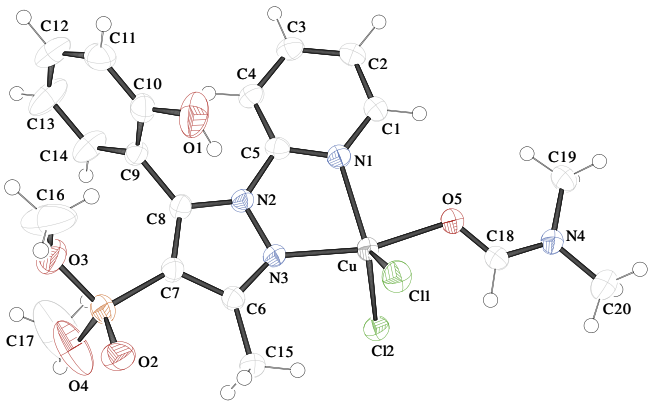

Fig. 4. Molecular structure of Cu(II)–complex **6a**.

Table 1
IR data (ν, cm^{-1}) for ligand **2a**, its complexes **3a–7a** and complex **7b**.

ν (cm^{-1})	C–OH	C=C, phenyl	P=O	C=O	P–O	O–CH_3	C–CH_3	M–N
2a	3170	1607	1228		807	1031	2940

7b	3383	1617		1723		1048	2951	569

3.2. Structural studies. Spectroscopic characterization of ligands **2a** and **2b** and their complexes

Spectroscopic characterization of ligand **2b** and its complexes with platinum(II) (**3b**), palladium(II) (**4b**) and copper(II) (**5b** and **6b**) have been described in our previous papers [39,40].

The assignments of the most important bands in the IR spectra for ligand **2a** and the platinum(II), palladium(II) and copper(II) complexes **3a–7a** and **7b** are listed in Table 1.

The IR-band at 3170 cm^{-1} of the free ligand is assigned to hydroxy group of the phenyl ring. Shift of this band to lower energy may indicate the presence of hydrogen bond OH···O in the ligand's structure. This band shifts to higher energy for the complexes. The IR spectra of ligand **2a** and complexes show a large number of absorptions in the 797–1723 cm^{-1} range, which can be assigned to the different vibration modes of phosphonic and carboxylate function. The characteristic band at 2940 cm^{-1} of the methyl group of the free ligand which is assigned to the C–H vibration shifts to higher energy for the complexes. The new bands at about 493–569 cm^{-1} in complexes may correspond to the metal–nitrogen vibrations involving the N-atoms of the pyrazole ring [56]. The new bands at 3061 and 1644 cm^{-1} in **6a** complex may correspond to the C–OH and C=O vibration, respectively, involving the atoms of DMF. The bands observed at 1102 and 622 cm^{-1} in the spectrum of **7a** and 1109 and 622 cm^{-1} in the spectrum of **7b** are characteristic for non-coordinated perchlorate ions [57].

The selected chemical shifts assigned in the ^1H NMR spectra of the ligand **2a** and its platinum(II) and palladium(II) complexes **3a** and **4a** are shown in Table 2. The spectra are quite similar.

The ligand **2a** and its complexes **3a** and **4a** show signals in the range δ 2.56–2.82 ppm for the methyl groups of pyrazole ring, 3.38–3.63 for O–CH_3 of phosphonic groups and 6.60–7.60 for phenyl groups. The ^1H NMR spectra of copper(II) complexes could not be measured due to their paramagnetism.

The main peaks in ESI MS spectra of copper(II) complexes were observed for cations without chlorido or perchlorido ligands.

Occurring of the complex **8b** has been confirmed by IR, UV–Vis, FAB-MS and elemental analysis. Some characteristic IR vibrations for the complex **8b** are given in experimental section. Significant differences in the IR spectra of complex **8b** have been observed in comparison with that of complex **5b**. The latter shows a strong band at 1717 cm^{-1} due to ν(C=O). This band is shifted by 4 cm^{-1} to lower frequencies in the spectra of complex **8b** [57]. Beside this we have observed the new bands characteristic for 9-methylguanine. In UV–Vis spectrum we have observed the change of λ_{max} from 287 nm for complex **5b** to 285.5 for complex **8b**.

The FAB mass spectrum of **8b** recorded in positive ion mode contains a peak at m/z 686 due to $[LCu9MeGCl_2+DMSO+H]^+$ ion and a strong peak at m/z 681(100%) attributed to $[LCu9MeGCl_2+4H_2O]$. The peaks at m/z 537 and 443, have been assigned to $[LCu9MeG]^{2+}$ and $[LCuCl_2]$, correspondingly. The purity of complex **8b** has been confirmed by elemental analysis.

Table 2
^1H NMR spectra of ligand **2a** and the corresponding complexes with platinum(II) (**3a**) and palladium(II) (**4a**) metal ions (chemical shifts are given in ppm).

	C–CH_3	O–CH_3	Aromaticity
2a	2.56	3.52–3.63	6.88–7.53
3a	2.56	3.38–3.50	6.67–7.53
4a	2.82	3.44–3.53	6.60–7.60

3.2.1. X-ray structure of platinum(II) complex **3a**

The molecular structure of complex **3a** is shown in Fig. 3, and selected bond lengths and angles are given in Table 1S. The monomeric complex **3a** contains the bidentate pyridine–pyrazole ligand and two chlorido ligands in *cis*-position. **3a** exhibits a distorted tetragonal planar configuration at the Pt(II) centre; the sum of the angles around Pt1 is exactly 360.00°. While the two Pt–Cl bonds are equal (Pt1–Cl1 2.2875(12), Pt1–Cl2 2.2871(13) Å), both Pt–N bond lengths differ slightly (Pt1–N1 2.020(3), Pt1–N3 2.030(4) Å). The angle N1–Pt1–N3 (80.11(13)°) of the chelate ligand is the smallest, then follows the angle Cl1–Pt1–Cl2 (86.38(5)°), whereas the two angles Cl1–Pt1–N3 = 94.00(9)° and Cl2–Pt–N1 = 99.51(11)° are significantly larger than 90°, because of the small angle of the *N*,*N*′-chelate system.

The five- and six-membered rings of pyridine–pyrazole lie in the same plane together with the substituents (C9, C10 and P1) at the pyrazole.

The phenolic substituent at atom C3 is bent out from this molecular plane, because of steric hindrance and the OH group at C11, which forms the hydrogen bridge O4–H4–O5′ (2.603(6) Å and 174°) with the O atom of a CH_3OH molecule associated with **3a**.

The phosphite substituent at C2 shows a distorted tetrahedral configuration at the P(III) centre with two similar P–O distances (P1–O2 1.571(4), P1–O3 1.557(4) Å) but a short P1–O1 distance (1.459(4) Å) indicating the P=O double bond of the P(III) ester function.

3.2.2. X-ray structure of copper(II) complex **6a**

The molecular structure of complex **6a** is shown in Fig. 4, and selected bond lengths and angles are given in Table 2S. The monomeric Cu(II) complex **6a** with the coordination number 5 for the central Cu(II) contains the bidentate pyrazole ligand, two chlorido ligands and an O-coordinated DMF solvent molecule. **6a** exhibits a distorted trigonal bipyramidal configuration at the Cu centre, whereby the two chlorido ligands Cl1 and Cl2 as well as the N1 atom of the chelate system form the equatorial plane, whereas the second N atom N3 together with the O5 atom of the DMF molecule lie in the axial positions. The Cu–Cl bonds differ more (Cu–Cl1 2.3677(9), Cu–Cl2 2.2982(9) Å) than in a similar complex published earlier by us [40], and the equatorial Cu–N bond (Cu–N1 2.101(2) Å) is surprisingly longer than the axial Cu–N3 bond (2.006(2) Å).

The Cu–O5 bond length (1.962(2) Å) is the shortest observed in **6a** around Cu, but is similar with those found in related Cu(II) complexes. The distortion of the trigonal bipyramide results from the three different angles within the trigonal plane (Cl1–Cu–Cl2 113.98(3), Cl1–Cu–N1 114.15(7), Cl2–Cu–N1 131.87(7)° and from the non-linear angle N3–Cu–O5 164.91(9)°).

The angle N1–Cu–N3 of 77.85(8)° is the smallest one observed in the trigonal bipyramide, and the other are larger than 90°C (Cl1–Cu–N3 96.83(7), Cl2–Cu–N3 96.02(6), Cl1–Cu–O5 92.38(7), Cl2–Cu–O5 91.09(6)°) with the only exception of N1–Cu–O5 angle (87.49(9)°).

The phosphite substituent at C7 shows a distorted tetrahedral configuration at the P(III) centre with two similar P–O distances (P–O3 1.551(3), P–O4 1.545(4) Å) but a short P–O2 distance (1.464(3) Å) indicating the P═O double bond of the P(III) ester function.

The bidentate heterocycle together with the connected atoms C9 and P of the substituents is nearly planar, with a maximum deviation from planarity of 1° (at C4).

The only exception is the phenyl substituent which shows the distortion angle N2–C8–C9–C10 of 70.2(4)°.

A view to the crystal packing of **3a** shows that the associated MeOH molecule forms two short and almost linear O–H–O bridges (O4–H4–O5′ 2.603(6) Å/173(7)°; O5–H5–O1′ 2.689(6) Å/174(6)° resulting in a polymeric chain shown in Fig. 5. Compound **6a**, however, forms a dimmer because of the hydrogen bonds (O1–H1–O2′ 3.009(2) Å/137.5(2)°) which are longer and significantly bent (Table 3).

3.3. Biological activity

In our recent publication [40] we presented the cytotoxicity assays of the ligand **2b** and its complexes **3b**–**5b** performed on L1210 and K562 leukemia cell lines. Here we present biological studies of these compounds as well as newly synthesized ligand **2a** and its complexes on human acute leukemia HL-60 and NALM-6 and melanoma WM-115 cell lines in order to compare the influence of the functional group on cytotoxic activity (Table 4). Compounds **6a** and **6b** were not tested for biological activity, as they were obtained only to establish X-ray structures. It can be supposed that their cytotoxicity would be strictly related to the presence of DMF molecule in their structure and DMF is highly cytotoxic by itself. That is why the test of biological activity of the clear complexes **5a** and **5b** without DMF molecule was only provided. Cisplatin and carboplatin were used as the reference compounds. Ligands **2a** and **2b** have very low cytotoxic activity. Most phosphonic compounds exhibited lower cytotoxicity than carboxylic analogs. The cytotoxic effect of platinum(II) and palladium(II) complexes are rather low. All copper(II) complexes exhibited relatively high cytotoxic activity with the IC_{50} values in micromolar range against leukemia cell

Table 4
IC_{50} values (in μM) of the ligands **2a** and **2b** and their complexes.

Compound	HL-60	NALM-6 IC_{50}[a]	WM-115
2a	716.5 ± 28.9	875.1 ± 119.9	>1000
2b	649.4 ± 74.4	>1000	>1000
3a	613.1 ± 22.2	766 ± 40.4	549.0 ± 68.5
3b	58.1 ± 2.2	55.1 ± 3.8	76.7 ± 13.4
4a	610.2 ± 40.8	804.2 ± 57.2	591.3 ± 51.9
4b	133.9 ± 28.8	413.7 ± 40.4	483.6 ± 22.3
5a	56.96 ± 4.97	49.88 ± 2.23	90.5 ± 11.69
5b	48.9 ± 1.7	54.1 ± 2.4	93.4 ± 5.0
7a	43.9 ± 3.6	47.6 ± ± 4.6	81.7 ± 3.2
7b	6.5 ± ± 0.3	40.7 ± 5.5	8.0 ± 0.3
Cisplatin	0.8 ± 0.1	0.7 ± 0.3	18.2 ± 4.3
Carboplatin	4.3 ± 1.3	0.7 ± 0.2	422.2 ± 50.2

[a] IC_{50} – concentration of a tested compound required to reduce the fraction of surviving cells to 50% of that observed in the control, non-treated cells. Mean values of IC_{50} (in μM) ± S.D. from four experiments are presented.

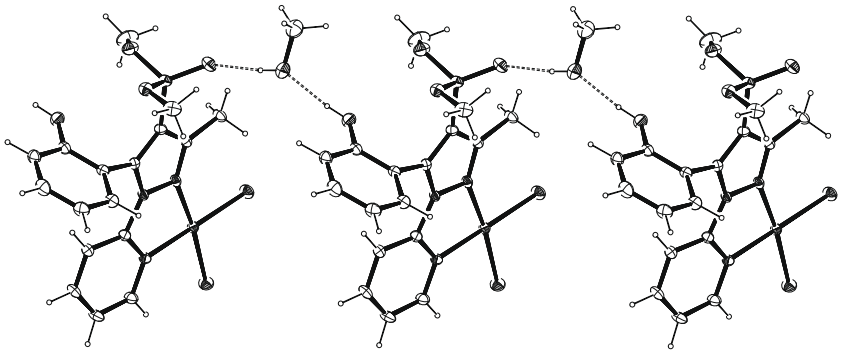

Fig. 5. Part of the crystal packing of **3a** with the intermolecular hydrogen bridges with MeOH.

lines although their cytotoxic effectiveness was lower in comparison to cisplatin and carboplatin. The copper(II) complex **7b** exhibited the highest cytotoxic activity with IC_{50} values in the range of 6.5 μM for HL-60 and 8.0 μM for WM-115 cell lines. So, cytotoxic effectiveness of compound **7b** against melanoma WM-115 cells was two times better than that of cisplatin. The result strongly support the view that the observed cytotoxicity can be confidently attributed to the presence of the metal centres.

4. Conclusions

In this paper, we presented the synthesis and investigation of highly substituted phosphonic pyrazole ligand and its complexes with platinum(II), palladium(II) and copper(II). Cytotoxic activity of these new compounds was compared with activity of their carboxylic analogs in order to assess the influence of chemical groups on cytotoxic activity of the compounds.

The new phosphonic ligand **2a** was obtained in the reaction of dimethyl 2-methyl-4-oxo-4*H*-chromen-3-yl-phosphonate with 2-hydrazinopyridine in methanolic solution.

By monitoring the reaction by ^{31}P NMR spectroscopy we observed only one product after the opening of the γ-pyrone ring and cyclization to pyrazole derivative. This is in accordance to the fact that 2-hydrazinopyridine has only one dissociation constant for N2 and this nitrogen atom is responsible for nucleophilic attack at the chromone derivative C2 atom.

The highly substituted phosphonic pyrazole **2a** was used as ligand for the synthesis of novel neutral platinum(II), palladium(II) and copper(II) complexes **3a–7a**. Phosphonic compounds were compared with previously synthesized carboxylic analogs **2b**–**7b**, whose cytotoxic assay had been performed on L1210 and K562 leukemia cell lines. Copper(II) complexes with both phosphonic and carboxylic ligands were synthesized in 1:1 and 2:1 molar ratio. The structure of the ligands and their metal complexes was confirmed by spectral and elemental analyses. The molecular structures of phosphonic complexes of platinum(II) **3a** and copper(II) **6a** were confirmed by X-ray analysis. The complexes exhibit distorted tetragonal planar configuration and trigonal bipyramidal configuration at the platinum(II) and copper(II) centres, respectively.

Studies on the cytotoxicity evaluated on leukemia and melanoma cell lines showed that in most cases carboxylic compounds have higher activity than that of phosphonic analogs. Cytotoxic effectiveness of compound **7b** against melanoma WM-115 cells was two times better than that of cisplatin. Copper(II) complexes were more active in the induction of melanoma cell death than the platinum(II) and palladium(II) complexes. Higher cytotoxic activity of investigated copper(II) complexes suggests that the mechanism of actions of these compounds may differ from the mechanism of action of platinum(II) or palladium(II) complexes. The reaction of complex **5b** with 9-methylguanine has been investigated and we have obtained a new compound **8b** of the formula $LCu9MeGCl_2$.

ABSTRACT

It is of interest that the hydrous 3D metal-organic framework (MOF) $\{[Pb_2(fum)_2(H_2O)_4]\cdot 2H_2O\}_n$ (**1**) has been synthesized by the reaction of the fum dianion with the lead(II) ion (fum = fumarate) in the presence of pyrazole, while the anhydrous 3D MOF $[Pb(fum)]_n$ (**2**) is obtained by the reaction of the fum dianion with the lead(II) ion in the presence of pyrazine. These complexes were further characterized by FT-IR spectroscopy, thermogravimetric analysis (TG), X-ray analysis and solid state photoluminescence spectra. The arrangement of the ligands displays a coordination gap around the Pb atom, occupied possibly by a stereoactive lone pair of electrons on lead(II), with the coordination around both the eight-coordinated lead atom in **1** and six-coordinated lead atom in **2** exhibiting a hemidirected geometry. The fum ligand shows different ligation behavior toward the lead(II) ions in these complexes. These compounds exhibit photoluminescence with the maximum emission located in the UV region.

1. Introduction

Recently, the design and syntheses of metal-organic frameworks (MOFs) has been an impetus for supramolecular chemistry and property-oriented crystal engineering. Yaghi, Williams, Kitagawa, Férey, Chen and co-workers have worked in the area of coordination polymers and considered diverse problems restricting the development of porous MOFs, and successfully developed a strategy to design porous materials [1–3]. However, most of the work so far has been focused on d-block transition metal-organic frameworks; main group metal-organic frameworks remain less developed. In contrast to transition metal ions, the Pb(II) ion also has a tendency to form polynuclear complexes and the potential to provide a stable framework structure [4]. In particular, the Pb(II) ion possesses evidence of coordination sphere distortions as a consequence of the presence of a $6s^2$ lone-pair. The intrinsic features of Pb(II), the presence of a $6s^2$ electron configuration, cause chemists' intense interest in coordination chemistry, photophysics and photochemistry [5]. So, the coordination chemistry of lead(II) has recently been investigated and frequently discussed with regard to the coordination and stereoactivity of the valence shell lone electron pair, in addition to its great potential use to extract this harmful metal from the environment [6–11]. There have been some well-defined cluster-type lead(II) polymers reported, such as $Pb_4(OH)_4$, $Pb_6O(OH)_6$, $Pb_6(OH)_4O_4$, Pb_8O_8 [4]. Few lead(II) carboxylate-bridged complexes with layered or 3D network structures have been reported [12–16]. The rigid fum ligand is a suitable candidate for assembling complexes with novel structures and functional properties [17]. The rigid fum ligand is expected to more likely form novel hybrid materials with porous 3D network architectures through the self-assembly with the lead(II) ion. To the best of our knowledge, there are no lead(II) coordination polymers based on the rigid fum ligand reported as yet.

In the present paper, we report the syntheses and characterization of two lead(II) MOFs, $\{[Pb_2(fum)_2(H_2O)_4]\cdot 2H_2O\}_n$ (**1**) and $[Pb(fum)]_n$ (**2**), based on the fum ligand. This is a case that reveals some N-containing compounds, such as pyrazine and pyrazole, may have an influence on the structure of some MOFs in this system. Photoluminescence properties of the two complexes have been examined in the solid state at room temperature.

2. Experimental

2.1. Materials and characterization

All the reagents were used as purchased. Elemental analyses (C, H and N) were carried out on a 240 °C Elemental analyzer. Infrared spectra (400–4000 cm^{-1}) were recorded from KBr pellets in a Magna 750 FT-IR spectrophotometer. The solid state emission spectra of the compounds were recorded using a 48000DSCF fluorescence spectrometer.

2.2. Synthesis of $[Pb_2(fum)_2(H_2O)_4] \cdot 2H_2O_n$ (**1**)

Pyrazole (0.0136 g, 0.2 mmol) was dissolved in water (8 ml) and then a solution of $Pb(NO_3)_2 \cdot 4H_2O$ (0.0333 g, 0.1 mmol) in water (6 ml) was added. To this solution a mixture of H_2fum (0.0116 g, 0.1 mmol) and NaOH (0.5000 mol/l, 0.40 ml) in water (20 ml) was added and then filtered. The filtrate (pH 4.1) was kept at ambient temperature for several days and colorless block crystals were formed. They were filtered and washed with methanol and dried in vacuum (yield: 42.1% based on H_2fum). *Anal.* Calc. for: $C_8H_{16}O_{14}Pb_2$: C, 12.80; H, 2.15. Found: C, 12.68; H, 2.11%.

2.3. Synthesis of $[Pb(fum)]_n$ (**2**)

Pyrazine (0.0160 g, 0.2 mmol) was dissolved in water (8 ml) and then a solution of $Pb(NO_3)_2 \cdot 4H_2O$ (0.0330 g, 0.2 mmol) in water (6 ml) was added whilst stirring. To this solution a mixture of H_2fum (0.0116 g, 0.1 mmol) and NaOH (0.5000 mol/l, 0.40 ml) in water (20 ml) was added. The filtrate (pH 6.1) was kept at ambient temperature for several days and white crystals were formed (47.3% based on H_2fum). *Anal.* Calc. for $C_4H_2O_4Pb$: C, 14.95; H, 0.63. Found: C, 14.77; H, 0.59%.

2.4. X-ray single-crystal structure determination

Crystallographic data for the two compounds were collected at 293(2) K with a Siemens SMART CCD diffractometer using graphite-monochromated (Mo Kα) radiation ($\lambda = 0.71073$ Å), with ψ and ω scans mode. The structures were solved by direct methods and refined by the full-matrix least-squares on F^2 method using the SHELXL-97 program [18]. Intensity data were corrected for Lorenz and polarization effects and an empirical absorption correction was performed. All non-hydrogen atoms were refined anisotropically. All the hydrogen atoms were added geometrically and allowed to ride on their respective parent atoms. The contribution of these hydrogen atoms was included in the structure factor calculations. Details of the crystal data, collection and refinement are listed in Table 1.

3. Results and discussion

3.1. Preparation

It is of great interest that the hydrous lead(II) fumarate **1** was obtained in the presence of pyrazole, while the anhydrous lead(II) fumarate **2** was obtained in the presence of the pyrazine. It should be noted that the hydrous compound **1** was also obtained when the lead(II) ion reacts only with the fum ligand without the presence of pyrazole, but the anhydrous complex 2 cannot be obtained without the presence of pyrazine. These facts indicate that some N-containing compounds, such as pyrazine and pyrazole, may have great influence on the structures of some MOFs in this system, which may be attributed to the different initial pH values of the mixed reaction solution (4.1 for **1** and 6.1 for 2).

3.2. Structural description of **1**

The hydrous lead(II) fumarate $\{[Pb_2(fum)_2(H_2O)_4] \cdot 2H_2O\}_n$, **1**, has a 3D porous structure with an asymmetric unit of 24 non-hydrogen atoms. There are two crystallographically equivalent hemidirected Pb^{2+} ions, two fum anions, four coordinated water molecules and two lattice water molecules in the asymmetric unit (Figs. 1 and 3). From a chemical point of view, the coordinated water in this formula cannot be replaced by oxygen or hydroxyl groups. The fum anion acts as a tetradentate ligand and exhibits

Scheme 1. Coordination modes of the complexes. g: **1**; h: **2**.

only one coordination mode (Scheme g; Fig. 2A). The lead ion is eight-coordinated (PbO_8), two oxygens are from the coordinated water molecules and six are from four different fum anions. Four of these oxygens (two O1 and two O2) have μ_2 connections, linking one Pb(1) with two different Pb(1) atoms. Two Pb atoms are linked by two μ-O atoms of fum ligands, forming two planar four-membered rings Pb1–O1–Pb1A–O1A and Pb1–O3–Pb1A-O3A. The two four-membered rings link each other to form a 1D Pb–O chain through a corner-sharing Pb polyhedron along the *a*-axis (Fig. 2B), where the angle between the two neighboring planes is 74.99°. The Pb_2O_2 units are bridged by two fum ligands along the *a*-axis and by two other fum ligands along the *c*-axis, yielding a 3D framework with 1D channels running parallel to the *a* and *b*-axes as shown in Fig. 3A and B, respectively. The guest water molecules, (O3W), which do not show any covalent interactions, fill in the channel. Thus, the $Pb(1)O_8$ polyhedral share edges with each other forming a dimeric $Pb(1)_2O_{14}$ unit. The Pb–O bond lengths are in the range 2.542(4)–2.893(6) Å (Table 2). The dimers are connected to each other by one of the two fum ligands into a 2D Pb–O–Pb layer. The layers are further connected by the other fum ligand, forming a 3D porous structure (Fig. 3). Hydrogen bonds exist extensively in **1**, which further stabilize the 3D metal-organic framework structure. The details of the hydrogen bonds are listed in Table 3.

3.3. Structural analysis of **2**

The anhydrous complex Pb(fum) adopts a 3D structure wherein 1D channels are arranged along the *c* direction (Fig. 6), while the reported complex lead(II) maleate (PbMAL) exhibits a quite different 2D layered structure [19]. This fact indicates that the rigid fum ligand is more likely to form a 3D porous structure with the lead(II) ion than the flexible maleate ligand. The single independent lead atom is bonded to six oxygen atoms [with distances ranging from 2.399(5) to 2.811(4) Å] (Table 2), belonging to five symmetry-equivalent deprotonated fumarate ligands, as seen in Fig. 4. The

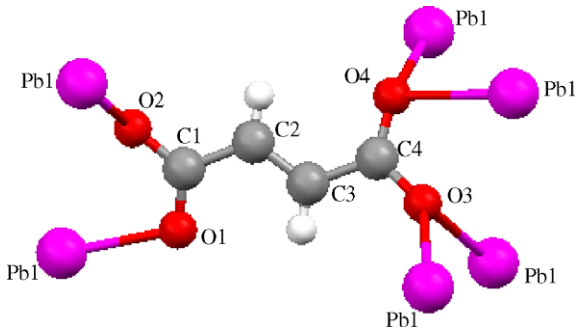

Fig. 5. Coordination mode of the tetradentate fum ligand in **2**.

coordination sphere around the Pb^{2+} is asymmetric and hemidirected. It is of interest that the fumarate units in this structure lie parallel, with a nearest C2C3 distance of 3.721 Å, which indicates that there are ππ stacking interactions between the nearest fumarate dianions. Intramolecular hydrogen bonds exist between the C3 and O1 atoms, with a C3–H3O1 distance of 2.789(10) Å. Each fum ligand is bonded to six lead atoms: O1 and O2 are each bonded to one lead atom; whereas O3 and O4 are each bonded to two lead atoms (Scheme h, Fig. 5). This coordination mode is observed for the first time for the fum ligand. Thus, a 14-membered macrometallocycle is formed as depicted in Fig. 4.

3.4. Coordination geometry of lead(II)

Researchers have found that the coordination geometry of the PbO_n polyhedral in Pb(II) compounds is hemidirected for low coordination numbers (2–5) and holodirected for high coordination numbers (9, 10), and either a hemidirected or holodirected stereochemistry is found for intermediate coordination numbers (6–8) [20–21]. It has been found through *ab* initial molecular orbital studies of Pb(II) complexes in the gas-phase that a hemidirected geometry occurs if the ligands are hard, the ligand coordination number is low and attractive interactions exist between the ligands [22–23]. For the PbO_8 polyhedra in **1**, a hemidirected geometry is exhibited (Fig. 1B). The six-coordinated Pb(II) cations in **2** also exhibit a hemidirected geometry (Fig. 4B).

3.5. FT-IR spectra

The FT-IR spectrum of compound **1** shows broad peaks in the range of 3600–3200 cm^{-1} due to the existence of water molecules. In the middle of the stretching vibrations, IR results are commonly employed to distinguish the coordination modes of carboxylate

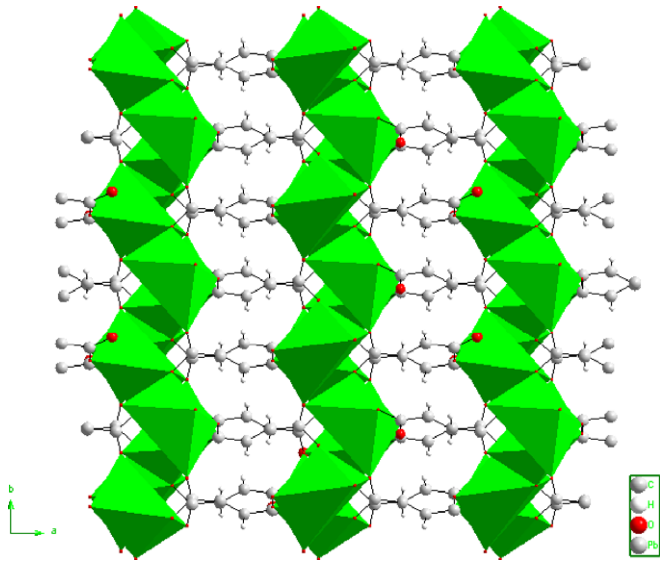

Fig. 6. 3D MOF viewed along the c direction.

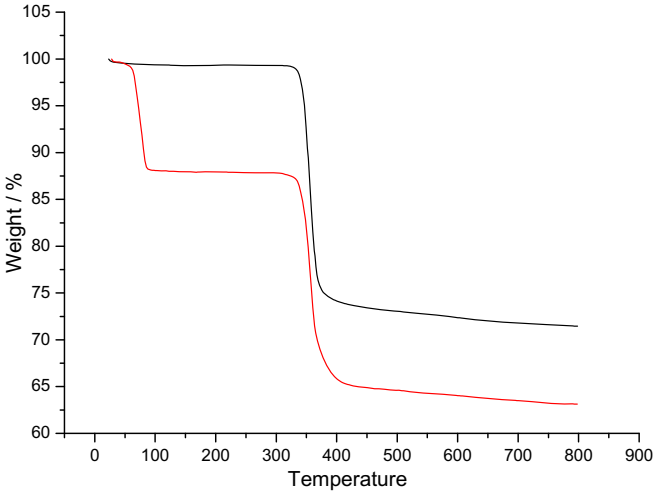

Fig. 7. TG curves of the complexes (**1**: red; **2**: black). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

groups. A correlation of the carboxylate coordination mode to metal ions is usually made by examining the difference $\Delta\nu(\mathrm{COO}) = \nu_{as}(\mathrm{COO}) - \nu_{s}(\mathrm{COO})$ of the compound [24]. The vibrations of $\nu_{as}(\mathrm{COO})$ and $\nu_{s}(\mathrm{COO})$ are at 1523 and 1377 cm^{-1} for **1**, and at 1554, 1532 and 1378 cm^{-1} for **2**, respectively. These facts indicate that the carboxylate groups of the fum ligand exhibit different coordination modes in these two complexes. In all these cases, the results of the X-ray analysis allowed us to assign unambiguously the binding modes of the carboxylate groups.

3.6. Thermogravimetric analysis

To study the thermal stability of the compounds, thermogravimetric analysis (TG) was performed on polycrystalline samples under a nitrogen atmosphere in flowing N_2 with a heating rate of 10 °C min^{-1} (Fig. 7).

The thermogravimetric analysis (TGA) of **1** revealed two distinct thermal events. The first step is ascribed to the gradual loss of both

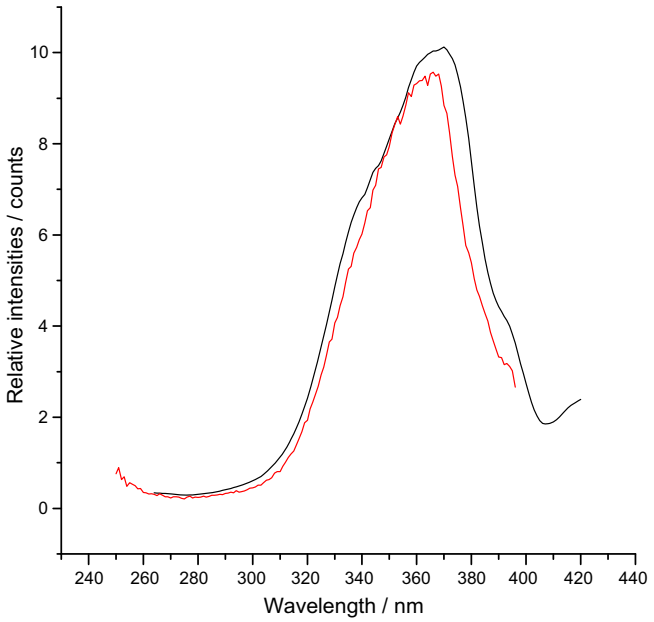

Fig. 8. Solid-state emission spectra of the complexes at room temperature (red: **1**, λ_{ex} = 208 nm; black: **2**, λ_{ex} = 213 nm). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the coordinated and lattice water molecules, starting at around 50 °C, and leading to a corresponding weight loss of 12.62% (calculated 14.38%). This dehydration step is followed by decomposition of the compound. The decomposition is achieved at about 425 °C, and no further thermal events are observed. One main weight loss event was noted in the TGA of **2**, corresponding to the decomposition of the compound with an onset temperature of 330 °C. No weight loss is observed below 250 °C, confirming the absence of lattice water in the phase.

3.7. Photoluminescence properties

The solid-state photoluminescence spectra of the title complexes at room temperature are depicted in Fig. 8. Fumaric acid exhibits a broad fluorescent emission centered on 323 nm with an excitation maximum at 302 nm. In the case of the MOFs **1** and **2**, a large red-shifted photoluminescence with the main emission at 368 nm (λ_{ex} = 208 nm) and 374 nm (λ_{ex} = 213 nm), respectively, is observed, which is red-shifted about 45 nm and 51 nm, respectively compared to that of free H_2fum acid. Apparently, these strong fluorescence emissions may arise from the Pb^{2+} lone pair to ligand charge transfer [25], and the red-shifted effect may be due to both the coordination or an excited metal-perturbed intraligand state and the fact that the ΔE value [ΔE = E(LUMO)-E(HOMO)] of the fumarate dianion (0.18181 a.u) is smaller than that of fumarate acid (0.19165 a.u), which was obtained through DFT calculations using the b3lyp/lan12mb method [26]. The fluorescent intensity of complex **1** is weaker than that of the complex **2**, which may be due to the existence of both the coordinated and lattice water molecules in complex **1**.

4. Conclusion

In summary, two new lead(II) fumarate MOFs with 1D channels, **1** and **2**, have been successfully synthesized. Both the eight-coordinated lead atom in **1** and the six-coordinated lead atom in **2** show hemidirected geometries. The fum ligands in these complexes exhibit different coordination modes. The fact that complex **1** is hy-

drous while complex **2** is anhydrous shows that some N-containing compounds, such as pyrazine and pyrazole, may have great influence on the structure and composition of some MOFs in this system, which may partially result from the different intial pH values of the reaction solutions. A new strategy to design anhydrous MOFs may be found through further thoroughly investigation on how anhydrous complex **2** was formed. In addition, the solid state photoluminescence properties of the coordination polymers **1** and **2** have been studied.

ABSTRACT

Three new supramolecular assemblies of co-crystallized metal complexes and aliphatic dicarboxylic acids, $\{[Cu(pic)_2(H_2O)_2](H_2mal)\}_n$ (**1**), $\{[Cu(pic)_2(H_2O)_2](H_2mal)_2(H_2O)_2\}_n$ (**2**) and $\{[Cu(pic)_2(MeOH)](H_2succ)\}_n$ (**3**) {Hpic = 2-picolinic acid, H_2mal = malonic acid and H_2succ = succinic acid} have been synthesized and characterized by X-ray single-crystal structure determination. The crystal packings of the complexes reveal that supramolecular associations of the monomeric complex units lead to the formation of layers through hydrogen bonding. In all the complexes, the dicarboxylic acid units connect the 2-D layers to act as pillars. The interaction between water molecules and the dicarboxylic acid plays an important role in the overall supramolecular assembly.

1. Introduction

Self-assembly of molecular components give rise to composite molecular aggregates with specific structures and activities, and is at the heart of various biological processes which are very sophisticated and complex. The first step in understanding these complicated processes is to unravel the interplay of non-covalent interactions [1–3] (such as hydrogen bonding, π–π, C–H···π, C–H···O, metal–π interactions, etc.) that are responsible for crystal or solid formation.

The dicarboxylic acids [HOOC–$(CH_2)_n$–COOH] represent supramolecular connectors that can generate infinite high-dimensional networks through complementary hydrogen bonds involving a variety of basic building blocks such as amines, dipyridines and pyrazins, and their analogues have been documented recently [4–6]. However, there are only a very few examples where dicarboxylic acid molecules and metal complexes are used as supramolecular building blocks [7,8].

Cu–picolinate complexes are simple systems [9], but the reported self-assembled structures of this system are diverse [10–13], and the controlling factors pertaining to the robust features of the self-assembly can be only explored through a systematic study. In the present study we have adopted the principle of co-crystallization [14–16] by choosing aliphatic dicarboxylic acids in the Cu–picolinate system bearing a complementarity relationship. Co-crystallization is an emerging area of research, despite appearing in the literature for a considerable time under various guises, and has provided a venue for the practical application of crystal engineering. A co-crystal is a crystalline material made up of two or more components [17–20], usually in a stoichiometric ratio, each component being an atom, ionic compound or molecule. Numerous authors have investigated the co-crystallization of carboxylic acid-functionalized molecules with organic derivatives [21–26], but examples utilizing inorganic derivatives are scant [7,8]. Generally, these studies focus on the isolation of organic co-crystals, giving less emphasis to metal-containing co-crystal systems. Here, we are concerned with co-crystals of dicarboxylic acids with the [Cu(picolinate)$_2$(H_2O)$_2$] moiety to understand the role of non-covalent interactions occurring in the solid-state structure.

We are reporting in this paper three co-crystal supramolecular assemblies, $\{[Cu(pic)_2(H_2O)_2](H_2mal)\}_n$, $\{[Cu(pic)_2(H_2O)_2](H_2mal)_2(H_2O)_2\}_n$ and $\{[Cu(pic)_2(MeOH)](H_2succ)\}_n$, of Cu(pic)$_2$ (Hpic = 2-picolinic acid) with malonic acid (H_2mal) or succinic acid (H_2succ = succinic acid). The effect of the short malonic acid and relatively longer and flexible succinic acid in the self-assembled structures is investigated. We also report the effect of the increased concentration of dibasic acids and discuss the effect of the solvent on the self-assembly.

2. Experimental

2.1. Reagents

All chemicals were commercial products of reagent grade and were used without further purification.

2.2. Preparations

2.2.1. Synthesis of $\{[Cu(pic)_2(H_2O)_2](H_2mal)\}_n$ (**1**)

A methanol solution (30 ml) of copper(II) malonate (1.859 g, 5 mmol) was mixed with a methanol solution (10 ml) of 2-picolinic acid (0.615 g, 5 mmol) followed by the addition of a methanol solution (5 ml) of malonic acid (0.520 g, 5 mmol). The resultant mixture was refluxed for ca. 2 h and then allowed to cool to ambient temperature. The resulting solution was filtered to remove a small amount of $Cu(pic)_2$ that separated out immediately, and the filtrate was kept at room temperature. Blue colored single crystals suitable for X-ray analysis were obtained from the filtrate after several days.

Yield: 1.30 g (58%) based on Cu. *Anal.* Calc. for $C_{15}H_{16}CuN_2O_{10}$: C, 40.23; H, 3.60; N, 6.26. Found: C, 40.45; H, 3.47; N, 6.58%. μ_{eff} = 1.75 BM (per copper ion); IR (KBr, cm^{-1}): 3391 for υ(O–H), 2927 for υ(C–H), 1708 for υ(C–O of COOH), 1628 and 1601 for υ(C–O and C–C), 1568 for υ(C–N) and 1400 for υ(C–H). λ_{max} (solid, reflectance): 675 nm.

2.2.2. Synthesis of $\{[Cu(pic)_2(H_2O)_2](H_2mal)_2(H_2O)_2\}_n$ (**2**)

Complex **2** was obtained by following a similar procedure to that of **1**, but 10 mmol of malonic acid were added in place of 5 mmol. Dark blue colored single crystals suitable for X-ray analysis were obtained from the filtrate after two weeks.

Yield: 1.62 g (55%) based on Cu. *Anal.* Calc. for $C_{18}H_{24}CuN_2O_{16}$: C, 36.77; H, 4.11; N, 4.76. Found: C, 36.96; H, 4.23; N, 4.59%. μ_{eff} = 1.77 BM (per copper ion); IR (KBr, cm^{-1}): 3385 for υ(O–H), 2960 for υ(C–H), 1714 for υ(C–O of COOH), 1628 and 1603 for υ(C–O and C–C), 1571 for υ(C–N), 1477 for υ(C–H). λ_{max} (solid, reflectance): 680 nm.

2.2.3. Synthesis of $\{[Cu(pic)_2(MeOH)](H_2succ)\}_n$ (**3**)

This was synthesized by following a similar procedure to that adopted for **1**, but using a methanol solution of succinic acid (5 mmol, 0.590 g) instead of a methanol solution of malonic acid. Overnight, light-blue single crystals of **3**, suitable for X-ray diffraction, were obtained.

Yield: 1.24 g (54%) based on Cu. *Anal.* Calc. for $C_{17}H_{18}CuN_2O_9$: C, 44.59; H, 3.96; N, 6.12. Found: C, 44.45; H, 3.07; N, 6.15%. μ_{eff} = 1.71 BM (per copper ion); IR (KBr, cm^{-1}): 3441 for υ(O–H), 2931 for υ(C–H), 1699 for υ(C–O of COOH), 1642 and 1600 for υ (C–O and C–C), 1475 for υ(C–H). λ_{max} (solid, reflectance): 688 nm.

2.3. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 240 C elemental analyzer. IR spectra in KBr (4500–500 cm^{-1}) were recorded using a Perkin–Elmer RXI FT-IR spectrophotometer. Electronic spectra in acetonitrile (1200–350 nm) were recorded in a Hitachi U-3501 spectrophotometer. The magnetic susceptibility measurements were done with an EG&PAR vibrating sample magnetometer, model 155 at room temperature and diamagnetic corrections were made using Pascal's constants. Thermal analyses (TG-DTA) were carried out on a Mettler Toledo TGA/SDTA 851 thermal analyzer in a dynamic atmosphere of dinitrogen (flow rate = 30 cm^3 min^{-1}). The samples were heated in an alumina crucible at a rate of 10 °C min^{-1}.

2.4. X-ray crystallography

Data were measured with Mo Kα radiation at 150 K using an X-Calibur CCD diffractometer from Oxford Instruments. The crystals were positioned at 50 mm from the CCD and 330 frames were measured with a counting time of 10 s. Data analysis was carried out with the Crysalis program [27] to provide 2626, 6071 and 5048 independent reflections, respectively. The structures were solved using direct methods with the SHELX97 program [28]. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. All the hydrogen atoms bonded to oxygen were located in difference Fourier maps and refined with distance constraints. The structures were refined on F^2 using SHELX97 [28]. Crystal data for the three crystals are given in Table 1.

3. Results and discussion

3.1. Synthesis of the complexes

To construct the hydrogen-bonded molecular self-assemblies of $Cu(pic)_2$ with aliphatic dicarboxylic acids we dissolved the individual components, copper salts (malonate or succinate), picolinic acid and the corresponding dicarboxylic acid (H_2mal or H_2succ) in methanol in 1:2:1 ratios. The complex compound $Cu(pic)_2$, which is formed immediately by the reaction of the Cu(II) salts and picolinic acid, remains in solution in the acidic pH of the resulting solution and the desired supramolecular H-bonded assemblies **1** and **3** were separated out on slow evaporation of methanol. In order to investigate the possibility to obtain any other assembly, we increased the proportion of the respective dicarboxylic acid in solution and got crystals of compound **2** when the H_2mal:$Cu(pic)_2$ ratio was 2:1 or higher. For H_2succ we did not get any compound other than **3**, even on increasing the H_2succ:-$Cu(pic)_2$ ratio up to 5:1.

3.2. Crystal structures of complexes

X-ray crystallographic analysis reveals that all three structures consist of a copper complex containing two bidentate 2-picolinate ligands in an equatorial plane, together with 1 or 2 solvent molecules weakly bound in axial positions. In addition, in each case a dicarboxylic acid co-crystallises with the complex but is not bonded to the metal, instead it forms a hydrogen-bonded network

with the complex. Dimensions in the metal coordination spheres are given in Table 2, with details of the hydrogen bond networks in Table 3.

3.2.1. Structure of $\{[Cu(pic)_2(H_2O)_2](H_2mal)\}_n$ (**1**)

The ORTEP diagram (Fig. 1) reveals that the asymmetric unit of **1** consists of a half of a Cu atom, a 2-picolinate molecule and half of the malonic acid molecule. The metal complex $[Cu(pic)_2(H_2O)_2]$ is situated on a centre of symmetry. The two bidentate 2-picolinate ligands occupy the equatorial plane, coordinated by the pyridine N atoms (N11) and the carboxylate O atoms (O18) with Cu–N and Cu–O bond lengths as expected, being 1.987(2) and 1.944(2) Å, respectively. There are water molecules (O100) in axial positions at 2.497(2) Å. One of the carboxylate oxygen atoms (O19) remains uncoordinated and acts as hydrogen bond acceptor site for the uncoordinated malonic acid donor molecule, which has a crystallographic twofold axis through the central carbon atom.

The supramolecular association of the monomeric units through hydrogen bonding leads to layers (*ab* plane) of $[Cu(pic)_2(H_2O)_2]$ monomeric units, in which the adjacent monomers are united through coordinated water mediated hydrogen bonding. Water molecules in association with the uncoordinated picolinate carboxylate oxygen atoms (O19) form a $R_4^2(8)$ hydrogen bonding synthon [29–32]. Diagonally opposite corners of this rectangular

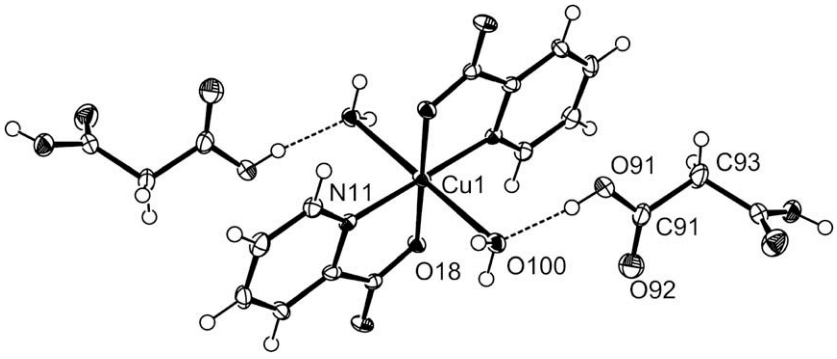

Fig. 1. The structure of **1** with ellipsoids at 50% probability. Hydrogen bonds shown as dotted lines.

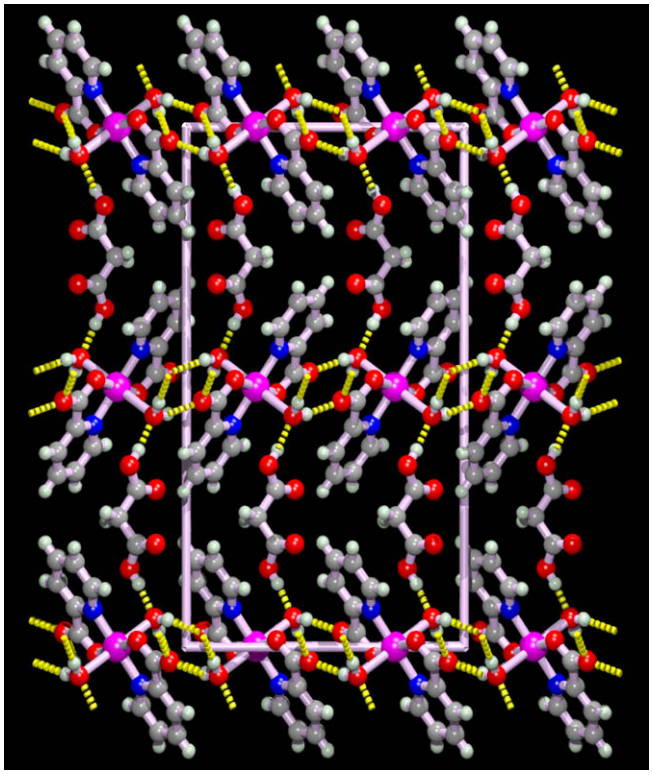

Fig. 3. Pacing of successive $[CuL_2(H_2O)_2]_n$ layers. Malonic acid molecules act as pillars separating the layers.

motif are occupied by water molecules (O100) and picolinate carboxylate O19 atoms, respectively (Table 3), and these form an infinite two-dimensional four-connected sublayer 4^4-net along the [1 1 0] direction (Fig. 2). The copper–copper distances within this 4^4-net are 11.23 and 6.12 Å. In this supramolecular assembly the malonic acid molecule is attached directly to the coordinated water molecule O(1 0 0) of the Cu–picolinate moiety, through an O–H···O H-bond, exhibiting the recognition phenomenon of the dicarboxylic acid by the neutral coordination complex.

Successive $[Cu(pic)_2(H_2O)_2]_n$ layers are stacked (along the *c*-axis) in such a way that malonic acid units connect them in a one to one fashion by acting as hydrogen bond donors to coordinated water molecules on adjacent layers. The malonic acid molecules thus act as pillars between the layers (Fig. 3, Table 3). A characteristic of this structure is that all the available hydrogen bond donors and acceptors are engaged in a fully supramolecular assembly.

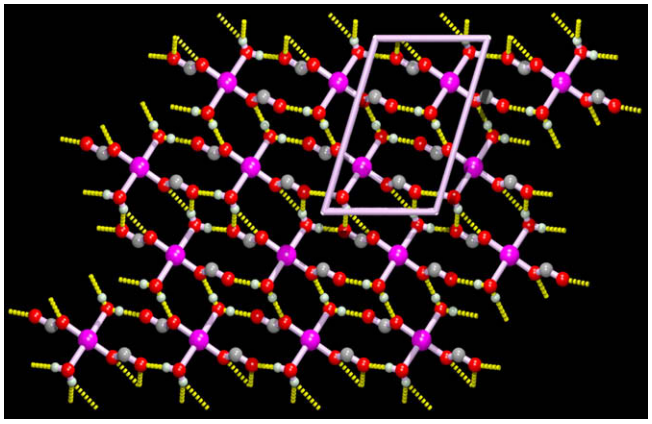

Fig. 5. The supramolecular layer of $[CuL_2(H_2O)_2]$ units in **2** (picolinate pyridine rings have been omitted for clarity).

3.2.2. Structure of $\{[Cu(pic)_2(H_2O)_2](H_2mal)_2(H_2O)_2\}_n$ (**2**)

The crystal structure determinations reveal that complex **2** is a pseudo-polymorph of complex **1**. The ORTEP diagram (Fig. 4) reveals that the asymmetric unit of **2** consists of a Cu atom, two 2-picolinate ligands, two malonic acid molecules and four water molecules (two coordinated and two lattice). Analyses of crystal packing of **2** shows that the $[Cu(pic)_2(H_2O)_2]$ complex is in a general position, although the structure is equivalent to that found in **1**. There are two acid groups per complex, unlike **1** where the ratio is 1 to 1. The bond lengths to the pyridine nitrogen atoms (N11 and N21) are 1.955(3) and 1.966(3) Å, to the acid oxygen atoms (O18 and O28) 1.943(2) and 1.963(2) Å and the bonds to the water molecules (O100 and O200) in the axial positions 2.538(2) and 2.574(2) Å. Two lattice water molecules (O300 and O400) and two malonic acid molecules remain as independent units and take part only in hydrogen bonding.

The supramolecular assembly of the monomeric units of **2** is also in the form of hydrogen-bonded layers of $[Cu(pic)_2(H_2O)_2]$ (Fig. 5). The layers are the (1 1 0) planes. The mode of hydrogen bonding association in this layer is slightly different from that in **1**. While the similar $R_4^2(8)$ hydrogen-bonded rectangular motifs be-

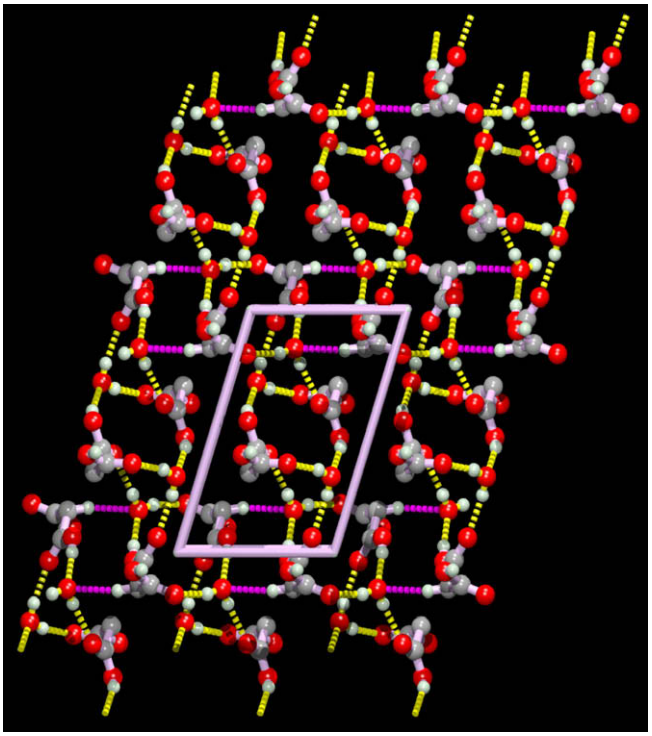

Fig. 7. The malonic acid water hydrogen-bonded supramolecular layer in **2**. Dotted lines represent H–bond.

tween the coordinated O100 water molecules and the uncoordinated carboxylate O19 atoms of picolinate still persists in **2**, due to perturbation another elongated ring motif $R_4^4(12)$ arises which is the result of hydrogen bonding between coordinated water molecules (O200) and both coordinated (O28) and uncoordinated (O29) carboxylate oxygen atoms of the 2-picolinate moiety (Table 3). These two ring motifs co-exist and the $R_4^2(8)$ motif slightly adjusts itself so that in this motif the hydrogen bond is bifurcated and the water oxygen atom (O100) donate its proton (H2) simultaneously to both the coordinated (O18) and uncoordinated carboxylate (O19) atoms of picolinate.

Successive $[Cu(pic)_2(H_2O)_2]_n$ layers are stacked along the *c*-axis (Fig. 6), but unlike **1**, the single malonic acid molecules do not act as pillars in **2**. Two sets of malonic acid molecules and lattice water molecules O300 and O400 self-assemble into hydrogen-bonded (Table 3) centro-symmetric layers (Fig. 7) in **2**, on both sides of which carboxylate terminals of malonic acid molecules protrude out and act as hydrogen bond donors for the coordinated water molecules that are part of the $[Cu(pic)_2(H_2O)_2]_n$ layers on either side. The O300 water molecule forms two donor hydrogen bonds to malonic acid carboxylate O59 atoms at 2.824(5) Å and with O44 atoms at 2.756(4) Å, and also acts as an acceptor of a hydrogen

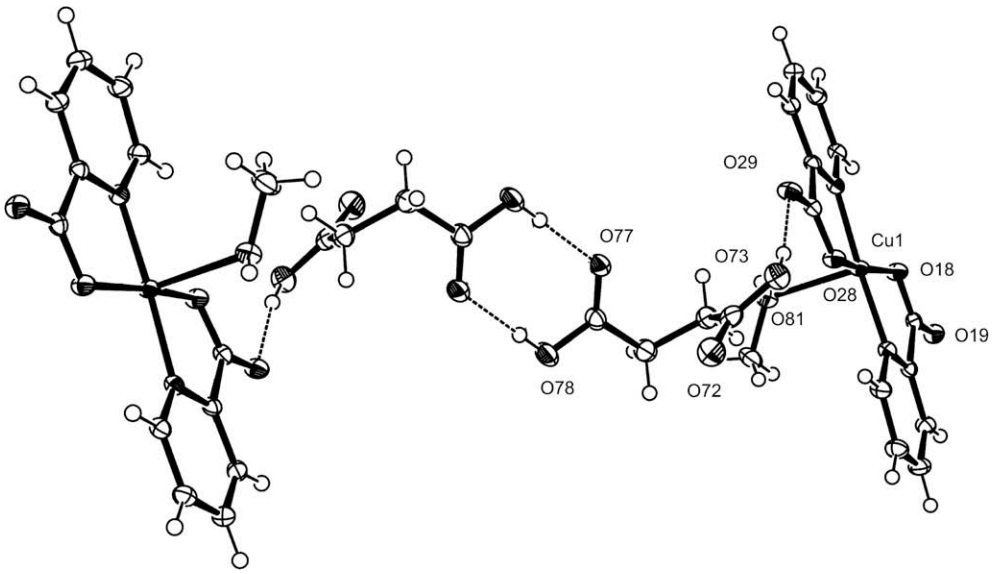

Fig. 8. The structure of **3** with ellipsoids at 50% probability. Hydrogen bonds shown as dotted lines.

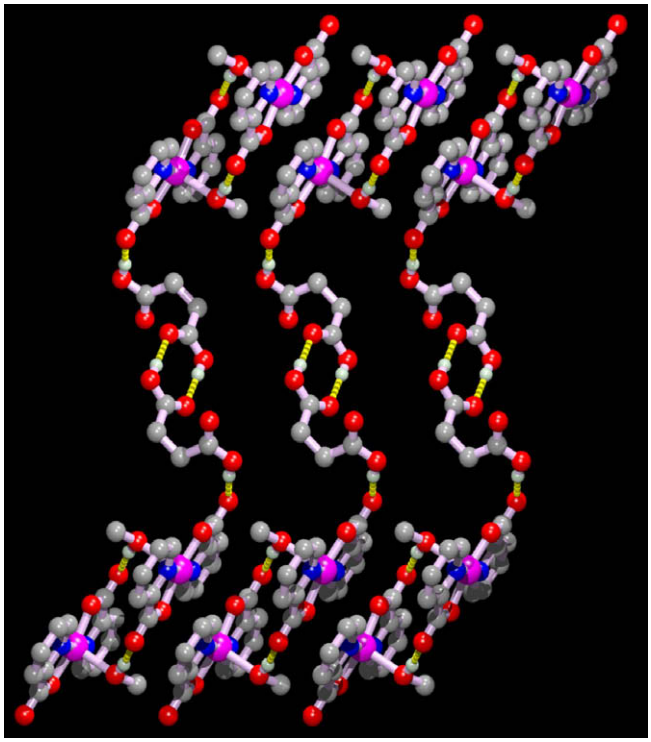

Fig. 9. The mode of binding of dimeric succinic acid pillars in complex **3**.

bond to O48 at 2.589(4) Å. On the other hand, the lattice water O400 molecule forms only one donor hydrogen bond with O54 at 2.739(4) Å and one accepter hydrogen bond with O58 at 2.611(4) Å, (Table 3), which leads to one dimensional hydrogen-bonded ribbons of malonic acid and water molecules along the [0 1 0] direction (Fig. 7). The supramolecular entity of two malonic acid molecules and two lattice water molecules here act as pillars between $[Cu(pic)_2(H_2O)_2]_n$ layers, and this entity is part of the water–malonic acid supramolecular layer.

3.2.3. Structure of $\{[Cu(pic)_2(MeOH)](H_2succ)\}_n$ (**3**)

The ORTEP diagram (Fig. 8) reveals that the asymmetric unit of **3** consists of a Cu atom, two 2-picolinate ligands, one succinic acid molecule and one coordinated methanol molecule. The crystal packing analyses of **3** shows that the copper complex $[Cu(pic)_2(MeOH)]$ is five coordinate with a square pyramidal environment in which the methanol occupies an axial position with a Cu–O(81) distance of 2.312(9) Å. In the equatorial plane, the Cu–O distances are 1.953(8) and 1.948(8) Å, and the Cu–N distances are 1.968(10) and 1.969(10) Å. This complex is unique in that the dicarboxylic acid forms a hydrogen bond to O(29) of the 2-picolinate ligand rather than to the solvent methanol.

Like the previous complexes, the $[Cu(pic)_2(MeOH)]$ units in **3** are also self-assembled into supramolecular layers which are pillared by dimeric units of succinic acid molecules (Fig. 9). The $[Cu(pic)_2(MeOH)]_n$ supramolecular layers have been depicted in Fig. 10. The basic supramolecular unit in this layer is the centrosymmetric dimer of $[Cu(pic)_2(MeOH)]$ monomers, which is the result of hydrogen bonding between coordinated methanol (O81) and the uncoordinated picolinate carboxylate oxygen O19 atoms of complementary monomers (Table 3). These dimeric units are arranged in the form of a 1D supramolecular chain as a result of C–H···O hydrogen bonding, shown in Fig. 10 (Table 3). These 1D chains are aligned side by side due to π···π interactions (Table 4) between the pyridine rings of adjacent chains, resulting in the supramolecular layer which is the (0 0 1) plane. Two succinic acid molecules form an end to end dimeric unit through the formation a $R_2^2(8)$ hydrogen bonding synthon (Table 3) and through the other terminals form hydrogen bond with the picolinate carboxylate O29 oxygen atoms (Fig. 9), and thus act as pillars between the layers.

3.3. Discussion

To facilitate an easy comparison, the structural features have been summarized in Table 5. Pseudo-polymorphs **1** and **2** have identical building blocks, but whereas for **1** $Z = 4$, for **2** $Z = 2$. Complex **1** possesses higher symmetry than **2**. The environmental parameter that is responsible for this is the increased concentration of malonic acid in **2**. The structural features discussed in the previous section reveals that the robust feature of the self-assembly in all three complexes is that the 2-picolinate ligands and the Cu(II) ions form monomeric complexes which are self-organized into distinct layers and the organic acid molecules also organize themselves in a separate region in between the Cu–picolinate layers and act as pillars for these layers. In the self-organization of the metal picolinate layers, in the case of complexes **1** and **2** coordinated water molecules play a very important role to steer successive monomeric units through the formation of a $R_4^2(8)$ hydrogen-

Table 5
Comparison of salient features of complexes **1**–**3**.

	1	**2**	**3**
Coligand	malonic acid	malonic acid	succinic acid
Crystal system	monoclinic	triclinic	triclinic
Space group	$C2/c$	$P\bar{1}$	$P\bar{1}$
Asymmetric unit	Cu(II) at the symmetry position	Cu(II) not at the symmetry position	One Cu(II) center
Coordination environment	octahedral	octahedral	square pyramidal
Axial sites occupied by	water molecules	water molecules	methanol
Supramolecular architecture	pillared layered	pillared layer	pillared bilayer
Supramolecular interaction	H-bonding $R_4^2(8)$ synthon, water tetramer analogue and only O–H···O	H-bonding $R_4^4(8)$ and $R_2^2(12)$ synthon, water tetramer analogue and both O–H···O and C–H···O	H-bonding $R_2^2(8)$ synthon and π–π

bonded synthon [29,31,32] with the uncoordinated carboxylate oxygen atom of picolinate. In **2** the organization has accommodated an additional synthon $R_4^4(12)$ and as a result the original synthon is distorted. This indicates the labile but robust nature of the $R_4^2(8)$ synthon, and it should be noted that this kind of organization has been observed in many other cases. This motif can be assumed to be the analogous motif of the planar water tetramer in which two water molecules have been replaced by picolinate oxygen atoms. In complex **2**, in between the Cu–picolinate layers malonic acid water supramolecular layers position themselves, but the basic pillaring action of malonic acid remains unchanged. In complex **3** though, instead of water, a methanol molecule is coordinated to Cu which has a square pyramidal coordination environment, yet the same Cu–picolinate layer structure is achieved through the formation of supramolecular dimeric complexes that organize themselves through hydrogen bonding and π···π interactions. The succinic acid molecules in this case act as pillars between the layers; in this process it forms a dimeric unit.

3.4. Thermal studies

To examine the thermal stabilities of the co-crystalline complexes, thermal gravimetric (TG) analyses were carried out in air on powdered samples of **1**–**3**. In **1**, the first endothermic weight loss of 7.92%, corresponding to the departure of two water molecules (Calc. 8.04%), was observed between 50 and 100 °C, the second endothermic weight loss of 22.92% was observed between 120 and 200 °C due to the removal of one malonic acid molecule (Calc. 22.99%). On further heating the $Cu(pic)_2$ complex start to decompose endothermally at 240 °C. Similarly the TG curve of **2** exhibits three endothermic weight loss in the temperature ranges 50–100 °C, 130–190 °C and 290–340 °C, corresponding to the release of four water molecules (Found 12.3%, Calc. 12.25%), two malonic acid molecules (Found 34.5%, Calc. 35.03%) and decomposition of $Cu(pic)_2$, respectively. Complex **3** also shows weight loss stages in the temperature ranges 80–120 °C, 130–190 °C and 270–360 °C corresponding to the release of one methanol molecule (Found 6.83%, Calc. 6.99%), one succinic acid molecule (Found 27.5%, Calc. 25.55%) and decomposition of $Cu(pic)_2$, respectively.

4. Conclusions

The viability of a crystal engineering approach to the identification of stable co-crystals has been demonstrated through the rational synthesis of metal-containing co-crystals of picolinate with malonic and succinic acids. In all three cases the organic acid was found to interact through hydrogen bonds act as a pillar to the $R_4^2(8)$ synthon assisted Cu–picoinate layer. Research with other neutral carboxylic acids is in progress to explore the metal-containing co-crystals.

ABSTRACT

[Ru(bpy)($dcbH_2$)(TCNQ)Cl] · (Ru–TCNQ) and [Ru(bpy)($dcbH_2$)(TCNE)Cl] · (Ru–TCNE) complexes, where bpy = 2,2'-bipyridine, $dcbH_2$ = 4,4'-dicarboxy-2,2'-bipyridine, TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane, and TCNE = tetracyanoethylene, were synthesized and characterized by spectroscopic and electrochemical techniques. Comparatively to the TCNX ligands (TCNQ and TCNE) free of coordination, the infrared vibrational spectra of the complexes indicate that the coordination to the ruthenium atom occurs through only one nitrile group. Also, the downshift of these bands is indicative of the TCNX reduced form ($TCNX^{\cdot-}$). This conclusion is reinforced by EPR spectra with $g = 2.005$ and 2.010 for the Ru–TCNQ and Ru–TCNE complexes, respectively. In addition, the structured absorption spectra observed for both complexes indicate that the TCNX moieties are coordinated as anion radicals, ($TCNX^{\cdot-}$). Preliminaries luminescence studies indicate that the Ru–TCNX complexes present emission properties with reasonable lifetimes. The degree of charge transfer for the Ru–TCNQ and Ru–TCNE compounds was evaluated as 0.66 and 0.78, respectively. The $Ru^{III/II}$ redox potentials (E_{ox}) for the Ru–TCNQ and Ru–TCNE complexes are observed, respectively, at 0.70 V and 1.30 V versus NHE. The data, all together, suggest that the TCNE species presents a higher charge uptake capability than TCNQ ligand.

1. Introduction

Photophysical and photochemical properties of ruthenium polypyridyl complexes have been extensively studied for many years mainly due to their potential applications in energy conversion processes [1–6]. An extensive literature [7] coverage of spectroscopic properties and performance in solar cells has been limited for a series of ruthenium(II) complexes of bis(dicarboxylic acid bipyridine), *cis*-[Ru($dcbH_2$]LL′], in which $dcbH_2$ is 4,4'-$(CO_2H)_2$-2,2'-bipyridine and L and/or L' are ancillary ligands, and for ruthenium complexes with polypyridine ligands having non-carboxylic acid anchoring groups. The field of donor–acceptor compounds involving metallic fragments and organic acceptor molecules challenges synthetic work to design interesting supramolecular systems [8] which, depending on the electronic properties and relative arrangement, present different physical properties. Conjugated TCNX polynitrile ligands such as tetracyanoethylene (TCNE) and 7,7,8,8-tetracyano-*p*-quinodimethane (TCNQ) are very unusual because of their variable coordination behaviour, proven ability to bridge up to four metal centers, tendency to form aggregates via π–π interaction, and "non-innocence", i.e. their very facile reduction to anion radicals and further to dianionic forms [9–13]. The design of dπ–pπ molecular systems with efficient electronic communication is a long-standing goal in the field of inorganic chemistry. The first organic magnet [14] was $[Fe(C_5Me_5)_2]^{\cdot+}[TCNQ^{\cdot-}]$. Several related compounds were studied to identify a structure–function relationship that could be used to aid in preparing new magnets [15]. Recently, studies have been developed on Ru_2–CNX type complexes in order to prepare new magnets with higher critical temperatures [16–18]. Indeed, several papers have been reported on the dependence of the electronic characteristics of Ru–TCNX compounds and on the nature of the metallic fragment [11–13].

The aim of this work is to investigate physical properties such as charge uptake, absorption, emission, and oxidation state of the TCNX ligands in the [Ru(bpy)($dcbH_2$)(TCNQ)Cl] and [Ru(bpy)($dcbH_2$)(TCNE)Cl] complexes, hereafter named Ru–TCNQ and Ru–TCNE, respectively, where bpy = 2,2'-bipyridine and $dcbH_2$ = 4,4'-dicarboxy-2,2'-bipyridine. The planar representations of the complexes are illustrated in Fig. 1.

2. Experimental

2.1. Materials and methods

Equipments: UV–Vis absorption spectra were measured with a Hewlett-Packard 8453 diode array spectrophotometer. IR spectra were recorded on an ABB Bomem FTLA 2000-102 FTIR instrument. EPR spectra were recorded in the X band on a Bruker System ESP 300. Electrochemical experiments were performed on a BAS 100 W electrochemical analyzer (Bioanalytical Systems – BAS, West Lafayette, IN) at 25 ± 0.2 °C. A three-electrode glass cell was used with used as working and auxiliary electrodes in the characterization of the complexes. An Ag/AgCl electrode, for which the ferrocene/ferrocenium ($Fc^{+/0}$) redox process was observed at 0.51 V in *N*,*N*-dimethilformamide (DMF) containing 0.1 mol L^{-1} tetrabutylammonium perchlorate (TBAP) was prepared 1 h prior to the beginning of the experiments and used as reference electrode.

Materials: $RuCl_3$ (Aldrich), dimethylformamide (DMF, Merck), acetone, methanol were all used as received. Tetracyanoquinodimethane (TCNQ) and tetracyanoethylene (TCNE) were purchased from Aldrich and used upon recrystallization. All manipulations had to be carried out in rigorously dried solvents under an argon atmosphere.

2.2. Synthesis

2.2.1. cis-[Ru(bpy)(dcbpy)Cl_2]

This compound was prepared by following the method described by Meyer and co-workers [19].

2.2.2. cis-[Ru(bpy)(dcbpy) · (TCNQ)Cl]

A solution of *cis*-[Ru(bpy)(dcbpy)Cl_2] (50 mg, 0.086 mmol) in water (5 mL) was added slowly to TCNQ (21 mg, 0.103 mmol) dissolved in acetone (5 mL). After stirring for 24 h, a brown precipitate was collected and dried under vacuum. Yield: 80%. *Anal.* Calc. for $C_{33}H_{20}N_8O_4ClRu$ (728.57): C, 55.13; H, 2.70; N, 15.13. Found: C, 55.08; H, 2.80, N, 15.90%. UV–Vis (DMF) λ_{max} in nm (ε in mol L^{-1} cm^{-1}): 295 (2.6×10^4), 315 (1.8×10^4), 403 (2.5×10^4), 489 (3.2×10^3), 750 (3.3×10^3), 850 (5.0×10^3).

2.2.3. cis-[Ru(bpy) · (dcbpy)(TCNE)Cl] · H_2O

A solution of *cis*-[Ru(bpy)(dcbpy)Cl_2] · (50 mg, 0.086 mmol) and TCNE (13.2 mg, 0.103 mmol) in water/methanol solution (10 mL) was kept under stirring and reflux for 8 h. The brown precipitate was collected and dried under vacuum. Yield: 85%. *Anal.* Calc. for $C_{27}H_{18}N_8O_5ClRu$ (670.57): C, 49.22; H, 2.63; N, 16.40. Found: C, 49.15; H, 2.72, N, 16.00%. UV–Vis (DMF) λ_{max} in nm (ε in mol L^{-1} cm^{-1}): 295 (2.4×10^4), 398 (1.1×10^4), 420 (1.2×10^4), 461 (1.0×10^4).

3. Results and discussion

TCNQ and TCNE ligands react with one molar equivalent of Ru(bpy)(dcbpy)Cl_2 to yield Ru–TCNX complexes. The electronic spectra in the ultraviolet and visible regions (UV–Vis) of the Ru–TCNE and Ru–TCNQ complexes (Fig. 2) present, besides the intraligand transitions of the bpy and $dcbH_2$ ligands [20], lower energy absorptions which, based on the solvent dependence, are assigned as charge transfer (CT) transitions. The maximum of these transitions are observed at 489 and 461 nm in DMF medium for the Ru–TCNQ and Ru–TCNE complexes, respectively. The electronic spectrum of the Ru-TCNQ complex in DMF exhibits the typical long-wavelength absorptions of the TCNQ radical anion ($TCNQ^{\cdot-}$) at 850, 750 and 403 nm. Absorptions at 295 and 489 nm are also observed and assigned to the bpy ($\pi^* \leftarrow \pi$) and charge transfer transition, $\pi^*(bpy) \leftarrow d\pi(Ru^{II})$, respectively. For the Ru–TCNE complex, the bands assigned to the TCNE ligand are observed at 398 and 420 nm. The very distinct, partially structured absorption spectra observed for both complexes indicate that the TCNX moieties are coordinated as anion radicals, $TCNQ^{\cdot-}$.

The luminescence spectra, with excitation at 500 nm in DMF, exhibited emission with maximum of intensity at 605 and 570 nm for the Ru–TCNE and Ru–TCNQ complexes, respectively. The luminescence decay of the complexes with excitation at 500 nm follows a biexponential behaviour. For the Ru–TCNQ complex, the lifetimes are 11 and 503 ns whereas for the Ru–TCNE complex are 15 and 563 ns. The short lifetime is related to the singlet–singlet energy transfer of the TCNX ligands while the long lifetime component is suggested to be due to an energy transfer between the close lying triplet states of the TCNX moieties and the ruthenium metal center.

The infrared (IR) vibrational spectra of the Ru–TCNE and Ru–TCNQ complexes, illustrated in Fig. 3, are dominated by the vibrational modes of the bipyridine ligands.

The bands assigned to the OH and C=O bonds of the $dcbH_2$ ligand [21] are observed at *c.a.* 3120 and 1721 cm^{-1}, respectively.

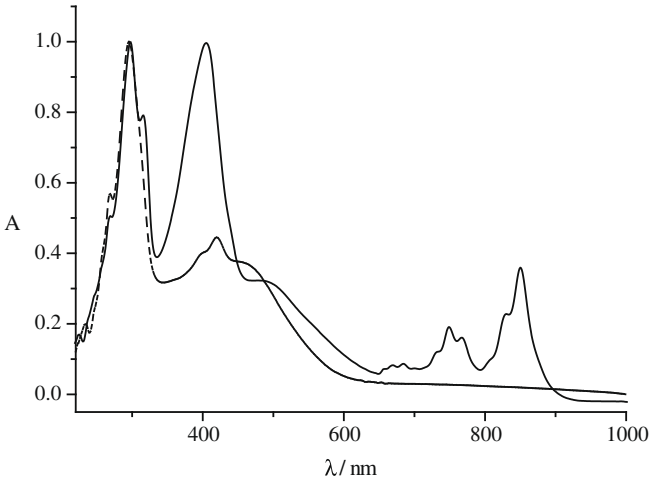

Fig. 2. Electronic spectra of the complexes: (a) Ru–TCNQ and (b) Ru–TCNE, in DMF (10^{-5} M) at 293 K.

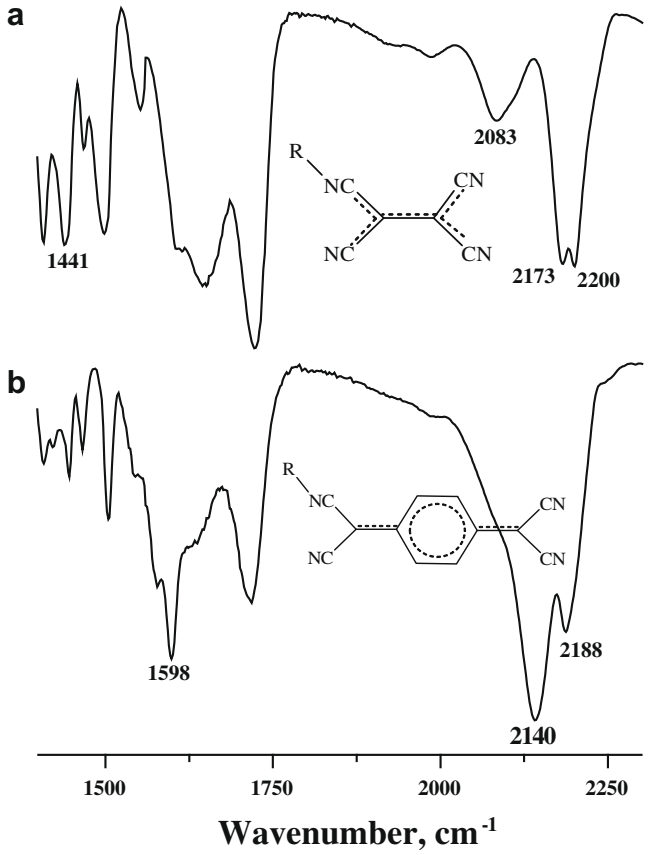

Fig. 3. Infrared spectra of (a) Ru–TCNE and (b) Ru–TCNQ complexes dispersed in KBr.

Concerning the TCNX ligands, as expected for single nitrile-N coordinated ($TCNQ^{n-}$ ligands [9,22–24], multiple bands are observed in the cyanide vibrational region (from 2050 to 2300 cm^{-1}). For the Ru–TCNQ complex these bands are observed at 2188 and 2140 cm^{-1}. For the Ru–TCNE complex, three bands relative to the nitrile group are observed at 2200, 2173 and 2083 cm^{-1}. Compared to the free non-reduced ligands (2224 cm^{-1} for TCNQ [25] and 2262 cm^{-1}, and 2230 cm^{-1} for TCNE [26] ligands), the absorption of the νCN modes of the complexes are more intense and shifted to lower frequency values. This result is assigned to an electronic density enhancement on the TCNX ligands which populates antibonding orbitals of the nitrile moiety thus decreasing the CN bond order and, as consequence, the frequency value of the respective vibrational mode. Also, the bands observed at 1441 and 1598 cm^{-1}, assigned to the C=C stretching mode, νCC, of the TCNE [27,28] and TCNQ [22,23] ligands, respectively, reinforce the assignment of the reduced form for the TCNX ligands. In fact, whereas isolated $([TCNQ]^{\cdot-}$ exhibits two νCN absorptions at 2183 and 2144 cm^{-1} and a νCC peak at 1421 cm^{-1}, deviations from these values suggest that $([TCNQ]^{\cdot-}$ is bonded to a metal ion [29]. In addition, according to Miller [29], the lower symmetry $([TCNQ]^{\cdot-}$ motif frequently exhibits more than two bands as it is the case for the Ru–TCNE complex. These observations indicate the reduced form for the TCNE moiety, indeed.

By accounting for the fact that the absorption of radiation by CT complexes involves electron transfer between appropriate energy levels of donor and acceptor species, the CT degree can be estimated based on energy displacements, $\Delta\nu$, of certain vibrational modes observed in a vibrational spectra [30]. If the observed shifts are small, then the relation between $\Delta\nu$ and the degree of CT, Z, is described in a first approximation [31,32] by Eq. (1)

$$Z = 2\left(\frac{\Delta\upsilon}{\upsilon_0}\right)\cdot\left[1-\left(\frac{\upsilon_1^2}{\upsilon_0^2}\right)\right]^{-1} \quad (1)$$

where υ_0 e υ_1 are the frequency values of the investigated bands in the spectra of the "free" component and its radical ion, respectively. Table 1 shows Z values for the Ru–TCNE and Ru–TCNQ complexes by considering the displacements of the νCN b_{2u} active mode of the related TCNX ligand in the oxidized form, $TCNX^0$, upon coordination to the ruthenium metal center.

The calculated values show a characteristic distribution over the range of Z between zero and one. It is well known that CT-complexes with values in the range of $0.35 < Z < 0.75$ are electronic conductors with even metallic conductivity [33].

The Ru–TCNE and Ru–TCNQ complexes were also electrochemically characterized by means of cyclic voltammetry in non-aqueous medium. Table 2 displays electrochemical data obtained for the for TCNX free and coordinated ligands (E_{red}) as well as for the ruthenium metal atom (E_{ox}).

For the Ru–TCNQ complex, the half-wave potentials observed at 0.51 and 0.1 V vs NHE are assigned to the $(TCNQ^{\cdot-}/TCNQ^0$ and $(TCNQ^{2-}/TCNQ^{-}$ redox processes, respectively. A third process at 0.70 V is observed and assigned to the $Ru^{III/II}$ process, thus indicating a stabilization of the ruthenium metal atom in the reduced state, Ru^{II}, since this process is observed at 0.61 V in the starting complex. For the Ru-TCNE complex, the $(TCNE^{\cdot-}/TCNE^0$ and $(TCNE^{2-}/(TCNE^{\cdot-}$ redox processes are observed 0.78 and 0.10 V while that of the ruthenium metal atom is observed at 1.30 V.

For both complexes, the decrease in the potential difference between the two redox processes of the TCNX ligands, comparatively to the free ligand, is indicative of the coordination [11]. Also, this potential difference ($\Delta E = E_{red1} - E_{red2}$) changes indicates the charge uptake by the coordinated TCNX ligands in the complexes [34]. The comproportionation constants (K_c) calculated based on Eq. (2) and displayed in Table 2 reinforce this conclusion

$$RT.\ln K_c = nF.\Delta E,$$
$$K_{=}10^{\Delta E/0.059V}\ (T = 298\ K) \quad (2)$$

The difference between the K_c values calculated for the TCNX ligands before and after coordination (ΔK_c) indicates the overlapping level between the ligand π^* and Rudπ orbitals. Accounting for the fact that the value calculated for the TCNE ligand ($\Delta K_c = 10^{16.6} - 10^{11.5} = 10^{5.1}$) is higher than that calculated for the TCNQ ligand

Table 1
νCN and $\nu_1 - \nu_0$ frequency values (cm^{-1}), and Z values for $TCNX^-$ and Ru–TCNX species.

Compound	ν_1[a] (cm^{-1})	$\nu_1 - \nu_0$[b] (cm^{-1})	Z
$(TCNQ^{\cdot-}$	2183	41	1
Ru–TCNQ	2197	27	0.66
$(TCNQ^{\cdot-}$	2183	79	1
Ru–TCNE	2200	62	0.78

[a] ν_1 = values of νCN b_{2u} mode of the $TCNX^-$ ligands.
[b] ν_0 = 2224 and 2262 cm^{-1} for $TCNQ^0$ and $TCNE^0$ species, respectively.

Table 2
Electrochemical data (in V vs. NHE) of the ligands and complexes in 0.1 mol L^{-1} TBAP solution at 100 mV s^{-1}.

Compound	Solvent	E_{ox}	E_{red1}	E_{red2}	K_c^*
TCNQ	DMF	–	0.65	0.05	$10^{10.1}$
Ru–TCNQ	DMF	0.70	0.51	0.10	$10^{6.9}$
TCNE	CH_3CN	–	0.50	−0.48	$10^{16.6}$
Ru–TCNE	DMF	1.30	0.78	0.10	$10^{11.5}$

$Fc^{+/0}$: 0.23 V in DMF; 0.37 V in CH_3CN.
* Comproportionation constant for monoanion from Eq. (2).

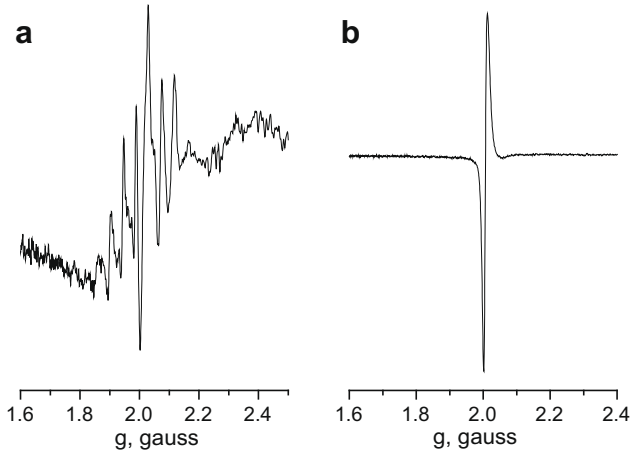

Fig. 4. EPR spectra of the solid (a) Ru–TCNE and (b) Ru–TCNQ complexes at 77 K.

($\Delta K_c = 10^{10.1}-10^{6.9} = 10^{3.2}$) there is a stronger mixing of TCNE ligand π^* and Rudπ orbitals.

In order to confirm the oxidation states of the Ru–TCNX complexes, EPR measurements of the species were carried out. The X-band EPR spectra were acquired at 77 K and are shown in Fig. 4. The Ru–TCNQ complex showed one single signal at $g = 2.005$ while, for the Ru–TCNE complex, hyperfine lines centered at $g = 2.010$ are observed. Based on the literature [12,35,36], the observation of these lines are assigned to the interaction of an unpaired electron and a magnetic nucleus. The occurrence of these g tensors values is consistent with the assignment of the anion radical form for the TCNX ligands upon coordination. This conclusion is reinforced by the partially structured absorption spectra observed for both complexes.

The spectra are showing that the electrons are centered on the ligands and that the interactions of the metal with the TCNE species are stronger than with the TCNQ ligand. The electrochemical experiments reinforce this conclusion since the half-wave potential for the $Ru^{III/II}$ redox couple is observed at 1.30 and 0.70 V for the Ru–TCNE and Ru–TCNQ complexes, respectively. The different EPR spectral profiles observed for both the complexes are explained based on the assumption that, for the Ru–TCNE complex, the unpaired electron is probably closer to the ruthenium which, as consequence, results in the observation of the hyperfine lines.

4. Conclusions

The results presented in this work show that the TCNQ and TCNE ligands are coordinated to the ruthenium metal center through only one nitrile group. The UV–Vis and EPR spectra acquired for the Ru–TCNX complexes strongly suggest the anion radical form, $(TCNQ^{\cdot-}$, for the TCNX ligands upon coordination. Preliminaries luminescence studies indicate that the Ru–TCNX complexes present emission properties with reasonable lifetimes. Photophysical measurements are currently under investigation in order to establish the decay mechanism. The electrochemical and vibrational data indicate that the charge transfer process of the TCNX ligands is enhanced upon coordination. Therefore, these η^1-coordinated $(TCNQ^{\cdot-}$ containing complexes may be suitable as components with special magnetic, optical, or conductive properties.

ABSTRACT

Two concomitant polymorphic coordination complexes (dark blue – **I** and black – **II**) with the formula ($Cu_2C_{44}H_{60}N_4O_4$) have been synthesized and characterized crystallographically. Magnetic measurements show the presence of a strong antiferromagnetic interaction and the 2*J* value corresponds extremely well to the theoretically calculated one, indicating the fact that it follows nicely the magneto-structural relationship. Immobilization of the copper(II) complex **1** on a 2D-hexagonal mesoporous silica showed good catalytic efficiency in the liquid phase partial oxidation of olefins in the presence of TBHP as an oxidant.

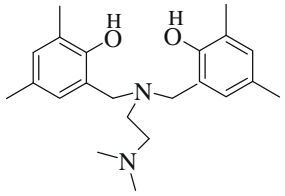
1. Introduction

The designed synthesis of coordination complexes towards functional materials has become an active area of research during the last decade. Judicious choice of organic ligands and suitable transition metals has led to the controlled synthesis of transition metal complexes of different nuclearities with desired functionalities, such as catalytic activity, magnetism, non-linear optical properties, which have found promising industrial applications. Dinuclear copper complexes, in many cases, have shown interesting functional properties and the rational syntheses of these complexes have received current interest. Bulky Schiff-base ligands with O-donor atoms in many cases have been successfully used to control the synthesis of dinuclear copper complexes and phenolate/bis-phenolate ligands, in particular, have shown great promise towards this end [1–7].



Copper(II)–bisphenolate complexes are also important for their catalytic activity and during recent times they have been used as functional models of various biomolecules [1–6]; as a functional model of galactose oxidase (GO) [7], copper amine oxidases, etc. Immobilization of copper complexes over silica supports can be an effective methodology for the synthesis of active heterogeneous catalysts in the liquid phase partial oxidation of alkenes using peroxides as the oxidant [8,9]. The channels of hexagonal mesoporous silica (**HMS**) materials provide a confined space (2–50 nm) for stabilization and enhancement of the catalytic performance by influencing the chemo-, regio- and shape-selectivity of the reaction, and offer further opportunity to study "single molecular chemistry", which could take place in nano-restricted environments. Detailed studies of chemical reactions in a confined space would allow us to gain a fundamental understanding of the effects of local environment on the control of reaction pathways and the increase of product yield. A transition metal present at the surface of a mesoporous material with a very high surface area particularly showed excellent catalytic activity in liquid phase partial oxidation

reactions in the presence of *tert*-butyl hydroperoxide (TBHP) as an oxidant [10]. In the present contribution, we report the syntheses and crystal structures of two binuclear copper(II) complexes (**I** and **II**) of a tetra-coordinated amine-bisphenol ligand (H_2L), which are interestingly concomitant polymorphs. We have also shown that the immobilization of the soluble copper(II) complex **I** over highly ordered mesoporous silica resulted in a heterogeneous catalyst, which showed very good catalytic activity and epoxide selectivity in the oxidation of cyclohexene and styrene in the presence of TBHP as an oxidant. A low temperature magnetic study on complex **I** shows strong antiferromagnetic coupling between the two phenoxo-bridged Cu(II) centers.

H_2L

2. Experimental

2.1. Materials and methods

Starting materials for the synthesis of the ligand *N*,*N*-amine-bis(4,6-dimethylphenol)-*N*,*N*-dimethylethylenediamine(H_2L) viz 2,4-dimethylphenol (Lancaster), *N*,*N*-dimethylethylenediamine (Lancaster) and formaldehyde (E-Merck, Germany) were of reagent grade and were used without further purification. Solvents including acetone, methanol, dichloromethane (Merck, India) and triethylamine (SRL, India) were of reagent grade and were dried by standard methods before use. The hydrated salt of copper(II) acetate (A.R. Loba, India) was used as received.

2.1.1. Synthesis of the ligand (H_2L)

The ligand *N*,*N*-amine-bis(4,6-dimethylphenol)-*N*,*N*-dimethylethylenediamine (H_2L) was prepared by the reported method [11].

2.1.2. Synthesis of the complex [$Cu_2(L)_2$]

H_2L (0.356 gm, 1 mmol) dissolved in dry methanol/dichloromethane mixture (1:1, v/v) (20 ml) was refluxed with triethylamine (0.20 gm, 2 mmol) for 15 min to yield a yellow solution. To this solution was added $[Cu(OAc)_2] \cdot 2H_2O$ (0.20 gm, 1 mmol), and the solution was refluxed for another 5 h and filtered to remove the slight brown precipitate. Single-crystals were grown by slow evaporation at room temperature (~27 °C). The dark blue needle shape crystals (**I**) appeared within 2 days at the upper part of the vessel, while black block shape crystals (**II**) were obtained after 5 days (Fig. 1). Yield, black needles ~30%, dark blue blocks ~40%.

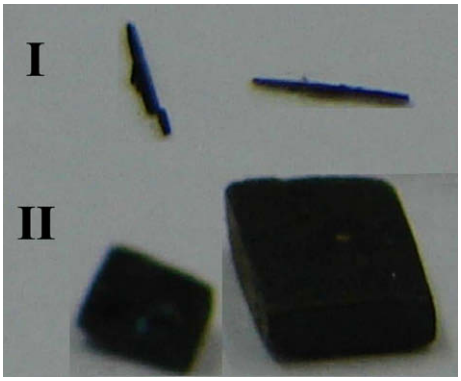

Fig. 1. Photograph of the two forms of $[Cu_2(L)_2]$ growing in $MeOH/CH_2Cl_2$ (1:1 v/v). Complex **I** gives needle-like crystals growing at the upper part of the beaker, while **II** is the block like crystals that grow at the lower part of the beaker.

Attempts to grow single-crystals at relatively low temperature (~5 °C) resulted in only **II** in 5–7 days, with no trace of **I**. *Anal.* Calc. for $C_{44}H_{60}Cu_2N_4O_4$ (836.06 g mol^{-1}): C, 63.21; H, 7.23; N, 6.70 Found: C, 62.94; H, 7.11; N, 6.41%. IR (cm^{-1}): 3423(br), 2993–2831(s), 1610(s), 1475(s), 1319(s), 1251(s), 858, 800.

2.2. Immobilization of complex **1** on 2D-hexagonal mesoporous silica

Highly ordered 2D-hexagonal mesoporous silica has been synthesized by using a mixture of cationic (cetyltrimethylammonium bromide, CTAB) and non-ionic (Brij-35, $C_{12}H_{25}$–$(OC_2H_4)_{23}$–OH, a polyether and aliphatic hydrocarbon chain) surfactant system as the supramolecular structure directing agent, by the method reported elsewhere [12]. This ordered mesoporous material was used as the catalyst support in this study. Immobilization of the metal complexes was carried out by dispersing 0.5 g of the mesoporous silica in a solution containing 120 mg of the metal complex dissolved in 25 ml dry acetonitrile. The resultant slurry was vigorously stirred at room temperature for 4 h. Then the solid was filtered, washed with acetonitrile and dried under vacuum. Hexagonal mesoporous silica and its corresponding immobilized analogs of **I** are designated as **HMS** and **HMS-Cu-I**, respectively. Both the host and the immobilized catalysts were characterized by powder XRD, electron microscopy and spectroscopic techniques.

2.3. Physical measurements

Elemental analyses were carried out using a Perkin–Elmer 240 elemental analyzer. The infrared spectrum (400–4000 cm^{-1}) was recorded from KBr pellets on a Nickolet Magna IR 750 series-II FTIR spectrophotometer. The variable-temperature magnetic susceptibility of complex **I** was performed using a SQUID magnetometer on a crystalline sample in the temperature range 300–2 K with an applied field of 0.5*T*. DSC thermograms were recorded on a Perkin–Elmer Pyris Diamond TGA/DTA thermal analyzer under a dynamic nitrogen environment.

2.4. X-ray crystallography

For complex **1**, data were measured at 293(2) K on a Bruker SMART APEX CCD area detector system [λ(Mo K_α) = 0.71073 Å], graphite monochromator with an ω-scan, crystal-detector distance 60 mm, collimator 0.5 mm. Data reduction by SAINTPLUS [13], absorption correction using an empirical method (SADABS) [14], structure solution using SHELXS-97 [15] and refined using SHELXL-97 [16]. All non-H atoms were refined anisotropically. Hydrogen atoms on the ligand were introduced in calculated positions and included in the refinement, riding on their respective parent atoms. For complex **II**, data were collected at 293(2) K with Mo K_α radiation using the MAR research image plate system positioning the crystals at 70 mm away from the image plate. One hundred frames were measured at 2° intervals with a counting time of 2 min. Data analysis was carried out with the XDS program [17]. The structure of **II** was solved by the direct method, and refined by full-matrix least-squares techniques on F^2 using SHELXS-97 [15] and SHELXL-97 [16]. The thermal parameters of all non-H-atoms were treated anisotropically. H-atoms were located from the difference Fourier map and refined isotropically. Crystal data for **I** and **II** are provided in Table 1.

Samples (**HMS** and **HMS-Cu-I**) were identified by powder XRD (PXRD) using a Seifert 3000P X-ray diffractometer on which small and wide-angle goniometers were mounted. The X-ray source was Cu K_α radiation (α = 0.15406 nm) with an applied voltage and current of 40 kV and 20 mA, respectively. Mesophases of different samples were analyzed using a JEOL, JEM 2010 TEM at an accelerating voltage of 200 kV. N_2 adsorption measurements were carried out using a Quantachrome Autosorb-1C-TCD at 77 K. Pre-treatment of the sample was done at 423 K for 3 h under high vacuum. For the Fourier transform infrared (FT-IR) measurement a Nicolet Magna IR 750 Series II was used. A Shimadzu AA-6300 double beam atomic absorption spectrophotometer was used for studying the loading of Cu through wet chemical analysis. UV–visible diffuse reflectance spectra for the immobilized catalysts were recorded on a Shimadzu 2401PC UV–visible spectrophotometer with an integrating sphere attachment using $BaSO_4$ as a background standard.

The oxidation reactions were carried out using 0.5 g of substrate and 0.10 g of loaded catalyst in 6 ml of CH_3CN under stirring in a two-neck round-bottom flask fitted with a water condenser and placed in an oil bath at 333 K. *tert*-Butylhydroperoxide (TBHP, 70 wt% aqueous, equimolar with respect to the substrate) was added immediately before the start of the reaction. Aliquots of the reaction mixture were withdrawn at various time intervals to study the progress of the reaction. In a typical operation, 0.5 cm^3 solution was taken out with the help of a micro-pipette and the solution was subjected to multiple ether extraction and the extract was concentrated. From this, 1 μl solution was withdrawn with the help of a gas tight syringe and injected to the GC port (Agilent 6890A, FID). For the identification of the products the GC retention times of different reaction products were compared with those of commercial standards.

3. Results and discussion

3.1. Structure of I and II

Both polymorphic forms, (**I**) and (**II**) (Figs. 2 and 3), of the title complex crystallize in the orthorhombic system with almost similar lattice constants (Table 1). The similarity of the unit cell dimensions of the two polymorphs suggests that the crystal structures of **I** and **II** are also related, although the space group for polymorph **I** is non-centrosymmetric, $P2_12_12_1$, with $Z = 4$, while that of polymorph **II** is a centric one, Pbnn, with $Z = 4$. Consequently, the asymmetric unit of **I** consists of a dinuclear Cu_2L_2 molecule with two phenolate O atoms acting as a $(\mu\text{-O})_2$ bridge between the metal centers. In **II**, however, only half of the complex molecule, i.e. a mononuclear CuL moiety, forms the asymmetric unit.

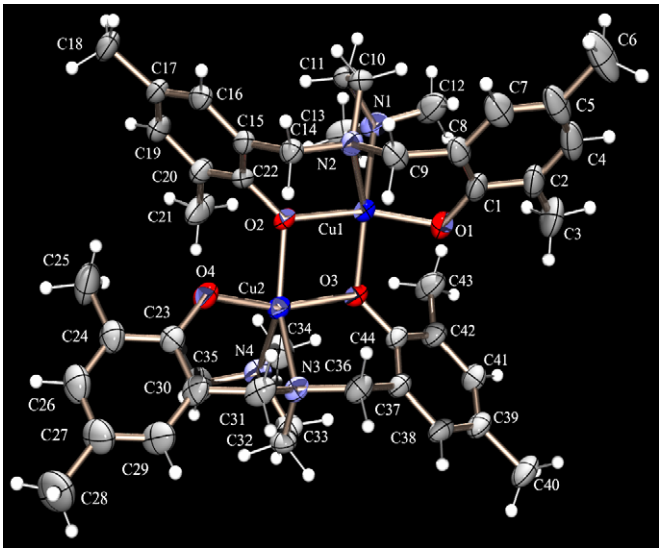

Fig. 2. ORTEP diagram (30% probability) of **I** with the atom numbering scheme.

The coordination geometry about the Cu-centers in both polymorphs can be best described as distorted square pyramidal with one phenolate oxygen, one amine nitrogen and two bridging oxygen atoms [N2, O1, O2, O3 around Cu1 and O4, N3,O3,O2 around Cu2 in **I**; O1, N2, O2, O2* (* = $x, 3/2-y, -z$) around Cu1 in **II**] defining the basal plane; the remaining amine N atoms N1, N4 in **I** and N1 in **II** occupy the apical sites. The displacement of the metal center towards the axial N atom from the least-squares plane through the basal atoms are 0.322(1) and 0.314(1) Å for Cu1 and Cu2 in **I** and 0.3146(2) Å for Cu1 in **II**. The dihedral angle of 63.74(12)°

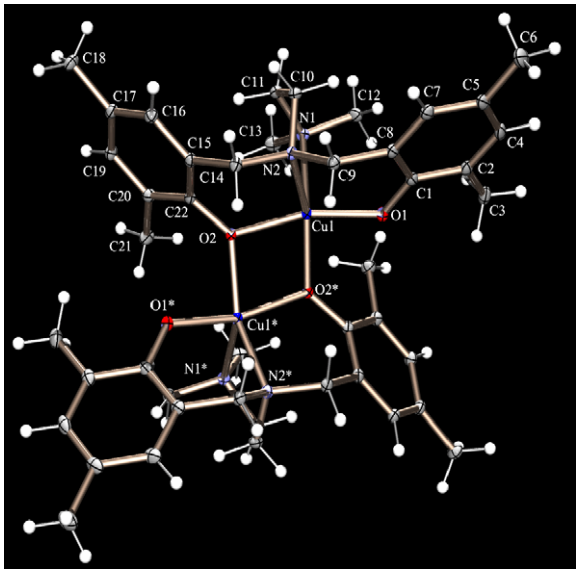

Fig. 3. ORTEP diagram (30% probability) of **II** with the atom numbering scheme.

between the two basal planes in **I** indicates a *syn-clinial* arrangement. The trigonality index parameter τ [$=(\phi_1-\phi_2)/60$, where ϕ_1 and ϕ_2 are the two largest L-M-L angles of the coordination sphere] has been calculated for the pentadentate copper sites [18,19]. The τ values of 0.25 and 0.13 for Cu1 and Cu2, respectively, in **I** indicate a different degree of distortion of the two metal sites (for a perfect square pyramid $\tau = 0$ and for a perfect trigonal bipyramid $\tau = 1$). In **II** the τ parameter for Cu1 is 0.24.

The Cu–O bond distances in the two polymorphs, lying in the range 1.866(3)–2.016(3) Å, are in agreement with that reported for analogous copper(II) systems [20–22]. The Cu–N (equatorial) bond lengths in **I** and **II**, ranging between 2.059(1) and 2.072(3) Å, are consistent with the corresponding values for similar Cu^{II}-diamine complexes [20–22]. The shortening of the Cu–N (equatorial) bond lengths [2.072(3)–2.078(3) Å in **I**, and 2.059(1) Å in **II**] in comparison to the Cu–N (axial) distances [2.352(3)–2.377(3) Å] is typical for a d^9 configuration of the Cu^{II} ion. The intramolecular Cu···Cu separations in the two polymers [2.950(1) and 3.007(1) Å] fall within the range of known Cu···Cu distances in double-bridged copper polynuclear systems [20–22]. The Cu1··O2··Cu2 angle is 96.76° and Cu1··O3··Cu2 is 96.24° for **I** and the Cu1··O2···Cu1 angle is 99.33° for **II**.

Both polymorphs exhibit a similar type of intramolecular C–H··· (arene) hydrogen bond (Table 2) involving the ethylene H- atoms and terminal phenyl rings, which influence the overall molecular conformations. In **I**, besides the intramolecular C–H··· interactions, there exists an additional intermolecular C–H··· interaction (Table 3), through which the individual dinuclear entities self assemble in the form of helices along the crystallographic *b*-axis (Fig. 4). The inherently curved nature of the dinuclear entities facilitates this helical assembly in which successive units of opposite curvature are united by CH···π interactions. The pitch of the helix is 15.33 Å. Adjacent helices are arranged in such a way that a central helix is surrounded by six other helices (Fig. 5).

The packing of the dinuclear units in **II** is also in the form of a helix, but now there are no intermolecular CH···π interactions, instead only weak van der Waals interactions leading to the association of successive units. The axis of the helix now is the crystallographic *a*-axis (Fig. 6). Inherently, the curved nature of the dinuclear entities facilitates this helical assembly in which successive units of opposite curvature stand up around a common axis. The pitch of the helix is 12.65 Å. Three-dimensional packing of these helices again is in the form of a hexagon, in which a central helix is flanked by six other helices (Fig. 7).

3.2. Heterogeneous catalysis

From the small angle powder diffraction patterns of **HMS** and **HMS-Cu-I** (SUP Fig. 1) it is clear that all four planes (100, 110, 200 and 210) of the 2D-hexagonal mesophase of **HMS** have been retained in **HMS-Cu-I**. BET surface areas and mesopore volumes for **HMS** and **HMS-Cu-I** are 1438 m^2g^{-1} and 0.93 ccg^{-1}; 976 m^2g^{-1} and 0.65 ccg^{-1}, respectively. The peak pore diameters for these two samples employing BJH pore size distribution are 2.8 and 2.1 nm, respectively. The decrease in surface area, pore diameter and pore volume of HMS after the loading of the Cu complex suggests that the metal complex has occupied the internal channel of the mesopores and is distributed uniformly inside the mesoporous channels, which is essential for utilizing the high surface area of the mesoporous host in liquid phase partial oxidation reactions.

In Table 4, the results of the catalytic activity of complex **I** immobilized over silica surfaces, **HMS-Cu-I,** are shown. Acetonitrile has been used as the solvent in all these liquid phase reactions. The major products for the partial oxidation of both styrene and cyclohexene were their respective epoxides. In Fig. 8, the time-on-stream for the conversion and epoxide selectivities in these reactions are plotted. It is clear from the figure that the selectivity of the epoxide for both substrates was high at the initial stage of the reaction. However, with time as the conversions reach

the respective maximums, the epoxide selectivities go down to some extent. This could be attributed to the hydrolysis of the epoxides to the respective diols, which is quite common for the liquid phase partial oxidation of olefins over a heterogeneous catalyst [10], as water coming from the oxidant in the reaction mixture promotes the epoxide ring opening. In Table 4, the TOF (turn over frequency) for different catalytic runs are also given. The TOF for cyclohexene conversion was relatively more than that for styrene. The immobilized catalyst shows moderately high TOFs for both the substrates. In order to show the superiority of the heterogeneous catalysts over the homogeneous ones, these reactions were carried out under homogeneous conditions and it was observed that the TOFs were found to be very poor (Table 4). These results suggest that the immobilization of complex **1** in the mesoporous matrix drastically enhances the catalytic activity. Nevertheless, the relatively high TOFs for the oxidation of styrene and cyclohexene suggest high catalytic efficiency for the Cu-hydroperoxo species that could form at the active sites in the presence of the TBHP oxidant [10]. For both the substrates the corresponding diols are the other major products. Hydrophobic aromatic ligands attached to the Cu-centers in the immobilized catalyst could provide the affinity towards the olefinic substrates. This may facilitate the adsorption of the substrates near the vicinity of the active sites and their subsequent oxidations. This could be responsible for high TOFs in these partial oxidation reactions.

3.3. Low temperature magnetic studies

The magnetic susceptibility of complex **I** was measured at 0.5*T* in the temperature range 2–300 K, and this is shown in Fig. 9. At 300 K, the $_{m}T$ value of 0.412 $cm^3\,Kmol^{-1}$ is significantly smaller than the expected value for two uncoupled Cu(II) ions. On lowering the temperature $_{m}T$ undergoes a monotonic decrease down to 80 K, suggestive of strong antiferromagnetic interactions operating. Below this temperature the $_{m}T$ value shows a constant non-zero value which may be due unaccounted background noise, as due to the strong antiferromagnetic nature we expect a zero $_{m}T$ value in this region. The magnetic data were properly fitted using the Bleaney–Bowers Eq. (1), derived from an isotropic exchange Hamiltonian $H = -JS_1 \cdot S_2$, and considering a small amount of non-coupled Cu(II) species (ρ).

$$\chi_m = (1-\rho)(2Ng^2\beta^2/kT)/[3+\exp(-J/kT)] + \rho(Ng^2\beta^2/2kT) \quad (1)$$

A best fit gives magnetic parameters of $g = 2.07$, $J = -341\ cm^{-1}$ and $\rho = 0.06$. The large negative J value indicates that the strong antiferromagnetic interactions are transmitted between Cu spins via the phenoxide linkage. The magnitude of the magnetic exchange coupling constant falls into the usual range of hydroxo-bridged Cu(II) dimers [23–25]. As depicted in SUP Fig. 2, the field dependence of the magnetization shows that the experimental magnetization value of 0.093 Nβ at 7 T is significantly lower that

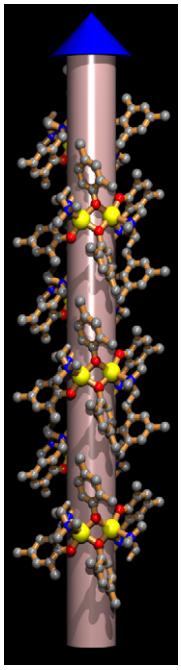

Fig. 6. Helical arrangement of dinuclear units through van der Waals interactions in **II**.

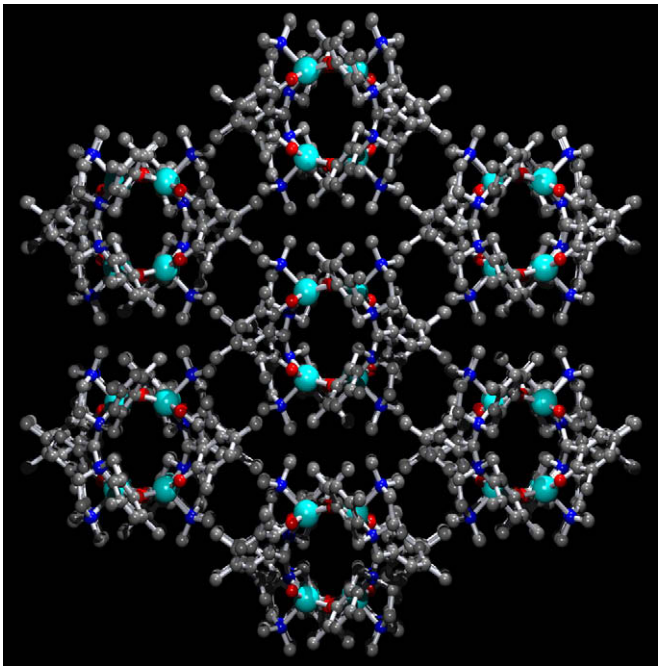

Fig. 7. Packing of helical units in **II** viewed along the *b*-axis.

the theoretical value (2.04 Nβ per Cu_2), confirming the presence of strong antiferromagnetic coupling between the Cu(II) ions through the phenoxide bridges.

3.4. Magneto-structural correlation

It is well known that the magnetic behavior of divalent copper complexes bridged equatorially by a pair of hydroxide [23–25], alkoxide [26,27] or phenoxide [28–38] oxygen atoms is highly dependent on the Cu–O–Cu bridge angle. Also it can be influenced

Table 4
Catalytic activity of **HMS-Cu-I** in the partial oxidation of olefins.[a]

Substrate	Time (h)	Conversion (%)	Epoxide (%)	Diol (%)	Others (%)	Turn over frequency (TOF)[b]

to a smaller measure by the Cu–O (bridge) distance, the Cu···Cu separation, the geometry around the copper(II) centers and the geometry around the bridging oxygen atom. The magneto structural correlations in bis(μ-phenoxide)-bridged macrocyclic copper(II) complexes with flat dinuclear centers and no electronic perturbations have been studied [30], and a linear relationship between the exchange integral (J) and the phenoxide bridging angle (ϕ) of the form: $2J = -31.95\phi + 2462$ has been proposed. Using this

relationship a bridging angle of 96.76° for **I** leads to an expected 2*J* value of $-629.5\ cm^{-1}$, contrary to the experimental 2*J* value of $-341\ cm^{-1}$. This is probably due to the many other factors affecting the 2*J* values, especially the non-flat nature of the dinuclear unit in the present case.

3.5. Study of polymorphism

The gross composition of the complexes has been determined via elemental analysis, which is consistent with the single-crystal X-ray study. Qualitatively, the physical differences of the two polymorphs are revealed in their color, shape and melting points. The synthetic method was both reliable and predictable as under repeated crystallization experiment two polymorphs could concurrently be obtained. It is interesting that though the polymorphs are concomitant in nature due to kinetic factors, complex **I** appeared more quickly (within 2 days), on the upper part of the vessel when there was no trace of the complex **II**, and could be collected easily. With the gradual evaporation of the reaction mixture and increasing concentration of the solution, growth of complex **I** was inhibited and complex **II** was favored, and this complex appeared in the lower part of the vessel. This provided an easy way of isolating the two polymorphs. It is to be noted that when the crystallization experiment was conducted at relatively low temperature only complex **II** was favored, indicating the temperature sensitivity of the nucleation processes.

As mentioned earlier, complexes **I** and **II** are concomitant polymorphs of each other. Concomitant polymorphs arise when a material crystallizes in two or more forms out of the same reaction mixture [39]. It is also the subtlest and most challenging type of polymorphism, as screening out different crystal forms is often difficult. We were lucky that the two polymorphic forms could easily be separated as the crystals of polymorph **II** have been obtained at the later stage of the crystallization. The densities of complexes **I** and **II** are 1.268 and 1.337 g/cm^3, respectively, and according to the well known 'density rule', [39] the polymorph **II** with the higher density is most likely to be more stable and should appear latter. This is consistent with the fact that crystals of polymorph **II** have been obtained at the later stage of crystallization. Melting point determination provides a convenient means of assessing the relative stabilities of the different polymorphic forms of a substance [40–44]. Accordingly, attempts have taken to carry out DSC measurements to investigate melting behavior of complexes **I** and **II** (SUP. Fig. 3). The solid-state reaction corresponds to the large endothermic peak in the regions of 253 and 258 °C for **I** and **II,** respectively, which shows sharp mass loss in the TGA curves, indicating that the melting points of the two polymorphs are slightly different. In the case of **I**, an additional small endothermic peak at temperature 197 °C is observed, indicating the fact that it is stable up to 197 °C and after this temperature a phase transition occurs [45].

4. Conclusions

Using established crystal engineering methodologies we have been able to synthesize two dinuclear Cu(II)-bisphenolate complexes having interesting functional properties. The complexes are concomitant polymorphs and the X-ray crystal structure determination reveals the versatility of the self-assembly phenomena in which the weak interactions such as C–H···π and van der Waals forces crucially determine the molecular packing within the crystal, giving rise to two different modes of self-assembly and consequently two concomitant polymorphs. The strong antiferromagnetic property of the polymorph **I** strongly correlates with the crystal structure. The efficient heterogeneous catalytic activity of the copper(II) complex **1**, due to immobilization on a 2D-hexagonal mesoporous silica, in the liquid phase partial oxidation of olefins to epoxide in the presence of TBHP as an oxidant is noteworthy. We have confined our studies to complex **I**, as the complexes **I** and **II** differ from each other only by weak non-covanent interactions, and they are expected to behave identically, particularly in solution.

ABSTRACT

Three new neutral monoamidinate nickel complexes [(2,6-^{i}Pr–C_6H_3)N=C(Ar^1)–N(Ar^2)]Ni(Ph)(PPh_3) (**1**, Ar^1 = phenyl, Ar^2 = 2,6-diispropyphenyl; **2**, Ar^1 = *p*-tolyl, Ar^2 = 2,6-dimethylphenyl; **3**, Ar^1 = *p*-tolyl, Ar^2 = pentafluorophenyl) have been synthesized and characterized. The molecular structure of **3** has been determined by X-ray diffraction analysis. The nickel complexes activated with MAO were found to exhibit very high activity, up to 1.94×10^7 g PNBE/(mol Ni h), for vinyl-addition polymerization of norbornene and oligomerize ethylene producing a mixture of dimers and trimers with a moderate turnover frequency.

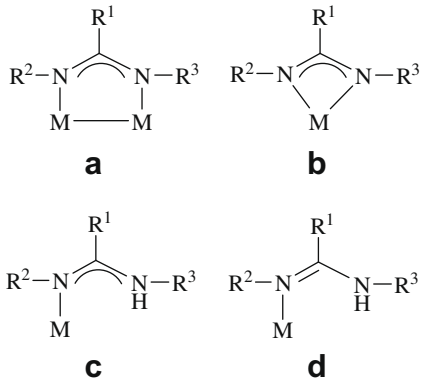
1. Introduction

Amidinates of the type [$R^1C(NR^2)(NR^3)$] (R^1, R^2, R^3 = H, alkyl, aryl or $SiMe_3$) have been widely used in recent years to form a multitude of complexes with main group and transition metals [1–3]. Due to the fact that they can be modified by tuning the substituents R^1, R^2, and R^3, different steric and electronic properties are achieved easily. Amidinates are considered as a steric equivalent of the cyclopentadienyl (Cp) moiety, and its anionic ligand $[R^1C(NR^2)(NR^3)]^-$ can provide four electrons, which promote higher electrophilicity at the metal center compared to six-electron of $[Cp]^-$. Therefore, various group IV and rare earth metal complexes bearing amidinate ligands have been developed as non-Cp olefin polymerization catalysts [4–20].

Besides, it has been found that the amidinate ligands are very useful in the preparation of new late transition metal complexes [2]. This type of ligands are extremely flexible in bonding mode (shown in Scheme 1), thus various well-characterized complexes, such as iron, cobalt, nickel, palladium, platinum and so on, have been reported [21–25]. In comparison with early transition complexes, late transition metal complexes bearing chelating amidinate ligands were less applied in olefin polymerization field due to their instability and small bite angle (62–69°). Eisen and co-workers synthesized nickel complexes with chelating monobenzamidinate or bisbenzamidinate ligands, and found that the reaction of nickel metal compounds with amidinate ligands is complicated [26–28]. In the presence of methylaluminoxane (MAO), these nickel complexes showed high activity for the addition polymerization of norbornene and also efficiently oligomerized ethylene and propylene.

Recently, much attention has been focused on neutral nickel catalysts such as salicylaldiminato Ni(II) complexes because they are less oxophilic and therefore able to tolerate polar functional-containing monomers [29–32]. In an effort to develop bulky neutral monoamindinate nickel complexes as olefins polymerization catalysts, we synthesized and characterized a series of bulky monoamindinate nickel complexes with triphenylphosphine ancillary ligand. Furthermore, ethylene oligomerization and norbornene polymerization catalyzed by neutral monoamindinate nickel complexes after activation with MAO were also investigated.



2. Experimental

2.1. General procedures

All manipulations were performed under nitrogen atmosphere using glove box and Schlenk techniques. Polymerization-grade ethylene and extra-pure-grade nitrogen were further purified

Scheme 1.

before feeding into the reactor by passing through a DC-IB gas purification instrument. Norbornene was purified by distillation over potassium and used as a solution (0.4 g/ml) in toluene. Toluene and hexane were refluxed over metallic sodium for 24 h before use. Dichloromethane was dried over phosphorus pentoxide for 8 h, and distilled under nitrogen atmosphere. 2,6-Diisopropylaniline and 2,6-dimethylaniline were purchased from Aldrich Chemical Co. and distilled under reduced pressure before use. Pentafluoroaniline, *p*-toluoyl chloride and *n*-butyllithium (2.6 M) in hexane were purchased from Aldrich Chemical Co. and used as received. Benzoyl chloride was purchased from Guangzhou Chemical Reagent Co. and used without further purification. *Trans*-chloro(phenyl)bis(triphenylphosphine) nickel(II) was synthesized according to the procedure in the literature [33]. Methylaluminoxane (MAO) was prepared by partial hydrolysis of trimethylaluminum (TMA) in toluene at 0–60 °C with $Al_2(SO_4)_3 \cdot 18H_2O$ as the water source. The initial $[H_2O]/[Al]$ in molar ratio was 1.3.

2.2. Characterization

NMR spectra were recorded on a Varian Mercury-Plus 300 MHz NMR spectrometer and referenced versus TMS as standard. Elemental analyses were determined with a Vario EL series elemental analyzer from Elementar. MS-FAB spectra were obtained with a VG ZAB-HS scan instrument, using *m*-nitrobenzylalcohol as matrix. The GC–MS data were recorded with a Finnigan Voyager GC-8000 Top series GC–MS system with DB-5MS GC column. Gel permeation chromatography (GPC) analyses of the molecular weight and molecular weight distribution of the polymers were performed on a Waters Alliance GPC-2000 instrument using standard polystyrene as the reference and with 1,2,4-trichlorobenzene as the eluent at 135 °C. The polymer samples were processed into KBr thin films for IR measurements. Fourier transform infrared (FTIR) spectra were recorded on a Nicolet NEXUS–670 FTIR spectrometer. The X-ray diffraction data of single crystal of complex **2** was obtained with the $\omega-2\theta$ scan mode on a Bruker SMART 1000 CCD diffractiometer with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) at 173 K. The structure was solved using direct methods, and further refinement with full-matrix least squares on F^2 was obtained with the SHELXTL program package. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced in calculated positions with the displacement factors of the host carbon atoms except disordered hexane molecule.

2.3. Ethylene oligomerization

Ethylene oligomerization reactions were performed in a 50 ml glass flask equipped with magnetic stirrer, oil control of temperature, and continuous feed of ethylene was used. A typical reaction was performed by adding proper amount of MAO solid and introducing toluene (19 ml) into the reactor under ethylene atmosphere. The toluene catalyst solution (1 ml, [Ni] = 5 μmol) was injected into the reactor *via* syringe. Ethylene was continuously fed in order to maintain the ethylene pressure at 0.5 atm. After 30 min, the reaction was stopped by cooling the system to 0 °C, and terminated by addition of cold acidic ethanol (ethanol–HCl, 95:5). The organic layer was analyzed quickly by gas chromatography (GC) for determining the composition and mass distribution of oligomers.

2.4. Norbornene polymerization

Norbornene polymerization reactions were performed in a 50 ml glass flask equipped with magnetic stirrer, oil control of temperature. A typical reaction was performed by adding proper amount of MAO solid and introducing toluene (14 ml) into the reactor under nitrogen atmosphere. Toluene solution of norbornene (10 ml, 0.4 g/ml) and the toluene catalyst solution (1 ml, [Ni] = 1 μmol) was injected into the reactor *via* syringe. After 10 min, the reaction was terminated by adding 200 ml of the acidic ethanol (ethanol–HCl, 95:5). The precipitated polymer was collected and treated by filtering, washing with ethanol several times, and then drying in vacuum at 60 °C to a constant weight.

2.5. Synthesis of bis(2,6-diisopropylphenyl)benzamidine (*L1*)

Benzoyl chloride (1.1 ml, 10 mmol) and triethylamine (1.6 ml, 11 mmol) were added to a vigorously stirred solution of 2,6-diisopropylaniline (1.9 ml, 10 mmol) in CH_2Cl_2 (45 ml). After 3 h, the precipitate of $(C_2H_5)_3N \cdot HCl$ was filtrated, and white solid benzamide was obtained by evaporating the solvent. Then, an excess of thionyl chloride (2.0 ml, 28 mmol) was added to the benzamide, and the reaction mixtures were stirred for 2 h at 80 °C. The remainder thionyl chloride was distilled off under reduced pressure, to obtain the imidoyl chloride as yellow, slowly solidifying oil. Successively, toluene (50 ml), triethylamine (1.6 ml, 11 mmol) and 2,6-diisopropylaniline (1.9 ml, 10 mmol) were added to the reaction system. The mixtures were heated to reflux for 12 h under the protection of nitrogen atmosphere. $(C_2H_5)_3N \cdot HCl$ was removed by filtration, and toluene was evaporated from the filtrate. After recrystallization of the product from ethanol/water, bis(2,6-diisopropylphenyl)benzamidine (**L1**) as a colorless crystal was obtained in 60% yield (2.65 g, 6.02 mmol). EI-MS (*m*/*z*): 441 $[M]^+$. ^1H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.35–6.85 (m, 11H, Ar–*H*), 5.65 (s, 1H, N*H*), 3.25 (m, 4H, C*H*$(CH_3)_2$), 1.31 (d, 12H, CH(C*H*$_3)_2$), 0.94 (d, 12H, CH(C*H*$_3)_2$). ^{13}C NMR (300 MHz, $CDCl_3$), δ (ppm): 153.43 (*C*=N), 145.19, 143.81, 139.27, 135.05, 134.02, 129.11, 128.78, 127.66, 127.47, 123.61, 123.42, 123.22, 28.57, 25.15 (*C*H$(CH_3)_2$), 22.45, 22.30 (CH(*C*H$_3)_2$). Anal. *Calc*. for $C_{31}H_{40}N_2$: C, 84.49; H, 9.15; N, 6.36. Found: C, 84.07; H, 9.20; N, 6.28%.

2.6. Synthesis of 2,6-diisopropylphenyl-4-methyl-N-(2,6-dimethylphenyl) benzamidine (*L2*)

L2 was prepared according to the method described above in 72% yield. EI-MS (*m*/*z*): 400 $[M]^+$. ^1H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.36–6.90 (m, 10H, Ar–*H*), 5.73 (s, 1H, N*H*), 3.24 (m, 2H, C*H*$(CH_3)_2$), 2.38 (s, 3H, 4-C*H*$_3C_6H_2$), 1.38 (s, 6H, C*H*$_3$), 1.04 (d, 12H, CH(C*H*$_3)_2$). ^{13}C NMR (300 MHz, $CDCl_3$), δ (ppm): 154.20 (*C*=N), 145.18, 143.68, 139.44, 134.77, 131.75, 129.10, 128.40, 128.05, 127.48, 126.33, 123.55, 122.89, 28.53 (*C*H$(CH_3)_2$), 24.52 (CH_3–Ph), 22.08 (*C*H$_3$–Ph), 18.98 (CH(*C*H$_3)_2$). Anal. *Calc*. for $C_{28}H_{34}N_2$: C, 84.37; H, 8.60; N, 7.03. Found: C, 84.18; H, 8.51; N, 6.92%.

2.7. Synthesis of 2,6-diisopropylphenyl-4-methyl-N-(pentafluorophenyl)benzamidine (**L3**)

L3 was prepared according to the method described above. The resulting product was purified by column chromatography on silica gel using petroleum ether/ethyl acetate (10/1) as eluent, and then recrystallized from ethanol in 49% yield. EI-MS (*m*/*z*): 461 $[M]^+$. ^1H NMR (300 MHz, $CDCl_3$), δ (ppm): 7.35–7.17 (m, 7H, Ar–*H*), 6.16 (s, 1H, N*H*), 3.43 (m, 2H, C*H*$(CH_3)_2$), 2.35 (s, 3H, 4-C*H*$_3C_6H_2$), 1.37 (d, 12H, CH(C*H*$_3)_2$). ^{13}C NMR (300 MHz, $CDCl_3$), δ (ppm): 162.26 (C=N), 146.80, 140.73, 138.73, 138.63, 136.33, 132.00, 131.71, 129.59, 128.79, 127.17, 126.58, 123.69, 28.93 (*C*H$(CH_3)_2$), 24.21 (*C*H$_3$–Ph), 21.36 (CH(*C*H$_3)_2$). Anal. *Calc.* for $C_{26}H_{25}F_5N_2$: C, 67.82; H, 5.47; N, 6.08. Found: C, 67.93; H, 5.32; N, 6.02%.

2.8. Synthesis of [(2,6-^{i}PrC$_6$H$_3$)N=C(ph)-N(2,6-^{i}PrC$_6$H$_3$)]Ni(PPh$_3$)(Ph) (**1**)

n-BuLi (0.43 ml, 2.6 M, 1.1 mmol) in hexane was added dropwise to a solution of **L1** (0.44 g, 1 mmol) in toluene (20 ml) at −78 °C. The mixtures were warmed up to room temperature and stirred overnight. *Trans*-chloro(phenyl)bis(triphenylphosphine) nickel(II) (0.69 g, 1.0 mmol) in toluene (20 ml) was added and continuously stirred overnight at room temperature. After filtration, the filtrate was concentrated to a volume of *ca.* 5 ml under reduced pressure, and then *n*-hexane (20 ml) was added. Solvent was removed from the precipitate via cannula filtration, and the residual orange powder was washed with *n*-hexane (3 × 5 ml). Drying in vacuo produces the desired nickel complex in 45% yield. FAB$^+$-MS: *m*/*z*: 836, 837, 838, $[M]^+$; 574, 575, 576, 577, $[M-PPh_3]^+$; 497, 498, $[M-PPh_3-Ph]^+$; 440, 441, 442, $[L1]^+$; 262, 263, 264, $[PPh_3]^+$. Anal. *Calc.* for $C_{55}H_{59}N_2NiP$: C, 78.85; H, 7.10; N, 3.34. Found: C, 78.32; H, 7.00; N, 3.15%.

2.9. Synthesis of [(2,6-^{i}PrC$_6$H$_3$)N=C(4-CH$_3$C$_6$H$_4$)-N(2,6-MeC$_6$H$_3$)]Ni(PPh$_3$)(Ph) (**2**)

Complex **2** was prepared according to the same method described for **1**. Because of the good solubility in hexane, **2** was obtained in 26% yield. FAB$^+$-MS: *m*/*z*: 794, 795, 796, $[M]^+$; 532, 533, 534, $[M-PPh_3]^+$; 455, 456, 457, $[M-PPh_3-Ph]^+$; 398, 399, 400, $[L2]^+$; 262, 263, 264, $[PPh_3]^+$. 2.10. Synthesis of [(2,6-^{i}PrC$_6$H$_3$)N=C(4-CH$_3$C$_6$H$_4$)-N(pentafluorophenyl)]Ni(PPh$_3$)(Ph) (**3**)

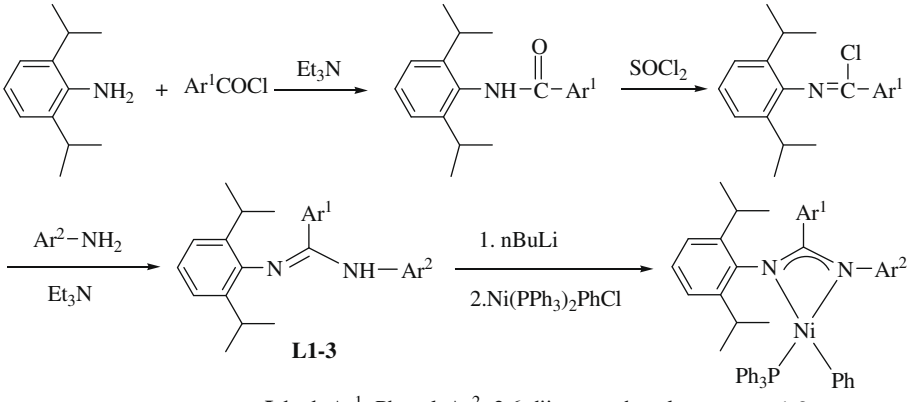
Complex **3** was prepared according to the same method described for **1** in 52% yield. FAB$^+$-MS: *m*/*z*: 836, 837, 838, $[M]^+$; 556, 557, 558, 559, 860, $[M-PPh_3]^+$; 594, 595, 596, 597, $[M-PPh_3-Ph]^+$; 460, 461, 462, $[L3]^+$; 262, 263, 264, $[PPh_3]^+$. Anal. *Calc.* for $C_{50}H_{44}F_5N_2NiP$: C, 70.03; H, 5.17; N, 3.27. Found: C, 70.55; H, 5.05; N, 3.04%.

3. Results and discussion



3.1. Synthesis and characterizations of complexes

As shown in Scheme 2, the ligands were prepared according to a modified literature procedure in high yield [16]. Among these ligands, **L1** has been reported [17,34]. Benzamides were easily available from 2,6-diisopropylaniline and benzoyl chloride. Imidoyl chloride could be produced by the dehydration reaction between benzamide and the excess of thionyl chloride. After distilling the residue of thionyl chloride off, the crude products were obtained by the reaction between the quantitative anilines and imidoyl chlorides in refluxing toluene. Pure ligands **L1** and **L2** were recrystallized from ethanol/water solution, while **L3** was purified using silica chromatography and then recrystallized from ethanol. All of these ligands had been characterized by EI-MS, NMR and elemental analysis.

After the amidinate ligands were treated with *n*-butyllithium in toluene, an equimolar amount of *trans*-chloro(phenyl)bis(triphenylphosphine) nickel(II) was added to the solution and nickel complexes **1**–**3** were obtained as orange solids in a moderate yield.

Single crystal of complex **3** suitable for X-ray diffraction was grown from toluene/hexane solution under nitrogen atmosphere at ambient temperature. The diagram of the single-crystal structure is presented in Fig. 1 along with selected bond lengths and bond angles. Besides, the data collection and structure refinement parameters are summarized in Table 1.

Complex **3** in the solid state cocrystallizes with half a hexane molecule, which does not interact with the metal center and is omitted for clarity. As seen in Fig. 1, complex **3** contains one chelating amidinate, one phenyl, and one triphenylphosphine ancillary ligand around the nickel metal center, adopting a slightly distorted square planar coordination geometry (the sum of the angles around the nickel atom is near 360°). The aryl rings in aniline

moieties are tilted to the chelate ring, the dihedral angles being 65° for the ring bonded to N(1), and 75° for the ring bonded to N(2), respectively. The C(7)–N(1) and C(7)–N(2) bond length are 1.350(4) and 1.317(4) Å, respectively. It is similar to typical C(sp^2)–N(sp^2) single and double bonds length, which indicate rather significant delocalization in the amidinate complex. The C_{ph}–Ni bond length (1.883(3) Å) in **3** is similar to that of neutral salicylaldiminato Ni(II), while P–Ni bond length (2.139(1) Å) in **3** is slightly shorter than that of neutral salicylaldiminato Ni(II) (2.172(2) Å) [29], suggesting there is a stronger interaction between nickel metal center and the triphenylphosphine. The N(1)–Ni–N(2) bite angle in **3** is 66.9(1)°, smaller than that of Ni(II) monoamidinate acetylacetonate complexes (69.7(1)°) and bisamidinate nickel complex (68.6(1)°) [28,35].

3.2. Ethylene oligomerization

As reported in the literature, for neutral salicylaldiminato Ni(II) complexes, Ni(COD)$_2$ usually was used as phosphine scavenger in ethylene polymerization [29–32]. The phosphine scavenger bound PPh_3 more strongly than the nickel(II) center, effectively removing phosphine from the salicylaldiminato nickel catalysts. However, in attempts to polymerize ethylene with **1** or **3** combined with two or 20-fold Ni(COD)$_2$, neither polymers nor oligomers of ethylene were obtained. The similar phenomenon was also found in neutral iminophosphonamide (PN_2) nickel complex [36,37]. In contrast, these neutral nickel complexes could be activated for ethylene oligomerization upon the addition of MAO. **1**–**3**/MAO showed moderate turnover frequency (TOF) of *ca.* 5×10^3 mol ethylene/(mol Ni h) for ethylene oligomerization at 0.5 atm of ethylene pressure (see Table 2).

The structure of the nickel complexes slightly influences their catalytic activities. Bulky nickel complex **1** showed a higher TOF than **2**, while **3** with an electron-withdrawing pentafluorophenyl group exhibited the highest TOF for ethylene oligomerization. A reasonable explanation for the TOF enhancement is that the introducing of an electron-withdrawing group would generate a more electrophilic nickel center, thus reducing activation energy for ethylene insertion, and favoring the olefin coordination and insertion [38,39].

GC–MS analysis (Fig. 2) confirmed that the oligomer obtained at 20 °C mainly contained dimers (*ca.* 65%) and trimers (*ca.* 35%) of ethylene. In addition, with an increase in the reaction temperature from 20 to 40 °C, the TOF and selectivity of products were also enhanced. At 40 °C, **3** showed a high selectivity of dimerization of ethylene, up to 94%.

Even though **1** has two bulky 2,6-diisopropylphenyl substituents, only low-molecular-weight oligomers were obtained from the catalysis reaction. Obviously, the results can be attributed to the unique structure of the complex. Recent DFT-based stochastic simulation on amidinate nickel complexes in ethylene polymerization indicated that the insertion barrier versus chain transfer is lower than 0.8 kcal/mol, suggesting there is a relatively rapid rate of chain transfer in ethylene oligomerization [37]. Moreover, as shown in X-ray single-crystal structure of **3**, the coordinated bite angle of four-membered ring complex is 66.9(1)°, resulting in the steric substituents in axial location being far away from the nickel center. The unshielded metal center easily leads to rapid β-H elimination or chain transfer in the process of polymerization. Therefore, low-molecular-weight oligomers rather than high-molecular-weight polymers were obtained.

Table 2
The results of ethylene oligomerzation with **1**–**3**/MAO.

Entry	Complex	T (°C)	Oligomers (mol%)			TOF[c]
			C_4	C_6	C_8–C_{12}	
1[a]	**1** or **3**	20	–	–	–	inactive
2	**1**	20	63.4	36.0	0.6	4.6
3	**2**	20	68.5	31.5	–	4.3

[a] Two or 20-fold Ni(COD)$_2$ instead of MAO.
[b] Ni, 5 μmol.
[c] 10^3 mol ethylene/(mol Ni h).

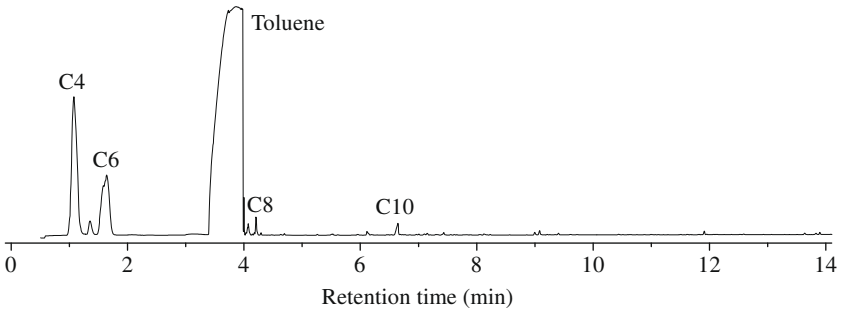

Fig. 2. GC spectrum of oligomer obtained by **1**/MAO at 20 °C (entry 2 in Table 2).

3.3. Norbornene polymerization

The monoamidinate nickel complexes were also tested for norbornene (NBE) polymerization with MAO as cocatalyst and the polymerization results are summarized in Table 3. These three complexes showed very high activities (*ca.* 10^7 g PNBE/mol Ni h) for norbornene polymerization. As shown in Table 3, the reaction temperature strongly affected the catalytic activities. With an increase in reaction temperature, the catalytic activity for norbornene polymerizations increased and then decreased. All of the complexes showed the highest activities for norbornene polymerization at 60 °C. Polymerization temperature also affected the molecular weights of the polymers. The M_n values of the obtained polymers decreased with an increase in polymerization temperature, suggesting that chain transfer or termination began to accelerate at a high temperature. The molecular weight distributions (MWDs) were close to 2 and appeared as a single modal in GPC chromatograms, which indicated that the polymerizations occur at the single active site.

Table 3
The results of norbornene polymerization with **1**–**3**/MAO.

Entry	Complex	T (°C)	Yield (g)	Activity[a]	M_n (kg/mol)	MWD
1	**1**	0	0.96	0.58	375.8	2.31
2	**1**	40	1.59	0.95	335.0	2.55
3	**1**	60	2.47	1.48	304.0	2.44
4	**1**	80	2.38	1.43	265.3	2.63
5	**2**	0	1.08	0.65	311.1	2.70
6	**2**	40	1.62	0.97	284.3	2.52
7	**2**	60	2.34	1.40	209.4	2.47
8	**2**	80	1.76	1.06	146.2	2.58
9	**3**	0	2.01	1.21	282.8	2.67
10	**3**	40	2.58	1.55	195.8	2.66
11	**3**	60	3.24	1.94	123.6	2.71
12	**3**	80	2.94	1.76	82.5	2.46

Reaction conditions: Ni complex, 1 μmol; norbornene, 4 g; Al/Ni = 600; t_p, 10 min; total solution volume, 25 ml toluene.
[a] In unit of 10^7 g PNBE/(mol Ni h).

Moreover, a comparison between the polymerization results of three catalytic systems at 60 °C showed that the structure of the nickel complex played effects on the polymerization. Through the comparison between **1** and **2**, it is found that the steric hindrance of complex did not clearly affect the catalytic activity, but obviously affected the molecular weight of the polymer. The M_n values of the obtained polynorbornenes by different catalysts were in the order of **1** > **2** > **3**, which is well consistent with the steric bulk of these complexes. Additionally, complex **3** with an electron-withdrawing pentafluorophenyl group exhibited the highest catalytic activity for norbornene polymerization, which might result from a more electrophilic nickel center allowing the rapid olefin insertion.

All of the obtained polynorbornenes are soluble in chlorobenzene, *o*-dichlorobenzene and cyclohexane at room temperature, and show similar IR and ^{1}H NMR spectra. The IR spectrum revealed no traces of double bond which often appeared at 1620–1680, 966 and 735 cm^{-1}, while the existence of vibration bands of bicyclics of norbornene units was at 941 cm^{-1}. The ^{1}H NMR spectrum (0.86–2.38 ppm) (Fig. 3) also proved no traces of any double bond, ensuring the occurrence of vinyl-type polymerization rather than ring-opening metathesis polymerization [40–43]. TGA curves of the obtained polynorbornenes showed that the polymer samples were stable up to 450 °C. Attempts to measure glass transition temperature (T_g) of the polynorbornenes by DSC were unsuccessful

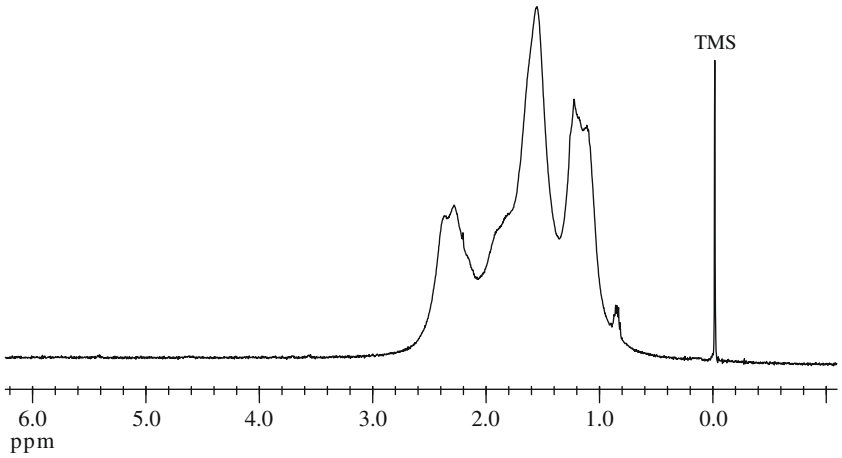

Fig. 3. ^{1}H NMR spectrum of polynorbornene prepared by **1**/MAO at 60 °C.

because T_g was close to the decomposition temperature [44]. The wide-angle X-ray diffraction analysis of the obtained polynorbornene showed two major broad peaks ($2\theta = 9–11^\circ$ and $17–19^\circ$), which indicated that the obtained polymer was non-crystalline and had low stereoregularity [45,46].

4. Conclusion

Three monoamidinate nickel complexes have been synthesized and characterized. The solid-state structure of complex **3** reveals four-coordination and a rough planar geometry with nickel center. Though monoamidinate nickel complexes had bulky steric hindrance, the small bite angle of four-membered ring complex led to ethylene oligomerization in the presence of MAO, and the obtained products were mainly dimers and trimers. However, complexes **1**–**3** activated with MAO showed very high catalytic activities for vinyl-addition polymerization of norbornene. Complex **1** with the most steric hindrance groups produced the highest molecular-weight polynorbornene, while complex **3** with an electron-withdrawing group exhibited the highest catalytic activity for norbornene polymerization.

Acknowledgments

The financial Supports by NSFC (Projects 20734004, 20674097 and 20604034), the Science Foundation of Guangdong Province (Projects 8251027501000018 and 06300069) and the Ministry of Education of China (Foundation for Ph.D. Training) are gratefully acknowledged. We thank Dr. Wei-Xiong Zhang for single-crystal X-ray technical assistance.

Appendix A. Supplementary data

CCDC 700699 contains the supplementary crystallographic data for complex **1**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2008.12.019.

X-ray diffraction

ABSTRACT

Based on the versatile ligand 3,5-bis(4-pyridyl)-1*H*-1,2,4-triazole (Hbpt) derived from an in situ metal/ligand reaction, a series of coordination compounds $CoCl_4(H_3bpt)(H_2O)$ (**1**), $Cu(H_2bpt)_2(SO_4)_2(H_2O)_6$ (**2**), $[Ag(bpt)]_n$ (**3**), $[Co(Hbpt)(pa)]_n$ (**4**), $[Co(Hbpt)(pda)]_n$ (**5**) and $[Cu(Hbpt)(pda)(H_2O)]_n$ (**6**) have been constructed (pa = phthalate, pda = 1,3-phenylenediacetate). The structures of these targeted complexes have been characterized by X-ray single-crystal diffraction techniques. Structural analysis reveals that Hbpt adopts versatile coordination modes to arrange the metal ions in 0-D point, simple (4,4) layers and dinuclear core chains in **1**–**3**, which are further extended via the benzenedicarboxylate connectors to give rise to a variety of coordination networks such as (4,4), $(4^{12}\cdot 6^3)$, $(6^4\cdot 8^2)$ topologies in **4**–**6**. The supramolecular organization through hydrogen bonds is analyzed for these complexes and thermal stability of these crystalline materials has been explored by TG-DTG.

1. Introduction

In coordination and supramolecular chemical fields, metal–organic frameworks (MOFs) have intrigued great interest for their potential application in catalysis, gas absorption, non-linear optics, ion-exchange, luminescence, magnetism and many other fields [1–7]. In principle, the design and syntheses of metal–organic networks via the self-assembly of metal ions and multifunctional ligands greatly depend on the organic ligands (spacers) and metal ions (nodes). Linear 4,4′-bipyridine(4,4′-bpy) and 4,4′-bipyridine-like N,N′-donor ligands are often used as spacers to form open metal–organic frameworks [8–11]. Through introducing moieties between the two 4-pyridyl groups, several couples of bent N,N′-donor ligands, such as 2,5-bis(4-pyridylethynyl) thiophene and 4-amino-3,5-bis(4-pyridyl)-1,2,4-triazole, have been used as building blocks to extend metal–organic frameworks [12–17]. Here we introduce the 1*H*-1,2,4-triazole moiety between the two 4-pyridyl groups due to the following considerations. First, it can act as a bridge between metal centers, thus mediating exchange coupling, and represents a hybrid of pyrazole and imidazole with regard to the arrangement of its three heteroatoms thus promising a rich and versatile coordination chemistry. Second, the prototropy and conjugation between the 1*H*-1,2,4-triazole and 4-pyridyl groups not only alter the electron density in different parts of the molecule, but also make the ligand more flexible, in addition, the wide application in spin-crossover materials and pharmacologically active compounds also makes this moiety more attractive [18–20]. Benzenedicarboxylate species such as phthalate (pa), isophthalate (ip), 1,3-phenylenediacetate (pda) and terephthalate (tp) are widely used in the construction of MOFs, because of their abilities to form non-covalent cooperative forces such as hydrogen bonding and/or aromatic stacking, and to compensate the charge for the neutral ligand [21–24].

Nowadays in situ metal/ligand reactions show great merit in both coordination chemistry and organic synthesis [25,26]. Herein, by using a coordination compound as an intermediate, 3,5-bis(4-pyridyl)-1*H*-1,2,4-triazole has been synthesized via an in situ metal/ligand reaction.

With this understanding, one crucial aim of this work is to explore the introduction effect of 1*H*-1,2,4-triazole for tuning the structural assembly, which may provide further insights in designing new hybrid crystalline materials. In the present work, we report the synthesis of Hbpt and six new coordination polymers, namely $CoCl_4(H_3bpt)(H_2O)$ (**1**), $Cu(H_2bpt)_2(SO_4)_2(H_2O)_6$ (**2**), $[Ag(bpt)]_n$ (**3**), $[Co(Hbpt)(pa)]_n$ (**4**), $[Co(Hbpt)(pda)]_n$ (**5**) and $[Cu(Hbpt)(pda)(H_2O)]_n$ (**6**). The compounds have been structurally determined by single-crystal X-ray diffraction, and characterized by IR and TG-DTG.

2. Experimental

2.1. Materials and analytical methods

All of the reagents were commercially available without further purification. C, H, N contents were determined on a Vario EL III

analyzer. IR spectra were recorded on a Tensor 27 spectrometer (Bruker Optics, Ettlingen, Germany). All NMR spectra were measured on a Varian INOVA 400 MHz spectrometer. Thermogravimetric analysis was performed on a Netzsch STA 449C simultaneous TGA with a heating rate of 10 °C min^{-1} under nitrogen.

2.2. Syntheses and characterization

2.2.1. 3,5-Bis(4-pyridyl)-1H-1,2,4-triazole (Hbpt)

The Hbpt ligand was synthesized via an in situ metal/ligand reaction and demetallation as followed (Scheme 1): a mixture of 4-cyanopyridine (1.04 g, 10.0 mmol), aqueous ammonium (2.0 mL), $CuSO_4 \cdot 5H_2O$ (0.249 g, 1.0 mmol) and water (5 mL) in a 20-mL Teflon-lined autoclave was treated at 140 °C for 72 h. The resulting mixture was filtered to give crystalline $[Cu_2(bpt)_2]$ in 40% yield based on 4-cyanopyridine.

The product then underwent a process of demetallation: the powder was placed in a 200 mL flask containing 100 mL water, into which 2 mL ammonium sulfide was dropped with stirring. After 0.5 h the solution became dark, and then was boiled to make CuS crystallize out completely. It was then filtered to give a colorless solution and concentrated to afford 3,5-bis(4-pyridyl)-1*H*-1,2,4-triazole (Hbpt) (390 mg, 35% based on 4-cyanopyridine) as a white powder.

Mp 296–297 °C; IR (cm^{-1}, KBr): 3408(w), 3088(m), 2623(m), 1606(s), 1580(s), 1447(m), 1423(m), 1378(m), 1362(m), 1152(s), 1015(m), 987(m), 832(s), 720(m), 709(m), 528(s); ^1H NMR (400 MHz, DMSO-d_6, δ ppm): 8.010–8.025 (4H, d, J = 4.4 Hz), 8.768–8.779 (4H, d, J = 4.4 Hz), 15.232 (1H, s, Triazole-H); *Anal.* Calc. for $C_{12}H_9N_5$: C, 64.56; H, 4.06; N, 31.37. Found:C, 64.63; H, 4.19; N, 32.00%.

2.2.2. $CoCl_4(H_3bpt)(H_2O)$ (**1**)

$CoCl_2 \cdot 6H_2O$ (0.047 g, 0.2 mmol) was added to a methanol solution (10 mL) of Hbpt (44.6 mg, 0.2 mmol) with stirring. The resulting solution was filtered and kept at room temperature for crystallization. After 10 days, light blue crystals of **1** suitable for an X-ray crystallographic study were obtained in a yield of 27% (based on Co). *Anal.* Calc. for **1** ($C_{12}H_{13}Cl_4CoN_5O$): C, 32.46; H, 2.95; N, 15.77. Found: C, 32.41; H, 2.87; N, 15.76%. IR (cm^{-1}, KBr): 3404(w), 3085(m), 2617(m), 1636(m), 1606(w), 1570(s), 1445(s), 1374(m), 1366(m), 1154(s), 1045(m), 967(m), 812(s), 710(m), 521(s).

2.2.3. $Cu(H_2bpt)_2(SO_4)_2(H_2O)_6$ (**2**)

The same synthetic procedure as that for **1** was used except that $CoCl_2 \cdot 6H_2O$ was replaced by $CuSO_4 \cdot 5H_2O$, and blue block X-ray-quality crystals were obtained in a yield of 27% (based on Cu). *Anal.* Calc. for **2** ($C_{24}H_{32}CuN_{10}O_{14}S_2$): C, 35.49; H, 3.97; N, 17.24. Found: C, 35.57; H, 3.88; N, 16.98%. IR (cm^{-1}, KBr): 3409(w), 3085(m), 3019(w), 2617(m), 1626(w), 1570(s), 1426(s), 1374(m), 1366(m), 1154(s), 1017(m), 967(m), 840(s), 736(m), 521(s).

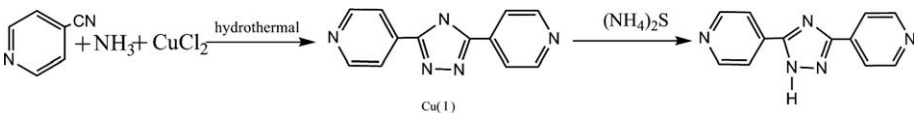
2.2.4. $[Ag(bpt)]_n$ (**3**)

A solution of Hbpt (4.46 mg, 0.020 mmol) in MeOH (10 mL) was carefully layered onto a solution of $AgNO_3$ (3.40 mg, 0.020 mmol) in H_2O (10 mL). The solution was left for 6 days at room temperature, and colorless crystals were obtained in a yield of 78% (based on Ag). *Anal.* Calc. for **3** ($C_{12}H_8AgN_5$): C, 43.66; H, 2.44; N, 21.22. Found: C, 43.54; H, 2.60; N, 21.34%. IR (cm^{-1}, KBr): 3502(w), 3321 (w), 1635(s), 1375(vs), 1532(w), 1482(w), 1307(s), 1215(m), 1037(w), 834(s), 735(w).

2.2.5. $[Co(Hbpt)(pa)]_n$ (**4**)

A mixture containing $Co(OAc)_2 \cdot 4H_2O$ (24.9 mg, 0.10 mmol), Hbpt (22.3 mg, 0.10 mmol), H_2pa (16.6 mg, 0.10 mmol) and water (6 mL) was sealed in a 20 mL Teflon-lined stainless steel vessel, which was heated at 140 °C for 3 days and then cooled to room temperature at a rate of 5 °C/h. Red prism crystals of **4** were collected in a yield of 55% (based on Co). *Anal.* Calc. for **4** ($C_{20}H_{15}CoN_5O_5$): C, 51.74; H, 3.26; N, 15.08. Found: C, 51.65; H, 3.31; N, 15.15%. IR (cm^{-1}, KBr): 3345(s), 3260(s), 1643(w), 1604(s), 1550(s), 1485(s), 1461(s), 1403(s), 1378(s), 1225(m), 1038(w), 1060(w), 1020(s), 995(m), 952(w), 839(m), 771(m), 731(m), 704(s), 604(s), 508(m).

2.2.6. $[Co(Hbpt)(pda)]_n$ (**5**)



The same synthetic procedure as that for **4** was used except that H_2pa was replaced by H_2pda, and red prismatic crystals of **5** were collected in a yield of 50% (based on Co). *Anal.* Calc. for **5** ($C_{22}H_{17}CoN_5O_4$): C, 55.71; H, 3.61; N, 14.76. Found: C, 55.65; H, 3.58; N, 14.85%. IR (cm^{-1}, KBr): 3332(s), 1635(s), 1615(s), 1581(m), 1544(s), 1456(s), 1399(s), 1220(m), 1036(w), 917(w), 836(s),740(s), 720(s), 615(m), 521(m), 433(m).

2.2.7. $[Cu(Hbpt)(pda)(H_2O)]_n$ (**6**)

The same synthetic procedure as that for **5** was used except that $Co(OAc)_2 \cdot 4H_2O$ was replaced by $Cu(OAc)_2 \cdot 4H_2O$, and blue prismatic crystals of **6** were collected in a yield of 57% (based on Cu). *Anal.* Calc. for **6** ($C_{22}H_{19}CuN_5O_5$): C, 53.17; H, 3.85; N, 14.09. Found: C, 53.22; H, 3.88; N, 14.14%. IR (cm^{-1}, KBr): 3410(w), 1635(s), 1605(s), 1575(m), 1537(s), 1404(s), 1378(s), 1235(m), 1112(w), 1032(w), 910(w), 854(s),735(s), 700(s), 613(m), 523(m), 444(m).

2.3. Crystal structure determination and structure refinement

All diffraction data for complexes **1–6** were collected on a Bruker/Siemens Smart Apex II CCD diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at 293(2) K. Cell parameters were retrieved using SMART [27] software and refined using SAINTPLUS [28] for all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPLUS software. Absorption corrections were applied using SADABS [29]. All structures were solved by the direct methods using the SHELXS program of the SHELXTL-97 [30] package and refined with SHELXL. Metal atoms in all the complexes were located from the E-maps and other non-hydrogen atoms were located in successive difference Fourier syntheses. The final refinements were performed by full-matrix least squares methods with anisotropic thermal parameters for non-hydrogen atoms on F^2. The H atoms of triazole and pyridyl(N) in Hbpt were located from difference Fourier maps, all other hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms. The oxygen atoms (O(1), O(2)) of pda anions in **6** are disordered and an occupancy ratio of 0.6:0.4 was found. Details of the data collection and refinement are given

Scheme 1. In situ synthesis of the Hbpt ligand.

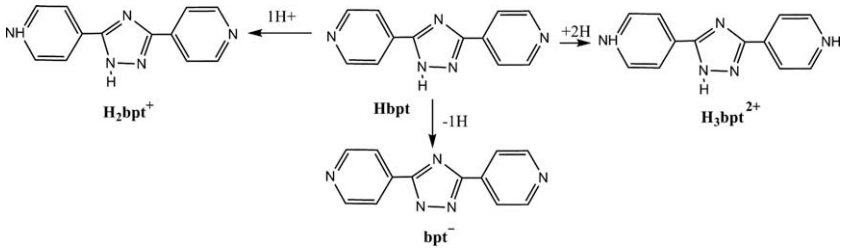
3. Results and discussion

3.1. Syntheses of the compounds and IR spectroscopy

3,5-Bis(4-pyridyl)-1*H*-1,2,4-triazole (Hbpt) can be considered as a new member of the group of five-membered heterocyclic ring bridging organic ligands. Compared with other widely investigated N,N′-bipyridine-type ligands, Hbpt is endowed with more structural information, especially for the diverse configurations of the protons on the N atoms. The nitrogen atoms of Hbpt are potential acceptors and donors for hydrogen bonds to expand polymeric frameworks. Interestingly, in the MOFs **1–6**, the ligand exhibits four different states: bpt^-, Hbpt, H_2bpt^+ and H_3bpt^{2+}, which results in the formation of abundant hydrogen bonds (Scheme 2). It is worth noting that ammonium sulfide is an excellent agent for the demetallation of the copper complex. The current approach provides a novel facile route to synthesize this kind of compound.



Three synthetic approaches were applied to construct these coordination polymers. With regard to MOFs **4–6**, they were prepared under hydrothermal conditions, whereas assemblies of the others were carried out under aqueous conditions or using diffusion. In each synthetic case, an approximate metal/ligand composition of 1:1:1/1:1 was utilized for the starting materials. Coordination polymers **1–6** are air stable with the maintenance of their crystallinity for at least several weeks.

In the IR spectra of complexes **1**, **2** and **6**, the broad band centered at 3400 cm^{-1} indicates the O–H stretching of the aqua molecules. The absorption band resulting from the skeletal vibrations of the aromatic rings for all three complexes appears in the 1400–1600 cm^{-1} region. In complexes **4–6**, the characteristic bands of the dicarboxylate groups unit are found at 1610 and 1490 cm^{-1} for asymmetric stretching and 1380 cm^{-1} for symmetric stretching. The strong bands between 1640 and 1630 cm^{-1} and near 1037 cm^{-1} are assignable to the characteristic bands of 1,2,4-triazole. All these spectral features are consistent with the crystal structures as described below.

3.2. Descriptions of crystal structures

3.2.1. Structure of $CoCl_4(H_3bpt)(H_2O)$ (**1**)

As shown in Fig. 1 **1** contains one H_3bpt^{2+} ion, one $[CoCl_4]^{2-}$ ion and one lattice water (Fig. 1). The cobalt cation is coordinated by four chloride anions, which forms a tetrahedral structure. The average Co–Cl bond length is 2.28 Å and the Cl–Co–Cl bond angles are in the range 104.75(6)–112.45(6)°, which are close to the ideal tetrahedral value and are in good agreement with the previously reported bond lengths and angles of a tetrahedral cobalt compound [31]. The Hbpt ligand is protonated by two protons which are attached to the two terminal N atoms (N4, N5). All the three N–H groups (include triazole-H) interact with the chlorides and the water molecule, forming many hydrogen bonds, with O···Cl distances of 3.203(5), 3.106(5), N···Cl distances of 3.222(4), 3.257(5) and N···O distances of 2.700(6), 3.173(3) Å (Fig. 2, Table S2). As is well-known, a water molecule has two hydrogen atoms and two lone-electron pairs, which enables it to participate in four

Scheme 2. Different forms of the Hbpt ligand in **1–6**.

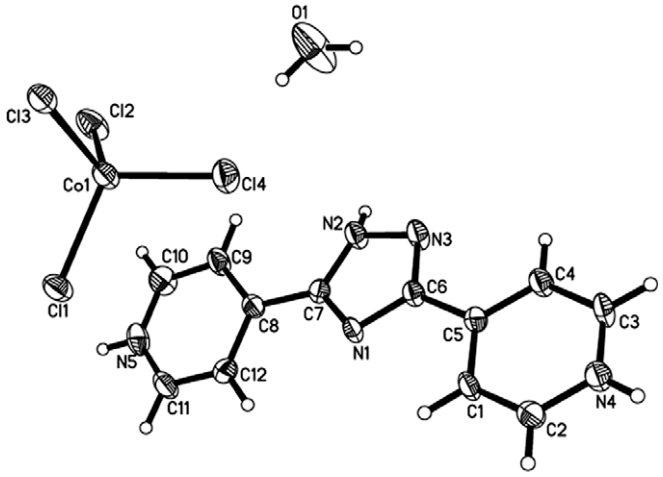


Fig. 1. Thermal displacement diagrams (30%) for **1**.

hydrogen bonds in a tetrahedral configuration, but it also frequently shows a 3-coordinate configuration [32]. In **1**, the lattice water O1 also shows a 3-coordinate mode. Through these hydrogen bonds, the molecule is assembled into a three-dimensional structure (Fig. 2).

3.2.2. Structure of $Cu(H_2bpt)_2(SO_4)_2(H_2O)_6$ (**2**)

Compound **2** consists of a discrete centrosymmetrical $[Cu(H_2bpt)_2(H_2O)_4]^{4+}$ cation, two $[SO_4]^{2-}$ anions and two lattice water molecules, it is more accurate to describe the complex as $[Cu_{0.5}(H_2bpt)(H_2O)_2](SO_4)(H_2O)$. The crystal structure of the cationic mononuclear unit is depicted in Fig. 3. The Cu^{II} ion is located at a crystallographic inversion center, and six coordinated to four aqua ligands in the equatorial plane, as well as two H_2bpt^+ ligands in axial positions. To the two N atoms in the terminal pyridyl (N1, N5) of Hbpt ligand, N5 is coordinated to Cu, while the other is saturated with a proton, forming a +1 cation. The coordination geometry of the metal center can be described as a slightly distorted octahedron with O–Cu–N and O–Cu–O angles in the range

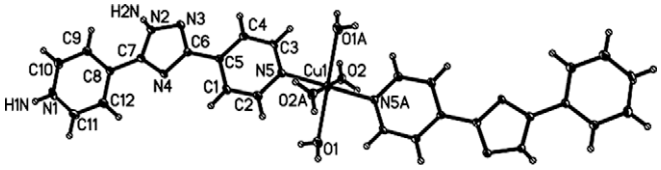

Fig. 3. Thermal displacement diagrams (30%) for **2** ($[Cu(H_2bpt)_2(H_2O)_4]^{4+}$ cation).

86.41(6)–93.59(6)°. The two pyridine rings within each ligand form dihedral angles of 10.03 and 3.42°, respectively, with the central triazole plane, and a dihedral angle of 8.59° with each other.

Herein the Hbpt ligand uses only one of the pyridyl nitrogen atoms to bind the metal center. The other uncoordinated pyridyl nitrogen serves as the hydrogen bond donor to the sulfate anions with a O···N distance of 2.696(4) Å. In the S_4 tetramer of the coordinated aqua molecules (the tetramer of water can be defined as having S_4 symmetry), every monomer acts as a donor for the oxygen atoms from the sulfate ion. The lattice water O7 also serves as a hydrogen bond donor to form two hydrogen bonds with N4 from Hbpt and O4 from the sulfate ions, resulting in a $R_2^2(8)$ ring [33]. All the water molecules show a 2-coordinate configuration hydrogen bond. It is noteworthy that the four oxygen atoms of the sulfate ion form seven different hydrogen bonds with the Hbpt, coordinated water and lattice water. A $R_4^4(12)$ hydrogen bond ring is formed by the two adjacent sulfate anions and two coordinated water molecules (Fig. 4b) [33]. In **2**, the sulfate anions act as a binder extending the block $Cu(H_2bpt)_2(SO_4)_2(H_2O)_6$ into a three-dimensional network by mass hydrogen bonds (Fig. 4a).

3.2.3. Structure of $[Ag(bpt)]_n$ (**3**)

Single-crystal analysis of **3** reveals (Fig. 5) that the Ag^I lies in a trigonal planar (sum of N–Ag–N angles = 359.97°) coordination environment, which consists of two $N_{triazole}$ donors (N(3)–Ag(1) = 2.303(5) and Ag(1)–N(2) = 2.214(5) Å) from two $Hbpt^-$ ligands (the Hbpt ligand loses $H_{triazole}$ forming the bpt^- ion) and one $N_{pyridyl}$ donor (Ag(1)–N(1) = 2.254(5) Å) from the third Hbpt ligand. The Ag–$N_{triazole}$ bond length is considerably longer than those of the Ag–$N_{pyridyl}$ bonds, but all the Ag–N bond distances in

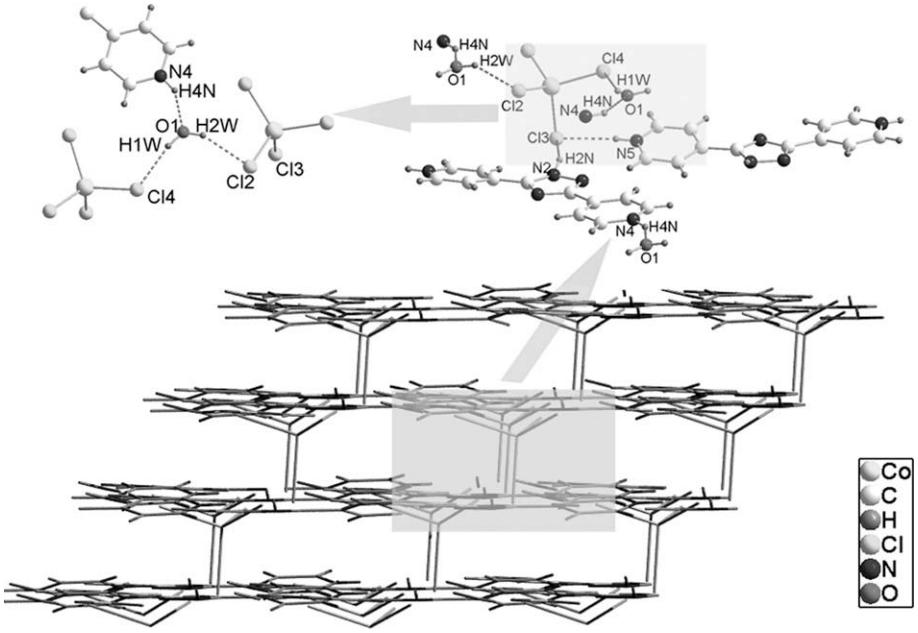

Fig. 2. The supramolecular structure formed by hydrogen bonds (H-bonds: dashed lines) for **1**.

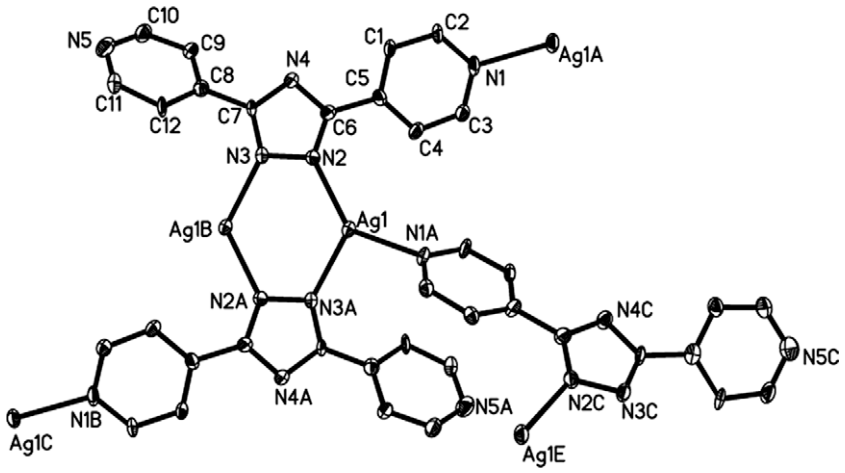

Fig. 5. Thermal displacement diagrams (30%) for **3**.

3 are within the normal range for N-containing heterocyclic Ag(I) complexes [17,34,35]. Each ligand is bonded to three Ag(I) centers (N1–Ag1A, N2–Ag1, N3–Ag1B). Interestingly, the two similar $N_{pyridyl}$ atoms of the Hbpt ligand have very different coordination behavior: N1 coordinates to one Ag atom while the N5 does not. Two Ag(1) atoms are bridged by four $N_{triazole}$ atoms into a dinuclear core with a short Ag···Ag contact of 3.492 Å (Fig. 6), which reveals the existence of an attractive metallophilic interaction [36,37]. The ligand itself is not planar, the corresponding dihedral angles between the three rings are [N(1)···C(5)]–[N(2)···N(3)] = 14.11°, [N(1)···C(5)]–[N(5)···C(12)] = 45.95° and [N(2)···N(3)]–[N(5)···C(12)] = 33.54°.

In the solid state, the Ag(I) centers and bpt^- ligands are linked together into a novel two-dimensional sheet, which is parallel to the [1 1 0] plane. As shown in Fig. 7, the single net mainly consists of a large ring. The large ring comprises a tetrameric unit, in which four Ag(I) centers are linked together by bpt^- ligands into an elliptical 32-membered macrocycle. While the two uncoordinated

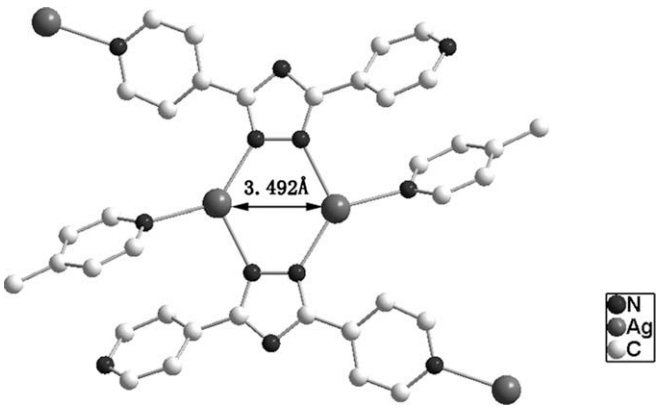

Fig. 6. Short Ag···Ag contacts in compound **3**.

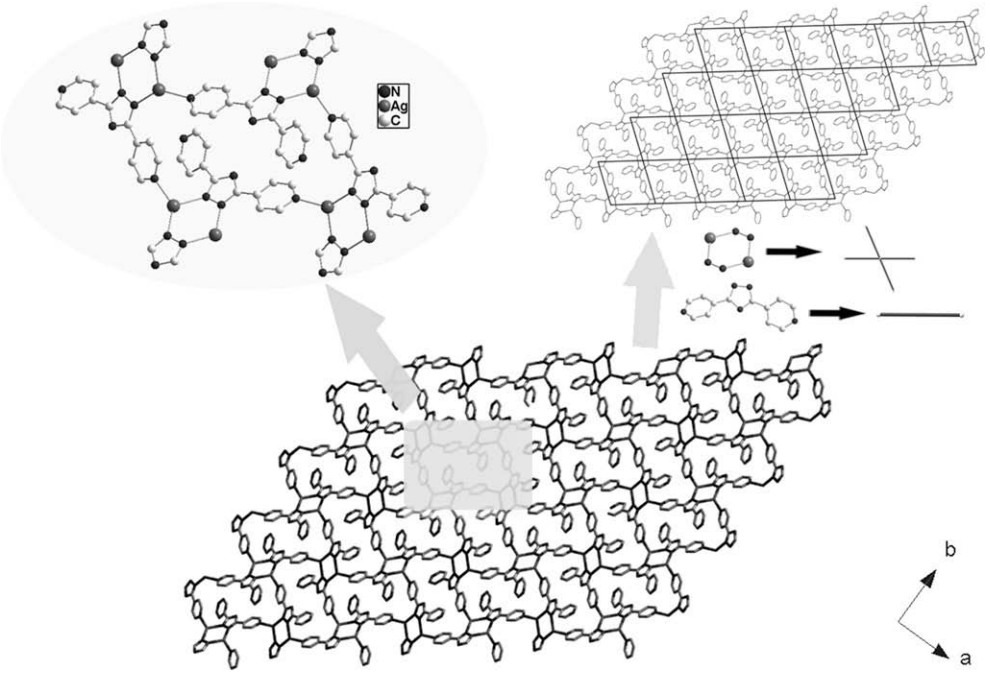

Fig. 7. The two-dimensional (4,4) sheet of compound **4**.

pyridyls of the bpt$^-$ ligands are embedded in this macrocycle. A schematic presentation for the construction of the two-dimensional (4,4) sheet is shown in Fig. 7.

3.2.4. Structure of $[Co(Hbpt)(pa)]_n$ (**4**)

The asymmetric coordination unit of **4** (see Fig. 8a) consists of a pair of Co^{II} ions, one Hbpt, one pa dianion and one aqua ligand. Both crystallographically independent Co^{II} ions lie on inversion centers and display a similar octahedral environment, which are provided by two pyridyl N donors and four carboxylate/water O atoms. As illustrated in Fig. 8b, one carboxylate is monodentate whereas the other adopts a *syn–anti* bridging mode. As a consequence, each Co^{II} ion forms a 7-membered chelated ring with pa, and the adjacent Co^{II} centers are connected by pa components with a separation of 5.245 Å to furnish a polymeric chain along the [0 1 0] direction, with phenyl decorating both sides alternatively. These 1-D arrays are further interlinked through Hbpt spacers to generate a 2-D (4,4) coordination layer along the *bc* plane with a Co···Co separation of 14.237 Å.

Further investigation of the crystal packing reveals that these parallel 2-D arrays are extended via interlayer N2–H2N···O5 interactions (see Table S2 for details) along [1 0 1] to build a 3-D architecture (see Fig. 8c). These hydrogen bonds show a pattern of R_2^2 (18) rings and a large R_2^2 (44) ring [33].

3.2.5. Structure of $[Co(Hbpt)(pda)]_n$ (**5**) and $[Cu(Hbpt)(pda)(H_2O)]_n$ (**6**)

Compounds **5** and **6** display a similar coordination environment as depicted in Fig. 9. Each distorted octahedral Co^{II}/Cu^{II} center is defined by four equatorial oxygen donors and two axial nitrogen atoms from three pda and a pair of Hbpt ligands (see Table S1 for detailed bond parameters). The carboxylate groups in each pda ligand function as a chelated bidentate and in a *syn–syn* bridging mode.

In **5** and **6**, the flexible carboxylate groups ($-CH_2COO^{2-}$) exhibit a *trans* configuration, which has a lesser steric hindrance effect and favors crystal growth [38]. However, the two terminal carboxylates ($-COO^{2-}$) of H_2pda are placed with two different patterns as shown

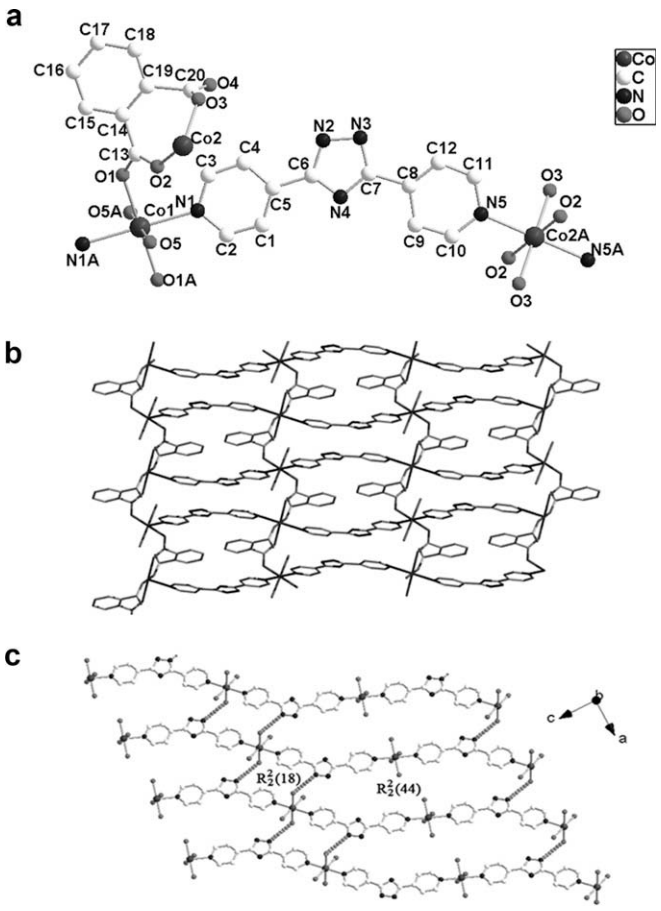

Fig. 8. (a) A portion view of **4** with the atom labelling of the asymmetric unit and Co^{II} coordination. The symmetry code is listed in Table S1. (b) 2-D (4,4) layered coordination framework of **4**. All hydrogen atoms are omitted for clarity. (c) The interlayer hydrogen-bonding interactions construct the 2-D layers into a 3-D network (H-bonds: dashed lines, the phenyl group of the pa ligand was omitted).

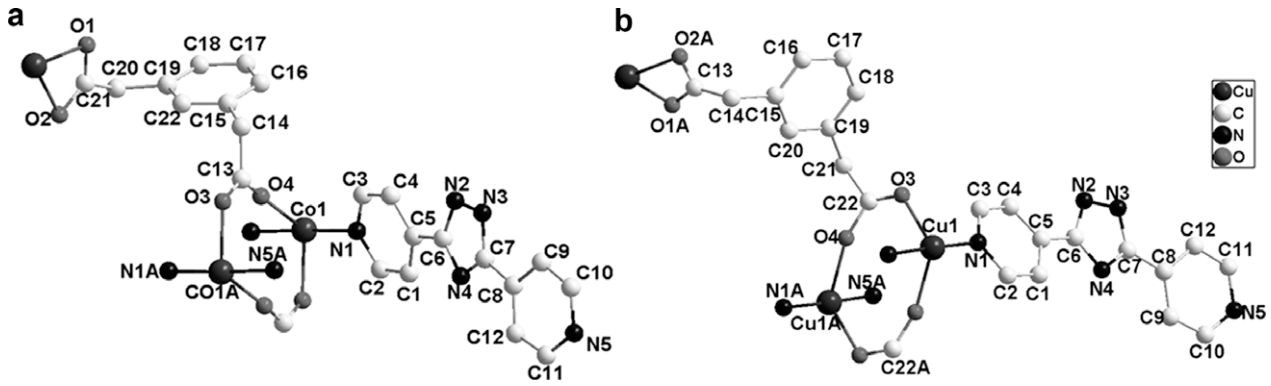

Fig. 9. A portion view of **4** with the atom labelling of the asymmetric unit and Co^{II} coordination. The symmetry code is listed in Table S1: (a) complex **5**; (b) complex **6**.

in Fig. 10, which significantly influences the final 3-D structure of these two similar complexes.

For **5**, as illustrated in Fig. 11a, the carboxylate adopts a chelated bidentate and *syn–syn* mode to bridge the adjacent Co^{II} centers together into a novel two-dimensional sheet parallel to the [1 0 0] plane. The 2-D sheet is composed of two different individual rings. A small dinuclear 7-membered-ring consists of two Co^{II} with two carboxylate groups of pda (Co···Co = 4.118 Å). The larger one comprises a tetrameric unit, in which four dinuclear core Co^{II} centers are linked by pda ligands into an elliptical 40-membered macrocycle. The two-dimensional macrocycle-containing nets can also be represented as a (4,4) net as Fig. 11b. From the *b* axes, the 2-D sheet can further assemble into a 3-D network through Hbpt ligands (Fig. 11c and d). A schematic presentation for the construction of the 3-D network is shown as Fig. 11b and e, the 3-D structure can be simplified as a $(4^{12}\cdot 6^3)$ or α-Po topology.

In **6**, a similar carboxylate group bridges the adjacent Cu^{II} centers together into a novel infinite chain rather than a plane view along the *c* axis; another similar chain is also formed in a different direction, and the pattern of these two similar chains is depicted in Fig. 12c. As shown in Fig. 12b, two Hbpt spacers bridge two adjacent dinuclear cores into a double-strand chain. The chains show an interconnected style as shown in Fig. 12d, the angle between the former two chains and the latter chain is 53.631(1)°. A schematic presentation for the construction of the 3-D network is shown in Fig. 12e, which is very different from **5** and can be simplified as $(6^4\cdot 8^2)$ or $CdSO_4$ topology.

It is also noteworthy that the hydrogen bond of $N_{triazole}$–$H_{triazole}$–O_{pda} links the adjacent Hbpt chains, which further stabilizes the 3-D network. A $R_2^2(18)$ hydrogen bond ring is also found in **6** as depicted in Fig. 13 [33].

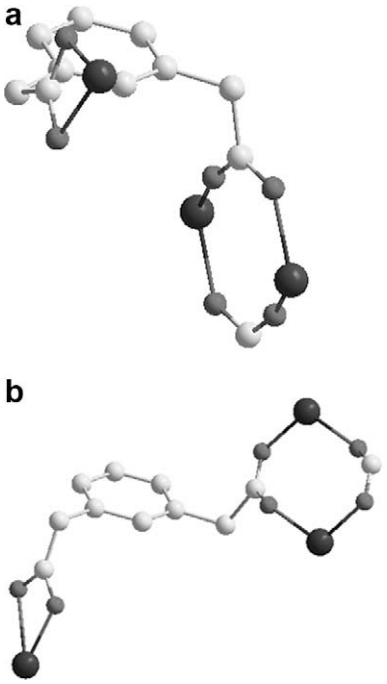

Fig. 10. The two patterns of Hpda in complex **5** (a) and **6** (b).

3.2.6. The coordination modes for the 3,5-bis(4-pyridyl)-1H-1,2,4-triazole ligand

It is noteworthy that Hbpt displays versatile valance states and abundant coordination modes in these metal–organic frameworks. In MOFs **1–6**, the ligand exhibits +2, +1, 0, −1 valance states and several coordination patterns, as illustrated in Schemes 2 and 3, respectively. When Hbpt acts as a neutral ligand, it behaves as a uniform bidentate connector in the 2-D, 3-D coordination networks in **4**, **5** and **6**. While Hbpt present in the form of H_2bpt^+ adopts a monodentate mode in **2**. No coordination action is found in **1** when all the two pyridyls are saturated by protons. An interesting tridentate mode is found in **3** where Hbpt loses the triazole proton.

It is obvious that the introduction of auxiliary dicarboxylate ligands greatly influences the coordination modes of Hbpt as well as the final supramolecular structures. In MOFs **1–3**, Hbpt exhibits abundant coordination modes, whereas it mostly behaves as a uniform bidentate connector in the mixed-ligand complexes **4–6**. In **4–6**, the carboxylate groups adopt the unidentate, chelating and bridging modes, which would be mostly responsible for the structural diversity. In MOFs **4** and **5**, with the variation of the phenyl dicarboxylate building blocks (from pa to pda), their network arrays are changed from 2-D isolated layer (4,4 topology) to 3-D network ($(4^{12}\cdot 6^3)$ topology). On the other hand, the choice of metal center plays a significant role in the resultant networks of MOFs, as shown in **5** and **6**.

The formation of many hydrogen bonds also accompanies the change of Hbpt ligand. In the complexes, except the deprotoned form of **3**, all the hydrogen atoms of the $N_{triazole}$ atoms serve as a donor forming strong hydrogen bonds with oxygen from water or the benzenedicarboxylate ligand with N···O distances ranging from 2.47(2) to 3.23(1) Å [39,40]. The protoned $N_{pyridyl}$ in **1** and **2** also serves as a donor, while the others serve as acceptors in the hydrogen bonds.

3.3. Thermal gravimetric analyses

All the compounds are air stable and can retain their crystallinity at room temperature for at least several weeks. Hence, TGA

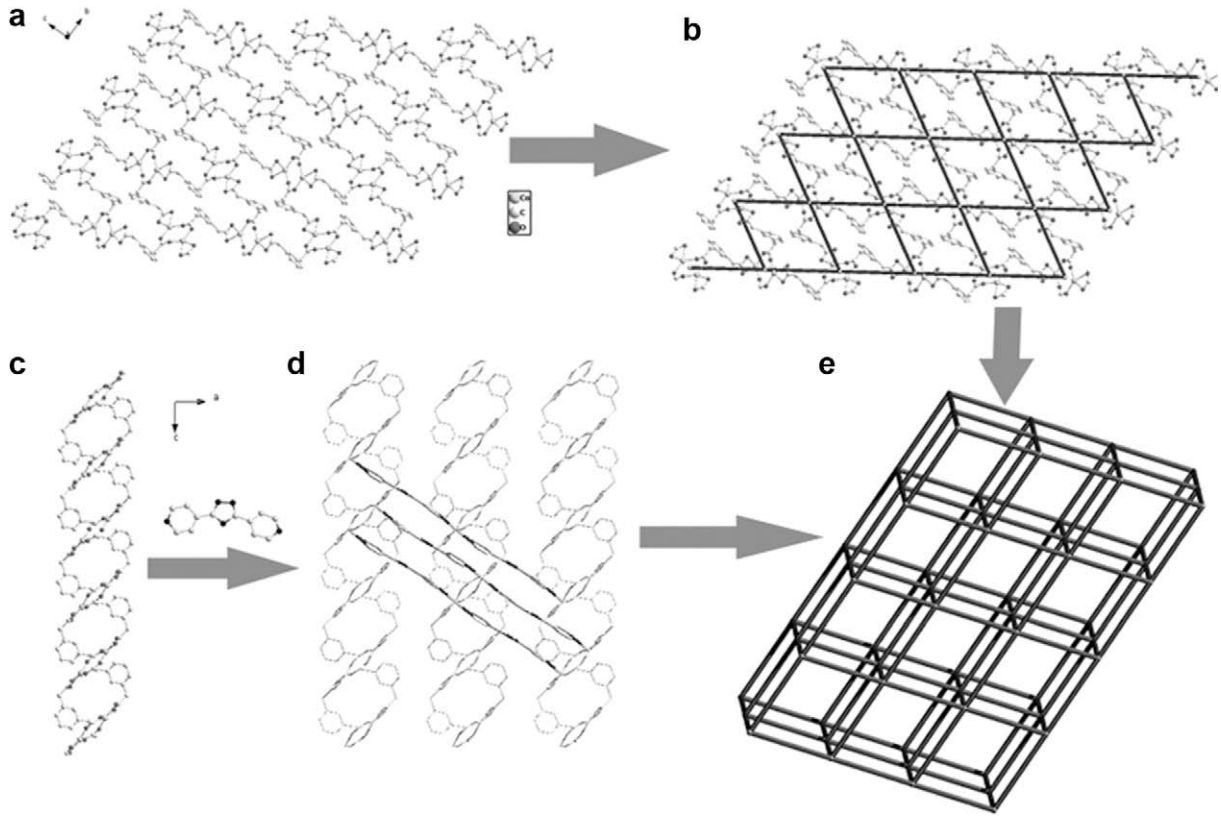

Fig. 11. Construction of the 3-D network for compound **5**: (a) 2-D sheet; (b) simplified 2-D sheet; (c) the 2-D sheet view from the *b* axis; (d) bridge the 2-D to 3-D network; (e) schematic presentation of the $(4^{12} \cdot 6^3)$ network.

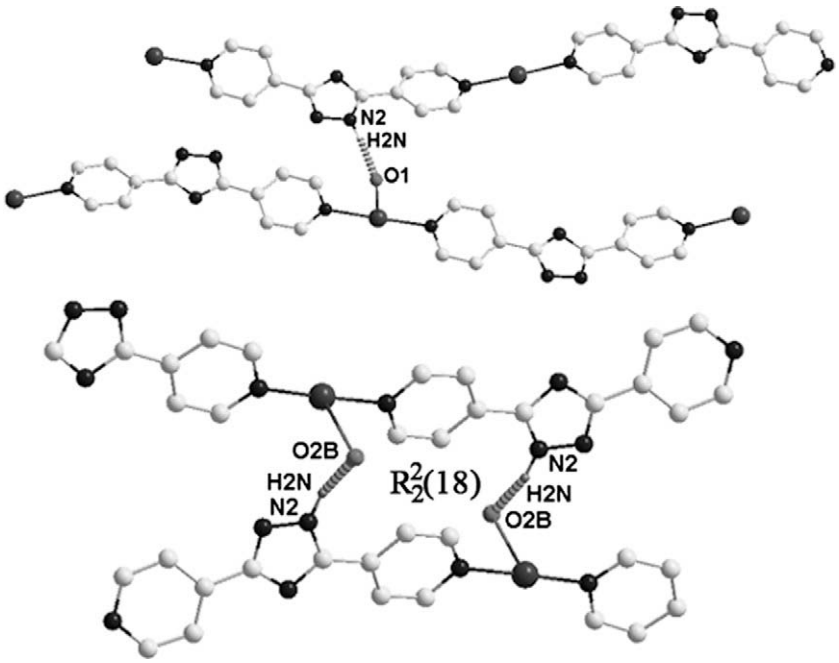

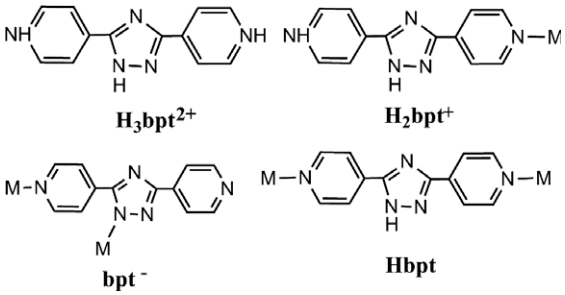

Fig. 13. The hydrogen-bonding interactions for compounds **5** (a) and **6** (b) (H-bonds: dashed lines).

Scheme 3. Coordination modes of the Hbpt ligand in **1**–**6**.

experiments were carried out to explore their thermal stability (see Figs. S1–S5 for TGA curves), which is an important parameter for coordination polymers. **1** quickly loses the free Hbpt ligand and lattice water and is completely converted to the corresponding oxide. In the TGA curve of **2**, the first weight loss of 4.40% in the range 177–243 °C (peak: 227 °C) corresponds to the expulsion of lattice water. The remaining substance is thermally stable up to 310 °C, following that, a series of weight losses occur, which do not end until 810 °C. **3** undergoes consecutive steps of weight loss (peaks: 372.5 and 393.1 °C) from 330.1 °C, which do not stop until 850 °C. For **4**, it remains stable up to 295.5 °C, and then undergoes two step weight losses, corresponding to the loss of the pa and Hbpt ligands, respectively before 675 °C. In **5**, we cannot see two such steps as in **4**, instead a total weight loss from 440 to 750 °C is present. **6** firstly loses the lattice water around 150 °C, and then is stable until 230.5 °C, after that a series of weight losses up to 750 °C are found. In this study, the lattice water molecules in **6** can be facilely excluded upon heating, the residuals have moderate thermal stability. Compound **5** shows the best thermal stability and is stable up to 375 °C, which could be ascribed to the stable 3-D network without lattice guests.

4. Conclusion

In summary, by using the new ligand 3,5-bis(4-pyridyl)-1*H*-1,2,4-triazole (Hbpt), six coordination compounds have been synthesized and characterized. Among them Hbpt exhibits various conformations and adopts different coordinate modes, which may be ascribed to the interactions between the 4-pyridyl and 1*H*-1,2,4-triazole groups. The introduction of dicarboxylate ligands greatly influences the coordination modes of Hbpt as well as the final supramolecular structures. Many hydrogen bonds are formed by the protonated and deprotonated forms of the Hbpt ligand. The results of this study not only illustrate the coordinated behavior of the versatile ligand, but also represent a new inorganic-assisted organic synthesis method. It is anticipated that more metal complexes containing this interesting ligand, as well as more ligands based on this method, will be synthesized.

ABSTRACT

Arsenic(III), antimony(III) and bismuth(III) compounds of the type, $[M\{S_2P(OR)_2\}_3]$ (where M = As, Sb and Bi; R = *o*-, *m*-, *p*-C_6H_4Me) were obtained by reactions of MCl_3 with ammonium salts of the corresponding *O*,*O*′-ditolyl dithiophosphate on refluxing in benzene. These compounds were characterized by elemental analysis, IR, ^1H NMR and ^{31}P NMR spectroscopy. The single crystal X-ray structures of three representative compounds were determined. $[As\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]\cdot 0.5C_6H_{14}$ crystallizes as triclinic in the space group $P\bar{1}$ with $a = 10.9396(1)$, $b = 14.1891(2)$, $c = 17.5359(2)$ Å, $\alpha = 70.731(1)$, $\beta = 84.734(1)$, $\gamma = 74.205(1)^\circ$, $Z = 4$, $V = 2472.37(5)$ Å^3. $[Sb\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ and $[Bi\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ both crystallize as monoclinic in the space group $P2_1$ with $a = 12.4520(3)$, $b = 22.8760(5)$, $c = 16.2165(4)$ Å, $\beta = 93.022(1)^\circ$, $Z = 4$, $V = 4612.9(2)$ Å^3 and with $a = 12.4903(2)$, $b = 22.9554(4)$, $c = 16.1032(3)$ Å, $\beta = 92.4300(10)^\circ$, $Z = 4$, $V = 4612.96(14)$ Å^3, respectively. In all three molecules, the central metal atom is surrounded by all six sulfur atoms of the three chelating anisobidentate *O*,*O*′-ditolyl dithiophosphate groups in a pseudo trigonally distorted octahedron with a lone pair positioned on one of the triangular octahedral faces. The three metal sulfur bonds adjacent to the lone pair (capped face) are longer than the three furthest from the lone pair (uncapped face). Inter-ligand angles between the longer bonds are greater than those between the shorter bonds.

1. Introduction

Ligands containing the $-S_2P$ grouping are known to exhibit a remarkable diversity in their coordination patterns towards metals which can be classified as monodentate [1,2], bidentate [3,4] and bridging [5]. The most interesting results are obtained when the dithiophosphate ligand is attached to a non-transition metal atom. The presence of a stereochemically active lone pair of electrons on the group 15 elements, arsenic, antimony and bismuth, combined with small ligand bites and molecular associations, adds to the interest in structural variations. Over the past several decades, various dithio ligating systems in, arsenic, antimony and bismuth complexes have been studied with *O*,*O*′-dialkyl [1–10], alkylene [11,12] and mixed ligand [13–15] dithiophosphates. Although only one X-ray structure of an arsenic compound, $[As\{S_2P(OMe)_2\}_3]$ [16], has been reported, there have been several of antimony and bismuth including $[Sb\{S_2P(OMe)_2\}_3]$ [17], $[Sb\{S_2P(OEt)_2\}_3]$ [18], $[Sb\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ [17], $[Bi\{S_2P(OMe)_2\}_3]$ [6], $[Bi\{S_2P(OEt)_2\}_3]$ [7], $[Bi\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ [2], $[Bi\{S_2POCHMeCHMeO\}_3]$ [12] and $[Bi\{S_2POCH_2CEt_2CH_2O\}_3]$ [12].

O,*O*′-Dialkyl dithiophosphate derivatives of arsenic, antimony and bismuth are used in industry as analytic reagents [19,20], lubricant additives [21] and show tribological activity to improve anti-friction and antiwear properties [22]. The anticancer activity of $[Ph_2Sb\{S_2P\{O(i\text{-}Pr)\}_2]$ has been investigated [23,24] and the use of $[Sb\{S_2P(OEt)_2\}_3]$ [18] and $[Bi\{S_2P(OEt)_2\}_3]$ [7] as passivation agents for decontaminant metals in the catalytic cracking of petroleum has been reported.

The literature contains substantial amount of work on arsenic, antimony and bismuth derivatives of *O*,*O*′-dialkyl and alkylene dithiophosphates but much less information on their bulky analogous derivatives of *O*,*O*′-(*o*-, *m*-, *p*-ditolyl) dithiophosphate ligands. However, some metal complexes with the *O*,*O*′-ditolyl dithiophosphate ligands have been synthesized and characterized by us [25–27] and, chlorobis(ditolyl dithiophosphate)arsenic(III) compounds were reported recently [28]. $[NMe_4][Zn\{S_2P(OC_6H_4Me\text{-}p)_2\}_3]$ [29] and some derivatives of antimony [30] and cobalt [31,32] ditolyl

dithiophosphates have industrial applications and tributyltin(IV)*O*,*O*′-diaryl dithiophosphates are useful in agriculture [33,34].

In this paper, we report the synthesis, characterization and comparative study of *O*,*O*′-ditolyl dithiophosphate complexes of $[As\{S_2P(OR)_2\}_3]$, $[Sb\{S_2P(OR)_2\}_3]$ and $[Bi\{S_2P(OR)_2\}_3]$ (R = *o*-, *m*-, *p*-C_6H_4Me), along with the single crystal X-ray diffraction of $[As\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]\cdot 0.5C_6H_{14}$, $[Sb\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ and $[Bi\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$.

2. Results and discussion

Tris(*O*,*O*′-ditolyl dithiophosphato)arsenic(III)/antimony(III)/bismuth(III) have been synthesized by the reactions of the corresponding metal chloride with the ammonium salts of *O*,*O*′-ditolyl dithiophosphoric acid in 1:3 molar ratio. These reactions are quite facile but to ensure completion reaction solutions were refluxed with stirring for 4–5 h in anhydrous benzene.

$$MCl_3 + 3NH_4S_2P(OR)_2 \xrightarrow{4-5\ h\ refluxing} [M\{S_2P(OR)_2\}_3] + 3NH_4Cl$$
$$(M = As, Sb, Bi, R = o\text{-}, m\text{-}, p\text{-}C_6H_4Me)$$

These newly synthesized novel derivatives are pale yellow crystalline solids, with the exception of viscous $[As\{S_2P(OC_6H_4Me\text{-}p)_2\}_3]$, $[Sb\{S_2P(OC_6H_4Me\text{-}o)_2\}_3]$, $[Sb\{S_2P(OC_6H_4Me\text{-}p)_2\}_3]$ and $[Bi\{S_2P(OC_6H_4Me\text{-}p)_2\}_3]$. All of these compounds are soluble in common organic solvents such as benzene, chloroform, toluene and acetone, and also in coordinating solvents such as DMSO and DMF and conversely are insoluble in non-polar organic solvents such as carbon tetrachloride and n-hexane. The complexes are moisture sensitive but are stable when kept moisture free in an inert atmosphere. The products were characterized by elemental analysis and IR, ^1H and ^{31}P NMR spectroscopy.

2.1. IR spectra

The relevant assignments of the IR bands have been made on the basis of comparisons with the spectra of ammonium salts of *O*,*O*′-(*o*-, *m*-, *p*-ditolyl) dithiophosphoric acids [35–37] and the analogous tris(*O*,*O*′-dialkyl dithiophosphato)-arsenic(III)/antimony(III)/bismuth(III) compounds [38]. The two strong intensity bands present in the regions 1114-1173 and 900–952 cm^{-1} are assigned to ν[(P)–O–C] and ν[P–O–(C)] stretching vibrations, respectively, in the complexes **1**–**9**. Two strong bands due to ν(P=S) or $\nu(P\text{–}S)_{asym}$ that are observed in the regions 680–690 and 596–598 cm^{-1} in the parent ammonium salts are shifted to lower wave-number in the corresponding tris(*O*,*O*′-ditolyl dithiophosphato)-arsenic(III)/antimony(III)/bismuth(III) compounds consistent with coordination to metal atom. Bands of strong to medium intensities present in the region 510–563 cm^{-1} are due to ν(P–S) or $\nu(P\text{–}S)_{sym}$ stretching vibrations.

2.2. ^1H NMR spectra

The ^1H NMR spectra for complexes **1**–**9** were recorded in $CDCl_3$ solutions at room temperature. The spectral data for tris(*O*,*O*′-ditolyl dithiophosphato)-arsenic(III)/antimony(III)/bismuth(III) compounds are remarkably similar to those of the corresponding ammonium salts of *O*,*O*′-ditolyl dithiophosphoric acids probably due to the large separation between metal and protons. In complexes **1**–**9**, the methyl protons, observed as singlets in the region 2.19–2.31 ppm, display negligible shifts compared to those in the corresponding salts. Similarly, the phenyl protons, which appear in the range 6.61–7.41 ppm, only undergo a negligible downfield shift compared to their positions in the free ligand as a consequence of coordination of the ligand.

2.3. ^{31}P NMR spectra

The proton decoupled ^{31}P NMR spectra of complexes **1**–**9** recorded in $CDCl_3$ all exhibit a sharp singlet, which, is in the region 83.95–85.58 ppm for the compounds of arsenic (**1**–**3**), 87.45–88.70 ppm for those of antimony (**4**–**6**) and 94.23–95.27 ppm for those of bismuth (**7**–**9**). On examining the proton decoupled ^{31}P NMR chemical shifts of a number of metal dialkyldithiophosphates, Glidewell [39] concluded that complexes containing bidentate ligands had signals in the range 82–101 ppm while those with signals less than 82 ppm had monodentate ligands. This suggests that in solution any bidentate coordination of the dithiophosphate groups is relatively strong for bismuth and becomes progressively weaker for antimony and arsenic. The observation of only one sharp singlet for all compounds **1**–**9** reflects the equivalent nature of phosphorous nuclei and the purity of the compound.

2.4. Molecular structures of $[As\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]\cdot 0.5C_6H_{14}$, $[Sb\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ and $[Bi\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$

$[As\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]\cdot 0.5C_6H_{14}$ (**2**) crystallizes as triclinic in space group $P\bar{1}$ whereas, $[Sb\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ (**5**) and $[Bi\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ (**8**) both crystallize as monoclinic in space group $P2_1$. There are two molecules in the asymmetric units of **5** and **8** and in both cases one of the molecules is disordered so for clarity only the molecules that are not disordered are shown in Figs. 2 and 3, respectively. Similarly, for purposes of comparison, the component of n-hexane in the asymmetric unit of **2** is not included in Fig. 1.

$[Sb\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ (**5**) and $[Bi\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ (**8**) are isostructural, as are the corresponding analogues $[Sb\{S_2P(OEt)_2\}_3]$ [18] and $[Bi\{S_2P(OEt)_2\}_3]$ [7]. However, $[Sb\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ [17] and $[Bi\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ [2] are not isostructural nor are $[As\{S_2P(OMe)_2\}_3]$ [16], $[Sb\{S_2P(OMe)_2\}_3]$ [17] and $[Bi\{S_2P(OMe)_2\}_3]$ [6], but all of these structures consist of similar discrete

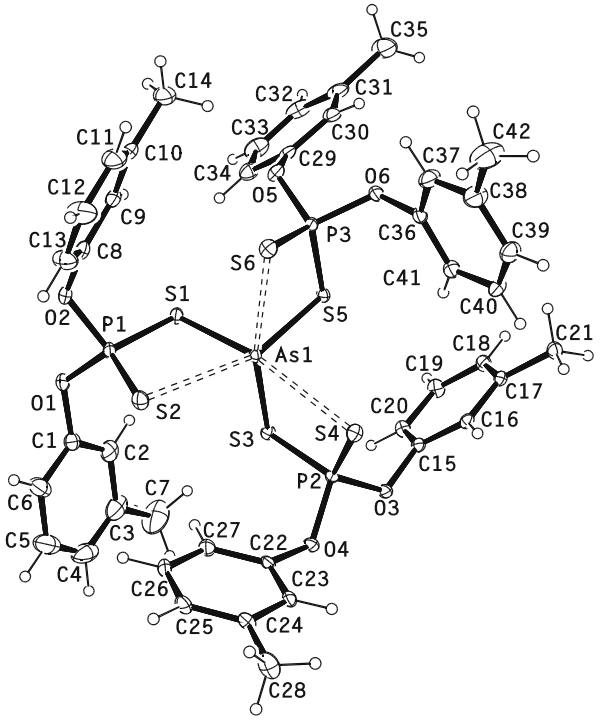

Fig. 1. ORTEP plot of the molecule of $[As\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]\cdot 0.5C_6H_{14}$. The fraction of the C_6H_{14} molecule in the asymmetric unit is omitted for clarity. The non-hydrogen atoms are drawn with 30% probability ellipsoids.

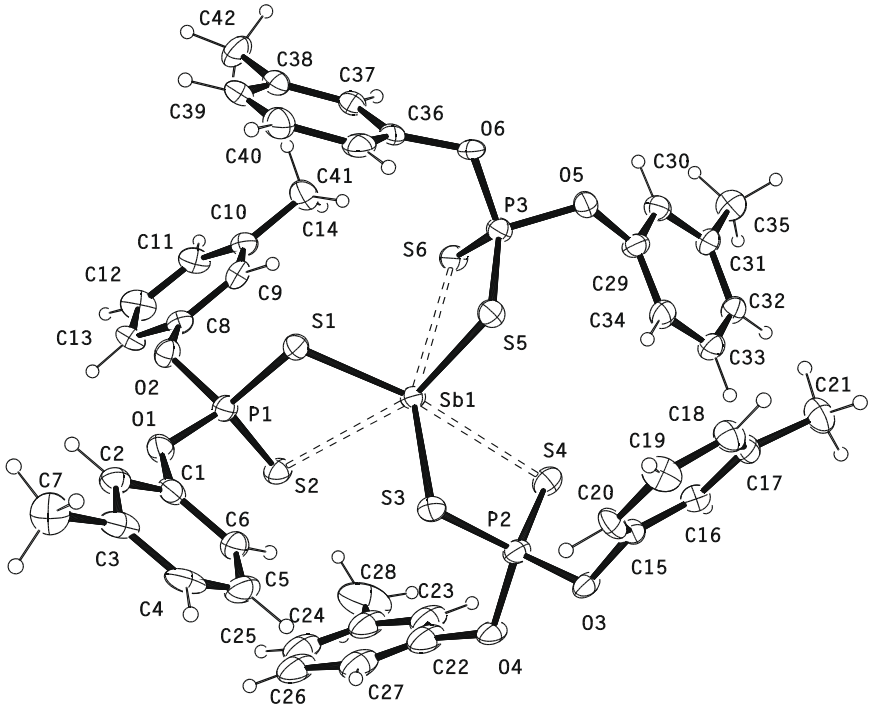

Fig. 2. ORTEP plot of the molecule of $[Sb\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ in the asymmetric unit that is not disordered. The non-hydrogen atoms are drawn with 30% probability ellipsoids.

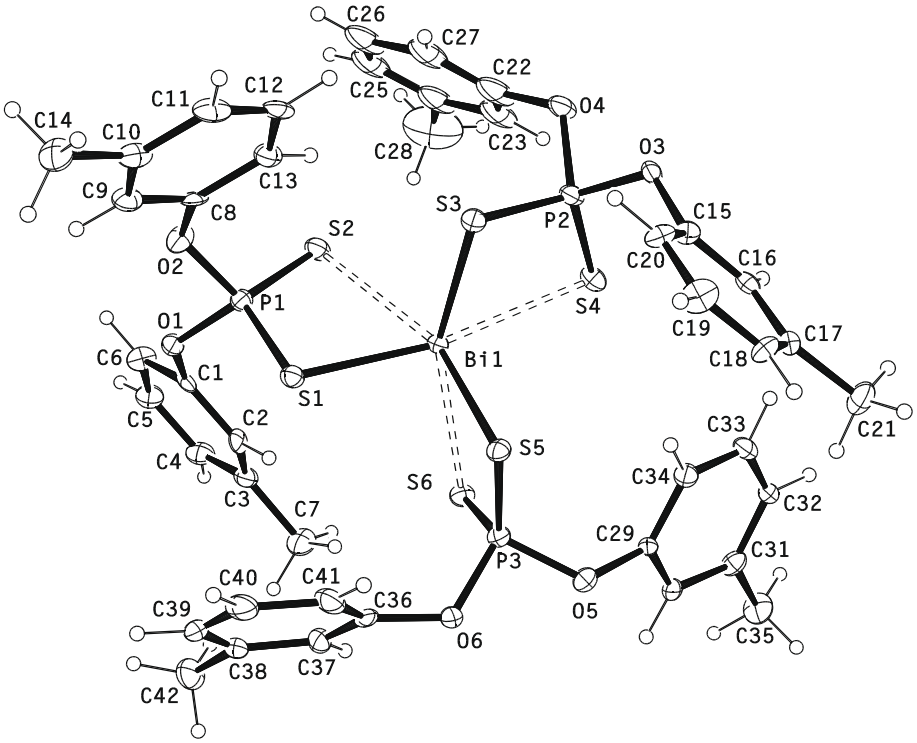

Fig. 3. ORTEP plot of the molecule of $[Bi\{S_2P(OC_6H_4\text{-}Me\text{-}m)_2\}_3]$ in the asymmetric unit that is not disordered. The non-hydrogen atoms are drawn with 30% probability ellipsoids.

$[M\{S_2P(OR)_2\}_3]$ units with a distorted octahedral arrangement of sulfur atoms. This can be seen in the ORTEP diagrams of **2**, **5** and **8** in Figs. 1–3. These demonstrate the anisobidentate coordination of the phosphorodithioate ligands in **2**, **5** and **8** with the longer (secondary) bonds identified by dashed lines and that there are no inter-molecular associations. The coordination polyhedron on the metal atom can be described as a distorted capped octahedron with a stereochemically active lone pair of electrons in the capping position and approximately on a molecular pseudo triad axis, which passes through the metal atom. The vertices of the distorted octahedron are occupied by the six sulfur atoms of the three anisobidentate phosphorodithioate ligands.

It is assumed that lone pair-bond pair repulsions in the metal coordination sphere [2,7,17,18] result in longer M–S bonds (2.9345(6)–3.0284(6) Å in **2**, 2.980(2)–3.031(2) Å in **5** and 2.926(2)–2.953(2) Å in **8**) for those bonds adjacent to the lone pair and shorter M–S bonds (2.3242(6)–2.3415(6) Å in **2**, 2.543(2)–2.549(2) in **5** and 2.678(2)–2.705(2) Å in **8**) for those more remote. These ranges are consistent with typical values reported for the short and long ligand bonds in $[As\{S_2P(OMe)_2\}_3]$ (2.320(1) and 3.029(1) Å) [16], $[Sb\{S_2P(OMe)_2\}_3]$ (2.535(2) and 3.006(2) Å) [17], $[Sb\{S_2P(OEt)_2\}_3]$ (2.583(1) and 2.86(1) Å) [18], $[Sb\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ (2.519(4) and 3.000(5) Å) [17], $[Bi\{S_2P(OEt)_2\}_3]$ (2.747(14) and 2.795(12) Å) [7] and $[Bi\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ (2.702(6) and 2.8784(6) Å) [2]. The overall difference between long and short M–S distances decreases in the order As (0.65) > Sb (0.47) > Bi (0.25 Å) emphasizing that for **2**, **5** and **8** and other related $[M\{S_2P(OR)_2\}_3]$ derivatives, the As compounds are clearly anisobidentate, and possibly close to monodentate. The longest As–S bond for $[As\{S_2P(OC_6H_4Me\text{-}m)_2\}_3]$ is 3.0284(6) Å comparable to 3.025(1) Å for $[As\{S_2P(OMe)_2\}_3]$ [16] so regardless of whether R is the smallest alkyl group or a relatively large aryl group, the longer As–S distance is essentially unchanged. By contrast, the shorter and longer bonds are relatively similar in length in **8** as well as in $[Bi\{S_2P(OEt)_2\}_3]$ [7] and $[Bi\{S_2P\{O(i\text{-}Pr)\}_2\}_3]$ [2].

The small S–M–S bite angles (75.51(2)–77.47(2)° for **2**), (72.52(7)–72.98(7)° for **5**) and (72.10(6)–72.45(6)° for **8**), which are also similar in the related compounds, might be expected to inevitably result in considerable distortion of the remaining angles from 90.00°. However, this is not the case for the angles involving the three stronger M–S bonds from each ligand in **2** (S(1)–M(1)–S(5), S(3)–M(1)–S(5) and S(1)–M(1)–S(5) which have angles of 91.26(2)°, 91.90(2)° and 92.05(2)°, respectively. This is consistent with the ligands in **2** being close to monodentate. By contrast, the corresponding S–M–S bite angles in **5** and **8** cover a wider range of 84.87(7)–91.81(8)° and 84.45(6)–93.06(7)°, respectively. The interligand angles involving the longer M-S bonds are all considerably larger ranging from 91.74(2)° to 102.46(2)° (for **2**), 94.90(7)–112.29(7)° (for **5**), and 95.27(6)–111.46(6)° (for **8**), with once again values for **5** and **8** being similar and differing from those of **2**.

Finally, unsymmetrical chelation is also reflected in the P–S bond distances which fall into two classes; the shorter distances (ave. 1.927(2) in **2**, 1.940(5) in **5** and 1.961(2) Å in **8**) are associated with S atoms forming the longer M–S interactions while the longer P–S bonds (ave. 2.060(4) in **2**, 2.032(3) in **5** and 2.010(4) Å in **8**) are allied with S atoms forming the shorter bonds to the metal, as is plausible to maintain bond order conservation around sulfur. Notably the largest difference in these bond lengths is for **2** where the difference in the longer and shorter M–S bonds is greatest. Thus the crystal structures provide confirmation of the structural conclusions reached on the basis of the ^{31}P NMR spectra of **2**, **5** and **8** as discussed earlier.

3. Experimental

As_2O_3, $BiCl_3$ and P_2S_5 were purchased from E. Merck and used as such. $SbCl_3$, $SOCl_2$, *o*-, *m*-, *p*-cresols (E. Merck) were distilled prior to use. Solvents (benzene, n-hexane and petroleum ether) were dried and distilled before use. Because the starting materials and newly synthesized compounds readily undergo hydrolysis, stringent precautions were taken to exclude atmospheric moisture throughout all experimental manipulations. Literature methods were used for the preparation of *O*,*O*′-ditolyl dithiophosphoric acids [35–37]. Ammonium salts of the dithiophosphoric acids were prepared by reaction of the parent acid with ammonia in benzene. $AsCl_3$ was prepared by the reaction of arsenic trioxide and thionyl chloride [40].

Sulfur was estimated gravimetrically as barium sulfate (Messenger's method). Arsenic and antimony were estimated iodometrically and bismuth by titration against standard EDTA solution using xylenol-orange as indicator. IR spectra were recorded on an ABB Bomem FTLA 2000-100 FT-IR spectrometer in KBr pellets in the range (4000–350) cm^{-1}. ^1H and ^{31}P NMR spectra were recorded on a Bruker DRX-300 spectrometer in $CDCl_3$ solutions using tetramethylsilane as an internal standard and H_3PO_4 as an external standard, respectively.

3.1. Preparations

3.1.1. [As{$S_2P(OC_6H_4Me$-o)$_2$}$_3$] (**1**)

Typically, a suspension of $NH_4S_2P(OC_6H_4Me$-o$)_2$ (1.13 g, 3.47 mmol) in benzene (10 ml) was added to a benzene solution of arsenic trichloride (0.21 g, 1.15 mmol) in 3:1 molar ratio with constant stirring followed by refluxing for 5 h at room temperature. The precipitate of ammonium chloride was removed by filtration under anhydrous conditions and excess solvent was removed from the filtrate in vacuo resulting in a pale yellow viscous oily liquid, which was crystallized by adding n-hexane and keeping the solution refrigerated for 2–3 days to obtain yellow crystals. Yield: 1.10 g, 94%; m.p. 60 °C. *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3As$: As, 7.47; S, 19.18. Found: As, 7.60; S, 19.17%. ^1H NMR ($CDCl_3$): δ 2.19 (s, CH_3, 18H), 6.91–7.10 (m, 24H, OC_6H_4); ^{31}P NMR ($CDCl_3$): δ 83.95 ppm; IR (KBr) (cm^{-1}): 1114s, ν\{(P)–O–C\}; 934s, ν\{P–O–(C)\}; 710s, 664s, ν(P═S); 529m, ν(P–S).

3.1.2. [As{$S_2P(OC_6H_4Me$-m$)_2$}$_3$] (**2**)

Method as above gave yellow needle shaped crystals. Yield: 1.10 g, 90%; m.p. 46 °C. *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3As$: As, 7.47; S, 19.18. Found: As, 7.58; S, 19.23%.^1H NMR ($CDCl_3$): δ 2.30 (s, CH_3, 18H), 7.00–7.26 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 84.64 ppm; IR (KBr) (cm^{-1}): 1140s, ν\{(P)–O–C\}; 952s, ν\{P–O–(C)\}; 691s, 662s, ν(P═S); 545m, ν(P–S).

3.1.3. [As{$S_2P(OC_6H_4Me$-p$)_2$}$_3$] (**3**)

Method as above gave a yellow oily viscous liquid. Yield: 1.05 g, 86%; *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3As$: As, 7.47; S, 19.18. Found: As, 7.52; S, 19.27%. ^1H NMR ($CDCl_3$): δ 2.21 (s, CH_3, 18H), 6.61–7.08 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 85.58 ppm; IR (KBr) (cm^{-1}): 1170s, ν\{(P)–O–C\}; 940s, ν\{P–O–(C)\}; 690s, 631s, ν(P═S); 563m, ν(P–S).

3.1.4. [Sb{$S_2P(OC_6H_4Me$-o$)_2$}$_3$] (**4**)

Method as above gave a yellow viscous liquid. Yield: 1.179 g, 99.06%; *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3Sb$: Sb, 11.60; S, 18.33. Found: Sb, 11.80; S, 18.32%. ^1H NMR ($CDCl_3$): δ 2.26 (s, CH_3, 18H), 7.04–7.24 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 87.45 ppm; IR (KBr) (cm^{-1}): 1170s, ν\{(P)–O–C\}; 934s, ν\{P–O–(C)\}; 709s, 656s, ν(P═S); 533m, ν(P–S).

3.1.5. [Sb{$S_2P(OC_6H_4Me$-m$)_2$}$_3$] (**5**)

Method as above gave a yellow crystalline solid. Yield: 1.2807 g, 88.23%; m.p. 50 °C. *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3Sb$: Sb, 11.60; S, 18.33. Found: Sb, 11.20; S, 18.30%. ^1H NMR ($CDCl_3$): δ 2.31 (s, CH_3, 18H), 7.04–7.24 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 88.70 ppm; IR (KBr) (cm^{-1}): 1142s, ν\{(P)–O–C\}; 948s, ν\{P–O–(C)\}; 690s, 649s, ν(P═S); 522m, ν(P–S).

3.1.6. [Sb{$S_2P(OC_6H_4Me$-p$)_2$}$_3$] (**6**)

Method as above gave a yellow viscous liquid. Yield: 1.006 g, 90.81%; *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3Sb$: Sb, 11.60; S, 18.33. Found: Sb, 11.40; S, 18.35%. ^1H NMR ($CDCl_3$): δ 2.31 (s, CH_3, 18H), 7.00–7.10 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 87.65 ppm; IR (KBr) (cm^{-1}): 1165s, ν\{(P)–O–C\}; 936s, ν\{P–O–(C)\}; 700s, 643s, ν(P═S); 510m, ν(P–S).

3.1.7. [Bi{$S_2P(OC_6H_4Me$-o$)_2$}$_3$] (**7**)

Method as above gave a yellow crystalline solid. Yield: 1.12 g, 76%; m.p. 110 °C. *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3Bi$: Bi, 18.38; S, 16.92. Found: Bi, 13.80; S, 16.32%. ^1H NMR ($CDCl_3$): δ 2.30 (s, CH_3, 18H), 6.95–7.21 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 94.82 ppm; IR (KBr) (cm^{-1}): 1173s, ν\{(P)–O–C\}; 900s, ν\{P–O–(C)\}; 679s, 641m, ν(P═S); 546m, ν(P–S).

Table 2
Selected bond lengths (Å) and angles (°) for [As{$S_2P(OC_6H_4Me$-m$)_2$}$_3$]·0.5C_6H_{14} (**2**), [Sb{$S_2P(OC_6H_4Me$-m$)_2$}$_3$] (**5**) and [Bi{$S_2P(OC_6H_4Me$-m$)_2$}$_3$] (**8**).[a]

[a] Data are not included in **2** for C_6H_{14} and in **5** and **8** for the molecules that are disordered.

*3.1.8. [Bi{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$] (**8**)*

Method as above gave a yellow crystalline solid. Yield: 0.95 g, 95%; m.p. 40 °C. *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3Bi$: Bi, 18.38; S, 16.92. Found: Bi, 14.20; S, 16.94%. ^{1}H NMR ($CDCl_3$): δ 2.23 (s, CH_3, 18H), 6.65–7.41 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 94.23 ppm; IR (KBr) (cm^{-1}): 1139s, ν\{(P)–O–C\}; 950s, ν\{P–O–(C)\}; 691s, 634s, ν(P═S); 556m, ν(P–S).

*3.1.9. [Bi{$S_2P(OC_6H_4Me\text{-}p)_2$}$_3$] (**9**)*

Method as above gave a yellow viscous liquid. Yield: 1.10 g, 93%. *Anal.* Calc. for $C_{42}H_{42}O_6S_6P_3Bi$: Bi, 18.38; S, 16.92. Found: Bi, 14.20; S, 16.93%. ^{1}H NMR ($CDCl_3$): δ 2.30 (s, CH_3, 18H), 6.69–7.12 (m, 24H, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 95.27 ppm; IR (KBr) (cm^{-1}): 1167s, ν\{(P)–O–C\}; 934s, ν\{P–O–(C)\}; 697s, 639s, ν(P═S); 524s, ν(P–S).

3.2. Crystallography

A colorless block crystal of [As{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$]·0.5$C_6H_{14}$ (**2**), a colorless fragment of [Sb{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$] (**5**) and a yellow block crystal of [Bi{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$] (**8**) were mounted on glass fibres. Data were collected on a Bruker–Nonius CCD area detector diffractometers, with φ and ω scans chosen to give a complete asymmetric unit. Cell refinement [41] gave cell constants corresponding to a triclinic cell for **2** and monoclinic cells for **5** and **8** whose dimensions are given in Table 1 along with other experimental parameters. An absorption correction was applied [42].

The structures were solved by direct methods [43] and were refined using the WINGX version [44] of SHELX-97 [45]. All of the non-hydrogen atoms were treated anisotropically. All of the hydrogen atoms were included in idealized positions, with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. The 58/42 (for **5**) and 77/23 (for **8**) disorder in one of the two molecules of the asymmetric unit was successfully modelled by placing restraints on distances and thermal parameters within the groups. The final cycle of full-matrix least-squares refinement was based on 8694 for **2**, 16232 for **5** and 13992 for **8** observed reflections (7602 for **2**, 10886 for **5** and 12758 for **8** for $F^2 > 4\sigma(F^2)$) and 557 for **2**, 1017 for **5** and 1008 for **8** variable parameters and converged (largest parameter shift was 0.001 times its esd).

Selected bond distances and angles are given in Table 2 and the molecules are displayed as ORTEP diagrams in Figs. 1–3. Additional material available from the Cambridge Crystallographic Data Centre comprises the final atomic coordinates and thermal parameters for all atoms and a complete listing of bond distances and angles.

4. Concluding comments

We have prepared and characterized the following compounds of the type, [M{$S_2P(OR)_2$}$_3$] (where M = As, Sb and Bi; R = *o*-, *m*-, *p*-C_6H_4Me). The IR, ^{1}H and ^{31}P NMR spectral data of these compounds are consistent with the presence of complexes containing bidentate ligands and hence a distorted octahedral structure. The molecular structures of [As{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$]·0.5$C_6H_{14}$, [Sb{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$] and [Bi{$S_2P(OC_6H_4Me\text{-}m)_2$}$_3$] confirm this to be the case and that in the solid state the ligands are more accurately described as anisobidentate.

condensation of 5-bromosalicyldehyde and ethanolamine (Scheme 1). The salicylidene-2-ethanolamine (H_2sae) type of ligands can act with both bridging and chelating coordination modes and they have a strong tendency to participate in different kinds of phenoxide or alkoxide bridges, exploiting the property of terminal oxygens as good bridging groups. Previously H_2sae and its derivatives have been incorporated into a number of alkoxo- or phenoxo-bridged tetranuclear Cu^{II}, Ni^{II} and Fe^{II} clusters with cubane structures [25–28]. However, in our case, the chelating ability of this ONO donor ligand has been utilized selectively to achieve the desired chloro-bridged complex. Complex **1** has been completely characterized with elemental analysis, FT-IR, UV–Vis, EPR spectra, and single crystal X-ray diffraction analysis. In this paper, we report a combined structural and magnetic study of complex **1**. Magnetic susceptibility measurements (2–300 K) show a prominent ferromagnetic interaction in the dimer with J = +43.2(5) cm^{-1}, and a weak interdimer antiferromagnetic interaction of J' = –0.276(8) cm^{-1}. To the best of our knowledge, complex **1** presents the highest ferromagnetic coupling reported till date in any doubly chloro-bridged Cu^{II} dimer. Additionally, the catalytic activity of the complex towards the oxidation of hydrocarbons using H_2O_2 as terminal oxidant has also been investigated. The results of this study reveal that complex **1** behaves as active catalyst for oxygenation of cyclohexane and cycloheptane to their corresponding hydroxylated and oxygenated products affording good yield and turnover number (TON).

2. Experimental

2.1. Materials

$CuCl_2 \cdot 2H_2O$ was purchased from Merck India Ltd. and 5-bromosalicylaldehyde and ethanolamine from Sigma–Aldrich, USA. All the chemicals and solvents employed for the syntheses were of analytical grade and used as received without further purification. Cyclohexane, cycloheptane, cyclohexanone, cyclohexanol, cycloheptanone, cycloheptanol, cyclopentanone were purchased from Sigma–Aldrich, USA, and used as received. Solvents used for spectroscopic studies were purified and dried by standard procedures before use [29].

Scheme 1.

2.2. Syntheses

2.2.1. Synthesis of the Schiff base ligand [2-((E)-(2-hydroxyethylimino)methyl)-4-bromophenol] (***H_2L***)

Ethanolamine (0.12 ml, 2 mmol) was added to a solution of 5-bromosalicylaldehyde (0.402 g, 2 mmol) in 20 ml methanol and the mixture was refluxed for 1 h at 65 °C. A yellow solid was formed which was filtered, washed with methanol and vacuum dried. Yield: 0.141 g (85%). *Anal.* Calc. for $C_9H_{10}BrNO_2$: C, 44.29; H, 4.13; N, 5.74. Found: C, 44.32; H, 4.10; N, 5.81%. FT-IR (KBr, cm^{-1}): ν(C=N) 1640. UV–Vis (λ, nm): 261, 393.

2.2.2. Synthesis of the complex $[Cu(HL)Cl]_2 \cdot H_2O$ (***1***)

The appropriate quantity of solid Schiff base ligand **H_2L** (0.165 g, 1 mmol) was dissolved in 20 ml of methanol. This ligand solution was added dropwise to a 10 ml methanolic solution of $CuCl_2 \cdot 2H_2O$ (0.160 g, 1 mmol) with constant stirring. The mixture was refluxed for 45 min at 65 °C. The resulting deep green solution was then left undisturbed. After 7 days blue block-shaped X-ray diffraction quality single crystals appeared. Yield: 82%. *Anal.* Calc. for $C_{18}H_{20}Br_2Cl_2Cu_2N_2O_5$: C, 30.79; H, 2.87; N, 3.99. Found: C, 30.72; H, 2.89; N, 3.94%.

2.2.3. Experimental procedure for oxidation of cyclohexane and cycloheptane

The catalytic hydrocarbon oxidation reactions by complex **1** involving cyclohexane and cycloheptane as substrates were carried out with the following procedure: 2.5–10 mmol of hydrogen peroxide (30% in H_2O) was added to the metal complex (0.025 mmol) in 3 ml of acetonitrile in a two-neck round bottom flask fitted with a condenser. To this solution, HNO_3 (0.25 mmol) was added followed by the addition of 0.927 mmol of substrate. The reaction was initiated by stirring the above mixture for 48 h at room temperature under atmospheric pressure. Aliquots were collected after regular time intervals and 90 μl of cyclopentanone was added as internal standard. The substrate and products from the reaction mixture were extracted with 10 ml of diethyl ether and they were analyzed by gas chromatography. The identification was achieved by comparison with known standards.

2.3. Physical measurements

The Fourier transform infrared spectra of the ligand and the complex were recorded on a Perkin–Elmer Spectrum RX I FT-IR spectrophotometer with a KBr pressed pellet in the range 4000–200 cm^{-1}. The electronic spectra were recorded on a Perkin–Elmer Lambda 40 (UV–Vis) spectrometer using HPLC grade acetonitrile as solvent in the range 800–200 nm. Elemental analyses were carried out on a Perkin–Elmer 2400 II Elemental Analyser. Electron paramagnetic resonance (EPR) spectrum of **1** was recorded on a polycrystalline sample or in CH_3CN and *N*,*N*-dimethylformamide (DMF) solutions with an X-band Bruker EMX spectrometer at 298 and 120 K. The spectra were simulated with the computer program Bruker WinEPR SimFonia. The magnetic susceptibility measurements were carried out in the temperature range 2–300 K with an applied magnetic field of 0.1 T on a polycrystalline sample of complex **1** (mass = 45.00 mg) with a Quantum Design MPMS-XL-5 SQUID magnetometer. The isothermal magnetization was performed on the same sample at 2 K with magnetic fields up to 5 T. The susceptibility data were corrected for the sample holders previously measured using the same conditions and for the diamagnetic contributions of the salt as deduced by using Pascal's

constant tables ($\chi_{dia} = -332.3 \times 10^{-6}$ emu mol^{-1}). Gas chromatography analysis was performed with an Agilent Technologies 6890N network GC system equipped with a fused silica capillary column (30 m × 0.32 mm) and a FID detector.

2.4. Crystallographic data collection and structure refinements

A diffraction quality single crystal of **1** was mounted on a Bruker X8 Apex 2 CCD diffractometer equipped with a graphite monochromator and Mo Kα radiation ($\lambda = 0.71073$ Å). Data collection was carried out using the Bruker APEX2 software [30]. Multiscan absorption correction was applied using SADABS [31]. The structure of the complex was solved by direct methods with SHELXS, and refined by full-matrix least squares based on F^2 with SHELXL [32]. All non-hydrogen atoms were refined anisotropically. The C-bound H atoms were constrained to ideal geometry and were included in the refinement in the riding model approximation while those of the water molecules were located in difference Fourier maps. Further crystallographic analysis and figure production were carried out using PLATON99 [33] and ORTEP [34] programs. Details of the data collection parameters and crystallographic information for the complex are summarized in the Table 1.

3. Results and discussion

3.1. Infrared and electronic spectra

In the IR spectrum of complex **1**, the strong absorption band at 1603 cm^{-1} can be assigned to the imine stretching frequency of the coordinated ligand, whereas for the free ligand molecule the same band is observed at 1640 cm^{-1}. The shift of this band towards lower frequency on complexation with the metal suggests coordination to the metal ion through imine nitrogen atom [35,36]. The ν(C–O) mode is present as a very strong band at about 1195 cm^{-1}. Ligand coordination to the metal center is substantiated by prominent bands appearing at 445 and 370 cm^{-1} which can be attributed to ν(Cu–N) and ν(Cu–O), respectively. The two bands observed at 310 and 297 cm^{-1} are characteristic of Cu–Cl vibrations [37]. The broad band at 3440–3255 cm^{-1} is attributable to O–H stretching vibrations of lattice water molecule.

The electronic spectral data for the complex in HPLC grade acetonitrile solvent are in good agreement with its geometry. The two strong absorption bands in the region 350–385 nm are clearly charge transfer in origin [38] attributed to the transition from the coordinated unsaturated ligand to the metal ion (LMCT). Again, the intense high energy bands at about 245 and 380 nm may be assigned to the intraligand $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions, respectively. The broad low-intensity absorption band centered at 605 nm is a typical *d*–*d* band for the copper(II) ion [38,39].

3.2. Crystal structure description of complex *1*

A perspective ORTEP view with the atom-labeling scheme of complex **1** is presented in Fig. 1. Selected bond lengths and angles for the complex are given in Table 2. The asymmetric unit of **1** consists of a $[Cu(HL)Cl]_2$ dimeric unit with a lattice water molecule. In the complex, the Schiff base 2-((*E*)-(2-hydroxyethylimino)methyl)-4-bromophenol (**H_2L**) behaves as a monoanionic, tridentate ligand which coordinates to the metal center through its imine nitrogen, alkoxy oxygen and deprotonated phenolic oxygen atoms. The crystal structure determination reveals that complex **1** is a double chloro-bridged dimer in which the copper ions are pentacoordinated, being bonded to three coordinating donor sites of the Schiff base ligand and two bridging chloride anions as shown in Fig. 1. The coordination number 5 for Cu^{II} is very common and usually presents either a square-pyramidal (SP) or a trigonal–bipyramidal (TBP) geometry (or any of the distorted intermediate geometries). For a pentacoordinated metal center, the distortion of the coordination environment from TBP to SP can be evaluated by the Addison distortion index, τ defined as $\tau = [|\theta - \Phi|/60]$, where θ and Φ are the two largest coordination angles and $\tau = 0$ for perfect SP and 1 for ideal TBP [40,41]. In complex **1**, the calculated τ values for Cu1 and Cu2 are 0.147 and 0.200, respectively, clearly suggesting a distorted SP geometry for each copper ion. The square base of each of the two structurally similar copper atoms is constructed by

the imine nitrogen atom, the alkoxy and phenoxy oxygen atoms from the Schiff base ligand and a bridging chlorine atom, while the apical position of the pyramid is occupied by the other bridging chlorine atom. The Cu–N_{imine} and Cu–$O_{phenolic}$ bond distances are in the ranges observed for similar systems [24]. The Cu–O(phenolic) distances are slightly shorter than those of the Cu-O(alkoxy). The substantial elongation of the axial Cu–Cl bonds [2.685(2) and 2.668(2) Å for Cu1 and Cu2, respectively] compared to the equatorial Cu–Cl bonds [2.267(2) and 2.268(2) Å for Cu1 and Cu2, respectively] is caused by the active Jahn–Teller distortion of the copper(II) ion. Interestingly, for the Cu1 center, Cl2 occupies the basal position of the pyramid and Cl1 is apical, whereas in case of the other copper center (Cu2), Cl1 is in the basal plane and Cl2 is in the apical position. As a result, the geometry of the complex consists of two square pyramids sharing one base-to-apex edge but with nearly parallel basal planes [13,21,42]. The axial–equatorial configuration of the two chloro bridges is depicted clearly in Fig. 2. Both Cu1 and Cu2 are displaced from the mean equatorial plane towards the corresponding axial chloro bridging atoms, Cl1 and Cl2, by 0.183 and 0.167 Å, respectively.

Within the Cu(μ-Cl)$_2$Cu core, the Cu–Cu distance of 3.3371(10) Å is much shorter than the average value for chloro-bridged copper(II) dimers (3.499 Å) in CSD [43]. The Cu_2Cl_2 core is considerably distorted from an ideal square as reflected from the average Cl–Cu–Cl and Cu–Cl–Cu bond angles of 92.97° and 84.45°, respectively, both deviating from the ideal angle of 90°. Moreover, these small Cu–Cl–Cu angles play an important role in determining the magnetic coupling within the dimer. The asymmetric nature of the double bridge is also evident from the different Cu–Cl bond lengths. Both basal (ca. 2.27 Å) and axial (ca. 2.67 Å) Cu–Cl distances are comparable with the average literature values of 2.309 Å for short and 2.554 Å for long Cu–$Cl_{bridging}$ distances, respectively.

On one side of the dimer, the two Schiff base ligands are intramolecularly connected through a hydrogen bond between atoms H2H on alkoxy O2 and phenolic O3 (Fig. 1). As a consequence, the two ligands are moved away from each other on the opposite side to maintain the structural integrity of the complex. This segregation generates a hole where a H_2O solvent molecule is inserted, optimizing the interactions at this site by creating a double hydrogen bond. Thus the interaction between phenolic oxygen O1 and alkoxy oxygen O4 is mediated through the intermolecular hydrogen bonds O1W–H12W···O1 and O4–H4H···O1W (Table S1, Supplementary data). Finally, there are two very short Br···Br contacts between adjacent dimers of only 3.6906(11) and 4.0550(2) Å connecting the dimers in the *ac* plane and a longer Br···Br contact of 4.99 Å connecting the dimers in the *b* direction (Fig. S2, Supplementary data).

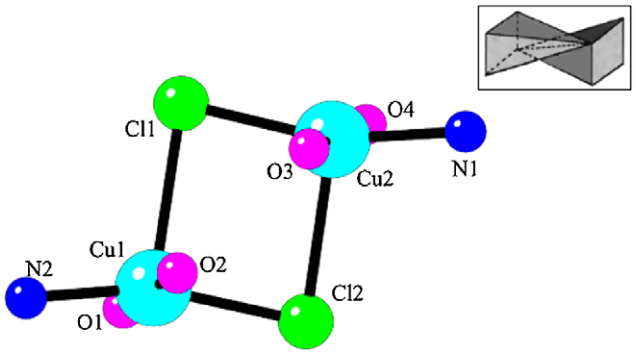

Fig. 2. Coordination environment of the two Cu^{II} ions in complex **1** showing the axial–equatorial configuration of the two Cl bridges (*inset:* arrangement of the two square pyramids).

3.3. EPR spectra

EPR spectra recorded at 298 and 120 K on polycrystalline complex **1** are characterized by two *g* values ($g_{||}$ = 2.222 and $g_{\perp}$ = 2.094), which follow the trend $g_{||} > g_{\perp} > g_e$ (Fig. 3). The forbidden singlet-triplet transition ($\Delta Ms = \pm 2$), often detected at half-field for dimeric copper(II) complexes, is observable only with high instrumental gains. The EPR spectral features can be associated to an axial symmetry having $d_{x^2-y^2}$ as ground state [44,45], where the geometry can correspond to an elongated octahedral, a square-pyramidal or a square planar. The observed *g* values confirm that the geometry of the binuclear species is close to the square pyramid with the deprotonated phenolic and alkoxy oxygens, the imine nitrogen and the bridging Cl^- ion in the equatorial plane and a second Cl^- in the axial position.

The double chloro bridge is destroyed when complex **1** is dissolved in a coordinating solvent like DMF or CH_3CN and the mononuclear unit is formed. This happens because the solvent molecules can easily replace the labile chloride ligands in the coordination sphere of copper ion as found in many other similar complexes [46,47]. EPR spectrum of **1** dissolved in DMF or CH_3CN shows an axial symmetry (Fig. 4). The spectral parameters: $g_{||}$ = 2.270 and $A_{||} = 169.0 \times 10^{-4}\ cm^{-1}$ in DMF and $g_{||}$ = 2.275 and $A_{||} = 176.5 \times 10^{-4}\ cm^{-1}$ in CH_3CN, can be explained postulating a five-coordinated structure with phenolic-O^-, imine-N, alkoxo-O and a Cl^- in

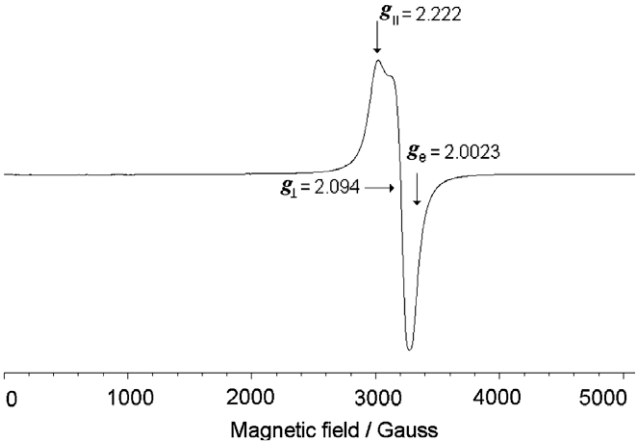

Fig. 3. X-band EPR spectrum of polycrystalline complex **1** at 120 K.

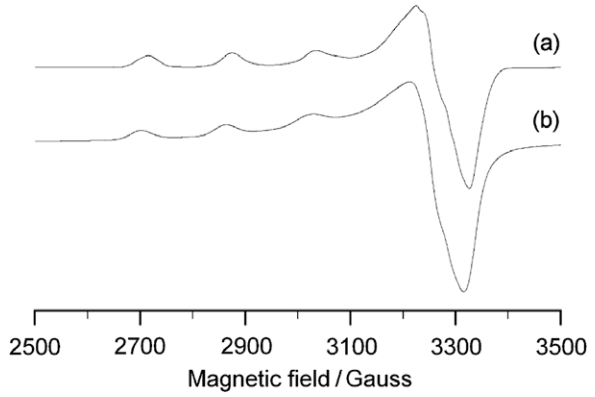

Fig. 4. X-band EPR anisotropic spectra of complex **1** recorded at 120 K in: (a) DMF and (b) CH_3CN.

the equatorial plane and one molecule of solvent weakly bound in the axial position.

3.4. Magnetic studies

The thermal variation of the molar magnetic susceptibility times the temperature ($\chi_m T$) for complex **1** is shown in Fig. 5. At room temperature, the value for $\chi_m T$ is ca. 0.92 emu K mol^{-1} which is slightly higher than the expected one for two non interacting copper(II) $S = 1/2$ ions (0.75 emu K mol^{-1} for $g = 2.0$). When cooling down the sample, the $\chi_m T$ product remains constant down to 180 K and below this temperature it shows a continuous increase to reach a maximum of ca. 1.14 emu K mol^{-1} at 12 K. Below 12 K, $\chi_m T$ decreases to reach a value of ca. 1.07 emu K mol^{-1} at 2 K. This behavior indicates that complex **1** presents predominant ferromagnetic interactions, as suggested by the increase in $\chi_m T$ observed at low temperatures. The $\chi_m T$ value of the maximum (1.14 emu K mol^{-1}) is close to the expected value for the $S = 1$ spin ground state arising from the ferromagnetic coupling of two $S = 1/2$ spins. The decrease observed at low temperatures can be attributed to the presence of antiferromagnetic interactions between the $S = 1$ dimers at low temperatures and/or to a zero field splitting (ZFS) of the $S = 1$ ground spin state. Since the structure of this complex shows the existence of Cu^{II} dimer connected by double chloride bridges, we have fitted the magnetic properties of complex **1** to a simple ferromagnetic $S = 1/2$ dimer with an interdimer exchange interaction (J') to account for the decrease of $\chi_m T$ at low temperatures (the Hamiltonian is written as $H = -JS_iS_{i+1}$) [48]:

$$\chi = 2Ng^2\beta^2[kT - \frac{2J'}{3 + e^{-x}}]^{-1}[3 + e^{-x}]^{-1},$$

where $x = J/kT$.

This model reproduces very satisfactorily the magnetic data of complex **1** in the whole temperature range with the following set of parameters: $g = 2.156(1)$, $J = 43.2(5)$ $K = 30.0(4)$ cm^{-1} and $J' = -0.276(8)$ $K = -0.192(6)$ cm^{-1} (solid line in Fig. 5). As expected (see below), the intradimer magnetic coupling is ferromagnetic and the interdimer one is much weaker and antiferromagnetic.

An additional proof of the ferromagnetic nature of the coupling in complex **1** comes from the isothermal magnetization measurements at low temperature (Fig. 6). This measurement shows a saturation value of ca. 2.2μ_B, very close to the expected value for an $S = 1$ spin state, resulting from the ferromagnetic coupling of the two $S = 1/2$ Cu^{II} ions. Furthermore, the magnetization can be reproduced well with a Brillouin function for an $S = 1$ with a g value of 2.131(4) (solid line in Fig. 6).

As already mentioned in the introduction, there have been several attempts to establish magneto-structural correlations in dinuclear dichloro-bridged Cu^{II} complexes, from the pioneering work of Willett and co-workers [49] and Hatfield and co-workers [9,15] that related the magnetic coupling with the Cu–Cl–Cu angle (α) and with the α/R ratio, respectively (where R is the Cu–Cl_{bridge} distance), to the more recent works of Rodríguez et al. [50], Mrozinski and co-workers [51] and Julve and co-workers [8]. All these correlations indicate that the exchange coupling constant J depends on the value of the Cu–Cl–Cu bridging angle, α, as well as on the bond length of the axial (longer) Cu–Cl bond, R in SP geometry. However, these parameters are not the only factors playing an important role in determining the magnetic coupling. The different types of arrangement of the two copper(II) polyhedra have a great influence on the magnetic behavior of such complexes. The global arrangement of the two square pyramids gives rise to three types of geometries: (a) square pyramids sharing one base-to-apex edge but with parallel basal planes (Type-I), (b) square pyramids sharing one base-to-apex edge with the two bases nearly perpendicular to one another (Type-II) and (c) square pyramids sharing a basal edge with coplanar basal planes (Type-III). Complex **1** belongs to the Type-I class of compounds, as evident from its structural features (Fig. 2). Thus, for the parallel bases arrangement (Type-I as in the case of the title complex), extended Hückel calculations [50] show that the magnetic interaction occurs through a π^* type interaction

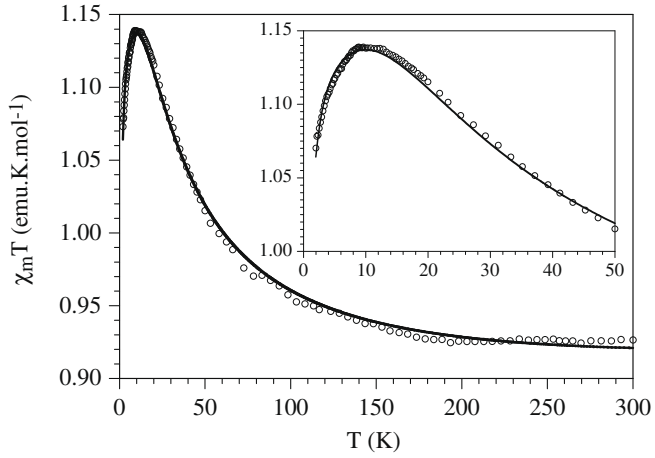

Fig. 5. Thermal variation of the $\chi_m T$ product for complex **1**. Solid line represents the best fit to the model (see text). Inset shows the low temperature region.

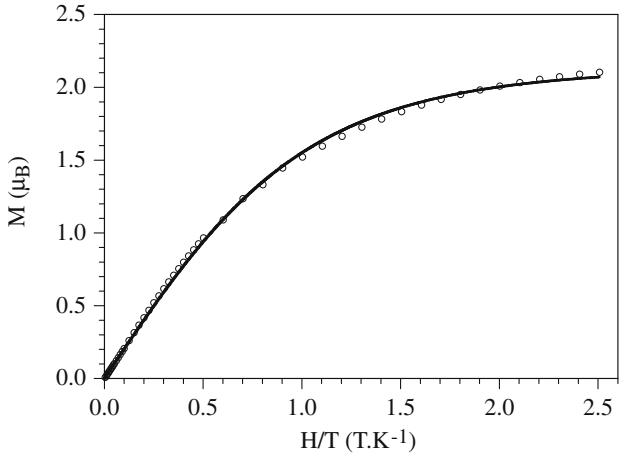

Fig. 6. Isothermal magnetization at 2 K of complex **1**. Solid line represents the best fit to the Brillouin function for an $S = 1$ spin state (see text).

between the $d_{x^2-y^2}$ Cu orbital and the p orbital of the chlorine atoms. The extent of this magnetic coupling is decided by the small structural deviations from the ideal square Cu_2Cl_2 core. Recently, Mrozinski and co-workers [51] established a theoretical correlation between the magnetic coupling and both parameters (α and R) showing that for small α values and short Cu–Cl distances the magnetic coupling is ferromagnetic. When the α and R values of complex **1** [α = 84.66(5)° and 84.25(5)° and R = 2.6853(16) and 2.6685(16) Å] are reported to this relationship, a moderately strong ferromagnetic coupling is predicted, which is in agreement with the experimental results. Furthermore, these α and R values are expected to produce the strongest ferromagnetic coupling of all the known Cu^{II} dimers involving a similar dichloro bridge. Interestingly, corroborating with the theoretical predictions, complex **1** is found to present the highest ferromagnetic coupling [J = +43.2(5) cm^{-1}] reported so far for any bis(μ-chloro) copper(II) dimers. An analysis of the α and R values of the other known dichloro-bridged Cu^{II} complexes [8,15,50,51] shows that the main reason explaining this particular situation are the small α values of complex **1**, which are about 5° smaller than the average value of 89.40(5)° [14]. Previously, the smallest α value reported was 82.9° for the complex $[Cu_2(baamo)_2Cl_2]$ (baamo = 8-amino-5-aza-4-methyl-3-octene-2-onate), where a ferromagnetic coupling of 12 cm^{-1} had been found even when the Cu–Cl distance was as high as 2.81 Å [52]. In the present complex the small α values are accompanied by much shorter R values (ca. 2.67 Å) compared to the above complex, giving rise to the unusually strong ferromagnetic coupling. A detailed look at the structure of complex **1** reveals that the presence of the intradimer hydrogen bonds (Fig. 1) may be responsible for the unusually small Cu–Cl–Cu angles since both intra- and intermolecular hydrogen bonds force the copper(II) ions to be closer, decreasing the Cu–Cl–Cu bond angle.

Finally, the antiferromagnetic weak interdimer exchange can be attributed to the presence of some short interdimer Br···Br contacts (Fig. S2, Supplementary data).

3.5. Catalytic oxidation of cyclohexane and cycloheptane

The study of the oxidation of various hydrocarbons catalyzed by a metal complex has now become an important research topic since it involves conversion of crude oil and natural gas constituents into oxygenated derivatives of immense industrial importance, such as alcohols or carbonyl compounds.

Here, we have examined the catalytic activity of the complex towards cyclohexane and cycloheptane oxidation using hydrogen peroxide as oxidant under the same experimental conditions for both the substrates. It is found that complex **1** behaves as active catalyst for the liquid biphasic (acetonitrile/water) oxidation of cyclohexane and cycloheptane by H_2O_2 in a slightly acidic medium at room temperature and atmospheric pressure. The corresponding products are cycloalkanol and cycloalkanone. Optimization has been achieved by varying the relative proportions of nitric acid, hydrogen peroxide as well as time period of the reactions. In the literature [53,54], it has been clearly pointed out that the presence of nitric acid has a positive role. The catalyst activation is created by the increase of unsaturation at the metal center with simultaneous increase in oxidation properties. As a result decomposition of peroxide is retarded and the peroxo intermediate gets stabilized.

During the present study, we have verified that the addition of nitric acid is mandatory in the hydrogen peroxide oxidation of cyclohexane and cycloheptane in presence of complex **1** as the catalyst. The amount of oxidized products remains almost unchanged in the 10–50 range of $n(HNO_3)/n$(catalyst), whereas further increase of such ratio decreases the yield. When the oxidation of the substrate was carried out in absence of nitric acid, the reaction did not proceed at all. The highest conversion of the substrate is achieved when $n(HNO_3)/n$(catalyst) is 10. The geometry around the Cu center in the catalyst is pentacoordinated having labile sites like Cu–Cl. These would require nitric acid so as to increase unsaturation at the metal site as a result of ligand protonation. Such observations evoked us to maintain a ratio of $n(HNO_3)/n$(catalyst) = 10 in the rest of the studies.

The results of cyclohexane oxidation are shown in Table 3a. It is clearly seen from the table that the maximum conversions of cyclohexane to the corresponding cyclohexanol and cyclohexanone are 31.4% and 20.9%, respectively, when $n(H_2O_2)/n$(catalyst) ratio is 300 with the reaction time 48 h. Table 3b contains the details of the conversion of cycloheptane influenced by the relative amounts of hydrogen peroxide, amount of nitric acid and the reaction period. The maximum conversions of cycloheptane to the corresponding cycloheptanol and cycloheptanone achieved are 24.0% and 15.0%, respectively. The results of these oxidation reactions are comparable with those obtained for other copper complexes reported earlier [53,55,56]. In contrast, simple copper salt like, $Cu(NO_3)_2$ under the same reaction conditions exhibits a much lower activity towards oxidation of the substrates with 3.9–5.4% yield, under the same peroxide-to-catalyst molar ratio. Thus it is evident that the presence of N,O donor ligands are quite relevant.

In the case of complex **1**, the coordination environment around the copper(II) ion is easily accessible for an external ligand, as a result copper(II) can bind the peroxo-group on treatment with peroxides. This *in situ* generated intermediated peroxo-type species seems to be capable of transferring the oxo functionality to the organic substrates to give the corresponding oxidized products. In order to find out the probable mechanisms, we have carried out the catalytic reaction of cyclohexane with complex **1** maintaining $n(HNO_3)/n$(catalyst) ratio of 10 and $n(H_2O_2)/n$(catalyst) ratio of 300 in presence of TEMPO (2,2,6,6-tetramethylpiperidin-1-oxyl) and diphenylamine. The yield of the reaction is greatly suppressed in presence of these compounds. TEMPO and diphenylamine are

well known as carbon-radical and oxygen-radical traps respectively [57]. This indirectly indicates that oxidation reactions occur mainly by mechanisms involving the formation of both carbon-centered and oxygen-centered radicals. An electrophilic attack of an oxidized metal-peroxo, metal-superoxo or metal-oxo center to a C–H bond of the substrate with heterolytic cleavage of this bond to form an organocopper intermediate can be proposed which has been noted for other metals [58].

4. Conclusion

The present complex shows the feasibility of the ONO donor Schiff bases to form dinuclear dichloro-bridged Cu^{II} complexes with an unusually strong ferromagnetic coupling. In fact, complex **1** presents the strongest ferromagnetic coupling observed till date in any doubly (μ-chloro)-bridged Cu^{II} complex. The previously established magneto-structural correlations attribute this strong ferromagnetic coupling to the unusually small Cu–Cl–Cu bond angles. A detailed structural analysis reveals that the intradimer hydrogen bonds of both intra- and intermolecular types are responsible for bringing the two copper centers closer, thereby decreasing the bridging angle. Besides this, the complex is also found to possess efficient catalytic properties in the oxidation of cyclohexane and cycloheptane by H_2O_2 to their corresponding alcoholic and carbonyl derivatives.

Acknowledgements

Santarupa Thakurta gratefully acknowledges the Council of Scientific and Industrial Research, New Delhi, India, for the award of Research Fellowship to her (CSIR Sanction No. 09/096(0519)/2007-EMR-I) and thanks are extended to Prof. P. Banerjee of Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Kolkata 32, for providing valuable supports. Carlos J. Gómez-García acknowledges the European Union for financial support (MAGMANet network of excellence) and the Spanish Ministerio de Educación y Ciencia (Projects MAT2007-61584 and Consolider-Ingenio 2010 CSD 2007-00010 in Molecular Nanoscience).

Appendix A. Supplementary data

CCDC 703082 contains the supplementary crystallographic data for complex **1**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2008.12.016.

$[Bi_2(4\text{-bpdh})Br_9]\cdot 3(4\text{-Hbpdh})$ (**3**) {3-bpdb = 1,4-bis(3-pyridyl)-2,3-diaza-1,3-butadiene, 3-bpdh = 2,5-bis(3-pyridyl)-3,4-diaza-2,4-hexadiene and 4-bpdh = 2,5-bis(4-pyridyl)-3,4-diaza-2,4-hexadiene} (Fig. 1)}.

The three nitrogen donor-based ligands 3-bpdb, 3-bpdh and 4-bpdh that were used have been selected, amongst other reasons, as they are capable to act as bridging ligands and thus may be able to form polymeric structures. Recent investigations have addressed the use of these three ligands for the preparation of coordination polymers with other metal ions [45–54]. These studies have demonstrated that the long conjugated rigid ligands are capable of coordinating transition metal centers via both the terminal pyridyl and the diaza nitrogen donors and that they are able to generate novel coordination polymers. We will show that subtle changes in the use of these conformationally flexible ligands as spacers in the design and construction of coordination polymers may lead to new polymeric networks with different structural motifs and topologies. As the counter-ion in these Bi(III) coordination polymers we decided to use bromide anions, which may be able to act as additional bridges between the metal centers.

2. Experimental

With the exception of the ligands 3-bpdb, 3-bpdh and 4-bpdh, which were prepared according to the literature procedures [55,56], all reagents and solvents for the synthesis and analysis were commercially available and were used as received. IR spectra were recorded using Perkin–Elmer 597 and Nicolet 510P spectrophotometers. Microanalyses were carried out using a Heraeus CHN-O-Rapid analyzer. Melting points were measured on an Electrothermal 9100 apparatus and are uncorrected. The thermal behavior was measured with a PL-STA 1500 apparatus. Single crystal diffraction measurements were made at 100(2) K using a Bruker AXS SMART APEX CCD diffractometer. The intensity data were collected using graphite monochromated Mo Kα radiation. The structures were solved by direct methods and refined by full-matrix least-squares techniques on F^2. All hydrogen atoms were placed in calculated positions and were refined with an isotropic displacement parameter 1.2 times that of the adjacent carbon atom. The molecular structure plots were prepared using Mercury [57] and ORTEPIII [58] (see Tables 1 and 2).

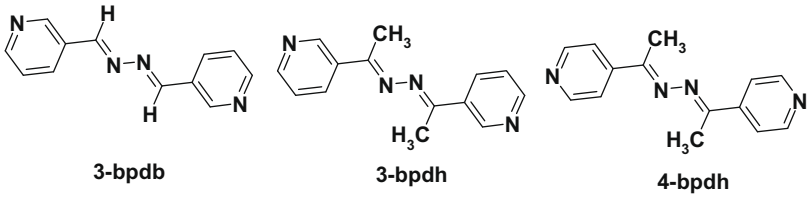

Fig. 1. Organic nitrogen donor-based ligands used in the construction of bismuth(III) bromide coordination polymers.

To isolate single crystals of $[Bi_2(3\text{-bpdb})_2Br_8]\cdot(3\text{-}H_2bpdb)$ (**1**), $[Bi_2(3\text{-Hbpdh})_2Br_8]$ (**2**) and $[Bi_2(4\text{-bpdh})Br_9]\cdot 3(4\text{-Hbpdh})$ (**3**), one mmol of each of the ligands 3-bpdb, 3-bpdh and 4-bpdh and one mmol of bismuth(III) bromide were placed in the main arm of a branched tube. Methanol was carefully added to fill both arms. The tube was sealed and the ligand-containing arm immersed in an oil bath at 60 °C while the other arm was kept at ambient temperature. After 7–10 days, yellow, yellow and red crystals of compounds **1–3**, respectively, that deposited in the cooler arm were isolated. The single crystals were filtered off, washed with acetone and ether, and air dried.

Product **1**: m.p. = 290 °C. *Anal*. Calc. for $C_{36}H_{32}Bi_2Br_8N_{12}$: C, 25.56; H, 1.89; N, 9.94. Found: C, 25.40; H, 1.70; N, 9.80%. IR (cm^{-1}, KBr): 493w, 678m, 801m, 858w, 1039w, 1299m, 1407w, 1615s.

Product **2***:* m.p. = 274 °C. *Anal.* Calc. for $C_{28}H_{28.55}Bi_2Br_{6.55}N_8$: C, 23.68; H, 2.01; N, 7.89. Found: C, 23.50; H, 2.10; N, 7.50%. IR (cm^{-1}, KBr): 406m, 566w, 642w, 817s, 1006m, 1050w, 1363w, 1596s.

Product **3***:* m.p. = 270 °C. *Anal.* Calc. for $C_{56}H_{59}Bi_2Br_9N_{16}$: C, 32.10; H, 2.81; N, 10.70. Found: C, 32.20; H, 2.70; N, 10.55%. IR (cm^{-1}, KBr): 631w, 659m, 778s, 847w, 1032w, 1287w, 1370m, 1526m, 1600m, 1939w, 3045vs.

3. Results and discussion

The reaction between 3-bpdb, 3-bpdh and 4-bpdh with bismuth(III) bromide provided crystalline materials of the general formulae $[Bi_2(3\text{-bpdb})_2Br_8]\cdot(3\text{-}H_2bpdb)$ (**1**), $[Bi_2(3\text{-Hbpdh})_2Br_8]$ (**2**) and $[Bi_2(4\text{-bpdh})Br_9]\cdot 3(4\text{-Hbpdh})$ (**3**), respectively. The IR spectra of these compounds show characteristic absorption bands for the 3-bpdb, 3-bpdh and 4-bpdh ligands, such as the typical pyridyl vibrations in the frequency range 1400–1580 cm^{-1}, and the elemental analysis data agree well with the numbers expected for the respective formulae given above.

Detailed solid state structures of all three complexes were determined by single crystal X-ray diffraction analysis (Figs. 2–7). For compound **2**, the occupancies were refined for all bromine atoms and the sum of these occupancies was set to the sum of the positive charges from the bismuth ions and the occupancy of the pyridinium hydrogen atoms. In compound **3**, the bromine atom Br10 is disordered across an inversion center. This induces a 1:1 disorder of the neighboring bromine atom Br9. Complex **1** is a salt in the solid state and consists of a $[Bi_2(3\text{-bpdb})_2Br_8]^{2-}$ anion and a $3\text{-}H_2bpdb^{2+}$ cation. The complex anion is dinuclear in nature and the bismuth atoms are coordinated to the nitrogen atoms of the 3-bpdb ligand and also to the five bromide atoms, two of which are bridging between the two different Bi atoms. The metal coordination number in this complex is six and the coordination around Bi is distorted octahedral. An interesting point is that the $3\text{-}H_2bpdb^{2+}$ cations must have been created by proton transfer between the molecular species in solution. The $3\text{-}H_2bpdb^{2+}$ cations are linked by hydrogen bonding (Fig. 5) via their protonated pyridyl nitrogen atoms as N–H hydrogen bond donors. Hydrogen bond acceptors are the uncoordinated and unprotonated pyridyl N

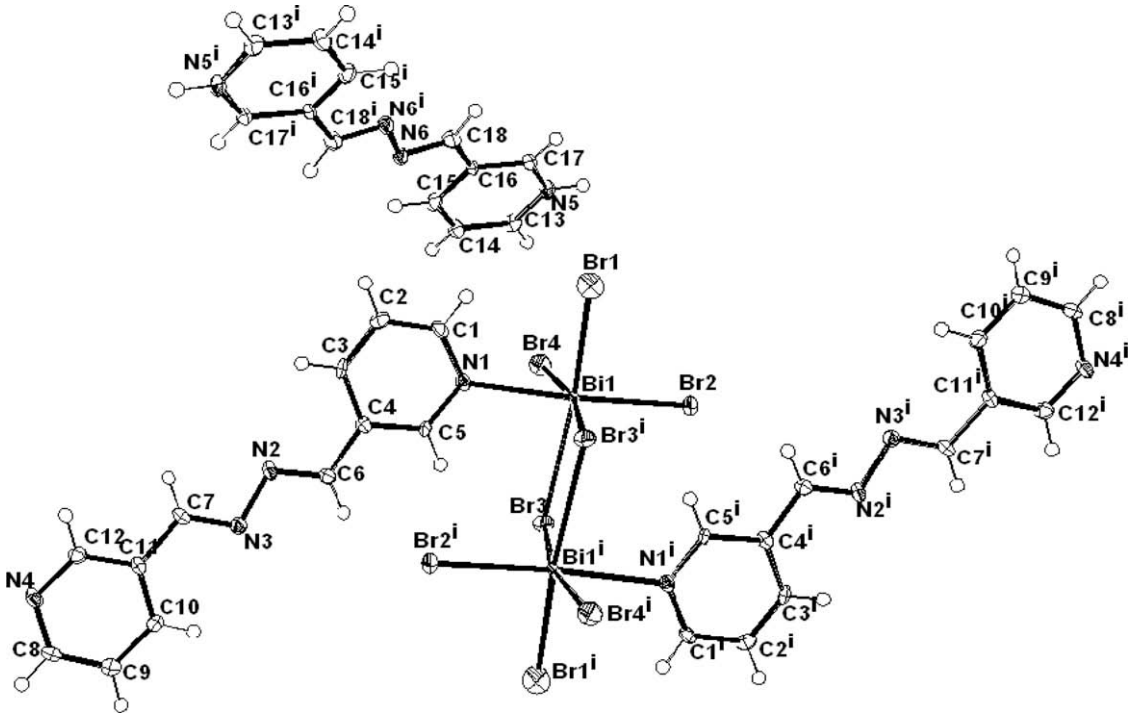

Fig. 2. X-ray crystal structure showing the linking and non-coordination of the ligands 3-bpdb and 3-Hbpdb in $[Bi_2(3\text{-bpdb})_2Br_8]\cdot(3\text{-}H_2bpdb)$ (**1**), respectively, (30% thermal displacement ellipsoids).

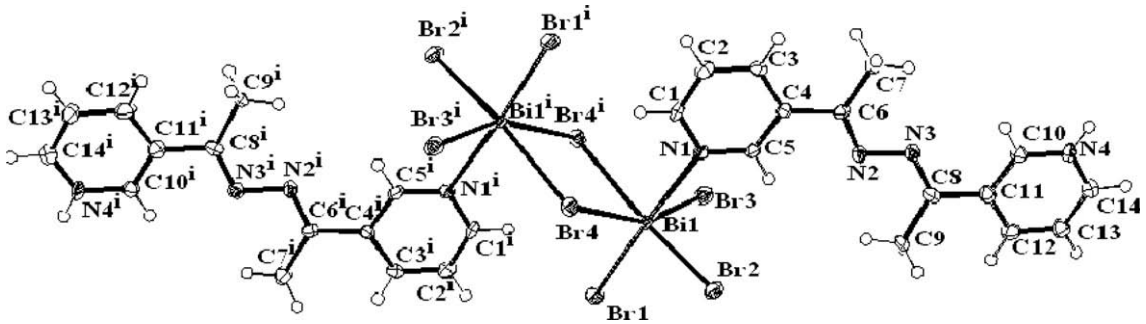

Fig. 3. X-ray crystal structure of $[Bi_2(3\text{-Hbpdh})_2Br_8]$ (**2**), (50% thermal displacement ellipsoids).

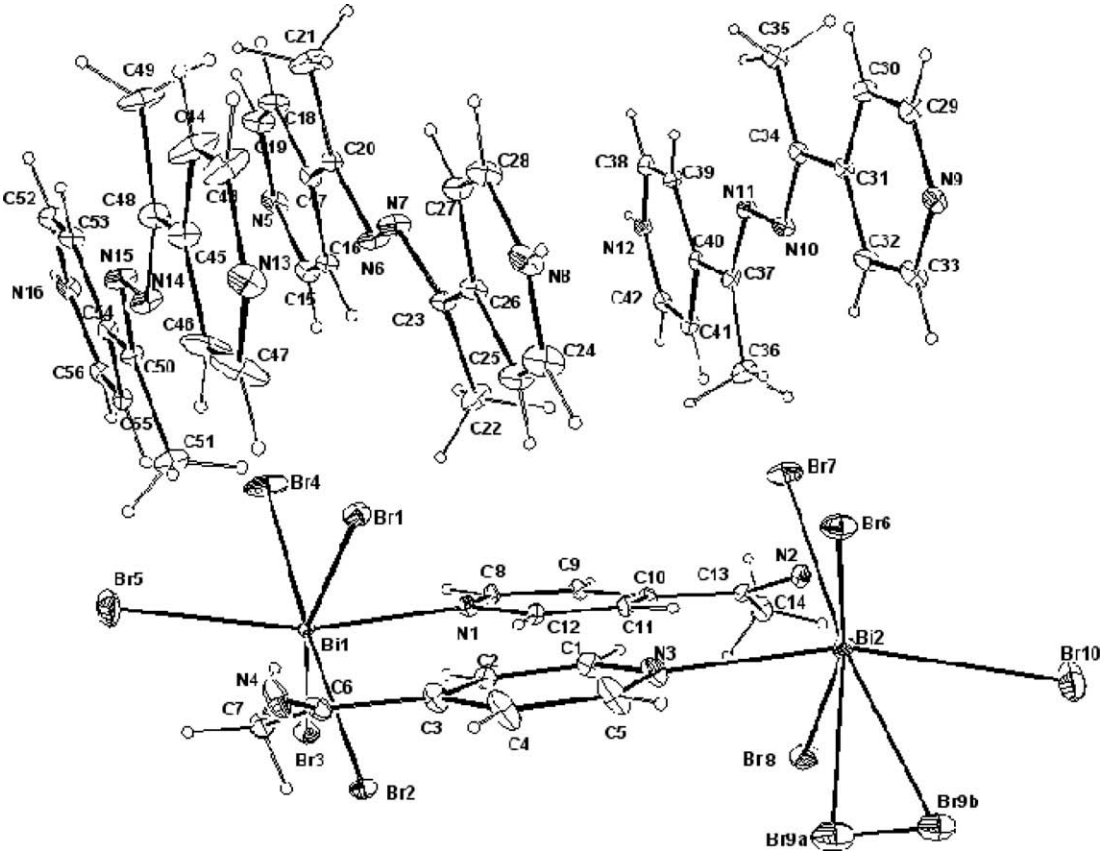

Fig. 4. X-ray crystal structure showing the linking and non-coordination of the ligands 4-bpdh and 3-Hbpdh in $[Bi_2(4\text{-bpdh})Br_9]\cdot 3(4\text{-Hbpdh})$ (**3**), respectively, (30% thermal displacement ellipsoids).

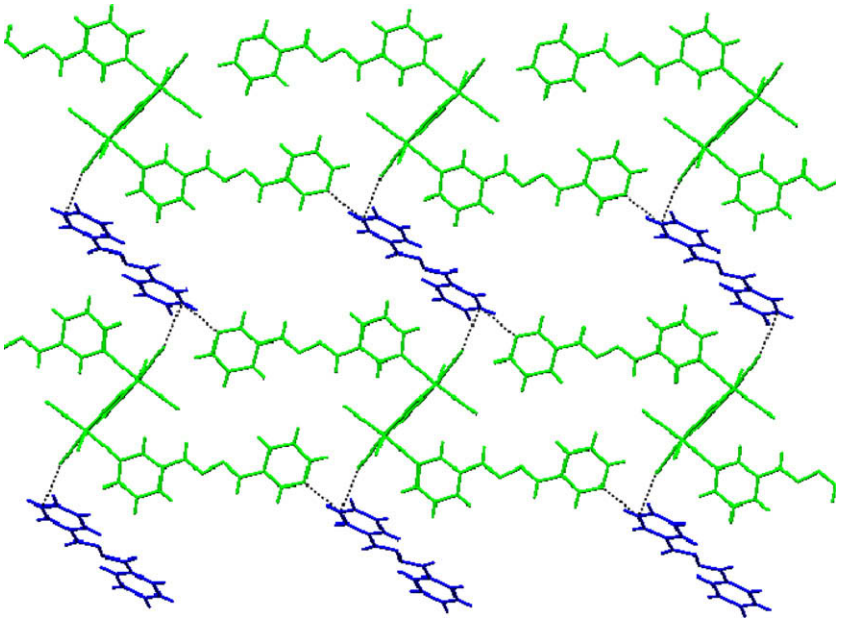

Fig. 5. The 2D supramolecular structure generated via the N-H···N and N-H···Br interactions in $[Bi_2(3\text{-bpdb})_2Br_8]\cdot(3\text{-}H_2bpdb)$ (**1**).

atoms of the $[Bi_2(3\text{-bpdb})_2Br_8]^{2-}$ anions. Hydrogen bond distances d(D–H), d(H···A), d(D···A), and angles <(DHA)} for N5–H5A···N4 are 0.86, 1.87, 2.681(12) Å, and 157.7°, respectively, and for N7–H7A···N6^{i} they are 0.88, 1.83, 2.694(9) Å, and 167.7°, respectively [symmetry operator $i = -1 + x, 1 + y, z$]. Another interesting feature of this complex is that there is a short Br···H–N interaction (Fig. 5) with a distance of 3.348(9) Å. Consequently, the dimeric structure is grown by the hydrogen bonds and Br···H–N interactions into a

two-dimensional network (Fig. 5). Supramolecular compounds generated from hydrogen bonding between protonated ligands have been reported before [30,54,59,60].

Determination of the structure of compound **2** by X-ray crystallography showed the complex in the solid state to consist of dimeric units (Fig. 3). The bismuth atoms are linked by one nitrogen atom of the 3-Hbpdh ligand and by five bromide atoms, and can be considered to be six-coordinate with a Br_5N array of donor atoms. The coordination environment around Bi is distorted octahedral. One pyridyl nitrogen atom of the 3-bpdh ligand is not coordinated to Bi atoms (Fig. 3) and is instead protonated. The aromatic rings of the coordinated 3-Hbpdh ligand are coplanar with a dihedral angle between the two pyridyl rings of only 1.27(17)°. The hydrogen atoms of the protontated and uncoordi-

N12–H12A···N9	0.86	1.84	2.704(12)	178.2
N16–H16A···N13	0.86	1.83	2.7694(12)	178.1

nated nitrogen atoms are involved in N–H···Br interactions, thus acting as weak hydrogen-bond donors towards the Br atoms. Consequently, the dimeric structure is grown by the weak hydrogen bonds into a two-dimensional network (Fig. 6).

The molecular structure of complex **3** consists of one $[Bi_2(4\text{-bpdh})Br_9]^{3-}$ anionic unit and three 4-Hbpdh$^+$ cationic entities (Fig. 4). The anions form infinite one dimensional polynuclear $[Bi_2(4\text{-bpdh})Br_9]_n^{3n-}$ chains in which the bismuth atoms are bridged by both the 4-bpdh ligands and the bromide ions. The Bi coordination number in these chains is six and the coordination around Bi is distorted octahedral. Similar to compounds **1** and **2** the 4-Hbpdh$^+$ cations in **3** seem to result from a proton transfer between molecular species in solution. The 4-Hbpdh$^+$ cations are linked to each other by hydrogen bonding (Fig. 7 and Table 3). As shown in Fig. 7, the hydrogen bonding yields infinite chains of 4-Hbpdh$^+$ relatively perpendicular to the one-dimensional chains of $[Bi_2(4\text{-bpdh})Br_9]_n^{3n-}$. Consequently, the two perpendicular 1D chain systems, produced by the covalent coordination polymer of $[Bi_2(4\text{-bpdh})Br_9]_n^{3n-}$ and the non-covalent hydrogen-bonding polymer of $[4\text{-Hbpdh}]_n^{n+}$, forms into a hybrid three-dimensional network. There are π–π stacking and $\pi_{centroid}$–N interactions between the pyridine groups of the 4-Hbpdh$^+$ cations with centroid to centroid and $\pi_{centroid}$–N distances of 4.664(4) and 3.696(5) Å, respectively (Fig. 7). However, the hydrogen bonding, π–π stacking and N···π interactions may control the packing of complex **3**.

4. Thermogravimetric analysis

To examine the thermal stability of the compounds $[Bi_2(3\text{-bpdb})_2Br_8]\cdot(3\text{-}H_2bpdb)$ (**1**), $[Bi_2(3\text{-Hbpdh})_2Br_8]$ (**2**) and $[Bi_2(4\text{-bpdh})Br_9]\cdot 3(4\text{-Hbpdh})$ (**3**), thermal gravimetric (TG) and differential thermal analyses (DTA) were carried out between 30 and 700 °C in a static atmosphere of nitrogen. Compound **1** is stable and does not decompose up to 174 °C. At this temperature the decomposition of compound **1** starts and the final decomposition

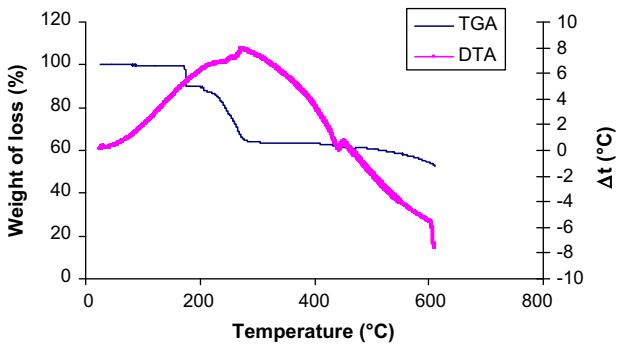

Fig. 8. Thermal behavior of compound **1**.

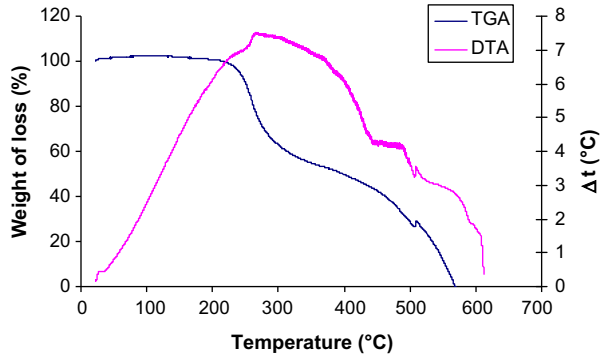

Fig. 9. Thermal behavior of compound **2**.

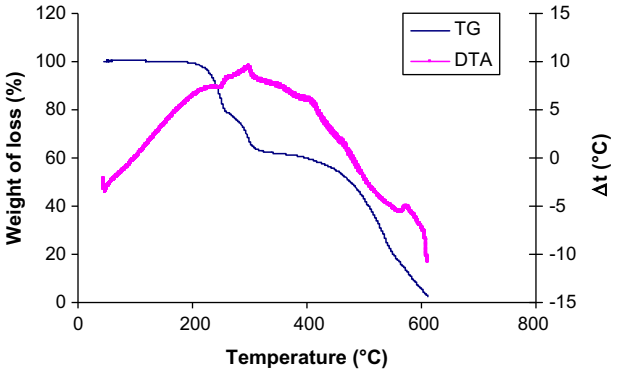

Fig. 10. Thermal behavior of compound **3**.

product is suggested to be $BiBr_3$ (mass loss of 46.80%, calc. 45.80%). The DTA curve displays an exothermic peak at 280 °C and an endothermic peak at 445 °C (Fig. 8). The TG curve of compound **2** indicates that this compound does not melt and is stable up to 220 °C at which temperature it begins to decompose. Decomposition is finished at 500 °C with an exothermic peak at 270 °C and an endothermic peak at 515 °C (Fig. 9). Compound **3** is stable and does not decompose up to 200 °C. At this temperature decomposition of compound **3** starts. Removal of three 4-Hbpdh units occurs between 200 and 315 °C with a mass loss of 63.5% (calc. 65%) and decomposition is continued up to 610 °C with no residue, indicating complete sublimation of $BiBr_3$. The DTA curve displays two endothermic peaks at 255 and 570 °C and an exothermic peak at 302 °C (Fig. 10).

5. Conclusions

Three new bismuth(III) coordination polymers with 1,4-bis (3-pyridyl)-2,3-diaza-1,3-butadiene (3-bpdb), 2,5-bis(3-pyridyl)-3,4-diaza-2,4-hexadiene (3-bpdh) and 2,5-bis(4-pyridyl)-3,4-diaza-2,4-hexadiene (4-bpdh), namely $[Bi_2(3\text{-bpdb})_2Br_8]\cdot(3\text{-}H_2bpdb)$ (**1**), $[Bi_2(3\text{-Hbpdh})_2Br_8]$ (**2**) and $[Bi_2(4\text{-bpdh})Br_9]\cdot 3(4\text{-Hbpdh})$ (**3**), have been synthesized using a thermal gradient approach, the branched tube method. In the assembly processes of compounds **1–3**, all factors such as the metal, inorganic anions, solvent medium and metal/ligand ratio are kept constant and the only variable parameter is the nature of the ligand, 3-bpdb, 3-bpdh and 4-bpdh. The compounds are structurally diverse, showing dimeric and polymeric structures. The coordination polymers obtained from $BiBr_3$ with the ligands 3-bpdb and 3-bpdh are dimeric in nature and in these compounds the $BiBr_3$ units are connected to each other via the Br^- anions and the ligands 3-bpdb and 3-bpdh

coordinating to the Bi atoms through each of the pyridyl nitrogen atoms. The 3-bpdh ligand in compound **3** acts as a bridging ligand via two pyridyl nitrogen atoms. Interestingly in all three compounds the ligands 3-bpdb, 3-bpdh and 4-bpdh were protonated – similar to that observed in $[4,4'\text{-bipyH}]_n^{n-}[\text{Bi}(4,4\text{-bipy})\text{Br}_4]_n^{n-}$ [30]–to yield the cations H_2bpdb^{2+}, 3-$Hbpdh^+$ and 4-$Hbpdh^+$, an observation only rarely seen for the other metal ion coordination polymers with this type of ligand [47–57]. This shows that the Bi^{+3} ion may be the ion of choice when one wants to prepare supramolecular compounds that contain protonated pyridyl ligands. Thus this research not only shows the significant influences of the coordination modes and flexibilities of the ligands 3-bpdb, 3-bpdh and 4-bpdh on the structural topology, but also illustrates the effect of the metal ion, here Bi^{+3} ions, on the polymeric components, which provides valuable information for the rational design of coordination polymers with specific molecular architectures.

when another pyrimidine derived hydrazone ligand ($H_2L'_1$) was employed for complexation with $MoO_2(acac)_2$, a similar ligand transformation occurred and the complex $[MoO_2(L_4)Cl]$ (**4**) was produced. These ligand transformations are probably initiated by a Mo mediated C=N bond cleavage of the used ligands in the reaction medium.

2. Experimental

2.1. Materials and physical measurements

$MoO_2(acac)_2$ was prepared as described in the literature [25]. Reagent grade solvents were used as received. 4,6-Dimethyl 2-hydrazino pyrimidine and 2,4-dihydrazino pyrimidine were prepared as described in the literature [26]. Salicylaldehyde, *o*-hydroxy acetophenone and tetraethyl ammonium perchlorate (TEAP) used for electrochemical work were purchased from Aldrich Chemical Company, USA and were used as received. Elemental analyses (C, H and N), IR spectra (KBr disks, 4000–200 cm^{-1}), ^1H NMR spectra (d_6-DMSO)/$CDCl_3$ of the ligands and the complexes and UV–Vis spectra (DMF) of the complexes were recorded with a Perkin–Elmer Model 240 C CHN analyzer, a Jasco FTIR model 420 spectrophotometer, Bruker AM300L (300 MHz) superconducting FT-NMR and a Hitachi U-3501 spectrophotometer, respectively. Cyclic voltammetry (CV) experiments were carried out using Sycopel Model 77 AEW2 1820F/S instrument. The measurements were performed at 300 K in a DMF solution containing 0.2 M TEAP and 10^{-3}–10^{-4} M Mo(VI) complexes **1–4** deoxygenated by bubbling with nitrogen. A platinum wire, a platinum coil and a SCE were used as working, counter and reference electrodes, respectively.

2.2. Crystallographic measurements

The crystals were measured on an Enraf-Nonius CAD-4 diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) and a graphite monochromator at −80 °C. The unit cell dimensions were obtained from a least squares fit to the setting angles of 25 accurately determined reflections. The data were collected using the $\omega-2\theta$ scan technique with a 2θ range of 4−55° and were corrected by an empirical method for absorption, Lorentz and polarization effects. Calculations were carried out using XCAD-49 (data reduction) and SHELXTL (absorption corrections, structure solution refinements and molecular graphics). The structures were solved using direct methods and refined on F^2 using full matrix least squares techniques with anisotropic displacement factors for all non-hydrogen atoms. Positions of the hydrogen atoms were calculated from the geometry of the molecular skeleton and their thermal displacement parameters were refined isotropically on a groupwise basis.

2.3. Synthesis of the ligands HL_1 and HL_2

The ligands HL_1 and HL_2 were synthesized in a similar way by refluxing an ethanolic solution (20 mL) of 4,6-dimethyl 2-hydrazino pyrimidine (10 mmol, 1.38 g) as a common reagent with salicylaldehyde (10 mmol,1.22 g for HL_1) and *o*-hydroxy acetophenone (10 mmol, 1.36 g for HL_2), respectively, also taken in ethanol solution (20 mL). Refluxing was continued for ca. 2 h at water bath temperature. The mother liquor was cooled and left for slow evaporation for the final separation of a solid compound. It was filtered, washed with ethanol and dried over fused $CaCl_2$. The crude product was recrystallized from an ethanol–water mixture (4:1 v/v). The ligand HL_1 has been prepared and used in one of our previous works [27].

HL_1: M.p.: 165 °C. Yield: 1.936 g (80%). Elemental *Anal.* Calc. for $C_{13}H_{14}N_4O$: C, 64.4; H, 5.78; N, 23.14. Found: C, 64.2; H, 5.66; N, 23.05%. IR (KBr pellet) ν/cm^{-1}: 3283 (N–H), 3175 (O–H), 1546.9 (C=N), 1609 (C=C). ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS) δ/ppm: 6.68 (s, 1H, C_5–H Pyrimidine), 6.8–7.3 (m, 4H, $-C_6H_4$), 8.2 (s, 1H, –CH=N–), 12.8 (s, 1H, aromatic-OH), 2.28 (s, 1H, N–H of hydrazone), 2.46–2.53 (m, 6H, CH_3, t).

HL_2: M.p.: 169 °C. Yield: 1.98 g (80%). Elemental *Anal.* Calc. for $C_{14}H_{16}N_4O$: C, 65.88; H, 6.27; N, 21.96. Found: C, 65.62; H, 6.11; N, 21.46%. IR (KBr pellet) ν/cm^{-1}: 3274 (N–H), 3180 (O–H), 1537 (C=N), 1609 (C=C). ^1H NMR (300 MHz, $CDCl_3$, 25 °C, TMS) δ/ppm: 6.62 (s, 1H, $-C_5$–H Pyrimidine), 6.8–7.5 (m, 4H, $-C_6H_4$), 2.57 (s, 3H, $-C(CH_3)$ =N–), 12.8 (s, 1H, aromatic-OH), 2.28 (s,1H, N–H of hydrazone), 2.46–2.53 (m, 6H, CH_3) 2.4.

2.4. Synthesis of the ligand $H_2L'_1$

The ligand $H_2L'_1$ was synthesized by refluxing an aqueous solution (10 mL) of 2,4-dihydrazino pyrimidine (10 mmol, 1.40 g) with salicylaldehyde (10 mmol,1.22 g), taken in ethanol (20 mL). Refluxing was continued for ca. 2 h at water bath temperature, during which time the solid ligand started to precipitate. The reaction mixture was cooled and the ligand was filtered, washed with ethanol and dried over fused $CaCl_2$. The crude product was recrystallized from an ethanol–water mixture (4:1 v/v).

$H_2L'_1$: M.p. above 200 °C. Yield: 2.20 g (63%). Elemental *Anal.* Calc. for $C_{18}H_{16}N_6O_2$: C, 62.06; H, 4.59; N, 24.13. Found: C, 61.67; H, 4.23; N, 23.79%. IR (KBr pellet) ν/cm^{-1}: 3303 (N–H), 3159 (O–H), 1533.9 (C–N), 1616 (C=C). ^1H NMR (300 MHz, d_6-DMSO, 25 °C, TMS) δ/ppm: 7.6 (d, ^2J(H,H) = 6,1H, $-C_5$–H Pyrimidine), 8.1 (d, ^2J(H,H) = 6,1H, $-C_4$–H Pyrimidine), 6.5–7.3 (m, 8H, $-C_6H_4$), 8.2, 8.4 (s, 2H, –CH=N–), 11.2, 11.8 (s, 2H, aromatic-OH), 2.46, 3.2 (s, 2H, N–H of hydrazone).

2.5. Synthesis of complex **1**

The complex $[MoO_2(L_1)Cl]$ (**1**) was prepared by mixing an ethanolic solution (10 mL) of $MoO_2(acac)_2$ (0.5 mmol, 0.163 g), acidified with 5–6 drops of concentrated HCl, (or an ethanolic solution of $(NH_4)_2MoO_4$ dissolved by adding 5–6 drops of HCl) with an ethanolic solution of HL_1 (0.5 mmol, 0.122 g). On mixing the two components an orange color was immediately observed. The mixed solution was refluxed and the complex was separated as orange crystals within 5 min. These were filtered, washed with ethanol and dried over fused $CaCl_2$. It was observed that due to poor solubility, complex **1** separated from the reaction mixture even at room temperature within 5 min.

$[MoO_2(L_1)Cl]$ (**1**): Yield: 0.120 g (60%). Elemental *Anal.* Calc. for $C_{13}N_4O_3H_{13}MoCl$ (403.5): C, 38.6; H, 3.22; N, 13.87. Found: C, 37.75; H, 3.55; N, 13.46%.

2.6. Synthesis of complex **2**

When an ethanolic solution (10 mL) of $MoO_2(acac)_2$ (0.5 mmol, 0.163 g), acidified with 5–6 drops of concentrated HCl, was mixed with an ethanolic solution of HL_2 (0.5 mmol, 0.128 g), an orange yellow color was immediately observed. On keeping the solution for slow evaporation after filtration, X-ray quality crystals of **2** appeared within 48 h, with the gradual disappearance of the solution color. The crystals were filtered, washed with ethanol and dried over fused $CaCl_2$.

$[MoO_2(L_3)Cl_2]$ (**2**): Yield: 0.050 g (25%). Elemental *Anal.* Calc. for $C_{11}N_4O_2H_{14}MoCl_2$ (400): C, 33.0; H, 3.5; N, 14.0. Found: C, 32.91; H, 3.65; N, 13.30%.

2.7. Synthesis of complex **3**

When an ethanolic solution (10 mL) of $MoO_2(acac)_2$ (0.5 mmol, 0.163 g), acidified with 5–6 drops of concentrated HCl, was added

to an ethanolic solution of HL_2 (0.5 mmol, 0.128 g), an orange color was immediately observed. This orange solution was refluxed for several hours, during which time its color changed to light pink. The solution was then cooled and filtered. On keeping the solution for slow evaporation after filtration, light pink crystals of **3** appeared within 48 h. These were filtered, washed with ethanol and dried over fused $CaCl_2$.

$[Mo_2O_5(L_3)_2Cl_2]$(**3**): Yield: 0.093 g (25%). Elemental *Anal.* Calc. for $C_{22}N_8O_5H_{28}Mo_2Cl_2$ (745): C, 35.43; H, 3.75; N, 15.03. Found: C, 34.91; H, 3.65; N, 13.80%.

2.8. Synthesis of the complex 4

Complex $[MoO_2(L_4)Cl]$ (**4**) was prepared by adding an acidified (by a few drops of conc. HCl) ethanolic solution (10 mL) of $MoO_2(acac)_2$ (0.5 mmol, 0.163 g) to an ethanolic solution of H_2L_1' (0.25 mmol, 0.087 g). On mixing the two components, the solution immediately turned orange yellow. The complex separated as dark red crystals on slow evaporation of the filtered reaction mixture. The crystals were filtered, washed with ethanol and dried over fused $CaCl_2$.

$[MoO_2(L_4)Cl]$ (**4**): Yield: 0.058 g (50%). Elemental *Anal.* Calc. for $C_{16}N_6O_3H_{16}MoCl$ (454.5): C, 40.80; H, 3.40; N, 17.85. Found: C, 40.18; H, 3.51; N, 17.15%. Relevant IR, UV–Vis, NMR and electrochemical characterization data for the complexes are summarized in Table 1.

3. Results and discussion

3.1. Synthesis

The ligands HL_1 and HL_2 were isolated as 1:1 condensation products of 4,6-dimethyl 2-hydrazino pyrimidine with salicylaldehyde (for HL_1) and *o*-hydroxy acetophenone (for HL_2). The complexes **1–3** were prepared by simply mixing $MoO_2(acac)_2$ and the respective ligands in a dehydrated ethanol medium at room temperature or at reflux under acidic conditions maintained by adding conc. HCl. Complex **4** was prepared using the same method with the ligand H_2L_1'. As the ligands can act, at best, as a tridentate monoanionic ligands, a few drops of HCl were added to furnish the Cl^- ion to satisfy the sixth coordination position as well as for the requirement of charge balance of the MoO_2^{2+} core.

An ethanolic solution of the ligand HL_1, when added to an acidified ethanolic solution of $MoO_2(acac)_2$, either at room temperature or under refluxing conditions, yielded $[MoO_2(L_1)Cl]$ (**1**) which separated in the crystalline form within 5 min. No other products were obtained on keeping the mother liquor for several days for slow evaporation. When $(NH_4)_2MoO_4$ was used instead of $MoO_2(acac)_2$ the same observations were recorded. With HL_2 and $MoO_2(acac)_2$ complex **2** was isolated at room temperature as the exclusive product over a period of 48 h. Contrary to this observation, under refluxing conditions, the same reaction mixture yields complex **3** as the only product. The conditions which favor the formation of **2**, the mononuclear complex of the transformed ligand L_3, or **3**, its oxo bridged binuclear analog, could not be ascertained. However, from the reaction conditions it is implied that **3** demands a higher temperature for its formation as it is the thermodynamically controlled product. It should be mentioned that using $(NH_4)_2MoO_4$ as the metal precursor with HL_2 only a green residue could be found, which could not be characterized. In order to explain these results we suggest that for the formation of complexes **2** and **3** from HL_2, an in situ ligand transformation takes place. This is triggered by Mo(VI) mediated C=N bond cleavage of the used ligand. The C=N bond cleavage of the hydrazone part of ligand sets the 2-hydrazino 4,6-dimethyl pyrimidine free, which on subsequent condensation cum cyclization with the acetyl acetonate anion obtained from $MoO_2(acac)_2$ produces the substituted pyrimidyl pyrazole ligand (L_3). This L_3 ligand, in turn, partially encapsulates the MoO_2^{2+} core to give complexes **2** and **3**. The role of the metal was ascertained by the fact that the ligands, when subjected to similar acid media in the same solvents, did not undergo any C=N cleavage. Complex **1** was found to have a completely different absorption behavior from the complexes of the transformed ligand L_3, i.e. **2** and **3**. When HL_2 was used as a ligand towards the $MoO_2(acac)_2$ target, initially the reaction mixture showed an absorption pattern similar in nature to complex **1**. Gradually, this peak diminished and peaks characteristic of **2** appeared. This implies that after the formation of the expected complex in solution, HL_2 slowly converts to the pyrimidyl pyrazole derivative via metal catalyzed C=N bond cleavage with the concomitant chelation of the original metal center by the newly formed ligand (L_3). This also explains the non-responsive behavior of the ligand HL_1 towards the ligand transformation reaction. It was found that on mixing $MoO_2(acac)_2$ and the ligand in ethanolic solution acidified by HCl, complex **1** precipitated within 5 min. The metal mediated ligand transformation could not take place as complex **1** did not remain soluble long enough in the reaction mixture to allow it. This view was reinforced by employing another salicyl hydrazone ligand,

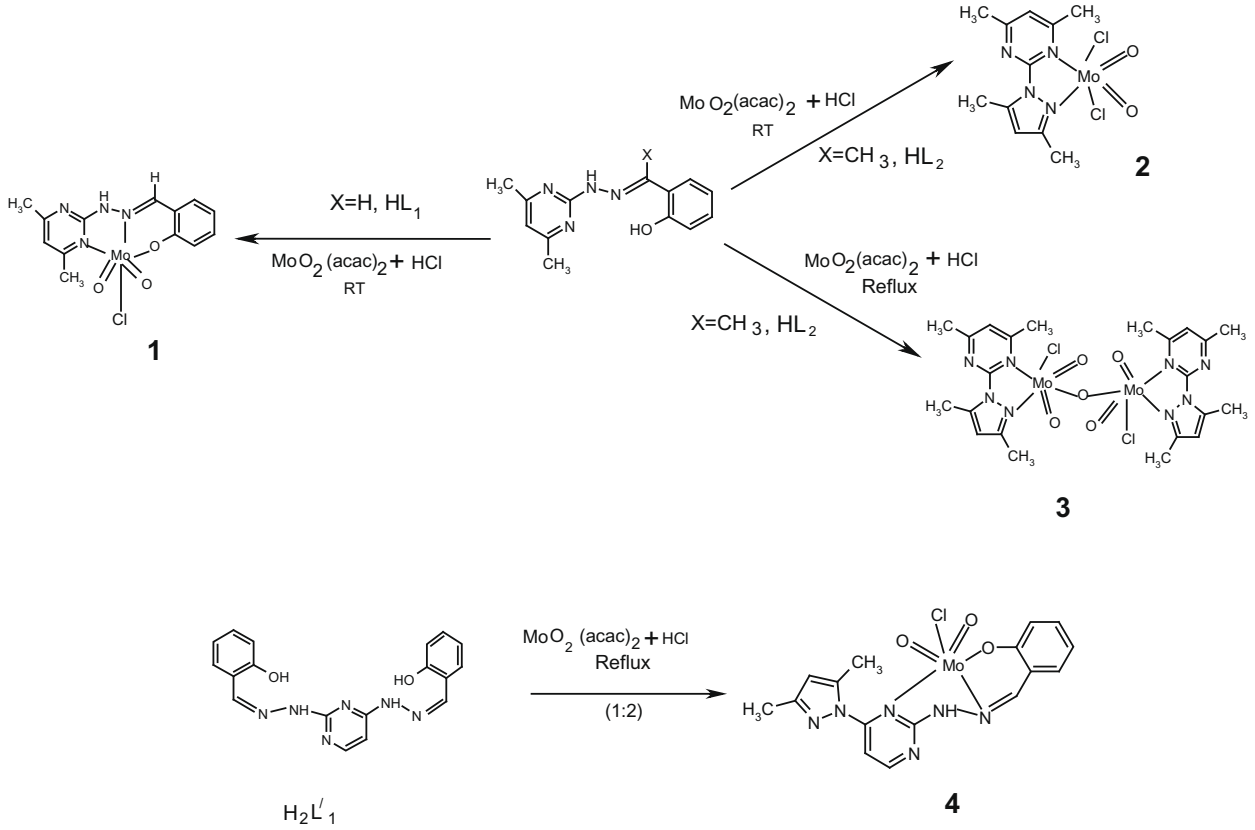
$H_2L'_1$ (the bis salicyl hydrazone of 2,4-dihydrazino pyrimidine) for complexation with $MoO_2(acac)_2$ under similar conditions as with the ligands HL_1 and HL_2.The formation of complex **4**, where the used ligand was found to have transformed into L_4 (the deprotonated form of the salicyl hydrazone of 2-hydrazino-4-(3,5-dimethyl-1-pyrazolyl) pyrimidine) via a partial Mo mediated reaction showed that such ligand transformation can also take place with salicyl hydrazones if the resulting complex remains soluble in the reaction medium. All these synthetic observations are summarized in Scheme 1.



3.2. Spectroscopic characterization

1D proton NMR spectra of the Mo(VI) complexes as well as the ligands were recorded. The aromatic OH signal at δ 11.2–12.8 [28,29], which is found in the ligands HL_1, HL_2 and $H_2L'_1$ is absent in the spectra of the complexes. This may be attributed to the complexation by the ligand in a mononegative fashion and/or ligand transformation during complex formation. The azomethine (CH=N) signal, which is found at δ *8.2–8.25* [30] in the spectra of the ligands [HL_1, and $H_2L'_1$], shifts downfield in the complexes **1** and **4** due to a shift of electron density from the C=N bond as a result of complexation. Appearance of a signal at δ *6.2–6.3* [31], corresponding to the pyrazole C–H in the spectra of complexes **2**, **3** and **4**, provides the evidence for the ligand transformation that takes place while forming these complexes.

IR spectra of the ligands HL_1, HL_2 and $H_2L'_1$ shows bands at 3159–3191 cm^{-1} for H-bonded O–H stretching and at 3274–3322 cm^{-1} for N–H stretching vibrations [32,33]. In complex **1** the O–H peak of HL_1 is absent as the ligand gets deprotonated prior to complexation. Absence of both the signals for O–H and N–H stretching vibrations of HL_2 in complexes **2** and **3** indicates that ligand transformation has taken place in these cases. However, in complex **4**, the N–H peak of $H_2L'_1$ is retained and the O–H peak of $H_2L'_1$ disappears because formation of complex **4** results from only a partial transformation of $H_2L'_1$. The signals of C=N and C=C stretching [34] vibrations appear up to 30 cm^{-1} lower in energy in the complexes as compared to the free ligands. The Mo=O asymmetric and symmetric stretching frequencies in the dioxomolybdenum(VI) complexes **1–4** appear at 904–911 cm^{-1} and 935–944 cm^{-1} [35,36]. In the μ-oxo Molybdenum(VI) complex **3**, ν(Mo–O–Mo) exhibits a strong peak at 754 cm^{-1} [37].

The electronic spectrum of complex **1** in DMF displays two strong absorption bands at 334 and 304 nm. These peaks may be assigned as charge transfer transitions of the type N(pπ)–Mo(dπ) LMCT and O(pπ)–Mo(dπ) LMCT, respectively [38,39], as the ligand based orbitals are either N or O donor types. The ligand HL_2 yields only complexes **2** and **3**, which are the outcome of a ligand transformation process. Both complexes **2** and **3** show no peaks in the visible range in their electronic spectra recorded in DMF solution. However, charge transfer bands at 261–264 nm, assigned to N(pπ)–Mo(dπ) transitions, are observed in both complexes. As the coordination sphere in **2** is approximately similar to that of **3**, barring the substitution of a chloride donor in **2** by a bridging oxo group in **3**, the peaks obtained are very similar in both complexes. An additional peak appearing at 257 nm [37] in **3** is assigned as a characteristic [μ-oxo → Mo(VI)] LMCT band.

Complex **2** or **3** is obtained as the exclusive product with the ligand HL_2 under different reaction temperatures. On mixing HL_2 and $MoO_2(acac)_2$ in EtOH solution, acidified by adding conc. HCl, first an orange color develops with an absorption maxima at 327 nm, but gradually over a period of 36 h this peak disappears and a peak at 261 nm appears. This shows that catalysis by MoO_2^{2+} in the C=N bond cleavage of the hydrazone portion takes place slowly following complexation by the ligand HL_2.

Scheme 1. Reaction schemes showing the syntheses of **1–4**.

The diffuse reflectance spectra (DRS) of complex **1** show an absorption band at lower energy compared to those in solution. This may be attributed to a greater destabilization of the metal LUMO than the ligand HOMO in DMF solution. Interestingly, complex **3**, which shows no absorption peaks in DMF solution in the visible region, exhibits a peak at 479 nm in its DRS indicating that solvation with DMF brings out an appreciable change in the coordination sphere in this complex. Complex **4** has a coordination sphere which is very similar to that in complex **1** and shows LMCT transition bands at 319 and 305 nm.

3.3. Electrochemistry

The electrochemical behavior of all the complexes **1–4** were examined in DMF solution using cyclic voltammetry at a platinum electrode with 0.1 M TEAP as a supporting electrolyte. The corresponding data are supplied in Table 1. In the potential range −1.0–1.5 V the complexes show two reductive responses during a cathodic scan for Mo(VI)/Mo(V) and Mo(V)/Mo(IV) [21]. Each one is assigned to a one electron process established by comparison of current heights with an authentic one electron process. Complexes **2** and **3** show two reductive responses on a cathodic scan, which are again of an irreversible type. However, in both complexes the peak corresponding to Mo(VI)/Mo(V) tends to disappear and a single two electron reductive response appears for Mo(VI)/Mo(IV) when the scan rate is increased. Comparing the reductive responses of **2** and **3** with those of **1**, it was observed that the Mo(VI)/Mo(V) peak appears at greater negative potentials for complexes **2** and **3**. Complex **4** shows two irreversible reductive responses at −0.9 and −1.2 V. Despite the similar environment, a slight change in the geometry of the coordination sphere (as has been found from the X-ray structure) from **1** may be responsible for the slight deviation of the redox behavior of **4**.

3.4. EPR and magnetic properties

All the complexes **1–4** were found to be diamagnetic and epr silent.

3.5. Description of the structures

Crystal data and details of the data collection are listed in Table 2. Selected bond angles and bond lengths are supplied in Table 3.

3.5.1. Structure of the ligand HL_2

The crystal structure of the ligand HL_2 has been investigated as a representative of the hydrazone ligands. The ligand crystallizes in the $P2(1)/a$ space group with 8 molecules per unit cell. The crystal is centrosymmetric with a dihedral angle of ca. 60° between the mean planes of the two molecules in the asymmetric unit. There is one strong intramolecular H-bonding interaction among O1–H1–N1 and another comparatively weaker intermolecular interaction among N2–H2–N3 (between the two asymmetric units, atoms labeled using A and B suffixes in Fig. 1). Comparable bond lengths

of the free ligand have been found to have altered somewhat in complexes **2** and **3** both as a result of ligand transformation as well as complexation.

3.5.2. Structure of complexes *1* and *4*

A perspective view of complexes **1** and **4** along with the atom numbering scheme is shown in Figs. 2 and 3. In both these complexes, the coordination environment of the Mo atoms are roughly similar. All of them bear a distorted octahedral geometry where the ligand HL_1 (for **1**) or HL_4 (for **4**) occupies three equatorial positions in their deprotonated form. Two oxo atoms and one chloride complete the coordination sphere. The ligand binds through the enolate oxygen, pyrimidine nitrogen and the azomethine nitrogen, and forms a five membered and a six membered chelate ring at the metal center in the equatorial XY plane [40]. One oxo group is present in the same plane, *trans* to the azomethine nitrogen. The other oxo group is in the axial position, *trans* to a chloride donor. In complex **4** the two axial bonds are disordered over two positions. Between the two structures the deviation of the Mo atoms from the mean plane containing the equatorial donors is higher in complex **4** (0.3 Å). Also the ligand assumes a more planar arrangement in **4** than in **1**. This ensures a better electron delocalization in complex **4** and probably explains its better redox stability as compared to **1**. The bond distances in the coordination sphere are unexceptional [41]. Among the Mo–N bonds the one *trans* to the equatorial oxo group is longer in each case due to the *trans* effect of the Mo=O bond [28]. In the coordination sphere of complexes **1** and **4** the axial angle bears the highest value (164°). None of the bond angles in the coordination sphere in the three complexes corroborate to an ideal octahedral geometry. Weak H-bond interactions are found in the superstructures of each complex. In complex **1**, there is an intermolecular H-bond interaction between N3–H3B–Cl, while in complex **4** it is between Cl1–H3B–N3.

3.5.3. Structure of complex *2*

The structure of complex **2** is again best described as a distorted octahedral one. Here, the ligand is 2-(3,5-dimethyl-1-pyrazolyl)4,6-dimethyl pyrimidine (L_3). This ligand is typically a bidentate neutral NN donor and occupies two coordination positions in the equatorial plane. Two other positions in the equatorial plane are occupied by the two oxo groups [42] (Fig. 4). This is unlike complex **1** where the oxo groups occupy one axial and one equatorial position. The two chloride donors are present in the axial plane. The two heterocyclic rings of the ligand are essentially coplanar with the maximum deviation of any atom from the mean plane containing the ring atoms not exceeding 0.174 Å. The metal is situated in the same plane as the equatorial donors (N1, N2, O1 and O2) but

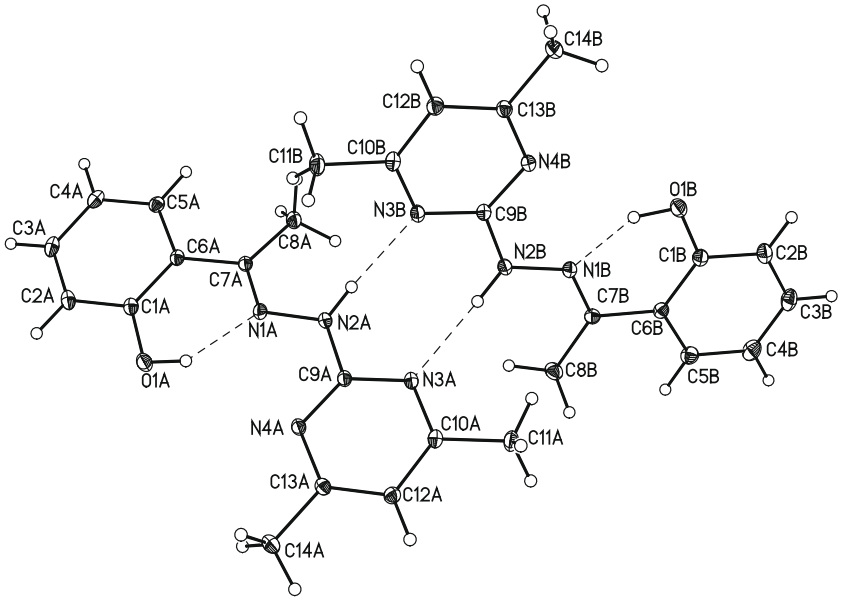

Fig. 1. Structural representation of HL_2.

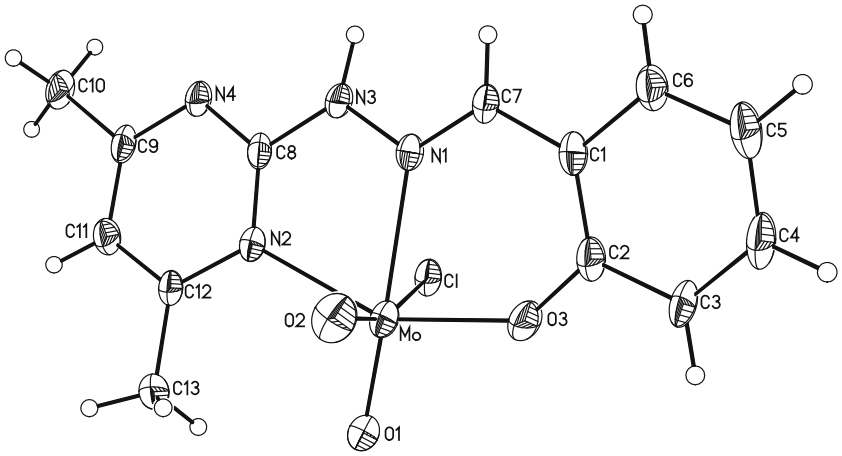

Fig. 2. Structural representation of **1**.

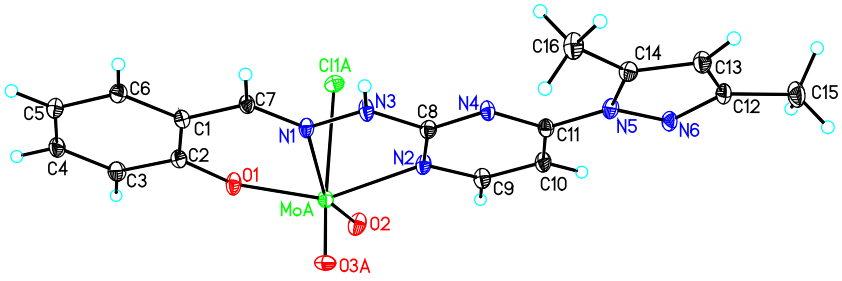

Fig. 3. Structural representation of **4** (disordered positions of the Mo and Cl atoms are omitted for clarity).

the five membered chelate ring formed at the metal center assumes an envelope conformation with Mo at the tip of the envelope. The bond distances in the coordination sphere are found to be similar to other reported complexes of the general formula MoO_2X_2L (where L is a neutral bidentate ligand) [43]. Interestingly, there is a notable difference between the Mo–N1 and Mo–N2 bond distances. This may be rationalized considering the better donor capacity of the pyrazole nitrogen over the pyrimidine nitrogen. Both Mo–N1 and Mo–N2 bonds are slightly elongated due to the *trans* effect of the oxo groups. The two axial Mo–Cl bonds are very similar. The Mo–$N_{(pym)}$ bond is found to be slightly longer in complex **2** than in complex **1**, indicating that the extent of binding of the pyrimidine N is affected by the ligand geometry. When comparable bond lengths of L_3 (in **2**) and the parent ligand HL_2 are studied, only slight deviations are observed. Bond angles in the equatorial plane of complex **2** closely obey the VSEPR theory's con-

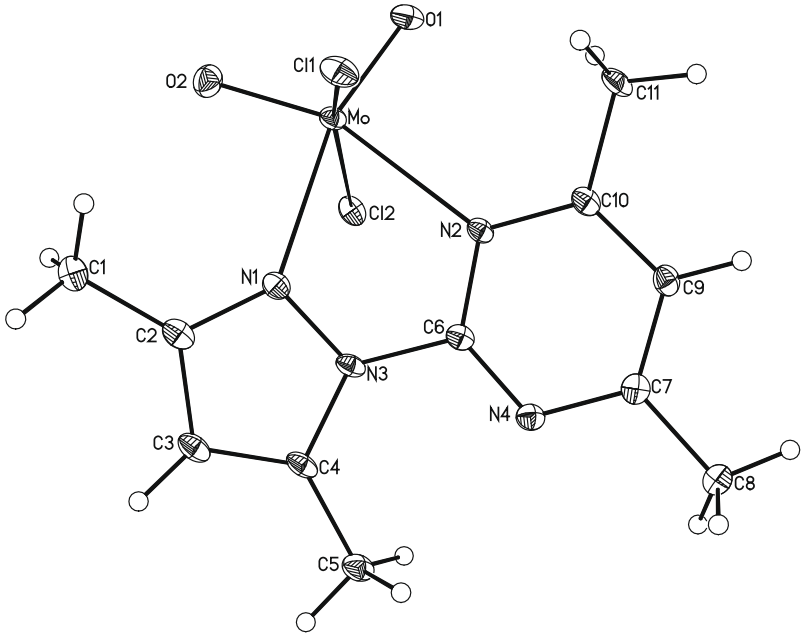

Fig. 4. Structural representation of complex **2**.

sideration that repulsion between adjacent bonds follows the order:

- double bond–double bond > double bond–single bond > single bond–single bond.

Thus, the observed order of values for the angles O2–Mo–O1 > N1–Mo–O2 ~ N2–Mo–O1 > N1–Mo–N2 can be easily explained. Similarly the axial angles Cl2–Mo–N1 and Cl2–Mo–N2 are found to be smaller than the angles Cl2–Mo–O1 and Cl2–Mo–O2 [44]. No appreciable H-bonding interactions, either intra- or intermolecular, could be ascertained.

*3.5.4. Structure of complex **3***

Complex **3** is an oxo bridged dimer of complex **2**. Here, the geometry around each molybdenum is approximately the same as in complex **2**. The only difference is that the Mo atom in complex **2** is ligated by two chloride ions from the axial end whereas in complex **3** an oxo group bridges the two monomeric units by substituting one chloride from each unit and occupying the common axial position of the two octahedral moieties (Fig. 5). The non bridging oxo groups share equatorial positions with the ligand donor atoms. As in complex **2**, here also the ligand plane and the mean equatorial plane at the metal center are not coplanar. The deviation is found to be slightly greater (dihedral angle 20.69° as

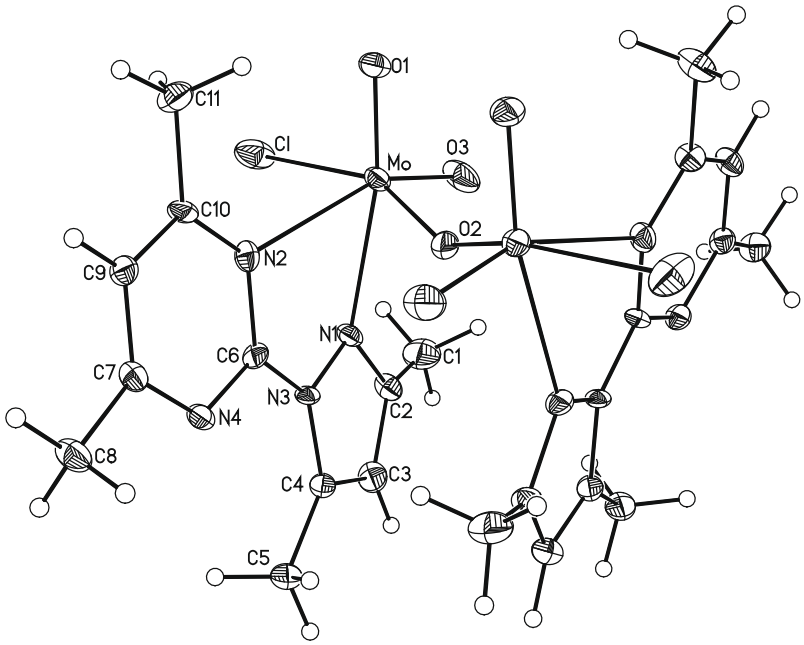

Fig. 5. Structural representation of complex **3** (the disordered nature of the ligand is omitted for clarity).

compared to 18° in **2**). The mean equatorial planes at the two Mo centers make a dihedral angle of 12.24° between themselves. No remarkable deviation of the bond lengths are observed in **3** as compared to **2** and other oxo bridged dimeric Mo complexes [45,46]. Both the Mo–O2 bond lengths are same indicating equivalence of the Mo centers. The bridging oxo groups are further away from each Mo center (1.887 Å) than the terminal oxo groups (1.664–1.697 Å). The Mo–Mo distance of 3.363 Å indicates that no me-

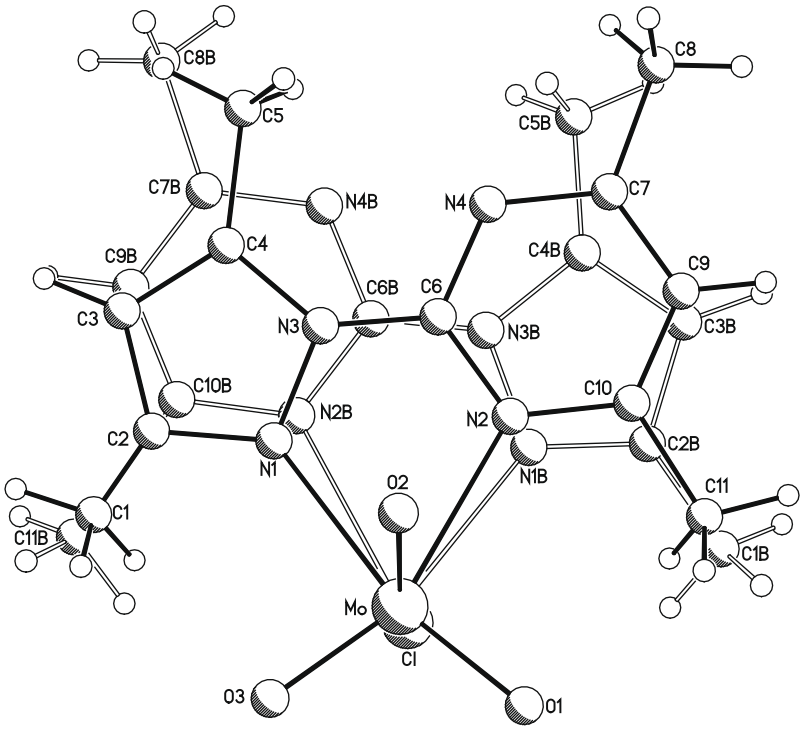

Fig. 6. Disordered nature of the ligand in complex **3** (shown at one Mo center).

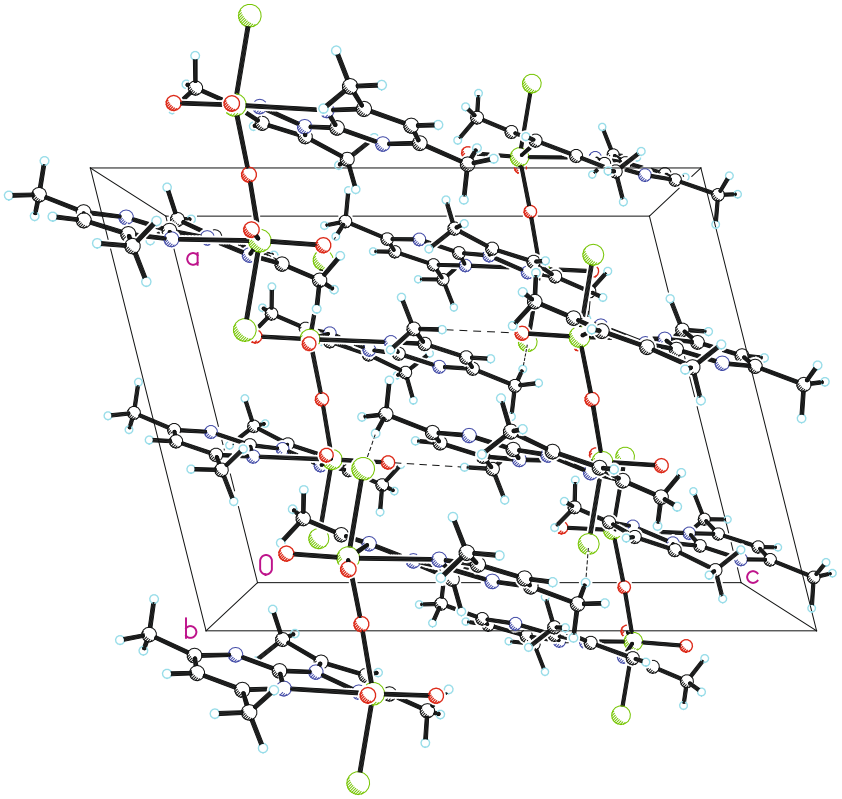

Fig. 7. Packing diagram of **3**.

tal–metal bonding is present [45–47]. The angles surrounding the metal centers are comparable to those in complex **2**. The Mo–O2–Mo bridge angle has a value of 148.87 Å, which is to the lower side of the range observed for singly oxo bridged binuclear Mo complexes (values may range up to 180°) [37].

An interesting feature of the structure is that the ligand has two disordered configurations, with the Mo–N1 and Mo–N2 bonds almost interchanging positions as a result of flipping of the ligand moieties (Fig. 6). When the structure of the complex is viewed along the Mo–O2–Mo bond, it is found that while one of the oxo groups (O1) is *syn* to the one another, the axial chloro groups are anti to one another, and the other oxo group (O3) and the chelate ring bear a mutually skewed configuration. The skewed configuration of the ligands at the two Mo centers ensures that the π-clouds of the pyrazole rings (pyrazole and pyrimidine rings, if the disordered position is considered) are close enough to allow a considerable π–π interaction. The centroid to centroid distance between the heterocyclic rings is calculated to be within the range 3.69–3.73 Å. The angle of inclination (dihedral angle) of 18° between the two ligand planes and the smaller value of the Mo–O2–Mo angle also facilitate the closing in of the π-clouds for an appreciable interaction. A packing mode for **3** is shown in Fig. 7.

4. Conclusion

The syntheses, spectroscopic, electrochemical studies and structural characterization of four molybdenum(VI) complexes have been described here. The complexes are not exceptional with regard to their structural features, however the notable observation in this work is the ligand based chemistry which leads to the transformation of the used ligands (HL_2 and $H_2L'_1$) in the reaction media. Molybdenum catalyzed oxidative cleavage of C=N in a tosyl hydrazone was reported long ago [48]. Numerous hydrazone based ligands have been reported for complexation with Mo(VI) ions. However, the novelty of this work lies in the fact that the ligands reported here are the only examples in which the metal center cleaves the C=N bond intrinsically. Perhaps some speciality in the ligand structure or environment plays the key role for such unusual behavior. Again, the previous example of Mo catalyzed C=N cleavage using the Mo(VI) species MoF_6 or the Mo(V) species $MoOCl_3$ resulted in reduction of the metal center. In this work formation of the complexes **2**, **3** and **4** has occurred with no change in the oxidation state of the Mo(VI) precursor. A closer look at the used ligands vis-a-vis the ligands L_3 and HL_4 (the transformed ligand in **2, 3** and **4,** respectively) reveals that one C=N bond cleavage has taken place at the cost of the formation of two other C=N bonds with acetylacetone in order to gain stability through the formation of an aromatic pyrazole ring. However, in the absence of acetyl acetone (i.e. when $(NH_4)_2MoO_4$ is used as the metal precursor), the ligands generated by the initial C=N cleavage process cannot stabilize the MoO_2^{2+} core.

with vinylsilanes, which should exhibit better thermal stability and volatility than the β-diketonate derivatives. Moreover, Cu(I) carboxylate complexes with vinylsilanes can form dimeric or oligomeric structures, with difficult to predict modes of ligand arrangements around the central ions. Besides that, carboxylates of Cu(I) are much more air and moisture sensitive than their Cu(II) analogs and their thermal decomposition processes have not been studied. Literature data on the perfluorinated carboxylate complexes of the copper triad metals give no direct dependences between the thermal stability of the M–O bond and the perfluorinated chain length [4]. To the best of our knowledge, there is a lack of reports on Cu(I) organometallics with hard σ donor ligands such as perfluorocarboxylates and π acceptor vinylsilanes.

In the present paper, variable temperature spectroscopic and thermal studies of $[Cu(L)(\mu\text{-}O_2CR)]_n$, where $L = CH_2{=}C(H)SiMe_3$ (VTMS), $CH_2{=}C(H)SiEt_3$ (VTES), $CH_2{=}C(H)Si(OMe)_3$ (VTMOS); $R = CF_3$, C_2F_5; $n = 2$ or 3, are described. It is known that perfluorinated carboxylates improve the volatility of complexes and organometallic compounds [1], but the Cu(I)–O bond is not stable, hence in this paper vinylsilanes as secondary, stabilizing ligands are applied. The results of EI-MS and variable temperature IR studies are used for elucidation of the thermal decomposition mechanisms and selection of compounds suitable for CVD experiments.

2. Experimental

2.1. Materials

Vinyltrimethylsilane (VTMS) (97%), vinyltriethylsilane (VTES) (97%), vinyltrimethoxysilane (VTMOS) (98%), copper powder (99%) and CF_3COOH (99%) and C_2F_5COOH (97%) were purchased from Aldrich, whereas $CuCO_3 \cdot Cu(OH)_2$, was purchased from Riedel–Han, and all were used as received. $[Cu(O_2CC_2F_5)_2]$, $[Cu(O_2CCF_3)_2]$ and the sodium salts were prepared as reported [21]. Acetonitrile (Aldrich; 99.93%), was dried and deoxygenated by standard methods.

2.2. Instrumentation

Mass spectra were detected with a Finnigan MAT 95 mass spectrometer, using the EI ionization method in the temperature range 303–573 K. IR spectra were measured with a Perkin–Elmer Spectrum-2000 FT-IR spectrometer, using KBr (400–4000 cm^{-1}) and polyethylene disks or plates (100–400 cm^{-1}). Variable temperature IR (VT IR) spectra of solid samples, deposited on a KBr disk, were measured with a SPECAC cell over the temperature range 303–523 K, at dynamic vacuum $p = 100$ Pa using the same instrument. The complete inertness of the studied compounds in contact with KBr was tested at different temperatures before the registration of the VT IR spectra. VT IR spectra of vapors, transported in Ar (carrier gas) were registered in a specially constructed reactor, described previously [22]. The glass vessel with the precursor sample (~100 mg) was placed in the reactor tube and heated ($T = 303$–623 K), under dynamic vacuum ($p = 100$ Pa). The content of Cu was determined with a Carl–Zeiss Jena AAS spectrophotometer. Thermal studies (TGA/DTA) were performed on a SDT 2960 TA analyzer (dry N_2; heating rate – 2.5° min^{-1}, for (**1**) – 1° min^{-1}; sample mass 12–18 mg). Gaseous products of the thermal decomposition (TGA/DTA) of (**1**) were detected by a FT-IR BioRad Excalibur spectrometer equipped with a thermal connector ($T_L = 343$ K in the range 285–463 K and $T_L = 413$ K over 463 K) for gases. Powder X-ray diffraction data of the residues from the thermal analysis were collected with a Philips X'PERT diffractometer using a Cu Kα line.

Deposition experiments were carried out using a horizontal *hot-wall* CVD reactor as described in the literature [23–25]. Copper films were deposited on the following substrates: Si(1 1 1), stainless steel, ITO (In_2O_3/SnO_2) and quartz, under 100 Pa, at the vaporization temperature 483 K for (**1**) and 503 K for (**2**), whereas the substrate temperatures were between 693 and 793 K. Morphology studies were carried out using scanning electron microscopy (SEM – LEO 1460 V, operating voltage 28 kV). XPS spectra were obtained with monochromatized Al Kα radiation (1486.6 eV) at room temperature using a PHI 5700/660 ESCA spectrometer, after 30 min Ar^+ ion sputtering.

2.3. Synthesis

The syntheses were carried out using Schlenk glassware under an argon atmosphere, according to a slightly modified method [21,26–30]. In the general procedure, copper(II) carboxylate (0.5×10^{-3} mol) was dissolved in 20 cm^3 of dried and deoxygenated acetonitrile, and copper powder (2.5×10^{-3} mol) was added. The obtained reaction mixture was stirred until the acetonitrile solution turned pale yellow. Next vinylsilane was added (1.1×10^{-3} mol), the suspension was stirred for 12 h at ambient temperature and filtered. The final product was isolated at 273 K by solvent evaporation under reduced pressure. The yields were 70–85%. No crystals suitable for an X-ray structure determination were obtained. The results of elementary analyses and spectroscopic data are given below:

$[Cu(VTMS)(\mu\text{-}O_2CC_2F_5)]_n$ **(1)**: Cu (calc./found) % 19.3/18.7. 3. Results and discussion

The obtained compounds **1–4** were dark brown, fine-crystalline powders, stable under an inert atmosphere for few months, while **5** was isolated as a brown oil, highly air and moisture sensitive.

The absorption bands of the carboxylic group asymmetric and symmetric stretching vibrations were detected at: $\nu_{as}(COO) = 1681$–1690 cm^{-1} and $\nu_s(COO) = 1410$–1438 cm^{-1}. The calculated $\Delta\nu = \nu_{as}(COO) - \nu_s(COO)$ parameter for the compounds $[Cu(L)(\mu\text{-}O_2CC_2F_5)]_n$ (**1**, **2**, **5**) was $\Delta\nu = 269$–278 cm^{-1}, whereas in the case of $[Cu(L)(\mu\text{-}O_2CCF_3)]_2$ (**3**, **4**) the values of Δ were 247 and 246 cm^{-1}. These values are close to the same parameter found for the appropriate sodium salts: $\Delta\nu(C_2F_5COONa) = 268$ cm^{-1} and $\Delta\nu(CF_3COONa) = 223$ cm^{-1}, which suggests a bridging coordination mode of the carboxylate groups [21,31]. The bridging mode

of the carboxylates is in favor of dimeric or trimeric structures of the complexes in the solid state. The vinylsilane absorption band of the C=C stretching vibrations were detected as a shoulder at 1632 cm^{-1}, whereas Cu–|| was in the range 523–543 cm^{-1} [31], which confirms the coordination of the vinylsilane. Assuming the bridging coordination of the carboxylates and dihapto coordination of the vinylsilane, a C_{2v} microsymmetry for the coordination sphere of Cu(I) appears in the studied complexes. The calculated irreducible representations of the metal–ligand bond vibrations are: Cu–O stretching ($A_1 + B_1$) and O–Cu–O deformation (A_1). Spectra in the range of the metal–ligand vibrations (400–50 cm^{-1}) revealed bands which can be assigned to Cu–O stretching vibrations (A_1 = 227–253 cm^{-1} symmetric and B_1 = 279–299 cm^{-1} asymmetric).

Thermal analysis of **1**–**4** indicates multistage, endothermic decomposition processes followed by metallic copper formation in the range 537–548 K (Supplementary data Fig. S1). In the case of **5**, besides the endothermic processes, one exotherm was detected in the range 593–643 K, whereas the reaction completed at a significantly higher temperature (823 K). TGA analysis suggests mainly vinylsilane detachment for the first stage of the thermal decomposition. The band at 2357 cm^{-1}, characteristic for CO_2, was detected in the studied temperature range. X-ray powder diffractograms of the final products revealed lines at 43.50°, 50.59° and 74.26° 2θ, which correspond to those reported for Cu: 43.47°, 50.37° and 73.99° 2θ by the JCPDS International Center for Diffraction Data [32].

3.1. Mass spectra analysis

Mass spectra (MS-EI) of studied compounds were measured between 303 and 573 K and used for structural characterization and identification of metallated fragments, which can be transported in the CVD process.

In the case of $[Cu(VTMS)(\mu\text{-}O_2CC_2F_5)]_n$ (**1**) (Table 1) and $[Cu(VTMS)(\mu\text{-}O_2CCF_3)]_2$ (**3**) the following silicon atoms binding fragments, characteristic for vinyltrimethylsilane, were detected: $[CH_2{=}C(H)SiMe_3]^+$ (m/z = 100), $[SiCH_3]^+$ (43 m/z), $[SiCH]^+$ (41 m/z) and $[SiC]^+$ (40 m/z), among which the $[SiCH]^+$ ion exhibits RI = 100% for **1** over 309–471 K, whereas for **3** RI was 90% over 377–551 K. The MS specta of $[Cu(VTES)(\mu\text{-}O_2CC_2F_5)]_n$ (Supplementary data Table S1) exhibited the following fragments: $[SiCH_2]^+$ (42 m/z), $[SiCH_3]^+$ (43 m/z), $[SiC_2H_5]^+$ (57 m/z), $[SiC_2H_6]^+$ (58 m/z), indicative for VTES fragmentation. Among the latter fragments the most abundant silicon embodying ion $[SiCH_3]^+$, (RI = 100%) was observed in the range 309–573 K. Simultaneously the intensity of $[SiC_2H_6]^+$ changed from 95%, (below 445 K), to 35% in the range 473–549 K. Moreover, for $[Cu(VTMOS)(\mu\text{-}O_2CC_2F_5)]_2$ (**5**) the VTMOS ligand fragments: $[SiCH]^+$ (41 m/z, RI 100–2%, 334–485 K), $[Si(OMe)_3]^+$ (121 m/z, RI 7–4%, 334–374 K) and $[CSi(OMe)_3]^+$ (133 m/z, RI 2%, 334 K) were detected. Analysis of these data indicates a low thermal stability of the metal–alkene bond in the studied Cu(I) complexes and detachment of the vinylsilane ligands in the first step of the thermal decomposition.

The following di- and trimetallic ions: $[Cu_3(O_2CR)_2]^+$, $[Cu_3(O_2CR)_3]^{+\cdot}$, $[Cu_3(O_2CR)_5]^+$, $[Cu_2(CO_2)(O_2CR)]^+$, $[Cu_2(O_2CR)_2]^{+\cdot}$, $[Cu_2(O_2CR)]^+$, $[Cu_2(L')(O_2CR)_2]^{+\cdot}$ and $[Cu_2(L')(O_2CR)]^+$ (L′ = vinylsilane or its parts), $[Cu_2CF_3]^+$, $[Cu_2F]^+$, $[Cu_2]^{+\cdot}$ were noted in the gas phase of the complexes studied (Table 1, Fig. 1). These stable fragments suggest the presence of di- or trimeric structures of the studied compounds in the solid phase (Supplementary data Fig. S2), which are retained during vaporization. The dimeric or trimeric forms give further support for the carboxylates bridging coordination mode in the synthesized complexes that have been postulated from IR spectral analysis. The ions $[Cu_2(O_2CR)]^+$ and $[Cu_2(O_2CR)_2]^{+\cdot}$ (for **1**–**5**) revealed the highest signal intensity among the metallated fragments. In the case of **1**, the ion $[Cu_2(O_2CC_2F_5)]^+$ showed the highest intensity (RI = 100%) over the temperature range 489–507 K (Table 1), whereas for **5** the same ion exhibited RI = 100% above 452 K. However, for complex **2**, the $[Cu_2(O_2CR)]^+$ and $[Cu_2(O_2CR)_2]^{+\cdot}$ ions exhibited much lower RI values (8–12%) over 433–445 K (Supplementary data Table S1). Moreover, the vaporization temperature onset was lower for the pentafluoropropionate complexes $[Cu(L)(\mu\text{-}O_2CC_2F_5)]_n$ (443–463 K) than for the trifluoroacetate complexes $[Cu(L)(\mu\text{-}O_2CCF_3)]_2$ (511–553 K) [33], which suggests that precursors with the pentafluoropropionate ligand can be more promising for CVD purposes than those with the trifluoroacetate ligand. The ion $[Cu_2F]^+$ is also important because its intensity reached 20–30% depending of the compound and temperature. Moreover, $[Cu_2]^{+\cdot}$ (126 m/z, RI < 4%) and $[Cu]^+$ (63 m/z, RI < 24%) ions were noted for the studied complexes as the terminal products of the fragmentation.

The low population of the $[Cu_2(L')(O_2CR)_2]^{+\cdot}$ and $[Cu_2(L')(O_2CR)]^+$ ions (L′ = vinylsilane or its parts) and the lack of copper–vinylsilane fragments confirm the TGA results that vinylsilanes are detached at the first stage of the thermal decomposition.

To the best of our knowledge there is a lack of data on the mass spectra of Cu(I) pentafluoropropionate complexes, however, MS studies of copper(I) carboxylates $[Cu(O_2CR)]$ (R = H, Me, Bu^t, CF_3) [34,35] revealed that these carboxylates are thermally stable and sublime without decomposition, forming in the gas phase copper

Table 1

$[C_2F_5]^+$	119	1<	3	4	36	37	45	99		85
$[VTMS]^+/[C_2F_4]^+$	100	6	3	5	40	19	52	89	88	83
$[Cu]^+$	63				7	15	22	8	7	10
$[Cu_2]^{+\cdot}$	126				1	4	4	2	2	3
$[Cu_2F]^+$	145				8	13	21	8	10	12
$[Cu_2CF_3]^+$	195					1	2			
$[Cu_2(O_2CC_2F_5)]^+$	289	1	2	2	57	100	99	33	11	51
$[Cu_2(O_2CC_2F_5)_2]^{+\cdot}$	452	1<	1<	1<	38	57	68	12	17	21
$[Cu_3(O_2CC_2F_5)_2]^+$	517				2	2	2			
$[Cu_2(O_2CC_2F_5)_3]^+$	615				1	2	2			
$[Cu_3(O_2CC_2F_5)_3]^{+\cdot}$	680				1	1	1			
$[Cu_3(O_2CC_2F_5)_5]^+$	1006				11	11	8			

bonded fragments: $[Cu_2(O_2CR)]^+$, $[Cu_2(O_2CR)_2]^{+\cdot}$ and $[Cu_2(CO_2)(O_2CR)]^+$. On the other hand, MS spectra of Cu(I) salts with unsaturated carboxylates $[Cu(O_2CR)]$ (R = C_2H_3, C_3H_5, Ph) demonstrate, besides the $[Cu_2(O_2CR)]^+$ and $[Cu_2(O_2CR)_2]^+$ ions, the organometallic fragments $[Cu_2(O_2CR)(R)]^{+\cdot}$ are also observed. The latter salts appeared to be thermally unstable and decompose during sublimation.

In the case of the trifluoroacetate complexes **3** and **4** MS spectra exhibit the $[Cu_2(CO_2)(O_2CCF_3)]^+$ ion over 455–551 K (RI 4–18%), which correlates with the simultaneous high intensity of the $[CF_3]^+$ ion (RI 100%). On the other hand, the $[Cu_2(CO_2)(O_2CC_2F_5)]^+$ ion was not observed in the MS of **1**, **2** and **5**. The latter can be related to properties of the CF_3COO^- ion (Lewis base), which is a harder ligand than $C_2F_5COO^-$ and thus can decrease the stability of the $[Cu_2(O_2CCF_3)_2]^{+\cdot}$ ion in relation to $[Cu_2(O_2CC_2F_5)_2]^{+\cdot}$.

The presence of the tricopper ion $[Cu_3(O_2CR)_5]^+$ (RI = 11–8%) over 471–507 K for **1** and the dicopper ion $[Cu_2(O_2CR)_3]^+$ for **2** suggests for these complexes different than the dimeric structure or formation of tricopper derivatives during thermolysis. The tricopper ion formation can be related to the following reactions:

$$3[Cu(L)(\mu\text{-}O_2CR)]_2 \xrightarrow{-6L} 3[Cu_2(O_2CR)_2] \rightarrow 3Cu^0 + [Cu_3(O_2CR)_6]$$

$$[Cu_3(O_2CR)_6] \xrightarrow{-RCOO^-} [Cu_3(O_2CR)_5]^+.$$

For the studied organometallic compounds the fragmentation pattern is presented at Fig. 1. One can conclude that the availability of copper for CVD comes from stable dimeric Cu(I) carboxylate binding species such as $[Cu_2(O_2CR)_2]$.

The complex **5** was isolated as an oil and the MS demonstrate intensive dicopper ions signals over 452–573 K, which is in favor of CVD applications. However, the compound exhibits low air and moisture resistance along with a high final temperature of the thermal decomposition.

The above discussed results (MS, TGA) and the physicochemical properties prompted us to carry out CVD studies of **1** and **2** as copper precursors. However, the proper determination of CVD parameters demands further characterization of precursor's stability and transport mechanism in the gas phase.

3.2. Variable temperature IR studies of *1* and *2*

Variable temperature IR (VT IR) spectra of solid samples were registered in order to study the thermal stability of the complexes and to characterize the structural changes caused by the thermolysis processes (Figs. 2, and 3, Supplementary data Fig. S3). The previous experiments confirm the completely inertness of the samples in contact with KBr plates. Moreover, absorption spectra of vapors, formed during the decomposition process of **1** and **2** were examined by the VT IR method and the results for **1** are presented in Fig. 4.

The most important changes in the spectra of **1** and **2** over 303–523 K were noted in the range 1360–1750 cm^{-1}, where absorption bands of coordinated carboxylate (ν_{as}(COO), ν_s(COO)) and VTMS/VTES ligands (ν(C=C), $\delta(CH_2,CH_3)$) were detected (Fig. 2). In order to assign the COO and C=C vibrations properly, the second derivative spectra were calculated and the frequencies are listed in Table 2. The stretching vibrations of the COO group were noted at: ν_{as}(COO) = 1657–1720 cm^{-1} and ν_s(COO) = 1389–1415 cm^{-1}, whereas ν(C=C) = 1631–1633 cm^{-1} and $\delta(CH_2,CH_3)$ = 1436–1439 cm^{-1}. The following spectral effects caused by the heating of **1** and **2** were detected: (a) intensity decrease of ν(C=C) and $\delta(CH_2,CH_3)$ bands between 303 and 433 K, (b) reduction of the ν_{as}(COO) and ν_s(COO) band numbers in the range 303–523 K.

The above mentioned effects can be correlated with the integral intensity changes of the ν_{as}(COO) and $\nu(CF_2,CF_3)$ bands presented at Fig. 3 (Supplementary data Fig. S3). On the other hand, the stretching bands of $\nu(CH,CH_2,CH_3)$ = 2800–3100 cm^{-1} and ν(Si–C) at 823 cm^{-1} revealed an intensity reduction (Fig. 2). Simultaneously in the spectra of vapors, collected over 373–413 K, the vibrations bands of CH, CH_2, CH_3 and $Si(CH_3)_n$ (2800–3100, 1042, 934, 906, 728 and 701 cm^{-1}) exhibit higher intensity (Fig. 4a), which suggests the detachment of the VTMS/VTES ligands during the thermolysis of **1** and **2**. Therefore, the following decomposition reaction for **1** and **2** can be proposed (Eq. (1)):

$$2[Cu(VTAS)(\mu\text{-}O_2CC_2F_5)]_n(s) \xrightarrow{350-433\ K} [Cu_2(O_2CC_2F_5)_2]_n(s) + 2n\ VTAS(g), \quad (1)$$

where VTAS = VTMS, VTES.

The integral intensities of the ν_{as}(COO) and $\nu(CF_2,CF_3)$ bands (over 413–433 K) were only slightly changed in the spectra of the solid samples, which can be related to the formation of stable copper carboxylate derivatives, Fig. 3 (Supplementary data Fig. S3). At temperatures above 433 K, the reduction of the $\nu(CF_2,CF_3)$ integral intensity bands was noted in the solid state, along with the simultaneous appearance of these bands in the spectra of the vapors (Supplementary data Fig. S3). Therefore, the latter can be re-

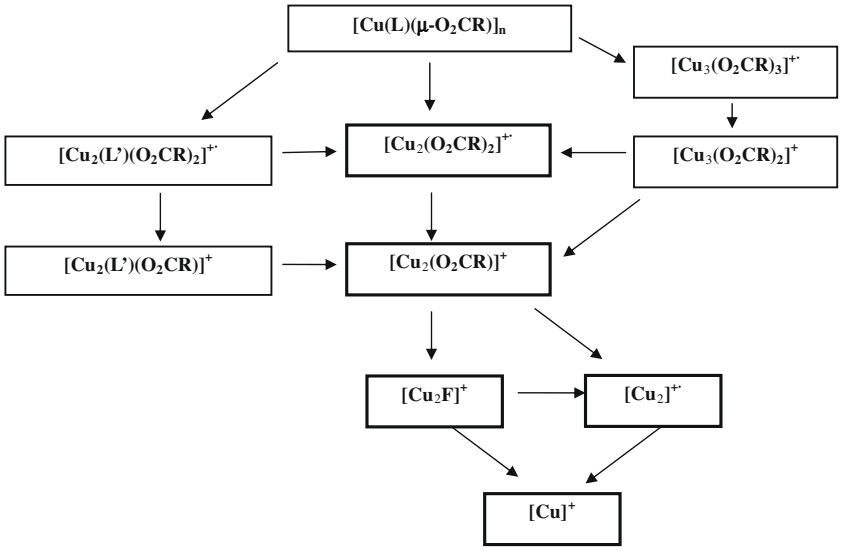

Fig. 1. Fragmentation scheme for the metallated fragments of $[Cu(L)(\mu\text{-}O_2CR)]_n$.

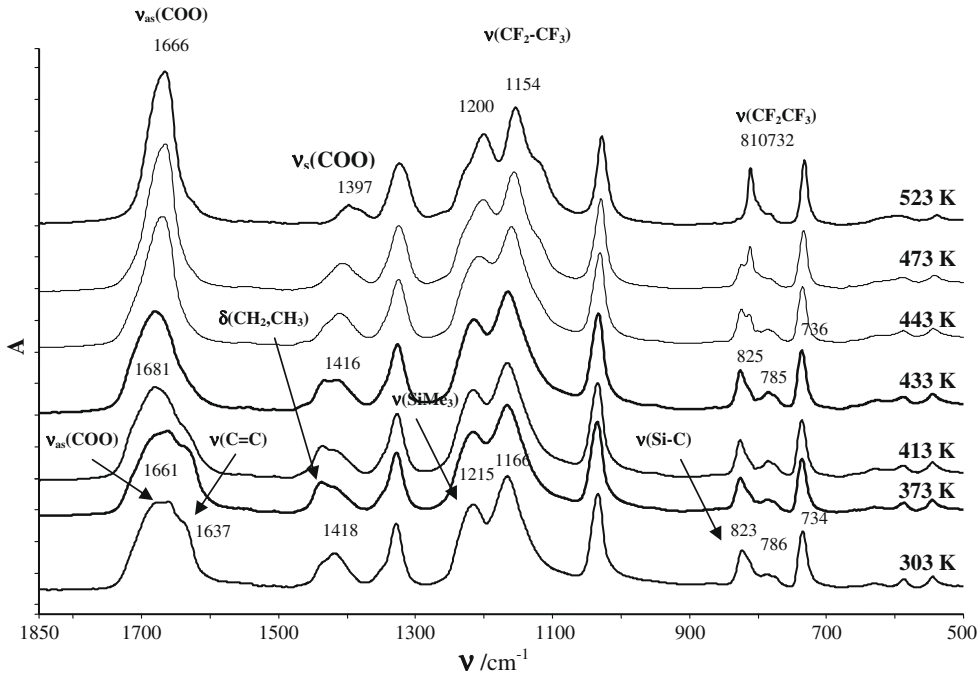

Fig. 2. Variable temperature spectra of $[Cu(VTMS)(\mu\text{-}O_2CC_2F_5)]_n$ (**1**) in the solid state (303–523 K).

lated to the decomposition processes of the studied precursors with the formation of the volatile C_xF_{2x+2}, $[Cu_2(CF_3)_n]$ and $[Cu_2(O_2CC_2F_5)_2]$ species above 433 K.

Moreover, the spectra of the vapors evolved from **1** (413 K) exhibit absorption bands at 1776, 1228, 1193 and 1158 cm^{-1}, from the species containing –C═O, $-CF_2$ and $-CF_3$ groups. In the spectra of **1**, registered at 433 K, new components in the vapors were noted. Among them acid anhydride bands at 1819 and 1776 cm^{-1}, Cu(I) carboxylate species (weak bands $\nu_{as}(COO) = 1649$ and $\nu_s(COO) = 1419$ cm^{-1}) and fluorocarbon species (strong C–F, C–C stretching bands at 1337, 1223, 1172, 1140 and 1031 cm^{-1}) (Fig. 4a) were observed. Moreover, the intensity of the latter bands was stronger in the range 453–493 K (Fig. 4b and S3). The highest concentration of the volatile Cu–O_2CR derivatives was achieved at 493 K. Two $\nu_{as}(COO)$ bands, which appear at 1706 and 1645 cm^{-1} (Fig. 4b), suggest that two types of volatile Cu–carboxylate species are transported in the vapors. The latter conclusion is further supported by the two values of the $\Delta\nu$ parameter (262 and 201 cm^{-1}), which comes from the carboxylate groups bound to Cu(I) in different ways. The geometry of the dicopper species in the gas phase is presented at Fig. 5. Simultaneously, the absorption bands, which can be assigned to Cu–carboxylate fragments, were not detected in the spectra registered at higher temperatures. According to the above, this stage of thermolysis for **1** and **2** can be exemplified by Eq. (2)

$$[Cu_2(O_2CC_2F_5)_2]_n(s) \overset{433-493K}{\rightarrow} n[Cu_2(O_2CC_2F_5)_2](g) \quad (2)$$

The intensity of VT IR absorption bands collected for **2** at 513 K exhibits the highest concentration of the volatile Cu–O_2CR derivatives ($\nu_{as}(COO) = 1699$ cm^{-1}; $\nu_s(COO) = 1436$ cm^{-1}; $\Delta\nu = 263$ cm^{-1}), although the intensity of these bands decreases at higher temperatures, similarly as for **1**.

The structural features of the Cu–carboxylate species transported in the vapors are important for the elaboration of the deposition parameters for CVD and the precursor selection. MS studies of copper carboxylates revealed that thermal decomposition proceeds with the formation of volatile dimeric species [34,35]. Ogura and Fernando postulated the formation of four types of Cu(I) carboxylate dimers in the vapors [35], similar to that presented in Fig. 5. In the spectrum of **1** (at 493 K) the band at 1706 cm^{-1} can be attributed to $\nu_{as}(COO)$ in dimeric Cu(I) carboxylates linked by bidentate O_2CR bridges ($\Delta\nu = 262$ cm^{-1} Fig. 5a). Simultaneously, the band at 1645 cm^{-1} ($\Delta\nu = 201$ cm^{-1}) can be assigned to asymmetric stretching vibrations of carboxylate groups, which form a chelate with an additional monoatomic bridge in the $[Cu_2(O_2CC_2F_5)_2]$ dimers (Fig. 5b). The spectrum of **2** exhibits a broad band for $\nu_{as}(COO)$ at 1699 cm^{-1}, which suggests the presence of different dimeric species in the vapors. The above proposed decomposition mechanism of **1** and **2** indicates the formation of volatile dimers $[Cu_2(O_2CC_2F_5)_2]$ between 433 and 493 K. The preliminary CVD experiments revealed that metallic copper films can be manufactured between 693 and 793 K using **1** and **2** as precursors [25]. Considering the proposed thermolysis

pathway, one can conclude that the formation of copper layers is affected by the decomposition of $[Cu_2(O_2CC_2F_5)_2]$ on the substrate surface upon heating (Fig. 6).

The decomposition pathway assumes precursor adsorption on the substrate, followed by disproportionation to Cu^0 and $[Cu(O_2CC_2F_5)_2]_2$, and desorption of the copper(II) derivatives. The proposed mechanism of deposition assumes that in the first step the VTMS, VTES ligands are detached and Cu(I) carboxylate derivatives are formed (Eq. (2)). This is followed by a disproportionation

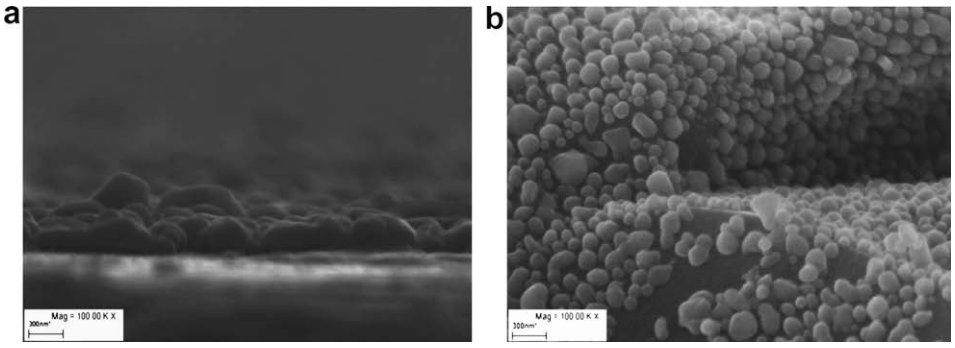

Fig. 7. SEM images of copper films cross section, deposited from **1**, on: (a) flat surface and (b) surface of the shaped composite (T_V = 493 K, T_D = 693 K, p = 100 Pa, Ar, Si(1 1 1), r_D = 2.0 μg min^{-1}).

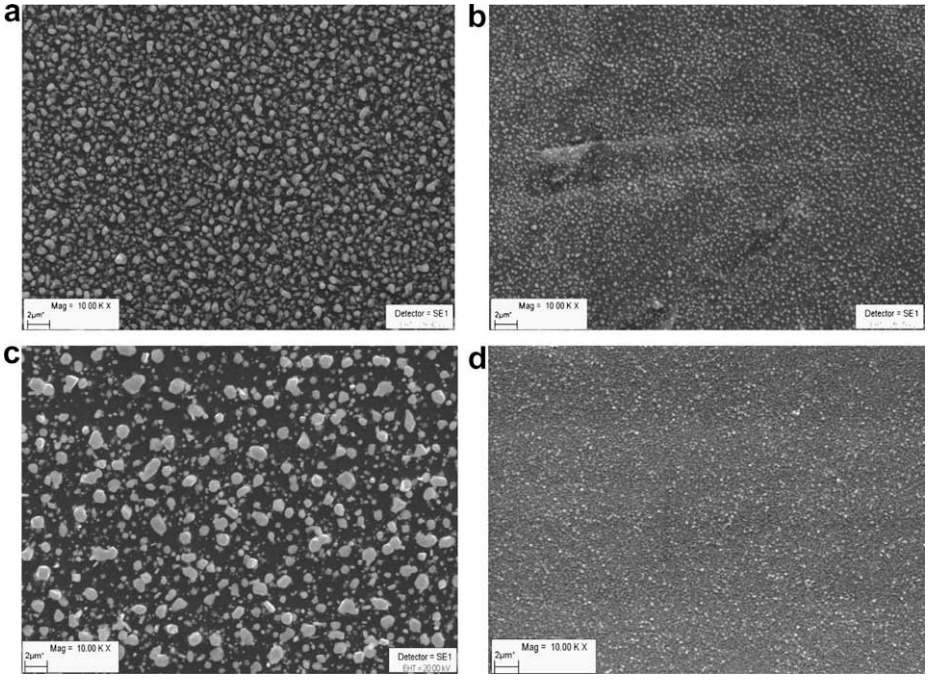

Fig. 8. SEM images of copper films deposited from **1** on different substrates: (a) Si(1 1 1), (b) steel, (c) ITO and (d) quartz (precursor **1**, T_V = 493 K, T_D = 713 K, p = 100 Pa, Ar, t = 60 min).

reaction (Fig. 6), which results in deposition of a metallic copper film.

3.3. CVD of copper layers using **1** and **2** as precursors

Detected in the vapors of **1** and **2** (by MS-EI and VTIR) are volatile and stable metal containing species, which prompted us to use these complexes as precursors for *hot-wall* CVD. According to the proposed decomposition mechanism, copper films were deposited between 693 and 793 K. The SEM images (Fig. 7) demonstrate that Cu monolayers, obtained at 693 K, are composed of loosely packed grains, the diameter of which changes from 50 to 300 nm. The average film thickness, deposited under these conditions, was between 100 and 300 nm.

The morphology studies (SEM) proved that the copper films prepared from the selected precursors uniformly coated not only the flat substrate surfaces (Figs. 7a and 8a), but also the three-dimensional trench-like structure (Fig. 7b). The conformal Cu^0 films growth is important for applications in microelectronic technologies. Variations in the morphology of copper films deposited at 713 K on different substrates are presented at Fig. 8. On smooth surfaces of Si(1 1 1), the metallic film revealed dense compacted grains (diameter 100–800 nm) (Fig. 8a) and XRD patterns demonstrate strong peaks, which correspond to cubic copper [25]. In the case of the steel substrate, uniform layers composed of metallic grains (200–400 nm) were noted (Fig. 8b), whereas for the ITO substrate layers of loosely packed Cu monocrystals (300–2000 nm) were detected (Fig. 8c). Simultaneously amorphic smooth copper films composed of densely packed grains were obtained on the surface of quartz plates (Fig. 8d). This leads to the conclusion that the morphology of the copper layers depends on the properties of the substrate, such as the smoothness and structure of the surface.

XPS studies revealed that the copper films obtained from **1** and **2** are slightly contaminated by carbon (<9%) and oxygen (<5%) [25] and there is a lack of fluorine and silicone impurities. The low content of carbon impurities and the lack of silicone ones can be related to the detachment of the VTMS/VTES ligands below the precursor vaporization temperature (>433 K). However, the possible adsorption of $[Cu_2(O_2CC_2F_5)_2]$ and dissociation of C_2F_5COO species on the substrate surface and their further decomposition can cause inclusion of carbon and oxygen impurities (C, CO) to the copper layers (Fig. 6).

4. Conclusions

The coordination sphere of Cu(I) in compounds $[Cu(L)(\mu\text{-}O_2CR)]_n$ (R = CF_3, C_2F_5; L = VTMS, VTES, VTMOS) consists of dihapto bonded vinylsilanes and bridging carboxylates. The results of MS (MS-EI) suggest that the solid structures of $[Cu(L)(\mu\text{-}O_2CCF_3)]_2$ (L = VTMS, VTES) and $[Cu(VTMOS)(\mu\text{-}O_2CC_2F_5)]_2$ are dimeric, however, in the case of $[Cu(L)(\mu\text{-}O_2CC_2F_5)]_2$ (L = VTMS, VTES,) the structure is more complicated than dimeric, or copper(II) carboxylates are the products of a disproportionation reaction in the source of the spectrometer. Moreover, results of MS (MS-EI) and variable temperature IR studies proved that dimeric carboxylate species are the main source of copper for CVD processes. The thermal decomposition pathway, qualitative and quantitative composition of vapors for **1** and **2** indicate that these complexes are more promising CVD precursors than **3** and **4**. Therefore, only **1** and **2** have been applied as precursors in CVD experiments and the obtained copper layer confirmed their usefulness at a deposition temperature above 573 K. The formation of copper layers is affected by the decomposition of $[Cu_2(O_2CC_2F_5)_2]$ on the heated substrate. The decomposition pathway is based on the adsorption of the precursor on the substrate material and disproportionation to Cu^0 and $[Cu(O_2CC_2F_5)_2]_2$, followed by desorption of the Cu(II) compound.

The presented results of VT IR and MS studies suggest the usefulness of the proposed methodology for CVD precursor selection and allowed a preliminary determination of CVD experimental parameters.

The product was filtered by aspiration and was washed thrice, alternating methanol and acetone. Water was also used as a wash only if preliminary XRD analysis indicated a water-soluble phase. The product was dried for at least 20 min by aspiration and placed in a 120 °C oven overnight. Cadmium containing compounds were dried in a Drierite-filled desiccator.

2.2. Analysis

Constituent ions were analyzed qualitatively by first dissolving the compound in 3 M nitric acid. Phosphate was identified qualitatively using 0.5 M ammonium molybdate reagent. Chloride, bromide, and iodide were identified qualitatively with 0.1 M silver nitrate. The cations were identified qualitatively by standard methods.

The identities of the products were determined by XRD using a Philips 3520 XRD system with a monochrometer and a copper X-ray tube. Phase identity was established using figure of merit (FOM) values as well as careful visual matching of peaks with those in the International Center for Diffraction Data (ICDD) PDF-2 Sets 1–44 Inorganics (includes zeolites and minerals) (1994) database. The presence of fluoride was confirmed by dissolving the sample in 3 M HNO_3, followed by a search for an ^{19}F resonance on a Varian INOVA 500 MHz NMR spectrometer at 470.12 MHz.

3. Results and discussion

3.1. Nonaqueous syntheses

Apatites of barium, calcium, cadmium, lead, and strontium were successfully prepared by the reaction routes shown below, where M and X are the cation and anion incorporated into $M_5(PO_4)_3X$ (MApX):

(A) $5MX_2 + 3Na_3PO_4 \rightarrow M_5(PO_4)_3X + 9NaX$
(B) $5MX_2 + 3Na_3PO_4 \cdot 12H_2O \rightarrow M_5(PO_4)_3X + 9NaX + 12H_2O$
(C) $5MX_2 + 3K_3PO_4 \rightarrow M_5(PO_4)_3X + 9KX$
(D) $5MX_2 + 3(NH_4)_2HPO_4 \rightarrow M_5(PO_4)_3X + 6NH_4X$
(E) $5M(NO_3)_2 + 3Na_3PO_4 + NaX \rightarrow M_5(PO_4)_3X + 10NaNO_3$
(F) $5M(NO_3)_2 + 3Na_3PO_4 + NH_4X \rightarrow M_5(PO_4)_3X + 9NaNO_3 + NH_4NO_3$
(G) $5MX_2 + 3(CH_3O)_3PO \rightarrow M_5(PO_4)_3X + 9CH_3X.$

The solvents differed depending on M and X and no single route was found to be superior for the preparation of all apatite products. In addition, product formation could not be predicted solely from the solubility of the starting materials. Most reactions were run at 80–120 °C for at least 1 day to increase the dissolution of the starting materials and the yield of product. Yields ranged from 50% to 70% with no apparent relationship to route or solvent. As evidenced in a PbApCl synthesis in DMSO, increased temperature seemed to improve the purity as indicated by a decrease in the XRD figure of merit values. In many cases, the powder diffraction pattern contained sharper lines than are routinely obtained using aqueous methods. The routes and conditions for successful preparations are summarized in Table 1. The xrd line patterns for PbApF, prepared using TMP in DMSO, and for BaApCl, prepared in anisole, are shown in Figs. 1 and 2.

3.2. Barium apatites

The syntheses of barium apatites in DMSO generally require the absence of sodium ion because of preferential formation of $NaBaPO_4$. For example, attempted preparation of BaApF in anisole and 18-crown-6 using route B produced a precipitate identified as $NaBaPO_4$. The insolubility of BaF_2 in all solvents probably contributed to the difficulty in obtaining the apatite.

Barium chloroapatite was obtained in anisole using routes B and C, and in anisole with 18-crown-6 by routes B and C.

The attempted preparation of BaApCl in DMSO, routes A, B, C, and D yielded Na_3PO_4, $NaBaPO_4$, an amorphous product, and $BaHPO_4$, respectively. In phenol, route C produced $BaHPO_4$. The formation of barium hydrogen phosphate may be due to the protic nature of phenol and ammonium hydrogen phosphate. Barium bromoapatite was not prepared successfully in anisole with 18-crown-6 using routes B and C which yielded barium phosphate. The preparation of barium hydroxyapatite was unsuccessful in anisole with 18-crown-6 by route B and in pyridine by route D.

3.3. Cadmium apatites

Cadmium fluoroapatite was obtained using route F in anisole with 2 mL of glacial acetic acid presumably because cadmium nitrate tetrahydrate and sodium phosphate were soluble in anisole and ammonium fluoride was moderately soluble in glacial acetic acid. It was identified by ^{19}F NMR and XRD. Cadmium chloroapatite was successfully prepared by route A in a 1:1 anisole and ethanol mixture. The purity of the product improved with repeated washings with distilled water due primarily to the removal of the NaCl byproduct. The reactions were done in mixed solvents because sodium phosphate showed the highest solubility in anisole while cadmium chloride was most soluble in DMSO or ethanol.

The synthesis of cadmium fluoroapatite was attempted in DMSO using route A, but resulted in CdF_2. Attempts to prepare CdApCl using route B in anisole with 18-crown-6 ether produced a mixture of NaCl and Na_3PO_4. An attempt using route A in DMSO produced sodium phosphate. Although $CdBr_2$ is soluble in DMSO, CdApBr could not be obtained by route A in a 1:1 DMSO and anisole mixture (sodium phosphate was obtained). An attempt at cadmium hydroxyapatite by route E in anisole produced sodium nitrate and $Cd(OH)NO_3$.

3.4. Calcium apatites

Calcium fluoroapatite was obtained using route F with anisole and 2 mL glacial acetic acid). Although the XRD of the product indicated a mixture of CaF_2 and either the fluoro or hydroxy apatite (the patterns for the hydroxy- and fluoroapatites are very similar), the acidic reaction mixture confirms the presence of the fluoroapatite. Calcium hydroxyapatite was produced with route E in anisole. Route E, using NaOH, was preferred to the use of calcium hydroxide for solubility reasons.

Attempts to prepare CaApF using route B in ethanol and route A in a 1:1 DMSO and anisole mixture resulted in calcium fluoride. Calcium chloroapatite could not be obtained using route A or B in ethanol, route A in 1:1 ethanol and anisole mixture, route A in 1:1 ethanol–anisole containing 15-crown-5 ether, and when a solution of calcium chloride in ethanol was titrated into anisole with sodium phosphate. In DMSO, route A resulted in sodium phosphate, route B produced sodium phosphate and sodium chloride, route D produced NH_4HPO_4, route A with 2:1 anisole and DMSO mixture and 18-crown-6 ether resulted in sodium phosphate. Route A with methanol and 15-crown-5 ether was attempted because of the solubility of starting materials in this mixture, but resulted in Na_2HPO_4. Attempts to prepare CaApOH using route B in anisole with 18-crown-6 ether and in ethanol produced calcium hydroxide, as did route A in TMP and DMSO.

Table 1
Summary of solvents and conditions for successful preparations of apatites.

Compound	Route	Solvent(s)	Reaction time (days)	Temperature (°C)
BaApCl	B	anisole	1	110
	C	anisole	1	123
	A	anisole + 18-crown-6	6	125
	B	anisole + 18-crown-6	2	125
	C	anisole + 18-crown-6	2	110
CaApF	F	anisole + glacial acetic acid	2	115
CaApOH	E	anisole	2	130
CdApF	F	anisole + glacial acetic acid	3	120
CdApCl	A	anisole + EtOH	2	81
PbApBr	D	DMSO	4	21
PbApCl	C	anisole + 18-crown-6	4	125
	D	DMSO	1	115
	C	phenol	4	110
	G	DMSO	2	150
PbApF	D	DMSO	2	114
	G	DMSO	4	150
PbApOH	D	pyridine	3	85
SrApCl	G	DMSO	3	130
SrApOH	A	anisole + 18-crown-6	4	115

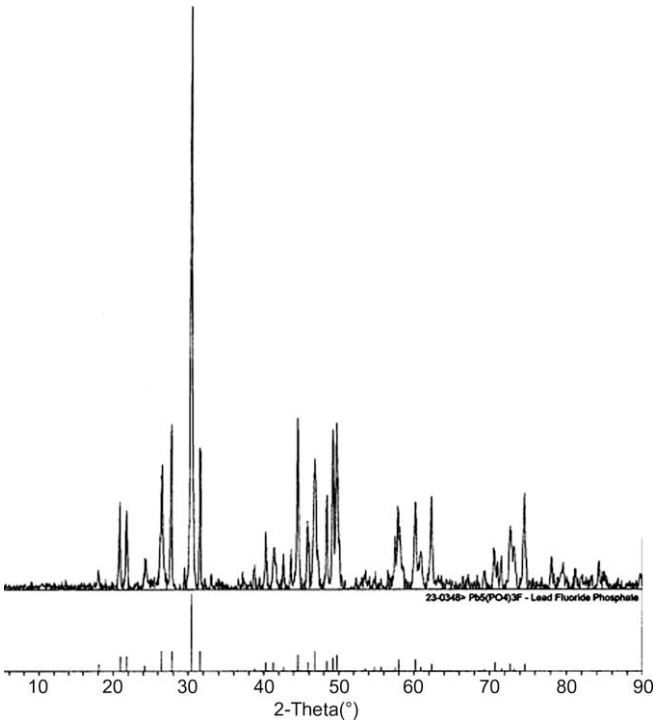

Fig. 1. The XRD line pattern, and its database comparison, for PbApF synthesized with TMP in DMSO.

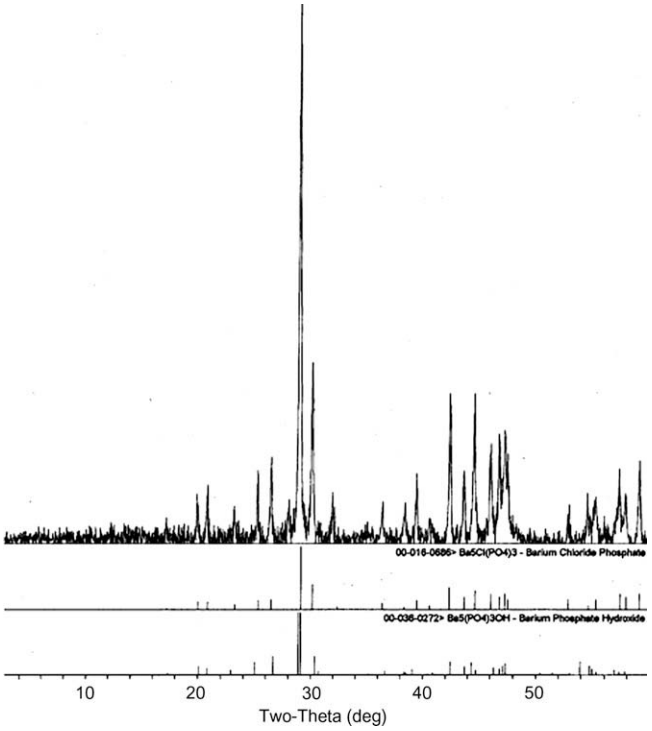

Fig. 2. The XRD line pattern, along with the database comparison, for BaApCl, prepared in anisole.

3.5. Lead apatites

In most of the solvents used, the formation of sodium lead phosphate double salts $NaPb_4(PO_4)_3$ or $NaPbPO_4$ were obtained as the main product. The presence of potassium ion (route C) resulted in the formation of $KPb_4(PO_4)_3$ in DMSO and the apatite in anisole with 18-crown-6 ether as well as in phenol. Most successful lead apatite syntheses utilized route D.

Lead fluoroapatite was successfully prepared by route D in DMSO. It was identified by both XRD and ^{19}F NMR spectroscopy. Lead chloroapatite was obtained with route C in anisole with 18-crown-6 for 4 days (heating for 2 days produced lead chloride) and in phenol. It was also successfully prepared by route D in DMSO at room temperature or with heating. The purity of the product increased with heating as indicated by XRD figure of merit values. Lead bromoapatite was obtained with route D in DMSO at room temperature. The preparation of lead hydroxyapatite was successful using route D in pyridine (chosen because of the solubility of lead hydroxide and NH_4HPO_4 and its basicity), as well as with a 1:1 mixture of pyridine and DMSO.

Attempts to prepare PbApF using route B in anisole with 18-crown-6 ether produced $NaPb_4(PO_4)_3$. The chloroapatite could not be obtained with anisole and DMSO; all attempts using route B in DMSO or anisole with 18-crown-6 gave $NaPb_4(PO_4)_3$. Due to its insolubility only the starting lead chloride was isolated in route A in anisole with 18-crown-6 ether. Attempts to prepare PbApOH using route E with 1:1 anisole and DMSO resulted in $NaPb_4(PO_4)_3$.

Table 2
Comparison of aqueous and nonaqueous syntheses [1,2][a].

Compound	Synthesis in aqueous solution	Synthesis in nonaqueous solvent
BaApBr	no	no
BaApCl	yes	yes
BaApF	yes	no
BaApOH	yes	no
CaApBr	no	no
CaApCl	no	no
CaApF	yes	yes
CaApOH	yes	yes
CdApBr	no	no
CdApCl	yes	yes
CdApF	yes	yes
CdApOH	yes	no
PbApBr	yes	yes
PbApCl	yes	yes
PbApF	yes	yes
PbApOH	yes	yes
SrApBr	no	no
SrApCl	yes	yes
SrApF	yes	no
SrApOH	yes	yes

[a] Including syntheses with TMP.

3.6. Strontium apatites

Even under anhydrous conditions, strontium hydroxyl apatite forms preferentially to all other strontium apatites: SrApOH was formed in routes B and C in anisole with 18-crown-6 ether in syntheses for hydroxy-, chloro-, and bromoapatites.

Syntheses of SrApF were attempted by route D in DMSO, but only the starting material SrF_2 was isolated. Attempts to prepare SrApF produced the hydroxyapatite. Sodium phosphate was formed when preparations were attempted in DMSO by routes A and B and in anisole by route A.

3.7. Trimethylphosphate as a phosphate source and solvent

Trimethylphosphate (TMP) was used as a phosphate source in the reaction with the following metal salts: $BaCl_2$, BaF_2, $SrCl_2$, SrF_2, $SrBr_2$, $CaCl_2$, $Ca(OH)_2$, CaF_2, $CdCl_2$, $PbCl_2$, $Pb(OH)_2$, and PbF_2. Lead fluoroapatite, lead chloroapatite, and strontium chloroapatite were formed with TMP in DMSO.

4. Conclusions

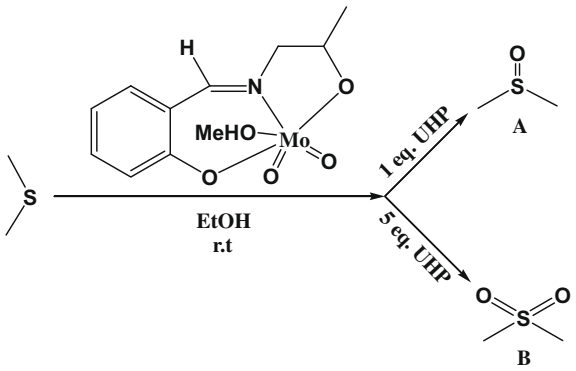
Of the 20 apatites listed in Table 2, 15 have been prepared in aqueous solution and 10 have now been prepared in nonaqueous solvents. In general, the solubilities of the starting materials in the solvents studied were very limited and the reactions required heating from 1 to 6 days. Because some hydrated salts are more soluble in these solvents, the hydrates were utilized in some reactions. The formation of hydrogen phosphates of the divalent cation, which hinders formation of CaApCl, CaApBr, and PbApOH in aqueous solution [1], was alleviated in routes A through F. The formation of nonapatitic double salts, such as $NaPb_4(PO_4)_3$, $NaPbPO_4$, $KPb_4(PO_4)_3$, $Cd(OH)NO_3$, and $NaBaPO_4$ occurred with some regularity due to the limited solubility of these salts in the solvents used. Although the use of the crown ether did improve the solubility of some salts, it was not helpful in all solvents. It was used with anisole because of its effect on the solubility of the hydrated sodium phosphate and barium salts, and with methanol to dissolve anhydrous sodium phosphate and calcium chloride.

Understandably, there was no single route or solvent that could be employed for all preparations. Moreover, the solubilities of the starting materials was not always an indication of the success of the synthesis. It was often the case that the complete dissolution of the simple salts was not necessary. For example, the starting materials in the preparation of CdApCl using route A in EtOH and anisole formed a white slurry but the reaction successfully produced the chloroapatite. However, anisole was used more frequently than the other solvents in the successful preparations (Table 1).

The reaction of metal salts with trimethyl phosphate was of interest because of the easy formation of the lead apatites in the reaction:

$$3(CH_3)_3PO_4 + 5PbX_2 \rightarrow Pb_5(PO_4)_3X + 9CH_3X.$$

This method produced PbApCl, PbApF, and SrApCl in TMP/DMSO mixtures. However, numerous attempts to prepare other apatites, including BaApF, BaApCl, CaApCl, CaApBr, SrApF, and SrApBr, using this method were unsuccessful. The reaction as written above for the formation of PbApCl, for example, is thermodynamically favorable and is easily accomplished with due caution for the toxicity of TMP. Reaction with TMP produces SrApCl, which could not be obtained using inorganic phosphates in nonaqueous solvents.



A combination of nonaqueous and TMP methods, therefore, can be used to prepare most apatites that have previously been prepared in aqueous solution. The nonaqueous conditions also produce double salts that may be of interest for other reasons. These include $NaPb_4(PO_4)_3$, $NaPbPO_4$, $KPb_4(PO_4)_3$, $Cd(OH)NO_3$, and $NaBaPO_4$.

Scheme 1.

accomplished by GC on a Shimadzu GC-16A instrument using a 25 m CBP1-S25 (0.32 mm ID, 0.5 μm coating) capillary column. IR spectra were recorded on a Perkin–Elmer 780 instrument. UV–Vis spectra were recorded on a 160 Shimadzu spectrophotometer. NMR spectra were recorded on a Brucker Avance DPX 300 and 500 MHz instrument. Mass spectra were recorded on a Shimadzu GC–MS-QP5050A.

2.3. General oxidation procedure

To a solution of sulfides (1 mmol), $[MoO_2(L)(CH_3OH)]$ (0.05 mmol) in 5 ml ethanol was added urea hydrogen peroxide (1 mmol for sulfoxide formation and 5 mmol for sulfones formation) and the reaction mixture was stirred under air at room temperature for required time. The reaction progress was monitored by TLC and the yield of products was determined by GC analysis.

Table 1
Crystal data and structure refinement for $[MoO_2(L)(CH_3OH)]$ complex.

Entry	Compound	$[MoO_2(L)(CH_3OH)]$
1	empirical formula	$C_{11}H_{15}MoNO_5$

7	unit cell dimensions	
	a (Å)	10.3301(17)
	b (Å)	9.3971(15)
	c (Å)	13.695(2)
	α (°)	90
	β (°)	109.643(3)
	γ (°)	90
8	V (Å^3)	1252.1(3)
9	Z	4
10	D_{calc} (Mg/m^3)	1.789
11	absorption coefficient (mm^{-1})	1.060
12	$F(000)$	680
13	crystal size (mm^3)	0.5 × 0.4 × 0.2
14	θ range for data collection	2.68–30.04°
15	index ranges	$-14 \leqslant h \leqslant 14$ $-13 \leqslant k \leqslant 13$ $-19 \leqslant l \leqslant 19$
16	reflections collected	13329
17	independent reflections [R_{int}]	3627 [0.0306]
18	completeness to θ = 30.04° (%)	98.8
19	absorption correction	semi-empirical from equivalents
20	max. and min. transmission	0.811 and 0.610
21	refinement method	full-matrix least-squares on F_2
22	data/restraints/parameters	3627/0/165
23	goodness-of-fit on F^2	1.013
24	final R indices [$I > 2\sigma(I)$]	R_1 = 0.0226, wR_2 = 0.0632
25	R indices (all data)	R_1 = 0.0242, wR_2 = 0.0642
26	largest difference in peak and hole	0.815 and −0.954 (e Å^{-3})

Higher purification of products was achieved by chromatography over silica gel (Eluent: n-hexane/ethyl acetate 70:30 for solfoxides isolation and 90:10 for sulfones isolation). Assignments of products were made by comparison with authentic samples or were identified by their IR, ^{1}H NMR, and MS spectral data.

2.4. X-ray crystallography

The yellow single crystals of complex $[MoO_2(L)(CH_3OH)]$ obtained by slow evaporation of solvent from acetonitrile solution of $[MoO_2(L)CH_3OH)]$ at room temperature. All the measurements were performed using graphite-monochromatized Mo Kα radiation at 100 K: $C_{11}H_{15}MoNO_5$, M_r 337.18, monoclinic, space group $P2_1/c$, a = 10.3301(17) Å, b = 9.3971(15) Å, c = 13.695(2) Å, V = 1252.1(3) Å^3, Z = 4, D_{calc} = 1.789 g cm^{-3}, μ = 1.060 mm^{-1}. A total of 13329 reflections were collected (θ_{max} = 30.04°), from which 680 were unique (R_{int} = 0.0226), with 1605 having $I > 2\sigma(I)$. The structure was solved by direct methods (SHELXS-97) [25] and refined by full-matrix least-squares techniques against F^2 (SHELXL-97) [26]. Final R indices of R_1 = 0.0226 and wR_2 = 0.0632 (Goodness-of-fit = 1.013) were obtained. The data collection and refinement processes are summarized in Table 1. Fig. 1 shows the stereoscopic ORTEP [27] plot of $[MoO_2(L)(CH_3OH)]$ complex at 50% probability level with atomic numbering along with selected bond lengths (Å) and angles (°). The stereo view of the unit cell of $[MoO_2(L)(CH_3OH)]$ compound and showing the atomic numbering scheme is shown in Fig. 2.

3. Results and discussion

3.1. Structural discussion of $[MoO_2(L)(CH_3OH)]$

Dioxo-molybdenum complex $[MoO_2(L)(CH_3OH)]$ was prepared by the reaction of 2-[(2-hydroxypropylimino)methyl]phenol and dioxo-molybdenum(VI) acetylacetonate which was characterized

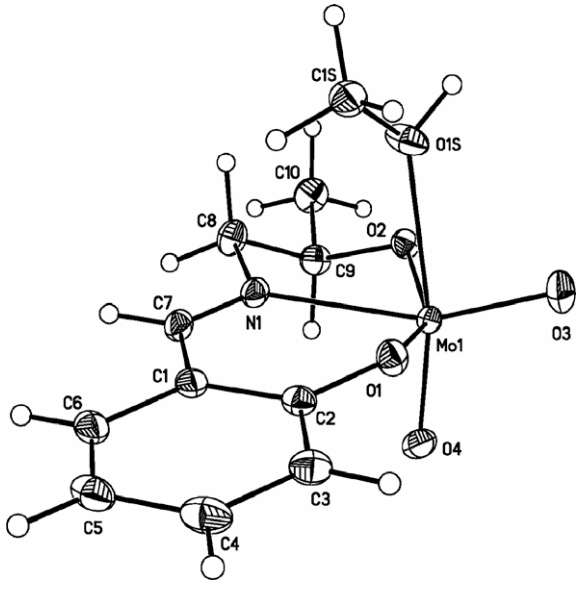

Fig. 1. ORTEP of complex $[MoO_2(L)(CH_3OH)]$ at 50% probability level with atomic numbering. Selected bond lengths (Å) and angles (°): Mo(1)–O(4) 1.7038(12), Mo(1)–O(3) 1.7094(11), Mo(1)–O(2) 1.9529(10), Mo(1)–O(1) 1.9603(11), Mo(1)–N(1) 2.2747(12), Mo(1)–O(1S) 2.3556(12), N(1)–C(7) 1.283(2), N(1)–C(8) 1.4679(19), O(1)–C(2) 1.3426(18), O(4)–Mo(1)–O(3) 107.05(6), O(4)–Mo(1)–O(2) 98.01(5), O(3)–Mo(1)–O(2) 97.34(5), O(4)–Mo(1)–O(1) 97.80(5), O(3)–Mo(1)–O(1) 101.00(5), O(2)–Mo(1)–O(1) 151.04(4), O(4)–Mo(1)–N(1) 93.07(5), O(4)–Mo(1)–N(1)–C(7) 79.85(13), O(3)–Mo(1)–N(1)–C(7)–112.65(17), O(2)–Mo(1)–N(1)–C(7) 177.32(13), O(1)–Mo(1)–N(1)–C(7)–17.54(12), O(1S)–Mo(1)–N(1)–C(7) 99.98(13).

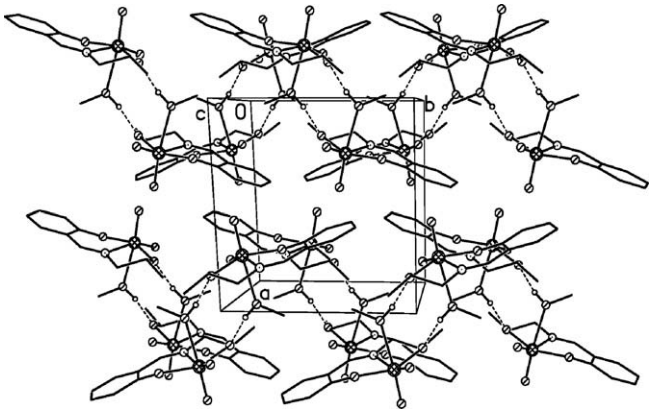

Fig. 2. The unit cell of $[MoO_2(L)(CH_3OH)]$ (Fragment of crystal packing along *c* crystal axes. Hydrogen atoms that do not take part in hydrogen bonding are not depicted for clarity. H-bonds are shown with dashed lines).

by elemental analysis, IR, NMR, and UV–Vis spectral data. The Schiff base ligand is bonded to the MoO_2^{+2} ion through two phenolic oxygen atoms and an imine nitrogen atom, which is trans to an oxo group. The IR spectra of $[MoO_2(L)(CH_3OH)]$ in KBr matrix confirm the presence of imine bond (C=N) mode at 1638 cm^{-1} and the C=C vibration band of the aromatic ring at 1584 cm^{-1} and the Mo–O vibration band at 900 and 924 cm^{-1}. All crystal data for $[MoO_2(L)(CH_3OH)]$ complex is shown in Table 1, and the relevant bond distances and angles collected in Fig. 1. The O=Mo=O angle is 107.05° and Mo=O distances are 1.7038 and 1.7094 Å.

3.2. The catalytic activity of $[MoO_2(L)(CH_3OH)]$ in the oxidation of sulfides using UHP

The oxidation of thioanisole using UHP which did not proceed in the absence of catalyst under mild conditions was used as a model reaction. To find optimum reaction conditions, the influence of different factors affecting the conversion and selectivity of the oxidation reaction such as catalyst concentration, solvent nature and the molar ratio of UHP/sulfide, were investigated in this study. Performing the oxidation reaction of thioanisole in the presence of 1 mol% of molybdenum catalyst and equimolar ratio of UHP and sulfide in methanol improved markedly the conversion of substrate (67%), however, the same yields of the related sulfoxide and sulfone were obtained (Table 2, entry 2). It was observed that the highest yield and selectivity to sulfoxide were achieved in the presence of 5 mol% of the catalyst within 30 min. Also an increase in the catalyst/sulfide molar ratio up to 10 mol% does not affect the reaction rate and yield of sulfoxide product in this catalytic system (Table 2).

The influence of solvent nature on the selectivity and reaction rate in this reaction system was also studied. From the examination of five reaction solvents such as dichloromethane, acetone, acetonitrile, methanol and ethanol in this catalytic reaction, it was observed that two protic solvents, methanol and especially ethanol, significantly enhanced the yield and the selectivity of sulfoxide product (Fig. 3). The eco-friendly property of ethanol strongly induced us to employ it as the reaction solvent in this oxidation system. In this green solvent we obtained 92% yield of sulfoxide without any overoxidation to sulfone. It should be mention that the use of dried ethanol as the reaction media decreases the selectivity of sulfoxide (90%) and no affect on the conversion rate was observed.

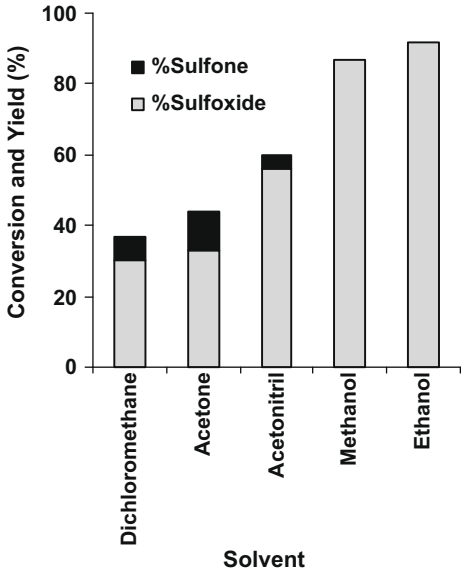

Fig. 3. The solvent effect on the conversion rate and selectivity of thioanisole oxidation using UHP catalyzed by $[MoO_2(L)(CH_3OH)]$.

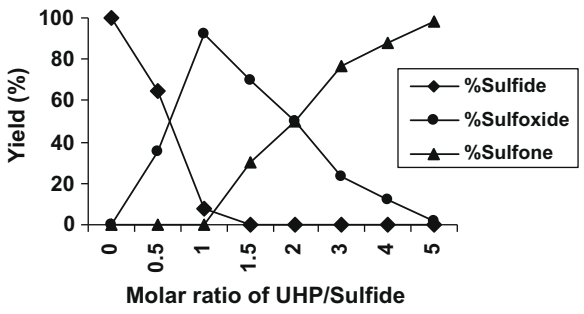
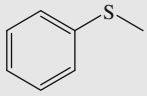
To improve the conversion rate and yield of sulfoxide, the various molar ratios of UHP/sulfide in the catalytic oxidation of thioanisole were performed in ethanol (Fig. 4). As outlined in Fig. 4 while, the conversion of thioanisole oxidation improved from 92% to 100% as the molar ratio increase from 1 to 1.5, the selectivity of sulfoxide dropped remarkably from 100% to 70%. Thus, the reaction gave optimal yields and selectivities of sulfoxide at an equimolar ratio of UHP/sulfide. Moreover, according to Fig. 4 the employment of an excess amount of UHP (up to five equivalents) promoted considerably the overoxidation of sulfoxide in the reaction and sulfone was achieved in excellent yield and selectivity (98% for oxidation of thioanisole after 30 min). Thus, the method worked well for oxidation of sulfide to both sulfoxide and sulfone selectively.

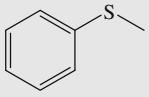
Table 2
The influence of Mo-catalyst concentration on the oxidation of thioanisole using UHP in methanol.[a]

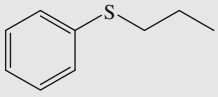
Entry	mol% catalyst	Conversion (%)	Sulfoxide yield (%)[b]	Selectivity (%)
1	0	0	0	0
2	1	67	34	50
3	3	72	63	87
4	5	87	87	100
5	7	88	88	100
6	10	85	85	100

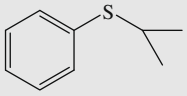
[a] The reactions were run for 30 min under air at rt in methanol and the molar ratio of thioanisole/UHP was 1:1.
[b] GC yields based on the starting sulfide.

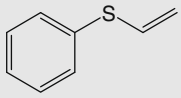


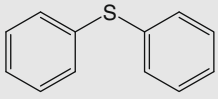


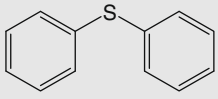


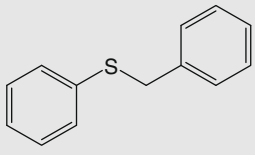












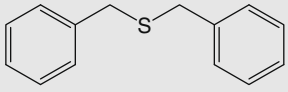


Fig. 4. Reaction profile for the oxidation of thioanisole using various molar ratios of UHP/sulfide.

Table 3
Oxidation of various sulfides by UHP catalyzed by $[MoO_2(L)(CH_3OH)]$ in ethanol.[a]

Entry	Sulfide	UHP/sulfide	Conversion (%)[b]	Selectivity (%)[b,c]	
				Sulfoxide	Sulfone
1		1	100	100	0
2		5	100	0	100
3		1	100	100	0
4		1	92	100	0
5		5	100	2	98
6		1	90	97	3
7		1	87	>98	<2
8		1	93	>99	<1
9		1	75	93	7
10		5	95	<3	>97
11		1	95	>98	<2
12		1	93	100	0

[a] The reactions were run under air at room temperature and in the present of 5 mol% of $[MoO_2(L)(CH_3OH)]$.
[b] The conversion and yield % were measured by GC based on the starting sulfides after 10 min for entries 1 and 3, and 30 min for others.
[c] All products were identified by their IR, ^1H NMR, and MS spectral data in comparison with literature [29,30].

The influence of axial nitrogenous bases having dramatic effects on the rate and selectivity in the oxidation reaction catalyzed by various transition metal complexes such as porphyrin and salen catalysts [28] has also been studied. In the present oxidation meth-

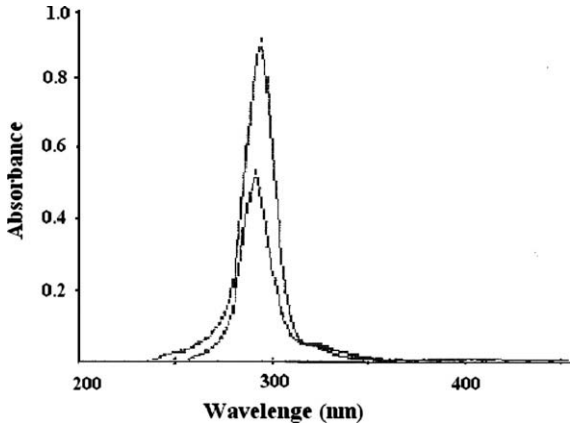

Fig. 5. UV–Vis spectral changes of $[MoO_2(L)(CH_3OH)]$ complex (λ_{max} = 290 nm) during the oxidation of diphenyl sulfide (30 min) using UHP in ethanol.

od, however, the same yields and selectivity were obtained for thioanisole oxidation in the presence or in the absence of various nitrogen donors such as imidazole and pyridine.

Encouraged by the excellent catalytic performance for the thioanisole oxidation to sulfoxide, different sulfides were subjected to the reaction system in the presence of UHP, and the results are listed in Table 3. All substrates could be smoothly converted to sulfoxides with good to high conversion rates, and excellent selectivities were obtained under mild conditions. The highest yields were obtained for dialkyl and diallylsulfide (98–100%) after 10 min. The replacement of one or both alkyl or aryl groups with phenyl or benzyl group enhanced the reaction times (30 versus 10 min); however, no regular trends in electronic and steric requirements have been observed. It should be mentioned that the present catalytic system was highly selective. Sulfoxides could be nearly stoichiometrically produced and the generation of the corresponding sulfones was well controlled, which makes this process a good alternative for sulfoxide production.

However, the increasing of molar ratio of UHP/sulfide up to five readily conduct a new procedure for easy access to sulfone products with high/excellent yields under the influence of the same concentration of catalyst (Table 3, entries 2, 5 and 10).

Another salient feature of the present sulfoxidation system is its excellent chemo-selectivity. A sulfide also having a carbon–carbon double bond (Table 3, entries 3 and 8), was cleanly transformed into the corresponding sulfoxide in excellent yield. In addition, benzyl phenyl and dibenzyl sulfides (Table 3, entries 11 and 12) were selectively oxidized to their corresponding sulfoxide without formation of any benzylic oxidation by-products.

The high yields of oxidation products (70–100%) obtained by this catalytic system in desired times (10–30 min) indicate the high efficiency of Mo–Schiff base catalyst. More evidences for this important feature of the present catalyst have been obtained by determining of the turnover frequency (TON/*h* = TOF) and total turnover numbers of Mo-catalyst, indicating the activity and stability of catalyst during the oxidation reaction, respectively (TON = mol product/mol catalyst). We performed the oxidation of thioanisole under mild conditions using 2000:2000:1 molar ratio for sulfide:UHP: catalyst. The relative high TOF (300) and TON (940/24 h) obtained in the oxidation of thioanisole, confirmed clearly the high activity and also relative stability of Mo-catalyst towards oxidative degradation in the oxidation of thioanisole. While, the lower TOF (20) and TON (80/24 h) observed in the oxidation of less reactive diphenyl sulfide can be related to competing destruction of the catalyst, as shown by UV–Vis spectral changes of Schiff base complex (λ_{max} = 290 nm) during the oxidation reaction (Fig. 5). However, by comparing of the absorbance (at λ_{max}) at the end of the reaction (*A* = 0.57 at 30 min) with that observed before the addition of UHP (*A* = 0.89) we found that 64% of the catalyst remained intact, which is a promising result for stability of a Schiff base complex.

4. Conclusion

In summary, the synthesis of a new Mo complex $[MoO_2(L)(CH_3OH)]$ with 2-[(2-hydroxypropylimino)methyl]phenol ligand (H_2L), has been developed by reaction between 2-[(2-hydroxypropylimino)methyl]phenol and dioxo-molybdenum(VI) acetylacetonate. The crystal structure of $[MoO_2(L)(CH_3OH)]$ showed a monoclinic space group $P2_1/c$.

Oxidation of sulfides using UHP was efficiently enhanced under the influence of $[MoO_2(L)(CH_3OH)]$ catalyst in ethanol under mild conditions. The high/excellent selectivity of this oxidation method combined with the use of UHP and ethanol as green oxygen source and solvent respectively, makes it more attractive for oxidation of sulfides to both sulfoxides and sulfones. The promising results for stability of this Mo–Schiff base complex and high turnover rates obtained in the oxidation reactions highlight the novelty of this new Mo-catalyst.

Acknowledgments

Support for this work by Research Councils of Shahid Bahonar University of Kerman and the University of Birjand are highly appreciated.

Scheme 1. Showing the products of the bis(propane-1,3-diamine)copper(II) perchlorate acetone reaction.

N-rac-[Cu(*cis*-Me_6[15]diene)]$_2Cl(ClO_4)_3$ (*cis*-Me_6[15]diene = 6,8,8,13,13,15-hexamethyl-1,5,9,12-tetraazacyclopentadec-5,15(1)-diene) [12], *N-meso*-[Cu(*cis*-Me_6[18]diene)]$(ClO_4)_2$ and *N-rac*[Cu-(*trans*-Me_6[18]diene)]$(ClO_4)_2$ [10]. Structures have been reported for the nickel(II) analogues *N-rac*- [17,18] and *N-meso*-[Ni(*trans*-Me_6[14]diene)]$(ClO_4)_2$ [17], *N-meso*-[Ni(*cis*-Me_6[14]diene)]$(ClO_4)_2$ [19] and *N-rac*-[Ni(*trans*-Me_6[15]diene)]$(ClO_4)_2$ (*trans*-Me_6[15]-diene = 5,7,7,13,15,15-hexamethyl-1,4,8,12-tetraazacyclopentadec-4,12-diene) [20].

Compound [Cu([16]ane)]$(ClO_4)_2$ ([16]ane = 1,5,9,13-tetraazacyclohexadecane) has a centrosymmetrical (configuration III) cation with alternating chair and boat conformation chelate rings [21]. Compounds [Cu(*trans*-Me_6[16]ane)][$ZnCl_4$] and –$(ClO_4)_2$ both have *R,R,R,R* nitrogen configurations with NH groups alternating on opposite sides of the molecular 'plane' around the ring [6]. They have saddle shaped conformations of the macrocycle; with the substituted chelate rings in similar chair conformations with both axial methyl substituents on the same side of the CuN_4 group. For the perchlorate salt both unsubstituted chelate rings have twist-boat conformations while for the tetrachlorozincate salt one has a chair and the other a twist-boat conformation. Compound [Cu($Me(NO_2)$[16]ane)]$(ClO_4)_2$ ($Me(NO_2)$[16]ane = 3-methyl-3-nitro-1,5,9,13-tetraazacyclohexadecane) has the *RRSR* configuration, with the (N1)–H and (N5)–H groups of the substituted chelate ring on the same side and the (N9)–H and (N13)–H groups of the "opposite" chelate ring on opposing sides of the plane, with both chelate rings in boat conformations [22]. Both "side" chelate rings have "somewhat twisted" chair conformations with (N5)–H and (N9)–H on the same side, (N13)–H and (N1)–H on opposing sides of the plane.

Significant dimensions for these compounds are shown in Table 1.

2. Structural studies

Diffraction data was collected for a crystal of the perchlorate salt of the condensation product of bis-(propane-1,3-diamine)copper(II) perchlorate with acetone, [Cu($C_{18}H_{36}N_4$)]$(ClO_4)_2$ [1,2], grown from water, of a tetrachlorozincate salt [Cu($C_{18}H_{36}N_4$)]-[$ZnCl_4$] which crystallized from a solution of this perchlorate salt in methanol containing zinc chloride, of a thiocyanato compound, [Cu($C_{18}H_{36}N_4$)(NCS)]ClO_4, which similarly crystallised from an aqueous solution containing sodium thiocyanate and of a very sparingly soluble tetracyanonickelate(II) compound, [Cu($C_{18}H_{36}N_4$)Ni(CN_4)]·H_2O, also crystallised from water. See Section 4.2 for crystallographic details.

2.1. The structure of N-rac-(6,8,8,14,16,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,13-diene)copper(II) · N-meso-(6,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II) perchlorate

The solution of this structure presented problems with space group selection. Solutions were attempted in space groups *C2/m*, *P*$\bar{1}$ and *P*1 in attempts to resolve this, with solutions with R_1 = 0.063, 0.063 and 0.055, respectively. In all three solutions the presence of 16-membered (1,5,9,13-tetraazacyclohexadecadiene)copper(II) cations of two types, both with equatorially oriented methyl substituents at ring positions 6, 8, 14 and 16 is unambiguous.

One cation type has the Cu atom on a crystallographic ($C2/m$) or approximate ($P1$ and $P\bar{1}$) twofold axis, normal to the CuN_4 group, which is compatible with the *N-rac*-[Cu(*trans*-Me_6[16]diene)]$^{2+}$ cation. These cations have the CuN_4 group appreciably folded, with ca. 2.4 Å Cu–O axial interactions with perchlorate ion oxygen atoms. The other type of cation site has atoms C3, Cu and C11 on a crystallographic ($C2/m$) or approximate ($P1$ and $P\bar{1}$) mirror plane, normal to the CuN_4 group, which is compatible with the *N-meso*-[Cu(*cis*-Me_6[16]diene)]$^{2+}$ cation. These cations have coplanar (or near coplanar) CuN_4 groups and the Cu atoms have no close axial interactions.

For both cation types disorder is associated with the location of the imine functions and associated axial components of the *gem*-dimethyl groups present. The perchlorate ions also exhibit severe disorder of the oxygen atoms and final *R*-factors are largely determined by treatment of this, although the perchlorate treatment has little impact on the dimensions of the cations. The solutions in space groups $C2(m)$ and $P\bar{1}$ are discussed below.

2.1.1. Solution in space group P1 (R_1 = 0.055)

The solution in space group $P1$ has as asymmetric unit four independent [Cu(azamacrocycle)]$^{2+}$ cations, labelled {Cu1}–{Cu4}, with ring atoms labelled N1–C16, N21–C36, etc., and eight perchlorate ions with chlorine atoms labelled Cl1–Cl8, with poorly ordered oxygen atoms labelled O11, O12, etc. There is no imposed symmetry.

The four (tetraazamacrocycle)copper(II) cations have saddle shaped conformations with the secondary amine NH groups and both unsubstituted 1,3-diamine chelate rings tilted towards one side of the CuN_4 "plane" and both trimethyl-substituted 1,3-amine-imine chelate rings tilted towards the other side of this plane.

The cations {Cu1} and {Cu2} have approximate twofold symmetry, with the axis through the Cu, normal to the CuN_4 group, with appreciable folding of the CuN_4 group, each with a ca. 2.4 Å Cu–O axial interaction with a perchlorate ion oxygen atom on one side of the CuN_4 "plane" and with two longer off-axial interactions with oxygen atoms from different perchlorate ions on the other side of the plane. The tetrahedral twisting of the N_4 group and displacement of the Cu atom from this plane are ±0.10(1) and 0.16(1) Å for {Cu1} and ±0.09(1) and 0.19(1) Å for {Cu2}.

The cations {Cu3} and {Cu4} have approximate mirror symmetry, with the plane through C3, Cu and C11, normal to the CuN_4 group, with the CuN_4 group near coplanar and with no close axial interactions by the Cu atom. The tetrahedral twisting of the N_4 group and displacement of the Cu atom from this plane are ±0.02(1) and 0.07(1) Å for {Cu3} and ±0.02(1) and 0.04(1) Å for {Cu4}.

For all cations equatorially oriented methyl substituents are present at ring sites C6, C8, C14 and C16, labelled C61, C81, etc.

For the cation {Cu1} two axially oriented methyl substituent sites were resolved on ring atoms C8 and C16 (labelled C82 and C162), oriented to the same side of the plane, with the NH groups oriented to the other side, i.e. compatible with the *N-rac*-[Cu(*trans*-Me_6[16]diene)]$^{2+}$ cation. The Cu–N and C–N distances and associated bond angles are in agreement with the assigned imine character for the nitrogen atoms N5 and N13 and secondary amine character for atoms N1 and N9, see Fig. 1 and Table 2.

The cation {Cu2} has similar overall geometry, but with appreciable electron density peaks in the axial substitution sites associated with atoms C26, C28, C34 and C36. These were assigned as partial occupancy axially oriented methyl groups (labelled C262, C282, etc.) all oriented towards the side of the CuN_4 "plane" towards which the unsubstituted chelate rings are tilted, with partial occupancy H(N) atoms on the opposite side. Site occupancy factors (sof) were refined, linking the sof for the axial methyl substituent group atoms and the adjacent H(N) atom, which indicates the fractional secondary amine/imine character of the nitrogen atom. Refinement with complementary sof for the methyl substituents on each chelate ring resulted in similar sof for the pairs (C262 and C342), (C282 and C362), suggesting the presence of the *trans*-diene macrocycle. Refinement with common sof for these pairs gave sof of 0.52(2) for (C282 and C362), 0.48(2) for (C262 and C342), indicating equal occupancies of all axial methyl sites within the relevant uncertainties. For the final refinement the sof of all axial groups were fixed at 0.5 with, no change in *R*-values, which are insensitive to these ratios.

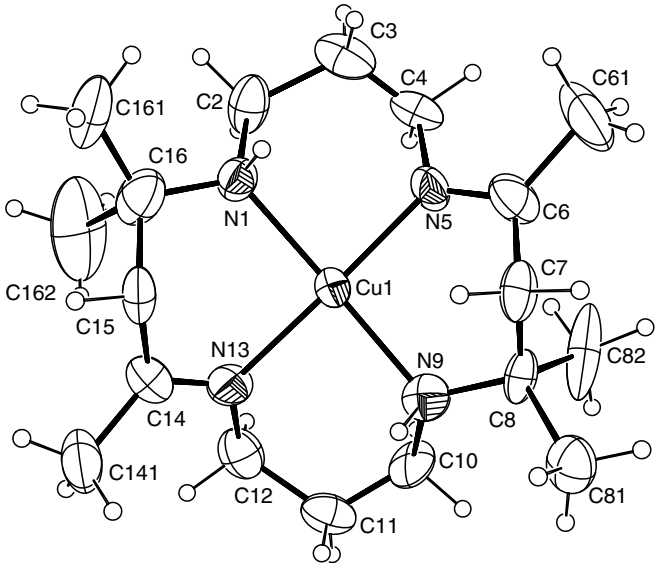

Fig. 1. The cation {Cu1} of *N-rac*-(6,8,8,14,16,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,13-diene)copper(II) *N-meso*-(6,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II) perchlorate, with probability ellipsoids drawn [28] at the 30% confidence level. Hydrogen atoms are represented by circles of arbitrary radii. The cation {Cu2} is similar, but with half-occupancy axially oriented methyl substituents at C6, C8, C14 and C16.

A similar pattern was observed for cations {Cu3} and {Cu4}. Cation {Cu3} has the dimensions expected for *N-meso*-[Cu(*cis*-Me_6[16]diene)]$^{2+}$, with near mirror symmetry, with dimensions supporting assignment with imine functions at N41 and N45, secondary amine functions at N49 and N53 and with axial methyl substituents (C482)H_3 and (C542)H_3, oriented to the same side of the plane, with the NH groups oriented to the other side, see Fig. 2 and Table 2.

Cation {Cu4} also has near mirror symmetry, with broad regions of electron density in the axial substituent regions C66–C68 and C74–C76. This was resolved as partial occupancy axial methyl substituents at sites C662, C682, C742 and C762. Refinement of sof as for {Cu2} gave sof for {(C682)H_3 + H69} of 0.67(2) and for {(C742)H_3 + H73} of 0.60(2), with complementary values for the C662 and C762 groups, indicating the presence of the *cis*-diene isomer. Refinement as for cation {Cu3}, i.e. with common sof for the (C662 and C762), (C682 and C742) groups, gave sof of 0.67(2) for C682 and C742, with complementary values for the C662 and C762 groups, though the *R*-values are insensitive to this ratio. Final refinement used fixed sof of 0.667 and 0.333 for these disorder components without change in the *R*-values.

The presence of these partial occupancy axial methyl sites for cations {Cu2} and {Cu4} can be explained if these sites are occupied by cations with reversed orientations of the amine-imine chelate rings N25–N29 and N33–N21 for {Cu2}, N65–N69 and N73–N61 for {Cu4}. The saddle-like macrocycle conformations for all cations require that both NH groups of each cation lie on the same side of

Table 2
Dimensions (Å/°) of $[Cu(Me_6[16]diene)]^{2+}$ compounds (space group *P*1 solution for perchlorate salt).

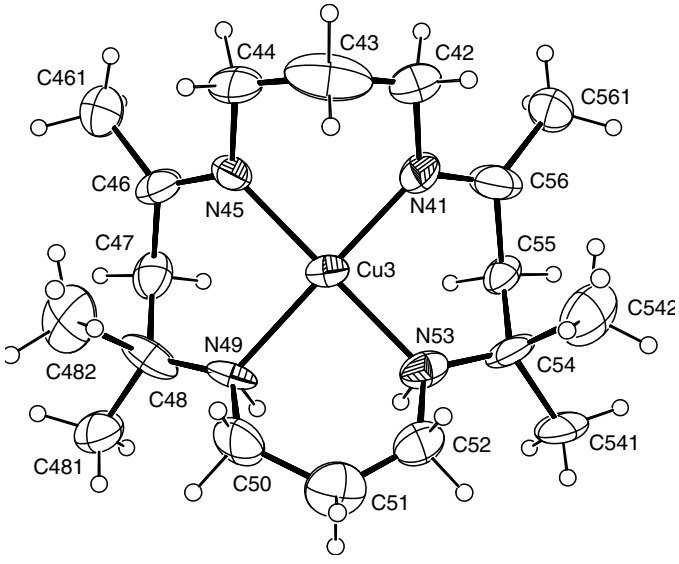

Fig. 2. The cation {Cu3}, represented similarly to Fig. 1. The cation {Cu4} is similar, but with partial-occupancy axially oriented methyl substituents at C6, C16 (sof = 0.333) and C8 and C14 (sof = 0.667).

the macrocycle 'plane', permitting the presence of only the *N-rac*-isomer for the [Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ cation for {Cu1} and of only the *N-meso*-isomer for the [Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ cation for {Cu3}. In principle, for cation site {Cu2} with sof = 0.5 for all axial substituents and hence equal occupancies for the two chelate ring orientations, either *cis* or *trans* diimine arrangements could be present in equal proportions. However, site {Cu2} has overall near-twofold symmetry, with the cation overall geometry very similar to that of cation {Cu1}. The superimposed forms are most probably the *RR*- and *SS*-enantiomorphs of the *N-rac*-[Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ cation. Since the {Cu1} site has the *RR* configuration (the Flack parameter [23] is reported by SHELXL as 0.00, with no s.u.) the asymmetric unit contains the enantiomers in 3:1 ratio. Cation {Cu4} has overall near-mirror symmetry and overall geometry similar to that of cation {Cu3}, so the disorder components are most probably the same *N-meso*-isomer of the [Cu(*cis*-Me$_6$[16]-diene)]$^{2+}$ cation, rotated by 180° about an axis through Cu4, present in 2:1 proportions. Structural features supporting these assignments include the unsubstituted chelate ring conformations, the locations of the axial methyl groups, and the CuN_4 group geometry and axial interactions, which are all similar for the pair of cations {Cu1} and {Cu2} and the pair {Cu3} and {Cu4}.

The Cu–N and C–N distances and associated bond angles for cations {Cu1} and {Cu3} are in agreement with the assigned amine or imine character of the nitrogen atoms, though the differences are smaller than observed for [Cu(*cis*-Me$_6$[16]diene)][$ZnCl_4$], below, or [Ni(*trans*-Me$_6$[16]diene][Zn(NCS/Cl)$_4$] [3]. For the cations {Cu2} and {Cu4} these dimensions have intermediate values, see Table 2.

The substituted six-membered amine-imine chelate rings of the disordered macrocycle cations {Cu2} and {Cu4} have superimposed arrangements with a chelate ring with one planar trigonal coordinated imine nitrogen atom and one tetrahedral coordinated secondary amine nitrogen atom. The two disorder components of the macrocycle occupying these cation sites would have these chelate ring arrangements reversed. The reversed chelate ring components would not conform well, leading to anomalous calculated bond lengths and angles and larger adp values for the chelate ring atoms and the methyl substituents, particularly the axial substituents. This disorder would be expected to extend to the nitrogen atoms and also to the adjacent atoms of the linking chelate rings, and be manifest largely as anomalous adp values.

For all the cations the trimethyl-substituted amine-imine chelate rings have asymmetric boat conformations. For the [Cu(*trans*-Me_6[16]diene)]$^{2+}$ cations {Cu1} and {Cu2} the unsubstituted 1,3-diamine chelate rings have chair conformations, the overall conformation being similar to that of the analogous nickel(II) cation [3]. For the [Cu(*cis*-Me_6[16]diene)]$^{2+}$ cation {Cu3} the diimine chelate ring N31–N35 has a boat conformation and the diamine chelate ring N39–N43 has a chair conformation. For the mixed occupancy [Cu(*cis*-Me_6[16]diene)]$^{2+}$ cation site {Cu4}, the conformation of the chelate ring N69–N73 is a chair and that of N61–N65 has N61, C62, C63, C64 and N65 close to coplanar, though both show indications of positional disorder for the central methylene group, as would be expected for superimposed components with the {Cu3} structure reversed. The chair–chair conformations of these chelate rings observed for {Cu1} and {Cu2} are most compatible with the *trans*-diimine macrocycle, while the chair–boat conformation observed for {Cu3} is more compatible with the *cis*-diimine macrocycle. For comparison, for *N-rac*-[Cu(*cis*-Me_6-[16]diene)][$ZnCl_4$] (below) the N9–N13 (diamine) chelate ring has a chair conformation, and the N1–N5 (diimine) chelate ring has a twist conformation. Displacements of atoms from selected mean planes for the chelate rings are listed in the Supplementary data.

Each of the cations is associated with three perchlorate anions, one approximately axially located on the less crowded side of the CuN_4 'plane' and two off-axis on the more crowded side with the axial substituents and N–H groups. The perchlorate oxygen atom sites are generally poorly defined, but there is a significant axial interaction on the less crowded side for {Cu1} and {Cu2} and probable hydrogen bonds formed by all cations on the other side toward which the NH groups are directed. The treatment of the perchlorate ion disorder and hydrogen bonding is described in the Supplementary data.

The closest approaches of perchlorate ions to copper(II) ions (less crowded side first) are: Cu1···Cl1, 3.69(2); Cu1···Cl3 and Cl7, ca. 4.72; Cu2···Cl5, 3.69(2); Cu2···Cl3 and Cl7, ca. 4.7; Cu3···Cl3, 4.63(2); Cu3···Cl2, 4.48(2); Cu3···Cl6, 4.78(2); Cu4···Cl4, 4.63(2); Cu4···Cl6, 4.48(2) and Cu4···Cl2, 4.80(2) Å. Cations {Cu1} and {Cu2} are approximately inversion related, with Cu1···Cu2 = 7.27(2) Å, linked by perchlorate ions Cl2 and Cl3. Similarly, cations {Cu3} and {Cu4} are approximately inversion related, with Cu3···Cu4 = 6.79(2) Å and linked by perchlorate ions Cl6 and Cl7. Perchlorate ions Cl4 and Cl8 have no close association with cations. See Fig. 3 for a representation of the contents of the unit cell. The rotational disorder of the perchlorate ions probably arises because these ions are only weakly restrained by hydrogen bonding and the closest neighbours of many perchlorate oxygen atoms are hydrogen atoms of partial occupancy axial methyl groups.

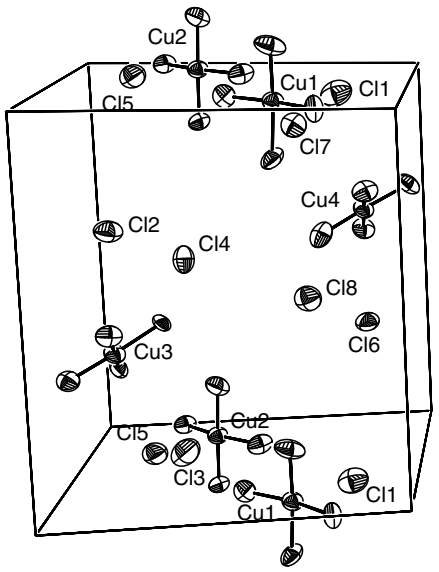

Fig. 3. The unit cell contents for *N-rac*-(6,8,8,14,16,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,13-diene)copper(II) *N-meso*-(6,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II) perchlorate, projected normal to the 100 plane, showing only the Cu, N and Cl atoms.

2.1.2. Solution in space group C2/m (cell: a, 14.740(4); b, 23.452(4); c, 14.364(3) Å; , 96.54(3)°; R_1 = 0.063)

The asymmetric unit consists of the halves of two (tetraazacycohexadecadiene)copper(II) cations, {Cu1} and {Cu2}, with the CuN_4 groups of {Cu1} and {Cu2} approximately normal. Cation {Cu1} has atom Cu1 on a twofold axis, normal to the CuN_4 group, compatible with the *N-rac-trans*-[16]diene macrocycle. Cation {Cu2} has atoms Cu2, C23 and C31 on a mirror plane, compatible with the *N-meso-cis*-[16]diene macrocycle. The chlorine atoms Cl1–Cl4 of four "half" perchlorate ions and a number of the perchlorate oxygen atoms are also in special positions, with Cl1 on the same twofold axis as Cu1 and with Cl3 and Cl4 (and O32, O33, O41, O42 and O43) on the same plane as Cu2, C23 and C31.

Both cations have saddle conformations with the substituted and the unsubstituted chelate rings tilted to opposite sides of the CuN_4 group, requiring the two NH groups to lie on the same side of this group, determining the *N-rac-trans*-configuration for {Cu1} and the *N-meso-cis*-configuration for {Cu2}. The two-fold symmetry {Cu1} cation has appreciable folding of the N_4 group, with *trans*-N–Cu–N angles of 176.0(3)° and 163.7(2)°, while for cation {Cu2} the CuN_4 group is inherently planar. For both cations the unsubstituted chelate rings have chair conformations and the substituted chelate rings have boat conformations.

For both cations equatorially oriented methyl substituents are present for C6 and C8 and hence also for the symmetry related atoms C14 and C16. Significant electron density peaks are present at axial substituent sites near the same ring atoms, all lying on the same side of the CuN_4 "plane" towards which the unsubstituted chelate rings are tilted. Assigning these as partial occupancy methyl groups and refinement of site occupancy factors, (linking the sof for the axial methyl substituent group and adjacent NH group, with complementary sof for the methyl substituents on each chelate ring, as discussed above), resulted in values for sof of the C62 group of 0.61(2) for {Cu1} and of 0.63(2) for {Cu2}. The *R*-values were unchanged when these sof were fixed at 0.667, indicating a 2:1 ratio of the *trans*-enantiomers for {Cu1} and of the rotated forms of the *cis*-isomer for {Cu2}, within the relevant uncertainties. The disorder components have the N5–N9 amine-imine chelate ring reversed and the two arrangements of the chelate ring would not conform well, so the dimensions observed are likely to be anomalous, as discussed above. The C–N distances within the amine-imine chelate ring are intermediate to the usual C–N and C=N distances.

2.1.3. Solution in space group $P\bar{1}$ (R_1 = 0.063)

For the solution in space group $P\bar{1}$, there are two full [Cu(azamacrocycle)]$^{2+}$ cations and four perchlorate ions in the asymmetrical unit, with no imposed symmetry. The cation {Cu1} has approximate twofold symmetry (axis through Cu1, normal to the CuN_4 "plane"), with appreciable folding of the N_4 group and a ca. 2.4 Å Cu–O axial interaction with a perchlorate ion oxygen atom. The cation {Cu2} has approximate mirror symmetry (plane through C23, Cu2 and C31), a planar CuN_4 group, and no close axial interaction.

The ring conformations and axial substituent patterns are similar to those in the *P*1 and *C*2/*m* solutions, with partial occupancy

axial methyl sites present for both cations. For each chelate ring the site occupation factors for the axial methyl groups and adjacent H(N) atoms were refined with complementary values, as for the *P*1 solution. For cation {Cu1} the values of the sof for the pairs C62 and C142, C82 and C162 and for cation {Cu2} the values for the pairs C62, C162 and C82, C142 were similar and the structure was refined with common sof for the pairs. The resulting value for cation {Cu1} for the sof for C62 and C142 was 0.65(1) and for cation {Cu2} the sof for C62 and C162 was 0.66(1), both approximating to 0.667 within the relevant uncertainties. The sof values were fixed at 0.667 for the final refinement cycles, with no change in the *R*-values. These results are compatible with sites {Cu1} having *N-rac*-[Cu(*trans*-Me_6[16]diene)]$^{2+}$ cations with enantiomers present in 2:1 proportions and with sites {Cu2} having *N-meso*-[Cu(*cis*-Me_6[16]diene)]$^{2+}$ cations, with rotated arrangements also present in 2:1 proportions. The C-N distances within the amine–imine chelate ring are intermediate to the usual C–N and C=N distances.

The closest interactions between Cu and oxygen atoms for Cu1 are half occupancy O47 at 2.48(1)} and O48 at 2.50(1) Å, with the closest axial approach for Cu2 with O11 at 3.61(1) Å. The cation {Cu1} of the $P\bar{1}$ solution becomes approximately inversion related pairs of cations, {Cu1} and {Cu2} in the *P*1 solution and likewise {Cu2} of $P\bar{1}$ become the pairs {Cu3} and {Cu4} in *P*1. Similarly the perchlorate ions including Cl1, Cl2, Cl3 and Cl4 in $P\bar{1}$ become approximately inversion related pairs Cl1 and Cl5, Cl2 and Cl6, Cl3 and Cl7, Cl4 and Cl8 in *P*1.

The closest axial interactions between copper and oxygen atoms for Cu1 is with O11 at 2.50(1) Å, while the closest axial approach for Cu2 is with O41 at 3.61(1) Å. The four full perchlorate ions present show individualistic rotational disorder, treated similarly to the *P*1 solution.

2.2. The structure of N-rac-(5,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II) tetrachlorozincate N-rac-[Cu(cis-Me_6[16]diene)][$ZnCl_4$]

The structure was determined for the blue product which crystallized when a solution of the perchlorate salt in methanol containing zinc chloride was allowed to evaporate.

The structure of this compound shows no disorder and unequivocally confirms the presence of *N-rac*-(5,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II) cations, *N-rac*-[Cu(*cis*-Me_6[16]diene)]$^{2+}$, shown in Fig. 4, with the *cis* locations of the imine functions supported by N1–C16 and N5–C6 distances, see Table 2, and the trigonal angles about these atoms. The group N9–H9 and axial methyl substituent (C142)H_3 are oriented to one side of the CuN_4 "plane" and groups N13–H13 and axial methyl group (C82)H_3 are oriented to the other side, confirming the *N-rac* configuration. The asymmetric unit contains the *RR* enantiomer (Flack parameter [23] = 0.007(7)).

The Cu–N distances are similar to values for related [Cu(tetraazamacrocycle)]$^{2+}$ cations with ring sizes ranging from 14- to 18-members, see Table 1. The mean Cu–N_{imine} distance {2.006(3) Å} is slightly shorter than the mean Cu–N_{amine} distance {2.023(3) Å}, though this difference is less than the ca. 0.03 Å observed for related compounds.

The CuN_4 group has irregular geometry, approximately midway between square-planar and tetrahedral. The diamine chelate rings have conformations Cu, N1, N5, twist; Cu, N9, N13, chair {dihedral angle between CuN_2 planes 46.7(1)°}; amine-imine chelate rings Cu, N5, N9 and Cu, N13, N1, twist-boat {dihedral angle between planes 45.7(1)°}. Displacements of atoms from the relevant least squares planes are listed in the Supplementary data.

The cation and tetrachlorozincate anion are linked by hydrogen bonds [D–H···A, distances D–H, H···A, D···A (Å); angle D–H···A (°): N9–H9···Cl3 [0.90, 2.55, 3.370(2); 152]; N13–H13···Cl2: [0.84, 2.86, 3.465(2); 130°] and N13–H13···Cl4 [0.84, 2.89, 3.649(2); 151], with the closest axial interaction Cu1···Cl2 = 3.340(2) Å.

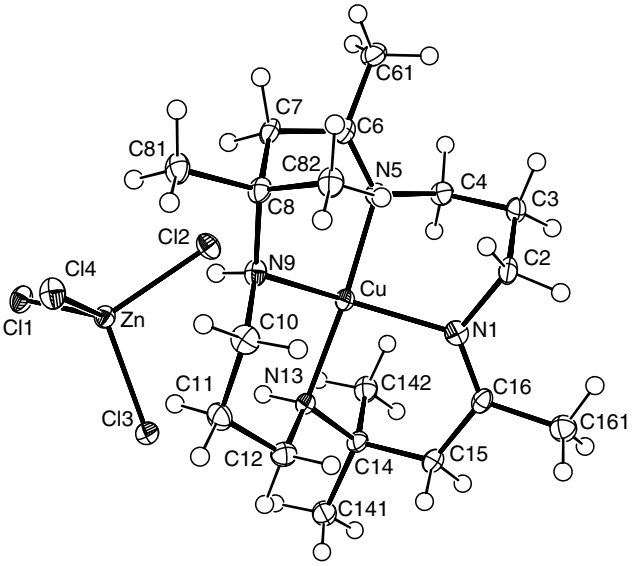

Fig. 4. The asymmetric unit of *N-rac*-(5,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II) tetrachlorozincate drawn as for Fig. 1, but with probability ellipsoids drawn at the 50% confidence level.

2.3. The structure of (hexamethyl-1,5,9,13-tetraazacyclothexadecadiene)(isothiocyanato)copper(II) perchlorate, [Cu(Me_6[16]diene)(NCS)]ClO_4

The structure was determined for the blue product which crystallized when a solution of the perchlorate salt in water containing sodium thiocyanate evaporated. Poor data and disorder precluded a fully satisfactory refinement; though the main structural features are clear.

The asymmetric unit has a square pyramidal hexamethyl-1,5,9,13-tetraazacyclohexadecadiene)(isothiocyanato)copper(II) cation, see Fig. 5, and a perchlorate anion. The cation has the Cu

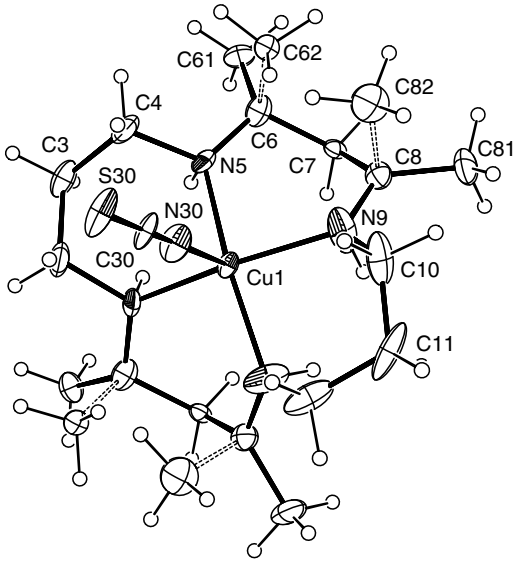

Fig. 5. The cation of (hexamethyl-1,5,9,13-tetraazacyclothexadeca-diene)(isothiocyanato)copper(II) perchlorate, drawn as for Fig. 1, with atoms of the asymmetric unit labelled. Methyl sites C62 and C82 have complementary sof.

atom and the C30, N30 and S30 atoms of the coordinated thiocyanate ion on a twofold axis. The Cu atom is displaced by 0.329(4) Å from the coplanar CuN_4 group, towards the N-atom of the linear thiocyanate group, which has dimensions N30–C30 = 1.16(1) and C30–N30 = 1.64(1) Å. The azamacrocycle has an overall saddle conformation; with the unsubstituted (1,3-diamine) chelate ring tilted towards the same side of the N_4 plane as the *N*-thiocyanato ligand with a chair conformation (which distances the central methylene group $(C3)H_2$ from the thiocyanato ligand atoms). The trimethyl-substituted 1-amine-3-imine chelate ring is tilted to the opposite side of the N_4 plane from the thiocyanate ligand with a boat conformation, which places the axial groups on the opposite side of the N_4 plane. Displacements of atoms from the relevant CuN_2 chelate planes are listed in the Supplementary data.

Significant electron density is present in the axial substitution sites near both C6 and C8 (and symmetry related sites near C14 and C16). This was assigned as partial occupancy methyl groups $(C62)H_3$ and $(C82)H_3$ (with associated partial occupancy H5 and H9) as discussed above. Refinement with complementary sof for $\{(C62)H_3 + H5\}$ and $\{(C82)H_3 + H9\}$ gave values of sof of 0.59(1) and 0.41(1), respectively.

The twofold symmetry of the cation is most compatible with the *N-rac*-[Cu(*trans*-Me_6[16]diene)]$^{2+}$ cation, with the cation site occupied by the enantiomers in approximately equal proportions. The N5–C6 and C8–N9 distances are similar, intermediate to the values usual for secondary amine and imine functions, see Table 2. As discussed above, the differing conformations of the superimposed reversed forms of the amine–imine chelate ring would be expected to result in non-standard dimensions, particularly of distances to axial substituents (see Table 2).

The saddle conformation of the cation is also compatible with the *N-meso*-[Cu(*cis*-Me_6[16]diene)]$^{2+}$ cation, with the observed twofold symmetry requiring the presence of equal proportions of the rotated arrangements, which would result in equal half-occupancies for the $(C62)H_3$ and $(C82)H_3$ methyl sites. However, R_1 increased from 0.064 to 0.065 when the sof of these groups were fixed at 0.5.

It is concluded that the structure determination supports the assignment as *N-rac*-[Cu(*trans*-Me_6[16]diene)]$^{2+}$, but does not permit unambiguous assignment of configuration.

The rotationally disordered perchlorate ion has the chlorine atom Cl1 and oxygen atom O1 on a mirror plane. The remaining oxygen atoms are effectively in free rotation about the Cl1–O1 axis, modelled with six equally half-occupied oxygen atom sites.

The unit cell contains interlinked columns of cations, with alternating orientations of the axial thiocyanate group, with Cu···Cu ($x, -y, -z$) = 7.416 Å and S30···S30 ($x, -y, -z$) = 4.591 Å. The S-atoms from an intersecting cation column, normal to the first, lie between the cations (on the side remote from the thiocyanate ion) on the same plane and interacting equally with N5–H and N9–H, with Cu1···S30 ($-x, -y + ½, z + ½$) and Cu1···S30 ($-x, y + ½, -z + ½$) = 4.356 Å. The perchlorate ions form columns between the cation columns; with oxygen O1 located midway between the pairs of S···S atoms of adjacent columns (O1···S30 = 6.818 Å), with all O-atoms remote from NH groups. Hydrogen bonds [D–H···A, distances D–H, H···A, D···A (Å); angle D–H···A (°)]: N5–H5···S30 ($-x + 1, -y + 3/2, z - ½$) [0.93, 2.81, 3.705(6); 160.9]; N9–9···S30 ($x, y - ½, -z + 3/2$) [2.91, 3.789(7); 158.6] are present.

[e] Information lost.

2.4. The structure of {Hexamethyl-1,5,9,13-tetraazacyclothexadecadiene)copper(II)}–cyano-{tetracyanonickelate(II)} hydrate, $[Cu(Me_6[16]diene)(\mu\text{-}NC)Ni(CN)_3] \cdot H_2O$

The structure was determined for this very sparingly water-soluble blue compound, which precipitated as very fine crystals when a solution of $Na_2[Ni(CN)_4] \cdot 3H_2O$ was added to an aqueous solution of the perchlorate salt. The compound was recrystallised from water, with repeated thermal cycling, but the crystals remained tiny and generally poorly formed. Disorder and poor data precluded a fully satisfactory analysis, but the essential structural features are clear.

The asymmetric unit contains two similar "molecules", each with copper(II) ions in square-pyramidal coordination by the four nitrogen atoms of a hexamethyl-1,5,9,13-tetraazacycloretradecadiene azamacrocycle, each with one cyanide nitrogen atom of a tetracyanonickelate(II) ion coordinated axially, and two independent water molecules. The geometries of the (azamacrocycle)copper(II) cations, labelled {Cu1} and {Cu2}, are similar and generally similar to that of the thiocyanate compound, 2.3 above, but with no imposed symmetry.

For both cations the N_4 groups are near-coplanar, with the Cu displaced towards the axial cyanide nitrogen [tetrahedral twisting of N_4 group, displacement of Cu from N_4 plane/Å: {Cu1}, ±0.013(8), 0.308(1); {Cu2}: ±0.053(8), 0.307(8)]. The macrocycles have saddle-shaped conformations. The unsubstituted diamine chelate rings have chair conformations; tilted to the same side of the azamacrocycle as the *N*-coordinated cyano group while the substituted amine–imine chelate ring have boat conformations tilted to the other side, see Fig. 6. Displacements of atoms from relevant mean planes for chelate rings are listed in the Supplementary data.

For both cations there is appreciable electron density in the axial sites associated with C6, C8, C14 and C16 for {Cu1} and C26, C28, C34 and C36 for {Cu2}. This was assigned as axially oriented methyl substituents, refined with complementary sof for the methyl groups and associated H(N) atoms for each chelate ring as for the previous compounds. For cation {Cu1} the sof values for C62 and C142 are 0.45(2) and 0.54(2), respectively, in agreement with approximately equal occupancy of the axial sites, which could occur for equal proportions of either the *trans*- or the *cis*-cation. For cation {Cu2} the values are 0.39(2) and 0.62(2), respectively, in best agreement for the *cis*-cation in ca. 2:1 ratio of 180° rotated arrangements. The *R*-values obtained were insensitive to the sof ratios for the axial substituents so do not permit unambiguous assignment of configuration but it seems probable that this compound has equal proportions of the *N-rac*-[Cu(*trans*-Me_6[16]-diene)]$^{2+}$ and *N-meso*-[Cu(*cis*-Me_6[16]diene)]$^{2+}$ cations.

The tetracyanonickelate(II) moities are close to square-planar, with mean distances Ni1–C = 1.81(4); C–N = 1.11(4) and Ni2–C 1.87(2); C–N = 1.17(4) Å and angles Cu1–N17–C17 = 172.2(2) and Cu2–N37–C37 = 164.9(1)°.

The "molecules" are arranged in stacks with parallel azamacrocyles, aligned with the *X* axis. Cations {Cu1} and {Cu2} form separate columns, with alternating columns reversed, with Cu-atom separation in the columns of 11.252(4) Å (the *a* cell dimension). A $Ni(CN)_4$ group lies between adjacent Cu(azamacrocyle) groups, with cyanide groups N-coordinated to copper(II) on one side, and with the *trans*-cyanide group hydrogen bonded to NH groups of the next azamacrocyle on the other side. Columns of water molecules lie between the azamacrocyle columns, with O18 hydrogen bonded to cyanide N40 ($-x$, $y + ½$, $-z + ½$) and O38 to N38 ($-x$, $-y$, $-z$), and also to N–H groups. These cyanide-N and water-O atoms are approximately symmetrically positioned off the tetragonal axis with respect to the Cu atoms, with Cu1···N19 = 3.85(4), Cu1···O38 ($-x$, $-y$, $-z$) = 3.68(4) and Cu2···N39 = 3.85(4), Cu2···O18 ($-x$, $y + ½$, $-z + ½$) = 3.65(4) Å.

Hydrogen bonds [D–H···A, distances H···A, D···A (Å); angle D–H···A (°), N–H = 0.91 Å] are: N1–H1···O38^{i} [2.22, 3.06(4); 154.4]; N5–H5···O38^{i} [2.38, 3.25(2); 159.5]; N9–H9···N19^{ii} [2.32, 3.19(2); 160.3]; N13–H13···N19^{ii} [2.36, 3.249(2); 161.5]; N21–H21···O18^{iii} [2.42, 3.24(2); 151.8]; N25–H25···O18^{iii} [2.32, 3.15(2);, 153.0]; N29–H29···N39^{iv} [2.40, 3.27(2); 158.3]; N33–H33···N39^{iv} [2.32, 3.21(2); 165.9]; symmetry operators: i = $-x + 1$, $-y + 1$, $-z + 1$; ii = $x - 1$, y, z; iii = $-x + 2$, $y - ½$, $-z + ½$; iv = $x + 1$, y, z. Hydrogen atoms of the water molecules were not located.

The structure of a μ-cyano-bridged tetracyanonickelate(II) compound of (13-ethyl-5,7,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetradeca-4-ene)copper(II), with a tetracyanonickelate ion similarly axially coordinated to copper(II) has been reported [24].

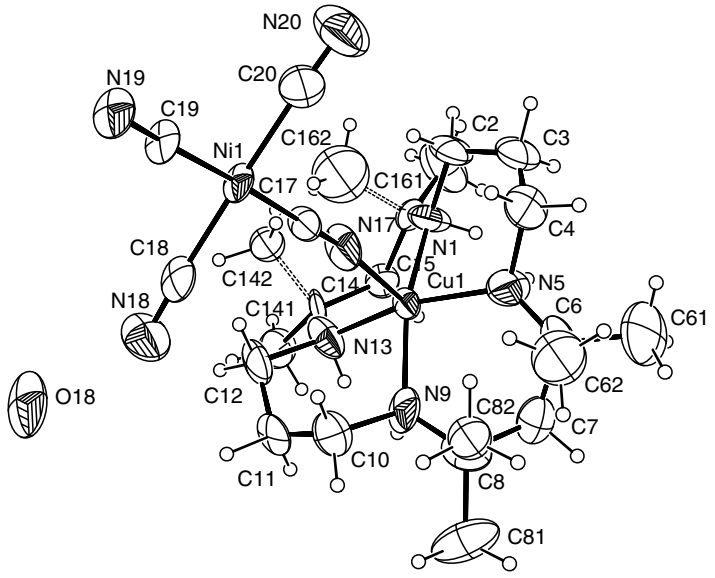

Fig. 6. The molecule containing {Cu1} and associated water molecule O18 of {(hexamethyl-1,5,9,13-tetraazacyclothexadecadiene)copper(II)}-μ-cyano-{tetracyanonickelate(II)} hydrate, drawn as for Fig. 1. Methyl sites C62, C82, C142 and C162 have sof of 0.5. The molecule including {Cu2} and associated water molecule O28 is similar.

The structures of compounds with two [Cu(*cis*-[14]diene)]$^{2+}$ cations linked by a [Ni(CN)$_4$]$^{2-}$ bridging group [16] and of chain polymeric [–Ni(*trans*-Me$_6$[14]diene)-NC–Ni(CN)$_2$–CN–]$_n$ [20] have been reported.

3. Discussion

The only azamacrocycle cations likely to be formed from the reaction of bis(propane-1,3-diamine)copper(II) perchlorate with acetone are [(5,8,8,14,16,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,13-diene)copper(II)]$^{2+}$, [Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ and [(5,8,8,14,14,16-hexamethyl-1,5,9,13-tetraazacyclohexadeca-5,16(1)-diene)copper(II)]$^{2+}$, [Cu(*cis*-Me$_6$[16]diene)]$^{2+}$. The structural determination for crystals of a tetrachlorozincate salt, crystallised in low yield from the original perchlorate salt, unambiguously confirms the presence of the *N-rac*-[Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ cation, so that the condensation reaction produces *at least some* of the [Cu(*cis*-Me$_6$-[16]diene)]$^{2+}$ cation. Thus, the original perchlorate salt must either have only the [Cu(*cis*-Me$_6$-[16]diene)]$^{2+}$ cation, or contain both the [Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ and [Cu(*trans*-Me$_6$-[16]diene)]$^{2+}$ cations, as a mixture, or in some co-crystallised form.

The structural solutions for the perchlorate salt in space groups *P*1, $P\bar{1}$, and *C*2/*m* all indicate the presence of cations of two types, with increasing levels of averaging over sites. One type has twofold or approximate two-fold symmetry, appreciably bent CuN$_4$ group and a relatively short Cu-O interaction; properties which fit best for the *N-rac*-[Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ cation. The other type has mirror, or approximate mirror symmetry, near planar CuN$_4$ group, and no close axial interaction, properties which fit best for the *N-meso*-[Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ cation.

For both cation types in all three space group solutions there is disorder in the location of the imine functions and axial methyl substituents. For the *P*1 solution there are four cation sites; the cation {Cu1} unambiguously has the 5,13-diene *trans*-diimine structure as a single *RR*-enantiomer and the site {Cu2} most probably has the 5,13-diene *trans*-diimine structure, with equal proportions of the *RR* and *SS*-enantiomers. The {Cu3} site unambiguously has the 9,16(1)-diene *cis*-diimine cation and the {Cu4} site has the *cis*-diimine cation, with two disorder components, with rotated arrangements of the cation present in 2:1 proportions.

The solutions in space groups *C*2/*m* and $P\bar{1}$ also support the conclusion that both geometric isomers of the cation are present in the crystal, both with disorder in the location of the imine function and axial methyl substituents. In the $P\bar{1}$ solution for the [Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ cation {Cu1} this is described by the presence of the *N-rac* stereo-isomers in 2:1 ratio. For the [Cu(*cis*-Me$_6$[16]-diene)]$^{2+}$ cation it is described by the presence of rotated arrangements, also in 2:1 ratio.

The solutions in the three space groups thus all indicate the presence of both *N-rac*-[Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ and *N-meso*-[Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ cations. All agree that the *N-meso*-[Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ cation is present with disorder in the locations of the imine functions and axial methyl substituents, with the disorder components present in 2:1 ratio. All agree that the *N-rac*-[Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ cation is present as the *RR* and *SS* enantiomorphs, present in 3:1 proportions for the P1 solution but in 2:1 proportions for the $P\bar{1}$ and *C*2/*m* solutions. These ratios are determined by the sof for the axial substituents, which are determined by the separation of a broad volume of electron density in the axial substituent region into distinct methyl groups, with these carbon atom sites having large adp's and separated by ca 1.7–1.9 Å. The ratios are also influenced by the treatment of the perchlorate ion disorder as partial occupancy oxygen atoms are in the vicinity of the axial methyl substituents.

From a chemical perspective the structures in all space groups indicate that the synthesis yields both the *cis*- and *trans*-diimine isomers of the azamacrocycle cation. The perchlorate salt contains the *N-rac-trans*-cation and the *N-meso-cis*-cation. The latter is present with a preponderance of the *RR*-enantiomer, so the crystal must be chiral.

The thiocyanato perchlorate and tetracyanonickelate(II) compounds both have appreciable disorder which precluded unambiguous assignment of configuration. The thiocyanato compound has the cation on a twofold axis, which is most compatible with the presence of the *N-rac*-[Cu(*trans*-Me$_6$[16]diene)]$^{2+}$ cation.

The tetracyanonickelate(II) compound is very sparingly soluble in water, so the product initially precipitated in high yield from a solution of the perchlorate salt which contains both isomers. The recrystallisation from water also gave the product in high yield so the recrystallised product probably contains both isomers. The structural study shows the presence of two independent cations, with somewhat different geometries, both with disorder of the imine functions and axial substituents. The sof values indicate that cation {Cu2} most probably has the *cis*-structure, while the cation {Cu1} could have either structure. The occupancy values are similar to those of cations {Cu2} and {Cu4}, respectively, of the perchlorate salt, which were assigned with *trans*- and *cis*-structures, respectively, so it seems likely that the two "molecules" of the tetracyanonickelate compound with the {Cu1} and {Cu2} cations have *N-rac-trans*- and *N-meso-cis*- arrangements, respectively.

It is concluded that the reaction of bis-(propane-1,3-diamine)copper(II) with acetone produces both the *cis*- and *trans*-diene macrocyclic cations, as observed for the analogous reactions with ethane-1,2-diamine and butane-1,4-diamine complexes. These isomers co-crystallize as the perchlorate salt, but the *cis*-macrocycle cation crystallises preferentially for the tetrachlorozincate salt.

The [Cu(*cis*-Me$_6$[16]diene)]$^{2+}$ cation present for the tetrachlorozincate salt has the *N-rac* configuration and for the perchlorate salt the *N-meso* configuration. For the perchlorate salt, with co-crystallised *cis* and *trans*-isomeric cations, the *N-meso-cis*-cation is approximately mirror symmetrical, with the CuN$_4$ group near coplanar, with no significant axial interactions. In contrast, the *N-rac-cis*-cation of the tetrachlorozincate salt has an asymmetric, highly twisted CuN$_4$ group, with one diamine chelate ring in a twist conformation, again with no significant axial interactions. The nearest comparisons are with *N-meso*-[Cu(*cis*-Me$_6$[18]-diene)](ClO$_4$)$_2$ and *N-rac*-[Cu(*trans*-Me$_6$[18]diene)](ClO$_4$)$_2$ where the CuN$_4$ group for the *cis*-cation is highly twisted and that for the *trans*-cation is closer to planar, but with a more puckered macrocycle [10].

The Cu–N bond lengths for the compounds are similar to those reported for tetraaza-amine-imine macrocycle compounds with 14–18 ring members, see Table 1. Strain energy calculations indicate the optimal ring-sized tetraaza macrocycle for Cu(II) has a 14-membered ring, with strain energy increasing for larger rings. This strain for larger rings is accommodated by increased ring puckering and/or distortion of the coordination geometry, rather than by increasing the Cu-N distances, as also observed for the analogous nickel(II) compounds [16].

Several of the compounds described show a form of disorder associated with reversal of 2,4,4-trimethyl-1-imine-5-amine chelate rings. The phenomenon has been reported for compounds of 5,7,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradeca-4-ene (and the 13-ethyl homologue) with copper(II) [24,25] and nickel(II) [26] and also occurs for compounds of these macrocycle with the imine and/or nitro groups reduced [27]. In some cases (as for [Cu(*trans*-[16]diene]$^{2+}$) the disorder can be described as co-crystallisation of enantiomorphs, in others (as for [Cu(*cis*-[16]diene]$^{2+}$) as orientational disorder.

4. Experimental

4.1. Preparation of compounds

4.1.1. Perchlorate salt

This was prepared by reaction of bis(propane-1,3-diamine)copper(II) perchlorate with acetone as reported [1,2] and recrystallised from water.

4.1.2. Tetrachlorozincate salt

The perchlorate salt was dissolved in methanol, zinc chloride added and the solution evaporated. Blue crystals which separated in low yield were filtered off and washed with methanol.

4.1.3. Thiocyanato perchlorate compound

This was prepared as for the tetrachlorozincate salt, by evaporation of an aqueous solution of the perchlorate salt containing sodium thiocyanate. IR, band maxima/cm^{-1}: ν(NH) 3169; ν(C≡N) 2082; ν(C=N) 1657.

4.1.4. Tetracyanonickelate(II) compound

This very sparingly soluble compound precipitated when an aqueous solution of $Na_2[Ni(CN)_4] \cdot 3H_2O$ was added to an aqueous solution of the perchlorate salt. This was filtered off and recrystallised from water, using repeated thermal cycling, which still resulted in a mass of tiny, poorly formed crystals. IR, band maxima/cm^{-1}: ν(OH), 3549, 3468, 3461; ν(NH) 3214, 3166; ν(C≡N) 2154, 2122(str); ν(C=N) 1661.

4.2. Crystallography

See Table 3 for details. Diffraction data was collected [29] by using Bruker CCD diffractometers with Mo Kα radiation (0.71073 Å) from fine-focus sealed tubes with graphite monochromators, using phi and omega scans. Multi-scan absorption corrections were applied [29]. The structures were solved by direct methods and full-matrix refined [30], with anisotropic parameters for all non-H atoms (except where specified). Axially oriented methyl substituents were located from difference maps and their sof refined as separate SHELXL parts, as discussed in the text. Hydrogen atoms are in calculated positions and refined using a riding model with SHELXL defaults.

The perchlorate ions exhibit severe rotational disorder. For $[Cu(Me_6[16]diene)](ClO_4)_2$, the model used is reported in the Supplementary data. The details of the treatment had little impact on the dimensions of the cations, but did influence the sof of the axial substituents. For $[Cu(Me_6[16]diene)(NCS)]ClO_4$ the Cl and one O of the perchlorate ion lie on a mirror plane, with the ion effectively in free rotation about this Cl–O direction. This was modeled with six other oxygen sites with sof = 0.5, with default SADI restraints [30] for the Cl–O distances.

Appendix A. Supplementary data

CCDC 6985234, 698522, 698524, 698525 contain the supplementary crystallographic data for $[Cu(Me_6[16]diene)](ClO_4)_2$, *N-rac*-$[Cu(cis\text{-}Me_6[16]diene)][ZnCl_4]$, $[Cu(Me_6[16]diene)(NCS)]ClO_4$, $[Cu(Me_6[16]diene)(\mu\text{-}NC)Ni(CN)_3] \cdot H_2O$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2008.12.029.

demonstrated that the initial precipitate was not in most cases the thermodynamically stable phase [17]. Consequently, the evolution with time of a carbonate-containing suspension of $Fe(OH)_2$, stored at room temperature in anoxic conditions, was also studied. The results presented in this paper rely mainly on the use of Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy (ATR/FT-IR) as characterisation method. A specific analytical procedure under controlled atmosphere was developed to protect from air the synthetic Fe(II) hydroxides and hydroxysalts that are very sensitive to the oxidising action of O_2. Infrared micro-spectroscopy was also used to characterise chukanovite in corrosion layers of an archaeological sample. Finally, the vibration bands of the infrared spectrum of chukanovite were interpreted by comparison with the spectra of malachite $Cu_2(OH)_2CO_3$, rosasite $(Cu,Zn)_2(OH)_2CO_3$ and pokrovskite $Mg_2(OH)_2CO_3$ [14,18–22].

2. Materials and methods

2.1. Archaeological sample: description and characterisation methods

An iron nail coming from the archaeological site of Glinet (France, Seine Maritime) was analysed. The site corresponds to an ancient forge and is dated from the 16th century. The nail was excavated in July 2004 and stored in ethanol, without having been cleaned, until its sampling for analysis. It corresponds to a set of nails, analysed previously by other techniques [3,23–25] and presenting a large amount of $Fe_2(OH)_2CO_3$ as certified by micro X-ray diffraction [9,10].

The archaeological nail was embedded in epoxy resin and cut with a diamond wire saw in order to work on cross sections. Nujol was used as lubricant to provide an oily protective film for the surface exposed to air during the cutting. To avoid any use of water, the section was polished in hexane with silicium carbide to grade 4000 (grain size of 5 μm). The analyses were performed using a Continuum microscope coupled with a Nexus spectrometer (Thermo-Nicolet). The microscope is equipped with a 15× objective, 10× oculars and a MCT-A detector. The background was acquired using a gold mirror as a sample. Spectra were obtained with the Omnic acquisition software at a resolution of 8 cm^{-1} and by averaging at least 128 scans. After acquisition, the specular reflectance spectra were treated by Kramers-Krönig transform. Previous experiments proved that natural Fe(II) hydroxysalts could remain unaffected by an exposure to air during several hours [26]. The analysis time being short enough, experiments were carried out without specific protection to avoid exposure of the sample to the atmosphere. Note that the MCT-A detector of the microscope limits the spectral window to 650–4000 cm^{-1}.

When necessary, the infrared spectroscopy study was completed with a Raman spectroscopy analysis. Raman measurements were carried out at room temperature on a Jobin Yvon High Resolution Raman spectrometer (LabRAM HR) equipped with a microscope (Olympus BX 41) and a Peltier-based cooled charge coupled device detector. Excitation was provided by a He–Ne laser at a wavelength of 632.8 nm. The laser power was reduced by filters to avoid any transformation of the matter by heating. Spectra were recorded with the Labspec acquisition software at a resolution of 2 cm^{-1}.

2.2. Synthesis of iron(II) precipitate in carbonate-containing media

Solutions prepared with $FeCl_2 \cdot 4H_2O$ (Fluka, 99%), NaOH (Riedel de Haën, concentrated 32% solution) and $Na_2CO_3 \cdot 10H_2O$ (Fluka, 99%) dissolved in water deaerated with an argon flow, were mixed together. Three concentrations of Fe^{2+} ions were considered: 0.12, 0.16 and 0.22 mol L^{-1} for a concentration of OH^- ions kept constant at 0.2 mol L^{-1}. The experimental conditions will be given using the concentration ratio of the reactants $R = [FeCl_2 \cdot 4H_2O]/[NaOH]$, that is equal to 0.6, 0.8 and 1.1. For each value of R, the $Na_2CO_3 \cdot 10H_2O$ concentration was varied. It is expressed similarly via the concentration ratio $R' = [Na_2CO_3 \cdot 10H_2O]/[NaOH]$. Five values of R′ were considered: 0.1, 0.3, 0.5, 0.7 and 0.9. This range of R and R′ values correspond to the domain of pH and carbonate concentration that extends from $Fe(OH)_2$ (smallest R and R′ values) to $Fe_2(OH)_2CO_3$ (largest R and R′ values). The mixing of the solutions led immediately to the formation of a precipitate. Each suspension was then poured in a flask filled up to the brim, closed hermetically to avoid dissolution of oxygen in the liquid and aged 24 h at room temperature before analysis. The resulting solid products were analysed by ATR/FT-IR spectroscopy.

A previous similar study devoted to the Fe(II) hydroxychloride β-$Fe_2(OH)_3Cl$ showed that the thermodynamically stable compound could be sometimes obtained after long times of ageing [17]. It was more precisely observed that $Fe(OH)_2$ could be obtained in conditions where β-$Fe_2(OH)_3Cl$ was the stable phase, and that the complete transformation of $Fe(OH)_2$ into β-$Fe_2(OH)_3Cl$ required months. In order to show if a similar phenomenon could occur in carbonate-containing media, a specific experiment was carried out. First, $Fe(OH)_2$ was synthesised by mixing a solution of $FeCl_2 \cdot 4H_2O$ and a solution of NaOH, prepared in deaerated water. The concentration ratio $R = [FeCl_2 \cdot 4H_2O]/[NaOH]$ was equal to 0.6, and the NaOH concentration to 0.2 mol L^{-1}. According to [17], these conditions are adequate for the formation of $Fe(OH)_2$ and β-$Fe_2(OH)_3Cl$ should not form. The suspension was aged 24 h at room temperature. Then, a deaerated solution of $NaHCO_3$ (Fluka, 99%) was added to the suspension so that the ratio $R'' = [NaHCO_3]/[NaOH]$ became equal to 0.9. The resulting precipitate was analysed 24 h and 2 months after the addition of carbonate species in the medium. The pH of the suspension was measured at the same times.

2.3. FT-IR analysis of synthetic Fe(II) hydroxides and hydroxysalts

Synthetic Fe(II) hydroxides and hydroxysalts are very sensitive to the oxidising action of O_2 and a specific procedure had to be developed [17]. The measurements were performed with the Thermo-Nicolet Nexus spectrometer equipped with a KBr beamsplitter and a DTGS detector by use of a Smart MIRacle ATR accessory with a diamond crystal. The precipitate was filtered under vacuum and rinsed with ethanol while being sheltered from air. The paste was then rapidly set on the crystal and covered by a cell insulating the sample holder and allowing a nitrogen flow to pass through. After a complete evaporation of the ethanol remaining in the filtered product, verified by the spectrum pre-visualisation option of the Omnic acquisition software, spectra were recorded with a resolution of 8 cm^{-1} and at least 128 scans. The background was also acquired under the nitrogen flow.

3. Results

3.1. Characterisation of $Fe_2(OH)_2CO_3$ on an archaeological sample

Fig. 1 shows the infrared spectra of two carbonated Fe(II) compounds detected in the inner corrosion layer of the nail of Glinet. The first spectrum (Fig. 1a) corresponds to siderite $FeCO_3$. It is characterised by a large and intense band at 1415 cm^{-1} and sharp peaks at 864 and 737 cm^{-1}. This mineral was already identified in the rust layers of archaeological artefacts [2]. The other spectrum (Fig. 1b) is similar to that of chukanovite reported by [14]. Note that the same spectrum has been reported earlier, and attributed to a "basic ferrous carbonate", that is a hydroxycarbonate [11].

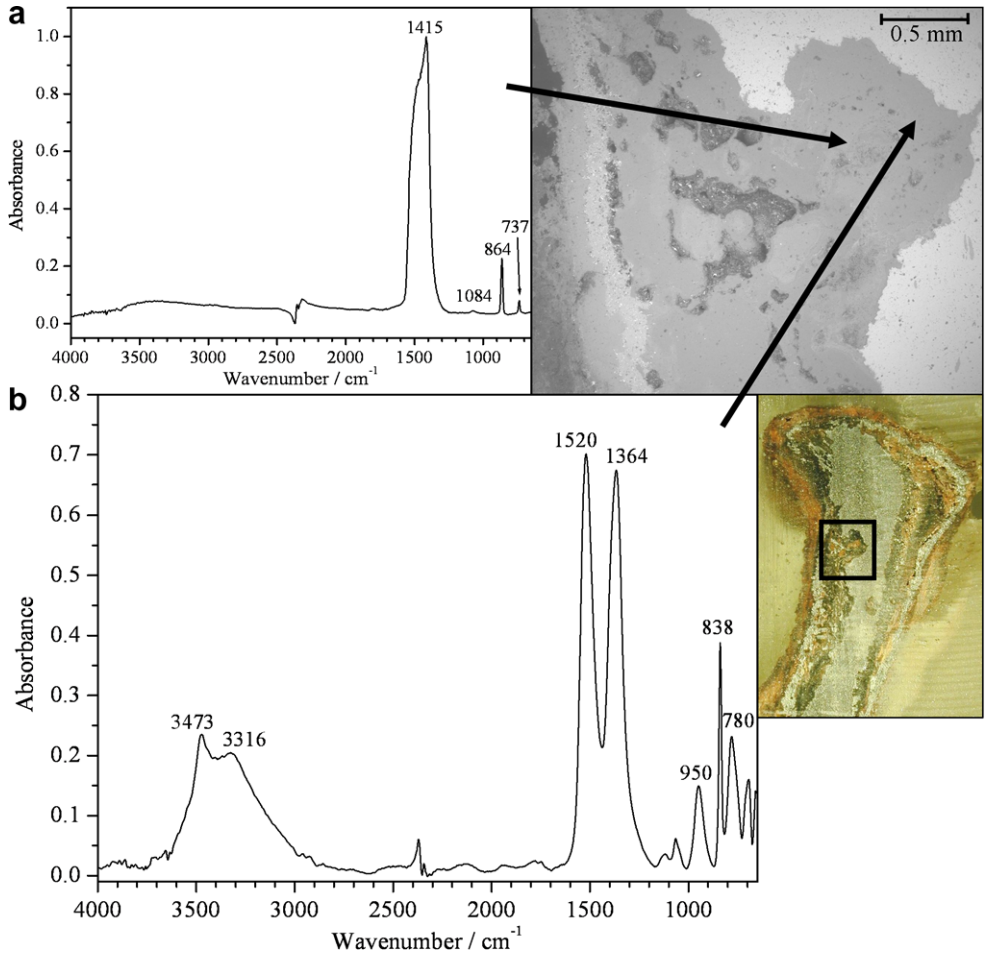

Fig. 1. Photography, micrography and micro-FT-IR spectra of carbonated phases identified on an archeaological iron nail. (a) Siderite, (b) chukanovite.

So, siderite and chukanovite were the only carbonated iron compounds identified in the whole corrosion layer of this sample. Chukanovite was detected on large zones since the surface lightened by the infrared beam during the acquisition could vary between 400 and 2500 μm^2. It was rather localised at the metal/rust layer interface. The products present in the outer parts of the rust layer were mainly magnetite and goethite. These observations are in agreement with previous analyses of similar archaeological nails, achieved using various other techniques [9,10].

3.2. Synthesis of chukanovite

Precipitates obtained with R = 0.6, 0.8 and 1.1 and R′ = 0.1, 0.3, 0.5, 0.7 and 0.9 were analysed. The influence of the concentration of dissolved carbonate species on the nature of the Fe(II) precipitate is studied through the parameter R′. Each precipitate was analysed 24 h after its preparation (Figs. 2–4). An evolution of the composition of the precipitates with R′ can be observed for each R value. Two compounds are clearly identified: Fe(II) hydroxide $Fe(OH)_2$ and chukanovite $Fe_2(OH)_2CO_3$. $Fe(OH)_2$ is identified via the characteristic band at 3624 cm^{-1} [27]. The spectrum of synthetic chukanovite is the same as the spectrum of the corrosion product formed on the archaeological nail. A typical example is the spectrum obtained for R = 1.1 and R′ = 0.9 (Fig. 4).

For the smallest ratio R considered in this study, R = 0.6 (Fig. 2), $Fe(OH)_2$ is present whatever the amount of carbonate species in the medium, as testified by the sharp typical peak of $Fe(OH)_2$ at 3624 cm^{-1}. The spectrum obtained for R′ = 0.1 does not show the

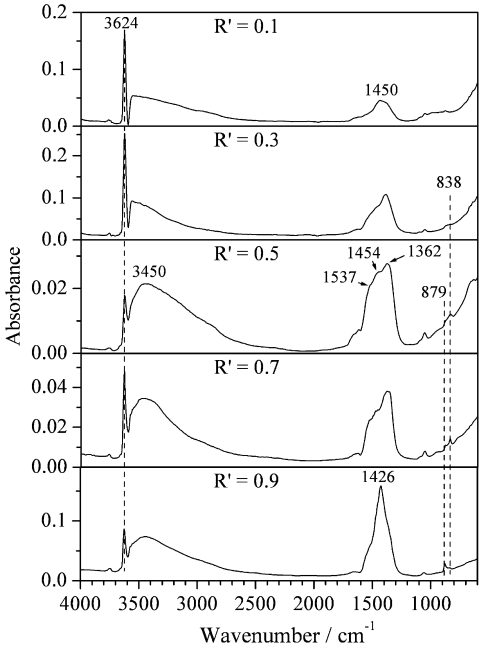

Fig. 2. FT-IR spectra of the Fe(II) precipitates obtained by mixing $FeCl_2 \cdot 4H_2O$, NaOH (0.2 mol L^{-1}) and $Na_2CO_3 \cdot 10H_2O$ solutions with R = $[FeCl_2 \cdot 4H_2O]$/[NaOH] = 0.6 for various R′ = $[Na_2CO_3 \cdot 10H_2O]$/[NaOH] concentration ratios. The precipitates were aged 24 h at room temperature.

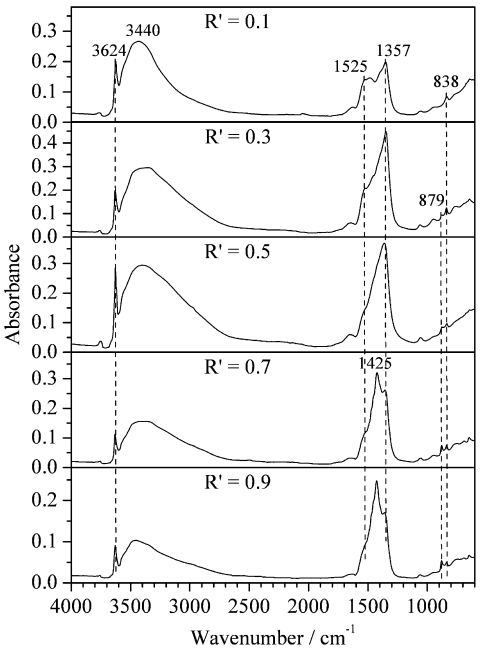

Fig. 3. FT-IR spectra of the Fe(II) precipitates obtained by mixing $FeCl_2 \cdot 4H_2O$, NaOH (0.2 mol L^{-1}) and $Na_2CO_3 \cdot 10H_2O$ solutions with R = $[FeCl_2 \cdot 4H_2O]/[NaOH]$= 0.8 for various R′ = $[Na_2CO_3 \cdot 10H_2O]/[NaOH]$ concentration ratios. The precipitates were aged 24 h at room temperature.

characteristic peaks of chukanovite. However, it presents a large vibration band at 3450 cm^{-1}. This OH stretching mode is more likely due to adsorbed water molecules. This spectrum also shows a weak band at ~1450 cm^{-1}. This band becomes more and more intense as R′ increases which indicates that it relates to carbonate species. As a matter of fact, it is located in the wavenumber region characteristic of the antisymmetric-stretching mode of CO_3^{2-} ions. It does neither correspond to siderite nor to chukanovite (see Fig. 1 for instance) and may correspond to carbonate ions adsorbed on the surface of the $Fe(OH)_2$ crystals or to a hydroxycarbonate with an intermediate composition between $Fe(OH)_2$ and $Fe_2(OH)_2CO_3$, that is $Fe_2(OH)_{4-2x}(CO_3)_x$ with $0 < x < 1$. On the spectra obtained for R′ = 0.5–0.9, a small peak at 838 cm^{-1} is visible. It may also be present for R′ = 0.3. For these R′ values, the band located in the wavenumber region of the antisymmetric-stretching mode of CO_3^{2-} is broad and seems to be constituted of many overlapping peaks. It may result from the superimposition of the doublet of chukanovite at 1537 and 1362 cm^{-1} with the band at ~1425–1455 cm^{-1}. This indicates that a small amount of chukanovite is present.

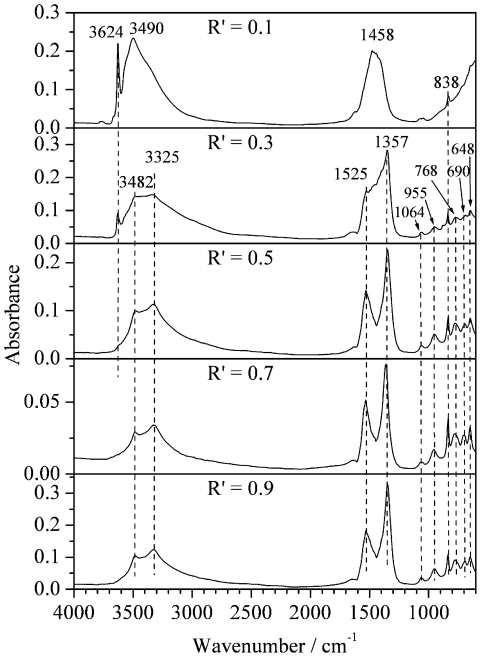

Fig. 4. FT-IR spectra of the Fe(II) precipitates obtained by mixing $FeCl_2 \cdot 4H_2O$, NaOH (0.2 mol L^{-1}) and $Na_2CO_3 \cdot 10H_2O$ solutions with R = $[FeCl_2 \cdot 4H_2O]/[NaOH]$ = 1.1 for various R′ = $[Na_2CO_3 \cdot 10H_2O]/[NaOH]$ concentration ratios. The precipitates were aged 24 h at room temperature.

For the largest value of R considered in this study, that is R = 1.1, $Fe(OH)_2$ is precipitated only for the weakest values of R′, 0.1 and 0.3 (Fig. 4). A small shoulder near 3620 cm^{-1} suggests that it is still present for R′ = 0.5. Chukanovite is present whatever the R′ value, as testified by the presence of its characteristic peak at 838 cm^{-1}. For the largest ratios R′ = 0.7 and 0.9, chukanovite is the only product to precipitate.

For the intermediate ratio R = 0.8, an intermediate situation is observed (Fig. 3). $Fe(OH)_2$ and chukanovite are formed together for every values of R′. The band at ~1425–1455 cm^{-1} already observed for R = 0.6 increases with the value of R′, so that it overlaps with the doublet of chukanovite at 1525 and 1357 cm^{-1}. The increase of a small peak at 879 cm^{-1} with increasing values of R′ is also noticed and this trend is observed for R = 0.6 as well. So the band at ~1425–1455 cm^{-1} and the peak at 879 cm^{-1} are associated and could correspond to the same carbonated species.

3.3. Transformation of $Fe(OH)_2$ into $Fe_2(OH)_2CO_3$

$Fe(OH)_2$ was prepared by mixing deaerated $FeCl_2 \cdot 4H_2O$ and NaOH solutions. The ratio R was chosen equal to R = 0.6, a value sufficiently low to avoid the formation of β-$Fe_2(OH)_3Cl$, i.e. to insure that ferrous hydroxide is the only compound to precipitate. The suspension was aged 24 h in a flask and the solid was analysed by ATR/FT-IR spectroscopy. The spectrum presented in Fig. 5a shows a single sharp peak at 3624 cm^{-1}, which confirms that the only solid phase present at that time was $Fe(OH)_2$. A deaerated solution of $NaHCO_3$ was then added to the suspension, so that the resulting R″ = $[NaHCO_3]/[NaOH]$ ratio was equal to 0.9. The system was then aged at room temperature.

The pH of the suspension was measured 24 h and 2 months after the addition of carbonate species. It increased from

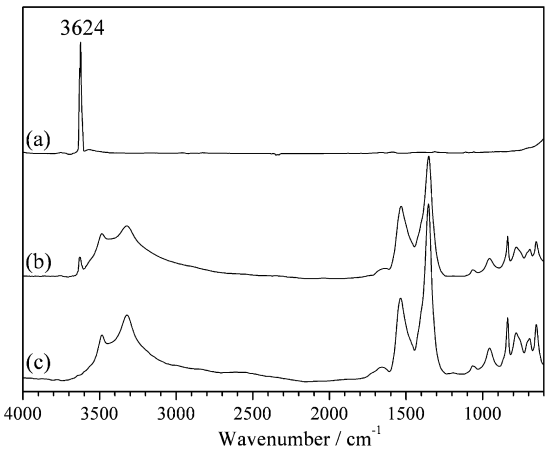

Fig. 5. FT-IR spectra of the Fe(II) precipitate obtained by mixing $FeCl_2 \cdot 4H_2O$ and NaOH solutions with R = $[FeCl_2 \cdot 4H_2O]/[NaOH]$ = 0.6 after 24 h of ageing (a) and after addition of a $NaHCO_3$ solution so that R″ = $[NaHCO_3]/[NaOH]$ = 0.9 and 24 h of ageing (b) or 2 months of ageing (c).

9.06 ± 0.01 to 9.43 ± 0.01. The ATR/FT-IR spectra of the precipitate obtained after the same ageing times are presented in Fig. 5b and c, respectively. It can be seen that after 24 h, the precipitate was already mainly composed of chukanovite. The characteristic peak of $Fe(OH)_2$ at 3624 cm^{-1} was still present, indicating that the transformation was not complete. After 2 months, only chukanovite was obtained.

3.4. Spectral interpretation

The initial precipitate corresponding to R = 1.1 and R′ = 0.9 was analysed after two months of ageing. The spectrum proved to be made of sharper lines as ageing led to an increase of particle size and crystallinity. The spectrum recorded was thus considered as a reference suitable for spectral interpretation. Baseline adjustment and smoothing were performed with the Origin® software. The fitting procedure was performed by use of the Fityk® fitting peaks software with a Voigt function for each peak (Fig. 6).

Chukanovite is related to the minerals of the rosasite group. Comparison was made on the one hand with assignments proposed by [11] and on the other hand with bands of malachite [$Cu_2(OH)_2CO_3$], rosasite [$(Cu,Zn)_2(OH)_2CO_3$] and pokrovskite [$Mg_2(OH)_2CO_3$] between 4000 and 600 cm^{-1} (Table 1). First of all, two main bands are observed at 3481 and 3326 cm^{-1}, that is in the region corresponding to OH stretching vibrations. The fitting of this spectral region revealed four other bands (Fig. 6a). According to the interpretation for rosasite [19,21], the bands at 3538 and 3426 cm^{-1} could be assigned to OH stretching vibrations while the bands at 3222 and 2992 cm^{-1} could be attributed to water adsorbed on the surface of the crystals.

The carbonate C–O stretching region (Fig. 6b) shows two intense bands centred on 1357 and 1525 cm^{-1} corresponding to the ν_3 antisymmetric mode. [11] mentioned three bands at 1530, 1400 and 1355 cm^{-1}. But in fact these are resolved into four bands at 1535, 1500, 1392 and 1358 cm^{-1}. The presence of four bands is interpreted by a lifting of degeneracy due to the site symmetry C_1 of the CO_3^{2-} ions in minerals of the rosasite group [19]. For the same reason, the bands assigned to the ν_4 in-plane bending mode of carbonate ions, centred on 775, 700 and 650 cm^{-1} are splitted in two (Fig. 6c). The band at 1070 cm^{-1} was assigned to the ν_1 symmetric CO_3^{2-} stretching mode because the Raman spectrum collected on the archaeological sample showed the same characteristic peak (Fig. 6d). On the infrared spectrum, it overlaps with a small band at 1053 cm^{-1} that was assigned to a δ OH bending mode. [20] mentioned that in theory the band corresponding to the ν_1 symmetric CO_3^{2-} stretching mode should not be active in infrared but explained its presence by symmetry reduction of the carbonate anion. The band at 955 cm^{-1} can correspond to the one at 880 cm^{-1} for malachite and the one at 870 cm^{-1} of rosasite. For malachite it is assigned to δ OH deformation mode [18,19] since for rosasite the band was mentioned as due to the ν_2 out-of-plane bending mode of carbonate ions [20,21]. Frost et al. [21] indeed mentioned a lifting of degeneracy of this mode characterised by two associated bands at 870 and 818 cm^{-1}. In the case of chukanovite, the sharp band at 836 cm^{-1} is in fact accompanied by a small one at 840 cm^{-1}. It is not quite clear on the considered spectrum. But on the spectrum of natural chukanovite showed by [14] the two peaks are clearly distinguished. They can be assigned to the ν_2 out-of-plane (CO_3^{2-}) bending mode. The band at 955 cm^{-1} can thus be assigned to δ OH bending mode. Bellow 600 cm^{-1}, bands

corresponding to Fe–O interactions can be expected but the ATR SmartMIRacle accessory did not allow to observe them.

4. Discussion

Chukanovite could be obtained alone, that is without $Fe(OH)_2$ or $FeCO_3$, for R = 1.1 and with R′ between 0.5 and 0.7. In other cases, $Fe(OH)_2$ was present together with chukanovite after 24 h of ageing, except for the smallest values of R and R′ where it was obtained alone.

The precipitation reaction of $Fe_2(OH)_2CO_3$ from $FeCl_2$, NaOH and Na_2CO_3 can be written as followed:

$$RFe^{2+} + OH^- + R'CO_3^{2-} + 2RCl^- + (2R'+1)Na^+ \rightarrow 1/2Fe_2(OH)_2CO_3 + (R'-1/2)CO_3^{2-} + (R-1)Fe^{2+} + 2RCl^- + (2R'+1)Na^+ \quad (1)$$

So R = 1 and R′ = 0.5 correspond to the stoichiometric conditions of the formation of chukanovite. For $R \geqslant 1$ and $R' \geqslant 0.5$, Fe^{2+} and CO_3^{2-} ions would remain in excess in the solution while all the OH^- ions are consumed. In agreement, chukanovite was observed as the unique compound forming when R = 1.1 and $R' \geqslant 0.5$ (Fig. 4).

In contrast, $Fe(OH)_2$ was obtained for R = 0.6 and R = 0.8, whatever the R′ value (Figs. 2 and 3), and for R′ = 1.1 with R′ = 0.1 and 0.3 (Fig. 4). This means that, when at least one of the conditions $R \geqslant 1$ or $R' \geqslant 0.5$ is not verified, $Fe(OH)_2$ precipitates. The reaction leading to the formation of $Fe(OH)_2$ is

$$RFe^{2+} + OH^- + R'CO_3^{2-} + 2RCl^- + (2R'+1)Na^+ \rightarrow 1/2Fe(OH)_2 + R'CO_3^{2-} + (R-1/2)Fe^{2+} + 2RCl^- + (2R'+1)Na^+ \quad (2)$$

The stoichiometric conditions are R′ = 0 and R = ½. For R′ > 0 and R > ½, conditions considered in this study, an excess of carbonate species and dissolved Fe(II) species remains in solution.

However, $Fe(OH)_2$ and $Fe_2(OH)_2CO_3$ may precipitate together in proportions related to the values of R and R′. Omitting Cl^- and Na^+ ions that are not involved in the process, the reaction could be written as

$$RFe^{2+} + OH^- + R'CO_3^{2-} \rightarrow \alpha/2Fe(OH)_2 + \beta/2Fe_2(OH)_2CO_3 + (R'-\beta/2)CO_3^{2-} + (R-\alpha/2-\beta)Fe^{2+} \quad (3)$$

with

$$\alpha + \beta = 1 \quad (4)$$

The proportions α and β of $Fe(OH)_2$ and $Fe_2(OH)_2CO_3$ would then be governed by the amount of (i) Fe(II) or (ii) carbonate species available. In the first case, the concentration of Fe(II) dissolved species is negligible after precipitation and the proportions α and β are such that

$$\alpha/2 + \beta = R \quad (5)$$

Eqs. (4) and (5) lead to $\alpha = 2(1-R)$ and $\beta = 2R-1$, with $\beta/2 \leqslant R'$, according to Eq. (3).

If the proportions α and β are governed by the amount of carbonate species available then

$$\beta = 2R' \quad (6)$$

This leads to $\alpha = 1 - 2R'$, with $\beta \leqslant 2R - 1$ according to Eq. (3).

The values of α and β computed for all the experimental conditions considered in the study are listed in Table 2. For R = 0.6, the smallest $[Fe^{2+}]/[OH^-]$ concentration ratio, the proportion of chukanovite is limited to $\beta = 0.2$ whatever R′ by the lack of Fe(II) species. For the value R′ = 0.1, its is simultaneously limited by the lack of Fe(II) and carbonate species. For R = 0.8, the proportion of chukanovite is limited at R′ = 0.1 to $\beta = 0.2$ by the lack of carbonate species and, for larger R′ values, to $\beta = 0.4$ by the lack of Fe(II). This explained why the increase of R′ did not favour the formation of chukanovite. Finally, for R′ = 1.1, the condition $R' \geqslant 1.0$ is verified and the amount of Fe(II) is sufficient to form chukanovite. So, the formation of the hydroxycarbonate is limited by the lack of carbonate species when R′ < 0.5, and chukanovite is the only phase obtained when $R' \geqslant 0.5$.

The pH of the suspensions, measured after 24 h of ageing, is also clearly linked to the species that controlled the formation of chukanovite. Where the amount of chukanovite obtained is limited by the amount of carbonate species, the pH is slightly acidic, since al-

most all the carbonate species are incorporated inside the solid phase and Fe(II) dissolved species are left in excess in the solution. Where the amount of chukanovite is limited by the amount of Fe(II) species, the pH is larger than 10, as CO_3^{2-} anions are in excess in the solution while the Fe(II) species are incorporated inside the solid phase.

Some discrepancies between the computations listed in Table 2 and the experimental results presented in Figs. 2–4 are observed. For instance, at R = 0.6, chukanovite was clearly observed only for $R' \geqslant 0.5$, whereas the same proportion of chukanovite could have been obtained for R′ = 0.1 and 0.3. Three explanations can be given

1. Carbonate species are not only present in chukanovite, as testified by the vibration bands detected on most of the IRTF spectra at 1426 and 879 cm^{-1}.
2. $Fe(OH)_2$ may have formed in some cases as a metastable compound that would transform into chukanovite after a long period of ageing. In the pH range where HCO_3^- predominates (6.4 < pH < 10.3), the corresponding reaction is

$$2Fe(OH)_2 + HCO_3^- \leftrightarrow Fe_2(OH)_2CO_3 + H_2O + OH^- \quad (7)$$

The addition of a $NaHCO_3$ solution to a suspension of $Fe(OH)_2$ led to the formation of chukanovite and to a complete transformation after two months. In agreement with Eq. (1), the pH increased as the transformation proceeded. This experiment was achieved in conditions where R = 0.6 and $R'' = [NaHCO_3]/[NaOH] = 0.9$. It indicates that in similar conditions, that is with small R values and large R′ values, a long period of ageing should lead to the transformation of the initially precipitated $Fe(OH)_2$ into chukanovite.

3. In contrast with the previous explanation, $Fe(OH)_2$ may be stable with respect to chukanovite in the conditions corresponding to the smallest carbonate concentration and the largest pH values. This corresponds to the smallest R and R′ values, i.e. R = 0.6 and R′ = 0.1 or 0.3.

In the absence of any thermodynamic data about chukanovite, it is not possible to argue for one of these explanations. The thermodynamic study of chukanovite, the equilibrium conditions between $Fe(OH)_2$, $FeCO_3$ and $Fe_2(OH)_2CO_3$, and the oxidation process of chukanovite will be the object of another study.

Finally note that in spite of the presence of Cl^- ions in the solutions, brought by the Fe(II) salt $FeCl_2 \cdot 4H_2O$, up to a concentration of 0.44 mol L^{-1} for R = 1.1, no chlorinated compounds were detected. The Fe(II) hydroxychloride β-$Fe_2(OH)_3Cl$ could have been expected in precipitates corresponding to R = 0.8 and R = 1.1, because in these cases, the ratio $[Cl^-]/[OH^-]$ equal respectively to 1.6 and 2.2 is consistent with its formation [17]. This proves that the hydroxycarbonate $Fe_2(OH)_2CO_3$ has formed preferentially to β-$Fe_2(OH)_3Cl$. This is also observed in the case of Fe(II–III) hydroxysalts of the green rust type: Carbonated green rust forms preferentially to chlorinated green rust when both CO_3^{2-} and Cl^- anions are present in the environment [28].

5. Conclusion

Chukanovite $Fe_2(OH)_2CO_3$ could be prepared by precipitation from $FeCl_2 \cdot 4H_2O$, NaOH and $Na_2CO_3 \cdot 10H_2O$ solutions at room temperature. It was characterised by FTIR spectroscopy and each vibration band could be interpreted. In the experimental conditions considered here, that is $[NaOH] = 0.2$ mol L^{-1}, $[FeCl_2 \cdot 4H_2O] = R\,[NaOH]$ and $[Na_2CO_3] = R'\,[NaOH]$, the formation of chukanovite is mainly controlled by the amount of Fe(II) and carbonate species available. $Fe(OH)_2$ is obtained together with chukanovite when the concentration of one of these reactants is not sufficient. The absence of chukanovite for the smallest Fe(II) and carbonate concentrations (R = 0.6 and R′ = 0.1 or 0.3) could not be completely elucidated.

Chukanovite was also identified as one of the main corrosion products of ferrous archaeological artefacts. So, $Fe_2(OH)_2CO_3$ is one of the Fe(II) compounds, with siderite, that has been observed as the result of long term corrosion of iron, while $Fe(OH)_2$ has never been detected in the corrosion layers of the analysed objects reported in literature. Since it was demonstrated that $Fe(OH)_2$ could gradually transform into $Fe_2(OH)_2CO_3$ after long periods of ageing, more likely via a dissolution/reprecipitation mechanisms, it can be suggested that $Fe(OH)_2$ was observed in some of our experiments as a metastable phase that will transform with time into chukanovite. To give ruling on this question, it is necessary to determine the standard Gibbs free energy of formation of chukanovite, which will constitute the next study.

band of the semiconductor, and the ground state potential match the redox level of the redox couple in the electrolyte, thus avoiding energetic losses during the processes of electron transfer and regeneration. Desirably, the dye should contain ligands, most often carboxylate or phosphonate groups, which may firmly attach to the surface of the nanostructured semiconductor [9].

Titanium dioxide electrodes have been successfully sensitized with different polypyridyl–ruthenium complexes. The nc-DSCs sensitized with a *cis*-dithiocyanatobis(4,4′-dicarboxyl-2,2′-bipyridine-)ruthenium(II) complex, dye N3, have shown a high incident photon-to-current conversion efficiency (IPCE) and provided an overall light-to-electricity conversion efficiency of about 10–11% (AM 1.5, 100 mW cm^{-2}). The amphiphilic dyes N-719 and Z-907 both contain two thiocyanates, but have different electron donating ligands attached to their bipyridyl groups. In Z-907 one of the 4,4′-dicarboxyl-2,2′-bipyridine has been replaced with 4,4′-dinonyl-2,2′-bipyridine, thus increasing the hydrophobic character of the dye. The purpose is to improve the stability of the solar cell performance, emerging from the water insolubility of the dye. In previous studies, nc-DSCs sensitized with Z-907 have reached IPCE of 74% (at 540 nm) yielding an overall conversion efficiency of 5.3% (AM 1.5, 100 mW cm^{-2}) [10]. In conjunction with a quasi-solid-state polymer gel electrolyte, an efficiency of more than 6% was reached, and the device sustained heating and showed excellent stability under long-term soaking at 55 °C in full sunlight [11].

As co-adsorbent, the amphiphile hexadecylmalonic acid, HDMA, has been added to sensitizers [12]. Like the dyes N-719 and Z-907, HDMA contains two carboxylate groups by which it is anchored on the TiO_2 surface. By co-grafting, the amphiphiles all together formed an insolating hydrophobic barrier (spacer) for the unwanted back transfer of electrons from the semiconductor to oxidizing species in the electrolyte. nc-DSCs with Z-907 as light harvester and HDMA as co-adsorbent generated improved results as compared to the Z-907 cells lacking the additive, resulting in an overall conversion efficiency of 7.8% under simulated full sunlight (AM 1.5) [12].

A series of polypyridyl–ruthenium complexes with strongly electron donating β-diketonatos replacing the two thiocyanates as an ancillary ligand, have shown good light absorption over the whole visible spectrum extending into the near IR region, resulting in high performances in photoelectrochemical solar cells [13]. The one-electron oxidation of the bidentate diketonato complexes proved to be reversible, contrarily to the irreversible process occurring in monodentate dithiocyanate compounds, a certainly desirable feature for dye molecules, thus offering an improved electrochemical stability of the solar cells. The chelating structure of the β-diketonato ligand is assumed to prevent possible ligand loss processes and nc-DSCs sensitized with the dye $[(dcbpy)_2$-Ru(acetylacetonate)$]Cl^-$ reached a conversion efficiency of 6% (AM 1.5). Long-chain hydrocarbon substituents have been introduced on the β-diketonato ligands in order to suppress unwanted aggregation of dye molecules on the TiO_2 surface [14].

In this work, the performance of nc-DSCs sensitized with a dye composed of N-719, Z-907 or a β-diketonato Ru-complex, and containing room-temperature ionic liquids or a standard organic-liquid-based electrolyte, has been studied. The effect from adding a co-adsorbent of HDMA to the dye or TiO_2 nanoparticles (P25) to the electrolyte was also investigated.

2. Experiments

2.1. Preparation of dye-sensitized nanocrystalline solar cells (nc-DSCs)

Photoelectrodes (also called working electrodes, WE) consisting of a transparent, nanocrystalline, mesoporous titanium dioxide film (12 μm thickness, average particle size 12 nm) on a conducting glass substrate, were prepared from a solution of 36.6 wt% TiO_2 (Degussa P25) in MQ-water. TiO_2 was applied to the fluorine-doped tin oxide glass (Hartford Glass Company Inc.), fixed by Scotch tape, by using the doctor blading technique, and then compressed (600 kg cm^{-2}) [15]. The photoelectrodes were sintered for 30 min at 450 °C in a hot airflow, cooled to 80 °C before transferred into a dye solution and left for at least 4 h. The typical area of the photoelectrode was around 1 cm^2.

The counter electrodes (CE) were platinized by putting a few droplets (0.2 ml) of 5 mM H_2PtCl_6 (Aldrich) in 2-propanol on conducting glass substrates and then heated for 30 min at 380 °C.

The sandwich-structured solar cell was constructed by placing a transparent CE on top of a WE. All solar cells studied were sealed and the electrodes separated by using a thermoplastic thin film, consisting of a 60 μm thick Surlyn frame, as a spacer. The sandwich complex was heated to 120 °C in vaccum for 2 min. An electrolyte was applied to the CE through prefabricated, drilled holes. After being covered by Surlyn and a microscope cover plate, the holes were laminated and a sealed solar cell thus prepared. Finally, silver paint was applied (“Leitsilber”, Hans Wolbring GbmH) on the conducting side of each electrode.

2.2. Photosensitizers

polypyridyl–ruthenium complexes with different electron donating ligands were studied while used as photosensitizers in nc-DSCs. The amphiphilic dyes N-719 and Z-907 have two thiocyanate ligands, but different substituents attached to their bipyridyl groups, see Fig. 1. The chemical formulas of N-719 and Z-907 are $[cis\text{-}Ru(II)(H_2dcbpy)_2(NCS)_2(TBA)_2]$ and $[cis\text{-}Ru(II)(H_2dcbpy)(dnbpy)(NCS)_2]$, respectively, where dcbpy is 4,4′-dicarboxyl-2,2′-bipyridine, dnbpy is 4,4′-dinonyl-2,2′-bipyridine, NCS is thiocyanate and TBA is tetra-n-butylammonium. The sensitizers were both purchased from Solaronix S.A. A batch of Z-907 was also provided as a gift from Dr. M. Zakeeruddin at the Swiss Federal Institute of Technology (EPFL), Switzerland, synthesized as previously described in literature [11].

A polypyridyl–ruthenium complex with a strongly electron donating β-diketonato ligand, $[(dcbpy)_2Ru(acetylacetonate)]Cl^-$, was synthesized according to the procedure described in literature [13]. The dye solutions containing N-719 or the β-diketonato complex were prepared by using 99.9% ethanol as solvent and for Z-907, a mixture of acetonitrile and *tert*-butanol in a volume ratio (1:1) was used, see Table 1.

As co-adsorbent, the amphiphile hexadecylmalonic acid, HDMA (Solaronix S.A.) was added to the sensitizers (Fig. 1).

2.3. Electrolytes

A selection of ionic liquids and one organic-liquid-based standard was prepared to be used as electrolytes in nc-DSCs, see Table 2. The standard electrolyte was prepared by grinding the chemicals into fine particles, before dissolving in an appropriate solvent at room temperature. The iodine-doped, molten-salt electrolytes were prepared by mixing organic sulfonium or imidazolium iodides with elemental iodine, in an iodide-to-iodine-molar proportion 100:1. The organic sulfonium and imidazolium iodides were prepared according to methods that have previously been described, see Refs. [2,8].

The effect of dispersed nanoparticles of titanium dioxide (Degussa P25) in the electrolyte was also studied for solar cells sensitized by the dye N-719. A suspension of typically 1 wt% of P25 TiO_2 in the electrolyte was grinded in an agate mortar, thus forming a gel phase.

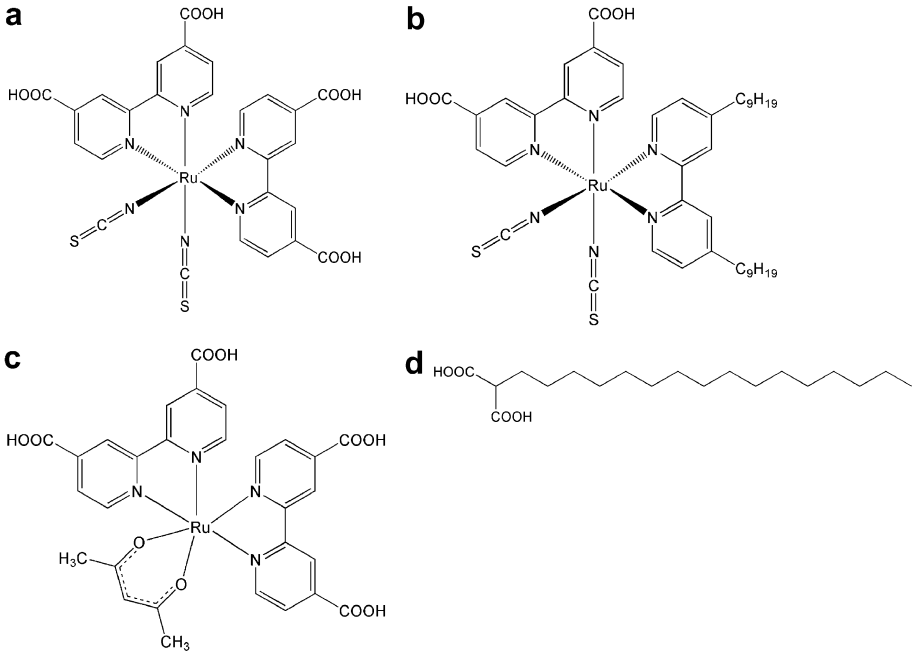

Fig. 1. The molecular structures of the dyes (a) N-719 (b) Z-907 and (c) β-diketonato complex (monopositively charged), and the co-adsorbent (d) HDMA.

Table 1

2.4. Photoelectrochemical measurements

2.4.1. Photocurrent density-photovoltage measurements

The photocurrent density-photovoltage (*J*–*V*) characteristics of a solar cell represents its electrical output, which depends on the collaborative efficiencies of the cell processes, such as excitation by light, separation and migration of mobile charge carriers, injection, transfer and collection of charges. In *J*–*V* diagrams the short-circuit photocurrent density (J_{sc}) and the open-circuit voltage (V_{oc}) are displayed. The fill factor (FF) and overall light-to-electric energy conversion efficiency (η) may be determined using the defined equations:

$$F = (JV)_{MAX}/(J_{sc}V_{oc}) \quad (1)$$

$$\eta = J_{sc}V_{oc}FF/P_s \quad (2)$$

P_s represents the intensity of the incident light (W m^{-2}). The *J*–*V* diagrams were monitored and recorded using a computerized Keithley Model 2400 source/meter. As solar simulator a microwave–powered sulfur plasma lamp, Light drive™ 1000 was used. The obtained electrical power is calibrated versus solar light making the presented efficiencies (η) to correspond to the use of an AM 1.5 simulated solar light spectrum with the light intensity 100–1000 W m^{-2}).

2.4.2. IPCE measurements

The incident monochromatic photon-to-current conversion efficiency, IPCE, or external quantum efficiency, is the product of the quantum absorptivity, the injection efficiency and the current collection quantum efficiency. It expresses the ratio of the number of electrons that reaches the external circuit of the solar cell to the number of incident photons absorbed. It can be described as:

$$\mathrm{IPCE} = hcJ_{ph}/(e\lambda P_s) = 1240J_{ph}/(\lambda P_s) \quad (3)$$

where J_{ph} is the photocurrent density (A m^{-2}), λ the wavelength of monochromatic light (nm) and P_s the input light power density (W m^{-2}), 1240 is the product of the constants *h*, *c* and *e* being the

Planck's constant, the speed of light in vacuum and the elementary charge, respectively. IPCE was recorded as a function of illumination wavelength for a two-electrode solar cell using a computer-controlled potentiostat. IPCE-action spectra were recorded using a computerized set-up consisting of a 300 W arc lamp, a high-intensity monochromator, a Keithley Model 2400 source/meter and appropriate filters and lenses. A Newport 1830-C power-meter with 818-UV detector-head was used for calibration.

3. Results and discussion

3.1. Comparison of the dyes N-719 and Z-907

Photoelectrochemical measurements of nc-DSCs with the dye N-719 showed higher overall light-to-electricity conversion efficiencies than solar cells sensitized with the more hydrophobic dye Z-907, see Table 3. It should be noted, that the results reported represents the calculated average data achieved from measuring two identical solar cells, sensitized with the same dye and containing the same electrolyte. The deviation of the efficiency results was typically ±0.3. The trend, showing the N-719 cells being superior to the Z-907 cells, was applicable to all electrolytes studied and basically due to the higher short-circuit photocurrent densities and open-circuit voltages achieved by the N-719 cells. This was an unexpected result, since the dye Z-907 is more hydrophobic than N-719, based on the long-chain nonyl substituent attached to the bipyridyl ligand. The nonyl group is assumed to form an insolating hydrophobic barrier (spacer) for the unwanted back transfer of electrons from the semiconductor to oxidizing species in the electrolyte, thus expected to result in higher current densities due to reduced dark currents. Also the IPCE results were higher for the N-719-sensitized cells, for all electrolytes studied. However, in 100 W m^{-2} illumination, higher fill factors were achieved by the Z-907 cells, which was most apparent for those containing the most viscous electrolyte, the iodine-doped (HxMeIm)I.

The results achieved by nc-DSCs sensitized with either the dye Z-907 Sol (from Solaronix) or Z-907 Zak (from M. Zakeeruddin, EPFL), were almost identical or within experimental errors, for all electrolytes studied in this work (Table 3).

3.2. Comparison of the dyes N-719 and β-diketonato complex

Nc-DSCs sensitized with the β-diketonato complex $[(dcbpy)_2$-Ru(acetylacetonate)]Cl^- showed lower photoelectrochemical results in comparison to the N-719 cells, see Table 3. However, good overall conversion efficiencies were achieved, especially for those solar cells containing the standard, organic-liquid-based electrolyte, reaching at most 2.1% (100 W m^{-2}, AM 1.5). The β-diketonato sensitized solar cells containing ionic liquid electrolytes obtained open-circuit potentials and fill factors that were comparable to the values produced by the organic-liquid-based cells. However, the short-circuit current densities were poorer, thus resulting in lower conversion efficiencies.

3.3. Addition of co-adsorbent HDMA to the dye

The amphiphile hexadecylmalonic acid, HDMA, was added as a co-adsorbent, to dye solutions of N-719, Z-907 or the β-diketonato complex. Like the dyes, HDMA contains two carboxylate groups by which it may be anchored to the TiO_2 surface, in order to form a

Table 3
Results from *J–V* measurements of solar cells sensitized with different dyes, using a solar simulator with light intensity of 100 or 1000 W m^{-2} (AM 1.5 illumination). The results reported here are calculated average data achieved by two identically sensitized solar cells, containing the same electrolyte.

hydrophobic spacer for unwanted electron transfer to species in the electrolyte. This effect was assumed to be most apparent for solar cells sensitized with Z-907, incorporating the most hydrophobic character of the dyes, due to the long-chain nonyl groups. By co-grafting on the TiO_2 layer the two amphiphiles, Z-907 and HDMA that may form a mixed monolayer, more tightly packed than when the dye is adsorbed alone, the aim was to produce a more efficient insulating barrier to reduce so-called dark currents.

From the photocurrent density-photovoltage measurements, the nc-DSCs containing the standard organic-liquid-based electrolyte, using Z-907 as light harvester and HDMA as co-adsorbent, generated improved overall conversion efficiencies and short-circuit currents, as compared to Z-907 cells without the additive, see Table 3. For the Z-907-sensitized solar cells, an addition of HDMA entailed increased results of η (from 3.7% to 4.0%) and J_{sc} (from 0.94 to 1.07 mA cm^{-2}), thus attaining the highest short-circuit current density achieved in 100 W m^{-2} illumination of all dyes studied in this work (see Table 3). The Z-907 + HDMA-sensitized solar cells containing electrolytes of sulfonium or imidazolium iodide-based ionic liquids gave essentially the same almost similar results, concerning η, J_{sc}, V_{oc} and FF, as those Z-907 cells without the co-adsorbent.

However, for the β-diketonato-sensitized solar cells containing ionic liquid electrolytes, the addition of HDMA to the dye generally gave improved results concerning the short-circuit current densities, the open-circuit voltages, the fill factors as well as the conversion efficiencies. For the solar cells sensitized with the dye N-719, the overall conversion efficiencies were in fact reduced by the addition of HDMA, basically due to decreased short-circuit current densities, observed for all electrolytes studied.

3.4. Addition of TiO_2 nanoparticles to the electrolyte

Titanium dioxide nanoparticles (P25), spherical with a diameter of about 25 nm, were dispersed in the electrolytes, resulting in ionic, nanocomposite, gel electrolytes. Photoelectrochemical measurements of nc-DSCs sensitized with dye N-719 showed that the overall light-to-electricity conversion efficiencies were improved only for those cells containing the standard, organic-liquid-based electrolyte, from 4.1% to 4.6%, and the iodine-doped (HxMeIm)I, from 1.4% to 1.7%, see Table 3. Concerning the organic-liquid-containing cells, the improved η was due to increased V_{oc} and fill factors, and for the (HxMeIm)I cells due to increased J_{sc} and fill factors. For solar cells containing the organic sulfonium iodide-based electrolytes, the results were unaffected by the addition of TiO_2 nanoparticles.

3.5. Variation of the light intensity

For nc-DSCs containing the standard organic-liquid-based electrolyte, the short-circuit photocurrent densities were almost proportionally increased upon changing the light intensity of the solar simulator from 100 to 1000 W m^{-2}, for all sensitizers studied, see Fig. 2. The solar cells sensitized with the dyes N-719 or Z-907 generally showed higher J_{sc} values as compared to the β-diketonato cells, within the light intensity interval studied. However, for each electrolyte the best J_{sc} results were obtained for solar cells of different dye compositions. For the organic sulfonium iodides, solar cells using sensitizers based on Z-907 were most efficient, meanwhile the N-719 based dyes were superior using the imidazolium iodide electrolyte.

In 1000 W m^{-2} illumination (AM 1.5), the highest short-circuit current density, 9.3 mA cm^{-2}, was achieved by the N-719-sensitized cells containing the TiO_2 nanocomposite electrolyte (Table 3). The dye-sensitized solar cells containing the standard, organic-liquid electrolyte achieved short-circuit current densities

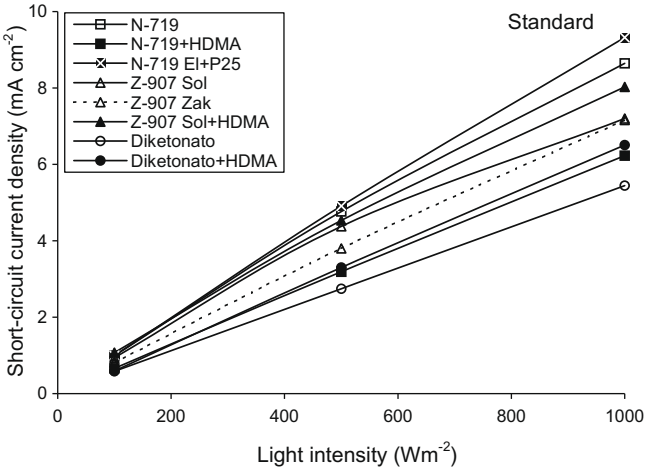

Fig. 2. The short-circuit current density measured at different light intensities for solar cells containing a standard organic-liquid-based electrolyte sensitized with different dyes.

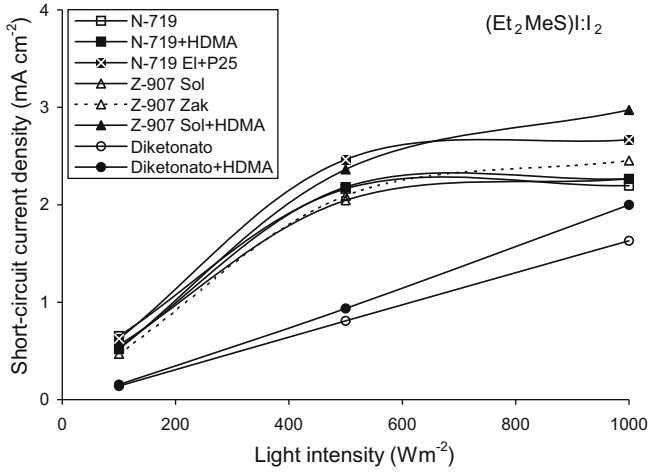

Fig. 3. The short-circuit current density measured at different light intensities for solar cells containing an iodine-doped (Et_2MeS)I electrolyte sensitized with different dyes.

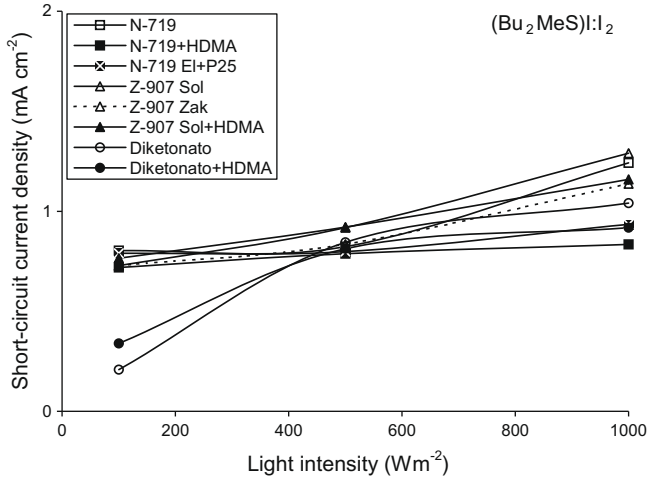

Fig. 4. The short-circuit current density measured at different light intensities for solar cells containing an iodine-doped (Bu_2MeS)I electrolyte sensitized with different dyes.

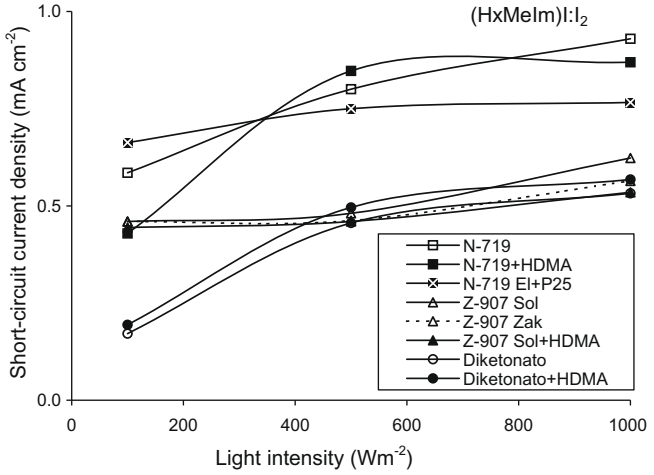

Fig. 5. The short-circuit current density measured at different light intensities for solar cells containing an iodine-doped (HxMeIm)I electrolyte sensitized with different dyes.

ranging from 5.4 to 9.3 mA cm^{-2}, meanwhile the ionic liquid-based cells showed J_{sc} values of 1.6–2.7 mA cm^{-2} for $(Et_2MeS)I:I_2$ (Fig. 3), 0.7–1.2 mA cm^{-2} for $(Bu_2MeS)I:I_2$ (Fig. 4) and 0.5–0.9 mA cm^{-2} for $(HxMeIm)I:I_2$ (Fig. 5).

For most nc-DSCs containing ionic liquid electrolytes, there seem to exist a limited short-circuit current density, a J_{lim} value, which emerges at different light intensities going from 100 to 1000 W m^{-2}. For some sensitizers this saturation phenomenon was observed already at 100 W m^{-2}. A short-circuit current density limitation has formerly been reported for N-719-sensitized solar cells using sulfonium or imidazolium iodide-containing ionic liquids [16].

However, for the solar cells sensitized with the β-diketonato complex containing the $(Et_2MeS)I:I_2$ electrolyte, no short-circuit current density limitation was observed within the intensity interval studied, see Fig. 3. The material transport and the diffusion of triiodides are not limited in these systems because of the low short-circuit current densities.

4. Conclusions

The solar cells sensitized with the dye N-719 showed higher overall light-to-electricity conversion efficiencies than the Z-907 cells, for all electrolytes studied. This is caused by the higher short-circuit photocurrent densities and open-circuit voltages. Since the dye Z-907 is more hydrophobic, expected because of the long-chain nonyl group, it is assumed to form an insulating barrier for the unwanted back transfer of electrons to oxidizing species in the electrolyte, thus resulting in higher current densities due to reduced dark currents.

The addition of an amphiphilic co-adsorbent, the hexadecylmalonic acid (HDMA), resulted in increased overall light-to-electricity conversion efficiencies only for the Z-907 solar cells with an organic-liquid electrolyte. The efficiencies of cells containing sulfonium or imidazolium iodide-based ionic liquids were almost unaffected. The improvement may be explained by co-grafting, as the amphiphilic dye and HDMA together form an insolating hydrophobic barrier.

The presence of TiO_2 (P25) nanoparticles is assumed to support electron transfer reactions in the electrolyte. The dispersion of TiO_2 nanoparticles resulted in improved overall conversion efficiencies only for the N-719 solar cells containing the standard, organic-liquid electrolyte, caused by increased open-circuit voltages and fill factors. The N-719-sensitized solar cells with the nanocomposite-containing, organic-liquid electrolyte achieved the highest short-circuit current density of all cells studied in this work. For solar cells containing the organic sulfonium iodide-based electrolytes, the results were essentially unaffected by the addition of TiO_2 nanoparticles.

In summary, for solar cells sensitized with N-719, Z-907 or the β-diketonato complex and containing electrolytes of sulfonium or imidazolium iodide ionic liquids, no striking improvement concerning the overall conversion efficiency could be noticed by an addition of HDMA to the dye or nanoparticles to the electrolyte.

Acknowledgements

The Swedish National Research Council is acknowledged for financial support. We thank Anna Holmberg, Erik Pettersson and William Kylberg at the Department of Physical Chemistry, Uppsala University, for their help in preparing the solar cells. Henriette Wolpher at the Department of Organic Chemistry, Stockholm University, is acknowledged for the help in the synthesis of the β-diketonato complex. We are grateful to M. Zakeeruddin at Swiss Federal Institute of Technology (EPFL), Switzerland, for his kindness to provide us with a sample of dye Z-907.

co-workers [13]. This protonation constant, which is lower because of the structural difference due to the second nitrogen atom in the ring and to the aliphatic substituents, led us to study the aspergillic acid–Fe(III) system. In fact, in a recent paper [14], we pointed out how a decrease in the basicity of coordinating groups, which induces a decrease of both protonation and complex formation constants, can be accompanied by an increase of pFe, i.e. of the real chelating ability of the ligand. The major problem we encountered was the commercial unavailability of aspergillic acid, which lead us to prepare it via a biosynthetic method starting from *Aspergillus flavus*.

2. Experimental

2.1. Reagents

NaOH, HCl, $HClO_4$, $NaClO_4$, NaCl, KCl, $CHCl_3$, $CDCl_3$, CH_3OH and $FeCl_3$ were purchased from Aldrich. Tryptone was purchased from Microbiol S.n.c.

2.2. Synthesis of aspergillic acid

2.2.1. Growth of Aspergillus flavus

The *A. flavus* strain ATCC 46283 was used in all the experiments (Fig. 1). Spores were grown for 7 days on LB Petri dishes at 25 °C in the dark. An inoculum of 10^5–10^6 spores was grown in 1 L of 2% Tryptone, 5% NaCl at 25 °C for 5 days in the dark without shaking. Heavy, white and wrinkled pellicle was formed 48 h after inoculation. After 5 days the pH of the liquid under the pellicle was 7.5–8. The aspergillic acid yield from a litre of culture was 5–10 mg. The Aspergillic acid production did not change significantly with the use of a yeast extract medium and longer growth time.

2.2.2. Isolation of pure aspergillic acid

The growth medium after 5 days was filtered to separate the spores from the medium solution. One litre of medium was concentrated by low pressure evaporation to a 100–200 mL final volume. The concentrated medium was then extracted with $CHCl_3$. After chloroform evaporation, the crude aspergillic acid was sublimated at low pressure at 75–80 °C. The isolation of pure product from the culture filtrate performed according to the MacDonald procedure [15] did not allow a significantly higher amount of pure product.

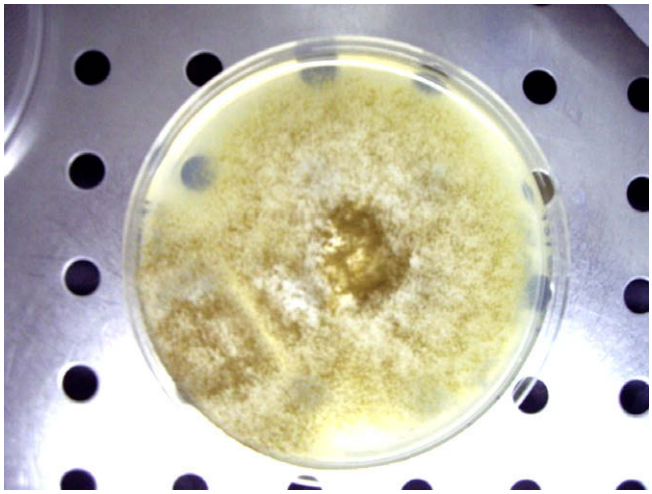

Fig. 1. The *Aspergillus flavus* ATCC 46283 on the LB Petri dish.

2.3. Purity check

The MS experiment was carried out with an Agilent 1200 Series mass spectrometer. Spectra were acquired in the positive ion mode and the solutions were injected into the MS source with a solvent flow rate of 3 μL/min. The temperature of the spray chamber was 200 °C. A capillary 4000 V voltage was applied. Data were obtained in 50–1000 *m/z* range. Purity was also checked by ^{1}H NMR spectra in $CDCl_3$.

2.4. Potentiometric measurements

Potentiometric titrations were performed on CH_3OH:H_2O 80:20 w/w solutions (1.5 mL total volume) using a MOLSPIN automatic titrator with a Russel CMAW 711 microcombined glass electrode (KCl aqueous solution was replaced with 0.1 M NaCl in CH_3OH:H_2O 80:20 w/w) at constant temperature (25 °C) and ionic strength (0.1 M $NaClO_4$) under argon flow using NaOH as the titrant. The pH-meter was calibrated daily in terms of hydrogen ion concentration using $HClO_4$ and a pK_w 14.42 was established. The purity of the ligand and its exact concentration were determined by the Gran method [16]. NaOH was added using a 0.250 mL micrometer syringe calibrated both by weight titration and by standard material titration. The ligand concentration was 4.7×10^{-4} M and the metal:ligand ratios were 1:1 and 1:3. Protonation constants and Fe(III) complex formation constants were calculated using SUPERQUAD [17] and HYPERQUAD [18] programs. The standard deviations computed by SUPERQUAD and HYPERQUAD refer to random errors only; they are, however, good indicators of the importance of a particular species at equilibrium [19].

2.5. UV–Vis absorption spectroscopy

Absorption spectra were recorded on a Cary 300 Bio spectrophotometer. The spectra were obtained in the 2–10.5 pH range on solutions containing metal:ligand molar ratios 1:1 and 1:3 at constant ligand concentration 2.4×10^{-3} M. The molar absorptivities were calculated at the maximum concentration of each species obtained from the potentiometric results.

2.6. NMR measurements

^{1}H NMR spectra were determined on a Varian Inova-400 spectrometer at 399.94 MHz, with a 5 mm diameter sample tube at 25 °C. ^{1}H NMR spectra were recorded in $CDCl_3$, and chemical shifts were referenced to TMS.

2.7. Quantum chemical calculations

Theoretical calculations were performed with the SPARTAN'06 program [20]. The geometries were optimised using semi-empirical [21] methods, with the AM1 [22] and AM1/SM2 [23,24] for ligands and PM3 [25] basis sets for metal complexes.

3. Results and discussion

3.1. Pure ligand

The purity of aspergillic acid obtained with the procedure described in the Section 2 was checked using MS and ^{1}H NMR spectra. The MS spectrum of pure aspergillic acid ($C_{12}H_{20}N_2O_2$), showing an ion at 225.1585 *m/z* and isotope forms at 226.1618 and 227.1562 *m/z*, is shown in Fig. 2. The aspergillic acid exists also in the minor oxidised form at 223.1439 *m/z*. The signal due to the isotope form of the oxidised species at 225.1505 *m/z* is masked

by the signal at 225.1585 *m/z* of aspergillic acid. All the obtained results are in good agreement with the freeware ISOPRO 2.1 computer calculations (Table 1) and confirm that the synthesized product was aspergillic acid. The ^{1}H NMR spectrum of aspergillic acid (Fig. 3) also confirms the purity of product. The δ (ppm) values of the signals agree with those reported by Brotzu et al. [26], even though a different appearance of the 400 MHz spectrum with respect to that at 100 MHz presented in the cited paper. In Table 2 ^{1}H NMR data with their relative assignments are reported. As can be observed in Fig. 3, the signals of the different protons are split in two distinct parts that can be attributed to two different isomers of aspergillic acid. Impurities of the same magnitude order of the main molecule can in fact be ruled out on the basis of the mass spectrum in Fig. 2. We can then hypothesize, in agreement with Brotzu et al. [26], that there exist two isomers in which the two

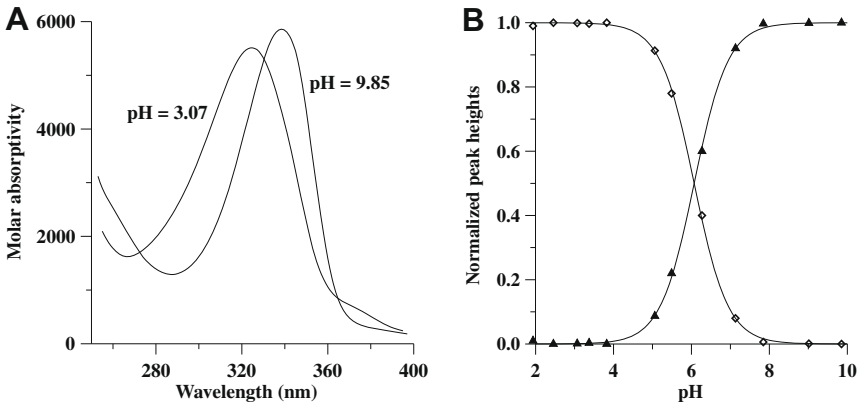

Fig. 4. (A) Absorptivity spectra of aspergillic acid in the acidic and basic forms. (B) Distribution plots of aspergillic acid calculated with log$K$ = 6.07 potentiometrically determined (continuous lines), and normalized heights (symbols) of the peaks at 308 nm (acidic form HL) and 344 nm (basic form L^-).

alkylic groups are interchanged. This is supported by the findings of MacDonald [27] who, working with radioactive ^{14}C leucine and isoleucine, demonstrated that these compounds were incorporated in the formed aspergillic acid. It would be thus equivalent to obtain one or the other of the two isomers, since the aspergillic acid biosynthesis occurs from these two amino acids. Aspergillic acid is a monoprotic acid (HL) characterized by a hydroxamic acid proton. The potentiometric titration in methanol:water 80:20 w/w solution shows one protonation with log$K$ 6.07, which seemingly differs from the log$K$ 5.3 reported by Dutcher [9], or from the log$K$ 5.5 reported in the Merck Index [28]. It should be noted that the medium is reported neither by Dutcher nor by the Merck Index. The log$K$ value of 6.07 obtained by potentiometric titrations is supported by the results of spectrophotometric measurements. Twelve spectra were collected in the pH interval 2–10, of which those at pH 3.07 and 9.85 are reported in Fig. 4A as an example. The 12 spectra were decomposed into the component Gaussian peaks with the SPECPEAK program [29]. The normalized heights of the band centred at 308 nm (attributable to the acidic form HL) and of the band at 344 nm (attributable to the basic form L^-) are reported as symbols in Fig. 4B. On the same figure, the distribution plots are also reported as continuous lines, calculated with the log$K$ = 6.07 obtained from potentiometric measurements; a perfect agreement can be observed.

3.2. Iron complexes

The complex formation equilibria between aspergillic acid and Fe(III) were studied both potentiometrically and spectrophotometrically. In fact, since iron was almost completely complexed at the starting of the potentiometric titration, the first complex formation constant of ML species had to be determined only spectrophotometrically. A set of 12 solutions in the ~1–2.5 pH range was prepared by additions of HCl, then spectra were collected. In all the work pH represents –log[H^+] at constant ionic strength 0.1 M; in strongly acidic solutions the ionic strength 0.1 M was reached by proper amount of HCl and NaCl. The spectra show a band centred at ~470 nm of increasing intensity, whose appearance changes when the pH further increases (Fig. 5). The visible bands in the molar ratio 1:3 solutions progressively disappear after pH ~6 with an increase of the baseline, indicating the breaking of iron complexes with the formation of iron hydroxides and free ligand. In solutions with a 1:1 molar ratio, the precipitation of iron takes place at pH 4. The analysis of the spectrophotometric data in the pH range ~1–2.5 with the SPECFIT program [30–32] allowed the evaluation of

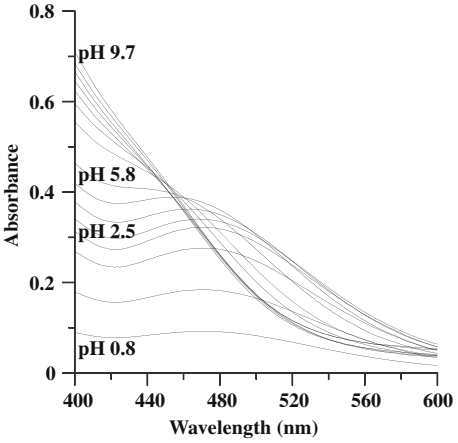

Fig. 5. Visible spectra of the system Fe(III)–aspergillic acid with a total iron concentration of 8×10^{-4} M and a total ligand concentration of 2.4×10^{-3}, optical path 0.5 cm.

Table 3
Complex formation constants estimated from potentiometric and spectrophotometric measurements for the Fe(III)–aspergillic acid system*. Wavelengths of maxima and absorptivities for ligand and all complex species.

Species	Logβ	λ (nm)	ε (cm^{-1} mol^{-1} L)
HL	6.07(4)	324 (HL)	5400
		339 (L^-)	5900
FeL	7.92(2)	310	6000
		464	772
$FeH_{-1}L$	3.69(5)	310	6255
$FeH_{-2}L$	−0.13(5)	311	6872

* Hydroxide formation constants were FeH_{-1} −2.56, FeH_{-2} −6.20, FeH_{-3} −11.41, FeH_{-4} −21.88, Fe_2H_{-2} −2.84 and Fe_3H_{-4} −6.05 [34].

the formation constant 7.92 for FeL^{2+} complex. The potentiometric data relative to the titrations at different molar ratios were then processed with the HYPERQUAD program [18] keeping fixed the value 7.92 for FeL^{2+} formation. The complex formation model reported in Table 3 with the relative stability constants was obtained, and the distribution curves are illustrated in Fig. 6. The chelating behaviour of aspergillic acid can be compared with those of 1-hydroxy-2-pyridinone and 1,4-dihydroxy-2-pyridinone (Table 4 and Fig. 7), both of which are characterized by a hydroxamic group inserted into an aromatic ring. The distribution curves together with the numerical values enable a direct comparison of the formation constants, taking into account the proton competition and the different stoichiometries. As far as the 1-hydroxy-2-pyridinone is

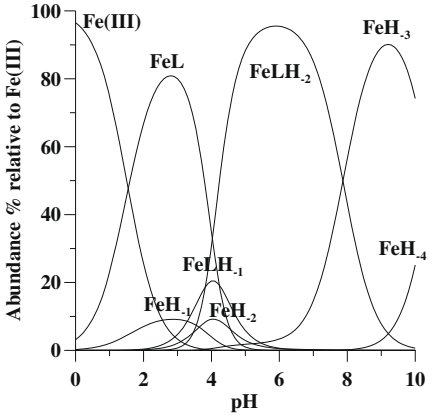

Fig. 6. Distribution plot of the Fe(III)–aspergillic acid system at 1:3 metal/ligand ratio, with a total iron concentration of 1.5×10^{-4} M, and a total ligand concentration of 4.7×10^{-4}.

Table 4
Literature protonation and iron(III) complex formation constants for 1-hydroxy-2-pyridinone and 1,4-dihydroxy-2-pyridinone.

Species*	1-Hydroxy-2-pyridinone		1,4-Dihydroxy-2-pyridinone [11]
	[12]	[13]

concerned, we remark the significative difference between the second protonation constants of Li and Martell [12] and Scarrow et al. [13], $\log K_2$ 1.2 and −0.9, respectively, that at acidic pH values greatly affects the distribution plots for the pure ligand and for iron complexes. The found differences are to be ascribed to the fact that potentiometric and/or spectrophotometric measurements were used to determine the protonation constant β_{H2L} and the complex formation constant β_{FeL}. In the actual cases in which the equilibria lie outside the range of potentiometric measurements, the use of spectrophotometric measurements allows to obtain more reliable results. At any rate, the formation of the FeL^{2+}, FeL_2^{+} and FeL_3 complexes is unquestionable, as for most hydroxypiridinones, with the last complex completely formed at pH 4. More interesting is the case of 1,4-dihydroxy-2-pyridinone that results in the formation of $FeLH^{2+}$, $FeL_2H_2^{+}$ and $FeL_3H_2^{-}$ (similar to the previous FeL^{2+}, FeL_2^{+} and FeL_3 complexes with the phenolic group in the protonated form). These occur at pH values higher than those observed in the case of 1-hydroxy-2-pyridinone complexes. In our opinion, this is to be ascribed to the fact that the two protonation constants are in reality macroconstants, and that the protonation of the hydroxamic group takes place at a pH higher than in the case of 1-hydroxy-2-pyridinone. The proton competition with iron for the hydroxamic group is consequently higher and the complex formation is delayed. The binding modes of aspergillic acid are completely different from those of the other cyclic hydroxamates; in fact, it does not form complexes of 1:2 and 1:3 stoichiometries, but the FeL^{2+} complex stabilizes with the loss of two protons from the coordinated water molecules, with p*K* values of 3.8 and 4.2. This is in strong contrast with the behaviour of the two hydroxypyridinones, especially taking into account the medium used. In order to find an explanation for this different behaviour of aspergillic acid, we performed a quantum mechanical study of the most stable isomer of the complexes with different stoichiometries, i.e. FeL_2^{+} and FeL_3 on one side, and $FeLOH^{+}$ and $FeL(OH)_2$ on the other. Apart from the energetic results, which are not directly comparable, the analysis of the structures presented in Fig. 8 allows us to obtain some significant insight: the FeL_2^{+} and above all the FeL_3 structures show that hydrophobic cages around the central metal ion are formed when aspergillic acid coordinates FeL^{2+}, at the same time neutralizing the charge of the complex. This fact, also observed

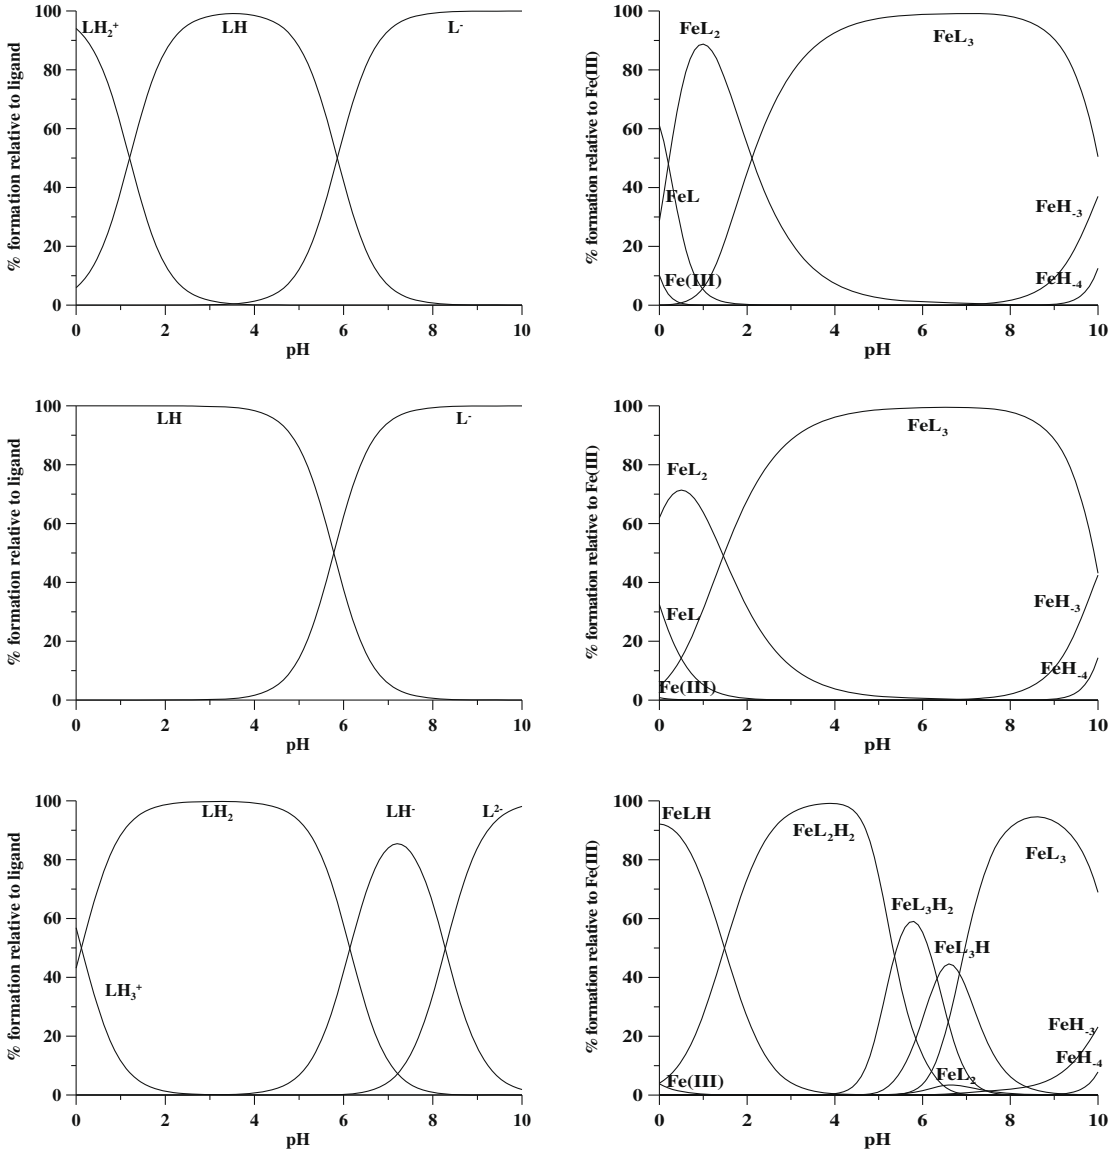

Fig. 7. Protonation and Fe(III) complex distribution plots for system at a total metal concentration of 1×10^{-3} M and a total ligand concentration of 3×10^{-3} M; in the upper plots the ligand is 1-hydroxy-2-pyridinone, stability constants from Ref. [12]; in the medium plots the ligand is 1-hydroxy-2-pyridinone, stability constants from Ref. [13] and in the lower plots the ligand is 1,4-dihydroxy-2-pyridinone, stability constants from Ref. [11].

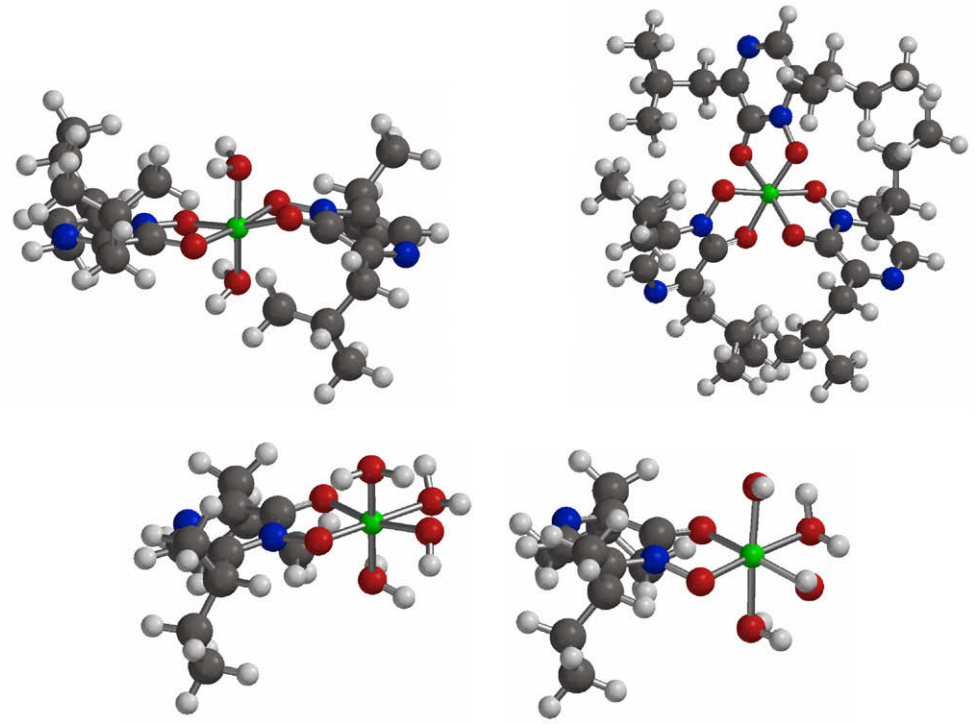

Fig. 8. SPARTAN'06 calculated structures of the most stable isomer of the FeL_2^+ (upper left), FeL_3 (upper right), $FeLOH^+$ (lower left), and $FeL(OH)_2$ (lower right) complexes.

in the low water medium used in our study, prevents a positive interaction of the FeL_2^+ and FeL_3 complexes with the solvent, and therefore, creates unfavourable conditions for the formation of such complexes. On the other hand, the formation of the hydroxo complexes $FeLOH^+$ and $FeL(OH)_2$ stabilizes the already hydrophobic 1:1 complex FeL^{2+} by creating positive interactions of the coordinated OH^- groups via hydrogen bonds with the solvent. Summing up, even though aspergillic acid cannot be classified as an iron chelator and taken into account for the treatment of iron overload, its characteristic coordination model is useful to clearly demonstrate the effect of a hydrophobic side chain in determining the coordination modes of the ligand.

Acknowledgements

V.M.N. thanks Fondazione Banco di Sardegna for the financial support. J.I.L. is in-debt with Prof. H. Kozlowski for the availability of the Molspin titrator and for the helpful discussions and with N. Zinnarosu for NMR spectra collection. All the authors express gratitude to Prof. S. Cosentino and Dr. B. Pisano for their useful advice and assistance in biological procedures.

Complex **2** can be also prepared in reaction of $Na_4[Rh_2(CO_3)_4] \cdot 2.5H_2O$ with ethanimidamide hydrochloride ($CH_3C(=NH)NH_2 \cdot HCl$) in water containing 20% of DMSO, however, the yield of reaction is low.

Single crystals of $[Rh_2\{HN(HN{=})CCH_3\}_4\{OS(CH_3)_2\}_2]Cl$, **2**, for X-ray measurements were obtained in tubes (diameter 5 mm) by slow diffusion of THF into the solution of complex **1** in DMSO.

2.3. X-ray crystallographic measurements

X-ray data were collected at low temperature using an Oxford Cryosystem device on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated MoKα radiation ($\lambda = 0.71073$ Å). Accurate cell parameters were determined and refined by least-squares fit of the strongest reflections. The data were corrected for Lorentz and polarization effects as well as for analytical absorption correction. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) Sp. z o.o. programs. The structure was solved by direct methods (program SHELXS97 [17]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL97 [18] programs. Non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms were included from geometry of molecules and $\Delta\rho$ maps. They were fixed or treated as riding groups during refinement of the structure.

2.4. Computational details

The molecular and electronic structure UV–Vis and IR spectra of the complex **2** of C_i symmetry have been studied with the GAUSSIAN

3. Results and discussion

Complex $[Rh_2\{\mu\text{-}HN(HN{=})CCH_3\}_4(H_2O)_2]Cl \cdot H_2O$, **1**, can be easily obtained in reaction of the $Na_4[Rh_2(CO_3)_4] \cdot 2.5H_2O$ with ethanimidamide hydrochloride ($CH_3C(=NH)NH_2 \cdot HCl$) what allows to decompose sodium tetracarbonatorodate with evolving of CO_2. During reaction in air rhodium(II) is easily oxidized by oxygen: $2Na_4[Rh_2(CO_3)_4] + 10CH_3C(=NH)NH_2 \cdot HCl + 0.5O_2 \rightarrow 2Rh_2\{HN(HN{=})CCH_3\}_4(H_2O)_2]Cl + CH_3C(=NH)NH_2 + 8CO_2 + 8NaCl + 7H_2O$

The complexes **1** and **2** are soluble in water, dimethyl sulfoxide, *N*,*N*-dimethylformamide and similar solvents. They are stable in air both in solutions and solid state. Ligands coordinated in axial positions are easily substituted by solvent molecules giving $[Rh_2\{HN(HN{=})CCH_3\}_4(solv)_2]^+$ cations (*c.f.* UV–Vis spectra). An X-ray crystallography revealed that complex **2** crystallizes in the $P\bar{1}$ space group crystallographic data are given in Table 1 and selected bond lengths and angles in Table 2. The ORTEP view of the complex **2** is depicted in Fig. 1. There are two independent molecules in the crystal. Each of rhodium atoms has distorted octahedral coordination. The equatorial positions are occupied by four nitrogen atoms of bridging ethanimidamidato ligands. The remaining axial coordination sites are occupied by the sulfur atom of dimethyl sulfoxide ligand and rhodium atom. The Rh1–Rh#1 and Rh2–Rh#2 distances differ only sightly and are equal to 2.5108(14) Å and 2.5104(15) Å, respectively. Thus the Rh–Rh bonds in compound **2** are longer for *c.a.* 0.05–0.06 Å than those in other amidine Rh_2^{5+} complexes (Table 3) [1,9–11], however, the Rh–N distances are similar to those in other $[Rh_2(RC(=NR')NR'')_4]^+$ compounds. The elongation of Rh–Rh bond is caused by coordination of dimethyl sulfoxide ligands via S atoms, which are considerably more soft Lewis bases than O or N ligands and show relatively strong trans influence. Both molecules have eclipsed conformation. Torsion angles are very small: N2–Rh1–Rh#1–N#4 = 2.1°, N3–Rh1–Rh#1–N#1 = 1.3°, N12–Rh2–Rh#2–N#14 = 0.2°, N11–Rh2–Rh#2–N#13 = 0.0°. The O atoms are in transoidal positions, the torsion angle O1–S1–S#1–O#1 = 180°.

with that in the crystal in complex **2**, the molecular and electronic structures of this cation have been studied with unrestricted DFT methods. The B3LYP functional with 3-21G* basis set was applied for geometry optimization and IR spectra calculations. The excitation energies were calculated with MPW1PW91 TD method with a 3-21G* basis set. The optimized interatomic distances and angles agree well with the crystallographic data (Table 2). The greater differences were observed for Rh–Rh bond, shorter by 0.03 Å, and Rh–S bond, longer by 0.1 Å, than those in solid state. This suggests strong mutual trans influence of Rh–Rh and Rh–S bonds, the shorter Rh–Rh distance the longer Rh–S bond. The energy of molecular orbitals increase in the series: $\sigma_{RhRh}\sigma_{RhS} < \sigma^*_{RhRh}\sigma_{RhS} < \pi_{HNCNH} < \pi_{RhRh}\pi_{RhS} < \delta_{RhRh} < \sigma_{RhRh}\sigma^*_{RhS} < \pi^*_{RhRh}\pi_{RhS} < \delta^*_{RhRh}$(SOMO) $< \pi^*_{NCN} < \sigma^*_{RhRh}\sigma^*_{RhS}$ (Fig. 2, Table 4). The rhodium d orbitals are relatively delocalized, the σ_{RhRh} and π_{RhRh} orbitals are at the same time bonding or antibonding rhodium–ligand orbitals (Fig. 3). The δ^*_{RhRh} (SOMO) orbital is also, to some extent, delocalized onto the bridging HN–C–NH groups with the $\pi^*_{RhndashHNCNH}$ character. The calculated excitation energies agree very well with electronic spectrum of complex **2** (Table 5). The most intense band in the visible region observed at 16500 cm^{-1} in the spectrum of $[Rh_2\{HN(HN{=})CCH_3\}_4\{OS(CH_3)_2\}_2]Cl$, **2**, in DMSO should be mainly assigned to the $(\sigma_{RhRh}\sigma^*_{RhS}) \rightarrow (\delta^*_{RhRh}\pi^*_{NCN})$ (SOMO), $(\pi_{RhRh}\pi_{RhS}) \rightarrow (\delta^*_{RhRh}\pi^*_{NCN})$ (SOMO) and $(\delta_{RhRh}\pi^*_{NCN}) \rightarrow (\delta^*_{RhRh}\pi^*_{NCN})$ (SOMO) transitions. The participation of other transitions is much lower. The participations of δ^*_{RhL} and π_{RhL} orbitals to the Rh–Rh orbitals explain the dependence of energy of this band on the ligands L coordinated along the Rh–Rh axis. Thus transitions in the spectra in the region 12000–19500 cm^{-1} should be assigned to the transition between orbital with prevailing participation of d orbitals of rhodium and bands of energy above 25000 cm^{-1} to the MLCT from d orbitals to π^*_{HNCNH} antibonding orbitals. The most intensive band in the visible region in the spectrum of **2** is shifted to higher energy when hard ligands are coordinated in the axial coordination sites and to lower energy in the case of soft ligands (Table 6). Thus this band for compound **1** in water solution is observed at 18500 cm^{-1}, in $H_2O + 3Br^-$ at 17700 cm^{-1}, in $H_2O + 3I^-$ at 17500 cm^{-1} and in DMSO at 16500 cm^{-1}.

The EPR spectrum of complex **2** in DMSO solution shows an axial signal with $g_\perp = 2.0670$ and $g_\parallel = 1.9627$ at 78 K, the latter of which is split into a 1:2:1 triplet ($A_\parallel = 2.5$ mT) by the two equivalent rhodium nuclei. The $g_\parallel < g_e < g_\perp$ is consistent with the main occupation of δ^*_{RhRh} SOMO orbital and confirms the results of calculations. Very similar spectra were observed for *N,N′*-diarylamidine Rh_2^{5+} complexes [9,10]. The EPR spectra of complex **2** in DMSO in the presence of $[NEt_4]CN$ revealed that CN^- anions are coordinated along Rh–Rh axis (Fig. 4). At the **2**:CN = 1:1 EPR spectrum shows

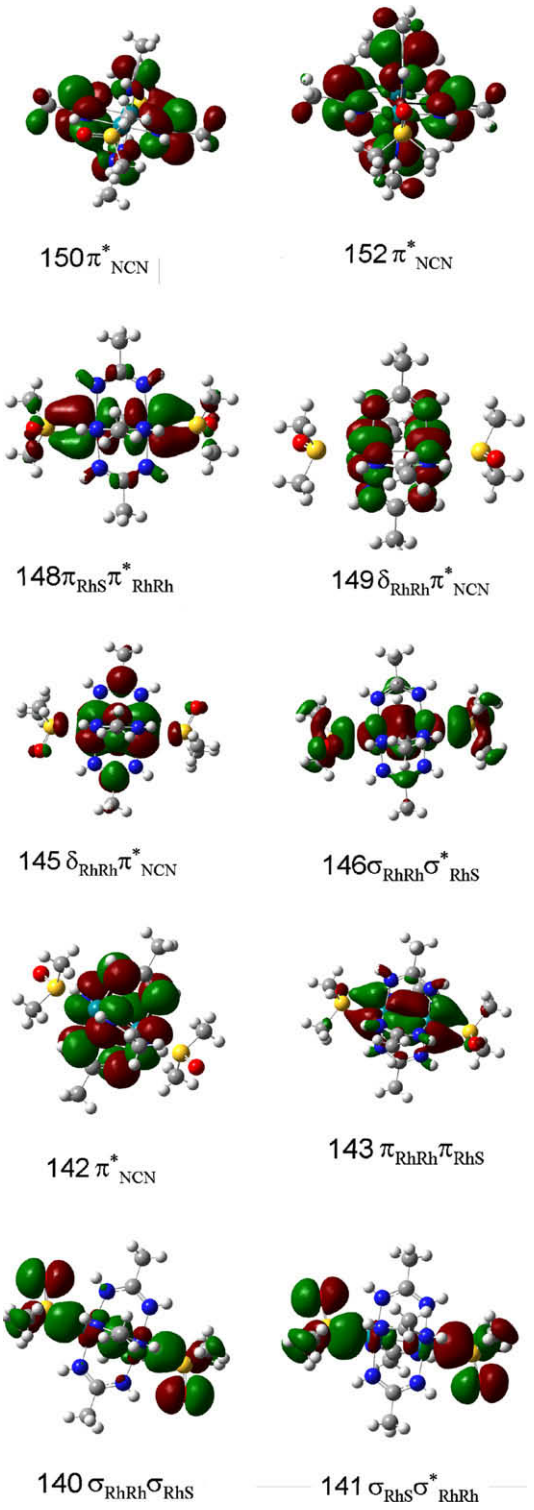

Fig. 3. Molecular orbitals of $[Rh_2\{HN(HN{=})CCH_3\}_4\{OS(CH_3)_2\}_2]^+$ (Rh – blue, N – deep-blue, O – red, S – yellow). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

the presence of two compounds: [Rh_2(μ-HN(HN=)CCH_3)$_4$($DMSO)_2$]$^+$ ($g_\perp$ = 2.0670 and $g_\parallel$ = 1.9635) and [Rh_2(μ-HN(HN=)CCH_3)$_4$(CN)(DMSO)]$^+$ ($g_\perp$ = 2.0892, $g_\parallel$ = 2.0206 and $g_\parallel$ = 2.0072) of similar concentration. The latter complex shows two $g_\parallel$ values because rhodium atoms are not equivalent. At the **2**:CN = 1:2 only small amount of complex [Rh_2(μ-HN(HN=)CCH_3)$_4$(CN)(DMSO)] is observed, the prevailing form is [Rh_2(μ-HN(HN=)CCH_3)$_4$$(CN)_2$]$^-$ ($g_\perp$ = 2.0884 and $g_\parallel$ = 1.9470). The spectrum of complex **2** in DMSO:H_2O = 1:1.5 at **2**:NaCN = 1:3 revealed that in solution was present only dicyano complex [Rh_2(μ-HN(HN=)CCH_3)$_4$$(CN)_2$]$^-$ ($g_\perp$ = 2.0813 and $g_\parallel$ = 1.9552).

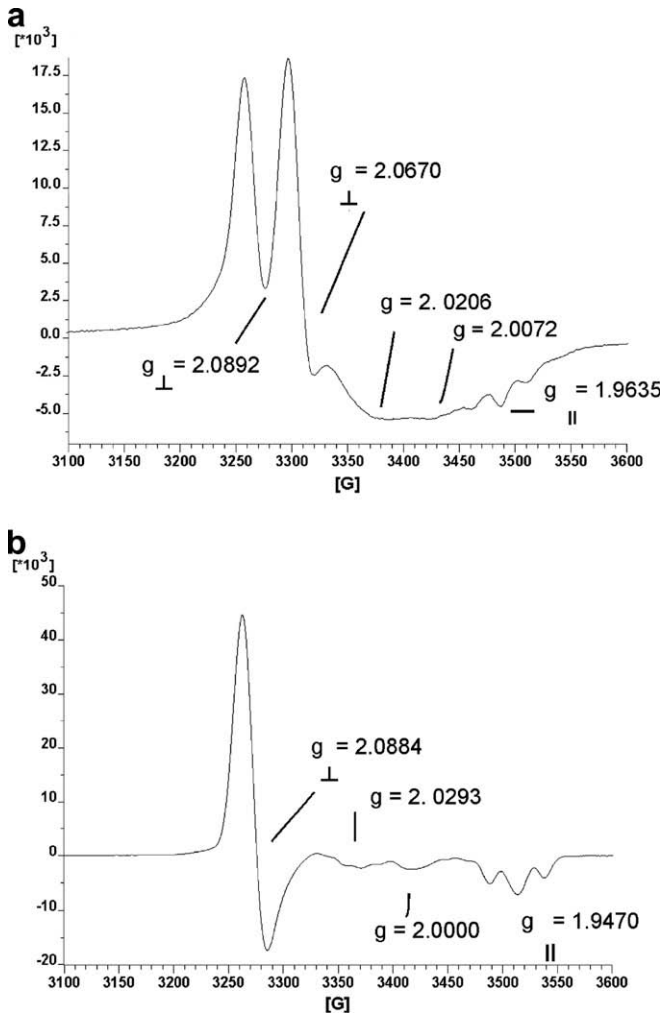

Fig. 4. EPR spectra (77 K) of frozen DMSO solutions of [Rh_2{HN(HN=)CCH_3}$_4$-{$OS(CH_3)_2$}$_2$]Cl + [NEt_4]CN at molar ratios: a – 1:1, b – 1:2.

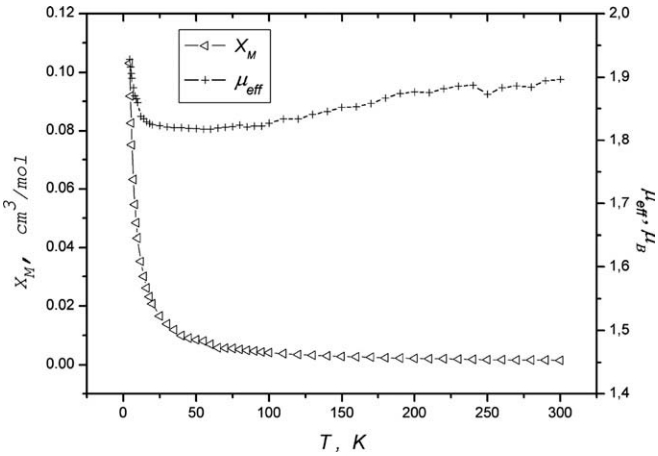

Fig. 5. Temperature dependences of molar magnetic susceptibility and effective magnetic moment for [Rh_2{HN(HN=)CCH_3}$_4${$OS(CH_3)_2$}$_2$]Cl, **2**.

The IR spectrum of complexes **1** and **2** shows very intense ν(OH) and ν(NH) vibrations in the region 3550–3250 cm^{-1}. The strong bands assigned to the ν^{as}(CNN) and ν^{s}(CNN) stretching vibrations are observed at 1503 and 1295 cm^{-1}, respectively. They have also δ(NH) character. The band at 1060 cm^{-1} in the spectrum of **2** should be assigned to the ν^{as}(S=O) vibration with some participation of $\delta(CH_3)$ of ethanimidamidato and DMSO ligands and band at 1022 cm^{-1} to the ν^{s}(S=O) with participation of $\delta(CH_3)$ of DMSO. These bands were not observed in the spectrum of compound **1**. The energy of these vibrations is relatively low as compared with mononuclear DMSO complexes with M–S bond [20].

The dependences of the magnetic susceptibility and magnetic moment for the complex **2** on temperature are shown in Fig. 5. The magnetic moment at 300 K is equal to 1.986 μ_B and is slightly greater than the spin only moment. This suggests slight orbital contribution to the magnetic moment. The magnetic moment slightly diminishes with decreasing of temperature to about 50 K and at lower temperatures again increases to the 1.928 μ_B.

4. Conclusion

Dinuclear Rh(II)Rh(III) complex [[Rh_2(μ-HN(HN=)CCH_3)$_4$($H_2O)_2$]Cl · H_2O (**1**) containing Rh_2^{5+} core can be easily prepared in the reaction of $Na_4[Rh_2(CO_3)_4] \cdot 2.5H_2O$ with ethanimidamide hydrochloride (CH_3C(=NH)NH2 · HCl) at molar ratio of 1:10. Aqua ligands can be easily substituted by DMSO giving complex [Rh_2(μ-HN(HN=)CCH_3)$_4$$(DMSO)_2$]Cl (**2**) The EPR spectra of complexes **1** and **2** and calculations accomplished for [Rh_2{μ-HN(HN=)CCH_3}$_4$$(DMSO)_2$]$^+$ cation using DFT B3LYP and MPW1PW91 methods with 3-21G* basis set indicate that δ^*_{RhRh} is SOMO orbital. The rhodium atoms are equivalent, both in solid state in complex **2**

and in solutions in $[Rh_2\{\mu\text{-}HN(HN{=})CCH_3\}_4L_2]^+$ cations and non-equivalent in complexes containing two different axial ligands $[Rh_2\{\mu\text{-}HN(HN{=})CCH_3\}_4LL']^+$. The intense bands in the electronic spectra in the range 13 000–19 000 cm^{-1} are caused by transitions with prevailing d–d character and should be assigned to the $(\sigma_{RhRh}\sigma^*_{RhS}) \rightarrow (\delta^*_{RhRh}\pi^*_{NCN})$ (SOMO), $(\pi_{RhRh}\pi_{RhS}) \rightarrow (\delta^*_{RhRh}\pi^*_{NCN})$ (SOMO) and $\delta_{RhRh} \rightarrow (\delta^*_{RhRh}\pi^*_{NCN})$ (SOMO) transitions. The very intense bands above 25 000 cm^{-1} are MLCT transition from Rh d orbitals to π^*_{HNCNH} antibonding orbitals. The participations of δ^*_{RhL} and π_{RhL} orbitals to the Rh–Rh orbitals explain the dependence of energy of the bands in the visible region on the ligands L coordinated along the Rh–Rh axis. The UV–Vis and EPR spectra proof fast exchange of axial ligands. Effective magnetic moment (1.986 μ_B at 300 K), suggests slight orbital contribution to the magnetic moment.

Supplementary data

CCDC 702638 contains the supplementary crystallographic data for compound **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

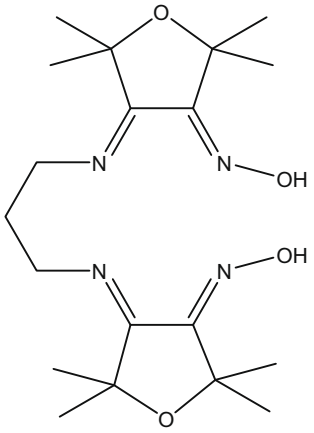

Chart 1. TMFPreH ligand.

dianionic when complexed to a metal, this new ligand is monoanionic on coordination to Cu(II) thereby producing a monocationic copper complex.

The synthesis of the ligand proceeded as expected, and when the Cu(II) and Ni(II) complex were prepared in ethanol, the crystal structures were similar to those of other diiminedioxime complexes. However, when the Cu(II) complex was prepared from $Cu(OAc)_2$ in warmed mixture of acetonitrile and acetone, the crystal structure revealed an unusual example of the acetone bound to the carbon atom of what had formerly been one of the imine double bonds.

2. Experimental

All manipulations were performed in aerobic conditions using reagents as received except for ethanol, which was distilled from sodium under argon immediately before use. FTIR spectra were obtained using a Bruker Vector 22 (Billerica, MA) equipped with a Pike MIRacle single-bounce ATR accessory (Madison, WI). Elemental analyses were performed by Atlantic Microlab, Inc. (Atlanta, GA). ^{1}H NMR spectra were obtained using a Varian Gemini 200 or 500 MHz spectrometer (Palo Alto, CA), and chemical shifts are reported relative to the TMS. Proton shifts are annotated as follows: assignment, integration, multiplicity, coupling constant.

Caution: Although no problems were observed with these complexes, perchlorate salts are potentially explosive and should be handled with care and only in small quantities.

2.1. 2,2,5,5-Tetramethyl-furan-3,4-dione monooxime (TMF oxime)

The oxime was prepared by treating 2,2,5,5-tetramethyldihydrofurane-3(2*H*)-one (TMF, Aldrich) with MeONO as described by Finke [10]. Briefly, a solution of TMF (50 mmol, 8.53 g) in ether (25 mL) and concentrated HCl (0.75 mL) was treated with methyl nitrite, which was bubbled directly into the reaction mixture over a period of approximately 2 h. The reaction mixture was then opened to the atmosphere, the excess methyl nitrite allowed to dissipate, and the HCl was neutralized with 5 mL 5% (w/v) $NaHCO_3$. The solution was extracted with ether (4×7 mL), dried over $MgSO_4$, filtered (Whatman #1), and the ether removed by rotary evaporation. The resulting oil was placed in the refrigerator overnight to give the product as a white crystalline solid. The product was collected on a sintered glass filter, washed with hexane, and allowed to air dry. The yield was 50%. m.p. (uncorrected) 118–119 °C. *Anal.* Calc. for $C_8H_{13}NO_3$: C, 56.13; H, 7.65; N, 8.18; O, 28.04. Found: C, 56.42; H, 7.67; N, 7.91; O, 28.02%. Selected IR data (cm^{-1}): 1635 cm^{-1}, 1743 cm^{-1}; $\nu_{C=N}$. ^{1}H NMR (200 MHz, DMSO-d_6): δ 1.61 (–CH_3, 6H, s), 1.36 (–CH_3, 6H, s).

2.2. 4-[3-(4-Hydroxyimino-2,2,5,5-dimethyl-dihydro-furan-3-ylideneamino)-propylimino]-2,2,5,5-tetramethyl-dihydro-furan-3-one oxime) (**LH$_2$**)

The diiminedioxime ligand was prepared by Schiff base condensation of TMF oxime and 1,3-diaminopropane in ethanol [11]. Briefly, a solution of 1,3-diaminopropane (346 mg, 4.67 mmol) in ethanol (10 mL) was added dropwise (1.5–2 h) to a solution of the oxime (1.6 g, 9.35 mmol) in 10 mL warm ethanol (35–40 °C) under argon, and the reaction mixture was stirred for 18 h. On cooling, a white precipitate formed which was collected on a sintered glass frit, washed with cold ethanol and acetone, and dried in a vacuum desiccator. Yield – 30%. *Anal.* Calc. for $C_{19}H_{32}N_4O_4$: C, 59.98; H, 8.48; N, 14.73; O, 16.82. Found: C, 59.73; H, 8.54; N, 14.76; O, 17.14%. Selected IR data (cm^{-1}): $\nu_{C=N}$ 1599, 1664 cm^{-1}. ^{1}H NMR (200 MHz, DMSO-d_6) 1.226 (–CH_3, 12H, s), 1.439 (–CH_3, 12H, s), 1.959 ($CH_2CH_2CH_2$, 2H, t, 0.035), 3.825 ($CH_2CH_2CH_2$, 4H, t, 0.032), 12.082 (NO*H*, 1H, s).

2.3. {Cu[Cu(**LH**)]$_2$}(ClO$_4$)$_2$ (**1**)

Solid $Cu(ClO_4)_2 \cdot 6H_2O$ (82.5 mg, 0.221 mmol), suspended in 5 mL absolute ethanol, was added dropwise to a suspension of **LH$_2$** (100 mg, 0.262 mmol) in warm (30–35 °C) absolute ethanol (15 mL), and the reaction mixture was stirred for 2 h without further heating. The solvent was removed under vacuum, the product was suspended in water, collected on a medium frit, and washed with cold water. A crystalline red–brown product was obtained by addition of ether to a methanolic solution of the complex. Crystals suitable for X-ray diffraction were grown by slow diffusion of ether into a solution of the complex in methanol. Yield – 30–35% *Anal.* Calc. for $C_{38}H_{60}Cl_2Cu_3N_8O_{16}$: C, 39.81; H, 5.28; Cl, 6.18; Cu, 16.63; N, 9.77; O, 22.33. Found: C, 39.96; H, 5.29; N, 9.77%. Selected IR data (cm^{-1}): $\nu_{C=N}$ 1560 cm^{-1}.

2.4. [Cu(**L'H**)]ClO$_4$ (**2**)

Solid $Cu(OAc)_2 \cdot H_2O$ (23 mg, 0.12 mmol) dissolved in 1 mL acetonitrile was added to the suspension of **LH$_2$** (70 mg, 0.18 mmol) in 3 mL acetone. The reaction mixture was refluxed for 1.5 h. and the solvent was allowed to evaporate slowly to produce a reddish-brown semi-solid to which water was added. Red crystals of **1** suitable for X-ray diffraction precipitated from this solution. Because of its instability, no elemental analysis or IR spectra were obtained for this product.

2.5. [Ni(**LH**)]ClO$_4$ (**3**)

The nickel(II) complex was prepared similarly to **1**. $Ni(NO_3)_2 \cdot 6H_2O$ (38.21 mg, 0.131 mmol) was dissolved in 5 mL of absolute ethanol, and this solution was added dropwise to a suspension of **LH$_2$** (50 mg, 0.131 mmol) in ethanol (5 mL). The color of the reaction mixture became reddish-brown as the Ni^{II} solution was added. The deep orange product was isolated as the perchlorate salt by addition of a saturated aqueous solution of $NaClO_4$. The solution was cooled in the refrigerator, the product collected on a sintered-glass frit, and washed with cold H_2O. Yield – 30 mg (42%). Crystals suitable for X-ray diffraction were obtained by slow diffusion of saturated aqueous $NaClO_4$ into an ethanolic solution of the product. Yield – 40% *Anal.* Calc. for $C_{19}H_{31}ClN_4NiO_{16}$: C, 42.45; H, 5.81; Cl, 6.59; N, 10.42; Ni, 10.92; O, 23.81. Found: C, 42.55; H, 5.84; N, 10.37%. Selected IR data (cm^{-1}): $\nu_{C=N}$ 1561 cm^{-1}.

2.6. X-ray data collection and refinement

Data were collected using a Bruker SMART CCD (charge coupled device) diffractometer equipped with an LT-3 low-temperature apparatus operating at 213 K. Suitable crystals were chosen and mounted on glass fibers using grease. Data collection parameters are summarized in Table 1. All non-hydrogen atoms were refined anisotropically. Except as noted, hydrogens were calculated by geometrical methods and refined as a riding model. Data were measured using omega scans of 0.3° per frame for 30 s, such that a hemisphere of data was collected. The first 50 frames were recollected at the end of data collection to monitor for decay. None of the crystals used for the diffraction study showed any decomposition during data collection. Cell parameters were retrieved using SMART software [12] and refined using SAINT [13] on all observed reflections. Data reduction was performed using the SAINT software, which corrects for Lp and decay. The structures were solved by the direct method using the SHELXS-97 program and refined by least squares method on F^2 using SHELXL-97 [14], incorporated in SHELXTL-PC V 5.10 [15]. Crystal structure drawings were prepared using ORTEP-3 for Windows [16]. Least-squares planes were calculated using Platon for Windows [17].

For complex **3**, the disorder in C10 was refined to ratio of C10/C10B = 0.77. The hydrogen between O1 and O2 was modeled 50% on O1 and 50% on O2.

3. Results and discussion

A new furanone-containing diiminedioxime ligand and its Cu(II) and Ni(II) complexes were prepared and characterized. The ligand itself is unusual in that there are very few examples of ligands in which furanone is incorporated into the ligand backbone. One example of this is the Tc-Q12 complexes referred to previously [9]. In the Q12 case, the furanone replaces the benzene ring in the Schiffs base salen, and the ligand has a −2 charge when complexed to a metal. Another example is found in the work of Gottschaldt, et al in which furanone replaces the ethylenediamine backbone of a salen-type ligand and the ligand again has a −2 charge when complexed to the metal [18]. For Cu(II), these ligands would produce neutral complexes that would not be expected either to accumulate in the myocardium or be substrates for Pgp. The diiminedioxime derivative is, we believe, the first example of a monoanionic furanone-functionalized ligand.

3.1. Synthesis

The tetramethyl furanone ligand, $\mathbf{LH_2}$, was prepared using a method analogous to that used previously to prepare linear alkyl derivatives of the diiminedioxime ligand system [6]. In contrast to previous derivatives of the diiminedioxime system, the TMF derivative contains a cyclic ether moiety, which is expected to improve the rate at which the ^{64}Cu complex is cleared from the blood and liver. It may also be the case that the increased ligand rigidity imposed by the TMF system increases the in vivo stability of the ^{64}Cu complex. This possibility will be evaluated when the ^{64}Cu complex is prepared.

The syntheses of the Cu(II) and Ni(II) complexes were readily accomplished when the reactions were carried out in ethanol. However, an unexpected result was encountered when the copper complex was prepared from $Cu(OAc)_2$ with acetone in the solvent mixture. In this case, there was significant decomposition of the reaction mixture and a product was isolated that contained an acetone adduct of the ligand. This is an unusual, but not unprecedented, result. There are several examples of acetone adducts of imine ligands in the literature [19–21] including one Cu(II) complex [19]. This is, however, apparently the first example of this being observed in a ligand of this type.

3.2. Descriptions of the structures

3.2.1. {Cu[Cu(**LH**)]$_2$}(ClO$_4$)$_2$ (**1**)

An ORTEP drawing of **1** is shown in Fig. 1. Selected bond lengths and angles are summarized in Table 2. The complex crystallizes as a Cu(II)-bridged dimer with the central Cu(II) atom bonded to four oxime oxygens. The two halves of the dimer are related by a center of symmetry at Cu1, and the molecules are linked in infinite chains along the c axis by weak interactions between Cu2 and the per-

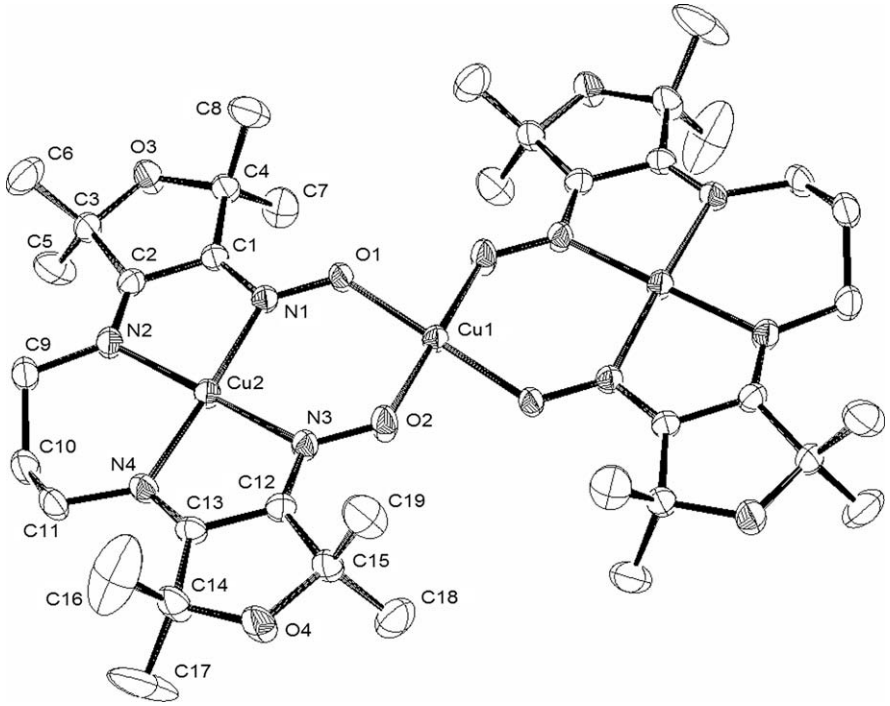

Fig. 1. Molecular structure of $\{Cu[Cu(\mathbf{LH})]_2\}^{2+}$ dimer (**1**) showing atom labeling scheme.

chlorate counter-ions (Cu2–O5, 2.532(3) Å, Cu2–O8 2.577(3) Å) (Fig. 1).

The bridging Cu(II) atom is coplanar with the four oxime oxygen atoms, while the second Cu(II) atom sits slightly (0.0400(4) Å) above the plane defined by the four nitrogen atoms. The four Cu–N bonds are very similar in length (range 1.990(2) Å to 1.994(2) Å) and are somewhat longer than the Cu–N values observed in the prototypical complex of this series, $[Cu(PreH)]^+$ ($PreH_2$ = 3,3'-(trimethylenedinitrilo)bis(2-butanone oxime)), where they range between 1.945(7) Å and 1.972(7) Å [22]. The difference in bond lengths is apparently due to spreading of the ligand by the bridging copper atom. This spreading can be seen in the greater distance between the oxime oxygen atoms in **1** versus $[Cu(PreH)]^+$, 3.021 Å for **1** compared to 2.492 Å for $[Cu(PreH)]^+$, and in the smaller displacement of the Cu(II) atom from the basal plane (0.0400 Å versus 0.097 Å).

N(4)–Cu(2)–O(5)	87.5(1)

[a] Symmetry transformations used to generate equivalent atoms: #1 $-x+1,-y,-z+1$.

There are relatively few examples of oxime-bridged Cu(II)-dimers. One example is $[Cu(Cu(PreH))_2][ClO_4]_2$ [23], the Cu(II)-bridged dimer of $[Cu(PreH)H_2O]^+$. The structures of the two dimers are, however, strikingly different. Complex **1** is almost planar with O2–Cu1–O2 and O1–Cu1–O1 angles of 180° and the Cu atom located in the plane defined by the four oxime oxygen atoms. The coordination environment about the central Cu atom in $[Cu(Cu(PreH))_2][ClO_4]_2$ is, in contrast, distorted tetrahedral with O–Cu–O angles of 152.26(7)° and 158.47(7)°. And while **1** is essentially planar, in $[Cu(Cu(PreH))_2][ClO_4]_2$ the two sides of the dimer are bent upwards at almost 60° relative to the CuO_4 core, and the two CuN_4 centers are loosely connected through the ClO_4^- counter-ion (Cu–O 2.838(2) Å). In contrast to this intramolecular ClO_4^- bridge, in complex **1** the dimers are linked in infinite chains along *b* by the perchlorate counter-ion (Fig. 2). One possible reason for the difference in conformations between the two complexes is the steric effect of the methyl groups on the furanone rings. Examination of space-filling models suggests that these groups will interact with those on the opposite side of the dimer if the two sides are folded towards each other, as they are in $[Cu(Cu(PreH))_2][ClO_4]_2$.

3.2.2. $[Cu(\mathbf{L'H})]ClO_4$ (**2**)

Selected interatomic distances and angles for **2** are summarized in Tables 3 and 4, and an ORTEP drawing of the complex is shown in Fig. 2. The coordination geometry around the Cu(II) atom approximately square planar with the Cu(II) atom 0.0268(6) Å above the plane defined by the four nitrogen atoms.

The most distinctive feature of this complex is the reduction of the N2–C3 double bond by addition of acetone across the imine bond with concomitant acetone adduct formation at C3 and addition of a hydrogen atom to N2. The C3 atom is clearly sp3, in con-

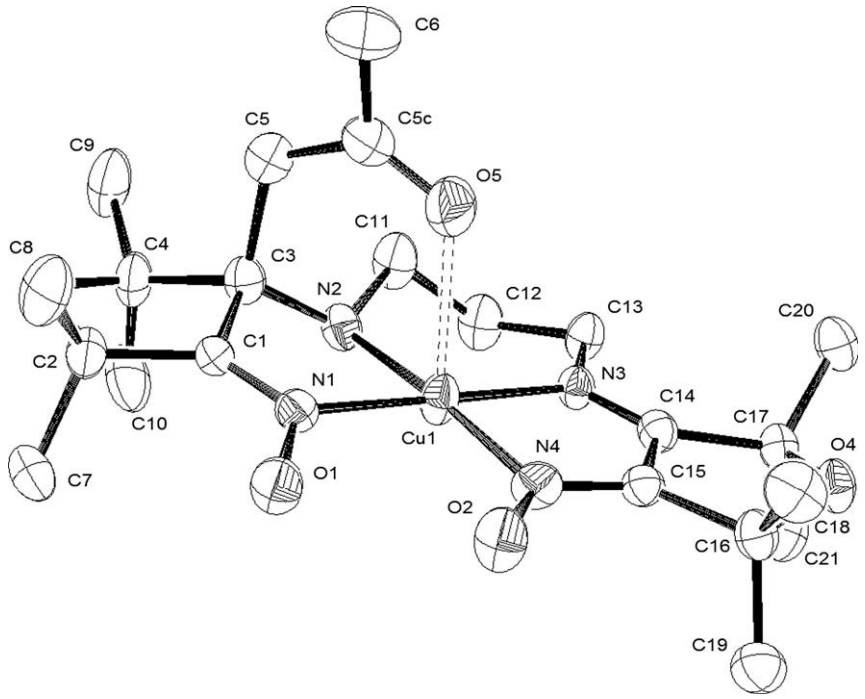

Fig. 2. Molecular structure of $[Cu(\mathbf{L'H})]^+$ cation (acetone adduct) (**2**) showing atom labeling scheme.

trast to C14, the corresponding atom in the second furanone ring in the complex, which is sp2. The difference between the two carbon atoms can be clearly seen in the differences in the bond lengths and angles as well as the differences between the amine and imine nitrogen atoms, N2 and N3 (Tables 3 and 4). The parameters for the imine nitrogen are similar to those observed in the *diimine*dioxime complex $[Cu(PreH)H_2O]^+$ [22], while the parameters for the amine nitrogen are similar to those observed in the *diamine*dioxime complexes $[Cu(ReO_4)(PnAO)]$ (HPnAO = 2,2′-(1,3-diaminopropane)bis(2-methyl-3-butanone oxime)) [24] and [Cu(CN)(PnAO)] [25]. This pattern is also observed when N2- and N3-Cu bonds are compared. The remainder of the ligand is structurally similar to **1** and to $[Cu(PreH)H_2O]^+$ [22].

In contrast to the other examples of acetone adducts [19–21] in which the oxygen atom is oriented away from the metal, in this case the oxygen atom occupies an axial position in the complex; Cu–O 2.399(4) Å. This compares to the 2.294(6) Å Cu–O distance for an acetone oxygen in a Cu-dien complex [26]. The somewhat greater distance in this case is perhaps a consequence of geometric constraints imposed by the ligand which displaces the oxygen away from an ideal apical location (N2–Cu–O5 = 82.3(1)°).

Table 3

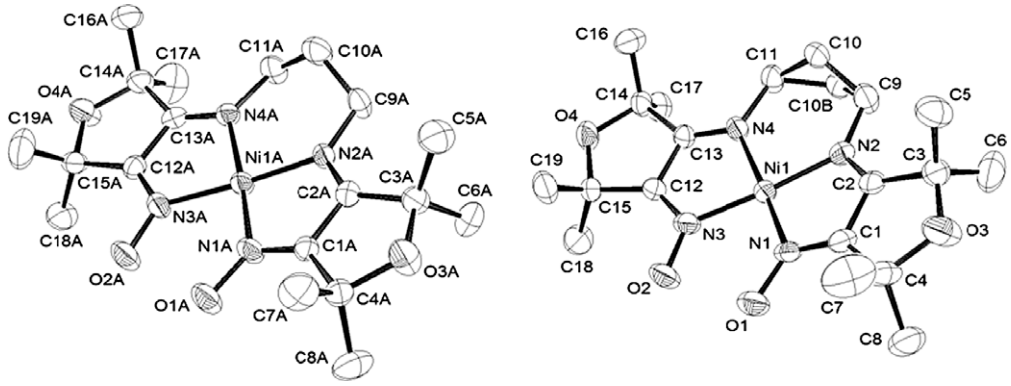

Fig. 3. Molecular structure of [Ni(**LH**)]$^+$ cations (**3**) showing atom labeling scheme.

on, molecule A is slightly more distorted from planarity than molecule B as evidenced by the larger displacements of the ether oxygen atoms in the furanone ring from the N_4 plane. In molecule A, the O3 and O4 atoms are −0.385(4) Å and −0.623(4) Å below the plane versus −0.271(4) Å and −0.202(4) Å for molecule B.

The coordination environment around the two independent Ni(II) atoms is unremarkable. The Ni–N bond lengths range from 1.884(4) to 1.921(4) Å, slightly longer than those observed for [Ni(PreH)]ClO_4, which range from 1.869(5) to 1.892(5) Å [27] and Ni–Me_2PreH, which range from 1.866(5) to 1.887(3) Å [28]. The lengthening of the Ni–N bonds is presumably due to the greater displacement of the Ni atom from the plane in this complex than in the two previous examples (0.018 Å for Ni–PreH [27] and 0.056 Å for Ni–Me_2PreH [28]) and shorter Ni–O(perchlorate) distance (2.504(5) Å and 2.512(4) Å) in this complex compared to the two Ni–PreH complexes (2.84 Å and 2.902(5) Å). The structure of the ligand itself is similar to that seen in **1** and **2** except that in this case the central carbon atom of the trimethylene bridge is disordered in molecule B. There are no significant intermolecular interactions.

4. Conclusions

The tetramethylfuranone diiminedioxime ligand 4-[3-(4-Hydroxyimino-2,2,5,5-dimethyl-dihydro-furan-3-ylideneamino)-propylimino]-2,2,5,5-tetramethyl-dihydro-furan-3-one oxime) (**LH_2**) was successfully synthesized as were its Cu(II) and Ni(II) complexes. However, when the synthesis of the Cu(II) complex was attempted in a mixture of acetonitrile and acetone, an unusual example of an acetone adduct of the ligand was observed. This observation suggests that caution should be observed when using acetone as a solvent to prepare copper–imine complexes.

Efforts are currently underway to prepare the corresponding ^{64}Cu complex so that the effect of the tetramethylfuranone moiety on the biodistribution of the complex can be determined.

Scheme 1.

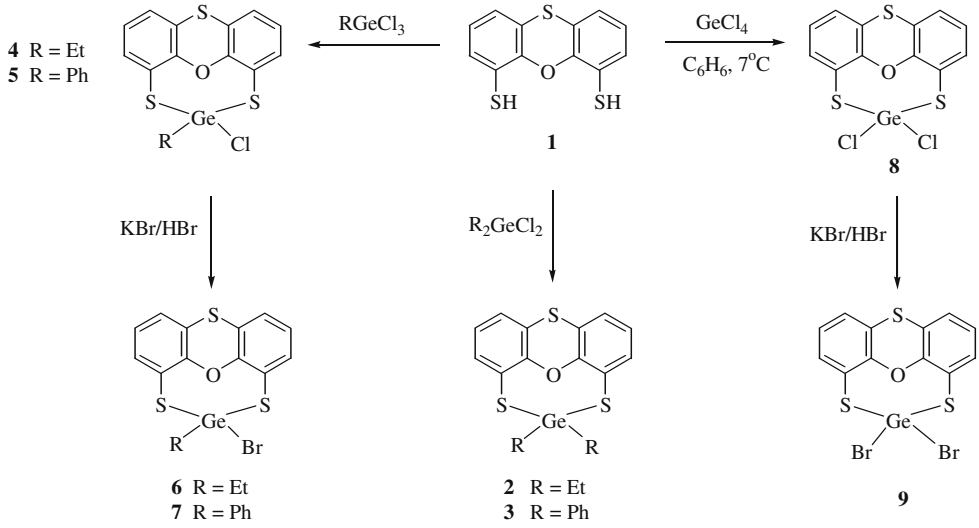
differences were observed between the diorganyl- and halogen-containing compounds in both solution and solid state. The detailed description of the synthesis, spectroscopic characterization and crystallographic data are presented and discussed below.

According to our results, the acidity of the $GeRHal^{2+}$ fragment in **4**–**6** enhances the transannular O···Ge interaction, prompting a boat–boat eight-membered ring conformation and a trigonal bipyramidal germanium local geometry; the GeR_2^{2+} less acid fragment present in **2** and **3** has an opposite effect.

2. Experimental

2.1. Materials and methods

All manipulations were performed under a dry, oxygen-free nitrogen atmosphere using standard Schlenk techniques. Solvents were dried by standard methods and distilled prior to use. All organogermanium chlorides, $GeCl_4$ and phenoxathiin were obtained commercially (Aldrich). Melting points were determined with a Mel-Temp II instrument and are uncorrected. Spectra were recorded with the following instruments. Mass spectra for EI, a Hewlett–Packard 5989A mass spectrometer was used. Elemental analyses were recorded with a Perkin–Elmer Series II CHNS/O Analyzer. The IR spectra were recorded in the 4000–400 cm^{-1} range with a Perkin–Elmer System 2000 FT-IR spectrometer, as KBr pellets. NMR: Jeol Eclipse 400 spectrometer at 25 °C; with the residual protio-solvent signal used as referenced for ^1H NMR (399.78 MHz) spectra. $^{13}C\{^1H\}$ NMR (100.53 MHz) spectra were referred through the solvent peaks. Chemical shifts are quoted on the δ scale (downfield shifts are positive) relative to tetramethylsilane (^1H, $^{13}C\{^1H\}$ NMR spectra).



2.2. Synthesis of the ligand $S(C_6H_3SH)_2O$ (**1**)

Phenoxathiin (7.00 g, 34.95 mmol) and TMEDA (15.20 mL, 101.36 mmol) were dissolved in THF (80 mL). The mixture was immersed in an ice-bath and a solution of *n*BuLi in hexanes (0.5 M, 160.80 mL, 80.39 mmol) was added dropwise. The solution was stirred for 24 h keeping the ice-bath. Elemental sulfur (3.36 g, 104.86 mmol) was added with vigorous stirring, and the resulting yellow suspension was stirred for 36 h. Then, $LiAlH_4$ (1.99 g, 185.25 mmol) was added in small portions. ***Caution: A vigorous reaction takes place and the reaction suspension starts to foam.*** Subsequently, the suspension was stirred by 4 h and the resulting mixture was cautiously added in small portions to a mixture of crushed ice (60 g) and concentrated hydrochloric acid (25 mL) immersed in an ice-bath. ***Caution: Vigorous evolution of H_2S occurs, and this reaction must be carried out in a well ventilated fumehood.*** After the ending of the vigorous reaction, further concentrated hydrochloric acid (15 mL) was added. The resulting suspension was extracted with $CHCl_3$ (3 × 50 mL). The combined organic phases were passed through a column of celite and anhydrous sodium sulphate, and evaporation of the solvent yielded a yellow solid. The compound is recrystallized with a mixture of toluene–hexane at −30 °C. Yield: 5.54 g (60%) p.f. 64–67 °C, ^1H NMR ($CDCl_3$): δ = 7.12 (m, 2H, H3) 6.91 (m, 4H, H2, H1), 4.10 (s, 2H, SH), ppm, $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 148.2, 128.7, 125.0, 124.1, 121.9, 121.4 ppm.

2.3. Synthesis of the phenoxathiin-4,6-dithiolate germanium compounds $[\{S(C_6H_3S)_2O\}GeR_nHal_{2-n}]$

2.3.1. Synthesis of $[\{S(C_6H_3S)_2O\}GeEt_2]$ (**2**)

$S(C_6H_3SH)_2O$, (0.27 g 1.01 mmol) was added to a solution containing 15 mL of dry methanol at room temperature. After the solution was stirred for 30 min, a white suspension resulted, and Et_2GeCl_2, (0.15 mL, 1.02 mmol) was added via a syringe. The solution was refluxed overnight; during this time the mixture acquired homogenous clear brown coloration. It was filtered while hot; an oily compound was separated from the methanolic mother liquor, and dissolved when chloroform was added. The mother liquor and chloroform solution were slowly evaporated, yielding colourless crystals. Yield: 0.11 g (28%) Mass spectrum (EI-MS, $CHCl_3$, 30 eV) *m*/*z* (rel. int.) = 394(30) $[M]^{+\cdot}$, 365 (base peak) $[M-Et]^+$, 336(12)

Scheme 2.

2.3.7. Synthesis of [{S(C6H3S)2O}GeCl2] (8)

$GeCl_4$ (0.4 mL, 3.51 mmol) was dissolved in dry benzene (20 mL) at 7 °C and added via a syringe to a solution of $S(C_6H_3SH)_2O$ (0.90 g, 3.40 mmol) in dry benzene (20 mL). The solution was kept at 7 °C overnight. It was filtered and the benzene was slowly evaporated. A yellow solid was obtained. Yield: 0.88 g (60%); Mass spectrum (EI-MS, $CHCl_3$, 30 eV) *m/z* (rel. int.) = 406(20) $[M]^{+\cdot}$, 371(5) $[M-Cl]^+$. M.p. 132–133 °C. *Anal.* Calc. for S $(C_6H_3S)_2OGeCl_2$ 0.5 C_6H_6: C, 40.49; H, 2.04. Found: C, 40.07; H, 2.99%. ^1H NMR ($CDCl_3$): δ = 7.28 (m, 2H, H3), 7.11 (m, 4H, H1, H2) ppm $^{13}C\{^1H\}$ NMR($CDCl_3$): δ = 146.1, 128.2, 126.5, 125.6, 123.0, 122.0 ppm.

2.3.8. Synthesis of [{S(C6H3S)2O}GeBr2] (9)

This compound was prepared in a similar fashion to compound **6**. [{$S(C_6H_3S)_2O$}$GeCl_2$] (0.100 g, 0.25 mmol), KBr (0.59 g, 4.93 mmol) and HBr 48% (3 mL, 55.23 mmol). Yellow solid. Yield: 0.05 g (40%); Mass spectrum (EI-MS, $CHCl_3$, 30 eV) *m/z* (rel. int.) = 496 (base peak) $[M]^{+\cdot}$, 415(95) $[M-Br]^+$, 336 (15) $[M-2Br]^{+\cdot}$, 246 (50) $[C_{12}H_6S_3]^{+\cdot}$, 214 (15) $[C_{12}H_6S_2]^{+\cdot}$. M.p. 198.1–201.6 °C. ^1H NMR ($CDCl_3$): δ = 7.32 (m, 2H, H3) 7.14 (m, 4H, H1, H2) ppm $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ = 147.6, 129.4, 126.3, 126.2, 124.5, 121.9 ppm.

2.4. X-ray crystallography

Suitable single crystals of the compounds **2–6** were grown by slow evaporation from a chloroform solution. X-ray diffraction data on **2–6** were collected at room temperature on a CCD Smart 6000 diffractometer through the use of Mo Kα radiation (λ = 0.71073 Å, graphite monochromator). Data were integrated, scaled, sorted, and averaged using the SMART software package. The structures were solved by direct methods, using SHELXTL NT Version 5.10 and refined by full-matrix least squares against F^2 [18]. An empirical absorption correction based on the multiple measurement of equivalent reflections was applied by using the program SADABS [19]. The displacement parameters of non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were kept fixed with a common isotropic displacement parameter. Selected crystallographic data are given in Table 1.

3. Results and discussion

3.1. Synthesis

The 4,6-dimercaptophenoxathiin ligand (OS_2–H_2 **1**) was prepared via a four-step reaction from phenoxathiin by modification of a reported method [10] (See Section 2 for details). The reaction of **1** with the corresponding organylgermanium(IV) chloride in dry methanol yielded the corresponding Ge(IV) compounds **2–5**. Treatment of **1** with $GeCl_4$ in benzene at 7 °C afforded the dichlorogermanium compound **8**. A subsequent treatment of **4**, **5** and **8** with

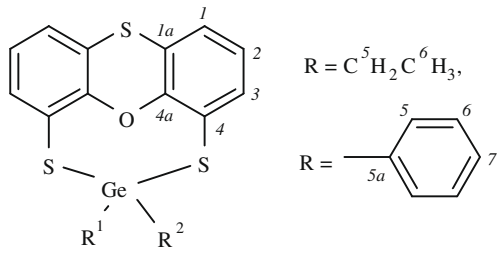
a mixture of KBr/HBr in benzene yielded the corresponding bromo compounds **6**, **7** and **9** (Scheme 2). All germanium compounds are air-stable, soluble in chloroform and benzene.

3.2. Mass spectra

Electron impact mass spectra for all compounds [{$S(C_6H_3S)_2O$}-GeR^1R^2] exhibit a variable intensity ion with the appropriate isotopic ratio representing the molecular ion ($M^{\cdot+}$). In all cases the M–R^1, M–R^2 and M–R^1–R^2 fragments were observed with variable intensity confirming the binding of germanium to the sulfur thiolate-like atoms [R^1 = Et (**2**), Ph (**3**), Cl (**4**), Cl (**5**), Br (**6**), Br (**7**), Cl (**8**), Br (**9**); R^2 = Et (**2**), Ph (**3**), Et (**4**), Ph (**5**), Et (**6**), Ph (**7**), Cl (**8**), Br (**9**)]. In compounds **5** and **9** the base peak corresponds to the molecular ion, whereas in **2**, **3**, **4** and **6** corresponds to the M–R^2 fragment. More assigned peaks are listed in Section 2.

3.3. NMR spectroscopy

NMR spectra were recorded in $CDCl_3$ solutions at 25 °C. ^{1}H and ^{13}C{^{1}H} spectroscopic data for the free OS_2–H_2 ligand and germanium compounds **2**–**9** are given in Tables 2 and 3, Scheme 3. The assignments were carried out by heteronuclear and homonuclear correlation two-dimension experiments (HETCOR, COLOC and COSY).



In solution both $S(C_6H_3S)O$ halves are equivalent. The ^{1}H spectrum of free OS_2–H_2 ligand displayed the –SH group at 4.10 ppm as a singlet. The formation of compounds **2**–**5** and **8** was confirmed by the vanishing of the –SH signal. All germanium compounds and free ligand spectra showed three signals in the aromatic region for the $\{S(C_6H_3S)_2O\}$ moiety as an ABC pattern. Because of the electron withdrawing effect of the halogen substituents on the germanium atom, the protons of the ethyl groups in **4** and **6** are more shifted to high frequencies than those of **2**.

^{13}C{^{1}H} NMR spectrum for the free ligand showed six signals at 121.4–148.2 ppm. The comparison of the chemical shift values of the C1a and C4 carbons for the ligand OS_2–H_2 respect to those of the compounds **2**–**9** showed a deshielding effect attributable to

Scheme 3.

the formation of the S–Ge bond, see Table 2. In the mono- and dihalogenate germanium compounds **4**–**9**, the C4a carbon is shifted to lower frequencies respect to OS_2–H_2, whereas it is shifted to higher frequencies in the diorganyl-germanium complexes **2** and **3**. The observed shielding may be attributed to a change in the chemical environment of the oxygen atom, which could be accounted for either by the existence of different conformational isomers – involving the eight-membered ring with a more or less constrained oxygen atom – or by means of electron density transference from the oxygen to the germanium acceptor atom. This later proposal supports an increase of the germanium coordination number in complexes **4**–**9**.

3.4. X-ray structures of compounds 2–6

The molecular structures in crystalline solid state of **2**–**6** were determined by single crystal X-ray diffraction analyses. The unit cell of **5** has two crystallographic independent molecules (**5a** and **5b**). The molecular ORTEP drawings are depicted in Fig. 1 and selected bond lengths, angles and torsion angles are given in Table 4.

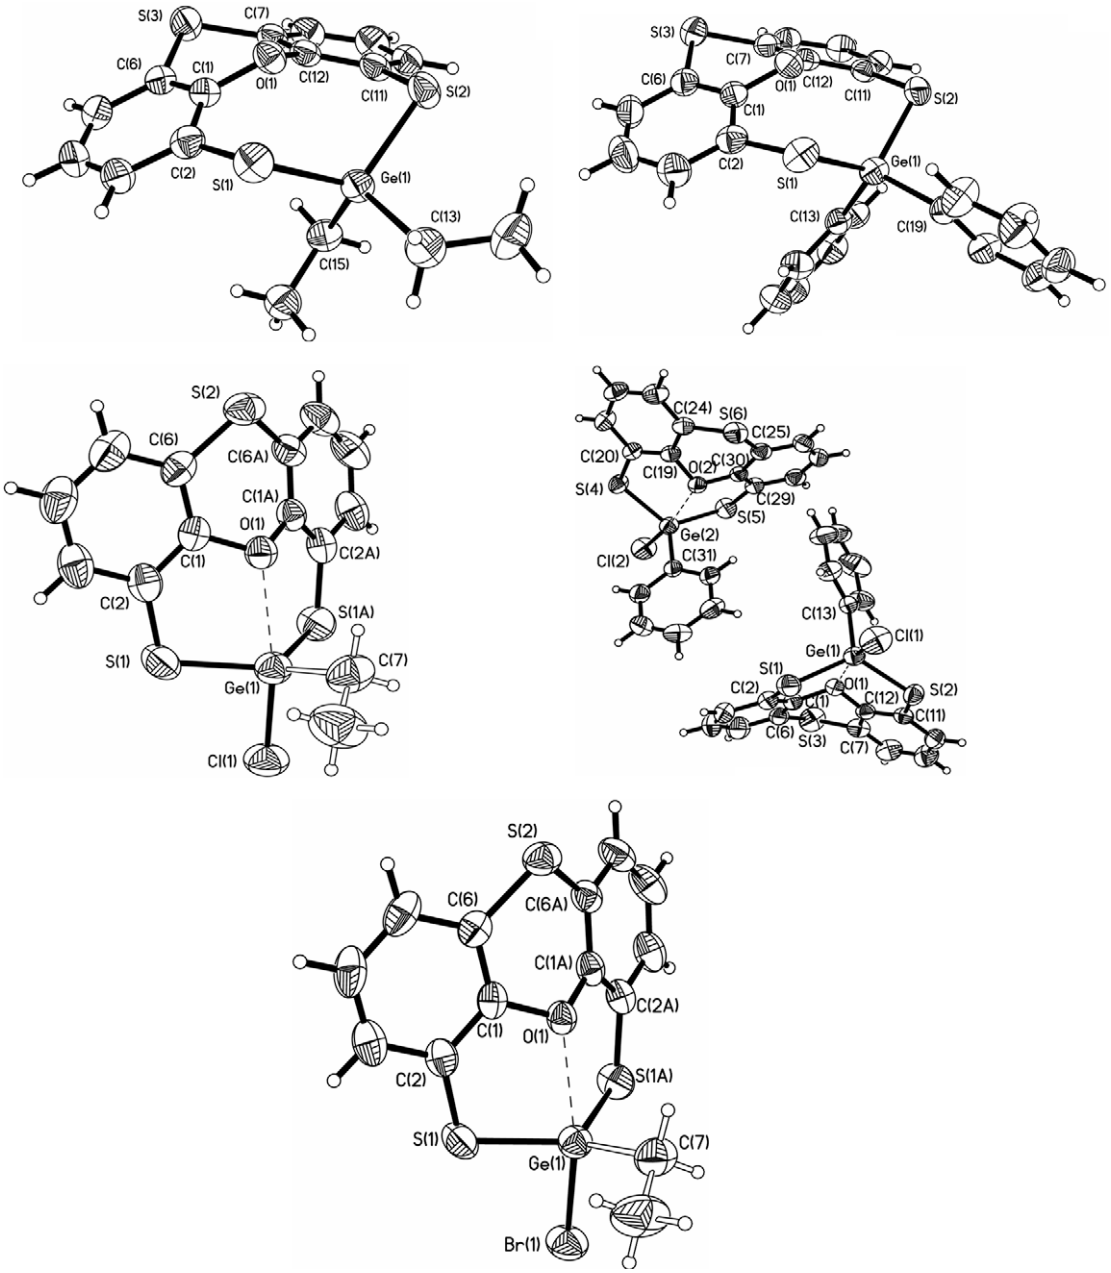

Fig. 1. Molecular structures of [{S(C6H3S)2O}GeEt2] (**2**), [{S(C6H3S)2O}GePh2] (**3**), [{S(C6H3S)2O}GeEtCl] (**4**), [{S(C6H3S)2O}GePhCl] (**5**) and [{S(C6H3S)2O}GeEtBr] (**6**). (In **4** and **6** only one disordered ethyl group is shown).

[a] R^1 and R^2 mean an atom directly attached to the central germanium atom (v.gr. carbon in the ethyl group).
[b] Molecules with mirror symmetry.
[c] Average distances; their e.s.d. values were calculated from the sample standard deviation formula.

In all compounds there are not intermolecular interactions between no hydrogen atoms shorter than the van der Waals radii sum, being essentially monomeric molecules. Compounds **4** and **6** crystallized with mirror symmetry in space group *Pnma*; the two S(C$_6$H$_3$S)OGe halves are related by a mirror plane containing the S–O–Ge atoms; in both compounds the ethyl groups are mirror disordered over two sites. The unit cell of **5** has two crystallographically independent molecules (**5a** and **5b**).

All the germanium–sulfur, germanium–carbon and germanium–halogen bond distances agree very well with the corresponding covalent radii sum [20]. In the diorganylgermanium compounds **2** and **3**, the S–Ge–S bond angles [117.12(4)° and 118.84(4)°] are significantly shorter than those found in compounds **4**, **5** and **6** [ranging from 120.60(7)° to 122.89(8)°], though they are larger than the ideal tetrahedral angles. Since the presence of the two organyl groups attached to the central germanium in **2** and **3** can not be the only reason for this shortening, it is convenient to carry out a more detailed examination of the molecular structure of the compounds in order to explain these subtle structural differences. Firstly, the germanium compounds display two different conformations on the eight-membered central ring. The conformation of the central ring in **2** and **3** is described as boat–chair-shaped whereas in **4**, **5** and **6** is boat–boat-shaped (Fig. 2). This later conformation has been found in nearly every dibenzometallocine complex known to date (type I, Scheme 1), certainly exhibiting different distortion degrees. The boat–chair conformation has only been observed in some phosphorus and silicon similar compounds [12–14].

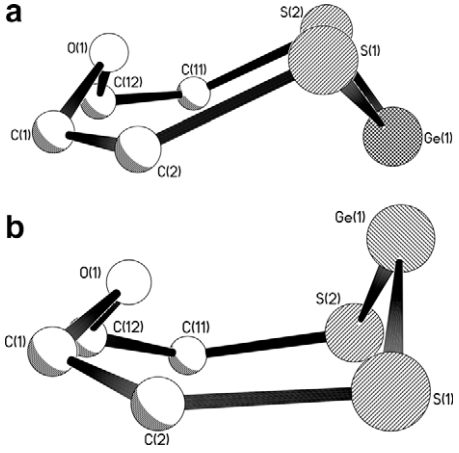

Fig. 2. Eight-membered central ring conformation observed in compounds [{S(C$_6$H$_3$S)$_2$O}GeR^{1}R^2]: (a) boat–chair; (b) boat–boat.

Secondly, in the monohalogenate compounds **4**–**6** was observed a relatively short transannular distance between the O and Ge atoms. The O···Ge bond distances in **4**, **5** and **6** are 2.482(4), 2.452(3) and 2.488(4) Å, respectively, which are 32%, 30% and 32% longer than the covalent radii sum of Ge and O (1.88 Å) but significantly shorter than the van der Waals radii sum (3.47 Å) [20], and are considered as secondary bonds [21]. These O···Ge bond distances are slightly longer than those reported for O(CH$_2$CH$_2$S)$_2$GeCl$_2$ [2.36(1) and 2.39(1) Å], a flexible germocane with a GeCl$_2^{2+}$ acid fragment [22]. On the other hand, in compounds **2** and **3** with two organyl exocyclic ligands, the O···Ge distances are 3.019(2) and 3.043(2) Å, respectively, which are 60% and 62% longer than covalent radii sum. This weakening of the transannular interaction is also reflected on the R^1–Ge–R^2 bond angles, which are the shortest angles observed in our systems.

In order to assign the local geometry of the germanium atom and compare the title compounds with other dibenzogermocines, were determined the degree of geometrical displacement [23–25] at Ge from tetrahedral to trigonal bipyramidal (TBP), and the Pauling-type bond order [26,27] for the transannular interaction. The results are reported in Table 5.

Table 5
Comparison of O···Ge–R^1 geometrical bond parameters in compounds **2**–**6**; bond lengths (Å), bond angles (°), % TBP and Pauling bond order (BO).

	R^1	Central ring conformation	O···Ge	O···Ge–R^1	% TBP	Δd[a]	BO[b]
2	Et	boat–chair	3.019(2)	90.21(10)	28	1.139	0.0248
3	Ph	boat–chair	3.043(2)	95.54(10)	27	1.163	0.0229
4	Cl	boat–boat	2.482(4)	165.32(11)	62	0.602	0.1416
5[a]	Cl	boat–boat	2.440(3)	167.43(9)	65	0.560	0.1623
5b	Cl	boat–boat	2.464(3)	167.91(10)	63	0.584	0.1502
6	Br	boat–boat	2.488(4)	165.09(10)	62	0.608	0.1389

[a] Bond widening, $\Delta d = [d_{exp} - \Sigma r_{cov}(Ge,O)]$, according to standard bond distances (O···Ge) 1.88 Å.
[b] Mode of calculation of bond order for the O···Ge interaction: $BO = 10^{-(1.41\ \Delta d)}$.

It is clear that the TBP% and the bond order for the diorganylgermanium compounds **2** and **3** displaying a boat–chair conformation are the shortest in the series, whereas the corresponding values for the monohalogenate compounds **4**–**6** displaying a boat–boat conformation are the largest. In this respect, it is also noteworthy to note that these values are indeed the largest know to date for related dibenzogermocine complexes.[11] Therefore, the local geometry of the germanium atom in **2** and **3** is best described as tetrahedral, whereas in **4**–**6**, the geometry is best described as TPB, considering the O···Ge interaction. From these data it is reasonable to conclude that there exist a very close connection between the strength of the transannular interaction, the ring conformation as well as the coordination geometry, and the nature of the atoms in *trans* position to the secondary bonding.

4. Conclusion

In order to study the phenomena of hypervalence in germanium heterocyclic compounds we have synthesized and structurally characterized eight new $[\{S(C_6H_3S)_2O\}GeR_nHal_{2-n}]$ compounds (R = Et, Ph; Hal = Cl, Br; n = 2–0) by employing an efficient $\{S(C_6H_3S)_2O\}^{2-}$ ligand. In the solid state, the compounds with two organyl exocyclic ligands display a distorted tetrahedral local geometry at Ge(IV) center. On the other hand, the compounds with halogen pendant ligands exhibit a trigonal bipyramidal coordination geometry, and considerable strong O···Ge intramolecular interactions, due to an increase of the Lewis acidity on the germanium atom. In addition, the conformation is significantly influenced by the intramolecular interaction being boat–boat if the secondary bonding is strong enough and boat–chair if it may be neglected.

[13], and di-isocyanates OCNCb^{m}NCO (Cb^{m} = 1,7-$C_2B_{10}H_{10}$) have been converted into diamines $H_2NCb^{m}NH_2$ for use in polymers [14]. The nitrosyl chloride–lithio-carborane reaction by contrast appears to have been studied by only two research groups, and not at all during the past thirty years, despite the range of C–N carborane derivatives in principle accessible *via* nitroso-carboranes [1,3]. Unfortunately the early reports by Kauffman et al. and Zakharkin et al. gave conflicting yields of nitroso derivatives (25–80%) and limited experimental details.

2. Results and discussion

2.1. Synthetic aspects

In our studies of low-temperature reactions between the lithio-carboranes, MeCb°Li or PhCb°Li, and nitrosyl chloride in equivalent amounts (Scheme 1), we used 1:1 mixtures of diethyl ether and pentane, or of diethyl ether and dimethoxyethane (DME), as solvent. The products obtained were broadly in line with those reported by Zakharkin et al. [2,3]. In diethyl ether and pentane, the nitroso-carboranes RCb°NO were the main product (42–77%), though some dicarboranylamine $(RCb^{\circ})_2NH$ could normally also be isolated (0–22%). However, when diethyl ether and DME were used as a solvent mix, the secondary amines $(RCb^{\circ})_2NH$ were the main products (55–63%), yields of nitroso-carboranes being 10% or less. Although overall yields varied with the temperature at which the reaction was carried out, the product balance did not. Our work-up procedure involved treatment with aqueous potassium hydrogen carbonate followed by sublimation to obtain the blue nitroso compounds RCb°NO. The strong NO stretching absorptions at *ca.* 1565 cm^{-1} in the IR spectra of these compounds show that their CNO units are bent at nitrogen [15], with the nitrosyl groups acting as one-electron ligands to the carborane cages. The colourless secondary amines $(RCb^{\circ})_2NH$ were recovered after treatment of the unsublimed material with methanol (for details, see Section 4).

We infer that the nitroso-carboranes are formed in the first stage of the reaction (Eq. (1)) and that the secondary amines result from the reaction of the nitroso-carborane with a second mole of lithio-carborane, despite competition from excess nitrosyl chloride (Eq. (2));

$$RCb^{\circ}Li + NOCl \rightarrow RCb^{\circ}NO + LiCl \quad (1)$$

$$RCb^{\circ}NO + RCb^{\circ}Li \rightarrow (RCb^{\circ})_2NOLi \quad (2)$$

It is not clear, however, how the lithio-hydroxylamine $(RCb^{\circ})_2NOLi$ is then reduced to the amine, $(RCb^{\circ})_2NH$. It may be significant that the bidentate coordinating solvent, 1,2-dimethoxyethane, $MeOCH_2CH_2OMe$, favours reaction (2). There are parallels here with aromatic ring chemistry, in that both aryl nitroso compounds ArNO and diarylamines Ar_2NH are accessible from ArLi or ArMgX and NOCl [16].

Our early preparations of anionic species $[RCb^{\circ}X]^{-}$ from neutral parent species used proton sponge, PS, $C_{10}H_6(NMe_2)_2$, to deprotonate the hydroxycarborane PhCb°OH and the thiol PhCb°SH [6,7]. We therefore attempted to deprotonate the amine $(PhCb^{\circ})_2NH$ in toluene by proton sponge. This failed; the amine crystallised unchanged from these solutions. However, addition of a solution of potassium *t*-butoxide and an equimolar proportion of 18-crown-6 deposited pale yellow crystals, with 77% yield of the salt $[K(18\text{-crown-6})]^{+}[(PhCb^{\circ})_2N]^{-}$. This pale yellow salt is, surprisingly, stable to air and moisture, though the parent amine, $(PhCb^{\circ})_2NH$ is regenerated by ethanoic acid. In previous studies we were unable to obtain the amide $PhCb^{\circ}NH^{-}$ by deprotonation of the amine $PhCb^{\circ}NH_2$; cage degradation occurred instead [9]. Although the yellow salt appears to crystallise well from 1,2-dichlorobenzene, single crystals suitable for X-ray diffraction were grown from a solution in diethyleneglycol dimethyl ether, $(MeOC_2H_4)_2O$, into which cyclohexane diffused slowly from an upper layer. The colourless salt $[K(18\text{-crown-6})]^{+}[(MeCb^{\circ})_2N]^{-}$ was similarly formed in 86% yield from a solution of potassium *t*-butoxide and an equimolar proportion of 18-crown-6 with amine $(MeCb^{\circ})_2NH$. The contrast in the formation and stability between the anions $PhCb^{\circ}NH^{-}$ and $(RCb^{\circ})_2N^{-}$ suggests that the $PhCb^{\circ}NH^{-}$ anion is capable of a nucleophilic attack on a second carborane molecule leading to cage degradation, whereas the two bulky cages in the anion $(RCb^{\circ})_2N^{-}$ inhibit the capacity of this amide to attack a second carborane molecule.

2.2. Structural aspects

In crystalline PhCb°NO (Fig. 2), the N=O bond (length 1.182(2) Å) lies roughly in the C(2)–C(1)–N(1) plane. The phenyl ring is perpendicular to this plane. The C(1)–N(1) bond length of 1.490(2) Å is consistent with negligible *exo*-C–N π-bonding, as is the C(1)–C(2) cluster bond length of 1.677(2) Å, virtually identical to that in the computed geometry of PhCb°F (1.674 Å), and slightly different from that in the computed geometry of PhCb°H (1.659 Å) with a similarly orientated phenyl group [9]. Reported X-ray-derived geometries of PhCb°H with the orientation of the phenyl group roughly coplanar with the H(1)–C(1)–C(2) plane reveal shorter C(1)–C(2) bond distances of 1.643(2) and 1.649(2) Å [5,17–19]. The C(1)–N=O bond angle of 113.0(2)° is midway between typical trigonal planar and tetrahedral bond angles. As a comparison nitrosobenzene, PhNO, has N=O and C–N bond lengths of 1.241(7) and 1.421(7) Å, respectively, and its C–N=O bond angle is 114.8(5)° [20]. All of these features imply that the NO substitu-

The molecular structures of the secondary amines, $(MeCb^{\circ})_2NH$ and $(PhCb^{\circ})_2NH$, and of the anion $(PhCb^{\circ})_2N^-$ of the salt $[K(18\text{-crown-}6)]^+[(PhCb^{\circ})_2N]^- \cdot 0.5(MeOC_2H_4)_2O$, are shown in Fig. 3. Selected bond distances and angles are given in Table 1. There are small differences between the lengths of corresponding bonds in the two cages in each compound that are not regarded as significant; average values for equivalent bonds are used in the discussion where appropriate. The conformations of the two amines and amide anion in their respective crystal structures are very similar, and the trigonal nitrogen atoms of the two amines have a planar configuration. Fig. 4 shows the environment surrounding the amide anion in the salt, including the cation and diglyme molecule.

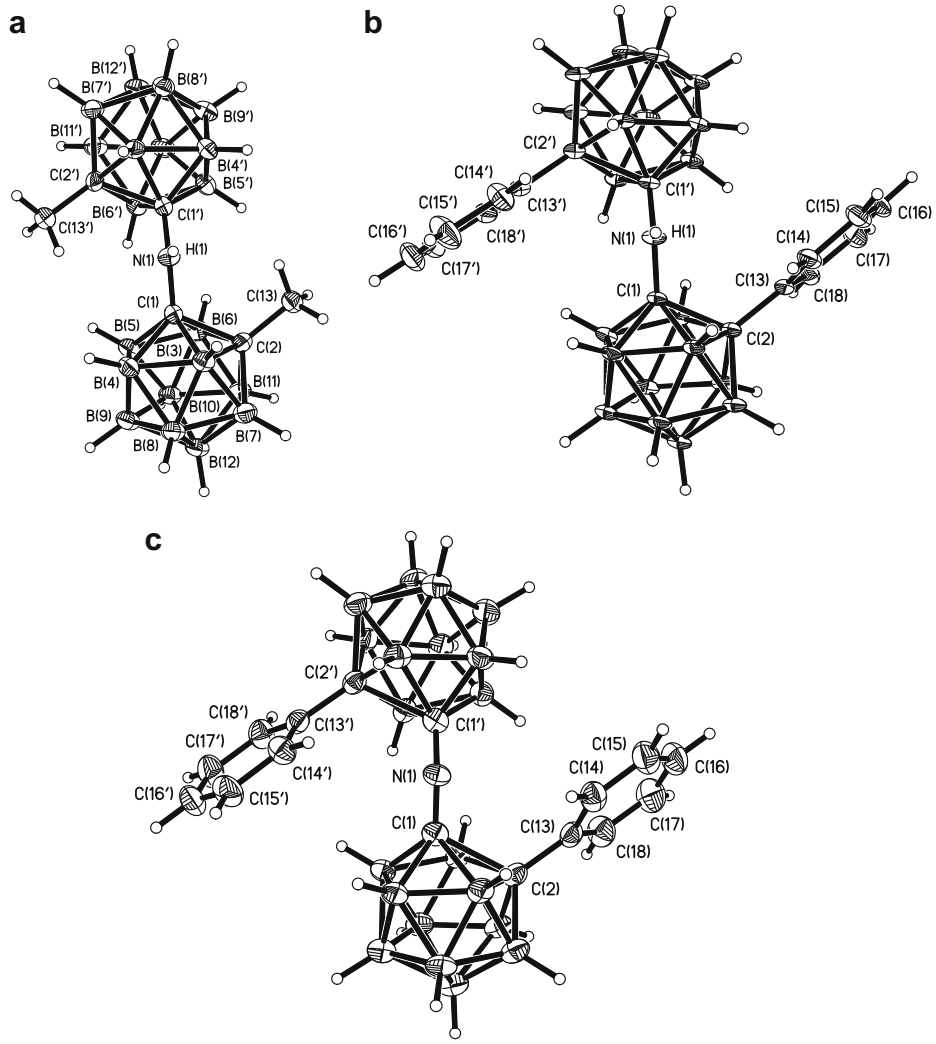

Fig. 3. Molecular structures of the dicarboranyl amines, (a) $(MeCb^{\circ})_2NH$ (**2**) and (b) $(PhCb^{\circ})_2NH$ (**3**), and (c) the $(PhCb^{\circ})_2N^-$ anion of the salt $[K(18\text{-crown-}6)][(PhCb^{\circ})_2N] \cdot 0.5(MeOC_2H_4)_2O$ (**4**).

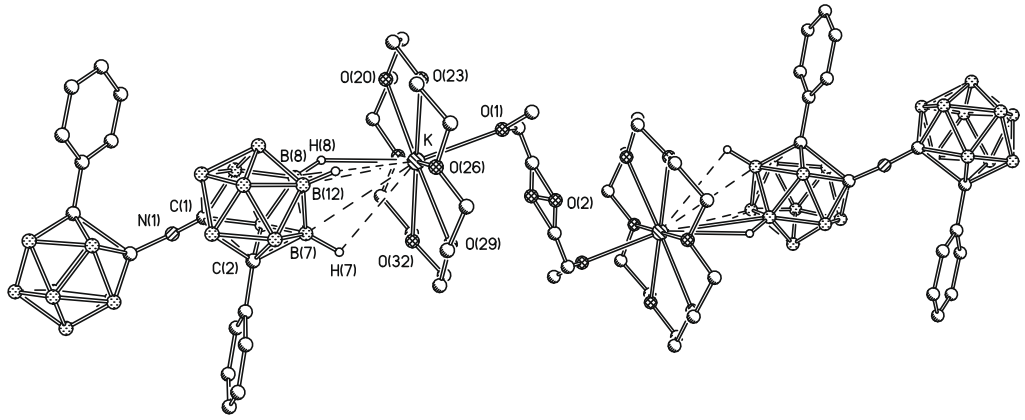

Fig. 4. Crystal structure of the salt $[K(18\text{-crown-6})][(PhCb^{\circ})_2N]\cdot 0.5(MeOC_2H_4)_2O$ (**4**) showing interactions between the cation and anion and between cation and solvent. Selected distances in Å, B(8)...K 3.53, B(7)...K 3.85, B(12)...K 3.74, O(1)...K 2.756(4). Both disorder components are shown for the solvent molecule. H atoms have been omitted except for those involved in the cation-anion interactions.

The potassium cation effectively caps a triangular face of one of the two cages (a face remote from the two cage carbon atoms) in a manner common in potassium-18-crown-6 salts of carborane anions [21]. The diglyme molecule, with its central oxygen atom O(2) disordered over two sites in the crystal structure, is coordinated through its outer oxygen atoms to two cations.

The structures of the amines and amide anion differ from that of the nitroso derivative PhCb°NO in showing clear evidence, in their conformations, bond distances and angles, of significant *exo*-N=C dative π-bonding from one nitrogen *p*-AO to both cages, which show concomitant distortion (C(1)–C(2) bond lengthening). The features that lead us to this conclusion are as follows (see Table 1).

The CNC angle in the phenyl amine $(PhCb^{\circ})_2NH$ is 132° and falls to 127° in the amide anion $[(PhCb^{\circ})_2N]^-$, showing that the nitrogen atom remains sp^2 hybridised on deprotonation, the 'lone pair' having greater repulsive effect than the NH bond which it replaces. The CNC angles are perhaps slightly affected by the repulsion between the two cages since the closest H···H separation between the cages is *ca.* 2.47 Å, longer than corresponding distances of 2.27 and 2.25 found in the related biscarboranyl sulfide, $(PhCb^{\circ})_2S$, and sulfoxide, $(PhCb^{\circ})_2SO$, respectively [8]. The CNC angle in diphenylamine Ph_2NH is 129° and falls to 121° in the Ph_2N^- anion [22,23].

In all three compounds the radial planes of the C–C bonds of both cages, *i.e.* their CCN planes, are roughly perpendicular to the trigonal nitrogen CNC plane so that the nitrogen *p*-orbital containing an electron pair is aligned with the cage C–C bonds. The closely similar conformation of the three compounds effectively precludes the possibility that this conformation is the fortuitous result of crystal packing forces, since these are unlikely to have the same effect in the crystal structures of the amines, still less in that of the ionic amide with large counter-ions.

We conclude that both carborane cages in each amine $(RCb^{\circ})_2NH$, and in the anion $(PhCb^{\circ})_2N^-$, are oriented to allow dative π-bonding from the *p*-orbital perpendicular to the C–N–C plane into the *p*-orbital on C1 that is aligned for cage C1–C2 σ-bonding (Fig. 1). Evidence for that *exo*-C=N π-bonding is provided by the C–N distances in these systems (Table 1), which at 1.404(2)–1.410(4) Å in the amines $(RCb^{\circ})_2NH$ and 1.354(4)–1.355(4) Å in the amide $(PhCb^{\circ})_2N^-$ are far shorter than would be appropriate for single C–N bonds between three- or even two-coordinate nitrogen and six-coordinate carbon atoms. The shorter C=N bond in the amide $(PhCb^{\circ})_2N^-$ is intelligible in that deprotonation of the amine $(PhCb^{\circ})_2NH$ increases the π-donor capacity of the nitrogen atom. The average C–N distances in diphenylamine Ph_2NH and in the diphenylamide Ph_2N^- anion are 1.400(4) and 1.370(5) Å, respectively [22,23].

Involvement of the tangentially orientated *p*-AO at C1 in the X–C1–C2 plane as the acceptor orbital for dative *exo*-π-bonding from nitrogen reduces the C1–C2 σ-bonding contribution to the cage bonding orbital, and so lengthens the cage C–C bond (Fig. 1). The effect is most marked in the amide anion $(PhCb^{\circ})_2N^-$, which has C–C bonds of length 1.980(3) and 1.995(3) Å, effectively the same length as in the anion $[PhCb^{\circ}O]^-$ (2.001(3) and 2.065(7) Å) [6,9], even though one nitrogen lone pair is shared between two cages. In the amines $(RCb^{\circ})_2NH$, the cage C–C bonds, 1.748(4) and 1.752(4) Å when R = Me and 1.794(3) and 1.799(3) Å when R = Ph, are understandably shorter than those in the amide. The difference of 0.05 Å between the two amines can be attributed to a π-bonding contribution from the phenyl group [5].

3. Conclusions

This paper reports improved low-temperature procedures by which reactions between lithio-carboranes and nitrosyl chloride can be used as preparative routes to two important categories of carborane derivatives, *viz.* nitroso derivatives $RCb^{\circ}NO$, and dicarboranylamines $(RCb^{\circ})_2NH$, the former using mixtures of diethyl ether and pentane as solvent and the latter using 1,2-dimethoxyethane instead of pentane in the solvent mix. Deprotonation of the amines $(RCb^{\circ})_2NH$ in toluene by potassium *t*-butoxide in the presence of the macrocyclic ether 18-crown-6 afforded the air- and moisture-stable salts $[K(18\text{-crown-6})]^+[(RCb^{\circ})_2N]^-$.

The crystal structures of $PhCb^{\circ}NO$, $(PhCb^{\circ})_2NH$, $(MeCb^{\circ})_2NH$ and $[K(18\text{-crown-6})]^+[(PhCb^{\circ})_2N]^-\cdot 0.5(MeOC_2H_4)_2O$ have been determined, and shown to shed further useful light on the capacity of the *ortho*-carborane cage to function as a sensitive probe of the π-donor characteristics of cage C-attached ligands. The cage C1–C2 and the *exo*-C–N bond lengths and the ligand orientations in these compounds reinforce the generalisation that π-donor ligands attached to an *ortho*-carborane carbon atom adopt an orientation that involves in *exo*-π-bonding the *p*-orbital on carbon that otherwise participates in cage C1–C2 σ-bonding.

4. Experimental

All air-sensitive manipulations were carried out under dry, oxygen-free N_2. Stirring refers to use of a magnetic stirrer. Pentane was distilled over sodium. 1,2-Dimethoxyethane was dried by reflux and distillation over potassium; ether refers to diethyl ether dried, where appropriate, over sodium. Ether solutions were dried over magnesium sulfate and evaporated near room temperature. 1-

Methyl-*ortho*-carborane [24] and 1-phenyl-*ortho*-carborane [25] were prepared by literature methods and dried by sublimation at 0.01 mm Hg. Commercial nitrosyl chloride (BDH Chemicals Ltd.) was used as received.

Melting points were measured in capillary tubes with an Electrothermal 9200 heating block. Infrared spectra were recorded from KBr discs on Perkin–Elmer 1600 series FTIR or Perkin–Elmer 1720× FTIR spectrometers and ultraviolet spectra with a Shimadzu UV 1201. Elemental carbon, hydrogen and nitrogen analyses were performed using Exeter Analytical CE-440 or Carlo Erba Strumentazione EA Model 1106 instruments. Mass spectra (MS) were recorded on a VG Micromass 7070E instrument under E.I conditions (EI) at 70 eV. Values of *M* show the isotope range $^{10}B_n$ to $^{11}B_n$ including a ^{13}C contribution if observed. NMR spectra were measured using Varian Unity-300 (^1H, ^{11}B, ^{13}C), Bruker AM250 (^1H, ^{13}C), Bruker Avance 400 (^1H, ^{11}B, ^{13}C) and/or Varian Inova 500 (^1H, ^{11}B) instruments. All chemical shifts are reported in δ (ppm) and coupling constants in Hz. ^1H NMR spectra were referenced to residual protio impurity in the solvent ($CDCl_3$, 7.26 ppm; CD_3CN, 1.85 ppm). ^{13}C NMR spectra were referenced to the solvent resonance ($CDCl_3$, 77.0 ppm; CD_3CN, 118.3 ppm). ^{11}B NMR spectra were referenced externally to $Et_2O \cdot BF_3$, $\delta = 0.0$ ppm. Peak assignments of cage boron and hydrogen atoms were determined where possible with the aid of 2D $^{11}B\{^1H\}$–$^{11}B\{^1H\}$ COSY, selective $^1H\{^{11}B\}$ and $^1H\{^{11}B\}$–$^{11}B\{^1H\}$ correlation spectra.

5. Reaction of 1-methyl- and 1-phenyl-*ortho*-carboranes with nitrosyl chloride

Nitrosyl chloride (5 ml) was condensed into a calibrated tube cooled to *ca.* −25 °C, transferred under reduced pressure into the co-solvent, ether or pentane (20 ml), at *ca.* −40 °C and the flask was brought to atmospheric pressure with dinitrogen. A solution of the lithio-carborane, prepared by slowly adding butyllithium (6.6 ml, 1.6 M in hexane; 10.5 mmol) to the substituted *ortho*-carborane (10.0 mmol) in 1,2-dimethoxyethane or pentane, (20 ml), was added dropwise with stirring at −40 °C (acetone/CO_2), −78 °C (acetone/CO_2) or −117 °C (ethanol/N_2) during *ca.* 35 min and the mixture was allowed to warm to room temperature during *ca.* 3 h. The solution was added in small portions to potassium hydrogen carbonate (40 g) in water (110 ml), the organic layer was diluted with ether, washed with water, dried and evaporated. The blue nitroso-compounds were separated from the resulting semi-solid by sublimation at *ca.* 70 °C/0.01 mm Hg and the residue was triturated with methanol (12 ml; the nitroso-carboranes are unstable to this solvent) to give the amines as white crystalline powders. The yields of nitroso-compounds and amines obtained using various bath temperatures and co-solvents are summarised in Scheme 1.

1-Methyl-2-nitroso-*ortho*-carborane formed volatile blue crystals identical with a sample prepared under the literature conditions; attempts to measure the melting point of this compound in open capillary tubes caused evaporation of the sample, leaving a colourless residue which melted sharply at the temperature, 208–210 °C, given in the literature [3] for the nitroso-derivative. A DSC scan showed a broad exotherm at 230 °C and the residue was shown by IR to consist of boric acid and *closo*-carborane products. 1-Phenyl-2-nitroso-*ortho*-carborane gave blue crystals m.p. 43–44 °C (literature [2] 54–55 °C).

6. Potassium-18-crown-6 salt of bis(2-phenyl-1-*ortho*-carboranyl)amide

Bis(2-phenyl-1-*ortho*-carboranyl)amine (255 mg, 5.6 mmol) in warm (*ca.* 55 °C) toluene (10 ml) was added under nitrogen to a solution of potassium *t*-butoxide (160 mg, 13.4 mmol) and 18-crown-6 (390 mg, 14.5 mmol) in toluene (5 ml). The mixture was heated briefly (*ca.* 90 °C, 1 min) and the blue–green oil which separated initially formed a pale yellow granular solid within a few

seconds. After standing overnight at room temperature the solid was washed with toluene to give the amide salt as a pale yellow powder (325 mg, 77%). Found: C, 44.2; H, 7.3; N, 1.7. $C_{28}H_{54}B_{20}KO_6N$ requires: C, 44.5; H, 7.2; N, 1.9%. Recrystallisation from 1,2-dichlorobenzene furnished yellow rectangular prisms, m.p. 254–257 °C, whose colour deepens reversibly on warming and which gave the same analysis as before. The crystalline amide is unchanged by exposure to air or contact with water but rapidly forms the parent amine in contact with ethanoic acid. Single crystals of the hemisolvate (**4**) suitable for X-ray diffraction were grown from a solution in diethyleneglycol dimethyl ether into which cyclohexane was diffused slowly from an upper layer.

M.p. 254–257 °C; MS (EI$^+$, *m*/*z*) 440–457; 453(100, M$^+$), MS (CI$^+$, NH_3, m/z) 282 (18-C-6+NH_4^+); IR (KBr disc, cm^{-1}): 3062w (Ar. CH); 2899, 1472, 1351, 1108s, 966, 838 (18-crown-6); 2575s, 2555s (BH); 1495, 1447 (Ar. skeleton); 1395s, br (CN); 1284; 1248; 1072; 1039, 1004w; 775, 883w, 806w, 775w; 745, 691 (C_6H_5 o.o.p.); 732w (carborane skeleton); 643w; 570w; 525. $^1H\{^{11}B\}$ NMR (CD_3CN), δ: 7.36 (d, 4H, *ortho* phenyl CH), 7.23 (t, 2H, *para* phenyl CH), 7.17 (t, 4H, *meta* phenyl CH); 3.47 (s, 24H, 18-C-6); 2.68 (s, 4H, H4,5), 2.13 (s, 10H, H3,6,7,9,11), 1.72 (s, 2H, H12), 1.58 (s, 4H, H8,10). $^{11}B\{^1H\}$ NMR (CD_3CN), δ: −4.4 (1B, B9), −8.3 (2B, B3,6); −10.5 (2B, B7,11); −12.6 (3B, B4,5,12); −16.3 (2B, B8,10). $^{13}C\{^1H\}$ NMR (CD_3CN), δ: 137.7 (C_6H_5 *ipso*); 129.3 (C_6H_5 *para*); 131.1, 128.8 (C_6H_5 *ortho* and *meta*); 129.5 (C1), 89.8 (C2); 70.9 (18-C-6). λ_{max} (THF, 20 °C): 317 nm (log ε, 3.92).

7. Potassium-18-crown-6 salt of bis(2-methyl-1-*ortho*-carboranyl)amide

By a similar procedure as above with bis(2-methyl-1-*ortho*-carboranyl)amine as the starting carborane, colourless crystals of the desired salt (86% yield) were obtained from toluene solution. M.p. 209–210 °C; Found: C, 34.3; H, 8.1; N, 1.8. $C_{18}H_{50}B_{20}KO_6N$ requires: C, 34.2; H, 8.0; N, 2.2%. MS (ES$^-$, *m*/*z*) 323–332; 328 (100, M$^-$), MS (ES$^+$, m/z) 303 (K18-C-6$^+$); IR (KBr disc, cm^{-1}): 2914, 1471, 1350, 1110s, 967, 839 (18-crown-6); 2560s (BH); 1413s, br (CN); 1369; 1283; 1246; 1072; 1034, 730w (carborane skeleton); 695w; 419. $^1H\{^{11}B\}$ NMR (CD_3CN), δ: 3.47 (s, 24H, 18-C-6); 2.30 (s, 4H, H4,5), 2.15 (s, 4H, H3,6), 1.98 (s, 4H, H7,11), 1.85 (s, 6H, CH_3), 1.82 (s, 2H, H9), 1.59 (s, 4H, H8,10), 1.53 (s, 1H, H12). $^{11}B\{^1H\}$ NMR (CD_3CN), δ: −7.5 (1B, B9), −8.8 (2B, B3,6); −11.3 (2B, B7,11); −12.3 (2B, B4,5); −13.7 (1B, B12), −15.4 (2B, B8,10). $^{13}C\{^1H\}$ NMR (CD_3CN), δ: 120.0 (C1), 87.0 (C2), 70.9 (18-C-6), 22.2 (CH_3).

8. Crystal structure determinations

Crystals of the compounds **1**–**4** were examined on Bruker SMART (**1**, **2**) and Stoe STADI4 (**3**, **4**) diffractometers with Mo Kα radiation (λ = 0.71069 Å; Cu Kα with λ = 1.54184 Å for **3**) at 160 K (180 K for **4**). Crystal data and other information are given in Table 2. Standard methods and software were employed, including refinement on all F^2 values [26]; no absorption corrections were applied, and no structural disorder was found.

[43–49] gave sterically hindered salen analogues which resulted in oligo- and polynuclear cobalt species with varied coordination geometry and oxidation states.

Our research group has been working on Schiff base cobalt complexes derived from different donor set ligands since the last decade and has successfully reported a few of them [52–54], though mixed valence cobalt Schiff base complexes are few. In this paper we report three new cobalt complexes of which two are mixed valence complexes and one is a dinuclear cobalt(III) species. The three different Schiff base ligands used to synthesise **1**, **2** and **3** were obtained by the selective and non-selective condensation of 1,3-diaminopropane and 1,3-diaminopentane with 2-hydroxyacetophenone (Fig. 1) and the chelating behaviour of the ligands with the cobalt ion has been investigated. Pseudohalides (NCO^- and N_3^-) have been used to increase the nuclearity of the complexes. To synthesise **1** we selectively condensed one of the two primary amines in 1,3-diaminopropane with 2-hydroxyacetophenone and obtained the N_2O donor Schiff base ligand $\mathbf{HL^1}$. Although similar N_2O donor Schiff bases complexes were obtained earlier with copper and nickel, the corresponding cobalt species were not obtained [55,56]. For **2** the N_2O donor Schiff base ligand $\mathbf{HL^2}$ was synthesised by condensing the less hindered $-NH_2$ functionality of 1,3-diaminopentane with 2-hydroxyacetophenone in order assess any structural variations arising from ethyl substitution at the uncondensed $-NH_2$ end of $\mathbf{HL^2}$. Single crystal X-ray diffraction studies on **1** and **2** confirmed this structural variation. In **1** the asymmetric unit comprises five mixed valence mononuclear cobalt centers, whereas **2** is a dinuclear cobalt(III) species with *end-on* azido bridges. In order to synthesise **3**, both 1,3-diaminopropane primary amine functionalities were non-selectively condensed with 2-hydroxyacetophenone to obtain the symmetric N_2O_2 donor Schiff base ligand $\mathbf{H_2L^3}$, which in the presence of the azide ion formed an *end-on* azido and μ_2-phenoxo bridged trinuclear Co^{III}–Co^{II}–Co^{III} core where the central cobalt(II) center is on a center of inversion. Earlier Mitra et al. reported a trinuclear copper complex with $\mathbf{H_2L^3}$ [57], but **3** is the first azido bridged cobalt complex with $\mathbf{H_2L^3}$. The complexes were characterized by physical techniques and their structures were confirmed from single crystal X-ray studies. EPR analyses were carried out for the mixed valence cobalt complexes **1** and **3**, and DNA binding studies were performed for all three complexes.

2. Experimental

2.1. Materials

All chemicals and solvents used for the syntheses were of analytical grade. 1,3-Diaminopropane, 1,3-diaminopentane, 2-hydroxyacetophenone, cobalt nitrate hexahydrate, sodium cyanate and sodium azide were purchased form Aldrich Chemical Co. and were used without further purification. The CT-DNA was purchased from Bangalore Genie, the Tris buffer, sodium chloride and hydrochloric acid (AR) were purchased from Merck.

2.2. Syntheses

2.2.1. Synthesis of the Schiff base ligands

2.2.1.1. HL^1. To a vigorously stirred cool dilute ethanolic solution (50 ml, $T = 5$–10 °C) of 1,3-diaminopropane (0.833 ml, 10 mmol), an absolute ethanolic solution (40 ml) of 2-hydroxyacetophenone (0.96 ml, 8 mmol) was added dropwise. After the addition was complete, the mixture was stirred for 15–30 min and then refluxed for 15–60 min. The resulting solution was evaporated under vacuum to remove the solvent and the excess diamine was extracted by benzene. The product was collected by filtration, washed with diethyl ether and dried in air. *Anal.* Calc. for $[C_{11}H_{16}N_2O]$: C, 68.72; H, 8.39; N, 14.57. Found: C, 68.67; H, 8.34; N, 14.45%.

2.2.1.2. HL^2. The same above method was adopted to synthesise $\mathbf{HL^2}$. 1,3-Diaminopentane (1.19 ml, 10 mmol) and 2-hydroxyaceto-

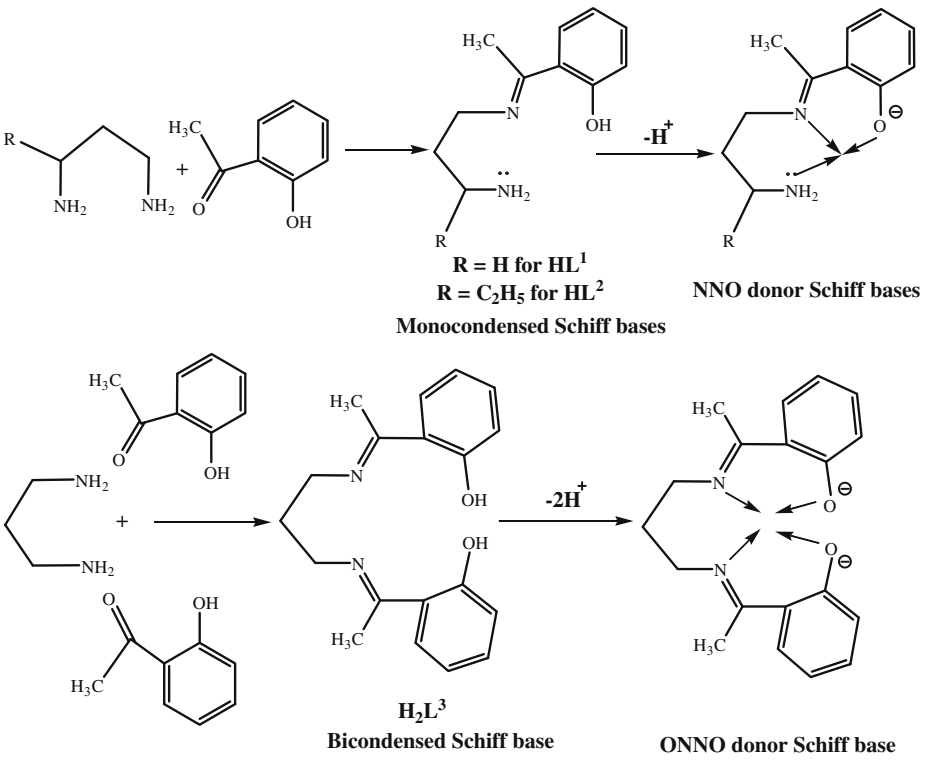

Fig. 1. Scheme of synthesis for the selectively and non-selectively condensed Schiff bases.

phenone (0.96 ml, 8 mmol) were used to obtain **HL²**. The resulting solution was evaporated under vacuum to remove the solvent, and the excess diamine was extracted by benzene. The product was collected by filtration, washed with diethyl ether and dried in air. *Anal.* Calc. for $[C_{13}H_{20}N_2O]$: C, 70.87; H, 9.15; N, 12.72. Found: C, 70.76; H, 9.09; N, 12.69%.

2.2.1.3. H_2L^3. The symmetrical **H_2L^3** was prepared following the literature method [57]. On refluxing a methanolic solution (100 ml) of 1,3-diaminopropane (0.83 ml, 10 mmol) with 2-hydroxyacetophenone (2.4 ml, 20 mmol) for 40 min an orange yellow Schiff base resulted. It was then cooled and the yellow crystalline product was collected by filtration, washed with diethyl ether and dried in air. *Anal.* Calc. for $[C_{19}H_{22}N_2O_2]$: C, 73.52; H, 7.14; N, 9.03. Found: C, 73.49; H, 7.06; N, 9.01%.

2.2.2. Syntheses of the complexes

*2.2.2.1. $[Co(L^1)_2]_2$ $[Co(NCO)_4]$ (**1**).* To a (20 ml) methanolic solution of cobalt nitrate hexahydrate (0.291 g, 1 mmol), a methanolic solution (30 ml) of **HL¹** (0.384 g, 2 mmol) was added dropwise and the mixture was stirred to produce a dark red solution. Sodium cyanate (0.0.65 g, 1 mmol) in a minimum volume of water–methanol mixture was added to the stirring solution to give a dark green colour and the resulting solution was further stirred for 3 h at 40 °C. The dark green solution was kept at 16 °C, yielding red needle shaped crystals suitable for X-ray diffraction after a week. The crystals were isolated by filtration and air-dried. *Anal.* Calc. for $[Co(L^1)_2]_2$ $[Co(NCO)_4]$: C, 51.89; H, 5.40; N, 15.14. Found: C, 51.86; H, 5.11; N, 15.12%.

*2.2.2.2. $[Co_2(\mu\text{–}N_3)_2(L^2)_2(N_3)_2]$ (**2**).* **HL²** (0.22 g, 1 mmol) was dissolved in (30 ml) methanol, and was added dropwise to a methanolic solution (20 ml) of cobalt nitrate hexahydrate (0.291 g, 1 mmol) to give an orange red solution. The solution was stirred for 20 min then sodium azide (0.130 g, 2 mmol) in a minimum volume of a water–methanol mixture was carefully added to produce a dark brown solution. The resulting solution was further stirred for 2 h at room temperature. The dark brown solution was kept at 20 °C yielding red needle shaped crystals suitable for X-ray diffraction after a week. The crystals were isolated by filtration and air-dried. *Anal.* Calc. for $[C_{26}H_{38}Co_2N_{16}O_2]$: C, 43.05; H, 5.24; N, 30.91. Found: C, 43.0; H, 5.21; N, 30.89%.

*2.2.2.3. $[(H_2O)_2Co(\mu\text{–}N_3)_2(\mu\text{–}L^3)_2Co_2(N_3)_{1.25}(CH_3O)_{0.75}]H_2O$ (**3**).* To a methanolic solution (20 ml) of cobalt nitrate hexahydrate (0.291 g, 3 mmol), a methanolic solution (30 ml) of **H_2L^3** (0.64 g, 2 mmol) was added dropwise to produce a dark red solution which was refluxed for 20 min and then cooled at room temperature. Sodium azide (0.130 g, 2 mmol) in a minimum volume of water–methanol mixture was added to the dark red solution to give a dark brown colour which was then stirred for 4 h at 40 °C. The dark brown solution was kept at 20 °C, yielding brown needle shaped crystals suitable for X-ray diffraction after ten days. The crystals were isolated by filtration and air-dried. *Anal.* Calc. for $[C_{38.75}H_{48.25}Co_3N_{13.75}O_{7.75}]$: C, 46.16; H, 4.79; N, 19.12. Found: C, 46.12; H, 4.75; N, 19.09%.

2.3. Procedure for DNA binding

Using the electronic absorption spectral method, the relative binding of the two complexes to calf thymus (CT)-DNA was studied in 5 mM Tris–HCl/NaCl buffer (pH 7.2). The solution of CT-DNA gave a ratio of UV absorbance at 260 nm and 280 nm, A_{260}/A_{280}, of 1.8–1.9, indicating that the DNA was sufficiently free of protein. The stock solution of CT-DNA was prepared in 50 mM Tris–HCl/NaCl buffer, pH 7.2 (stored at 4 °C). The concentration of CT-DNA was determined from its absorption intensity at 260 nm with a molar extinction coefficient of 6600 M^{-1} cm^{-1} with respect to base [58]. The binding constant was determined using the following equation [59]:

$$1/\Delta A = 1/\Delta A_{max} + 1/K_{app}\Delta A_{max} \times 1/(C_D - C_0) \quad (1)$$

where ΔA is the decrease in absorbance at 367 nm for **1** and 292 nm for **2**. ΔA_{max} indicates the same parameter where the complex is totally bound to DNA (saturation). C_D and C_0 denote the concentration of CT-DNA and initial concentration of the complexes, respectively. K_{app} is the apparent binding constant of the complexes to CT-DNA and is the reciprocal of K_d, where K_d is the dissociation constant of the complex DNA interaction.

2.4. Physical measurements

The Fourier Transform Infrared spectra of the complexes were recorded on a Perkin–Elmer Spectrum RX I FT-IR in the range 4000–300 cm^{-1} as a solid KBr disc. The electronic spectra were recorded at 300 K on a Perkin–Elmer λ-40 UV–Vis-spectrometer using HPLC grade acetonitrile as the solvent with 1 cm quartz cuvettes in the range 200–800 nm. C, H, N microanalyses were carried out with a Perkin–Elmer 2400 II elemental analyzer. Electrochemical measurements were performed on a VersaStat–PotentioStat II cyclic voltammeter using HPLC grade acetonitrile solution as the solvent, and tetrabutylammonium perchlorate was used as the supporting electrolyte at a scan rate 0.05 V/s. Platinum and a saturated calomel electrode (SCE) were the working and the reference electrodes in the process, respectively. The X band EPR spectra of polycrystalline samples were taken with Bruker ESP-300 spectrometer using a rectangular cavity equipped with 100 kHz field modulation. The EPR spectra were recorded at room temperature and at liquid nitrogen temperature using a liquid nitrogen dewar. DPPH was used for the calibration of g values. The g values were estimated by comparing the experimental spectrum with those obtained by the computer simulation program (WIN EPR SYMPHONIA) working at the second order of perturbation theory.

2.5. X-ray crystallography

The X-ray diffraction experiments were carried out at 100 K on a Bruker X8 Apex 2 diffractometer Single crystals were coated in Paratone-N heavy oil and mounted in a Cryoloop before being transferred to the cold stream on the diffractometer. Intensity data were collected using graphite monochromatised Mo Kα radiation (λ = 0.71073 Å). Data collection, reduction and absorption corrections were done with the APEX2 suite of programs [60]. All non-hydrogen atoms were refined anisotropically by full-matrix least-squares based on F^2 using SHELXTL. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atom isotropic displacement parameters were all treated as riding on the bound atom (1.2 Ueq C/N for all except methyl H atoms). All carbon bound H atoms were generated geometrically and were included in the refinement in the riding model approximation. In **1** all H atoms were constrained to idealised geometries, in **2** the coordinates of H atoms bound to amine N9 were freely refined, and there was disorder in the methylene portion of chelate ring, 60:40% occupancy ratio for C10A, C11A and C10B, C11B, respectively. In **3** all the water H atoms were found in the difference map and initially restrained to O–H 0.90(4) Å, H···H 1.50(2) Å before being fixed for the final cycles, as refinement of their positions was unstable. Selected crystallographic data are summarised in the Table 1.

3. Results and discussion

3.1. Infrared spectra

The IR spectra of **1**, **2** and **3** were analysed in comparison with that of their free ligands **HL^1** **HL^2** and **H$_2$L^3** in the region 4000–250 cm^{-1}. The strong sharp absorption band around 1627, 1617 and 1620 cm^{-1} in the spectra of the free ligands **HL^1**, **HL^2** and **H$_2$L^3** can be assigned to the C=N stretching, but in the complexes these bands are shifted to lower frequencies, which can be attributed to the coordination of the imine nitrogen to the metal center. The bands at 1598, 1596 and 1595 cm^{-1} are assigned to the imine stretching frequencies in the complexes **1**, **2** and **3**, respectively [35]. The three Schiff ligands show a well defined band at 3460, 3447 and 3449 cm^{-1} due to O–H stretching, which disappears in the respective complexes indicating the deprotonation of the respective Schiff base ligands upon complexation. The strong phenolic C–O stretching obtained at 1222, 1218 and 1206 cm^{-1} for **HL^1**, **HL^2** and **H$_2$L^3** shifts to a lower frequency in the respective complexes, at 1181, 1163 and 1159 cm^{-1}, supporting the coordination of the deprotonated phenolato oxygen atoms to the metal centers [61]. Two sharp bands obtained at 3472 and 3525 cm^{-1} for **1** and 3311 and 3368 cm^{-1} for **2** are assigned to the asymmetric and symmetric N–H stretching modes of the primary amine [62], indicating the coordination of the selectively condensed Schiff bases [**L^1**]$^-$ and [**L^2**]$^-$ to the respective metal centers, whereas no such bands are obtained for **3**. Complex **1** shows one strong band at 2208 cm^{-1}, which indicates the presence of NCO as terminal ligands [63]. In the spectra of **2** and **3** strong, well resolved sharp bands with a bifurcated peak at 2066, 2016 and 2060, 2015 cm^{-1} were obtained, respectively, which are assigned to $\upsilon_{N=N}$ of the azide moiety coordinated to two different metal centers simultaneously. The ligand coordination to the metal centre is substantiated by a υ_{M-N} band appearing at 420, 406 and 412 cm^{-1} for **1**, **2** and **3**, respectively.

3.2. Electronic spectra

The UV–Vis spectrum of **1** shows a d–d transition band at 586 nm and several CT bands are observed in the region 442–382 nm. The d–d band at 586 nm is due to the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition for the distorted octahedral cobalt(III) ion in the complex [64]. The higher energy band, $^1A_{1g} \rightarrow {}^1T_{2g}$, is obscured by ligand to metal charge transfer bands. The bands for the tetrahedral cobalt(II) center in $[Co(NCO)_4]^{2-}$, corresponding to the spin allowed transition $^4A_2 \rightarrow {}^4T_1(P)$, should be located on the higher energy side of the overlapping charge transfer bands. Similarly for **2**, a d–d transition band at 570 nm is obtained which again supports the presence of distorted octahedral cobalt(III) centers in the complex. The higher energy band $^1A_{1g} \rightarrow {}^1T_{2g}$ is obscured by ligand to metal charge transfer bands, obtained in the broad range 410–375 nm. The UV–Vis spectrum of **3** shows two very broad d–d transition bands at 542 and 625 nm, supporting the presence of both octahedral cobalt(II) as well as octahedral cobalt(III) ions in the complex. The band at 542 nm is due to the $^4T_{1g}(F) \rightarrow {}^4T_{1g}(P)$ transition and the weak shoulder at 656 nm is probably due to the $^4T_{1g}(F) \rightarrow {}^4A_{2g}$ transition for the octahedral cobalt(II) unit [64]. The band at 625 nm is due to a $^1A_{1g} \rightarrow {}^1T_{1g}$ transition for the distorted octahedral cobalt(III) ion in the complex. Apart from d–d bands, several charge transfer bands can be observed in the region 442–382 nm for **3** (see Fig. 1).

3.3. Cyclic voltammetry

The cyclic voltammetry experiments for **1**, **2** and **3** were performed in acetonitrile solution at ambient temperature (300 K) within the potential range ±2 V using platinum as the working electrode and a saturated calomel electrode (SCE) as the reference electrode in the process. In order to compare the cyclic voltammograms of **1**, **2** and **3** they have been represented in Fig. 2. The voltammograms of **1** and **3** are quite alike, but differ significantly from that of **2**. During the cathodic scan, **1** and **3** display two different irreversible reductive responses at −0.121, −0.946 and −0.392, −0.987 V, respectively, whereas a single irreversible reductive response at −0.18 V was obtained for **2**. Similarly during the anodic scan **1** and **3** exhibit two irreversible oxidative responses at +0.604, +1.132 and +0.801, +1.276 V, respectively, whereas a single irreversible oxidative peak at +0.36 V was observed for **2**. For **2** the peak at −0.18 V is attributed to the reduction of the $Co^{III} \rightarrow Co^{II}$ centers, whereas the oxidation of the $Co^{II} \rightarrow Co^{III}$ centers in the

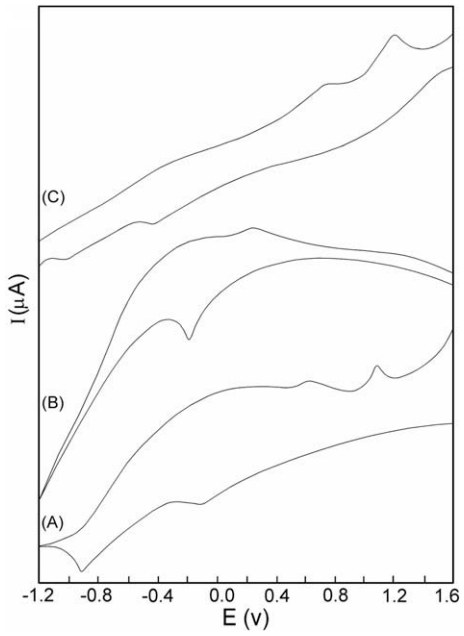

Fig. 2. A, **B** and **C** are the representative cyclic voltammograms of **1**, **2** and **3**, respectively, at room temperature in acetonitrile solvent.

complex is associated with the peak at +0.36 V. Such oxidations and reductions are similar to those of the earlier reported cobalt-(III) dinuclear species with cobalt(III) ions residing in a similar coordination environment [65]. Unlike **2**, for **1** and **3** the two different irreversible reductive responses obtained at −0.121, −0.946 (**1**) and −0.392, −0.987 V (**3**) are attributed to two different $Co^{III} \rightarrow Co^{II}$ reductions, and two irreversible oxidative responses at +0.604, +1.132 (**1**) and +0.801, +1.276 V (**3**) are associated with two different $Co^{II} \rightarrow Co^{III}$ oxidations. Such reductions are indicative of the presence of two types of structurally different cobalt(III) centers residing in non-identical coordination environments for **1** and **3**. Similarly the two different oxidative responses suggest the oxidations of two structurally dissimilar cobalt(II) centers in the respective complexes. Thus from the cyclic voltammograms of **1**, **2** and **3** we can propose that unlike **2**, **1** and **3** are mixed valence cobalt species containing cobalt(II) as well as cobalt(III) centers whereas **2** is a solely cobalt(III) species. The cyclic voltommograms of **1** and **3** are compared to that of the earlier reported mixed valence Co^{III}–Co^{II}–Co^{III} trinuclear species [34]. In contrast to that of **1** and **3**, for the earlier reported mixed valence trinuclear cobalt species only a single irreversible oxidative response at +1.72 V was followed by an irreversible reductive response at −1.44 V using a Ag–AgCl electrode with a three electrode configuration. From the structural studies of the trinuclear complex [34] it is found that the two cobalt(III) centers reside in similar coordination environments as a result of which only a single irreversible reductive response is observed, whereas for **1** and **3** the two irreversible reductive responses indicate that the cobalt(III) centers are expected to reside in two different coordination environments. A similar argument is applicable for the Co^{II} centers in the respective complexes.

3.4. EPR spectra

The X band EPR spectra of polycrystalline samples **1** and **3** are shown in Fig. 3. The EPR spectra were recorded both at room temperature and at liquid nitrogen temperatures. The EPR spectra were recorded to distinguish the valence and spin state of cobalt ion (S = ½ and 3/2) and also to get information about the coordination and symmetry around the transition metal ion. The cobalt ion exhibits two oxidation states (II and III), where cobalt(III) with a t_{2g}^6 configuration is diamagnetic in nature and hence EPR silent, whereas cobalt(II) exist in both low spin (S = 1/2) and high spin (S = 3/2) states and is paramagnetic, and so can be investigated by EPR spectroscopy. The EPR parameters observed for low spin hexacoordinated cobalt complexes with axial elongation along the z axis and a $^2A_1(d_{z2})$ ground state showed the trend $g_\perp$ ($\sim$2} < $g_{||}$ (2.02–2.01), $A_\perp^{Co} < A_{||}^{Co}$ and exhibit relatively small anisotropy in the g value [66–68]. In addition to this, the EPR of low spin cobalt complexes is observable at room temperature as its spin lattice relaxation time is sufficiently long. The ^4F ground state of isolated cobalt(II) (S = 3/2) in a purely octahedral crystal field splits into a $^4A_2$ (singlet) ground state and two $^4T_1$ and $^4T_2$ excited states (triplets). The combined effect of spin orbit coupling and lower crystal fields further splits the $^4A_2$ ground state into two Kramer's doublets, $E_{1/2}$ and $E_{3/2}$, with a zero field splitting equal to 2D. However if there is a very large zero field splitting, the EPR spectra can be described with an effective spin S = 1/2. If the energy gap between the two Kramer doublets is high enough ($\wedge E \geqslant kT$), only the ground state is expected to be sufficiently populated. Furthermore, the presence of low lying excited states above the orbital singlet state contribute towards fast electronic relaxation, hence the EPR spectrum is observed at low temperature.

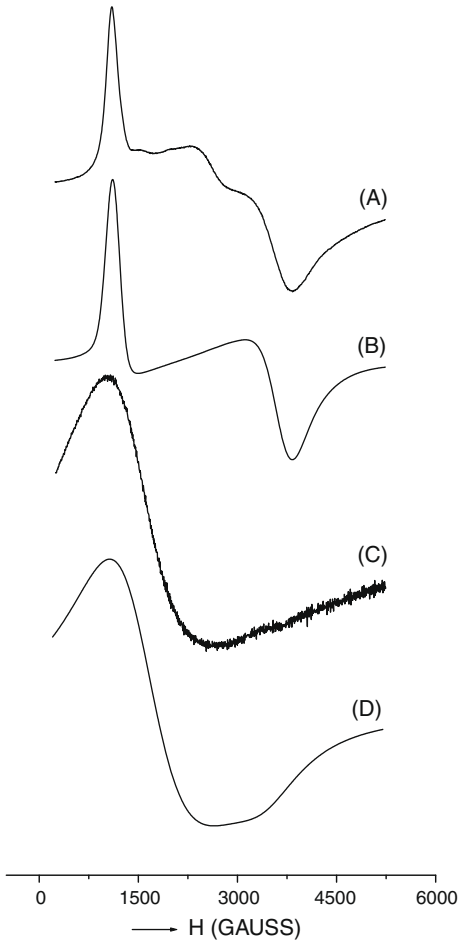

Fig. 3. EPR spectra of (A) Co complex **1** at 77 K. (B) Simulated spectrum with $g_{||}$ = 6.15 Δ_{pp} = 200 G, $g_\perp$ = 1.85, Δ_{pp} = 1200 G. (C) Co complex **3**. (D) simulated spectrum with $g_{||}$ = 2.00 Δ_{pp} = 1200 G, $g_\perp$ = 4.55, Δ_{pp} = 800 G.

The X band EPR spectra of polycrystalline samples of mixed valence cobalt complexes **1** and **3** were recorded in the temperature range 80–300 K. The EPR measurements were not recorded for **2** as

it is a Co(III)–Co(III) diamagnetic dinuclear species. Low temperature EPR spectra containing very broad and featureless signals (signals without any hyperfine structure, ^{57}Co, 100% abundance, $I = 7/2$) appeared for both the complexes. Increasing the temperature up to room temperature caused further broadening of the signals and the signals were broadened so much that the bands were not detected at room temperature. This behaviour is attributed to the short spin lattice relaxation time of high spin cobalt complexes in octahedral fields at room temperature. Fig. 3 shows the EPR spectra of polycrystalline samples of **1** and **3** at liquid nitrogen temperature. The EPR signal of complex **1** consists an intense signal with $g_{||} = 6.15$ ($\Delta_{pp} = 200$ G) and $g_{\perp} = 1.85$ ($\Delta_{pp} = 1200$ G) which is attributed to the $[Co(II)NCO_4]^{2-}$ anion having a tetrahedral arrangement of NCO [69,70]. The EPR spectrum of **3** could be interpreted in terms of an axial spectrum with $g_{\perp} = 4.550$ ($\Delta_{pp} = 1200$ G) and $g_{||} = 2.000$ ($\Delta_{pp} = 800$ G). The EPR spectrum is typical of distorted six coordinated cobalt(II) ions in a high spin configuration ($S = 3/2$) with the ground state being $S = 1/2$ [71,72]. In **3**, the cobalt ions are of mixed valence (II and III) and have a tendency to form trinuclear species viz, Co(III)–Co(II)–Co(III) [35]. The central cobalt(II) center is EPR active and has a highly distorted octahedral geometry (the equatorial sites are occupied by water of hydration and oxygen atoms of the bridging phenoxo group, whereas the axial sites are occupied by nitrogen atoms of two *end-on* bridging azido groups).

3.5. Description of the crystal structures

3.5.1. $[Co(L^1)_2]_2$ $[Co(NCO)_4]$ (**1**)

An ORTEP diagram of **1** is presented in Fig. 4 and relevant bond length and bond angle data are listed in Table 2. The structure consists of four $[Co^{III}\mathbf{L}^1{}_2]^+$ monocations, where the cobalt ions are on centres of inversion, and one $[Co^{II}(NCO)_4]^{2-}$ anionic unit [52]. Therefore the $[Co^{III}\mathbf{L}^1{}_2]^+$ ions are in a 2:1 ratio to $[Co(NCO)_4]^{2-}$. Structurally, there is no significant difference between the four $[Co\mathbf{L}^1{}_2]$ units, they are all six coordinate with distorted octahedral geometries with the Co–N bonds slightly longer than the Co–O bonds. The interligand bite angles for all four six coordinate cobalt centers differ slightly. Co(3) has the largest interligand bite angle of 96.20° whereas Co(2) has the shortest interligand bite angle of 93.56°. The Co(1) and Co(4) centres have similar interligand bite angles of 95.28° and 95.17°, respectively. The $[Co^{II}(NCO)_4]^{2-}$ anion has a cobalt(II) center with a tetrahedral arrangement of NCO^- ligands where all four NCO^- ligands are almost linear with N–C–O bond angles to within a degree of 179°. Several hydrogen bonding interactions are found in the structure (Table 3). The hydrogen atoms [H(10A), H(10G)] of the free amine fragment participate in hydrogen bonding with the deprotonated phenoxo oxygens [O(1D) and O(1A) respectively] and thereby connect the two adjacent mononuclear Co(1) and Co(4) units, as shown in Fig. 5. The Co(1) and Co(4) centres are connected to the tetrahedral Co(5) unit by hydrogen bonding interactions involving the remaining two hydrogen atoms [H(10B), H(10H)] of the other free amine functionality with oxygen atom O(21) of $[Co(II)NCO_4]^{2-}$. Similarly the H atoms of the free amine fragment of the Schiff bases coordinated to Co(2) and Co(3) participate in NH···O hydrogen bonding with oxygen atom O(24) of $[Co(II)NCO_4]^{2-}$. In **1** all five mononuclear

cobalt centres are interconnected to each other by H-bonding, forming a 3D network as shown in Fig. 6.

3.5.2. $[Co_2(\mu\text{–}N_3)_2(L^2)_2(N_3)_2]$ (**2**)

An ORTEP diagram of **2** with the atom numbering scheme is given in Fig. 7 and bond lengths and angles are listed in Table 4. It is a centrosymmetric dinuclear unit. The two cobalt(III) centers in **2** are six coordinate with a relatively shorter metal–metal separation of 3.0555(5) Å. Both cobalt(III) centers have slightly distorted octahedral coordination geometries, a consequence of the coordination of

the tridentate N_2O donor ligand $(\mathbf{L^2})^-$ and three azide ions. The equatorial sites of both cobalt(III) centers are occupied by four nitrogen atoms: one imine nitrogen atom of the deprotonated Schiff base, two azido nitrogen atoms coordinating in an *end-on* fashion and another terminally coordinated azido nitrogen atom. The two axial sites of each distorted octahedral cobalt(III) center are occupied by one deprotonated phenoxo oxygen atom and the nitrogen atom of the uncondensed amine of $(\mathbf{L^2})^-$. In the dinuclear unit, the imine nitrogen, the *end-on* and the two terminally coordinating azide ions are displaced by 0.052(1), 0.054(1) and 0.056(1), 0.057(1) Å, respectively, from the N_4 equatorial plane. The two $\mu_{1,1}$-bridging azide ions and the two terminally coordinated azide ions are almost linear, with N–N–N angles ranging from 177.22° to 177.7°. The 3+ oxidation state assigned to both cobalt ions is attributed to the coordination of the two terminal azide ions to each cobalt center. Both intramolecular and intermolecular hydrogen bonding interactions are found in **2** (Table 5). All four hydrogen atoms of the two uncondensed Schiff base $-NH_2$ functionalities participate in hydrogen bonding. Two hydrogen atoms participate

in intermolecular H-bonding interactions with the nitrogen atoms of the *end-on* bridging azide ions on two adjacent molecules whilst the other two hydrogen atoms form intramolecular hydrogen bonds with the deprotonated phenoxo oxygen atoms. Thus the dinuclear units are interconnected to each other by intermolecular H-bonding interactions to form a 1D chain (Fig. 8).

3.5.3. $[(H_2O)_2Co(\mu\text{-}N_3)_2(\mu\text{-}L^3)_2Co_2(N_3)_{1.25}(CH_3O)_{0.75}]H_2O$ (**3**)

An ORTEP view of **3** with the atom labelling scheme is shown in Fig. 9, and relevant bond distances and angles are listed in Table 6. In this trinuclear complex the bond distances around the Co(1) and Co(3) centers are considerably shorter than those around the Co(2) centre, which is attributed to the differing oxidation states where Co(1) and Co(3) are 3+ whilst Co(2) is 2+ thus generating a mixed valence cobalt complex of the (Co^{III}–Co^{II}–Co^{III}) type. Unlike the similar previously reported trinuclear cobalt Schiff base complexes [34,35], the coordination modes of the deprotonated phenoxo oxygen atoms differ despite the ligand $\mathbf{H_2L^3}$ being symmetrical. Two phenoxo oxygen atoms [O(2), O(4)] of the two units of doubly deprotonated Schiff base ligands $(\mathbf{L^3})^{2-}$ are terminally coordinated whereas the immediate neighbours on the other end [O(1), O(3)] bridge two cobalt centers simultaneously, which is rarely observed

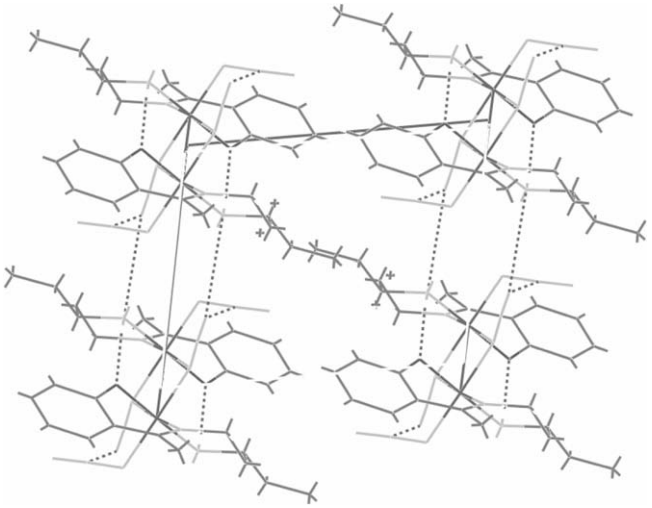

Fig. 8. Hydrogen bonding in **2** resulting in a 1D polymeric chain structure (H-bonding shown as dotted lines down the *c*-axis).

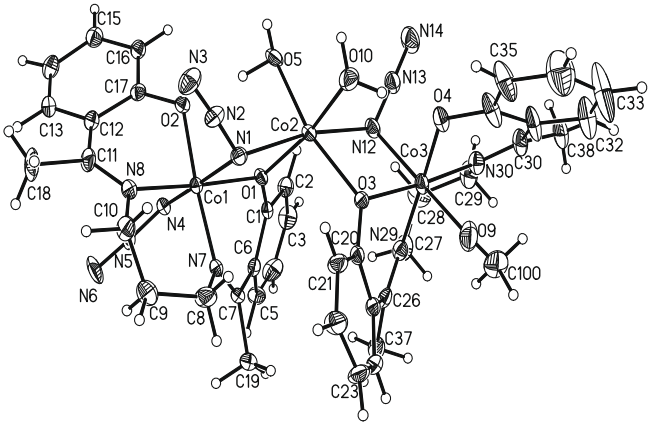

Fig. 9. ORTEP view of **3** drawn with 30% probability ellipsoids. The sites occupied by O9 and C100 are 75% MeO and 25% N_3. The minor azide is not shown and there is one molecule of water disordered over three sites.

in such salen-type Schiff base complexes [34,35,57]. Thus there are actually two different kinds of phenolato oxygen atoms present in the ligand: one of them is terminally coordinated to the individual cobalt centers and the other is in a μ-bridging mode which helps to interconnect the two adjacent cobalt centers. Co(1) has a six coordinated distorted geometry in which N(8), bridging O(1) of another unit of $(\mathbf{L^3})^{2-}$ and N(1), N(4) of the *end-on* and terminally coordinated azide ions constitute the equatorial plane. The axial sites of Co(1) are occupied by N(7) and the terminally coordinated O(2) atom of $(\mathbf{L^3})^{2-}$. Similarly Co(3) also resides in a six coordinated distorted octahedral geometry, but the equatorial sites are occupied by N(30), bridging O(3) of $(\mathbf{L^3})^{2-}$, *end-on* bridging N(12) atom of

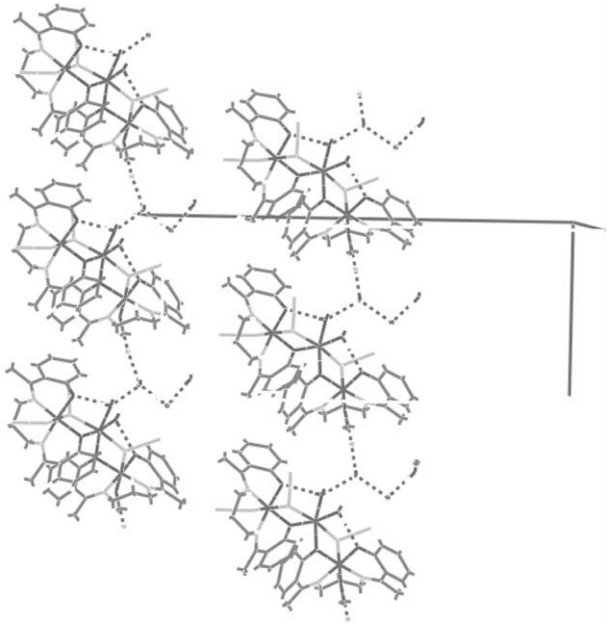

Fig. 10. Hydrogen bonded 1D polymeric chain structure of **3** (H-bonding shown as dotted lines down the *a*-axis).

the azido ligand and a terminally coordinated O(9) atom of the deprotonated methanol molecule. The two axial sites of Co(3) are occupied by N(29) and the terminally coordinated O(4) of $(\mathbf{L^3})^{2-}$. The central Co(2) center, being a d^7 species, is subjected to a *z*-out Jahn–Teller distortion and resides in a highly distorted octahedral geometry. The equatorial sites are occupied by O(5) and O(10) atoms of two water molecules and O(1) and O(3) atoms of the two μ-bridging phenoxo oxygens. The relatively longer axial sites are occupied by the N(1) and N(12) atoms of the two *end-on* bridging azido ligands connecting Co(2) with the adjacent Co(1) and Co(3) centers. The two imine nitrogen and the two deprotonated phenoxo oxygens of the Schiff base coordinated to Co(1) ion lie in the same plane, but the two aromatic rings of 2-hydroxyacetophenone and the three carbon atoms of the 1,3-diamino propane constituting the ligand $(\mathbf{L^3})^{2-}$ lie in three different planes. The dihedral angle between the planes containing the two aromatic rings with the almost planar N(7)N(8)O(1)O(2)Co(1) are 46.33° and 54.68° and the dihedral angle between the planes containing the two aromatic rings is 79.78°. Similarly for the other unit of the deprotonated $(\mathbf{L^3})^{2-}$ coordinated to Co(3) it is found that the dihedral angle between the planes containing the two aromatic rings with the almost planar N(29)N(30)O(3)O(4)Co(3) are 40.7° and 52.88° and the dihedral angle between the planes containing the two aromatic rings is 86.56°. Such dihedral angles suggest the coexistence of two saddle shaped moieties in **3** generated by the two Schiff base ligands coordinated to the Co(1) and Co(3) centers. Another interesting conformational vanity in the complex is that of the two six-membered rings, the one containing Co(1), the azomethine nitrogens and the three carbon atoms of the connecting 1,3-diamino propane is in a chair conformation whereas the other six-membered ring containing Co(3), the azomethine nitrogens and the three carbon atoms of the connecting 1,3-diamino propane is in a boat conformation. The hydrogen atoms of the two water molecules coordinated to Co(2) participate in intramolecular H-bonding with the nitrogen atoms of the *end-on* bridging azide ions and with the singly coordinated deprotonated oxygen atom of the Schiff base ligand. One of the hydrogen atoms of a water molecule coordinated to Co(2) participates in intermolecular hydrogen bonding with the oxygen atom of the disordered water molecule residing in the lattice. The oxygen atom of the lattice water molecule is further interconnected by hydrogen bonding to one of the hydrogen atoms of the deprotonated methanol molecule of the adjacent trinuclear unit. Thus the adjacent trinuclear units are interconnected by H-bonding interactions to generate a 1D polymeric chain (Fig. 10). The H-bonding parameters of **3** are listed in Table 7.

3.6. DNA binding

The DNA binding abilities of **1**, **2** and **3** were examined by UV–Vis absorption spectroscopy using calf-thymus DNA (CT-DNA) at biological pH. The stability of all three complexes in 50 mM Tris–HCl/NaCl buffer (pH 7.2) at room temperature was monitored by UV–Vis spectroscopy for 24 h and liberation of the ligand was not observed under these conditions. These suggest that the complexes are stable under the conditions studied and can be titrated with CT-DNA. Before titrating the complexes with CT-DNA, control experiments with the cobalt ion and the respective Schiff bases ($\mathbf{HL^1}$, $\mathbf{HL^2}$ and $\mathbf{H_2L^3}$) were performed with CT-DNA. The DNA absorption peak obtained for a particular concentration of CT-DNA was found to remain unaffected by increasing the cobalt ion concentration. Moreover no significant changes were observed at the three different regions (366–368, 292–295 and 256–260 nm) where the characteristic charge transfer bands appear in the spectra of **1**, **2** and **3**. Similar titration methods were adopted for $\mathbf{HL^1}$, $\mathbf{HL^2}$ and $\mathbf{H_2L^3}$ with CT-DNA in order to investigate whether certain changes appeared within the regions 366–368, 292–295 and 256–260 nm for the respective free Schiff bases. On varying the CT-DNA concentration with a constant amount of $\mathbf{HL^1}$, $\mathbf{HL^2}$ and $\mathbf{H_2L^3}$ it was found that although the 260 nm peak of the CT-DNA increased with increasing DNA concentration, no charge transfer bands at 366–368, 292–295 and 256–260 nm were detected for the respective Schiff bases. This clearly indicates that the characteristic charge transfer bands for **1**, **2** and **3** appearing at 366–368, 292–295 and 256–260 nm are of LMCT origin. The control studies ensure that the results obtained for **1**, **2** and **3** with CT-DNA are not due to the interaction of the cobalt ion with CT-DNA nor that of the free Schiff bases with CT-DNA.

The potential CT-DNA binding ability of **1**, **2** and **3** was studied by UV spectroscopy by following the intensity changes of the LMCT bands at 366–368, 292–295 and 256–260 nm for the respective complexes. All the complexes were kept in buffer solution of the order of 5 μM and it was found that on increasing the concentration of CT-DNA from 10 to 120 μM **1** shows an appreciable hypochromism whereas for **2** only a small degree of hypochromism was observed (shown in Fig. 11). The trinuclear complex **3** shows a reluctance to DNA binding as neither hyperchromism nor hypochromism were detected. From the observed spectral changes the value of the apparent binding constant K_{app} ($4.096 \times 10^4\ l\ mol^{-1}$ for **1** and $1.54 \times 10^4\ l\ mol^{-1}$ for **2**) was determined by regression analysis using Eq. (1) (under Section 2.3). As we know that the extent of hypochromism is commonly consistent with the strength of the DNA binding interaction [73], we can rationalise the DNA binding affinity of the three complexes by studying the rate of hypochromism as shown in the UV–Vis spectra of the complexes. It is very clear from the DNA binding constants of **1** and **2** that on increasing the nuclearity of the cobalt complexes from mononuclear to dinuclear there is a significant drop in the DNA binding ability, which can be attributed to the aspect of charge neutrality in **2**. Complex **1** comprises of relatively smaller mononuclear cationic units, and this is the reason why it shows a high affinity for the electron rich DNA double helix and therefore undergoes easy binding with the DNA strands, but **2**, being a neutral dinuclear unit, shows a lesser degree of DNA binding compared to **1**. On moving to the trinuclear complex **3**, we found that it is inactive toward DNA binding which can be explained by the non-planarity of the crystal structure of **3** which prevents the molecule from interacting with the strands of DNA.

Table 7
Hydrogen bond parameters of **3**.

4. Conclusions

In this paper the authors have skillfully increased the nuclearity of **1**, **2** and **3** by complexing cobalt(II) ions with three different Schiff bases obtained by selective and non-selective condensation of 1,3-diamines with 2-hydroxyacetophenone. By localising the two amine functionality at the 1,3-position in all the three Schiff bases we observed significant structural variations for **1**, **2** and **3** which have been elaborately described in this paper. This work

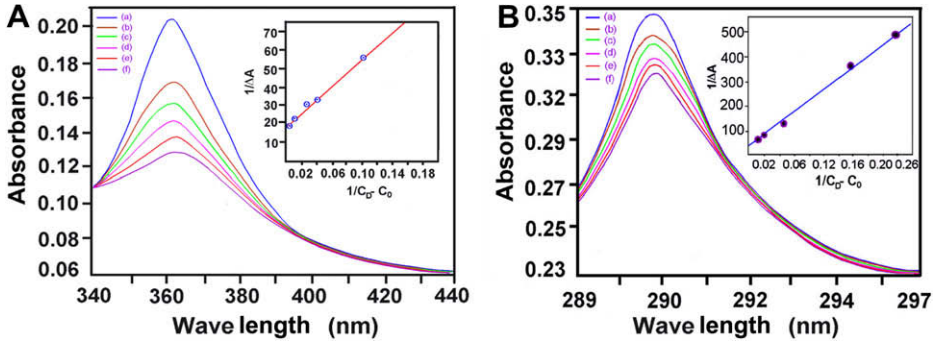

Fig. 11. (**A**) Absorption spectra of **1** (5.4 μM) in the absence (a) and in presence of increasing amounts of CT-DNA (0–120 μM; b–f) at room temperature in 5 mM Tris–HCl/NaCl buffer (pH 7.2). Inset: double reciprocal plot of $1/\Delta A$ against $1/(C_D - C_O)$; K_{app}: 4.096×10^4 l mol^{-1} for **1**. (**B**) Absorption spectra of **2** (5 μM) in the absence (a) and in presence of increasing amounts of CT-DNA (0–100 μM; b–f) at room temperature in 5 mM Tris–HCl/NaCl buffer (pH 7.2). Inset: double reciprocal plot of $1/\Delta A$ against $1/(C_D - C_O)$; K_{app}: 1.54×10^4 l mol^{-1} for **2**.

adds two new contributions to the rare class of mixed valence cobalt complexes and is supported by EPR analysis. From the DNA binding constants of the complexes it can be concluded that **1** shows greater affinity to DNA binding than that of **2**, whereas **3** was found to be inactive for DNA binding.

2. Experimental

All manipulations were carried out under an atmosphere of dry argon using Schlenk and glovebox techniques. Solvents were rigorously dried with sodium benzophenoate. *N*,*N*-Dimethylaminoethanol (dmaeH) was purchased from Aldrich and purified by refluxing over K_2CO_3 for 10 h and distilled immediately before use, while $Ba(dmae)_2$ was prepared by the literature procedure [19]. All other reagents were also purchased from Aldrich.

Elemental analyses were performed using a CHN analyzer LECO model CHNS-932. The melting point was determined in a capillary tube using an electrothermal melting point apparatus, model MP.D Mitamura Riken Kogyo (Japan) and is uncorrected. The FT-IR spectrum was recorded on a single reflectance ATR instrument (4000–400 cm^{-1}, resolution 4 cm^{-1}). TGA measurements were carried out by using a Seiko SSC/S200 model at a heating rate of 10 °C/min under N_2 flow. The mass spectrum was recorded on a Kratos concept IS instrument. XRPD studies were carried out by means of a Bruker AXS D8 diffractometer using monochromatic Cu Kα radiation. The morphology of the films was characterized by a FEG-SEM Philips XL30. Samples were carbon coated before observation and EDAX-DX_4 was used to calculate the composition (metallic ratio) of the films. The thickness of the films was measured with a Dektak 8 Stylus profilometer. The voltage–current characteristics of the thin films were measured with a Jandel Voltmeter, Model RM3, by the four-probe method.

2.1. Synthesis of $Ba_2(\mu\text{-}OAc)_4(OAc)_2Cu_4(\mu\text{-}dmae)_4(OH)_2$ (**1**)

To 0.5 g (2.5 mmol) of copper(II) acetate monohydrate [$Cu(OAc)_2 \cdot H_2O$] suspended in 20 ml of toluene in a 50 ml Schlenk tube fitted with a magnetic stirrer and a nitrogen line, was added drop by drop a solution of 0.35 g (1.12 mmol) of $Ba(dmae)_2$ in toluene. The mixture was stirred for 2 h at room temperature and then heated to 60 °C on oil bath for another 2 h. The excess of $Cu(OAc)_2 \cdot H_2O$ was separated by cannula filtration. The filtrate was evaporated to dryness under vacuum and the solid was redissolved in 5 ml of tetrahydrofuran to give a 70% yield of blue crystals after several days at room temperature, m.p.: 95 °C. The analysis of the resulting product resembled that for $Ba_2(\mu\text{-}OAc)_4(OAc)_2Cu_4(\mu\text{-}dmae)_4(OH)_2$, as determined by X-ray crystallography. *Anal.* Calc. for $C_{28}H_{60}Ba_2Cu_4N_4O_{18}$: C, 26.49; H, 4.76; N, 4.41. Found: C, 26.39; H, 4.56; N, 3.52%. FT-IR (KBr, cm^{-1}): 3421br, 2905w, 1654vs, 1554m, 1406s, 1340m, 1067m, 1020m, 595m, 528w, 503w, 480w. APCI-MS: *m*/*z* calcd. TGA: 90–130 °C (3.13 wt% loss), 130–210 °C (21.76 wt% loss), 210–367 °C (residue 48.96%).

2.2. X-ray crystallography

Single crystal X-ray data were collected on a Bruker Smart Apex CCD diffractometer using Mo radiation. Crystallographic and structure refinement data for complex (**1**): Empirical formula; $C_{28}H_{60}Ba_2Cu_4N_4O_{18}$, formula wt. 1269.64, temp. = 100(2) K, λ = 0.71073 Å, triclinic, space group $P\bar{1}$, a = 8.9330(11), *b* = 9.8500(12), *c* = 13.4880(17) Å, α = 101.705(2), β = 94.685(2), γ = 106.671(2)°, *V* = 1100.8(2) $Å^3$, *Z* = 1, ρ_{calc} = 1.915 Mg m^{-3}, μ = 3.728 mm^{-1}, 9204 reflections collected, 4906 unique (R_{int} = 0.0234), Refinement was by full-matrix least-squares on F^2; goodness-of-fit on F^2 was 1.114. Final *R* indices where $I > 2\sigma(I)$ are R_1 = 0.0759 and wR_2 = 0.2112. The *R* indices (all data)[a] are R_1 = 0.0838 and wR_2 = 0.2160 [a] $R_1 = \sum ||F_o| - |F_c|| / \sum |F_o|$ [b] $wR_2 = [\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2]^{1/2}$. The largest difference peak and hole are 4.016 and −3.689 e $Å^{-3}$, respectively.

2.3. Deposition of thin films

Thin film deposition was performed via aerosol-assisted chemical vapour deposition (AACVD) by dissolving 0.07 g of the precursor in 10 ml toluene in a two neck round bottomed flask. On one side, the flask was connected via tubing to a quartz reactor loaded with 2.5 × 1 cm glass substrates inside a carbolite tube furnace and a flow of argon gas was regulated using a Platon flow gauge on the other. The flask was set in an ultrasonic humidifier (Pifco) (Fig. 1) equipped with a piezoelectric modulator that generated droplets of the precursor solution which were then transferred by the carrier gas into the reactor chamber. Glass substrates were washed in concentrated nitric acid, subsequently washed with deionized water several times and then oven dried.

The deposition was carried out at 400 °C with a flow rate of 130 ml/min on glass substrates for 2.5 h.

3. Results and discussion

3.1. Synthesis and characterization

The synthetic procedure used for the heterobimetallic complex (**1**) is simple and involves the mixing of the reactants in the appropriate stoichiometric ratios. Dissolution of $Cu(OAc)_2 \cdot H_2O$ in the reaction mixture indicates completion of the reaction as given in Eq. (1).

$$4Cu(OAc)_2 \cdot H_2O + 2Ba(dmae)_2 \rightarrow Ba_2(dmae)_4Cu_4(OAc)_6(OH)_2 + 2HOAc + 2H_2O \quad (1)$$

Compound (**1**) was characterized by its melting point, elemental analysis, FT-IR spectroscopy, mass spectrometry and its structure was established by single-crystal X-ray diffraction. In the FT-IR spectrum, an absorption band at 3421 cm^{-1} is due to the O–H group in the complex. The three strong absorption bands between 1400 and 1700 cm^{-1} for the carboxylate group indicate the presence of different coordination modes for the acetate ligand [20–23]. The absorptions at low frequency are due to the ν(M–O) and ν(M–N) vibrations, those at 595 and 528 cm^{-1} are characteristic of Ba–OAc derivatives, whereas those at 503 and 480 cm^{-1} more likely belong to Cu(μ,η^2dmae) [24]. The atmospheric pressure chemical ion-

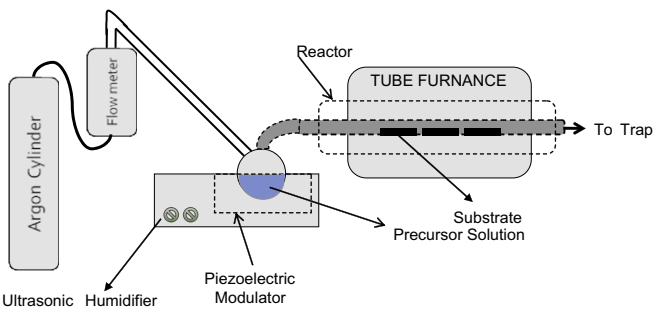

Fig. 1. Schematic diagram of the aerosol-assisted chemical vapour deposition process.

ization (APCI) negative scan mass spectrum does not exhibit a molecular ion peak for the complex. The complex breaks down under MS conditions and gives various fragments of different m/z ratios. The heaviest fragment observed is for $[Ba_2Cu_4(dmae)_4(OAc)_6(OH)]^+$ at m/z (1251.7), with the base peak at m/z (423.7) corresponding to $[BaCu(dmae)(OAc)_2(OH)]^+$, thus showing the instability of the complex under the MS conditions.

3.2. Structural analysis

Selected bond lengths and bond angles for (**1**) are listed in Table 1 and its molecular structure is shown in Fig. 2. The six metal atoms are linked together by oxygens belonging to the chelating-bridging dmae and acetate groups. The coordination sphere of the metal atoms in the complex is satisfied by the donor oxygen and nitrogen atoms of dmae and acetate ligands. The geometric environment of each metal centre is shown in Fig. 3.

Table 1

O(4)A–Ba(1)–O(4)	90.6(3)	Cu(1)–O(1)–Cu(2)	92.9(4)
O(7)A–Ba(1)–O(4)	123.5(3)		

Cu(1) is almost square pyramidal in geometry, having a coordination number of five, with a CuO_4N ligation set composed of a chelating-bridging dmae group [N(1),O(1)], {the oxygen of which is triply bridged to Cu(1), Cu(2) and Ba(1)}, an oxygen atom of the bridged dmae ligand [O(6)], connecting Cu(1) with the Cu(2) atom, an oxygen atom of the triply bridged acetate group [O_4], acting as bridge between Cu(1) and both Ba atoms, and an oxygen atom of the monodentate acetate group [O(2)]. The geometry of Cu(1) is not perfectly square pyramidal due to an O(2)–Cu(1)–O(4) angle of 101.1(4)° (greater than 90°) and O(6)–Cu(1)–O(4) 'bite' angle of 96.8(4)° (greater than 90°). Also the copper- oxygen bond distance of Cu(1) to the apical oxygen atom O(4) is much longer (2.262(11) Å) than all the other Cu–O bond lengths around Cu(1), which range from 1.922(11) to 1.969(10) Å, and they are close in value to the sum of the ionic radii, 1.92 Å. The coordination environment of Cu(1) is further augmented by a weak Cu···Cu interaction with Cu(2), with a metal–metal separation of 2.857(3) Å.

If the Cu···Cu interaction is omitted, Cu(2) has a coordination number of six with a coordination environment close to octahedral, with a CuO_5N core made up of a chelating-bridging dmae group [N(2), O(6)], (the oxygen of which acts as a bridge to both Cu atoms), an oxygen atom of the bridged dmae ligand [O(1)] (connecting Cu(2) with the Cu(1) and Ba(1)A atoms), two oxygen atoms of the chelating-bridging acetate group [O(7),O(8)], (O(7) of which also binds Cu(2) with the Ba(1)A atom), and an oxygen atom of a terminal hydroxyl anion [O(9)]. The coordination environment of Cu(2) is a tetragonally elongated octahedron with an O(9)–Cu(2)–O(7) angle of 146.97° (less than 180°), O(8)–Cu(2)–O(7) 'bite' angle of 55.88° (less than 90°), and an O(8)–Cu(2)–N(2) angle of 101.0(5)° (greater than 90°). Again the copper- oxygen bond distances of Cu(2) to the apical oxygen atoms O(9) and O(7) are much longer (2.295(11) and 2.763(12) Å, respectively) than all the other Cu–O bond lengths around Cu(2), which compare well with the sum of the ionic radii, 1.92 Å. A distortion in the octahedral geometry around Cu^{II}(2), expected from the Jahn–Teller theorem [25], is

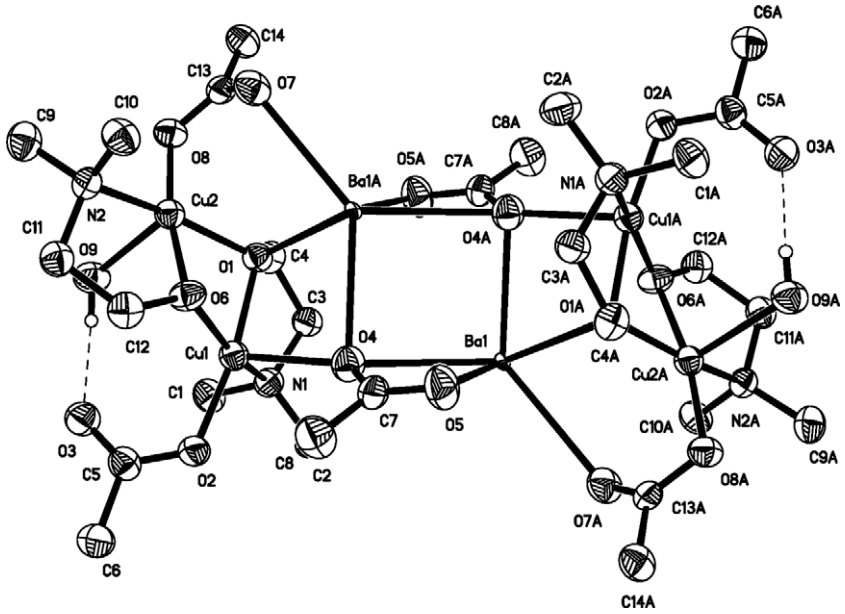

Fig. 2. ORTEP drawing showing the molecular structure of $[Ba_2(\mu\text{-}OAc)_4(OAc)_2Cu_4(\mu\text{-}dmae)_4(OH)_2]$ (**1**). Symmetry operation: #1, $-x+1$, $-y$, $-z+2$. All hydrogen atoms and the Cu···Cu interaction is omitted for clarity.

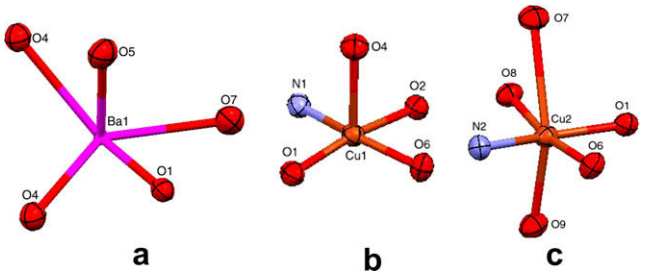

Fig. 3. The (a) distorted square pyramidal of Ba, (b) square pyramidal of Cu(1) and (c) octahedral of Cu(2) geometric spheres in complex (**1**).

due to the unequally occupied e_g (d_{z^2} and $d_{x^2-y^2}$) orbitals, the two axial oxygens O(7) and O(9) are repelled more strongly than the other four coordinating ligands.

Two different ligand sets with different 'bite' angles render the coordination sphere of the barium metal atoms irregular. Both the Ba atoms in the complex have identical geometries and the same coordination number of five, with a BaO_5 set of ligating atoms, composed of one chelating-bridging acetate group [O(4),O(5)] (the oxygen atom O(4) acts as a bridge between Cu(1), Ba(1) and Ba(1)A), the oxygen atom of a triply bridging acetate ligand [O(4)A] (connecting Cu(1)A, Ba(1) and Ba(1)A), the oxygen atom of a doubly bridged acetate ligand [O(7)A] (binding Ba(1) with Cu(2)A) and the oxygen atom of a triply bridging dmae ligand [O(1)A] (connecting Ba(1), Cu(1)A and Cu(2)A). The bonding environment around barium may be described as a distorted square pyramidal with the oxygen atom [O(5)] capping the square face. The average Ba–O distance of 2.769 Å is almost same in value as the sum of the ionic radii, 2.77 Å. All the Cu–N bond distances in the complex, ranging from 2.00 to 2.049 Å, are in good agreement with the reported values [26–28].

Both ligands coordinate in a range of coordination modes. The acetate groups are either monodentate [O(5), O(5)A], or both chelating-bridging two metals [O(7), O(8); O(7)A, O(8)A] and three metals [O(4), O(5); O(4)A, O(5)A]. As for the dmae ligands, they are chelating-bridging two metals [O(6), N(2); O(6)A, N(2)A] and chelating-bridging three metals [O(1), N(1); O(1)A, N(1)A].

Additional stability for the complex is provided by the intramolecular hydrogen bonding [O(9)–H(9)···O(3)] between the oxygen atom O(3) of the monodentate acetate group and the hydroxyl group hydrogen H(9).

3.3. Thermal decomposition studies and characterization of thin films

The thermal behaviour of complex (**1**) has been studied by thermogravimetric analysis over the range 50–500 °C, performed under an inert atmosphere of flowing nitrogen gas. The thermogram of the compound, obtained with a scanning rate of 10 °C/min is shown in the Fig. 4. The decomposition starts at 90 °C and is completed at 367 °C. The decomposition of the precursor proceeds in three steps and the maximum weight loss (approximately 26.15%) takes place between 210 and 367 °C. The residual weight of 48.96% for complex (**1**) is slightly less, but close to the expected composition for CuO–$Ba_2Cu_3O_{5+x}$ (49.2% for **1**), showing that the complex has poor sublimation properties and decomposes quantitatively to the oxide mixture according to following equation.

$$Ba_2(dmae)_4Cu_4(OAc)_6(OH)_2 \xrightarrow[400^\circ C]{AACVD} Ba_2Cu_3O_{5+x} + CuO + Volatiles$$

Coordinative saturation of each metal is obtained by the oxygen atoms of the chelating-bridging acetate and dmae ligands, thus there is no need of additional oxygen to form oxides. So, the new

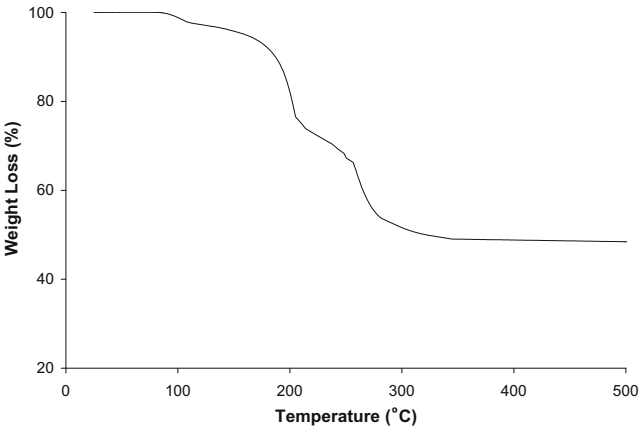

Fig. 4. Thermogravimetric plot of complex (**1**).

precursor has the potential application for deposition of mixed-metal oxide films at relatively low temperatures.

Thin films of mixed-metal oxide were characterized using XRPD, SEM and EDX. The X-ray powder pattern of the thin film obtained from complex (**1**) (Fig. 5) showed the formation of tetragonal $Ba_2Cu_3O_{5+x}$ and CuO phases. The relative peak intensities and the position of the diffraction peaks in the XRPD patterns are very similar to those reported in ICDD Card Nos. [00-040-312] [29] and [01-080-1916] [30], respectively.

The surface of the deposited films was analyzed by scanning electron microscopy (Fig. 6). The SEM image of the mixed-metal oxide thin film shows a smooth and compact film morphology. The particles are homogenously dispersed with clearly well defined grain boundaries and size ranges from 0.08 to 0.4 μm. The different sized particles are uniformly dispersed indicating two distinct phases, which was also proved by XRD analysis. The overall EDX analysis indicates that the metallic ratio of Ba:Cu in the films is close to 1:2, which also confirms the retention of same metallic ratio as that in the complex. The film exhibits a good adhesion to the substrate, which qualifies the "scotch tape test" and is stable towards air and moisture. Overall, the film seems to be of good quality with a slight reflecting nature.

The *V–I* curve is linear, as shown in the graph of voltage–current (Fig. 7), which indicates the sample prepared is found to be ohmic. From the slope of the curve, the resistance is $2.5 \times 10^3\ \Omega$ for the thin film deposited at 400 °C. The resistivity of the film was found to be 0.91 Ω cm, using $\rho = 4.532(V/I) \times d$, where ρ is the resistivity in Ω cm, 4.532 is the instrument constant, *V*/*I* is the slope of curve

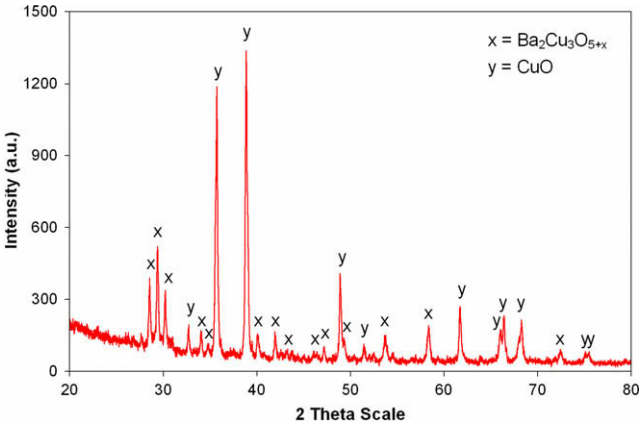

Fig. 5. X-ray powder diffractogram of CuO–$Ba_2Cu_3O_{5+x}$ thin films deposited at 400 °C from (**1**).

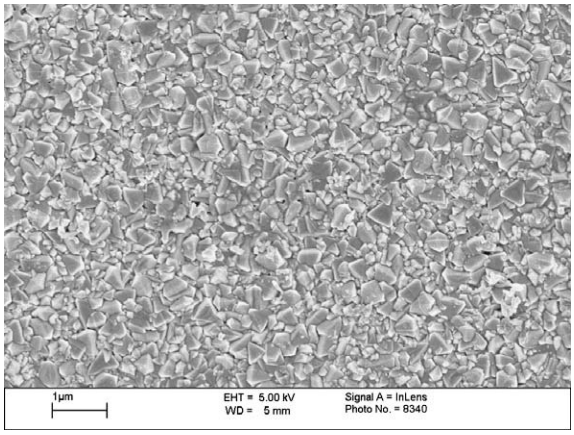

Fig. 6. SEM micrograph of films deposited from complex (**1**) at 400 °C.

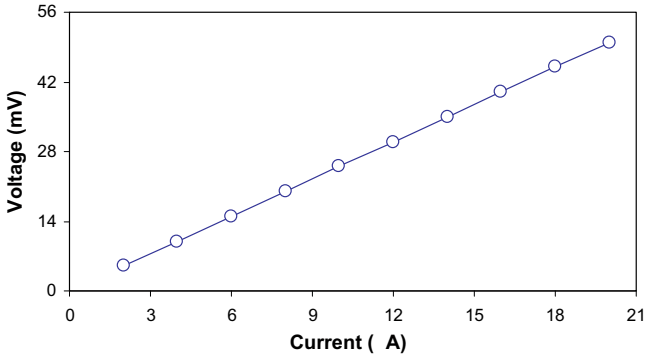

Fig. 7. *V–I* curve of the $CuO–Ba_2Cu_3O_{5+x}$ film deposited from complex **1**.

in Ω and d is the film's thickness (0.8 μm). The resistivity measurement, which is coherent to literature values (10^{-2}–10^{9}), suggests that the material deposited is of a semiconductor nature.

4. Conclusion

Heterobimetallic complex $[Ba_2(\mu\text{-}OAc)_4(OAc)_2Cu_4(\mu\text{-}dmae)_4(OH)_2]$ (**1**) has been synthesized by the direct reaction between $Ba(dmae)_2$ and $Cu(OAc)_2 \cdot H_2O$ in toluene under mild conditions. The complex has been characterized by spectroscopic and X-ray single crystal analysis. The high solubility of (**1**) in organic solvents and its low decomposition temperature makes it an attractive single-source precursor for the deposition of $CuO–Ba_2Cu_3O_{5+x}$ composite thin films.

We synthesized this compound in our laboratory, but also were unable to grow suitable crystals for analysis. However, mass spectrometric studies and elemental analysis confirmed the structure as reported by Costes et al. [10]. We attempted to isolate complexes of the symmetric ligand prepared from two molecules of diacetylmonoxime with these two diamines by various routes. With both amines, however, the desired complexes could not be isolated, instead the complexes isolated were of the tridentate monocondensed diamines (complexes **1**, $[Ni(HL^1)_2](ClO_4)_2$ and **2**, $[Ni(HL^2)_2](ClO_4)_2$).

2. Experimental

2.1. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed using a Perkin–Elmer 240C elemental analyzer. IR spectra in KBr (4500–500 cm^{-1}) were recorded using a Perkin–Elmer RXI FT-IR spectrophotometer. Electronic spectra in acetonitrile (1200–350 nm) were recorded on a Hitachi U-3501 spectrophotometer. The magnetic susceptibility measurements were done with an EG&PAR vibrating sample magnetometer, model 155 at room temperature and diamagnetic corrections were made using Pascal's constants. Electrochemical measurements were performed under a dry nitrogen atmosphere in a three-electrode configuration using Pt disc working electrode, Pt auxiliary electrode and SCE (reference electrode) on a Sycopel model AEW2 1820F/S instrument in this work and were uncorrected for junction contribution. The value for the ferrocenium–ferrocene couple under our conditions is 0.40 V.

2.2. Materials

All chemicals were of reagent grade and used without further purification.

Caution! Metal perchlorates in the presence of organic ligands are potentially explosive. Only a small amount of the material should be prepared and it should then be handled with care.

2.3. Synthesis of the complexes

2.3.1. $[Ni(HL^1)_2](ClO_4)_2$ (**1**)

A mixture of diacetylmonoxime (10 mmol, 1.011 g) and ethylenediamine (10 mmol, 0.8 cm^3) in methanol (25 cm^3) was refluxed for about 3 h. It was then cooled and a solution of $Ni(ClO_4)_2{\cdot}6H_2O$ (5 mmol, 1.828 gm) in methanol (20 cm^3) was added with continuous stirring. An orange–red compound precipitated out and was then recrystallised from acetonitrile solution to obtain single crystals suitable of **1** suitable for X-ray diffraction. Yield: (~70%). Anal. *Calc*. for $C_{12}H_{26}N_6O_2Ni(ClO_4)_2$: C, 41.77; N, 24.35; H, 7.59; Ni, 17.01. Found: C, 40.88; N, 23.94; H, 7.75; Ni, 16.52%.

2.3.2. $[Ni(HL^2)_2](ClO_4)_2$ (**2**)

Complex **2** was prepared by the same procedure as complex **1** but using 1,2-diaminopropane instead of 1,2-diaminoethane. An orange yellow compound separated out and was recrystallized from acetonitrile solution to provide single crystals of **2** suitable for X-ray diffraction. Yield: (~74%). Anal. *Calc*. For $C_{14}H_{30}N_6O_2Ni(ClO_4)_2$: C, 45.07; N, 22.52; H, 8.10; Ni, 15.73. Found: C, 44.23; N, 21.85; H, 7.52; Ni, 15.92%.

2.3.3. $[Ni(HL^3)]ClO_4$ (**3**)

A solution of 2,4-pentanedione (10 mmol, 1.1 cm^3) in chloroform (50 cm^3) was added drop-wise to a solution of 1,2-diaminopropane (10 mmol, 0.8 cm^3) in chloroform (50 cm^3). After completion of addition, the solution was stirred for an additional 3 h and chloroform was evaporated under reduced pressure, yielding the monocondensed 4-(2-aminopropylimino)pentan-2-one as a viscous liquid. It was dissolved in methanol (10 cm^3). Solid diacetylmonoxime (10 mmol, 1.011 g.) was added and the mixture was stirred for 24 h. A solution of $Ni(ClO_4)_2{\cdot}6H_2O$ (10 mmol, 3.657 g) in methanol (20 cm^3) was added to the resulting solution with continuous stirring to precipitate an orange-red solid. It was recrystallized from acetonitrile solution to obtain single crystals of **3** suitable for X-ray diffraction. Yield: (~70%). Anal. *Calc*. *for* $C_{12}H_{20}N_3O_2Ni(ClO_4)$: C, 48.53; N, 14.15; H, 6.79; Ni, 19.76. Found: C, 47.63; N, 14.85; H, 6.52; Ni, 19.62%.

2.4. X-ray crystallography

Crystal data are given in Table 1. Intensity data were measured at 150 K using the Oxford X-Calibur CCD System with Mo Kα radiation. The crystals were positioned at 50 mm from the CCD. Three hundred and twenty-one frames were measured with a counting time of 10 s. Data analyses were carried out with the CRYSALIS program [11]. The structures were solved using direct methods with the SHELXS97 program [12]. The two carbon atoms in the saturated chelating ring of complex **3** were disordered over two sites as was the substituent methyl group. All disordered atoms were refined with distance constraints, 50% occupancy and isotropic thermal parameters. The other non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bonded to carbon were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. Absorption corrections were carried out using the ABSPACK program [13]. The structures were refined on F^2 using SHELXL97 [12].

3. Results and discussion

3.1. Spectral studies

The presence of oxime –OH bond in these compounds (**1**–**3**) can be detected by IR bands which occur at 3337, 3334, and 3389 cm^{-1}, respectively. The bands for azomethine (C=N) groups present in all the compounds are distinct and occur within 1639–1603 cm^{-1}. Here also the lowering of the positions of the bands demonstrates their coordination to the metal centre. Single peaks with some slight splitting appear in the range 1108–1080 cm^{-1} indicating the presence of perchlorate with a slight distortion from ideal tetrahedral geometry which is substantiated in all the compounds from their crystal structures in which the perchlorate anion is shown to be involved in hydrogen bonding. The IR spectrum of the square planar compound **3** shows the absence of $\nu_{(NH_2)}$. For compound **1**, $\nu_{(NH_2)}$ appears at 3337, 3288 cm^{-1} along with NH_2 bending at 1673 cm^{-1}. For compound **2**, one peak at 3334 cm^{-1} with a shoulder shows the overlapping appearance of $-NH_2$ and –OH peaks along with NH_2 bending at 1660 cm^{-1}.

The electronic spectra of all the complexes were recorded in acetonitrile solution. The square planar arrangement of complex **3** is characterized by a broad band at 454 nm [14]. No other absorption peaks were observed in the higher wavelength region consistent with the square planar geometry found in the crystal structure. Complexes **1** and **2** show an absorption band in the region 610–580 and a broad band above 750 nm, assigned to υ_1 and υ_2 in the octahedral geometry of Ni(II) [14]. Other high energy bands below 350 nm are assigned as CT bands.

3.2. Magnetic properties

The effective magnetic moments 3.03 and 3.12 BM of the complexes **1** and **2**, respectively, confirm the presence of two unpaired electrons ($S = 1$) in a pseudo-octahedral environment, in agreement with a high-spin configuration ($t_{2g}^6 e_g^2$). Compound **3** is diamagnetic in accordance with the square planar Ni(II).

Table 2
Cyclic voltammetric data of the synthesized complexes **1**, **2** and **3** in acetonitrile solution vs. SCE.

Complex	E_a/V	E_c/V	$(E_a - E_c)/V$	$E_{1/2}/V = 1/2(E_a + E_c)/V$
$[Ni(HL^1)_2](ClO_4)_2$ (**1**)	0.443	0.280	0.163	0.361
$[Ni(HL^2)_2](ClO_4)_2$ (**2**)	0.453	0.310	0.143	0.381
$[Ni(HL^3)]ClO_4$ (**3**)	0.836	–	–	–

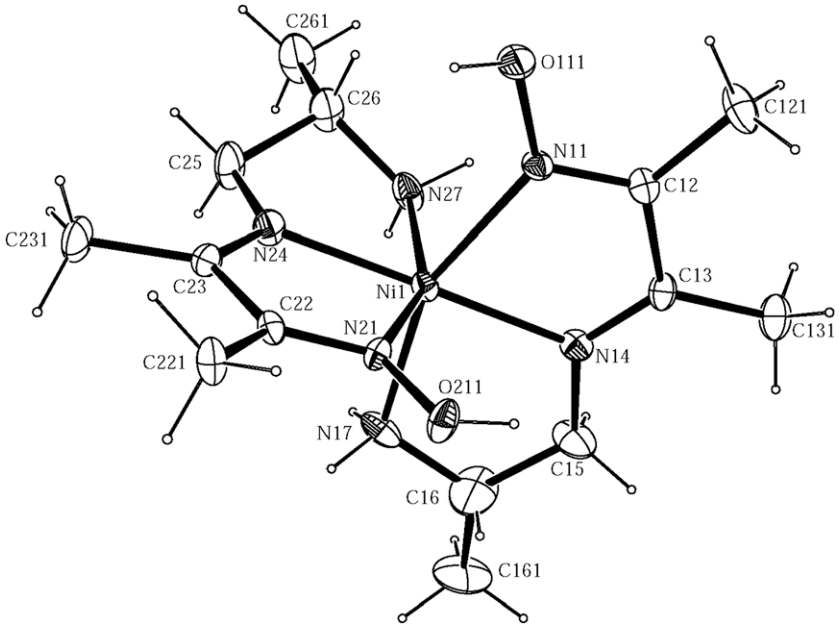

Fig. 3. ORTEP-3 picture for complex **2** with 30% ellipsoid probability. The perchlorate ion is not shown for clarity.

3.3. Cyclic voltammetric studies

Cyclic voltammetric studies of the complexes in acetonitrile solution versus SCE (scan rate 100 mV s^{-1}) reveal that the octahedral complexes **1** and **2** are quasi-reversible with the formal potential values ($E_{1/2}$) of 0.361 and 0.381 V, respectively. The low values of the redox potentials indicate that the higher oxidized species namely Ni^{3+} is stabilized in the presence of amine and oxime donor atoms as was previously established by Chakraborty and co-workers [9]. The formal potentials observed for ligand with oxime and amine as donors have higher values than is observed by us [15]. The anodic peak of complex **3** appears at 0.836 V but no reductive response is observed during the reverse scan. The higher value of the oxidation peak indicates that in the square planar geometry Ni(II) become more stabilized than the corresponding octahedral species **1** and **2**. Moreover, it seems that the oxidized complex undergoes decomposition or ligand rearrangement as no reduction peak is observed in the cathodic scan. Data from electrochemical studies are given in Table 2.

3.4. Structure description

3.4.1. Complex *1*

The structure of **1** contains discrete $[Ni(HL^1)_2]^{2+}$ cations together with perchlorate anions which contains a crystallographic twofold axis, and is shown in Fig. 1. The nickel atom is six-coordinate with a distorted octahedral environment being bonded to two tridentate ligands. The coordination polyhedron around nickel atom is best described as a distorted octahedron with the nickel atom bonded to N11, N14 and N17 of one terdentate ligand and N11∗, N14∗ and N17∗ of another (∗ designates symmetry element $0.5 - x, y, 1 - z$) with both ligands coordinating in the mer conformation.. The saturated five-membered ring, Ni(1)–N(14)–C(15)–C(16)–N(17), exhibits a half-chair conformation with puckering parameters $Q(2) = 0.418(3)$, and $\Phi(2) = 274.3(3)^\circ$ and is twisted around the C(15)–(16) bond. The N(17)–Ni(1)–N(14) angle is 81.5(1)° and is typical of a five-membered chelating ring. The Ni(1)–N bond lengths are Ni(1)–N(11) 2.121(2), Ni(1)–N(14) 2.005(2), and Ni(1)–N(17) 2.121(2) Å. Selected bond lengths and bond angles are given in Table 3.

The amine and hydroxyl (oxime) hydrogen atoms are involved in H-bonding (Table 4). The amine hydrogen, H(17B) forms an inter-molecular H-bond with symmetry related $(1/2 - x, y, 1 - z)$ hy-

N(15)–Ni(1) N(21)	168.79(15)
N(18)–Ni(1) N(21)	82.27(15)

The involvement of perchlorate ion in the H-bonded network has been observed in several other complexes [16,17].

3.4.2. Complex *2*

The structure consists of discrete $[Ni(HL^2)_2]^{2+}$ cations together with perchlorate anions. The metal atom is in a six-coordinate distorted octahedral environment being bonded to two tridentate ligands which coordinate meridionally. The structure of **2** is shown

Table 8
Hydrogen bond distances (Å) and angles (°) for complex **3**.

D–H···A	D···A	H···A	∠D–H···A
O(22)–H(22)···O(11)	2.904	2.32	127
O(22)–H(22)···(100)	2.643	2.01	132
O(100)–H(1)···O(43)′	2.886	2.21	136
O(100)–H(1)···O(44)′	2.958	2.12	173

Symmetry element ′ = $-x + 1, -y - 1, -z$.

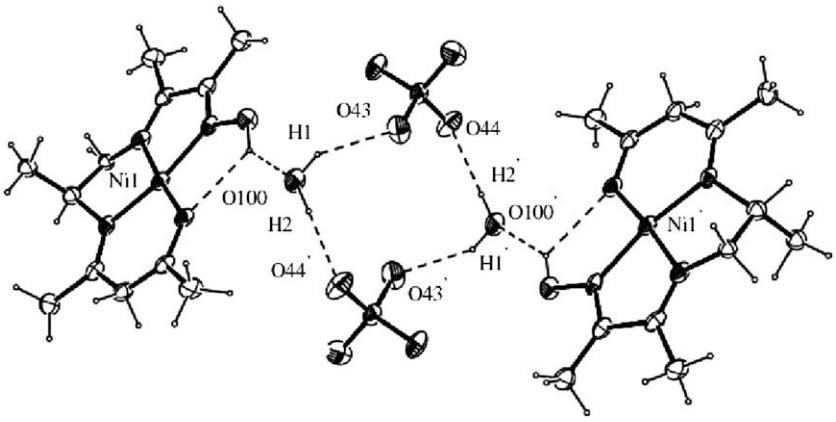

Fig. 6. The H-bonded dimeric structure of **3**.

in Fig. 3 together with the atom numbering scheme. The bond lengths from the metal are equivalent with Ni(1)–N(11), Ni(1)–N(21) at 2.129(4), 2.128(4) Å, slightly longer than Ni(1)–N(17), Ni(1)–N(27) 2.096(4), 2.100(4) Å but significantly longer than Ni(1)–N(14), Ni(1)–N(24) at 2.017(4), 2.006(4) Å. Selected bond lengths and bond angles are given in Table 5.

In this structure, one of the two independent perchlorates is disordered so that two independent tetrahedra of oxygen atoms were refined with 50% occupancy. Both O(1 1 1) and O(2 1 1) are involved in weak hydrogen bonds to disordered oxygen atoms; O(1 1 1) 2.76, 2.78 Å to O(73), O(76) and O(211) 2.77, 2.79 to O(71), O(77). In addition, all four hydrogen atoms on N(17) and N(27) form weak hydrogen bonds to perchlorate oxygen atoms at distances in the range 3.05–3.14 Å (Table 6) giving a closed tetranuclear H-bonded structure (Fig. 4).

*3.4.3. Complex **3***

The two molecules that make up the structure of **3** are shown in Fig. 5 together with the numbering scheme in the metal coordination sphere. The only significant difference between the two molecules is the position of the two carbon atoms in the saturated chelating ring of complex **3** which were disordered over two sites as was the substituent methyl group. Dimensions are given in Table 7. As is apparent from Fig. 5, the methyl group in the five-membered chelating ring is attached either to C(16) or C(17) in the two disordered molecules. It was found that the positions of C(16) and C(17) differed slightly in the two molecules and they were therefore refined independently.

The coordination of the metal is a square plane with an r.m.s. deviation of 0.01 Å for the four donor atoms. The nickel atom is 0.03 Å from this plane. There are no atoms bonding in axial positions. The Ni–N(21) bond is longer at 1.891(4) Å than the other three bonds from nickel which are 1.835(3) Å to N(15), 1.838(3) Å to N(18) and 1.821(3) Å to O(11). The hydrogen on O22 forms weak hydrogen bonds to both O(11) in the complex and the solvent water molecule (Table 8). Dimensions to O(1 0 0) are H···O 2.00, O–H···O 132° and O···O 2.64 Å while dimensions to O(11) are 2.32 Å, 126°, 2.90 Å, respectively. O(1 0 0) also forms donor hydrogen bonds to O(44) $(1-x, -y, -z)$ (2.11 Å, 173°, 2.96 Å) and O(43) $(x, y-1, z)$ (2.21 Å, 136°, 2.89 Å). Thus a dimeric structure of the complex is formed via a perchlorate anion and the water molecule (Fig. 6).

4. Conclusions

Three new Ni(II) compounds have been isolated and characterized by physico-chemical and structural studies. The aim of the work was to prepare symmetrical and unsymmetrical compounds of Schiff base ligands involving 1,2-diaminoethane or 1,2-diaminopropane and 2,4-pentanedione or diacetylmonoxime. Symmetrical compounds with two diacetylmonoxime functions could not be isolated but instead the monocondensed tridentate Schiff base yielded the bis six-coordinate complex. Two compounds with unsymmetrical ligand varieties involving 2,4-pentanedione and diacetylmonoxime were isolated and characterized. One of these involving 1,2-diaminoethane was previously reported by Costes et al. [10]. In our observation, we have concluded that symmetrical ligands which would involve three fused five-membered rings in the complex cation makes it compressed and strained as observed by Fritsky et al. [15] and the more stable, bis-ligand varieties were isolated as the sole products. The introduction of a six membered chelate in the form of 2,4-pentanedione gives a stable, less strained square planar environment around Ni(II).

establish interesting magneto-structural correlations. The d^9 configuration of the Cu^{II} ion has one unpaired electron ($S = 1/2$), and the nearly quenched orbital angular momentum of the Cu^{II} ion provides a g factor close to 2, suggesting the absence of any large internal magnetic fields. A comparison of key structural parameters and exchange integrals for the phenoxo-bridged copper(II) complexes reveals the dependence of J on (i) the Cu–O(phenolate)–Cu angle, (ii) the Cu—Cu distance, (iii) the geometry around the phenolate oxygen atom, and (iv) the deviation of the copper coordination geometry [29].

As an extension of our earlier works with phenoxo-bridged multinuclear transition metal complexes [30–32], we report herein a novel tetra(μ_3-phenoxo) bridged cubane core copper(II) complex, $[Cu_4L_4] \cdot Na \cdot ClO_4$ (**1**) using a potentially multidentate Schiff base ligand *N′*-(2-hydroxy-3-methoxybenzylidene)benzohydrazide (**H_2L**) which can be utilised with both bridging and chelating capacities. In this paper we describe the synthesis, characterizations, X-ray crystal structure and variable temperature magnetic (VTM) susceptibility measurements of this new copper complex. We also present here an appropriate magneto-structural correlation in order to explain the observed magnetic coupling showing both ferro- and antiferromagnetic interactions [$J_{11} = +13.6(4)\ cm^{-1}$ and $J_{12} = -34.9(4)\ cm^{-1}$].

2. Experimental

2.1. Materials

All the chemicals and solvents used for the syntheses were of analytical grade. Benzhydrazide, 3-methoxysalicylaldehyde and sodium hydroxide were purchased from Aldrich Chemical Co. Inc. and used without any further purification. Copper(II) perchlorate hexahydrate was prepared by the treatment of basic copper(II) carbonate, $CuCO_3 \cdot Cu(OH)_2$ (E. Merck, India) with 80% perchloric acid (E. Merck, India) followed by slow evaporation on a steam bath. It was then filtered through a fine glass-frit and preserved in $CaCl_2$ desiccator.

Caution! *Perchlorate salts in presence of organic materials are potentially explosive. It should be prepared in small amounts and handled with extreme care.*

2.2. Syntheses

2.2.1. Synthesis of the Schiff base ligand (**H_2L**)

The Schiff base chelator, *N′*-(2-hydroxy-3-methoxybenzylidene)benzohydrazide (**H_2L**), was prepared by following a method already reported in literature [33]. Benzhydrazide (1.36 g, 10 mmol) was refluxed with 3-methoxysalicylaldehyde (1.52 g, 10 mmol) in 50 ml methanol at 65 °C. After 2.5 h, a deep orange yellow solution was obtained. It was subjected to TLC which revealed the presence of some unreacted starting materials along with the Schiff base product. The Schiff base ligand was isolated by column chromatography in order to get it in the purified form. The purified ligand was then evaporated under reduced pressure to yield a gummy mass, which was dried and stored *in vacuo* over $CaCl_2$ for subsequent use. Yield: 2.35 g (87%). *Anal.* Calc. for $C_{15}H_{14}N_2O_3$: C, 66.66; H, 5.22; N, 10.36. Found: C, 65.82; H, 5.19; N, 10.40%. FT-IR (KBr, cm^{-1}): ν(CH=N) 1627.

2.2.2. Synthesis of $[Cu_4L_4] \cdot Na \cdot ClO_4$ (**1**)

The appropriate quantity of solid Schiff base ligand **H_2L** (0.27 g, 1 mmol) was dissolved in 20 ml methanol. This ligand solution was added dropwise to a 10 ml methanolic solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1 mmol) with constant stirring. After addition of 5 ml aqueous NaOH solution (0.40 g, 1 mmol) the reaction mixture was refluxed for 2 h at 65 °C. The resulting deep green solution was then left undisturbed. After 7 days green plate shaped X-ray diffraction quality single crystals were separated out. Yield: 80%. *Anal.* Calc. for $Cu_4H_{48}C_{60}N_8ClO_{16}Na$: C, 49.71; H, 3.34; N, 7.73. Found: C, 49.68; H, 3.31; N, 7.76%.

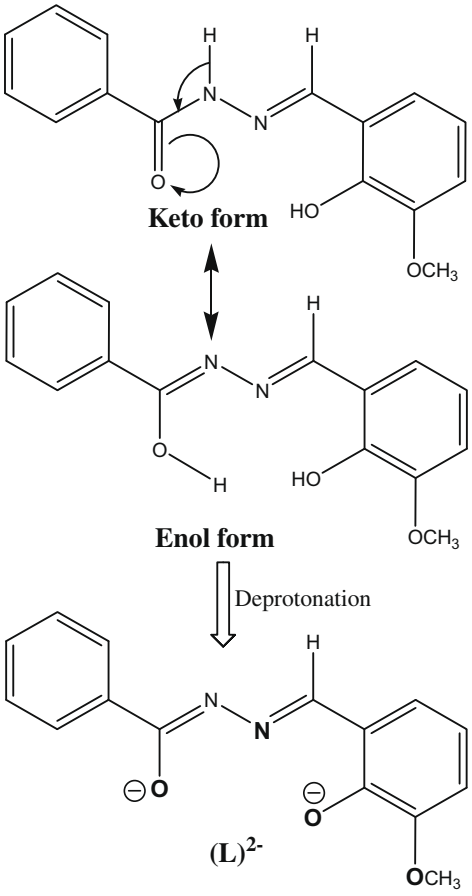
2.3. Physical measurements

The Fourier transform infrared spectra (4000–200 cm^{-1}) of the ligand and the complex were recorded on a Perkin–Elmer Spectrum RX I FT-IR spectrophotometer in the range 4000–200 cm^{-1} as solid KBr disc and electronic spectrum (800–200 nm) on a Perkin–Elmer Lambda 40 (UV–Vis) spectrometer using HPLC grade acetonitrile as solvent. Elemental analysis was carried out on a Perkin–Elmer 2400 II Elemental Analyser. Cyclic voltammetric measurement was performed using a PAR VersaStat-Potentiostat/Galvanostat II electrochemical analysis system under a dry Argon atmosphere using conventional, three electrode configurations in acetonitrile (HPLC grade) with tetrabutylammonium perchlorate as the supporting electrolyte. A platinised platinum milli electrode was used as the working electrode in cyclic voltammetry at a scan rate of $\nu = 50\ mV\ s^{-1}$. Cryomagnetic susceptibility measurement for the complex was carried out with a Quantum Designed SQUID MPMS-XL susceptometer apparatus, which works in the range 2–300 K under magnetic field of approximately 0.5 T on the polycrystalline sample. Diamagnetic corrections were estimated from Pascal's tables.

2.4. X-ray crystal structure determination

X-ray data of a green single crystal with dimension ($0.19 \times 0.32 \times 0.36$ mm) were collected at 150 K on a Nonius KAPPACCD diffractometer equipped with graphite monochromated focused X-ray tube bearing a molybdenum target (λ/Mo Kα = 0.71069 Å). Data collection was performed with COLLECT. The scaling as well as the global refinement of crystal parameters was performed by DENZO and SCALEPACK. Whole data processing was carried out using the KAPPACCD analysis software [34]. The structure was solved by direct methods with SIR-97 program [35] combined to Fourier difference syntheses and refined against F using reflections with $[I/\sigma(I) > 3]$ by CRYSTALS program [36]. The hydrogen atoms were initially refined with soft restraints on the bonds to regularize their geometry after which they were refined with riding constraints only. Those attached to carbon atoms were repositioned geometrically on the basis of the conformation of the supporting atom and also found by Fourier difference analysis. All non-hydrogen atoms were successfully refined with anisotropic thermal parameters. All calculations and graphical works were done using CAMERON [37] and WINGX [38] programs. Selected crystallographic data and refinement parameters are given in Table 1.

3. Results and discussion



3.1. Infrared spectra

The IR spectrum of the complex **1** has been analyzed in comparison with that of the free hydrazone ligand in the region 4000–200 cm^{-1}. The stretching frequency of the imine (CH=N) group in the uncomplexed hydrazone ligand is observed near 1627 cm^{-1}. It is shifted to the lower frequency value (~1590 cm^{-1}) upon complexation [39] with the metal by 37 cm^{-1} suggesting coordination via the imine group. The increase in ν(N–N) from 1005 to 1020 cm^{-1} in the IR spectrum of the complex is due to the increase in the double bond character of N–N, offsetting the loss of electron density via donation to the metal ion and is a further evidence of

Scheme 1.

coordination of the ligand through the imine nitrogen atom. In the complex, sharp bands appearing nearly at 425 and 395 cm^{-1} may be correlated to the Cu–N and Cu–O stretching frequencies respectively. The characteristic spectral band for ν_{str}(N–H) of the hydrazone ligand appears sharply at 3242 cm^{-1}. Interestingly this band disappears in the complex confirming the coordination via enol form instead of keto by deprotonation of N–H proton during the tautomerisation process [40]. A sharp band at ~1500 cm^{-1} indicates the newly formed uncomplexed C=N by enolisation. It further confirms that the coordination of hydrazone takes place in the form of the enol rather than the keto. The loss of the enolic proton is indicated by the absence of a band at ~3400 cm^{-1} in the complex [41,42]. The ν_{str}(C–O) also reduces from 1289 to ~1240 cm^{-1} in the complex when compared to the uncomplexed ligand.

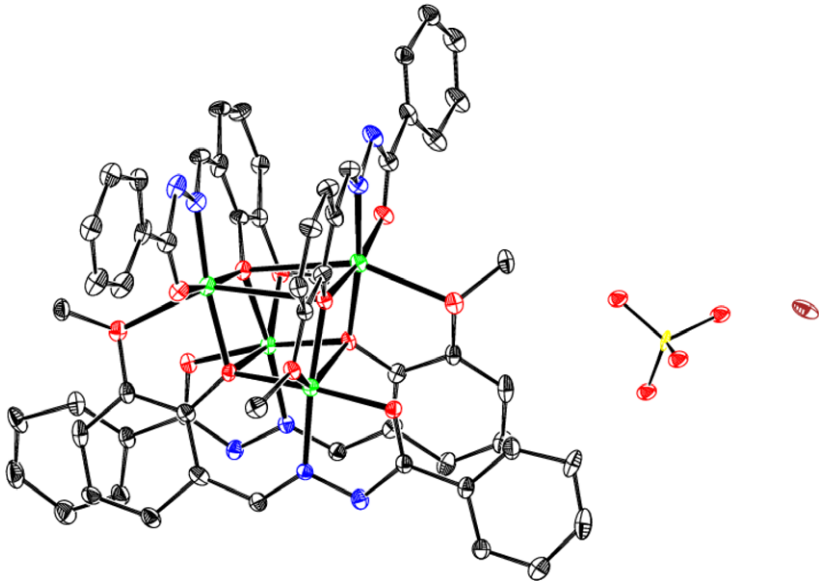

Fig. 1. ORTEP representation of the unit cell of complex **1** (hydrogen atoms are omitted for clarity). Thermal ellipsoids have been drawn at the 40% probability level. Colour code: copper – green, oxygen – red, nitrogen – blue, chlorine – yellow and sodium – brown. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3.2. Electronic spectra

A low intensity broad band appearing at 626 nm may be attributed to the *d*–*d* transition of the copper(II) ion [43]. The intense band in the region of 300–450 nm can be assigned for the $n \rightarrow \pi^*$ transition of the imine group and the higher energy bands below 300 nm may be correlated to the $\pi \rightarrow \pi^*$ intraligand charge transfer transitions. The complex displays strong absorption bands in the high energy range which are clearly charge transfer in origin. The LMCT band at 315–375 nm range can be assigned for the charge transfer transition from the coordinated unsaturated ligand to the metal ion [44].

3.3. Crystal structure description

The complex crystallizes in trigonal space group $P3_221$ and the unit cell consists of tetrameric Cu_4L_4 cubane moiety along with lattice sodium and perchlorate ions. The ORTEP representation of the unit cell of complex **1** is shown in Fig. 1. In the main structural unit of the complex it is seen that the Cu_4O_4 core consists of four phenoxo-bridged copper atoms, giving an approximately cubic array of alternating copper and oxygen atoms occupying the corners of the cube. The cubic core contains two crystallographically independent metal ions, and the two sets of metal ions are related by the crystallographic twofold axis passing through the middle of Cu1–Cu1* and Cu2–Cu2* vectors. The asymmetric unit, thus, consists of the half of the tetramer.

Although transition metal complexes having cubane structures are well studied class of complexes, to the best of our knowledge the case of complex **1** is an exclusive one as such kind of systems are quite rare especially with the tetradentate dianionic hydrazone ligand with $N_{azo}(O_{phenoxo})(O_{methoxo})(O_{enolato})$ donor set. Under the reaction condition the ligand molecule tautomerises from ketonic to enolic form (Scheme 1). After double deprotonation of the enolic and the phenolic OH groups, the dianionic form of the ligand ($\mathbf{L^{2-}}$) coordinates to the copper(II) center. Four such monomeric CuL entities eventually interconnect through the phenoxo bridges to produce the tetranuclear cubane core. A labeled representation of the chelating modes of the hydrazone ligands connected to copper atoms is presented in Fig. 2a and b. The most striking feature of the complex remains in the presence of unique type of μ_3-bridging phenoxo oxygen atoms carrying out the aggregation of the cubane core. Here each of the four phenoxo oxygens located at the four corners of the cube bridges the metal centers in a μ_3-fashion [O9: Cu1, Cu1*, Cu2; O29: Cu1*, Cu2, Cu2*; O9*: Cu1, Cu1*, Cu2* and O29*: Cu1, Cu2, Cu2*]. The occurrence of this kind of bridging mode in constructing the transition metal cubane core complexes is not very frequent and only limited examples are obtained in the literature [27]. Earlier in 2000, Yamashita et al. reported tetranuclear complexes of reduced Schiff base type tridentate dianionic ligands H_2L2X (X: H, Me, and Cl) derived from condensation reaction of the appropriate *o*-aminobenzyl alcohol and salicylaldehyde [27b]. The crystal structure of the complex $[CuL2H]_4$ (**A**) reported in that paper shows that the complex has a cubane like tetranuclear core attributed to the dimer-of-dimers structure by the stacking of alkoxo-bridged dicopper units.

In case of complex **1**, each copper atom is coordinated to three deprotonated bridging phenoxo oxygens, one enolate, one methoxy oxygen and one azo nitrogen atom to give an octahedral geometry. A detailed analysis of the coordination environment of each of

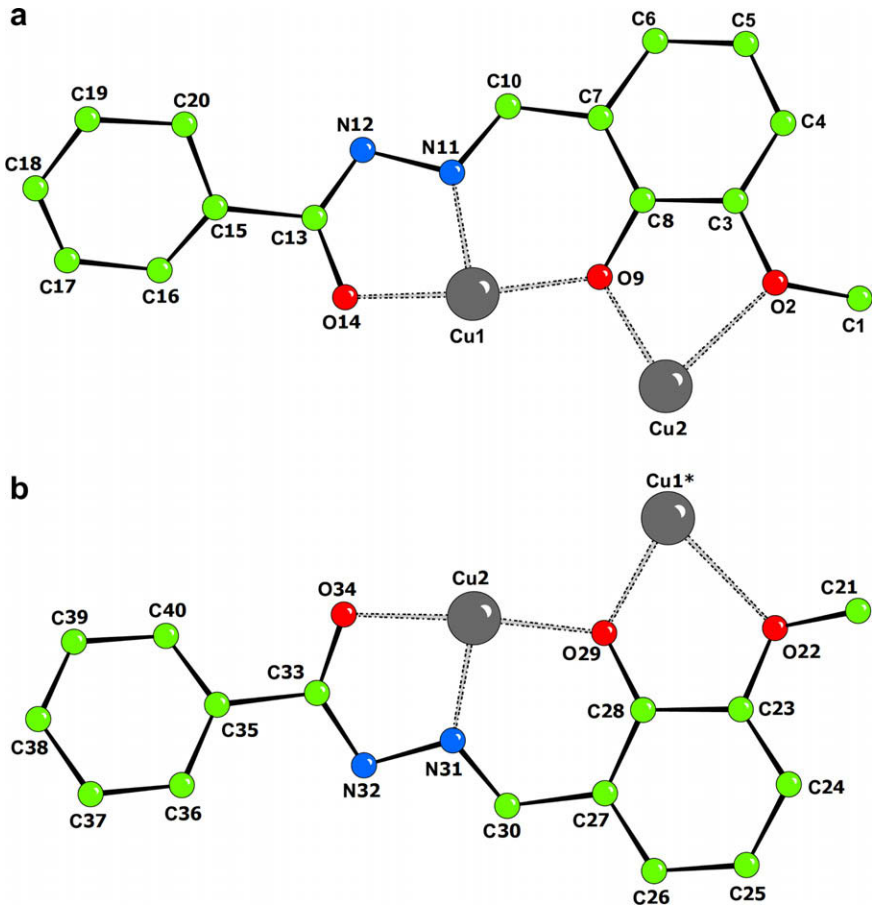

Fig. 2. (a) and (b) Labeled representation of the chelating modes of the hydrazone ligands connected to copper atoms.

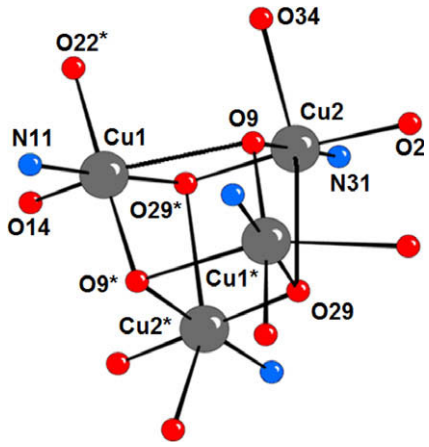

Fig. 3. Environments of copper atoms by oxygen and nitrogen atoms in the $[Cu^{II}_4L_4]$ cluster (only donor sites have been included). Symmetry code: * = *y*, *x*, −*z*.

the metal ions participating in the construction of the tetra(μ_3-phenoxo) bridged cubane core is given in Fig. 3. For Cu1 center the basal plane of the octahedron is constructed by two phenoxo oxygens (O9, O29*), one enolato oxygen (O14) and an azo nitrogen (N11), while the axial positions are occupied by another phenoxo oxygen (O9*) and a methoxy oxygen (O22*). The octahedron around Cu2 center can be described in a similar way where the two phenoxo oxygens (O9, O29), one enolato oxygen (O34) and an azo nitrogen (N31) are in the basal plane and the other phenoxo oxygen (O29*) and a methoxy oxygen (O2) occupy the axial positions (Fig. 3). The geometry of the metal center is considerably distorted from an ideal octahedron and can be best described as elongated octahedral which is clearly reflected from the different bond lengths and angles around the same. The mean lengths of the equatorial bonds around Cu1 are in the range of 1.910(10)–1.964(10) Å while the axial bond distances range from 2.242(7) to 2.679(6) Å owing to the Jahn–Teller effect which is typical for Cu^{II} d^9 system. The slight distortion in the basal plane may be attributed for the strain imposed by the ligand to the metal center during coordination. All the relevant bond lengths and angles are summarized in Table 2. Each pair of Cu atoms located at the corners of the cube is linked through double phenoxo bridges. The bridging bond angles of Cu–O(phenoxo)–Cu are in the range 86.2(3)–112.1(3)° (Table 3). It is evident from the different Cu–O body diagonal distances [Cu1–O29, 3.746; Cu2–O9*, 3.800 Å] as well as from the unequal metal–metal distances (Table 2) that

Table 2

Cu1 O29* Cu2*	3.922	112.1(3)

[a] *D* is the sum of the Cu–O bond lengths making the Cu–O–Cu bridge.

the cubane core is not a regular one, but rather distorted in shape. No significant π–π stacking interaction is observed in the crystal packing in spite of the presence of several planar moieties within the structure.

3.4. Electrochemical studies

Cyclic voltammogram of **1** shows two reductive responses on the negative side of SCE (at −0.40 and −1.16 V), both of which are irreversible in nature. The observed potential gap (620 mV) between the two reductions is moderately large and is believed to be due to the effective communication between the two adjacent paramagnetic Cu^{II} metal centers through the bridging ligands. The reduction may be assigned to copper(II) → copper(I) reduction. One irreversible oxidative response is observed on the positive side of SCE at +1.11 V and this is tentatively assigned to the oxidation of the coordinated ligands.

3.5. Magneto-structural correlations
