In [Bmim][Tf_2N] and [$MeBu_3N$][Tf_2N], UV–Vis and EXAFS spectroscopic measurements reveal that addition of four equivalents of bromide ions onto $UO_2(OTf)_2$ leads to the $[UO_2Br_4]^{2-}$ entity. This tetrabromouranyl complex is stable and is the dominating species. The U–Br distances are 2.821(2) and 2.827(2) Å and the U–O distances are 1.766(2) and 1.768(2) Å, respectively, in [Bmim][Tf_2N] and [$MeBu_3N$][Tf_2N]. In those Tf_2N-based ionic liquids, the coordination environment does not depend on the ionic liquid cation and is the same as in the solid state. EXAFS measurements tend to prove that neither solvent nor water molecules are included in the coordination sphere of uranyl.

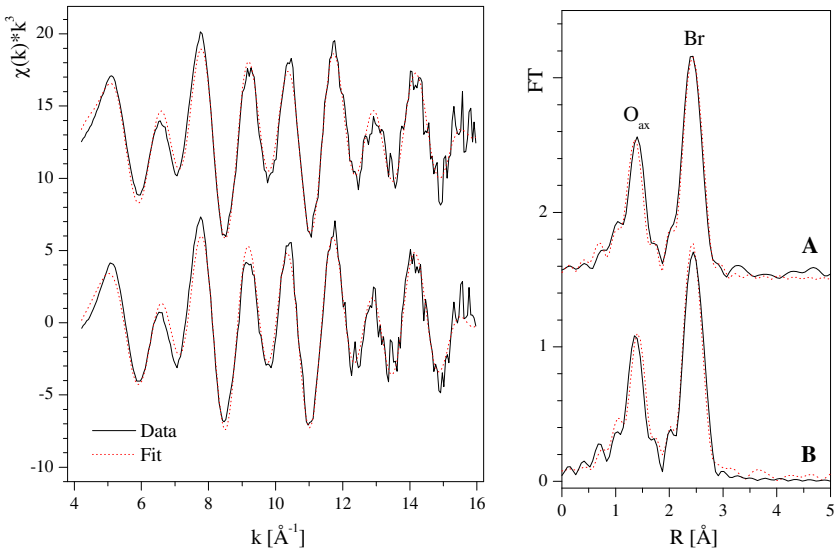

Fig. 5. U L_{III}-edge k^3-weighted EXAFS data (left) and the corresponding Fourier transforms (right) of a 0.02 M $[UO_2Br_4]^{2-}$ solution in [Bmim][Tf_2N] (A) and [$MeBu_3N$][Tf_2N] (B) at 25 °C, with raw data (solid line) and fit results (dotted line).

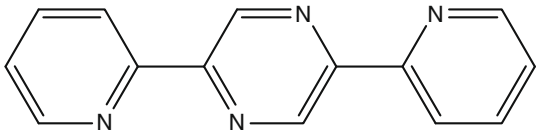
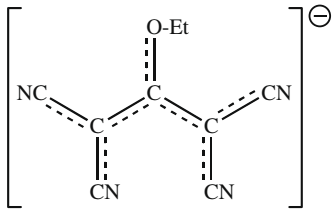
Further works will be focused on the redox properties of the $[UO_2Br_4]^{2-}$ complex in Tf_2N-based ionic liquids.

Supplementary data



CCDC 690078 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgments



We thank the European Actinet network and the GNR PARIS (French organization) for their financial support.

2,5-dpp

tcnoet$^-$

Scheme 1.

boxylato bridges [17,18] the magnetic coupling across the di-μ-chloro and bis-bidentate 2,5-dpp bridges being very weak [15,16].

Curiously the reaction of the $[Cu_2(2,5\text{-dpp})]^{4+}$ dinuclear unit with tricyanomethanide $[N(CN)_3^-$, tcm] in aqueous solution afforded the chain compound of formula $\{[Cu(2,5\text{-dpp})(tcm)]\cdot tcm\}_n$ where the tcm group acts as both terminally bound monodentate ligand and counterion [20]. This is surprising because of the well-known ability of the tcm ligand to act as a bridge in most of its metal complexes [21]. In the present work, we show the results that we obtained when the 1,1,3,3-tetracyano-2-ethoxypropenide anion [tcnoet$^-$; see Scheme 1 (bottom)] is used instead of the tcm$^-$ group. The synthesis and magneto-structural characterization of the new copper(II) complexes $[Cu_2(2,5\text{-dpp})(H_2O)_4(CF_3SO_3)_4]\cdot 2H_2O$ (**1**) and $[Cu_2(2,5\text{-dpp})(H_2O)_2(tcnoet)_4]_n$ (**2**) are described herein.

2. Experimental

2.1. Materials

Copper(II) triflate, copper(II) nitrate trihydrate, tetramethoxysilane and acetonitrile were purchased from commercial sources and used as received. The ligand 2,5-dpp was prepared according to the five-step procedure described previously [16] with a small modification in the last step [20]. The potassium salt of the 1,1,3,3-tetracyano-2-ethoxypropenide was synthesised by a previously reported procedure [22]. Elemental analyses (C, H, N) were carried out by the Microanalytical Service of the University of València.

2.2. Preparation of complexes

2.2.1. $[Cu_2(2,5\text{-dpp})(H_2O)_4(CF_3SO_3)_4]\cdot 2H_2O$ (**1**)

X-ray quality crystals of **1** as pale green parallelepipeds were grown from an acetonitrile solution containing 2,5-dpp (0.2 mmol) and copper(II) trifluoromethanesulphonate (0.4 mmol) by slow evaporation in a hood at room temperature. They were collected by filtration, washed with a small amount cold acetonitrile and diethyl ether and stored over calcium(II) chloride. The yield is practically quantitative. *Anal.* Calc. for $C_{18}H_{22}Cu_2F_{12}N_4O_{18}S_4$ (**1**): C, 20.29; H, 2.07; N, 5.26. Found: C, 20.17; H, 2.02; N, 5.21%.

2.2.2. $[Cu_2(2,5\text{-dpp})(H_2O)_2(tcnoet)_4]_n$ (**2**)

This compound was prepared by using the gel technique. Tetramethoxysilane (1 cm^3) was added under continuous stirring to a warm aqueous solution (10 cm^3) containing $Cu(NO_3)_2\cdot 3H_2O$ (0.22 mmol) and 2,5-dpp (0.11 mmol). The gel was formed on standing after one day at room temperature. An aqueous solution (10 cm^3) containing K(tcnoet) (0.5 mmol) was carefully added on the gel. Single crystals of **2** as brown needles were grown inside the gel on standing at room temperature after several weeks. They were mechanically separated and washed with cold water and dried on filter paper. The yield is *ca.* 80%. *Anal.* Calc. for $C_{50}H_{34}Cu_2N_{20}O_6$ (**2**): C, 52.24; H, 2.96; N, 24.36. Found: C, 52.11; H, 2.88; N, 24.21%.

2.3. Physical techniques

IR spectra were recorded on KBr pellets of **1** and **2** with a Bruker IF S55 spectrophotometer in the 400–4000 cm^{-1} region. Magnetic susceptibility measurements on polycrystalline samples of **1** and **2** were carried out with a Superconducting Quantum Interference Design (SQUID) magnetometer in the temperature range 1.9–300 K and under an applied magnetic field of 1 T ($T > 50$ K) and 1000 G ($T \leqslant 50$ K). The magnetic susceptibility data were corrected for the diamagnetic contribution of the constituent atoms through the Pascal constants [-447×10^{-6} (**1**) and -562×10^{-6} cm^3 mol^{-1} (**2**) per two copper(II) ions] [23] and also for the sample holder. A value of 60×10^{-6} cm^3 mol^{-1} was used for the temperature-independent paramagnetism (tip) of the copper(II) ion. X-band EPR spectrum on a polycrystalline sample of **2** was performed with a Brüker ER 200 spectrometer equipped with a helium continuous-flow cryostat.

2.4. X-ray data collection and structure refinement

Diffraction data on single crystals of **1** and **2** were collected with Bruker–Nonius X8APEXII CCD area detector (**1**) and Oxford Diffraction Xcalibur 2 CCD (**2**) difractometers using graphite-monochro-

Table 1
Summary of crystal data and structure refinement for $[Cu_2(2,5\text{-dpp})(H_2O)_4(CF_3SO_3)_4]\cdot 2H_2O$ (**1**) and $[Cu_2(2,5\text{-dpp})(H_2O)_2(tcnoet)_4]_n$ (**2**).[a]

mated Mo Kα radiation (λ = 0.71073 Å). These data were processed through the SAINT [24] reduction and SADABS [25] absorption software for **1** whereas the data collection and data reduction for **2** were performed with the CRYSALIS-CCD and CRYSALIS-RED programs [26,27]. Scattering factors and corrections for anomalous dispersion were taken from the *International Tables for X-ray Crystallography* [28]. Crystal parameters and refinement results are listed in Table 1. The structures of **1** and **2** were solved by direct methods and successive Fourier-difference synthesis, and they were refined on F^2 by weighted anisotropic full-matrix least-squares methods through the SHELXTL [29] (**1**) and SHELX97 [30] (**2**) software packages. All non-hydrogen atoms of **1** and **2** were refined anisotropically. All hydrogen atoms in **1** and those of the ethyl groups of the two tcnoet anions of **2** were placed in calculated positions and refined as riding atoms, where the hydrogen atoms of the coordinated water molecule [O(1W)] and those of the 2,5-dpp ligand of **2** were located by difference Fourier maps. A common isotropic displacement parameter was allowed for all the hydrogen atoms of **1** and **2**. The residual maximum in the final Fourier-difference maps of **1** was 1.884 and it is near the S(2) atom, which identifies the more thermally disordered triflate anion. The final geometrical calculations were performed with the PARST97 program [31]. The graphical manipulations were carried out with the DIAMOND program [32] and the XP utility of the SHELXTL system. Main interatomic bond lengths and angles are listed in Tables 2 and 3 for **1** and **2**, respectively.

3. Results and discussion

3.1. Synthesis and IR spectroscopy

The bis-bidentate character of the 2,5-dpp molecule accounts for the stability in solution of the dinuclear species $[Cu_2(2,5\text{-dpp})]^{4+}$. The neutralization of its charge by the poorly coordinating triflate anions or the polynitrile tcnoet$^-$ ligand led to the neutral complexes **1** and **2**, respectively. Interestingly, the presence in **1** of terminally bound water molecules and monodentate triflate anions (both of them being easy leaving groups) together with its high solubility in water, would make this complex a good precursor of homo- and heterometallic species when used as a Lewis acid toward preformed complexes that can as ligands.

The IR spectra of **1** and **2** in the high-frequency region have in common the occurrence of a broad and strong absorption centered at ca. 3500 (**1**) and 3450 cm^{-1} (**2**) which are due to the presence of hydrogen bonded water molecules [33]. The shift toward higher wavenumbers of the of the peaks of the ν(C=N) and ν(C=C)

stretchings of the 2,5-dpp group in **1** (a doublet at 1605 and 1570 cm^{-1}) and **2** (1610 and 1565 cm^{-1}) when compared to the free ligand (two peaks at 1580 and 1555 cm^{-1}) supports its coordination to the copper atom [16,20]. Evidence for unidenate sulfonate coordination of the triflate group (C_{3v} symmetry) in **1** is provided by the set of peaks due to this anion [34–36]: two SO_3 stretching modes at 1290s and 1250s cm^{-1} [ν_4(E)], a SO_3 deformation mode at 520m cm^{-1} [ν_5(E)] plus three features at 1035s [$\nu_1(A_1)$], 765w [$\nu_2(A_1)$] and 647s cm^{-1} [$\nu_3(A_1)$]. Finally, the occurrence of a doublet at 2243m and 2203s cm^{-1} in the infrared spectrum of **2** which is assigned to the ν(C≡N) stretching modes of the polynitrile tcnoet ligand [to be compared with the strong absorption at 2205 cm^{-1} in the IR spectrum of the K(tcnoet) salt] strongly supports the presence of coordinated and noncoordinated nitrile-tcnoet groups in this compound, agreement with other structurally characterized tcnoet-containing metal complexes [22,37,38]. All these spectroscopic suggestions of **1** and **2** have been confirmed by the corresponding X-ray structures (see below).

3.2. Description of the structures

3.2.1. Structure of $[Cu_2(2,5\text{-dpp})(H_2O)_4(CF_3SO_3)_4]\cdot 2H_2O$ (**1**)

The structure of **1** is made up of neutral and centrosymmetric dicopper(II) units of formula $[Cu_2(2,5\text{-dpp})(H_2O)_4(CF_3SO_3)_4]$ (Fig. 1) and crystallization water molecules which are interlinked by an extensive network of hydrogen bonds which involve all the water molecules and the uncoordinated triflate-oxygens (see end of Table 2), the whole leading to a three-dimensional network (Fig. 2). Interestingly, the layers shown in Fig. 2a are interconnected by hydrogen bonds through the O(2W) and O(3W) water molecules which form a R4 [39] quasi-planar water ring with a D_{2d} symmetry [graph set notation $R_2^2(8)$] [40] (Fig. 2b). This water ring and its nearest neighbours constitute an aesthetic butterfly-like motif (see center of Fig. 2b) which grows in the *ab* plane.

Each copper(II) ion atom in **1** exhibits an elongated octahedral CuN_2O_4 environment: a pyrazine-[N(2)] and a pyridyl-nitrogen [N(1)] atoms from a 2,5-dpp ligand and two water molecules

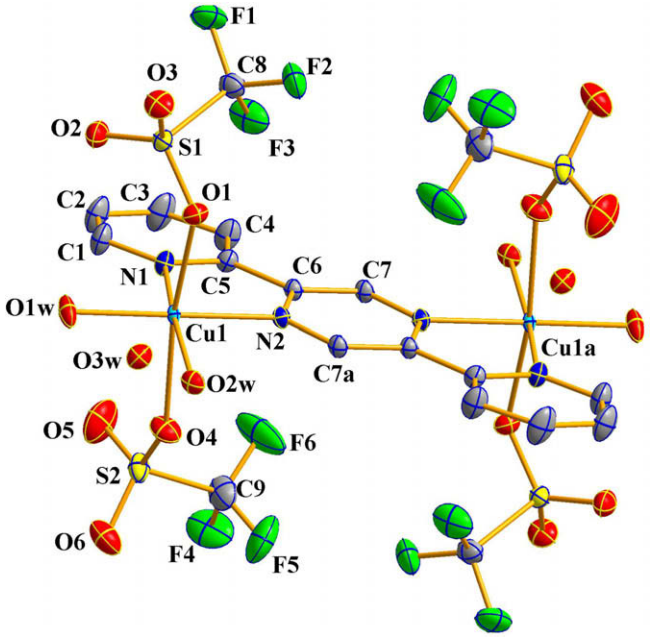

Fig. 1. Crystal structure of the complex $[Cu_2(2,5\text{-dpp})(H_2O)_4(CF_3SO_3)_4]\cdot 2H_2O$ (**1**) showing the atom numbering. Thermal ellipsoids are plotted at the 30% probability level and the hydrogen atoms have been omitted for simplicity. Symmetry code: (a) $-x+1,-y+1,-z+2$.

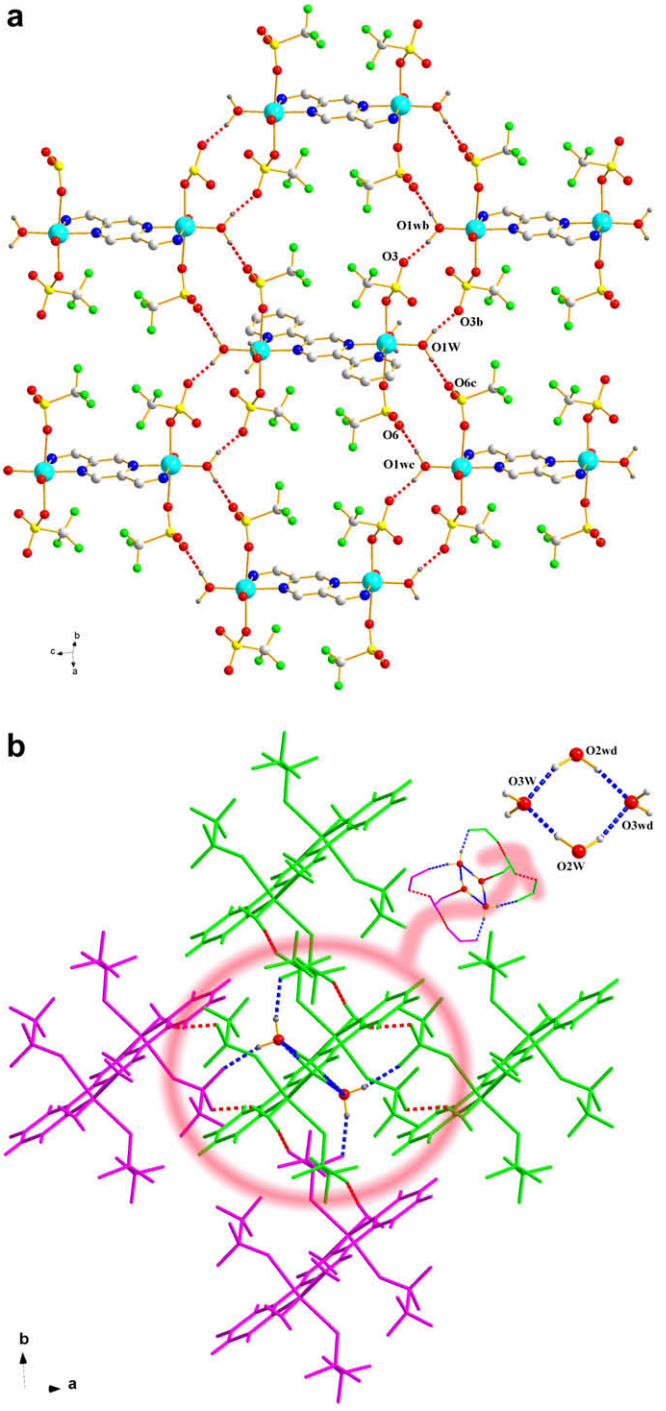

Fig. 2. View of the three-dimensional supramolecular structure of **1** through hydrogen bonds (blue and red dotted lines): (a) layered motif through hydrogen bonds involving the coordinated O(1W) water molecule and the uncoordinated and O(3) and O(6) triflate-oxygens; (b) interlayer connection by hydrogen bonds (blue dotted lines) through the O(3W)O(2W)O(2Wd)O(3Wd) tetrameric ring from the butterfly-shaped motif. Symmetry code: (b) $-x+1,-y+2,-z+1$; (c) $-x+2,-y+1,-z+1$; (d) $-x+1,-y+1,-z+1$. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

[O(1W) and O(2W)] build the basal plane whereas two sulfonate-oxygen atoms from two triflate anions [O(1) and O(4)] occupy the axial positions. The equatorial bonds at the copper atom vary in the narrow range 1.944(2)–2.020(2) Å, values which are shorter than the axial interactions [2.319(2) and 2.387(3) Å for Cu(1)–O(1)

and Cu(1)–O(4), respectively]. The main source of distortion of the environment of the copper atom in **1** is due to the short bite of the chelating 2,5-dpp group, the value subtended by this ligand at the metal atom being 80.9(1)° [N(1)–Cu(1)–N(2)]. This value lies with the range of those observed in the other five structurally characterized 2,5-dpp-bridged copper(II) complexes [77.6(2)–81.0(1)°] [2,17,18,20]. The copper(II) ion is shifted by 0.100(1) Å from the equatorial plane through the O(1) axial triflate-oxygen.

The bis-bidentate coordination mode of the 2,5-dpp ligand in **1** is the most common coordination mode of this group in its metal complexes [2,13,15,17–20], the bidentate 2,5-dpp being observed in the mononuclear $[ZnCl_2(2,5\text{-dpp})(dmf)]$ (dmf = dimethylformamide) and trinuclear $[Zn_3(OAc)_6(2,5\text{-dpp})_2]\cdot H_2O$ complexes [19]. The bond lengths and angles within the 2,5-dpp ligand agree with those observed for the free molecule [2] and its metal complexes [13,15,17–20]. The ligand as a whole is close to planarity, the largest deviation from the mean plane being 0.055(5) Å at C(3). The value of dihedral angle between the pyrazine and the pyridyl rings is only 4.3(2)°. The basal plane of the copper atom and the mean planes of the pyridyl and pyrazine rings form dihedral angles of 12.5(2)° and 8.3(2)°, respectively. The copper–copper separation across the 2,5-dpp bridging ligand is 6.763(1) Å [Cu(1)···Cu(1a); (a) = $-x+1,-y+1,-z+2$], whereas the shortest intermolecular metal–metal distance is 7.175(1) Å [Cu(1)···Cu(1d); (x) = $1-x,1-y,1-z$].

The structure of **1** contains monodentate triflate anions which exhibit a staggered-ethane conformation about the S–C bond. They occupy the axial positions at each copper(II) ion in agreement with their poor coordination ability [34,41]. Their structural parameters are very close to those found in other structures containing unidentate triflate groups [35,36,42].

3.2.2. Structure of $[Cu_2(2,5\text{-dpp})(H_2O)_2(tcnoet)_4]_n$ (**2**)

The structure of **2** is made up of zigzag chains of copper(II) ions of formula $[Cu_2(2,5\text{-dpp})(H_2O)_2(tcnoet)_4]_n$ running parallel to the [1–10] (Figs. 3 and 4). Regular alternating bis-bidentate 2,5-dpp and double μ-1,7-tcnoet bridges occurs in them, the electroneutrality being achieved by terminally bound tcnoet groups. The chains are interlinked through hydrogen bonds involving the coordinated water molecule and two of the uncoordinated nitrile-nitrogen atoms (see end of Table 3) to afford a layered structure which grows in the *ab* plane (Fig. 4).

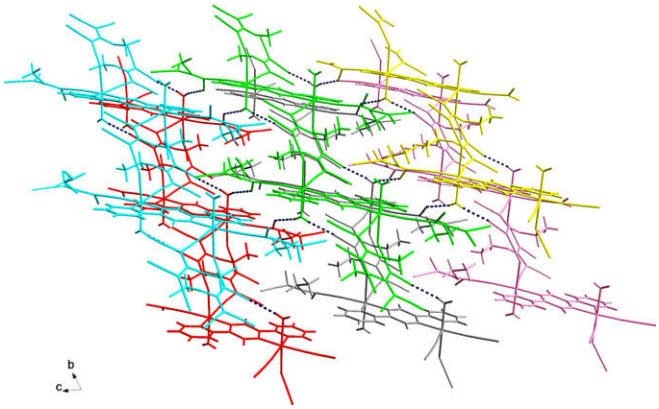

Fig. 4. A view of the packing of adjacent layers in **2** showing the interchain connection by hydrogen bonds (dashed lines) within each layer.

Each copper(II) ion exhibits an elongated octahedral CuN_5O environment: a pyrazine-[N(2)] and a pyridyl-nitrogen [N(1)] atoms from a 2,5-dpp ligand and two nitrile-nitrogen atoms from a terminal [N(11)] and a bridging [N(01)] tcnoet groups build the equatorial plane whereas a water molecule [O(1W)] and a nitrile-nitrogen [N(04b) from a bridging tcnoet ligand occupy the axial positions. The equatorial Cu–N bond distances vary in the narrow range 1.963(2)–2.010(2) Å, values which are shorter than the axial interactions [2.287(2) and 2.647(2) Å for Cu(1)–O(1W) and Cu–N(04b), respectively]. The angle subtended at the copper atom by the chelating 2,5-dpp ligand is 81.20(7)°, a value which is very close to that observed in **1**. The maximum deviation from the equatorial plane is 0.122(2) Å at N(01) and the copper atom is shifted only by 0.071(1) Å toward the O(1W) atom.

The pyridyl and pyrazine fragments of the bis-bidentate 2,5-dpp ligand form a dihedral angle of 7.93(6)°, a value which is practically identical to that of the free 2,5-dpp molecule [7.88(6)°] [2].

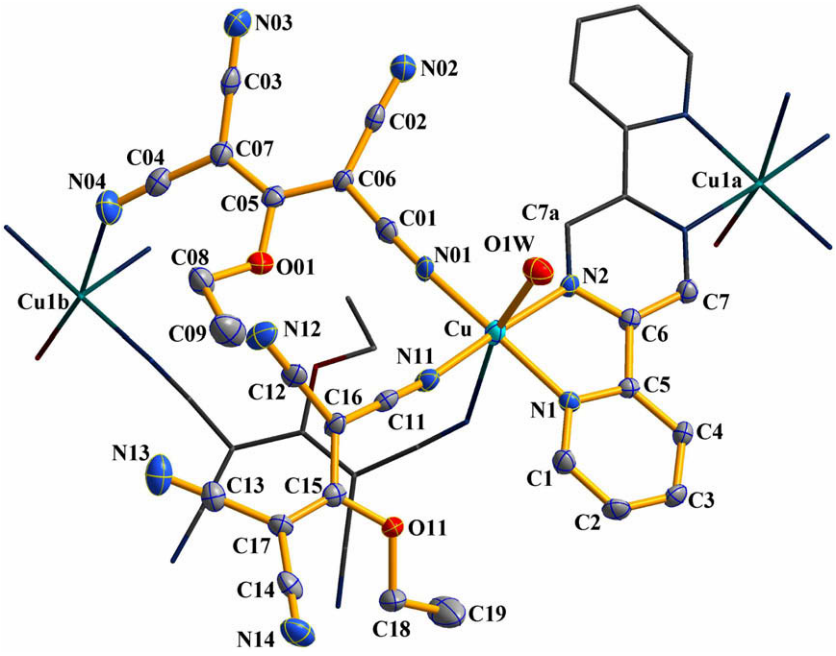

Fig. 3. Perspective view of a fragment of the chain $[Cu_2(2,5\text{-dpp})(H_2O)_2(tcnoet)_4]_n$ (**2**) showing the atom numbering. Thermal ellipsoids are plotted at the 50% probability level and the hydrogen atoms are omitted for the sake of clarity. Symmetry code: (a) $-x,2-y,2-z$; (b) $1-x,1-y,2-z$.

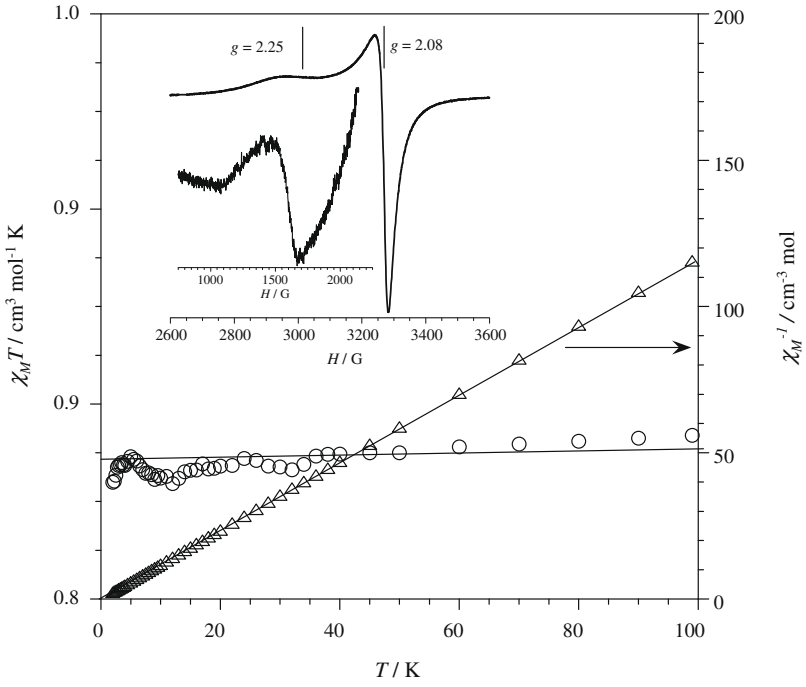

Fig. 5. Thermal dependence of the $\chi_M T$ product (○) and $1/\chi_M$ (△) for **1**. The solid line is the best fit through a Curie law (see text). The inset shows the X-band EPR spectra of a polycrystalline sample of **1** at 4.2 K.

The equatorial plane of the copper(II) ion and the mean planes of the pyridyl and pyrazine rings form dihedral angles of 10.62(6)° and 8.26(5)°, respectively. The central carbon atoms of the terminal [C(16), C(15) and C(17)] and bridging [C(06), C(05) and C(07)] tcnoet ligands have a sp^2-hybridization (sum of the bond angles around each atom being ca. 360°) (see Table 3). Both tcnoet groups exhibit a strong electronic delocalization as indicated by the six nearly equivalent carbon–carbon bond lengths [C–C values ranging in the ranges 1.381(3)–1.428(3) Å (terminal tcnoet) and 1.395(3)–1.421(3) Å (bridging tcnoet)], this delocalization including the C(15)–O(11) and C(05)–O(01) bonds which are approximately 0.10–0.12 Å shorter than the single C(18)–O(11) and C(08)–O(01) bonds [1.454(3) and 1.450(3) Å, respectively]. In spite of this π electronic delocalization, the two types of tcnoet ligands deviate significantly from planarity: the two planar $C(CN)_2$ units are tilted out of the plane containing the central C(16)C(15)C(17)O(11) and C(06)C(05)C(07)O(01) fragments, the values of the tilt angles being 41.51(8) (terminal tcnoet) and 18.27(8)° (bridging tcnoet). These geometrical features of the tcnoet groups in **2** are essentially similar to those observed for this polynitrile anion in a few structures of metal complexes [22,37,38,43].

The copper–copper separation across the bis-bidentate 2,5-dpp is 6.754(1) Å [Cu(1)···Cu(1a); (a) $-x, 2-y, 2-z$], a value which is shorter than that through the double tcnoet bridge [9.559(1) Å for Cu(1)···Cu(1b); (b) $1-x, 1-y, 2-z$] because of the larger size of the 16-membered [$Cu(NCCCCCN)_2Cu$] dimetallacycles involved in this last pathway. The value of the shortest interchain copper–copper distance is 8.275(1) Å [Cu(1)···Cu(1e); (e) $-x, 2-y, 1-z$].

3.3. Magnetic properties of **1** and **2**

The temperature dependence of $1/\chi_M$ and $\chi_M T$ for **1** [χ_M is the magnetic susceptibility per two copper(II) ions] is shown in Fig. 5. At room temperature, $\chi_M T$ is ca. 0.85 $cm^3\ mol^{-1}$ K, a value which is as expected for two magnetically isolated spin doublets. This value remains constant on cooling until 1.9 K. This Curie law behaviour is characterized by the parameters $C = 0.845\ cm^3\ mol^{-1}$ K and $g = 2.12$ where C is the Curie constant in the expression $\chi_M = C/T$. The lack of magnetic interaction between the local doublets through the bis-bidentate 2,5-dpp ligand in **1** is in line with the very poor ability of this molecule to mediate magnetic interactions between the paramagnetic centers that it links [16–20]. The X-band EPR spectra recorded on a polycrystalline sample of **1** show absorption bands of axial symmetry with $g_{\|} = 2.25$ and $g_{\perp} = 2.08$ (see inset of Fig. 5) and no significant variations from room temperature to 4.2 K. At very low temperatures, there appears a very weak half-field transition that could be interpreted as the $\Delta M_S = 2$ forbidden transition in the triplet in agreement with the dinuclear structure of **1**.

The lack of magnetic coupling though the pyrazine ring of 2,5-dpp in its copper(II) complexes is quite surprising. One can see in **1** that the unpaired electron on each copper(II) is described by a $d_{x^2-y^2}$ type magnetic orbital which is mainly located in the basal plane [the x and y axes being roughly defined the Cu(1)–N(1) and Cu(1)–(N(2) bonds]. Consequently, a significant overlap between these magnetic orbitals through the pyrazine ring (σ exchange pathway connecting equatorial bonds at the copper atoms) is predicted and then, an antiferromagnetic coupling would be expected. In fact, values of the antiferromagnetic coupling (J) covering the range -12.4 to $-5.6\ cm^{-1}$ (the Hamiltonian being defined as $(\hat{H} = -J\hat{S}_A \cdot \hat{S}_B)$ have been reported for magneto-structurally characterized pyrazine-bridged copper(II) complexes where the same exchange pathway (that is the one connecting equatorial bonds of adjacent copper atoms) is involved [44–47]. This antiferromagnetic interaction attains larger values in the tppz-bridged copper(II) [tppz = 2,3,5,6-tetrakis(2-pyridyl)pyrazine] with values of J covering the range -61.1 to $-19.9\ cm^{-1}$ [48–51]. These features suggest that the energies of the HOMOs of the appropriate symmetry of the pyrazine (pyz) molecule which interact with the magnetic orbitals of the copper(II) ions in the pyz-bridged copper(II) complexes are dependent on both the degree and substitution pattern of the pyz molecule. Theoretical calculations which are beyond the scope of the present work are needed to give a clearcut answer to this assumption.

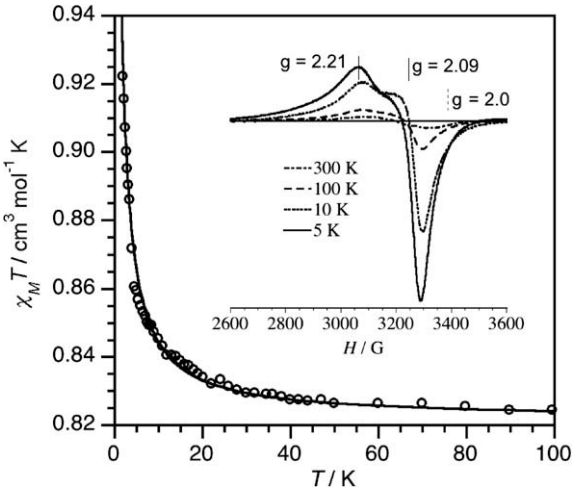

Fig. 6. Thermal dependence of the $\chi_M T$ product for **2** at $T \leqslant 100$ K: (○) experimental data; (–) best-fit curve (see text). The inset shows the X-band EPR spectra of a polycrystalline sample of **2** at different temperatures.

The magnetic properties of **2** under the form of $\chi_M T$ versus T plot [χ_M is the magnetic susceptibility per two copper(II) ions] is shown in Fig. 6. At room temperature, $\chi_M T$ is equal to 0.80 $cm^3\ mol^{-1}$ K, a value which is as expected for two magnetically noninteracting spin doublets. Upon cooling, this value remains constant until $T = 30$ K and it increases further to reach a value of ca. 0.92 $cm^3\ mol^{-1}$ K at 1.9 K. This small increase of $\chi_M T$ of **2** in the low temperature domain indicates the occurrence of a very weak ferromagnetic coupling. Although there are two bridging ligands in **2** (namely the bis-bidentate 2,5-dpp ligand and the double tcnoet bridges) and then two possible intrachain exchange pathways, that through the 2,5-dpp ligand can be discarded in the light of the lack of magnetic coupling which is observed in **1**. Consequently, the exchange pathway for the small ferromagnetic coupling observed in **2** is most likely provided by the double tcnoet bridges. The analysis of the magnetic data of **2** through a simple Bleaney–Bowers expression through the Hamiltonian $H = -JS_1 \cdot S_2$ leads to $J = +0.78\ cm^{-1}$ and $g = 2.13$. Variable-temperature X-band EPR spectra of **2** (see inset of Fig. 6) support the occurrence of a low-lying spin triplet with a very small zero field splitting in agreement with the susceptibility data.

Given the Curie law behaviour observed in **1**, the out-of-plane exchange pathway through the double tcnoet bridges seems to be responsible for the weak ferromagnetic interaction observed in **2**. The unpaired electron (magnetic orbital) on each copper(II) ion of **2** is described by a $d_{x^2-y^2}$ type orbital which is mainly located in the basal plane [the x and y axes corresponding roughly to the Cu(1)–N(01) and Cu(1)–N(11) bonds]. A small spin density is expected in the axial site occupied by the N(04b) atom [Cu(1)–N(04b) = 2.647(2) Å] that is in the tcnoet-nitrogen which connect this axial site with one equatorial position of the symmetry related Cu(1b) atom. So, the overlap between the magnetic orbitals of the adjacent Cu(1) and Cu(1b) atoms is expected to be poor and thus, the magnetic coupling would weak either antiferro- (net overlap) or ferromagnetic [case of accidental orthogonality which depends on some structural parameters such as the angle at the axial bridging atom, that is 134.3(2)° for Cu(1)–N(04b)–C(04b)]. The ferromagnetic coupling in **2** is most likely due to the accidental orthogonality between the magnetic orbitals within the [Cu(1)(NCCCCCN)$_2$Cu(1b)] dimetallacycle (out-of-plane exchange pathway), a situation which has been previously observed in oximato- [52], di-μ-chloro- [53] and double end-on azido/cyanato-dicopper(II) complexes [54].

4. Conclusions

The present study shows that the 2,5-dpp ligand is a suitable connector of metal ions to yield dinuclear species (**1**) that can be used as precursors of alternating chain compounds in the presence of potential bridging coligands such as tcnoet (**2**). The bis-bidentate 2,5-dpp molecule appears as a very poor mediator of magnetic interactions in its copper(II) complexes whereas the polynitrile tcnoet ligand is able to transmit weak ferromagnetic interactions between copper(II) ions separated by more than 9.5 Å through the out-of-plane exchange pathway.

Supplementary data

CCDC 711506 and 711507 contain the supplementary crystallographic data for **1** and **2**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

deionized water (50 mL) in a 100 mL beaker with stirring at room temperature or 60 °C for 0.5–15 h. The resulting solid was filtered and washed with deionized water until the supernatant became neutral and then the wet products were dried in an oven at 80 °C overnight. These samples are designated as M^{n+}/K-CoKBL, where the M^{n+} stands for the metal ions.

2.4. Characterization

Powder X-ray diffraction (XRD) patterns were recorded on a Shimadzu XD-D1 diffractometer using Cu Kα radiation and a carbon monochromator. For Rietveld analysis, the XRD pattern was measured on another diffractometer (Rigaku Rint 2500) and analyzed by the RIETAN-FP program [8]. The TCH pseudo-Voigt profile function was used. The parameters were optimized according to the following order: the unit cell parameter [3], the fractional coordinates, the site occupancies, and the isotopic displacement parameters. The morphology of the product was observed with a scanning electron microscope (SEM), Hitachi S-5000H. The specific surface area was calculated using the BET single-point method from nitrogen uptake measured at 77 K. The samples were pretreated in an N_2 flow at 300 °C for 30 min prior to the measurements. The elemental analyses were performed using a Shimadzu ICPS-1000 IV, inductively coupled plasma (ICP) emission spectrometer, after the samples were dissolved in HCl.

2.5. Catalyst test

Catalyst tests were carried out in a fixed-bed flow reactor. The Co_3O_4 catalyst prepared by calcination of the precursor at 400 °C in air for 4 h was tabletted, pulverized into 10–22 mesh, and set in the reactor. The catalyst bed was heated to 500 °C in a helium gas flow and held at that temperature for 30 min. Then, the reaction gas composed of 5000 ppm N_2O, 2% O_2, and He balance was introduced to the catalyst bed at $W/F = 0.3$ g s mL^{-1}. The effluent gases from the reactor were analyzed every 5 min at 500 °C with an on-line micro-gas-chromatograph (CP 2002, Chrompack, Netherlands) (columns: 10-m Molecular Sieve 5A at 80 °C; 10-m Porapak Q at 40 °C). After the steady state was attained, reaction temperature was decreased from 500 °C to the temperature where the catalyst showed negligible N_2O conversion. The catalyst activity is expressed by the T_{50} value, which is defined as the temperature at which the catalyst exhibits 50% N_2O conversion under the above-mentioned conditions.

3. Results and discussion

3.1. Preparation of alkali-metal cobalt kambaldaites (M-CoKBL)

Although Petrov et al. reported the synthesis of sodium or ammonium cobalt kambaldaite (CoKBL), there are no reports on the synthesis of the other alkali-metal analogues of CoKBL. Therefore, we tried to prepare them by the precipitation method.

When the precipitate, obtained by the addition of a cobalt nitrate solution to a potassium bicarbonate solution at 50 °C, was aged at that temperature, the K-CoKBL phase (ideal structure, $K_2Co_8(CO_3)_6(OH)_6{\cdot}6H_2O$) appeared. Similarly, synthesis of M-CoKBL requires aging at relatively high temperatures and transformation of cobalt carbonate into the kambaldaite phase took place during aging. This process is accompanied by the change in color of the precipitate as described in Section 2. The preparation method adopted in this paper is much simpler than that reported previously [3,4].

Fig. 1 shows XRD patterns of the products. All the XRD patterns had kambaldaite-like features. In the case of lithium and sodium, however, cobalt carbonate was formed as a by-product. Although we briefly reported the direct synthesis of Na-CoKBL by precipitation of cobalt nitrate with sodium bicarbonate at 35 °C followed by aging at that temperature for 24 h [5], detailed examination of the XRD patterns by the Reitveld method (vide infra) revealed that these products (Li- and Na-CoKBL) were always contaminated with a small amount of $CoCO_3$ irrespective of the reaction conditions.

The SEM images of NH_4- and alkali-metal-CoKBL are shown in Fig. 2. NH_4-CoKBL was composed of rod-shaped particles. Twined particles and star-burst type particles were also observed. Li-CoKBL had a hexagonal-rod morphology. In the SEM image, small $CoCO_3$ particles were also observed. Na-CoKBL particles are hexagonal prisms. Besides much smaller contaminated $CoCO_3$ particles, well-developed Na-CoKBL particles with faceted surfaces were observed. This morphology is completely different from that of Na-CoKBL prepared by Petrov et al. who reported that the sample consisted of globular crystals with a rough surface [3].

K-CoKBL was composed of unique caterpillar-like spindles. However, close examination of each particle revealed that caterpillar-like morphology was formed by stacking of hexagonal or hexagonal-like plates, indicating that stacking defects frequently occurred during the crystal growth toward the *c*-axis direction. Although many X-shaped twined particles were observed in the SEM photographs of K-CoKBL, particles having morphologies other than caterpillar-like one were not observed, indicating that the product was phase-pure K-CoKBL.

During the course of the preparation of K-CoKBL, a sharp color change of the precipitate in a few minutes was noted after a rather long aging time (~1 h). This observation indicates that nucleation of K-CoKBL crystals occurred in a relatively short period followed by rapid crystal growth. Therefore, the particle-size distributed in a narrow range.

Cs-CoKBL also had the caterpillar-like morphology but overall shape of each particle was hexagonal bipyramidal. For Rb-CoKBL, spindle-like particles without the caterpillar-like morphology and irregularly shaped particles were observed. The latter particles may be due to an amorphous phase.

3.2. Rietveld analysis of alkali-metal cobalt kambaldaite

All the XRD peaks of the products (except for Li-CoKBL and Na-CoKBL) can be indexed according to the space group of $P6_3$ [9]. The unit cell parameters, *a* and *c*, and empirical formula of M-CoKBL calculated by Rietveld method are summarized in Table 1.

The unit cell parameters of Na-CoKBL obtained by the precipitation method were slightly larger than the reported values [3]. The empirical formula of Na-CoKBL was $Na_{1.83}Co_{7.99}(CO_3)_6(OH)_{5.82} \cdot 5.35H_2O$, which is much closer to the ideal formula than that reported by Petrov et al. ($Na_{0.84}Co_{4.04}(CO_3)_{2.99}(OH)_{2.81} \cdot 3.32H_2O$) [3]. They attributed this deviation to partial elution of Na^+ ions by washing with water because the Na^+ ions in kambaldaite are relatively mobile, and the absence of distinct smooth crystal faces was attributed to the elution phenomenon. However, the present product had smooth surfaces in spite of the fact that the sample was

Table 1

K-CoKBL	8.68	10.4100(13)	6.1483(6)			$K_{1.31}Co_8(CO_3)_{5.69}(OH)_{5.93} \cdot 4.40H_2O$	this work
Rb-CoKBL	11.9	10.4541(22)	6.1424(9)			$Rb_{0.06}Co_{7.79}(CO_3)_{4.79}(OH)_6 \cdot 8.07H_2O$	
Cs-CoKBL	11.4	10.4385(26)	6.1482(11)			$Cs_{0.35}Co_{7.02}(CO_3)_{4.20}(OH)_6 \cdot 5.43H_2O$	
Na-CoKBL	7.04	10.4405(5)	6.1663(7)			$Na_{0.84}Co_{4\ 04}(CO_3)_{2.99}(OH)_{2.81} \cdot 3.32H_2O$	[3]
NH_4-CoKBL	7.91	10.4028(5)	6.1250(3)			$(NH_4)_{1.89}Co_{7.88}(CO_3)_6(OH)_6 \cdot 4.27H_2O$	[4]

Space group: CoKBL, $P6_3$ (No. 173); $CoCO_3$, $R\bar{3}c$ (No. 167).

completely washed with water with prolonged immersion of the sample in water. These facts suggest that partial elution of Na^+ ions was prevented by faceted surfaces of Na-CoKBL.

Fig. 3 shows the observed, calculated and difference profiles for the final refinement of XRD of K-CoKBL. The refinement led to residual values of $R_{wp} = 8.68\%$, $R_p = 6.73\%$, $R_e = 5.08\%$ and $S = 1.709$. The empirical formula of K-CoKBL was close to the ideal one. The unit cell parameters, a and c were 10.4100 ± 0.0013 and 6.1483 ± 0.0006 Å, respectively, which were slightly smaller than the reported values for Na-CoKBL [3]. The kambaldaite structure is built by infinite chains of $[Co(1)(OH)_2(OCO_2)_4]$ octahedra sharing opposite edges, parallel to the twofold screw axis. These chains are connected via bridging CO_3^{2-} groups and $[Co(2)(OH)_3(OCO_2)_3]$ octahedra, resulting in formation of tunnels in which $[M(H_2O)_6]$ octahedra are located to cancel the negative charge of the framework. The result maintained above (smaller unit cell volume of K-CoKBL as compared with that of Na-CoKBL) may be due to the fact that hydrated radius of alkali-metal cation decreases with the increase in the period of the periodic table. The site occupancy of potassium in the lattice was low, and the K/Co ratio calculated by the Rietvald method was 0.16 (theoretical value for the ideal structure, 0.25). This value was essentially identical with the K/Co molar ratio determined by ICP analysis (0.13). This result may suggest that elution of K^+ ions took place because the surface of the particle was rather rough. The final positional and thermal parameters for K-CoKBL are listed in Table 2.

For Rb-CoKBL, calculated Rb content was much smaller than ideal one. Since the product particles had rough surfaces, elution of Rb ions accompanied by elimination of a part of counter anions might have occurred during washing the particles.

Because the 2a sites of the $P6_3$ space group where alkali-metal cations are accommodated have O_h-like surroundings, NH_4^+ having the T_d structure cannot locate in the 2a site. Therefore, Rietveld analysis of NH_4-CoKBL was not carried out in this work.

3.3. Ion-exchange of K-CoKBL

Since kambaldaite has a unique one-dimensional channel structure, we tried to ion-exchange the K^+ ions in the channels of K-CoKBL with various metal ions for application of the ion-exchanged K-CoKBL as the precursor of catalysts for direct decomposition of nitrous oxide.

The XRD patterns of the products are shown in Fig. 4 and K/Co molar ratios of M^{n+}/K-CoKBL before/after the ion-exchange treatment analyzed by the ICP emission spectrometry are shown in Table 3. When the samples were treated in the solutions of with aluminum, iron and gallium nitrates, the K/Co molar ratio after the treatment decreased. However, the K-CoKBL phase collapsed and a hydrotalcite-like phase appeared except for Fe^{3+}/K-CoKBL. Although the K-CoKBL phase was maintained in the case of nickel nitrate, K/Co molar ratio after the ion-exchange treatment was almost as same as before ion-exchange; therefore ion-exchange

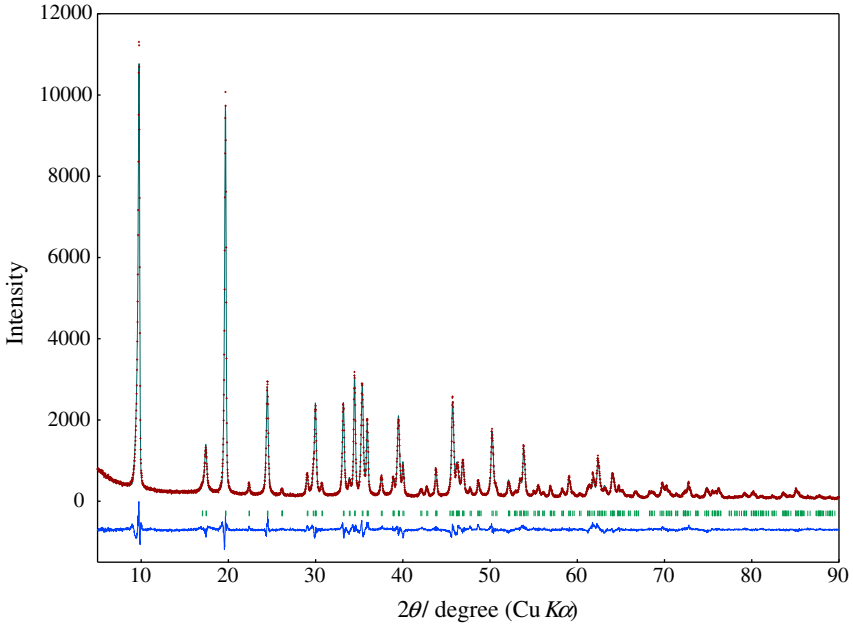

Fig. 3. Observed, calculated, and difference patterns obtained by Rietveld analysis of K-CoKBL as-synthesized by precipitation of cobalt nitrate with potassium bicarbonate at 50 °C followed by aging at that temperature for 3 h.

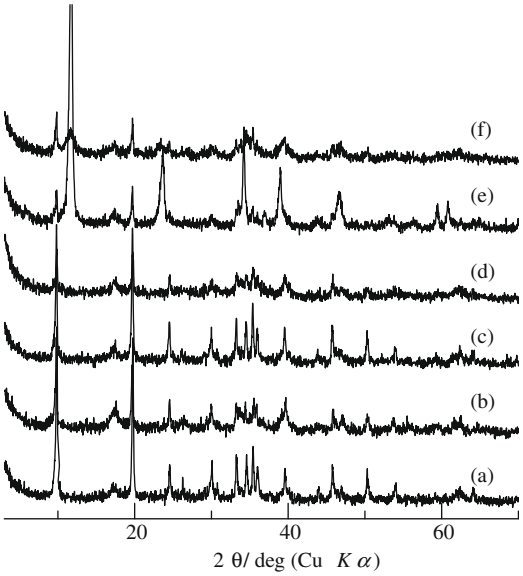

Fig. 4. XRD patterns of (a) K-CoKBL; (b) Li^+/K-CoKBL; (c) Ni^{2+}/K-CoKBL; (d) Fe^{3+}/K-CoKBL; (e) Ga^{3+}/K-CoKBL; and (f) Al^{3+}/K-CoKBL.

reaction might not proceed well. In the case of lithium, ion-exchange might proceed because the solution of lithium acetate is slightly basic. These results suggest that the K-CoKBL structure is weak even in slightly acidic solutions, the K-CoKBL phase dissolving in the ion-exchange solution because of low concentration of hydroxide and carbonate ions. In other words, collapse of the structure took place more quickly than the ion-exchange of K-CoKBL, and the hydrotalcite-like phase seems to be formed by a dissolution–recrystallization mechanism.

The XRD patterns of the samples obtained by calcination of M^{n+}/K-CoKBL at 400 °C for 4 h showed the formation of Co_3O_4 having a spinel structure. Similarly, when the parent K-CoKBL sample was calcined at the same temperature, it transformed into Co_3O_4. The BET surface area of the Co_3O_4 obtained from K-CoKBL (75 $m^2\ g^{-1}$) was larger than that obtained from $CoCO_3$ (57 $m^2\ g^{-1}$) [7]. As mentioned in Section 1, the CoKBL phase was formed by a transformation sequence of: hydrotalcite-like phase → cobalt carbonate → CoKBL phase. This transformation sequence was also observed by increasing the precipitation temperature. Therefore, the CoKBL phase was well crystallized as compared with the $CoCO_3$. However, the BET surface area of Co_3O_4 obtained by decomposition of the CoKBL phase was larger than that obtained from $CoCO_3$. This result can be explained by the disturbance of the development of Co_3O_4 crystals by the K^+ ions present in the precursor, K-CoKBL.

3.4. N_2O decomposition over Co_3O_4 catalysts

The catalytic activities of the modified Co_3O_4 catalysts obtained by calcination of M^{n+}/K-CoKBL are shown in Fig. 5. Although the catalyst obtained from K-CoKBL itself exhibited only a low activity (T_{50} value ~330 °C), all the catalysts obtained from M^{n+}/K-CoKBL by the ion-exchange treatment showed higher activities. Especially, the catalysts obtained from Al^{3+}/K-CoKBL, Fe^{3+}/K-CoKBL, and Ga^{3+}/K-CoKBL showed much higher activity and the T_{50} values of these catalysts were 176 °C, 171 °C, and 178 °C, respectively. Then, we prepared the M^{3+}/K-CoKBL samples (M = Al, Fe, and Ga) having various M^{3+}/Co molar ratios by varying the treatment conditions such as stirring temperature (r.t. or 60 °C) and stirring

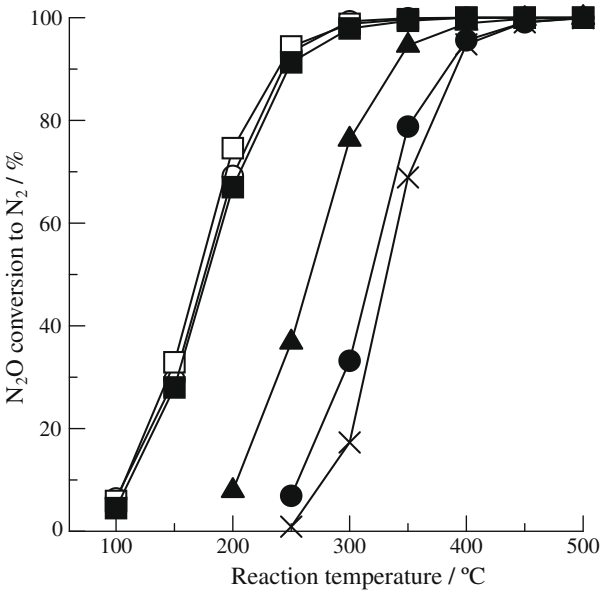

Fig. 5. N_2O decomposition activities of Co_3O_4 catalysts derived from K-CoKBL (×) and K-CoKBL "ion-exchanged" with: (□), Fe^{3+}; (○), Al^{3+}; (■), Ga^{3+}; (▲), Ni^{2+}; (●), Li^+. Reaction conditions: N_2O, 5000 ppm; O_2, 2%; He balance; W/F = 0.3 g s mL^{-1}.

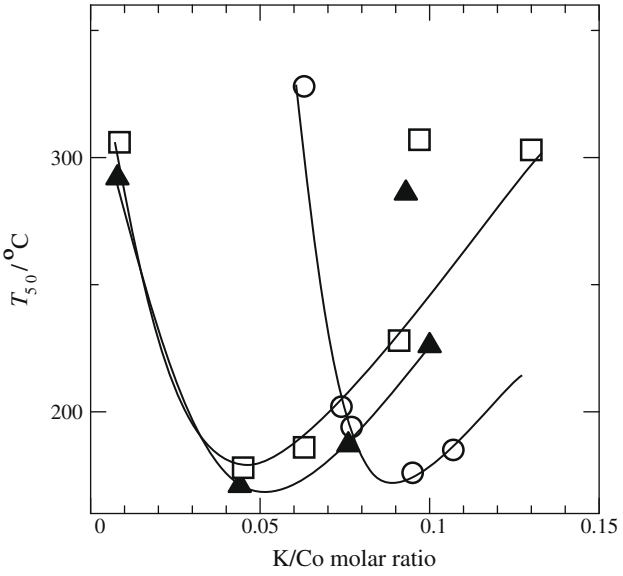

Fig. 6. Temperature of 50% N_2O conversion (T_{50}) versus K/Co molar ratio of the catalyst obtained by calcination of M^{n+}/K-CoKBL. "Ion-exchange" solution: ○, $Al(NO_3)_3$; ▲, $Fe(NO_3)_3$; □, $Ga(NO_3)_3$. Reaction conditions: N_2O, 5000 ppm; O_2, 2%; He balance; W/F = 0.3 g s mL^{-1}.

time (from 0.5 h to overnight), and examined the activities of the modified Co_3O_4 catalysts obtained by calcination of M^{3+}/K-CoKBL. The K/Co and M^{3+}/Co molar ratios and T_{50} values of the catalysts are summarized in Table 4. The catalyst activity was plotted against the K/Co ratio in Fig. 6 which clearly shows that the catalytic activity was closely connected with the K/Co molar ratio. When the catalyst activity was plotted against M^{3+}/Co ratio, no correlation was observed (data not shown), indicating that the amount of M^{3+} ions introduced in the precursor was not connected with the catalytic activity. The T_{50} value of the K-doped Co_3O_4 catalyst prepared by impregnation of commercial $CoCO_3$ with potassium nitrate is about 150 °C [7]. Therefore, the activity of the catalyst obtained by calcination of M^{3+}/K-CoKBL was slightly lower than that of the impregnation catalyst and almost equal to that of the Co_3O_4 catalyst prepared by a precipitation method (172 °C) [5,6].

4. Conclusions

Ammonium- and alkali-metal cobalt kambaldaites (M-CoKBL; ideal formula, $M_2Co_8(CO_3)_6(OH)_6 \cdot 6H_2O$) were directly obtained by precipitation of a cobalt nitrate solution with ammonium or alkali-metal bicarbonate at 50 °C followed by aging at that temperature for 2–3 h. The XRD patterns of the kambaldaites can be simulated by the structure with the $P6_3$ space group. Na-CoKBL had a well-developed hexagonal prism morphology and had an empirical formula close to the ideal one. When K-CoKBL was soaked in the solution of metal nitrate, the collapse of the structure of K-CoKBL took place faster than the ion-exchange by metal ions.

The Co_3O_4 catalysts obtained by calcination of the K-CoKBL "ion-exchanged" with Al^{3+}, Fe^{3+}, and Ga^{3+} exhibited high activities for direct decomposition of nitrous oxide. However, the activity strongly depended on the content of potassium ions remaining in the catalyst but not on the contents of Al^{3+}, Fe^{3+} and Ga^{3+} ions.

Technology. Column chromatographic separations were carried out on neutral Al_2O_3 from Aldrich. Alumina TLC plates D-5160 Duran from Macherey–Nagel were used for selecting eluants and controlling the separation process. The literature procedure was used for the syntheses of the 4-aminophenyl alkyloxybenzoates [49–54].

2.1.1. Ferrocenylketoacetaldehydate sodium (**2**)

Ethyl formate (1.2 mL, 14.9 mmol) and **1** (2.00 g, 8.77 mmol) in absolute benzene (Caution: carcinogen! Consult MSDS) (15 mL) were refluxed for 6 h in the presence of metallic sodium (Caution: highly reactive material! Consult MSDS) (0.60 g, 26.1 mmol) [55]. A precipitate of sodium enolate was filtered off and recrystallized from ethanol. Yield 2.44 g (86%), orange powder. Used without further characterization.

2.1.2. 1-Ferrocenyl-1-{[4-(4-dodecyloxybenzoyloxy) phenyl]amino}propen-2-one (**3a**)

The *p*-aminophenyl ester of *p*-dodecyloxy benzoic acid (1.165 g, 2.93 mmol) and **2** (0.815 g, 2.93 mmol) were dissolved separately in hot ethanol, and then mixed together. Concentrated aqueous HCl (26 μL, 0.30 mmol) was added dropwise to the mixture by a syringe, and then the mixture was refluxed for 30 min. An orange precipitate was filtered out after the mixture cooled down. The precipitate was dissolved in CH_2Cl_2 and filtered through Celite 545. The solvent was evaporated using a rotary evaporator. Recrystallization from *n*-butanol gave 0.472 g (25%) of an orange powder. ^{1}H NMR (250 MHz): δ 0.89 (t, 3H, CH_3), 1.27 (br. s, 16H, CH_2), 1.48 (m, 2H, $OCH_2CH_2CH_2$), 1.82 (quintet, 2H, OCH_2CH_2), 4.04 (t, 2H, OCH_2), 4.19 (s, 5H, C_5H_5), 4.47 (t, 2H, C_5H_4), 4.80 (t, 2H, C_5H_4), 5.61 (d, $J_{H,H}$ = 7.5 Hz, 1H, H1), 6.98 (d, $J_{H,H}$ = 10 Hz, 2H, H6), 7.09 (d, $J_{H,H}$ = 8 Hz, 2H, H3), 7.17 (d, $J_{H,H}$ = 8 Hz, 2H, H4), 7.30 (dd, $J_{H,H}(1)$ = 7.5 Hz, $J_{H,H}(2)$ = 12.5 Hz, 1H, H2), 8.13 (d, $J_{H,H}$ = 10 Hz, 2H, H5), 11.84 (d, $J_{H,H}$ = 12.5 Hz, 1H, NH). FT-IR (cm^{-1}): 2915 (C–H), 2846 (C–H), 1727 (C=O), 1627 (C=O), 1602 (COC=C), 1515 (C=C aryl), 1508 (C=C aryl), 1489 (C=C aryl), 1256, 1199, 1165, 1083, 1072, 1029, 1010, 823, 788, 759, 525, 504, 486. *Anal.* Calc. for $C_{38}H_{45}FeNO_4$: C, 71.81; H, 7.13; N, 2.20. 2.1.3. 1-Ferrocenyl-1-{[4-(4-hexadecyloxybenzoyloxy) phenyl]amino}propen-2-one (**3b**)

This compound was prepared in an analogous manner to the previous reaction from 3.295 mmol of the appropriate reagents. Yield 0.64 g (28%). ^{1}H NMR (250 MHz): δ 0.88 (t, 3H, CH_3), 1.26 (br. s, 24H, CH_2), 1.48 (m, 2H, $OCH_2CH_2CH_2$), 1.82 (quintet, 2H, OCH_2CH_2), 4.04 (t, 2H, OCH_2), 4.20 (s, 5H, C_5H_5), 4.47 (t, 2H, C_5H_4), 4.80 (t, 2H, C_5H_4), 5.61 (d, $J_{H,H}$ = 7.5 Hz, 1H, H1), 6.97 (d, $J_{H,H}$ = 10 Hz, 2H, H6), 7.09 (d, $J_{H,H}$ = 9 Hz, 2H, H3), 7.18 (d, $J_{H,H}$ = 9 Hz, 2H, H4), 7.31 (dd, $J_{H,H}(1)$ = 7.5 Hz, $J_{H,H}(2)$ = 12.5 Hz, 1H, H2), 8.13 (d, $J_{H,H}$ = 10 Hz, 2H, H5), 11.84 (d, $J_{H,H}$ = 12.5 Hz, 1H, NH). FT-IR (cm^{-1}): 2917 (ν, C–H), 2849 (ν, C–H), 1727 (ν, C=O), 1626 (ν, C=O), 1603 (ν, COC=C), 1514 (ν, C=C aryl), 1509 (ν, C=C aryl), 1490 (ν, C=C aryl), 1257, 1201, 1164, 1082, 1072, 1030, 1008, 824, 790, 757, 524, 509, 489. *Anal.* Calc. for $C_{42}H_{53}FeNO_4$: C, 72.93; H, 7.72; N, 2.02. Found: C, 72.85; H, 7.69; N, 1.98%.

2.1.4. Bis-{1-ferrocenyl-1-{[4-(4-dodecyloxybenzoyloxy) phenyl]amino}propen-2-onato} copper(II) (**4a**)

The ligand **3a** (104.3 mg, 0.1641 mmol) and $Cu(OAc)_2{\cdot}H_2O$ (17.1 mg, 0.0856 mmol) were dissolved separately in hot ethanol. The solutions were mixed and refluxed for 15 min. A brown precipitate was formed after cooling, which was centrifuged and washed 3 times with ethanol using the centrifugation method. Yield 90.0 mg (82%). FT-IR (cm^{-1}): 2924 (C–H), 2850 (C–H), 1735 (C=O), 1597 (C=N), 1567 (C=C), 1515 (C=C aryl), 1508 (C=C aryl), 1489 (C=C aryl), 1424, 1338, 1333, 1247, 1201, 1199, 1161, 1070, 1014, 1009, 849, 815, 771, 578, 564, 549, 523, 490. *Anal.* Calc. for $C_{76}H_{88}CuFe_2N_2O_8$: C, 68.49; H, 6.65,; N, 2.10. Found: C, 68.59; H, 6.58; N 2.26%.

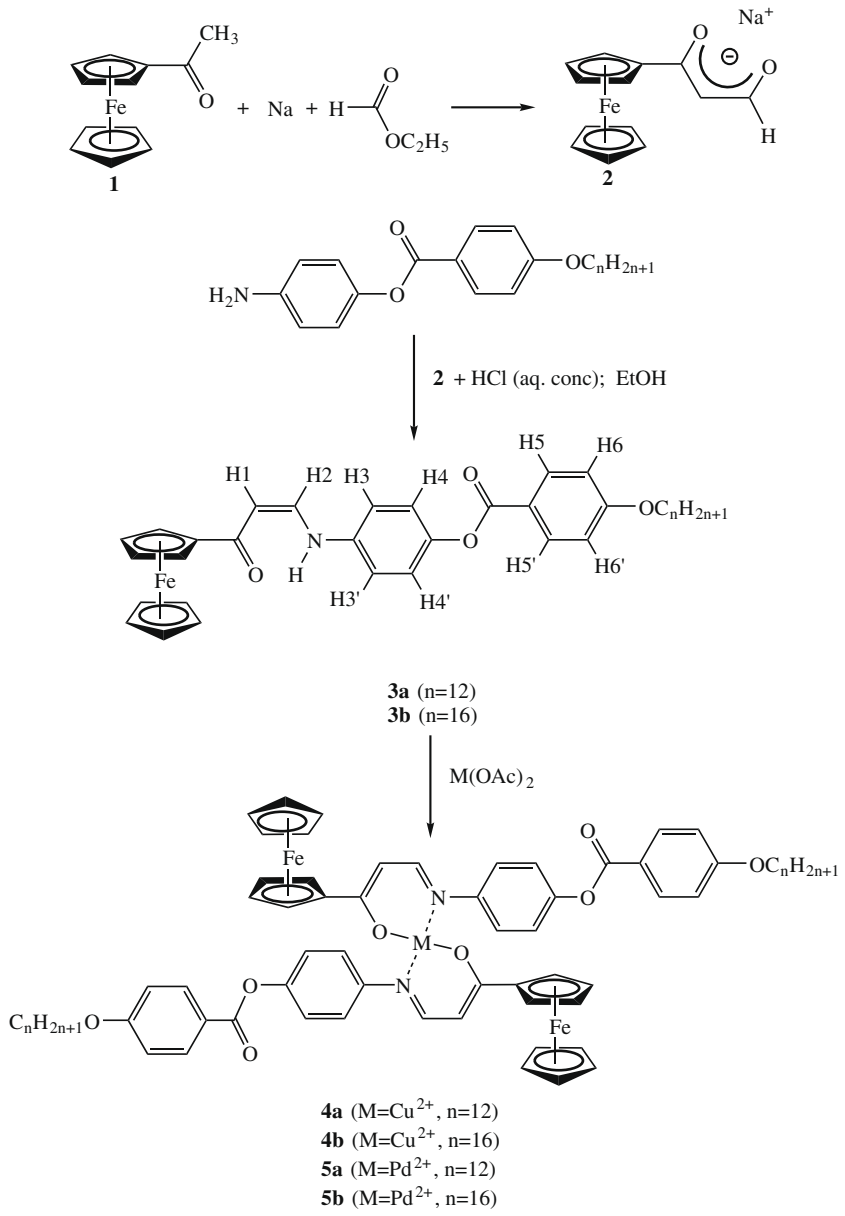
2.1.5. Bis-{1-ferrocenyl-1-{[4-(4-hexadecyloxybenzoyloxy) phenyl]amino}propen-2-onato} copper(II) (**4b**)

This complex was synthesized in an analogous manner to the previous reaction. Yield 97.0 mg (87%). FT-IR (cm^{-1}): 2923 (C–H), 2848 (C–H), 1734 (C=O), 1599 (C=N), 1568 (C=C), 1513 (C=C aryl), 1509 (C=C aryl), 1490 (C=C aryl), 1425, 1337, 1331, 1250, 1201, 1198, 1160, 1072, 1014, 1009, 847, 811, 770, 579, 564, 550, 524, 489. *Anal.* Calc. for $C_{84}H_{104}CuFe_2N_2O_8$: C, 69.82; H, 7.25; N, 1.94. Found: C, 69.58; H, 7.19; N, 2.04%.

2.1.6. Bis-{1-ferrocenyl-1-{[4-(4-dodecyloxybenzoyloxy) phenyl]amino}propen-2-onato} palladium(II) (**5a**)

The ligand **3a** (98.8 mg, 0.154 mmol) was dissolved completely in freshly distilled 1,4-dioxane (2 mL) in a one-neck 25 mL round flask. $Pd(OAc)_2$ (20.4 mg, 0.091 mmol) was dissolved in 1,4-dioxane (1 mL) in a separate flask. The prepared solutions were mixed and refluxed for 15 min. The product was precipitated by adding ethanol (~4 mL). The precipitate was filtered off and recrystallized from hot ethanol. Yield 48.2 mg (45.5%), brown powder. ^{1}H NMR (250 MHz): δ 0.89 (t, 3H, CH_3), 1.28 (br. s, 16H, CH_2), 1.50 (m, 2H, $OCH_2CH_2CH_2$), 1.83 (quintet, 2H, OCH_2CH_2), 3.96 (m, 2H, C_5H_4), 4.07 (s overlapped with t, 7H, OCH_2 and C_5H_5), 4.23 (t, 2H, C_5H_4), 5.31 (d, $J_{H,H}$ = 7.5 Hz, 1H, H1), 6.91 (d, $J_{H,H}$ = 7.5 Hz, 1H, H2), 7.01 (d, $J_{H,H}$ = 9 Hz, 2H, H6), 7.25 (d overlapped with $CDCl_3$, 2H, H3), 7.44 (d, $J_{H,H}$ = 8 Hz, 2H, H4), 8.20 (d, $J_{H,H}$ = 9 Hz, 2H, H5). FT-IR (cm^{-1}): 2920 (C–H), 2850 (C–H), 1731 (C=O), 1605 (C=N), 1575 (C=C), 1506 (C=C aryl), 1500 (C=C aryl), 1411, 1350, 1251, 1191, 1165, 1074, 1014, 1010, 845, 811, 759, 564, 560, 500, 490. *Anal.* Calc. for $C_{76}H_{88}Fe_2N_2O_8Pd$: C, 66.36; H, 6.45; N, 2.04. Found: C, 65.70; H, 6.43; N, 2.26%.

2.1.7. Bis-{1-ferrocenyl-1-{[4-(4-hexadecyloxybenzoyloxy) phenyl]amino}propen-2-onato} palladium(II) (**5b**)



This complex was synthesized in an analogous manner to the previous reaction. Yield 44.0 mg (37%). ^{1}H NMR (250 MHz): δ 0.88 (t, 3H, CH_3), 1.27 (br. s, 24H, CH_2), 1.50 (m, 2H, $OCH_2CH_2CH_2$), 1.84 (quintet, 2H, OCH_2CH_2), 3.96 (m, 2H, C_5H_4), 4.07 (s overlapped with t, 7H, OCH_2 and C_5H_5), 4.23 (t, 2H, C_5H_4), 5.31 (d, $J_{H,H}$ = 7.5 Hz, 1H, H1), 6.91 (d, $J_{H,H}$ = 7.5 Hz, 1H, H2), 7.01 (d, $J_{H,H}$ = 9 Hz, 2H, H6), 7.25 (d overlapped with $CDCl_3$, 2H, H3), 7.44 (d, $J_{H,H}$ = 8 Hz, 2H, H4), 8.19 (d, $J_{H,H}$ = 9 Hz, 2H, H5). FT-IR (cm^{-1}): 2924 (C–H), 2849 (C–H), 1732 (C=O), 1604 (C=N), 1576 (C=C), 1504 (C=C aryl), 1502 (C=C aryl), 1410, 1350, 1250, 1192, 1164, 1074, 1013, 1011, 847, 810, 760, 563, 561, 503, 489. *Anal.* Calc. for $C_{84}H_{104}Fe_2N_2O_8Pd$: C, 67.81; H, 7.05; N, 1.88. Found: C, 67.99; H, 7.01; N, 1.96%.

3. Results and discussion

3.1. Synthesis and characterization

The syntheses of the compounds reported in this paper were performed according to Scheme 1. Acetyl ferrocene **1** can be prepared using a Friedel-Crafts acylation procedure, as was established in the early classical works on ferrocene [55–58]. The addition of $AlCl_3$ catalyst in small portions to equimolar amounts of ferrocene and acetyl chloride allowed the yield of the monoacylated product to increase to over 70%. Compound **1** was separated by column chromatography on Al_2O_3 from the mixture of products.

The crossed Claisen condensation of the acetyl ferrocene **1** with ethyl formate gave the sodium salt of the appropriate ketoalde-

Scheme 1. Syntheses of ligands **3a–b** and heteronuclear complexes **4a–b** and **5a–b**.

hyde **2**. The reaction of compound **2** with *p*-alkoxybenzoyloxy aniline in ethanol in the presence of an equimolar amount of concentrated HCl (aq) led to the β-aminovinyl ketones **3a–b**. The copper(II) complexes **4a–b** and palladium(II) complexes **5a–b** were obtained by treatment of **3a–b** with the corresponding acetate salts in ethanol and 1,4-dioxane, respectively.

The chemical compositions of the synthesized compounds are in good agreement with the data of elemental analyses. The FT-IR spectra of **3a–b** are distinguished by characteristic stretching bands of the ester carbonyl near 1726 cm^{-1}, and ketone carbonyl at 1627 cm^{-1}. In addition, the C=C bond stretching of the ethenyl group is exposed near 1603 cm^{-1}. There is a group of absorption peaks in the area 1480–1515 cm^{-1} which are connected with the deformations of the aromatic rings. Metal-ring vibrations of the ferrocene moiety are displayed in the long-wave area, at 485–525 cm^{-1}. The C=O stretches of the ester group are shifted in the complexes **4a–b** and **5a–b** to a higher frequency region by 8 and 4 cm^{-1}, respectively. The valence vibration of the ketone carbonyl near 1627 cm^{-1} disappears upon complex formation and additional peaks connected with the C=N and C=C bonds in the region 1570–1600 cm^{-1} are generated. In addition vibration modes of the M–O and M–N bonds in the area 560–600 cm^{-1} are displayed in the IR spectra of the metallochelates. Thus, considerable changes occur in the infrared spectra of **4a–b** and **5a–b** in comparison with the free ligands **3a–b**, undoubtedly indicating the successful complex formation.

The UV–Vis spectra of the ligands **3a–b** are represented by three absorption bands (see Table 1). The first band with a maxima near 260 nm is associated with π–π^* electronic transitions of the aromatics rings. The next band is related to the carbonyl chromophore, which is shifted bathochromically to 366 nm due to the conjugational effect of the adjacent ethenyl and cyclopentadienyl groups [59]. The less intensive band at ~465 nm belongs to d–d type transitions of the electrons of the iron atoms [60–62].

An additional shoulder appears near 292–298 nm upon complex formation, which is connected to a ligand-to-metal charge transfer transition in the case of the copper(II) complexes **4a–b** [63], and a metal-to-ligand charge transfer transition in the case

Table 1
UV–Vis spectral data for **3a–b**, **4a–b** and **5a–b**.

Compound	Absorption max, nm (log ε, L × cm^{-1} × mol^{-1})			
	I band	II band (shoulder)	III band	IV band
3a	260 (4.40)		366 (4.36)	465 (3.43)
4a	263 (4.94)	278 (4.39)	383 (4.47)	454 (3.82)
5a	259 (4.75)	295 (4.45)	374 (4.60)	462 (4.08)
3b	260 (4.50)		367 (4.51)	466 (3.50)
4b	262 (4.64)	290 (4.36)	382 (4.47)	450 (3.77)
5b	263 (4.74)	298 (4.25)	388 (4.28)	457 (3.68)

of the palladium(II) complexes **5a–b** [64]. It is noteworthy, that in the metal complexes an absorption band associated with the carbonyl group is bathochromically shifted in comparison with the free ligand. The shift can be explained by the added electronic conjugational effect due to involving this group into the metallochelate cycle. The ferrocenyl group in the complexes **4a–b** and **5a–b** reveals d–d electronic transitions in the same area, 465 nm, as the free ligands **3a–b**.

The ligands **3a–b** and complexes **5a–b** are also characterized by ^{1}H NMR. It is interesting to note that the proton signals of the

substituted cyclopentadiene ring of the ferrocene moiety in **5a–b** are high-field shifted by 0.6 ppm in relation to comparable signals in the free ligands **3a–b**. Such a significant shift is due to the fact that the ferrocene unit in these complexes is situated very close to the central chelate core, and there is a considerable electron-donor effect from the Pd(II) ion on it. As for the protons of the ethenyl link, a similar high-field shift is also observed, though the effect is weaker in this case.

3.2. Mesomorphism

Liquid crystal properties of the new synthesized metallomesogens have been investigated by thermal polarizing optical microscopy (POM) and differential scanning calorimetry (DSC). The obtained data on the thermal behaviour of the ligands **3a–b** and two series of heteronuclear complexes **4a–b** and **5a–b** are presented in Table 2.

In the first heating cycle of the DSC measurements, crystal-to-crystal phase transition peaks were observed for the ligands **3a–b** (Fig. 1), although it was small in the case of $n = 12$. In the cooling course, there are several broad responses in the DSC thermogram of **3a** and two sharp peaks in a case of **3b**. During the second heating cycle exothermic peaks appeared in both cases between the first crystal-to-crystal and crystal-to-isotropic liquid phase transitions. This can be explained by partial vitrification of the samples in the first cooling cycle, accomplishing a low energy crystal packing at higher temperatures when increased mobility of molecules allows it to be completed. Enthalpy values of the first DSC peaks after cooling from the isotropic liquid state are relatively high in both **3a** and **3b**. Presumably, these peaks are the result of the transition from the isotropic liquid to a highly disordered soft crystal phase. Two other smaller peaks in the cooling cycle can be assigned to crystal polymorphic phase transitions. A series of microphotographs in Fig. 2 illustrates the development of spherical domains on cooling from the isotropic liquid state in a sample of **3a** under a polarizing microscope. The spherical shape of the domains reveals a possible organization into supramolecular assemblies. The last assumption is founded on the presence of C=O and polar NH groups in **3a–b**, which are capable of forming intermolecular hydrogen bonds. Upon further cooling these spherical formations are transformed into big spherulitic crystals, similar to those observed frequently during crystallization from smectic mesophases. Exactly the same textures were observed under a polarizing microscope in the case of **3b**.

Two DSC peaks corresponding to the crystal-to-crystal and crystal-to-isotropic liquid transitions were observed in the first heating cycle of **4a**, and only one peak from the isotropic liquid phase transition was observed in the case of **4b** (Fig. 3). In the cooling cycle any phase transition peaks were not resolved. The main information about the phase transition behaviour of **4a–b** in the cooling path was obtained from POM observations. Typical optical textures developed from the isotropic liquid state of **4a–b** under a polarizing microscope are presented in Fig. 4. Most likely the observed star-like and flower-like formations are associated with a disordered soft crystal phase. Samples in this state had limited flowability when subjected to stress.

Similar DSC thermograms were obtained for **5a–b** in the heating cycle: two peaks corresponding to the crystal-to-crystal and crystal-to-isotropic liquid transitions in the case of **5a**, and only one peak due to an isotropic liquid transition in the case of **5b**

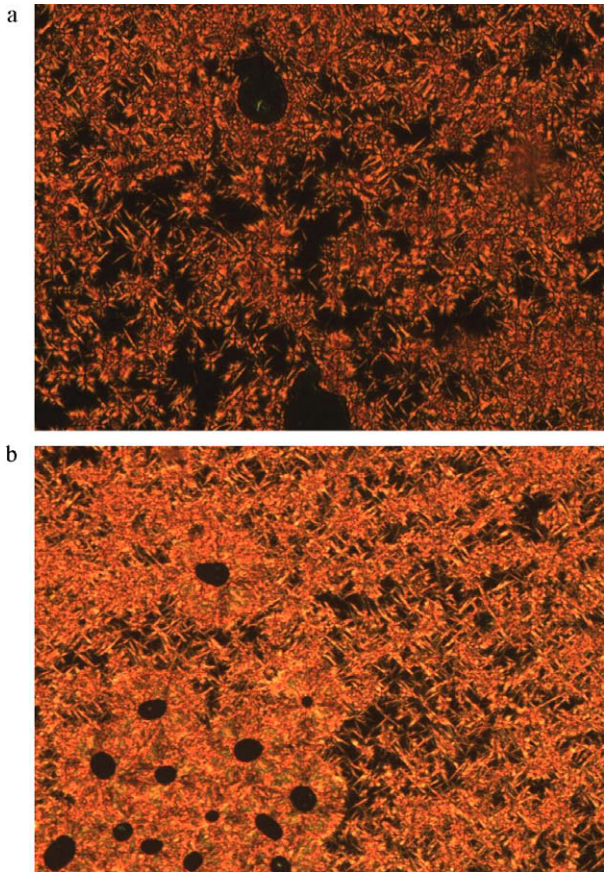

Fig. 4. Emergence of star-like and flower-like domains from the isotropic liquid state in: (a) **4a** and (b) **4b**.

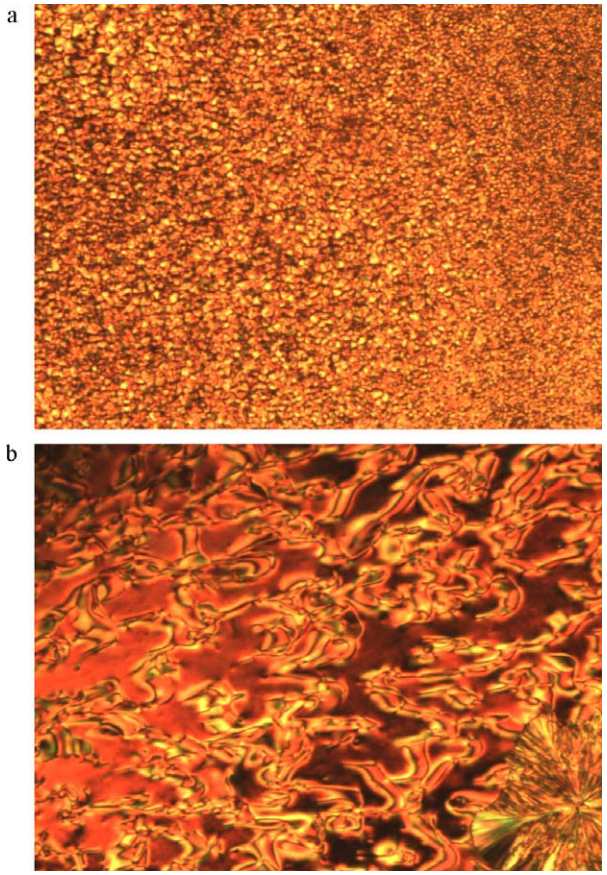

Fig. 5. Optical textures of **5a** under a polarizing microscope: (a) sand-like optical texture and (b) schlieren texture of smectic C.

(Fig. 3). DSC peaks were not revealed on cooling. Monotropic smectic C mesophases were identified for both Pd(II) complexes **5a** and **5b** by polarizing optical microscopy. The typical sand-like and schlieren textures of smectic C were observed upon cooling from the isotropic liquid state (Fig. 5).

Thus, in comparison with the earlier synthesized heteronuclear mesogens with ferrocene- [17] and ferrocenophane-containing [21] β-aminovinylketones, the present compounds exhibited rather poor mesomorphism. In fact the bulky ferrocene moieties in the latter case pile up the central rigid core of a mesogenic molecule rather than being considered as terminal substituents. As a consequence, the geometrical anisotropy of the present complexes is smaller and less favourable for exhibiting liquid crystal properties.

4. Conclusions

Novel ferrocene-containing β-aminovinylketone derivatives containing terminal alkyl chains with 12 and 16 carbon atoms have been synthesized and fully characterized by elemental analyses, ^{1}H NMR, FT-IR and UV–Vis spectroscopies. The synthesized ligands exhibited disordered soft crystal phases. New heteropolynuclear metallomesogen systems were generated from these ligands by incorporating Cu(II) and Pd(II) ions into the enaminoketone chelating site. The synthesized heteronuclear complexes of copper(II), like the free ligands, showed a soft crystal phase. The Pd(II) complexes exhibited a monotropic smectic C mesophase.

some studies on cyanide-bridged metal complexes and particularly on mixed-valence Cu^{II}/Cu^{I} compounds showed non-negligible exchange interactions between second nearest-neighbor paramagnetic metal ions [15]. We report here the syntheses, structures and magnetic properties of two novel mixed-valence Cu^{II}/Cu^{I} complexes $[Cu^{II}(bpy)Cu^{I}(CN)_3]_n$, (**1**) (bpy = 2,2′-bipyridine) and $\{[Cu^{II}(tn)_2][Cu^{I}_4(CN)_6]\}_n$ (**2**) (tn = 1,3-diaminopropane). The ultimately aim of this work is to assess the effect of the rigidity and volume of the ancillary ligands on the architectures of the Cu^{II}/Cu^{I} mixed-valence polymeric systems, as well as to determine and explain the magnitude of the magnetic coupling through the Cu^{II}–NC–Cu^{I}–CN–Cu^{II} exchange pathway in **1**.

2. Results and discussion

2.1. Syntheses and general characterization

Both compounds (**1** and **2**) were prepared under aerobic conditions, by diffusion through silica gel [16] in a U-tube of aqueous solutions of $K_4[Mo(CN)_8]$ [17] (**1**) or $K_3[Cr(CN)_5(NO)] \cdot H_2O$ [18] (**2**). The opposite positions of the U-tubes were filled by a mixture of a methanolic solution of 2,2′-bipyridyl and $CuCl_2 \cdot 2H_2O$ with an aqueous solution of sodium adipate for **1**, and by an aqueous solution of $CuCl_2 \cdot 2H_2O$ and 1,3-diaminopropane for **2**. Crystal structures determinations of both compounds showed that some of the starting materials ($[Mo(CN)_8]^{4-}$ and $[Cr(CN)_5(NO)]^{3-}$ anions) were not present in the final products and that each asymmetric unit contains a Cu^{I} ion and cyanide anions which were not included as starting materials. This fact indicates that these cyanide metal complexes are acting as source of cyanide anions, as already observed in parent compounds involving copper (II) metal complexes and hexacyanometallate anions [19]. Besides their crucial role as constituent ions in both compounds, these cyanide anions also act as reducing agents for the reduction of a fraction of the aqueous Cu^{II} ions into Cu^{I}, presumably with formation of cyanogen or cyanate as previously reported for other cases [20]. All attempts to obtain compound **1** by direct combination, using aqueous solution of NaCN instead of the cyanometallate complexes, failed. In contrast, when NaCN and $[Cu(tn)_2]^{2+}$ ions were used as starting materials (tn = 1,3-propanediamine), compound **2** was obtained as a mixture with a second phase, of formula $[Cu(tn)_2][Cu_2(CN)_4]$, analogue to the previously reported complexes $[Cu(en)_2(H_2O)][Cu_2(CN)_4]$ [14e] and $[Cu(pn)_2(H_2O)][Cu_2(CN)_4]$ [13d] (pn = 1,2-propanediamine), which exhibit a single diamond-like mixed-valence network. The infrared spectra of **1** and **2** exhibit the bands expected for compounds built with $[Cu(bpy)]^{2+}$ (for **1**), $[Cu(tn)_2]^{2+}$ (for **2**) and CN units (in both compounds). The presence of the CN ligands is clearly indicated by strong absorption bands assignable to ν_{CN} stretching vibrations in the 2080–2187 cm^{-1} range. Previous studies have shown that the positions and number of these absorption bands in compounds involving cyanide bridges can be used as a diagnostic tool for identifying the oxidation state and the coordination of the metal ion, as well as for detecting the presence of cyanide bridges [19,21]. Free CN ion is typically characterized by an absorption band at *ca.* 2080 cm^{-1} [22]; its coordination to on or more metal ions results in an increase for these wave numbers and increase of the metal coordination number can result in a decrease in the ν(CN) band by about 20–40 cm^{-1} [21]. For compound **1**, the three absorption bands observed at 2187, 2114 and 2080 cm^{-1} are in agreement with the presence in **1** of μ_2- and μ_3-cyanide bridges. In contrast, for compound **2**, only one absorption band is observed at 2110 cm^{-1}. It is also well known that IR spectroscopy can be used as a diagnostic tool for identifying the coordination mode of the bpy ligand [23]; chelate coordination mode usually splits the strong γ(CH) absorption observed as an intense and sharp band at 757 cm^{-1} in the free bpy in an asymmetric doublet. The presence of such doublet on the spectrum (764(s) and 729(m) cm^{-1}) clearly indicates that the bpy ligands present their usual chelating coordination mode. Finally, the 1,3-diaminopropane ligand is easily characterized by the presence on the IR spectrum of bands due to ν_{NH} stretching vibrations of the NH_2 groups at 3302 and 3245 cm^{-1} and to the ν_{CH} stretching vibrations of the CH_2 groups around 2900 cm^{-1} [19,24].

2.2. Crystal structures of **1** and **2**

Both compounds **1** and **2** crystallize in the monoclinic space group $P2_1/n$. ORTEP plots and perspective views are shown in Figs. 1–5; selected inter-atomic distances and angles for compounds **1** and **2**, and pertinent crystal data are listed in Tables 1–3, respectively.

*$[Cu^{II}(bpy)Cu^{I}(CN)_3]_n$ (**1**):* The asymmetric unit of compound **1** consists of two Cu atoms, one bpy unit and three CN ions, all in general positions (Fig. 1, Table 1). The two non-equivalent copper ions strongly differ in their environments. Thus, the Cu1 ion, presumably a Cu^{I} centre, presents a CuC_4 coordination involving four carbon atoms from four cyano ligands; the environment is pseudo-tetrahedral as clearly shown by the respective C–Cu–C angles (in the range 102.3–118.3°, with an average value of 109.5°). The C1 carbon atom acts as an almost symmetrical bridge towards two Cu1 ions with Cu1–C1 bond distances of 2.160(9) and

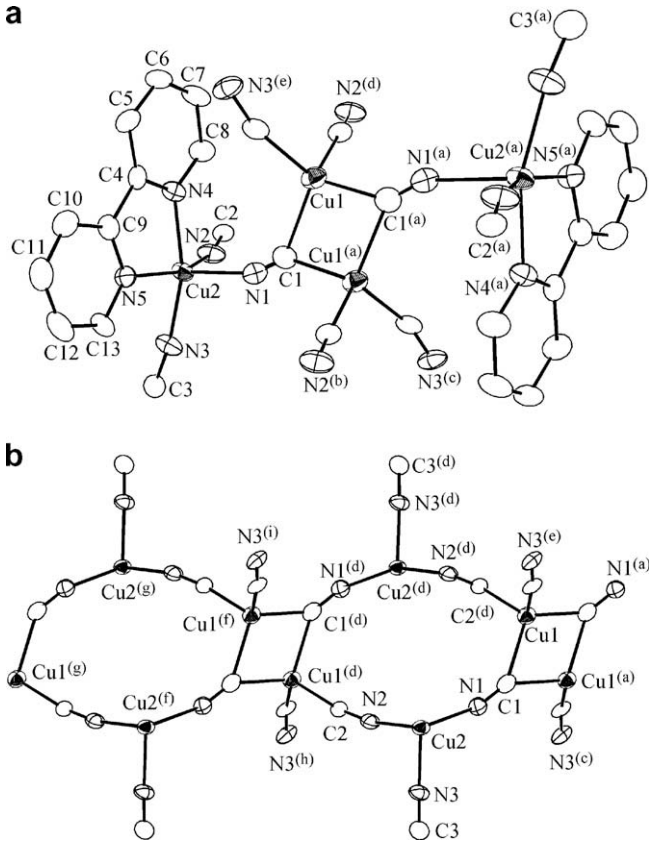

Fig. 1. ORTEP views of compound **1** showing: (a) the atom labelling scheme and the Cu^{I} and Cu^{II} environments and (b) the μ_2- and the μ_3-cyanide bridges (the bpy ligands are omitted for the sake of clarity). The shortest Cu···Cu distances (Å) are: $Cu1\cdots Cu1^{(a)}$ = 2.536(1), Cu1···Cu2 = 4.863(1), $Cu1\cdots Cu2^{(e)}$ = 4.963(1) and $Cu1\cdots Cu2^{(d)}$ = 5.012(1). Symmetry transformations used to generate equivalent atoms: (a) $-x,-y,-z$; (b) $-1+x,y,z$; (c) $-1/2+x,1/2-y,-1/2+z$; (d) $1-x,-y,-z$; (e) $1/2-x,-1/2+y,1/2-z$; (f) $1+x,y,z$; (g) $2-x,-y,-z$; (h) $1/2+x,1/2-y,-1/2+z$; (i) $3/2-x,-1/2+y,1/2-z$.

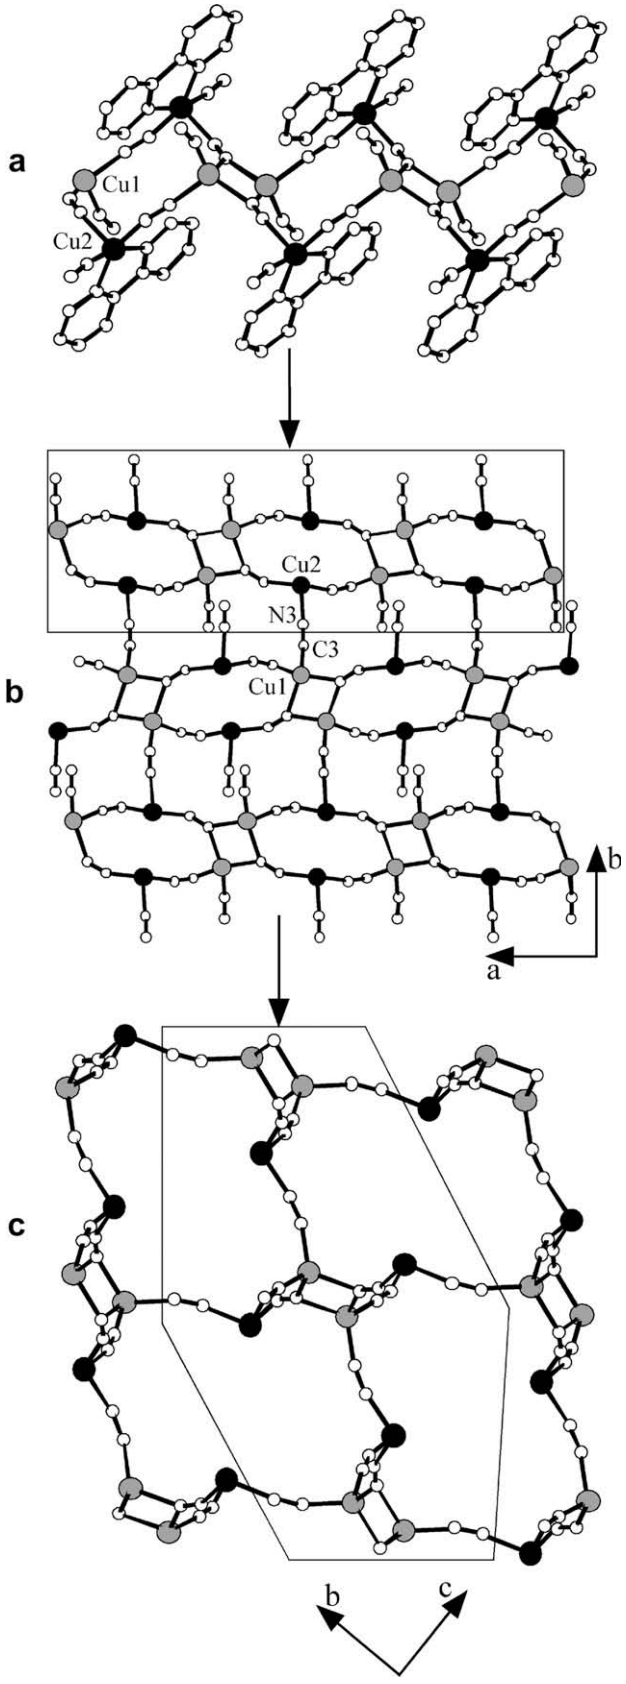

Fig. 2. (a) Schematic view of **1** showing the simplest way to describe the sophisticated three-dimensional structure: 1-D motifs (a) bridged through N3–C3 generates the 2-D units (b) which are connected each other through the N3–C3 bridges to lead to the 3-D structure of **1** (c) Cu1···Cu2 distance through the C3N3 bridges: 4.962 Å. The bpy ligands are omitted for the sake of clarity.

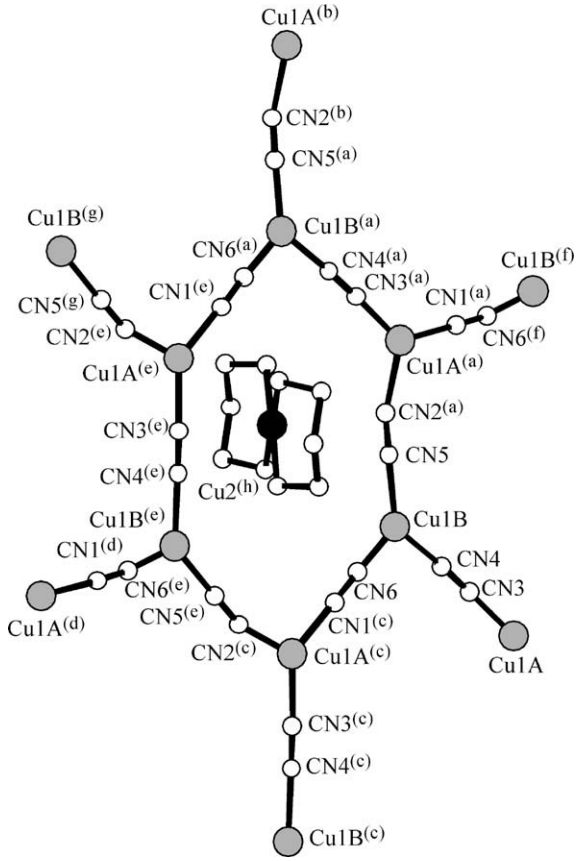

Fig. 3. Perspective view of compound **2** showing the atom labelling scheme and the Cu_6 metallacycles. The shortest Cu···Cu distances (Å) are: Cu^{I}–CN–Cu^{I}: $Cu1A^{(c)}$···Cu1B = 5.008(1), Cu1B···$Cu1A^{(a)}$ = 4.959(1) and $Cu1A^{(a)}$···$Cu1B^{(a)}$ = 4.997(1); Cu^{II}···Cu^{I}: $Cu2^{(h)}$···$Cu1A^{(c)}$ = 6.222(1), $Cu2^{(h)}$···Cu1B = 4.396(1), $Cu2^{(h)}$···$Cu1A^{(a)}$ = 4.133(1), $Cu2^{(h)}$···$Cu1B^{(a)}$ = 5.492(1), $Cu2^{(h)}$···$Cu1A^{(e)}$ = 5.322(1) and $Cu2^{(h)}$···$Cu1B^{(e)}$ = 5.633(1). Symmetry transformations used to generate equivalent atoms: (a) $x, 1+y, z$; (b) $x, 2+y, z$; (c) $1/2+x, -1/2-y, 1/2+z$; (d) $1+x, 1+y, 1+z$; (e) $1/2+x, 1/2-y, 1/2+z$; (f) $-1/2+x, 1/2-y, -1/2+z$; (g) $1/2+x, 3/2-y, 1/2+z$.

2.121(10) Å. These distances are significantly longer than the other two Cu1–C ones (1.951(9) and 1.965(10) Å). The Cu2 ion, presumably a Cu^{II} centre, has a CuN_5 coordination environment involving two nitrogen atoms from a bidentate bpy ligand and three nitrogen atoms from three non-equivalent CN ligands. The metal ion is located in an almost perfect square-pyramidal geometry as indicated by the low value of the trigonality Addison index, τ, of 0.10 [$\tau = (\beta - \alpha)/60$, where α and β are the two greatest basal plane angles ($\beta \geqslant \alpha$) when the polyhedron is viewed as a square-pyramid; for a perfectly square-pyramidal geometry τ is equal to zero and it becomes unity for a perfectly trigonal bipyramidal geometry [25]. For Cu2 α = N2–Cu2–N5 = 158.4(2)° and β = N3–Cu2–N4 = 164.3(2)°]. This slightly distorted square-pyramidal geometry is in good agreement with the structural data which indicate that the four equatorial bond lengths are essentially equivalent (from 1.968(8) to 2.047(6) Å) with the two Cu–N_{bpy} bond lengths only *ca.* 0.02 Å longer than the two basal Cu–NC ones; the Cu2–N1 apical bond length is significantly longer (2.170(8) Å). The three cyano ligands differ in their coordination modes. The C2N2 and C3N3 groups have μ_2 coordination modes with the carbon and nitrogen atoms bonded to Cu1 and Cu2, respectively (Cu1–C and N–Cu2 *ca.* 1.96 and 1.97 Å, respectively). The C1N1 cyano group acts with a μ_3 coordination mode; this ligand, which bridges two Cu1 and one Cu2 ions, involves Cu–C and Cu–N bond lengths longer than those given above (*ca.* 2.14 and 2.17 Å, respectively). These coordination modes lead to the 3-D structure shown in Fig. 2. The sim-

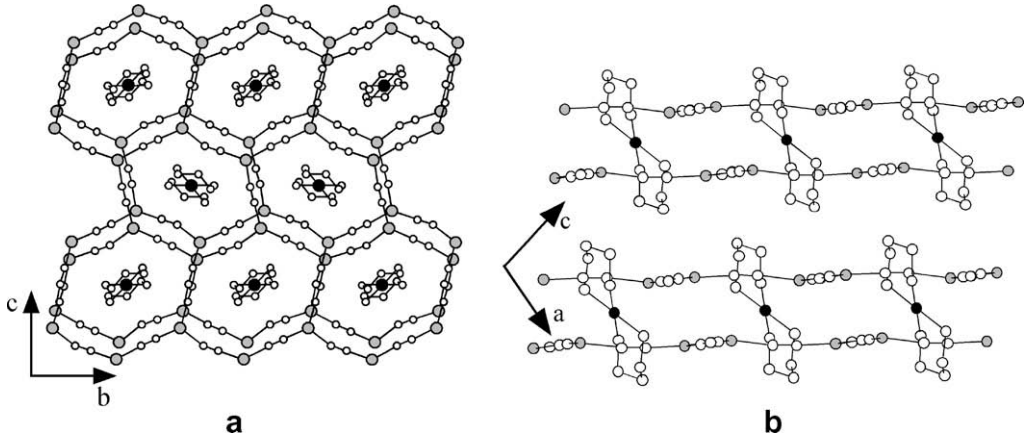

Fig. 4. Extended structure of **2**: (a) 2-D sheets showing the hexagonal infinite cavities and (b) projection of the overall structure in the *ac* plane.

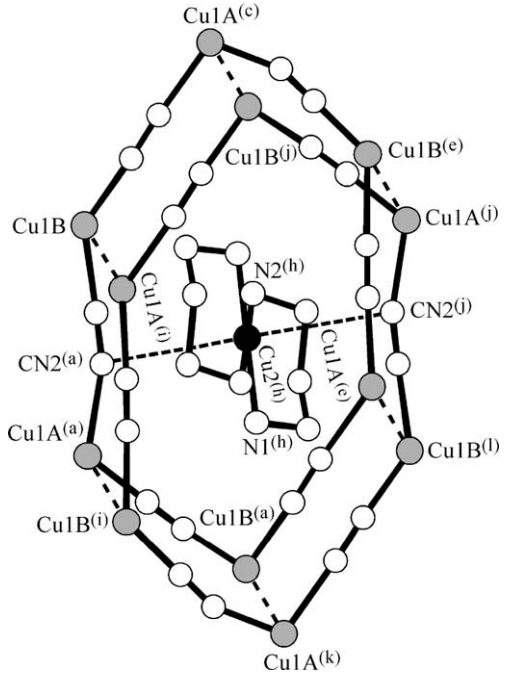

Fig. 5. Compound **2**: perspective view of two adjacent Cu_6 metallacycles showing the tn ligand and the elongated octahedral environment of the Cu2 metal ion as two steric constrains in the molecular arrangement depicted in Fig. 4. Shortest Cu···Cu inter-metallacycle distance: 3.382(1) Å; Cu2(h)···CN2$^{(a)}$ (CN2$^{(j)}$) 3.107(1) Å. Symmetry transformations used to generate equivalent atoms: (a) $x,-1+y,z$; (c) $1/2+x,-1/2-y,1/2+z$; (e) $1/2+x,1/2-y,1/2+z$; (h) $2-x,-y,1-z$; (i) $3/2-x,1/2+y,3/2-z$; (j) $2-x,-y,2-z$; (k) $3/2-x,3/2+y,3/2-z$; (l) $2-x,1-y,2-z$.

Symmetry transformations used to generate equivalent atoms: (a) $x,1+y,z$; (c) $1/2+x,-1/2-y,1/2+z$; (f) $-1/2+x,1/2-y,-1/2+z$.

plest way to describe this complicated 3-D molecular arrangement is to consider as initial building block the infinite chains formed by alternating 12-membered and four-membered cycles (Figs. 1b and 2a). The first cycle, involving four Cu ions (two Cu1 and two Cu2), is a tetranuclear mixed-valence cycle alternating Cu^{I} and Cu^{II} ions which are bridged by end-on cyanide anions, with a shortest Cu···Cu distance of 4.863(1) Å; the second cycle, involving only two Cu1 ions, is generated by the two Cu^{I} ions bridged by the C1 atoms of the μ_3-cyanide anions, the short Cu···Cu distance of 2.536(2) Å is considered nonbonding but shorter than the sum of van der Waals radii for copper (2.8 Å) [26], suggesting significant Cu–Cu interactions. These mixed-valence copper chains are bridged each other through the C3N3 cyano ligand to generate 2-D layers (Fig. 2b) in which the shortest interchain Cu–NC–Cu distance is 4.963(1) Å. The union of adjacent layers by additional C3N3 cyano ligands generates the 3-D structure depicted in Fig. 2c.

*$\{[Cu^{II}(tn)_2][Cu^{I}_4(CN)_6]\}_n$ (**2**):* The asymmetric unit of compound **2** consists of three crystallographically different Cu ions (Cu1A, Cu1B and Cu2) one tn unit and three CN anions (Fig. 3, Table 2); except the Cu2 atom, which lies on an inversion centre in the $[Cu(tn)_2]^{2+}$ units, all these elements are located on general positions. Since there are four Cu^{I} and one Cu^{II} atoms per formula unit, the Cu2

[a] For compound **2**, the asymmetric unit contains 0.5 of the empirical formula.
[b] $R_1 = \sum|F_o - F_c|/F_o$.
[c] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.
[d] Goodness-of-fit = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(N_{obs} - N_{var})\}^{1/2}$.

atoms must be Cu^{II} whereas Cu1A and Cu1B must be Cu^{I} since the asymmetric unit contains two Cu1A, two Cu1B and one Cu2 per formula unit. Nevertheless, the disorder affecting the CN groups (see Section 3) precludes an unambiguous assignment of the oxidation state. The non-equivalent copper ions strongly differ in their environments. Thus, the Cu2 atom presents a centrosymmetric CuN_4 coordination environment involving four nitrogen atoms from two bidentate tn ligands with an almost perfect square planar geometry; while the Cu1A and Cu1B atoms are coordinated to three cyano groups acting as bridging ligands (Fig. 3). The coordination modes of the cyano ligands generate eighteen-membered cycles having six metallic centres (Figs. 3 and 4); the Cu_6 core is a pseudo hexagon with Cu···Cu distances of *ca.* 5.0 Å. Each hexametallacycle forms a cavity in which the $[Cu(tn)_2]^{2+}$ unit is located; the shortest Cu2–Cu1 distance is 4.133(1) Å. The Cu1 atoms lead to essentially planar metallocycles that are connected to their six neighbors to generate hexagonal graphite-like 2-D sheets (Fig. 4); these sheets stack in an eclipsed way forming hexagonal channels as shown in Fig. 4a. These hexagonal sheets are similar to those found in $K[Cu_2(CN)_3]\cdot H_2O$ [27]; the difference is that in $K[Cu_2(CN)_3]\cdot H_2O$ the large hexagonal holes are filled by isolated potassium ions and water molecules, whereas in **2**, the hexagonal channels are filled with planar $[Cu(tn)_2]^{2+}$ units that point their two axial vacant positions towards two CN atoms ($CN2^{(a)}$ and $CN2^{(j)}$ at a distance of 3.107(1) Å) of two adjacent eclipsed hexagonal sheets. The presence of these $[Cu(tn)_2]^{2+}$ units confers electroneutrality to the layers and keeps them at a close distance, with a relatively short inter-planar Cu1···Cu1 distance of 3.382(1) Å, as shown in Fig. 5. Such interaction between the $[Cu(tn)_2]^{2+}$ units and the hexagonal layers suggests that the geometry and size of the cation may play a crucial role in determining the interlayer spacing, the metallacycle topology, the channel dimensions, and therefore, the overall structure of the copper cyanide networks.

2.3. Magnetic properties

The thermal variation of the product of the molar magnetic susceptibility times the temperature ($\chi_m T$) for compound **1** shows at room temperature a value of *ca.* 0.39 emu K mol^{-1} per formula unit, that remains constant when the temperature is decreased down to *ca.* 25 K (Fig. 6). Below *ca.* 25 K the $\chi_m T$ product gradually increases to reach a value of *ca.* 0.44 emu K mol^{-1} at 2 K. The room temperature value confirms the presence of one paramagnetic Cu^{II} ion per formula unit (the spin only value is 0.375 emu K mol^{-1}). Nevertheless, from the structure of compound **1**, it should be expected the absence of any significant magnetic interaction since all the Cu^{II} ions (Cu2) are only connected by long –NC–Cu^{I}–CN– bridges (Figs. 1 and 2). The presence of a weak, although noticeable ferromagnetic interaction in compound **1** suggests that the "diamagnetic" –NC–Cu^{I}–CN– bridge is able to transmit such kind of magnetic interaction, as found in other similar "diamagnetic" –NC–Fe(II)–CN– bridges [28]. Note that this result resembles the coupling found in the Prussian blue derivatives with the "a priori" also "diamagnetic" –NC–Fe(II)–CN– bridges [29]. Since the structure of compound **1** shows the presence of several –NC–Cu^{I}–CN– bridges connecting the Cu^{II} ions in the three directions, we have tried to fit the magnetic properties of compound **1** with a simple Curie–Weiss law: $\chi_m = C/(T-\theta)$. This model reproduces very satisfactorily the magnetic properties of compound **1** with a Curie constant, $C = 0.3872(1)$ emu K mol^{-1}, corresponding to a g value of 2.0323(2) and with a weak and positive Weiss temperature, $\theta = 0.239(1)$ $K = 0.166(1)$ cm^{-1} that confirms the ferromagnetic character of the magnetic coupling (solid line in Fig. 6). Compound **2** also shows at room temperature a $\chi_m T$ value of *ca.* 0.39 emu K mol^{-1} that remains constant down to *ca.* 20 K (Fig. 6). Below *ca.* 20 K the $\chi_m T$ product smoothly decreases to reach a value of *ca.* 0.37 emu K mol^{-1} at 2 K. This tiny decrease suggests the presence of very weak, almost negligible, antiferromagnetic interactions. The structure of compound **2** shows that the Cu^{II} ions are quite well isolated except for the long Cu^{II}–(CN2)–Cu^{II} bridge (Fig. 5). This long monoatomic bridge (C/N) connects the Cu^{II} ions forming regular ···Cu^{II}–(C/N)–Cu^{II}··· chains where the magnetic coupling is expected to be almost negligible given the long bond distance (*ca.* 3.1 Å). Accordingly, we have fit the magnetic properties of compound **2** to a regular $S = 1/2$ antiferromagnetic chain with the model of Hatfield and co-workers [30]. This model reproduces very satisfactorily the magnetic properties of compound **2** with $g = 2.0297(1)$ and a very small intra-chain coupling constant $J = -0.11(1)$ K $= -0.075(1)$ cm^{-1} (solid line in Fig. 6), the Hamiltonian is written as $H = -JS_iS_{i+1}$.

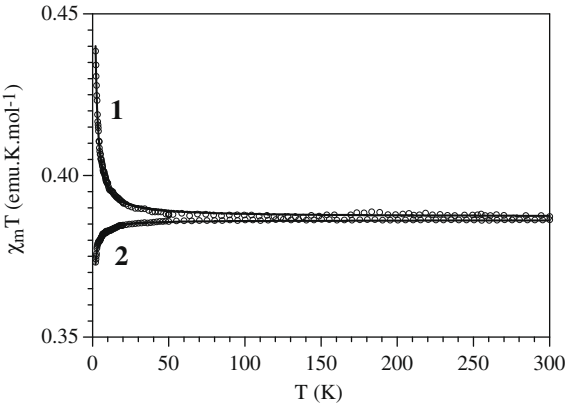

Fig. 6. Thermal variation of the $\chi_m T$ product for compounds **1** and **2**. Solid lines represent the best fit to models (see text).

The isothermal magnetizations at 2 K of the two compounds confirm the presence of very weak magnetic interactions in both compounds (Fig. 7). Thus, the magnetization of compounds **1** and **2** can be well reproduced with a Brillouin function for an $S = 1/2$ spin ground state with g values of 2.085(8) and 2.0262(2), respectively (solid lines in Fig. 7). As expected, the obtained g value is

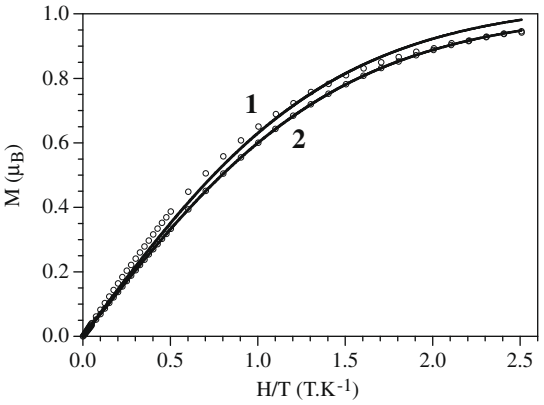

Fig. 7. Isothermal magnetization at 2 K of compounds **1** and **2**. Solid lines show the best fit to the Brillouin function.

slightly higher in compound **1** and the experimental points are above the curve fit at low fields, confirming the presence of a weak ferromagnetic interaction whereas in compound **2** the *g* value is very similar to that found in the fit of the thermal variation of the magnetic susceptibility, confirming the absence of any significant magnetic interaction. Although the magnetic properties of compound **2** could be easily anticipated given the well isolation of the Cu^{II} ions in the structure, those of compound **1** are more surprising. Compound **1** is expected to be paramagnetic since the Cu^{II} ions are connected through the "diamagnetic" –NC–Cu^{I}–CN– bridges. Nevertheless, as for previous Prussian blue and its derivatives containing diamagnetic –NC–Fe(II)–CN– bridges [28,29], such magnetic coupling (even ferromagnetic), can be explained thanks to the presence of some spin density in the Cu^{I} ions.

3. Experimental

3.1. Materials and physical techniques

The reagents 2,2′-bipyridine, 1,3-diaminopropane, copper(II) chloride dihydrate and sodium cyanide were used as received. Silica gel [16], $K_4[Mo(CN)_8] \cdot 2H_2O$ [17] and $K_3[Cr(CN)_5(NO)] \cdot H_2O$ [18] were prepared according to the reported procedures. Infrared spectra were recorded in the range 4000–200 cm^{-1} as KBr pellets on a FT-IR NEXUS NICOLET Spectrometer. Variable temperature susceptibility measurements were carried out in the temperature range 2–300 K with an applied magnetic field of 0.1 T on polycrystalline samples of both compounds with a Quantum Design MPMS-XL-5 SQUID magnetometer. The susceptibility data were corrected for the sample holders previously measured using the same conditions and for the diamagnetic contributions of the salt as deduced by using Pascal's constant tables ($\chi_{dia} = -184 \times 10^{-6}$ and -287.4×10^{-6} emu mol^{-1} for **1** and **2**, respectively). Elemental analyses were obtained from the Service Central d'Analyses (Vernaison).

3.2. Syntheses of compounds *1* and *2*

*$[Cu^{II}(bpy)Cu^{I}(CN)_3]_n$ (**1**):* Under aerobic conditions, a methanolic solution (10 mL) of 2,2′-bipyridine, $C_{10}H_8N_2$ (312 mg, 2.0 mmol) was added, with stirring at room temperature to a methanolic solution (5 mL) of $CuCl_2 \cdot 2H_2O$ (341 mg, 2.0 mmol). A pale green precipitate quickly appeared in the green solution; a 0.2 M aqueous solution of sodium adipate $Na_2O_2C(CH_2)_4CO_2$ was then slowly added with stirring until complete dissolution of the precipitate (*ca.* 10 mL). Silica gel was placed into a U-tube. Diffusion in opposite directions of an aqueous solution (15 mL) of $K_4[Mo(CN)_8]$ (2.048 g, 5.0 mmol) and the blue solution prepared above (15 mL) for two weeks led to dark brown prismatic single crystals of **1** suitable for X-ray structure analysis. For **1**: *Anal.* Calc. for $C_{13}H_8N_5Cu_2$: C, 43.2; H, 2.2; N, 19.4. Found: C, 43.0; H, 2.1; N, 19.7%. Selected IR data: ν/cm^{-1}: 3436sbr, 3081w, 2187m, 2114s, 2080s, 1608m, 1598s, 1575w, 1566w, 1470m, 1444s, 1311w, 1247w, 1172m, 1161m, 1104m, 1065m, 1028m, 1015w, 764s, 729m, 650w, 417w.

*$\{[Cu^{II}(tn)_2][Cu^{I}_4(CN)_6]\}_n$ (**2**):* Under aerobic conditions, 1,3-diaminopropane (2.0 mL, 23.7 mmol) was added with stirring at room temperature to an aqueous solution (30 mL) of $CuCl_2 \cdot 2H_2O$ (4.04 g, 23.7 mmol). A pale green precipitate quickly appeared in the green solution, a 1 M aqueous solution of NaOH was slowly added with stirring until complete dissolution of the precipitate (*ca.* 24 mL) leading to a dark blue solution. Silica gel was placed into a U-tube; diffusion in opposite directions of 15 mL of an aqueous solution of $K_3[Cr(CN)_5(NO)] \cdot H_2O$ (1.737 g, 5 mmol) and 15 mL of the dark blue solution prepared above for four weeks afforded compound **2** as pink prismatic crystals. They were filtered and separated manually from the gel. For **2**: *Anal.* Calc. for $C_{12}H_{20}N_{10}Cu_5$: C, 23.2; H, 3.2; N, 22.5. Found: C, 23.0; H, 3.3; N, 22.7%. Selected IR data: ν/cm^{-1}: 3442br, 3302s, 3245s, 2942w, 2891w, 2110s, 1586s, 1565m, 1285m, 1179m, 1095w, 1028s, 901m, 884w, 668m, 626w, 495m, 362m.

3.3. X-ray crystallography

Data for compounds **1** and **2** were collected on a Xcalibur 2 Diffractometer (Oxford Diffraction) using a graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The unit cell determination and data reduction were performed using the CRYSALIS program suite [31] on the full set of data. For the two compounds, the crystal structures were solved by direct methods and successive Fourier difference syntheses with the SIR97 program [32] and refined on F^2 by weighted anisotropic full-matrix least-square methods using the SHELXL97 program [33]. Both softwares were used within the WINGX package [34]. After locating all the non-hydrogen atoms in each structure, the models were refined, first using isotropic and finally anisotropic thermal displacement parameters. The position of hydrogen atoms were then calculated and included as isotropic fixed contributors to F_c. Since there is a tendency for the bridging CN groups to have end-for-end disorder in these compounds we have performed several refinements for each structure. For **1**, the best refinement corresponds unambiguously to the model without disorder, the nitrogen atoms of the three CN groups (N1, N2 and N3) were bonded to the Cu^{II} metal ion (Cu2) while the three carbon atoms were bonded to the Cu^{I} metal ion (Cu1). For **2**, the bridging cyano groups were disordered and then each position of the N and C atoms was modeled with a pseudo atom having 50% of C and 50% of N character; the corresponding fictive atom of each position was labelled CN (CN1, CN2, etc.), as reminder of the crystallographic disorder.

4. Conclusion

In summary, we have shown that it is possible to prepare novel mixed-valence Cu^{II}/Cu^{I} cyano compounds with different neutral co-ligands as 2,2′-bipyridine (compound **1**) and 1,3-diaminopropane (compound **2**) presenting extended (3-D in **1** and 2-D in **2**) structures. Compound **1** presents a weak ferromagnetic coupling between the Cu^{II} ions through the "diamagnetic" –NC–Cu^{I}–CN– bridges. This unexpected behavior shows that this kind of bridge is able to transmit weak ferromagnetic coupling, as the –NC–Fe(II)–CN– bridges in the Prussian blue and derivatives.

Supplementary data

CCDC 703838 and 703839 contain the supplementary crystallographic data for compound **1** and **2**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

2.2. Zirconium-lactate (henceforth abbreviated as **ZrL**) solution

Zirconium-lactate (henceforth abbreviated as **ZrL**) solution was prepared following a recipe of Halliburton, slightly modified as below: A clear solution of 0.9415 g of $ZrOCl_2 \cdot 8H_2O$ (Fluka) in 1.0 mL water was stirred with 1.895 mL of refluxed lactic acid (90%) (Merck). The white slurry thus formed was dissolved in a minimum volume (~1.0 mL) of conc. NH_3 and quantitatively transferred to a 5 mL volumetric flask, and the volume was made up to the mark with water. This mixture has a molar ratio, $[Zr^{IV}]$:[lactate] = 1:3 and pH 7.5. In all subsequent studies, this was the source for Zr^{IV}.

2.3. Kinetics

The kinetics were determined spectrophotometrically at 25.0 °C in a thermostated cell housing (CPS 240A) of a Shimadzu (UV-1601) spectrophotometer under the conditions: $T_L \gg T_{Zr} \gg T_{HT}$, where the symbols represent the total analytical concentrations of lactic acid, Zr^{IV} and 2-thenoyltrifluoroacetone, respectively. Thus, first-order reaction conditions were maintained, formation of only a 1:1 complex of Zr^{IV} with HT was ensured and the reaction media was efficiently buffered (by excess lactic acid).

pH jump as well as lactate concentration jump experiments were performed to verify the reversible nature of the reactions studied. A sudden pH drop was induced by the addition of two drops of 5.0×10^{-2} mol dm^{-3} $HClO_4$. A jump in lactate concentration was achieved by the rapid addition of lactic acid. All the concentration jumps (H^+ or L^-) were induced under conditions otherwise the same.

The ionic strength (I) of the media was maintained with $NaClO_4$, prepared and standardized as stated before [13].

3. Results and discussion

3.1. Tautomeric equilibrium of HT

It is known that in solution, the keto (HK) and the enolate (E^-) forms of HT coexist in a pH-dependent equilibrium [14–17]:

$$HK \rightleftharpoons H^+ + E^- \quad K_T \tag{1}$$

The UV spectra of a fixed amount of HT in excess lactic acid at different pH (Fig. 1) pass through two isosbestic points [18]. Their existence suggests that the absorption in this region is essentially accounted for by two species. The curve at pH 8 is characteristic of E^- while that at pH 3 is characteristic of HK. The isosbestic points indicate that the system can be described by the species HK and E^- (Eq. (1)) [14,15] and that over the experimental range pH 3–8, there is no other interfering reaction like hydrolysis of HT.

Under such presumptions, Eq. (2) can be derived (see Appendix 1) from Eq. (1):

$$A = \frac{\varepsilon_{HK} T_{HT}[H^+] + \varepsilon_E K_T T_{HT}}{([H^+] + K_T)} \tag{2}$$

A is the absorption measured at 339 nm, ε_{HK} and ε_E, respectively, are the molar extinction co-efficients of the keto (HK) and the enolate (E^-) forms of HT.

But, $\varepsilon_{HK} \sim 0$ at 339 nm, hence at this wavelength,

$$\frac{A}{T_{HT}} = \frac{(\varepsilon_E K_T)}{([H^+] + K_T)} \quad \text{or,} \quad \frac{T_{HT}}{A} = \frac{1}{\varepsilon_E} + \frac{[H^+]}{K_T \varepsilon_E} \tag{3}$$

The absorbance–pH data at 339 nm (Fig. 1), fitted to Eq. (3) yielded an excellent straight line (Fig. 1). The ratio of its intercept to slope yielded $K_T = 7.15 \times 10^{-7}$. Earlier values [15,17,19], measured by pH-potentiometric titration to pH > 9, are imprecise

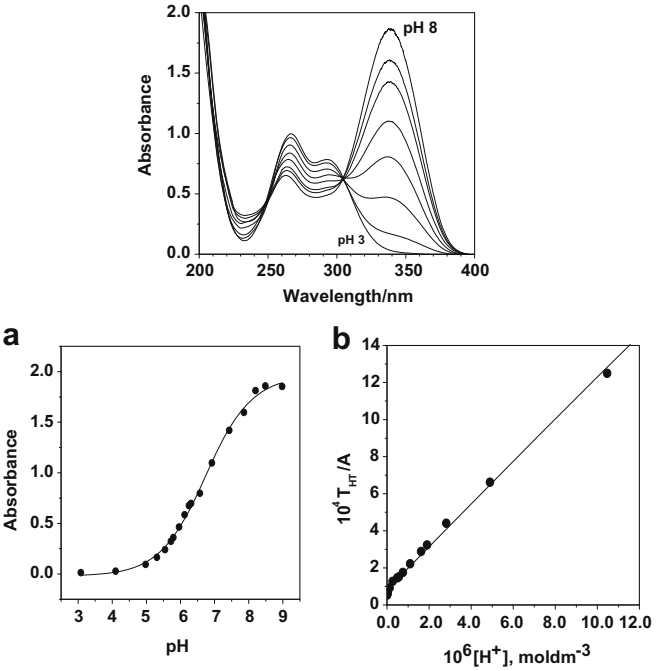

Fig. 1. UV spectra of HT (1.0×10^{-4} mol dm^{-3}), pH 3–8 in lactate buffer (1.0×10^{-2} mol dm^{-3}). (a) Absorption at 339 nm vs. pH. T = 25.0 °C. I = 0. (b) Evaluation of K_T, Eq. (3). T = 25.0 °C. I = 0.

[14] because HT rapidly and nearly completely hydrolyses at pH ⩾ 9. The present spectrophotometric studies carefully avoided the range pH > 8. Hence, HT suffered no hydrolysis and thus no error due to its hydrolysis entered into the measured K_T.

3.2. Reaction between Zr-lactate (ZrL) and HT

Addition of an excess of ZrL at pH 4 to a fixed amount of HT develops a new spectral band at 363 nm, which gains intensity with time, maintaining two isosbestic points (see Fig. 2). The final spectra at equilibrium (Fig. 2) are almost same to those reported [20,21] for ZrE. Evidently, ZrL and HT react to form ZrE. In addition, the existence of the two isosbestic points in Fig. 2 indicates that the absorption in this region is essentially accounted for by two absorbing species, HK (HT at pH 4) and ZrE (represented by the final spectra at equilibrium in Fig. 2):

$$ZrL + HT \rightleftharpoons HL + ZrE; \quad K \tag{4}$$

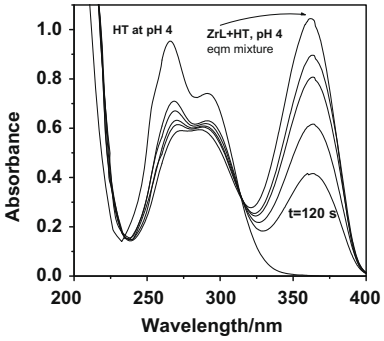

Fig. 2. Kinetic spectra for the reaction between ZrL and HT. T_{Zr} 1.5×10^{-3} mol dm^{-3}, T_{HT} 1.0×10^{-4} mol dm^{-3}, T_L 1.0×10^{-2} mol dm^{-3}, pH 4, T = 25.0 °C, $I = 1.0 \times 10^{-2}$ mol dm^{-3}. Also shown for comparison are the spectra of HT (1.0×10^{-4} mol dm^{-3}) at pH 4.

Within this spectral region, ZrL does not absorb. The rise in absorbance at the peak (363 nm) maintaining the isosbestic points therefore can be interpreted [20] as being due to the gradual formation of ZrE at the expense of HT via the dynamic equilibrium (4).

3.3. The reversible nature of reaction (4)

Fig. 3 illustrates how the absorbance of an equilibrated mixture of ZrL with HT in excess lactate slowly drops if T_L jumps to a higher value under otherwise identical conditions.

Fig. 4 demonstrates that equilibrium (4) can be approached from either direction – forward as well as reverse. Figs. 2–4 together strongly suggest a clean reversible reaction (Eq. (4)).

3.4. Equilibrium study

Absorbances for mixtures of ZrL with HT at equilibrium in excess lactate buffer at different pH are displayed in Table 1. For equilibrium (4), one can derive Eq. (5) (see Appendix 2):

$$\frac{T_{HT}}{A_e} = \frac{T_L[H^+]}{(K_a + [H^+])KT_{Zr}\varepsilon} + \frac{1}{\varepsilon T_{Zr}} \quad (5)$$

where A_e, K_a, ε, K and $[H^+]$, respectively, represent the equilibrium absorbance of the mixture, dissociation constant of lactic acid, molar extinction co-efficient of the absorbing species ZrE, overall equilibrium constant for reaction (4) and molar concentration of the hydrogen ion.

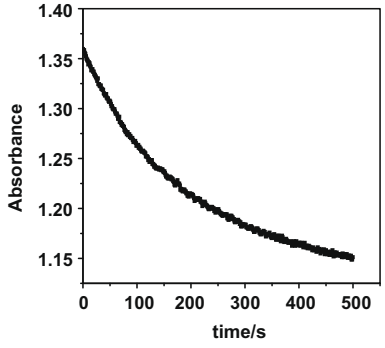

Fig. 3. Effect of T_L jump on the equilibrium absorbance of a mixture of T_{Zr}, 1.5×10^{-3} mol dm^{-3}; T_L, 5.0×10^{-3} mol dm^{-3}and T_{HT}, 1.0×10^{-4} mol dm^{-3} at pH 4.35, $T = 25.0$ °C. Rapid addition of excess lactic acid (T_L, 1.5×10^{-2} mol dm^{-3}) under otherwise the same conditions brings down the absorbance. Least squares fit of absorbance–time data (black points) to first-order decay are shown.

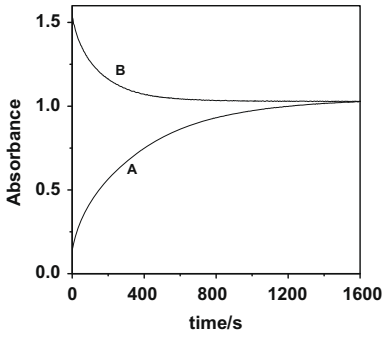

Fig. 4. (A) Rise in absorbance: T_{Zr} 1.5×10^{-3} mol dm^{-3}, T_{HT} 1.0×10^{-4} mol dm^{-3}, T_L 1.0×10^{-2} mol dm^{-3}, $T = 25.0$ °C, pH 4.02. (B) Decay in absorbance: The pH of (A) is suddenly decreased from 5.02 to 4.02. Absorbance decreases from 1.51 to an equilibrium value, the same as that for (A) at pH 4.02.

Table 1
Equilibrium absorbencies at 363 nm of mixtures of ZrL with HT (1.0×10^{-4} mol dm^{-3}). T_L 5.0×10^{-1} mol dm^{-3}; I 1.0 mol dm^{-3}, T 25.0 °C.

[Zr^{IV}] (mol dm^{-3})	pH	Absorbance
0.10	3.97	1.465
0.10	2.33	0.891
0.10	2.99	0.955
0.10	3.41	1.063
0.10	4.07	1.385
0.10	4.56	1.759
0.10	5.01	2.085
0.10	3.98	1.400

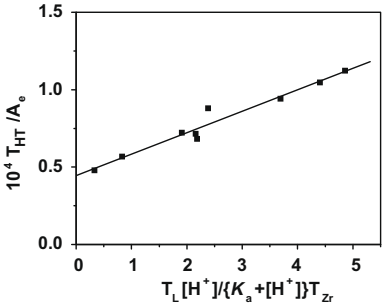

Fig. 5. Evaluation of the equilibrium constant K from Eq. (5).

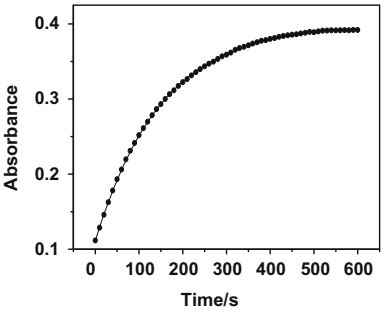

Fig. 6. Abs.–t data (λ, 363 nm) and its fit to the first-order decay equation. T_{Zr}, 5.0×10^{-2} mol dm^{-3}; T_{HT}, 1.0×10^{-4} mol dm^{-3}; T_L, 1.0 mol dm^{-3}; pH 3.5; $I = 2.0$ mol dm^{-3} ($NaClO_4$). The solid line shows the least-squares fit of the experimental data points to Eq. (6).

A plot (Fig. 5) of $\frac{T_{HT}}{A_e}$ versus $\frac{T_L[H^+]}{(K_a+[H^+])T_{Zr}}$ at a constant T_{Zr}, using Table 1 yielded a reasonably good straight line with an equilibrium constant $K = 3.2$ for reaction (4) at 25.0 °C, ionic strength 1.0 mol dm^{-3}.

The tautomerisation equilibrium (1), mentioned above, is attained at a rate much faster [15] than the reactions measured here. This is why the tautomerisation step is kinetically silent in the present reactions, which followed simple first-order kinetics (see below).

3.5. Overall reaction kinetics

The absorbance–time data at 363 nm for reaction (4) under the conditions, $T_{HT} \ll T_{Zr} \ll T_L$ obeyed first-order kinetics for more than 95% to their way to equilibrium (see Figs. 6 and 7). The regression co-efficient in all the cases is better than 0.999.

Representative first-order rate constants, k_0 have been collected in Table 2. Individual values are reproducible to within ±5%.

k_0 increases with increasing pH and T_{Zr} (see Table 2) but decreases with increasing T_L (given below are values for k_0 at differ-

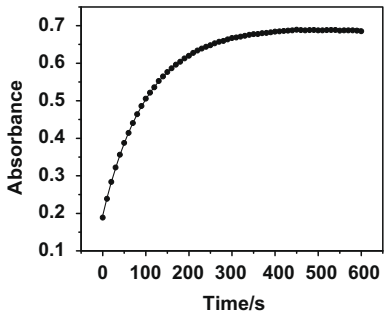

Fig. 7. Abs.–t data (λ, 363 nm) and their fit to Eq. (6), pH 4.5, other conditions the same as for Fig. 6.

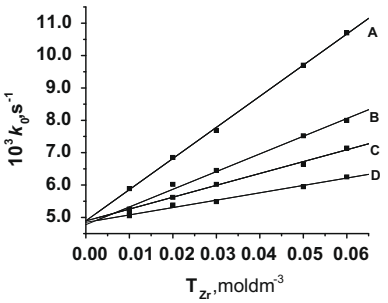

Fig. 8. Variation of k_0 with T_{Zr} at different fixed pHs. T_{HT} 1.0×10^{-4} mol dm^{-3}; T_L 1.0 mol dm^{-3}, I = 2.0 mol dm^{-3}; T = 25.0 °C. pHs are 4.5 (A), 4.0 (B), 3.5 (C) and 3.0 (D).

Table 2
Some representative values of the first-order rate constant k_0 for reaction (4): T_{HT} 1.0×10^{-4} mol dm^{-3}; T_L 1.0 mol dm^{-3}, T 25.0 °C, I 2.0 mol dm^{-3} ($NaClO_4$).

T_{Zr} (mol dm^{-3})	pH	$10^3 k_0$ (s^{-1})	T_{Zr} (mol dm^{-3})	pH	$10^3 k_0$ (s^{-1})
0.01	3.0	5.0	0.01	4.0	5.2
0.02		5.4	0.02		6.0
0.03		5.5	0.03		6.4
0.05		6.0	0.05		7.5
0.06		6.2	0.06		8.0
0.01	3.5	5.3	0.01	4.5	5.9
0.02		5.6	0.02		6.8
0.03		6.0	0.03		7.7
0.05		6.6	0.05		9.7
0.06		7.1	0.06		10.7

ent T_L at pH 3.0 and T_{Zr} 2.0×10^{-2} mol dm^{-3}, I 2.0 mol dm^{-3}, T 25.0 °C):

T_L, mol dm^{-3}:	0.60	0.80	0.90	1.2	1.4
$10^3 k_0$, s^{-1}:	7.2	6.8	6.5	5.1	4.1

These simple kinetic observations clearly indicate (a) fast, reversible replacement of one L with two H_2O molecules and (b) rapid hydrolysis of the diaqua species forming the conjugate base, and (c) a reversible, rate determining (k_1, k_{-1}) entry of the enolate form (E^-) of HT into the coordination sphere of Zr^{IV}.

Unfortunately, the exact composition of "zirconium-lactate" in excess lactate buffer is unknown, but studies by Rose et al. [7] firmly establish that it is mainly the dimer, Zr_2L_6. Accordingly, we propose the following reaction scheme consisting of Eqs. (A)–(C), indeed an abbreviated form of the steps (a)–(c) mentioned above (Scheme 1).

We presume that reactions (A) and (B) precede the rate determining step and none can be the rate steps. This is necessary to explain the inverse dependence of rate on [L] and [H^+]. Assuming kinetic activity of the diaqua species $Zr_2L_5(OH_2)_2^+$ to be negligible compared to that of the hydroxo-aqua species $Zr_2L_5(OH_2)(OH)$, and that $K_AK_B \ll 1$, one can derive from the scheme above (see Appendix 3):

$$k_0 = \frac{k_1 K_{AB} T_{Zr}}{[H^+][L^-]} + k_{-1} \quad (6)$$

As expected from equation (6), k_0 versus T_{Zr} plots are linear (see Fig. 8) with intercepts independent of pH in the range 3.0–4.5. The common intercept of a bunch of four straight lines (Fig. 8) is $k_{-1} = 4.9 \times 10^{-3}$ s^{-1}. Slopes of these lines yielded an average value for $k_1K_{AB} = 2.62 \times 10^{-6}$ dm^6 mol^{-2} s^{-1}; [L] at a given pH was calculated using a pK_a value of lactic acid of 3.86 at T = 25.0 °C [22].

In the absence of any idea of the magnitude for K_{AB} (=K_AK_B), we could not evaluate k_1. Nevertheless, it can be shown (see Appendix 3) that $K_a = \frac{K_{AB}k_1}{k_{-1}}$, where from p$K_a$ is found to be 3.8, in close agreement with the literature [22] value. "ZrL", as prepared by us, most likely contains several oligomeric and polymeric zirconium complexes, [23] along with the main component Zr_2(lactate)$_6$ established by Rose et al. [7]. Nevertheless, the observed simplicity of the kinetic pattern surely indicates that only one Zr^{IV} species (probably the dimer) takes part in the kinetics. Otherwise, much more complex kinetics would have been expected.

4. Conclusion

"Zirconium-lactate" is a transparent mixture containing Zr^{IV} and lactic acid in a 1:3 molar ratio at pH 7.5. It reversibly exchanges one bidentate lactate for the bidentate O,O-donor, 2-thenoyltrifluoroacetone (HT). In excess lactate buffer, this process exhibits simple kinetics and seems to proceed *via* fast dissociation of one lactate, rapid loss of a proton to form the conjugate base and rate determining, reversible entry of HT in its enolate form (E^-) to the coordination sphere of Zr^{IV}. The observance of simple kinetics suggests only one Zr^{IV} species (plausibly the dimer, Zr_2L_6) is kinetically active, though "zirconium-lactate" is a complex mixture of several oligomeric and polymeric Zr^{IV} species. It also appears that replacement of a lactate ligand precedes the entry of HT in the coordination sphere of Zr^{IV}. A similar situation can be expected to happen when "zirconium-lactate" works with guar during the oil-field application. Use of lactate binds and solubilises Zr^{IV} but does not bind it too tightly so that it is easily replaced at the time of necessity. It seems important to control the lactate/guar proportion in oil-field applications.

$$Zr_2L_6 + 2H_2O \rightleftharpoons Zr_2L_5(OH_2)_2^+ + L^- \qquad K_A \text{ (rapid equilibrium)} \qquad (A)$$

$$Zr_2L_5(OH_2)_2^+ \rightleftharpoons Zr_2L_5(OH_2)(OH) + H^+ \qquad K_B \text{ (rapid equilibrium)} \qquad (B)$$

$$Zr_2L_5(OH_2)(OH) + HT \rightleftharpoons Zr_2L_5E + 2H_2O \qquad k_1, k_{-1} \text{ (slow r.d.s)} \qquad (C)$$

Appendix. Derivation of Eqs. (2), (5), and (6) in the main text

Appendix 1. Derivation of Eq. (2)

$$HK \rightleftarrows H^+ + E^-; \quad K_T = \frac{[H^+][E^-]}{[HK]} \tag{i}$$

$$T_{HT} = [HK] + [E^-] = [HK] + \left(\frac{K_T[HK]}{[H^+]}\right) = [HK]\left([H^+] + \frac{K_T}{[H^+]}\right)$$

$$\text{or, } [HK] = \frac{T_{HT}[H^+]}{([H^+] + K_T)} \text{ and } [E^-] = \frac{K_T T_{HT}}{([H^+] + K_T)}$$

The absorbance, A, at 339 nm (the absorption maximum for the E^- form) of such an equilibrated solution is:

$$A = \varepsilon_{HK}[HK] + \varepsilon_E[E^-] = \frac{\varepsilon_{HK} T_{HT}[H^+]}{([H^+] + K_T)} + \frac{\varepsilon_E K_T T_{HT}}{([H^+] + K_T)}$$

$$= \frac{\varepsilon_{HK} T_{HT}[H^+] + \varepsilon_E K_T T_{HT}}{([H^+] + K_T)} \tag{2}$$

$$\text{or, } \frac{A}{T_{HT}} = \frac{(\varepsilon_{HK}[H^+] + \varepsilon_E K_T)}{([H^+] + K_T)} \tag{ii}$$

ε_{HK} and ε_E are the molar extinction co-efficients of HK and E^-, respectively, at 339 nm.

But $\varepsilon_{HK} \sim 0$ at 339 nm. Hence Eq. (ii) further simplifies to:

$$\frac{A}{T_{HT}} = \frac{(\varepsilon_E K_T)}{([H^+] + K_T)} \text{ or, } \frac{T_{HT}}{A} = \frac{1}{\varepsilon_E} + \frac{[H^+]}{K_T \varepsilon_E} \tag{3}$$

Appendix. 2. Derivation of Eq. (5)

The overall reaction between zirconium-lactate (ZrL) and 2-thenoyltrifluoroacetone (HT) produces lactic acid (HL) along with ZrE, the zirconium complex of the enolate ion (E^-) of HT:

$$ZrL + HT \rightleftharpoons HL + ZrE; \quad K$$

Initial conc.:	T_{Zr}	T_{HT}	T_{HL}	0
Eqm. conc.:	$(T_{Zr} - x)$	$(T_{HT} - x)$	$(T_{HL} + x)$	x

Here, x is the extent of reaction at equilibrium.

Under the conditions: $T_{HL} \gg T_{Zr} \gg T_{HT}$, $K = \frac{[ZrE][HL]}{[ZrL][HT]} = \frac{xT_{HL}}{T_{Zr}(T_{HT} - x)}$.

At a wavelength where only ZrE absorbs, $x = \frac{A_e}{\varepsilon}$. Hence,

$$K = \frac{\frac{A_e T_{HL}}{\varepsilon}}{T_{Zr}\left(T_{HT} - \frac{A_e}{\varepsilon}\right)} = \frac{A_e T_{HL}}{T_{Zr}(T_{HT}\varepsilon - A_e)}; \quad \text{or, } KT_{Zr}T_{HT}\varepsilon - KA_e = A_e T_{HL} \tag{iii}$$

where ε is the molar extinction co-efficient for ZrE at the experimental wavelength. Dividing both sides of Eq. (iii) with $KT_{Zr}\varepsilon A_e$,

$$\frac{T_{HT}}{A_e} = \frac{T_{HL}}{KT_{Zr}\varepsilon} + \frac{1}{\varepsilon T_{Zr}}$$

Now, substituting, $T_{HL} = \frac{T_L[H^+]}{K_a + [H^+]}$, where T_L and K_a are, respectively, the total conc and the deprotonation constant of lactic acid we get,

$$\frac{T_{HT}}{A_e} = \frac{T_L[H^+]}{(K_a + [H^+])KT_{Zr}\varepsilon} + \frac{1}{\varepsilon T_{Zr}} \tag{5}$$

Appendix. 3. Derivation of Eq. (6)

For the scheme consisting of Eqs. (A)–(C)

$$Zr_2L_6 + 2H_2O \rightleftharpoons Zr_2L_5(OH_2)_2{}^+ + L^- \quad K_A \text{ (rapid equilibrium)} \tag{A}$$

$$Zr_2L_5(OH_2)_2{}^+ \rightleftharpoons Zr_2L_5(OH_2)(OH) + H^+ \quad K_B \text{ (rapid equilibrium)} \tag{B}$$

$$Zr_2L_5(OH_2)(OH) + HT \rightleftharpoons Zr_2L_5E + 2H_2O \quad k_1,\ k_{-1} \text{ (slow r.d.s.)} \tag{C}$$

$$K_{AB} = K_A K_B = \frac{[Zr_2L_5(OH_2)(OH)][H^+][L^-]}{[Zr_2L_6]};$$

$$\text{or, } [Zr_2L_5(OH_2)(OH)] = \frac{K_{AB}[Zr_2L_6]}{[H^+][L^-]} \text{ (Assuming, } K_{AB} \ll 1)$$

Hence,

$$\text{Rate} = k_1[Zr_2L_5(OH_2)(OH)][HT] + k_{-1}[Zr_2L_5E]$$

$$= \frac{k_1 K_{AB}[Zr_2L_6]}{[H^+][L^-]} + k_{-1}[Zr_2L_5E] = \frac{k_1 K_{AB} T_{Zr}}{[H^+][L^-]} + k_{-1}[Zr_2L_5E]$$

So that the first-order rate constant,

$$k_0 = \frac{k_1 K_{AB} T_{Zr}}{[H^+][L^-]} + k_{-1} \tag{6}$$

In addition, it can be shown that $\frac{K_A K_B k_1}{k_{-1}} = \frac{K_{AB} k_1}{k_{-1}} = KK_a$. Hence, $K_a = \frac{\frac{K_{AB} k_1}{k_{-1}}}{K}$, where K is the equilibrium constant for reaction (4), and K_a is the deprotonation constant for lactic acid:

$$ZrL + HT \rightleftharpoons ZrE + HL \quad K$$
$$HL \rightleftharpoons H^+ + L^- \quad K_a \tag{4}$$

Substituting known values, $K_a = (2.62 \times 10^{-6}/4.9 \times 10^{-3}) \times (1/3.2) = 1.67 \times 10^{-4}$ or, $pK_a = 3.8$ (reported pK_a 3.86).

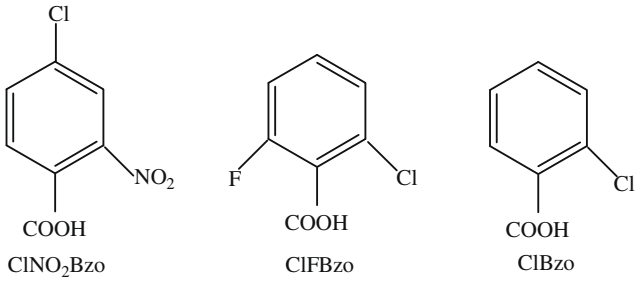

Fig. 1. Chemical structure and abbreviation for the ligands.

synthesis, characterization and nuclease activity of **1**–**3**, together with their antiproliferation and antibacterial activity is reported. The ligands in complexes **1**–**3** are shown in Fig. 1 and the abbreviated formula of the complexes are $[Cu(II)(ClNO_2Bzo)(H_2O)]_2$, $[Cu(II)(ClFBzo)(H_2O)]_2$ and $[Cu(II)(ClBzo)(H_2O)]_2$, respectively.

2. Experimental

2.1. Synthesis of tetrakis(μ-4-chloro-2-nitrobenzoato-κ^2O,O') bis[aquacopper(II)] (*1*)

Copper(II) chloride hydrate (3.00 g, 0.018 mol) was dissolved in ethanol solution (50 ml). To this solution was added 50 ml ethanol solution of 4-chloro-2-nitrobenzoic acid (7.26 g, 0.036 mol). The resultant solution was stirred and refluxed for 2 h. The green solution was then filtered and allowed to cool down to room temperature. Crystals of the title compound were obtained after 3 days of slow evaporation at room temperature. Yield 32.5%. *Anal.* Calc. for **1**: C, 34.84; H, 1.67; N, 5.80. Found: C, 35.19; H, 1.42; N, 5.52%.

2.2. Synthesis of tetrakis(μ-2-chloro-6-fluorobenzoato-κ^2O,O') bis[aquacopper(II)] (*2*)

Copper(II) chloride hydrate (3.00 g, 0.018 mol) was dissolved in ethanol solution (50 ml). To this solution was added 50 ml ethanol solution of 2-chloro-6-fluorobenzoic acid (6.28 g, 0.036 mol). The resultant solution was stirred and refluxed for 2 h. The green solution was then filtered and allowed to cool down to room temperature. Crystals of the title compound were obtained after 3 days of slow evaporation at room temperature. Yield 34.2%. *Anal.* Calc. for **2**: C, 39.23; H, 1.89. Found: C, 39.02; H, 1.46%.

2.3. Synthesis of tetrakis(μ-2-chlorobenzoato-κ^2O,O') bis[aquacopper(II)] (*3*)

Copper(II) chloride hydrate (3.00 g, 0.018 mol) was dissolved in ethanol solution (50 ml). To this solution was added 50 ml ethanol solution of 2-chlorobenzoic acid (5.64 g, 0.036 mol). The resultant solution was stirred and refluxed for 2 h. The green solution was then filtered and allowed to cool down to room temperature. Crystals of the title compound were obtained after 3 days of slow evaporation at room temperature. Yield 35.2%. *Anal.* Calc. for **3**: C, 42.82; H, 2.57. Found: C, 42.51; H, 2.17%.

2.4. Physical measurements

Elemental analyses were performed using a Perkin–Elmer 2400 series-11 CHN/O analyzer. Infrared spectra (KBr pellets) were recorded using a Perkin–Elmer 2000 Infrared Spectrometer. The solution UV–Vis spectra were obtained from a Jasco V-530 Spectrophotometer. The cyclic voltammetric experiments were performed on a BAS-Epsilon electrochemical system. Voltammograms were recorded using a standard three electrode arrangement consisting of a platinum working electrode, a platinum auxiliary electrode and a Ag/AgCl reference electrode. The complexes were dissolved in Tris–NaCl (TN) pH 7.5 buffer prior to measurement.

2.5. X-ray crystallography

Diffraction data were collected using a Bruker APEX2 [30] CCD area-detector, graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at 100(1) K for **1** and 297(2) K for **2** and the Oxford Cyrosystem Cobra low-temperature attachment. The data was reduced using SAINT [31]. A semi-empirical absorption correction was applied to the data using SADABS [31]. The structure was solved by direct methods and refined against F^2 by full-matrix least squares using SHELXTL [32]. Hydrogen atoms were placed in calculated positions. Crystal data and experimental details of the structure determinations are listed in Table 1.

2.6. DNA cleavage experiments

The electrophoresis experiments were performed on a horizontal gel electrophoresis system. Agarose gel electrophoresis experiments were carried out on plasmid pBR322 DNA. All samples in Tris–NaCl buffer at pH 7.5 were incubated at 37 °C for 2 h, and then electrophoresed on 1% agarose gel for 1 h at 80 V. Essentially samples with an increasing concentration of complexes with a given concentration of DNA (0.25 μg/μl) for each sample were incubated in the absence or presence of hydrogen peroxide. The resultant bands for each set of experiments were photographed under UV light by using a Polaroid camera, GelCam, fixed with an electrophoresis hood.

2.7. Cell line and cell culture

Human cancer cell lines, namely MCF-7, DU 145, HeLa, HepG2 and Chang were obtained from the American Type Culture Collection (ATCC, Manassas, VA, USA). The cancer cells were maintained in Dulbecco's modified Eagle's medium (DMEM; Invitrogen Co., Carlsbad, California, USA) supplemented with 10% heat-inactivated fetal calf serum (Invitrogen Co., Carlsbad, California, USA), 100 U/ml penicillin and 100 μg/ml streptomycin (Flowlab, Sydney, Australia). Cells were kept in the logarithmic growth phase by routine passage every 2–3 days using 0.025% trypsin–EDTA treatment.

2.8. In vitro antiproliferation assay

The antiproliferative and cytotoxic activity of **1**–**3** towards MCF-7, DU 145, HeLa, HepG2 and Chang cell lines was evaluated by using the sulforhodamine B (SRB) method, as previously described [33–37]. Cells were seeded 24 h prior to treatment in a 96-well plate at plating densities ranging from 10000 to 20000 cells/well depending on the doubling time of individual cell lines in order to obtain semi-confluent cultures. One plate from each cell line was fixed in situ with sodium trichloroacetate, TCA (Sigma Chemical Co.), to represent a measurement of the cell population for each cell line at the time of drug addition (T_z). Test agents were dissolved in DMSO (Sigma Chemical Co.) and followed by a 2× serial dilution for six points ranging from 6.25 to 200 μg/ml. The final concentration of DMSO used in the corresponding wells did not exceed 1% (v/v), which affect cell viability. Control cultures received the same concentration of solvent alone. Following drug addition, the plates were incubated for an additional 48 h period.

At the end of incubation, cells were fixed in situ with 50 μl of cold 50% (w/v) TCA and incubated for 1 h at 4 °C. The plates were then washed with tap water and air dried. SRB (Sigma Chemical

Co.) solution (100 μl) at 0.4% (w/v) in 1% acetic acid was added to the corresponding wells and further incubated for 10 min at room temperature. After staining, unbound dye was washed out by 1% acetic acid and the bound stain was subsequently solubilised with 10 mM trizma base (Sigma Chemical Co.). The absorbance at 505 nm was read on a spectrophotometric plate reader.

Dose–response curves were constructed to obtain the response parameters which were the GI_{50}, TGI and LC_{50}. Percentage growth is calculated as: $[(T_i - T_z)/(C - T_z)] \times 100$ where (T_z) is time zero, (C) is control growth and (T_i) is test growth in the presence of the drug at the six concentration levels. The GI_{50} value (growth inhibitory activity) corresponds to the concentration of test agents causing 50% decrease in net cell growth which was calculated from $[(T_i - T_z)/(C - T_z)] \times 100 = 50$, the TGI value (cytostatic activity) is the concentration of test agents resulting in total growth inhibition which was calculated from $T_i = T_z$, and the LC_{50} value (cytotoxic activity) is the concentration of the test agents causing net 50% loss of initial cells at the end of the incubation period which was calculated from $[(T_i - T_z)/T_z] \times 100 = (-50)$. All data were derived from three independent experiments.

2.9. Antibacterial screening (inhibition zone)

The antibacterial activity of **1**–**3** was determined by screening against Gram negative bacteria: *Enterobacter aerogenes, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Shigella sonnei* and Gram positive bacteria: *Bacillus cereus, Bacillus subtilis* and *Staphylococus aureus* using the well diffusion method. Sensitivity plates were inoculated with Gram negative bacteria and Gram positive bacteria and the well was loaded with 75 μl of test compound solution using a sterilized micropipette. The incubation was done for 24 h at 37 ± 2 °C. Inhibition was recorded by measuring the diameter of the inhibitory zone after the period of incubation. Three replicas were made for each treatment. To evaluate the effect of concentration on antibacterial activity, three different concentrations (125, 250 and 500 μg/ml) of the test compounds

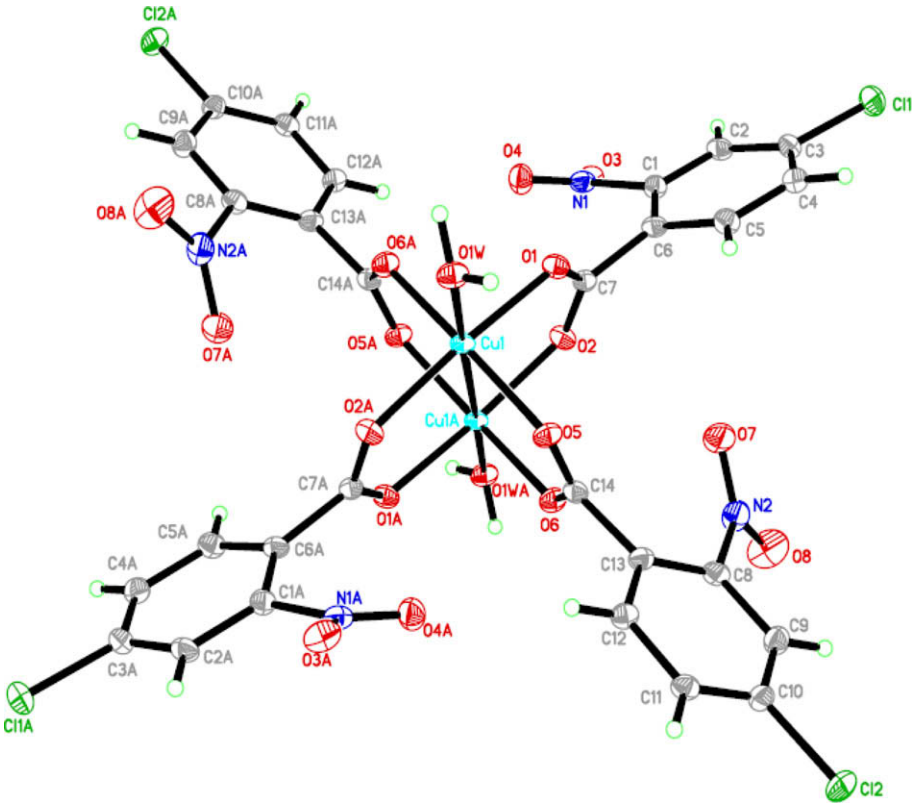

Fig. 2. The molecular structure of **1**, showing 50% probability displacement ellipsoids and the atomic numbering.

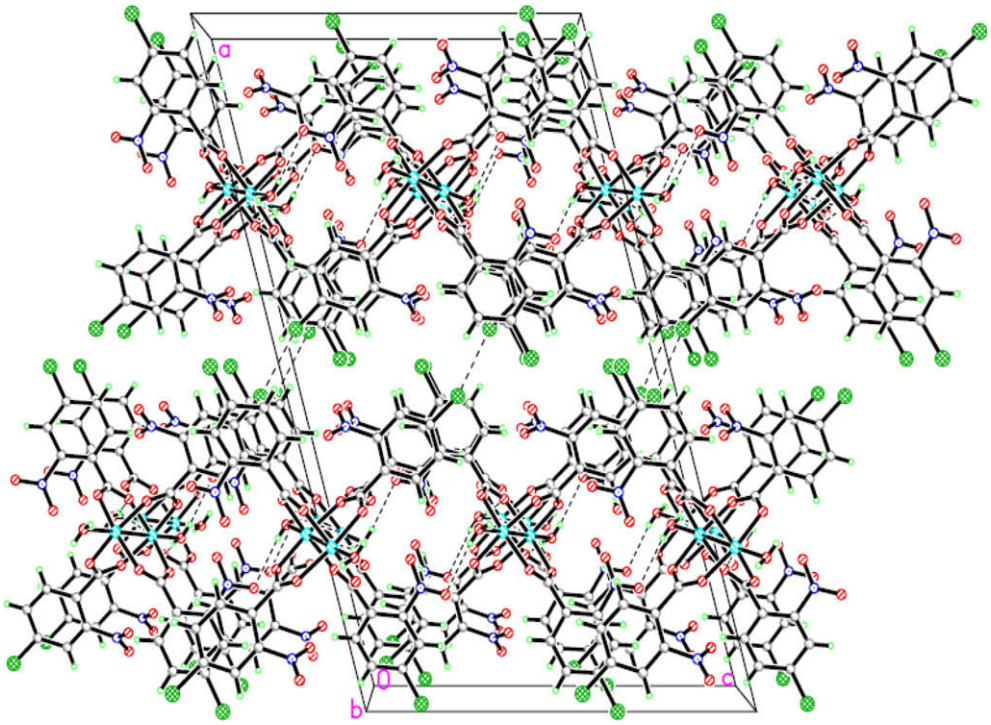

Fig. 3. The crystal packing of **1**.

were used. DMSO, which exhibited no antibacterial activity, was used as a negative control. The stability of the complexes in DMSO medium (2% v/v) were checked by using UV–Vis technique whereby no apparent changes were observed in the absorption peaks of the complexes for two weeks.

2.10. Antibacterial screening (MIC)

The MIC (minimum inhibitory concentration) value for the complexes which showed positive result towards antibacterial activity was further determined using the microdilution broth method. Sample solutions were added to the broth at different concentrations. Measured samples of each bacterial suspension were added to the serial dilution of the test substances. The inoculated test tubes were incubated at 37 ± 2 °C. After 24 h, the turbidity was evaluated. The MIC was defined as the lowest antibacterial concentration of the test samples that inhibit more than 99% of the bacterial population. The experiments were repeated three times and the results were expressed as average values. The solvent showed no antibacterial action.

3. Result and discussion

3.1. Characterization of complex *1*

The crystal structure of **1** is depicted in Fig. 2 and the crystal packing in the solid state is depicted in Fig. 3. Selected interatomic distances and angles are given in Table 2. Complex **1** which is neutral, centrosymmetric and dinuclear consists of two Cu(II) centers bridged by four carboxylate groups of the four ligands. Each Cu(II) center is coordinated by four O atoms of carboxylate groups in the basal plane and the O atom of a water molecule in the apical position, giving a square-pyramidal coordination environment. The Cu···O bond distance of water molecule is markedly longer than the Cu···O bond distance of carboxylate groups. The intramolecular Cu···Cu distance in the dinuclear unit 2.6356(8) Å, which is in the normal range of tetracarboxylatocopper(II) dimers such as diamminetetrakis-μ-(*O*,*O*′-indole-3-carboxylate)dicopper(II), $Cu(L)_4(H_2O)_2$ [LH = (1S, 3R)-3-carbamoyl-2,2,3-trimethylcyclopentane-1-carboxylic acid] and $[Cu_2(taa)_4(dmf)]_2$ [taa = 2-thiopheneacetate anion] [38–40]. The carboxylate bridging angles of O(2)–C(7)–O(1) and O(5)–C(14)–O(6) are similar at 126.7(3)° and 127.3(3)°, respectively. The bond distances of Cu(1)–O(5), Cu(1)–O(6A), Cu(1)–O(2A), Cu(1)–O(1) and Cu(1)–O(1W) are 1.964(2), 1.964(2), 1.967(2), 1.987(2) and 2.130(3) Å, respectively, while the bond angles of O(5)–Cu(1)–O(1W), O(6A)–Cu(1)–O(1W),

#1: $-x + 1/2, -y + 1/2, -z$.

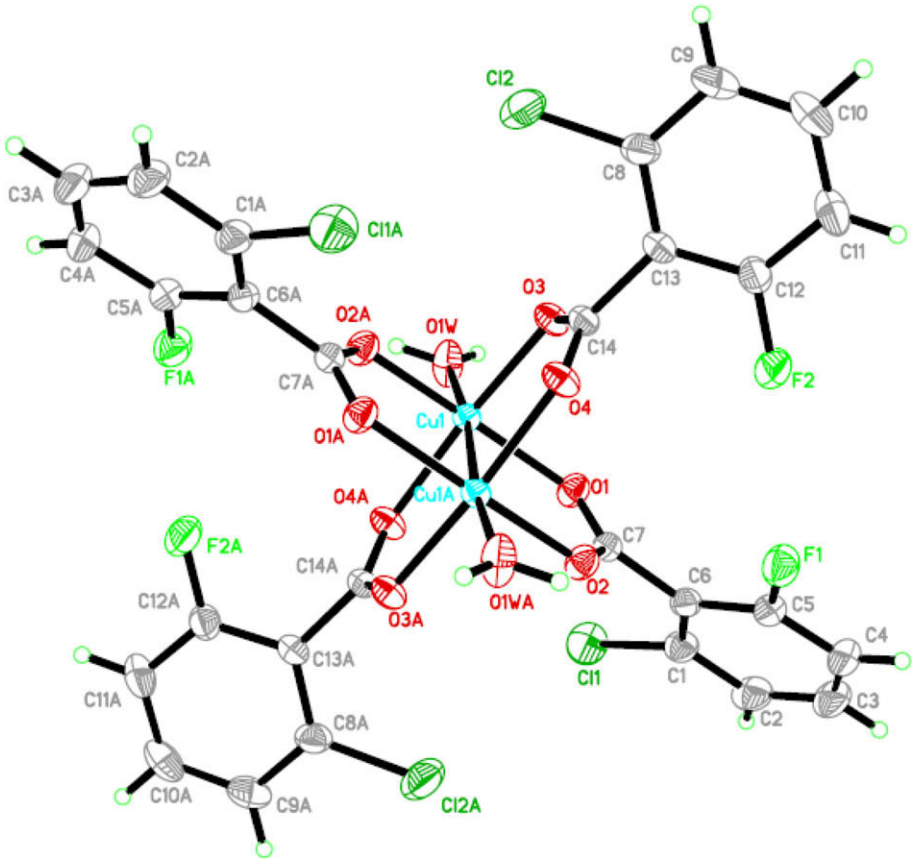

Fig. 4. The molecular structure of **2**, showing 50% probability displacement ellipsoids and the atomic numbering.

O(2A)–Cu(1)–O(1W) and O(1)–Cu(1)–O(1W) are 94.79(10)°, 96.30(10)°, 97.28(10)° and 94.01(10)°, respectively, with a tau value $\tau \approx 0$, indicating a square-pyramidal coordination geometry. The crystal structure of **2** is depicted in Fig. 4 and the crystal packing in the solid state is depicted in Fig. 5. Similar to complex **1**, complex **2** also is neutral, centrosymmetric and dinuclear in which there are two crystallographically independent molecules, both situated over their centers of inversion. Each Cu(II) center displays a square-pyramidal coordination environment where the four O atoms of carboxylate groups from the ligands form the basal plane and the O atom of a water molecule occupies the apical position. The Cu···O bond distance of the water molecule is clearly longer than the Cu···O bond distance of the carboxylate groups. The intramolecular Cu···Cu distance in the dinuclear unit is 2.6334(4) Å, which is almost similar with **1** and also in normal range of tetracarboxylato copper(II) dimers [38–40]. The carboxylate bridging angles of O(1)–C(7)–O(2) and O(4)–C(14)–O(3) show almost parallel values at 126.46(18)° and 126.23(15)°, respectively. The bond distances of Cu(1)–O(1), Cu(1)–O(2A), Cu(1)–O(4A), Cu(1)–O(3) and Cu(1)–O(1W) are 1.9515(14), 1.9584(14), 1.9734(13), 1.9845(13) and 2.1177(14) Å, respectively, and the bond angles of O(1)–Cu(1)–O(1W), O(2A)–Cu(1)–O(1W), O(4A)–Cu(1)–O(1W) and O(3)–Cu(1)–O(1W) are 98.90(6)°, 92.85(7)°, 95.62(6)° and 95.96(6)°, respectively, with a tau value $\tau \approx 0$, indicating a square-pyramidal coordination geometry. The hydrogen bondings that exist in the crystal formation of $[Cu(II)(NO_2Bzo)(H_2O)]_2$ and $[Cu(II)(ClFBzo)(H_2O)]_2$ are shown in Tables 3 and 5. These hydrogen bonding sites could allow the complexes to interact with DNA through hydrogen bonding. In addition, the benzene rings of **1** (interplanar distances = 3.758(2) Å) and **2** (interplanar distances = 3.7936(15) Å) could also allow the complexes to interact with DNA through van der Waals interaction. The crystal structure of **3** was earlier reported elsewhere [41].

The IR spectrum of **1** shows a broad absorption band at 3440 cm^{-1} corresponding to H···O stretching of coordinated water molecules in the complex. The C=C–H absorption band can be observed at 3095 cm^{-1}. The $\nu_{asym}(COO^-)$ and $\nu_{sym}(COO^-)$ absorption can be observed as strong bands at 1614 and 1411 cm^{-1}, respectively [39,42,43].

The $\Delta[\nu_{asym}(COO^-) - \nu_{sym}(COO^-)]$ for **1** is 203 cm^{-1} indicating that the coordination of carboxylate groups are closer to bidentate rather than to monodentate mode [39,42,43]. This result is in agreement with the crystal structure of **1** which shows the carboxylate groups forming bidentate bridging groups in the complex. The strong NO_2 absorption band is not much affected by the complex formation, with ligand and complex showing the NO_2 absorption at 1537 and 1536 cm^{-1}, respectively, indicating that the NO_2 groups are not involved in the coordination to the metal. The IR spectrum of **2** exhibits H···O stretching of coordinated water molecules as a broad absorption band centered at 3419 cm^{-1}. The C=C–H absorption bands can be observed at 3093 and 3065 cm^{-1}. The strong antisymmetric and symmetric carboxylate stretching can be observed as strong bands at 1617 and 1404 cm^{-1}, respectively. The calculated $\Delta[\nu_{asym}(COO^-) - \nu_{sym}(COO^-)]$ for **2** is 213 cm^{-1} indicating the coordination of the carboxylate groups are bidentate in nature. This result concurs with the crystal structure of **2** which shows the carboxylates group forming bidentate bridges in the complex. For complex **3**, the H···O stretching of coordinated water molecules can be seen as a broad absorption band centered at 3416 cm^{-1}. The peaks at 3078 and 3035 cm^{-1} can be assigned to the C=C–H stretching. The $\nu_{asym}(COO^-)$ and $\nu_{sym}(COO^-)$ stretching can be observed as strong bands at 1599 and 1399 cm^{-1}, respec-

tively. The calculated $\Delta[\nu_{asym}(COO^-) - \nu_{sym}(COO^-)]$ for **3** is 200 cm^{-1} indicating a bidentate mode of coordination for the carboxylate groups. This result is in agreements with crystal structure of **3** which shows the carboxylate groups forming bidentate bridges in the complex [41].

As this paper reports the nuclease property of the complexes in the Tris–NaCl pH 7.5 buffer solution, the electronic spectral data of the complexes was obtained in the Tris–NaCl pH 7.5 buffer solution. The UV–Vis spectrum of **1** displays a broad absorption band at λ_{max} = 698 nm which can be assigned to the d–d transition while the bands at 263 and 218 nm in UV region can be assigned to the π–π^* transitions. For complex **2**, a broad d–d transition absorption band occurs at 736 nm while π–π^* transitions occur at 263 and 212 nm. In complex **3**, the d–d transition band can be observed at 732 nm while π–π^* transitions can be observed at 271 and 212 nm.

The cyclic voltammogram of **1**–**3** were recorded in the Tris–NaCl (TN) pH 7.5 buffer solution whereby all the complexes show redox activity. Complex **1** shows two cathodic reduction peaks at −159 and −304 mV and two anodic oxidation peaks at −54 mV and 100 mV which correspond to the $Cu^{II}Cu^{II}$ to $Cu^{II}Cu^{I}$ and $Cu^{II}Cu^{I}$

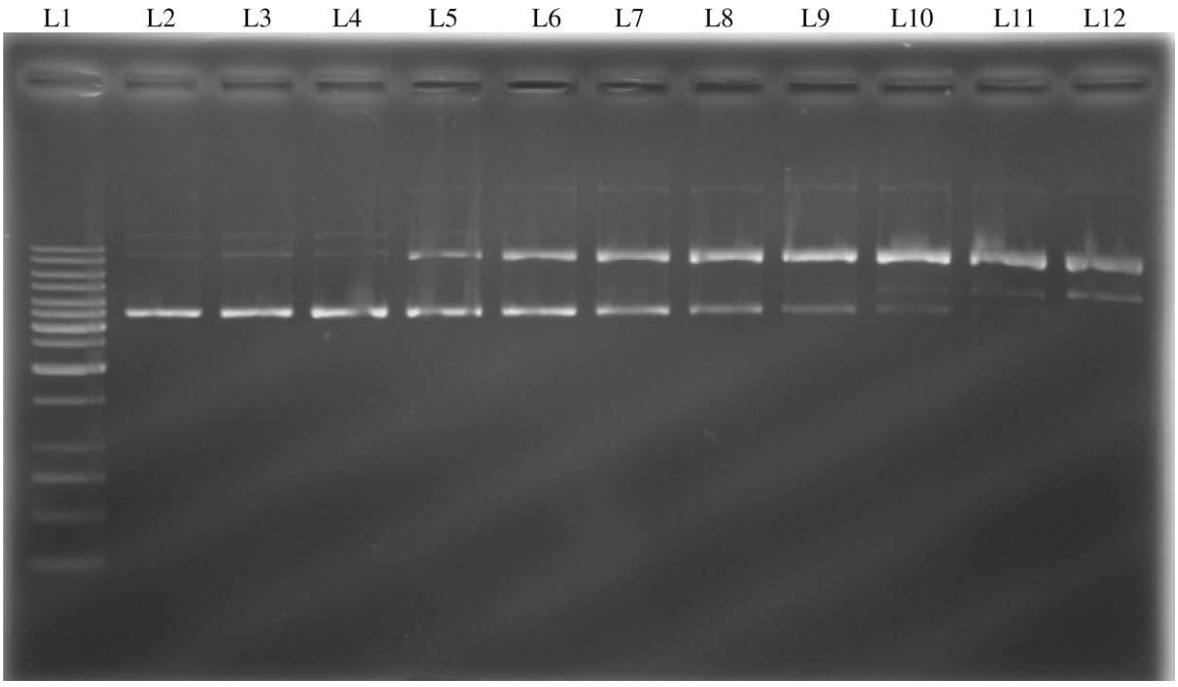

Fig. 6. Cleavage of supercoiled pBR322 by complex **1** at different concentrations in TN buffer pH 7.5. L1 Gene Ruler 1 kb DNA ladder, L2 DNA alone, L3 DNA + H_2O_2 alone, L4 DNA + 40 μM complex **1** alone (without H_2O_2). Lanes 5–12, DNA with increasing concentration of complex **1** + H_2O_2: lane 5, 5 μM; lane 6, 10 μM; lane 7, 15 μM; lane 8, 20 μM; lane 9, 25 μM; lane 10, 30 μM; lane 11, 35 μM; lane 12, 40 μM.

to $Cu^{I}Cu^{I}$ redox process [44–46]. Similar to complex **1**, complex **2** also exhibits two cathodic reduction peaks and two anodic oxidation peaks at −92, −291, −42 and 115 mV, while for complex **3**, the two cathodic reduction peaks and two anodic oxidation peaks can be observed at −77, −274, −26 and 120 mV. All complexes display a quasi-reversible redox behaviour, as judged from the anodic to cathodic peak separation value, ΔEp (=Epa − Epc); ΔEp of **1**–**3** for process $Cu^{II}Cu^{II}$ to $Cu^{II}Cu^{I}$ are 259, 207 and 197 mV, respectively, and ΔEp of **1**–**3** for process $Cu^{II}Cu^{I}$ to $Cu^{I}Cu^{I}$ are 250, 249 and 248 mV, respectively (ΔEp ⩽ 59 mV for reversible process). The $E_{1/2}$ redox potential, taken as the average of Epa and Epc, of **1**–**3** for process $Cu^{II}Cu^{II}$ to $Cu^{II}Cu^{I}$ are −130, −104 and −99 mV, respectively, while $E_{1/2}$ of **1**–**3** for process $Cu^{II}Cu^{I}$ to $Cu^{I}Cu^{I}$ are −179, −167 and −150 mV, respectively. The $E_{1/2}$ values of **1** are at a more negative potential compared to **2** and **3** indicating that **1** has a more stable Cu(II) state compared to **2** and **3**.

3.2. DNA cleavage studies

Fig. 6 shows the result of the plasmid pBR322 DNA cleavage reaction by using an increasing concentration of **1** in the presence of H_2O_2. Control experiments in lanes 3 and 4 show that neither with H_2O_2 alone nor with complex alone (40 μM) can result in any DNA cleavage. However, DNA cleavage can be induced by increasing complex concentration in the presence of H_2O_2, as shown in lanes 5–12, Fig. 6. In general, if scission occurs on one strand of the DNA, the supercoil (Form I) will relax to generate a slow moving open circular or nicked form (Form II) while if scission occurs on both strands, a linear form (Form III) that migrates in between Form I and Form II will be generated. At complex concentration as low as 5 μM (lane 5, Fig. 6), clear cleavage can be observed wherein a small amount of supercoil was converted to the nicked form. Further increases in the complex concentration from 10 to 40 μM (lanes 6–12, Fig. 6), builds up both the more intense band of nicked form and the less intense linear band and diminishes the supercoil band. Formation of the linear band implies that **1** is capable of inducing double strand scission. At 40 μM (lane 12, Fig. 6), the supercoil was completely cleaved. The requirement of H_2O_2 for DNA cleavage indicates an oxidative cleavage mechanism. Similar oxidative cleavage mechanisms have been reported by various Cu(II) complexes with different ligands [20,29,30,47–49]. In contrast, some Cu(II) complexes require a coreductant, such as ascorbate and mercaptoethanol to trigger oxidative DNA cleavage [15,50–53].

Fig. 7 shows the result of the plasmid pBR322 DNA cleavage by an increasing concentration of **2** in the presence of H_2O_2. Once again, no DNA cleavage is observed in the control lanes (lanes 3 and 4, Fig. 7), wherein pBR322 DNA was incubated with H_2O_2 alone or **2** alone. DNA cleavage by **2** occurs in the presence of H_2O_2 and cleavage can be seen at complex concentration as low as 5 μM (lane 5, Fig. 7). On increasing the complex concentration from 10 to 40 μM (lanes 6–12, Fig. 7), the nicked and linear bands build up and the supercoil band diminishes, indicating single and double strand scission. At 40 μM (lane 12, Fig. 7), the supercoiled form was completely cleaved. The necessity of H_2O_2 for DNA cleavage indicates oxidative cleavage. Complex **3** shows a similar DNA cleavage pattern observed in **1** and **2**, with total cleavage occurring at 40 μM.

From the DNA cleavage results of **1**–**3**, it is obvious that **1**–**3** are effective DNA cleavers comparable to other Cu(II) compounds already described in the literature [20,29,30,47–49]. All complexes exhibit similar DNA cleavage efficiency which means different functional groups attached to the benzene ring in **1** (Cl and NO_2), **2** (Cl and F) and **3** (Cl only) do not influence the DNA cleavage efficiency. In addition the DNA cleavage experiment of $CuCl_2$ in the presence of H_2O_2 was carried out and the results show that no DNA cleavage was observed up to 40 μM. This shows that chelation of the benzoate derivative ligands to Cu(II) can lead to the appearance of DNA cleavage activity. Interestingly, research papers on H_2O_2 oxidative DNA cleavage system of water soluble tetracarboxylatocopper(II) dimers with benzoate derivative ligands appear to be scarce.

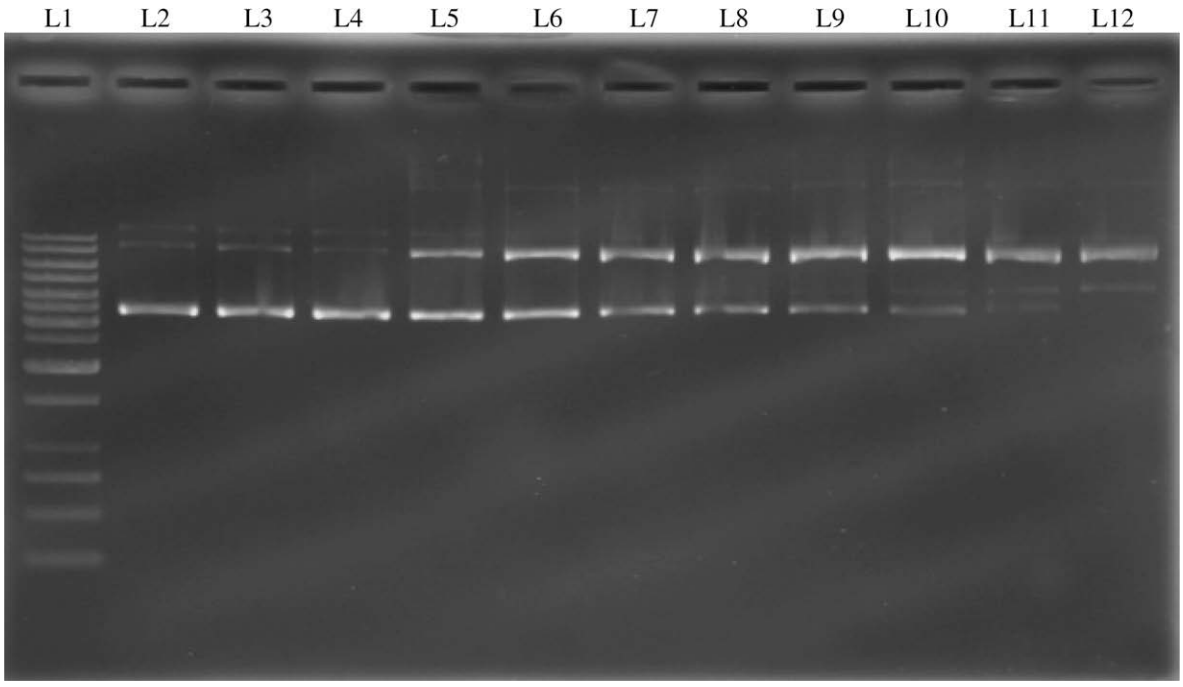

Fig. 7. Cleavage of supercoiled pBR322 by complex **2** at different concentrations in TN buffer pH 7.5. L1 Gene Ruler 1 kb DNA ladder, L2 DNA alone, L3 DNA + H_2O_2 alone, L4 DNA + 40 μM complex **2** alone (without H_2O_2). Lanes 5–12, DNA with increasing concentration of complex **2** + H_2O_2: lane 5, 5 μM; lane 6, 10 μM; lane 7, 15 μM; lane 8, 20 μM; lane 9, 25 μM; lane 10, 30 μM; lane 11, 35 μM; lane 12, 40 μM.

A mechanistic study on the DNA cleavage by **1** and **2** with various inhibiting agents such as *t*-butanol, mannitol, DMSO and NaN_3 has been carried out and the results are depicted in Figs. 8 and 9. The results reveal that hydroxyl radical inhibitors such as *t*-butanol and DMSO (lanes 4 and 6, Figs. 8 and 9) are able to quench the cleavage induced by both complexes to some degree. This suggests that the hydroxyl radical is the reactive oxygen species (ROS) that is involved in the mechanism. Several Cu(II) complexes such as bis(*N*,*N*′-dimethylglycinato)copper(II), bis[*N*-(*N*′-methylacetamido)-L-alaninato)copper(II) and Cu(II) chelated with 1,10-phenantroline-derived ligands have shown the same mechanism in the presence of H_2O_2 [19,29,30]. On the other hand, the cleavage reaction by both complexes are not inhibited by the singlet oxygen inhibitor NaN_3 (lanes 7–12, Figs. 8 and 9) but instead shows an

3.3. Cytotoxic studies

The antiproliferative activities of **1**–**3** on human cell lines have been evaluated by obtaining GI_{50}, TGI, and LC_{50} values as shown in Table 4. MCF-7, DU 145, HeLa, HepG2 and Chang cells were exposed to graded concentrations of **1**–**3** for 48 h. All the copper-containing complexes exhibit 50% growth inhibition (GI_{50}) in all cancer cell types at concentration <200 μg/ml. The data reveals an interesting finding in which **1**–**3** show the same selective trend against the cancer cell lines whereby they exhibit higher cytotoxic effect against HepG2 cancer cell lines (GI_{50} = 63–82 μg/ml) compared to MCF-7, DU 145, HeLa (GI_{50} = 140–180 μg/ml) cancer cell lines. Another interesting finding is that **1**–**3** show more than two-fold selective cytotoxicity against HepG2 human liver cancer cells compared to Chang human normal liver cells (GI_{50} = 178–>200 μg/ml). This finding is in contrast with the compound bis(phenanthroline)-4-methylcoumarin-6,7-dioxacetatocopper(II), $[Cu(4\text{-Mecdoa})(phen)_2]$ which shows selective cytotoxic effect against Chang human normal liver cells compared to HepG2 human liver cancer cells [54]. Furthermore, **1**–**3** have almost similar cytotoxic effect against Hela cells and **2**–**3** have slightly higher cytotoxic effect against MCF-7 and DU 145 cells compared to **1**. In HepG2 cells, all GI_{50}, TGI, and LC_{50} values of **1**–**3** can be obtained within the testing concentration range.

3.4. Antibacterial studies

The antibacterial screening of **1**–**3** have been carried out against nine pathogenic bacterial species using disc diffusion method and the results are presented in Table 5. Referring to Table 5, it is noted that **1**–**3** exhibit very selective antibacterial activity, being active against Gram negative *E.* aerogenes while inactive against other tested pathogenic bacteria. This finding is interesting because usually copper complexes which exhibit antibacterial activity against Gram *E.* aerogenes will also exhibit antibacterial activity against other bacteria. For example heterotrinuclear thiocyanato bridged Cu(II)–Hg(II)–Cu(II) complexes and valine-derived Schiff base copper(II) complexes not only show antibacterial activity against *E.* aerogenes but are also active against *Staphylococcus aureus, Escherichia coli, P. aeruginosa* and *Proteus vulgaris* [55,56]. This shows that the antibacterial activity of **1**–**3** is very selective within the testing concentration range. For comparison, **2** appears to be the most active complex against Gram negative bacteria *E.* aerogenes compared to **1** and **3**, as **2** has the widest inhibition zone and can exhibit antibacterial activity at the lowest concentration. Antibacterial tests of $CuCl_2$ against the nine pathogenic bacterial species have also been carried out. The results show that the $CuCl_2$ is inactive against all the tested pathogenic bacterial. From these results it may be inferred that the benzoate derivatives chelated to Cu(II) can induce the antibacterial activity against Gram negative bacteria *E. aerogenes*. The MIC experiments of **1**–**3** against the Gram negative bacteria *E.* aerogenes were further carried out and the results are presented in Table 6. The MIC results consistently show that **2** (MIC = 125 μg/ml) is the most active complex against *E.* aerogenes compared to **1** (MIC = 250 μg/ml) and **3** (MIC = 250 μg/ml). The MIC results of **1**–**3** against *E.* aerogenes show higher activity compared to some cobalt complexes [57] (see Tables 7–9).

4. Conclusion

Three water soluble dicopper(II) complexes, tetrakis(μ-4-chloro-2-nitrobenzoato-*O*,*O*′)bis[aquacopper(II)] (**1**), tetrakis(μ-2-chloro-6-fluorobenzoato-*O*,*O*′)bis[aquacopper(II)] (**2**) and tetrakis(μ-2-chloro-benzoato-*O*,*O*′)bis[aquacopper(II)] (**3**), have been synthesized. All the complexes have been tested for their nucleolytic, antiproliferation and antibacterial activity. For nucleolytic activity, all complexes can induce oxidative DNA cleavage in the presence of H_2O_2. Complexes **1**–**3** show good DNA cleavage ability comparable to other Cu(II) complexes described in the literature. Different functional group attached at the benzene ring in **1** (Cl and NO_2), **2** (Cl and F) and **3** (Cl only) do not influence the DNA cleavage efficiency. Hydroxyl radical is the reactive oxygen species that responsible for the cleavage reactions. In antiproliferation studies, all complexes show the same selective trend exhibiting higher cytotoxic effect against HepG2 cancer cell lines compared to MCF-7, DU 145 and HeLa cancer cell lines. It is interesting to note that **1**–**3** show more than twofold cytotoxic effect against HepG2 human liver cancer cells compared to Chang human normal liver cells, which means **1**–**3** are more potent against cancer cells than normal cells. The antibacterial activity of **1**–**3** exhibit a very selective trend whereby they are active against Gram −ve bacteria *E.* aerogenes while inactive against all other pathogenic bacteria. However, **2** appears to be the most active against the Gram negative bacteria *E.* aerogenes compared to **1** and **3**. The cleavage or fragmentation of DNA by the ROS generated by the complexes could be responsible for the antiproliferative activity exhibited by the complexes.

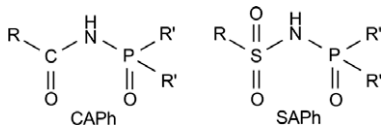

Chart 1. P, N-substituted analogues of β-diketones.

2. Experimental

2.1. Synthesis of H**L** (**1**)

The dimethyl(phenylsulfonyl)amidophosphate was prepared according to the early published procedures [19]. *Anal.* Calc. for $C_8H_{12}NO_5PS$ (M_r = 265.22): C, 36.23; H, 4.56; N, 5.28; S, 12.09. Found: C, 36.12; H, 4.39; N, 5.24; S, 12.1%. IR (KBr, cm^{-1}): 3000(s), 2745(m), 1455(m), 1410(s), 1320(vs), 1260(vs), 1185(vs), 1100(s), 1075(vs), 1060(vs), 955(vs), 885(m), 855(s), 780(s), 695(m), 605(m), 585(s), 535(s), 495(w), 435(w) cm^{-1}. M.p. 121 °C. ^{1}H NMR (DMSO): 3.57 (d, 6H, CH_3, $^3J_{P-H}$ = 12 Hz), 7.58 (m, β-H, 2H, C_6H_5), 7.65 (m, γ-H, 1H, C_6H_5), 7.91 (m, α-H, 2H, C_6H_5) ppm. ^{31}P NMR (DMSO): −2.17 (g, $^3J_{P-H}$=12 Hz) ppm.

2.2. Synthesis of [Cu(**L**)$_2$ · **o-bpe**]$_n$ (**2**)

A solution of H**L** (2 mmol) in isopropanol (10 ml) was mixed with isopropanol solution of sodium (2 mmol). To the resulting sodium salt the methanol solution of $Cu(NO_3)_2 \cdot 6H_2O$ (5 ml) (1 mmol) was added. After 20 min the precipitate of $NaNO_3$ was filtered off and was added to 10 ml of isopropanol solution of **o-bpe** (1 mmol). The resulting clear solution was left at ambient temperature for crystallization in air. The blue/green fine crystals were collected by filtration after 20 min, washed thoroughly with cool isopropanol and finally dried on filter. A well-formed crystal was used for the single X-ray structural analysis. Yield: 0.65 g (85%). *Anal.* Calc. for $C_{28}H_{32}N_4O_{10}P_2S_2Cu$ (M_r = 774.2): C, 43.44; H, 4.17; N, 7.24; S, 8.28. Found: C, 43.31; H, 4.08; N, 7.22; S, 8.49%. IR (KBr, cm^{-1}): 2965(w), 2865(w), 1610(w), 1575(w), 1485(m), 1455(m), 1255(s), 1230(vs), 1185(vs), 1075(s), 1040(vs), 940(w), 840(s), 790(m), 750(m), 740(m), 720(m), 700(m), 615(s), 580(m), 555(s), 510(w), 450(m) cm^{-1}. The compound **2** is soluble in MeOH, EtOH, DMSO and DMF.

2.3. Physical measurements

Elemental analysis (C, H, N and S) were performed using EL III Universal CHNOS Elemental Analyzer.

IR spectra were recorded as KBr pellets using UR-10 spectrometer in the 4000–400 cm^{-1} region using conventional techniques.

NMR spectra were obtained using Varian Mercury 400 NMR spectrometer at 25 °C. ^{1}H and ^{31}P spectra were recorded at 400 and 162.1 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ (^{1}H) and H_3PO_4 (^{31}P).

Electron paramagnetic resonance (EPR) spectra were recorded using CMS 8400 spectrometer at X-band frequency (9.38 GHz) at 298 and 77 K. The solid sample for EPR measurements was carefully pounded with pestle.

Variable-temperature magnetic susceptibility data (2–300 K) were acquired on a powdered sample with the use of a Quantum Design MPMS-5 SQUID magnetometer. Corrections for the diamagnetism of the ligand were applied using Pascal's constants [20].

2.4. X-ray structure determination and refinement

The crystals of **1** ($C_8H_{12}NO_5PS$) are orthorhombic. At 293 K a = 7.521(3), b = 8.174(3), c = 18.919(5) Å, V = 1163.09(7) Å^3, M_r = 265.22, Z = 4, space group $P2_12_12_1$, D_{calc} = 1.515 g/cm^3, μ (Mo Kα) = 0.421 mm^{-1}, $F(000)$ = 552. Intensities of 5011 reflections (3154 independent, R_{int} = 0.0198) were measured on the «Xcalibur-3» diffractometer (graphite monochromated Mo Kα radiation, CCD detector, ω-scaning, $2\Theta_{max}$ = 60°).

The crystals of **2** ($C_{28}H_{32}N_4O_{10}P_2S_2Cu$) are monoclinic. At 293 K a = 28.255(2), b = 7.764(6), c = 18.600(6) Å, β = 125.57(3)°; V = 3318.9(3) Å^3, M_r = 774.18, Z = 4, space group $C2/c$, D_{calc} = 1.549 g/cm^3, μ (Mo Kα) = 0.941 mm^{-1}, $F(000)$ = 1596. Intensities of 12 937 reflections (4628 independent, R_{int} = 0.028) were measured on the «Xcalibur-3» diffractometer (graphite monochromated Mo Kα radiation, CCD detector, ω-scaning, $2\Theta_{max}$ = 60°).

The structures were solved by direct method using SHELXTL package [21]. Positions of the hydrogen atoms were located from electron density difference maps and refined by "riding" model with $U_{iso} = nU_{eq}$ of the carrier atom (n = 1.5 for methyl group and n = 1.2 for other hydrogen atoms).

Full-matrix least-squares refinement of the structures against F^2 in anisotropic approximation for non-hydrogen atoms using 3108 (**1**) and 4594 (**2**) reflections was converged to: wR_2 = 0.073 (R_1 = 0.032 for 2500 reflections with $F > 4\sigma(F)$, S = 0.928) for structure **1** and wR_2 = 0.105 (R_1 = 0.040 for 3404 reflections with $F > 4\sigma(F)$, S = 1.028) for structure **2**.

3. Results and discussion

3.1. Synthesis and spectroscopic characterization

Sodium salt Na**L** was obtained by the reaction of *i*-PrONa with *i*-PrOH solution of H**L**. Cu(**L**)$_2$ was prepared by the reaction of Na**L** with $Cu(NO_3)_2$ in alcohol solution. The presence of unsaturated coordination sphere of copper ion in Cu(**L**)$_2$ can be used for obtaining a wide number of mix-ligand compounds by interaction of Cu(**L**)$_2$ with various donor agents. In our work we used **o-bpe** as the bidentate bridging ligand. The reaction of Cu(**L**)$_2$ with an equimolar amount of **o-bpe** in *i*-PrOH leads to the formation of polymeric complex with the general formula [Cu(**L**)$_2$ · **o-bpe**]$_n$ (**2**). Syntheses of all compounds were carried out in air.

The vibration of the amide group ν(N–H) in IR spectra of H**L** appears in the region of 2800–3200 cm^{-1} with the maxima at 3000 cm^{-1}. This band absents in the spectra of Na**L** and [Cu(**L**)$_2$ · **o-bpe**]$_n$, which can be consequence of the ligand's coordination in deprotonated form (**L**$^-$). Two sharp bands which are observed in the spectrum of free ligand with maxima at 1260 and 1320 cm^{-1} are assigned to ν(PO) and ν(SO) vibrations [22]. In the spectra of sodium salt and **2** these bands are shifted to lower frequencies (1185, 1230 and 1250 cm^{-1} for Na**L**, 1180, 1230 and 1250 cm^{-1} for **2**) that can be explained by coordination to the metal ion. The analysis of IR spectra suggests a bidentate coordination of the anionic form **L**$^-$ *via* the oxygen atoms of phosphoryl and sulfonyl groups.

3.2. Crystal structure of **1**

White needle-shaped crystals of H**L** were grown over a period of 5 days from the *i*-PrOH–hexane solution. The molecular structure and the numbering scheme of **1** and crystal packing diagram are shown in Fig. 1, selected bond lengths and angles are listed in Table 1.

Thus as CAPh, namely $CCl_3C(O)NHP(O)(OCH_3)_2$ [23], the geometry around the phosphorus atom in H**L** (**1**) can be described as a distorted tetrahedron. The P(1)–O(3) and P(1)–N(1) bond lengths for **1** have values 1.456(1) and 1.662(2) Å, which are typical for CAPh with ether-type substituents [23–25]. The S(1)–O(1) (1.418(2) Å), S(1)–O(2) (1.428(2) Å) and S(1)–N(1) (1.642(2) Å)

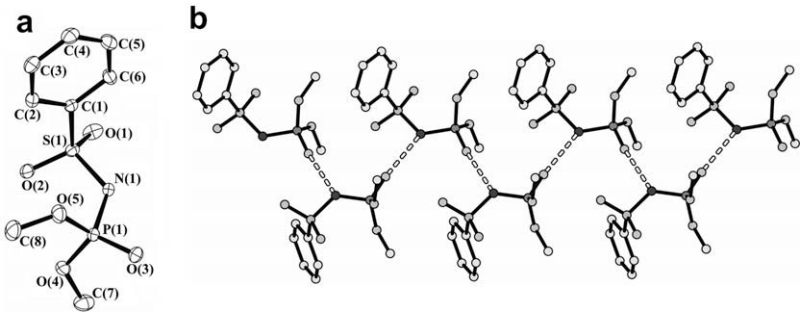

Fig. 1. Structural representation of **1** (a) with atom numbering scheme and 30% probability thermal ellipsoids, and fragments of the crystal packing in the structure of **1** (b). The hydrogen atoms are omitted for clarity. Hydrogen bonds are indicated by dashed lines.

Table 1
Selected geometrical parameters (distances (Å) and angles (°)) for **1**.

P(1)–O(3)	1.456(1)	S(1)–O(2)	1.428(1)
P(1)–O(4)	1.550(1)	S(1)–N(1)	1.642(2)
P(1)–O(5)	1.548(2)	S(1)–C(1)	1.760(2)
P(1)–N(1)	1.662(2)	O(4)–C(7)	1.426(3)
S(1)–O(1)	1.418(2)	O(5)–C(8)	1.433(3)
O(3)–P(1)–O(4)	115.6(1)	O(2)–S(1)–N(1)	107.4(1)
O(3)–P(1)–O(5)	116.0(1)	O(1)–S(1)–C(1)	108.0(1)
O(4)–P(1)–O(5)	103.7(1)	O(2)–S(1)–C(1)	108.7(1)
O(3)–P(1)–N(1)	108.1(1)	N(1)–S(1)–C(1)	105.6(1)
O(4)–P(1)–N(1)	108.4(1)	C(7)–O(4)–P(1)	120.9(1)
O(5)–P(1)–N(1)	104.4(1)	C(8)–O(5)–P(1)	127.7(2)
O(1)–S(1)–O(2)	119.7(1)	S(1)–N(1)–P(1)	125.1(1)
O(1)–S(1)–N(1)	106.6(1)		

bond lengths values depend on the substituent near the sulfur atom and have the typical values for sulfonylamide derivatives [26].

The values of the O–P–N bond angles are 108.4(1)°, 104.4(1)° and 108.1(1)° for the O(4)–P(1)–N(1), O(5)–P(1)–N(1) and O(3)–P(1)–N(1), respectively. It was early published that the presence of small substituents at phosphorus atom possesses a weak effect on the value of the O–P–N angle which falls in the range 107.5–108.9° [27]. Due to the steric effects the O(3)–P(1)–O(4) and O(3)–P(1)–O(5) angles are 115.6(1)° and 116.0(1)°, respectively, which are usually more than those in the ideal tetrahedron. The sulfur atom in the sulfonyl group has a distorted tetrahedral environment too (Table 1).

The O(2) and O(3) oxygen atoms of sulfonyl and phosphoryl groups are located in *anti*-positions to each other similar to most of CAPh [27]. The P═O bond adopts conformation with respect to the N(1)–S(1) bond, O(3)–P(1)–N(1)–S(1) fragment is practically planar (the torsion angle is −167.0(1)°). The deviations of the O(1) and O(2) from the P(1)–N(1)–S(1) plane are 0.583 and 0.579 Å, respectively.

In the crystal packing molecules of **1** are linked to each other by intermolecular hydrogen bonds where amide nitrogen atom of one molecule acts as donor and oxygen atom of phosphoryl group of neighboring molecule acts as acceptor (H···O′ 1.96 Å, N–H···O′ 170°) and form the infinite zigzag chains along [1 0 0] crystallographic direction. Neighboring chains are connected by the C(7)–H(7A)···π′ ($x-1, y-1, z$) hydrogen bonds (H···C′ 2.84 Å, C–H···π′ 153°).

3.3. Crystal structure of *2*

The molecular structure of **2** is shown in Fig. 2 (H atoms are omitted for clarity); selected bond distances and angles are presented in Table 2. The compound has 1D polymer chain structure along [0 1 0] crystallographic direction and consists of Cu(**L**)$_2$ units bridged by **o-bpe** ligands. Two sulfamide ligands are coordinated to metal ion in *trans*-positions because of the presence of steric effects concerning to the asymmetric (chiral) feature of coordinated SO-group. The Cu(1) atom is located in the special position in the center of symmetry. The coordination environment of Cu(II) ion can be described as a distorted square-bipyramidal polyhedron (4 + 2). The CuO_4N_2 chromophore is constructed from two pyridyl nitrogen atoms from two **o-bpe** linkers and four oxygen atoms of phosphoryl and sulfonyl groups from two ligands which are coordinated in bidentate chelate mode forming with central ion six-membered chelate rings. The Cu–O and Cu–N bond distances and O–Cu–O′, O–Cu–N, N–Cu–N′ angles (Table 2) are typical for square-bipyramidal copper complexes with clear presence of

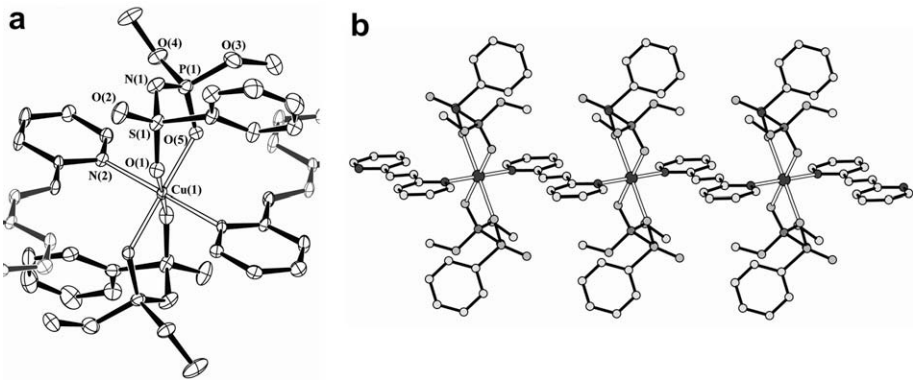

Fig. 2. Structural representation of **2** (a) with atom numbering scheme and 20% probability thermal ellipsoids, and fragments of the crystal packing in the structure of **2** (b). The hydrogen atoms are omitted for clarity.

O(1)–S(1)–N(1)	109.6(1)	C(9)–N(2)–Cu(1)	115.6(1)
O(2)–S(1)–C(1)	106.0(1)	C(13)–N(2)–Cu(1)	125.7(1)
O(1)–S(1)–C(1)	106.9(1)	S(1)–N(1)–P(1)	126.4(1)

Symmetry transformations used to generate equivalent atoms: (#1) <$-x+1/2, -y+1/2, -z+1$>.

Jahn–Teller distortion. The Cu–O(S), Cu–O(P) and Cu–N bond values are 2.588(2), 1.950(1) and 2.053(2) Å, respectively. The six-membered chelate ring adopts a twist-boat conformation (the puckering parameters are $S = 0.67$, $\theta = 86.32$, $\psi = 17.43$) [28]. The deviations of the N(1) and Cu(1) atoms from the O(1)–S(1)–P(1)–O(5) mean plane are 0.40 and 0.74 Å, respectively. The chelate angles values fall in the range 82.5(6)–99.3(6)° which are typical for Cu(II) complexes with octahedral coordination.

The amide nitrogen atom of ligand is deprotonated that leads to the decrease of the S(1)–N(1) and N(1)–P(1) bond length values (Table 2) in comparison with the same values for neutral ligand (structure **1**). In spite of the deprotonation of amide group the O–P–N–S–O backbone is not flat. The P(1)–O(3) and S(1)–O(2) bond values are elongated due to the coordination, the conformation of the O–P–N–S–O fragment is changed owing to the turn of the phosphoryl group relatively the N(1)–S(1) bond (the O(3)–P(1)–N(1)–S(1) is −35.1(2)°).

In the crystal packing neighboring polymer chains are connected by the C(11)–H(11)···π′ ($x, 1-y, z-0.5$) weak hydrogen bonds (H···C′ 2.85 Å, C–H···π′ 130°) and form layers which are parallel to *OYZ* plane. The **o-bpe** ligands are coordinated to the 3d-metals forming *trans*-isomers of complexes which are typical for the ligands of this type [29]. The Cu···Cu′ separations in chain are 7.75 Å.

3.4. EPR studies and magnetochemistry

The X-band EPR spectrum of a solid sample of **2** at 77 K shows the presence of elongated axial symmetry signal with not resolved hyperfine structure (Fig. 3a). The values of anisotropic parameters of the spectrum are $g_{\|} = 2.365$, $g_{\perp} = 2.095$, which are typical for copper(II) ions with $d_{x^2-y^2}$ ground state. The "half-field" signal is not observed which can be suggested as the absence of magnetic exchange interaction between copper(II) ions or the value of it is very weak.

The EPR spectrum of frozen diluted solution at 77 K (Fig. 3b) is not similar to that observed in the solid state with the presence of hyperfine splitting in the parallel orientation region. The values of parameters are $g_{\|} = 2.450$, $g_{\perp} = 2.105$ and $A_{\|} = 126 \cdot 10^{-4}\ cm^{-1}$ which are typical for CuO_6 octahedral coordination environment [30]. Such behavior can be explained by dissociation of polymeric

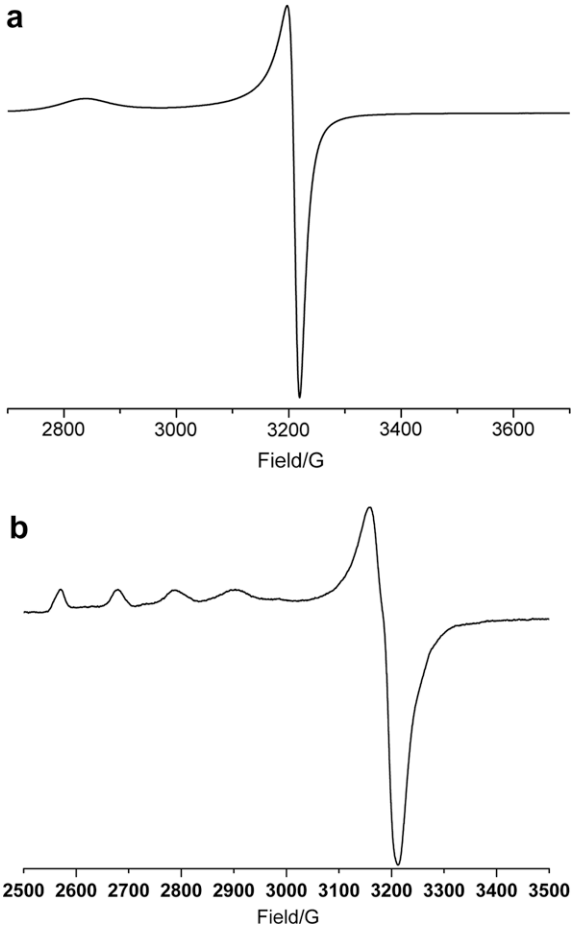

Fig. 3. X-band EPR spectra of compound **2**: (a) solid **2** at 77 K and (b) frozen $CHCl_3$/CH_3OH (1:1, v/v) solution of **2** at 77 K.

complexes in solution and ligand exchange (**o-bpe** molecules to solvent alcohol molecules).

Variable-temperature magnetic susceptibility studies for compound **2** were carried out over the temperature range 2–295 K. The magnetic moment of **2** at room temperature was 1.94μ_B (corresponds to $\chi_M T$ of 0.467 $cm^{-3}\ K\ mol^{-1}$) which is a typical value for copper(II) and slightly greater than the expected spin-only value.

The susceptibility (χ_M) of **2** showed steady increase upon cooling, without maximum (□ in Fig. 4). The plot of $\chi_M T$ (per mole) versus temperature (● in Fig. 4) shows that $\chi_M T$ first negligible decreased from 0.467 $cm^{-3}\ K\ mol^{-1}$ at 295 K to 0.439 $cm^{-3}\ K\ mol^{-1}$ at 10 K (1.94μ_B and 1.88μ_B, respectively), then sharply decreased to 0.404 $cm^{-3}\ K\ mol^{-1}$ at 2 K (1.80μ_B). This is clearly indicative the presence of week antiferromagnetic behavior within the chain. A simulation of these data was based on the Hamiltonian (Eq. (1)) and derived by Bonner and Fisher for infinite chain model with magnetically identical $S = ½$ metal centers (Eq. (2)) [31]:

$$\hat{H} = -J\left(\sum \hat{\mathbf{S}}_i \cdot \hat{\mathbf{S}}_{i+1}\right) \tag{1}$$

$$\chi' = \left(\frac{Ng^2\beta^2}{kT}\right)\left(\frac{0.25 + 0.074975\left(\frac{|J|}{kT}\right) + 0.075235\left(\frac{|J|}{kT}\right)^2}{1 + 0.9931\left(\frac{|J|}{kT}\right) + 0.172135\left(\frac{|J|}{kT}\right)^2 + 0.757825\left(\frac{|J|}{kT}\right)^3}\right) \tag{2}$$

In Eq. (2) J, N, g, β and k have their usual meanings. However, the presence of unlinked copper ions and/or short odd-numbered

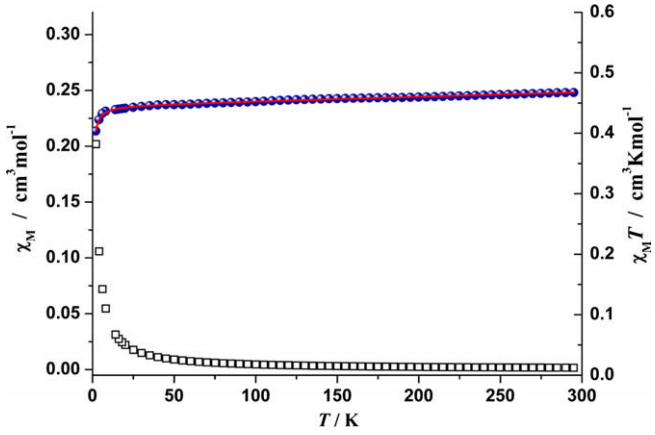

Fig. 4. Plot of χ_M and $\chi_M T$ vs. T for **2**; the solid line represents the simulated curve.

chains was taken into account; the experimental $\chi_M T$ of **2** was fitted using the Eq. (3) in which ρ – the fraction of paramagnetic impurity. Temperature independent paramagnetism (P_{TI}) was also added in calculations:

$$\chi = (1-\rho)\chi' + \frac{Ng^2\beta^2}{4kT}\rho + P_{TI} \quad (3)$$

The best fit calculated for **2** gave the following parameter values: $g = 2.180(1)$, $J = -0.21(1)\,cm^{-1}$, $\rho = 0\%$, $P_{TI} = 74(1)\cdot 10^{-6}$ $cm^3\,mol^{-1}$, $R = 1.49\cdot 10^{-3}$, where $R = [\sum(X_{obs} - X_{calc})^2/\sum X^2_{calc}]^{1/2}$. The small negative value of J confirms the presence of weak predominant antiferromagnetic coupling within the chain. The small decreasing in $\chi_M T$ in the 10–300 K temperature range can be explained by existence of temperature independent paramagnetism. The obtaining value of isotropic g-factor is close to those calculated from EPR spectrum as g_{av} (Eq. (4)):

$$g_{av} = \frac{(g_{\parallel} + 2g_{\perp})}{3} \quad (4)$$

However, the Cu···Cu′ distance in chain is sizeable enough the exchange interaction between copper(II) ions are mediated by the system of conjugated C=C bonds of **o-bpe**. The value of J cannot be compared because there is only one record concerning using **o-bpe** for bridging copper(I) [31] and no records for copper(II) ions reported to date.

4. Conclusion

The paper is devoted to coordination chemistry of sulfonyl phosphoramide ligands and their complex with copper(II). The new copper(II) complex containing deprotonated sulfamide ligands and **o-bpe** as bridging ligand has been obtained. The X-ray crystal structures for H**L** and $[Cu(\mathbf{L})_2\cdot\mathbf{o\text{-}bpe}]_n$ have been determined. In contrast to fully characterized CAPh ligands, which usually form dimer structure by means of hydrogen bonds, the molecules of **1** form a hydrogen bonded chain in which they are linked to each other due to identical (P)O···H–N contacts. The compound **2** has 1D polymeric chain structure. The magnetic study of **2** shows the presence of weak intrachain antiferromagnetic exchange interaction between copper(II) ions.

Supplementary data

CCDC 710779 and 710780 contains the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge *via* http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

the reaction. Hence, it is very likely that the mechanism of the OsO_4-catalysed oxidation of any given substrate by $Fe(CN)_6^{3-}$ may prove identical with the mechanism of the oxidation of the same substrate with OsO_4. However, the results of the study of the OsO_4-catalysed oxidation of HPO_3^{2-} by $Fe(CN)_6^{3-}$ [10] and that by OsO_4 [30] did not prove so. The OsO_4-catalysed study did not provide evidence for complex formation between OsO_4 and HPO_3^{2-} ion. The OH^- ion increased the rate which reached a saturation value in the OsO_4-catalysed study [10] whereas the rate decreased with increasing OH^- ion in the OsO_4 oxidation study [30].

It was, therefore, decided to investigate the kinetics of oxidation of $H_2PO_2^-$ and $C_6H_5HPO_2^-$ ions by OsO_4 to compare it with the OsO_4-catalysed oxidation by $Fe(CN)_6^{3-}$ ion [11] and that of HPO_3^{2-} by alkaline OsO_4 [30]. The results described in this paper are identical with those observed in the OsO_4-catalysed oxidation by $Fe(CN)_6^{3-}$ ion [11].

2. Experimental

2.1. Material

Sodium hypophosphite (M.B., AnalaR) is analysed for phosphite ion by published method [31]. It is found that the concentration of HPO_3^{2-} ion <0.1% is present in the sample. The freshly prepared aqueous solution is standardised against a known Ce(IV) solution [32]. Thereafter the solutions are freshly prepared by the dissolution of the required weight of the sample in a known NaOH solution for each set of the experiments. Phenylphosphinic acid (Fluka, Technical) is crystallised twice from hot water. The m.p. of the recrystallised sample is 70–71 °C (lit. 71 °C [33]). The sample is standardised against Ce(IV). The experimental solution is prepared by neutralisation and dilution with a known NaOH solution.

The 50 wt% solution of D_3PO_2 (Aldrich) is used as received. It is suitably diluted in D_2O (99.8 at%, BARC Trombay). The solution is standardised by cerimetry [32]. The experimental solution is prepared by neutralisation and dilution with a known NaOH solution prepared in D_2O just before the start of the rate measurement to avoid any exchange during the course of the experiments.

NaOH (Sarabhai-M, GR) solution is freshly prepared and standardised against a standard potassium hydrogen phthalate (BDH, AnalaR) solution. Solutions of KCl and NaCl (BDH, AnalaR), used for adjusting the ionic strength of the reaction mixtures, are prepared by weighing the respective samples.

The OsO_4 solution is prepared by dissolution of the weighed sample (Johnson Matthey) in 0.1 mol dm^{-3} NaOH and stored in the refrigerator. The solution is standardised by iodometry [10] and spectrophotometrically ($\varepsilon_{316} = 500\ dm^3\ mol^{-1}\ cm^{-1}$) [28]. Suitable dilutions are carried out with standard NaOH solutions as and when needed.

The water is first distilled under mild alkaline conditions using a pinch of potassium permanganate. The first distillate is once again distilled and the second distillate is used for the preparation of the solutions. These solutions, if needed, are purged with nitrogen gas before use.

2.2. Stoichiometry

Several reaction mixtures with different concentration ratios of $RHPO_2^-$ and OsO_4 are prepared at different $[OH^-]$. The OsO_4 is always in excess. The corresponding blanks are also prepared. The optical density of the unreacted OsO_4 in the reaction mixtures is measured at different intervals of time on a HP 8452A diode array spectrophotometer having a band-width of 2 nm and an integration time of 1 s till a constant value is obtained at 320 nm. The blank solutions are similarly treated. The results indicated that mean $\Delta[OsO_4]/\Delta[RHPO_2] = 1 \pm 0.1$. The oxidation product HPO_3^{2-} is identified by TLC [34], $R_f = 0.76$ (lit. value 0.75 [22]). The stoichiometric equation (1) is supported by the quantitative estimation of HPO_3^{2-} [31]. The species OsO_4OH^- is the considered reactive OsO_4 species. The formation of Os(VI) in the reaction mixture is

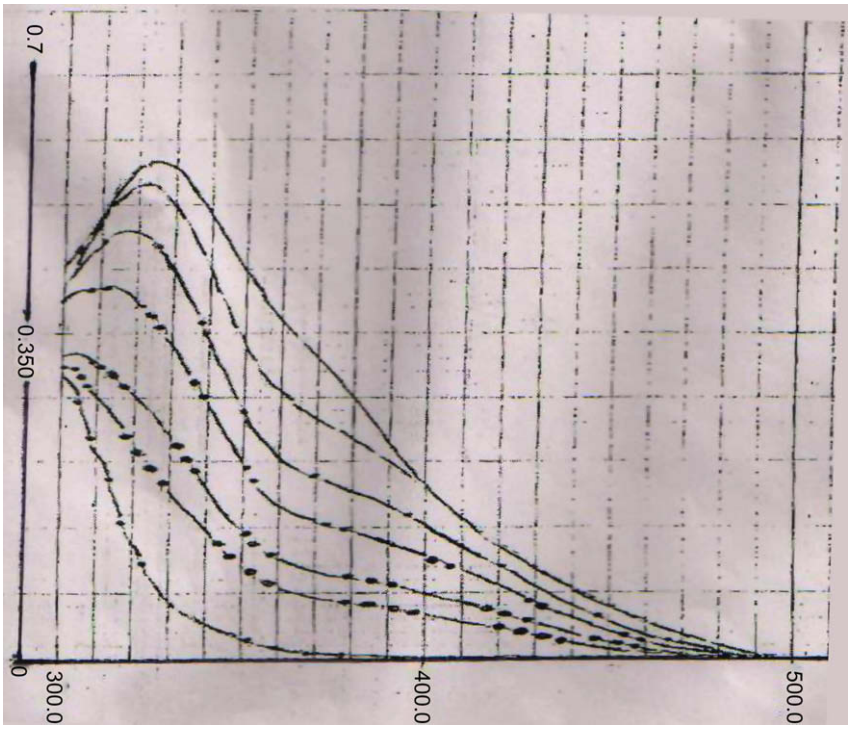

Fig. 1. The spectra of $10^4[OsO_4] = 3.24$ mol dm^{-3} between 300 and 500 nm in $[OH^-] = 0.001$ (---), 0.005 (·····), 0.01 (-·-·-), 0.02 (-··-), 0.05 (-×-) and 0.5 (- - - -) and 2.0 (—) mol dm^{-3} at room temperature.

confirmed by the matching spectra of the spent reaction mixture and that of K_2OsO_4 (Johnson Matthey) in solution of the same alkalinity:

$$OsO_4OH^- + RHPO_2^- \rightarrow OsO_3 + RPO_3^{2-} + H_2O \quad (1)$$

2.3. Spectra of OsO_4 in NaOH

The spectra of $10^4[OsO_4] = 3.24$ mol dm^{-3} in varying [NaOH] solutions is recorded between 300 and 500 nm on a Shimadzu spectrophotometer. The spectra, Fig. 1, show increasing optical densities with the increasing NaOH concentrations. The first and second spectra from bottom corresponding to NaOH = 0.001 and 0.005 mol dm^{-3} have no peaks. The peak starts appearing in the third and fourth spectra from bottom for NaOH = 0.01 and 0.02 mol dm^{-3} and is well defined in the fifth, sixth, and seventh spectra for NaOH = 0.05, 0.5 and 2 mol dm^{-3}. The peaks are slightly red-shifted from 320 nm with increasing [NaOH] which is inconsistent with the observation that alkaline OsO_4 solutions absorb strongly at 316 nm ($\varepsilon_{316} = 500$ dm^3 mol^{-1} cm^{-1}) [35]. The red shift in the peak and increasing ε value with the λ_{max}, $10^{-3}\varepsilon(\lambda_{max}) = 1.43(316)$, 1.58(322) and 1.66(325) at [NaOH] = 0.05, 0.5 and 2.0 mol dm^{-3}, respectively, is consistent with OsO_4 solutions showing a darker hue with increasing alkali concentration.

2.4. Rapid scan of the reaction mixture

The rapid scan spectra of the reaction mixture ($10^4[OsO_4] = 6.0$, $10^3[H_2PO_2^-] = 3.0$ and [NaOH] = 0.1 mol dm^{-3}, and the blank (in the absence of $H_2PO_2^-$) are recorded on an Union-Giken RA-401 stopped-flow spectrophotometer with RA-415 rapid scan attachment. Water is used as the reference and 350 nm is selected as the central wavelength so that the spectral span of the spectra was over 302–398 nm. The gate time (time required for the scan over 96 nm) is 100 ms and interval time (time between two successive scans) is zero. The lower peak in the rapid scan, Fig. 2, is for the OsO_4 solution at 314 nm and the upper peak, which has the higher optical density at 312 nm, is for the reaction mixture. This indicated the likely formation of some newer species probably a complex formed by reactive OsO_4 species and $H_2PO_2^-$ ion. A similar scan was obtained for the reaction of $C_6H_5HPO_2^-$ ion. The height of the peak in case of $C_6H_5HPO_2^-$ happens to be higher than in the case of $H_2PO_2^-$ of the same concentration.

2.5. Spectra of OsO_4 in presence of Cl^- ions

A similar set up as described above is used to study the OsO_4 spectra in presence of Cl^- ions. The spectra of $10^4[OsO_4] = 3$ mol dm^{-3} in 0.1 mol dm^{-3} [NaOH] in presence of Cl^- ions (3.0×10^{-5}–6.0×10^{-3} mol dm^{-3}) does not show any change in λ_{max} indicating that OsO_4 and Cl^- ions do not form any new species.

2.6. Rate measurements

The rates are measured under pseudo-first-order conditions ($[RHPO_2^-] \gg [OsO_4]$) on Union-Giken RA-401 stopped-flow spectrophotometer hooked to a microcomputer which controls the complete operation of the instrument including data acquisition and calculation of the rate constant. The appropriately prepared solutions of OsO_4 and $RHPO_2^-$ at an ionic strength = 1.0 mol dm^{-3} (NaCl) are stored under nitrogen atmosphere in two separate reservoirs that are maintained at the desired temperature (±0.1 °C) by circulating water from a Haake D8G refrigerated circulatory water bath. The rates are measured at 320 nm (disappearance of OsO_4). A total of seven to ten replicate runs for each set of the experiment are studied. The pseudo-first-order rate k_{obs} (s^{-1}) are calculated from the individual runs and the averaged run that are stored in the memory. The two values agreed within ±3%. The k_{obs} values obtained from the averaged runs are reported in the tables.

It is assumed that HPO_3^{2-} ions present as impurity in the $H_2PO_2^-$ sample do not affect the k_{obs} values because the reaction between OsO_4 and HPO_3^{2-} ions is relatively much slower ($10^3 k_{obs} = 4.0$ at 50 °C, $10^4[OsO_4] = 5.0$, $10^3[HPO_3^{2-}] = 5.0$, $[OH^-] = 0.2$ and $\mu = 2.5$ mol dm^{-3} [30]) than the rate of reaction between OsO_4 and $H_2PO_2^-$ ion. The kinetics is studied at temperatures lower than 50 °C because $H_2PO_2^-$ solution undergoes oxidation at high temperatures (50–90 °C) for which the rate law is $-d[H_2PO_2^-]/dt = k[H_2PO_2^-]$ [36].

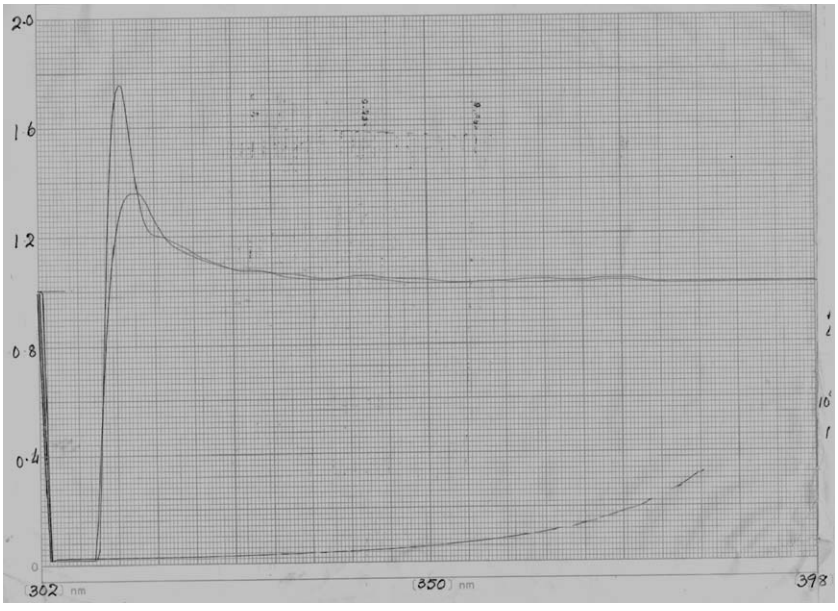

Fig. 2. The rapid scan spectra of the reaction mixture ($10^4[OsO_4] = 6.0$, $10^3[H_2PO_2^-] = 3.0$ and [NaOH] = 0.1 mol dm^{-3}) and the blank ($H_2PO_2^-$ is absent). Water is used as the reference. The gate time (time required for the scan over 96 nm) is 100 ms and interval time (time between two successive scans) is zero. The lower peak is for the blank OsO_4 solution and the upper peak is for the reaction mixture.

Table 1
Dependence of k_{obs} on the initial [OsO_4] at 25 °C. [$RHPO_2^-$] = 0.1, [OH^-] = 0.5 and μ = 1.0 mol dm^{-3}.

	10^3[OsO_4] (mol dm^{-3})							
Substrate	0.3 k_{obs} (s^{-1})	0.6	0.8	1.2	1.6	2.4	3.2	Mean
$H_2PO_2^-$	0.0928	0.0932	0.0917	0.0926	0.0922	0.0928	0.0925	0.0925 ± 0.0005
$C_6H_5HPO_2^-$	0.0602	0.0598	0.0598	0.0604	0.0594	0.0602	0.0590	0.0598 ± 0.0005

3. Results

The first-order dependence in OsO_4 is indicated by the linearity of the log(optical density) against time generated by the computer program from the stored data for the disappearance of OsO_4. The same is confirmed further by studying the k_{obs} values over 10^{-3}[OsO_4] = 0.4–4.2 mol dm^{-3}. The k_{obs} values, Table 1, are independent of the initial OsO_4 concentration. It is further noted that the k_{obs} value for $H_2PO_2^-$ is almost two times the value obtained in the oxidation of $C_6H_5HPO_2^-$ ion. The effect of $RHPO_2^-$, Table 2, indicated that k_{obs} do not increase in the same proportion as the concentration of $RHPO_2^-$ is increased. It is further noted that k_{obs} values are higher for $H_2PO_2^-$ oxidation compared to the k_{obs} values for $C_6H_5HPO_2^-$ oxidation for the same concentration. An analysis of the results indicated that the plots of k_{obs}^{-1} against $[RHPO_2^-]^{-1}$, Fig. 3, were linear with intercepts on the rate ordinates. This behaviour is similar to that observed in the earlier study on OsO_4-catalysed oxidation of $RHPO_2^-$ by $Fe(CN)_6^{3-}$ ion [11]. Hence empirical rate law of the reaction is given by Eq. (2).

Table 2
Dependence of k_{obs} on the initial [$RHPO_2^-$] at different temperatures. 10^3[OsO_4] = 1.6, [OH^-] = 0.5 and μ = 1.0 mol dm^{-3}.

10^2k_{obs} (s^{-1}, M = Na)	2.74	3.16	3.68	4.19	4.34	4.41
10^2k_{obs} (s^{-1}, M = K)	2.77	3.12	3.65	4.21	4.31	4.44

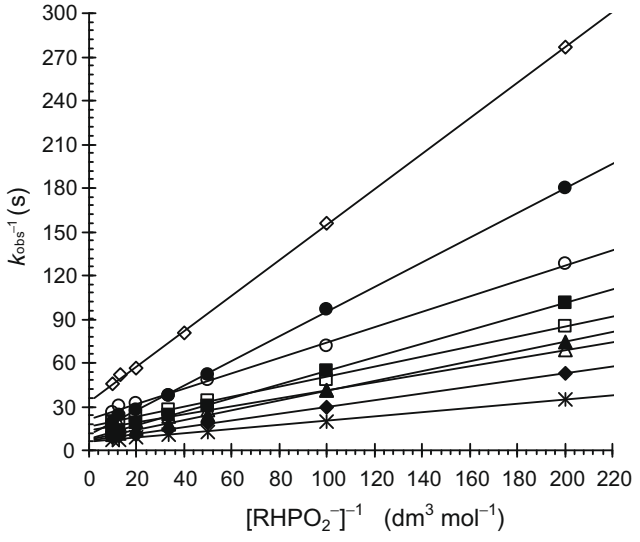

Fig. 3. The plots are between k_{obs}^{-1} and $[RHPO_2^-]^{-1}$ at 10 (●), 20 (■), 25 (▲), 30 (♦) and 40 °C (∗) for $H_2PO_2^-$, 10 (○), 20 (□) and 25 (△) for $C_6H_5HPO_2^-$ and (◇) for $D_2PO_2^-$ at 25 °C. The plots corresponding to 30 and 40 °C for $C_6H_5HPO_2^-$ are excluded for clarity. (10^3[Os(VIII)] = 1.6, [OH^-] = 0.5 and μ = 1.0 mol dm^{-3}).

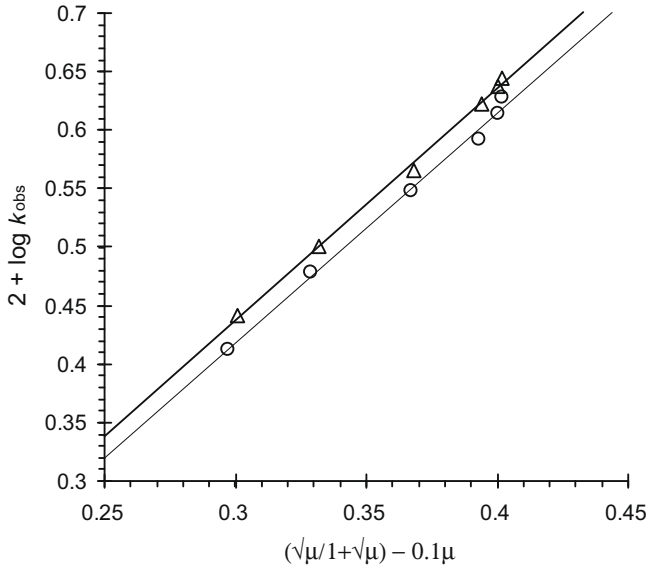

Fig. 4. The plot between log k_{obs} and $\sqrt{\mu}/(1+\sqrt{\mu}) - 0.1\mu$ for $H_2PO_2^-$ (○) and $C_6H_5HPO_2^-$ (△) at 25 °C and 10^3[Os(VIII)] = 1.6, [OH^-] = 0.1, [$H_2PO_2^-$] = 0.02 and [$C_6H_5HPO_2^-$] mol dm^{-3}.

Table 5
Dependence of k_{obs} on the initial $[D_2PO_2^-]$ at 25 °C. $10^3[Os(VIII)] = 1.6$, $[OH^-] = 0.5$ and $\mu = 1.0$ mol dm^{-3}.

$10^2[D_2PO_2^-]$ (mol dm^{-3})	0.5	1.0	2.5	5.0	7.50	10.0
10^2k_{obs} (s^{-1})	0.361	0.641	1.24	1.76	1.93	2.18

The effect of OH^- on the k_{obs}, Table 3, indicated that the k_{obs} is independent of $[OH^-]$. The result is similar to the observation in the earlier study in which one component of the rate is independent of OH^- concentrations [11]. The component dependent on the OH^- concentrations is missed in the present investigation because of the slow nature of the reaction on the stopped-flow scale:

$$k_{obs} = \frac{a[RHPO_2^-]}{1 + b[RHPO_2^-]} \quad (2)$$

The rate increased with the increase in the ionic strength, Table 4, though the k_{obs} had almost the same value in the presence of NaCl and KCl of similar concentrations. This indicated that the reaction does not show specific ion effect. The plot of log k_{obs} against $(\sqrt{\mu}/(1+\sqrt{\mu}) - 0.1\mu)$ is linear, Fig. 4, and consistent with the Davies equation (3) [37]. The slope of the plots for $H_2PO_2^-$ and $C_6H_5HPO_2^-$ oxidations are 1.97 and 2.01, respectively, which is consistent with the disproportionation of the intermediate complex $[OsO_4(OH)\ RHPO_2]^{2-}$ bearing a total charge of two:

$$\log k_{obs} = z_a z_b \left(\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.1\mu\right) + C \quad (3)$$

The rates measured with $D_2PO_2^-$, Table 5, indicated that the k_{obs} is considerably lower than the value obtained with $H_2PO_2^-$. The result is consistent with the empirical rate equation (2) and the plot of k_{obs}^{-1} against $[D_2PO_2^-]^{-1}$ is included in Fig. 3. The intercept of the plot is 33.6 s and the slope is 1.22 mol dm^{-3} s.

4. Discussion

The nature of the OsO_4 spectra in NaOH concentration 0.001–2.0 mol dm^{-3}, Fig. 1, is almost same except that a peak starts appearing for NaOH concentrations > 0.01 mol dm^{-3} which becomes well defined around 315 nm for NaOH concentration > 0.05 mol dm^{-3}. The peak is slightly red-shifted with increasing NaOH concentration. The pale yellow colour of OsO_4 in dilute alkali solution corresponding to the species $[OsO_4(OH_2)OH]^-$ progressively changes to a red coloured solution with increasing alkali concentration because of the formation of red coloured $[OsO_4(OH_2)(OH)_2]^{2-}$ species [38].

The spectra show a peak around 320 nm which is slightly red-shifted with increasing NaOH concentration due to the solution acquiring a dark hue at higher alkali concentrations. The spectra does not show a maximum at 340 nm as reported by Mohan and Gupta [10], who very likely missed the peak around 320 nm since their measurements started from 340 nm onwards only. Since the spectra has no other peak or a shoulder, therefore formation of the species $[OsO_5(OH_2)(OH)]^{3-}$ from $[OsO_4(OH_2)(OH)_2]^{2-}$, equilibrium (4), proposed in the oxidation of phosphite by alkaline OsO_4 [30], is considered unlikely. It might be mentioned that the potassium and cesium salts, $M_2[OsO_4(OH)_2]$, have been prepared by dissolution of OsO_4 in respective strong MOH solutions [39]:

$$[OsO_4(OH_2)(OH)_2]^{2-} + OH^- \overset{K_3}{\rightleftharpoons} [OsO_5(OH_2)(OH)]^{3-} \quad (4)$$

The reaction's first-order dependence in OsO_4, the Michaelis–Menten kinetics with respect to $RHPO_2^-$ and the rapid scan of the reaction mixture, Fig. 2, support the formation of an intermediate complex. The larger consistency in the kinetics of the present reaction and the earlier study is expected because Os(VIII) happened to be the effective oxidant in the earlier study [11]. The reason for the absence of the OH^- ion dependent term, as discussed later, is due to the slow nature of the OH^- ion dependent reaction. The empirical rate law in Eq. (2) is the modified form of the similar equation found in the earlier study [11].

Therefore, the proposed mechanism consisting of reactions (5)–(9) is similar to that considered in the earlier study [11]:

$$OsO_4 + OH^- \overset{K_1}{\rightleftharpoons} [OsO_4OH]^- \quad (5)$$

$$[OsO_4OH]^- + OH^- \overset{K_2}{\rightleftharpoons} [OsO_4(OH)_2]^{2-} \quad (6)$$

$$[OsO_4(OH)]^- + RHPO_2^- \overset{\beta}{\rightleftharpoons} [OsO_4(OH)RHPO_2]^{2-} \quad (7)$$

$$[OsO_4(OH)RHPO_2]^{2-} \overset{k}{\rightarrow} OsO_3 + RPO_3^{2-} + H_2O \quad (8)$$

$$[OsO_4(OH)_2]^{2-} + RHPO_2^- \overset{k_2}{\rightarrow} [OsO_3(OH)]^- + RPO_3^{2-} + H_2O \quad (9)$$

The values of the equilibrium constants K_1 (5.55×10^{13}) and K_2 (16.6) are derived from the relation $K_n = K_{na}/K_w$ where K_{1a} (1×10^{-2}) and K_{2a} (3×10^{-15} mol dm^{-3}) are the first and second ionisation constants [40]. The K_2 value (16.6) is in good agreement with the values (24 ± 4) [10], and (19.5 ± 4) [28] at 25 °C. The consideration of the value of the equilibrium constant K_1 indicates that OsO_4 exists as $[OsO_4(OH_2)OH]^-$ in very dilute alkali solutions viz. ⩽0.01 mol dm^{-3}.

The rate-law derived from the reactions (6)–(9), with the assumption that the analytical $[OsO_4] \cong [OsO_4(OH)^-]$ in view of the very high vale of K_1 mentioned above, is given in Eq. (10), which is same as obtained in the OsO_4-catalysed oxidation by $Fe(CN)_6^{3-}$ ion [11]:

$$k_{obs} = \frac{(k\beta + k_2K_2[OH^-])[RHPO_2^-]}{1 + K_2[OH^-] + \beta[RHPO_2^-]} \quad (10)$$

However, the present reaction is significantly different from the OsO_4-catalysed reaction [11] because k_{obs} is independent of OH^- ions. Eq. (10) has to be suitably modified to make it independent of the hydroxyl terms. The assumption that $1 + \beta[RHPO_2^-] \gg K_2[OH^-]$ might be factually incorrect in view of the derived values of β and K_2 mentioned in the previous study [11]. This problem is rectified by considering the reaction (11) in place of the reaction (9) in the above mechanism:

$$[OsO_4(OH)RHPO_2]^{2-} + OH^- \overset{k_2}{\rightarrow} [OsO_3(OH)]^- + RPO_3^{2-} + H_2O \quad (11)$$

Thus the consideration of the mechanism consisting of the reactions 6, 7, 8, and (11) would give the rate equation (12):

$$k_{obs} = \frac{(k\beta + k_2\beta[OH^-])[RHPO_2^-]}{1 + \beta[RHPO_2^-]} \quad (12)$$

Eq. (12) is reduced to Eq. (13) with the assumption that $k\beta \gg k_2\beta[OH^-]$ because the reaction is independent of OH^- ion concentration. The assumption is rationalised by considering that the reaction (11) is so slow that its contribution to the observed rate is not measured over the timescale of the stopped-flow instrument. The reaction, however, does contribute to the observed rate of the Os(VIII)-catalysed slow reaction with $Fe(CN)_6^{3-}$ ion [11]. Eq. (13) is similar to the empirical rate equation (2) with $a = k\beta$ and $b = \beta$:

$$k_{obs} = \frac{k\beta[RHPO_2^-]}{1 + \beta[RHPO_2^-]} \quad (13)$$

The assumption of the slow nature of the reaction (11) is substantiated by considering the k_2K_2 values, 0.5 and 0.257 dm^3 mol^{-1} s^{-1}, respectively, for $H_2PO_2^-$ and $C_6H_5HPO_2^-$ ions at 30 °C [11]. Since these values are now equivalent to $k_2\beta$, the evaluated value of k_2 is 0.0178 and 0.00459 s^{-1} using presently obtained β values of 28 dm^3 mol^{-1} for $H_2PO_2^-$ and 56 dm^3 mol^{-1} for

$C_6H_5HPO_2^-$ at 30 °C. Thus the k_2 values at 30 °C are about eight times and 19 times less than the k values for $H_2PO_2^-$ and $C_6H_5HPO_2^-$, respectively.

Eq. (13) is consistent with the double reciprocal plots between k_{obs}^{-1} against $[RHPO_2^-]^{-1}$ shown in Fig. 3. The least square values of the intercepts and slopes of the plots in Fig. 3 are in Table 6. The calculated values of k and β, Table 7, are comparable to the values obtained earlier in the OsO_4-catalysed oxidation [11] viz. The present $k = 0.153$ at 30 °C and 0.180 (s^{-1}) at 40 °C is in fair agreement with the values 0.149 and 0.187 (s^{-1}) at the same temperatures in the Os(VIII)-catalysed oxidation of $H_2PO_2^-$ ion by $Fe(CN)_6^{3-}$ ion [11]. The $k = 0.0893$ at 30 °C and 0.114 (s^{-1}) at 40 °C compare well with the values 0.086 and 0.117 at the same temperatures in the oxidation of $C_6H_5HPO_2^-$ ion [11].

The presently obtained β values 28 and 39 $dm^3\ mol^{-1}$ for $H_2PO_2^-$ and 56 and 63 $dm^3\ mol^{-1}$ for $C_6H_5HPO_2^-$ at 30 and 40 °C, respectively, are comparable with the values 25 and 37 $dm^3\ mol^{-1}$ for $H_2PO_2^-$ and 55 and 61 $dm^3\ mol^{-1}$ for $C_6H_5HPO_2^-$ in the previous Os(VIII)-catalysed study [11]. The higher values of β for OsO_4–$C_6H_5HPO_2^-$ complex in comparison to the value for OsO_4–$H_2PO_2^-$ complex is consistent with the larger peak height obtained in the rapid scan spectra of OsO_4–$C_6H_5HPO_2^-$ reaction mixture and is attributed to the stabilising action of phenyl group which is supported by the smaller values of the specific rate constant for the disproportionation of OsO_4–$C_6H_5HPO_2^-$ complex compared to the rate for the disproportionation of OsO_4–$H_2PO_2^-$ complex.

The activation and thermodynamic parameters are calculated from Eqs. (14) and (15), respectively, where k and h are the Boltzmann and Planck constants, respectively, are reported in Table 5. The required plots are in Fig. 5. It might be noted that there is fair agreement between the present values and those obtained previously in the Os(VIII)-catalysed study [11]:

$$k = \frac{\kappa t}{h} \exp\frac{(-\Delta H^{\ddagger})}{RT} \exp\frac{\Delta S^{\ddagger}}{R} \quad (14)$$

$$\log\beta = \frac{-\Delta H^0}{RT} + \frac{\Delta S^0}{R} \quad (15)$$

The rate acceleration with OH^- ion in the $Fe(CN)_6^{3-}$ oxidation of $H_2PO_2^-$ ion has been explained by considering HPO_2^{2-} as the reactive entity [41] which is formed through the equilibrium (16). The species is supported by the conductivity data of sodium hypophosphite [42]. HPO_2^{2-} has been suggested as an intermediate in the base catalysed exchange of hydrogen on hypophosphite anion [43], and is the considered reactive entity in the oxidations by Ru(VII) [22] and $[Ag(OH)_4]^-$ ions [25] in alkaline solution. The equilibrium (14) is not presently considered for the reason that the composite second pK of H_3PO_2 is above 14 which means that the equilibrium amount of HPO_2^{2-} is small under basic conditions used beside OsO_4 forms various species with OH^- ions which are in equilibrium with each other:

$$H_2PO_2^- + OH^- \rightleftharpoons H_3PO_3^{2-} \text{ or } (HPO_2^{2-} + H_2O) \quad (16)$$

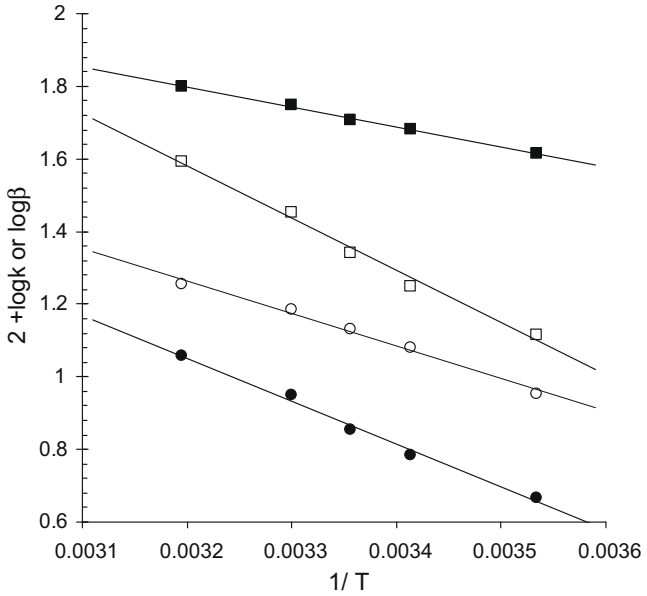
$-\Delta S^{\ddagger}$ (J K^{-1} mol^{-1})	196 ± 3	182 ± 4	ΔS^0 (kJ mol^{-1})	118 ± 5	258 ± 1
$-\Delta G^{\ddagger}$ (kJ mol^{-1})	73	74	$-\Delta G^0$ (kJ mol^{-1})	8	10



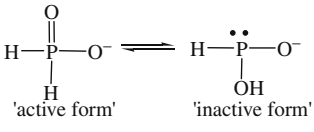


Fig. 5. The plots between log k and $1/T$ for $H_2PO_2^-$ (○) and $C_6H_5HPO_2^-$ (●), and between log β and $1/T$ for $H_2PO_2^-$ (□) and $C_6H_5HPO_2^-$ (■).

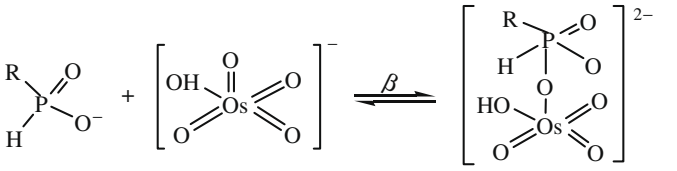
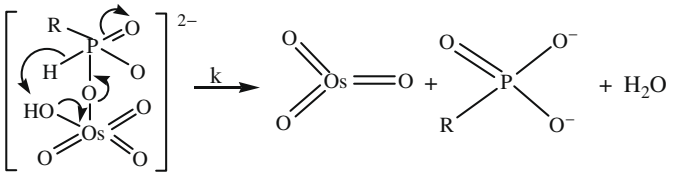
The rate constant k_{PH} for the proton exchange of phosphorus-bonded hydrogen in the $H_2PO_2^-$ ion in basic medium is 6×10^{-5} $dm^3\ mol^{-1}\ s^{-1}$ at 25 °C, and the $\Delta H^{\ddagger}$ is 79 kJ mol^{-1} [43]. Thus the net change in enthalpy of the reactions involving HPO_2^{2-} as the reactive species is expected to be greater than the enthalpy change for the reactions proceeding through with $H_2PO_2^-$ species. Alternately, the rate determining constants for the reactions involving HPO_2^{2-} as the reactive species ought to be less than the rate constant for proton exchange mentioned above. The above criterion is well supported by the reactions with RuO_4^- in which the rate determining constant is 248 ± 14 $dm^6\ mol^{-2}\ s^{-1}$ at 24.8 °C ($\Delta H^{\ddagger}$ = 7.8 ± 0.8 kJ mol^{-1} [22], the corresponding value for OH^- independent path is 0.069 ± 0.014 $dm^3\ mol^{-1}\ s^{-1}$ (82 ± 10 kJ mol^{-1}) and 1.13 ± 0.02 $dm^6\ mol^{-2}\ s^{-1}$ (39 ± 5 kJ mol^{-1}) for OH^- dependent path in the oxidation by $Ag(OH)_4^-$ ion at 25 °C [25], and 0.141 ± 0.008 s^{-1} (19 ± 6 kJ mol^{-1}) in the Os(VIII)-catalysed oxidation by $Fe(CN)_6^{3-}$ [11]. In all these reactions the considered reactive entity is $H_2PO_2^-$ ion. Hence in the present reaction with the rate determining constant equal to 0.135 s^{-1} at 25 °C, it is only rational to assume $H_2PO_2^-$ ion as the reactive entity. Since $H_2PO_2^-$ ion is the reactive entity therefore it is the inactive form which is reactive in all these oxidations. The structures of the 'inactive' and 'active' forms are given below:



(17)

It might be noted that HPO_2^{2-} is the considered reactive entity in the oxidation with $Fe(CN)_6^{3-}$ in alkaline medium has a $\Delta H^{\ddagger} = 96 \pm 4$ kJ mol^{-1}. The comparison of the rate constant is not made because the same is not available at 25 °C.



The substantial kinetic isotope effect, $k_H/k_D = 4.53$ at 25 °C, is comparable to $k_H/k_D = 4 \pm 0.5$ obtained in the internal redox of $(NH_3)_5Co(H_2PO_2)^{2+}$ [24] and much different from $k_H/k_D = 2.5 \pm 0.5$ obtained for the OH^- independent path in Ag(III) oxidation [25]. The observed value, suggestive of the fission of P–H bond in the rate determining step, is smaller than the theoretical value 5.5 obtained from Eq. (16) [44] by using $\upsilon_{P-H} = 2400$ cm^{-1} and $\upsilon_{P-D} = 1700$ cm^{-1} for free hypophosphite ion [43]. The smaller value is due to concerted bond making and breaking [45]:

$$\frac{k_H}{k_D} = e\left(\frac{hc(\upsilon_{P-H} - \upsilon_{P-D})}{2\kappa T}\right) \tag{18}$$

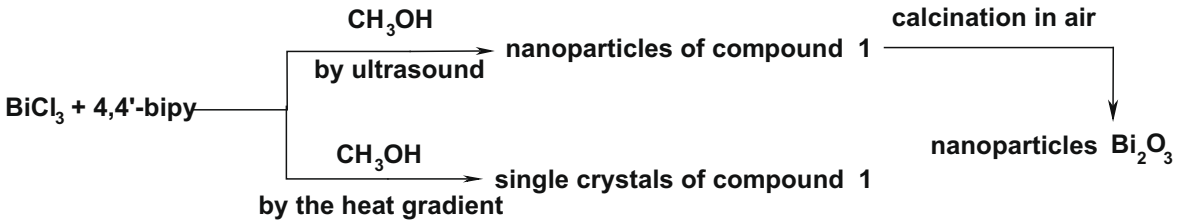
The P–H bond fission is heterolytic in nature. A proton and an electron are simultaneously transferred from $H_2PO_2^-$ to the oxidant producing HPO_2^{2-} and Os(VI). The described mode of electron transfer might be equivalent to the transfer of a hydrogen atom. The hydrogen atom transfer is not considered because the energy required for hydrogen atom transfer is expected to be greater than the activation energy obtained for the redox reaction. The probable structure of the Os(VIII)–$RHPO_2^-$ complex and the fission of bonds is considered below:

(19)

(20)

Hence, the oxidation of hypophosphite or phenylphosphinite ion to the corresponding phosphite or phenylphosphonite ion involves a total change of two electrons.

5. Concluding remark



The kinetics of the reaction is similar to the kinetics observed in the OsO_4-catalysed oxidation of the oxo-phosphorus acids with hexacyanoferrate(III) ion [11] except that the present reaction has no OH^- ion dependence. This is attributed to the slow nature of the reaction between OH^- ion and the intermediate and therefore it does not register itself on the time scale of the stopped-flow measurements. The OH^- ion dependent reaction of the previous study [11] has been suitably modified so that the assumption of the inequality is rational. The presently obtained values of k and β are in fair agreement with the values obtained in the earlier study [11]. The result of this study indicates that the alkaline oxidation of hypophosphite ion with different metal ions has different dependence of the rate on [OH^-]. However, the results of the studies so far indicate that the dependence on OH^- is not due to the HPO_2^- ion except in the oxidation of hypophosphite ion by hexacyanoferrate(III) ion because $Fe(CN)_6^{3-}$ does not react with OH^- ions. The rate determining constant for this particular reaction is much slower than the rate for the proton exchange of phosphorus-bonded hydrogen in the $H_2PO_2^-$ ion and the $\Delta H^{\ddagger}$ of the reaction is significantly higher than $\Delta H^{\ddagger}$ for the exchange reaction [43]. This makes this reaction significant in the sense that this is probably the only reaction in alkaline medium in which the active form of hypophosphite ion is the reactive entity.

a maximum power output of 600 W, was used for the ultrasonic irradiation. The ultrasonic generator automatically adjusts the power level. The wave amplitude in each experiment was adjusted as needed. IR spectra were recorded using Perkin–Elmer 597 and Nicolet 510P spectrophotometers. Microanalyses were carried out using a Heraeus CHN-O-Rapid analyzer. Melting points were measured on an Electrothermal 9100 apparatus and are uncorrected. X-ray powder diffraction (XRD) measurements were performed using a Philips diffractometer manufactured by X'pert with monochromatized Cu Kα radiation and simulated XRD powder patterns based on single crystal data were prepared using the program Mercury [19]. The crystallite sizes of selected samples were estimated using the Sherrer method. The samples were gold coated for characterization with a scanning electron microscope. The elemental composition of the film was analyzed using energy dispersive X-ray (EDX) spectrometer attached with the JEOL JSM-35 CF SEM instrument. Single crystal diffraction measurements were made at 100(2) K using a Bruker AXS SMART APEX CCD diffractometer. The intensity data were collected using graphite monochromated Mo Kα radiation. The structure was solved by direct methods and refined by full-matrix least-squares techniques on F^2. Crystal data for $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-bipyH}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**): monoclinic space group $P2_1/n$, a = 17.920(4), b = 7.4770(16), c = 36.060(8) Å, β = 92.857(4)°, V = 4825.4(18) Å^3, Z = 4, T = 100(2) K. The refinement of 571 parameters on the basis of 11 944 independent reflections (of a total of 31 180) converged at R_1 = 0.0610, wR_2 = 0.1007. The observed anisotropic thermal parameters, the calculated structure factors, and full lists of bond distances, bond angles and torsion angles are given in the supplementary material.

To prepare nano-particles of $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**), 10 ml of a 0.3 M solution of bismuth(III) chloride (0.1 M) in MeOH were positioned in a high-density ultrasonic probe, operating at 20 kHz with a maximum power output of 600 W. Into this solution 10 ml of a 0.3 M solution of the ligand 4,4′-bipy (0.1 M) were added dropwise. The obtained precipitates were filtered off, washed with methanol and then dried in air. m.p. > 300 °C. *Anal.* Calc. for $C_{40}H_{40}Bi_2Cl_{10}N_8O_2$: C, 33.44; H, 2.65; N, 7.80. Found: C, 33.20; H, 2.50; N, 7.54%. IR bands: 476m, 621w, 749s, 805s, 1000m, 1204m, 1479m, 1595s and 3045m.

Different concentrations of metal and ligand solutions (0.02, 0.05 and 0.08 M) with different power settings for the ultrasonic irradiation were tested (60, 120 and 180 W). Appropriate nano-sized particles of compound **1** were obtained only under the above mentioned conditions and the produced nano-particles were used for the thermal analyses.

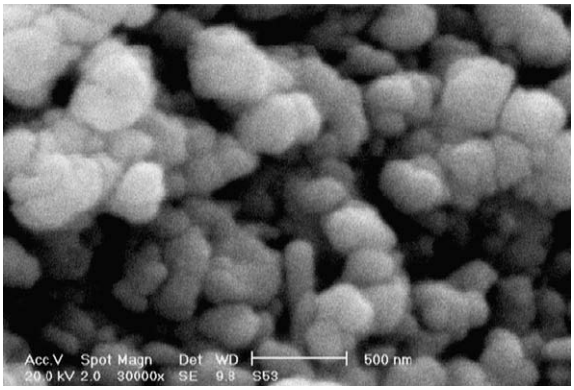

Fig. 3. SEM photographs of $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**) nano-particles.

To isolate single crystals of $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**), 4,4′-bipy (1 mmol) and bismuth(III) chloride (1 mmol) were placed in the main arm of a branched tube [20]. Methanol was carefully added to fill both arms. The tube was sealed and the ligand-containing arm immersed in an oil bath at 60 °C while the other arm was kept at ambient temperature. After 7–10 days, colorless crystals deposited in the cooler arm were isolated. The single crystals were filtered off, washed with acetone and ether and air dried. Yield: 0.174 g, 40%, m.p. > 300 °C. *Anal.* Calc. for $C_{40}H_{40}Bi_2Cl_{10}N_8O_2$: C, 33.44; H, 2.65; N, 7.80. Found: C, 33.30; H, 2.55; N, 7.54%. IR bands: 476m, 621w, 749s, 805s, 1000m, 1204m, 1479m, 1595s and 3045m.

3. Results and discussion

Scheme 1 gives an overview of the methods used for the synthesis of $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**) using two different routes. Nano-particles of **1** were obtained by ultrasonic irradiation of a mixture of 4,4′-bipy and bismuth(III) chloride in a methanolic solution. Single crystalline material was

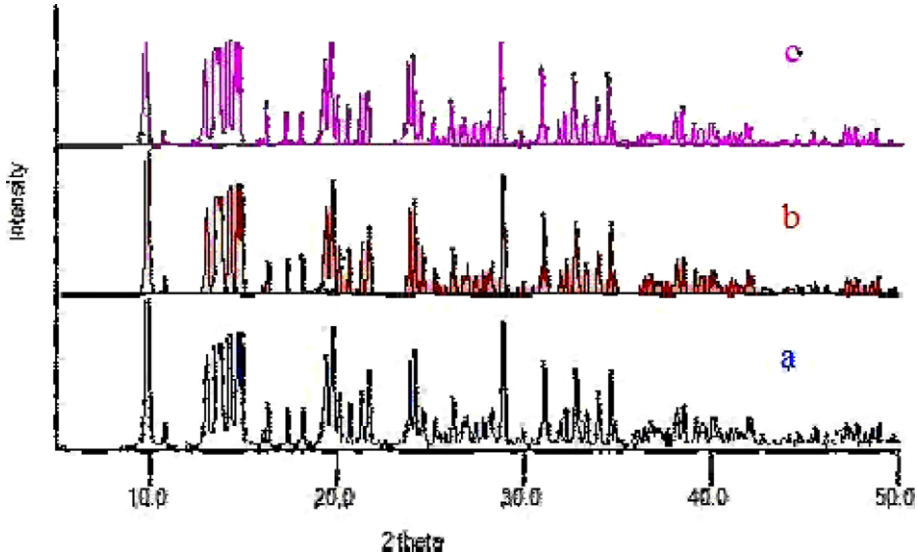

Fig. 2. The XRD patterns of (a) simulated from single crystal X-ray data of compound $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**); (b) bulk materials as synthesized of compound $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**) by heat gradient, (c) nano-structure of compound $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy) \cdot 2H_2O\}$ (**1**) by ultrasound.

obtained using a heat gradient applied to a solution of the reagents (the "branched tube method").

The IR spectra of the nano-particles and of the single crystalline material are indistinguishable and show characteristic absorption bands for the 4,4′-bipy ligands. The absorption bands with variable intensity in the frequency range 1400–1580 cm^{-1} correspond to ring vibrations of the pyridyl moieties of the 4,4′-bipy ligands.

The single crystals of **1** were analyzed by X-ray diffraction (Fig. 1a–c). The molecular structure of the complex is built by one $[Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}]^{4-}$ anion, two singly protonated 4,4′-Hbipy$^+$ cations and one doubly protonated 4,4′-H_2bipy^{2+} cation and two H_2O molecules. The 4,4′-bipy ligand in the dinuclear anionic complex is linking the two Bi atoms with each other which have a slightly distorted octahedral $BiCl_5N$ coordination environment. With the $BiCl_3$ starting material as the only chlorine source and protic methanol as the solvent one thus can to assume partial hydrolysis of the bismuth chloride with the HCl released in the process as the source of the chloride anions and protons needed to form the $BiCl_5^{2-}$ dianions and the protonated bipy-cations. In the solid state the 4,4′-Hbipy$^+$ cations are linked by hydrogen bonding. The hydrogen atoms of the uncoordinated and monoprotonated 4,4́-Hbipy$^+$ cations form infinite hydrogen bonded chains via N–H···H hydrogen bonds. The doubly protonated 4,4′-H_2bipy^{2+} cations, on the other hand, are involved in short Cl···H–N interactions (Fig. 1b) with distance around 2.6 Å. The anions and cations thus connected via Cl···H–N hydrogen bonds are also π-stacked atop of each other with alternating 4,4′-H_2bipy^{2+} cations and $[Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}]^{4-}$ anions. The stacks are further connected via O–H···Cl hydrogen bonds of the interstitial water molecule towards chlorine of the same stack, and are laid out in parallel to each other. The $\{[Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}][4,4'\text{-}H_2bipy]\}^{4-}$ stacks and the infinite chains of the monoprotonated 4,4́-Hbipy$^+$ cations, on the other hand, are only loosely connected with each other thus suggesting a microphase separation within the crystal with largely independent layers of each of the two constituent phases.

Fig. 2a shows the XRD patterns simulated from the single crystal X-ray data. Fig. 2b and c shows the XRD patterns of typical samples of compound **1** prepared by the branched tube and the sonochemical process, respectively. Acceptable matches are observed indicating the presence of only one crystalline phase in all samples regardless of the method of preparation. Using the Sherrer formula for the calculation of particle sizes from the broadening of the XRD peaks ($D = 0.891\lambda/\beta\cos\theta$, where D is the average grain size, λ is the X-ray wavelength (0.15405 nm) and θ and β are the diffraction angle and full-width at half maximum of an observed peak, respectively) the average size of the particles prepared via the sonochemical method was found to be around 90 nm, which is in agreement with the value obtained from the SEM images (Fig. 3).

Thermal decomposition of the nano-sized particles of **1** in air produced Bi_2O_3: as established by its powder XRD pattern. The broadening of the peaks indicated that the particles were of nano-

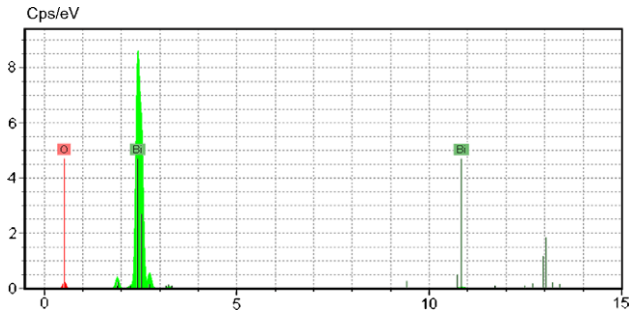

Fig. 4. EDAX analysis of Bi_2O_3 nano-particles (produced by calcination of compound **1** under air atmosphere).

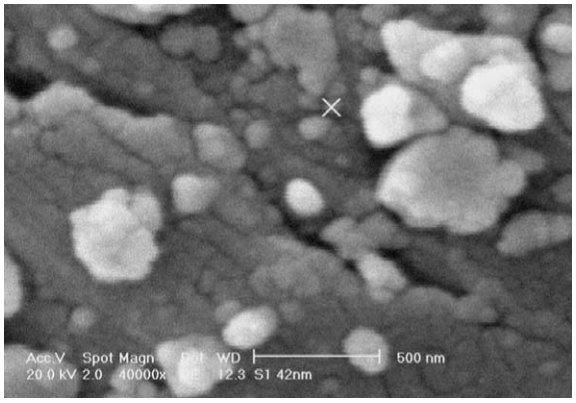

Fig. 5. SEM photographs of Bi_2O_3 nano-particles (produced by calcination of compound **1** under air atmosphere).

meter scale. EDAX was performed in support of XRD observation and to further confirm of the composition of the α-Bi_2O_3 nano-particles produced by calcination of compound **1** under air atmosphere. The EDAX spectrum (Fig. 4) of stoichiometric Bi_2O_3 shows only the bismuth and oxygen peaks appear. The atomic percentage of Bi and O present in the compound are calculated and are found to be 2.00:3.03 showing perfect stoichiometry of the particle surface. Fig. 4 shows that sample Bi_2O_3 nano-particles is composed of Bi and O only, and this spectrum show that there are no impurities within this sample. Fig. 5 shows the SEM images of nano-structured Bi_2O_3 obtained from calcinations of compound **1** under air atmosphere [21]. It is interesting that the calcination of the normal-sized crystals of compound **1** produces Bi_2O_3 but the particle sizes were not at nano-scale.

4. Conclusion

A new Bi(III) supramolecular compound, $\{Bi_2(\mu\text{-}4,4'\text{-bipy})Cl_{10}] \cdot 2(4,4'\text{-Hbipy}) \cdot (4,4'\text{-}H_2bipy)\cdot 2H_2O\}$ (**1**) {4,4′-bipy = 4,4′-bipyridine}, has been synthesized using a thermal gradient approach and by a sonochemical method. In compound **1** similar to its bromo analogue $[4,4'\text{-bipyH}]_n^{n-}[Bi(4,4'\text{-bipy})Bi_4]_n^{n-}$ [22], two of 4,4′-bipy ligands are protonated. Calcination of compound **1** under air atmosphere, produces nano-structured α-Bi_2O_3. There are only three reports discussing the preparation of Bi_2S_3 nano-structures from the solvent thermolysis of bismuth trisxanthate [23], (benzylthiolato)bismuth [24] and bismuth tris(methyl-*n*-hexyldithiocarbamate) [25] precursors. These studies demonstrate supramolecular compounds may be suitable precursors for the preparation of nano-scale materials with interesting morphologies. To the best of our knowledge, this is the first report on the synthesis of nano-structured α-Bi_2O_3 from a supramolecular precursor. From this perspective, further systematic studies of other supramolecular compounds with bismuth(III) and different metal ions are ongoing in our laboratory, which may offer new insight into metal-organic supramolecular assembly and nano-chemistry.

$Cu(NO_3)_2 \cdot 3H_2O$ in 10 ml of methanol and stirred for 6 h. The resulting precipitate of $[Cu(pybzim)_2(NO_3)](NO_3)$ was filtered off and dried. Yield 60%. The crystals suitable for X-ray investigation were obtained by recrystallization from methanol.

IR (KBr; ν/cm^{-1}): 3060 (ν_{N-H}); 1609, 1594(m), 1494 and 1488(m) ($\nu_{C=C}$, $\nu_{C=N}$), 1462(s), 1446(s), 1409(s), 1384(vs), 1323(s), 1301(s), 1007(m), 988(m), 817(m), 765 and 745 ($\nu_{nitrate}$).

Anal. Calc. for $[Cu(pybzim)_2(NO_3)](NO_3)$: C, 49.87; H, 3.14; N, 19.39. Found: C, 48.98; H, 3.30; N, 18.89%.

2.3. X-ray diffraction studies

A green crystal of $[Cu(pybzim)_2(NO_3)](NO_3)$ was mounted on a KM-4-CCD automatic diffractometer equipped with a CCD detector, and used for data collection. X-ray intensity data were collected with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 293(2) K. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and empirical absorption correction using spherical harmonics implemented in SCALE3 ABSPACK scaling algorithm [12,13] were applied. The structure was solved by the Patterson method and subsequently completed by the difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. All the hydrogen atoms were found from difference Fourier synthesis after four cycles of anisotropic refinement, and refined as "riding" on the adjacent carbon atom with individual isotropic temperature factor equal 1.2 times the value of equivalent temperature factor of the aromatic parent atom. SHELXS97 [14], SHELXL97 [15] and SHELXTL [16] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.4. Computational details

The gas phase geometry of the $[Cu(pybzim)_2(NO_3)]^+$ cation was optimized without any symmetry restrictions in the doublet state with the DFT method using the hybrid B3LYP functional of GAUSSIAN-03 [17–19]. The calculations were performed by using the standard 6–311 + G(d,p) basis for Cu atom, 6–31 + G** basis for nitrogen, 6–31G* for carbon and 6–31G for hydrogen atoms. The optimized geometry of the $[Cu(pybzim)_2(NO_3)]^+$ cation was verified by per-

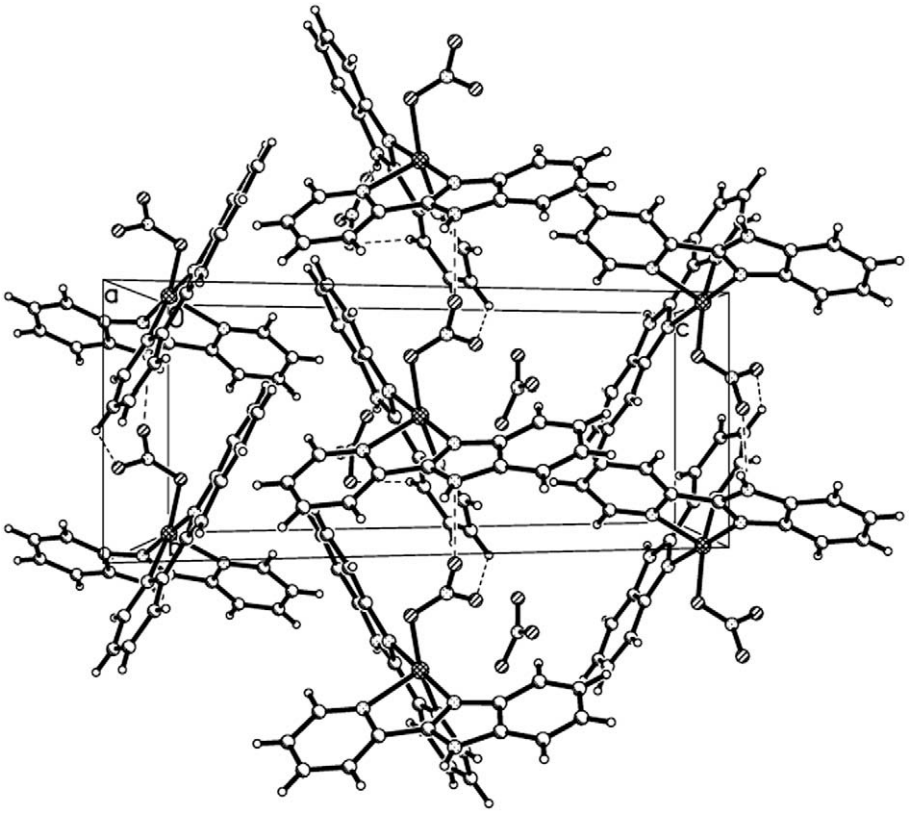

Fig. 1. The cell packing of $[Cu(pybzim)_2(NO_3)](NO_3)$.

forming a frequency calculation. All the vibrations in the calculated vibrational spectrum of $[Cu(pybzim)_2(NO_3)]^+$ were real, thus the optimized geometry corresponds to true energy minimum.

The electronic spectrum of the $[Cu(pybzim)_2(NO_3)]^+$ cation was calculated with the TDDFT method starting from the ground-state geometry optimized in the gas phase. The solvent (methanol) effect was simulated using the polarizable continuum model with the integral equation formalism (IEF-PCM) [20].

Natural bond orbital (NBO) calculations were performed with the NBO code [21] included in GAUSSIAN-03.

3. Results and discussion

The $[Cu(pybzim)_2(NO_3)](NO_3)$ complex was prepared in good yield by the reaction of 2-(2-pyridyl)benzimidazole (pybzim) with copper(II) nitrate trihydrate in molar ratio 2:1. The elemental analysis of the complex is in good agreement with its formulation. The characteristic bands of the C=C and C=N stretching modes of 2-(2-pyridyl)benzimidazole are observed in the range 1610–1480 cm^{-1}. The peak at 3060 cm^{-1} can be attributed to the ν(N–H) stretching frequency of the pybzim ligand. The bands assignable to the coordinated nitrate group of $[Cu(pybzim)_2(NO_3)](NO_3)$ appear at 1462, 1446, 1323, 1301, 1007, 988, 765 and 745 cm^{-1}, whereas the strong band at 1384 and 817 cm^{-1} (of medium intensity) confirm the presence of uncoordinated nitrate ion. The small splitting of in-plane bending NO_3 vibrations (ν_4; at 765 and 745 cm^{-1}, 20 cm^{-1}) indicates the presence of monodentate nitrate group [22].

Table 2
Intermolecular hydrogen bonding contacts detected in the $[Cu(pybzim)_2(NO_3)](NO_3)$ complex.

3.1. Crystal structure

The crystallographic data of $[Cu(pybzim)_2(NO_3)](NO_3)$ are summarized in Table 1. $[Cu(pybzim)_2(NO_3)](NO_3)$ crystallises in the monoclinic space group $P2_1/c$. The cell packing of $[Cu(pybzim)_2(NO_3)](NO_3)$ is given in Fig. 1. A summary of intramolecular hydrogen bonding contacts detected in $[Cu(pybzim)_2(NO_3)](NO_3)$ structure is given in Table 2 [23,24]. The outer sphere nitrate anion is connected to pybzim molecule by N(5)–H(5N)···O(6) hydrogen bonds. Other intermolecular by N–H···O hydrogen bonds links molecules to the cyclic dimers. Additionally in the structure exists short intermolecular C–H···O interactions, which can be classified as weak hydrogen bonds. These interactions expand hydrogen bonded dimer to the three dimensional net.

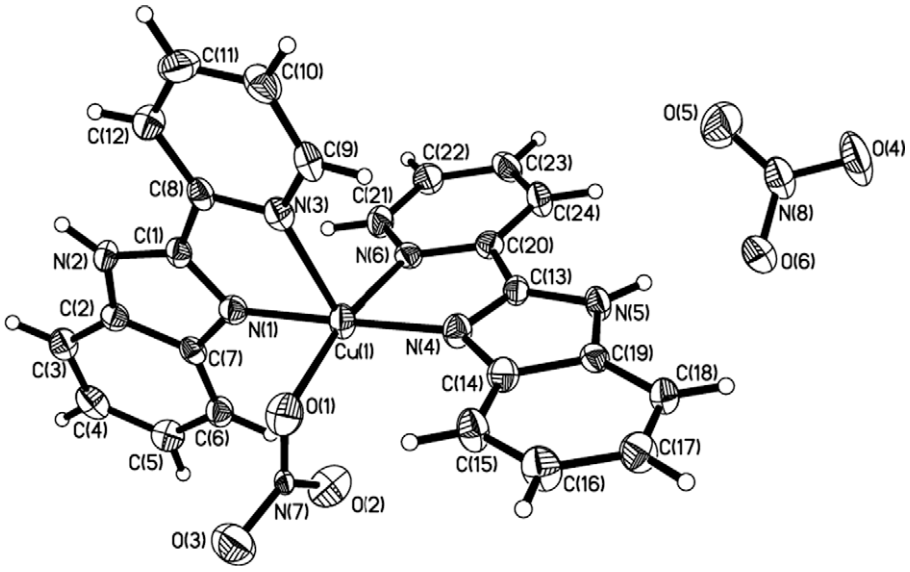
The asymmetric unit of the title complex consists of the $[Cu(pybzim)_2(NO_3)]^+$ cation and nitrate ion. The molecular structure of the $[Cu(pybzim)_2(NO_3)](NO_3)$ is presented in Fig. 2, and the selected bond distances and angles of $[Cu(pybzim)_2(NO_3)]^+$ are collected in Table 3.

According to the criteria for the assignment for nitrate modes introduced by Kleywegt et al. [25] and presented in Table 4, the nitrate binding mode in the title complex can be classified as monodentate.

The Cu(II) centre of $[Cu(pybzim)_2(NO_3)]^+$ is five-coordinated by four N donors from two 2-(2-pyridyl)benzimidazole ligands and oxygen atom of nitrate anion. The bite angles of 78.70(10)° and 81.23(10)° show no variation from the values reported for $[Cu_2(CN)(2\text{-PyBIm})]n$ – 80.3(2)° [26].

The angular structural index parameter τ [27] expressed here as the difference between the bond angles N(1)–Cu(1)–N(4) and N(6)–Cu(1)–O(1) divided by 60 has a value of 0.16. Compared with the ideal values of 1 for an equilateral bipyramid and 0 for a square pyramid, the τ descriptor of the examined structure indicates a square-pyramidal stereochemistry (Scheme 1).

The equatorial plane of the title complex is defined by three nitrogen and one oxygen atoms. The maximum deviation from the weighted least-squares N(1), N(4), N(6), O(1) plane exists for N(4) atom and it is equal to 0.1000(12) Å. The metal ion Cu is displaced from above mentioned weighted least-squares plane by 0.1083(12) Å. The apical site is occupied by N3 atom with Cu–N distance 2.223(2) Å, ca. 0.25 Å longer than the Cu–N distances in



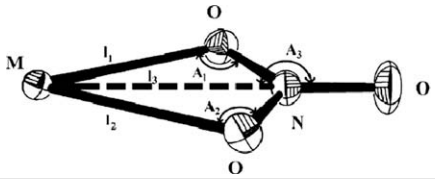


Fig. 2. The molecular structure of the $[Cu(pybzim)_2(NO_3)](NO_3)$. Displacement ellipsoids are drawn at 50% probability.

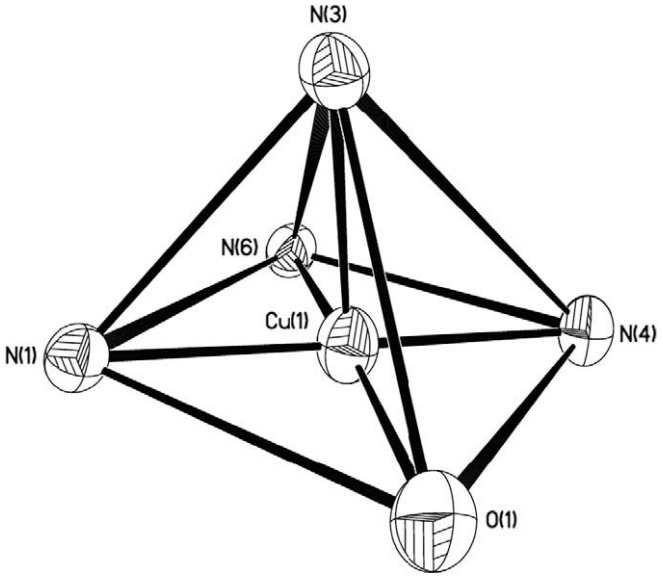

Table 3
The experimental and optimized bond lengths (Å) and angles (°) for $[Cu(pybzim)_2(NO_3)](NO_3)$.

Bond lengths	Experimental	Optimized	Bond angles	Experimental	Optimized
Cu(1)–N(1)	1.982(2)	2.030	N(1)–Cu(1)–N(4)	177.40(10)	174.79
Cu(1)–N(3)	2.223(2)	2.412	N(4)–Cu(1)–N(6)	81.23(10)	79.78
Cu(1)–N(4)	1.964(2)	2.021	N(1)–Cu(1)–N(6)	96.21(9)	96.49

			N(6)–Cu(1)–O(1)	167.83(9)	162.85
			N(4)–Cu(1)–N(3)	102.24(9)	101.68
			N(1)–Cu(1)–N(3)	78.70(10)	75.56
			N(6)–Cu(1)–N(3)	102.17(9)	103.74
			O(1)–Cu(1)–N(3)	89.87(9)	93.00

Table 4
Parameters used for assigning nitrate coordination modes [25] and parameters of the coordinated nitrate group in the $[Cu(pybzim)_2(NO_3)]^+$ cation.

	Monodentate	Anisobidentate	Bidentate	$[Cu(pybzim)_2(NO_3)]^+$
l_2–l_1 (Å)	>0.6	0.3–0.6	<0.3	0.5922
A_1–A_2 (°)	>28	14–28	<14	28.93
l_3–l_2	<0.1	0.1–0.2	>0.2	0.0466
A_3 (°)	<162	162–168	>168	160.54

Scheme 1.

the equatorial plane. This elongation of the fifth-ligand is typical of a square-based pyramidal stereochemistry [28].

To confirm five coordination, the bond valences were computed as $v_{ij} = \exp[(R_{ij} - d_{ij})/0.37]$ [29–32], where R_{ij} is the bond-valence parameter (in the formal sense R_{ij} is the single bond length between i and j atoms), d_{ij} – bond length between i and j atoms and b was taken as 0.37 [33].

The R_{Cu-O} and R_{Cu-N} were taken as 1.679 [34] and 1.713 [32], respectively. The computed bond valences of the copper are $v_{Cu(1)-O(1)} = 0.374$, $v_{Cu(1)-N(1)} = 0.486$, $v_{Cu(1)-N(3)} = 0.253$, $v_{Cu(1)-N(4)} = 0.507$ and $v_{Cu(1)-N(6)} = 0.410$ v.u. (valence units), thus the computed valence of the Cu(1) atom is 2.03 v.u. Because only deviation of valence sum rule larger than 0.5–0.1 v.u. can indicate omission or misinterpretation of coordination sphere [35], it can be stated that in considered compound the copper atom is five-coordinated and even weak interactions are not omitted. Noteworthy is the fact that the Cu(1)–O(1) bond is slightly stronger than Cu(1)–N(3) bond, but it is weaker than other Cu–N bonds. The pybzim molecule indicated by N(1) atom is weaker-bonded to the central atom (0.739 v.u.) than molecule containing N(3) atom (0.917 v.u.).

3.2. Geometry optimization and population analysis

The geometry of the $[Cu(pybzim)_2(NO_3)]^+$ cation was optimized in doublet state using the DFT method with the B3LYP functional. The optimized geometric parameters are gathered in Table 3. In general, the predicted bond lengths are somewhat longer in comparison with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

None of the natural bond orbitals between central ion and nitrogen and oxygen atom donors were detected, indicating a conceivable predominant Coulomb-type Cu–ligand interaction in the $[Cu(pybzim)_2(NO_3)]^+$ cation.

The calculated charge on the copper atom in $[Cu(pybzim)_2(NO_3)]^+$ is equal to 0.964 and it is lower than the formal charge +2. It is a result of charge donation from the donor atoms of ligands. Table 5 presents electron population of the valence core of the central ion, nitrogen donors and oxygen atoms the $[Cu(pybzim)_2(NO_3)]^+$ cation.

3.3. Electronic spectrum

The nature of the transitions observed in the UV–Vis spectrum of the title complex has been studied by the time-dependent density functional (TDDFT) method. The calculated electronic spec-

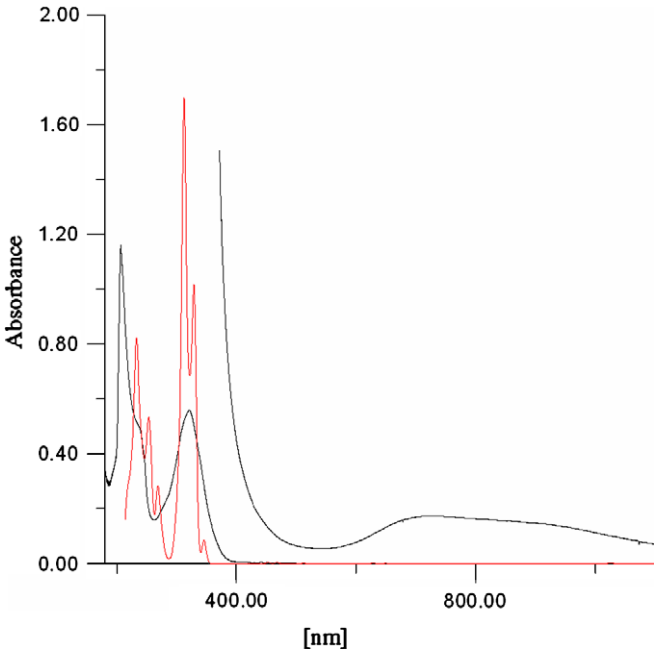

Fig. 3. The experimental (black) and calculated (red) electronic absorption spectra of methanolic solution of $[Cu(pybzim)_2(NO_3)](NO_3)$. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

trum of $[Cu(pybzim)_2(NO_3)]^+$ in comparison with the experimental one is presented in Fig. 3. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}.

Table 6 presents the most important electronic transitions calculated with the TDDFT method for $[Cu(pybzim)_2(NO_3)]^+$ and their assignments to the observed absorption bands of the complex. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.0300 are listed in Table 6. The assignment of the calculated orbital excitations to the experimental bands was based on an overview of the contour plots and relative energy of occupied (HOMO) and unoccupied (LUMO) molecular orbitals involved in the electronic transitions (Fig. 4).

The TDDFT/PCM calculations show that the longest wavelength experimental band at 984.2 nm originates in the HOMO-4(β) → LUMO(β) transition. As can be seen from the Fig. 3, the LUMO orbital with β-spin is mainly $d_{x^2-y^2}$ copper orbital in character, the β-spin HOMO-4 orbital are composed of d_{z^2} copper orbital and the π-bonding orbitals of nitrate group and pybzim ligand. The experimental band at 678.6 nm originates predominately in the transitions between β-spin HOMO-13, HOMO-12, HOMO-11 and LUMO. The HOMO-13, HOMO-12 and HOMO-11 and HOMO-9 are composed of ligand (nitrate and 2-(2-pyridyl)benzimidazole) π-bonding orbitals and d_{Cu} orbitals. Accordingly, the transitions assigned to the two longest wavelength experimental bands (at 984.2 and 678.6 nm) can be seen as mixed nitrate/pybzim → Cu (*ligand–metal charge transfer*; *LMCT*) and d → d (*ligand field; LF*) transitions.

Table 6
The spin-allowed doublet–doublet electronic transitions calculated with the TDDFT method and the assignments of the calculated transitions to the experimental absorption bands of $[Cu(pybzim)_2(NO_3)](NO_3)$.

ε – molar absorption coefficient ($dm^3\ mol^{-1}\ cm^{-1}$).
f – oscillator strength.
H – highest occupied molecular orbital.
L – lowest unoccupied molecular orbital.

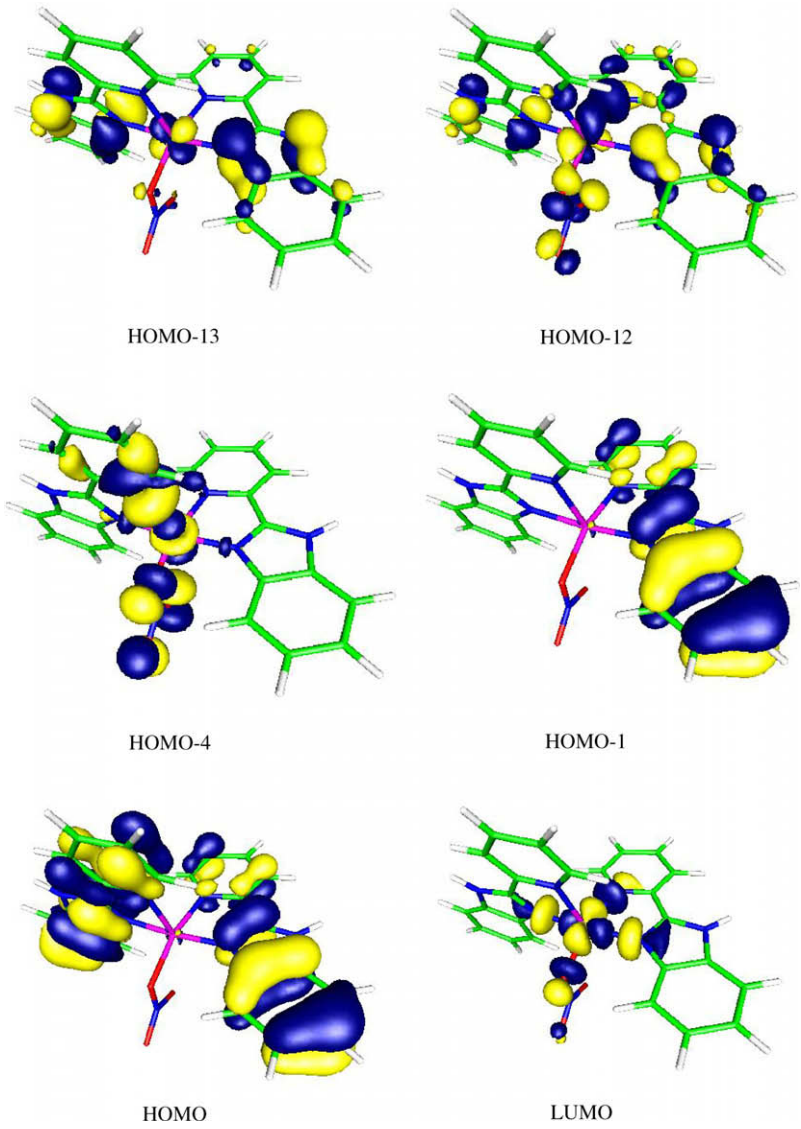

Fig. 4. Contour plots and energy of the selected β-spin HOMO and β-spin LUMO orbitals active in the electronic transitions. The orbitals were plotted with contour values −0.04 (yellow) and 0.04 au (blue). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

The experimental bands at 322.1, 235.0 and 210.4 nm originates predominately in the *intraligand* (IL) and *ligand–ligand charge transfer* (*LLCT*) transitions. However some contribution of the *ligand–metal charge transfer* from the nitrate and 2-(2-pyridyl)benzimidazole orbitals to the d copper orbitals in the band at 235 nm is also confirmed by the calculations.

complexes, as well as laying the foundation for the rational design of new photoprobes and photonucleases of DNA.

2. Experimental

2.1. Materials and chemicals

Solutions of DNA in 5 mM Tris–HCl buffer (pH 7.0), 50 mM NaCl gave a ratio of UV absorbance at 260 and 280 nm of 1.8–1.9:1, indicating that the DNA was sufficiently free of protein [16]. The concentration of calf thymus DNA (CT-DNA) was determined spectrophotometrically using the molar absorption 6600 M^{-1} cm^{-1} (260 nm) [17].

CT-DNA was purchased from the Sino-American Biotechnology Company and pBR322 DNA from the Sangon (Canada) Biotechnology Company. All reagents and solvents were purchased commercially and were used without further purification, unless specially noted. At the same time, doubly distilled water was used to prepare buffer solutions.

2.2. Synthesis

5-Nitro-1,10-phenanthroline, 5-nitro-6-amino-1,10-phenanthroline, *cis*-$[Ru(bpy)_2Cl_2]\cdot 2H_2O$, *cis*-$[Ru(phen)_2Cl_2]\cdot 2H_2O$, $[Ru(bpy)_2$(5-amino-6-nitro-1,10-phenanthroline)$]^{2+}$, $[Ru(phen)_2$-(5-amino-6-nitro-1,10-phenanthroline)$]^{2+}$, $[Ru(bpy)_2$(5,6-diamino-1,10-phenanthroline)$]^{2+}$ and $[Ru(phen)_2$(5,6-diamino-1,10-phenanthroline)$]^{2+}$ were prepared and characterized according to the literature references [18–22]. Pyrimidine-2-iminoacetate was obtained from the reaction of 2-cyanopyrimidine with sodium methoxide and a few drops of glacial acetic acid, refluxing the mixture for 2 h.

2.2.1. $[Ru(bpy)_2(pmip)](PF_6)_2\cdot 2H_2O$ (**1**)

$[Ru(bpy)_2$(5,6-diamino-1,10-phenanthroline)$]^{2+}$ (200 mg, 0.22 mmol) was dissolved in glacial acetic acid (10 mL) and pyrimidine-2-iminoacetate (82 mg, 0.6 mmol) was added. The mixture was refluxed for 4 h under an argon atmosphere. The cooled reaction mixture was diluted with water (40 mL) and filtered to remove solid impurities, neutralized with aqueous ammonia, and then ammonium hexafluorophosphate was added. The red solid was collected and washed with small amounts of H_2O, EtOH and Et_2O, dried under vacuum, and purified by chromatography over alumina, using MeCN–toluene (5:1, v/v) as an eluent, yield: 164 mg, 72%. The sample shows good solubility in solvents such as MeCN, DMSO and acetone. ^1H NMR [$(CD_3)_2SO$]: δ 9.22 (s (singlet), 1H), 9.07 (d (doublet), 2H), 8.85 (t (triplet), 4H), 8.21 (t, 2H), 8.10 (m (multiplet), 4H), 7.94 (t, 2H), 7.82 (d, 2H), 7.69 (t, 1H), 7.62 (d, 2H), 7.58 (t, 2H), 7.34 (t, 2H). *Anal.* Calc. for $C_{37}H_{30}F_{12}N_{10}O_2P_2Ru$: C, 42.83; H, 2.91; N, 13.50. UV–VIS (UV–visible) (λ (nm), ε (M^{-1} cm^{-1})) (CH_3CN): 459 (17200), 286 (86550), 261 (27700).

2.2.2. $[Ru(phen)_2(pmip)](PF6)_2\cdot 2H_2O$ (**2**)

With 0.22 mmol, 221 mg $[Ru(phen)_2$(5,6-diamino-1,10-phenanthroline)$]^{2+}$ in place of $[Ru(bpy)_2$(5,6-diamino-1,10-phenanthroline)$]^{2+}$, this complex was obtained by a procedure similar to that described for **1**. Yield: 167 mg, 70%. ^1H NMR [$(CD_3)_2SO$]: δ 9.32 (s, 1H), 9.07 (d, 2H), 8.76 (d, 4H), 8.37 (s, 4H), 8.17 (d, 2H), 8.06 (d, 2H), 8.01 (d, 2H), 7.76–7.65 (m, 8H). *Anal.* Calc. for $C_{41}H_{30}F_{12}N_{10}O_2P_2Ru$: C, 45.36; H, 2.79; N, 12.90. Found: C, 45.34; H, 2.80; N, 12.89%. ESI-MS: *m/z* 759 (M-2PF_6-H), 380 (M-2PF_6/2). UV–VIS (λ (nm), ε (M^{-1} cm^{-1})) (CH_3CN): 455 (22200), 263 (103000), 241 (34000).

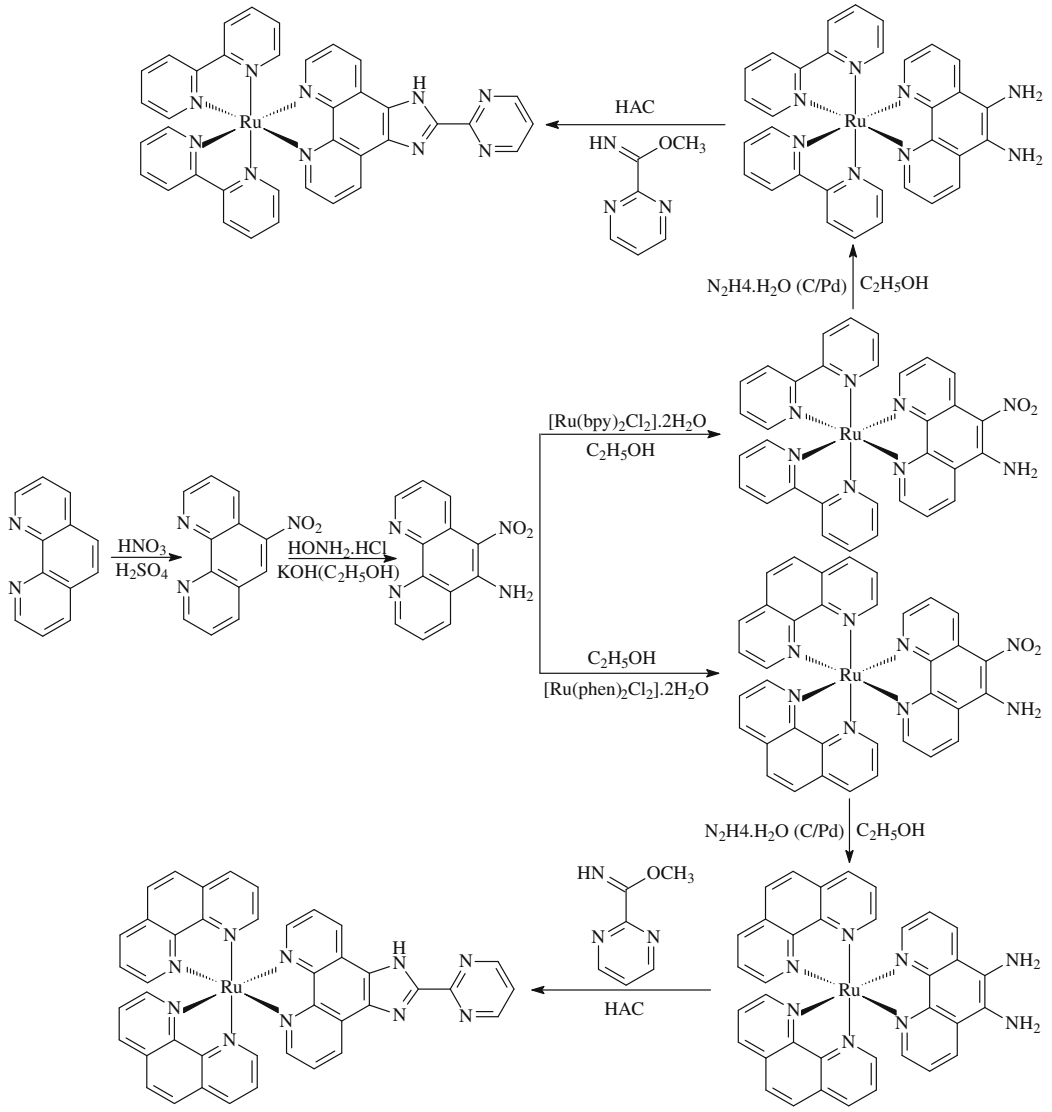
2.3. Physical measurements

Elemental analyses (C, H and N) were carried out with a Perkin–Elmer 240C elemental analyzer. ^1H NMR spectra were recorded on a Bruker DRX-500 NMR spectrometer with $(CD_3)_2SO$ as the solvent and $SiMe_4$ as an internal standard. Electrospray ionisation mass spectra (ESI-MS) were acquired on a Thermo Finnigan LCQ DECA XP ion trap mass spectrometer, equipped with an ESI source. Emission spectra were measured on a Shimadzu RF-5000 spectrofluorophotometer with excitation at 459 nm. Circular-dichroism (CD) spectra were measured on a JASCO J-810 spectropolarimeter and high-frequency noise was filtered out using JASCO J-600 software.

Electronic spectroscopic titrations were carried out at room temperature to determine the binding affinity between DNA and the complexes. Initially, 3000 L solutions of the blank buffer and the ruthenium complex sample (20 M) were placed in the reference and sample cuvettes (1 cm path length), respectively, and then the first spectrum was recorded in the range of 200–600 nm. During the titration, an aliquot (1–10 L) of buffered DNA solution (concentration of ~5–10 mM in base pairs) was added to each cuvette to eliminate the absorbance of DNA itself, and the solutions were mixed by repeated inversion. After the solutions were mixed for ~5 min, the absorption spectra were recorded. The titration processes were repeated until there was no change in the spectra for four titrations at least, indicating binding saturation had been achieved. The changes in the metal complex concentration due to dilution at the end of each titration were negligible.

Viscosity measurements were carried out using an Ubbelohde viscometer maintained at a constant temperature of 30.0 (±0.1) °C in a thermostatic bath. The DNA samples contained approximately 200 bp. Flow time was measured with a digital stopwatch and each sample was measured three times and an average flow time was calculated. Data are presented as $(\eta/\eta^0)^{1/3})$ versus binding ratio [23,24], where η is the viscosity of DNA in the presence of complex and η^0 is the viscosity of DNA in the absence of complex.

Thermal DNA denaturation experiments were carried out with a Perkin–Elmer Lambda 850 spectrophotometer equipped with a Peltier temperature-control programmer (±0.1) °C. The temperature of the solution was increased from 30 to 90 °C at a rate of 1 °C min^{-1}, and the absorbance at 260 nm was continuously monitored for solutions of CT-DNA (50 M) in the absence and presence of the Ru(II) complexes (5.0 M). The data are presented as $(A - A_0)/(A_f - A_0)$ versus temperature, where A_f, A_0 and A are the final, the initial, and the observed absorbance at 260 nm, respectively.



For the gel electrophotolysis experiments, supercoiled pBR322 DNA (10 μM) was treated with the enantiomers in 50 mM Tris–HCl (Tris = Tris(hydroxymethyl)methylamine) buffer (pH 8.3), 18 mM NaCl, and the solutions were then irradiated at room temperature with a UV lamp (365 nm, 10 W) for 60 min. The samples were analysed by electrophotolysis for about 2–3 h at 50 V on 1% agarose gel in Tris–boracic acid–EDTA (EDTA, ethylenediamine tetraacetate) buffer. The gel was stained with 0.5 μg ml^{-1} ethidium bromide (EB) and photographed with an Alpha Innotech IS-5500 fluorescence chemiluminescence and visible imaging system.

All the results obtained from the experiments were performed at least in triplicate.

3. Results and discussion

3.1. Synthesis and common spectral characteristics

The synthetic route to the complexes is summarized in Scheme 1. Both Ru(II) complexes were synthesized by treating $[Ru(L)_2$(5,6-diamino-1,10-phenanthroline)$]^{2+}$ (where L = 2,2′-bipyridine (bpy)

Scheme 1. Synthetic routes for the preparation of the complexes $[Ru(bpy)_2(pmip)]^{2+}$ (**1**) and $[Ru(phen)_2(pmip)]^{2+}$ (**2**).

or 1,10-phenanthroline (phen)) with pyrimidine-2-iminoacetate in glacial acetic acid. Each synthetic step involved here is straightforward and provides a good-to-moderate yield of the desired product in the pure form. These products were characterized by elemental analysis, ^{1}H NMR, electrospray ionisation mass spectra (ESI-MS) and UV/VIS spectroscopy.

The electronic spectra of these Ru(II) complexes in water (CH_3CN) are characterized by an intense ligand-centered transition (LC) in the UV region, at 286 and 263 nm, and a metal-to-ligand charge transfer (MLCT) in the visible region, at 459 and 455 nm for $[Ru(bpy)_2(pmip)]^{2+}$ and $[Ru(phen)_2(pmip)]^{2+}$, respectively, typical of any polypyridyl ruthenium(II) complex [25–28]. The visible bands around 455 nm are attributed to the overlap of Ru(dπ) → bpy/phen (π^*) and Ru(dπ) → pmip (π^*) transitions. Apart from these, ultraviolet bands around 284 and 238 nm for $[Ru(bpy)_2(pmip)]^{2+}$ can be attributed to (bpy) $\pi \rightarrow \pi^*$ transitions; the bands centered at 286 and 263 nm are attributed to (phen) $\pi \rightarrow \pi^*$ transitions for $[Ru(phen)_2(pmip)]^{2+}$.

3.2. UV/VIS spectroscopic studies

The application of electronic absorption spectroscopy is one of the most useful techniques in DNA-binding studies [29]. Complex binding with DNA through intercalation usually result in hypochromism and bathchromism, due to the intercalative mode involving a strong stacking interaction between an aromatic chromophore and the base pairs of DNA. The extent of the hypochromism commonly parallels the intercalative binding strength. Both **1** and **2** were titrated with CT-DNA. The changes in the spectral profiles during titration are shown in Fig. 1a and b. As the DNA concentration is increased, $[Ru(bpy)_2(pmip)]^{2+}$ and $[Ru(phen)_2(pmip)]^{2+}$ show hypochromicity (22.7% and 28.2%) and isosbestic points (478 and 475 nm), respectively. From the decay of the absorbance of complexes **1** and **2** monitored at 459 and 456 nm upon addition CT-DNA, an intrinsic binding constant K is obtained using Eq. (1), which was first developed by Bard [30]:

$$C_b = (b - (b^2 - 2K^2C_t[DNA]/s)^{1/2})/2K \quad (1a)$$

$$b = 1 + KC_t + K[DNA]/2s \quad (1b)$$

where C_b is the concentration of the bound complex, K is the microscopic binding constant for each site, [DNA] is the concentration of DNA in the nucleotide, C_t is the total metal complex concentration, and s is the site size in base pairs. This treatment is valid for cases of non-cooperative, non-specific binding to DNA [30]. The values of K and s for complexes **1** and **2** obtained from Marquart–Levichberg non-linear least-squares analysis are 5.13×10^5 M^{-1} (s = 2.41) and

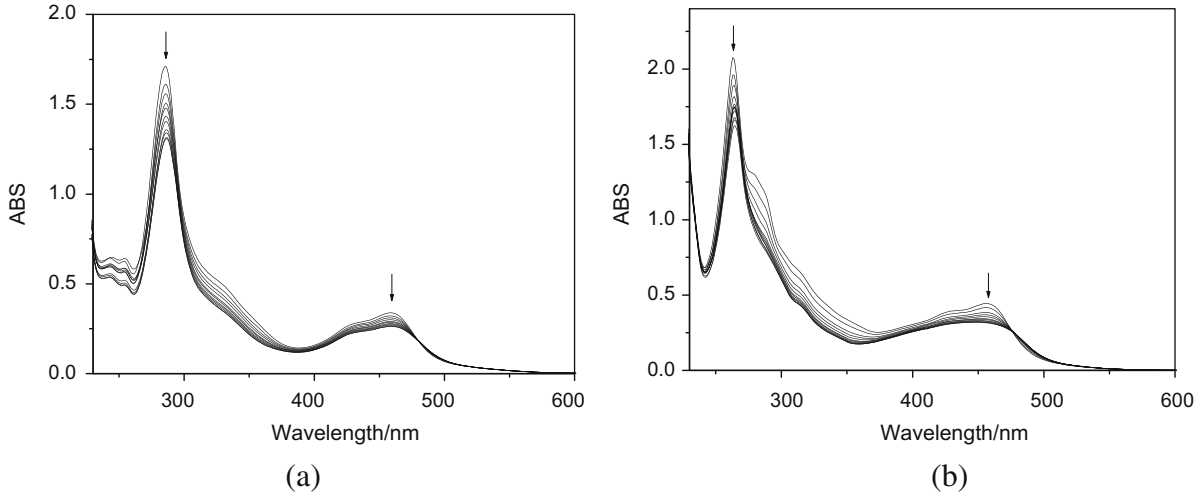


Fig. 1. Absorption spectra of **1** (a) and **2** (b) in 5 mM Tris buffer, pH 7.0, in the presence of calf thymus DNA ([Ru] = 20 μM, [DNA] = 0–200 μM). Arrow shows the absorbance changes upon increasing DNA concentration.

6.64×10^5 M^{-1} (s = 2.06), respectively, which are virtually identical to the values obtained for the ruthenium analogues [31,32]. Based on the measurement of the spectroscopic properties and binding constants, the DNA-binding affinity of complex **2** is greater than that of **1**. The results are due to the different ancillary ligands. On going from bpy to phen, the plane area and hydrophobicity increase, leading to a greater DNA-binding affinity for complex **2**.

3.3. Luminescence studies

In the absence of DNA, both complexes **1** and **2** can emit luminescence in Tris buffer at ambient temperature, with a maximum appearing at 599 and 598 nm, respectively. The results of the emission titrations for complexes **1** and **2** with DNA are illustrated in Fig. 2. Upon addition of CT-DNA, the emission intensities of complexes **1** and **2** increase to around 2.14 and 2.78 times larger than the original intensities, respectively (Fig. 3). This implies that both complexes can strongly interact with DNA and be protected by DNA efficiently, since the hydrophobic environment inside the DNA helix reduces the accessibility of solvent water molecules to the complex and the complex mobility is restricted at the binding site, leading to a decrease of the vibrational modes of relaxation.

3.4. Viscosity studies

To further clarify the nature of the interaction between the complexes and DNA, viscosity measurements were carried out. Optical photophysical probes provide necessary, but not sufficient, evidence to support the model of binding of the Ru(II) complexes with DNA. Hydrodynamic measurements that are sensitive to length change (i.e., viscosity and sedimentation) are regarded as the least ambiguous and the most critical tests of a binding model in solution in the absence of crystallographic structural data [33,34]. Intercalation is expected to lengthen the DNA helix as the base pairs are pushed apart to accommodate the bound ligand, leading to an increase in the DNA viscosity. In contrast, a partial, non-classical intercalation of the ligand could bend (or kink) the DNA helix, reduce its effective length and, concomitantly, its viscosity. The effects of complexes **1** and **2**, together with $[Ru(bpy)_3]^{2+}$ and EB on the viscosity of rod-like DNA are shown in Fig. 4. The well-known DNA intercalator EB increases the viscosity of DNA with increments of the concentration. On the other hand, for $[Ru(bpy)_3]^{2+}$, which has been well known to bind with DNA through the electrostatic mode, there is no effect on the relative viscosity of the DNA solution. Upon increasing the amount of **1** or **2**, the relative

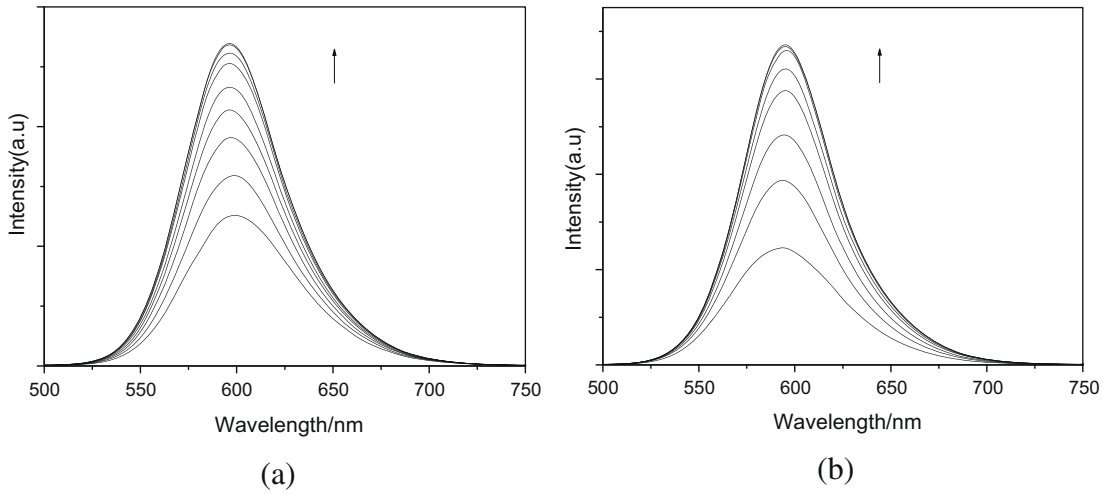

Fig. 2. Emission spectra of **1** (a) and **2** (b) in the presence of increasing amounts of CT-DNA, [Ru] = 20 μM, [DNA] = 0–500 μM. Arrow shows the emission intensity changes upon increasing DNA concentrations.

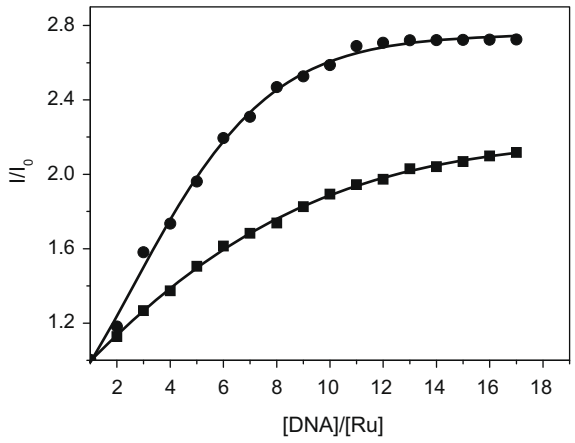

Fig. 3. Plots of relative emission intensity (I/I_0) vs. the [DNA]/[Ru] ratio for Ru(II) complexes **1** (■) and **2** (●) in 5 mM Tris–HCl buffer (pH 7.0), 50 mM NaCl, [Ru] = 20 μM.

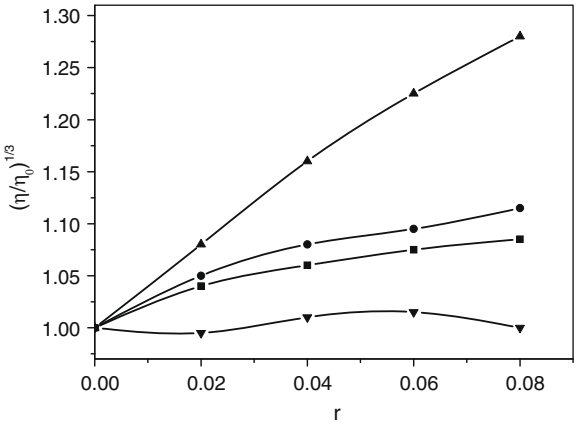

Fig. 4. Effects of increasing amounts of complexes **1** (■); **2** (●); EB (▲); $[Ru(bpy)_3][PF_6]_2$ (▼) on the relative viscosities of CT-DNA at 30 (±0.1) °C; [DNA] = 0.5 mM; r = [Ru]/[DNA].

viscosity of DNA increased steadily, similarly to the case of EB. The increase of the relative viscosity, expected to correlate with the DNA-intercalating potential of a compound, follows the order EB > **2** > **1** > $[Ru(bpy)_3]^{2+}$. These results suggest that the both title complexes intercalate between the base pairs of DNA, the difference in binding strength probably being caused by the different ancillary ligands.

3.5. Thermal denaturation studies

The thermal behavior of DNA in the presence of complexes can give insight into their conformational changes when the temperature is raised, and offer information about the interaction strength of the complexes with DNA. It is well known that when the temperature in the solution increases, the double stranded DNA gradually dissociates to single strands, generating a hyperchromic effect in the absorption spectra of the DNA bases (λ_{max}, 260 nm). To identify this transition process, the melting temperature T_m, which is defined as the temperature where half of the total base pairs are unbonded, is usually determined. According to the literature [35,36], the intercalation of metallo-intercalators generally results in a considerable increase of T_m. The melting curves of CT-DNA in the absence and presence of the complexes are presented in Fig. 5. Here, the thermal denaturation experiment carried out

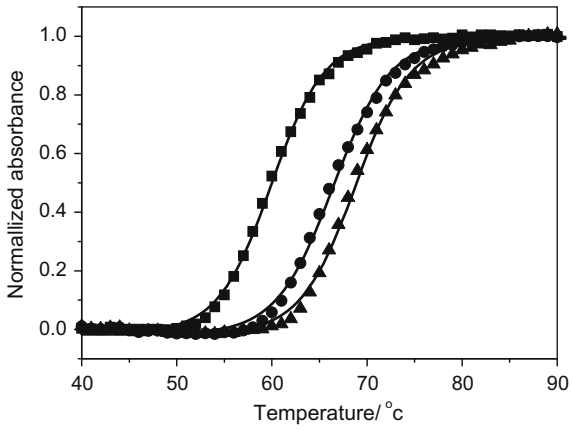

Fig. 5. Melting temperature curves of CT-DNA in the absence (■) and presence of complexes **1** (●) and **2** (▲). [Ru] = 5 μM, [DNA] = 50 μM.

for DNA in the absence of the Ru(II) complexes revealed a T_m of 60.0 °C under our experimental conditions. On addition of **1** or **2**, T_m of DNA increased to 66.5 and 68.8 °C, respectively, at a concentration ratio [DNA]/[Ru] of 10:1. The large increase (6.5 and 8.8) in T_m is comparable to that observed for classical intercalators [35,36].

The DNA intrinsic binding constant at T_m can be obtained from the McGhee equation (Eq. (3)) [37], where T_m^0 is the melting temperature of CT-DNA alone, T_m is the melting temperature in the presence of the Ru(II) complex, ΔH_m is the enthalpy of DNA (per base pair), R is the gas constant, K is the DNA-binding constant at T_m, L is the free complex concentration (approximated at T_m by the total complex concentration) and n is the size of the binding site

$$\frac{1}{T_m^0} - \frac{1}{T_m} = \left(\frac{R}{\Delta H_m}\right) \ln(1 + KL)^{1/n} \quad (2)$$

For the CT-DNA used in these studies, under identical solution conditions, a melting enthalpy of 6.9 kcal mol^{-1} was determined by differential scanning calorimetry [34]. On the basis of the absorption spectra titration experiment and the neighbor-exclusion principle, the value of n for both complexes was assumed to be 2.0 bp. K was determined to be 1.99×10^4 M^{-1} at 66.5 °C for **1** and 2.74×10^4 M^{-1} at 68.8 °C for **2** by substitution of the required parameters into Eq. (2). The standard enthalpy, standard entropy and standard free-energy change of the binding of **1** and **2** to CT-DNA were determined by the van't Hoff's equations (3)–(5), where K_1 and K_2 are the DNA-binding constants of the metal complex at temperatures T_1 and T_2, respectively, and ΔH^0, ΔG^0 and ΔS^0 are the standard enthalpy, standard free-energy and standard entropy changes of the metal-complex-binding to DNA, respectively:

$$\ln\left(\frac{K_1}{K_2}\right) = \frac{\Delta H^0}{R}\left(\frac{T_1 - T_2}{T_1 T_2}\right) \quad (3)$$

$$\Delta G^0 = -RT \ln K \quad (4)$$

$$\Delta G^0 = \Delta H^0 - T\Delta S^0 \quad (5)$$

The values of ΔH^0, ΔG^0 and ΔS^0 were found to be −65.9 kJ mol^{-1}, −32.6 kJ mol^{-1} and −111.7 J mol^{-1} K^{-1} for **1**, and −61.6.1 kJ mol^{-1}, −33.2 kJ mol^{-1} and −95.4 J mol^{-1} K^{-1} for **2**, respectively. The negative ΔG^0 values suggest that the energy of the complex–DNA adduct is lower than the sum of the energies of the free complex and DNA. The negative ΔH^0 values suggest that the binding of the complex to DNA at 25 °C is exothermic and is driven by enthalpy. The negative entropy values indicate that the degree of freedom of the Ru(II)

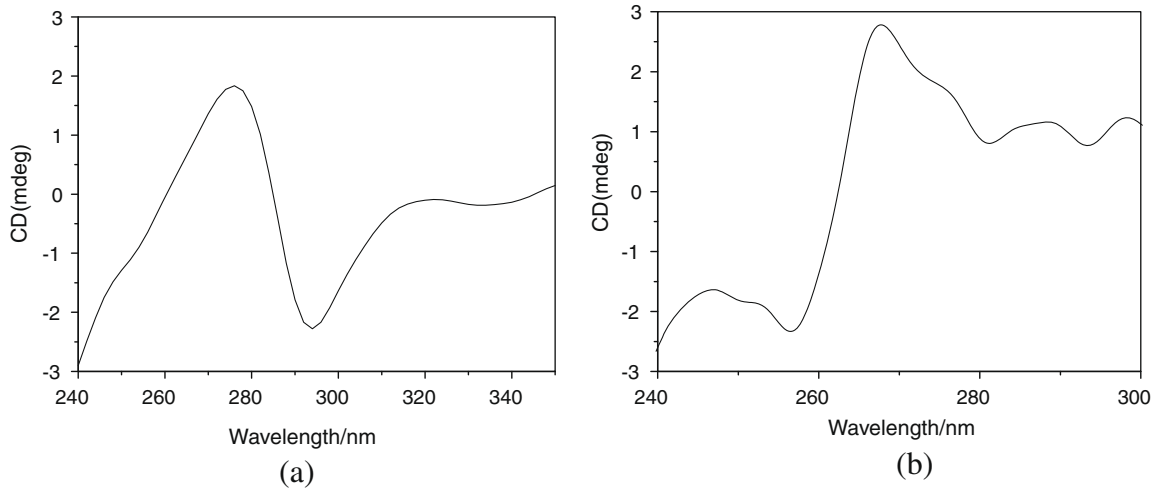

Fig. 6. CD spectra of dialysates of **1** (a) and **2** (b) against CT-DNA for 24 h with the solution stirred; [Ru] = 50 μM, [DNA] = 1.0 mM).

complexes is decreased after the binding, and that the DNA conformational freedom is also reduced upon complex–DNA binding.

3.6. Enantioselective DNA binding

Equilibrium dialysis experiments offer the opportunity to examine the enantioselectivity of complexes binding to DNA. According to the proposed binding mode [38], the Δ-enantiomer of the complex, a right-handed propeller-like structure, will display a greater affinity to the right-handed calf thymus DNA helix than the Λ-enantiomer, due to the appropriate steric matching. The enantiospecific binding of a complex to DNA can be observed clearly from circular-dichroism spectra. The presence of CD signals indicates enrichment of the enantiomer binding less favorably to DNA in the dialysate. Thus, racemic solutions of the two complexes were dialyzed against CT-DNA for 24 h and then subjected to circular-dichroism (CD) analysis. The CD spectra in the UV region of dialysates of **1** and **2** are shown in Fig. 6. The dialysate of complex **1** shows two strong CD signals with a positive peak at 276 nm and a negative peak at 294 nm, while complex **2** shows strong CD signals with a positive peak at 271 nm and a negative peak at 256 nm. Although neither of the complexes is resolved into the pure enantiomer, and we cannot determine which enantiomer binds preferentially to CT-DNA, it is evident that both **1** and **2** bind to CT-DNA enantioselectively.

3.7. DNA photocleavage

There is substantial and continuing interest in DNA endonucleolytic cleavage reactions that are activated by metal ions. The cleavage reaction on plasmid DNA can be monitored by agarose gel electrophoresis. When circular plasmid DNA is subjected to electrophoresis, relatively fast migration will be observed for the intact supercoil form (form I). If scission occurs on one strand (nicking), the supercoil will relax to generate a slower-moving open circular form (form II). If both strands are cleaved, a linear form (form III) that migrates between forms I and II will be generated [39]. The photocleavage of pBR 322 DNA in the absence and presence of the Ru(II) complexes was carried out in 50 mM Tris–HCl buffer (pH 8.3), 18 mM NaCl under UV-irradiation, as seen in Fig. 7. Almost no DNA cleavage was observed for the control, in which metal complex was absent (lane 0). With increasing concentrations of the Ru(II) complexes (lanes 1–4 and 5–8), the amount of form I of pBR322 DNA diminishes gradually, whereas form II increases. Under comparable experimental conditions, complex **2** exhibits more

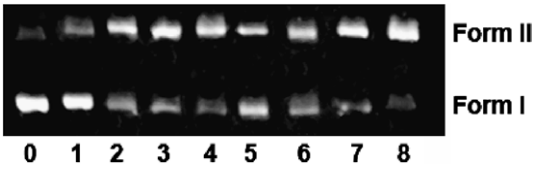

Fig. 7. Photoactivated cleavage of pBR 322 DNA in the absence (lane 0) and presence of **1** (lanes 1–4) or **2** (lanes 5–8) of 20, 40, 60, 80 μM, respectively; all lanes were irradiation at 365 nm for 60 min.

effective DNA cleavage activity than complex **1**. This may be related to the different binding affinity of **1** and **2** to DNA. Further detailed studies are currently underway to clarify the cleavage mechanism.

4. Conclusions

In summary, two new Ru(II) complexes, $[Ru(bpy)_2(pmip)]^{2+}$ and $[Ru(phen)_2(pmip)]^{2+}$, were synthesized and characterized. Their DNA-binding and photocleavage properties were also investigated. Spectroscopic studies, thermal denaturation study and viscosity experiments support that the two complexes can intercalate into DNA base pairs via the pmip ligand. When irradiated at 365 nm, the two Ru(II) complexes are efficient photocleavers of the plasmid pBR 322 DNA.

1720 spectrophotometer, from KBr pellets in the 4000–370 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from polyethylene pellets in the 500–150 cm^{-1} range. Electronic spectrum in a solution of ATHAc was measured on a Shimadzu UV-3101 PC spectrophotometer using a 10 mm quartz cell. The UV–Vis–NIR reflectance spectra for nickel complexes in the 200–1200 nm range were registered from a pellet of the sample, using a Shimadzu UV-3101 PC spectrophotometer and $BaSO_4$ as a reference. Magnetic measurements were made in the temperature range 2–300 K with a magnetometer with a pendulum MANICS DSM8, equipped with a helium continuous-flow cryostat and an electromagnetometer DRUSCH EAF 16 UE. Data were corrected for diamagnetic contributions, which were estimated from the Pascal constants. ^1H and ^{13}C NMR spectra for ATHAc were obtained with a Bruker AM 400 instrument at 400 and 100 MHz, respectively, in $CDCl_3$ using Me_4Si as the internal standard.

2.2. Synthesis of 2-acetyl-2-thiazoline semicarbazone (ATsc)

The synthesis of ATsc was performed according to the procedure reported elsewhere [18].

2.3. Synthesis of 2-acetyl-2-thiazoline acetylhydrazone (ATHAc)

To a solution containing 2-acetyl-2-thiazoline (800 mg, 6.20 mmol) in 5 mL absolute ethanol were added a solution of acetylhydrazine 90% (510 mg, 6.43 mmol) in 15 mL absolute ethanol and 1 mL of glacial acetic acid, and the resulting solution was heated to reflux for 3 h. Then the solution was cooled and a white solid appeared (671 mg, 59%). This solid was recrystallized from dichloromethane, yielding prismatic crystals, of considerable size, suitable for X-ray diffraction.

^1H NMR ($CDCl_3$): δ 9.77 (s, 1H, NH), 4.43 (t, J = 8 Hz, 2H, CH_2–N), 3.27 (t, J = 8 Hz, 2H, CH_2–S), 2.35 (s, 3H, C(7)H_3), 2.24 (s, 3H, C(5)H_3); ^{13}C NMR ($CDCl_3$): δ 174.4 C(1), 169.6 C(6), 144.0 C(4), 65.2 C(2), 32.1 C(3), 20.4 C(7), 12.1 C(5). *Anal.* Calc. for $C_7H_{11}N_3SO$: C, 45.39; H, 5.98; N, 22.68; S, 17.31. Found: C, 45.47; H, 6.05; N, 22.81; S, 17.18%. IR(KBr): ν(NH) 3183, 3119, 3086; ν(C=O) 1677; ν(C=N) 1620; ring vibrations 1584, 1008, 921, 738, 722, 672, 601, 549, 442 cm^{-1}. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 264 (35 720).

2.4. Preparation of [{Ni(ATsc)(MeOH)}$_2$(μ-Cl)$_2$]Cl$_2$ (**1**)

This complex was prepared by reacting a methanol solution (2 mL) of $NiCl_2 \cdot 6H_2O$ (121 mg, 0.51 mmol) with a methanol solution (40 mL) of ATsc (100 mg, 0.51 mmol). The resulting solution was surrounded with ether using a liquid–vapour diffusion method to obtain green crystals (103 mg, 55%). The crystals were filtrated, washed with cold ether and finally air dried. *Anal.* Calc. for $C_{14}H_{28}Cl_4N_8Ni_2O_4S_2$: C, 24.16; H, 4.05; N, 16.10; S, 9.21. Found: C, 23.94; H, 3.83; N, 16.17; S, 8.96%. IR(KBr): $\nu(NH_2)$ 3295; ν(NH) 3230, 3177; ν(C=O) 1679; ν(C=N) 1654; ring vibrations 1601, 1019, 856, 747, 690, 630, 574, 539, 446 cm^{-1}.

2.5. Preparation of [{Ni(ATHAc)(H_2O)}$_2$(μ-Cl)$_2$]Cl$_2$ (**2**)

$NiCl_2 \cdot 6H_2O$ (64 mg, 0.27 mmol) dissolved in ethanol (2 mL) was added to a ethanol solution (20 mL) of ATHAc (50 mg, 0.27 mmol). The resulting solution was allowed to evaporate slowly at room temperature. After a few days, green prismatic crystals of considerable size were isolated from the solution (77 mg, 86%). Crystals were separated by filtration, washed with cold ether and air dried. *Anal.* Calc. for $C_{14}H_{26}Cl_4Ni_2N_6O_4S_2$: C, 25.26; H, 3.94; N, 12.62; S, 9.63. Found: C, 25.29; H, 3.93; N, 12.22; S, 9.40%. IR(KBr): $\nu(H_2O)$ 3421; ν(NH) 3044; ν(C=O) 1643; ν(C=N) 1629; ring vibrations 1572, 1006, 956, 760, 715, 688, 602, 501, 443 cm^{-1}.

2.6. Crystal structure determinations

Experimental details of the crystal structure determinations, including crystal data, data collection, structure determination and refinement parameters for ATHAc, **1** and **2** are listed in Table 1. X-ray diffraction measurements were performed using a Bruker SMART CCD diffractometer with Mo Kα radiation (λ = 0.71073 Å, graphite monochromator). The first fifty frames were measured at the end of the data collection to monitor instrument and crystal stability. Absorption corrections were applied using the program SADABS [20]. The structures were solved by direct methods and subsequent Fourier differences using the SHELXS-97 [21] program and refined by full-matrix least-squares on F^2 with SHELXL-97 [22], included in WINGX [23] package assuming anisotropic displacement parameters for non-hydrogen atoms. The hydrogen atoms on ATHAc were obtained from a difference Fourier synthesis and refined without any constraints, excepting hydrogen atoms of methyl groups which were calculated in ideal positions. In complexes, all hydrogen atoms attached to carbon and nitrogen atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding carbon and nitrogen atoms. The crystal structure of **1** presents a disorder affecting the methyl group of the methanol molecule. Due to the impossibility of modelizing the disorder, the EADP restraints were applied to the disordered atom C(7), remaining two Fourier peaks corresponding carbon disorder positions, Q1 (*0.1049, 0.8578, 0.9479*) and Q2 (*0.0059, 0.9334, 0.9247*), located approx. at 0.8 Å of C(7). Diagrams were generated using ORTEP3 for Windows [24].

3. Results and discussion

3.1. Description of the structures

An ORTEP diagram of the molecular structure of ATHAc is shown in Fig. 1. Selected bond lengths, angles and hydrogen-bond parameters are listed in Table 2.

In the S–C(1)–N(1)–C(2)–C(3) ring the short endocyclic C=N bond [C(1)–N(1) = 1.266(3) Å] is accompanied by a high N–C–S angle [N(1)–C(1)–S = 118.7(2)°] and a relatively long S^{II}–C(sp^2) bond [S–C(1) = 1.757(2) Å], which is characteristic of a thiazoline ring [25]. It is known that the imino tautomers can exist as two geometric isomers, *syn* (*Z*) and *anti* (*E*), but in this crystal, only the *E* isomers have been observed.

Both thiazoline ring and acetylhydrazone group are essentially planar with maximum least square plane deviations for C(3) [0.012 Å] and N(3) [0.026 Å], respectively.

The molecular units of ATHAc are linked by hydrogen bonds in which carbonyl oxygen atom acts as acceptor of hydrogen, whereas the nitrogen atom N(3) acts as donor. A diagram showing the hydrogen bonds is given in Fig. 1.

The X-ray study of **1** revealed that the crystals are made up of monoclinic unit cells, each containing two dimeric [{Ni(ATsc)(MeOH)}$_2$(μ-Cl)$_2$]$^{2+}$ cations and four Cl anions. The molecular structure of the dimeric cation with the atomic labelling is shown in Fig. 2. Selected bond lengths, angles and hydrogen-bond parameters are given in Table 3. In dimeric cations there are two six-coordinate nickel(II) centres, each of which is bonded to a tridentate NNO ATsc ligand. The remaining coordination sites on each metal are occupied by a methanol ligand and two bridging chloride ligands. The bridging Ni_2Cl_2 unit is strictly planar by the presence of the crystallographic inversion centre in the middle of the dimer.

The environment around each nickel(II) atom may be described as a distorted octahedral geometry with the ligand–metal–ligand

bite angles varying between 76.8(1)° [N(2)–Ni–N(1)] and 103.2(1)° [N(1)–Ni–Cl(1)].

The {Ni(μ-Cl)$_2$Ni} motif is asymmetrical with Ni–Cl bond lengths of 2.348(1) and 2.396(1) Å. The Ni···Ni distance within dimer is 3.399(1) Å. The Ni–Cl and Ni···Ni bond lengths have been compared with the mean value calculated using the data of 49 dichloride-bridged six-coordinate nickel(II) dimers obtained from CSD [9]. The short Ni–Cl$_{bridging}$, the long Ni–Cl$_{bridging}$ and the Ni···Ni distances are shorter than the calculated average values 2.416(45), 2.471(56) and 3.60(11) Å, respectively. Likewise, the Ni–O$_{methanol}$ bond length is similar to the average value [2.115(44) Å] calculated using the data of 188 six-coordinated nickel(II) complexes containing this kind of union from CSD [9]. In the same way, the Ni–O$_{ketone}$

and Ni–N_{imine} bond lengths have been compared with the mean value calculated with the data of eight nickel(II) complexes bonded to a semicarbazone moiety obtained from the CSD [9]. Thus, these bond lengths are in good agreement with the mean value of 2.105(29) Å for the Ni–O_{ketone} distance and 2.000(23) Å for the Ni–N_{imine} distance. Finally, the Ni–$N_{thiazoline}$ bond length is comparable to the calculated average value [2.049(53) Å] for eight nickel(II) complexes with the 2-thiazoline ligand collected in CSD [9].

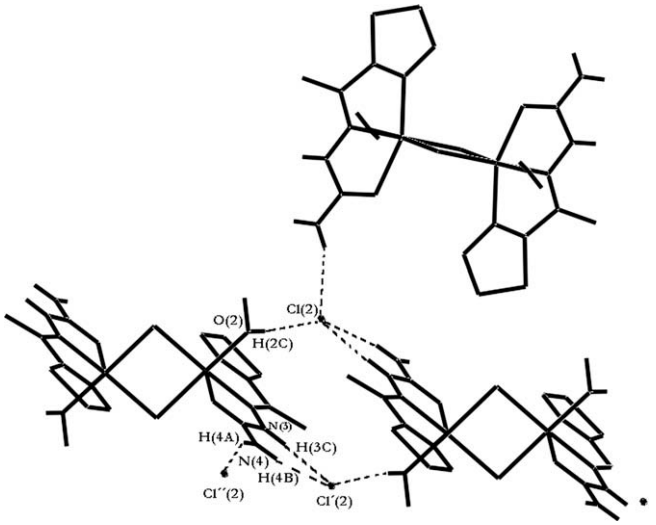

Fig. 3. View of the hydrogen bonds of **1**. Symmetry codes: $'-x,-y+2,-z+1$; $''-x,y+0.5,-z+1.5$.

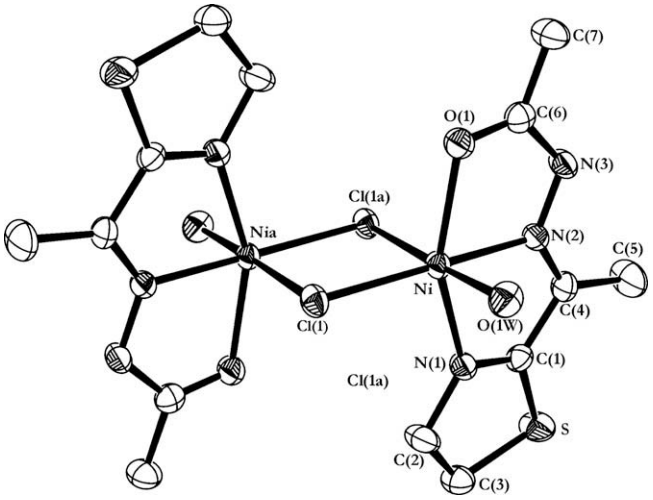

Fig. 4. Molecular structure of cation complex $[\{Ni(ATHAc)(H_2O)\}_2(\mu\text{-}Cl)_2]^{2+}$, showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 40% probability level.

The five-membered chelate rings are essentially planar with maximum deviation in relation to the corresponding mean plane for C(4) (0.031 Å) [chelate ring Ni–N(1)–C(1)–C(4)–N(2)] and C(6) (0.039 Å) [chelate ring Ni–N(2)–N(3)–C(6)–O(1)].

Finally, the crystal structure is stabilized by a hydrogen-bond network in which chloride ions Cl(2) act as acceptors of hydrogen, whereas the OH group of the methanol ligand and nitrogen atoms N(3) and N(4) act as donors. A diagram showing this network is given in Fig. 3.

The crystal structure of **2** with the atomic labelling is shown in Fig. 4. Selected bond lengths, angles and hydrogen-bond parameters are given in Table 3.

The structure of **2** is very similar to that of **1**, which has been already described, being the methanol molecule substituted by a water molecule in the coordination sphere of **2**, and having the organic ligand ATHAc a terminal methyl group instead of an amine one as in ATsc. Thus, the structure of **2** shows a Ni(II)–Ni(II) dinuclear unit in which the chromophore group around each nickel atom is also $NiCl_2N_2O_2$. The distance between the two Ni(II) atoms [3.475(1) Å] is longer than that found in **1**. The octahedral coordination sphere of the Ni centres is distorted, as is indicated by the bond angles around the metal (Table 3).

The Ni–O_{water} bond distance is comparable to the mean value [2.105(70) Å] calculated with the data of six six-coordinated Ni(II) complexes containing the chromophore group $NiCl_2N_2O_2$ found in CSD [9]. The asymmetry of Ni–Cl_{bridge} distances [δ = 0.144 Å] is larger than that found in **1**. Likewise, the rest of the Ni–ligand distances are similar to those of **1**.

The five-membered chelate rings Ni–N(1)–C(1)–C(4)–N(2) and Ni–N(2)–N(3)–C(6)–O(1) are essentially planar with maximum mean plane deviation for C(1) (0.040 Å) and C(6) (0.014 Å), respectively.

The crystal structure presents a network of hydrogen bonds in which the amine group and the water molecule act as hydrogen donors and Cl ions act as acceptors, as it is shown in Fig. 5.

Finally, it should be pointed out that the main difference in both complexes with respect to the structure of free ligands ATsc and ATHAc is due to the different degree of rotation of the thiazoline rings around the C(1)–C(4) bond, which permits the coordination through thiazoline nitrogen atoms [torsion angle S–C(1)–C(4)–N(2) = −173.5° in **1**; 4.4° in ATsc [18]; S–C(1)–C(4)–

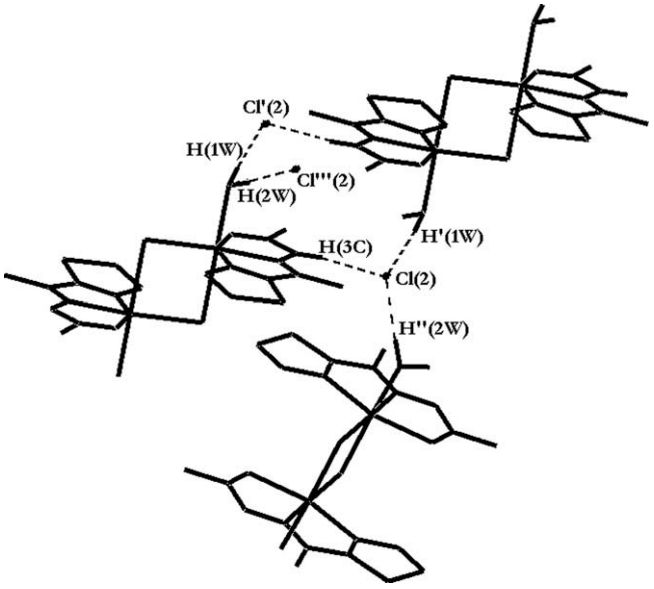

Fig. 5. View of the hydrogen bonds of **2**. Symmetry codes: $'-x+2,-y+1,-z$; $''-x,y+1.5,z+0.5$; $'''x,-y+1.5,z-0.5$.

N(2) = −172.4° in **2**; 3.2° in ATHAc]. The formation of the complexes requires also rotation around the C(6)–N(3) bond, which permits the coordination through the carbonyl oxygen atoms [N(2)–N(3)–C(6)–O(1) = 1.2° in **1**; 177.5° in ATsc [18]; N(2)–N(3)–C(6)–O(1) = 1.1° in **2**; −177.4° in ATHAc].

3.2. IR spectra

The IR spectrum of ATHAc in the 4000–370 cm^{-1} region shows the presence of bands registered at 1677 and 1620 cm^{-1} that can be assigned to ν[C=O] and ν[C=N] vibrations, respectively [26,27]. Moreover, in the IR spectra of the complexes **1** and **2** relevant bands are registered at 1679 [ν(C=O)] and 1654 cm^{-1} [ν(C=N)] for **1** and at 1643 [ν(C=O)] and 1629 cm^{-1} [ν(C=N)] for **2**.

The far IR spectra of these complexes show the appearance of bands due to metal–ligand stretching vibrations. Thus, the band that is registered at 244 cm^{-1} in the spectrum of **1** has been tentatively assigned to the $\nu(Ni–O_{methanol})$ vibration, while the band at 329 cm^{-1} for **2** corresponds to the $\nu(Ni–O_{water})$ vibration [28–30]. The bands that appear at 203 and 226 cm^{-1} for **1** and at 196 and 233 cm^{-1} for **2** can be assigned to ν(Ni–Cl) vibrations, in accord with the literature data for this type of bond [26,31,32]. The bands at 294 cm^{-1} for **1** and at 293 cm^{-1} for **2** are attributed to the $\nu(Ni–N_{thiazoline})$ vibration [28,33] and the bands registered at 309 cm^{-1} for **1** and at 311 cm^{-1} for **2** are assigned to the $\nu(Ni–N_{imino})$ vibration [33–36]. Finally, the $\nu(Ni–O_{ketone})$ vibration corresponds to the bands at 347 cm^{-1} for both complexes [26].

3.3. Electronic spectra

The reflectance spectra of complexes **1** and **2** (see Fig. 6) are very similar and show one intense band at 32 890 cm^{-1} (304 nm) for **1** and another one at 32 260 cm^{-1} (310 nm) for **2**, that are assigned to charge transfer bands. Moreover, the spectra exhibit bands at 8820, 12 740 (sh), 14 080 and 24 450 (sh) cm^{-1} for **1** and at 9210, 12 820 (sh), 14 580 and 25 000 (sh) cm^{-1} for **2**. These bands may be assigned for each spectrum as $\nu_1[^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)]$, $[^3A_{2g}(F) \rightarrow {}^1E_g(D)]$, $\nu_2[^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)]$ and $\nu_3[^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)]$ transitions, respectively, in an idealized O_h symmetry. The ligand field parameters, 10Dq and B, has been calculated from the position of the observed d–d transitions, using the following known relationships [37]:

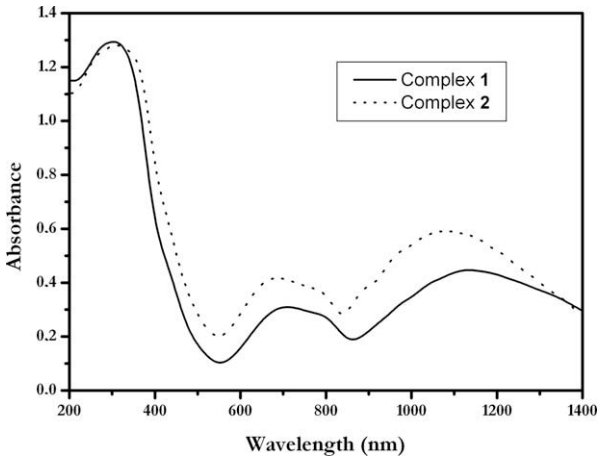

Fig. 6. Electronic spectra in the solid state for **1** and **2**.

$$\nu_1 = 10Dq \quad (1)$$

$$\nu_2 = (1/2)(15B + 30Dq) - (1/2)[(15B - 10Dq)^2 + 12B \cdot 10Dq]^{1/2} \quad (2)$$

$$\nu_3 = (1/2)(15B + 30Dq) - (1/2)[(15B - 10Dq)^2 + 12B \cdot 10Dq]^{1/2} \quad (3)$$

[a] *Abbrevations for ligands:* TTF, 4,5-bis(2piridylmethylsulfanyl)-4′,5′-ethylenedithiotetrathiafulvene; TPA, tris-(2-pyridylmethyl)amine; eg, ethylene glycol; en, ethylendiamine; bipy, bipyridine; L, 3,11-dithia-7,17-diazabicyclo[11.3.1]heptadeca-1(17),13,15-triene. Ni–Cl_s is the shorter of the two Ni–Cl bonds, Ni–Cl_l is the longer of the two Ni–Cl bonds, and X is the sum of Ni–Cl_s and Ni–Cl_l.

The calculated values of the ligand field parameters $10Dq = 8675\ cm^{-1}$ and $B = 827\ cm^{-1}$ for **1** and $10Dq = 9040\ cm^{-1}$ and $B = 791\ cm^{-1}$ for **2** are similar to those found in other octahedral nickel(II) complexes [33,38].

3.4. Magnetic properties

The temperature dependence of the magnetic susceptibility of **1** and **2**, in the form of χ_m and $\chi_m T$, is shown in Fig. 7, being χ_m the magnetic susceptibility per dinuclear Ni(II) compound and T the temperature. The high-temperature data ($T > 140$ K) were fit to a Curie–Weiss relationship, yielding $C = 2.70\ cm^3\ mol^{-1}\ K$ and $\theta = 3.36$ K for **1** and $C = 2.73\ cm^3\ mol^{-1}\ K$ and $\theta = 4.60$ K for **2**, which clearly indicate that magnetic interaction between nickel(II) ions is ferromagnetic. The corrected magnetic moments measured were 3.30 BM for **1** and 3.34 BM for **2**, which can be related to an octahedral environment in nickel(II) complexes [39]. The room-temperature $\chi_m T$ product is $2.73\ cm^3\ K\ mol^{-1}$ for **1** and $2.79\ cm^3\ K\ mol^{-1}$ for **2**, which is slightly larger than that expected for two magnetically isolated ions ($2.0\ cm^3\ K\ mol^{-1}$) [40]. $\chi_m T$ increases with decreasing temperature to a maximum of $3.42\ emu\ K\ mol^{-1}$ for **1** and $3.62\ emu\ K\ mol^{-1}$ for **2** at 14.0 K due to a ferromagnetic exchange coupling and then $\chi_m T$ decreases sharply to 2.1 K, which could be due to intermolecular interactions and/or single-ion zero-field splitting [41]. Inclusion of zero-field splitting terms in the analysis of the magnetic susceptibility data means Ginsberg's equation [41] provided poor data fittings. Moreover, the decrease in magnetic moment below 5 K as well as structural data that indicate the presence of a hydrogen-bond network in the packing of the structure suggest antiferromagnetic interdimer interactions [42]. Therefore, the experimental data were fitted considering the molecular field approximation given by Khan (Eq. (4)) [1]:

$$\chi_m = \frac{\chi_{dimer}}{1 - (2zJ'/Ng^2\mu_B^2)\chi_{dimer}} \tag{4}$$

$$\chi_{dimer} = \frac{2Ng^2\mu_B^2}{kT}\left[\frac{\exp(2J/kT) + 5\exp(6J/kT)}{1 + 3\exp(2J/kT) + 5\exp(6J/kT)}\right]$$

Here J is the intradimer exchange interaction, zJ' is the interdimer coupling constant, and the other symbols have their usual meaning. The parameters for the best fit were $g = 2.291(3)$, $J = 5.7(2)\ cm^{-1}$ and $zJ' = -0.253(3)\ cm^{-1}$ for **1** and $g = 2.302(5)$, $J = 6.6(3)\ cm^{-1}$ and $zJ' = -0.153(4)\ cm^{-1}$ for **2**, respectively. The agreement factor R, defined as

$$R = \sum[(\chi T_{Mj}^{obs} - \chi T_{Mj}^{calc})/\chi T_{Mj}^{obs}]$$

is then equal to 1.71×10^{-4} for **1** and 5.52×10^{-4} for **2**. These results indicate ferromagnetic intradimer exchange behaviour and weak antiferromagnetic interdimer exchange behaviour. The ferromagnetic coupling is in good agreement with pseudo-octahedral geometry around nickel(II) ions where the degeneracy of e_g level is maintained [43]. Comparable J and zJ' values are obtained, in agreement with the similarities in structure.

To our knowledge, this is the first analysis of magnetic properties for dinuclear chloro-bridged Ni(II) compounds with tridentate ligands. More structural and magnetic data on related compounds will be necessary for rationalize the magnetic properties. In this way, we have collected all chloride-bridged nickel dimers found in CSD [9] with octahedral Ni(II) ions and magnetic properties which are indicated in Table 4. Although several authors as Tamayo et al. [44] or Bkouche-Waskman et al. [45] have established a correlation between J value and the length of the superexchange pathway for compounds with a close structural resemblance, from the analysis of some more examples can be deduced that Ni–Cl–Ni angle and Ni–Cl distances do not determine in a clear form the value of the exchange constant. In fact, in our compounds the major value of J appears in **2**, where this angle and these distances are larger, but this tendency is not clearly observed in Table 4.

4. Conclusion

We prepared and characterized a new ligand, 2-acetil-2-thiazoline acetylhydrazone (ATHAc), and two new chloride-bridged dinuclear nickel(II) complexes with tridentate NNO ligands, namely, $[\{Ni(ATsc)(MeOH)\}_2(\mu\text{-}Cl)_2]Cl_2$ (**1**) and $[\{Ni(ATHAc)(H_2O)\}_2(\mu\text{-}Cl)_2]Cl_2$ (**2**). The complexes have similar structures features with octahedral Ni(II) centres bridged by two chloride ligands. Variable temperature magnetic susceptibility measurements for the solid samples of **1** and **2** in the range 2–300 K show that ferromagnetic interactions occur in both complexes. To our knowledge, this is the first analysis of magnetic properties for dinuclear chloro-bridged Ni(II) compounds with tridentate ligands. We tried to relate the magnetic properties to the structure of nickel dimers with bridging chloride ligands, finding that no relation exists according to our results and bibliographic data. From the results of diffuse reflectance for **1** and **2** we could deduce that H_2O ligand have a higher d orbital splitting ability than MeOH ligand.

The reaction of **1a** with equimolar amounts of *cis*-[$PtCl_2(dmso)_2$] and $Na(CH_3CO_2)$ was also carried out in methanol at 65 °C for 72 h; under these conditions reduction of platinum was minimized and the yield was increased up to 45%. It is interesting to note that the use of a molar ratio amine:metal = 1:1 and of polar solvents such as methanol are among the key factors that have been reported to facilitate *ortho*-palladation of primary amines [2].

In an attempt to isolate the coordination compounds which are postulated as precursors of the cyclometallated derivatives, the reactions of *cis*-[$PtCl_2(dmso)_2$] with amines **1a** and **1b** were also carried out in methanol at room temperature with continuous stirring for 24 h. Under these conditions, compound **Ia** in which (*S*)-(−)-α-methylbenzylamine is coordinated to platinum was obtained while the corresponding reaction for (*R*)-(+)-1-(1-naphthyl)ethylamine produced cyclometallated compound **2b**.

As shown in the scheme, it was confirmed that compound **Ia** evolves to **2a** under adequate conditions. Although the *trans*-configured complexes [MX_2L_2] of palladium and platinum are considered intermediates in the cyclometallation [1b,5], **Ia** displays a *cis* arrangement. As reported for mixed ligand platinum(II) complexes containing sulfoxide and N-donor ligands [12], the *cis* compounds are more stable than the *trans* isomers.

On the other hand, the easy formation of compound **2b** is an interesting result indicating that this cycloplatinated derivative is produced in mild reaction conditions, at room temperature and without requiring the presence of an external base. Previously reported cycloplatination reactions of primary amines took place only in the presence of either sodium acetate [4] or an excess of the amine [5].

The reaction of compounds **2a** and **2b** with triphenylphosphine were carried out in acetone at room temperature to produce compounds **3a** and **3b** in which a triphenylphosphine ligand replaces the dimethylsulfoxide. In addition, the reaction of **2b** with 1,2-bis(diphenylphosphine) was also studied; both the dimethylsulfoxide and the chloro ligands are replaced by the chelated diphosphine leading to ionic cyclometallated compound **4b**. These results suggest that the metallacycles are stable and do not cleave upon reaction with phosphines.

All compounds were characterized by elemental analyses, electrospray mass spectrometry and nuclear magnetic resonance spectra. In the ^1H NMR spectra of **Ia**, **2a** and **2b** anisotropy was observed for both the dimethylsulfoxide and the amino protons. For the cyclometallated derivatives **2a** and **2b**, both the amino protons and the aromatic proton adjacent to the metallated position (H^1) are coupled to platinum with values in the range 59–69 Hz for the former and 44–48 Hz for the latter. 2D-COSY and NOESY spectra confirm the proposed assignments of the observed resonances while the presence of four (**2a**) or six (**2b**) cross-peaks in the aromatic region of the ^1H–^{13}C HSQC spectra confirm the activation of an aromatic C–H bond.

For the triphenylphosphine derivatives **3a** and **3b**, the amino protons are non-equivalent and in each case one of them is coupled to platinum with lower values (51–52 Hz) than those observed for **2a** and **2b**. Conversely, the values of the coupling of the aromatic proton H^1 to platinum (53–57 Hz) are higher than those obtained for the parent compound. The ^1H NMR spectra of **4b** is more complex and the resonances were assigned using 2D-COSY and NOESY spectra. Both amino resonances are strongly shielded when compared to those of **2b**, and one of them is coupled to platinum (^3J(Pt–H) = 43 Hz). In the ^{31}P NMR spectra, one resonance coupled to platinum (*J*(P–Pt) *ca.* 4320 Hz) is observed for compounds **3a** and **3b**, while two resonances with *J*(P–Pt) values of 3706 and 1691 Hz are observed for **4b**. In the latter case, the higher *J* value is assigned to the phosphorous atom *trans* to the amino and the lower to that *trans* to the metallated carbon in agreement with the expected values [13].

2.2. Crystal structure of [$PtCl_2\{NH_2CH(CH_3)C_6H_5\}\{SOMe_2\}$] (**Ia**)

Crystals of compound **Ia** were grown from dichloromethane-methanol. The crystal structure is composed of discrete molecules separated by van der Waals interactions. The structure is shown in Fig. 1 and selected molecular dimensions are listed in Table 1. The coordination sphere of platinum is square-planar with two mutually *cis* chloro ligands, the S-bound dimethylsulfoxide and the N-donor ligand completing the coordination sphere. The stereochemistry of the asymmetric carbon is *S*. The angles between adjacent atoms in the coordination sphere of platinum lie in the range 87.3(2)–91.11(9)° and Pt–Cl, Pt–N and Pt–S bond lengths are well within the range of values obtained for similar complexes of platinum [12,14]. As expected from the high *trans* influence of the dimethylsulfoxide, the Pt–Cl bond length *trans* to this ligand is slightly longer (2.322(2) Å) than that *trans* to a N-donor ligand (2.300(2) Å). When compared to the reported structure for *trans*-[$PtCl_2\{NH_2CH_2(4\text{-}ClC_6H_4)SOMe_2\}$] [14], the Pt–N bond length is shorter (2.034(7) versus 2.079(10) Å) which can be related to the presence of a chloro versus a dimethylsulfoxide ligand in a *trans* position. The amino hydrogen atoms are involved in intramolecular interactions, one with O(1) (d(N···O) = 2.933(10) Å) and the other with Cl(1) (d(N···Cl) = 3.364(8) Å).

The shortest distance between platinum and the *ortho* hydrogen atoms is 4.702 Å for Pt···H(5), a similar value to that obtained for *trans*-[$PtCl_2\{NH_2CH_2(4\text{-}ClC_6H_4)SOMe_2\}$] (4.668 Å) [14]. These values are significantly larger than those obtained for imines [13] or oximes [15] which are in the range 2.6–3.3 Å in agreement with the lower proclivity to cyclometallate observed for primary amines.

2.3. Conclusions

The results here obtained indicate that cycloplatination of primary amines can be achieved in high yield using *cis*-[$PtCl_2(dmso)_2$] when appropriate amines are used. While cycloplatination of 4-chlorobenzylamine gives poor yields [4], cycloplatination of α-methylbenzylamine was achieved with 45% yield, and a higher yield (95%) was obtained for the naphthylethylamine. Moreover, the latter amine could also be metallated at room temperature in the absence of sodium acetate. It is therefore evident that the ease to cyclometallate follows the sequence: 4-chlorobenzylamine < α-methylbenzylamine < naphthylethylamine. In agreement with the results reported for analogous reactions [5], electronic effects could account for the low reactivity of 4-chlorobenzylamine compared to the easier cyclometallation of **1a** and **1b** which contain an electron-donor methyl group. However, no significant differences are expected between **1a** and **1b** for which the basicity is in the same range [16]. Therefore, the results here reported suggest that the higher bulk of the amine arising from both the methyl group in the α-position (in **1a** and **1b**) and the presence of a naphthyl substituent (in **1b**) might be decisive in promoting the cyclometallation. Steric promotion has been reported for palladium analogues [2,9] and attributed to both an increase in the electrophilicity of the metallic centre in the coordination intermediate and to a less favoured coordination of a second amine leading to unreactive bis-amine coordination compounds. As a whole, cycloplatination of primary amines share common features with those reported for cyclopalladation; for instance the use of molar ratio amine: metal = 1:1, the use of polar solvents and the use of sterically hindered amines grant successful syntheses.

In addition, the easy displacement reactions of dimethylsulfoxide in **2a** and **2b** for mono or diphosphines without cleaving the metallacycle makes them promising candidates to be used as resolving agents for Lewis bases as reported for palladium analogues [10,11] and as chiral reagents in stoichiometric and catalytic processes.

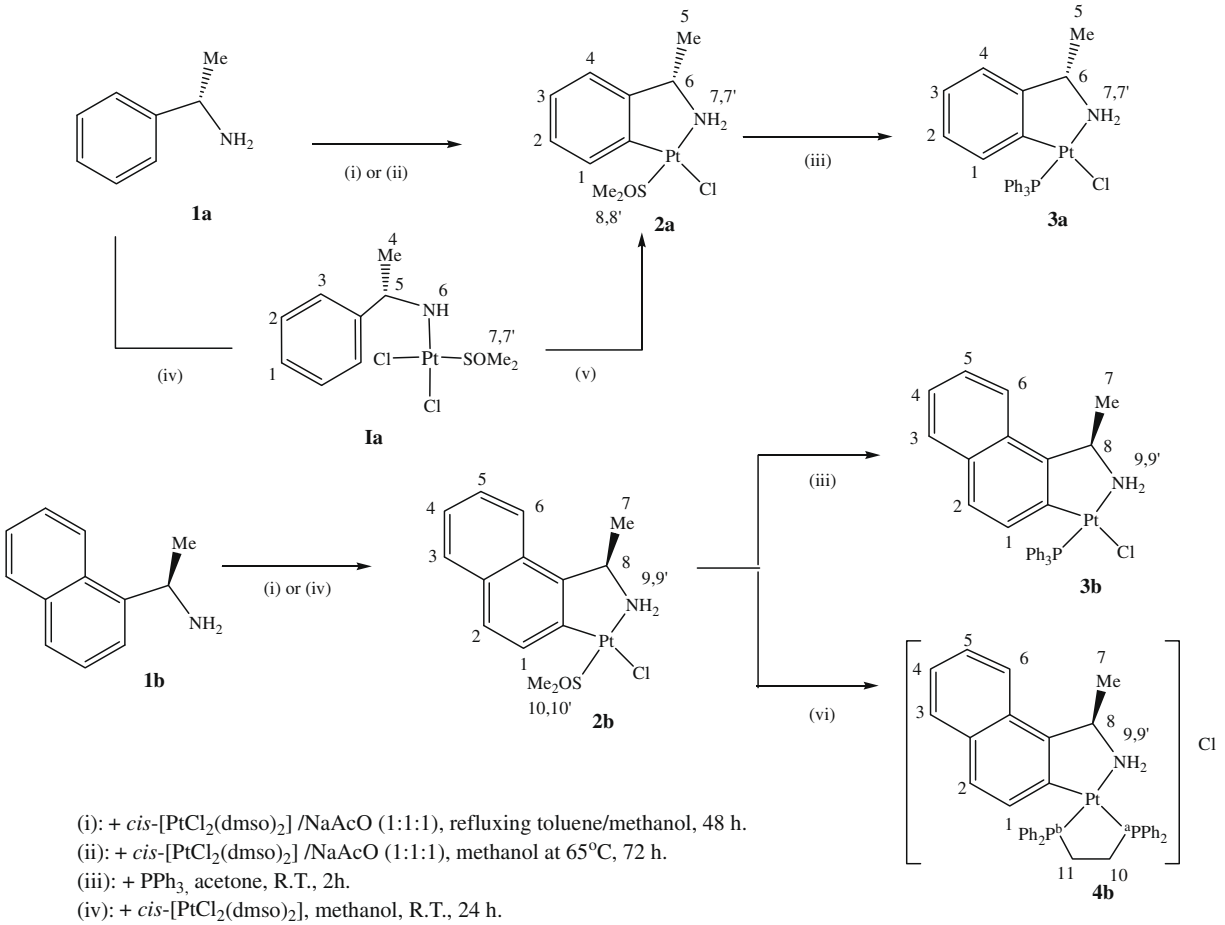
3. Experimental

3.1. General

Microanalyses were performed by Serveis Cientifico-tècnics (Universitat de Barcelona) and by Servei de Recursos Científics i Tècnics de la Universitat Rovira i Virgili (Tarragona). Mass spectra were performed at Servei d'Espectrometria de Masses (Universitat de Barcelona). Electrospray mass spectra were carried out in a LC/MSD-TOF spectrometer using H_2O–CH_3CN 1:1 to introduce the sample. NMR spectra were performed at Unitat de RMN d'Alt Camp de la Universitat de Barcelona using Varian Unity 300 (^{1}H, 300 MHz; ^{31}P–{^{1}H}, 121.4 MHz) and Mercury-400 (^{1}H, 400 MHz; ^{1}H–^{1}H NOESY, ^{1}H–^{1}H COSY, ^{1}H–^{13}C gHSQC) spectrometers, and referenced to $SiMe_4$ (^{1}H, ^{13}C) and H_3PO_4 (^{31}P). δ values are given in ppm and J values in Hz. *Abbreviations used: s,* singlet; d, doublet; t, triplet; q, quadruplet; se, sextuplet; m, multiplet; br, broad; NMR labelling as shown in Scheme 1.



3.2. Preparation of the compounds

cis-[$PtCl_2$(dmso)$_2$] was prepared using a reported procedure [17]. Amines **1a** and **1b** were obtained from commercial sources and used as received.

cis-[$PtCl_2${$NH_2CH(CH_3)C_6H_5$}{$SOMe_2$}] (**Ia**) was obtained as colourless crystals from 100 mg (0.23 mmol) of *cis*-[$PtCl_2${$SOMe_2$}$_2$] and 29 mg (0.23 mmol) of (*S*)-(−)-α-methylbenzylamine which were stirred in methanol at room temperature for 24 h. The solvent was removed and the residue was allowed to crystallize in CH_2Cl_2:MeOH (1:1) at room temperature. Yield 77 mg (70%). ^{1}H NMR (400 MHz, $CDCl_3$): δ = 7.54 [dd, ^3J(H^3–H^2) = 8.0, ^4J(H^3–H^1) = 1.4, 2H, H^3]; 7.39–7.46 [m, 3H, H^{1,2}]; 4.65 [se, ^3J(H^5–H^4) = ^3J(H^5–H^6) = ^3J(H^5–H$^{6\prime}$) = 6.8, 1H, H^5]; 4.32 [br s, 1H, H^6]; 4.26 [br s, 1H, H$^{6\prime}$]; 3.39 [s, 3H, ^3J(H^7–Pt) = 21.2, H^7]; 2.90 [s, 3H, ^3J(H$^{7\prime}$–Pt) = 19.6, H$^{7\prime}$]; 1.74 [d, ^3J(H^4–H^5) = 6.8, 3H, H^4]. ESI-MS, *m*/*z*: 895.05 [2M−Cl]$^+$; 430.04 [M−Cl]$^+$. *Anal.* Calc. for $C_{10}H_{17}Cl_2NOPtS$: C, 25.81; H, 3.68; N, 3.01; S, 6.89. Found: C, 26.4; H, 3.7; N, 3.0; S, 6.9%.

[PtCl{$NH_2CH(CH_3)C_6H_4$}{$SOMe_2$}] (**2a**) was obtained from 153 mg (0.36 mmol) of *cis*-[$PtCl_2${$SOMe_2$}$_2$], 44 mg (0.36 mmol) of (*S*)-(−)-α-methylbenzylamine and 29 mg (0.36 mmol) of sodium acetate dissolved in methanol (2 mL). The mixture was refluxed in 25 mL of toluene under nitrogen atmosphere for 48 h, and a small amount of metallic platinum was filtered off. The solvent was removed in a rotary evaporator to yield an oily residue that was crystallized in CH_2Cl_2:MeOH (1:1) at low temperature, to produce a white solid. Yield: 51 mg (33%). Alternatively, the reaction between equimolar amounts of *cis*-[$PtCl_2${$SOMe_2$}$_2$], (*S*)-(−)-α-methylbenzylamine and sodium acetate was carried out in methanol at 65 °C for 72 h and compound **2a** was obtained with 45% yield. In addition, the reaction of 25 mg (0.05 mmol) of **Ia** and the equimolar amount of sodium acetate (4.5 mg) in methanol at 65 °C for 72 h produced compound **2a** with 46% yield. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.95 [dd, ^3J(Pt–H^1) = 48.2, ^3J(H^1–H^2) = 7.2, ^4J(H^1–H^3) = 1.8, 1H, H^1]; 7.10–7.02 [m, 2H, H^{2,3}]; 6.92 [dd, ^3J(H^3–H^4) = 6.9, ^4J(H^2–H^4) = 2.0, 1H, H^4]; 4.85 [br s, ^2J(Pt–H^7) = 64.3, 1H, H^7]; 4.40 [q, ^3J(H^5–H^6) = 6.2, 1H, H^6]; 3.98 [br s, ^2J(Pt–H$^{7\prime}$) = 69.6, 1H, H$^{7\prime}$]; 3.41 [br s, 3H, H^8]; 3.39 [br s, 3H, H$^{8\prime}$]; 1.60 [d, ^3J(H^5–H^6) = 6.6, 3H, H^5]. gHSQC (400 MHz, $CDCl_3$): δ = 134.2 [C^1]; 126.7 [C^2]; 125.3 [C^3]; 122.9 [C^4]; 60.2 [C^6]; 46.6 [C$^{8\prime}$]; 46.2 [C^8]; 24.5 [C^5]. ESI-MS, *m*/*z*: 858.06 [2M+H]$^+$; 430.03 [M+H]$^+$; 393.06 [M−Cl]$^+$. *Anal.* Calc. for $C_{10}H_{16}ClNOPtS$: C, 28.01; H, 3.76; N, 3.27; S, 7.47. Found: C, 28.4; H, 3.7; N, 3.3; S, 7.3%.

[PtCl{$NH_2CH(CH_3)C_{10}H_6$}{$SOMe_2$}] (**2b**) was obtained from 150 mg (0.355 mmol) of *cis*-[$PtCl_2${$SOMe_2$}$_2$], 61 mg (0.356 mmol) of (*R*)-(+)-1-(1-naphthyl)ethylamine and 29 mg (0.36 mmol) of sodium acetate using the same procedure as for **2a**. A white solid was obtained. Yield: 162 mg (95%). Alternatively, the reaction of equimolar amounts of *cis*-[$PtCl_2${$SOMe_2$}$_2$] and (*R*)-(+)-1-(1-naphthyl)ethylamine was carried out in methanol at room temperature for 24 h and compound **2b** was crystallized with 75% yield within three days. ^{1}H NMR (400 MHz, $CDCl_3$): δ = 8.09 [d, ^3J(Pt–H^1) = 44.5, ^3J(H^1–H^2) = 8.6, 1H, H^1]; 7.71 [dd, ^3J(H^3–H^4) = 7.2, ^4J(H^3–H^5) = 2.2, 1H, H^3]; 7.48 [d, ^3J(H^1–H^2) = 8.8, 1H, H^2]; 7.35 [d, ^3J(H^5–H^6) = 8.3, 1H, H^6]; 7.33–7.28 [m, 2H, H^{4,5}]; 5.43 [br s, ^2J(Pt–H^9) = 63.9, 1H, H^9]; 4.90 [m, ^3J(Pt–H^8) = 69.7, ^3J(H^8–H^{7,9}) = 6.1, 1H, H^8]; 3.91 [d, ^2J(Pt–H$^{9\prime}$) = 59.6, ^3J(H^9–H$^{9\prime}$) = 10.3, 1H, H$^{9\prime}$]; 3.40 [br s, 3H, H^{10}]; 3.25 [br s, 3H, H$^{10\prime}$];

(i): + *cis*-[$PtCl_2(dmso)_2$] /NaAcO (1:1:1), refluxing toluene/methanol, 48 h.
(ii): + *cis*-[$PtCl_2(dmso)_2$] /NaAcO (1:1:1), methanol at 65°C, 72 h.
(iii): + PPh_3, acetone, R.T., 2h.

(v): + NaAcO (1:1), methanol at 65°C, 72 h.
(vi): + dppe, acetone, R.T., 5h.

Scheme 1.

1.69 [d, $^3J(H^7–H^8) = 6.4$, 3H, H^7]. gHSQC (400 MHz, $CDCl_3$): $\delta = 132.2$ [C^1]; 128.7 [C^3]; 126.3 [C^2]; 126.2 [C^5]; 124.6 [C^4]; 123.6 [C^6]; 58.6 [C^8]; 46.8 [C^{10}]; 45.7 [$C^{10\prime}$]; 24.5 [C^7]. ESI-MS, *m*/*z*: 921.12 [2M−Cl]$^+$; 443.07 [M−Cl]$^+$. *Anal.* Calc. for $C_{14}H_{18}ClNOPtS \cdot H_2O$: C, 33.84; H, 4.06; N, 2.82; S, 6.45. Found: C, 34.1; H, 3.9; N, 2.9; S, 6.0%.

[$PtCl\{NH_2CH(CH_3)C_6H_4\}\{P(C_6H_5)_3\}$] (**3a**) was obtained from 34 mg (0.08 mmol) of compound **2a** and 21 mg (0.08 mmol) of triphenylphosphine which were allowed to react in acetone at room temperature for 2 h. The solvent was removed in a rotary evaporator and the residue was washed with ether and dried in vacuo. A white solid was obtained after re-crystallisation in CH_2Cl_2:MeOH. Yield 39 mg (79%). ^{1}H RMN (300 MHz, $CDCl_3$): $\delta = 7.77–7.70$ [m, 6H, $H^{o\text{-}PPh3}$]; 7.45–7.31 [m, 9H, $H^{m,p\text{-}PPh3}$]; 6.92 [dd, $^3J(H^3–H^4) = 7.3$, $^4J(H^2–H^4) = 1.7$, 1H, H^4]; 6.87 [td, $^3J(H^3–H^{2,4}) = 7.2$, $^4J(H^1–H^3) = 1.19$, 1H, H^3]; 6.51 [ddd, $^3J(Pt–H^1) = 56.9$, $^3J(H^1–H^2) = 8.0$, $^4J(H^1–H^3) = 2.8$, $^5J(H^1–H^4) = 1.1$, 1H, H^1]; 6.40 [td, $^3J(H^2–H^{1,3}) = 7.3$, $^4J(H^2–H^4) = 1.8$, 1H, H^2]; 4.66–4.45 [m, 2H, $H^{6,7}$]; 3.87 [br s, $^2J(Pt–H^{7\prime}) = 51.0$, 1H, $H^{7\prime}$]; 1.70 [d, $^3J(H^5–H^6) = 6.6$, 3H, H^5]. ^{31}P RMN (121 MHz, $CDCl_3$): $\delta = 23.84$ [s, $^1J(Pt–P) = 4326.8$]. ESI-MS, *m*/*z*: 577.14 [M−Cl]$^+$. *Anal.* Calc. for $C_{26}H_{25}ClNPPtS$: C, 50.94; H, 4.11; N, 2.28. Found: C, 51.0; H, 4.1; N, 2.4%.

[$PtCl\{NH_2CH(CH_3)C_{10}H_6\}\{P(C_6H_5)_3\}$] (**3b**) was obtained as a white solid from 44 mg (0.09 mmol) of compound **2b** and 24 mg (0.09 mmol) of triphenylphosphine using the same procedure than for **3a**. Yield 52 mg (87%). ^{1}H RMN (400 MHz, $CDCl_3$): $\delta = 7.77–7.71$ [m, 6H, $H^{o\text{-}PPh3}$]; 7.68 [d, J(H–H) = 8.4, 1H, H^{ar}]; 7.56 [d, $^3J(H^5–H^6) = 8.3$, 1H, H^6]; 7.42–7.23 [m, 11H, 2 H^{ar} + $H^{m,p\text{-}PPh3}$]; 6.88 [d, $^3J(H^1–H^2) = 8.6$, 1H, H^2]; 6.72 [dd, $^3J(Pt–H^1) = 52.7$, $^3J(H^1–H^2) = 8.6$, $^4J(P–H^1) = 2.8$, 1H, H^1]; 5.40 [q, $^3J(Pt–H^8) = 55.5$, $^3J(H^7–H^8) = 6.0$, 1H, H^8]; 4.70 [br s, 1H, H^9]; 4.13 [m, $^2J(Pt–H^{9\prime}) = 52.4$, 1H, $H^{9\prime}$]; 1.89 [d, $^3J(H^7–H^8) = 6.3$, 3H, H^7]. ^{31}P RMN (121 MHz, $CDCl_3$): $\delta = 24.32$ [s, $^1J(Pt–P) = 4318.5$]. ESI-MS, *m*/*z*: 627.15 [M−Cl]$^+$. *Anal.* Calc. for $C_{30}H_{27}ClNPPt \cdot 1/2CH_2Cl_2$: C, 51.92; H, 4.10; N, 1.99. Found: C, 52.0; H, 4.1; N, 1.9%.

[$Pt\{NH_2CH(CH_3)C_{10}H_6\}\{(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2\}$]Cl (**4b**) was obtained as a white solid from 40 mg (0.08 mmol) of compound **2b** and 32 mg (0.08 mmol) of 1,2-bis(diphenylphosphine)ethane (dppe) using the same procedure than for **3a** and a reaction time of 5 h. Yield 63 mg (99%). ^{1}H RMN (400 MHz, $CDCl_3$): $\delta = 8.11–8.06$ [m, 2H, $H^{2,3}$]; 7.91–7.83 [m, 4H, H^{PPh2}]; 7.77 [d, $^3J(H^5–H^6) = 8.3$, 1H, H^6]; 7.67–7.43 [m, 16H, H^{PPh2}]; 7.38–7.28 [m, 2H, $H^{4,5}$]; 7.05 [m, 1H, H^1]; 5.98 [q, $^3J(Pt–H^8) = 59.4$, $^3J(H^7–H^8) = 6.2$, 1H, H^8]; 4.58 [d, $^2J(Pt–H^{9\prime}) = 43.0$, $^2J(H^9–H^{9\prime}) = 12.1$, 1H, $H^{9\prime}$]; {2.85–2.67 [m, 1H]; 2.61–2.44 [m, 1H]; 2.31–2.15 [m, 1H]; 2.18–2.03 [m, 1H]; $H^{10,11}$}; 1.80 [br s, 1H, H^9]; 1.59 [d, $^3J(H^7–H^8) = 6.3$, 3H, H^7]. ^{31}P RMN (121 MHz, $CDCl_3$): $\delta = 47.67$ [s, $^1J(Pt–P) = 1691.4$, 1P, P^a]; 43.75 [s, $^1J(Pt–P) = 3706.3$, 1P, P^b]. ESI-MS, *m*/*z*: 763.20 [M]$^+$. *Anal.* Calc. for $C_{38}H_{36}ClNP_2Pt \cdot CH_2Cl_2$: C, 52.9; H, 4.33; N, 1.58. Found: C, 52.63; H, 4.54; N, 1.7%.

3.3. X-ray structure analysis

A prismatic crystal was selected and mounted on a MAR345 diffractometer with an image plate detector. Unit cell parameters were determined from 4749 reflections ($3° < \theta < 31°$) and refined

Table 2
Crystal data and structure refinement for **Ia**.

Empirical formula	$C_{10}H_{17}Cl_2NOPtS$
Molecular weight	465.30
Temperature (K)	293(2)
Wavelength (Å)	0.71073
Crystal system, space group	monoclinic, $P2_1$
Unit cell dimensions (Å, °)	a = 8.492(4)
	b = 9.761(4)
	c = 9.501(3)
	β = 108.61(2)
Volume (Å^3)	746.4(5)
Z, D_{calc} (Mg m^{-3})	2, 2.070
Absorption coefficient (mm^{-1})	9.879
F(000)	440
Crystal size (mm)	0.2 × 0.2 × 0.2
Theta range for data collection (°)	2.81–32.19
Reflections collected/unique [R_{int}]	7088/3909 [0.0659]
Completeness to θ = 25.00	95.8%
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	3909/7/145
Goodness-of-fit on F^2	1.136
Final R indices [$I > 2\sigma(I)$]	R_1 = 0.0356, wR_2 = 0.1021
R indices (all data)	R_1 = 0.0361, wR_2 = 0.1024
Absolute structure parameter	−0.010(12)
Largest difference in peak and hole (e Å^{-3})	0.639 and −0.532

by least-squares method. Intensities were collected with graphite monochromatized Mo Kα radiation. 7088 reflections were measured in the range $2.81° < \theta < 32.19°$; 3909 were non-equivalent by symmetry [R_{int} (on I) = 0.065] and 3800 were assumed as observed applying the condition $I > 2\sigma(I)$. Lorentz polarization and absorption corrections were made.

The structure was solved by direct methods, using SHELXS Computer Program [18] and refined by the full-matrix least-squares method, with the SHELX97 computer program using 7088 reflections (very negative intensities were not assumed). The function minimized was $\Sigma w||F_o|^2 - |F_c|^2|^2$, where $w = [\sigma^2(I) + (0.0667P)^2 + 0.5181P]^{-1}$, and $P = (|F_o|^2 + 2|F_c|^2)/3$. f, f' and f'' were taken from International Tables of X-ray Crystallography [19]. The chirality of the structure was defined from the Flack coefficient [20], which is equal to −0.010(12) for the given results. All hydrogen atoms were computed and refined using a riding model with an isotropic temperature factor equal to 1.2 times the equivalent temperature factor of the atom to which they are linked. Further details are given in Table 2.

Supplementary data

CCDC 713902 contains the supplementary crystallographic data for compound **Ia**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

(EB), a phenanthridine drug, is a cationic molecule able to interact with polynucleotides. Ethidium bromide (EB) is a well-known intercalator, which is often used as a spectral probe to establish the mode of binding of small molecules to double-helical DNA. The present study deals with the interaction between DNA and colloidal TiO_2 nanoparticles, which is useful in the biomedical field.

2. Materials and methods

2.1. Materials

Calf thymus-deoxyribonucleic acid (DNA), titanium (IV) 2-propoxide and ethidium bromide (EB) were purchased from Aldrich (Bangalore, India). The DNA used in this work was double-stranded DNA (dsDNA). The stock solution of DNA was prepared by dissolving an appropriate amount of DNA in phosphate buffer overnight and storing at 4 °C in the dark. The concentration of the DNA stock solution (2.4×10^{-4} M) was determined from the UV absorption spectrum at 260 nm using the molar absorption coefficient $\varepsilon_{260} = 6600\ M^{-1}\ cm^{-1}$. The purity of the DNA was checked by monitoring the ratio of the absorbance at 260 nm to that at 280 nm. The resulting ratio, $A_{260}/A_{280} > 1.8$, indicated that the DNA was sufficiently free from protein [44,45]. All measurements were performed at ambient temperature.

2.2. Preparation of colloidal TiO_2 nanoparticles

The colloidal TiO_2 nanoparticles was prepared by the hydrolysis of titanium(IV) 2-propoxide, based on the literature procedure [46]. Typically, titanium(IV) 2-propoxide (153 μl) in 2-propanol (10 ml) was injected by using syringe into 40 ml of water with constant stirring under nitrogen atmosphere (for 8 h), resulting in a 1×10^{-2} M titania stock solution. No stabilizing agent was used during the hydrolysis process. The colloidal suspensions of TiO_2 prepared by this method were stable for 3–5 days. Fresh colloidal TiO_2 dispersed in water was prepared before each set of experiments. The stock suspension was diluted with water to obtain the desired concentrations of TiO_2. No attempts were made to exclude the traces of 2-propanol present in the colloidal TiO_2 nanoparticles and it was confirmed separately that the presence of 2-propanol did not affect the photochemical measurements, as earlier reported [47].

2.3. Steady-state measurements

The fluorescence quenching measurements were carried out using a JASCO FP-6500 spectrofluorimeter (Tokyo, Japan). The excitation wavelength of EB–DNA was 480 nm and the emission was monitored at 597 nm. The excitation and emission slit widths (each 5 nm) and scan rate (500 nm/min) were kept constant for all the measurements. The samples were deoxygenated by bubbling with pure nitrogen gas.

Absorption spectral measurements were recorded by using a Cary 300 UV–Vis spectrophotometer (USA). A 3 ml solution, containing the appropriate concentration of DNA (1×10^{-6} M), was titrated by successive addition of 30 μl stock solutions of colloidal TiO_2 nanoparticles (1×10^{-3} M). Titrations were manually done by using micro pipette for the addition of colloidal TiO_2. UV–Vis spectra of all the solutions were recorded in the range of 200–800 nm.

2.4. Time resolved fluorescence measurements

Fluorescence lifetime measurements were carried out in a picosecond time correlated single photon counting (TCSPC) spectrometer. The excitation source was a tunable Ti-sapphire laser (Tsunami, Spectra Physics, USA). The fluorescence decay was analyzed by using the software provided by IBH (DAS-6).

2.5. XRD measurements

X-ray powder diffraction patterns were recorded on a Bruker AXS B8 Discover model using Cu Kα radiation ($\lambda = 0.154$ nm) and a graphite monochromator in the diffracted beam. The TiO_2 sample was in the form of powder. A scan rate of $0.05^\circ\ min^{-1}$ was applied to record the XRD pattern in the 2θ range 20–80°.

2.6. Fourier transform infrared spectroscopy (FT-IR) measurements

FT-IR spectra were obtained using a Perkin–Elmer Spectrum RXI FT-IR Spectrometer (USA) at room temperature in the range 4000–400 cm^{-1}. The samples were placed in a liquid cell between two windows (CaF_2). The mirror velocity was 0.3 cm/s and the number of co-added scans was 4, and the total collection time was less than 2 min.

3. Results and discussion

3.1. XRD characterization of TiO_2 nanoparticles

Fig. 1 shows the XRD pattern of typical powdered TiO_2 nanoparticles obtained by rotary evaporation of colloidal TiO_2 at 30 °C. The XRD peaks are found to be broad, indicating the fine size of the sample grains. The pattern exhibits prominent broad peaks at 2θ values of 25.6°, 38.4°, 48.4°, 54.8° and 63.2°, which are similar to the reported [48] values for anatase TiO_2.

3.2. Determination of particle size of colloidal TiO_2 nanoparticles

For the anatase phase TiO_2, the absorption wavelength (λ) and the corresponding band gap energy (E_g) are well known, $\lambda = 385$ nm and $E_g = 3.2$ eV, respectively. The particle size of the prepared colloidal TiO_2 nanoparticles was determined from the relationship between the band gap shift (ΔE_g) and the radius (R) of the quantum size particles using the following Eq. (1) [49],

$$\Delta E_g = \frac{\pi^2 h^2}{2\mu R^2} - \frac{1.8e^2}{\varepsilon R} + \text{Polarization terms} \quad (1)$$

where h is Planck's constant, R is the radius of the particle, ε is the relative permittivity of the semiconductor, ΔE_g is the band gap shift. The calculated band gap shift for colloidal TiO_2 is 0.3 eV (extrapolating the spectral curve, the band gap energy of the colloidal TiO_2 was measured, $E_g = 3.5$ eV corresponding to $\lambda = 350$ nm, Fig. 2), as com-

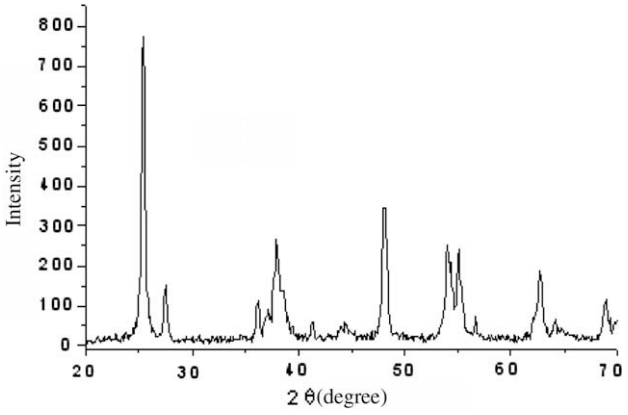

Fig. 1. X-ray diffraction (XRD) spectrum of the prepared TiO_2 nanoparticles.

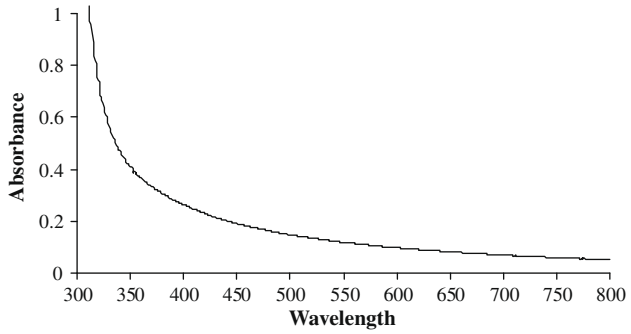

Fig. 2. Absorption spectrum of colloidal TiO_2 (1×10^{-3} M).

pared to bulk anatase. 'μ' is the reduced mass of the exciton, i.e., the reduced effective mass of the electron and the hole ($1/\mu = l/m_c^* + l/m_h^*$) in the semiconductor, '*e*' is the electronic charge, and '*c*' is the dielectric constant of the semiconductor. The value of $\mu = 1.63m_e$ (m_e is the electron rest mass) [50]. Since the optical dielectric constant of bulk titanium dioxide is very large ($\varepsilon = 170$), the columbic and polarization terms in Eq. (1) are neglected. The ΔE_g value of 0.3 eV for this blue shift compared to bulk anatase TiO_2 particles indicated a size of TiO_2 crystallites smaller than 10 nm, due to the so called quantum size effect [51]. The calculated size of the prepared colloidal TiO_2 is 1.1 nm.

3.3. Absorption characteristics of DNA–TiO_2

Fig. 3 shows the absorption spectra of DNA in the absence and presence of colloidal TiO_2 at various increasing concentrations. In the presence of colloidal TiO_2 nanoparticles, the absorbance of DNA increases markedly, without any change in the location of the peak (260 nm). This shows that while adding colloidal TiO_2 nanoparticles to the solution of DNA, the DNA gets adsorbed on the surface of the colloidal TiO_2 and is involved in the formation of a ground state complex of the type DNA···TiO_2. The formed complex also has an absorption at 260 nm. This may be the reason for the increase in absorbance of DNA with the addition of colloidal TiO_2, as supported by a similar observation made earlier [52]. The absorbance change that we observed in the spectrum of the complex was not due to the experimental error because baseline corrections were done for all measurements. These results indicate that there is an interaction between colloidal TiO_2 nanoparticles and DNA in the ground state via complex formation which is electrostatic in nature.

The equilibrium for the formation of the complex between DNA and colloidal TiO_2 nanoparticles is given by Eq. (2), where K_{app} represents the apparent association constant:

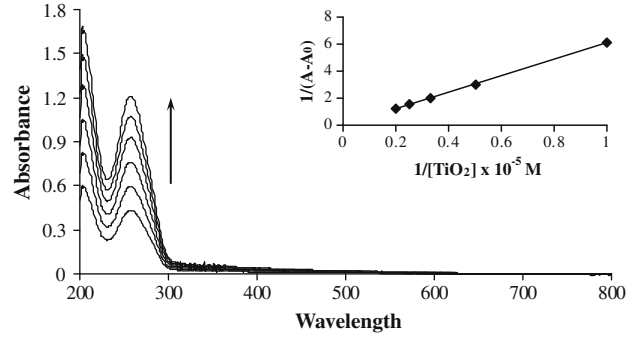

Fig. 3. Absorption spectra of DNA (1×10^{-6} M) in the presence of colloidal TiO_2 in the concentration range 0–5×10^{-5} M. The inset is the straight line dependence of $1/(A_{obs} - A_0)$ on the reciprocal concentration of colloidal TiO_2.

$$\mathrm{DNA} + \mathrm{TiO_2} \overset{K_{app}}{\rightleftharpoons} \mathrm{DNA}\cdots\mathrm{TiO_2} \tag{2}$$

$$K_{app} = \frac{[\mathrm{DNA}\cdots\mathrm{TiO_2}]}{[\mathrm{DNA}]\cdot[\mathrm{TiO_2}]}$$

K_{app} is obtained according to the method reported by Benesi and Hildebrand [53]:

$$A_{obs} = (1-\alpha)C_0\varepsilon_{DNA}l + \alpha C_0\varepsilon_c l \tag{3}$$

where A_{obs} is the observed absorbance of the solution containing different concentrations of colloidal TiO_2 nanoparticles at 260 nm, α is the degree of association between DNA and TiO_2, ε_{DNA} and ε_c are the molar extinction coefficients at the defined wavelength ($\lambda = 260$ nm) for DNA and the formed complex, respectively, C_0 is the initial concentration of DNA and '*l*' is the optical path length (always taken as unity). Eq. (3) can be expressed as Eq. (4), where A_0 and A_c are the absorbances of DNA and the complex at 260 nm, respectively, with a concentration of C_0:

$$A_{obs} = (1-\alpha)A_0 + \alpha A_c \tag{4}$$

At relatively high TiO_2 concentrations, α can be equated to $(K_{app}[TiO_2])/(1 + K_{app}[TiO_2])$. In this case, Eq. (4) can be changed to Eq. (5):

$$\frac{1}{A_{obs} - A_0} = \frac{1}{A_c - A_0} + \frac{1}{K_{app}(A_c - A_0)[TiO_2]} \tag{5}$$

Based on the enhancement of the absorbance at 260 nm due to absorption of the surface complex, we would expect a linear relationship between $1/(A_{obs} - A_0)$ and the reciprocal concentration of colloidal TiO_2, with a slope equal to $1/K_{app}(A_c - A_0)$ and an intercept equal to $1/(A_c - A_0)$ [Fig. 3, inset]. The value of the apparent association constant (K_{app}) determined from this linear plot is 2.85×10^3 M^{-1} ($R^2 = 0.9998$).

3.4. Fluorescence quenching of EB–DNA by colloidal TiO_2 nanoparticles

To study the interaction between DNA and TiO_2 nanoparticles in the excited state, we have chosen EB as a fluorescence probe for DNA. EB has a weak fluorescence, but in the presence of DNA it shows intense fluorescence at 597 nm on excitation at 480 nm, due to its strong intercalation with the adjacent DNA base pairs. It was previously reported that the enhanced fluorescence of EB–DNA can be quenched by the addition of a second molecule [54,55]. Based on the reports, in the present system we have studied the effect of colloidal TiO_2 nanoparticles on the fluorescence emission spectrum of EB bound DNA (Fig. 4). From the figure we observed that the addition of colloidal TiO_2 to a solution of EB bound DNA resulted in a decrease in fluorescence emission intensity of EB–DNA. This shows that quenching has occurred by the addition of colloidal TiO_2. The possible scattering due to the colloidal nature of TiO_2 has been omitted because of the fact that baseline correction was done for all the spectral measurements and also even after adding the highest concentration of colloidal TiO_2 nanoparticles the solution remains clear. So we inferred that the fluorescence quenching is only due to the interaction between DNA and colloidal TiO_2 and not due to scattering.

The fluorescence quenching is described by the Stern–Volmer relation:

$$I_0/I = 1 + K_{SV}[Q] = 1 + k_q\tau_0[Q] \tag{6}$$

where, I_0 and I are the emission intensities of the fluorophore in the absence and presence of quencher, respectively, K_{SV} is the Stern–Volmer constant related to the bimolecular quenching rate constant, k_q, by $K_{SV} = k_q \cdot \tau_0$, and τ_0 is the lifetime of the fluorophore in the excited state, which is 23 ns (EB bounded to double-stranded DNA has a maximum fluorescence lifetime) [56], [Q] is concentra-

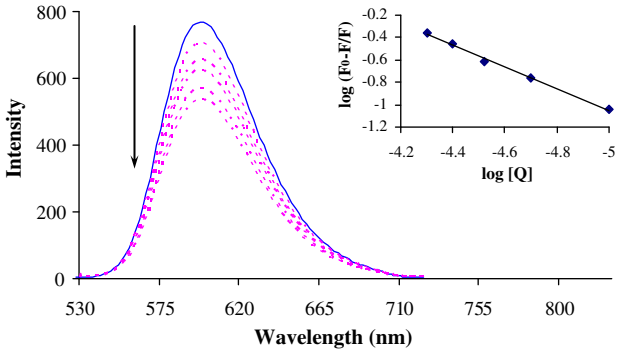

Fig. 4. Fluorescence quenching of EB–DNA (λ_{exi} = 480 nm; λ_{emi} = 597 nm) in the presence of various concentrations of colloidal TiO_2, [TiO_2] = 0–5 × 10^{-5} M. The inset shows the plot of log $[F^0 - F/F]/F$ vs. log[Q].

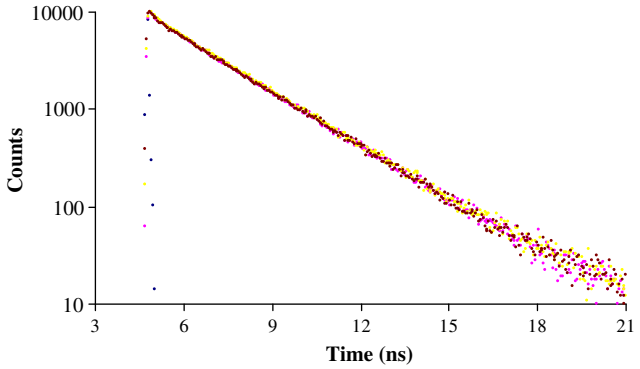

Fig. 6. Fluorescence decay profiles for EB–DNA in the absence and presence of colloidal TiO_2 (0–5 × 10^{-5} M).

tion of the quencher. According to Eq. (6) we obtained a linear plot [Fig. 5] for I_0/I against [TiO_2]. From the slope (K_{SV} = 8.61 × 10^3 M^{-1}) we have calculated the quenching rate constant (k_q) as 3.74 × 10^{11} M^{-1} s^{-1}. The obtained bimolecular quenching constant (k_q) is much larger than the limiting value of 1 × 10^{10} M^{-1} s^{-1} [57], which is considered the largest possible value in aqueous medium. Thus dynamic quenching may be ruled out for the quenching of EB–DNA fluorescence.

3.5. Fluorescence lifetime measurements

Fluorescence lifetime measurement is useful for understanding the interactions between donor and acceptor systems. The observation of a linear Stern–Volmer plot in the steady state measurement alone does not prove a dynamic nature of the quenching. Sometimes static quenching also results in a linear Stern–Volmer plot. In general, time resolved measurement is the most definitive method for differentiating static and dynamic quenching processes [57].

Fig. 6 shows the fluorescence decay curve of EB–DNA in the absence and presence of colloidal TiO_2 nanoparticles. EB–DNA exhibits its single exponential decay, not only in dilute solutions but also in the presence of colloidal TiO_2 nanoparticles. On increasing the concentration of colloidal TiO_2 there is no change in the fluorescence lifetime of EB–DNA. This observation shows that the quenching follows a static mechanism. It also supports the adsorption of DNA on the surface of colloidal TiO_2 and the formation of a ground state surface complex. In Fig. 6, though the decay traces of EB–DNA in the absence and presence of colloidal TiO_2 nanoparticles were plotted, the lifetime of EB–DNA remains the same under both conditions, hence the plot looks like a single decay curve due to the merging of the kinetic traces. This result proves that the quenching

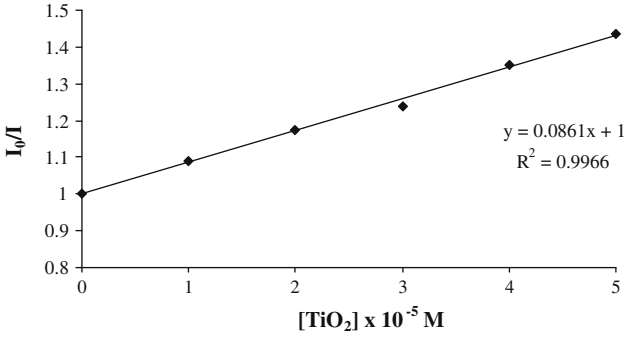

Fig. 5. Stern–Volmer plot for the steady state fluorescence quenching of EB–DNA by colloidal TiO_2 (0–5 × 10^{-5} M).

of EB–DNA by colloidal TiO_2 nanoparticles is static in nature. Static quenching arises from the formation of a complex between the fluorophore and the quencher. Hence the binding constant (K) was calculated by the method given in the following section.

3.6. Binding constant and number of binding sites

Fluorescence quenching data were used to determine the binding constant (K) and the binding sites (n) for the complex formation of TiO_2 with ct-DNA. Fig. 4 shows the fluorescence spectra of EB–DNA in the presence of different concentrations of colloidal TiO_2 nanoparticles. It can be seen that the fluorescence intensity at 597 nm decreases in the presence of colloidal TiO_2 nanoparticles. This change in fluorescence intensity at 597 nm was used to estimate K and n.

If it is assumed that there are similar and independent binding sites in EB–DNA, the relationship between the fluorescence intensity and the quencher medium can be deduced from the following Eq. (7):

$$nQ + B \rightarrow Q_n \cdots B \tag{7}$$

where B is the fluorophore, Q is the quencher, nQ + B is the postulated complex between the fluorophore and n molecules of the quencher. The constant K is given by

$$K = \frac{[Q_n \cdots B]}{[Q]^n [B]} \tag{8}$$

If the overall amount of biomolecules (bound or unbound with the quencher) is B_0, then $[B_0] = [Q_n \cdots B] + [B]$, where [B] is the concentration of unbound biomolecules, and then the relationship between the fluorescence intensity and the unbound biomolecule as $[B]/[B_0] = F/F_0$, that is:

$$\log\left[\frac{F_0 - F}{F}\right] = \log K + n \log[Q] \tag{9}$$

where K is the binding constant of colloidal TiO_2 with DNA, which can be determined from the intercept of $\log[(F_0 - F)/F]$ versus log[Q], as shown in the inset of Fig. 4. The calculated value of the binding constant (K) is 6.68 × 10^3 M^{-1} and the number of binding sites (n) is 0.97. The value of "n" approximately equals 1, and thus indicates the existence of just a single binding site in DNA for TiO_2.

3.7. FT-IR characterization

To verify the electrostatic type of interaction, FT-IR measurements were performed in the absence and presence of TiO_2 with DNA (shown only in the region of 1150–1400 cm^{-1} [Fig. 7]). Usually the phosphate peak position for DNA occurs in the region of

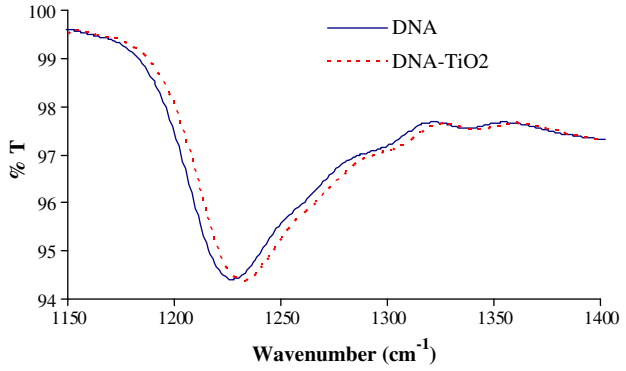

Fig. 7. The FT-IR spectra of DNA in the absence and presence of TiO_2 (shown only in the region of 1150–1400 cm^{-1}).

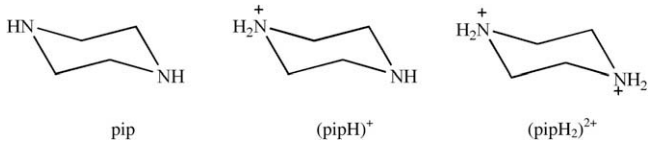
1222 cm^{-1}, but in the presence of TiO_2 the phosphate peak was shifted to 1226 cm^{-1}. From the shift in peak position we confirmed that the mode of interaction between DNA and TiO_2 is electrostatic in nature.

4. Summary

The interaction between colloidal TiO_2 nanoparticles and ct-DNA has been studied by using various spectroscopic measurements. The interaction between colloidal TiO_2 nanoparticles and DNA occurs through an electrostatic mode and the quenching follows a static mechanism. The quenching rate constant, binding constant and number of binding sites were calculated according to the relevant fluorescence data. The binding constants obtained from both absorbance and fluorescence methods are matched well. The present work is a viable model study to understand the conditions which can be optimized to carefully analyze the interaction of TiO_2 with DNA for later applications in photodynamic therapy.



Acknowledgements

R.R. and A.K. thank CSIR, Government of India (Ref. No. 01(2217)/08/EMR-II, Date 06/05/2008), for the project and fellowship, respectively.

We are thankful to Prof. P. Ramamoorthy, NCUFP, University of Madras, Chennai, for lifetime measurements.

Scheme 1.

$(pipH)^+$ on the metal–sulfur distances as well as the thermal decomposition products. It is interesting to note that the synthesis of such a $[MS_4]^{2-}$ compound containing the $(pipH)^+$ cation could be accomplished by a mechanical grinding of the reactants. The results of these investigations are described in this paper.

2. Experimental

2.1. Materials and methods

All the chemicals used in this study were of reagent grade and were used as received. The ammonium salts of the group VI tetrasulfidometalates were prepared by a published procedure [28]. Far-IR spectra (range 80–500 cm^{-1}) were recorded using a Bruker IFS 66 infrared spectrometer in pressed polyethylene disks. MIR spectra were recorded in a KBr matrix using a Shimadzu (IR Prestige-21) FT-IR spectrometer and a ATI Mattson Genesis infrared spectrometer in the range 4000–400 cm^{-1}. Raman spectra were recorded in the region 100–3500 cm^{-1} on a Bruker FRA 106 Fourier Transform Raman spectrometer. UV–Vis spectra were recorded on a Shimadzu UV-2450 double beam spectrophotometer using matched quartz cells. TG-DTA measurements were performed in nitrogen atmosphere, in Al_2O_3 crucibles on a STA-409CD simultaneous thermal analyzer from Netzsch. A heating rate of 4 K min^{-1} was employed for all measurements.

2.2. Preparation of $(pipH)_2[MS_4]$ (M = W **1**; M = Mo **2**)

Anhydrous piperazine (1.72 g, 10 mmol) was mixed with $(NH_4)_2[WS_4]$ (0.696 g, 2 mmol) and the solid mixture was mechanically ground in a mortar with a pestle for ~5 min. The resulting fine powder was dissolved in water (~10 mL) and briefly warmed on a water bath to expel traces of ammonia. The reaction mixture was filtered and the yellow filtrate was left aside for crystallization to obtain yellow needles. The crystalline product was isolated by filtration, washed with 2-propanol, followed by diethyl ether and air dried to yield 0.5 g of compound **1** in 51% yield. The use of freshly prepared $(NH_4)_2[MoS_4]$ (0.520 g, 2 mmol) instead of $(NH_4)_2[WS_4]$ in the above reaction afforded compound **2** as red needles in 60% yield. The needles of **1** and **2** thus obtained are suitable for X-ray structure determination.

2.3. X-ray crystal structure determination

Intensity data were collected on a STOE-Image Plate diffraction System (IPDS 1) for compound **1** and on an AED-2 four-circle diffractometer for compound **2** using graphite-monochromated Mo Kα radiation. The structures were solved with direct methods using SHELXS-97 [51] and refinement was done against F^2 using SHELXL-97 [51]. All non-hydrogen atoms were refined anisotropically. The C–H hydrogen atoms were positioned with idealized geometry and refined using a riding model. The N–H hydrogen atoms were located in the difference map, their bond lengths set to ideal values and afterwards they were refined isotropic using a riding model. The technical details of data acquisition and some selected refinement results are summarized in Table 1.

3. Results and discussion

3.1. Synthesis and spectroscopy

In earlier work we have shown that the reaction of an aqueous solution of $(NH_4)_2[MS_4]$ with piperazine (pip) in a 1:1 ratio results in the formation of $(pipH_2)[MS_4]$ compounds [26,27] containing the diprotonated cation of pip namely $(pipH_2)^{2+}$ (Eq. (1)). All our efforts to prepare $(pipH)_2[MS_4]$ compounds, which contain a monoprotonated cation of pip by the reaction of aqueous solutions

of $(NH_4)_2[MS_4]$ with pip in a 1:2 mole ratio, or use of an excess of pip or alternatively the aqueous reaction of $(pipH_2)[MS_4]$ with pip always resulted in the isolation of products containing either the known $(pipH_2)[MS_4]$ compound or a mixture of products containing $(pipH_2)[MS_4]$ as the major product. As different solution methods of synthesis did not result in the formation of a $[MS_4]^{2-}$ compound containing monoprotonated pip, the reaction of $(NH_4)_2[MS_4]$ with pip was investigated by mixing the reagents in the solid state. A mechanical grinding of solid $(NH_4)_2[MS_4]$ with pip (Eq. (2)) in a mortar and pestle afforded the new $(pipH)_2[MS_4]$ title compounds. The presence of a monoprotonated organic cation in the product can be readily evidenced by a comparison of the infrared spectra of the solid state reaction products with those of the previously reported $(pipH_2)[MS_4]$ compounds. The IR spectrum of $(pipH)_2[WS_4]$ exhibits two N–H vibrations for the free and protonated amine functionalities (Fig. 1). The sharp signal at 3227 cm^{-1} can be assigned to the N–H vibration of the free amine, while the doublet at around 3000 cm^{-1} can account for the vibration of the protonated amine $(N–H)^+$. In contrast, the IR spectrum of $(pipH_2)[WS_4]$ in which both amine N atoms are protonated, shows a single strong and broad signal centered around 3000 cm^{-1} assignable to the vibrations of the identical $(>N–H_2)^+$ groups. The presence of a free as well as a protonated amine group in the Mo compound **2** can be similarly inferred from its infrared spectrum (Supplementary Fig. 1). In order to prepare suitable crystals of **1** and **2** for structure determination, the reaction conditions were optimized which involves the use of excess pip during grinding followed by recrystallization from water. The products thus obtained, analyzed satisfactorily for new organic $[MS_4]^{2-}$ compounds containing $(pipH)^+$ and $[MS_4]^{2-}$ in a 2:1 mole ratio.

$$(NH_4)_2[MS_4] + pip \xrightarrow{H_2O} (pipH_2)[MS_4] + 2NH_4OH \quad (1)$$

$$(NH_4)_2[MS_4] + 2pip \xrightarrow{grinding} (pipH)_2[MS_4] + 2NH_3 \quad (2)$$

Compounds **1** and **2** which were crystallized from a strongly alkaline medium are not stable in acidic medium and are decomposed to insoluble metal sulfide products. However, on reaction with an aqueous solution of $[Ni(en)_3]Cl_2$ both compounds are converted quantitatively into the insoluble $[Ni(en)_3][MS_4]$ [25,36]. The electronic spectra of the colored compounds **1** and **2** exhibit signals which can be assigned to the intra-ligand charge transitions of the $[MS_4]^{2-}$ moiety and the observed values are in very good agreement with the reported data for $[MS_4]^{2-}$ chromophores [1,26,27].

The title compounds **1** and **2** exhibit several signals in their mid-infrared spectra above 500 cm^{-1} all of which originate from the organic cation, while the M–S vibrations of the $[MS_4]^{2-}$ moiety are observed at lower energies below 500 cm^{-1}. The isotypic $(pipH)_2[MS_4]$ compounds exhibit IR spectra which are identical in terms of their profile as well as number of signals. The only difference is in terms of the W–S vibrations which occur at slightly lower energies as compared to the corresponding isostructural Mo compounds. A comparison of the infrared spectra of both compounds **1** and **2** with those of $(pipH_2)[MS_4]$ reveals that all these spectra are very similar excepting for an additional band assignable for the N–H group of unprotonated N observed in **1** and **2**. The several signals observed above 500 cm^{-1} in the title compounds **1** and **2** can be assigned for the vibrations of the organic cations. For the free tetrahedral $[MS_4]^{2-}$ anion four characteristic vibrations $\upsilon_1(A_1)$, $\upsilon_2(E)$, $\upsilon_3(F_2)$ and $\upsilon_4(F_2)$ are expected. All four bands are Raman active while only υ_3 and υ_4 are IR active. When the tetrahedron is distorted the symmetry is reduced and as a result the symmetric vibration $\upsilon_1(A_1)$ appears in the infrared spectrum at 481 cm^{-1} as a signal of medium intensity and an intense signal for the triply degenerate $\upsilon_3(F_2)$ asymmetric stretching M–S vibration at 465 cm^{-1}. The assignments of these vibrations are in agreement with the literature reports (26, 27, 35–38). The distortion of the tetrahedron is also evident from the appearance of an additional signal at 445 cm^{-1}. The Raman spectra of both the compounds exhibit intense signals for the vibrations of the free and protonated N–H groups as well as the vibrations of the $[MS_4]^{2-}$ moiety (Supplementary Fig. 2). The observed Raman spectral data for the vibrations of the $[MS_4]^{2-}$ unit are in the expected range and add credence to the infrared data. The Mo compound **2** exhibits a similar behavior with the appearance of the $\upsilon_1(A_1)$ vibration in its infrared spectrum as well as additional signals and its IR and Raman spectra can be similarly explained [35–38].

3.2. Description of crystal structures of $(pipH)_2[MS_4]$ (M = W **1**; M = Mo **2**)

The title compounds **1** and **2** are isostructural and crystallize in the centrosymmetric triclinic space group $P\bar{1}$. It is interesting to note that the related isostructural compounds $(pipH_2)[MS_4]$ containing the diprotonated $(pipH_2)^{2+}$ dication crystallize in the monoclinic space group $P2_1/c$ [26,27]. The crystal structures **1** and **2** consist of a tetrahedral $[MS_4]^{2-}$ dianion (M = W **1**; M = Mo **2**), two crystallographically independent piperazin-1-ium cations, all of which are located in general positions (Fig. 2). The monoprotonated cyclic organic ammonium cations adopt a chair confirma-

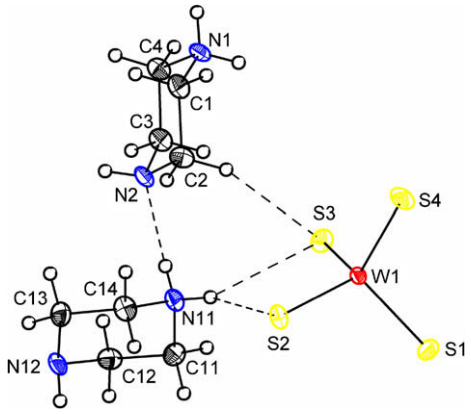

Fig. 2. The crystal structure of $(pipH)_2[WS_4]$ **1** showing the atom-labeling scheme. Displacement ellipsoids are drawn at the 50% probability level except for the H atoms, which are shown as circles of arbitrary radius. Intramolecular H-bonding is shown as broken lines. *Colour code:* C, black; N, blue; W, red; S, yellow. For the structure of the isostructural Mo compound **2**, see Supplementary data. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

tion. In each cation, two of the C–N bond distances (Table 2) associated with the protonated N atoms (N1–C1 = 1.483(7) and N1–C4 = 1.499(6) Å in **1**) are elongated compared to the other two C–N distances made by the free N atom (N2–C2 = 1.466(6) and N2–C3 = 1.461(7) Å in **1**). A similar feature is observed for the C–N bond lengths of the cations in compound **2** (Table 3). This observation can explain the protonation of one of the amine groups of the cyclic diamine in both compounds. In compound **1** the WS_4 tetrahedron is slightly distorted as indicated by the S–W–S bond angles ranging between 108.82(5) and 110.41(5)° (Table 2). The W–S distances vary from 2.1789(7) to 2.2131(7) Å with a mean W–S bond length of 2.1915 Å. In the isostructural $[MoS_4]^{2-}$ compound the Mo–S bonds vary from 2.1734(12) to 2.2115(12) Å with a mean Mo–S bond length of 2.1908 Å (Table 3). The difference Δ between the longest and shortest M–S bond distances is 0.0342 and 0.0368 Å for compounds **1** and **2**, respectively. These Δ values are comparable with the reported Δ value of 0.0385 and 0.0431 Å, respectively, for $(pipH_2)[WS_4]$ and $(pipH_2)[MoS_4]$. Based on an analysis of such Δ values of several $[WS_4]^{2-}$ and $[MoS_4]^{2-}$ compounds, as a structural criterion, we demonstrated that for compounds with Δ larger than 0.033 Å the distortion induces a split M–S vibration in the infrared spectrum [35–38] as observed in the IR spectra of compounds **1** and **2**.

In compound **1**, three of the observed W–S distances (W1–S3, W1–S1 and W1–S4) are shorter than the mean W–S distance of 2.1915 Å indicating a distorted WS_4 tetrahedron. In compound **2** a similar distribution of one long and three short Mo–S bonds is observed. In the related $(pipH_2)[MS_4]$ compounds, a distribution of two short and two long M–S bonds were explained based on the strength and number of hydrogen bonding interactions between the cations and anions. Likewise, the distinct M–S bond lengths in **1** and **2** can be attributed to the several weak hydrogen bonding interactions observed among the $[MS_4]^{2-}$ anions, and the $[pipH]^+$ organic cations. A scrutiny of the structure of **1** reveals a total of 18 weak H-bonding interactions comprising of six N–H···S, two N–H···N and 10 C–H···S contacts the details of which are summarized in Table 4. Thus each $[WS_4]^{2-}$ ion is linked to 10 different piperazin-1-ium cations (Supplementary Fig. 3) with the aid of six N–H···S and 10 C–H···S interactions. One unique $(pipH)^+$ cation (N1, N2) is hydrogen bonded to four different tetrasulfidotungstate anions via three N–H···S and four C–H···S bonds and is further linked to two different cations with the aid of an intramolecular (N11–H5N···N2) and an intermolecular N–H···N interaction. Cation pairs are formed as a result of the intramolecular N–H···N interaction, and the pairs of cations thus formed are extended by the intermolecular N1–H2N···N12 bond into a one-dimensional chain of cations (Fig. 3). The second unique cation is hydrogen bonded to six $[WS_4]^{2-}$ anions and to two different cations with the aid of three varieties of interactions (Supplementary Fig. 4). As a result of H-bonding, a three-dimensional network of H-bonds is formed (see Fig. 4). A detailed analysis of the several H-bonds reveals that the S2 atom which makes the longest W–S distance is involved in two very short N–H···S bonds (N1–H1N···S2 and N11–H4N···S2) at 2.486 and 2.471 Å accounting for its elongation. The isotypic Mo compound **2** exhibits an identical H-bonding behavior (Supplementary Figs. 5–8) and the geometric parameters of its H-bonding interactions are listed in Supplementary Table 1.

3.3. Thermal studies

All the observed thermal events for compounds **1** and **2** as well as the previously reported compounds $(pipH_2)[MS_4]$ containing the diprotonated piperazinediium cation are endothermic and occur below 350 °C. The W compound **1** is thermally more stable as compared to its Mo analogue **2**. An elemental analysis of the residue of all four compounds at 350 °C indicates the presence of considerable amounts of C and N (Table 5). Electron microscopic investigations reveal a porous morphology for the residues and for all the compounds the metal:sulfur ratio of the residue is very close to 1:2. It is well documented that the ammonium salts of the group VI tetrasulfidometalates decompose in two steps resulting in the formation of group VI metal disulfide [52]. The first endothermic

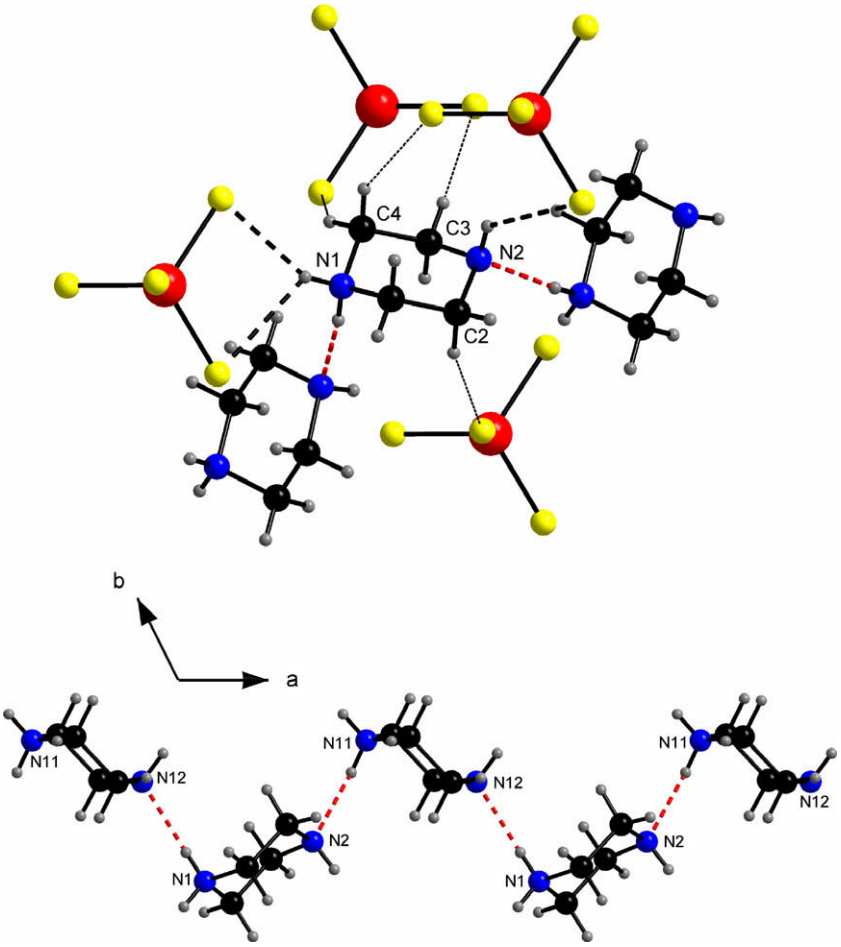

Fig. 3. H-bonding surroundings of one of the unique piperazin-1-ium (N1, N2) cation showing the three varieties of H-bonding interactions (top). The intra and intermolecular N–H···N interactions result in the formation of a one-dimensional H-bonded network of cations in the *ab* crystallographic plane. *Colour code:* C, black; H, medium grey; N, blue; W, red; S, yellow. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

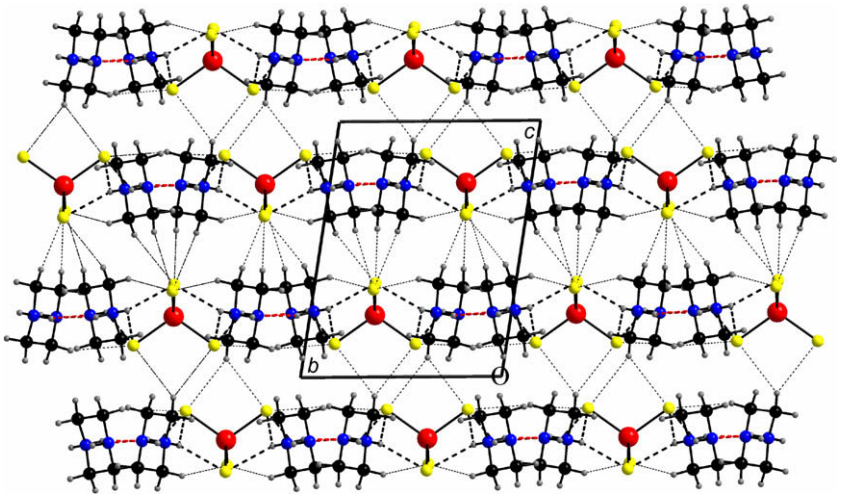

Fig. 4. A view along a axis of the crystallographic packing in compound **1** showing the intricate H-bonded network. H-bonds are shown as broken lines. *Colour code:* C, black; H, medium grey; N, blue; W, red; S, yellow. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

step results in the formation of the amorphous trisulfide accompanied by loss of ammonia and H_2S. In the second step the MS_3 decomposes exothermically above 350 °C into MS_2 losing elemental S. In contrast, organic ammonium $[MS_4]^{2-}$ compounds decompose endothermically at lower temperatures and the decomposition processes are very complex involving structural phase transitions as well as emission of different organic fragments like disulfides and amines [53–55].

The thermal profile of compound **1** (Fig. 5) exhibits two closely related endothermic events centered at 227 and 245 °C as opposed

Table 5
Analytical data of residue at 350 °C.

Compound	C (wt%)	H (wt%)	N (wt%)	S (wt%)	M (wt%)	Composition
$(pipH)_2[WS_4]$ **1**	5.63	0.43	2.52	24.1	67.32	$WS_2C_{1.2}N_{0.5}H_{1.2}$
$(pipH)_2[MoS_4]$ **2**	9.22	0.55	4.18	33.57	52.48	$MoS_{1.9}C_{1.4}N_{0.5}H$
$(pipH_2)[WS_4]$	6.35	0.57	3.02	24.52	65.54	$WS_{2.1}C_{1.4}N_{0.6}H_{1.5}$
$(pipH_2)[MoS_4]$	9.64	0.65	4.32	35.285	50.08	$MoS_{2.1}C_{1.5}N_{0.5}H_{1.2}$

to a single endothermic event for $(pipH_2)[WS_4]$ which shows a single endothermic peak at 290 °C (Supplementary Fig. 9). The observed mass loss of 13.7% is almost twice that expected for the loss of only H_2S, indicating the complex nature of the process. Although the exact nature of thermal event cannot be commented upon in the absence of the mass spectral data of the emitted fragment, it is noted that the TG curve shows a steep drop indicating that the removal of the first fragment leads to further decomposition of **1**. The observed weight loss of 43.5% is lower than the calculated value of 49.4% for the loss of 2 m of pip, H_2S and S. In accordance with this, the observed residue of 56.5% is more than that expected for the formation of WS_2. The analytical data of the residue indicates the composition as $WS_2C_{1.2}N_{0.5}H_{1.2}$.

The DTA curve of $(pipH)_2[MoS_4]$ **2** (Fig. 6) exhibits endothermic events at 165 and 214 °C, respectively, and is very similar to that of $(pipH_2)[MoS_4]$ (see Supplementary Fig. 10). The observed first mass loss is 9.8% is more than the expected value for the removal of only H_2S. The total mass loss of 51.6% till 350 °C is also lower than the expected value of 59.83% for the loss of 2 mol of pip, H_2S and S leading to the formation of MoS_2 indicating incomplete removal of the volatile organic part. This is also evidenced by the presence of C and N in the residue. It is interesting to note that the composition of the residues obtained by the thermal decomposition of the carbon rich starting compounds $(pipH)_2[WS_4]$ **1** and $(pipH)_2[MoS_4]$

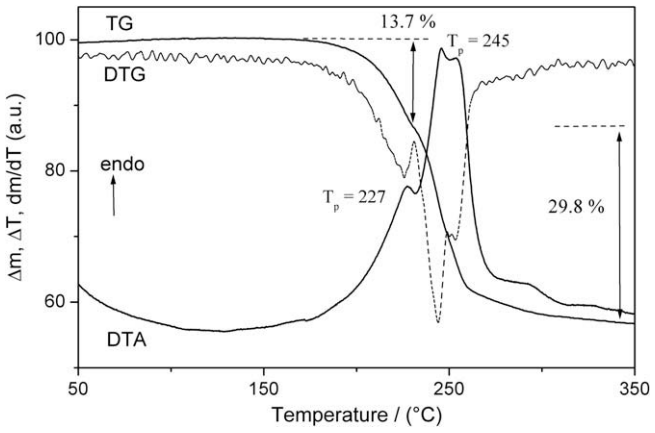

Fig. 5. TG-DTA thermogram of compound **1**.

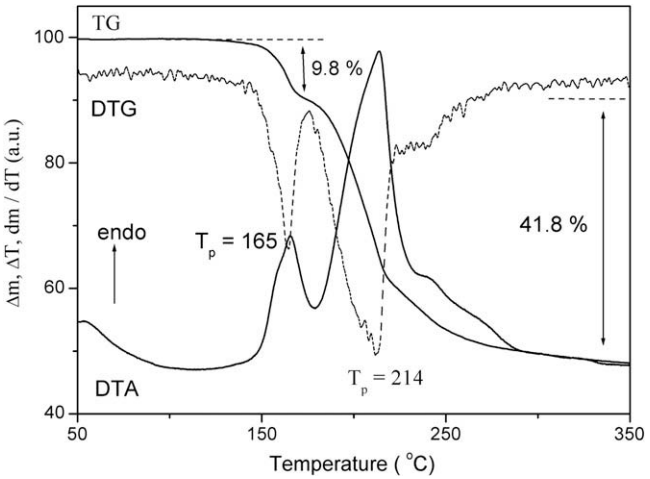

Fig. 6. TG-DTA thermogram of compound **2**.

2 as well as the $(pipH_2)[MS_4]$ compounds which contain the diprotonated piperazine cation are very nearly the same. The results clearly indicate that the carbon content of the precursor tetrasulfidometalates influences the starting decomposition temperature but it does not affect the final carbon content suggesting that the decomposition path for the tetrasulfidometalates containing piperazine cations is very similar and it does not proceed by the formation of MS_3. The formation of the trisulfide as an intermediate is a well documented thermal event for $(NH_4)_2MS_4$.

3.4. Comparative study of tetrasulfidometalates containing piperazine based cations

In addition to the title compounds **1** and **2** described in this work, three more compounds namely $(pipH_2)[WS_4]$, $(pipH_2)[MoS_4]$ and $(2\text{-pipH-1-EtNH}_3)[MoS_4]\cdot\frac{1}{2}H_2O$ (2-pipH-1-EtNH$_3$ = 4-(2-ammonioethyl)piperazin-1-ium) are known. A comparative study of these five compounds (Table 6) reveals certain interesting features. All the compounds which crystallize in centrosymmetric space groups exhibit a very long metal–sulfur bond distance above 2.2005 Å accompanied by Δ values greater than 3 pm and exhibit several weak hydrogen bonding interaction between the organic cation and the $[MS_4]^{2-}$ anion. All compounds including $(pipH_2)[MS_4]$ exhibit N–H···S and C–H···S interactions while the title compounds are additionally involved in N–H···N interactions resulting in the formation of a H-bonded chain of cations. The observed N–H···N interactions in **1** and **2** can be attributed as a possible explanation for the formation of these compounds in the solid state reaction. The hemihydrate $(2\text{-pipH-1-EtNH}_3)[MoS_4]\cdot\frac{1}{2}H_2O$ exhibits four varieties of H-bonding interactions. All compounds decompose endothermically resulting in the formation of residues which contain metal:sulfur in a 1:2 ratio with considerable amounts of C and N.

4. Conclusions

In the present report, we have described a solid state method for the preparation of two new organic tetrasulfidometalates **1** and **2** containing the monoprotonated piperazin-1-ium cation. The title compounds constitute two new examples to the growing list of structurally characterized organic tetrasulfidometalates. The isostructural compounds exhibit three varieties of weak H-bonding interactions between the organic cations and tetrasulfidometalate anion and decompose endothermically resulting in the formation of carbon containing metal sulfide residues.

Scheme 1. Types of [N,N] six-membered ring ligands.

chloride, *p*-anisoyl chloride, 2-amino-6-methylpyridine and 2-amino-5-nitropyridine were purchased from Aldrich Chemical Co. and used as received. Benzoyl chloride was purchased from Guangzhou Chemical Reagent Factory and used without further purification. 2-Aminopyridine was purchased from Shanghai Chemical Reagent Factory and used after recrystallization from ethanol. Methylaluminoxane (MAO) was prepared by partial hydrolysis of trimethylaluminum (TMA) in toluene at 0–60 °C with $Al_2(SO_4)_3 \cdot 18H_2O$ as the water source. The initial $[H_2O]/[Al]$ in molar ratio was 1.3.

2.3. Measurement

^1H and ^{13}C NMR spectra were recorded on a Varian Mercury-Plus 300 MHz NMR spectrometer and referenced versus TMS as standard. Elemental analyses were determined with a Vario EL Series Elemental Analyzer from Elementar. The GC–MS data were recorded with a Finnigan Voyager GC-8000 Top Series GC–MS System with DB-5MS GC column. The following temperature program of the oven was adopted: keeping 40 °C for 2 min, increasing the temperature by 5 °C/min heating to 110 °C, and then by a 15 °C/min heating until 250 °C which was kept constant for a further 2 min.

2.4. X-ray structure determination

The X-ray diffraction data of single crystals were obtained with the $\omega-2\theta$ scan mode on a Bruker SMART 1000 CCD diffractiometer with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) at 173 K. The structure was solved using direct methods, and further refinement with full-matrix least squares on F^2 was obtained with the SHELXTL program package. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced in calculated positions with the displacement factors of the host carbon atoms.

2.5. Ethylene oligomerization

Ethylene oligomerization reactions were performed in a 50 mL glass flask equipped with a magnetic stirrer, and continuous feed of ethylene was used. A typical reaction was performed by adding proper amount of MAO solid and solvent (19 mL) into the reactor under ethylene atmosphere. The catalyst in dichloromethane solution (1 mL, Ni = 5 μmol) was injected into the reactor *via* syringe. Ethylene was continuously fed in order to maintain the ethylene pressure at 0.5 atm. After 30 min, the reaction was terminated by addition of cold acidic ethanol (ethanol–HCl, 95:5). The organic layer was analyzed quickly by gas chromatography (GC) for determining the composition and mass distribution of the oligomers.

2.5.1. Synthesis of 2,6-$iPr_2C_6H_3$–N=C(Ph)–NH–Py (**L1**)

Benzoyl chloride (1.1 mL, 10 mmol) and triethylamine (1.6 mL, 11 mmol) were added to a vigorously stirred solution of 2,6-diisopropylaniline (1.9 mL, 10 mmol) in CH_2Cl_2 (45 mL). After 3 h, the precipitate of $(C_2H_5)_3N \cdot HCl$ was filtrated, and white solid powder benzamide was obtained by evaporating the solvent. Then excess of thionyl chloride (2.0 mL, 28 mmol) was added to the benzamide and the reaction mixtures were stirred for 2 h at 80 °C. The remainder thionyl chloride was distilled off under reduced pressure, to give the imidoyl chloride as yellow and slowly solidifying oil. Successively, toluene (40 mL), triethylamine (1.6 mL, 11 mmol) and 2-aminopyridine (0.94 g, 10 mmol) were added to the reaction system. The mixtures were heated to reflux for 24 h under the protection of nitrogen atmosphere. $(C_2H_5)_3N \cdot HCl$ was removed by filtration, and toluene was evaporated from the filtrate. After recrystallization of the product from ethanol, **L1** was obtained as light yellow crystal in 48% yield (1.72 g, 4.83 mmol). Melting point: 156 °C. ^1H NMR (300 MHz, $CDCl_3$), δ (ppm) [an isomer (*E-syn* and *E-anti*) ratio of 1.2:1] major isomer: 13.31(s, 1H, N*H*), 8.25 (br, 1H, pyridyl α-H), 7.66–6.92 (m, 11H, pyridyl and phenyl protons), 3.26 (m, 2H, C*H*$(CH_3)_2$), 1.14 (d, 12H, CH(C*H*$_3)_2$). Minor isomer: 13.31 (s, 1H, N*H*), 8.25 (br, 1H, pyridyl α-H), 7.66–6.92 (m, 11H, pyridyl and phenyl protons), 3.04 (m, 2H, C*H*$(CH_3)_2$), 0.94 (d, 12H, CH(C*H*$_3)_2$). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm) major isomer: 162.79, 144.99, 144.56, 137.27, 136.04, 134.41, 129.12, 128.80, 128.29, 127.47, 127.10, 123.30, 117.47, 113.26, 28.65, 25.19. Major isomer: 160.53, 144.99, 144.56, 137.27, 136.04, 134.41, 129.12, 128.80, 128.29, 127.47, 127.10, 123.30, 117.47, 113.26, 28.27, 21.83. EI-MS (*m*/*z*): 358 $[M]^+$; 264 $[M-C_5H_5N_2]^+$. Elemental *Anal.* Calc. for $C_{24}H_{27}N_3$: C, 80.63; H, 7.61; N, 11.75. Found: C, 80.47; H, 7.59; N, 11.64%.

2.5.2. Synthesis of 2,6-$iPr_2C_6H_3$–N=C(Ph)–NH–(5-NO_2–Py) (**L2**)

L2 was prepared according to the method described for **L1**, the mixtures were purified by column chromatography on silica gel using petroleum ether/ethyl acetate (10/1) as eluent, and then recrystallized from ethanol in 31% yield. Melting point: 140 °C. ^1H NMR (300 MHz, $CDCl_3$): δ (ppm) [an isomer ratio of 2.3:1] major isomer: 13.12 (s, 1H, N*H*), 9.13 (br, 1H, pyridyl α-H), 8.38 (br, 1H, pyridyl γ-H), 7.40–7.06 (m, 9H, pyridyl and phenyl protons), 3.13 (m, 2H, C*H*$(CH_3)_2$), 1.13 (d, 12H, CH(C*H*$_3)_2$). Minor isomer: 13.12 (s, 1H, N*H*), 9.13 (br, 1H, pyridyl α-H), 8.38 (br, 1H, pyridyl γ-H), 7.40–7.06 (m, 9H, pyridyl and phenyl protons), 2.94 (m, 2H, C*H*$(CH_3)_2$), 0.92 (d, 12H, CH(C*H*$_3)_2$). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm) major isomer: 163.38, 144.08, 142.95, 138.56, 134.92, 132.01, 130.18, 129.04, 128.54, 128.50, 127.99, 122.70, 123.65, 122.35, 28.49, 25.12. Minor isomer: 163.05, 144.08, 142.95, 138.56, 134.92, 132.01, 130.18, 129.04, 128.54, 128.50, 127.99, 122.70, 123.65, 122.35, 28.39, 21.79. EI-MS (*m*/*z*): 403 $[M]^+$; 264 $[M-C_5H_4N_2O_2]^+$. Elemental *Anal.* Calc. for $C_{24}H_{26}N_4O_2$: C, 71.62; H, 6.51; N, 13.92. Found: C, 71.40; H, 6.61; N, 14.08%.

2.5.3. Synthesis of 2,6-$iPr_2C_6H_3$–N=C(4-$CH_3OC_6H_4$)–NH–Py (**L3**)

L3 was prepared according to the method described for **L1** in 46% yield. Melting point: 169 °C. ^1H NMR (300 MHz, $CDCl_3$): δ (ppm) [an isomer ratio of 1.3:1] major isomer: 13.25 (s, 1H, N*H*), 8.23 (br, 1H, pyridyl α-H), 7.64 (br, 1H, pyridyl γ-H), 7.38–6.68 (m, 9H, pyridyl and phenyl protons), 3.72 (s, 3H, OC*H*$_3$), 3.24 (m, 2H, C*H*$(CH_3)_2$), 1.13 (d, 12H, CH(C*H*$_3)_2$). Minor isomer: 13.25 (s, 1H, N*H*), 8.23 (br, 1H, pyridyl α-H), 7.64 (br, 1H, pyridyl γ-H), 7.38–6.68 (m, 9H, pyridyl and phenyl protons), 3.72 (s, 3H, OC*H*$_3$), 3.02 (m, 2H, C*H*$(CH_3)_2$), 0.94 (d, 12H, CH(C*H*$_3)_2$). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm) major isomer: 162.82, 144.97, 144.47, 137.19, 134.72, 130.50, 128.56, 126.98, 123.56, 122.41, 117.20, 113.67, 113.21, 112.85, 55.15, 28.65, 25.12. Minor isomer:

160.25, 144.97, 144.47, 137.19, 134.72, 130.50, 128.56, 126.98, 123.56, 122.41, 117.20, 113.67, 113.21, 112.85, 55.15, 28.25, 21.94. EI-MS (*m*/*z*): 388 $[M]^+$; 294 $[M-C_5H_4N_2]^+$. Elemental *Anal.* Calc. for $C_{25}H_{29}N_3O$: C, 77.48; H, 7.54; N, 10.84. Found: C, 77.55; H, 7.64; N, 10.76%.

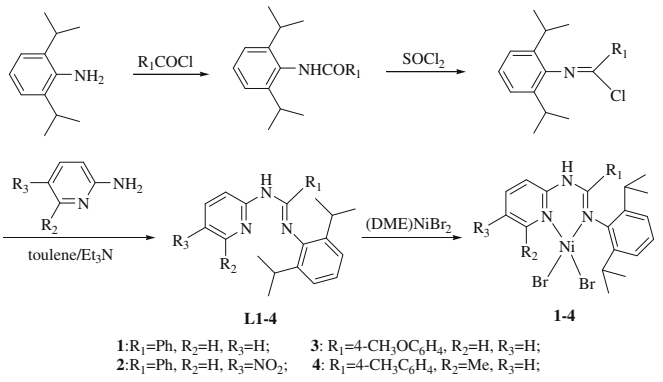
*2.5.4. Synthesis of 2,6-iPr$_2$C$_6$H$_3$–N=C(4-CH$_3$C$_6$H$_4$)–NH–(6-CH$_3$–Py) (**L4**)*

L4 was prepared according to the method described for **L1**. The mixtures were purified by column chromatography on silica gel using petroleum ether/ethyl acetate (10/1) as eluent, and then recrystallized from ethanol in 63% yield. Melting point: 119 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ (ppm) [an isomer ratio of 1.5:1] major isomer: 13.35 (s, 1H, N*H*), 7.56–6.80 (m, 10H, pyridyl and phenyl protons), 3.30 (m, 2H, C*H*$(CH_3)_2$), 2.45 (s, 3H, methyl protons on pyridyl), 2.50 (s, 3H, CH_3), 1.15 (d, 12H, CH(CH_3)$_2$). Minor isomer: 13.35 (s, 1H, N*H*), 7.56–6.80 (m, 10H, pyridyl and phenyl protons), 3.04 (m, 2H, C*H*$(CH_3)_2$), 2.45 (s, 3H, methyl protons on pyridyl), 2.50 (s, 3H, CH_3), 0.99 (d, 12H, CH(CH_3)$_2$). ^{13}C NMR (75 MHz, $CDCl_3$), δ (ppm) major isomer: 162.39, 153.65, 152.72, 144.70, 139.00, 137.50, 134.56, 133.31, 128.76, 128.08, 126.97, 123.20, 119.41, 116.62, 28.53, 25.43, 24.29, 21.81. Minor isomer: 160.50, 153.65, 152.72, 144.70, 139.00, 137.50, 134.56, 133.31, 128.76, 128.08, 126.97, 123.20, 119.41, 116.62, 28.23, 24.29, 21.81, 21.36. EI-MS (*m*/*z*): 386 $[M]^+$; 278 $[M-C_6H_7N_2]^+$. Elemental *Anal.* Calc. for $C_{26}H_{31}N_3$: C, 81.00; H, 8.10; N, 10.90. Found: C, 80.93; H, 8.05; N, 10.91%.

*2.5.5. Synthesis of [2,6-iPr$_2$C$_6$H$_3$–N=C(Ph)–NH–Py]NiBr$_2$ (**1**)*

L1 (358 mg, 1.0 mmol) was dissolved in 40 mL anhydrous dichloromethane under nitrogen atmosphere. (DME)$NiBr_2$ (308 mg, 1.0 mmol) was added under room temperature. The light yellow solution changed into purple quickly, and the solution was stirred for another 12 h. Then the reaction mixture was filtrated and 20 mL hexane was added. After being filtrated from Celite, the solid was washed by hexane (2 × 10 mL). Drying in vacuum, 532 mg of complex **1** was obtained in 92% yields. Decomposition temperature: 289 °C. FAB$^+$-MS: *m*/*z*: 575, 576, 577, 578 $[M]^+$; 495, 496, 497 $[M-Br]^+$; 415, 416, 417 $[M-2Br]^{2+}$; 264, 265 $[L1-C_5H_5N_2]^+$. Elemental *Anal.* Calc. for $C_{24}H_{27}Br_2N_3Ni$: C, 50.05; H, 4.72; N, 7.30. Found: C, 49.72; H, 4.83; N, 7.16%.

*2.5.6. Synthesis of [2,6-iPr$_2$C$_6$H$_3$–N=C(Ph)–NH–(5-NO$_2$–Py)]NiBr$_2$ (**2**)*



Complex **2** was prepared according to the method described for **1** in 77% yields as brown solid. Decomposition temperature: 277 °C. FAB$^+$-MS: *m*/*z*: 619, 620, 621, 622 $[M]^+$; 539, 541, 542 $[M-Br]^+$; 460, 461, 462 $[M-2Br]^{2+}$; 264, 265 $[L2-C_5H_4N_2O_2]^+$. Elemental *Anal.* Calc. for $C_{24}H_{26}Br_2N_4NiO_2$: C, 46.42; H, 4.22; N, 9.02. Found: C, 46.15; H, 4.13; N, 8.89%.

*2.5.7. Synthesis of [2,6-iPr$_2$C$_6$H$_3$–N=C(4-CH$_3$OC$_6$H$_4$)–NH–Py]NiBr$_2$ (**3**)*

Complex **3** was prepared according to the method described for **1** in 89% yields as purple solid. Decomposition temperature: 302 °C. FAB$^+$-MS: *m*/*z*: 605, 606, 607, 608 $[M]^+$; 525, 526, 527 $[M-Br]^+$; 445, 446, 447 $[M-2Br]^{2+}$; 294, 295 $[L3-C_5H_4N_2]^+$. Elemental *Anal.* Calc. for $C_{25}H_{29}Br_2N_3NiO$: C, 49.55; H, 4.82; N, 6.93. Found: C, 49.34; H, 4.91; N, 6.86%.

*2.5.8. Synthesis of [2,6-iPr$_2$C$_6$H$_3$–N=C(4-CH$_3$C$_6$H$_4$)–NH–(6-CH$_3$–Py)]NiBr$_2$ (**4**)*

Complex **4** was prepared according to the method described for **1** in 76% yields as purple solid. Decomposition temperature: 305 °C. FAB$^+$-MS: *m*/*z*: 603, 604, 605, 606, 607 $[M]^+$; 523, 524, 525, 526 $[M-Br]^+$; 443, 444, 445 $[M-2Br]^{2+}$; 278, 279 $[L4-C_6H_7N_2]^+$. Elemental *Anal.* Calc. for $C_{26}H_{31}Br_2N_3Ni$: C, 51.70; H, 5.17; N, 6.96. Found: C, 51.51; H, 5.34; N, 6.83%.

Scheme 2. Preparation of nickel complexes **1**–**4**.

3. Results and discussion

3.1. Ligand and nickel complex syntheses

Four new 2-pyridylbenzamidine ligands with various steric and electronic substituents were synthesized following a classical route for *N*,*N*-disubstituted amidines [49,50]. The synthetic procedures are outlined in Scheme 2, and the particulars of each step were detailed in the Section 2. Benzamide could be easily available from 2,6-diisopropylaniline and substituted benzoyl chloride in high yield with triethylamine as the precipitator. Imidoyl chloride could be produced by the dehydration reaction between benzamide and excess of thionyl chloride. After distilling the residue of thionyl chloride, the 2-pyridylbenzamidine ligands were obtained by the reaction between the quantitative 2-aminopyridine derivatives and imidoyl chlorides in refluxing toluene. Pure **L1** and **L3** were obtained as light yellow crystals by recrystallization in ethanol, while **L2** and **L4** were purified using silica chromatography and then recrystallized in ethanol. All of these ligands were proved by ^{1}H and ^{13}C NMR, MS and elemental analyses. A single crystal of **L2** grown from ethanol solution also assuredly confirmed the ligand structure.

The nickel complexes **1**–**4** were synthesized by mixing (DME)-$NiBr_2$ and corresponding ligand in anhydrous dichloromethane in high yield. Because of paramagnetism, nickel complexes **1**–**4** were

not characterized by ^{1}H NMR but were characterized by MS, elemental analysis, and X-ray crystallography.

3.2. Molecular structure

A previous reference [48] reported that the *N*,*N*-phenylpyridylbenzamidine forms a dimer in the solid state which results from the presence of weak inter-molecular hydrogen bond involving the hydrogen atom in the amidine nitrogen atom and the pyridyl groups. In contrast, the X-ray structure of ligand **L2** (Fig. 1) shows that the 2-pyridylbenzamidine ligand exhibits a monomer structure, and adopts *E-syn* rather than *E-anti* geometry. In addition, the bond lengths of N(4)–C(6) and N(3)–C(6) are 1.276(2) and 1.393(2) Å, indicative of double and single bonds, respectively.

Nickel complexes suitable for X-ray diffraction determination were grown from dichloromethane/hexane or tetrahydrofuran/hexane at ambient temperature under a nitrogen atmosphere. ORTEP diagrams are given in Figs. 2–4 along with selected bond

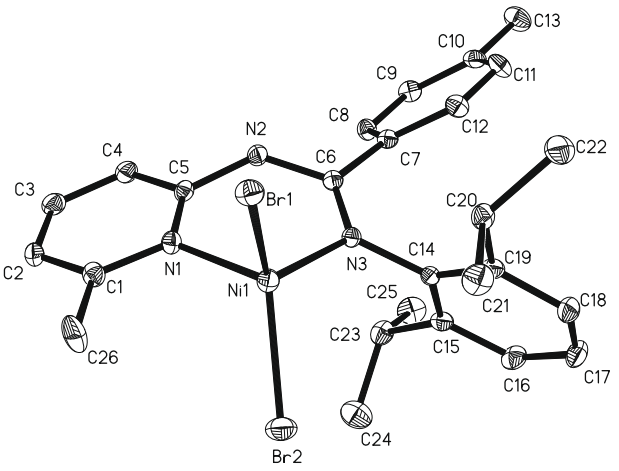

Fig. 4. Molecular structure of **4** depicted with 30% thermal ellipsoids and with hydrogen atoms omitted. Selected bond lengths (Å) and angles (°): C(5)–N(2) 1.399(4), C(6)–N(2) 1.368(3), C(6)–N(3) 1.299(3), C(14)–N(3) 1.458(3), Ni(1)–N(1) 1.997(2), Ni(1)–N(3) 1.989(2), Ni(1)–Br(1) 2.3997(5), Ni(1)–Br(2) 2.3483(5), N(1)–Ni(1)–N(3) 95.8(1), N(1)–Ni(1)–Br(1) 100.79(7), N(3)–Ni(1)–Br(2) 104.98(7), N(3)–Ni(1)–Br(1) 114.28(7), N(3)–Ni(1)–Br(2) 104.98(7), Br(1)–Ni(1)–Br(2) 126.25(1).

lengths and bond angles, respectively. The data collection and structure refinement parameters are summarized in Table 1.

Similar to the β-diimine nickel complexes [36], all of the nickel complexes reveal a distorted tetrahedral geometry around the nickel metal center and the [N,N] six-membered chelating rings exhibit a boat conformation with metal atom. The nickel atom is surrounded by a pyridyl nitrogen atom, an imine N atom, and two terminal Br atoms. In addition, there is no *intra-* or *inter*-molecular hydrogen bonding (Ni···H) between the hydrogen on the amidine nitrogen atom and nickel metal atom. Bearing the similar steric hindrance of ligand, the Ni–$N_{pyridine}$ and Ni–N_{imine} bond lengths of **1** and **3** are nearly the same. In contrast, the Ni–$N_{pyridine}$ and Ni–N_{imine} bond lengths of **4** are 1.997(2) and 1.989(2) Å, respectively, which are longer than those of **1** and **3**. The result indicates that the introduction of methyl on the *ortho* position of pyridyl decreases the bonding ability between pyridine, imine and nickel metal. Moreover, the N–Ni–N bite angles of **1** and **3** are 92.6(1)° and 92.7(1)°, respectively, which are smaller than that of **4** (95.8(1)°), well in accordance with those observed for nickel complexes bearing bulky substituents oriented in a more open environment [46–47,51].

3.3. Ethylene oligmerization

Ethylene oligomerizations were carried out with the nickel complexes in the presence of MAO in order to study their catalytic properties. Initially, toluene was used as the reaction media for ethylene oligomerization, and consumption of ethylene was observed. However, it was surprising that the obtained liquid mixtures were complicated and only small amount of ethylene oligomers was detected by GC–MS (Fig. 5). According to the GC–MS analysis, peak **A** and **B** can be assigned to butene and hexene, respectively, while peaks **C**–**G** can be attributed to alkylated toluene and the collected peaks **H** should be ascribed to ditolylmethanes. The existence of oligomers of ethylene, alkylated toluene and ditolylmethanes in the products means that there are multiple catalytic processes in the system, involving ethylene oligomerization and toluene alkylations by either ethylene or the oligomers by a Friedel–Crafts process [52–55] and disproportionation [56]. Very recently, nickel complexes bearing [N,P] five-membered chelating ring were reported to catalyze reactions with ethylene producing oligomers and alkylated toluene [57].

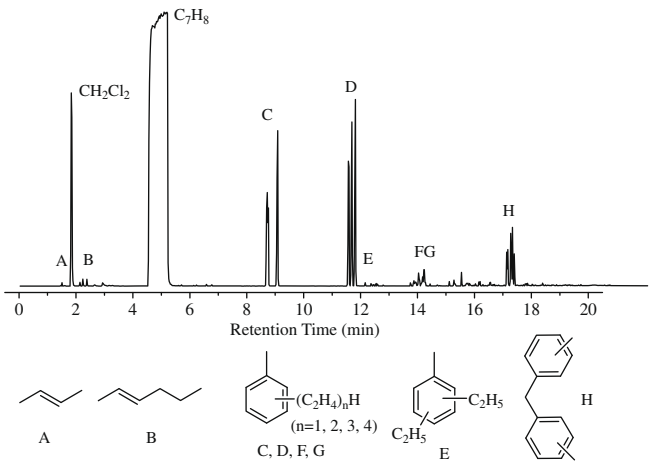

Fig. 5. GC–MS analysis of the products obtained from **2**/MAO in toluene at 0 °C.

In order to obtain the onefold oligomers, dichloromethane was used as solvent instead of toluene and the results of the catalytic reactions are summarized in Table 2. It was shown that four complexes exhibited moderate catalytic activities (TOF *ca.* 10^3–10^4 mol ethylene/mol Ni h). To evaluate the effect of the catalyst structure on TOF, **1**–**4** complexes were screened under the same conditions of T = 20 °C and Al/Ni = 600. In comparison to **1**, **4** with methyl on the *ortho* position of pyridine, and **3** containing electron-donating methoxy on the *para* position of the phenyl exhibited a lower TOF. Meanwhile, **2** containing electron-withdrawing nitro group on the *meso* position of pyridine showed the highest TOF up to 10.5 × 10^3 mol ethylene/(mol Ni h). A reasonable explanation for the TOF enhancement is that the introduction of an electron-withdrawing group would generate a more electrophilic nickel center, resulting in reduction of activation energy for ethylene insertion and favoring ethylene monomer coordination and insertion [9,58].

Furthermore, the structure of the complexes also affects the distribution of oligomers. GC–MS analyses confirmed that the oligomers obtained by **1**, **3** and **4**/MAO at 20 °C mainly contained butene and hexene. Besides butene and hexene, the products obtained by **2**/MAO also contained higher oligomers such as octene and decene (Fig. 6).

Compared with other nickel complexes with [N,N] six-membered chelating ring, it revealed that complexes **1**–**4** show higher

Table 2

Reaction conditions: Ni complex, 5 μmol; t_p, 0.5 h; CH_2Cl_2, 20 mL; ethylene pressure, 0.5 atm.
[a] 10^3 mol ethylene/(mol Ni h).
[b] Not detected or in trace.
[c] Toluene was used instead of CH_2Cl_2 as solvent.

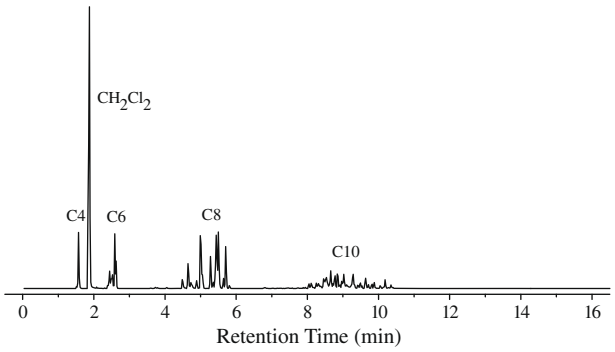

Fig. 6. GC–MS analysis of ethylene oligomers obtained by **2**/MAO in CH_2Cl_2 at 0 °C (run 6 in Table 2).

activity than that of quinolylimine nickel complex(III) [45]. It is supposed that the hydrogen atom on the amidine nitrogen may lose in the presence of MAO. In this case, the neutral amidine ligand transfers to anionic ligand, resulting in a stronger strength of the Ni–N_{imine} bond. As a result, it may stabilize the transition state for ethylene insertion, and increase the activity of the ethylene oliogmerization [26,19,40]. However, they are one or two orders of magnitude lower than those of β-pyridylimine(IV) [46] and dipyridylamine(V) nickel complexes [47]. Moreover, the carbon lengths of oligomers produced by **1**–**4**/MAO are shorter than those by dipyridylamine(V) nickel complexes. Considering the hydrogen atom on the amidine nitrogen atom is being replaced by one bulky alkyl substituent in dipyridylamine(V) nickel complexes, there is increased steric hindrance in the axial position in the dipyridylamine(V) nickel complexes, which could protect the active species, thus enhancing the catalytic activity and obtaining higher oligomers in the process of oligomerizaion.

To test the role of reaction parameters in catalytic properties, further studies were performed with **2**/MAO system as the representative. The reaction temperature greatly influenced the TOF. With an increase in the reaction temperature from −10 to 20 °C, the TOF increased consistently. Meanwhile, the distribution of oligomers changed with the increase of temperature. In general, increasing temperature led to a decrease in the proportions of higher oligomers, which suggested that the process of β-H elimination accelerates in ethylene oligomerization at high temperature.

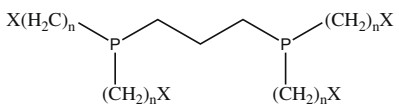
Besides, the amount of cocatalyst also influenced the catalytic performances. The enhancement of Al/Ni molar ratio from 400 to 800 resulted in an increase of TOF up to 11.7×10^3 mol ethylene/(mol Ni h). However, a further increase of the Al/Ni molar ratio showed a slightly negative effect on TOF. The oligomers were confirmed as olefins, and no alkanes were observed, which indicated that the termination of propagation chain is via β-H elimination rather than transferring to MAO.

4. Conclusion

Four 2-pyridylbenzamidine nickel complexes with different steric and electronic substituents (**1**–**4**) have been synthesized and characterized. The solid state structures of **1**, **2** and **4** confirmed that the nickel complexes adopt distorted tetrahedral geometry, forming a six-membered chelating ring. All of these nickel complexes showed a moderate TOF for ethylene oligomerization after activated with MAO. The solvent had a great influence on products of the catalytic reactions. In toluene, ethylene oligomers, alkylated toluene and ditolylmethanes were detected. In contrast, only ethylene oligomers were obtained in dichloromethane. Moreover, the catalyst structure showed important effects on TOF and distribution of oligomers. Bearing an electron-withdrawing substituent, complex **2** exhibited the highest TOF and obtained higher order oligomers. Besides, the reaction temperature and Al/Ni molar ratio also proved to affect the catalytic properties.

Supplementary data

CCDC 713921, 713922, 713923 and 713924 contains the supplementary crystallographic data for **L2**, **1**, **3** and **4**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.



Acknowledgments

The financial Supports by NSFC (Projects 20604034, 20674097 and 20734004), the Science Foundation of Guangdong Province (Project 8251027501000018 and 06300069) and the Ministry of Education of China (Foundation for Ph.D. Training) are gratefully acknowledged.

2. Experimental

2.1. Materials

All experiments were carried out under an atmosphere of argon, unless otherwise stated. Solvents were dried by standard methods and distilled under nitrogen prior to use. Palladium(II) acetate and allylamine were purchased from Across and Fluka, respectively. The diprimary phosphine $H_2P(CH_2)_3PH_2$ was prepared according to reported procedures [15]. The alkenyl phosphonates $CH_2{=}CH{-}(CH_2)_n{-}P(O)(OEt)_2$ were obtained either from commercial suppliers (n = 0, 1) or prepared by literature methods (n = 2–4, 6) [16,17]. The synthesis and the physical characterization of the ligand 1,3-bis[di(6-hydroxyhexyl)phosphino]propane (**a**) and the complex *cis*-[Pd(**a**)(OAc)$_2$] (**1**) have been described previously [12] and the X-ray structure of **1** is report herein for the first time.

2.2. Instrumentation

Elemental analyses were carried out with an Elementar Vario El analyzer. The NMR measurements were obtained using a Bruker DRX 250 at 20 °C using $CDCl_3$ as the solvent. ^{1}H (250.13 MHz) and $^{13}C\{^1H\}$ (62.9 MHz) NMR chemical shifts are reported in ppm downfield from the external standard TMS. $^{31}P\{^1H\}$ spectra were measured relative to 85% H_3PO_4. Mass spectra were acquired by a Finnigan MAT 711A instrument modified by AMD and reported as mass/charge (m/z). The IR spectra were recorded on a Bruker IFS 48 FTIR spectrometer.

2.3. General procedure for the preparation of the diphosphines (*L*)

In a quartz Schlenk tube 1,3-diphosphinopropane (600 mg, 5.55 mmol) and an excess amount of the corresponding olefin were magnetically stirred, and the resultant mixture was irradiated with the ultraviolet light of a mercury high pressure lamp at 20 °C. After 10 h, the excess olefin was removed under reduced pressure. Further purification was not necessary.

2.3.1. 1,3-Bis[bis(2-diethylphosphonatoethyl)phosphino]propane (*b*)

Yield: 4.0 g (95%). *Anal.* Calc. for $C_{27}H_{62}O_{12}P_6$: C, 42.41; H, 8.17. solutions, have proven to be unsuccessful so far [12]. Here, we succeeded in crystallizing this complex by slow diffusion of ether into a concentrated solution of **1** in dichloromethane. The crystal data and the details of data collection for complex **1** are listed in Table 1. The crystal was mounted on a glass fiber and transferred to a P4 Siemens diffractometer, using graphite-monochromated Mo Kα radiation. The lattice constants were determined by 25 precisely centered high-angle reflections and refined by least-squares methods. The structure was solved by direct methods and refined by full-matrix least-squares on F^2 using SHELXTL-97 [19,20]. All non-hydrogen atoms were refined anisotropically (based on F^2). Hydrogen atoms were placed in calculated positions, except for hydrogen atoms of water that were located by a difference Fourier map and were then refined isotropically.

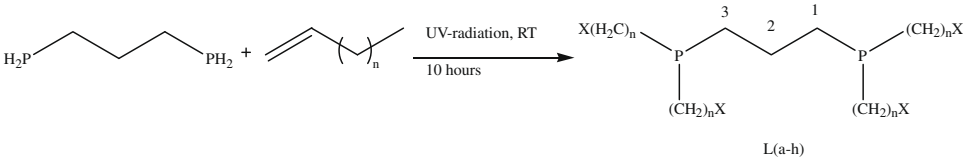
3. Result and discussion

3.1. Synthesis

The new water-soluble diphosphine ligands **a**–**h** have been prepared photochemically by hydrophosphination of the corresponding excess 1-alkene (CH_2=CH–$(CH_2)_n$–X (n = 4, X = OH; n = 2–6, 8, P(O)$(OEt)_2$; n = 3 X = NH_2) with $H_2P(CH_2)_3PH_2$, as shown in Scheme 1.

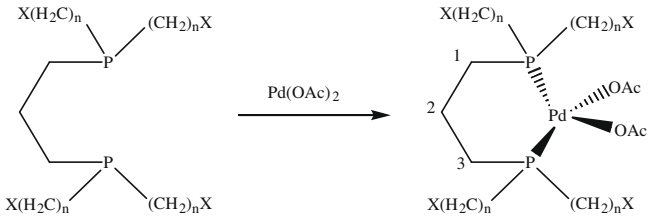
It is worth mentioning that this method of synthesis can be considered as a good way to prepare a wide spectrum of functionalized bis(phosphines) ligands. All the diphosphine ligands (**a**–**h**) are air-sensitive and the oily products are soluble in water and chlorinated hydrocarbons like dichloromethane and chloroform. All the new compounds were characterized by various spectroscopic techniques. Their chemical constitution was confirmed by ^{1}H and ^{31}P NMR spectroscopy. The ^{31}P NMR spectra for the ligands (**b**–**h**) may be explained in terms of an AX_2 spin pattern, where A correspond to the two phosphorus (P1) centers and X to the four phosphonate phosphorus (P2) centers. As a representative example, Fig. 1 shows the $^{31}P\{^1H\}$ NMR spectrum of the phosphonate ligand **b**. The two signals between δ −22 and 32, in a 1:2 ratio, represent an AX_2 spin system. The two singlets at higher field ($\delta \sim 32$) with a coupling constant of about 50 Hz are assigned to the phosphonate phosphorus (X_2), whereas the triplet at lower field ($\delta \sim -22$) is assigned to the phosphine phosphorous (A). This phenomenon of phosphorus coupling was not observed previously [14]. The $^{31}P\{^1H\}$ NMR spectra of the ligands **a** and **h** reveal only a singlet at $\delta \approx -31$.



In addition, the chelating nature of the functionalized ligands **L** (**a**–**h**) provides useful avenues for the development of new classes of transition metal complexes **1**–**8**. The synthesis of *cis*-[Pd(**L**)$(OAc)_2$] was achieved by the reaction of palladium(II) acetate with the ligands **L** in a 1:1 mixture of dichloromethane and acetonitrile at room temperature (Scheme 2).

The hydrophilic nature of **1**–**8** has presented significant problems in getting the complexes as a solid. The complexes tend to be waxy solids even after drying in vacuum for 48 h. These neutral complexes **1**–**8** are air stable, diamagnetic and their structures were confirmed by ^{1}H, ^{31}P NMR spectra, and X-ray diffraction for complex **1**. The aliphatic region in the ^{1}H NMR spectra of complexes **1**–**8** consists of several coupled multiplets due to aliphatic protons of the alkyl group of **L**. There is a marked downfield shift and significant change of the multiplicity in the $^{31}P\{^1H\}$ NMR spectra for the phosphine group upon coordination of the ligands **b**–**g** to the Pd metal (Fig. 2). Similar chemical shift trends were also noted for the rhenium(V) and palladium complexes derived from water-soluble hydroxymethylphosphines [12,14].

The phosphine phosphorous (A) peaks are shifted from a triplet (δ = −22) to a multiplet (δ = 22) upon coordination. The $^{31}P\{^1H\}$ NMR spectra of the phosphine complexes **2**–**7** are characterized by two signals in a 1:2 ratio, representing an $AX_2A'X'_2$ spin system, which are assigned to the phosphonate ($X_2X'_2$) and phosphine (AA′) groups. As a representative spectrum, Fig. 2 shows the $^{31}P\{^1H\}$ NMR spectrum for complex **2**. The two singlet signals located at higher field (δ = 32) are assigned to the phosphonate function ($X_2X'_2$), whereas that at lower field (δ = 22) is traced back to the phosphines (AA′). Complexes **1** and **8** give rise to a singlet at δ = 19 and 15 ppm, respectively.



3.2. Crystal structure

The structure of complex **1** was further confirmed by X-ray crystallography and an ORTEP figure of complex **1** is shown in Fig. 3. Selected inner coordination sphere bond parameters of **1**

n	6	2	3	4	5	6	8	3

L	a	b	c	d	e	f	g	h

Scheme 1.

Scheme 2.

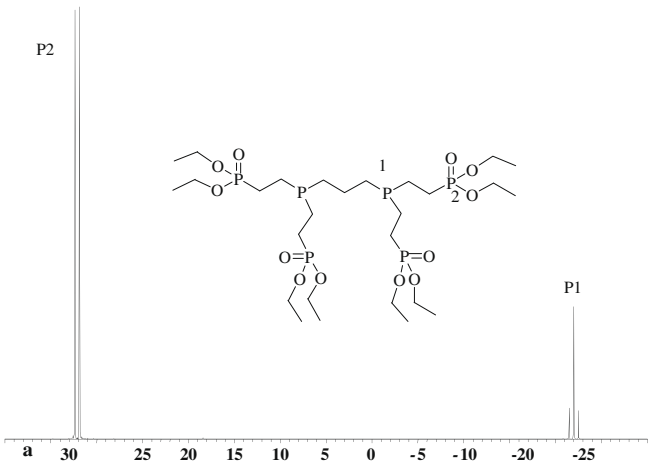

Fig. 1. $^{31}P\{^{1}H\}$ NMR spectrum of the ligand **b** showing an AX_2 pattern.

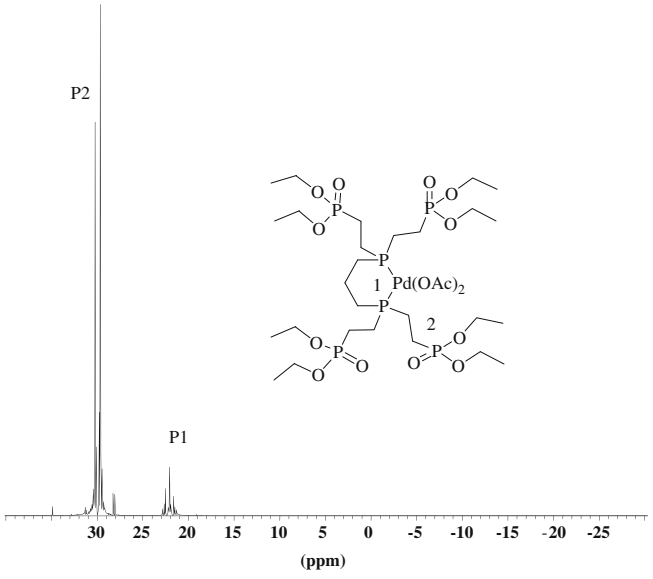

Fig. 2. $^{31}P\{^{1}H\}$ NMR spectrum of complex **2** showing an $AX_2A'X'_2$ spin pattern.

are listed in Table 2. Complex **1** crystallizes in the triclinic space group $P\bar{1}$ with two formula units per unit cell. The bond angles P1–Pd–P2 (95.29(6)°) and O5–Pd–O7 (92.47(14)°) differ slightly from an ideal square planar geometry. Pd, P1, P2, O5 and O7 deviate by less than 0.12 Å from a planar arrangement. Remarkably, the six-membered ring, formed by the diphosphine ligand and the metal atom, is flattened at the metal, and Pd1 and C2 deviate by −0.095(3) and 0.700(7) Å, respectively. The diphosphine unit is

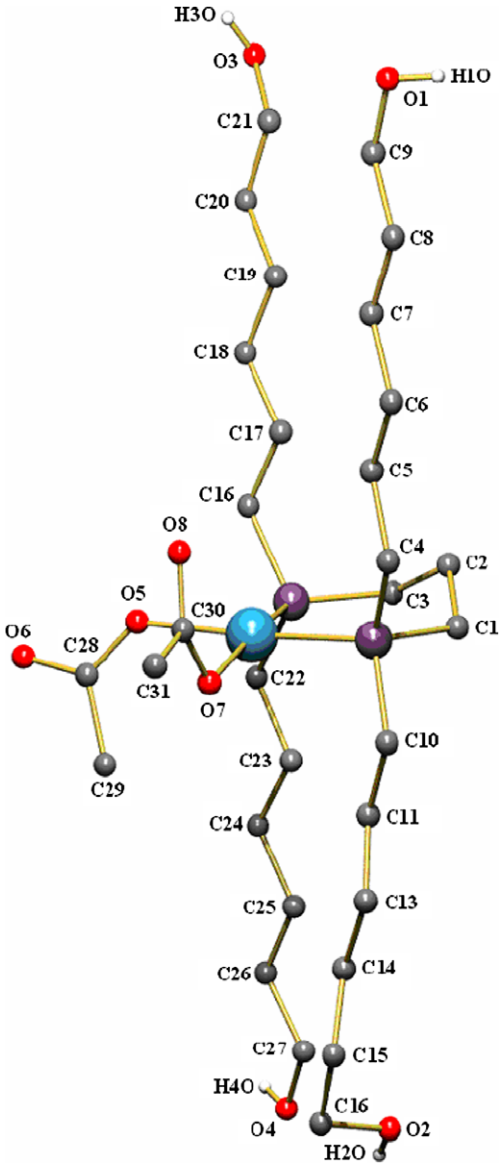

Fig. 3. Thermal ellipsoid plot (20%) of complex **1**. Solvent molecules are omitted for clarity.

coordinated to the metal in a chelating fashion. The Pd1–P1 and Pd–P distances are 2.2225(15) and 2.2276(15) Å, respectively. The Pd1–O5 and Pd1–O7 distances are 2.108(3) and 2.116(3) Å, respectively. The P1–Cl and P2–C3 distances are 1.806(5) and 1.815(5) Å. For complex **1**, The Pd–P distances (average, 2.2251 Å) are shorter than the Pd–P distances (average, 2.2504 Å) in similar reported dicationic palladium(II) complexes $([(R_2P(CH_2)_3PR_2)Pd(NCCH_3)_2][BF_4]_2$, R = $(CH_2)_2CH_3$) by 0.03 Å [12]. This shortening may be due to greater π-back donation from the electron rich Pd → d orbital to the empty d orbital of the phosphorous atom of the diphosphine ligand.

Extensive hydrogen bonding links the hydroxyl oxygens (O1, O2, O3 and O4) to the acetate oxygens (O5, O6 and O8) and to the water oxygen (O9). It is noted from Table 3 that the water molecule behaves as a H-donor and a H-acceptor. H20O of the O9 water molecule makes a bifurcated hydrogen bond with O6 and O5 of the acetate group, the later being a rather weak and acute bond, at symmetry positions $-x+2$, $y+1$, $z+1$. H21O of the O9 water molecule makes a single hydrogen bond with the hydroxyl O4. Further O9 of the water molecule, via its lone pairs, forms a

hydrogen bond with the hydroxyl groups (O3 and O4) from different asymmetric units.

4. Conclusion

New family of water-soluble functionalized bis(phosphine) ligands **L** (**a**–**h**) of the general formula $CH_2(CH_2PR_2)_2$, where for **a**: R = $(CH_2)_6OH$; **b**–**g**: R = $(CH_2)_nP(O)(OEt)_2$, $n = 2$–6 and $n = 8$; **h**: R = $(CH_2)_3NH_2$ (Scheme 1), have been prepared photochemically by hydrophosphination of the corresponding 1-alkenes with $H_2P(CH_2)_3PH_2$. The reactions of these ligands with $Pd(OAc)_2$ in dichloromethane–acetonitrile produced water-soluble palladium complexes of the general formula *cis*-[Pd(**L**)$(OAc)_2$] (**1**–**8**). The $^{31}P\{1H\}$ NMR spectra of **L** and its palladium(II) complexes display two signals in a 2:1 ratio, assigned to the phosphonate and phosphine substituents. A marked shift and a significant change of the multiplicity in the $^{31}P\{^1H\}$ NMR spectra for the phosphine group in this ligand from a triplet ($\delta = -22$) to a multiplet at $\delta = 22$ upon reaction of palladium(II) acetate with $R_2P(CH_2)_2PR_2$ have been observed. Crystallographic studies of **1** show that the diphosphine units are coordinated to the metal in a chelating fashion. The square planar geometry formed from the acetate ligands and the diphosphine ligand deviate by less than 0.12 Å from the ideal planar arrangement.

Structure of mandelic acid

2. Experimental

Reagent grade mandelic acid and hafnium oxychloride were used for the present experiment. Humic acid (ACROSS) was used. Ten milligrams of hafnium oxychloride was irradiated in Dhruva reactor of Bhabha Atomic Research Centre, Trombay (flux $\sim 10^{14}$ n cm^{-2} s^{-1}) for a time period of 7 days to obtain high specific activity ^{181}Hf. For the preparation of mandelate complex, zirconium was used as a carrier for hafnium. Zirconyl chloride solution containing ^{181}Hf activity was mixed with a mandelic acid solution in 1 M HCl under hot condition. The complex was precipitated, filtered and washed with distilled water. In the case of Hf–humate complex, a small aliquot from the ^{181}Hf stock solution was evaporated to dryness and humic acid solution, having pH 2 (20 mg/l) was added to it. Hafnium concentration in the solution was around 10^{-7} M, which is small compared to the humic acid concentration (10^{-4} M). The solution, equilibrated for 48 h, was subsequently centrifuged. The solid residue was found to contain 99% of the Hf activity. Three BaF_2 detectors of a fast-slow coincidence setup, coupled to multi-parameter data acquisition system, were used for TDPAC counting. The time resolution for 133–482 keV cascade of ^{181}Hf was 0.8 ns.

3. Results and discussion

Fig. 1 shows the TDPAC spectrum of the Hf–mandelate complex calculated using the formula,

$$A_2G_2(t) = 2\frac{W(180^\circ,t) - W(90^\circ,t)}{W(180^\circ,t) + 2W(90^\circ,t)} \quad (1)$$

where $W(180^\circ,t)$ and $W(90^\circ,t)$ are the coincidence counts between 133 and 482 keV gamma rays at 180° and 90°, respectively. The attenuation factor ($G_{22}(t)$) contains the information about the interaction frequencies (ω_n) and the asymmetry parameter η:

$$G_{22}(t) = S_{k0} + \sum_{n=1}^{3} S_{kn}\cos\omega_n t \quad (2)$$

where S_{kn} are the amplitudes of the corresponding frequencies (ω_n). The data were analyzed using the software DEPAC to obtain the interaction frequency (ω_1) and asymmetry parameter (η) of the EFG [17]. The quadrupole interaction frequency (ω_q) was obtained from ω_1 using the following relation [18]:

$$\omega_Q = \frac{\omega_1}{4[7(3+\eta^2)]^{1/2}\sin\left[\frac{1}{3}(\cos^{-1}\beta)\right]} \quad (3)$$

The EFG can be deduced from quadrupole interaction frequency (ω_Q) by the equation

$$\omega_Q = eQV_{ZZ}/4I(2I-1)\hbar \quad (4)$$

where Q is the quadrupole moment of the intermediate level and I is its spin. The asymmetry parameter (η) is given by

$$\eta = (V_{XX} - V_{YY})/V_{ZZ} \quad (5)$$

where $|V_{ZZ}| > |V_{XX}| > |V_{YY}|$.

The Fourier transform of TDPAC spectrum (Fig. 1) of Hf–mandelate complex shows two ω_Q values. The data for quadrupole interaction frequencies for two sites are given in Table 1. The existence of two sites was also observed by Baussaha et al. [19] while Barbieri et al. [20] observed only one quadrupole frequency. The two ω_Q values indicate that in Hf–mandelate, Hf is complexed in two types of well defined environments. The IR spectroscopy of Hf–mandelate shows bands at 2600, 2300 and 1850 cm^{-1} which are typical of compounds with hydrogen bonds and these bonds link alcoholic oxygen of one bridging mandelate and carboxylic oxygen of second bridging mandelate [21]. These results show the possible existence of monomeric and dimeric species which could be present in Hf–mandelate. The existence of other complexes, like, $Hf(L)_3OH$ or $Hf(L)_2OH$ (L = mandelate) could also lead to different electronic environments around Hf nuclei and thus in different quadrupole frequencies.

Table 1
TDPAC experimental data for two Hf sites in Hf–mandelate complex.

Abundance (%)	ω_Q (Mrad/s)	η	δ	V_{ZZ} ($\times 10^{18}$) (V/cm^2)
26.9	77 ± 0.4	0.7	0.054 ± 0.005	0.80 ± 0.004
73.0	111 ± 3.1	0.3	0.57 ± 0.04	1.16 ± 0.03

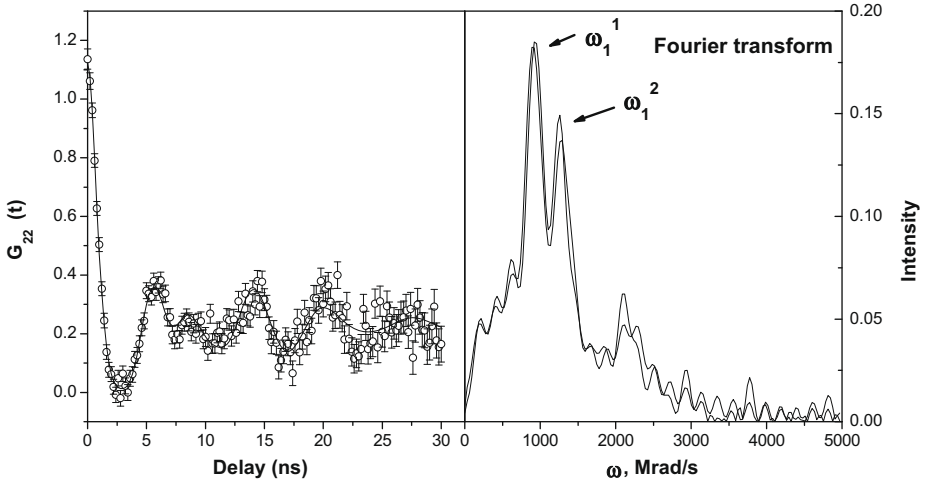

Fig. 1. TDPAC spectrum of Hf–mandelate complex at 300 K and its Fourier transform showing interactions frequencies $\omega_1{}^1$ and $\omega_1{}^2$ for the site 1 and 2, respectively.

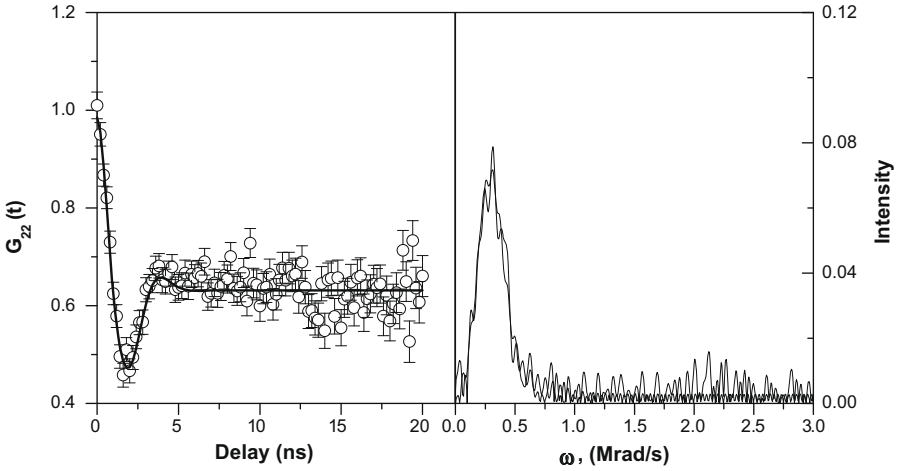

Fig. 2. TDPAC spectrum of Hf–humate complex and its Fourier transform.

In the case of humate complex, the Fourier transform of the TDPAC spectrum showed a broad distribution of quadrupole interaction frequencies (Fig. 2). This indicates absence of specific binding site in HA. Metal ions may be bound to the humic acid by direct association with the donor groups (specific site binding model) [22] or they may be associated with anionic macromolecule as a whole (polycondensate model) [23]. While in the case of specific site binding, we expect well defined quadrupole interaction frequencies, in the case of polycondensate model any such specific coordination site may be absent. The present observations point towards the polyconsendate model. Stability constants of metal–humate complexes are known to decrease with increasing metal ion concentration, indicating the presence of different binding sites with widely varying affinity for the metal ions [24]. The fraction of high affinity binding sites is expected to be small. These sites cannot selectively bind the metal ion at concentration levels of μg/ml, as in the present case (0.9 μg/ml). Similar results were obtained in the case of ^{111m}Cd–humate complex by Kupsch et al. [15]. Therefore, it would be interesting to carry out these studies at concentration level of ng/ml. It is possible with carrier free radioisotopes.

Table 2
Experimental and theoretical values of EFG (V_{ZZ}) and asymmetry parameter (η).

Species	Theoretical values		Experimental values	
	η	EFG (au)	η	EFG (au)
L_3 Hf (μ-L)$_2$Hf L_3	0.38	0.35	0.3	0.19 ± 0.01

4. Theoretical calculations

To find out the present species exactly, we independently calculated the EFG on the Hf nuclei using ab initio molecular orbital methods. Theoretical calculations were done using GAMESS. The Gaussian Orbital Valence basis sets were used for Hf. The 60 core electrons of Hf were described by the effective core potential of Hay et al. [25] which incorporates mass velocity and Darwin relativistic effects into the potential and the valence electrons by a (5s6p3d)/[3s3p2d] Gaussian function basis set. To reduce the number of atoms for ab initio calculation of Hf with large ligand, the phenyl groups were replaced by hydrogen. Table 2 gives the theoretically calculated EFG for dimeric species of Hf–mandelate and is compared with experimentally obtained EFG. The structure of dimeric species used for EFG calculation is given in Fig. 3. The reasonably good agreement between theoretical and experimental values confirms the presence of dimeric Hf–mandelate species.

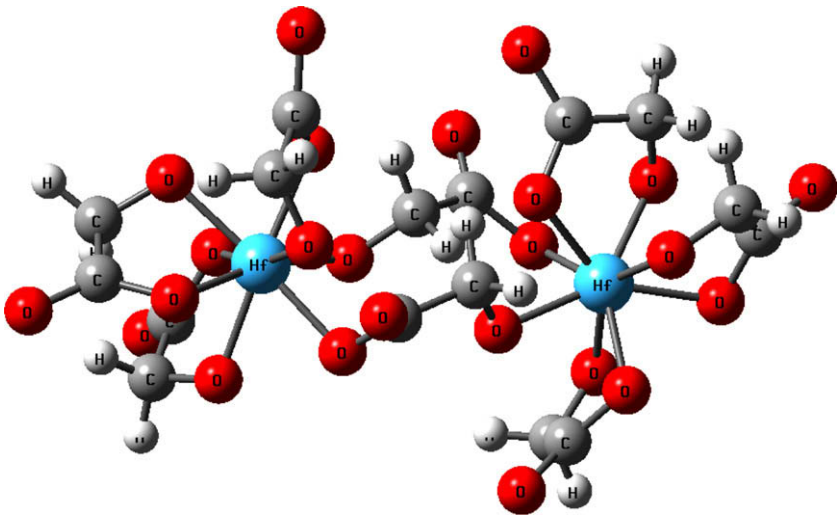

Fig. 3. Structure of L_3 Hf (μ-L)$_2$Hf L_3 used for EFG calculation.

5. Conclusion

The TDPAC spectrum of Hf–mandelate showed two well defined chemical environments around Hf nuclei. The experimentally obtained perturbation parameters show good agreement with the theoretically obtained parameters using GAMESS code. The TDPAC data confirm that Hf–mandelate exist predominantly as dimeric species while the minor species could be a mixed hydroxy mandelate complex of hafnium. The TDPAC of Hf–humate, on the other hand, indicates non specific site binding of metal ion.

Acknowledgement

Authors thank A. Bhattacharya for his help in the theoretical calculations of EFG.

2.2. Physical measurements

NMR spectra were obtained on a Bruker Avance 300 MHz spectrometer at 25 °C. ^{1}H and ^{31}P NMR spectra were recorded at 299.948 and 121.420 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ (^{1}H) and H_3PO_4 (^{31}P). Elemental analyzes were performed on a CHNS HEKAtech EuroEA 3000 analyzer.

2.3. Crystal structure determination and refinement

The X-ray data for both **1** and **2** were collected on a STOE IPDS-II diffractometer with graphite-monochromatized Mo Kα radiation generated by a fine-focus X-ray tube operated at 50 kV and 40 mA. The images were indexed, integrated and scaled using the X-area data reduction package [11]. Data were corrected for absorption using the PLATON program [12]. The structures were solved by direct methods using SHELXS-97 [13] and refined first isotropically and then anisotropically using SHELXL-97 [13]. Hydrogen atoms were revealed from $\Delta\rho$ maps and those bonded to C were refined using appropriate riding models. H-atoms bonded to N were freely refined. The isopropyl group in **2** shows signs of disorder, but no split model could be found.

3. Results and discussion

The compounds **1–3** were synthesized by treatment of 1,2-diaminoethylene, 1,2-diaminophenylene or hydrazine hydrate with the isothiocyanate $(i\text{PrO})_2\text{P(O)NCS}$ in high yields. Their composition was proved by microanalysis data.

The ^{31}P NMR spectra of **1** and **2** in $CDCl_3$ each contain a triplet signal at −6.5 and −6.6 ppm, respectively, which is typical for *N*-phosphoryl thioureas [1]. In the ^{1}H NMR spectra of **1** and **2**, the ethylene and phenylene proton signals are at 3.90–3.97 and 7.30–7.71 ppm, respectively. The spectra of both bis-thioureas contain a set of signals for the *i*PrO protons: a triplet or doublet for the

[a] Measurements at 173(2) K using Mo Kα radiation with λ = 0.71073 (Å). Structure solution using direct methods in monoclinic $P2_1/n$ (Z = 4) and $P2_1/c$ (Z = 8) for **1** and **2**, respectively.

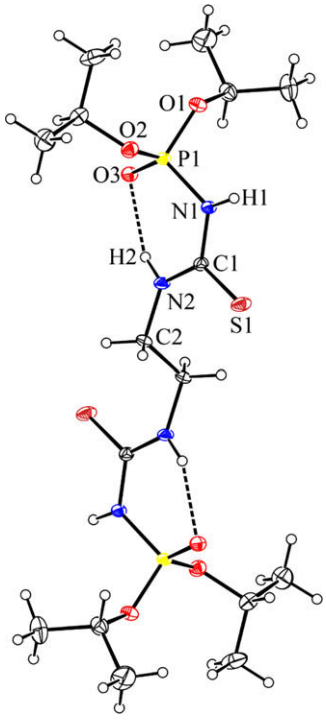

Fig. 2. Thermal ellipsoid representation of one of the two independent molecules of **1**. Ellipsoids are drawn at the 30% probability level.

CH_3 protons at 1.36–1.39 ppm and a doublet of septets for the CH proton in the area 4.70–4.81 ppm. The signals at 6.43 and 6.98 ppm correspond to the PNH protons in **1** and **2**, respectively. The main difference involves the signals at 9.17 ppm in the spectrum of **1** and at 10.36 ppm for **2**, corresponding to the NH hydrogen atoms. Thus, the ^{1}H NMR spectra of the thioureas **1** and **2** clearly show the presence of strong intramolecular N—H···O=P hydrogen bonds [1].

Surprisingly, there are four signals in the ^{31}P NMR spectrum of **3** in $CDCl_3$ solution: a major signal at −5.7 and minor peaks at −20.7, −6.4 and −0.6 ppm with integral intensities 4.6:1:1:1.9, respectively (Fig. 1). We suppose that the major signal corresponds to the *E*-*E*-isomer, which is stabilized by intramolecular hydrogen bonds, whereas the peak at −0.6 ppm shows the formation of *Z*–*Z*-form, as was previously observed for the *N*-thiophosphorylated analog $[NHC(S)NHP(S)(OiPr)_2]_2$ [14] (Scheme 2). The signal at −20.7 ppm corresponds to the phosphorus atom of $(iPrO)_2P(O)NCS$ (Scheme 2). This testifies that compound **3** partially decomposes in $CDCl_3$ solution, with elimination of an isothiocyanate molecule. The same behavior was observed for the tetrafunctional *N*-thiophosphorylated thiourea, based on a cyclam backbone [2]. The signal at −6.4 ppm is rather close to the value of the *E*-*E*-isomer of **3**. This peak corresponds to the monosubstituted *N*-phosphorylated hydrazine $NH_2NHC(S)NHP(O)(OiPr)_2$ (**4**), showing the *E*-isomeric form in $CDCl_3$ solution (Scheme 2). No $E \leftrightarrow Z$ equilibrium is observed for **4**. In the ^{1}H NMR spectrum of **3** in $CDCl_3$ solution, beside several sets of signals corresponding to the *i*PrO, PNH and NH

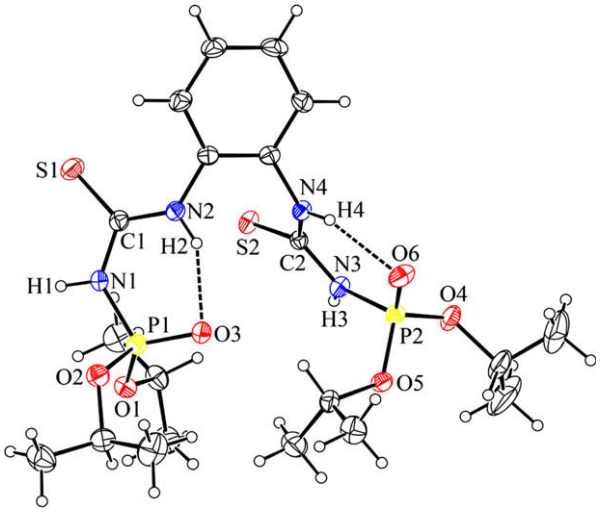

Fig. 3. Thermal ellipsoid representation of one of the two independent molecules of **2**. Ellipsoids are drawn at the 30% probability level.

protons, there is a multiplet signal for the NH_2 protons at 2.36–2.93 ppm. This testifies to the presence of the non-substituted NH_2 group of the parent hydrazine.

Only two signals were observed in DMSO-d_6 solution: the peaks appeared at −5.4 and −2.8 ppm (Fig. 1). The integral intensity ratio is 1:2.4 for the high- and low-field signals, respectively. Only doubling of the signals is observed in the ^{1}H NMR spectrum of **3** in DMSO-d_6 solution. There is no evidence for the dissociation reaction leading to the hydrazine **4**.

The chemical shifts of phosphorus are in the area which is characteristic for the *E*- and *Z*-isomers of *N*-phosphorylthioureas related by structure to the investigated compound **3** [1].

Crystals of **1** and **2** were obtained by recrystallization from a 1:5 (v/v) mixture of dichloromethane and *n*-hexane (Table 1). The molecular conformations of **1** and **2** are shown in Figs. 2 and 3, and geometric parameters are given in Tables 1 and 2. The NMR probes and the crystals for the X-ray determination were taken from the same samples. The parameters of the C═S, C—N, P—N and P═O bonds observed for both compounds (Tables 2 and 3) are in the typical range for *N*-phosphorylated thiourea derivatives [1].

The two N—C(S)—N—P(O) moieties in **1** and **2** are significantly flattened. The two chelate backbones, C(S)—N—P(O), in **1** are in

[a] Symmetry transformations used to generate equivalent atoms: #1 –x + 2, –y + 2, –z + 1; #2 –x + 1, –y, –z + 1; #3 –x + 1, –y + 1, –z + 1; #4 –x + 3/2, y–1/2, –z + 1/2.

[b] Symmetry transformations used to generate equivalent atoms: #1 –x, y + 1/2, –z + 1/2; #2 –x + 1, y–1/2, –z + 1/2.

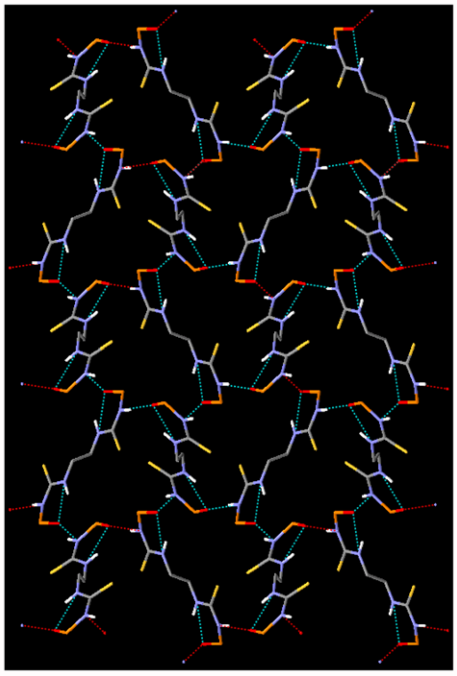

Fig. 4. Crystal packing of **1**. *i*PrO groups and H-atoms, not involved in hydrogen bonding, are omitted for clarity.

an *anti*-disposition relative to the ethylene spacer, whereas in **2** these fragments are on the same side of the phenylene fragment.

The bis-thioureas crystallize in the monoclinic space groups $P2_1/n$ and $P2_1/c$ for **1** and **2**, respectively. The asymmetric unit contains two independent molecules.

There are intra- and intermolecular hydrogen bonds of the type N—H···O=P in the crystal of **1** (Table 4), whereas intramolecular hydrogen bonds of the type N—H···O=P and intermolecular H-bonds of types N—H···O=P and N—H···S=C are observed in the crystal of **2** (Table 4). The intramolecular H-bonds are formed between the oxygen atoms of the P=O groups and the hydrogen atoms of the —$NHCH_2CH_2NH$— (**1**) or —NHC_6H_4-2-NH— (**2**) fragments, which in turn leads to the *E*-*E*-conformation of the S—C—N—P backbones. The intermolecular H-bonds in **1** are formed between the oxygen atoms of the P=O groups and the hydrogen atoms of the PNH groups. In **2**, these bonds are formed between the H-atom of one PNH group of a molecule, and the P=O oxygen atom of the neighboring molecule, while the H-atom of the other PNH group forms intermolecular hydrogen bonds with the C=S sulfur atom of a further neighboring molecule. As a result of the intermolecular H-bonds 3D structures are formed in the crystals of **1** and **2** (Figs. 4 and 5).

4. Conclusions

In summary, we have demonstrated the syntheses of two new *N*-phosphorylated bis-thioureas and a dithiobiurea by addition of phosphorylisothiocyanate to the corresponding bis-amine or hydrazine. An *E*-*E*-arrangement of the C=S and P—N bonds in the SCNPS backbones was found both in the crystal phase and in $CDCl_3$ solution for the bis-thioureas **1** and **2**. The 2,5-dithiobiurea **3** is present as a mixture of *E*- and *Z*-conformation isomers, stabilized by H-bonds in DMSO-d_6 and $CDCl_3$ solutions. Comparison of the ^{31}P NMR data indicates the superiority of the *E*-*E*-isomer. Moreover, according to the NMR data the dithiobiurea **3** partially decomposes in $CDCl_3$ solution, with the elimination of an isothiocyanate molecule. Single crystal X-ray diffraction studies showed the bis-thioureas **1** and **2** to form both intra- and intermolecular hydrogen bonds, which in turn lead to the formation of 3D structures.

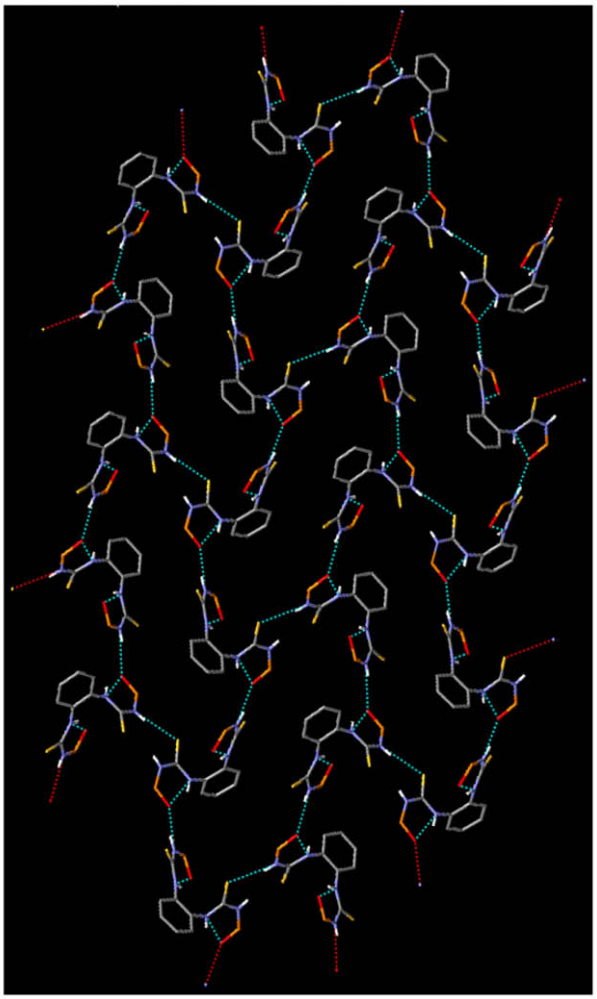

Fig. 5. Crystal packing of **2**. *i*PrO groups and H-atoms, not involved in hydrogen bonding, are omitted for clarity.

5. Supplementary data

CCDC 719775 and CCDC 719776 contain the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk.

upon the formation constant and the free energy of the complexes formed was studied.

2. Experimental

2.1. Reagents

The salicylaldehyde, 4-methoxysalicylaldehyde, 5-methoxysalicylaldehyde, 5-chlorosalicylaldehyde, 5-bromosalicylaldehyde, 5-nitrosalicylaldehyde, 5-sodium sulfitesalicylaldehyde, 2,4-dihydroxysalicylaldehyde, 2-hydroxyacetophenone, 2-hydroxybenzophenone, 1,2-ethylendiamine, 1,2-diaminopropane, ammonia solution, carbon disulfide, dimethylsulfate, cyclopentanone, methanol, ethanol, chloroform, hydrochloric acid and nickel acetate tetrahydrate were commercially obtained from Merck or Fluka and were used without further purification. Spectrograde solvents were used for spectral measurements.

2.2. Physical measurements

UV–Vis measurements were carried out in JASCO V-530 and Perkin–Elmer (LAMBDA 2) UV–Vis spectrophotometers. The NMR spectra were recorded on a Bruker Avance DPX 250 MHz spectrometer. IR spectra were recorded by a Shimadzu FT-IR 8300 infrared spectrophotometer. Elemental analyses were carried out by a Termo Sininngan-Flash-1200 and mass spectra were obtained on a Perkin–Elmer R MU-6E instrument.

2.3. Synthesis

Methyl-2-{N-(2′-aminoethane)}-amino-1-cyclopentenedithiocarboxylate (Hcden) and methyl-2-(1-methyl-2′-aminoethane)-amino-1-cyclopentenedithiocarboxylate (HcdMeen) were prepared by published methods [24–27]. The ligands were prepared by the addition of an equimolar amount of the appropriate salicylaldehyde derivatives and other diketones to a methanolic solution of Hcden and HcdMeen. The yellow products were recrystallized from methanol/chloroform 1:1 (V:V). To a solution of the appropriate ligand (0.1 mmol) in 10 mL of chloroform/methanol 2:1 (V:V), a solution of nickel(II) acetate (0.1 mmol) in 10 mL of methanol was added. The solution was stirred for 15 min and then allowed to stand at room temperature for 24 h. After filtering, the crude product was recrystallized from acetonitrile/methanol 1:1 (V:V), (see Scheme 1).

2.4. Thermodynamic studies

The formation constant measurements were carried out by spectrophotometric titration of the ligands H_2cdXsalen and H_2cdXsalMeen with a solution of nickel ions at constant ionic strength 0.1 M ($NaClO_4$) at 25 °C. In a typical measurement, 2.5 mL solution of the ligand (10^{-5} M) in DMF was titrated with various concentrations of the metal acetate (10^{-5}–10^{-4} M) in DMF. UV–Vis spectra were recorded in the range 290–700 nm about 5 min after each addition. The formed product showed a different absorption from the free ligand, while the metal ion solution showed no absorption at those wavelengths. As an example, the variation of the electronic spectra for [H_2cd5Clsalen] titrated with various concentrations of Ni(II) acetate at 25 °C in DMF is shown in Fig. 1. The same is valid for the other systems. Also the electronic spectra of the complexes formed during the titrations were the same as the electronic spectra of the separately synthesized complexes (Fig. 2).

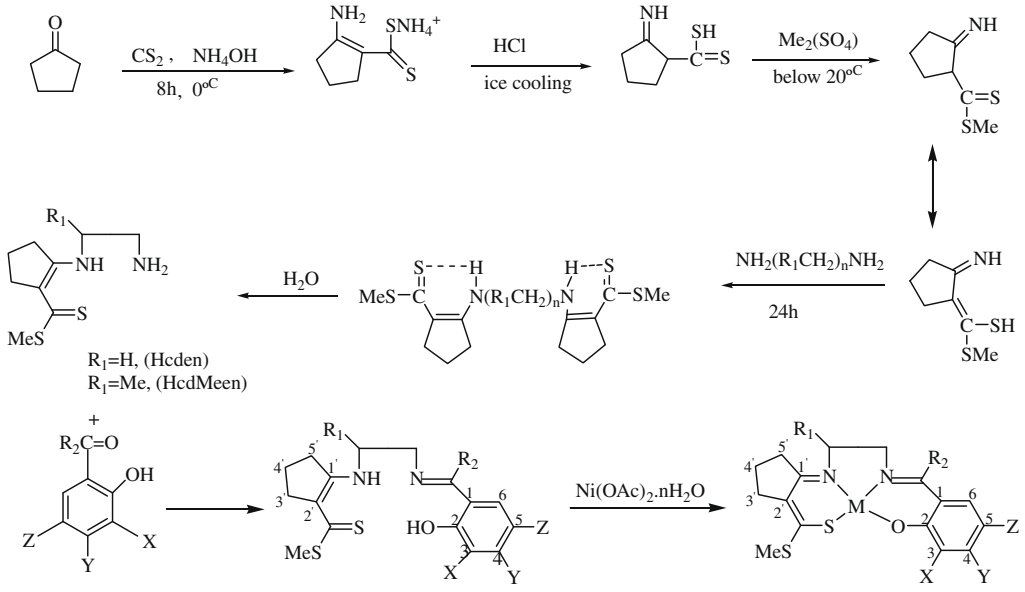
2.5. Crystal structure determination

The data for the nickel(II) complex were collected on a Bruker SMART APEXII CCD area detector diffractometer with MoKα radiation (λ = 0.71073 Å) equipped with an Oxford cryosystem Cobra low temperature attachment. Cell parameters were retrieved using SMART [28] software and refined using SAINT [29] on all observed reflections. Data reduction and correction for Lp and decay were performed using SAINT PLUS software. Absorption corrections were applied using SADABS [30]. The structure was solved by direct methods and refined by the least squares method on F^2 using the SHELXTL program package [31]. All non-hydrogen atoms were refined anisotropically. A riding model was used in the refinement process of the geometrically calculated hydrogen positions of the [Ni(cdClsalen)] complex.

3. Results and discussion

The elemental analyses and the physical constants of the prepared ligands and their complexes are shown in Tables 1 and 2. All the ligands and their complexes gave satisfactory elemental analysis.

3.1. IR and ^{1}H NMR spectra



The IR and ^{1}H NMR spectra are in accord to the proposed structures. The ^{1}H NMR spectra of the ligands and the nickel Schiff base complexes are collected in Tables 3 and 4. The OH proton signals in the ^{1}H NMR spectra of the free ligands are observed at 12.45–15.58 ppm and NH or SH proton signals are observed around 12.18–12.52 ppm, and these disappear in the Ni(II) complexes, indicating that the OH and NH or SH groups have been deprotonated and bond to the metal ions [32]. The azomethine proton signals of the ligands (8.22–8.63 ppm), are shifted to higher fields in the Ni(II) complexes, confirming the coordination of the metal ion to those groups. On the other hands, the FT-IR spectra of all the complexes, compared with those of the corresponding ligands, indicate that the ν(C=N) band around 1600 cm^{-1} [33], ν(C—O) band at 1220–1286 cm^{-1} [34,35], ν(C=C) band in the region of 1456–1496 cm^{-1} [36], ν(C—S) band at 700–790 cm^{-1} and ν(C—S)+ν(C—N) cm^{-1} bands between 1099 and 1180 cm^{-1} are shifted to lower energies. These results show that the Ni(II) ion is coordinated through the nitrogen atoms of the amine group, oxygen atom of the phenolic group and sulfur of the C=S group for all the complexes [37–39] (see Tables 5 and 6).

The ^{1}H NMR spectra of the substituted phenyl ring of the Schiff bases show additional signals. A singlet signal at δ = 3.77–3.90 ppm is assigned to those Schiff bases and their complexes that have a OMe group. The Schiff base compound which has a methyl group in the azomethine position (C(CH_3)=N) shows a singlet signal at δ = 2.41 ppm. The signals due to OMe, CH_3 and aromatic protons are also affirmed, showing an upfield change in chemical shift for the Ni(II) complexes.

In IR spectra the appearance of two sharp peaks around 1300 and 1550 cm^{-1} in the ligands H_2L^7 and H_2L^{17} and two absorption bands around 650 and 1200 cm^{-1} in the ligands H_2L^8 and H_2L^{18} are assigned to nitro group and S=O stretching, which undergo minor changes in the corresponding complexes. It may therefore indicate that they are not coordinated to the metal ions [40].

3.2. The electronic spectra

The electronic spectra of the Schiff base ligands in the DMF solvent show a low intensity band in the 310–316 nm region, which is assigned to a π–π^* transition, and a relatively intense band in the 391–400 nm region, which is due to n–π^* excitation [41,42]. The electronic spectra of the Ni(II) complexes of the H_2cdXsalen and H_2cdXsalMeen ligands are very similar, where two or three intense bands in the region 320–476 nm are observed (see Tables 7 and 8).

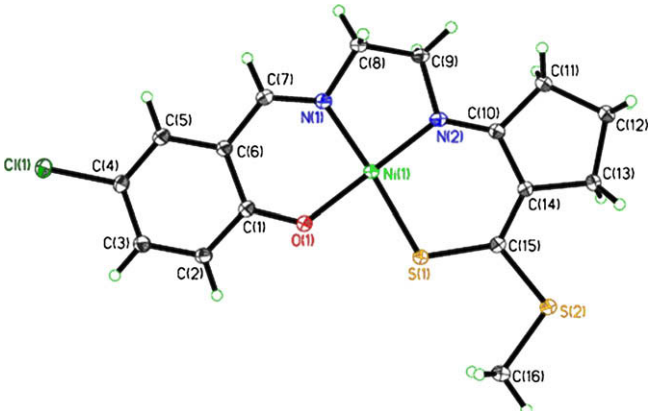

Fig. 3. Molecular structure of the complex [Ni(cd5Clsalen)] with the atom numbering scheme. Displacement ellipsoids are drawn at the 50% probability level.

Table 11
Crystal data, data collection and structure refinement parameters of Ni(cd5Clsalen)].

Crystal shape	prismatic needle
Chemical formula	$C_{16}H_{17}ClN_2NiOS_2$
Formula weight	411.60
Crystal system	triclinic
Space group	$P\bar{1}$
Unit cell dimensions	
a (Å)	8.261(2)
b (Å)	9.261(2)
c (Å)	10.802(2)
α (°)	93.636(10)
β(°)	98.111(10)
γ(°)	91.278(10)
Cell volume (Å^3)	816.15(3)
Z value	2
Calculated density (g/cm^3)	1.675
μ (mm^{-1})	1.612
F(0 0 0)	424
Crystal size (mm)	0.43 × 0.18 × 0.12
θ range for data collection (°)	2.2–40.0
Index range	h – 14 to 14, k – 16 to 15, l –19 to 19
Independent reflections	10,025 (R_{int} = 0.044)
Reflections with [$I > 2\sigma(I)$]	7727
Minimum and maximum transmission	0.542 and 0.833
Structure solution	direct method
Goodness of fit on F^2	1.07
Largest and mean shift/su	0.00 and 0.00
Largest diff, peak and hole (eÅ^3)	1.24 and −0.88
Final R indices [$F^2 > 2\sigma$]	R = 0.0373, wR_2 = 0.095
$(\Delta/\sigma)_{max}$	0.001

$w = 1/[\sigma 2(F_o)^2 + (0.0462P)^2 + 0.0079\ P]$ where $P = (F_o^2+2F_c^2)/3$.

Table 12
Selected bond lengths(Å) and angles (°) for the complex [Ni(cd5Clsalen)].

Ni1–O1	1.867(8)	N1–C8	1.463(15)
Ni1–N1	1.872(10)	N2–C9	1.478(15)
Ni1–N2	1.875(9)	N2–C10	1.314(14)
Ni1–S1	2.166(3)	C1–C6	1.420(15)
S1–C15	1.714(11)	C1–O1	1.307(14)
S2–C15	1.760(11)	C6–C7	1.436(16)
S2–C16	1.795(13)	C10–C14	1.425(15)
N1–C7	1.286(15)	C14–C15	1.371(16)
O1–Ni1–N1	93.53(4)	N1–Ni1–N2	86.43(4)
O1–Ni1–N2	176.64(4)	N1–Ni1–S1	173.68(3)
O1–Ni1–S1	82.28(3)	N2–Ni1–S1	98.04(3)

The observed bands in the region 460–476 nm are probably due to S–M and O–M, LMCT transitions, and occur at energies similar to those found for the corresponding symmetric metal complexes [M(salen)] [43] and [M(cd$_2$en)] [32]. The d–d bands are not ob-

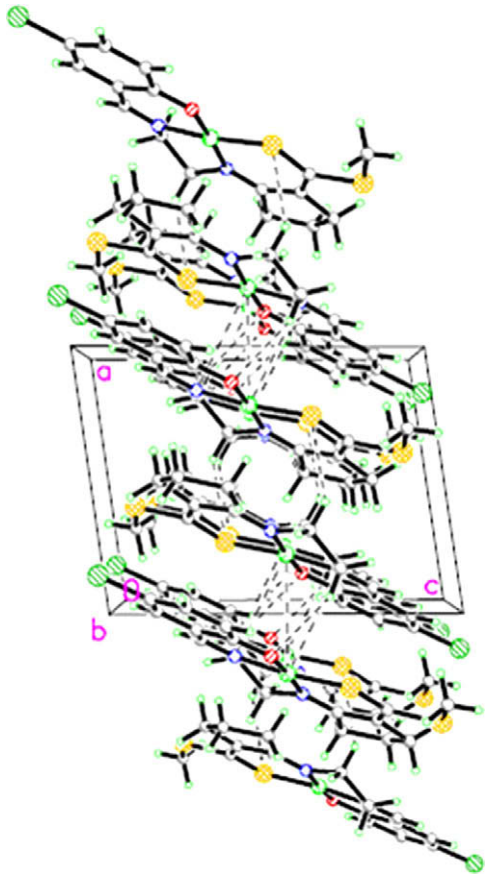

Fig. 4. The crystal packing in [Ni(cd5Clsalen)], showing the one-dimensional infinite chain along the *a*-axis. Intermolecular interactions are shown as dashed lines.

Table 13
Selected bond lengths (Å) and bond angles (°) for [Ni(cdsalen)], [Ni(cdClsalen)], [Ni(cd_2en)] and [Ni(salen)].

Complex	[Ni(cdClsalen)]	[Ni(cdsalen)]	[Ni(cd_2en)]	[Ni(salen)]
Ni1–N1	1.872(10)	1.872(5)	1.893(6)	1.853(2)
Ni1–N2	1.875(9)	1.867(5)	1.902(11)	1.843(2)
Ni1–O1	1.867(8)	1.860(4)	–	1.850(2)
Ni1–O2	–	–	–	1.855(2)
Ni1–S1	2.166(3)	2.163(3)	2.174(4)	–
Ni1–S2	–	–	2.170(2)	–

served due to the low concentration ($\sim 10^{-4}$ M) of the complexes in solution. These bands should be low in intensity in the region of 600–700 nm.

Analysis of the results shows that the positions of the *d*–*d* and LMCT bands are not very sensitive to the different substituents (R_1, R_2, *X*, *Y*, *Z*) of the ligand, and may not be directly related to the electron donor/acceptor ability of the substituent. This behavior has been observed for square planar Ni(II) complexes and was explained by the electronic and structural effects induced by the substituents which may have opposite effects [44].

Fig. 2 shows the electronic spectral change observed in DMF solution when the Ni^{2+} ion was added to the Schiff base ligand [H_2cd5Clsalen]. In the absence of the Ni^{2+} ion, the yellow [H_2cd5Clsalen] solution showed absorption bands at 314 and 396 nm. As the Ni^{2+} ion solution was added, the signals of [H_2cd5Clsalen] decreased and those of the complex [Ni(cd5Clsalen)], at 324, 428 and 466 (sh) nm increased in intensity with isosbestic points at 304, 319, 363, 418 and 512 nm. The last spectrum

of the titration was similar to the spectrum of the [Ni(cd5Clsalen)] complex that has been synthesized by published methods [24–27] and characterized separately.

3.3. Mass spectra

The mass spectra of all the ligands show intense molecular ion peaks *m*/*z* $[M]^+$. The mass spectra of some compounds also show a prominent peak corresponding to *m*/*z* $[M+1]^+$ (see Tables 9 and 10).

3.4. Crystal structure of [Ni(cd5Clsalen)]

The molecular structure of the complex [Ni(cd5Clsalen)] is shown in Fig. 3, in conjunction with the numbering scheme used. Crystal data and details of structure refinement are summarized in Table 11. Relevant bond lengths, bond angles, deviations from best coordination plane are given in Table 12. Full lists of bond lengths, bond angles and anisotropic displacements are available as supplementary material (Fig. 4).

The complex has a N_2OS coordination sphere, with the two nitrogens coordinated in a *cis* configuration. The coordination around nickel is essentially square-planar with a small tetrahedral distortion (dihedral angle of 5.43(3)° between coordination planes NNiO and SNiN). The molecular structures of [Ni(salen)] [43], [Ni(cd_2en)] [32] and [Ni(cdsalen)] [26] have been determined previously and may be compared with the structure of [Ni(cd5Clsalen)]. All bond lengths and bond angles are similar to those reported for the [Ni(salen)] and [Ni(cd_2en)] complexes, and there are only minor differences in the metal-ligand bond lengths. The Ni—N and Ni—O bond lengths of the [Ni(cdClsalen)] complex are 0.019–0.029 Å and 0.012–0.017 Å larger than in [Ni(salen)], while the Ni—N and Ni—S bond lengths are 0.021–0.030 Å and 0.004–0.011 Å shorter than in [Ni(cd_2en)] (see Table 13). These differences indicate that the NO fragment behaves as a weaker ligand, the NS fragment seems to be more tightly bound to the metal ion than in the corresponding symmetric complexes, and may be related to the different steric requirements of the O and S donors.

In addition, bond lengths and bond angles within the ligand are indicative of a strong delocalization of π-electron density in both

the NO and NS six-membered chelate rings, suggesting that the dithioester fragment behaves essentially as a Schiff base ligand, coordinating via an imine nitrogen and a thiolate sulfur.

The molecular structure of [Ni(cdsalen)] [26] has been determined and may be compared with the structure of [Ni(cdClsalen)]. Some selected structural parameters for the complexes are collected in Table 13. The most striking difference lies in the extent of tetrahedral distortion, which is more pronounced in the present complex than in the other one, which has an almost planar structure. The bond lengths are almost independent of the different NO fragments, although the Ni—S bond length is slightly shorter in [Ni(cdsalen)].

3.5. The formation constants and the thermodynamic free energy calculations for unsymmetrical Schiff bases with Ni^{+2} ion in DMF solvent

The formation constants have been determined by UV–Vis absorption spectroscopy through titration of the ligands with various concentrations of the metal ion at 25 °C. The complex formation constants, K_f, were calculated using the SQUAD computer program [45], designed to calculate the best values for the formation constants of the proposed equation model (Eq. (1)) by employing a non-linear, least-squares approach.

$$M(OAc)_2 \cdot nH_2O + H_2L^X \rightarrow ML^X + 2HOAc + (n-2)H_2O \quad (X = 1-18) \tag{1}$$

Also, the free energy change, $\Delta G°$, of the complexes were determined by $\Delta G° = -RT \ln K_f$, at 25 °C where K_f is the complex formation constant, R is the gas constant and T is the temperature in Kelvin. The formation constants and the free energy data are collected in Table 14.

The formation constants in DMF for the series H_2cdXsalMeen are larger than of the H_2cdXsalen series. It was observed that the addition of a methyl group to Schiff base ligands increases the formation constant of the complexes.

3.5.1. The electronic effect of para substituted Schiff base ligands

In this part of the work, we have studied the electronic effect of the *para* substitutional groups bonded to the Schiff base ligands complexed to the Ni(II) ion. The formation constants and the thermodynamic free energies are collected in Tables 15 and 16. On the bases of the thermodynamic results, the formation of the complexes follows the sequence below:

Ni(cd5OMsalen) > Ni(cdsalen) > Ni(cd5Brsalen) > Ni(cd5Clsalen) > Ni(cd5SO_3Nasalen) > Ni(cd5NO_2salen).
and
Ni(cd5OMsalMeen) > Ni(cdsalMeen) > Ni(cd5BrsalMeen) > Ni(cd5ClsalMeen) > Ni(cd5SO_3NasalMeen) > Ni(cd5NO_2salMeen).

This trend is in contrast to our previous work where the charge donation from M(II) (M = Ni, Cu) ion into Schiff base π^* molecular orbital is increased by electron withdrawing groups on the Schiff base ligands [22]. In the *para* substituted Schiff base ligands, the formation constants vary as can be expected according to the electronic effects of the substituents at position 5. Thus, the formation constants decrease according to the sequence OMe > H > Br > Cl > SO_3 > NO_2, i.e. in order of the increase in both electron-withdrawing and π-acceptor qualities of the substituents and the donor ability of the ligand groups (mainly the phenoxy groups). Similar results have been reported previously for the electrochemical properties of the analogous Cu(II), Ni(II) and Co(III) systems [46–48]. The withdrawing functional groups make the Schiff base a poorer donor ligand and decrease the formation constants, while the electron donor groups increase the formation constants because they lead to an increase of the donor ability of Schiff base ligands. Therefore ligands having NO_2 and SO_3 groups, i.e. (H_2cd5NO_2salen), (H_2cd5NO_2salMeen), (H_2cd5SO_3Nasalen) and (H_2cd5SO_3NasalMeen), have the smallest formation constants, while ligands with an OMe group have the highest formation constants because OMe is a donating group [22]. Therefore, in the stabilization of the tetra-coordinated complexes, the donation power of the Schiff base is important, and hence the formation constants, K_f, of Schiff bases with donor groups are higher.

3.5.2. The effect of the position of the methoxy substituents of the Schiff base

In continuation of our studies on the formation constants of the complexes, we have studied the effect of the position of substituents on the phenyl ring of the Schiff base on the formation constant of the complexes, using H_2cd3OMesalen, [26] H_2cd4OMesalen and H_2cd5OMesalen (H_2L^2 and H_2L^3), H_2cd3OMesalMeen, H_2cd4OMesalMeen and H_2cd5OMesalMeen (H_2L^{11}, H_2L^{12} and H_2L^{13}) with the Ni(II) ion. The results show the following trend of complex formation for a given cation towards the Schiff bases:

Ni(cd5OMesalen) > Ni(cd3OMesalen) > Ni(cd4OMesalen)
and
Ni(cd5OMesalMeen) > Ni(cd3OMesalMeen) > Ni(cd4OMesalMeen)

Table 17

H_2cd3OMesalen [26]	4.78(0.13)	−27.26(0.32)
H_2cd4OMesalen	4.75(0.18)	−27.09(0.44)

The numbers in parentheses are the standard deviations.

Table 18
The formation constants, log K_f, and the free energy, $\Delta G°$, data for [(Ni(cd3-, 4-, 5-OMesalMeen)] complexes at 25 °C, in DMF.

Ligand	Ni^{2+}	
	log K_f	$\Delta G°$ (kJmol^{-1})
H_2cd5OMesalMeen	4.89(0.08)	−27.88(0.19)
H_2cd3OMesaMeen	4.83(0.17)	−27.54(0.42)
H_2cd4OMesaMeen	4.80(0.15)	−24.37(0.37)

The numbers in parentheses are the standard deviations.

Table 19
The formation constants, logK_f, and the free energy, $\Delta G°$, data for [(Ni(cdMesalen)], [(Ni(cdsalen)] and [(Ni(cdPhsalen)] complexes at 25 °C, in DMF.

Ligand	Ni^{2+}	
	logK_f	$\Delta G°$ (kJmol^{-1})
H_2cdMesalen [26]	4.85(0.12)	−27.66(0.29)
H_2cdsalen [26]	4.21(0.08)	−24.01(0.19)
H_2cdPhsalen	3.63(0.04)	−20.70(0.09)

The numbers in parentheses are the standard deviations.

Table 20
The formation constants, logK_f, and the free energy, $\Delta G°$, data for [(Ni(cdMesalMeen)], [(Ni(cdsalMeen)] and [(Ni(cdPhsalMeen)]complexes at 25 °C, in DMF.

Ligand	Ni^{2+}	
	logK_f	$\Delta G°$ (kJmol^{-1})
H_2cdMesalMeen	4.87(0.14)	−27.77(0.34)
H_2cdsalMeen [27]	4.23(0.22)	−24.12(0.54)
H_2cdPhsalMeen	3.63(0.13)	−20.70(0.32)

The numbers in parentheses are the standard deviations.

In the case of H_2cd5OMesalen and H_2cd5OMesalMeen, the methoxy group situated in the *para* position to the phenolic oxygen of the NNOS backbone can release electron directly to the phenyl and is better than that of the *meta* position in H_2cd4OMesalen and H_2cd4OMesalMeen [46], and H_2cd3OMesalen, H_2cd3OMesalMeen, which show steric effects (see Tables 17 and 18).

3.5.3. The electronic effect of the equatorial Schiff base ligands

The substitutional effects on the imine bond were studied by determining the formation constants for [Ni(cdMesalen)][26] and [Ni(cdPhsalen)], and [Ni(cdMesalMeen)] and [Ni(cdPhsalMeen)]. The results show the following trend in complex formation between the ligand Schiff bases H_2(cdMesalen), (H_2L^1), (H_2L^9) and (H_2L^{10}) with the Ni(II) ion (see Tables 19 and 20):

Ni(cdMesalen) > Ni(cdsalen) > Ni(cdPhsalen)
and
Ni(cdMesalMeen) > Ni(cdsalMeen) > Ni(cdPhsalMeen)

The values for electron releasing methyl Schiff bases were more than those for electron withdrawing phenyl Schiff bases. The phenyl group makes the Schiff base a poor donor ligand (and a good acceptor ligand), and decreases the formation constant, while the methyl group is a donating group and increases the formation constant [49].

4. Conclusions

By considering the formation constants and free energy data of formation for the unsymmetrical Schiff base ligands as a donor and Ni^{2+} ion as an acceptor, the following conclusions have been drawn:

1. The formation constants for the nickel(II) Schiff base complexes follow the sequence: cdXsalMeen > cdXsalen
2. The complex formation of the *para* substitutional groups bonded to the Schiff base ligands complexed to the Ni(II) ion decrease as follows:cd5OMsalen > cdsalen > cd5Brsalen > cd5Clsalen > cd5SO_3Nasalen > cd5NO_2salen and cd5OMsalMeen > cdsalMeen > cd5BrsalMeen > cd5ClsalMeen > cd5SO_3NasalMeen > cd5NO_2salMeen
3. The formation constants for [Ni(cd3-, 4-, 5-OMsalen)] and [Ni(cd3-, 4-, 5-OMsalMeen)] complexes have the following trend:cd5OMesalen > cd3OMesalen > cd4OMesalen and cd5OMesalM een > cd3OMesalMeen > cd4OMesalMeen
4. The complex formation with substitution on the imine bond of the Schiff base ligands complexed to the Ni(II) ion decreases as follows:cdMesalen > cdsalen > cdPhsalen and cdMesalMeen > cdsalMeen > cdPhsalMeen
5. In the series [H_2cdXsalen] and [H_2cdXsalMeen], it seems that the combination of strain, strength of the ligand field, the electronic effect, the geometry of the ligand, the electron configuration and the ionic radii of the metal can affect the complex formation constants.

Supplementary data

CCDC 693382 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

C, H and N contents were determined using a GmbH VariuoEL V3.00 automatic elemental analyzer. Elemental analysis for Cu was detected by an IRIS ER/S · WP-1 ICP atomic emission spectrometer. IR spectra were recorded on a VERTEX70 FT-IR spectrophotometer, with samples prepared as KBr (500–4000 cm^{-1}) and CsI (100–500 cm^{-1}) pellets. UV–Vis absorption spectra in the 200–800 nm range were recorded on a Hitachi UV-3010 spectrophotometer in DMF solution. TG-DTA analyses were carried out on a ZRY-1P thermoanalyzer at a heating rate of 3 °C/min. ^1H NMR spectra were recorded on a Mercury-400BB spectrometer at room temperature using DMSO–d_6 as the solvent. X-ray single crystal structures were determined on a Bruker Smart 1000 APEX CCD area detector. Melting points were measured by the use of a microscopic melting point apparatus made by the Beijing Taike Instrument Limited Company, and the thermometer was uncorrected. Molar conductance value measurements were carried out on a model DDS-11D type conductivity bridge using a 1.0×10^{-3} mol dm^{-3} solution in DMF at 25 °C.

2.2. Synthesis and characterization of 6,6′-dihydroxy-2,2′-[ethylenediyldioxybis(nitrilomethylidyne)]diphenol (H_4L)

The major reaction steps involved in the synthesis of 6,6′-dihydroxy-2,2′-[ethylenediyldioxybis(nitrilomethylidyne)]diphenol (H_4L) are given in Scheme 1.

1,2-Bis(phthalimidoxy)ethane was prepared according to the literature [10]. Yield: 95.6%. m.p. 250 °C.

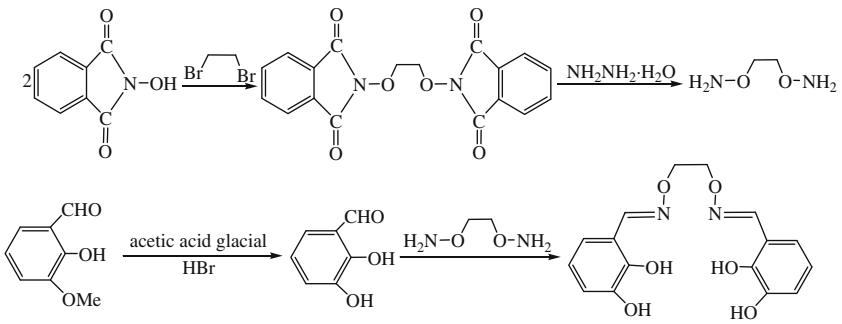
1,2-Bis(aminooxy)ethane was synthesized according to an analogous method reported earlier [10]. ^1H NMR (400 MHz, $CDCl_3$, δ, ppm): 3.79 (s, 4H), 5.52 (s, 4H).

2,3-Dihydroxybenzaldehyde was synthesized according to an analogous method reported earlier [11]. The Salen-type bisoxime ligand H_4L was synthesized according to an analogous method reported earlier in the literature [11,12]. The reaction of 1,2-bis(aminooxy)ethane (0.0924 g, 1.00 mmol) with two equivalents of 2,3-dihydroxybenzaldehyde (0.277 g, 2.00 mmol) in ethanol (7 ml) afforded the desired ligand as a colorless microcrystalline powder. Yield: 0.130 g (39.1%). m.p. 114–116 °C. ^1H NMR (400 MHz, $CDCl_3$, δ, ppm): 2.34 (s, 6H), 4.50 (t, J = 3.4 Hz, 4H), 6.89 (dd, J = 5.8 Hz, 2H), 6.95 (dd, J = 1.2 Hz, 2H), 7.25 (dd, J = 1.6 Hz, 2H), 7.41 (dd, J = 1.4 Hz, 2H), 11.10 (s, 2H). UV–Vis (DMF): λ_{max} (ε_{max}) 274 and 322 nm (2985.38 and 6.52 M^{-1} cm^{-1}). IR (KBr, cm^{-1}) 3410(s), 3175(b), 2949(w), 2880(w), 1610(s), 1580(m), 1475(s), 1265(s). *Anal.* Calc. for $C_{18}H_{20}N_2O_4$: C, 65.84; H, 6.14; N, 8.53. Found: C, 65.76; H, 6.24; N, 8.46%.

2.3. Synthesis of complexes **1**, **2**, **3** and **4**

The four solvent-induced Cu(II) complexes **1**, **2**, **3** and **4** are obtained by the reaction of the Salen-type bisoxime ligand H_4L with $Cu(OAc)_2 \cdot H_2O$ in a 1:1 (or 2:3 for complex **3**, because single crystals were not obtained from the reaction in a molar ratio of 1:1) molar ratio in absolute methanol, ethanol, n-propanol and n-butanol solvents, respectively. Single crystals of complexes **1**, **2**, **3** and **4** suitable for X-ray diffraction analysis were grown using the gaseous diffusion method.

2.3.1. [{Cu(HL)(CH_3OH)}$_2$Cu] · CH_3OH (**1**)



A pale-blue methanol solution (3 ml) of $Cu(OAc)_2 \cdot H_2O$ (0.0037 g, 0.019 mmol) was added dropwise to a colorless methanol solution (3 ml) of H_4L (0.0063 g, 0.019 mmol) at room temperature. The color of the mixed solution turned to dark-brown immediately. The solution obtained was placed in an n-hexane atmosphere and stored at room temperature for two weeks. With the diffusion of n-hexane into the mixed solution of the complex, dark-brown block-shaped single crystals suitable for X-ray crystallographic analysis were obtained. Yield: 0.0063 g (35.1%). UV–Vis (DMF): λ_{max} (ε_{max}) 294 and 379 nm (816.58 and 6.01 M^{-1} cm^{-1}). IR (KBr, cm^{-1}) 3576(w), 3384(b), 2945(w), 2876(w), 1616(s), 1591(s), 1549 (s), 1452(s), 1260(b), 534(w), 465(w), 401(w). *Anal.* Calc. for [{Cu(HL)(CH_3OH)}$_2$Cu] · CH_3OH ($C_{35}H_{38}Cu_3N_4O_{15}$): C, 44.47; H, 4.05; N, 5.93; Cu, 20.17. Found: C, 44.56; H, 4.21; N, 5.72; Cu, 20.21%.

2.3.2. [{(Cu(HL))$_2$(CH_3CH_2OH)$_2$}Cu] (**2**)

The single crystals of complex **2** were grown by a similar procedure to that aforementioned, taking $Cu(OAc)_2 \cdot H_2O$ (0.0050 g, 0.025 mmol) and H_4L (0.0078 g, 0.024 mmol) in 5 ml absolute ethanol solution. The obtained dark-brown mixture was placed in an n-hexane atmosphere and stored at room temperature for one month. With the diffusion of n-hexane into the mixed solution of the complex, dark-brown block-shaped single crystals suitable for X-ray crystallographic analysis were obtained. Yield: 0.0077 g (32.5%). UV–Vis (DMF): λ_{max} (ε_{max}) 294 and 379 nm (199.07 and 4.13 M^{-1} cm^{-1}). IR (KBr, cm^{-1}) 3420(b), 2945(w), 2879(w), 1612(s), 1591(s), 1551(s), 1452(s), 1263(s), 536(w), 463(w), 401(w). *Anal.* Calc. for [{(Cu(HL))$_2$(CH_3CH_2OH)$_2$}Cu] ($C_{36}H_{38}Cu_3N_4O_{14}$): C, 45.93; H, 4.07; N, 5.95; Cu, 20.25. Found: C, 45.80; H, 4.17; N, 5.81; Cu, 20.17%.

2.3.3. [{CuL(H_2O)}$_2$$Cu_2$] · 2$CH_3CH_2CH_2OH$ (**3**)

The single crystals of complex **3** were grown by a similar procedure to that aforementioned, taking $Cu(OAc)_2 \cdot H_2O$ (0.0052 g, 0.026 mmol) and H_4L (0.0058 g, 0.017 mmol) in 6 ml n-propanol solution. The obtained dark-brown mixture was placed in an n-hexane atmosphere and stored at room temperature for two months. With the diffusion of n-hexane into the mixed solution of the complex, dark-brown block-shaped single crystals suitable for X-ray crystallographic analysis were obtained. Yield: 0.0083 g (29.8%). UV–Vis (DMF): λ_{max} (ε_{max}) 294 and 379 nm (2187.76 and

Scheme 1. Major reaction steps involved in the synthesis of 6,6′-dihydroxy-2,2′-[ethylenediyldioxybis(nitrilomethylidyne)]diphenol (H_4L^1).

8.28 M^{-1} cm^{-1}). IR (KBr, cm^{-1}) 3427(b), 2958(w), 2872(w), 1614(s), 1593(s), 1551(s), 1452(s), 1261(s), 557(w), 536(w), 463(w), 405(w). *Anal.* Calc. for $[\{CuL(H_2O)\}_2Cu_2]\cdot 2CH_3CH_2CH_2OH$ ($C_{38}H_{44}Cu_4N_4O_{16}$): C, 48.37; H, 4.46; N, 5.63; Cu, 19.15. Found: C, 48.26; H, 4.48; N, 5.52; Cu, 19.28%.

2.3.4. [{(Cu(HL))$_2$(CH$_3$CH$_2$CH$_2$CH$_2$OH)$_2$}Cu] (**4**)

The single crystals of complex **4** were grown by a similar procedure to that aforementioned, taking $Cu(OAc)_2\cdot H_2O$ (0.0038 g, 0.019 mmol) and H_4L (0.0063 g, 0.019 mmol) in 6 ml n-butanol solution. The obtained dark-brown mixture was placed in an n-hexane atmosphere and stored at room temperature for three months. With the diffusion of n-hexane into the mixed solution of the complex, dark-brown block-shaped single crystals suitable for X-ray crystallographic analysis were obtained. Yield: 0.0056 g (28.9%). UV–Vis (DMF): λ_{max} (ε_{max}) 294 and 379 nm (413.85 and 5.33 M^{-1} cm^{-1}). IR (KBr, cm^{-1}) 3437(b), 2957(w), 2866(w), 1614(s), 1591(s), 1551(s), 1452(s), 1261(s), 536(w), 453(w), 417(w). *Anal.* Calc. for $[\{(Cu(HL))_2(CH_3CH_2CH_2CH_2OH)_2\}Cu]$ ($C_{40}H_{44}Cu_3N_4O_{14}$): C, 42.78; H, 4.16; N, 5.25; Cu, 23.82. Found: C, 42.92; H, 4.24; N, 5.09; Cu, 23.68%.

2.4. Crystal structure determination

Single crystal X-ray diffraction data were collected on a Bruker AXS single crystal X-ray diffractometer using a Bruker Smart 1000 CCD area detector. The X-ray generator was operated at 50 kV and 35 mA using Mo Ka radiation (λ = 0.71073 Å). The raw intensities were corrected for Lorentz and polarization effects, and a numerical absorption correction was applied for all complexes. The data were reduced by SAINT-PLUS [13] and an empirical absorption correction was applied using the package SADABS [13]. All the structures were solved by direct methods using SHELXS and refinement was done against F^2 using SHELXL [14]. Molecular and packing diagrams were generated by ORTEP-32 [15] and CAMERON [16] present in the WINGX (Version 1.64.03b) [17] program suite. The geometric calculations were done by PARST-95 [18] and PLATON [19]. All non-hydrogen atoms were refined using anisotropic displacement parameters. The hydrogen atoms were located in the difference map, but in most cases were positioned with an idealized geometry and refined isotropically using a riding model. The technical details of data acquisition and some selected refinement results for complexes **1**, **2**, **3** and **4** are summarized in Table 1.

3. Results and discussion

3.1. Molar conductances

The complexes **1**, **2**, **3** and **4** are soluble in DMF, DMSO, chloroform and dichloromethane, but not soluble in ethanol, methanol, acetonitrile, acetone, THF, ethyl acetate and n-hexane. Molar conductance values of complexes **1**, **2**, **3** and **4** at 25 °C of 10^{-3} mol dm^{-3} DMF solutions are 12.7, 13.5, 19.2 and 18.0 Ω^{-1} cm^2 mol^{-1}, respectively, indicating that these complexes are non-electrolytes.

3.2. Spectral investigation

3.2.1. IR spectra analyses

The IR spectra of H_4L and its corresponding Cu(II) complexes show a characteristic C=N stretching band. For the free ligand H_4L this band appears at 1610 cm^{-1}, while the C=N bands of the Cu(II) complexes **1**, **2**, **3** and **4** are observed at 1616, 1612, 1614 and 1614 cm^{-1}, respectively. The shifts toward higher wavenumbers of the C=N absorption of about 2–6 cm^{-1} on going from the

free ligand H_4L to the complexes suggest a weak π-accepting ability of the coordinated ligand.

The Ar–O stretching frequencies appear as a strong band within the 1263–1213 cm^{-1} range, as reported for similar Salen-type ligands. These bands occur at 1265 cm^{-1} for H_4L, 1260 cm^{-1} for complex **1**, 1263 cm^{-1} for complex **2** and 1261 cm^{-1} for complexes **3** and **4**. The Ar–O stretching frequency is shifted to a lower value, indicating that Cu–O bonds are formed between the Cu(II) ions and the oxygen atoms of the phenolic groups [20].

The O–H stretching frequency of the free ligand H_4L appears at 3410 cm^{-1}. The bending vibration of the phenolic alcohols in H_4L appears at 1238 cm^{-1}, and this is observed at 1238–1242 cm^{-1} in complexes **1**, **2** and **4**, but disappears in complex **3**. This phenomenon indicates the oxygen atoms in the phenolic alcohols of complex **3** have been completely deprotoned and coordinated to Cu(II) ions, while the ligand is partially deprotoned in complexes **1**, **2** and **4**. In addition, the broad absorption centered on 3384, 3420, 3427 and 3437 cm^{-1} in complexes **1**, **2**, **3** and **4**, respectively, which may be assigned to the O–H stretching vibration of the solvent or water molecules.

The far-infrared spectra of complexes **1**, **2**, **3** and **4** were also obtained in the region 500–100 cm^{-1} in order to identify frequencies due to Cu–O and Cu–N bonds. The IR spectra of complexes **1**, **2**, **3** and **4** show ν(Cu–N) (or ν(Cu–O)) vibrational absorption frequencies at 465, 463, 463 and 453 (or 401, 401, 405 and 417) cm^{-1}, respectively, which are consistent with the literature frequency values [21]. These bands are observed as new peaks for complexes **1**, **2**, **3** and **4**, and are not present in the spectrum of the free ligand H_4L. As pointed out by Percy and Thornton [22], the metal–oxygen and metal–nitrogen frequency assignments are at times very difficult.

3.2.2. UV–Vis spectra analyses

The absorption spectra of H_4L and its corresponding Cu(II) complexes **1**, **2**, **3** and **4** in diluted DMF solution show that the spectra of the complexes **1**, **2**, **3** and **4** are similar to each other, but are different from the spectrum of the ligand (H_4L). The UV–Vis spectrum of the free ligand H_4L exhibits two absorption peaks at *ca.* 274 and 322 nm. The former absorption peak at 274 nm can be assigned to the π–π^* transition of the benzene rings and the latter one at 322 nm can be attributed to the intra-ligand π–π^* transition of the C=N bonds [23].

Compared with the absorption peak of the ligand, a corresponding absorption peak at 294 nm is observed in complexes **1**, **2**, **3** and **4**, which is bathochromically shifted by *ca.* 20 nm, indicating the coordination of Cu(II) ions with the ligand. Meanwhile, a new absorption peak is observed at 379 nm in complexes **1**, **2**, **3** and **4**, which is assigned to the n–π^* charge transfer transition from the filled pπ orbital of the bridging phenolic oxygen to the vacant d-orbital of the Cu(II) ions [24]. It is noteworthy that the same UV–Vis absorption spectra of complexes **1**, **2**, **3** and **4** clearly indicate that the structures of the four complexes are similar to each other.

3.3. Thermal properties

Thermal stability studies were performed for complexes **1**, **2**, **3** and **4**. The TG curve of complex **1** can be divided into three stages. The first stage is at 41–64 °C. The TG curve shows that the weight loss corresponding to this temperature range is 3.8%, which roughly coincides with the value of 3.4% calculated for the loss of one crystallizing methanol molecule from the outer coordination sphere of complex **1**. The second stage starts from 87 to 98 °C with a weight loss of 7.5%, which corresponds to the loss of two methanol molecules (theoretical mass loss, 6.8%) which takes part in coordination to the Cu(II) ions. The solid remains stable up to 216 °C and the third weight loss starts at around 223 °C, with decomposition of the compound. The TG curve shows around 77% total mass loss at 800 °C, indicating the complete removal of the $(HL)^{3-}$ units. The main residual product was CuO, with a value of 23% (theoretical residual value was 25.2%). TG curves of complexes **2** and **4** are similar to those of the second and third stages of complex **1**.

The thermal decomposition process of complex **3** appears in three stages. The initial weight loss occurs in the range 75–96 °C. The TG curve shows that the weight loss corresponding to this temperature range is 10.5%, consistent with the 11.3% calculated for the loss of two crystallizing n-propanol molecules. The second stage is from 114 to 126 °C, with a weight loss of 4.5%, which corresponds to the loss of two water molecules (theoretical mass loss, 3.4%) coordinated to Cu. The solid remains stable up to 217 °C and the third weight loss starts at around 224 °C, with further decomposition of the compound. Subsequently, a continuous mass loss was observed up to 800 °C. At this temperature, CuO is formed. The total mass loss found (73%) was approximately consistent with that calculated (70.2%).

3.4. Description of the crystal structures

Selected bond lengths and bond angles are presented in Table 2. A list of hydrogen bonds in complexes **1**, **2**, **3** and **4** is given in Table 3.

3.4.1. Structure of complex *1*

The X-ray crystal structure analysis of complex **1** shows the molecule consists of three Cu(II) ions, two partially deprotonated $(HL)^{3-}$ units, two coordinated and one crystallizing methanol molecules (Fig. 1). The terminal Cu(II) (Cu1) ion is five-coordinated by two oxime nitrogen (N1 and N2) and two phenolic oxygen (O3 and O5) atoms of the pentadentate Salen-type $(HL)^{3-}$ trianion in the basal plane, and by one oxygen (O7) atom from one coordinated methanol molecule in the apical position. The coordination geometry around the terminal Cu(II) (Cu1) ion is found to be slightly distorted square pyramidal. The two phenolic oxygen atoms and two oxime nitrogen atoms are in mutually *cis* positions. The primary distances of Cu–N and Cu–O are in the normal ranges (Cu1–N1 = 2.019(4), Cu1–N2 = 1.961(4), Cu1–O3 = 1.969(3) and Cu1–O5 = 1.885(3) Å) (Table 2) though, with the exception of Cu1-O5, all these lengths are slightly larger than the corresponding bond lengths found in the complexes Cu(salen), Cu(5-MeOsalen) and Cu(5-Clsalen), reported earlier [25]. The bond length (Cu1-O7) between the Cu(II) ion and the apical oxygen (O7) atom is 2.485(4) Å, which is obviously longer than the distances between the Cu(II) ion and the basal oxygen and nitrogen atoms. This significant elongation has been observed in the Cu(II) complex with the Salen ligand (in the complex Cu(salen), Cu-N1 = 1.953(4), Cu-N2 = 1.952(4), Cu–O1 = 1.905(3), Cu–O2 = 1.946(3) Å, with the apical bond Cu–O(2a) = 2.423(3) Å) [26].

The "Sal1" and "Sal2" planes are bent asymmetrically, making angles of 15.09(2)° and 49.37(1)°, respectively, with respect to the N_2O_2 plane. In addition, the ethylenedioxime carbon atoms (C1 and C2) in complex **1** are buckled asymmetrically from the Cu1N1N2 plane, with the displacement for C1 being 1.789(3) Å towards the plane and for C2 only 1.272(3) Å in the same direction. It is anticipated that the two oxime nitrogen atoms and its carbon chain form a seven-membered chelate ring with the Cu(II) ion (Cu1) in complex **1**; the chelating bite angle (∠N1Cu1N2) in the seven-membered ring is 95.34(2)°. The coordination sphere of the other terminal Cu(II) centre ($Cu1^{\#1}$) is the same as that of the Cu1 ion.

The central Cu(II) ion (Cu2) is tetra-coordinated by four phenoxo oxygen atoms from two $[Cu(HL)(CH_3OH)]^-$ anions, discussed above, and adopts a square planar geometry distorted tetrahedrally

Symmetry transformations used to generate equivalent atoms: $^{\#1}$: $-x+1, y, -z+3/2$, $^{\#2}$: $-x, y, -z+1/2$, $^{\#3}$: $-x+1, y, -z+1/2$ and $^{\#4}$: $-x+2, y, -z+1/2$ for complexes **1**, **2**, **3** and **4**, respectively.

by 19.58(3)° (defined by the angle between two sites of the coordination planes O3–Cu2–O4 and O3$^{\#1}$–Cu2–O4$^{\#1}$), indicating the four phenoxo oxygen donors are not rigidly co-planar. A similar distortion was also observed for the complexes Cu(Salen) [26] and Cu(Saltn) [27], although the analogues Cu(Salamo) and Cu(3-MeOSalamo), with a shorter carbon chain, showed more distortion [28]. In addition, the four phenoxo oxygen donors are distributed symmetrically with the displacement for O3 (or O3$^{\#1}$) and O4 (or O4$^{\#1}$) being 0.196 Å, in opposite directions from the O3–O3$^{\#1}$–O4–O4$^{\#1}$ plane. The Cu–O bond lengths show a significant difference (Cu2–O3 = 1.899(3) and Cu2–O4 = 1.978(3) Å), which can be explained by the large steric repulsion force mainly resulted from the pentadentate $(HL)^{3-}$ units. The Cu2 ion has a displacement of 0.123(2) Å above the mean plane. The central Cu(II) (Cu2) ion sits on a crystallographic inversion center in the crystal, therefore the whole Cu(II) complex is rigorously centrosymmetric.

The Cu1···Cu2 (or Cu1$^{\#1}$···Cu2) distance is 3.540(3) Å, which is not particularly short, implying a weak metal–metal bonding interaction. The Cu1–O3–Cu2 bridging angle (or Cu1$^{\#1}$–O3$^{\#1}$–Cu2) is 127.5(2)°, indicating non-collinear Cu–O–Cu fragments, not suitable for significant electronic exchange [29].

In complex **1**, the two coordinated methanol molecules attached to the terminal Cu(II) ions (Cu1 and Cu1$^{\#1}$) lie in trans positions toward the terminal Cu(II) ions. There are eight strong intramolecular hydrogen bonds (Table 3) providing strong stabilizing forces, the bond lengths of the hydrogen bonds are 2.186 (O6–H6···O5), 2.241 (O6–H6···O4), 1.887 (O7–H7···O4) and 2.568 Å (O7–H7···O5). The hydrogen bonds are formed between the undeprotonated hydroxyl (O6–H6 or O6$^{\#1}$–H6$^{\#1}$) groups at the 3-position of the salicylidene moieties or the coordinated methanol molecules (O7–H7 or O7$^{\#1}$–H7$^{\#1}$) and the deprotonated oxygen atoms (O5 and O4 or O5$^{\#1}$ and O4$^{\#1}$) in the pentadentate $(HL)^{3-}$ units.

3.4.2. Structures of complexes *2* and *4*

X-ray crystal structure analyses of complexes **2** and **4** reveal that they have the same individual trinuclear neutral molecular unit [{(Cu(HL))$_2$(solvent)$_2$}Cu] (the solvents are ethanol and n-butanol in complexes **2** and **4**, respectively), as shown in Figs. 2 and 3, while the different solvents observed lead to the formation of the typical solvent-induced Cu(II) complexes [8].

The terminal Cu(II) ions lie in a penta-coordinated environment and adopt distorted square pyramidal geometries, where the inner N_2O_2 cavities of the pentadentate $(HL)^{3-}$ units comprise the basal planes, and one oxygen atom from the coordinated solvent molecules (ethanol or n-butanol) occupies the apical position. The primary Cu–O bond length (Cu1–O5 = 1.886(3) Å in complex **2** and Cu2–O5 = 1.875(3) Å in complex **4**) is close to the typical value of the Cu–O bonds found in the related Salen-type Cu(II) complexes Cu(Saltn), Cu(3-MeOSalamo) and Cu(PnSalen) [26,28], while the other Cu–O bond length (Cu1–O5 = 1.969(3) Å in complex **2** or Cu2–O3 = 1.961(3) Å in complex **4**) is not close to those found in the related complexes mentioned above. Although the primary

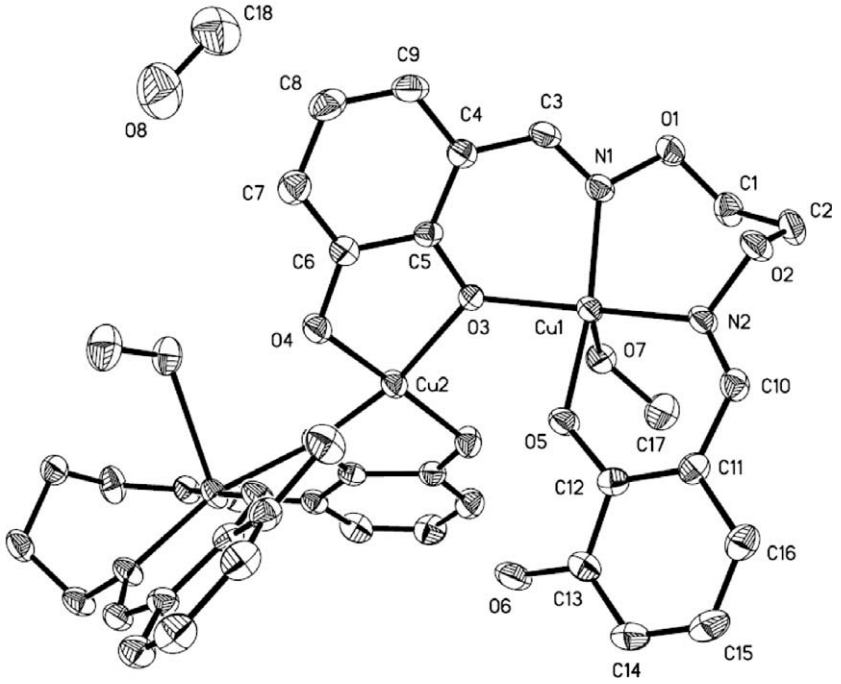

Fig. 1. Molecular structure of complex **1** with the atom numbering. The hydrogen atoms are omitted for clarity.

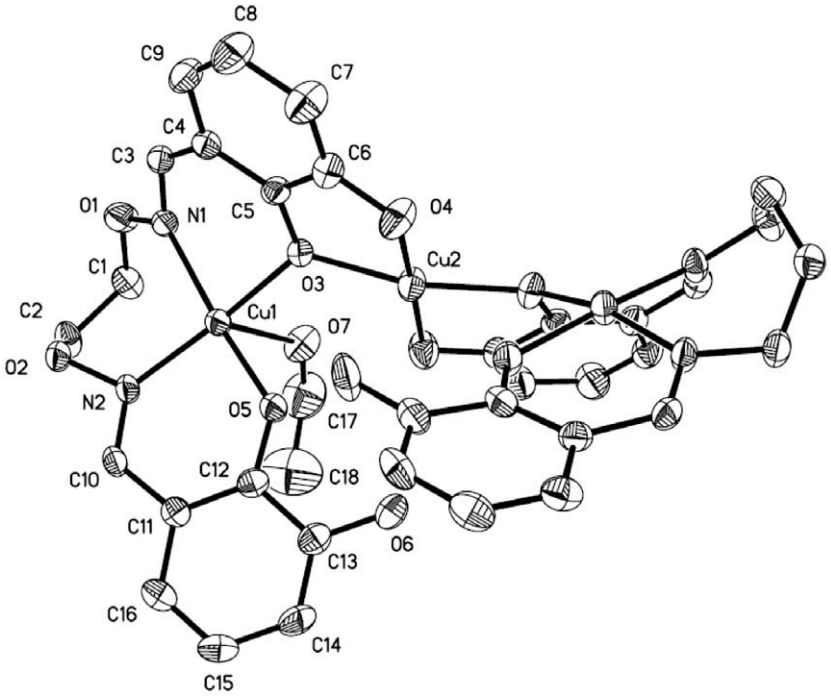

Fig. 2. Molecular structure of complex **2** with the atom numbering. The hydrogen atoms are omitted for clarity.

Cu–N bond length (Cu1–N1 = 2.021(4) Å in complex **2** and Cu2–N1 = 2.020(4) Å in complex **4**) is longer than those of the reported Cu(II) complexes, the other Cu–N bond length (Cu1–N2 = 1.958(4) Å in complex **2** or Cu2–N2 = 1.955(4) Å in complex **4**) approaches that observed in Cu(Salen) and $[Cu(Saltn)]_2$ [25,26]. The dihedral angle between the two coordinated planes of O3–Cu1–N1 and O5–Cu1–N2 (or O3–Cu2–N1 and O5–Cu2–N2) is 15.36° in complex **2** (or 14.01° in complex **4**). The four primary coordination atoms (two N and two O) give a mean plane with a slight tetrahedral distortion, with N2 and O3 below average by 0.0555 Å and with N1 and O5 above average by the same deviation as that mentioned above in complex **2** (or 0.0825 Å in complex **4**). The Cu(II) ion is situated above the mean plane with a deviation of 0.179(3) Å (or 0.148(3) Å in complex **4**).

The central Cu(II) ions are both tetra-coordinated, surrounded by four oxygen atoms from the two $[Cu(HL)(solvent)]^-$ anions,

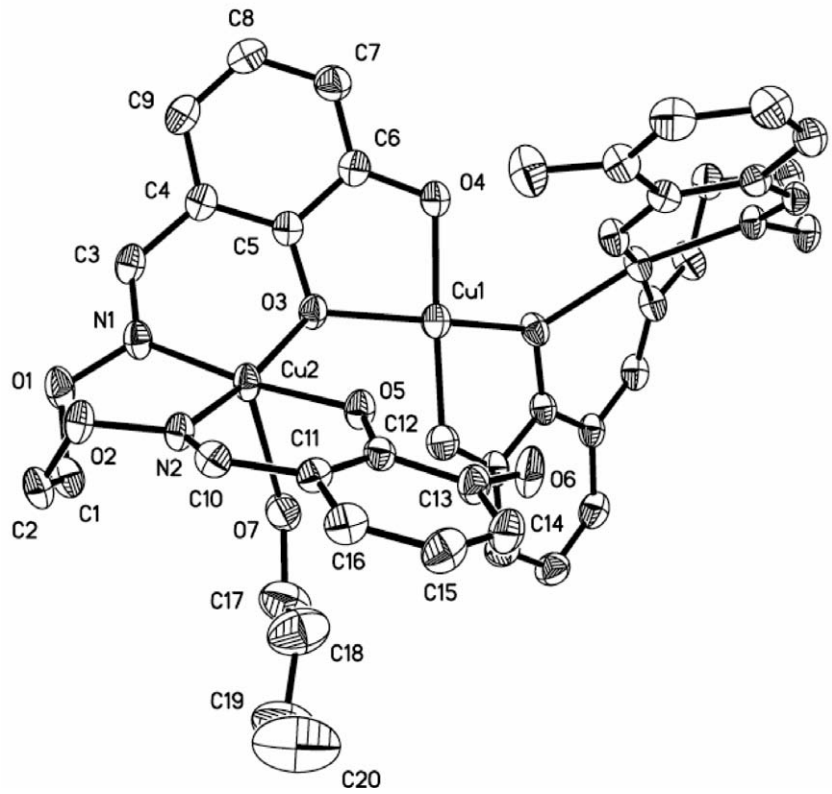

Fig. 3. Molecular structure of complex **4** with the atom numbering. The hydrogen atoms are omitted for clarity.

with the same coordination environment as that of the central Cu(II) ion in complex **1**. Two phenoxo oxygen donors (O3 and $O3^{\#2}$ or $O3^{\#3}$) bridge the terminal and central Cu(II) ions with a separation of 3.530(2) Å in complex **2** (or 3.525(5) Å in complex **4**), which is not sufficiently short to imply a strong metal–metal bonding interaction. The bridging angle of Cu1–O3–Cu2 is 126.7(2)° in complex **2** (Cu2–O3–Cu1 is 127.0(2)° in complex **4**), indicating non-collinear Cu–O–Cu fragments, not suitable for significant electronic exchange.

In complexes **2** and **4**, the two coordinated ethanol or n-butanol molecules attached to the terminal Cu(II) ions lie in trans positions toward the terminal Cu(II) ions, which are similar to what that observed in complex **1**. In these two complexes, there are six strong intramolecular hydrogen bonds (Table 3) providing strong stabilizing forces. Hydrogen bonds between the hydroxyl groups (O7–H7) and the oxygen atom (O5) are not formed in these two complexes, which is different from complex **1**.

*3.4.3. Structure of complex **3***

The crystal of this complex consists of four Cu(II) ions, two completely deprotonated L^{4-} ligand units, two coordinated water and two crystallizing n-propanol molecules. A perspective view of this is shown in Fig. 4, together with the atomic labelling of the coordinated polyhedrons. The two Cu(II) centres (Cu1 and Cu2) are linked by one phenoxo oxygen atom (O3) from one L^{4-} unit, forming an μ-phenoxo bridged Cu1–Cu2 motif. Another Cu(II) centre ($Cu2^{\#4}$) is again bonded with the Cu1–Cu2 motif via a similar bridging segment ($O3^{\#4}$) and generates the Cu2–Cu1–$Cu2^{\#4}$ core. The fourth Cu(II) centre (Cu3) is bonded to the terminal Cu(II) centres (Cu2 and $Cu2^{\#4}$) by two phenoxo oxygen atoms (O5 and $O5^{\#4}$), so there exists a Cu–O–Cu–O–Cu–O–Cu–O eight-membered ring.

The geometries of the terminal $\{CuO_2N_2O'\}$ coordination cores can be classified as trigonal bipyramidal, with an oxime nitrogen (N1) and an oxygen atom (O5) from the completely deprotonated L^{4-} ligand units being located in the axial positions; the N1–Cu2–O5 angle is 172.4(3)°. The phenoxo oxygen (O3) atom lies in the position just perpendicular to the nearly linear arrangement with N1–Cu2–O3 and O3–Cu2–O5 bond angles of 87.5(3)° and 89.4(2)°, respectively. The other oxime nitrogen atom (N2) and one oxygen atom (O7) from the coordinated water molecules are bound equatorially and form an N2–Cu2–O7 angle of 132.8(3)°, lying just in-between that of an ideal trional bipyramid (120°) and a square-planar arrangement (180°). Unexpectedly, the bond lengths of Cu2–O5 (1.963(6) Å) and Cu2–N2 (1.970(7) Å) are almost equal, while the bond lengths of Cu2–N1 (2.023(7) Å) and Cu2–O7 (2.050(6) Å) are correspondingly longer, within the $\{CuO_2N_2O'\}$ coordination units, which is distinct from those of [Co(^{t}Bu)(Me)(salmdptn)] and [Cu(^{t}Bu)(Me)(salmdptn)] [30]. The weakest bond in the $\{CuO_2N_2O'\}$ coordination unit is that to the equatorial oxygen atom (O3) from the deprotonated L^{4-} ligand units, with a Cu2–O3 bond distance of 2.067(5) Å, which is considerably shorter than those in the [Co(^{t}Bu)(Me)(salmdptn)] and [Cu(^{t}Bu)(Me)(salmdptn)]. The coordination polyhedron thus resembles a trigonal bipyramid (3 + 2 coordination) rather than the tetragonal pyramid (4 + 1 coordination) in the complex [Cu(^{t}Bu)(Me)(salmdptn)] [30]. The "sal" moieties in each L^{4-} ligand unit are twisted with respect to each other (twist angle 31.6°) and make angles of 20.56° and 30.15° with the best plane of the N_2O_2 donors.

The central Cu(II) ion (Cu1) is tetra-coordinated by four phenoxo oxygen atoms (O3, O4, $O3^{\#4}$ and $O4^{\#4}$) from the two completely deprotonated L^{4-} ligand units. The donors do not form a perfect plane but deviate by *ca.* ±0.291 Å from their best plane to form a tetrahedrally distorted square planar geometry around the Cu1 centre. The four Cu–O bonds (Cu1–O3, Cu1–O4, Cu1–$O3^{\#4}$ and Cu1–$O4^{\#4}$) are similar and compare well with the literature values [25]. These Cu–O distances are somewhat shorter than those in the terminal $\{CuO_2N_2O'\}$ coordination cores, perhaps due to the decrease in the coordination number of Cu from 5 to 4. In

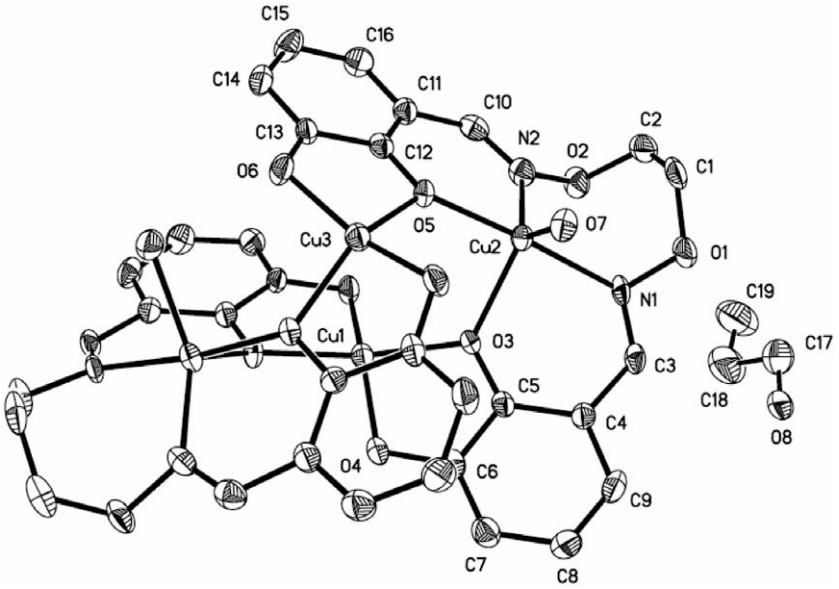

Fig. 4. Molecular structure of complex **3** with the atom numbering. The hydrogen atoms are omitted for clarity.

this complex, the other Cu(II) centre (Cu3) possesses the same coordination environment as that of the Cu1 atom. The only exception is the donors, which take part in coordination to Cu3, namely O5, O6, $O5^{\#4}$ and $O6^{\#4}$.

The structure of complex **3** contains a tetrametal eight-membered ring which sits on a crystallographic symmetric axis across the line of Cu1···Cu3. The intracomplex metal–metal separations are 3.527 Å (for Cu1···Cu2 or Cu1···$Cu2^{\#4}$) and 3.486 Å (for Cu3···Cu2 or Cu3···$Cu2^{\#4}$), which is not sufficiently short to imply strong metal–metal bonding interactions. The Cu1–O3–Cu2 (or Cu1–$O3^{\#4}$–$Cu2^{\#4}$) and Cu3–O5–Cu2 (or Cu3–$O5^{\#4}$–$Cu2^{\#4}$) bridging angles are 123.6(3)° and 122.4(3)°, respectively, indicating non-collinear Cu–O–Cu fragments, not suitable for significant electronic exchange.

Complex **3** is distinct from complexes **1**, **2** and **4** in that the two coordinated water molecules attached to the terminal Cu(II) ions lie on the same side of the terminal Cu(II) ions. There are four strong intramolecular and two strong intermolecular hydrogen bonds (Table 3) existing in the structure of complex **3**. The intramolecular hydrogen bonds are formed between the hydroxyl groups (O7–H7A and O7–H7AB) from the coordinated water molecules and the deprotonated oxygen atoms (O6 and $O6^{\#4}$) in the L^{4-} ligand units or the oxygen atom (O8) from the crystallizing n-propanol molecules. The intermolecular hydrogen bonds are found between the hydroxyl groups (O8–H8) from the crystallizing n-propanol molecules and the deprotonated oxygen atoms (O4 and $O4^{\#4}$) of the L^{4-} ligand units in the adjacent molecule. Meanwhile, the crystallizing n-propanol molecules link two other adjacent complex molecules into a self-assembling infinite 2D supramolecular structure via the intermolecular hydrogen bond O8–H8···O4 (Fig. 5).

3.4.4. Solvent effect

As shown in Fig. 6, because of the introduction of different solvent molecules, complexes **1**, **2**, **3** and **4** present two kinds of stoi-

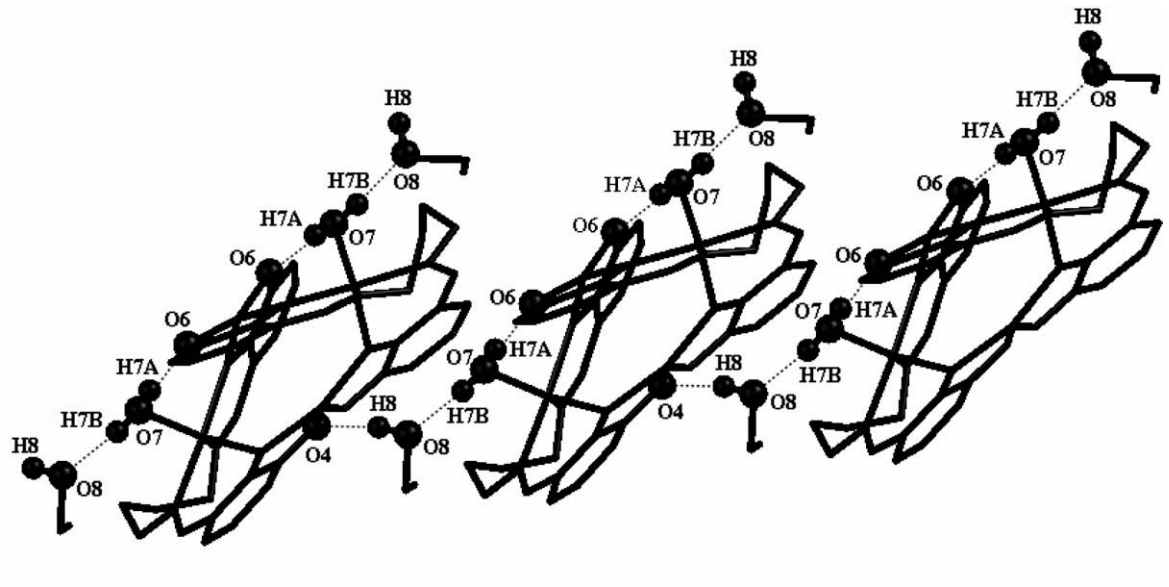

Fig. 5. Infinite 2D supramolecular structure of complex **3** showing intra- and intermolecular hydrogen bonds.

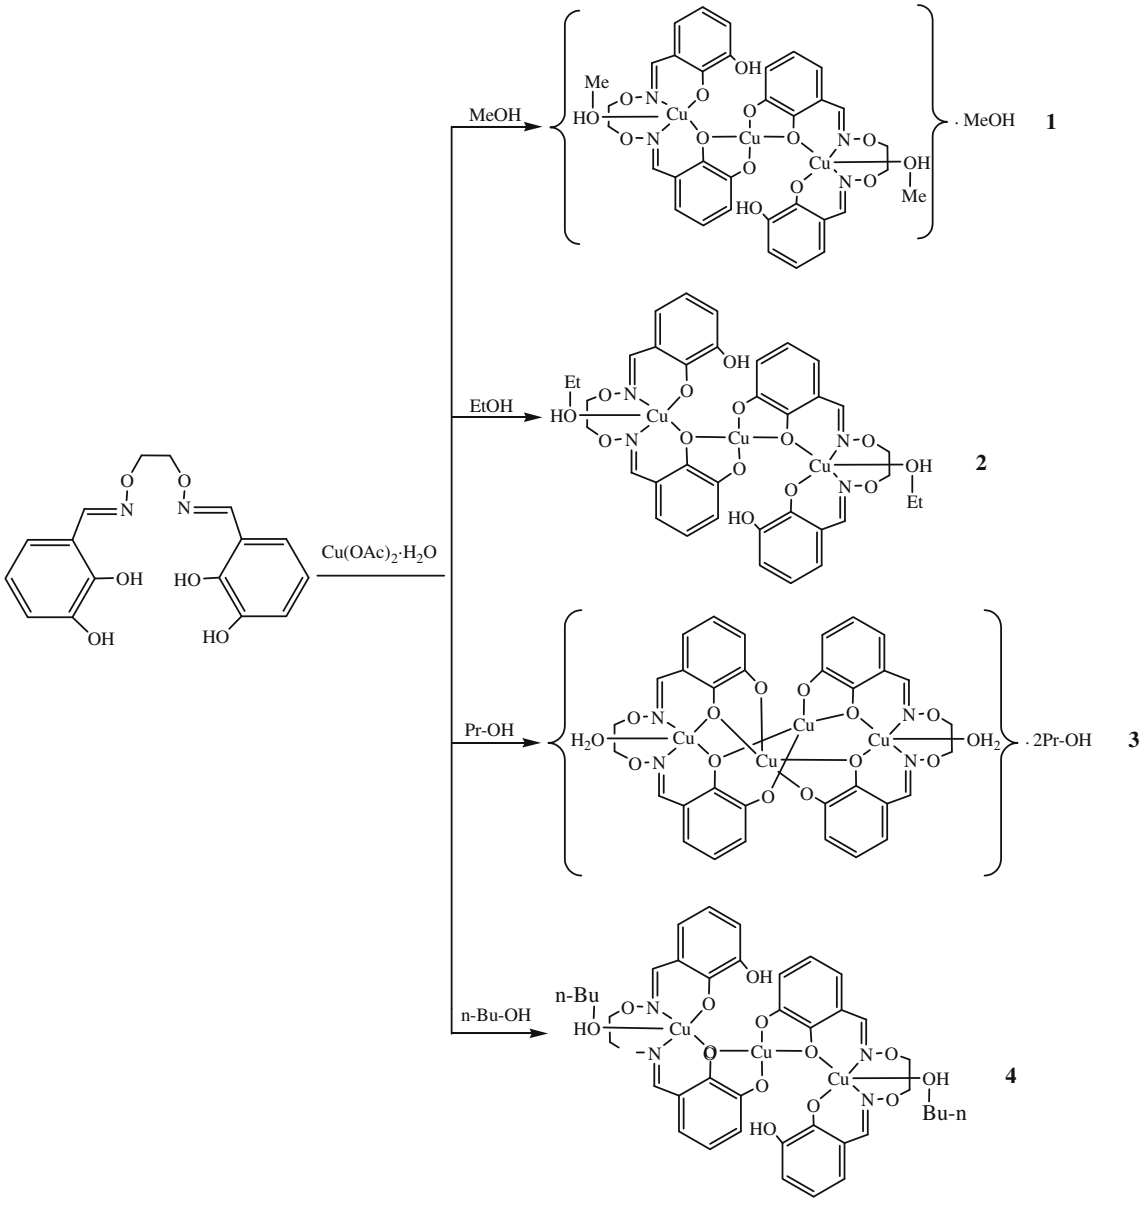

Fig. 6. Controlled design of solvent-induced Cu(II) complexes **1**, **2**, **3** and **4**.

chiometric ratio: the ratio of ligands and the Cu(II) ions are all 2:3 in complexes **1**, **2** and **4**, while it is 2:4 in complex **3**.

These complexes possess different structural features, mentioned above, with different performances of the ligand. In complexes **1**, **2** and **4**, the ligands are partially deprotonated as pentadentate $(HL)^{3-}$ trianions coordinating to three Cu(II) ions, and there are two solvent molecules coordinating to the two terminal Cu(II) ions, while in complex **3** the ligands are completely deprotonated as hexadentate L^{4-} tetraanions coordinating to four Cu(II) ions, and there are two water molecules coordinating to the two terminal Cu(II) ions.

The influence of solvent effect is clearly revealed in selected bond distances (Å) and bond angles (°) for complexes **1**, **2**, **3** and **4** (Table 2). It is noteworthy that the bond lengths from the oxygen atoms (O7) of coordinated solvent molecules (methanol, ethanol or n-butanol) to the terminal Cu(II) ions in complexes **1**, **2** and **4** are 2.485(4), 2.444(4) and 2.619(4) Å, respectively, which do not present a regular elongation when the steric hindrance successively becomes larger from methanol, ethanol to n-butanol.

4. Conclusion

As mentioned above, four solvent-induced Cu(II) complexes, $[\{Cu(HL)(CH_3OH)\}_2Cu]\cdot CH_3OH$ (**1**), $[\{(Cu(HL))_2(CH_3CH_2OH)_2\}Cu]$ (**2**), $[\{CuL(H_2O)\}_2Cu_2]\cdot 2CH_3CH_2CH_2OH$ (**3**) and $[\{(Cu(HL))_2(CH_3CH_2CH_2CH_2OH)_2\}Cu]$ (**4**), have been synthesized and structurally characterized. Because of the different performance of the ligand and the introduction of different solvent molecules, these complexes present two different structural features.

In complexes **1**, **2** and **4**, the ligands are partially deprotonated as pentadentate $(HL)^{3-}$ trianions coordinating to three Cu(II) ions and there are two solvent molecules coordinating to the two terminal Cu(II) ions. These complexes have elongated square-pyramidal coordination environments with an unusually long bond from the penta-coordinated Cu(II) centres to the oxygen atoms of the apical coordinated solvent molecules for the terminal Cu(II) ions, and square planar geometries distorted tetrahedrally for the central Cu(II) ions. While in complex **3**, the ligands are completely deprotonated as hexadentate L^{4-} tetraanions coordinating to four Cu(II)

ions, and there are two water molecules coordinating to the two terminal Cu(II) ions. In this complex the terminal Cu(II) ions lie in trigonal bipyramidal coordination geometries constituted by equatorial O_2N donor sites, with one oxygen atom from one of the coordinated water molecules and one nitrogen atom from a completely deprotonated L^{4-} ligand unit in the axial positions, and the central Cu(II) ions are in slightly tetrahedrally distorted square planar geometries constituted by four phenoxo oxygen donors from two completely deprotonated L^{4-} ligand units, and these form a tetrametal Cu–O–Cu–O–Cu–O–Cu–O eight-membered ring.

These complexes exhibit strong hydrogen bonding interactions in the solid state. In the case of complex **1**, the undeprotonated hydroxyl groups at the 3-position of the salicylidene moieties and the coordinated solvent molecules behave as hydrogen bond donors in contrast to the deprotonated oxygen atoms from the ligand $(HL)^{3-}$ units acting as receptors. Similar donor–acceptor modes are also witnessed in complexes **2** and **4**. In complex **3**, the hydroxyl groups of coordinated water molecules behave as hydrogen bond donors and the deprotonated oxygen atoms from the ligand $(HL)^{3-}$ units act as receptors in contrast to the crystallizing n-propanol molecules acting both as donors and acceptors. Moreover, the crystallizing n-propanol molecules link two other adjacent complex molecules into a self-assembling infinite 2D supramolecular structure via the intermolecular hydrogen bond O8–H8···O4.

Supplementary data

CCDC 670376, 696132, 712171 and 696144 contain the supplementary crystallographic data for **1**, **2**, **3** and **4**. The positions of bands were found by Gaussian multi-peak fitting in ORIGINPRO 7.

All of the drawings of the structures in this paper were prepared in MERCURY program, version 1.4.2, or ORTEP-3 version 1.08 for Windows [20].

2.3. Synthesis of the complexes

Usually, either an appropriate metavanadate MVO_3 (M = Li, Na, K, Rb or Cs) or V_2O_5 are used as a starting substrate in the synthesis of the peroxo complexes of vanadium [21]. We applied both methods in order to test and compare them.

2.3.1. Method 1(metavanadate)

Ten millimole of the proper MVO_3 (M = alkali metal ion) was dissolved in 10% H_2O_2 (used in excess, with a molar ratio vanadium:H_2O_2 = 1:2.6). To the obtained transparent, yellow solution, which was cooled in an ice bath, 20 ml of an ethanol solution of 2,2′-bipyridine (1.56 g, 10 mmol) was added dropwise with constant stirring. The temperature of the reaction mixture should not exceed 10 °C (exothermic reaction) during the synthesis. Subsequently, 50 ml of ice-cooled ethanol was added to form a crystalline, yellow product. The solid phase was filtered off via a glass frit, washed with 10 ml of cold ethanol and dried in air, in a dark place, for 24 h, then was stored in a refrigerator (ca. −10 °C). Yield: 70–80%. *Anal.* Calc. for $C_{10}H_{18}LiN_2O_{10}V$, MW = 384.14, **Li[VO(O$_2$)$_2$(bpy)] · 5H$_2$O (LibpV)**: C, 31.3; H, 4.7; N, 7.3; O_2^{2-}, 16.7; V, 13.3. Found: C, 31.7; H, 4.5; N, 7.2, O_2^{2-} 16.6; V, 13.4%. *Anal.* Calc. for $C_{10}H_{24}N_2NaO_{13}V$, MW = 454.24, **Na[VO(O$_2$)$_2$(bpy)] · 8H$_2$O (NabpV)**: C, 26.4; H, 5.3; N, 6.2; O_2^{2-}, 14.1; V, 11.2. Found: C, 30.3; H, 4.1; N, 7.0%. *Anal.* Calc. for $C_{10}H_{10}CsN_2O_7V$, MW = 454.05, **Cs[VO(O$_2$)$_2$(bpy)]·H$_2$O$_2$ (CsbpV)**: C, 25.4; H, 2.6; N, 5.9; V, 10.8. Found: C, 25.8; H, 2.4; N, 6.0; V, 10.9%.

2.3.2. Method 2 (V_2O_5)

All of the complexes were also synthesised using V_2O_5 as starting: 5 mmol (0.91 g) V_2O_5 was dissolved in aqueous solution of alkali metal hydroxide with gentle heating, until complete dissolution. To this mixture, 30% H_2O_2 was added dropwise until the pH reached 4. The transparent, yellow solution was then treated as in Method 1.

Results of elemental analysis of the complexes prepared by Method 2 were the same within experimental uncertainties as for the complexes prepared according to Method 1.

The rubidium salt could only be obtained by the latter method. Yield: 70-80%. *Anal.* Calc. for $C_{10}H_{16}N_2O_9RbV$, MW = 444.65, **Rb[VO(O$_2$)$_2$(bpy)] · 4H$_2$O (RbbpV)**: C, 27.0; H, 3.6; N, 6.3. Found: C, 27.0; H, 3.7; N, 6.3%.

2.4. X-ray structure determination

Single crystals of LibpV, NabpV, KbpV and RbbpV were grown by slow precipitation from their water–ethanol reaction solutions at a temperature of ca. −10 °C. Diffraction data for the lithium and rubidium salts were collected on a Bruker Smart Apex CCD diffractometer with graphite monochromatized Mo Kα radiation (λ = 0.71073 Å), equipped with an Oxford Cryosystems cryostat, at 153(2) K, and processed using the SAINT and SADABS program systems. The space group was found using the XPREP program, and the structures were solved by the heavy-atom method with SHELXS-97 [22]. Diffraction data for the sodium and potassium salts were collected on a Nonius KappaCCD diffractometer with graphite monochromatized Mo Kα radiation at 100(1) K using Oxford Cryostream 700 low temperature device and processed using the DENZO/SCALEPACK program package [23]. The empirical absorption correction method implemented into this package was applied during data processing. Crystal data and a summary of data collection and structure refinement parameters are given in Table 1. The structure of NabpV was solved by the heavy-atom method with SHELXS-97, while the structure of KbpV was solved by direct methods using the SIR program [24]. All structures were refined on F^2 using all data by full matrix least-squares procedures with SHELXL-97 with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms of the bpy molecule were included at calculated positions while those of the water molecules were localized on difference Fourier maps and refined with geometry constrains.

Attempts to obtain a good quality single crystals for the caesium salt, Cs[$VO(O_2)_2$bpy] · H_2O_2, were not successful probably because of the multiple twinning or high absorption. Therefore, powder diffraction data were collected using Philips X' Pert Pro diffractometer, and Cu Kα radiation (λ = 1.54177 Å), at 293(1) K. The XRD pattern was taken in the 2θ range from 5.0° to 60.0° with step size 0.02° and time per step 20 s. The lattice parameters were determined using the PROSZKI package [25].

The structure model was built on the basis of a global optimization method, using the FOX program [26]. The obtained model was used for the Rietveld refinement performed using the XRS-82 program [27]. Weak geometric restraints on bond distances and angles were applied during the refinement procedure. The preferred orientation correction was applied according to the March–Dollase formula. The preferred orientation direction was chosen, by trial and error method, along the [1 1 0]. The crystal data, summary of data collection and structure refinement parameters are given in Table 2, while the Rietveld plot is presented in Fig. 1.

3. Results and discussion

The complexes were prepared either by reacting solutions of peroxovanadate, generated from metavanadate $M[VO_3]$ (M = Li, Na, K, Cs) and H_2O_2, with bipyridine, or by dissolving V_2O_5 in aqueous MOH (M = Li, Na, K, Rb and Cs), followed by treatment with H_2O_2 and bpy. Both synthetic methods provide products with similar purities and yields. However, Method 1 turned out to be more convenient one. In Method 2, some problems arise with dissolving V_2O_5 in hydroxide, moreover, the reaction can proceed violently when H_2O_2 is added too fast and/or the temperature of the reaction mixture is too high.

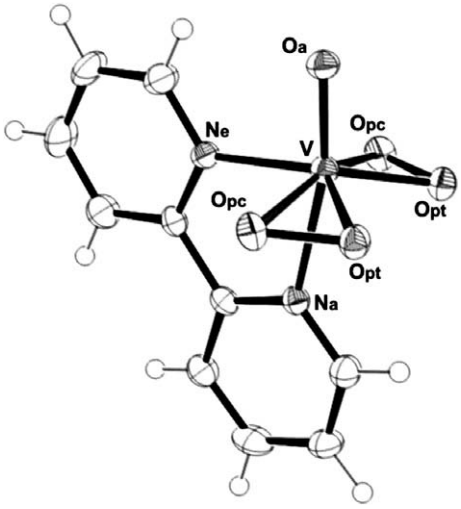

Fig. 2. General view of the coordination sphere of V with marked position of coordinating atoms: O_a – vanadyl oxygen atom, O_p – peroxo oxygen atoms in cis (O_{pc}) and trans (O_{pt}) positions, N_e and N_a – nitrogen atoms in equatorial and axial positions, respectively.

3.1. X-ray structures of $M[VO(O_2)_2bpy] \cdot nH_2O$ (M = Li^+, Na^+, K^+ and Rb^+) and $Cs[VO(O_2)_2bpy] \cdot H_2O_2$

The crystal structure of $Na[VO(O_2)_2(bpy)] \cdot 8H_2O$ has been reported previously by Fedorova et al. [28]. In the present paper, comparison of structure parameters of the sodium compound with those of the other alkali metal compounds is based on our own data reported below.

The coordination sphere of vanadium with the atom labeling scheme is shown in Fig. 2 and selected structural parameters are

[a] The distance between V atom and mean plane α formed from all O_p and N_e atoms in coordination sphere of V.

[b] The distance between two interacting bpy rings (π-stacking), calculated as mean distance between planes formed from all non-hydrogen atoms of two bpy rings.

given in Table 3. All complexes have the same inner coordination sphere, containing vanadium (coordination number 7) in the center of distorted pentagonal bipyramid. KbpV and RbbpV are isomorphous. Vanadium is coordinated to two peroxo groups, O_2^{2-}, in the side-on mode, and one of the nitrogen atoms of 2,2'-bipyridine, N_e, in the equatorial plane. The axial positions are occupied by the oxidovanadium(V) oxygen O_a, and the second nitrogen atom of bpy, N_a. The axial V–N_a bonds, on average, are 0.136 Å longer than the equatorial V–N_e bonds reflecting the *trans* influence of the oxidovanadium(V) oxygen (O_a). For the isomorphous potassium and rubidium salts, a weak influence of the alkali metal ion on the bond distance V=O_a is observed. For KbpV the distance equals 1.624 Å, while for RbbpV it is shorter (1.606 Å). This fact can be explained by the size of the cation M^+ which interacts with O_a possessing a partial negative charge. The $M^+ \cdots O_a$=V interactions are stronger, and the V=O_a bond increases for a cation with a smaller radius and thus a more pronounced polarizing power. The distance $d(\alpha \cdots V)$ of vanadium from a mean plane α (formed by all atoms in equatorial positions) ranges from 0.32 to 0.33 Å, showing a similar degree of deformation of the vanadium coordination polyhedra, except for the Cs salt, where $d(\alpha \cdots V)$ is 0.436 Å. This difference possibly reflects that the deformation is not simply driven by the nature of the alkaline metal cation. Rather, the nature of the molecules in the hydration sphere (H_2O_2 for CsbpV and H_2O for all other cations) also plays a role.

The lengths of the vanadium–peroxo oxygen bonds, V–O_p, differ (Table 3), as commonly observed for this type of compounds. The bond lengths V–O_{pc} (peroxo oxygen in *cis* position to the nitrogen atom in the equatorial plane (N_e)) are longer than the V–O_{pt} in (*trans* position). For the nomenclature (subscript "pc" and "pt") cf. ref.[29].

The crystal structures are stabilized by π-stacking of the 2,2'-bipyridine rings and by hydrogen bond networks. The interacting bpy rings form columns, where the vanadium atoms are placed alternately on the left and right sight of the column (see Fig. 3). The distances between two interacting bpy rings are ca. 3.4-3.7 Å for all compounds (for detailed data see Table 3). The hydrogen bond networks will be described in detail in Section 3.3.

The alkali metal ion is surrounded by oxygen atoms stemming from oxidovanadium(V) O_a, coordinated peroxide (except for M = Li) and water or (M = Cs) · H_2O_2. Coordination numbers differ, except for the isomorphous potassium and rubidium salts. In LibpV (Fig. 4) the lithium cation has the coordination number 4 (tetrahedral coordination mode: $[LiO_a(H_2O)_3]$). In the structure, separate units of $\{[Li(H_2O)_3]–\mu\text{-}O_a–[V(O_2)_2(bpy)]\}$ can be identified. Two remaining water molecules present in the structure link the units by hydrogen bonds formed between water molecules and also between water molecules and the O_p atoms of both peroxo ligands.

In NabpV, the sodium cation is in the octahedral coordination mode, surrounded by five water molecules and one O_a. The octahedra $[NaO_a(H_2O)_5]$ are linked together by bridging oxygen atoms O6,

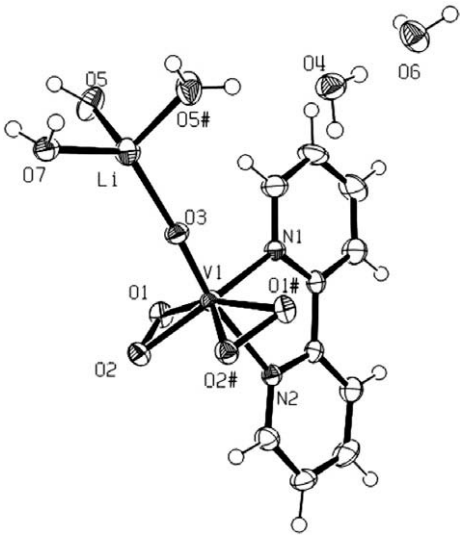

Fig. 4. Asymmetric unit of $Li[VO(O_2)_2(bpy)] \cdot 5H_2O$.

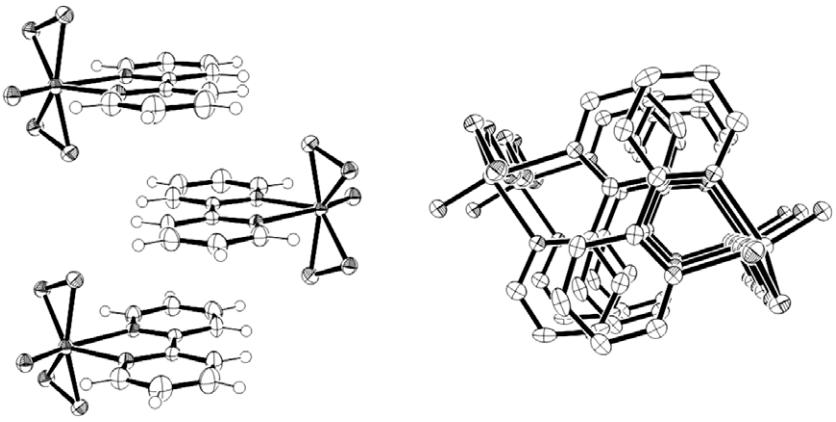

Fig. 3. π-stacking of bpy rings (view along (001) on the left and view along (010) on the right). Hydrogen atoms in the drawing on the right have been removed for clarity.

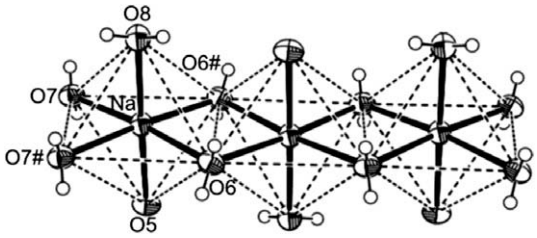

Fig. 5. Coordination sphere of Na^+ in NabpV.

O6#, O7, O7# coming from water molecules (Fig. 5) thus forming a pseudopolymeric chain. Atoms marked with # are related by symmetry and formally belong to an adjacent polyhedron. The remaining water molecules form water channels, where an extensive system of hydrogen bonds is linking the pseudopolymeric chains together. Such water channels are found only in the sodium salt, see Fig. 6.

In KbpV and RbbpV the coordination number for the alkaline metal cation is 8 (Fig. 7). The coordination geometry of M^+ resembles a distorted dodecahedron, which is shown in Fig. 8 for potassium. In the coordination sphere of M^+, 4 water molecules, 2 O_p and 2 O_a are present. The polyhedra $[M(O)_4(H_2O)_4]$, like in NabpV are linked together to form a pseudopolymeric chain. The bridging oxygen atoms O7 and O7# are coming from water molecules and the other two oxygens, O5 and O5# are oxidovanadium(V) O_a atoms. One water molecule (O9 in Fig. 7), which does not belong to the coordination sphere of M^+, connects two chains through hydrogen bonds.

The caesium salt (Fig. 9) is the only one containing a hydrogen peroxide molecule. The caesium cation attains coordination number 9 (Fig. 10).

In the coordination sphere of Cs^+, following oxygen atoms are present: two O_a atoms from two V=O groups (O1, $O1^{\#}$), six O_p atoms, and one H_2O_2. Each coordination polyhedron is sharing three edges (containing O_a and O_p oxygen bridging atoms) with neighboring polyhedra to form layers resembling a two-dimensional network.

The coordination number for alkali metal ions increases with increasing the ionic radius and adopts typical values for each alkali metal: Li (4), Na (6), K, Rb (8) and Cs (9).

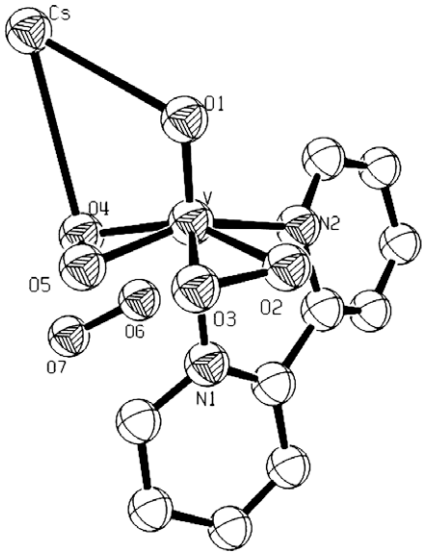

Fig. 9. Asymmetric unit of CsbpV.

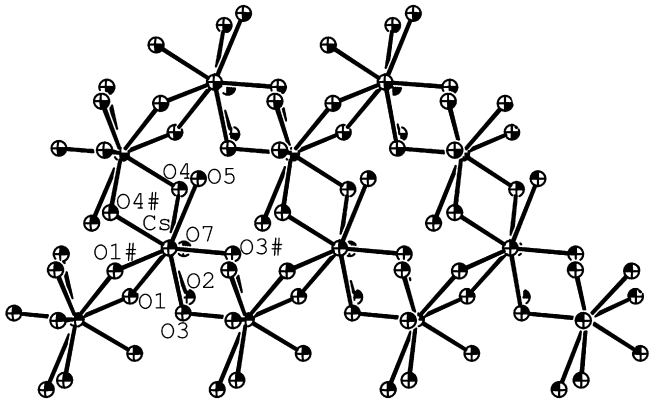

Fig. 10. Coordination sphere of Cs^+ in CsbpV.

The proximity between the M^+ cation and the peroxido ligands (O_p) suggests that an interaction exists which influences the tendency to shift electron density from the peroxido ligand to the vanadium cation which, in turn, has an impact on oxygen liberation by auto-decomposition of the complex. In the case of the K, Rb and Cs salts, this influence opposes the electron density shift, thus making the complex more stable. In the Na and Li complexes, where the cation is farther away from the peroxo ligands, this influence is minimized, and therefore the compounds are expected to be less stable. Similarly, distances between M^+ and the oxidovanadium(V) oxygen (O_a) can also, in principle, have impact on the complex stability. However, in this case the influence on electron density transfer between the peroxido ligand and the central cation is expected to be negligible. The effect by hydrogen bonds from the water molecules follows the same scheme: bonds to peroxo ligands stabilize the complex, while bonds to the oxidovanadium(V) ion have virtually no effect.

3.2. Hydrogen bond networks

Hydrogen bonds play a very important role in stabilizing crystal structures. Two types of hydrogen bonds can be found in the investigated compounds: (i) formed between water molecules (O–H···O) and (ii) formed between a water molecule and an oxygen atom of a peroxo group (O–H···O_p). Water molecules act both as donors and acceptors in type (i) hydrogen bonds and only as donors in type (ii).

There are many different ways to define the strength of a hydrogen bond given in the literature [30–32]. The geometric parameters of the hydrogen bonds and the hydrogen bond strengths according to the [32] for the Li, Na, K, Rb salts are given in Table 4 and hydrogen bond networks is shown in Fig. 11.

The hydrogen bonds formed between lattice water molecules are present in all salts and are most numerous in Na salt.

In Li and Na salts water molecules form hydrogen bonds to both oxygen atoms (O_{pt} and O_{pc}) of each peroxo ligand while in K and Rb salts only to O_{pt} atoms.

In the potassium and rubidium complexes some hydrogen bonds are replaced by interactions between the alkali metal ion and the oxygen atom from the peroxo ligand in *cis* position, $M^+\cdots O_{pc}$. This may be traced back to (i) the relatively large size of alkali metal ions and (ii) opposite charges on these interacting fragments of the structure – the cation is positively charged while the peroxo ligand has a partial negative charge. In CsbpV, almost all oxygen atoms forming the coordination sphere of vanadium belong also to a coordination sphere of caesium cations (from the same or an adjacent complex).

3.3. IR and UV–VIS characterisation

All of the complexes display typical spectral patterns in the infrared region, involving absorptions due to oxidovanadium(V) group, coordinated peroxido and 2,2'-bipyridine groups, lattice water and/or hydrogen peroxide. The positions of all bands are in good agreement with previously reported data [28,33]. Selected IR bands are given in Table 5.

Interestingly, the IR spectrum of NabpV in KBr pellet shows the ν(V=O) band shifted to 927 cm^{-1} with respect to 946 cm^{-1} in nujol, with other bands retaining their positions. This shift can be explained by cation exchange of Na^+ to K^+ (from KBr) under experimental conditions. The positions of ν(O–O) and $\nu(VO_2)$ are typical for a side-on coordination mode of O_2^{2-}.

In the Li–Cs series the positions of ν(V=O) band is passing through a maximum for NabpV and indicating complex effect of: (i) the V=O bond length (the correlation between ν(V=O) and

oxido group to vanadium. The next two bands (in the UV region) can be assigned to π–π^* transitions within the bpy ligand.

4. Conclusions

The synthesis of oxido-bis(peroxido)vanadates(V) is more convenient when using metavanadate(V) as a starting substrate. The crystal structures of all complexes show a vanadium atom in the centre of a distorted pentagonal bipyramid. Except for LibpV, all complexes form pseudopolymeric chains, exploiting electrostatic interactions. Extensive hydrogen bonding networks are formed, which are interlinking the coordination polyhedra of vanadium through acceptor peroxo (O_p) atoms with water molecules. With increasing ionic radius of alkali metal cation, the degree of hydration decreases, causing an increase in the number of ionic-like ($M^{+\cdots}O_2^{2-}$ interactions. In the compounds containing water of hydration (i.e. all except CsbpV, which contains H_2O_2) the type of alkali metal cation influences the network of hydrogen bonds which in turn define the crystallographic structure.

It is interesting to compare the complexes K[VO(O2)2(bpy)]?8-H2O and $Rb[VO(O_2)_2(bpy)] \cdot 4H_2O$ which are isostructural and therefore only the alkali metal cation can be the source of differences in the physicochemical properties. Both salts have a similar hydrogen bond network. The structure of the complex KbpV (smaller cation) reveals a somewhat stronger hydrogen bond network than RbbpV.

All of these findings have a large impact on spectroscopic properties. We have observed shifts of certain bands in the IR spectra. The position of the band depends on two main factors: type of the crystal structure and the polarizing power of the alkali metal ion.

5. Supplementary data

CCDC 298937, 706501 and 298936 contain the supplementary crystallographic data for LibpV, KbpV and RbbpV. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgments

Wojciech Przybylski wants to thank Prof. Alina Samotus' family for awarding a scholarship to Hamburg University. He is also grateful to Prof. Dr. Ulrich Behrens and Prof. Dr. Jürgen Kopf (from Hamburg University) for consultation and all the help in solving the crystal structures.

above 3 MΩ in-house. Thermogravimetric analysis was performed on a TA Instruments TGA 2050 Thermogravimetric Analyzer with a heating rate of 10 °C/min up to 900 °C. Elemental Analysis was carried out using a Perkin–Elmer 2400 Series II CHNS/O Analyzer. IR spectra were recorded on powdered samples on a Perkin–Elmer Spectrum One DRIFT-IR instrument. The luminescence spectrum for **3** was obtained with a Hitachi F-4500 Fluorescence Spectrometer on solid crystalline samples anchored to quartz microscope slides with Rexon Corporation RX-22P ultraviolet-transparent epoxy adhesive.

2.2. Preparation of $[Co(aze)(dpa)(H_2O)]_n$ (**1**)

$CoCl_2 \cdot 6H_2O$ (88 mg, 0.37 mmol), dpa (63 mg, 0.37 mmol) and azelaic acid (70 mg, 0.37 mmol) were added to 10 mL of distilled H_2O in a 23 mL Teflon lined Parr acid digestion bomb. The bomb was sealed, heated to 120 °C for 48 h, and then gradually cooled to ambient temperature. Magenta blocks of **1** (80 mg, 0.18 mmol, 50% yield based on Co) were obtained after filtration, washing with distilled water and acetone, and drying in air. Crystals of **1** were stable indefinitely in air. *Anal.* Calc. for $C_{19}H_{25}CoN_3O_5$ **1**: C, 52.54; H, 5.80; N, 9.67. Found: C, 52.72; H, 5.39; N, 9.75%. IR (cm^{-1}): 3156 w, 2927 w, 1588 s, 1538 m, 1507 s, 1483 m, 1455 m, 1434 m, 1403 m, 1331 s, 1309 m, 1203 m, 1100 w, 1060 w, 1017 m, 1008 m, 921 w, 900 w, 870 w, 842 m, 822 s, 740 m, 731 m, 673 w, 660 w.

2.3. Preparation of $[Ni(aze)(dpa)(H_2O)]_n$ (**2**)

The procedure for the synthesis of **1** was followed but with $NiCl_2 \cdot 6H_2O$ (88 mg, 0.37 mmol), as the metal source. Green blocks of **2** (76 mg, 0.17 mmol, 47% yield based on Ni) were obtained after filtration, washing with distilled water and acetone, and drying in air. Crystals of **2** were stable indefinitely in air. *Anal.* Calc. for $C_{19}H_{25}N_3NiO_5$ **2**: C, 52.57; H, 5.81; N, 9.68. Found: C, 52.67; H, 5.47; N, 9.82%. IR (cm^{-1}): 3271 w br, 1612 w, 1595 m, 1522 s, 1442 m, 1412 m, 1376 m, 1352 s, 1250 w, 1213 m, 1147 w, 1120 w, 1059 w, 1018 s, 1000 w, 977 w, 903 w, 848 w, 815 m, 783 s, 732 s, 677 w.

2.4. Preparation of $\{[Cd(aze)(dpa)] \cdot 2H_2O\}_n$ (**3**)

$Cd(ClO_4)_2 \cdot 6H_2O$ (100 mg, 0.30 mmol), dpa (110 mg, 0.64 mmol) and azelaic acid (60 mg, 0.32 mmol) were added to 10 mL of distilled H_2O in a 23 mL Teflon lined Parr acid digestion bomb. The bomb was sealed, heated to 120 °C for 48 h, and then gradually cooled to ambient temperature. Colorless blocks of **3** (45 mg, 0.045 mmol, 30% yield based on Cd) were obtained after filtration, washing with distilled water and acetone, and drying in air. Crystals of **3** were stable indefinitely in air. *Anal.* Calc. for $C_{38}H_{50}Cd_2N_6O_{12}$ **3**: C, 45.29; H, 5.00; N, 8.34. Found: C, 44.90; H, 5.36; N, 8.21%. IR (cm^{-1}): 3266 w, 2940 w, 2853 w, 1592 m, 1524 s, 1419 s, 1396 m, 1348 m, 1335 m, 1316 w, 1270 w, 1229 w, 1211 m, 1102 w, 1059 w, 1014 m, 929 w, 903 w, 839 w, 813 m, 786 w, 776 w, 709 m, 662 w, 624 w.

3. X-ray crystallography

Single crystals of **1**–**3** were subjected to X-ray diffraction using either a Bruker APEX2 (**3**) or a Bruker-AXS SMART 1000 (**1** and **2**) CCD instrument at 173(2) K. Reflection data were acquired using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The data was integrated via SAINT [21]. Lorentz and polarization effect and empirical absorption corrections were applied with SADABS [22]. The structures were solved using direct methods and refined on F^2 using SHELXTL [23]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms bound to carbon atoms were placed in calculated positions and refined isotropically with a riding model. The hydrogen atoms bound to the central nitrogen of the dpa moieties and the ligated or unligated water molecules were found via Fourier difference maps, restrained at fixed positions, and then refined isotropically with thermal parameters 1.2 times the average U_{ij} values of the atoms to which they are bound. Hydrogen atoms could not be located for the disordered water molecules of crystallization in **3**. Disordered carbon atoms in **1** and **2** were modeled with partial occupancies and anisotropic thermal parameters; their occupancies were allowed to refine freely in early stages of the refinement and then were fixed. Pertinent crystallographic data is listed in Table 1.

4. Results and discussion

4.1. Synthesis and spectral characterization

The coordination polymers **1**–**3** were prepared under hydrothermal conditions via combination of 4,4′-dipyridylamine and azelaic acid with cobalt chloride, nickel chloride or cadmium perchlorate. Their infrared spectra were consistent with their crystal structures. Sharp, medium intensity bands in the range of ~1600 to ~1200 cm^{-1} were ascribed to stretching modes of the pyridyl rings of the dpa moieties [24]. Features corresponding to pyridyl ring puckering mechanisms were evident in the region between 820 and 600 cm^{-1}. Asymmetric and symmetric C–O stretching modes of the carboxylate groups were marked by very strong, slightly broadened bands at ~1590 and ~1340 cm^{-1}. Broad bands in the region of ~3400 to ~3200 cm^{-1} in all three cases represent N–H stretching modes within the dpa ligands and O–H stretching modes within the bound and/or unligated water molecules. The broadness of these spectral features is caused by hydrogen-bonding patterns within these materials.

4.2. Structural description of $[Co(aze)(dpa)(H_2O)]$ (**1**)

Compound **1** possesses an asymmetric unit consisting of a divalent cobalt atom, one azelate dianion, one dpa ligand and one aqua ligand. Although the carbon positions at each end of the α,ω-dicarboxylate aliphatic chain are fully occupied, its methylene carbons atoms are disordered over two sets of positions in an 80/20 ratio (*aze-A*, C11–C12–C13–C14–C15–C16–C17–C18–C19; *aze-B*, C11–C12A–C13A–C14A–C15A–C16A–C17A–C18A–C19). The coordination environment at cobalt is depicted in Fig. 1, showing both *aze-A* and *aze-B* disordered positions.

The coordination sphere about cobalt is a distorted $[MO_4N_2]$ octahedron, with *cis* disposed nitrogen donor atoms from two different dpa molecules. Two of the oxygen donors are part of a chelating carboxylate endcap of an aze ligand, and the aqua ligand is oriented in a *cis* fashion with respect to an oxygen donor atom from a monodentate aze carboxylate group. Bond lengths and angles (Table 2) at cobalt are standard for octahedral coordination complexes with one chelating ligand.

Extension of the cobalt coordination environments of **1** through their dpa ligands generates 1-D $[Co(H_2O)(dpa)]_n^{2n+}$ chains that course along the *b* crystal direction (Fig. 2), with Co···Co through-ligand distances of 11.679 Å. The inter-ring torsion within the dpa ligands measures 37.6°. These cationic chains are subsequently linked into two idealized $[M(aze)(dpa)(H_2O)]_n$ coordination polymer layer patterns by crystallographically disordered aze ligands in their *A* and *B* orientations, heretofore denoted *layer-A* and *layer-B*.

The *aze-A* ligands adopt a *gauche–anti–anti–anti–anti–gauche* conformation (four C-atom torsion angles = 60.6°, 178.0°, 175.8°,

presence of this hydrogen-bonding interaction prevents the occurrence of a bis(chelating) dicarboxylate bridging mode, thereby providing a modicum of structure direction during self-assembly.

The *aze-B* ligands instead adopt a more spread out *anti–anti–anti–gauche–gauche–gauche* conformation (four C-atom torsion angles = 164.2°, 163.2°, 174.0°, 55.0°, 43.8° and 44.4°). Despite the conformational difference between *aze-A* and *aze-B*, they both connect cobalt atoms through the same chelating/monodentate bridging mode. If all the dicarboxylate ligands were considered to adopt the *aze-B* orientation, idealized $[Co(aze\text{-}B)(dpa)(H_2O)]_n$ (4,4) grid-like layers are constructed (*layer-B*, shown in Fig. 4 as face-on and edge-on perspectives); these align parallel to the (1 0 1) crystal plane.

The splayed-open conformation of *aze-B* ligands in layer-*B* promotes Co···Co through-ligand contact distances of 10.677 Å,

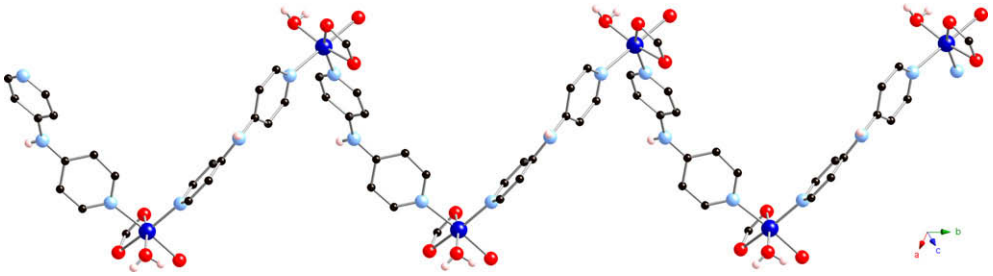

Fig. 2. A single $[Co(H_2O)(dpa)]_n^{2n+}$ chain motif in **1**.

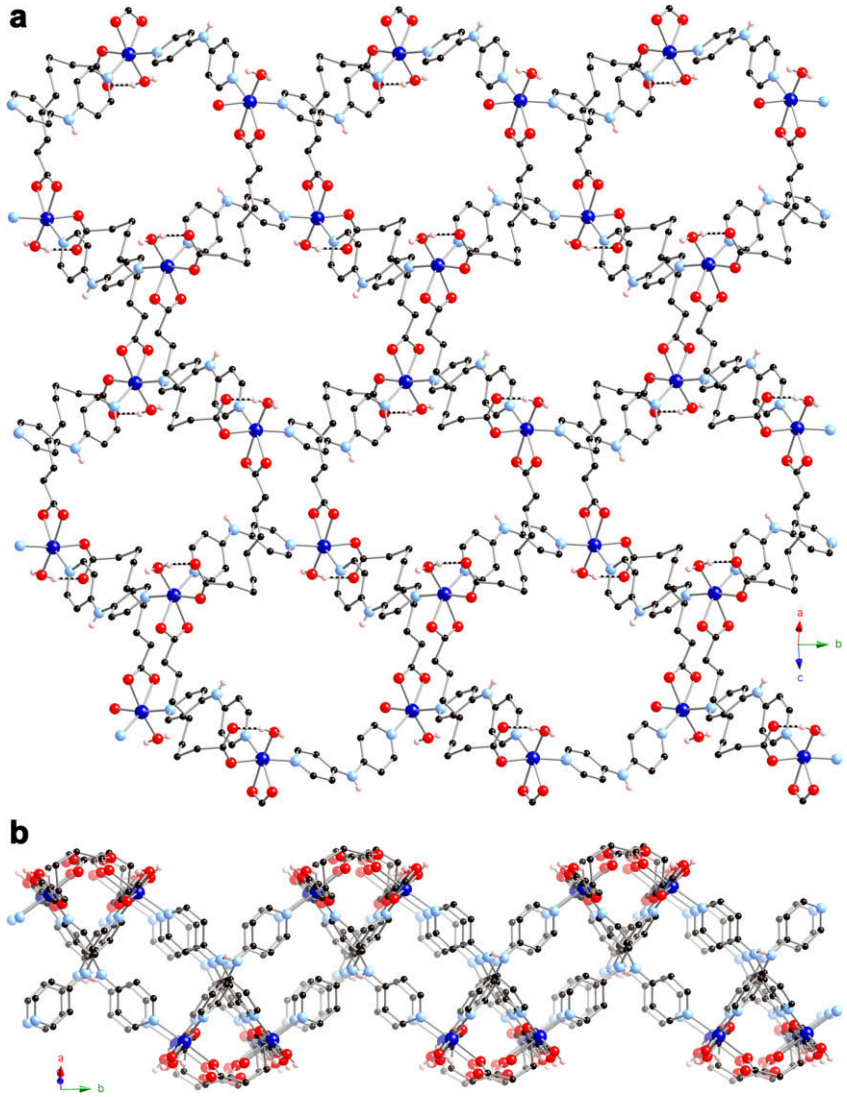

Fig. 4. Idealized layer-*B* motif in **2**. Hydrogen-bonding interactions are shown as dashed lines. (top) Face-on view; (bottom) edge-on view.

approximately 1.6 Å longer than those in layer-*A*. In contrast to *layer-A*, the ruffled *layer-B* pattern exhibits two distinct apertures, with Co···Co distances of 14.187 and 17.037 Å in one and 12.172 and 18.779 Å within the other. The Co···Co···Co angles around these apertures' respective perimeters are 78.6° and 101.4°, and 65.8° and 114.2°.

Crystallographic disorder among the aze ligands produces a three-dimensional structure for **1** that represents a weighted average of idealized *layer-A* and *layer-B* patterns in a 4:1 ratio. If the atomic positions within idealized layers were both fully occupied, the overarching coordination polymer network would be a six-connected α-Po primitive cubic lattice. Yet, each cobalt atom can only be 4-connected within the structure of **1**, with only two connections possible through aze ligands. Thus it is proper to view the covalent framework of **1** as a primitive cubic lattice with "ligand vacancies", wherein every fifth *aze-A* position is missing and every fifth *aze-B* position is occupied (Fig. 5). A similar topology was seen in the suberate analog of **1** [25]. Hydrogen-bonding interactions between the central amine groups of the dpa ligands and the ligated oxygen atoms of the monodentate aze termini, and between the aqua ligands and one of the chelating aze oxygen atoms, act in tandem to stabilize the three-dimensional structure of **1**. Geometric parameters for the hydrogen-bonding interactions in **1** are given in Table 3.

4.3. Structural description of [Ni(aze)(dpa)(H_2O)] (**2**)

The asymmetric unit of **2** (Fig. 6) is similar to that of **1**, with a very closely related $\{NiO_4N_2\}$ coordination environment and an identical geometrical arrangement of donor atoms and dicarboxylate binding modes. Here, the disordered *aze-A* and *aze-B* conformations refine best with a 70/30 ratio. Unlike **1**, the aze ligand conformations in **2** share the two carbon atoms at the ends of the aliphatic chain. Bond lengths are slightly contracted relative to **1**, consistent with well-established ionic radius trends (Table 4) [26]. These subtle variances propagate themselves in the shortened Ni···Ni contact distances within the 1-D $[Ni(H_2O)(dpa)]_n^{2n+}$ chains (11.554 Å), and lengthened Ni···Ni distances in the $[Ni(aze\text{-}A)(dpa)(H_2O)]_n$ and $[Ni(aze\text{-}B)(dpa)(H_2O)]_n$ idealized (4,4) grid-like layers (9.202 and 10.889 Å, respectively) present in the structure of **2**.

As in **1**, the structure of **2** is a three-dimensional "ligand vacancy" primitive cubic lattice consisting of a weighted average of $[Ni(aze\text{-}A)(dpa)(H_2O)]_n$ and $[Ni(aze\text{-}B)(dpa)(H_2O)]_n$ idealized layers, which are arranged parallel to the (0 0 1) and (1 0 −2) crystal planes, respectively. Similar hydrogen-bonding mechanisms to those in **1** are evident within the structure of **2**, serving an additional role in network generation and/or stabilization (Table 3).

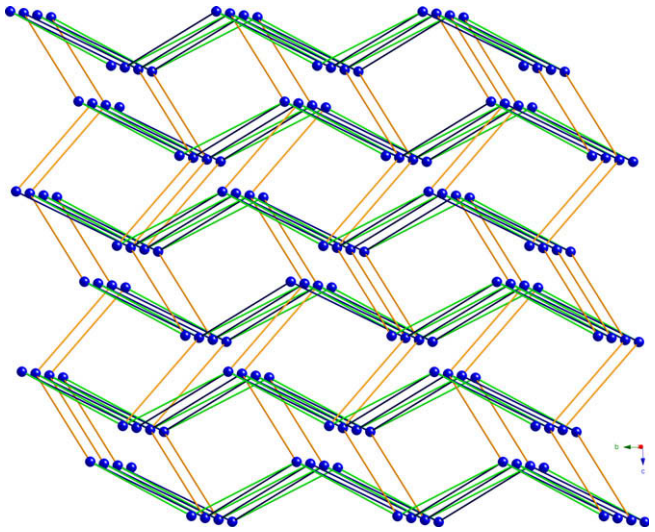

Fig. 5. Simplified perspective of the 3-D four-connected lattice of **1** and **2**, based on a primitive cubic network with "ligand vacancies". Metal atoms are shown as spheres. Linkages through-azelate dianions in orientations *A* and *B* are illustrated as green and red sticks, respectively. Linkages through dpa tethers are shown in blue. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

4.4. Structural description of $\{[Cd(aze)(dpa)] \cdot 2H_2O\}_n$ (**3**)

The asymmetric unit of compound **3** (Fig. 7) contains two crystallographically distinct divalent cadmium atoms, aze ligands (*aze-A*, C21–C29/O1–O4; *aze-B*, C31–C39/O5–O8), and dpa ligands (*dpa-A*, C1–C10/N1–N3; *dpa-B*, C11–C20/N4–N6), along with four water molecules of crystallization, two of which are distributed over multiple disordered positions. In contrast to **1** and **2** which exhibit octahedral coordination environments, the $\{CdO_5N_2\}$ environment about each crystallographically distinct cadmium atom is best described as a slightly distorted pentagonal bipyramid. In both environments the nitrogen donor atoms from two crystallographically distinct dpa ligands occupy the axial positions. The equatorial plane of each pentagonal bipyramid contains donor atoms from two chelating carboxylate aze termini along with a single oxygen donor atom from a third aze ligand. Bond lengths and angles are standard for a chelated seven-coordinated cadmium complex and are listed in Table 5.

Cd2 atoms are connected through *aze-A* ligands, which adopt a *gauche–anticlinal–anticlinal–anti–anti–gauche* conformation (four C-atom torsion angles = 75.7°, 140.3°, 123.2°, 169.2°, 167.8°, 24.3°). While both *aze-A* carboxylate termini bind to cadmium ions in a chelating fashion, one of the carboxylate oxygen atoms (O5) also binds to a second cadmium atom. Thus, the *aze-A* ligand is exotridentate, constructing a $[Cd(aze\text{-}A)]_n$ double chain motif (*chain-A*, Fig. 8a) containing $[Cd_2O_2]$ rhomboid dinuclear units. The Cd···Cd and O···O distances across the rhombs are 3.815 and 2.923 Å, respectively, with inscribed angles of 74.9° and 105.1°. The "staple" like conformation of *aze-A* results in bis(chelating) bridged Cd···Cd distance of 8.598 Å within *chain-A*.

Exotridentate *aze-B* ligands with a similar binding mode connect Cd1 atoms into a $[Cd(aze\text{-}B)]_n$ double chain motif (*chain-B*, Fig. 8b), which also contain $[Cd_2O_2]$ dinuclear units. The *aze-B* aliphatic chain rests in a *gauche–anti–anti–anti–gauche* conformation with torsion angles of 60.8°, 174.4°, 179.7°, 173.0°, 178.1° and 74.8°. This "S-shaped" conformation results in a significantly longer bis(chelating) bridged Cd···Cd distance of 11.355 Å. The Cd···Cd and O···O distances across the rhombic units in *chain-B* are slightly shorter than those in *chain-A*, measuring, respectively, 3.787 and 2.828 Å; the Cd–O–Cd and O–Cd–O angles within the $[Cd_2O_2]$ units are 106.5° and 73.5°, respectively.

Sets of *chain-A* and *chain-B* motifs are arranged parallel to the *a* and *b* crystal directions, respectively. These sets of chains are connected together into a three-dimensional coordination polymer network (Fig. 9) *via* tethering *dpa-A* and *dpa-B* ligands, which result in Cd1···Cd2 contact distances of 12.100 and 11.818 Å, respectively. The differences between these distances are likely causes by subtle variances in the inter-ring torsion angles within the dpa ligands (34.1° for *dpa-A*, 35.0° for *dpa-B*). If the centroids of the $[Cd_2O_2]$ rhombs are considered as nodes, and pairs of aze and dpa ligands as linkers, a 4-connected $6^5 8$-**cds** topology network ($CdSO_4$ lattice) can be invoked for **3**.

Entrained in the incipient voids within the 3-D framework of **3**, which occupy 11.2% of the unit cell volume according to a calculation with PLATON [27], are isolated water molecules of crystallization and water molecule trimers held in place by hydrogen-bonding donation by the central amine groups of the *dpa-B* ligands and hydrogen-bonding acceptance on the part of the *aze-A* and *aze-B* carboxylate oxygen atoms. Covalent connectivity within the coordination polymer framework is supplemented by hydrogen bonding between central amines of the *dpa-A* ligands and carboxylate oxygen atoms belonging to *aze-A* tethers. In addition, significant π–π stacking interactions between the pyridyl rings of *dpa-A* and *dpa-B* ligands (ring centroid-to-ring centroid distances = 3.622(2) and 3.837(2) Å) across the $[Cd_2O_2]$ rhombs serve an ancillary stabilization role. Metrical parameters for the identified hydrogen-bonding pathways in **3** are given in Table 3.

4.5. Luminescence behavior of *3*

Upon irradiation with ultraviolet light (λ_{ex} = 300 nm), a solid polycrystalline sample of **3** exhibited blue-violet visible light emission (Fig. 10), although the maximum emission wavelength fell in the ultraviolet region (λ_{max} = 360 nm). Similar emissive behavior has been observed for several other cadmium coordination polymers containing aromatic ligands [6], including $[Cd(glu)(dpa)]_n$ [16]. Unligated dpa also photoluminesces [17], showing a weak broad emission with λ_{max} = 420 nm with (λ_{ex} = 300 nm). Thus, the most plausible origin for the photoluminescence of **3** is π–π^* or a π–n electronic transition behavior within the molecular orbital manifolds of the aromatic ligands of the dpa ligands.

4.6. Thermogravimetric analysis

Thermogravimetric analyses were performed in order to evaluate the thermal stability of the coordination polymers in this study. Dehydration of **1** began at ~130 °C, with a mass loss by ~200 °C of 4.5%, roughly consistent with loss of the ligated water molecules (4.1% calculated). Combustion of the organic components occurred at ~250 °C, with a mass remnant of 19% at 900 °C, matching reasonably well with production of CoO (17% calculated). According to the TGA trace of **3**, the sample had lost one equivalent of water molecules on long-term standing, as the mass loss of 3.6% by ~60 °C matches well with elimination of one equivalent of water (3.7% calculated). Ejection of the organic components from **3** commenced at ~200 °C. Mass elimination was virtually complete by ~450 °C, with the mass remnant of 21% corresponding well with a deposition of Cd metal (23% calculated). A slow mass decrease above 450 °C likely indicates some evaporation of Cd metal (bp 767 °C). TGA traces for **1** and **3** are depicted in Supplementary Figs. S1 and S2, respectively.

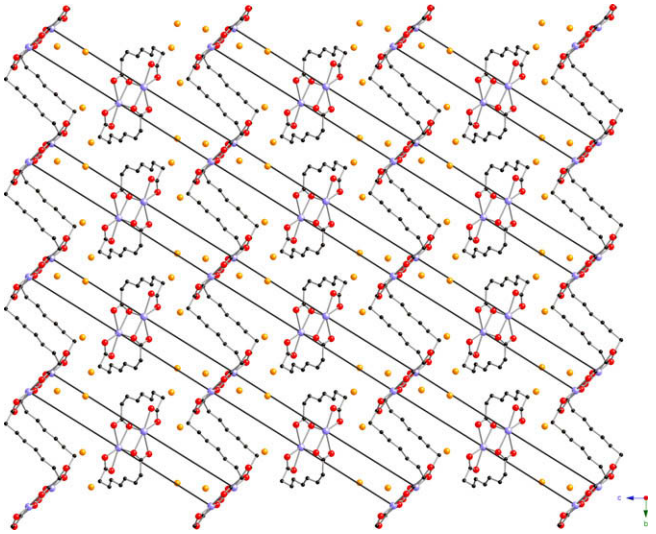

Fig. 9. The non-interpenetrated $6^5 8$ $CdSO_4$ topology 3-D structure of **3**. For clarity, dpa ligands are shown as green sticks. Water molecules of crystallization are indicated as isolated spheres. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

5. Conclusions

Self-assembly of divalent transition metal ions with a very long-spanning aliphatic α,ω-dicarboxylate ligand and the kinked

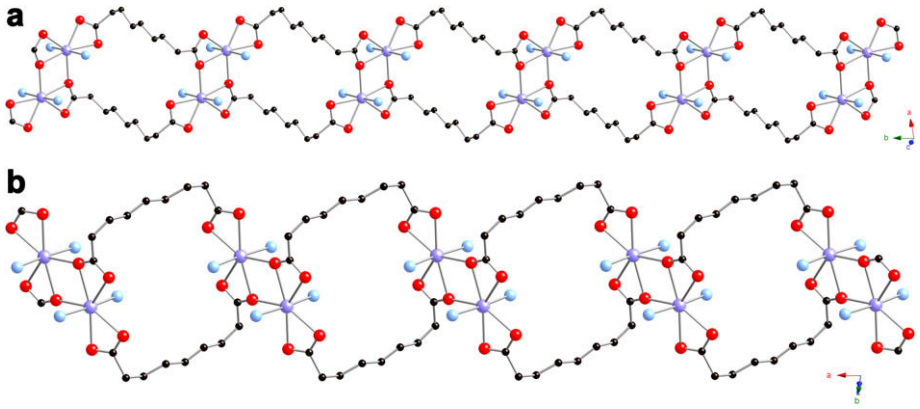

Fig. 8. The two crystallographically distinct $[Cd(aze)]_n$ ribbon patterns in **3** (top, *chain-A*; bottom, *chain-B*).

and hydrogen-bonding capable 4,4′-dipyridylamine ditopic tethering ligand has resulted in three-dimensional coordination polymers whose structural elements depend greatly on coordination geometry preferences at the metal and the conformations of the azelate ligands. The ability of the flexible dicarboxylate tethers to access energetically similar conformations during self-assembly promoted crystallographic disorder that resulted in an intriguing 4-connected "ligand vacancy" 3-D primitive cubic-type covalent network in the cobalt and nickel derivatives. The larger ionic radius of cadmium allowed an exotridentate binding mode for the azelate carboxylate termini, generating a relatively uncommon non-interpenetrated $6^5 8$ 3-D topology constructed from orthogonally disposed sets of $[Cd(aze)]_n$ 1-D double chain motifs. Hydrogen-bonding mechanisms instilled by the dpa ligands' central amine groups also play an important structure-directing role in these extended complexes, likely by influencing the conformational reorganizations of the flexible azelate ligands. Further efforts towards the synthesis and characterization of dual-ligand coordination polymers using underutilized long, conformationally flexible α,ω-dicarboxylates are underway in our laboratory.

Complexes of fluorinated tpzb ligand often show very different physicochemical properties to their non-fluorinated analogs [17]. For example, the carbonyl stretching frequency of 2137 cm^{-1} in [Cu(Lf6)(CO)] is the highest value in the known copper(I) carbonyl complexes with tpzb ligands; this value is 71 cm^{-1} higher than that of 2066 cm^{-1} in [Cu(L0)(CO)] [19,20]. However, the Cu–CO bond length of 1.808(4) Å in [Cu(Lf6)(CO)] is experimentally equivalent to that of the corresponding distance in non-fluorinated analogs; 1.785(4) Å in [Cu(L0)(CO)] [19,21]. In addition, $^{31}P\{^{1}H\}$ NMR spectroscopy of the copper(I) triphenylphosphine complex [Cu(Lf6)(PPh_3)] showed distinctive behavior unlike that of [Cu(L0)(PPh_3)] [19b,22]. The partially trifluoromethylated L0f$^-$ ligand has also been demonstrated to be a useful ligand for systematic studies. For copper complexes with L0f$^-$, the structures of [Cu^{II}(L0f)(ONO)], [Cu^{II}(L0f)(O_2CMe)], [Cu^{II}(L0f){O_2CCH(OH)Me}], [Cu^{I}(L0f)(NCMe)], [Cu^{I}(L0f)]$_2$, and [{Cu(L0f)}$_2$(μ-O_2)] have been reported [23–27]. It is well known that the oxygen reactivity of copper(I) complexes with alkyl-substituted tpzb is carried out at low temperature [2,3]. Interestingly, when the copper(I) complex [Cu^{I}(L0f)]$_2$ was investigated by Gorun and co-workers, the resulting μ-η^2:η^2-peroxo binuclear copper(II) complex [{Cu(L0f)}$_2$(μ-O_2)] showed reversible binding property towards dioxygen even at room temperature [26,27].

Although the copper(I) complexes derived from L0f$^-$ display interesting behavior, there are only a few reports of their study [18,23–27]. In this paper, the full descriptions of the syntheses and structural characterization of new copper(I) complexes, i.e. [Cu^{I}(L0f)(CO)] (**1**) and [Cu^{I}(L0f)(PPh_3)] (**2**), derived from L0f$^-$ are described. Their structures were determined by an X-ray analysis. Further, all complexes were characterized by IR, far-IR, and NMR spectroscopy. Finally, the reactivity of copper(I) complexes toward CO/MeCN/PPh_3 was investigated.

2. Experimental

2.1. Materials

Preparation and handling of all the complexes was performed under an argon atmosphere using standard Schlenk tube techniques or in a VAC inert atmosphere glovebox containing an argon gas. Dichloromethane and toluene were carefully purified by refluxing and distilling under an argon atmosphere over phosphorous pentoxide and over sodium benzophenone kethyl, respectively [28]. Deuteriumed solvents and ^{13}C-enriched carbon monoxide were obtained from Cambridge Isotope Laboratories, Inc. Anhydrous solvent (acetone) was purchased from Aldrich Chemical Company, Inc. and stored in a glovebox. Copper(I) chloride and triphenylphosphine purchased from Wako Pure Chemical Ind. Ltd. This copper(I) chloride was purified according to a published method [29]. Other reagents are commercially available and were used without further purification. The copper(I) acetonitrile complex [Cu(L0f)(NCMe)] (**3**) was prepared by a literature procedure [23]. The synthesis of [Cu(L0f)(CO)] (**1**) and [Cu(L1)(PPh_3)] (**4**) have been reported before, however, their crystal structures have not been reported [23,29].

2.2. Measurements

IR and far-IR spectra were recorded on KBr pellets in the 4000–400 cm^{-1} region and on CsI pallets in the 650–150 cm^{-1} region, respectively, using a JASCO FT/IR-550 spectrophotometer. Abbreviations used in the description of vibration data are follows: vs, very strong; s, strong; m, medium; w, weak. For *in situ* solution IR, the sample solution was stirred in the Schlenk tube purged with carbon monoxide atmosphere for a few minutes and stirred for a day at room temperature. Then this solution was transferred to a Spectralys Specac KBr plate of solution-IR cell. ^{1}H NMR (600 MHz), ^{13}C NMR (150 MHz), and ^{31}P NMR (242 MHz) spectra were obtained on a Bruker AVANCE-600 NMR spectrometer at room temperature (296 K) in $CDCl_3$ or CD_2Cl_2. ^{19}F NMR (470 MHz) and ^{13}C NMR (125 MHz) spectra were obtained on a Bruker AVANCE-500 NMR spectrometer at room temperature (296 K) in $CDCl_3$ or CD_2Cl_2. ^{1}H and ^{13}C chemical shifts were reported as δ values downfield from the internal standard tetramethylsilane and the residual solvent peaks. ^{31}P and ^{19}F chemical shifts were referenced relative to an external standard of PPh_3 (δ 0.0 ppm) in CD_2Cl_2 and trifluorobenzene (δ 164.9 ppm) in $CDCl_3$, respectively. The elemental analysis (C, H, N) was performed by the Department of Chemistry at the University of Tsukuba.

2.3. Preparations of complexes

2.3.1. [Cu{HB(3-CF_3-5-Mepz)$_3$}(CO)], [Cu(L0f)(CO)] (*1*)

A solution of NaL0f (0.30 g, 0.62 mmol) in acetone (20 cm^3) was added to a solution of CuCl (0.066 g, 0.67 mmol) in acetone (10 cm^3) in a glovebox. After stirring for 1 h, the argon gas in the Schlenk tube was replaced by carbon monoxide. After stirring for 24 h, the solvent was evaporated under reduced pressure. The resulting solid was extracted with dichloromethane (20 cm^3). The filtrate was evaporated under reduced pressure and a white powder was obtained. Crystallization from dichloromethane/toluene at −50 °C afforded colorless crystals. Yield: 71% (0.25 g, 0.45 mmol). *Anal.* Calc. for $C_{16}H_{13}N_6BCuF_9O$: C, 34.90; H, 2.38; N, 15.26. Found: C, 34.62; H, 2.42; N, 14.90%. IR (KBr, cm^{-1}): 3140m, 2995w, 2575m, 2107vs (^{12}C≡O), 1495, 1471s, 1261s, 1173s, 1063s, 1002s, 842s, 643s. far-IR (CsI, cm^{-1}): 591w, 561w, 467s, 455m, 438m, 422s (Cu–^{12}C), 389m, 365w, 343w, 295s, 216m. ^{1}H NMR (CD_2Cl_2) (δ): 2.44 (s, 9H, *Me*), 6.26 (s, 3H, pz-4*H*). ^{13}C NMR (CD_2Cl_2) (δ): 12.5 (*C*H_3), 104.2 (pz-4*C*), 121.0 (*C*F_3, q, $J_{C,F}$ = 269 Hz), 142.2 (pz-3*C*, q, $J_{C,F}$ = 37 Hz), 145.1 (pz-5*C*). ^{19}F NMR ($CDCl_3$) (δ): −61.9 (C*F*$_3$).

A ^{13}CO labeled complex was prepared by the same method as the corresponding unlabeled complex, but using ^{13}CO gas. IR (KBr, cm^{-1}): 2058s (^{13}C≡O). far-IR (CsI, cm^{-1}): 419w (Cu–^{13}C). ^{1}H NMR (CD_2Cl_2) (δ): 172.9 (*^{13}CO*).

2.3.2. [Cu{HB(3-CF_3-5-Mepz)$_3$}(PPh_3)], [Cu(L0f)(PPh_3)] (*2*)

A solution of NaL0f (0.30 g, 0.62 mmol) in acetone (20 cm^3) was added to a solution of CuCl (0.061 g, 0.62 mmol) in acetone (10 cm^3) in a glovebox. After stirring for 1 h, a solution of PPh_3 (0.17 g, 0.66 mmol) in acetone (10 cm^3) was added to the solution. After stirring for 1 h, the solvent was evaporated under reduced pressure. The resulting solid was extracted with dichloromethane (20 cm^3). The filtrate was evaporated under reduced pressure and a white powder was obtained. Crystallization from dichloromethane/toluene at −50 °C afforded colorless crystals. Yield: 59% (0.28 g, 0.36 mmol). *Anal.* Calc. for $C_{33}H_{28}N_6BCuF_9P{\cdot}CH_2Cl_2$: C, 46.95; H, 3.48; N, 9.66. Found: C, 47.23; H, 3.43; N, 9.69%. IR (KBr, cm^{-1}): 3447w, 3138m, 3057m, 2564m, 1496m, 1467s, 1437s, 1257vs, 1197vs, 1165vs, 1134vs, 1065vs, 994s, 796s, 743s, 695s, 647m. far-IR (CsI, cm^{-1}): 619w, 561w, 528s, 502s, 468m, 439m, 426w, 390m, 346w, 299m, 252w, 225m, 193m. ^{1}H NMR (CD_2Cl_2) (δ): 2.49 (s, 9H, *Me*), 6.23 (s, 3H, pz-4*H*), 7.26–7.40 (m, 9H, P*Ph*$_3$(o,p)), 7.48–7.55 (m, 6H, P*Ph*$_3$(m)). ^{13}C NMR ($CDCl_3$) (δ): 13.5 (*C*H_3), 105.1 (pz-4*C*), 121.2 (*C*F_3, q, $J_{C,F}$ = 270 Hz)), 143.2 (pz-3*C*, q, $J_{C,F}$ = 37 Hz)), 145.3 (pz-5*C*). ^{19}F NMR ($CDCl_3$) (δ): −60.2 (C*F*$_3$). ^{31}P NMR (CD_2Cl_2) (δ): 10.60 (s, br, *P*Ph_3).

2.3.3. [Cu{HB(3,5-iPr_2pz)$_3$}(PPh_3)], [Cu(L1)(PPh_3)] (*4*)

The preparation was carried out by the same method as that for the complex **2** using CuCl (0.063 g, 0.64 mmol), KL1 (0.32 g, 0.63 mmol), and PPh_3 (0.16 g, 0.63 mmol) in acetone (50 cm^3) in

a glovebox [13]. Crystallization from dichloromethane/propionitrile (1/2) at −50 °C gave colorless crystals. Yield: 25% (0.16 g, 0.16 mmol).

*2.3.4. Reaction of [Cu(L0f)(CO)] (**1**) or [Cu(L0f)(PPh$_3$)] (**2**) with MeCN*

In a Schlenk tube, complex **1** or **2** was dissolved in acetonitrile and stirred at room temperature for 72 h under an argon gas. The resultant solution was evaporated to dryness under reduced pressure, and then the white solid obtained was characterized by IR and ^{1}H NMR spectroscopy, showing almost negligible formation of [Cu(L0f)(NCMe)] (**3**) from both reactions.

*2.3.5. Reaction of [Cu(L0f)(CO)] (**1**) or [Cu(L0f)(NCMe)] (**3**) with PPh$_3$*

In a Schlenk tube, complex **1** or **3** and PPh$_3$ (10 eq) was dissolved in dichloromethane and stirred at room temperature for 72 h under an argon gas. The resultant solution was evaporated to dryness under reduced pressure, and then the white solid obtained was characterized by IR and ^{1}H NMR spectroscopy, showing almost quantitative formation of [Cu(L0f)(PPh$_3$)] (**2**) from both reactions.

*2.3.6. Reaction of [Cu(L0f)(PPh$_3$)] (**2**) or [Cu(L0f)(NCMe)] (**3**) with CO*

In a Schlenk tube, complex **1** or **3** was dissolved in dichloromethane under an argon gas. The atmosphere was replaced by carbon monoxide, and the solution was stirred at room temperature for 72 h. The resultant solution was evaporated to dryness under reduced pressure, and the white solid obtained was characterized by IR and ^{1}H NMR spectroscopy, showing small quantity of [Cu(L0f)(CO)] (**1**) from complex **2** and almost quantitative formation of complex **1** from **3**.

2.4. Crystal structure determination

The diffraction data for complexes **1**, **2**, and **4** were measured on a Rigaku/MSC Mercury CCD system with graphite monochromated Mo Kα (λ = 0.71069 Å) radiation at −89 ± 1 °C. Each crystal was mounted on the tip of a glass fiber by highly viscous oil. The unit cell parameters of each crystal were determined from 6 image frames using Rigaku Daemon software and refined using CRYSTALCLEAR [30]. Data were collected in 0.5° intervals for 48 s/frame (**1**) and for 32 s/frame (**2** and **4**) in ϕ and ω to a maximum 2θ value of 55°. A total of 744 oscillation images were collected. The highly redundant data sets were reduced using CRYSTALCLEAR and corrected for Lorentz and polarization effects. An empirical absorption correction was applied [30–32]. The structures were solved by direct methods (SIR97 [33] or SHELX97 [34]). The position of the metal atoms and their first coordination sphere were located from the *E*-map; other non-hydrogen atoms were found in alternating difference Fourier syntheses (DIRDIF99 [35]). Least-squares refinement on *F* was conducted using CRYSTALSTRUCTURE with anisotropical displacement parameters for non-hydrogen atoms, and hydrogen atoms were placed in calculated positions [31,32]. One of CF_3 group of **1** was highly disordered, and each fluorine atoms was refined with a site occupancy factor of 0.50. Higher *R* and GOF values of **4** are due to the disordered dichloromethane molecules in the unit cell. Crystal data and refinement parameters for **1**, **2**, and **4** are as follows. For **1**: formula: $C_{16}H_{13}BCuF_9N_6O$, crystal system: monoclinic, space group: $P2_1/m$ (No. 11), lattice parameters: a = 8.1639(4), b = 13.7720(5), c = 9.8864(4) Å, β = 106.1026(5)°, V = 1067.95(8) Å^3, Z = 2, D_{calc} = 1.712 g cm^{-3}, μ = 11.222 cm^{-1}, reflections collected = 8677, unique reflections = 2531, R_{int} = 0.018, no. of observations = 2281 ($I > 3\sigma(I)$), R = 0.033, Rw = 0.047. For **2**·CH_2Cl_2: formula: $C_{34}H_{30}BCl_2CuF_9N_6P$, crystal system: triclinic, space group: $P\bar{1}$ (No. 2), lattice parameters: a = 11.445(7), b = 11.456(5), c = 18.471(4) Å, α = 72.05(13), β = 72.16(13), γ = 60.03(11)°, V = 1961.4(14) Å^3, Z = 2, D_{calc} = 1.473 g cm^{-3}, μ = 8.097 cm^{-1}, reflections collected = 15 479, unique reflections = 8587, R_{int} = 0.020, no. of observations = 6961 ($I > 3\sigma(I)$), R = 0.050, Rw = 0.060. For **4** · 3CH_2Cl_2: formula: $C_{48}H_{67}BCl_6CuN_6P$, crystal system: monoclinic, space group: $P2_1/n$ (No. 14), lattice parameters: a = 12.5017(2), b = 19.0580(5), c = 22.8008(5) Å, β = 95.7520(4)°, V = 5405.1(2) Å^3, Z = 4, D_{calc} = 1.285 g cm^{-3}, μ = 7.674 cm^{-1}, reflections collected = 42 294, unique reflections = 12 301, R_{int} = 0.034, no. of observations = 9327 ($I > 3\sigma(I)$), R = 0.066, Rw = 0.089.

3. Results and discussion

3.1. Synthesis

All copper(I) complexes were prepared in a glovebox to avoid reaction with atmospheric dioxygen and moisture. Copper(I) carbonyl complex **1** was obtained from the reaction of the unpurified reactive [Cu(L0f)]$_2$ with carbon monoxide [23,24]. Copper(I) triphenylphosphine complex **2** was obtained in the same manner as for complex **1** but using PPh$_3$. Finally, copper(I) triphenylphosphine complex **4** was obtained as crystals using the ligand L1$^-$ by the reported method similar to that used for complex **2** [29].

3.2. Crystal structures

The structures of complexes **1**, **2**, and **4** were determined by X-ray crystallography, indicating that all complexes are mononuclear. Molecular structures of these complexes with selected bond distances and angles in the respective figure captions are shown in Figs. 1–3. All the complexes feature a tetrahedral coordination geometry defined by the three nitrogen atoms of L0f$^-$ or L1$^-$ and the carbon atom of carbon monoxide in complex **1**, or the phosphorus atom of triphenylphosphine in complexes **2** and **4**.

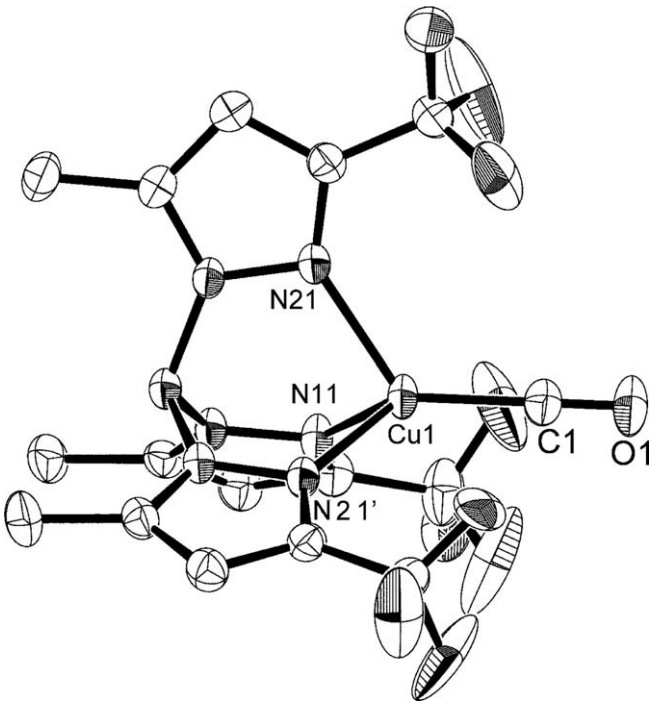

Fig. 1. Molecular structure of [Cu(L0f)(CO)] (**1**) showing 50% displacement ellipsoids and the atom labeling schemes. All hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°) are as follows: Cu1–C1, 1.799(3); Cu1–N11, 2.042(2); Cu1–N21, 2.062(2); C1–O1, 1.122(3); Cu1–C1–O1, 180.0(2); N11–Cu1–C1, 123.52(10); N21–Cu1–C1, 125.43(6), N11–Cu1–N21, 90.96(6); N21–Cu1–N21′, 90.09(6). Symmetry operators: $x, -y + 1/2, z$.

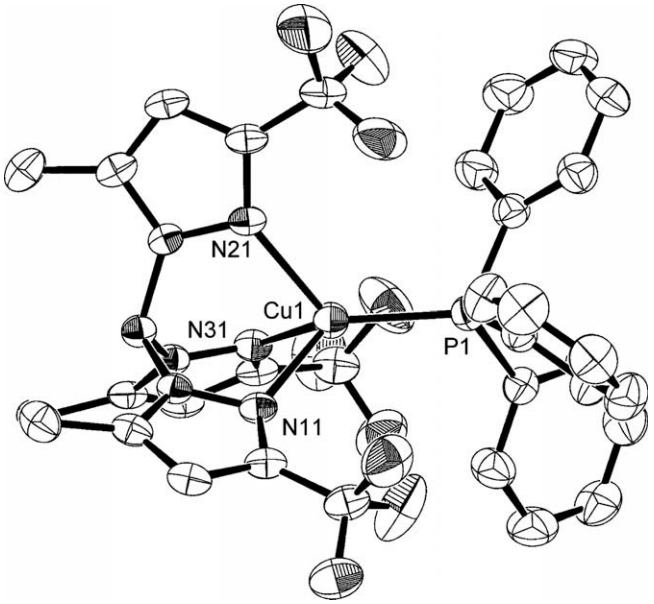

Fig. 2. Molecular structure of [Cu(L0f)(PPh_3)] (**2**) showing 50% displacement ellipsoids and the atom labeling schemes. All hydrogen atoms and CH_2Cl_2 molecules of crystallization are omitted for clarity. Selected bond distances (Å) and angles (°) are as follows: Cu1–P1, 2.2150(7); Cu1–N11, 2.170(2); Cu1–N21, 2.177(2); Cu–N31, 2.176(2); N11–Cu1–P1, 125.33(5); N21–Cu1–P1, 125.50(5), N31–Cu1–P1, 125.49(8); N11–Cu1–N21, 89.76(9); N11–Cu1–N31, 89.71(9); N21–Cu1–N31, 89.79(8).

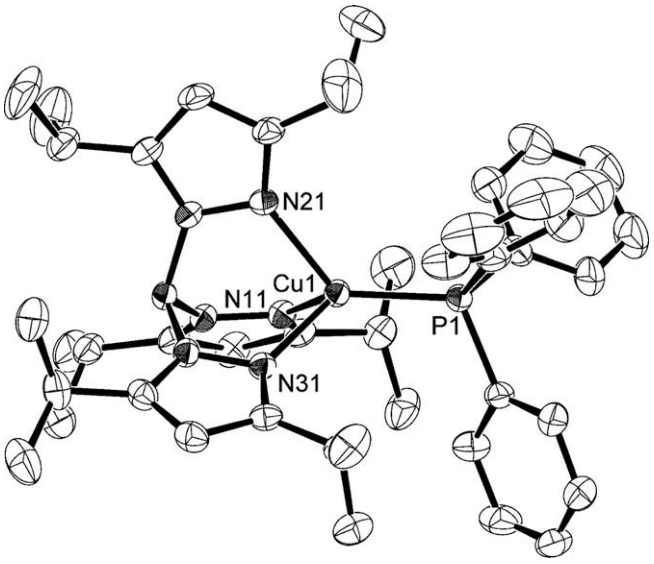

Fig. 3. Molecular structure of [Cu(L1)(PPh_3)] (**4**) showing 50% displacement ellipsoids and the atom labeling schemes. All hydrogen atoms and CH_2Cl_2 molecules of crystallization are omitted for clarity. Selected bond distances (Å) and angles (°) are as follows: Cu1–P1, 2.1635(10); Cu1–N11, 2.065(3); Cu1–N21, 2.093(3); Cu–N31, 2.088(3); N11–Cu1–P1, 125.01(9); N21–Cu1–P1, 127.69(9), N31–Cu1–P1, 121.90(8); N11–Cu1–N21, 90.82(12); N11–Cu1–N31, 90.89(12); N21–Cu1–N31, 89.82(11).

Complex **1** has a crystallographically imposed plane of symmetry containing one of the pyrazolyl rings, boron atom, copper atom, and the carbon and oxygen atoms of the carbon monoxide molecule. In complex **1** as in the previously described copper(I) carbonyl complexes with other tpzb ligands, the copper(I) ions are almost linearly ligated by carbon monoxide with Cu–C≡O angles in the range of 176–180° (Table 1). The Cu–C distance of 1.799(3) Å in complex **1** is experimentally equivalent to the Cu–C distances of 1.808(4) Å in [Cu(Lf6)(CO)], 1.785(4) Å in [Cu(L0)(CO)], 1.783(7) Å in [Cu(L1′)(CO)](PF_6) [8,19a,21], and 1.769(8) Å in [Cu(L1)(CO)] [29]. Thus, crystallography does not reliably differentiate between the structures. Differences were expected, as explained in the following. It is noted that carbon monoxide is weak σ-donor and strong π*-acceptor ligand. The Cu(I)–CO interaction is entirely dominated by π back-bonding between the two degenerate π* orbitals of CO and two t_2 type d orbitals of copper(I) ion [8]. The levels of electron densities around copper(I) center in the complexes with tpzb ligands are influenced by substituents at third and/or fifth position(s) of the pyrazolyl rings. As the number of the electron-withdrawing substituents increase, the levels of electron density around copper(I) center decrease. In addition, the electron densities of copper(I) center in the complexes with tpzm ligands are lower than those of copper(I) center in the complexes with alkyl group substituted tpzb ligands because of effect of the total charge of the N3 type ligands [8]. According to the above consideration, the C≡O distance is supposed to be shorter as the electron density around copper(I) ion is lower. However, this trend was not also observed from X-ray crystallography; 1.122(3) Å in **1**, 1.118(10) Å in [Cu(L0)(CO)], and 1.110(5) Å in [Cu(Lf6)(CO)] [19a,21]. This observation is consistent with no relationships between structural parameters and some properties for Cu–C, C≡O, and Cu–P bonds in other system [8,11–13].

The Cu–P bond distance of 2.2150(7) Å in complex **2** is experimentally equivalent to 2.219(1) Å found in [Cu(Lf6)(PPh_3)] and both are longer than the corresponding distances of 2.166(6) Å in [Cu(L0)(PPh_3)] and 2.1635(10) Å in complex **4**, as collated in Table 2. Both complexes **2** and **4** have crystallographic pseudo C_{3v} symmetry so that three pyrazolyl rings of ligand and the three phenyl rings of triphenylphosphine are alternately placed to avoid the steric repulsion. Triphenylphosphine is a strong σ-donor ligand, which is entirely different from carbon monoxide. As the electron density around copper(I) ion is lower, triphenylphosphine coordinates strongly to copper(I) ion. Therefore, the Cu–P distance in complex **2** with electron-withdrawing CF_3 group should be shorter than the Cu–P distances with other alkyl group substituted tpzb ligands. Again, this trend was not confirmed by X-ray crystallography. However, the spectroscopic results do follow the expected trends as detailed below.

3.3. IR spectra

The C≡O stretching frequencies of the copper(I) carbonyl complexes with tpzb and tpzm ligands are also listed in Table 1. The copper(I) carbonyl complexes exhibit intense C≡O stretching vibrations in 2050–2100 cm^{-1} middle-IR region [8,44]. The C≡O stretching frequency of 2107 cm^{-1} in complex **1** is 41 cm^{-1} higher than 2066 cm^{-1} observed for [Cu(L0)(CO)] and is 30 cm^{-1} lower than 2137 cm^{-1} in [Cu(Lf6)(CO)]. These C≡O stretching frequency shifts are consistent with expected trends in electron density around copper(I) ion in these carbonyl complexes. That is to say, as the electron density around copper(I) ion in the carbonyl complex is lower, the C≡O stretching frequency is shifted to higher energy side as explained in Section 3.2. The C≡O stretching frequencies in complex **1**, the other carbonyl complexes with tpzb ligands containing halogenated substituents, and the carbonyl complexes with tpzm ligands are shifted to higher energy side than those in the complexes with tpzb ligands containing alkyl side chains. In addition, the electron-donating substituents such as the *i*Pr or *t*Bu groups lead to the lower C≡O stretching frequencies compared to methyl or aryl substituents in both the tpzm and tpzb complexes. These comparisons lead to the following order in the C≡O stretching frequencies for the pyrazolyl substituents in the tpzb ligands:

Table 1
Selected structural parameters and C–O streching frequencies of copper(I) carbonyl complexes with coordinated tpzb and tpzm ligands.

In the middle-IR region, no characteristic bands were observed in copper(I) triphenylphosphine complexes.

3.4. Far-IR spectra

The copper(I) carbonyl complexes exhibit intense Cu–C stretching vibrations in 420–470 cm^{-1} far-IR region [8,44]. The Cu–C stretching frequency of 422 cm^{-1} in complex **1** is confirmed by the ^{13}CO labeling experiment (419 cm^{-1} (Cu–^{13}C)). This value is 20–40 cm^{-1} lower than the Cu–C stretching frequencies of 466 cm^{-1} in [Cu(L1)(CO)] and of 445 cm^{-1} in [Cu{HB(3-*t*Bu-5-*i*Prpz)$_3$}(CO)] [8]. These Cu–C stretching frequency shifts are consistent with the expected variations in electron density around copper(I) ion in these carbonyl complexes, demonstrating the anticipated electron-withdrawing effects.

The far-IR spectra of the copper(I) triphenylphosphine complex **2** show two strong bands at 528 and 502 cm^{-1}, which are assignable to Cu–P stretching vibration and C–P–C bending vibrations [13,44,45]. Unfortunately, the Cu–P stretching vibration could not be identified from the spectra. This observation is consistent with the bands in other alkyl group substituted tpzb and tpzm ligands due to these broad peaks [13].

3.5. NMR spectra

^{1}H, ^{13}C, and ^{19}F NMR spectra were measured for L0f$^-$ ligand and the copper(I) complexes **1**, **2**, and **3**. In all cases, the expected signals of the protons, carbon, and fluorine atoms are observed with the exception of the signal due to the BH proton which was not observed experimentally, in accord with expectation [8]. In addition, ^{31}P NMR spectra were measured for complexes **2** and **4**. The ^{31}P chemical shifts of copper(I) triphenylphosphine complexes are listed in Table 2.

In the carbonyl complex **1**, the signal of the carbonyl carbon atom can be detected by ^{13}C NMR spectroscopy. In general, ^{13}C NMR resonances for the terminal CO ligands in classical metal carbonyls appear in the range of 184–223 ppm [8,43]. Complex **1** prepared in this study using unlabeled CO showed no signal due to the carbonyl cabon atom owing to the low natural abundance of ^{13}CO. Therefore, complex **1** was also prepared using ^{13}C-enriched carbon monoxide. Using the labeled compound of **1**, a broad signal of the carbonyl carbon atom is observed at 172.9 ppm as shown in Fig. 4. The ^{13}C NMR signals of the carbonyl carbons in [Cu(L1′)(CO)][PF_6) (174.0 ppm) and [Cu(L1′)(CO)][ClO_4) (173.8 ppm) also appear as a broad resonance. It is noted that the ^{13}C NMR signals due to

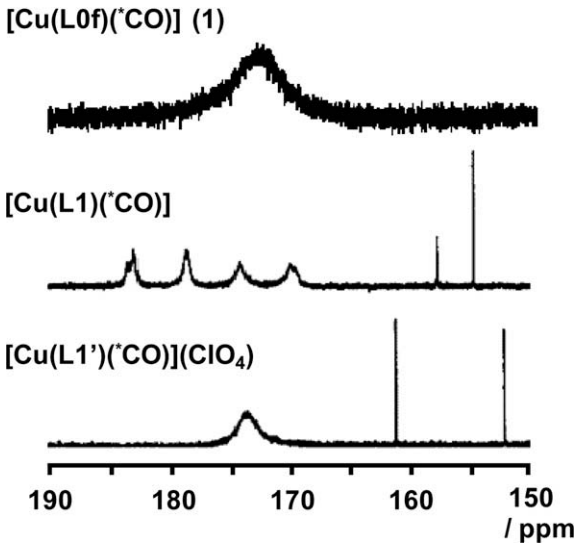

Fig. 4. ^{13}C NMR spectra of the ^{13}CO enriched copper(I) carbonyl complexes.

the carbonyl carbons are split into four broad resonances in [Cu(L1)(CO)] (centered at 176.4 ppm) and [Cu{HB(3-*t*Bu-5-*i*Prpz)$_3$}(CO)] (174.0 ppm) [8]. The splitting of each of these signals is effected by the bonding strength of Cu–C. As the bonding strength of Cu–C becomes stronger, the coupling between ^{13}C and ^{65}Cu ($I = 3/2$) is observed. Thus, the signals of the carbonyl carbon atoms with a strong Cu–C bond in the tpzb complexes are split into four broad resonances. Conversely, the signals in the carbonyl complexes with a weak Cu–C bond in tpzm ligands are not split and appear rather as a broad resonance. Interestingly, even although complex **1** is carbonyl complex with tpzb, the signal of the carbonyl carbon atom appear as a broad resonance. This result indicates that the electric differences of L0f$^-$ (including electron-withdrawing CF_3 group) are similar to tpzm ligands, whereby both ligands decrease the electron density around copper(I) ion.

In the triphenylphosphine complex **2**, the signal of the phosphorus atom in PPh_3 can be detected by ^{31}P NMR spectroscopy as shown in Fig. 5. The ^{31}P chemical shifts of PPh_3 in complex **2** and other triphenylphosphine complexes appear downfield from the free triphenylphosphine resonance ($\delta = 0.0$), indicating a decrease in shielding due to the presence of the metal, which is the expected for a σ-donor ligand like phosphine. Moreover, the ^{31}P NMR signals of the phosphorus atom in these complexes are broad. The half width of the signal of 445.9 Hz in complex **2** is narrower than the half widths of the signals, i.e. 1885.9 Hz in [Cu(L0)(PPh_3)] and 1628.5 Hz in [Cu(L1)(PPh_3)] (Table 2). On the other hand, the half width of the signal of 323.5 Hz in the tpzm triphenylphosphine complex [Cu(L1′)(PPh_3)](ClO_4) is also narrower than the half widths of these signals. According to the literature, the differences in broadness of these signals are due to the inherent instability of the complexes in solution [13] and therefore, correlate with the bonding strength of the Cu–P bond in solution. The bonding strength of each Cu–P bond is consistent with the differences in electron density around the copper(I) ion in each complexes. That is to say, as the electron density around copper(I) ion is lower, the bonding strength of Cu–P is stronger as explained in the Section 3.2. Therefore, the bonding strength of Cu–P bond in complex **2** with electron-withdrawing CF_3 group is stronger than the bonding strengthes of Cu–P in other complexes with alkyl-substituted tpzb ligands. Moreover, these differences of the broadness of the signals may be caused by differences of bulkiness of the substituents at the third position of the pyrazolyl rings. However, the broadness of the signal of complex **2** is narrower than that of [Cu(L0)(PPh_3)], whose bulkiness is much small than that of L0f$^-$. Thus, these differences are due to electron-withdrawing CF_3 group, not due to their gross structural differences.

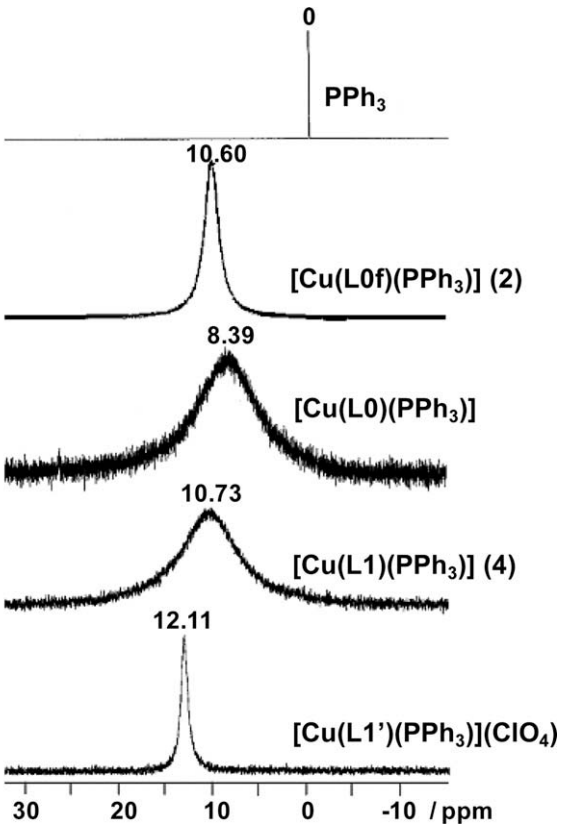

Fig. 5. ^{31}P NMR spectra of copper(I) triphenylphosphine complexes.

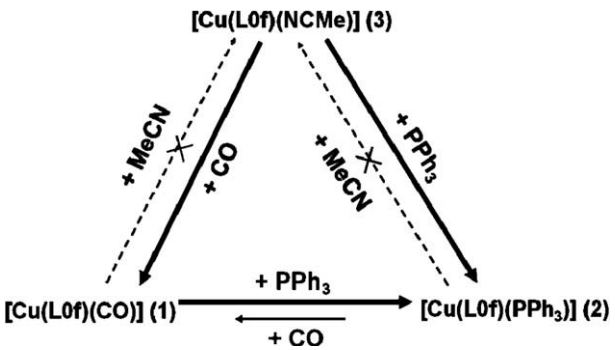

3.6. Reactivity of each complex

In this work, the reaction cycle of the copper(I) complexes between **1**, **2** and **3** was also studied. The reactivity of each complex is described in Scheme 1.

First, the reactivity between complexes **1** and **2** in Scheme 1 is discussed. The reaction of **1** with 1 equivalent of PPh_3 was performed in dichloromethane solution. The C≡O stretching frequency at 2107 cm^{-1} in complex **1** was not observed which indicates that this reaction proceeds to completion to generate the triphenylphosphine complex **2**; ^1H NMR spectrum supports this observation. The reverse reaction was also attempted. Thus, the reaction of complex **2** with CO was also performed in dichloromethane. After this reaction, a weak C≡O stretching frequency of 2107 cm^{-1} due to complex **1** was observed. This result indicates that the reaction of **2** with CO generates a small amount of carbonyl complex **1**; the ^1H NMR spectrum supports this indication. In addition, the solution-IR spectrum of the reaction mixture corresponds to the result obtained from the solid-state IR spectra. ^1H NMR spectra of reaction solution ($CDCl_3$) also corresponds the same result of the above ^1H NMR spectra. In summary, the stability experiments between **1** and **2** revealed that **2** is more stable than **1**.

Second, the reactivity between **1** and **3** in Scheme 1 was investigated. The reaction of complex **1** with MeCN and the reverse reaction of complex **3** with CO were performed. After reaction, the strong C≡O stretching frequency of 2107 cm^{-1} in complex **1** is observed in both reaction products indicating that the reaction of complex **1** with MeCN does not proceed and the reaction of complex **3** with CO proceeds to generate carbonyl complex **1**. ^1H NMR spectra confirm these indications. The stability experiments between **1** and **3** revealed that **1** is much more stable than **3**.

Finally, the reactivity between **2** and **3** in Scheme 1 was investigated. In this system, the reaction products were analyzed with only ^1H NMR spectra, since no characteristic bands such as

Scheme 1. Reaction cycle between **1**, **2**, and **3**.

carbonyl bands are observed in these copper(I) triphenylphosphine and acetonitrile complexes. After the reaction of complex **2** with MeCN, the resonances of complex **2** were observed in the NMR spectrum, indicating no discernable reaction. It is acknowledged that these results may be due to dissociation of the coordinated MeCN molecule under reduced pressure. However, the ^{1}H NMR spectrum of reaction solution (CD_3CN) corresponds the same result. Conversely, after reaction of complex **3** with PPh_3, only the resonances due to complex **2** were observed in ^{1}H NMR spectrum. The stability experiments of **2** and **3** revealed that **2** is much more stable than **3**. Concluding this investigation of the above reactivity tests, the descending order of the stability of the complexes **1**–**3** is **3** < **1** < **2**.

4. Conclusion

In this paper, two novel copper(I) complexes **1** and **2** with L0f$^-$ were reported. The electron density around copper(I) in the complexes with L0f$^-$ is lower than those in the other complexes with alkyl-substituted tpzb ligands. Therefore, the copper(I) complexes with L0f$^-$ may show very different physicochemical properties compared with the non-fluorinated analogs.

First, in copper(I) carbonyl complexes, as the electron density around copper(I) ion is lower, the strength of Cu–C is weaker and strength of C≡O is stronger. While not shown by X-ray crystallography, these results were confirmed by far-IR and ^{13}C NMR spectra. The Cu–C stretching frequency in complex **1** is by 20–40 cm^{-1} lower than the Cu–C stretching frequencies in [Cu(L1)(CO)] and [Cu{HB(3-*t*Bu-5-*i*Prpz)$_3$}(CO)]. The ^{13}C NMR signals of the carbonyl carbons in **1** and the complexes with tpzm ligands appear as a broad peak. On the other hand, the ^{13}C NMR signals of the carbonyl carbons appear to be split into four broad peaks in the complexes with alkyl group substituted tpzb ligands. Additionally, the C≡O distances were supposed to be shorter as the electron density around copper(I) ion is lower, but this trend was not observed by X-ray crystallography. However, the C≡O stretching frequency in complex **2** is 40 cm^{-1} higher than that in [Cu(L0)(CO)] and is 31 cm^{-1} lower than that in [Cu(Lf6)(CO)] in IR spectra.

Second, in copper(I) triphenylphosphine complexes, as the electron density around copper(I) ion is lower, triphenylphosphine coordinates strongly to copper(I) ion. In the ^{31}P NMR spectra, the broadness of the signal in complex **2** is different from the signals of the phosphorus atom in copper(I) triphenylphosphine complexes with tpzb ligands, in which the signals appear as a broader resonance. The half widths of the signals in complex **2** and the complexes with tpzm ligands are narrower than those in the complexes with alkyl group susbtituted tpzb ligands. This means that the electron density of complex **2** is very close to that of neutral tpzm due to electron-withdrawing CF_3 group.

Finally, the reaction cycle of the copper(I) complexes between the complexes **1**–**3** was studied by ^{1}H NMR, solid-state IR, and *in situ* solution IR spectroscopy. The descending order of the stability of the complexes **1**–**3** is **3** < **1** < **2**. These stabilities of the complexes with the electron-withdrawing CF_3 ligand are consistent with the complexes with alkyl group substituted tpzb ligands [29].

Supplementary data

CCDC 695036, 695037, and 695038 contain the supplementary crystallographic data for **1**, **2**, and **4**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

spectroscopy. The TEM images were obtained on a Philips EM208 transmission electron microscope with an accelerating voltage of 100 kV. Fourier transform infrared (FT-IR) spectra were recorded on Shimadzu Varian 4300 spectrophotometer in KBr pellets. The magnetic measurements were carried out in a vibrating sample magnetometer (VSM, BHV-55, Riken, Japan) at room temperature.

2.3. Synthesis of $NiFe_2O_4$ nanocrystals

In a typically synthesis, a 0.4 M (25 mL) solution of iron chloride ($FeCl_3 \cdot 6H_2O$) and a 0.2 M (25 mL) solution of nickel chloride ($NiCl_2 \cdot 6H_2O$) were mixed in double distilled deionized water. Deionized distilled water was used as the solvent in order to avoid the production of impurities in the final product. A specified amount of octanoic acid was added to the solution as a surfactant and coating material. A 1.5 M (25 mL) solution of sodium hydroxide (NaOH) was prepared and slowly added to the salt solution dropwise. The pH of the solution was constantly monitored as the NaOH solution was added. The reactants were constantly stirred using a magnetic stirrer until a pH level of 7–8 was reached. The liquid precipitate was then brought to a reaction temperature of 80 °C and stirred for 1 h. The product was then cooled to room temperature. To get particles free from sodium and chlorine compounds, the precipitate was washed twice with distilled water and then with ethanol to remove the excess surfactant from the solution. To isolate the supernatant liquid, the beaker contents were then centrifuged for 15 min at 3000 rpm. The supernatant liquid was then decanted, and then centrifuged until only thick black precipitate remained. The obtained products were dried at 100 °C for 8 h. The acquired substance was then ground into a fine powder. At this stage the product ($NiFe_2O_4$) contains some associated water (up to 10 wt%), which was then removed by heating at 600 °C for 4 h (Fig. 1). The final samples were then confirmed by different techniques, such as XRD, SEM, TEM, etc.

3. Results and discussion

Fig. 2 shows the XRD pattern of the $NiFe_2O_4$. XRD peaks for the nanometer sized nickel ferrite (n-$NiFe_2O_4$) sample are significantly broader than those for a micrometer sized sample, indicating a very small particle size [17]. The crystallinity and structure of the $NiFe_2O_4$ nanocrystals were also confirmed by powder X-ray diffraction (XRD). Fig. 2a shows the XRD diffractograms for the studied sample. All the characteristic peaks of $NiFe_2O_4$ are present: 30.29° (220), 35.7° (311), 37.31° (222), 43.36° (400), 53.80° (422), 57.36° (511), 62.92° (440) and 74.64° (533). The diffractogram exhibits sharp lines; this indicates that the sample has high crystallinity. From the XRD data, the crystallite size (D_c) of the as-prepared $NiFe_2O_4$ particles was calculated to be 22 nm, using the Debye–Scherrer equation [18],

$$D_c = \frac{K\lambda}{\beta \cos\theta}$$

where β is the breadth of the observed diffraction line at its half-intensity maximum, K is the so-called shape factor, which usually takes a value of about 0.9, and λ is the wavelength of the X-ray source used in the XRD. No characteristic peaks of impurities can be detected. The strong and sharp reflection peaks suggest that the as-prepared nanocrystals are well crystallized. Fig. 2b shows the XRD patterns of the standard $NiFe_2O_4$ from JCPDS No. 74–2081.

The morphology and particle sizes of the as-prepared sample were determined by SEM and TEM. The SEM images of $NiFe_2O_4$ are shown in Fig. 3. These indicate that sphere-like $NiFe_2O_4$ nanostructures obtained by this method are uniform in both morphology and particle size, but have agglomeration to some extent. Fig. 4 shows a typical TEM image of $NiFe_2O_4$. The average size was calculated to be 25 ± 5 nm from the measurements on the TEM micrographs.

The IR spectra of the $NiFe_2O_4$ samples show small differences in the range 4000–1000 cm^{-1}. In the range 1000–100 cm^{-1}, the IR bands of solids are usually assigned to vibration of ions in the crys-

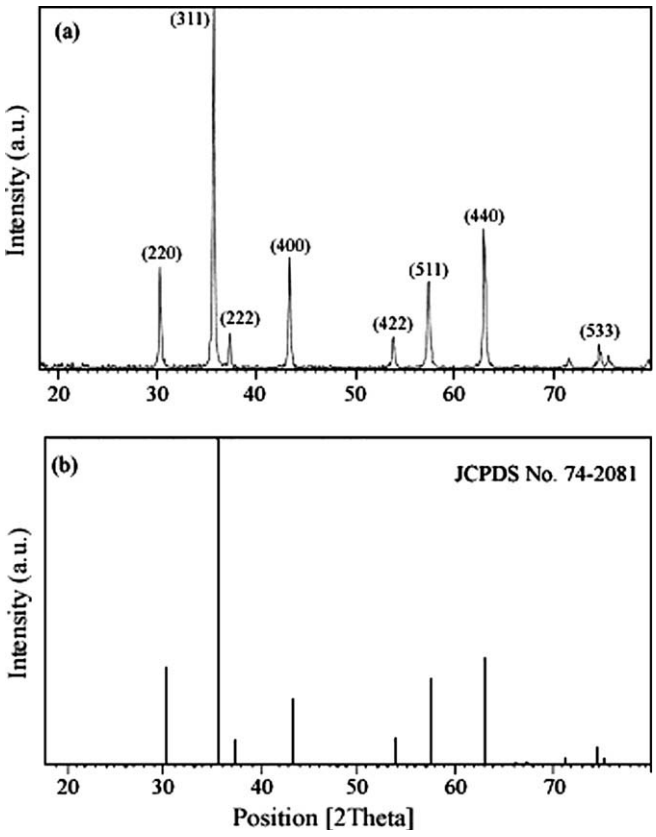

Fig. 2. (a) XRD pattern of the $NiFe_2O_4$ nanocrystals. (b) The standard $NiFe_2O_4$ from JCPDS No. 74–2081.

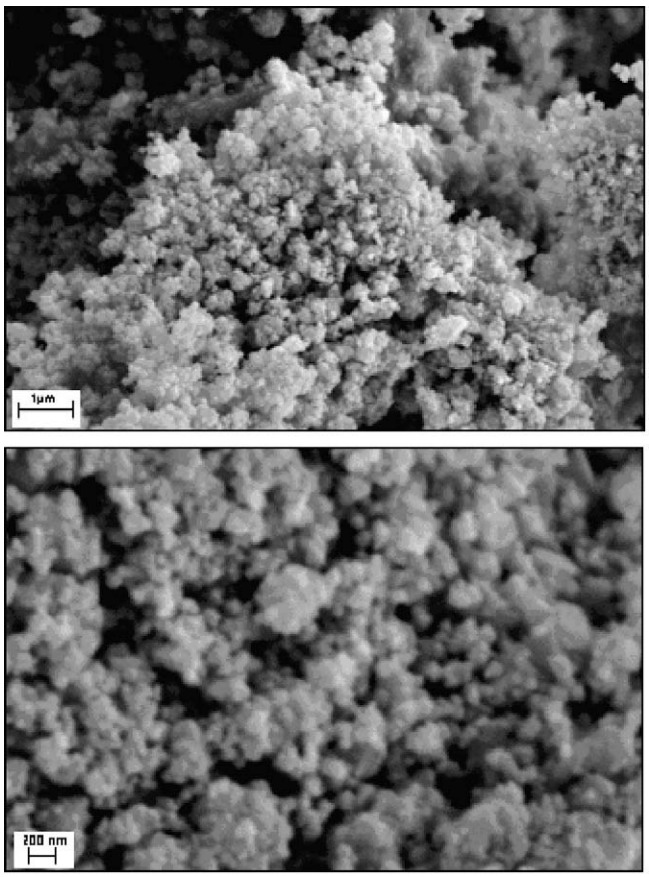

Fig. 3. SEM images of the $NiFe_2O_4$ nanocrystals.

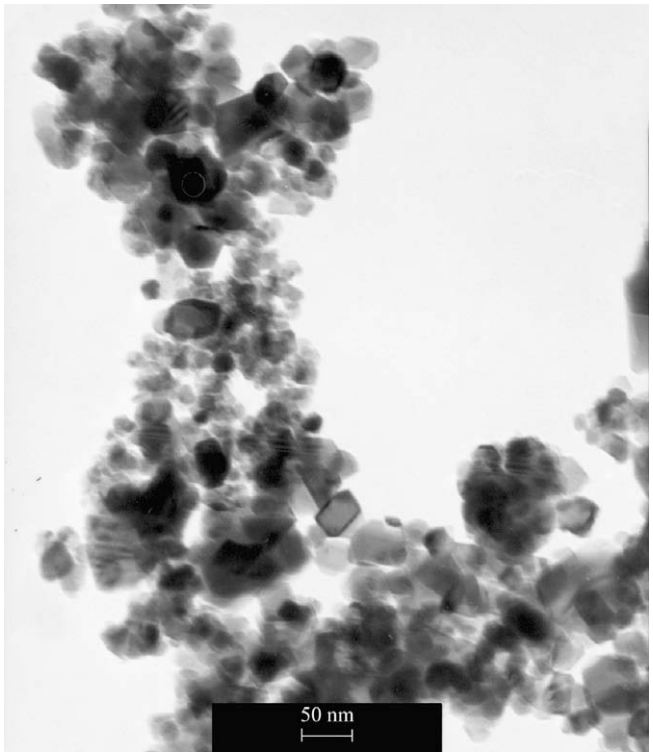

Fig. 4. TEM image of the $NiFe_2O_4$ nanocrystals prepared after calcination at 600 °C for 4 h.

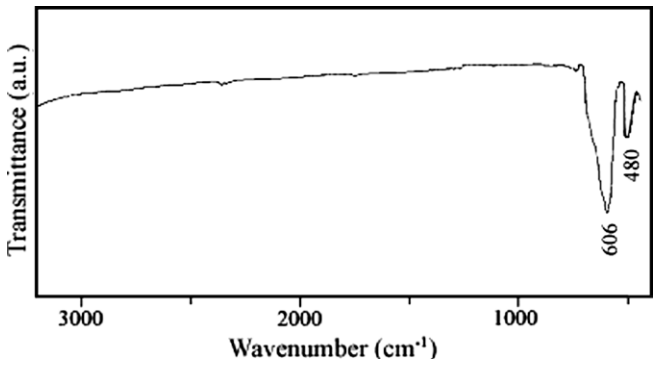

Fig. 5. IR spectrum of the $NiFe_2O_4$ nanocrystals calcined at 600 °C (4 h).

tal lattice [15]. Two main broad metal–oxygen bands are seen in the IR spectra of all spinels, and ferrites in particular. The highest one ν_1 (Fig. 5), observed at 606 cm^{-1}, corresponds to intrinsic stretching vibrations of the metal at the tetrahedral site, $M_{tetra} \leftrightarrow O$, whereas the ν_2-lowest band, usually observed at 480 cm^{-1}, is assigned to octahedral-metal stretching, $M_{octa} \leftrightarrow O$ [19,20]. However, no clear peak due to octahedrally coordinated metal ions was observed, which would be expected to be around 400 cm^{-1}. This may be due to the broadening of this peak attributed to very small particles of spinel ferrites [21].

The room temperature magnetization curve of the $NiFe_2O_4$ is shown in Fig. 6. The magnetic properties of the sample were measured by using a VSM, which showed that the sample exhibited typical ferromagnetic behavior at room temperature, while a finite coercivity of 245.5 Oe was present at 300 K (Fig. 6). The observed value of saturation magnetization of the sample (23.13 emu/g) is significantly lower than that for the reported multidomain bulk particles (55 emu/g). In the particle size range 10–100 nm, the decrease in the saturation magnetization has been explained in terms of its non-collinear spin arrangement at or near the surface of the particle. In addition, the magnetic hysteresis measured shows that the nanoparticles obtained display low ferromagnetic properties at room temperature. We found that for smaller crystals the saturation magnetization had a value that was significantly lower than the bulk value, while larger sized crystals have values approaching those of the bulk. In comparison with Fe_3O_4, these nanoparticles have low coercivity because of the non-magnetic Ni^{2+} ion presence in the lattice. The nickel ions are located between the grains and increase the affect of the grains on each other. The value of M_S in the crystals is attributed to the greater fraction of surface spins in these crystals that tend to be in a canted or a spin glass-like state with a smaller net moment.

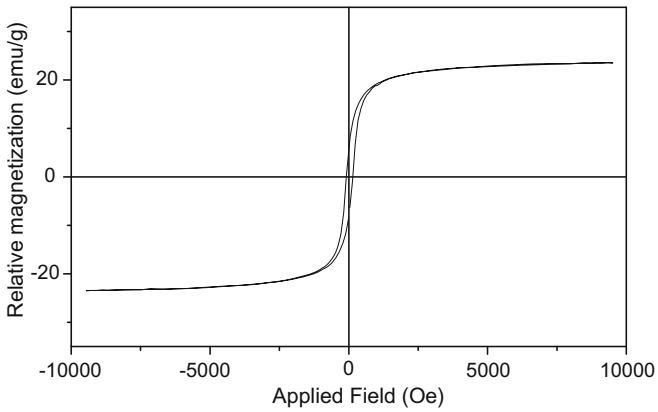

Fig. 6. Hysteresis loop for $NiFe_2O_4$ nanocrystals at room temperature.

4. Conclusion

In summary, nickel ferrite crystals with a normal spinel structure were obtained, with octanoic acid as a surfactant. Co-precipitation is a suitable method for the control of nanoparticle sizes with variation of the reaction conditions. The diameter of the nanocrystals is about 25 ± 5 nm. The size of the nanocrystals was measured both by XRD and TEM and the results were in very good agreement with each other. According to the TEM image there was some agglomeration of nanoparticles, but the size distribution of the prepared nanocrystals was small. The results of VSM indicate that the saturation magnetization of $NiFe_2O_4$ shows a maximum of 23.13 emu/g at room temperature.

2.2. Kinetic data

Rate data (25.0 °C, $[Co]_T = 2.5 \times 10^{-3}$ M, $I = 1.0$ M) for the acid hydrolysis of $[Co(uns\text{-}penp)(O_2CO)]^+$ and $[Co(dppa)(O_2CO)]^+$ were obtained using a Varian 500 Scan UV–Vis NIR spectrometer by observing the absorbance decrease at 493 and 494 nm, respectively. Data were fitted to a single exponential to obtain k_{obs} values.

2.3. X-ray structure determinations

X-ray data were collected at temperatures between 85 and 90 K on a Bruker Kappa APEX-II system using graphite-monochromated Mo Kα radiation with exposures over 0.5°, and were corrected for Lorentz and polarisation effects using SAINT [12]. All structures were solved using SIR-97 [13] running within the WINGX package [14] and weighted full-matrix refinement on F^2 was carried out using SHELXL-97 [15]. Hydrogen atoms attached to carbon and nitrogen were included in calculated positions, and were refined as riding atoms with individual (or group, where appropriate) isotropic displacement parameters. Only water hydrogen atoms which could be found in the difference map were included in the final cycles of refinement. Disorder was present in the three propyl chains of the complex $[Co(trpn)(O_2CO)]ClO_4 \cdot H_2O$ due to two different chelate ring conformations of similar energies. This was successfully modelled using a 70:30 distribution of the two conformations.

2.4. DFT calculations

Geometries of the complex cations were fully optimised using the gradient-corrected B3LYP density functional [16–18] with the 6-31G* basis set, in both gas and aqueous phase using the GAUSSIAN 03 program package [19]. In order to include solvent polarity effects, we have adopted the SCRF (self-consistent reaction field) [20–23] approach with a polarised continuum model (PCM) [24], using the dielectric constant of water. The nuclear magnetic shieldings σ were calculated at the optimised geometries using the B3LYP/6-31G* method. ^{59}Co chemical shifts (δ) were calculated from $\delta = |\sigma_{ref} - \sigma|$, where $[K_3Co(CN)_6]$ was used as the reference compound. The σ_{ref} value was calculated as −5825.8489 ppm. TD-DFT (time-dependent density functional theory) [25], as implemented in GAUSSIAN 03, [19] was used to calculate electronic transition energies. The vertical excitation energies and oscillator strengths were calculated using different combinations of functionals (B3LYP, MO5, PBE, BP86) and basis sets (6-31G*, 6-311G*, TZVP). From the data calculated using the B3LYP/6-31G* method, UV–Vis absorption spectra in the 800–335 nm wavelength range were simulated by convoluting each electronic transition with a Gaussian function having an area proportional to the oscillator strength and a full width at half maximum of 3000 cm^{-1} to match the experimental widths.

2.5. Synthesis

2.5.1. (3-Aminopropyl)bis(2-pyridylmethyl)amine · 3HCl · 0.5H$_2$O (dppa)

$NaBH(OAc)_3$ (6.00 g, 28.3 mmol) was added to a solution of *N*-acetylpropylenediamine (1.16 g, 10.0 mmol) and 2-pyridinecarbaldehyde (2.14 g, 20.0 mmol) in 1,2-dichloroethane (100 mL). The resulting suspension was stirred at room temperature for 3 h and the reaction was then quenched with 2 M NaOH(aq) (100 mL). The organic layer was separated and the aqueous layer extracted with CH_2Cl_2 (2 × 100 mL). The organic fractions were combined and washed with saturated NaCl(aq) (100 mL), then dried over anhydrous Na_2SO_4, filtered, and reduced to dryness (rotavap) to yield an orange oil. This was dissolved in 5 M HCl(aq) (100 mL) and heated at reflux for 20 h. Following cooling and removal of solvent (rotavap), the resulting oil was dissolved in the minimum volume of ethanol, added dropwise to ether (400 mL) and stirred for 3 days. The resulting brown solid was crystallised from hot ethanol to give dppa · 3HCl · 0.5H$_2$O (1.26 g, 31%). *Anal.* Calc. for $C_{15}H_{24}N_4O_{0.5}Cl_3$: C, 48.08; H, 6.46; N, 14.95; Cl, 28.38. Found: C, 48.24; H, 6.68; N, 14.72; Cl, 28.56%. ESI-MS. Calcd for $C_{15}H_{21}N_4^+$, 257. Found, 257. ^{1}H NMR (D_2O) δ 8.39 (2H, m), 8.19 (2H, m), 7.73 (2H, d), 7.62 (2H, m), 3.96 (4H, s), 2.60 (2H, t), 2.44 (2H, t), 1.60 (2H, m); ^{13}C NMR (D_2O) δ 152.86, 147.60, 141.66, 127.35, 126.62, 55.44, 51.76, 37.56, 23.96 ppm.

2.5.2. [Co(baep)(O$_2$CO)]ClO$_4$

Solid baep · 4HCl · 1.5H$_2$O (1.35 g, 4.05 mmol) was added to a suspension of $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ (2.50 g, 7.00 mmol) in H_2O (30 mL). The mixture was heated at 65 °C for 5 min, evolving CO_2 and giving a dark red solution which was then filtered through celite, diluted to 800 mL with distilled water and loaded onto a Sephadex SP C-25 cation exchange column. The pink band which eluted with 0.1 M $NaClO_4$(aq) was reduced to near dryness (rotavap) and cooled on ice to give a pink solid. This was removed by filtration, washed with ethanol and ether, and dried under vacuum. The product was crystallised by dissolution in the minimum volume of warm water, addition of isopropanol dropwise until the solution just became cloudy, and subsequent cooling. The resulting pink solid was removed by filtration and washed with isopropanol. Dissolution of the product in the minimum volume of water and layering with isopropanol gave X-ray quality red crystals of [Co(baep)O$_2$CO]ClO$_4$ (0.29 g, 17%). *Anal.* Calc. for $CoC_8H_{20}N_4O_7Cl$: C, 25.36; H, 5.28; N, 14.80; Cl, 9.38. Found: C, 25.40; H, 5.40; N, 14.68; Cl, 9.59%. ESI-MS. Calcd for $CoC_8H_{20}N_4O_3^+$, 279. Found, 279. UV–Vis (H_2O) [λ_{max}, nm (ε, dm^3 mol cm^{-1})]: 508 (107), 352 (90). ^{1}H NMR (D_2O) δ 2.67 (6H, m), 2.49 (3H, m), 2.36 (2H, m), 2.22 (1H, m), 1.71 (2H, m); ^{13}C NMR (D_2O) δ 166.86, 65.93, 59.20, 57.89, 41.92, 41.10, 39.60, 24.14 ppm. ^{59}Co NMR (D_2O): δ 8728 ppm. X-ray crystallography showed the complex to exist as a hemihydrate with complete desolvation occurring upon drying.

2.5.3. [Co(abap)(O$_2$CO)]ClO$_4$

Solid abap · 4HCl · 3H$_2$O (0.45 g, 1.20 mmol) was added to a suspension of $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ (0.50 g, 1.20 mmol) in H_2O (10 mL). The mixture was heated at 60 °C for 15 min, evolving CO_2 and giving a red solution which was filtered through celite, diluted with H_2O and loaded onto a Sephadex SP C-25 cation exchange column. A magenta band was eluted with 0.1 M $NaClO_4$. This was reduced in volume to ~5 mL, and then added dropwise to EtOH (100 mL) to give the product as a magenta solid, which was removed by filtration, washed with EtOH and Et_2O, and air-dried. (0.24 g, 50%). *Anal.* Calc. for $CoC_9H_{22}N_4O_7Cl$: C, 27.53; H, 5.65; N, 14.27; Cl, 9.03. Found: C, 27.24; H, 5.64; N, 14.03; Cl, 9.31%. UV–Vis (H_2O) [λ_{max}, nm (ε, dm^3 mol cm^{-1})]: 524 (125), 362 (136). ^{1}H NMR (D_2O) δ 3.18 (1H, m), 3.04 (4H, m), 2.88 (1H, m), 2.75 (1H, m), 2.59 (1H, m), 2.43 (3H, m), 2.23 (2H, m), 1.90 (3H, m). ^{13}C NMR (D_2O) δ 167.87, 66.18, 60.39, 56.00, 43.27, 39.77 and 39.65 (doublet), 38.63, 25.39, 24.33 ppm. ^{59}Co NMR (D_2O): δ 9117 ppm.

2.5.4. [Co(uns-penp)(O$_2$CO)]ClO$_4$

Solid uns-penp · 3HCl (2.67 g, 7.60 mmol) was added to a suspension of $Na_3[Co(O_2CO)_3] \cdot 3H_2O$ (2.75 g, 7.60 mmol) in H_2O (60 mL). The mixture was heated at 65 °C for 5 min, evolving CO_2 and giving an orange-red solution which was filtered through celite, diluted with H_2O and loaded onto a Sephadex SP C-25 cation-exchange column. An orange band was eluted with 0.1 mol L^{-1} $NaClO_4$, reduced to near dryness (rotavap) and refrigerated to give an orange solid which was removed by filtration (1.19 g, 34%). The crude product was crystallised by dissolution in the minimum vol-

ume of hot water, addition of $NaClO_4$(s) and subsequent cooling to give X-ray quality crystals of [Co(uns-penp)(O_2CO)]ClO_4 which were filtered off and washed with isopropanol (0.41 g, 12%). *Anal.* Calc. for $C_{15}H_{18}N_4O_7ClCo$: C, 39.10; H, 3.94; N, 12.16; Cl, 7.69. Found: C, 39.29; H, 4.08; N, 12.00; Cl, 7.95%. UV–Vis (H_2O) [λ_{max}, nm (ε, L mol^{-1} cm^{-1})]: 493 (180), 352 (173). ESI-MS: Calcd for $CoC_{15}H_{18}N_4O_3^+$ 361; Found 361. ^{1}H NMR (D_2O): δ 8.61 (2H, dd), 8.21 (2H, td), 7.76 (4H, m), 5.15 (2H, d), 4.71 (2H, d), 3.19 (2H, t), 2.23 (2H, t) ppm. ^{13}C (D_2O): δ 167.09, 163.40, 151.06, 142.45, 127.29, 123.85, 67.82, 64.17, 42.75 ppm. ^{59}Co NMR (D_2O): δ 8132 ppm. X-ray crystallography showed the complex to exist as a monohydrate with complete desolvation occurring upon drying.

2.5.5. [Co(dppa)(O_2CO)]ClO_4

Solid dppa · 3HCl · 0.5H_2O (1.00 g, 2.49 mmol) was added to a suspension of Na_3[Co($O_2CO)_3$] · 3H_2O (0.900 g, 2.49 mmol) in H_2O (20.0 mL). The mixture was heated at 65 °C for 5 min to give an orange-red solution which was then filtered through celite, diluted to 800 mL with distilled water and loaded onto a Sephadex SP C-25 cation exchange column. The red band eluted with 0.1 M $NaClO_4$(aq) was reduced to low volume (rotavap) and the crude product was obtained as an oil upon addition of isopropanol. Trituration with ether gave the solid the red/orange product, which was collected by filtration and dried under vacuum. Red crystals of [Co(dppa)O_2CO]ClO_4 suitable for X-ray structure determination were obtained on dissolution of the product in the minimum volume of water and layering with isopropanol (0.13 g, 10%). *Anal.* Calc. for $CoC_{16}H_{20}N_4O_7Cl$: C, 40.48; H, 4.25; N, 11.80; Cl, 7.47. Found: C, 40.49; H, 4.11; N, 11.82; Cl, 7.53%. ESI-MS. Calc. for $CoC_{16}H_{20}N_4O_3^+$, 375. Found, 375. UV–Vis (H_2O) [λ_{max}, nm (ε, dm^3 mol cm^{-1})]: 494 (134). ^{1}H NMR (D_2O) δ 8.41 (2H, dd), 7.94 (1H, td), 7.85 (1H, td), 7.60 (2H, dd), 7.52 (1H, t), 7.44 (1H, t), 7.28 (1H, dd), 4.80 (2H, dd), 4.68 (1H, d), 4.45 (1H, d), 3.20 (2H, m), 2.61 (1H, m), 2.41 (1H, q), 2.11 (1H, dd), 1.71 (1H, q); ^{13}C NMR (D_2O) δ 166.51, 163.00, 158.15, 149.40, 149.31, 141.46, 141.09, 126.90, 126.69, 122.86, 122.28, 73.16, 66.27, 61.61, 39.13, 24.79 ppm. ^{59}Co NMR (D_2O): δ 8365 ppm.

2.5.6. [Co(trpn)(O_2CO)]ClO_4

Trpn (1.82 g, 9.60 mmol) in H_2O/MeOH (1:1, 50 mL) was added to a solution of [Co($H_2O)_6$]($ClO_4)_2$ (3.51 g, 9.60 mmol) in H_2O (40 mL). To this were added $NaHCO_3$ (0.806 g, 9.60 mmol) and PbO_2 (0.344 g, 1.44 mmol) and the resulting suspension was stirred overnight at room temperature. After filtering through celite, the purple filtrate was diluted with H_2O and loaded onto a Sephadex SP C-25 cation exchange column. The purple band eluted with 0.1 mol L^{-1} $NaClO_4$ was reduced to near dryness (rotavap) to give crystalline purple [Co(trpn)O_2CO]ClO_4, which was removed by filtration, washed with isopropanol and dried *in vacuo* (1.32 g, 34%). *Anal.* Calc. for $C_{10}H_{24}N_4O_7ClCo$: C, 29.53; H, 5.95; N, 13.78; Cl, 8.72. Found: C, 29.36; H, 6.17; N, 13.49; Cl, 8.82%. ESI-MS: Calc. for $CoC_{10}H_{24}N_4O_3^+$ 307; Found 307 [M$^+$]. UV–Vis (H_2O) [λ_{max}, nm (ε, L mol^{-1} cm^{-1})]: 534 (120), 367 (147). ^{1}H NMR (D_2O): δ 2.87 (2H, m), 2.57 (10H, m), 2.05 (4H, m), 1.87 (2H, m) ppm. ^{13}C NMR (D_2O): δ 167.76, 58.21, 56.17, 38.47, 37.61, 23.93, 21.52 ppm. ^{59}Co NMR (D_2O): δ 9574 ppm. Crystallisation of the crude product from an aqueous solution layered with isopropanol gave X-ray quality purple crystals of the monohydrate of the complex.

3. Results and discussion

3.1. Synthesis and characterisation

Fig. 1 shows the structures of the ligands used in this work. The dppa ligand was prepared via an adaptation of a method used for the synthesis of the related ligand uns-penp [9]. Schiff base condensation of *N*-acetylpropylenediamine with 2 equiv. of 2-pyridinecarbaldehyde, reduction with $NaBH(OAc)_3$ and deacetylation with HCl, gave dppa as the trihydrochloride hemihydrate. This contrasts with previous syntheses of dppa which involve reaction of di(2-pyridylmethyl)amine with either acrylonitrile [26–28] or *N*-(3-bromopropyl)phthalimide [29,30] and subsequent reduction or deprotection, respectively. As the abap, dppa, uns-penp and baep ligands were all isolated as hydrochloride salts, the Co(III) complexes containing these ligands were most conveniently pre-

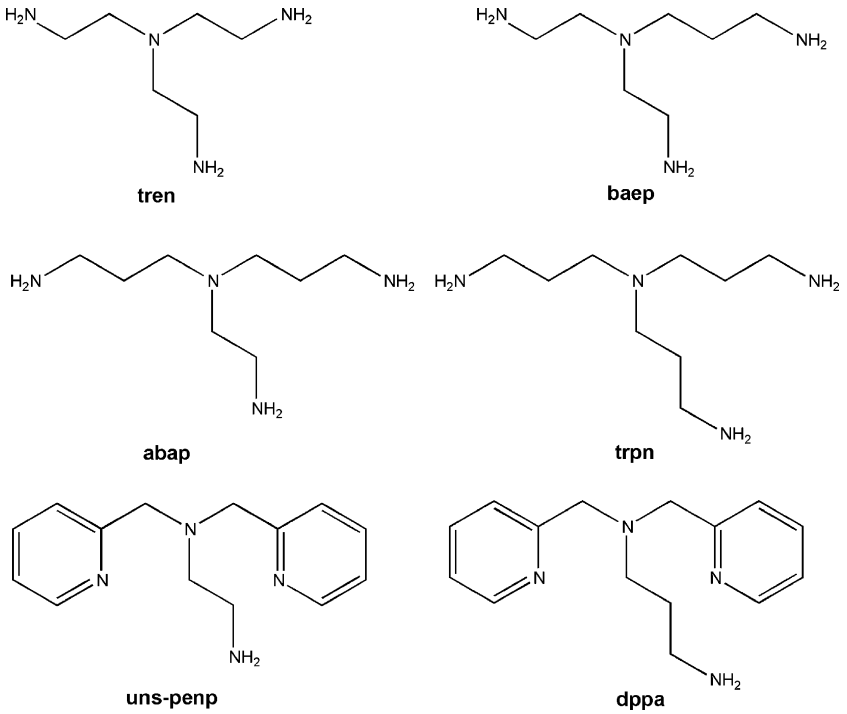

Fig. 1. Structures of the tripodal tetraamine ligands.

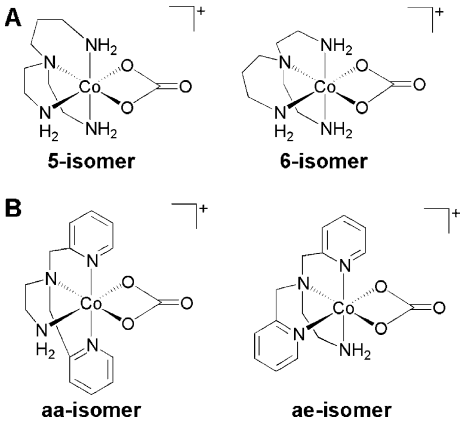

Fig. 2. Isomeric possibilities in $[Co(L)(O_2CO)]^+$ complexes. (A) 5- and 6-isomers of $[Co(baep)(O_2CO)]^+$. The five- and six-descriptors refer to the size of the chelate ring in the same plane as the carbonate ligand. Such isomers are possible for L = baep, abap and dppa. B) aa- and ae-isomers of $[Co(uns\text{-}penp)(O_2CO)]^+$. The aa- (axial, axial) and ae- (axial, equatorial) descriptors refer to the positioning of the pyridyl donors relative to the plane containing the Co ion and the coordinated O atoms of the carbonate ligand. Such isomers are possible for L = uns-penp and dppa.

pared by reaction with $Na_3[Co(O_2CO)_3] \cdot 3H_2O$. In aqueous solution at 60–65 °C, these reactions gave rapid evolution of CO_2 and colour changes to red or orange-red. $[Co(trpn)(O_2CO)]ClO_4$ was prepared by PbO_2 oxidation of a solution of Co(II), HCO_3^- and the free base ligand in aqueous solution. Purification of all complexes was effected by cation exchange chromatography on Sephadex SP-C25 resin and the complexes were crystallised as perchlorate salts. Elemental analysis and mass spectral data were consistent with the proposed formulae in all cases. All complexes except $[Co(trpn)(O_2CO)]^+$ can potentially form two geometric isomers, owing to the different possible relative positionings of either the five- and six-membered chelate rings (baep, abap, dppa) or the two pyridine rings (dppa, uns-penp) (Fig. 2), and NMR proved unequivocal both in showing that the syntheses of these complexes proceeded in a stereoselective manner and in characterising the single isomer formed. Central to the identification of the isomers is the $[Co(trpn)(O_2CO)]^+$ ion for which, somewhat ironically, there are no geometric isomeric possibilities. Although the solid state structure of this ion (Fig. 5) shows that all of the CH_2 carbon atoms are chemically inequivalent, the presence of disorder in each of the three chelate rings implies that there is a very low energy barrier to chelate ring inversion even in the solid state, and this is borne out by the observation of 6, rather than 9, CH_2 peaks in the ^{13}C NMR spectrum of $[Co(trpn)(O_2CO)]^+$ in D_2O, 3 of which are approximately twice the intensity of the other 3 [31]. Therefore, each pair of C atoms in the 'axial' chelate rings is rendered equivalent on the NMR timescale by chelate ring inversion processes, thereby giving the ion an apparent mirror plane through the cobalt ion and the four equatorial donor atoms. Such ring inversion processes are generally facile for all but the most rigid of chelate rings [4] and allow the definitive assignment of the possible geometric isomers formed when the tripodal ligand has only two of the three arms identical. For example the observation of 7 CH_2 peaks of approximately equal intensity in the ^{13}C NMR spectrum of $[Co(baep)(O_2CO)]^+$ shows all the CH_2 carbon atoms are chemically inequivalent, implying that the ion exists exclusively as the 5-isomer [32] in which a five-membered chelate rings lies in the same plane as the carbonate ligand. The 5-isomer was also observed in the two other crystallographically characterised 6-coordinate complexes containing baep [33] while the related complex $[Co(baep)(NO_2)_2]^+$ also displays 7 ^{13}C NMR peaks in solution, consistent with formation of the 5-isomer [7]. The presence of 8 peaks [34] in the ^{13}C NMR spectrum of $[Co(abap)(O_2CO)]^+$ shows that this complex is formed as the 6-isomer, and such a preference has been found in the three other structurally characterised 6-coordinate abap complexes in which the remaining coordination sites are occupied by a chelating ligand [8,33,35]. Interestingly, X-ray crystallographic data show that the 5-isomer appears to be preferred when two monodentate ligands, rather than a single chelating ligand, are present [33,36–38], although solution studies of 5-$[Co(abap)(OH_2)_2]^{3+}$ at varying pH have shown that isomerisation to the 6-isomer does occur [32]. The observation of only a single set of pyridine C resonances in the ^{13}C NMR spectrum of the $[Co(uns\text{-}penp)(O_2CO)]^+$ cation show this to be the aa isomer (Fig. 2), in which the aliphatic N atoms are situated in the same plane as the coordinated carbonate O atoms. This appears to be the preferred isomer in all but one of the structurally characterised 6-coordinate complexes containing uns-penp, regardless of whether the complex contains one bidentate or two monodentate ligands. The one exception is the bis(μ-oxo) manganese (III,IV) dimer $[(uns\text{-}penp)Mn(O)_2Mn(uns\text{-}penp)]^{3+}$ in which an uns-penp ligand coordinates to each Mn ion such that one pyridine ring is equatorial and one axial [39]. There are two observations concerning the ^{13}C NMR spectrum of the $[Co(dppa)(O_2CO)]^+$ ion that are consistent with its assignment as the ae-isomer in solution. Firstly, 10, rather than 5 peaks due to the pyridine C atoms are observed, and these appear as 5 closely spaced pairs of peaks. Secondly, the presence of five peaks in the aliphatic region of the spectrum shows that the two CH_2 carbon atoms adjacent to the pyridine rings are

inequivalent. The ae-isomer is also found in the other crystallographically characterised 6-coordinate complexes containing dppa [30,40].

3.2. X-ray crystal structures

Table 1 gives crystallographic data for the complexes studied, while ORTEP diagrams of the cations of 5-[Co(baep)(O_2CO)]$ClO_4 \cdot 0.5H_2O$, 6-[Co(abap)(O_2CO)]ClO_4, [Co(trpn)(O_2CO)]$ClO_4 \cdot H_2O$, aa-[Co(uns-penp)(O_2CO)]$ClO_4 \cdot H_2O$ and ae-[Co(dppa)(O_2CO)]ClO_4 and are given in Figs. 3–7 respectively. In all cases, the four N atoms of the tripodal ligand are coordinated to the central Co(III) ion, whose primary coordination sphere is completed by two O atoms from a chelating carbonate ligand. The geometry of the chelated carbonate ligand is similar across all five complexes; the two Co–O bonds in each complex are of different lengths, and this leads to a slight asymmetry in the chelate, while the O–Co–O angles range between 68.45° and 69.61°. The complexes $[Co(L)(O_2CO)]^+$ (L = tren [41–43], baep, abap, trpn) form an homologous series and a comparison of their geometries is instructive. The average Co–N distance increases across the series (L = tren, 1.943 Å; baep, 1.962 Å; abap, 1.964 Å; trpn, 1.976 Å), presumably as a result of the increasing number of six-membered chelate rings. Such lengthening has been seen before in related homologous series of complexes [4,5] and corresponds to a weakening in the ligand field strength of the tripodal ligand. The bond to the tertiary N atom increases in length significantly across the series (1.927–2.027 Å) but there are no consistent trends in the other Co–N distances. The N–Co–N bond angles involving six-membered chelate rings are consistently larger than those involving five-membered chelate rings, and this effect is most marked when the chelate ring lies in the equatorial plane. Thus while the N–Co–N bond angles of the axial six-membered chelate rings in the baep, abap and trpn complexes range from 90.98° to 93.85°, those in the equatorial plane range from 98.74° to 100.27°, and this presumably is a consequence of the presence of a rigid *trans* disposed four-membered chelate ring, thus allowing expansion of this angle. Some similar trends in bond

lengths and angles are seen in the [Co(uns-penp)(O_2CO)]$^+$ and [Co(dppa)(O_2CO)]$^+$ cations. The average Co–N distance increases as the number of six-membered chelate rings increases and the N–Co–N bond angle involving the six-membered chelate ring in the dppa complex is larger than the other angles about Co in both complexes. In addition, Co–N bond lengths to pyridyl N atoms are shorter than those to aliphatic N atoms in both complexes. As discussed above, the complexes containing the baep, abap, uns-penp and dppa ligands can all potentially form two geometric isomers, and in all cases, the isomer obtained in the solid state is identical to that observed in solution via NMR (see Table 2).

3.3. Acid hydrolysis

The complexes described herein all undergo hydrolysis in aqueous acidic solution at various rates to give the corresponding diaqua species as the final product. Of particular interest are the hydrolysis rates for the [Co(uns-penp)(O_2CO)]$^+$ and [Co(dppa)(O_2CO)]$^+$ cations; in 1.0 M $HClO_4$(aq) at 25.0 °C, k_{obs} values for the hydrolysis reactions are 2.9×10^{-2} s^{-1} and 2.7×10^{-4} s^{-1}, respectively, a two order of magnitude difference for complexes containing very similar ancillary ligands. This surprising difference is probably attributable to the different isomeric preferences of the two cations. We [4,5,44] and others [45,46] have previously shown that the wide variety of acid hydrolysis reaction rates in complexes containing chelated carbonate is due to the ease with which the coordinated *endo* O atoms of the carbonate ligand can be protonated, and steric hindrance by the ancillary ligand is crucial in stabilising such complexes in aqueous acidic solution. As discussed above, the [Co(uns-penp)(O_2CO)]$^+$ cation exists in solution as the aa isomer, while the less reactive [Co(dppa)(O_2CO)]$^+$ cation exists as the ae isomer. As a result, the steric accessibility of the coordinated *endo* O atoms is quite different in the two cations, as shown in the space-filling diagrams (Fig. 8). One of the coordinated O atoms is hindered by the CH_2 protons from one arm of the tripodal ligand in [Co(uns-penp)(O_2CO)]$^+$ while access to the other coordinated O atom is relatively open. However, in [Co(dppa)(O_2CO)]$^+$, both coordinated O atoms undergo significant hindrance. As above, the CH_2 protons hinder approach to one O atom, while the 6-proton of the pyridyl ligand now lies in very close proximity to the other O atom; this latter interaction can only occur when the pyridyl group is situated in the same plane as the carbonate ligand.

3.4. ^{59}Co NMR

Despite its quadrupolar $I = 7/2$ spin, which leads to broad peaks, the 100% abundance of the NMR active ^{59}Co isotope usually allows facile detection of the ^{59}Co NMR signal, and ^{59}Co NMR data for a large number of complexes are available [47,48]. We have previously shown that the ^{59}Co chemical shift of [(L)Co(O_2CO)]$^+$ complexes is very dependent on the identity of the tripodal tetradentate ligand L, with a range of over 2000 ppm observed as L is varied from tpa to either tepa or Me_3tpa. [4,5] We have now recorded ^{59}Co NMR chemical shifts for the homologous series of complex cations [(L)Co(O_2CO)]$^+$ (L = tren, baep, abap, trpn) as well

Table 2

[a] The high energy *d*–*d* band appears as a shoulder on an intense charge-transfer band and cannot be resolved.

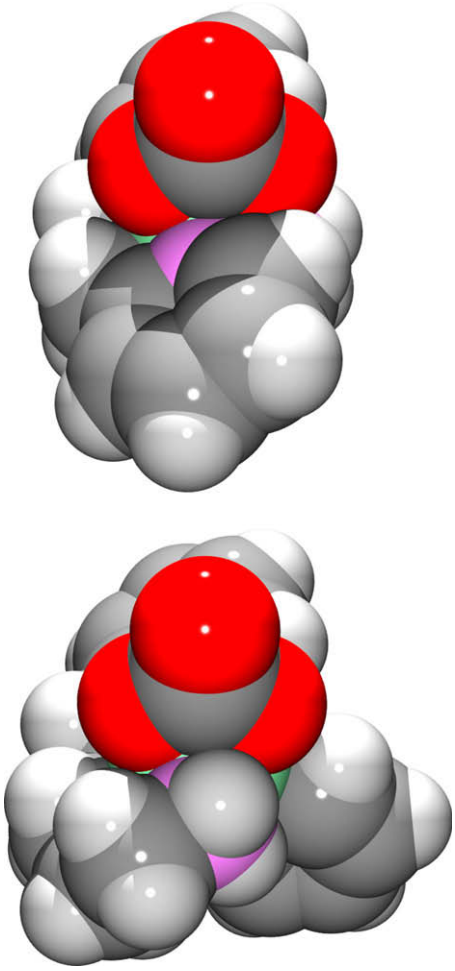

Fig. 8. Space filling diagrams of the aa-[Co(uns-penp)(O_2CO)]$^+$ (top) and ae-[Co(dppa)(O_2CO)]$^+$ (bottom) cations emphasising the hindrance of the *endo* O atoms of the chelated carbonate ligands by atoms of the ancillary tripodal ligand.

as the mixed donor complex cations [Co(dppa)(O_2CO)]$^+$ and [Co(uns-penp)(O_2CO)]$^+$, and again find a large range of chemical shifts. Values of 8450, 8728, 9117 and 9574 ppm, respectively, for the complex cations [(L)Co(O_2CO)]$^+$ (L = tren, baep, abap, trpn) show that the ligand field strength of the tripodal ligand decreases as the number of six-membered chelate rings increase, as was also found for complex cations containing the pyridyl analogues of these ligands. The increase in chemical shift is concomitant with an increase in the average Co–N bond distance across the series of complexes (1.949 Å, L = tren; 1.962 Å, L = baep; 1.965 Å, L = abap; 1.976 Å, L = trpn) and a corresponding decrease in Δ, the *d*-orbital splitting parameter (21 542 cm^{-1}, L = tren; 21 414 cm^{-1}, L = baep; 20 775 cm^{-1}, L = abap; 20 413 cm^{-1}, L = trpn). A similar dependence of the chemical shift on the size of the chelate rings has been previously observed in a series of complexes containing an N_4S_2 donor set [49], although the effect in the current case is somewhat more marked. The complex cations [(L)Co(O_2CO)]$^+$ (L = uns-penp, dppa) display smaller chemical shifts (δ = 8132 and 8395 ppm, respectively) than their aliphatic analogues (L = tren, δ = 8450 ppm; L = baep, δ = 8728 ppm), suggesting that the presence of two pyridyl donors leads to an increased ligand field compared to that exerted by solely aliphatic N atoms. This is borne out in the Δ value for the uns-penp complex of 21 906 cm^{-1} (Δ for the dppa complex could not be determined, owing to partial obscuring of the high energy *d*–*d* band by an intense charge transfer band). The predicted linear relationship (R^2 = 0.962) between the wavelength of the lowest energy *d*–*d* transition (λ_{max}) and γ, the magnetogyric ratio of the ^{59}Co nucleus,[50,51] is observed for the [(L)Co(O_2CO)]$^+$ complex cations (L = tren, baep, abap, trpn, uns-penp, dppa) (Fig. 9, top) and extrapolation gives γ_o = (10.03 ± 0.02) MHz T^{-1} for the bare ^{59}Co nucleus, a value comparable to that obtained previously from an extensive study of Co(III) complexes with O_6, N_6, S_6, Se_6, C_6 P_6 and As_6 donor sets [52].

We have also found an excellent correlation between Δ and δ(^{59}Co) for [(L)Co(O_2CO)]$^+$ complexes, as outlined in Fig. 9 (bottom, R^2 = 0.95). While the majority of these complexes contain a tripodal tetradentate N_4 ancillary ligand, those having L = $(en)_2$ (Δ = 21 199 cm^{-1}, δ = 9181 ppm) and L = $(NH_3)_4$ (Δ = 20 746 cm^{-1}, δ = 9620 ppm) [53] also show an acceptable fit. Thus it appears that this correlation exists regardless of the aliphatic or aromatic nature of the N donor atoms, and whether the N donor atoms are part of a chelating ligand. However, the correlation is not solely dependent on the identity of the donor atoms bound to the Co(III) ion; for example, inclusion of data for the [Co$(en)_2(OH_2)_2$]$^{3+}$ ion, which, like the above complexes, contains an N_4O_2 donor set, worsens the fit noticeably. It appears that the geometric constraint provided by the chelated carbonate ligand is necessary for this correlation, and a different ligand field obtains when such a constraint is not present. An analogous correlation, albeit using fewer data points, can be seen in the structurally similar [Co(RN_4S_2amp)]$^{3+}$ series of

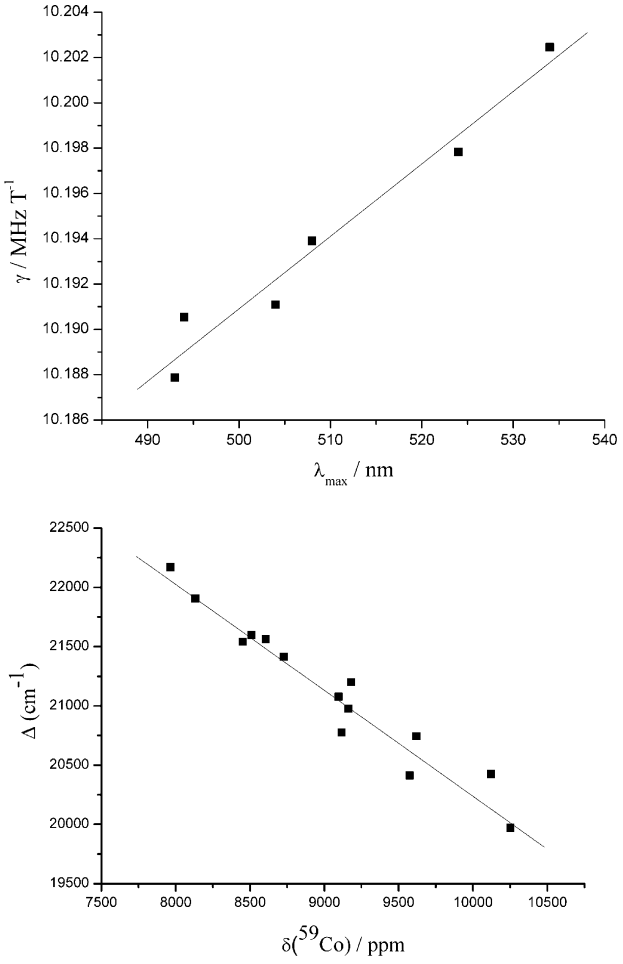

Fig. 9. Top: Plot of γ vs λ_{max} for [(L)Co(O_2CO)]$^+$ complex cations (L = tren, baep, abap, trpn, uns-penp, dppa). Bottom: Plot showing the correlation between Δ and δ(^{59}Co) for [(L)Co(O_2CO)]$^+$ complex cations (L = a tripodal tetraammine ligand, $(en)_2$, $(NH_3)_4$).

complexes (R = Et, Pr, Bu, Xy) [49]; however, again this does not extend to all complexes having an N_4S_2 donor set.

3.5. DFT calculations

As discussed above, geometric isomers are possible for the $[(L)Co(O_2CO)]^+$ (L = baep, abap, dppa, uns-penp) complex cations, and we were interested to see if the lower energy isomer predicted by DFT calculations corresponded to the isomer isolated experimentally. We also included the $[(L)Co(O_2CO)]^+$ (L = pmap, pmea) complex cations, for which geometric isomers are possible, from our previous work, both of which are isolated (ClO_4^- salts) as the 6-isomer [4]. Results of these calculations are given in Table 3. The energy differences between each pair of geometric isomers range span an order of magnitude, from 2.49 to 25.5 kJ mol^{-1}. As can be seen, the calculated lower energy isomer is the one isolated experimentally in all cases except for the $[Co(uns\text{-}penp)(O_2CO)]^+$ cation, where the ae-isomer is predicted, but the aa-isomer is isolated. It should be noted that the calculated energy difference between these, as well as the isomers of the abap and pmea complexes, is small, and some uncertainty as to the lowest energy isomer is to be expected. However, the same relative energy ordering of the isomers is found for the range of functionals and basis sets outlined in Section 2. NMR analysis of the crude reaction products, prior to crystallisation, show that the formation reactions of these complexes are remarkably stereoselective, and only the $[Co(pmea)(O_2CO)]^+$ complex shows any evidence of the presence of both isomers. The reasons for such stereoselectivity are unclear; given the small calculated energy differences between the isomers, particularly in the cases of the abap, pmea and uns-penp complexes, it might be expected that isomerisation between these would be relatively facile, especially at the elevated temperatures used in their syntheses. However, such a process would probably have a significant activation barrier; assuming a dissociative mechanism typical of ligand substitution reactions at Co(III) centres [54], isomerisation would require Co–O bond cleavage, followed by significant reorganisation within the resulting 5-coordinate intermediate, and subsequent rechelation of the carbonate ligand. The fact that there is no 'spontaneous' hydrolysis pathway for Co(III) carbonate complexes [46] implies that unassisted Co–O bond cleavage in such complexes would be expected to be extremely slow, thereby rendering isomerisation difficult. On the other hand, small amounts of Co(II) present in the reaction mixtures could serve to labilise the complexes, thus allowing formation of the thermodynamically preferred isomer.

Table 3
Energy differences between $[(L)Co(O_2CO)]^+$ isomers (ΔE), as calculated by DFT (B3LYP/6-31G*).

Experimentally isolated isomer	Calculated lowest energy isomer	ΔE (kJ mol^{-1})
6-$[Co(abap)(O_2CO)]^+$	6-$[Co(abap)(O_2CO)]^+$	2.50
5-$[Co(baep)(O_2CO)]^+$	5-$[Co(baep)(O_2CO)]^+$	15.5
6-$[Co(pmap)(O_2CO)]^+$	6-$[Co(pmap)(O_2CO)]^+$	25.5
6-$[Co(pmea)(O_2CO)]^+$	6-$[Co(pmea)(O_2CO)]^+$	3.05
ae-$[Co(dppa)(O_2CO)]^+$	ae-$[Co(dppa)(O_2CO)]^+$	6.59
aa-$[Co(uns\text{-}penp)(O_2CO)]^+$	ae-$[Co(uns\text{-}penp)(O_2CO)]^+$	2.49

Table 5
Calculated and observed λ_{max} values for $[(L)Co(O_2CO)]^+$ complexes.

Complex	Observed λ_{max} (nm)	Calculated λ_{max} (nm)
6-$[Co(abap)(O_2CO)]^+$	524, 362	493, 362
6-$[Co(pmap)(O_2CO)]^+$	515, 360	526, 373
5-$[Co(baep)(O_2CO)]^+$	508, 352	493, 352
6-$[Co(pmea)(O_2CO)]^+$	500, 357	497, 362
ae-$[Co(dppa)(O_2CO)]^+$	494[a]	487, 352
aa-$[Co(uns\text{-}penp)(O_2CO)]^+$	493, 352	496, 358

[a] The higher energy band appears as a shoulder on an intense charge-transfer band and cannot be resolved.

Table 4 shows observed and calculated ^{59}Co NMR chemical shifts for the experimentally isolated isomer of the $[(L)Co(O_2CO)]^+$ complexes (L = abap, pmap, baep, pmea, dppa, uns-penp) in aqueous solution. Although the calculated chemical shifts are less than the observed chemical shifts in each case, with differences in the order of 900–1400 ppm, the calculated data successfully reproduce the observed trends in the experimental values. Differences of this magnitude have been observed in previous similar studies [6,55]. Inclusion of solvent appears vital in obtaining acceptable agreement between observed and calculated chemical shifts, as the same calculations carried out in the gas phase lead to chemical shift differences in the range 2100–2600 ppm. The importance of including solvent effects parallels recent observations made by Hocking et al. with respect to geometry optimisations of Co and Pt complexes [56].

Similarly, it is necessary to include solvent in order to obtain good agreement between observed and calculated (TD-DFT) UV–Vis spectra of the complexes. Table 5 gives the observed and calculated λ_{max} values for the $^1A_{1g} \rightarrow {}^1T_{1g}$ and $^1A_{1g} \rightarrow {}^1T_{2g}$ d–d electronic transitions [57] of the complexes while Fig. 10 shows the measured and calculated UV–Vis spectra for two representative examples. When calculations were carried out in the absence of solvent, the resulting spectra generally displayed markedly poorer agreement with the observed spectra, with three, rather than two, bands often predicted. In a previous paper [6], we calculated the HOMO/LUMO gap (ΔE_{H-L}) as a measure of Δ, the d-orbital splitting parameter, for a number of $[(L)Co(O_2CO)]^+$ complexes using the PBE functional, and obtained good agreement with observed values. We carried out such calculations using the B3LYP functional for the complexes reported herein, but consistently obtained Δ values that were too large by a factor of ~2 compared to the experimental values. We therefore carried out TD-DFT excitation energy and HOMO/LUMO calculations on the 'model' complex $[Co(NH_3)_4(O_2CO)]^+$ using a variety of functionals and basis sets, and results of these are given in Table 6. From this it can be seen that, while the TD-DFT vertical excitation energies are essentially independent of the functional and basis set, and are consistent with previous calculations [6], the same is not true of the calculated values of the HOMO/LUMO gap. The ΔE_{H-L} values calculated using the hybrid functionals (B3LYP, M05) are approximately a factor of two larger than the values obtained from pure functionals (PBE, BP86).

Table 4
Calculated and observed ^{59}Co NMR chemical shifts for $[(L)Co(O_2CO)]^+$ complexes.

Cation	Observed chemical shift (ppm)	Calculated chemical shift (ppm)	Chemical shift difference (ppm)
6-$[Co(abap)(O_2CO)]^+$	9117	7784	1333
6-$[Co(pmap)(O_2CO)]^+$	9096	8189	907
5-$[Co(baep)(O_2CO)]^+$	8728	7309	1419
6-$[Co(pmea)(O_2CO)]^+$	8509	7341	1168
ae-$[Co(dppa)(O_2CO)]^+$	8395	7012	1383
aa-$[Co(uns\text{-}penp)(O_2CO)]^+$	8132	6839	1293

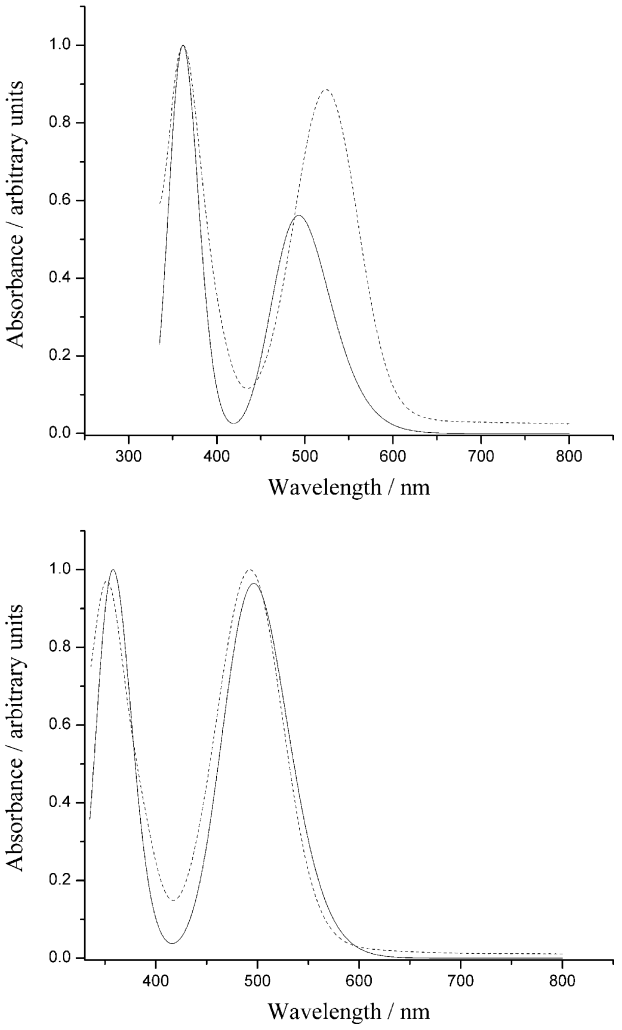

Fig. 10. Measured (dotted line) and calculated (solid line) UV–Vis spectra of 6-$[Co(abap)(O_2CO)]^+$ (top) and aa-$[Co(uns\text{-}penp)(O_2CO)]^+$ (bottom).

Table 6
The TD-DFT first vertical excitation energy (ΔE_{TDDFT}) and HOMO–LUMO energy gap (ΔE_{H-L}) of $[Co(NH_3)_4(O_2CO)]^+$ determined using different functionals and basis sets. Energies are in cm^{-1}.

Functional	Basis set	ΔE_{TDDFT}	ΔE_{H-L}
B3LYP	6-31G*	19438	45812

BP86	6-31G*	20890	20325

4. Conclusions

The results outlined above show that DFT can be used as a predicative tool to determine the geometric isomeric preference of Co(III) complexes, as well as their UV–Vis and ^{59}Co spectroscopic properties. The observed correlation between Δ and $\delta(^{59}Co)$ also allows determination of an approximate value of one of these when the other is known; such cases may occur when the higher energy UV–Vis transition of the complex is obscured by charge transfer transitions, or when the complex is of sufficiently low solubility to preclude collection of a ^{59}Co NMR spectrum. The kinetic data for the hydrolysis of the carbonate complexes further serve to emphasise the importance of steric effects in stabilising the chelated carbonate ligand under acidic conditions, and our investigations into the stabilisation of other oxyanion chelates are ongoing.

5. Supplementary data

CCDC 717930, 717931, 717932, 717933 and 717934 contain the supplementary crystallographic data for $[(L)Co(O_2CO)]ClO_4 \cdot xH_2O$ (L = abap, $x = 0$; L = trpn, $x = 1$; L = uns-penp, $x = 1$; L = dppa, $x = 0$; L = baep, $x = 0.5$). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

We thank staff at the X-ray crystallographic facilities at the University of Auckland and the University of Canterbury for the collection of some X-ray data. We also thank the Department of Chemistry, University of Otago, for support of this research. L.F.M. thanks the Foundation of Research, Science and Technology for the award of a Bright Futures Ph.D scholarship.

directional associative protocol of the naphthalimide group with the well-studied chemistry of the $[Ru(bipy)_3]^{2+}$ core [6], in order to determine the effect of the 1,8-naphthalimide moiety on the properties of the ruthenium complex.

2. Experimental

2.1. General considerations

Unless otherwise specified, all operations were carried out under a nitrogen atmosphere by using either standard Schlenk techniques or a Vacuum Atmospheres HE-493 inert atmosphere dry box. Solvents for synthetic procedures and spectroscopic studies were dried by conventional methods and distilled under a N_2 atmosphere immediately prior to use. All chemicals were purchased from Aldrich Chemicals. Mass spectrometric measurements recorded in ESI(±) mode were obtained on a Micromass Q-Tof spectrometer. NMR spectra were recorded by using a Varian Mercury/VX 300 or Unity Inova 500 (PGSE-NMR spectra). Chemical shifts were referenced to solvent resonances at δ_H 7.26 for $CDCl_3$ and δ_H 6.00 for $C_2D_2Cl_4$. 5-Methyl-2,2'-bipyridine was synthesized by modification of a literature preparation [7a] and 5-(bromomethyl)-2,2′-bipyridine was synthesized according to the literature [7b]. Fluorescence measurements were performed using an SLM-Aminco 8100 spectrofluorometer using degassed dichloromethane as solvent. The excitation wavelengths used are 333 and 450 nm with a slit width setting of 8. All spectral and NMR measurements for {ruthenium[bis(bipyridyl)][N-(5-methyl-2,2'-bipyridyl)-1,8-naphthalimide]}$(PF_6)_2$ (**1**) were performed using the powder form of the product. Voltammetric experiments were performed in a three-compartment cell with potentiometric control by an RDE4 bipotentiostat (Pine Instrument). Electrode potentials used in voltammetric experiments were measured and reported versus the saturated calomel electrode (SCE). The working and auxillary electrodes for all voltammetric experiments were platinum. Voltammetric data were collected using a personal computer equipped with a BNC-2110 data acquisition interface (National Instruments) and Labview data acquisition software (National Instruments). The electrolyte used in the voltammetric experiment was 0.1 M tetra-*n*-butyl ammonium hexafluorophosphate in acetonitrile.

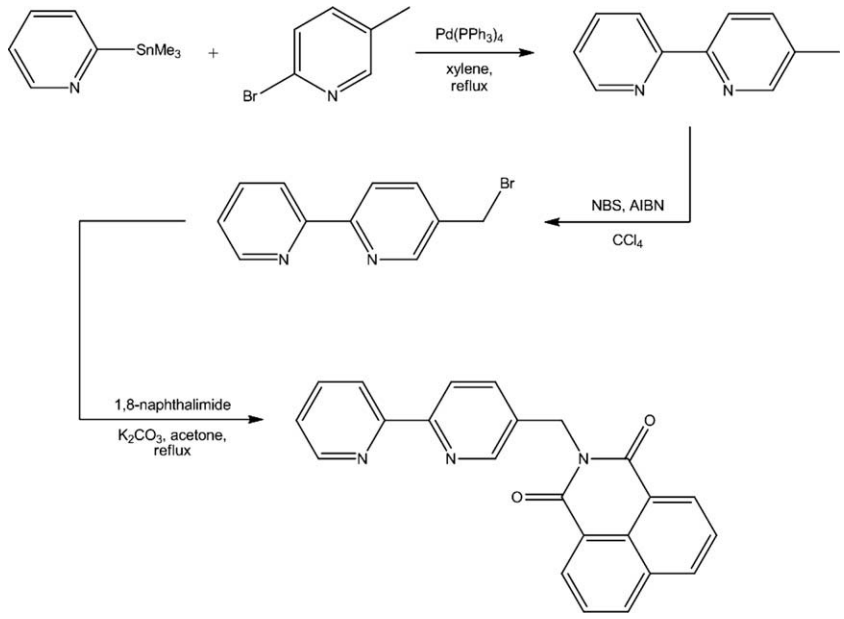
2.2. N-(5-methyl-2,2'-bipyridyl)-1,8-naphthalimide (*L*)

A solution of 5-(bromomethyl)-2,2'-bipyridine (1.00 g, 4.01 mmol) and 1,8-naphthalimide (0.791 g, 4.01 mmol) in acetone (40 mL) was heated at reflux over potassium carbonate (3.00 g, 22.1 mmol) under ambient atmosphere for 18 h. The resulting transparent, golden brown mixture was filtered and the solvent removed via rotary evaporation resulting in 0.582 g (40% yield) of off-white solid. This compound was used without further purification. ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): δ 8.92 (s, 1H, *py*), 8.66 (br d, 2H, *py*), 8.62 (d, J = 8.4 Hz, 2H, *napht*), 8.39 (br t, 2H, *py*), 8.25 (d, J = 8.4 Hz, 2H, *napht*), 8.03 (br d, 1H, *py*), 7.78 (t, J = 7.6 Hz, 2H, *napht*), 7.30 (br t, 1H, *py*), 5.46 (s, 2H, $-CH_2-$). ES^+/MS for $\{C_{23}H_{15}N_3O_2 + H\}^+$: Calc. = 366.1242; Obs. = 366.1243.

2.3. {Ruthenium[bis(bipyridine)][N-(5-methyl-2,2′-bipyridine)-1,8-naphthalimide]}$(PF_6)_2$ (*1*)

An ethanol solution (30 mL) of N-(5-methyl-2,2′-bipyridine)-1,8-naphthalimide (0.236 g, 0.65 mmol) and *bis*(2,2′-bipyridine)ruthenium(II) dichloride · $2H_2O$ (0.336 g, 0.65 mmol) was heated at reflux for 12 h. The solution was condensed to a smaller volume (~5 mL) via rotary evaporation and saturated, aqueous ammonium hexafluorophosphate was added, resulting in a copious quantity of bright red powder. The powder was filtered and air dried giving a yield of 0.563 g (82%) of solid. ^{1}H NMR (500 MHz, $C_2D_2Cl_4$, 25 °C): δ 8.58–7.39 (m, 29H, all aromatics), 5.26, 5.13 (d, d; J = 14.5; 1H, 1H; CH_2). ES^+/MS for $[(C_{43}H_{31}N_7O_2Ru)(PF_6)]^+$: Calc. = 924.1237; Obs. = 924.1272.

2.4. X-ray crystallographic determination



X-ray quality crystals of **1** · C_3H_6O were grown from acetonitrile via diethyl ether vapor-phase diffusion. X-ray diffraction intensity data from a flat red needle crystal were measured at 150(1) K on a Bruker SMART APEX diffractometer (Mo Kα radiation, λ = 0.71073 Å) [8]. Raw area detector data frame integration was performed with SAINT+ [8]. Final unit cell parameters were determined by least-squares refinement of 5112 strong reflections from the data set. Analysis of the data showed negligible crystal decay during collection. Direct methods structure solution, difference Fourier calculations and full-matrix least-squares refinement against F^2 were performed with SHELXTL [9].

The compound crystallizes in the triclinic system. The space group $P\bar{1}$ was assumed and confirmed by the successful solution and refinement of the data. The asymmetric unit consists of one Ru(II) complex, two independent PF_6^- ions, an acetone molecule of crystallization and another region of unidentified electron density. Disorder is prevalent in the crystal, not all of which could be modeled successfully. The displacement ellipsoids of the naphthalimide group atoms C47–C53 are severely elongated, indicating some disorder most noticeably affecting the extremity of this group. A satisfactory, stable disorder model could not be achieved however, and the elongated ellipsoids were allowed to account for the disorder. One PF_6^- anion (P2) is disordered and was modeled as occupying two orientations (P2A/P2B) in the ratio 60/40. A total of 63 distance restraints were used to assist in modeling the disorder. Unusual displacement ellipsoids and the presence of several residual electron density peaks in the vicinity of this anion indicate the disorder is not fully described by a two-component model. There is a region of unidentifiable residual electron density centered at (0,0,0), which was assumed to be disordered solvent molecules. No reasonable disorder model could be achieved for these species, and they were accounted for with the Squeeze routine in PLATON [10]. Squeeze calculated a solvent-accessible void volume of 290.0 Å^3, corresponding to 67 electrons per unit cell. The contribution of these diffusely scattering species was removed from subsequent structure factor calculations. The reported F(000), D_{calc} and FW reflect known unit cell contents only. All non-hydrogen atoms were refined with anisotropic displacement parameters except for the fluorine atoms of P2B (common isotropic displacement parameter). Hydrogen atoms were placed in geometrically idealized positions and included as riding atoms.

3. Results and discussion

3.1. Synthesis

The new ligand, *N*-(5-methyl-2,2′-bipyridyl)-1,8-naphthalimide, was synthesized by the reaction of commercially available 1,8-naphthalimide, 5-(bromomethyl)-2,2′-bipyridine and potassium carbonate in refluxing acetone (Scheme 1). Reaction of this ligand and bis(bipyridyl)ruthenium(II) dichloride in refluxing ethanol and subsequent exposure to saturated, aqueous ammonium hexafluorophosphate resulted in high yield of {ruthenium-[bis(bipyridyl)][N-(5-methyl-2,2′-bipyridyl)-1,8-naphthalimide]}-$(PF_6)_2$ (**1**) as a bright red powder.

Scheme 1. Synthesis of *N*-(5-methyl-2,2'-bipyridyl)-1,8-naphthalimide (**L**).

3.2. Solid-state and supramolecular structure

The ORTEP diagram, shown in Fig. 1, shows the cation of **1** · C_3H_6O. The naphthalimide-functionalized ligand chelates the ruthenium(II) in the standard fashion for a 2,2'-bipyridine ligand (for crystallographic information, see Table 1). The Ru–N bond lengths (see Table 2) match with other literature values and have an average value of 2.054 Å [11]. The ruthenium(II) cation is further organized by the 1,8-naphthalimide synthon [4a]. The naphthalimide moieties are stacked in a 180° antiparallel fashion accompanied by a naphthalimide centroid–centroid slip angle of 21° (Fig. 2a). The π–π stacking distance between the adjacent naphthalimide groups is 3.325 Å, a distance indicating a strong π–π stacking interaction (Fig. 2b) [3]. The crystal structure does not contain any additional explicit non-covalent interactions but is further organized by standard electrostatic and van der Waals interactions.

3.3. PGSE-NMR experiments

With the solid-state structure analysis showing the strong π–π stacking of the 1,8-naphthalimide moiety, we performed the

pulsed-field gradient spin-echo NMR experiment (PGSE-NMR) to determine if this interaction persists in solution. Described in detail elsewhere [12], the PGSE-NMR technique provides an indirect measure of molecular size by allowing the determination of the diffusion coefficient of a given species in solution. Subsequent application of the Stokes–Einstein relation then yields the hydrodynamic radius, which typically falls within ca. 20% of the crystallographic radius. This technique has been successfully used in many different applications, including establishing the presence or absence of dimeric species in solution [13]. For the ruthenium(II) complex, the PGSE-NMR method radius (12.98 Å) is in accordance with that found from the X-ray data (13.44 Å) for the dimeric units, with a difference of only 3.4%, indicating that the 1,8-naphthalimide groups are associated in solution and that their dipole vectors are oriented at approximately 180°. Any significant deviation from linearity would produce smaller radii values in the PGSE-NMR experiment. For comparison, similar experiments with $Re(CO)_3Br[(3\text{-pyrenyl-pz})_2CH(^nPr)]$ (pz = pyrazolyl ring) that we have reported previously showed the complexes were monomeric in solution even though the solid state structure showed association by π–π stacking of the pyrene groups [13b]. While we had previously demonstrated that the π–π stacking interaction of metal complexes containing 1,8-naphthalimide persists in solution, this is the first demonstration that cationic species organized by the 1,8-naphthalimide synthon persist in solution.

3.4. UV–VIS and fluorescence spectral data

The UV–VIS and fluorescence spectra of **1** are shown in Figs. 3 and 4, respectively. The UV–VIS spectrum (Fig. 3), which shows that the absorbance intensity decreased linearly as concentration decreased, is characterized by a λ_{max} peak located at 452 nm for the MLCT (metal-to-ligand charge transfer) transition for the $[Ru(bipy)_3]^{2+}$ core. This $[Ru(bipy)_3]^{2+}$ core transition is red shifted by approximately 12 nm in relation to that of an unsubstituted $[Ru(bipy)_3]^{2+}$. The naphthalimide group shows a complicated set of transitions with an absorbance at 288 nm, a series of absorbances in the range of 315–350 nm, and a broad absorbance centered at 428 nm. While somewhat similar to those reported previously for naphthalimides substituted on the ring nitrogen [14], the substitution on the ring is influencing the behavior when compared to simple alkyl substituted naphthalimides.

The fluorescence spectrum (Fig. 4), which also had a linear decrease of intensity as concentration decreased, was obtained using samples of the same concentrations as those used for UV–VIS analysis. The excitation wavelength was 333 nm with a slit width setting of 8. The spectrum is characterized by a peak located a λ_{max} 595 nm that is very similar to the fluorescence associated with the $[Ru(bipy)_3]^{2+}$ core of other systems [15]. There are also peaks

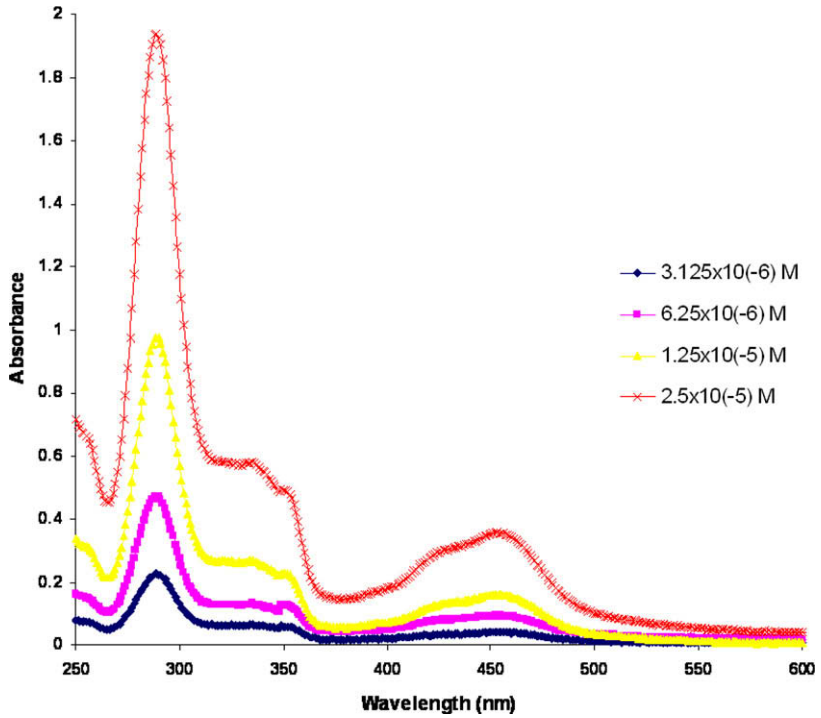

Fig. 3. UV–VIS spectra of **1** in degassed methylene chloride.

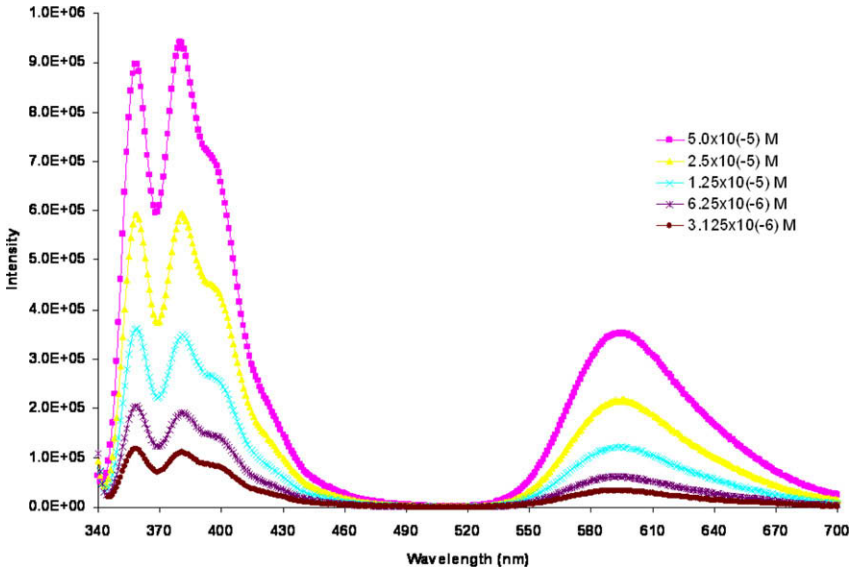

Fig. 4. Fluorescence spectra of **1** in degassed methylene chloride with an excitation wavelength of 333 nm.

at 360 (λ_{max} at concentrations 1.25×10^{-5} M and lower) and 382 (λ_{max} at concentrations 2.5×10^{-5} M and higher) with a shoulder at 398 nm, indicative of the fluorescence associated with the 1,8-naphthalimide moiety. The fluorescence efficiency of the 1,8-naphthalimide moiety was calculated relative to the $[Ru(bipy)_3]^{2+}$ core (fluorescence efficiency of 5.3×10^{-2}) and was found to have a value of 3.58×10^{-2}, an increase from 2.9×10^{-2} for unsubstituted 1,8-naphthalimide [14]. Increases of this magnitude are comparable to increases achieved by organic substitution of the naphthalimide system [14].

3.5. Electrochemical Measurements

The cyclic voltammogram of **1** (Fig. 5) shows two significant areas. A major reversible electrochemical process is centered on a potential of approximately 1.30 V, which suggests that this couple is due to the ruthenium (II) ion in the complex. This observed potential is in close agreement with the work conducted by De Cola et al. for other $[Ru(bipy)_3]^{2+}$ core molecules [15]. The other significant area is in the −1.00 V to −1.50 V range. Although not as distinct as the ruthenium (II) ion couple, there appears to be at least two elec-

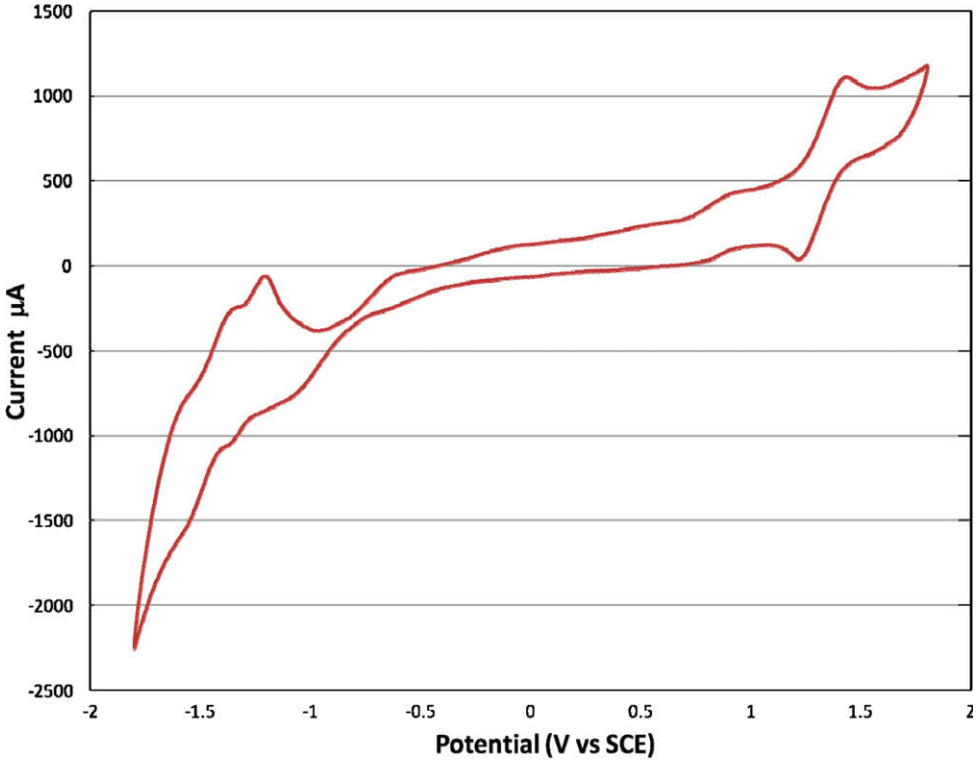

Fig. 5. Cyclic voltammogram of **1** in acetonitrile with 0.1 M tetra-*N*-butyl ammonium hexafluorophosphate as supporting electrolyte.

trochemical processes in this range. In comparison to the work by Martin et al. [5], the reversible process seen at approximately −1.35 V is due to the 1,8-naphthalimide portion of the ligand, although its appearance is more complex than a simple naphthalimide compound [5].

4. Conclusion

The synthesis of *N*-(5-methyl-2,2'-bipyridyl)-1,8-naphthalimide and {ruthenium[bis(bipyridyl)][N-(5-methyl-2,2'-bipyridyl)-1,8-naphthalimide]}$(PF_6)_2$ has been successfully carried out. In the solid state structure of **1**, the 1,8-naphthalimide groups are π–π stacked in a 180° antiparallel arrangement. This π–π stacking interaction was also shown to be present in solution by PGSE-NMR analysis, further demonstrating the utility of the 1,8-naphthalimide synthon to organize the structures in both the solid state and in solution of metal systems, either neutral [4a] or cationic, as shown here. Thus, we have now demonstrated that the strong, directionally oriented π–π stacking of the 1,8-naphthalimide synthon can be easily transferred to a variety of metal based systems. UV–VIS, fluorescence spectroscopy analysis and the electrochemical experiments show that the behavior of the $[Ru(bipy)_3]^{2+}$ group is only slightly changed by the presence of the naphthalimide group and its highly organized π–π stacking interactions.

5. Supplementary data

CCDC 715283 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

obtained commercially and dried before use. Potassium carbonate (K_2CO_3), urea, 1-chloronaphthalene (1-CNP), deuterated chloroform ($CDCl_3$), phenol, 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU), lead acetate, 4-*tert*-butylphenol and 4-benzyloxyphenol were purchased from Aldrich and used as received. Dimethylsulfoxide (DMSO) was purchased from SAARCHEM, and dried over alumina before use. 4-Nitrophthalonitrile (**1**) [13] and 4,5-dichlorophthalonitrile (**2**) [14] were synthesized and purified according to literature procedures. Column chromatography was performed on silica gel 60 (0.04–0.063 mm).

2.2. Equipment

Ground state electronic absorption spectra were performed on a Varian Cary 500 UV–Vis–NIR spectrophotometer; infra-red spectra (KBr pellets) on Perkin Elmer Spectrum 2000 FT-IR Spectrometer and ^{1}H nuclear magnetic resonance (^{1}H NMR) spectra on a Bruker EMX 600 NMR spectrometer. Triplet lifetimes (τ_T) and yields were obtained using an Nd-YAG laser providing 400 mJ, 90 ns of laser light at 10 Hz, pumping a Lambda-Physik FL 3002 dye laser. A 300 W xenon arc lamp (Thermo Oriel) provided the analysing light. Kinetic curves were averaged over 256 laser pulses using a Tektronix TDS 360 digital oscilloscope. The τ_T values were obtained by fitting an exponential curve to the kinetic data using ORIGIN Pro 6.0. Elemental analyses were obtained using Elementar Vario Micro Cube CHNS Analyser). Microwave irradiations were carried out in a Defy DM206T microwave oven at a power of 1000 W.

2.3. Photophysical properties

Fluorescence quantum yields (Φ_F) were determined by the comparative method, using the following equation [15,16]:

$$\Phi_F = \Phi_F^{std}\frac{F\cdot A_{std}\cdot n^2}{F_{std}\cdot A\cdot n_{std}^2} \tag{1}$$

where F and F_{std} are the areas under the fluorescence curves of the MPc derivatives and the standard, respectively. A and A_{std} are the respective absorbances of the sample and standard at the excitation wavelengths (which was ~0.05 in all solvents used), and n and n_{std} are the refractive indices of the solvents used for sample and standard, respectively. ZnPc was employed as a standard in DMSO (Φ_F = 0.20) [15].

The triplet quantum yields were determined using the following equation:

$$\Phi_T = \Phi_T^{std}\frac{\Delta A_T\cdot \varepsilon_T^{std}}{\Delta A_T^{std}\cdot \varepsilon_T} \tag{2}$$

where ΔA_T and ΔA_T^{std} are the changes in triplet state absorbance of MPc derivatives and the standard, respectively. ε_T and ε_T^{std} are the triplet state molar extinction coefficients for the MPc derivatives and the standard, respectively. Φ_T^{std} is the triplet quantum yield for the standard, ZnPc (Φ_T = 0.65 in DMSO [17], 0.58 in DMF [18] and 0.65 in toluene [19]). Quantum yields of internal conversion were obtained from Eq. (3), which assumes that only three processes (fluorescence, intersystem crossing and internal conversion), jointly deactivate the excited singlet state of a Pc molecule

$$\Phi_{IC} = 1 - (\Phi_F + \Phi_T). \tag{3}$$

2.4. Nonlinear optical parameters

The important parameters in this section are (i) k: the ratio of the absorption cross-sections of the ground (σ_g) and excited (σ_{ex}) states, I_{lim} (the threshold limit intensity), $I_m[\chi^{(3)}]$ and γ, the third and second order susceptibilities, respectively.

k can be calculated using Eq. (4). A good optical limiter should have k of more than one

$$k = \frac{\sigma_{ex}}{\sigma_g} \tag{4}$$

The I_{lim} values were calculated using Eq. (5) [4,20]:

$$I_{lim} = \frac{h\omega^*}{2\pi\sigma_g\tau_T} \tag{5}$$

where ω^*, σ_g and τ_T are the frequency at which the system absorbs, singlet absorption cross-section and triplet lifetimes, respectively.It therefore makes sense in this regard to mention that an ideal optical limiter should have a low threshold limit value (I_{lim}), if it is too high, it becomes less reliable in terms of protection of light-sensitive elements.

2.4.1. Third order susceptibility $\chi^{(3)}$ and second hyperpolarizability, γ

The third order susceptibility, $I_m[\chi]^{(3)}$, is given by [20]

$$I_m[\chi^{(3)}] = \frac{2c^2n^2\beta}{\pi\omega^*}\times 10^{-22} \tag{6}$$

where n, c and ω^* are, respectively, the linear refractive index (n = 1.478 in DMSO), the speed of light and the frequency. β represents a nonlinear absorption term which averages the molar extinction coefficient ε_g and ε_{ex} according to the following equation [20]:

$$\beta = 5.3\varepsilon_g\varepsilon_{ex}[C]\Phi_{ISC} \tag{7}$$

where ε_g and ε_{ex} are extinction coefficients for the ground and excited state, respectively, $[C]$ is the concentration of active species in the triplet state and Φ_{ISC} is the intersystem crossing quantum yield.

At a molecular level, $I_m[\chi]^{(3)}$ is directly related to the second hyperpolarizability, γ, through the following equation [4,21,22]:

$$\gamma = \frac{I_m[\chi^{(3)}]}{f^4[C]N_a} \tag{8}$$

where N_a is Avogadro's constant, C is the concentration of the active species in the triplet state and f is Lorentz local field factor, $f = (\eta^2 + 2)/3$, where η is the viscosity.

These nonlinear parameters, $I_m[\chi^{(3)}]$ and γ, are used to quantify the nonlinear absorption.

2.5. Synthesis

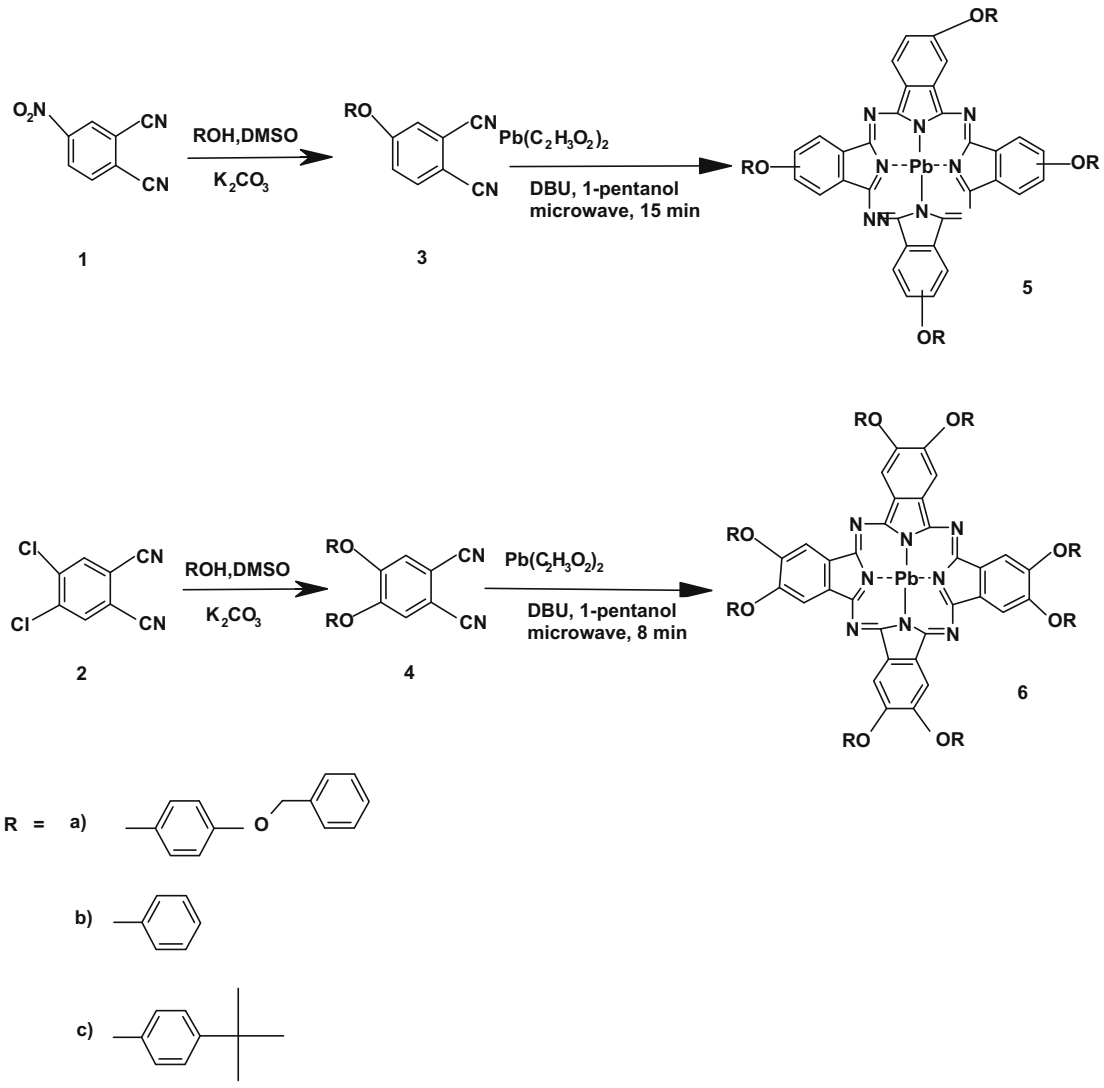
4-(4-Benzyloxyphenoxy)phthalonitrile (**3a**) and 4,5-bis(4-benzyloxyphenoxy) phthalonitrile (**4a**) were synthesized and characterized according to reported procedures [23].

2.5.1. 2,(3)-Tetrakis(4-benzyloxyphenoxy)phthalocyaninato lead (**5a**)

A mixture of compound **3a** (0.10 g, 0.29 mmol), lead acetate (0.05 g, 0.14 mmol), DBU (0.2 ml) and 5 ml *n*-pentanol was irradiated at 1000 W in a microwave for 15 min. After cooling, the product was washed with methanol and chromatographed over silica gel with hexane as eluent to remove impurities. The column was then eluted with THF and then hexane and the solvents were evaporated off, thus affording **5a**. Yield: 80 mg (19%). UV–Vis (DMSO): λ_{max}, nm (log ε) 710 (4.98), 641 (4.32), 346 (4.46). IR [(KBr) ν_{max}/cm^{-1}]: 2948 (CH_2), 1605 (C=C), 1218(C–O–C), 941, 827, 734, 696 (Pc skeletal). ^{1}H NMR (DMSO-d_6): δ, ppm 7.52–7.58 (4H, m, Pc–H), 7.44–7.49 (8H, m, Pc–H), 7.35–7.42 (20H, m, phenyl–H), 7.22–7.28 (16H, m, phenyl–H), 5.20 (8H, s, CH_2). *Anal.* Calc. for $C_{84}H_{56}N_8O_8Pb$.hexane: C, 67.63; H, 4.38; N, 7.01. Found: C, 68.35; H, 4.70; N, 7.33%.

*2.5.2. 2,3-Octakis(4-benzyloxyphenoxy)phthalocyaninato lead (**6a**)*

Synthesis and purification was as outlined for **5a** except **4a** instead of **3a** was employed. The amounts of the reagents employed were as follows: **4a** (0.25 g, 0.36 mmol), lead acetate (0.06 g, 0.18 mmol), DBU (0.2 ml) and *n*-pentanol (5 ml). Irradiation was for 8 min. Yield: 0.75 g (46%). UV–Vis (DMSO): λ_{max}, nm ($\log\varepsilon$) 712 (5.01), 638 (4.34), 347 (4.45) IR [(KBr) ν_{max}/cm^{-1}]: 2925 (CH_2), 1504 (C=C), 1231 (C–O–C), 1000, 875, 839, 739, 694 (Pc skeletal). ^{1}H NMR (DMSO-d_6): δ, ppm 7.54–7.56 (8H, br, Pc–H), 7.44–7.48 (32H, br, phenyl–H), 7.22–7.38 (40H, br, phenyl–H), 5.09–5.26 (16H, s, CH_2). *Anal.* Calc. for $C_{136}H_{96}N_8O_{16}Pb$: C, 70.85; H, 4.20; N, 4.86. Found: C, 71.31; H, 4.30; N, 5.38%.



3. Results and discussion

3.1. Syntheses and characterization

Scheme 1 gives the synthetic pathways for the PbPc complexes discussed in this work. The general procedure for synthesis of substituted phthalonitrile derivatives has been well documented [24] and the preparation of the substituted 4-benzyloxyphenoxy derivatives was carried out as reported before [23]. PbPcs can be synthesized using many methods including treatment of phthalonitrile with lead acetate without solvent [25] or heating in the presence of high boiling solvent [12,26] or by addition of lead acetate to a solution of Li_2Pc or H_2Pc in alcohol [26,27] and can also be obtained by microwave method [28]. In this work, we employed microwave method to prepare the target PbPcs.

The complexes were characterized by UV–Vis, IR and ^{1}H NMR spectroscopies, and elemental analyses. The analyses were consistent with the predicted structures as shown in Section 2. The sharp peak for the C≡N vibrations in the IR spectra of phthalonitriles **3a** and **4a** at ~2230 cm^{-1} disappeared after conversion into PbPcs, indicative of metallophthalocyanine formation. All compounds showed vibrational peaks between 700 and 1000 cm^{-1} which may be assigned to phthalocyanines skeletal vibrations [29]. The characteristic vibrations corresponding to ether groups (C–O–C) at ca. 1200–1235 cm^{-1}, C=C at ca. 1500–1600 cm^{-1} and aliphatic CH stretching at ca. 2900–3000 cm^{-1} were observed for the substituted MPc derivatives.

The PbPc derivatives were found to be pure by ^{1}H NMR with all the substituents and ring protons observed in their respective regions. The CH_2 protons were observed at 5.20 ppm for compound **5a** integrating for 8 protons and 5.09–5.26 ppm for **6a** integrating for 16 protons. The resonances belonging to aromatic protons were observed between 7.22 and 7.58 ppm as multiplets for

Scheme 1. Synthesis of tetra- and octa-substituted lead phthalocyanines.

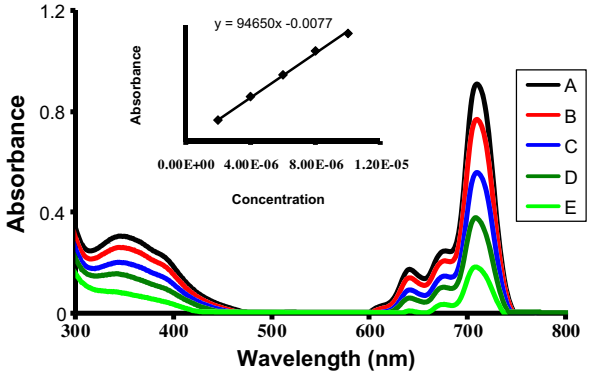

Fig. 2. Absorption spectra of compound **5a** in DMSO at different concentrations: (A) 1×10^{-5}, (B) 6×10^{-6}, (C) 4×10^{-6}, (D) 2×10^{-6}, (E) 2×10^{-6} M

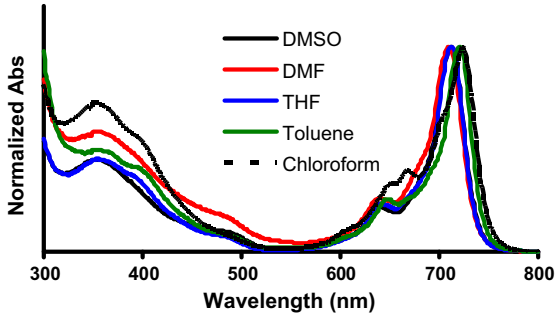

Fig. 3. Absorption spectra of complex **6a** in different solvents (~2×10^{-6} M).

tetra-substituted complex (**5a**) integrating for a total of 48 protons while for octa-substituted complex (**6a**), the aromatic protons were observed as broad peaks from 7.22 to 7.56 ppm, integrating for a total of 80 protons expected. Although the presence of isomers for tetra-substituted complex as well as phthalocyanine aggregation at the concentration used for the NMR measurements may lead to broadening of the aromatic signals [30–32], the NMR peaks were relatively well-resolved.

The ground state electronic absorption spectra of **5** and **6** show sharp Q-bands, Fig. 1. The Q-bands were observed at 710 and 712 nm in DMSO (Fig. 1) for complexes **5a** and **6a**, respectively. The Q-bands are slightly red shifted in the complexes when compared to unsubstituted PbPc [33], suggesting a small electron donating ability of the substituents, hence lowering HOMO–LUMO gap. The B-bands are broad due to the superimposition of the B_1 and B_2 bands in 300–400 nm region.

Aggregation is usually depicted as a coplanar association of rings progressing from monomer to dimer and higher order complexes. It is dependent on the concentration, nature of the solvent, nature of the substituents, complexed metal ions and temperature [34]. The aggregation behaviour of complexes **5a** and **6a** were investigated at different concentrations in DMSO (Fig. 2 for complex **5a**). The intensity of the Q- and B-bands increased with increase in concentration and there were no new bands observed due to aggregated species. Beer–Lambert's law was obeyed for both compounds at concentrations ranging from 2.0×10^{-6} to 1.0×10^{-5} mol dm^{-3}, even though **6a** shows some broadening in the Q-band area. The aggregation behaviour was also investigated in different solvents (Fig. 3 for complex **6a** in DMSO, DMF, Toluene, THF and $CHCl_3$). There was evidence of new bands in the 650 nm region (in some solvents) suggesting aggregation [35]. Fig. 3 and Table 1 show that the largest red-shift of the Q-band was observed in chloroform, which could partly be explained by considering the refractive indices of the solvents. It is known that red-shifting of absorption spectra is a function of the solvent's refractive index [36].

3.2. Photophysical properties

3.2.1. Fluorescence spectra and quantum yields

All complexes showed similar fluorescence behaviour. The fluorescence and absorption spectra are shown in Fig. 4. No emission was observed to the red of the Q-band absorption spectra. The excitation spectra were different from absorption spectra in all solvents due to demetallation upon excitation, as judged by the blue shifted and split Q-band. The excitation spectra were similar to the absorption spectra of the corresponding demetallated H_2Pc derivatives, confirming demetallation upon excitation. Emission spectra for all compounds were from the demetallated species. Metal free

	THF	709	702	699, 671	0.02	[a]	[a]	8

[a] Values not obtained in THF and $CHCl_3$ due to lack of reference standards.

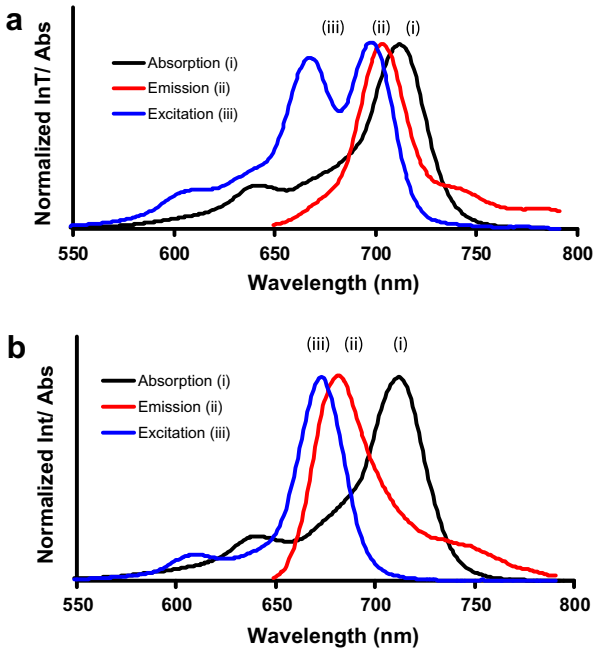

Fig. 4. (a) Absorption (i), emission (ii) and excitation (iii) spectra of compound **6a** in toluene ($\sim 2 \times 10^{-6}$ M). (b) Absorption (i), emission (ii) and excitation (iii) spectra of compound **6a** in DMSO ($\sim 2 \times 10^{-6}$ M).

Pcs are known to emit with only one main peak in non-aqueous media which has been assigned as the 0–0 transition [37]. Complete splitting of the Q-band in excitation spectra was observed in THF, $CHCl_3$, toluene and DMF. In DMSO (Fig. 4), the Q-band was not split. It has been documented that in basic solvents such as DMSO, the inner pyrrole hydrogens are acidic enough to dissociate resulting in an unsplit Q-band [35].

The fluorescence quantum yields (Φ_F) of complexes **5a** and **6a** are given in Table 1. The Φ_F values were found be less than 0.1, hence less than typical values for MPc [38]. The small Φ_F values (Table 1) were due to the presence of heavy atom (Pb), which enhances intersystem crossing to populate the triplet state, consequently reducing the number of fluorescing molecules. The fact that the PbPc complexes become demetallated on excitation suggests that the Φ_F values are for the fully or partially demetallated complexes in different solvents.

3.2.2. Triplet quantum yields and lifetimes

Table 1 lists the triplet state parameters, Φ_T, Φ_{IC} and τ_T for complexes **5a** and **6a** in different solvents. The triplet quantum yield (Φ_T) is a measure of the fraction of absorbing molecules that undergo intersystem crossing to the metastable triplet excited state. Since intersystem crossing and fluorescence are two competing deactivating processes for the excited singlet state, their values for a particular species are expected to be complementary. Thus Table 1 shows high Φ_T values (0.80–0.86) in DMSO, DMF and toluene, corresponding to low Φ_F values. These values are high due to the presence of lead. Since PbPc demetalates on excitation, the reported Φ_T values are of demetallated species, but since Pb is still in solution, the values are high due to the heavy atom effect. The Φ_T values in $CHCl_3$ and THF could not be determined due to the lack of standard Φ_T values in those solvents. The triplet lifetimes τ_T Table 1, were relatively short compared to, for example ZnPc with a triplet lifetime of 350 μs, in DMSO [38]. The short triplet lifetimes could be due to their large triplet state quantum yields. Quantum yields of internal conversion (Φ_{IC}) were calculated using Eq. (3).

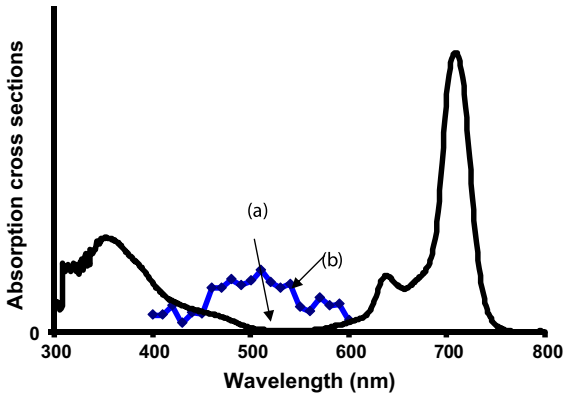

Fig. 5. Absorption cross-sections for the ground (a) and excited triplet (b) state for compound **5c** in DMSO ($\sim 1 \times 10^{-6}$ M).

Table 1 shows that the values of Φ_{IC} were similar and relatively low, Table 1.

3.3. Nonlinear optical properties

The nonlinear optical parameters were calculated for PbPc complexes (**5a–c**, **6a–c**) in DMSO. The absorption cross-sections were determined from Fig. 5 (for complex **5c**). $k(\sigma_{ex}/\sigma_g)$ values >1 were obtained, Table 2. As mentioned above, a good optical limiter should have a k of more than one. The higher the k, the better limiting power, thus octa-substituted PbPcs (**6**) are the better optical limiters than their corresponding tetra-substituted PbPc derivatives (**5**).

The limiting threshold intensity (I_{lim}) values (Table 2) were found to be small, compared to those reported in the literature for GaPcs and InPcs [39]. An optical limiter should possess a low threshold limit value in order to be reliable in terms of protection of optical elements. The smaller the liming intensity (I_{lim}), the better optical limiter. The value of 10^2 W/cm^2 is generally taken as the standard value for the minimum intensity using the human eye as the reference light-sensing element [4]. The I_{lim} values obtained in Table 2 showed that PbPc derivatives are good optical limiters.

Table 2 shows the values of third order susceptibility ($I_m[\chi^{(3)}]$) and second hyperpolarizability (γ) for PbPc complexes. For a good optical limiter, $I_m[\chi^{(3)}]$ should fall within the 10^{-15} to 10^{-9} esu range and γ within the 10^{-34} and 10^{-29} esu range [40–44]. These values were lower than those reported for InPc and GaPc [39]. This is most likely due to the heavy atom effect because it has been reported that the value of $I_m[\chi^{(3)}]$ decreased in MPcs with increasing atomic number of a metal [4], hence the low values for PbPc are not surprising. Except for complexes containing 4-benyloxyphenoxy substituent (**a**), the $I_m[\chi^{(3)}]$ values for octa-substituted PbPcs were marginally larger than tetra-substituted PbPc derivatives (compare **5b** with **6b** and **5c** with **6c**). The second hyperpolarizability (γ) values were well within the range of the values reported in the literature for Ga and InPc derivatives [39].

Table 2
Nonlinear optical parameters of PbPc derivatives in DMSO.

MPc in DMSO	τ_T (μs)	$I_m[\chi^{(3)}]$ (esu)	γ (esu)	(k) σ_{ex}/σ_g	I_{lim} (W cm^{-2})
5a	40	6.3×10^{-12}	1.6×10^{-34}	27	3.1
5b	20	3.3×10^{-12}	0.9×10^{-34}	23	6.6
5c	30	5.3×10^{-12}	1.3×10^{-34}	26	3.9
6a	30	4.8×10^{-12}	2.8×10^{-34}	35	2.1
6b	20	4.2×10^{-12}	2.2×10^{-34}	26	3.8
6c	50	5.6×10^{-12}	2.9×10^{-34}	33	2.3

4. Conclusion

From the results obtained in this work, it can be concluded that the fluorescence spectra were different from absorption spectra due to the loss of symmetry as a result of demetallation upon excitation. The high triplet quantum yields and low triplet lifetimes were observed as the result of heavy atom (Pb) effect. The optical limiting threshold intensity (I_{lim}) values for the PbPc derivatives confirm that they are good limiters. The I_{lim} values obtained were far less than of 10^2 W cm^{-2}, which is generally taken as the standard value for the minimum intensity using the human eye as the reference light-sensing element.

CCD detector and using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The raw data were integrated with the CRYSALIS Data Reduction Program (version 1.172.32.6) [8] taking into account an absorption correction. The intensities of the reflections were corrected for Lorentz and polarization effects. The crystal structures were solved by direct methods [9] and refined by a full-matrix least-squares method using the SHELXL-97 program [9]. Non-hydrogen atoms were refined with anisotropic displacement parameters. H-atoms were located from the difference Fourier maps and refined assuming a 'ride-on' model.

2.3. Spectroscopic and magnetic measurements

IR spectra were recorded as KBr pellets or Nujoll mulls using Perkin–Elmer FTIR-2000 and Perkin–Elmer 1600 spectrophotometers in the range 4000–50 cm^{-1}. The NIR–Vis–UV solid state-reflectance and absorbance electronic spectra in DMSO solution for complexes **1** and **2** and the L-tyrosine disodium salt (L) were obtained on a Cary 500 Scan Spectrophotometer in the range 5000–50 000 cm^{-1} with a resolution of 10 cm^{-1} and concentration [L] = 1.78 × 10^{-3} M, [**1**] = 8.66 × 10^{-4} M, [**2**] = 1.00 × 10^{-3} M. The variable digital filter method and deconvolution of the spectral contour into Gaussian components were applied for analysis of DMSO solution spectra in the range 11 000–23 000 cm^{-1} for **2** [10].

EPR spectra were recorded at room temperature and 77 K on a Bruker ESP 300 spectrometer operating at the X-band equipped with an ER 035 M Bruker NMR gaussmeter and HP 5350B Hewlett–Packard microwave frequency counter. Magnetic measurements in the temperature range 1.8–300 K were performed using a Quantum Design SQUID-based MPMSXL-5-type magnetometer. The SQUID magnetometer was calibrated with a palladium rod sample (Materials Research Corporation, measured purity 99.9985%). The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T. Measurements were made at a magnetic field of 0.5 T. Corrections are based on subtracting the sample holder signal and a contribution χ_D estimated from Pascal constants [11]. A temperature–independent paramagnetism of 60 × 10^{-6} cm^3 mol^{-1} K for each copper(II) ion was used for calculations. Magnetization measurements were carried out at 2 K in the magnetic field from 0 to 5 T.

3. Results and discussion

3.1. Crystal structure characterization of {[Zn(tyr)$_2$(H$_2$O)]H$_2$O}$_n$ (**1**) and [Cu(tyr)$_2$]$_n$ (**2**)

The crystal data and refinement details for {[Zn(tyr)$_2$(H$_2$O)]-H$_2$O}$_n$ (**1**) and [Cu(tyr)$_2$]$_n$ (**2**) are presented in Table 1. {[Zn(tyr)$_2$(H$_2$O)]H$_2$O}$_n$ (**1**) and [Cu(tyr)$_2$]$_n$ (**2**) [5,6] crystallize in the non-centrosymmetric space groups $P2_1$ and $P2_12_12_1$, respectively (Table 1).

The coordination spheres in {[Zn(tyr)$_2$(H$_2$O)]H$_2$O}$_n$ (**1**) and [Cu(tyr)$_2$]$_n$ (**2**) are created by two symmetrically independent anions of tyrosine in both studied compounds. Fig. 1 shows the coordination sphere for **1** and **2** with the atom numbering. One tyrosine anion (A) coordinates by the nitrogen atom from the amino group, N1A, and two oxygen atoms from the carboxylate group, O1A and O2A, whereas the second tyrosine anion (B) coordinates via the nitrogen atom, N1B, and only one oxygen atom from the carboxylate group (Fig. 1). Both tyrosinate anions act as chelating ligands to the Zn^{2+} and Cu^{2+} ions, and additionally L-Tyr(A) acts a bridging entity through the carboxylate group. This arrangement occurs in compounds **1** and **2**, also the *trans* coordination of the N1A and N1B

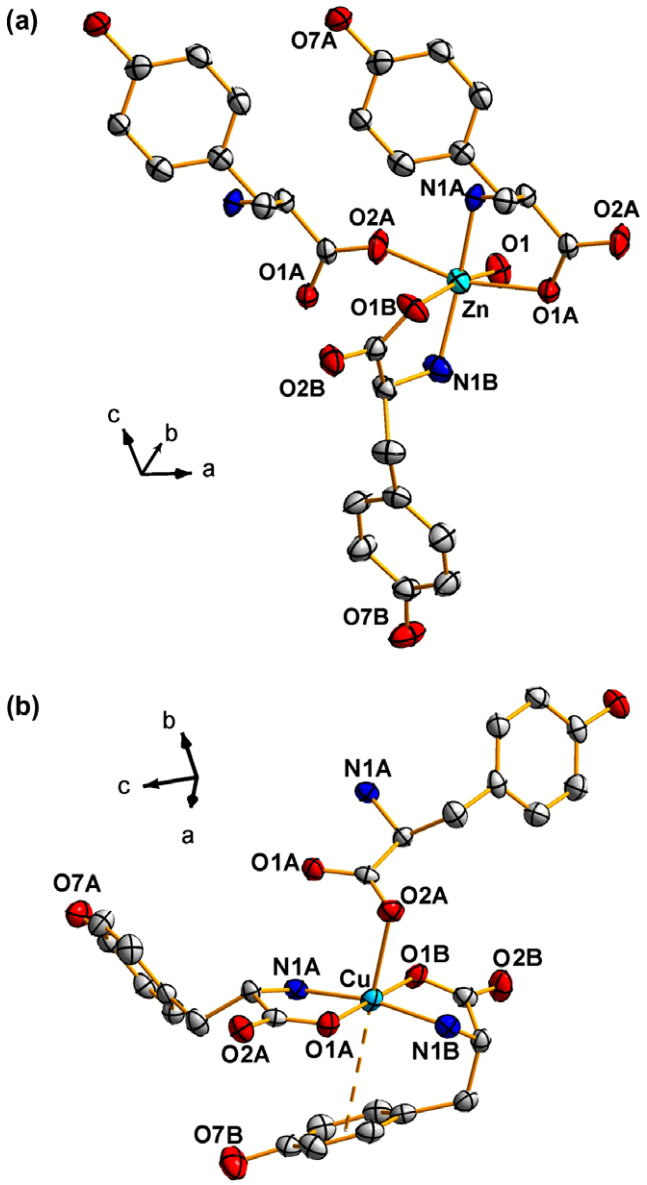

Fig. 1. Coordination sphere for $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) and $[Cu(tyr)_2]_n$ (**2**). Hydrogen atoms are omitted for clarity.

atoms is maintained. A six-coordination sphere is created around the Zn^{2+} ion by the N and O atoms from two tyrosine anions and is completed by an O atom from a water molecule. The $Zn–O(1)_{water}$ bond distance is comparable with other six-coordinated zinc(II) complexes with aminoacids [12–14]. The coordination polyhedron around the Zn^{2+} ion is compressed along the Zn–N bonds (Table 2).

In the case of the compound $[Cu(tyr)_2]_n$ (**2**), a penta-coordinated geometry of the copper ion is well determined [5,6]. Three oxygen atoms and two nitrogen atoms form a square-pyramidal arrangement around the copper ion (Fig. 1b). A flexible chain of carbon atoms in tyrosine provide an aromatic ring which interacts with a copper ion ($Cu\cdots\pi_{centroid}$ = 3.409 Å) [4h,4i]. Thus, an extended six-coordination sphere occurs when the Cu···π interaction is taken into account. Two maximal angles, namely β = O(1A)–Cu(1)–O(1B) and α = N(1A)–Cu(1)–N(1B), result in an angular parameter $\tau = (\beta - \alpha)/60 = 0.19$ [15] which is associated with a distorted pyramidal geometry (Table 2). The Cu–N distances in compound (**2**) are comparable with the Cu–O distances, because O1A, O1B, N1A and N1B create a base of the square pyramid. The vertex of this pyramid is occupied by the O2A atom from the bridging tyrosine. The Cu–O2A bond length, 2.387(2) Å, is longer than the Cu–N and Cu–O distances in the base of the square pyramid. The respective O2A atom from the bridging tyrosine in $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) lies in the base of the octahedron and the Zn–O2A bond length, 2.145(3) Å, is comparable with other Zn–O distances.

Symmetry transformations used to generate equivalent atoms: (i) $x+1,y,z$; (ii) $x-1/2,-y+3/2,-z$.

One-dimensional coordination polymeric structures exist in $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) and $[Cu(tyr)_2]_n$ (**2**) (Figs. 2 and 3), due to one tyrosine ligand acting as a bridging ligand. In the case of the compound (**1**), the coordination polymer is created as an unstranded chain (Fig. 2) with *trans* coordination of the carboxylate groups of L-Tyr(A). The distance between the Zn^{2+} ions in the chain is associated with the parameter a = 6.0255(8) Å. The distance between the Zn^{2+} ions in the neighbouring chains equals 10.951(1) Å. However, the chains are slightly shifted with respect to each other along the a-axis as a result of crystallization with

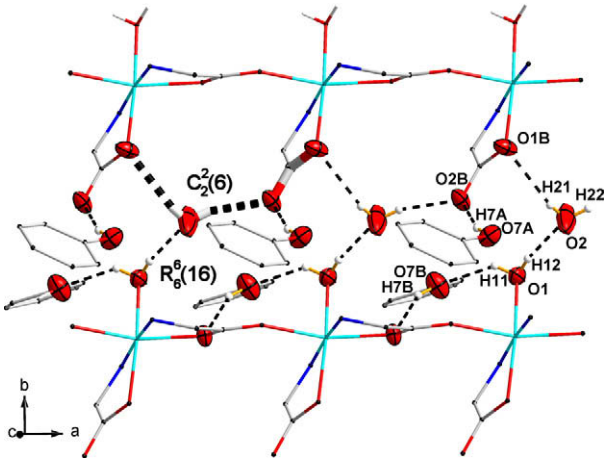

Fig. 2. Two chains of the 1D coordination polymer connected by a hydrogen bonding network in the structure of $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**). Some atoms were omitted for clarity.

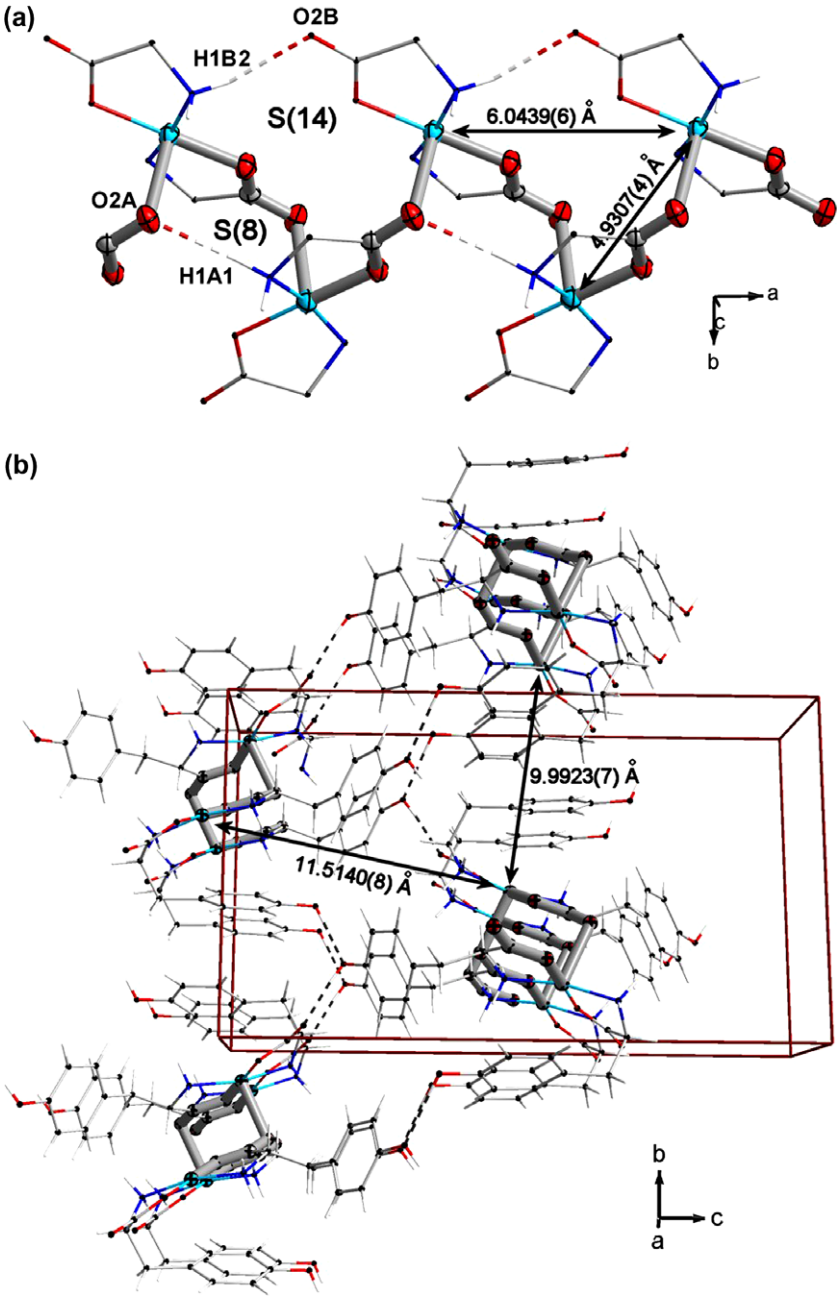

Fig. 3. (a) A helical chain of $[Cu(tyr)_2]_n$ (**2**) stabilized by two intramolecular hydrogen bonds. (b) Hydrogen bonding interactions between helixes viewed down [1 0 0].

the monoclinic space group with $\beta = 95.532(9)^\circ$. Contrary to the unstranded 1D polymeric structure of **1**, $[Cu(tyr)_2]_n$ (**2**) has a left-handed helical arrangement. The helix is extended along the *a*-axis and undergoes a complete turn every two copper ions, which are distanced from each other by 4.9307(4) Å (Fig. 3).

The most important reason for the unstranded structure formation of **1** and the helical structure of **2** is a different stereo geometry of the bridging carboxylate group in the coordination sphere of the Zn^{2+} and Cu^{2+} ions. A *trans* coordination results in the unstranded chain in **1**, whereas the *cis* coordination in **2** facilitates the helical structure which is also allowed by the symmetry element (2_1 axis). Overall, it appears that helical coordination polymers can be formed when the bridging ligands realize a *cis* coordination mode, as in the case of *catena*-(μ-CrO_4-O,O′)[$Ni(HIm)_3(H_2O)$] (HIm = 1H-imidazole) [16]. Additionally, if no enantiomeric molecule acts as a ligand, then left- and right-handed helixes exist simultaneously in the structure.

The polymeric structures of the compounds {$[Zn(tyr)_2(H_2O)]$-H_2O}$_n$ (**1**) and $[Cu(tyr)_2]_n$ (**2**) are stabilized by intra- and interchain hydrogen bonds (Figs. 2 and 3b; Table 3). However, intrachain hydrogen bonds exist only in the helical chain of compound (**2**). They are formed between the amino and carboxylate groups from L-Tyr(A), N(1A)–H(1A1)···O(2A), and this hydrogen bonding pattern is denoted by the S(8) graph set (Fig. 3a) [17]. The second intrachain hydrogen bond is created by the L-Tyr(B) anion, N(1B)–H(1B2)···O(2B), and the pattern is described by the S(14) graph set [17]. This arrangement resembles the hydrogen bond network in the α-helical structure of proteins. The helical structure of (**2**) is stabilized by two interchain hydrogen bonds created by the hydroxyl group from L-Tyr(A). This group is involved as a donor in the

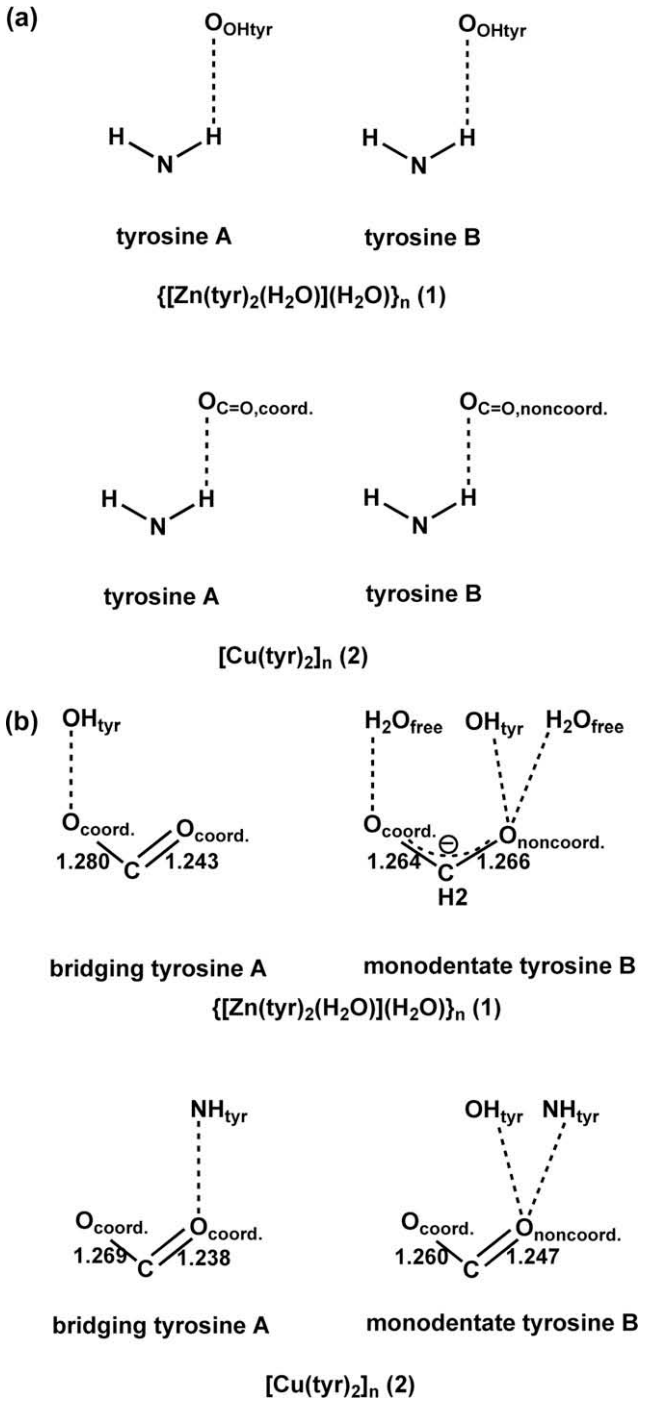
O(7A)–H(7A)···O(2B) hydrogen bond as well as an acceptor in the O(7B)–H(7B)···O(7A) hydrogen bond.



Contrary to the structure of (**2**), the amino groups create only interchain hydrogen bonds in the structure of $\{[Zn(tyr)_2(H_2O)]\text{-}H_2O\}_n$ (**1**) (Table 3). Each of the amino groups from two independent L-tyrosinate anions, L-Tyr(A) and L-Tyr(B), is involved in one hydrogen bond with the hydroxyl group as an acceptor. Besides, two molecules of water exist in the asymmetric unit of $\{[Zn(tyr)_2\text{-}(H_2O)]H_2O\}_n$ (**1**) (Table 3, Scheme 1). A non-coordinated molecule, H_2O_{free}, interacts with the carboxylate group from L-Tyr(B) resulting in a binary chain pattern, $C_2^2(6)$ (Fig. 2). A coordinated molecule of water interacts with H_2O_{free}, O(1)–H(12)···O(2), and the hydroxyl group of L-Tyr(B), O(1)–H(11)···O(7B), giving a large ring pattern designated as $R_6^6(16)$. Therefore, it appears that the presence of molecules of water is essential for the stabilisation of the Zn–COO–Zn backbone of the coordination polymer and additionally for stabilisation of the L-tyrosinate residue.

3.2. Vibrational IR–FIR spectroscopy

In the spectra of $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) and $[Cu(tyr)_2]_n$ (**2**), a broad absorption presents a multiple structure in the frequency range 3310–2500 cm^{-1}, which is assigned to ν_{as} and ν_s of the N–H and C–H vibrations [18,19]. These bands are observed at the same frequencies as for the ligand spectrum. An additional band, which appears at 3552 cm^{-1} in the spectra of complex **1**, is correlated with the ν(O–H) vibration of water molecules.

The region 1610–1290 cm^{-1} is characteristic of ν_{as} and ν_s vibrations of the carboxylate groups [1,20–22]. The coordination mode of the carboxylate group can be determined according to the correlation reported in [1,20a], where the value of the relation $\Delta\nu(COO) = \nu_{as}(COO) - \nu_s(COO)$ follows the order: $\Delta\nu_{monodentate}$ (much longer than 50 cm^{-1}) > $\Delta\nu_{ionic} \approx \Delta\nu_{bridging} > \Delta\nu_{chelate}$ (less than 50 cm^{-1}). The band assigned to the ν_{as} COO group vibrations is found at 1600 cm^{-1} for tyrosine salt and at 1604 and 1602 cm^{-1} for **1** and **2**, respectively. The ν_s COO vibration frequency equals 1422 cm^{-1} for sodium L-tyrosinate, whereas for both complexes the ν_s vibration is found as a doublet with components centred at 1450, 1404 cm^{-1} (**1**) and 1458, 1402 cm^{-1} (**2**). The magnitudes of separation $\Delta\nu = \nu_{as} - \nu_s$ for the complexes (154 cm^{-1} (**1**) and 144 cm^{-1} (**2**)) are close to the value for L-tyrosine salt (the ionic value is 175 cm^{-1}) and imply a bridging coordination mode of the carboxylate, which is in good agreement with the structural data.

In the ligand spectrum an intensive absorption at 1559 cm^{-1} is correlated with the δ NH_2 vibration, whereas very strong bands at

Scheme 1. The hydrogen bonds created by amino and carboxylate groups.

1279 and 1265 cm^{-1} are assigned to ρ_r NH_2 [20a,b,18]. The δ NH_2 bands are centred at 1592 cm^{-1} (**1**) and 1581 cm^{-1} (**2**), whereas the respective ρ_r vibrations are correlated with very strong bands at 1255, 1243 cm^{-1} (**1**) and 1247, 1234 cm^{-1} (**2**). A single band at 1101 cm^{-1} found in the spectrum of the tyrosine salt is correlated with the ρ_t and ρ_w NH_2 vibrations [20a,b,18]. This band becomes more intensive and is split into two well resolved components at 1099 cm^{-1}, 1080 cm^{-1} for (**1**) and 1093 cm^{-1}, 1078 cm^{-1} for (**2**). In addition, these bands are shifted to lower energy and this effect can be connected with the weak hydrogen bond interaction of the NH_2 group (Scheme 1).

In the range 650–50 cm^{-1} the spectra of the $\{[Zn(tyr)_2(H_2O)]\text{-}H_2O\}_n$ (**1**) and $[Cu(tyr)_2]_n$ (**2**) show the bands located at 496(m)

(**1**) and 488(s) cm^{-1} (**2**), which are tentatively assigned to ν_{asym} M–N vibrations. The ν_{asym} M–$O_{carboxylate}$ vibrations are found at 349 and 333 cm^{-1} for **1** and **2**, respectively [1,20e,23,24]. Additionally, the spectrum of $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) exhibits a broad and weak band at 589 cm^{-1} which is connected with H_2O librations.

3.3. Electronic NIR–Vis–UV spectroscopy

Fig. 4 presents the NIR–Vis–UV electronic spectra of $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**), $[Cu(tyr)_2]_n$ (**2**) and the L-tyrosine disodium salt (L). The reflectance spectra of the free ligand and the compounds show intense and slightly resolved bands in the region 27000–50000 cm^{-1}, related to the intraligand charge transfer π–π^* and n–π^* transitions in the L-tyrosine salt. The intraligand transition bands are blue-shifted upon coordination. These bands are observed for $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) as a clearly marked maxima at *ca.* 36000 and 42370 cm^{-1} (Fig. 4a).

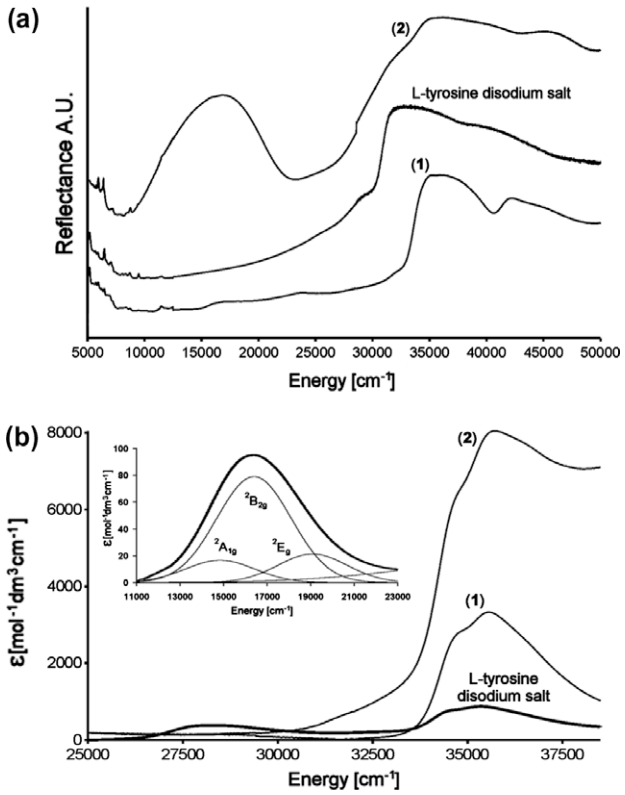


Fig. 4. (a) The reflectance spectra of $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**), $[Cu(tyr)_2]_n$ (**2**) and the L-tyrosine disodium salt. (b) The absorbance spectra for **1**, **2** and the L-tyrosine disodium salt in DMSO solution. The inset shows the gaussian analysis of the spectrum of $[Cu(tyr)_2]_n$ (**2**) in the 11000–23000 cm^{-1} region.

The spectrum of the free ligand dissolved in DMSO presents two broad absorption bands at 28300 cm^{-1} (ε = 400 mol^{-1} dm^3 cm^{-1}) and 35400 cm^{-1} (ε = 880 mol^{-1} dm^3 cm^{-1}) with a shoulder at 34580 cm^{-1} (ε = 780 mol^{-1} dm^3 cm^{-1}). For the solution spectra of both complexes slight blue-shifted bands appear at 35700 cm^{-1} (ε = 8000 mol^{-1} dm^3 cm^{-1}) and 35620 cm^{-1} (ε = 3300 mol^{-1} dm^3 cm^{-1}) for **1** and **2**, respectively, and they are related to the n–π^* charge transfer transition (Fig. 4b). Such an absorption at 35700 cm^{-1} (ε = 2940 mol^{-1} dm^3 cm^{-1}) was noticed for $[Zn(tyr)_2] \cdot 2H_2O$ in DMSO solution by Refat et al. [2]. Additionally, these authors have observed a broad band at 30770 cm^{-1} (ε = 500 mol^{-1} dm^3 cm^{-1}) and have assigned it to the charge transfer Zn(II) ← L transition for $[Zn(tyr)_2] \cdot 2H_2O$ [2]. For the spectra of $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$ (**1**) dissolved in DMSO we expected an analogous intensive band at 30770 cm^{-1}, but it was not observed. The band at 30770 cm^{-1} observed for $[Zn(tyr)_2] \cdot 2H_2O$ by Refat et al. [2] probably is correlated with a n–π^* transition in pure L-tyrosine, but not with a Zn(II) ← L transition. However, a broad absorption without a distinct maximum for the $[Cu(tyr)_2]_n$ (**2**) solution and solid state spectra in the energy range 27000–33000 cm^{-1} can be tentatively related to a Cu(II) ← L-tyrosine charge transfer transition (Fig. 4).

3.3.1. d–d transitions in $[Cu(tyr)_2]_n$ (2)

It follows from the crystal structure of $[Cu(tyr)_2]_n$ (**2**) that the five-coordinate geometry around the Cu^{2+} ions results in a *trans*-CuN_2O_2O' chromophore (Fig. 1b). Such a chromophore involving the Cu^{2+} ion has been formed by other bidendate N,O-coordinated amino acids in $[Cu(L\text{-}Arg)_2(H_2O)]^{2+}$ [21], $[Cu(L\text{-}Arg)_2(H_2O)]_2^{4+}$ [25], $[Cu(DL\text{-}alaO)_2(H_2O)]^{2+}$ [26] and $[Cu(DL\text{-}pipe\text{-}3)_2(H_2O)]$ [22]. The reflectance spectrum of **2** exhibits an asymmetric single broad band with a maximum at 16790 cm^{-1} and a slightly marked shoulder at 12360 cm^{-1}, which is characteristic of a penta-coordinated geometry of the Cu^{2+} ion. A pseudo-octahedral geometry with $Cu\cdots\pi_{centroid}$ = 3.409 Å as a six-coordination place (see Section 3.1) should be rejected from a spectroscopic point of view.

The five-coordinated geometry can be described as an ideal square-pyramidal (SP) when the angular structure parameter $\tau = 0$, or an ideal trigonal-bipyramidal (TBP) with $\tau = 1$ [15]. For $[Cu(tyr)_2]_n$ (**2**), the value of the τ parameter is 0.19 which implies that the geometry can be described as a slightly distorted square pyramid. In addition, the value of the tetragonality parameter T (T = the average four-in-plane distance/the axial out-of plane distance) also displays a slight axial distortion, with T = 0.824.

Table 4 presents the values of τ, T and electronic energy transitions for a series of compounds with a distorted square-pyramidal geometry and the CuN_2O_2O' chromophore. The electronic spectra of $[Cu(L\text{-}Arg)_2(H_2O)]^{2+}$ [21], $[Cu_2(\mu\text{-}O_2CCH_3)_2(\mu\text{-}OCOCH_3)(dpyam)_2](BF_4)$ [28] and $[Cu(DL\text{-}pipe\text{-}3)_2(H_2O)]$ [22] exhibit a single band and the value of τ is almost 0. The reflectance electronic spectra of $[Cu(L\text{-}Arg)_2]_2(pma) \cdot 4H_2O$ [18], $[Cu_2(\mu\text{-}O_2CCH_3)(\mu\text{-}OH)(\mu\text{-}OH_2)(phen)_2](ClO_4)_2$, $[Cu_2(\mu\text{-}O_2CCH_2CH_3)(\mu\text{-}OH)(\mu\text{-}OH_2)(bpy)_2]$

Table 4
The spectroscopic data of compounds with a square-pyramidal geometry and the CuN_2O_2O' chromophore.

τ, angular structure parameter (index of trigonality); T, tetragonality; L-Arg, L-arginine; dpyam, di-2pyridylamine; DL-pipe-3, DL-piperidine-3-carboxylic acid; pma, 1,2,4,5-tetracarboxylate (pyromellitate); Phen, phenantroline; bpy, 2,2′-bipyridine.

$(ClO_4)_2$ [28] and $[Cu(tyr)_2]_n$ (**2**) show a broad band at ~16500 cm^{-1} with a lower energy shoulder at ~13500 cm^{-1}. The τ parameters found for these compounds are in the range 0.14–0.20 and the Cu^{2+} environments can be more precisely analysed as a near square based pyramid (SBP), showing a slight distortion towards trigonal bipyramid. This distortion probably results in the shoulder at ~13500 cm^{-1}. The spectrum of $[Cu(phen)_2Cl](BPh_4)$ exhibits a high-energy peak at 14500 cm^{-1} with a clearly resolved shoulder at 11500 cm^{-1}, and the τ parameter is equal to 0.19, such as for $[Cu(tyr)_2]_n$ (**2**). However, a bathochromic effect is observed due to the chlorine anion coordinated to the Cu^{2+} in $[Cu(phen)_2Cl](BPh_4)$ [27].

The $[Cu(tyr)_2]_n$ (**2**) reflectance spectrum was analysed for the one-electron ground state configuration in square-pyramidal geometry, $d_{x^2-y^2} \gg d_{z^2} > d_{xy} > d_{xz} \approx d_{yz}$ [27–30]. The principal high-energy band at 16500 cm^{-1} results from $d_{xy}, d_{xz} \approx d_{yz} \rightarrow d_{x^2-y^2}$ transitions [27], whereas the shoulder band at 13500 cm^{-1} can be assigned to the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition (Fig. 4a). In the tetragonal ligand field (D_{4h} or C_{4V} symmetry), the ground state term $^2E_g(O_h)$ is split into $^2B_{1g}(d_{x^2-y^2})$ and $^2A_{1g}$ (d_{z^2}) states, whereas the state term $^2T_{2g}(O_h)$ is also split into $^2B_{2g}$ (d_{xy}) and ^2E_g (d_{xz}, d_{yz}). Thus, for C_{4V} (sP) symmetry three spin allowed electronic transitions $^2B_1$ ($d_{x^2-y^2}$) → $^2A_1$ (d_{z^2}), $^2B_2$ (d_{xy}) and ^2E (d_{xz}, d_{yz}) are expected as single overlapped bands under the broad absorption shape [31,32]. The band analysis was performed with a maximum of three Gaussian curves centred at 14850 cm^{-1} (ε = 16.5 mol^{-1} dm^3 cm^{-1}), 16410 cm^{-1} (ε = 78.9 mol^{-1} dm^3 cm^{-1}) and 19100 cm^{-1} (ε = 21.1 mol^{-1} dm^3 cm^{-1}) corresponding to the transitions $^2B_1 \rightarrow {}^2A_1$, $^2B_1 \rightarrow {}^2B_2$ and $^2B_1 \rightarrow {}^2E$, respectively (Fig. 4b).

3.4. EPR and magnetic characterization of $[Cu(tyr)_2]_n$ (**2**)

A study of the magnetic susceptibility data for the examined complex has been performed within the temperature range 1.80–300 K. The experimental data, plotted as thermal variations of χ_M and $\chi_M T$, are shown in Fig. 5a. The χ_M values increase slowly with the decrease of temperature, but in the low-temperature region a rapid increase of the molar susceptibility occurred without showing a peak.

The value of $\chi_M T$ at room temperature is equal to 0.41 cm^3 mol^{-1} K (1.82 B.M.) as expected for an uncoupled copper(II) ion [33]. The $\chi_M T$ value decreases smoothly over a wide range of temperatures and decreases rapidly at the lowest temperatures to 0.34 cm^3 mol^{-1} K (1.65 B.M.). The slight decrease of $\chi_M T$ in the low-temperature range is caused by the occurrence of an antiferromagnetic interaction between the nearest Cu(II) ions.

To quantitatively interpret the susceptibility data, we have used a one-dimensional model [2] in which the magnetic chain is provided by an array of equally spaced copper(II) ions with S_{Cu} = ½ local spins. The relevant spin Hamiltonian in a zero-field adapted to describe the isotropic interaction between the nearest neighbour ions is defined by Eq. (1) [31,34]:

$$H = -J\sum_{i=1}^{n} S_{A_i} \cdot S_{A_{i+1}} \quad (1)$$

The magnetic susceptibility for $J < 0$ is defined by the Bonner and Fischer equation (2):

$$\chi_M = \frac{Ng^2\beta^2}{kT}\frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3} \quad (2)$$

with

$$x = |J|/kT$$

where N is Avogadro's number, g is the spectroscopic splitting factor, β is the Bohr magneton, k is the Boltzmann constant and J is the intramolecular exchange parameter.

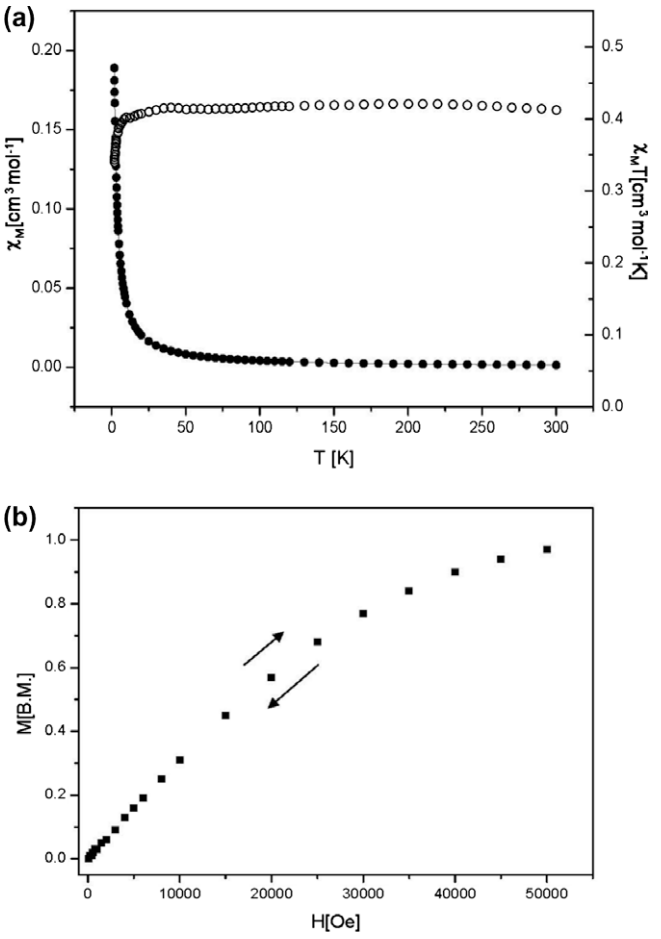

Fig. 5. (a) The thermal dependence of $\chi_M T$ (○) and χ_M (●) for $[Cu(tyr)_2]_n$ (**2**), the solid line is the calculated curve and (b) the field dependence of the magnetization for **2**.

The best fit parameters of g = 2.17 and J = −0.10 cm^{-1} were obtained with a good agreement factor for $R = 1.46 \times 10^{-6}$:

$$\left[R = \sum (M_{exp} - M_{calc})^2 \Big/ \sum (M_{exp})^2\right].$$

The values of the Curie and Weiss constants determined from the relation $1/\chi_M T = f(T)$ over the temperature range 50–300 K are equal to 0.42 cm^3 mol^{-1} and −0.47 K. A negative value of the Weiss constant and intramolecular exchange parameter obtained from the calculation confirm the occurrence of a weak antiferromagnetic interaction between the nearest copper centres.

The variation of the magnetization versus magnetic field at 2 K (Fig. 5b), clearly supports the occurrence of spontaneous magnetic moments in the examined compound with M_s = 0.97 B.M. at 5 T. The obtained value is typical of a $S = {}^1/_2$ ground state of the Cu(II) ion. Very weak antiferromagnetic interactions in the examined complex could be assigned to the intramolecular interactions between the copper centres inside the polymeric chain, which may be transmitted through the L-tyrosinate ligand. As mentioned in the structure discussion, this complex can be viewed as a one-dimensional chain, which is stabilized by the hydrogen bond network formed between the uncoordinated C=O oxygen atoms with tyrosine OH group. These features create further possibilities for the magnetic exchange pathway. Unfortunately the distances between the copper ions in the neighbouring chains are equal to 9.9923(7) or 11.5140(8) Å and are much longer than the intramolecular distances between the metallic centres in the same chain,

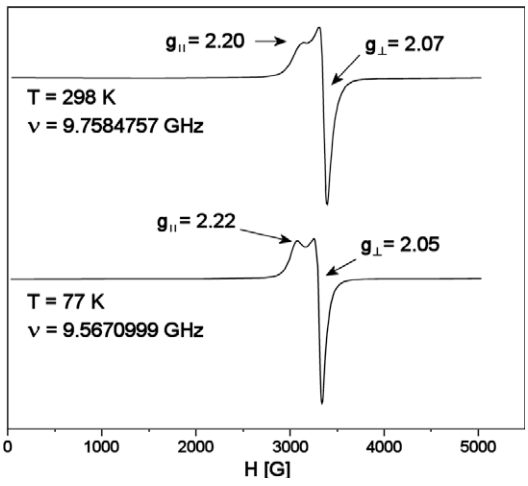

Fig. 6. EPR spectra for $[Cu(tyr)_2]_n$ at room temperature and 77 K.

4.9307(4) and 6.0439(7) Å. This fact suggests that an interchain interaction (J') can be ruled out.

The EPR spectrum of a polycrystalline sample of the examined compound measured at room temperature and 77 K presents an anisotropic signal composed of two line at $g_{II} = 2.20$ and $g_{\perp} = 2.07$ (298 K) and $g_{II} = 2.22$ and $g_{\perp} = 2.05$ (77 K) (Fig. 6). The structure is associated only with the electronic configuration ($S = {}^1/_2$) of the $d_{x^2-y^2}$ ground state for a distorted square based pyramidal ligand field.

Supplementary data

CCDC 707764 contains the supplementary crystallographic data for $\{[Zn(tyr)_2(H_2O)]H_2O\}_n$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

strategy in our study to obtain soluble polymer-substituted phthalocyanines, poly-THF-terminated side chains were initially introduced onto the Pc core. Poly-THF side chains, together with an aliphatic hexylthio moieties on the periphery of CoPcLC (**3**), provide both solubility and discotic mesogenic behaviour to rigid phthalocyanine core. To our knowledge, no other example of a liquid crystal polymeric MPc bearing poly-THF side chains has been published to date.

In the present work, we have described the design and the liquid crystal properties of a new discotic mesogen CoPcLC (**3**) derived from the flexible 6-(3,4-dicyanophenylthio)-hexyl-2-polytetrahydrofuranacetatephthalonitrile polymeric ligand.

2. Experimental

4-(6-Hydroxyhexylthio)-1,2-dicyanobenzene and 4-nitrophthalonitrile were prepared according to the literature procedures [17,24]. Chloroform ($CHCl_3$), 2-chloroethylchloride, triethylamine, tetrahydrofuran (THF), silvertetrafluoroborate ($AgBF_4$) and $CoCl_2$ were purchased from Merck and Alfa Aesar, and were used as received. All other reagents were obtained from Fluka, Aldrich and Alfa Aesar Chemical Co. and were used without purification. The purity of the products was tested in each step by TLC (SiO_2, $CHCl_3$, hexane and MeOH). FTIR (KBr) spectra were recorded on an ATI UNICOM-Mattson 1000 spectrophotometer. Chromatography was performed with silica gel (Merck grade 60 and sephadex) from Aldrich. Elemental analysis (C, H and N) was performed at the instrumental Analysis Laboratory of Marmara University. UV–Vis spectra were obtained in a quartz cuvette on an Agillent Model 8453 diode array spectrophotometer. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker 300 spectrometer instrument. The liquid crystal behaviour of CoPcLC (**3**) doped with 4-cyano-4′-n-pentylbiphenyl (5CB) was examined by temperature-controlled polarizing microscopy, differential scanning calorimetry (DSC) and capacitance–voltage measurements.

2.1. Synthesis of 6-(3,4-dicyanophenylthio)-hexyl-2-chloroacetate (*1*)

One gram of (3.84 mmol) of 4′-(6-hydroxyhexylthio)-1,2-dicyanobenzene and ca 0.32 mL (excess) of triethylamine were dissolved in 20 mL of THF at room temperature. The mixture was placed in an ice-bath. 0.45 mL (4.20 mmol, excess 10%) of 2-chloroethylchloride was added dropwise to the stirred solution at −5 °C. The mixture was stirred at 0 °C for 3 h and at room temperature for 12 h and finally heated for 1 h at 30 °C. The reaction mixture was poured into water and the resulting precipitate was filtered and washed with an excess amount of water. It was dried under vacuum for 12 h at room temperature, then chromatographed over a silica gel column using a mixture of $CHCl_3$:MeOH 100/5 as eluent, giving yellow 6-(3,4-dicyanophenylthio)-hexyl-2-chloroacetate. Finally the pure powder was dried in vacuum.

Yield: 1.04 g (80.47%), m.p.: 80 °C. *Anal.* Calc. for $C_{16}H_{17}ClN_2O_2S$ (336.5 g/mol) (%): C, 57.05; H, 5.09; N, 8.32; S, 9.52. Found: C, 56.77; H, 5.11; N, 8.08; S, 9.36%. 2.2. Synthesis of 6-(3,4-dicyanophenylthio)-hexyl-2-polytetrahydrofuranacetate (*2*) (typical cationic polymerization of THF)

Experiments were carried out in a N_2 atmosphere. Freshly distilled THF (57.60 g, 0.80 mol) was put into a two-neck round bottom flask heated in vacuum with a heat gun and flushed with dry N_2. Stoichometric amounts of 6-(3,4-dicyanophenylthio)-hexyl-2-chloroacetate (0.61 g, 2.00 mmol) and $AgBF_4$ (0.78 g, 4.00 mmol) solution in THF were added under efficient stirring at room temperature. After 24 h, methanol was added to the reaction mixture to terminate the polymerization. After centrifuging, the polymer was poured into a methanol–water mixture (1/1 (V/V)) and cooled. The precipitated polymer was filtered off and dried in vacuum. Molecular weight (M_{an}) of the polymer was found to be 1500 from GPC measurements.

Yield: 2.05 g. 2.3. Synthesis of 2,9,16,23-Tetrakis-{6-(polytetrahydrofuran-2-carboxylate)-hexylthio-phthalocyaninatocobalt(II) (*3*)

6-(3,4-Dicyanophenylthio)-hexyl-2-polytetrahydrofuranacetate (0.150 g, 0.405 mmol) and $CoCl_2$ (0.014 g, 0.103 mmol; left one night in an oven at 110 °C) was heated in dry N,N′-(dimethylamino)-ethanol (0.5 mL) under stirring and refluxing for 8 h. After cooling, the dark-green-blue crude product formed during the reaction was treated with MeOH several times and filtered off. The dark-green-blue colored compound **3** was treated with CH_3CN several times and then filtered until the impurities were removed. The residue was then purified by column chromatography with silica gel (first with $CHCl_3$/MeOH 100/1 and then with THF/hexane 10/1). The desired compound is moderately soluble in $CHCl_3$, CH_2Cl_2 and acetone, and has good solubility in THF.

Yield: 0.020 g. FTIR (KBr) ν/cm^{-1}: 3307 (w, NH), 3084 (w), 2934, 2954, 2852 (aliph-CH_2), 1751 (–COOR, strong), 1713 (–COOR, strong, sh), 1587, 1535, 1442, 1357, 1327, 1266 (Ar–S–CH_2), 1167, 1159, 1088, 1002, 973, 858, 740, 722. UV–Vis (THF), λ_{max}/nm: 684 (Q; π–π^*), 650 (agg), 618 (n–π^*), 344 (B; deeper π–π^*).

3. Results and discussion

The novel amphiphilic disc-like polymeric cobalt phthalocyanine, CoPcLC (**3**), was synthesized according to the conventional method by heating a pulverized mixture of 6-(3,4-dicyanophenylthio)-hexyl-2-polytetrahydrofuranacetate (**2**) with anhydrous

$CoCl_2$ salts at ca. 150 °C under N_2 atmosphere in the presence of N,N-dimethylaminoethanol (Fig. 1) [18,19,21–22]. The presence of isomers of tetrasubstituted MPc (M = Co) could be verified by the slight broadening observed in the UV–Vis absorption bands when compared with those of octa substituted phthalocyanines composed of a single isomer [21,22,24]. The blue cyclotetramerization product, MPc (M = Co), was purified by column chromatography in moderate yield (ca 20 mg). The structure of **3** was verified by FTIR and UV–Vis spectrophotometry. All spectral data are consistent with the predicted structures.

The introduction of poly-THF chains into the disc-like molecules induced the assembly of the inorganic sources. The synthesized phthalocyanine derivative exhibited excellent solubility in THF and moderate solubility in $CHCl_3$. Fig. 2 shows the UV–Vis spectrum of CoPcLC in THF. Cyclotetramerization of **2** was confirmed by the disappearance of the sharp –C≡N vibration at 2226 cm^{-1} and two different strong COOR bands in compound **3** at around 1755 and 1726 cm^{-1} came out with a small shift compared to the starting compound. The IR spectra of phthalocyanines **1** and **2** are very similar, with the exception of small shifts. In the FTIR spectrum of **3**, the absence of characteristic bands for the N–H groups also confirms its formation. The ^1H NMR spectra of compound **1** and polymeric ligand **2** are somewhat similar, except for the poly-THF moiety in **2**. The resonances related to $OOCCH_2$, $COOCH_2$, CH_2, SCH_2 and Ar–H protons in the ^1H NMR spectrum of **2** are very similar to those of compound **1** and show the typical chemical shifts for protons of $-COCH_2O$ aliph. at 4.40, CH_2CH_2–OCO at 4.15, poly-OCH_2CH_2 at 3.40, –S–CH_2–CH_2– at 3.00, –O–CH_2CH_2–CH_2– –OCH_2 CH_2CH_2–CH_2–, –S–CH_2–CH_2–CH_2–CH_2 and terminal CH_2–CH_2–CH_2–CH_2 at 1.40–1.27 ppm. The UV–Vis spectrum of CoPcLC exhibits characteristic Q and B bands, one in the visible region at ca. 600–750 nm (Q-band) attributed to the π–π^* transition from the HOMO to the LUMO of the Pc^{2-} ring, and the other in the UV-region at ca. 300–400 nm (B-band) arising from deeper

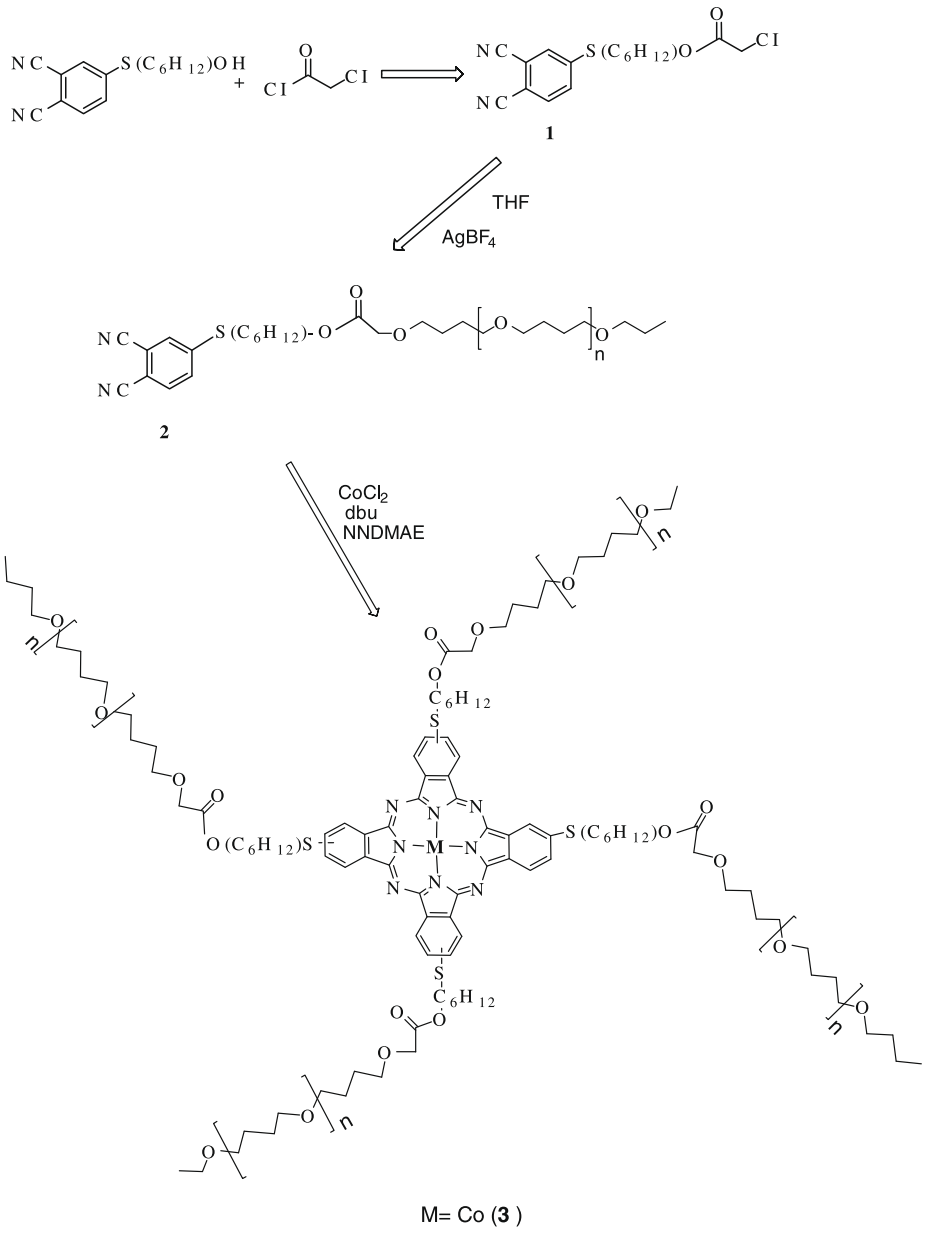

Fig. 1. Synthetic route to 6-(3,4-dicyanophenylthio)-hexyl-2-chloroacetate (**1**), 6-(3,4-dicyanophenylthio)-hexyl-2-polytetrahydrofuranacetate (**2**) and 2,9,16,23-tetrakis-{6-(polytetrahydrofuran-2-carboxylate)-hexylthio-phthalocyaninatocobalt(II) (**3**).

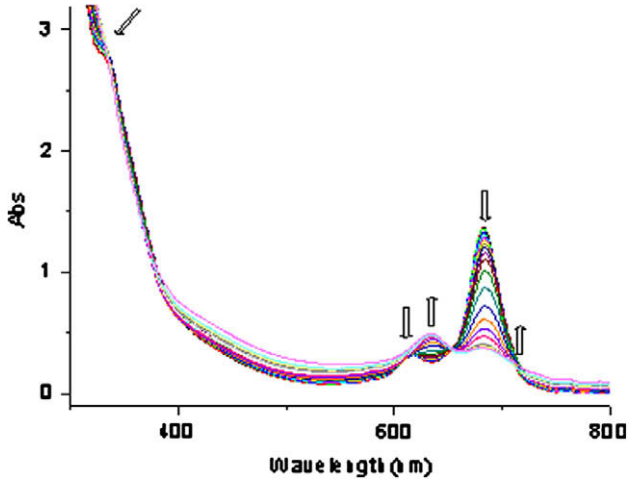

Fig. 2. UV–Vis spectra of **3** in THF during titration by Ag^{+} (in THF/MeOH (1:1)).

π–π^{*} transitions [25]. The divalent CoPcLC (**3**) gave a single Q-band of high intensity due to a single π–π^{*} transition, typical of a non-aggregated phthalocyanine, as expected from the result of the D_{4h} symmetry [18,26]. The Q-band absorption of **3** in THF was observed at 684 nm, with a shoulder at the slightly higher energy side of the Q-band. The B bands are broad due to the superimposition of the B1 and B2 bands in the 330–350 nm region in the case of compound **2** [26].

3.1. Spectroscopic metal ion binding titrations

The absorption spectrum of CoPcLC (**3**) in THF was evaluated in terms of monomer–dimer–trimer and oligomer formation. It is known that sulfur donor atoms on the periphery of the tetra or octa-substituted phthalocyanines act as low-valent transition metal ionophores (IB and IIB) and impart a preference for coordination especially with Ag^{I} and Pd^{II}, resulting in the formation of aggregates when the peripheral heteroatoms are able to interact with the same soft metals [18–23]. These interactions are readily monitored by UV–Vis spectroscopy. In the aggregated state, the electronic structure of the peripherally complexed phthalocyanine ring is perturbed resulting in alternation of the ground and excited state electronic structures [11,23,26].

In this study, titrations were carried out using a THF solution of the MPc's to ensure complete dissolution of $AgNO_3$ dissolved in THF/MeOH (1/1). Here, the concentration of the MPc and the metal salt were *ca.* 10^{-5} and 10^{-3} mol dm^{-3}, respectively. The reason for the higher concentration of the metal salt was to produce negligible changes by dilution after its addition to the phthalocyanine solution. A blank test was applied before the titration with heavy metal ions. No significant aggregation was observed in this mixture of solvents.

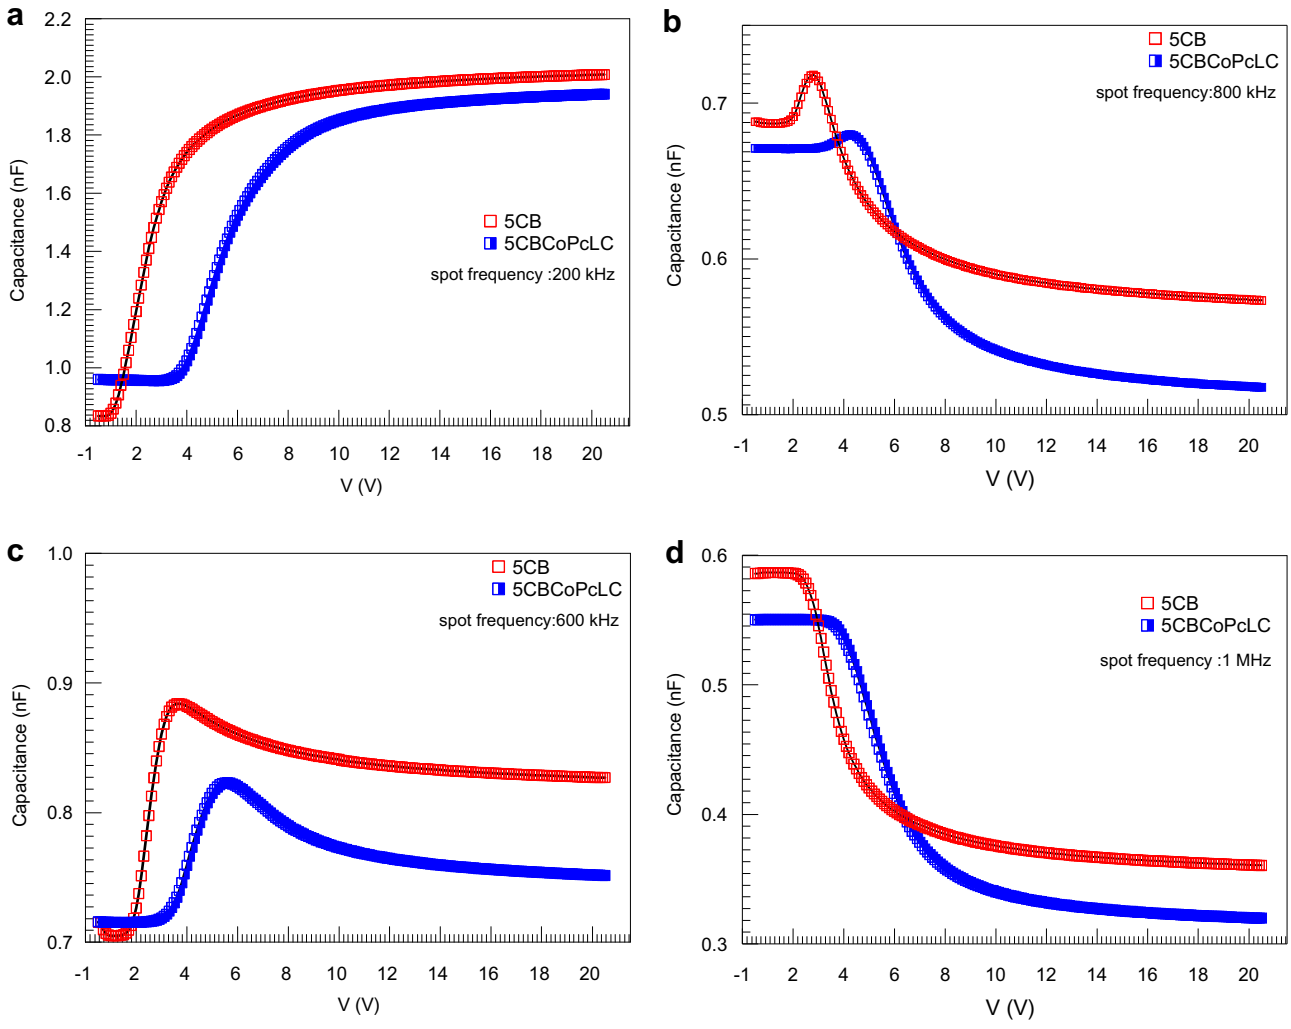

Fig. 3. *C–V* plots of the liquid crystals at different spot frequencies.

Table 1
Dielectric anisotropy and phase transition temperature of the 5CB and 5CBCoPcLC liquid crystals.

Liquid crystal	$\Delta\varepsilon$ at 200 kHz	$\Delta\varepsilon$ at 1 MHz	T_p (°C)
5CB	8.53	−1.71	34.8
5CBCoPcLC	7.17	−1.68	40.5

Gradual addition (μL) of Ag^I to the THF solution of CoPcLC caused a gradual color change from blue-green to an intractable less soluble dark-green aggregated CoPcLC. The binding of Ag^I to the donor atoms of CoPcLC results in pronounced effects in the Q and B bands (blue shift) (Fig. 2). This observation is in accord with previously reported studies [18–23]. As shown in Fig. 2, addition of small increments of Ag^I to CoPcLC leads to a gradual disappearance of the monomeric species, which show absorptions for CoPcLC at 684, 650, 618 and 344 nm, and an enhancement of the intensity of the oligomeric aggregated species around 635 nm. B bands of CoPcLC shift to the higher energy side, by about 5–10 nm, with a change in intensity. These spectroscopic changes indicate the coordination of Ag^I by the donor atoms of CoPcLC to form less soluble oligomeric aggregated species. As demonstrated in Fig. 2, the titrations show clear isobestic points at 713, 653, 615, 383 and 334 nm for CoPcLC.

3.2. Liquid crystal properties

We have evaluated that the mesomorphic properties of the CoPc can exhibit a columnar phase because it is well known that phthalocyanines form columnar liquid crystals [27–28] and mesomorphic properties of phthalocyanines depend on the number, position and character of the substituents, and the nature of the central metal atom. Fig. 3 shows the plots of capacitance–voltage (*C–V*) of 5CB and CoPcLC doped with 5CB liquid crystal at different spot frequencies. The capacitance values of the liquid crystals increase from the initial value to the final value. At lower voltages, the capacitance hardly changes with voltage, and then it increases with increasing voltage and reaches saturation. As seen in Fig. 3, the *C–V* plots of the liquid crystals show a threshold voltage. The CoPcLC doping increases the threshold voltage. This suggests that the ability of molecular reorientation decreases with CoPcLC doping. For liquid crystals, the dielectric anisotropy is expressed by the following relation [29],

$$\Delta\varepsilon = \varepsilon_{||} - \varepsilon_{\perp} \quad (1)$$

where $\varepsilon_{||}$ is the dielectric constant in the direction parallel to the director and $\varepsilon_{\perp}$ is the dielectric constant perpendicular to the director. Materials with $\Delta\varepsilon > 0$ are called p-type, in which their molecules are aligned with the director parallel to the electric field, whereas in n-type materials, with $\Delta\varepsilon < 0$, they align perpendicular to the electric field [30]. Fig. 3b shows *C–V* plots of the LC for $\Delta\varepsilon > 0$. As seen in Fig. 3b, the parallel capacitance decreases with increasing voltage. This indicates the reorientation of the molecules in parallel to the applied electrical field and this variation is completed for 1 MHz. The *C–V* curves of the LCS show that the structure changes from the positive to negative type. The dielectric anisotropy values of the LCs were calculated from the *C–V* curves of the liquid crystals and are given in Table 1. The $\Delta\varepsilon$ value of the 5CB li-

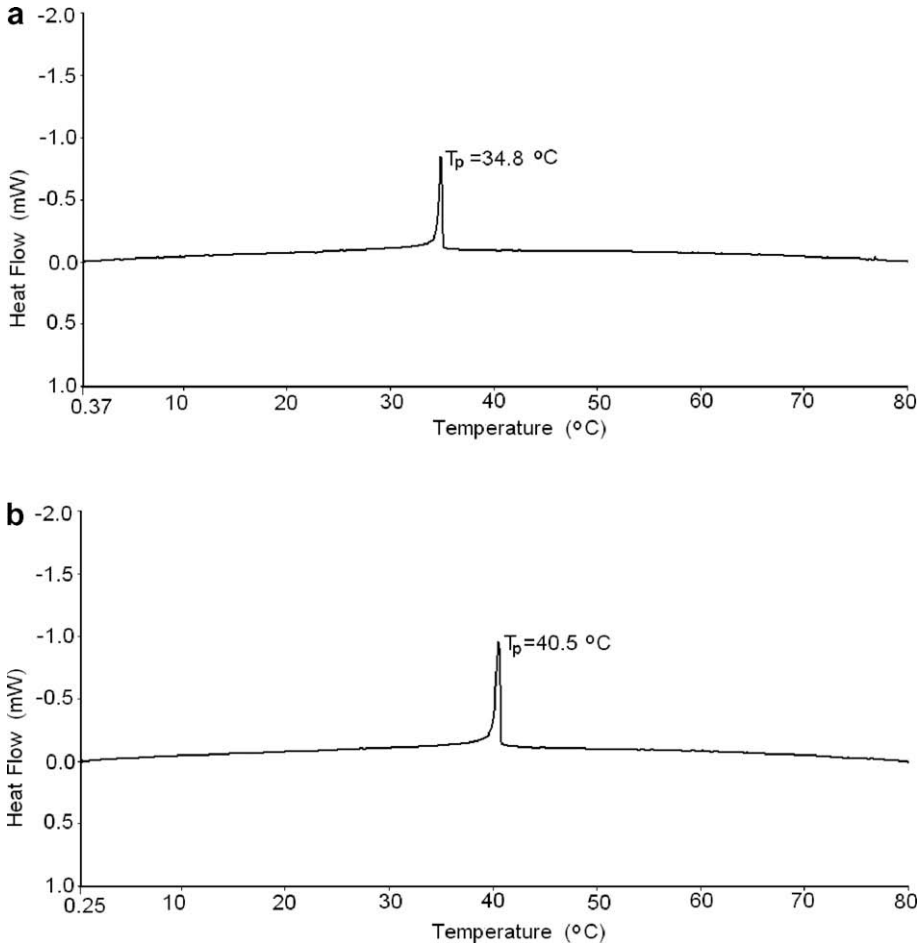

Fig. 4. DSC curves of the liquid crystals: (a) 5CB and (b) 5CBCoPcLC.

quid crystal is higher than that of 5CBCoPcLC liquid crystal. This suggests that the CoPcLC doping decreases the dielectrical anisotropy value of the 5CB liquid crystal.

The differential scanning calorimetry (DSC) curves of the 5CB and 5CBCoPcLC liquid crystals are shown in Fig. 4a and b. The curves indicate a peak, corresponding to the phase transition temperature. For 5CB liquid crystal, the phase transition temperature was found to be 34.8 °C, and this temperature is in agreement with the literature [31]. In this temperature, a phase transition from the nematic (N) to isotropic (ISO) phase is taking place. For the 5CBCoPcLC composite liquid crystal, the phase transition temperature was found to be 40.5 °C, as shown in Fig. 4b. This suggests that the CoPcLC dopant increases the phase transition temperature of the 5CB liquid crystal. Thus, we have evaluated that CoPCLc has liquid crystal properties. The DSC curves of the liquid crystals confirm the phase transition temperatures, detected under a microscope (Fig. 4). Fig. 5 shows the textures of the 5CB and 5CBCoPcLC liquid crystals at different temperatures. The nematic phase transition in 5CBCoPcLC liquid crystal takes place at 30 °C. The nematic phase of 5CBCoPcLC at 40 °C is shown in Fig. 5b. Fig. 5c shows a phase transition from nematic to isotropic and then at 50 °C, an isotropic phase occurs (Fig. 5d). Fig. 5e shows the texture of the nematic phase of 5CB liquid crystal at 30 °C.

Fig. 6a and b show the current–voltage (I–V) characteristics of the 5CB and 5CBCoPcLC liquid crystals. The current–voltage characteristics of the liquid crystals show non-linear behaviour. The current for 5CB liquid crystal does not increase with illumination, whereas at higher voltages illumination increases the electrical

conductivity of the 5CBCoPcLC liquid crystal. The increase in the conductivity of 5CBCoPcLC is attributed to the optical properties of CoPcLC.

interaction of "ionic" nitrate with H-bonding molecules can lead to infrared spectra which are essentially the same as for a coordinated nitrate.

4. Structures

4.1. General points

Details of the data collection and refinement for the crystal structures are given in Table 1 and selected bond lengths in Table 2.

The Ln–O distances show the effect of the lanthanide contraction showing a linear decrease in both Ln–O(N) and Ln–O(P) with decreasing ionic radius of the lanthanide as shown in Fig. 1. The Ln–O(N) distances are consistently longer than the Ln–O(P) which is a general feature of PO complexes with lanthanide nitrates. The magnitude of the difference in Ln–O(N) – Ln–O(P) (=Δ) appears to reflect the degree of strain in the bonding region. Due to the strongly ionic nature of the interaction between the PO oxygen and the lanthanide ion a linear Ln^{3+}–O^{-}–P^{+} arrangement is favoured on electrostatic grounds. Values of Δ calculated from literature structures show that for non-chelated PO such as in $Ln(NO_3)_3(Ph_3PO)_n$ [17] and $Y(NO_3)_3(Ph_3PO)_n$ [18] values of Δ in the region of 0.21 Å are found. Constraining the PO in a six membered chelate ring in complexes such as $Ln(NO_3)_3[(^iPrO)_2P(O)C_5H_4N(O)]_2$ [19], $Ln(NO_3)_3[(EtO)_2P(O)CH_2P(O)(OEt)_2]_2$ [20] and $Ln(NO_3)_3[(MeO)_2P(O)CMe(OH)P(O)(OMe)_2]$ [21] lengthens the Ln–O(P) distance and hence reduces Δ to about 0.13–0.14 Å (interesting exceptions to this are complexes of $Ph_2P(O)CH_2P(O)Ph_2$ where a smaller Δ of 0.06 Å is observed [16]). Increasing the size of the chelate ring might be expected to increase the flexibility of the structure and allow Ln–O–P angles to approach linearity and thus values of Δ approaching those of an "unconstrained" ligand. Complexes with 10-membered chelate rings 1,3-$[Ph_2P(O)]_2C_6H_4$ [22] do indeed show this effect with Δ of 0.21 Å. In this study, a value of Δ = 0.22 Å is found, again implying relatively unconstrained coordination of the PO groups. This is further seen in the values of the Ln–O–P angles which average 161.8° (range 152.3–177.3°) over all the lanthanide complexes reported here.

It has been previously observed that small bite angle ligands such as nitrate should preferentially bind to larger metal ions [23]. Although it should be noted that all the metals here fall in to the category of large ions it is still interesting in this respect to examine the changes in Ln–O bond distances. When the Ln–O(N) distances are corrected for the lanthanide contraction, by subtracting the ionic radius of the lanthanide ion with the appropriate coordination number [24], the difference should be constant if no other effects are significant. Single factor Anova analysis of the data reveals that significant differences occur between the sets of distances. Post hoc analysis of the results was carried out by unpaired *t*-test assuming a null hypothesis of no difference between the means and unequal variance at a 95% confidence level. The results of such an analysis show that there are significant differences between the La–O(N) and other Ln–O distances, with La–O(N) being shorted than expected. The differences between the Eu–O(N), Ho–O(N) and Lu–O(N) are not significant once the effect of the lanthanide contraction is taken into account. The average Ln–O distances corrected for the lanthanide ion size are significantly larger for the Eu and Ho complexes. In the Eu and Ho complexes the larger residual differences with averages of 1.314(2) Å, compared with 1.256(2) Å for the La and Lu complexes, can be ascribed to the hydrogen bonding between chloroform and the coordinated nitrate ions. In the La complex this interaction is considerably weaker with a shortest (N)O···$HCCl_3$ of 2.547 Å compared with 2.246 and 2.232 Å, respectively, for the Eu and Ho complexes and this may in part account for the stronger La–O interaction. There are short contacts between one of the H atoms on the cyclopentadiene ring and one of the O(N) atoms in all the complexes. These distances, in the region of 2.3 Å, are shorter than the sum of van der Waals radii of O and H (2.60 Å), but, as such interactions occur in all complexes, they cannot account for the variations in distances observed.

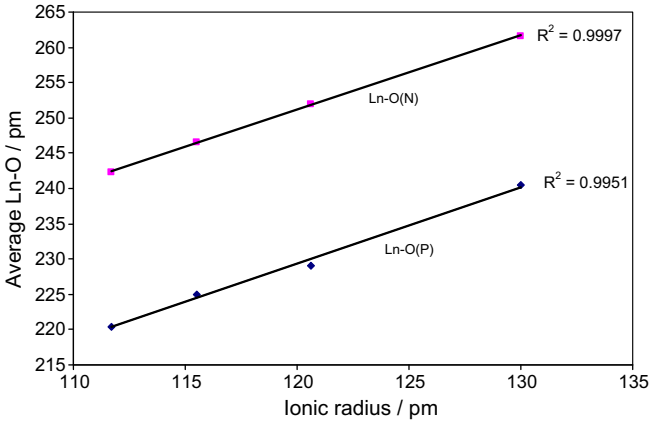

Fig. 1. The relationship between the Ln–O(P) and Ln–O(N) distances and the ionic radius of the lanthanide ion for complexes **1**–**4**.

A similar analysis for the Ln–O(P) distances for the chelate rings reveals significant differences between the La–O(P) distances and those for the other complexes. The values of Ln–O(P) corrected for the size of the lanthanide ion, again indicate a stronger La–O interaction with residual distances of 1.048 Å for La and 1.085, 1.094 and 1.087 Å for the Eu, Ho and Lu complexes respectively. It is difficult to see a reason for this. The non-bonded (P)O···O(P) distances within the chelate rings are larger for the Eu and Ho complexes (3.262 (Eu) and 3.212 Å (Ho) compared with 3.160 and

P(4)–O(4)			1.499(4)	1.493(5)	1.496(2)	1.4987(19)

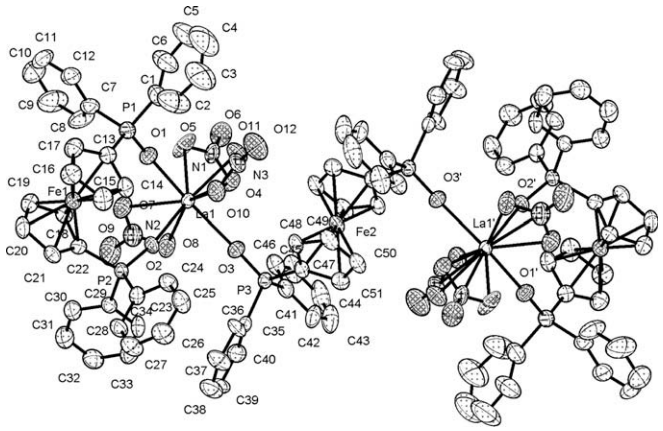

Fig. 2. The structure of $[LaL(NO_3)_3]_2\mu$-L. The Fe2 atom is located on a centre of symmetry. Symmetry related atoms generated by $1-x, 1-y, -z$.

3.175 Å for the La and Lu complexes, respectively) implying smaller electrostatic repulsions, which in turn suggests that stronger binding to the metal might be possible. The other obvious candidate for repulsive interactions which might lead to a weakening of the Ln–O(P) bonds are the non-bonded interactions between the (P)O and (N)O atoms. Significant differences are also indicated by single factor Anova analysis for the non-bonded P(O)···O(N) distances. A post hoc analysis of the non-bonded P(O)···O(N) distances by *t*-tests between the pairs of complexes shows a trend of increasing significance in the differences of the means. The differences between the La and Eu, complex is only significant at an 88.3% confidence level, whilst this increases to 98.9% and 99.9% for the differences between the La complex and the Ho and Lu complexes, respectively. For the La complex the shortest of these non-bonded interactions is over 3 Å whilst for all the others it is lower, showing a trend in values of 2.885 (Eu), 2.814 (Ho) and 2.768 Å (Lu). This trend mirrors the confidence levels at which the differences in the P(O)···O(N) means between the La complex and the respective sets of distances for the other complexes become significant.

The structures of the complexes have a number of features in common. The twist angles of the cyclopentadiene rings, measured from the torsional angles between the vectors from the ring centroid and ring carbon atoms on corresponding positions of the two rings, vary depending on whether the ligand is chelating or bridging. In the bridging mode observed in the lanthanum complex, the ligand is able to adopt a similar structure to that of the free ligand itself, namely with staggered rings and the diphenylphosphine oxide groups in a *trans* arrangement. Here the twist angle between the rings averages at 38.0 ± 0.7°, which is in good agreement with the average values of 37.7 ± 0.5° in the free ligand [25], 36.1 ± 1.5° found in the polymeric form of CoI_2L [2], and 26.6 ± 0.9° found for the bridging ligands in the zinc chloride complex of $[C_5H_4P(O)(OEt)_2]_2Fe$ [14]. The formation of chelate rings imposes a more eclipsed conformation on the ferrocenyl nucleus. The twist angles for the chelating ligands in the complexes are similar, with those in the lanthanum complex averaging at 8.6 ± 0.4° with averages of 12.8 ± 0.6° and 5.9 ± 0.5° (Eu), 12.1 ± 0.8° and 5.6 ± 0.3° (Ho) and 6.8 ± 0.3° and 4.5 ± 0.3° (Lu). These values are similar to that found in $PdCl_2L$ (7.3 ± 1.4°) but larger than observed in monomeric form of CoI_2L which has an average twist angle of 1.8 ± 0.6°.

4.2. The structure of $LLa(NO_3)_3$-μL–$La(NO_3)_3L$ (**1**)

The lanthanum nitrate complex (**1**) crystallised as a dimer, $LLa(NO_3)_3$-μL–$La(NO_3)_3L$ in which each La is nine coordinate. The structure is shown in Fig. 2. The coordination geometry does not conform to any simple polyhedron, but can be considered as a somewhat distorted octahedron if the nitrates are visualised as monodentate ligands bonded via the N-atoms. The octahedron thus conceptualised is a *mer*-isomer with "*cis*" angles at La averaging 92.4 ± 9.3° whilst the corresponding "*trans*" angles average 162.1 ± 9.4°. The La–O(P) distances for the chelating phosphine oxide are essentially identical (2.404(5) Å) and shorter than that from the bridging PO group (2.425(5) Å). These differences are not reflected in the PO distances themselves which are apparently equal at 1.4978(5) Å regardless of whether the PO groups are in the chelating or bridging mode. The nitrate groups bond asymmetrically to the lanthanum ion with one short and one long La–O distance, with averages of 2.592(8) and 2.639(10) Å, respectively. These differences are reflected in the bond distances within each nitrate ion itself, with a short O–N distance (1.254(6) Å)corresponding to the short La–O and the longer N–O associated with the longer La–O (1.276(9) Å). The P–O–La angles approach the idealised linear geometry for all the phosphoryl groups, as expected for predominantly ionic bonding where the structure imposes relatively few constraints on ligand architecture.

4.3. The structures of $[Eu(NO_3)_2L_2]_2[Eu(NO_3)_5]$ (**2**), $[Ho(NO_3)_2L_2]_2[Ho(NO_3)_5]$ (**3**) and $[Lu(NO_3)_2L_2][NO_3]$ (**4**)

In general, the reduction of the ionic radius tends to lower the coordination number of the metal. The cations in these complexes have eight-coordinate lanthanide ions and are rather similar in motif; the structure of the cation in **2** is shown as a representative example in Fig. 3. The coordination geometries can be visualised as distorted octahedra if the nitrate ions are considered as pseudomonodentate ligands attached via the N-atom. The *trans*-N–Ln–N angles are 176.21(15)° (Eu), 176.63(17)° (Ho) and 177.53(7)° (Lu) whilst the average corresponding *trans*-O–Ln–O angles are 163.6 ± 0.3°, 162.9 ± 0.4° and 164.9 ± 4.1°. The *cis*-N–Ln–O angles give averages close to 90°, at 90.1 ± 8.5° (Eu), 90.0 ± 8.7° (Ho) and 90.0 ± 10.1° (Lu) whilst the *cis*-O–Ln–O angles are rather more uniform with averages of 91.2 ± 1.0°, 91.3 ± 0.8° and 91.7 ± 0.8° for Eu, Ho and Lu, respectively. The $Ln(NO_3)_5^{2-}$ ions contain 10-coordinate lanthanide ions but are readily envisaged as trigonal bipyramids,

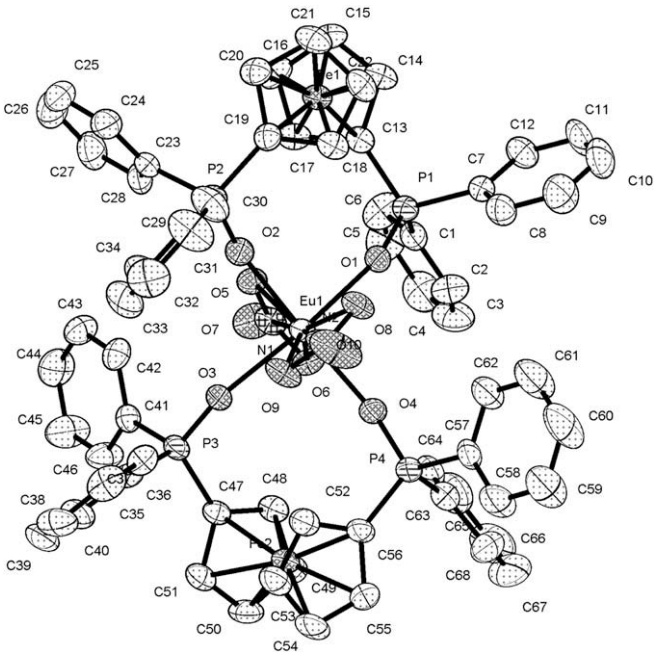

Fig. 3. The cation in $[EuL_2(NO_3)_2]_2^+$ $[Eu(NO_3)_5]^{2-}$.

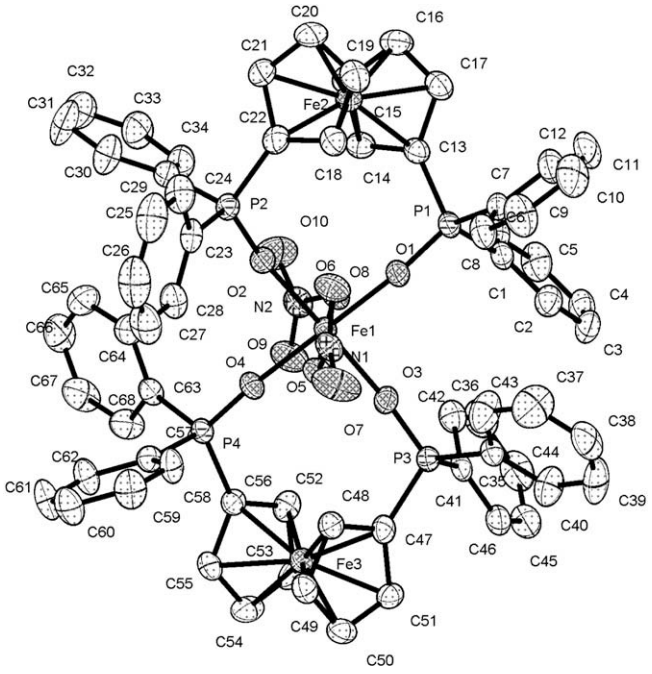

Fig. 4. The structure of $[FeL_2(NO_3)_2]NO_3$.

again taking the nitrate ions as pseudomonodentate ligands. The equatorial nitrogen atoms and the lanthanide ion are coplanar in both structures, the N_{ax}–Ln–N_{ax} angles are 177.9°, the N_{eq}–Ln–N_{eq} average to 120.0° (range 118.77–122.45°) whilst the N_{eq}–Ln–N_{ax} angles average at 91.7 ± 5.3° and 90.0 ± 6.2° for the Eu and Ho complexes, respectively. There are many examples of $Ln(NO_3)_5^{2-}$ counter-ions in the literature [26].

4.4. The structure of $[FeL_2(NO_3)_2]NO_3$

The structure of $[FeL_2(NO_3)_2]NO_3$ (**5**) is shown in Fig. 4 and shows interesting differences with the Lu complex with which it is superficially analogous. The iron is six-coordinate with the nitrate ions bound in a monodentate manner. The geometry about the metal is essentially octahedral with the *trans-O–Fe–O* angles averaging at 177.1 ± 1.1° and the *cis-O–Fe–O* at 90.0 ± 3.3°. The cyclopentadiene rings are eclipsed with twist angles of 2.6 ± 0.5° and 0.3 ± 0.1° for the two ligands. The P–O–Fe angles have a slightly larger range than the corresponding angles in the lanthanide complexes with one ligand having angles approaching linearity, whilst the other is significantly bent. This seems to have little effect on the Fe–O or P–O distances which are in essence independent of the angle at the oxygen atoms.

5. Mass spectrometry

Electrospray mass spectra were recorded for all the complexes in CH_2Cl_2. The base peak in all cases is $[L+H]^+$. The loss of a single nitrate to give $[LnL_2(NO_3)_2]^+$ is observed for all the complexes generally as a low intensity signal. The most notable feature of the mass spectra is the presence of ions formed as the result of ligand redistribution reactions. Thus signals of significant intensity are observed for ions such as $[LnL_4]^{3+}$ (5–10%), $[LnL_3]^{3+}$ (70–10%), $[LnL_3(NO_3)]^{2+}$ (40–5%) and $[LnL(NO_3)]^{2+}$ (10–30%). Some trends in the relative intensities of the signals from the ions are explicable by the lanthanide contraction. Thus the intensity of the peak assigned as $[LnL_3]^{3+}$ decreases from 70% for La to 10% for the Yb complex. Similarly the intensity of the peak due to $[LnL_3(NO_3)]^{2+}$ decreases from 40% (La) to below 5% (Yb) reflecting the increased steric interactions as the ionic radius decreases.

The negative ion spectra of the complexes showed a base peak at $m/z = 62.1$ assigned as NO_3^- and no other peaks of significant intensity. A much lower intensity signal (<1%) at $m/z = 648$ which is assigned as $[L+NO_3]^-$. There were no observed peaks which could be assigned to species such as $Ln(NO_3)_4^-$ or $Ln(NO_3)_5^{2-}$. Such species might have been anticipated given the solid state structures of the Ho and Eu complexes.

Table 3
Peak potentials[a] for selected complexes.

	1	**2**	$Dy(NO_3)_3L_2 \cdot 2H_2O$	**4**
$E_{½}$ (complex) (mV)[b]	628	661	681	683
ΔE (ferrocene) (mV)	70	77	70	78
ΔE (complex) (mV)	57	66	75	83

[a] Relative to ferrocene as internal reference.
[b] All peak potentials are measured with respect to ferrocene using a pseudoreference Ag wire.

6. Cyclic voltammetry

The oxidation behaviour of L, **1**, **2**, $Dy(NO_3)_3L_2 \cdot 2H_2O$ and **4** was studied by cyclic voltammetry in 0.1 M Bu_4NClO_4 solution in acetonitrile, with ferrocene as internal standard. Ligand L and each complex display a single reversible oxidation event corresponding to each {L} unit; in no case is any other wave evident, such as might suggest inequivalent L environments, or any degree of electronic communication between equivalent environments. Nevertheless, in the case of **1**, we clearly have a case of a complex which possesses inequivalent L environments in the solid state. We can offer no explanation for the single redox wave, other than a solution fluxionality or lability of the complex over the approximate 700 ms duration of the oxidation and re-reduction waves. All complexes, as written above, display a continuous shift toward more positive oxidation potentials with atomic number (Table 3). Ligand L itself is shifted some +458 mV with respect to ferrocene in good agreement with the literature value of +430 mV afforded by a previous determination in a different solvent system [10]. The Ln complexes follow a clear pattern which offers evidence for a closely associated molecular complex between Ln and L, albeit fluxional, being present in solution in each case. The trend is consistent with increasing polarising power of the smaller lanthanide metals drawing electron density onto the O atoms of the L ligand and away from the Fe centre. We attempted to reduce the Eu complex **2** in the same electrolyte solution after deoxygenation by nitrogen sparging, but no reduction peaks were observed in the potential window of the solvent/electrolyte system used.

7. Experimental

7.1. Crystallography

Crystals were transferred to and handled under a dried mineral oil to minimise the deterioration of the crystals prior to data collection. All X-ray data for the complexes were measured on a Bruker SMART diffractometer with a 2 K CCD area detector using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Absorption corrections, based on comparison of Laue equivalents, were applied to the data sets. The structures were solved by Patterson methods and refined by full-matrix least-squares cycles on F^2 for all data, using SHELXTL [27]. All non-hydrogen atoms of the metal complexes were refined with anisotropic displacement parameters and all

hydrogen atoms were included in refinement cycles riding on bonded atoms. For all structures the metal complex was unambiguous and refined satisfactorily. For **1**, **2** and **3** lattice $CHCl_3$ was located and refined. However, all the structures were found to have regions of unresolved disordered solvent, thought to be $CHCl_3$, that could not be modelled satisfactorily. The SQUEEZE option of the programme PLATON [28] was used to omit the data for the disordered regions for each of the structures. The solvent accessible void volume and estimated solvent electron count for each structure is given in Table 1.

7.2. Infrared spectroscopy

Infrared spectra were recorded on a Thermo Nicolet Avatar 370 FT-IR spectrometer operating in ATR mode. Samples were compressed onto the optical window and spectra recorded without further sample pre-treatment.

7.3. Electrospray mass spectrometry

Electrospray mass spectra were obtained by the EPSRC National Mass Spectrometry Service Centre at Swansea University as described previously [29]. The spectra were recorded on a VG Quattro II triple quadrupole mass spectrometer. Samples dissolved in CH_2Cl_2 were loop injected into a stream of MeOH passing through a steel capillary held at high voltage (+3.5 kV for positive mode and −3.0 kV for negative mode). Nebulisation of the resulting spray was pneumatically assisted by a flow of nitrogen bath gas and heated source (70 °C). Declustering and molecular fragmentation were promoted by increasing the cone voltage from 8 to 50 V.

7.4. Electrochemistry

The oxidation behaviour of L, **1**, **2**, $Dy(NO_3)_3L_2 \cdot 2H_2O$ and **4** was studied using a PC-driven Bioanalytical Systems BAS100B Electrochemical Analyzer/BAS PA1 Preamplifier combination operating in cyclic voltammetry mode with a sweep width of 1400 mV and sweep rate of 200 mV s^{-1}. The working electrode was polished Pt disc, the auxiliary electrode Pt wire and the pseudoreference electrode Ag wire. Approximately 1–5 mg samples were dissolved in approximately 20 ml of 0.1 M Bu_4NClO_4 in acetonitrile solution, with ferrocene as internal standard. Commercial white-spot nitrogen was used as spargent for reduction experiments.

7.5. Synthesis

$(C_5H_4P(O)Ph_2)_2$ Fe: $(C_5H_4PPh_2)_2Fe$ (5.17 g) was suspended in 50 ml acetone and H_2O_2 (3.00 g 30% aqueous solution) slowly added at such a rate as to maintain a gentle reflux. The suspension was stirred overnight, filtered and the resulting yellow solid washed with a little acetone and diethyl ether and dried at the pump to give 5.31 g (93% as the hydrate) yellow powder. Infrared/cm^{-1} (ATR) ν_{PO} 1165(s) ν_{OH} 3409(m).

$[La(NO_3)_3]_2L_3 1.5CHCl_3$: $La(NO_3)_3 6H_2O$ (0.38 g 0.87 mmol) in 3 ml EtOH was added in portions to a solution of L (0.25 g 0.42 mmol) in 5 ml hot EtOH. A yellow-brown precipitate was formed on each addition. On cooling, the yellow-brown solid formed, and was filtered, washed with a little EtOH and dried at the pump to yield 0.23 g. Crystals suitable for X-ray analysis were grown by slow diffusion of toluene into a $CHCl_3$ solution to give dark brown crystals.

Infrared (ATR) ν_{NO} 1436(s) 1295(s), ν_{PO} 1138(s). *Anal.* Calc.: C, 48.03; H, 3.33; N, 3.25. Found: C, 47.88; H, 3.39; N, 3.51%.

$[Eu(NO_3)_3L_2]_2[Eu(NO_3)_5]2.5CHCl_3$: $Eu(NO_3)_3 6H_2O$ (0.29 g, 0.65 mmol) in 2 ml EtOH was added in portions to a solution of L (0.32 g, 0.55 mmol) in 3 ml hot EtOH as for the La complex above and gave 0.41 g yellow-brown powder. Crystals for X-ray analysis grown by slow diffusion of toluene into a $CHCl_3$ solution rapidly lost solvent on exposure to air.

Infrared/cm^{-1} (ATR) ν_{NO} 1473(s) 1282(s), ν_{PO} 1142(s). *Anal.* Calc. for $[Eu(NO_3)_2L_2]_2[Eu(NO_3)_5]2.5CHCl_3$: C, 45.48; H, 3.16; N, 3.45. Found: C, 45.11; H, 3.66; N, 3.81%.

$[Ho(NO_3)_3L_2]_2[Ho(NO_3)_5]2CHCl_3$: $Ho(NO_3)_3 6H_2O$ (0.32 g, 0.70 mmol) in 2 ml EtOH was added in portions to a solution of L (0.30 g, 0.50 mmol) in 3 ml hot EtOH as for the La complex above gave 0.24 g yellow-brown powder. Crystals for X-ray analysis grown by slow diffusion of toluene into a $CHCl_3$ solution rapidly lost solvent on exposure to air.

Infrared/cm^{-1} (ATR) ν_{NO} 1473(s) 1287(s), ν_{PO} 1146(s). *Anal.* Calc. for $[Ho(NO_3)_2L_2]_2[Ho(NO_3)_5]2CHCl_3$: C, 45.57; H, 3.16; N, 3.47. Found: C, 45.37; H, 3.24; N, 3.63%.

$Dy(NO_3)_3L_2 \cdot 2H_2O$: A solution of $Dy(NO_3)_3 6H_2O$ (0.12 g) in 1.0 ml EtOH was added to a solution of L (0.36 g) in 2 ml EtOH. A yellow-brown precipitate formed on each addition. On complete addition the solid was filtered, washed with EtOH and dried at the pump (0.25 g).

Infrared (ATR) ν_{NO} 1477(s) 1283(s), ν_{PO} 1142(s). *Anal.* Calc.: C, 52.45; H, 3.88; N, 2.70. Found: C, 52.08; H, 3.79; N, 2.54%.

$Lu(NO_3)_3L_2 \cdot 2H_2O$: A solution of $Lu(NO_3)_3 6H_2O$ (0.10 g) in 1.5 ml EtOH was added to a solution of L (0.27 g) in 10 ml EtOH. On reduction of the volume of the solution to about 5 ml brown crystals were deposited which were filtered washed with EtOH and dried at the pump to give the product (0.25 g).

Infrared/cm^{-1} (ATR) ν_{OH} 3400(w) ν_{NO} 1499(s) 1482(s) 1359(m) 1337(m) 1307(m) 1288(s), ν_{PO} 1152(s). *Anal.* Calc.: C, 52.03; H, 3.85; N, 2.68. Found: C, 52.30; H, 3.81; N, 2.74%.

$Fe(NO_3)_2L_2NO_3 \cdot 3.5H_2O$: A solution of L (2.01 g) and silver nitrate (1.03 g) in 40 ml ethanol was heated under reflux for 8 h. The solution was cooled, filtered and allowed slowly to evaporate to 25 ml when dark brown crystals formed. These were filtered, washed with a small quantity of ethanol, and dried at the pump to give dark brown crystals (0.59 g).

Chart 1.

In this contribution we report the synthesis, structures, and chemical properties of complexes of *N*-(diisopropoxyphosphoryl)-*p*-bromothiobenzamide *p*-Br$C_6H_4C(S)NHP(O)(OiPr)_2$ (**HL**) [45] with Zn(II) ([Zn(L-*O*,*S*)$_2$], **1**) and Cd(II) ([Cd(*p*-Br$C_6H_4C(S)NH_2$-*S*)(L-*O*,*S*)$_2$], **2**; [Cd(HL-*O*)$_2$(L-*O*,*S*)$_2$], **3**) cations. In the ligand **HL** both –C(X)R and –P(Y)R′R″ functional groups are combined (X = S, Y = O, R = *p*-C_6H_4, R′ = R″ = O*i*Pr), and bonded by the NH fragment. The phosphorylated thiobenzamide **HL** is easily deprotonated in alkaline medium, leading to a thioamide with the negative charge delocalized in the O–P–*N*–C–S backbone [23].

The luminescence properties of the novel compounds and previously described [24] complexes of thiobenzamide $C_6H_5C(S)NHP(O)(OiPr)_2$ (**HQ**) with Zn(II) and Cd(II) cations: [Zn(Q-*O*,*S*)$_2$] (**4**), [Cd$_2$(Q-*O*,*S*)$_4$] (**5**), [Cd(HQ-*O*)$_2$(Q-*O*,*S*)$_2$] (**6**), were also measured.

2. Results and discussion

The ligand **HL** was prepared by the reaction of *p*-bromothiobenzamide *p*-Br$C_6H_4C(S)NH_2$ with diisopropyl chlorophosphate $(iPrO)_2P(O)Cl$ [45]. The product was carefully purified by extraction and recrystallization, and it definitely contains no traces of starting thioamide according to the spectral and microanalysis data.

Complexes **1**–**3** were prepared by the following procedure: the ligand was deprotonated *in situ* using KOH, followed by reaction with salts of the corresponding metals. The compounds obtained are crystalline solids, which are soluble in most polar solvents. The corresponding reaction using $ZnCl_2$ in aqueous EtOH leads exclusively to the formation of the complex [ZnL$_2$] (**1**), while the same reaction with $Cd(CH_3COO)_2$ leads to the formation of two complexes: [Cd(*p*-Br$C_6H_4C(S)NH_2$)L$_2$] (**2**) and [Cd(HL)$_2$L$_2$] (**3**) (Scheme 1). Complex **3** was separated from the mixture by extraction with *n*-hexane.

The properties of complexes of the "soft", easily polarizable Cd(II) cation differ considerably from those of Zn(II) derivatives with the same ligands. The coordination environment of CdO_2S_2 turns out to be considerably less stable than that of CdS_4 or ZnO_2S_2. As a result, the complexes are hydrolytically unstable and tend to increase the coordination number of the central atom even in dry solvents [24,25].

We assume that the reason for the propensity of Cd(II) complexes to hydrolysis is the formation of dimeric molecules [Cd$_2$L$_4$] in the aqueous ethanol medium:

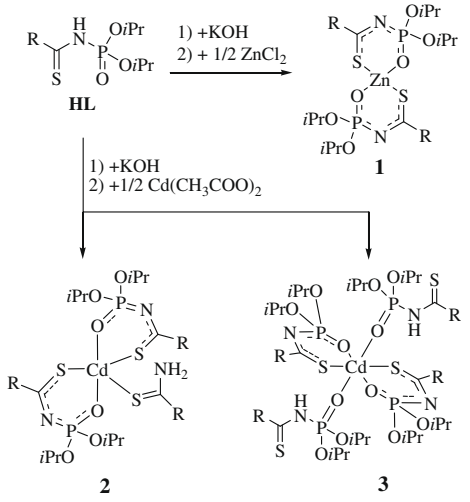
$$2Cd(CH_3COO)_2 + 4KL \rightarrow [Cd_2L_4] + 4CH_3COOK$$
$$[Cd_2L_4] \leftrightarrows 2CdL_2 \quad (1)$$

The structure of a similar dimeric complex **5** was reported earlier [24]. In the dimeric molecule of composition [Cd$_2$Q$_4$] the complex units [CdQ$_2$] are connected by bridging Cd–S–Cd bonds (Scheme 2).

X-ray data have shown that the cyclic bonds in the bridging tridentate ligands **Q** are significantly elongated in comparison with terminal bidentate ones. Decrease of the electron density, introduced by the electron-withdrawing effect of the two Cd(II) cations might result in the facilitation of the nucleophilic attack of H_2O molecules and, thus, promote hydrolysis. An assumed reaction of that type is shown in the following equation:

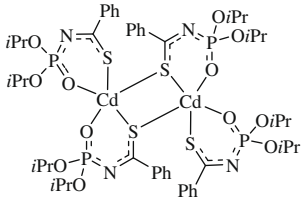
$$[Cd_2L_4] + 3H_2O \rightarrow [CdL_2] + p\text{-}BrC_6H_4C(S)NH_2 + (iPrO)_2P(O)OH + Cd(OH)_2 + HL \quad (2)$$

Recently, we have established [24] that the complex **5** is unstable in solution and dissociates to the mononuclear complexes. However, even if the equilibrium is almost quantitatively shifted to the right (Eq. (1)), the small amount of easily hydrolyzing dimer molecules could provide the accumulation of the hydrolysis product in the reaction mixture. Interestingly, Zn(II) complexes exhibit no dimer formation under the same reaction conditions.



N-Phosphoryl-*p*-bromothiobenzamide **HL** and *p*-Br$C_6H_4C(S)NH_2$, which are formed as a result of hydrolysis (Eq. (2)), can serve as neutral ligands in the coordination sphere of [CdL$_2$] as in complexes **2** and **3**. In the $^{31}P\{^1H\}$ spectrum of the reaction mixture there is also a signal at −1.7 ppm, which might correspond to $(iPrO)_2P(O)OH$ (δ_P 2.98 ppm in THF-d_8 [46]).

The molecular structures of these compounds were investigated by MALDI, IR, ^1H, $^{31}P\{^1H\}$ NMR spectroscopy and by microanalysis.



In the IR spectrum of **HL** there are bands of all characteristic groups. The P═O group is observed as an intense band at 1256 cm^{-1}. The band at 1504 cm^{-1} corresponds to the S═C–N fragment. The NH group shows a band at 3080 cm^{-1}.

The IR spectrum of **1** in Nujol is similar to the spectrum of **2**. The resonances of the P═O group of the anionic forms of **L** in complexes **1** and **2** are shifted by approximately 100 cm^{-1} to low frequencies relative to the band of the parent ligand **HL**. This confirms their participation in chelate formation. The spectra contain very intense bands corresponding to the conjugated SCN group at 1512–1544 cm^{-1}. This fact also confirms the formation of the anionic forms of **L** [23–25].

The main difference between the two complexes **1** and **2** involves the absorption bands of the NH_2 group in the IR spectrum of complex **2** while for complex **1** no signals are observed in the

Scheme 1. Preparation of complexes **1**–**3** (R = *p*-BrC_6H_4).

Scheme 2. Structure of **5** [24].

characteristic area of the NH group. There is an intense band at 1664 cm^{-1} and two bands of low intensity at 3104 and 3280 cm^{-1}.

The IR spectrum of **3** shows two bands for different phosphorus groups. Along with the above band corresponding to the **L** form at 1156 cm^{-1}, a strong P=O band is observed at 1248 cm^{-1} due to the bound neutral molecules of **HL**. Its frequency also decreases relative to that of the band of the free ligand; however, the shift is only 8 cm^{-1}. The band for the NH group at 3160 cm^{-1} also indicates the presence of **HL** molecules in complex **3**. The SCN group shows an intense band at 1528 cm^{-1} and indicates the presence of the anionic form of **L**.

The IR spectra of **HL** and complexes **1**–**3** exhibit a very intense band at 1000–1008 cm^{-1} corresponding to the POC group.

The $^{31}P\{^1H\}$ NMR signals of complexes **1** and **2** appear at $\delta = 6.9$ and 4.3 ppm, respectively, and a down-field shift, relative to that of the free ligand **HL** ($\delta = -5.9$ ppm), is observed.

The ^1H NMR spectra of complexes **1** and **2** contain a single set of signals for the $(i\text{PrO})_2P(O)$ and C_6H_4 protons of the anionic form **L**. The *o*-phenylene proton signals in **1** and **2** are shifted down-field relative to that of the free ligand ($\Delta\delta = 0.36$ ppm), while the *m*-C_6H_4 proton signals are practically not shifted ($\Delta\delta = 0.01$–0.04 ppm). The signal for the NHP(O) group proton is absent in the ^1H NMR spectra. This confirms the presence of the **HL** anionic form in the structures of complexes **1** and **2**.

The main difference involves the proton signals of the *p*-$BrC_6H_4C(S)NH_2$ group in the ^1H NMR spectrum of complex **2**. The signals for the C_6H_4 protons of the *p*-bromothiobenzamide are observed at $\delta = 7.55$ and 7.68 ppm. There are two singlets at $\delta = 7.35$ and 9.61 ppm corresponding to the NH_2 group protons due to the constrained rotation around the CN bond, typical for the thioamide group.

There are two singlets at $\delta = -5.3$ and 4.4 ppm, which have identical integrated intensities, in the $^{31}P\{^1H\}$ NMR spectrum of complex **3**. The signal at $\delta = -5.3$ ppm is in the region characteristic for neutral *N*-phosphorylated thioamides and thioureas, whereas the second signal corresponds to the amidophosphate environment in complexes of *N*-acylamidophosphate anions.

The ^1H NMR spectrum contains a double set of equal intensity signals for the $(i\text{PrO})_2P(O)$ and C_6H_4 protons. The assignment of the ^1H NMR spectrum of compound **3** is executed by comparing the spectrum of **3** with those of **HL** and complex **2**. For more exact reference of OCH and C_6H_4 proton signals of complex **3,** the spectrum of a mixture of **3** and **HL** was recorded at a molar ratio of 2:1. The increase in intensities of the low-field OCH group signal and the signals for the *m*- and *o*-C_6H_4 protons at $\delta = 7.47$ and 7.81 ppm, respectively, concerning the neutral **HL** form, confirms the reference made by comparison of the spectra. The ^1H NMR spectrum of complex **3** shows a signal for the NH group of the phosphorylamide fragment as a doublet ($^2J_{P,H} = 10.1$ Hz).

MALDI experiments on complexes **1** and **2** show peaks for the molecular ions $[M+H]^+$, $[M+Na]^+$ and $[M+K]^+$. These peaks are very intense in the mass spectrum of **1** but have low intensities (less than 8%) in the spectrum of complex **2**. In the MALDI mass spectrum of **2** there are molecular ion peaks corresponding to the additional *p*-bromothiobenzamide ligand.

The molecular ion peak of **3** is not observed under the same measurement conditions, only ions characteristic for the $[CdL_2]$ complex core, $[CdL_2 + H]^+$, $[CdL_2 + Na]^+$ and $[CdL_2 + K]^+$, are found in the MALDI spectrum.

The MALDI data of **1**–**3** show propensity to dimer formation. The intensity of the $[M_2L_3]^+$ peak in the spectra of complexes **1**–**3** is in the range of 12–19%. The peaks corresponding to the dimer formation were also observed in the ES (electrospray) mass spectra of complexes **4**–**6** [24].

The data of the emission spectra for complexes **1**–**6** in the solid state at room temperature are listed in Table 1 (note that neither parent ligands **HL** and **HQ** nor *p*-$BrC_6H_4C(S)NH_2$ show any emission under the same conditions). On first view, all compounds **1**–**6** exhibit practically the same fluorescence properties, respectively.

Table 1
Photophysical data for complexes **1**–**6**[a].

Complex	Emission max, nm	Complex	Emission max, nm
1	395	4	392
2	331, 397	5	322, 394
3	394	6	397

[a] Excitation at 249 nm.

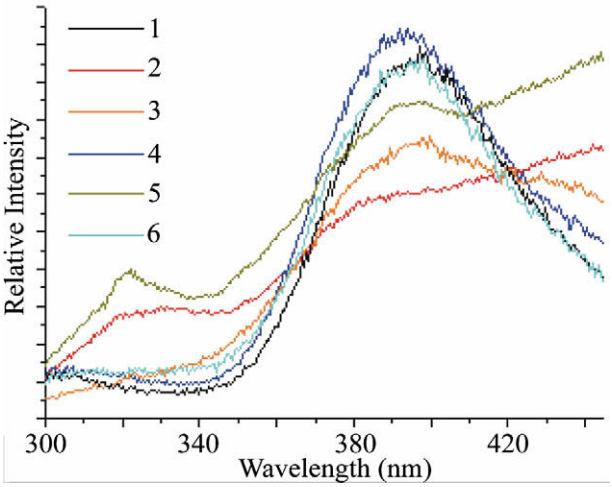


Fig. 1. Emission spectra of complexes **1**–**6** (the excitation wavelength was 249 nm).

Complexes **1**, **3**, **4** and **6** show a blue emission band with the maximum intensity at 392–397 nm upon excitation at 249 nm (Table 1, Fig. 1). Complexes **2** and **5** give a blue emission band at 394–397 nm and additionally exhibit bands of low intensity at 322–331 nm (Table 1, Fig. 1). The emissions of **1**–**6** are proposed to be the result of the coordination of **L**, **Q** and *p*-$BrC_6H_4C(S)NH_2$ to Zn(II) or Cd(II), and according to previous data [32,33], these emission bands can be assigned to the emission from a an excited ligand-to-metal charge transfer (LMCT) state.

In the solid state, the emission bands of complexes **1** and **6** have equal intensities. Replacing the *p*-bromosubstituted ligand to the nonsubstituted analog in the complexes with the same environment of the metal cation (compare complexes **1** to **4** and, **3** to **6** respectively), leads to an increase in intensity, which may be due to stronger σ-donation from **Q** and **HQ** than **L** and **HL**.

Emission spectra of **2** and **5** are practically isomorphic and the intensities of both bands in **2** are smaller than in **5**. The Cd(II) cation in complexes **2** and **5** is pentacoordinated with trigonal-bipyramidal O_2S_3 environment, which may lead to the appearance of the low-intensive band at 322–331 nm. There are two metal atoms in a molecule of **5** and only one central cation in **2**. Thus, this fact together with more electron donation from **Q** leads to an increase in intensity of both emission bands in complex **5** compared with **2**.

Crystals of **1**–**3** were obtained by slow evaporation of the solvent from dichloromethane/*n*-hexane solutions of the complexes. The crystals were measured and the structures were solved under the conditions and with the results outlined in Table 2.

According to the X-ray data, complex **1** in a crystal is a spirocyclic chelate with a distorted tetrahedral ZnO_2S_2 core (Fig. 2). S(1)–Zn–O(1) and O(1)–Zn–O(1)a ($1 - x$, $1 - y$, $-z$) angles are reduced whereas S(1)–Zn–O(1)a ($1 - x$, $1 - y$, $-z$) and S(1)–Zn–S(1)a ($1-x$, $+1$, $-y$, $-z$) are increased in comparison with an ideal tetrahedral

angle of 109.5° (Table 3). Similarly to those of the [Co(II)Q_2] [28,29] and complex **4** [24], investigated by us earlier, the six-membered chelate rings are practically planar in the molecule of **1**. The maximum deviation from the best plane Zn–O–P–*N*–C–S is observed for P(1) phosphorus and O(1) oxygen atoms. The phenylene ring is rotated relative to the plane of the conjugated SCN moiety [torsion angles are N(2)–C(1)–C(2)–C(3) 16.1(3)° and S(1)–C(1)–C(2)–C(7) 17.8(3)°].

Complex **2** (Fig. 3) crystallizes in the chiral space group *P*2(1). The asymmetric unit contains two independent molecules.

There are intra- and intermolecular hydrogen bonds of the type N–H···O in the crystal of complex **2**. The intramolecular H-bond is formed between the oxygen atom of the P═O group of the anionic ligand **L** and one of the hydrogen atom of the NH_2 fragment of *p*-bromothiobenzamide. The intramolecular hydrogen bond parameters in Molecule 1 are as follows: N(3)–H(3 M)···O(4), *d*(H···O) 2.2(1) Å, *d*(N···O) 2.93(1) Å, ∠(N–H···O) 158(1)°. The hydrogen bond parameters in Molecule 2 are as follows: N(6)–H(6 M)···O(10), *d*(H···O) 2.1(1) Å, *d*(N···O) 2.86(1) Å, ∠(N–H···O) 157(1)°.

As a result of the intermolecular H-bonds chains along the *b* axis are formed. The intermolecular H-bonds are as follows: N(3)–H(3 N)···O(1) (−1 − *x*, 1/2 + *y*, 2 − *z*), *d*(H···O) 1.91(9) Å, *d*(N···O) 2.93(1) Å, ∠(N–H···O) 172.1(8)° N(6)–H(6 N)···O(7) (−1 − *x*, 1/2–*y*, 3–*z*), *d*(H···O) 2.3(1) Å, *d*(N···O) 3.0(1) Å, ∠(N–H···O) 169(1)°.

The Cd(II) cations are present in a distorted trigonal-bipyramidal environment (O_2S_3). The axial positions are occupied by the oxygen atoms of the phosphoryl groups. Three sulfur atoms, corresponding to the two anionic forms **L** and one *p*-bromothiobenzamide, lie in its base. The six-membered Cd–O–P–*N*–C–S cycles have a distorted boat conformation with the C═S sulfur atom and the P═O oxygen atom in apical positions (Table 4). The lengths of the Cd–S bonds in the chelate rings of the Molecule 1 are practically equivalent, but in the Molecule 2 the difference is about 0.014(1) Å. The third Cd–S bonds in both molecules are almost equal to each other ($\Delta \approx 0.003$ Å). The bonds with the oxygen atoms in the chelate rings of the Molecule 1 differ on 0.08 Å, but the Cd–O bonds difference in the Molecule 2 is only 0.03 Å. The Cd(1)–O(1) and Cd(2)–O(7) bonds in the Molecules 1 and 2, respectively, deviate from the normal to the CdS_3 plane [O(1)–Cd(1)–O(4) 169.3(2)° and O(7)–Cd(2)–O(10) 171.1(2)°], while the Cd(1)–O(4)

and Cd(2)–O(10) bonds stay practically perpendicular to the CdS_3 plane.

The molecule of complex **3** in the crystal is located in a special position at the symmetry centre. The coordination geometry of the Cd(II) atom is tetragonal bipyramidal ($D_{2\,h}$) (Fig. 4). Isostructural complexes of Co(II) [28,29], Ni(II) [35] with **HQ**, and Cd(II), Ni(II) with **HL** [24,45] have been synthesized and structurally characterized by us previously.

The equatorial positions of the bipyramid are occupied by two *N*-phosphoryl-*p*-bromothiobenzamide anions **L**, bonded through sulfur atoms and oxygen atoms of thiocarbonyl and phosphoryl groups, respectively. The six-membered Cd–O–P–*N*–C–S cycle lies between a boat and a chair conformations since the O–P–*N*–C–S backbone is flat (Table 5). The ligands show *trans* configuration. Neutral ligand molecules are coordinated in the axial positions through the oxygen atoms of the phosphoryl groups. The lengths of the Cd–O bonds in the chelate rings are 2.300(9) Å while the bonds with the axial oxygen atoms are 2.419(9) Å.

There are two intramolecular NH···O bonds between the oxygen atom of the P═O group of the anionic ligand **L** and the hydrogen atom of the NH fragment of the neutral ligand **HL** in the crystal of complex **3**. The hydrogen bond parameters are as follows: N(1B)–H(1B)···O(1A) $(1-x, -y, -z)$, d(H···O) 2.11 Å, d(N···O) 2.92(1) Å, ∠(N–H···O) 157°.

3. Experimental

Infrared spectra (Nujol) were recorded with a Specord M-80 spectrometer in the range 400–3600 cm^{-1}. NMR spectra were obtained on a Varian Unity-300 NMR spectrometer at 25 °C. ^1H and $^{31}P\{^1H\}$ NMR spectra ($CDCl_3$) were recorded at 299.948 and 121.420 MHz, respectively. Chemical shifts are reported with reference to $SiMe_4$ (^1H) and H_3PO_4 ($^{31}P\{^1H\}$). MALDI mass spectra of **1**–**3** were obtained using a Bruker Reflex IV spectrometer. Fluorescence measurements were made on a SLM Aminco 500 spectrofluorometer at room temperature. Elemental analyses were performed on a Perkin–Elmer 2400 CHN microanalyser.

3.1. Syntheses

p-$BrC_6H_4C(S)NHP(O)(OiPr)_2$ (***HL***). *N*-(diisopropoxyphosphoryl)-*p*-bromothiobenzamide was prepared according to previously described methods [45].

[ZnL_2] (***1***)**.** A suspension of **HL** (1.9 g, 5 mmol) in aqueous ethanol (20 mL) was mixed with an ethanol solution of potassium hydroxide (0.28 g, 5 mmol). An aqueous (20 mL) solution of $ZnCl_2$ (0.82 g, 2.8 mmol) was added dropwise under vigorous stirring to the resulting potassium salt. The mixture was stirred at room temperature for further 3 h and left overnight. The complex was obtained by extraction of the reaction mixture by dichloromethane, washed with water and dried using anhydrous $MgSO_4$. The solvent was then removed in vacuo. A colorless precipitate was recrystallized from a dichloromethane/*n*-hexane mixture. Yield 1.73 g (84%), m.p. 143 °C. (Found: C, 37.82; H, 4.47; N, 3.31%. $C_{26}H_{36}Br_2N_2O_6P_2S_2Zn$ requires C, 37.90; H, 4.40; N, 3.40%.). ν_{max}/cm^{-1} 1544 (SCN), 1152 (P═O), 1000 (POC). δ_H 8.14 (4H, m, ^3J 8.4, *o*-H, C_6H_4), 7.50 (4H, m, ^3J 8.4, *m*-H, C_6H_4), 4.71 (4H, d sept, ^3J 6.2, OCH), 1.36 (12H, d, ^3J 5.6, CH_3), 1.35 (12H, d, ^3J 5.6, CH_3). δ_P 6.9. *m*/*z* (MALDI) 826 (81) $[M+H]^+$, 849 (100) $[M+Na]^+$, 864 (52) $[M+K]^+$, 1271 (12) $[Zn_2L_3]^+$.

*[Cd(p-$BrC_6H_4C(S)NH_2$)L_2] (**2**) and [Cd(HL)$_2$$L_2$]* (***3***)**.** A suspension of **HL** (1.91 g, 5 mmol) in aqueous ethanol (20 mL) was mixed with an ethanol solution of potassium hydroxide (0.28 g, 5 mmol). An aqueous (20 mL) solution of $Cd(CH_3COO)_2 \cdot 2H_2O$ (0.82 g, 2.8 mmol) was added dropwise under vigorous stirring to the resulting potassium salt. The mixture was stirred at room temperature for a further 3 h and left overnight. The complex was obtained by extraction of the reaction mixture by dichloromethane, washed with water and dried with anhydrous $MgSO_4$. The solvent was then removed in vacuo. The residue was extracted using *n*-hexane. The hexane insoluble residue was recrystallized from a dichloromethane/*n*-hexane mixture, and complex **2** was isolated. Complex **2** was obtained as colorless crystals. Yield 0.44 g, mp 129 °C. (Found: C, 36.35; H, 3.96; N, 3.81%. $C_{33}H_{42}Br_3CdN_3O_6P_2S_3$ requires C, 36.46; H, 3.89; N, 3.87%.). ν_{max}/cm^{-1} 3280, 3104, 1664 (NH_2), 1512 (SCN), 1157 (P═O), 1000 (POC). δ_H 9.61 (1H, br. s, NH_2), 8.14 (4H, m, ^3J 8.5, *o*-H, C_6H_4, L), 7.68 (2H, m, ^3J 8.4, *o*-H, C_6H_4), 7.55 (2H, m, ^3J 8.4, *m*-H, C_6H_4), 7.47 (4H, m, ^3J 8.5, *m*-H, C_6H_4, L), 7.35 (1H, s, NH_2), 4.72 (4H, d sept, ^3J 6.3 Hz, OCH), 1.34 (24H, d, ^3J 6.1, CH_3). δ_P 4.3. *m*/*z* (MALDI) 217 (100) [*p*-$BrC_6H_4C(S)NH_2 + H]^+$, 240 (13) [*p*-$BrC_6H_4C(S)NH_2 + Na]^+$, 217 (5) [*p*-$BrC_6H_4C(S)NH_2 + K]^+$, 873 (34) $[CdL_2 + H]^+$, 896 (48) $[CdL_2 + Na]^+$, 1089 (6) $[M + H]^+$, 1112 (3) $[M + Na]^+$, 1128 (7) $[M + K]^+$, 1364 (19) $[Cd_2L_3]^+$. At the solvent-removal stage (hexane soluble), product **3** was isolated. Complex **3** was obtained as orange crystals. Yield 0.21 g, m.p. 114 °C. (Found: C, 38.37; H, 4.46; N, 3.50%. $C_{52}H_{74}Br_4CdN_4O_{12}P_4S_4$ requires C, 38.28; H, 4.57; N, 3.43%.). ν_{max}/cm^{-1} 3160 (NH), 1528 (SCN), 1248 (P═O, HL), 1156 (P═O, L), 1004 (POC). δ_H 9.00 (2H, d, ^3J 10.1, NH), 8.13 (4H, m, ^3J 7.9, *o*-H, C_6H_4, L), 7.81 (4H, m, ^3J 8.3, *o*-H, C_6H_4, HL), 7.53 (4H, m, ^3J 7.9, *m*-H, C_6H_4, L), 7.47 (4H, m, ^3J 7.9, *m*-H, C_6H_4, HL), 4.83 (4H, d sept, ^3J 6.3, OCH, HL), 4.65 (4H, d sept, ^3J 6.2, OCH, L), 1.36 (12H, d, ^3J 6.3, CH_3, L), 1.30 (36H, br s, CH_3, L + HL). δ_P 4.4 (2P, L), −5.3 (2P, HL). *m*/*z* (MALDI) 873 (67) $[CdL_2 + H]^+$, 896 (100) $[CdL_2 + Na]^+$, 912 (17) $[CdL_2 + K]^+$, 1364 (15) $[Cd_2L_3]^+$.

3.2. Structure determination

The data for **1** and **3** were collected at 20 °C using a Bruker Smart Apex2 diffractometer and graphite-monochromated Mo Kα radiation generated from Diffraction X-ray tube operated at 50 kV and 30 mA. The images were indexed, integrated and scaled using the APEX2 data reduction package [47]. All raw data were corrected for absorption using SADABS [48] The structure was solved by heavy atom and direct method using SIR [49] program and the

refinement was carried out with SHELXL [50] using anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were added to the structure model on calculated positions and were refined as rigid atoms. All calculations were performed on PC computer using WINGX [51] program.

X-ray diffraction data for **2** were collected on a Enraf Nonius Kappa CCD diffractometer equipped with a rotating anode generator and with Mo $K\alpha$ radiation. The structure solutions were found with SHELXS [52], and the refinement was carried out with SHELXL [50] using anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were added to the structure model on calculated positions and were refined as rigid atoms.

All figures were made using the program PLATON [53].

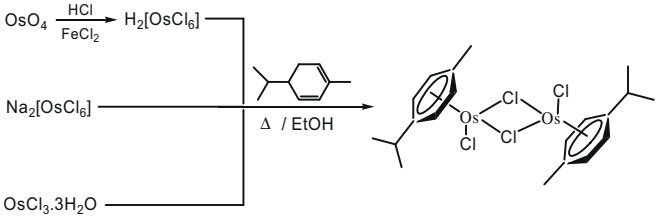
4. Conclusions

The data obtained testify that the structure of the chelate complexes of 12 Group metal cations with *N*-phosphorylated thioamides of general formula RC(S)NHP(O)R′R″ depends on the nature of the central ion, and unlike dithioanaloges RC(S)NHP(S)R′R″ which form only complexes with a MS_4 core. For the ligands containing different donor atoms, sulfur and oxygen simultaneously, the increase in the coordination number of the central atom by dimerization or interaction with nucleophilic species is observed for complexes of Cd(II), while only tetracoordinated [M{RC(S)NP(O)R′R″}-*O*,*S*)$_2$] complexes of Zn(II) have been obtained [24,25].

We assume, that dimerization of the Cd(II) compounds in aqueous ethanol media can promote their hydrolysis, while the mononuclear Zn(II) compounds are obtained in good yield and show no tendency to hydrolytic destruction.

The luminescent properties of the new complexes has shown that the observed emission bands can be assigned ligand-to-metal charge transfer (LMCT).

Acknowledgments



This work was supported by the Russian Science Support Foundation and partly by University of Wroclaw. M.G.B. and D.A.S. thank DAAD for the scholarships (Forschungsstipendien 2008/2009). We also thank Dr. P. Mayer for collecting the data sets for the crystal structure determination.

Appendix A. Supplementary data

CCDC 664765, 682366 and 664766 contain the supplementary crystallographic data for (**1**), (**2**) and (**3**). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1. Reported synthetic methods for dimeric η^6-*p*-cymene osmium(II) complexes [1,2].

using Xenon gas and all matrices were made with 3-nba (3-nitrobenzyl alchohol). Microanalyses were conducted with a Thermo Flash 1112 Series CHNS-O Analyzer instrument. FT-IR spectra were recorded on a Perkin–Elmer Spectrum One FT-IR Spectrometer, using solution cells with NaCl windows.

Melting points were recorded with a Kofler hot stage microscope (Riechert Thermovar). GC analyses were carried out using a Varian 3900 gas chromatograph equipped with an FID and a 30 m × 0.32 mm CP-Wax 52 CB column (0.25 μm film thickness). The carrier gas was helium at 5.0 psi. The oven was programmed to hold at 32 °C for 4 min and then to ramp to 200 °C at 10 °C/min and hold 5 min.

2.3. Preparation of arene-osmium complexes

2.3.1. Synthesis of $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**)

$K_2[OsO_2(OH)_4]$ (5.070 g, 13.760 mmol) was dissolved in HBr (50 ml, 48% aq) and EtOH (100 ml 96%) and refluxed for 18 h. To the solution was added α-phellandrene (10 ml) and refluxed for a further 18 h. The solvent was removed under vacuum to give a red oil. The product was extracted with CH_2Cl_2 (5 × 80 ml) and the solution concentrated to approximately 50 ml and diethyl ether added. The solution was cooled at −15°C overnight to give orange-red crystals. Yield (4.39 g, 66%); m.p. 246–249 °C. Elemental *Anal.* Calc. for $C_{20}H_{28}Br_4Os_2$: C, 24.78; H, 2.89. Found: C, 24.93; H, 2.87%. ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.12–1.30 (m 6H) CH*Me*$_2$, 2.17 (s, 3H) C*Me*, 2.45–2.76 (m, 1H) C*H*Me$_2$, 6.02 (d, 2H J = 5.65 Hz) C$_6$*H*$_4$, 6.15 (d, 2H J = 5.64 Hz) C$_6$*H*$_4$.

2.3.2. Synthesis of $[(\eta^6\text{-}C_6Me_6)OsBr_2]_2$ (**2**)

$[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (500 mg, 0.516 mmol) and hexamethylbenzene (4.00 g 24.648 mmol) were transferred into a sealable tube. The tube was evacuated and heated at 175–180 °C. After 24 h the melt was allowed to reach room temperature and extracted with CH_2Cl_2 (25 ml). The solvent was removed using a rotary evaporator and a brown-orange solid was obtained and washed with (4 × 50 ml) of *n*-hexane to remove the excess hexamethylbenzene and dried under vacuum for 3 h. Yield (315 mg, 60%); decomposes without melting at 280 °C. Elemental *Anal.* Calc. for $C_{24}H_{36}Br_4Os_2$: C, 28.13; H, 3.54. Found: C, 28.49; H, 3.57%. ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 2.25 (s 36H) 2{C$_6$*Me*$_6$}.

2.3.3. Synthesis of $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PPh_3)Br_2]$ (**3**)

To a suspension of $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (1.070 g, 1.032 mmol) in *n*-hexane (80 ml) was added PPh_3 (560 mg, 2.064 mmol) and heated to reflux. After 4 h the solvent was removed using a rotary evaporator to give an orange solid residue. The solid was dissolved in a minimum of CH_2Cl_2 (15 ml), filtered and diethyl ether added to give an orange solid. Yield (1.424 g, 92%). Elemental *Anal.* Calc. for $C_{28}H_{29}Br_2OsP$: C, 45.03; H, 3.88. Found: C, 45.07; H, 3.86%; m.p. 223–225 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ ppm: 1.19 (d, 6H J = 6.93 Hz) CH*Me*$_2$, 1.97 (s, 3H) C*Me*, 2.99 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 5.13 (d, 2H J = 5.82 Hz) C$_6$*H*$_4$, 5.47 (d, 2H J = 5.90 Hz) C$_6$*H*$_4$, 7.30–7.82 (m, 15H) P*Ph*$_3$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: −17.57 (s), $^1J(^{187}Os\text{–}^{31}P)$ = 283 Hz.

Complexes **4**–**8** were prepared using the same procedure as described for the preparation of complex **3**.

2.3.4. $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PEt_3)Br_2]$ (**4**)

Complex **4** was prepared using $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (200 mg, 0.206 mmol) and PEt_3 (48 mg, 0.413 mmol). The product was obtained as an orange solid and dried under vacuum for 2 h. Yield (191 mg, 73%). Elemental *Anal.* Calc. for $C_{16}H_{29}Br_2OsP$: C, 31.90; H, 4.85. Found: C, 31.02; H, 4.99%; m.p. 119–122 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.04–1.22 (m, 9H) P–(CH$_2$*Me*)$_3$, 1.27 (d, 6H J = 6.86 Hz) CH*Me*$_2$, 2.05–2.18 (m, 6H) P–(*CH*$_2$Me)$_3$, 2.28 (s, 3H) C*Me*, 2.88 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 5.55 (d, 2H J = 4.98 Hz) C$_6$*H*$_4$, 5.61 (d, 2H J = 5.71 Hz) C$_6$*H*$_4$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: −28.35 (s) $^1J(^{187}Os\text{–}^{31}P)$ = 269 Hz.

2.3.5. $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PMePh_2)Br_2]$ (**5**)

Complex **5** was prepared using $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (460 mg, 0.475 mmol) and $PMePh_2$ (190 mg, 0.950 mmol). The product was isolated as an orange-yellow solid. Yield (566 mg, 87%). Elemental *Anal.* Calc. for $C_{23}H_{27}Br_2OsP$: C, 40.36; H, 3.98. Found: C, 40.11; H, 3.52%; m.p. 196–198 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ ppm: 1.22 (d, 6H J = 6.97, Hz) CH*Me*$_2$, 2.02–2.15 (m, 3H) P–*Me*Ph$_2$, 2.18 (d, 3H J = 10.68 Hz) C*Me*, 2.89 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 5.40 (d, 2H J = 5.75 Hz) C$_6$*H*$_4$, 5.49 (d, 2H J = 5.71 Hz) C$_6$*H*$_4$, 7.39–7.76 (m, 10H) P–Me*Ph*$_2$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: −26.68 (s) $^1J(^{187}Os\text{–}^{31}P)$ = 274 Hz.

2.3.6. $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os\{P(OMe)_3\}Br_2]$ (**6**)

Complex **6** was prepared using $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (200 mg, 0.206 mmol) and $P(OMe)_3$ (51 mg, 0.413 mmol). The product was obtained as a red-orange crystalline solid. Yield (185 mg, 74%). Elemental *Anal.* Calc. for $C_{13}H_{23}O_3Br_2OsP$: C, 25.66; H, 3.78. Found: C, 25.29; H, 3.73%; m.p. 154–157 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ ppm: 1.25 (d, 6H J = 6.95 Hz) CH*Me*$_2$, 2.33 (d, 3H J = 1.71 Hz) C*Me*, 2.99 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 3.58 (d, 9H J = 10.90 Hz) P–(O*Me*)$_3$, 5.49 (d, 2H J = 5.88 Hz) C$_6$*H*$_4$, 5.64 (d, 2H J = 5.93 Hz) C$_6$*H*$_4$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: 68.06 (s) $^1J(^{187}Os\text{–}^{31}P)$ = 455 Hz.

2.3.7. $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os\{P(OBu^n)_3\}Br_2]$ (**7**)

Complex **7** was prepared using $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (1.000 g, 1.032 mmol) and $P(OBu^n)_3$ (516 mg, 2.065 mmol). The product was isolated as a bright orange solid. Yield (1.284 g, 85%). Elemental *Anal.* Calc. for $C_{22}H_{41}O_3Br_2OsP$: C, 35.97; H, 5.58. Found: C, 35.95; H, 5.39%; m.p. 57–60 °C; ^{1}H NMR (400 MHz, $CDCl_3$) δ ppm: 0.83–0.95 (m, 9H) P–{O(CH$_2$)$_3$*CH*$_3$}$_3$, 1.21 (d, 6H J = 6.95 Hz) CH*Me*$_2$, 1.36 (qd, 6H J = 14.38, 7.24, 7.24, 7.15 Hz) P–{O(CH$_2$)$_2$*CH*$_2$CH$_3$}$_3$, 1.52–1.69 (m, 6H) P–{OCH$_2$*CH*$_2$CH$_2$CH$_3$}$_3$, 2.28 (s, 3H) C*Me*, 2.87–2.92 (m, 1H) C*H*Me$_2$, 3.76 (dd, 6H J = 6.90, 13.90 Hz) P–{OC*H*$_2$(CH$_2$)$_2$CH$_3$}$_3$, 5.43 (d, 2H J = 5.76 Hz) C$_6$*H*$_4$, 5.57 (d, 2H J = 5.72 Hz) C$_6$*H*$_4$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: 62.43 (s) $^1J(^{187}Os\text{–}^{31}P)$ = 449 Hz.

2.3.8. $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os\{P(OPh)_3\}Br_2]$ (**8**)

Complex **8** was prepared using $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ (**1**) (500 mg, 0.516 mmol) and $P(OPh)_3$ (320 mg, 1.033 mmol). The product was isolated as an orange solid. Yield (662 mg, 81%). Elemental *Anal.* Calc. for $C_{28}H_{29}Br_2O_3OsP$: C, 42.33; H, 3.68. Found: C, 42.45; H, 3.18%; m.p. 175–177 °C; ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.20 (d, 6H J = 6.99 Hz) CH*Me*$_2$, 2.23 (s, 3H) C*Me*, 2.55–2.78 (m, 1H) C*H*Me$_2$, 5.16 (d, 2H J = 5.92 Hz) C$_6$*H*$_4$, 5.48 (d, 2H J = 5.92 Hz) C$_6$*H*$_4$, 7.09–7.36 (m, 15H) P(O*Ph*)$_3$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: 52.28 (s), $^1J(^{187}Os\text{–}^{31}P)$ = 476 Hz.

*2.3.9. Synthesis of [(η^6-p-MeC$_6$H$_4$Pr^i)Os(CO)Br$_2$] (**9**)*

CO gas was bubbled through a suspension of [(η^6-*p*-MeC$_6$H$_4$-Pr^i)OsBr$_2$]$_2$ (**1**) (500 mg, 0.195 mmol) in *n*-hexane (25 ml). After 45 min the solvent was removed using a rotary evaporator to give a red-orange solid which was dried under vacuum for 1 h. Yield (482 mg, 91%). Elemental *Anal.* Calc. for $C_{11}H_{14}Br_2OOs$: C, 25.79; H, 2.75. Found: C, 25.55; H, 2.66%; decomposes without melting above 200 °C; IR (CH_2Cl_2, cm^{-1}): ν(C≡O) 2022; ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.20 (d, 6H J = 6.99 Hz) CH*Me*$_2$, 2.13 (s, 3H) C*Me*, 2.77 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 5.14 (d, 2H J = 5.82 Hz) C$_6$*H*$_4$, 5.47 (d, 2H J = 5.90 Hz) C$_6$*H*$_4$.

*2.3.10. Synthesis of [(η^6-C$_6$Me$_6$)Os(CO)Br$_2$] (**10**)*

CO gas was bubbled through a solution of [Os(η^6-C$_6$Me$_6$)Br$_2$]$_2$ (**2**) (200 mg, 0.195 mmol) dissolved in dry chloroform (40 ml). After 45 min the solvent was removed using a rotary evaporator to give a dark orange solid which was dried under vacuum for 1 h. Yield (89 mg, 42%). Elemental *Anal.* Calc. for $C_{13}H_{18}Br_2OOs$: C, 28.90; H, 3.33. Found: C, 28.52; H, 3.85%; decomposes without melting above 280 °C; IR ($CHCl_3$, cm^{-1}): ν(C≡O) 2005; ^{1}H NMR (300 MHz, $CDCl_3$) δ ppm: 1.98 (s, 18H) {C$_6$*Me*$_6$}.

*2.3.11. Synthesis of [(η^6-p-MeC$_6$H$_4$Pr^i)(PPh$_3$)Os{(CH$_2$)$_3$CH=CH$_2$}$_2$] (**11**)*

[(η^6-*p*-MeC$_6$H$_4$Pr^i)Os(PPh$_3$)Br$_2$] (**3**) (1.000 g, 1.420 mmol) was transferred into a Schlenk tube and dissolved in freshly dried THF (30 ml). To this was added BrMg(CH$_2$)$_3$CH=CH$_2$ (0.54 M, 10.56 ml, 5.690 mmol) under N_2 at −78 °C. The solution was then allowed to reach room temperature and stirred for 18 h, during which time it had turned from orange to yellow. A saturated NH_4Cl solution (15 ml) was added drop wise to the solution at −78 °C in order to hydrolyze the excess Grignard reagent. After reaching room temperature dichloromethane (20 ml) was added and the organic layer was separated, dried over anhydrous $MgSO_4$ and filtered. The volatiles were removed using a rotary evaporator to give a yellow-brown oil which was dried under vacuum for 30 min. Yield (745 mg, 72%); ^{1}H NMR (300 MHz, C_6D_6) δ ppm: 0.82–0.91 (m, 4H) Os–C*H*$_2$, 1.21 (d, 6H J = 6.99 Hz) CH*Me*$_2$, 1.40–1.88 (m, 8H) C*H*$_2$, 1.99 (s, 3H) C*Me*, 2.98 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 4.52–5.04 (m, 4H) =C*H*$_2$, 5.32 (d, 2H J = 5.90 Hz) C$_6$*H*$_4$, 5.53 (d, 2H J = 5.88 Hz) C$_6$*H*$_4$, 5.61–5.79 (m, 2H) C*H*=, 7.28–7.82 (m, 15H) P*Ph*$_3$; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: 12.61 (s).

Complexes **12**–**14** were prepared using the same procedure as described for the preparation of complex **11**.

*2.3.12. [(η^6-p-MeC$_6$H$_4$Pr^i){P(OBu^n)$_3$}Os{(CH$_2$)$_3$CH=CH$_2$}$_2$] (**12**)*

Complex **12** was prepared using [(η^6-*p*-MeC$_6$H$_4$Pr^i)Os{P(OBu^n)$_3$}Br$_2$] (**7**) (190 mg, 0.259 mmol) in freshly dried THF (35 ml) and BrMg(CH$_2$)$_3$CH=CH$_2$ (2.0 M, 0.5 ml, 1.035 mmol). The product was obtained as a yellow oil. Yield (178 mg, 97%); ^{1}H NMR (300 MHz, C_6D_6) δ ppm: 0.78–0.89 (m, 13H) Os–C*H*$_2$ and P–{O(CH$_2$)$_3$C*H*$_3$}$_3$, 1.24 (d, 6H J = 6.93 Hz) CH*Me*$_2$, 1.40–1.70 (m, 16H) C*H*$_2$ and P–{OCH$_2$(C*H*$_2$)$_2$CH$_3$}$_3$, 1.87–2.03 (m, 4H) C*H*$_2$, 2.28 (s 3H) C*Me*, 2.92 (m, 1H) C*H*Me$_2$, 3.77 (dd, 6H J = 6.90, 13.90 Hz) P–{OC*H*$_2$(CH$_2$)$_2$CH$_3$}$_3$, 4.72–5.05 (m, 4H) =C*H*$_2$, 5.56 (d, 2H J = 5.76 Hz) C$_6$*H*$_4$, 5.62 (d, 2H J = 5.72 Hz) C$_6$*H*$_4$, 5.68–5.84 (m, 2H) C*H*=; ^{31}P NMR (121 MHz, $CDCl_3$) δ ppm: 79.41 (s), $^1J(^{187}Os–^{31}P)$ = 476 Hz.

*2.3.13. [(η^6-p-MeC$_6$H$_4$Pr^i)(CO)Os{(CH$_2$)$_3$CH=CH$_2$}$_2$] (**13**)*

Complex **13** was prepared using [(η^6-*p*-MeC$_6$H$_4$Pr^i)Os(CO)Br$_2$] (**9**) (150 mg, 0.291 mmol) in freshly dried THF (25 ml) and BrMg(CH$_2$)$_3$CH=CH$_2$ (0.32 M, 3.64 ml, 1.167 mmol). This compound was obtained as a dark brown oil after an aqueous work-up. Yield (96 mg, 68%); IR (CH_2Cl_2, cm^{-1}): ν(C≡O) 1965; ^{1}H NMR (300 MHz, C_6D_6) δ ppm: 0.77–0.91 (m, 4H) Os–C*H*$_2$, 1.18 (d, 6H J = 6.99 Hz) CH*Me*$_2$, 1.20–1.88 (m, 8H) C*H*$_2$, 1.96 (s, 3H) C*Me*, 2.68 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 4.83–5.08 (m, 4H) =C*H*$_2$, 5.10 (d, 2H J = 5.67 Hz) C$_6$*H*$_4$, 5.35 (d, 2H J = 5.77 Hz) C$_6$*H*$_4$, 5.45–5.90 (m, 2H) C*H*=.

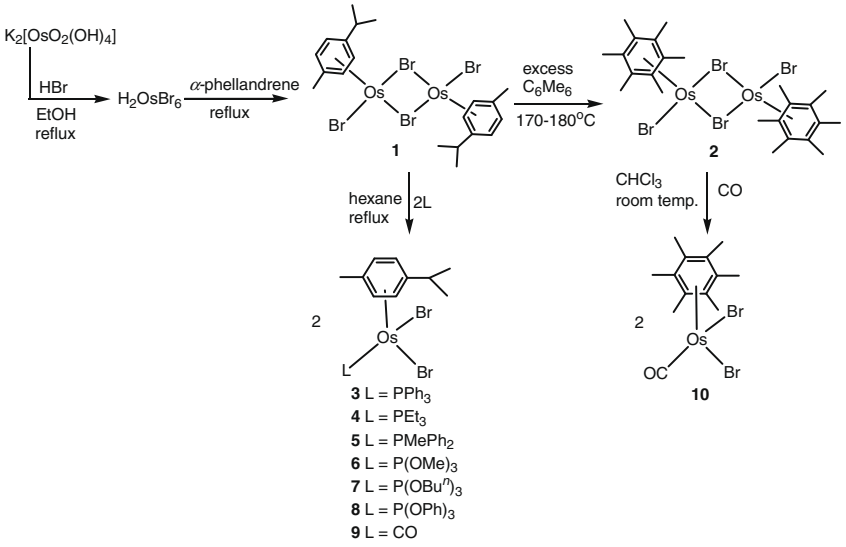
*2.3.14. [(η^6-C$_6$Me$_6$)(CO)Os{(CH$_2$)$_3$CH=CH$_2$}$_2$] (**14**)*

Complex **14** was prepared using [Os[(η^6-C$_6$Me$_6$)(CO)Br$_2$] (60 mg, 0.111 mmol) in dry benzene and BrMg(CH$_2$)$_3$CH=CH$_2$ (1.66 M, 0.26 ml, 0.444 mmol). The product was obtained as a brown oil. Yield (28 mg, 49%); IR ($CHCl_3$, cm^{-1}): ν(C≡O) 1897; LRMS (FAB) $C_{23}H_{26}OOs$: m/z = 519.3 [M]$^+$, 451.2 [M−(CH$_2$)$_3$CH=CH$_2$]$^+$, 383.1 [M−2((CH$_2$)$_3$CH=CH$_2$)]$^+$; ^{1}H NMR (300 MHz, C_6D_6) δ ppm: 0.82–0.89 (m, 4H) Os–C*H*$_2$, 1.02–1.80 (m, 8H) C*H*$_2$, 2.03 (s, 18H) {C$_6$*Me*$_6$}, 4.93–5.20 (m, 4H) =C*H*$_2$, 5.55 (d, 2H J = 5.18 Hz) C*H*=.

*2.3.15. [(η^6-p-MeC$_6$H$_4$Pr^i)(CO)Os(CH$_3$)$_2$] (**15**)*

A solution of [(η^6-*p*-MeC$_6$H$_4$Pr^i)Os(CO)Br$_2$] (**9**) (200 mg, 0.390 mmol) in dry THF (30 ml) was cooled to −78 °C. MeLi (0.66 M, 2.5 ml, 1.560 mmol) was then added drop wise to this solution. The solution was allowed to reach room temperature and stirred for 10 h, during which time it turned from orange to yellow. After 10 h the solvent was removed using a rotary evaporator to give a brown oil residue. The product was extracted with *n*-hexane (3 × 15 ml) and the solvent was removed to give a brown oil of [(η^6-*p*-MeC$_6$H$_4$Pr^i)(CO)Os(CH$_3$)$_2$] (**15**). Yield (106 mg, 71%); IR (CH_2Cl_2, cm^{-1}): ν(C≡O) 1923; ^{1}H NMR (400 MHz, C_6D_6) δ ppm: 0.95 (s, 6H) Os–C*H*$_3$, 0.99 (d, 6H J = 6.90 Hz) CH*Me*$_2$, 1.71 (s, 3H) C*Me*, 2.88 (q, 1H J = 7.04, 7.23, 7.23 Hz) C*H*Me$_2$, 5.47(d, 2H J = 5.80 Hz) C$_6$*H*$_4$, 5.81 (d, 2H J = 5.80 Hz) C$_6$*H*$_4$.

2.4. X-ray crystal structures



The data for **1** were collected at 293 K on a Siemens P4 diffractometer fitted with a Bruker 1 K CCD detector and SMART control software using graphite-monochromated, Mo Kα radiation by means of a combination of phi and omega scans. Data reduction was performed using SAINT+ and the intensities were corrected for absorption using SADABS [8]. The structure was solved by direct methods using SHELXTS [8] and refined by full-matrix least-squares using SHELXTL [8] and SHELXL-97 [9].

The data for **3** were collected at 293 K on a Nonius Kappa-CCD diffractometer using graphite-monochromated Mo Kα radiation. The strategy for the data collection was evaluated using the Bruker Nonius "COLLECT" program. Data were reduced and scaled using DENZO-SMN software [10]. Face indexed absorption corrections were made using the program XPREP. The structure was solved by direct methods and refined employing full-matrix least-squares with the program SHELXL-97 [9] refining on F^2, using the graphic interface X-seed [11]. All non-H atoms were first refined isotropically followed by anisotropic refinements. Hydrogen atoms were first located in the difference electron density maps then positioned geometrically and allowed to ride on their respective parent atoms.

3. Results and discussion

3.1. Syntheses and characterization of arene-osmium dimeric complexes

The dimer [(η^6-*p*-MeC$_6$H$_4$Pr^i)OsBr$_2$]$_2$ (**1**) was prepared by heating a solution of potassium osmate, $K_2[OsO_2(OH)_4]$, in concentrated HBr and aqueous ethanol at reflux for 18 h followed by addition of α-phellandrene and further heating for an additional 18 h (Scheme 2). The complex was isolated in a moderate yield of 66% as a red-brown stable solid which was also found to be stable in

Scheme 2. The syntheses of arene-osmium dimers **1** and **2** and osmium dibromide complexes **3**–**10**.

solution, including in chlorinated solvents. Syntheses of the chloride and iodide analogues of this complex have been reported before using OsO_4 and $OsCl_3 \cdot 3H_2O$ as starting materials, respectively [12]. The iodo complex $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsI_2]_2$ was prepared by halide metathesis of the analogous chloro complex with NaI [12d]. Synthesis of $[(\eta^6\text{-}C_6Me_6)OsBr_2]_2$ (**2**) was achieved by following a reported protocol for the chloride analogue [13]. Using this method, complex **2** and excess hexamethylbenzene were heated at 170–180 °C in a sealed and evacuated tube for 24 h (Scheme 2). After extraction with dichloromethane, the complex **2** was obtained as a stable brown solid which decomposes without melting at 280 °C.

The ^{1}H NMR spectrum of complex **1** displayed characteristic *p*-cymene ligand chemical shifts, while a singlet at 2.25 ppm corresponding to the methyl groups of the hexamethylbenzene ligands in complex **2** was observed in its ^{1}H NMR spectrum (Table 2). The signal for these methyl groups appeared at a slightly higher frequency when compared to the chloride analogue (1.92 ppm) [13]. This is evidence of less electronic interaction between the bromide ion and the metal centre as opposed to when the more electronegative chloride ion is present. Satisfactory elemental analyses were obtained for both complexes **1** and **2** (Table 2).

3.2. Syntheses and characterization of arene-osmium dibromide complexes

A series of arene-osmium dibromide complexes **3**–**8** of the type $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsLBr_2]$ (L = tertiary phosphine and phosphite ligands) were prepared by heating suspensions of the dimeric compound **1** in refluxing *n*-hexane with two equivalents of the appropriate ligand over 4 h (Scheme 2). These complexes were obtained as stable red-orange to orange solids in yields ranging from

Table 2

[a] Spectra recorded in $CDCl_3$, internal standard was tetramethylsilane (TMS).
[b] Calculated values in parentheses.

73% to 92%. Furthermore, complexes **3**–**8** were found to be stable in solution including in chlorinated solvents, with compound **3** showing remarkable stability in chloroform on the bench top for 2 weeks and thereafter decomposing to a brown unidentified species.

Only one example was found in the literature of a similar dibromide complex, i.e. $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PMe_3)Br_2]$. This complex was prepared by a method involving metathesis of the chlorides in $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PMe_3)Cl_2]$ with NaBr [14]. All other reports found described dichloride and di-iodide complexes [5,12,14]. Thus, to the best of our knowledge complexes **3**–**8** and its precursor **1** are all new. Complexes **9** and **10** were formed by bubbling CO gas through a suspension of compound **1** in *n*-hexane or a solution of compound **2** in chloroform at room temperature over 45 min (Scheme 2). Red-orange, solids of complexes **9** and **10** were afforded in good yields of 91% and 62%, respectively.

The carbonyl complexes $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(CO)Br_2]$ (**9**) and $[(\eta^6\text{-}C_6Me_6)Os(CO)Br_2]$ (**10**) were remarkably thermally stable, only decomposing to black unidentified species at and above 200 °C, respectively. The complexes with tertiary phosphine ligands **3**–**5** all had high melting points of between 196 and 225 °C while, phosphite containing complexes **6**–**8** showed melting points of between 85 and 177 °C.

The ^{1}H NMR spectra of complexes **3**–**9** all exhibited signals characteristic of *p*-cymene ligands. These signals are similar to those reported for the analogous dichloride and di-iodide compounds [14], with slight shifts as a result of the different halides present. In general, the aromatic proton signals for the bromide complexes appeared downfield relative to the chloride analogues and upfield relative to the iodo complexes. $[(\eta^6\text{-}C_6Me_6)Os(CO)Br_2]$ (**10**) displayed a singlet corresponding to the methyl groups of hexamethylbenzene at 1.98 ppm, slightly more downfield than that reported for the chloride derivative $[(\eta^6\text{-}C_6Me_6)Os(CO)Cl_2]$ (1.96 ppm) [13].

The phosphine containing complexes **3**–**5** showed low field ^{31}P NMR peaks together with satellites due to coupling with ^{187}Os (Table 3). Larger coupling constants were seen in the phosphite bearing complexes **6**–**8**, whose ^{31}P NMR signals appeared as singlets in the more deshielded region, when compared to their phosphine counterparts (Table 3). This clearly shows that the type of phosphorus donor ligand, affects the ^{31}P NMR chemical shifts in $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsLBr_2]$ type complexes. Similar coupling of ^{187}Os and ^{31}P has been reported for related (η^6-arene)osmium(II) complexes [14].

Comparison of the ^{31}P NMR signals and $^1J(^{187}Os\text{–}^{31}P)$ coupling constants of complexes **3**–**8** with those of chloride and iodide analogues reveals that the complexes exhibit halide dependence, with deshielding of the ^{31}P NMR signal in the order of Cl > Br > I, thus replacement of the bromide ligands of complexes **3**–**8** with chlorides results in an upfield shift of the ^{31}P NMR signal. The opposite effect can be seen when the bromide ligands are replaced by iodide ligands (Table 3) [14]. A slight increase in $^1J(^{187}Os\text{–}^{31}P)$ coupling constants can also be seen from I^- to Br^- and Cl^- containing complexes.

Complexes **9** and **10** showed expected terminal ν(CO) bands at 2022 and 2005 cm^{-1}, respectively.

3.3. Crystal structures of $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ and $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PPh_3)Br_2$

Red crystals of **1** and **3** were obtained by slow evaporation of dichloromethane solutions at room temperature. The crystallographic details and selected bond distances and angles for both structures are given in Tables 1 and 4, respectively. The molecular structures and atomic numbering schemes for **1** and **3** are presented in Figs. 1 and 2, respectively.

The molecular structures are similar to those reported for the analogous chloride complexes $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsCl_2]_2$ [15] and $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PPh_3)Cl_2$ [14]. The C_6 ring in both **1** and **3** is planar in contrast to the puckering of the aromatic ring observed in $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PPh_3)Cl_2$. For **1** the asymmetric unit consists of one complete dimeric complex plus half of a second one as this molecule lies across a centre of inversion. Each asymmetric unit was found to contain half a water molecule and hence there is one water molecule per three molecules of the complex. As in the chloride complex, each Os of the dimer is bonded to two bridging Br ligands and one terminal Br ligand, with a slightly long bond measured for the bridging Br ligand. No direct interaction was observed between the osmium centres.

Complex **3** exhibits a three-legged piano-stool geometry at osmium and many of the corresponding distances and angles are

similar to those found for the analogous chloride complex. As expected, slightly longer Os–X bond lengths were measured in the $(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PPh_3)Br_2$ complex (2.55 Å) when compared to the analogous Cl complex (2.42 Å) since the difference in covalent radii of Cl and Br is 0.15 Å. However, exchange of the chloride ligands for bromide ligands left the Os–P bond length unchanged at 2.35 Å.

3.4. Reactivity of arene-osmium dibromide complexes

In an attempt to prepare osmium bis(alkenyl) complexes, the dibromide complexes **3**, **7**, **9** and **10** were reacted with excess 5-pentenyl Grignard reagents in THF and yellow to brown oily products were isolated from these reactions. These oils proved to be very unstable, therefore difficult to characterize completely. However, ^{1}H and ^{31}P NMR data as well as IR data obtained for the products, were consistent with the formation of bis(1-pentenyl)osmium(II) complexes **11**–**14** (Scheme 3). In addition, the bis(1-pentenyl) complexes **11**–**14** all decomposed at room temperature to give black species and when the residues were extracted and analysed by GC, the results showed that the complexes decompose to yield 1,4-pentadiene and 1-pentene exclusively as the organic products. These are similar decomposition products to those reported in the thermal decomposition studies of platinum bis(1-alkenyl) complexes containing mono- and diphosphine ligands [16].

In addition to shifts corresponding to the protons of the respective tertiary phosphine or phosphite ligands, the ^{1}H NMR spectra of complexes **11**–**13** all displayed expected signals for the *p*-cymene ligand. Complex **14** showed a signal for the methyl groups of the hexamethylbenzene at 2.03 ppm.

The alkenyl chains of all the complexes showed similar ^{1}H NMR patterns. The Os–C*H*$_2$ protons appeared furthest downfield as broad multiplets integrating for four protons at *ca.* 0.78–0.91 ppm. Osmium has a shielding effect on the methylene protons adjacent to it. This shielding effect has also been observed in similar Pt and Pd bis(1-alkeny) [17]. Signals for the remaining methylenes of the pentenyl chains gave rise to broad multiplets in the region of *ca.* 1.02–2.03 ppm, while the pendant alkenyl functionality gave rise to distinct multiplets in the region of *ca.* 4.52 and 5.20 for the =C*H*$_2$ protons and *ca.* 5.45 and 5.90 for the C*H*= protons.

The PPh_3 derivative **11** exhibited deshielding of its ^{31}P NMR signal from −17.57 ppm in complex **3** to 12.61 ppm. The $P(OBu^n)_3$ containing complex **12** also exhibited deshielding of its ^{31}P NMR signal from 62.43 ppm in complex **7** to 79.41 ppm, together with an increase in $^1J(^{187}Os–^{31}P)$ coupling constant from 449 to 476 Hz.

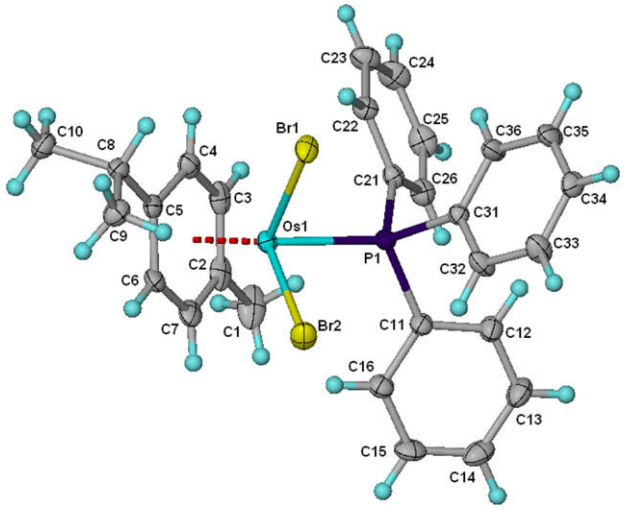

Fig. 2. Molecular structure of $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)Os(PPh_3)Br_2]$ (**3**) with ellipsoids shown at the 30% probability density level.

IR spectra of complexes **13** and **14** displayed strong ν(C≡O) bands at 1965 and 1897 cm^{-1}, respectively. These bands occurred at lower frequencies when compared to their starting materials **9** and **10**, and these shifts may be attributed to the change in basicity of the ligands on the osmium.

A satisfactory mass spectrum was obtained for complex **10**. The spectrum showed a peak corresponding to the parent ion (m/z = 519.3[M]$^+$) with a fragmentation pattern that corresponds to the sequential loss of the pentenyl moieties (m/z = 451.2[M−C_5H_9]$^+$) and (m/z = 383.1[M−$(C_5H_9)_2$]$^+$).

Reaction of $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)(CO)OsBr_2]$ (**9**) with excess MeLi resulted in the formation of the di-methyl complex **15** (Eq. (1)) as evidenced by ^{1}H NMR and IR spectral data. We expected this complex **15** to be more stable than the bis(1-pentenyl) analogue **13** since it has no β-hydrogens, however the compound was isolated as a brown oil and was also found to be very unstable and difficult to handle. Unlike complex **15**, the di-alkyl complex *cis*-$[Os(CO)_4Me_2]$ exists as a stable white crystalline solid [18]. The related complex $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)(PPh_3)OsMe_2]$ was isolated as a brownish yellow oil by Maitlis and co-workers [12c].

4. Conclusions

The dimers $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)OsBr_2]_2$ and $[(\eta^6\text{-}C_6Me_6)OsBr_2]_2$ can be prepared from potassium osmate following the procedures reported herein. From these dimers a series of new arene-osmium dibromide complexes containing CO, tertiary phosphines and phosphites were obtained. The osmium dibromide complexes reacted with 5-pentenyl Grignard and MeLi to give the putative bis(1-pentenyl)osmium(II) complexes and $[(\eta^6\text{-}p\text{-}MeC_6H_4Pr^i)(CO)OsMe_2]$, respectively, which were isolated as unstable yellow to brown oils. The bis(1-pentenyl)osmium(II) complexes decomposed to yield 1,4-pentadiene and 1-pentene exclusively as the organic products. This is consistent with the formation of these compounds prior to their decomposition.

Supplementary data

CCDC 706183 and 707752 contain the supplementary crystallographic data for **1** and **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

We would like to thank the Anglo Platinum Corporation, University of Cape Town and University of South Africa. We also thank the National Research Foundation (NRF) of South Africa and NRF-DST Centre of Excellence in Catalysis (C^* Change) for financial support and David Liles at the University of Pretoria for solving the crystal structure of complex **1**.

Yield: 14.2 mg (0.018 mmol, 55.8% assuming the 0.10 mmol of Cu(II) in the starting solution).

The ^{63}Cu and ^{65}Cu labeled isotopologues were prepared exactly as the compound with natural copper. Yields: 11.0 mg (0.014 mmol, 42.2%) for ^{63}Cu and 11.8 mg (0.015 mmol, 45.4%) for ^{65}Cu. The copper isotopes were purchased from Trace Sciences International Corp., Canada.

2.2. Spectroscopy

The IR spectra were measured on Perkin–Elmer 2000 FT spectrometer with sample in KBr pellet or Nujol mull for middle and far-IR regions, respectively. The spectra were obtained as the average of 64 scans, collected with 2 cm^{-1} resolution.

The Raman spectrum was recorded on Bruker RFS-100 instrument equipped with Nd:YAG laser (1064 nm) operating at 300 mW. Final spectrum was computed from 32 scans measured with 2 cm^{-1} resolution at the back-scattering geometry.

2.3. DFT calculations

In order to support the interpretation of the recorded vibrational spectra, the quantum calculations based on the Density Functional Theory (DFT) approach have been performed using the GAUSSIAN 03 package [9]. The B3LYP functional [10] operating on the LanL2DZ basis set [11], expanded with d-polarization functions on C and N atoms, was applied. The structure optimization and subsequent computation of normal vibrations were carried out on the $[Cu(biz)_2]^{2+}$ cation and $[Cu_2Br_4]^{2-}$ anion, separately. For both ions, the optimization of molecular geometry started from the X-ray structural parameters, reported here. The optimized structure of the $[Cu(biz)_2]^{2+}$ ion very well corresponds to that measured. The RMS for skeletal bond distances is 0.02 Å and for skeletal angles 0.71°. The geometry optimization of the $[Cu_2Br_4]^{2-}$ ion resulted in the RMS deviations of 0.38 Å and 10.6° for bond lengths and angles, respectively. The higher RMS for angles is due to the elongation of the Cu–Cu distance (observed 2.6806(9) Å, calculated 3.3779 Å). The quasi-flat and centrosymmetric structures of both ions were preserved.

Based on the optimized structures, the wavenumbers, IR intensities, Raman activities and atom displacements for all normal vibrations were computed with harmonic approximation. The computed frequencies were not scaled. The visual animations of normal vibrations were generated using the MOLEKEL program [12], whereas the theoretical IR and Raman spectra were simulated employing the MOLDEN application [13].

2.4. Crystallography

Data collection was carried out on KUMA KM4CCD diffractometer with graphite-monochromatized Mo Kα radiation for a crystal cut out from a larger needle. Data reduction and analytical absorption correction were carried out using CRYSALIS software [14].

The structure was solved by direct methods in SHELXS97 [15] and refined in SHELXL97 [15]. All H atoms were found on the difference Fourier map. Subsequently, H atoms bonded to C atoms were constrained using AFIX 23 constraints. For H atoms bonded to N atoms DFIX restraints were used setting the N–H bond distances at 0.860(2) Å. Subsequently, H atoms bonded to N atoms were constrained using AFIX 3 constraints. All H atoms were refined with $U_{eq} = 1.2U_{eq}$ (parent atom). On the final difference Fourier map the highest peak of 1.77 e/Å^3 was located at 0.73 Å from the Br2 atom.

Pertinent data for the structure determination are listed in Table 1. All figures and packing diagrams were made using ORTEP program [16].

3. Results and discussion

3.1. Description of the structure

The investigated mixed-valence copper compound is build of discrete complex cations with Cu(II) as central atoms and well known $[Cu_2Br_4]^{2-}$ anions. Both ions, presented in Fig. 1, are centrosymmetric and roughly planar, their selected structural parameters are listed in Table 2.

In the $[Cu(biz)_2]^{2+}$ cation, the Cu1 atom lies on an inversion center and its coordination environment is perfectly planar and nearly square. The copper–nitrogen bond lengths are almost the same, equal 1.984(3), 1.987(3) Å and are very similar to those reported for $[Cu(biz)_2](ClO4)_2$ [8], being 1.982(4) and 1.965(4) Å. The deviation from the square shows the N1–Cu1–N4 angle, equal 82.2(1)° as it may be expected for the five-membered chelate ring. The inspection of contacts in the axial direction shows that the nearest are the Br1 atoms of two opposite $[Cu_2Br_4]^{2-}$ anions. The Cu1···Br1^{v} (v: $x, -y + 1/2, +z - 1/2$) distance, equal 3.323(1) Å, is much longer than typical Cu–Br bond length and it is beyond the semi-coordinate category (about 3.1 Å [17,18]). Thus, the metal coordination environment is a regular rectangle.

Fortunately, the X-ray data are available for similar cation formed by Cu(II) and 2,2′-biimidazole (bim) [19]. Comparison of the copper–nitrogen bond lengths shows that the partial saturation of the imidazole rings, giving the biimidazoline, does not change significantly the chelation abilities of these systems. The present Cu–N distances are only slightly shorter than in the $[Cu(bim)_2]^{2+}$ being 2.03(1) Å. Similar differences (<0.05 Å) were found in the remaining bond lengths of whole chelate ring.

Despite the high symmetry of the free ligand [20], in the present complex, the imidazoline rings show some differences in bond lengths, angles and deviation from planarity. As results from the data in Table 2, the differences between the lengths of corresponding bonds are small and not exceed 1%. Similar conclusion can be formulated about the skeletal angles. The largest differences are in the planarity of the imidazoline rings. The ring with N1 atom is close to planar (the maximum deviation from the best plane is

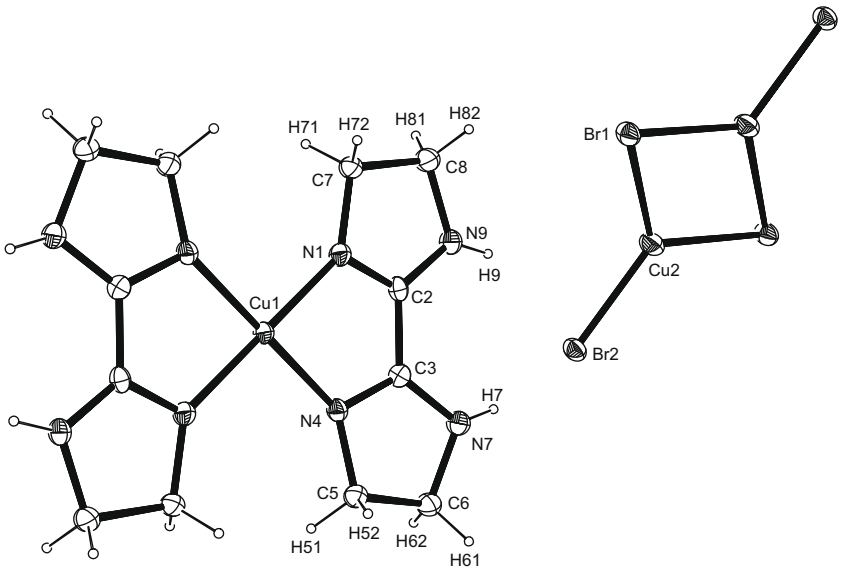

Fig. 1. Structure of $[Cu(biz)_2][Cu_2Br_4]$ showing the atomic numbering. The unlabeled atoms are generated by the symmetry operations. Thermal ellipsoids enclose the 50% probability.

i: $-x, -y, -z$; ii: $-x+1, -y+1, -z+1$.

0.012(4) Å for C8 atom) and it is nearly parallel to the N1–Cu1–N4 plane (corresponding dihedral angle is 3.0(1). The second imidazoline ring is more distorted with the N4, C5, C6 and N7 atoms being +0.045(3), −0.127(4), +0.140(4) and −0.070(3) Å displaced from the best plane, respectively. The dihedral angle between this best plane and metal vicinity is 10.5(1)°. The chelate ring is also not planar, due to the N1, N4 and C3 atoms which are slightly displaced from the best plane by +0.060(3), 0.026(3) and −0.062(3) Å, respectively. This best plane forms the dihedral angles of 8.7(1) and 1.2(1)° with the best planes of both imidazoline rings which in turn form a dihedral angle of 7.5(1)°. All those relatively small dihedral angles support the final conclusion that the geometry of the $[Cu(biz)_2]^{2+}$ cation is close to planar.

It is interesting to trace how the metal chelation influences the imidazoline ring geometry. Comparison with the respective data of pure ligand [20] (Table 2) surprisingly shows that not all bonds between carbon and coordinated nitrogen atoms are markedly affected. The N1–C7 and N4–C5 bond lengths are almost the same as in the uncoordinated ligand. The neighbor N1–C2 and N4–C3 bonds are elongated by 0.015 and 0.025 Å, respectively. The bonds by the N9 and N7 atoms are also affected, but in different extent; these positioned closer to the center of the ligand are shortened whereas two others are elongated. However, in the explanation of this phenomenon, the involvement of the N–H groups into the hydrogen bonding must also be taken into account.

In the di-μ-bromo-dibromocuprate(I) anion, two copper(I) and two bridging bromide ligands form a perfect plane, whereas two terminal bromide ligands are positioned slightly above and below this plane, making the very-flat-chair structure of whole anion. The displacement of Br2 atoms from the central plane is well represented by the Br2–Cu2–Cu2^{ii} (ii: $-x+1, -y+1, -z+1$) angle being

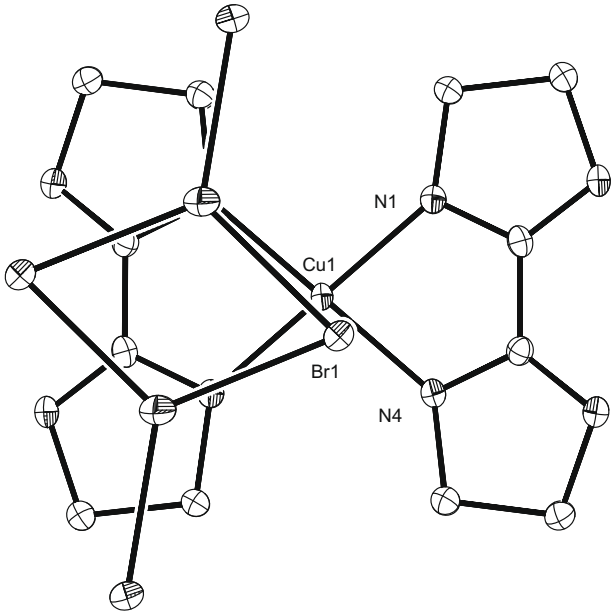

Fig. 2. Mutual orientation of $[Cu(biz)_2]^{2+}$ and $[Cu_2Br_4]^{2-}$ skeletons, viewed normal to the $[Cu1–N_4]$ plane. Only one $[Cu_2Br_4]^{2-}$ ion has been shown for clarity, the second anion is positioned as required by the inversion center, located at the Cu1 atom.

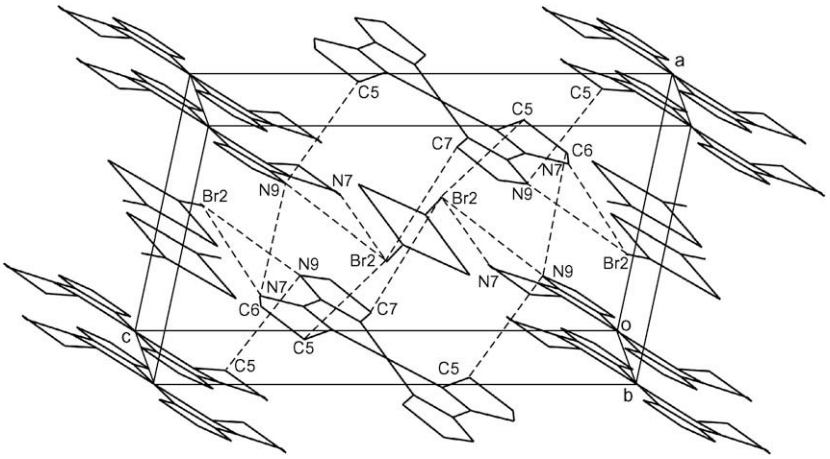

Fig. 3. Crystal packing described as the layers of cations and anions expanding parallel to the (1 0 0) plane, or two sets of ribbons expanding along (1 1 1) and (1 $\bar{1}$ 1) directions. Broken lines connect the donor and acceptor atoms of the formed the hydrogen bonds. Hydrogen atoms were omitted for clarity.

173.49(3)°. Other structural parameters, like bond lengths and angles are within the corresponding values observed for similar $[Cu_2Br_4]^{2-}$ anions, accompanied by different organic cations [21–23].

In the crystal lattice, the mutual orientation of complex cation and anion is close to parallel; the dihedral angle between [Cu1–N_4] plane and that formed by Cu(I) and Br1 atoms is 8.9(1)°. Both ions are such oriented, that the Br1 atom is almost above the Cu1 atom, as has been shown in Fig. 2, presenting the view normal to the [Cu1–N_4] plane.

The crystal packing may be presented as layers of cations and anions expanding parallel to the (1 0 0) plane, as has been demonstrated in Fig. 3. However, if strong hydrogen bonds between cations and anions will be taken into account, then two sets of ribbons expanding along (1 1 1) and (1 $\bar{1}$ 1) directions can be distinguished (Fig. 3).

For the strong hydrogen bonding, each ligand molecule offers only two centers, namely the N7–H7 and N9–H9 groups. Both these donors interact with the same Br2 atom of the $[Cu_2Br_4]^{2-}$ anion, but these H-bonds are not the same, as results from Table 3. The interaction between mentioned ribbons is mainly electrostatic, but it is enhanced by two C–H···Br and two C–H···N type hydrogen bonds, shown in Fig. 3. The hydrogen bonds are also partially responsible for mentioned differences in the geometry of two imidazoline rings present in the organic ligand. Each ring is involved in three hydrogen bonds, but all these bonds have different lengths and directions. The structural details of all hydrogen bonds have been given in Table 3.

3.2. Vibrational spectroscopy

The ionic structure of presented compound suggests that part of its IR and Raman spectra may be covered by bands resulting from the $[Cu(biz)_2]^{2+}$ cation and $[Cu_2Br_4]^{2-}$ anion. In order to recognize the wavenumber range of such overlap, the vibrations of both ions have been calculated and respective spectra computed. The resulted theoretical spectra are presented in Fig. 4, which demonstrates that the vibrations of heavy-atom $[Cu_2Br_4]^{2-}$ anion have very low frequencies, not exceeding the 220 cm^{-1} limit. Unfortunately, the IR spectrum is not well structured in this region, whereas the Raman spectrum is obscured by the strong Rayleigh scattering. Therefore, the vibrations of the $[Cu_2Br_4]^{2-}$ ion will not be further discussed, due to the lack of enough experimental data. The location of the $[Cu_2Br_4]^{2-}$ vibrations below 220 cm^{-1} simultaneously shows that the rests of the observed spectra are covered by the $[Cu(biz)_2]^{2+}$ bands, exclusively.

The $[Cu(biz)_2]^{2+}$ cation is built of 41 atoms which perform 117 normal vibrations, classified into $57A_g$ and $60A_u$ modes under the C_s symmetry. According to the mutual exclusion rule, the A_g vibrations are active in the Raman spectrum, whereas the A_u are observed as the IR absorptions. In contrast to the above numbers

Table 3
Hydrogen bond parameters (Å, °) with e.s.d.'s in parentheses.

Bond	D–H	D···A	H···A	D–H···A

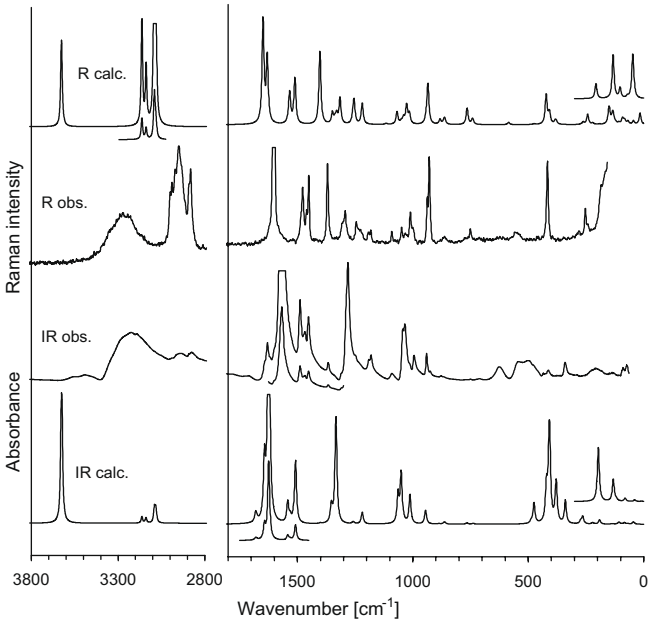

Fig. 4. Observed and calculated spectra of $[Cu(biz)_2][Cu_2Br_4]$. The computed spectra of $[Cu_2Br_4]^{2-}$ are presented as low frequency insets placed above the respective spectra of $[Cu(biz)_2]^{2+}$.

of expected bands, the collected spectra show about two times less bands. The explanation of that phenomenon is provided by performed calculations. First reason is the similarity of vibrational frequencies observed for normal vibrations of similar molecular fragments. In the $[Cu(biz)_2]^{2+}$ cation, there are four such fragments, namely the imidazoline rings. The rings are separated by the Cu–N or C–C bonds which cause that the vibrational coupling between some atomic motions, similar in all rings, is rather weak. As a consequence, the normal modes composed of similar internal vibrations have very close frequencies and contribute in the same IR or Raman band. Second reason is important when the wavenumbers computed for the symmetry related modes are more separated; then the large differences between their relative intensities may decide that only one, the strongest mode is observed. Finally, the analysis of the computed IR intensities and Raman activities shows that some transitions are so much weak that cannot be distinguished from the background noises.

The above conclusions are supported by the theoretical spectra, presented in Fig. 4, together with the observed ones. Visual comparison of the computed and observed Raman spectra shows a big similarity between their band positions and relative intensities. In the case of the IR spectra, such similarity is somewhat disturbed by hydrogen bonding effects, being intense in the IR absorption. The most visible difference is in the region above 3000 cm^{-1}, where the predicted stretching vibrations of the N–H groups are monitored by one sharp and strong band at about 3620 cm^{-1}, but its observed IR counterpart is a broad absorption with maximum at 3220 cm^{-1}, being typical for the H-bonded systems, as those of N–H···Br, found in the present compound. Except some computed frequency overestimations, typical for theoretical methods, the calculations performed here provided a very good overall reproduction of the observed spectra, which allows for the unambiguous transfer of the computed mode assignments to the observed bands.

The computer animation of calculated vibrations shows that the D_{2h} symmetry can be used for the approximate description of the atom displacements in all normal modes. Despite that the symmetry of $[Cu(biz)_2]^{2+}$ cation is lower (C_i), the classification of normal vibrations into irreducible representations of the D_{2h} group could be done basing only on the phases of atom displacements during given normal vibrations; the related amplitudes mostly do not follow the D_{2h} symmetry requirements. Such classification simplifies

Table 4
Observed IR and Raman band positions (cm^{-1}) and their attribution to computed normal vibrations classified in terms of approximate D_{2h} symmetry.

Abbreviations: ν, stretching; δ, bending; τ, torsion; γ, twisting; ω, wagging; ρ, rocking; π, out-of-plane bending; *s,a*, symmetric; asymmetric with respect to local plane symmetry of CH_2 group or imidazoline ring, respectively.

[a] Wavenumbers of normal modes most contributing into intensities of respective theoretical bands are boldfaced.

[b] IR band positions below 300 cm^{-1} are given in parentheses because they may also origin from $[Cu_2Br_4]^{2-}$ vibrations.

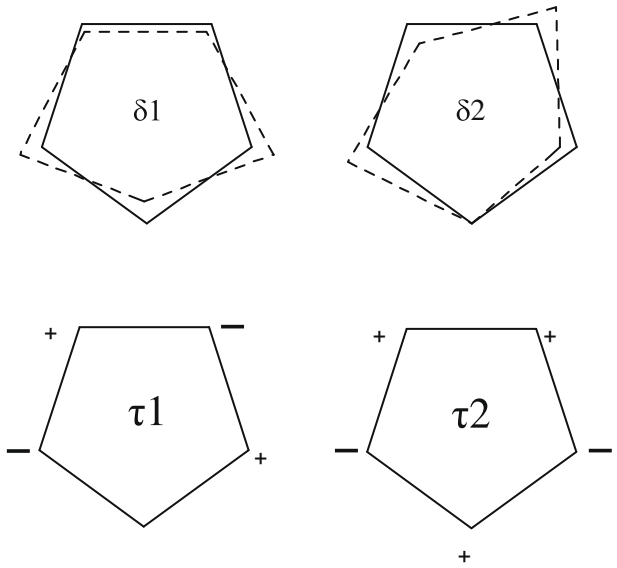

Fig. 5. In-plane and out-of-plane deformations of the five-membered chelate and imidazoline rings. The plus and minus signs represent the atom displacements out of the ring plane.

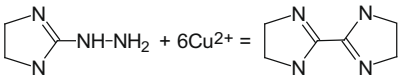
the description of normal vibrations and has been used in Table 4, listing the observed band positions and their attribution to the calculated normal vibrations.



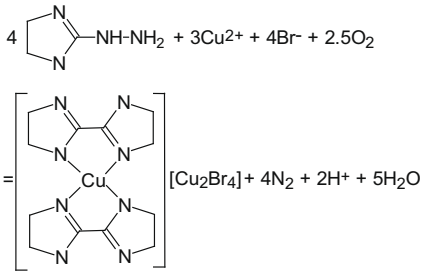
As results from Table 4, most of the symmetry related normal modes have very similar frequencies and have been attributed to the same observed band. The most outstanding exception is noted for the Cu–N stretching vibrations with wavenumbers calculated between 340 and 130 cm^{-1}. Such phenomenon is understandable because the Cu–N bonds are joined with common metal atom and mechanical coupling of their motions is very strong. Despite these frequency differences, only one observed ν(Cu–N) band is listed. This band was detected applying the metal isotope technique. The comparison of the far-IR spectra measured for complexes with ^{63}Cu and ^{65}Cu pure isotopes monitored only one, 3 cm^{-1} down-shift of 342 cm^{-1} band. The vibrational effects due to ^{63}Cu–^{65}Cu substitution have also been reproduced in performed DFT calculations, giving the 3.3 and 2.8 cm^{-1} frequency shifts of two asymmetric ν(Cu–N) normal vibrations calculated at 339 and 273 cm^{-1}. First vibration very well corresponds to the observed 342 cm^{-1} band; the second transition is predicted to be relatively weak, which explains why more isotope shifted bands were not detected. The remaining ν(Cu–N) normal vibrations at 151 and 132 cm^{-1} are symmetric with respect to the inversion center, which cause that the metal atom is not oscillating, than these vibrations are not sensitive to the different masses of applied copper isotopes.

Some modes listed in Table 4 were described as combinations of two internal coordinates, which represents their strong vibrational coupling. This coupling, especially between the deformation modes of the imidazoline and chelate rings is a consequence of molecular structure where mentioned rings have common carbon and nitrogen atoms. The same reason is for the coupling between stretching vibrations of the inter-ring C–C bond and neighbor C–N bonds. The abbreviations used for chelate and imidazoline ring deformation modes have been explained in Fig. 5.

3.3. Chemical reactions

The X-ray detection of the 2,2′-biimidazoline (biz) as the chelating agent, undoubtedly shows that the starting ligand, 2-hydrazino-2-imidazoline (hi) has undergone the chemical conversion to biz. Such transformation is very similar to that of phenylhydrazine which under oxidation with silver or mercuric oxides gives the diphenyl as one of the isolated products [24].

In the present case, the oxidizing agent is copper(II), because without these ions, the hi ligand is stable in the methanol/ethanol solution. Finally, we propose the following reaction of the hi oxidation leading to biz:



(1)

Since the mother solution was prepared by dissolving the $Cu(OH)_2$ precipitate in the hi·HBr solution, the Cu: hi ratio was 1:2. With such ratio, all Cu^{2+} ions should be converted into Cu^{+} in the reaction (1). However, the presence of copper(II) in the final complex suggests the partial reoxidation of Cu^{+} ions by the atmospheric oxygen.

$$4Cu^{+} + O_2 + 4H^{+} = 4Cu^{2+} + 2H_2O \quad (2)$$

In order to prove the necessity of the above process, the special experiment was carried out where the mother solution was kept in the fully filled capped vial, without contact with air oxygen. Under such conditions, the complex was not obtained.

Taking into account the reactions (1) and (2), the total complex formation process can be written as:

(3)

The yield of the above reaction is not high – between 20% and 50% with respect to the Cu^{2+} content in the mother solution and depends on the applied substrate concentrations. Such low yield may be due to the Cu^{2+} deficiency in relation to hi, and the self-acidification, which shifts the reaction equilibrium toward the substrates. An experiment with hi: $CuBr_2$ ratio required in reaction (3) was unsuccessful, which suggests that the relative concentrations of used reagents are important in this complicated process.

4. Conclusion

The reaction of copper(II) hydroxide and 2-hydrazino-2-imidazoline hydrobromide produced a coordination compound which, according to the X-ray analysis, appeared to be a complex salt with copper atoms at different oxidation states. The copper(I) is present in the $[CuBr_2]^{2-}$ anion, whereas the counter cation contains copper(II) chelated by two new biimidazoline ligands resulted from the oxidation of starting 2-hydrazino-2-imidazoline substrate. The analysis of the reaction conditions leads to the conclusion that copper(II) ions act partially as oxidizing reagent and partially as the catalyst of the 2-hydrazino-2-imidazoline oxidation by the atmospheric oxygen.

Preface

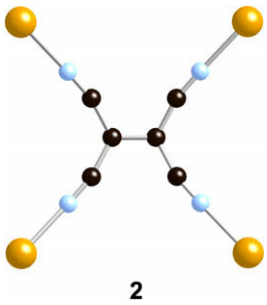
The International Conference of Molecule-based Magnets, ICMM, has a longstanding tradition of collaboration with *Polyhedron*, which is taking care of the publication of the papers presented in the 2008 edition held in Florence on September 21–24, 2008. In fact, it is by no means trivial the choice of the Journal hosting the proceedings of a largely interdisciplinary conference like ICMM. Anyway, good traditions must be conserved and I am glad to express my gratitude to George Christou for giving us the opportunity of exploiting the professional efficiency of this important Journal.

Molecule-based Magnets, or as anybody would say, Molecular Magnetism, is enjoying another period of expansion being more and more eager to export towards other disciplines its original approach to magnetism, and to learn from others how to find new challenging areas to develop. The organization of ICMM 2008 was based on these views of strong interactions with such diverse fields as spintronics and biomedicine. In fact the Plenary Lectures were delivered by George Whitesides, who showed how even diamagnetism can produce exciting effects; by Susumu Kitagawa who fascinated the audience with beautiful porous coordination polymers; and by Albert Fert who showed the relevance of carbon nanotubes in spintronics. The main area of Molecular Magnetism was firmly occupied by Joel Miller, who was the second Olivier Kahn Lecturer, and gave a brilliant resume of his achievements in a field which he largely contributed to develop.

The Olivier Kahn International Award, reserved by the European Network of Excellence MAGMANet, to a young researcher was assigned too Josè Ramon Galan Mascaros who delivered a brilliant lecture explaining his synthetic chemist's view of Molecular Magnetism.

There were on the whole 46 oral presentations, including 15 keynotes and two hot results. The decrease in the number of oral presentations compared to that of ICMM2006 (65) was more than compensated by the number of posters which jumped to 399. In fact the Conference was attended by ca. 500 people coming from 31 different countries.

The ICMM tradition of experimental demonstrations has been continued in a series of events organized by Michel Verdaguer and Françoise Villain in the campus of the University of Florence, first for the general public and then for the schools, from primary to college. The demonstrations were so entertaining that the children did not want to go home!



A Conference with 500 attendants is not easy to organize, but everything is fine if you have excellent collaborators. I must say that I was lucky enough. The International Advisory Board gave excellent suggestions for organizing the scientific content of the Conference and the format. The Local Organizing Committee found a great help in parallel organizations, like OIC, coordinated by Viviana Vitali and Annalisa Batistini, who were the clever interfaces with the participants, and INSTM coordinated by Claudia Bettaccini who gave the administrative help to the organization. I must express my gratitude to Anna Maria Papini who enthusiastically accepted the idea of the organization of conference on the magnetism for the general public and one week of demonstrations for primary and secondary schools at the OPENLab, at the University of Florence.

Finally let me thank the two Andreas who were the true motors of ICMM: Andrea Cornia who made an accurate work in the hectic phase when there was the storm of abstracts coming in all together, and Andrea Caneschi who coordinated in an efficient way all the activities.

four Fe^{II} ions in parallel, but undulating layers. These layers are connected in the former material via $S = 0$ μ_4-$[C_4(CN)_8]^{2-}$ bridging to four Fe^{II} ions, and capped by two $S = 0$ MeCN molecules in the latter material. Hence, both materials are layered magnets, and the presence $S = 1/2$ μ_4-$[TCNE]^{\cdot-}$ bridging to four V^{II} ions in parallel, but undulating layers were instantly thought to be present for $V[TCNE]_x$.

2

The lack of planarity of the $Fe^{II}_4[TCNE]^{\cdot-}$-based (**2**) magnetic layers that leads to the observed undulating layers is attributed to the competition between the octahedral environment about each Fe^{II} ion (i.e. preferred 90° *cis*-CN–Fe–NC linkages) and linear coordination of the nitriles to the Fe^{II} ions (i.e. preferred 180° sp-hybridized Fe–N–C linkages) that from simple geometrical considerations cannot coexist, as 165° Fe–N–C angles are needed (assuming 90° *cis*-CN–Fe–NC). Hence, to be more linear, i.e. Fe–N–C angle >165°, adjacent Fe^{II}-based octahedra cant with respect to each other and the layers buckle. This lack of planarity is also reported for some [11], but not all [11e,12], reduced μ_4-TCNQ-based materials.

The factor-of-four higher T_c for $V[TCNE]_x$ (400 K) with respect to these iron-containing magnets (~100 K) suggests that $V[TCNE]_x$ may have different structure that stabilizes the higher T_c. The Mean Field expression for T_c

$$T_c = \frac{2JzS(S+1)}{3k_B} \quad (1)$$

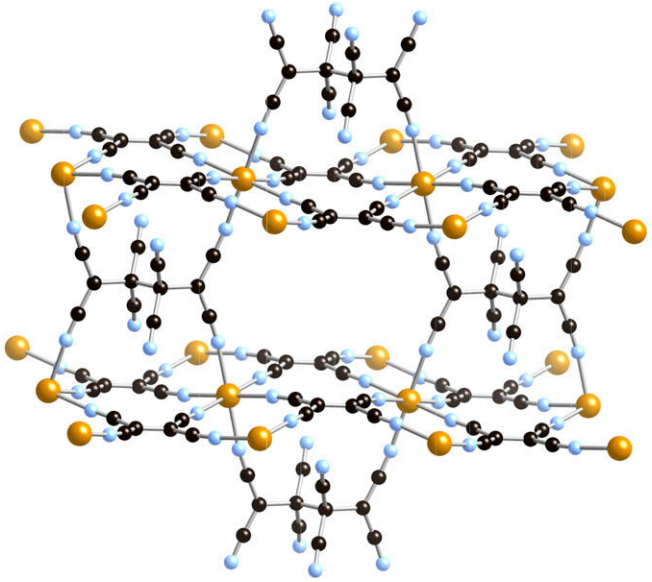

Fig. 1. Structure of $Fe^{II}[TCNE]_2 \cdot yCH_2Cl_2$ best formulated as $Fe^{II}[\mu_4\text{-}TCNE][\mu_4\text{-}C_4(CN)_8]_{1/2} \cdot yCH_2Cl_2$ (CH_2Cl_2 is disordered and resides in the channels within the porous framework structure) [9]. Each Fe^{II} is bonded to 6 nitrogens, and only some μ_4-$[C_4(CN)_8]^{2-}$ are shown for clarity.

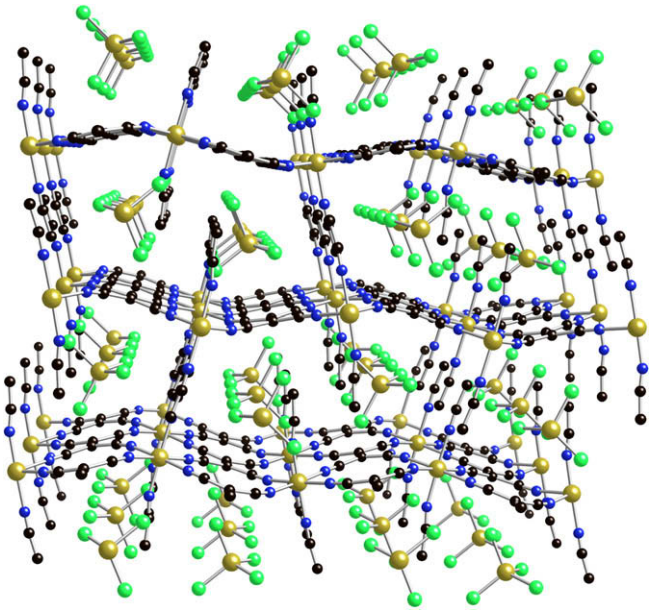

Fig. 2. Structure of $[Fe^{II}[TCNE](NCMe)_2][Fe^{III}Cl_4]$ [10].

(J is the nearest neighbor exchange coupling, z is the number of nearest neighbors, and k_B is Boltzmann's constant) reveals that by increasing the number of nearest neighbors (z) from 4 to 6, T_c increases by 50%. Hence, a 3-D structural motif should have a higher T_c, and it is appealing to consider that $V[TCNE]_x$ has a 3-D magnetic structure, as originally postulated [1a]. For a ferrimagnet with two different spin sites, i and j, with z_i and z_j nearest neighbors, respectively, the Mean Field expression is expanded to Eq. (2) [13,14]

$$T_c = \frac{2|J|[z_i z_j S_i(S_i+1)S_j(S_j+1)]^{1/2}}{3k_B} \quad (2)$$

Assuming a constant J, increasing z from 4 to 6 for each V site (3-D) [15], and reducing S from 2 (Fe^{II}) to 3/2 (V^{II}) should result in a small reduction in T_c by 3.2%, which is at variance to the observed factor-of-four increase. Hence, a 3-D structural motif is insufficient, and an enhanced J is needed to account for the factor-of-four increase in T_c.

1.1. Structural aspects

A 3-D magnetic structure can be envisaged via bridging $S = 1/2$ μ_4-$[TCNE]^{\cdot-}$ magnetic layers with μ-$[TCNE]^{\cdot-}$ (Fig. 3), among other possibilities [8a]. While this structural model is attractive, as it is consistent with the EXAFS and XANES data, it per se does not account for the enhanced T_c. Furthermore, this simplistic model is inconsistent with the diffraction data, as the structure would be ordered, and thus should diffract to some extent. Thus, the enhanced T_c must arise, at least in part, from a larger exchange coupling, J.

From an analysis of the saturation magnetization temperature dependence, $M_s(T)$, by the Block law for spin wave theory, J/k_B is estimated to be 100 K for $V[TCNE]_x$ [3]. Using Eq. (2) and $z_V = 4$ (and 6), a 447 K (and 548 K) T_c is expected. While both 2- and 3-D structural models predict a T_c above room temperature, the former is sufficient and closer to the observed value. While sufficient, magnetic anisotropy is needed for magnetic ordering in 2-D (Ising), which is not present for $V[TCNE]_x$.

Although the structure for $V[TCNE]_x$ is unknown, direct exchange coupling is expected to occur via V–NCCCN–V and V–NCCCCN–V spin-bearing linkages that are analogous to the Fe–NCCCN–Fe and Fe–NCCCCN–Fe linkages solely present for both layered (2-D) $Fe^{II}[TCNE][C_4(CN)_8]_{1/2}$ and $[Fe^{II}[TCNE](NCMe)_2][Fe^{III}Cl_4]$,

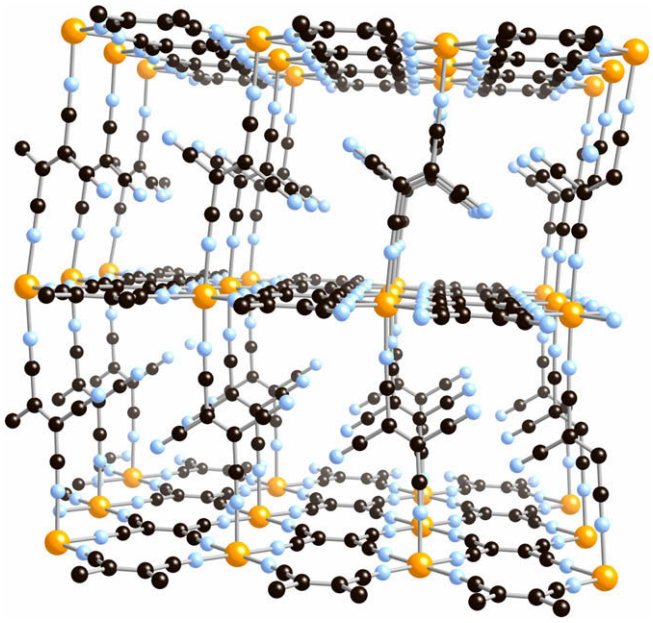

Fig. 3. An idealized proposed 3-D structure of $V^{II}[TCNE]_x$ ($x = 2$) possessing a 3-D magnetic motif with layers possessing μ_4-$[TCNE]^{\cdot-}$ being connected by μ-$[TCNE]^{\cdot-}$.

and more linkages, and as expected for a 3-D motif, would increase z and lead to a higher T_c, albeit offset due the reduced value of S for V.

For comparison, based on the 100-K T_c for $Fe[TCNE]_2$ a 12.5 K J is calculated via Eq. (2) [16]. The larger J for V^{II} with respect to Fe^{II} is expected due to greater mixing of the $[TCNE]^{\cdot-}$ π^* SOMO with the V^{II} d_π (t_{2g}-like) orbitals with respect to the Fe^{II} orbitals due to less nuclear shielding and thus being closer in energy, Fig. 4.

Note that a significantly enhanced J for V^{II} with respect to Fe^{II} ions, as reflected by a greater T_c, has also been noted for Prussian blue structured magnets. Prussian blue structured magnets with

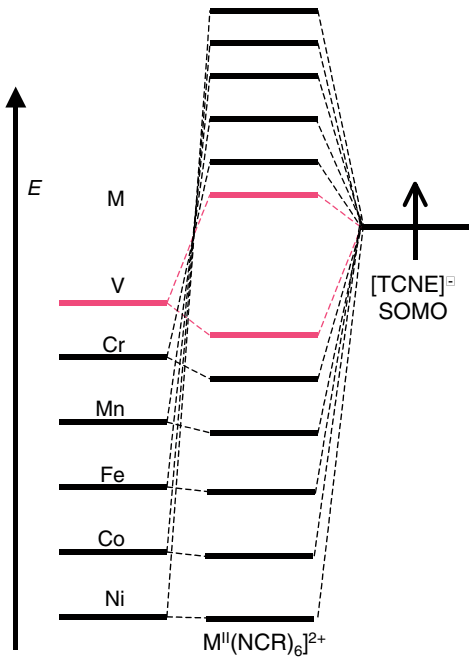

Fig. 4. Schematic illustration of the increasing M^{II} (M = V > Cr > Mn > Fe > Co > Ni) orbital interactions with the $[TCNE]^{\cdot-}$ π^* SOMO orbital with the M^{II} d_π (t_{2g}-like) orbitals.

V^{II}–NC–Cr^{III} linkages have T_c's exceeding room temperature [13,17], whereas those with Fe^{II}–NC–Cr^{III} linkages have substantially lower T_c's, by a factor of 15 {21 K for $Fe^{II}_3[Cr^{III}(CN)_6]_2 \cdot 15H_2O$ [18]}. This greater than an order of magnitude increase in T_c (and J) is also attributed to the better overlap of the orbitals on V^{II} with the CN^- π^* that leads to indirect coupling with the $S = 3/2$ Cr^{III} [19]. This overlap is likewise qualitatively valid for $M[TCNE]_x$. Hence, the higher T_c for $V[TCNE]_x$ with respect to $Fe[TCNE]_2$ is primarily attributed to stronger coupling. $[TCNE]^{\cdot-}$ is expected to provide strong coupling as it is directly coupled, not indirect as occurs for cyanide.

2. Composition of $V[TCNE]_x$

Since the discovery of $V[TCNE]_x$ in 1991 [1a], numerous characteristic properties have been established that reflect its composition and structure. Insight into the bulk composition can be obtained from the combustion analyses whereby the %C, H, N etc. is obtained, and fit to plausible formula by computational analysis [20]. The results of numerous elemental percentages have been garnered over the years, but the situation continues to be as it was when it was first reported. Namely "For $V[TCNE]_x{\cdot}yCH_2Cl_2$ a range of x and y is observed for preparations differing in solvents and mole ratios of the starting materials; oxygen and perhaps a benzene in small amounts are present in some cases. For the material discussed herein $x \sim 2$, and $y \sim 1/2$. Magnetic materials with $1.5 \leqslant x \leqslant 2$ and $0 \leqslant y \leqslant 1$ have also been prepared. Elemental analysis. Calc. (observed) for $C_{12.5}HClN_8V$: %C = 42.95 (42.81, 43.20, 43.00), and %H = 0.29 (0.14, 0.68, 0.35), %N = 32.05 (30.63, 30.00, 21.04), and %V = 14.57 (15.31), % chlorine was not reproducible." Additionally, strong ν_{CN} IR absorptions at 2188 ± 9 and 2099 ± 5 cm^{-1} were also reported [1]. The magnetization of ~6000 emuOe/mol was also reported to be in accord with the expectation of 5585 emuOe/mol for a ferrimagnet of $V[TCNE]_x{\cdot}yCH_2Cl_2$ ($x = 2$) composition.

Since the first report of this magnet, additional elemental percentages, IR spectra, as well as magnetic data etc. have obtained. The elemental analyses continue to be hampered by its oxygen sensitively, as well as solvent loss, but it is clear that $1.5 < x < 2$ and $0 \leqslant y \leqslant 1$ for materials made from solvent, and, of course, $y = 0$ for solvent-free films made via CVD [3,21]. It should be noted that co-formation of vanadium metal along with $V[TCNE]_2$ would give an effective composition of $V[TCNE]_x$ ($x < 2$); however, evidence for V^o was not identified from XPS [1c], EXAFS, and XANES [4] studies [21a]. As noted above, several IR absorptions assignable to ν_{CN} in the 2100 ± 100 cm^{-1} region exit for these magnetic materials, however, slight shifts, shoulders having different maxima, and differences in the relative intensities occur (Fig. 5a) [1–3].

The presence of $[TCNE]^{2-}$ is evident from the ν_{CN} IR absorptions. TCNE can be found in many forms in several oxidation states, i.e. $[TCNE]^n$ ($n = 0$, 1-, 2-) and its ν_{CN} absorptions are diagnostic of the oxidation states, and to a lesser extend the coordination environment [22]. ν_{CN} absorptions below 2150 cm^{-1} are indicative $[TCNE]^{2-}$, and are not present for either $[Fe^{II}\mu_4\text{-}[C_4(CN)_8](MeCN)_2]$ [23], $[Fe^{II}\mu_4\text{-}[TCNE](NCMe)_2][FeCl_4]$ [10], or $[Fe^{II}\mu_4\text{-}[TCNE]^{\cdot-}\{\mu_4\text{-}[C_4(CN)_8]^{2-}\}_{1/2}$ [9] (Fig. 5a). Absorptions below 2150 cm^{-1}, however, are present for $V^{II}[TCNE]_x$ prepared by several different routes [1–3] (Fig. 5b), and, thus, indicate that $[TCNE]^{2-}$ is present in some form. Recently $[VCp_2]_2[TCNE] \cdot 2B(C_6F_5)_3]$ and $\{[VCp_2][TCNE] \cdot 2B(C_6F_5)_3\}_2$ (Cp = cyclopentadienide) was characterized to possess μ_4-$[TCNE]^{2-}$ with ν_{CN} absorptions at 2200 and 2152 cm^{-1} [24], while absorptions at 2176 and 2097 cm^{-1} occur for *trans*-μ-$[TCNE]^{2-}$ that is present in $[Ir^I(CO)(PPh_3)_2]_2[TCNE]$ [25].

Monoreduced TCNE can occur in many forms, e.g. σ-$[TCNE]^{\cdot-}$, μ-$[TCNE]^{\cdot-}$, μ_4-$[TCNE]^{\cdot-}$, μ_4-$[C_4(CN)_8]^{2-}$, and π-$[TCNE]_2^{2-}$, and thus can coordinate to a metal ion in several modes, via the terminal

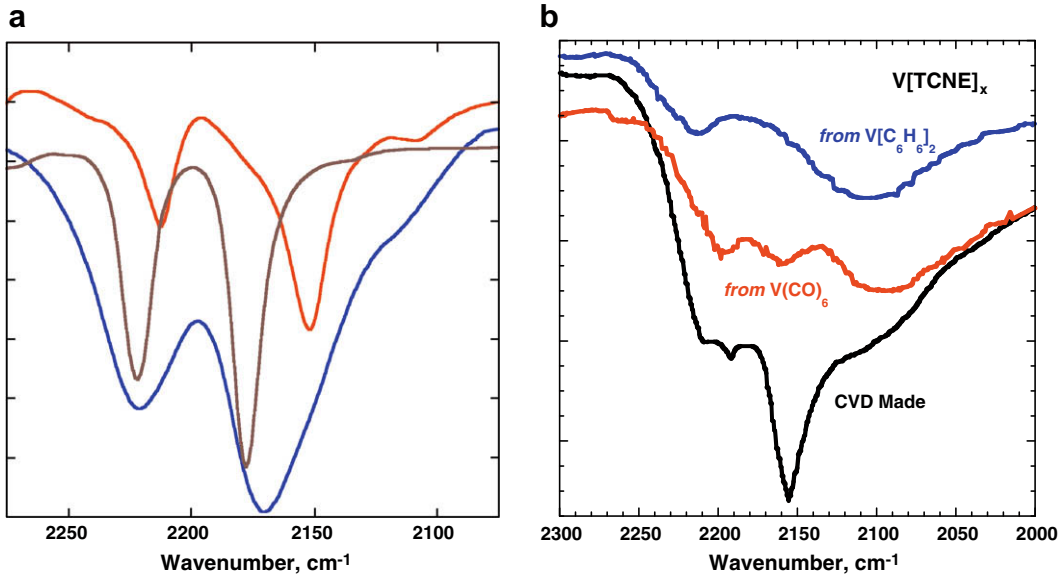

Fig. 5. ν_{CN} region for $[Fe^{II}\mu_4\text{-}[C_4(CN)_8](MeCN)_2$ (top), $[Fe^{II}\mu_4\text{-}[TCNE](NCMe)_2][FeCl_4]$ (middle), and $[Fe^{II}\mu_4\text{-}[TCNE]^{\cdot-}\{\mu_4\text{-}[C_4(CN)_8]^{2-}\}_{1/2}]$ (bottom) (a), $V[TCNE]_x \cdot yCH_2Cl_2$ prepared from $V(C_6H_6)_2$, $V(CO)_6$, [2], and a $V[TCNE]_x \cdot$ CVD-prepared thin film (b) [3a].

nitrogens [22]. Each of these forms have different ν_{CN} absorptions occurring above 2150 cm^{-1} [22], however, due to broadness and variability of the observed ν_{CN} absorptions (Fig. 5a) their presence cannot be conclusively identified for $V[TCNE]_x$, except to note that they arise from $[TCNE]^{\cdot-}$, and not from either $TCNE^o$ or $[TCNE]^{2-}$.

The magnetization also varies with sample, and values exceeding 10,000 emuOe/mol have been noted [2]. Hence, while magnetic materials ordering above room temperature are reproducibly made, the details of their physical properties differ. Thus, based on the lack of significant diffraction, and sample-to-sample as well as within-a-sample variability with respect to the elemental percentages, ν_{CN} absorptions, as well as magnetization, and as noted above this material was ascribed to being nonstoichiometric and inhomogeneous [1–3]. Hence, developing a structural model and theoretical insight for this material has been elusive.

The magnetization data is also consistent with the presence of $[TCNE]^{2-}$. The observed low field magnetization nominally ranges from 5000 to more than 10000 emuOe/mol [2], and its sample-to-sample variability has made the understanding of this material challenging. The limiting stoichiometry of $V^{II}[TCNE]_2$ with the $S = 3/2$ V^{II} antiferromagnetically coupled to two $S = 1/2$ $[TCNE]^{\cdot-}$ s, each with $g = 2$, leads to the expectation of a magnetization of 5585 emuOe/mol (or 27,925 emuOe/mol, if ferromagnetically coupled). Hence, values in the range ~5000 to ~6000 emuOe/mol are reasonable for antiferromagnetic coupling, especially due to the presence of solvent that is easily lost. Higher magnetization values, however, are expected if $S = 0$ $[TCNE]^{2-}$ or any diamagnetic form of $[TCNE]^{\cdot-}$ {e.g. $[C_4(CN)_8]^{2-}$ observed for $Fe[TCNE]_2$, or $[TCNE]_2{}^{2-}$} is present, as there would be only antiferromagnetic coupling with the single $S = 1/2$ $[TCNE]^{\cdot-}$ present. Thus, if $x = 1.5$, then $z = 0.5$, and V^{II} could only antiferromagnetically couple with one $[TCNE]^{\cdot-}$ s leading to an expected magnetization of 11,170 emuOe/mol. Hence, for $2 > x > 1.5$ the magnetization will be between 5585 and 11,170 emuOe/mol, as depicted in Fig. 6. These values would, however, be reduced if in actuality the composition (molecular weight) was assumed to be $V[TCNE]_2$, but would still be significantly larger than 5585 emuOe/mol (Fig. 6). The determination of the molar magnetization is further complicated due to the presence of solvent, which varies with sample, and some of it is easily lost. Nonetheless, $= V^{II}[TCNE]^{\cdot-}{}_z[TCNE]^{2-}{}_{1-z/2}$ will have higher magnetization than $V[TCNE]_x$.

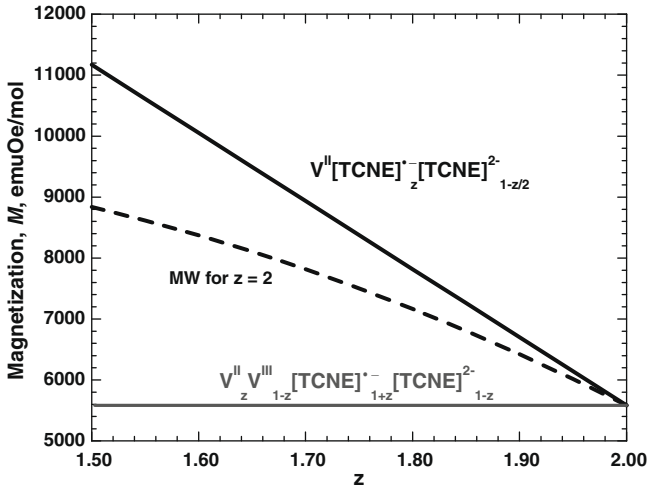

Fig. 6. Magnetization of the $V^{II}[TCNE]^{\cdot-}{}_z[TCNE]^{2-}{}_{1-z/2}$ formulation as a function of z assuming its molecular weight (top), and the molecular weight (MW) for $z = 2$ (dashed), and the constant magnetization for $V^{II}{}_zV^{III}{}_{1-z}[TCNE]^{\cdot-}{}_{1+z}[TCNE]^{2-}{}_{1-z}$ formulation.

Excluding the solvent from the solvated form, $V^{II}[TCNE]^{-}{}_z[TCNE]^{2-}{}_{1-z/2}$ is a good description for $V[TCNE]_x$. This is based upon full consideration of all of the data, although more complex formulations additionally possessing $\mu_4\text{-}[C_4(CN)_8]^{2-}$ [9,23] and/or $\pi\text{-}[TCNE]_2{}^{2-}$ [22,26,23c,27] etc. cannot be excluded. This formulation is predicated on the presence of $[TCNE]^{2-}$, and the TCNE:V ratio, x [$= z + 1 - z/2 = 1 + z/2 < 2$ ($z \neq 0$)], will vary with the amount of $[TCNE]^{2-}$ present, but will always be less than 2 when present, due to charge conservation.

While evidence for the presence of $[TCNE]^{2-}$ is presented, a mechanism for its formation is elusive. The reactions of TCNE with $V(C_6H_6)_2$ and $V(CO)_6$ to form $V[TCNE]_x$ appear to proceed by distinctly different mechanisms [28]. The reversible one-electron reduction potential for $V(C_6H_6)_2$ is −0.36 V (versus SCE), but its irreversible oxidation to V^{II} is +0.24 V [29a,b]; hence, it is insufficient to form $[TCNE]^{2-}$ {TCNE [$E^{-/o} = +0.25$; $E^{2-/-} = -0.83$ V (CH_2Cl_2) [30]}. Likewise, due to the irreversible, high oxidation potential of

$V(CO)_6$ (+0.88 V) [29c] its reaction with TCNE must not initially proceed by electron transfer [31]. Hence, in both mechanisms intermediates must form, at least transiently, that reduce the oxidation potential of the V species enabling the formation of $[TCNE]^{2-}$; but the details of this are not known.

Nonetheless, reduction of $[TCNE]^{\cdot-}$ to $[TCNE]^{2-}$ requires an oxidation, and oxidation of V^{II} to V^{III} seems reasonable, although based on the above discussion of oxidation potentials, it is not obvious. Thus, $V[TCNE]_x$ could be formulated as ${V^{II}}_z{V^{III}}_{1-z}[TCNE^-]_{1+z}-[TCNE]^{2-}{}_{1-z}$, and thus also possess the experimentally observed $[TCNE]^{2-}$. This formulation, however, is less likely due to requiring a TCNE:V ratio of 2 that is not observed. Also, the presence of V^{III} via XPS, EXAFS, or XANES studies has not been identified, but may be obscured or below the limits of measurements [3a,4,21]. Furthermore, V^{III} unlike V^{II}, and is not known to be stabilized by six nitrile-containing ligands, although coordinating halides stabilize V^{III}-acetonitrile complexes [32]. Finally, the expected magnetization for ${V^{II}}_z{V^{III}}_{1-z}\,[TCNE]^-_{1+z}[TCNE]^{2-}{}_{1-z}$ is inconsistent with the observed magnetization, as it is independent of z (Fig. 6) and values greater than 5585 emuOe/mol, as observed, should not occur.

Reduction of $[TCNE]^{\cdot-}$ to form $[TCNE]^{2-}$ might also be a consequence of oxidation of a second V^{I} (or V^{o}) site, and form V^{II}-$[TCNE]^-_z[TCNE]^{2-}{}_{1-z/2}$ This route requires that some of the oxidized V^{o} does not end up in the product, and while it might stay in solution for solution-made $V[TCNE]_x \cdot yCH_2Cl_2$, it cannot be reconciled for CVD-made $V[TCNE]_x$.

As models tend to be simplistic, the presence of TCNE:V < 2 could arise from the presence of V^{III}, such that ${V^{II}}_z{V^{III}}_{1-z}[TCNE]^-_a[TCNE]^{2-}_b$ ($b > 0$; $a + b = 2$; $a + 2b = 3 - z$; $a \neq 1 + z$; $b \neq 1 - z$) occurs with the same caveats as noted above.

The $V^{II}[TCNE]^-_z[TCNE]^{2-}{}_{1-z/2}$ formulation is in accord with the elemental analyses, ν_{CN} IR data, EXAFS, XANES, XPS, as well as magnetization data. Evaluation of elemental percentages, as noted earlier, show $1.5 < x < 2$ in accord with the $V^{II}[TCNE]^-_z[TCNE]^{2-}{}_{1-z/2}$ ($z < 2$) formulation. Note that this differs from $Fe[TCNE]_2$ where one of the $[TCNE]^{\cdot-}$ species is present as one-half of a $[C_4(CN)_8]^{2-}$. Diamagnetic $[C_4(CN)_8]^{2-}$ being the σ-dimer of $[TCNE]^{\cdot-}$ could as well as be replaced by its diamagnetic π-dimer, π-$[TCNE]_2{}^{2-}$ to maintain the charge and stoichiometry.

Thus, while $V^{II}[TCNE]^-_z[TCNE]^{2-}{}_{1-z/2}$ ($z < 2$) is formulated for $V[TCNE]_x$, the additional presence of these and/or other monoreduced forms of TCNE cannot be excluded, and likely are present to some extent. The presence of these and/or other monoreduced forms of TCNE, however, will maintain a 2:1 TCNE:V ratio, and only the presence of $[TCNE]^{2-}$, assuming no V^{III}, will reduce the ratio, as is observed [33].

3. Structural models for $V^{II}[TCNE]_x$

A limiting structure for the $V^{II}[TCNE]^-_z[TCNE]^{2-}{}_{1-z/2}$ formulation, i.e. $z = 1$ {$x = 1.5$: $V^{II}[TCNE]_{1.5}$}, is proposed to have $S = 1/2$ μ_4-$[TCNE]^{\cdot-}$ (**2**) layers bridged by $S = 0$ μ_4-$[TCNE]^{2-}$, Fig. 7. All V^{II} ions would be surrounded by six nitriles from six different reduced TCNEs in accord with the EXAFS and XANES data, and in this idealized structure there is 1.5 reduced TCNEs per V^{II}, of which one is $[TCNE]^{\cdot-}$ and one-half is $[TCNE]^{2-}$. This proposed structure portrays both μ_4-$[TCNE]^{\cdot-}$ and μ_4-$[TCNE]^{2-}$ as being planar ($\sim D_{2h}$). Planarity is expected for $[TCNE]^{\cdot-}$, but not necessarily for $[TCNE]^{2-}$. $[TCNE]^{2-}$ has a central C–C bond order of one; thus, free rotation is expected, and its structurally characterized examples are nonplanar [24,25,34]. Nonetheless, $[TCNE]^{2-}$ could be planar in this solid-state motif, as depicted in Fig. 7.

Planar $[TCNE]^{2-}$ should be ~0.1 Å wider than $[TCNE]^{\cdot-}$, i.e. the M1 Fe···Fe separation should be 7.32 Å versus an observed average of 7.22 Å (Table 1), due to the central C–C single bond [22], and while this should be kept in mind, this increase in length is sufficiently small that the structural parameters for the more extensively structurally characterized $[TCNE]^{\cdot-}$ can be used to model $[TCNE]^{2-}$.

The question arises as to the validity of $[TCNE]^{2-}$ being a structural replacement for $[C_4(CN)_8]^{2-}$ observed for $Fe[TCNE]_2$ [9] for $V[TCNE]_x$. The reported M···M separations for μ_4-$[TCNE]^{\cdot-}$ and μ_4-$[C_4(CN)_8]^{2-}$ are presented in Table 1. The *cis*-1,2-Fe–NCCCCN–Fe (M1), *cis*-1,1-Fe–NCCCN–Fe (M2), and *trans*-Fe–NCCCCN–Fe for μ_4-$[TCNE]^{\cdot-}$ distances, and thus for $[TCNE]^{2-}$, are 7.22 (M1), 7.29 (M2), and 10.26 Å (M3), respectively. The M1 distances lies within the range observed for $[C_4(CN)_8]^{2-}$; i.e. 7.17 to 9.37 Å for M1, but is ~0.3 Å less than the 7.56 to 8.70 Å range for M2, and 1.0 Å below the shortest reported M3 distance that ranges from 11.27 to 12.04 Å. From geometrical considerations, the M1–M3 distances can be estimated assuming a 90° rotation about the central C–C bond, i.e. D_{2d}, to be 8.32, 8.24, and 8.33 Å, respectively – almost cubic (Table 1). As a consequence, the M2 value falls within the observed range for μ_4-$[C_4(CN)_8]^{2-}$, but M3 is now ~3 Å below the observed range. This suggests that planar μ_4-$[TCNE]^{2-}$ is more compatible, but a small deviation from planarity may occur. The system is quite forgiving, as noted by the large range for the M1, M2, and M3 distances reported for the known μ_4-$[C_4(CN)_8]^{2-}$-containing structures (Table 1).

From a modeling perspective by increasing the relative canting of the adjacent Fe-based octahedra, such that, for example, M1 = 6.42, M2 = 7.73, and M3 = 10.05 Å, planar $[TCNE]^{2-}$ can fit the system, as illustrated in Fig. 7. Nonplanar, twisted $[TCNE]^{2-}$ likely can also be accommodated, and would alter the 3-D structural framework to some extent. The presence of both μ_4-$[TCNE]^{\cdot-}$ and μ_4-$[TCNE]^{2-}$ in the above discussion has magnetic layers possessing the μ_4-$[TCNE]^{\cdot-}$ separated by μ_4-$[TCNE]^{2-}$. In all cases channels exist within the structure to accommodate the solvent.

However, via movement of the electron among adjacent sites (hopping) both of μ_4-$[TCNE]^{\cdot-}$ and μ_4-$[TCNE]^{2-}$ species would be randomly located. This could explain the observed relatively high electrical conductivity that approaches 10^{-2} S/cm at room temperature that is attributed to electron hopping [35] between the structurally similar $[TCNE]^{\cdot-}$ and $[TCNE]^{2-}$ sites, i.e. μ_4-$[TCNE]^{\cdot-}$ + μ_4-$[TCNE]^{2-}$ = μ_4-$[TCNE]^{2-}$ + μ_4-$[TCNE]^{\cdot-}$, with a 0.5 V band gap.

Additionally, why does $[TCNE]^{2-}$ exist for V^{II}, while $[C_4(CN)_8]^{2-}$ {$= \sigma-[TCNE]_2{}^{2-}$} exists for Fe^{II}? The latter is physically twice the size as the latter, but the nominal space available for it, as well as charge, is the same. Perhaps V, being an earlier transition metal, has a sufficiently larger radii than Fe consistent with the expected trend [36] that it requires M1, M2, and M3 distances that are incompatible with stabilizing $[C_4(CN)_8]^{2-}$, as the central C–C bond is long and weak [10,23], but the observed V-NCMe distances, 2.11 ± 0.03 Å [5], are comparable and even less than that 2.16 ± 0.06 Å for $[Fe^{II}\mu_4$-$[TCNE](NCMe)_2][FeCl_4]$ [10] and $[Fe^{II}\mu_4$-$[TCNE]^{\cdot-}\{\mu_4$-$[C_4(CN)_8]^{2-}\}_{1/2}]$ [9]. Hence, this is an unlikely explanation. More likely is the stronger reducing ability (lower ionization potential) of V^{II} with respect to Fe^{II} that leads to the reduction of $[TCNE]^{\cdot-}$ to $[TCNE]^{2-}$, albeit by an unknown mechanism (vide supra).

The ideal $V^{II}[TCNE]_{1.5}$ and $V^{II}[TCNE]_2$ limiting compositions provide a basis to understand the material. The actual compositions lie between these extremes, i.e. $V^{II}[TCNE]^-_z[TCNE]^{2-}{}_{1-z/2}$ ($1 < z < 2$), and may possess a small amount of V^{III} [23c]. For intermediate values of z, μ_4-$[TCNE]^{2-}$ could be randomly replaced with μ-$[TCNE]^{\cdot-}$, but each V^{II} ion should maintain its octahedral coordination environment. This replacement should occur between the layers, but since electrons could hop between μ_4-$[TCNE]^{\cdot-}$ and μ_4-$[TCNE]^{2-}$ sites, i.e. μ-$[TCNE]^{\cdot-}$ + μ_4-$[TCNE]^{2-}$ = μ-$[TCNE]^{2-}$ + μ_4-$[TCNE]^{\cdot-}$, in addition to between the aforementioned μ_4-$[TCNE]^{\cdot-}$ and μ_4-

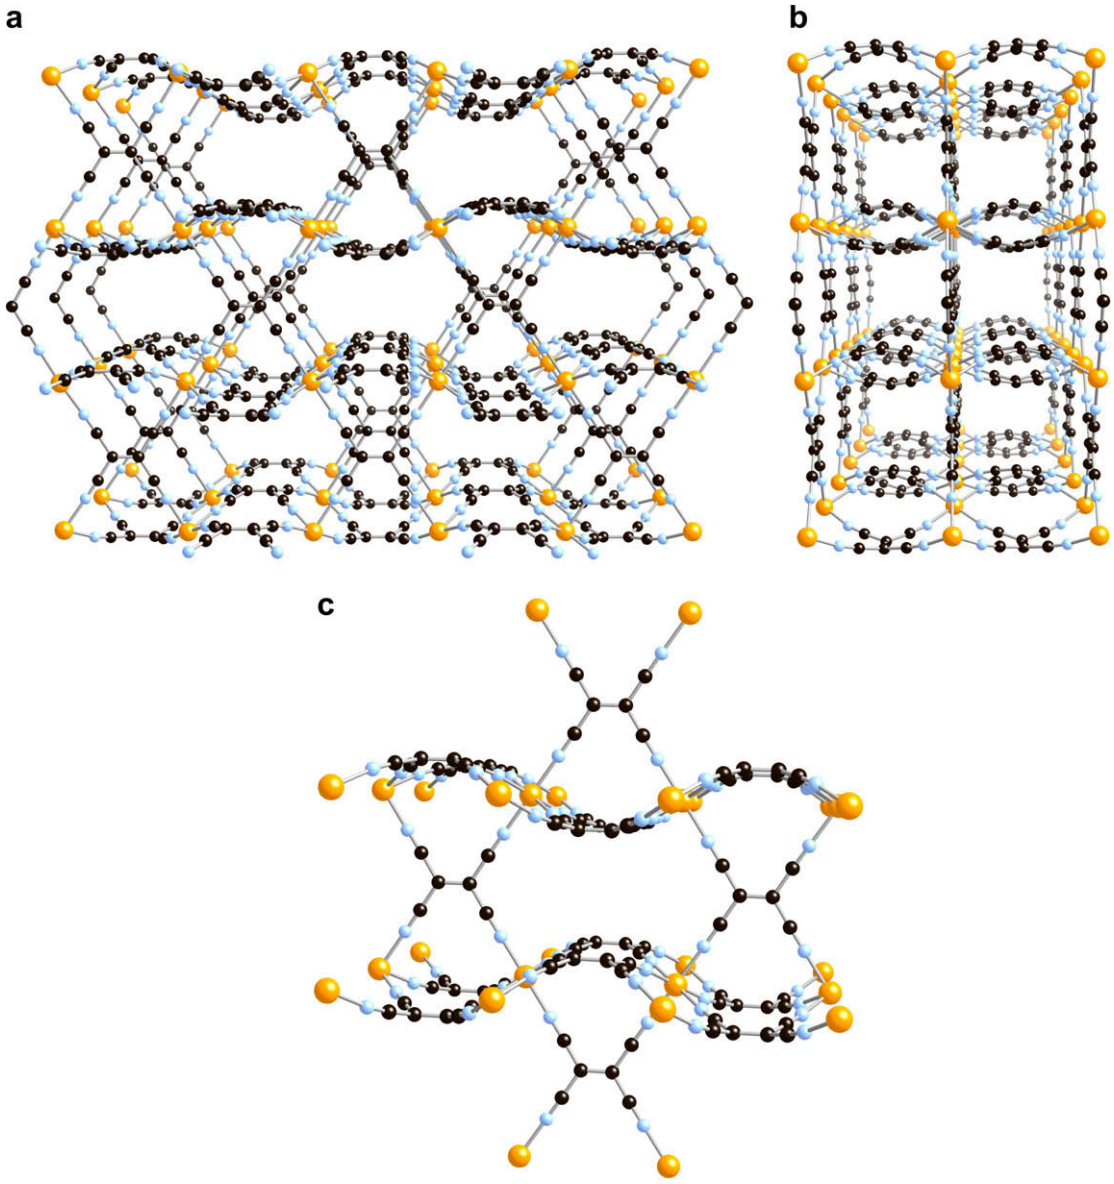

Fig. 7. A proposed limiting structure for $V^{II}[TCNE]^{\cdot-}{}_{z}[TCNE]^{2-}{}_{1-z/2}$ ($z = 1$) {$= V^{II}[TCNE]^{\cdot-}[TCNE]^{2-}{}_{1/2} = V^{II}[TCNE]_{1.5}$} possessing $S = 1/2$ μ_4-$[TCNE]^{\cdot-}$ layers bridged by $S = 0$ μ_4-$[TCNE]^{2-}$ through the hexacoordinate V^{II} ion; side view (a), end view (b). Note that the solvent would reside with the 2-D channels of this porous framework structure, and each V^{II} is bonded to 6 nitrogens, and only some μ_4-$[TCNE]^{2-}$ are shown for clarity.

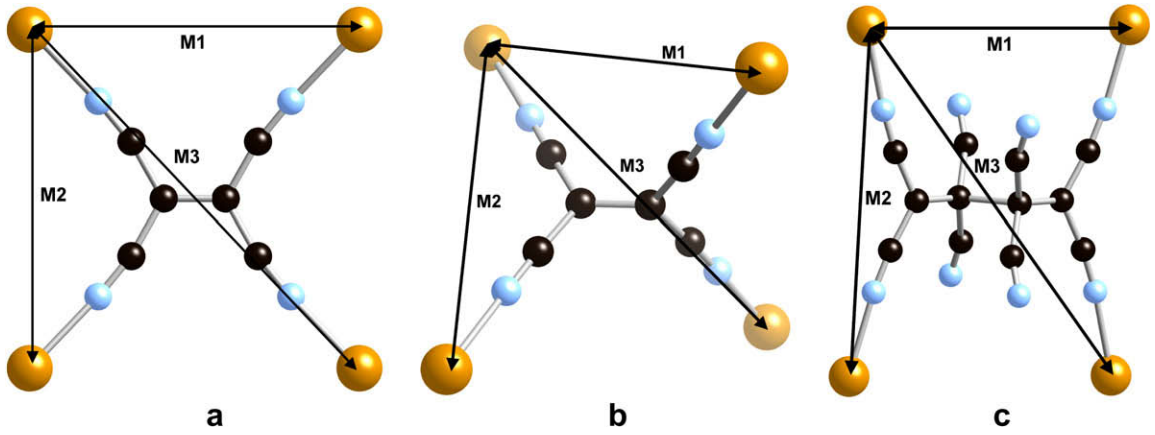

$[TCNE]^{2-}$ sites in accord with the observed high electrical conductivity. Furthermore, as the material immediately precipitates, the μ-$[TCNE]^{\cdot-}$ would be randomly located contributing to the structural disorder.

The intralayer replacement of μ_4-$[TCNE]^{2-}$ with *trans*-μ-$[TCNE]^{\cdot-}$ suggests a geometrical mismatch, as it should have a V···V separation comparable to the M3 Fe···Fe values in Table 1, which are significantly larger than the M2 distance noted for μ_4-$[TCNE]^{2-}$. The M2 Fe···Fe separation (Table 1) for μ_4-$[TCNE]^{\cdot-}$ (7.24–7.33 Å) and μ_4-$[C_4(CN)_8]^{2-}$ (7.56–8.70 Å) is ~3 Å shorter than the reported M3 distances for μ_4-$[TCNE]^{\cdot-}$ (~10.26 Å) and μ_4-$[C_4(CN)_8]^{2-}$ (11.27–12.04 Å). Nonetheless, the M3 distance for [MnTP*P][TCNE] · 2PhMe [H_2TP*P = *meso*-tetrakis(3,5-di-*t*-butyl-4-hydroxyphenyl)porphyrin], which like the large family of [MnTPP][TCNE] · *x*S (H_2TPP = *meso*-substituted tetraphenylporphyrins; S = solvent) magnetically order as ferrimagnets [1c], is 8.59 Å [37]. Hence, by reducing the M–N–C angle from the idealized 180° to a much lower values, such as 129° angle for [MnTP*P][TCNE] · 2PhMe, the μ-$[TCNE]^{\cdot-}$ moiety can replace either μ_4-$[TCNE]^{2-}$ or μ_4-$[C_4(CN)_8]^{2-}$ moieties.

Furthermore, the *trans*-μ-$[TCNE]^{\cdot-}$ intralayer replacement of μ_4-$[TCNE]^{2-}$ should enhance the magnetic coupling. In addition to the obvious existence of direct magnetic coupling available with $S = 1/2$ μ-$[TCNE]^{\cdot-}$ that is not present for $S = 0$ μ_4-$[TCNE]^{2-}$, the required reduced M–N–C angle should lead to stronger intralayer coupling, with respect to larger M–N–C angles approaching 180°. The inverse correlation between the M–N–C and the coupling has been established for the [MnTPP][TCNE]·*x*S family of ferrimagnets [1c,38]. Thus, the smaller M–N–C angle needed to accommodate μ-$[TCNE]^{\cdot-}$ should strengthen the coupling.

The aforementioned discussion refers to two limiting structures that should exhibit some degree crystalline order, and, thus, diffract to some extent, which does not occur. These two limiting structures could exit in different regions, inter-grow, or occur randomly. For example for a limiting structure for $V[TCNE]_{1.75}$ alternate layers of μ_4-$[TCNE]^{\cdot-}$ and μ-$[TCNE]^{2-}$, which via electron

hopping will randomize the location of the unpaired spin, again accounting for the high electrical conductivity, and providing a means for 3-D Mean Field-like magnetic coupling.

The lack of diffraction for the V[TCNE]$_x$ can be attributed to either very small crystallites (<10 Å) or the material being an amorphous glass. The particle size radius, assuming uniform spherical particles, is estimated to be 250 Å based on its 100 m^2/g surface area [1b,39]. This is sufficiently large and diffraction, albeit broadened, is expected, and even if it were a magnitude smaller, i.e. 25 Å, diffraction albeit with enhanced broadening, would likewise be anticipated. The direct measurement of its particle size distribution has been thwarted due to the extreme oxygen and water sensitivity. Very small spatial domains may result from the instantaneous formation of V[TCNE]$_x$; however, TEM studies do not provide evidence for this. TEM photographs reveal a featureless morphology consistent with a glassy material, Fig. 8. Hence, the lack of diffraction is most likely due to V[TCNE]$_x$ being a glassy material, i.e. an inhomogeneous, nonstoichiometric material composed differing components and linkages, as exists for window glass or coal. Nonetheless, several attempt to grow a more crystalline form of the V[TCNE]$_x$ magnet was pursued.

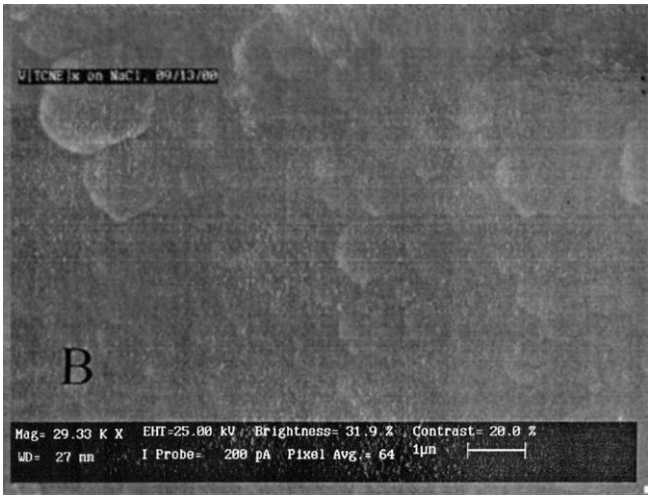

Fig. 8. Transmission electron micrograph (TEM) of a V[TCNE]$_x$ film on NaCl.

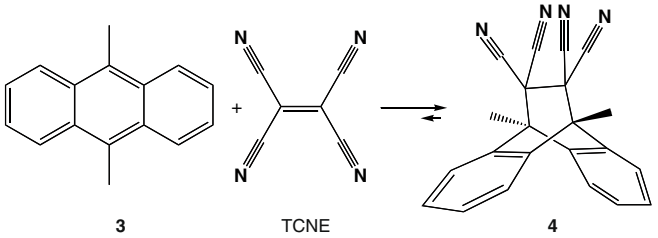
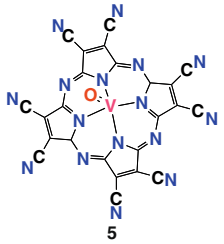
4. Attempts to grow crystalline V[TCNE]$_x$ by slow diffusion



The growth of crystalline V[TCNE]$_x$ in any form has yet to be successful. Being a material, different preparative routes may form materials with different degrees of crystallinity and/or different structural modifications, and physical properties, if not differing variations of the composition for nonstoichiometric materials. Since its discovery, the V[TCNE]$_x$ magnet has been successfully prepared (i.e. T_c > room temperature) innumerable times via different vanadium sources {e.g. $V(C_6H_6)_2$, $V(PhMe)_2$, $V(CO)_6$, $[V(CO)_6]^-$, and $[V(NCMe)_6]^{2+}$}, and solvents (e.g. PhMe, CH_2Cl_2, THF, and n-C_6H_{14}), as well as by chemical vapor deposition [3a], and while powder X-ray diffraction (PXRD) analysis was not performed on every sample, it was obtained for many samples, especially those via new routes. Significant diffraction, except for that associated with the presence of an amorphous component, was not obtained.



Specific attempts to grow crystals by traditional methods for growing crystals have been unsuccessful. Many strategies and tactics have been established through the decades to grow crystals,

and certainly not all have been tried (or are even suitable) for $V[TCNE]_x$. Generally for an insoluble, rapidly precipitating material such as $V[TCNE]_x$, which instantaneously forms when TCNE is reacted with a suitable vanadium source, as discussed above, reducing the rate of reaction may lead to its slow formation and greater crystallinity. Attenuation of the reaction rate, in practice, in complicated by the extreme air and water/protic solvent sensitivity of the $V[TCNE]_x$ product, not to mention of the vanadium source. Using slower and more dilute solutions enabled the increasingly slower dropwise addition of reactants in solution to form the product, but even using a syringe pump this was not successful.

Slowing a reaction down via diffusing the reactants through a sol–gel is a known method that has been quite successful for many materials, and has been used to grow crystals of the quite air-sensitive, but not water sensitive, $KV[Cr(CN)_6] \cdot 2H_2O$ room-temperature Prussian blue-structured magnet [17j]. The medium used for sol–gel crystal growth is typically aqueous/alcohol based, which is completely incompatible with the reactants as well as the $V[TCNE]_x$ product, even under achievable anaerobic conditions (<1 ppm O_2). Hence, $V(C_6H_6)_2$ and TCNE were reacted using polystyrene and polyvinyl chloride gels, as they were similar to the solvents (toluene and CH_2Cl_2) that were typically used to form the bulk magnetic material. This procedure led to formation of an expected black precipitate, but it neither diffracted nor magnetically ordered.

An alternate route for the slow formation of $V[TCNE]_x$ would be to react a vanadium source with slow release source of TCNE. The in situ slow generation of TCNE would limit the rate of the formation of $V[TCNE]_x$, due to it low availability. TCNE is a dienophile and forms Diels-Alder products with numerous dienes, and while these products are quite stable, in principle this reaction is reversible. Due to the stability of the Diels-Alder products, virtually no release of the TCNE was expected; hence, one with reduced stability was sought, and a sterically hindered diene was targeted. 9,10-Dimethylanthracene (**3**) was identified as a sterically hindered diene, and its Diels-Alder product with TCNE (**4**) forms [40]. The rate constant for the dissociation of **4** to **3** and TCNE is reported to be $2 \times 10^{-4}\ s^{-1}$ at 25 °C in 1,2-$C_2H_4Cl_2$, hence, it was suitable slow-release source for TCNE. The reaction of **4**, which slowly generates TCNE, slowly reacts with $V(C_6H_6)_2$ and $V(CO)_6$ to form an expected black precipitate over a several day period, but while paramagnetic, it neither diffracted nor magnetically ordered. Hence, these, and other attempts to slowly form a more crystalline form of the $V[TCNE]_x$ magnet were not only unsuccessful, but did not form a magnetically ordered material. The later may be due to the known thermal instability of the $V[TCNE]_x$ magnet whereby the magnetic ordering is lost upon thermal treatment [1–3]. The vanadyl-containing compound **5** has been identified as a thermal/oxidative product [41].

These results suggest that the $V[TCNE]_x$ room temperature magnet is a kinetic product, and the thermodynamic product does not magnetically order; hence, preparing a crystalline kinetic product will be challenging.

5. Current status of the structure of $V[TCNE]_x$

The formulation $V^{II}[TCNE]^-_z[TCNE]^{2-}_{1-z/2}$ $(1 < z < 2)$ for $V[TCNE]_x$ $(x = 1 + z/2)$ is sufficient to explain its observed ν_{CN} IR absorptions, elemental percentages, XANES, EXAFS, XPS, and magnetization data [42]. Foremost is the presence of ν_{CN} IR absorptions characteristic of $[TCNE]^{2-}$. This differs from $Fe^{II}[TCNE]_2$ and $[Fe^{II}[TCNE](NCMe)_2][Fe^{III}Cl_4]$ which lack both these absorptions and $[TCNE]^{2-}$. $Fe^{II}[TCNE]_2$, however, possesses $[C_4(CN)_8]^{2-}$, and like $[C_4(CN)_8]^{2-}$ $[TCNE]^{2-}$ is envisioned to bridge the Fe^{II}-[μ_4-$[TCNE]^{\cdot-}$ layers. $[TCNE]^{2-}$ may twist, due to the free rotation about the central C–C single bond, but it is likely close to planar, perhaps due to geometrical constraints from the lattice. This is a plausible description for the limiting $z = 1$ case. Thus, this limiting structure could possess a layered (2-D) structure, as observed for $Fe^{II}[TCNE]_2 \cdot yCH_2Cl_2$ and $[Fe^{II}[TCNE](NCMe)_2][Fe^{III}Cl_4]$, and while stronger magnetic coupling between $[TCNE]^{\cdot-}$ and V^{II} with respect to Fe^{II}, as discussed above, is expected, the isotropic nature of the $S = 1/2$ $[TCNE]^{\cdot-}$ and $S = 3/2$ V^{II} spin sites is inconsistent with 2-D Ising magnetic ordering.

The mechanism for the formation of $[TCNE]^{2-}$ {as well as $V[TCNE]_x$} and why $Fe^{II}[TCNE]_2$ possesses $[TCNE]^{2-}$ and not $[C_4(CN)_8]^{2-}$ are unknown, but lower ionization potential of vanadium with respect to iron likely is important.

The presence of both μ_4-$[TCNE]^{\cdot-}$ and μ_4-$[TCNE]^{2-}$, especially planar μ_4-$[TCNE]^{2-}$, about each V^{II} site should enable facile electron hopping among these sites randomizing the location of the reduced TCNE's and enabling the observed relatively high dc electrical conductivity, and forming an extended 3-D magnetic structure, and explain the observed T_c that exceeds room temperature.

For the limiting $z = 2$ case, planar $[TCNE]^{\cdot-}$ is envisioned to bridge the $Fe^{II} - [\mu_4 - TCNE]^{\cdot-}$ layers, as *trans*-μ-$[TCNE]^{\cdot-}$ forming an extended 3-D magnetic structure, and for the observed solid solution where $1 < z < 2$ an appropriate random distribution of $[TCNE]^{\cdot-}$ and $[TCNE]^{2-}$ would exist.

This intralayer replacement of μ_4-$[TCNE]^{2-}$ with *trans*-μ-$[TCNE]^{\cdot-}$ suggests a lattice mismatch; however, suitable distances can be accommodated by substantially reducing the idealized 180° M–N–C angle, as occurs for $[MnTP^*P][TCNE] \cdot 2PhMe$ [37]. Furthermore, in addition to the additional direct magnetic coupling, the attenuated M–N–C angle should lead to stronger intralayer coupling.

These to two limiting structures should exhibit some degree crystalline order, and, thus, diffract to some extent, which does not occur. These limiting structures, however, could exit in different regions, inter-grow, or occur randomly, with very small spatial domains such that diffraction is sufficiently broadened such that it is not evident. More likely, such very small spatial domains results for the instantaneous formation of $V[TCNE]_x$, and based on TEM data, which show a featureless morphology, it is a glassy material. Hence, the lack of diffraction is most likely due to $V[TCNE]_x$ being a glassy material, i.e. an inhomogeneous, nonstoichiometric material composed differing components and linkages, as exists for window glass or coal. Nonetheless, several attempt to grow a more crystalline form of the $V[TCNE]_x$ magnet was pursued.

This is in contrast the formation of $Fe[TCNE]_2$ that requires several days by either the reaction of $Fe(CO)_5$ or $FeI_2 \cdot x$MeCN with TCNE [43], and yields magnetic materials that diffract [9]. Retardation of the rate of $V[TCNE]_x$ formation; however, neither resulted in a form that diffracted, nor magnetically order. The later is attributed thermal instability of $V[TCNE]_x$ whereby the magnetic order-

ing is lost upon thermal treatment [1–3], and suggests that the $V[TCNE]_x$ room temperature magnet is a kinetic product, and the thermodynamic product does not magnetically order. Thus, formation a diffracting kinetic phase of the $V[TCNE]_x$ room temperature magnet will be demanding.

The $V^{II}[TCNE]^{-}{}_{z}[TCNE]^{2-}{}_{1-z/2}$ formulation is in accord with the observed physical and chemical properties. This is simplest formulation as some V^{III} as well as other reduced forms of TCNE than the $[TCNE]^{\cdot-}$ and $[TCNE]^{2-}$ species may be present, and vary in occurrence within and between samples. Additionally, structural defects such that terminal, *cis*-1,1-, *cis*-1,2-, *trans*-1,2-μ-$[TCNE]^{\cdot-}$, μ_3-$[TCNE]^{\cdot-}$ and $[TCNE]^{2-}$ etc. may be present to enhance the complexity of the material, and further contribute to its disordered and amorphous nature.

This description for $V[TCNE]_x$ room temperature magnet lacks many answers and begs a plethora of additional questions, but provides for a status report from the author's perspective. As such, future studies will provide additional data to enable greater clarity of the description of this material, and undoubtedly new perspectives will emerge.

Acknowledgments

We appreciate the helpful discussions with Prof. Arthur J. Epstein (The Ohio State University), Konstantin I. Pokhodnya (North Dakota State University), Prof. Fernando Palacio (Universidad de Zaragoza), and William W. Shum (University of Utah), and the continued partial support by the Department of Energy Division of Materials Science (Grant Nos. DE-FG03-93ER45504 and DE-FG02-01ER4593) and Army Research Office (Grant No. DAAD19-01-1-0562) is appreciated.

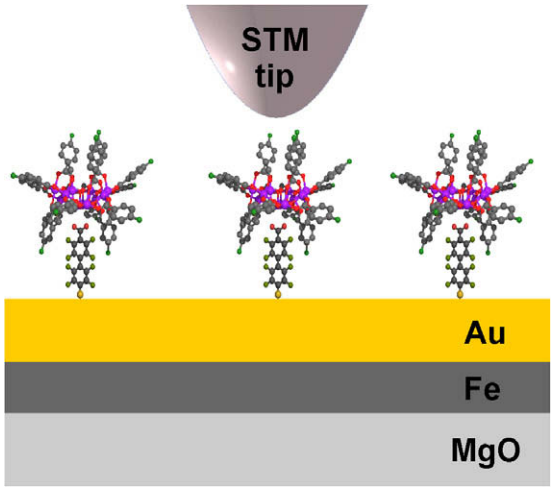

Fig. 1. Schematic representation of the STM investigation of Mn_{12}-pfb deposited on Au(100)/Fe(100)/MgO(100) via ligand exchange reaction with 4-MOBCA.

evaporated onto MgO from an electron beam evaporator at room temperature at a rate of 1.5 Å/min. (3) After the Fe deposition the sample was annealed at 870 K for 30 min. (4) Finally, Au was evaporated from a thermal evaporator (effusion cell) at a rate of 6.5 Å/min at a sample temperature of 600 K. After the preparation and investigation of Au(100)/Fe(100)/MgO(100), Mn_{12}-pfb was deposited on the surface via ligand exchange reaction with 4-MOBCA as described elsewhere [10e]. A sketch of the sample configuration is shown in Fig. 1. STM, STS and X-ray photoelectron spectroscopy (XPS) measurements were performed in an Omicron Multiprobe UHV system at room temperature. For the STM/STS measurements, electrochemically etched tungsten tips, flash-annealed by electron bombardment were used. XPS spectra were obtained with Al Kα radiation ($h\nu$ = 1486.6 eV) with the resolution of the EA 125 energy analyzer set to 0.65 eV.

3. Results and discussion

Fig. 2 shows two STM images obtained from Fe(100)/MgO(100) (a; 16 nm thick iron layer) and from Au(100)/Fe(100)/MgO(100) (b; 20 nm thick gold layer). In Fig. 2a, Fe terraces along with monoatomic steps with perpendicular edges are visible which is in agreement with previous studies [15a,b]. Fig. 2b shows terraces and monoatomic steps of the Au(100) surface. The inset of Fig. 2b shows the surface reconstruction of Au(100) which appears as a straight line pattern in contrast to the herringbone reconstruction of Au(111). The surface morphology is in agreement with previous studies [16]. In the present study, the preparation parameters were optimized to fabricate surfaces with low roughness and sufficiently large Au terraces facilitating the addressing of Mn_{12} monolayers deposited on the surface by means of STM.

Fig. 3 shows an STM image obtained after deposition of Mn_{12}-pfb on Au(100)/Fe(100)/MgO(100) via ligand exchange reaction with 4-MOBCA. A monolayer of clusters is visible which is in agreement with previous STM studies on Mn_{12} monolayers deposited on Au(111) single crystals [10e,12a]. The shape of the subjacent terraces and steps can be estimated due to slight differences of the apparent height that are visible in the image. The individual molecules have been further investigated by means of scanning tunneling spectroscopy (STS; see inset of Fig. 3) which revealed the presence of a large conductance gap in agreement with previous studies [17]. In addition, XPS confirmed the presence of the Mn 2p peaks also observed in previous works (see Fig. 4) [10e,12a]. The agreement with previous studies demonstrates that Mn_{12}-pfb was successfully deposited on Au(100)/Fe(100)/MgO(100). Furthermore, the results demonstrate that details of the gold surface morphology, like different surface reconstructions or terrace shapes in the case of Au(100) and Au(111) do not significantly influence the arrangement of the Mn_{12} molecules. This observation is in agreement with a previous study which suggested a statistical arrangement of Mn_{12} on 4-MOBCA/Au [10e].

To investigate a possible influence of the wet chemical deposition of Mn_{12} on the properties of the Au-covered iron layer, XPS measurements were performed in order to detect a possible oxidation of the iron. Fig. 5a shows a Fe 2p spectrum obtained from Fe(100)/MgO(100). The peak positions (Fe $2p_{1/2}$: 719.9 eV, Fe

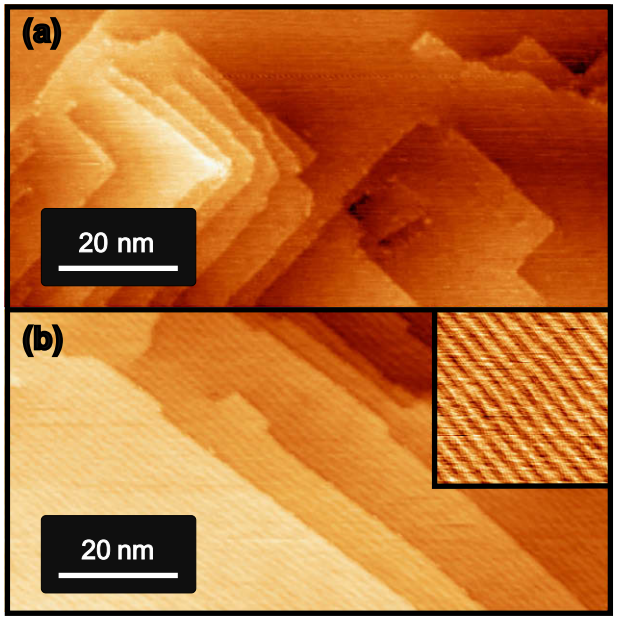

Fig. 2. STM images (100 × 50 nm^2) of (a) Fe(100)/MgO(100) and (b) Au(100)/Fe(100)/MgO(100). The inset of (b) shows a 20 × 20 nm^2 STM image of the surface reconstruction of Au(100).

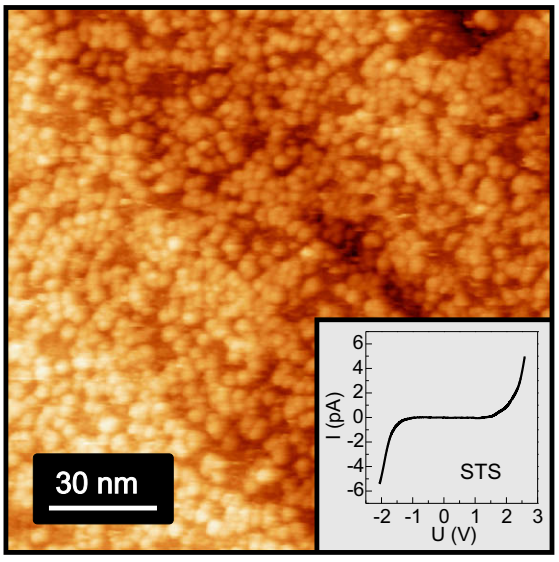

Fig. 3. STM image (150 × 150 nm^2) of Mn_{12}-pfb molecules (U_T = 2.5 V; I_T = 8.6 pA). The inset shows an STS spectrum of a single Mn_{12}-pfb molecule obtained at a set voltage of 2.7 V (set current 6.9 pA).

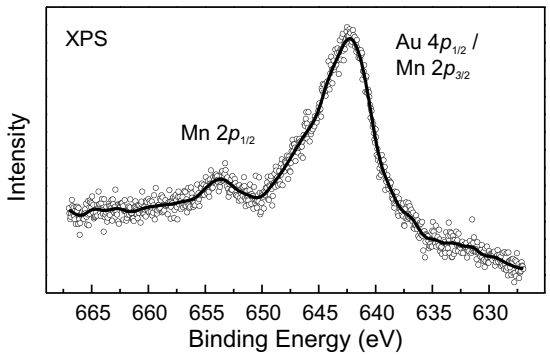

Fig. 4. XPS Mn 2*p*/Au 4$p_{1/2}$ spectrum obtained after deposition of Mn_{12}-pfb on Au(100)/Fe(100)/MgO(100).

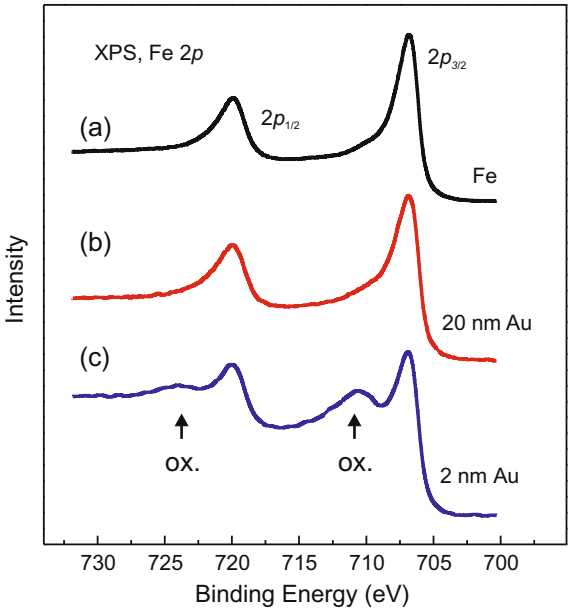

Fig. 5. XPS Fe 2*p* spectra of (a) Fe(100)/MgO(100) (after in situ Fe evaporation), (b) Mn_{12}-pfb on Au(100)[20 nm]/Fe(100)/MgO(100) after removal of Mn_{12}, 4-MOBCA, and Au via sputtering, (c) Mn_{12}-pfb on Au(100)[2 nm]/Fe(100)/MgO(100) after removal of Mn_{12}, 4-MOBCA, and Au via sputtering.

$2p_{3/2}$: 706.8 eV) as well as the shape of the spectrum are consistent with metallic iron [18]. This measurement was performed immediately after the deposition of Fe on MgO. It is well known that removing the unprotected iron layer from the UHV would result in an oxidation. Hence, sensitive samples are usually covered with protection layers like gold thin films prior to sample transfers or further processing. Nevertheless, it is important to carefully investigate the Mn_{12}/Au(100)/Fe(100)/MgO(100) system since the adopted preparation steps (immersion in solvents [19], possibly corrosive 4-MOBCA etc.) are significantly different from an ordinary sample transfer. To study a possible oxidation of the iron layer during the preparation ex situ, the Mn_{12}/4-MOBCA/Au(100) layers had to be removed from the sample because the information depth of XPS is limited to a few nm [20]. To this end, the sample was continually sputtered with Ar^+ ions at 800 eV for 10 min in each step. After each sputtering cycle, an XPS spectrum was recorded. Due to the XPS information depth of a few nm the transition from a pure Au to a mixed Au/Fe signal could be easily identified and the sputtering was terminated at this time to avoid an accidental removal of a possibly oxidized iron layer. Subsequently, a XPS Fe 2*p* spectrum was recorded. Fig. 5b shows the spectrum obtained from the sample previously covered with Mn_{12}. The spectrum coincides with those of metallic iron and thus provides evidence that the iron layer was not oxidized. In the next step, a control experiment was performed with an only 2 nm thick Au layer while all different parameters and preparation steps were identical to those of the previous sample. Fig. 5c shows an Fe 2*p* spectrum that reveals the occurrence of additional Fe 2*p* peaks after the exposure to ambient conditions. The comparison of the position of the additional Fe $2p_{3/2}$ peak (710.5 eV) with previous studies indicates a partial oxidation of the iron layer [18].

The comparison of the XPS spectra demonstrates that the iron layer underneath the 20 nm Au layer is not oxidized during the wet chemical deposition of Mn_{12} while in the case of a thin layer an oxidation cannot be ruled out. This observation suggests a trade-off between oxidation protection and spin polarization. Although the spin diffusion length in Au can be significantly larger than 20 nm [21], a thin buffer layer may be preferable to achieve a sufficient spin injection.

In conclusion, a possibility to fabricate samples for future spin-polarized transport studies on Mn_{12} single molecule magnets was investigated. The results demonstrate that Mn_{12} molecules can be deposited on Au(100)/Fe(100)/MgO(100) layer systems by means of wet chemical deposition methods without altering the metallic nature of the ferromagnetic iron which is required as a source for spin-polarized electrons. The insights will contribute to future transport studies on Mn_{12} and possibly different single molecule magnets.

The "pump" and "probe" beams traversed the same optical path close to the sample, but the focusing lens was systematically removed from the way of the pump beam to obtain a large spot size of *ca.* 5 mm. Under these conditions the experiments could be repeated many times on the same sample without degrading it.

3. Results and discussion

3.1. Experimental observations

Vibrational spectroscopy is known to be a valuable tool to investigate spin crossover phenomena due to the strong electron-lattice coupling in these materials [7]. In particular, in the Fe(pyrazine)[$M(CN)_4$] (M = Pt, Pd, Ni) family of compounds the intensity ratio of various Raman modes have been identified as excellent markers to track the change of HS/LS fractions [8]. Notably, the mode characteristic of in-plane bending vibrations of the pyrazine ring is associated with two frequencies, around 647 and 677 cm^{-1} for HS and LS states, respectively [8,9], and these are selected to follow the light-induced spin state change (Fig. 1).

Fig. 1 reveals a typical photo-induced LS → HS spin transition observed in Fe(pyrazine)[$Pt(CN)_4$] by applying a single 20 mJ/cm^2 green pulse (532 nm) at 301 K. Such an excitation produces a marked colour change from deep red (LS state) to yellow-orange (HS state) of the irradiated sample area. This photoinduced state remains stable in ambient conditions for (at least) several weeks without particular storage precautions.

To investigate the efficiency of the spin conversion process as a function of the excitation power, we irradiated the same sample with single laser pulses of different energy and controlled the resulting spin state of the system by Raman spectroscopy (Fig. 2). After each measurement the sample was converted in the pure LS state (by cooling down to 240 K) and then slowly heated up to 298 K again. In this way we ensure that every experimental point in Fig. 2 corresponds to the spin transition from the pure LS state. Two observations deserve particular attention.

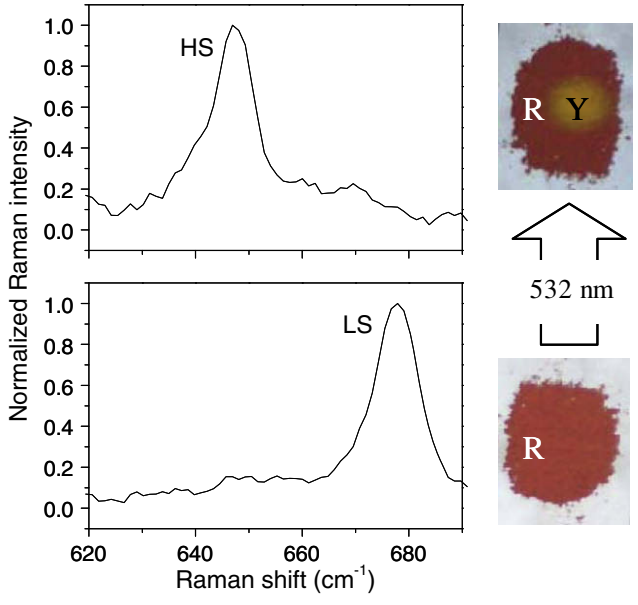

Fig. 1. Colour change (right) and Raman spectra (left) in the Fe(pyrazine)[$Pt(CN)_4$] powder sample before (bottom) and after (top) a single-shot irradiation of 20 mJ/cm^2 at 301 K. In the photographs, the powder sample is deep red (R) in the LS state and turns to yellow-orange (Y) in the HS state after the laser excitation. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

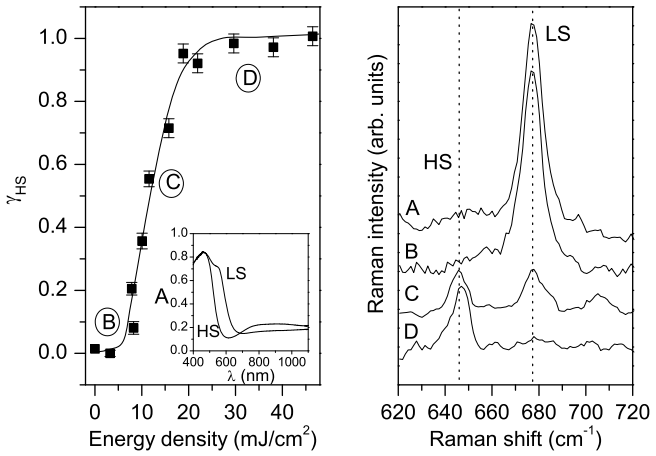

Fig. 2. Conversion efficiency as a function of the laser pulse energy density at 298 K (left panel) evaluated from the intensity ratio of spectral bands around 647 and 677 cm^{-1} (right panel). Typical spectra associated to the regions B, C and D are plotted in the right panel. The spectrum A was recorded before any pulsed excitation. A threshold energy density of *ca.* 5 mJ/cm^2 and a saturation value of *ca.* 20 mJ/cm^2 can be inferred. The inset shows absorption spectra in the HS and LS states extracted from diffuse reflectance measurements [4]. The solid line in the left panel is a guide for the eye.

First of all the observed 100% conversion efficiency (for high energy pulses) refers directly to the involvement of cooperative phenomena in this photo-induced phase transition. Indeed, as the absorption coefficient is significantly higher at 532 nm than at 633 nm in the LS state (inset of Fig. 2), the red probe beam penetrates necessarily deeper in the material than the green pump laser pulse. In the absence of interactions between the spin state changing iron ions, we should not observe a 100% spin conversion of the probed area since the thickness of the sample is much bigger than the laser penetration depth whatever the wavelength.

The occurrence of cooperative interactions is also confirmed by the existence of an energy density threshold (Fig. 2) in the conversion efficiency curve as has already been pointed out by several

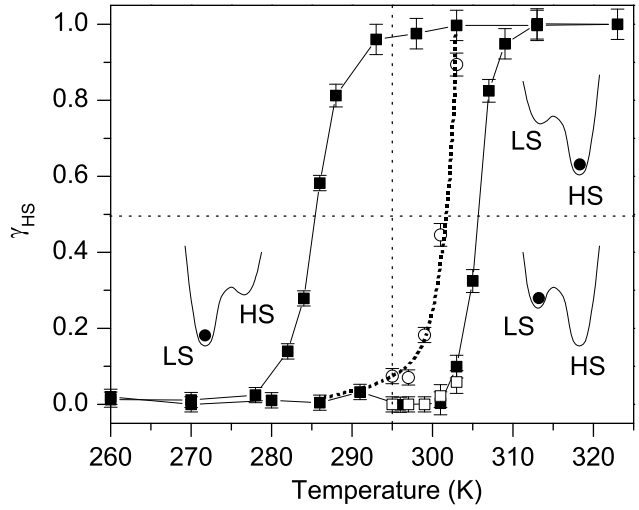

Fig. 3. Conversion efficiency as a function of the temperature for a fixed pulse energy density (11 mJ/cm^2) calculated from the intensity ratio of spectral bands around 645 and 675 cm^{-1}. Black squares describe the thermal hysteresis loop determined from Raman measurements, open squares the initial state of the material before excitation by the light pulse and open circles the final state after excitation. From 270 K up to T_c = 295 K, the system is in the stable LS state (see schematic free energy curves in inset). On heating from 295 K, the LS state becomes metastable and the stable HS state is progressively populated.

authors on various materials [3,10]. In our case three regions appear in the conversion efficiency versus energy density curve. Below the threshold value of *ca.* 5 mJ/cm^2, no conversion happens after a 532 nm laser shot (region B). The molecules remain in the LS state. It is important to note that the application of a large number of shots (typically 300 pulses at a rate of 1 Hz) weaker than 5 mJ/cm^2 did not affect the Raman spectra and thus the spin state of the system. Between 5 and 20 mJ/cm^2, the spin conversion efficiency increases rapidly with the energy density. The 677 cm^{-1} LS marker band sharply falls and the 647 cm^{-1} HS marker band grows (region C). Beyond 20 mJ/cm^2, a saturation corresponding to a pure HS state is reached (region D).

Fig. 3 shows the temperature dependence of the conversion on the ascending branch of the hysteresis loop induced by a fixed 11 mJ/cm^2 laser pulse energy. With increasing temperature the spin conversion efficiency rises significantly. It is noteworthy that conversion from both the metastable LS state to the stable HS state (above T_c) and from the stable LS state to the metastable HS state (below T_c) are possible, but the latter case is much less efficient at 11 mJ/cm^2 and requires a higher energy density to reach a full conversion (>27 mJ/cm^2).

3.2. Theoretical description

A qualitative explanation of the observed photo-induced spin state conversion can be proposed using the mean-field model of Slichter and Drickamer [11], as already suggested by Tokoro et al. for a Prussian blue analogue [12]. From this theoretical approach, the free energy (G) of a system whose thermal evolution of the HS fraction (γ_{HS}) exhibits an hysteresis loop is described by the equation

$$G = \gamma_{HS}\Delta H + \Gamma\gamma_{HS}(1-\gamma_{HS}) + T[R(\gamma_{HS}\ln\gamma_{HS} + (1-\gamma_{HS}) \times \ln(1-\gamma_{HS})) - \gamma_{HS}\Delta S], \quad (1)$$

where R is the gas constant, Γ is a phenomenological interaction parameter expressing the cooperative phenomena accompanying the spin crossover, ΔH (=$H_{HS} - H_{LS}$) is the transition enthalpy and ΔS (=$S_{HS} - S_{LS}$) the transition entropy.

Fig. 4 depicts the free energy of the system as a function of γ_{HS} in the temperature range of the hysteresis loop (286–310 K). The curves have been calculated using Eq. (1) with the parameters ΔH = 25 kJ mol^{-1}, ΔS = 84 J K^{-1} mol^{-1} and Γ = 7.11 kJ mol^{-1} in nice agreement with our previous investigations [5,13]. The larger parameter Γ compared to the value evaluated for single crystals allows for the wider hysteresis loop (24 K for the microcrystalline powder instead of 14 K for the single crystal [5]).

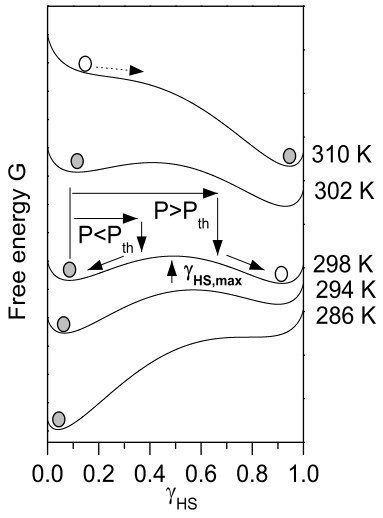

Fig. 4. Temperature dependence of the free energy as a function of the HS fraction calculated using Eq. (1) with the parameters ΔH = 25 kJ mol^{-1}, ΔS = 84 J K^{-1} mol^{-1} and Γ = 7.11 J mol^{-1}. Grey spheres indicate the thermal population and white spheres the photo-induced population with one laser shot at 532 nm.

The minimum of the potential energy curve increases from $\gamma_{HS} \approx 0$ to ≈ 1 with the temperature. At 298 K, an energy barrier stands at $\gamma_{HS} \approx 0.49$ (noted $\gamma_{HS,max}$). These potential energy curves provide information on the mechanism at the origin of the photo-excitation energy density threshold (P_{th}). Before irradiation the sample is in the LS state ($\gamma_{HS} \approx 0$). After a pulsed excitation is applied, the HS fraction rises instantaneously. When the converted HS fraction is lower than $\gamma_{HS,max}$, the system recovers its initial state. However, as soon as γ_{HS} exceeds $\gamma_{HS,max}$, the irradiated sample reaches a pure HS state. In the frame of our model, the material is considered homogeneous, that is as a single domain. Therefore the mixed states arising from either a distribution of complexes with different macroscopic energy barriers or the nucleation and growth of photo-induced spin domains [8,14] cannot be reproduced. The occurrence of such phenomena should be investigated by considering other models [15], which is far beyond the scope of this paper.

The decrease in the threshold value P_{th} under heating can be also understood with the potential energy curves of Fig. 4. Within the hysteresis loop, the value of $\gamma_{HS,max}$ depends on the temperature. For instance, $\gamma_{HS,max}$ is higher at 294 K ($\gamma_{HS,max}$ = 0.57) than at 298 K ($\gamma_{HS,max}$ = 0.49). To jump over the energy barrier located at $\gamma_{HS,max}$ at 298 K, a lower laser energy density is required, and consequently, for a given excitation energy density, the conversion efficiency will increase with temperature, which nicely matches our experimental results reported in Fig. 3. However we cannot exclude the possibility that some laser-induced heating is able to contribute more efficiently to the switching process at higher temperature.

4. Conclusions

The single-laser-pulse-induced LS to HS photo-conversion has been investigated on the polycrystalline SCO complex Fe(pyrazine)[Pt(CN)$_4$]. The main finding of this work is the clear observation of an energy density threshold of *ca.* 5 mJ/cm^2, below which no photo-induced phase transition occurs. On the other hand, above this value, a rapid increase in photoconversion occurs up to an energy density of *ca.* 20 mJ/cm^2. For higher values a complete phase transformation takes place. The experimental observation of the decrease of this threshold with increasing temperature is corroborated by a simple theoretical description which does not take nucleation and growth of spin domains into account.

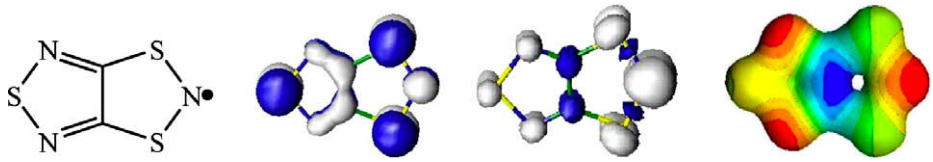

Fig. 1. Left to right: molecular structure, SOMO (white indicates positive values and blue negative ones), spin density (white indicates positive values and blue negative ones), and molecular electrostatic potential map (MEP map, red indicates regions of negative electron density, minimum −0.15259 atomic units, and blue regions of positive electron density, maximum +0.28326 a.u.) of **1**.

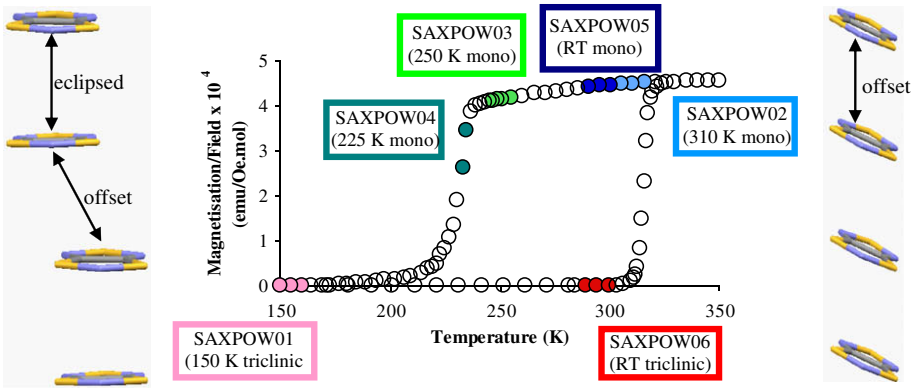

Fig. 2. *Centre*: Magnetization curve of **1** as a function of the temperature (two polymorphs are known, and their structures have been recorded at various temperatures, as identified in the figure); *Left*: structure of one of the stacks in the low temperature (triclinic) phase; *Right*: structure of one of the stacks in the high temperature (monoclinic) phase.

level provides values [2,3] of $J_{intra} = -220\ cm^{-1}$ and $J_{inter} = -42\ cm^{-1}$ (both J_{AB} values refer to the $\hat{H} = -2\Sigma_{A>B} J_{AB}\hat{S}_A\hat{S}_B$ Heisenberg Hamiltonian). In our studies, we began by investigating the mechanism of the magnetic interaction of both polymorphic forms using the first principles bottom-up methodology [7]. In this work we report the results for the high temperature phase as the first step in the study. The first principles bottom-up procedure is an advanced theoretical methodology that derives the macroscopic magnetic properties from the microscopic J_{AB} interactions in a rigorous way. In this manner, one can gain an insight into how the individual magnetic interactions are modified when the phase transition occurs, irrespective of the exact pathway followed during the transition. This is a preliminary step of the overall project, which is aimed at understanding the structural factors that result in the existence of these two minimum energy structures on the potential energy surface of the crystal. In other words, we are studying the way in which the phase transition takes place between the two polymorphs and why it follows a different pathway when going from the low towards the high temperature polymorph, compared to the reverse transition.

2. Computational details

The first principles bottom-up methodology computes the macroscopic magnetic properties using the crystal structure data as the only input, in other words without making any starting assumptions about the nature or strength of the magnetic interactions that couple the radicals of the crystal. The methodology is described in the following four steps [7]:

(1) Analysis of the crystal structure to find all unique radical–radical pairs present in the crystal, in this case the room temperature data set of **1** (see Fig. 2), whose refcode in the Cambridge Structural Database is SAXPOW05. All the other high temperature data sets (SAXPOW02, 03 and 04) give the same crystal analysis results;
(2) Computation of the radical–radical magnetic exchange coupling interactions (J_{AB}) for each unique radical–radical pair found in the crystal;
(3) Determination of the magnetic topology of the crystal and some possible magnetic models derived from the infinite magnetic topology;
(4) Calculation of the macroscopic magnetic properties of the crystal using the full energy spectrum obtained by diagonalisation of the matrix representation of the appropriate Heisenberg Hamiltonian (the matrix representation is computed in the space of the spin functions of the magnetic models). This matrix representation is a function of the J_{AB} pair interactions whose values were computed in step 2. The smallest model that leads to a magnetic susceptibility curve that most closely agrees with the experimental data is called the *minimal magnetic model*.

The procedure is called *bottom-up* because the macroscopic magnetic properties are obtained from the microscopic radical–radical magnetic interactions without making any assumptions of the type of mechanism acting between the radicals of the crystal. It is referred to as *first principles* because the J_{AB} for each pair is obtained from the energy difference between the appropriate states computed by first principles methods (accurate *ab initio* [8] or DFT methods [9]). Once the J_{AB} values have been computed, one can diagonalise the corresponding matrix representation of the Heisenberg Hamiltonian. We have used the following Heisenberg Hamiltonian, which allows the use of faster computer codes:

$$\hat{H} = -2\sum_{A,B} J_{AB}(\hat{S}_A \cdot \hat{S}_B + \frac{1}{4}\hat{I}_{AB}) \quad (1)$$

where $\hat{I}_{AB}$ is the identity operator while $\hat{S}_A$ and $\hat{S}_B$ are the spin operators acting on radicals A and B. The energy spectrum computed using this Hamiltonian results in the same energy differences between eigenvalues as those obtained using the more common expression (Eq. (2)) and thus in the same susceptibility curve:

$$\hat{H} = -2\sum_{A,B} J_{AB}\hat{S}_A \cdot \hat{S}_B \qquad (2)$$

The energy spectra for these Hamiltonians are obtained by diagonalisation of their matrix representation on the basis of the spin-eigenfunctions of a finite crystal model that mimics the magnetic properties of the infinite crystal (the so-called *minimal magnetic model space*). This allows the rigorous computation of the macroscopic magnetic properties using the appropriate statistical mechanical expressions.

The minimal magnetic model space is selected once the magnetic topology of the crystal is determined (step 3 in the first principles bottom-up procedure) in terms of the magnetic connectivity that the non-negligible $\boldsymbol{J}_{AB}$ pair interactions define between the radicals. It is formed by the smallest group of radicals whose propagation along the three crystallographic axes reproduces the topology and therefore the infinite crystal. This model must include all significant $\boldsymbol{J}_{AB}$ interactions in proportions as similar as possible to those found in the infinite crystal. Furthermore, the macroscopic properties computed using these finite spaces should converge towards the experimental data (which would theoretically correspond to the infinite crystal) as they are enlarged. Note that the index of the matrix representation of the Heisenberg Hamiltonian increases with the number N of doublet radical centres as $N!/[(N/2)!(N/2)!]$. In practice, this means that we are limited to a maximum of 16 different spin centres.

The only spin-carrying units in the crystals of **1** are the 1,3,5-trithia-2,4,6-triazapentalenyl (abbreviated to TTTA) radicals. Each molecular unit is a doublet radical, with the radical electron formally ascribed to the deprotonated N atom present in the dithiazolyl five-membered ring (see Fig. 1). However, as illustrated in Fig. 1, the unpaired electron is in fact delocalised over both heterocyclic rings due to spin polarization, although most of it remains located at the parent N atom. This delocalisation is potentially important in terms of magnetic exchange, and is consistent with results from EPR studies on dilute solutions [3,10,11] and with previous DFT calculations [3,11].

Only two states are therefore possible when two TTTA radicals interact in any of the radical–radical pairs found in crystals of **1**: a singlet state and a triplet state. The value of $\boldsymbol{J}_{AB}$ for each pair is thus obtained from the energy difference between the open-shell singlet and triplet states, computed at the crystal geometry of the pair. Both energies were calculated for the room temperature data set (SAXPOW05) using the B3LYP functional [12,13] and 6-31+G(d) basis set [14,15], and for the 250 K data set (SAXPOW03) using the same functional and the aug-c-pVTZ basis set [16]. All these calculations were done using the GAUSSIAN 03 package [17]. Note that the broken-symmetry approximation [18,19] was used to compute the open-shell singlet, thus allowing a proper description of the energy of this state. Within this approximation the value of $\boldsymbol{J}_{AB}$ for Hamiltonians (1) and (2) is obtained as $2\boldsymbol{J}_{AB} = 2(E^S_{BS} - E^T)$, where E^T is the energy of the triplet state and E^S_{BS} is the energy of the singlet state found using the broken-symmetry approach (the expression for $\boldsymbol{J}_{AB}$ derives from the original broken-symmetry equations when the SOMO orbitals of the two radicals do not overlap or their overlap is small, which is the usual situation in through-space magnetic interactions, such as those found in the TTTA crystal). Our experience indicates that this expression gives results closer to the experimental values than other approaches where projection is used [20,21]. The first principles bottom-up methodology has been successfully applied to a series of crystals representative of a variety of macroscopic behaviours [22–29].

3. Results and discussion

The first principles bottom-up procedure begins with the search for all unique radical pairs in the SAXPOW05 crystal. The selection was made by taking all pairs whose centroid–centroid (calculated centre of mass) separation was smaller than 8.0 Å (this includes all first nearest neighbours, and some second nearest neighbours). The 11 unique radical pairs resulting from this selection are those given in Fig. 3, where the shortest interatomic contacts between the two molecules of the pair are highlighted. The radical centres that are linked by these pairs and their relative positions within the SAXPOW05 crystal are indicated in Fig. 4. In some of these pairs (A, D, J, and K) the radicals of the pair approach each other in a π–π sense that allows a more efficient overlap of their π-type SOMO orbitals (dependent on distance), while in the remaining pairs the radicals are either placed such that the SOMO–SOMO overlap is restricted to being in a lateral sense, or the pair geometry is a compromise between these two extremes. Particularly relevant is Pair A, the intra-stack radical pair that was taken in previous studies as being responsible for the observable magnetic properties of this crystal (its propagation gives rise to the π-stacks perpendicular to the *ac* plane). The radicals in Pair A associate with a slipped π–π geometry with one radical slightly laterally offset relative to the other (see Fig. 2, right). It should be pointed out that Pair A does not in fact contain the shortest intermolecular atom-atom contact distance between two radicals.

The value of $\boldsymbol{J}_{AB}$ was computed (step 2 of the first principles bottom-up procedure) for each of the 11 unique pairs using the procedure indicated above from the values of the energy computed at the B3LYP/6-31+G(d) level for the triplet and the broken-symmetry singlet. The dependence on the basis set of the Pair A value was tested by doing B3LYP calculations on the $\boldsymbol{J}_{AB}$(A) value for the room temperature data set (SAXPOW05) using the 6-31+G(d), aug-cc-pVDZ and aug-cc-pVTZ basis sets. The results obtained with these basis sets, using the B3LYP functional, were −134.5, −149.0 and −155.6 cm^{-1}, respectively, thus confirming the convergence of the $\boldsymbol{J}_{AB}$(A) value as the basis set is increased. This convergence, coupled with the better agreement with the experimental data of the susceptibility curve calculated from the SAXPOW03 (250 K) data, led us to focus on the SAXPOW03 data set and the larger basis set (aug-cc-pVTZ). The 8 magnetically significant $\boldsymbol{J}_{AB}$ values (Pairs A–H) were therefore recalculated under these conditions. These 8 pairs include all 12 first nearest neighbours and are shown as a group in Fig. 5). The results thus obtained are collected in the last column of Table 1 (the $\boldsymbol{J}_{AB}$ values for the three disregarded dimers (I, J and K) are given for completeness although they were not recalculated under the new conditions). Three of these $\boldsymbol{J}_{AB}$ parameters have absolute values smaller than 0.5 cm^{-1}, seven absolute values in the range 0.5–10 cm^{-1}, and the remaining value is an order of magnitude larger, −183.8 cm^{-1}. The presence of a similar number of ferromagnetic and antiferromagnetic interactions among these values should also be noted, although the dominant magnetic interaction is antiferromagnetic.

Using the $\boldsymbol{J}_{AB}$ values the magnetic topology can be constructed and a proper minimal magnetic model space that represents the magnetic structure of the crystal can be extracted from the infinite topology. The magnetic topology that is constructed from $\boldsymbol{J}_{AB}$ pair interactions whose absolute value is larger than 0.5 cm^{-1} is shown in Fig. 6a. This is a 3D topology that can be qualitatively described as a set of weakly interacting antiferromagnetic 1D chains (the geometrical and magnetic details of each 1D chain are shown from a side-on perspective in Fig. 6b). From this topology, and from

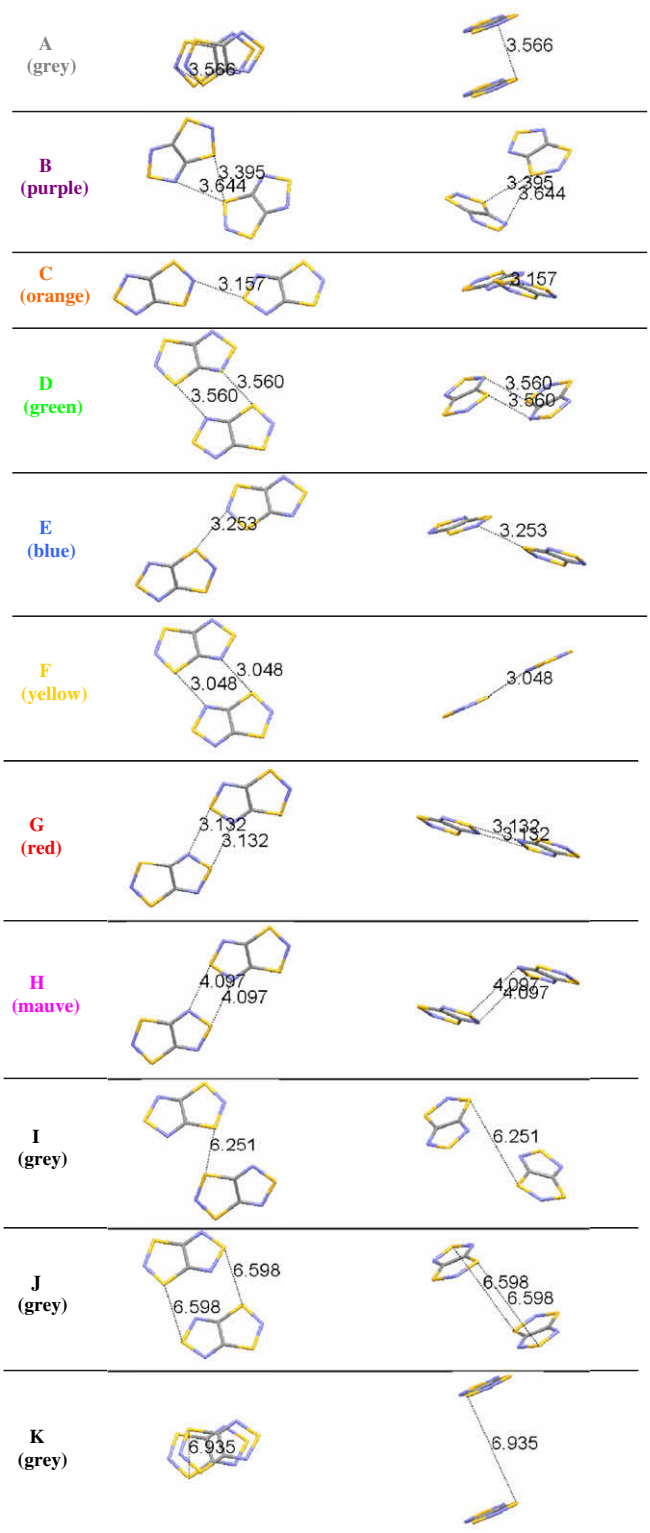

Fig. 3. Top and side views (left- and right-hand columns, respectively) of the geometry of the 11 unique pairs found in the high temperature (monoclinic) structure of **1**. Contact distances correspond to the room temperature data set, SAXPOW05. The shortest interatomic contacts found within each pair are indicated. Each pair is identified with the letters A to K, where the colour of each letter reflects the atomic colouring scheme used in Fig. 3 for letters A to H (its name is also given in parentheses). The molecules in this figure are coloured according to atom type, N: blue, S: yellow and C: grey. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

testing the susceptibility that is calculated with a wide range of different finite magnetic models, we conclude that the most

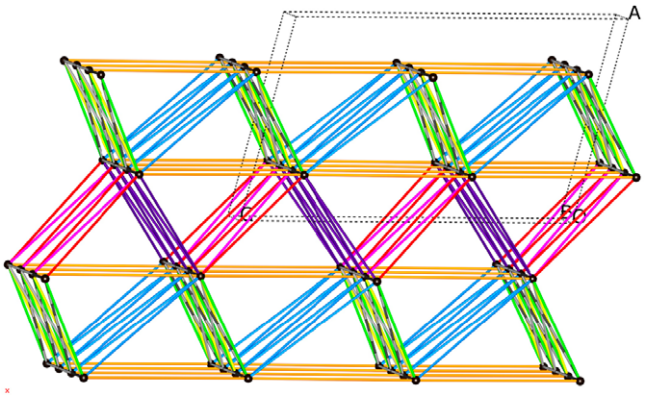

Fig. 4. Arrangement of the linkages in the 11 unique pairs in the high temperature structure of **1**. Each pair is identified by a coloured line that links the two radicals of the pair. Black dots denote the calculated centroids of the radicals. Some of the radical pairs are not clearly observed (I, J, K) because their exchange lines overlap with those for other pairs. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

appropriate 3D minimal magnetic model space involving a maximum of 16 centres is that depicted in Fig. 7, which is a set of four 1D chains connected via their intra- and inter-chain interactions (and thus will be referred to hereafter as the 4-4s model). Note that when only the strongest J_{AB} interaction ($J_{AB}(A) = -183.8\ cm^{-1}$) is considered to be magnetically relevant this is equivalent to making all inter-stack interactions equal to zero, and in this case the minimal magnetic model space would be just a chain of four spin sites, as depicted in Fig. 6b (hereafter referred to as the 1-4s model).

Using the 4-4s magnetic model one can compute the energy spectra of the magnetic states in this finite space (this is done by diagonalising the matrix representation of the Heisenberg Hamiltonian that is based on the spin functions of the spin states of this finite space, corresponding to step 4 of the first principles bottom-up procedure). From there, one can compute the magnetic susceptibility curve for the high temperature polymorph of **1** at temperatures above 250 K (see Fig. 2). The calculation was also carried out using the 1-4s model to compare the results for the 3D magnetic model space with those where the inter-stack interactions have been omitted, and with the results from a chain of 16 nodes (hereafter identified as the 1-16s model). As shown in Fig. 8, the magnetic susceptibilities computed using the 4-4s and 1-4s models overlap with each other and also closely coincide with the experimental curve in the region above 250 K. It is also observed in Fig. 8 that when the 1-16s model is used the computed curve nearly matches the experimental one. The small differences that remain between the 1-16s and experimental curve are probably due to the thermal variation in the geometry of the radical pairs due to thermal expansion that leads to differences in the magnitude of J_{AB}. For instance, in the room temperature structure the shortest S...S distance in Pair A is 3.711 Å, which becomes 3.681 Å in the 250 K structure. Note that the magnetic susceptibility curve in Fig. 8 was computed using only the J_{AB} pair interactions computed from the 250 K structure. One can also expect that results computed using a 4-16s model should be identical to those obtained with the 1-16s model, but this model is to large to allow its calculation with our current resources.

We have also investigated why the 1-4s and 4-4s models give nearly identical magnetic susceptibility curves above 250 K. Fig. 9 shows the energy spectra computed with these two models. Obviously the number of spin states is a lot larger in the 4-4s space, a fact that explains the higher density of states of this model. However, the calculation of the magnetic susceptibility using statistical mechanical methods depends only on the energy difference

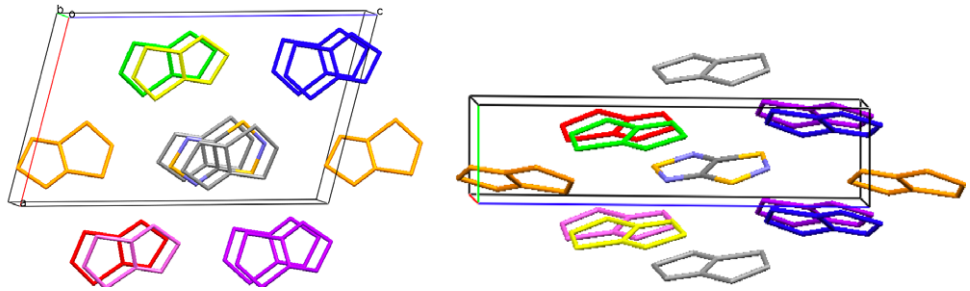

Fig. 5. Top (left) and side (right) views of the crystal structure of the high temperature phase of **1** at room temperature (SAXPOW05). The central molecule is the multicoloured one in the centre, and the neighbours are identified according to the colouring scheme employed in Figs. 3 and 4. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 1
Values of the J_{AB} parameters (in cm^{-1}) computed for the 11 unique radical pairs found in the SAXPOW03 crystal. The values have been computed by doing B3LYP/aug-cc-pVTZ calculations, except the smallest three, which were computed using the 6-31+G(d) basis and the room temperature structure (SAXPOW05) and given their small size were not recomputed. The centroid–centroid separation and the value and nature of the closest atom-atom contact are also described (as π–π, twisted or a lateral contact).

Pair	Centroid sepn. (Å)	Shortest atom–atom contact (Å)	Between atoms	J_{AB}
A	3.681	3.553	S···N (π–π)	−183.8
B	5.805	3.379	S···S (twist)	+9.9
C	7.536	3.146	S···N (twist)	−8.9
D	5.162	3.539	S···N (π-π)	+6.5
E	7.134	3.242	S···N (twist)	+2.7
F	5.501	3.038	S···N (lateral)	−0.9
G	6.720	3.119	S···N (lateral)	−1.4
H	6.984	4.071	S···N (lateral)	+0.8
I[a]	7.832	6.251	S···S (twist)	−0.2
J[a]	7.109	6.598	S···S (π–π)	−0.1
K[a]	7.422	6.935	S···S (π–π)	−0.1

[a] Structural parameters and J_{AB} for I, J and K correspond to the SAXPOW05 data set. J_{AB} are calculated using the 6-31+G(d) basis set. Thus only I, J and K correspond to the contacts given in Fig. 4 and contacts (and J_{AB}) given here for A–H correspond to the 250 K data set. Data for I, J and K was not re-calculated with the larger basis set due to their numerically small size.

between consecutive spin states. The energy difference between states that lie close together (i.e. are almost degenerate) is negligible, so the only differences expected to have an impact on the susceptibility are those between states that are far apart in energy. We can see from Fig. 9 that the lowest lying and therefore most easily thermally populated states are in fact well separated. Looking only at the lowest energy states of singlet and triplet multiplicity, the $[E_0(T) - E_0(S)]$ value for the lowest two states is 177.2 E_h in the 1-4s model and 166.0 E_h in the 4-4s model. A similar energy gap is observed when comparing the two lowest energy singlets ($[E_1(S) - E_0(S)]$, 465.8 and 337.8 E_h, respectively), or the two lowest energy triplets of groups of close-lying states ($[E_1(T) - E_0(T)]$, 190.2

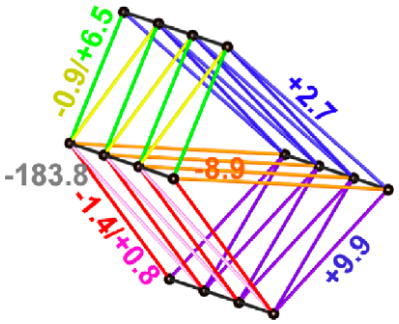

Fig. 7. Minimal 3D magnetic model space (4-4s) that reproduces the properties of the magnetic topology shown in Fig. 6.

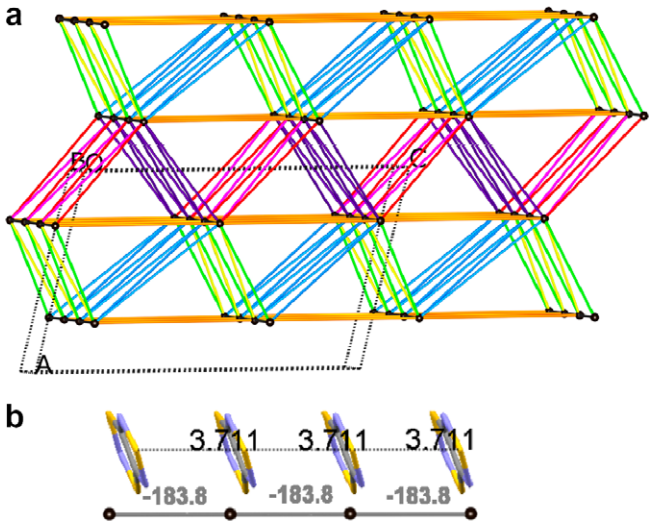

Fig. 6. (a) Magnetic topology generated within the room temperature structure of **1** by the 8 non-negligible radical pairs (A to H). The strongest-interacting J_{AB} pair is drawn in grey, connecting the stacks along the *b*-direction (note the 3D character of the magnetic topology); (b) lateral view of the π-stacks chains found along the *b* axis (showing the J_{AB} magnetic exchange interactions and the relative geometry and regular atomic spacing between neighbouring radicals in the chains).

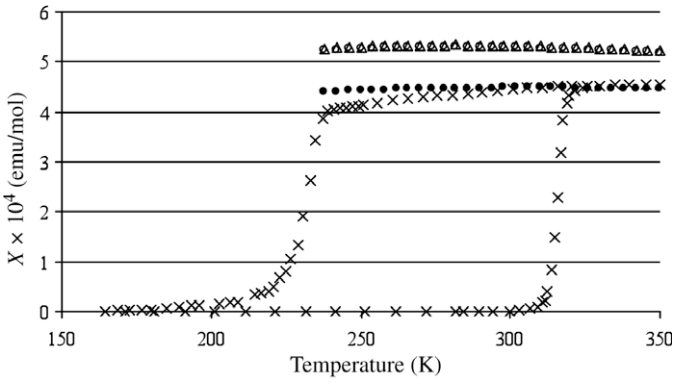

Fig. 8. Magnetic susceptibility curve computed for the 250 K data set of **1** (SAXPOW03) using the 4-4s (△), 1-4s (○), and 1-16s (●) models. The experimental results (×) are given for comparison. It is important to keep in mind here that the high temperature polymorph of **1** only exists above 250 K. Within this range the qualitative agreement between the computed and experimental values is good for the *x*-4s models and excellent for the 1-16s model.

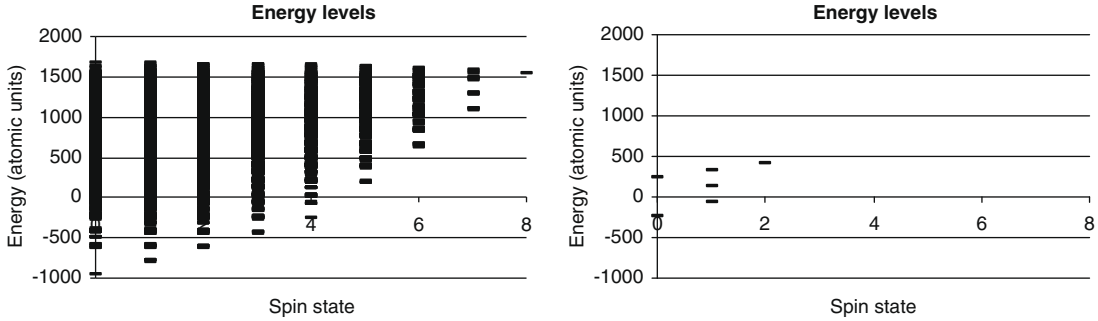

Fig. 9. Energy spectra for the 4-4s model (left) and 1-4s model (right).

E_h in the 1-4s model and $[E_5(T) - E_0(T)]$ 165.0 E_h in the 4-4s model). Similar trends are also observed in other cases. Therefore, as the dominant terms in the expression of the macroscopic magnetic susceptibility are those including a non-negligible ΔE, the reason behind the similarity in the magnetic susceptibility curves computed using the 1-4s and 4-4s models is a likeness in the non-negligible ΔE terms.

4. Conclusions

The first principles bottom-up study of the high temperature phase of the TTTA radical at room temperature indicates that there are 11 unique radical pairs. When the value of the $\boldsymbol{J}_{AB}$ pair interactions are computed for all these pairs at the B3LYP/aug-cc-pVTZ level one finds 8 that have absolute values larger than 1 cm^{-1}, some of them ferromagnetic and others antiferromagnetic, with one very large interaction (-183.8 cm^{-1}) and all other interactions having an absolute value smaller than 11 cm^{-1}. After making improvements based on basis set and the temperature at which the data set is recorded, a second set of 8 $\boldsymbol{J}_{AB}$ values is calculated for the 250 K data set using the aug-cc-pVTZ basis set. These values have been used to calculate the bulk magnetic susceptibility above 250 K and we obtain good agreement with the experimental curve and reveal a higher level of detail than that available from previous experimental fitting studies. The magnetic topology of these interactions is clearly 3D and is characterised by weakly interacting antiferromagnetic 1D chains. However, the magnetic susceptibility curves computed using the full 3D model or one comprising only isolated 1D chains are practically identical. This fact is explained by the fact that the magnetic susceptibility expression depends on energy differences, and that the energy differences in the smaller model are similar to those for the larger model. However, the 3D nature of the magnetic topology suggests that the origin of the bistability of this material must be fully investigated by considering not only at the changes within the stacks but also the interstack interactions. This is the aim of further studies that will compare this data with the magnetic properties of the low temperature phase of the TTTA radical, looking for the main microscopic differences between the polymorphs and how they are related to the intermolecular bonds being created and broken.

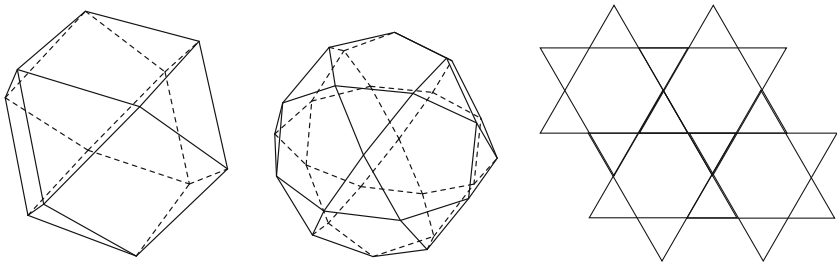

Fig. 1. Cuboctahedron, icosidodecahedron, and (part of the) kagome lattice.

3. The regular cuboctahedron

The regular cuboctahedron belongs to the class of geometrically frustrated antiferromagnets built of corner-sharing triangles. Such systems possess an extended magnetization plateau at 1/3 of the saturation magnetization $\mathscr{M}_{\rm sat}$ caused by dominant up–up–down contributions [23,24], an unusually high jump of the magnetization at the saturation field due to independent magnons [22,6] as well as low-lying singlets below the first triplet level [29,30,24]. These features are shared for instance by the icosidodecahedron and by the kagome lattice.

Fig. 2 shows the magnetization curves at $T = 0$ for the regular cuboctahedron with $s = 1/2$, $s = 1$, and $s = 3/2$. These curves show besides the plateau at $\mathscr{M}_{\rm sat}/3$ a jump to saturation of height $\Delta M = 2$. Both features are reflected by the differential susceptibility function which is displayed in Fig. 3. Each step in Fig. 2 corresponds to a peak in Fig. 3. One notices that the peaks are washed out for higher temperatures, but that the minimum that corresponds to the plateau at $\mathscr{M}_{\rm sat}/3$ persists up to temperatures of the order of the exchange coupling.

As a function of the intrinsic spin s the differential susceptibility $\mathrm{d}\mathscr{M}/\mathrm{d}B$ exhibits two properties. With increasing spin quantum number s the individual peaks oscillate more and more with smaller relative amplitude, but the minimum at 1/3 is actually sharpened. It is known that in the classical limit, i.e. for $s \to \infty$, the differential susceptibility is practically flat below the saturation field except for the dip at 1/3 [23].

For zero-field Fig. 4 shows the low-lying energy levels. In the case of $s = 1/2$ (l.h.s. of Fig. 4) one notices the low-lying singlets below the first triplet. These states are a cornerstone of geometric frustration and as well present in the kagome lattice and the icosidodecahedron with $s = 1/2$ [29]. It is interesting to note that with increasing s, i.e. towards a more classical behavior, the number of these states decreases. For $s = 1$ (middle of Fig. 4) the first excited singlet level is already (slightly) above the lowest triplet level. For $s = 3/2$ (r.h.s. of Fig. 4) a doubly degenerate excited singlet level remains below the lowest triplet, the others have disappeared. This behavior, i.e. no excited singlets below the lowest triplet for integer spins and a doubly degenerate excited singlet below the lowest triplet, does not change anymore for higher spin quantum numbers as can be checked e.g. by Lanczos methods.

The rather high symmetry of the cuboctahedron leads to many degenerate energy levels. As examples we label some low-lying energy levels in Fig. 4 by their multiplicity d_S, i.e. by the degeneracy of the whole multiplet. The full degeneracy including the multiplicity of the magnetic sublevels d_M is then $d = d_S \times d_M$. Clearly, such high multiplicities have an important impact on the magnetocaloric behavior since they increase the entropy for low temperatures [30,31]. In the following we would like to discuss the impact of low-lying singlets below the first triplet which in the case of extended lattices are supposed to condense in infinite number onto the ground state.

Fig. 5 compares the heat capacity (l.h.s.) and the zero-field susceptibility (r.h.s.) for the regular cuboctahedron with $s = 1/2$, $s = 1$, and $s = 3/2$. The heat capacity shows a pronounced double peak structure for $s = 1/2$ and $s = 1$ which dissolves into a broad peak with increasing spin quantum number. The broad peak also moves to higher temperatures with increasing s. The reason for the first sharp peak is twofold. Since there are several gaps between the low-lying levels the density of states has a very discontinuous structure which results in the double peak structure. For $s = 1/2$ the low-lying singlets provide a very low-lying non-magnetic density of states which is responsible for the fact that the first sharp peak is at such low temperatures. For $s = 1$ the first sharp peak results from both excited singlet as well as lowest triplet levels. For $s = 3/2$ a remnant of the first sharp peak is still visible; it is given by the low-lying singlets, but since they are so few, also influenced by the lowest triplet levels.

The behavior of the heat capacity is contrasted by the susceptibility on the r.h.s. of 5 which reflects mostly the density of states of magnetic levels and is only weakly influenced by low-lying singlets. Therefore, the first sharp peak, or any other structure at very low temperatures, is absent.

4. The irregular cuboctahedron

In this section we investigate how the magnetic properties of the cuboctahedron change if random variations of the exchange coupling parameters are introduced. This study is motivated by

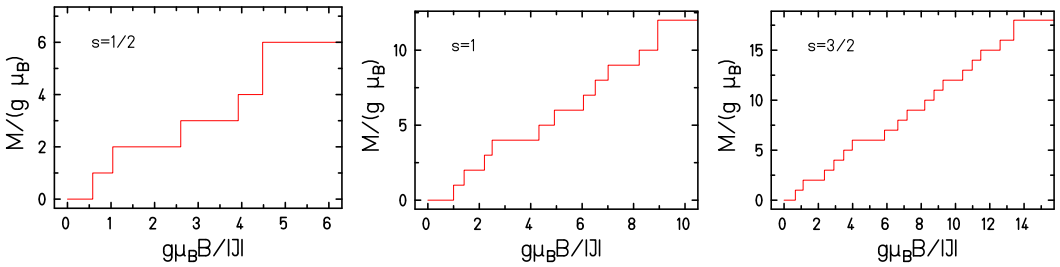

Fig. 2. Magnetization as a function of applied field at $T = 0$ for the regular cuboctahedron with $s = 1/2$, $s = 1$, and $s = 3/2$. The extended plateau at $\mathscr{M}_{\rm sat}/3$ is clearly visible.

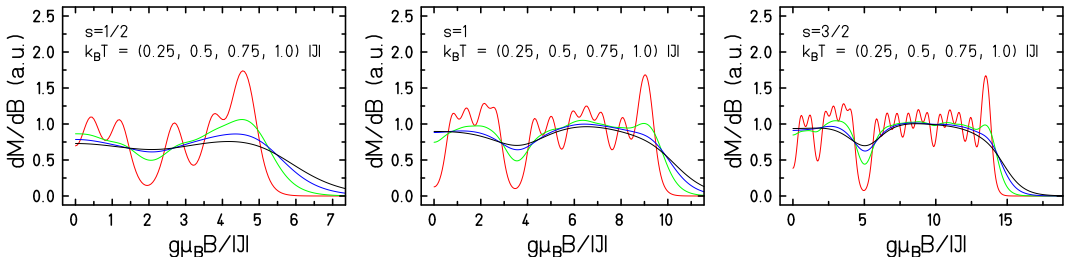

Fig. 3. Differential susceptibility as a function of applied field at $k_BT/|J| = 0.25, 0.5, 0.75, 1.0$ for the regular cuboctahedron with $s = 1/2$, $s = 1$, and $s = 3/2$. The smoother the curve, the higher the temperature.

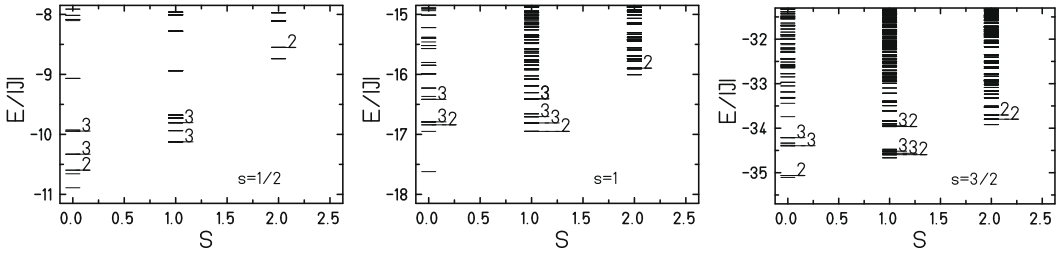

Fig. 4. Low-lying energy levels for the regular cuboctahedron with $s = 1/2$, $s = 1$, and $s = 3/2$. Numbers attached to selected levels denote their multiplicities d_S; unlabeled levels below the highest labeled level have $d_S = 1$.

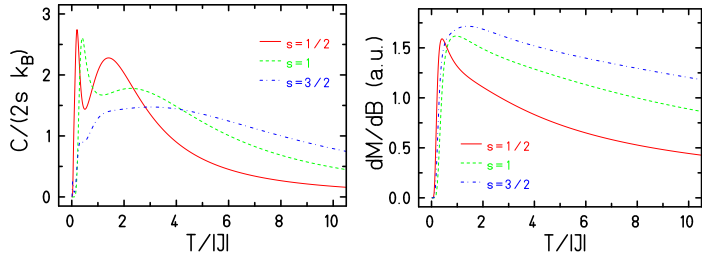

Fig. 5. Heat capacity (l.h.s.) and zero-field susceptibility (r.h.s.) for the regular cuboctahedron with $s = 1/2$, $s = 1$, and $s = 3/2$.

recent magnetization measurements of the icosidodecahedral molecules $\{Mo_{72}Fe_{30}\}$ [18] and $\{Mo_{72}Cr_{30}\}$ [20] published in Ref. [28], which were interpreted by assuming random distributions of exchange parameters in a classical Heisenberg model description.

We introduce variations of the exchange parameters of the Hamiltonian (1) by replacing the common nearest-neighbor exchange parameter $J_{uv} = J$ with values of a flat random distribution $J - 0.5\Delta \leqslant J_{uv} \leqslant J + 0.5\Delta$. Thus the mean exchange parameter is kept to be J. In order to gain sufficient statistical certainty we use ensembles of 10 000 spectra for realizations of the irregular cuboctahedron with $s = 1/2$; the results do not deviate from those for 1000 realizations. For larger s the production of sufficiently large ensembles is hindered by prohibitively many diagonalizations of larger matrices.

Fig. 6 shows the differential susceptibility that results from averages using distributions with various Δ. The figure on the l.h.s. compares $\mathrm{d}\mathscr{M}/\mathrm{d}B$ at the rather low temperature of $k_BT = 0.1|J|$ for $\Delta = 0$, i.e. the regular cuboctahedron, with $\Delta = 0.5|J|$, $\Delta = 1.0|J|$, and $\Delta = 2.0|J|$. One clearly sees that the pattern which mainly originates from ground state level crossings does not change much for $\Delta = 0.5|J|$ and $\Delta = 1.0|J|$. It needs a variation as large as $\Delta = 2.0|J|$, i.e. ferromagnetic interactions occur, to qualitatively change the differential susceptibility function. The reason is that smaller variations do no alter the structure of low-lying energy gaps. The

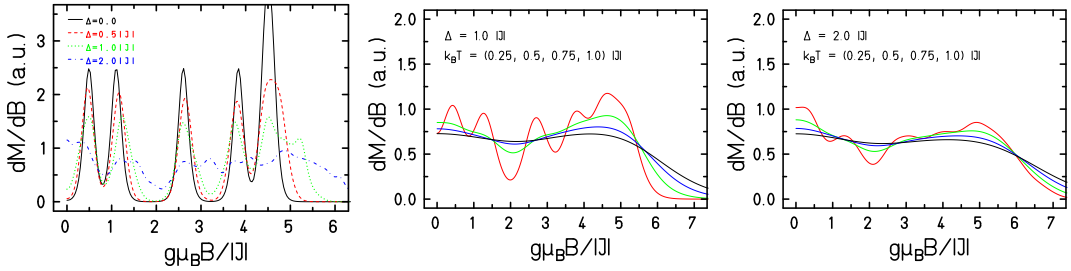

Fig. 6. Differential susceptibility as a function of applied field for the irregular cuboctahedron with $s = 1/2$. L.h.s.: dependence on the width Δ of the random distribution. Middle: dependence on the temperature $k_BT/|J| = 0.25, 0.5, 0.75, 1.0$ for $\Delta = 1.0|J|$. R.h.s.: same as middle for $\Delta = 2.0|J|$.

singlet–triplet gap, which is approximately 0.765 $|J|$, does not vary very much for the ensembles with smaller Δ, and so does the singlet–triplet crossing which is determined by the singlet–triplet gap. It needs an appreciable variance of the exchange parameter distribution in order to impose large variations of the level crossing fields.

The middle and the r.h.s. of 6 display $\mathrm{d}\mathscr{M}/\mathrm{d}B$ for temperatures $k_BT/|J| = 0.25, 0.5, 0.75, 1.0$ and $\Delta = 1.0|J|$ and $\Delta = 2.0|J|$, respectively. As already explained, there is only very little difference between the behavior of an irregular cuboctahedron with $\Delta = 1.0|J|$ (middle) and the regular one. For $\Delta = 2.0|J|$ (r.h.s.) the differential susceptibility is much more smeared out which includes an appreciable broadening at the saturation field. Considering the irregular cuboctahedron we can conclude that the magnetic properties are rather stable against random fluctuations of the exchange parameters. This means that the striking behavior especially of the experimental differential susceptibility of $\{M0_{72}Fe_{30}\}$ and $\{Mo_{72}Cr_{30}\}$ which shows no signs of level crossings at all [28] needs further theoretical exploration of the microscopic origin.

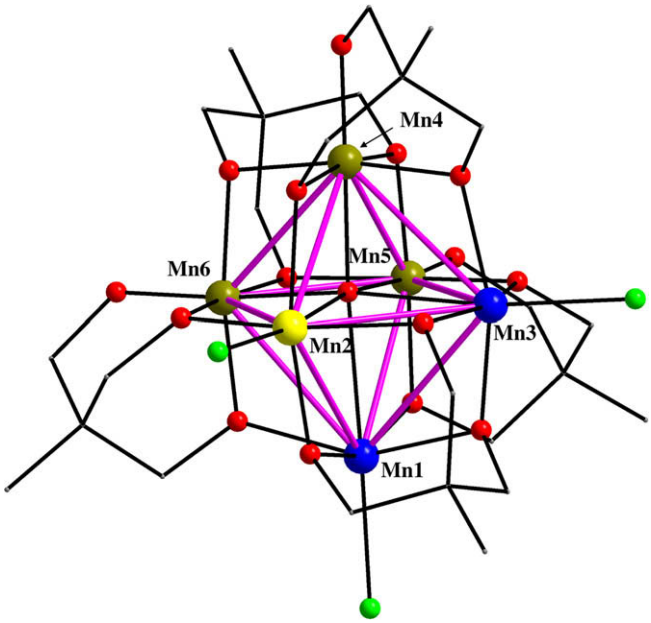

Fig. 1. Partially labeled representation of complex **1** with Mn–Mn vectors shown in purple to emphasize the Mn_6 octahedron. H atoms have been omitted for clarity. Colour scheme: Mn^{II} yellow; Mn^{III} blue; Mn^{IV} olive; O red; Cl green; C grey. (For interpretation of the references to colour in figure legends, the reader is referred to the web version of this article.)

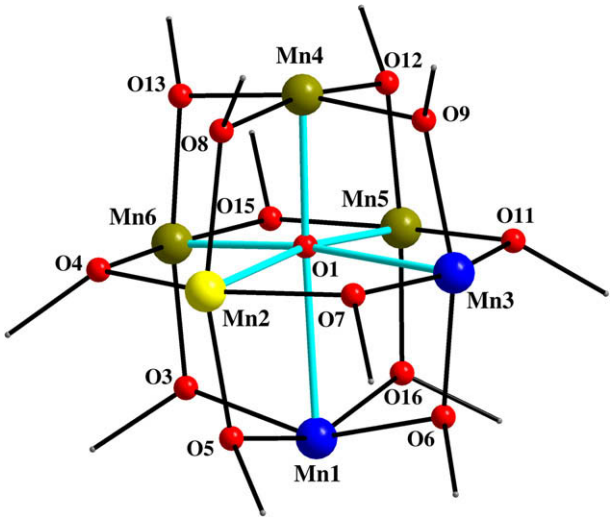

Fig. 2. Labeled PovRay representation of the complete $[Mn_6(\mu_6\text{-}O)(\mu\text{-}OR)_{12}]^{6+}$ core, emphasizing the central $[Mn_6(\mu_6\text{-}O)]^{18+}$ unit. Colour scheme as in Fig. 1.

Mn(1)–Mn(3), with the C_3 axis passing through central O1 and perpendicularly through the midpoint of the Mn(1)–Mn(3) triangular plane. Atoms Mn(1) and Mn(2) are thus related by a virtual mirror plane, and it is perhaps not unreasonable that they would be statically disordered about it. In fact, the virtual symmetry of the molecule is C_S if we distinguish Mn^{III} atom Mn(3) from the disordered pair Mn(1)/Mn(2), the mirror plane passing through Mn(3), Mn(6), O(1), O(5) and O(12) (Fig. 2).

All Mn atoms are six-coordinate with distorted octahedral geometry, and only Mn(3) atom shows clearly the Jahn-Teller (JT) distortion expected for a high-spin, Mn^{III} (d^4) ion in near-octahedral geometry, taking the form of an axial elongation of the two *trans* Mn(3)–Cl(2) (2.329(1) Å) and Mn(3)–O(1) bonds (2.398(3) Å). There are no strong intermolecular hydrogen-bonds, only weak

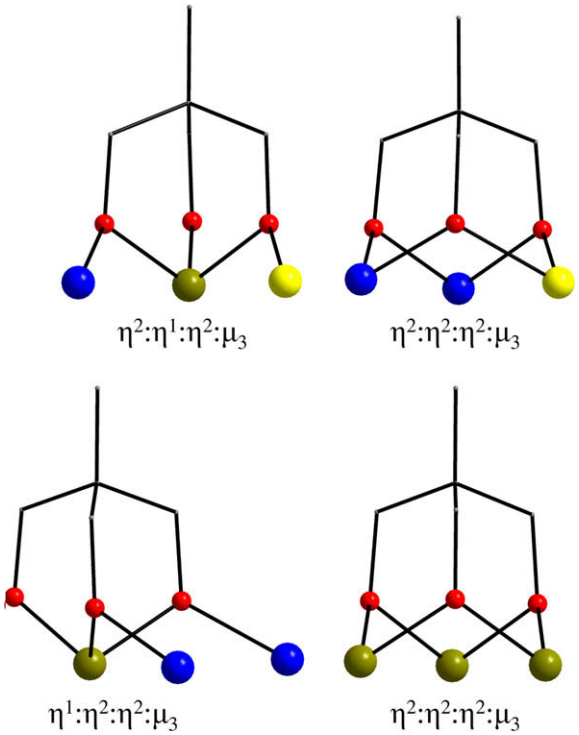

Fig. 3. The coordination modes of $thme^{3-}$ found in complex **1**. Colour scheme as in Fig. 1.

C–H···Cl contacts between C–H bonds of $thme^{3-}$ and lattice CH_2Cl_2 groups and the terminal Cl^- ions. Complex **1** is the first Mn_6 cluster at the Mn^{2+}, $2Mn^{3+}$, $3Mn^{4+}$ level, as well as a rare example of a hexanuclear molecular species with the $[M_6(\mu_6\text{-}O^{2-})]$ octahedral core [7], and the first in Mn coordination chemistry.

Solid-state DC (direct current) magnetic susceptibility (χ_M) data for complex **1** were collected in the temperature range 5.0–300 K in an applied field of 1 kOe (0.1 T). The $\chi_M T$ value steadily increases from 21.04 cm^3 K mol^{-1} at 300 K to a maximum of 54.48 cm^3 K mol^{-1} at 25 K, before dropping to 46.42 cm^3 K mol^{-1} at 5.0 K (Fig. 4). The spin-only ($g = 2$) value for a non-interacting $[Mn^{II}\text{-}Mn^{III}_2Mn^{IV}_3]$ unit is 16.0 cm^3 K mol^{-1}. This indicates ferromagnetic exchange interactions within **1**, and the 25 K data strongly suggest a very large ground-state spin (S) value for the complex, with the sharp decrease at the lowest temperatures assigned to Zeeman ef-

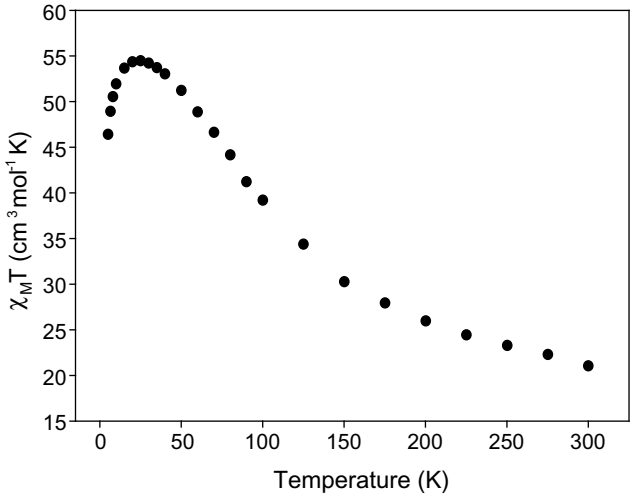

Fig. 4. $\chi_M T$ vs. T plot for **1** in a 1 kG field.

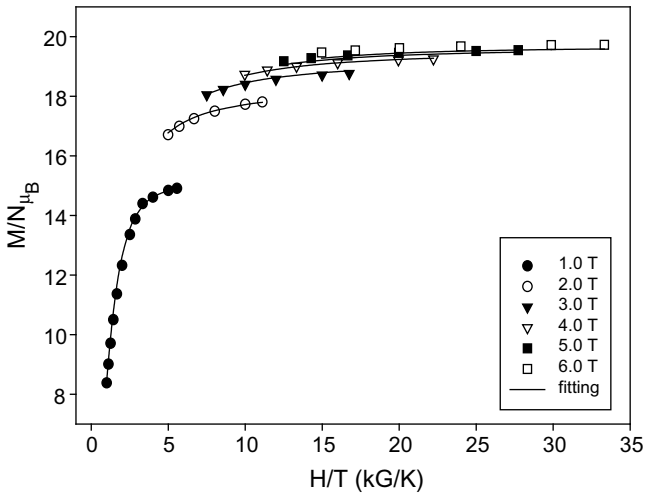

Fig. 5. Magnetization (M) vs. field (H) and temperature (T) data, plotted as reduced magnetization ($M/N\mu_B$) vs. H/T, for complex **1** at applied fields of 1.0–6.0 T and in the 1.8–10 K temperature range. The solid lines are the fit of the data; see the text for the fit parameters.

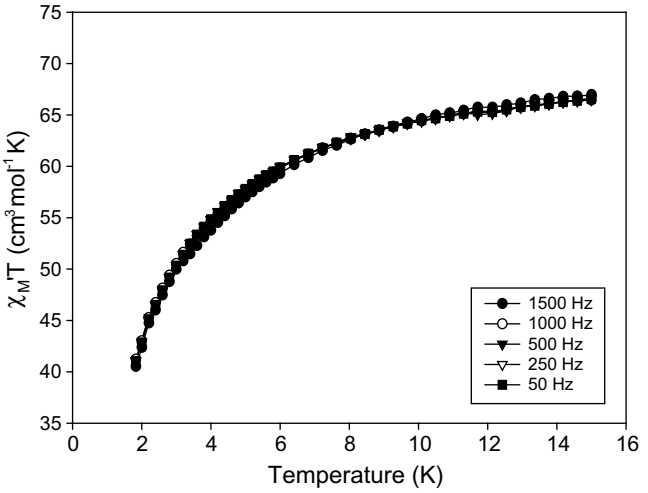

Fig. 6. Plot of the in-phase (χ'_M) as $\chi'_M T$ AC magnetic susceptibility vs. T in a 3.5 G field oscillating at the indicated frequencies for complex **1**.

fects, zero-field splitting and/or weak intermolecular interactions. The 25 K value is consistent with an $S = 10$ or 11 ground state, the latter being the maximum possible, and a g value of 2.0 or slightly below, as expected for a $Mn^{II}/Mn^{III}/Mn^{IV}$ system [5]; the spin-only ($g = 2$) values for $S = 10$ and 11 state are 55 and 66 $cm^3\,K\,mol^{-1}$.

In order to determine the ground state of **1**, magnetization (M) data were collected in the 1–6 T and 1.8–10.0 K ranges, and these are plotted as $M/N\mu_B$ versus H/T in Fig. 5. The data were fit by matrix-diagonalization to a model that assumes only the ground state is populated, includes axial zero-field splitting ($D\hat{S}_z^2$) and the Zeeman interaction, and carries out a full powder average. The best fit (solid lines in Fig. 5) gave $S = 11$, $g = 1.97(2)$ and $D = -0.07(3)\ cm^{-1}$, indicating a very high ground state spin with little magnetic anisotropy; an alternative fit with $S = 10$ is less favoured due to an unreasonable value for g of ~1.72. We conclude that **1** has ground state of $S = 11$ and the small D value is consistent with the small content of JT-distorted Mn^{III} atoms within the molecule.

The $S = 11$ ground state was further supported by AC (alternating current) magnetic susceptibility experiments, in which a weak field of 3.5 G oscillating at a particular frequency (ν) was applied to the sample. Ac susceptibility studies use no dc field and thus are an excellent complementary tool for determining S by avoiding potential complications from a large dc field and/or low-lying excited states. For **1**, the in-phase (χ'_M) AC signal, shown as $\chi'_M T$ in Fig. 6, is only slightly decreasing with decreasing temperature in the 8–15 K region; extrapolation of the data above 8 K (to avoid the effects of weak intermolecular interactions at lower temperatures, both dipolar and superexchange in nature) down to 0 K gives ~60 $cm^3\,K\,mol^{-1}$, indicating an $S = 11$ ground state with $g \sim 1.91$, in good agreement with the DC magnetization fits.

There is no out-of-phase (χ''_M) AC susceptibility signal down to 1.8 K, which indicates an insignificant barrier (versus kT) to magnetization relaxation. To explore whether slow relaxation might become apparent at even lower temperatures, magnetization versus dc field scans are required to be performed at low enough temperatures using the micro-SQUID apparatus [8]. Such studies are currently in progress and the corresponding results will be reported in due course.

In summary, the employment of the $thme^{3-}$ ligand in higher oxidation state Mn cluster chemistry has yielded a mixed-valence-(II/III/IV) molecule with a $[Mn_6(\mu_6\text{-}O)]^{18+}$ octahedral core and a high $S = 11$ ground state. Note that the $S = 11$ for **1** is the maximum for a Mn^{II}, $2Mn^{III}$, $3Mn^{IV}$ species, indicating all interactions to be ferromagnetic. This might at first glance seem strange for a complex that contains a Mn^{IV}_3 triangular subunit, since $Mn^{IV}Mn^{IV}$ interactions are almost always antiferromagnetic, but note that the Mn^{IV} atoms are within a $[Mn_3(\mu_3\text{-}O)(\mu\text{-}O)_3]$ defect-cubane subunit involving bis-monoatomically-bridged $[Mn(\mu\text{-}O)_2Mn]$ pairs, and this results in acute Mn^{IV}–O–Mn^{IV} angles (95–101°) that can reasonably yield ferromagnetic interactions [9]. In fact, this is in accord with the ferromagnetic interactions seen within the central $[Mn^{IV}_4(\mu_3\text{-}O)_4]$ cubane of $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ complexes [9d], which have Mn–O–Mn angles in the 95.0–100.7° range. Similarly for the interactions in **1** between Mn^{IV} and Mn^{II} or Mn^{III} atoms, and interactions amongst the Mn^{II}/Mn^{III} atoms, which all again involve bis-monoatomically-bridged Mn_2 pairs and particularly acute Mn–O^{2-}–Mn angles in the 89.19–90.62° and 83.37–84.25° ranges, respectively. A completely ferromagnetically coupled Mn_6 complex **1** is thus reasonable. These points will be analyzed in greater detail in the full paper.

states [27–44]. This is an example of a known fact that the KS-DFT with a semilocal approximation such as local density approximation (LDA) and generalized gradient approximation (GGA), does not work for the cation radical, in particular at the dissociated limit. The one-electron self-interaction error (SIE) is the spurious classical Coulomb of the excess electron with itself and inevitable in any semilocal approximation of the exchange-correlation functional [45]. Miehlich et al. pointed out that this spurious SIE leads to a spurious stability of a delocalized electronic structure for many ion–radical systems [27]. In fact, the B3LYP method [26], a de facto standard hybrid DFT method, fails to describe the potential surface of the cation radical as shown below. Furthermore, recent surveys on ion–radical systems using various types of HF and hybrid DFT reveal that the problem is more complicated: Gräfenstein, Kraka, and Cremer found that the exact correction for one-electron self-interaction error developed by Perdew and Zunger (PZ-SIC) also suffers from the 'size-inconsistency' error [28]. This result implies that the problem of the ion–radical systems is beyond the scope of the usual PZ-SIC method [45], by which almost all problems involved with the KS-DFT applications were resolved. Mori-Sanchez, Cohen, and Yang (MCY) have emphasized that it is needed for the energy functional to satisfy a relation proposed by Perdew, Parr, Levy, and Balduz (the PPLB relation) to treat correctly ion–radical systems as described in details below [33,36,39]. We suggested that combining exact exchange in KS-DFT with a resonating correction provides a possible answer for this problem [43]. In fact, it is shown that the double exchange interaction, which is an essential source of ferromagnetism for hole-doped magnetic systems, is correctly described by this method [44]. Thus, following the studies of Refs. [43,44], we employ the resonating (Res) broken-symmetry (BS) configuration interaction (CI) using spin unrestricted HF solutions as bases. At first, we examine the chemical bonding of a simplified model of $\mathbf{1}_2^+$ by B3LYP, UHF, and Res-BS CI methods. Furthermore, using Res-BS CI method, we investigate acetylene-bridged and methylene-bridged phenalenyl dimeric cations. The results are discussed from the viewpoint of the relation between the mediate unit (vacuum, acetylene, and methylene) in the phenalenyl dimeric compounds and fundamental characters of electronic structures.

2. Theoretical background

As described above, the electronic structure of the ion–radical systems now becomes an important issue in the field of computational physics-and-chemistry. In this section, we will briefly review this topic from the viewpoint of the 2-center 3-electron bond and the PPLB relation for our theoretical approaches examined in this study.

2.1. General discussion for the electronic structure of ion–radical systems

In order to consider importance of the description of the excess electron in ion–radical systems, we shall recall the Robin and Day's three types of mixed valence transition metal (MV-TM) systems in the field on inorganic chemistry [46,47]: according to the excess electron (hole) behavior, they classified the MV-TM compounds into three classes, the localized (Class I), the intermediate (Class II), and the fully delocalized (Class III) ones. These classes exhibit the class-specific magnetic, conductive, and optical properties [46,47]. If an ab initio method favors the specific one among them, it is difficult to determine the electronic properties correctly.

For simplicity, consider a two-atomic mono-cationic system A_2^+, of which two sites are equivalent each other. Roughly speaking, if the overlap between SOMO of the cationic site (A^+) and the HOMO of the neutral site (A) is not zero, the bond-order of A_2^+ is 0.5. So the dependency on the charge distribution of the energy is expected to be given by

$$E(A^{+0.5} + A^{+0.5}) < 0.5\,E(A + A^+) + 0.5\,E(A^+ + A). \quad (1)$$

Here, $E(A + A^+)$ and $E(A^+ + A)$are energies of the hypothetical electronic structures, in which the charges assume to localize at right and left sites respectively, while $E(A^{+0.5} + A^{+0.5})$ is the energy of the bonding state. As the intersite distance increases, the bond-order reduces to be 0. Then, the energy relation must be

$$E(A^{+0.5} + A^{+0.5}) = 0.5\,E(A + A^+) + 0.5\,E(A^+ + A). \quad (2)$$

This simplest example exemplifies the PPLB relation [40] for cation radical species. In the theoretical framework of an extended version of DFT at the zero temperature, PPLB state that the exact energy functional for fractional number of electrons, $N + \omega (0 \leqslant \omega \leqslant 1)$, depends linearly on the number of electrons as

$$E_{\mathrm{PPLB}}(N + \omega) = (1 - \omega)E_{\mathrm{PPLB}}(N) + \omega E_{\mathrm{PPLB}}(N + 1). \quad (3)$$

Obviously, this is a generalized version of Eq. (2).

2.2. KS-DFT description of ion–radical systems

Mori-Sanchez, Cohen, and Yang (MCY) have showed [33,36,39] that the dependency of electron numbers of various DFT-XC functionals is given by

$$E_{\text{KS-DFT}}(N+\omega) < (1-\omega)E_{\text{KS-DFT}}(N) + \omega E_{\text{KS-DFT}}(N+1). \quad (4)$$

This holds also for the usual hybrid XC functional such as B3LYP. Therefore, if we compute the phenalenyl (P) cationic dimer at the dissociation limit, the relation is given by

$$E_{\text{KS-DFT}}(P^{+0.5} + P^{+0.5}) < 0.5\, E_{\text{KS-DFT}}(P + P^{+}) + 0.5\, E_{\text{KS-DFT}}(P^{+} + P), \quad (5)$$

implying that the phenalenyl cationic dimer energy at the dissociation limit is lower than the sum of neutral and cationic phenalenyls: the potential surface of P_2^+ is expect to break down.

This indicates the usual DFT and hybrid-DFT favor the Class III in the context of the Robin and Day's classification. This discussion is consistent with a well-known result that the DFT and hybrid DFT methods favor delocalized electronic structure states for transition states of chemical reactions and metallic states of solids [39].

2.3. Hartree–Fock treatment of ion–radical systems

In contrast, the dependency of the UHF energy on the electron numbers is given by [33,36,39]

$$E_{\text{UHF}}(N+\omega) > (1-\omega)E_{\text{UHF}}(N) + \omega E_{\text{UHF}}(N+1). \quad (6)$$

As a result, the UHF calculation of the dissociation limit of the phenalenyl cationic dimer will be given by

$$E_{\text{UHF}}(P^{+0.5} + P^{+0.5}) > E_{\text{UHF}}(P + P^{+}) = E_{\text{UHF}}(P^{+} + P). \quad (7)$$

In other words, the UHF potential surface of P_2^+ is expected to reduce to the energy sum of P plus P^+. In energetic view of the potential surface of P_2^+, this is correct. However, note that the excess electron described by the UHF method prefers the localized state too much. Among the Robin and Day's three classes, the UHF method energetically favors the Class I. This feature causes known artifacts of the UHF method, i.e., the overestimation of band-gaps of some semiconductors and the over-stabilization of the spurious magnetic states for some cases [48]. This is because a localized solution obtained using the UHF method often corresponds to a hole-localized configuration, missing conductivity due to hole-delocalization effects illustrated in Fig. 1c. In principle, the resonating effect is essential for conductivity emerging from the hole-(or charge-) doping [23,41].

2.4. Resonating broken-symmetry CI treatment of ion–radical systems

A goal of this issue is to construct the exchange-correlation functional, by which the PPLB relation given by Eq. (3) holds for all atomic and molecular species. MCY have indeed designed two functionals called MCY3 and rCAM-B3LYP to satisfy Eq. (3) *approximately* [36]. On the other hand, we consider that this type of the problem is related to the resonating effects among several valence bond configurations [23,41]. In fact, the magnetic metal states of hole-doped bis-and-tris (methylene) amines were well described by MR plus perturbation treatment [23], by which we include all possible configurations in the variational (complete-active) space. Recently, we present that not only the variational space for wavefunctions, but also the linearity of the working equation are important to obtain the resonating state for ion–radical systems consisting of two equivalent sites (i.e., A_2^+) [43,44]. In these recent studies [43,44], we suggest an ab initio recipe in order to correctly treat ion–radical systems as follows:

(i) First, we obtain possible broken-symmetry solutions by implementing a mean-field theory, of which the electron-number dependency satisfies the Eq. (6). A simple choice is the UHF theory: UHF calculations of A_2^+ at dissociation limit are expected to yield two equivalent solutions, in which the charge localizes at left and right sites as denoted by $|L\rangle$ and $|R\rangle$, respectively.

(ii) Using $|L\rangle$ and $|R\rangle$ as bases, solve a non-orthogonal CI equation with employing ab initio Hamiltonian to yield the resonating CI solution given by

$$|\text{Res}\rangle = C_L|L\rangle + C_R|R\rangle. \quad (8)$$

In Refs. [43,44], we analyzed the dependence of the Res-HF CI energy on the Mulliken charge distribution by varying the set of CI coefficients, $\{C_L, C_R\}$ in Eq. (8). As a result, we presented that the relation,

$$E_{\text{Res-HF CI}}(A^{+0.5} + A^{+0.5}) < 0.5\, E_{\text{Res-HF CI}}(A + A^{+}) + 0.5\, E_{\text{Res-HF CI}}(A^{+} + A), \quad (9)$$

holds for finite intersite distances, and the relation,

$$E_{\text{Res-HF CI}}(A + A^{+}) = E_{\text{Res-HF CI}}(A^{+\omega} + A^{+(1-\omega)}) = E_{\text{Res-HF CI}}(A^{+} + A), \quad (10)$$

holds for the dissociation limits of various cationic dimmers [43,44]. This fact implies that the Res-HF CI satisfy the PPLB relation, which is the reason for that we employ this method for ion–radical systems.

3. Computational results

In the following calculations, we use Gaussian 03 [44] for UHF and DFT calculations, and a non-orthogonal CI code developed by S.N. for Res-CI calculations. The cc-pVDZ basis [49] is employed. In order to cut computational costs, we employed a simplified phenalenyl (P) unit, in which we replace all *tert*-butyl groups in the X-ray structure by hydrogen atoms. The molecular structure of this simplified monomer is shown in Fig. 2a. This is similar to that employed in the previous computational studies [13–16], and the authors of these studies confirmed that this simplification does not affect computational results significantly.

Now, we shall examine an antiparallel staggered cationic dimer (P_2^+), of which the geometry is illustrated in Fig. 2b. The potential surfaces computed by several methods are plotted in Fig. 3. We

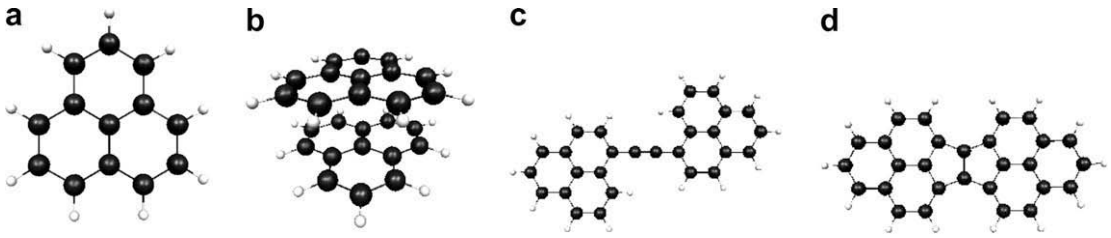

Fig. 2. Geometries of (a) the simplified phenalenyl (P) radical monomer, (b) the cationic dimer of Ps with the antiparallel stacking conformation, (c) an acetylene-bridged P cationic dimeric compound, and (d) an ethylene-bridged P cationic compound.

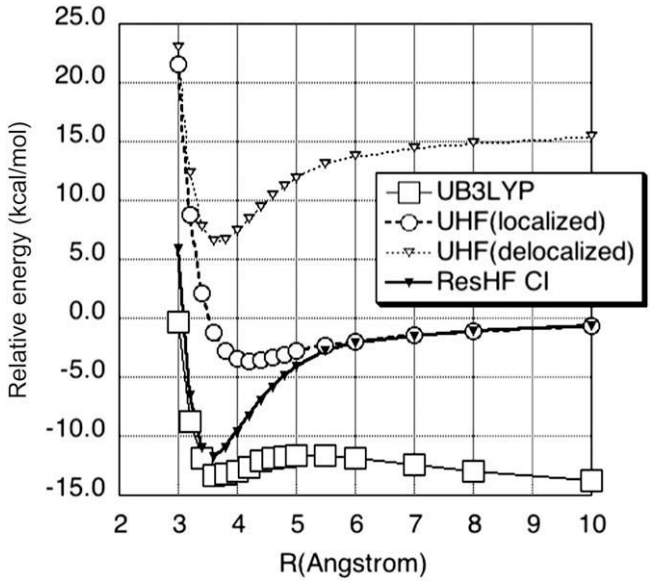

Fig. 3. The potential surfaces for cationic dimer of phenalenyls calculated by the UB3LYP, UHF, and Res-HF CI methods.

show the corresponding Mulliken charges on the relatively cationic site in Fig. 4. The UB3LYP curve in Fig. 3 obviously fails to converge the dissociation limit and all of the solutions along the surface, which are presented in Fig. 4, are delocalized ones, as in the results for other ion–radicals pointed out by DFT researchers [27–44]. On the other hand, there are two UHF solutions, of which the plus charge is localized and delocalized respectively. We can see from Fig. 3 that the delocalized UHF solution is unstable for all regions and the stable UHF solution is localized one, being consistent with the above discussion. Further, there are two equivalent localized UHF solutions, denoted as $|L\rangle$ and $|R\rangle$. Thus, our recipe to reach the resonating HF CI solution, of which the solution is given Eq. (8)

$$|\mathrm{Res}\rangle = C_L|L\rangle + C_R|R\rangle,$$

was implemented. The potential surface and charge distributions of these Res-HF CI solutions are also plotted in Figs. 3 and 4, respectively. Of course, the charge delocalization effect is recovered by the Res-HF CI treatment as shown in Fig. 4. The resonating energy that is the energy gap between the localized UHF solution and the corresponding Res-HF CI solution, however, reduces to zero as the intermolecular distance becomes large. This fact implies the relation,

$$E_{\mathrm{UHF}}(A + A^+) = E_{\text{Res-HF CI}}\,(A^{+0.5} + A^{+0.5}) = E_{\mathrm{UHF}}(A^+ + A) \qquad (11)$$

approximately holds for large intermolecular distances. Comparing Eq. (10) with Eq. (11), it can be concluded that the Res-HF CI method satisfies the PPLB condition for this system. This result is similar to the situation emphasized in the previous study for the small ion–radicals and double-exchange systems [43,44]. In addition, a point is that the resonating energy is considerably large for all region of potential surface: the binding energy of Res-HF CI solutions is approximately 12 kcal/mol, which is larger than that of UHF solution by 8 kcal/mol. The experimentally reported value (the enthalpy change upon formation of the cation radical) is 6.5 kcal/mol [16], which is smaller than our Res-HF CI value, but, as pointed out by Small et al. it is expected that the solvation effects considerably contribute (may reduce) to this experimental value.

Next, we proceed to the case that two phenalenyl units are bridged by acetylene and ethylene units as shown in Fig. 2c and d, respectively. The nonlinear optical properties of these compounds were examined previously for the neutral case [8,14] to utilize the phenalenyl unit as a constituent of supermolecules. Now, according to the recipe described in the Section 2.4, we shall examine the fundamental characters of these cationic dimeric compounds in compared with the through-space case described above. In the context of antiferromagnetic interactions, the through-bond (super-exchange) interactions are much larger than the through-space (direct exchange) interactions [50].

The optimized geometries of the bridged parts which are obtained in Ref. [14], are used, while that of phenalenyl unit is fixed to be experimental one. For the acetylene-bridged one, there is only the delocalized UHF (ROHF) solution, of which charge distribution is illustrated in Fig. 5. Comparing the through-space dimer case, the acetylene bridge is expected to play a enhancement factor for the conductivity of hole-doped phenalenyl compounds. In contrast, there are three low-lying spin-density wave (SDW) type of UHF solutions within 0.13 eV for the ethylene-bridged one, of which the charge distributions on phenalenyl units and the ethylene bridge, together with relative energies, are summarized in Table 1. We can see from this table that these solutions are similar each other. However, the spin distributions, which are summarized in Table 2, are different each other. Obviously, the bridged ethylene contributes to spin-density waves for all of SDW1, SDW2, and SDW3. Then using these solutions as bases,

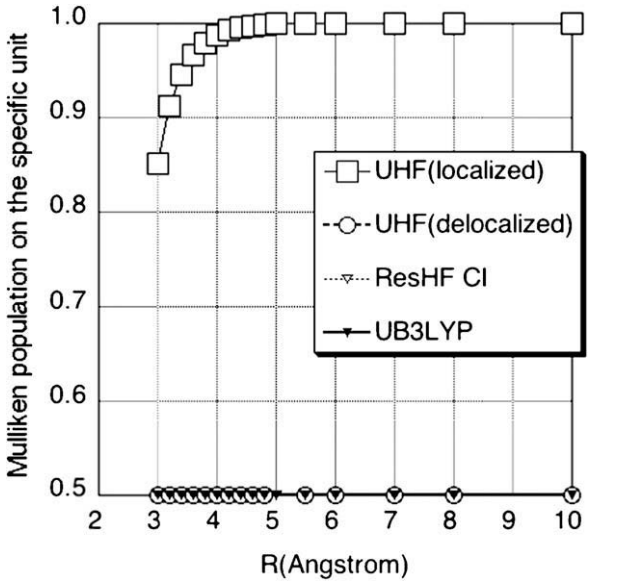

Fig. 4. Calculated Mulliken charge distributions on a relatively cationic site of cationic dimer of phenalenyls for various intersite distances.

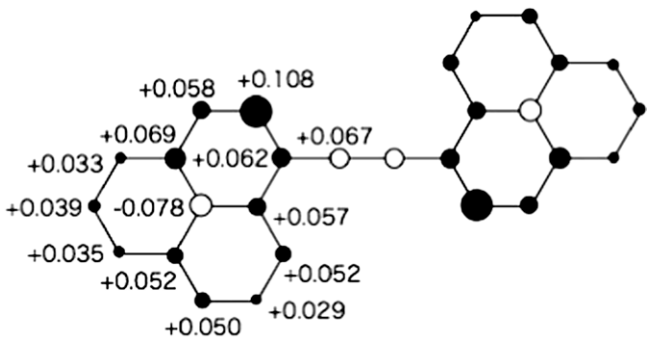

Fig. 5. Charge distributions of the acetylene-bridged phenalenyl cationic dimer calculated by the UHF method. The distribution at the right unit is symmetric to the left one.

Table 1
Charge distributions of low-lying UHF solutions for ethylene-bridged phenalenyl cationic dimer, together with the relative energies.

	Phenalenyl (right)	Ethylene (bridge)	Phenalenyl (left)	Relative energies to SDW3solution (eV)
SDW1	0.583461	−0.146494	0.563033	0.128
SDW2	0.563047	−0.146507	0.583458	0.128
SDW3	0.555383	−0.110767	0.555383	0

Table 2
Spin distributions of low-lying UHF solutions for ethylene-bridged phenalenyl cationic dimer.

	Phenalenyl (right)	Ethylene (bridge)	Phenalenyl (left)
SDW1	0.837411	0.950317	−0.787728
SDW2	−0.787708	0.950265	0.837444
SDW3	0.904001	−0.808006	0.904001

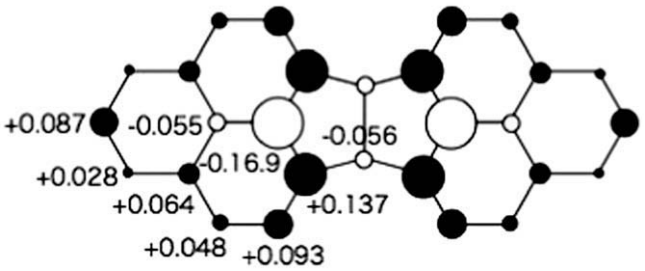

Fig. 6. Charge distributions of Res-HF CI solutions for the ethylene-bridged phenalenyl cationic dimer. The distribution at the right unit is symmetric to the left one.

we implemented Res-HF CI calculations. The resulting wavefunction is given by

$$|\mathrm{Res}\rangle = C_{\mathrm{SDW1}}|\mathrm{SDW1}\rangle + C_{\mathrm{SDW2}}|\mathrm{SDW2}\rangle + C_{\mathrm{SDW3}}|\mathrm{SDW3}\rangle, \quad (12)$$

with $C_{\mathrm{SDW1}} = C_{\mathrm{SDW2}} = 0.139$ and $C_{\mathrm{SDW3}} = 0.981$, indicating that the most stable UHF solution, the SDW3 type, is dominant for this Res-HF CI solution. The resulting charge distribution is shown in Fig. 6. This is similar to that of the SDW3 solution, due to the large CI coefficient in Eq. (12). When we see this solution as a charge-density wave from this figure, it is found that the ethylene plays a small amount of contribution. Thus the ethylene-bridge plays a role for the spin density wave, but little role for charge density wave.

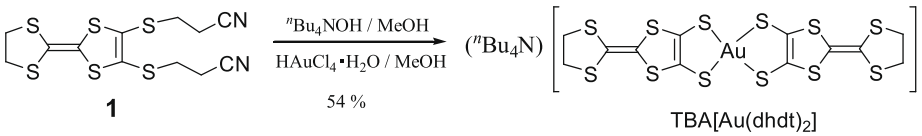
4. Conclusions

We investigated phenalenyl cationic dimer systems using ab initio methods. First, the potential surface of the antiparallel staggered cationic dimer of the simplified phenalenyl molecules is examined with focusing our attention on the hole-behavior and the shapes of the potential surfaces by UB3LYP, UHF, and Res-HF CI methods. The results are similar to those of other ion–radical systems: the UB3LYP calculations always yield the delocalized state, and the UB3LYP energy at the dissociation limit is lower than the sum of neutral and phenalenyl cationic monomers. In contrast, the UHF method yields the correctly dissociated curve and the localized solutions for the long intermolecular distances. Then the Res CI computation based on the left-and-right localized UHF solutions is implemented. The results are that the charge delocalized effect for long inter units distances is recovered and that the resonating energies reach at approximately 8 kcal/mol at the equilibrium distance and reduce to zero at the dissociation limit, implying that these Res-HF CI solutions satisfy the PPLB condition of exact solutions for the ion–radical systems.

Then, we applied the Res-HF CI method for the acetylene-bridged and ethylene-bridged phenalenyl cationic dimers. However, we obtained only delocalized type of the UHF solutions for the former case. This result indicates that the acetylene-bridge works as a conductivity-enhanced-bridge for hole-doped phenalenyl compounds. On the other hand, there are three low-lying spin-density wave types of UHF solutions within 0.13 eV for the ethylene-bridged phenalenyl cationic compound. However, the Res-HF CI calculation shows that the most stable spin-density wave type of the UHF solution is dominant for the ground-state Res-HF CI wavefunction. For both acetylene-and-ethylene bridge cation dimmers, main distributions of holes are on both phenalenyl sites equivalently, but the small amount of holes is delocalized on the bridge part. Judging from our computational results in this study, different bridges-or-stacks lead to different hole behaviors, implying the possibility of various electronic functionalities of the hole-doped phenalenyl compounds.

A remaining, and important problem is that we omit the distortion of molecules in this study. Introducing this effect might change the situation drastically: a most possible situation is forming the (spin) polaron in which the distortion of the molecular geometry and the charge (spin) density distribution are coupled [51]. This effect is a disturbing factor if we intend to model organic magnetic metals, so the examination of this effect will be important issue. From the viewpoint of computational chemistry, the geometry optimization is needed. A noteworthy point here is that, as just presented also in this study, the potential surfaces of ion–radical species for various geometries strongly depend on the method we employed. In our recent studies of ion–radical systems [43,44], a many-electron self-interaction free method is needed to described the equivalent-sites limit of ion–radical species. There are two possible ways towards this line: one is to improve the hybrid-DFT as MCY suggested [36] and another is the resonating approach based on a wavefunction theory such as CASSCF (Res-CASSCF) and spin unrestricted coupled-cluster (Res-CC) [43]. Note that the latter way, which is never developed by the precursors in this field, is expected to provide precise information of ion–radical systems even at unstable geometries that are beyond the scope of experimental studies at present. On the basis of such information, the former way, i.e., construction of an accurate hybrid DFT functional will be refined. Because both the former and the later are not trivial extensions of the present work, these are theme in the future studies. We limited the Res-HF CI treatment in this study. However, it is noteworthy that most of results presented here are not affected by introducing electron correlations. In particular, the acetylene-bridged phenalenyl compounds are expected to exhibit strong conductivity by doping a hole, because the UHF method, which usually favors the localized state in general, leads to the delocalized hole. Even if the Res-CC will be implemented, this conclusion is expected to remain true because the CC method is expected to include the delocalization effects of ion–radical systems,[1] but not the localization effects, compared with the UHF method.

Acknowledgements



We acknowledge Dr. M. Shoji and Mr. T. Ukai for valuable discussions of the electronic structure of mixed-valence systems. This work is supported by both the CREST project by Japan Science and Technology Agency (JST). We are also grateful to the Ministry of Education, Culture, Sports, Science and Technology (MEXT) for a grant-in-aid for Research and Development of the Next-Generation

diethyl ether to the filtrate afforded (n-Bu$_4$N)[Au^{III}(dhdt)$_2$] as brown powder in 54% yield.

Tetraphenylphosphonium salt, (Ph$_4$P)[Au^{III}(dhdt)$_2$], was obtained by slow diffusion of THF–methanol solution of tetraphenylphosphonium bromide to THF–methanol solution of (n-Bu$_4$N)[Au^{III}(dhdt)$_2$] to give black needle crystals suitable for X-ray structural analysis.

2.3. Preparation of neutral complex [Au(dhdt)$_2$]

Neutral complex, [Au(dhdt)$_2$], was prepared by electrochemical oxidation of (n-Bu$_4$N)[Au^{III}(dhdt)$_2$] at a constant current of 0.2–0.5 μA in benzonitrile or benzonitrile with 5–20% methanol or ethanol containing n-Bu$_4$NBr as a supporting electrolyte at 25 °C. All the solvents were purified before use. Concentration of (n-Bu$_4$N)[Au^{III}(dhdt)$_2$] and n-Bu$_4$NBr were 0.3–3.0 and 25 mM, respectively. For all the reaction condition, only powder samples were obtained. *Anal.* Calc. for [Au(dhdt)$_2$] (C$_{12}$H$_8$AuS$_{12}$): C, 19.64; H, 1.10. Found: C, 19.77; H, 1.22%.

2.4. X-ray crystallography

Diffraction data were collected at 293 K on a Bruker SMART APEX diffractometer fitted with a CCD type area detector, and a full sphere of data were collected using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The data frames were integrated using SAINT and merged to give a unique data set for structure determination. Total reflections collected were 18646 of which independent reflections were 5686 (R_{int} = 0.0531). The structure was solved by direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELEX 5.1 package (Bruker Analytical X-ray Systems). Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those the parent atoms.

Crystal data for (Ph$_4$P)$_2$[Au^{III}(dhdt)$_2$]$_2$: C$_{72}$H$_{56}$Au$_2$P$_2$S$_{24}$, F.W. = 2146.48; black needle, monoclinic, space group $P2_1/c$, a = 8.304(1), b = 22.249(3), c = 21.571(3) Å, β = 95.738(2)°, V = 3965.5(8) Å^3, Z = 2, R = 0.0521, Rw = 0.1339.

2.5. Electrical conductivity and magnetic susceptibility

Temperature dependence of resistivity was measured on a compressed pellet of a powder sample of [Au(dhdt)$_2$] by the four-probe dc method using gold wire contacted to the pellet by carbon paste. Magnetic susceptibility was measured for a powder sample in the temperature range of 2–300 K using a superconducting quantum interference device magnetometer with 20000 Oe field application. The diamagnetic contribution of [Au(dhdt)$_2$] was calculated to be -305.46×10^{-6} emu mol^{-1} using Pascal's law. Magnetization data were collected as a function of the applied field up to 5 T at 1.8 K.

3. Results and discussion

3.1. Electrochemical property of Au complex

The redox potentials of (Ph$_4$P)[Au^{III}(dhdt)$_2$] were investigated by cyclic voltammetry at 25 °C in acetonitrile containing n-Bu$_4$NPF$_6$ as a supporting electrolyte at a scan rate of 50 mV s^{-1}, using glassy-carbon working and platinum counter electrodes and a saturated calomel electrode (SCE) as the reference electrode. The redox potentials of Au complex were summarized in Table 1 together with those of Ni complex, (Ph$_4$P)[Ni^{III}(dhdt)$_2$]. While the irreversible step corresponding to the oxidation from monovalent [Au(dhdt)$_2$]$^-$ to neutral Au complex was observed at −0.06 V, the reduction step from [Au(dhdt)$_2$]$^-$ to divalent [Au(dhdt)$_2$]$^{2-}$ at −0.85 V. Compared with the corresponding potentials of the Ni complex, oxidation to the neutral complexes occurs at almost same potentials, but the reduction potential to the divalent species of the Au complex is more negative than that of the Ni complex.

3.2. Crystal structure of (Ph$_4$P)[Au^{III}(dhdt)$_2$]

X-ray structural analysis for (Ph$_4$P)[Au^{III}(dhdt)$_2$] revealed that the complex crystallized in the monoclinic space group $P2_1/c$ consisting of two [Au^{III}(dhdt)$_2$]$^-$ anions and one tetraphenylphosphonium cation. The Au(III) ions are located on the center of inversion, so that the stoichiometry of tetraphenylphosphonium cation and [Au^{III}(dhdt)$_2$]$^-$ anion is 1: 1. Fig. 1a shows the molecular structure of the [Au^{III}(dhdt)$_2$]$^-$ anion. The Au(III) ions of both the crystallographically independent [Au^{III}(dhdt)$_2$]$^-$ anions adopt a square planar coordination surrounded by four sulfur atoms from dhdt^{2-} ligands. The Au–S bond lengths are 2.288(3)–2.308(3) Å, which are comparable to the mean Au–S bond length (2.296 Å) observed in [Au^{III}(tmdt)$_2$] [6], suggesting the Au ions in [Au(dhdt)$_2$]$^-$ anions are trivalent Au(III). The [Au(dhdt)$_2$]$^-$ anions are arranged in a windmill manner [7] in the bc plane and they stacked along the a-axis as shown in Fig. 1b. The cations are located in the hollow surrounded by four [Au(dhdt)$_2$]$^-$ anions. There is no sulfur–sulfur contacts shorter than the sum of van der Waals radii between the [Au(dhdt)$_2$]$^-$ anions.

3.3. Electrical conductivity and magnetic susceptibility of [Au(dhdt)$_2$]

Fig. 2 shows the temperature dependence of resistivity of the neutral complex [Au(dhdt)$_2$] measured on a compress pellet. The electrical conductivity at room temperature was σ_{rt} = 8.3 S cm^{-1}, which is higher than that of the corresponding Ni complex, [Ni(dhdt)$_2$], measured for a single crystal (σ_{rt} = 0.084 S cm^{-1}) [5]. As seen in Fig. 1, the conducting behavior was the activation-type, and the activation energy was calculated to be E_a = 23 meV from the Arrhenius plot, $\rho(T) = A\exp(\Delta E/k_BT)$, where A is a temperature-independent constant, k_B, the Boltzmann constant, and ΔE, the activation energy. The activation energy of the Au complex is smaller than that of the Ni complex (E_a = 40 meV).

Since the Au(III) ion has d^8 electronic configuration, the neutral Au dithiolato complex has one unpaired electron. Thus magnetic

Redox potentials of (Ph$_4$P)[M^{III}(dhdt)$_2$] (M = Au and Ni) in acetonitrile (V vs. SCE, 25 °C).

Compound	E_1	E_2
(Ph$_4$P)[Au^{III}(dhdt)$_2$]	−0.06	−0.85
(Ph$_4$P)[Ni^{III}(dhdt)$_2$]	−0.12	−0.52

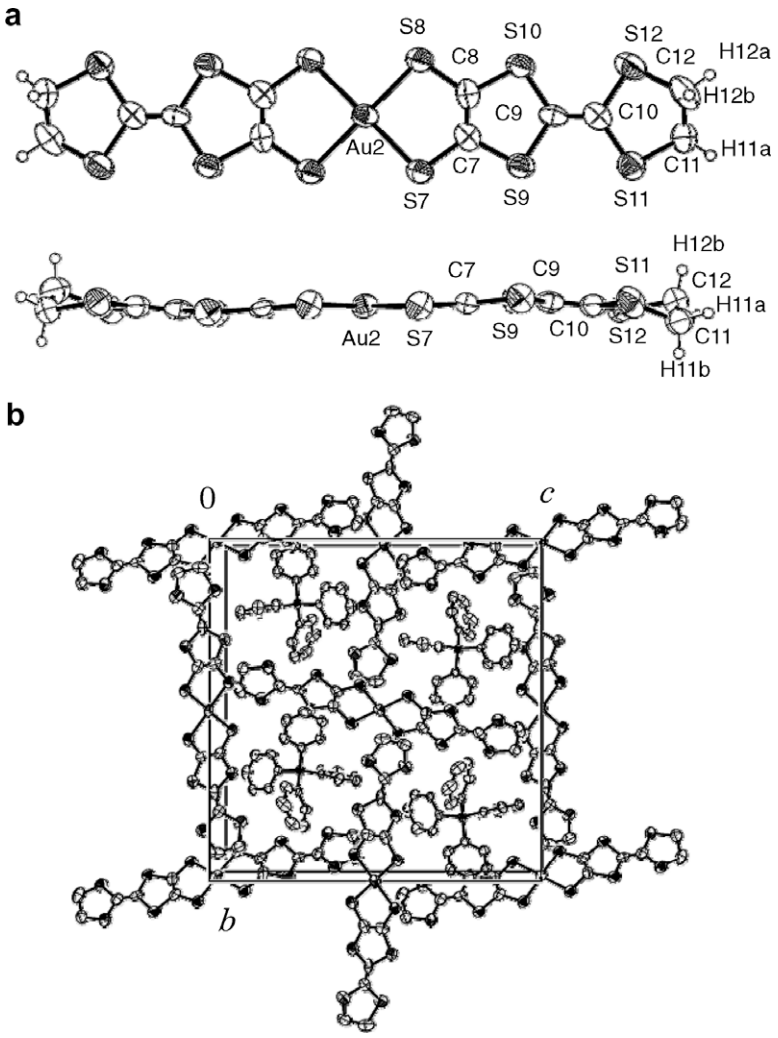

Fig. 1. Crystal structure of $(Ph_4P)[Au(dhdt)_2]$. (a) Molecular structure of $[Au(dhdt)_2]^-$ anion. (b) Crystal structure viewed along *a*-axis.

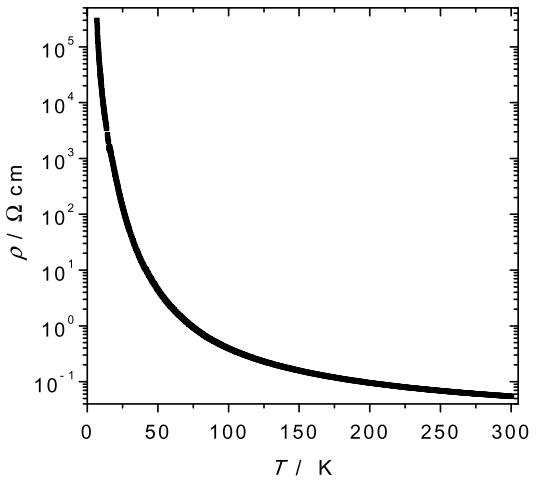

Fig. 2. Temperature dependence of resistivity of $[Au(dhdt)_2]$.

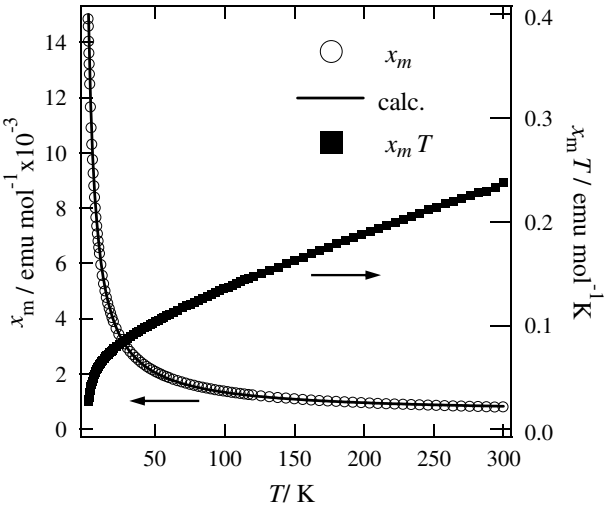

Fig. 3. Temperature dependence of magnetic susceptibility and $\chi_m T$ of $[Au(dhdt)_2]$. The solid line is a fit by the sum of the Curie–Weiss law and temperature independent component.

properties of the neutral Au complex should be very attractive [6]. In order to investigate magnetism of the neutral complex $[Au(dhdt)_2]$, temperature dependence of the magnetic susceptibility was measured by using a SQUID magnetometer at 20 000 Oe from 300 to 2 K (Fig. 3). The susceptibility at 300 K was 7.94×10^{-4} emu mol^{-1}. The $\chi_m T$ value was 0.238 emu mol^{-1} K at 300 K, which is smaller than the expected value of 0.375 emu mol^{-1} K for $S = 1/2$, and decreased gradually with

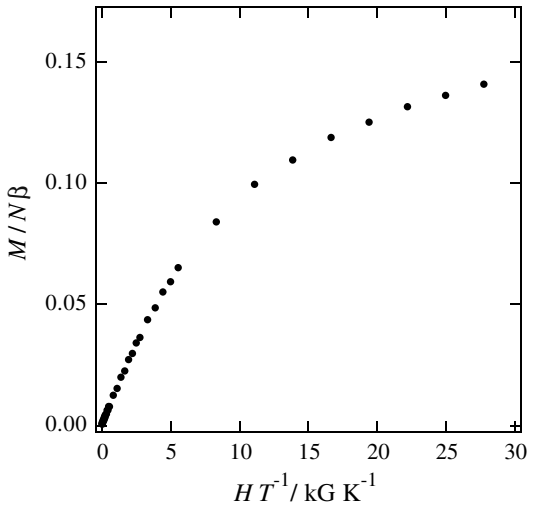

Fig. 4. Magnetization (M) vs. magnetic field strength (H/T) plot for [Au(dhdt)$_2$].

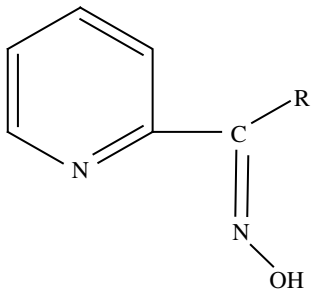
decrease of temperature, and then sudden drop was observed at 20 K. The magnetic susceptibility was well reproduced by the sum of the Curie–Weiss law and the temperature independent component attributable to the conduction π-electron over the whole temperature range as shown by the solid line in Fig. 3. The least-squares fit is found for the Curie constant $C = 7.98 \times 10^{-2}$ emu mol^{-1} K, Weiss temperature $\theta = -3.46$ K, and $\chi_\pi = 5.75 \times 10^{-4}$ emu mol^{-1}, respectively. The value of Curie term is about 20% of the $S = 1/2$ paramagnetic system, which is fairly large for impurity. Fig. 4 shows the magnetic field dependence of magnetization measured at 1.8 K up to 5 T with a SQUID magnetometer. The $M/N\beta$ values increased with increasing magnetic filed strength, and did not show saturation up to 5 T. Although the saturation was not complete, the magnetization under the applied field of 5 T was *ca.* 0.15 $N\beta$ which is much smaller than the value for $S = 1/2$ and comparable to the result obtained by the magnetic susceptibility measurement.

4. Conclusion

A gold dithiolato complex coordinated by the dihydro-TTF ligand of which π-electron system is reduced compared with those of TTF-dithiolato metal complexes was newly synthesized and isolated as tetra-*n*-butylammoium salt of [Au(dhdt)]$^-$ monoanion. Crystal structure of tetraphenylphosphonium salt, (Ph_4P)[Au(dhdt)], was revealed by X-ray crystallography. The Au(III) ions in the [Au(dhdt)]$^-$ anions have a square planar coordination and the mean Au–S bond length suggests the Au ions are in the trivalent Au(III) state. A neutral complex [Au(dhdt)$_2$] was obtained by the electrochemical oxidation of (n-Bu_4N)[Au(dhdt)$_2$] to give a dark brown powder sample. Conducting behavior of the neutral [Au(dhdt)$_2$] complex was semiconductive with room temperature conductivity of $\sigma_{rt} = 8.3$ S cm^{-1} and activation energy of $E_a = 23$ meV, indicating higher conductivity than those of the neutral Ni complex [Ni(dhdt)$_2$] ($\sigma_{rt} = 0.084$ S cm^{-1}, $E_a = 40$ meV). Magnetic susceptibility of [Au(dhdt)$_2$] was well explained by the sum of the Curie component and the constant value attributable to the conduction π-electron. The Curie term is about 20% of the $S = 1/2$ paramagnetic system. Details on the electronic and magnetic structure of this complex is continuously investigated as well as preparation of a single crystal of the neutral [Au(dhdt)$_2$] complex for X-ray structural analysis and further investigation on the physical properties.

5. Supplementary data



CCDC 702730 contains the supplementary crystallographic data for (Ph_4P)$_2$[Au^{III}(dhdt)$_2$]$_2$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

100 instrument. Magnetic susceptibility measurements were performed at room temperature by the Faraday method using a Cahn-Ventron RM-2 balance standardized with $HgCo(NCS)_4$. Pascal's constants were used to estimate the diamagnetic corrections which were subtracted from the experimental susceptibilities to give the corrected molar magnetic susceptibilities. The variable-temperature magnetic susceptibility properties of complex **2** were investigated using a M600 SQUID magnetometer.

2.2. Compound preparation

2.2.1. $[Co(pao)_3]$ (**1**)

Method A. A pink suspension of $Co(O_2CMe)_2 \cdot 4H_2O$ (0.13 g, 0.50 mmol) in MeCN (25 ml) was treated with solid paoH (0.18 g, 1.50 mmol). The resulting orange slurry was refluxed for 2.5 h, during which time the solids dissolved and the colour of the solution turned to dark red. The solution obtained was stirred at ambient temperature for a further 1 h, during which time a dark orange microcrystalline solid rapidly precipitated. The solid product was isolated by filtration, washed with cold MeCN (2 × 3 mL) and Et_2O (2 × 5 mL), and dried in air for 1 h. Dissolution of the solid in MeOH (20 mL) and slow evaporation of the resulting filtrate at room temperature gave dark orange crystals of **1** after 8 days. The crystals were collected by filtration, washed with cold MeOH (1 × 2 mL) and Et_2O (2 × 5 mL), and dried in air. Yield 60% (based on the ligand). *Anal.* Calc. for $C_{18}H_{15}CoN_6O_3$: C, 51.19; H, 3.59; N, 19.91%. Found: C, 51.06; H, 3.52; N, 19.88%. Selected IR data (KBr pellet, cm^{-1}): 1602s, 1484vs, 1426s, 1348s, 1298w, 1224m, 1180m, 1148m, 1022w, 890w, 806m, 764m, 676m, 580w, 452w.

Method B. Solids $Co(O_2CMe)_2 \cdot 4H_2O$ (0.13 g, 0.50 mmol) and paoH (0.18 g, 1.50 mmol) were dissolved under refluxing conditions in a solvent mixture comprising MeCN/DMF (20 ml, 1:1 v/v) to give a dark red solution. The obtained solution was allowed to stand undisturbed at room temperature for 10 days, during which time well-formed, X-ray quality dark orange crystals of **1** appeared. The crystals were collected by filtration, washed with cold MeCN (1 × 3 mL) and Et_2O (2 × 5 mL), and dried in air. Yield 40% (based on the ligand). The identity of the product was confirmed by elemental analyses (C, H, N) and IR spectroscopic comparison with authentic material from Method A.

2.2.2. $[Co_3(pao)_6](ClO_4)_2$ (**2**)

Method A. An orange suspension of **1** (0.42 g, 1.00 mmol) in MeCN (30 ml) was treated with solid $Co(ClO_4)_2 \cdot 6H_2O$ (0.19 g, 0.50 mmol). The resulting orange-red slurry was refluxed for 12 h, during which time the solids dissolved and the colour of the solution turned to dark red. The solution was filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 5 days, dark red crystals of **2** were collected by filtration, washed with cold MeCN (2 × 2 mL) and Et_2O (2 × 5 mL), and dried in air. Yield 80%. *Anal.* Calc. for $C_{36}H_{30}Co_3N_{12}O_{14}Cl_2$: C, 39.22; H, 2.75; N, 15.25. Found: C, 39.26; H, 2.90; N, 15.28%. Selected IR data (KBr pellet, cm^{-1}): 1606s, 1564m, 1522s, 1476m, 1438m, 1350m, 1232s, 1205m, 1148vs, 1112m, 1086vs, 902m, 770m, 678m, 628m, 590m, 466m.

Method B. A pink solution of $Co(ClO_4)_2 \cdot 6H_2O$ (0.19 g, 0.50 mmol) in MeOH (20 mL) was added to a colourless solution of paoH (0.12 g, 1.00 mmol) and $Me_4NOH \cdot 5H_2O$ (0.18 g, 1.00 mmol) in the same solvent (10 mL). The resulting dark red solution was stirred for 20 min, filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 2 days, dark red crystals of **2** were collected by filtration, washed with cold MeOH (2 × 2 mL), and dried in air. Yield 50% (based on the ligand). The identity of the product was confirmed by elemental analyses (C, H, N) and IR spectroscopic comparison with authentic material from Method A.

2.2.3. $[Co(ppko)_3] \cdot 0.25H_2O$ (**3** · $0.25H_2O$)

A pink suspension of $Co(O_2CMe)_2 \cdot 4H_2O$ (0.13 g, 0.50 mmol) in MeCN (30 ml) was treated with solid ppkoH (0.30 g, 1.50 mmol). The resulting orange slurry was refluxed for 1.5 h, during which time the solids dissolved and the colour of the solution turned to dark red. The solution obtained was stirred at ambient temperature for a further 30 min, during which time a dark orange microcrystalline solid rapidly precipitated. The solid product was isolated by filtration, washed with cold MeCN (2 × 3 mL) and Et_2O (2 × 5 mL), and dried in air for 1 h. Dissolution of the solid in DMF (15 mL) and slow evaporation of the resulting filtrate at room temperature gave dark orange crystals of **3** · $0.25H_2O$ after 12 days. The crystals were collected by filtration, washed with cold DMF (1 × 2 mL) and Et_2O (2 × 5 mL), and dried under vacuum. Yield 40% (based on the ligand). The dried sample analyzed as solvent-free (**3**). *Anal.* Calc. for $C_{36}H_{27}CoN_6O_3$: C, 66.46; H, 4.19; N, 12.92. Found: C, 66.44; H, 4.12; N, 12.88%. Selected IR data (KBr pellet, cm^{-1}): 1598m, 1522m, 1464vs, 1438s, 1222m, 1146m, 1030w, 976w, 780m, 748m, 708s, 614m, 470m.

2.2.4. $[Co_3(ppko)_6](PF_6)_2 \cdot 6MeCN$ (**4** · 6MeCN)

Method A. An orange suspension of **3** (0.65 g, 1.00 mmol) in MeCN (30 ml) was treated with a pink aqueous solution (5 mL) of $CoCl_2 \cdot 6H_2O$ (0.12 g, 0.50 mmol) and $NaPF_6$ (0.17 g, 1.00 mmol). The resulting orange-red slurry was refluxed for 5 h, during which time the solids dissolved and the colour of the solution turned to dark red. The solution was filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 6 days, dark red crystals of **4** · 6MeCN were collected by filtration, washed with cold MeCN (2 × 2 mL), and dried under vacuum. Yield 65%. The dried sample analyzed as solvent-free (**4**). *Anal.* Calc. for $C_{72}H_{54}Co_3N_{12}O_6P_2F_{12}$: C, 46.61; H, 2.94; N, 9.06. Found: C, 46.54; H, 2.92; N, 9.18%. Selected IR data (KBr pellet, cm^{-1}): 1598m, 1524m, 1464vs, 1438m, 1358w, 1216m, 1146m, 1030w, 977w, 842vs, 776m, 746m, 706s, 658w, 612w, 558m, 466m.

Method B. Solids $Co(O_2CMe)_2 \cdot 4H_2O$ (0.13 g, 0.50 mmol), ppkoH (0.30 g, 1.50 mmol) and $NaPF_6$ (0.17 g, 1.00 mmol) were dissolved under refluxing conditions in MeCN (30 ml) to give a dark red solution. The obtained solution was stirred for a further 15 min, filtered, and the filtrate was layered with Et_2O (60 mL). After 4 days, dark red crystals of **4** · 6MeCN were collected by filtration, washed with cold MeCN (2 × 2 mL) and Et_2O (2 × 5 mL), and dried under vacuum. Yield 70% (based on the ligand). The identity of the product was confirmed by elemental analyses (C, H, N) and IR spectroscopic comparison with authentic material from Method A.

Method C. A pink solution of $CoCl_2 \cdot 6H_2O$ (0.12 g, 0.50 mmol) and $NaPF_6$ (0.17 g, 1.00 mmol) in MeOH (10 mL) was added to a pale yellow solution of ppkoH (0.20 g, 1.00 mmol) and $Me_4NOH{\cdot}5H_2O$ (0.18 g, 1.00 mmol) in MeCN (20 mL). The resulting dark red solution was stirred for 30 min, filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 3 days, dark red crystals of **4** · 6MeCN were collected by filtration, washed with cold MeCN (2 × 2 mL), and dried under vacuum. Yield 55% (based on the ligand). The identity of the product was confirmed by elemental analyses (C, H, N) and IR spectroscopic comparison with authentic material from Method A.

2.2.5. $[Co(mpko)_3] \cdot 3MeNO_2$ (**5** · $3MeNO_2$)

Method A. A pink suspension of $Co(O_2CMe)_2 \cdot 4H_2O$ (0.13 g, 0.50 mmol) in $MeNO_2$ (30 ml) was treated with solid mpkoH (0.20 g, 1.50 mmol). The resulting orange slurry was refluxed for 3 h, during which time the solids dissolved and the colour of the solution turned to dark red. The obtained solution was stirred for a further 30 min, filtered, and the filtrate was layered with a solvent mixture comprising Et_2O/*n*-hexane (60 mL, 1:1 v/v). After 5 days, dark orange crystals of **5** · $3MeNO_2$ were collected by filtration, washed with cold $MeNO_2$ (1 × 3 mL) and Et_2O (2 × 5 mL), and dried under vacuum. Yield 50% (based on the ligand). The dried sample analyzed satisfactorily as **5** · $3MeNO_2$. *Anal.* Calc. for $C_{24}H_{30}CoN_9O_9$: C, 44.51; H, 4.68; N, 19.47. Found: C, 44.42; H, 4.62; N, 19.58%. Selected IR data (KBr pellet, cm^{-1}): 3056w, 2964w, 1636w, 1600s, 1472vs, 1430s, 1302m, 1228vs, 1156m, 1118m, 1084w, 986w, 768s, 692m, 504w, 454w.

Method B. A pink solution of $CoCl_2{\cdot}6H_2O$ (0.12 g, 0.50 mmol) in MeOH (5 mL) was added to a colourless solution of mpkoH (0.20 g, 1.50 mmol) and $Me_4NOH \cdot 5H_2O$ (0.27 g, 1.50 mmol) in $MeNO_2$ (20 mL). The resulting dark red solution was stirred for 45 min, filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 10 days, dark orange crystals of **5** · $3MeNO_2$ were collected by filtration, washed with cold $MeNO_2$ (1 × 3 mL) and Et_2O (2 × 5 mL), and dried under vacuum. Yield 35% (based on the ligand). The identity of the product was confirmed by elemental analyses (C, H, N) and IR spectroscopic comparison with authentic material from Method A.

2.2.6. $[Co_3(mpko)_6](PF_6)_2$ (**6a**)

An orange suspension of **5** · $3MeNO_2$ (0.65 g, 1.00 mmol) in MeCN (30 ml) was treated with a pink aqueous solution (5 mL) of $CoCl_2{\cdot}6H_2O$ (0.12 g, 0.50 mmol) and $NaPF_6$ (0.17 g, 1.00 mmol). The resulting orange-red slurry was refluxed for 7 h, during which time the solids dissolved and the colour of the solution turned to dark red. The solution was filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 4 days, a dark red microcrystalline solid appeared, which was collected by filtration, washed with cold MeCN (2 × 2 mL) and Et_2O (2 × 3 mL), and dried under vacuum. Yield 55%. The dried sample analyzed as solvent-free (**6a**). *Anal.* Calc. for $C_{42}H_{44}Co_3N_{12}O_6P_2F_{12}$: C, 39.48; H, 3.32; N, 13.16. Found: C, 39.44; H, 3.42; N, 13.18%. Selected IR data (KBr pellet, cm^{-1}): 1601m, 15548w, 1495s, 1434m, 1417w, 1223w, 1088vs, 948s, 843vs, 782m, 695w, 629s, 559m, 461m.

2.2.7. $[Co_3(mpko)_6](ClO_4)_2$ (**6b**)

An orange suspension of **5** · $3MeNO_2$ (0.65 g, 1.00 mmol) in MeCN (30 ml) was treated with solid $Co(ClO_4)_2 \cdot 6H_2O$ (0.19 g, 0.50 mmol). The resulting orange-red slurry was refluxed for 10 h, during which time the solids dissolved and the colour of the solution turned to dark red. The solution was filtered, and the filtrate left undisturbed at room temperature to concentrate slowly by evaporation. After 6 days, a dark red microcrystalline solid appeared, which was collected by filtration, washed with cold MeCN (2 × 2 mL) and Et_2O (2 × 3 mL), and dried under vacuum. Yield 60%. The dried sample analyzed as solvent-free (**6b**). *Anal.* Calc. for $C_{42}H_{44}Co_3N_{12}O_{14}Cl_2$: C, 42.50; H, 3.57; N, 14.17. Found: C, 42.54; H, 3.62; N, 14.38%. Selected IR data (KBr pellet, cm^{-1}): 1602m, 1554w, 1490s, 1438m, 1414w, 1222w, 1088vs, 948s, 782m, 696w, 624s, 460m.

2.3. Single-crystal X-ray crystallography

The crystallographic data and structure refinement details for the five, structurally characterized complexes are summarized in Table 1. Selected crystals of **1** (0.12 × 0.16 × 0.22 mm), **2** (0.15 × 0.16 × 0.20 mm), **4** · 6MeCN (0.05 × 0.10 × 0.55 mm) and **5** · $3MeNO_2$ (0.30 × 0.40 × 0.50 mm) were mounted in capillary,

whereas a selected crystal of **3** · 0.25H_2O (0.08 × 0.15 × 0.40 mm) was mounted in air. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11 < 2\theta < 23°$. Intensity data were recorded using a $\theta - 2\theta$ scan to a maximum 2θ value of 50°. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization corrections were applied using Crystal Logic software. All five structures were solved by direct methods using SHELXS-86 [11a] and refined on F^2 by full-matrix least squares techniques with SHELXL-97 [11b]. All H atoms were located by Fourier difference maps and refined isotropically, except those on the solvent molecules (**3** · 0.25H_2O, **4** · 6MeCN and **5** · 3$MeNO_2$) which were introduced at calculated positions as riding on bonded atoms. All non-H atoms were refined anisotropically.

3. Results and discussion

3.1. Brief synthetic comments and IR spectra

Aerobic reactions of $Co(O_2CMe)_2 \cdot 4H_2O$ with the appropriate 2-pyridyl oximes in an 1:3 ratio in various solvents under reflux gave dark red solutions, from which were subsequently isolated the orange mononuclear Co^{III} complexes **1**, **3** and **5**, upon conventional workup. The formation of the representative compound **1** can be represented by Eq. (1)

$$2Co^{II}(O_2CMe)_2 \cdot 4H_2O + 6paoH + 1/2O_2 \rightarrow 2[\underset{\mathbf{1}}{Co^{III}(pao)_3}] + 4MeCO_2H + 9H_2O \quad (1)$$

The $MeCO_2^-$ ions act as a base deprotonating the two-thirds (2/3) of the amount of the organic ligand. Note that **1** and **3** have the *trans* (or *mer*) configuration, whereas complex **5** is the *cis* (or *fac*) isomer (vide infra). The three complexes can be also prepared by the 1:3 aerobic reactions between $CoCl_2 \cdot 6H_2O$ and the oximes in various solvents *in the presence of a base*, see Eq. (2). A typical such preparation is reported in Section 2.2.5 (Method B)

$$2Co^{II}Cl_2 \cdot 6H_2O + 6mpkoH + 4Me_4NOH + 1/2O_2 \rightarrow 2[\underset{\mathbf{5}}{Co^{III}(mpko)_3}] + 4Me_4NCl + 17H_2O \quad (2)$$

Since **1**, **3** and **5** each possesses three free, i.e. uncoordinated, oximate oxygen atoms, we suspected that these mononuclear Co^{III} complexes could act as "ligands" (the so-named "metal complexes as ligands strategy" [5]) and would further react with Co^{II} sources leading to mixed-valent Co^{II}/Co^{III} clusters; such clusters are of great current magnetochemical interest [12]. This, indeed, turned out to be the case and led to the trinuclear $Co_2^{III}Co^{II}$ clusters **2**, **4**, **6a** and **6b**; typical preparations are illustrated by Eqs. (3) and (4). The three oximate oxygen atoms that had been free in the

$$2[\underset{\mathbf{1}}{Co^{III}(pao)_3}] + Co^{II}(ClO_4)_2 \cdot 6H_2O \rightarrow [\underset{\mathbf{2}}{Co^{III}_2Co^{II}(pao)_6}](ClO_4)_2 + 6H_2O \quad (3)$$

$$2[\underset{\mathbf{3}}{Co^{III}(ppko)_3}] + Co^{II}Cl_2 \cdot 6H_2O + 2NaPF_6 \rightarrow [\underset{\mathbf{4}}{Co^{III}_2Co^{II}(ppko)_6}](PF_6)_2 + 2NaCl + 6H_2O \quad (4)$$

mononuclear precursors **1**, **3** and **5** were indeed coordinated to the Co^{II} center in **2**, **4**, **6a** and **6b**. Two Co centers are in the oxidation state III and the products are thus cationic. Therefore, an appropriate counteranion should be present in the reaction mixture, either as the inorganic anion of the Co^{II} source (ClO_4^-) or added externally (PF_6^-). The trinuclear clusters have the three oximate groups of each corresponding Co^{III} metalloligand in a *fac* configuration around the Co^{II} center (vide infra). Since the oximate disposition is different in **1**, **3** and **5** (*mer* versus *fac*), we anticipated different products from the reactions of the metalloligands **1** and **3** with the Co^{II} source compared with the product from the reaction of **5** with Co^{II}. In a sense, complexes **1** and **3** can be considered as bidentate-monodentate bridging "ligands" (due to the *mer* geometry of the three, free oximate oxygens), whereas complex **5** can be viewed as a tridentate chelating "ligand" (due to the *fac* geometry of the three, free oximate oxygens). Somewhat to our surprise, however, the molecular structures of the trinuclear cations seem to be very similar. This means that the geometry of **5** only is preserved in the trinuclear cluster cation (**6a** and **6b**). The *mer* isomers **1** and **3** are also converted to mixed-valent, trinuclear cations (**2** and **4**) that contain the *fac*-$[Co^{III}(pao)_3]$ and *fac*-$[Co^{III}(ppko)_3]$ metalloligand units, respectively. This may suggest the occurrence of an equilibrium between *mer* and *fac* mononuclear, 1:3 Co^{III} species in solution (at least for **1** and **3**), which shifts to the *fac* isomer upon addition of external Co^{II}.

Complexes **2**, **4**, **6a** and **6b** can be also prepared under aerobic conditions by "one-pot" procedures involving the appropriate reaction mixture of a Co^{II} starting material, counteranion and 2-pyridyl oxime, in the presence (when the inorganic anions present are ClO_4^-, Cl^-/ClO_4^- or Cl^-/PF_6^-) or absence (when $MeCO_2^-$ ions are present) of external OH^- ions. Typical preparations are reported in Sections 2.2.2 (Method B) and 2.2.4 (Methods B and C) and illustrated by Eqs. (5) and (6)

$$3Co^{II}(ClO_4)_2 \cdot 6H_2O + 6paoH + 4Me_4NOH + 1/2O_2 \rightarrow [\underset{\mathbf{2}}{Co^{III}_2Co^{II}(pao)_6}](ClO_4)_2 + 4Me_4NClO_4 + 23H_2O \quad (5)$$

$$3Co^{II}(O_2CMe)_2 \cdot 4H_2O + 6ppkoH + 2NaPF_6 + 1/2O_2 \rightarrow [\underset{\mathbf{4}}{Co^{III}_2Co^{II}(ppko)_6}](PF_6)_2 + 2NaCO_2CMe + 4MeCO_2H + 13H_2O \quad (6)$$

The IR spectra of complexes **2** and **6a** exhibit bands near 1090 and 625 cm^{-1}, due to the $\nu_3(F_2)[\nu_d(ClO)]$ and $\nu_4(F_2)[\delta_d(OClO)]$ modes of the uncoordinated T_d ClO_4^- ions, respectively [13]. A strong band at ~840 cm^{-1} and a medium-intensity band at ~560 cm^{-1} in the spectra of **4** and **6b** are assigned [13] to the $\nu_3(F_{1u})[\nu(PF)]$ and $\nu_4(F_{1u})[\delta(FPF)]$ vibrations of the O_h PF_6^- ion, confirming its ionic nature. Two bands, one of variable intensity at 1228–1205 cm^{-1} assigned to ν(N–O) and one of medium to strong intensity at 1606–1598 cm^{-1} assigned to $\nu(C{=}N)_{oximate}$, are common in the spectra of all the prepared complexes [14]; the higher-wavenumber band most probably overlaps with a 2-pyridyl stretch. The ν(N–O) band is located at a slightly lower wavenumber in **2**, **4**, **6a** and **6b** than for their corresponding metalloligand Co^{III} complexes **1**, **3** and **5**, respectively, consistent with the oximate O-coordination in the trinuclear clusters. The in-plane deformation bands of the 2-pyridyl ring of the free paoH, ppkoH and mpkoH ligands at 620–650 cm^{-1} shift upwards (708–676 cm^{-1}) in the spectra of the mononuclear and trinuclear compounds, confirming the involvement of the ring-N atom in coordination [15]. The similar spectral behaviour of **6a** and **6b** (we could not grow single crystals of these complexes suitable for their X-ray structural characterization) in the regions of the $\nu(C{=}N)_{oximate}$, ν(N–O) and δ(Py) vibrations, compared with that of the structurally characterized trinuclear complexes **2** and **4**, is a strong evidence that the cations of the former are structurally analogous to the cations of **2** and **4**.

3.2. Description of structures

The molecular structures of the mononuclear complexes **1**, **3** and **5** are depicted in Figs. 1–3, respectively. Selected interatomic

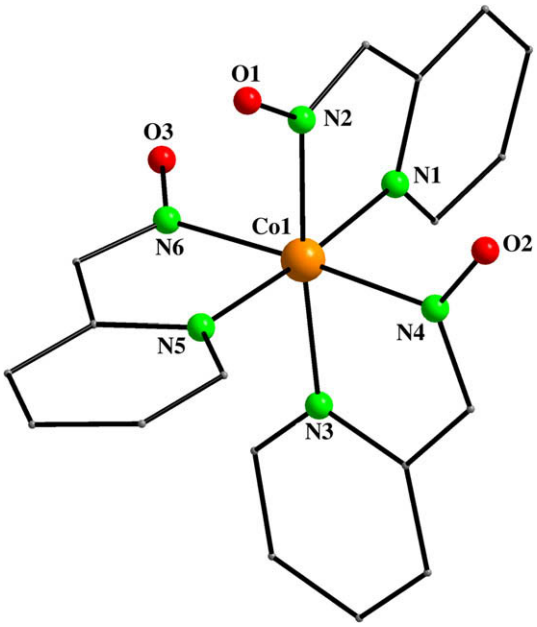

Fig. 1. Molecular structure of complex **1** with selected atom labelling. H atoms have been omitted for clarity. Colour scheme: Co^{III}, orange; O, red; N, green; C, gray.

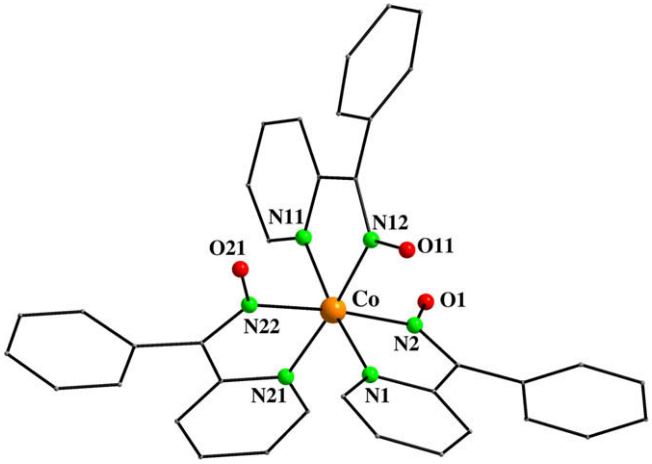

Fig. 2. Partially labelled plot of complex **3**; colour scheme as in Fig. 1. H atoms have been omitted for clarity.

distances and angles for the same compounds are listed in Table 2. Partially labelled representations of the cations of complexes **2** and **4** are shown in Figs. 4 and 5, respectively, while their selected interatomic distances and angles are listed in Table 3.

Complex **1** crystallizes in the orthorhombic space group *Pbca*. Its structure consists of well-separated [Co(pao)$_3$] molecules. The Co^{III} ion is coordinated by three N,N′-bidentate chelating (or 1.011 [16]) pao$^-$ ligands. The pao$^-$ donor atoms are the nitrogen atoms of the deprotonated oxime and the 2-pyridyl groups. The six-coordinate molecule is the *mer* (or *trans*) isomer. Complex **3** · 0.25H_2O crystallizes in the monoclinic space group $P2_1/c$ and its structure comprises mononuclear [Co(ppko)$_3$] units and solvate H_2O molecules; the latter will not be further discussed. The six-coordinate Co^{III} ion possesses a distorted octahedral geometry and is (similarly to **1**) the *mer* isomer. The coordination sphere of the Co^{III} atom in **3** · 0.25H_2O consists of three N,N′-bidentate chelating (or 1.011 [16]) ppko$^-$ ligands. The molecular structures of **1** and **3** are very similar, and the replacement of the H atom by the

[a] Unprimed, primed and doubly-primed atoms have the symmetry operators (−1 + *x* − *y*, 1 − *y*, *z*), (*x*, *y*, *z*) and (1 − *x*, 2 − *x* + *y*, *z*), respectively.

Ph group has thus little structural effect. Complex **5** · 3$MeNO_2$ crystallizes in the hexagonal space group $R\bar{3}$, with mononuclear [Co(mpko)$_3$] units and solvate $MeNO_2$ molecules in general positions. The Co^{III} ion, which sits on a 3-fold axis of symmetry, is coordinated by three N,N′-bidentate chelating (or 1.011 [16]) mpko$^-$ ligands. Surprisingly, and by contrast with **1** and **3**, the six-coordinate complex **5** · 3$MeNO_2$ is the *fac* (or *cis*) isomer. The Co-N bond lengths agree well with values expected for low-spin Co^{III} in octahedral environments [4]. The observed, similar coordination modes of the oximate ligands in complexes **1**, **3** and **5** are interesting because the deprotonated oxygen atom remains uncoordinated.

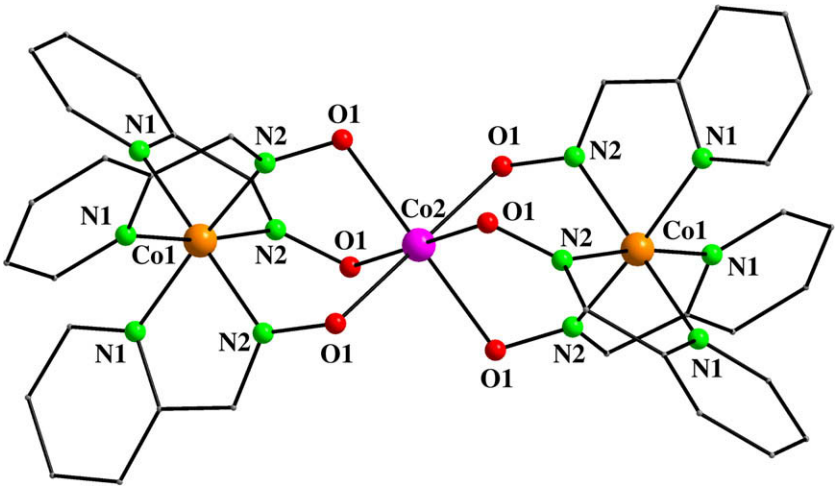

Fig. 4. Partially labelled representation of the mixed-valence(III/II/III) cation $[Co_3(pao)_6]^{2+}$ present in complex **2**. Identical numbers are used for atoms generated by symmetry. H atoms have been omitted for clarity. Colour scheme: Co^{II}, pink; Co^{III}, orange; O, red; N, green; C, gray.

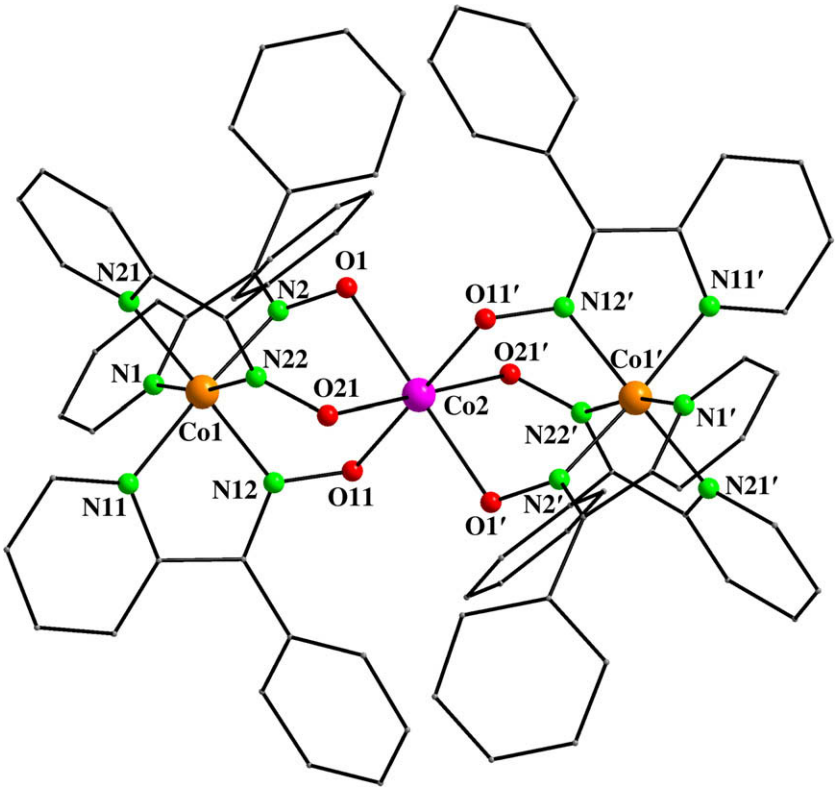

Fig. 5. Molecular structure of the mixed-valence (III/II/III) cation $[Co_3(ppko)_6]^{2+}$ present in complex **4**·6MeCN with selected atom labelling; colour scheme as in Fig. 4. Primes are used for symmetry-related $(-x,-y,-z)$ atoms. H atoms have been omitted for clarity.

The cations of **2** (Fig. 4) and **4** (Fig. 5) are structurally similar in many aspects, except the nature of the coordinated 2-pyridyl oximate group (pao^- versus $ppko^-$) and the counteranion (ClO_4^- versus PF_6^-), and thus only the structure of complex **2** will be described in detail. The crystal structure of **2** reveals the formation of a linear trinuclear cation. The central metal ion, Co(2), sits on a 3-fold inverse axis of symmetry, while the terminal metal ion, Co(1), sits on a 3-fold symmetry axis. The central metal ion is octahedrally coordinated by six oxygen atoms [O(1), and its symmetry-related partners] belonging to six pao^- ligands. The six coordination sites on each of the distorted octahedral, terminal Co ions are occupied by the nitrogen atoms [N(1), N(2), and their symmetry-related partners] that belong to the "chelating" part of three pao^- ligands, with the three oximate N atoms in the facial (or *cis*) configuration. The core for **2** (and **4**) appears to be $[Co^{II}Co_2^{III}(\mu\text{-}ONR')_6]^{2+}$. Charge considerations require a formal $2Co^{III}$,Co^{II} description of **2** (and **4**), and the terminal metal ions are clearly low-spin Co^{III} ions based on their Co–N bond lengths (all <1.96 Å), which have lengths similar to Co^{III}–N bond lengths in other structurally characterized cobalt(III) complexes with

[a] Primes are used for symmetry-related ($-x$, $-y$, $-z$) atoms.

N-ligation [4]. The central cobalt center [Co(2)] has all six Co–O distances 2.102(2) Å indicating that this is a Co^{II} ion [4]. The pao^- ions in **2** (and the $ppko^-$ groups in **4**) function as $\eta^1{:}\eta^1{:}\eta^1{:}\mu$ ligands (or as $2.1_1 1_2 1_2$ ligands using Harris notation [16]); each ligand chelates one Co^{III} ion through the 2-pyridyl and the oximate nitrogen atoms forming a five-membered chelating ring, and bridges this metal center with the central Co^{II} ion through the terminally ligated, deprotonated oxygen atom. Complexes **2** and **4** join a handful of structurally characterized linear, valence-trapped $Co^{III}Co^{II}Co^{III}$ clusters [17].

3.3. Magnetochemistry and ligand-field spectra

Complexes **1**, **3** · $0.25H_2O$ and **5** · $3MeNO_2$ are diamagnetic, as expected. The room-temperature, effective magnetic moment (μ_{eff}) values of **2**, **4**, **6a** and **6b** are 4.81, 5.13, 4.99 and 5.07 B.M. per trimer, respectively; these values are consistent with the presence of one high-spin Co^{II} ion with octahedral stereochemistry [18].

The μ_{eff} value of the representative trinuclear cluster **2** decreases gradually to 4.01 B.M. per trimer at 25 K and then drops to 3.53 B.M. at 2.0 K. This behaviour may be understood as arising from the combined effects of orbital degeneracy and zero-field splitting [17h].

The solid-state (diffuse reflectance) UV–Vis spectra of **1**, **3** · $0.25H_2O$ and **5** · $3MeNO_2$ are typical for low-spin $Co^{III}N_6$ chromophores [19]. The low-spin octahedral ground term is $^1A_{1g}$ and there are two relatively low lying spin allowed transitions, with lower lying spin triplet partners, all derived from $(t_{2g})^5(e_g)$. Under this scheme, the bands in the spectrum of **5**, for example, at 29.13, 21.35, 17.10 and 13.36 kK are assigned [19] to the $^1A_{1g} \rightarrow {}^1T_{2g}, {}^1T_{1g}, {}^3T_{2g}$ and $^3T_{1g}$ transitions, respectively. The spectra of the trinuclear $Co^{III}Co^{II}Co^{III}$ clusters exhibit bands at approximately the same energies with those of their corresponding mononuclear Co^{III} complexes, and maxima characteristic of octahedral $Co^{II}O_6$ chromophores [19]. For instance, the spectrum of **6a** shows bands/shoulders at 29.27, 21.55, 17.50 and 13.00 kK due to its *fac*-$[Co^{III}(mpko)_3]$ units (and assigned as above), and additional bands at 19.23 and 15.80 kK due to its high-spin octahedral $Co^{II}(O_{oximato})_6$ unit and assigned (under O_h symmetry) to the $^4T_{1g} \rightarrow {}^4T_{1g}(P), {}^4A_{2g}$ transitions, respectively [19]. The electronic spectra of **2**, **4** and **6b** are very similar supporting similar structures.

4. Conclusions

This work extends the body of results that emphasize the ability of the anionic 2-pyridyl oximate ligands to form interesting structural types in 3d-metal chemistry. The initial use of pao^-, $ppko^-$ and $mpko^-$ in Co non-carboxylate chemistry has provided access to diamagnetic mononuclear Co^{III} complexes and to paramagnetic mixed-valence $Co_2{}^{III}Co^{II}$ clusters. The incorporation of only one Co^{II} center in the trinuclear clusters precludes the observation of interesting magnetic properties as these complexes behave as mononuclear Co^{II} species. The flexibility of the 2-pyridyl oximate ligands and some very recent results in our group let us believe that we have only seen the tip of the iceberg in Co/2-pyridyl oximate chemistry and that some new clusters with interesting magnetic properties await discovery. From the synthetic inorganic chemistry viewpoint, this work demonstrates the utility of the "metal complexes as ligands" approach in transition metal cluster chemistry. Preliminary experiments show that the reactions of **1**–**3** with sources of other divalent 3d metals lead to a variety of mixed-metal Co^{III}/M^{II} complexes (M = Fe, Mn, Ni, Cu).

5. Supplementary data

CCDC 264168, 264167, 264166, 264165 and 264169 contains the supplementary crystallographic data for **1**, **2**, (**3** · $0.25H_2O$), (**4** · 6MeCN), and (**5** · $3MeNO_2$). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1. The structural formulae of the ligands discussed in the text. The neutral ligand is written in the amide (ketoamine) tautomeric form, while the dianionic ligand in the hydroxylamine (or iminol) tautomeric form; these forms have been established by single-crystal X-ray crystallography (see text for details). Due to the different tautomeric forms involved, different abbreviations are used for the free neutral molecule and the dianionic ligand (H_2L' vs L^{2-}).

2. Experimental

2.1. General and spectroscopic measurements

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received. Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory using an EA 1108 Carlo Erba analyzer. IR spectra (4000–450 cm^{-1}) were recorded on a Perkin-Elmer 16 PC FT-spectrometer with samples prepared as KBr pellets. Magnetic susceptibility measurements in the range 2–300 K were carried out on a polycrystalline sample of **1** using a Quantum Design SQUID magnetometer, under a magnetic field of 0.1 T, at the Magnetochemistry Service of the University of Barcelona. Diamagnetic corrections were estimated from Pascal tables.

2.2. Compound preparation

2.2.1. $[Cu_3L_2Cl_2(DMF)_4]_n$ (**1**)

Method A: A solution of $[Cu_2(O_2CMe)_4(H_2O)_2]$ (0.12 g, 0.30 mmol), $CuCl_2$ (0.013 g, 0.10 mmol) and H_2L' (0.049 g, 0.30 mmol) in DMF (8 ml) was heated at 130 °C in a sealed tube for 6 h, followed by slow cooling down to ambient temperature over a period of 2 days. X-ray quality dark green crystals of $[Cu_3L_2Cl_2(DMF)_4]_n$ (**1**) were obtained directly from the reaction solution. The crystals were collected by filtration under vacuum, washed with cold DMF (2 ml) and Et_2O (5 ml) and dried in air. Typical yields (based on the ligand) were in the 50–55% range. FT-IR (KBr pellet, cm^{-1}): 3421wb, 2924w, 1640vs, 1586m, 1560s, 1545vs, 1492s, 1473sh, 1419w, 1389m, 1375m, 1276m, 1156vw, 1118vw, 1104w, 1060vw, 955w, 754m, 693w, 642m. *Anal.* Calc. for $C_{28}H_{36}N_8O_8Cl_2Cu_3$ (874.26): C, 38.46; H, 4.16; N, 12.82. Found: C, 38.27; H, 4.18; N, 12.88%.

Method B: DMF (25 ml) was added to a mixture of $CuCl_2$ (0.061 g, 0.45 mmol), H_2L' (0.049 g, 0.30 mmol) and $LiOH \cdot H_2O$ (0.025 g, 0.60 mmol). The solids soon dissolved upon stirring. The resulting pale green solution was refluxed for 4 h and then layered with Et_2O (20 ml). Slow mixing gave a dark green microcrystalline solid which was isolated by filtration, washed with DMF (1 ml) and Et_2O (2 × 5 ml), and dried in air. Yield: 70%. The identity of the product was confirmed by elemental analyses and IR comparison with the authentic material prepared by Method A.

2.3. Single-crystal X-ray crystallography

The data were collected using a Bruker APEXII CCD diffractometer on station 16.2 of the Synchrotron Radiation Source at Daresbury Laboratory UK. Crystal data and selected parameters for data collection and processing are listed in Table 1. The data were integrated using SAINT v7.23a and the absorption correction was applied by SADABS. The SHELXTL suite of programs was used to solve the structure using direct methods and perform the least squares refinement. All non-hydrogen atoms were refined anisotropically, with displacement parameter restrains being used in the modeling of the ligands. Hydrogen atoms were placed geometrically where possible, the methyl hydrogen atoms were found in a rotational Fourier map; all were constrained and refined with a riding model.

Table 1
Crystallographic data for complex **1**.

Parameter	**1**
Chemical formula	$C_{28}H_{36}N_8Cu_3O_8Cl_2$
Formula weight	874.17

[a] $w = 1/[\sigma^2(F_o^2) + (\alpha P)^2 + bP]$ and $P = (\max\ F_o^2, 0) + 2F_c^2/3$, $R_1 = \sum(|F_o| - |F_c|)/\sum(|F_o|)$ and $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$.
[b] For 4234 reflections with $F^2 > 2\sigma(I)$.

3. Results and discussion

3.1. Brief synthetic comments and IR spectra

Complex **1** was initially obtained by solvothermal synthesis. Heating a solution of $[Cu_2(O_2CMe)_4(H_2O)_2]$, $CuCl_2$ and H_2L' in a 3:1:3 ratio in DMF at 130 °C in a sealed tube under autogenous pressure for 6 h, followed by slow cooling at room temperature, gave dark green crystals of the product. The $MeCO_2^-$ ions act as a base helping the deprotonation of the ligand. The usefulness of superheated fluids, i.e. solvothermal conditions, for preparing extended frameworks based on metal–ligand interactions has been demonstrated by several groups [7]. The temperature regime available in solvothermal techniques, intermediate between low-temperature solution chemistry and high-temperature solid-state chemistry, can favour the formation of metastable kinetic products rather than the thermodynamic products favoured at high temperature.

With the identity of **1** established by single-crystal, X-ray crystallography, we sought a convenient synthesis of the pure material under alternative, mild reaction conditions. It was logical to impose upon the knowledge of the chemical composition of **1** to select the starting materials and their ratios. Thus, the reaction of three equivalents of $CuCl_2$ with 2 equiv. of H_2L' and 4 equiv. of $LiOH \cdot H_2O$ in DMF gave, after convenient workup, the product in ~70% yield. The formation of the complex can be summarized by Eq. (1):

$$3n\mathrm{CuCl_2} + 2n\mathrm{H_2L'} + 4n\mathrm{LiOH{\cdot}H_2O} + 4n\mathrm{DMF} \xrightarrow{\mathrm{DMF}} \underset{1}{[\mathrm{Cu_3L_2Cl_2(DMF)_4}]_n} + 4n\mathrm{LiCl} + 8n\mathrm{H_2O} \quad (1)$$

Note that the ligand in the product is not the doubly deprotonated amide, i.e., L'^{2-}, but instead the di-iminolate (-2) [or diolate (-2)], i.e., L^{2-} (vide infra), see Scheme 1.

The IR spectrum of free H_2L' shows the characteristic bands of the *cis* secondary amide groups with the bands at ~3100, 1682, 1472 and 1392 cm^{-1} assigned to ν(NH), ν(C=O), $\nu(CN)_{amide}$ and δ(NH), respectively [8,9]. This spectral behaviour is consistent with the solid-state structure of the ligand (vide infra). The spectrum of **1** does not exhibit a band in the region for the amide carbonyl stretching, as expected from the absence of L'^{2-} in the product. The ν(C=O) and δ(OCN) vibrational modes of the coordinated DMF molecules appear at 1640 and 693 cm^{-1}, respectively [10]. Due to coordination, the ν(C=O) and δ(OCN) bands are shifted to lower and higher wavenumbers, respectively, when compared with the corresponding bands in the spectrum of free DMF [11].

3.2. Description of structure

Various structural features of **1** are shown in Figs. 1–3. Selected interatomic distances and angles are listed in Table 2.

Complex **1** is a 3D coordination polymer built from centrosymmetric trinuclear $[Cu_3L_2Cl_2(DMF)_4]$ units containing 2,3-dioxyquinoxalinate(-2) (L^{2-} in Scheme 1, vide infra) ligands that are responsible for the polymer formation. A perspective view of the trinuclear unit is shown in Fig. 1. Within the crystallographic asymmetric unit there are two, structurally different Cu^{II} sites, Cu(1) and Cu(2). The central Cu(1) ion sits on a crystallographically imposed inversion centre exhibiting *trans* coordination to two terminal chlorides and to two symmetry related L^{2-} ligands *via* the one of nitrogen atoms [N(1)] in each ligand. Each of the two "terminal" Cu^{II} ions [Cu(2), Cu(2′)] is bonded to two oxygen atoms of two terminal DMF molecules, both oxygen atoms from one L^{2-} ligand and to one nitrogen atom [N(2)] from an equivalent ligand in a different asymmetric unit.

The coordination geometry around Cu(1) is square planar. The Cu(1)–Cl(1) bond length of 2.277(1) Å is typical for square planar copper(II) complexes involving chloro ligands [12]. The Cu(2) coordination geometry is well described as square pyramidal with the DMF oxygen O(3) occupying the apical position. Analysis of the shape-determining angles using the approach of Reedijk and Addison [13] yields a value for the trigonality indet τ of 0.26 for Cu(2)

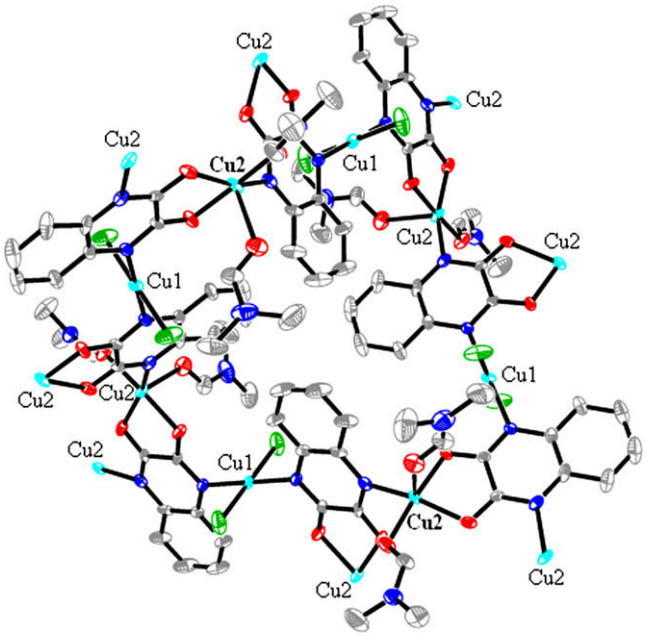

Fig. 2. The half folded square ring which makes up the substructure of **1**, with the fold along the Cu^{II} ions labeled in bold and the rest of the molecule being further away from the viewer. Displacement parameters are plotted at the 50% probability level.

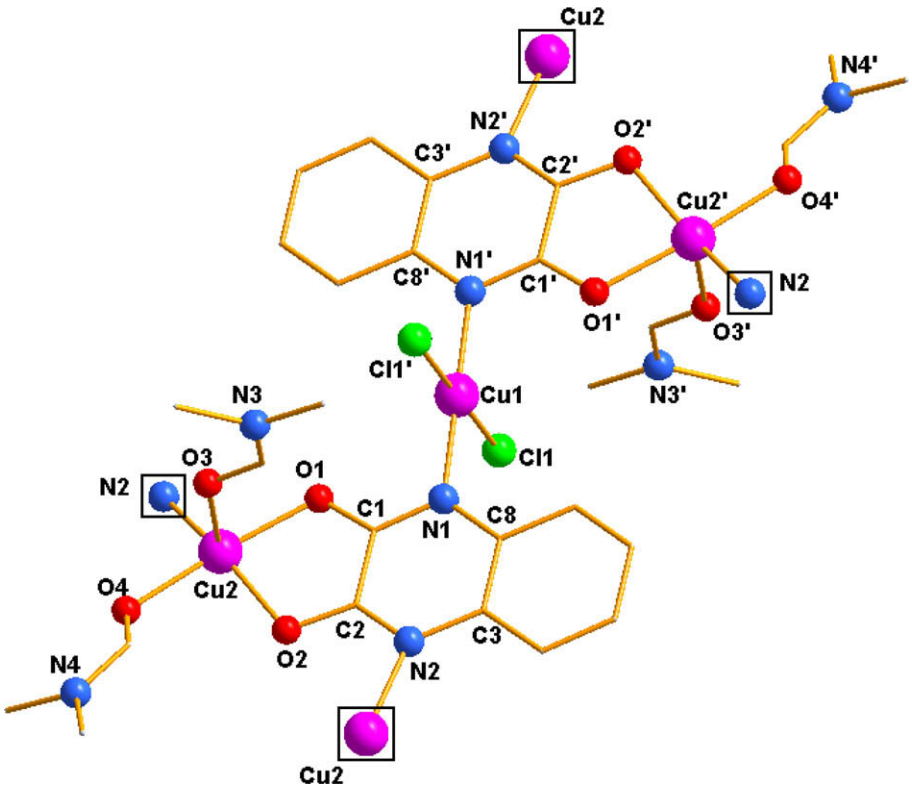

Fig. 1. The molecular structure of the repeat, centrosymmetric trinuclear unit present in the 3D network of **1**. The squared atoms belong to neighbouring units. The primed and unprimed atoms within the trinuclear unit are related by the symmetry operation $-x+2$, $-y+1$, $-z$.

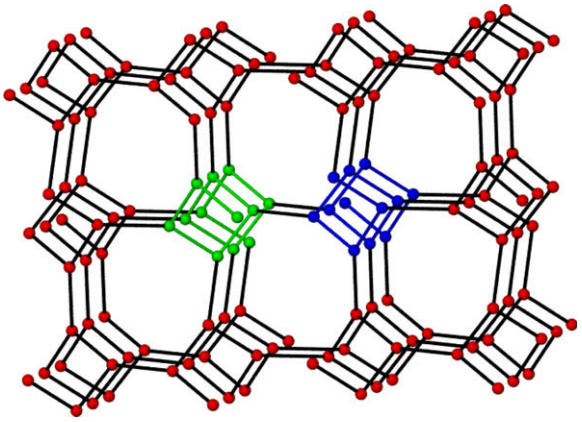

Fig. 3. Schematic representation of the (8^2.10)-a net of **1,** viewed along the *c* axis, containing 4-fold helices with opposite handedness (blue and green). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 2
Selected interatomic distances (Å) and angles (°).

Distances			
Cu(1)···Cu(2)	4.898(1)	Cu(2)–O(2)	1.972(2)
Cu(1)–Cl(1)	2.277(1)	Cu(2)–O(3)	2.336(2)
Cu(1)–N(1)	1.973(2)	Cu(2)–O(4)	1.988(2)
Cu(2)–O(1)	1.965(2)	Cu(2)–N(2″)	1.987(2)
Bond Angles			
Cl(1)–Cu(1)–Cl(1′)	180.0	O(1)–Cu(2)–N(2″)	93.8(1)

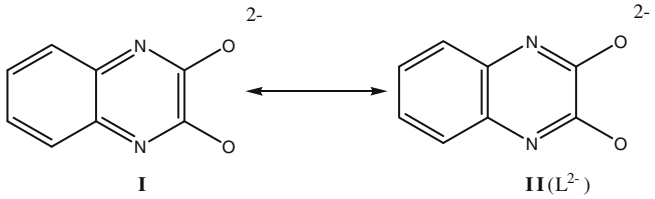
Cl(1)–Cu(1)–N(1)	89.8(1)	O(2)–Cu(2)–O(4)	89.9(1)
Cl(1)–Cu(1)–N(1′)	90.2(1)	O(2)–Cu(2)–N(2″)	158.9(1)
O(1)–Cu(2)–O(2)	89.5(1)	O(3)–Cu(2)–O(4)	87.0(1)
O(1)–Cu(2)–O(3)	90.5(1)	O(3)–Cu(2)–N(2″)	110.0(1)
O(1)–Cu(2)–O(4)	173.8(1)	O(4)–Cu(2)–N(2″)	92.4(1)



Symmetry operations used to generate equivalent atoms:
(′) $-x+2, -y+1, -z$; (″) $x-1/4, -y+5/4, z-1/4$.

(τ = 0 and 1 for perfect square pyramidal and trigonal bipyramidal geometries, respectively) suggesting a distorted stereochemistry. As expected, the axial Cu(2)–O(3) bond is the longest [2.336(2) Å].

In solution, 1,4-dihydro-2,3-quinoxalinedione (H_2L', Scheme 1) is in equilibrium with the tautomers with one and two hydroxyl groups [14]. The question of which tautomer is predominant in the solid state was answered with the help of single-crystal X-ray crystallography some 30 years ago [14]; this technique revealed that the molecule is a dione (H_2L' in Scheme 1). A comparison of the structural data for the dianionic ligand in complex **1** with those of the free ligand H_2L' [14] shows that the excess electron density of the deprotonated nitrogen atom is partially delocalized over the oxygen atoms of the amido groups; this permits the formulation of the resonance structures **I** and **II** [15], see Scheme 2. In the case of **1**, the C–O bonds appear to be weaker than in H_2L' (1.278 and 1.284 versus 1.232 and 1.225 Å), whereas the C(1)–C(2) bond is stronger (1.484 versus 1.552 Å). This indicates less double-bond character in the CO bonds and more double-bond character in the CC bond for L^{2-}; this may suggest at first glance the dominance of the resonance form **I** (Scheme 2) in the real structure of the coordinated dianionic ligand. On the other hand, the CN bond lengths between the carbon atoms of the phenyl ring and nitrogen atoms in the heterocyclic ring for **1** (1.384 and 1.390 Å) are typical of those of a single C–N bond, as in the case of the free ligand (1.392 and 1.398 Å) [14]. Moreover, the C–$N_{\text{"amide"}}$ bond distances in **1** [(C(1)–N(1) = 1.316 Å, C(2)–N(2) = 1.318 Å)], which are less than the corresponding distances in the free ligand (1.337 and 1.345 Å), indicate the existence of double bonds. Thus, the CN bond distances of **1** are consistent with the dominance of the resonance form **II** (see Scheme 2) in the real structure of the coordinated dianionic ligand [15]; for this reason, the dianionic ligand is represented using the form **II** in Scheme 1 and Fig. 4 (vide infra).

The structural elements that are present in the repeat trinuclear unit of **1** arrange into a half folded square ring consisting of four Cu(1) and four Cu(2) ions and eight L^{2-} ligands (Fig. 2); each of these ligands is then coordinated through a square pyramidal copper [Cu(2)] *via* either nitrogen or both oxygens alternately to form a 3D coordination polymer. In this arrangement, the L^{2-} ligands serve as "T" shaped three-connected nodes while the Cu^{II} centres serve as linear bridges creating a rather uncommon three-connected (8^2.10)-a network, known also as **lig** (LiGe) (Fig. 3) [16,17]. This contains 4-fold helices with opposite handedness (Fig. 3). Although the (8^2.10)-a net has been predicted by Wells [18], it remains rare in coordination polymer chemistry. To the best of our knowledge, there are only five examples of coordination polymers adopting the **lig** topology [19], two of which are 2-fold interpenetrating [20]. Therefore, **1** represents the fourth example of a non-interpenatrating (8^2.10)-a topology and the sixth example of a (8^2.10)-a network. Given the relative roles of the ligands which serve as nodes and metal centres which serve as bridges within the (8^2.10)-a network, **1** can be characterized as an Inverted Metal–Organic Framework (IMOF) [21].

The ligand L^{2-} adopts the 3.1111 (using Harris notation [22]) coordination mode in **1** (Fig. 4). This is a novel coordination mode for this ligand. Complex **1** joins a handful of structurally character-

Scheme 2. Two resonance structures for the 2,3-dihydroxyquinoxalinate(-2) ion.

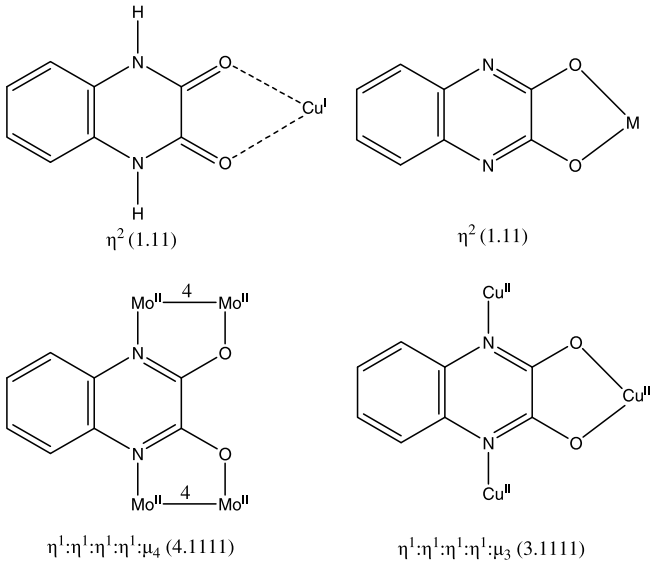


Fig. 4. The up-to-date crystallographically established coordination modes of 1,4-dihydro-2,3-quinoxalinedione (H_2L') and its 2,3-dioxyquinoxalinate(-2) dianionic ligand; the description of the modes by using the Harris notation [17] is shown in parentheses. The dashed lines represent weak interactions. M = Fe^{III}, Ru^{III}.

ized metal complexes containing H_2L' or L^{2-} as ligands [5,15,23,24]. The previously reported complexes are $[Mo^{II}_4(DAniF)_6(L)]$ [5], $[Fe^{III}(L)_3]^{2-}$ [15], $[Cu^{I}(CN)(H_2L')]_n$ [23] and the organometallic compound $[(Cp^*)Ru(NO)(L)]$ [24], where $DAniF^-$ is the *N*,*N*′-di-*p*-anisylformamidinate(-1) ligand. The ligands H_2L' and L^{2-} have been observed in four ligation modes in these complexes (including **1**). The observed coordination modes are shown in Fig. 4. The metric parameters of L^{2-} in all the previous complexes support its formulation as shown in Scheme 1, i.e. the dominance of the resonance form **II** (see Scheme 2). Thus compound **1** is the first crystallographically characterized metal complex in which 2,3-dioxyquinoxalinate(-2) coordinates in the ene-1,2-diolate mode as a bridging ligand.

3.3. Magnetochemistry

Solid-state dc magnetic susceptibility data (Fig. 5) were collected on dried **1** under a constant field of 0.1 T in the temperature range 2.0-300 K. The product $\chi_M T$ at room temperature is 1.17 $cm^3\ mol^{-1}\ K$ per trinuclear unit, close to the value of 1.24 $cm^3\ mol^{-1}\ K$ expected for three non-interacting Cu^{II} ions with a *g* value of 2.1. The value of the $\chi_M T$ product decreases gradually upon cooling until ca. 60 K, and below this temperature it decreases rapidly down to a value of 0.62 $cm^3\ K\ mol^{-1}$ at 6 K, before increasing sharply at lower temperatures; the $\chi_M T$ value is 0.81 $cm^3\ K\ mol^{-1}$ at 2.0 K. Magnetization experiments performed at 2.0 K in the field range 0–5 T indicate a saturation value close to one electron per Cu^{II}_3 unit exhibiting a Brillouin shape for $S = 1/2$ and $g = 2.06(4)$, see inset of Fig. 5.

For a 3D compound in which all the superexchange pathways were operative and antiferromagnetic in nature, an $S = 0$ "ground state" would be expected in the absence of competitive interactions. The non-zero "ground" state of **1** can be explained by considering carefully the structural details of the complex. There are two different superexchange pathways, both provided by the ligand L^{2-}, and thus two different kinds of *J* values (Fig. 6; from now onwards the numbering scheme that will be used is the same with that used in the real structure of **1**, see Fig. 1). J_1 is associated with the *inter*trimer Cu(1)···Cu(2) interaction through the "pyrazine" portion of L^{2-} and J_2 is associated with two equivalent [one *intra*trimer Cu(1)···Cu(2) and one *inter*trimer Cu(2)···Cu(2)] interactions through the NCO^- and $NCCO^-$ moieties of L^{2-}. The magnetic data, which are indicative of the presence of one unpaired electron

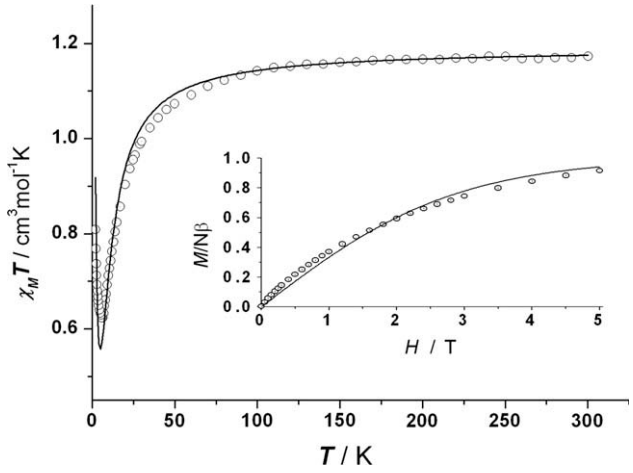

Fig. 5. $\chi_M T$ vs *T* for **1**; the solid line represents the best fit of the experimental data (see the text for the fit parameters). The inset shows magnetization data for the Cu^{II}_3 subunit; the solid line represents the Brillouin curve for the $S = 1/2$ state.

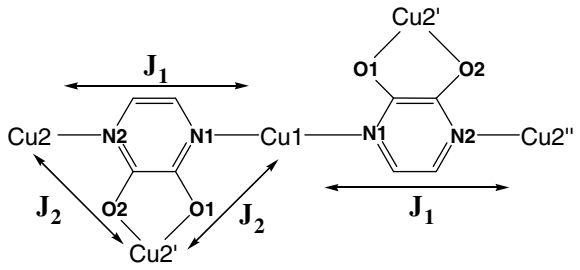

Fig. 6. The 2-*J* magnetic model initially considered for complex **1**; see the text for details. The benzene 'part' of the ligand L^{2-} has been omitted for clarity.

for each Cu^{II} triad, suggest that one of the pathways is not magnetically operative. Taking into account that (i) J_2 propagates the antiferromagnetic interaction in the three dimensions, and (ii) the quinoxaline bridge is a weak to moderate, but effective mediator of magnetic exchange interactions [25], we decided to fit the data assuming a negligible value of J_2. Since the J_1 interaction creates *pseudo*isolated Cu(2)···Cu(1)···Cu(2) subunits of the type shown in Fig. 6 (see also Fig. 1), we used the Hamiltonian of Eq. (2), including a Θ term in an attempt to adjust the low temperature data. Best-fit parameters are $J_1 = -10.4(3)\ cm^{-1}$, $g = 2.057(6)$ and $\Theta = +1.1(1)$ K.

$$H = -J_1(S_2 \cdot S_1 + S_1 \cdot S_{2''}) \quad (2)$$

The obtained *J* value is in good agreement with reported values involving the exchange interaction between Cu^{II} ions through the quinoxaline bridging ligand, which is always weakly to moderately antiferromagnetic [25]. The minimum in the $\chi_M T$ versus T plot at 6 K (Fig. 5) indicates that J_2 (see Fig. 6) is not strictly zero. It is not possible to calculate accurately the value of this coupling constant for a 3D system with the observed topology, but the positive sign and low value of the Θ term clearly indicate that a very weak ferromagnetic interaction is mediated by the $NCO^-/NCCO^-$ moieties of L^{2-}.

4. Concluding comments and perspectives

The commercially available compound 1,4-dihydro-2,3-quinoxalinedione (H_2L') has fulfilled its promise as a good ligand for the preparation of coordination polymers with interesting structures and properties. The ligand has been transformed to the 2,3-dioxyquinoxalinate (L^{2-}) form upon complexation with copper(II). The obtained 3D coordination polymer **1** is novel in multiple ways, as described, but it also provides a rare example of a complicated structural type where the main magnetic exchange interaction is propagated through only one pathway. We also believe that the 'catecholate'-type deprotonated oxygen atoms of L^{2-} can each bridge two Cu^{II} ions, thus increasing its coordination potential to μ_4 or μ_5, a fact that may favour new structural types. Complexes of L^{2-} with Mn^{II}, Fe^{II}, Co^{II} and Ni^{II} are not known to date, and it is currently not evident whether the chemical identity and structure of such compounds are dependent on the particular nature of the metal ion; based on the unique nature of Cu^{II} among the divalent 3d-metals, we predict that the Mn^{II}, Fe^{II}, Co^{II} and Ni^{II}/L^{2-} polymers will have different structures and magnetic properties. Efforts to test the above expectations are currently in progress.

Supplementary data

CCDC 663054 contains the supplementary crystallographic data for **1**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

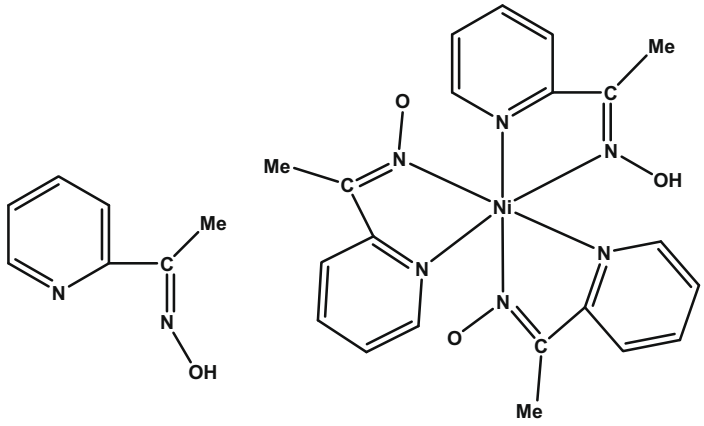

Fig. 1. The organic ligand (left) and the metalloligand (right) used in our efforts.

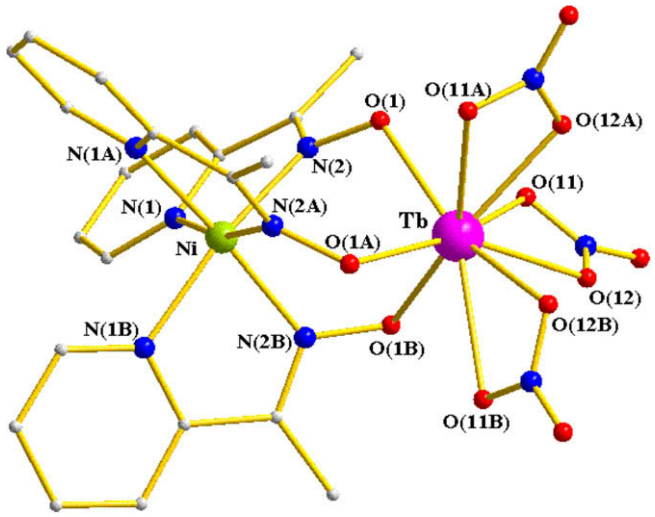

Fig. 2. The molecular structure of **2**.

crystallographic axis. The Ni^{II} center has an octahedral $Ni^{II}N_6$ chromophore. The three oximate/oxime O atoms that were free in the precursor complex **1** are coordinated to the Tb^{III} center in **2**; three chelating NO_3^- groups complete 9-coordination at Tb^{III}. The *cis–cis–cis* disposition of the oxime/oximate groups is preserved in the product. It is very likely that the C_3 symmetry axis is masking the presence of a proton statically disordered among the three ligand groups. Note that the O(1)···O(1A), O(1A)···O(1B), and O(1)···O(1B) distances [3.208(11) Å] are consistent with a (33%) hydrogen bond. It should also be mentioned that a vacuum-dried sample of **2** exhibits an IR band (KBr, hexachlorobutadiene) at ~3400 cm^{-1} assignable to the $\nu(OH)_{oxime}$ mode.

$$[\underset{\mathbf{1}}{Ni\{(py)C(Me)NO\}_2\{(py)C(Me)NOH\}} + Tb(NO_3)_3 \cdot 6H_2O \rightarrow [\underset{\mathbf{2}}{NiTb\{(py)C(Me)NO\}_2(NO_3)_3\{(py)C(Me)NOH\}} + 6H_2O \quad (1)$$

In the starting metalloligand **1** and the dinuclear product **2**, one of the three organic ligands is formally neutral. We suspected that the presence of a base could affect the product identity and this has, indeed, turned out to be the case. *Keeping all the other synthetic parameters constant*, the presence of one (or more) equivalents of base, e.g., Et_3N, per metalloligand **1** gave the nitrate-free clusters $[Ni_2Dy_2\{(py)C(Me)NO\}_6(NO_3)_4]$ (**3**) and $[Ni_2Tb_2\{(py)C(Me)NO\}_6(NO_3)_4]$ (**4**)[1] depending on the lanthanide used in good yield, see Eq. (2). The molecular structure[2] of **3** is shown in Fig. 3. The molecule lies on a crystallographic inversion center and consists of two dimeric $NiDy\{(py)C(Me)NO\}_2(NO_3)_2$ units which have a structural resemblance to the dinuclear molecules of **2**. The formerly neutral oxime group is now deprotonated and bridging providing the interdimer linkage. Thus, four $(py)C(Me)NO^-$ anions behave as $\eta^1{:}\eta^1{:}\eta^1{:}\mu$ ligands and two as $\eta^1{:}\eta^1{:}\eta^2{:}\mu_3$ ligands. As expected, treatment of **2** with base leads to **4**.

$$2[\underset{\mathbf{1}}{Ni\{(py)C(Me)NO\}_2\{(py)C(Me)NOH\}} + 2Ln(NO_3)_3 \cdot 6H_2O + 2Et_3N \xrightarrow{MeOH} [\underset{\mathbf{3,4}}{Ni_2Ln_2\{(py)C(Me)NO\}_6(NO_3)_4}] + 2Et_3NH(NO_3) + 12H_2O \quad (2)$$

In the above described dinuclear and tetranuclear clusters, the molar ratio of the metal ions is 1:1. Since the coordination sphere of the Tb^{III} ion in **2** is completed by three terminal NO_3^- groups, we suspected that using a 2:1 metalloligand to Tb^{III} reaction ratio would lead to trinuclear clusters. The reaction of $Tb(NO_3)_3 \cdot 6H_2O$ with 2 equiv. of **1** and 2 equiv. of base in MeOH gave complex $[Ni_2Tb\{(py)C(Me)NO\}_6](NO_3)$ (**5**)[2] in moderate yield, see Eq. (3). The molecular structure of the centrosymmetric cation of **5** is

$$2[\underset{\mathbf{1}}{Ni\{(py)C(Me)NO\}_2\{(py)C(Me)NOH\}} + Tb(NO_3)_3 \cdot 6H_2O + 2Et_3N \xrightarrow{MeOH} [\underset{\mathbf{5}}{Ni_2Tb\{(py)C(Me)NO\}_6}](NO_3) + 2Et_3NH(NO_3) + 6H_2O \quad (3)$$

shown in Fig. 4. The $(py)C(Me)NO^-$ anions behave as $\eta^1{:}\eta^1{:}\eta^1{:}\mu$ ligands. The cation can be viewed as a six-coordinate Tb^{III} complex featuring two deprotonated, tridentate chelating metalloligands. Complex **5** can also be prepared by the reaction of **2** with 1 equiv. of **1** in MeOH in the presence of a base, see Eq. (4).

$$[\underset{\mathbf{2}}{NiTb\{(py)C(Me)NO\}_2(NO_3)_3\{(py)C(Me)NOH\}}] + [\underset{\mathbf{1}}{Ni\{(py)C(Me)NO\}_2\{(py)C(Me)NOH\}}] + 2Et_3N \xrightarrow{MeOH} [\underset{\mathbf{5}}{Ni_2Tb\{(py)C(Me)NO\}_6}](NO_3) + 2Et_3NH(NO_3) \quad (4)$$

Complexes **2**–**5** were also prepared by the 'one-pot' approach, i.e., by the direct reactions between $Ni(ClO_4)_2 \cdot 6H_2O$, $Ln(NO_3)_3 \cdot 6H_2O$ and (py)C(Me)NOH using the appropriate reactants ratios (those imposed on by the stoichiometric formulae of the compounds) and base equivalents.

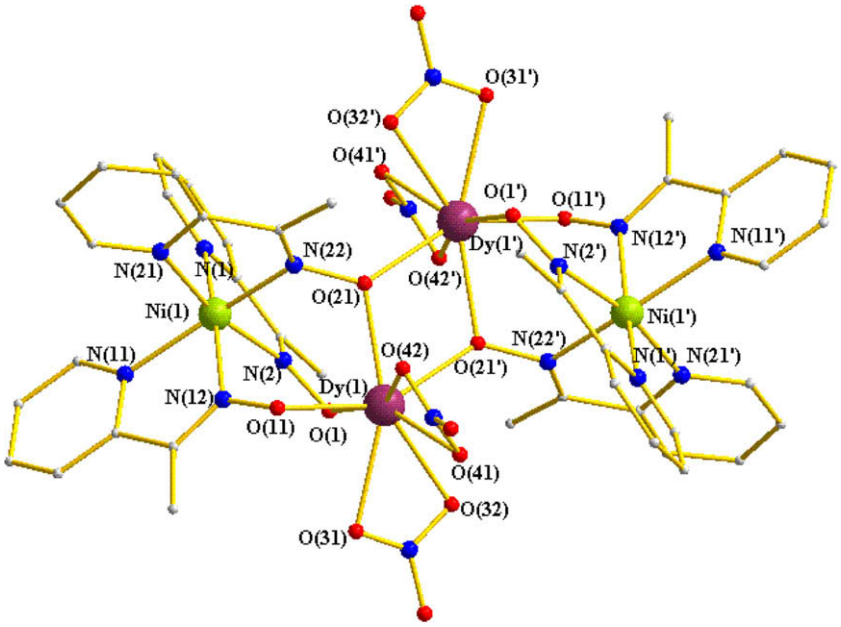

Fig. 3. The molecular structure of **3**.

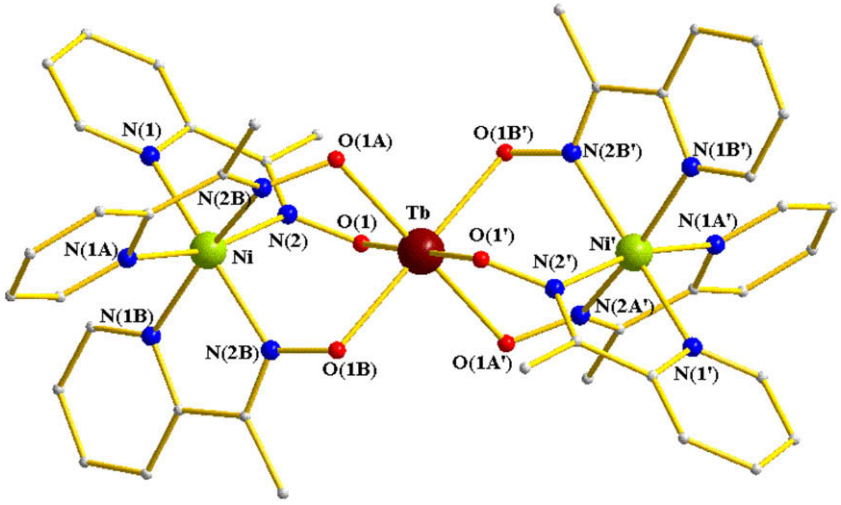

Fig. 4. The molecular structure of the cation present in complex **5**.

Solid-state dc magnetic susceptibility data (χ_M) data for the representative complexes **2** and **5** were collected in the 2.0–300 K range in a 5 KG (0.5 T) field. Data in the form of $\chi_M T$ versus T plots are shown in Fig. 5. The room temperature $\chi_M T$ value of 13.34 $cm^3\ mol^{-1}\ K$ for **2** (Ni^{2+}, $S = 1$; Tb^{3+}, $^7F_6$, $S = 3$, $L = 3$, $J = 6$) decreases slightly upon cooling to ~75 K, where it begins to drop sharply to a value of 4.16 $cm^3\ mol^{-1}\ K$ at 2.0 K. An analogous behavior is observed for **5** with the $\chi_M T$ values at 300 and 2.0 K being 13.54 and 2.80 $cm^3\ mol^{-1}\ K$, respectively. The field dependence of the magnetization (M) was also measured at 2.0 K. Data are shown in Fig. 6. The experimental M value of **2** and **5** reaches a value of 6.71 and 6.41 $N\mu_B$ at 5 T, respectively.

The observed decrease of the $\chi_M T$ product as T decreases is mainly governed by the thermal depopulation of the ground-state sublevels (Stark sublevels) that result from the spin–orbit coupling and a low symmetry crystal field [9]. Moreover, the 4f electrons are little involved in chemical bonding due to the inner nature of the 4f orbitals, thus inducing very weak superexchange and magnetic

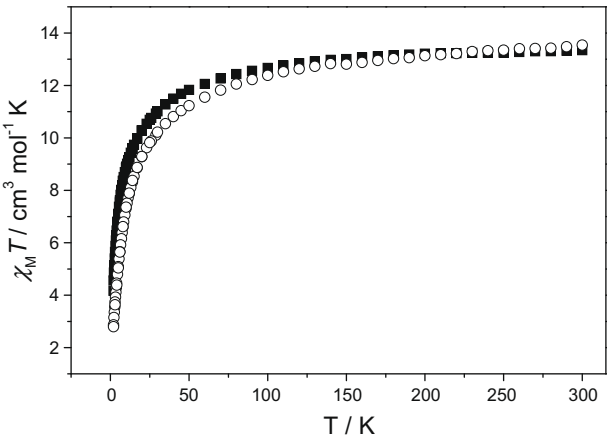

Fig. 5. Plot of $\chi_M T$ as a function of T for **2** (black squares) and **3** (open circles).

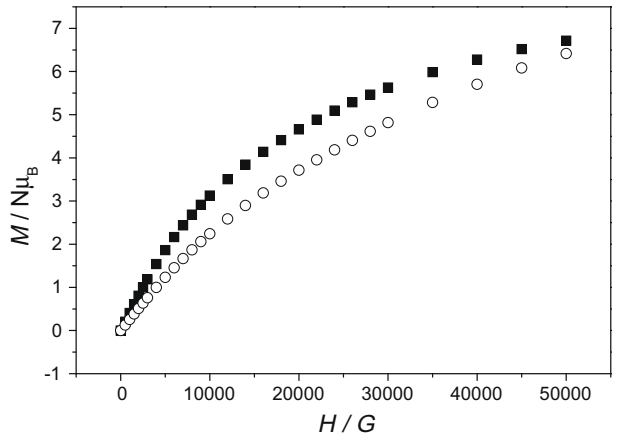

Fig. 6. Magnetic field (H) dependence of the magnetization (M) at 2 K for **2** (black squares) and **5** (open circles).

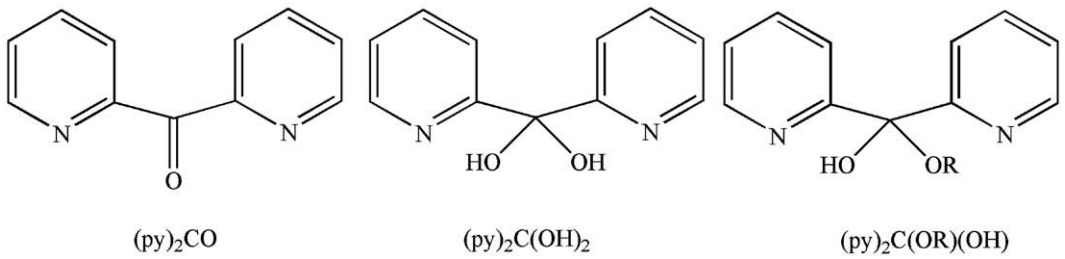
couplings with the 3d-metal electrons [9]. Hence, it is very difficult to determine the relative contributions of the thermal depopulation of the Stark sublevels versus the intramolecular magnetic interactions [9]. To extract some information on the absence/presence and the nature of the Ni^{II}–Tb^{III} interaction in the two complexes, the approach of Kahn et al. [10] should be applied. The approach requires the preparation and magnetic study of the corresponding dinuclear and trinuclear Ni^{II}/La^{III}, Lu^{III} or Y^{III}, Ni^{II}/Gd^{III} and Zn^{II}/Tb^{III} complexes, and this effort is currently in progress.



In summary, complexes **2**–**5** are new valuable additions in the relatively small family of mixed Ni^{II}/Ln^{III} clusters. The magnetic properties of these clusters are complicated by the large spin–orbit coupling effects of Tb^{III} and Dy^{III}, making difficult the quantitative study of the magnitude of the exchange parameters and their resulting ground state description. This preliminary work also demonstrates the utility of the 'metal complexes as ligands' approach based on the use of 2-pyridyloximates for the preparation of mixed 3d/4f-metal complexes. We do believe that the use of Ln^{III} ions to modulate the magnetic properties of transition-metal clusters, high-spin molecules and SMMs is still an interesting area that promises new science as it matures.

Scheme 1. The $(py)_2CO$-based ligands discussed in the text; note that $(py)_2C(OH)_2$ and $(py)_2C(OR)(OH)$ and their anions exist *only* in their respective metal complexes (R = Me, Et, etc.).

give an extraordinary structural flexibility in the $(py)_2CO/R'CO_2^-/N_3^-$ mixed ligand system. This has, indeed, turned out to be the case. Preliminary results of this work have been communicated [13].

2. Experimental

2.1. General and physical measurements

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received. $Cu(O_2CPh)_2 \cdot 2H_2O$ was prepared as described elsewhere [14]. *Caution*! Although no such behavior was observed during the present work, azide salts are potentially explosive; such compounds should be synthesized and used in small quantities, and treated with utmost care at all times.

Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory using an EA 1108 Carlo Erba analyzer. IR spectra (4000–450 cm^{-1}) were recorded on Perkin–Elmer 16 PC and Nicolet 520 FTIR spectrometers with samples prepared as KBr pellets. Magnetic susceptibilities were measured on polycrystalline powders with a Cryogenic S600 SQUID magnetometer. Powders were pressed in a pellet to prevent preferential crystallite orientation with the magnetic field.

2.2. Compound preparation

2.2.1. $[Cu_6(O_2CPh)_4(N_3)_2\{(py)_2CO_2\}_2\{(py)_2C(OH)O\}_2] \cdot 2H_2O \cdot 4.5MeCN$ (**1** $\cdot 2H_2O \cdot 4.5MeCN$)

Method A: To a stirred solution of $(py)_2CO$ (0.06 g, 0.30 mmol) and $LiOH \cdot H_2O$ (0.01 g, 0.30 mmol) in MeCN (20 ml) was added solid NaN_3 (0.02 g, 0.30 mmol). The mixture was stirred for 15 min and then solid $Cu(O_2CPh)_2 \cdot 2H_2O$ (0.21 g, 0.60 mmol) was added under vigorous stirring, which caused a rapid color change from blue to dark green. The resulting solution was stirred for a further 1 h, filtered, and the filtrate was layered with Et_2O (40 ml). After 10 days, X-ray quality dark-green prismatic crystals of **1** $\cdot 2H_2O \cdot 4.5MeCN$ were collected by filtration, washed with MeCN (2×5 ml) and Et_2O (2×5 ml), and dried in air. Yield 55%. The dried sample analyzed as **1** $\cdot 2H_2O$. *Anal.* Calc. for $C_{72}H_{58}Cu_6N_{14}O_{18}$: C, 48.35; H, 3.27; N, 10.96. Found: C, 48.51; H, 3.14; N, 10.91%. Selected IR data (KBr pellet, cm^{-1}): 3428m, 2058vs, 1602s, 1562s, 1474m, 1442m, 1382vs, 1298w, 1224w, 1158w, 1126w, 1078s, 980w, 776w, 722m, 684w, 652w, 462w, 424w.

Method B: To a stirred solution of $(py)_2CO$ (0.06 g, 0.30 mmol) in MeCN (20 ml) was added solid NaN_3 (0.02 g, 0.30 mmol). The mixture was stirred for 35 min and then solid $Cu(O_2CPh)_2 \cdot 2H_2O$ (0.21 g, 0.60 mmol) was added under vigorous stirring, which caused a rapid color change from blue to dark green. The resulting solution was stirred for a further 1 h, filtered, and the filtrate was layered with Et_2O (40 ml). After 13 days, X-ray quality dark-green prismatic crystals of **1** $\cdot 2H_2O \cdot 4.5MeCN$ were collected by filtration, washed with MeCN (2×5 ml) and Et_2O (2×5 ml), and dried in air. Yield 13%. The identity of the product was confirmed by elemental analysis (C, H, N) and IR spectroscopic comparison with authentic material from Method A.

2.2.2. $[Cu_4(O_2CPh)_2(N_3)_4\{(py)_2C(OMe)O\}_2]_n$ (**2**) and $[Cu_2(O_2CPh)(N_3)_2\{(py)_2C(OMe)O\}]_n$ (**3**) in a mixture

To a stirred solution of $(py)_2CO$ (0.06 g, 0.30 mmol) in MeOH (20 ml) was added solid NaN_3 (0.02 g, 0.30 mmol). The mixture was stirred for 15 min and then solid $Cu(O_2CPh)_2 \cdot 2H_2O$ (0.21 g, 0.60 mmol) was added under vigorous stirring, which caused a rapid color change from blue to dark green. The solution was stirred for a further 30 min, filtered, and the filtrate was layered with Et_2O (40 ml). After 20 days, X-ray quality dark-green plate-like crystals of **2** *and* dark-green needles of **3** were collected by filtration, washed with cold MeOH (2×5 ml) and Et_2O (2×5 ml), and dried in air. The two products were separated manually and individually identified as complexes **2** and **3** (both by single-crystal X-ray crystallography), respectively. Typical yields were ~20% (**2**) and ~10% (**3**).

2.3. Single-crystal X-ray crystallography

The crystallographic data and structure refinement details for the three complexes are summarized in Table 1. Selected crystals of **1** $\cdot 2H_2O \cdot 4.5MeCN$ ($0.30 \times 0.40 \times 0.65$ mm) and **3** ($0.05 \times 0.10 \times 0.55$ mm) were mounted in capillary, whereas a selected

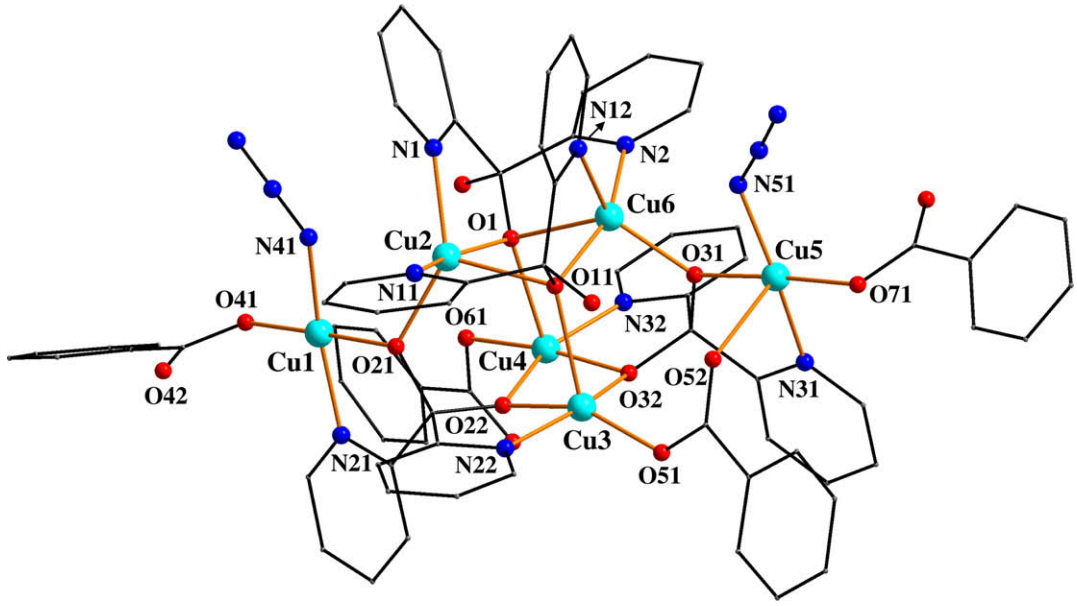

Fig. 1. Molecular structure of **1**. Color scheme: Cu^{II}, sky blue; O, red; N, dark blue; C, gray. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

crystal of **2** (0.05 × 0.15 × 0.25 mm) was mounted in air. Diffraction measurements for **1** · $2H_2O$ · 4.5MeCN were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation. Crystallographic data for complexes **2** and **3** were collected on a $P2_1$ Nicolet diffractometer upgraded by Crystal Logic using graphite-monochromated Cu radiation. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11° < 2\theta < 23°$ (for **1** · $2H_2O$ · .5MeCN) and $22° < 2\theta < 54°$ (for **2** and **3**). Intensity data were recorded using a θ–2θ scan to a maximum 2θ value of 50° (for **1** · $2H_2O$ · 4.5MeCN) and 118° (for **2** and **3**). Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization corrections were applied using CRYSTAL LOGIC software. All three structures were solved by direct methods using SHELXS-97 [15a] and refined on F^2 by full-matrix least squares techniques with SHELXL-97 [15b]. All H atoms were located by Fourier difference maps and refined isotropically, except those on the solvent molecules (**1** · $2H_2O$ · 4.5MeCN) which were introduced at calculated positions as riding on bonded atoms. All non-H atoms were refined anisotropically.

3. Results and discussion

3.1. Syntheses and IR spectroscopy

The reaction of $Cu(O_2CPh)_2 \cdot 2H_2O$, $(py)_2CO$, LiOH and NaN_3 in a 2:1:1:1 molar ratio in MeCN gave a dark green solution which upon conventional workup gave cluster **1** (as the **1** · $2H_2O$ · 4.5MeCN solvate) in good yield, see the balanced equation (1). The Cu^{II}-mediated nucleophilic attack of H_2O (from the solvent and/or the starting material) is responsible for the formation of the *gem*-diolate(-1) ligand $(py)_2C(OH)O^-$ (Scheme 1) [10]. Complex **1** was also obtained in the absence of

$$6Cu(O_2CPh)_2 \cdot 2H_2O + 4(py)_2CO + 2NaN_3 + 2LiOH \xrightarrow{MeCN} [Cu_6(O_2CPh)_4(N_3)_2\{(py)_2CO_2\}_2\{(py)_2C(OH)O\}_2] + 2NaO_2CPh + 2LiO_2CPh + 4PhCO_2H + 10H_2O \quad (1)$$

external OH^-s, but the yields were appreciably lower. In this case, the deprotonation of '$(py)_2C(OH)_2$' is achieved solely by the $PhCO_2^-$ groups and the formation of the cluster can be summarized by the balanced equation (2):

$$6Cu(O_2CPh)_2 \cdot 2H_2O + 4(py)_2Co + 2NaN_3 \xrightarrow{MeCN} [Cu_6(O_2CPh)_4(N_3)_2\{(py)_2CO_2\}_2\{(py)_2C(OH)O\}_2] + 2NaO_2CPh + 6PhCO_2H + 8H_2O \quad (2)$$

with the identity of **1** established, we also tried several other $Cu(O_2CPh)_2/(py)_2CO/OH^-/N_3^-$ ratios, and particularly with a large excess of N_3^- ions, to see if azido-bridged products could be obtained, but in all cases **1** was the isolated product, in varying yields.

The chemical and structural identity of the products from the $Cu(O_2CPh)_2/(py)_2CO/N_3^-$ reactions systems depends on the solvent used. Exactly the same preparative and crystallization

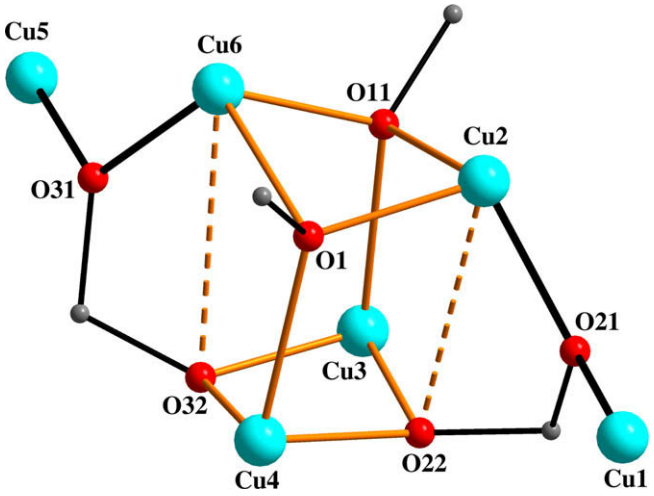

Fig. 2. The $[Cu_6^{II}(\mu_3\text{-}OR'')_2(\mu\text{-}OR'')_4]^{6+}$ core of **1**, emphasizing the central defective cubane subcore (orange thick lines). The orange dashed lines represent the two missing edges of the cubane unit. Color scheme: Cu^{II}, sky blue; O, red; C, gray. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.).

procedures as those of **1** but employing MeOH instead of MeCN, gave a mixture of dark-green plate- and needle- like crystals, crystallographically characterized as the 1D and 2D coordination polymers $[Cu_4(O_2CPh)_2(N_3)_4\{(py)_2C(OMe)O\}_2]_n$ (**2**) and $[Cu_2(O_2CPh)(N_3)_2\{(py)_2C(OMe)O\}]_n$ (**3**), respectively. Although polymeric in nature, the non-optimized yields were rather low (~20% and ~10% for **2** and **3**, respectively). The formation of the complexes can be summarized by the balanced equations (3) and (4):

$$4n\mathrm{Cu(O_2CPh)_2\cdot 2H_2O} + 2n\mathrm{(py)_2CO} + 4n\mathrm{NaN_3} + 2n\mathrm{MeOH} + 2n\mathrm{LiOH} \overset{\mathrm{MeOH}}{\rightarrow} \underset{\mathbf{2}}{[\mathrm{Cu_4(O_2CPh)_2(N_3)_4\{(py)_2C(OMe)O\}_2]_n}} + 4n\mathrm{NaO_2CPh} + 2n\mathrm{LiO_2CPh} + 10n\mathrm{H_2O} \quad (3)$$

$$2n\mathrm{Cu(O_2CPh)_2\cdot 2H_2O} + n\mathrm{(py)_2CO} + 2n\mathrm{NaN_3} + n\mathrm{MeOH} + n\mathrm{LiOH} \overset{\mathrm{MeOH}}{\rightarrow} \underset{\mathbf{3}}{[\mathrm{Cu_2(O_2CPh)(N_3)_2\{(py)_2C(OMe)O\}]_n}} + 2n\mathrm{NaO_2CPh} + n\mathrm{LiO_2CPh} + 5n\mathrm{H_2O} \quad (4)$$

Mainly due to the identical $Cu^{II} : PhCO_2^- : N_3^- : (py)_2C(OMe)O^-$ (2:1:2:1) ratio present in the two complexes, the two polymeric compounds could not be isolated separately. Changes in the crystallization procedures also failed to lead to the separate isolation of the two materials.

The IR spectra of **1**–**3** do not exhibit a band in the region of the carbonyl stretching vibration [ν(CO)] as expected, with the nearest bands at ~1600 cm^{-1} assigned as a 2-pyridyl stretching vibration [this band also has a $\nu_{as}(CO_2)$ character] raised from 1582 cm^{-1} on coordination as observed earlier [16] upon complex formation involving hydration of $(py)_2CO$. In the spectrum of **1**, the strong band at 1562 cm^{-1} is also assigned [17] to $\nu_{as}(CO_2)$; the $\nu_s(CO_2)$ modes appear at 1442 and 1382 cm^{-1}. The appearance of two distinct bands for each mode reflects the presence of two different types of $PhCO_2^-$ ligands in the complex. The 1602 and 1382 cm^{-1} pair [$\Delta = \nu_{as}(CO_2) - \nu_s(CO_2) = 220\ cm^{-1}$] are assigned [17] to the monodentate $PhCO_2^-$ groups, while the 1562 and 1442 cm^{-1} pair ($\Delta = 120\ cm^{-1}$) to the bidentate bridging $PhCO_2^-$ group. The differ-

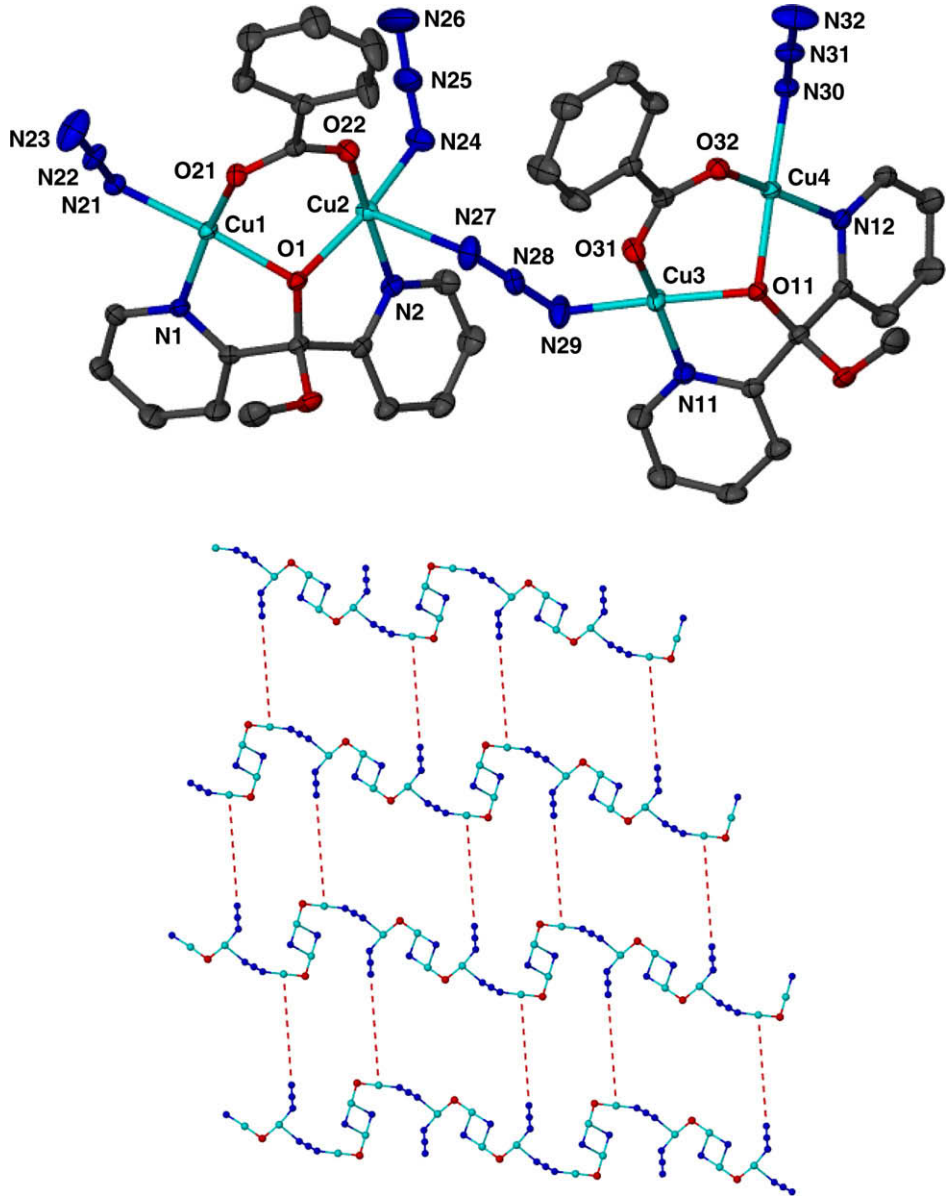

Fig. 3. ORTEP view of the asymmetric unit of **2** at the 30% probability level (top) and a view (with many atoms omitted) of the zig-zag chains and the herringbone layer (bottom) formed by artificially connecting (red dashed lines) the terminal azide (on Cu2) to Cu3. Color scheme as in Fig. 1. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

ences are more (220 cm^{-1}) and less (120 cm^{-1}) than the Δ value for NaO_2CPh (184 cm^{-1}), as expected for the monodentate and bidentate modes, respectively, of carboxylate ligation. The Δ values for **2** and **3** are ~140 cm^{-1} in accordance with the crystallographically established bidentate bridging ligation mode of the $PhCO_2^-$ groups [17]. The strong band at 2045–2065 cm^{-1} in the spectra of **1**–**3** is assigned to the asymmetric stretching mode of the azido ligands [18].

3.2. Description of structures

The molecular structure of complex **1** is depicted in Fig. 1, whereas ORTEP representations of the asymmetric units of **2** and **3** are shown in Figs. 3 and 4, respectively. Selected interatomic distances and angles for compounds **1**–**3** are listed in Tables 2 and 3.

Complex **1** crystallizes in the triclinic space group $P\bar{1}$. The hexanuclear molecule (Fig. 1) is held together by two 4.2211 (Harris notation [19]) $(py)_2CO_2^{2-}$ ligands, two 3.3011 $(py)_2C(OH)O^-$ groups and a single *syn,anti*-2.11 $PhCO_2^-$ group. Peripheral ligation is provided by three monodentate (1.10) $PhCO_2^-$ groups and two terminal (1.100) N_3^- ligands. The new core (Fig. 2) consists of four, 5-coordinate Cu^{II} atoms [Cu(2,3,4,6)] located at four alternate vertices of a central defective cubane unit (a cubane missing two opposite edges), two μ_3 O atoms (O1, O11) from the 3.3011 $(py)_2C(OH)O^-$ groups and two μ O atoms (O22, O32) from two different 4.2211 $(py)_2CO_2^{2-}$ ligands (these four O atoms occupy the remaining vertices of the cube), two additional satellite Cu^{II} atoms (Cu1 is square planar; Cu5 is 5-coordinate) across the missing edges, and two μ O atoms (O21, O31) that belong to the two different $(py)_2CO_2^{2-}$ groups and each links the cubane unit with a satellite metal ion.

Analysis of the shape-determining angles using the approach of Reedijk, Addison and co-workers [20] yields trigonality index, τ, values of 0.35, 0.08, 0.22, 0.18 and 0.28 for Cu2, Cu3, Cu4, Cu5 and Cu6, respectively (τ = 0 and 1 for perfect *spy* and *tbp* geometries, respectively). This suggests that the coordination geometry of Cu(3,4,5,6) is slightly to moderately distorted square pyramidal; the coordination polyhedron of Cu2 is very distorted and can be considered either as a square pyramid or as a trigonal bipyramid.

Complex **1** joins a very small family of hexanuclear Cu_6^{II}/N_3^- clusters; however, in the three previous examples the azido ligands were bridging [21]. This nuclearity is the second highest in copper(II) azide chemistry [12] after the impressive $(Cu_7^{II})_2/N_3^-$ cluster synthesized by Thompson's group [22].

The asymmetric unit of **2** (Fig. 3, top) consists of two similar $Cu_2^{II,II}$ subunits A (Cu1, Cu2) and B (Cu3, Cu4) bridged by a single end-to-end (EE or $\mu_{1,3}$) N_3^- ligand through the square pyramidal Cu2 (τ = 0.07) and the square planar Cu3 ions. The two Cu^{II} centers within each dinuclear unit are bridged by one 2.2011 $(py)_2C(OMe)O^-$ ligand and one *syn,syn*-2.11 $PhCO_2^-$ group. Two end-on (EO or $\mu_{1,1}$) N_3^- ligands bridge two Cu1 atoms from two dinuclear units A. Similarly two dinuclear units B are bridged through two EO N_3^- ligands via two Cu4 centers. Both Cu1 (τ = 0.21) and Cu4 (τ = 0.19) are in distorted square pyramidal environments with azido nitrogens at the apical positions. Thus, tetranuclear units A = A and B = B form, while one EE azido ligand bridges the tetranuclear units A═A and B═B, giving rise to a an octanuclear repeating unit of –A═A–B═B–, where "═" and "–" denote double EO and single EE azide bridges, respectively. The AABB repeating unit forms an infinite zigzag chain running along the *ac* diagonal (Fig. 3, bottom). Therefore, chemically **2** is best formulated as $[Cu_8(O_2CPh)_4(N_3)_8\{(py)_2C(OMe)O\}_4]_n$.

The asymmetric unit of **3** (Fig. 4, top) consists of dinuclear $[Cu_2(O_2CPh)(N_3)_2\{(py)_2C(OMe)O\}]$ moieties, where the two square pyramidal Cu^{II} centers (Cu1, τ = 0.13; Cu2, τ = 0.25) are bridged (as in **2**) by one 2.2011 $(py)_2C(OMe)O^-$ ligand and one *syn,syn*-2.11 $PhCO_2^-$ group. The dinuclear units assemble with two EO azido ligands that bridge the Cu2 atoms to form a tetranuclear unit (Fig. 4, middle). The latter are linked through the Cu1 centers via four EE azido ligands to form a 2D layer along the (1 0 −1) plane (Fig. 4,

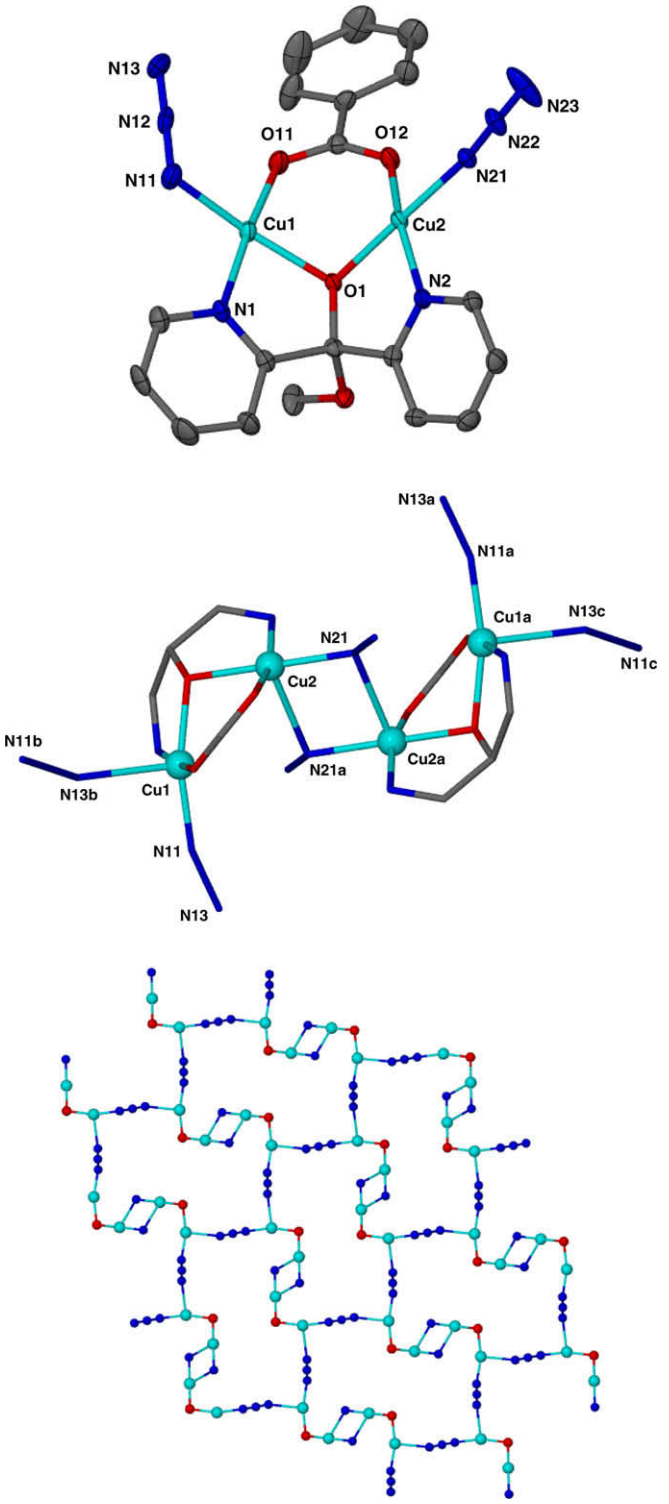

Fig. 4. ORTEP view of the asymmetric unit of **3** at the 30% probability level (top), the assembly of two dinuclear units (middle) of **3** and the 2D layer running along the (1 0 −1) plane (bottom). Symmetry code: a: 2 − *x*, −*y*, −*z*; b: 1.5 − *x*, 0.5 + *y*, 1.5 − *z*; c: 0.5 + *x*, −0.5 − *y*, 0.5 + *z*. Color scheme as in Fig. 1. [a] Atoms designated by a and b are related by symmetry operators.

bottom). The 2D layer of **3** adopts the "herringbone" or "parquet floor" architecture. The familiar herringbone network is based on T-shaped 3-connected nodes bridged by linear spacers (Fig. 5, left), while in **3** each tetranuclear unit serves as two fused 3-connected nodes that self-assemble to create the herringbone architecture (Fig. 5, right). Alternatively, **3** can be described as the assembly of tetranuclear clusters bridged by four EE azido ligands that serve as linear spacers. To the best of our knowledge, **3** joins only a handful of extended 2D networks that adopt the herringbone architecture which is *not* based on T-shaped nodes [23].

A detailed examination of the crystal structures of **2** and **3** reveals that the 2D structure of the latter "contains" the 1D chains of the former. Complex **3** could have derived from **2** if the terminal azide ligand on Cu2 in **2** (Fig. 3) had bridged the Cu3 atom in an EE fashion (Fig. 6). Complexes **2** and **3** are the first copper(II) coordination polymers with any $(py)_2CO$-based ligand/N_3^- combination; this combination has been found in the recently reported tetranuclear structure $[Cu^{II}_4(N_3)_2\{(py)_2C(OMe)O\}_4][Cu^{I}Cl_2]$ [24].

3.3. Magnetochemistry

Solid-state direct current magnetic susceptibility (χ_M) data on dried **1** · $2H_2O$ were collected in an 0.1 T field in the 2.0–300 K range and are plotted as $\chi_M T$ versus T, and χ_M versus T in Fig. 7. χ_M increases from 48×10^{-4} emu mol^{-1} at room temperature to a maximum value of 56×10^{-4} emu mol^{-1} at 170 K and then decreases drastically to a minimum of 3×10^{-4} emu mol^{-1} at 20 K, before increasing again to the value of 21×10^{-4} emu mol^{-1} at 6 K. Based on the room-temperature $\chi_M T$ value of 1.43 emu mol^{-1} K, which is lower than the value expected for six $S = 1/2$ uncoupled spins (2.25 emu mol^{-1} K with $g = 2.0$) and the maximum in the χ_M versus T plot at 170 K, we conclude that strong antiferromagnetic exchange interactions between the Cu^{II} atoms are operative within the cluster. The Curie tail in the low temperature susceptibility data reveals the existence of a paramagnetic, possibly monomeric, impurity. According to the core (Fig. 2) a simplified spin Hamiltonian that describes the exchange interactions in **1** is

$$H = -2J_1(S_1 \cdot S_2 + S_5 \cdot S_6) - 2J_2 S_2 \cdot S_6 - 2J_3 S_3 \cdot S_4 \quad (5)$$

Magnetic susceptibility data were fitted using the MAGPACK [25] program (based on the Irreducible Tensor Operator method for diagonalization of the energy matrix) employed with the non-linear, least-squares curve-fitting program, DSTEPIT [26]. Best-fit (solid lines in Fig. 7) parameters are $J_1 = -94(5)$ cm^{-1}, $J_2 = -110(5)$ cm^{-1}, $J_3 = -116(5)$ cm^{-1}, $g = 2.05$, and $\rho = 0.15\%$, leading to an overall $S = 0$ ground state. Antiferromagnetic exchange interactions are often found in copper(II) complexes with $(py)_2CO$-based bridging ligands [27]. A fourth exchange parameter (J_4) incorporating the

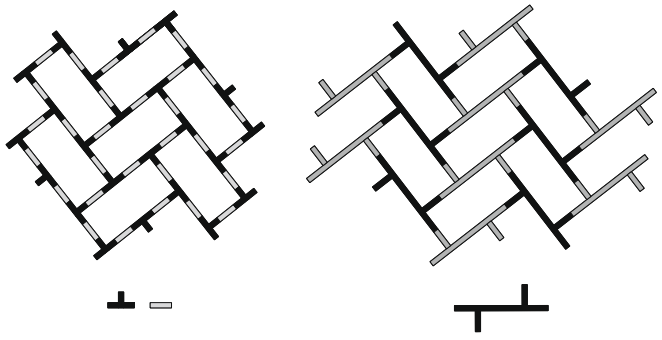

Fig. 5. The familiar herringbone motif based on T-shaped 3-connected nodes and spacers (left), and the herringbone architecture of **3** based on the tetranuclear units which serve as two fused 3-connected nodes (right).

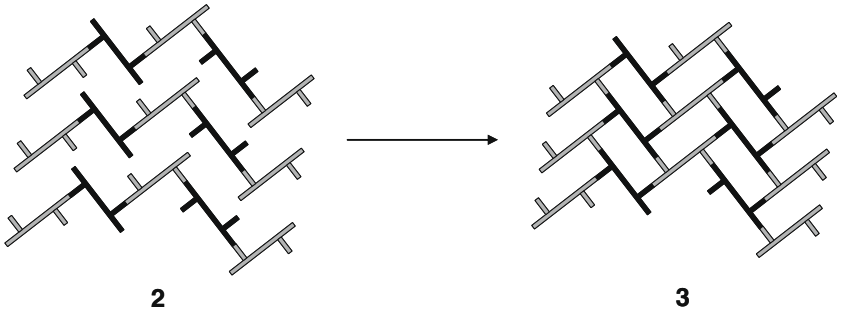

Fig. 6. The transformation of the one-dimensional polymer **2** to the two-dimensional polymer **3**.

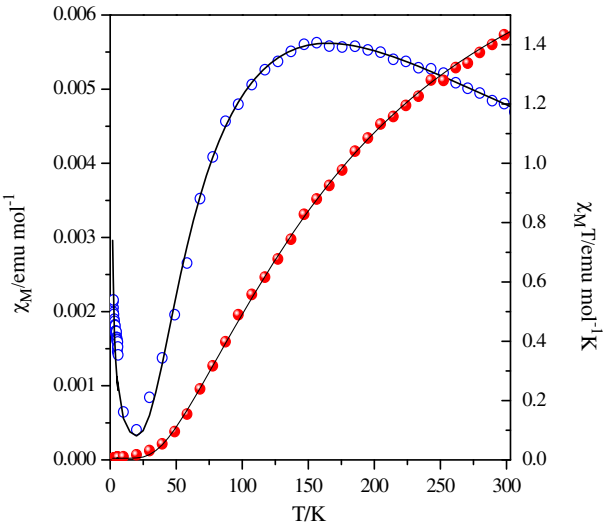

Fig. 7. χ_M vs. T (open blue cycles) and $\chi_M T$ vs. T (solid red cycles) plots for **1** · $2H_2O$ in a 1 kG field. The solid lines are the fit of the data; see the text for the fit parameters.

S_2S_3, S_2S_4, S_3S_6 and S_4S_6 magnetic interactions was not considered because the relevant Cu···Cu distances are rather long (3.56–3.73 Å, see Table 1); incorporation of J_4 leads to significant correlations between the fitted parameters. Efforts to employ a 2-J model, assuming $J_2 = J_3$, did not give a satisfactory fit.

4. Conclusions

An important chemical message from this work is that the $(py)_2CO/PhCO_2^-/N_3^-$ ligand combination looks like a promising candidate system for the generation of interesting copper(II) clusters and coordination polymers. The hexanuclear cluster **1** has a novel core, while the coordination polymers **2** and **3** exhibit interesting structural features. The products provide an example of the dependence of the structural type (cluster versus polymers) on the reaction solvent. The three complexes augur well that they are merely the first member of a new family of $Cu^{II}/(py)_2CO$-based ligands/$R'CO_2^-/N_3^-$ compounds. Preliminary results reveal that the nature of the carboxylate ligand, i.e. the nature of R′, affects the identity of the products.

5. Supplementary data

CCDC 702630, 702631 and 702629 contain the supplementary crystallographic data for **1** · $2H_2O$ · 4.5MeCN, **2** and **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

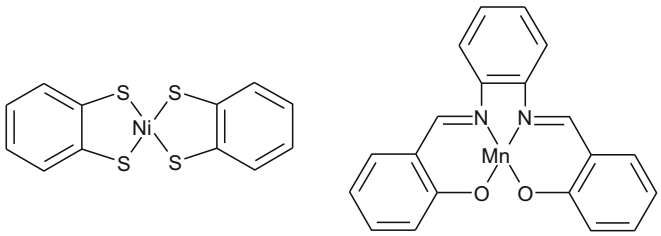

Fig. 1. The molecular structures of $[Ni(bdt)_2]^-$ (left) and $[Mn(Saloph)]^+$ (right).

respectively. A unit cell of the crystal contains a half crystallographically independent $[Mn_2(Saloph)_2(\mu\text{-}OH)]^+$ and $[Ni(bdt)_2]^-$. The bridging $[OH]^-$ groups should be originated from the proton dissociation of H_2O molecules contained in the raw material $[Mn(Saloph)(H_2O)(ClO_4)]$. The dimerization of $[Mn(Saloph)]^+$ units mediated by a $[OH]^-$ group occurs in some cases depending on the crystallization conditions [15]. The bond lengths of Mn–O (1.882(3) and 1.905(2) Å) and Mn–N (1.986(3) and 1.991(3) Å) in the [Mn(Saloph)] unit are in agreement with those of [Mn(III)(Saloph)] complexes reported [11,15,16], suggesting the trivalent state of manganese cation. Mn–OH bond length of 2.046(1) Å is identical with the literature value of $[Mn(III)_2(Saloph)_2(\mu\text{-}OH)]^+$ [15], and clearly shorter than Mn(III)–OH_2 bond lengths ranging from 2.2 to 2.3 Å [11,16]. The Mn–OH–Mn bond angle of 153.2(2)° is roughly the same as that of the literature value, while the torsion angle of ca. 55.6° between two $[Mn(Saloph)]^+$ units is approximately twice that of the literature value of 30.7° [15]. In the crystal, $[Mn_2(Saloph)_2(\mu\text{-}OH)]^+$ cations are stacked one dimensional elongated parallel to the *c*-axis.

$[Ni(bdt)_2]^-$ anions form square lattice in the *bc*-plane as shown in Fig. 2b. In the anion sheet, terminal carbon atoms of benzenedithiolate ligands are placed over the sulfur atoms of adjacent anions with the short CH–S contacts of 3.63 and 3.92 Å. There is no other short contact between anion molecules, therefore magnetic interaction between anions is owing to these CH–S contacts. It is noted that this T-shaped stacking of $[Ni(bdt)_2]^-$ is uncommon. The anion prefers to stack in the side-by-side manner in ordinary cases [8–10] where the size of intermolecular cavities are minimized. In the present case, a cavity surrounded by four $[Ni(bdt)_2]^-$ anions is filled up with a phenyl ring protruding from a cation, resulting in the stabilization of the T-shaped stacking of anions. Though the intra-molecular bond lengths of $[Ni(bdt)_2]^{n-}$ ($n = 0$–2) are approximately independent of the valence *n* [17], we can conclude that the valence state is $[Ni(III)(bdt)_2]^-$ based on the charge neutrality of a unit cell. The anion layers and cation layers are stacked alternately, resulting in the 2D character of the magnetic interaction as shown later.

$R_1 = \sum(||F_o| - |F_c||)/\sum|F_o|$, $wR_2 = [\sum w(|F_o|^2 - |F_c|^2)^2/\sum w(|F_o|^2)^2]^{1/2}$.

3.2. Magnetic property

Fig. 3 shows the temperature and field dependence of the χT value and the magnetization, respectively. The χT value of 3.23 emu K mol^{-1} at 300 K is obviously smaller than that expected

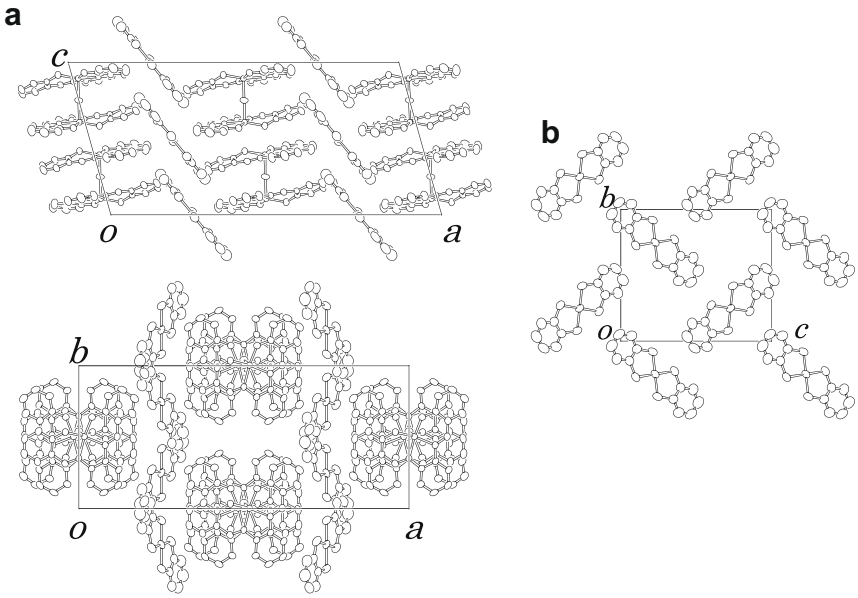

Fig. 2. Thermal ellipsoid plot (50% probability) of (a) the crystal structure and (b) an anion layer of $[Mn_2(Saloph)_2(\mu\text{-}OH)][Ni(bdt)_2](CH_3CN)_2$ drawn by ORTEP-3 for Windows [18]. Acetonitrile molecules and hydrogen atoms are omitted for clarity.

from the sum of the spin only value of $[Mn(III)_2(Saloph)_2(\mu\text{-}OH)]^+$ (two $S = 2$ units) and $[Ni(III)(bdt)_2]^-$ ($S = 1/2$), suggesting the strong antiferromagnetic interaction between the oxygen-bridged two $[Mn(Saloph)]^+$ fragments. The value gradually decreases as the temperature decreases, and reaches a minimum of 0.622 emu K mol^{-1} at around 20 K, followed by a rapid rise indicating the existence of a ferromagnetic interaction. No magnetic transition was observed down to 1.8 K. The χT value coincides with the sum of the theoretical values as follows. The susceptibility of $[Mn_2(Saloph)_2(\mu\text{-}OH)]^+$ and $[Ni(bdt)_2]^-$ were calculated based on the $S = 2$ Van Vleck dimer model [19]:

$$\chi_{Mn} = \frac{Ng_{Mn}^2\mu_B^2}{k_BT}\left[\frac{30 + 14x^8 + 5x^{14} + x^{18}}{9 + 7x^8 + 5x^{14} + 3x^{18} + x^{20}}\right],$$

$$x = \exp\left(-\frac{J_{Mn}}{k_BT}\right)$$

and the $S = 1/2$ Heisenberg square lattice model with constant coupling approximation [20]:

$$\chi_{Ni} = \frac{Ng_{Ni}^2\mu_B^2}{4k_BT}\exp\left(\frac{2J_{Ni}}{k_BT}\right)$$

where χ_{Mn}, χ_{Ni}, N, g_{Mn}, g_{Ni}, μ_B and k_B are the susceptibilities of $[Mn(Saloph)]^+$ units and $[Ni(bdt)_2]^-$ anions, the Avogadro constant, the g-values for $[Mn(Saloph)]^+$ units and $[Ni(bdt)_2]^-$ anions, the Bohr magneton and the Boltzmann constant, respectively. The typical g-values of $[Mn(Salen)]^+$ type complexes ($g = 2.0$) [21] and $[Ni(bdt)_2]^-$ ($g = 2.1$) [9] are employed for the calculation. The exchange interactions J between Mn–Mn (J_{Mn}) and Ni–Ni (J_{Ni}) are defined in the following Hamiltonian:

$$H = -2J\sum\nolimits_{\{ij\}} S_i \cdot S_j$$

The best fit with the parameters of $2J_{Mn} = -92.4$ and $2J_{Ni} = +4.5$ K is nearly indistinguishable from the experimental data as shown in Fig. 3a. The origin of the ferromagnetic interaction between $[Ni(bdt)_2]^-$ anions is discussed later.

The strong antiferromagnetic interaction between $[Mn(Saloph)]^+$ units and ferromagnetic interaction between $[Ni(bdt)_2]^-$ are also evidenced by the magnetization curve measured at 1.8 K. Below $H < 2$ T, the magnetization exhibits a rapid rise reaching a value of ca. 1 μ_B followed by a slight rise. This field dependency of the magnetization is in consistent with the model that the material is consists of strongly antiferromagnetically coupled $[Mn_2(Saloph)_2(\mu\text{-}OH)]^+$ binuclear cations which bring the slight rise of the magnetization, and ferromagnetically coupled $S = 1/2$ $[Ni(bdt)_2]^-$ anions which cause the rapid rise in the low field region. The absence of hysteresis indicates that the magnetic ordering temperature is lower than 1.8 K, which is consistent with the temperature dependence of the χT value as mentioned above.

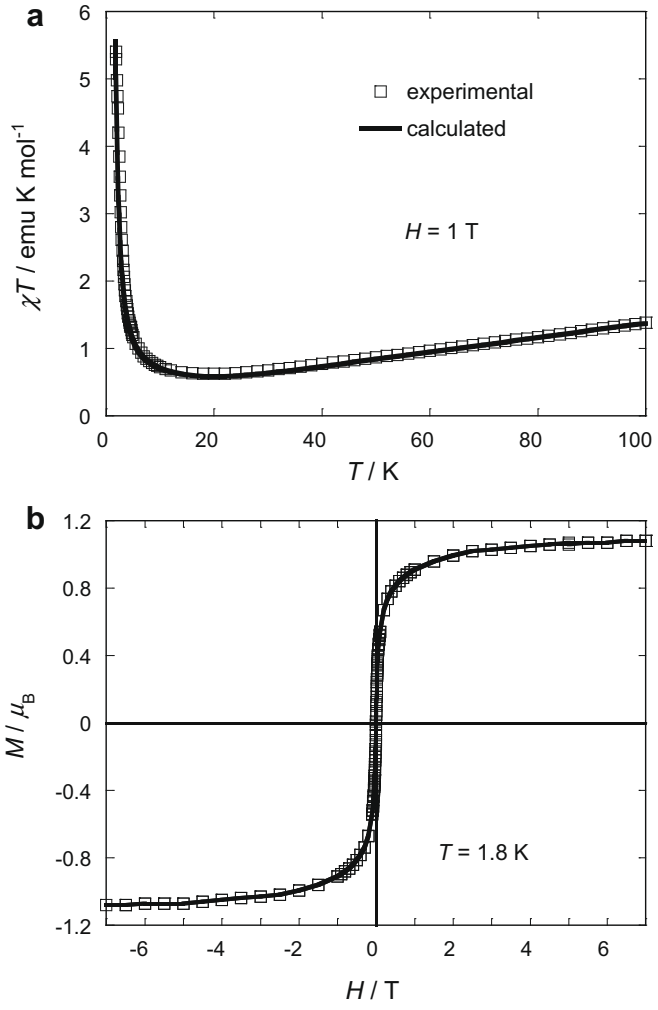

Fig. 3. (a) Temperature dependence of the χT value of $[Mn_2(Saloph)_2(\mu\text{-}OH)][Ni(bdt)_2](CH_3CN)_2$ measured under a field of $H = 1$ T. The solid line indicates the best fit to the experimental data (see text). (b) The magnetization curve of $[Mn_2(Saloph)_2(\mu\text{-}OH)][Ni(bdt)_2](CH_3CN)_2$ at 1.8 K.

3.3. Origin of ferromagnetic interaction

The origin of the ferromagnetic interaction between $[Ni(bdt)_2]^-$ anions can be explained by the modified McConnell-II model [22,23]. Fig. 4 shows the T-shaped intermolecular orbital overlap modes between adjacent $[Ni(bdt)_2]^-$ anions. As mentioned before, the spins on neighboring two anions can interact through the intermolecular contact between the sulfur atoms and the carbon atoms at the edge of the benzene ring. The molecular orbital has the same sign on these two carbon atoms in both cases of the SOMO and the NHOMO. On the other hand, the SOMO has different signs on the neighboring two sulfur atoms, while the NHOMO has the same sign as shown in Fig. 4, resulting in the small intermolecular overlap between the SOMOs and the large overlap between the SOMO and the NHOMO.

In the case of the charge transfer between the SOMOs, antiferromagnetic arrangement of radical spins is required to transfer the electron from one side to another. In other words, the SOMO–SOMO overlap stabilizes an antiferromagnetic arrangement of adjacent radicals, and the small SOMO–SOMO overlap of $[Ni(bdt)_2]^-$ anions weakens the intermolecular antiferromagnetic interaction. On the other hand, the charge transfer from the NHOMO to the SOMO of adjacent $[Ni(bdt)_2]^-$ brings a ferromagnetic interaction. When a radial molecule (named "R_A") has an up spin electron in the SOMO, only a down spin electron can be transferred from the NHOMO of an adjacent radial ("R_B") to the SOMO of R_A. Consequently, the spin of the residual electron in the NHOMO of R_B is up, which ferromagnetically interacts with the electron in the SOMO of R_B because of the intra-molecular electron–electron repulsion like as Hund's rule. As a result, the NHOMO–SOMO overlap brings a ferromagnetic interaction between adjacent $[Ni(bdt)_2]^-$ anions like as the galvinoxyl radical [24].

4. Conclusion

A new molecule-based magnetic material $[Mn_2(Saloph)_2(\mu\text{-}OH)][Ni(bdt)_2](CH_3CN)_2$ is reported. The material consists of one dimensional chains of $[Mn_2(Saloph)_2(\mu\text{-}OH)]^+$ and square lattices of $[Ni(bdt)_2]^-$. Its magnetism is well described by the sum of the

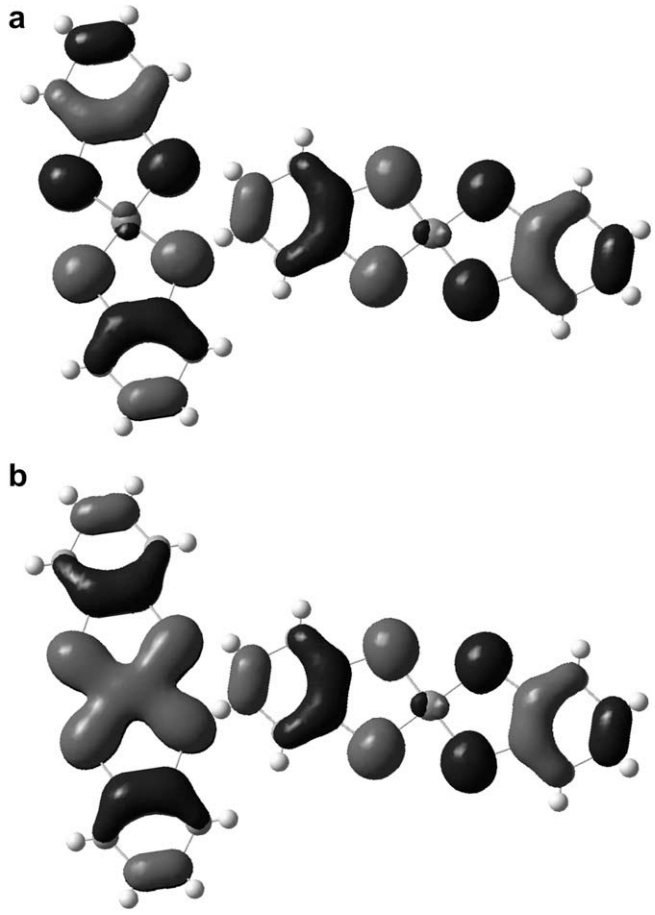

Fig. 4. Orbital overlap modes of adjacent $[Ni(bdt)_2]^-$ anions. (a) SOMO–SOMO and (b) NHOMO–SOMO.

antiferromagnetically coupled two $[Mn(Saloph)]^+$ units with $2J = -92.4$ K and ferromagnetically coupled square lattice of $[Ni(bdt)_2]^-$ anions with $2J = +4.5$ K. The origin of the ferromagnetic interaction is attributed to the small SOMO–SOMO overlap which diminishes the antiferromagnetic interaction, and the large NHOMO–SOMO overlap which brings the ferromagnetic interaction. This result evidences the usefulness of the $[Ni(bdt)_2]^-$ anion for constructing strong intermolecular interaction due to its large coefficient of molecular orbitals on the benzene ring.

5. Supplementary data

CCDC 702069 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

CDW and the CP structures. Next, the intra-chain and the inter-chain exchange interactions between spins on Pt_2 units in the CP structure are calculated by using those model structures.

2. Calculated models

In order to carry out DFT calculations, we constructed two model structures for $K_4[Pt_2(pop)_4X] \cdot 2H_2O$ (X = Cl and Br) complexes *i.e.* the single chain and the double chain models as illustrated in Fig. 1A and B, respectively. The models approximate an infinite chain as a cluster model. The whole geometry was taken from data of X-ray crystal structure analyses by Yamashita and Toriumi [7], although all water molecules in the crystal were removed. There are two positions for one halogen ion in the X-ray data as illustrated in Fig. 1C. If we consider a total symmetry of the crystal, this disorder makes two combinations of the position of halogen ions as illustrated in Fig. 1D and E. The former reproduces the CDW structure and the latter is the CP structure. Pt–Pt and Pt–X distances in Cl and Br complexes are summarized in Table S1 in Supplementary data. The positions of hydrogen atoms of pop ligands were determined by partial optimization that was carried out only for hydrogen atoms. Terminals of the chains were capped by point charges of +1.7*e* and +1.6*e* reproducing Pt ions. A slight difference between left and right charges expresses a charge imbalance caused by the difference in Pt–X distance. In order to examine the effect of potassium ions around the MMX chains, we examined two models *i.e.* the real potassium and point charge (Pc) models. In case of the real potassium model (K^+ model), potassium ions are included in the UB3LYP calculations however they are replaced by point charges (+1.0*e*) in case of the Pc model.

3. Computational details

All calculations were performed by use of LANL2DZ [16] basis set for Pt atoms and 4-31G basis set for pop ligands. 6-31+G and 6-31G basis sets were used for axial halogen atoms and K atoms, respectively. The unrestricted hybrid DFT method (UB3LYP [17]) was applied for all calculations on GAUSSIAN98 [18].

4. Calculated results and discussion

4.1. Difference in stability between CDW and CP structures

First, we calculated total energies of the CDW and the CP structures by using the single chain model. Calculated total energies are summarized in Table S2 in Supplementary data. The calculated results indicate that the CDW structure is stable in comparison with CP structure in both Cl and Br complexes. And those results are consistent with the experiment of iodine complex [12]. The differences in total energies between the two structures ($\Delta^{CP-CDW} = E(CP) - E(CDW)$) are summarized in Table 1. The values of Cl complex are about 0.3 eV, which is larger than that of Br complex (ca. 0.2 eV). Matsuzaki et al. reported a relation between the Pt–I–Pt distance (d(Pt–I–Pt)) and the optical gap energy (E_{CT}) [13]. The values of d(Pt–I–Pt) of Cl and Br complexes are 5.768 Å and 5.756 Å, respectively. Calculated Δ^{CP-CDW} values are smaller than an estimated value (ca. 0.5 eV) from "E_{CT} versus d(Pt–I–Pt) plot" in the paper [13] but are reproducing the value, qualitatively. The results also indicate that charge transfer from one Pt_2 unit to adjoining one occurs easily in the Br complex than the Cl complex.

Differences in the Δ^{CP-CDW} values between the K^+ and the Pc models are 0.02 eV and 0.01 eV for Cl and Br complexes, respectively. These very small differences indicate that orbitals of K^+ ions do not affect to the stability of CDW and CP structures, however the results do not deny the importance of ion sizes and positive charges of K^+ ions.

4.2. Intra-chain magnetic interaction in CP structure

In the CP structure, one spin ($S = 1/2$) is supposed to be on one Pt_2 unit, while there is no local spins in the CDW structure as illustrated in Fig. 2. Calculated spin densities of Cl and Br complexes summarized in Tables S3 and S4 in Supplementary data also support the predicted spin structures. The intensity of spin densities of the Br complex is slightly smaller than that of the Cl complex, suggesting a larger SOMO–SOMO ($d\sigma^*$–$d\sigma^*$) overlap between Pt_2 units in the Br complex than the Cl complex.

Calculated energy gaps between the CP structure and the CDW structure (Δ^{CP-CDW}).

X	Δ^{CP-CDW} (eV)	
	Pc model	K^+ model
Cl	0.32	0.34
Br	0.24	0.23

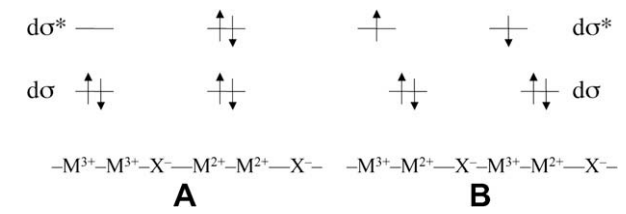

Fig. 2. Illustration of spin structures of (A) the CDW structure and (B) the CP structure.

The spins on the Pt_2 units in the CP structure cause intra- and inter-chain magnetic interactions as illustrated in Fig. 3A and C. The magnetic properties of transition metal complexes are usually investigated by the use of Heisenberg Hamiltonian [19–21],

$$\hat{H}^{H} = -2\sum J^{H}_{ab}\hat{S}_a \cdot \hat{S}_b, \quad (1)$$

where J^{H}_{ab} is the orbital-averaged effective exchange integrals between the spin site a and b with total spin operators $\hat{S}_a$ and $\hat{S}_b$, respectively. Yamaguchi et al. has proposed that J^{H}_{ab} value can be calculated from the energy splitting between a broken-symmetry (BS) low spin (LS) and a high spin (HS) states by using an equation,

$$J^{H}_{ab} = \frac{E^{LS} - E^{HS}}{\langle \hat{S}^2 \rangle^{HS} - \langle \hat{S}^2 \rangle^{LS}}, \quad (2)$$

where E^X and $\langle \hat{S}^2 \rangle^X$ denote the total energy and total spin angular momentum for the spin state X (X = LS and HS), respectively [22,23]. The definition of LS and HS states in the single chain model is explained in Fig. 3B. We note that the Eq. (2) can eliminate a spin contamination error, which is a problem of the BS method, from calculated J^{H}_{ab} values [24]. On the other hand, Ising Hamiltonian is also often used for a consideration of the magnetic interaction between fully localized spins,

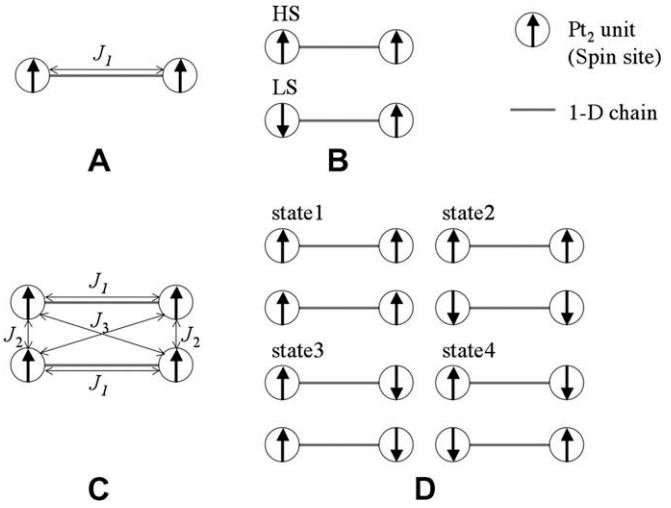

Fig. 3. Illustration of spin–spin interactions in each model and of spin states required for the calculation of J values. (A) Spin–spin interactions in the single chain model and (B) two spin states required for the calculation of J_1. (C) Spin–spin interactions in the double chain model and (D) four spin states required for the calculation of J_1, J_2 and J_3.

$$\hat{H}^{I} = -2\sum J^{I}_{ab}\hat{S}^{z}_a \cdot \hat{S}^{z}_b, \quad (3)$$

where J^{I}_{ab} is the exchange integrals of Ising Hamiltonian with total spin operators for z-axis; $\hat{S}^{z}_a$ and $\hat{S}^{z}_b$, respectively [14]. And J^{I}_{ab} between two Pt_2 units in the single chain model can be calculated by

$$J^{I}_{ab} = E^{LS} - E^{HS}. \quad (4)$$

By using those Eqs. (2) and (4), the intra-chain magnetic interactions are examined. Calculated results are summarized in Table 2. Those J values indicate the strong anti-ferromagnetic (AF) interaction between Pt_2 units and are consistent with our previous result for $Pt_2(dta)_4I$ complex ($-1274\ cm^{-1}$) [15]. Such a strong AF interaction means a large SOMO–SOMO overlap between adjoining Pt_2 units. It is also expected that the Br complex, which shows a stronger AF interaction, has the larger SOMO–SOMO overlap than the Cl complex.

In order to examine the overlap between two Pt_2 units, natural orbital (NO) analysis is carried out for both complexes. The SOMO–SOMO overlap (T_{SOMO}) can be calculated by using occupation number (n_{occ}) of NO [14],

$$T_{SOMO} = n_{occ} - 1. \quad (5)$$

Calculated NOs and n_{occ} numbers are illustrated in Figs. S1 and S2 in Supplementary data. The calculated T_{SOMO} values of the Cl and the Br complexes that are 0.45 and 0.67, respectively, indicate that the Br complex has a larger SOMO–SOMO overlap. Kumoo and Clark pointed out that a mixing of halogen pσ orbitals in the dσ Pt–Pt wave functions was in the order Cl < Br < I [10]. The order of T_{SOMO} (Cl < Br) strongly suggests the contribution of halogen pσ orbitals to the orbital overlap.

On the other hand, we find that K^+ ions slightly decrease $|J|$ values for both Cl and Br complexes. A decrease of the AF coupling means a decrease of SOMO–SOMO overlap. However they do not change qualitative properties.

4.3. Inter-chain magnetic interaction in CP structure

In previous section, we indicated that the intra-chain spin–spin interaction is a strong AF coupling. Therefore a spin density wave (SDW)-like order is expected in the single chain of CP phase. However it is important to know the inter-chain magnetic interaction to consider a spin order in a bulk system. In order to calculate the inter-chain interaction, we apply Ising Hamiltonian to the double chain model because Eq. (2) is not applicable to multi-J systems. The schematic view of spin–spin interactions in the double chain model is illustrated in Fig. 3C. In this model, there are two types of inter-chain spin–spin interactions *i.e.* J_2 and J_3. For the calculation of J_1, J_2 and J_3, we have to calculate total energies of four spin states (state1 ~ state4) illustrated in Fig. 3 and have to solve simultaneous equations below,

$$J_1 = \frac{1}{4}\left[\left(E^{state3} + E^{state4}\right) - \left(E^{state1} + E^{state2}\right)\right], \quad (6)$$

$$J_2 = \frac{1}{4}\left[\left(E^{state2} + E^{state4}\right) - \left(E^{state1} + E^{state3}\right)\right], \quad (7)$$

$$J_3 = \frac{1}{4}\left[\left(E^{state2} + E^{state3}\right) - \left(E^{state1} + E^{state4}\right)\right], \quad (8)$$

Table 2
Intra-chain J values for the CP structures of the Cl and the Br model structures calculated by Heisenberg model (J^{H}_{ab}) and Ising model (J^{I}_{ab}).

X	J^{H}_{ab} (cm^{-1})		J^{I}_{ab} (cm^{-1})	
	Pc model	K^+ model	Pc model	K^+ model
Cl	−912	−889	−1104	−1072
Br	−1573	−1537	−2290	−2230

Table 3
Intra- and inter-chain J values calculated by double chain models. Definitions of J_1, J_2 and J_3 are illustrated in Fig. 3C.

J (cm^{-1})	Cl complex		Br complex	
	Pc model	K^+ model	Pc model	K^+ model
J_1	−1029.8	−1011.2	−2208.1	−2172.4
J_2	−0.1	0.0	−0.1	0.0
J_3	0.0	0.0	0.1	0.0

where $E^{\text{state}X}$ is a total energy of state X [14]. Calculated J values are summarized in Table 3. The intra-chain exchange (J_1) is consistent with the values of the previous single chain models. In contrast to the large AF exchange coupling in the chain, the inter-chain interactions are negligible within the calculated models here. As explained above, water molecules in the crystal are removed from the original X-ray data, therefore magnetic interaction paths through hydrogen bonds were not included in these models. Because the hydrogen bonds may increase spin–spin interaction, it is desirable to include those water molecules for a further study about the inter-chain magnetic interaction. On the other hand, we can not find significant efficiency of K^+ ions however they also seem to decrease the absolute values of J values.

5. Conclusion

In this study, electronic structures, CDW/CP stability and magnetic properties of $K_4[Pt_2(pop)_4X]\cdot 2H_2O$ (X = Cl, Br) complexes are examined. Calculated total energies support that the CDW state is the ground state and the CP state is the excited state for both complexes. Calculated J values indicated the strong AF intra-chain interaction but suggest the negligible inter-chain interaction. In addition, it is also elucidated that orbitals of potassium ions scarcely affect to $\Delta^{\text{CP–CDW}}$ and J values. Therefore, the experimental result, which the ordering structures depend on the counter ion, seems to originate from only the ion size but not from orbitals of counter ions [8]. Recent experimental result, which E_{CT} depends on d(Pt–I–Pt) [13] also consistent with our result.

$$\chi_{mol} = C/(T - \theta_{cw}) \quad (1)$$

2.2. Complex of cyclamNN$_2$ with copper(II) ion

We planned host–guest complexation using cyclamNN$_2$ and transition metal ions, giving a three-centered radical–metal–radical system as depicted in Scheme 3. We utilized copper(II) and nickel(II) perchlorates as a metal source. In case of copper(II) compounds, coordination structures such as a square planar or square pyramid are also possible.

Complexation reaction of cyclamNN$_2$ with $Cu(ClO_4)_2$ in dichloromethane–ethanol gave dark purple crystals of $[Cu(cyclamNN_2)] \cdot (ClO_4)_2 \cdot 0.5(CH_2Cl_2)$ (**1**). The formula was determined from the elemental analysis and X-ray crystallographic analysis. The crystallographic analysis was successfully performed, but the thermal displacement factors remained somewhat large (Fig. 2), especially for terminal methyl groups probably owing to conformational disorder. The geometry around Cu1 seems sufficiently reliable. We found a semi-folded structure (Scheme 3) in the $[Cu(cyclamNN_2)]^{2+}$, giving a five-coordination sphere at Cu1.

The copper ion is located at the center of the cyclam cavity as indicated with the Cu–N bonds (2.121(6), 2.057(9), 2.131(7), and 1.975(8) Å for Cu1–N1, Cu1–N2, Cu1–N3, and Cu1–N4, respectively). One radical arm is coordinated at an axial position with the Cu1–O1 distance of 2.196(7) Å. These structural features imply that the copper ion in **1** is regarded to possess an intermediate structure between a square-pyramid and a trigonal-bipyramid. However, the relatively long Cu1–O1 bond suggests that the former is more likely. The other radical group does not participate in coordination.

The magnetic susceptibility of a polycrystalline sample of **1** was measured on a SQUID magnetometer (Fig. 3). On cooling from 300 K, the $\chi_{mol}T$ value once increased, reached a maximum around 15 K, and finally decreased. The increase of the $\chi_{mol}T$ value down to 15 K indicates the presence of ferromagnetic interaction in **1**.

The ferromagnetic coupling can be attributed to the copper-radical direct coordination, and accordingly the magnetic susceptibility is formulated as the sum of a singlet–triplet model [19] and a doublet. The final $\chi_{mol}T$ drop below 10 K indicates the presence of antiferromagnetic interaction among the singlet–triplet and doublet species. The Weiss mean field parameter θ is introduced. We utilized Eq. (2) for the analysis of the magnetic data on **1**, giving the best fit parameters as follows: $2J/k_B = +44(3)$ K, $g_{avg} = 2.091(6)$ and $\theta = -0.67(5)$ K. The calculated curve reproduced well the experimental data. The small θ implies small intermolecular exchange coupling.

$$\chi_{mol} = \frac{Ng_{avg}^2\mu_B^2}{k_B(T-\theta)}\left[\frac{1}{4} + \frac{2}{3+\exp(-2J/k_BT)}\right] \quad (2)$$

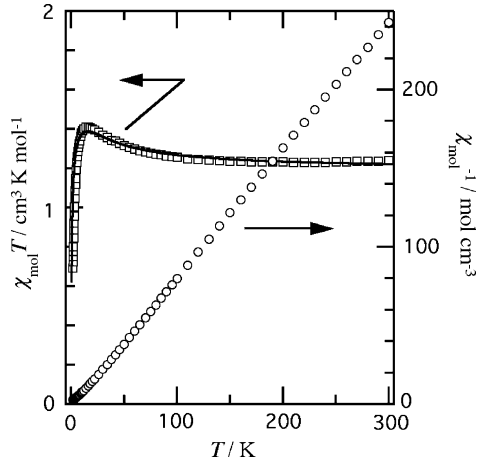

Fig. 3. Temperature dependence of $\chi_{mol}T$ and χ_{mol}^{-1} for **1**. A solid line represents a calculated curve. For the equation and parameters, see the text.

2.3. Complex of cyclamNN$_2$ with nickel(II) ion

Similarly to the case of the copper(II) complex, reaction of cyclamNN$_2$ with $Ni(ClO_4)_2$ gave red powder of $[Ni(cyclamNN_2)] \cdot (ClO_4)_2 \cdot (CH_2Cl_2)$ (**2**). Unfortunately, no single crystal suitable for X-ray crystallographic analysis could be obtained. The formula was determined from the elemental analysis.

The magnetic susceptibility of a polycrystalline sample of **2** was measured and the result is displayed in Fig. 4. On cooling from 300 K, the $\chi_{mol}T$ value drastically increased and reached to a maximum of 5.5 cm^3 K mol^{-1} around 16 K. The increase of the $\chi_{mol}T$ value indicates the presence of ferromagnetic interaction in **2**. Furthermore the Ni ion has a $S = 1$ spin state and possibly possesses an octahedral sphere as a folded structure.

The magnetic data above 20 K were analyzed according to Eq. (1), to give $C = 1.270(6)$ cm^3 K mol^{-1} and $\theta_{CW} = +13.5(6)$ K. The largely positive θ_{CW} value implies the presence of appreciable ferromagnetic coupling. The maximum $\chi_{mol}T$ value is larger than the theoretical spin-only value (3.0 cm^3 K mol^{-1} for the maximum high-spin $S_{total} = 2$ state in a molecule), indicating that the ferromagnetic coupling is operative beyond a formula unit; namely the complex would have a polymeric or polynuclear structure. A final drop of the $\chi_{mol}T$ value may be attributed to the interchain or intercluster antiferromagnetic interaction.

The Curie constant is smaller than the theoretical paramagnetic limit (1.75 cm^3 K mol^{-1}) for **2**. The reason is not clear at present, but a possible explanation is that the specimen would contain $[H_2cyclamNN_2] \cdot (ClO_4)_2$ (**3**) as an impurity. In fact, this salt was

Hydrogen bonds are indicated with dotted lines. Symmetry operation code of # is $1-x, -y, 2-z$. (b) Temperature dependence of $\chi_{mol}T$ and χ_{mol}^{-1} for **3**.

isolated from a second crop of the reaction mixture and characterized by means of X-ray crystallographic analysis (Fig. 5a). Note that **3** possesses an anti-folded form with the aid of hydrogen bonds. The O1–O1# distance is 7.018(2) Å. Compound **3** exhibited negligible ferromagnetic coupling (θ_{CW} = +0.23(2) K with C = 0.756(1) $cm^3\,K\,mol^{-1}$ from Eq. (1)) (Fig. 5b). The steep $\chi_{mol}T$ upsurge in Fig. 4 is attributed to the magnetic properties of **2**.

3. Discussion

The ferromagnetic coupling in metal–radical hybrid solids originates from the orthogonal arrangement between the magnetic orbitals (metal dσ and radical π*) [8,13–15]. In the present work, the ferromagnetic coupling was successfully achieved, and the magnitude of the magnetic coupling in **1** was determined as $2J/k_B$ = +44(3) K. Similar axial NN–Cu geometries have been reported on the one-dimensional polymer $[Cu(hfac)_2 \cdot (CH_3\text{–}NN)]_n$ [20] for example, where Hhfac and CH_3–NN stand for 1,1,1,5,5,5-hexafluoropentane-2,4-dione and 2,4,4,5,5-pentamethylimidazolin-1-oxyl 3-oxide, respectively. The NN oxygen atoms are located at the axial positions of the Cu center, and the exchange couplings are reported to be 37 K, which is comparable to that of **1**, though the magnitude of the couplings largely depends on many geometrical parameters such as O–Cu lengths and N–O–Cu angles. There have been many reports regarding this argument [8,21,22]. The ferromagnetic exchange was operative in the axial coordination of the NN radical to the square-pyramidal copper(II) ion in **1**.

In the complexation reactions with copper(II) ions, we obtained only the singly NN-coordinated compound (**1**) so far. There have been several reports on the six-coordinated copper(II) complexes from bis(2-pyridylmethyl)-substituted cyclam derivatives and related host compounds [23]. In that case the chelate rings at the arms are five-membered, whereas **1** has a six-membered chelate ring. Doubly NN-coordinated (fully folded) compounds may hardly be formed for such a steric reason.

The crystal structure of **2** is unknown. The poor crystallinity suggests that **2** would consist of polymeric coordination compounds. In the literature, however, the ferromagnetic coupling in radical-nickel coordination compounds seems rare. The mononuclear compound $[Ni(hfac)_2 \cdot (proxyl)_2]$ exhibited antiferromagnetic coupling to give a singlet ground state [24], where proxyl stands for 2,2,5,5-tetramethylpyrrolidin-1-oxyl. Furthermore, polymeric $[Ni(hfac)_2 \cdot (CH_3\text{–}NN)]_n$ also exhibited antiferromagnetic coupling ($2J/k_B < -500$ K) [25]. Some paramagnetic ligands involving a 2-pyridyl group are reported to favor strictly planar chelate rings and accordingly to exhibit ferromagnetic couplings between the nickel(II) and nitroxide spins [15,26–28].

In the case of **2**, the ferromagnetic coupling is operative but the magnitude is moderate. Assuming that the curvature of the increase of the $\chi_{mol}T$ on cooling is ascribable to the coupling between Ni S = 1 spin and the radical S = 1/2 spin, we can preliminarily estimate $2J/k_B$ as ca. +18 K. The moderate exchange coupling may be caused by partial violation from the strict orthogonal arrangement of the nickel dσ and radical π* orbitals.

4. Conclusions

We prepared [M(cyclamNN$_2$)](ClO$_4$)$_2$ (M = Cu (**1**), Ni (**2**)). The molecular structures of cyclamNN$_2$ and **1** were determined by means of X-ray crystal structure analysis. The copper ion is located at the center of the cyclam cavity and one radical arm is coordinated at an axial position. They showed ferromagnetic coupling as indicated by an increase of the $\chi_m T$ value on cooling. As for **2**, intermolecular ferromagnetic coupling is suggested as well as intramolecular one. These paramagnetic hosts (tacnNN$_3$, cyclenNN$_4$, and cyclamNN$_2$) seem to be promising building blocks for the development of supramolecular-switchable magnetic materials as well as metal–radical hybrid magnets.

5. Experimental

5.1. Materials

CyclamNN$_2$: an acetonitrile solution (8 mL) containing 2-chloromethyl-4,4,5,5-tetramethylimidazolin-1-oxyl 3-oxide [18] (NN–CH$_2$Cl; 400 mg; 1.9 mmol) was added to a mixture of acetonitrile (8 mL), 1,8-dimethyl-1,4,8,11-tetraazacyclotetradecane (1,8-dimethylcyclam, Aldrich) (200 mg; 0.88 mmol), and K_2CO_3 (740 mg; 5.4 mmol). The resultant mixture was stirred at 45 °C for 4 h. After addition of chloroform (ca. 100 mL), the organic layer was washed with water, dried over Na_2CO_3, and filtered, to give a deep violet solution. The solvent was removed under reduced pressure, and a solidified product was obtained by adding ether (ca. 100 mL). The crude product of cyclamNN$_2$ was collected on a filter and dried (267 mg; 0.47 mmol) in 54% yield. M.p. 89–91 °C. IR (KBr disc): 541, 1137, 1375, 1411, 1457, 2798, 2991 cm^{-1}. MS (ESI): m/z 567.3 (100%, M+H$^+$) (calc. 567.3 for $C_{28}H_{54}N_8O_4$+H), 589.3 (33%, M+Na$^+$) (calc. 589.4 for $C_{28}H_{54}N_8O_4$+Na). ESR (X-band, toluene, room temperature) five lines with an intensity ratio of 1/2/3/2/1. a_N = 7.18 G, g = 2.0066. *Anal.* Calc. for $C_{32}H_{68}N_8O_7$: C, 56.78; H, 10.13; N, 16.54. Found: C, 56.06; H, 9.07; N, 16.85%. The crystals tend to incorporate solvent molecules.

[Cu(cyclamNN$_2$)] · (ClO$_4$)$_2$ · 0.5(CH$_2$Cl$_2$) (**1**): after gently adding an ethanol solution (2 mL) of Cu(ClO$_4$)$_2$ · 6H$_2$O (35 mg; 0.094 mmol) over a dichloromethane solution (2 mL) of cyclamNN$_2$ (47 mg; 0.083 mmol), the two solutions were slowly diffused each other in a refrigerator. Dark violet crystals were formed. *Anal.* Calc. for [Cu(cyclamNN$_2$)] · (ClO$_4$)$_2$ · 0.5(CH$_2$Cl$_2$): C, 39.27; H, 6.36; N, 12.85. Found: C, 39.01; H, 6.79; N, 12.74%.

[Ni(cyclamNN$_2$)] · (ClO$_4$)$_2$ · (CH$_2$Cl$_2$) (**2**): after adding an ethanol solution (3 mL) of Ni(ClO$_4$)$_2$ · 6H$_2$O (43 mg; 0.12 mmol) over a dichloromethane solution (5 mL) of cyclamNN$_2$ (65 mg; 0.12 mmol), a red powdery product was precipitated immediately. The product was separated on a filter. *Anal.* Calc. for [Ni(cyclamNN$_2$)] · (ClO$_4$)$_2$ · (CH$_2$Cl$_2$): C, 39.49; H, 6.40; N, 12.63. Found: C, 39.48; H, 6.78; N, 12.53%. Red crystals were precipitated from the above filtrate as an undesired product, [H$_2$cyclamNN$_2$] · (ClO$_4$)$_2$ · (CH$_2$Cl$_2$) (**3**). *Anal.* Calc. for [H$_2$cyclamNN$_2$] · (ClO$_4$)$_2$ · (CH$_2$Cl$_2$): C, 40.85; H, 6.86; N, 13.14. Found: C, 40.40; H, 6.96; N, 13.38%. The latter formula was also determined by the X-ray crystallographic analysis and magnetic measurements.

5.2. X-ray crystallographic analysis

X-Ray diffraction data of cyclamNN$_2$, **1**, and **3** were collected on a Rigaku *R*-axis RAPID diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71069 Å). The structures were directly solved by a heavy-atom method and expanded using Fourier techniques in the CRYSTALSTRUCTURE 3.8.2 program package [29]. Numerical absorption correction was used. All of the hydrogen atoms were experimentally found and the parameters were refined isotropically for cyclamNN$_2$ and **3**. On the other hand, all of the hydrogen atoms were located at calculated positions and the parameters were refined as "riding" for **1**. The thermal displacement parameters of non-hydrogen atoms were refined anisotropically for both compounds. Full-matrix least-squares methods were applied using all of the unique reflection data. Selected crystallographic data are listed in Table 1.

5.3. Magnetic measurements

Magnetic properties of polycrystalline specimens of cyclamNN$_2$, **1**, **2**, and **3** were measured at 5000 Oe in a temperature range 1.8–300 K on a Quantum Design MPMS SQUID magnetometer. The magnetic responses were corrected with diamagnetic blank data of the sample holder measured separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants.

6. Supplementary data

CCDC 702736, 702737, and 702738 contain the supplementary crystallographic data for cyclamNN$_2$, **1**, and **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

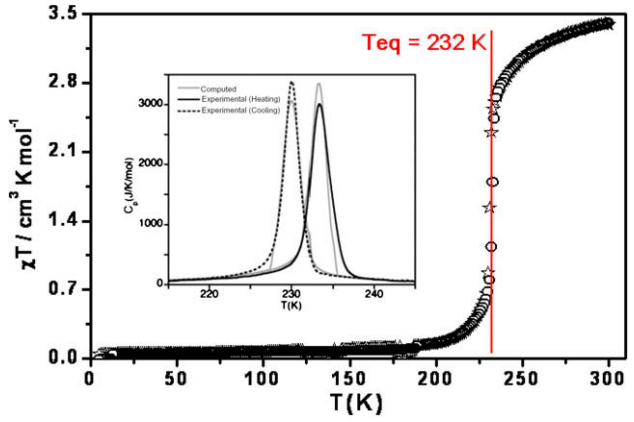

Fig. 1. The steep thermal transition with narrow hysteresis ~2 K wide, showing the presence of elastic interactions. Inset: calorimetric data (after [2]).

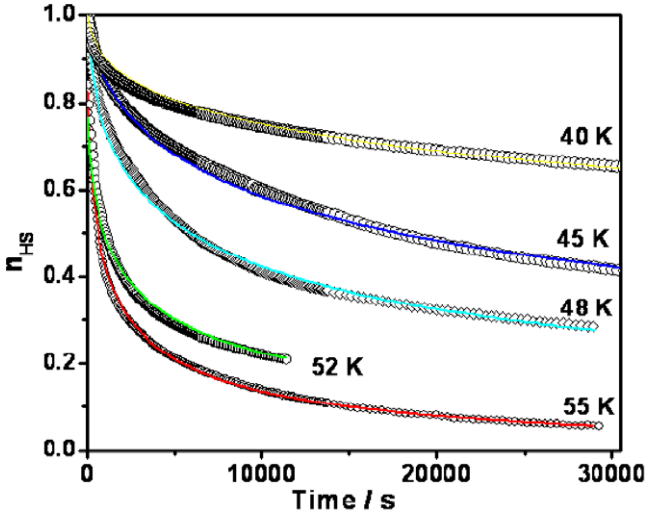

Fig. 2. Isothermal relaxation curves independently fitted by macroscopic Gaussian distributions of barrier energies, in absence of elastic interactions (after [2]).

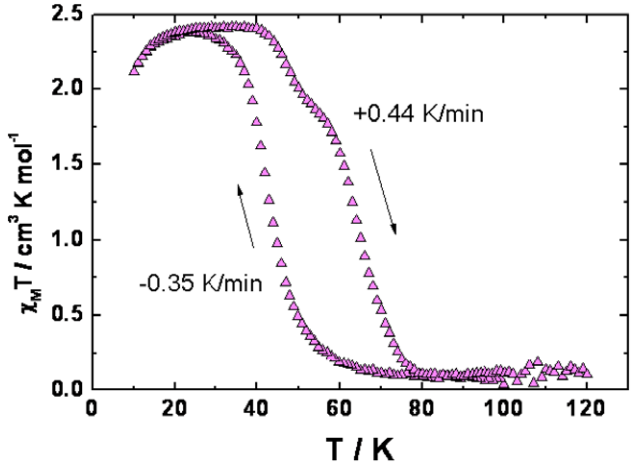

Fig. 3. The light-induced thermal hysteresis (LITH) loop of the compound under permanent laser irradiation (514.5 nm, 25 mW) (present work).

("macroscopic") distributions. We focus on the static hysteresis loop and the set of isothermal relaxation curves with the goal of elucidating the problem of the correlations between the parameters of opposite or identical effects. By the way, we found the present results poorly consistent with the LITH and T(LIESST) experimental data of the present compound, and we suggest here possible underlying mechanisms for explaining the observed discrepancies.

1.1. Mean-field model with short- and long-range distributions of parameters

At variance from the first macroscopic model developed by Hauser [10], we take advantage of the Master Equation formalism which provides a straightforward solution for both the dynamic and static case (the latter is obtained at the limit of vanishing temperature scan rate). Simple analytical considerations showing how the static case can be derived from the master equation can be found in [11]. The master equation writes (after [11])

$$dn/dt = [1 - n(t)][I_{LH}\eta_{LH}\sigma_{LH} + k_{LH}(T,n)] - n(t)[I_{HL}\eta_{HL}\sigma_{HL} + k_{HL}(T,n)], \quad (1)$$

where, $n = n_{HS}$ is the population of the metastable state and $I_{LH}\eta_{LH}\sigma_{LH}$, $I_{HL}\eta_{HL}\sigma_{HL}$ are the photo-excitation terms accounting for light intensities, quantum yields and absorption cross sections; k_{HL} and k_{LH} are the $HS \rightarrow LS$ and $LS \rightarrow HS$ relaxation rate constants, respectively.

The assumption of a linear dependence of the barrier energy on the population of the metastable state leads to simple mean-field expressions of the $HS \rightarrow LS$ cooperative relaxation rate [12]. The present expressions refer to the properties of isolated molecules, obtained when the effects of *HS* and *LS* neighboring molecules cancel each other (that is, when $n = 1/2$)

$$k_{HL}(T,n) = k_{HL}(T,1/2)\exp[-\alpha(n-1/2)], \quad (2)$$

$$k_{LH}(T,n) = k_{LH}(T,1/2)\exp[+\alpha(n-1/2)] \quad (3)$$

where, the ± signs in the exponential factors result from opposite variations of the E_{HL} and E_{LH} barrier energies driven by the internal pressure effect. The self-acceleration parameter α is associated with elastic interactions in the solid. In the thermal activation regime, according to both experiments [13], mean-field [12,14] and microscopic [15] models, it is written

$$\alpha = 2zJ/k_B T \quad (4)$$

with z the number of interacting neighbors, and J the intermolecular interaction parameter. Accordingly, the relaxation rate constants are written

$$k_{HL}(T,n) = k_\infty \exp(-E_{HL}/k_B T)\exp[-\alpha(n-1/2)] \quad (5)$$

$$k_{LH}(T,n) = g k_\infty \exp(-E_{LH}/k_B T)\exp[+\alpha(n-1/2)] \quad (6)$$

with $g = g_{HS}/g_{LS}$ the "effective" degeneracy ratio of the states, accounting for both electronic and vibrational effects [16].

In addition to the thermal contribution to the relaxation process, we also considered a tunneling contribution, phenomenologically written

$$k_{HL}(\text{tunnel}) = k_0 \exp(-\alpha_0 n) \quad (7)$$

where, the values given to the constants $k_0 = 5 \cdot 10^{-6}\ s^{-1}$, $\alpha_0 = 19$ mainly arises from the analysis of the 20 K relaxation curve (see below).

The numerical resolution of the master equation is straightforward. Time is incremented by suited values $dt \sim 0.01'$ or longer, according to the evolution rate of the system. At time t, dn/dt is computed using $n(t)$ values so as to obtain $n(t + dt)$.

In the present work, the system is considered to be made up of independent domains possessing similar spreading of their param-

eters around different central values. Intra-domain parameter spreading will be denoted "short-range distribution", and the inter-domain one, "long-range distribution", corresponding to the "microscopic" and "macroscopic" variants of the model, respectively. As in Ref. [2] we considered Gaussian distributions of the barrier energy E_{HL} for the low temperature kinetic properties, and of the energy gap Δ_{el} for the thermal transition. These distributions are characterized by their standard deviations denoted σ_{SR}, σ_{LR}. The possible relationship between the E_{HL} and Δ_{el} distributions was discussed in [2], and will not be addressed here.

Models including short-range distributions basically differ from the usual macroscopic models which are based on long-range distributions. The latter describe independent domains in the sample and lead to a set of independent macroscopic equations which can be solved straightforwardly in both the static and the dynamic cases. On the contrary, the "short-range" models lead to a set of coupled equations because the self-acceleration factor $\alpha\ (n - 1/2)$ is calculated in average over the different spin-crossover units (according to the mean-field approximation). The set of coupled equations is not tractable in the static case. But, we easily solve the problem numerically in the dynamic case thanks to the Master Equation formalism, and the (quasi) static case is obtained at the limit of vanishing temperature scan rates. It is worth noting that in absence of interactions the difference vanishes between macroscopic and microscopic models, as long as the thermal activation process is considered alone. Indeed, when the tunnel contribution is introduced, as tiny difference appears due to the separate treatment of the tunneling terms in the independent domains.

In practice, the total system is divided into 40 domains, each of them being divided into 40 different spin-crossover sites representing the microscopic (short-range) distribution. For convenience, the distributions are introduced using a Gaussian histogram which gives equal weights to all fractions. For each domain, the set of coupled equations is treated numerically at each time step of the simulation. The different domains are treated separately, and finally the average value of the HS fraction over all domains is expressed.

2. Results and discussion

We show in Figs. 4 and 5 the transition curve of the compound, modeled with the microscopic variant of the model (Fig. 4, after [2]), taking into account both short-range and long-range distributions (Fig. 5). Obviously, the short- and long-range distributions have different impacts. The short-range distribution merely competes against the long-range interaction but does not impede the abrupt character of the transition. In other words, the short-range distribution effect is averaged by the long-range character of the interaction, and only tends to decrease the final cooperativity of the transition. The parameters associated with interactions (zJ) and short-range distribution ($\sigma_{SR}(\Delta_{el})$) cannot be measured separately. They are strongly correlated. On the other hand, the long-range distribution does not reduce the cooperativity of the transition, it trivially gives the hysteresis loop a bent character and can be determined separately.

The experimental data were fitted at best by combining short- and long-range distributions with various values of the interaction parameter zJ, see Fig. 5. There is no sizable correlation between $\sigma_{LR}(\Delta_{el})$ and the set of strongly correlated parameters zJ, $\sigma_{SR}(\Delta_{el})$. Only $\sigma_{LR}(\Delta_{el}) \approx 5$ K was unambiguously determined.

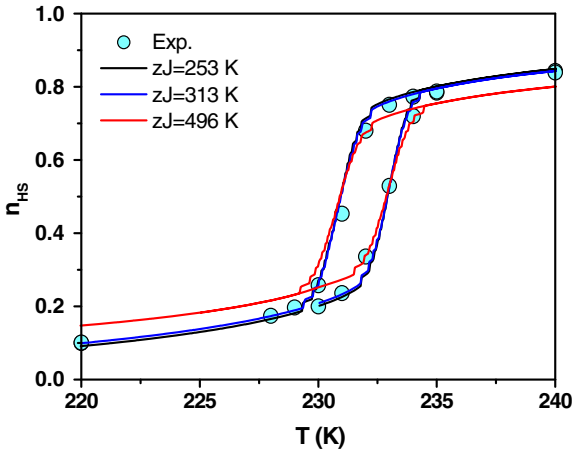

Fig. 5. The hysteresis loop of the spin transition, modeled using the present model, with $\sigma_{LR}(\Delta_{el}) = 5$ K and the sets of parameters: $zJ = 253$ K, $\sigma_{SR}(\Delta_{el}) = 0$ K (black curve); $zJ = 313$ K, $\sigma_{SR}(\Delta_{el}) = 260$ K (blue curve); $zJ = 496$ K, $\sigma_{LR}(\Delta_{el}) = 640$ K (red curve). The stepped character of the curves is due to the discretization of the "macroscopic" Gaussian distribution. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

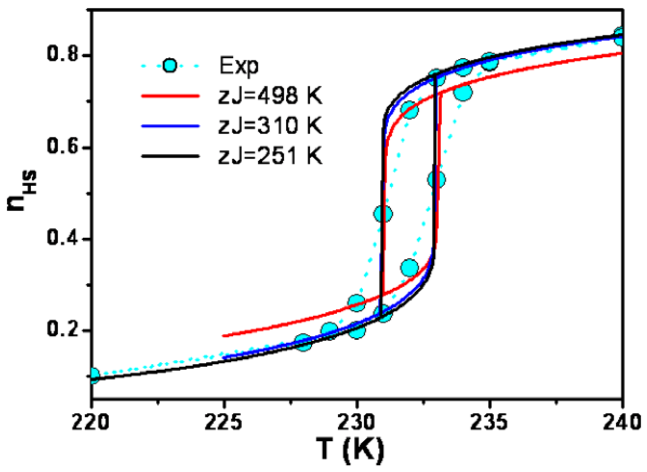

Fig. 4. The hysteresis loop of the spin transition, modeled using the microscopic variant of the model, with the sets of parameters: $zJ = 251$ K, $\sigma_{SR}(\Delta_{el}) = 0$ K (black curve); $zJ = 310$ K, $\sigma_{SR}(\Delta_{el}) = 260$ K (blue curve); $zJ = 498$ K, $\sigma_{SR}(\Delta_{el}) = 640$ K (red curve) (after [2]). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

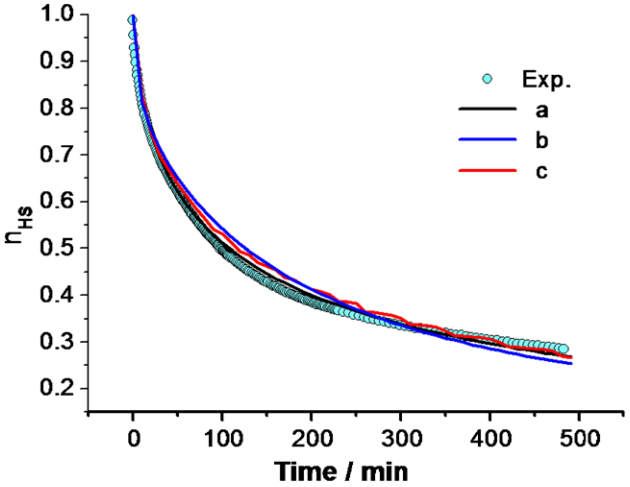

Fig. 6. A typical relaxation curve, in shape of stretched exponential, with fitted curves using the present model. The parameter values are given in Table 1. *(a) non-cooperative, (b) microscopic distribution, (c) macroscopic distribution.* The stepped character of the last curve reflects the discretization of the Gaussian distribution: the computed curve is an envelop of sigmoidal curves.

Table 1
Fitted parameters for the relaxation curve at 48 K (Fig. 6), with model including the tunnel contribution. The χ^2 (variance) parameter refers to a small number of data, corresponding to n_{HS} values in arithmetic progression (0.9, 0.8, 0.7,...).[a]

[b] For interpretation to color in Fig. 6, the reader is referred to the web version of this article.

A typical relaxation curve is shown in Fig. 6, with computed curves according to various assumptions, which are summarized in Table 1. It is observed that the relaxation curve does not allow to discriminate the short-range or long-range character of the E_{HL} distributions, which remain tightly correlated to the zJ value. The presence of interactions is hidden by the distribution effects. In other words, the sigmoidal character of cooperative relaxation is blurred out by the stretchening effect of the distributions. For example the non-cooperative solution (top row) and the cooperative solution with zJ = 250 K (bottom row) can be accepted as well due to their similar χ^2 values. In Table 1 it can be observed that the relationships between zJ and $\sigma_{SR}(E_{HL})$ or $\sigma_{LR}(E_{HL})$ are somewhat different.

The strong impact of the present indetermination upon k_{HL} makes it extremely unsafe for any further determination of E_{HL} and k_∞ using the familiar Arrhenius plot. Instead, the global fitting of the whole set of relaxation curves is needed. Several attempts have been made which are shown in Fig. 7, with the fitted parameter values listed in Table 2. It can be observed that a rough agreement is obtained is all cases (cooperative, non-cooperative, short-range or long-range disorder). However the agreement is sizably better when interactions are not taken into account. This is indeed a puzzling result with respect to the existence of the LITH loop. In addition, the "best-fit" value of the limiting frequency, $k_\infty \sim 20\ s^{-1}$,

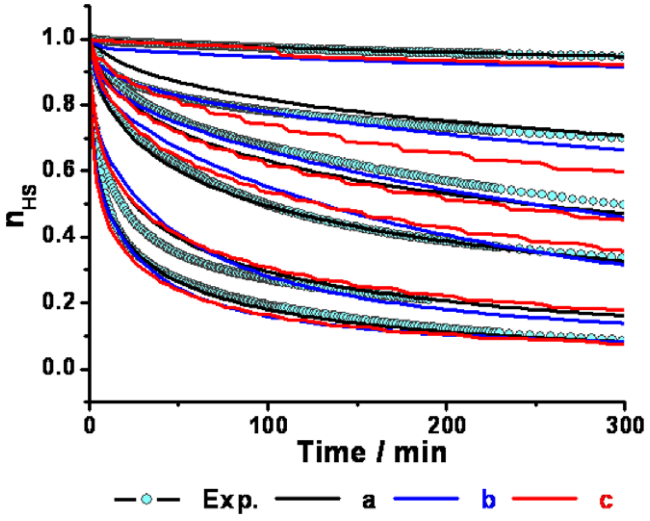

Fig. 7. Global fitting of the set of isothermal curves, for selected set of parameters listed in Table 2. *(a) non-cooperative, (b) microscopic distribution, (c) macroscopic distribution.* The difference with the previous fitting of the 48 K curve originates from the choice of a logarithmic time scale for fine-tuning the parameters, which puts the emphasis on the short-time data.

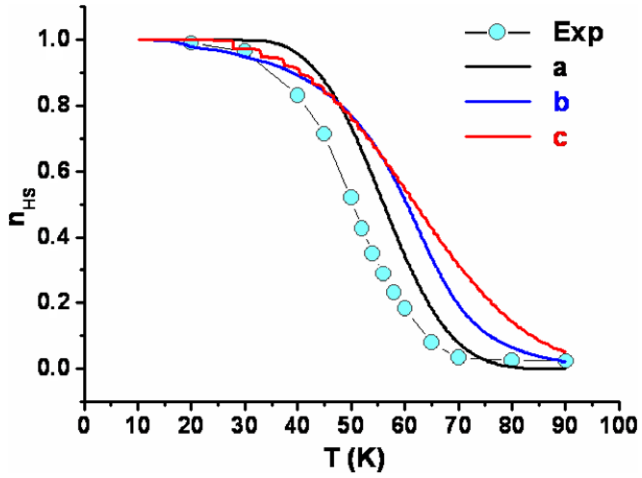

Fig. 8. The experimental T(LIESST) curve recorded in the dark at scan rate 0.3 K/min (after [2]), and simulations using the sets of parameters selected in Table 2. *(a) non-cooperative, (b) microscopic distribution, (c) macroscopic distribution.*

is incredibly low with respect to the molecular vibration frequencies which are usually relevant to the relaxation process [17]. This low value cannot be ascribed, as in previous works, to the vicinity of the tunneling regime, since the tunneling contribution has been explicitly accounted for. A possible explanation might be the presence of a strong "tail effect", resulting from the onset of correlations [18] due to short-range interactions, which mainly develop at long times [19] and may contribute to the stretched shape of the relaxation curves. Further experiments following the strategy defined in [18], are needed for establishing this crucial point.

3. Discussion

We were intrigued by the unusually low value of the frequency factor (k_∞) and because of that we tried to simulate experimental data further, see Figs. 8 and 9. The T(LIESST) procedure [20] provides a convenient fingerprint of the thermal activation of relaxation, and the LITH loop was previously shown as a solid cue for the presence of interactions in the system. A glance at Figs. 8 and

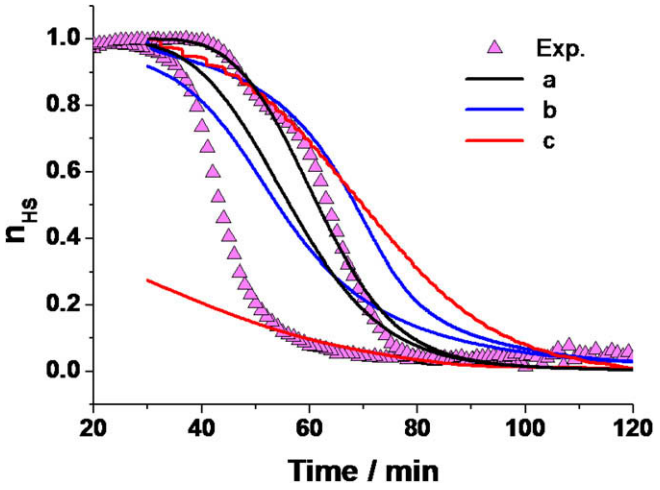

Fig. 9. The experimental LITH loop and simulations using the sets of parameters selected in Table 2. *(a) non-cooperative, (b) microscopic distribution, (c) macroscopic distribution.*

9 show strong discrepancies. Fig. 8 shows that the timescale is not convenient and explains why a lower barrier energy had to be assigned to the T(LIESST) process in Ref. [2]. Fig. 9 confirms the unconvenience of the timescale and suggests that strong interactions and distributions of short- and long-range character are both present.

We have also performed independent analyses of the T(LIESST) curve and LITH loop, and obtained conclusions somewhat similar to those obtained in the previous section: the T(LIESST) does not lift the correlations between the interaction and distribution parameters. The LITH loop is more informative and disentangles the short-range distribution effect from the correlated set of parameters: mean-field interaction and short-range distribution parameter. We present the LITH data in Fig. 10, along with the T(LIESST) curves simulated using the same sets of parameters, which are listed in Table 3. The figure shows the T(LIESST) and LITH data are rather coherent with each other, from the viewpoint of the timescale. It also suggests that the LITH process is slightly more cooperative than the T(LIESST) one.

The discrepancies evident in Figs. 8 and 9 might be attributed to the tail effect (short-range interactions) already quoted, which

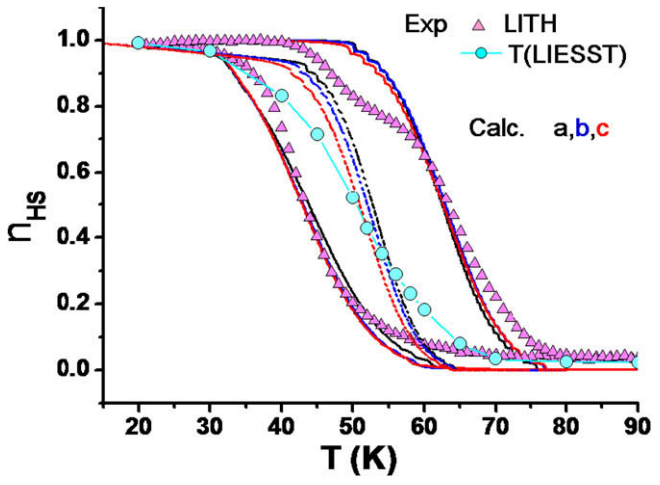

Fig. 10. The experimental LITH loop fitted by independent simulations (full lines), and the resulting simulated T(LIESST) curves (dotted lines). The sets of parameters are listed in Table 3.

only occurs at long times, and tend to slowdown the relaxation process. Theoretical work on the grounds of Ref. [19] is needed for investigating the possible impact of short-range interactions on the T(LIESST) curve and LITH loop. It is speculated that such correlations should not occur to a large extent in both experiments, because of the random effect of light [21] on the LITH loop and relatively shorter time needed for recording the T(LIESST) curve at usual scan rate (0.3 K/min). An alternative or complementary origin of the discrepancies might be the coupling between the spin equilibrium and the structural effects associated with the temperature-dependent orientational disorder of the solvent molecules and anions, observed in [2]. The presence of a structural reorganisation might contribute to the slow but strongly cooperative character of the relaxation process, in addition to the relaxation tail effect. Unfortunately the crystallographic structure of the photoexcited state could be not determined, due to the loss of quality induced by the thermal transition on cooling the crystal [2].

4. Conclusion and prospects

We have shown that a square-shaped hysteretic transition can hide short-range disorder which is "averaged" by the mean-field treatment of the long-range elastic interaction. Conversely, stretched relaxation curves can hide disorder, at both the long and short ranges. Disorder and interactions have opposite effects, which can hardly be disentangled. In other words, the fitting of relaxation curves is an over-parameterised problem when interactions and disorder coexist. The effect of short-range interactions which enhance the stretched character of the relaxation curves remains to be investigated and increases the complexity of the problem.

For the present compound, we have found sizable discrepancies between the refined data of the relaxation curves, the T(LIESST) curve, and LITH loop. Further experiments are planned for evidencing the eventual presence of short-range interactions, and for investigating the possible influence of a structural transformation coupled with the spin state switching.

Fig. 1. The three elastic constants in function of the two neighbor atoms spin state.

$$H_{phon} = E_c + E_p, \tag{2}$$

is the phonon Hamiltonian.

The chain potential energy:

$$E_P = \sum_{i=1}^{N} \frac{1}{2} e_{i,i+1} q_i^2, \tag{3}$$

where $q_i = u_{i+1} - u_i$ is the displacement of the ith atom from its equilibrium position which we assume to be independent of the electronic states of the atoms. Due to the periodic condition, $q_{p+N} = q_p$ for $p = 1, 2, \ldots, N$; and $e_{i,i+1}$ is elastic force constant which is given by

$$e_{i,i+1} = \frac{\lambda + 2\mu + \nu}{4} + \frac{\nu - \lambda}{4}(\hat{\sigma}_i + \hat{\sigma}_{i+1}) + \frac{\lambda - 2\mu + \nu}{4}\hat{\sigma}_i\hat{\sigma}_{i+1}. \tag{4}$$

The potential energy can be decomposed as

$$V_o = \sum_{i=1}^{N} \frac{\lambda + 2\mu + \nu}{8} q_i^2, \tag{5}$$

$$V_1 = \sum_{i=1}^{N} \frac{\nu - \lambda}{8}(q_1^2 + q_{i+1}^2)\hat{\sigma}_i, \tag{6}$$

$$V_2 = \sum_{i=1}^{N} \frac{\lambda - 2\mu + \nu}{8} q_i^2 \hat{\sigma}_i\hat{\sigma}_{i+1}, \tag{7}$$

V_1 has a Zeeman-like energy form; each spin $\hat{\sigma}_i$ is submitted to an effective field h_i given by:

$$h_i = \frac{\nu - \lambda}{8}(q_i^2 + q_{i+1}^2) = h_0(q_i^2 + q_{i+1}^2), \tag{8}$$

and V_2 has an exchange-like energy form. In the V_2 expression,

$$J_{i,i+1} = \frac{\lambda - 2\mu + \nu}{8} q_{i+1}^2 = J_0 q_{i+1}^2, \tag{9}$$

can be seen like a exchange parameter.

In the following we take $\hbar\omega_M(\lambda)$ as the unit energy, where $\omega_M(\lambda)$ is the maximum phonon frequency when the chain is periodic with an elastic force λ is given by $\omega_M(\lambda) = 2\sqrt{\frac{\lambda}{M}}$, where M is the atom mass.

In this contribution we introduce the same reduced parameters as in [6]:

- Reduced temperature: $t_r = \frac{k_B T}{\hbar\omega_M(\lambda)}$;
- The dimensionless electronic excitation energy: $\delta = \frac{\Delta}{\hbar\omega_M(\lambda)}$;
- The elastic force constant ratio: $x = \frac{\nu}{\lambda}$;
- The dimensionless parameter y defined by: $\mu = \frac{\lambda+\nu}{2} + \frac{\lambda-\nu}{2}y$.

3. Monte Carlo–Metropolis simulation for 1D spin crossover

The Metropolis algorithm provides most representative configurations of the thermodynamical system through a Markov chain of elementary transformations yielding a limit which corresponds to the canonical equilibrium distribution.

For finding all configurations, Metropolis et al. [10] proposed the using of a Markov configurations chain where ith configuration is obtained from $(i-1)$th configuration due to the near $W(i-1 \to j)$ transition probability. A sufficient condition for that, the states distributions generated to strive to the equilibrium one, when the number of configurations $N \to \infty$, is to satisfied the detailed balance equation.

$$P(i,T)W(i \to j,T) = P(j,T)W(j \to i,T) \tag{10}$$

From Eq. (16) one may observe that, the transition probabilities ratio for a $i \to j$ step and the inverse step $j \to i$ depends only on the ratio:

$$W(i \to j) = \begin{cases} 1 & \text{if } P(j) \geqslant P(i) \\ \frac{P(j)}{P(i)} & \text{if } P(j) < P(i) \end{cases}. \tag{11}$$

The probability $P(\alpha)$ of a configuration (α) is given by $P(\alpha) = \frac{e^{-\frac{E_\alpha}{k_B T}}}{Z}$, where E_α, the energy of the configuration, is the sum of the electronic and phonon energies.To obtain the phonon frequency of a chain, first we consider the dynamical equation for each atom's displacement u_i:

$$\begin{cases} M\ddot{u}_1 = e_{1,2}(u_2 - u_1) + e_{1,N}(u_N - u_1) \\ M\ddot{u}_2 = e_{2,3}(u_3 - u_2) + e_{2,1}(u_1 - u_2) \\ \vdots \\ M\ddot{u}_N = e_{1,N}(u_1 - u_N) + e_{N-1,N}(u_{N-1} - u_N) \end{cases}. \tag{12}$$

Then we construct the dynamical matrix of the system. The eigenvalues of this matrix are the phonon frequencies.

For each phonon frequency we obtain

$$\sum_{n=0}^{\infty} e^{-\beta\hbar w_i\left(n+\frac{1}{2}\right)} = \frac{1}{2\sinh\left(\frac{\beta\hbar w_i^\alpha}{2}\right)}, \tag{13}$$

and then for a chain of N atoms:

$$P(\alpha) = \frac{1}{Z} e^{-\beta\left(\frac{\Delta - k_B T \ln r}{2} m_\alpha\right)} \prod_{i=1}^{N} \left(\frac{1}{2\sinh\frac{\beta\hbar w_i^\alpha}{2}}\right), \tag{14}$$

where $m = <\hat{\sigma}>$.

Fig. 2 shows some typical results obtained for 1D spin crossover: no thermal hysteresis is obtained. In this "atom–phonon coupling" model, $x = \frac{\nu}{\lambda}$ affects at the same time the "short" and "long" range interactions but this last contribution is not enough to produce phase transition at 1D (see also [11]).

In order to reproduce thermal hysteresis for 1D systems, as has been obtained experimentally [12] we propose, as in [13,14] to introduce a long-range interaction $-G\langle\hat{\sigma}\rangle$.

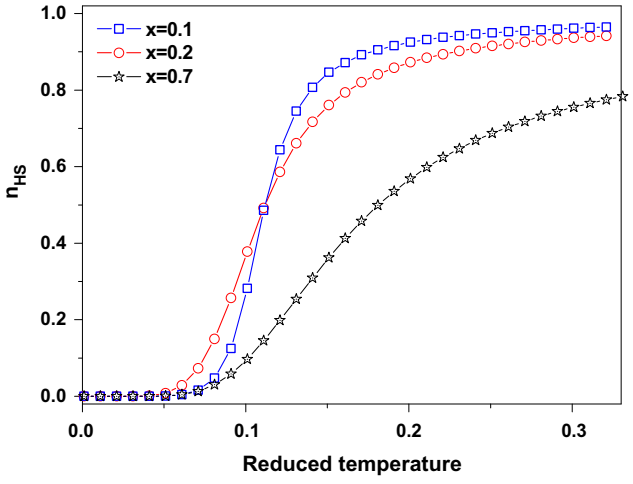

Fig. 2. The high spin fraction evolution in function of the reduced temperature, obtained for 1D system for different x values, using: $N = 100$ molecules, $y = 0$, $r = 15$, $\delta = 0.55$, $G = 0.0$.

This means that we consider that the molecular chains interact with each other. This long-range interaction is due to elastic coupling mediated by the lattice. The Hamiltonian for one chain of N atoms may be written in this case as

$$H = \sum_{i=1}^{N} \left(\frac{\Delta}{2} - G\langle\hat{\sigma}\rangle \right) \hat{\sigma}_i, \tag{15}$$

which means that Δ in the Eq. (1) must be replaced by $\Delta - 2 * G * \langle\hat{\sigma}\rangle$.

With this new long-range interaction parameter a thermal hysteresis is now obtained (see Fig. 3): it means, as has been noted in [13,14] a first-order phase transition accompanied by a hysteresis loop is obtained.

For a fixed G, y, r and Δ values, the width of the hysteresis loop is controlled by the x value as it is shown in Fig. 4. If we compare this result with what is reported in [13] we can conclude that $x = \frac{v}{\lambda}$ is essentially a "short-range" interaction type.

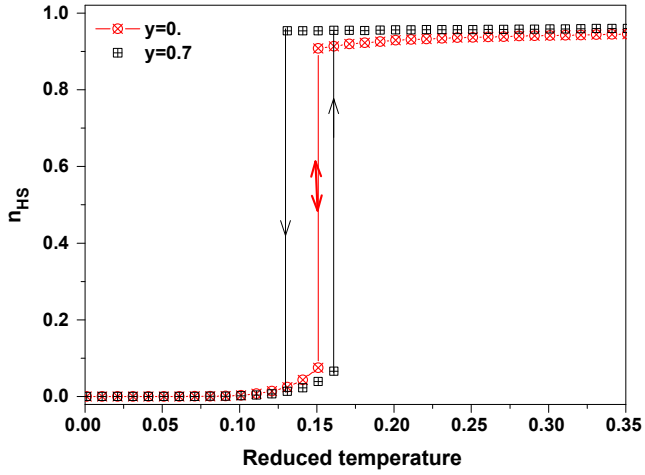

Fig. 3. The high spin fraction evolution in function of the reduced temperature, obtained for 1D system, for different y values, using: $N = 100$, $x = 0.4$, $r = 15$, $\delta = 0.55$, $G = 0.41$.

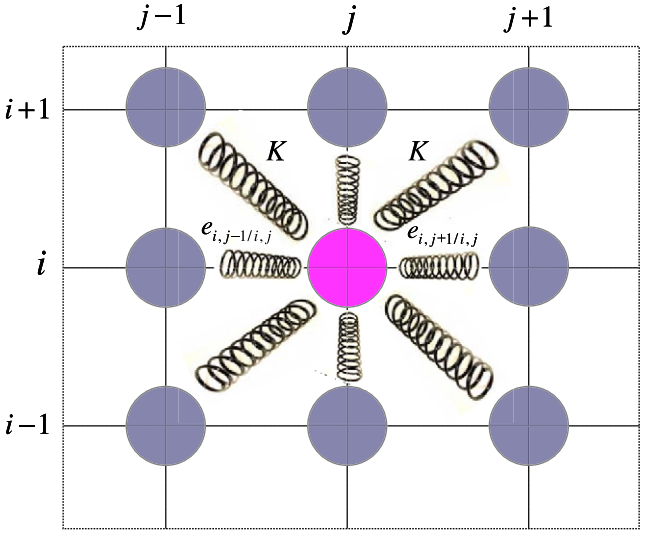

Fig. 4. The 2D network with the elastic constants corresponding to the nearest and the next-nearest neighbors.

4. Monte Carlo–Metropolis simulations for 2D spin crossover systems

The next step in our simulation is to consider a 2D square lattice of spin crossover compounds; nearest as well as next-nearest interactions have been taken into account. As we have assumed in the 1D case the elastic constant between nearest atoms is func-

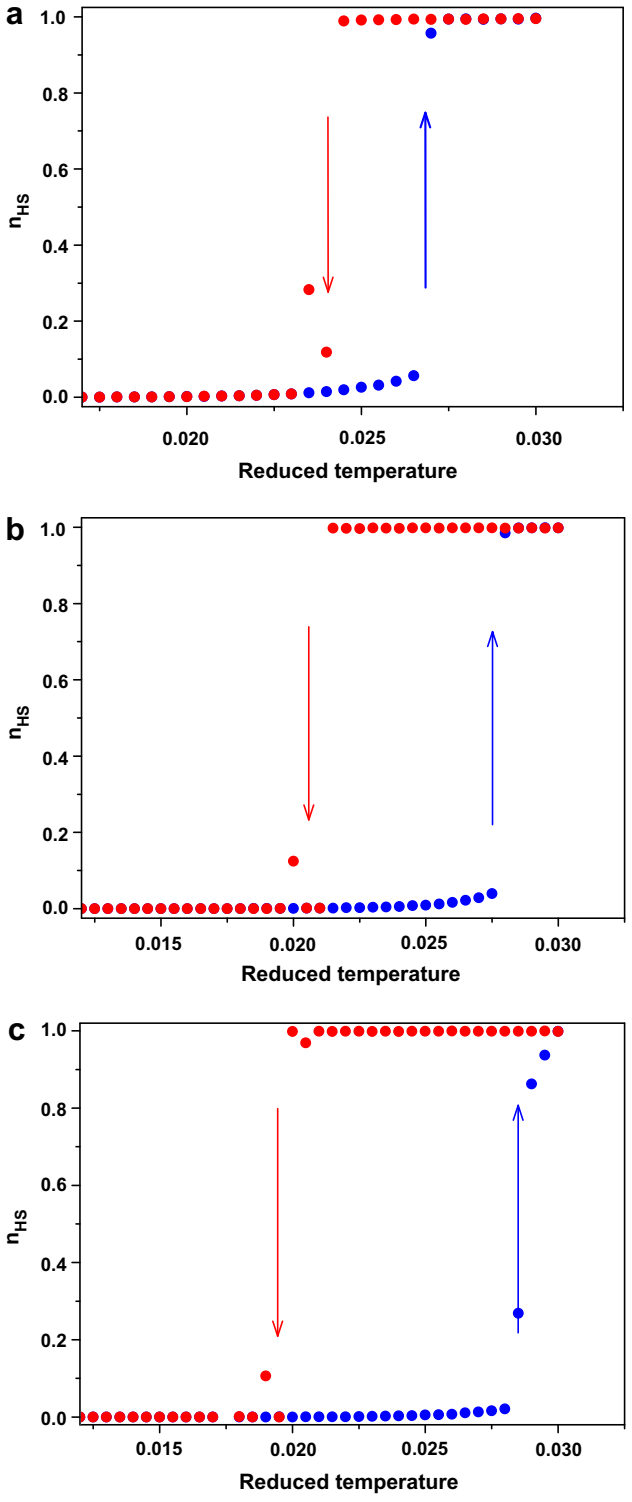

Fig. 5. The high spin fraction evolution in function of the reduced temperature, obtained for 2D system using: $N = 10 \times 10$, $x = 0.1$, $r = 15$, $\delta = 0.55$, K = 0.01 for (a) $y = 0.02$, (b) $y = 0.10$, (c) $y = 0.15$.

tion of the spin states of these atoms. The elastic constant for the next-nearest atoms are smaller than the previous one and in order to simplify the calculations we have taken this elastic constant as a constant K (see Fig. 4).

The dynamical equation for each displacement's atom and for a perpendicular wave is given by

$$m\ddot{\mathbf{u}}_{i,j} = \mathbf{I}_1 + \mathbf{I}_2, \tag{16}$$

with

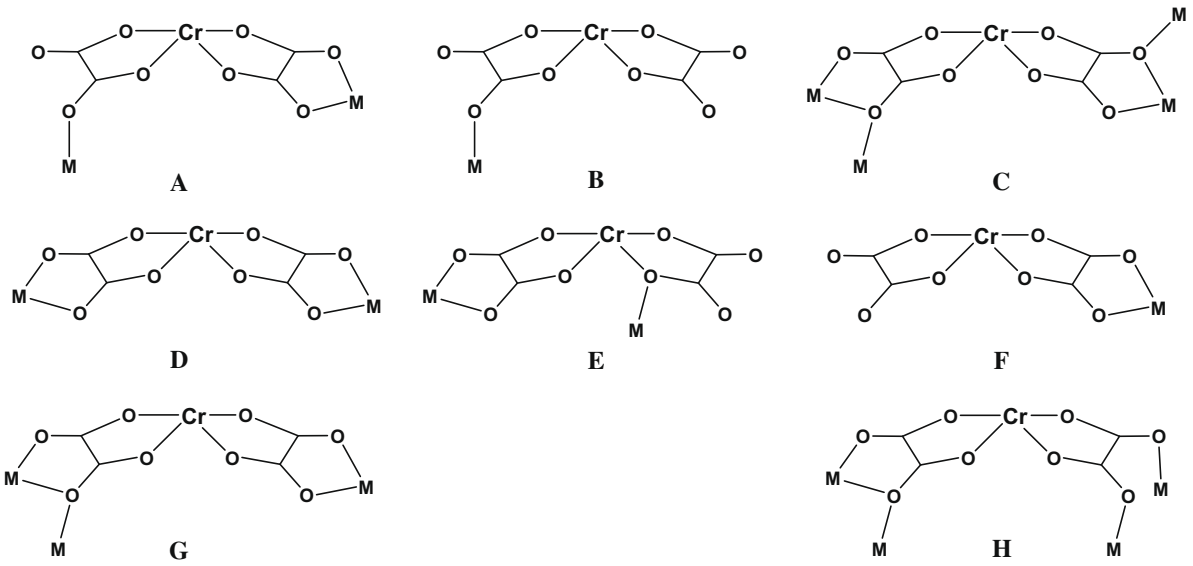
$$\mathbf{I}_1 = e_{i-1,j/i,j}(\mathbf{u}_{i-1,j} - \mathbf{u}_{i,j}) + \mathbf{e}_{i,j+1/i,j}(\mathbf{u}_{i,j+1} - \mathbf{u}_{i,j}) + \mathbf{e}_{i+1,j/i,j}(\mathbf{u}_{i+1,j} - \mathbf{u}_{i,j}) + \mathbf{e}_{i,j-1/i,j}(\mathbf{u}_{i,j-1} - \mathbf{u}_{i,j}), \tag{17}$$

and

$$\mathbf{I}_2 = K(\mathbf{u}_{i-1,j} + \mathbf{u}_{i,j+1} + \mathbf{u}_{i+1,j} + \mathbf{u}_{i,j-1} - 4\mathbf{u}_{i,j}) \tag{18}$$

As for a one dimensional case, the eigenvalues of the dynamical matrix give the phonon frequencies. Fig. 5 shows a thermal hysteresis obtained for a square lattice with periodic conditions.

5. Conclusion



In the framework of the "atom–phonon coupling" model the thermal hysteresis is not obtained for a single chain. If we introduce a long-range interaction, which means to introduce interactions between the molecular chains, the hysteresis is reproduced. The rate of the ν and λ elastic constants parameters plays a crucial role in the hysteresis' width. For 2D spin crossover systems, the hysteresis is obtained without this G "long-range" interaction. In this case the $x = \frac{\nu}{\lambda}$ controls also the width of the hysteresis.

Scheme 1.

well as other diamines, such as dipyridylamine, 2,2′-bipyrimidine), are extremely versatile tectons for the synthesis of heteropolynuclear complexes [7]. They exhibit various coordination modes toward the second metal ion. Those already observed experimentally are depicted in Scheme 1. We also have shown that the auxiliary ligands attached to the assembling cations play a crucial role in the self-assembly process [7].

Manganese(III) complexes with salen type ligands are valuable starting materials for obtaining heterometallic Mn(III)–M(II/III) complexes [9]. The related ligands obtained from *o*-vanillin (H_2valen being the simplest case) are largely used to obtain heterometal complexes, especially 3d–4f [10]. Others and we have shown that the second compartment, O_2O_2', when it is not occupied by a second metal ions, can act as a hydrogen bond acceptor, directing the packing of the molecules in the crystal [11].

Here we present the first oxalato-bridged Mn(III)–Cr(III) complexes, which are obtained by employing $[Cr(AA)(C_2O_4)_2]^-$ building-blocks. As assembling cation we employ a manganese(III) complex, $[Mn(valen)(H_2O)(CH_3CN)]^+$ (H_2valen is a bicompartmental Schiff-base proligand, resulting from the 2:1 condensation of 3-methoxysalicyladehyde with ethylenediamine).

2. Experimental

2.1. Synthesis

The manganese precursor, $[Mn(valen)(H_2O)(CH_3CN)](ClO_4)\cdot CH_3CN$, has been obtained as already reported [11c] The two chromium precursors were synthesized as described in previous papers[7c,d].

The two Mn(III)–Cr(III) compounds, $[\{Mn(H_2O)(valen)\}\{Cr(bipy)(C_2O_4)_2\}]\cdot 3H_2O$ **1** and $[\{Mn(H_2O)(valen)\}\{Cr(phen)(C_2O_4)_2\}]\cdot 3H_2O$ **2,** have been synthesized by the same procedure to a solution of $[Mn(valen)(H_2O)(CH_3CN)](ClO_4)\cdot CH_3CN$ (0.05 mmol) in 20 mL 1:1 CH_3CN/H_2O mixture, were added 20 mL solution of $AsPh_4[Cr(ox)_2(AA)]$ (0.05 mmol in 1:1 CH_3CN/H_2O mixture). The resulting brown solution was stirred for about 1.5 h and then filtered. The slow evaporation of the filtrate, at room temperature, yielded black crystals, suitable for X-ray diffraction. IR data (KBr, cm^{-1}): Compound **1**: 3413, 2926, 2854, 1719, 1680, 1620, 1551, 1468, 1439, 1398,1358, 1302, 1254, 1220, 850, 807, 739, 723, 550. Compound **2**: 3415, 2927, 2853, 1711, 1684, 1645, 1620, 1552, 1468, 1439, 1398, 1358, 1302, 1254, 1220, 850, 807, 739, 723, 550.

2.2. Physical measurements

The IR spectra were recorded on KBr pellets with a Bio-Rad FTS 135 spectrophotometer in the 4000–400 cm^{-1} range. Magnetic data were obtained with a Quantum Design MPMS SQUID susceptometer. Magnetic susceptibility measurements were performed in the 1.95–300 K temperature range in a 1000 Gauss applied magnetic field, and diamagnetic corrections were applied by using Pascal's constants.

2.3. X-ray crystallography

X-ray diffraction measurements were performed on Oxford Diffraction XCALIBUR diffractometer for **1,** and on a STOE IPDS II diffractometer for **2**, both operating with a Mo Kα (λ = 0.71073 Å) X-ray tube with a graphite monochromator. The structures were solved by direct methods and refined by full-matrix least squares techniques based on F^2. The non-H atoms were refined with anisotropic displacement parameters. Calculations were performed using SHELX-97 crystallographic software package.

3. Results and discussion

3.1. Crystal structures

The two new Mn(III)–Cr(III) complexes, $[\{Mn(H_2O)(valen)\}\{Cr(AA)(C_2O_4)_2\}]\cdot 3H_2O$, have been obtained by reacting $[Mn(valen)(H_2O)(CH_3CN)](ClO_4)\cdot CH_3CN$ with $AsPh_4[Cr(AA)(C_2O_4)_2]$ (AA = 2,2′bipyridine (bipy) **1**; 1,10-phenahroline (phen) **2**). During the assembling process, the anionic chromium complex replaces the acetonitrile molecule coordinated into the apical position of the Mn(III) ion. Since their molecular structures are quite similar, they will be discussed together Table 1.

The crystallographic investigation of the two compounds reveals neutral binuclear $[\{Mn(H_2O)(valen)\}\{Cr(AA)(C_2O_4)_2\}]\cdot$ species along with crystallization water molecules. The $[Cr(AA)(C_2O_4)_2]^-$ ion acts as a monodentate ligand through an oxalato oxygen atom toward the $\{Mn(valen)(H_2O)\}$ moiety (Scheme 1 **A**, Fig. 1). The intramolecular Cr···Mn distances are as follows 5.329

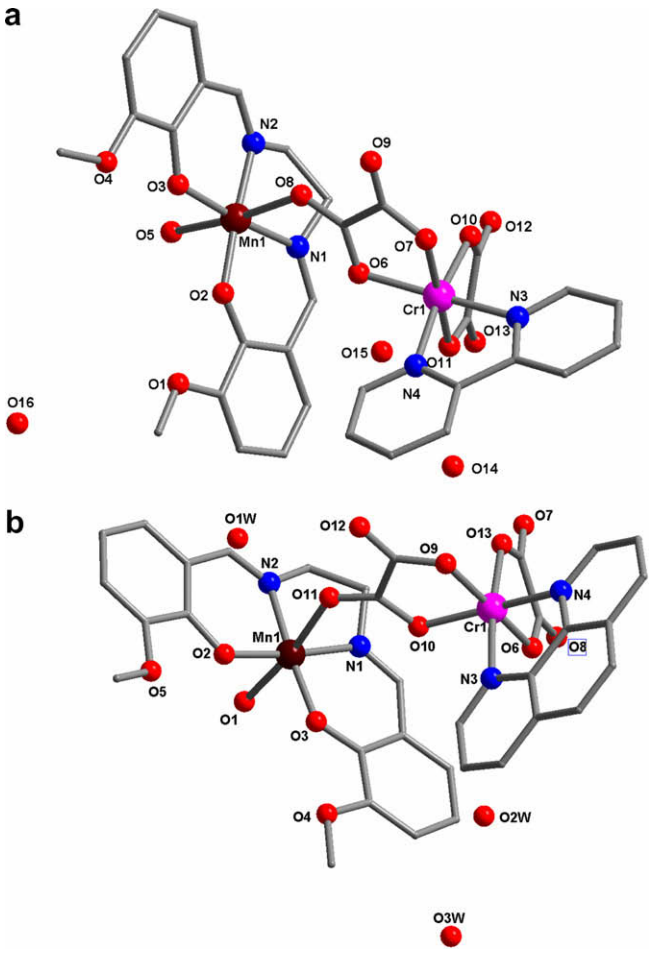
(**1**); 5.442 Å (**2**). The manganese ions exhibit the characteristic elongated octahedral geometry, with two nitrogen and two oxygen atoms from the inner compartment of the Schiff-base ligand describing the basal plane, and one oxalato oxygen and one aqua ligand into the apical positions. The apical Mn–O(oxalato) distances for the two compounds are 2.2681(15) (**1**) and 2.289(3) Å (**2**), and the Mn–O(aqua) ones are 2.2767(15) (**1**) and 2.314(3) Å (**2**). The basal Mn–N and Mn–O distances are in the range 1.9697(18)–1.9820(17) Å, and, respectively, 1.8627(15)–1.8804(14) Å. The chromium atoms are coordinated by two nitrogen atoms arising from the chelating diamine, and by four oxalato oxygen atoms, adopting a distorted octahedral geometry. The short bites of the heterocyclic diamines and oxalato ligands are the main factors responsible for the distortion of the [CrN_2O_4] chromophore. The Cr–N bond distances (ave 2.045 for **1** and 2.066 Å for **2**] are somewhat longer than the Cr–O(ox) ones. The Cr–O bond distances are slightly shorter for the terminal oxalato ligand [ave 1.949 Å for **1**, and 1.946 Å for **2**] than for the bridging ones [ave 1.961 for **1**, and 1.968 Å for **2**]. Selected bond distances and angles are gathered in Table 2.



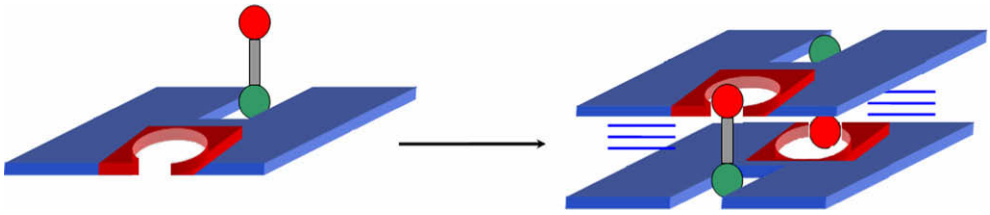


Fig. 1. Perspective view of the binuclear complexes (a) [{Mn(H_2O)(valen)}{Cr(bipy)(C_2O_4)$_2$}] **1**; (b) [{Mn(H_2O)(valen)}{Cr(phen)(C_2O_4)$_2$}] **2**.

The central problem in crystal engineering concerns the control over the intermolecular forces, especially the strongly directional ones, that allows the construction of crystals with desired structures and properties. For compounds **1** and **2**, the packing of the molecules in the crystal, up to certain level, can be easily predicted. There are two organizing forces intervening here: hydrogen bond and $\pi-\pi$ stacking interactions. In a preceding paper [11c], we have shown that the {Mn(valen)(H_2O)} moieties are self-complementary, that is, the aqua ligand from one moiety is hydrogen bonded to the oxygen atoms from the free O_2O_2' compartment of another one (Scheme 2). Moreover, the stability of the resulting dimer of complexes is reinforced by $\pi-\pi$ stacking interactions established between the aromatic rings of the Schiff-base ligands. Let us take the case of compound **1**. The {Mn(valen)(H_2O)} moieties from two [MnCr] units are hydrogen bonded, as expected, resulting in a tetranuclear supercomplex (Fig. 2a). These dimers are then interconnected through aromatic interactions occurring between the bipy ligands coordinated to the chromium ions (3.38–3.91 Å). Supramolecular chains are thus formed (Fig. 2a). This structural

Scheme 2.

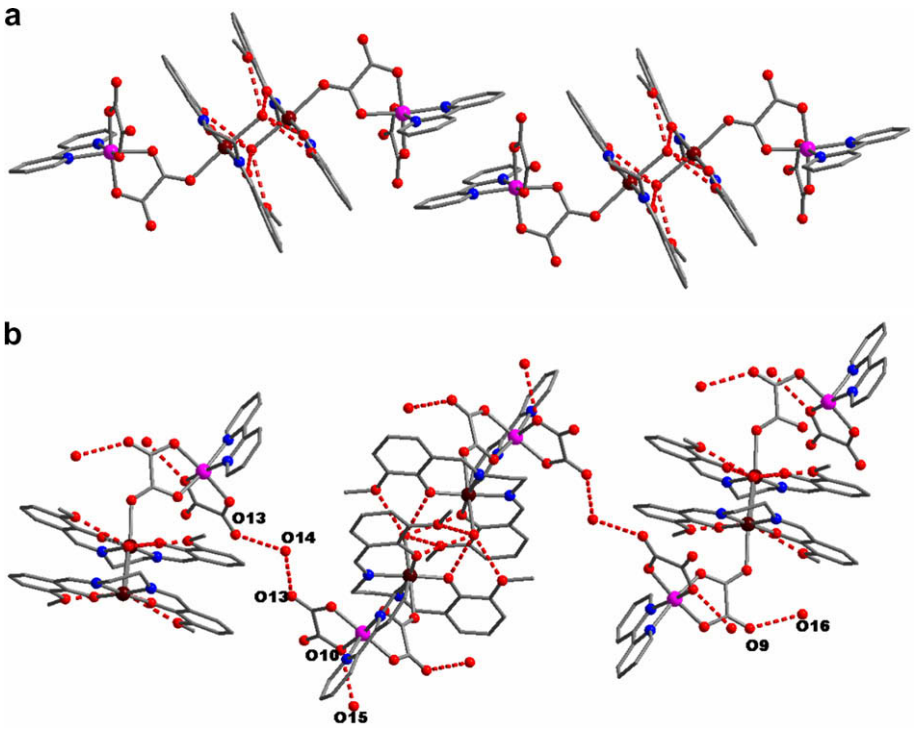

Fig. 2. Packing diagram for crystal **1**: (a) formation of the tetranuclear supercomplex and of the supramolecular chains through aromatic interactions; (b) hydrogen bonds established between the supramolecular tetramers and the water molecules.

motif has already been observed with other heterometallic systems constructed from $[Cr(AA)(C_2O_4)_2]^-$ building-blocks [7]. The structure is expanded into the second direction through hydrogen bonds involving one water molecule (O14) and two oxygen atoms from two terminal oxalato ligands (O13 and $O13^i$, i = 1 – *x*, *y*, 1.5 – *z*) as illustrated in Fig. 2b. The two other water molecules (O15 and O16) are hydrogen bonded to oxalato oxygen atoms ($O15\cdots O10^{ii}$ = 2.867 Å, ii = *x*, –*y*, –0.5 + *z*; $O16\cdots O9^{iii}$ = 2.854 Å, iii = 0.5 – *x*, 0.5 – *y*, 1 – *z*). Surprisingly, although the binuclear complexes in two compounds are similar and they crystallize with the same number of water molecules, the hydrogen bond pattern involving the crystallization water molecules is different for the two compounds. The formation of the tetranuclear supercomplexes, which are interconnected through aromatic interactions, occurs for compounds **2** as well. For compound **2**, the supramolecular chains are connected by all the crystallization water molecules, which form hydrogen bonds with the oxalato oxygen atoms as well as with the aqua ligand (O1) coordinated to the manganese ion (Fig. 3).

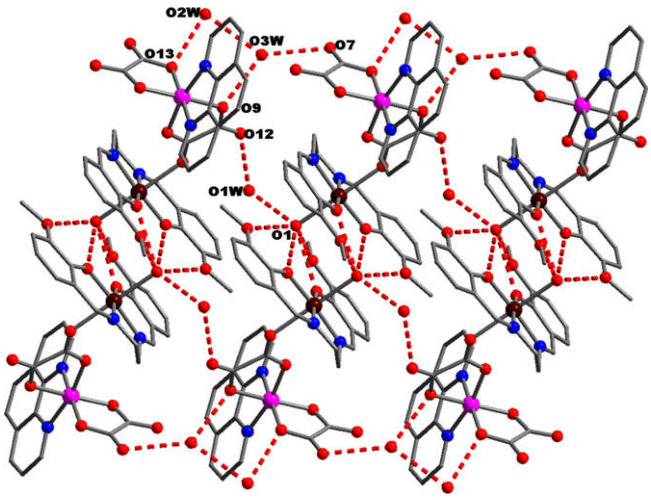

Fig. 3. Packing diagram for crystal **2**.

3.2. Magnetic properties

The magnetic behavior of the two compounds has been investigated from 1.9 to 300 K. The $\chi_M T$ versus *T* curves are represented in Fig. 4 (χ_M is the molar paramagnetic susceptibility). At room temperature, the values of the $\chi_M T$ products for compounds **1** and **2** are, respectively: 4.77 and 5.07 $cm^3\ mol^{-1}$ K, which correspond to

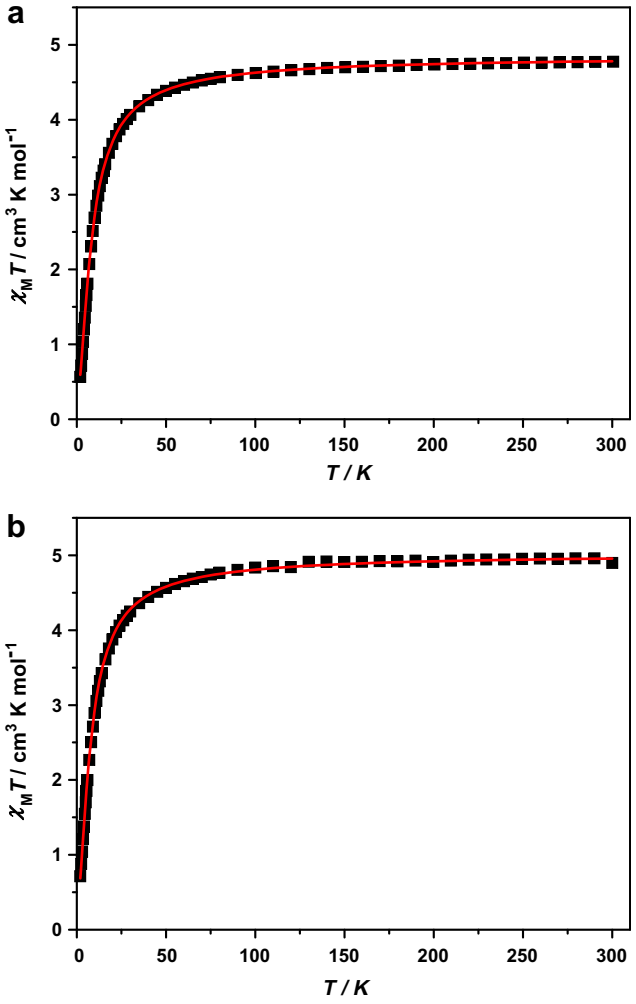

Fig. 4. Thermal variation of the $\chi_M T$ product for compound **1** (a), and **2** (b).

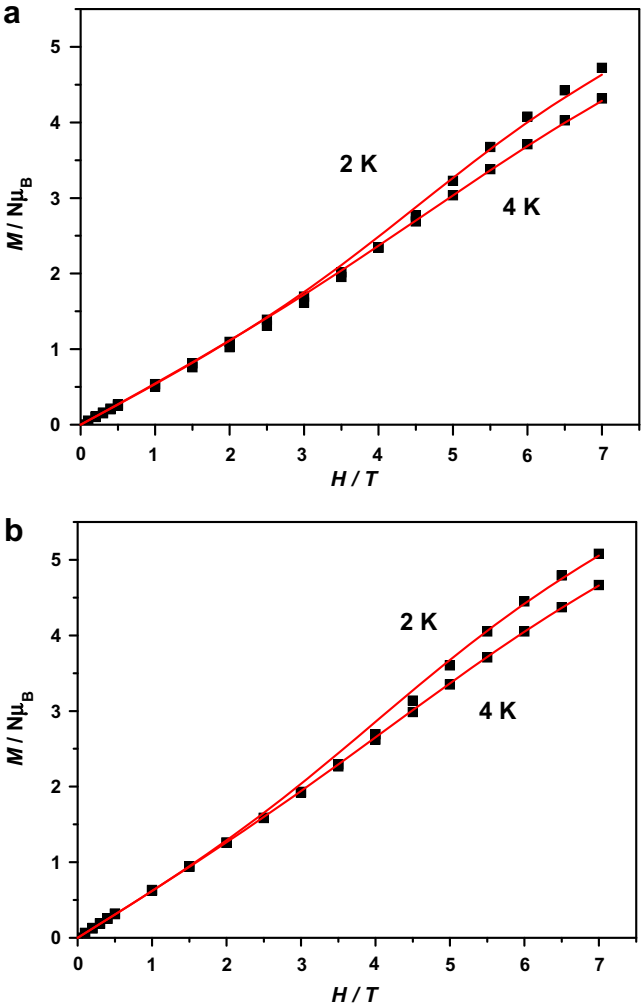

Fig. 5. Magnetization vs. field curves for compound **1** (a), and compound **2** (b).

the expected values for uncoupled Cr(III) and Mn(III) ions (4.88 cm^3 mol^{-1} K, assuming $g_{Cr} = g_{Mn} = 2$).

For both compounds, by decreasing the temperature, the $\chi_M T$ product remains constant down to 100 K, then it decreases more and more rapidly reaching 0.56 cm^3 mol^{-1} K (for **1**) and 0.65 cm^3 mol^{-1} K (for **2**). This behavior is ascribed to the antiferromagnetic exchange interaction between the Mn(III) and Cr(III) ions, mediated by the oxalato group, and/or to the zero-field-splitting effects associated to the axially elongated Mn(III) ion.

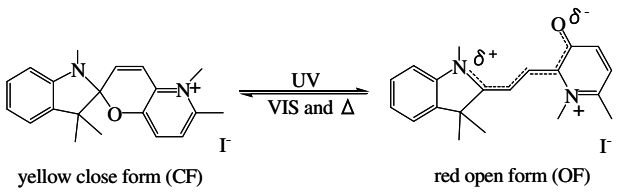
The magnetization *versus* field curves are illustrated in Fig. 5. The slow saturation of the magnetization is due to the antiferromagnetic interaction between Mn(III) and Cr(III), as well as to the large zero-field-splitting of the Mn(III) ion.

Both magnetization and susceptibility data were simultaneously fitted by full-matrix diagonalization of the following spin Hamiltonian:

$$H = -2JS_{Mn}S_{Cr} + D_{Mn}[S^2_{Mnz} - 1/3S_{Mn}(S_{Mn}+1)] + D_{Cr}[S^2_{Crz} - 1/3S_{Cr}(S_{Cr}+1)]$$

The first term refers to the exchange interaction between the manganese(III) and chromium(III) ions within the binuclear species. The second and the third ones take into account the zero-field-splitting (ZFS) effects for the two manganese and the chromium ions. In view of the axially elongated structure around Mn(III), a negative sign is expected for D_{Mn} [12], thus D was constrained to negative values in our calculations. In order to avoid oveparametrization, we used fixed values for the g parameters: $g_{Mn} = 2.04$; $g_{Cr} = 1.98$. The best set of parameters which match the experimental data were found to be: $J = -1.06$ cm^{-1}, $D_{Mn} = -2.4$ cm^{-1}, $|D_{Cr}| = 0.16$ cm^{-1}, (for **1**); $J = -1.01$ cm^{-1}, $D_{Mn} = -2.1$ cm^{-1}, $|D_{Cr}| = 0.11$ cm^{-1}, (for **2**). The solid lines in Figs. 4 and 5 correspond to the calculated curves. As expected, according to the crystal structures, the values of the J parameters are very close. The D values are in the usual range (-1 to -4 cm^{-1}) observed for manganese(III) complexes with Schiff-base ligands [12,13].

4. Supplementary data



CCDC 704112 and 704113 contain the supplementary crystallographic data for 1 and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1. Molecule structure of cationic pyrido-spiropyran.

and the photo-isomerization of spiropyran (photo-isomerization-induced charge transfer phase transition).

In this paper, we present the detailed ^{57}Fe Mössbauer study comparing unirradiated sample of (SP-Me)[$Fe^{II}Fe^{III}$(dto)$_3$] with irradiated one. Although ^{57}Fe Mössbauer spectroscopy is a microscopic probe for iron including oxidation and spin state, the ^{57}Fe Mössbauer spectra of this system are hard to analyze because of the complicated shape. In this case, it is helpful to use ^{57}Fe isotope enriched material. Therefore, we describe here the ^{57}Fe Mössbauer spectra of (SP-Me)[$^{57}Fe^{II}Fe^{III}$(dto)$_3$] with isotope enrichment in Fe^{II} starting from ^{57}Fe metal.

2. Results and discussions

Fig. 1 shows the ^{57}Fe Mössbauer spectra of (SP-Me)[$^{57}Fe^{II}Fe^{III}$-(dto)$_3$] at 200, 70, 10 and 6 K. The Mössbauer parameters are summarized in Table 1 in Supplementary data. At 200 K, the spectrum clearly indicates the presence of two quadrupole doublets similar to (n-C_nH_{2n+1})[$Fe^{II}Fe^{III}$(dto)$_3$] (n = 3–6) [7], which are assigned to Fe^{II} (S = 2) and Fe^{III} (S = 1/2) as described in Fig. 1. Although only ferrous iron was enriched with ^{57}Fe isotope, the observed spectra show a considerable amount of ferric ^{57}Fe ion (ca. 40% at 200 K). This result indicates that both reorientation of the dto ligand and redox reaction between $^{57}Fe^{II}$ and Fe^{III} occurs, and as a result Fe^{II}–$O_2C_2S_2$–$^{57}Fe^{III}$ linkage isomer appears in the precipitation process. According to Hard and Soft Acids and Bases principle (HSAB), a hard acid, Fe^{III} tends to prefer the hard base sites (O_2) in dto ligand and a soft acid, Fe^{II} tends to prefer the soft base sites (S_2) in dto ligand [10], which induces the linkage-isomerization. Moreover, the linkage-isomerization associates the charge transfer from Fe^{II} to Fe^{III} because the HTP is more stable than the LTP in (SP-Me)[$Fe^{II}Fe^{III}$(dto)$_3$] around room temperature. At 70 K, the peak at 2.0 mm s^{-1} corresponding to Fe^{II} (S = 2) decreases and new peaks between 0.1 and 0.9 mm s^{-1} corresponding to the superposition of Fe^{II} (S = 0) and Fe^{III} (S = 5/2) appear. The spectrum at 70 K is assignable using four quadrupole doublets, Fe^{II} (S = 2), Fe^{III} (S = 1/2), Fe^{II} (S = 0), and Fe^{III} (S = 5/2), as shown in Fig. 1. This feature is quite similar to the ^{57}Fe Mössbauer spectra of (n-C_3H_7)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] and (n-C_4H_9)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] at 77 K [7], which indicates that the LTP appears in (SP-Me)[$^{57}Fe^{II}Fe^{III}$(dto)$_3$] between 200 and 70 K due to the CTPT. The hyperfine parameters of the LTP in (SP-Me)[$^{57}Fe^{II}Fe^{III}$(dto)$_3$] are consistent with those of (n-C_3H_7)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$] and (n-C_4H_9)$_4$N[$Fe^{II}Fe^{III}$(dto)$_3$], including relatively larger value of the quadrupole splitting of Fe^{III} (S = 5/2). The same trend has been observed in A[$Fe^{II}Fe^{III}$(ox)$_3$] (ox = oxalato) complexes where the high-spin Fe^{III} is expected to be in the highly distorted octahedral environment [11]. The coordination environment of ^{57}Fe ion in (SP-Me)[$^{57}Fe^{II}Fe^{III}$(dto)$_3$] at 200 and 70 K is displayed in Fig. 2. From the relative area of the ^{57}Fe Mössbauer spectrum, almost the half of ^{57}Fe ion undergoes the CTPT in Fe^{III}–$S_2C_2O_2$–$^{57}Fe^{II}$ site (normal coordination site) and Fe^{II}–$O_2C_2S_2$–$^{57}Fe^{III}$ site (linkage-isomer site), respectively. The one component with the charge transfer phase transition is named A phase and the other without the charge transfer phase transition is named B phase [9].

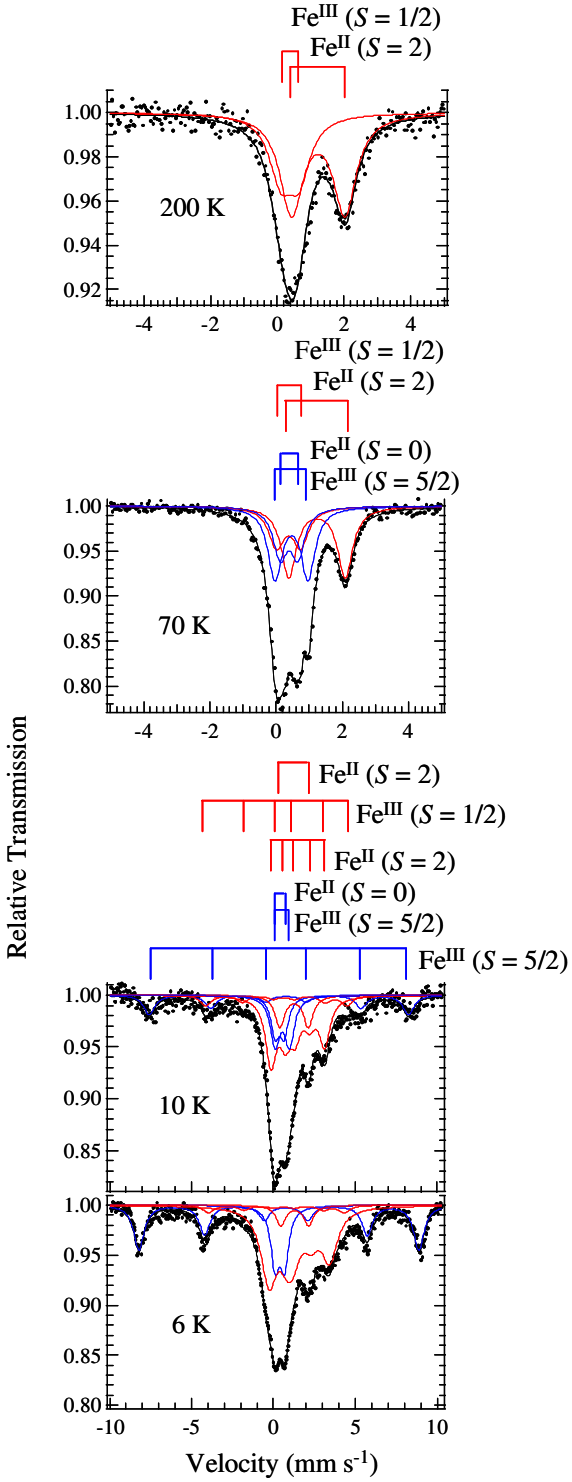

Fig. 1. ^{57}Fe Mössbauer spectra of (SP-Me)[$^{57}Fe^{II}Fe^{III}$(dto)$_3$] before UV-irradiation at 200, 70, 10 and 6 K.

At 10 and 6 K, the ^{57}Fe Mössbauer spectra show an obvious change in shape and reveal some broad sextets, exhibiting the magnetically ordered spectra. The sextet with a large hyperfine field from −8 to 8 mm s^{-1} is typical of the magnetically ordered spectrum of Fe^{III} (S = 5/2) and the quadrupole doublet around 0.3 mm s^{-1} can be assigned to non-magnetic Fe^{II} (S = 0), which is the clear evidence of the presence of the LTP corresponding to the A phase. The magnetic sextets of Fe^{II} (S = 2) and Fe^{III} (S = 1/2) and the quadrupole doublet of Fe^{II} (S = 2) are also required to fit

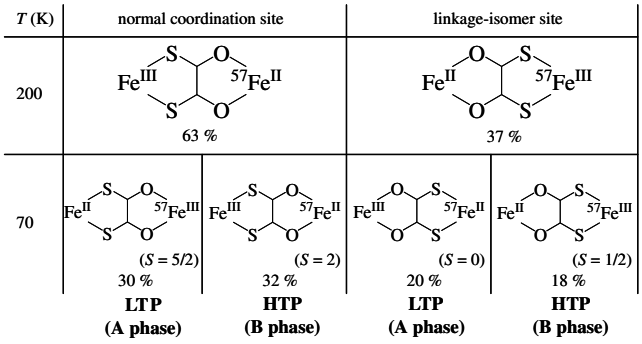

Fig. 2. Coordination environments of ^{57}Fe ion and their fractions calculated from the ^{57}Fe Mössbauer spectra in (SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$] before UV-irradiation at 200 and 70 K. A and B phases are explained in the text.

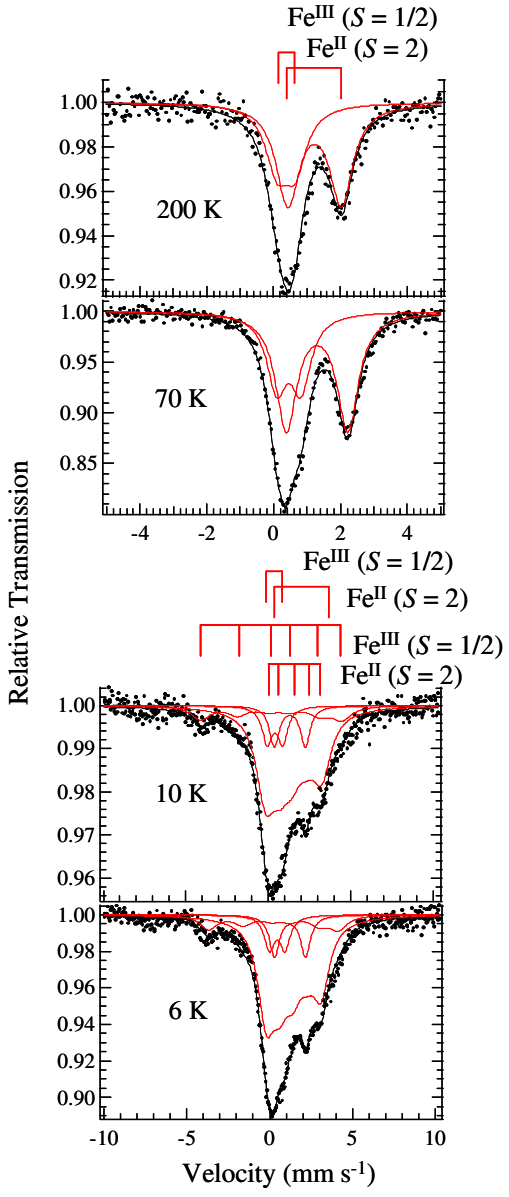

Fig. 3. ^{57}Fe Mössbauer spectra of (SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$] after UV-irradiation at 200, 70, 10 and 6 K.

the spectra, corresponding to the B phase. The angle (θ) between the internal magnetic field (H) and the principal axis of V_{zz} as the Mössbauer nucleus in (SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$] was estimated by applying the following approximate equation for axial symmetry; $\Delta\varepsilon_1 - \Delta\varepsilon_2 = -1/2eV_{zz}(3\cos^2\theta - 1)$, where $\Delta\varepsilon_1$ and $\Delta\varepsilon_2$ represent the interval between the lowest-energy and the second lowest-energy peaks, and that between the highest-energy and the second highest-energy peaks, respectively. The θ values could not be determined uniquely, because the $\Delta\varepsilon_1 - \Delta\varepsilon_2$ value is not informative about the sign of V_{zz} for this case. On the assumption of positive V_{zz}, θ is estimated at 90°, while θ is estimated at 40° on the assumption of negative V_{zz}. Here, it is reasonable to take the principal axis of V_{zz} along the D_3 axis which goes through the iron atom in [Fe^{II}Fe^{III}(dto)$_3$] layer and consider θ to be 90°, because the internal magnetic field (H) appears to be parallel to the basal layers according to the anisotropic magnetization measurement of (n-C$_3$H$_7$)$_4$N[Fe^{II}Fe^{III}(dto)$_3$] [12]. Note that (SP-Me)[Fe^{II}Fe^{III}(dto)$_3$] has two ferromagnetic transition temperatures, 22 and 5 K. The spectrum at 10 K is a superposition of the paramagnetic quadrupole doublet and the magnetic sextet of Fe^{III} (S = 5/2) in the ratio of 1:1. This behavior results from the dynamic behavior of the short-range magnetic exchange correlations and the short-range magnetic ordering gives the sextet despite of the temperature above ferromagnetic transition temperature of 5 K. As temperature is decreased to 6 K, the doublet disappears and the sextet grows. On the other hand, the sextets of Fe^{II} (S = 2) and Fe^{III} (S = 1/2) almost shows no change between 10 and 6 K. This result supports that the ferromagnetic transition temperatures of the HTP and LTP in (SP-Me)[Fe^{II}Fe^{III}(dto)$_3$] are 22 and 5 K, respectively.

Fig. 3 shows the ^{57}Fe Mössbauer spectra of (SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$] at 200, 70, 10 and 6 K after UV-irradiation of 350 nm for 3 h at room temperature. The Mössbauer parameters are also summarized in Table 1 in Supplementary data. In this case, the spectrum at 200 K shows the same line profile as that of unirradiated sample at 200 K, but remains unchanged with decreasing temperature to 70 K, unlike the unirradiated one. At 10 K, the spectrum exhibits a superposition of broadened sextets and paramagnetic doublets and it is also unchanged with decreasing temperature to 6 K. The magnetically ordered spectra are assignable to Fe^{II} (S = 2) and Fe^{III} (S = 1/2), indicating that the charge transfer phase transition is suppressed and the HTP is more stable than LTP between 200 and 6 K in the UV-irradiated sample. The spectral change derived from the UV-irradiation proves that the photo-isomerization of spiropyran in (SP-Me)[Fe^{II}Fe^{III}(dto)$_3$] induces the transformation from the A to B phase, as described in the literature [9].

3. Conclusion

^{57}Fe Mössbauer measurement have been performed between 200 and 6 K to probe the microscopic state of iron ions in (SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$] before and after UV-irradiation. The ^{57}Fe Mössbauer spectra of the sample without UV-irradiation below 70 K clearly show the appearance of the LTP arising from the charge transfer phase transition. In the case of the UV-irradiated sample, on the contrary, the charge transfer phase transition is not observed and only the HTP exists between 200 and 6 K. The ^{57}Fe Mössbauer spectra at 10 and 6 K show the broad sextets corresponding to the magnetically ordered state and support that the ferromagnetic transition temperatures of the HTP and LTP in (SP-Me)[Fe^{II}Fe^{III}(dto)$_3$] are 22 and 5 K, respectively.

4. Experimental

4.1. Materials

4.1.1. Preparation of (SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$]

(SP-Me)[^{57}Fe^{II}Fe^{III}(dto)$_3$] was prepared in a similar way to that reported in the literature [9]. In this process, ^{57}FeCl$_2 \cdot 4$H$_2$O used

as Fe^{II} source was prepared by dropping hydrochloric acid to powdered ^{57}Fe under N_2. Elemental *Anal.* Calc. for $C_{26}H_{23}N_2O_7S_6Fe_2$: C, 40.06; H, 2.97; N, 3.59. Found: C, 40.11; H, 5.00; N, 3.76%.

4.2. Physical measurements

For ^{57}Fe Mössbauer spectroscopic measurement, ^{57}Co in Rh was used as a Mössbauer source. The spectra were calibrated by using the six lines of a body-centered cubic iron foil (α-Fe), the center of which was taken as zero isomer shift. Mössbauer spectra were fitted with a MOSSWINN 3.0 program [13]. In the fit of the magnetically ordered state, the adjustable hyperfine parameters for a given component in the spectral fits are the isomer shift δ, the amplitude of the relaxing magnetic field H, the quadrupole interaction ΔE_Q, the component of the electric field gradient (EFG) V_{zz}, the asymmetry parameter of the EFG η, the angle θ between the principle axis of the electric field gradient and the magnetization direction, and the line-width Γ. The V_{zz} parameter has the unit: 10^{21} [V/m^2]. The model is calculated by solving the exact Hamiltonian for mixed magnetic and quadrupole interaction with arbitrary relative orientation [14]. In all fits reported herein, $\eta = 0$. In addition, at a given temperature, the δ, ΔE_Q, and Γ values associated with a given iron oxidation and spin states have been constrained to be equal. The sample irradiation was performed under N_2 with a Xe lamp Asahi Spectra Co. LAX-101 (350 nm, 40 mW/cm^2) as UV source using band pass filters.

2.2. Preparations

2.2.1. $[Mn^{III}_2La_2(bdea)_2(bdeaH)_2(piv)_6]\cdot 2MeCN$(**1**)

A solution of N-bdea (0.64 g, 4.0 mmol) in 10 ml of MeCN and $La(NO_3)_3\cdot 6H_2O$ (0.22 g, 0.5 mmol) as a solid were added to a stirred solution of $Mn(OAc.)_2\cdot 4H_2O$ (0.12 g, 0.5 mmol) and pivalic acid (0.20 g, 2.0 mmol) in 10 ml of MeCN resutling in a dark brown solution. After 48 h, brown crystals were collected by filtration and washed with acetonitrile. Yield 57% (based on Mn). Elemental *Anal.* Calc. for **1**: $C_{63.2}H_{125.8}Mn_2La_2N_{4.6}O_{20}$ (corresponds to loss of 1.4 MeCN): C, 45.76; H, 7.65; N, 3.89. Found: C, 45.60; H, 7.53, N, 3.90. IR (KBr disk, cm^{-1}): 3434 (b), 2957 (vs), 2932 (s), 2865 (m), 1606 (vs), 1539 (vs), 1481 (vs), 1457 (w), 1423(s), 1397 (s), 1344 (vs), 1222 (s), 1088 (s), 1072 (w), 1042 (w), 911 (w), 891 (m), 804 (w), 786 (w), 761 (w), 655 (w),622 (s), 596 (s), 543 (w), 474 (m).

2.2.2. $[Mn^{III}_2Ce_2(bdea)_2(bdeaH)_2(piv)_6]\cdot 2MeCN$(**2**)

This was prepared in a similar way as **1** but using $Ce(NO_3)_3\cdot 6H_2O$. Yield 30% (based on Mn). Elemental *Anal.* Calc. for **2**: $C_{63.2}H_{125.8}Mn_2Ce_2N_{4.6}O_{20}$ (corresponds to loss of 1.4 MeCN): C, 45.71; H, 7.64; N, 3.88. Found: C, 45.44; H, 7.38, N, 4.07. IR data (KBr disk, cm^{-1}): 3421 (b), 2956 (vs), 2932 (s), 2864 (m), 1606 (vs), 1542 (vs), 1481 (vs), 1458 (w), 1424 (s), 1397 (s), 1357 (s), 1343 (vs), 1223 (s), 1089 (s), 1070 (w), 1042 (w), 912 (w), 892 (m), 805 (w), 787 (w), 760 (w), 656 (w), 623 (s), 598 (s), 544 (w), 475 (m).

2.2.3. $[Mn^{III}_2Pr_2(bdea)_2(bdeaH)_2(piv)_6]\cdot 2MeCN$(**3**)

This was prepared in a similar way as **1** but using $Pr(NO_3)_3\cdot 6H_2O$ Yield 36% (based on Mn). Elemental *Anal.* Calc. for **3**: $C_{63.2}H_{125.8}Mn_2Pr_2N_{4.6}O_{20}$ (corresponds to loss of 1.4 MeCN): C, 45.65; H, 7.63; N, 3.88. Found: C, 45.22; H, 7.38, N, IR data (KBr disk, cm^{-1}): 3414 (b), 2956 (vs), 2931 (s) , 2865 (m), 1608 (vs), 1542 (vs), 1482 (vs), 1456 (w), 1425 (s), 1406 (s), 1397 (s), 1357 (s), 1342 (vs), 1223 (s), 1090 (s), 1071 (w), 1042 (w), 912 (w), 893 (m), 805 (w), 790 (w), 760 (w), 657 (w), 623 (s), 599 (s), 545 (w), 475 (m).

2.2.4. $[Mn^{III}_2Nd_2(bdea)_2(bdeaH)_2(piv)_6]\cdot 2MeCN$(**4**)

This was prepared in a similar way as **1** but using $Nd(NO_3)_3\cdot 6H_2O$). Yield 60% (based on Mn). Elemental *Anal.* Calc. for **4**: $C_{63}H_{125.5}Mn_2Nd_2N_{4.5}O_{20}$ (corresponds to loss of 1.5 MeCN): C, 45.57; H, 7.62; N, 3.80. Found: C, 45.61; H, 7.42, N, 3.74. IR data (KBr disk, cm^{-1}): 3418 (b), 2957 (vs), 2930 (s) , 2866 (m), 1609 (vs), 1542 (vs), 1482 (vs), 1456 (w), 1426 (s), 1407 (m), 1397 (s), 1357 (s), 1343 (vs), 1223 (s), 1092 (s), 1071 (w), 1042 (w), 912 (w), 893 (m), 806 (w), 790 (w), 761 (w), 657 (w), 624 (s), 599 (s), 544 (w), 476 (m).

2.3. Physical measurements

IR spectra were measured on Perkin Elmer Spectrum One spectrometer with samples prepared as KBr discs.

The magnetic susceptibility measurements on compounds **1**–**4** were obtained with the use of a Quantum Design SQUID magnetometer MPMS-XL. This magnetometer works between 1.8 and 400 K for dc applied fields ranging from −7 to 7 T. Measurements were performed on polycrystalline samples of 15.0, 9.1, 10.1 and 9.5 mg for complexes **1**, **2**, **3** and **4**, respectively. ac susceptibility measurements have been measured with an oscillating ac field of 3 Oe and ac frequencies ranging from 1 to 1500 Hz. *M* versus *H* measurements were performed at 100 K to check for the presence of ferromagnetic impurities; none were found. The magnetic data were corrected for the sample holder and the diamagnetic contribution.

2.4. Powder diffraction/crystal structure determination

The X-ray powder diffraction pattern for **4** was measured at room temperature using a Stoe STADI-P diffractometer with a Cu Kα radiation.

X-ray data for **1**–**3** were collected at 100 K on a Bruker SMART Apex CCD diffractometer using graphite-monochromated Mo Kα radiation. Crystallographic details and detail of data collection and refinement are summarized in Table 1. Semi-empirical absorption corrections were made using SADABS[14a]. The structures were solved using direct methods, followed by full matrix least-squares refinement against F^2 (all data) using SHELXTL[14b]. Anisotropic refinement for all ordered non-H atoms; organic H atoms were placed in calculated positions, while coordinates of the hydroxo H atom H(3) were refined with the O–H distance re-

3. Results and discussion

3.1. Synthesis

Various strategies have been utilized in the synthesis of Mn-4f complexes. Many complexes have been prepared by self- or serendipitous assembly using small nuclearity preformed carboxylate species of $[Mn_3O]^{6+/7+}$ [6d,7], $[Mn_4O_2]^{8+}$ [7b] or $[Mn_6O_2]^{10+}$ [8,9,15] cores. However, our aim of this work is to use simple manganese salts to see the nuclearity of the final products. Small changes have been made in terms of the ratio of N-bdea: Ln:Mn: pivalic acid and/or the use of $Mn(NO_3)_2 \cdot 4H_2O$ in place of $Mn(OAc)_2 \cdot 4H_2O$ leading to compounds $[Mn^{III}_2Ln_2(bdea)_2(bdeaH)_2(piv)_6] \cdot 2MeCN$ discussed in this work. The synthetic procedures presented herein resulted in four isomorphous tetranuclear Mn–Ln (Ln = La, Ce, Pr and Nd) complexes, however, it should be noted that they were not reproducible for lanthanides such as Sm, Eu and Gd. With heavier lanthanides situated on the right side of Gd pentanuclear Mn_2Ln_3 compounds have been obtained which will be reported elsewhere. One of the explanations could be the ionic radius of the employed lanthanides.

3.2. Structural analysis

X-ray crystallographic studies reveal that complexes **1**–**3** crystallize isomorphously in the triclinic space group $P\bar{1}$ with $Z = 1$ (Table 1); showing $[Mn^{III}_2Ln^{III}_2]$ butterfly cores with centrosymmetric site symmetry. The crystal structure and its polyhedral representation (along the *a*-axis) of the Pr analogue (**3**) are representatively shown in Fig. 1. Compound **4** gave rather poor quality crystals, but was shown to be isomorphous (Fig. 2) with the other three complexes by comparison of its X-ray powder diffraction pattern with those simulated from the single-crystal structures of **1**–**3**.

The "butterfly" core comprises two outer "wingtip" nonacoordinate Ln^{III} ions and two inner hexacoordinate Mn^{III} ions, and these four cations are strictly coplanar. The oxidation states of Mn(1) and Ce(1) were determined by consideration of its coordination geometry (bond lengths, coordination numbers and the presence of Jahn–Teller elongation axes for Mn(1)) and by bond valence sum analysis [16]. Selected bond lengths and angles for complexes **1**–**3** are listed in Table 2.

The Mn centre Mn(1) is chelated by a doubly-deprotonated $(bdea)^{2-}$ ligand, of which one alkoxo oxygen O(1) forms a μ_3-bridge between the two manganese and one of the lanthanide cations, and the other, O(2) is edge bridging between Mn(1) and the inversion-related lanthanide centre Ln(1′). The singly deprotonated (bdeaH) ligands each chelate a lanthanide centre, Ln(1). The deprotonated alkoxide oxygens O(3) bridge between Ln(1) and Mn(1′), while the protonated oxygen, O(4), coordinates terminally to Ln(1). The three independent pivalate ligands in the asymmetric unit exhibit three different coordination modes. One forms a *syn–syn* bidentate bridge between Mn(1) and Ln(1′), one chelates Ln(1), and the third coordinates in a unidentate mode to Ln(1), with the non-coordinated oxygen accepting a hydrogen bond from O(4). Overall, Mn(1) shows the expected Jahn–Teller elongated octahedral geometry, with the Jahn–Teller axis defined by O(1′) and N(1), while the coordination geometry of the nonacoordinate Ln^{III} ions approximates to a tricapped trigonal prism.

The lanthanide cations in **1**, **3** and **4** are trivalent. However, although the four complexes are isomorphous, one must consider the possibility that the cerium cation Ce(1) in **2** might be Ce^{IV} rather than Ce^{III}, or that the crystal contains a mixture of the

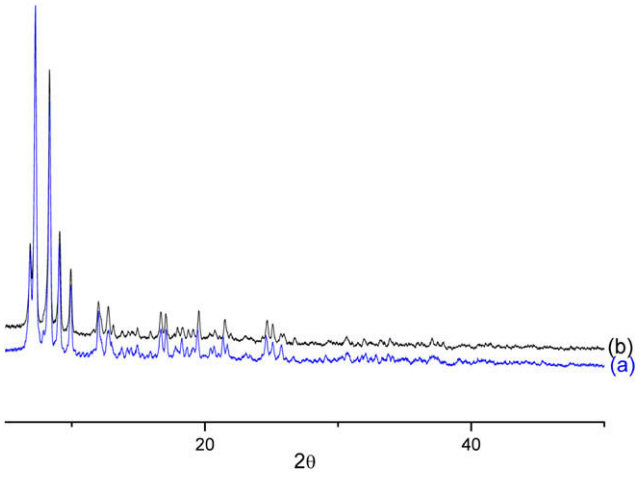

Fig. 2. X-ray powder diffraction: measured for complex **1** (a) and **4** (b).

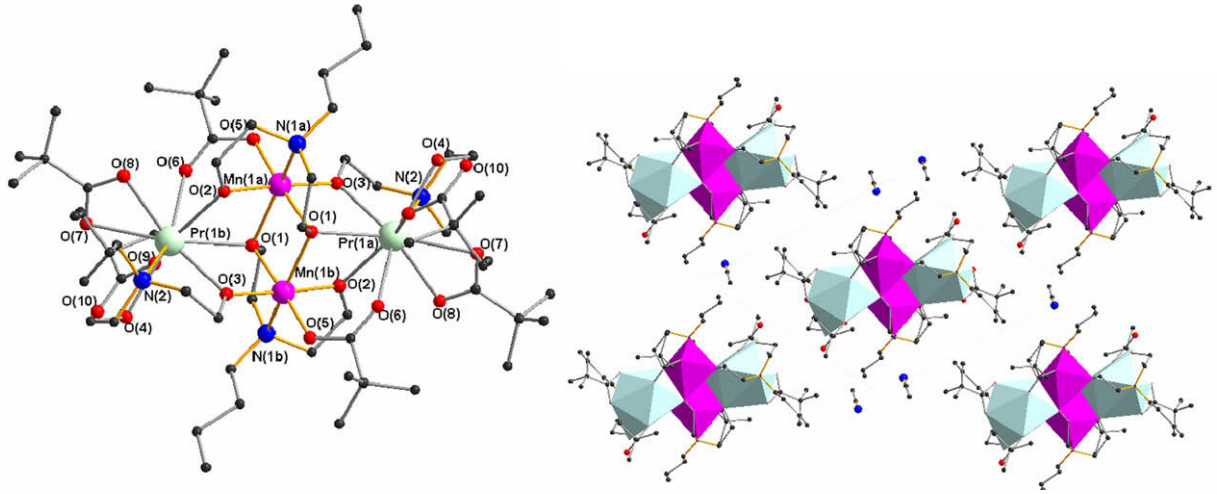

Fig. 1. $[Mn^{III}_2Pr_2(Bu\text{-}dea)_2(Bu\text{-}deaH)_2(piv)_6] \cdot 2MeCN$ (**3**) in the crystal (left). Polyhedral representation of **3** along the *a*-axis (right). The dimensions of the nitrogen atoms of MeCN solvent molecules are inflated for better view. Hydrogen atoms have been omitted for clarity.

Mn_2Pr_2 (**3**)	1.60	9.2	10.0	15	12.8
Mn_2Nd_2 (**4**)	1.64	9.3	10.1	3.7	21.1

two valences. However, the oxidation state calculated from bond valence sum analysis [16b] is 2.96, indicating that Ce(1) is in fact "pure" Ce^{III}.

Similar "butterfly" complexes $[Mn_2Ln_2O_2(piv)_8(pivH)_2(MeOH)_2]$ (Ln = Dy and Gd) have been published by Winpenny [15], while Brechin and co-workers have also reported a $[Mn^{III}_2Dy^{III}_2]$ complex [7]. Complexes **1**–**4** are the first examples of this type of Mn_2Ln_2 complex with the lighter lanthanides.

3.3. Magnetic properties of *1*–*4*

Dc magnetic susceptibility (χ) data for compounds **1–4** were collected in the 1.8–300 K temperature range under a field of 0.1 T. All these compounds show a similar thermal evolution of the susceptibility, with results summarized in Table 3. For all four compounds, the χT product at 300 K is close to the expected value for two Mn^{III} ($g = 2$, $S = 2$, $C = 3$ cm^3 K/mol) and two respective Ln^{III} ions [5]. On lowering the temperature, χT increases continuously to reach a maximum value, and then rapidly drops with further cooling to 1.8 K, indicating dominant ferromagnetic interactions within the complexes (Fig. 3 and ESI 1–4). The final decrease of χT suggests the presence of weak antiferromagnetic intermolecular interactions and/or a significant magnetic anisotropy.

As well as the two diamagnetic La^{III} ions, compound **1** contains two Mn^{III} ions linked directly *via* two single-O bridges, and these are likely to mediate ferromagnetic interactions between the Mn^{III} ions as observed in related Mn_4 compounds [17]. This would lead to a total spin ground state of $S_T = 4$, and the expected χT value at low temperature would be 10 cm^3 K/mol (taking $g_{av} = 2$), which is in good agreement with the experimental $(\chi T)_{max}$ (11.0 cm^3 K/mol) at 10 K. The $S_T = 4$ ground state is also qualitatively supported by the field dependence of the magnetization at low temperatures, which approaches 8 μ_B without saturating, reaching 7.4 μ_B at 7 T and 1.8 K (Fig. ESI 1).

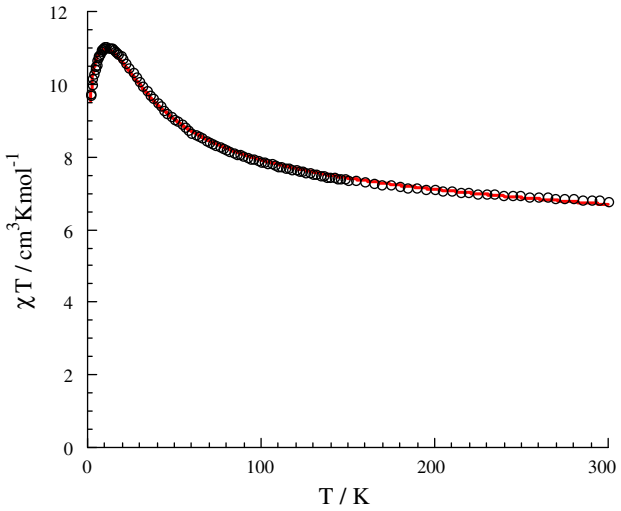

Fig. 3. Temperature dependence of magnetic susceptibility at 1000 Oe for Mn_2La_2 (**1**). Experimental data (open circles); fitting (red solid line), see the discussion in the text. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Given the difficulty of modeling complexes such as **2**–**4** containing Ce^{III}, Pr^{III} and Nd^{III}, in consequence of the spin–orbit coupling found for these lanthanide ions and the low symmetry of their crystal field, the only compound that can be easily modeled is **1** with diamagnetic La^{III} ions. The temperature behaviour of the magnetic susceptibility of this compound can be modeled using a simple isotropic Heisenberg dimer model of $S = 2$ spins with the following spin Hamiltonian $H_d = -2JS_1S_2$, where J is the exchange interaction between Mn^{III} ions. Application of the van Vleck equation [18,19] allows a determination of the low field analytical expression of the magnetic susceptibility:

$$\chi_{Mn2La2} = \frac{g_{av}^2 N\mu_B^2}{k_B T}\frac{2e^{\frac{2J}{k_BT}} + 10e^{\frac{6J}{k_BT}} + 28e^{\frac{12J}{k_BT}} + 60e^{\frac{20J}{k_BT}}}{1 + 3e^{\frac{2J}{k_BT}} + 5e^{\frac{6J}{k_BT}} + 7e^{\frac{12J}{k_BT}} + 9e^{\frac{20J}{k_BT}}}$$

This model was able to reproduce very well the experimental data from 300 K to 15 K. The best set of parameters found is: J/k_B = 5.0(1) K and g = 2.12(1). In order to fit the low temperature χT product below 15 K, inter-complex interactions have been introduced in the frame of the mean field theory [20]. The following definition of the susceptibility has been used:

$$\chi = \frac{\chi_{Mn2La2}}{1 - \frac{2zJ'}{Ng^2\mu_B^2}\chi_{Mn2La2}}$$

where χ_{Mn2La2} is the susceptibility of the non-interacting Mn_2La_2 complexes, z is the number of nearest neighbours and J' is the intermolecular magnetic interaction. The best set of parameters found is now: J/k_B = 4.9(1) K, g = 2.14(1) and zJ'/k_B = −0.014(1) K (Fig. 3). The value of the Mn^{III}–Mn^{III} interaction J is indeed comparable to those observed in related compounds [17]. It should be noticed that the inter-complex interactions, zJ', also include phenomenologically the magnetic anisotropy of the system, and therefore this value should be taken with caution and certainly not as a direct accurate measure of the magnitude of the inter-complex interactions but more as a higher limit value. The sign of the magnetic interaction confirms the $S_T = 4$ ground state of this compound and also indicates that in the other compounds of this family the Mn^{III}–Mn^{III} interactions are probably similarly ferromagnetic. However, the Mn^{III}–Ln^{III} magnetic interactions are likely of smaller magnitude and are difficult to evaluate due to the complicated intrinsic magnetic properties of the Pr^{III}, Ce^{III} and Nd^{III} metal ions (spin–orbit coupling and low symmetry of the crystal field).

The field dependence of the magnetization at 1.8 K for each of the compounds **1**–**4** shows a relative rapid increase of the magnetization at low fields, followed by an almost linear increase without clear saturation up to 7 T, when it reaches 7.3, 8.7, 9.6 and 12.7 μ_B for **1**, **2**, **3** and **4**, respectively (Fig. ESI 1-4). The high-field linear variation of M suggests the presence of low-lying excited states that can be populated under applied field in agreement with weak intra-molecular magnetic interactions (vide supra), and/or a significant magnetic anisotropy in those compounds. Indeed, when plotting M versus H/T at different fields, the curves are not all superposed on a single master-curve, further indicating the presence of these two effects.

Due to the likely presence of magnetic anisotropy in those compounds, ac susceptibility measurements were made under zero dc field. No out-of-phase signals could be measured above 1.8 K for **1** and **3**. However, frequency-dependent out-of-phase signals were

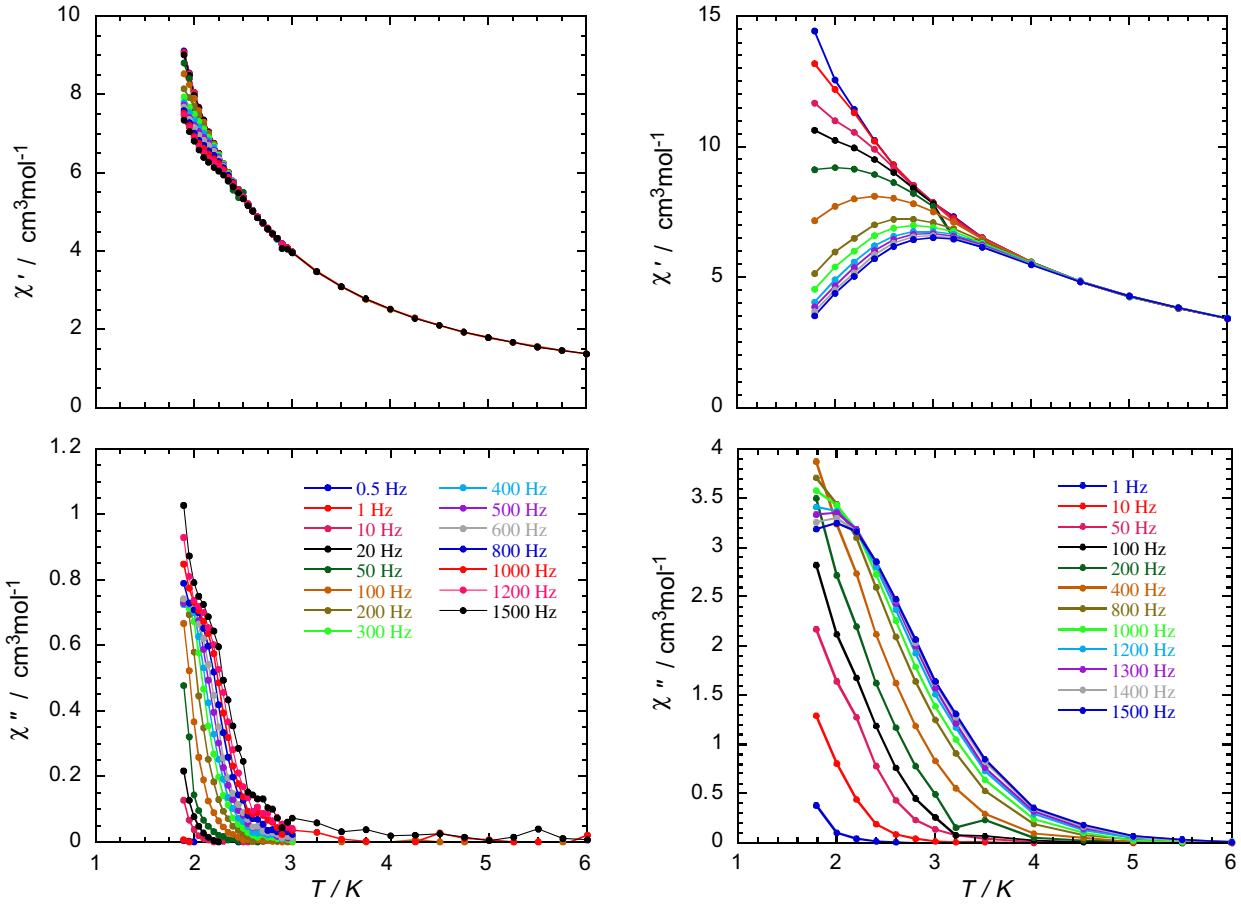

Fig. 4. Temperature dependence of the in-phase (top) and out-of-phase (bottom) component of the ac magnetic susceptibility in zero dc field; compound **2** (left) and **4** (right).

detected for compounds **2** and **4** (Fig. 4). In the case of **2**, the out-of-phase signal is clearly observed up to 4 K (for a frequency of 1500 Hz). This out-of-phase signal suggests that this compound exhibits slow relaxation of its magnetization, but with a blocking temperature still below 1.8 K, even at 1500 Hz. However, compound **4** clearly exhibits slow relaxation of its magnetization above 1.8 K and both in-phase and out-of-phase signals are frequency-dependent up to 5 K in the same frequency range. The out-of-phase signal showed a maximum at 2.0 K at a frequency of 1500 Hz. This feature (shape and frequency dependence) strongly suggests it might be a SMM. Fitting the frequency-dependent ac susceptibility data (Fig. ESI 5) of **4** by an Arrhenius law (Fig. ESI 6) leads to the characteristic SMM energy gap (Δ) of 10.0 K and the relaxation time (τ_0) at 1.4×10^{-6} s.

In order to study further this relaxation and check for any quantum tunnelling effect above 1.8 K, the frequency dependence of the ac susceptibility measurements at 1.8 K was measured with the application of a small dc field for compound **4** (Fig. ESI 7). In zero field, the characteristic frequency is 500 Hz at 1.8 K. With an increasing field, this frequency decreases to reach 18 Hz at 1500 Oe. Therefore a small dc field is indeed slowing down the relaxation time by suppressing quantum tunnelling of the magnetization, as has been observed previously for other SMMs [13,21].

4. Conclusions

A convenient one-step route for the synthesis of Mn–Ln polynuclear complexes is demonstrated, based on a simple reaction between manganese acetate, the corresponding lanthanide nitrate, pivalic acid and *N*-butyldiethanolamine. We have reported the structural and magnetic properties of four isostructural Mn_2Ln_2 tetranuclear compounds with Ln = La, Ce, Pr and Nd. The magnetic susceptibility of the Mn_2Ce_2 complexe **2** showed strong frequency-dependent out-of-phase signals (without maxima) which could be the tails of peaks lying at a temperature below 1.8 K. However, that of the Mn_2Nd_2 complex **4** showed out-of-phase signals with a clear maximum at 2.0 K, and the data could be fitted to the Arrhenius law to give an energy gap Δ of 10.0 K. Although much of the published research on SMMs based on combinations of manganese and lanthanides has concentrated on the heavier lanthanides (typically Dy), the work presented here shows that incorporation of lighter lanthanides can also lead to SMM behavior. Further experiments are underway to modify the structures reported here, using other lanthanides and tridentate ligands, with the aim of enhancing the SMM properties.

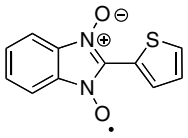
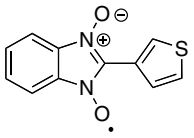
1



2



Earlier work on the effect of heterocyclic substitution on the structure of benzonitronyl nitroxides revealed that the benzonitronyl nitroxides are excellent electron acceptors, with reduction potentials on the order of 0.0 V vs. SCE [35]. Herein we present the magnetic behavior, spin density distribution, and electronic structure of acceptor–donor benzannelated nitronyl nitroxides in which the C-2 phenyl substituent of the parent radical (**2a**) has been replaced by an electron-rich thiophene (**2b**, **2c**). The SOMO–LUMO gap, spin density distribution, and solid-state magnetic behavior were found to be dependent on both the nature and position of substitution.

2c

2. Experimental

2.1. General methods

The synthesis of radicals **2b–c** are reported elsewhere [35]. Absorption spectra were recorded on an Agilent 8453 UV–Vis spectrometer with photodiode array and Peltier temperature controller, and a Carey 5 UV–Vis-NIR Spectrophotometer.

2.2. Computations

Quantum mechanical calculations were carried out at the B3LYP/6-31G(d,p) level of theory using the Gaussian 03 package [40]. Geometry optimizations were performed without symmetry constraints (starting from C_1) and tight convergence limits. Vibrational frequencies were used to characterize the nature of stationary points. Electronic excitation energies for the radical **2a** were obtained at the UB3LYP/6-31G(d,p) level using Time Dependent DFT calculations [41] supplied in the Gaussian 03 package.

2.3. Magnetic measurements

Magnetic measurements were performed on a Quantum Design MPMS 5.0 system, with fields in the range of 1–5 T, and temperature ranges between 2 and 300 K. The polycrystalline samples of radicals **2b** and **2c** were prepared by the macroscale evaporation of a saturated radical *n*-pentane solution over several days, followed by triturating the crystals with *n*-pentane and methanol, and drying under vacuum. Measurements were made on 6 independently synthesized and prepared samples in order to assure that the magnetic behavior observed was not due to the presence of impurities, which are expected to vary from sample to sample. The diamagnetic corrections for radical **2b** and **2c** were performed by using the experimentally measured diamagnetic susceptibility of the radical precursors (3.03E−04 emu K/mol).

2.4. X-ray crystallography

Crystals suitable for X-ray diffraction studies were obtained by slow evaporation of radical–pentane solutions. The diffraction intensity measurements were carried out on a Nonius KappaCCD (1997) diffractometer.

2.5. 2,2′-Thienylbenzimidazole N,N′-dioxide (**2b**)

A maroon crystal plate 0.48 × 0.12 × 0.02 mm was mounted on a glass capillary with oil. Data was collected at −143 °C with one set of exposure as follows: Type: φ, Scanlength 183.0°, with start v 3.70, φ −1.5, $\Omega = 160$, and $\kappa = 0$. Crystal-to-detector distance was 30 mm and exposure time was 90 s per degree for all sets. The scan width was 1.3°. Data collection was 87.5% complete to 25.00° in v. A total of 5877 partial and complete reflections were collected covering the indices, $h = -9$ to 9, $k = -6$ to 6, $l = -19$ to 19. 1662 reflections were symmetry independent and the $R_{int} = 0.1030$ indicated that the data was of average quality (0.07) consistent with the difficulties in obtaining suitable crystals for X-ray diffraction in these systems. Indexing and unit cell refinement indicated a monoclinic *P* lattice. The space group was found to be $P2_1/c$ (No. 14). The data was integrated and scaled using *hkl*-SCALEPACK [42]. This program applies a multiplicative correction factor (S) to the observed intensities (I) and has the following form: $S = \exp(2B(\sin q/\lambda)^2)/\text{scale}$. S is calculated from the scale and the B factor is determined for each frame and is then applied to I to give the corrected intensity (I_{corr}). Solution by direct methods (SIR92/7) [43] produced a complete heavy atom phasing model consistent with the proposed structure. All hydrogen atoms were located using a riding model. All of the non-hydrogen atoms were refined anisotropically by full-matrix least-squares. Due to the disorder of the system constraints were placed upon the thermal parameters of several atoms to ensure positive definite matrix elements. The model used to resolve the disorder of the system was the superposition of two molecules on top of one another. The asymmetric unit consists of the one unique half of the dimer pair. The full dimer is generated by a C_2 rotation perpendicular to the molecular plane. The oxygen atom positions are shared by both molecules and thus have full site occupancy. All other atoms were refined with 50% site occupancy.

2.6. 2,3′-Thienylbenzimidazole N,N′-dioxide (**2c**)

A dark red plate 0.41 × 0.05 × 0.02 mm was mounted on a glass capillary with epoxy. Data was collected at −143 °C with one set of exposure as follows: Type: φ, Scanlength 128.6°, with start v 3.70, φ −9.27, $\Omega = 160$, and $\kappa = 0$. Crystal-to-detector distance was 30 mm and exposure time was 120 s per degree for all sets. The scan width was 1.0°. Data collection was 59.2% complete to 23.77° in v. A total of 13828 partial and complete reflections were collected covering the indices, $h = -4$ to 4, $k = -14$ to 19, $l = -14$ to 13. 865 reflections were symmetry independent and the $R_{int} = 0.3254$ indicated that the data was of average quality (0.07) consistent with the difficulties in obtaining suitable crystals for X-ray diffraction in these systems. Indexing and unit cell refinement indicated a monoclinic *P* lattice. The space group was found to be $P2_1/c$ (No. 14). The data was integrated and scaled using *hkl*-SCALEPACK [42]. This program applies a multiplicative correction factor (S) to the observed intensities (I) and has the following form: $S = \exp(2B(\sin q/\lambda)^2)/\text{scale}$. S is calculated from the scale and the B factor is determined for each frame and is then applied to I to give the corrected intensity (I_{corr}). Solution by direct methods (SIR92/7) [43] produced a complete heavy atom phasing model consistent with the proposed structure. All hydrogen atoms were located using a riding model. All non-hydrogen atoms were refined aniso-

tropically by full-matrix least-squares. The structure was refined as a structure containing disorder in the C_1 and S_1 positions. The positions were refined as both atoms having a site occupancy of 50% in both sites.

3. Results and discussion

3.1. Optical spectroscopy of acceptor–donor radicals

The electronic absorption spectra of the benzonitronyl nitroxides **2a–c** were measured in solution in order to investigate the effect of acceptor–donor interactions on the electronic structure of nitronyl nitroxides (Fig. 1). Solutions of radicals **2a**-**c** were bright green/yellow in color and exhibited absorption spectra with strong absorptions in the UV region (λ_{max} 240–480 nm) and a weak absorption in the near-IR (one broad transition at 1000 nm, $\varepsilon \sim 600\ M^{-1}\ cm^{-1}$) which was red-shifted relative to the parent radical **2a**. The absorption spectrum of the imidazolidinyl nitroxide **1** exhibits similar absorption bands in the UV region with an absorption band in the visible region at 600 nm assigned to a n–π^* transition [24].

The low energy transition was found to vary dramatically with substitution, and exhibit significant solvatochromism [35], consistent with a charge transfer band. Given the strong acceptor strength found for the benzonitronyl moiety (0.0 vs. SCE), the CT band can be rationalized as a benzonitronyl nitroxide (A)–thiophene (D) interaction. Using the theory of Mulliken and Hush [44–47] the strength of the electronic donor–acceptor coupling parameter (V_{ab}) was determined. The magnitude of the A–D interaction can be calculated using band shape analysis of the optical charge transfer transition using Eq. (1) in which v_{max} is the band energy (in cm^{-1}), $\Delta v_{1/2}$ is the bandwidth at half-height (in cm^{-1}), ε is the molar extinction coefficient (in $M^{-1}\ cm^{-1}$), and r_{DA} is the distance between the opposite charges in the charge separated $D^{\cdot+}A^{-}$ excited state (in Å).

$$V_{ab} = (2.05 \times 10^{-2}) \frac{[\varepsilon_{max} \Delta \upsilon_{1/2} \upsilon_{max}]^{1/2}}{r_{DA}} \quad (1)$$

When applying Hush theory, determination of the diabatic electron transfer distance (r_{DA}) in organic compounds suffers from the typically delocalized nature of the acceptor and donor, distinct from traditional inorganic systems in which the redox centers are localized and the metal–metal distance can be explicitly determined. Here r_{DA} has been estimated to be the length of the benzonitronyl nitroxide–thiophene carbon–carbon bond (1.43 Å) as determined from the X-ray crystallography, an appropriate estimation for these systems as the charge on the benzonitronyl nitroxide moiety is highly delocalized over the ONCNO atoms and thiophene is aromatic.

The electronic coupling energy V_{ab} for **2b** and **2c** was found to be the same within experimental error, that is, a coupling energy of 1900 cm^{-1} was calculated for both systems. The similarity in coupling energy is not unexpected as the magnitude of V_{ab} depends strongly on bridge length and differences in redox potential between the donor and acceptor. Since neither of these variables differs dramatically between **2b** and **2c**, the donor–acceptor electronic coupling is comparable. The magnitude of the donor–acceptor coupling is moderate to strong suggesting that radicals **2b–c** fall on the borderline between Robin-Day class II and class III A–D systems, consistent with the symmetrical band shape observed.

In order to better understand the nature of the low energy transition, vertical excitation energies and oscillator strengths for the parent radical **2a** were computed by TDDFT using the UB3LYP functional with 6-31G(d,p)+ basis set (Fig. 2). TDDFT is known to predict vertical excitation energies of open-shell PAHs to within 0.3 eV of the experimental data and oscillator strengths that are consistent with the measured absorption spectra [48]. For the first excited state, the largest coefficients in the CI expansion were found to be for the HOMO–LUMO (β) 0.96 (77%) and the HOMO–LUMO (α) transition (23%) for the unrestricted model with an excitation energy of 1.6 eV (775 nm) and oscillator strength of 0.0158. This corresponds well with the energy of the lowest energy band at 885 nm in pentane (825 in acetonitrile) and suggests that the transition is due primarily to a HOMO–SOMO transition (restricted model), with a 30% component due to the SOMO–LUMO transition. This transition into the half-filled orbital is consistent with the triphenylmethyl [49] and benzothiazinyl radicals [50], both of which have weak low energy transitions assigned to a HOMO–SOMO transition.

Substitution of the phenyl ring in **2a** with 2-pyridyl or 4-pyridyl leads to shifts in the low energy band by 6 nm (bathochromic) and 60 nm (hypsochromic), respectively, [35] while 2-thienyl (**2b**), and 3-thienyl (**2c**) substitution leads to bathochromic shifts of 150, and 105 nm, respectively. As the SOMO is primarily localized on the benzonitronyl nitroxide moiety, the changes in transition energy are consistent with localization of both the HOMO and LUMO on the C-2 aryl ring, leading to significant changes in the SOMO–HOMO and SOMO–LUMO gaps with substitution. Analysis of the charge distribution in the SOMO and HOMO suggests that the charge transfer transition occurs from the HOMO localized on the thienyl to the BNN moiety (SOMO). The extent of population overlap between the two states is consistent with the moderate couplings derived from a Mulliken–Hush analysis.

3.2. Structural analyses by X-ray crystallography

Maroon crystal plates of **2b** and dark red plates of **2c** were grown by slow evaporation of saturated *n*-pentane solutions, and their structures determined by X-ray diffraction. The 2-thienyl derivative **2b** crystals were twinned and severely disordered. Refinement of the structure led to monoclinic packing in the $P2_1/c$ space group. The crystal structure is disordered with respect to rotation about a C_2 axis perpendicular to the plane of the molecule, leading to superposition of two orientations each with 50% occupancy, as shown in Fig. 3. The molecule adopts an essentially planar geometry with a torsion angle between the benzimidazole and thiophene moieties of 1.7°. The 3-thienyl derivative **2c** exhibits monoclinic packing in the space group $P2_1/c$ with disorder with respect to rotation about a C_2 axis parallel to the long axis of the molecule, with 50% occupancy in each orientation, as shown in Fig. 3.

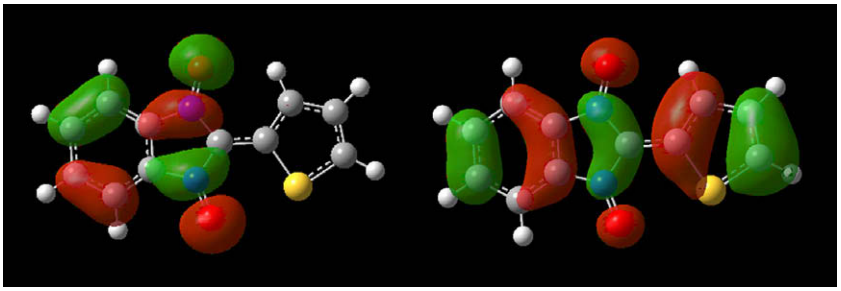

Fig. 2. Computational (DFT UB3LYP/6-31G(d,p)+) SOMO (left) and HOMO (right) of **2b** generated with GAUSSVIEW 03 (isovalue 0.02).

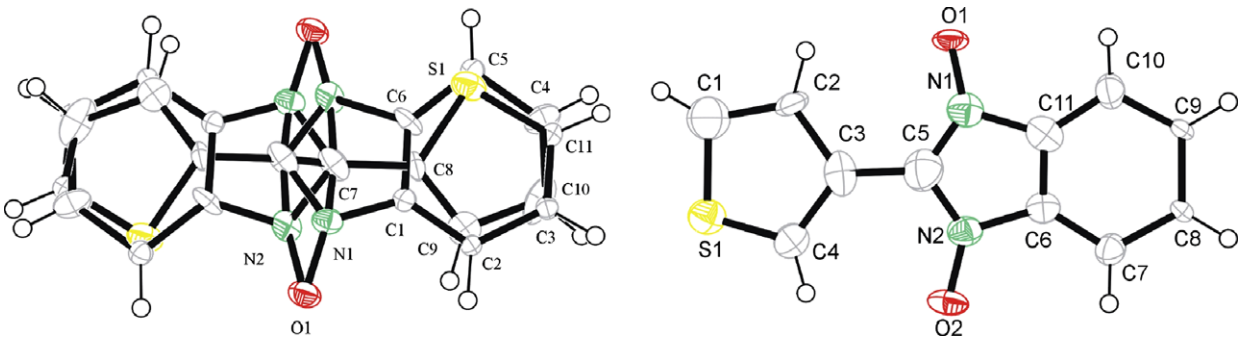

Fig. 3. ORTEP representations of radical **2b** (left) and **2c** (right) with 50% probability thermal ellipsoids. The packing disorder in **2b** arises from rotation about an axis perpendicular to the long axis of the molecule, while the disorder in **2c** arises form rotation about a C_2 axis parallel to the long axis of the molecule.

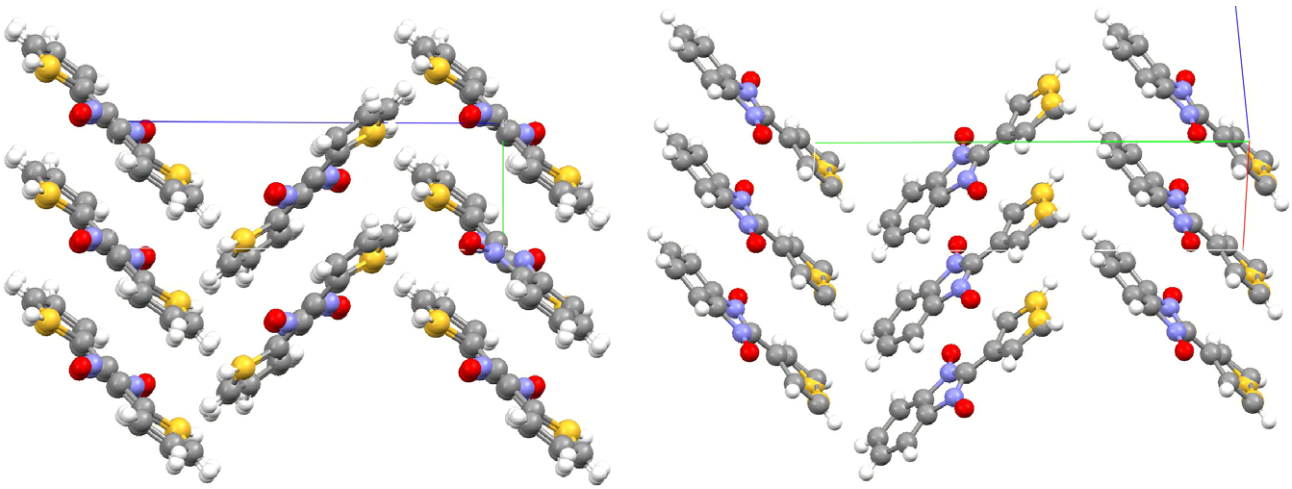

Fig. 4. Packing diagram of radical **2b** viewed along the *a*-axis, and **2c** viewed along [1 1 0]′.

The degree of planarity is slightly less than that of **2b**, with a torsion angle of 4.6°. The parent radical, **2a**, exhibits a larger torsional angle of 10° [37], and phenyl substituents containing *ortho* subtitution (Cl, F) exhibit much larger torsional angles of 54–76° [38].

The structural features of radicals **2b** and **2c** involve edge-to-face and π-stacking interactions leading to herringbone motifs (Fig. 4). The packing modes can be discussed within the context of structural types for aromatic hydrocarbons which depend on the relative importance of C···C, C···H, and H···H interactions [51,52]. The parent radical **2a** [37] packs in a sandwich herringbone motif which straddles the structural gap between γ and herringbone modes. The sandwich herringbone packing motif for aromatics is one in which both C···C and C···H interactions are important, leading to effective glide and stack stabilization [51]. In both radicals **2b** and **2c**, both the surface area available for stacking C···C interactions and the edge surface area available for C···H interactions is nearly equal, leading to packing in which both stacking and edge-to-face interactions are efficient. Analysis of the interplanar angle between molecules creating an edge-to-face interaction (84.86° (**2b**) and 89.23° (**2c**)) and shortest crystallographic axes for **2b** (*a*-axis) and **2c** (*b*-axis), is consistent with a γ phase herringbone motif. Both C···C stacking and C···H edge-to-face interactions are energetically favored in the γ phase herringbone motif, consistent with prediction of packing based solely on topology [51].

The nature of the edge-to-face interactions in **2c** arises from thiophenyl S···benzimidazole face interactions, with a closest dis-

tance 3.50 Å for the benzimidazole plane-to-sulfur distance. The interplanar distance between stacked molecules is 3.42 Å for **2b**, and 3.41 Å for **2c**, giving rise to short radical–radical contacts through π-stacking interactions. Unlike the parent radical **2a**, and electron deficient derivatives, no closest radical–radical O···O contacts exist below 6.0 Å in **2d**, and **2e**, thus, the magnetic interactions in these systems arise from through-space π-stacking and C···H interactions rather than radical–radical contacts.

3.3. Magnetic behavior of stable radicals *2b*, *2c*

The molar magnetic susceptibilities ($\chi_{m,p}$) were measured for polycrystalline samples of radicals **2b**/**2c** using a Quantum Design SQUID magnetometer in the temperature range of 2–300 K at DC fields of 0.1–5 T (Figs. 5 and 6). Diamagnetic corrections of the susceptibilities were made using experimental measurement of the diamagnetic susceptibilities of the radical precursors. The 2-thienyl (**2b**) and 3-thienyl (**2c**) derivatives exhibit magnetic moments close to the expected spin only value for a spin = 1/2 system (0.375 emu K/mol), with temperature independent magnetic moments above 100 K. In both systems, the magnetic moments (χT) decrease with decreasing temperature, consistent with antiferromagnetic exchange interactions.

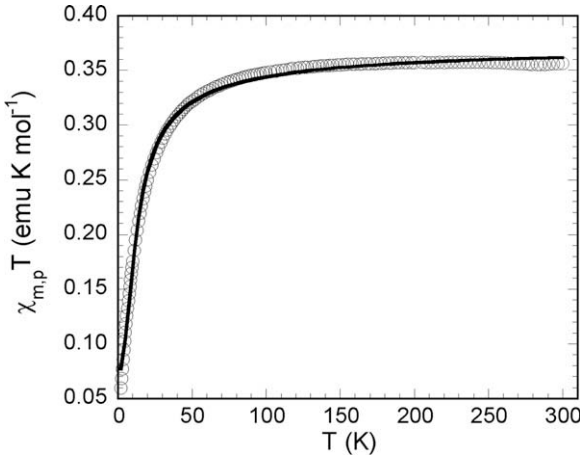

Fig. 5. Temperature dependence of the magnetic moment (χT) for radical **2b** (2–300 K) at 0.1 T with the fit to a Bonner–Fisher model: experimental (○) and fit (–).

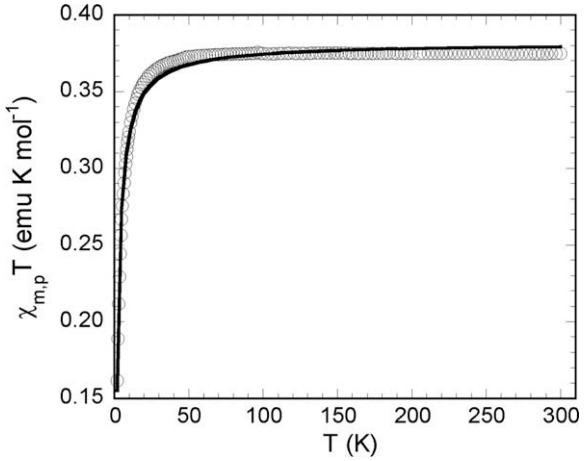

Fig. 6. Temperature dependence of the magnetic moment (χT) for radical **2c** (2–300 K) at 0.1 T with the fit to a Bonner–Fisher model: experimental (○) and fit (–).

Analysis of the crystal structure suggests that the dominant pathway for magnetic exchange interactions is through the slipped π-stack, with weak interchain interactions contributing to a minor extent. A fit of the magnetic moment (χT) as a function of temperature was obtained using the numerical solution for a Bonner–Fisher model [53]with the inclusion of a mean-field parameter according to equation:

$$\chi T = \rho \frac{\chi T'}{1 - \left(\frac{2zJ'}{Ng^2\beta^2}\right)\chi T'} + (1-\rho)\frac{C}{T}$$

$$\chi T' = \frac{Ng^2\beta^2}{k_B} \cdot \frac{0.25 + 0.074975x + 0.075235x^2}{1.0 + 0.9931x + 0.172135x^2 + 0.757825x^3}$$

$$x = \frac{|J|}{k_B T}$$

$$J \leqslant 0$$

The *g*-value was fixed to the experimentally derived value of 2.007, to give $J = -9.4\ \mathrm{cm}^{-1}$, $2zJ' = -0.7\ \mathrm{cm}^{-1}$, and a purity factor of 0.99822 (SI) for radical **2b**. Weaker exchange was found in radical **2c**, in which the exchange coupling was found to be $-2.0\ \mathrm{cm}^{-1}$ with $2zJ' = -0.4\ \mathrm{cm}^{-1}$, and a purity factor of 0.99725. Inclusion of the mean-field parameter did not alter the fit substantially, consistent with chain interactions dominating the magnetic exchange. The surprisingly weak exchange relative to other benzannelated nitronyl nitroxides is attributed to the disorder observed in the crystal packing.

Difficulties in fitting the temperature dependent magnetic susceptibilities to reasonable magnetic models for both the parent radical **2a** [37] and a class of electron deficient benzannelated nitronyl nitroxides radicals [38] have been previously noted. Such effects have been attributed to "a mysterious diamagnetic impurity invisible by MS and IR spectroscopy" [38], or the formation of high-spin spin clusters at low temperatures [39]. Polymorphism has also been observed in several of the known derivatives of **2a** [37,38]. This class of radicals is unique in that they are fully delocalized planar radicals that are stable toward dimerization in the solid state, unlike the phenalenyl or thiazyl classes of radicals. Directional non-covalent interactions are expected to be extremely weak or entirely absent, leading to little preference for molecular orientation in the crystalline state. The resulting disorder can cause complication of the dominant through-space pathways for magnetic exchange. Structural analysis of our systems indicates significant structural disorder in the solid state, leading to little preference for head-to-head (HH) versus head-to-tail (HT) π-stacking, or inversion about the molecular axis within chains. The distinction

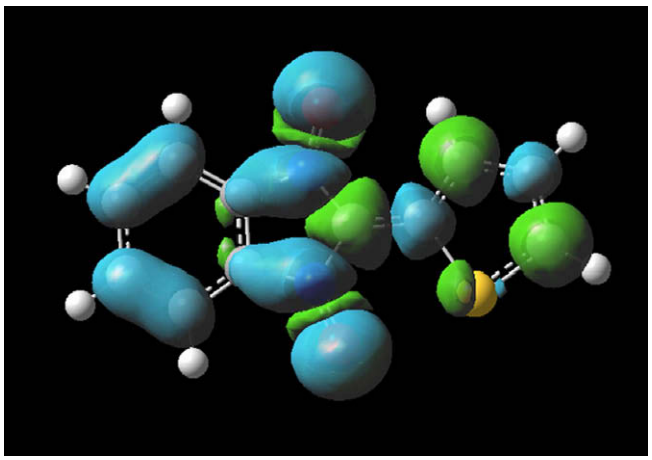

Fig. 7. Computational (DFT UB3LYP/6-31G**) spin density distribution of **2b** generated with GAUSSVIEW 03 (isovalue 0.002).

between HT and HH interactions discriminates between radical–radical contacts versus radical–aromatic contacts, providing two distinct pathways for magnetic exchange. As the spin density is highly delocalized (Fig. 7), this may give rise to different exchange parameters as a function of topology (HH vs. HT). This effect is expected to be present in the 2-thienyl derivative, giving rise to competing exchange interactions and a weak overall exchange parameter.

4. Conclusions

The magnetic behavior and structural characterization of acceptor–donor spin-delocalized radicals **2b** and **2c** are reported. Electronic absorption spectroscopy accompanied by computation reveals that the near-IR band can be assigned to a HOMO → SOMO charge transfer transition with electronic coupling of 1900 cm^{-1} between the benzimidazole and thiophene moiety. Structural analysis of the thienyl radicals in the crystalline state reveals disorder due to the high symmetry of the planar delocalized radicals, and the dominance of slipped π-stacks. Magnetic susceptibility measurements reveal weak antiferromagnetic interactions that are consistent with a linear chain Bonner–Fisher model. The magnetic properties are therefore dictated by the topology of the radical and not by perturbations in the spin density induced by substitution at C-2, which are minimal. The low reduction potentials and strength of the through-space magnetic exchange interactions demonstrated in the solid state make these extremely interesting systems for the development of multifunctional magnetic materials.

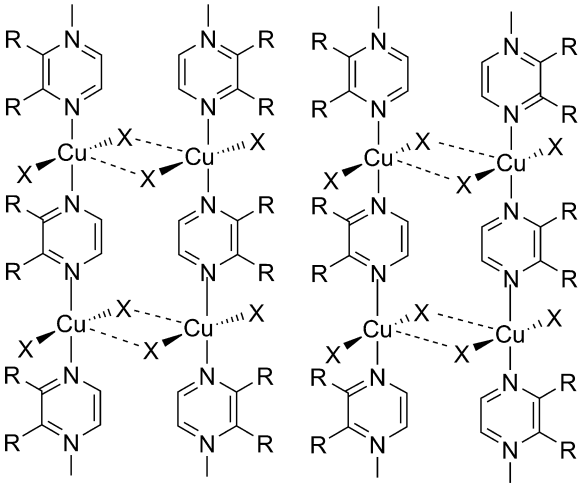

Fig. 2. A Cu(II) ladder complex resulting from a 2,3 di-substituted pyrazine ligand.

the monoclinic space group $C2/m$. The molecular unit of $[Cu(meSpz)Br_2]_n$ is shown in Fig. 3. A crystallographic mirror plane bisects the meSpz ring with the methylthio group disordered across the plane. The sulfur atom occupies each site (S1,S1A) to the extent of 50%. The C1–S1 bond length (1.735(5) Å) is in the normal range for a C–S bond, such as is seen in $Ru(meSpz)(CO)_3Cl_2$ (1.757 Å) [15]. The initial solution placed the methyl carbon on the mirror, but this resulted in a very long S1–C3 bond (1.947(6) Å) in comparison to the terminal S–CH_3 bond in $Ru(meSpz)(CO)_3Cl_2$[17] (1.806 Å) and relative to typical aryl-S-methyl bonds [1.777–1.858 Å] [16], suggesting that the carbon was also disordered and actually displaced toward the sulfur relative to the mirror plane.

Disordered sulfur atoms and methyl carbons are shown as dotted ellipses. Hydrogen atoms are shown as spheres of arbitrary size. Selected bond lengths [Å] and angles [°] for **1**: Cu1–Br1 = 2.4218(14), Cu1–Br1A = 2.8944(16), Cu1–Br2 = 2.3900(13), Cu1–N1 = 2.028(4), C3–S1 = 1.783(12); N1–Cu1–N1B = 175.3(2), N1–Cu1–Br2 = 89.36(10), N1–Cu1–Br1 = 90.19(10), Br1–Cu1–Br2 = 168.70(5), N1–Cu1–Br1A = 92.32(11), Br2–Cu1–Br1A = 101.26(4), Br1–Cu1–Br1A = 90.04(4), Cu1–Br1–Cu1A = 89.96(4), C(1)–S(1)–C(3) = 106.8(4). Symmetry transformations used to generate equivalent atoms: $A = -x + 1, -y, -z + 1$, $B = x, 1 - y, z$.

Placement of the methyl carbon off the mirror led to a stable refinement with the methyl hydrogen atoms placed in fixed positions. The new C3–S1 bond length (1.783(12) Å) is in much better agreement with expected values. Bond lengths and angles within the meSpz ring are otherwise unremarkable; the mean deviation of the constituent atoms from the ring is 0.016 Å with the sulfur and methyl carbon atoms displaced ~0.33 Å toward the Br2 face of the ring.

The copper coordination sphere is 5-coordinate and composed of two nitrogen atoms from two meSpz ligands and three bromide ions (see Fig. 4). The Cu–N bond length (2.023 Å) is in the normal range in comparison to other 5-coordinate compounds, such as Cu(quinoxaline)Br_2 [13] (2.068 Å) and Cu(((4-pyridylcarbonyl)-oxy)$_2$-1,3,4-oxadiazole)Br_2 [17] (2.002 Å). The Cu–Br bonds are somewhat shorter than seen in related five-coordinate bibridged dimer systems [18], but comparable to those seen in the isostructural quinoxaline complex [13].

As determined by the continuous symmetry measure (CSM) approach [19,20], the Cu polyhedron is very nearly square pyramidal [$S_{C4v} = 0.801$, $S_{D3h} = 5.487$] as is typical of Cu(II) halide coordination compounds with trans amine ligands. A symmetry related pair of Br1 ions form an unsymmetrical bihalide bridge between two copper ions ($d_{Br1-Cu1} = 2.4218(14)$ Å, $d_{Br1-Cu1A} = 2.8944(16)$ Å, Cu1–Br1–Cu1A = 89.96(4)°) forming the rungs of the ladder, while the bridging meSpz ligands form the rails.

The ladders pack parallel to the b-axis (Fig. 5). Short S···S contacts (3.169(5) Å) and S···Br contacts (3.564(4) Å) exist between adjacent ladders parallel to the c-axis. However, these are unlikely to propagate magnetic exchange due to the very large number of bonds in the pathways between Cu ions, and the closest interladder Cu···Br contact is 5.741(6) Å, suggesting that the ladders are magnetically well isolated along the c-direction.

However, close Br···Br contacts exist between adjacent ladders parallel to the a-axis. The resulting two-halide exchange pathway along the a-axis has the parameters $d_{Br\cdots Br} = 4.226$ Å, $\angle_1$ $_{Cu-Br\cdots Br} = 118.94°$, $\angle_2$ $_{Br\cdots Br-Cu} = 144.06°$, and $\tau_{Cu-Br\cdots Br-Cu} = 11.5°$. This

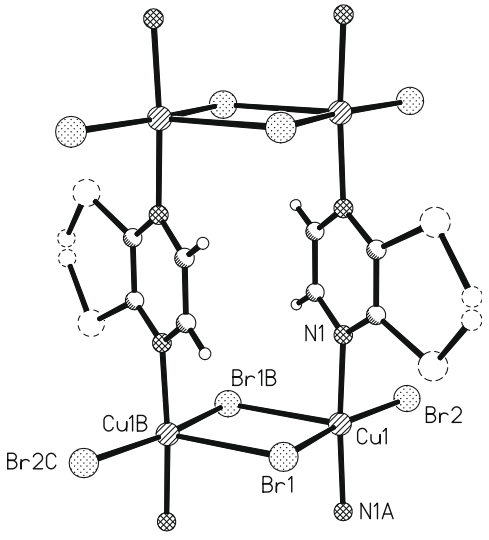

Fig. 4. A rung unit and copper coordination sphere of $[Cu(meSpz)Br_2]_n$ (**1**). Disordered sulfur atoms are shown as dotted circles. Hydrogen atoms on the disordered methyl groups have been excluded for clarity.

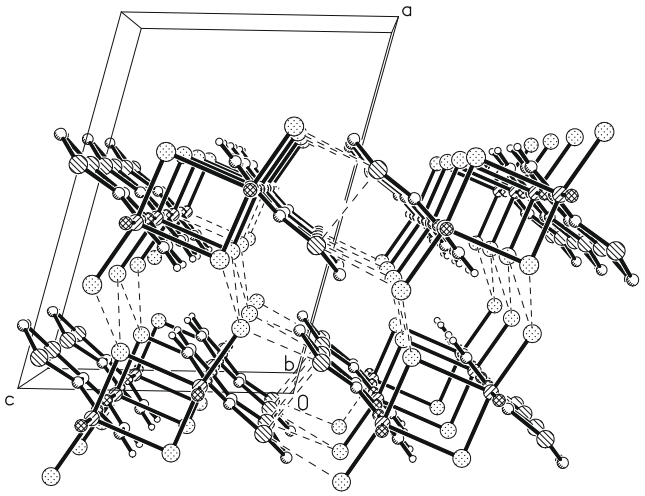

Fig. 5. The crystal structure of **1** viewed parallel to the *b*-axis. Hydrogen atoms on the disordered methyl groups have been excluded for clarity.

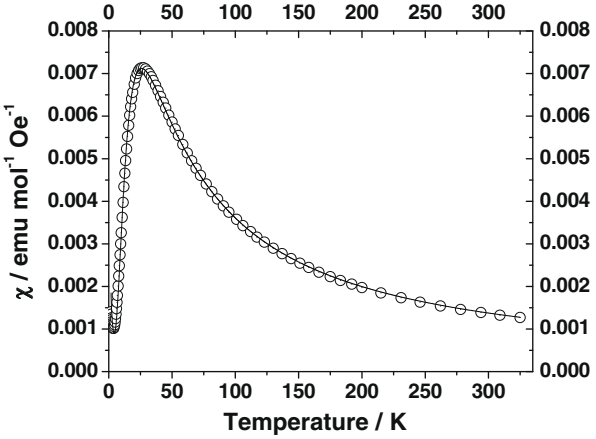

Fig. 6. Left: Magnetic susceptibility data (circles) for $[Cu(meSpz)Br_2]_n$ (**1**) and the fit (solid line) to a strong-rung ladder model.

opens the potential for magnetic exchange between the structural ladders.

All magnetic data have been interpreted in terms of the single *J* form of the Heisenberg Hamiltonian where a negative value of *J* corresponds to antiferromagnetic interactions.

$$H = -J\sum S_i \cdot S_{i+1}$$

Magnetic susceptibility data for $Cu(meSpz)Br_2$ show a rounded maximum at 26 K, followed by a rapid decrease in χ with decreasing temperature (Fig. 6)[3] The value of χT decreases with temperature over the range studied as expected for an antiferromagnetic material and the Curie–Weiss constant is negative ($\theta_{CW} = -27.5$ K) also indicating antiferromagnetic interactions. The susceptibility data show excellent agreement with the model for a strong-rung magnetic ladder [21] yielding the parameters $C = 0.440(12)$ emu K mol^{-1}, $J_{rung}/k_B = -39.8(2)$ K, $J_{rail}/k_B = -18.0(4)$ K, and a paramagnetic impurity of 0.75(3)%, which can be seen as a very small tail below 3.2 K in Fig. 5.

[3] Magnetic studies were performed on a Quantum Designs MPMS-XL SQUID magnetometer. External field dependent magnetic measurements at 1.8 K were measured in fields up to 5 T. Temperature dependent magnetic susceptibility data were collected in the range 1.8–325 K. Corrections were made for diamagnetic contributions (DIA) of the samples according to Pascal's constants and for temperature independent paramagnetism (TIP).

Table 1
Exchange values J_{rung} and J_{rail} for $Cu(2,3dmpz)Br_2$, $Cu(quinoxaline)Br_2$, and $Cu(meSpz)Br_2$.

	J_{rung}/k_B (K)	J_{rail}/k_B (K)	Ref.
$Cu(2,3\text{-}dmpz)Br_2$	−28.4(3)	−21.4(4)	[14]
$Cu(quinoxaline)Br_2$	−37	−27	[13]
$Cu(meSpz)Br_2$	−39.8(2)	−18.0(4)	this work

The values for J_{rung} and J_{rail} are reasonable in comparison to other neutral $CuBr_2$ ladder complexes bridged by diamine ligands, as shown in Table 1. The Cu–Br···Cu angle along the rungs of the ladder is 89.96(4)° in $[Cu(meSpz)Br_2]_n$. The value for J_{rung} in **1** is close to that observed in the dimeric complex $Cu(3,5dmpy)_2Br_2$ [22], which also has a Cu–Br···Cu angle of 89.96° and an exchange constant $J/k_B = -42$ K assigned to the bibridged halide exchange pathway.

Although there are close Br···Br contacts between ladders along the *a*-axis, giving the possibility of magnetic exchange between ladders, the strong-rung model fits the data well. This may result from the poor interladder Cu–Br···Br contact angles (118.9°, 114.06°) when angles approaching 180° have been shown to be optimum for providing a superexchange pathway [23]. The absence of a deviation from the isolated strong-rung ladder model may also be an effect of the reduced moment of the system due to the stronger antiferromagnetic interactions within the ladder.

Structurally, $[Cu(meSpz)Br_2]_n$ exhibits dibromide bridges forming the rungs and bridging meSpz ligands form the rails of a ladder motif parallel to the crystallographic *b*-axis. Moreover, $[Cu(meSpz)Br_2]_n$ is isostructural with the $[Cu(2,3dmpz)Br_2]_n$ and $[Cu(quinox)Br_2]_n$ coordination polymers. Magnetic data also suggest that the material behaves as a strong-rung ladder and that interactions between ladders are negligible. Theoretical calculations are in progress to verify the assignment of exchange strengths from the susceptibility experiments. Additionally, initial powder X-ray data indicate that the chloride analogue of **1** is isostructural to it. Work is in progress to obtain single crystals of $[Cu(meSpz)Cl_2]_n$.

Supplementary data

Atomic coordinates and isotropic thermal parameters, a full listing of bond lengths and angles, observed and calculated structure factors and anisotropic thermal parameters are available through the CCDC (**1**, 700680).

Acknowledgments

The MPMS-XL SQUID magnetometer was purchased with the assistance of funds from the National Science Foundation (IMR-0314773) and the Kresge Foundation.

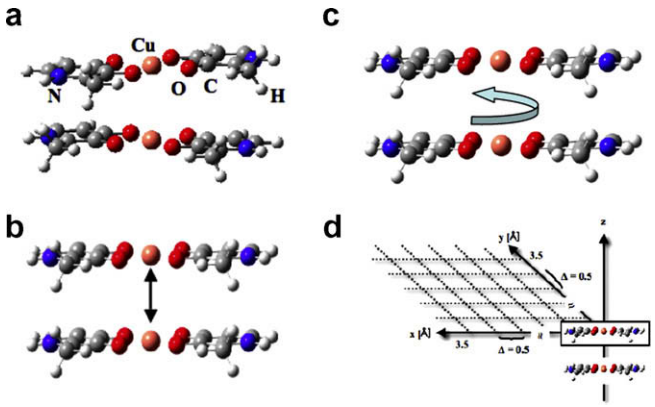

Fig. 1. The Calculated dimer models of Cu^{2+} mediated base pairs of hydroxypyridone nucleobases. Sugar-phosphate backbone is replaced by H atoms in the models. The structure (a) is the undistorted and (b)–(d) are distorted ones. Changed parameters are (b) the distance, (c) the rotation angle and (d) the slip in *X*–*Y* plane between two monomers.

$$\hat{H} = -2\sum_{a>b} J_{ab}\hat{S}_a\hat{S}_a, \tag{1}$$

where the parameter J_{ab} is a coupling parameter between localized spins *S* on metal ions a and b. The J_{ab} can be calculated by

$$J_{ab} = \frac{E^{LS} - E^{HS}}{\langle\hat{S}^2\rangle^{HS} - \langle\hat{S}^2\rangle^{LS}}, \tag{2}$$

where E^X and $\langle\hat{S}^2\rangle^X$ are total energy and total spin angular momentum of spin state X (X = low-spin (LS) and high spin (HS) states), respectively [8,9]. The positive (negative) J_{ab} value means ferromagnetic (anti-ferromagnetic) interaction. The total energies and $\langle\hat{S}^2\rangle$ values are calculated by UB3LYP [10] method with the use of 6-31+G* basis set for ligand, and Huzinaga MIDI+p basis set [11] for Cu^{2+} atoms on GAUSSIAN 03 program [12].

All J_{ab} values between Cu^{2+} ions in Cu^{2+}–DNA systems are calculated by two-unit dimer model as illustrated in Fig. 1a–d. Previous to the calculation of J_{ab} values with the dimer model, a structure of the monomer unit is optimized because there is no available information about the complex except for the inter-plane distance. The optimized structural parameters of the monomer unit are summarized in Table S1 in Supplementary material. A spin state of the monomer is doublet and one spin exists on $d_{x^2-y^2}$ orbital of Cu^{2+} as illustrated in Fig. S1 in Supplementary material. The dimer models are constructed by using the optimized monomers as described in later sections.

3. Results and discussion

3.1. J_{ab} values between Cu^{2+} ions with the reported structure

First, the J_{ab} value between two Cu^{2+} ions is calculated for the reported structure [4]. As described above, we are only able to use the structural information of the complex that the system is a right-handed DNA helix and the distance of adjacent planes are 3.7 Å [4]. Therefore it is assumed that the Cu–Cu axis is perpendicular to monomer plane and the rotational angle of the dimer is 36° based on B-DNA [3,4,13] which is the right-handed DNA. By using those information and assumptions, we constructed the model system as illustrated in Fig. 1a. Calculated total energies and $\langle\hat{S}^2\rangle$ values for a broken-symmetry (BS) LS and the HS states and J_{ab} value are summarized in Table S2 in Supplementary material.

The calculated energy splitting between the BS LS and the HS states is small. However the BS LS state is slightly stable and the calculated J_{ab} value is negative indicating an anti-ferromagnetic interaction. This result agrees with a metal–DNA (M-DNA) based on a natural B-DNA ($J = -0.0483\ cm^{-1}$) [5].

Also we consider solvent (water) effect for this system by PCM method because ESR measurement carried out under condition of aqueous solution. The calculation result of the J_{ab} value is $-1.4\ cm^{-1}$ and it is equal to non-solvent model. In other word, the J_{ab} value does not depend on the solvent effect in our model.

3.2. Change in J_{ab} values with deformations

It is well known that the DNA is flickered and changed its form such as A-, B- and Z-forms by solvent [13]. In this sense, a structural disorder of the DNA strand must be examined for the consideration of the origin of high spin species. Therefore we, next, consider three possibilities of deformations i.e. the distance, the rotation angle and the slip in *X*–*Y* plane between two monomers as illustrated in Fig. 1b–d, and examine a change in J_{ab} values with those deformations.

Calculated results for the distance and the rotation angle are summarized in Fig. 2. The range of Cu–Cu distance, and rotation angle are 3.0–5.0 Å and 0–180°, respectively. The experimental distance between two base pairs is 3.7 Å in B-form DNA. The calculated J_{ab} values are small in all range of distances and angles. The J_{ab} values simply depend on Cu–Cu distance and the anti-ferromagnetic interaction becomes stronger as the distance between two Cu ions becomes shorter, such as it was expected [14]. On the other hand, J_{ab} values show a periodic dependency on the rotation angle. For example, there are minima around 0°, 90° and 180°. The reason of this phenomenon stems from the symmetry of $d_{x^2-y^2}$ orbitals of Cu^{2+} ions of adjacent planes because the J_{ab} values depend on overlap between two spin orbitals on Cu^{2+} ions.

In order to explain the detail, the natural orbitals (NOs) of the system are examined for several angles. The NOs are obtained by diagonalization of a first order density matrix as

$$\rho(r, r') = \sum n_i\{\phi_i(r)\}^*\phi_i(r'), \tag{3}$$

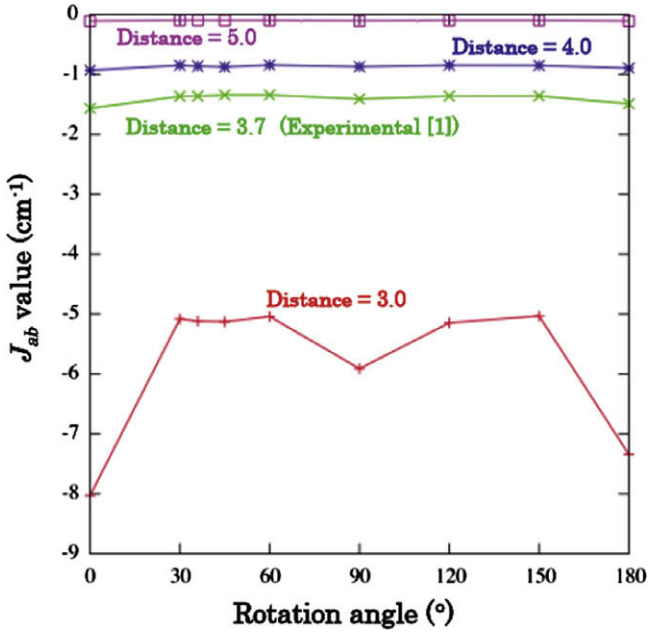

Fig. 2. J_{ab} values when the distance and the rotation angle between two base pairs are changed.

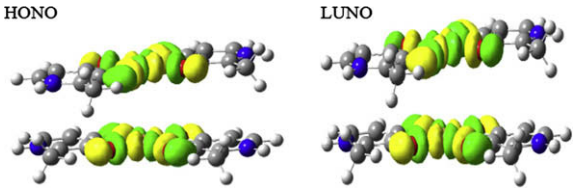

Fig. 3. Depicted HONO and LUNO of $[H–Cu^{2+}–H]_2$ for the BS LS state. The distance and angle between two base pairs are 3.7 Å and 36°, respectively.

where n_i denotes the occupation number of NO (ϕ_i) [8]. The occupation number is in proportion to the overlap between α and β orbitals, so that one can estimate SOMO–SOMO overlap from the number. The overlap is calculated by $n_i - 1$. Therefore, if an occupation number of a magnetic orbital is close to 1.0, then two electrons in the orbital are almost localized on each spin site. On the other hand, n_i should be equal to 2.0 if the two spins are delocalized on two spin sites. The NOs and their occupation numbers for the BS LS state are depicted in Fig. 3 and Table S3 in Supplementary material, respectively. The highest occupied natural orbital (HONO) and the lowest unoccupied natural orbital (LUNO) mainly consist of $d_{x^2-y^2}$ orbitals of Cu^{2+} ions, and their occupation numbers are almost 1.0 indicating overlap between two spins on Cu^{2+} ions are very small, allowing us to understand the weak magnetic interaction. Around 36° which is the angle of the B-DNA, overlap shows minimum but it is not completely orthogonal, while overlap shows maxima around 0°, 90° and 180°. The difference between 0° and 180° seems to originate from asymmetric methyl groups.

In case of 36°, the overlap estimated by the occupation number is 0.0001. In these systems, a slight structural change easily makes a change in overlap. If two orbitals are perpendicular each other, there is a possibility of the ferromagnetic interaction. As explained above, it is expected that the DNA backbone is always flickered by outer environment. So, we also investigate the slipping of two monomers in *X*–*Y* plane as illustrated in Fig. 1d. In this model, rotation angle is fixed to 36°. As summarized in Fig. 4, the J_{ab} values become smaller and close to zero but they show anti-ferromagnetic interaction in whole region.

3.3. Dependence on the J_{ab} values for various calculation methods

It has been reported calculated J_{ab} values sometimes depend on the DFT functional sets quantitatively, but not qualitatively. Therefore, we next investigated the dependency of the J_{ab} values on calculation methods such as BHandHLYP, PW91PW91, MPW91PW91, HF and MP2. Calculated results are shown in Table 1. Although the double helix of DNA is stabilized by π–π interaction, the DFT methods which cannot include π–π interaction give systematic J_{ab} values. MP2 can evaluate a dispersion interaction accurately. MP2 method shows an unreasonable weak ferromagnetic interaction at longer distance. On the other hand, the J_{ab} values calculated by DFT methods are almost equal each other. Tsuzuki et al. reported that the MP2 calculation overestimate π–π interaction such as benzene or naphthalene [15,16]. Our results also suggest the method may not be applicable to the long-distance $[H–Cu^{2+}–H]$ dimer.

Table 1
The J_{ab} values[a] of the dimer model calculated by several methods.

Distance[b]	BHandHLYP	PW91PW91	MPW1PW91	HF	MP2
3	−5.1	−3.5	−4.5	−2.4	−4.6
3.7	−1.2	−0.8	−0.9	−0.4	−0.4
4	−0.7	−0.6	−0.6	0.0	0.4
5	−0.1	−0.1	−0.1	0.0	2.1

[a] In cm^{-1}.
[b] In Å.

Table 2
Total energies, $\langle \hat{S}^2 \rangle$ values and J_{ab} values of trimer ($n = 3$), tetramer ($n = 4$) and pentamer ($n = 5$) models calculated by UB3LYP method.

n	HS state		LS state		J_{ab}[b]
	Total energy[a]	$\langle \hat{S}^2 \rangle$	Total energy[a]	$\langle \hat{S}^2 \rangle$	
3	−7545.34013157	3.7570	−7545.34014415	1.7572	−1.4

5	−12575.5689211	8.7617	−12575.5689460	2.7620	−1.4

[a] In a.u.
[b] In cm^{-1}.

3.4. The J_{ab} values of trimer, tetramer and pentamer

In order to examine the dependency of the J_{ab} values on a chain length, we calculated the J_{ab} values of trimer, tetramer and pentamer models. In these methods, the distance between adjacent planes are 3.7 Å and rotation angle are 36°. Eq. (2) is rewrite like Eq. (4) when spin sites are more than three [17]:

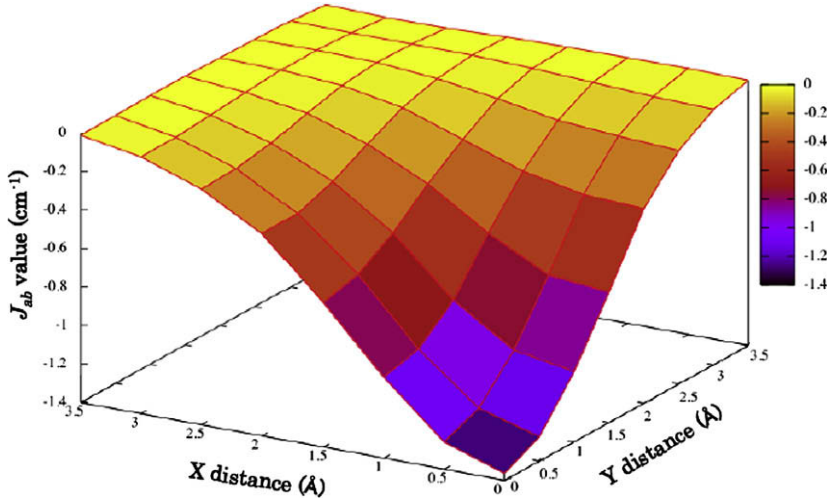

Fig. 4. The change in J_{ab} values when two monomers are slipped in *X*–*Y* plane. The distance and angle between two base pairs are 3.7 Å and 36°, respectively.

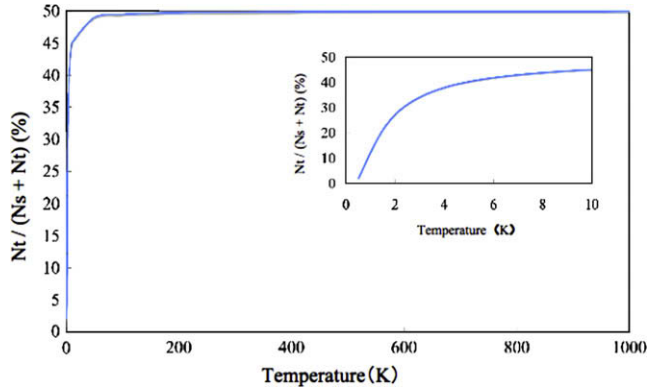

Fig. 5. The ratio of the population on triplet states by Boltzmann distribution simulation. The distance and angle between two base pairs are 3.7 Å and 36°, respectively. Ns and Nt means the population of singlet and triplet states, respectively. The enlarged picture shows the range of low temperature.

$$J_{ab} = \frac{E^{LS} - E^{HS}}{\langle \hat{S}^2 \rangle^{HS} - \langle \hat{S}^2 \rangle^{LS} + c}, \tag{4}$$

where

$$C = -S_a g(N)[\langle S^2 \rangle^{LS} - S_r(S_r + 1)]$$

and S_r denotes the exact spin angular momentum for molecules under discussion

$$S_r = n(S_a - S_b) \quad (N = 2n),$$
$$S_r = n(S_a - S_b) + S_a \quad (N = 2n + 1),$$

where the S_a and S_b are the sizes of spin at sites a and b. The results are shown in Table 2.

Their total energies of HS and BS LS states are energetically degenerate but the BS LS is slightly stable. Interestingly, the calculated J_{ab} values are equal to dimer model. In other words, we cannot find a dependency of J_{ab} values on the chain length.

3.5. Possibility of thermal excitation

From the calculated results, we cannot find the structure in which the HS state is more stable than the BS LS state, although EPR spectra show the existence of the HS species. On the other hand, the HS and the BS LS states are energetically degenerate. So, we examine a possibility of the thermal excitation from the LS state to the HS state. The ratio of population in the HS (triplet) and in the LS (singlet) is estimated by the Boltzmann distribution:

$$\frac{N(\text{triplet})}{N(\text{singlet})} = \exp\left(-\frac{E^{\text{triplet}} - E^{\text{singlet}}}{KT}\right), \tag{5}$$

at the various temperature (T) [18] in case that the distance and the rotation angle between two monomers are 3.7 Å and 36°. As illustrated in Fig. 5, a percentage of the triplet state $\left(\frac{N(\text{triplet})}{N(\text{singlet})+N(\text{triplet})} \times 100\right)$ is estimated to be about 21% at 1.5 K (ESR measurement temperature) and about 50% at 300 K. The result suggests that the HS species exist by the thermal excitation even at 1.5 K.

4. Conclusion

We theoretically investigated an origin of HS species of Cu^{2+} bridged hydroxypyridone pairs observed by EPR spectra. To our knowledge, this is the first report of a quantitative calculation for J_{ab} value between Cu^{2+} ions in metal–DNA systems. In all calculated results, the total energies of the HS and the BS LS states are degenerate but J_{ab} values show weak anti-ferromagnetic couplings within the examined model structures. These results agree with metal–DNA based on natural B-DNA [5]. Also J_{ab} value for dimer model is equal to more than trimer models that the distance and the angel are 3.7 Å and 36°. Together with the result of the Boltzmann distribution simulation, it is expected that the thermal excitation from the LS state to the HS state occurs in the system and the HS species are observed by the EPR spectroscopy.

Mo Kα (λ = 0.71073 Å) radiation). The structures were solved by a direct method and expanded by using Fourier techniques using SHELXTL program. Empirical absorption corrections by SADABS (G.M. Sheldrick, 1994) were carried out. In the structure analyses, non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms. Crystal data of **1** at −73 °C: $C_{67}H_{84}B_2Fe_3N_{26}O$, M = 1458.77, monoclinic space group $P2_1/c$, a = 14.2844(19), b = 14.844(2), c = 34.938(5) Å, β = 93.485(3)°, V = 7394.5(17) Å^3, Z = 4. A total of 43614 was collected ($3° < 2\theta < 56°$) of which 16202 unique reflections (R_{int} = 0.0575) were measured. Residual R and wR were 0.0629 and 0.1503, respectively, from the refinement on F^2 with $I > 2\sigma(I)$. Crystal data of **2** at −73 °C: $C_{82}H_{88}F_{24}Fe_4N_{28}O_{10}P_4$, M = 2429.08, triclinic space group $P\bar{1}$, a = 13.104(4), b = 13.935(4), c = 16.130(4) Å, α = 68.671(4)°, β = 88.352(4)°, γ = 74.264(4)°, V = 2632.9(12) Å^3, Z = 1. A total of 10724 was collected ($4° < 2\theta < 47°$) of which 7364 unique reflections (R_{int} = 0.0252) were measured. Residual R and wR were 0.0627 and 0.1733, respectively, from the refinement on F^2 with $I > 2\sigma(I)$.

2.3. Mössbauer spectral measurements

Mössbauer spectra of **1** and **2** were measured using a ^{57}Co/Rh source in a constant-acceleration transmission spectrometer. The spectra were recorded at 20 K, and Mössbauer parameters were calibrated relative to α-Fe foil.

2.4. Magnetic measurements

DC magnetic susceptibility data of **1** and **2** were collected by using a Quantum Design MPMS-XL SQUID magnetometer at temperatures ranging from 5 to 365 K for **1** and from 5 to 400 K for **2**, respectively.

3. Results and discussion

3.1. Descriptions of crystal structures

3.1.1. $[Fe^{III}_2Fe^{II}(CN)_6(tp^*)_2(tpa)] \cdot 4MeCN \cdot t\text{-}BuMeO$ (**1**)

X-ray crystal structure analysis for **1** was performed at 200 K, and ORTEP diagram of the complex molecule was depicted in Fig. 1. Compound **1** crystallized in monoclinic space group $P2_1/c$, and has a right angled trinuclear core composed of two $[Fe(CN)_3(tp^*)]^-$ and one $[Fe(tpa)]^{2+}$ units. Two $[Fe(CN)_3(tp^*)]^-$ units are bridged by $[Fe(tpa)]^{2+}$ via bridging cyanide ions with a bridging angle (N1–Fe2–N2) of 92.2(1)°. In $[Fe(CN)_3(tp^*)]^-$ units, Fe ions have FeC_3N_3 octahedral coordination geometry. Coordination bond lengths of Fe1–C are in the range of 1.926(4)–1.933(4) Å, while those of Fe1–N are 2.007(4)–2.009(4) Å, respectively. A coordination structure of Fe3 ion is very similar to that of Fe1 ion, and coordination bond lengths are 1.914(5)–1.923(5) Å and 1.990(4)–2.014(4) Å for Fe3–C and Fe3–N, respectively. The coordination structure of Fe2 ion in $[Fe(tpa)]^{2+}$ is six-coordinated octahedron with an FeN_6 chromophore, and Fe2 ion is coordinated by four nitrogen atoms from the tetradentate tpa ligand and two nitrogen atoms from the bridging cyanide ions. An average coordination bond length of Fe2 ion is 1.963 Å, which is very similar to those in Fe1 (1.969 Å) and Fe3 (1.960 Å) ions, and the structural feature of Fe1–Fe3 ions are characteristic of LS Fe(II) or Fe(III) ions. The coordination bond lengths in LS Fe(II) and Fe(III) ions are known to be very similar, and the assignment of oxidation states for each Fe ions is, therefore, difficult only by considering their structural parameters.

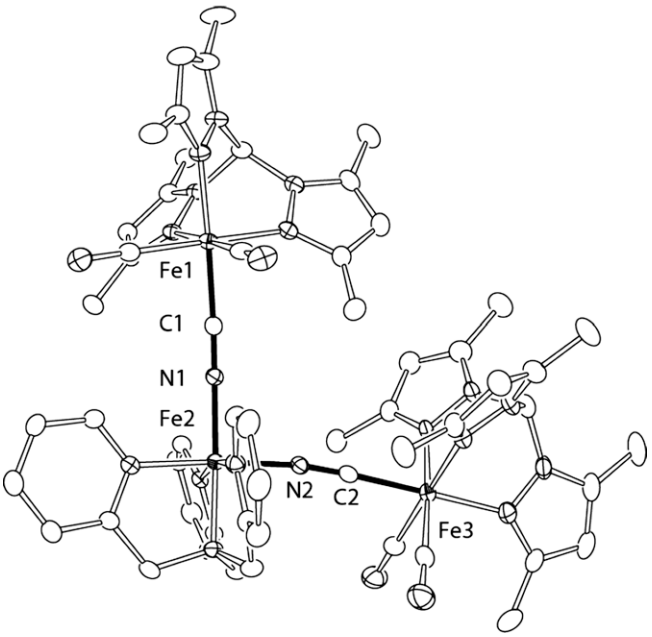

Fig. 1. ORTEP diagram of **1**.

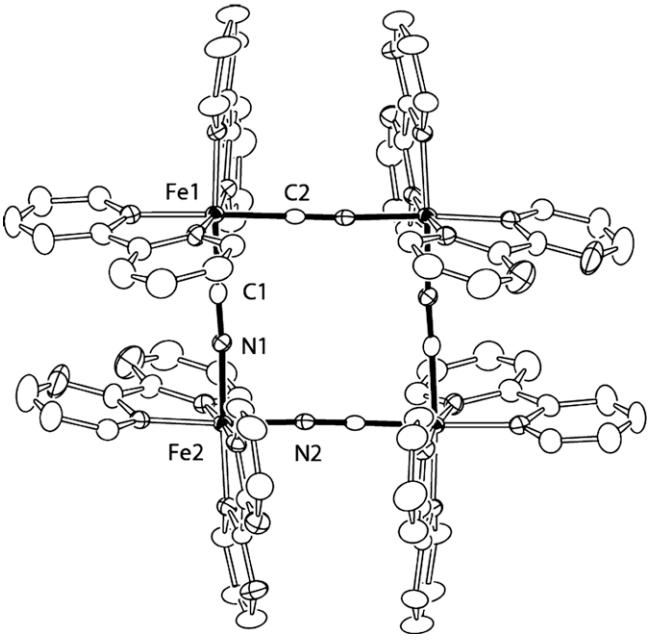

Fig. 2. ORTEP diagram of the cation in **2**.

3.1.2. $[Fe^{II}_4(CN)_4(bpy)_4(bpym)_4](PF_6)_4 \cdot 6MeOH \cdot 4H_2O$ (**2**)

2 crystallized in triclinic space group $P\bar{1}$ and a tetranuclear core locates on the centre of symmetry. The tetranuclear core in **2** is composed of four cyanide-bridged Fe(II) ions, and the overall core geometry is almost square (Fig. 2). Bridging angles of C1–Fe1–C2 and N1–Fe2–N2 are 87.3(2)° and 90.9(2)°, respectively. In the square, two $[Fe(bpy)_2]^{2+}$ centres and two $[Fe(bpym)]^{2+}$ centres are alternately bridged by four CN groups with the carbon atoms coordinated to the Fe(II) ions in $[Fe(bpy)_2]^{2+}$. The Fe(II) ions have

octahedral coordination geometry, and four of the coordination sites are occupied by nitrogen atoms from two bpy or bpym ligands. The two remaining *cis* positions are coordinated by either carbon or nitrogen atoms from the cyanide groups. The Fe1–N_{bpy} coordination bond lengths are ranging from 1.955(5) to 1.986(5) Å, and Fe1–C are 1.885(6) and 1.890(6) Å, respectively, while coordination bond lengths about Fe2 ions are 1.927(5)–1.966(5) Å. The average coordination bond lengths are 1.946 Å and 1.948 Å for Fe1 and Fe2 ions, respectively, which are characteristic of LS Fe(II) ions.

3.2. Mössbauer spectra of **1** and **2**

^{57}Fe Mössbauer spectra of **1** and **2** were recorded at 20 K and depicted in Fig. 3a and b, respectively. The spectrum of **1** is composed of two doublets (Fig. 3a), and their Mössbauer parameters were $\delta = 0.11$ and $\Delta E_Q = 1.28$ mm s^{-1} and $\delta = 0.45$ and $\Delta E_Q = 0.28$ mm s^{-1} at 20 K, characteristic of LS Fe(III) and LS Fe(II) species, respectively. The peak area ratio of the two peaks suggest that LS Fe(III) and Fe(II) ions correspond to two $[Fe(CN)_3(tp^*)]^-$ and one $[Fe(tpa)]^{2+}$ units, respectively.

A Mössbauer spectrum of **2** consists two doublets corresponding to LS Fe(II) ions with the Mössbauer parameters of $\delta = 0.22$ and $\Delta E_Q = 0.69$ mm s^{-1} (LS1) and $\delta = 0.40$ and $\Delta E_Q = 0.36$ mm s^{-1} (LS2) (Fig. 3b). The peak area ratio of LS1 and LS2 doublets was 0.52/0.48, suggesting different LS Fe(II) species in 1:1 ratio. The deviation of the area ratio is caused by the different Lamb–Mössbauer factors for each species. The LS Fe(II) ion (Fe1) in the $[Fe(CN)_2(bpy)_2]$ moiety has smaller isomer shifts than the Fe2 ions in $[Fe(NC)_2(bpym)]$ moieties, which is due to strong π back donation to cyanide ions. Therefore, the LS1 and LS2 doublets were assigned to the Fe1 and Fe2 ions, respectively.

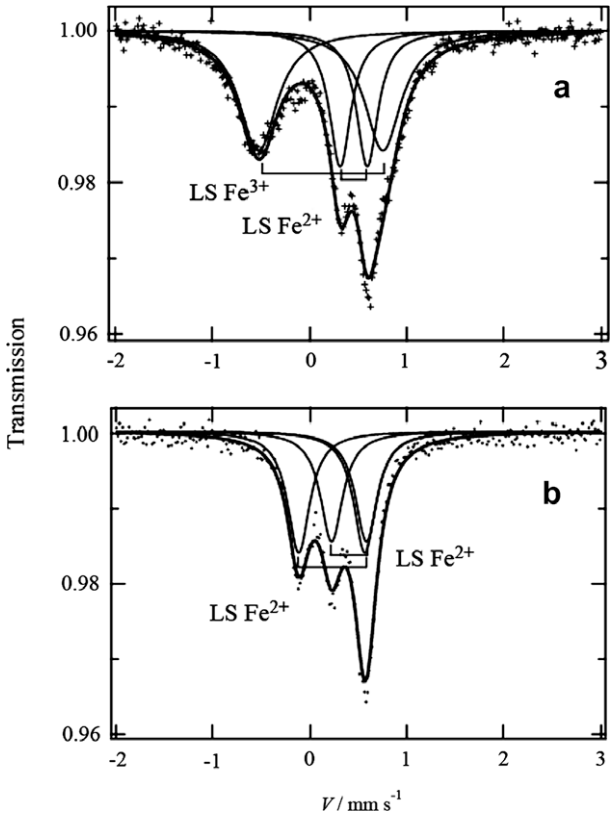

Fig. 3. Mössbauer spectra of (a) **1** and (b) **2** at 20 K.

3.3. Magnetic susceptibility measurements of **1** and **2**

Magnetic susceptibility measurements were carried out in the temperature range of 5–365 K and 5–400 K for **1** and **2** (Fig. 4). In **1**, the $\chi_m T$ values below 250 K are almost constant (1.34 emu mol^{-1} K at 250 K), which corresponds to the theoretical value (1.36 emu mol^{-1} K with $g = 2.7$) [11] for the uncorrelated two LS Fe(III) ions (Fig. 4a). As the temperature was increased, the gradual increase of $\chi_m T$ values was observed and the $\chi_m T$ value reached a maximum value of 2.86 emu mol^{-1} K at 340 K. It should be noted that this increase was recovered in the cooling process, suggesting an occurrence of a reversible thermal spin-crossover phenomenon. The Curie constant for HS Fe(II) ions is 3.00 emu mol^{-1} K ($g = 2.0$), and the $\chi_m T$ value (2.86 emu mol^{-1} K) at 340 K corresponds to ca. 50% of the Fe(II) ion being in the high-spin state.

The $\chi_m T$–T plot for **2** revealed that **2** is diamagnetic below 250 K (Fig. 4b), which agree with the X-ray and Mössbauer data suggesting the existence of the four diamagnetic LS Fe(II) ions in this temperature range. Upon heating, the $\chi_m T$ values increased gradually, and reached a maximum value of 3.42 emu mol^{-1} K at 400 K, suggesting the occurrence of spin transition from LS to HS state on Fe(II) ions. The $\chi_m T$–T curve in the cooling process is iden-

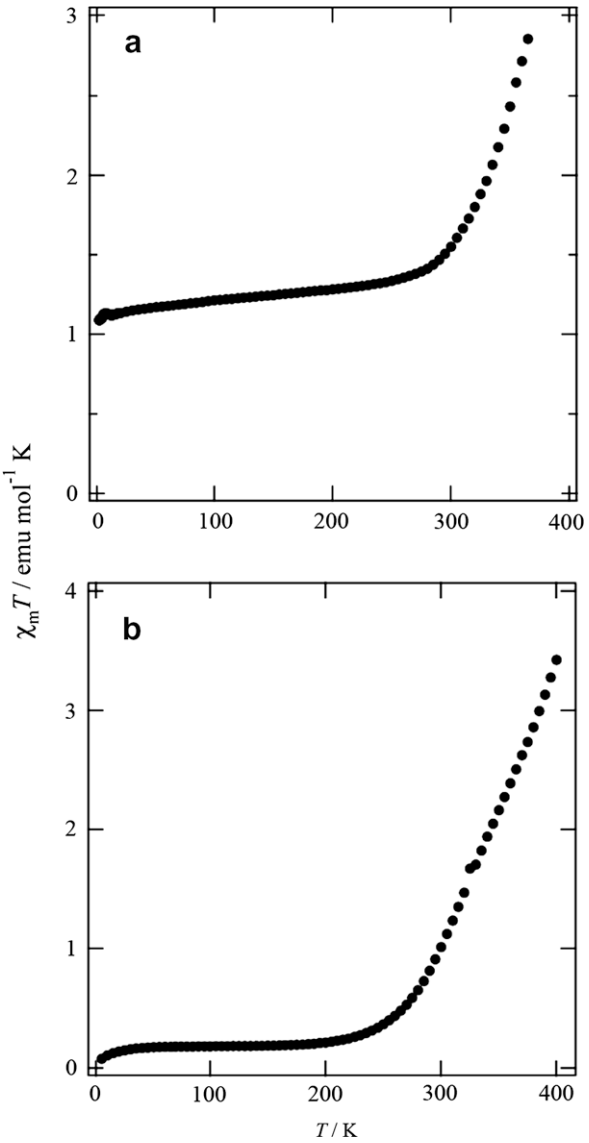

Fig. 4. $\chi_m T$–T plots for (a) **1** and (b) **2**.

tical with that in the heating process, suggesting that the spin transition in **2** was reversible. Compound **2** has crystallographically independent two Fe(II) ions (Fe1 and Fe2) in $[Fe(CN)_2(bpy)_2]$ and $[Fe(NC)_2(bpym)]$ centres. Fe1 is in the stronger ligand field than Fe2, because the bpy ligand is a strong π acid and the cyanide carbon atoms act as π acceptors [12]. Therefore, spin crossover sites in **2** must be two Fe2 ions in $[Fe(NC)_2(bpym)]$ units. Two Fe2 ions, which are related by the inversion centre, have the same coordination environment, and underwent one-step spin crossover.

4. Conclusion

We prepared novel cyanide-bridged tri- and tetra-nuclear complexes, and their structures and magnetic properties were studied. Magnetic susceptibility measurements revealed that introduction of medium ligand-field strength to the cyanide-bridged multi-nuclear cores leads to thermally induced spin crossover for both materials.

5. Supplementary data

CCDC 702339 and 702340 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

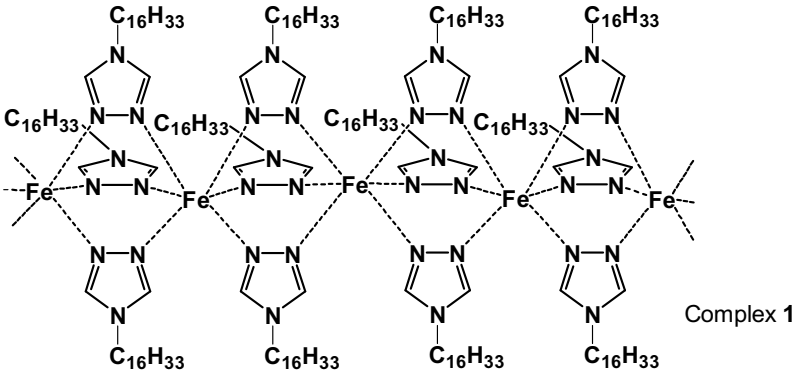
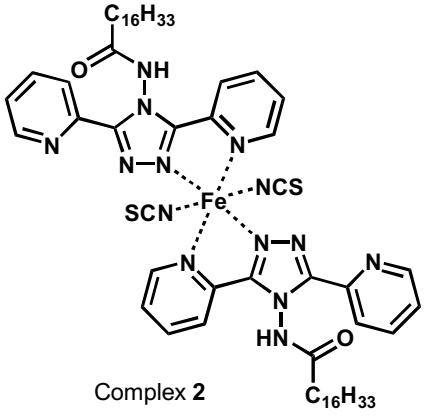
and ~8 times (Co^{II}, $S = 3/2$) for Ni^{II} complex ($S = 0$), respectively [7]. Létard et al. have investigated a series of octahedral high-spin metal complexes, and showed that β value is corresponds to number of unpaired electrons [8]. These important suggestions may show that the spin-crossover compounds which exhibit interconversion of electronic configurations are able to switch the NLO response.

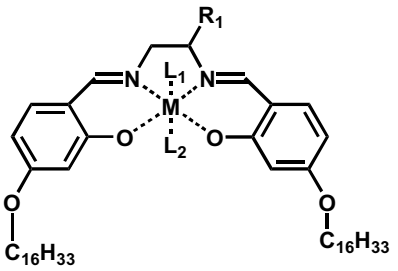
The goal of this study is to develop novel materials with switchable NLO response by using of the spin-crossover (SCO) phenomenon and photo-induced spin transition (LIESST) phenomena. It should be noted that no macroscopic non-linearities for the relationship between NLO properties and nature of metal have been investigated in solid so far. However, the macroscopic NLO response is essential for application, which is difficult to realize owing to request of non-centrosymmetry. To achieve macroscopic NLO response, we have attempted two methods; (i) chiral SCO complexes, (ii) Langmuir–Blodgett (LB) film. The LB film can be obtained a SHG-active non-centrosymmetric structure by transfer oriented single molecular layer from gas–water surface to the substrate, and the LB film is generally made of amphiphilic molecules. Therefore we introduced long alkyl chains into complexes in order to make the LB film. Here, we will report the evaluation of the second-order NLO response for these complexes in the LB film.



2. Experimental



2.1. Synthesis



4-Hexadecyl-1,2,4-triazole (C_{16}-trz): formic hydrazine (1.20 g, 20 mmol) and triethyl orthoformate (3.56 g, 24 mmol) were refluxed in methanol (30 ml) for 24 h in inert atmosphere. After cooling, *n*-hexadecacyl amine (4.83 g, 20 mmol) were added and refluxed further 24 h was obtained by removing the solvent under reduced pressure and recrystallizing from methanol.

2.1.1. $\{[Fe(C_{16}\text{-}trz)_3](ClO_4)_2\}_n$ (**1**)

This compound was reported by Roubeau et al. already [9]. $Fe(ClO_4)_2 \cdot 4H_2O$ (0.18 g, 0.5 mmol) in methanol was added to the

3: M = Fe, R_1 = H, L_1 = Cl
4: M = Fe, R_1 = CH_3, L_1 = Cl
5: M = Fe, R_1 = H, L_1 = CN, L_2 = CN (**5** has K^+ as a counter ion)
6: M = Fe, R_1 = CH_3, L_1 = CN, L_2 =CN (**6** has K^+ as a counter ion)
7: M = Fe, R_1 = CH_3, L_1 = CN, L_2 =CN (**7** has Na^+ as a counter ion)
8: M = Mn, R_1 = H, L_1 = Cl
9: M = Ni, R_1 = H
10: M = Cu, R_1 = H

Scheme 1. Structures of complexes **1**–**10**.

solution of C_{16}-trz (0.59 g, 2 mmol) in methanol, and then precipitate was appeared. The solid was collected, washed methanol, and dried under the reduced pressure.

2.1.2. 3,5-Di(2-pyridyl)-4-amino-1,2,4-triazole (ABPT)

A mixture of 2-cyanopyridine (25 g, 0.24 mol) and an excess of hydrazine hydride (25 ml, 0.53 mol) was heated for 3 h at 100 °C. The collected solid was suspended in 2 N HCl (200 ml) and the mixture was boiled for 10 min. The mixture was cooled and made alkaline with ammonia solution. The thick precipitate was collected and crystallized aqueous ethanol in colorless needle. The yield was 4.90 g (8.6%). ^{1}H NMR ($CDCl_3$): 7.35 (dd, 2H), 7.76 (td, 2H), 8.06 (d, 2H), 8.56–8.60 (m, 3H).

2.1.3. N-(3,5-Di-2-pyridinyl-4H-1,2,4-triazol-4-yl)-hexadecanecarboxamide (C_{15}-BPT)

Palmitoyl chloride (0.55 g, 2 mmol) in chloroform was added dropwise to ABPT (0.47 g, 2 mmol) and triethylamine (0.20 g, 2 mmol) in chloroform at 0 °C and stirred overnight at room temperature. The mixture was filtered and the solvent removed under reduced pressure. The residue was recrystallized from methanol/water (1:1 v/v) and then recrystallized from acetone. ^{1}H NMR ($CDCl_3$): 0.88 (t, 3H), 1.1–1.4 (m), 2.32 (t, 2H), 7.38 (dd, 2H), 7.87 (td, 2H), 8.29 (d, 2H), 8.63 (d, 2H), 10.14 (s, 1H).

*2.1.4. [Fe(NCS)$_2$(C_{15}-BPT)$_2$] (**2**)*

$FeCl_2 \cdot 4H_2O$ (0.10 g, 0.5 mmol) and small amount of ascorbic acid in methanol (5 ml) and KNCS (0.10 g, 0.5 mmol) in methanol (5 ml) were mixed and stirred for 15 min. Then, 2,2′-dimethoxypropane (0.5 ml) was added and stirred further 5 min. The solution was filtrated, and dropwise to C_{15}-BPT (0.48 g, 1 mmol) in $CHCl_3$/CH_3OH (1:1 v/v, 10 ml). After few days, the compound crystallized upon slow evaporation of the solvent at room temperature. Red solid were collected and dried under reduced pressure.

2.1.5. 4-(Hexadecyloxy)-2-hydroxy-benzaldehyde (C_{16}-aldehyde)

2,4-Dihydroxybenzaldehyde (10.0 g, 72.4 mmol) and $KHCO_3$ (21.4 g, 70.1 mmol) and KI (catalytic amount) were suspended in acetone (200 ml) and refluxed for 24 h under argon. The reaction mixture was filtered while the solution was hot. The filtrate was acidified to ca. pH 6 by addition of 1 N HCl. The solution was concentrated, extracted by chloroform, and dried over $MgSO_4$. The solvent was removed under reduced pressure and purified by column chromatography on a silica gel (chloroform/hexane 1:1, Rf = 0.4). The yield was 6.64 g (26%). ^{1}H NMR ($CDCl_3$): 0.88 (t, 3H), 1.2–1.5 (m), 1.79 (m, 2H), 4.00 (t, 2H), 6.41 (d, 1H), 6.52 (dd, 1H), 7.40 (d, 1H), 9.71 (s, 1H), 11.49 (s, 1H).

2.1.6. N,N-Bis[4-(hexadecyloxy)salicylidene]ethylenediamine (C_{16}-salen)

C_{16}-aldehyde (1.45 g, 4 mmol) and ethylenediamine (0.12 g, 2 mmol) in chloroform (50 ml) were refluxed for 6 h. The solvent was removed under reduced pressure. The recrystallization from chloroform/methanol (1:1 v/v) gave yellow needle. The yield was 1.35 g (90.1%). ^{1}H NMR ($CDCl_3$): 0.87 (t, 6H), 1.3–1.5 (m), 3.84 (s, 4H), 3.94 (t, 4H), 6.36 (dd, 2H), 6.40 (d, 2H), 7.06 (d, 2H), 8.19 (s, 2H). C_{16}-salmmen was prepared using 1,2-diaminopropane instead of ethylenediamine.

*2.1.7. [FeCl(C_{16}-salen)] (**3**)*

$FeCl_3$ (0.29 g, 1.80 mmol) in chloroform/methanol (1:1 v/v, 10 ml) was added to C16-salen (1.35 g, 1.80 mmol) in chloroform/methanol (1:1 v/v, 30 ml) and refluxed for 3 h. The solvent was removed under reduced pressure and residue was recrystallized from acetone. The red brown solid was obtained (1.21 g, 80.1%). [FeCl(C_{16}-salmmen)] (**4**) was also synthesized the same preparation procedure.

*2.1.8. Na[Fe(C_{16}-salen)(CN)$_2$] (**5**)*

[FeCl(C_{16}-salen)] was dissolved in chloroform. To this solution, NaCN dissolved small amount of methanol/water (1:1 v/v) was added. The precipitated green solid was collected and dried under reduced pressure. *Anal.* Calc. for $C_{50}H_{78}Fe_1N_6K_1N_4O_4$: C, 67.17; H, 8.79; N, 6.27. Found: C, 67.00; H, 8.77; N, 6.04%. Na[Fe(C16-salmmen)(CN)$_2$] (**6**) was synthesized the same preparation procedure, and K[Fe(C16-salmmen)(CN)$_2$] (**7**) was prepared using KCN instead of NaCN.

*2.1.9. [Mn(C_{16}-salen)Cl] (**8**), [Ni(C_{16}-salen)] (**9**), and [Cu(C_{16}-salen)] (**10**)*

M(CH_3COO)$_2$ (M = Mn, Ni, Cu) in methanol was added to the equivalent C_{16}-salen in chloroform/methanol (1:1 v/v). The precipitate was appeared for Ni and Cu. In the case of Mn, the precipitate was obtained by addition of equivalent NaCl. The solid was filtered off and recrystallized from chloroform/methanol (1:1 v/v).

2.2. Film preparation

Complexes **1**–**10** dissolved in chloroform were spread onto the surface of the water. The floating film of complexes was compressed up to the surface pressure of 20 mN m^{-1}. The floating films of complexes were transferred onto the gas–water surface of glass substrates by vertical dipping.

2.3. Physical experiments

All elemental analyses date were obtained at the Service Center of the Elemental Analysis of Organic compounds, Department of Chemistry, Kyushu University. Metal analyses were done on a Shimadzu AA-625-11 Atomic Absorption/Flame Emission Spectrometer. Infrared spectra were recorded using KBr disk with a JASCO FT-IR-410. All NMR measurements were performed on a Bruker AVANCE SERIES DPX 400 instrument operating at 400 MHz. The magnetic susceptibilities $\chi(T)$ were measured between 5 K and 400 K with a superconducting quantum interference device magnetometer (Quantum Design MPMS-5S) in an external field of 0.5 T. Illumination experiment was done with using an Ar^+ laser (λ = 532 nm, continuous wave) as a light source. The measurements of SHG were carried out to detect at 532 nm upon irradiation with a 1064 nm laser.

3. Results and discussion

3.1. Materials

The prepared compounds can be expected to possess some advantage for second-order NLO materials. The analogue for compound **1** has been reported that the LB film for the analogue can make on the glass substrate [10], and it is able to expect for the formation of the LB film for **1**. Furthermore, compound **1** in the HS state is transparent in the visible region, and then the sample of **1** is an advantage example for SHG experiment. Because the SHG responses was enhanced when the light of the SHG is resonated with absorption band for compounds [2b], and the resonance effects make it difficult to estimate the intensity of the essential non-linearity of the materials.

For compound **2**, the C_{15}-BPT ligand is expected to coordinate to the metal asymmetrically by one of nitrogen atom of pyridine and triazole moiety. Because it has been reported that the compound [Fe(ABPT)$_2$(NCS)$_2$] with ABPT ligands forms asymmetric conforma-

tion in the ligand [11]. The asymmetrical conformations generate anisotropic charge transfer and large molecular hyperpolarizability. If two thiocyanato ions coordinated to metal center in *cis*-form, complex **2** is non-centrosymmetry in the single molecule. However, it is suggested that the thiocyanato ions for **2** are in *trans*-form because of the observation of the singlet peak in 2091 cm^{-1} by the IR measurement. Therefore the observation of NLO-active cannot be expected for **2**.

Compounds **5**–**7** have two axial ligands (CN^-). It is expected that the molecular array in the LB film affects the ligand field strengths for the compounds. The adequate ligand field strength closed to the SCO point can be controlled by changing axial ligands easily for the compounds.

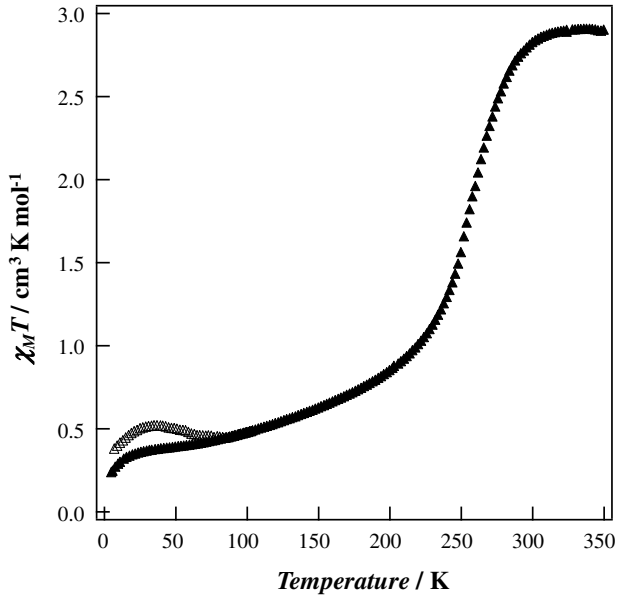


Fig. 1. Temperature dependence of $\chi_M T$ for complex **1**: (▲) data recorded in the warming mode without irradiation; (△) data recorded in the warming mode after the light irradiation, then turned off.

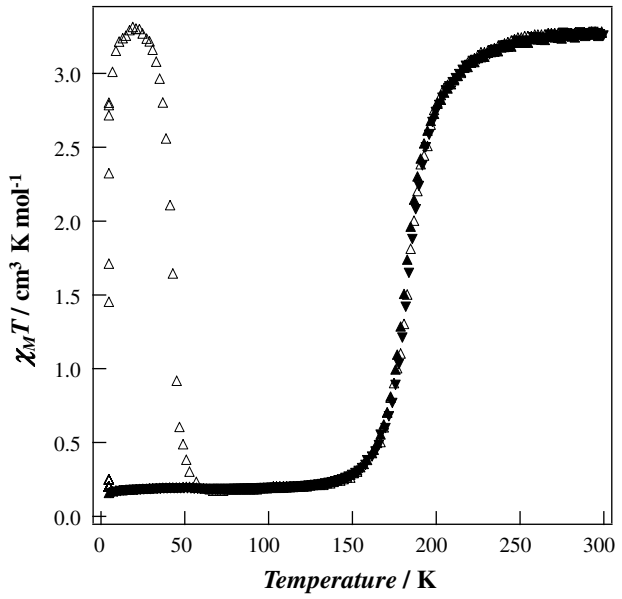

Fig. 2. Temperature dependence of $\chi_M T$ for complex **2**: (▲) and (▼) data recorded in the warming mode and cooling mode without irradiation, respectively; (Δ) data recorded in the warming mode (2 K min^{-1}) after the light irradiation, then turned off.

3.2. Magnetic properties

Temperature dependence of $\chi_M T$ for compound **1** is shown in Fig. 1. Compound **1** exhibited the SCO behavior. The $\chi_M T$ value is 2.92 cm^3 K mol^{-1} at 350 K and 0.39 cm^3 K mol^{-1} at 50 K. The residual high-spin (HS) fraction at 50 K is 13%, regarded the $\chi_M T$ value of 2.92 cm^3 K mol^{-1} at 350 K as in the HS state of 100% and the $\chi_M T$ value of low-spin (LS) state as zero. The LIESST effect was observed in a part of **1** by light irradiation at 5 K.

Temperature dependence of the $\chi_M T$ for compound **2** is shown in Fig. 2. The SCO behavior of compound **2** is abruptly transition. The $\chi_M T$ value is ca. 3.08 cm^3 K mol^{-1} above 250 K and ca. 0.16 cm^3 K mol^{-1} below 150 K and $T_{1/2}$ = 183 K. The hysteresis was not observed. The LIESST phenomenon was observed for compound **2**. The increase of the $\chi_M T$ value to 2.62 cm^3 K mol^{-1} was observed by light irradiation at 5 K. After the light irradiation stopped, the $\chi_M T$ value was increased according to warming in the temperature range <20 K. This increase of the $\chi_M T$ value corresponds to zero-field splitting. In the temperature range 20–50 K, the $\chi_M T$ value was decreased as a result of HS → LS thermal relaxation. It was estimated that the T(LIESST) was 43 K. This behavior is similar to that of $[Fe(ABPT)_2(NCS)_2]$ [11]. The substitutions of long alkyl chains are not influenced cooperative effect.

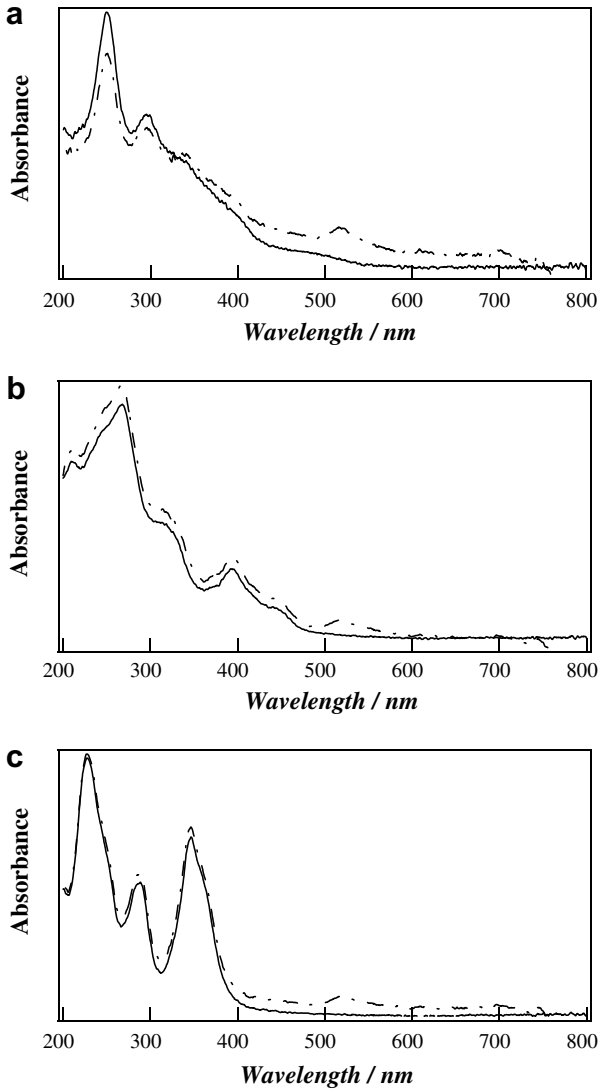

Fig. 3. UV–Vis spectra for **8** (a), **9** (b) **10** (c) in LB film. The solid line is 90° of incident angle, and dashed line is 45° of incident angle.

Compounds **3** and **4** were in the HS state ($t^3_{2g}e^2_g$; $S = 5/2$) in the temperature range of 5–300 K. In contrast, compounds **5**–**7** were in the LS state ($t^5_{2g}e^0_g$; $S = 1/2$) because of the axial coordination of the CN^- ligands between 5 and 300 K. Mn(III) compound **8** was in the HS state ($t^3_{2g}e^1_g$; $S = 2$), and compounds **9** and **10** were in $S = 0$ ($t^6_{2g}e^2_g$) and $S = 1/2$ ($t^6_{2g}e^3_g$), respectively.

3.3. UV–Vis spectra in the LB film

It was confirmed by UV–Vis spectra that compounds **3**–**10** on the water were transferred onto the glass substrates. All complexes showed absorption bands in the region $\lambda > 400$ nm originated from intraligand charge transfer and anisotropic bands in the region 500–600 nm assigned to d–d transition (Fig. 3). It is expected that the anisotropic d–d transitions are able to act favorably to the non-linearities. It should note that compounds **5**, **6** and **7** were in the LS state, and the d–d bands must red-shift compared with that for the HS compounds. Compounds **5**, **6** and **7** are unstable in solution, and the compounds were decomposed and transformed to the oxygen bridged complexes. UV–Vis spectra show that compounds **5**, **6**, and **7** in LB film are contained impurities.

3.4. Second-harmonic-generation (SHG) measurements

The powder samples were put onto surface of glass plates for **1**–**10**, and this glass plates were irradiated 1064 nm laser. However, no SHG signal was observed. The reason of this SHG-inactivity was caused by their crystal structures. The directions of the dipole moments are almost perpendicular for the screw axes, and the dipole moments are cancelled out each other. Furthermore, dipole moments remaining along the screw axes were also cancelled out by alternate arrangement of screw axes. The observation of the SHG responses in LB films was attempted because of no responses in solid. However, SHG signal could not be observed for compounds **1** and **2** in LB film. It is assumed that the compounds have inversion center in the molecules.

On the other hand, SHG signals could be observed for compounds **3**–**10**. The maker fringe patterns for the complexes are shown in Figs. 4–6. For compounds **3** and **4**, the SHG responses are relatively large value in the systems measured in this study. In complex **4**, the SH intensity is smaller than that of complex **3**, which is analogue of complex **4**. This difference of SHG response could not explain except for experimental factors. In spite of the similar structures, compounds **5**, **6** and **7** exhibit considerably difference SHG responses. The difference of the SHG responses between complex **6** and **7** could be explained by difference of cation sizes. It is suggested that compound **7** with small cation Na^+ forms more tight orientation on the glass substrate, and compound **7** exhibited larger non-linearity. The decompositions from compounds **5**, **6** and **7** to μ-oxo species can be shown in the UV–Vis spectra for LB film, and the SHG responses were different from the original ones. The differences of SHG intensities between complex **3** and complexes **8**–**10** which have different metal centers was also revealed. The clear Maker fringe patterns were obtained for complexes **3** and **8**, whereas the Maker fringe patterns for complexes **9** and **10** were poor S/N. The SH intensities are dependent

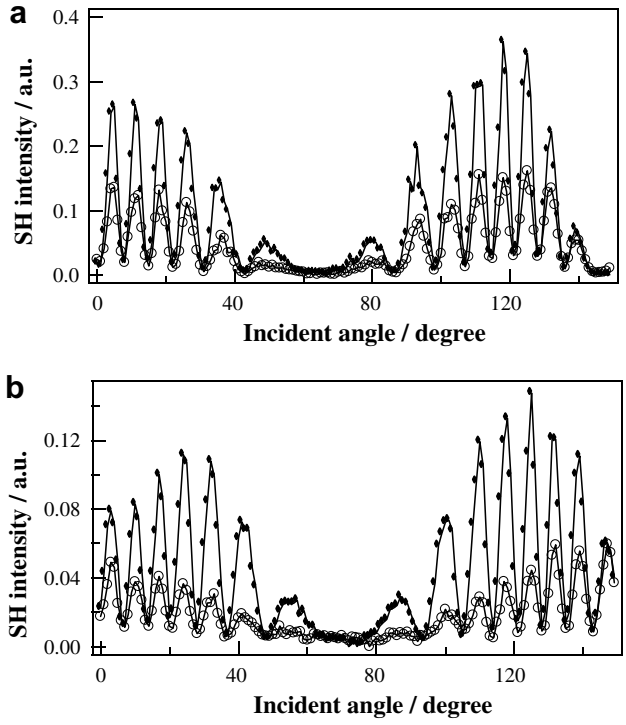

Fig. 4. Maker fringe pattern for **3** (a) and **4** (b). (♦) is irradiate laser polarized p (parallel) and (○) is irradiate lase polarized s (perpendicular).

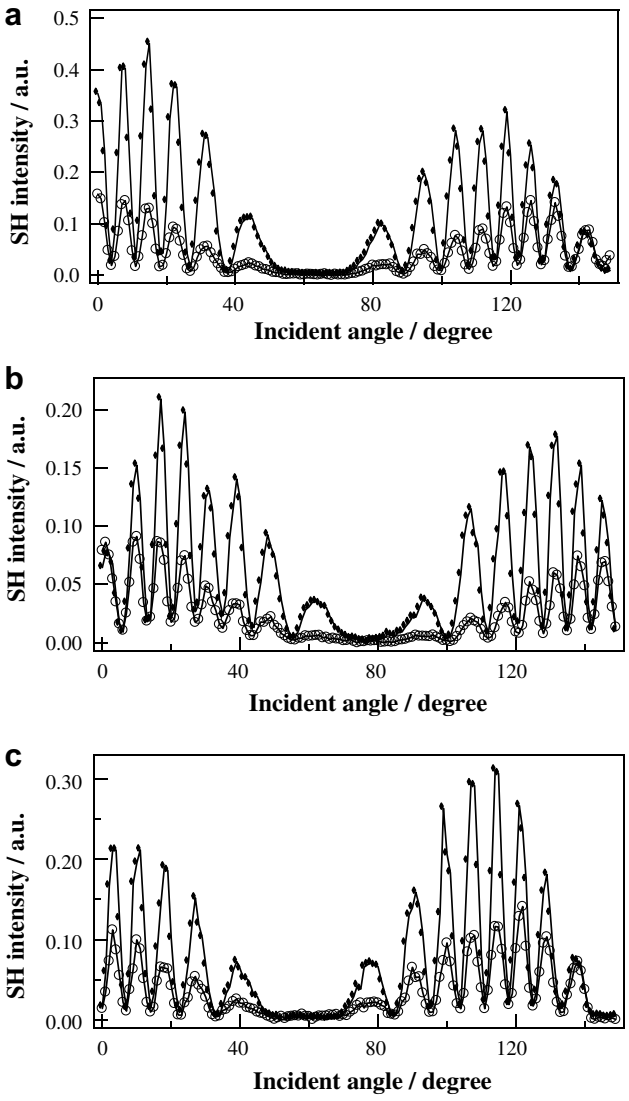

Fig. 5. Maker fringe pattern for **5** (a), **6** (b) and **7** (c). (♦) is irradiate laser polarized p (parallel) and (○) is irradiate lase polarized s (perpendicular).

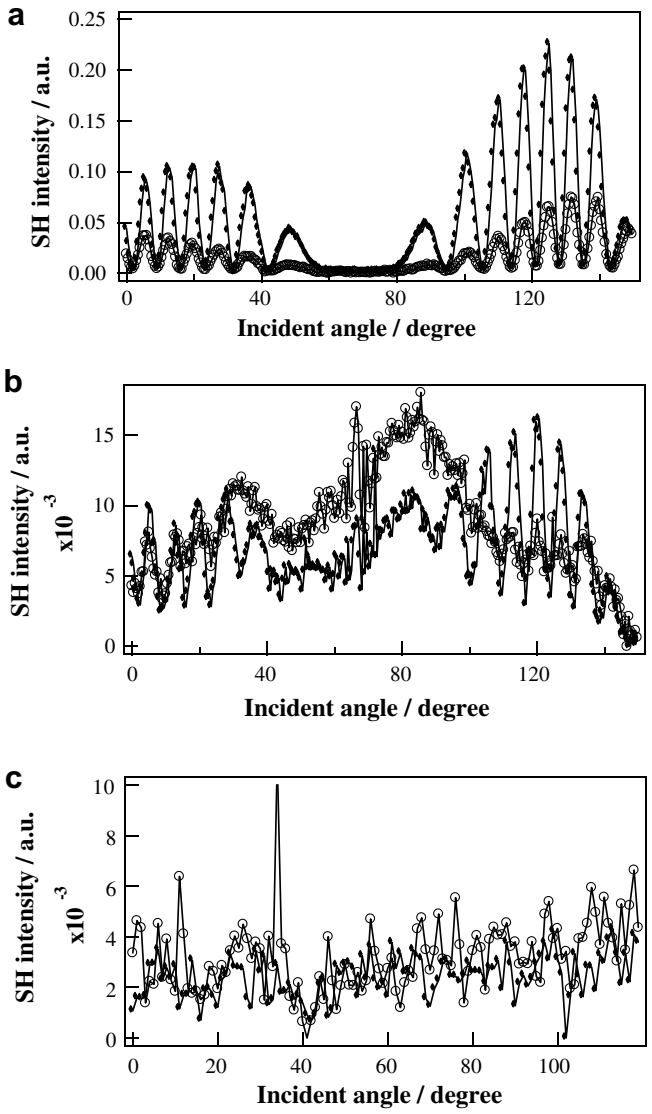

Fig. 6. Maker fringe pattern for **8** (a), **9** (b) and **10** (c). (♦) is irradiate laser polarized p (parallel) and (○) is irradiate lase polarized s (perpendicular).

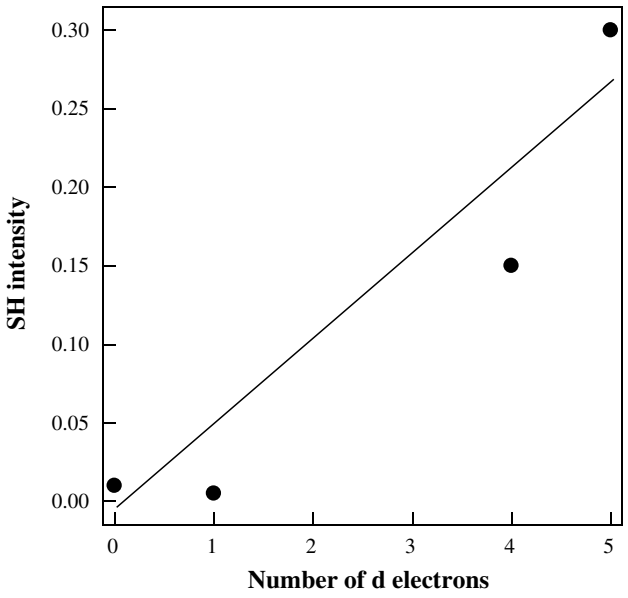

Fig. 7. The relation of number of d electrons and SH intensities.

on the kind of the metal ions, and the order of the intensities are **3** (Fe^{III}; $S = 5/2$) > **8** (Mn^{III}; $S = 2$) > **9** (Ni^{II}; $S = 0$) > **10** (Cu^{II}; $S = 1/2$) (Fig. 7). This order does not correspond to number of d electrons at the order of compounds **9** and **10**. However, this result is reasonable by taking the magnitude of SHG response for **9** and **10** into account.

4. Conclusions

Complexes **1**–**10** which have long alkyl chains to form LB films easily synthesized for the purpose of observing macroscopic second-order non-linearities. The preparation of LB films were succeed for complexes **1**–**10**. The SHG responses were investigated for the complexes in LB films, and the response was observed for the LB film form by some metal complexes. Especially, relatively large SHG signals were observed for compounds with salen or salmmen ligand. In complexes **3** and **8**–**10**, relationship between d electron and SHG intensities is similar to that of microscopic non-linearity. The goal of this study is switching of NLO response by using of SCO and LIESST effect. LB film formed by complex which can easy to change axis ligands is expected to good approach to achieve the purpose. However, complex **5**–**7** using in this study have a problem of stability in solution. Therefore, other complexes suitable for LB film (i.e. complex with stable orientation in LB film) are required. Furthermore, the evaluation of quality of LB film and the estimation method of SHG response are also needed.

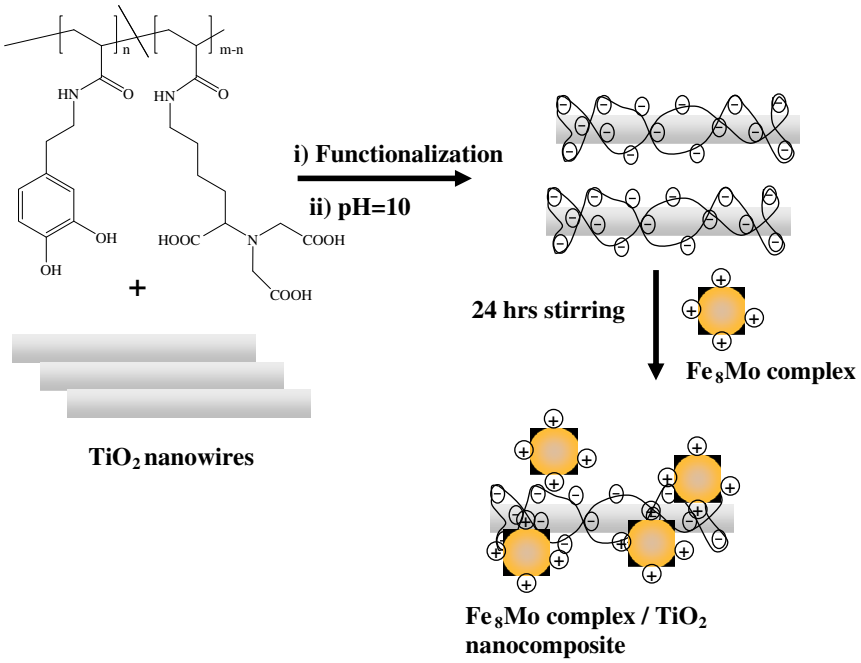
docking to the central Mo atom. The resulting dendrimer-type $[(LFe^{III}NC)_8Mo^{IV}]Cl_4$ clusters may display a maximum of eight multiple spin-crossovers, e.g. it may contain between 8 and 40 unpaired electrons and it exhibits a thermally induced spin crossover between the low-spin (LS; ^2T; $S = 1/2$) and the high-spin (HS; ^6A; $S = 5/2$) states.

Any practical application of molecular magnets as functional units for information storage requires the addressing of individual molecules, which is, imaging, probing, and eventually manipulating individual molecules [32,33]. This goal can be realized most easily by depositing target molecules on a suitable substrate with monolayer or submonolayer coverage [34–39] and by addressing those individually using scanning probe microscopy techniques [40]. While gold surfaces are important substrates for the examination of possible molecular transistor behaviour, other surfaces such as oxides might provide some advantages because interactions between molecule and substrate will be quite different [37]. In this contribution we describe the immobilization of $[(LFe^{III}NC)_8Mo^{IV}]^{4+}$ cation complexes onto the surface of TiO_2 nanowires using electrostatic interactions.



2. Results and discussion

We have used a multifunctional polymeric ligand to functionalize TiO_2 nanowires [41,42]. The high reactivity of pentafluorophenylacrylate active ester polymers with amines allows the formation of the corresponding poly (acrylamides) and opens the possibility to obtain multifunctional polymeric materials [43,44]. We have demonstrated the versatile use of these multifunctional polymers by covalent immobilization of functional molecules onto nanomaterials to build hierarchically organized nanoarchitectures [41,42,45]. As a step further, we exploit here the importance of these polymeric ligands to construct nanoarchitectures based on electrostatic interactions.

The synthesis of the multifunctional polymeric ligand starting from the precursor polymer was carried following the strategy outline in Refs. [41–44]. The resulting polymer exhibits two different properties: (i) 3-hydroxytyramine as an anchor group for the attachment onto the TiO_2 nanowires surface and (ii) multi-carboxylic groups in the back bone of polymeric ligand to create negatively charged surfaces. The multifunctional polymers were

Scheme 1. (a) Structural formula of the $[Mo^{IV}\{(CN)Fe^{III}(L)\}_8]Cl_4$ (Fe_8Mo) molecular switch. (b) Hyperchem7 calculated structure Mo and Fe atoms are enhanced.

Scheme 2. General scheme of the functionalization of TiO_2 nanowires followed by immobilization of Fe_8Mo single-molecular switch.

analyzed by ^{1}H NMR, FT-IR and GPC in order to determine the composition of the polymers. Within the polymeric ligand the respective NTA content was determined to 80 mol%, while the remaining 20 mol% of the functional groups was 3-hydroxytyramine.

Functionalization of TiO_2 nanowires was achieved by sealing a mixture of TiO_2 nanowires (synthesized from concentrated NaOH and titanium isopropoxide) [41,42] and 10 ml of polymeric ligand in benzyl alcohol under inert conditions and stirring at 60 °C for 4 h. The product was repeatedly washed with CH_2Cl_2 to remove unreacted ligand. The functionalized TiO_2 nanowires were characterized by IR and UV–Vis spectroscopy.

The immobilization of multistable molecular switches onto TiO_2 nanowires was carried out by stirring a suspension of functionalized TiO_2 nanowires in an ethanolic solution of as synthesized Fe_8Mo clusters. The structural formula of the molecular switch is shown in Scheme 1a. Scheme 1b shows the structure of the multistable Fe_8Mo complex as obtained by a molecular simulation. The approximate size of the cluster complex is about 2 nm. The fabrication of the TiO_2 nanowires decorated with spin switching iron clusters is illustrated in Scheme 2. In the first step the TiO_2 nanowires (grey) are functionalized with the multifunctional polymer ligand (black) by complexation through the catecholate groups thereby tailoring the surface of the TiO_2 nanowires with NTA groups. In the second step, the carboxylic groups were deprotonated by increasing the pH of the mixture to 10. The Fe_8Mo molecular switches were immobilized by the electrostatic interaction resulting from the net +4 charge of each Fe_8Mo cluster cation and the negatively charged functionalized TiO_2 nanowires.

Fig. 1 shows FTIR spectra of the synthesized molecular switches before and after immobilization onto TiO_2 nanowires. The absorption bands at 2847 cm^{-1} and 2920 cm^{-1}, observed in the infrared spectra show the presence of the non-aromatic C–H stretching vibrations. The aromatic C–H stretching bands seen in the free molecular switches are superimposed in the composite material. The band at 2117 cm^{-1} is assigned to the stretching vibrations of the cyano groups which indicate the presence of Fe_8Mo cluster onto TiO_2 nanowires. The absorption at 1738 cm^{-1} in the IR spectra of Fe_8Mo clusters on the TiO_2 nanowires corresponds to the C=O stretching vibrations of the polymeric ligand used for the functionalization and immobilization of the Fe_8Mo clusters on the TiO_2 nanowires.

As a comparison, the UV–Vis spectra of the as synthesized TiO_2 nanowires (black line), as synthesized Fe_8Mo molecular switches (red line), and the immobilized complexes (green line) were measured. The absorptions at 265, 236, 222 nm of the Fe_8Mo clusters (black line) in the composite material indicative the binding of Fe_8Mo clusters onto the TiO_2 nanowires (Fig. 2).

The immobilization of the Fe_8Mo clusters onto the TiO_2 nanowires was confirmed by high resolution transmission electron microscopy (HRTEM). Representative HRTEM images of iron clusters immobilized on functionalized TiO_2 nanowires are shown in Fig. 3b and c. These images show a nearly uniform dense coverage of the TiO_2 nanowires with isolated Fe_8Mo clusters over the entire length of the nanostructure. The local HRTEM image in Fig. 3c indicates that the iron clusters are spherical with approximate diameters of 2 nm. This is in good agreement with the values obtained from molecular modelling as shown in Scheme 1a. The EDX spectrum in Fig. 3d confirms the presence of Fe, Mo, along with Ti, O, and other expected elements.

Table 1 shows the results of a temperature-dependent Mössbauer study of the as-synthesized and surface bound nonanuclear Fe_8Mo cluster; Fig. 4 shows the Mössbauer spectrum of the as-synthesized cluster at room temperature and 20 K the unbound cluster undergoes a partial thermally induced spin-crossover from the high-spin (HS) to the low-spin (LS) state. The Mössbauer spectrum at room temperature exhibits a single doublet with an isomer shift IS = 0.35(1) mm s^{-1} and a quadrupole splitting ΔE_Q = 0.82(2) mm s^{-1}. These values are characteristic for Fe^{III} in the HS state. When the temperature is decreased a second quadrupole doublet appears, i.e. the transition is gradual and a low-spin fraction appears smoothly down to low-temperatures. At 20 K about 25% of the sample is present in the low-spin state. The situation changes only slightly when the Fe_8Mo cluster is immobilized on the TiO_2 nanowire surface. Similar as for the unbound cluster the spectrum at 300 K contains a single quadrupole doublet. While the IS value of 0.13(1) mm s^{-1} still is in the accepted range for Fe^{III}, its shift to lower values reflects a reduced shielding of the Fe nucleus due to the influence of the surface charge of the functionalized TiO_2 nanowire. Upon decreasing the temperature a second doublet appears whose Mössbauer parameters (IS = 0.15(1) mm s^{-1}, ΔE_Q = 2.50(2) mm s^{-1}) indicate the presence of $Fe^{(III)}$ in the LS state [46]. At 20 K the area fraction of the respective doublets A(HS-Fe^{III}):A(LS-Fe^{III}) is 83:17. These findings

Table 1
Mössbauer data of immobilized and unbound Fe_8Mo clusters.

T(K)	Site 1 (HS)				Site 2 (LS)			
	IS (mm s^{-1})	QS (mm s^{-1})	Area (%)	HWHM (mm s^{-1})	IS (mm s^{-1})	QS (mm s^{-1})	Area(%)	HWHM (mm s^{-1})
Fe_8Mo clusters immobilized on TiO_2 nanowire								
300	0.13(1)	0.55(2)	100	0.47(2)				
20	0.36(1)	0.79(2)	83.0	0.23(2)	0.15(1)	2.50(2)	17	0.25(2)
Unbound Fe_8Mo clusters								
300	0.35(1)	0.82(2)	100	0.38(2)				
20	0.37(1)	0.80(2)	83	0.39(2)	0.15(1)	2.50(2)	17	0.25(2)

indicate (i) that in the unbound state the nona-nuclear Fe_8Mo cluster undergo a thermally induced transition from the HS and to the LS state. (ii) The surface charge has some influence on the shielding of the Fe nucleus, and (iii) the spin HS → LS transition occurs for both, unbound and immobilized clusters. This important finding indicates that an isolated surface bound molecular switch still acts as a switch and remains addressable in a potential information storage step. As several $Fe^{(III)}$ centres are present in the Fe_8Mo clusters, multiple electronic transitions of surface bound molecules can be envisaged.

In summary, a Fe_8Mo molecular switch was deposited onto functionalized TiO_2 nanowires by electrostatic interactions

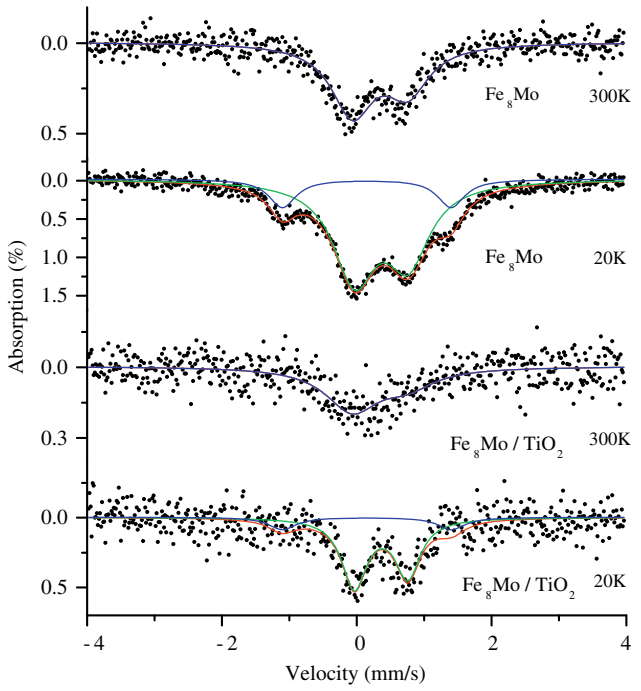

Fig. 4. Mössbauer spectra of Fe_8Mo cluster and Fe_8Mo onto TiO_2 at 300 K and 20 K.

between the cluster cations and the polymer functionalized titanium dioxide nanowire. The surface binding of the cluster molecule was demonstrated using IR and UV–Vis spectroscopy. (HR)TEM images indicate a homogeneous coverage of the TiO_2 nanowires by discrete and individual Fe_8Mo clusters. Given the small quantities of available material, a magnetic proof of the existence of SMMs on the surface cannot be obtained from bulk measurements. However, temperature-dependent Mössbauer spectroscopic studies show that the HS → LS transition observed in the free cluster molecules is preserved upon surface binding. Our results emphasize the possibility of fabricating molecule-based low-dimensional structures by using traditional bottom-up approaches based on the electrostatic interaction between the cluster cations and polymer functionalized nanowires (or oxide surfaces in general). These results can be generalized for the application to both charged and non-charged molecules.

3. Experimental

Precursor complex [Fe^{III}(L)Cl]: 12.5 mmol of the 3-methyl-salicylaldehyde were dissolved in approx. 8 mL of MeOH. 6.25 mmol of the corresponding di(aminopropyl)amine were added dropwise. This solution was boiled for 10 min. Subsequently, 6.25 mmol of $FeCl_3$ dissolved in approx. 80 mL of MeOH were added and stirred for 10 min at 50 °C. 12.5 mmol of triethylamine were added dropwise and stirred for 1 h at 50 °C. After cooling to room temperature some solvent was evaporated and the solution cooled until some precipitate appeared. This precipitate was filtered using a frit IV filter, cleaned with cold MeOH and diethylether and dried under vacuum for 24 h. Yield: 92% MS [EIMS, $C_{22}N_3H_{24}FeCl$] 421 *m/z*. C, H, N-analysis: (calc./exp.) 57.3/57.8, 6.7/5.9,9.3/9.2.

[Mo^{IV}{(CN)Fe^{III}(L)}$_8$]Cl_4 (Fe_8Mo): 10 ml of an aqueous methanol (1:1) solution of $K_4[Mo(CN)_8] \cdot 2H_2O$ (0.1 mmol) was added dropwise to 100 mL of a solution of [Fe^{III}(L)Cl] (0.8 mmol) in methanol. This mixture was stirred at room temperature for 30 min. The dark-blue solution was filtered and reduced under pressure to 50 mL at a temperature below 35 °C. For precipitation 50 mL of distilled cooled water were added. This product was filtered slowly through a frit IV funnel. The dark-blue-black molecular switch was washed with distilled water and diethyl ether and finally dried under vacuum for 24 h. Yield: 48% MS [EIMS, $(C_{22}N_3H_{24}Fe)_5$ Mo^+] 2411.8 *m/z*. MS [EIMS, C_{22} $N_3H_{24}FeCl$] 421 *m/z*. The molecular ion peak 3816.5 was not visible in EIS-MS.

The synthesis of the polymeric ligand and of the TiO_2 nanowires was carried out at as reported in Refs. [41,42].

Functionalization of TiO_2 nanowires: TiO_2 nanowires (5 mg) were dispersed in 10 mL of benzyl alcohol and sonicated for 15 min. In a separate vial 10 mg of the polymer ligand were dissolved in 10 mL of benzyl alcohol. Both suspension and solution were mixed under inert conditions and stirred at 60 °C for 4 h. Then the polymer functionalized nanowires were isolated and purified by repeated washing with CH_2Cl_2 using centrifugation. Subsequently they were dried under vacuum at room temperature.

Dried TiO_2 nanowires (3 mg) were suspended in an aqueous NaOH (0.001 M) solution and stirred at 25 °C for 1 h. The mixture was separated by filtration and washed with deionized water. Subsequently, it was dried in vacuo at 25 °C for 6 h to give the carboxylate-functionalized TiO_2 nanowires sodium salt. The functionalized TiO_2 nanowires were charged in 30 mL of ethanol, and 50 mg of Fe_8Mo, dissolved in 5 mL of ethanol were added followed by stirring for 48 h. The solid was then separated from the mixture by centrifugation and washed several times with excess ethanol. The black brown solid was collected and dried overnight in vacuo at 25 °C.

Mössbauer spectroscopy: Mössbauer measurements were performed in transmission geometry using a constant-acceleration spectrometer and a helium bath cryostat. ^{57}Fe Mössbauer spectra were recorded between room temperature and 4.2 K using the 50 mCi source ^{57}Co(Rh). The RECOIL 1.03 Mössbauer Analysis Software was used to fit the experimental spectra [47]. Isomer shift values are quoted relative α-Fe at 293 K.

2.4. X-ray crystal structure determination

A suitable crystal of **1**, **2** or **3** was mounted on a glass fiber. The X-ray measurements were made on a Rigaku/MSC Mercury CCD diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71069 Å). The diffraction data were collected at 110 K for complex **1**, 150 K for complex **2** and 106 K for complex **3** using the multi scan technique and totals of the 30107, 12902 and 10827 reflections were collected for **1**, **2** and **3**, respectively. The linear absorption coefficients μ were 0.632, 0.865 and 1.124 for **1**, **2** and **3**, respectively. Data were collected and processed using the CRYSTALCLEAR program (Rigaku). The structures were solved by direct methods (SIR-92 for **1** and SIR-97 for **2** and **3**) [3] and expanded using Fourier techniques [4]. All the non-hydrogen atoms of complexes **1** and **3** were refined anisotropically, while in complex **2**, disordered EtOH oxygen atoms O2 and O3 were refined isotropically with site occupation factors of 0.15 and 0.35, respectively, and the other non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. The final cycle of full-matrix least squares refinements [5] were based on 5846 reflections ($I > 2\sigma(I)$) and 370 variable parameters for **1**, 2122 reflections ($I > 2\sigma(I)$) and 135 variable parameters for **2**, and 4237 reflections ($I > 2\sigma(I)$) and 263 variable parameters for **3**. The unweighted and weighted agreement factor of $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_w = [\sum[w(F^2_o - F^2_c)^2]/\sum w(F^2_o)^2]^{1/2}$ are used. The R_1 and R_w values were (0.097 and 0.1953), (0.076 and

0.1392) and (0.0328 and 0.0820) for complexes **1**, **2** and **3**, respectively. All calculations were performed using the TEXSAN crystallographic software package of Molecular Structure Corporation.[2] Crystal data and details of the structure determination are summarized in Table 1.

2.5. Magnetic susceptibility measurements

Magnetic susceptibility data were collected on fresh microcrystalline samples on a Quantum Design MPMS2 SQUID magnetometer equipped with a 1 T magnet and capable of achieving temperatures of 1.7–400 K. A diamagnetic correction to the observed susceptibilities was applied using Pascal's constants.

3. Results and discussion

3.1. Sample preparation

Although the preparation of **1** and **2** were conducted with the excess bridging ligands, the dimer or monomer complexes were obtained. Possible reason is the low solubility of this type of complex, especially having extended p system such as naphthalene moiety. The low solubility of dimers prevents further coordination of bridging ligand to form one-dimensional chain in solution. Changing solvents may induce different results.

3.2. Crystal structure of $[Fe_2(L1)_2(4,4'\text{-bpy})] \cdot 2MeOH$ (**1**)

The molecular structure of **1** together with the atom numbering scheme is shown in Fig. 1a. Selected bond lengths and angles are summarized in Table 2. Two Fe(II)–L1 moieties are connected through 4,4′-bpy bridge and the molecule has an inversion center at the center of the 4,4′-bpy ligand. Each Fe(II) ions has a penta-coordinate square pyramidal geometry with a 0.296 Å lift of Fe(II) ion from the basal N_2O_2 plane. Bond lengths around the Fe(II) ion are shown in Table 2. The average Fe–O and Fe–N bond lengths are 1.97 and 2.11 Å, respectively, which are clearly longer than those reported for low-spin complexes (1.952 and 1.946 Å) [2c], indicating that the Fe(II) ion has a high-spin state. The dihedral angle of two naphthalene planes in each Fe(II)–L1 moiety is 41.6°. This is clear difference in one-dimensional chain complex bridged by pyz, [Fe(3-MeO–salophen)pyz] · CH_2Cl_2 [2c], where the corresponding dihedral angle is almost 0°. A molecular structure viewed from Fe–bpy–Fe′ direction is shown in Fig. 1b. Two pyridine planes in 4,4′-bpy are completely parallel. They are also parallel to the plane defined by N1–O2–N1′–O2′. This implies a possibility of interaction between two Fe(II) ions through p-orbitals of 4,4′-bpy, although Fe···Fe′ distances through 4,4′-bpy bridge is 11.431 Å and the magnetic interaction through 4,4′-bpy bridge is thought to be negligibly small [6,7]. Another interesting feature of this compound is the possibility of Fe···π interaction. As can be seen from the molecular packing view shown in Fig. 2, a phenyl ring of L1 belonging to the neighboring molecule is near the vacant site of Fe(II) ion with Fe···C3 distance of 3.486 Å, which leads to the Fe···Fe distance of 6.038 Å for the neighboring molecule. Since there are rich π–π interaction between the phenyl ring and naphthalene moieties, the Fe···π interaction may be induced by these π–π interactions. From the bond valence sum (BVS) analysis [8] of the Fe center, the oxidation state was estimated to be +2.37, which is, although slightly larger than expected, consistent with the valence of +2 for the Fe(II) ion.

3.3. Crystal structures of [Fe(L2)(EtOH)] (**2**) and [Fe(L3)(MeOH)] (**3**)

The ORTEP drawings of molecular structures of **2** and **3** including their molecular packing views are shown in Figs. 3 and 4, respectively. Both complexes show mononuclear structures with penta-coordinate square pyramidal geometries. The Fe(II) ions are surrounded by bis-Schiff base N_2O_2 donors from the equatorial position and an alcohol oxygen from the apical position. Bond

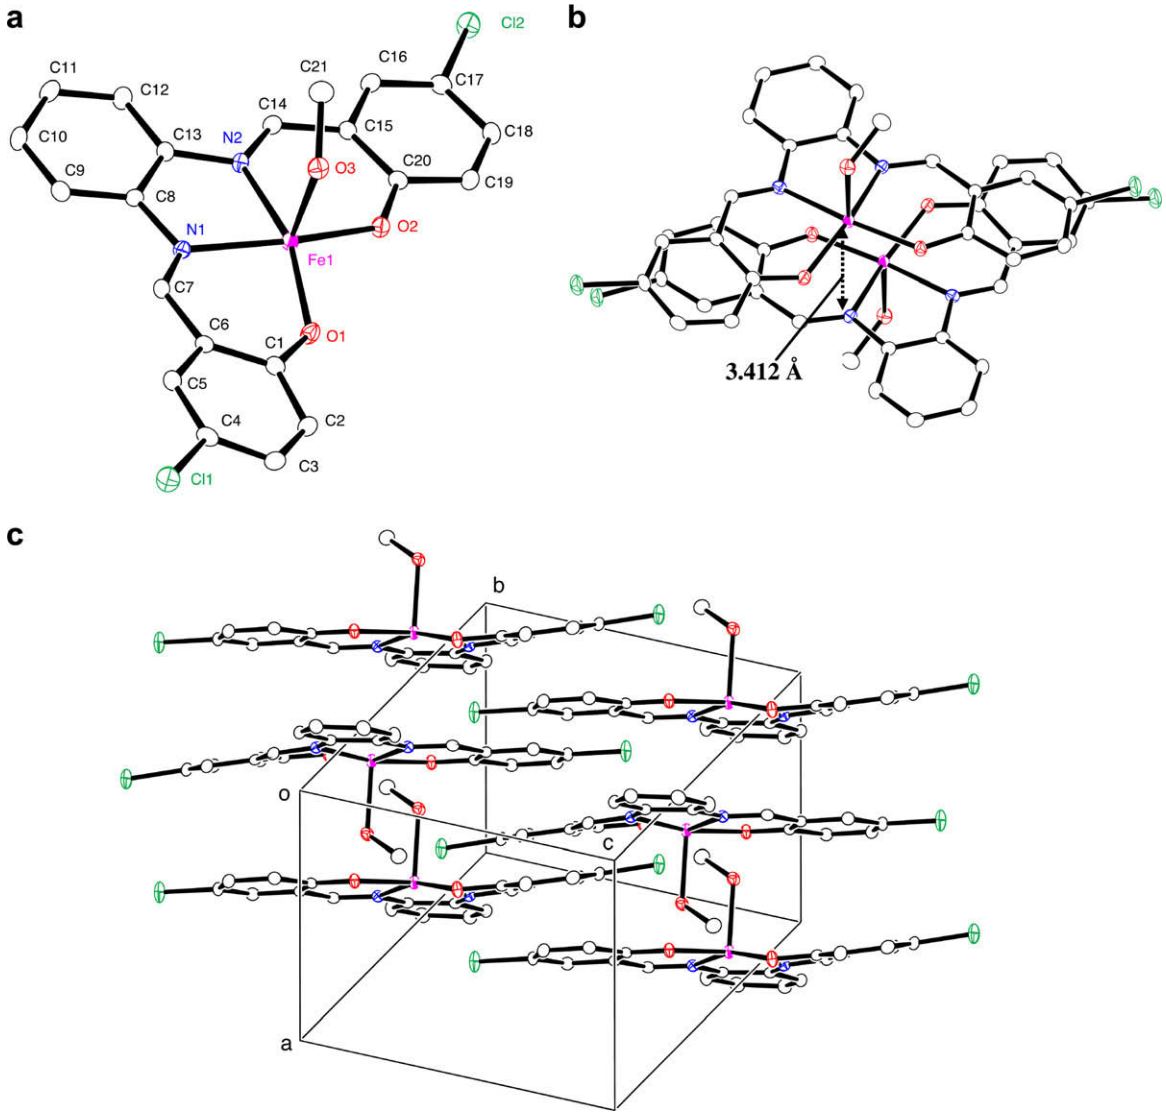

Fig. 4. (a) ORTEP drawing of **3**, showing the 50% probability ellipsoids. Hydrogen atoms have been omitted for clarity. (b) Dimeric structure of **3** through π–π interaction. (c) A molecular packing view of **3**.

lengths and angles around Fe(II) ions are tabulated in Table 2, which clearly indicates both Fe(II) ions are HS states. BVS analyses of Fe(II) ions gave the oxidation states of the iron ions to be +2.31 and +2.01 for complexes **2** and **3**, respectively. These values are again consistent to the valences of these iron ions. The dihedral angles of wing phenyl rings for **2** and **3** are 32.34° and 11.37°, respectively. The larger dihedral angle is corresponds to the larger displacement of the Fe(II) ion in **2** (0.356 Å) from the basal plane compared to that of **3** (0.223 Å). As can be seen from the molecular packing of **2** shown in Fig. 3b, each mononuclear complex is connected through π–π interaction (C4···C9′: 3.316 Å) and hydrogen bonds (O1···O2′: 2.9 Å) to form one-dimensional structure. Intrachain Fe···Fe′ distance is 5.168 Å. On the other hand, the molecular packing of **3** shown in Fig. 4b indicates a formation of a dimer structure through π–π interaction (C6···C16′:3.30 Å, O1···C14′: 3.106 Å) or Fe···π interaction (Fe1···N2′: 3.412 Å). The neighboring dimers are further connected through hydrogen bonds between coordinated alcohol oxygen and L3 (O1···O3′: 2.657 Å) as shown in Fig. 4c. Intra-dimer Fe···Fe′ distance is 4.021 Å while inter-dimer Fe···Fe′ distance is 4.721 Å. These rather short Fe···Fe′ separations indicate this structure can be seen as a dimer chain or an alternating one-dimensional chain.

3.4. Magnetic properties of *1*–*3*

Thermal variations of the $\chi_M T$ products for **1**–**3** are shown in Fig. 5. The $\chi_M T$ product of complex **1** at room temperature is 6.1 $cm^3\,K\,mol^{-1}$, being close to what is expected for two HS Fe(II) ions with $S = 2$. As the temperature is lowered, it increases below 50 K and reaches to 6.9 $cm^3\,K\,mol^{-1}$ at 14 K. The ferromagnetic interactions are also observed in complexes **2** and **3**. The $\chi_M T$ products of them at room temperature are around 3 $cm^3\,K\,mol^{-1}$ and again consistent to the existence of one HS Fe(II) ions with $S = 2$. As decreasing temperature, they are almost constant until 50 K and then gradually increase to show peak maxima of 4.14 $cm^3\,K\,mol^{-1}$ at 15 K for **2** and of 3.3 $cm^3\,K\,mol^{-1}$ at 10 K for **3**, then both decrease at lower temperatures. Since Fe(II) ion can be treated as Heisenberg-like in its behavior [9], except at very low temperature where some anisotropy may be important, we carried out data-fitting for the observed data above 15 K by using a simple spin Hamiltonian (1) for a dimer model.

$$\hat{H} = -2J_1 S_1 S_2 + g\mu_B(S_1 + S_2)B \quad (1)$$

The best fits are shown in Fig. 5 as solid lines and the obtained parameters are appeared in Table 3 together with those of related

$[Fe_2(salen)_2(4,4'\text{-bpy})(NCS)_2]$[a]	2.03	−0.38
$[Fe_2(salpn)_2(\mu\text{-}N_3)_2]$[b]	1.964	1.054

[a] From Ref. [10].
[b] From Ref. [11].

complexes. Although these ferromagnetic interactions observed in **1**–**3** are small, some explanations are needed. As for the ferromagnetic interaction in complex **1**, there are two possible interaction pathways: through bpy ligand and through Fe···π interaction. As mentioned in the structure section, the perfect planarity of the bpy ligand together with the coincidence of the bpy plane and the coordinating plane (N1–O2–N1′–O2′) implies effective Fe···Fe′ interaction through bpy π-orbital, although antiferromagnetic interaction was reported for the bpy-bridged Fe(III) dimer with similar bis-Schiff base ligand [10]. However, we should abandon this idea because the complex **2** with uniform one-dimensional structure exhibits ferromagnetic behavior. The possible explanation for this phenomenon is the dimerization through Fe···π interaction occurred at lower temperature than X-ray measurement (150 K). If this type of dimerization can be occurred in complex **2**, the reason for the appearance of ferromagnetic behavior in **1** is also ascribed to the dimerization through Fe···π interaction at low temperature, not through bpy-bridge. The ferromagnetic interaction observed in **3** is reasonably understood by the dimer structure through π–π interaction together with relatively short Fe···Fe′ distance of 4.021 Å.

4. Concluding remarks

The Schiff base complexes are so famous but still many things remain unclear especially in solid state properties. Tetradentate bis-Schiff base macrocyclic ligands studied here forms unprecedented structures together with ferromagnetic behaviors. The origin of ferromagnetic interaction in complexes **1** and **2** are still unclear. They show significant Fe···π interaction, indicating dimerizations induced by this interaction maybe occurred at low temperature.

Supplementary data

CCDC 702693, 702694, 702695 contains the supplementary crystallographic data for **1**, **2** and **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

that bracket T_c [9]. Both the inverse, low-temperature transition $T_{JT}^{(l)}$ and the normal, high-temperature transition $T_{JT}^{(u)}$ are first order or discontinuous when the elastic parameters are appropriately chosen. A comparison with recent experiments [10] allows us to estimate the normal JT transition temperature $T_{JT}^{(u)}$ for Fe(II)Fe(III) bimetallic oxalates that exhibit MC. For normal Fe(II)Fe(III) compounds, the JT distortion either persists down to $T = 0$ if the doublet lies below the singlet or is absent altogether if the singlet lies below the doublets.

This paper contains an extended description of the JT transition first discussed in Ref. [9]. Section 2 develops the phenomenological model for MC and the JT distortion, with results discussed in Section 3. First-principles calculations are described in Section 4 and a summary is presented in Section 5.

2. Model

Bimetallic oxalates are characterized by three energy scales. The dominant energy is the Hund's coupling that determines the spins $S = 2$ and $S' = 5/2$ on the Fe(II) ($3d^6$) and Fe(III) ($3d^5$) sites. Next in importance is the C_3-symmetric crystal field V generated by the 6 oxygen atoms around each of the Fe sites. These 6 oxygen atoms form two triangles of slightly different sizes rotated by about 48° with respect to each other, one above and the other below the plane of Fe atoms. Because the two triangles have different sizes, the six oxygen atoms do not span a trigonally-compressed octahedron [11] and C_3 symmetry is the only point-group symmetry obeyed by the crystal-field potential. The weakest energies are the antiferromagnetic exchange coupling $J_c\mathbf{S}_i \cdot \mathbf{S}'_j$ between the Fe(II) and Fe(III) moments within each bimetallic layer, the spin–orbit coupling $\lambda\mathbf{L}_i \cdot \mathbf{S}_i$ on the Fe(II) sites ($\lambda \approx -12.65$ meV [12]), and any non-C_3-symmetric contributions of the crystal potential.

As shown in Fig. 1b, the C_3-symmetric potential V splits the $L = 2$ multiplet of the Fe(II) sites into two doublets $\psi_{1,2}$ and $\psi_{4,5}$, and a singlet ψ_3. We demonstrated in Ref. [8b] that the low-energy doublet $\psi_{1,2}$ carries an average orbital angular momentum $L_z^{cf} = |\langle\psi_{1,2}|L_{iz}|\psi_{1,2}\rangle|$ between 0 and 2, depending on the crystal-field parameters. Of course, the singlet state ψ_3 does not carry any orbital angular momentum.

Keep in mind that the orbital angular momenta L_z^{cf} of the low-energy doublet is modified by the crystal fields. It is not the same as the total angular momenta L of the Fe(II) multiplet before the crystal field is taken into account. Because $\langle\psi_{1,2}|\mathbf{L}_i|\psi_{1,2}\rangle = \pm L_z^{cf}\mathbf{z}$, the average orbital angular momentum of the doublet is an Ising-like degree of freedom.

So the effective Hamiltonian of the Fe(II)Fe(III) bimetallic oxalates is given by

$$H = J_c \sum_{\langle i,j\rangle} \mathbf{S}_i \cdot \mathbf{S}'_j - |\lambda| \sum_i S_i^z L_i^z, \tag{1}$$

where the $\langle i,j\rangle$ sum runs over all nearest-neighbors and the i sum runs over all Fe(II) sites. The antiferromagnetic exchange J_c is positive. As discussed above, $L_i^z = \pm L_z^{cf}$. This model has recently been generalized [13] to treat any bimetallic oxalate, with possible spin–orbit coupling on both the M(II) and M′(III) sites.

Including its orbital contribution, the Fe(II) magnetic moment can be written $M(T) = M_S(T) + M_L(T) \leqslant 0$, where $M_S = 2\langle S_i^z\rangle$ and $M_L = \langle L_i^z\rangle$. The Fe(III) magnetic moment $M'(T) = M_{S'}(T) = 2\langle S_j^{z'}\rangle \geqslant 0$ contains no orbital contribution. Mean-field (MF) theory is used to treat the nearest-neighbor exchange

$$J_c\mathbf{S}_i \cdot \mathbf{S}'_j \approx J_c\left\{\left(M_S S_j^{z'} + S_i^z M_{S'}\right)/2 - M_S M_{S'}/4\right\} \tag{2}$$

between neighboring Fe(II) and Fe(III) spins. The MF eigenvalues of $\psi_{1,2;\sigma}$ and $\psi_{3\sigma}$ with z spin component $\sigma = 0, \pm 1$ or ± 2 are

$$\epsilon_{1\sigma} = (-|\lambda|L_z^{cf} + 3J_c M_{S'}/2)\sigma, \tag{3}$$

$$\epsilon_{2\sigma} = (|\lambda|L_z^{cf} + 3J_c M_{S'}/2)\sigma, \tag{4}$$

$$\epsilon_{3\sigma} = (3J_c M_{S'}/2)\sigma + \Delta, \tag{5}$$

so that the doublet $\psi_{1,2;\sigma}$ is split by the spin–orbit coupling with $|\epsilon_{2\sigma} - \epsilon_{1\sigma}| = 2|\lambda\sigma|L_z^{cf}$. Because the crystal-field potential is assumed much larger than the spin–orbit and exchange energies, $|\Delta| \gg J_c$ or $|\lambda|$.

Using Eqs. (3) and (4) for the eigenvalues $\epsilon_{1,2;\sigma}$, it is straightforward to evaluate $M(T), M'(T)$, and the average magnetization $M^{avg}(T) = (M(T) + M'(T))/2 = (|M'(T)| - |M(T)|)/2$. When $l_c \approx 0.238 < L_z^{cf} < 1, M^{avg}(T)$ passes through 0 at the compensation temperature $T_{comp} < T_c$. Just below $T_c, M^{avg}(T) < 0$ because the parallel spin–orbit coupling between $\mathbf{L}_i$ and $\mathbf{S}_i$ causes the Fe(II) moment $M(T)$ to increase in amplitude more rapidly than the Fe(III) moment $M'(T)$. But at $T = 0$, the Fe(III) moment saturates at the larger value $|M'(0)| = 2S' > |M(0)| = 2S + L_z^{cf}$ so that $M^{avg}(0) > 0$.

After comparing the observed values of $T_{comp}/T_c \approx 0.62$ and $T_c \approx 45$ K with the theoretical predictions, we estimated [8] that $J_c \approx 0.46$ meV and $L_z^{cf} \approx 0.28$ in MC compounds. Normal compounds can fall into two categories. Either the doublet remains lower than the singlet ($\Delta > 0$) but with $L_z^{cf} < l'_c \approx 0.234$ or the singlet lies lowest in energy ($\Delta < 0$). Our model also predicted that two compensation points were possible in the narrow window $l'_c < L_z^{cf} < l_c$. The recent observation by Tang et al. [10] of two compensation points in the compound $N(n\text{-}C_4H_9)_4[Fe(II)Fe(III)ox_3]$ (data shown in the inset to Fig. 2a) would seem to confirm that prediction.

In the absence of spin–orbit coupling, a doubly-degenerate level occupied by a single electron is always split by a local displacement of the ion, which linearly lowers the electronic energy while incurring a quadratic cost in the elastic energy. The mixing of the Fe(II) eigenstates $\psi_{1\sigma}$ and $\psi_{2\sigma}$ due to the JT distortion is described by the Hamiltonian[1]

$$\underline{H}_\sigma^{mix} = \begin{pmatrix} \epsilon_{1\sigma} & \xi \\ \xi & \epsilon_{2\sigma} \end{pmatrix}, \tag{6}$$

where ξ is independent of σ. If $\epsilon_{1\sigma} = \epsilon_{2\sigma}$ are given by the MF result $\epsilon_{0\sigma} \equiv 3J_c M'\sigma/2$, then the eigenstates of $\underline{H}_\sigma^{mix}$ are

[1] Diagonal terms in $\underline{H}_\sigma^{mix}$ involving ξ can be neglected because the doublet states are related by the time-reversal operations $\psi_{1\sigma} = -K\psi_{2,-\sigma}$ and $\psi_{2\sigma} = -K\psi_{1,-\sigma}$, where K is the time-reversal operator. So for any spin-independent electrostatic potential $V = K^{-1}VK, \langle\psi_{1\sigma}|V|\psi_{1\sigma}\rangle = \langle\psi_{2,-\sigma}|K^{-1}VK|\psi_{2,-\sigma}\rangle = \langle\psi_{2\sigma}|V|\psi_{2\sigma}\rangle$, leading only to a shift of the doublet with respect to the singlet.

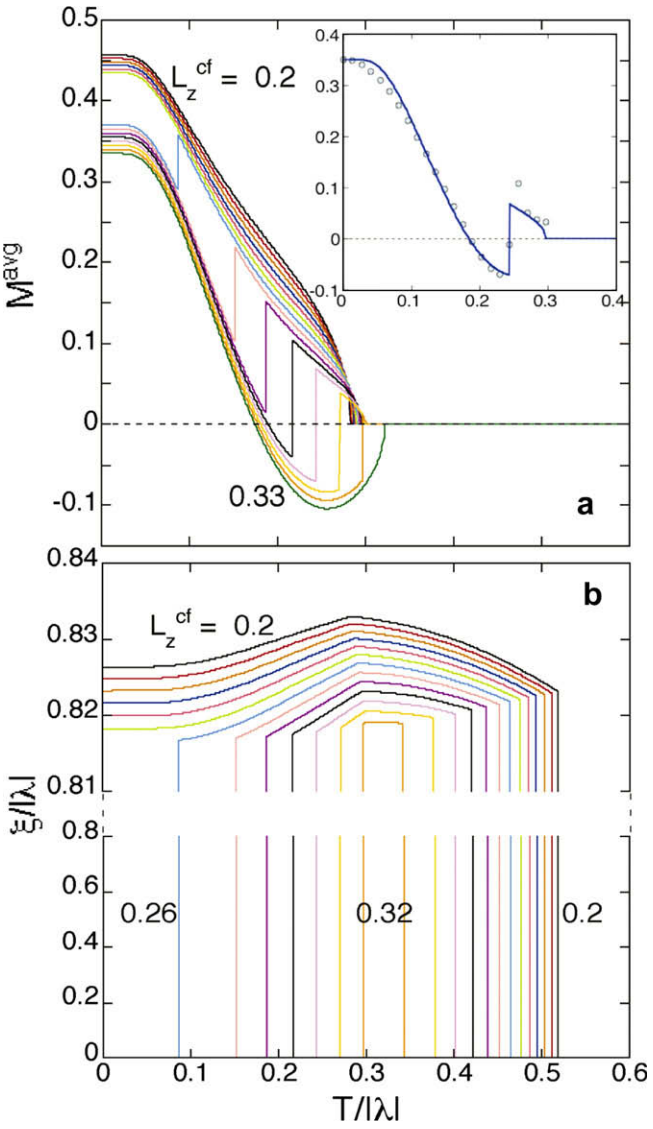

Fig. 2. (a) The average magnetization and (b) the JT energy ξ normalized by $|\lambda|$ versus temperature $T/|\lambda|$ for a range of L_z^{cf} in increments of 0.01 using $J_c/|\lambda| = 0.037$ and the elastic constants given in the text. Inset in (a) is the average magnetization for $L_z^{cf} = 0.3$ together with the experimental data of Ref. [10] rescaled so that $M^{avg}(0) = 0.35$.

$\psi_{a\sigma} = (1/\sqrt{2})(\psi_{1\sigma} + \psi_{2\sigma})$ and $\psi_{b\sigma} = (1/\sqrt{2})(\psi_{1\sigma} - \psi_{2\sigma})$, with $L_{a,b;\sigma} = \langle\psi_{a,b;\sigma}|L_i^z|\psi_{a,b;\sigma}\rangle = 0$ and eigenvalues $\epsilon_{a,b;\sigma} = \epsilon_{0\sigma} \pm \xi$. So in the absence of spin-orbit coupling, the average orbital angular momentum is quenched by the JT distortion and the doublet $\psi_{a,b;\sigma}$ is split by $2|\xi|$. The $T = 0$ energy is then given by

$$\frac{E}{N} = -3J_cSS' - \xi + \alpha\frac{\xi^2}{|\lambda|}, \tag{7}$$

where the final term is an elastic restoring potential and N is the number of Fe(II) or Fe(III) sites in each bimetallic layer. Since $\alpha > 0$, the $T = 0$ equilibrium value for ξ is $\xi(0) = |\lambda|/2\alpha > 0$.

Including the spin–orbit interaction $-|\lambda|\mathbf{L}_i \cdot \mathbf{S}_i$ and using the MF values $\epsilon_{1\sigma}$ and $\epsilon_{2\sigma}$ given by Eqs. (3) and (4), the eigenvalues of $\underline{H}_\sigma^{mix}$ are

$$\epsilon_{a\sigma} = \epsilon_{0\sigma} + t_\sigma, \tag{8}$$
$$\epsilon_{b\sigma} = \epsilon_{0\sigma} - t_\sigma, \tag{9}$$

where

$$t_\sigma = -\mathrm{sgn}(\sigma)\sqrt{(\lambda L_z^{cf}\sigma)^2 + \xi^2}. \tag{10}$$

Hence, the doublet splitting $\delta \equiv 2|t_\sigma|$ is enhanced by the JT effect (strictly speaking, the pseudo-JT effect when $\epsilon_{1\sigma} \neq \epsilon_{2\sigma}$). Because there is no spin-orbit coupling when $\sigma = 0, t_0 = \xi$ and $L_{a0} = L_{b0} = 0$. Since $t_{-2} > 0$ and $\epsilon_{0,-2} < 0$, the lowest eigenvalue of $\underline{H}_\sigma^{mix}$ is $\epsilon_{b,-2}$.

For $\sigma \neq 0$, the spin-orbit coupling maintains a nonzero average orbital angular momentum $L_{a\sigma} = -L_{b\sigma}$ even in the presence of a JT distortion:

$$L_{a\sigma} = (L_z^{cf})^2|\lambda|\sigma\frac{|\lambda|L_z^{cf}\sigma - t_\sigma}{(\lambda L_z^{cf}\sigma)^2 - |\lambda|L_z^{cf}\sigma t_\sigma + \xi^2}, \tag{11}$$

so that $L_{a\sigma} = L_{a,-\sigma}$. Since $\sigma t_\sigma < 0$, we see that $L_{a\sigma} \geqslant 0$. When $\xi \neq 0$, the JT distortion suppresses the average orbital angular momenta $L_{a\sigma} < L_z^{cf}$ for $\sigma = \pm 1$ and ± 2, as described in Ref. [8b].

With a correction to avoid double counting, the MF free energy can be written

$$\frac{F}{N} = -T\log\{Z_{II}Z_{III}e^{3J_cM_SM_{S'}/4T}\} + \alpha|\lambda|\left\{\left(\frac{\xi}{|\lambda|}\right)^2 + \gamma_3\left(\frac{\xi}{|\lambda|}\right)^3 + \gamma_4\left(\frac{\xi}{|\lambda|}\right)^4\right\}, \tag{12}$$

where

$$Z_{II} = 2\sum_\sigma e^{-3J_cM_{S'}\sigma/2T}\cosh(t_\sigma/T), \tag{13}$$

$$Z_{III} = 2\sum_{\sigma'} e^{-3J_cM_S\sigma'/2T}. \tag{14}$$

The sums in the partition functions Z_{II} and Z_{III} are over $\sigma = 0, \pm 1, \pm 2$ and $\sigma' = \pm 1/2, \pm 3/2, \pm 5/2$. The second line in Eq. (12) corresponds to the elastic energy.

Breaking C_3 symmetry, a local JT distortion with $\pm\xi$ involves the displacement of an Fe(II) atom either into one of the three open hexagons or towards one of the three neighboring Fe(III) atoms. The former distortions are sketched in Fig. 1a. The $\gamma_3(\xi/|\lambda|)^3$ term in Eq. (12) reflects the different energy costs for those two types of distortions. Thus, an anharmonic restoring potential arises quite naturally on the open honeycomb lattice. The sign of γ_3 does not affect any physical results and is chosen to be negative only for convenience so that the free energy is minimized when $\xi \geqslant 0$. Any fluctuations between the distorted atomic configurations are assumed slow compared to the electronic time scales.

It is simple to obtain the equilibrium values for M_S and $M_{S'}$ from the extremal conditions $\partial F/\partial M_S = \partial F/\partial M_{S'} = 0$:

$$M_S = \frac{4}{Z_{II}}\sum_\sigma \sigma e^{-3J_cM_{S'}\sigma/2T}\cosh(t_\sigma/T), \tag{15}$$

$$M_{S'} = 2S'B_{S'}(-3J_cM_SS'/2T), \tag{16}$$

where $B_{S'}(x)$ is the spin S' Brillouin function. Because the spin-orbit energy $-|\lambda|\mathbf{L}_i \cdot \mathbf{S}_i$ is treated exactly, M_L is not a variational parameter in the MF free energy and must be determined separately from the condition

$$M_L = -\frac{2}{Z_{II}}\sum_\sigma L_{a\sigma}e^{-3J_cM_{S'}\sigma/2T}\sinh(t_\sigma/T). \tag{17}$$

At $T = 0$, the $\sigma = -2$ term dominates in both the numerator and denominator of Eq. (17) and $M_L(0) = -L_{a2} = L_{b,-2} < 0$. Of course, the equilibrium value for the JT energy is obtained from the extremal condition $\partial F/\partial\xi = 0$.

3. Model results

The average magnetization and JT energy ξ are plotted versus temperature in Fig. 2a and b for $\alpha = 3.7, \gamma_3 = -1.9$, and $\gamma_4 = 1.1$.

As expected, the MC threshold $l_c \approx 0.282$ is enhanced by the JT distortion. When $L_z^{cf} < 0.260$, the JT distortion $\xi(T)$ persists down to $T = 0$. For $L_z^{cf} = 0$ (but still taking $\Delta > 0$), $\xi(0) \approx 0.842|\lambda| \approx 10.5$ meV and $T_{JT}^{(u)} \approx 0.578|\lambda|$. For $L_z^{cf} = 0.2$, the JT distortion would increase the splitting of the $\sigma = 2$ doublet from $4|\lambda|L_z^{cf} = 10$ meV to $2\sqrt{(2\lambda L_z^{cf})^2 + \xi^2} \approx 23$ meV.

When $L_z^{cf} \geqslant 0.260$, the JT distortion is quenched at $T = 0$ due to the strong orbital ordering. For $0.324 \geqslant L_z^{cf} \geqslant 0.260$, we obtain both lower and upper JT transitions, $T_{JT}^{(l)}$ and $T_{JT}^{(u)}$. Notice that ξ vanishes below $T_{JT}^{(l)}$ and is nonzero above $T_{JT}^{(l)}$. The temperature range $T_{JT}^{(u)} - T_{JT}^{(l)}$ decreases as L_z^{cf} increases and vanishes when $L_z^{cf} > 0.324$. We find that the JT transitions at $T_{JT}^{(u)}$ and $T_{JT}^{(l)}$ always bracket T_c. The first-order or discontinuous nature of the JT transitions at $T_{JT}^{(u)}$ and $T_{JT}^{(l)}$ is caused by the anharmonic term $\gamma_3(\xi/|\lambda|)^3$ in the free energy of Eq. (12).

Because the orbital contribution $M_L(T)$ to the Fe(II) moment drops as ξ jumps at the inverse JT transition, $T_{JT}^{(l)}$ is marked by a discontinuous increase in $M^{avg}(T)$. With decreasing L_z^{cf}, both the orbital contribution $M_L(T)$ and the magnitude of the change in $M^{avg}(T)$ become smaller. For $l_c < L_z^{cf} \leqslant 0.324$, the inverse JT transition is associated with a change in sign of $M^{avg}(T)$, as shown in the inset to Fig. 2a for $L_z^{cf} = 0.30$.

This inset shows the striking agreement between the theoretical prediction for $L_z^{cf} = 0.30$ and the measurements of Ref. [10] for A = N(n-C_4H_9)$_4$. So rather than indicating two compensation points, Ref. [10] provides compelling evidence for an inverse JT transition at $T_{JT}^{(l)} \approx 42$ K. According to Fig. 2b, a normal JT transition will be found at $T_{JT}^{(u)} \approx 70$ K. Indeed, recent X-ray measurements [14] on the same compound confirm that the hexagonal symmetry present at room temperature is absent in the monoclinic lattice below 60 K.

Measurements on several Fe(II)Fe(III) compounds [14,7] suggest that most MC compounds exhibit a small jump in the magnetization between T_c and T_{comp}. The predicted jumps in Fig. 2a are much too large to explain those measurements. X-ray diffraction studies [15] reveal that stacking faults in several compounds promote the coexistence of two phases: one with a six-layer repeat and the other with a two-layer repeat. The small magnetization jumps observed [14,7] in most MC compounds are likely caused by a mixture of those two stacking types. Indeed, a mixture of two phases, type 1 with $L_z^{cf} = 0.30$ (5% of the sample) and type 2 with $L_z^{cf} = 0.33$ (95% of the sample),[2] produces a small jump that is quite similar to the ones observed. The much larger jump found by Tang et al. [10] may be caused by the greater fraction of type 1 ($L_z^{cf} \approx 0.30$) stacking in their sample.

While there is no JT distortion ($\xi = 0$) when $\Delta < 0$, $\xi(T)$ remains nonzero down to $T = 0$ when $\Delta > 0$ and $L_z^{cf} < 0.260$. So our model predicts that normal bimetallic oxalates with $L_z^{cf} < 0.260$ will not exhibit a discontinuity in the magnetization, which may explain why such a jump has never been observed in a normal compound [7]. Nevertheless, normal Fe(II)Fe(III) compounds with $\Delta > 0$ (so that the doublet remains lowest in energy) should manifest a normal JT transition at $T_{JT}^{(u)} \approx 0.58|\lambda|$ or about 85 K.

But any non-C_3-symmetric cation like N(n-C_4H_9)$_4$ will also induce a permanent distortion of the hexagonal lattice. Depending on the size and shape of the cation, this distortion can be weakly-correlated or long-ranged. A non-C_3-symmetric potential can be included within our model by changing the off-diagonal terms in $\underline{H}_\sigma^{mix}$ from ξ to $\xi + \xi_0$. In the absence of spin–orbit coupling and a spontaneous JT distortion ξ, the doublet splitting δ is then $2\xi_0$. Since the anharmonic elastic potential proportional to ξ^3 favors $\xi > 0$, it acts to enhance the total distortion $|\xi + \xi_0|$when $\xi_0 > 0$ and to suppress the total distortion when $\xi_0 < 0$. For any nonzero ξ_0, there is a spontaneous JT distortion $\xi(T) \neq 0$ at all temperatures due to the linear term of order $-\xi\xi_0/|\lambda|$ in the free energy.

As shown in Fig. 3 for $L_z^{cf} = 0.3$ and the elastic parameters given earlier, increasing ξ_0 for a fixed L_z^{cf} decreases $T_{JT}^{(l)}$ while keeping T_{comp} almost unchanged until $T_{JT}^{(l)} < T_{comp}$. When $\xi_0 > 0.047|\lambda| \approx 0.6$ meV, the spontaneous JT distortion ξ at $T = 0$ jumps to a value near $0.81|\lambda| \approx 10$ meV and the lower JT transition disappears. When $\xi_0 < -0.019|\lambda| \approx -0.2$ meV, the spontaneous JT distortion is eliminated but MC survives until $\xi_0 < -0.43|\lambda| \approx -5.4$ meV, as seen in the inset to Fig. 3a. Except in the narrow window $0 > \xi_0 > -0.019|\lambda|$, the permanent distortion ξ_0 and the electronic distortion ξ have the same sign. For either sign of ξ_0, MC is eliminated when the violation of C_3 symmetry and $|\xi_0|$ become sufficiently large.

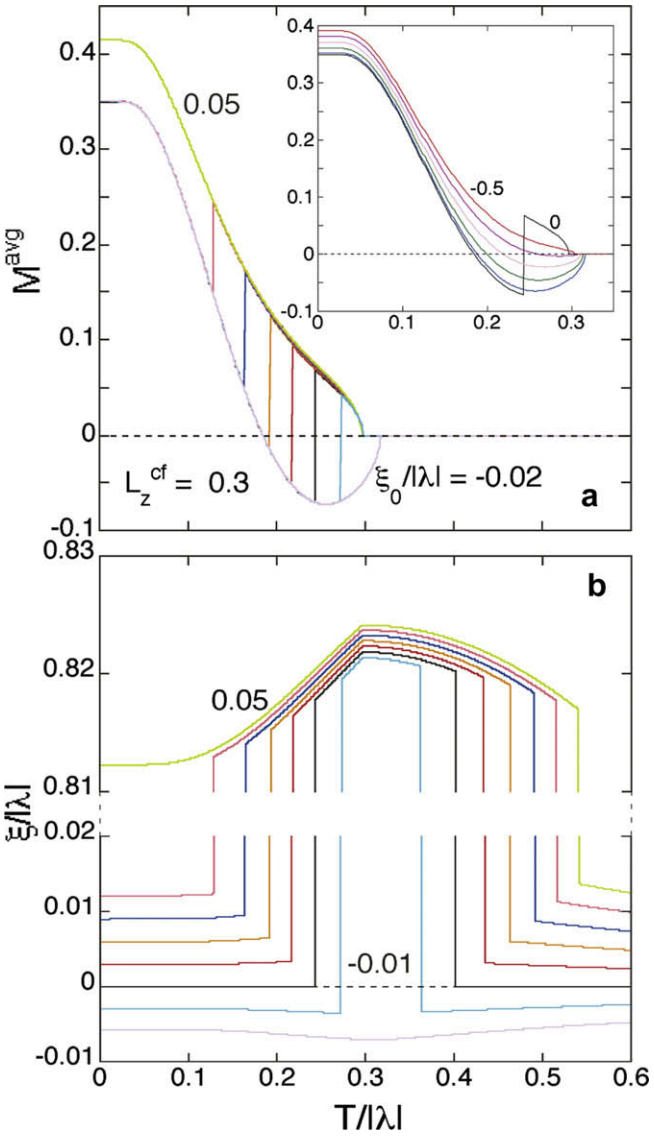

Fig. 3. (a) The average magnetization and (b) the JT mixing energy ξ normalized by $|\lambda|$ versus temperature $T/|\lambda|$ for several values of the permanent distortion $\xi_0/|\lambda|$ from -0.02 to 0.05 in increments of 0.01. Inset in (a) is the magnetization versus $T/|\lambda|$ for $\xi_0/|\lambda|$ between -0.5 and 0 in increments of 0.1. These plots use $L_z^{cf} = 0.3$, $J_c/|\lambda| = 0.037$ and the elastic constants given in the text.

[2] In a Mn(II)Fe(III) compound, Ref. [15a] reported a mixture of two stacking types with a faulting probability between 20% and 30%. In the Fe(II)Fe(III) family, MC compounds were found to be more monophasic.

Clearly, the electronic JT distortion ξ vanishes if the Fe(II) singlet lies below the doublet with $\Delta < 0$. So two conditions are required for C_3 symmetry to remain unbroken at $T = 0$. First, the cation itself must preserve C_3 symmetry so that there is no permanent distortion ξ_0. Second, either $\Delta < 0$ or if $\Delta > 0$, the average orbital angular momentum L_z^{cf} of the doublet must be sufficiently large to quench the spontaneous JT distortion ξ ($L_z^{cf} \geqslant 0.260$ in Fig. 2). Specific examples of symmetry breaking will be discussed in the next section.

4. First-principles calculations

In order to estimate the orders of magnitude of the spontaneous JT distortion ξ and the permanent distortion ξ_0, a series of first-principles calculations within the framework of density-functional theory (DFT) were performed. We employed the local spin-density approximation (SDA) in the plane-wave-pseudopotential approach with the PBE [16] exchange correlation functional as implemented in the Quantum-ESPRESSO package [17]. These calculations used Vanderbilt ultrasoft pseudopotentials [17–19] including, for the case of Fe [17,19], d electrons in the valence and non-linear core corrections. An energy cut-off of 600 eV was applied. Since the orbitals at the Fermi level are very localized in this ionic solid, we used a single **k**-point. Spin orbit coupling was not included. In order to stabilize the electronic density, the calculations were performed at an electronic temperature of 270 meV.

Predictions of the experimental electronic and magnetic structure in highly localized systems pose significant challenges for most approximations of DFT. Indeed, we find that the energy difference between ferromagnetic and antiferromagnetic configurations is below the resolution of our theory. Moreover, the charge-density wave observed experimentally (which results in inter-penetrated Fe(II) and Fe(III) networks) is not predicted to be the ground state. This discrepancy possibly signals the presence of strong self-interaction errors for the localized d orbitals [20]. The observed ferrimagnetic Fe(II)/Fe(III) ordering is stabilized by enforcing the net spin within each unit cell to equal 1/2.

Calculations were performed for several possible stackings (*ab*, *aab*, *abc*) of the bimetallic Fe(II)-Fe(III) layers with A = N(n-C_3H_7)$_4$ cations. As expected from the high degree of polymorphism and the low energy cost for stacking faults [15], the total energy differences between these three stackings were below the accuracy of our theory. Since the relative energy difference Δ between the doublet and singlet is quite sensitive to the stacking of the bimetallic planes, the angular momentum L_z^{cf} of the ground state may also depend on the stacking of the bimetallic planes.

The doublet splittings and the order of magnitude of the JT distortions were estimated by focusing on a single bimetallic layer with different cations A. Within hexagonal supercells, we studied the cations A = NH_4 (1) and N(n-C_3H_7)$_4$ (2). We also considered A = N(n-C_3H_7)$_4$ (3) in a non-hexagonal supercell.

(1) Because it is too small to stabilize the stacking of open honeycomb lattices, no oxalates actually contain the cation NH_4. However, calculations using this cation allow us to estimate the JT distortion in a C_3-symmetric environment. First, we relaxed the forces on all atoms while enforcing C_3 symmetry. The Fermi level for the majority band then lies at a doublet localized at the Fe(II) sites and occupied by a single electron. This configuration is consistent with our model, which requires the partial occupation of a doublet to explain the MC and the JT distortion. Second, the Fe(II) ion was displaced from the symmetric position on a grid of points **r**. From the *ab-initio* calculations, we extracted the total energy $E(\mathbf{r})$ of the configuration and the energy splitting $\delta(\mathbf{r})$ induced in the partially-occupied doublet. Because calculations where performed at an electronic temperature much larger than the splittings, both electronic levels of the doublet have an equal occupation of 1/2. At this large electronic temperature, no JT electronic energy was gained and the symmetric point $\mathbf{r} = 0$ remained the position with minimum energy, as expected.

Nevertheless, the energy gain at $T = 0$ can be estimated as $E(\mathbf{r}) - \delta(\mathbf{r})/2$. This expression assumes that the total energy difference is given by the sum of the occupied eigenvalues at zero temperature and neglects a small change in the electronic density [21]. Within this approximation, we can estimate the Fe(II) position and doublet splitting at zero temperature. In the absence of the spin-orbit coupling, we find that the Fe(II) moves 0.03 Å (the nearest-neighbor Fe(II)–Fe(III) distance is about 5.4 Å) with an energy gain of 2 meV and a doublet spitting of 8 meV. This JT splitting is quite close to the spin–orbit coupling $|\lambda| L_z^{cf} S \approx 7.5$ meV with $L_z^{cf} = 0.3$.

(2) Because moderately-sized cations such as N(n-C_3H_7)$_4$ are themselves non-C_3-symmetric, they will break the C_3 symmetry of the crystal-field potential at the Fe(II) sites. While a N(n-C_3H_7)$_4$ isomer with three C_3H_7 radicals below the oxalate plane would preserve C_3 symmetry, the remaining propyl chain oriented towards the hexagonal hole in the oxalates plane must then break C_3 symmetry. This symmetry violation produces a crystal-field splitting $2\xi_0$ of the doublet and a permanent distortion of the open honeycomb lattice.

Calculations were performed in a hexagonal unit-cell containing a single A = N(n-C_3H_7)$_4$ cation with periodic boundary conditions, corresponding to to an ordered configuration where every N(n-C_3H_7)$_4$ cation is oriented in the same way. After relaxing the positions of the atoms, we obtained an intrinsic doublet splitting $2\xi_0$ of about 10 meV at an electronic temperature of 270 meV.

These calculations also indicate that the intrinsic distortion introduced by the cation will be increased at low temperature by the electronic energy gain of the Fe(II) JT distortion. So in the absence of spin-orbit coupling, the parameters ξ and ξ_0 of our model have the same sign for this cation.

(3) The molecule N(n-C_3H_7)$_4$ is just small enough to allow individual cations to rotate independently of each other. Hence, a uniform distortion of the crystal is possible. Such a uniform distortion of the open honeycomb structure has been observed in bimetallic oxalates with radical cations [22]. For an ordered arrangement of A = N(n-C_3H_7)$_4$ cations and allowing the supercell to break hexagonal symmetry, we obtain a doublet splitting $\delta \sim 20$ meV, which should increase to about 30 meV when the electronic temperature approaches zero.

By contrast, larger cations such as A = N(n-C_4H_9)$_4$ studied in Ref. [10] are unable to independently rotate within each unit cell. Locked into a highly-disordered configuration during synthesis, such cations will break the local C_3 symmetry around each Fe(II) ion but not the overall C_3 symmetry of the bimetallic planes. Since the spin–orbit coupling competes with the small, local lattice distortions, MC is still possible when the cations are large and disordered. This leads to an interesting conjecture: due to their ability to spatially order, smaller cations like N(n-C_3H_7)$_4$ may be more effective at enhancing the departure from C_3 symmetry and suppressing MC than larger cations like N(n-C_4H_9)$_4$.

5. Conclusion

The simple Hamiltonian introduced in Eq. (1) explains all of the important properties of Fe(II)Fe(III) bimetallic oxalates. It provides a natural explanation for the origin of the magnetic anisotropy on the Fe(II) sites due to the splitting of the $L = 2$ multiplet by the crystal-field potential. Unlike models [23,24] that rely on the interlayer coupling, Eq. (1) explains the appearance of MC in compounds with large layer separations [6,7]. Because flipping the orbital angular momentum L_i^z requires an energy $2|\lambda| L_z^{cf} S \approx 175$ K

$\gg T_{comp}$, Eq. (1) explains the persistence of negative magnetization below T_{comp} in small fields. Due to the enhanced magnetic anisotropy and orbital moment, this model also explains why MC compounds have higher transition temperatures and Curie constants than normal compounds [6,7]. Finally, Eq. (1) explains the recently-observed jump [10] in the magnetization between T_{comp} and T_c, which is produced by an inverse JT transition.

Although these conclusions were based on a MF treatment of Eq. (1), Monte-Carlo calculations [25] have recently confirmed almost all of our earlier results [8], including the development of MC above a threshold value of L_z^{cf}. So we are confident that a more sophisticated analysis would also confirm our predictions for the lower and upper JT transitions.

Indeed, the robustness of the predicted inverse JT transition is easy to demonstrate. At high temperatures, fluctuations of the neighboring magnetic moments that are neglected within MF theory will also break the local C_3 symmetry and compete with the spin–orbit interaction. At low temperatures, however, magnetic fluctuations are suppressed and the spin-orbit interaction will act to restore C_3 symmetry. Therefore, the predicted inverse JT transition cannot be eliminated by magnetic fluctuations.

Our first-principles allow us to make more specific conclusions than are possible based on a phenomenological model alone. The calculations discussed in the previous section imply that large cations like N(n-C_4H_9)$_4$ induce a significant local distortion ξ_0 of the hexagonal lattice but are unable to reach an ordered ground state. On the other hand, smaller cations like N(n-C_3H_7)$_4$ can order at low temperatures. For an ordered configuration of N(n-C_3H_7)$_4$ cations with $|\xi_0| \approx 5$ meV (the value suggested by our first-principles results), the model results in Fig. 3 imply that an inverse JT transition will be absent and that, if present at all, MC will be rather weak with a high T_{comp}/T_c. Indeed, N(n-C_3H_7)$_4$[Fe(II)Fe(III)ox$_3$] bimetallic oxalates [6] show no signs of a JT transition below T_c and a rather high compensation temperature of about $0.75T_c$.

With the spin–orbit coupling set to zero ($L_z^{cf} = 0$), the doublet splitting $\delta = 2\xi(0) \approx 21$ meV obtained using the model parameters of Fig. 2 is more than twice as large as that obtained from first-principles calculations in a C_3-symmetric environment. So it is likely that the organic cation N(n-C_4H_9)$_4$ plays a significant role in breaking the local C_3 symmetry and enhancing the doublet splitting. A more sophisticated description of the experimental measurements may be possible once additional information about the atomic structure becomes available.

Observation of the JT distortion between $T_{JT}^{(l)} \approx 42$ K and $T_{JT}^{(u)} \approx 70$ K in MC compounds would provide unambiguous support for the model of Eq. (1). We hope that this work will inspire systematic X-ray scattering measurements that will verify the predictions made in this paper, including the long-range ordering of small, non-C_3-symmetric cations in this important class of layered, molecule-based magnets.

and this type of materials are expected to exhibit interesting magnetic properties, i.e. the photo-induced magnetization [18]. The SQUID chip on which the microcrystal was mounted by using an optical microscope manipulator were set in the dipstick unit, including a 3D magnetic coil system for the measurement. Our measurement procedure consisted of measuring the critical current of the SQUID while sweeping the external magnetic field. Because the critical current exhibited a modulation with a period of $1\Phi_0$ as a function of magnetic flux as it passed through the SQUID loop, the magnetization curve could be deduced by counting the number of detected fluxes in the SQUID loop.

3. Results and discussion

According to previous work using a large single crystal, this material exhibits a long range magnetic ordering below 40 K and a saturation magnetization of 9 $\mu_B N$ where μ_B is Bohr magneton and N is the Avogadro's number [17]. As shown in Fig. 1, we cut a section of the large crystal into a microcrystal, and mounted it on the SQUID. Fig. 2 represents the magnetization curves of the microcrystal at 35 K [16]. The microcrystal exhibited hysteresis with a coercive field of 7 Oe, and reached a saturated value of $40\Phi_0$ around 300 Oe.

However, to understand obtained data, the relative arrangement of the sample and the SQUID loop must be considered. We roughly calculated the flux passing through the SQUID loop, which was produced by the sample with a saturation magnetic moment in $\mathbf{H_{ex}}$. We assumed that the sample shape was a rhombic prism and that the line joining the median points of the sample bottom face and the SQUID loop paralleled $\mathbf{H_{ex}}$. According to previous work, the effective area of the SQUID loop is $7 \times 11\ \mu m^2$ [16]. Because the crystal sample of **1** was uniformly magnetized below 40 K, the intensity of magnetization $I = I_{sat} = 9\mu_0\mu_B N D_{crystal}/M_A$ where I_{sat} is the saturation magnetization, $D_{crystal}$ is the crystal density of 2.198 g cm^{-1}, and M_A is the molar weight of 632.97 g mol^{-1}. We equally partitioned the sample into volume elements with an equal edge length of dr_m, and also partitioned the flux detection area of the SQUID into area elements with an equal side length of dr_s (Fig. 3). The volume element of the sample possesses a magnetic moment, $\mathbf{m} = I_{sat}\ \Delta V_m\ \mathbf{n}$, where $\Delta V_m = \sin\theta\ (dr_m)^3$ is the volume of the element, $\theta = 72°$ is the angle between the edges of the bottom face rhombus, $\mathbf{n}$ is the unit vector of the magnetic moment and in the present case the magnetic moment is in the same direction as $\mathbf{H_{ex}}$. We defined the coordinates of the volume elements in the sample as the center of the element and expressed as $\mathbf{r_m} = \mathbf{r_{m0}} + A_m\mathbf{e_a} + B_m\mathbf{e_b} + C_m\mathbf{e_c}$, where $\mathbf{r_{m0}}$ is the coordinate of one of the vertices of the sample bottom face, $\mathbf{e_a}$, $\mathbf{e_b}$, $\mathbf{e_c}$ are the unit vectors parallel to the prism edges from $\mathbf{r_{m0}}$, and A_m, B_m, C_m are the coefficients. We also defined the coordinates of the area elements in the SQUID as the center of the element and expressed as $\mathbf{r_s} = X_s\mathbf{e_x} + Y_s\mathbf{e_y}$, where $\mathbf{e_x}$, $\mathbf{e_y}$ are the unit vectors and X_s, Y_s are the coefficients. Here $\mathbf{e_a} = -\cos(\theta/2)\mathbf{e_x} + \sin(\theta/2)\mathbf{e_y}$, $\mathbf{e_b} = -\cos(\theta/2)\mathbf{e_x} - \sin(\theta/2)\mathbf{e_y}$, and $\mathbf{e_c} = \mathbf{e_z}$. By applying the point-dipole approximation to this volume element, the magnetic flux density $\mathbf{b(r_s)}$ at $\mathbf{r_s}$ produced by $\mathbf{m(r_m)}$ is given by the following equation

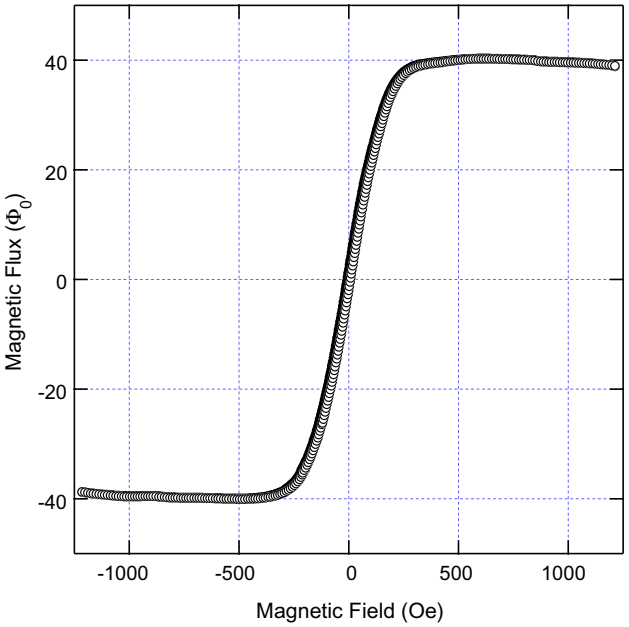

Fig. 2. Magnetization curves for microcrystal sample in a magnetic field of $\mathbf{H_{ex}}$. Filled and open markers indicate the plots in the field-reducing and -increasing processes, respectively.

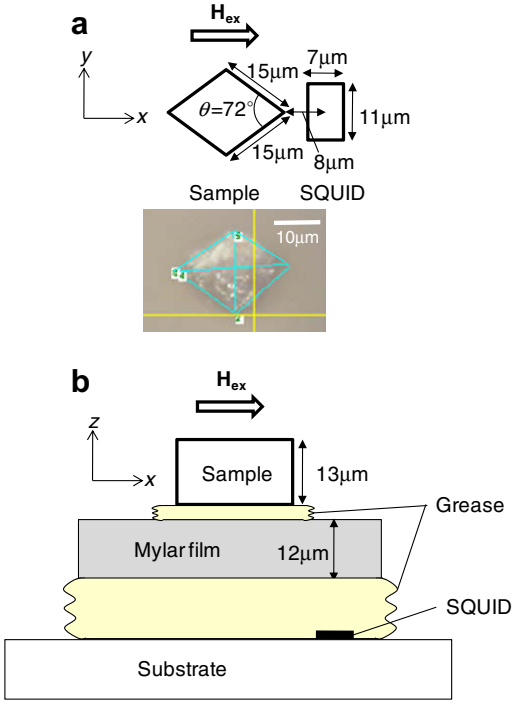

Fig. 1. Schematic illustration of the relative arrangement of microcrystal sample and the SQUID loop. Sample is fixed with grease on a 12 μm thick Mylar sheet covering the SQUID. (a) Top view of the illustration and the photo by the laser microscope and (b) horizontal sectional view of the illustration.

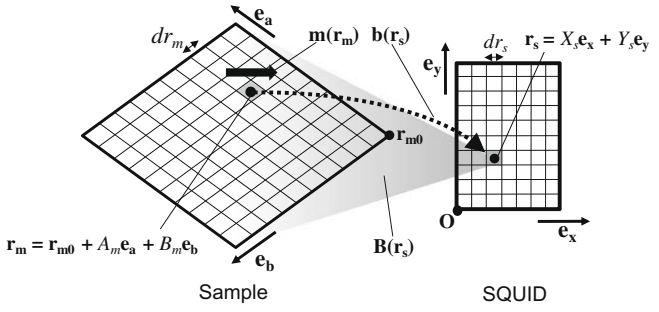

Fig. 3. Illustration of an equally partitioned sample and the SQUID loop. Parameters in the figure are explained in the text.

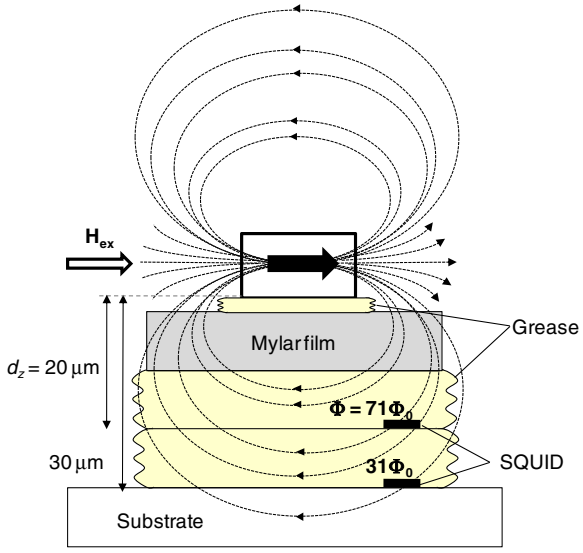

Fig. 4. Schematic illustration of the sample flux.

$$\mathbf{b}(\mathbf{r_s}) = \frac{1}{4\pi}\left(-\frac{\mathbf{m}}{r^3}+\frac{3(\mathbf{m}\cdot\mathbf{r})\mathbf{r}}{r^5}\right) = \frac{I_{sat}\Delta V_m}{4\pi}\left(-\frac{\mathbf{n}}{r^3}+\frac{3(\mathbf{n}\cdot\mathbf{r})\mathbf{r}}{r^5}\right). \quad (1)$$

Here $\mathbf{r} = \mathbf{r_s}-\mathbf{r_m}$ and $r = |\mathbf{r}|$. Then the magnetic flux density from the entire sample at $\mathbf{r_s}$ is

$$\mathbf{B}(\mathbf{r_s}) = \sum_{A_m}\sum_{B_m}\sum_{C_m}\frac{I_{sat}\Delta V_m}{4\pi}\left(-\frac{\mathbf{n}}{r^3}+\frac{3(\mathbf{n}\cdot\mathbf{r})\mathbf{r}}{r^5}\right). \quad (2)$$

The flux $\phi(\mathbf{r_s})$ from $\mathbf{m}$, which is detected by the square element with an area of $\Delta S = (dr_s)^2$ at $\mathbf{r_s}$ within the SQUID loop, is

$$\phi(\mathbf{r_s}) = (\mathbf{B}(\mathbf{r_s})\cdot\mathbf{e_x})\Delta S. \quad (3)$$

The total flux from the sample through the SQUID loop is obtained as

$$\Phi = \sum_{X_m}\sum_{Y_m}(\mathbf{B}(\mathbf{r_s})\cdot\mathbf{e}_z)\Delta S. \quad (4)$$

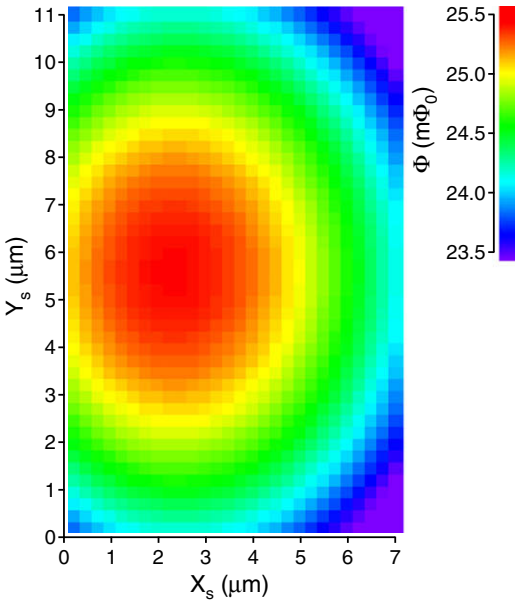

Fig. 5. The calculation result of the distribution of the intensity of the flux detected by the SQUID loop with $dr_m = dr_s = 0.25$ and $d_z = 30$ μm. The inset indicates the relationship between the intensity of the flux detected in the area element and the color gradation.

In the present case, the SQUID substrate was covered with a 12 μm thick Mylar sheet, and grease was used to mount the crystal sample onto the film. From our experience, the grease penetrates the substrate and the film. Thus, the distance between the bottom face of the sample and the SQUID plane d_z becomes ~10 μm longer than the thickness of the film (Fig. 4). Hence, grease thickness was considered when calculating the flux with $d_z = 20$ and 30 μm. We found that the flux value almost converged with $dr_m = dr_s < 0.2$ μm. With $dr_m = dr_s = 0.2$ μm, we obtained flux values $\Phi = 71\Phi_0$ and $31\Phi_0$ at $d_z = 20$ and 30 μm, respectively. These values are reasonable compared to the experimental value of $40\Phi_0$. We also show the calculation result of the distribution of the intensity of the flux detected by the area elements in the SQUID loop with $dr_m = dr_s = 0.25$ and $d_z = 30$ μm (Fig. 5). We can guess where to mount the sample on the SQUID loop in order to detect the flux most effectively.

4. Conclusion

Using the dipole approximation, we verified the flux value of $40\Phi_0$ from the saturation magnetic moment of a ferrimagnetic microcrystal of $[Mn_2(H_2O)_2(CH_3COO)][W(CN)_8]\cdot 2H_2O$. This flux value was obtained by the magnetization measurement using the HTS micro SQUID magnetometer. Upon considering the thickness of the film and the grease between the sample as well as the SQUID plane d_z, we obtained flux values of $\Phi = 71\Phi_0$ and $31\Phi_0$ at $d_z = 20$ and 30 μm, respectively. The obtained values are consistent with the experimentally measured one. We are now planning to measure the magnetic flux reversal with Prussian blue analogs, which exhibit a compensation temperature [19] or an inverted magnetic hysteresis loop [20] using the present HTS micro SQUID.

Acknowledgments

The authors are grateful to Professor Mizushi Matsuda from the Muroran Institute of Technology for his assistance fabricating the micro SQUID chips. The present research was supported in part by a GCOE Program for Chemistry Innovation, a Grant-in-Aid for Young Scientists (S) and (B) from Japan Society for the Promotion of Science, Inamori Foundation, and the Kurata Memorial Hitachi Science and Technology Foundation.

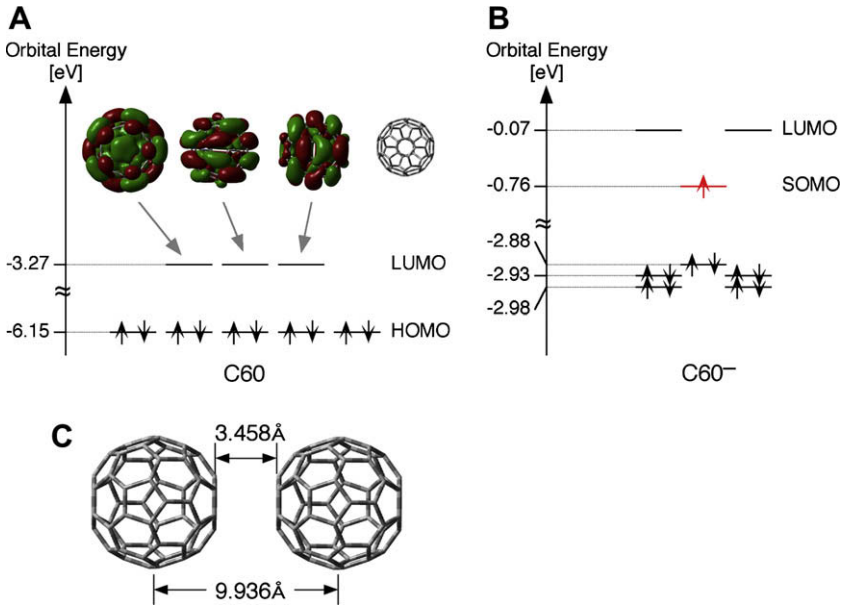

Fig. 1. (A) Calculated HOMOs and LUMOs of C_{60}, (B) calculated SOMO, HOMOs and LUMOs of C_{60}^-, and (C) calculated model structure of C_{60}^- dimer.

3. Calculated results

3.1. C_{60} and C_{60}^-

First we examined the electronic structures of C_{60} and C_{60}^-. Calculated total energies and $\langle S^2 \rangle$ values were summarized in Table 1. The calculated HOMOs and LUMOs of C_{60} molecule were depicted in Fig. 1A. HOMOs were five-fold degenerated and LUMOs were three-fold degenerated reflecting its I_h symmetry. The orbital energies of HOMOs and LUMOs were −6.15 and −3.27 eV, respectively. Calculated C_{60}^- orbital energies around SOMO were also depicted in Fig. 1B. The orbital energy of SOMO was −0.76 eV. By one electron doping, the five-fold degenerated HOMOs of neutral C_{60} were divided into two doubly degenerated and one non-degenerated orbitals although LUMOs were still remaining the degeneracy. An energy difference between C_{60} and C_{60} anion that corresponds to adiabatic electron affinity (EA), was 2.0 eV as mentioned in Table 1. The calculated EA was smaller than experimental value (2.65 eV [16]) because the experimental structure of neutral C_{60} was substitutionally used for the calculation of C_{60} anion. However the value is consistent with the experiment qualitatively.

3.2. Effective exchange integrals (J_{ab}) between two C_{60}^-s

One of the characteristic of three LUMOs depicted in Fig. 1A has a major node in their equatorial planes. In terms of the equatorial nodes, it is considered that those three LUMOs are very similar to p-type orbitals in a coarse view as illustrated in Fig. 2A. Because the SOMO of C_{60} anion is constructed by LUMOs of neutral C_{60}, there are four types of interactions between two SOMOs of two

Table 1
Calculated total energies[a], $\langle S^2 \rangle$ values of C_{60} and C_{60}^-. Electron affinity of C_{60} was calculated by the energy difference between C_{60} and C_{60}^-.

Molecule	Total energy (a.u.)	$\langle S^2 \rangle$	EA (eV)
C_{60}	−2283.138544	0.0000	2.00 (2.65)[b]
C_{60}^-	−2283.212188	0.7543	

[a] Convergence threshold is 10^{-6} (a.u.) in densities.
[b] Experimental value by Yang et al. [16] is in parenthesis.

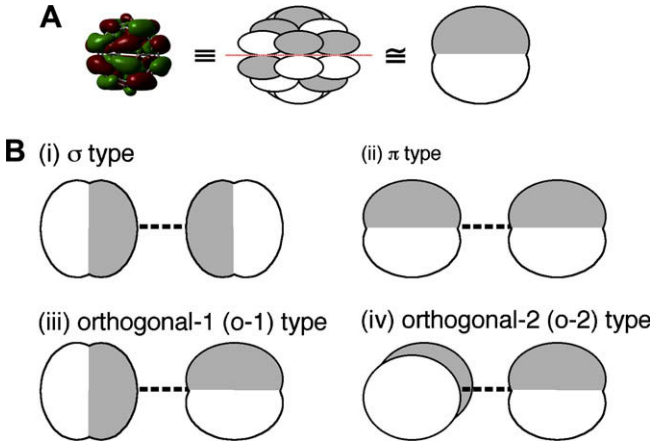

Fig. 2. (A) Illustrations of LUMOs of C_{60} as a conceptual view and (B) four types of interactions between two C_{60}^-s.

C_{60}^-s if we regard those LUMOs as p-type orbitals, i.e. **σ**–, **π**– and **o-1**, **o-2** type interactions as illustrated in Fig. 2B. Among the four type interactions, the **σ**- and **π**-type interactions have SOMO–SOMO overlap. Therefore anti-ferromagnetic interaction is easily expected. While other interactions (**o-1**, **o-2**) seems to be orthogonal. If the SOMO–SOMO overlap is zero, a ferromagnetic interaction is expected by analogy with Kanamori-Goodenough rule [17].

The magnetic properties are usually investigated by the use of the Heisenberg Hamiltonian,

$$\hat{\mathbf{H}} = -2\sum J_{ab}\hat{\mathbf{S}}_a \cdot \hat{\mathbf{S}}_b, \tag{1}$$

where J_{ab} is the orbital-averaged effective exchange integral between the spin sites a and b (or C_{60} anions a and b) with total spin operators $\hat{\mathbf{S}}_\mathbf{a}$ and $\hat{\mathbf{S}}_\mathbf{b}$, respectively [18–20]. Our group has proposed a calculation method for J_{ab} values based on broken-symmetry methods as follows:

$$J_{ab} = \frac{E^{LS} - E^{HS}}{\langle \hat{\mathbf{S}}^2 \rangle^{HS} - \langle \hat{\mathbf{S}}^2 \rangle^{LS}}, \tag{2}$$

Table 2
Total energies[a] and $\langle S^2 \rangle$ values for the LS (singlet) and the HS (triplet) states, respectively. Effective exchange integrals (J_{ab}) and the energy differences (ΔE) were calculated by using Eqs. (2) and (3), respectively.

Type	LS (singlet)		HS (triplet)		J_{ab} (cm^{-1})	ΔE (eV)
	Total energy (a.u.)	$<S^2>$	Total energy (a.u.)	$<S^2>$		
σ	−4566.373044	1.0067	−4566.373028	2.0087	−3.5	0.000
o-1	−4566.372846	1.0086	−4566.372844	2.0086	−0.4	0.005
o-2	−4566.372560	1.0086	−4566.372581	2.0086	4.6	0.013
π	−4566.372539	1.0003	−4566.372497	2.0087	−9.1	0.014

[a] Convergence threshold is 10^{-7} (a.u.) in densities.

where E^X and $\langle \hat{\mathbf{S}}^2 \rangle^X$ denote the total energy and the total spin angular momentum for the spin state X (X = low spin (LS) and high spin (HS)), respectively [21–23].

The calculated results are summarized in Table 2. First, we focus on the energy difference among **σ**–, **π**–, **o-1** and **o-2** type models. Because the most stable model is the **σ**-type one, we assessed the energy difference as follows:

$$\Delta E(X) = \text{Total energy}(\sigma\text{-}type) - \text{Total energy}(X) \quad (3)$$

where *X denotes* **π**-, **o-1** and **o-2** interactions. As summarized in Table 2, ΔE values are quite small. The results suggest that interactions between each spin site (C_{60}^-) are very weak.

The calculated J_{ab} values by using Eq. (2) are summarized in Table 2. Small absolute values of those J_{ab} values are also indicating weak spin–spin interactions. Among the four interactions, **σ**- and **π**-type interaction show a weak anti-ferromagnetic interaction, while **o-2** interaction shows a weak ferromagnetic interactions as expected. J_{ab} value of **o-1** model is almost zero, meaning that an energy gap between singlet and triplet is negligible. Interestingly, J_{ab} values suggested that **π**-type interaction is stronger than **σ**-type one. In case of interactions between usual p type atomic orbitals (AOs) e.g. 2p AOs in carbon atom, **σ**-type interaction is stronger than **π**-type one because an overlap between two AOs in **σ**-type is larger than that of **π**-type. Therefore it suggests that overlap of **π**-type interaction is larger than **σ**-type one. The reason is understandable from a distribution of the SOMO of C_{60}^- on the axial axis as depicted in Fig. 1A. An insufficient distribution of the SOMO on the axial axis seems to lead the small SOMO–SOMO overlap in **σ**-type interaction.

In order to clarify the relations between the effective exchange interactions and the overlaps, we introduced natural orbitals (NOs), which were determined by diagonalizing their first order density matrices as

$$\rho(r, r') = \sum n_i \{\phi_i(r)\}^* \phi_i(r'), \quad (4)$$

where n_i denoted the occupation number of NO ϕ_i [24,25]. In the case of C_{60}^- dimer, ϕ_i and ϕ_i^* means bonding and anti-bonding orbitals constructed by singly occupied natural orbitals (SONOs) of each C_{60}^-, namely magnetic orbitals. If an occupation number (n_i) is close to 1.0, then two electrons in the orbital are almost localized on each C_{60}^-. On the other hand, n_i should be equal to 2.0 if two spins on C_{60}^-s are completely delocalized and stable chemical bond is constructed between them. To assess a degree of spin localization, instability value (y_i) for an orbital *i* is sometimes introduced,

$$y_i = 2W_D^2 = \frac{n_i^2 - 4n_i + 4}{n_i^2 - 2n_i + 2}, \quad (5)$$

where W_D denotes the weight of double excitation for orbital *i* [26]. y_i value is usually expressed by using a percentage. If two spins are localized as a radical at each C_{60}^- sites, y_i is close to 100%. On the other hand, y_i value close to zero if two spins are fully delocalized on both C_{60}^- sites.

Table 3
Occupation numbers (NOs) of HONO and LUNO for each models. Instability value (y_i) was calculated by Eq. (5).

NOs	**σ**	**π**	**o-1**	**o-2**
LUNO	0.956	0.909	0.994	1.000
HONO	1.044	1.091	1.006	1.000
y_i (%)	91	82	99	100

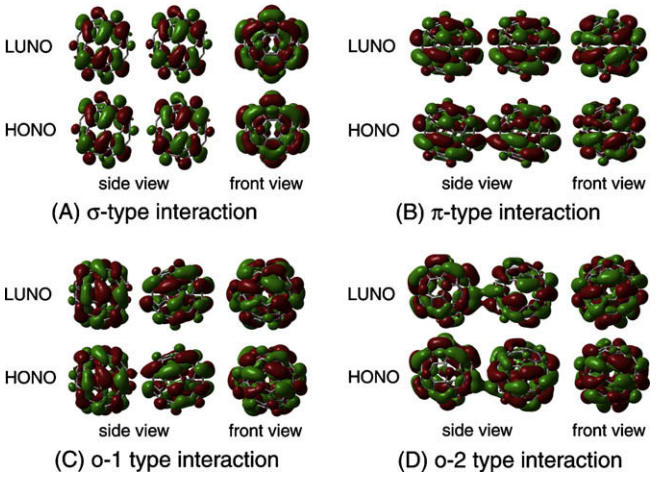

Fig. 3. Highest occupied natural orbitals (HONO) and lowest unoccupied natural orbitals (LUNO) of calculated four types C_{60}^- dimer.

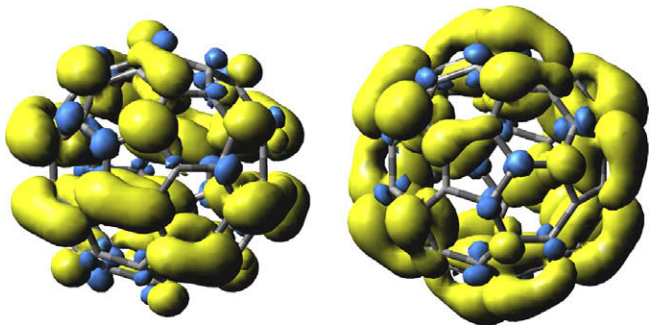

Fig. 4. Calculated spin densities of **o-2** model. Yellow and blue are indicating high spin density and low spin density, respectively. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Calculated occupation numbers of the highest occupied natural orbitals (HONOs), the lowest unoccupied natural orbitals (LUNOs) and their y_i values are summarized in Table 3. All occupation numbers of HONOs are closed to 1.0 and y_i values are closed to 100%,

indicating that spins are considerably localized on each C_{60}^- site as radicals. Among them, **o-2** type interaction indicates a fully localizing spin structure. In other words, two SONOs are orthogonal in the **o-2** model. The results also shows that overlap in π-type model is larger than that of σ-type one as we expected above. Those NOs depicted in Fig. 3 significantly support them.

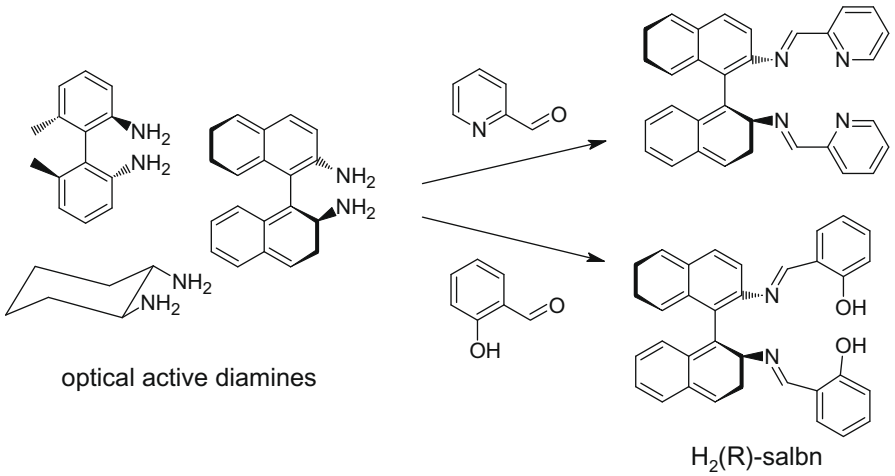
Finally we depicted the spin density of the HS state of **o-2** type C_{60}^- dimer to examine whether the DSP occurs or not. In case of the DSP mechanism, the down spin and up spin densities appear alternately on their connecting face as described in Ref. [10]. However, the up spin density is distributed to all carbon atoms as depicted in Fig. 4. Therefore, the result supports the orbital orthogonality as the mechanism for the ferromagnetic interaction rather than the DSP.

4. Conclusions

Four types of magnetic interactions between C_{60}^- anions were examined by using UB3LYP calculations. Although all of calculated J_{ab} values were small, the results indicated that three of four interactions were anti-ferromagnetic but **o-2** type was only the ferromagnetic interaction. The mechanism of such exchange coupling was explained orbital orthogonality. In this study, we assumed that a structure of C_{60}^- is consistent with that of C_{60}. Bond alternation, however, will be occurred on C_{60} molecule by one electron doping into LUMO. For the further discussion, structural optimization should be carried out for C_{60}^- molecule.

By using the Langevin–Weiss mean field approximation, T_c can be estimated as follows [27]:

$$k_B T_c = \frac{2}{3} \sum_{a<b} S(S+1) J_{ab} \tag{6}$$



By substituting the obtained J_{ab} value of **o-2** type model (4.6 cm^{-1}) into Eq. (6), we obtain T_c = 8.7 K. The lower T_c than that of C_{60}-TDAE indicates the necessity of stronger ferromagnetic interaction. There are some candidates to promote the ferromagnetic interaction. One is the double exchange interaction between C_{60}^- and C_{60}^{2-}. If we can synthesize mixed valence like state of C_{60}^- and C_{60}^{2-}, much stronger ferromagnetic interaction will be realized. The second is the distance between C_{60}^-s. The distance seems to be important because SOMO–SOMO overlap is not negligible in spite of 9.936 Å interval from neighboring C_{60}^- (face to face distance is 3.458 Å as illustrated in Fig. 1C). In case of C_{60}-TDAE complex, an interval of nearest neighboring C_{60}^-s is 9.859 Å [28], closer in comparison with *fcc* C_{60}'s one. The shorter C_{60}^-–C_{60}^- distance may bring strong interactions. In addition, there is a possibility that C_{60}^-–TDAE– C_{60}^- interaction increases the ferromagnetic interaction. In those points of view, an appropriate design of counter cation is required to control the SOMO–SOMO overlap between C_{60} anions for the ferromagnetic interaction.

Scheme 1. Syntheses of tetradentate chiral ligands.

resultant solution was added $FeCl_3 \cdot 6H_2O$ (27 mg, 0.1 mmol) in methanol (2 ml). Brown prismatic crystals of **2** were obtained by slow diffusion of Et_2O vapor into the methanol solutions in a sealed tube. *Anal. Calc.* for $C_{70}H_{54}Fe_2N_4O_8$: C, 70.60; H, 4.57; N, 4.70. Found: C, 70.98; H, 4.76; N, 4.83%.

2.3. X-ray crystal structure analyses

Each single crystal was mounted on the tip of a glass fiber with epoxy resin. Diffraction data were collected at −73 °C on a Bruker SMART APEX diffractometer fitted with a CCD-type area detector using monochromated Mo Kα radiation (λ = 0.71073 Å). The data frames were integrated using SAINT (Bruker Analytical X-ray Systems). Empirical absorption corrections were applied to the data for **1** by SADABS (G.M. Sheldrick, 1994) and Gaussian face-indexed corrections were applied to the data for **2** by XPREP (Bruker, 2001). The structures were solved by direct methods and refined by the full-matrix least-squares method on all F^2 data using the SHELXTL program package (Bruker Analytical X-ray Systems). Non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms.

Crystal data for **1**: $C_{76}H_{57}ClN_8Ni_2O_8$, formula weight = 1363.17, orthorhombic, space group $P2_12_12_1$, a = 12.0058(16), b = 16.646(2), c = 32.682(4) Å, V = 6531.4(15) Å^3, Z = 4, ρ_{calcd} = 1.386 g cm^{-3}, T = 200(2) K, 26 191 reflections collected, 11 961 unique, (R_{int} = 0.0794), R_1 = 0.0745, wR_2 = 0.1378, Flack x = 0.019(17) using 11 961 reflections with $I > 2\sigma(I)$.

Crystal data for **2**: $C_{78}H_{74}Fe_2N_4O_{10}$, formula weight = 1339.11, tetragonal, space group $P4_12_12$, a = 13.597(4), c = 37.891(15) Å, V = 7005(4) Å^3, Z = 4, ρ_{calcd} = 1.270 g cm^{-3}, T = 200(2) K, 33 563 reflections collected, 6662 unique, (R_{int} = 0.0812), R_1 = 0.0592, wR_2 = 0.1562, Flack x = 0.02(2) using 6662 reflections with $I > 2\sigma(I)$.

2.4. Magnetic susceptibility measurements

Magnetic susceptibility measurements in temperature range of 1.8–300 K were carried out on powdered samples of complex **1** and **2** with applying magnetic field of 500 Oe, using a Quantum Design MPMS XL-5 type magnetometer. Corrections were based on subtracting the sample-holder signal and the diamagnetic contribution was estimated from the Pascal constants [10].

3. Results and discussion

3.1. Crystal structure of *1*

Complex **1** crystallized in the chiral space group $P2_12_12_1$, and an ORTEP diagram of complex molecule in **1** is given in Fig. 1. Complex **1** is a dinuclear Ni(II) complexes in which two Ni(II) ions are doubly linked by μ_2-phenoxo groups, each having NiN_3O_3 core. Bridging bond angles of Ni–O–Ni are 98.79(18) and 100.98(18)°, and the interatomic separation of Ni1···Ni2 is 3.1317(11) Å. A mono-cationic complex molecule of **1** contains two Ni(II) ions and two tetradentate ligands. Charge consideration suggests that three of four protons in the ligands are deprotonated. Note that the difference Fourier map showed an extra-peak between O1 and O3 atoms, which can be assigned to the hydrogen bonded proton. Each Ni(II) ion has six coordination geometry with Δ configuration. (*R*)-salbn^{2-} occupied four coordination sites of the Ni(II) ions with coordination of two imino nitrogen and two phenoxo oxygen atoms, and the asymmetric structure of (*R*)-salbn^{2-} results in Δ configuration on the Ni(II) ions. The remaining two coordination sites of Ni(II) ions are occupied by the acetonitrile molecule and the μ_2-phenoxo group of (*R*)-salbn of the other side of the Ni(II) unit. Coordination bond lengths of Ni1–O are 2.038(4), 2.047(4) and 2.104(5) Å, while those of Ni1–N_{amine} are 2.042(5) and 2.047(4) Å. Coordination bond length with nitrogen atom from acetonitrile (2.122(6) Å) is slightly longer than those of Ni1–N_{amine}

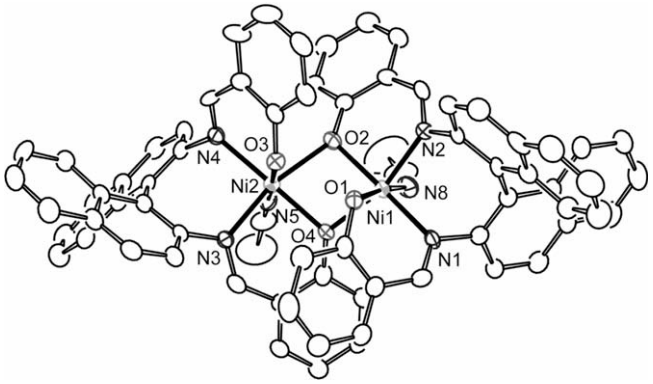

Fig. 1. ORTEP diagram of **1**.

bonds. The structural feature around the Ni2 ion is similar to those for the Ni1 ion. The Ni2 ion with Δ configuration was coordinated to similar manner to the Ni1 ion, and the coordination bond lengths in the Ni2 ion are in the range of 2.021(4)–2.095(4) Å.

3.2. Crystal structure of **2**

An ORTEP diagram of a complex molecule in **2** is shown in Fig. 2. Complex **2** crystallized in the chiral space group $P4_12_12$, and a crystallographic twofold axis passes through Fe1 and Fe2 ions. The complex molecule contains two Fe(III) ions, two (*R*)-salbn^{2-}, and two methoxy ions. The (*R*)-salbn^{2-} acts as a bis-bidentate ligand, and each N/O donor set coordinates to the iron(III) ion to form six-membered chelate rings. Each Fe(III) ion is coordinated by two (*R*)-salbn^{2-} ligands, leading to a Fe(III) dinuclear core which is supported by two μ_2-methoxo bridges. A bridging angle of Fe1–O3–Fe2 is 106.54(12)° with the intermetallic distance of Fe1···Fe2 being 3.1947(15) Å. The Fe(III) ions has an octahedral FeN_2O_4 chromophore with Λ configuration, and the six coordination sites are occupied by two imino nitrogen and two phenoxo oxygen atoms from two chelating salicylideneamino moieties and two μ_2-methoxo oxygen atoms. Coordination bond lengths with the axial ligands are 2.191(3) Å for Fe1 and 2.181(3) Å for Fe2. The equatorial coordination bond lengths are in the ranges of 1.917(3)–1.997(3) Å for Fe1 and 1.942(3)–1.989(3) Å for Fe2.

3.3. Magnetic properties

Magnetic susceptibility measurements for **1** and **2** were performed in the temperature range of 1.8–300 K (Fig. 3). The χ_mT value of **1** is 2.19 emu mol^{-1} K at 300 K, which is slightly larger than the value expected for the uncorrelated two Ni(II) ions (2.0 emu mol^{-1} K with $g = 2.0$). The χ_mT values gradually decreased as the temperature was lowered, suggesting the occurrence of the antiferromagnetic interaction between Ni(II) ions. The magnetic susceptibility data above 20 K were analyzed using the isotropic spin Hamiltonian $H = -2J\mathbf{S}_1 \cdot \mathbf{S}_2$, and the J value was estimated to be −18.6(1) cm^{-1} with $g = 2.21(1)$ for **1**.

The χ_mT value of **2** at 300 K is 4.79 emu mol^{-1} K, which is almost half of the value expected for the uncorrelated two Fe(III) ions (8.75 emu mol^{-1} K with $g = 2.0$), and this suggests the existence of the relatively strong antiferromagnetic interaction. The χ_mT values monotonically decreased as the temperature was lowered. The magnetic susceptibility data above 20 K were analyzed by using the isotropic spin Hamiltonian $H = -2J\mathbf{S}_1 \cdot \mathbf{S}_2$ and the J value was estimated to be −18.0(1) cm^{-1} for **2**.

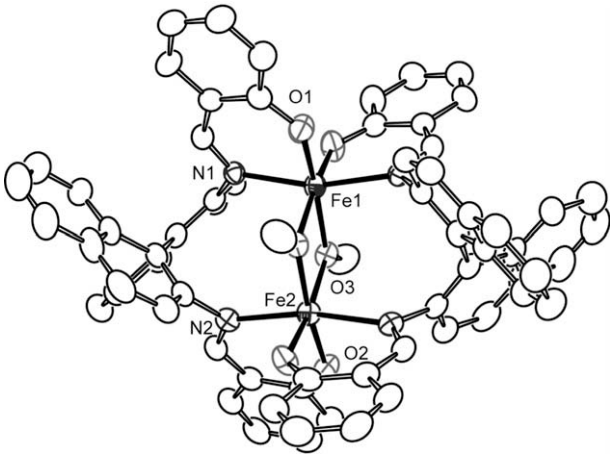

Fig. 2. ORTEP diagram of **2**.

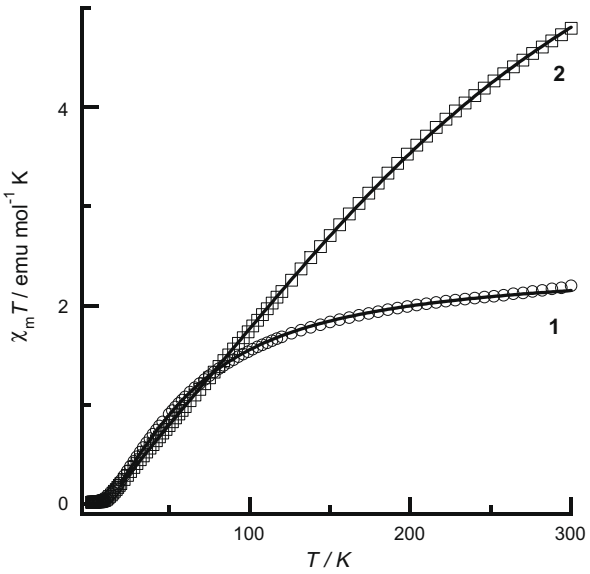

Fig. 3. Plots of χ_mT versus temperature for **1** and **2**.

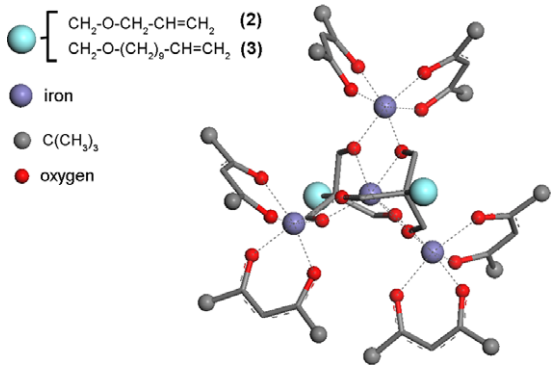
4. Conclusion

Novel chiral dimer complexes of **1** and **2** were prepared. X-ray structure analyses revealed that the Δ and Λ configurations are selectively formed around metal centers in **1** and **2**, respectively, by using chiral tetradentate ligand of H_2(*R*)-salbn. Dc magnetic susceptibility measurements showed the occurrence of antiferromagnetic interactions between metal centers both in **1** and **2**.



Supplementary data

CCDC 705073 and 705074 contains the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Scheme 1. Schematic structures of single molecule magnets **2** and **3**.

diethyl ether (6 × 50 ml). The combined organic extracts were dried over $MgSO_4$ and the solvent was evaporated at reduced pressure to give (according to ^1H NMR analysis) 1-methyl-4-undec-10-enyloxymethyl-2,6,7-trioxa-bicyclo[2.2.2]octane *plus* the elimination product undeca-1,10-diene (2.25 g). The mixture was dissolved in methanol (4 ml) and treated overnight with HCl 0.01 M (16 ml, 0.16 mmol) to accomplish acid deprotection. Solid $NaHCO_3$ (0.60 g, 7.0 mmol) was added and the solution was stirred over a 6-h period until complete liberation of the trimethylol function (TLC, SiO_2, toluene:EtOAc 2:1). The solvent was removed under vacuum with moderate heating (40–45 °C) and the solid was purified by column chromatography on silica gel (CH_2Cl_2:MeOH 97.5:2.5) to give pure H_3L^2 (0.90 g, 50% vs. 4-(hydroxymethyl)-1-methyl-2,6,7-trioxabicyclo[2.2.2]octane over two reaction steps). ^1H NMR (200 MHz, $CDCl_3$, 25 °C): δ (ppm) = 5.81 [m, 1H, $-HC{=}CH_2$], 5.04–4.88 [m, 2H, $-HC{=}CH_2$], 3.70 [s, 6H, $-CH_2OH$], 3.45 [s, 2H, $-OCH_2C(-CH_2OH)_3$], 3.41 (t, J = 6.5 Hz, 2H, $-OCH_2CH_2-$), 2.89 [s, br, 3H, OH], 2.03 [m, 2H, $-CH_2-HC{=}CH_2$], 1.55 [m, 2H, $-OCH_2CH_2-$], 1.44–1.21 (m, 12 H, Aliph).

*$[Fe_4(L^2)_2(tmhd)_6]$ (**3**):* Compound **1** (0.0607 g, 0.0402 mmol) was dissolved in dry Et_2O (25 ml) to give a yellow solution. Then the triol H_3L^2 (0.0554 g, 0.192 mmol) was added with stirring. Vapor diffusion of dry methanol (40 ml) in the clear yellow solution afforded yellow-orange prisms, which were washed with the external diffusion mixture, with dry methanol and then vacuum dried (0.0687 g, 90% assuming no crystallization solvent). *Anal.* Calc. for $C_{98}H_{172}Fe_4O_{20}$: C, 62.15; H, 9.15. Found: C, 62.48; H, 9.18%.

2.1. Monolayer preparation

Direct anchoring: Solutions of Fe_4 complexes (**2** or **3**) in mesitylene (10^{-3} M) were placed in a chamber with a quartz window and were deoxygenated by stirring in a dry box for at least 1 h. A Czochralski grown boron doped Si(100) substrate was treated in a piranha solution for 12 min, rinsed in water for 2 min, etched in 1.0% hydrofluoric acid for 90 s, quickly rinsed in water, dried under N_2 and immediately placed in the cluster solution. The chamber remained under UV irradiation (254 nm) for 90 min. The sample was then removed from the solution, rinsed with mesitylene and dichloromethane and sonicated in dichloromethane for 5 min.

*Ligand exchange reaction with **4**:* After the 90-min photochemical grafting of **3** at 254 nm, the silicon sample was taken away from the solution, rinsed in mesitylene and diethyl ether and finally introduced in a solution of **4** in diethyl ether for 6 h at room temperature. Subsequently, the sample was removed from the solution, copiously rinsed with diethyl ether, sonicated in the same solvent and analyzed.

One pot anchoring: Similarly to the direct anchoring procedure, a solution of **2** or **3** in mesitylene was placed in a photochemical reactor and was deoxygenated by stirring in a dry box for at least 1 h. Subsequently, a Czochralski grown boron doped Si(100) substrate, treated as described above, was placed in the solution and was submitted to the photochemical hydrosilylation at 254 nm for 90 min. After the photochemical treatment, the sample was left undisturbed in the solution for 6 h. The sample was then removed from the solution, washed many times with mesitylene and sonicated in dichloromethane for 10 min in order to remove any physisorbed clusters.

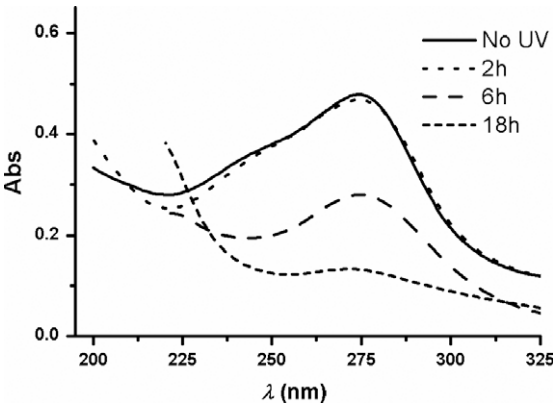

Fig. 1. Spectral changes upon irradiating cluster **2** in cyclohexane solution at 254 nm at various times.

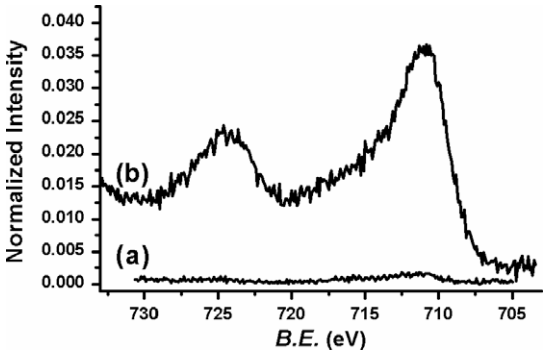

Fig. 2. High resolution Fe 2p XPS region of samples (a) exposed to direct photochemical grafting of **3** and (b) exposed to direct photochemical grafting of **3** followed by the ligand exchange reaction with **4**. The intensities are normalized to the total Si 2p intensity. Take off photoelectron angle was 45° relative to the surface.

2.2. Surface characterization techniques

The XPS spectra were recorded with a PHI ESCA/SAM 5600 Multy technique spectrometer equipped with a monochromatized Al Kα X-ray source. The analyses were carried out at 45° photoelectron take off angle relative to the sample surface with an acceptance angle of ±7°. Binding Energy (BE) scale was calibrated by centering the adventitious/hydrocarbon carbon C1s at 285.0 eV [8].

ATR-IR spectra of the monolayers were recorded on JASCO FT-IR 430 equipped with a Harrick GATR germanium single reflection accessory, collecting the spectra with 80 scans at 2 cm^{-1} resolution from 4000 to 400 cm^{-1}.

AFM images were obtained in high amplitude mode (tapping mode) by a NT-MDT instrument. The noise level before and after each measurement was 0.01 nm.

3. Results and discussion

Direct photochemical grafting: The photochemical stability of Fe_4 derivatives was tested by UV–Vis spectroscopy on a solution of **2** in cyclohexane.

Table 1
XPS quantitative data (%) relative to the functionalized silicon surfaces. Take off photoelectron angle was 45° relative to the surface.

2, *one pot* route	1.4	36.3	26.3	36.0	/
3, *one pot* route	1.5	37.4	21.5	39.6	/

The room temperature UV–Vis spectrum registered in the range between 200 and 325 nm is shown in Fig. 1 as a function of irradiation time at 254 nm, the wavelength to be used for the photochemical hydrosilylation [5].

The UV–Vis spectrum before irradiation is dominated by an absorption around 274 nm, which is assigned to the $\pi \rightarrow \pi^*$ transition of the β-diketonate ligand [9]. After 2 h of exposure at 254 nm the spectrum does not change significantly. After 6-h irradiation the intensity of the band centered at 274 nm decreases and a shift of absorbance to higher frequency is noted. After 18-h irradiation, the characteristic bands of the Fe_4 complex become negligible thus indicating that Fe_4 clusters undergo extensive decomposition upon prolonged irradiation.

To perform the photochemical hydrosilylation while avoiding significant complex decomposition, the irradiation time for the SMM grafting was set lower than 2 h. Therefore, direct photochemical Si-anchoring of **2** and **3** was attempted by exposing H-terminated silicon surfaces to the respective complex solutions under 90 min of UV irradiation [5].

After the photochemical reaction, XPS spectra of the silicon substrates show the presence of carbon, silicon and oxygen. The intensity of the Fe 2p doublet is very low (Fig. 2a), suggesting a negligible presence of iron on the surface.

The elemental compositions of the samples after the direct grafting process are reported in Table 1. Moreover, XPS data of two reference samples, a freshly etched Si(100) and the same sample after 18 h immersion in a solution of **2** with no irradiation are also reported for comparison.

The iron concentration of the grafted samples is similar to that detected in the reference sample exposed to a solution of **2** with no UV irradiation and, hence, comparable to the contribution of physisorbed clusters. Therefore, the direct photochemical grafting appears to have sever drawbacks presumably due to the scarce reactivity of the functionalized tetrairon(III) complexes with the H-terminated surface.

However, the amount of carbon after direct photochemical grafting is much higher than in the two reference samples (see Table 1), indicating the presence of a carbonaceous overlayer on the substrates.

The carbonaceous overlayer can be due to the hydrosilylation reaction between the Si surface and the free tripodal ligands in equilibrium with **2** and **3**.

AFM lithography has been used to determine if the thickness of the organic overlayers is consistent with monolayers of H_3L^1 and

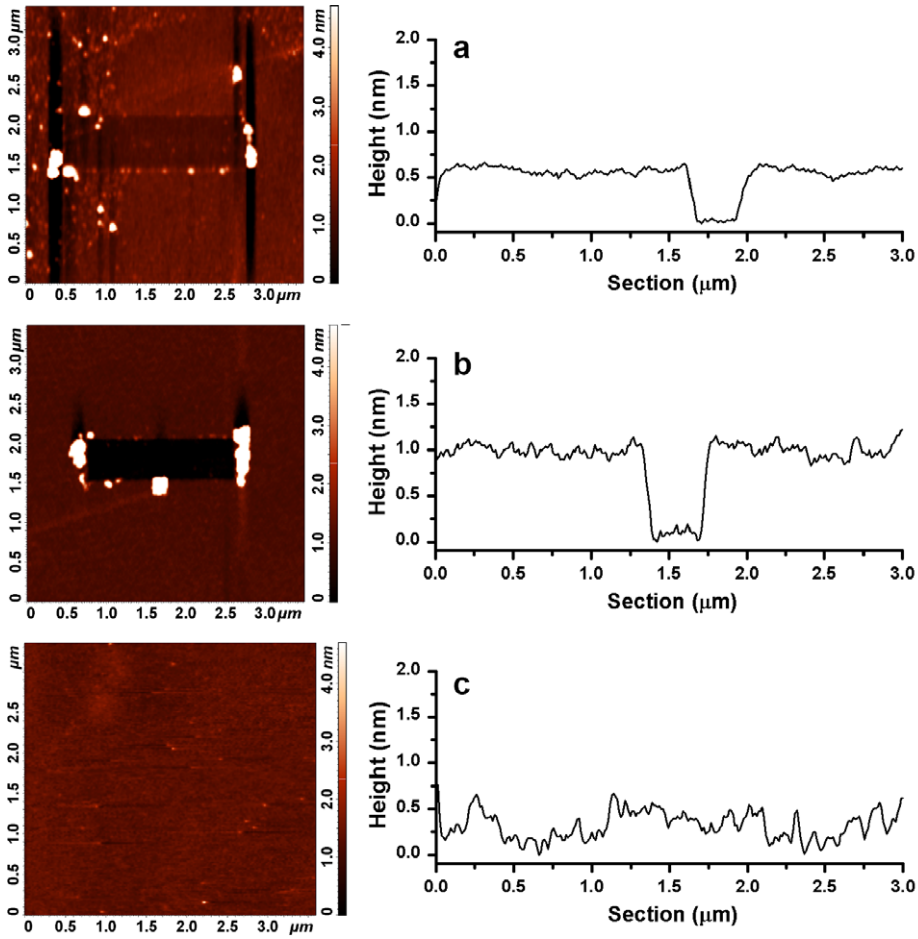

Fig. 3. The semi-contact AFM topography images and the relative height profiles after the lithography procedure, recorded on (a) a H-terminated silicon surface after 90-min photochemical grafting in a solution of **2**, (b) in a solution of **3** and (c) a H-terminated silicon surface after immersion of 18 h in a solution of **2** with no irradiation.

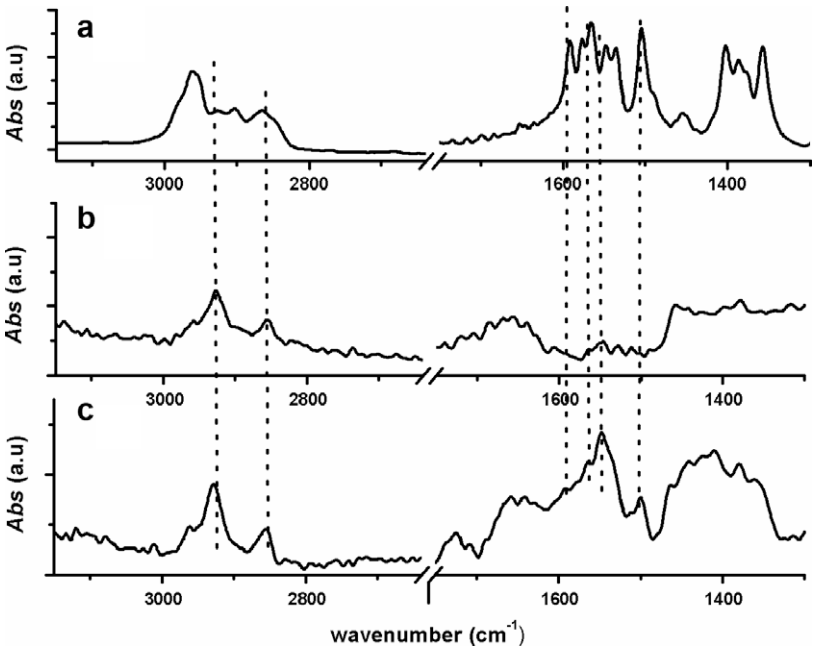

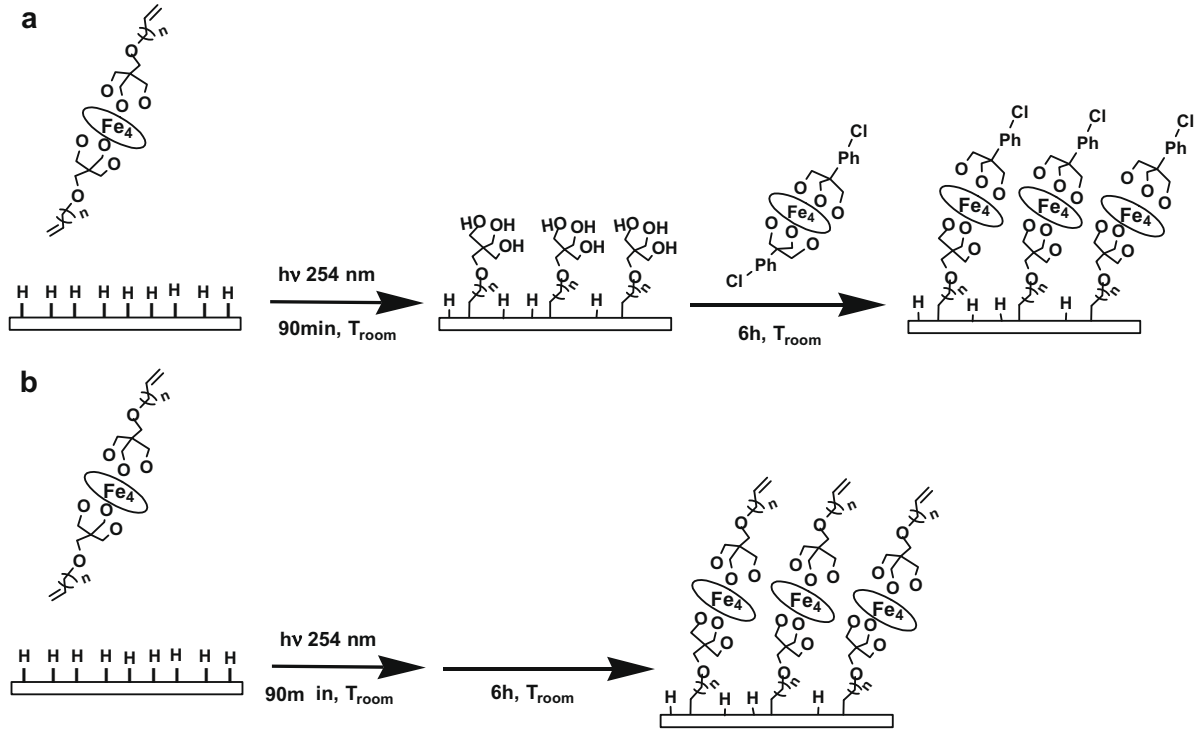

Fig. 4. (a) FT-IR spectrum of a microcrystalline sample of **2**, (b) ATR-IR spectrum of an H-terminated silicon surface after 90 min photochemical grafting in a solution of **2** and (c) of the H-terminated silicon surface after *one pot* procedure using **2**.

H_3L^2 grafted on the Si surface. The technique consists in removing the molecular film by applying a significant force on the layer with the AFM tip. The AFM lithography was used to scratch an area of 2 μm × 0.5 μm, by rastering the AFM tip (30 nm of curvature radius) in contact mode and applying a force of ~180–200 nN [10,11]. A larger area 3.5 μm × 3.5 μm containing the rastered zone was scanned for a second time in semi-contact regime to acquire a topographic image (Fig. 3).

It was observed that the organic material on the surface is displaced as a consequence of the high pressure applied on the sample: regular scratches were produced on samples obtained by photochemical grafting with solutions of both **2** and **3**, thus indicating the presence of monolayers on the silicon surface (Fig. 3a and b).

The depth of these scratches, evaluated in the cross sections, is considered equal to the layer thickness and amounts to ~0.6 nm

Scheme 2. (a) Photochemical grafting followed by ligand exchange with chlorine-marked cluster **4** and (b) Fe_4 cluster anchoring with *one pot* route.

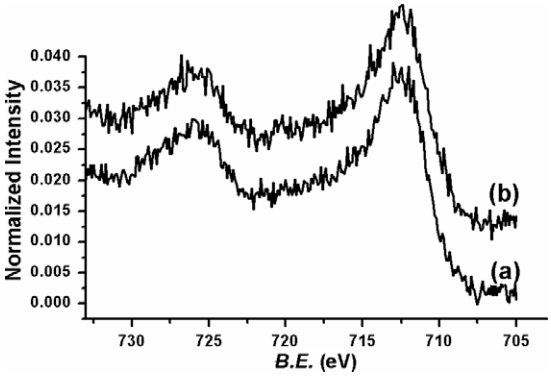

Fig. 5. High resolution Fe 2p XPS region relative to the silicon surface after the *one pot* procedure with **2** (a) and **3** (b). The intensities are normalized to the total Si 2p intensity. For clarity, the spectrum of **3** is reported with a 0.01 *y*-axis shift. Take off photoelectron angle was 45° relative to the surface.

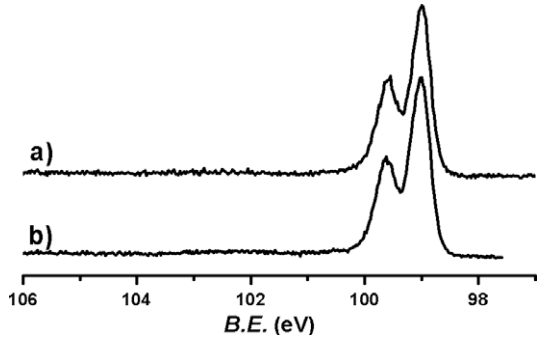

Fig. 6. High resolution XPS Si 2p region of (a) **2** and (b) **3** grafted silicon via *one pot* process.

and ~0.9 nm for **2** and **3**, respectively. These values are lower than the lengths of the respective tripodal ligands (H_3L^1 = ~0.8 nm and H_3L^2 = ~1.6 nm) optimized with a QM-DFT modeling package. This is consistent with the presence of H_3L^1 and H_3L^2 monolayers with a bent configuration of the alkyl chains.

To prove that the applied lithography conditions cannot scratch the substrate but only the organic overlayer, the same lithography process was applied to the reference sample obtained after 18 h immersion in a solution of **2** with no irradiation. In this case, no scratch was created by the AFM tip in the same operative conditions (Fig. 3c).

ATR-IR measurements have been used to determine the nature of the carbon overlayer. Fig. 4b shows the ATR-IR spectrum of the grafted silicon sample immersed in the solution of complex **2** for 90 min under UV irradiation.

The stretching modes of CH_x moieties in the range 2800–3000 cm^{-1} are easily detectable indicating the presence of the ligand alkyl chain, however, no significant further information can be obtained. The analysis does not allow to identify the diagnostic signals of species at the surface like hydroxyl functionalities of the tripodal receptors ($\nu \sim 3450$ cm^{-1}), since they are hidden beneath the broad band of H_2O adsorbed on the surface whose bending vibration is also visible at ca. 1650 cm^{-1}. The hydrophilic behavior of the surface can be due to the presence of terminal –OH functionalities of the tripodal receptors H_3L^1 and H_3L^2 at the surface. At lower wave numbers, no signal from β-diketonate C–O stretching is observed around 1560 cm^{-1}.

To confirm the nature of the H_3L^1 and H_3L^2 monolayers formed after the photochemical grafting from **2** and **3**, respectively, we attempted a ligand exchange reaction using a previously-described chlorine-marked Fe_4 cluster $[Fe_4(L^3)_2(tmhd)_6]$ (**4**), where H_3L^3 = 2-(4-chloro-phenyl)-2-hydroxymethyl-propane-1,3-diol [5].

The XPS spectrum of the sample after photochemical grafting using a solution of **3** and after the ligand exchange reaction shows the presence of all the elements expected: O, C, Si, Fe and Cl.

Both XPS quantitative analysis (Table 1) and the intensity of the Fe 2p XPS bands (Fig. 2b) indicate the presence of the anchored Fe_4 cluster on the tripodal ligands. Moreover, the Cl/Fe intensity ratio is halved as compared with that observed on a microcrystalline sample of **4**, as expected for the exchange of one L^{3-} ligand with one surface-bound tripodal receptor (Scheme 2a).

One pot procedure: The formation of ligand monolayers as result of the direct photochemical grafting of **2** and **3** suggested to extend the immersion time after UV irradiation so as to allow subsequent ligand exchange. The new approach thus consists in a 90-min UV irradiation of the Fe_4 solution (**2** or **3**), followed by a 6-h waiting time in which the Si substrate is left undisturbed in the solution with no irradiation. This novel procedure will be named *one pot* reaction, since it requires just one reaction environment.

The XPS spectra of samples obtained by *one pot* process present all the expected elements: O, C, Si and Fe. The high resolution XPS region of Fe 2p shows the presence of the doublet 3/2 and 1/2 with the $2p_{3/2}$ peak centered at 711.0 eV as expected (Fig. 5). The position and the shape of Fe 2p band are similar to those detected on microcrystalline samples of **1** and **4** and are in good agreement with the presence of Fe^{+3} species. XPS atomic concentrations for samples obtained by *one pot* route are reported in Table 1.

The intensity of the Fe 2p peaks (Fig. 5 and Table 1) for both **2** and **3** is notably higher as compared to the signal observed in the case of the direct photochemical grafting (Fig. 2 and Table 1) and indicates the successful anchoring of the iron cluster.

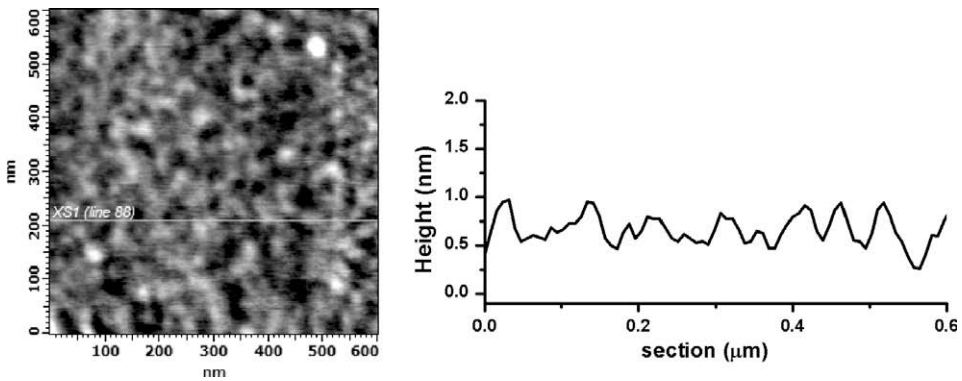

Fig. 7. (a) The semi-contact AFM morphology image and (b) height profile of a Si (100) surface after the "one pot" process using **3**.

As compared with previously-reported [5] multistep procedures, the herein proposed one-step approach is faster and has lesser manipulation requirements. Indeed, while the Si 2p XPS regions observed after the three-step Fe_4 anchoring shows a component centered at ~102.5 eV [5] indicating the presence of surface oxidation, nearly no detectable oxide component is observable after the *one pot* procedure with both **2** and **3** (Fig. 6).

The morphology of the surfaces was evaluated by AFM (Fig. 7): as seen previously for the three-step procedure [5], the presence of iron clusters slightly modifies the morphology of the surface that appears more structured (R.M.S. = 0.21) if compared with the monolayer of ligands (R.M.S. = 0.11) shown in Fig. 3.

The profile in the cross section shows that the average size of the structures is ~0.7 nm consistent with the expected height of the magnetic complex.

ATR-IR spectra were also recorded after *one pot* procedure using **2**. Fig. 4c shows new bands around 1550–1600 cm^{-1}, which compare well with those observed in microcrystalline **2** (Fig. 4a) and are attributed to the β-diketonate ligands [5,12].

4. Conclusions

A novel route for the *one pot* grafting of Fe_4-type SMM on H-terminated Si using photochemical hydrosilylation has been developed. Two Fe_4 complexes have been used which contain tripodal ligands featuring alkene-terminated hydrocarbon chains of different length. Direct photochemical hydrosilylation reaction from cluster solutions leads to the formation of ligand layers. Further contact of the substrate with the cluster solutions without UV irradiation leads to cluster anchoring via ligand exchange.

This one-step anchoring procedure is simpler and faster than the previously reported [5] three-step approach. Furthermore, it requires lesser surface manipulation and thus affords cleaner and less oxidized surfaces.

In this paper, we will report on a novel family of highly π-extended tetraaryl-*m*-phenylenediamines (**4a–c**), where aryl groups are directly attached to the peripheral aromatic rings of the diamine framework (Fig. 2). We also describe molecular design rules to stabilize the oligocationic state.

2. Results and discussion

2.1. Molecular design and synthesis of the diamines by Suzuki coupling

During the last two decades, much efforts have been paid to design, generation and detection of triarylamine-based positively charged high-spin molecules. The stability of the corresponding mono- and dicationic states is a key issue to realize them. Generally, introduction of electrodonating groups raises the HOMO energy level, leading to the thermodynamically more stable oxidized states. Thus, one may consider that the more electron donating groups are introduced, the more stable the corresponding oligocationic states are. This strategy worked well enough for the generation and characterization of triarylamine-based high-spin molecules as exemplified by **1**. However, taking into account their applications to molecular devices and supramolecular systems, more sophisticated molecular design rules should be established. In concrete terms, both (i) facile π-extension of molecular structures and (ii) high stability of the corresponding oxidized states should be satisfied.

Generally, aryl halides are widely used as convenient compounds in conventional and modern organometallic syntheses. Until now, numerous organic syntheses using aryl halides have been reported. Among them, Suzuki coupling [4] is an attractive and powerful method for syntheses of biaryls in excellent yields. In fact, the coupling has been utilized in many laboratories for syntheses of natural and artificial molecules. *N,N,N′,N′-tetrakis(4-iodophenyl)-4,6-dimethyl-1,3-phenylenediamine* (**5**) was prepared by the method reported by us [2m]. A series of π-extended tetraaryl-*m*-phenylenediamines were prepared by Suzuki coupling as shown in Fig. 3. The synthetic procedure of **4a** is described below.

The mixture of compound **5**, catalytic amount of Pd $(PPh_3)_4$, excess amount of K_3PO_4 and 5 equivalents of phenyl boronic acid in *n*-butanol, was refluxed for 18 h under argon atmosphere. The obtained crude powder was repeatedly washed with ethanol to give **4a** as pale yellow crystals in 72% yield. Compounds **4b–c** were also prepared in the similar manner. The NMR spectra and HRMS data for these molecules are consistent with their assigned structures as shown below:

4a: ^{1}H NMR($CDCl_3$); δ 2.08 (s, 6H), 7.08 (d, 8H, *J* = 8.8 Hz),7.11 (s, 1H), 7.20 (s, 1H), 7.28 (t, 4H, *J* = 7.3 Hz), 7.39 (t, 8H, *J* = 7.3 Hz) 7.45 (m, 5H, *J* = 8.8 Hz) 7.54 (d, 8H, *J* = 7.3 Hz).

HRMS(FAB): *m*/*z*: calc. for $C_{56}H_{44}N_2$ $[M]^+$: 744.3505. Found: 744.3506%.

4b: ^{1}H NMR($CDCl_3$); δ 2.08 (s, 6H), 2.38 (s, 12H) 7.07 (d, 8H, *J* = 8.8 Hz), 7.11 (s, 1H), 7.19 (m, 9H), 7.43 (d, 16H, *J* = 8.8 Hz).

HRMS(FAB): *m*/*z*: calc. for $C_{60}H_{52}N_2$ $[M]^+$: 800.4131. Found: 800.4131%.

4c: ^{1}H NMR($CDCl_3$); δ 2.07 (s, 6H), 3.84 (s, 12H), 6.92 (d, 8H, *J* = 8.8 Hz), 7.05 (d, 8H, *J* = 8.8 Hz), 7.08 (s, 1H), 7.17 (s, 1H), 7.39 (d, 8H, *J* = 8.8 Hz), 7.46 (d, 8H, *J* = 8.8 Hz).

HRMS(FAB): *m*/*z*: calc. for $C_{60}H_{52}N_2O_4$ $[M]^+$: 864.3927. Found: 864.3924%.

2.2. UV/Vis and emission spectra

We previously reported the UV/Vis and emission spectra of **3a–c**. Compound **3a** exhibited a broad absorption band around 360 nm in THF. Upon excitation at 360 nm, **3a** exhibited blue emission at 410 nm. This was the first report of fluorescent tetraaryl-1,3-phenylenediamines. On the other hand, Compounds **4a** exhibited a broad absorption band around 330 nm in THF, which is remarkably red-shifted in comparison with that of **1** (λ_{max} = 295 nm). Compound **4b-c** exhibited similar absorption peaks around 330–350 nm, respectively. Upon excitation at 330 nm, **4a** exhibited a strong emission at 400 nm. Compound **4b-c** exhibited similar strong emission peaks around 400–420 nm upon excitation at the absorption peak wavelength around 330–350 nm, respectively. The absorption and emission spectra of **4a** are shown in Fig. 4 as representative cases. These compounds can also be regarded as fluorescent high-spin molecule precursors.

2.3. Cyclic voltammetry

Redox potentials of tetraaryl-1,3-phenylenediamines are important factor to predict the stability of the corresponding mono- and dicationic states. For example, compound **1** [2b,c,j], which gives very stable mono- and dicationic states, has the lowest oxidation potentials in a series of tetraaryl-1,3-phenylenediamines we have examined ($E_1^0 = 0.21$ V, $E_2^0 = 0.37$ V versus Fc/Fc^+). Upon cyclic voltammetry in *n*-butyronitrile with 0.1 M Bu_4NPF_6 as a

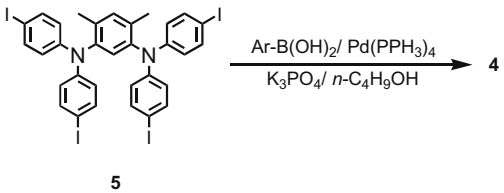

Fig. 3. Synthetic route of **4**.

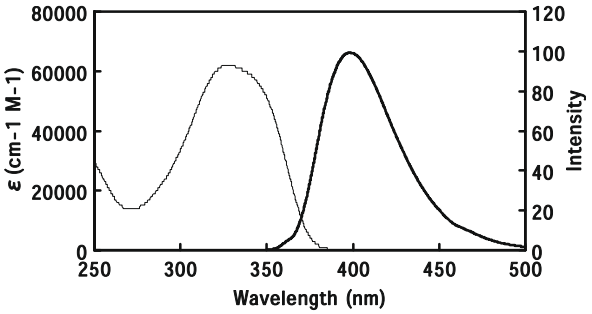

Fig. 4. Absorption (plain) and emission (bold) spectra of **4a** in THF.

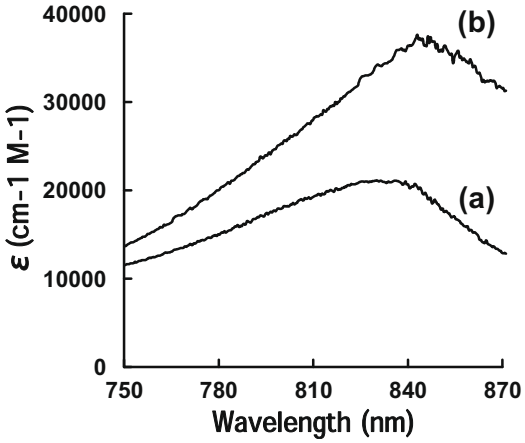

Fig. 6. Absorption spectra observed after mixing of an AN solution of 0.10 mM $TDBPA^{+\cdot}$ with an AN solution of (a) 0.10 mM and (b) 0.050 mM of **4a**.

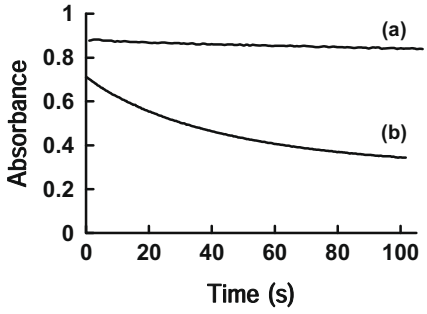

Fig. 7. Time profiles in the absorbance maximum observed after mixing of an AN solution of 0.10 mM $TDBPA^{+\bullet}$ with an AN solution of (a) 0.10 mM and (b) 0.050 mM of **4a**.

supporting electrolyte, compound **4a** showed two sets of reversible redox couples ($E_1^0 = 0.45$ V, $E_2^0 = 0.60$ V versus Fc/Fc^+), indicating stable mono- and dicationic states. The cyclic voltammograms of **3a** and **4a** are shown in Fig. 5 as representative cases. Similarly, compounds **4b** and **4c** exhibited similar reversible redox couples, respectively (**4b**: $E_1^0 = 0.42$ V, $E_2^0 = 0.59$ V versus Fc/Fc^+, **4c**: $E_1^0 = 0.37$ V, $E_2^0 = 0.52$ V versus Fc/Fc^+). Previously, we reported that compounds **3a–c** with acetylene moieties, give very unstable monocationic states, respectively. As we have expected, compounds **4a–c** without acetylene moieties, give stable mono- and dicationic states in the time scale of CV measurements. Direct introduction of four aryl groups endowed tetraaryl-1,3-phenylenediamine with high stability of the mono- and dicationic states.

2.4. Electron transfer stopped-flow (ETSF) measurements

In order to examine the absorption spectra of oxidized species of **4a–c**, ETSF measurements were conducted. The detail of the ETSF method was described previously [5,6]. The ETSF measurements were carried out in dehydrated acetonitrile (AN) as solvent at ambient temperature. In this study, tris (2,4-dibromophenyl) amine cation radical ($TDBPA^{+\cdot}$) [7] was employed. Compound **4a**, upon mixing with one equivalent of $TDBPA^{+\cdot}$, exhibited a broad absorption peak at 830 nm (Fig. 6), which is remarkably red-shifted in comparison with that of $\mathbf{1}^{+\cdot}$ (λ_{max} = 685 nm), and no decrease in the peak intensity was observed over 100 s, indicating the generation of the stable monocation $\mathbf{4a}^{+\cdot}$ (Fig. 7). The molar absorptivity (ε) of $\mathbf{4a}^{+\cdot}$ was determined to be $2.11 \times 10^4\ M^{-1}\ cm^{-1}$ at 830 nm.

Upon mixing with two equivalents of $TDBPA^{+\cdot}$, **4a** exhibited an absorption peak of the dication $\mathbf{4a}^{2+}$ at 846 nm. The ε value for $\mathbf{4a}^{2+}$ was $3.75 \times 10^4\ M^{-1}\ cm^{-1}$ at 846 nm (Fig. 6). The ratio of ε for the monocation:dication of **4a** was nearly 1:2 as expected. The peak gradually decreased over 40 s, indicating unstable dication $\mathbf{4a}^{2+}$ (Fig. 7). Compared to **3a** with phenylacetylene units, the stability

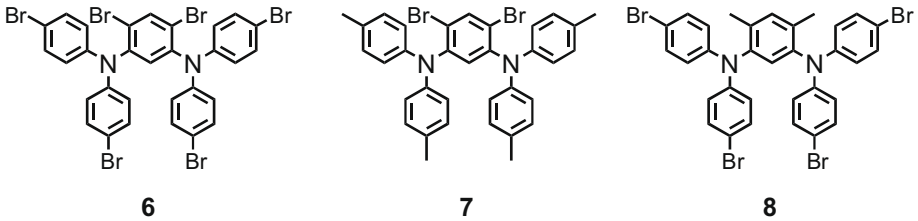

Fig. 8. Structures of **6–8**.

of the monocation $\mathbf{4a}^{+\cdot}$ was remarkably increased, whereas the dication $\mathbf{4a}^{2+}$ was still unstable. Cyclic voltammetry measurements showed **4b** and **4c** are easily oxidized than **4a**, thus, monocations, $\mathbf{4b}^{+\cdot}$ and $\mathbf{4c}^{+\cdot}$, are expected to be thermodynamically more stable than **4a**.

Surprisingly, similar ETSF measurements for **4b** and **4c** revealed that the monocations, $\mathbf{4b}^{+\cdot}$ and $\mathbf{4c}^{+\cdot}$, were less stable than $\mathbf{4a}^{+\cdot}$ ($\mathbf{4b}^{+\cdot}$; λ_{max} = 869 nm, $\mathbf{4c}^{+\cdot}$; λ_{max} = 876 nm). These monocations slowly decomposed over 30 s, respectively. Introduction of electrodonating groups is an effective strategy to stabilize the oxidized states as described above; however that is not the sole one. For example, we have systematically designed and synthesized three types of brominated tetraaryl-*m*-phenylenediamine (**6–8**) (Fig. 8). Cyclic voltammetry and ETSF measurements have revealed that only **6** and **7** give very stable dicationic states, i.e., the bromo groups on the central aromatic ring stabilize the dicationic states effectively. We are currently exploring effective substitution groups that can stabilize the mono- and dicationic states.

3. Conclusion

In conclusion, we have designed and successfully synthesized highly π-extended tetraaryl-1,3-phenylenediamines in excellent yields by Suzuki coupling. Direct introduction of four aryl groups endowed tetraaryl-1,3-phenylenediamine with fluorescent property. The ETSF measurements showed that **4a** gives the very stable monocation and fairly stable dication. The fluorescent property of $\mathbf{4a}^{+\cdot}$ is now under study. Unfortunately, **4b–c** gave less stable monocation radicals. Molecular designs and syntheses of novel photochemically or electrochemically active diamines derived from **5** by organometallic methods are also in progress.

The ferromagnetic phase transition temperature is calculated by the Langevin–Weiss mean-field theory in combination with the calculated J values as shown [13–15]:

$$k_B T_c = \frac{2}{3} S(S+1) \sum J_{ij} \quad (3)$$

Moreover, in order to detail analysis of the magnetic transition temperatures of β- and γ-phase *p*-NPNN crystals, Monte Carlo ising spin simulation was also carried out. In these simulations, $12 \times 12 \times 12$ lattice with a periodic boundary condition was used. Especially, Wolff type cluster flipping method was applied for γ-phase *p*-NPNN model system [16].

3. Results and discussion

3.1. β-Phase p-NPNN

Fig. 1a illustrates the crystal structure of the β-phase *p*-NPNN with the Fdd2 space symmetry. Fig. 1a shows 12 nearest-neighbor p-NPNN molecules exist around the central *p*-NPNN. They are classified into three groups, which are denoted by the white, shaded and black circles. The effective exchange integrals between the central *p*-NPNN and the nearest neighbors in each group are equivalent and therefore one of them is explicitly defined as J_{1n} (n = 2–4) without loss of generality as shown in Fig. 1. Additionally, we have also examined the exchange interactions in the extended oligomers as illustrated in Fig. 2 in order to clarify the reliability of the nearest-neighbor approximation. The effective exchange integrals in the oligomers illustrated in Fig. 2a–c named J_{12}, J_{13}, and J_{14}, respectively. The Table 1 summarizes the total energies, $\langle S^2\rangle$ and J_{1n} values for clusters of β-phase *p*-NPNN by UB3LYP method. The $\langle S^2\rangle$ values of the dimers should be about 1.0 and 2.0, respectively, for the singlet and triplet broken symmetry solutions of the pure diradicals without spin polarizations of nonradical orbital

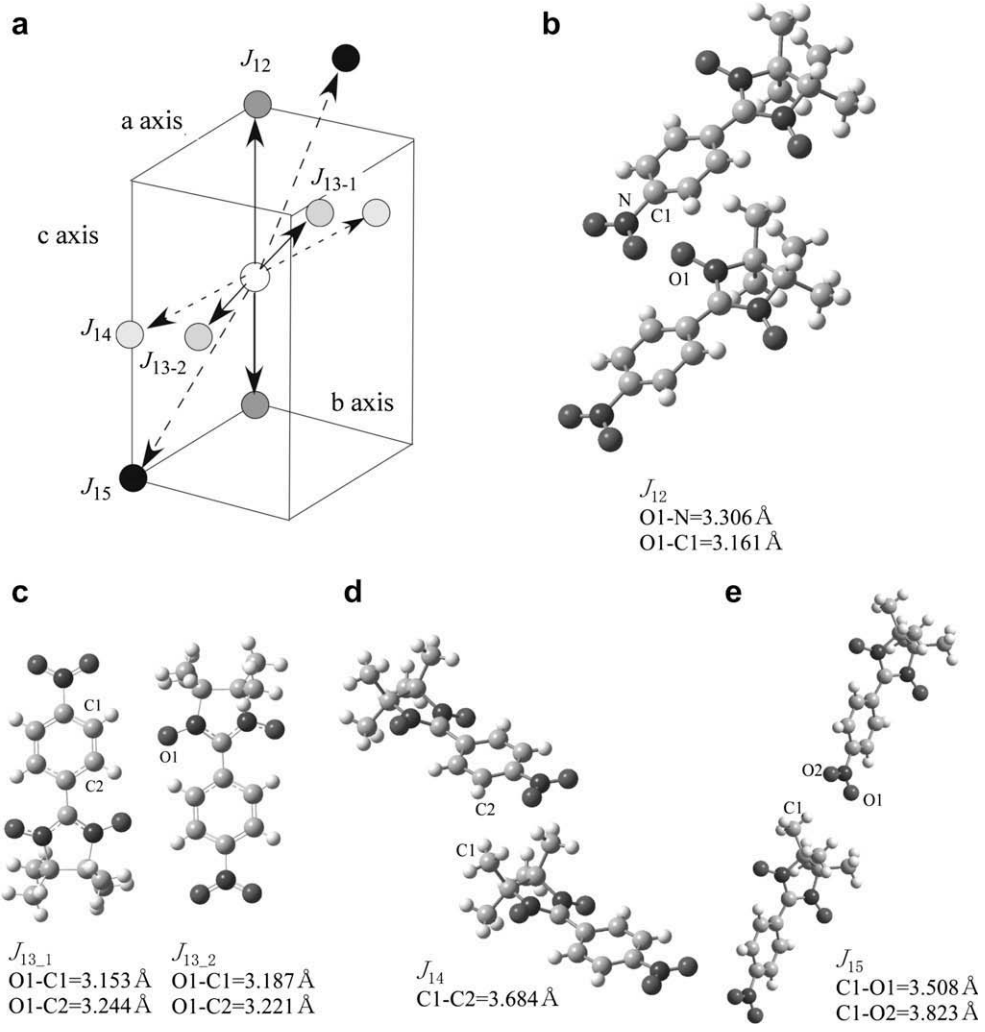

Fig. 3. (a) The crystal structure of the γ-phase *p*-NPNN with the $P\bar{1}$ space symmetry. J_{1n} (n = 2, 3_1, 3_2, 4, 5) denotes the effective exchange interactions, of (b) J_{12} type intermolecular interaction in the *c* direction of the γ-phase, (c) J_{13_1} and J_{13_2} type intermolecular interactions in the *bc* plane, (d) J_{14} type intermolecular interaction and (e) J_{15} type intermolecular interaction.

[a] UB3LYP/6-31G**.

pairs. The deviations of $\langle S^2\rangle$ values from the normal $\langle S^2\rangle$ values of the singlet and triplet broken symmetry solutions are about 0.1 for both states of the *p*-NPNN dimer, indicating the spin polarization effect. From Table 1, the J_{12} values for the clusters in Fig. 1b were calculated to be in the range 0.248–0.254 cm^{-1} at the experimental geometry. From the crystal structure in Fig. 1a, it is concluded that the ferromagnetic interaction is operative within the *ac* plane in accord with the experiment. The effective exchange integral (J_{13}) for the clusters in Fig. 1c is ferromagnetic in the range 0.652–0.519 cm^{-1}. From the spin density population analysis, it was found that the so-called McConnell-type spin density-product term between O–C1 and O–C2 atomic pairs are positive and negative, respectively. The net interaction after the mutual cancellation remains ferromagnetic in this stacking mode. The J_{14} values for clusters in Fig. 1d are almost zero. Therefore, the net interplane magnetic interaction is ferromagnetic. These results indicate the adequacy of the quasi three-dimensional Heisenberg-type model. In the next, UB2LYP (0.35) method was also applied to the β-phase *p*-NPNN dimmers. The obtained J_{1n} values were summarized in Table 6. The calculated J_{12} and J_{13} values also show the same signs with those using UB3LYP while the calculated J_{13} value by UB2LYP (0.35) is much smaller than that by UB3LYP. On the other hand, the J_{14} value by UB2LYP (0.35) has negative while that by UB3LYP is zero. However, the three-dimensional magnetic order in the β-phase *p*-NPNN crystal was ferromagnetic as the absolute values of J_{12} and J_{13} are larger than that of J_{14}. Therefore, it could be concluded that the calculation results by both hybrid-DFT methods predict the long-range three-dimensional ferromagnetic ordering in the β-phase *p*-NPNN crystal.

Then the ferromagnetic transition temperatures (T_c) calculated by Langevin–Weiss model and Monte Carlo simulation using the *J* values calculate by UB3LYP are 2.2 and 1.7 K, respectively. These values are slightly larger than the experimental value (T_c = 0.60 K). On the other hand, the ferromagnetic transition temperatures (T_c) calculated by Monte Carlo simulation using the *J* values calculate by UB2LYP (0.35) are 0.7 K. The obtained ferromagnetic transition temperature is much closer to the experimental result. Therefore, it could be concluded that the obtained results are in qualitatively agreement with the experimental results.

J_{1n} (n = 2–5) denotes the effective exchange interactions, of (b) J_{12} type intermolecular interaction, (c) J_{13} type intermolecular interaction, (d) J_{14} type intermolecular interaction and (e) J_{15} type intermolecular interaction.

3.2. γ-Phase p-NPNN crystal

Fig. 3a shows the schematic diagram of the crystal structure of the γ-phase *p*-NPNN with $P\bar{1}$ space symmetry. From Fig. 3a, there are eight nearest-neighbor *p*-NPNN molecules in this monoclinic crystal. According to this space symmetry, the effective exchange interactions among these molecules are classified into five different types which are defined by J_{12}, J_{13_1}, J_{13_2}, J_{14} and J_{15} as shown in Fig. 3b–e illustrate intermolecular interactions which are responsible for the above mentioned *J* values. UB3LYP calculations of the dimmers were carried out to examine the *J* values. Table 2 summarizes the total energies, $\langle S^2\rangle$, and *J* values. The deviations of the $\langle S^2\rangle$ values form the normal values are about 0.1 for both states of the *p*-NPNN dimer. This tendency is similar to the results of β-phase *p*-NPNN model clusters. The effective exchange integral

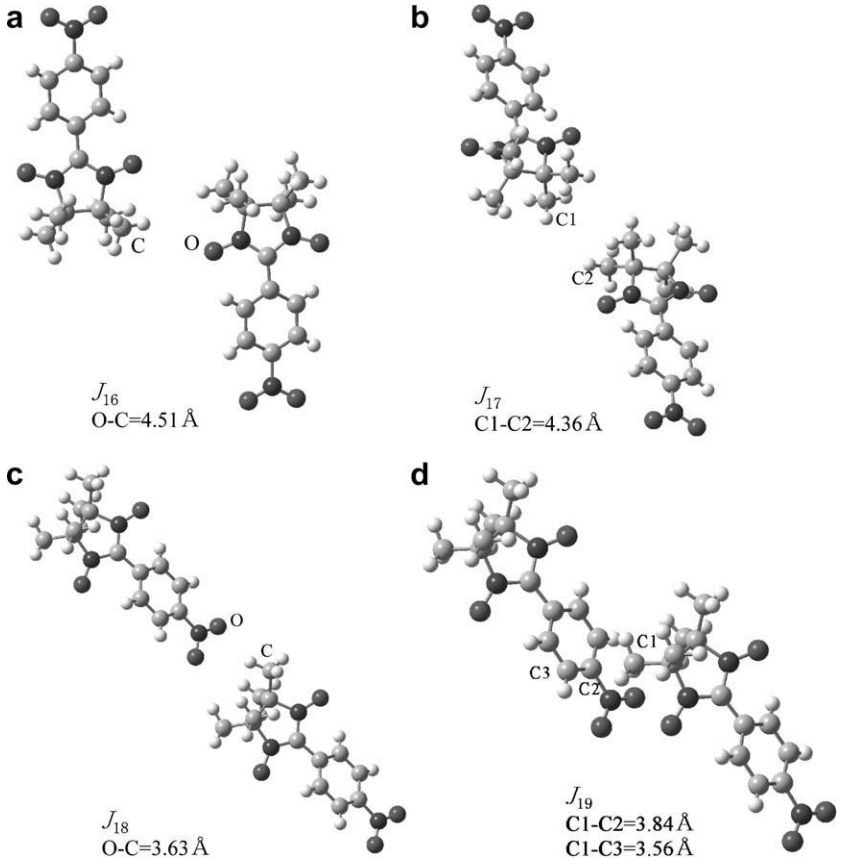

Fig. 5. (a) J_{1n} (n = 6–9) denotes the effective exchange interactions, of (b) J_{16} type intermolecular interaction, (c) J_{17} type intermolecular interactions, (d) J_{18} type intermolecular interaction and (e) J_{19} type intermolecular interaction.

(J_{12}) between the spins on *p*-NPNN molecules shown in Fig. 3b is positive (ferromagnetic) and is the largest in magnitude among the calculated J values in Table 2. The oxygen atom (O1) of the nitronyl nitroxide group of *p*-NPNN interacts with the C1 of its nearest-neighbor *p*-NPNN in the *bc* plane, as illustrated in Fig. 3b. Judging from the spin density analysis, the McConnell-type spin-density-product term between the O1–C4 pair should be negative and the resulting effective exchange integral is positive (ferromagnetic). Consequently, the through-space interaction gives rise to a parallel spin alignment of the SOMO spins via the spin polarization mechanism.

Fig. 3c illustrates the neighboring dimer of γ-phase *p*-NPNN depicted as the J_{13} type interaction in Fig. 3a. As the geometries of these dimers in Fig. 3a are slightly different, they named J_{13_1} and J_{13_2} type interactions, respectively. The sign of J_{13_1} and J_{13_2} are also positive. The oxygen atom (O1) of the nitronyl nitroxide group of *p*-NPNN interacts with C1 and C2 of its nearest neighbor in the *bc* plane. From the populations of the spin densities on these atoms, the McConnell-type spin-density-product terms between the O1–C2 pair and between the O1–C3 pair should be ferromagnetic and antiferromagnetic, respectively. The net through-space interaction is positive (ferromagnetic), giving rise to the parallel spin alignment of the SOMO spins via the spin polarization mechanism. Consequently, the two-dimensional ferromagnetic magnetic interactions would be presented by the J_{12} and J_{13} type stacking modes as shown in Fig. 7a.

Fig. 3d and e shows the J_{14} and J_{15} type interactions. The sign of J_{14} is calculated to be negative by the UB3LYP method, whereas that of J_{15} is positive. The magnitude of the former is a little larger than the latter, giving rise to the net antiferromagnetic interplane interaction the γ-phase. Therefore, the γ-phase crystal should exhibit an antiferromagnetic long-range order at a low temperature as the magnetic interaction between the neighboring two-dimensional ferromagnetic layers is antiferromagnetic.

In the next, UB2LYP (0.35) method was also applied to the γ-phase *p*-NPNN dimmers. The obtained J_{1n} values were summarized in Table 6. The calculated J values by UB2LYP (0.35) show the same signs and the similar absolute values with those using UB3LYP. Consequently, the calculation results by both HDFT methods suggest that the γ-phase crystal would exhibit an antiferromagnetic long-range order at a low temperature.

The Néel temperature of the γ-phase of *p*-NPNN can be estimated by using the J values calculated by the UB3LYP method:

$$k_B T_N = \frac{2}{3} S(S+1)(2J_{12} + J_{13_1} + J_{13_2} + 2|J_{14} + J_{15}|)$$

The calculated T_N is 5.7 K which is about 5 K larger than the experimental value (0.65 K). This is due to the low-dimensional antiferromagnetic interactions in the γ-phase *p*-NPNN crystal. Therefore, Wolff type Monte Carlo ising spin simulation was carried out in order to consider the effect of the low-dimensional magnetic interactions in the γ-phase *p*-NPNN. The Néel temperature is estimated to be 2.0 K by Monte Carlo simulation using the J values calculated by the UB3LYP method. The deviation from the experimental value was greatly reduced as the calculated T_N is about 1.3 K higher than the experimental value. The Néel temperature estimated by Monte Carlo simulation using the J values calculated by UB2LYP (0.35) method is almost same as the obtained J values are not so different from those by UB3LYP method. From the calculation results of the Néel temperature, it could be

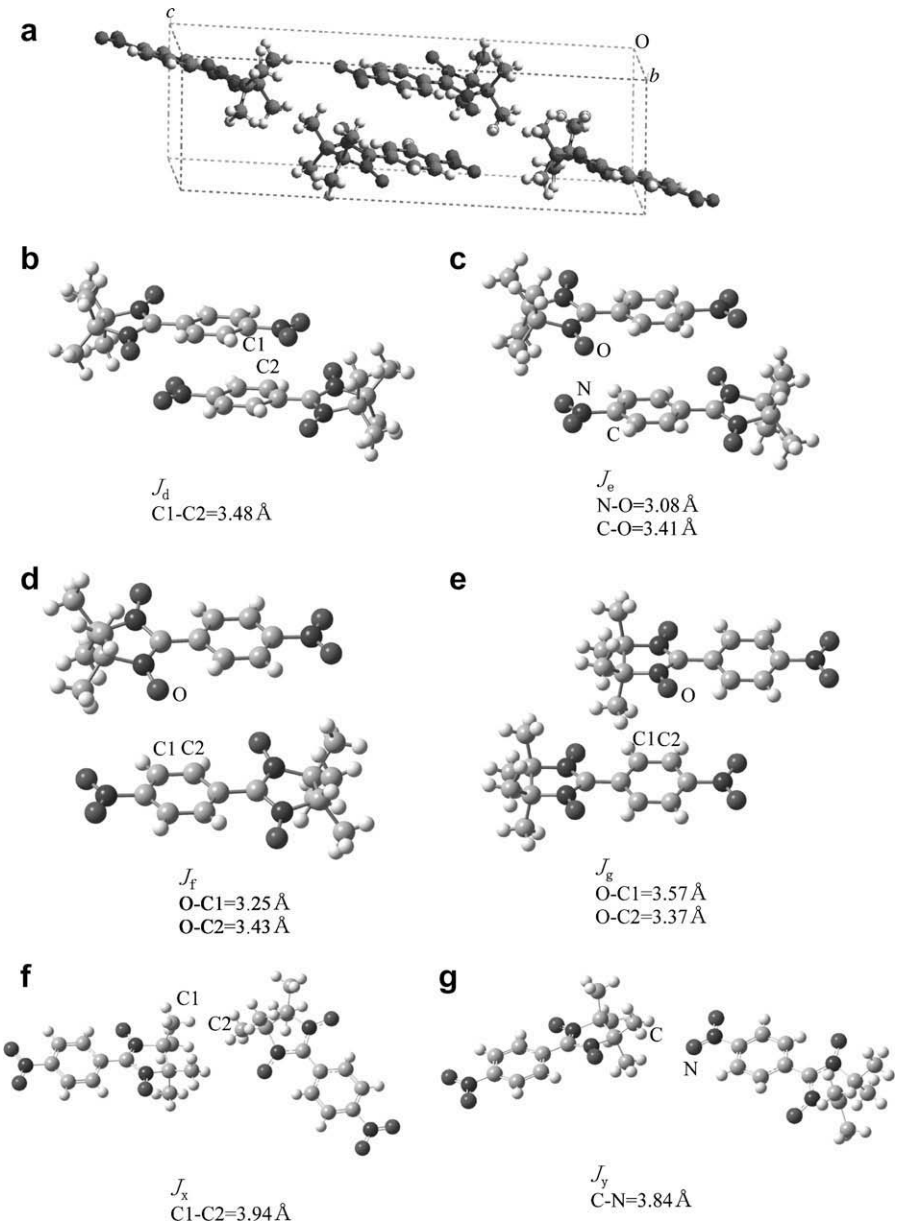

Fig. 6. (a) The crystal structure of the α-phase *p*-NPNN with the $P2_1/c$ space symmetry. J_{1n} (n = 2–7) denotes the effective exchange interactions, of (b) J_{12} type intermolecular interaction, (c) J_{13} type intermolecular interaction, (d) J_{14} type intermolecular interaction, (e) J_{15} type intermolecular interaction, (f) J_{16} type intermolecular interaction and (g) J_{17} type intermolecular interaction.

presumed that the magnetic interaction of J_{12} and J_{13} type model clusters were overestimated. This is due to the overestimation of the spin polarization on the phenyl group in *p*-NPNN molecule as the inclusion of Hartree Fock exchange integral into the hybrid E_{ec} functional enhances this effect.

3.3. δ- and α-phase p-NPNN crystals

The space symmetry of the δ-phase *p*-NPNN crystal is $P2_1/c$. The crystal structure of δ-phase *p*-NPNN was displayed in Fig. 4a. In this phase, there is a head-to-tail NO···NO_2 stacking mode running along the *c*-axis with the translational symmetry as shown in Fig. 4b. Other stacking modes are the side-by-side intermolecular interactions between the NO···phenyl groups illustrated in Fig. 4c and e. In the δ-phase *p*-NPNN, another kind of NO···phenyl interaction is found as a result of the *c*-glide symmetry of the δ-phase. This stacking mode is also depicted in Fig. 4d. Therefore, these structures suggest that there is a relatively strong 2D intermolecular network in the δ-phase and these 2D networks are connected with weak methyl···methyl interactions.

The calculations of the magnetic interactions between the neighboring *p*-NPNN dimers in the δ-phase depicted in Fig. 4 were carried out by UB3LYP method. The obtained results are summarized in Table 3. The J_{12} and J_{14} type interactions depicted in Fig. 4a and c have relatively large positive values (ferromagnetic) while J_{13} and J_{15} have smaller positive values than J_{12} and J_{13} values. Consequently, the through-space interaction in this 2D layer gives rise to parallel spin alignment of the SOMO spin as shown in Fig. 7b. These calculation results are in qualitative agreement with the experimental results for the mean-field Curie–Weiss behavior of the χ_p^{-1} versus T plot of δ-phase *p*-NPNN. In the next, magnetic interaction between the ferromagnetic 2D layers were examined. The magnetic interactions between the neighboring *p*-NPNN molecules are classified into four models. These models depicted in Fig. 5

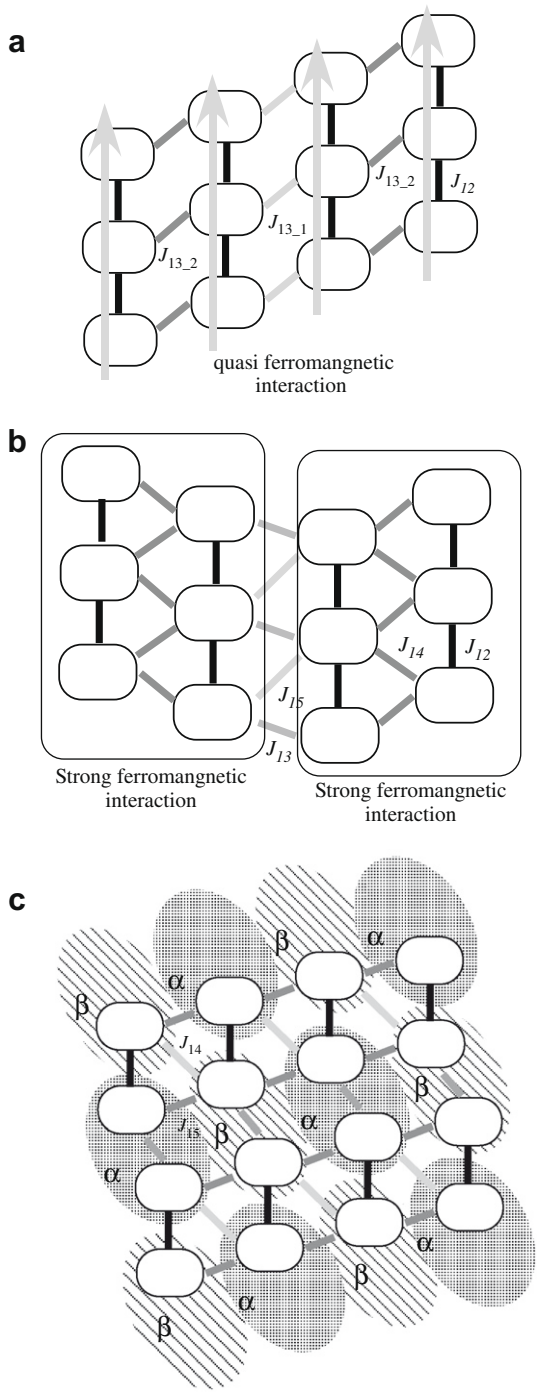

Fig. 7. The two-dimensional magnetic interactions in (a) γ-phase *p*-NPNN, (b) δ-phase *p*-NPNN and (c) α-phase *p*-NPNN.

were also examined by UB3LYP method. The obtained *J* values are also summarized in Table 3. As these dimers are connected with weak methyl. . .methyl interactions, the absolute values of the obtained *J* values are much smaller than those of the intralayer *J* values in the δ-phase. From the calculation results, it was found that there are three negative *J* values and one positive *J* value between the neighboring 2D layers. As the summation of these four *J* values is negative, it seems that the magnetic interaction between the 2D layers is negative (antiferromagnetic).

In the next, α-phase *p*-NPNN was investigated. The space symmetry of the α-phase *p*-NPNN crystals is also $P2_1/c$. The crystal structure is depicted in Fig. 6a. The figures depicted in Fig. 6

suggest that the NO···NO_2 and NO···phenyl interactions are the important stacking modes in the α-phase as the distance between two molecules are relatively close. The crystal structure of the α-phase *p*-NPNN by X-ray analysis shows that two molecular layers, which are crystallographically equivalent but have different orientations due to the *c*-glide or to the twofold screw symmetry [6]. The layer consists of the twofold stacking along the *a*-axis. The stack comprises two types of intermolecular stacking modes. The one is face-to-face phenyl–phenyl staking depicted in Fig. 6b. The other one is NO···NO_2 stacking mode depicted in Fig. 4c. There are also two different types of intermolecular contact between the above mentioned stack. They are depicted in Fig. 4d and e. The schematic view of the molecular layer which consists of these

intermolecular contacts is illustrated in Fig. 7c. This molecular layer also interacts with the neighboring molecular layers with the intermolecular contacts. They are depicted in Fig. 6e and f.

As shown in Fig. 6, the magnetic interactions between the neighboring *p*-NPNN molecules are classified into six models. For these model dimers, the UB3LYP calculations were also carried out. The obtained results are summarized in Table 4. The calculation results indicate that there are two large effective exchange integrals with different signs (J_{12} and J_{13}) and two relatively small negative exchange integrals (J_{14} and J_{15}: ~ -0.1 cm^{-1}). The two-dimensional layer consist of the above mentioned four J values are antiferromagnetically ordered as shown in Fig. 7c. These calculation results are in qualitative agreement with the experimental results for the mean-field Curie–Weiss behavior of the χ_p^{-1} versus T plot of α-phase *p*-NPNN. Additionally, it seems that the magnetic interaction between the neighboring two-dimensional layers in the crystal is antiferromagnetic as all the J values (J_{16} and J_{17}) for the interactions between the neighboring layers are negative. Therefore, the calculation results suggest that the three-dimensional antiferromagnetic ordering would be achieved (Table 5).

The computations of *p*-NPNN clusters with their α- and δ-phase crystal geometries suggest three-dimensional antiferromagnetic interactions, which are crucial for the occurrence of the long-range magnetic order in the Heisenberg model. However, such a long-range magnetic order was not observed in the real α- and δ-phases of *p*-NPNN. There are two possibilities to explain this discrepancy. One is the nonuniformity of their crystal structures due to the experimental conditions and the other is a lack of the computational accuracy. Especially, there is a tendency that the absolute values of the J values calculated by HDFT method, such as B3LYP, are relatively overestimated those of the experimental J values in the view point of the computational accuracy as the calculated magnetic phase transition temperature for β- and γ-phases *p*-NPNN are larger than those of the experimental values. Therefore, further investigation using much more accurate post-Hartree Fock calculations for the small J values ($|J| < 0.1$ cm^{-1}) that are closely related to the occurrence of the three-dimensional long-range magnetic order in the *p*-NPNN crystals must be needed. The elucidation of the weak magnetic interactions in the *p*-NPNN crystals would be the next task as it is currently impossible to examine the weak magnetic interactions in the *p*-NPNN crystals by using much more accurate post-Hartree Fock methods.

4. Conclusions

The present theoretical calculations have revealed theoretical explanations of the organic ferromagnetism observed for the β-phase of *p*-NPNN and the organic antiferromangnetism observed for the γ-phase of *p*-NPNN. For the α- and δ-phases of *p*-NPNN, our calculation results are in qualitative agreement with the experimental results for the mean-field Curie–Weiss behavior of the χ_p^{-1} versus T plots of their crystals. However, there is a discrepancy between the obtained calculation results and the experimental results for the α- and δ-phases of *p*-NPNN in the view point of the occurrence of the three-dimensional long-range magnetic orders. These results suggest the necessity of the much more accurate post-Hartree Fock calculations for the investigation of the weak magnetic interactions ($|J| < 0.1$ cm^{-1}).

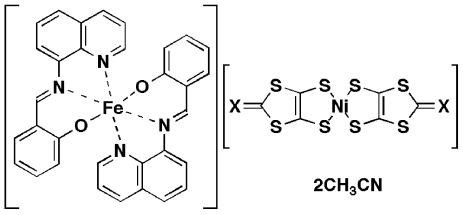

Fig. 1. Molecular structures of $[Fe(qsal)_2][Ni(dmise)_2] \cdot 2CH_3CN$ **1** (X = Se) and $[Fe(qsal)_2][Ni(dmit)_2] \cdot 2CH_3CN$ **2** (X = S).

droxy-1-naphtaldimine], demonstrated an almost complete spin transition between the low-spin (LS) and high-spin (HS) states, which is coupled with not only an electrical conducting modulation but also a uniaxial crystal lattice deformation [13]. The crystal structures before and after a spin conversion revealed that the anisotropic intermolecular $\pi-\pi$ interactions between the SCO cations as well as the change in volume of an SCO cation play an key role in the electrical conducting modulation. These results clearly indicate the importance of supramolecular interactions and their dimensionality.

It is well-known for large elastic contribution of lattice and molecular vibration for an SCO behavior. The modulation of the molecular size and electronic state by substitution gives an opportunity to clarify the mechanism of a spin transition of an SCO complex. In the further efforts to develop a new SCO materials, we have focused on $[Fe(qsal)_2][Ni(dmit)_2]\cdot 2CH_3CN$ **2**, which was the precursor of an SCO molecular conductor and showed a cooperative but irreversible spin transition [11]. In this paper we will disclose the magnetic properties and the crystal structures of the selenium analogue of **2**, namely, $[Fe(qsal)_2][Ni(dmise)_2]\cdot 2CH_3CN$ **1** (Fig. 1) and discuss the importance of intermolecular interactions for a cooperative spin transition.

2. Experimental

All chemicals were purchased and used without further purification. $[Fe(qsal)_2]Cl \cdot 1.5H_2O$ [14] and $TBA[Ni(dmise)_2]$ [15] were prepared according to the procedure of the previous literatures.

2.1. Synthesis of $[Fe(qsal)_2][Ni(dmise)_2] \cdot 2CH_3CN$ 1

The complex **1** was prepared by slow diffusion methods. An H-type glass cell where one arm placed $[Fe(qsal)_2]Cl \cdot 1.5H_2O$ (20 mg) and the other arm placed $TBA[Ni(dmise)_2]$ (25 mg) was slowly filled with acetonitrile (40 ml). Black prism crystals were grown within two weeks. The composition of **1** was determined by microanalysis.

Anal. Calc. for $C_{42}H_{28}N_6O_2FeNiS_8Se_2$: C, 42.83; H, 2.40; N, 7.14. Found: C, 42.70; H, 2.66; N, 6.96%.

2.2. Magnetic data collections

Variable temperature DC magnetic susceptibilities of polycrystalline samples (20 mg) were measured on a Quantum Design MPMS XL magnetometer with a field of 0.5 T and a scan speed of 2 K min^{-1} in the temperature range of 2–300 K.

2.3. X-ray data collections and refinement

A black prism crystal of **1** having approximate dimensions of $0.15 \times 0.10 \times 0.08$ mm was mounted in a nylon loop. All measurements were made on a Rigaku Mercury CCD area detector with graphite monochromated Mo Kα radiation generated by Rigaku CMF007 optics. The data were collected to a maximum 2θ value of 55.0°. A total of 720 oscillation images were collected. Data were collected and processed using CrystalClear (Rigaku). A numerical absorption correction was applied which resulted in transmission factors ranging from 0.617 to 0.799. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model. All calculations were performed using the CrystalStructure crystallographic software package (Rigaku).

2.4. Calculations of transfer integrals

The transfer integrals (t) were calculated by the extended Hückel molecular orbital calculation method by using lowest unoccupied molecular orbital (LUMO) of $Ni(dmise)_2$ and $Ni(dmit)_2$ for **1** and **2** as the basis functions within the tight-binding approximation [16]. The semiemperical parameters of Ni and Se for Slater-type atomic orbitals were taken from Refs. [17] and [18], respectively. The t between each pair of molecules is assumed to be proportional to the overlap integral (S), $t = ES$, where E is a constant value of -10.0 eV.

3. Results and discussion

3.1. Synthesis of $[Fe(qsal)_2][Ni(dmise)_2] \cdot 2CH_3CN$ 1

The $[Fe(qsal)_2][Ni(dmise)_2] \cdot xCH_3CN$ complexes were prepared by metathesis of $[Fe(qsal)_2]Cl \cdot 1.5H_2O$ and $TBA[Ni(dmise)_2]$ according to the previous report [11]. Slow addition of a filtered acetonitrile solution of $[Fe(qsal)_2]Cl \cdot 1.5H_2O$ to a filtered acetonitrile solution of $TBA[Ni(dmise)_2]$ gave black microcrystals, whose compositions were $[Fe(qsal)_2][Ni(dmise)_2] \cdot xCH_3CN$ (x = 1–1.5) by microanalysis. The $\chi_M T$ versus T products of these complexes showed sample dependence on the width and reproducibility of a thermal hysteresis loop. On the other hand, single crystals of $[Fe(qsal)_2][Ni(dmise)_2] \cdot 2CH_3CN$ **1** were obtained by a slow diffusion method. The composition of the complex **1** was confirmed by both microanalysis and crystal structural analysis (*vide infra*). Since the complex **1** showed reproducible magnetic properties, we will hereafter describe the magnetic properties and crystal structures of by using single crystalline samples.

3.2. Magnetic susceptibilities of 1

The temperature dependence of magnetic susceptibilities for **1** is shown in Fig. 2. The $\chi_M T$ value of **1** at 300 K is 4.22 cm^3 K mol^{-1}, suggesting that the Fe(III) ion is almost in the HS state.

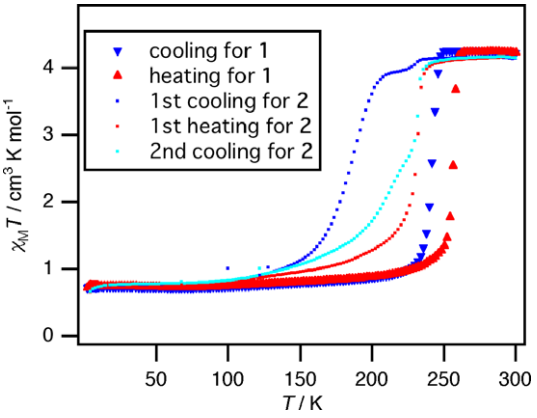

Fig. 2. $\chi_M T$ vs. T products for **1** and **2**.

On lowering the temperature, the $\chi_M T$ value decreased abruptly at 250 K. The spin conversion from the HS to LS states finished within 20 K ($T_{1/2}\downarrow$ = 241 K). The 87.5% Fe(III) ion of **1** is in the LS state at 200 K. On heating, the gradual spin conversion from the LS to HS states occurred at around 240 K and the $\chi_M T$ value recovered the original HS value at 260 K ($T_{1/2}\uparrow$ = 256 K). The reproducibility of the $\chi_M T$ versus T products of **1** on repeating the cooling and heating cycles reveals that the complex **1** exhibits a reversible spin transition with a thermal hysteresis loop of 15 K. The $\chi_M T$ values of **1** in both the low and high temperature phases are quite similar to those of the parent isostructural complex **2** [11] (*vide infra*), suggesting that the spins on the Ni(dmise)$_2$ molecules are antiferromagnetically coupled. The spin transition temperature of **2** in the first cooling process ($T_{1/2}\downarrow$ = 185 K) was different from that of **1** ($T_{1/2}\downarrow$ = 241 K). The similar increase in the spin transition temperatures induced by displacement with a heavy atom was reported for well-known Fe(II) SCO complexes, $Fe^{II}(phen)_2(NCX)_2$ [X = S and Se] [19]. On the other hand, the thermal hysteresis loop for the parent complex **2** in the first cooling and heating cycle disappeared in the second cycle, suggesting an irreversible structural change in **2** may occur after the first spin transition from the HS to the LS states.

3.3. Crystal structures for **1** at 273 and 200 K

The crystal analyses of **1** were performed at 273 and 200 K by using a Rigaku CMF007 Mercury CCD system. The molecular structures and the numbering schemes for Fe(qsal)$_2$ and Ni(dmise)$_2$ molecules of **1** are shown in Figs. 3 and 4, respectively. The crystallographic data are summarized in Table 1. The crystal of **1** at 273 K belongs to triclinic space group $P\bar{1}$ and is isostructural to that of the parent complex **2** [11]. As compared with the parent complex **2**, displacement of sulfur atoms with selenium atoms on the Ni(dmit)$_2$ molecule afforded about 0.7% expansion of the unit cell volume. The crystal structure viewed along the *b* axis at 273 K is shown in Fig. 5. One Fe(qsal)$_2$, one Ni(dmise)$_2$, and two acetonitrile molecules are crystallographically independent in an unsymmetrical unit. The crystal system and space group of **1** at 200 K does not change despite the spin transition from the HS to the LS states. The unit cell volume at 200 K is reduced by 1.5%.

3.3.1. Molecular structure and arrangement for Fe(qsal)$_2$ cation

Two qsal anion molecules as tridentate π-ligands were coordinated to the central iron (III) atom in an almost perpendicular manner, giving the distorted octahedral FeN_4O_2 coordination environments. Selected bond lengths and the sums of deviations (Σ) of

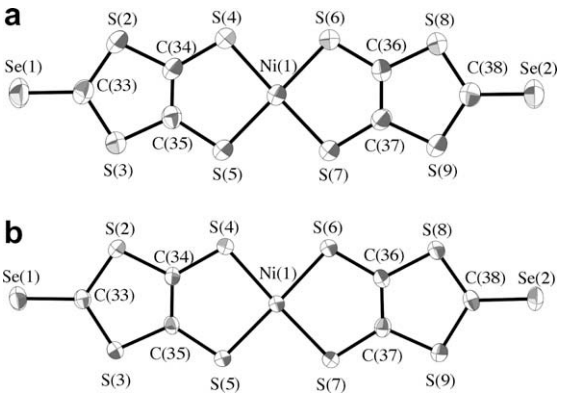

Fig. 4. ORTEP drawings (50% probability) of the molecular structures and numbering schemes for Ni(dmise)$_2$ cations in **1** at (a) 273 K and (b) 200 K .

the bite angle from 90° are given in Table 2. The coordination bond lengths and the distortion of the coordination sphere around the Fe(III) ion of **1** at 273 K are very similar to those of the parent complex **2**, suggesting that the Fe(qsal)$_2$ cation of **1** at 273 K is in the HS state. This is consistent with the similar $\chi_M T$ values in the high temperature phases of **1** and **2**. On the other hand, the coordination bond lengths are remarkably shortened (Δ_{Fe-O} = 0.032 Å, Δ_{Fe-N} = 0.17 Å) and the Σ value is also much smaller at 200 K. The coordination bond lengths and angles at 200 K are in good agreement with those in the LS state for [Fe(qsal)$_2$]NCSe · CH_2Cl_2 **3** reported previously [20], indicating that the Fe(III) ion of **1** at 200 K is almost in the LS state.

The intermolecular arrangements at 200 and 273 K are shown in Fig. 6. Each π-ligand in an Fe(qsal)$_2$ cation overlaps that in the neighboring cations, forming one-dimensional molecular arrays along the *b* axis. The mean distances between π-planes [C(6)–C(7)–N(1)–C(8) and C(22)–C(23)–N(3)–C(24)] along the one-dimensional array are 3.351 and 3.345 Å at 273 K, and 3.179 and 3.214 Å at 200 K, respectively. Those for the parent complex **2** are 3.367 and 3.340 Å at 273 K. This observation indicates that the molecular arrangements of the Fe(qsal)$_2$ for **1** and **2** are similar to each other. No short π–π contacts between these one-dimensional arrays of Fe(qsal)$_2$ molecules for the *a* direction are not observed due to the existence of acetonitrile molecule inbetween one-dimensional molecular arrays.

3.3.2. Molecular structure and arrangement for Ni(dmise)$_2$ molecule

Ni(dmise)$_2$ molecules are almost planar and dimerized in a face-to-face manner (Fig. 7). The mean distances between π-dimer

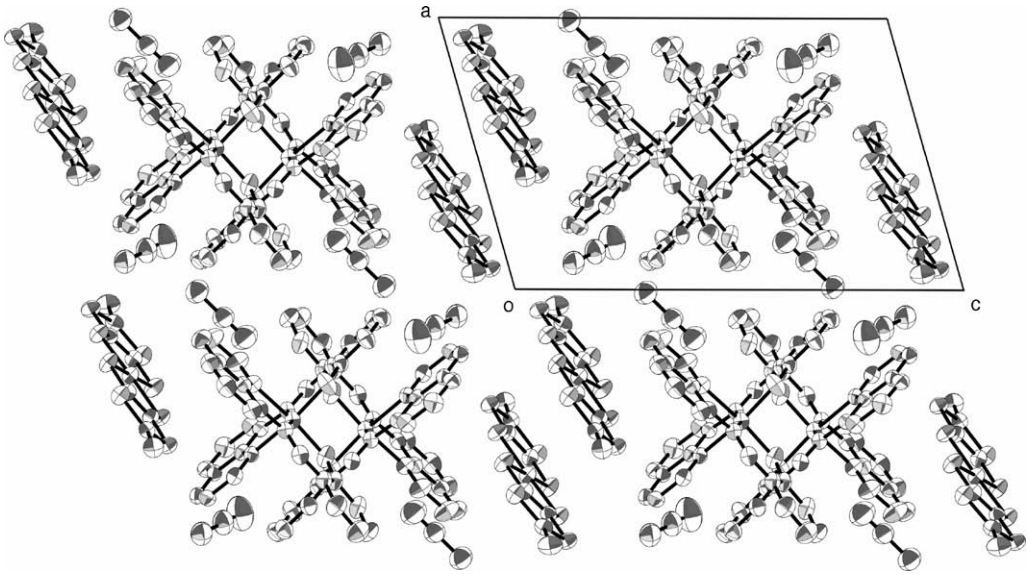

Fig. 5. Crystal structures of **1** viewed along the *b* axis at 273 K. Hydrogen atoms are omitted to clarify.

are 3.659 Å and 3.608 Å at 273 and 200 K, respectively. The short interdimer contacts within the sum of van der Waals radii are observed, affording two-leg ladder-like arrangement along the *b* axis [Se(2)–S(9): 3.4473(13), S(2)–S(9), 3.5563(13) Å at 273 K; Se(1)–S(9): 3.5748(9), Se(2)–S(2): 3.6596(9), S(2)–S(9): 3.4809(12) Å at 200 K]. No short contacts between these ladder chains for the *a* direction are observed due to the existence of acetonitrile molecule, either. It should be noted that remarkable slipping along the molecular long axis for π-dimer of $Ni(dmise)_2$ is observed before and after spin transition (Fig. 7, upper). This large structural modification results in reconstruction of the interdimer short contacts.

3.3.3. Intermolecular contacts between $Fe(qsal)_2$ and $Ni(dmise)_2$ molecules

The π−π stacking between dmise and quinolyl moieties is observed. Although the π-plane between dmise and quinolyl rings is not parallel, the distances between the π-plane of quinolyl ring and the atoms of dmise are in the range of 3.30−3.57 Å and 3.27–3.59 Å at 273 and 200 K, respectively. Furthermore, van der Waals contacts between qsal and dmise moieties in a face-to-edge molecular arrangement are also observed [273 K: S(3)–C(14∗): 3.504(3), S(3)–C(15∗), 3.586(3), S(6)–C(12): 3.535(3), S(6)–C(14): 3.478(3), S(6)–C(15): 3.579(4), S(8)–C(15): 3.578(4), S(8)–C(16): 3.520(4) Å; 200 K: Se(2)–C(10): 3.602(3), Se(2)–C(11): 3.629(3), S(3)–C(14∗): 3.394(3), S(3)–C(15∗): 3.586(2), S(6)–C(14): 3.483 (3), S(6)–C(15): 3.424(3), S(6)–C(16): 3.507(3) Å, ∗ indicates the atoms on the molecule translated by one-unit along the *a* axis]. It should be noted that the short intermolecular contacts between S(3) and C(14∗) or C(15∗) exist between two-dimensional layers composed of one-dimensional arrays of $Fe(qsal)_2$ molecules and two-leg ladder arrangements of $Ni(dmise)_2$ dimers. As mentioned above, intermolecular interactions between $Fe(qsal)_2$ molecules or between $Ni(dmise)_2$ molecules afford only one-dimensional

	Ref. [11]	this work	this work	Ref. [20]

interactions. However, our previous reports [12,13] suggest a cooperative spin transition should originate from two- or three-dimensional intermolecular interactions. Therefore, not only intermolecular interactions between SCO cations or between $Ni(dmise)_2$ anions but also intermolecular interactions between SCO cation and $Ni(dmise)_2$ anion play a key role in the cooperative spin transition of **1**.

3.4. Transfer integrals and magnetic interactions between $Ni(dmise)_2$ and $Ni(dmit)_2$ molecules in **1** and **2**

Since the magnetic exchange interaction energy (J) between the localized spins is given by

$$|J| = 2t^2/U_{\mathrm{eff}}$$

where t is transfer integral between the adjacent molecules and U_{eff} is effective onsite Coulombic interaction, the magnitude of magnetic interactions can be estimated by transfer integrals between $Ni(dmit)_2$ molecules. Nakamura and co-workers reported systematic investigations on magnetic behaviors of $Ni(dmit)_2$-based magnetic materials [21]. First of all, we have calculated transfer integrals for the parent $Ni(dmit)_2$ complex **2** by using the same parameters in order to compare with the reported transfer integrals for $Ni(dmit)_2$-based magnetic materials. The intradimer transfer integral for **2** at 273 K was 14.51×10^{-2} eV, which is the largest value among those reported in Ref. [21]. This value suggests that π-dimer of $Ni(dmit)_2$ is in the spin singlet state. This is in good agreement with the spin state of $Ni(dmit)_2$ supposed by magnetic susceptibilities and Mössbauer spectra [11]. The other transfer integrals for **2** were less than -1.27×10^{-2} eV within two-leg ladder arrangement, but the largest transfer integral between two-leg ladders for the a direction was found to be 0.73×10^{-2} eV. For **1**, the intradimer transfer integrals were 13.00×10^{-2} and -13.02×10^{-2} eV at 273 and 200 K, respectively. These values also suggest that π-dimer of $Ni(dmise)_2$ is in the spin singlet state in the temperature of 2–300 K. Interestingly, the transfer integrals are almost the same values despite a large molecular slipping of π-dimer of

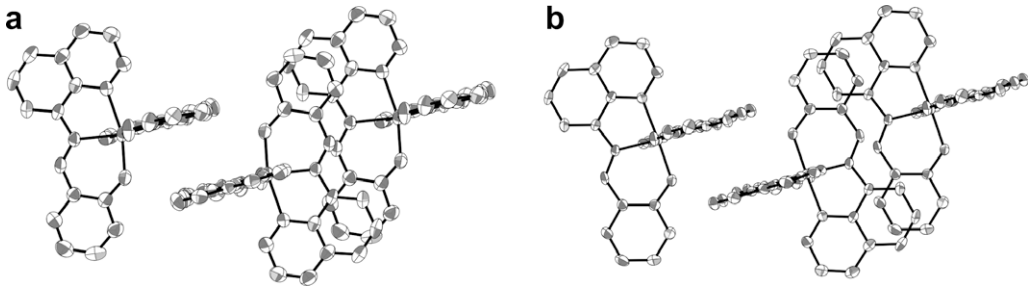

Fig. 6. Molecular arrangements of $Fe(qsal)_2$ molecules along the b axis at (a) 273 K and (b) 200 K. Hydrogen atoms are omitted to clarify.

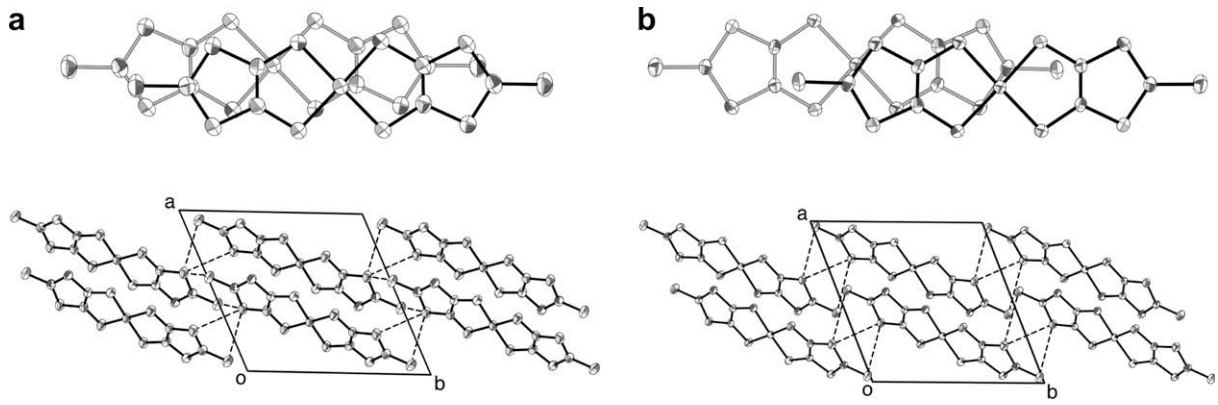

Fig. 7. Top views of the overlapping modes of $Ni(dmise)_2$ molecules and two-leg ladder-like molecular arrangements along the b axis at (a) 273 K and (b) 200 K. Dot lines indicate intermolecular short contacts.

$Ni(dmise)_2$ along the molecular long axis. This suggests that the overlapping positions of $Ni(dmise)_2$ molecules has bistability. The other transfer integrals for **1** were less than -2.57×10^{-2} and -1.04×10^{-2} eV within two-leg ladder arrangement at 273 and 200 K, respectively. On the other hand, the transfer integrals of 1.42×10^{-2} and -1.63×10^{-2} eV between two-leg ladders for the *a* direction were larger than those for **2**.

3.5. Consideration for spin-crossover mechanism of $[Fe(qsal)_2][Ni(dmise)_2] \cdot 2CH_3CN$ **1**

Detail investigations on the crystal structures of **1** in both the high and low temperature phases revealed a variety of $\pi-\pi$ interactions between $Fe(qsal)_2$ and $Ni(dmise)_2$ molecules throughout a crystal, which will result in strong cooperativity of the spin transition behavior of **1**. One of the important findings of structural investigation is a reversible molecular slipping of $Ni(dmise)_2$ involved in a remarkable structural change in size and geometry of Fe(III) SCO cation. This reversible structural change in $Ni(dmise)_2$ molecules is important to persist a thermal hysteresis loop, because preliminary temperature dependent crystal structural analyses for the parent complex **2** suggested that similar molecular slipping of $Ni(dmit)_2$ molecules occurred from the HS to the LS states in the first cooling process (see supplementary data: Nidmit_90K_cif), whereas the reverse molecular slipping was not observed after the heating process (see supplementary data: Nidmit_aged_cif).

4. Conclusion

We have prepared a novel Fe(III) SCO complex with $Ni(dmise)_2$ anion **1**. The magnetic susceptibility measurements revealed that **1** exhibited a cooperative spin transition with a thermal hysteresis loop of 15 K. The high and the low temperature structures of **1** indicated three-dimensional intermolecular $\pi-\pi$ interactions play a key role in the cooperative spin transition, accompanying a reversible molecular slipping of $Ni(dmise)_2$ molecules along the molecular long axis. The transfer integral calculations for **1** and **2** suggested π-dimer of $Ni(dmise)_2$ or $Ni(dmit)_2$ is in the spin singlet state, which is consistent with the previous supposed magnetic data of the parent complex **2**.

2.2. Synthesis of the complexes

2.2.1. Synthesis of $[Fe_2Pr(4\text{-Me-sal})_4(2,2'\text{-bipy})_2(H_2O)_6](NO_3)\cdot 2MeOH\cdot 1½H_2O$ (**1**)

A solution of $Pr(NO_3)_3\cdot 6H_2O$ (0.086 g, 0.2 mmol) in 5 ml of H_2O was added to a methanolic solution (10 ml) of 4-Me-salH_2 (0.122 g, 0.8 mmol) giving a pale yellow solution. To this was added a methanolic solution (10 ml) of $FeCl_3\cdot 4H_2O$ (0.054 g, 0.2 mmol) and 2,2′-bipy (0.031 g, 0.2 mmol), whereupon the colour of the solution changed to purple. After 1 h, Et_3N (0.052 ml, 0.4 mmol) was added slowly giving a pinkish purple solution. The solution was filtered and layered with ether. The next day small purple crystals were obtained. Yield: 55%. *Anal.* Calc. for $C_{55}H_{64}Fe_2PrN_5O_{24}$: C, 46.04; H, 4.24; N, 4.81. Found: C, 46.12; H, 4.47; N, 4.89%. Selected IR data (KBr disc, cm^{-1}): 3446 (br), 2919 (m), 1608 (s), 1558 (s), 1523 (m), 1443 (s), 1423 (s), 1320 (m), 1327 (s), 1249 (s), 1170 (m), 1024 (m), 959 (m), 764 (m), 635 (m), 612 (m), 416 (w).

2.2.2. Synthesis of $[Fe_2Gd(4\text{-Me-sal})_4(2,2'\text{-bipy})_2(H_2O)_5]Cl_{1/2}(NO_3)_{1/2}\cdot 5H_2O$ (**2**)

The synthesis of **2** was analogous to that of **1** using $Gd(NO_3)_3\cdot 6H_2O$ and by the same layering method purple crystals were isolated. Yield: 62%. *Anal.* Calc. for $C_{52}H_{60}Cl_{0.5}GdFe_2N_{4.5}O_{23.5}$: C, 44.27; H, 4.27; N, 4.47. Found: C, 44.24; H, 4.26; N, 4.47%. Selected IR data (KBr disc, cm^{-1}): 3382 (b), 2919 (m), 1607 (s), 1558 (s), 1520 (s), 1444 (s), 1425 (s), 1384 (s), 1249 (s), 1172 (s), 1025 (m), 959 (m), 767 (m), 635 (m), 613 (m), 416 (w).

2.2.3. Synthesis of $[Fe_2Dy(4\text{-Me-sal})_4(2,2'\text{-bipy})_2(H_2O)_5]Cl_{1/2}(NO_3)_{1/2}\cdot 5H_2O$ (**3**)

The synthesis of **3** was carried out as for **1** and **2** but using Dy$(NO_3)_3\cdot 6H_2O$, giving purple crystals in 84% yield. *Anal.* Calc. for $C_{52}H_{60}Cl_{0.5}DyFe_2N_{4.5}O_{23.5}$: C, 44.11; H, 4.27; N, 4.45. Found: C,

2.3. Magnetic measurements

Magnetic susceptibility measurements were obtained using a Quantum Design SQUID magnetometer (MPMS-XL). Measurements were performed on polycrystalline samples of 11.8 mg (**1**), 14.7 mg (**2**) and 11.2 mg (**3**), respectively. *ac* susceptibility measurements were measured with an oscillating *ac* field of 3 Oe and a frequency of 1000 Hz. The magnetic data were corrected for the sample holder and the diamagnetic contribution. The samples were checked for the presence of ferromagnetic impurities by measuring the magnetization as a function of the field at 100 K; perfect straight lines were observed indicating the absence of such impurities.

Table 4

[b] γ is defined as the angle between the normal to the plane of the π ring and the vector of the H-centroid interaction.

2.4. X-ray crystallography

Single-crystal X-ray crystallographic data were collected at 100 K on a Bruker SMART Apex CCD diffractometer (**1**) or at 150 K on a Stoe IPDS II diffractometer (**2**) using graphite-monochromated Mo Kα radiation and semi-empirical absorption corrections were applied [16a,b]. Crystallographic data and details of the measurements and refinements are summarized in Table 1. The structures were solved using direct methods followed by full-matrix least-squares refinement against F^2 (all data) using SHELXTL [16b]. Anisotropic refinement was used for all non-H atoms; organic H atoms were placed in calculated positions while coordinates of hydroxo H atoms were refined.

3. Results and discussion

From the X-ray powder diffraction patterns it was clear that compounds **2** and **3** are isomorphous (Fig. 1). Therefore, the structures of **1** and **2** were determined using single-crystal X-ray diffraction (Tables 1 and 2). Both compounds crystallize in the monoclinic space group $P2_1/c$ with $Z = 4$. The asymmetric unit contains two Fe^{III} and one Ln^{III} cations, four 4-Me-sal ligands and two 2,2′-bipyridine ligands forming monocationic heterometallic zigzag $[Fe_2Ln(4\text{-Me-sal})_4(2,2'\text{-bipy})_2(H_2O)_x]^+$ chains, where $x = 6$ for Pr (**1**) and $x = 5$ for Gd (**2**) and Dy (**3**), running parallel to the *b*-axis while lattice methanol and water molecules for **1** and water molecules for **2** and **3** are held with H-bonds (Fig. 1). Charge balance considerations require a single counteranion per $\{Fe_2Ln\}$ formula unit; a nitrate anion was found in the asymmetric unit of **1,** with a disordered chloride and nitrate (ratio 1:1) for **2** and presumably also **3**, the latter will not be further discussed (see Fig. 2).

The two Fe^{III} centres Fe1 and Fe2 are each hexacoordinated in a distorted octahedral environment. Each is chelated, through phenoxo and carboxylate oxygens, by two different 4-Me-sal ligands, with further chelation by the two nitrogen atoms of a 2,2′-bipyri-

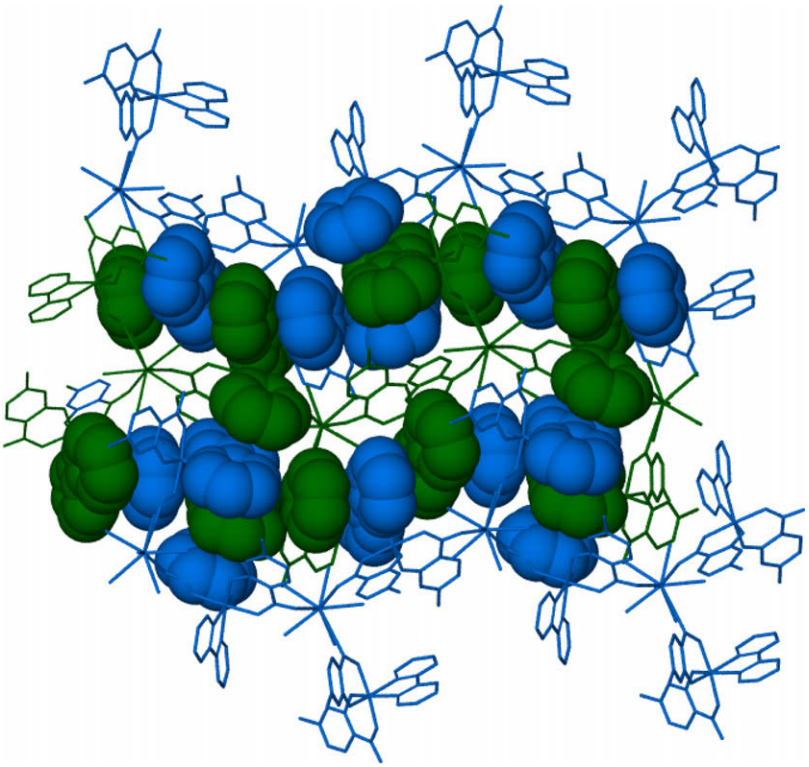

Fig. 3. A packing diagram of **1**, along the *b*-axis. The 1D chains are drawn in blue and green to emphasize the stacking interactions between the aryl rings that lead to a 2D robust layer in the plane of the paper. Organic hydrogen atoms have been omitted for clarity.

dyl ligand. This latter ligand is twofold disordered in the structure of **2**. The Fe–O bond lengths vary between 1.907 and 1.994 Å, with the mutually-*trans* Fe–O bonds systematically longer and the Fe–O bonds *trans* to nitrogen shorter. The Fe–N bond lengths were, as expected, longer, in the range 2.115–2.203 Å. In this way, two crystallographically independent anionic spacers, $[Fe1(2,2'\text{-bipy})(4\text{-Me-sal})_2]^-$ and $[Fe2(2,2'\text{-bipy})(4\text{-Me-sal})_2]^-$, can be defined. Each $[Fe2(2,2'\text{-bipy})(4\text{-Me-sal})_2]^-$ unit is linked to only one Ln^{III} by a *syn-anti* carboxylate bridge from one 4-Me-sal^{2-} ligand, whereas each $[Fe1(2,2'\text{-bipy})(4\text{-Me-sal})_2]^-$ is linked to two Pr1 by *syn-anti* carboxylate bridges from two 4-Me-sal^{2-} ligands.

Pr1 is nine-coordinate in **1**, while Gd1 is eight-coordinate in **2**, consistent with the expected smaller ionic radius for Gd^{III}. The coordination environment of each Pr^{III} consists of six water molecules (O13, O14, O15, O16, O17, O18) and three carboxylate oxygen atoms (O3, O6, O9) from three different bridging $\{Fe(2,2'\text{-bipy})(4\text{-Me-sal})_2\}^-$ units. For the Gd^{III} compound the lanthanide is coordinated by five water molecules (O13, O14, O15, O16, O17) and three carboxylate oxygen atoms (O3, O6, O9) from three different bridging $[Fe(2,2'\text{-bipy})(4\text{-Me-sal})_2]^-$ units. In **1**, the distances between Pr1 and three carboxylate oxygens are 2.451(4) Å (Pr1–O3), 2.430(6) Å (Pr1–O6) and 2.472(5) Å (Pr1–O9), whereas Pr1–Fe2 is 5.877(1) Å and Pr1–Fe1 is 5.698(1) Å. In **2**, the distances between Gd1 and three carboxylate oxygen atoms are 2.345(1) Å (Gd1–O3), 2.369(1) Å (Gd1–O6) and 2.290(1) Å (Gd1–O9). The Gd1–Fe2 distance is 6.221(2) Å and Gd1–Fe1 distance is 5.495(2) Å. The coordination environment around Pr in **1** can be described as tricapped trigonal prismatic, while for Gd in **2** it is square antiprismatic.

In this way, a trinuclear Fe_2Ln unit is formed and extended along the *b-axis* through the zigzag 1D polymeric chain. Adjacent 1D polymeric chains are connected through a combination of strong and medium π–π stacking interactions (Tables 3 and 4) between the aromatic rings of 2,2′-bipyridyl and 4-Me-sal^{2-} ligand forming robust 2D layers (Fig. 3) [17]. Furthermore, two such 2D layers are further linked though C–H···aryl interactions (Table 3), resulting in the formation of a metallosupramolecular structure.

4. Magnetic properties of compounds 1–3

Dc magnetic susceptibility measurements were performed on polycrystalline powder samples of **1**–**3** in the temperature range 1.8–300 K at 1000 Oe. Overall, the temperature dependences of magnetic susceptibilities of these three compounds show the same thermal evolution (Fig. 4). The experimental χT products at room

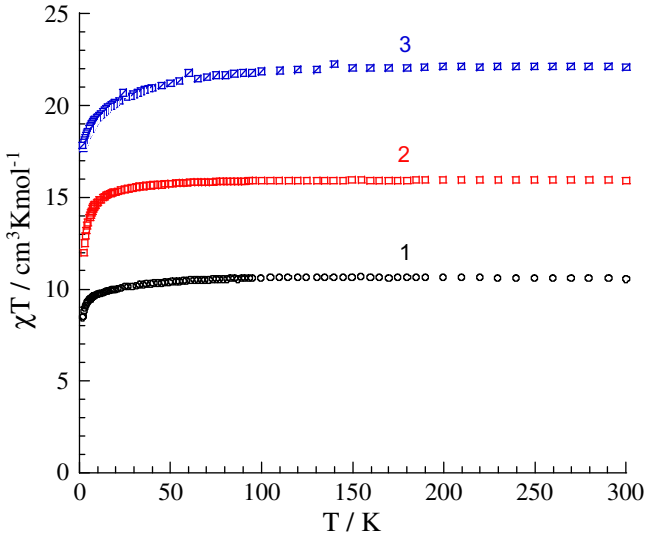

Fig. 4. χT vs. T plots for compounds **1**–**3**.

Table 5
Comparison of the χT products at room temperature between the expected and the experimental values for compounds **1**–**3**.

Compounds	χT ($cm^3\ K\ mol^{-1}$) theoretical value [18] for each Ln ion at RT	χT ($cm^3\ K\ mol^{-1}$) expected value for [Fe_2Ln] at RT	χT ($cm^3\ K\ mol^{-1}$) experimental value for [Fe_2Ln] at RT
[Fe_2Pr] (**1**)	1.60	10.35	10.5
[Fe_2Gd] (**2**)	7.875	16.63	15.9
[Fe_2Dy] (**3**)	14.17	22.92	22.2

temperature are in good agreement with the expected values for two Fe(III) ions ($S = 5/2$, $g = 2$) and one Ln(III) ion (Table 5). On decreasing the temperature, the χT product at 1000 Oe stays almost constant to about 30 K and then rapidly decreases to reach a minimum value at 1.8 K. This type of magnetic behavior indicates dominant antiferromagnetic interactions between the spin carriers. Since the Gd(III) has no orbital contribution and Fe(III) is a weakly anisotropic ion, the monotonic decrease of the susceptibility in **2** indicates the presence of antiferromagnetic interactions between Fe^{III} and Gd^{III}. A fit of the experimental data to a Curie–Weiss law above 2 K leads to a Curie constant of 16.0 $cm^3\ K\ mol^{-1}$ and Weiss constant of −0.85 K (Fig. S1). The small but negative Weiss constant also suggests the presence of very small interactions between Fe–Gd with a dominating antiferromagnetic contribution. The Fe^{III}–Ln^{III} magnetic interactions in **1** and **3** are hence probably antiferromagnetic, however, the depopulation of the Stark sublevels of the anisotropic Pr and Dy ions might be also partially responsible for the decrease of the χT product [19]. Therefore, the thermal decrease of the χT products might be due to a combination of those effects mentioned above.

For all three compounds, at low temperatures the magnetization smoothly increases with the applied dc field (Figs. S2–S4). In all cases, there is no clear saturation even at 7 T at which it reaches the value of 12.0, 15.9 and 15.1μ_B for compounds **1**, **2** and **3**, respectively, suggesting the presence of magnetic anisotropy and/or the population of low-lying excited states. This is also confirmed in the plots of the M versus H/T at low temperatures, in which the curves are not all superposed on a single master-curve as expected for isotropic systems. In the case of compound **2**, the magnitude of M at 15.9μ_B is fairly close to the value of 17μ_B expected for two Fe(III) ions ($S = 5/2$) and one Gd(III) ion ($S = 7/2$) if the spins are uncoupled. This observation indicates that the antiferromagnetic interactions are weak in this complex, as suggested by the χT versus T data and the small Weiss constant. In fact, at high field where the antiferromagnetic interactions are overcome, a saturation of the magnetization can be expected to occur at 17μ_B corresponding to all the spins being aligned parallel. Likewise, as can be seen from the M versus H plot of compound **3**, the magnetization is 15.1μ_B, which is in good agreement with the expected value (15.23μ_B) for all the spins aligned parallel arising from 10μ_B for two $S = 5/2$ Fe(III) ions and 5.23μ_B for one Dy(III) ion. This observation also indicates that very weak intramolecular antiferromagnetic interactions are present in this complex. However, despite the presence of anisotropy in these compounds, the ac susceptibility of compounds **1**–**3** in zero dc field shows a complete absence of out-of-phase components above 1.8 K, and no slow relaxation is observed in this series of compounds at this temperature.

5. Conclusion

The metal/methylsalicylate/co-ligand strategy towards heterometallic systems has successfully produced three new heterometallic 1D coordination polymers [Fe_2Pr(4-Me-sal)$_4$(2,2′-bipy)$_2$(H_2O)$_6$](NO_3) · 2MeOH · 1.5H_2O, (**1**) [Fe_2Gd(4-Me-sal)$_4$(2,2′-bipy)$_2$(H_2O)$_5$]$Cl_{1/2}$(NO_3)$_{1/2}$ · 5H_2O, (**2**) and [Fe_2Dy(4-Me-sal)$_4$(2,2′-bipy)$_2$(H_2O)$_5$]$Cl_{1/2}$(NO_3)$_{1/2}$ · 5H_2O (**3**). Efforts to increase the dimensionality of the final products are in progress. Magnetic studies show that the observed decrease of the χT value with decreasing temperature might be due to antiferromagnetic interactions between Fe–Ln centres and/or the depopulation of the Stark sublevels of the anisotropic Ln ions.

antiferromagnetic case, and must be taken into consideration when developing strategies for designing optimal SMMs. Indeed, it has recently been suggested that the barrier height may go as S^0 [12,13] as the spin value increases, thus implying that U does not change in the process. In this paper, we show experimentally that U does increase, and that it goes roughly as S^1 rather that S^2 or S^0.

2. Experiment details

Multi-high-frequency electron paramagnetic resonance (EPR) measurements were performed on single-crystals of $Mn_6^{III}O_2$(Me-sao)$_6$(O_2CCPh$_3$)$_2$(EtOH)$_4$ (**1**) and $Mn_6^{III}O_2$(Et-sao)$_6$(O_2CPh(Me)$_2$)$_2$(EtOH)$_6$ (**2**) at various frequencies from 50 to 350 GHz, and with dc fields applied along different crystallographic directions. Both complexes have monoclinic structures. However, magnetic data suggests complex **1** has a low spin ground state of $S = 4$, whereas complex **2** has a $S = 12$ ground state with a uniaxial molecular anisotropy $D = -0.43\ cm^{-1}$ [11]. Incidentally, it has been shown that **2** holds the record for the highest barrier for a SMM (U = 86.4 K [10]). EPR signals from single-crystals were detected using a sensitive cavity-perturbation technique in combination with a Millimeter-wave Vector Network Analyzer (described elsewhere [14,15]).

3. Data and discussion

The magnetic axial directions of **1** and **2** were determined using the one- and two-axis rotation techniques, respectively (described elsewhere [9,16,17]). Extensive measurements at various temperatures and frequencies were then performed with the dc field applied parallel to the easy-axis to determine the zero-field splitting (ZFS) in the ground state, i.e. the parameters in the simple spin Hamiltonian, $H = DS_z^2 + B_4^0\hat{O}_4^0 + g\mu_B\vec{B}\cdot\hat{S}$ (see [16] for an explanation of the operators/parameters).

Fig. 1 shows temperature-dependence spectra obtained at 331 GHz for complex **2** with the field applied approximately parallel to its easy-axis. A series of more-or-less evenly spaced resonances are seen (dips in transmission). As the temperature is reduced, intensity shifts from the higher field resonances to the lowest field transition. Based upon this observation, we can assign the peaks A1, A2, A3, A4, and A5 to the following EPR transitions: $m_S = -12 \rightarrow -11$, $-11 \rightarrow -10$, $-10 \rightarrow -9$, $-9 \rightarrow -8$, $-8 \rightarrow -7$, respectively, where m_S represents the spin projection along the easy (z-) axis of the crystal. Each of the peaks exhibits several fine structures on the high-field shoulders. This is quite a common observation

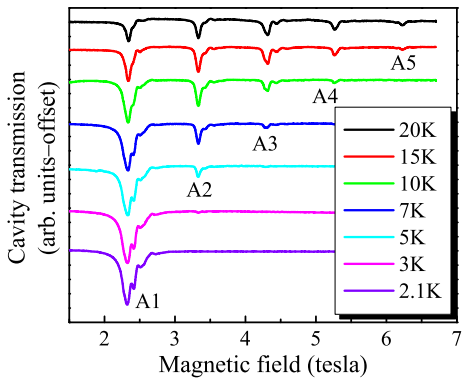

Fig. 1. Temperature dependence spectra obtained at 331 GHz for the easy-axis orientation for complex **2** ($S = 12$). See text for explanation.

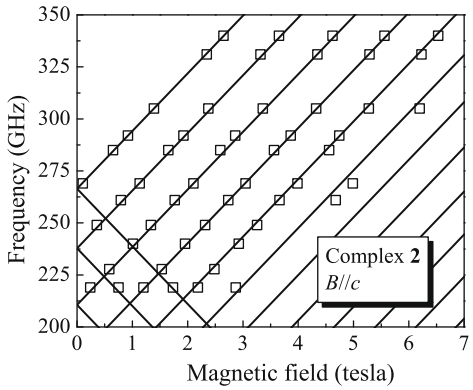

Fig. 2. Energy difference diagram constructed from frequency-dependent measurements for the easy-axis orientation for complex **2** at a temperature of 20 K. The solid lines are the simulations using the parameters given in the main text.

and likely signifies weak disorder in the crystal resulting in a distribution of microenvironments, i.e. a distribution in D [18].

Precise determination of the spin Hamiltonian parameters D, B_4^0 and g is made possible by recording EPR spectra at several high frequencies, as shown in Fig. 2 for this $S = 12$ complex (**2**). Simulations for the easy-axis direction suggest that the system is best described with $D = -0.360(5)\ cm^{-1}$, $B_4^0 = -5.7(5) \times 10^{-6}\ cm^{-1}$ and $g = 1.98(1)$. One can obtain a fairly reliable estimate of the barrier from these parameters, U = 75 K. This value is significantly lower than the one obtained from ac susceptibility measurements, though it remains the highest recorded value for any SMM. Similar discrepancies have been noted for many other SMMs, with ac susceptibility measurements consistently giving larger values for the 'effective' barrier in comparison to spectroscopic measurements [19].

Measurements performed on the $S = 4$ complex (**1**) give the following spin Hamiltonian parameters: $D = -1.272\ cm^{-1}$ and $B_4^0 = +1.3(3) \times 10^{-4}\ cm^{-1}$; g was not well determined because the field was only approximately aligned with the easy axis (within 15°). Fig. 3 shows the best simulation of the frequency dependent data for complex **1**. In addition to the main peaks corresponding to the $S = 4$ state (black squares), a weaker series of peaks is observed, as indicated in the figure by black circles and the dashed line. We note that it is not possible to simulate both sets of peaks simultaneously, even for spin values different from $S = 4$. We thus conclude that the extra peaks result from a low-lying excited state,

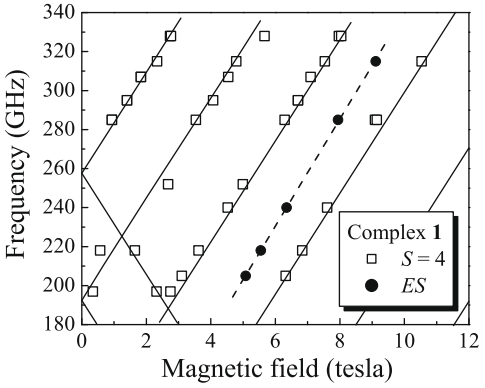

Fig. 3. Energy difference diagram constructed from frequency-dependent measurements for the field close to the easy-axis direction for complex **1**. The solid lines are the simulations using the parameters given in the main text for $S = 4$. The round data points and the dashed line correspond to excitations within a presumed low-lying excited state.

which is not surprising given the frustrated antiferromagnetic interactions within the Mn^{III} triangles. The sizeable positive B_4^0 value is also consistent with this observation. As we have shown previously, higher order terms (4th, 6th, etc.) are caused by ad-mixing of excited spin states to the ground state [20]. What is more, as a rule of thumb, the sign of the axial 4th order term usually reflects the sign of the exchange within the cluster [21]. Reliable evaluation of the spin and ZFS parameters on the basis of magnetic (thermodynamic) measurements for complexes with low-lying states can be problematic. Therefore, these EPR measurements provide an independent spectroscopic confirmation that the ground state of **1** really does correspond to $S = 4$.

An important conclusion from these experiments is that the factor $|D|S$ remains more-or-less unchanged as S increases for these two Mn_6 complexes, i.e. $|D|S = 4.3\ cm^{-1}$ for **2** and $5.1\ cm^{-1}$ for **1**—a 15% variation. Interestingly, the ZFSs between the ground and first excited states (Δ) are almost identical for the two complexes, i.e. $8.9\ cm^{-1}$ for **2** and $8.6\ cm^{-1}$ for **1**—a 3% variation. We note that, in the absence of 4th order anisotropy, $\Delta = D(2S - 1) \approx 2\,|D|S$ is roughly constant for large S. We emphasize that these are purely experimental observations that do not depend on any model or theory. Importantly, this suggests that as S increases, D decreases correspondingly, so that the barrier increases only as S^1, i.e. by a factor of 3 upon increasing S from 4 to 12. This prediction is in good agreement with ac susceptibility measurements which suggest an increase of ~2.7 [11].

4. Theoretical calculations

We next compare the experimental findings with calculations using: (i) projection operator techniques; and (ii) exact matrix diagonalization methods, where the total anisotropy of the molecule is determined in terms of the single-ion anisotropies, D_S, of the individual Mn^{III} atoms. The general expression for the spin Hamiltonian can be written as

$$H = \sum_{i<j}[J_{ij}\hat{S}_i \cdot \hat{S}_j + \hat{S}_i \cdot \vec{\vec{D}}_{ij} \cdot \hat{S}_j] + \sum_i[\hat{S}_i \cdot \vec{\vec{D}}_i \cdot \hat{S}_i + \mu_B \vec{B} \cdot \vec{\vec{g}}_i \cdot \hat{S}_i]. \quad (1)$$

The first summation parameterizes the isotropic (Heisenberg exchange) and anisotropic (dipolar) pairwise interactions between spins i and j in the cluster; the J_{ij} represent the pairwise scalar exchange constants, and the $\vec{\vec{D}}_{ij}$ dipolar tensors. The second sum accounts for the single-ion ZFS (spin–orbit) and Zeeman interactions for the ith spin in the cluster; $\vec{\vec{D}}_{ij}$ and $\vec{\vec{g}}_{ij}$ are the single-ion ZFS and Landé tensors.

We now make a number of approximations in order to simplify the calculations. We stress that it is not our goal to achieve precise agreement between experiment and theory, but rather to provide a general understanding of the factors that contribute to the raising of the anisotropy barrier in these Mn_6 complexes. The approximations are as follows:

(1) We neglect the dipolar contributions to the anisotropy, since these are at least an order of magnitude weaker than the Mn^{III} single-ion anisotropies.
(2) We consider only axial single-ion ZFS of the form $D_i\hat{S}_{zi}^2$. Furthermore, we assume that the ZFS tensors for all six Mn^{III} atoms are the same and aligned with the magnetic easy-axis. This reduces the problem to a single anisotropy parameter, D_S, representing the axial ZFS associated with a single Mn^{III} atom.
(3) We assume that D_S is the same for the ferromagnetic and antiferromagnetic cases, i.e. we assume that the structural modification that switches the sign of the exchange couplings (J_{ij}) does not significantly affect the spin-orbit coupling associated with the individual Mn^{III} centers.

Approximations (2) and (3) undoubtedly represent an oversimplification of the problem. However, our goal here is to obtain a simple correspondence between the molecular D value and the single-ion anisotropy D_S, which would not be possible without these simplifications.

In the strong exchange coupling limit ($J_{ij} \gg D_i$), one can project the anisotropies associated with individual spins onto the total spin state of the coupled system following the techniques described by Bencini and Gatteschi [22]. For a dinuclear system, the total anisotropy, D, is given by

$$D = d_1D_1 + d_2D_2 \quad (2)$$

where d_1 and d_2 are projection coefficients, and D_1 and D_2 are the anisotropies associated with the individual magnetic ions. This can be extended to the six particle case simply by adding spins one at a time to get a trimer, tetramer, etc., then re-computing the total anisotropy each time. Details of our calculations will be published in a longer paper [23].

A schematic of the model for the Mn_6 system, showing both the ferromagnetic and antiferromagnetic cases, is shown in Fig. 4. The calculation for the ferromagnetic case ($S = 12$) is trivial, and one obtains $D_{s=12} = 3D_s/23 = 0.13D_s$. The antiferromagnetic case ($S = 4$) is not as trivial, with the results depending on the coupling scheme: for scheme 1, $(((((S_1 + S_2) + S_4) + S_5) - S_3) - S_6)$, one obtains $D_{s=4} = 0.84D_s$, i.e. $D_{S=12}/D_{S=4} = 0.155$; and for scheme 2, $(((((S_1 + S_2) - S_3) + S_4) + S_5) - S_6)$, one obtains $D_{s=4} = 0.7D_s$, i.e. $D_{S=12}/D_{S=4} = 0.186$.

As an independent check, we set out to solve the problem numerically using a matrix diagonalization approach. For Mn_6, one has to deal with a Hilbert space of size $[(2S+1)^6]^2 = 15\,625\times$

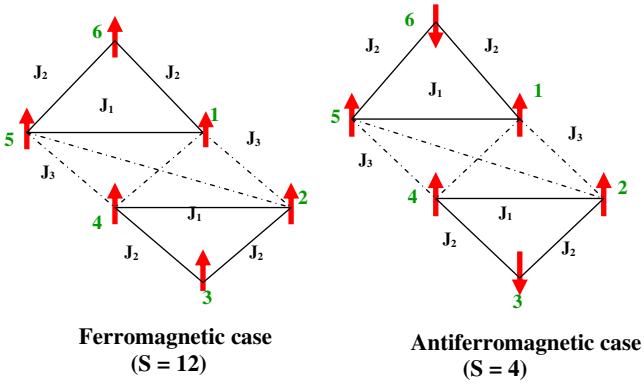

Fig. 4. Schematics of the two models used for the projection operator calculations.

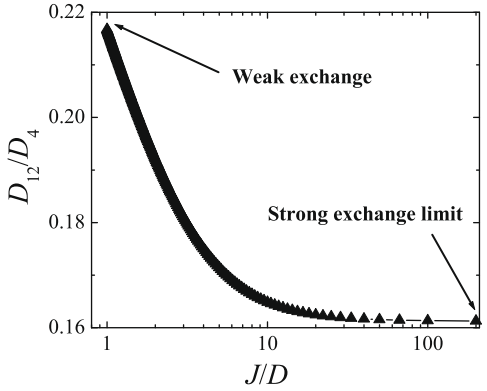

Fig. 5. Plot of the ratio $D_{S=12}/D_{S=4}$ versus J/D obtained from the matrix diagonalization calculations.

Table 1
Comparison between various theoretical and experimental ratios of the anisotropy associated with the $S = 12$ and $S = 4$ Mn_6 complexes (see also Fig. 4): D is the total molecular anisotropy; U is the magnetization reversal barrier; and Δ is the ZFS between the ground and first excited state. We note the somewhat artificial nature of this comparison given that the EPR measurements consider 4th order anisotropy, whereas the calculations do not.

Ratio	Projection operator[a]		Matrix diagonalization[b]		Experimental	
	Scheme 1	Scheme 2	$J \gg D_S$	$J = D_S$	EPR	ac χ''
$D_{S=12}/D_{S=4}$	0.155	0.186	0.160	0.216	0.283	
$U_{S=12}/U_{S=4}$	1.395	1.674	1.440	1.944	2.56	2.70
$\Delta_{S=12}/\Delta_{S=4}$	0.509	0.611	0.525	0.709	1.03	

[a] For the projector operator method the D values were computed exactly, then the other numbers in the table were obtained from these values via the following expressions: $U = DS^2$ and $\Delta = (2S - 1)D$.
[b] For the matrix diagonalization method, the ZFS (Δ) between the lowest two levels was calculated exactly. The other numbers in the table were then deduced by inverting the following expressions: $U = DS^2$ and $\Delta = (2S - 1)D$.

15 625. However, using the sparse matrix algorithm one can obtain the eigenvalues easily and, in the strong exchange limit, the ratio of anisotropies turns out to be $D_{S=12}/D_{S=4} = 0.160$, which differs by 3% and 16% from the ratios obtained using schemes 1 and 2, respectively. An advantage of the 'brute force' diagonalization approach is that one can relax the strong exchange condition and examine the more realistic situation in which $J_{ij} \sim D_S$ [11]. Results obtained assuming a single exchange constant ($J_{ij} = J$, for all i and j) are displayed in Fig. 5, where one sees that the $D_{S=12}/D_{S=4}$ ratio increases/diverges as J decreases. A summary of all experimental and theoretical results is presented in Table 1.

From inspection of Table 1, one can see that the numerical studies seem to suggest a much smaller increase in the barrier, U, than is found experimentally, i.e. a roughly 50% increase, rather than a threefold increase. This finding lends some weight to Waldmann's dire prediction that the barrier should increase as S^0 [12]. Naturally, it is quite likely that the differences between theory and experiment are due to the many approximations that were made in the present study. However, the weak exchange matrix diagonalization calculations ($J = D_S$) provide grounds for some optimism, where one notes that the numerical results start to approach the experimental numbers. We suspect that this may be due to an additional suppression of the barrier for the antiferromagnetic case caused by strong mixing of the $S = 4$ state with low-lying excited states. In other words, the barrier for the $S = 4$ Mn_6 complexes is far from optimized. Therefore, these findings do suggest that the idea of maximizing S by switching the sign of the exchange coupling in polynuclear transition metal complexes is a reasonable strategy for obtaining better SMMs.

5. Conclusion

Detailed high-frequency EPR studies on two Mn_6 complexes have enabled us to better understand how and why the barrier increases as the total molecular spin increases. The experimental results are compared with calculations which demonstrate that a significant increase of the barrier is possible in cases where the exchange and single-ion anisotropy within the cluster are comparable. Overall, our findings support this strategy of increasing S by switching as many exchange pathways in a molecule as possible from antiferromagnetic to ferromagnetic. However, one should not ignore other routes to obtaining better SMMs, particularly methods which maximize single-ion anisotropy and its projection onto the molecular spin ground state.

2.2. Effective exchange integrals

The applicability of the approximate spin-projected (AP) effective exchange integral (J_{ab}) scheme by the use of the Heisenberg Hamiltonian was shown in our previous work [1,2]. The AP method resolves the spin contamination problem in the total energy of LS state. The AP J_{ab} value can be obtained by the energy difference between the highest spin (HS) and lowest spin (LS) states. Especially, the AP J_{ab} scheme for the three-dimensional (3D) eight nuclear cube is given by

$$J_{ab} = \{{}^{LS}E - {}^{HS}E\}/\{{}^{HS}\langle \mathbf{S}^2\rangle - {}^{LS}\langle \mathbf{S}^2\rangle + 8\{\langle\downarrow\uparrow\rangle - \langle\uparrow\uparrow\rangle\}\} \quad (2)$$

where ${}^{X}E$ and ${}^{X}\langle \mathbf{S}^2\rangle$ denote the total energy and spin angular momentum for the spin state *X* (*HS* or *LS*), respectively, and $\langle\uparrow\downarrow\rangle$ and $\langle\uparrow\uparrow\rangle$ mean the expectation values for antiferromagnetic and ferromagnetic spin couplings, respectively, which are given by

$$\langle\uparrow\downarrow\rangle = -S_aS_b \quad (3a)$$

$$\langle\uparrow\uparrow\rangle = S_aS_b \quad (3b)$$

where S_c ($c = a, b$) denotes the size of the spin angular momentum at the site. The detailed derivation of these equations is shown in Ref. [2].

3. Results and discussion

3.1. Effective exchange integral

It is known that $KMnF_3$ and $RbMnF_3$ exhibit the antiferromagnetic G-type ordering [13]. In order to discuss the magnetic interactions quantitatively in $KMnF_3$ and $RbMnF_3$, AP J_{ab} values were obtained for **1** and **2**. The Mulliken spin density population, which is the double size of the total spin angular momentum, is used to obtain the expectation values for the ferromagnetic and antiferromagnetic spin couplings between manganeses. Table 1 shows J_{ab} values for **1** and **2** by UHF, UBHHLYP and UB3LYP. J_{ab} values by UBHHLYP are roughly consistent with the experimental ones, while UHF and UB3LYP underestimates and overestimates $|J_{ab}|$ values, respectively. As the experimental J_{ab} values in the perovskte-type fluorides often provide 20–30% error, UBHHLYP can be treated as one of the proper calculations for these species.

3.2. Spin density and charge density populations

The Mulliken spin and charge density populations are useful indices to estimate the magnitudes of electron and spin correlations in the perovstite-type manganese fluorides. Table 2 shows the spin density and charge density populations of **1** and **2** in LS state, by UBHHLYP. There is no atomic spin density population in potassium and rubidium. Namely, there exists no direct magnetic interaction between manganese and counter cation, as expected from no magnetic moment in counter cation. On the other hand, the atomic charge density populations in potassium and rubidium are 0.814 and 0.836, respectively. In spite of no direct magnetic interaction between manganese and counter cation, the charge transfer from counter cation to fluorines occurs.

3.3. Electron density population

The shapes of the electron density population were displayed by MOLEKEL 4.3 [14]. Fig. 2 depicts the shapes of the electron density populations of **1** and **2** in LS state, by UBHHLYP. The overlap between manganeses via bridge-fluorine causes the antiferromagnetic superexchange (SE) interaction. Rubidium is more overlapped with fluorines than potassium. Our calculation result shows that the cavity in $RbMnF_3$ is excessively filled in comparison with $KMnF_3$. It is empirically predicted from the *t* values in $KMnF_3$ (0.96) and $RbMnF_3$ (1.03). It is considered that no phase transition from cubic structure in $RbMnF_3$ comes from the perfect fitting, while $KMnF_3$ displays cubic to tetragonal phase transition.

3.4. Intrinsic roles of counter cation

Here, we consider only the cubic phase in $KMnF_3$ and $RbMnF_3$, and counter cation is displaced from the cubic center, in order to investigate the intrinsic size and ionic effects of counter cation on the magnetic interaction. Here, the variations of the total energy and J_{ab} value were examined, changing the displacement distance (*d*) from the cubic center toward <100> direction. In relation to the lithium ion conduction, the intrinsic roles of lithium on the magnetic interaction were also investigated in $K_{1-x}Li_xMnF_3$.

Table 2
The Mulliken spin density and charge density[a] populations of (**1**) KMn_8F_{12} and (**2**) $RbMn_8F_{12}$ models in LS state (UBHHLYP method).

	K (Rb)	Mn (up)	Mn (down)	*F*
1	0.000 (0.814)	4.915 (1.749)	−4.915 (1.749)	0.000 (−0.814)
2	0.000 (0.836)	4.917 (1.746)	−4.917 (1.746)	0.000 (−0.817)

[a] The charge density population is given in parenthesis.

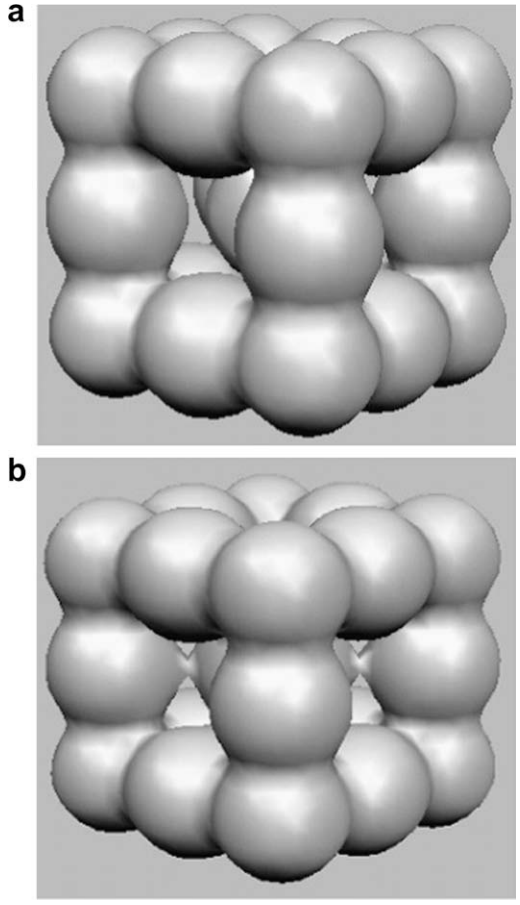

Fig. 2. The shapes of the electron density populations of (a) (**1**) KMn_8F_{12} model and (b) (**2**) $RbMn_8F_{12}$ model in LS state (UBHHLYP method, at the same threshold).

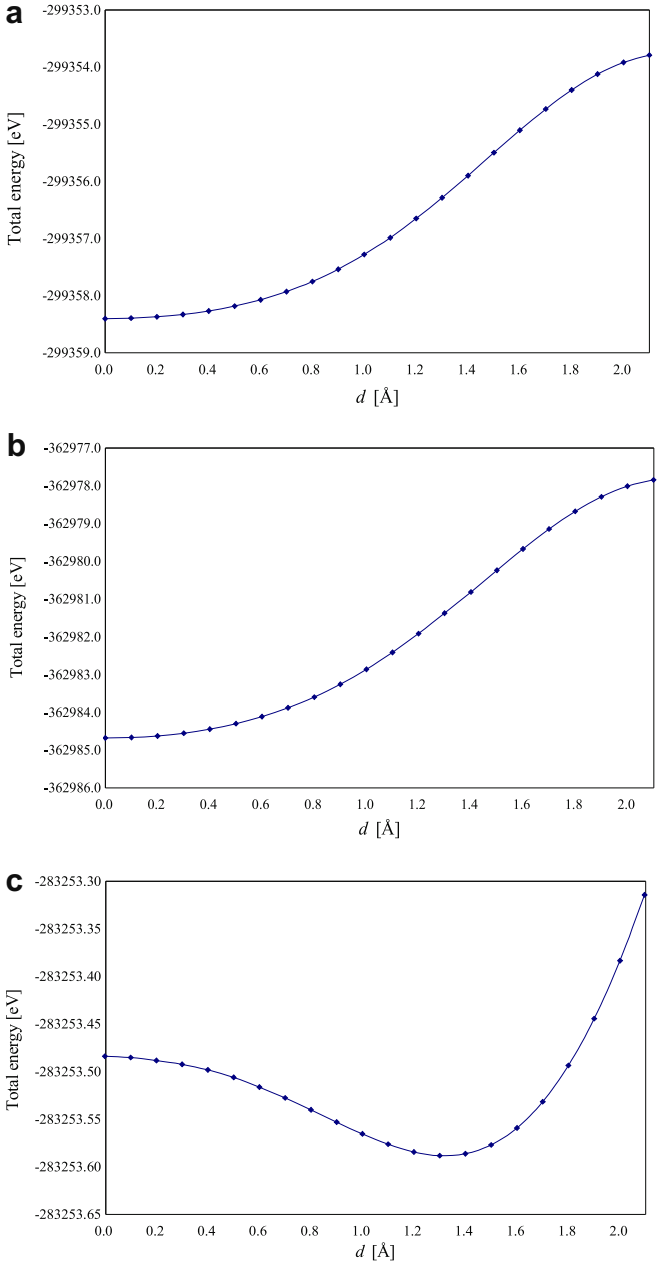

Fig. 3. The potential energy curves for (a) (**1**) KMn_8F_{12} model (b) (**2**) $RbMn_8F_{12}$ model and (c) (**3**) $LiMn_8F_{12}$ model, changing the displacement distance (*d*) from the cubic center toward <100> direction (UBHHLYP method).

Fig. 3 shows the potential energy curves for **1**, **2** and **3**, changing *d*, respectively. The potential energy curves for **1** and **2** increase monotonously. The energy differences between 0.0 Å and bottleneck, which is the Mn_4F_4 square part, in **1** and **2** are 4.612 and 6.837 eV, respectively. It shows that the steric repulsion between counter cation and bottleneck is large. In addition, the counter cation displacement makes the total energy in $RbMnF_3$ higher than that in $KMnF_3$. It comes from the perfect fitting of rubidium in the cubic center.

The potential energy curve for **3** has the minimum point at about 1.3 Å. It shows that lithium can move off the cubic center easily. The energy difference between the minimum point and cubic center (bottleneck) is 0.105 eV (0.274 eV). It is known that the activation energy of the lithium ion conduction in the perovskite-type titanium oxide of $La_{2/3-x}Li_{3x}TiO_3$ (LLT) is between 0.15 and 0.40 eV [15–17]. It is concluded that the lithium ion conduction in the perovskite-type manganese fluoride of $RMnF_3$ is possible, if the vacancy at R site exists as same as LLT. In addition, it shows that the steric repulsion between lithium and bottleneck is negligible, and the ionic bonds between lithium and other atoms are dominant.

Fig. 4 shows the J_{ab} curves for **1**, **2** and **3**, changing *d*, respectively. Eq. (2) is assumed even for the unsymmetrical configuration (*d* is not 0), under the approximation of the expectation values for ferromagnetic (25/4) and antiferromagnetic (−25/4) spin couplings. $|J_{ab}|$ values for **1** and **2** become larger by the increase of *d*. Because the orbital overlap between manganese and fluorine near the opposite bottleneck is more strengthened by the increase of *d*, due to the cavity of the electron density population of counter cation. It shows that potassium and rubidium in the cubic center control the strength of the magnetic interaction. On the other hand, $|J_{ab}|$ value variation for **3** by the increase of *d* is smaller in comparison with **1** and **2**. The orbital overlap between manganese and fluorine is little changed by the displacement of lithium. Hence,

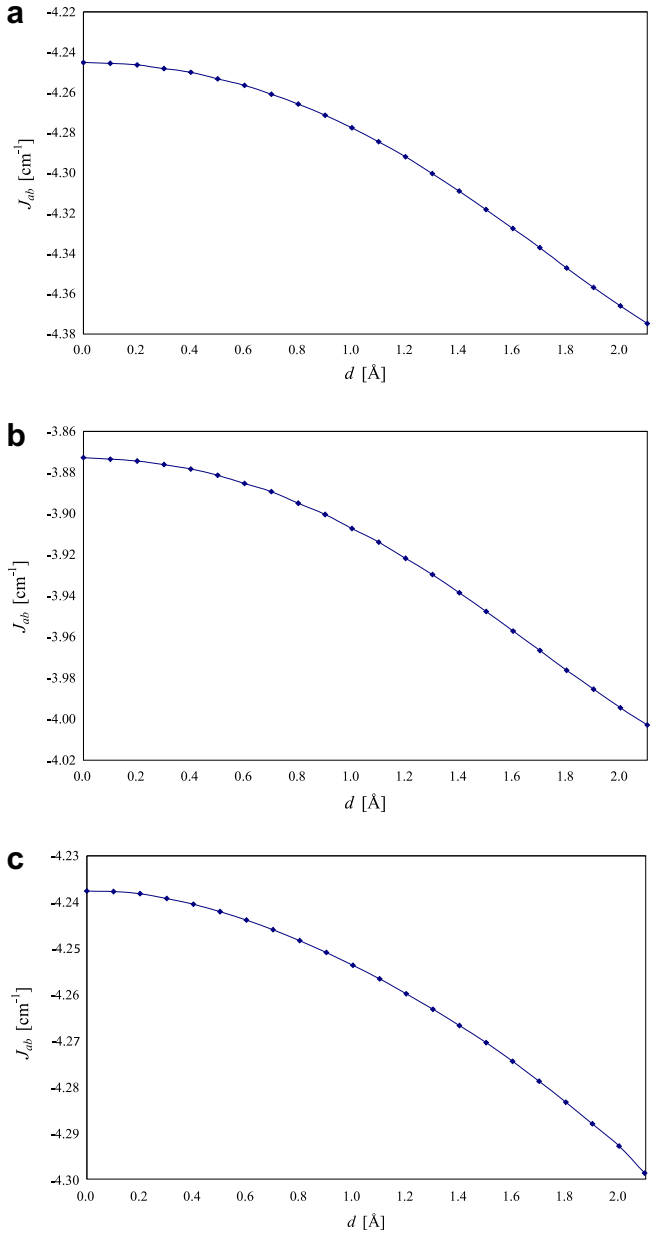

Fig. 4. The effective exchange integral (J_{ab}) curves for (a) (**1**) KMn_8F_{12} model, (b) (**2**) $RbMn_8F_{12}$ model, and (c) (**3**) $LiMn_8F_{12}$ model, changing the displacement distance (d) from the cubic center toward <100> direction (UBHHLYP method).

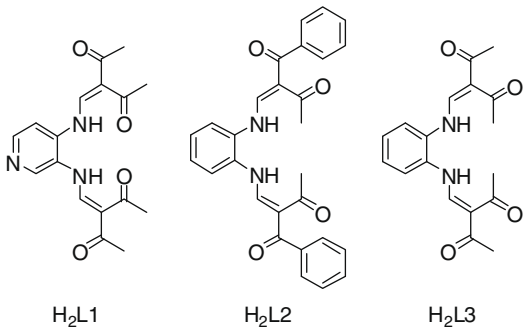
it is considered that the magnetic change is negligible, when the lithium ion conduction appears in $K_{1-x}Li_xMnF_3$.

4. Conclusion

We performed hybrid-DFT calculations for the perovskite-type manganese fluorides of $KMnF_3$, $RbMnF_3$ and $K_{1-x}Li_xMnF_3$. The J_{ab} value, spin density and charge density populations, electron density population and total energy were obtained. We concluded as follows:

1. UBHHLYP provided the reasonable J_{ab} value.
2. In $KMnF_3$ and $RbMnF_3$, there exists no direct magnetic interaction between manganese and counter cation. However, potassium (rubidium) has the role of controlling the strength of the magnetic interaction
3. No phase transition in $RbMnF_3$ comes from the perfect fitting.
4. The lithium ion conduction in $RMnF_3$ is possible, if the vacancy at R site exists. The magnetic change is negligible when the lithium ion conduction appears.



Our calculation results show that the antiferromagnetic perovskite-type fluorides are able to have the lithium ion conductivity. In comparison with the existing LLT, the degree of the structural distortion is small. In addition, the delocalization effect between manganese and fluorine is also small. Hence, the larger bottleneck of Mn_4F_4 square could be provided in spite of the existence of d-electron in manganese. It is considered that doping of the divalent counter cations such as Mg^{2+}, Ca^{2+}, Sr^{2+} and Ba^{2+} causes the vacancy at R site. In the near future, the vacancy doping technique would enable us to realize the new perovskite-type antiferromagnet with the lithium ion conductivity. From the viewpoint of the material science, $RMnF_3$ would be useful for the solid state electrolyte and positive electrode materials in the secondary lithium ion battery. For other perovskite-type transition metal fluorides such as $RNiF_3$, $RCoF_3$ and $RFeF_3$, our work is also in progress.

2.2. Magnetic measurements

Magnetic measurements of the samples were performed on a Quantum-Design-MPMSR2-SQUID-Magnetometer in a temperature range from 2 to 295 K. The measurements were carried out at a field strength of 0.05 T in the settle mode. The data were corrected for the magnetization of the sample holder and diamagnetic corrections were made using tabulated Pascal's constants.

2.3. X-ray crystallography

The intensity data of **1**(MeOH) and **3**(MeOH) were collected on an Oxford XCalibur diffractometer using graphite-monochromated Mo Kα radiation, the intensity data of **2**$(MeOH)_{0.5}$ were collected on a Nonius Kappa CCD diffractometer using graphite-monochromated Mo Kα radiation. Data were corrected for Lorentz and polarization effects. The structure was solved by direct methods (Sir 97) and refined by full-matrix least-square techniques against F_0^2 (SHELXL-97). The hydrogen atoms were included at calculated positions with fixed thermal parameters. ORTEP-III was used for structure representation. The crystallographic data are summarized in Table 1. Selected distances and angles are presented in Tables 2 and 3.

3. Results and discussion

3.1. Description of the X-ray structures

Crystals suitable for X-ray structure analysis were obtained for all complexes. The crystallographic data are summarized in Table 1. Fig. 1 displays an ORTEP drawing of the asymmetric unit of **1**(MeOH), **2**$(MeOH)_{0.5}$ and **3**(MeOH). Selected bond length and angles are summarized in Table 2.

In all complexes the iron centre is situated in an octahedral coordination sphere and the obtained bond lengths around the iron(II) centres of **1**(MeOH), **2**$(MeOH)_{0.5}$ and **3**(MeOH) are within the region reported for other octahedral iron(II) complexes of the same ligand type in the high-spin (HS) state [6–9]. The average values are 2.11 Å ($Fe–N_{eq}$), 2.03 Å ($Fe–O_{eq}$) and 2.23 Å ($Fe–L_{ax}$). The average $O_{eq}–Fe–O_{eq}$ angle with a value of 113° also indicates that all

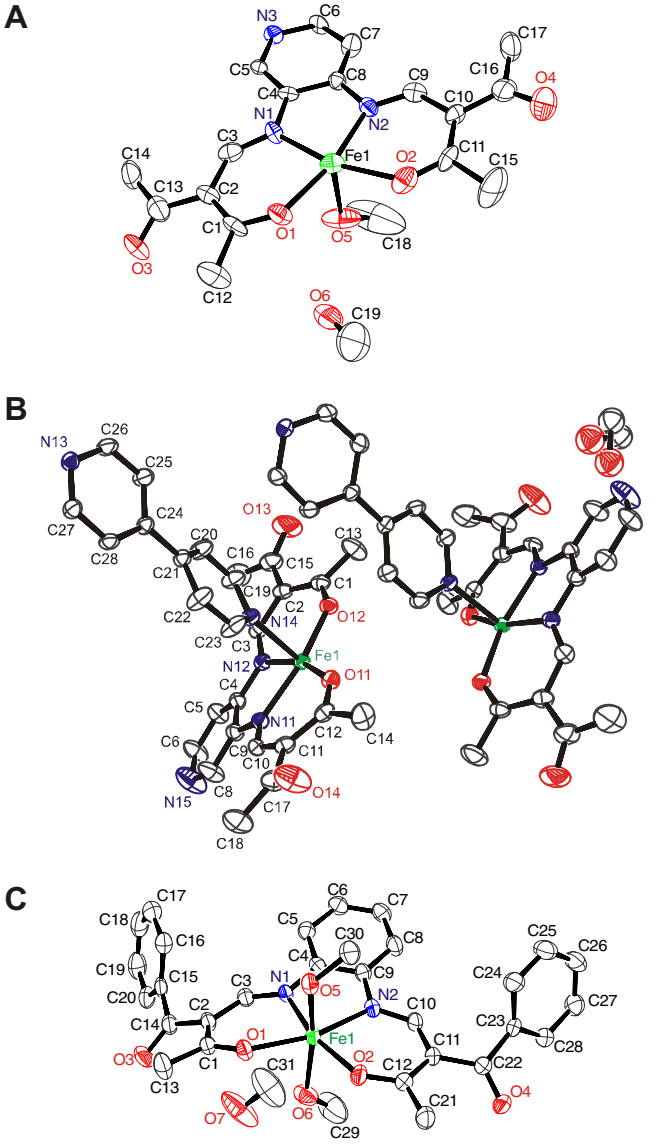

Fig. 1. ORTEP-drawing of the asymmetric unit of **1**(MeOH) (A), **2**$(MeOH)_{0.5}$ (B) and **3**(MeOH) (C). Hydrogen atoms were omitted for clarity. Thermal ellipsoids are shown at the 50% probability level.

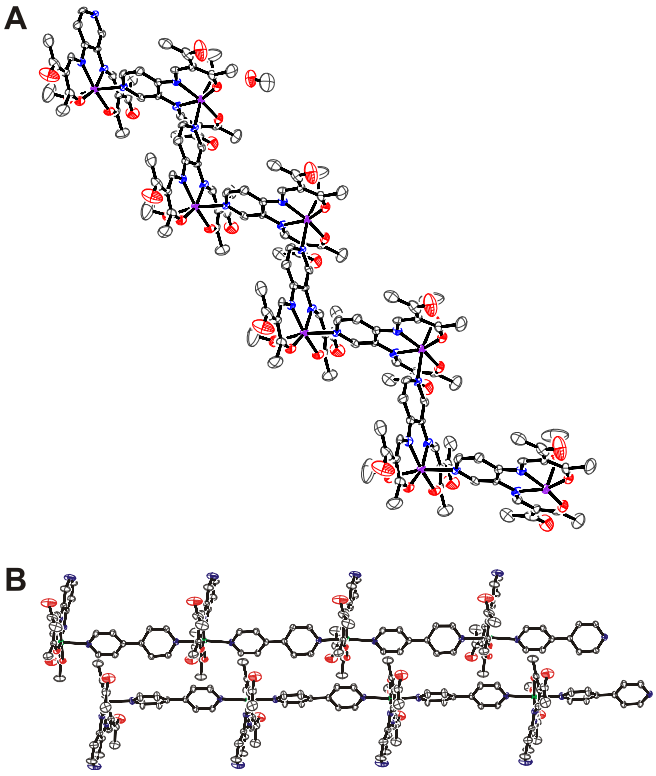

Fig. 2. ORTEP-drawing of the zigzag chain structure of **1**(MeOH) (A) and the linear chain structure of **2**$(MeOH)_{0.5}$ (B).

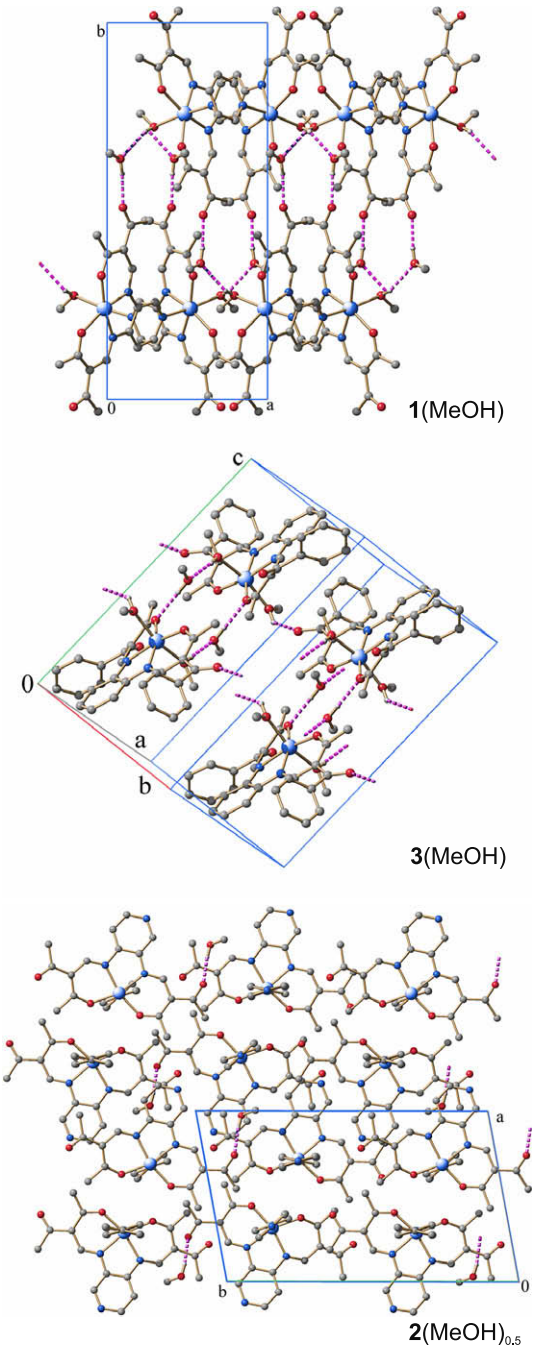

Fig. 3. A plot of the crystal packing of the molecules of **1**(MeOH) along [0 0 1] (top), **2**$(MeOH)_{0.5}$ (bottom) and **3**(MeOH) along [0 0 1] (middle).

complexes are clearly in the HS state. This angle typically changes from about 110° in the HS state to about 90° in the low-spin (LS) state for this type of complexes [6–9].

As expected, the pyridine nitrogen of the ligand H_2L1 in complex **1**(MeOH) acts as axial ligand at the neighbouring complex molecule. This result in the formation of 1D zigzag chain with an angle of 84° between two neighbouring equatorial ligands and an intermolecular Fe–Fe distance of 7.35 Å as shown in Fig. 2A. The second axial coordination side is occupied by a methanol molecule leading to a N_3O_3 coordination sphere at the iron centre. A similar motive was recently reported for a mononuclear complex of this ligand type with 3-aminopyridine and methanol as axial ligands [13]. If 4,4′-bipyridine is used as axial ligand instead of methanol (complex **2**$(MeOH)_{0.5}$) the bipy replaces the pyridine nitrogen of the equatorial ligand and a linear 1D chain with parallel equatorial ligands is obtained (Fig. 2B). The 4,4′-bipyridine occupies both coordination sides and an N_4O_2 coordination sphere is obtained. The inter-chain Fe–Fe distances in this example is with 11.60 Å in the same order of magnitude as reported for similar 4,4′-bipyridine bridged iron(II) complexes [8a]. Between two neighbouring chains the shortest Fe–Fe distances are 7.16 Å/6.03 Å for **1**(MeOH)/**2**$(MeOH)_{0.5}$. In complex **3**(MeOH) both axial coordination sides are occupied by a methanol molecule resulting in a N_2O_4 coordination sphere around the iron centre. For this example no chain formation is observed. The shortest Fe–Fe distance in the molecule packing of this complex is 7.12 Å.

Hydrogen bonding and π-stacking are always considered to play a central role for the mediation of cooperative interactions [5,6,9], independent of the discussed magnetic phenomena (spin crossover or long-range magnetic ordering). A plot of the crystal packing of the molecules of the three complexes is given in Fig. 3. The idea to used the phenyl group in H_2L2 to introduce π–π-interactions did not work for the complex **3**(MeOH) as no indication for this kind of interactions are observed. For the two methanol adducts **1**(MeOH) and **3**(MeOH) hydrogen bond interactions are found between the single molecules (**3**(MeOH)) or the 1D chains (**1**(MeOH)). The hydroxyl group of the axially coordinated methanol acts in both cases as hydrogen bond donor connecting two complex-molecules using the carbonyl oxygen of the neighbouring equatorial ligand as accepter. In both cases a 1D chain of hydrogen bond linked molecules is formed along [1 0 0]. For the monomer complex **3**(MeOH), half of the connections are communicated over the hydroxyl groups of the non-coordinating methanol molecules resulting in a 1D double-chain of linked molecules. For

the 1D chain compound **1**(MeOH), all connections include a non-coordinating methanol molecule that links two polymer chains together resulting in a 1D double-chain of linked molecules (Fig. 3, top).

For complex **2**$(MeOH)_{0.5}$ there are hydrogen bonds between carbonyl group of the equatorial ligand and hydroxyl group of non-coordinating methanol molecules without the formation of any additional network.

3.2. Magnetic properties

Magnetic susceptibility measurements for all compounds were performed in a temperature range from 295 to 2 K. The plots for $\chi_M T$ and $1/\chi_M$ versus T are given in Fig. 4. With decreasing temperature the $\chi_M T$ product decreases from a value of 3.86/3.29/3.60 $cm^3\ K\ mol^{-1}$ at 295 K to a value of 3.29/3.02/3.22 $cm^3\ K\ mol^{-1}$ at 25 K for the complexes **1**(MeOH), **2**$(MeOH)_{0.5}$ and **3**(MeOH), respectively. These susceptibility data can be fitted well with the Curie–Weiss law: $1/\chi_M = C/(T - \Theta)$. The parameters for complex **1**(MeOH) are $\Theta = -5.23$ K and $C = 3.91$ $cm^3\ K\ mol^{-1}$, for complex **2**$(MeOH)_{0.5}$ $\Theta = -3.22$ K and $C = 3.31$ $cm^3\ K\ mol^{-1}$ and for complex **3**(MeOH) $\Theta = -5.38$ K and $C = 3.64$ $cm^3\ K\ mol^{-1}$. The Curie constant is for all three complexes in a region expected for iron(II) HS complexes. The negative Weiss constant Θ and the decrease of the $\chi_M T$ product with decreasing temperature, both indicate weak antiferromagnetic interactions between the spin centres which are stronger for the methanol adducts **1**(MeOH) and **3**(MeOH). This is most likeably due to the missing hydrogen bond network in **2**$(MeOH)_{0.5}$. Below a temperature of 25 K the $\chi_M T$ product decreases further for **2**$(MeOH)_{0.5}$ and **3**(MeOH). This is due to weak antiferromagnetic exchange interactions (**3**(MeOH)) or zero-field splitting (**2**$(MeOH)_{0.5}$) or probably a combination of the two. For **1**(MeOH) the $\chi_M T$ product significantly increases below 10 K. Consequently field-cooled magnetization and zero-field-cooled magnetization (FCM/ZFCM) measurements were performed in a temperature range from 20 to 2 K for the complex **1**(MeOH) with $H = 30$ G. The results are shown in Fig. 5. The clear increase of the magnetization of complex **1**(MeOH) below 5 K shows the onset of long-range magnetic ordering with a critical temperature of $T_C = 3.5$ K. The high-temperature antiferromagnetic interactions in combination with the spontaneous magnetization at low temperatures are an indication for spin canting mechanism as the reason for the observed properties. The decrease of the magnetization below 3.5 K is most likely caused by antiferromagnetic interactions between the neighbouring 1D chains. These results are in good agreement with the results from X-ray structure analysis. The zigzag structure observed for **1**(MeOH) provides almost ideal foundations for spin canting with an optimal canting angle close to 90°. The obtained magnetization is significantly higher than that of analogue monomer complexes of this ligand type (e.g. [FeL3-$(MeOH)_2$], [5]). The destruction of the zigzag structure that can be equalized with going from the methanol adduct **1**(MeOH) to the corresponding 4,4′-bipyridine adduct **2**$(MeOH)_{0.5}$, results in a loss of spin canting and only weak antiferromagnetic interactions are observed. A similar observation is made for **3**(MeOH) where no canting angle between neighbouring molecules is observed and consequently no indication of a spontaneous magnetization below a critical temperature is obtained.

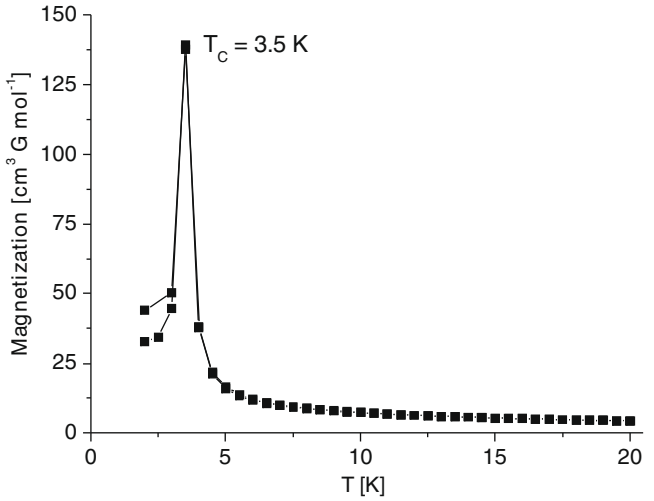

Fig. 5. Field-cooled magnetization and zero-field-cooled magnetization (FCM/ZFCM) measurements versus T plots under a week magnetic field of $H = 30$ G for complex **1**(MeOH).

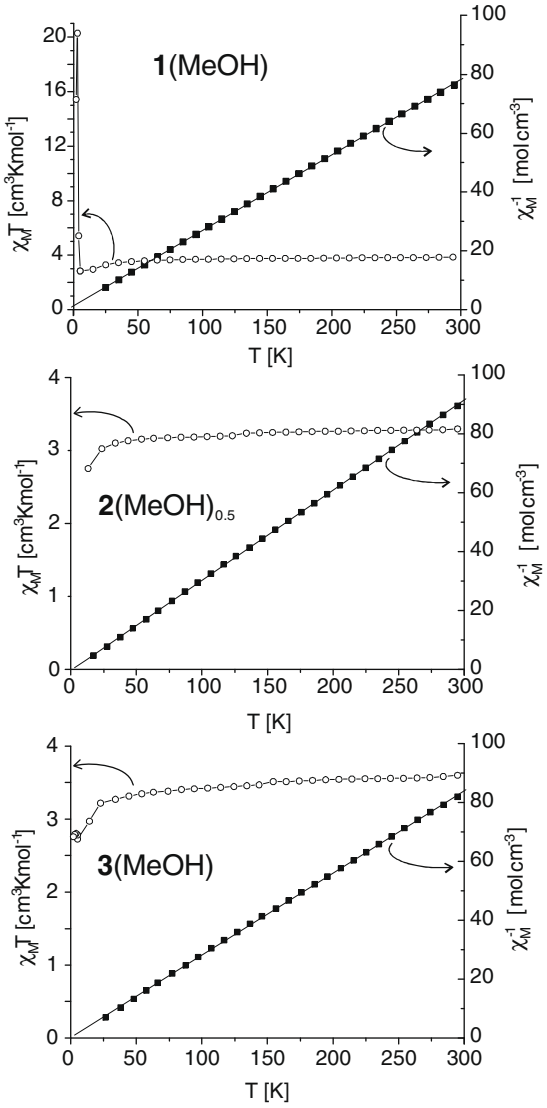

Fig. 4. Thermal variation of $\chi_M T$ (open circles), reciprocal molar susceptibility, $\chi_M{}^{-1}$ as function of temperature T (full squares) and the fits according to the Curie–Weiss law, $1/\chi_M = C/(T - \Theta)$, with the parameters $\Theta = -5.23$ K/$C = 3.91$ $cm^3\ K\ mol^{-1}$ for complex **1**(MeOH), $\Theta = -3.22$ K/$C = 3.31$ $cm^3\ K\ mol^{-1}$ for complex **2**$(MeOH)_{0.5}$ and $\Theta = -5.38$ K/$C = 3.64$ $cm^3\ K\ mol^{-1}$ for complex **3**(MeOH).

4. Conclusion

The introduction of the pyridine nitrogen in the tetradentate ligand H_2L1 provides an interesting possibility to control the magnetic exchange interactions. The nearly orthogonal arrangement of the neighbouring molecules results in ferromagnetic interactions due to spin canting. The only setback is the very low critical temperature. We will now try to further modify the ligand system in order to obtain shorter and by this more effective exchange pathways. This will be to topic of a subsequent paper.

units or clusters in order to fill the empty voids or channels generated in the crystal packing [8].

Our previous work on malonate-containing copper(II) complexes has been expanded toward the synthesis, structural and magnetic characterization of two new mixed-ligand polymers of copper(II) in which one component is the methylmalonate ligand and the other a blocking unidentate N-donor molecule, 3-Iodopyridine (3-Ipy) (**1**) and 2,4′-bipyridine (2,4′-bpy) (**2**).

2. Experimental

2.1. Material and methods

Copper(II)-methylmalonate has been prepared according to the synthesis previously reported [7]. The other reagents and solvents used in the syntheses were purchased from commercial sources and used without further purification. Elemental analyses (C, H, N) were performed on an EA 1108 CHNS-O microanalytical analyzer.

2.2. Preparation of the complexes

2.2.1. Synthesis of [Cu(3-Ipy)(Memal)(H_2O)] (**1**)

A methanolic solution (5 cm^3) of 3-Iodopyridine (1 mmol, 102 mg) was added dropwise to an aqueous solution (10 cm^3) of copper(II)-methylmalonate (1 mmol) under stirring. The resulting blue solution was allowed to evaporate at room temperature. Prismatic deep blue single crystals appeared in the beaker after a few weeks, when almost all the solution has been evaporated. Yield *ca.* 60%. *Anal.* Calc. for $C_9H_{10}CuINO_5$ (**1**): C, 26.85; H, 2.50; N, 3.48. Found: C, 26.97; H, 2.71; N, 3.56%.

2.2.2. Synthesis of [Cu(2,4′-bpy)(Memal)(H_2O)] · 3H_2O (**2**)

An aqueous solution (5 cm^3) of copper(II)-methylmalonate (0.5 mmol) was set in one arm of a water filled H-shape tube, while the other arm was filled with a methanolic solution (5 cm^3) of 2,4′-bipyridine (0.5 mmol, 156 mg). Deep blue needle crystals were grown after one month at room temperature. Yield *ca.* 40%. *Anal.* Calc. for $C_{14}H_{20}CuN_2O_8$ (**2**): C, 41.23; H, 4.94; N, 6.87. Found: C, 41.33; H, 5.09; N, 6.98%.

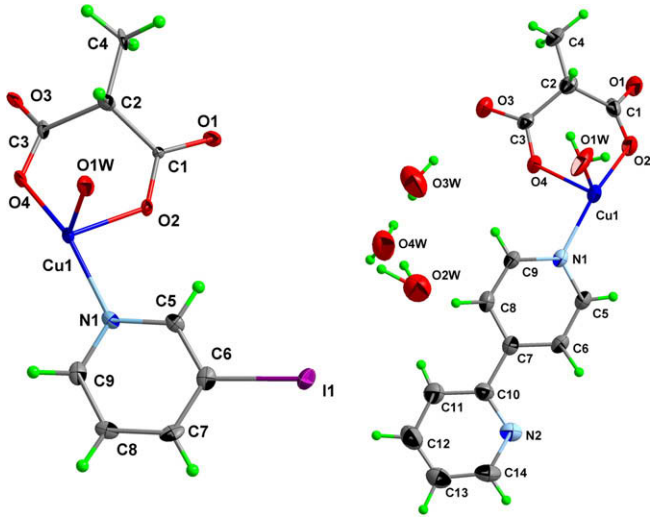

Fig. 1. An ORTEP view with the 50% probability of the asymmetric unit for the complexes **1** (left) and **2** (right) along with the numbering scheme.

2.3. Physical techniques

Magnetic susceptibility measurements on polycrystalline samples of **1** and **2** were performed in a Quantum Design SQUID magnetometer in the temperature range 2–300 K operating at 1 T (over the whole temperature range) and 0.1 T ($T < 15$ K) for compound **1** and operating at 1 T (over the whole temperature range), 0.1 T ($T < 20$ K) and 0.05 T ($T < 15$ K) for **2**. Diamagnetic corrections of the constituent atoms were estimated from Pascal's constants [9]. Experimental susceptibility values were also corrected for the temperature independent paramagnetism [60×10^{-6} cm^3 mol^{-1} per copper(II) ion] and the magnetization of the sample holder.

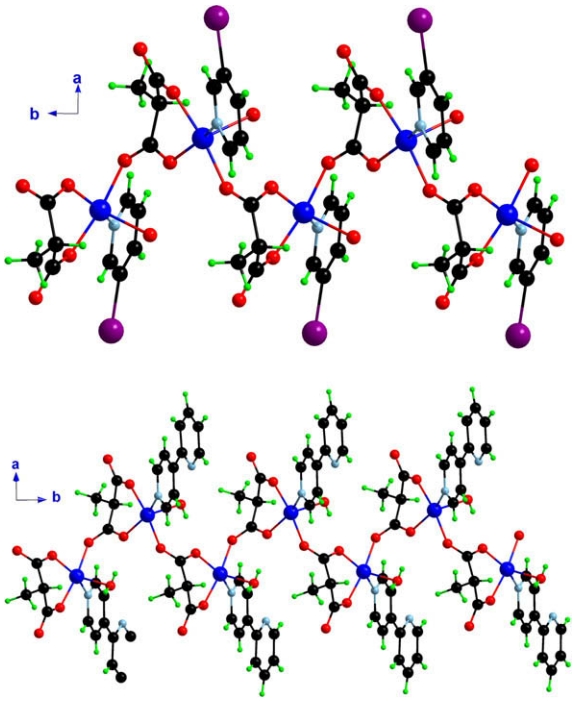

Fig. 2. A view of the carboxylate bridged copper(II) chains of **1** (up) and **2** (bottom) along the *c*-axis. Despite the different coligands, structurally the chains of both compounds are very similar.

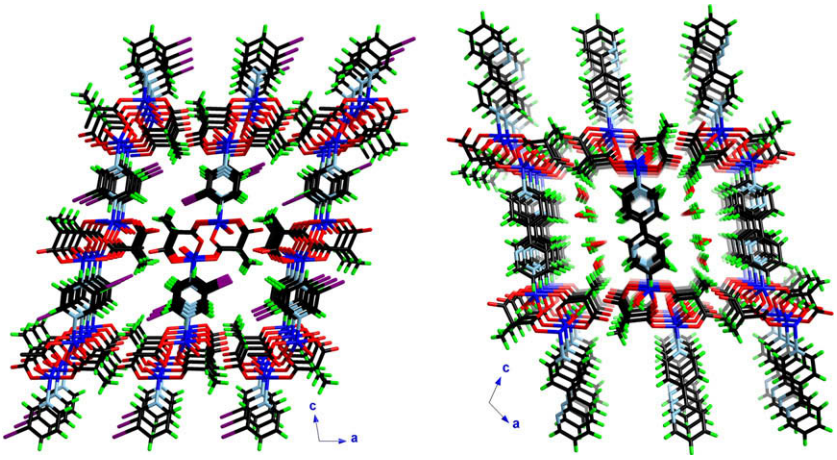

Fig. 3. Central projection of the crystal packing for **1** (left) and **2** (right) along the *b*-axis. The figures show the π–π stacking among the coligands and the crystallization water molecules which fill the channels of **2**.

2.4. X-ray crystallography

Single crystals of **1** and **2** were mounted on a Bruker-Nonius KappaCCD diffractometer and the crystallographic data were collected at 293(2) K using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The data collection was carried out with φ–ω scans in the 6.41–21.99° (**1**) and 4.23–27.52° (**2**) θ ranges. The crystal structures were solved by direct methods and refined with the full-matrix least-squares technique on F^2 using the SHELXS-97 and SHEXL-97 programs [10] included in the WINGX software package [11]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of **1** were geometrically positioned and refined using a riding model and those of **2** were located from difference Fourier maps and refined with isotropic temperature factors. The final geometrical calculations and the graphical manipulations were carried out with PARST95 [12] and DIAMOND [13] programs. A summary of the crystallographic data and structure refinement is given in the Table 1.

3. Results and discussion

3.1. Description of the crystal structures of *1* and *2*

The structures of the compounds **1** and **2** (Fig. 1) consist of *zig-zag* chains of *anti-syn* carboxylate-bridged copper(II) ions running along the *b* direction (Fig. 2). The pyridine-like ligands occupy one equatorial position of the copper environment avoiding the formation of the sheet-like arrangement observed in previously reported Memal complexes [7]. The chains are grouped together in hydrophilic layers [which grow in the (001) (**1**) and (101) (**2**) planes] through hydrogen bonds involving the coordinated water molecule and coordinated and uncoordinated methylmalonate oxygen atoms [O···O distances ranging from 2.677(7) to 2.729(7) Å]. The layers are pillared through the 3-Ipy (**1**) and 2,4′-bpy (**2**) ligands (Fig. 3) which are stacked through π–π interactions (Fig. 4) involving alternatively aromatic ligands from two adjacent chains. The two different separations between centroids of the 3-iodopyridine rings in **1** are 3.5371(7) and 3.6610(7) Å, whereas the off-set angles are 20.39(15)° and 23.23(15)°. These values are in agreement with those observed in pyridine-like ligands [14]. This is also true for the centroid–centroid distances [3.5689(7) and 3.8702(7) Å] and off-set angles [values ranging from 16.64(11)° to 28.66(11)°] between the 2,4′-bipyridine ligands in **2**. The pillared 2D sheets create interlayer 1D channels which are very small in **1** due to the small 3-iodopyridine ligand and the presence of the halogen atom, but large enough in **2** to include crystallization water molecules. These water molecules build a T5(2) pattern (following the nomenclature by Infantes et al.) [8] which is one of the most frequent tape motifs (Fig. 5) [8a]. The water pentagons exhibit a half-chair conformation with an axial length of the tape [distance between lower and upper atoms] of

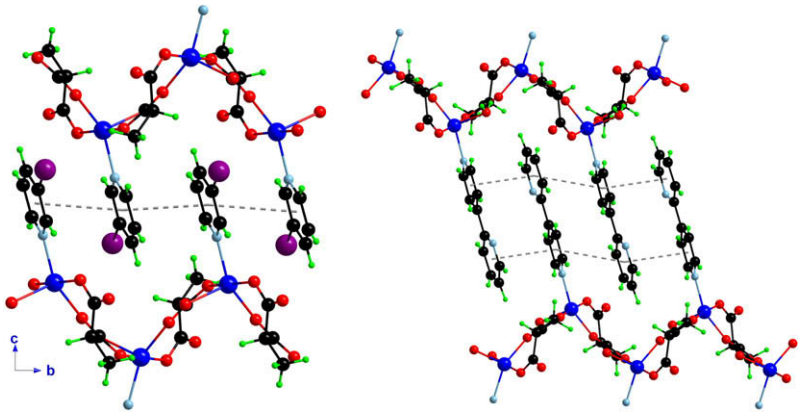

Fig. 4. Detail of the π–π stacking among the 3-iodopyridine groups in **1** (left) and among the 2,4′-bipyridine molecules in **2** (right). The dashed lines correspond to the centroid–centroid vectors.

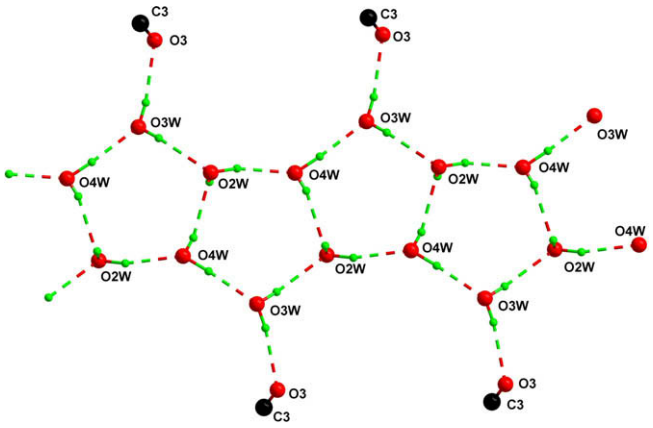

Fig. 5. T5(2) pattern formed by the crystallization water molecules in **2** with the numbering scheme.

6.939(9) Å. The water tape is anchored to the host through hydrogen bonds between a water molecule [O(3w)] from the tape acting as donor and an uncoordinated methylmalonate oxygen atom [O(3)] as acceptor. Selected H-bond distances and angles are listed in Table 2.

Each copper atom in **1** and **2** exhibits a distorted square pyramidal environment [the τ value [15] being 0.31 (**1**) and 0.32 (**2**)]. This feature is mainly due to steric effects of the 3-Ipy and 2,4′-bpy groups which are located in equatorial positions. Three oxygen atoms from two different methylmalonate ligands [O(2), O(3) and O(4)] and a nitrogen atom from a N-donor ligand [N(1)] build the basal plane. The average values of the Cu(1)–O(eq) bond are 1.952(5) for **1** and 1.950(3) Å for **2**, whereas those of Cu(1)–N are 2.040(6) Å (**1**) and 2.030(4) Å for (**2**). The apical position is filled by a water molecule [O(1w)], the Cu(1)–O(1w) bond distances being 2.205(5) (**1**) and 2.233(5) Å (**2**). The methylmalonate ligands act simultaneously as bidentate [through O(2) and O(4) with the angles subtended at the copper atom being 89.6(2)° (**1**) and 89.47(13)° (**2**)] and monodentate ligands [through O(3) in **1** and O(1) in **2**]. Selected bond lengths and bond angles are listed in Table 3.

The intrachain copper–copper separation in **1** through the *anti-syn* carboxylate bridge [5.1638(16) Å] is shorter than the interchain ones [the shortest separations being 6.671(2) Å between chains separated by the 3-iodopyridine ligand and 8.0206(16) Å between H-bonded chains]. A similar situation is observed in **2** where the intrachain separation between the copper atoms through the *anti-syn* carboxylate bridge is 5.0432(12) Å while the shortest interchain separations are 7.490(2) (between H-bonded chains) and 10.067(2) Å (between chains separated by the 2,4′-bipyridine ligand).

The inset shows a detail of the low temperature region.

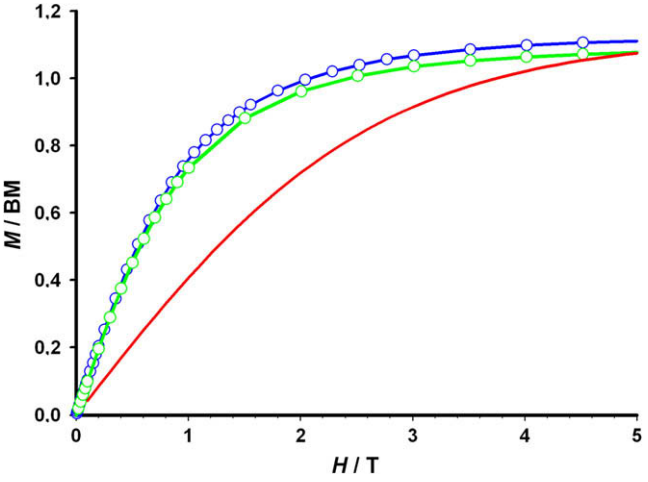

Fig. 7. M vs. H curve for **1** (blue) and **2** (green) together with the Brillouin function for a magnetically isolated spin doublet with the g value obtained from the fitting of the $\chi_M T$ curve of **1** [($g = 2.238(2)$] (red line). The blue and green lines are eye-guide lines.

Let us finish this structural description with a comparison of these structures with those synthesized with malonato or phenylmalonato-carboxylate ligands. The location of the 2,4′-bipyridine ligand in the equatorial position at the copper(II) environment is also observed in the Phmal-containing complex $[Cu(2,4'\text{-bpy})(Phmal)(H_2O)]_n$ [6c], in this case, however, a layered complex is formed. The static Jahn-Teller disorder of the copper(II) environment in that complex could be at the origin of the formation of the layers, a feature which is not observed in **2**. In the case of the malonic acid, to our knowledge, there are no complexes with the 3-Ipy ligand, but several compounds with the 2,4′-bpy ligand were reported [5e,5i]. A manganese(II) complex [5i] with similar layers as those formed in the Phmal compound [6c] and a copper(II) compound [5e] exhibiting a copper environment similar to that of **2**, where the 2,4′-bpy ligand occupies an equatorial position and a water molecule fills the apical one. However, in the malonate-containing complex the copper(II) chains are bent to form isolated tetranuclear entities with the copper atoms in the corners, the malonate ligands in the edges and the 2,4′-bpy ligands like paddles pointing outwards the unit.

3.2. Magnetic properties

The magnetic properties of the compounds **1** and **2** under the form of $\chi_M T$ versus T plot (χ_M being the molar susceptibility per copper(II) ion) are shown in Fig. 6. The $\chi_M T$ values at room temperature are 0.48 and 0.46 $cm^3\ mol^{-1}\ K$ for **1** and **2**, respectively. These values are as expected for a magnetically isolated spin doublet. Upon cooling, $\chi_M T$ increases smoothly until $T < 20$ K and then, it sharply increases to reach values of 1.13 (**1**) and 1.10 $cm^3\ mol^{-1}\ K$ (**2**) at 2.0 K. The magnetization (M) versus the applied magnetic field (H) plots for both compounds, which are depicted in Fig. 7, are clearly above the theoretical Brillouin curve for an isolated spin $S = 1/2$. The saturation of the magnetization is achieved for both compounds at *ca.* 3.0 T. All these features are indicative of the presence of ferromagnetic interactions between the copper(II) ions of **1** and **2**.

Given that the structures of these compounds consists of chains of copper(II) ions bridged by carboxylate-methylmalonate groups in the *anti-syn* conformation, their magnetic data were analysed by means of the numerical expression for an $S = 1/2$ ferromagnetic uniform chain [16]:

$$\chi_M = (N\beta^2 g^2/4kT)(A/B)^{2/3}$$
$$A = 1.0 + 5.7979916y + 16.902653y^2 + 29.376885y^3 + 29.832959y^4 + 14.036918y^5$$
$$B = 1.0 + 2.7979916y + 7.0086780y^2 + 8.6538644y^3 + 4.5743114y^4$$
$$\hat{H} = -J\sum\nolimits_i \hat{S}_i \cdot \hat{S}_{i+1}$$

with $y = J/2kT$, J is the intrachain magnetic coupling, and the other symbols have their usual meanings. Best least-squares fit parameters are: $J = +2.66(2)\ cm^{-1}$, $g = 2.238(2)$ and $R = 1.6 \times 10^{-5}$ for **1** and $J = +2.62(2)\ cm^{-1}$, $g = 2.188(2)$ and $R = 1.1 \times 10^{-5}$ for **2**, where R is the agreement factor defined as $\sum[(\chi_M T)_{obs} - (\chi_M T)_{calc}]^2 / \sum[(\chi_M T)_{obs}]^2$. The calculated curves match very well the experimental data in the whole temperature range (Fig. 6). At the same time, the values of J are practically identical for the two compounds, in agreement with their structural similarity.

The ferromagnetic nature of the magnetic interactions in **1** and **2** is in agreement with the data reported in the literature for the *anti-syn* equatorial–equatorial carboxylate bridge (see Table 4).

[a] Abbreviations used: H_2mal = malonic acid; 2,2′-bpy = 2,2′-bipyridine; 2,4′-bpy = 2,4′-bipyridine; 4,4′-bpy = 4,4′-bipyridine; bpe = 1,2-bis(4-pyridyl)ethylene; bpa = 1,2-bis(4-pyridyl)ethane; H_2Phmal = phenylmalonic acid; H_2cbdca = 1,1-cyclobutanedicarboxylic acid; H_2Memal = methylmalonic acid; azpy = 4,4′-azobispyridine.
[b] Separation between copper(II) ions through the operative carboxylate bridge.
[c] Dihedral angle between the mean equatorial planes of adjacent copper(II) ions.
[d] Value of the distortion of the five-coordinated environment ($\tau = 0$ being a perfect square pyramid and $\tau = 1$, a trigonal bipyramid). O_h refers to octahedral environments. When more than one value is listed, more than one crystallographically independent copper atom is present in the structure.
[e] Magnetic exchange coupling parameter. The type of system used to fit the experimental data is also indicated.
[f] More than one magnetic exchange pathway is considered in the fitting.
[g] A mean-field term was added to take into account other interactions.

According to the Kahn's model, the magnetic coupling for two interacting copper(II) ions can be decomposed in two different contributions of opposite nature, the *anti*-ferromagnetic one being dependent on square of the overlap of the magnetic orbitals (the smaller the overlap is, the lower the *anti*-ferromagnetic term) [20]. The magnetic orbitals at the copper atoms are of the $d(x^2 - y^2)$ type [the *x*- and *y*-axes roughly corresponding with the equatorial bonds of the copper environment] with some admixture of the dz^2 character [the *z*-axis being defined by the axial bond]. The angle between the basal planes of the magnetically coupled copper atoms are nearly orthogonal [84.76(12)° and 75.28(8)° for **1** and **2**, respectively], then the overlap is reduced to a minimum and the ferromagnetic contribution becomes predominant.

The magnitude of the interaction can be explained having in mind some structural considerations. The carboxylate exchange pathways link two equatorial positions at the adjacent copper(II) ions. This conformation is more favourable to the magnetic coupling (*J* values ranging from +3.0 to +23 cm^{-1}) (Table 4) than the equatorial–apical one. From the results listed in Table 4, the greater values for *J* are observed in the discrete polynuclear entities, despite other parameters. Within the complexes with a magnetic behaviour described by regular chains, complexes **1** and **2** lay in the lower limit of the *J* range. The large distortion of the square pyramidal environment in both compounds would be responsible for this situation.

4. Conclusion

In the present contribution, we show how the use of the methylmalonate as ligand toward the copper(II) ions affords other structures than the square grids previously reported. Complexes **1** and **2** consist of carboxylate-bridged chains of copper(II) atoms which build a pillared two-dimensional (2D) supramolecular network by means of weak $\pi\cdots\pi$ interactions and hydrogen bonds. The 3D network in **2** exhibits channels where water molecules are hosted, with a T5(2) pattern. Both compounds exhibit ferromagnetic interactions trough the carboxylate exchange pathway.

The preference of the pyridine-like ligands for the equatorial position at the copper atom has been observed previously in the $[Cu_2(4,4'\text{-bpy})(Memal)_2(H_2O)_2]_n$ [7] and $[Cu(2,4'\text{-bpy})(Memal)(H_2O)$ [6c] complexes. Thus, it is not surprising, although unexpected, that the two-dimensional (4,4) network of carboxylate-bridged copper ions has turned into carboxylate-bridged copper(II) chains due to the introduction of a terminal ligand in the basal plane of the copper atom environment.

therefore further research work requires temperatures below 2 K to investigate SMM behavior. On the other hand, research on J_{4f-3d} can afford fruitful results at the present stage without observation of SMM behavior. We focus our attention on determination of J_{4f-3d}'s and their comparison among the analogs. Magnetic study below 2 K is not necessarily required, but we measured the pulsed-field $M-H$ curves at 0.5 K, because the experiments at lower temperatures could exhibit better step-shaped magnetization curves.

The pulse-field magnetization measurements on a polycrystalline specimen of $[Tb_2Cu_2]_n$ were collected at 0.5 K (Fig. 2a). The saturation magnetization (M_s) of 15.7 μ_B at 10 T was close to the calculated value 17 μ_B with $|J^z| = 5$ and $g_J = 3/2$, and did not reach the calculated one with maximal $|J^z| = 6$. A parallel study on the same specimen using a SQUID magnetometer supported this result. This finding indicates that a ground state of the Tb ions may be given by the value of $|J^z| = 5$. The field-oriented data were usually obtained in these measurements (see Section 5), but the M_s value may not be a full-saturation value because of incomplete orientation.

The differentiated magnetization curve on $[Tb_2Cu_2]_n$ is shown in the bottom of Fig. 2a, clarifying that the magnetic field at the dM/dB peak is 5.6 T. The gap of the jump corresponds to 4 μ_B from two

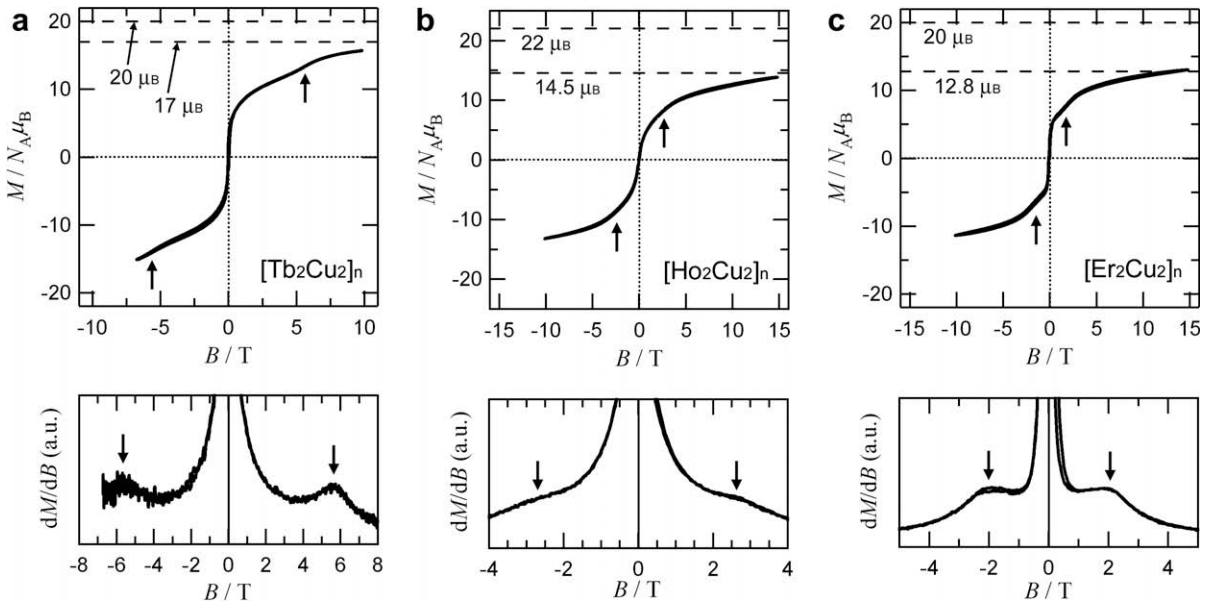

Fig. 2. Magnetization curves for $[Ln_2Cu_2]_n$ measured at 0.5 K, where Ln = Tb (a), Ho (b), and Er (c). Derivative curves are also shown in the bottom figures. The arrows show the positions of the magnetization jumps.

copper spins. Consequently, the jump is ascribable to the transition from the ground ferrimagnetic state ($[Tb(\uparrow)_2Cu(\downarrow)_2]_n$) to the ferromagnetic one ($[Tb(\uparrow)_2Cu(\uparrow)_2]_n$). In other words, the energy-level crossing takes place around 5.6 T in a Zeeman picture.

Similarly, the pulsed-field magnetization measurements on a polycrystalline specimen of $[Ho_2Cu_2]_n$ were collected at 0.5 K (Fig. 2b). The M_s value 13.8 μ_B at 15 T did not reach the calculated value with maximal $|J^z| = 8$ and $g_J = 5/4$. Assuming that the observed M_s is intrinsic, the ground state of the Ho ions would have a smaller moment such as $|J^z| = 6$ (the calculated M_s value 17 μ_B) or 5 (14.5 μ_B). The magnetic field at the dM/dB peak is 2.5 T (the bottom of Fig. 2b). The energy-level crossing between the ferrimagnetic ($[Ho(\uparrow)_2Cu(\downarrow)_2]_n$) and ferromagnetic ($[Ho(\uparrow)_2Cu(\uparrow)_2]_n$) states occurs around 2.5 T.

In the case of $[Er_2Cu_2]_n$ (Fig. 2c), the M_s value was 13.0 μ_B at 15 T, which did not reach the calculated value with maximal

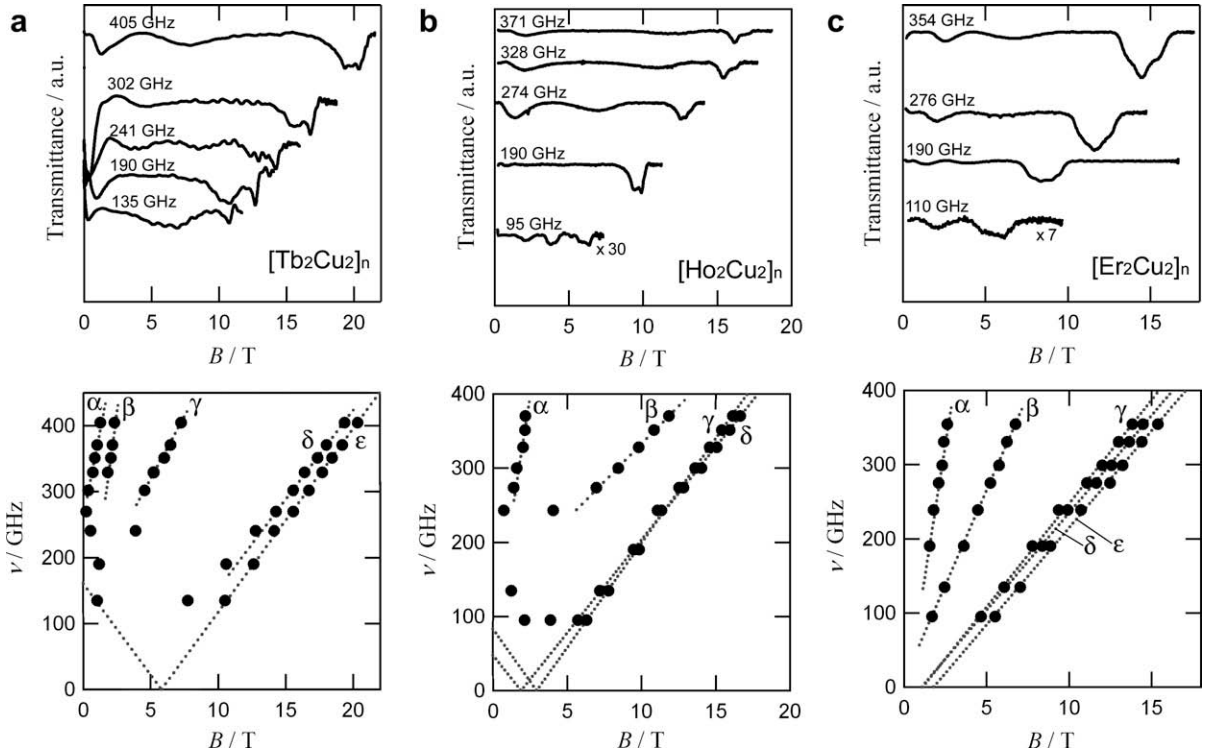

Fig. 3. (Top) Selected EPR spectra measured at 4.2 K as a function of frequency for (a) $[Tb_2Cu_2]_n$, (b) $[Ho_2Cu_2]_n$ and (c) $[Er_2Cu_2]_n$. The spectra are offset in a linear scale of the frequency. (Bottom) Frequency-field diagrams for (a) $[Tb_2Cu_2]_n$, (b) $[Ho_2Cu_2]_n$, and (c) $[Er_2Cu_2]_n$. Dotted lines are shown for a guide to the eye.

$|J^z| = 15/2$ and $g_J = 6/5$. The ground state of the Er ions may have a smaller moment such as $|J^z| = 11/2$ (the calculated M_s value 15.2 μ_B) or 9/2 (12.8 μ_B). The energy-level crossing between the ferrimagnetic and ferromagnetic states occurs around 2.5 T (the bottom of Fig. 2c). We have previously reported that the $M-H$ curves for $[Gd_2Cu_2]_n$ and $[Dy_2Cu_2]_n$, which exhibited a similar copper(II) spin-flip transition at ca. 7.0 and 5.56 T, respectively [5,11]. Therefore, the series of $[Ln_2Cu_2]_n$ involve 4f–3d antiferromagnetic couplings for all heavier-lanthanide ions investigated (Ln = Gd, Tb, Dy, Ho, and Er).

The precise level-crossing field is finally determined from the HF-EPR experiments. HF-EPR spectra of powder $[Tb_2Cu_2]_n$ were collected in a wide frequency range 95–405 GHz at 4.2 K (Fig. 3a). We found several series of signals shifted to a higher field with an increasing frequency ($\alpha-\varepsilon$ in Fig. 3b). The g value of the signals (ε) was 1.99(2) from the slope of the frequency-field plot. It is consistent with the Cu signal satisfying a conventional EPR selection rule of $\Delta m_s = \pm 1$. The g value slightly smaller than 2 was previously reported and discussed on $[Dy_2Cu_2]_n$ [5]. Extrapolation gives a critical field of 5.80(8) T, which implies the level-crossing of two states with respect to the Cu spin-flip. It is identical to the position of the magnetization jump in the $M-H$ curve, and the value from the HF-EPR is more precise than that of the $M-H$ measurements.

The g values of the other signals ($\alpha-\delta$) were ca. 10, ca. 15, 2.65(11) and 1.92(5), respectively. Some of them seem to be caused by transitions among $2J + 1$ multiplets of the Tb ions. For example, a transition of $\Delta m_J = \pm 10$ with $g_J = 3/2$ gives an apparent g value of 15; namely, the transition with g = ca. 15 (β) may be attributed to a forbidden transition with $\Delta m_J = \pm 10$ (e.g., $J^z = -5 \leftrightarrow +5$).

HF-EPR spectra of powder $[Ho_2Cu_2]_n$ were collected in a frequency range 95–371 GHz at 4.2 K. We found several series of signals shifted to a higher field with an increasing frequency ($\alpha-\delta$ in Fig. 3b). The g values of the γ and δ series were 2.01(2) and 1.79(4), respectively, from the slope of the frequency-field plot. They are assigned to the Cu signals, similarly to the $[Tb_2Cu_2]_n$ case. Extrapolations of their peaks give different critical fields of 1.9(2) T and 2.96(11) T. They may originate from different transitions. The Ho ions affect the internal field at the adjacent Cu ions in terms of exchange-bias fields. Accordingly, the position of the critical fields is in proportion to J^z. If the stronger peaks (γ) on a higher field are attributed to Er ions with maximal $J^z = \pm 8$, the weaker peaks (δ) might be to Er ions with $J^z = \pm 5$. The peaks of the δ series were stronger than those of the γ series in a small field region, indicating that a state with $J^z = \pm 5$ for Ho ions is the ground state among $2J + 1$ multiplets of the Ho ions while the first excited state has $J^z = \pm 8$ for Ho ions. This finding is consistent with the small M_s value of the magnetization measurements. The resonance-field positions of the α and β series were bent in a small field region, and their g values could not be calculated accurately. The g value of α is roughly estimated to be 8 or larger, and that of β to be 1.5 or larger. The origin of the α signals is ascribable to a forbidden transition among $2J + 1$ multiplets of the Ho ions. The β signals may be attributed to a transition with a smaller Δm_J value.

HF-EPR spectra of powder $[Er_2Cu_2]_n$ were collected in a frequency range 95–354 GHz at 4.2 K. We found several series of signals shifted to a higher field with an increasing frequency ($\alpha-\varepsilon$ in Fig. 3c). The g values of the γ, δ and ε series were 1.99(4), 1.88(6), and 1.87(3), respectively, which are ascribed to the Cu signals. Extrapolations of their peaks give different critical fields of 1.10(10) T, 1.35(15) T and 1.79(15) T. The presence of the various critical fields may be caused by different J^z values at Er ions ($J^z = \pm 15/2$, $\pm 13/2$, $\pm 11/2$, etc.). If the highest-field series (ε) is attributed to a species having Er ions with $J^z = \pm 15/2$, the other peaks (γ and δ) might be to molecules having Er ions with $J^z = \pm 11/2$ and $\pm 9/2$, respectively. The g values of the α and β series were 10.8(7) and 3.66(4), respectively. The former seems to be caused by transitions of the Er ion itself with a somewhat large J^z and possibly be assigned to a forbidden transition with $\Delta m_J = \pm 9$, because $\Delta m_J = \pm 9$ ($J^z = -9/2 \leftrightarrow +9/2$) with $g_J = 6/5$ gives an apparent g value of 10.8. The latter seems to be caused by transition between $J^z = -15/2 \leftrightarrow -9/2$, because $\Delta m_J = \pm 6$ with $g_J = 6/5$ gives an apparent g value of 3.6.

3. Discussion

For all compounds investigated here, 4f–3d couplings were antiferromagnetic, giving the ferrimagnetic ground state. The $M-H$ and HF-EPR measurements consistently indicate the critical field, ascribable to an energy-level crossing from the ferri- to ferromagnetic states. The present exchange-coupling model holds for $[Ln_2Cu_2]_n$ as well as $[Ln_4Cu]$ [4] and $[Ln_2M]$ [3]. Assuming the Ising character of Ln ions, the following general spin Hamiltonian is available for the repeating unit $[Ln_2Cu_2]$:

$$\hat{H} = -J_A(\hat{J}_2^z \cdot \hat{S}_1 + \hat{J}_3^z \cdot \hat{S}_4) - J_B(\hat{J}_3^z \cdot \hat{S}_1 + \hat{J}_2^z \cdot \hat{S}_4) + \mu_B H^z(g_1 S_1 + g_2 J_2^z + g_3 J_3^z + g_4 S_4)$$

Symbols J_2 and J_3 represent the total moments of Ln ions, while S_1 and S_4 the spins of Cu ions. The first and second terms stand for the Ising-type exchange interactions between Ln and Cu ions, where the coupling parameters are defined as $-J_A$ and $-J_B$, and the third term represents the Zeeman interaction (Fig. 4).

The EPR signals due to Ln ions were observed for the Tb, Ho, and Er analogs. These signals are originally "forbidden", but possible admixture of the states might violate the EPR selection rule and their signals become observable. In addition, in some case, the J^z value does not have a maximal value of $J = L + S$. Along this context, the Ising character is somewhat weakened, in contrast to the typical Ising character found in the Dy analog [5]. However, the anisotropic character of lanthanide ions is usually strong, and the moments are still large. The effective Ising-spin model seems to be valid in the analysis on J_{4f-3d}.

The parameter J_{4f-3d} was estimated using the above Hamiltonian; namely the energy gap between the ground ferrimagnetic state and first excited ferromagnetic state was derived directly from the magnitude of the level-crossing field. Since the level-crossing field found in the HF-EPR data has more accuracy than that of the $M-H$ data, we utilized the HF-EPR data. The results are summarized in Table 2. In the present analysis, we can estimate an average value on J_A and J_B. Separation of J_A and J_B requires more detailed analysis, according to the method already published elsewhere [5].

We obtained antiferromagnetic 4f–3d couplings in all compounds investigated here. A possible reason is stated as follows. Kahn et al. explained the magnetic couplings in 4f–3d compounds as follows [13]. When the number of 4f electrons is more than seven, the orbital and spin momenta of Ln ions are parallel, and the ferromagnetic spin coupling gives rise to an overall ferromagnetic interaction. There are ample reports on ferromagnetic J_{Dy-Cu} as well as J_{Gd-Cu} [13–15]. Antiferromagnetic couplings are explained

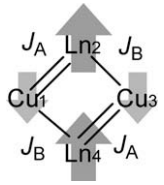

Fig. 4. Exchange coupling scheme for $[Ln_2Cu_2]$. The ground ferrimagnetic spin structure is drawn with arrows.

Table 2
Exchange parameter J_{4f-3d} for $[Ln_2Cu_2]_n$ determined from the HF-EPR study.

Ln	Gd[a]	Tb	Dy	Ho	Er
$J_{4f-3d}\ k_B^{-1}$ (K)	−1.3(2)[b]	−0.77(2)	−0.478(8)[c]	−0.250(12)	−0.149(15)

[a] The Gd moments are treated as Heisenberg spins.
[b] Estimated from the dc magnetic susceptibility as a function of temperature.
[c] Averaged from the reported values J_A and J_B for two crystallographically independent exchange couplings.

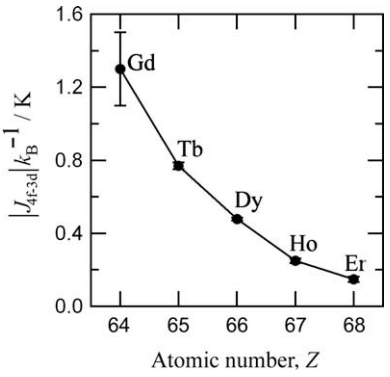

Fig. 5. Plot of the absolute values of the 4f–3d exchange coupling parameters in $[Ln_2Cu_2]_n$ as a function of the atomic number of the Ln ions. Solid line is shown for a guide to the eye.

in terms of the violation of the ferromagnetic interaction between the 4f spin portion and 3d spins [11,16]. In the present compounds, the severe torsion along the Ln–O–N–M linkage was found in common, and such out-of-plane geometry favors antiferromagnetic coupling, as previously discussed in $[Gd_2Cu_2]_n$ [11].

Furthermore, the absolute value of the exchange coupling parameter monotonically decreases with the atomic number from $_{64}$Gd to $_{68}$Er, as depicted in Fig. 5. The present simple relation is different from the typical trend of magnetic anisotropy as Dy > Tb > Ho > Er ≫ Gd [17]. On the other hand, the nominal number of 4f-electrons increases from $4f^7$ to $4f^{11}$, and accordingly the number of the 4f-spins decreases from seven to three, in the order from Gd^{3+} to Er^{3+}. This finding indicates that the exchange coupling takes place between the copper $3d_{x^2-y^2}$-spin and the lanthanide 4f-spin portion, regardless of the angular contribution or magnetic anisotropy from Ln ions. The observed antiferromagnetic coupling is approximately proportion to the overlap between the 4f and 3d magnetic orbitals, and the combination for the orbital overlap would increase with an increase of the number of magnetic 4f orbitals.

4. Concluding remarks

The advantages of HF-EPR are the extremely high resolution and the ability to identify quantum numbers of energy-levels by the EPR selection rule. The bias field at the copper(II) ions was detected, affording the information of exchange couplings. We have precisely evaluated J_{4f-3d} for $[Ln_2Cu_2]_n$, (Ln = Tb, Ho, and Er). These J_{4f-3d} values are comparable to those for Ln = Gd [11] and Dy [5], and the magnetic couplings in all compounds investigated here were antiferromagnetic. Furthermore, the $|J_{4f-3d}|$ value monotonically decreases in the order of Gd, Tb, Dy, Ho, and Er. The present methodology would be applicable to other 4f–3d heterometallic compounds. We are now investigating J_{4f-3d} in the $[Ln_2Cu_2]_n$ derivatives involving lighter-lanthanide ions.

5. Experimental

5.1. Materials

Complexes $[Ln_2Cu_2]_n$ ($[\{Ln(hfac)_2(CH_3OH)\}_2\{Cu(dmg)(Hdmg)\}_2]_n$; Ln = Tb, Ho, and Er) were synthesized by the complexation of $[Ln(hfac)_3(H_2O)_2]$ [18] and partially deprotonated $[Cu(Hdmg)_2]$ [19] in methanol (hfac stands for 1,1,1,5,5,5-hexafluoropentane-2,4-dionate; H_2dmg = dimethylglyoxime). $[Cu(Hdmg)_2]$ (15 mg, 0.050 mmol) was dissolved in 1.5 mL of MeOH containing 0.1 mmol of KOH. A methanol solution (1 mL) of $[Tb(hfac)_3(H_2O)_2]$ (82 mg, 0.050 mmol) was slowly added to the above solution. The resultant dark brown solution was allowed to stand at room temperature for a day, to give dark brown platelet crystals that were collected on a filter, washed with a small amount of MeOH, and dried in air. The yield of $[Tb_2Cu_2]_n$ was 23 mg (0.025 mmol; 50% on the repeating unit basis). Similarly, $[Ho_2Cu_2]_n$ and $[Er_2Cu_2]_n$ were prepared as brown prismatic crystals in 70% and 65% yield. The elemental analysis (C, H, N) of their complexes on a Fisons EA-1108 by a usual combustion method supported the chemical composition. $[Tb_2Cu_2]_n$: *Anal.* Calc. for $C_{19}H_{19}CuF_{12}N_4O_9Tb$: C, 25.42; H, 2.13; N, 6.24. Found: C, 22.60; H, 2.52; N, 5.65%. $[Ho_2Cu_2]_n$: *Anal.* Calc. for $C_{19}H_{19}CuF_{12}HoN_4O_9$: C, 25.25; H, 2.12; N, 6.20. Found: C, 23.35; H, 2.46; N, 5.78%. $[Er_2Cu_2]_n$: *Anal.* Calc. for $C_{19}H_{19}CuErF_{12}N_4O_9$: C, 25.18; H, 2.11; N, 6.18. Found: C, 24.94; H, 2.24; N, 5.81%.

5.2. X-ray crystallographic analysis

X-ray diffraction data of $[Ln_2Cu_2]_n$ (Ln = Tb, Ho, and Er) were collected on a Saturn70 CCD diffractometer with graphite monochromated Mo Kα radiation (λ = 0.71070 Å). The structures were directly solved by a heavy-atom method and expanded using Fourier techniques in the CRYSTALSTRUCTURE 3.8.2 program package [20]. Numerical absorption correction was used. All of the hydrogen atoms were located at calculated positions and the parameters were refined as "riding". The thermal displacement parameters of non-hydrogen atoms were refined anisotropically. Full-matrix least-squares methods were applied using all of the unique reflection data. Selected crystallographic data are listed in Table 1.

5.3. Magnetic measurements

The dc magnetic susceptibilities of $[Ln_2Cu_2]_n$ in a range of 1.8–300 K were measured on a Quantum Design SQUID magnetometer (MPMS-7). Typical sample masses were 20–50 mg. The magnetization curves were recorded from −7 to +7 T.

Low-temperature magnetization was measured by a conventional inductive probe in pulsed-magnetic fields, and the temperature was reached as low as 0.5 K using a ^{3}He cryostat [9]. Polycrystalline specimens (typically 20 mg) were mounted in a capillary made of polyimide Kapton (duPont). The sample was not fixed within the sample tube and then it aligned along the magnetic field direction. After we applied the magnetic field several times, the orientation effect was saturated, and the magnetization curves obtained in further shots were found to be identical.

5.4. HF-EPR measurements

HF-EPR spectrum for polycrystalline samples were obtained on the same pulsed-field generator [10]. The sample was packed in a case made of polyethylene. The radiation was produced by Gunn oscillators and backward traveling wave oscillators.

$(\mathbf{1}\cdot 2H_2O\cdot 2MeCN)_\infty$). When the same reaction was repeated with $mpdH_2$ instead of pdH_2, $\{[Mn_{17}(\mu_4\text{-}O)_8(N_3)_5(O_2CMe)_4(mpd)_{10}(py)_8]\}_\infty$ $(\mathbf{2}\cdot 2H_2O)_\infty$[1] was isolated in 35% yield (single crystals could be obtained as $(\mathbf{2}\cdot 2.2H_2O\cdot 2MeCN)_\infty$).

The crystal structures of $(\mathbf{1}\cdot 2H_2O\cdot 2MeCN)_\infty$[2] (Fig. 1a) and $(\mathbf{2}\cdot 2.2H_2O\cdot 2MeCN)_\infty$),[3] both having crystallized in the triclinic space group $P\bar{1}$, consist of a $[Mn_{17}(\mu_4\text{-}O)_8(\mu_3\text{-}N_3)_4(O_2CMe)_2(L)_{10}]^{3+}$ (L = pd^{2-} (**1**); mpd^{2-} (**2**)) unit with a flattened octahedral topology. Bond-valence sum calculations [9], charge considerations, and inspection of metric parameters revealed a mixed-valent complex containing six Mn^{II} and eleven Mn^{III} ions. The 15 Mn ions of the core (Fig. 1b) are disposed in three nearly planar rectangles stacked one above the other, and the remaining two Mn ions occupy the top and bottom capping positions. The central plane consists of seven Mn ions, four at the vertices, two on opposite edges, and the seventh near its center, whereas each of the other two planes contains four Mn ions all of which lie on the edges. All the Mn^{II} ions are located at the vertices of the octahedron whereas the Mn^{III} ions are placed on the edges and near the center of the octahedron. The Mn ions of the core are held together by eight $\mu_4\text{-}O^{2-}$ and four μ_3-1,1,1-N_3^- ligands. The structures also contain ten bridging pd^{2-} (or mpd^{2-}), two bridging and two chelating acetate ligands and one μ-1,3-N_3^- group. The peripheral ligation of compounds **1** and **2** is completed by six and eight terminal pyridine groups, respectively. The μ-1,3-N_3^- ligands bridge Mn7 ion of the Mn_{17} unit to its symmetry-related Mn ion of the neighboring Mn_{17} unit resulting in the formation of the 1-D coordination polymer (Fig. 2). The shortest Mn···Mn separation between different Mn_{17} units is ~6.24 Å in $(\mathbf{1}\cdot 2H_2O\cdot 2MeCN)_\infty$ and slightly longer (6.421 Å) in $(\mathbf{2}\cdot 2.2H_2O\cdot 2MeCN)_\infty$. The chains run parallel in the crystal, and although there are H_2O and MeCN molecules of crystallization there are no significant interchain interactions.

Variable-temperature, solid state magnetic susceptibility measurements were performed on powdered polycrystalline samples of $(\mathbf{1}\cdot 2H_2O)_\infty$ and $(\mathbf{2}\cdot 2H_2O)_\infty$ in a 1 kG (0.1 T) field in the 5.0–300 K range. The obtained data for both compounds are shown as $\chi_M T$ versus T plots in Fig. 3. The $\chi_M T$ for $(\mathbf{1}\cdot 2H_2O)_\infty$ and $(\mathbf{2}\cdot 2H_2O)_\infty$ increases from 82.5 and 88.4 $cm^3\ mol^{-1}$ K at 300 K to a maximum of 375.4 and 428.1 $cm^3\ mol^{-1}$ K at 40.0 and 35 K, respectively, before dropping rapidly to 67.9 and 156.4 $cm^3\ mol^{-1}$ K at 5.00 K. The 300 K $\chi_M T$ values are significantly larger than the value expected if the constituent $Mn_6^{II}Mn_{11}^{III}$ atoms were non-interacting (59.25 $cm^3\ mol^{-1}$ K for $g = 2$) suggesting the presence of predominant ferromagnetic exchange interactions within the Mn_{17} units. The maximum $\chi_M T$ values indicate a very large ground state spin [for example, the $\chi_M T$ value of 428.1 $cm^3\ mol^{-1}$ K for $(\mathbf{2}\cdot 2H_2O)_\infty$ is consistent with an $S = 29$ spin ground state, for which the spin-only ($g = 2$) value is 435.0 $cm^3\ mol^{-1}$ K].

The low temperature steep decrease is undoubtedly due to intermolecular antiferromagnetic exchange interactions mediated by the end-to-end N_3^- ligands, resulting in a diamagnetic ground state for both polymeric species. This was confirmed by the in-phase ac susceptibility (χ'_M), plotted as $\chi'_M T$ versus T in Fig. 4, for the two polymers, which are clearly heading for zero at 0 K. This shows that the steep decrease of $\chi_M T$ in Fig. 3 is not due to an artefact of the applied dc field but indeed due to intermolecular interactions within the 1-D polymers.

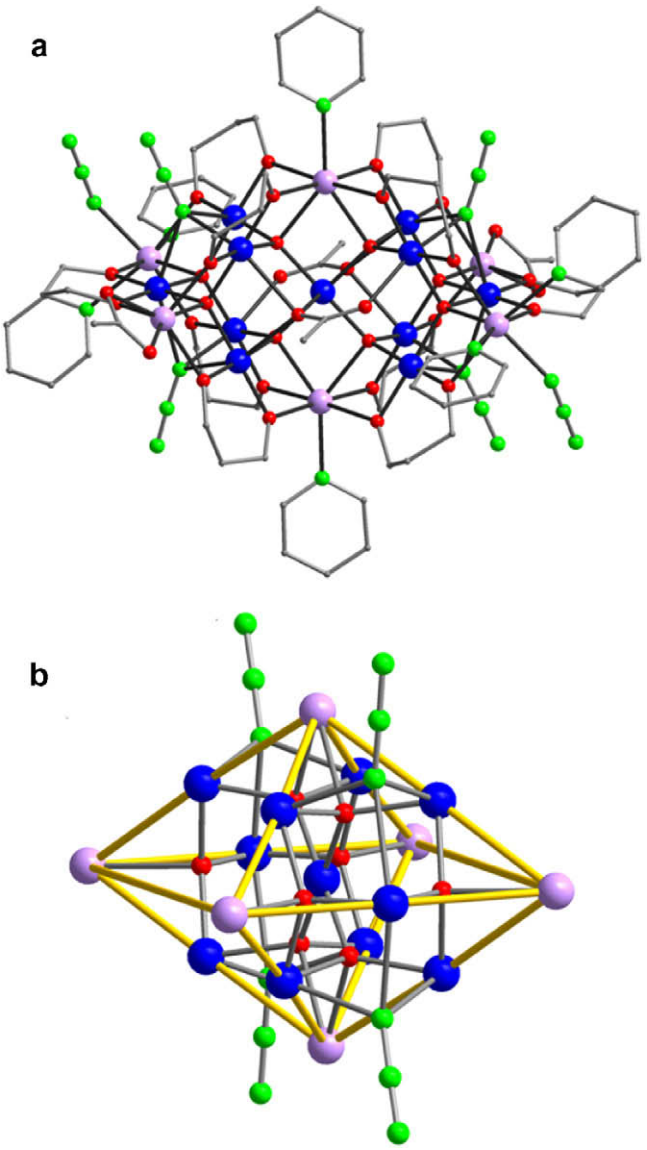

Fig. 1. (a) The molecular structure of **1**. (b) The $[Mn_{11}^{III}Mn_6^{II}(\mu_4\text{-}O)_8(\mu_3\text{-}N_3)_4]^{25+}$ octahedral core of **1** and **2**. Color code: Mn^{III}, blue; Mn^{II}, purple; O, red; N, green; C, grey. Hydrogen atoms have been omitted for clarity. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

In summary, the use of N_3^- ligands in Mn-propanediol chemistry has resulted in the isolation of two new one-dimensional coordination polymers based on a Mn_{17} repeating unit. Each Mn_{17} unit has an aesthetically-pleasing structure, in which the manganese ions have an octahedral topology. Furthermore, the repeating unit seems to have a giant ground spin state, but the connection of the clusters through the μ-1,3-N_3^- bridges results in antiferromagnetic intermolecular interactions between the neighboring Mn_{17} units and thus each polymer has an effective $S = 0$ spin ground state. The high-spin ground state for each Mn_{17} cluster is consistent with the presence of μ_3-1,1,1-N_3^- ligands, which are known to mediate ferromagnetic interactions [7]. Substitution of the μ-1,3-N_3^- ions with terminal ligands could lead to magnetically discrete Mn_{17} aggregates with interesting magnetic properties, instead of the present one-dimensional polymers, and such studies are in progress. Finally, the existence of a number of labile terminal ligands

[2] Crystallographic data for $(\mathbf{1}\cdot 2H_2O\cdot 2MeCN)_\infty$: $C_{72}H_{112}N_{23}O_{38}Mn_{17}$, M_r = 2841.80 g mol^{-1}, triclinic, space group $P\bar{1}$, a = 14.051(2) Å, b = 14.700(2) Å, c = 15.200(2) Å, α = 81.60(1)°, β = 66.66(2)°, γ = 78.31(1)°, V = 2815.2(6) $Å^3$, T = 100(2) K, Z = 1, ρ_{calc} = 1.676 g cm^{-3}, 43934 reflections collected, 12176 unique (R_{int} = 0.0424), R_1 = 0.0379, wR_2 = 0.0938, using 6131 reflections with $I > 2\sigma(I)$.

2.3.2. ESI-MS

For this work an "LCQ" mass spectrometer from Thermo-Finnigan GmbH, Bremen, Germany was used.

2.3.3. Mössbauer spectroscopy

The Mössbauer spectra were recorded using constant acceleration Mössbauer spectrometers from WissEl Electronics Starnberg (Germany) (295 and 78 K) and from the Institute for Analytical Instrumentation St. Petersburg (Russia) (CM-2201, for 295 K). The used Mössbauer source of ^{57}Co in chromium matrix had an average activity of about 0.4 GBq. The ^{119m}Sn source in $CaSnO_3$ matrix had an average activity of 0.35 GBq. Proportional counters (LND Inc., Ocean Side, New York, USA) were used with a voltage between 1800 and 1950 V to detect the spectra. The sample of 33.5 mg was placed into a sealable cylindrical polyethylene sample compartment with an inner diameter of 19 mm. The ^{57}Fe Mössbauer spectra were recorded with a maximum velocity of ±3.20 mm/s (T = 295 K) and ±3.6 mm/s (T = 78 K) because no magnetic splitting could be observed. In the case of the ^{119m}Sn the Mössbauer spectra were recorded with a maximum velocity of ±7.95 mm/s (T = 295 K) and ±6.15 mm/s (T = 78 K). All ^{57}Fe spectra were referred to a standard α-Fe foil (Goodfellow). The ^{119m}Sn spectra were referred to SnO_2 and a Sn foil.

3. Results and discussion

The structure of the $[(LFe^{III}–NC)_4Sn^{IV}]$ complex is shown in Fig. 2. This was confirmed by observation of the molecular peak (M^+) in the ESI-MS. The MM+ force field structure of the $[(LFe^{III}–NC)_4Sn^{IV}]Cl_4$ cluster is shown as POV-ray in Fig. 3. The complex is characterized by IR-spectroscopy. On bridging the typical CN-bond stretching vibration switched from 2080 cm^{-1} to higher wave numbers which are above 2100 cm^{-1}.

Figs. 4 and 5 show the ^{119m}Sn and ^{57}Fe Mössbauer spectra for the compound $[(LFe^{III}–NC)_4Sn^{IV}]$. The spectra show that the oxidation state of tin is +4 at room temperature. On cooling to 78 K beside the tin(IV) an additional minor doublet is present which is characteristic for tin(II). This indicates a valence tautomeric switching in the molecule at the tin-core. For iron(III) the situation is quite different. At 295 and 78 K two doublets are present indicative for iron(III) in the low-spin and high-spin state. On cooling the molar ratio shifts from the dominant high-spin state at room temperature towards the low-spin state at 78 K. This indicates, that some iron(III)-molecules can reversibly be converted between high-spin and low-spin state. This proves that $[(LFe^{III}–NC)_4Sn^{IV}]$ is a multistable, i.e. multiple spin transition, and valence delocalised system on the Sn side.

The compound $[(LFe^{III}–NCS)_4Sn^{IV}]$ is an example for a non-switching molecule. This complex has the same topology as the $[(LFe^{III}–NC)_4Sn^{IV}]$ complex. Just the bridging units change from cyanide to thiocyanate. This complex was prepared like its analogous described above and get measured at the same way. IR-spectroscopy shows that on bridging the typical SCN-bond stretching vibration switched from 2050 cm^{-1} to higher wave numbers which are above 2060 cm^{-1}.

Figs. 6 and 7 show the ^{119m}Sn and ^{57}Fe Mössbauer spectra for the compound $[(LFe^{III}–NCS)_4Sn^{IV}]$. The spectra show that the oxidation state of tin is +4 at room temperature and 78 K. In the iron Mössbauer spectra a doublet is observed. This is characteristic for iron(III) in the high-spin state at 295 and 78 K (Tables 1 and 2). This proves that $[(LFe^{III}–NCS)_4Sn^{IV}]$ shows no indication of molecular switching neither spin transition nor valence tautomerism.

4. Conclusion

The ^{57}Fe-Mössbauer data indicate that the $[(LFe^{III}–NC)_4Sn^{IV}]$ show multiple spin transition between iron(III) in the high-spin and low-spin state. The ^{119m}Sn-Mössbauer data indicate a valence tautomerism between Sn(IV) at room temperature and a partial

conversion to Sn(II) at 78 K. Changing the bridging unit from CN to NCS the [(LFe^{III}–NCS)$_4$Sn^{IV}] is in the Fe(III)-high-spin state and Sn(IV) between 295 and 78 K.

The results show that the compound [(LFe^{III}–NC)$_4$Sn^{IV}] is a switching molecular complex. We suggest that the electrons move between tin and iron, Sn(II) becomes Sn(IV) and two Fe(III) become Fe(II). An effect of 11.1% of switching tin causes 5.55% of Fe(II). Unfortunately this Fe(II)-signal is buried under the huge Fe(III)-absorption in the Mössbauer spectra. Further studies are in progress. Modification of the bridging unit from cyanide to thiocyanate turns the switchability off. This proves the usage of main group elements such as tin as central atoms in switching molecules.

allowed to stir for an additional 15 min while a milky suspension developed. After cooling the solution at 0 °C (ice bath), K_2(mto) was isolated by suction filtration and washed several times with ether.

*2.1.2. Preparation of (n-C_4H_9)$_4$N[$Fe^{II}Fe^{III}$(mto)$_3$] (**1**)*

In the formation process of **1**, according to HSAB principle (Hard and Soft Acids and Bases principle), the flipping of mto by 180° would take place here and there, which induces a linkage-isomerization from –Fe^{III}–SOC_2O_2–Fe^{II}– to –Fe^{III}–O_2C_2OS–Fe^{II}– [10]. In order to restrain the linkage-isomerization, **1** was synthesized at −20 °C. A methanol solution of iron(III) nitrate (0.14 g, 0.35 mmol) was added to a methanol solution of K_2(mto) (0.19 g, 1.05 mmol). After stirring for 5 min, $[Fe^{III}(mto)_3]^{3-}$ solution was given. This solution was filtered once to remove solid impurities. The filtrate was cooled at −20 °C, and was added a methanol solution (20 ml) of iron(II) chloride (68.9 mg, 0.35 mmol), (n-C_4H_9)$_4$NBr(112.8 mg, 0.35 mmol) and ascorbic acid (17.6 mg, 0.1 mmol). The mixture was stirred for 3 h. The dark-brown product was collected by suction filtration and dried in vacuo. Elemental *Anal.* Calc. for $C_{22}H_{36}NO_9S_3Fe_2$: C, 39.65; H, 5.45; N, 2.1. *2.1.3. Preparation of (n-C_4H_9)$_4$N[$^{57}Fe^{II}Fe^{III}$(mto)$_3$] (**2**)*

(n-C_4H_9)$_4$N[$^{57}Fe^{II}Fe^{III}$(mto)$_3$] was prepared in a similar way to Section 2.1.2. In this process, $^{57}FeCl_2 \cdot 4H_2O$ used as Fe^{II} source was prepared by dropping hydrochloric acid to powdered ^{57}Fe under N_2. Elemental *Anal.* Calc. for $C_{22}H_{36}NO_9S_3Fe_2$: C, 39.65; H, 5.45; N, 2.1. Found: C, 39.49; H, 5.65; N, 2.03%.

*2.1.4. Preparation of (n-C_4H_9)$_4$N[$Fe^{II}{}^{57}Fe^{III}$(mto)$_3$] (**3**)*

(n-C_4H_9)$_4$N[$Fe^{II}{}^{57}Fe^{III}$(mto)$_3$] was prepared in a similar way to Section 2.1.2. In this process, $^{57}Fe(NO_3)_3 \cdot 9H_2O$ used as Fe^{III} source was prepared by dropping nitric acid to powdered ^{57}Fe under N_2. Elemental *Anal.* Calc. for $C_{22}H_{36}NO_9S_3Fe_2$: C, 39.65; H, 5.45; N, 2.1. Found: C, 38.71; H, 5.51; N, 2.11%.

2.2. Measurements

The static magnetic susceptibility was measured by a Quantum Design, MPMS5 SQUID susceptometer under 5000 Oe between 2 and 300 K. The zero field cooled magnetization (ZFCM) and field cooled magnetization (FCM) were also measured for investigating the ferrimagnetic phase in the temperature range of 2–45 K under 30 Oe. The remnant magnetization (RM) was measured in the same temperature region under zero field. A sample was wrapped in polyethylene film and mounted inside the straw. The magnetic susceptibility obtained was corrected for the background and the core diamagnetism estimated from Pascal's constants.

The ^{57}Fe Mössbauer spectra were measured for **2** and **3**. The spectra were calibrated by using the six lines of a body-centered cubic iron foil (α-Fe), the center of which was taken as zero isomer shift. The ^{57}Fe Mössbauer spectra at low temperature were performed with a closed-cycle helium refrigerator cryostat (Iwatani Co., Ltd.).

The dielectric constant measurements were carried out between 4.2 and 300 K by an Agilent, 4284A LCR Meter with alternating electric fields of 1, 10 and 100 kHz. Polar plates were formed by carbon pastes and gold wires were fixed on the both faces of the pellet sample.

3. Results and discussion

Fig. 1 shows the molar magnetic susceptibility as a function of temperature, $\chi_M T$, for **1**. The effective magnetic moment, μ_{eff},

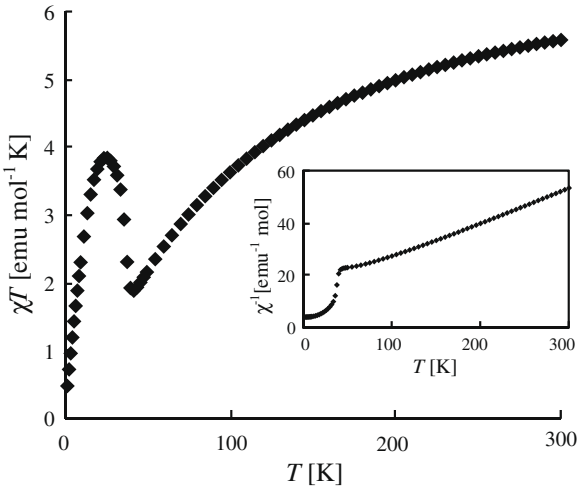

Fig. 1. Temperature dependence of the effective magnetic moment for **1**. Inset is temperature dependence of the inverse magnetic susceptibility for **1**.

decreases with decreasing temperature down to the minimum of 1.87 μ_B at 42 K, and it increases abruptly up to the maximum of 3.85 μ_B at 26 K, then decreases again. This behavior is typical of ferrimagnetism. The effective moment at room temperature is 5.60 μ_B. The spin-only magnetic moment is 7.68 μ_B for the combination of Fe^{III} ($S = 5/2$) and Fe^{II} ($S = 2$). On the other hand, that is 5.19 μ_B for the combination of Fe^{III} ($S = 1/2$) and Fe^{II} ($S = 2$). Therefore, the effective magnetic moment of **1** is situated in the middle value between the magnetic moment for the high-spin and the low-spin states of Fe^{III}. This implies the possibility that the spin state of Fe^{III} is the spin equilibrium of the high-spin ($S = 5/2$) and the low-spin ($S = 1/2$) states. The inverse magnetic susceptibility as a function of temperature is shown in the inset of Fig. 1. From the fitting of inverse magnetic susceptibility with the Curie–Weiss low, $\chi = C/(T-\theta)$, Weiss temperature, θ, is estimated at −93 K. In order to confirm the ferrimagnetic phase-transition, FCM, ZFCM and RM were investigated. This result is shown in Fig. 2. From the analysis of magnetization curves, the ferrimagnetic transition temperature is estimated at 38 K. The magnetic property of **1** is similar to that of (n-C_4H_9)$_4$N[$Fe^{II}Fe^{III}$(ox)$_3$] which shows the ferrimagnetic phase-transition at T_N = 43 K [11].

Fig. 3 shows the ^{57}Fe Mössbauer spectra of **2** and **3** at 200 and 77 K, respectively. The Mössbauer parameters are summarized in Table 1. In both of the ^{57}Fe Mössbauer spectra of **2** and **3**, the spectra clearly indicates the presence of two quadrupole doublets,

Table 1
^{57}Fe Mössbauer parameters for **2** and **3**. δ: Isomer shift, ΔE_Q: quadrupole splitting, Γ: line width.

	T (K)	δ (mms^{-1})	ΔE_Q (mms^{-1})	Γ (mms^{-1})	Area (%)
$(n\text{-}C_4H_9)_4N[^{57}Fe^{II}Fe^{III}(mto)_3]$					
Fe^{II} ($S = 2$)	200	0.84	2.34	0.75	38.4
	77	0.92	2.55	0.80	47.6
Fe^{III} ($S = 5/2$)	200	0.22	0.50	0.54	61.6
	77	0.24	0.51	0.48	52.4
$(n\text{-}C_4H_9)_4N[Fe^{II}{}^{57}Fe^{III}(mto)_3]$					
Fe^{II} ($S = 2$)	200	1.30	1.93	0.70	42.0
	77	1.43	2.16	0.77	50.8
Fe^{III} ($S = 5/2$, 1/2)	200	0.35	0.71	0.70	58.0
	77	0.37	0.73	0.70	49.2

which are assigned to Fe^{II} ($S = 2$) and Fe^{III} ($S = 5/2$). The spectra of ^{57}Fe coordinated by O_6 is observed in **2**, while that coordinated by S_3O_3 is observed in **3**. The value of the quadrupole splitting (ΔE_Q) of the Fe^{III} coordinated by S_3O_3 is larger than the Fe^{III} coordinated by O_6. Therefore, this implies that the Fe^{III} coordinated by S_3O_3 is in the highly distorted octahedral environment. Although only one of the two Fe sites was enriched with ^{57}Fe isotope in preparation, the observed spectra show a considerable amount of the other Fe site. This result suggests that the charge transfer occurs between Fe^{II} and Fe^{III}. If the time scale of the charge transfer between Fe^{II} and Fe^{III} is slower than the time window of the ^{57}Fe Mössbauer spectra (10^{-7} s), the charge transfer seems to be static in the ^{57}Fe Mössbauer spectra.

The dielectric constant measurements were carried out to investigate the dynamics of the charge transfer between Fe^{II} and Fe^{III}. Fig. 4 shows the results of the dielectric constant measurements. As shown in Fig. 4, an anomalous enhancement in the real and imaginary parts of the dielectric constant appears above T_N. The anomalous enhancement depends on the frequency of the alternating electric fields. In the imaginary part of the dielectric constant, the peak position of the anomalous enhancement shifts to the higher temperature side with increasing the frequency of alternating electric field. In the dielectric measurements of $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$, the anomalous enhancement attributed to the charge transfer phase transition are observed at 120 K with thermal hysteresis and it is independent on the frequency of alternating electric fields [12]. As mentioned above, it should be considered that the anomalous enhancement in the dielectric constant of **1** corresponds to the valence fluctuation between Fe^{II} and Fe^{III} whose time scale depends on temperature. From the analysis of the ^{57}Fe Mössbauer spectra and the dielectric constant, the time scale of the charge transfer between Fe^{II} and Fe^{III} is slower than 10^{-7} s.

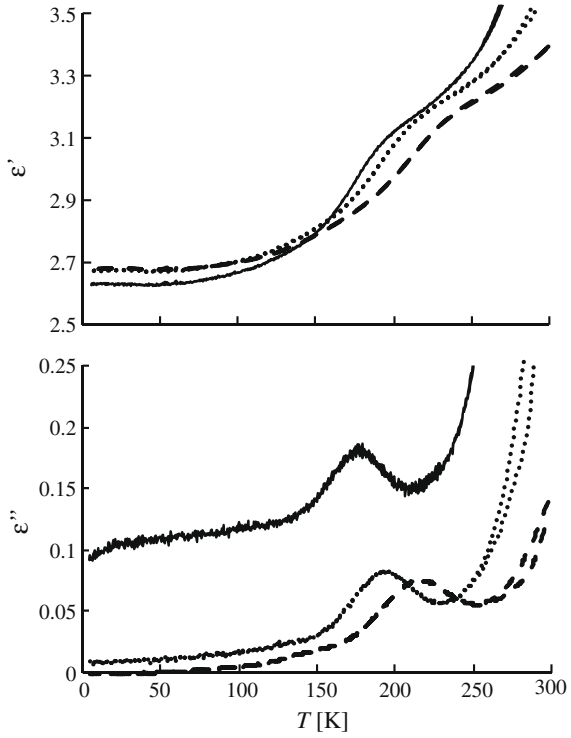

Fig. 4. Temperature dependence of the dielectric constants for **1**. Solid lines: 1 kHz, dotted lines: 10 kHz, dashed lines: 100 kHz.

From the fact that the anomalous enhancement in the dielectric constant of $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ appears only at the charge transfer phase transition, while that of **1** appears in a wide temperature range, it should be considered that the charge transfer of **1** is the valence fluctuation without phase transition.

4. Conclusion

$(n\text{-}C_4H_9)_4N[Fe^{II}Fe^{III}(mto)_3]$ behaves as a ferrimagnet with $T_N = 38$ K and $\theta = -93$ K. The effective magnetic moment of **1** at room temperature is the middle value between those of Fe^{III} ($S = 5/2$)–Fe^{II} ($S = 2$) and Fe^{III} ($S = 1/2$)–Fe^{II} ($S = 2$), which implies the possibility of the spin equilibrium between $S = 5/2$ and $S = 1/2$ in the $Fe^{III}O_3S_3$ site. In fact, the EPR signal of **1** suggests the coexistence of the Fe^{III} ($S = 5/2$) and Fe^{III} ($S = 1/2$) states in a wide temperature range [6]. In connection with this, the following should be mentioned. In the case of tris(monothio carbamato)iron(III) complexes, the effective magnetic moments at room temperature are the middle value between those of Fe^{III} ($S = 5/2$) and Fe^{III} ($S = 1/2$), and the ^{57}Fe Mössbauer spectra corresponding to the $Fe^{III}O_3S_3$ sites have only one doublet, reflecting the rapid spin equilibrium between $S = 5/2$ and $S = 1/2$ [7].

From the analysis of ^{57}Fe Mössbauer spectra for ^{57}Fe enriched complexes, **2** and **3**, the charge transfer between Fe^{II} and Fe^{III} exists in the paramagnetic phase. The dielectric constant measurements were performed to confirm the valence fluctuation between Fe^{II} and Fe^{III}. The anomalous enhancement in the dielectric constant, which depends on the frequency of alternating electric field, was found between 170 and 250 K. This anomalous enhancement in the dielectric constant is presumably attributed to the valence fluctuation between Fe^{II} and Fe^{III}. In order to investigate the detailed dynamics of the valence fluctuation between Fe^{II} and Fe^{III}, the dielectric constant measurement in more wide frequency range is indispensable and in progress.

previous paper [4], except for using appropriate amount of $ZnCl_2$ in place of $FeCl_2 \cdot 4H_2O$. Diluted complexes were characterized by chemical analysis. The Fe^{II}/Zn^{II} ratios of all the complexes were determined by a JEOL EX-23000BU energy-dispersive X-ray spectroscopy (EDS) with a JEOL JSM-6700F field emission scanning electron microscopy (SEM). We obtained five compositions, that is, $x = 0.00$, 0.26, 0.48, 0.96 and 1.00 in $(n\text{-}C_3H_7)_4N[Fe^{II}_{1-x}Zn^{II}_xFe^{III}(dto)_3]$, using atomic ratio of $ZnCl_2$ is equal to 0.00, 0.05, 0.10, 0.53 and 1.00 in the starting solutions, respectively. Hereafter, x denotes the complex with each concentration of Zn atom in $(n\text{-}C_3H_7)_4N[Fe^{II}_{1-x}Zn^{II}_xFe^{III}\text{-}(dto)_3]$. The powder X-ray diffraction patterns for all the samples were measured with Rigaku multiflex diffractometer with Cu Kα radiation at room temperature. The temperature dependence of the zero-field cooled magnetization (ZFC) and the field cooled magnetization (FC) were measured in the temperature range between 2 and 30 K under external field of 30 Oe for all the complexes using a Quantum-Design MPMS-5 SQUID susceptometer. The remnant magnetization (RM) was also measured under 0 Oe. The temperature dependence of the magnetic susceptibility for them was also measured in the temperature range between 2 and 300 K under field of 5000 Oe by same apparatus. For ^{57}Fe Mössbauer spectroscopic measurement, ^{57}Co in Rh was used as a Mössbauer source. The spectra were calibrated by using the six lines of a body-centered cubic iron foil (α-Fe), the center of which was taken as zero isomer shift.

3. Results and discussions

Fig. 1 shows the powder X-ray diffraction patterns of $x = 0.00$, 0.26, 0.48, 0.96 and 1.00. The complex with $x = 0.00$, whose composition is equal to that of $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$, shows the same diffraction pattern with previous report [10]. Moreover, the others show similar diffraction pattern with $x = 0.00$, although their peaks become broad due to the highly disordered structure by substitution between Fe^{II} and Zn^{II}. This result means that $(n\text{-}C_3H_7)_4N[Fe^{II}_{1-x}Zn^{II}_xFe^{III}(dto)_3]$ are forming isomorphous structure in the whole range of zinc concentrations. Therefore, the two-dimensional honeycomb network structure with an alternating array of M^{II} (M = Fe or Zn) and Fe^{III} atoms through dto bridges is kept by the substitution of metal atoms.

Fig. 2a indicates the $\chi T - T$ plots for all the complexes. High temperature tails of these plots decrease with increasing of zinc ratio. Moreover, the magnetic interaction changes from the ferromagnetic interaction to the antiferromagnetic one between $x = 0.48$ and 0.96. These concentration dependencies are quantitatively analyzed by fitting of the temperature dependence of the magnetic susceptibility with the Curie–Weiss low, $\chi = C/(T - \theta)$, where C and θ denote the Curie constant and the Weiss temperature, respectively. The spin moment, s, is calculated from the Curie constant. As shown in Fig. 3, the concentration of spin is proportional to the Fe^{II}/Zn^{II} ratio. The spin moment is consistent with the sum of $Fe^{III}(S = 1/2)$ site and the concentration of $Fe^{II}(S = 2)$. On the other hand, as shown in Fig. 3, the Weiss temperature decreases and changes from ferromagnetic interaction to antiferromagnetic one between $x = 0.48$ and 0.96. This threshold-type change is typical behavior for low dimensional magnet. In Fig. 2b, the thermal hysteresis in the magnetic susceptibility for $x = 0.26$ disappears, unlike $x = 0.00$ in the inset of Fig. 2b. This fact shows that the substitution from Fe^{II} to Zn^{II} prevent the cooperative effect on the CTPT. Judging from Fig. 4, the Curie temperature shifts from $T_C = 7$ to 10 K with substitution from $x = 0.00$ to 0.26. Then, it becomes $T_C = 6$ K for $x = 0.48$. Moreover, the ferromagnetic transition almost disappears above $x = 0.96$. In general, a ferromagnetic transition temperature monotonically decreases with increasing the diluted ratio. However, in this system, the Curie

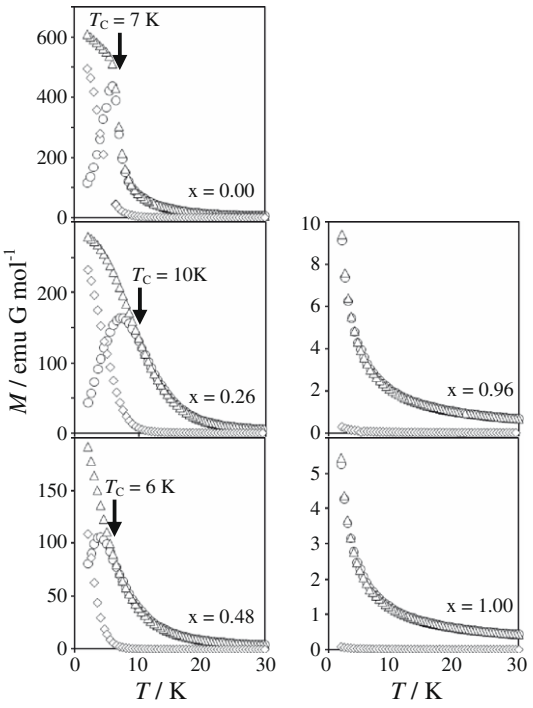

Fig. 4. ZFC (○), FC (△) and RM (◇) for x = 0.00, 0.26, 0.48, 0.96 and 1.00. Arrows show the ferromagnetic transition temperature.

temperature is once enhanced between x = 0.00 and 0.26, and then, it decreases with increasing x (see Fig. 5). This behavior can be explained as follows. For $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$, which is the same complex as x = 0.00, the ferromagnetic state is in the LTP with transition temperature of 7 K, while $(n\text{-}C_5H_{11})_4N[Fe^{II}Fe^{III}(dto)_3]$ shows T_C = 19.5 K with the HTP state in the ordering phase [4]. Therefore, HTP states are expected to give comparatively high transition temperature. It is noteworthy that x = 0.00 shows the two step ferromagnetic phase transition for a single crystal measurement with the LTP and the HTP. One transition temperature is 7 K in the LTP, while the other is 15 K in the HTP [3]. Judging from these facts, the Curie temperature monotonically decreases in the only HTP states. This anomalous enhancement of T_C between x = 0.00 and 0.26 is due to the conversion from the ferromagnetic transition in the LTP to that in the HTP.

To confirm the disappearance of the CTPT between x = 0.00 and 0.26 and the explanation for the shift of the Curie temperature, ^{57}Fe Mössbauer spectroscopy was carried out. Fig. 6 shows the ^{57}Fe Mössbauer spectra at 200 and 10 K for all the complexes. The magnetic state of x = 0.00 clearly changes from HTP to LTP, which is shown in Fig. 6a [4]. On the other hand, in Fig. 6d, x = 1.00 only indicates the Fe^{III}(S = 1/2) signal at 200 and 10 K. Its isomer shift, δ, and

quadrupole splitting, ΔE_Q, are listed in Table 1. x = 0.96 complex shows almost the same spectra with x = 0.00 at 200 and 10 K (Fig. 6c and Table 1). For x = 0.96, small amount of Fe^{II}(S = 2) signal is too small to find in the Mössbauer spectra due to the low S/N ratio

caused by the γ-ray absorption by Zn atoms. These Mössbauer parameters are quite similar to that for the $Fe^{III}(S = 1/2)$ in HTP of $x = 0.00$ except for ΔE_Q in low temperature. This increasing of ΔE_Q is due to the distortion caused by the substitution of M^{II} site to smaller Zn ion. As shown in Fig. 6b and c, x = 0.26 and 0.48 gives a corresponding spectra with HTP of $x = 0.00$ at 200 and 10 K except for Fe^{III}/Fe^{II} ratio. Mössbauer parameters for them are also listed in Table 1. These values are also similar to the value for HTP of $x = 0.00$. The ordering component of $Fe^{II}(S = 2)$ is not clear in Fig. 6b, because the measuring temperature is very close to T_C. Although it is hard to separate between the ordering component of $Fe^{II}(S = 2)$ and the other iron components in $x = 0.26$ and 0.48, HTP remains in low temperature region. The disappearance of the CTPT above $x = 0.26$ is consistent with the result of magnetic susceptibility measurements.

4. Conclusion

Magnetic dilution effect of $(n\text{-}C_3H_7)_4N[Fe^{II}_{1-x}Zn^{II}_xFe^{III}(dto)_3]$ is investigated. The structure of this compound is isostructural in whole x range. The magnetic susceptibility measurements and the ^{57}Fe Mössbauer spectra show that the CTPT in $(n\text{-}C_3H_7)_4N[Fe^{II}Fe^{III}(dto)_3]$ disappears by Fe^{II} substitution of 26%. To investigate the expected value of critical concentration for the ferromagnetic transition temperature, we have to prepare middle concentration complex and measure the detailed concentration dependence of magnetic properties in further experiment.

of the Fe_4 butterfly core. This binding mode has been observed for the $[Fe_6(Bic)_6]$ wheel [12]. The hydroxide ligand (O1) also bridges Fe1 to a body iron(III) center (Fe1–O1–Fe3). Four of the eight pivalate ligands span the butterfly body-wing vectors in the typical 1,3-bridging mode. In addition, two are capping Fe2 and Fe2a in the 1,1′ mode and the remaining two are monodentate bound to Fe1 and Fe1a and hydrogen-bonding to the two hydroxide groups (O1 and O1a). All Fe(III) centers are six-coordinate although the 1,1′ bridging pivalate results in a rather distorted geometry at Fe2 (and s.e.). The $Et_2NH_2^+$ cations are located above and below the Fe6 cluster, hydrogen-bonded to the bicine carboxylates (O11 and O11a) and the 1,1-bridging carboxylates (O24a and O24).[3] We note that in this Fe_6 cluster, one Fe_4 butterfly unit is capped by two {Fe(Bic)} units. It is interesting to compare this Fe_6 cluster to our Fe_{10} clusters with bis–tris [7] where two Fe_4 butterfly units are bridged together by two {Fe(bis–tris)} units. Hence, we can show that clusters of different nuclearity and topology can be prepared by

[3] One of the crystallographically independent $Et_2NH_2^+$ cations is disordered over two positions.

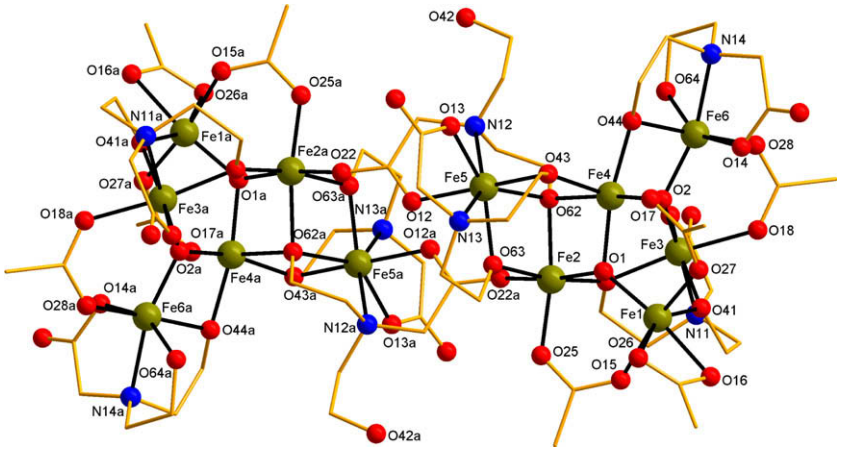

Fig. 3. Structure of **2** (ball and stick representation with Fe(III) gold; O, red; N, blue; C, brown; H atoms and Me groups of pivalate ligands omitted for clarity) [atom suffix a signifies the symmetry equivalent atom: $a = 0.5 - x, 2.5 - y, -z$]. Fig. 4. Core structure of **2**.

adjusting carefully the nature of the polydentate ligand, to build upon the Fe_4 butterfly unit.

For **1** the value of χT at 300 K is 9.87 $cm^3\ mol^{-1}$ K, significantly lower than for six uncoupled Fe(III) ions (26.25 $cm^3\ mol^{-1}$ K for $g = 2$), indicating strong antiferromagnetic interactions between the Fe(III) centers (see Fig. 2). The value of χT increases steadily to a maximum of 15.0 $cm^3\ mol^{-1}$ K at 14.0 K, then drops sharply to 13.6 $cm^3\ mol^{-1}$ K at 1.8 K. This drop can be attributed to either zero-field splitting or intermolecular antiferromagnetic interactions. The magnetisation was measured as a function of applied field at 2 K, rising to a maximum value of $M/N\beta = 10.0$ at 7 T. Both the low temperature maximum in χT and the magnetisation data are consistent with a spin ground state of $S = 5$ for **1**. However, further measurements including EPR are required to determine the magnitude and size of any anisotropy. Further Fe_6 clusters have been reported recently, with broadly similar topologies and $S = 5$ ground states [19].

The change of base from Et_2NH to NaOMe produces a dodeca-nuclear complex $[Fe_{12}O_4(Bic)_4(HBic)_4(O_2CCMe_3)_8] \cdot 5MeCN$ (**2** · 5MeCN), in 12% yield, which crystallizes in the monoclinic space group C2/c (Fig. 3).[4] Compound **2** can be described as a dimer of Fe_6 units, which have a different topology to the Fe_6 cluster found in **1**. The two Fe_6 units are separated by 6 Å, bridged by the carboxylate arms from the bicine ligands (Fig. 4). Unlike **1**, compound **2** is not composed of Fe_4 butterfly units: for **2**, more bicine is incorporated into the structure. The structure of each Fe_6 unit is unusual and is formed from two corner-sharing Fe_3O triangles (Fe3, Fe6, Fe4 and Fe1, Fe2, Fe4). In addition, Fe5 bridges to Fe2 and Fe4 through three $CH_2CH_2O^-$ arms (O62, O43, O63) from two bicine ligands, such that Fe2, Fe4 and Fe5 form an incomplete $\{Fe_3O_4\}$ cubane.

The triply deprotonated bicine ligands (with N11 bound to Fe3 or N13 bound to Fe5) bind in the same $\eta^2{:}\eta^2{:}\eta^1{:}\eta^1{:}\mu_3$ mode as that found in **1**. One of the doubly deprotonated ligands (with N14 bound to Fe6) caps Fe6, with one $CH_2CH_2O^-$ arm bridging Fe6 to Fe4 and the second CH_2CH_2OH arm protonated (O64). The remaining Hbic ligand (with N12 bound to Fe5) displays a new binding mode, bridging the two halves of the cluster through the carboxylate arm. The deprotonated $CH_2CH_2O^-$ arm (O62) is μ_3-bridging (Fe2, Fe4, Fe5) with the second CH_2CH_2OH arm protonated and unbound (O42). Fig. 5 illustrates the different binging modes of bicine present in compounds **1** and **2**. Six of the pivalate ligands are 1,3-bridging with the remaining two 1,1′-bridging (to Fe1, Fe1a) as found in **1**. All Fe centers are six-coordinate except Fe5 (and s.e.),

CCDC 707009.

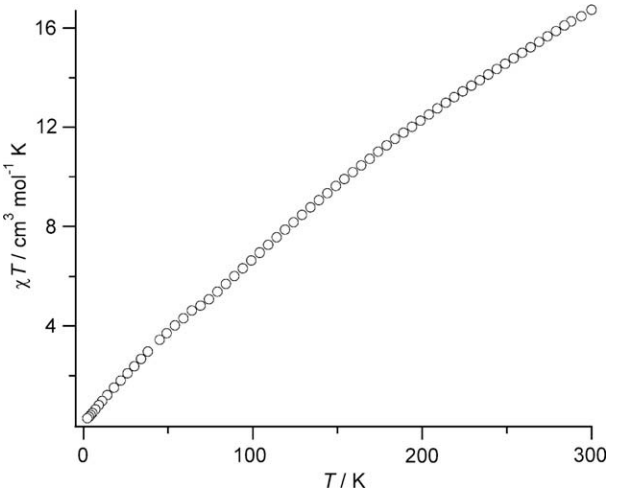

Fig. 6. Temperature dependence of χT for **2** from 300 to 1.8 K measured in a field of 1 kOe.

which are 7-coordinate showing a pentagonal bipyramidal geometry.

The value of χT for **2** at 300 K is 16.7 $cm^3\ mol^{-1}$ K, significantly lower than the expected value for 12 uncoupled Fe(III) ions (52.5 $cm^3\ mol^{-1}$ K for $g = 2$), indicating strong antiferromagnetic interactions between the Fe(III) centers (Fig. 6). The value of χT decreases steadily reaching a value of 0.09 $cm^3\ mol^{-1}$ K at 1.8 K consistent with an $S = 0$ ground state.

In conclusion, we have reported two new Fe(III) complexes that incorporate the bicine ligand together with pivalate ligands. We have shown the versatility of the ligand, which can exist in different binding modes and can act as a bridging unit within the structure. The nature of the base used in the reaction has an effect on the cluster produced and this warrants further investigation. Magnetic characterisation reveals $S = 5$ and $S = 0$ ground states for the hexa- and dodeca-nuclear complexes, respectively.

2.3. Susceptibility measurements

DC and AC magnetic susceptibility data were obtained on a Quantum Design MPMS-XL7 SQUID magnetometer. DC data were recorded from 1.8 K up to room temperature in a 0.1 T magnetic field, and the magnetic data were corrected for the diamagnetic contribution calculated from Pascal's constants. AC data were obtained for 1.8 K $\leqslant T \leqslant$ 4.2 K in an AC field of 5 Oe. Powder samples were wrapped in teflon tape. For measurements in frozen solution powder was dissolved in toluene, filled into gel capsules and sealed with cyanacrylate. Directly after preparation the solution was inserted into the magnetometer and thermally quenched to 4.2 K. For **2** a concentration of 0.5 mg/ml was used, whereas for **1** 5 mg/ml was chosen to obtain a better signal-to-noise ratio.

3. Results and discussion

3.1. Structure

The structures of **1** and **2** are analogous and can be described as centered Fe^{III} triangles consisting of a central Fe^{III} ion connected to three peripheral Fe^{III} ions through two fully deprotonated tripod^{3-} ligands that occupy the apical positions of the Fe_4 skeleton (Fig. 1). The tripod^{3-} ligands thus bridge in an η^2, η^2, η^2, μ^4-fashion. Six chelating acac$^-$ ligands complete the coordination sphere of the peripheral Fe ions. All metals are in distorted octahedral geometries with [FeO_6] coordination spheres. The molecules have principal C_3 symmetry axes perpendicular to the Fe_4 planes; with the peripheral Fe^{III} ions having a 2-fold axis perpendicular to the principal axis.

3.2. DC susceptibility

Fig. 2 shows the product of magnetic susceptibility and temperature ($\chi_{mol}T$) as a function of temperature. For **1** $\chi_{mol}T$ steadily decreases from 12.0 cm^3 mol^{-1} K at 300 K to a minimum of 10.3 cm^3 mol^{-1} K at 110 K, before strongly increasing to 14.3 cm^3 mol^{-1} K at 14 K, followed by a drop to 6.4 cm^3 mol^{-1} K at 1.8 K. For **2** $\chi_{mol}T$ steadily decreases from 11.1 cm^3 mol^{-1} K at 300 K to a minimum of 9.7 cm^3 mol^{-1} K at 120 K, before strongly increasing to 15.3 cm^3 mol^{-1} K at 16 K, followed by a drop to 6.2 cm^3 mol^{-1} K at 1.8 K. In both cases, the decrease of χT followed by an increase is indicative of antiferromagnetic exchange with a non-zero spin ground state. The susceptibility of **1** was fitted using the Kambe model. This model is applicable when the interacting spins can be divided into two groups where all members of one group have the same exchange interactions with all members of the other group [6]. In this case, group one is the central iron spin, and group two the three peripheral spins. The spin Hamiltonian and corresponding energies are:

$$\mathscr{H} = -2J(\hat{S}_1 + \hat{S}_2 + \hat{S}_3)\cdot\hat{S}_4 = J(\hat{S}_{123} - \hat{S}_T + \hat{S}_4)$$

$$E = J[S_{123}(S_{123}+1) - S_T(S_T+1) + S_4(S_4+1)].$$

For **1** the fit gives $J = -8.2 \pm 0.2$ cm^{-1}, with $g = 1.96 \pm 0.02$. The decrease in χT at the lowest measurement temperatures is due to zero-field splitting and is not reproduced, because it is not taken into account in the Kambe model. The resulting energy spectrum is shown in Fig. 3. The Kambe procedure did not result in an acceptable fit for **2**, presumably due to the presence of more than one exchange interaction.

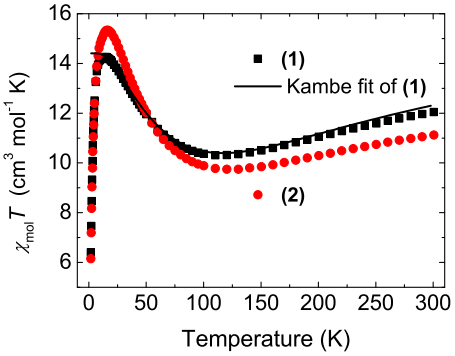

Fig. 2. Plot of measured DC susceptibility and Kambe fit (for 1) $\chi_{mol}T$ versus Temperature of powder samples of **1** and **2**.

3.3. AC susceptibility

AC susceptibility data on a powder of **1** show a slight decrease of χ' at low temperatures going from lower to higher frequencies (Fig. 4). The value of χ' at 1.8 K for 100 Hz is approximately 1.4% higher than at 997 Hz. AC susceptibility measurements on a powder sample of **2** also show a decrease of χ' for high frequencies at low temperatures, which is more pronounced than for **1** (Fig. 5). The value of χ' at 1.8 K for 100 Hz is ~7.7% higher than that seen for 997 Hz. For both **1** (Fig. 4) and **2** (Fig. 5) χ'' increases to low temperatures, but no peak can be observed in the experimental

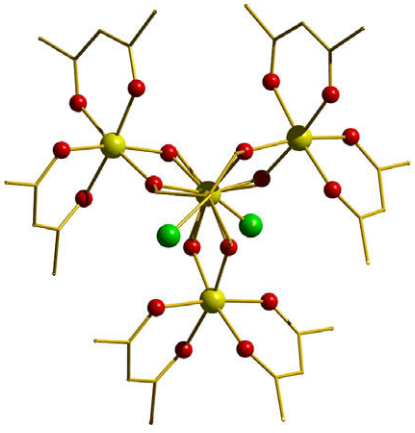

Fig. 1. Molecular structure of **1**. Fe: yellow, Br: green, O: red. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

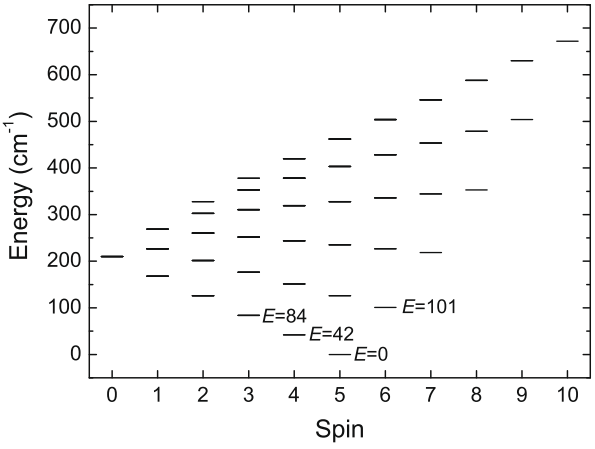

Fig. 3. The energy level spectrum resulting from the Kambe fit of the experimental magnetic susceptibility showing the $S = 5$ ground state for **1**.

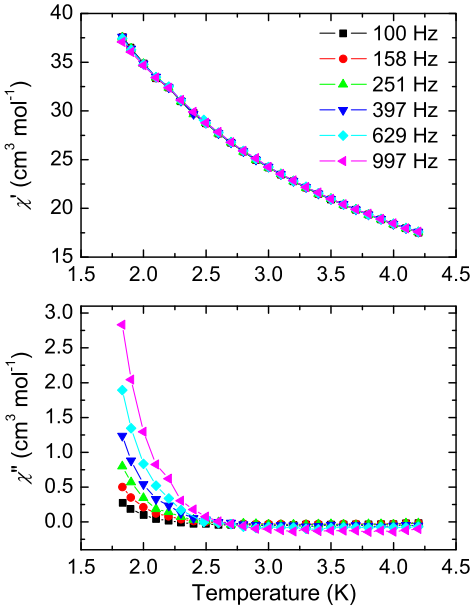

Fig. 4. Plot of the AC susceptibility χ' and χ'' versus T of a powder sample of **1**.

temperature range down to 1.8 K. The out-of-phase component χ'' is frequency dependent. This shows that the magnetization relaxation at these temperatures is slow compared to the timescale of the experiments. Slow magnetization dynamics can be due to SMM behaviour, but can also originate from long-range ordering [7], or spin glass behaviour [8]. The absence of a maximum in χ'' in the investigated temperature range precludes the unequivocal assignment of the origin of the observed slow dynamics.

To shed light on the slow magnetization dynamics, AC susceptibility measurements were performed on samples of **1** and **2** in solution. Both long-range ordering and spin glass behaviour will not be observed in solution, whereas SMM behaviour will most likely be preserved. For **1** in frozen solution, the decrease of χ' at higher frequencies is much more pronounced than in the powder

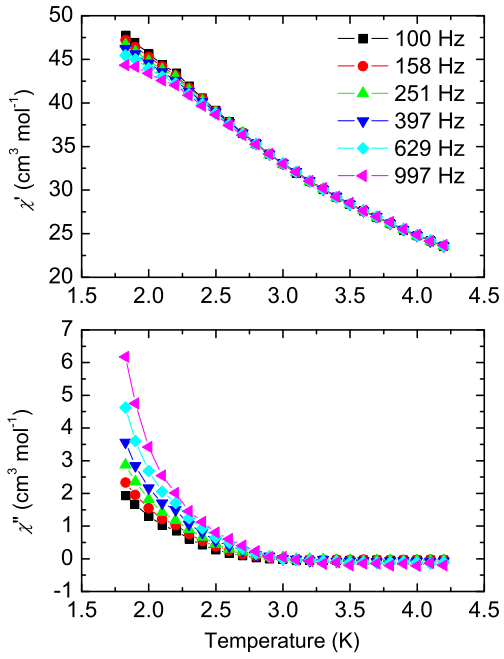

Fig. 5. Plot of the AC susceptibility χ' and χ'' versus T of a powder sample of **2**.

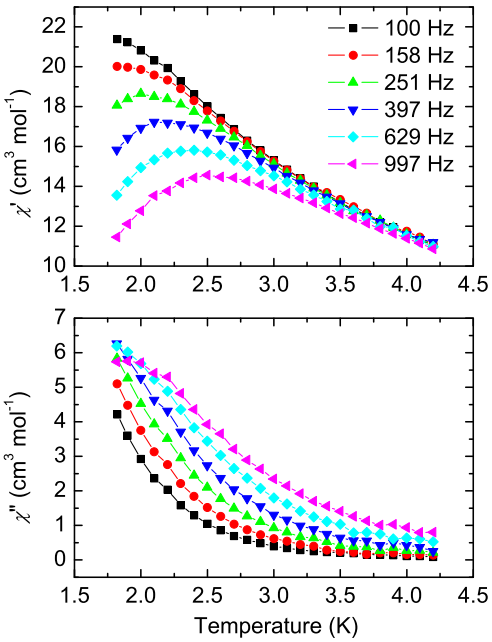

Fig. 6. Plot of the AC susceptibility χ' and χ'' versus T of a 5 mg/ml diluted frozen solution of **1** in toluene.

sample (Fig. 6). Thus, for 251–997 Hz a drop in χ' for low temperatures is observable. The strongly frequency dependent out-of-phase component χ'' is significantly larger in solution and has shifted to higher temperatures.

AC susceptibility measurements on **2** in frozen solution (Fig. 7) show that the frequency dependence of χ' is also much more pronounced than in the powder sample. The values of χ'' are higher than in the powder measurement. The signal-to-noise ratio for this measurement is worse than that for **1**, due to the lower concentration.

The clear observation of an out-of-phase signal in the AC susceptibility in frozen solution shows that both **1** and **2** are SMMs

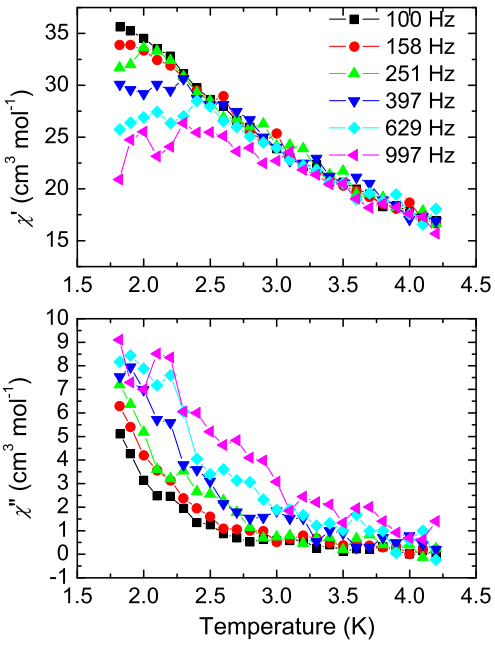

Fig. 7. Plot of the AC susceptibility χ' and χ'' versus T of a 0.5 mg/ml diluted frozen solution of **2** in toluene.

in solution. Interestingly, the shift of the peaks in χ'' to higher temperatures for **1** and **2** in solution compared to the powder sample evidence a higher activation energy of the magnetization of **1** and **2** in solution. This can be either due to an increased negative D value or to the decrease of tunnelling because intermolecular magnetic dipolar interactions have decreased.

4. Conclusion

To our knowledge this is the first study in which an increase of the energy barrier of a SMM in solution compared to the solid state has been observed.

compound $\{CuL_1[Co(NCS)_4]\}$ we used a stereoisomer of the macrocyclic complex $[CuL_1](ClO_4)_2$ and followed the procedure presented in the previous paper [2].

2.2. Magnetic measurements

Magnetic measurements in the temperature range 1.8–300 K were performed using a Quantum Design SQUID-based MPMSXL-5-type magnetometer. The SQUID magnetometer was calibrated with the palladium rod sample (Materials Research Corporation, measured purity 99.9985%). The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T. Measurements were made at a magnetic field of 0.5 T. Corrections are based on subtracting the sample – holder signal and contribution χ_D estimated from the Pascal constants [4].

3. Results

3.1. Structural description

Crystallographic data for the structure of the complex were reported in the paper [2]. The compound creates infinite polymeric *zig-zag* chain in the crystal lattice (Fig. 1), which is assembled from repeating units of the CuL_1 cations and $[Co(NCS)_4]$ complex anions. The Co(II) ions have tetrahedral coordination symmetry and are connected with the Cu(II) ions in the octahedral environment *via* thiocyanate bridges (Fig. 2). Hereafter we abbreviate the system $\{CuL_1[Co(NCS)_4]\}$ as CuCo sample or simply CuCo chain.

As far as the molecular structure of the complex is concerned it crystallizes in the orthorhombic group $P2_12_12_1$. In the presented compound the cobalt atom is adopting a slightly distorted tetrahedral coordination and coordinated to four nitrogen atoms of the thiocyanate groups. The coordination polyhedral of the copper atoms can be described as distorted tetragonal bipyramid with the sulfured atoms in axial positions. The shortest intramolecular M–M distances are 6.4152(9) Å (Cu–Co) and the nearest M–M interchain distances are 6.8609(9) Å (Cu–Co).

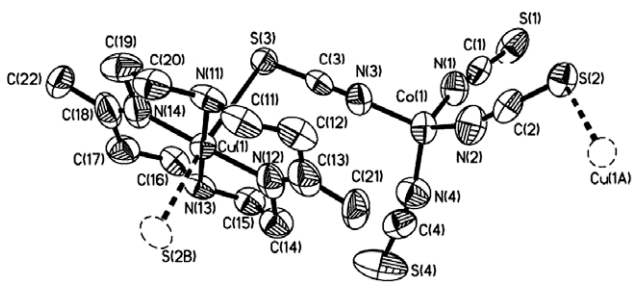

Fig. 2. Molecular structures of the complex $\{(CuL_1)[Co(NCS)_4]\}$ with atom labels.

3.2. Magnetic properties

For our analysis of the magnetic properties of the system $\{CuL_1[Co(NCS)_4]\}$, a quantum Heisenberg model with single-ion anisotropy in the Co(II) sites is applied:

$$H = \sum_{i=1}^{L/2}[J(s^x_{2i-1}S^x_{2i} + s^y_{2i-1}S^y_{2i} + s^z_{2i-1}S^z_{2i}) + [J(S^x_{2i}s^x_{2i+1} + S^y_{2i}s^y_{2i+1} + S^z_{2i}s^z_{2i+1}) + D(S^z_{2i})^2 - \mu_B H^x(g_{Cu}s^x_{2i-1} + g_{Co}S^x_{2i}) - \mu_B H^z(g_{Cu}s^z_{2i-1} + g_{Co}S^z_{2i})] \quad (1)$$

where spins $s = 1/2$ and $S = 3/2$ are located on the odd and even sites and refer to copper(II) and cobalt(II) ions, respectively, and L stands for the length of the chain. In our model the magnetic interactions are isotropic and the Co(II) ions are subject to the single-ion anisotropy. We assume that $g^x = g^y$ for both ions and the thermodynamic properties are isotropic in the xy plane. The Zeeman terms depend on the field directions but it is enough to consider the x and z orientations.

The thermodynamic quantities, as the free energy or magnetization, can be calculated by means of the partition function $Z = \mathrm{Tr}\exp(-H/k_BT)$ and exact diagonalization of the model (1) for a small size L only. In the exponential defining Z, k_B is the Boltzmann constant. To consider macroscopic CuCo chains, the quantum transfer matrix approach (QTM) is referred here [5,6]. Under the Suzuki-Trotter formula the partition function of the quantum chain can be converted into a series of approximants Z_M of the equivalent two-dimensional classical system [5], where M is called the Trotter number. In the limit $M \to \infty$ the partition function Z of the quantum system can be recovered. The computation of Z_M is possible for relatively small values of M so that the reliable estimates of the thermodynamic functions can be achieved by extrapolations only in a certain limited temperature region [5,6]. For M large enough, the linear dependence on $1/M^2$ is expected [5].

In order to overcome this restriction and cover the entire experimental 1.8–300 K temperature range, the density-matrix renormalization group approach (DMRG) [7–9] is applied. The DMRG method is a type of variational method, where the main idea is to find a representation of the Hilbert space of states in a restricted space which is much smaller than the original one. Both the QTM and DMRG methods are free from statistical errors and the negative sign problem which hampers convergence of physical quantities at low temperatures. For one-dimensional quantum systems DMRG approach offers a very efficient iterative truncation algorithm for constructing the effective transfer matrices with large Trotter numbers M.

For a given model, the convergence of the DMRG approximants depends on temperature and deteriorates with decreasing temperature. Before having analysed the experimental results, we have tested the M dependence of the approximants of the magnetic susceptibility in the region of low temperatures. In Fig. 3, the behaviour of the approximants as a function $1/M^2$ is plotted for two selected temperatures $T = 2$ K and $T = 10$ K and the model parameters $J/k_B = -1.0$ K, $D/k_B = 4.8$ K, $g_{Cu} = 2.08$ and $g_{Co} = 2.26$. The approximants correspond to relatively small values $3 \leqslant M \leqslant 6$, nevertheless the variation of the approximants is very weak and the linear scaling with respect to $1/M^2$ has been achieved. As can be estimated from Fig. 3, the uncertainty of the extrapolations is on the fourth decimal place for $T = 2$ K and on the sixth decimal place for $T = 10$ K. With increasing temperature the accuracy is still improving. We emphasize that the same variation of the finite-size data occurs in our calculations for other values of parameters

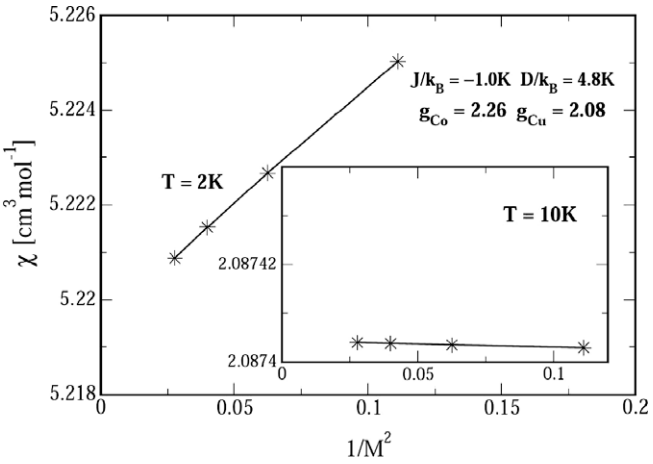

Fig. 3. Variation of the numerical finite-size data for the magnetic susceptibility along the z-axis against $1/M^2$ for two temperatures.

entering the Hamiltonian (1). The data shown in Fig. 3 demonstrate that the relative error bars of our simulation results are negligible (do not exceed 0.02%) and the DMRG technique is suitable for our analysis. The convergence is intensified by the presence of the 3/2 spins in the model (1). Hereafter the DMRG extrapolated data are reported.

In our analysis we have fitted simultaneously the magnetization and magnetic susceptibility data measured and calculated in the field $H = 0.5$ T. The typical results are shown in Figs. 4–6. Although the previous results [2] suggested ferromagnetic interactions through the thiocyanate bridge for the chain compound CuCo, we have scanned the positive and negative values of J. We have confirmed the conclusion about the ferromagnetic interactions, although our estimate $J/k_B = -1.0$ (±0.1) K is somewhat lower than that found before [2] and is justified by the large Cu(II)–Co(II) distance. In parentheses the uncertainty of a given value is defined.

Our simulations have revealed the importance of the Co(II) single-ion anisotropy which is crucial for the temperature behaviour of the χT susceptibility below the maximum (Figs. 4 and 5) and the low temperature magnetization profile (Fig. 6). However, using the experimental data available, only the absolute value $|D/k_B| = 4.6$ K (±0.6 K) can be determined. As to the g factors, we have

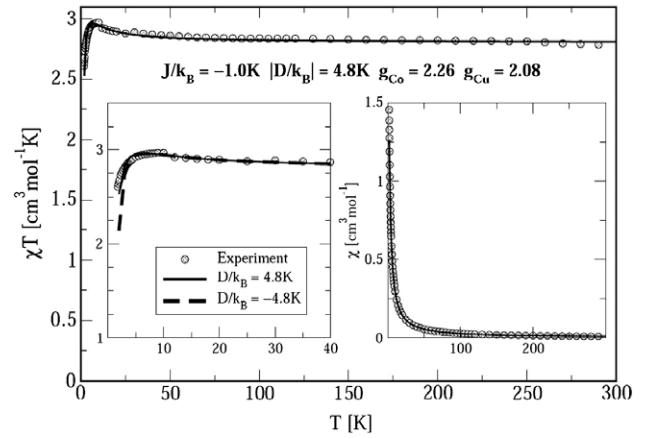

Fig. 4. Temperature dependence of the magnetic susceptibility for the CuCo sample plotted by the symbols and for the model with $|D/k_B| = 4.8$ K and the isotropic g factors. The results for the positive D are drawn by the solid lines and those for the negative D, by the dashed line. The left inset presents a comparison between experiment and our results for $D/k_B = \pm 4.8$ K in the low temperature regime. The right inset presents the average magnetic susceptibility vs. temperature.

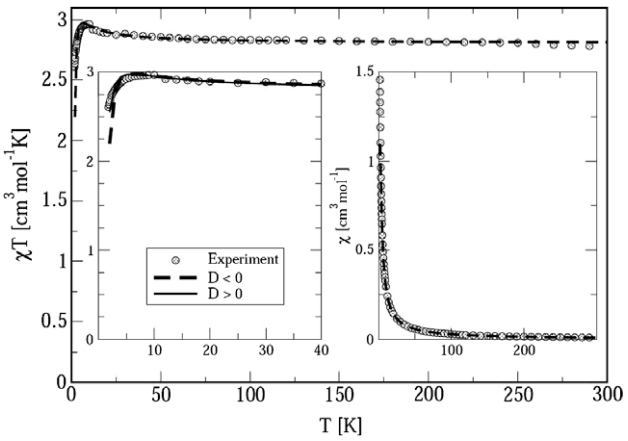

Fig. 5. Temperature dependence of the magnetic susceptibility for the CuCo sample and the models with anisotropic g factors. The dashed line corresponds to $J/k_B = -1$ K, $D/k_B = -4.8$ K, $g_{Co}^x = 2.27$, $g_{Co}^z = 2.22$ and $g_{Cu} = 2.14$ and the solid line to $J/k_B = -1$ K, $D/k_B = 4.5$ K, $g_{Co}^x = 2.25$, $g_{Co}^z = 2.27$ and $g_{Cu} = 2.14$. The left inset presents a comparison of experiment with the model χT curves in the low temperature regime. The right inset shows the magnetic susceptibility vs. temperature for the negative D.

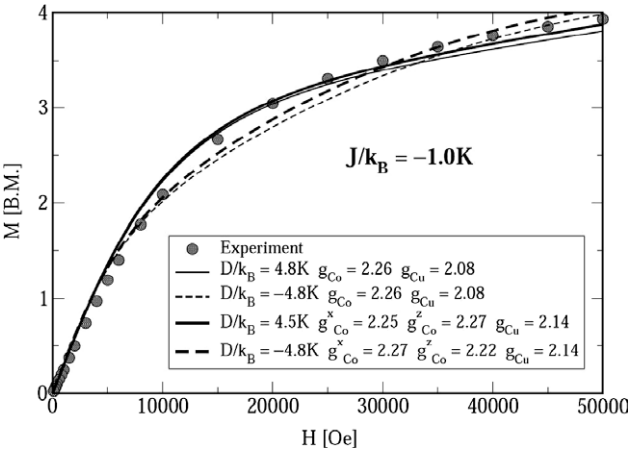

Fig. 6. Comparison of the field-dependent magnetization profiles for the experimental sample and theoretical models at $T = 2$ K. The values of the parameters are listed in the legend.

estimated the values: $g_{Cu}^{x,z} = 2.12$ (±0.04) and $g_{Co}^{x,z} = 2.25$ (±0.04). The condition [10] that the reliable determination of the single-ion parameter requires a low temperature (below $|D/k_B|$) data set is fulfilled here.

4. Discussion

In Fig. 4 we present a comparison between experiment and our simulation results for the anisotropy parameter $|D/k_B| = 4.8$ K and isotropic values $g_{Cu} = 2.08$ and $g_{Co} = 2.26$. The continuous lines refer to $D > 0$ and the dashed line to $D < 0$. The dashed line occurs if it can be distinguished from the continuous line. In the main panel, the χT product is plotted in the experimental temperature region, whereas in the left inset, in the low temperature region. Similar results for two sets of the anisotropic g_{Co} factors and a single g_{Cu} value are drawn in Fig. 5. In this case, the continuous line corresponding to the positive value D and $g_{Co}^x < g_{Co}^z$ is plotted if it can be distinguished from the dashed line for negative D and $g_{Co}^x > g_{Co}^z$. The magnetization profiles for the parameters selected from the domain found here are shown in Fig. 6. The symbols and curves are described in the legend.

The sign of D is difficult to fix for our CuCo sample. From the powder magnetic measurements only the average $\chi_{av} = 2/3\ \chi^x + 1/3\ \ \chi^z$ can be measured. The theoretical complication for the Co(II) with $S = 3/2$ in the tetrahedral environment follows from the existence of two Kramers doublets which differ only by the value of the spin component m. If D is negative then the lowest Kramers doublet corresponds to $m = \pm 3/2$, whereas for the positive D, it corresponds to $m = \pm 1/2$. This difference is not strong enough to be manifested clearly in the average thermodynamic functions. The independence of powder susceptibility data of the sign of the D parameter for some complexes, in particular those with $S = 3/2$, was noted in Ref. [10] and encountered in Ref. [11]. In the χT behaviour shown in the insets in Figs. 4 and 5 and in the magnetization profiles presented in Fig. 6, there is a signature that the results for $D > 0$ are somewhat superior to those for $D < 0$. However, this observation is not convincing enough. The sign of the Co(II) single-ion anisotropy could be determined, however, from the single-crystal magnetometry. This can be demonstrated from the results of our calculations of the longitudinal and perpendicular susceptibility (not presented here) and is also expected in literature [10].

There are cases [11,12] that Co(II) metal ions have a strong Ising-like anisotropy, so one could expect a negative D (an easy-axis) as a proper choice for our system. However, recently the systems have been found with Co(II) ions displaying the easy-plane anisotropy [10,13–15]. This conclusion is particularly strong in Ref. [13], where the high-field EPR experiments were performed and the transitions within the ground state Kramers doublet $m = \pm 1/2$ were identified.

Anticipating the presence of the Co(II) single-ion anisotropy in the CuCo compound, we have modelled the system using the anisotropic g_{Co} factors as their anisotropy has got the same origin [10]. *In such circumstances, there was no reason to neglect the g_{Co} anisotropy in the model (1).* We could afford an increase of the number of parameters, as we have exploited the accurate simulation technique. We have checked that the anisotropic g values which are theoretically expected, can model our system but the quality of the fits achieved using the powder data was not superior to those for the isotropic g values. The g values are estimated within 2% uncertainty and are consistent with the previous [2] isotropic estimates and the data published for the Cu(II) [10] and Co(II) [10,12] complexes. According to our findings, the difference in the magnitude $g_{Co}{}^x - g_{Co}{}^z$ can reach the value 0.08 which compares well with the differences reported in Ref. [12] for the Co(II) compounds.

The role of interchain interactions increases in low temperatures and may bring on the spontaneous magnetization. However, there is no experimental evidence of the long-range order down to 1.8 K so that an absence of such interactions in our Hamiltonian (1) and in our analysis is justified. It is worth adding that quite often they are accounted for within the molecular field approximation [10]. However, the molecular field corrections are meaningful only in the ordered phase, where an average value of magnetization is non-zero.

We emphasize that the lack of the molecular field term does not make our modeling task less demanding. In fact, it is challenging within the model (10) to find a maximum in the temperature behaviour of χT in the presence of the ferromagnetic coupling. We have accomplished the task due to the accurate simulations and taking into account the anisotropy term.

5. Conclusion

The modeling of the thiocyanate bridge compound $\{(CuL_1)[Co(NCS)_4]\}$ based on the anisotropic quantum spin-chain Hamiltonian has been carried out and the reliable DMRG technique has been exploited for the first time. The excellent convergence of the DMRG approximants has been demonstrated for relatively small values of the Trotter numbers $3 \leqslant M \leqslant 6$ and the high accuracy of the extrapolated data (not lower than 0.02%) has been reached for the estimates of susceptibility and magnetization.

The experimental susceptibility and field-dependent magnetization data have been fitted using the linear Heisenberg model with the single-ion anisotropy for the Co(II) ions and without the molecular field corrections, leading to the new set of the model parameters. The theoretical results for the thermodynamic functions agree quantitatively with experiment and the new parameters found are consistent with the literature data for the Cu(II) and Co(II) metal ions.

Our analysis has confirmed the weak ferromagnetic coupling between the Cu(II) and Co(II) ions, has revealed the importance of the anisotropy term for the Co(II) ions and has determined the absolute value of the parameter D, which was not resolved before.

Acknowledgements

We thank Prof. J. Krzystek and Prof. D. Gatteschi for some helpful and clarifying discussions. This work was supported by the EC 6th NoE Programme "MAGMANet" and by the Polish Ministry of Science and Higher Education through Grants No. N N202 309835 and 1 T09A12430. The numerical calculations were performed in PSNC Poznan, (Poland), TASK Gdansk (Poland) and the NIC Center in Juelich (Germany).

*2.1.1. $[Mn_6O_2(salox)_6(MeOH)_6(NCNCONH_2)_2]$ (**1**)*

$Mn(ClO_4)_2 \cdot 6H_2O$ (0.623 g, 1.72 mmol) was dissolved in MeOH (50 ml). To this was added H_2salox (0.240 g, 1.710 mmol), sodium dicyanamide (0.155 g, 1.74 mmol) and Et_3N (0.176 g, 1.74 mmol) resulting in a deep green solution, which was stirred for 10 min. Vapor diffusion of Et_2O into the solution slowly produced crystals, after one week dark-green crystals were obtained. Crystals were collected by filtration, washed with MeOH, Et_2O and dried in vacuo. The yield was 48% (based on Mn). *Anal.* Calc. for $C_{52}H_{58}Mn_6N_{12}O_{22}$ (1532.74): C, 40.75; H, 3.81; N, 10.97. Found: C, 40.44; H, 3.80; N, 10.95%. IR data (KBr disk, cm^{-1}): 3413 (m), 3330 (m), 3228 (m), 2201 (m), 2169 (s), 1627 (m), 1597 (s), 1543 (m), 1473 (m), 1438 (s), 1417 (m), 1323 (w), 1277 (s), 1245 (w), 1202 (m), 1146 (w), 1121 (w), 1024 (s), 944 (w), 914 (s), 756 (s), 680 (vs), 506 (w), 483 (w), 466 (w).

*2.1.2. $[Mn_6O_2(salox)_6(EtOH)_4(H_2O)_2Cl_2]$ (**2**)*

$MnCl_2 \cdot 4H_2O$ (0.405 g, 2.05 mmol) and H_2salox (0.276, 2.00 mmol) were dissolved in EtOH (20 ml). To this was added 10 wt% water solution of NEt_4OH (1.472 g, 1.00 mmol) resulting in a deep green solution, which was stirred for 1 h. The solution was filtered to eliminate any remaining solid and the filtrate was layered with two volumes of Et_2O to slowly give well-formed dark-green crystals. After one week, crystals were collected by filtration, washed with Et_2O and dried in vacuo. The yield was 34% (based on Mn). *Anal.* Calc. for $C_{50}H_{58}Cl_2Mn_6N_6O_{21}$ (1479.55): C, 39.72; H, 3.99; N, 5.74. Found: C, 40.05; H, 4.17; N, 5.60%. 2.2. X-ray crystallography

Data collection parameters for complexes **1** and **2** are listed in Table 1. Diffraction measurements for complexes **1** and **2** were carried out using a Brucker Smart ApexCCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.7107$ Å). Structures were solved by direct methods and refined using the SHELXL-97 program [26] by full-matrix least-squares on F^2 values. All non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms were placed in ideal, calculated positions, with isotropic thermal parameters riding on their respective carbon atoms. Complexes **1** and **2** crystallize in the triclinic space group $P\bar{1}$ and monoclinic space group $P2_1/n$, respectively, with a Mn_6 cluster in the asymmetric unit.

2.3. Physical measurements

Infrared spectra were recorded in the solid state (KBr pellets) on a Nicolet Magna 550 FTIR spectrometer in the 400–4000 cm^{-1} range. Elemental analyses have been carried out by using an Elementar vario EL III analyzer. Variable temperature dc and ac magnetic susceptibility measurements were collected on a microcrystalline sample, restrained in eicosane to prevent torquing, on a Quantum Design MPMS-XL SQUID magnetometer equipped with a 7.0 Tesla magnet and operating in the range of 1.8–300.0 K. Diamagnetic corrections were estimated from Pascal's constants [27] and subtracted from the experimental susceptibility data to obtain the molar paramagnetic susceptibility of the compound.

3. Results and discussion

3.1. Synthesis

The salicylaldoxime group (H_2salox) has been explored as a chelating ligand in the metal cluster chemistry. It has been observed in its singly-deprotonated (Hsalox$^-$) form as bidentate chelate with the protonated N–OH not bound [28], but it more commonly occurs in its doubly-deprotonated (salox^{2-}) form as a tridentate chelate [29,30]. These chelating forms can have a variety of possible binding modes, shown in Scheme 1 for Hsalox$^-$ and salox^{2-}. Based on this variety of possible binding modes of H_2salox, it may give rise to synthesize new nuclearities and topologies of complexes. Treatment of a methanolic solution of $Mn(ClO_4)_2$, NEt_3, $NaN(CN)_2$ and H_2salox in a 1:1:1:1 ratio leads to a reaction mixture comprising a dark-green solution. The residue was slowly diffused with Et_2O, to yield dark-green-brown triangle crystals of $[Mn_6O_2(salox)_6(MeOH)_6(NCNCONH_2)_2]$ (**1**) in a 48% yield. The IR spectra of complex **1** shows a simple ν_{as} absorption at 2201 cm^{-1} and a new moderately intense band at 1627 cm^{-1} in the carbonyl stretching region, together with enhanced intensity and complexity in the NH stretching region. X-ray crystallographic examination of this product readily explains the origin of the spectroscopic modifications. The dicyanamide $NCNCN^-$ has been changed to the corresponding amido $NCNCONH_2^-$, presumably through catalytic hydrolysis of the uncoordinated –CN link following attack by H_2O, activated by coordination to the Lewis acidic Mn^{III} ion. Consequently the IR spectrum demonstrates the presence of new CO and NH_2 absorptions, as well as simplification of the 2300–2100 cm^{-1} cyanamido region deriving from substitution of a single coupled NCN oscillator for the more complex NCNCN system. Catalytic hydration of nitriles is not unknown; indeed the dinickel salt of the pseudocryptand dipodand has been reported as a protein catalyst in the cooperative hydration of nitriles [31]. The activation of the β-carbon atom of the dicyanamido ligand by coordination to Cu^{II} against the reaction with methanol has been reported [32].

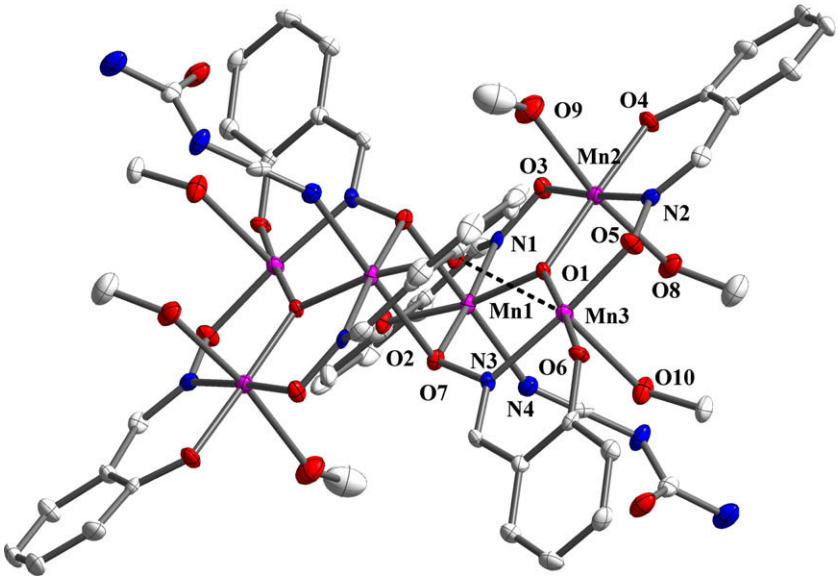

Fig. 1. ORTEP drawing of **1** with thermal ellipsoids set at 30% probability. H atoms have been omitted for clarity. The bond distance between O2′–Mn3 (dashed line) is 2.523 Å.

When the reaction process of complex **1** was carry out without $NaN(CN)_2$, complex **2** was obtained. Treatment of ethanolic solution of $MnCl_2$, with NEt_4OH and H_2salox in a 1:1:1 ratio produces a deep green solution. Layering of this solution with Et_2O leads dark-green crystals of $[Mn_6O_2(salox)_6(EtOH)_4(H_2O)_2Cl_2]$ (**2**) in 34% yield.

3.2. Description of structures

Selected interatomic distances and angles of complexes **1** and **2** are listed in Tables 2 and 3, respectively.

3.2.1. $[Mn_6O_2(salox)_6(MeOH)_6(NCNCONH_2)_2]$ (**1**)

Labeled ORTEP plot of $[Mn_6O_2(salox)_6(MeOH)_6(NCNCONH_2)_2]$ (**1**) is shown in Fig. 1. Complex **1** crystallizes in the triclinic space group $P\bar{1}$ with the molecule lying on an inversion center. The core of the complex **1** contains a nonplanar $[Mn^{III}_6(\mu_3\text{-}O^{2-})_2(\mu_3\text{-}OR)_2]^{12+}$ unit, whose topology consists of six Mn ions arranged as two $[Mn^{III}_3(\mu_3\text{-}O^{2-})]^{7+}$ triangular subunits bridged by two oximato O atoms (O7, O7′). Four of the $salox^{2-}$ ligands show the common $\eta^1{:}\eta^1{:}\eta^1{:}\mu_2$ coordination mode, while the other two adopt the $\eta^1{:}\eta^1{:}\eta^2{:}\mu_3$ mode. The three crystallographically independent MeOH ligands complete the six-coordination at Mn2 and five coordination at Mn3, while one crystallographically independent $NCN\text{-}CONH_2^-$ ligand completes the six-coordination at Mn1. Ions Mn1 and Mn2 display the Jahn–Teller elongation, as expected for high-spin $3d^4$ ions in near-octahedral geometry; the Jahn–Teller axes are O7–Mn1–N4 and O8–Mn2–O9. Mn3 has a distorted square-pyramidal geometry, with the MeOH oxygen O10 at the apical position. In addition, there is a shortening of the phenolato oxygen O2–

square-pyramidal Mn, Mn3, distance (~2.5 Å) within each Mn_3 subunit. Four intermolecular hydrogen bonding interactions in complex **1**, O1···O9 (2.688 Å), N5···O7 (2.779 Å), N6···O4 (2.972 Å) and N6···O6 (3.006 Å) link the clusters forming a 2D network (Fig. 2).

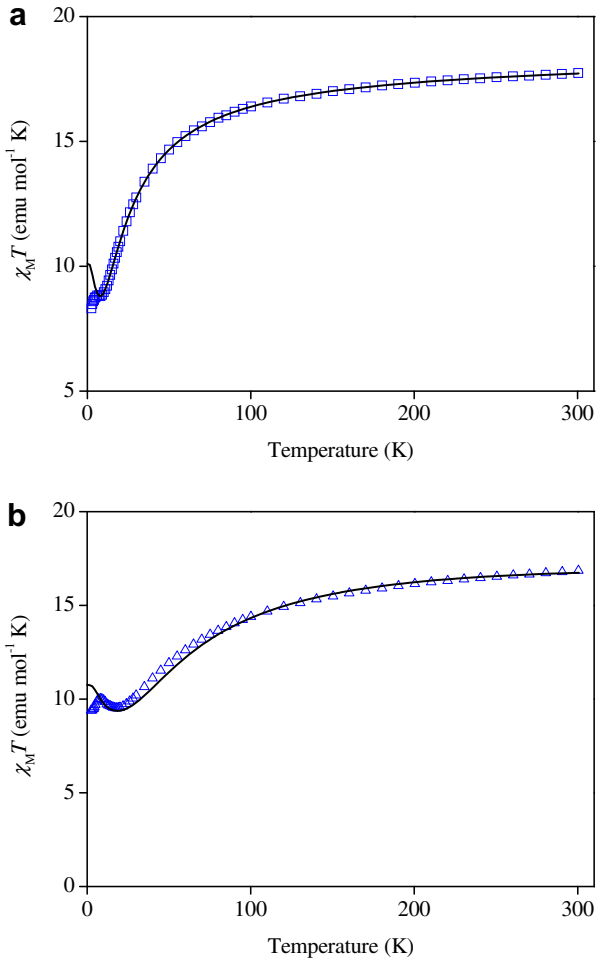

Fig. 5. Plots of $\chi_M T$ vs. temperature for a microcrystalline sample of complexes (a) **1** and (b) **2**. The solid line represents a least-squares fit of the data.

*3.2.2. $[Mn_6O_2(salox)_6(EtOH)_4(H_2O)_2Cl_2]$ (**2**)*

Labeled ORTEP plot of $[Mn_6O_2(salox)_6(EtOH)_4(H_2O)_2Cl_2]$ (**2**) is shown in Fig. 3. Complex **2** crystallizes in the monoclinic space group $P2_1/c$ with the molecule lying on an inversion center. The structure of complex **2** is quite similar to that of complex **1** with only difference of the terminal ligands. For complex **2**, there are two crystallographically independent EtOH and one water ligands complete the six-coordination at Mn1 and Mn2, while one crystallographically independent Cl^- ligand completes the five coordination at Mn3. Mn1 and Mn2 are bound to an O_5N set of donor atoms and display Jahn–Teller elongation and the Jahn–Teller axes are O7′–Mn1–O8 and O9–Mn2–O10. Mn3 has a distorted square-pyramidal geometry, with the terminal Cl^-, Cl1, at the apical position. The hydrogen bonding involved the O atom of phenol ring and

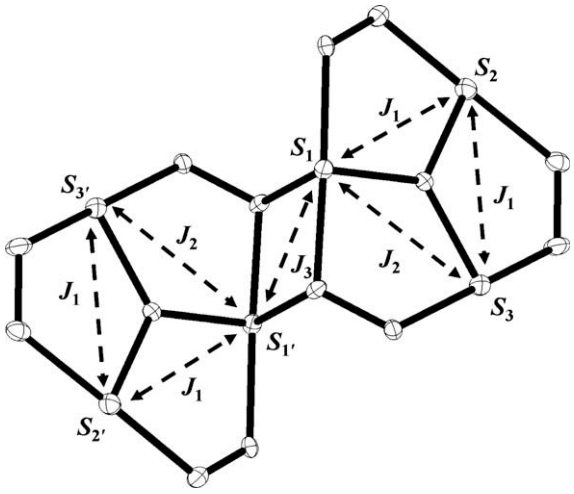

Fig. 6. Interaction path topology and magnetic exchange parameters for the complexes **1** and **2**.

the O atom from the terminal water ligand (O6···O10, 3.003 Å). These interactions link the clusters forming a 2D network (Fig. 4).

3.3. Direct current magnetic susceptibilities and magnetization

The variable temperature dc magnetic susceptibilities were collected for microcrystalline samples of complexes **1** and **2** in the temperature range of 2–300 K at a magnetic field of 1000 G. The experimental $\chi_M T$ versus temperature plots are depicted in Fig. 5a and b for complexes **1** and **2**, respectively. The value of $\chi_M T$ decreases from 17.74 emu K mol^{-1} for **1** and 16.85 emu K mol^{-1} for **2** at 300 K to reach a minimum of 8.80 emu K mol^{-1} at 8 K, and 9.52 emu K mol^{-1} at 18 K for **1** and **2**, respectively. Upon cooling the $\chi_M T$ increases slightly to 8.83 emu K mol^{-1} at 6 K, and 10.01 emu K mol^{-1} at 8 K for **1** and **2**, respectively, and then decrease to 8.45 emu K mol^{-1} at 2 K, and 9.74 emu K mol^{-1} at 2 K for **1** and **2**, respectively. The value of $\chi_M T$ at 300 K is slightly lower than the calculated spin-only value of 18.00 emu K mol^{-1} for a Mn_6^{III} complex with noninteracting metal centers with $g = 2.0$, suggesting that antiferromagnetic couplings dominate the overall intramolecular exchange interactions within the complexes. The maximum $\chi_M T$ values of 8.83 emu K mol^{-1} at 6 K and 10.01 emu K mol^{-1} at 8 K are consistent with the ground state $S = 4$ with $g = 1.90$ and 2.0 for **1** and **2**, respectively. The decreasing $\chi_M T$ at low temperature is likely due to the zero-field splitting and Zeeman effects of the high-spin ground state. The exchange interactions between manganese ions of complexes **1** and **2** were modelled taking into account the discussion by Brechin and co-workers for the hexanuclear analogue [33,34]. The topologies of the complexes afford the coupling scheme depicted in Fig. 6. Three inequivalent coupling constants are required and the spin Hamiltonian is given in Eq. (1):

$$H = -2J_1(S_1S_2 + S_2S_3 + S_{1'}S_{2'} + S_{2'}S_{3'}) - 2J_2(S_1S_3 + S_{1'}S_{3'}) - 2J_3(S_1S_{1'}) \quad (1)$$

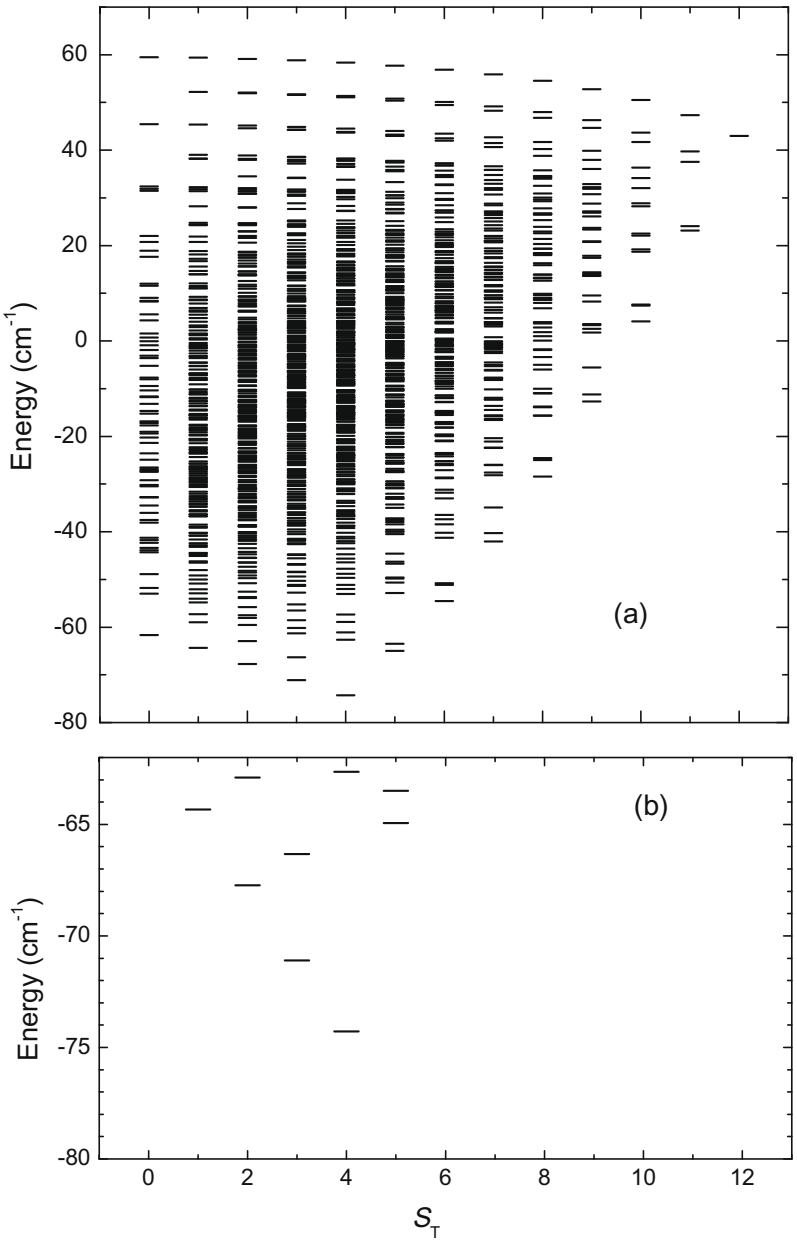

Fig. 7. (a) Diagram of all energy values for all S_T spin values of complex **1**. The ground-state spin corresponds to $S_T = 4$ with energy = −78 cm^{-1}. (b) Energy diagram of only and low-lying exciting states.

The Kambe approach for isotropic exchange-coupled systems [35] is very useful and facile method to yield energy eigenvalues and eigenvectors, however, is not applicable to the present systems because of entangled exchange paths which forbid to split a whole system into some interacting partial spin sums. An alternative approach, block diagonalization, is available for general isotropic spin systems [36–38]. It is based on the nature that the HDVV (Heisenberg–Dirac–Van Vleck) Hamiltonian preserves the z-component of total spin S, $S_Z = \sum_i S_Z(i)$, where $S_Z(i)$ stands for the z-component of spin on the ith metal ion in a molecule, owing to the commutation relation $[\hat{H}_{\mathrm{HDVV}}, S_Z] = 0$. In the $Mn(III)_6$ complexes, the full-matrix dimension is $(2S+1)^N = 15625$, which is not easily solved even by using a modern computer. However, the commutation relation allows us to solve each block matrix with different S_Z value separately and we can confine ourselves to an $S_Z = 0$ block matrix with its dimension of only 1751, much smaller than the full-matrix size.

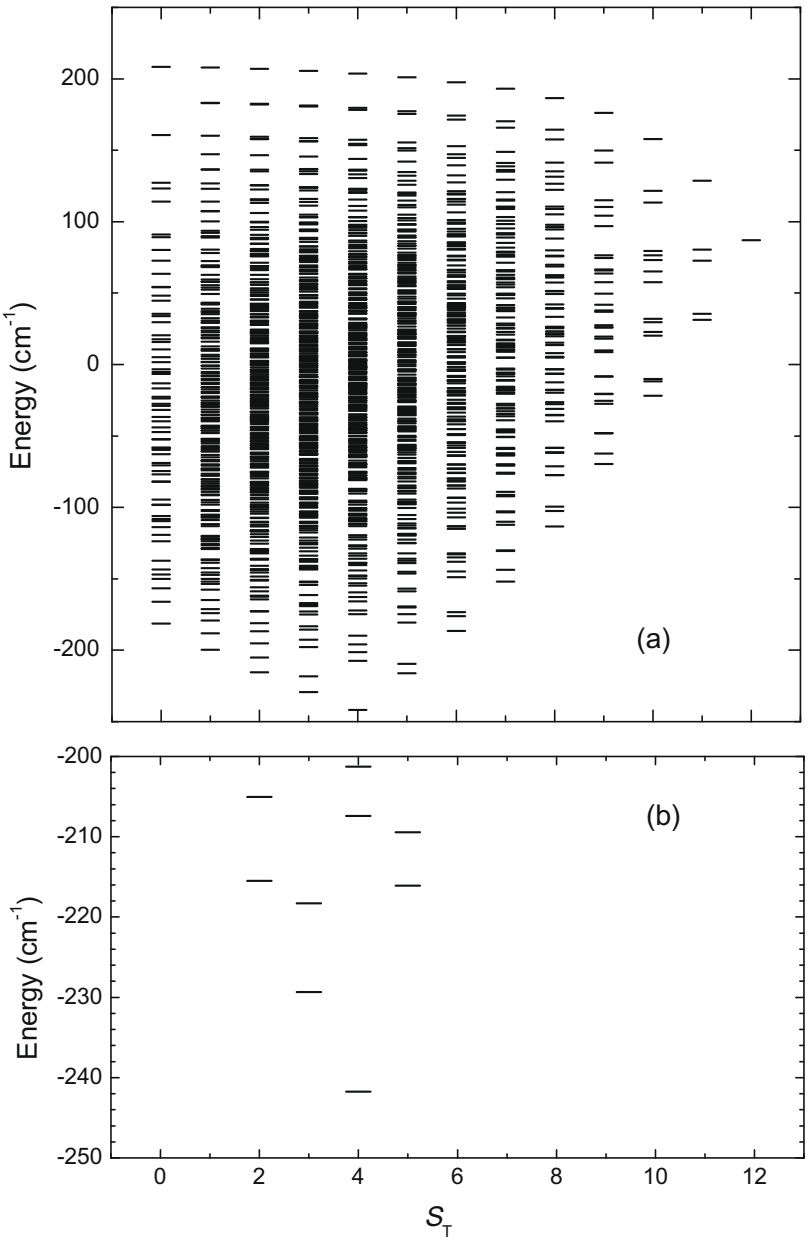

Fig. 8. (a) Diagram of all energy values for all S_T spin values of complex **2**. The ground-state spin corresponds to $S_T = 4$ with energy = -242 cm^{-1}. (b) Energy diagram of only and low-lying exciting states.

Table 4
Comparison of the exchange couplings and relative torsion angles of complexes **1** and **2** with Mn_6 analogous of $[Mn_6O_2(salox)_6(O_2CR)_2(S)_4]$.

Complex	Mn1–Mn2 (cm^{-1})	Mn2–Mn3 (cm^{-1})	Mn1–N1–O3–Mn2 (°)	Mn1–O7–N3–Mn3 (°)	Ref.
$[Mn_6O_2(salox)(O_2CMe)_2(EtOH)_4]$	−12.6	−3.5	10.70	22.83	[33]
$[Mn_6O_2(sao)(O_2CH)_2(MeOH)_4]$	−4.6	−1.8	25.57	18.01	[34]
$[Mn_6O_2(salox)_6(MeOH)_6(NCNCONH_2)_2]$ (**1**)	−1.65	0.29	19.89	37.45	this work
$[Mn_6O_2(salox)_6(EtOH)_4(H_2O)_2Cl_2]$ (**2**)	−4.66	0.53	22.97	31.24	this work

Although more aggressive reduction of matrix size can be sometimes attempted aided by topological symmetry of the molecule, S_Z block matrix diagonalization works without any symmetry restrictions and is applicable to general isotropic systems. Starting with decoupled basis vectors, $|S_Z(1), S_Z(2), S_Z(3), S_Z(4), S_Z(5), S_Z(6)\rangle$, the largest block matrix is constructed in the $S_Z = 0$ subspace for integer spin systems ($S_Z = -1/2$ subspace should be used for half-odd spin systems). The block matrix, being much easier to be solved than the full matrix is, is diagonalized to provide energy eigenvalues and eigenvectors expressed in terms of decoupled basis vectors. Invoking another commutation relation $[\hat{H}_{HDVV}, S_Z] = 0$, the square of total spin S^2 should be another good quantum number, which we require for labeling an eigenstate along with S_Z. In order to obtain S, the total-spin raising operator ($\hat{S}^+ = \sum_i \hat{S}^+(i)$) is evaluated for each eigenvector by $\rangle S_Z + 1|\hat{S}^+|S_Z\langle = \sqrt{(S - S_Z)(S + S_Z + 1)}$, yielding $S = \frac{1}{2}\left(\sqrt{1 + 4\rangle 1|\hat{S}^+|0\langle^2} - 1\right)$. For half-odd integer spin systems, $S = |\rangle + 1/2|\hat{S}^+|-1/2\langle| - \frac{1}{2}$ should be used instead.

Once the energy eigenvalues $E(S,S_Z)$ are obtained, the Van Vleck formula can be used to calculate magnetic susceptibilities as a function of temperature:

$$\chi_m = \frac{Ng^2\mu_B^2}{3k_BT}\frac{\sum_{\text{all } S} S(S+1)(2S+1)e^{[-E(S,S_Z)/k_BT]}}{\sum_{\text{all } S}(2S+1)e^{[-E(S,S_Z)/k_BT]}}$$

All the procedures were coded on IGOR PRO graphics software package [39], which is capable of performing non-linear least-squares optimization of a model Hamiltonian. In both cases, the data below 7 K were omitted in the fitting, because zero-field splitting and Zeeman effects are likely to have an effect on the susceptibilities in this temperature range. The simulation curves based on the fitting results are shown as solid lines in Fig. 5, with optimized parameters being $g = 2.00$, $J_1 = -1.65$ cm^{-1}, $J_2 = 0.29$ cm^{-1} and $J_3 = 0.81$ cm^{-1} for complex **1**; $g = 2.00$, $J_1 = -4.66$ cm^{-1}, $J_2 = 0.53$ cm^{-1} and $J_3 = 6.69$ cm^{-1} for complex **2**. In both cases, the temperature independent paramagnetism (TIP) was kept constant at 1200×10^{-6} emu mol^{-1}. Each set of parameters results in a ground state of $S = 4$ indicating that the Mn_6 complexes **1** and **2** have $S_T = 4$ ground states and the energy diagrams are given in Figs. 7 and 8, respectively. The first excited state is $S = 3$ expected at 3.1 and 12.4 cm^{-1} above the ground state for **1** and **2**, respectively.

The values obtained for exchange parameters of the two complexes are very similar. The comparison of the exchange couplings for complexes **1** and **2** with the analogous Mn_6 complexes are listed in Table 4. Exchange couplings for J_1, Mn^{III}–Mn^{III} bridged by one $\eta^1{:}\eta^1{:}\eta^1{:}\mu_2$ salox^{2-}, in these compounds are antiferromagnetic with values of -1.80 and -3.5 cm^{-1}, which close the values of -1.65 and -4.66 cm^{-1} for these interactions in **1** and **2**, respectively. The interactions of J_2, Mn^{III}–Mn^{III} bridged by one $\eta^1{:}\eta^1{:}\eta^2{:}\mu_3$ salox^{2-}, in complexes **1** and **2** are ferromagnetic with the values of 0.29 and 0.53 cm^{-1}, respectively, which show sharp difference to antiferromagnetic interaction observed in the Mn_6 analogue. These interactions may depend on the larger torsion angles of Mn1–O7–N3–Mn2 (37.45° and 31.24° for **1** and **2**, respectively). In the previous studies, it was reported that the larger torsion angle (usually >30°) causes ferromagnetic exchange interaction, and the exchange coupling of complexes **1** and **2** consistent with this results [40,41]. The exchange interactions of J_3, Mn^{III}–Mn^{III} bridged by two $\eta^1{:}\eta^1{:}\eta^2{:}\mu_3$ salox^{2-}, in the complexes **1** and **2** are consistent with the previously recognized fact that the exchange interaction is known to be ferromagnetic in complexes with the $[Mn^{III}_2(OR)_2]$ dimeric core [42].

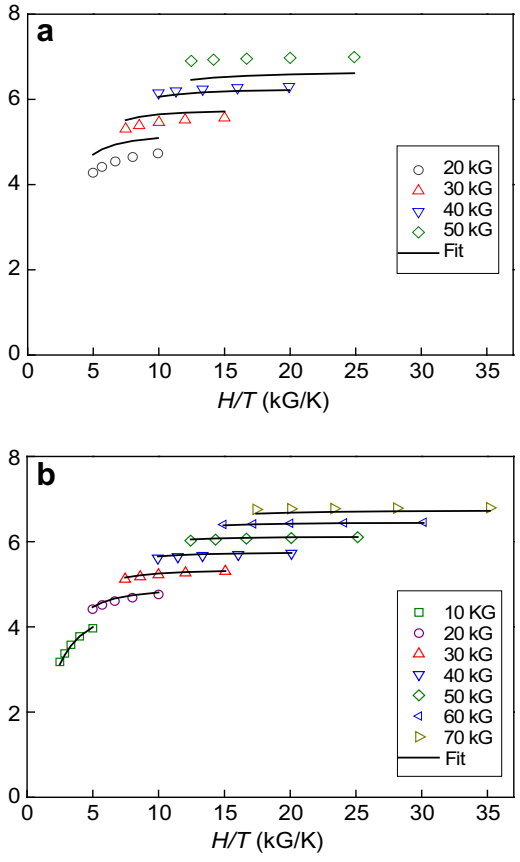

Fig. 9. The reduced magnetization of (a) **1** and (b) **2** plotted as $M/N\beta$ vs. H/T at indicated fields.

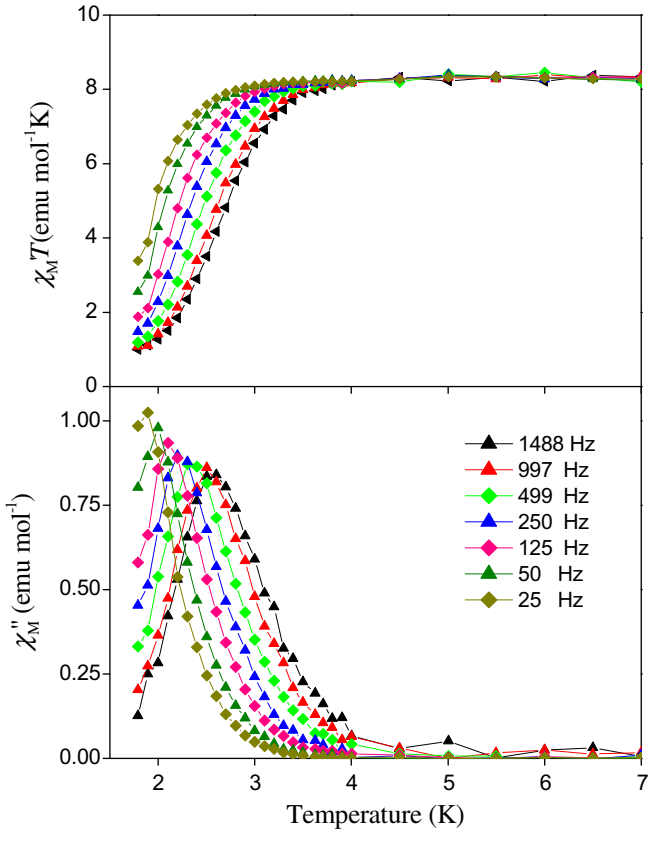

Fig. 10. Plots of $\chi'_M T$ (top) and χ''_M (bottom) vs. temperature for a microcrystalline sample of complex **1** in a 3.5 G ac field. The data were collected in an ac field oscillating at the indicated frequencies.

To determine the spin of the ground state, magnetization (M) measurements were also performed in the 2.0–4.0 K temperature range and the 1.0–70 kG dc magnetic field range. The data of complexes **1** and **2** are plotted as the magnetization ($M/N\beta$) versus H/T in Fig. 9a and b, respectively, where N is the Avogadro's number, β is the Bohr magneton, and H is the applied magnetic field. For a system characterized by a single S value and experiencing no zero-field splitting (ZFS), the various isofield curves of $M/N\beta$ would be superimposed on a Brillouin curve, saturating at a value of gS. The deviation of the isofield curves apart from a universal curve in Fig. 9 is indicative of the presence of significant ZFS. The data were fit using ANISOFIT software package [43] that assumes only the spin ground state of the molecule is populated. The best fit for complex **1** was given by $S = 4$, $g = 1.92$, $D = -0.82\ cm^{-1}$ and $E = 0.0015\ cm^{-1}$; $S = 4$, $g = 1.95$, $D = -1.18\ cm^{-1}$ and $E = -0.00005\ cm^{-1}$ for complex **2** (where D is the axial ZFS parameter and E is the rhombic ZFS parameter). The fitting for complex **1** is rather poor, which is likely due to significant populations of low-lying excited states even at low temperature, and it may introduce some ambiguity in the above ZFS values. The contrastive goodness of fitting reduced magnetization for those complexes is also consistent with the energy level scheme obtained from fitting of dc magnetic susceptibility (Figs. 7 and 8), with the lowest excited-level at $\sim 3.5\ cm^{-1}$ for complex **1** and at $13\ cm^{-1}$ for complex **2**. The ZFS parameters provide the upper bounds of spin-reversal energy barriers ($U = |D|S^2$) of 13 and 19 cm^{-1} (18.5 and 27 K) for complexes **1** and **2**, respectively.

3.4. Alternating current magnetic susceptibilities

The measurements of the ac magnetic susceptibility were performed on microcrystalline samples of complexes **1** and **2** in the temperature range 1.8–10 K in a zero dc field and a 3.5 G ac field oscillating at frequencies in the 25–1488 Hz range. The results for representative of complexes **1** and **2** are shown in Figs. 10 and 11, respectively. The observed frequency-dependent χ''_M signal is suggestive of the slow relaxation characteristic of the superparamagnetic-like properties of an SMM. Extrapolation of the plot of $\chi'_M T$ versus T to 0 K gives a value of ca. 8.15 and 9.84 emu K mol^{-1} for complexes **1** and **2**, respectively, indicative of an $S = 4$ ground state and these results are consistent with the dc magnetic susceptibility data and fitting of magnetization data. In addition, the temperature ranges of maximum position ac out-of-phase signals are slightly different for **1** and **2** in 1.9–2.6 and 2.1–3.2 K, respectively. The Arrhenius equation was applied to fit the data, and the rate of reversal of magnetization and the effective energy barrier of this molecule were obtained. The plot of the relaxation time as a function of inverse of temperature for complexes **1** and **2** are shown in Fig. 12. Good fits of the ac data were obtained, and the slope of the Arrhenius plot gave U_{eff} of 27.0(1) K and $\tau_0 = 3.8(2) \times 10^{-9}$ s for complex **1**, and U_{eff} of 25.1(6) K and $\tau_0 = 4.3(1) \times 10^{-8}$ s for complex **2**, which are consistent with the similar complexes reported in the literature [40].

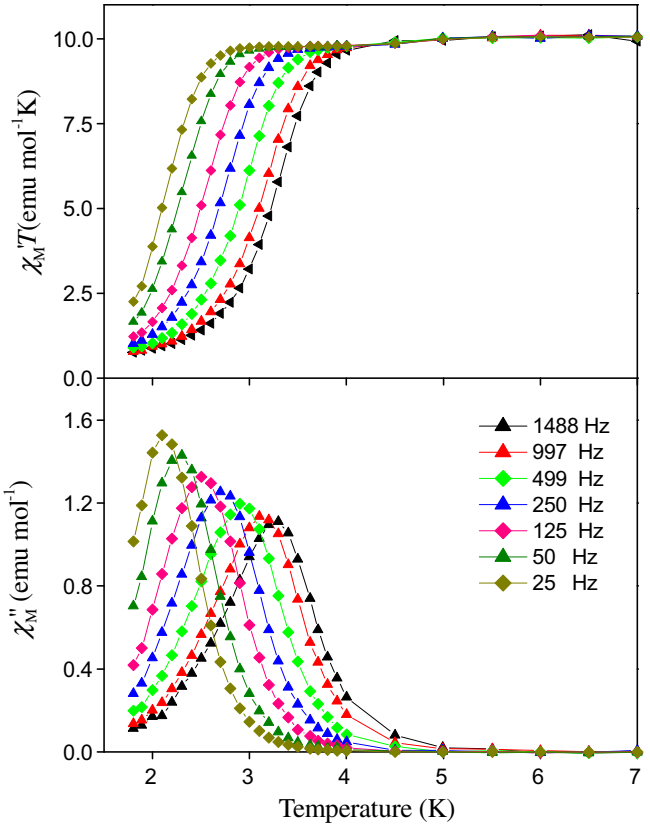

Fig. 11. Plots of $\chi'_M T$ (top) and χ''_M (bottom) vs. temperature for a microcrystalline sample of complex **2** in a 3.5 G ac field. The data were collected in an ac field oscillating at the indicated frequencies.

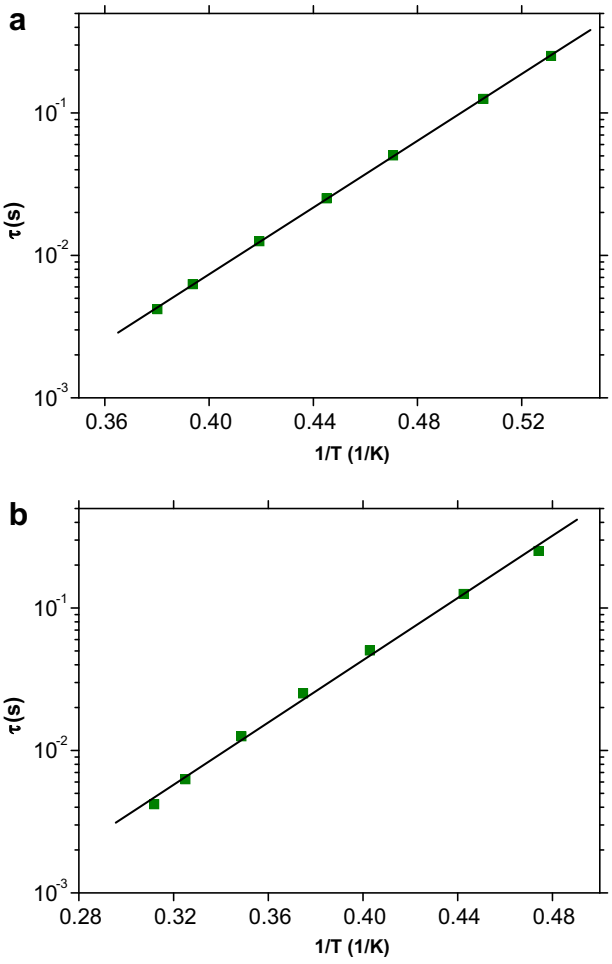

Fig. 12. Plots of τ vs. $1/T$ for (a) **1** and (b) **2** using ac χ''_M peak data. The solid lines correspond to a fit to the Arrhenius equation.

4. Conclusion

The use of H_2salox as a chelating ligand combined with $N(CN)_2^-$ or Cl^- with Mn^{II} sources afforded two Mn_6 complexes. Both Mn_6 complexes display SMM properties with $S = 4$ ground states from

dc and ac magnetic susceptibility measurements. Complexes **1** and **2** have slight variations of their magnetic properties due to the twisting of the structures. These difference of structural distortions in complexes **1** and **2** results in different magnetic interactions between the metal centers. With these two SMMs established, we have since managed to synthesize additional members of this Mn_6 family of SMMs using other linking groups.

Acknowledgements

The magnetic measurements were obtained from the SQUID magnetometer (MPMS XL-7) in NSYSU, and we thank the National Science Council of Taiwan (NSC-96-2113-M-006-010-MY3) for financial support.

Since our sample is polycrystalline we have to average theoretical results over three directions. Thus, a total susceptibility is calculated as an arithmetic average:

$$\chi = -\left(\frac{\partial^2 F}{\partial B^2}\right)_T = \frac{1}{3}\left(\chi_x + \chi_y + \chi_z\right), \tag{3}$$

$$\chi_{x,y,z} = -\frac{\partial^2 F}{\partial B_{x,y,z}^2} \tag{4}$$

where $B_{x,y,z}$ stand for x, y or z component of the magnetic field B. The same average is calculated for the magnetization $\langle S\rangle$:

$$\langle S\rangle = \frac{1}{3}\left(\langle S^x\rangle + \langle S^y\rangle + \langle S^z\rangle\right), \quad S^{x,y,z} = \sum_{j=1}^{7} s_j^{x,y,z} \tag{5}$$

In order to facilitate our QTM calculations we compute $\chi_{x,y}$ by numerical differentiation of F and χ_z using the formula:

$$\chi_z = \beta(g\mu_B)^2\left(\langle (S^z)^2\rangle - \langle S^z\rangle^2\right). \tag{6}$$

We exploit the symmetry of the model imposing that χ_y for the magnetic field B in the plane $y-z$ is equal to χ_x with B in the plane $x-z$ (see Eq. (1)). For the sake of theoretical discussion we also calculate magnetic torque τ which for the field in $x-z$ plane has only yth component:

$$\tau_y = -g\mu_B B\left(\langle S^x\rangle\cos\theta - \langle S^z\rangle\sin\theta\right) \tag{7}$$

The thermodynamic quantities are calculated directly by means of QTM. Using ED we determine the energy structure of Hamiltonian (1) and confirm the results obtained by the QTM technique. The details of the QTM and ED techniques can be found in [9], where we also discuss parallelization of our algorithms.

3. Results and discussion

Magnetic measurements presented in this paper were performed on polycrystalline samples, by using a Quantum Design MPMS XL SQUID magnetometer equipped with a 7 T magnet. The samples were prepared by the method described in [5] and restrained in eicosane. Magnetic susceptibility data were recorded in the 2–300 K temperature range in applied magnetic fields of 0.1, 0.5 and 1 T (perpendicular to the direction of the measurement). Data were corrected for the diamagnetism of the sample by using Pascal's constants. The sample holder diamagnetism was also measured and subtracted from the raw data.

There are already two sets of microscopic parameters for Cr_7Cd found by fitting the specific heat (C-fit: $J_\perp = J_\parallel = 15.3$ K, $D_\perp = 0, D_\parallel = -0.31$ K) [2] and EPR (EPR-fit: $J_\perp = 16.83$ K, $J_\parallel = 16.54$ K, $D_\perp = 0.069$ K, $D_\parallel = -0.14$ K) [3] data. The C-fit assumes only single ion anisotropy, whereas the EPR-fit assumes both single and exchange ion anisotropies [3]. We calculated the susceptibility for these two sets of parameters and found that they agree quite well with the experiment below $T = 5$ K (the deviation from the experiment is smaller then 2%). For higher temperatures they differ systematically from each other and from the experiment up to about 6%. This discrepancy together with a good agreement below $T = 5$ K suggests that the mean values of the exchange integrals should be tuned. Thus we keep the values of the anisotropies in both sets of parameters and change the mean values of the exchange integrals to fit the experimental data.

We obtained a very good fit (see Figs. 1 and 2) for the following sets of parameters: *a-fit* – $J_\perp = J_\parallel = 16.01$ K, $D_\perp = 0, D_\parallel = -0.31$ K and *b-fit* – $J_\perp = 15.92, J_\parallel = 15.63$ K, $D_\perp = 0.069$ K, $D_\parallel = -0.14$ K. In all cases we keep $g = 1.98$. We added to the theoretical results for χ a diamagnetic correction equal to 0.001, which includes also any temperature independent paramagnetism.

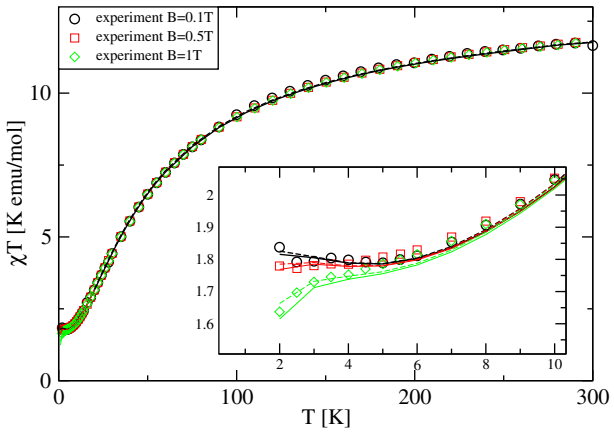

Fig. 1. Susceptibility χ of Cr_7Cd fitted with two theoretical curves. The a- and b-fits are depicted by full and broken lines, respectively.

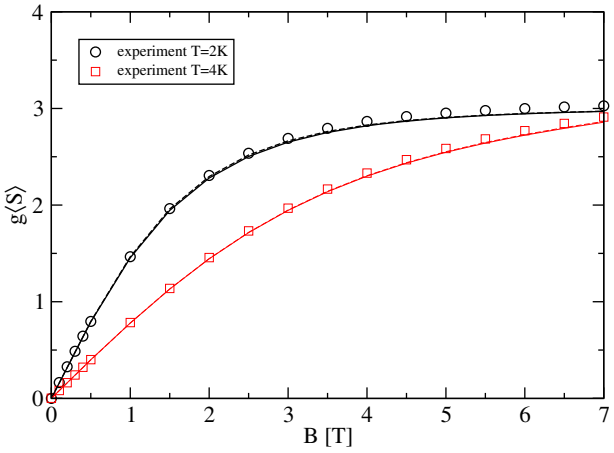

Fig. 2. Magnetization $\langle S\rangle$ of Cr_7Cd for $T = 2$ K and $T = 4$ K fitted by two theoretical curves. The a- and b-fits are depicted by full and broken lines, respectively.

The maximal difference between theory and experiment for both fits is smaller than 2% in whole temperature range. Thus, on the basis of these results we cannot decide whether there is only single ion anisotropy (a-fit), or also exchange anisotropy (b-fit) We notice that a good agreement of our two fits with each other is due to the fact that we calculate susceptibility and magnetization for a powder sample, i.e. we take the arithmetic average (3). The values of $\chi_{x,y,z}$ in low temperatures differ for a- and b-fits quite considerably (see Fig. 3).

Thus, in order to decide which anisotropy is present in Cr_7Cd one should perform measurements on a mono crystalline sample. As can be seen in Fig. 3 the susceptibility could be a good test quantity. However the magnetic torque seems to be much more suitable because it is very sensitive to anisotropy.

We have calculated the torque for various sets of parameters and found that the curves representing the torque as a function of the magnetic field B fall into two general categories determined by the anisotropy. With only one type of anisotropy (single ion or exchange) the τ curves exhibit sharp minima at the crossing fields. Depending on the sign of the anisotropy parameter (D or $J_\perp - J_\parallel$) the τ curves are ascending or descending with growing field B (see full and broken curves in Fig. 4).

However when we take into account both types of anisotropy (second category) the calculated curves have a quite different character (see dot-broken curves in Fig. 4. There are also descending

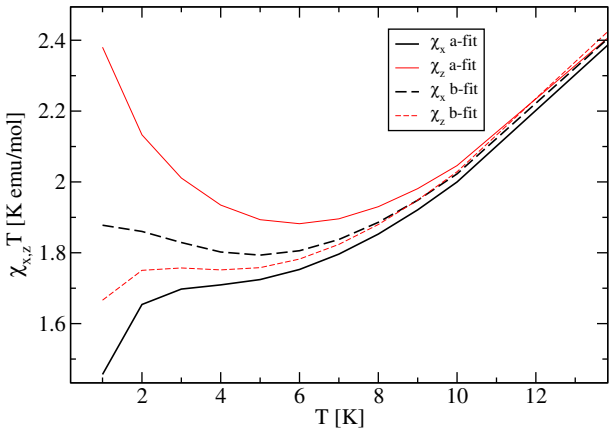

Fig. 3. Susceptibility χ of Cr_7Cd along x and z axes calculated for two sets of parameters.

curves for opposite sings of D and $J_\perp - J_\parallel$, not shown here for the sake of clarity.) They do not have characteristic peaks present in the first category of curves and ascribed to the anti-crossing (AC) gap [8]. We notice that a- and b-fits belong to two different categories.

The exact conditions for which this effect can be observed are currently under investigation. The preliminary results allow us to state, that to obtain a curve falling into the second category both exchange and single ion anisotropies should be of the same order and should have opposite character, i.e. one should be of an easy axis type and the other of an easy plane type. In the interesting for us case (b- and EPR-fits) a single ion anisotropy is of an easy axis type and the exchange one is of an easy plane type.

To understand better how these two kinds of behavior depend on the energy structure of the models we diagonalized Hamiltonian (1). We found that when two anisotropies (single ion and exchange) are present in the system the first AC gap between the ground state (from 3/2 multiplet) and the first excited state (from 5/2 multiplet) is considerably diminished. This effect does not appear if only one sort of anisotropy is taken into account (see Fig. 5). For some parameters the AC gap practically disappears for all values of angle θ (see diamonds in Fig. 5), or at least looses its strong θ dependence. This is why the peaks in the τ curves are swept out.

Furthermore we find that for the b-fit (EPR-fit) the ground (3/2) multiplet has an easy plane splitting and the lowest (5/2) multiplet has an easy axis splitting, i.e. precisely opposite to the situation in the a-fit (C-fit) [2].

As there are no experimental results of torque for Cr_7Cd we cannot directly verify our theoretical predictions. The most similar compound which, as concerns magnetic properties, should differ from our ring only in the quantitative way is the already mentioned Cr_7Zn. For this molecule there are results of the torque experiment available [8]. None of the shapes of τ curves presented in [8] resembles the one obtained by us for the mixed anisotropies. This would suggest that Cr_7Cd has only one type of anisotropy.

It is worth mentioning that the microscopic model used by us in this paper is not identical with the models employed in [2] and [3]. In the work of Affronte et al. [2] also the dipole–dipole intracluster interactions are taken into account, though only using the point-dipole approximation. Piligkos et al. [3] introduce rotational matrices into the Heisenberg like Hamiltonian with the site-dependent angles. Nevertheless a fact that the susceptibility in low temperature calculated by us using the parameters obtained from the C-fit agrees very well with that calculated with the EPR-fit parameters proves that the real differences between the models (at least for the quantities calculated) are very small. Though one cannot entirely exclude that it is a combined effect of approximations used here.

We neglected the small dipolar interactions and the changes in the directions of the local anisotropy axes. These effects could be incorporated in our scheme but the corresponding parameters were not available for us.

It has been already pointed out in [10] that though usually treated as equivalent single ion and exchange anisotropies may have qualitatively different influence on the properties of a system. Our calculations demonstrate that in case of Cr_7Cd both kinds of anisotropy have the same effect if they exist in separation. Their

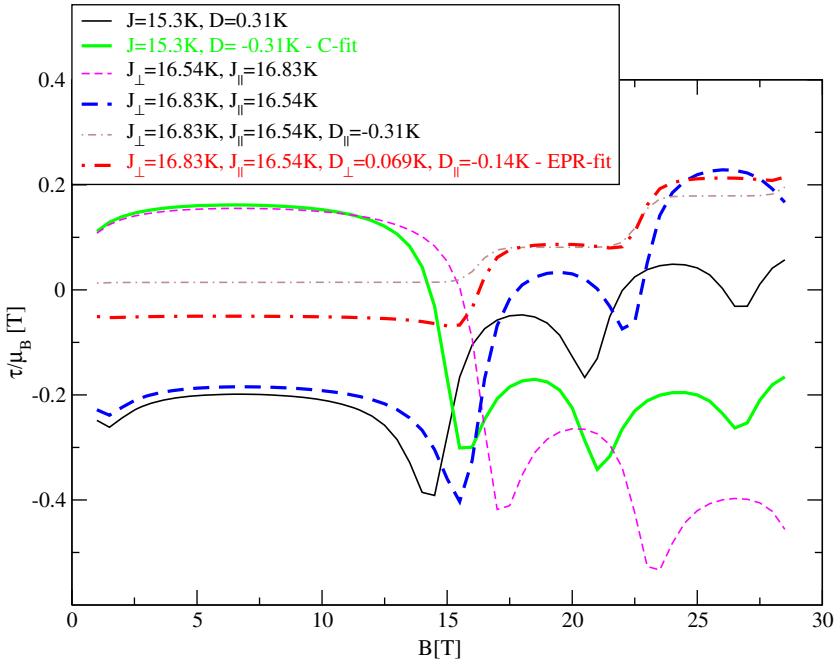

Fig. 4. Magnetic torque τ of Cr_7Cd calculated for pure and mixed anisotropies. $\theta = 5.5^\circ$ and $T = 0.4$ K.

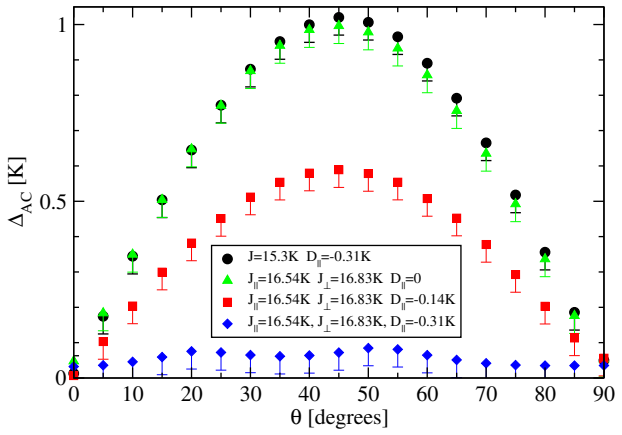

Fig. 5. Angular dependence of the first AC gap Δ_{AC} in Cr_7Cd calculated for few sets of parameters.

mixture however gives rise to qualitatively new behavior. It can be seen both on the level of measurable macroscopic quantities and on the level of the microscopic energy structure.

There remain many questions which are beyond the scope of this short communication. First of all it would be interesting to check whether this sort of quality change induced by mixing of two anisotropies can also be observed in models with different geometry/symmetry, e.g. in even membered or odd membered, but frustrated antiferromagnetic rings.

4. Conclusions

Starting from previously obtained theoretical results based on specific heat and EPR experiments we found two fits (a and b) to the measured by us magnetic susceptibility of polycrystalline Cr_7Cd. The a-fit assumes only single ion anisotropy, whereas the b-fit comprises a mixture of single ion and exchange anisotropy. Both fits are very good (the maximal deviation from the experiment is smaller than 2%) and none of them can be favored on the basis of a powder magnetic measurement. Therefore we calculated the magnetic torque for a mono crystal. We found that when only pure anisotropy (single ion or exchange) is present in the system the torque curves (torque versus magnetic field) have similar character. However if two types of anisotropy are taken into account and they are approximately of the same magnitude and different orientation (e.g. easy plane and easy axis) the properties of the system change significantly. The torque curves do not have characteristic peaks any more. On the microscopic level mixing of anisotropies corresponds to the vanishing of the AC gap between the ground and the lowest excited states and to a different splitting of first 3/2 and 5/2 multiplets.

Thus, in Cr_7Cd single ion and exchange anisotropy can lead to similar effects when existing in separation, but their mixture gives rise to qualitatively new behavior, both on the macroscopic and microscopic levels. On the basis of the torque experiment for a very similar compound (Cr_7Zn) we predict that there is no mixture of anisotropy in the Cr_7Cd, so the a-fit should be preferred to b. The definite answer to this question can be given by the torque experiment performed on a Cr_7Cd mono crystal.

Definitely more work on the interplay between single ion and exchange anisotropy in molecular magnets is needed. We hope to contribute to these efforts in the next paper where we are going to treat in more detail the problems discussed here and extend the discussion to other chromium-based rings, especially those with different geometry than Cr_7Cd.

colored/black precipitate was observed. It was then recrystallized from dimethyl sulfoxide (DMSO) over 2–3 week's period in the form of long black needles, suitable for single crystal X-ray diffraction. The small single crystalline product was directly obtained by slowly treating dilute solutions of TMPD and TCNB in benzene, giving yield over 90%. The precipitation from other solvents, like dichloromethane, chloroform, toluene, acetone, gave product indistinguishable with spectroscopic techniques.

3. Results and discussion

The crystal structure of the 1:1 complex formed between TMPD and TCNB has been determined by using single crystal X-ray diffraction at room temperature.[1] The complex crystallizes in the triclinic space group $P\bar{1}$ with cell dimensions: $a = 7.6772$ Å, $b = 8.0764$ Å, $c = 7.4986$ Å, $\alpha = 78.822°$, $\beta = 83.377°$, $\gamma = 86.289°$, volume 452.65 cm^3. The black color of these crystals ($1.0 \times 0.18 \times 0.1$ mm^3) suggests that there is a certain amount of charge transfer. The crystal structure of TMPD:TCNB reveals stacking of TMPD and TCNB molecules in infinite columns along the crystallographic *a*-axis, see Fig. 1.

Closer look at the crystal structure shows that along with this charge-transfer interaction, a prominent CN···HAr hydrogen bonded ribbon-like network is also present in a direction perpendicular CT interaction, see for detail Fig. 2. There are scarce of reports on the occurrence of CN···HAr hydrogen bonded network [12,14]. TCNB in the solid state exists as a dimer and its association is due to weak CN···HAr hydrogen bonding. I think, observed ribbon-like pattern is driven by charge-transfer interaction and its understanding is presently underway. On the other hand, presence of hydrogen bonded molecular tapes are common in literature, but they are normally observed through stronger synthon/synthons, and are rarely in electron donor–acceptor systems. In the present case, of CN···HAr hydrogen bonded ribbon network, distance observed between nitrogen of cyanide and hydrogen of neighboring aromatic carbon is 2.610 Å with angle of 147.19°. This is in agreement with the literature values for considering it as a weak hydrogen bonded interaction [12,14]. There is also a short distance interaction observed (as shown using dotted yellow line (see Fig. 2) amongst inter-ribboned TCNB molecules, which is at a distance of 2.935 Å with angle of 157.53°.

TCNB molecule is nearly planar with negligible deviation observed for the associated atoms from the mean plane. The TMPD molecule as a whole is not planar, but apart from the N-methyl groups, the rest of the atoms are nearly coplanar; the methyl groups are twisted away from the plane, as shown in Fig. 3a. The two molecules overlap each other with an interplanar spacing of 3.4 Å, though the molecular plane of the TCNB makes an angle of 7° with the mean plane passing through the phenylene ring and the two amine nitrogen atoms of TMPD. The two rings of TCNB and TMPD overlap only to a small extent contrary to Mulliken's prediction of large overlap of benzene rings in π-stacked complexes [15]. This is in accordance with the electronic orbital of the amine nitrogen atom, N(1), exhibiting tetrahedral character, and that the lone pair electrons of the nitrogen atom are not perfectly delocalized with π-electrons of the benzene ring. Thus, the structure does not show the usual π-π interaction between the two aromatic rings, but indicates n–π interaction localized between the nitrogen atoms of the donor and the cyano groups of the acceptor.

[1] The crystal analysis of the compound was carried out on a $1.0 \times 0.18 \times 0.10$ mm plate grown crystal. The data were collected with Mo Kα radiation with wavelength = 0.71073 Å, $T = 298$ K. Crystallographic coordinates and analysis summary in CIF format have been deposited with the Cambridge Crystallographic Database center (CCDC). Its reference number is CCDC 237161.

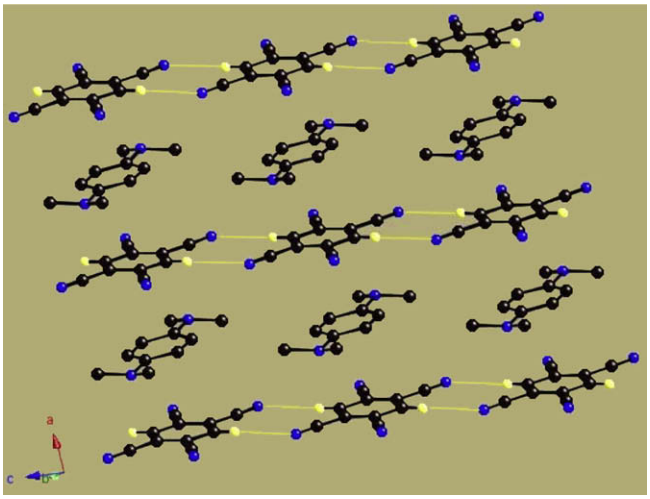

Fig. 1. Crystal packing of TMPD and TCNB molecules in TMPD:TCNB (C in black, H in off white, N in blue color; for clarity hydrogen atoms of TMPD are omitted). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

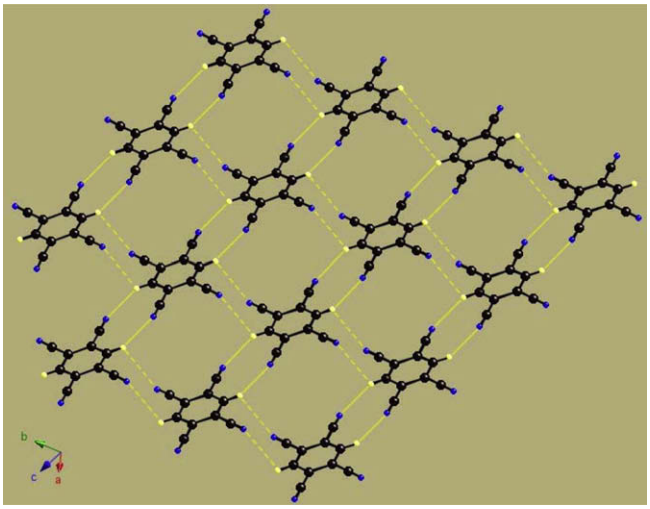

Fig. 2. Formation of ribbon-like network amongst TCNB molecules due to CN···HAr hydrogen bonding motif (shown in solid yellow line; dotted yellow line shows other close contacts amongst TCNB molecules). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

As shown in the Fig. 3b, the component molecules are tightly packed: the methyl groups of TMPD lie between the two cyano groups of TCNB, thus the TCNB molecule appears to be held together by the methyl groups. Consequently, the two N-methyl groups are closer to the ring carbon atoms of the TCNB molecule with the associated C–C distances of 3.502 and 3.620 Å. In the structure of TMPD–TCNQ complex [16,17] (TCNQ = 7,7,8,8-tetracyanoquinodimethane) however, the methyl groups do not affect the relative orientation, because of the geometry of TCNQ molecule. Also, the electron affinity of TCNQ is much larger than that of TCNB (0.17 eV; reversible in acetonitrile at room temperature versus SCE) which facilitates stronger π–π interaction for TCNQ than in the present complex. These facts indicate that the relative orientation of the two component molecules in the present complex is mainly determined by the packing of the molecules. On the basis of the observed short intermolecular distances, one can say that the lone pair electrons of the amine nitrogen atoms are partially

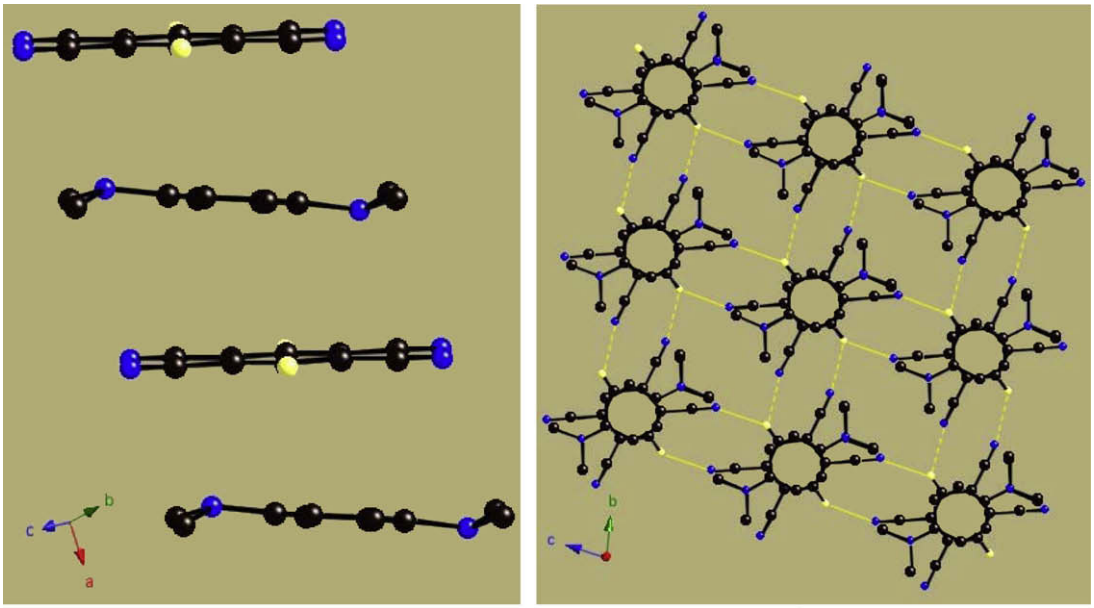

Fig. 3. The stacking of TMPD and TCNB molecules (a) showing tetrahedral nature of nitrogen and bending of dimethyl groups attached to phenylene nitrogen in TMPD and (b) showing tight packing of the N,N-dimethyl groups of TMPD and cyanide groups of TCNB.

transferred to the cyano groups through n–π interaction. The presence of n–π charge transfer is also supported by molecular orbital calculation showing the carbon atom of the cyano groups in a free molecule of TCNB is deficient in electron density [17].

Temperature dependent magnetic susceptibility χ measurements were carried out using a SQUID magnetometer on a powdered TMPD:TCNB. Fig. 4 shows a plot of product of χ (with the temperature independent diamagnetic contribution subtracted) and temperature versus temperature. Since $\chi = H\mu_{\text{eff}}^2/3kT$ where N is Avogadro's number, μ_{eff} is the effective magnetic moment ($\mu_{\text{eff}}^2 = g^2\mu_B^2 S(S+1)$) in Bohr magnetons, and k is the Boltzman constant, then, for a simple Curie law paramagnet, χT is constant. However, I observed an increase of χT as a function of temperature. This behavior indicates that short range antiferromagnetic interactions at higher temperatures between the stacked TMPD and TCNB radical ions, as has been observed in other charge-transfer complexes [18]. Thus, this data shows that in contrast to the diamagnetic precursors, the complex is magnetic, indicating substantial charge transfer.

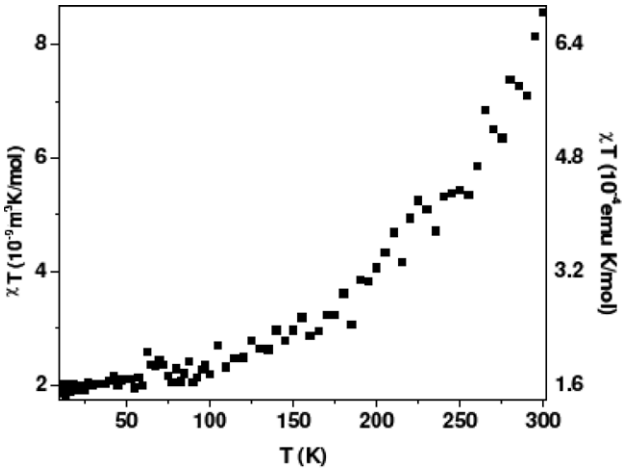

Fig. 4. Temperature dependent magnetic behavior of solid TMPD:TCNB.

Also, room temperature EPR data on powdered TMPD:TCNB shows two peaks, $g_\perp = 2.0009$ and $g_{||} = 2.0022$: the peak to peak linewidth, ΔH_{pp}, is 0.06 mT for $g_\perp$ and the width at half height, $\Delta H_{1/2}$, is 0.09mT for $g_{||}$ [13]. This result conforms TMPD:TCNB is magnetic and compares well to the literature g-values for the radical anions of ~2.002 for the similar acceptors like TCNQ and TCNE [19].

4. Conclusion

TMPD:TCNB complex showed presence of two distinct non-covalent interactions: (i) charge-transfer interaction and (ii) ribbon-like CN···HAr hydrogen bonding motif amongst electron acceptor molecules, which show interesting magnetic behavior. This latter type of hydrogen bonding interaction amongst electron acceptor molecules is a crucial element for engineering useful electron donor–acceptor type compounds without changing drastically electron donor or acceptor molecules. Although hydrogen bonding is a useful means to organize crystal scaffolding, its electronic effect on bulk magnetic and exchange behavior is not always straightforward to predict. Presently, I am expanding research to build new types of crystalline materials using non-covalent interactions amongst electron acceptor molecules, in the form of flexible host assemblies, and their possible magnetostructural relationship.

Scheme 1. Structures of Schiff base ligands described in the main text.

Figs. 1 and 2 show crystal structures of two complexes. Both complexes crystallized in triclinic crystal system with space group $P\bar{1}$, and each unit cell involves two molecules related by the inversion center. In each complex, the Schiff base ligand $\mathbf{L3}^{2-}$ behaves as tetradentate O_2N_2 ligand for Cu(II) ion and tetradentate O_4 ligand for Tb(III) ion, and Tb and Cu are doubly bridged by two phenoxo oxygens (O2 and O4). O_2N_2 donor atoms are almost coplanar (maximum deviations from ideal planes are 0.0030(19) and 0.104(3) Å, respectively), and each Cu atom is located on the plane with deviations of 0.1385(19) and 0.103(3) Å, respectively. Coordination distances are in a range of 1.957(3)–1.989(4) Å for **3** and 1.954(4)–1.975(6) Å for **4**, and each apical position of the Cu atom is occupied by water oxygen atom (O14) or nitrate oxygen atom (O12) with the distances of 2.299(4) and 2.405(5) Å, respectively. Both Cu atoms in **3** and **4** are in an axially elongated pyramidal coordination, and the magnetic orbital ($d_{x^2-y^2}$) of Cu(II) ion with d^9 electronic configuration is located on the equatorial plane directing toward four donating atoms. The Schiff-base ligands are slightly bending from the O_2N_2 plane, with the dihedral angles of two phenyl rings being 21.5(2)° and 43.1(3)°. In the O_4 site of the ligand, four donor atoms are also arranged in a quite flat manner (maximum deviations from the ideal planes are 0.009(2) Å (**3**) and 0.065(3) Å (**4**)), and the Tb(III) are located 0.711(3) Å (**3**) and 0.6262(19) Å (**4**) above the planes, with the bonding distances ranging in 2.331(3)–2.495(3) Å for **3** and 2.333(4)–2.589(5) Å for **4**, respectively. The bridging angles of Tb–O–Cu were found to be 107.48(13)° and 108.35(13)° for **3** and 106.94(19)° and 107.06(19)° for **4**, and as a result, the core structures of $\{TbCu(\mathbf{L3})\}^{3+}$ moieties are quite similar in both complexes. Tb in **3** were further coordinated by three nitrate anions in a bidentate manner to complete the deca-coordination. The coordination modes are unsymmetrical among three nitrate anions; one is parallel to the Tb–Cu axis whereas two are skew to the axis. Consequently, the coordination geometry of Tb(III) ion can be assumed as a square-antiprism capped by two methoxo oxygen atoms (O1 and O3) with quite large distortion, which would be advantageous to realize an SMM character. In **4**, the nona-coordination of Tb(III) ion was completed by three additional ligands, a nitrate anion (O5 and O6) and an *o*-vanilate anion (O9 and O10) both in a chelating fashion, and a methanol molecule (O11) in a monodentate fashion. The phenoxo oxygen of the *o*-vanilate anion (O9) is collinear with Tb(III) and Cu(II) ions, and located on the opposite side of the two phenoxo oxygens of $\mathbf{L3}^{2-}$. As was described in the previous paper, the negative charge distribution of phenoxo oxygen atom is larger than other oxygen donors such as oxygen atom(s) in a nitrate anion, a methoxo group, and also a methanol molecule. Consequently, the axial positions of Tb(III) is occupied with more negative phenoxo oxygen atoms (O2, O4, and O9) and the equatorial positions were occupied by less negative oxygen donors (O1, O3, O5, O6, O10, and O11). The uni-axial crystal filed found in **4** might be advantageous for the enhancement of the easy-axial magnetic anisotropy of Tb(III) ion.

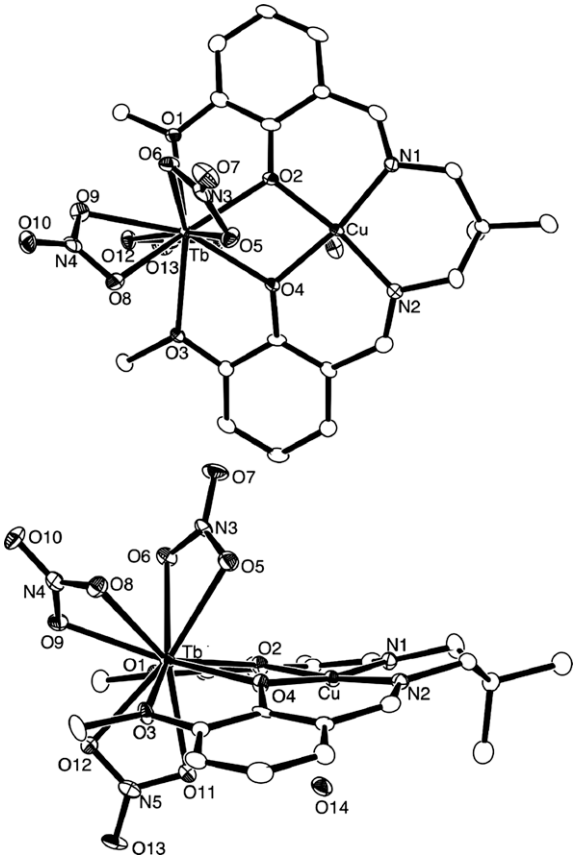

Fig. 1. Top view (upper) and side view (bottom) of ORTEP drawings of the complex **3** at 50% probability. Hydrogen atoms are omitted.

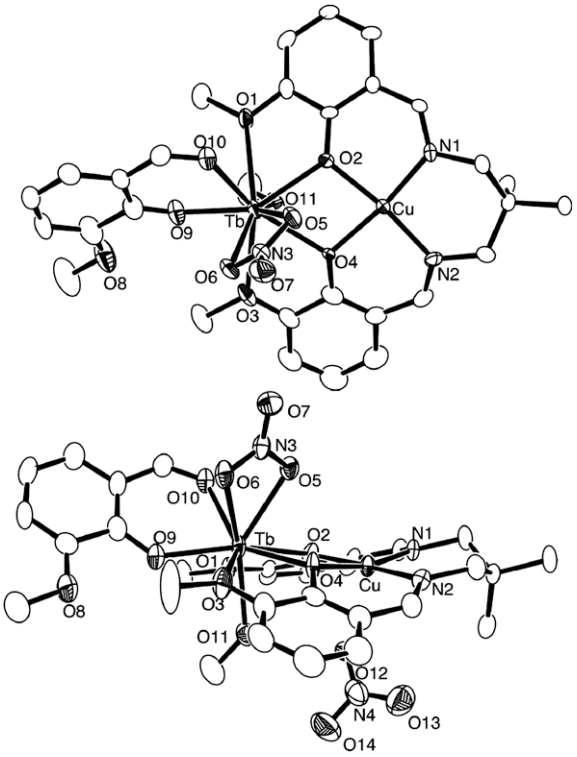

Fig. 2. Top view (upper) and side view (bottom) of ORTEP drawings of the complex **4** at 50% probability. Hydrogen atoms are omitted.

Dc susceptibility data were collected for poly crystalline samples of **3** and **4** (Fig. 3). The $\chi_M T$ values at room temperature, 13.06 (**3**) and 13.50 emu K mol^{-1} (**4**), were slightly larger than the expected value of 12.19 emu K mol^{-1} for magnetically independent Tb(III) ($J = 6$ and $g_{Tb} = 3/2$) and Cu(II) ($S = 1/2$ and $g_{Cu} = 2.0$) ions. The $\chi_M T$ gradually increased on lowering the temperature, which indicates the presence of weak ferromagnetic interactions between Tb(III) and Cu(II), as well as the presence of strong anisotropy of Tb(III) ions.

Ac magnetic susceptibility measurements were performed to observe the frequency dependence of χ'_M and χ''_M (Figs. 4 and 5). Both complexes showed a typical SMM behavior below 5 and 6 K. As the frequency was swept from 997 to 5 Hz, the temperature of maximum χ''_M shifted from 3.3 (997 Hz) to 2.0 K (5 Hz) for **3** and

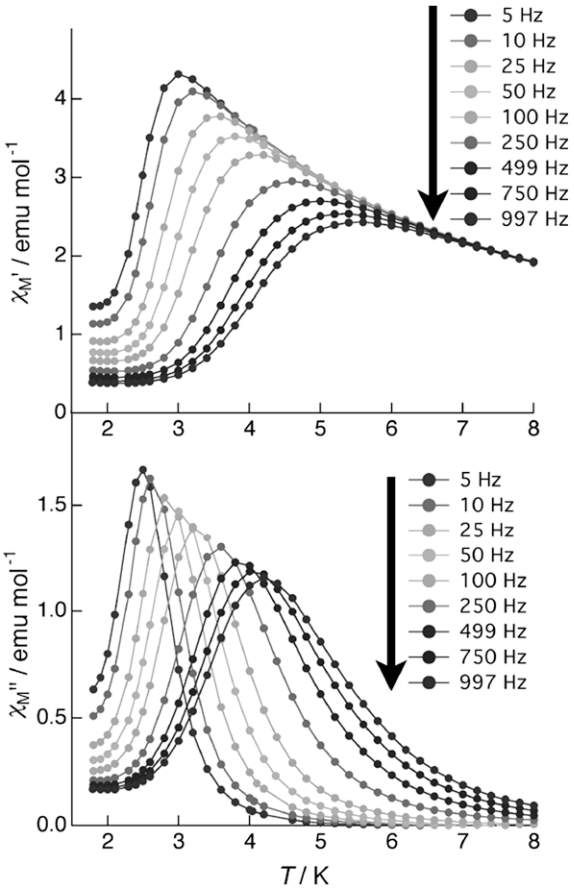

Fig. 5. Temperature dependences χ'_M (top) and χ''_M (bottom) of **4** measured in 1000 Oe external dc field.

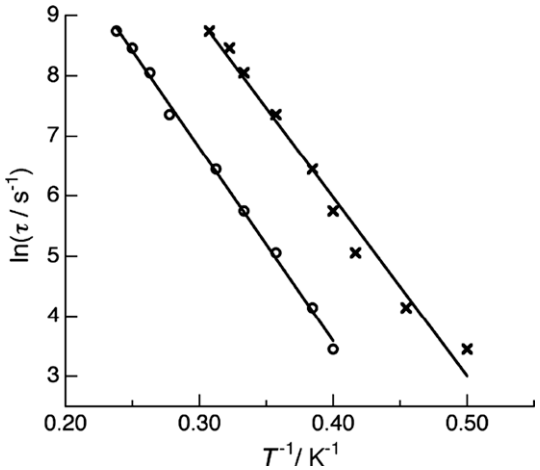

Fig. 6. Arrhenius plots of **3** (×) and **4** (o).

from 4.2 (997 Hz) to 2.5 K (5 Hz) for **4**, respectively. These observations indicate the presence of slow magnetic relaxations at low temperatures. Cole–Cole plots for **3** at the temperature range of 2.8–4.0 K showed semi-circle shapes with α parameters in the ranges of 0.27–0.41. Complex **4** showed smaller α parameters of 0.11–0.32 at the temperature range of 2.8–5.2 K. Complex **4**, having the smaller α-*values* in the wider temperature range, could be assumed as a better SMM compared with **3**. The energy barrier Δ/k_B, for the spin flipping in **3** and **4**, were estimated from the Arrhenius plot to be 29(2) and 32.2(6) K, respectively (Fig. 6). These values were larger than the previous complex **1**, which indicates the presence of larger magnetic anisotropy of Tb(III) in **3** and **4**. In **3**, the χ'_M below 3.0 K were reaching constant values and χ''_M below 2.5 K are increasing again, which is indicative for the presence of inter molecular interactions, reflecting on the larger α-*values* of 0.41 at 2.8 K. In fact, hydrogen bonding between terminal oxygen atom of nitrato anion and apical water molecule (O14 and O10$*$, 2.83 Å) was found in **3**, which could propagate a weak interaction between the adjoining molecules. In **4**, the balky *o*-vanilate anion prevents inter-molecular interaction which resulted into smaller α -*values* in wider temperature range (0.32 at 2.8 K).

From DFT calculations carried out for **1** and **2**, the negative charge distributions of the donor oxygen atoms were estimated that the Mulliken charge of phenoxo oxygen was larger than those of nitrate and methoxo oxygen atoms about twice in magnitude. The introduction of the phenoxo ligand on the Tb(III) ion at the opposite position from bridging phenoxo oxygens, which was found in **4**, would be effective to realize the uni-axial arrangement of negative charges, which also might enhance the easy-axis anisotropy of Tb(III) ion.

In conclusion, we have synthesized two Tb–Cu di-nuclear complexes both behaving as SMMs, to discuss the relationship between coordination morphology and the magnetic anisotropy. Tb(III) in **3** is in a more unsymmetrical crystal field compared with **1**, and as a result, **3** possesses higher barrier Δ/k_B compared with **1**. Tb(III) ion in **4** is located in an axial crystal field formed by two phenoxo oxygen atoms from $\mathbf{L3}^{2-}$ and one *o*-vanilate oxygen atom located on opposite sites around Tb(III) ion, and **4** showed large Δ/k_B. The larger Δ/k_B values can be explained by the enhancement of the easy-axis anisotropy of Tb(III) in a less symmetrical coordination (**3**) or uni-axial crystal field (**4**). The results here provide a useful guideline for designing the magnetic anisotropy of lanthanide ions, yielding novel SMM and single-chain magnet (SCM) families.

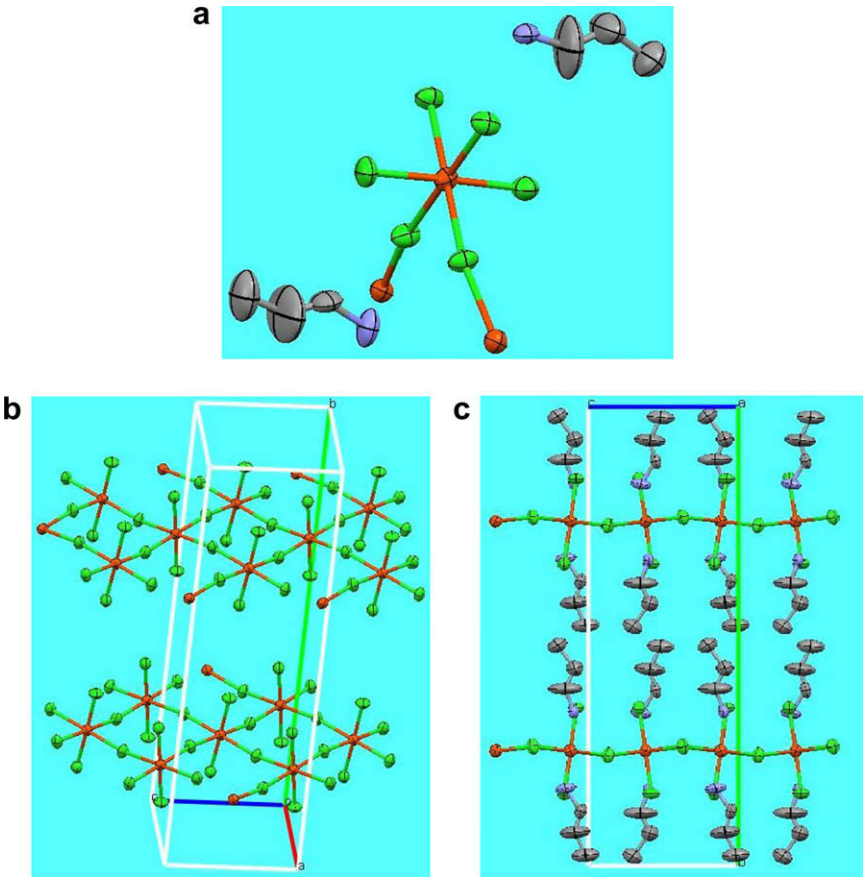

Fig. 1. Crystal structure of $(C_3)_2$–$FeCl_4$ showing, (a) asymmetric unit; (b) inorganic 2D network of $FeCl_4$ octahedra along *ac*-plane and (c) intercalation of organic ammonium salt in inorganic layers.

$b = 7.439(9)$ Å, $c = 25.303(8)$ Å with unit cell volume of 1359.95 cm^3, at room temperature. The structure parameters were refined with least square process to $R_1 = 0.067$. The overall structure consists of two-dimensional Fe(II)–chloride network, parallel to the *ac*-plane, interlayered by the ammonium ions with mirror plane perpendicular to the *a*-axis. The principal feature of interest in these structures is the Fe(II)–chloride layer as illustrated in Fig. 1b. In the layer, Fe–Cl distances (the four bridging chlorine atoms) are longer (2.587, 2.618 Å) than the two terminal Fe–Cl (2.364 Å) distances making compressed octahedral geometry around metal ions. Each octahedron shares four corners with neighboring octahedron in the layer to form a square 2D sheet. The Fe(II) ions occupy $2/m$ symmetry. The Fe–Cl–Fe bridges are symmetrical, but, as it is readily seen in Fig. 1, the bridging Fe–Cl–Fe angle (169.74°) is not linear. Therefore, the octahedra are alternately tipped forward and backward to produce the familiar puckering of the layer.

Each ammonium hydrogen atom participates in hydrogen bond to the chlorine atom in Fe–Cl layer. This not only ties down the NH_3^+ groups, for smaller liberational motion than the rest of ions, but possibly helps in puckering, that means altering Fe–Cl–Fe angle. Though, the latter effect looks smaller, it may have significant effect upon the interlayer exchange coupling since superexchange arguments predict the strength of the magnetic interaction should be dependent on the Fe–Cl–Fe bond angle. Thus, because of presence of stronger hydrogen bonding network N–H···Cl, there is virtually no contact between adjacent cations in the structure and it can be viewed as organic–inorganic hybrid layered structure.

The magnetic susceptibilities for both the compounds (both in single crystal and bulk form) were measured using SQUID magnetometer, in the 5–300 K range. Fig. 2a shows, representative temperature dependence of χT {zero-field cooled (ZFC) and field cooled (FC)} versus temperature measured at 10 and 1000 Oe for $(C_4)_2$–$FeCl_4$. The $\chi_{mol}T$ value, at 300 K was found out to be 2.5 emu K mol^{-1} (less than expected 3.0 emu K mol^{-1}, for high spin Fe^{2+} ions) decreases with decreasing temperature down to a minimum value of 1.1 emu K mol^{-1} at around 90 K. Upon further cooling $\chi_{mol}T$ value increases to a rounded maximum at about 90 K and then decreases on further cooling. Both compounds show similar behavior, where these features indicate a global antiferromagntic interaction. While, in the ZFC–FC magnetization measurements carried out with an applied field of 500 Oe as shown in Fig. 2b, we observed the onset of long range magnetic ordering below ~90 K.

Fig. 2c represents $M(H)$ curve taken at 85 K, on increasing the field from zero, we observed initial steep increase in the magnetization in a low field region, to a value much smaller than full Fe(II) moment. Subsequently, linear field dependence is found till 50 kOe. This behavior is of typical weak ferromagnet, where the steep increase at low H reflects spontaneous magnetization and the linear high-field behavior is due to the dominant antiferromagntic interactions. Large coercive field (3 kOe) classifies this compound as a hard magnet. Along with this, high remnant magnetization, $0.56\mu_B$ (corresponds to 11.53% canting) makes it among largest canted weak ferromagnets, which might be due to the competition between the local anisotropy vis-a-vis the antiferromagntic interaction [15].

We carried out some preliminary experiments on temperature dependence of AC-dielectric property using AG 4311B, Ando instrument, in the range 150–450 K. Fig. 3 shows permittivity

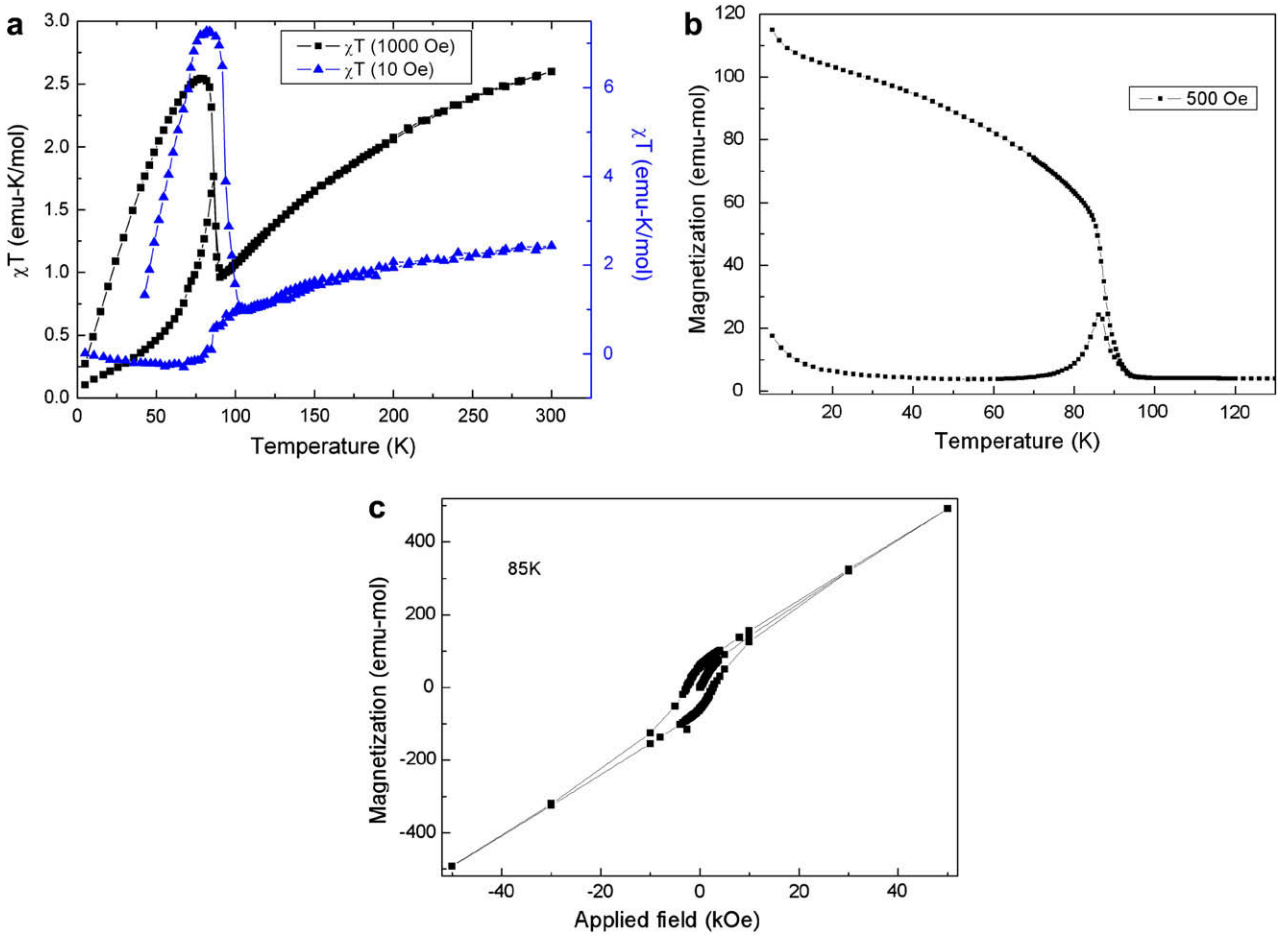

Fig. 2. Temperature dependent magnetic measurements on $(C_4)_2$–$FeCl_4$ (a) field dependent χT, (b) zero-field cooled–field cooled magnetization carried out at 500 Oe and (c) hysteresis taken at 85 K.

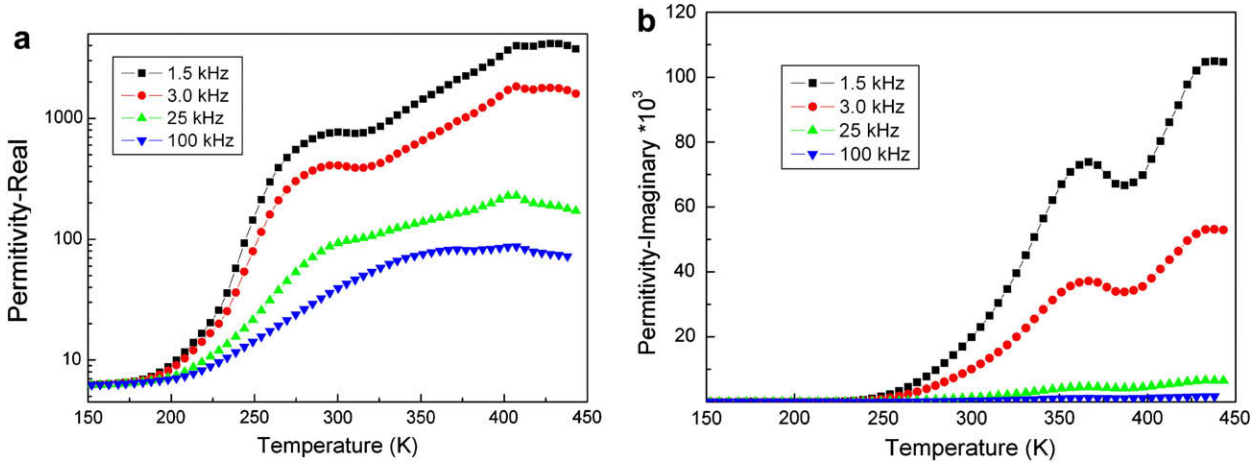

Fig. 3. Temperature dependent (a) real and (b) imaginary parts of the complex electric permittivity measured on polycrystalline $(C_4)_2FeCl_4$ at different frequencies.

versus temperature plot, for selected frequencies 1.5, 3.0, 25, 100 KHz, for $(C_4)_2FeCl_4$ compound. Both, imaginary as well as real permittivity show continuous increase of permittivity with increase in temperature, with a big hump around 300 K and a broad peak around 430 K. It is also clear that at higher temperature permittivity is frequency dependent. More detailed analysis is under investigation to understand the origin of the peak due to water absorption–desorption process, because of the moisture/water sensitive nature of the compounds [4,16]. DSC measurements carried out on $(C_4)_2FeCl_4$ have shown presence of reversible peak,

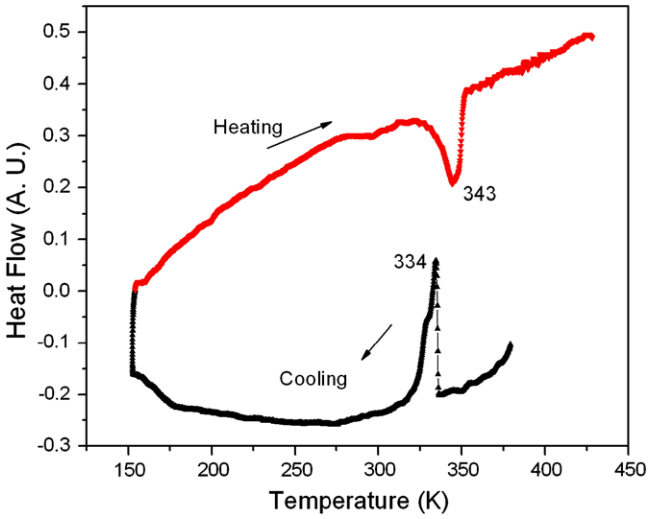

Fig. 4. DSC measurements on $(C_4)_2FeCl_4$.

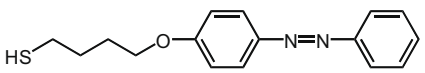
indicating phase transition around 350 K, with a small hysteretic behavior (see Fig. 4). To confirm our findings, we carried out conductivity and DSC measurements on $(C_2)_2FeCl_4$, which is studied in literature [13] for, its ferroelastic behavior below 320 K and, they have been predicted ferro or antiferroelectric behavior below 200 K. $(C_2)_2FeCl_4$ showed a phase transition at 200 K, similar to observed for $(C_4)_2FeCl_4$ at 350 K using DSC. Single crystal study at various temperatures were carried out, but due to the very thin plate like nature of crystals, structure determinations became difficult, but no apparent phase transition is observed at lower temperature as is for $(C_2)_2FeCl_4$. In short, the obtained relative permittivity and DSC data can be explained by proposing a ferro or antiferroelectric state below 350 K, triggered due to electronic, ionic and/or deformational polarization. There is also possibility that these compounds are ferroelastic above RT. More detailed studies are going on to understand this behavior.

In summary, we have succeeded in synthesizing a new family of layered organic–inorganic hybrid weak ferromagnets with a ferro or antiferroelectric behavior. All of these compounds form plate like transparent, yellow-orange colored single crystalline products, and have thus imparting added advantage for magneto-optical behavior [17,18]. More studies using single crystals are in progress to understand role played by the alkyl ammonium compounds, especially in the driving asymmetric structure by the use of non-covalent interactions. For this reason we are also working on chiral ammonium salts [19,20]. Thus, a new route is opened to synthesize novel multiferroic materials in the form of layered structure.

Supplementary data



Crystal structure of $C_6H_{20}Cl_4N_2Fe$, $M = 316$, orthorhombic, space group $Cmc2_1$, $a = 7.223(9)$ Å, $b = 7.439(9)$ Å, $c = 25.303(8)$ Å, $V = 1359.95$ cm^3, $\lambda = 0.71609$ Å, a total of 6321 reflections were collected, and 2080 were unique. R_1 and wR are 0.067, and 0.1829, respectively. Crystallographic coordinates and analysis summary in CIF format have been deposited with the Cambridge Crystallographic Database center (CCDC). Its reference number is CCDC 721801. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

AZ

2.2. Synthesis of AZ–Au NPs (AZ-passivated gold nanoparticles)

AZ–Au NPs were synthesized by a process based on the Brust method [13] with two different Au/S ratios. An Au/S ratio of 1:2 was used to synthesize relatively smaller AZ–Au NPs while an Au/S ratio of 2:1 was used for relatively larger AZ–Au NPs. The detailed procedure is as follows. An aqueous solution of hydrogentetrachloroaurate(III)hydrate (9 mg, 0.00228 mmol) was added dropwise to a stirred solution of tetraoctylammonium bromide (0.056 g, 0.102 mmol) in 5 mL toluene. AZ (7.1 mg, 0.0228 mmol or 1.5 mg, 0.0057 mmol) in 2 mL toluene was added to the above solution. After 1 h, an aqueous solution of sodium borohydride (9 mg, 0.23 mmol) was added dropwise and stirred for a further 3 h. The toluene phase was collected and suspended in methanol (100 mL). It was kept in a refrigerator overnight. This was centrifuged at 8000 rpm for 30 min at ambient temperature and the supernatant liquid was discarded. The precipitate that was obtained was again dispersed in methanol and the process was repeated three times to remove any unbound AZ.

2.3. Physical methods

The UV–Vis absorption spectra were recorded on a V-560 spectrometer (JASCO). UV illumination (filtered light, λ_{max} = 360 nm, 1.0 mW cm^{-2}) was applied with an ultra-high pressure mercury lamp (HYPERCURE 200, Yamashita Denso). Visible light (400–700 nm, 1.0 mW cm^{-2}) was provided by a xenon lamp (XFL-300, Yamashita Denso). The XPS spectra were obtained on a JPS-9000MC (JEOL) using an Al Kα line source. The X-ray diffraction patterns were recorded on a RAD-C (RIGAKU) using Ni-filtered Cu Kα radiation. The XANES were recorded using a spectrometer installed in BL39XU at the SPring-8 Synchrotron Radiation Facilities. The magnetic properties were investigated with a SQUID magnetometer (model MPMS-XL Quantum Design). The lamps were guided into the SQUID magnetometer by an optical fiber to study the photo-magnetic effects. Measurements of the work function were performed in KFM mode with a SPM-9600 (Shimadzu).

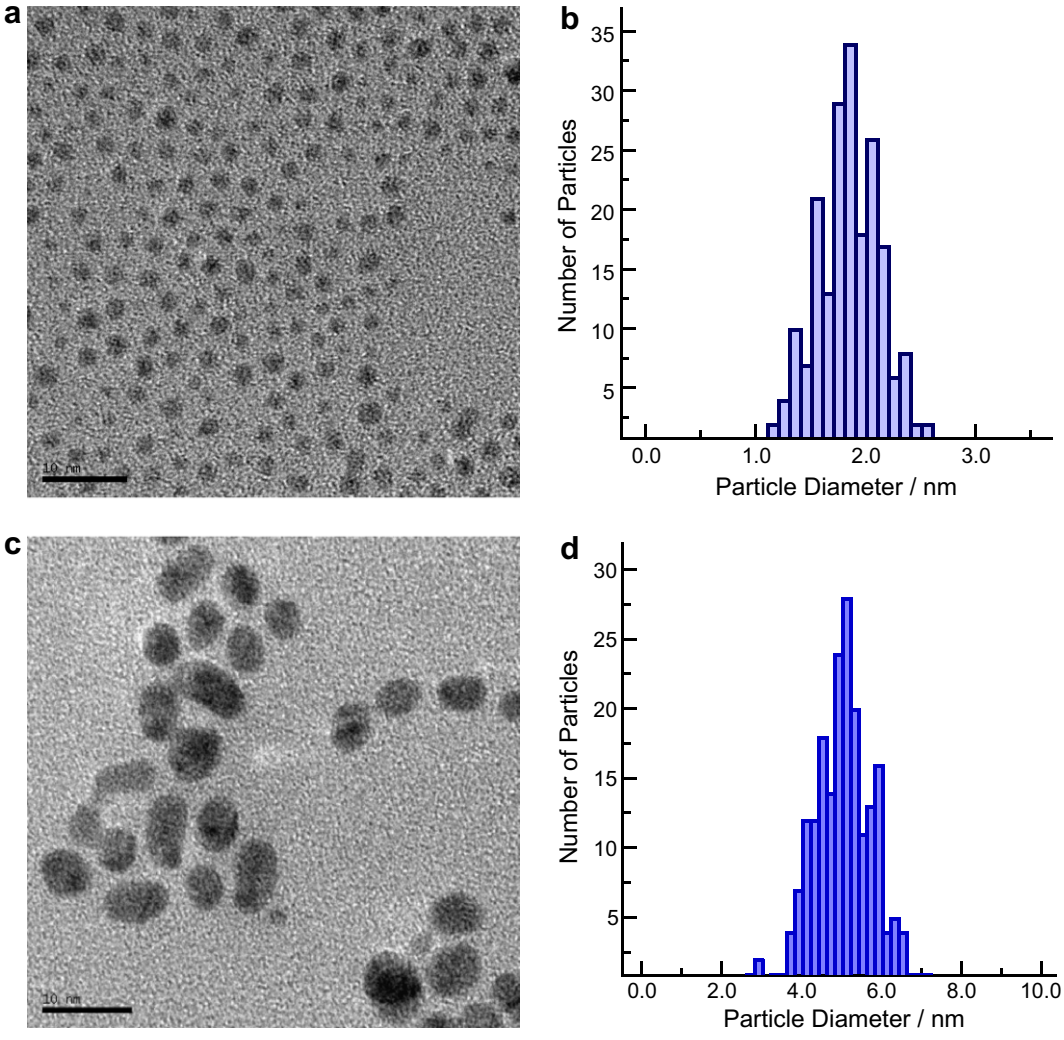

Fig. 1. (a) TEM micrograph and (b) size distribution histogram of AZ–Au NPs synthesized with an Au/S ratio of 1:2. (c) TEM micrograph and (d) size distribution histogram of AZ–Au NPs synthesized with an Au/S ratio of 2:1; scale bar = 10 nm.

3. Results and discussion

3.1. Basic characterization of AZ–Au NPs

Fig. 1 shows TEM images and size distribution histograms for the AZ-passivated gold nanoparticles (AZ–Au NPs) synthesized with Au/S ratio of 1:2 and with Au/S ratio of 2:1 deposited from a toluene dispersion onto a collodion coated copper grid. The AZ–Au NPs synthesized with Au/S ratio of 1:2 present a narrow size distribution with an average size of 1.7 nm ± 0.3 nm while the AZ–Au NPs synthesized with Au/S ratio of 2:1 present a relatively larger average size of 5.0 nm ± 0.8 nm. Here after each average size of AZ–Au NPs is denoted as AZ–Au NPs 1.7 and AZ–Au NPs 5.0, respectively. The reason of anisotropic shapes of AZ–Au NPs 5.0 is not clear at present. However, the percentage of the "odd" shapes nanoparticles is not substantial. Hence, the presence of anisotropic shapes particles would not be a big problem for following discussion.

The powder X-ray diffraction pattern of each AZ–Au NPs (Fig. 2) is consistent with a face-centered cubic crystal structure for the Au, with lattice constant $a = 2.33$ Å. The average particle size determined from the instrument corrected width β using the Scherrer relation: $D = K\lambda/\beta\cos\theta$ is 1.8 nm for AZ–Au NPs 1.7 and 5.2 nm for AZ–Au NPs 5.0 nm, which were in good agreement with the results from the TEM studies.

Fig. 3 shows the XANES spectra of the Au L_3-edge for the AZ–Au NPs 1.7 nm, AZ–Au NPs 5.0 nm and bulk-Au (foil). Typical XANES spectra of an fcc gold structure exhibit patterns with three peaks within the first 40 eV above the edge. The first resonance at the threshold associated with $2p_{3/2}$ to $5d_{5/2}$, $_{3/2}$ dipole transitions probes the density of the unoccupied d states (d-hole counts) at the Fermi level [14]. Although the 5d orbitals of bulk-Au are nominally full, a small concentration of itinerant holes at the d band can be detected in the XANES spectra of bulk-Au due to s–p–d level hybridization. In the case of the AZ–Au NPs 5.0, a small increase in the threshold resonance was detected when compared to the bulk-Au, indicating a little loss in 5d electron density due to d-charge transfer from the gold to the sulfur atoms. Furthermore, in the case of the AZ–Au NPs, the threshold resonance was significantly increased even when compared to the AZ–Au NPs 5.0, indicating the increase in specific surface area due to the size reduction that introduced a noticeable loss in 5d electron density.

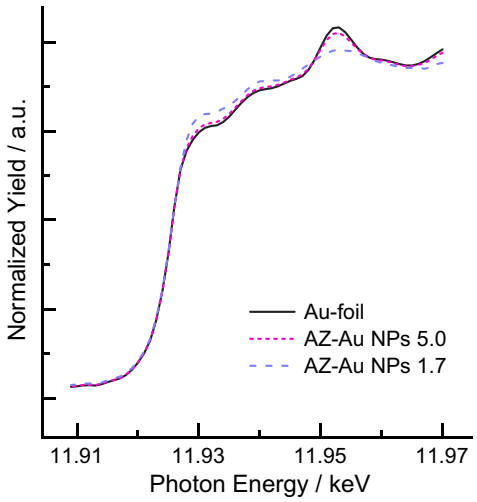

Fig. 3. Au L_3-edge XANES spectra for the AZ–Au NPs 1.7 (dashed line), the AZ–Au NPs 5.0 (dotted line) and gold foil (solid line).

3.2. Magnetic properties of AZ–Au NPs

The magnetization curves (M–H plots) measured at 300 K for AZ–Au NPs 5.0 and AZ–Au NPs 1.7 are shown in Fig. 4. The AZ–Au NPs 5.0 exhibit a diamagnetic behavior, similar to that of bulk gold (not shown here). On the other hand, typical hysteresis loops with coercivity (H_c) and remanent magnetization (M_r) were observed for AZ–Au NPs. The values of H_c and M_r were 100 G and 0.031 emu g_{Au}^{-1} at 300 K.

3.3. Optical absorption spectra of AZ–Au NPs

The photoisomerization of the AZ–Au NPs 5.0 and the AZ–Au NPs 1.7 in the solid state at room temperature were monitored by UV–Vis absorption spectroscopy (Fig. 5). Each spectrum of the initial state gave an intense absorption peak at 360 nm, which is ascribed to the π–π^* transition in the trans-isomer of the AZ ligands. After UV illumination of the AZ–Au NPs 5.0 for 1 min, the absorption at 360 nm decreased, suggesting the trans-to-cis photoisomerization of AZ occurred. Following subsequent illumi-

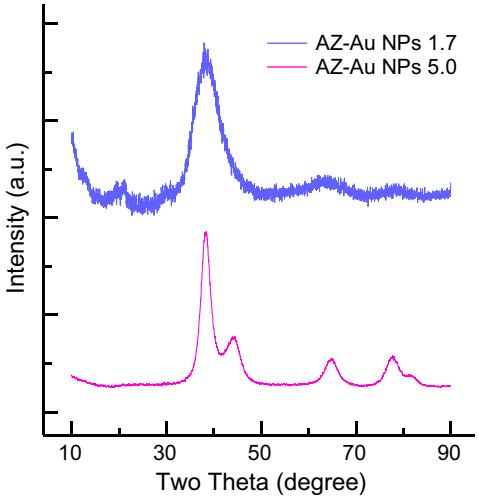

Fig. 2. XRD pattern for the AZ–Au NPs 1.7 (top line) and for the AZ–Au NPs 5.0 (bottom line).

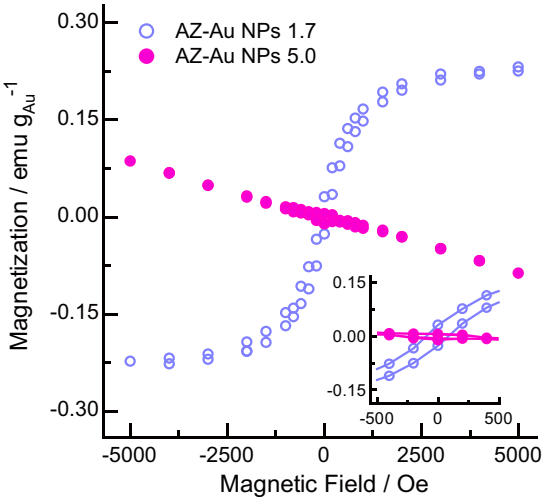

Fig. 4. Plot of magnetization M vs. applied magnetic field H at 300 K for the AZ–Au NPs 1.7 (open circles) and the AZ–Au NPs 5.0 (closed circles).

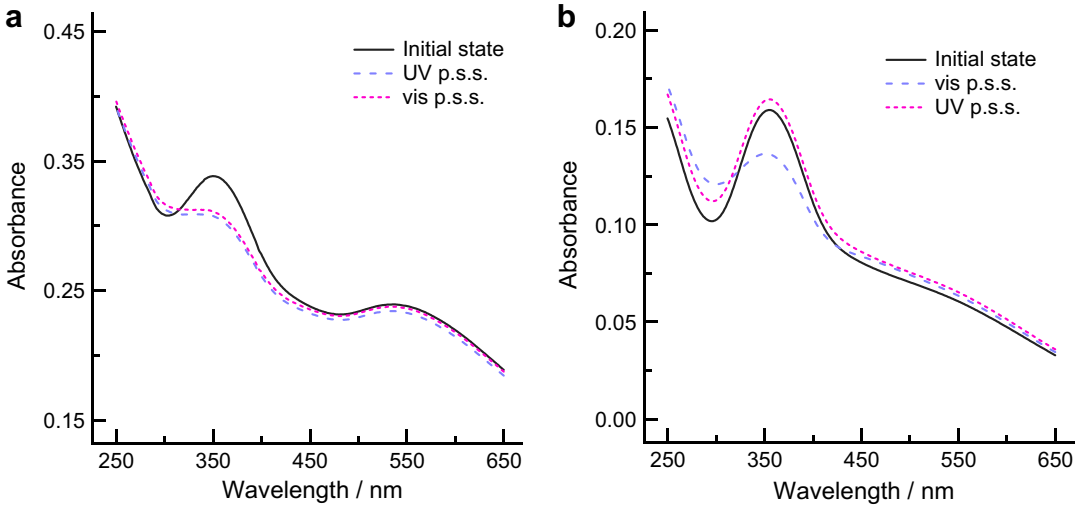

Fig. 5. Changes in the optical absorption spectra for the AZ–Au NPs 5.0 (a) and the AZ–Au NPs 1.7 (b) due to photoisomerization. The initial trans-state (solid line) was first illuminated with UV light for 1 min (dashed line). It was then illuminated with visible light for 1 min (solid line).

nation with visible light, the absorption at 360 nm showed almost no spectral changes, suggesting the cis-to-trans photoisomerization did not occur.

In the case of the AZ–Au NPs 1.7, the absorption at 360 nm also decreased after UV illumination of the trans-isomer for 1 min. Following subsequent illumination with visible light, the absorption at 360 nm increased again. After the second cycle, the cis-trans photoisomerization was repeated without any attenuation of the area between the curves. These reversible spectral changes indicate high-efficiency reversible photoisomerization, even in the solid state.

Normally, photoisomerization of azobenzene-containing compounds does not occur in the solid state because of the large volume changes that are involved [15]. In fact, reversible photoisomerization also does not occur in the absence of spacers when azobenzene-containing ligands are self-assembled on two-dimensional gold films [16]. The same tendency was also reported for azobenzen-passivated gold nanoparticles with average particle size of ca. 5.0 nm [17], that is consistent with observed phenomena for AZ–Au NPs 5.0. However, in the current system with its average particles diameter of 1.7 nm, reversible photoisomerization was observed in the solid state with high efficiency.

From the above observations, it is proposed that the decrease in particle size provided free volume between each of the AZ ligands because the adjacent angles between two neighboring AZ ligands would be increased with decreasing particle size. The average distance between two neighboring nitrogen double bonds on the AZ ligands could be estimated as 7.7 Å for the AZ–Au NPs 5.0, while it was 13.0 Å for the AZ–Au NPs 1.7. Fig. 6 shows a schematic illustration (not to scale) of geometric framework for the AZ–Au NPs 5.0 and the AZ–Au NPs 1.7.

Another important remark concerning the optical absorption spectra of AZ–Au NPs 1.7 (Fig. 5b) is almost no surface plasmon resonance around 550 nm despite the observation of significant surface plasmon resonance for the AZ–Au NPs 5.0, indicating the strong Au–S interactions make the 5d electrons of the core gold nanoparticles behave as partially-localized holes that have lost itinerancy [7a,14], because of the high-specific surface area for AZ–Au NPs 1.7.

The above observations are consistent with the observed d-charge transfer derived from the results of the XANES measurements and the observed ferromagnetism from the SQUID measurements. After all, reducing the particle size to 1.7 nm enhances not only the magnetic properties, but also the photo-responsibilities of the AZ–Au NPs.

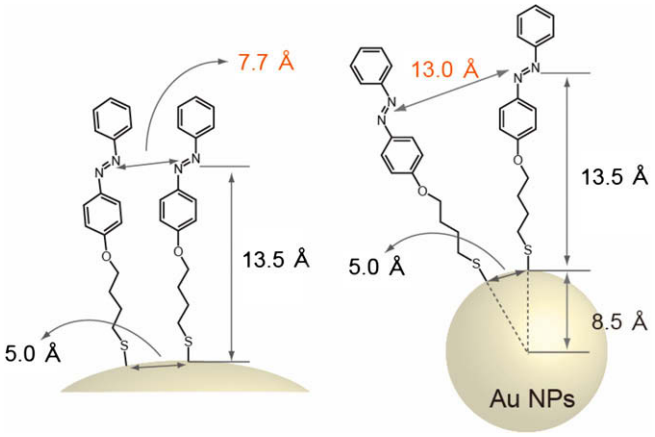

Fig. 6. Schematic illustrations (not to scale) of geometric framework for the AZ–Au NPs 5.0 (left) and the AZ–Au NPs 1.7 (right).

3.4. Photo-magnetic effects

Subsequently, we investigated the influence of photo-illumination on the magnetic properties of AZ–Au NPs 1.7 at 300 K (Fig. 7). During the UV illumination, the initial magnetization value under an applied field of 5 T decreased from 0.24 to 0.18 emu g_{Au}^{-1}. Even after the illumination was stopped, the decreased magnetization value was maintained for several hours at room temperature. The very slow recovery of the magnetization could be due to the cis-to-trans thermal back-isomerization of the AZ. We then illuminated AZ–Au NPs 1.7 with visible light, and the magnetization value increased from 0.18 to 0.24 emu g_{Au}^{-1}. After this process, the UV light-induced decrease and the visible light-induced increase in magnetization were repeated without any attenuation. The photo-induced changes in the magnetization values were estimated to be ca. 27%. We also observed such photo-induced magnetic transitions in field cooled magnetization curves for AZ–Au NPs 1.7 with external magnetic field of 5 T.

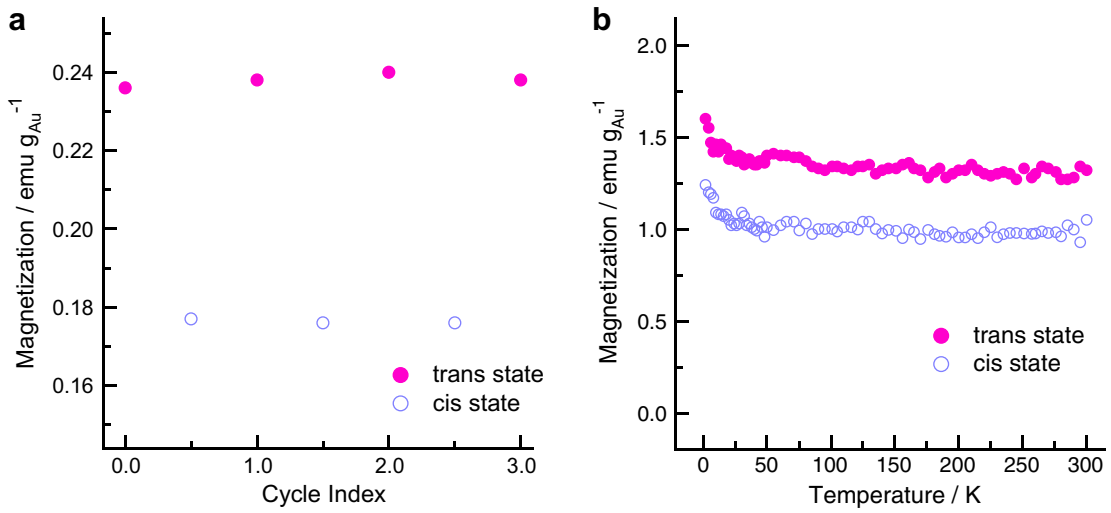

Fig. 7. (a) Changes in magnetization by photo-illumination at 300 K; AZ–Au NPs 1.7 were alternately illuminated with UV and visible light for 1 min each at 300 K under an external magnetic field of 5 T. (b) Changes in the field cooled magnetization curves by photo-illumination under the external magnetic field of 5 T; Plot of magnetization M vs. applied temperature T for trans-state (closed circles) and for cis-state (open circles).

We must mention that the observed photo-induced magnetic transition undoubtedly originated from the reversible photoisomerization of AZ. It might be argued that the observed behavior could be due to physical effects during photo-illumination, such as thermal effects or structural changes of the core-particles. Our comparative experiments show that gold nanoparticles coated with dodecanethiol (non-azo-ligands) did not show any photo-induced magnetic transitions, despite showing almost the same magnetic properties. Hence, the reversible photoisomerization of AZ was the origin of the observed phenomena.

3.5. Origin of photo-magnetic effects

As mentioned above, in AZ–Au NPs, the apparent ferromagnetism is associated with 5d localized holes in the 5d shell generated through Au–S bonding. The magnetic ordering is not due to the large exchange interaction, but rather is due to extremely high local magnetic anisotropy (estimated to be as high as 1×10^8 ergs cm^{-3}) which blocks the moments from switching, resulting in very high T_B in Au NPs [7a]. Hence, the observed photo-magnetic effects are not due to the changes in magnetic exchange interaction, but rather are due to the changes in absolute quantity of the magnetic moments. From the saturated magnetization value of the AZ–Au NPs under applied field of 5 T, the values of the magnetic moment per Au atom bound to sulfur in the trans-state and the cis-state are estimated to be 0.033 μ_B and 0.024 μ_B, respectively, where μ_B represents the Bohr magnetron. In a recent report concerning an XMCD (X-ray magnetic circular dichroism) study of thilated gold clusters, a considerable orbital magnetic moment of the Au 5d electrons was indicated, and the ratio of the orbital to the spin magnetic moment was estimated to be 12% [7b]. Therefore, the lower limit value of the d-hole counts per Au atom bound to sulfur in the trans-state and the cis-state are estimated as to be ca. 0.0039 e atom^{-1} and ca. 0.0027 e atom^{-1}, respectively. This result clearly suggests that the d-charge loss of ca. 0.0012 e atom^{-1} was decreased in the case of the cis-state. That is, the charge transfer from Au to S could be reversed with trans-to-cis photoisomerization.

These phenomena are also consistent with the reported cooperative effect of organic molecules in the electron transfer between a metal substrate and organic layers. In such organic–inorganic interfaces, charge transfer acts to reduce the dipole–dipole interaction between molecules but may either decrease or increase the molecules-to-surface dipole moment. The change in the work function is related to the dipole moment density perpendicular to the surface through the following relationship [11]:

$$\Delta\Phi = \frac{\mu N \cos\theta}{\varepsilon\varepsilon_0}$$

where N is the surface density of dipoles, μ is the effective dipole moment of the molecule, ε_0 is the permittivity of a vacuum, ε is the dielectric constant of the layer, and θ is the tilt angle of the molecule with respect to the surface normal.

In other words, the magnitude of the electron transfer to the organic layer becomes smaller for adsorbates with electro-negative end groups, while it becomes larger for adsorbates with electro-positive end groups. In fact, experimental evidence for such changes in the magnitude of the electron transfer from gold to the adsorbates has been reported previously [18].

In the current system, the values of $\mu\cos\theta$ for the AZ were calculated as −0.24 D (D = Debye) for the trans-state and 2.74 D for

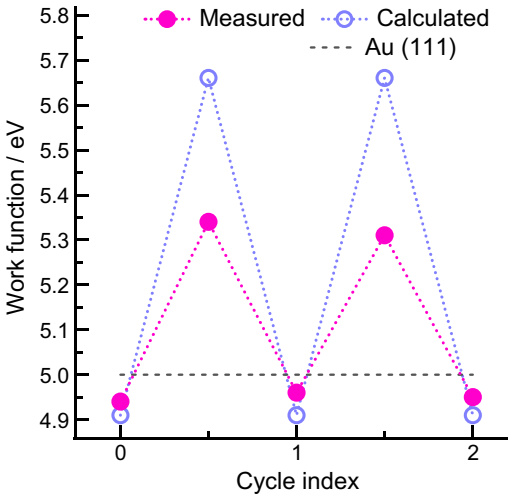

Fig. 8. Changes in work function values of the AZ–Au NPs 1.7 due to photoisomerization for the measured values (closed circles), the calculated values (open circles) and the known values for Au (1 1 1) (dashed line).

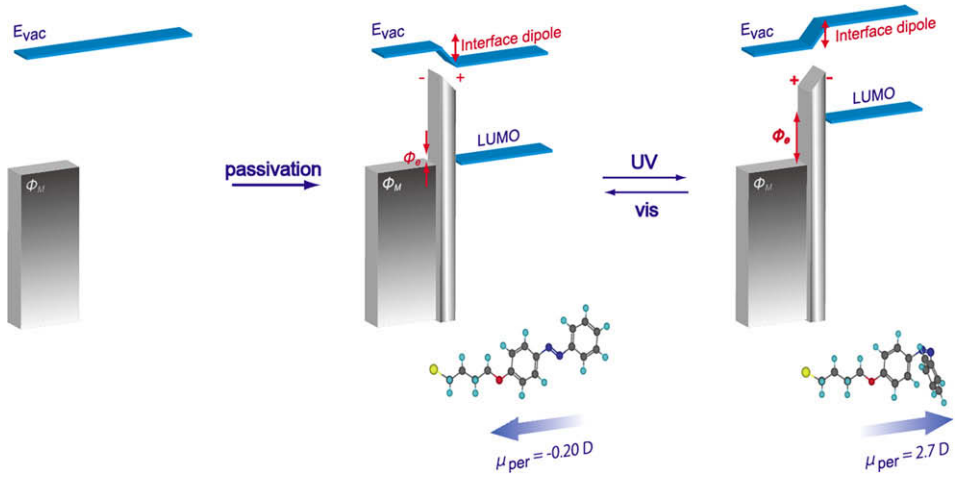

Fig. 9. Schematic illustrations of changes in the work function due to the photoisomerization. Left: schematic energy level diagrams for an untreated interface (without surface passivation). Middle: passivation of trans-AZ imposes an interface dipole that decreases local vacuum energy level (E_{vac}). Right: photoisomerization to cis-AZ imposes an interface dipole that increases local vacuum energy level (E_{vac}).

the cis-state, meaning that the sign of the work function change would be negative for the trans-state and positive for the cis-state (The $\mu\cos\theta$ values of AZ for the trans-state and cis-state were calculated with MOPAC/PM3 geometry. The tilt angles were taken to be 30° for both trans-state and cis-state according to the reported value [19,20]). Hence, the magnitude of electron transfer in the initial trans-state becomes smaller in the cis-state under UV light illumination, and it recovers to its initial value under visible light illumination. To elucidate this, we investigated the influence of photo-illumination on the work function value of the AZ–Au NPs 1.7 by means of Kervin probe analysis (Fig. 8). During the UV illumination, the initial work function value 4.94 eV of the AZ–Au NPs 1.7 increased to 5.34 eV, which were qualitatively in good agreement with the work function values calculated from the surface dipole value. The differences between the measured values and the calculated values observed especially in cis-state might be originated from the relatively disordered orientation of cis-AZ because of their larger volume. We then illuminated the AZ–Au NPs 1.7 with visible light, and the work function value decreased to near the value with initial state. After this process, the UV light-induced decrease and the visible light-induced increase in work function were repeated without any attenuation. These observations have provided clear evidence that the work function value of the AZ–Au NPs 1.7 can be effectively controlled with photoisomerization by employing alternating photo-illumination with UV and visible light. Schematic illustrations of the changes in the work function due to the photoisomerization of AZ are shown in Fig. 9. As a consequence, the magnetization value at Au–S interface could be controlled by employing alternating photo-illumination with UV and visible light, and are caused by changes in the d-charge loss due to the work function change with photoisomerization.

4. Conclusions

In conclusion, we have designed azobenzene-thiol-passivated gold nanoparticles with different sizes. In these systems, we have observed that size-reduction to 1.7 nm induced ferromagnetism even at room temperature, while diamagnetism was dominating with the particle size of 5.0 nm. The ferromagnetism could be controlled by alternating photo-illumination with UV and visible light in the solid state even at room temperature. The changes in the magnetization values were significant, and were estimated to be around 27%. This photo-magnetic effect could be attributed to photo-induced changes in the values of d-charge losses due to the photoisomerization of azo-ligands, which were accompanied by the inversion of surface dipole values to the opposite sign.

[39]. The molecular orbitals and the spin densities for these complexes were visualized by Gauss View 3.0 [40].

The geometries of **1** were directly taken from X-ray crystallography analysis. For the purpose of accumulating the knowledge on the magnetic property of Cu(II) complexes with axially coordinated nitronyl nitroxide radicals, the electronic structures of a simplified model were analyzed. Simplified complex **2** is extracted from the geometries of **1**. The bond lengths and the bond angles of hydrogen in these complexes are optimized at UB3LYP/6-31G* (Fig. 1) [41–43].

2.2. Evaluation of spin density and effective exchange integral

The spin densities of these complexes were performed at UB3LYP/6-311G** for the Cu atoms and UB3LYP/6-31G* for the ligands. In order to analyze the magnetic properties in detail, the spin population for **1** was performed at UB3LYP/LANL2MB [44–46] with minimum basis set for the Cu atoms using Hay–Wadt effective core potential and STO-3G for the ligands.

The effective exchange integrals J for these complexes were estimated by the following Eq. (1), where E and S^2 denoted, respectively, the total energy and the total spin angular momentum for the spin state, that is, singlet state (*LS*) and triplet state (*HS*) [47]. J values were also calculated at UB3LYP/6-311G** for the Cu atoms and at UB3LYP/6-31G* for the ligands. Tight convergence was used to discuss small energy differences (10^{-8} au). Highest occupied molecular orbital – lowest unoccupied molecular orbital (HOMO–LUMO) mixed initial guesses were created to estimate broken-symmetry singlet-state energies [48,49]. This method follows the proposal of Perdew et al. [50], who suggest that the broken symmetry single determinant should be the correct solution of the Kohn–Sham equations for single state.

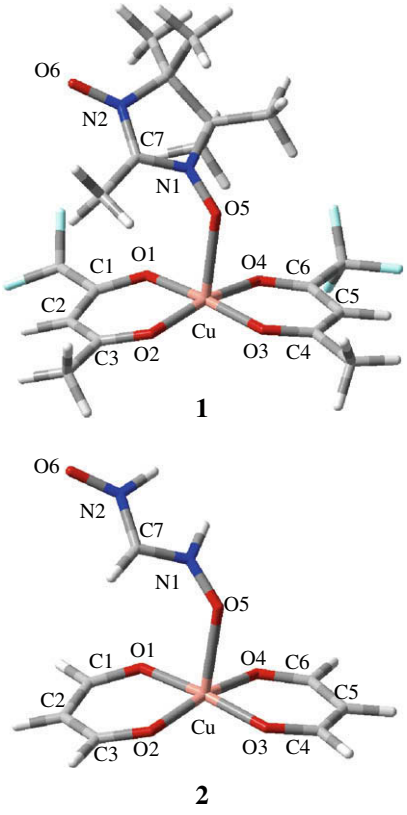

Fig. 1. Structures of **1** and **2**.

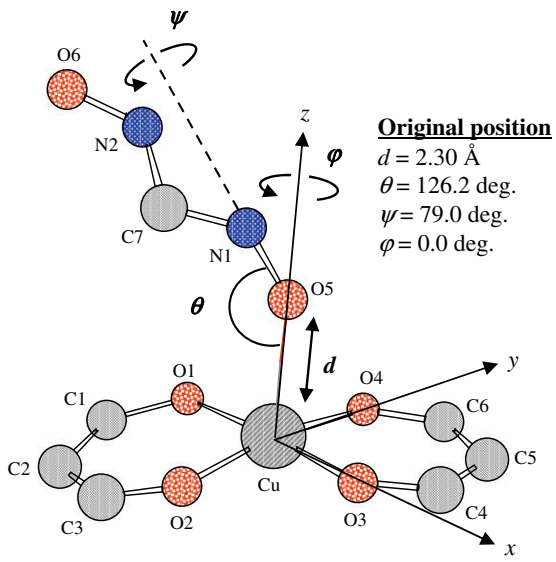

Fig. 2. Geometrical parameters of simplified complex **2** to examine the effect of overlap between magnetic orbitals.

$$J = \frac{E^{LS} - E^{HS}}{\langle S^2 \rangle^{HS} - \langle S^2 \rangle^{LS}} \tag{1}$$

2.3. Analysis of electronic structures for simplified complexes

The influence of the patterns of approach of the magnetic orbitals upon the magnetic interactions with **2** is described by using the values of the geometrical parameters d, θ, ψ and ϕ, which were the Cu–O5 distance, the Cu–O5–N1 angle, the Cu–O5–N1–C7 dihedral angle (being equal to the dihedral angle between the Cu–O5–N1 plane and the middle plane of the nitronyl nitroxide radical) and the O1–Cu–O5–N1 dihedral angle (being equal to the angle between the projection of the N1–O5 bond on the xy plane and the Cu–O1 (chelate ring) bond), respectively (Fig. 2). The coordinate of each moiety of bischelating Cu(II) and nitronyl nitroxide is fixed to the original position.

3. Results and discussion

The bonding pattern of the Cu(II) ion of **1** closely approximates a square pyramid, with the four oxygen atom of trifluoroacetylacetonate ligands in the basal plane and the nitronyl oxygen atom axially coordinated. There are two SOMO orbitals in **1** (Fig. 3). As the elongation axis is through Cu–O5, The SOMO_1 is an antibonding Cu–O orbital mainly localized onto the $3d_{x^2-y^2}$ atomic orbital, which is directed toward the equatorial oxygen atoms. On the other hand, the SOMO_2 is essentially formed by the N–O π^* orbital almost equally delocalized onto the N and O atoms of nitronyl nitroxide moiety. It is considered that the exchange interaction between the magnetic orbitals is attributed to the orthogonality of the Cu(II) $3d_{x^2-y^2}$ orbital with N–O π^* orbital [51].

DFT calculations often give good results for both signs and magnitudes of spin densities of open-shell molecules. It is found that the spin densities are mainly localized on the Cu(II) ion and the nitronyl nitroxide groups in both of the singlet and triplet states of **1** (Fig. 4). On the other hand, the sign of the spin density on the Cu(II) ion in the singlet state of **1** is opposite to that in the triplet state, despite the fact that the magnitudes of the spin densities on the Cu(II) ion and the nitronyl nitroxide groups remain unchanged (Table 1). This indicates that an antiferromagnetic spin

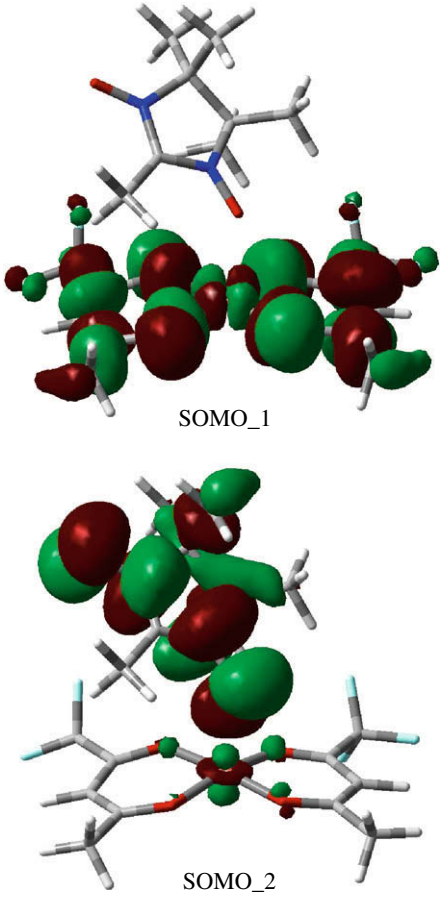

Fig. 3. SOMO distribution of **1** at UB3LYP/6-311G** for the Cu atoms and UB3LYP/6-31G* for the ligands.

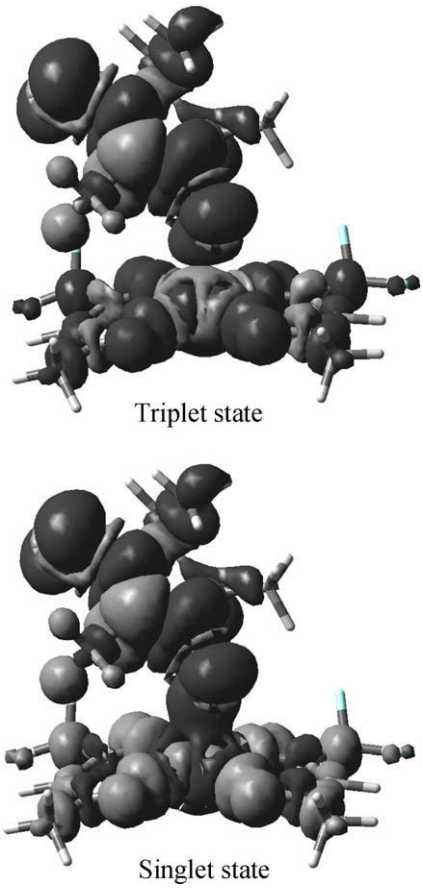

Fig. 4. Spin density for the triplet state of **1** at UB3LYP/6-311G** for the Cu atoms and UB3LYP/6-31G* for the ligands. The positive spin densities are shown in dark gray and the negative ones are in pale gray.

arrangement occurs in the singlet state of **1**, while a ferromagnetic spin arrangement occurs in the triplet state of **1**. The total spin population on the local nitronyl nitroxide (O5–N1–C7–N2–O6, see Fig. 1 for atom numbering.) group is close to integer 1 at triplet state. However, the net spin population on the Cu(II) ion is below integral 1 because of the spin polarization on the equatorial oxygen atoms of trifluoroacetylacetonate ligands coordinated to the Cu(II) ion. Moreover, the spin polarization on $3d_{z^2}$ orbital which contributes to the formation of Cu–O5 bond is observed at UB3LYP/LANL2MB (Table 2). SOMO_2 also indicates a non-negligible contribution of the $3d_{z^2}$ orbital which is perpendicular to the CuO_4 plane.

The result of the calculation for **2** reflects the electronic structure for **1**, because the SOMO distribution and spin density of **2** are similar to that of **1**. The orbital energies and the kinetic energies of **2** are also close to those of **1**. The *J* values of **1** and **2** estimated by the Eq. (1) are 47.5 cm^{-1} and 88.8 cm^{-1}, respectively. In contrast with the experimental value, it is considered that these values are within a permissible range of discussing the relationship between the geometrical parameters and the magnetic interaction of Cu(II) complexes with axially coordinated nitronyl nitroxide radicals [21].

Complex **2** is used for the purpose of describing the influence of the patterns of approach of the magnetic orbitals upon the magnetic interactions. In the case of shifting *d* under the fixed geometries of original θ, ψ and ϕ, *J* increases with decreasing in *d* (Fig. 5). Shorter Cu–O5 distance is better to form ferromagnetic coupling, and this result supports the tendency of the previous reports [37]. The behavior of the spin population on the Cu(II) ion in the triplet state of **2** shows the similar tendency of *J*, while the total spin population on the local nitronyl nitroxide (O5–N1–C7–N2–O6) group in the triplet state of **2** gradually decreases according to the decrease of *d* (Fig. 6). These results suggest the slight delo-

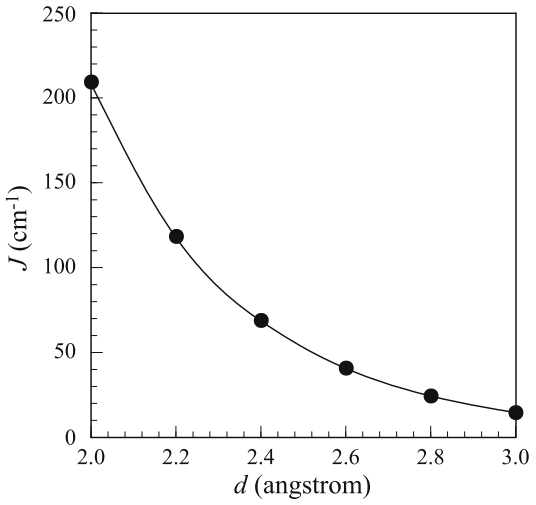

Fig. 5. Dependence of J on d for **2** under the fixed geometries of $\theta = 126.2°$, $\psi = 79.0°$ and $\phi = 0.0°$. Calculation is carried out at UB3LYP/6-311G** for the Cu atoms and UB3LYP/6-31G* for the ligands.

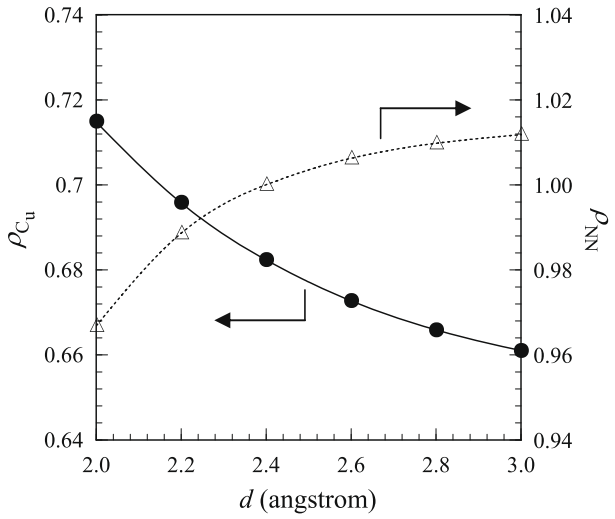

Fig. 6. Dependence of the spin densities of the Cu(II) ion (ρ_{Cu}) and the local nitronyl nitroxide (O5–N1–C7–N2–O6) group (ρ_{NN}) on d for **2** under the fixed geometries of $\theta = 126.2°$, $\psi = 79.0°$ and $\phi = 0.0°$.

calization of the unpaired electron from the π^*orbital of the nitronyl nitroxide group to the $3d_{z^2}$ atomic orbital of the Cu(II) ion. Therefore, the exchange parameter contains two main contributions, $J \cong J_{dir} + J_{del}$, where J_{dir} indicates the direct exchange mechanism and J_{del} indicates the delocalization mechanism [36]. On the other hand, there is only a low correlation between J and ϕ because the overlap integral between the $3d_{x^2-y^2}$ atomic orbital of the Cu(II) ion and N–O π^* orbital of the nitronyl nitroxide group is too small to lead to the change of J_{dir}. It is also suggested that the spin population on $3d_{z^2}$ atomic orbital of the Cu(II) ion should be approximately constant in the case of shifting ϕ under the fixed geometries of θ, d and ψ.

The values of the geometrical parameters θ and ψ play a key role in tuning the magnitude of the magnetic interaction in Cu(II) complexes with axially coordinated nitronyl nitroxide radicals as well as those of the geometrical parameter d (Fig. 7) [52]. When the value of θ is 180°, the $3d_{x^2-y^2}$ atomic orbital of the Cu(II) ion and N–O π^* orbital of the nitronyl nitroxide group are orthogonal to each other irrespective of ψ and ϕ. In this case the antiferromagnetic contribution vanishes, and a moderate ferromagnetic coupling can be developed. On the contrary, the decrease of θ considerably increases J_{del} except for the cases below θ = ca. 120° in which the ferromagnetic coupling may be prevented by the steric effect. This is due to the fact that the increase of θ leads to a more efficient overlap between the $3d_{z^2}$ atomic orbital of the Cu(II) ion and N–O π^* orbital of the nitronyl nitroxide group. The increase of ψ also contributes to the increase of J_{del}. When the value of ψ is 90°, the axes of N–O π^* orbital of the nitronyl nitroxide group are directed toward the Cu(II) ion. Such an orientation is especially favorable for the delocalization of an unpaired electron onto the $3d_{z^2}$ atomic orbital of the Cu(II) ion and, consequently, corresponds to the largest J_{del} value (Fig. 8).

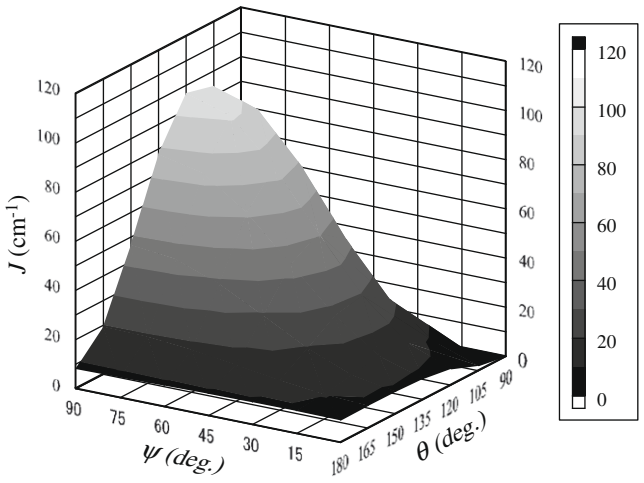

Fig. 7. Dependence of J on θ and ψ for **2** under the fixed geometries of d = 2.30 Å and $\phi = 0.0°$.

The calculated J values of other Cu(II) nitronyl nitroxide systems whose experimental results have been reported before are estimated by applying the values of their geometrical parameters to **2** (Fig. 9) [8,24,25]. Here the O1–Cu–O5 angles (see Fig. 2 for atom numbering.) are taken into account respectively [31,36], while these angular dependences are small in the range from 78° to 102° as a result of the computational analysis. The order of the experimental J values reported before is well reproduced by the calculated results for simplified complexes. It is indicated that the method described in this paper can be applied various Cu(II) complexes with axially coordinated nitronyl nitroxide radicals.

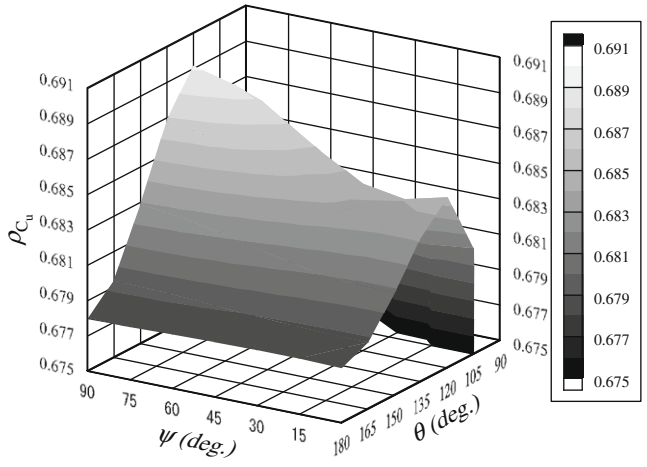

Fig. 8. Dependence of the spin density of the Cu(II) ion (ρ_{Cu}) on θ and ψ for **2** under the fixed geometries of d = 2.30 Å and $\phi = 0.0°$.

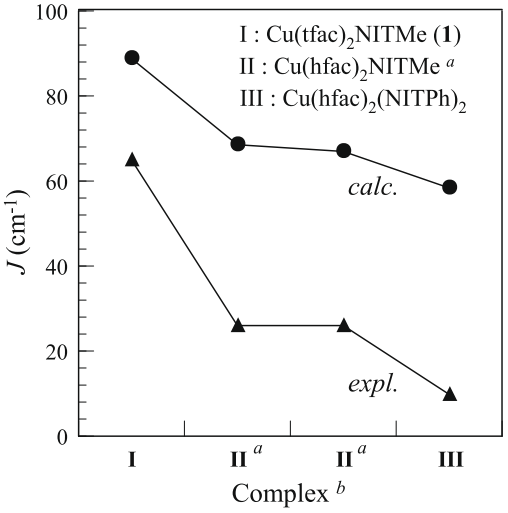

Fig. 9. Comparison between experimental *J* and calculated *J* for Cu(II) nitronyl nitroxide systems. The calculated *J* values are estimated by applying the values of their geometrical parameters to **2** respectively ([a]Two different Cu–O5 distances are observed in the cell. The experimental *J* for II is the averaged value. [b]tfac = trifluoroacetylacetonato, hfac = hexafluoroacetylacetonato, NITMe = 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazolyl-1-oxy-3-oxide, NITPh = 2-phenyl-4,4,5,5-tetramethyl-4,5-dihydro-1*H*-imidazolyl-1-oxy-3-oxide.).

4. Conclusion

It is important to investigate the primary structure of molecule-baesd magnets in order to encourage spin arrangement. The magnetic properties for Cu(II) complexes with axially coordinated nitronyl nitroxide radicals which exhibit ferromagnetic interaction are well reproduced by the results of DFT calculations. The electronic structures for these complexes are examined for the purpose of clarifying the mechanism of the ferromagnetic interaction. In summary, it is considered that the delocalization of the unpaired electron takes place from the π^* orbital of the nitronyl nitroxide group to the $3d_{z^2}$ atomic orbital of the Cu(II) ion. The delocalization mechanism is important for the ferromagnetic properties in Cu(II) complexes with axially coordinated nitronyl nitroxide radicals.

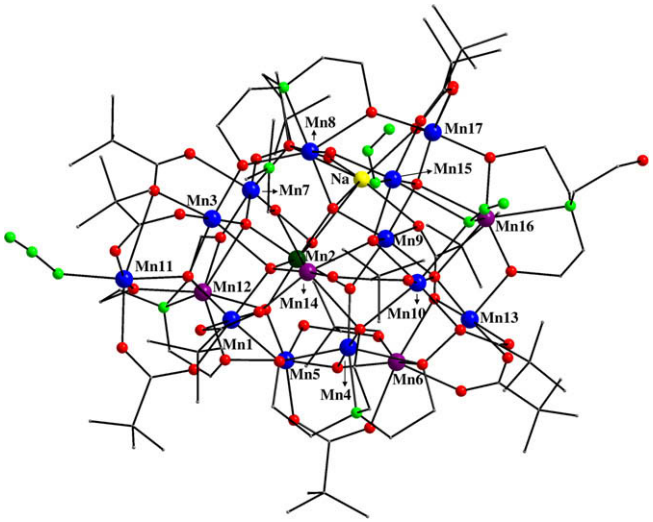

Fig. 1. Molecular structure of complex **1**. H atoms have been omitted for clarity. Color scheme: Mn^{II} purple; Mn^{III} blue; Mn^{IV} olive; Na yellow; O red; N green; C grey. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

$[Mn_4(\mu_3\text{-}O^{2-})_3(\mu_3\text{-}N_3)]$ cubane subunits at common atoms Mn2 and Mn9, respectively. All μ_3-O^{2-} ions in each cubane subunits convert to a μ_4 mode and bridge seven adjacent Mn atoms, three of which (Mn2,5,7) are fused to the corresponding triangular subunits. The three tea^{3-} groups are bound to up to six Mn atoms, acting as $\eta^3{:}\eta^1{:}\eta^2{:}\eta^3{:}\mu_6$, $\eta^2{:}\eta^1{:}\eta^3{:}\eta^2{:}\mu_5$ and $\eta^2{:}\eta^1{:}\eta^2{:}\eta^2{:}\mu_3$ ligands, the μ_6 mode being seen for a first time in the coordination chemistry of this group, while the only $teaH^{2-}$ group is bridging under the $\eta^2{:}\eta^1{:}\eta^2{:}\mu_3$ mode. Peripheral ligation about the core is provided by ten $\eta^1{:}\eta^1{:}\mu$, two $\eta^1{:}\eta^2{:}\mu$ and an $\eta^2{:}\eta^2{:}\mu_4$ $Me_3CCO_2^-$ groups, as well as two terminal N_3^- ions and a terminal DMF molecule. All Mn and Na atoms are near-octahedral, except five-coordinate Mn5 and seven-coordinate Mn12, which are square pyramidal ($\tau = 0.01$ [8]) and distorted pentagonal bipyramidal, respectively. The Mn^{II}/Mn^{III}/Mn^{IV}/Na^{I} oxidation states were established from the metric parameters, BVS calculations[3] [9], and the presence of Jahn–Teller (JT) distortions at octahedral Mn^{3+}. The protonation level of O^{2-}, OH^-, and OR^- groups was also confirmed by BVS calculations [9]. There are no significant intermolecular interactions of any kind, only strong intramolecular H-bonds between bridging OH^- and DMF and $Me_3CCO_2^-$ groups, respectively.

While the number of polynuclear complexes of 3d metals at intermediate oxidation states continues to grow rapidly, some nuclearities remain rare. Heptadecanuclear 3d metal complexes are particularly rare [10]; **1** is only the second Mn_{17} cluster ever reported [10a], and the first with such a closed-like structural topology.

Solid-state DC (direct current) magnetic susceptibility (χ_M) data for complex **1** were collected in the temperature range 5.0–300 K in an applied field of 1 kG (0.1 T). The data are plotted as $\chi_M T$ versus T in Fig. 2, and clearly indicate a relatively large ground-state spin (S) value. $\chi_M T$ for **1** steadily decreases from 44.74 cm^3 K mol^{-1} at 300 K to reach a plateau of ~35.50 cm^3 K mol^{-1} at 20–40 K, before further dropping to 33.49 cm^3 K mol^{-1} at 5.0 K; the latter decrease at the lowest temperatures is assigned to Zeeman effects, zero-field splitting and/or weak intermolecular interactions. The overall shape of the $\chi_M T$ versus T curve and the existence of the

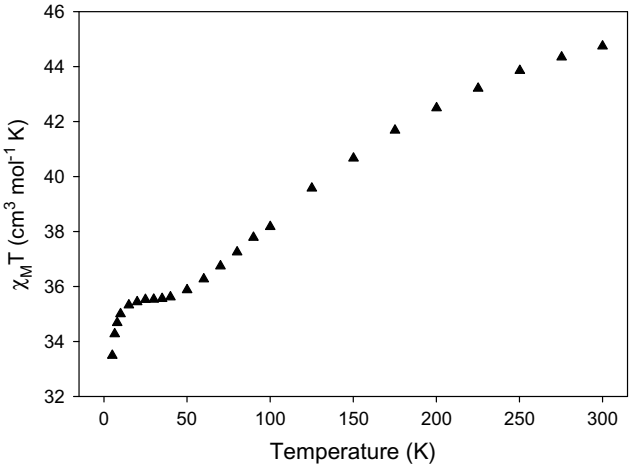

Fig. 2. $\chi_M T$ vs. T plot for **1** in a 1 kG field.

20–40 K plateau region are indicative of predominant antiferromagnetic exchange interactions within **1** and a well-isolated ground state S, respectively. The 20–40 K value is consistent with an $S = 17/2$ ground state and a g value slightly less than 2.0, as expected for a $Mn^{II,III,IV}$ complex; the spin-only ($g = 2$) value for an $S = 17/2$ state is 40.38 cm^3 K mol^{-1}.

In order to confirm the ground state of **1**, magnetization (M) data were collected in the 0.1–1.0 T and 1.8–10.0 K ranges, and these are plotted as $M/N\mu_B$ versus H/T in Fig. 3. We used only low field data ($\leqslant$1.0 T) to preclude problems from low-lying excited states, which are expected for high-nuclearity clusters with a high density of spin states and/or when Mn^{II} ions are present, which give weak exchange interactions. The data were fit by matrix-diagonalization to a model that assumes only the ground state is populated, includes axial zero-field splitting ($D\hat{S}_z^2$) and the Zeeman interaction, and carries out a full powder average. The best fit (solid lines in Fig. 3) gave $S = 17/2$, $g = 1.85$ and $D = -0.22$ cm^{-1}; alternative fits with $S = 15/2$ or 19/2 were rejected because they gave unreasonable values of g and D. We conclude that **1** has ground state of $S = 17/2$, respectively. This was further confirmed by AC (alternating current) susceptibility experiments.

As we have described before on multiple occasions [11], AC susceptibility studies in the 1.8–15 K range with a 3.5 G AC field oscil-

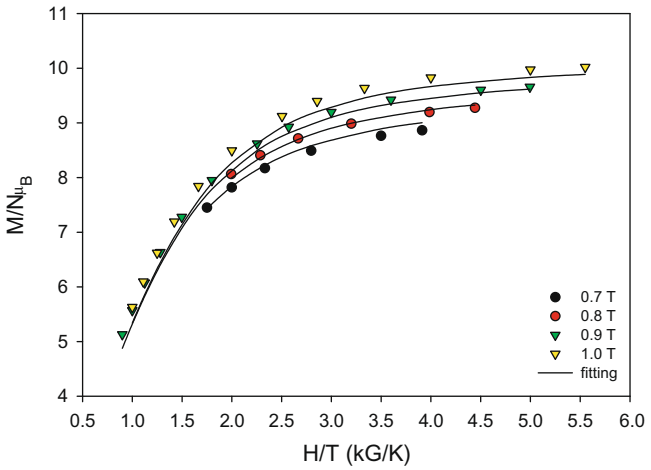

Fig. 3. Magnetization (M) vs. field (H) and temperature (T) data, plotted as reduced magnetization ($M/N\mu_B$) vs. H/T, for complex **1** at applied fields of 0.7–1.0 T and in the 1.8–10 K temperature range. The solid lines are the fit of the data; see the text for the fit parameters.

[3] Bond-valence sum (BVS) calculations for the Mn ions of **1** gave values of 1.77–1.94 for Mn^{2+} ions, 2.77–3.06 for Mn^{3+} ions, 4.03 for Mn^{4+} ion and 1.20 for Na^+ ion. BVS calculations for selected oxygen atoms in **1** gave values of 1.72–2.07 for O^{2-}, 0.90–1.01 for OH^-, 1.75–1.93 for RO^-, and 1.05–1.23 for ROH.

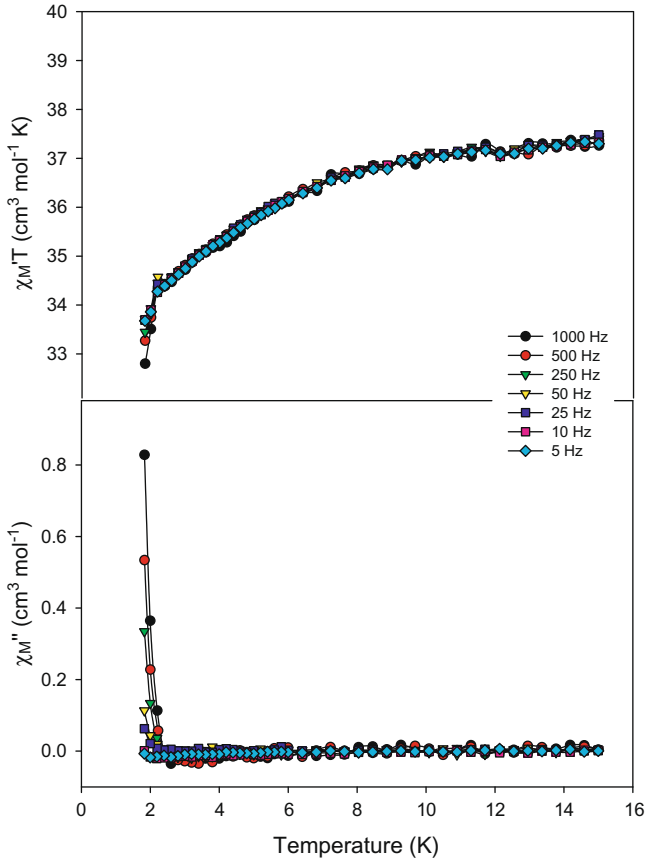

Fig. 4. Plots of the in-phase (χ'_M) as $\chi'_M T$ (top), and out-of-phase (χ''_M) (bottom) AC magnetic susceptibilities vs. T in a 3.5 G field oscillating at the indicated frequencies for complex **1**.

lating at 5–1000 Hz are a powerful complement to DC studies for determining the ground state of a system, because they preclude any complications arising from the presence of a DC field and/or low-lying excited states. For **1**, the in-phase (χ'_M) AC signal, shown as $\chi'_M T$ in Fig. 4 (top), is only slightly decreasing with decreasing temperature in the 8–15 K region; extrapolation of the data above 8 K (to avoid the effects of intermolecular interactions at lower temperatures) down to 0 K gives $\sim$36.5 $cm^3\,K\,mol^{-1}$, indicating an $S = 17/2$ ground state with $g \sim 1.95$, in good agreement with the DC magnetization fits.

The $S = 17/2$ ground state and the negative D value suggested that **1** might be SMM. The upper limit to the barrier is $U = (S^2\text{-}1/4)|D| = 15.70\ cm^{-1} = 22.59$ K, but the true, effective barrier (U_{eff}) will be significantly less due to QTM. At temperatures <3.0 K, frequency-dependent tails of out-of-phase (χ''_M) AC susceptibility signals for **1** were observed (Fig. 4, bottom) whose maxima lie below the operating minimum temperature of our SQUID instrument. Such signals are an indication of the superparamagnetic-like slow relaxation of an SMM. To confirm whether **1** is a SMM and shows hysteresis loops, the diagnostic property of a magnet, single-crystal magnetic studies are required to be performed at low enough temperatures using the micro-SQUID apparatus [12]. Such studies are currently in progress and the corresponding results will be reported in due course.

In summary, the combination of azide, carboxylate and $teaH_3$ ligands in Mn cluster chemistry has yielded an unprecedented heptadecanuclear, mixed-valence (II, III, IV) cage-like molecule with a fairly large $S = 17/2$ ground state and an appreciably large and negative D value. As a result, out-of-phase (χ''_M) AC tails of signals have been observed, indicative of the superparamagnetic-like slow relaxation of an SMM. Finally, the combined structural and magnetic results reported herein continue to emphasize how extensive is the ability of Mn chemistry to satisfy a variety of different tastes.

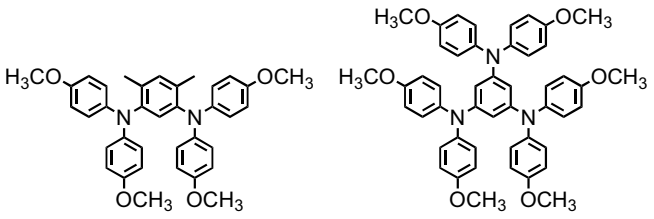

Fig. 1. Structures of *N,N,N′,N′*-tetrakis(4-anisyl)-4,6-dimethyl-1,3-phenylene-diamine (**1**) and *N,N,N′,N′, N″,N″*-hexakis(4-anisyl)-1,3,5-phenylenetriamine (**2**).

temperature. The electron transfer stopped-flow (ETSF) method allowed us to study the spectroscopic properties of the mono-, di- and tricationic states of **4**. These results are the first report on the detection of a one-dimensional oligoarylamine-based tricationic state [2j]. The enhancement of the thermodynamic and kinetic stability for oligo-cations of **4** is ascribed to the steric as well as electronic effects of the electrodonating methyl groups, which raise the HOMO energy level. The ESR study of the dication $\mathbf{4}^{2+}$ showed that the ground state is spin-triplet. The trication $\mathbf{4}^{3+}$ was not stable enough in a time scale for the conventional ESR sampling, indicating that chemical modification was not sufficient enough to stabilize the tricationic states in solution. We have also examined a highly alkylated triamine (**5**) with nine methyl groups at the peripheral aromatic rings, which gave stable mono- and dicationic state [2k]. Surprisingly, the peak of the trication $\mathbf{5}^{3+}$ completely disappeared in less than 0.2 s, indicating very unstable nature of the trication. The observations suggested that the introduction of extra methyl groups into the *meta* positions of the peripheral rings results in an unexpectedly large destabilizing effect on the tricationic states. An ESR study of the chemically oxidized **5** showed that the dication $\mathbf{5}^{2+}$ is spin-triplet in the ground state.

In this study, we have re-designed and synthesized a new alkylated triamine (**6**) with six methyl groups. The stabilities of the corresponding oligo-cationic states have been examined by using the cyclic voltammetry and ETSF method. The electronic states of the oligo-cationic states have been identified by cw-ESR measurements in rigid glass at low temperature.

2. Results and discussion

*2.2. Synthesis of 2,2′,4,4′-tetrabromo-3″,4″-dimethyl-5,5′-bis(di(4-methylphenyl)-amino)-triphenylamine (**6**)*

Compound **6** was synthesized and isolated as colorless powder by the similar method reported by Ito et al. [2g]. Dinitrotriarylamine (**7**) was reduced with $SnCl_2$/HCl to give diaminotriarylamine (**8**), which was reacted with 4-iodotoluene under Ullmann coupling condition to give a triamine (**9**). Compound **8** was brominated with benzyltrimethylammonium tribromide to give **6** in moderate yield (Fig. 3). All new compounds were fully characterized by spectroscopic methods. Data only for **6** and **9** are given below. Compound **9**: ^{1}H NMR ($CDCl_3$): δ 2.13 (s, 3H), 2.15 (s, 3H), 2.26 (s, 12H), 6.48–6.63 (m, 4H), 6.80 (t, 2H, J = 3.2 Hz), 6.87–7.05 (m, 21H), ^{13}C NMR ($CDCl_3$): 19.1, 19.9, 20.7, 116.9, 117.2, 118.4, 121.9, 123.8, 125.6, 129.3, 129.5, 130.2, 130.8, 131.7, 137.2, 145.0, 145.5, 148.3, 149.0. IR (KBr): 3019, 2916, 1570, 1508, 1292 cm^{-1}. M.p.: 84–85 °C.Compound **6**: ^{1}H NMR($CDCl_3$): δ 2.08 (s, 3H), 2.15 (s, 3H), 2.26 (s, 12H), 6.46 (dd, 1H, J = 8.0, 2.2 Hz), 6.52 (d, 1H, J = 2.2 Hz), 6.62 (s, 2H), 6.72 (d, 8H, J = 8.6 Hz), 6.87 (d, 1H, J = 8.6 Hz), 6.97 (d, 8H, J = 8.6 Hz), 7.72 (s, 2H), ^{13}C

NMR($CDCl_3$): δ 19.1, 19.8, 20.8, 117.1, 117.6, 119.0, 122.2, 123.1, 129.6, 129.8, 129.9, 131.2, 131.8, 137.2, 138.9, 143.5, 144.2, 145.8, 146.0. IR (KBr): 3024, 2917, 1570, 1506, 1463 cm^{-1}. M.p.: 109–110 °C. HRMS: Calc. for $C_{48}H_{41}N_3Br_4$, 975.0034; Obsd: 975.0031.

2.3. UV–Vis spectrum measurements

In order to examine the spectroscopic properties of **6**, UV–Vis spectroscopic measurements were carried out (Fig. 4). In chloroform solution, **6** exhibited a strong absorption around 300 nm, which is characteristic of triarylamine chromophores.

2.4. Cyclic voltammetry measurements

For the compound **6**, cyclic voltammetry in *n*-butyronitrile at ambient temperature revealed two couples of chemically reversible one-electron transfers (Fig. 5), indicating the generation of the corresponding stable mono-, di-, and trications in solution (E^0_1 = 0.60 V (2e transfer), E^0_2 = 1.00 V (1e transfer) versus Fc/Fc^+). No oxidation peak was observed upon further oxidation. Previously, we reported compound **4** gives stable mono-, di- and tricationic states. Comparing the first redox potentials of **6** and **4** (E^0_1 = 0.605 V versus Fc/Fc^+ (2e transfer)) [2j], **6** can be oxidized more easily, suggesting the occurrence of the elevated HOMO level. AM1 calculation also indicated that the HOMO energy level of **6** is slightly higher than that of **4**. Very recently, Bushby et al. have reported electrochemical and spectroscopic properties of a series of *meta*-connected oligoarylamines, where several methoxy groups

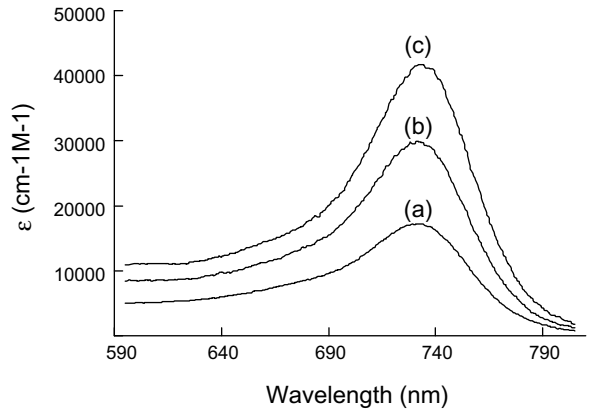

Fig. 6. Absorption spectra observed after mixing of an AN solution of 0.10 mM $TDBPA^{+\cdot}$ with an AN solution of (a) 0.10 mM, (b) 0.050 mM, (c) 0.033 mM of **6**.

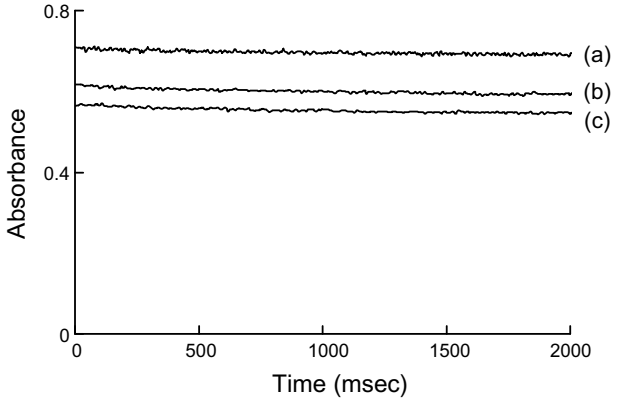

Fig. 7. Time profiles in the absorbance maximum observed after mixing of an AN solution of 0.10 mM $TDBPA^{+\cdot}$ with an AN solution of (a) 0.10 mM, (b) 0.050 mM, (c) 0.033 mM of **6**.

are introduced into the *ortho* positions of the triarylamine units [2l]. Compared with their systems, our diamines (**1**, **4**, **6**), where methyl or methoxy groups are introduced into the *para* positions, can be oxidized more easily [2c,j]. Thus, introduction of substituents into the *para* positions would be better strategy to obtain kinetically and thermodynamically stable *meta*-connected oligoarylamine-based high-spin systems.

2.5. Electron transfer stopped-flow (ETSF) method

The detail of the ETSF method was described previously [4,5]. The ETSF measurements were carried out in dehydrated acetonitrile (AN) as a solvent at ambient temperature. In this study, tris(2,4-dibromophenyl)amine cation radical ($TDBPA^{+\cdot}$)[1] was employed. Compound **6**, upon mixing with 1 equiv. of $TDBPA^{+\cdot}$, exhibited a broad absorption peak at 732 nm (Fig. 6), and no decrease in the peak intensity was observed for over 1 min, indicating the generation of the very stable monocation (Fig. 7). The molar absorptivity (ε) of $\mathbf{6}^{+\cdot}$ was determined to be 1.72×10^4 M^{-1} cm^{-1} at 732 nm.

Upon mixing with 2 equiv. of $TDBPA^{+\cdot}$, **6** exhibited an absorption peak of the dication $\mathbf{6}^{2+}$ at 732 nm. The ε value for $\mathbf{6}^{2+}$ was 3.00×10^4 M^{-1} cm^{-1} at 732 nm. No decrease in the peak intensity

[1] TDBPA was synthesized by WAKO Pure Chemicals Ltd. after receiving our special order. See also Ref. [5].

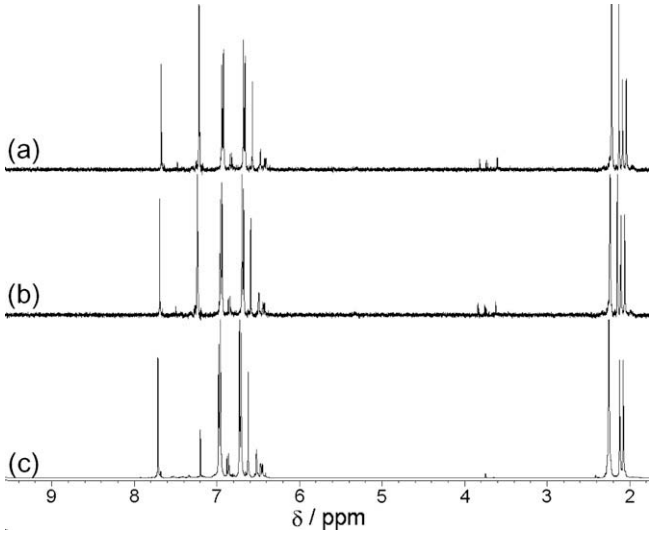

Fig. 8. ^{1}H NMR spectra of (a) product obtained by oxidation (4.5 equiv of $SbCl_5$) and following reduction of **6**, (b) product obtained by oxidation (10 equiv of $SbCl_5$) and following reduction of **6**, (c) **6**.

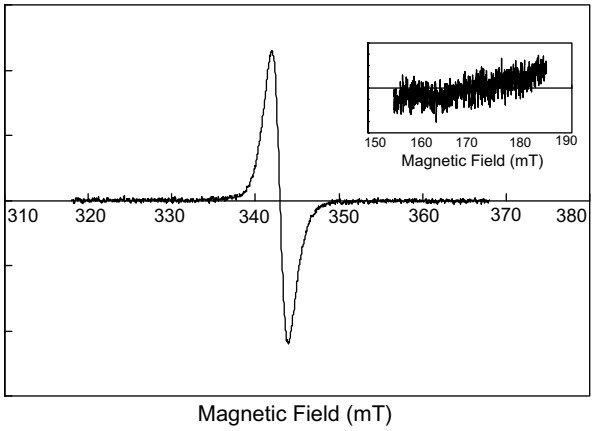

Fig. 9. ESR spectrum observed at 5 K for compound **6** after the oxidation by 10 equiv. of $SbCl_5$, in the allowed ESR transition region (inset: in the $\Delta Ms = \pm 2$ region).

was observed for over 1 min, indicating also that the very stable dication was generated.

Upon mixing with 3 equiv. of $TDBPA^{+\cdot}$, **6** exhibited an absorption peak of the trication $\mathbf{6}^{3+}$ at 734 nm ($\varepsilon = 4.18 \times 10^4\ M^{-1}\ cm^{-1}$). Similar to **4** and **5**, the ratio of ε for monocation:dication:trication of **6** was nearly 1:2:3, as expected. Previously we reported that compound **5** gives the very unstable trication with the lifetime of 0.2 s [2k]. Generally, introduction of electrodonating groups is effective to stabilize mono- and oligo-cationic states. The more electrodonating groups are attached, the more stable cationic states are expected to be generated. In the case of *meta*-connected one-dimensional triamines, introduction of the electrodonating group into the central phenyl ring would be effective to stabilize the corresponding tricationic states.

2.6. Stability of the trication generated by chemical oxidation

In order to examine the stability of the chemically generated trication, 4.5 equiv. of $SbCl_5$, minimum required amount to obtain the trication, was dropped to **6** in dichloromethane under nitrogen atmosphere at 15 °C. The color of the solution immediately turned purple, indicating the generation of oxidized species. The solution was stirred for 15 min at 15 °C and no change in color was observed. Upon addition of aqueous ascorbic acid, the color of the solution turned colorless. The obtained solution was extracted with chloroform, dried over sodium sulfate, and evaporated under reduced pressure to give white powder. The NMR spectrum of the product showed the quantitative recovery of **6**. Similar result was obtained using 10 equiv. of $SbCl_5$. Fig. 8 shows ^{1}H NMR spectra of the triamine and products obtained by reduction of the trication. Comparing the spectra, no significant difference was observed between before and after the $SbCl_5$/ascorbic acid treatment, indicating the generation of a room-temperature-stable trication. To our knowledge, this is the most stable *meta*-connected triamine-based tricationic state.

2.7. ESR measurements

In order to examine the electronic structures of the oligo-cationic states, cw-ESR measurements of chemically oxidized **6** were carried out at liquid-helium temperature. Upon addition of 10 equiv. of $SbCl_5$ into a CH_2Cl_2 solution of **6**, the color of the solution immediately turned blue, indicating the generation of oxidized species. The cw-ESR spectrum observed at 5 K for the oxidized species in the rigid glass is shown in Fig. 9. There appeared a broad line in the allowed ESR transition region and no forbidden transition $\Delta Ms = \pm 2$ of the appreciable intensity was observed in the $g = 4$ region. Judging from the result described in the previous section, one can rule out the possibility of the decomposition of the trication. Although we have successfully detected the quartet ground state for the two-dimensional triamine-based tricationic state, the ground state for the one-dimensional triamine-based tricationic state may not be quartet but doublet. Pulse-ESR based more sophisticated ESTN spectroscopy to identify the spin multiplicities of the ground- and thermally accessible excited states of the one-dimensional trication is underway.

3. Conclusions

Hexamethyl substituted triamine, 2,2′,4,4′-tetrabromo-3″,4″-dimethyl-5,5′- Bis(di(4-methylphenyl)amino)triphenylamine (**6**) has been designed and successfully synthesized. Cyclic voltammetry and ETSF measurements have revealed that **6** gives very stable mono-, di- and tricationic states at ambient temperature. The triamine was quantitatively recovered after chemical oxidation and following reduction at room temperature. ESR measurements of the trication suggested that the ground state is spin-doublet, contrasting to the high spin preference for the two-dimensional triamine-based trication.

22 spectrophotometer (KBr disc). Magnetic susceptibility data on polycrystalline sample were collected over the temperature range of 2–300 K using a MPMS-5S magnetometer (Quantum Design) in an external field of 0.2 T, the diamagnetism was corrected by Pascal constants [41].

2.3. Preparation of $Zn(TCNQ)_2 \cdot 2H_2O \cdot 2DMF$ (**1**)

To a solution of pyridine (348 mg, 4.4 mmol) in acetone (20 mL) was added $ZnCl_2$ (136.3 mg, 1.0 mmol) solid, the mixture was stirred at room temperature for 2 h. The white precipitate formed was filtered off, washed with acetone, and then dissolved in 25 mL water. To the stirred water solution was added Li(TCNQ) (426 mg, 2.0 mmol) in water (10 mL) at room temperature, and the green product immediately precipitated was filtered off and wished by methanol, then dissolved in 15 mL DMF. Dark-green plate crystals of **1** were obtained by dispersing Et_2O into the above DMF solution for *ca.* 6 days (Yield: ~50%). Elemental *Anal.* Calc. for $C_{30}H_{26}N_{10}O_4Zn$: C, 54.9; H, 3.99; N, 21.4. Found: C, 54.6; H, 4.01; N, 21.6%. IR(cm^{-1}): the bands at 2160 (sh), 2173 (sh) and 2195 (vs) are attributed to ν(CN) of $(TCNQ)^-$.

2.4. X-ray crystallography

Diffraction data of **1** were collected at 293 K on a SMART CCD diffractometer equipped with graphite-monochromated Mo Kα radiation. All computations were carried out using SHELXTL-PC program package [42]. Structure was solved by direct method and refined on F^2 by full-matrix least-squares method. All non-hydrogen atoms were anisotropically refined, and hydrogen atoms were placed in their calculated positions and refined following the riding model. Crystallographic details for **1** are summarized in Table 1.

2.5. DFT calculations

All density functional theory (DFT) calculations were carried out utilizing the GAUSSIAN 98 program [43]. The whole non-modelized molecular structure of the real complex **1**, was taken directly from X-ray crystallography complete structure, and calculations for magnetic exchange constants *J* are performed at ub3lyp level with the basis sets of Lanl2dz, the convergence criterion of SCF is 10^{-8}.

3. Results and discussion

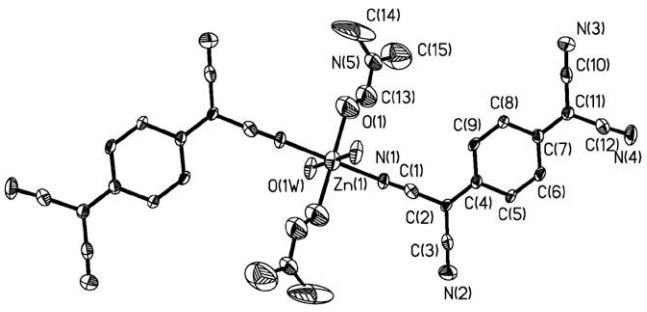
3.1. Crystal structure

Crystal of **1** crystallizes in the triclinic space group $P\bar{1}$. As shown in Fig. 1, the Zn^{2+} ion occupies at an inversion centre and it is surrounded by two N atoms from two TCNQ molecules and four O atoms which belong respectively to two H_2O and two DMF molecules to form an almost perfectly octahedral coordination geometry with the bond lengths Zn1–N1 = 2.113(5) Å, Zn1–O1 = 2.047(7) Å and Zn1–O1W = 2.185(5) Å as well as the bond angles ∠N1–Zn1–O1W = 89.6(2)°, ∠N1–Zn1–O1 = 91.3(3)° and ∠O1–Zn1–O1W = 91.6(3)°, respectively. For the TCNQ molecule, the averaged lengths of chemically similar bonds are listed in Table 2, and the values are in agreement with those in other reported compounds of $TCNQ^-$ [44,45,20,46], and the mean-molecule-plane with the eight heavy atoms of the quinodimethane group is tilted with respect to the equatorial plane of the coordination octahedron (formed by $N1/O1/N1^{\#1}/O1^{\#1}$, and the symmetric code #1 = $-x$, $2-y$, $2-z$) with the dihedral angle of 19.6°.

The noticeable structural feature in **1** is the strong H-bonding and π···π stacking interactions (cf. Fig. 2). Two types of H-bonding interactions are respectively observed along the crystallographic *a*-axis and *c*-axis directions, the N···O distance for the H-bonding of NC- group of TCNQ molecule and O atom of H_2O molecule is 2.910 Å; the O···O distance for the H-bonding of the neighboring H_2O molecules is 2.869 Å. Along the crystallographic *a*-axis direction, the neighboring TCNQ molecules adopt a cofacial arrangement, in which the centers are offset along the long molecular axis of TCNQ, and the dihedral angles between the mean-molecule-planes with the eight heavy atoms of the quinodimethane group are exactly equal to 0° due to they are related to each other by the inversion centre. In such a TCNQ stack, the distances of the mean-molecule-planes alternate as 3.1957 Å and 3.2908 Å, and the shorter atomic contacts are observed in the neighboring TCNQ molecules with $d_{C4-C11A} = 3.272$, $d_{C7-C7A} = 3.305$, $d_{C6-C8A} = 3.253$, $d_{C4-C11B} = 3.336$, $d_{C7-C7B} = 3.421$ and $d_{C6-C8A} = 3.368$ Å (the symmetric code A = $1-x$, $2-y$, $-z$; B = $-x$, $2-y$, $-z$). The intermolecular H-bonding and π···π stacking interactions lead to a supramolecular network sheet forming on the crystallographic *ac*-plane, as illustrated in Fig. 3.

3.2. Magnetic susceptibility and DFT calculations

Temperature dependences of magnetic susceptibility for **1** in the forms of χ_m versus *T* and $\chi_m T$ versus *T* are presented in Fig. 4, and the variation of magnetic susceptibility with temperature does not follow Curie–Weiss law, the $\chi_m T$ value is *ca.* 0.18 emu K mol^{-1} at 300 K, which is much smaller than the spin-only value for two $S = ½$ spin system with *g*-factor = 2



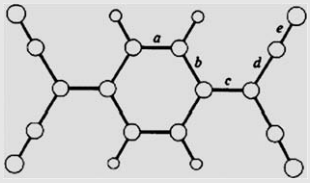


Fig. 1. ORTEP view of **1** with the displacement ellipsoids at 50% probability level (H-atoms omitted for clarity).

Table 2
Mean bond lengths (Å) of the TCNQ molecules in **1**.

	a	*b*	*c*	*d*	*e*
TCNQ in **1**	1.362	1.423	1.404	1.423	1.145
$TCNQ^0$ [47]	1.346	1.448	1.374	1.440	1.138
$TCNQ^{-1/2}$ [46]	1.355	1.433	1.396	1.424	1.145
$TCNQ^{-1}$ [45]	1.362	1.424	1.413	1.417	1.149

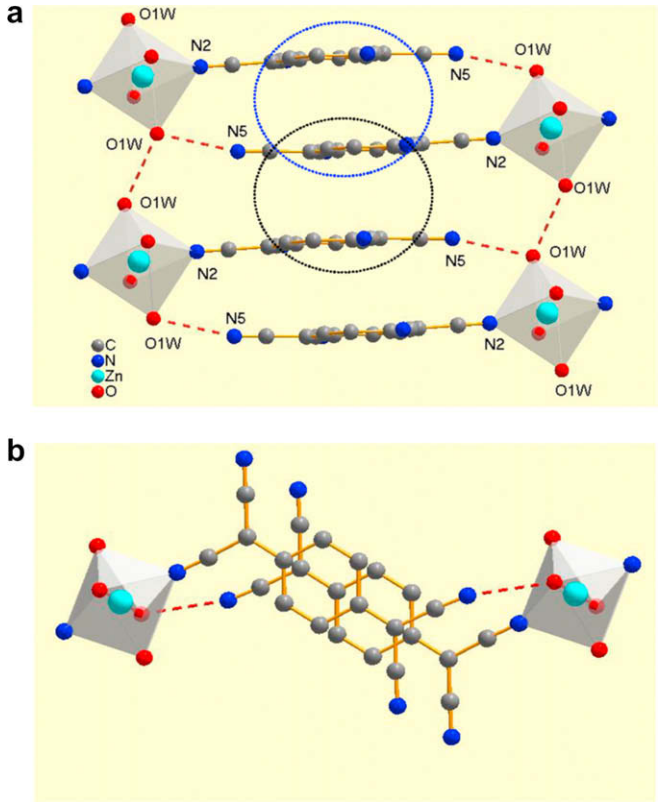

Fig. 2. H-bonding interactions between the coordinated water molecules and the CN groups of TCNQ species and $\pi\cdots\pi$ stacks between TCNQ species (a) the side view in which the blue and black circles represent two types of $[(TCNQ)_2]^{2-}$ dimers that are labeled as the dimer 1 (TCNQ and TCNQ($1-x$, $2-y$, $-z$)) and dimer 2 (TCNQ and TCNQ ($-x$, $2-y$, $-z$)), respectively and (b) the top view.

(0.75 emu K mol^{-1}). Upon cooling, the $\chi_m T$ value decreases linearly in the temperature range of 300–100 K, an inflect point occurs at around 100 K and after that the $\chi_m T$ value decreases linearly again.

In order to gain a deeper understanding of the magnetic behavior for **1**, the broken-symmetry DFT approach, which has being applied as a practical tool for investigating magnetic interactions on rather large systems with reasonable accuracy with partial consideration of electron correlation effects, was employed to evaluate the magnetic exchange constants [47–49]. The interaction between two spins $\vec{S}_1$ and $\vec{S}_2$ can be described with the Heisenberg–Dirac–van Vleck Hamiltonian [50–52]:

$$\hat{H} = -2J\vec{S}_1\vec{S}_2 \tag{1}$$

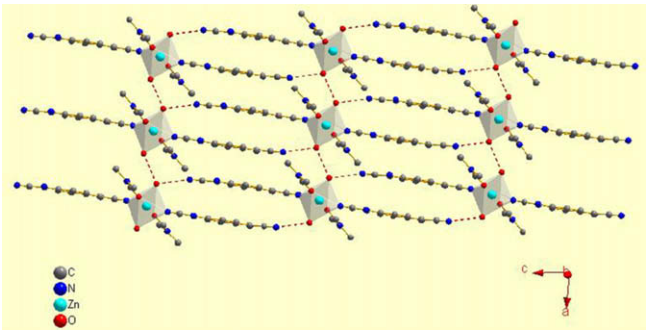

Fig. 3. Two-dimensional molecular sheet formed on the crystallographic *ac*-plane through intermolecular H-bonding interactions and $\pi\cdots\pi$ stacks in crystal of **1**.

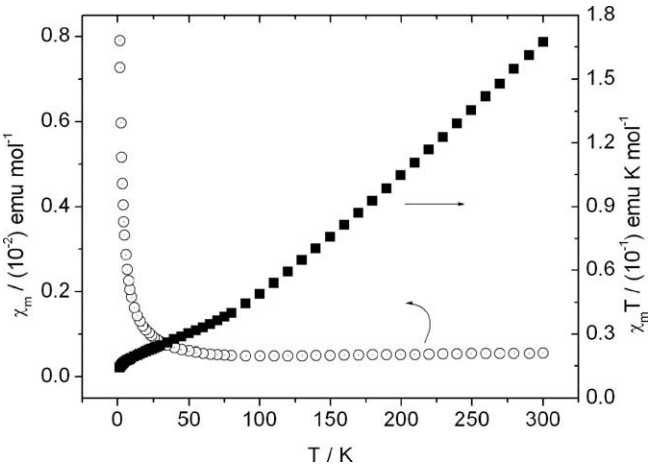

Fig. 4. Plots of $\chi_m - T$ and $\chi_m T - T$ for **1**.

where J is the magnetic exchange constant between $\vec{S}_1$ and $\vec{S}_2$. Assuming the so-called "weak bonding" regime, Noodleman et al. [53–55] evaluated J values within broken symmetry framework by

$$J^{(1)} = \frac{E_{BS} - E_T}{S^2_{max}} \tag{2}$$

where E_{BS} and E_T denote the total energies in the broken symmetry (BS) singlet state and triplet state, respectively, and S_{max} corresponds to the total spin of the high-spin state. It has been suggested that the following expression might give more reasonable solutions in the strong overlap region [56,57]:

$$J^{(2)} = \frac{E_{BS} - E_T}{S_{max}(S_{max}+1)} \tag{3}$$

However, Yamaguchi et al. claimed that J obtained by the approximate spin projection procedure reproduces the characteristic feature of J in the whole region [48,58,59]:

$$J^{(3)} = \frac{E_{BS} - E_T}{\langle S^2\rangle_T - \langle S^2\rangle_{BS}} \tag{4}$$

where $\langle S^2\rangle_T$ and $\langle S^2\rangle_{BS}$ denote the total spin angular momentum of triplet state and broken-symmetry singlet state, respectively. Thus the $J^{(3)}$ values obtained from Eq. (4) are employed in the following discussion.

In cases of both triplet and broken-symmetric states, the single point calculations for complex **1** have been performed on the non-modelized molecular geometry at the ub3lyp level with lanl2dz basis sets, and the molecular symmetry of **1** was restrained in the point group C_i owing to the feature of crystal structure. The cal-

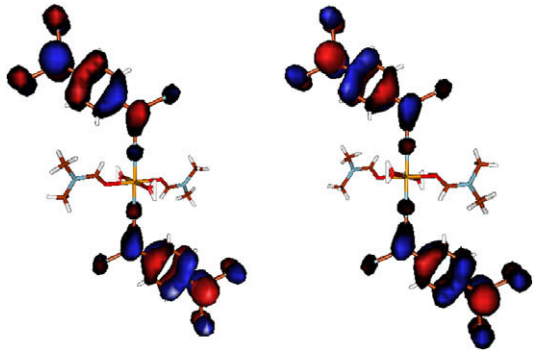

Fig. 5. Two SOMOs for the triplet state with E_{au} = −5.1277 eV and E_{ag} = −5.1201 eV.

culations indicated the singlet state is more stable than the triplet state, however, their energy gap is only 1.25×10^{-5} eV, and the estimated *J* value between two $TCNQ^-$ radicals is 0.145 K (the corresponding spin expected values for the triplet and broken-symmetric states are guesstimated as 2.0294 and 1.0294, respectively). Such small energy difference between the ground state and excited triplet state means the presence of partial population of excited triplet state (the two singly occupied molecular orbitals (SOMOs) with energy difference of 0.00762 eV is displayed in Fig. 5), and this prediction, is agreement with the paramagnetic character of this complex.

4. Conclusion

In summary, we synthesized and characterized structurally a new coordination compound consisting of Zn^{2+} with $TCNQ^-$ radical ligands. The crystal data indicates that the Zn^{2+} ion occupied at an inversion centre is bonded to two $TCNQ^-$ radical anions, two H_2O and two DMF molecules to form almost perfectly octahedral coordination geometry. The strong H-bonding (between the neighboring H_2O molecules as well as between H_2O molecule and $TCNQ^-$ radical anion) and $\pi\cdots\pi$ stack (between $TCNQ^-$ radical anions) interactions lead to a supramolecular network sheet forming on the crystallographic *ac*-plane, and the neighboring supramolecular network sheets further develop into three-dimensional supramolecular structure via weak van der Waals forces. Symmetry-broken approach in the theoretical formwork of DFT further disclosed that the ground state of **1** is singlet state, the excited triplet state is very closed to the nonmagnetic ground state with a small energy gap of 1.25×10^{-5} eV, and this prediction is in agreement with the paramagnetism of **1** observed in magnetic susceptibility. Within the TCNQ π-stacks, there exist antiferromagnetic (AFM) coupling interaction.

3. Results and discussion

3.1. Crystal structure

The prepared compound precipitated as green, plate-like crystals (Fig. 1a). In the Infrared (IR) spectra, CN stretching peaks were observed at 2155, 2159, 2165, 2195, 2207, and 2241 cm^{-1} (Fig. 1b). The peaks are attributed to the stretching vibrations of $[W(CN)_8]^{3-}$ ($\nu_{C\equiv N}$ = 2155, 2159, 2165, 2195, and 2207 cm^{-1}) and 3-cyanopyridine ($\nu_{C\equiv N}$ = 2241 cm^{-1}). The UV–Vis reflectance spectra showed absorption bands around 700 and 1100 nm due to the d–d transition on Cu^{II} (Fig. 1c). X-ray crystallographic analysis indicated that the asymmetric unit consists of a $[W(CN)_8]^{3-}$ anion, one-half of a $[Cu1(H_2O)_2]^{2+}$ cation, one-half of a $[Cu2(pyrimidine)_2]^{2+}$ cation, one-half of a $[Cu3(3\text{-cyanopyridine})]^{2+}$ cation, and a water molecule. Cu1 is coordinated to two nitrogen atoms from the CN ligands, two nitrogen atoms from the pyrimidine molecules, and two oxygen atoms from the H_2O molecules (Fig. 2a). Cu2 is coordinated to four nitrogen atoms from the CN ligands and two nitrogen atoms from the pyrimidine molecules, while Cu3 is coordinated to four nitrogen atoms from the CN ligands and two nitrogen atoms from the 3-cyanopyridine molecules.Fig. 2b and c shows the crystal structure for the *ac*-plane and *ab*-plane, respectively. The cyano-bridged-Cu2–W–Cu3-layer (Fig. 2b) is linked by a Cu1 pillar unit (Fig. 2c). In addition, a cavity exists along the *a* axis, which is occupied by 3-cyanopyridine molecules and zeolitic water molecules (Fig. 2d).

3.2. Magnetic properties

Fig. 3a and b shows the magnetic properties of the present compound. The field-cooled magnetization (FCM) curve at 10 Oe showed a spontaneous magnetization with a Curie temperature (T_c) of 7 K (Fig. 3a). The zero-field-cooled magnetization (ZFCM) and remnant magnetization (RM) curves also supported this T_c value. The magnetization versus external magnetic field curve at 2 K showed a coercive field (H_c) of 7 Oe and a saturation magnetization (M_s) value of 2.9 μ_B for the given formula (Fig. 3b). This M_s value indicates that this compound is a ferrimagnet where the W^{5+} ions ($S = 1/2$) and Cu^{2+} ions (Cu2 and Cu3) in the layer are ferromagnetically coupled, and W^{5+} ions and the bridged Cu^{2+} ions (Cu1) are antiferromagnetically coupled (Fig. 3c), i.e., $M_s = 2(S_{Cu} + S_{Cu} + 2S_W - S_{Cu}) = 3\ \mu_B$, assuming the *g*-factors of Cu^{II} and W^{V} are 2.0.

4. Conclusion

We prepared a new type of cyano-bridged Cu–W bimetallic assembly, $Cu_3[W(CN)_8]_2(pyrimidine)_2(3\text{-cyanopyridine})_2 \cdot 4H_2O$. This compound contains two types of organic ligands, and shows a ferrimagnetism with T_C of 7 K, M_s of 2.9 μ_B, and H_c of 7 Oe at 2 K. The framework of the present compound is analogous with $Co_3[W(CN)_8]_2(pyrimidine)_4 \cdot 6H_2O$, which shows thermally and optically charge-transfer phase transition [10]. Because one route to prepare nanoporous magnets with sophisticated geometrical

[a] UB3LYP/6-31G**.

the largest J_{ab} values calculated by INDO method was J_{12}. Therefore, the pressure effect for the β-phase *p*-NPNN crystal must be reinvestigated by UB3LYP that is more accurate than INDO method.

Since the X-ray structure of the β-phase *p*-NPNN under the high-pressure at low temperature is not known in detail, we have to consider the appropriate models for structure deformation which would be essential for qualitative understanding of the pressure effect. Takeda and co-workers reported relations between induced pressures and cell parameters. However, the geometry changes of *p*-NPNN molecules in the β-phase and the changes of the three dimensional stacking modes of the neighboring molecules were not known. Therefore, several sliding models of *p*-NPNN along the several lines were examined in order to elucidate variations of three J_{ab} values shown in Fig. 1a and b. In Table 1 the calculation results were summarized. The magnitude of the J_{12} value was variable with the sliding along the *x*- or *z*-axis, but its sign was invariant by this type of deformations. It could be concluded that the two dimensional ferromagnetic spin alignments in the *ac* plane remains intact after the sliding deformation of *p*-NPNN along the *x*- or *z*-axis.

As the J_{13} value is responsible for the effective exchange interaction between the *ac*-planes, the variation of J_{13} value is important for the creation of the three dimensional magnetic ordering. As a model for the pressure effects for the interplane interaction, *p*-NPNN (**3**) shown in Fig. 1 was shifted to the central *p*-NPNN (**1**) on the *xy*-plane. This means that the interplane distance between the *ac* planes is retained to be constant. The intermolecular distance (R) was expressed by the interatomic distance between the central carbon atoms of the nitronyl nitroxide groups, and the negative Δ*R* means the decrease of the intermolecular distance. From Table 1, it was found that the sign of J_{13} was changed in the case of *z*-axis sliding model. These results suggest that the J_{13} value is determined by the delicate balance of the two terms that are the ferromagnetic O–C1 interaction and the antiferro-magnetic O–C2 interaction in the normal condition as shown in Fig. 3. Therefore, this indicates that the radical spins in the neighboring *p*-NPNN molecules are aligned in parallel as the ferromagnetic O–C1 interaction overcome the antiferro-magnetic O–C2 interaction in the normal condition. However, the latter became predominant if Δ*R* was elongated, namely in the case of Δ*R* = 0.4–1.0 A.

The sign and magnitude of J_{14} were almost constant and small by the sliding deformations along the 1–4 line on the *xy*-plane and *z*-axis as shown in Table 1. Therefore, it was found that the J_{14} term is not essential for variations of the magnetism.

The rotations of substituents provide another possibility for modeling conformational changes under the high pressure conditions. We here examined variations of the interplane angle between nitronyl nitroxide and nitroxide groups. The side view of the rotational process was illustrated in Fig. 2a. The deformations were restricted to retain the crystal symmetry by assuming the concerted rotations of both components in Fig. 2. Fig. 4 shows variations of J_{12} with the rotational angles. The J_{12} value became negative by the rotation of nitroxide group at the ranges of the rotational angle from 25° to 45° and from 75° to 90°. Thus the ferromagnetic interaction within the *ac* plane can be destroyed by the rotation of nitroxide group of *p*-NPNN.

The rotation of nitrophenyl group was also examined as illustrated in Fig. 2b. Fig. 5 shows variations of J_{13} with the rotational angle. The calculated J_{13} values which exhibited antiferro-magnetic behavior at the ranges of the rotational angle from 15° to 25° and from −70° to −90°. Therefore, the ferro- to antiferro-magnetic transition for the interplane interaction was caused by the rotation which would be reasonable from the view point of the lattice compression by the high pressure.

Since the X-ray structure of β-phase under the high-pressure at low temperature is not known, we here consider plausible models for structure changes which would be essential for qualitative understanding of the effect. Takeda and co-workers reported relations between induced pressures (kPa) and cell parameters (a, b, c). Therefore, we examined the lattice compression dimer models with the internal rotation of nitronyl nitroxide group in *p*-NPNN

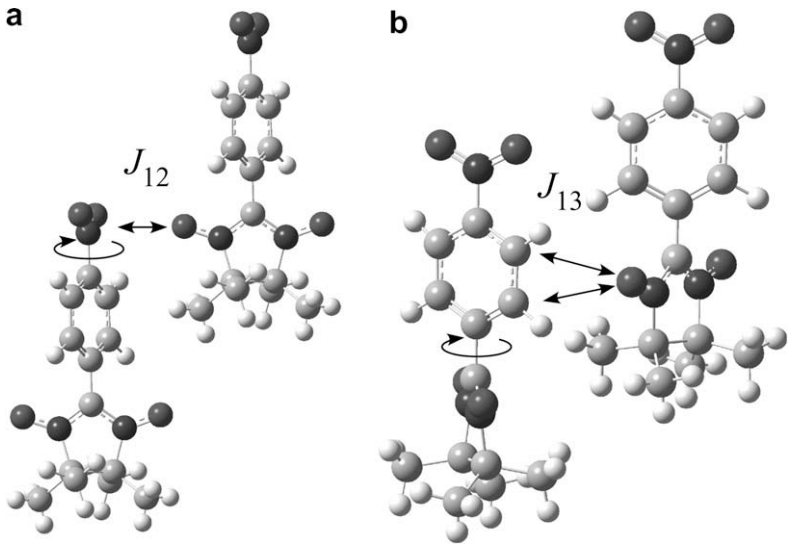

Fig. 2. The schematic diagrams of (a) rotational deformation of nitroxide group of *p*-NPNN which is responsible for variation of J_{12} and (b) rotational deformation of nitrophenyl group of *p*-NPNN which is responsible for variation of J_{13}.

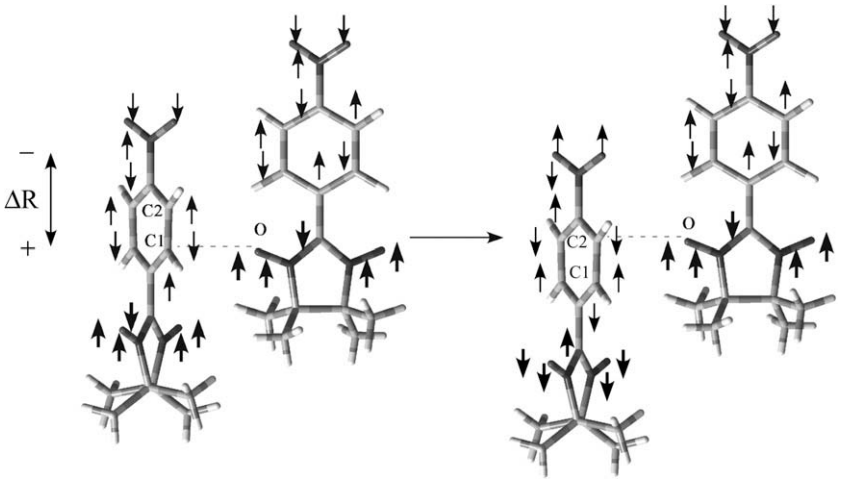

Fig. 3. The schematic illustrations of the magnetic interaction between the neighboring *p*-NPNN clusters in the case of sliding models along the *z*-axis.

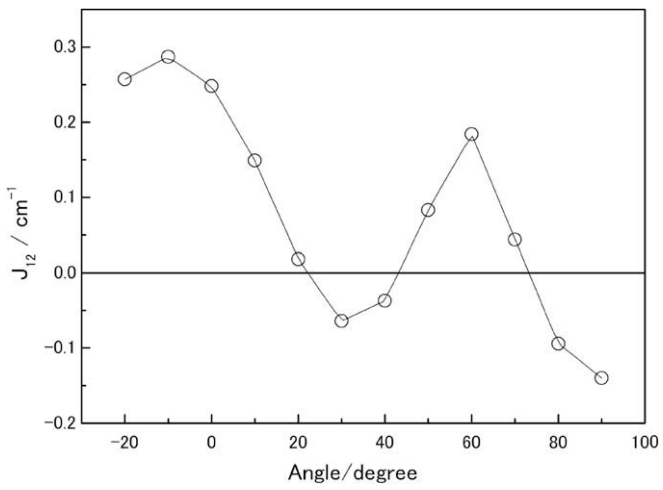

Fig. 4. Variations of the J_{12} values with the rotational process of nitroxide group of *p*-NPNN molecules.

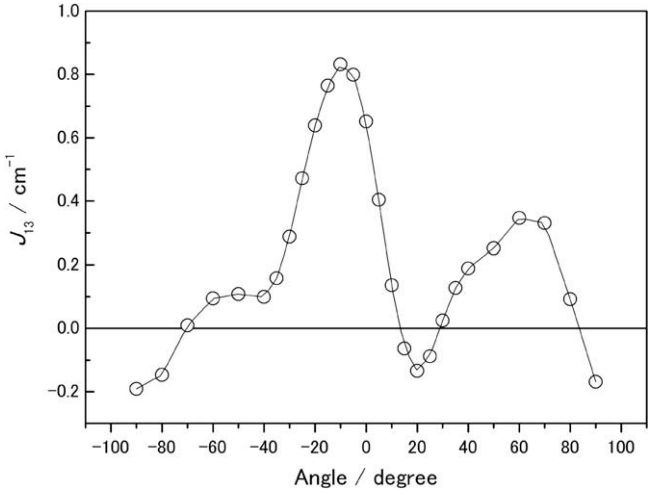

Fig. 5. Variations of the J_{13} values with the rotational process of nitrophenyl group of *p*-NPNN molecules.

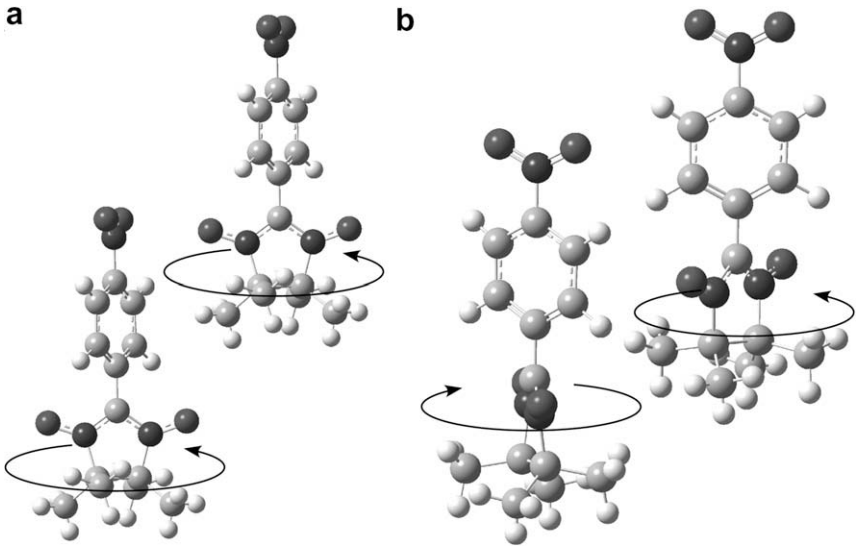

Fig. 6. The lattice compression models with the internal rotations of nitronyl nitroxide groups of *p*-NPNN molecules (a) J_{12} type and (b) J_{13} type dimer models.

Table 2
Variations of the J_{ab}[a] for the lattice compression dimer models with the internal rotations of nitronyl nitroxide group of *p*-NPNN molecules.

Angle (°)	J_{12} (cm^{-1})	J_{13} (cm^{-1})
−20.0	−0.176	0.845
−10.0	−0.070	0.209
0.00	0.651	1.488
10.0	0.691	5.849
20.0	0.235	5.655
30.0	−0.015	−0.386

that lattice constants were varied so as to account for the decrease of intermolecular distances between the neighboring molecules. The cell parameters used in these calculations were those in the highest pressure condition (12.6 kPa). The cluster models examined were displayed in Fig. 6. The obtained J_{12} and J_{13} values were summarized in Table 2. The signs of J_{12} and J_{13} values were changed when the large internal rotations occurred in these models. Thus, these results indicate that the ferro- to antiferro-magnetic transition is also presented in these model systems. From these calculations, it could be presumed that the complex structure changes for the β-phase *p*-NPNN crystal were essential to present the ferro- to antiferro-magnetic transition in the high pressure conditions.

4. Conclusions

Consequently, we found three characteristic modes to understand the observed pressure-induced ferromagnetic to antiferromagnetic transition in the β-phase

(1) The sliding of *p*-NPNN along the z-axis to alter the sign of the interplane exchange integral (J_{13}).
(2) The rotation of nitrophenyl group to provide the negative J_{13}.
(3) The rotation of nitro group to inverse the sign of the intraplane exchange integral (J_{12}).
(4) The combination of the modification of the intermolecular distances between the neighboring *p*-NPNN molecules and the internal rotations of the nitronyl nitroxide group in *p*-NPNN also changes the sign of the exchange integrals.

However, the first makes the lattice constant larger, so it is hardly acceptable unless other conformational changes are coupled together. The second induces the antiferro-magnetic interaction between the *ac*-planes, while the third destroys the two-dimensional ferromagnetic interaction in the *ac*-plane. Since the heat capacity data exhibit the two dimensional magnetic ordering under the high pressure, the second model is conceivable as the simplest model for possible theoretical explanation of the pressure effect in the β-phase of *p*-NPNN. Although the real conformational changes in the β-phase under the high pressure are much more complex, the third and forth model calculations demonstrated that the signs of effective exchange integrals are variable by conformational changes of *p*-NPNN molecules in the β-phase crystal under the high pressure condition.

The present calculations suggest that the pressure-induced ferro- to antiferro-magnetic (vice versa) transitions would be the typical characteristics for many other organic ferromagnets which have flexible structures.

btaOH

Scheme 1. Structural formula of 1-hydroxybenzotriazole (btaOH).

type of coordination sites available on a single metal site and the donor set supplied by the ligand. It is clear, however, that we cannot simply trust to luck in preparing 3d-metal clusters; there thus has to be considerable forethought in the ligands, metals and conditions (reaction ratio, 'pH', solvent, etc.) used for any significant progress to be made. As the field develops, the boundary between 'designed' and 'serendipitous' assembly is becoming blurred [1].

In the context of the several variations of 'serendipitous assembly', we have been exploring 'ligand blend' reactions involving carboxylates and the various anionic forms of di-2-pyridyl ketone [11] and 2-pyridyl oximates [12] as a means to high-nuclearity species; the latter two families of ligands have the ability to bridge two or more metal ions with the *simultaneous* formation of chelating rings. We relatively recently decided to extend the exploration of ligand combinations by employing ligands that cannot chelate. One such ligand is 1-hydroxybenzotriazole (btaOH, Scheme 1), a well-known peptide-coupling additive [13] which exhibits corrosion inhibitive properties towards Cu [14,15] and Fe [16]. The coordination chemistry of btaOH has not attracted the interest of inorganic chemists and only few metal complexes have been prepared and studied. The synthetic investigation of the $[Cu_2(O_2CMe)_4(H_2O)_2]$–btaOH reaction system in MeOH resulted in the isolation of the three-dimensional (3D), diamond-like coordination polymer $[Cu(btaO)_2(MeOH)]_n$ [17], which is a soft magnet exhibiting two critical temperatures at 6.4 and 4.4 K. The anion $btaO^-$ is the 1-hydroxybenzotriazolate ligand (since the –OH group of 1-hydroxybenzotriazole is deprotonated, an alternative name of $btaO^-$ would be 1-oxidobenzotriazolate). Later [18], the reaction of $Ni(NO_3)\cdot 6H_2O$ with btaOH in aqueous NH_3–DMF yielded the trinuclear complex $[Ni_3(btaO)_6(NH_3)_6]$. Reaction of zerovalent Mn with btaOH and NH_4SCN in DMF has allowed the isolation of the one-dimensional (1D) polymer $[Mn_3(btaO)_2(SCN)_4(DMF)_8]_n$ [19a]. The use of the $btaO^-/MeCO_2^-$ combination in manganese(II) chemistry has recently yielded the 2D coordination polymer $[Mn^{II}_3(O_2CMe)_2(btaO)_4(MeOH)_2]_n$; the intra- and inter-magnetic exchange coupling constants for this complex were obtained from Monte Carlo calculations [19b]. The investigation of the $[Ni(acac)_2(H_2O)_2]$–btaOH reaction mixture in MeCN yielded the novel heptanuclear cluster $[Ni_7(OH)_2(acac)_8(btaO)_4(H_2O)_2]$ [20a]. It should be mentioned at this point that complex $[Fe(btaOH)_6](ClO_4)_3$ has also been structurally characterized by Zhang [20b]. The octahedral cation contains formally neutral btaOH ligands; however, the ligands exist as zwitterions exhibiting the 1.100 ligation mode, see Scheme 2.

The coordinative flexibility and versatility of the carboxylate ion and the μ_2, μ_3 or μ_4 potential of the deprotonated ligand (Scheme 2), $btaO^-$, prompted us to combine the two ligands to aim for new types of clusters. The loss of some degree of synthetic control may be more than compensated for by the vast diversity of structures expected using the combination of the two potentially *bridging* ligands. We describe herein the preparation and characterization of the complexes $[Ni_{13}(OH)_6(O_2CMe)_8(btaO)_{12}(H_2O)_6(n\text{PrOH})_4]$

Scheme 2. The up-to-date crystallographically established coordination modes of btaOH (up left) and $btaO^-$ in metal complexes; M = Ni^{II}, Os and M′ = Mn^{II}, Ni^{II}. The Harris notation [21] for the description of the modes is given in parentheses.

· $6.6H_2O$ · 4(*n*PrOH) (**1** · $6.6H_2O$ · 4(*n*PrOH)) and $[Ni_{13}(N_3)_6(O_2CMe)_8(btaO)_{12}(MeOH)_{10}]$ (**2**), which are the first tridecanuclear nickel(II) clusters reported to date. The last 5 years have witnessed a remarkable growth in interest in nickel(II) clusters because few of them have proven to be SMMs [22]. This work can be considered as a continuation of our interest in the chemistry of clusters of the middle and late 3d-metal ions with O,N-ligation [23]. Portions of this work have been previously communicated [23h].

2. Experimental

2.1. General and physical measurements

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received. Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory using an EA 1108 Carlo Erba analyzer. IR spectra (4000–400 cm^{-1}) were recorded on a Perkin–Elmer 16 PC FT-spectrometer with samples prepared as KBr pellets. Variable-temperature magnetic susceptibility measurements were carried out on powdered samples in the 2–300 K temperature range, using a Quantum Design MPMS SQUID susceptometer in a 1 kG applied magnetic field. Magnetization measurements were carried out at 2 K in the field range 0–6.5 T. All samples were packed into gelatine capsules and placed in a drinking straw sample holder. All magnetic susceptibility values were corrected with Pascal's constants and corrections were applied for the sample holder (eicosane, gel capsule and drinking straw).

Safety note! Benzotriazoles, azides and their metal complexes are potentially explosive; such compounds should be synthesized and used in small quantities, and treated with utmost care at all times.

2.2. Compound preparation

2.2.1. $[Ni_{13}(OH)_6(O_2CMe)_8(btaO)_{12}(H_2O)_6(nPrOH)_4] \cdot 6.6H_2O \cdot 4(nPrOH)$ (**1** · $6.6H_2O$ · 4(*n*PrOH))

A colourless solution (15 ml) of btaOH (0.081 g, 0.60 mmol) in *n*PrOH was added to a green solution of $Ni(O_2CMe)_2 \cdot 4H_2O$ (0.149 g, 0.60 mmol) in *n*PrOH (10 ml). The obtained pale green solution was filtered and allowed to stand undisturbed in a closed flask at room temperature. Green prismatic crystals of **1** · $6.6H_2O$ · 4(*n*PrOH) formed within 24–36 h and these were collected by filtration, washed with Et_2O (2 × 3 ml) and dried in vacuo. Typical yields were in the 50–60% range. Selected IR (KBr pellet) data: ν = 3422mb, 3320sb, 1592s, 1579s, 1439s, 1405m, 1200m, 1170m, 1125m. The dried solid analyzed satisfactorily as **1** · $5H_2O$ · 3(*n*PrOH). *Anal.* Calc. for $C_{109}H_{156}O_{52}N_{36}Ni_{13}$ (3654.85): C, 36.72; H, 4.41; N, 14.14. Found: C, 37.08; H, 4.63; N, 13.88%.

2.2.2. $[Ni_{13}(N_3)_6(O_2CMe)_8(btaO)_{12}(MeOH)_{10}]$ (**2**)

A suspension of compound $[Ni_{13}(OH)_6(O_2CMe)_8(btaO)_{12}H_2O)_6(nPrOH)_4] \cdot 6.6H_2O \cdot 4(nPrOH)$(**1** · $6.6H_2O$ · 4(*n*PrOH)) (1.097 g, 0.30 mmol) in MeOH (20 ml) was treated with solid NaN_3 (0.156 g, 2.40 mmol). The mixture was refluxed overnight, filtered to remove a few quantity of undissolved material, and the resulting dark green solution was allowed to stand undisturbed in a closed flask at room temperature. Green microcrystalline solid of **2** was precipitated within 4 days and this was collected by filtration, washed with Et_2O (2 × 3 mL) and dried in vacuo. Typical yields were in the 30–40% range. Selected IR (KBr pellet) data: ν = 3310sb, 2077s, 1592s, 1578s, 1440m, 1403m, 1199m, 1173m, 1124m. The dried solid analyzed as **2** · $2H_2O$. *Anal.* Calc. for $C_{98}H_{116}O_{40}N_{54}Ni_{13}$ (3453.36): C, 34.09; H, 3.39; N, 21.90. Found: C, 34.37; H, 3.72; N, 22.06%.

2.3. Single-crystal X-ray crystallography

A crystal of **1** · $6.6H_2O$ · 4(*n*PrOH) with approximate dimensions 0.15 × 0.20 × 0.40 mm was mounted in capillary. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation. Complete crystal data and parameters for data collection and processing are listed in Table 1. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centred reflections in the range $11° < 2\theta < 23°$. Intensity data were recorded using the θ–2θ scan method. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization and Ψ-scan absorption were applied using the Crystal Logic software package.

The structure was solved by direct methods using SHELXS-86 [24] and refined by full-matrix least-squares techniques on F^2 with SHELXL-97 [25]. Hydrogen atoms of the $btaO^-$ and $MeCO_2^-$ ligands were introduced at calculated positions as riding on bonded atoms. Those of the hydroxo ligands, and coordinated H_2O and *n*PrOH molecules were located by difference maps and were refined isotropically. All non-hydrogen atoms were refined anisotropically, except those of the solvate molecules and the carbon atoms C94, C95 and C96 of a coordinated *n*PrOH which were refined isotropically. The monodentate $MeCO_2^-$ ligand and Ow3 coordinated on Ni7 were found disordered, switching positions in the coordination sphere, thus the $MeCO_2^-$ ligand was refined in two orientations with sum of occupation factors equal to one.

3. Results and discussion

3.1. Brief synthetic comments

Reaction of $Ni(O_2CMe)_2 \cdot 4H_2O$ with one equivalent of btaOH in propanol and storage of the obtained pale green solution at room temperature led to the precipitation of green prismatic crystals

[b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$.

of $[Ni_{13}(OH)_6(O_2CMe)_8(btaO)_{12}(H_2O)_6(n\text{PrOH})_4]\cdot 6.6H_2O\cdot 4Pr^nOH$ ($\mathbf{1}\cdot 6.6H_2O\cdot 4(n\text{PrOH})$) in ~55% yield (Eq. (1)). Obviously, btaOH is deprotonated by the basic $MeCO_2^-$ groups:

$$13Ni(O_2CMe)_2 4H_2O + 12btaOH + 4(n\text{PrOH}) \xrightarrow{n\text{PrOH}} \times [Ni_{13}(OH)_6(O_2CMe)_8(\underset{\mathbf{1}}{btaO})_{12}(H_2O)_6(n\text{PrOH})_4] + 18MeCO_2H + 40H_2O \quad (1)$$

Complex **1** seems to be the only product from the $Ni(O_2CMe)_2\cdot 4H_2O$/btaOH reaction mixture irrespective of the Ni^{II} to ligand reaction ratio. The addition of counterions such as ClO_4^- and PF_6^- (for the isolation of potentially existing cationic complexes) and the crystallization method have no influence on the identity of the product.

Following our well developed strategy [26], we tried to replace some or all the OH^- bridges in **1** with end-on N_3^- bridges in order to introduce ferromagnetic interactions (the end-on azido ligand is a ferromagnetic coupler [26]) in the superexchange scheme (vide infra) Thus, reaction of pre-isolated **1** with an excess (8–10 equivalents) of NaN_3 in MeOH under reflux gave a green solution from which microcrystalline $[Ni_{13}(N_3)_6(O_2CMe)_8(btaO)_{12}(MeOH)_{10}]$ (**2**) was precipitated in 30% yield upon storage at room temperature (Eq. (2)). Despite hundreds of experiments, we have failed to grow single crystals of the azido product suitable for crystallography due to poor diffraction and/or twinning problems (more than fifty crystals were examined). Thus, the characterization of complex **2** is based on the analytical and IR data (vide infra):

$$[Ni_{13}(OH)_6(O_2CMe)_8(\underset{\mathbf{1}}{btaO})_{12}(H_2O)_6(n\text{PrOH})_4] + 6NaN_3 + 10MeOH \xrightarrow[T]{MeOH} [Ni_{13}(N_3)_6(O_2CMe)_{\underset{\mathbf{2}}{8}}(btaO)_{12}(MeOH)_{10}] + 6H_2O + 4(n\text{PrOH}) \quad (2)$$

3.2. Description of structure

Partially labelled plots of the tridecanuclear molecule present in $\mathbf{1}\cdot 6.6H_2O\cdot 4(n\text{PrOH})$ is shown in Fig. 1. Selected interatomic distances and angles are listed in Table 2. Table 3 summarizes important hydrogen-bonding data.

Table 2

Symmetry operation used to generate equivalent atoms: $-x+1, -y, -z+1$.

The structure of $\mathbf{1}\cdot 6.6H_2O\cdot 4(n\text{PrOH})$ consists of the tridecanuclear molecule $[Ni_{13}(OH)_6(O_2CMe)_8(btaO)_{12}(H_2O)_6(n\text{PrOH})_4]$ (Fig. 1), and solvate H_2O and nPrOH molecules; the solvate molecules will not be further discussed. The centrosymmetric [Ni(1) is a crystallographic inversion center] tridecanuclear molecular assembly is held together by six μ_3 (or 3.1 using Harris notation

[a] A = acceptor atom, D = donor atom.
[b] Atoms W(1) and W(2) belong to coordinated water molecules.
[c] Atoms OP(1) and OP(2) (not shown in Fig. 1) belong to lattice propanol.

[21]) hydroxo ligands [O(61), O(62), O(63) and their symmetry equivalents] and twelve $\eta^1{:}\eta^1{:}\eta^1{:}\mu_3$ (or 3.1110 [21], see Scheme 2) btaO$^-$ groups [the deprotonated O atoms of the btaO$^-$ groups are O(1), O(11), O(21), O(31), O(41), O(51) and their symmetry counterparts]. Peripheral ligation is provided by six chelating (η^2 or 1.11) $MeCO_2^-$ ligands, two monodentate (η^1 or 1.10) $MeCO_2^-$ groups, six terminal aqua ligands [OW(1), OW(2), OW(3) and their symmetry equivalents] and four terminal *n*PrOH molecules [O(81), O(82) and their symmetry equivalents]. Thus, the core is $\{Ni_{13}(\mu_3\text{-}OH)_6(\mu_3\text{-}ONNNR)_{12}\}^{8+}$ (Fig. 2), where R– = C_6H_4–. As a result of the above described ligation, the distorted octahedral chromophores of the seven, crystallographically independent metal ions are $Ni(1)N_6$, $Ni(2)(O_{hydroxo})_3N_3$, $Ni(3)(O_{hydroxo})_3N_3$, $Ni(4)(O_{hydroxo})(O_{acetate})_2(O_{btaO^-})(O_{propanol})N$, $Ni(5)(O_{hydroxo})(O_{acetate})_2(O_{btaO^-})(O_{aquo})N$, $Ni(6)(O_{hydroxo})(O_{acetate})_2(O_{btaO^-})(O_{propanol})N$ and $Ni(7)(O_{acetate})(O_{btaO^-})_3(O_{aquo})_2$.

The Ni–O(μ_3-hydroxo), Ni–$O_{acetate}$, Ni–O_{btaO^-}, Ni–O_{aquo}, Ni–$O_{propanol}$ and Ni–N bond lengths are typical for high-spin, six coordinate Ni(II) complexes [23a,b,27]. Each μ_3-OH^- group forms one short and two longer bonds to the metal ions. The Ni–O bond to the monodentate acetate ligand [Ni(7)–O(77) 2.060(11) Å] is slightly shorter, as expected, than the Ni–O bonds to the bidentate acetate groups [average value: 2.115(8) Å].

There is an amount of hydrogen bonding in **1** · 6.6H_2O · 4 (*n*PrOH) (see Table 3). The cluster molecules are directly connected forming "chains" through an intermolecular hydrogen bond involving the *n*PrOH oxygen atom O(81) (and its symmetry partner) as donor and the acetate oxygen atom O(71) (−*x*, −*y*, −*z* + 1), and its symmetry partner, as acceptor. The six μ_3 hydroxo ligands [O(61), O(62), O(63) and their symmetry equivalents] are intramolecularly hydrogen bonded with O atoms from six different btaO$^-$ ligands [O(1), O(41), O(21) and their symmetry equivalents, respectively]. The crystal structure is also stabilized by a variety of hydrogen bonds between the cluster molecule and/or the lattice solvent molecule resulting in a 3D network.

The metal ions Ni(7), Ni(2), Ni(3), Ni(1), Ni(3′), Ni(2′) and Ni(7′) are coplanar and almost colinear; this view is emphasized in Fig. 3. Using the perspective view of this figure, Ni(5) is 3.130 Å above the Ni_7 plane, while Ni(4) and Ni(6) are 2.318 and 0.812 Å, respectively, below the Ni_7 plane. The shortest $Ni^{II}\cdots Ni^{II}$ distance within the molecule is Ni(2)···Ni(3) [2.759(2) Å]; this short distance is a consequence of the presence of three monoatomic hydroxo bridges. The Ni(7)···Ni(7′) distance is the longest one [21.252(2) Å].

In addition to the various triangular topologies that are present in **1**, several other subunits are clearly visible within the core of **1**: (i) The $\{Ni(2)(OH)_3Ni(3)\}^+$ (and its symmetry equivalent) subcore has never been identified in Ni(II) cluster or polymer chemistry; (ii) the metal ions Ni(1), Ni(4), Ni(5), Ni(6), Ni(4′), Ni(5′) and Ni(6′) adopt the topology of two tetrahedra sharing a common apex at Ni(1) (Fig. 4); this topology is extremely rare in Ni(II)

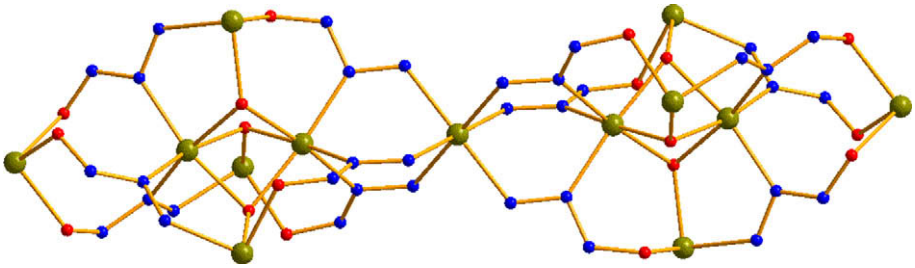

Fig. 2. The $\{Ni_{13}(\mu_3\text{-}OH)_6(\mu_3\text{-}ONNNR)_{12}\}^{8+}$ core of complex **1**, where R– = C_6H_4–. Colour code: Ni, green; O, red; N, blue. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

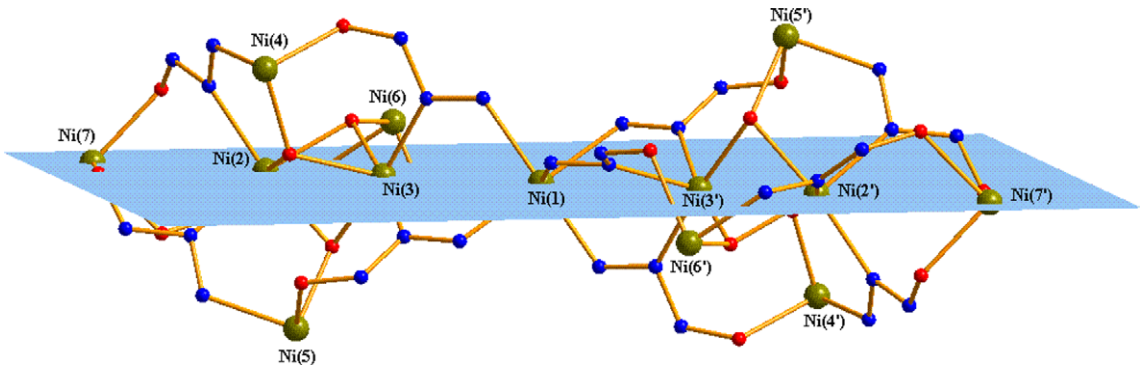

Fig. 3. A view of the core of complex **1** emphasizing the planarity and almost linearity of seven (out of 13) Ni^{II} ions.

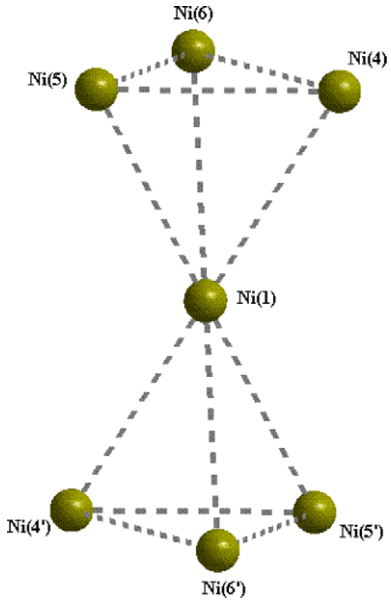

Fig. 4. The vertex-sharing, double tetrahedral topology of seven Ni^{II} ions.

chemistry and has been observed only in the chiral complex $[Ni_7(OH)_2L_3]$, where L is the tetra-anion of (2*R*,3*R*)-1,4-bis(3,5-di-*tert*-butylsalicylideneamino)-2,3-butanediol [28]; (iii) the {Ni(2)-Ni(3)Ni(4)Ni(5)Ni(6)(O(61)H)(O62)H)(O(63)H}$^{7+}$ subcore can be described as a 'mutant' butterfly, with Ni(2) and Ni(3) ions at the central ('body') and Ni(4), Ni(5), Ni(6) on its three end ('wingtip') positions (Fig. 5); tetranuclear Ni(II) clusters with a normal $\{Ni_4(\mu_3\text{-}OH)_2\}^{6+}$ topology have been structurally characterized [17]; and (iv) the central $\{Ni_3(\mu\text{-}NNR')_6\}$ subcore (R′– = C_6H_4NO–), which is present in **1** (Fig. 6), has been observed in the linear trinuclear cluster $[Ni_3(btaO)_6(NH_3)_6]$ [18]; in the latter the deprotonated oxygen atoms of the $btaO^-$ ligands are hydrogen bonded to the ammine ligands, whereas in the former the $btaO^-$ oxygen atoms are each coordinated to a Ni^{II} ion resulting in a higher nuclearity complex.

Compound **1** is the nineth structurally characterized complex of any metal containing $btaO^-$ ligands. Except the Werner-type complexes that are discussed in the Introduction [17–20], the other three compounds are the organometallic complexes $[Os_3H(CO)_{10}(btaO)]$, $[Os_3(C{=}NHPr^n)(CO)_{10}(btaO)]$ and $[Os_3(C{=}NHCH_2Ph)(CO)_{10}(btaO)]$ [29]. The 3.1110 coordination mode found in **1** has been observed only in $[Mn^{II}_3(O_2CMe)_2(btaO)_4(MeOH)_2]_n$ [19b]. Only the 2.0110 mode has been found in more than two complexes, i.e. in $[Ni_3(btaO)_6(NH_3)_6]$ [18], $[Ni_7(OH)_2(acac)_8(btaO)_4(H_2O)_2]$ [20] and in the Os organometallic compounds [29].

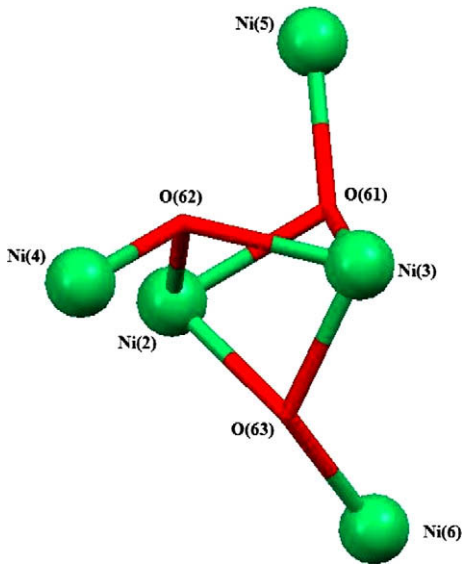

Fig. 5. The 'mutant' butterfly $\{Ni_5(\mu_3\text{-}OH)_3\}^{7+}$ subunit present in **1**.

Complex **1** joins a small but growing family of tridecanuclear metal complexes; these complexes have various metal topologies. Since most of these complexes have been reported only recently, we felt it timely to collect them in Table 4, together with their spin ground-state values, where there are available. Inspection of Table 4 shows that complex **1** is the first structurally characterized tridecanuclear Ni(II) cluster. While the number of polynuclear transition metal complexes reported continues to grow rapidly, some nuclearities remain extremely rare. Tridecanuclear complexes are particularly uncommon.

3.3. IR spectra

A characteristic feature in the IR spectrum of complex **1** is the appearance of a strong broad band at ~3320 cm^{-1} assignable to $\nu(OH)H_2O/n$PrOH. The presence of hydroxo ligands in the complex is manifested by a medium band at ~3420 cm^{-1} [34]. The broadness and relatively low frequency of these bands are both indicative of hydrogen bonding. The spectra of the sodium and potassium salts of 1-hydroxybenzotriazole (btaONa, btaOK) exhibit bands at 1180 and ca. 1105 cm^{-1}, associated with the ν(N=N) and ν(N–N) modes of vibration, respectively. These bands are shifted to 1200 and 1125 cm^{-1}, respectively, in the spectrum of the complex. The medium intensity band at 1170 cm^{-1} is assigned to ν(N–O) [20a]. This band has been shifted to lower wavenumber in **1** compared with its frequency (1224 cm^{-1}) in the IR spectrum of the potassium salt of 1-hydroxybenzotriazole, btaOK. Such a large shift to lower frequencies has also been observed [17,19,20a] in the spectra of other metal complexes where the deprotonated oxygen atom of $btaO^-$ is coordinated. The strong bands at 1592 and 1579 cm^{-1} are assigned [35] to the $\nu_{as}(CO_2)$ vibration; the $\nu_s(CO_2)$ vibrations appear [35] at 1439 and 1405 cm^{-1}. The presence of two distinct bands for each mode reflects the presence of two types of acetate ligands in the complex. The 1592 and 1405 cm^{-1} [$\Delta = \nu_{as}(CO_2) - \nu_s(CO_2) = 187\ cm^{-1}$] pair are assigned to the monodentate acetates, while the 1579 and 1439 cm^{-1} one ($\Delta = 140\ cm^{-1}$) to the chelating acetates [35]. The differences Δ are more (187 cm^{-1}) and less (140 cm^{-1}) than the Δ value for NaO_2CMe (164 cm^{-1}), as expected for the monodentate and bidentate of carboxylate ligation, respectively [35].

The IR spectrum of **2** is very similar to that of **1**, the main differences being the presence of one strong band at 2077 cm^{-1} and the absence of the band at ~3420 cm^{-1} in the former. This similarity supports analogous structures for **1** and **2**. The band at 2077 cm^{-1} is assigned to the asymmetric stretching mode of the azido ligand [36] and is situated at almost the same wavenumber observed in clusters containing end-on azido ligands [26d].

3.4. Magnetic properties

Variable-temperature dc magnetic susceptibility studies were performed on powdered samples of compounds **1** and **2** in an applied magnetic field of 0.1 T (1.0 KG) and in the 2.0–300 K range. The data are plotted as $\chi_M T$ versus T in Fig. 7. $\chi_M T$ at 300 K is 16.24 emu mol^{-1} K, lower than the 17.19 emu mol^{-1} K value (for $g = 2.3$) expected for a cluster of 13 non-interacting Ni^{II} ions. As T is lowered, the $\chi_M T$ product gradually decreases to 9.88 emu mol^{-1} K at 16 K where a plateau appears; the product

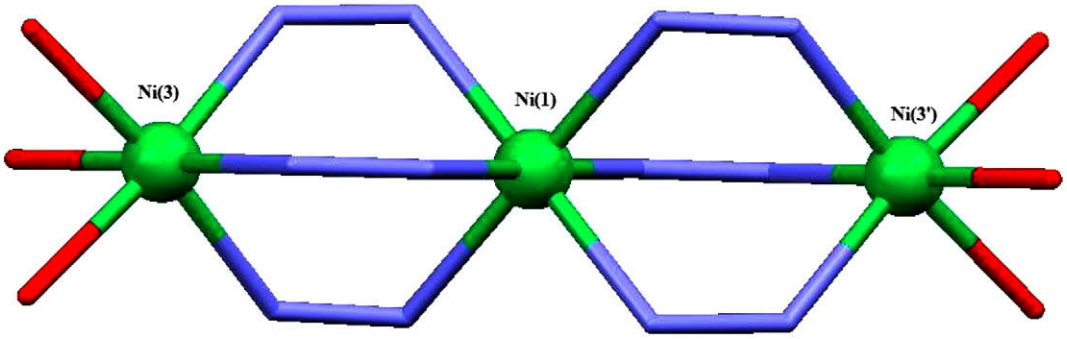

Fig. 6. The central $\{Ni_3(\mu\text{-}NNR')_6\}$ subcore (R′– = C_6H_4NO–) in **1**.

increases from this value at 9 K to 10.21 emu mol^{-1} K at 3.3 K before finally decreasing to 9.52 emu mol^{-1} K at 2.0 K. The low temperature behaviour is consistent with a frustrated magnetic system, where there are competitive antiferromagnetic exchange interactions, mainly within the pentanuclear Ni(2)Ni(3)Ni(4)Ni(5)-Ni(6)/Ni(2′)Ni(3′)Ni(4′)Ni(5′)Ni(6′) subunits (triangular spin topologies). From now onwards, the numbering scheme that will be used for the magnetic discussion of **1** is the same with that used in the real structure, see Figs. 1 and 3–5. We define spin frustration here in its more common, general sense of competing exchange interactions of similar magnitude that prevent the preferred spin alignments, rather than the original, most specific sense that competing interactions of the same magnitude lead to a degenerate ground state.

In an attempt to try to quantify the magnetic behaviour of the system, and since a phenomenological Hamiltonian of 13 $S = 1$ spins is a quite large system to be treated even with the ITO methods, some approximations were used. A simplified Hamiltonian of the system is given by Eq. (3):

$$H = -J_1(S_2S_3 + S_{2'}S_{3'}) - J_2[(S_2 + S_3)(S_4 + S_5 + S_6) + (S_{2'} + S_{3'}) \times (S_{4'} + S_{5'} + S_{6'})] - J_3[S_1(S_3 + S_{3'})] - J_4(S_2S_7 + S_{2'}S_{7'}) \quad (3)$$

To avoid parametrization, we decided to attempt to fit the susceptibility data considering that the main exchange interactions come from the pentanuclear subunits mentioned above, i.e. to use a 2-J model assuming that $J_3 = J_4 = 0$. These pentanuclear subunits contain monoatomic bridges (Fig. 5), derived from the μ_3-OH^- ligands, which give more effective coupling than the diatomic or triatomic bridges. Thus, in a simple approximation, the system can be considered as consisting of two pentanuclear subunits and three mononuclear Ni^{II} sites. Best-fit parameters are $J_1 = -24.5$ cm^{-1}, $J_2 = -12.6$ cm^{-1} and $g = 2.31$. The model used to fit the data does not take into account the decline of $\chi_M T$ below 3.3 K. This steep decrease, often occurring in polynuclear nickel(II) complexes, is associated [37] with the characteristic zero-field splitting of the Ni^{II} ion and probably with the intermolecular interactions present in the crystal structure of the complex. The fitting results are in accordance with the behaviour of the system, in which the existence of antiferromagnetic interactions within the triangular Ni(2)Ni(3)Ni(4,5,6) subunits leads to frustration (Scheme 3). It should be mentioned that despite the small Ni(2)–O(H)–Ni(3) angles [20a], the interaction J_1 is antiferromagnetic. We attribute this partly to the μ_3 character of the hydroxo ligands and partly to the frustrating behaviour of the system. Further investigation of the magnetic behaviour of **1** using Monte Carlo methodology [19b] is in progress in order to investigate the system without approximations; preliminary results indicate that our model is valid.

The $\chi_M T$ product for **2** at 300 K is 16.87 emu mol^{-1} K and remains practically constant in the 300–54 K range, below which it decreases drastically to a value of 5.93 emu mol^{-1} K at 2.2 K. *Assuming* a structural similarity between **1** and **2**, and employing

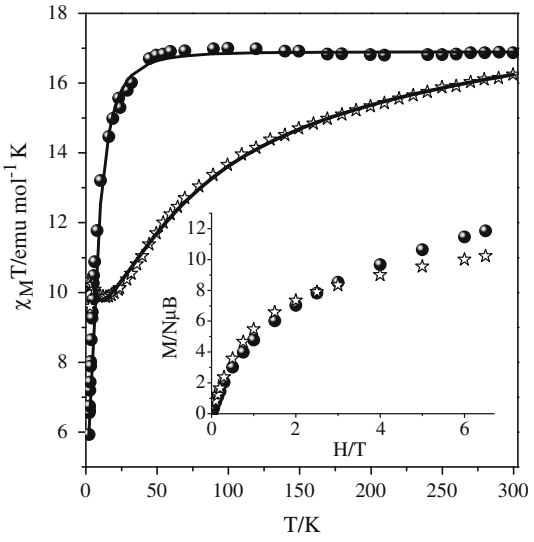
[a] Hchp = 6-chloro-2-hydroxypyridine.
[b] phth = phthalate.
[c] Me_2BtaH = dimethylbenzotriazole.
[d] ndc^{2-} = 1,8-naphthalenedicarboxylate.



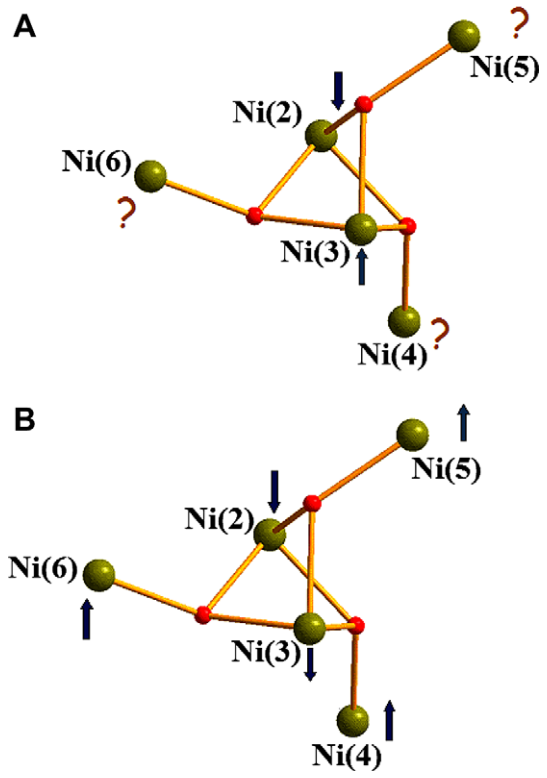


Fig. 7. Plot of $\chi_M T$ vs. T for powdered samples of **1** (open stars) and **2** (black circles); the solid lines represent the fit to the theoretical models (see text for the fit parameters). Plots of reduced magnetization ($M/N\mu_B$) vs. H at 2 K in the field range 0–6.5 T are shown in the inset.

Scheme 3. Spin topologies of the pentanuclear subunits present in complex **1** (A) and assumed to be present in complex **2** (B). The monoatomic bridges in A derive from the crystallographically established μ_3-OH$^-$ groups, while in B come from the nitrogen atoms of the μ_3 end-on N_3^- ligands which are proposed to be present in the azido product.

the same model and approximations used for **1**, best-fit parameters for **2** are $J_1 = 12.8\ cm^{-1}$, $J_2 = -1.93\ cm^{-1}$ and $g = 2.27$. Thus, the spin frustration observed in **1** seems to disappear in **2**, due to the existence of a ferromagnetic exchange interaction in the pentanuclear subunits of the latter (Scheme 3) [28].

According to Fig. 7, the ground-state spin of compound **2** is smaller than that of **1**. The most probable reason for this is the spin frustration in the latter which results in a larger S value compared with that in the former; it seems that the frustrated Ni^{II}_5 units have a larger spin value in the ground state than the non-frustrated ones. Thus the conversion of **1** into **2** represents an extremely rare case in which substitution of bridging hydroxo ligands by end-on bridging azide groups has led to a decrease in the ground-state S value; usually the addition of the latter is sought as a means of raising the value of S [26].

The magnetization curves of **1** and **2** are shown in the inset of Fig. 7; no saturation is observed indicating that many energy states are populated even at very low temperatures

4. Conclusions

The present work extends the body of results that emphasize the ability of the anionic ligand btaO$^-$ to form interesting structural types in 3d-metal chemistry. The initial use of the btaO$^-$/MeCO$_2^-$ combination in Ni(II) chemistry has provided access to cluster **1** with interesting structural and magnetic properties. This cluster is the highest nuclearity metal btaOH or btaO$^-$ to date and the first Ni_{13} complex, showing that btaO$^-$ can indeed support high nuclearity chemistry when coupled with appropriate ancillary ligands. Complex **1** is only the second complex of any metal in which btaO$^-$ and MeCO$_2^-$ groups coexist; the first one, namely $[Mn^{II}_3(O_2CMe)_2(btaO)_4(MeOH)_2]_n$, is a 2D coordination polymer [19b]. Another interesting point of this work is the rational reactivity of **1** with N_3^- ions which gave the – most probably – structurally analogous azido-bridged cluster **2** with different magnetic properties.

Complexes of 3d-metal ions other than Ni^{II} (this work) and Mn^{II} [19b] with the btaO$^-$/RCO$_2^-$ (R = H, Me, Ph, etc.) ligand combination are not known to date, and it is currently not evident whether the structural types (clusters versus polymers) of such compounds are dependent on the nature of the metal and the R group of the carboxylate ligand. Such matters are under intense investigation in our group.

of the real 1D chain, a proton was added to one terminal dca ligand. This hydrogen atom was placed at an ideal position and optimized with a simple molecular mechanics force field. In the case of the non-bridged Fe_3O complexes, the X-ray geometry was employed, running separately calculations for the two species co-crystallized in the structure [25], $[Fe_3O(Piv)_6(CH_3OH)_2dca]$ (**2**) and $[Fe_3O(Piv)_6(CH_3OH)_3]^+$ (**3**) (Fig. 1).

2.2. DFT calculations

Density functional theory (DFT) spin-unrestricted calculations were performed using the GAUSSIAN03 program [27] (revision D.01) at the B3LYP level employing the *LanL2DZ* basis set and in the case of the smaller complexes **2** and **3** the triple ζ valence split basis set from Ahlrichs with polarization functions (*TZVP*) was also used. Both basis sets were used as implemented in the Gaussian package. Tightly converged (10^{-8} Eh in energy) single point calculations were performed in order to analyze the exchange coupling between the iron centers. The methodology applied here relies on the broken symmetry formalism, originally developed by Noodleman for SCF methods [7], which involves a variational treatment within the restrictions of a single spin-unrestricted Slater determinant built upon using different orbitals for different spin. This approach has been later applied within the frame of DFT [8]. The HS (high spin) and BS (broken-symmetry) energies were then combined to estimate the exchange coupling parameter *J* involved in the widespread used Heisenberg–Dirac–van Vleck Hamiltonian:

$$\hat{H}_{\mathrm{HDvV}} = -2J\hat{S}_A\hat{S}_B \tag{1}$$

In the case of complexes **2** and **3**, we have calculated the three possible spin topologies of broken symmetry nature while in the case of the model complex **1** we have calculated seven broken-symmetry states (Table 1). The exchange coupling constants J_i can be obtained after considering the individual pair-like components spin interactions involved in the description of the different broken symmetry states. Three main reported methodologies can be followed: the Ising approach [28], where the broken symmetry states are directly considered as eigenstates of the HDvV Hamiltonian (Eq. (1)) with the corresponding equation:

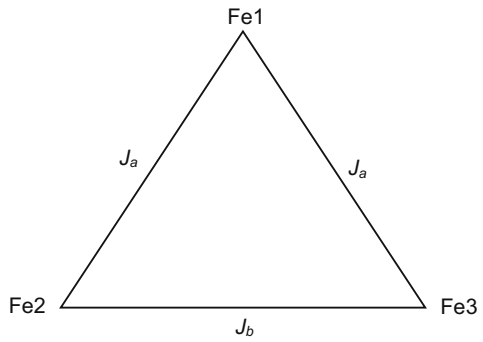
$$E_{BS} - E_{HS} = 2J_{12}(2S_1S_2) \tag{2}$$

the non-projected method proposed by Ruiz and co-workers [19], where the following equation is applied:

$$E_{BS} - E_{HS} = 2J_{12}(2S_1S_2 + S_2), \quad \text{with } S_2 < S_1 \tag{3}$$

and finally the generalized multi-spin Yamaguchi method [21], based in the equation:

$$E_{BS} - E_{HS} = 2J_{12}(\langle S_1S_2\rangle_F - \langle S_1S_2\rangle_{AF}) \tag{4}$$



where $\langle S_1S_2\rangle$ ($_F$ = ferromagnetic, $_{AF}$ = anti-ferromagnetic) are the spin correlation functions between the interacting spins.

In all cases a set of linear equations must be solved to obtain the *J* parameters.

Scheme 1. Exchange coupling pattern in the triangular core Fe_3O.

Further details about these methodologies can be found in Ref. [28,19,21].

Additionally, we have also employed the BS-type spin unrestricted solutions after a corresponding orbital transformation (COT) to visualize the interacting non-orthogonal magnetic orbitals [29]. These orbitals do not have a well-defined orbital energy, for this reason, orbital energies are not given explicitly but just their overlapping magnitudes as well as the spin-coupling exchange pathways.

Table 3
Crystallographic Fe-μ_3-O distances in the Fe_3O cores studied.

3. Results and discussion

3.1. Trinuclear Fe_3O complexes **2** and **3**

The calculated J values for the Fe_3O units in complexes **2** and **3** (Table 2) are in good agreement with the experimental ones [25]. As expected, two J values are essentially identical reproducing the usual 2J behavior experimentally observed for this type of triangular Fe_3O cores with three high spin ($S = 5/2$) Fe(III) ions, and ruled by the following HDvV Hamiltonian (Scheme 1):

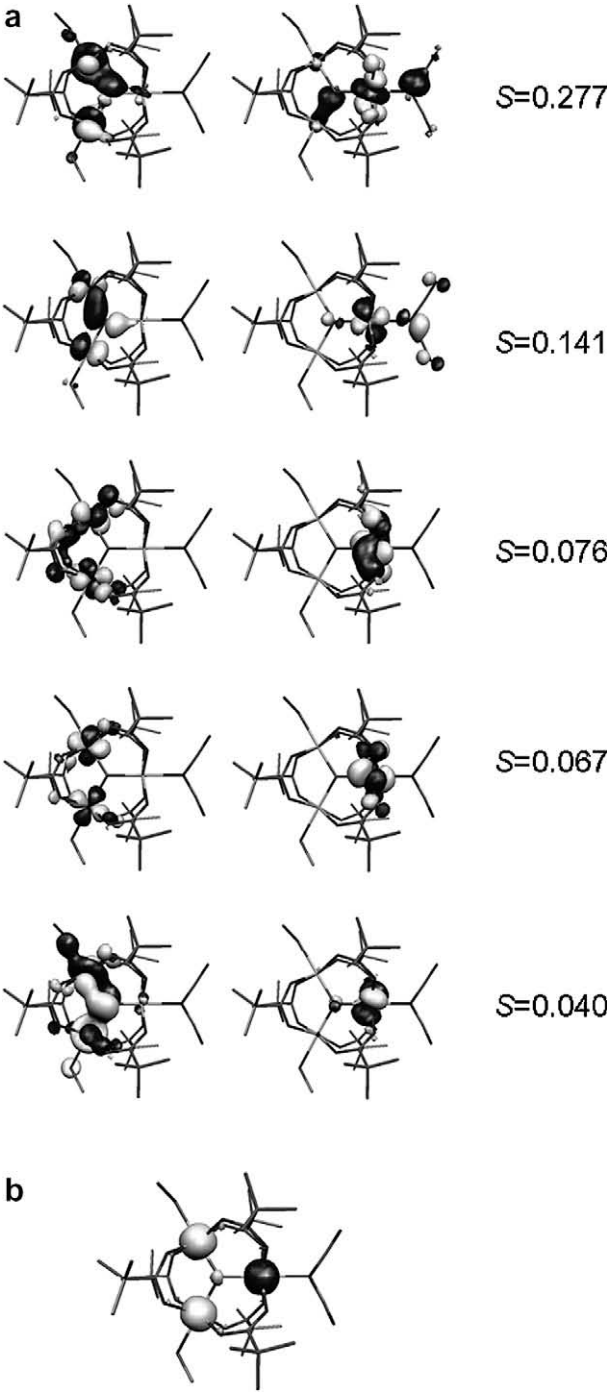

Fig. 3. (a) Magnetic orbitals arising from BS1 after a COT of complex **2** with their corresponding overlaps (S). Left: alpha orbitals, right: beta orbitals. (b) Spin density of BS1 of complex **2**, clear and dark regions corresponds to positive and negative spin densities.

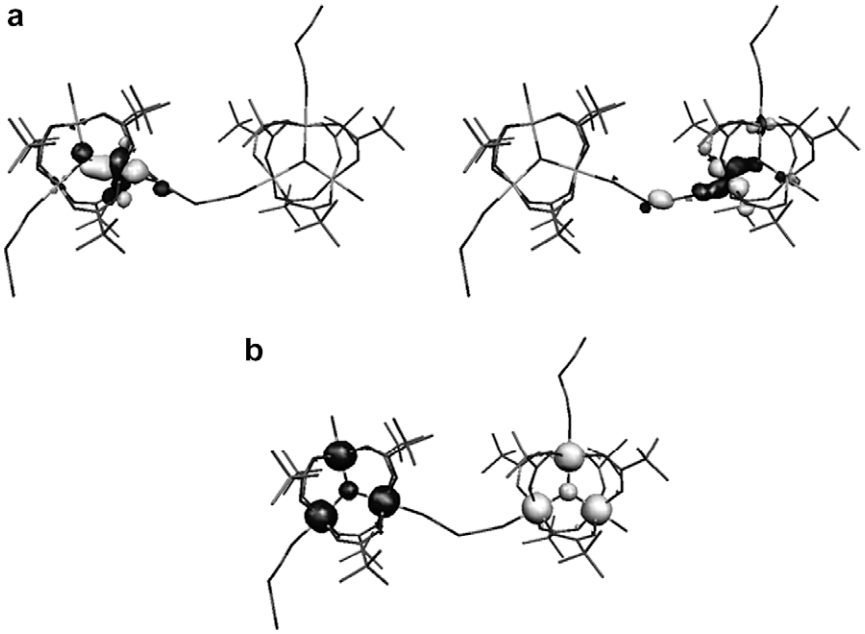

Fig. 4. (a) Magnetic orbitals of complex **1** arising from BS8 after a COT, with a non-negligible overlap trough the dca bridge. Left: alpha orbital, right: beta orbital. (b) Spin density of BS8 of complex **1**, clear and dark regions corresponds to positive and negative spin densities.

$$\hat{H} = -2J_a(\hat{S}_1 \cdot \hat{S}_2 + \hat{S}_1 \cdot \hat{S}_3) - 2J_b(\hat{S}_2 \cdot \hat{S}_3) \quad (5)$$

In the case of complex **2**, the lower obtained $|J|$ value corresponds to J_a, while in complex **3** it corresponds to J_b. This is compatible with experimental data as one short and two long Fe–O–Fe pathways are observed for **2** while the inverse pattern applies in the case of complex **3** (Table 3). It can be noticed that the use of a bigger basis set as *TZVP* instead of the core effective potential type *LanL2DZ* basis sets does not show an improvement in the final calculated values. It appears also that Ruiz methodology gives the more accurate results while the multi-spin Yamaguchi approach does not represent an improvement with respect to the Ising approximation. The $J_>/J_<$ ratio is well reproduced with the three methodologies, most noticeably in the case of the *LanL2DZ* basis set, with values of 1.14/1.16, in comparison to the experimental observed of $J_>/J_< = 1.2$. Hence, the $S = 1/2$ ground state experimentally observed is also reproduced by the calculations. Calculated χT versus T plots,[1] as the 1:1 contribution from complex **2** and **3**, are shown in Fig. 2. It is stressed that an almost identical plot is obtained when using averaged J values for both complexes and a factor of two is applied to the χT plot. This seems to be the most appropriate method as the former cannot be contrasted with experimental values because of severe over-parameterization. From the magnetic orbitals obtained after a COT, it can be observed that the exchange interactions occurred mainly through the central oxo bridging ligand, with two strongly σ-type overlapped magnetic orbitals, while the remaining ones, exhibit a considerably lower overlap, mediated by acetate ligands (Fig. 3). This characteristic is also found when analyzing the magnetic orbitals from the remaining BS states, but in these cases with three oxo mediated strongly overlapped set ($S = 0.258$, 0.243 and 0.153) instead of two. This difference between two or three strongly overlapped magnetic orbitals observed, depending on the spin topology of the BS state, reveals the existence of two different strength exchange interactions within the Fe_3O core, which nicely agrees with the 2J model employed.

[1] For details about calculation of simulated χ values refer to Ref. [25].

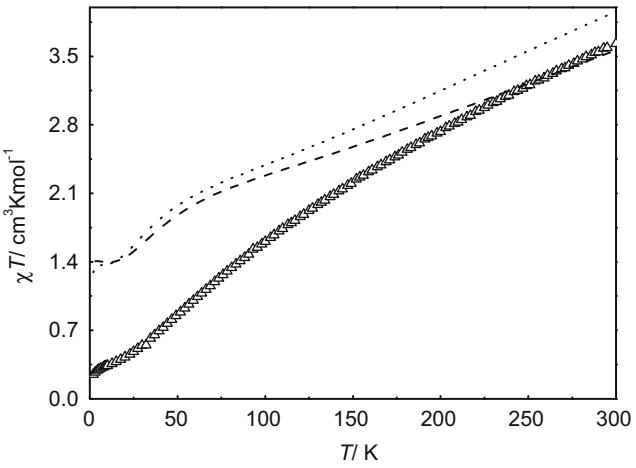

Fig. 5. χT vs. T plot for the model complex **1**. (Δ) Experimental data of the real 1D chain (Ref. [25]); (…) Ruiz method (*LanL2DZ*); (- -) Yamaguchi method (*LanL2DZ*).

3.2. Fe_3O-dca-Fe_3O dimer complex ***1*** model

The main task in the calculation with the complex **1** model was to evaluate its ability to reproduce the weak anti-ferromagnetic coupling (of the order of 1 cm^{-1}) between the Fe_3O units along the chain. Relying on the results obtained for the Fe_3O isolated complexes we used only the less computing demanding *LanL2DZ* basis set, as the bigger *TZVP* basis set did not show a real improvement in the calculated J values of the related complexes **2** and **3**. The calculated value around -0.1 cm^{-1} (Table 2) is far away in terms of the relative error (% Rel. error = $[|J_{calc} - J_{exp}|]/[(|J_{calc} + J_{exp}|)/2]$) with respect to -0.6 cm^{-1}, experimentally observed [25] (extracted employing a mean-field approximation correction, zJ', $z = 2$), however, it should be considered quite reasonable as it is in the limit of the computation precision. Noteworthy, direct

calculation of this J constant value from the BS8 energy,[2] afforded a positive value close to 1 cm^{-1}, clearly contradicting the experimental result. Only if all the other, much stronger J values are included by means of the remaining BS states, the right sign for this weak interaction is predicted. In spite of the ferromagnetic interaction obtained by the direct calculation, inspection of the involved magnetic orbitals after a COT shows that there is at least one small ($S = 0.032$) but non-negligible overlap of σ-nature between the Fe centers through the dca bridge (Fig. 4) providing a path for the anti-ferromagnetic coupling. As in the case of the Fe_3O complexes **2** and **3**, the calculated intra-Fe_3O core exchange interactions constants are in good agreement with the experimental values (Table 2). The almost identical values obtained for the pairs $J_1 - J_5$, $J_2 - J_6$ and $J_3 - J_7$ with the additional matching between the two latter pairs corroborates that the inclusion of the extra proton in our model system does not modify substantially the observed exchange coupling pattern in the real 1D complex. Concerning the method employed, a more accurate value for the $J_1 - J_5$ pair is obtained with the Yamaguchi methodology, while for the remaining J pair values Ruiz method appears more accurate. The bigger ratio $J_>/J_<$, due to an increased asymmetry in the Fe–μ_3O bonds length (Table 3), in comparison with the Fe_3O complexes **2** and **3** is also well reproduced. When the mean value between the calculated J constants in both Fe_3O moieties of complex **1** is considered, the $S = 1/2$ ground state of the weakly coupled Fe_3O cores in the 1D chain is correctly reproduced with all methods and basis sets. The simulated χT versus T plots are shown in Fig. 5.

4. Conclusions

We have employed a DFT broken-symmetry approach to calculate the different exchange coupling constants in two basic carboxylate iron complexes, $[Fe_3O(Piv)_6(CH_3OH)_2dca]$ and $[Fe_3O(Piv)_6(CH_3OH)_3]^+$, respectively, as well as in a 1D chain of dca linked Fe_3O units of formula $[Fe_3O(Piv)_6(H_2O)1,5\text{-}\mu\text{-}dca]_n$. The obtained values are in good agreement with experimental quantities and the weak anti-ferromagnetic exchange coupling constant between Fe_3O cores mediated by the dicyanamide ligand is reasonably well reproduced. Also the total ground state spin values are well reproduced by the theory. In order to tackle the problem of an infinite chain calculation we adopted a simplified model consisting of only a pair of Fe_3O units but preserving all the ingredients of the repetitive unit in the polymeric structure including the overall neutral charge. The successful results obtained suggest that this tool could be a promising methodology for calculating exchange coupling constants in 1D infinite systems at a lower computational cost.

[2] It can be easily realized that the only contribution to this broken symmetry state comes from J_4.

Scheme 1. Structural formulas.

prepared some chelated compounds with meopyNO according to the reported procedure [5,7,8]. Simply mixing of meopyNO with metal(II) perchlorates in appropriate organic solvents gave ML_2-type compounds of **1** and **2**. They were characterized by means of elemental analysis and IR spectroscopy, and finally their molecular structures were determined by means of X-ray crystallographic analysis. Table 1 summarizes selected crystallographic data of **1** and **2**, and their molecular structures are shown in Fig. 1.

We can find five-membered chelate rings involving a metal center and nitroxide group. Water molecules occupy the axial positions. Compounds **1** and **2** are isomorphous in the space group $P\bar{1}$, except for the following: the coordination structure of the nickel(II) ion in **1** is an almost octahedron (the Ni1–O1, Ni1–N1, and Ni1–O3 distances are 2.020(2), 2.011(2), and 2.091(2) Å, respectively). The octahedral structure of nickel(II) coordination sphere implies $S_{Ni} = 1$. On the other hand, copper(II) ion in **2** shows the Jahn–Teller distortion as indicated with the somewhat longer Cu1–O3 distance of 2.4292(17) Å than those of the Cu1–O1 and Cu1–N1 distances (1.9688(13) and 1.9404(15), respectively). The five-membered chelate rings are very planar for both; the M1–O1–N1–C1 torsion angles are 4.2(3)° and 6.87(19)° for **1** and **2**, respectively. Such structures guarantee the orthogonal arrangement between the metal dσ orbitals (i.e., $3d_{x^2-y^2}$ and $3d_{z^2}$) and nitroxide π^* orbitals. We have proposed that the torsion angle along M–O–N–C_{2py} is convenient for an indicator of the orthogonality [3,8]. The small size of water seems responsible for such a planar geometry. On the other hand, perchlorate anions are relatively bulky in $[Cu(phpyNO)_2(ClO_4)_2]$ [8] and $[Cu(2pyNO)_2(ClO_4)_2]$ [5]. The perchlorate oxygen atom has a considerably bent angle of M–O–Cl, giving rise to the large M–O–N–C_{2py} torsion angles.

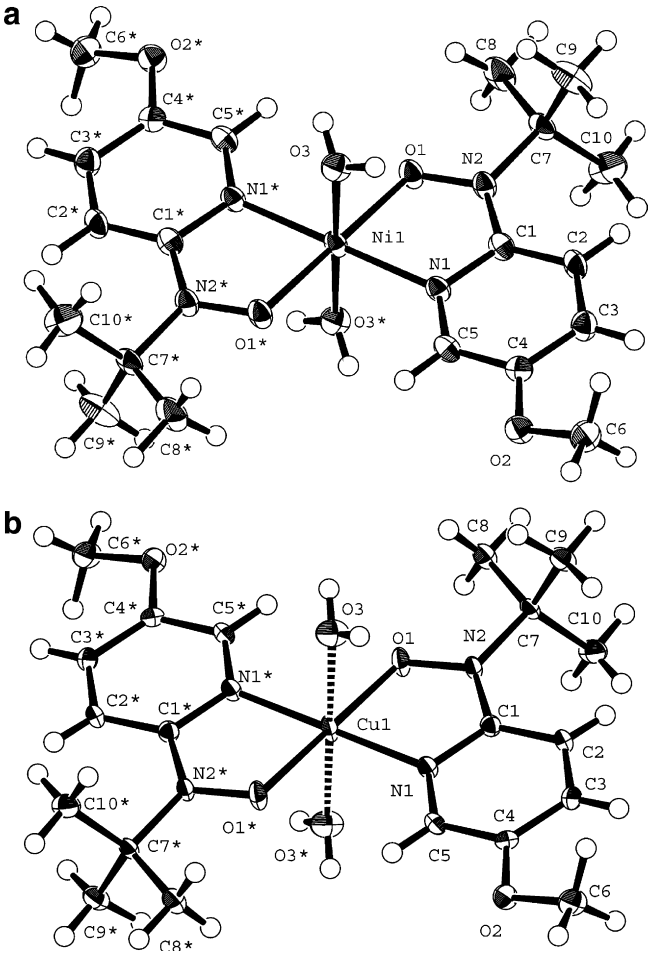

Fig. 1. Molecular structures of (a) **1** and (b) **2** with the thermal ellipsoids at the 50% probability level for non-hydrogen atoms. Atom numbering schemes are also shown. Counter anions are not shown for the sake of clarity.

[c] The cell parameters are modified for convenience of the comparison with those of **1**.

2.3. Intramolecular magnetic coupling in the copper(II) and nickel(II) complexes

Magnetic susceptibilities of **1** and **2** were measured on a SQUID magnetometer. Upon cooling from 300 to 2 K, the $\chi_{mol}T$ values of them once increased, indicating the presence of intramolecular ferromagnetic interactions, and then decreased (Fig. 2). The spin-only values are 3.0 and 1.88 cm^3 K mol^{-1} for **1** ($S_{total} = 2$) and for **2** ($S_{total} = 3/2$), respectively. The experimental $\chi_{mol}T$ values at their maximum clearly indicate that they have high-spin states. Final

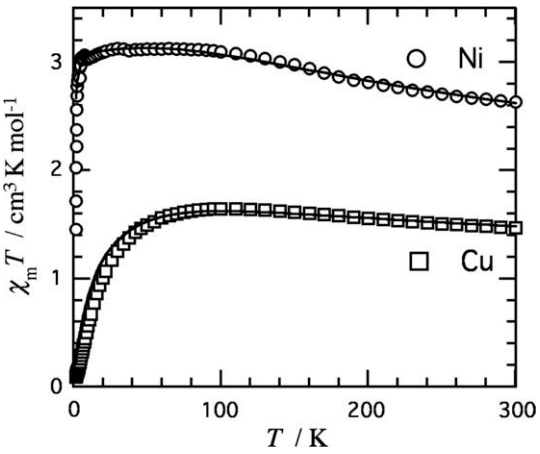

Fig. 2. Temperature dependence of $\chi_{mol}T$ for **1** (circles) and **2** (squares). Applied magnetic fields were 500 Oe for **1** and 1000 Oe for **2**. The solid lines represent calculated curves. See the text for the equations and optimized parameters.

drops of the $\chi_{mol}T$ values are assigned to intermolecular antiferromagnetic couplings, as well as zero-field splitting for the nickel(II) ions in **1**.

For all the complexes investigated here, the metal–radical geometry is unique due to the inversion symmetry, and accordingly the spin-Hamiltonian was defined as $H = -2J(S_1 \cdot S_2 + S_2 \cdot S_3)$ for the three-centered system, in which coupling between the terminal ions was disregarded. Thus, we applied the van Vleck equation to our systems, giving the following expressions, Eqs. (1 and 2) for the nickel(II) and copper(II) complexes, respectively [12].

$$\chi_{mol} = \frac{2Ng_{avg}^2\mu_B^2}{k_B(T-\theta)} \frac{\exp(-2J/k_BT) + 1 + 5\exp(2J/k_BT)}{\exp(-4J/k_BT) + 3\exp(-2J/k_BT + 3 + 5\exp(2J/k_BT)} \quad (1)$$

$$\chi_{mol} = \frac{Ng_{avg}^2\mu_B^2}{4k_B(T-\theta)} \frac{\exp(-2J/k_BT) + 1 + 10\exp(J/k_BT)}{\exp(-2J/k_BT) + 1 + 2\exp(J/k_BT)} \quad (2)$$

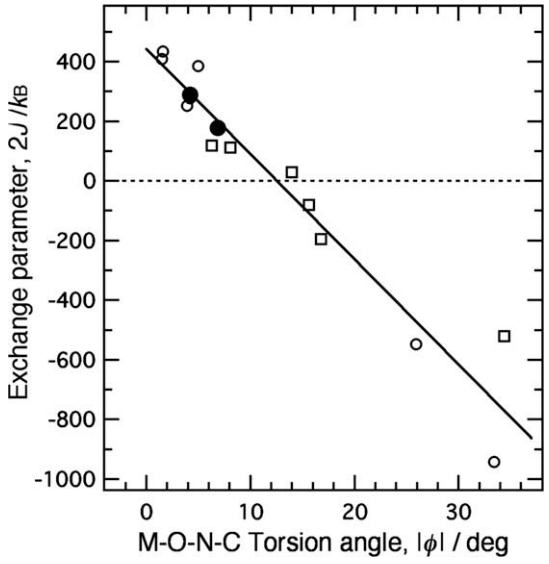
The experimental data were fitted to these equations and the optimized parameters are obtained as $g_{avg} = 2.050(2)$, $2J/k_B = +288(5)$ K, and $\theta = -0.32(2)$ K for **1**. On the other hand, we found that the accuracy of J and g_{avg} in **2** was somewhat unsatisfactory with an unrealistic statistical error, though the positive sign of J is meaningful. The J and g parameters interfere each other in this simulation, possibly leading to the considerable errors. The larger J value would give rise to the larger $\chi_{mol}T$ product in a high temperature region, but this bias can be compensated with an upward deviation of g, and vice versa. Thus, we fixed g_{avg} as a typical value of 2.05 [8], and analyzed the data again. The parameters were optimized as $2J/k_B = +178(3)$ K and $\theta = -13.7(3)$ K for **2**.

3. Discussion

As we mentioned above and discussed previously [8], the most important parameter is the M–O–N–C_{2py} torsion angle (ϕ), which indicates the out-of-plane dislocation from the chelate ring with respect to the N–O–M moiety. The ferromagnetic couplings observed here and for the related compounds are well explained in terms of the orbital orthogonality between radical π^* and nickel(II) or copper(II) $3d_{x^2-y^2}$ singly-occupied molecular orbitals (SOMOs) [13]. Now we have to check quantitatively the magnitude of J according to the magneto-structure relationship previously proposed [8].

We have already drawn a plot of J versus ϕ for the hexacoordinated copper(II) and nickel(II) complexes. It should be noted that the argument holds also for the chelates of nitronyl nitroxide (NN) radicals [3,4,14]. Here we superposed two points from **1** and **2** onto this plot (Fig. 3). The present results totally obey this relation. It is instructive to test the following equation, $2J/k_B = a + b|\phi|$ with $a = 440(50)$ K and $b = -35(3)$ K deg^{-1} previously proposed [8]. We calculated $2J/k_B = +293$ and +200 K from $\phi = 4.2°$ and 6.87°, respectively, which satisfactorily agree with the experimental values of $2J/k_B = +288(5)$ and +178(3) K. The expression is refined using all the data including those of **1** and **2**; $2J/k_B = a + b|\phi|$ with $a = 440(40)$ K and $b = -35(3)$ K deg^{-1}.

The present system has an advantage of strong exchange coupling because the spin density of the ligating oxygen atom is relatively high. The magnetic exchange coupling is proportional to the spin densities at the interacting atoms [11]. The spins on Ar–NN [3,4,14] (Scheme 1), Ar–iminonitroxide [4], Ar–verdazyl [15], and Ar–dithiazolyl radicals [16] (Scheme 2) are delocalized mainly onto conjugated N_2O_2, N_2O, N_4, and N_2S_2 systems, respectively, as clarified by the ESR hyperfine data, while the spin in the NO group is highly localized in two atoms. Thus, strong exchange couplings were realized in the present Ar–NO system.



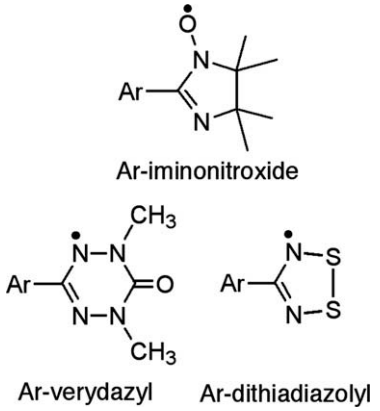


Fig. 3. A plot of the observed exchange coupling parameter ($2J$) vs. M–O–N–C_{2Ar} torsion angle (ϕ) as a magneto-structure relationship in the hexacoordinated nickel(II) or copper(II) complexes. Filled circles stand for the data points on **1** and **2**. Open circles and squares denote the data on known ArNO and ArNN complexes, respectively. The data of ArNO compounds were collected from Refs. [5,7,8], and those of ArNN complexes were from Refs. [3,14]. The line stands for a linear fit.

Scheme 2. Structural formulas.

4. Conclusion

We successfully utilized the new isolable synthetic intermediacy meopyNO, and complexation of nickel(II) and copper(II) perchlorates gave **1** and **2**, where the torsion angles (ϕ) around M–O–N–C_{2py} were as small as 4.2(3)° and 6.87(19)°, respectively. Both of them exhibit the considerably ferromagnetic metal–radical coupling. The 5-membered chelation in the 2-pyridyl–NO systems has an advantage over the 6-membered chelation in the 2-pyridyl–NN systems, with respect to the planarity and accordingly the $d\sigma$–π^* orbital orthogonality. 2-Pyridyl–NO system has another advantage; strong magnetic coupling owing to the high spin density on the ligating oxygen atoms.

5. Experimental

5.1. Materials

5.1.1. N-tert-Butyl N-(5-methoxy-2-pyridyl) hydroxylamine (meopyNOH)

The precursor 2-bromo-5-methoxypyridine [17] was prepared from 2-amino-5-methoxypyridine [18] by the Sandmeyer bromination. To the toluene solution (125 mL) containing 2-bromo-5-methoxypyridine (1.89 g; 10.0 mmol) was added a hexane solution (1.61 mol/L) of butyl lithium (6.8 mL; 11 mmol) at −78 °C under nitrogen atmosphere. After the mixture was stirred at −78 °C for 0.5 h, a toluene solution (25 mL) containing 2-methyl-2-nitrosopropane (1.23 g; 14.1 mmol) was added to the above mixture at −78 °C. The mixture was stirred, being allowed to warm gradually up to room temperature. The reaction mixture was quenched by aqueous NH_4Cl and neutralized with aqueous $NaHCO_3$ at room temperature. The organic layer was separated, dried over anhydrous Na_2SO_4, filtered, and concentrated under reduced pressure. A main product was purified by passing through a short column (silica gel) with 1/1 dichloromethane–ether as an eluent. Recrystallization from dichloromethane/hexane gave 0.238 g of a colorless solid of meopyNOH (1.30 mmol; 66%). M.p. 75–76 °C. ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.19 (s, 9H), 3.85 (s, 3H), 7.06 (d, 1H, J = 8.9 Hz), 7.15 (br s, 1H), 7.19 (dd, 1H, J = 3.0 and 8.9 Hz), 8.04 (d, 1H, J = 3.0 Hz). ^{13}C NMR (68 MHz, $CDCl_3$) δ 25.4, 55.8, 62.1, 121.6, 125.2, 127.7, 149.2, 150.3.

5.1.2. tert-Butyl (5-methoxy-2-pyridyl) nitroxide (meopyNO)

Freshly prepared Ag_2O (695 mg) was added to a dichloromethane solution (10 mL) containing 196 mg (1.00 mmol) of meopyNOH and the mixture was stirred at room temperature for 0.5 h. The supernatant immediately turned red. The solution phase was filtered and concentrated under reduced pressure. A main product was purified by passing a short column (silica gel; dichloromethane as an eluent). Red viscous oil of meopyNO was obtained after the removal of the solvent. We obtained 194 mg (0.99 mmol) of meopyNO in 99% yield. M.p. Ca. 10 °C. ESR (X-band, room temperature, in toluene; Bruker ESP300E X-band (9.7 GHz)) g = 2.0059, a_N = 1.076 mT. MS (ESI+) m/z 218.1 $(M + Na)^+$, 162.0 $(M–t\text{-}Bu + Na)^+$.

5.1.3. Coordination compounds

A dichloromethane solution (0.5 mL) containing 78 mg (0.40 mmol) of meopyNO was combined to an ethanol solution (1 mL) containing 73 mg (0.20 mmol) of $Ni(ClO_4)_2 \cdot 6H_2O$. A slow diffusion with ether gave dark red crystals of **1** after being kept in a refrigerator for a few days. The crystals were separated on a filter and washed with water. The yield was 108 mg (0.158 mmol; 79%). Single crystals suitable for the X-ray diffraction study were obtained by slow diffusion of ether into an acetone solution of **1**. M.p. 170–172 °C (decomp.). *Anal.* Calc. for $C_{20}H_{34}Cl_2N_4NiO_{14}$: C, 35.11; H, 5.01; N, 8.19. Found: C, 35.03; H, 5.18; N, 8.18%. Similarly, **2** was prepared in 58% yield. M.p. 168–170 °C (decomp.). *Anal.* Calc. for $C_{20}H_{34}Cl_2CuN_4O_{14}$: C, 34.87; H, 4.97; N, 8.13. Found: C, 34.83; H, 4.82; N, 8.13%.

5.2. Instruments

5.2.1. X-ray crystal structure analysis

X-ray diffraction data of single crystals of **1** and **2** were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Mo Kα (λ = 0.71069 Å) radiation. The structures were directly solved and the parameters were refined in the CRYSTAL STRUCTURE program package [19]. Numerical absorption correction was used. All of the hydrogen atoms were found experimentally for **1** and **2**. Thermal displacement parameters were refined anisotropically for non-hydrogen atoms and those of hydrogen atoms were treated isotropically. Selected crystallographic data are summarized in Table 1.

5.2.2. Magnetic measurements

Magnetic susceptibilities of the polycrystalline samples of **1** and **2** were measured on a Quantum Design MPMS SQUID magnetometer at an applied magnetic field of 500 or 5000 Oe in a temperature range down to 1.8 K. The magnetic response was corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constant.

Supplementary data

CCDC 700744 and 700745 contain the supplementary crystallographic data for **1** and **2**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk

2-hydroxymethylpyridine, R is an alkyl substituent and X^- is either Cl^- or Br^- [4]. A key finding of this work was the fact that crystals of the high (S_4) symmetry $[Ni(hmp)(dmb)Cl]_4$ complex contained no solvate molecules, resulting in exceptionally high quality high-frequency electron paramagnetic resonance (HFEPR) spectra [17]. Furthermore, HFEPR measurements for a Zn analog doped with small quantities of Ni^{II} enabled evaluation of the single-ion ZFS tensors [18]. The combined studies provided important insights concerning the physics of SMMs [19]. The success of these investigations thus provided motivation for investigating two isostructural compounds: $[Co(hmp)(dmb)Cl]_4$ (**1**) and $[Zn_{1-x}Co_x(hmp)(dmb)Cl]_4$ (**2**).

Single-crystal HFEPR studies of $[Zn_{1-x}Co_x(hmp)(dmb)Cl]_4$ were reported previously [20], demonstrating that the ground state of the Co^{II} ions can be modeled as an effective spin $S' = 1/2$ Kramers doublet. Such a model ignores the upper Kramers levels associated with the $S = 3/2$ Co^{II} ions. The strong anisotropy is instead parameterized via an anisotropic g-tensor associated with the effective $S' = 1/2$ ground state Kramers doublet. The HFEPR studies of **2** established a huge g-anisotropy ($g_z = 7.8$ and $g_{x,y} \approx 2.0$) of the easy-axis type. It was also found that the individual easy-axis directions are tilted away from the crystallographic c direction by 58°. The huge g-anisotropy is close to the maximum expected for an octahedral Co^{II} complex [21], suggesting a very significant ZFS separating the two Kramers doublets. However, it was not possible to determine the magnitude of this ZFS on the basis of the HFEPR studies of **2**.

The clear success in modeling the HFEPR spectrum of the Co^{II} ions in crystals of complex **2** as effective spin-1/2 particles begs the obvious question as to whether such a simple approach may be extended to the polynuclear complex **1**. First and foremost, we note that a rigorous treatment of the spin–orbit coupling is computationally challenging (the Hamiltonian matrix has dimensions of 20736×20736), and also requires far more information concerning the Co^{II} ZFS than obtained from HFEPR studies of **2**. Thus, in some sense, the coupled $S' = 1/2$ description offers the only realistic starting point. However, at first sight, it is not obvious how one could couple four $S' = 1/2$ particles, giving rise to SMM behavior. One associates the magnetic bistability of a SMM with the ZFS within its spin ground state. At a very basic level, this ZFS (or zero-field anisotropy) arises from the projection (or addition) of the ZFS associated with the individual ions onto the spin ground state of the molecule [9,22]. Herein lies the problem: a spin-1/2 object displays no anisotropy in the absence of a magnetic field, i.e. it exhibits no ZFS. Thus, such a projection by itself cannot give rise to ZFS for the coupled system. Viewed slightly differently – by ignoring the ZFS splitting associated with the Co^{II} ions, one is throwing away all details of their zero-field anisotropy.

The arguments given above ignore one crucial detail: in the case of the coupled Co_4 system, each Co^{II} ion experiences an exchange field due to its neighboring ions in the cluster. However, the projection method completely ignores this exchange coupling. The solution to this problem turns out to be relatively simple, and involves a multispin Hamiltonian consisting of just the pairwise interactions between the Co^{II} ions together with the individual Zeeman interactions. The anisotropic spin–spin interactions are then parameterized in terms of an exchange tensor, $\overleftrightarrow{J}_{ij}$, and the Hamiltonian may be expressed as:

$$H = \sum_{i<j} \hat{S}_i \cdot \overleftrightarrow{J}_{ij} \cdot \hat{S}_j + \sum_i \mu_B \vec{B} \cdot \overleftrightarrow{g}_i \cdot \hat{S}_i. \quad (1)$$

For the case of four coupled spin-1/2 particles, the full Hamiltonian matrix has dimensions $2^4 \times 2^4$, i.e. 16×16. The problem is thus easily tractable, and involves just a handful of parameters, many of which are already known from the HFEPR studies of complex **2** [20].

In this paper, we attempt to qualitatively account for the main features observed in the HFEPR spectra obtained for the Co_4 complex **1** on the basis of Eq. (1), and we additionally consider the possibility that anisotropic exchange could give rise to magnetic bistability and SMM behavior. Naturally, the exchange anisotropy is merely a manifestation of the strong single-ion anisotropy associated with the individual Co^{II} ions. Nevertheless, this offers a new way of thinking about magnetic anisotropy in polynuclear clusters, and complex **1** appears to represent a model compound for exploring these ideas in detail.

2. Experimental

Crystals of complex **1** were prepared according to a similar procedure to the previously reported $[Co(hmp)(MeOH)Cl]_4$ complex [11]; a detailed account of the synthesis will be published elsewhere [23]. Good sized, dark red crystals form in the shape of a square-based pyramid, reflecting the S_4 symmetry of the structure. One can easily identify the principal crystallographic directions on the basis of the crystal morphology, the c-axis being oriented perpendicular to the square base of the pyramid, i.e. in the direction defined by the apex of the pyramid. All of the data presented in this paper were obtained with the magnetic field applied parallel to the crystal c-axis, which also corresponds to the S_4 axis; angle-dependent studies will be published in a longer paper. The sample was mounted with its square base attached with vacuum grease to a flat copper disk at the end of the HFEPR probe/cavity.

Experiments were performed in a 9 T superconducting magnet, and temperature control achieved using a ^{4}He flow cryostat equipped with a calibrated temperature sensor. As a spectrometer, we utilized a Millimeter-wave Vector Network Analyzer (MVNA, described elsewhere [24,25]), enabling measurements from 8 to 715 GHz at the University of Florida. At the higher frequencies (>200 GHz), a pair of external Gunn diodes were associated with the MVNA on both source and detection sides, enabling phase sensitive measurements up to 715 GHz. A quasioptical spectrometer was used for frequencies above ~200 GHz. This spectrometer, which has been described previously [26], employs a tapered corrugated HE_{11} waveguide tube, enabling single-pass reflectivity measurements with good coupling to relatively small crystals (<1 mm^3). For frequencies below 200 GHz, a cavity perturbation technique was employed (see [24,25]).

3. Data and discussion

Fig. 1 shows low-temperature ($T = 2$ K) HFEPR spectra obtained at several frequencies in the range from 258 to 715 GHz. Multiple peaks are observed at all frequencies. The signal-to-noise diminishes at the higher frequencies due to the reduced dynamic range of the high-frequency spectrometer. Nevertheless, clear resonances are observable at all of the frequencies shown, and each spectrum is highly reproducible. Given that the temperature is rather low (much less than the microwave quantum, which ranges from 12 to 34 K), one may assume that all of the observed HFEPR intensity involves excitations from the ground state of the Co_4 complex. Several obvious resonance branches become apparent upon close inspection of Fig. 1; this point has been emphasized by means of the colored arrows in the figure.

A 2D frequency versus field plot for resonances observed at many different frequencies, spanning a wider range from 50 to 715 GHz, is displayed in Fig. 2. This figure emphasizes only the stronger resonances, particularly those observed at the lowest temperatures (though data points are included for a range of temperatures). The solid curves superimposed on the various resonance branches are simply guides to the eye. The first point to

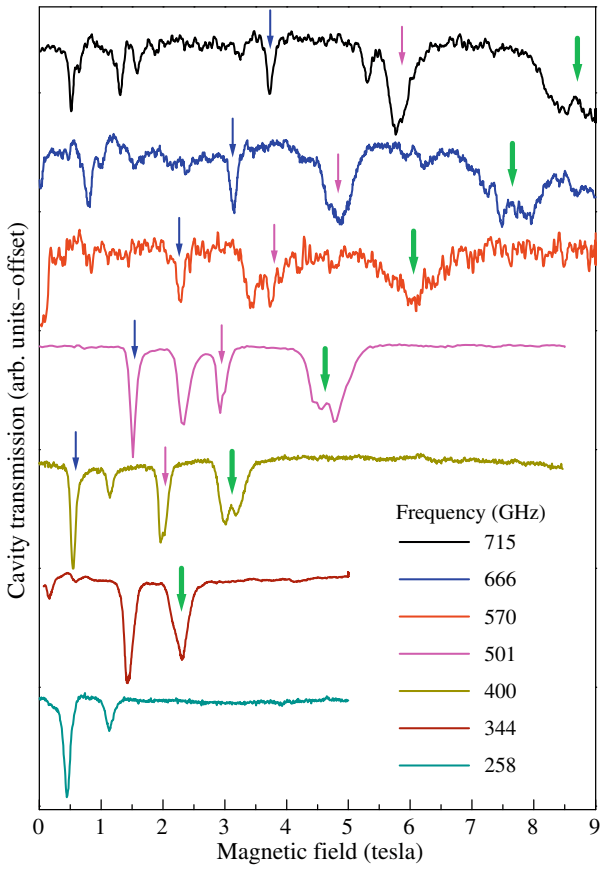

Fig. 1. Frequency dependence spectra obtained at $T = 2$ K with the magnetic field parallel to the *c*-axis of the crystal. The frequencies are given in the figure, and the colored arrows are included in order to differentiate between various resonance branches.

note from this figure is the fact that the different branches intersect the vertical zero-field axis at many different frequencies, suggesting that the Co_4 spectrum possesses many ZFS values ranging all the way from 50 GHz up to almost 700 GHz (and maybe higher?). It is also notable that the slopes of the branches correspond to *g*-values ranging from 2.0 (low-frequency branches) all the way up to ~7.4 (high-frequency branches). We note that this spread is comparable to the range of values found for the Co^{II} ions from HFEPR studies of complex **2** [20].

Representative temperature dependence measurements are shown for three different frequencies in Fig. 3. From this figure, one can conclude that the resonances observed at the highest frequencies (above ~250 GHz) correspond to excitations from the ground state. In contrast, at 99 GHz, all transitions except for the lowest field peak appear to originate from excited states, due to vanishing intensity as $T \rightarrow 0$. The corresponding data points in Fig. 2 have, therefore, been colored red so as to distinguish them from the strong ground state transitions. A particularly interesting observation is the fact that this Co_4 complex is almost EPR silent at fields above ~1 T for intermediate frequencies ranging from ~250 to 400 GHz. This frequency gap appears to separate the low- and high-*g* resonance branches.

The key finding from these experiments is the clear observation of significant ZFS associated with the low-lying spin states of complex **1**. Another important observation is the fact that it is completely impossible to fit the data in Fig. 2 using a giant-spin approximation. Based on such a model, one expects the 2D plot for the easy-axis (Fig. 2) to consist of more-or-less evenly spaced parallel branches of resonances, with only a single branch surviving to the lowest temperatures. As a check, we confirmed that the field was aligned with the easy-axis on the basis of detailed angle-dependent measurements (not shown [23]).

Many aspects of the data hint strongly at competing interactions/symmetries, such that neither the total spin, *S*, nor its projection, m_S, are good quantum numbers. First of all, the observation of multiple ground state resonances suggests an absence of simple selection rules. This contrasts the giant-spin case, where *S* and m_S are good quantum numbers and the $\Delta m_S = \pm 1$ EPR selection rule permits only one possible transition from the ground state. In addition, the non-linear character of some of the resonance branches, including obvious evidence for the repulsion between levels (e.g. red and black data in the 100–200 GHz range in Fig. 2), suggests a strong mixing of spin states. Finally, the observation of a wide range of *g*-values would again seem to suggest a complete absence of selection rules. Furthermore, the gap between low- and high-*g* resonance branches suggests a fundamentally different nature to the low- and high-frequency excitations, with the former perhaps occurring within a multiplet of low-energy states and the latter involving excitations from this multiplet to excited multiplets.

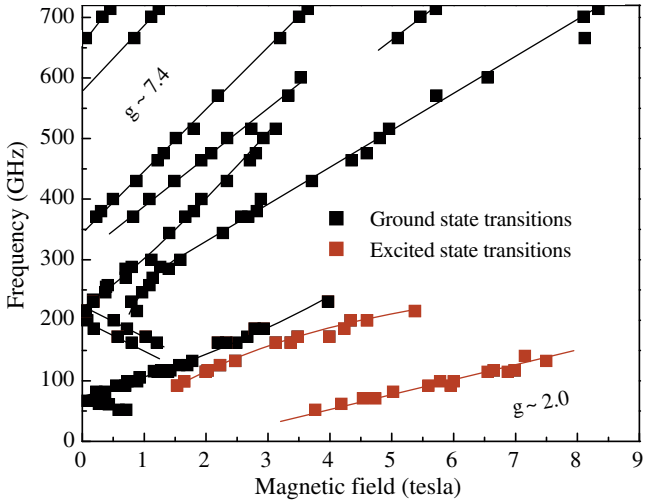

Fig. 2. A 2D frequency verses field plot representing the positions of the stronger resonances observed from the frequency dependence measurements with the field parallel to the *c*-axis. The solid curves are purely guides to the eye.

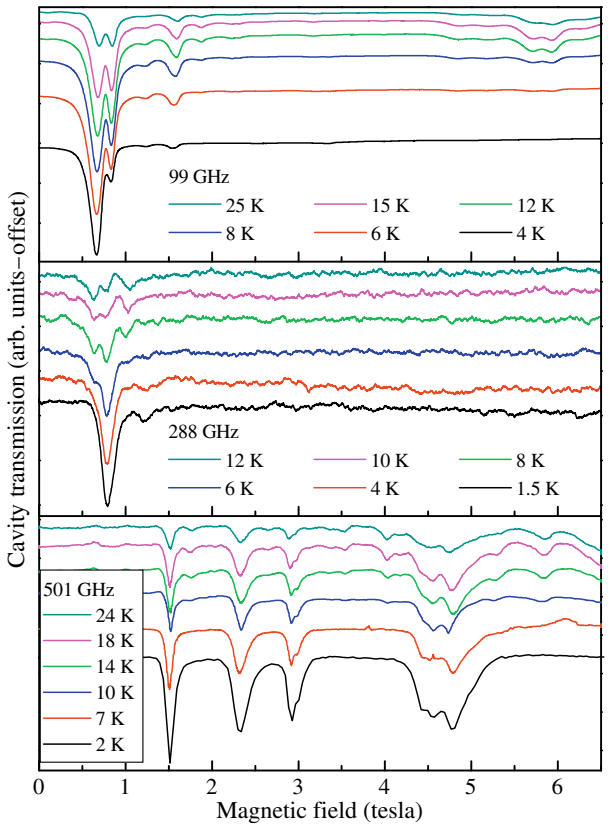

Fig. 3. Temperature dependence measurements ($B//c$) for three different frequencies; the temperatures and frequencies are given in the figures.

The idea of a 'spin multiplet' loses its meaning to some degree if there is strong mixing of spin states. Nevertheless, we use this concept as a basis for the discussion in the following section.

4. Numerical calculations

In this section, we attempt to account qualitatively for the experimental observations on the basis of Eq. (1). The results are summarized in Fig. 4. In the absence of exchange anisotropy, both S and m_S are exact quantum numbers. The zero-field solution to Eq. (1) is relatively straightforward in the case where one considers a single isotropic exchange coupling parameter, J: namely, the energy $E(S_T) = 1/2[S_T(S_T + 1) - 3]J$, where S_T (=0, 1 or 2) is the total spin of a given state. Application of a magnetic field simply lifts the degeneracy within each spin-multiplet, resulting in a set of $2S_T + 1$ levels whose energies shift according to the Zeeman interaction. This situation is illustrated in Fig. 4a, with $J = -200$ GHz, where we assumed that the axial single-ion g-tensors were all aligned parallel to the z-axis of the molecule. Likewise, the magnetic field was applied in this direction such that $\Delta E(B) = \mu_B g_z B m_S$, where B is the magnetic field strength; a value of $g_z = 6.0$ was used in this simulation.

It should be noted that each spin multiplet exhibits no ZFS in this simple isotropic case. Furthermore, the EPR selection rule forbids $\Delta S = \pm 1$ transitions. Thus, all resonance branches should depend linearly on the field, and intersect the 2D frequency/field plot (Fig. 2) at the origin. In fact, just a single EPR peak would be observed (see red arrows), since the energy spacing between successive levels is independent of m_S.

Fig. 4b considers an axial exchange anisotropy, also aligned with the molecular z-axis. We assume the same exchange between all ions (see below) and parameterize the interaction as follows:

$$H = J\sum_{i<j}\left[\hat{S}_{iz}\hat{S}_{jz} + \alpha\left(\hat{S}_{ix}\hat{S}_{jx} + \hat{S}_{iy}\hat{S}_{jy}\right)\right] + \sum_i \mu_B \vec{B}\cdot\overleftrightarrow{g}_i\cdot\hat{S}_i. \qquad (2)$$

Here, J characterizes the strength of the Ising component of the exchange, while the parameter α $(\leqslant 1)$ is a measure of the anisotropy. Obviously $\alpha = 1$ represents the isotropic limit; values of $\alpha = 2^{-1/2}$ and $J = -200$ GHz were used for the simulations in

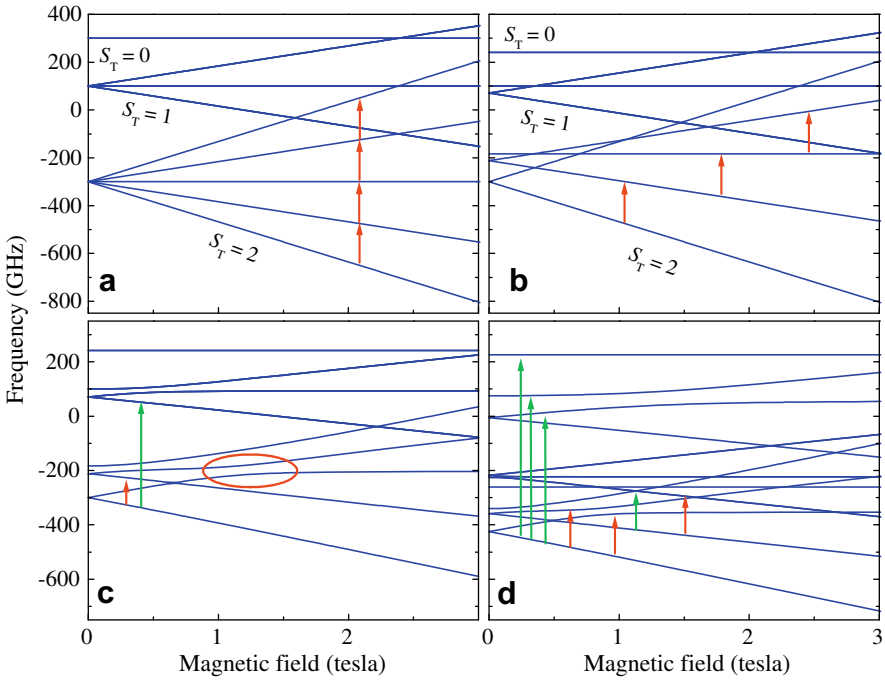

Fig. 4. Simulated Zeeman diagrams obtained for complex **1** on the basis of Eq. (1) (also Eq. (2)), using various different parameter sets: (a) represents the isotropic case; (b) adds an axial exchange anisotropy; (c) includes the effect of a tilting (58°) of the single-ion g-tensors away from the axial direction; and (d) considers two inequivalent exchange parameters within the cluster. See main text for details of the calculations (including values for the various parameters), and an in-depth discussion of these diagrams. The arrows represent possible HFEPR transitions.

Fig. 4b. Interestingly, S and m_S remain good quantum numbers for the situation in which the magnetic field is applied along z (Fig. 4b), due to the preservation of the axial symmetry. The effect of the exchange anisotropy is to lift the zero-field degeneracy within each spin multiplet. In fact, this is precisely the result we were looking for. The EPR spectrum would now be expected to exhibit multiple, albeit evenly spaced peaks (see red arrows) due to the ZFS within each spin multiplet. In fact, the ZFS within each multiplet could equally be parameterized using a giant-spin Hamiltonian.

It should be noted at this juncture that the spectrum displayed in Fig. 4b displays all of the hallmarks of a SMM, i.e. a relatively well isolated spin ground state possessing an axial anisotropy/ZFS. Any molecule possessing these characteristics should exhibit magnetization hysteresis below some characteristic blocking temperature. Thus, we have demonstrated that Eq. (1) can indeed give rise to SMM behavior. Nevertheless, we extend these calculations further, because the spectrum in Fig. 4b cannot yet account for many of the HFEPR observations.

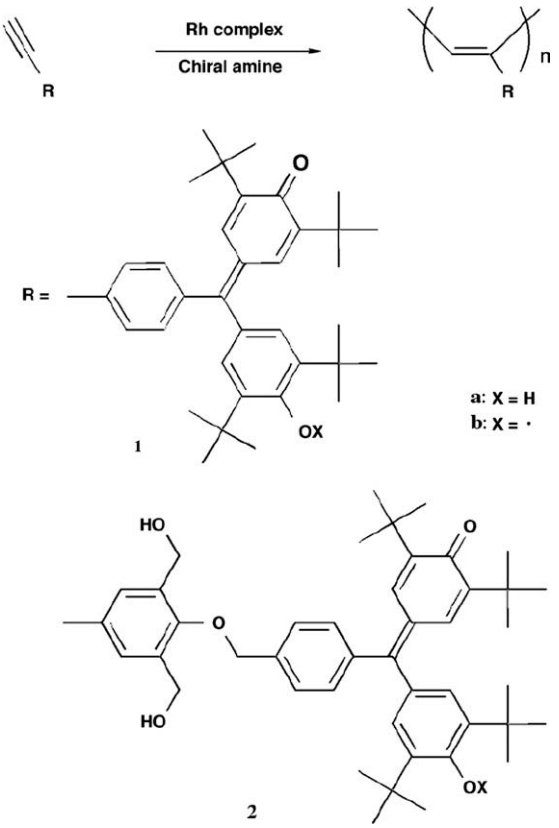
It was noted from HFEPR studies of complex **2**, that the Co^{II} single-ion g-tensors are tilted considerably with respect to the molecular z-axis. For Fig. 4c, the g-tensors were tilted 58° away from z, and the field was again applied parallel to z; J and α remained the same as before. Solutions to Eq. (2) were obtained via exact matrix diagonalization. A number of things become immediately apparent upon including such tilting. First of all, the molecular g-value decreases significantly, as seen from the slope of the line corresponding to the ground state. This is due to the reduced projection of the (larger) g_z component of the single-ion tensors onto the molecular axis; a value of $g_{x,y} = 2.0$ was used for these simulations. In addition, one can now observe level repulsions (circled) for the first time, i.e. m_S is no longer an exact quantum number. Indeed, due to competing interactions (Zeeman and anisotropic exchange), one would also expect S-mixing. Thus, one should in principle start to observe a breaking of the simple EPR selection rules.

Given the presence of exchange anisotropy, one would also expect antisymmetric exchange for this molecule, which does not possess a center of inversion. Inclusion of such an interaction would immediately result in additional S-mixing and further relaxation of the $\Delta S = 0$ EPR selection rule to the extent that one could expect to observe strong inter-spin multiplet transitions, i.e. multiple ground state resonances spanning a wide frequency range (see red and green arrows in Fig. 4c).[1] Inclusion of an antisymmetric term in Eq. (1) adds very little in terms of computation. Nevertheless, for the sake of simplifying the discussion, we do not include such an interaction in the present work. However, we note that, with the consideration of S-mixing, Fig. 4c begins to embody many of the characteristics that would account qualitatively for the experimental observations. Nevertheless, inspection of Fig. 2 reveals many different ZFSs spanning the range from about 65 GHz up to 650 GHz. However, there remain significant zero-field gaps in Fig. 4c. These gaps can be filled to some extent if one relaxes the assumption of a single exchange parameter. In doing so, one finally arrives at Fig. 4d, which considers two exchange constants, consistent with the S_4 symmetry of the Co_4 cluster, i.e. $J_1 = -250$ GHz(4 bonds) and $J_2 = +50$ GHz(2 bonds), with the same anisotropy constant, α, for both.

Fig. 4d represents a crude attempt to account qualitatively and semi-quantitatively for many of the features observed in the HFEPR experiments of complex **1**. However, the exact numbers used for the simulations should not be taken too seriously. Our intent is to show that Eq. (1) contains essentially all of the physics needed to account for the EPR data and, possibly, the hysteresis measurements. The parameters were chosen so that (a) the ZFS between the ground and first excited state roughly matches the smallest ZFS in the experiment, i.e. 67 GHz, and (b) the full spectrum spans around 650 GHz, which was the largest ZFS observed in the experiment. We have not yet reached the stage where we are able to fit the data exactly to Eq. (1). However, further refinements in the experiments are under way in order to provide further constraints, particularly detailed angle-dependent studies [23]. It remains to be seen whether the spectrum in Fig. 4c could give rise to magnetization hysteresis.

[1] For interpretation to color in Fig. 4, the reader is referred to the web version of this article.

5. Conclusions



We consider the effects of anisotropic exchange interactions between the effective spin $S' = 1/2$ Kramers ions within the tetranuclear Co complex. Our model can account qualitatively and semi-quantitatively for many features observed in HFEPR experiments. We also demonstrate that this model can give rise to SMM behavior, even for spin-1/2 particles that themselves do not possess any zero-field anisotropy, i.e. the molecular anisotropy (ZFS) arises purely via anisotropic spin–spin interactions.

Scheme 1.

were obtained by precipitation from the polymerization mixtures into methanol.

In the CD spectra of poly(**1a**) in chloroform, not only were negative Cotton effects observed in the absorption region (450–550 nm) of the backbone chromophore, but split-type induced CD signals also appeared in the absorption region (420 nm) of the hydrogalvinoxyl chromophore. CD and UV–Vis absorption spectra of poly(**1a**) exhibited the thermo- and solvatochromism [15]. The chiroptical thermo- or solvatochromism is novel for the one-handed helical polymers possessing no chiral moieties in the polymer chains, because they have two conformational enantiomers whose states are thermo-dynamically equivalent to one another, and the conformational rotations of polymers thermodynamically lead to the full racemization of polymers on the intra- and/or interchain. However, no Cotton effect was observed for the polyradical poly(**1b**) solution which was obtained by oxidizing poly(**1a**) by treatment of the polymer solution with fresh lead dioxide or potassium ferricyanide, while there was not significant change in the GPC elution curves of the polymer before and after the radical generation. But we succeeded in observing weak Cotton effects in the absorption region of the galvinoxyl radical chromophore through the chemical oxidation of the cast film of poly(**1a**) on a quartz plate. On the other hand, the split-type induced CD signals were observed for the chloroform solution of poly(**2a**) at 300 nm, and the CD intensities were nearly constant even when the solution was heated to 60 °C (Fig. 1). But the CD signals decreased and disappeared in CD spectra of poly(**2a**) by addition of DMF to the THF solution, which supported that the rigid and one-handed helical conformation was stabilized by intramolecular hydrogen bonds. The polyradical poly(**2b**) was obtained by oxidizing the polymer poly(**2a**) by treatment of the polymer solution in degassed THF with fresh lead dioxide under an oxygen-free atmosphere. The absorption maximum at 420 nm due to the hydrogalvinoxyl chromophore decreased, and a new absorption peak due to the galvinoxyl radical chromophore appeared at 470 nm. In the CD spectra of the polyradicals obtained by polymerization using (*R*)-PEA and (*S*)-PEA (abbreviated as poly(**2b**)$_R$ and poly(**2b**)$_S$, respectively), the split-type-induced CD signals at 300 nm, which are mirror images of each other, are still observed (Fig. 2), while no Cotton effect was observed for the polyradical which was obtained by polymerization using racemic PEA (abbreviated as poly(**2b**)$_{rac}$). It is clear that maintenance of the enantiomeric helical structure was achieved even after the oxidation reaction. In the MCD spectra of poly(**2b**) in THF, positive and negative Faraday effects were observed in the absorption region of the galvinoxyl chromophore (470 nm) corresponding to the negative and positive magnetic fields, respectively, which was independent of the conformation of poly(**2b**).

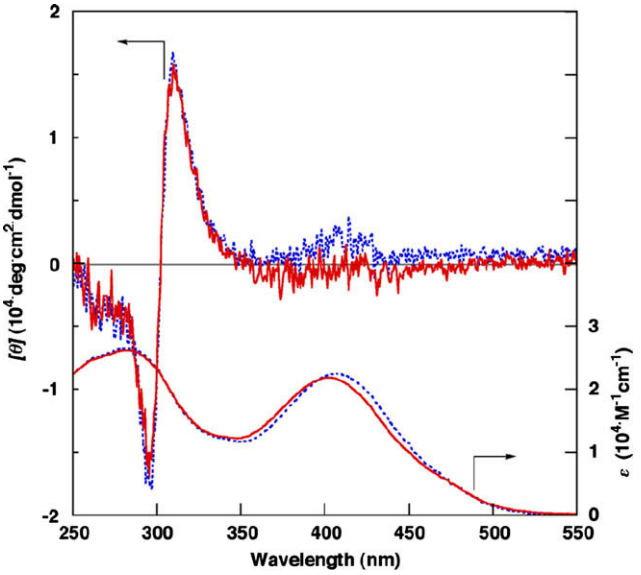

Fig. 1. CD and UV–Vis absorption spectra of poly(**2a**) at 20 (dashed line) and 60 (solid line) °C in chloroform (0.6 mM).

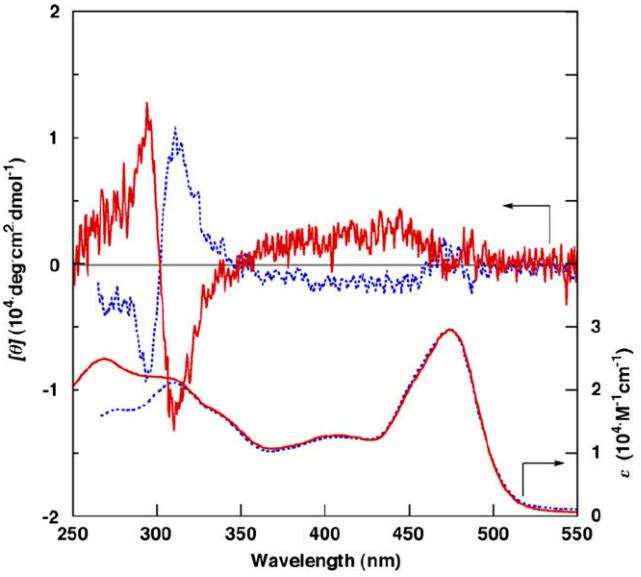

Fig. 2. CD and UV–Vis absorption spectra of poly(**2b**)$_R$ (solid line) and poly(**2b**)$_S$ (dashed line) at 20 °C in THF (0.5 mM).

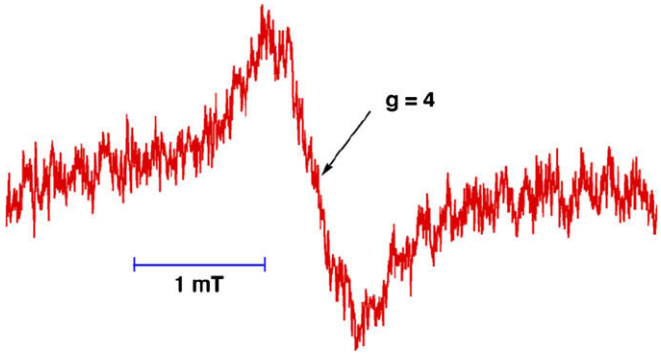

Fig. 3. ESR spectra of poly(**2b**)$_R$ in frozen 2-methyltetrahydrofuran glass at 77 K at $g = 4$.

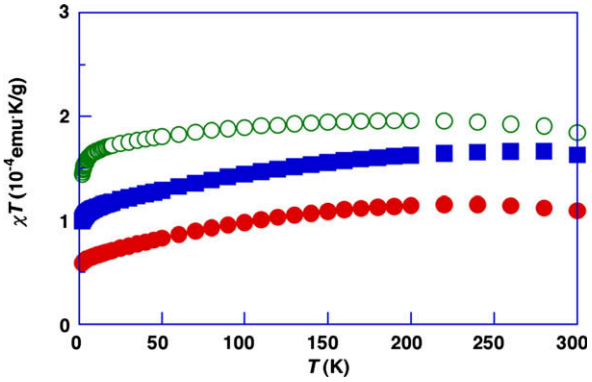

Fig. 4. χT vs. T plots of the powder samples of poly(**2b**)$_R$ (●), poly(**2b**)$_{rac}$ (○) and poly(**2b**)$_{RS}$ (■).

The polyradicals were appropriately stable for maintaining the initial spin concentration under the ESR and SQUID measurement conditions. The ESR spectrum of poly(**2b**) showed a broad signal at $g = 2.0047$, indicating formation of the phenoxyl radical. The $\Delta m_s = \pm 2$ forbidden transition was clearly observed at $g = 4$ in frozen 2-methyltetrahydrofuran glass at 77 K for poly(**2b**)$_R$, although no fine structure that gave zero-field splitting parameters D or E was detected at $g = 2$ (Fig. 3). This result suggests the magnetic interaction along the polymer chain because the sample was diluted in diamagnetic 2-methyltetrahydrofuran to minimize intermolecular interactions.

The static magnetic susceptibility (2–300 K at 0.5 T) of poly(**2b**) was measured using a SQUID magnetometer. The powder samples were prepared by evaporating solvent from the THF solution of poly(**2b**)$_R$, poly(**2b**)$_{rac}$ and the equivalent mixture of poly(**2b**)$_R$ and poly(**2b**)$_S$ (abbreviated as poly(**2b**)$_{RS}$), and by drying in vacuum. The χT *versus* T plots of poly(**2b**)$_R$, poly(**2b**)$_{rac}$ and poly(**2b**)$_{RS}$ are shown in Fig. 4. Downward deviation of the χT value of the polyradicals at lower temperatures indicates the antiferromagnetic interaction. The stronger antiferromagnetic interaction was observed for poly(**2b**)$_R$ synthesized by HSSP in comparison with poly(**2b**)$_{rac}$ whose helical conformation could racemize on the intrachain to be random conformation. The antiferromagnetic interaction of poly(**2b**)$_{RS}$ whose helical conformation racemized on the interchain was also stronger than that of poly(**2b**)$_{rac}$. These results and the above-mentioned ESR result of poly(**2b**)$_R$ suggest that the strong antiferromagnetic interaction of poly(**2b**)$_R$ was significantly affected by its helical conformation.

2.2. Preparation of the complexes

2.2.1. Preparation of {Fe^{II}(3-fluoropyridine)$_2$[Au^{I}(CN)$_2$]$_2$}$_n$ (**1**)

Complex **1** was prepared according to a procedure described in the literature Ref. [10c].

2.2.2. Preparation of {Mn^{II}(3-fluoropyridine)$_2$[Au^{I}(CN)$_2$]$_2$}$_n$ (**2**)

In 10 mL of water, $MnCl_2 \cdot 4H_2O$ (0.02 g, 0.1 mmol) and K[Au(CN)$_2$] (0.04 g, 0.2 mmol) were solved. The vapor diffusion method using 3-fluoropyridine as a source of ligand molecules provided colorless polycrystalline crystals suitable for X-ray diffraction of **2** over a period of two days. **2**: Elemental *Anal.* Calc. for $C_{14}H_8Au_2MnN_6F_2$: C, 22.51; H, 1.08; N, 11.25. Found: C, 22.24; H, 1.09; N, 11.27%. IR (Nujol method, cm^{-1}): 2156 (ν_{CN} (CN)).

2.3. X-ray crystal structural determinations

Crystal structures of **1** at 80 K and 123 K and **2** at 293 K were determined using a BRUKER APEX SMART CCD area-detector diffractometer with monochrometed Mo Kα radiation (λ = 0.71073 Å). The diffraction data was treated using SMART and SAINT, and absorption correction was performed using SADABS [18]. The structures were solved by using direct methods with SHELXTL [19]. All non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were generated geometrically. Pertinent crystallographic parameters are displayed in Table 1 and selected metric parameters for the complexes are presented in Table 2.

2.4. Magnetic measurement of **2**

Measurements of the temperature dependence of the magnetic susceptibility of **2** in the temperature range of 2–300 K with a cooling and heating rate of 1 K min^{-1} in a fixed field strength of 1 kOe field was measured on a MPMS-XL Quantum Design SQUID magnetometer. The molar susceptibility was corrected from the sample holder and diamagnetic contributions of all constituent atoms by using Pascal's constants.

3. Results and discussion

3.1. Synthesis and IR spectra

The reaction of an aqueous solutions of $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ or $MnCl_2 \cdot 4H_2O$ containing two equivalents of $K[Au(CN)_2]$ with a vapor diffusion method using pyridine-derivative ligand, 3-fluoropyridine, afforded colorless block single crystals of the coordination compounds $\{Fe^{II}(3\text{-fluoropyridine})_2[Au^{I}(CN)_2]_2\}_n$ (**1**) and $\{Mn^{II}(3\text{-fluoropyridine})_2[Au^{I}(CN)_2]_2\}_n$ (**2**).

The solid state IR spectra of **1** and **2** had C≡N bands at 2156 cm^{-1} for **1** and 2152 cm^{-1} for **2**, which are both at higher wavenumbers than that of free $[Au(CN)_2]^-$ (2135 cm^{-1}), at room temperature. This suggests that both of the CN groups of $[Au(CN)_2]^-$ act as bidentate bridging ligands.

3.2. Description of the crystal structures

3.2.1. Crystal structures of **1** (T = 80 K) and **2** (T = 293 K)

Coordination compounds **1** at 80 K and **2** at 293 K crystallized in the centrosymmetric space groups $P2_1/c$, respectively. The X-ray crystallographic analysis reveals that the asymmetric unit of **1** (80 K) and **2** (293 K) contains two 3-fluoropyridine ligands, one type of M^{2+} ion (M = Fe, Mn) and two types of crystallographically distinct $[Au(CN)_2]^-$ units. As shown in Fig. 1, the Fe^{II} and Mn^{II} centers have a slightly distorted octahedral geometry with a N_6 coordination sphere, which are tightly related to that of **1** at 293 K Refs. [10c,15c]. In the equatorial positions, four N atoms from bidentate CN^- moiety are coordinated to Fe(1) and Mn(1) centers. The pyridyl N ligation site at the two 3-fluoropyridine ligands occupy in the axial sites of octahedral metal centers. While the F(1) and F(2) in the 3-fluoropyridine ligand are disordered with each other, F(3) in the other 3-fluoropyridine ligand is not disordered. Thus the two 3-fluoropyridine ligands in $[Fe^{II}(3\text{-fluoropyridine})_2][Au^{I}(CN)_2]_2$ are not equivalent and coexist in *transoid* and *cisoid* conformations for Fe(1). The angles for **1** defined by C(13)–Au(1)–C(14) and C(11)–Au(2)–C(12) are 176.0(11) and 174.5(10) and for **2** defined by C(13)–Au(1)–C(14) and C(11)–Au(2)–C(12) are 179.2(3) and 177.5(3), respectively, which are close to a linear geometry. As depicted in Fig. 2, four M^{II} atoms and four $[Au(CN)_2]^-$ units form a rectangular ring $[M^{II}Au^{I}(CN)_2]_4$ and the rings are further connected by $[Au(CN)_2]^-$ units to generate a corrugated two-dimensional frameworks of **1** and **2** (shown in Fig. 2). In the macrometallacycle, the neighboring and diagonal distances are 15.064, 13.264 Å (Fe···Fe) and 15.594, 14.077 Å (Mn···Mn), respectively.

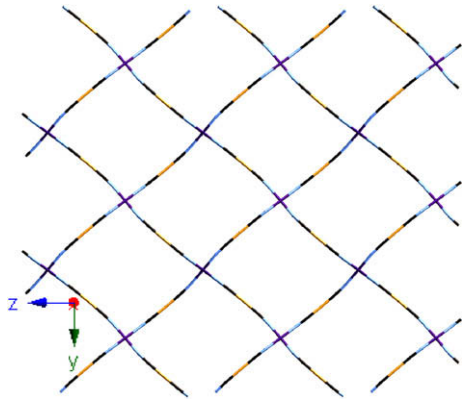

Fig. 2. The cylinder drawing, wave 2-D networks of **1** at 80 K. The 2-D frameworks of **1** at 123 K and **2** at 293 K are almost identical to that of **1** at 80 K. Consequently, we have used the same representation for these compounds. Atom code: Fe (purple), Au (yellow), N (blue), C (black). In this picture, hydrogen atoms and 3-fluoropyridine are omitted for clarity. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

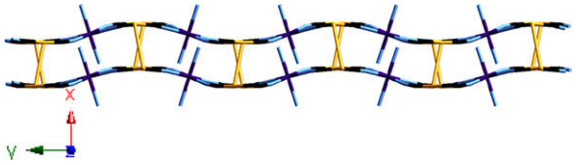

Fig. 3. Bilayer structure of **1** at 80 K with strong aurophilic interactions. The structure of **1** at 293 K is almost identical to that of **1** at 80 K. Consequently, we have used the same representation for both compounds. In this picture, H atoms and C atoms in the 3-fluoropyridine ligands are omitted for clarity.

It is worthy of note that the Au···Au interaction in the bilayer networks for **1** and **2** are very strong and the distance are 3.081 and 3.170 Å, which is well outside the range for a Au–Au bond (2.8–3.0 Å), even though these distances are less than the sum of the van der Waals radii of Au (3.60 Å) (shown in Fig. 3).

These Fe–N bond lengths for **1** at 80 K correspond quite well to those expected for LS state of Fe^{II} ion, which results agree completely with the magnetic behavior observed for **1** (see S1) Ref. [10c].

3.2.2. Crystal structures of **1** (T = 123 K)

Compound **1** at 123 K crystallizes in the space group $P\bar{1}$, in contrast to the **1** at 80 K ($P2_1/c$). The structure of **1** in this spin phase

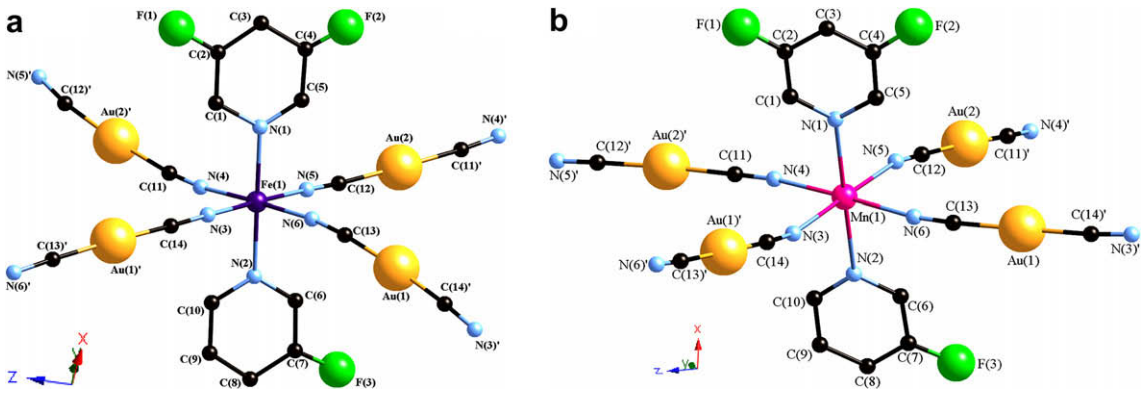

Fig. 1. Coordination structures of the Fe^{II} and Au^{I} ions in **1** at 80 K (a) and Mn^{II} and Au^{I} ions in **2** at 293 K (b). In this picture, hydrogen atoms are omitted for clarity. Atom code: Fe (purple), Mn (pink), Au (yellow), N (blue), C (black), F (green). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

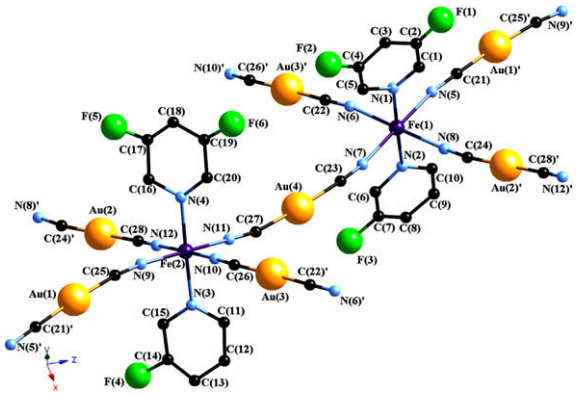

Fig. 4. Coordination structure of the Fe^{II} and Au^{I} ions in **1** at 123 K. In this picture, hydrogen atoms are omitted for clarity.

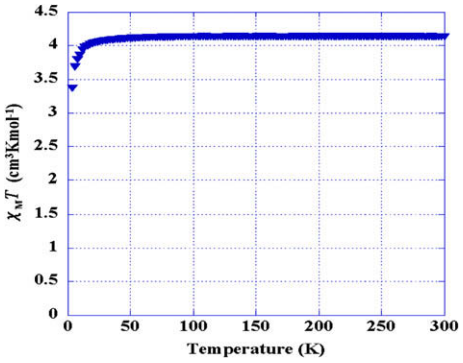

Fig. 5. Magnetic properties of **2**. $\chi_M T$ vs. T from 2 to 300 K.

has been already reported by Real et al. Ref. [15c], but its data were not good enough (R_1 [$I > 2\sigma(I)$] = 0.1649). Therefore, we have reexamined its structure (R_1 [$I > 2\sigma(I)$] = 0.0854).

The 2D grid frameworks of **1** at 123 K is almost identical to **1** at 80 K and **2** at 293 K (shown in Fig. 2). However, there are crystallographically different two Fe^{II} atoms defining distorted octahedral geometries, four 3-fluoropyridine ligands and four types of $[Au(CN)_2]^-$ units (shown in Fig. 4). The crystal packing of **1** at 123 K is also made up of a stacking of double layers interacted via strong aurophilic interactions [Au(1)···Au(2) = 3.128 and Au(3)···Au(4) = 3.072···Å]. These Fe–N bond lengths for **1** at 123 K correspond quite well to those expected for HS state of Fe(1) and LS state of Fe(2).

3.3. Magnetic properties of *2*

$\chi_M T$ versus T plots, with χ_M being the molar magnetic susceptibility and T the temperature, for **2** is shown in Fig. 5. At room temperature, the magnetic behaviors of the complexes **2** is characteristic of Mn(II) compounds in the high-spin state, $\chi_M T = 4.13\ cm^3\ K\ mol^{-1}$ the values of μ_{eff} are ($\mu_{eff} = 2.828\sqrt{(\chi_M T)}$) of **2** per one Mn^{II} ion at 300 K was 5.75. The value for **2** are slightly smaller than 5.92 ($=g\sqrt{(S(S+1))}$, $g = 2$, $S = 5/2$) that of a pure spin only system, whereas the values are similar to the μ_{eff} value at 300 K of other Mn^{II} compounds [20]. The $\chi_M T$ value was nearly constant in the range of 15–300 K; however, it decreased rapidly as the temperature was lowered less than 17 K. The profile is characteristic of HS state of the metallic Mn^{II} centers with zero-field splitting (ZFS) [21–23]. While the complex **1** shows spin-crossover behavior (see S1) Ref. [10c], the susceptibility data of **2** indicate the existence of HS Mn^{II} throughout the temperature range.

3.4. Photoluminescent properties of *1* and *2*

Coordination compounds containing Au atoms with aurophilic interactions usually exhibit photoluminescent properties [24], so we investigated the photoluminescent properties. The photoluminescent properties of **1** and **2** have been investigated in the solid state at room temperature. As shown in Fig. 6, the maximum emission peaks of complexes **1** and **2** are located at 452 and 435 nm upon excitation at 373 and 375 nm, respectively.

4. Conclusions

In conclusion, we have illustrated bimetallic coordination polymer with the formula $\{Fe^{II}(3\text{-fluoropyridine})_2[Au^{I}(CN)_2]_2\}_n$ (**1**), $\{Mn^{II}(3\text{-fluoropyridine})_2[Au^{I}(CN)_2]_2\}_n$ (**2**). In complexes **1** and **2**, M^{II} (M = Fe, Mn) and Au^{I} atoms constitute the building blocks of these structures. The quasi-linear bidentate $[Au(CN)_2]^-$ bridges octahedral M^{II} atoms, assemble to form a $\{M^{II}_4[Au^{I}(CN)_2]_4\}$ rectangular mesh 2D network. By the aurophilic interactions, compounds of **1** and **2** produces a bilayer structure.

The Fe–N bond lengths for **1** at 293 K, 123 K and 80 K correspond quite well to those expected for each spin state of Fe^{II} ion (Fe(1) at 293 K is the HS state, Fe(1) and Fe(2) at 123 K are the

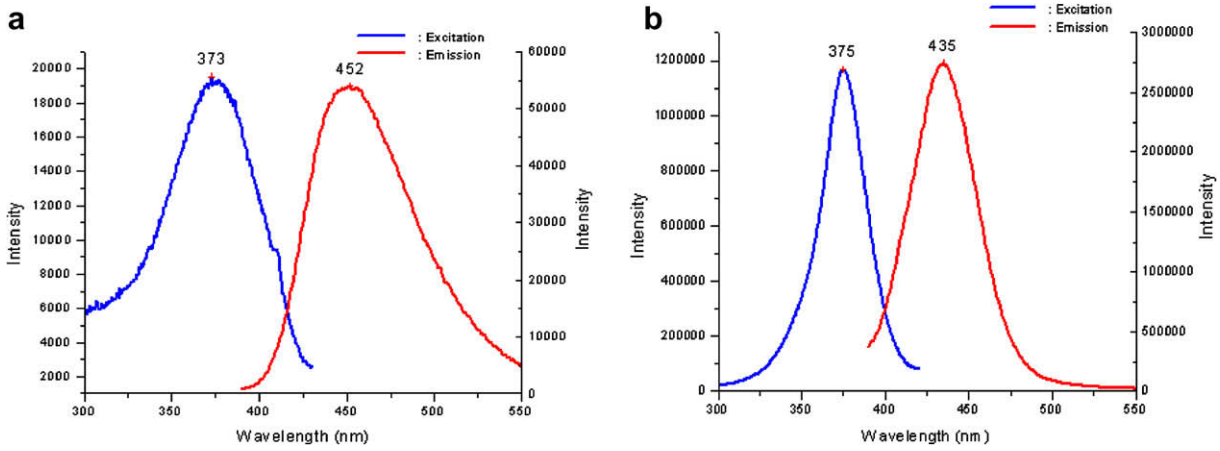

Fig. 6. Solid-state excitation (blue line) and emission (red line) spectra of **1** and **2** at room temperature. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

HS and the LS states, respectively, Fe(1) at 80 K is the LS state), which results agree completely with the magnetic behavior observed for **1** (see S1) Ref. [10c]. Moreover, single-crystal X-ray analysis also reveals that the spin transition is accompanied by a crystallographic phase transition from monoclinic $P2_1/c$ at 293 K to the triclinic $P\bar{1}$ at 123 K to monoclinic $P2_1/c$ at 80 K.

From the measurements of the temperature dependence of the magnetic susceptibility, the profile of the magnetic behaviors of the complex **2** is not occurrence of spin transition.

The solids of complexes **1** and **2** are occurrence of photoluminescence at room temperature, which can be attributed to the presence of aurophilic interactions.

In these result, complex **1** shows multifunctional material, spin-crossover phenomena and photoluminescence. Multifunctional properties are presently the subject of intensive studies by chemists and physicists, aiming at the eventual use of their multi applications.

2. Experimental

2.1. Synthesis of 4,4′4″-[*N*-(2-picoryl) aminomethyl] triphenylamine

To the solution of 4,4′,4″-triformyltriphenylamine (1.151 g) [8] in methanol (150 ml) 2-picorylamine (2.268 g) was added. Then the color of the solution changed to yellow. Acetic acid was slowly added until the color of the solution changed to orange. Sodium tetrahydroborate (6 g) was carefully added at 0 °C and stirred at ambient temperature for 3 days. The solution was neutralized with conc.-hydrochloric acid and evaporated under reduced pressure. The residue was dissolved into chloroform and dried over sodium sulfate. The obtained crude oil was purified by silica gel column chromatography (chloroform: methanol = 10:1) to give pale yellow oil (yield 1.02 g, 48.3%).

^{1}H NMR($CDCl_3$): δ 3.79 (s, 6H), 3.95 (s, 6H), 7.02 (d, 6H, J = 8.6 Hz), 7.16 (m, 3H), 7.21 (d, 6H, J = 8.6 Hz), 7.34 (d, 3H, J = 7.8 Hz), 7.64 (dt, 3H, J = 7.8 Hz, 1.7 Hz), 8.56 (d, 3H, J = 4.9 Hz).

2.2. Synthesis of 4,4′,4″-tris[N,N-bis(2-pyridylmethyl)aminomethyl]triphenylamine (*5*)

To the solution of 4,4′-dimethoxy-4-(2-picorylaminomethyl) triphenylamine (1.02 g) in dry THF (50 ml) was added 2-(bromomethyl) pyridimium hydrobromide (2.54 g) in dry THF (50 ml), triethylamine (1.48 g) and stirred at ambient temperature for 5 days. The solution was filtered and evaporated under reduced pressure. The residue was dissolved into chloroform and dried over sodium sulfate and evaporated under reduced pressure to give crude oil, which was purified by silica gel column chromatography (chloroform: methanol = 10:1) to give orange oil (yield 0.74 g, 50%).

^{1}H NMR($CDCl_3$): δ 3.63 (s, 6H), 3.82 (s, 12H), 6.97 (d, 6H, J = 8.6 Hz), 7.14 (t, 6H, J = 6.3 Hz), 7.23 (d, 6H, J = 8.6 Hz), 7.64 (d, 12H, J = 8.6 Hz), 8.52 (d, 6H, J = 4.62 Hz).

HRMS: Calc.: 878.4533 for $C_{57}H_{54}N_{10}$, Obsd: 878.4506.

2.3. Synthesis of palladium(II) dichloro(4,4′,4″-tris[N,N-bis-(2-pyridylmethyl)aminomethyl]- triphenylamine) triperchrorate (*6*)

4,4′4″-Tris[*N*,*N*-bis(2-pyridylmethyl)aminomethyl]triphenylamine (0.2 g), palladium(II) dichloride (0.13 g) and sodium perchlorate (0.48 g) were dissolved into a small amount of acetonitrile and refluxed for 3 h, which was concentrated to 5 ml and allowed to stand overnight at 5 °C to give pale yellow powders (yield 0.34 g, 93%).

^{1}H NMR(DMSO-d_6): δ 4.15 (s, 6H), 4.68 (d, 6H, J = 16.0 Hz), 5.58 (d, 6H, J = 16.0 Hz), 7.64 (m, 12H, 7.84(d, 6H, J = 8.0 Hz), 8.20 (t, 6H, J = 8.0 Hz), 8.51 (d, 6H, J = 5.6 Hz).

ESI-MS: m/z 434.2 $[M-3ClO_4^-]^{3+}$; 701.4 $[M-2ClO_4^-]^{2+}$.

2.4. Synthesis of copper(II) dichloro(4,4′,4″-tris[N,N-bis-(2-pyridylmethyl)aminomethyl]- triphenylamine) triperchrorate (*7*)

The copper complex (**7**) was prepared by the similar method for **6** (yield 0.33 g, 99%).

ESI-MS: m/z 391.9 $[M-3ClO_4^-]^{3+}$.

CAUTION: Although no problem was encountered in the preparation of the perchlorate salts, suitable care should be taken when handling such potentially hazardous compounds.

3. Results and discussion

3.1. Synthesis of the ligand, and the trinuclear complex

The ligand, 4,4′,4″-tris[*N*,*N*-bis(2-pyridylmethyl)aminomethyl]-triphenylamine, was synthesized as shown in Fig. 3. Treatment of 4,4′,4″-triformyltriphenylamine [8] with three equivalents of 2-picolylamine and sodium borohydride gave the secondary amine, 4,4′,4″-tris[*N*, *N*-bis(2-pyridylmethyl) aminomethyl] triphenylamine. This compound then was reacted with 2-(bromomethyl)pyridine hydrobromide under a basic condition to give the target compound **5**, in excellent isolated yield (50%). The complex **6** and **7** were prepared by reacting **5** with palladium(II) chloride and copper(II) chloride in the presence of sodium perchlorate, respectively.

3.2. UV–Vis spectrum and cyclic voltammetry measurements

In order to examine the spectroscopic properties of the ligand and the metal complexes, UV–Vis absorption spectroscopic measurements were examined in DMF. The ligand **5** exhibited a strong absorption around 300 nm. **6** and **7** also exhibited a strong absorption around 300 nm, which is characteristic of triarylamine chromophores [9]. In addition, **7** exhibited a weak absorption at 680 nm ($\varepsilon = 180\ M^{-1}\ cm^{-1}$). This peak can be assigned to the d–d transition of the copper(II) ion (Fig. 4).

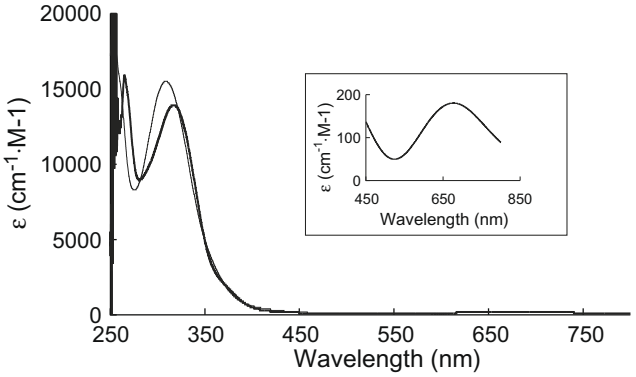

Fig. 4. UV–Vis spectra of **6** (plain) and **7** (bold) in DMF. Inset: UV–Vis spectrum of **7** in DMF.

3.3. Cyclic voltammetry measurements

Electrochemical behavior of the ligand **5** and the palladium complex **6** were studied by cyclic voltammetry in *n*-butyronitrile at ambient temperature. Upon sweeping anodically, **5** showed one set of reversible redox waves ($E^0 = 0.680$ V versus Fc/Fc^+), which can be assigned to the one electron oxidation process ($TAA/TAA^{+\cdot}$). Besides the oxidation peak, an irreversible shoulder oxidation peak ($Eox = 0.582$ V versus Fc/Fc^+) was also observed, which can be assigned to the one electron oxidation of the bis(2-picolylamino)aminomethylbenzene site. Similar electrochemical behavior was observed in our previous study for the ligand employed for the complex **1** [7a]. On the bother hand, **6** exhibited reversible redox waves ($E^0 = 0.782$ V versus Fc/Fc^+) as shown in Fig. 5, which can be assigned to the one electron oxidation process of the triarylamine unit. Compared to the redox potential of **1** ($E^0 = 0.464$ V versus Fc/Fc^+) and **3** ($E^0 = 0.473$ V versus Fc/Fc^+), the redox potential of **6** shifted more anodically, probably due to the tricationic structure. On the other hand, **7** showed a complicated

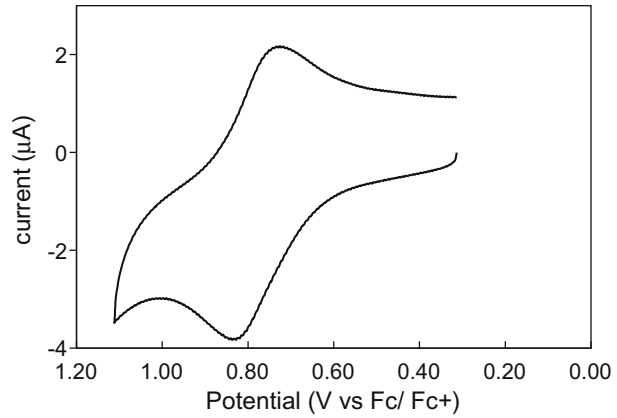

Fig. 5. Cyclic voltammogram of **6** in *n*-butyronitrile.

voltammogram upon sweeping anodically, indicating the decomposition of the oxidized species.

3.4. Two-dimensional NMR measurements

COSY (Correlated Spectroscopy) and ROESY (Rotating frame Overhauser Effect SpectroscopY) have been widely employed as powerful NMR techniques in organic chemistry. COSY and ROESY enable us to observe through-bond and through-space dipolar H–H interactions, respectively. ROESY cross peaks can be

observed only for nuclei that are proximate in space (<3.5 Å), which serve for the determination of the geometrical structure of molecules in solution. Previously, we have revealed that the dinuclear palladium complex **3** prefers a "folded conformation" at ambient temperature. COSY and ROESY measurements were applied to **6** to examine its conformation in DMSO-d_6 solution. In the ROESY spectrum of **6** at 25 °C, correlations were seen between the four hydrogen nuclei on the pyridine ring (Ha, Hb, Hc and Hd) and Hg peak. Similar correlations were also seen between the pyridine ring and He peak. These results indicate that the pyridine rings are proximate to the triarylamine unit in space. The findings clearly show that **6** prefers a "folded conformation" (Fig. 6) due to intramolecular stacking interactions. Even upon heating to 75 °C, the cross peaks did not disappear at all, indicating the occurrence of strong intramolecular stacking interactions.

3.5. Electron transfer stopped-flow (ETSF) method

The detail of the ETSF method was described previously [10]. The ETSF measurements were carried out in dehydrated acetonitrile as solvent at ambient temperature. In this study, tris(2,4-dibromophenyl)amine cation radical ($TDBPA^{+\cdot}$) [11] was employed. Complex **6**, upon mixing with one equivalent of $TDBPA^{+\cdot}$, exhibited a broad absorption peak at 687 nm ($\varepsilon = 1.40 \times 10^4$ cm $^{-1}$ M^{-1}), as shown in Fig. 7, which was gradually reduced for over 100 s (Fig. 8). Previously, we have reported the radical pen-

8

Fig. 9. Structure of complex **8**.

dant dinuclear palladium complex generated by one electron oxidation of **3**. The species showed no significant decrease in the peak intensity for 100 s. We have examined a similar complex **8** (Fig. 9), where the methyl group is attached instead of the methoxy group [12]. The radical pendant complex derived from **8** rapidly decomposed within 30 s. These result shows that a strong electrodonating group at least should be attached to the triarylamine unit to achieve persistent spin bearing ligands. The instability of the radical pendant complex derived from **6** would be attributed to its highly positively charged tetracationic structure.

4. Conclusion

A novel ligand having a redox active triarylamine group and two coordinating groups was designed and synthesized. The corresponding palladium and copper complex were also successfully prepared. The COSY and ROESY studies revealed that the palladium complex prefers the ‘‘folded conformation” in solution at ambient temperature. The cyclic voltammetry and ETSF study revealed that the palladium complexes gave novel complexes with a pendent radical upon one electron oxidation, which gradually decomposed at ambient temperature. These complexes can be regarded as prototypes for exploring redox active supramolecular metal clusters. A strong electrodonating group, such as the methoxy group, is essential to stabilize the corresponding oxidized states. Studies of self-assembled π-conjugated systems with intriguing magnetic properties are now underway.

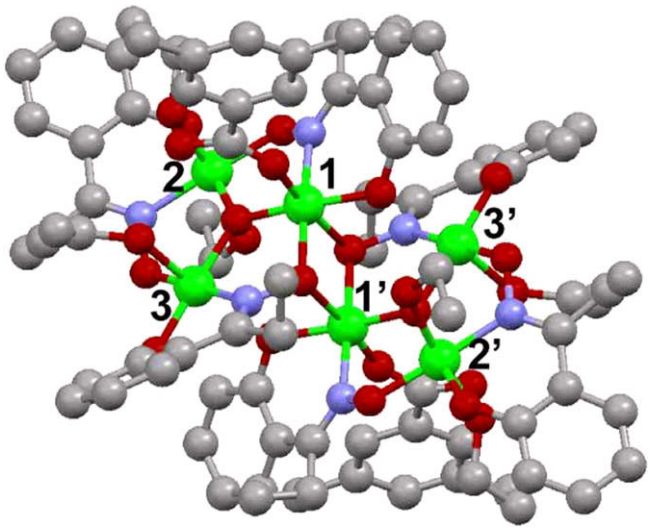

Fig. 1. Structure of the high-barrier Mn_6 molecule (H omitted for clarity). Green: Mn, red: O, blue: N, dark grey: C. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

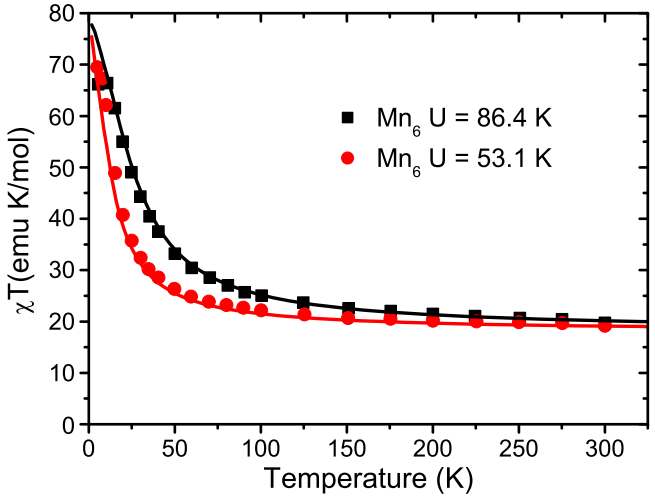

Fig. 2. Measured (points) and calculated (lines) T-dependence of the susceptibility for the two Mn_6 molecules. Calculations are made by including exchange interactions only, with the parameters determined by INS. $g = 2$ has been assumed.

Each Mn_6 molecule can be described by the following spin Hamiltonian [11]:

$$H = \sum_{i<j} J_{ij}\mathbf{s}(i)\cdot\mathbf{s}(j) + \sum_i d_i s_z^2(i) + \sum_i c_i(35s_z^4(i) + (25 - 30s(s+1))s_z^2(i)) + g\mu_B\mathbf{B}\cdot\mathbf{S} + H', \quad (1)$$

where $\mathbf{s}(i)$ are spin operators of the *ith* Mn ion and $\mathbf{S} = \sum_i \mathbf{s}(i)$ is the molecule's total spin. The first term is the isotropic exchange, while the second and third terms describe axial local crystal-fields (a z axis perpendicular to the triangles plane is assumed), and $\mathbf{B}$ is the external field [1]. H' (neglected in the following) represents additional small anisotropic terms. The minimal set of free parameters is given by three different exchange constants $J_{11'} \equiv J_1$, $J_{12} = J_{23} = J_{13} = J_{1'2'} = J_{2'3'} = J_{1'3'} \equiv J_2$, and $J_{13'} = J_{1'3} \equiv J_3$ (Fig. 1) and two sets of crystal-field (CF) parameters $d_1 = d_{1'}$, $c_1 = c_{1'}$, and $d_2 = d_{2'}$, $c_2 = c_{2'}$. The ligand cages of sites 1 and 3 are rather similar and we assumed the corresponding CF parameters to be equal. Since experimental information is insufficient to fix independently the two small c parameters,we have chosen to constrain the ratio c_1/c_2 to the ratio d_1/d_2. The anisotropic terms break rotational invariance and here lead to a large amount of mixing of different S multiplets (S mixing [12]). In the following we label the states by their leading S-component.

To determine the parameters appearing in (1), we have used the time-of-flight neutron spectrometers NEAT at the Helmholtz-Zentrum Berlin and IN5 at the Institute Laue Langevin (Grenoble). In addition, we have performed FDMRS measurements at the University of Stuttgart. Since FDMRS is sensitive to intra-multiplet transitions only, its use in conjunction with INS makes it easier to assess the character of the different observed excitations. Figs. 3 and 4 show examples of INS spectra together with theoretical simulations. The analysis of INS and FDMRS data leads to the following parameters for the higher (lower) barrier compounds: $J_1 = -0.84$

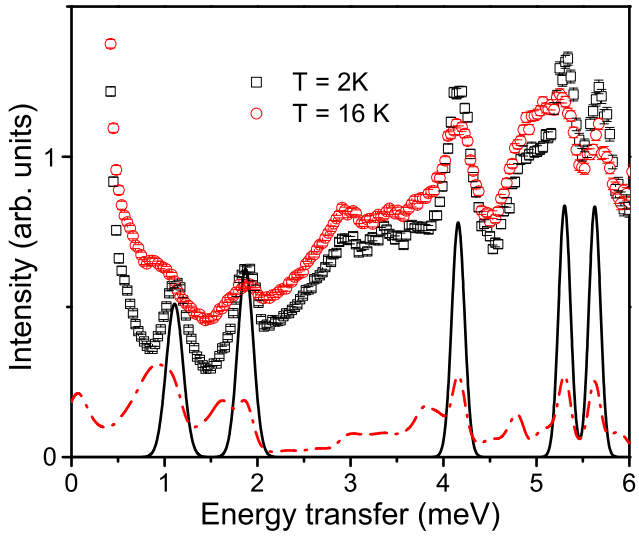

Fig. 3. INS spectra for the higher barrier molecule collected on IN5 with incident wavelength of 3.4 Å for $T = 2$ K (black) and $T = 16$ K (red). Lines are theoretical calculations with model (1). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

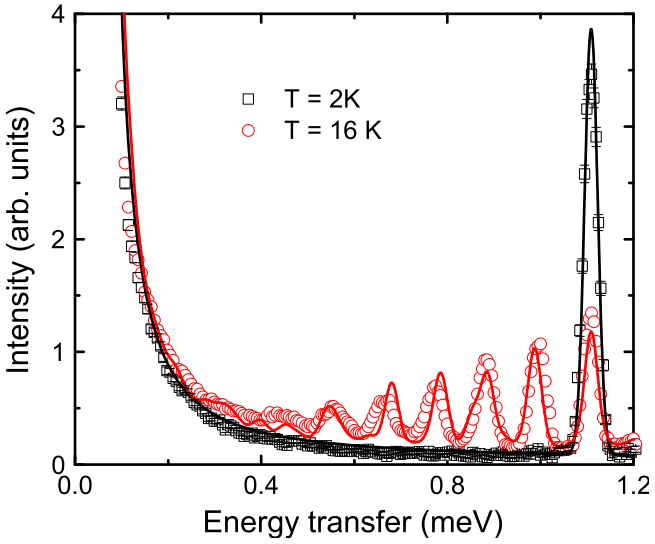

Fig. 4. INS spectra for the higher barrier molecule collected on IN5 with incident wavelength of 6.7 Å for $T = 2$ K (black) and $T = 16$ K (red). Lines are theoretical calculations with model (1). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

(−0.61) meV, $J_2 = -0.59$ (−0.31) meV, $J_3 = 0.01$ (0.07) meV, $d_1 = -0.20$ (−0.23) meV, $d_2 = -0.76$ (−0.97) meV and $c_1 = -0.001$ (−0.0008) meV [11]. The agreement between simulations and data in Figs. 3 and 4 is very satisfactory considering that only three independent crystal-field parameters have been assumed. The parameters are also consistent with susceptibility measurements (see Fig. 2). Hence, anisotropy is similar in the two variants whereas the dominant ferromagnetic exchange is substantially larger in the higher-barrier compound. Figs. 5 and 6 show the energies of the S-multiplets resulting from the exchange part of (1). It is evident from these figures that the exchange splitting between the ground $S = 12$ manifold and many excited multiplets, including low-S ones, is smaller than the energy scale of anisotropic terms in (1). In particular, Fig. 6 shows that in the lower-barrier compound the energy of the lowest-lying $S = 0$ multiplet is only about 4 meV larger than that of the ground one. Thus, the giant spin mapping completely breaks down in these two molecules, not only for the large S-mixing in the wavefunctions, but even for failing to account for the number of states located below the barrier. The presence of a center of inversion (characterizing the structure determined at 150 K) implies that exchange multiplets can be classified according to their parity with respect to the associated spin-permutation operation. For instance, the ground $S = 12$ states are even, whereas the lowest-lying $S = 11$ states are odd.

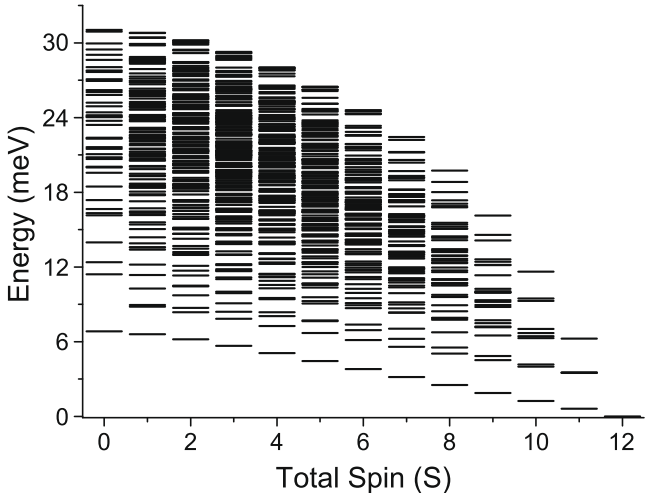

Fig. 5. Energy of all S-multiplets for the higher barrier compound, resulting from the exchange part of (1) with the parameters given in the text.

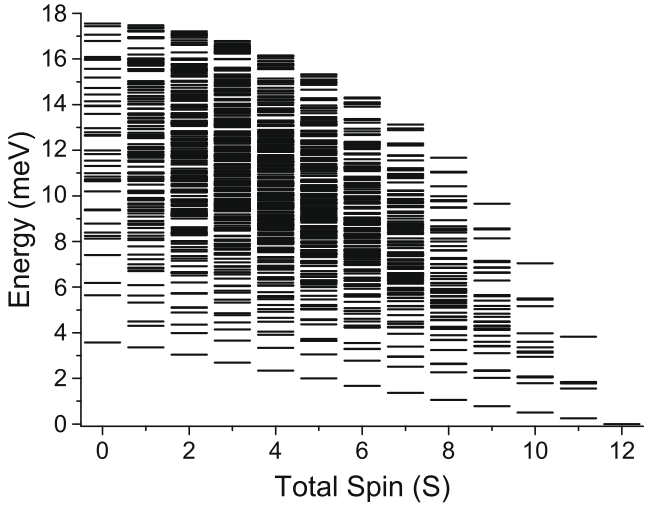

Fig. 6. Energy of all S-multiplets for the lower barrier compound, resulting from the exchange part of (1) with the parameters given in the text.

3. Relaxation of the magnetization

The main difference between the two Mn_6 variants is the position of the excited S manifolds, therefore the comparison between the relaxation behavior of these systems offers the opportunity to study the role played by low-lying excited multiplets. To address this issue, we adopt the well established framework presented in [13,14] for the irreversible evolution of the density matrix $\rho(t)$. By focusing on time scales much longer than the typical periods of free evolution of the system, the so-called "secular approximation" enables the time evolution of the diagonal matrix elements of the density matrix to be decoupled from that of the off-diagonal ones. In particular, the populations of the molecular eigenstates, $p_l(t)$, evolve through master equations:

$$\dot{p}_l(t) = \sum_m W_{lm} p_m(t), \tag{2}$$

where W_{lm} is the lm element of the rate matrix, i.e., the probability per unit time that a transition between levels $|m\rangle$ and $|l\rangle$ is induced by the interaction with the phonon heat bath. The latter can be calculated by perturbation theory once magnetoelastic (ME) interactions have been modelled. Experimental information is totally insufficient to fix all the many possible parameters appearing in the ME coupling potential. By assuming that the main contribution to this coupling arises from the modulation of the local rank-2 crystal fields and that quadrupole moments of each individual Mn ion are isotropically coupled to Debye acoustic phonons, we obtain [15]

$$W_{lm} = \gamma^2 \Delta_{lm}^3 n(\Delta_{lm}) \sum_{i,j,q_1,q_2} \langle l \mid O_{q_1,q_2}(\mathbf{s}_i) \mid m \rangle \times \langle m \mid O_{q_1,q_2}(\mathbf{s}_j) \mid l \rangle, \tag{3}$$

where i and j run over Mn ions, $O_{q_1,q_2}(\mathbf{s}_i)$ are the components of the cartesian quadrupole tensor operator, $n(x) = (e^{\hbar x/k_B T} - 1)^{-1}$ and $\Delta_{lm} = (E_l - E_m)/\hbar$. The single free parameter γ is proportional to the ME coupling strength. In spite of the complexity of their energy spectrum, for both variants the resulting relaxation spectrum at low T is dominated by a *single* relaxation time displaying a nearly Arrhenius behavior $\tau(T) = \tau_0 \exp(U/K_B T)$, in agreement with experiments [11]. In particular, the effective energy barrier for the magnetization reversal is crucially dependent on the position of low-lying excited S multiplets. Indeed, the large difference between the barriers of the two molecules mainly results from the variation of the ferromagnetic exchange constants and not from a variation in anisotropy. It is also worth to note that in the present case U is not set by the energy of the lowest-lying $M_S = 0$ state as one could naively expect.

The existence of several total-spin multiplets partially overlapping with the ground one implies that a magnetic field applied along the molecule's easy axis induces crossings involving states which are absent in a giant spin description. These can be turned into anticrossings (ACs) by the small transverse terms contained in H'. Fig. 7 shows that besides the "traditional" intra-$S = 12$ crossings at about 0, 0.4 (e.g., the square) and 0.8 T, many more occur for intermediate values of B. In particular, there are three different kinds of "non-traditional" field-induced crossings, i.e., absent in the giant spin description of the molecule. First of all there are crossings involving a pair of states belonging to a single low-energy S multiplet different from the ground one (for instance the higher-lying ellipsis at 0.3 T in Fig. 7). These crossing may lead to relaxation shortcuts if the dominant relaxation path passes

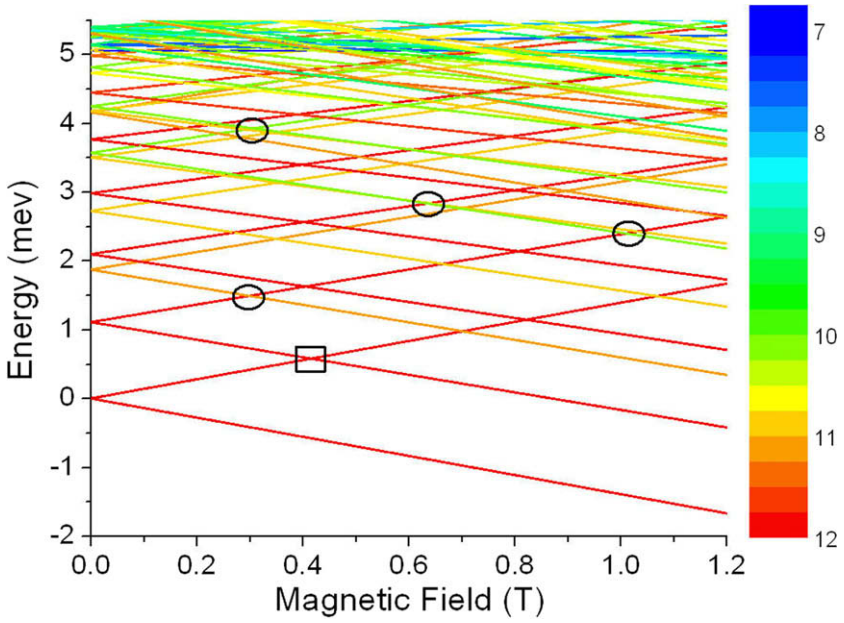

Fig. 7. Energy levels of the higher-barrier compound as a function of B, applied along the z axis. The color maps for each state the value of S_{eff}, where $\langle S^2 \rangle := S_{\text{eff}}(S_{\text{eff}}+1)$. Ellipses and the square indicate representative examples of level crossings.

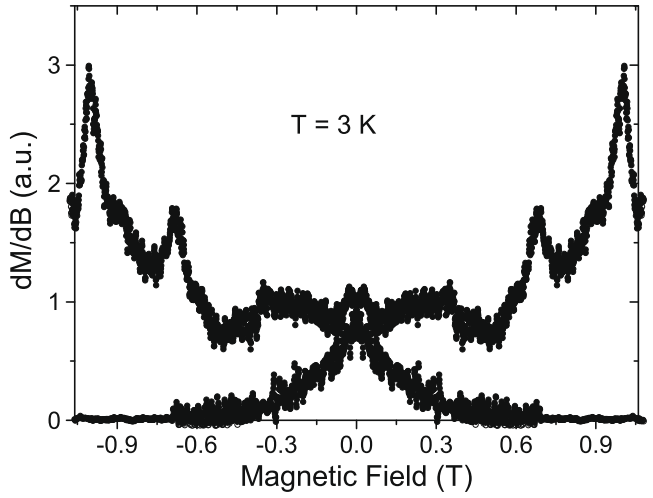

Fig. 8. Example of derivative of the hysteresis curves measured for the higher-barrier molecule in [6]. For each value of B, there are two points corresponding to increasing or decreasing B in the hysteresis cycle.

through them. The other two kinds of crossings (e.g. the other ellipses in Fig. 7) involve pairs of states belonging to different S-manifolds. The distinction arises from the symmetry properties of the two crossing states, i.e., they may have the same parity or not. In the first case (e.g., the crossings between red and green curves in the two ellipses at about 0.6 and 1 T) H' usually leads to an AC, whereas in the second case (e.g., the ellipse at about 0.3 T) an AC may occur to the extent that at low T the inversion center is removed by a distortion, leading to terms with low-enough symmetry in H'. Even if there are no structural data below 150 K, it is not unlikely for magnetic molecules to undergo a symmetry lowering at low T (see, e.g., [16,17]). "Non-traditional" ACs with the associated resonant incoherent tunneling, may result in relaxation shortcuts leading to additional steps in hysteresis cycles, absent in a giant-spin picture. For instance, Fig. 8 shows an example of derivative of the hysteresis curves measured at $T = 3$ K for the higher-barrier molecule [6]. The "traditional" ACs produce minor features in these curves, and the two main peaks are associated with "non-traditional" ACs. The effect of low-field ACs is more evident at higher T [11]. For instance, there are features at 0.3 T which may a priori originate from both crossings marked in Fig. 7.

4. Conclusions

By exploiting INS and FDMRS we have determined the microscopic Hamiltonian of two different high-spin variants of the Mn_6 nanomagnet. We have found that excited S multiplets overlapping with the ground one strongly affect the magnetic relaxation process. Moreover, we have demonstrated the existence of tunnelling pathways involving pairs of states belonging to different total spin manifolds. Hence, the energy separation between the ground and excited multiplets may be a key ingredient in determining the relaxation and tunnelling dynamics of molecular nanomagnets.

The structure (a) is the undistorted and (b)–(d) are distorted ones. Changed parameters are (b) the distance, (c) the rotation angle and (d) the slip in *X*–*Y* plane between two monomers.

rotation angle and discrepancy in *XY*-plane, are changed in the model dimer structure as illustrated in Fig. 1b–d.

2. Theoretical background

An interaction between localized spins can be expressed by using Heisenberg Hamiltonian,

$$\hat{H} = -2\sum_{a,b} J_{ab}\hat{S}_a \cdot \hat{S}_b, \tag{1}$$

where the parameter J_{ab} is a coupling parameter between localized spins *S* on metal ions *a* and *b*.

A broken-symmetry (BS) method such as UHDFT and unrestricted Hartree–Fock (UHF) approximately involves the static correlation correction by splitting α and β electrons into two different orbitals, namely different orbitals for different spins (DODS) approach [9–12]. The low-spin species of BS method, however, suffer from a spin contamination of higher spin states, which influence total energy, optimized geometry, excited energy, and so on. Yamaguchi et al. have proposed approximate spin projection (AP) procedure by using Heisenberg Hamiltonian to eliminate the spin contamination [10,13]. Hence, we discuss J_{ab} values with the AP procedure.

$$J_{ab} = \frac{E_{BS}^{LS} - E_{BS}^{HS}}{\langle \hat{S}^2 \rangle_{BS}^{HS} - \langle \hat{S}^2 \rangle_{BS}^{LS}}. \tag{2}$$

Eq. (2) is the equation for the calculation of J_{ab} values with AP procedure [10,13]. The positive (negative) J_{ab} value means ferromagnetic (anti-ferromagnetic) interaction.

3. Computational details

In this study, we mainly use Becke's three parameter exchanges with Lee–Yang–Parr correlation functionals (E_c^{LYP}) known as B3LYP [14]. The equation of the exchange-correlation energy is as follow:

$$E_{xc} = c_1 E_x^{HF} + c_2 E_x^{Slater} + c_3 E_x^{Becke88} + c_4 E_c^{VWN} + c_5 E_c^{LYP}, \tag{3}$$

where E_x^{HF}, E_x^{Slater}, $E_x^{Becke88}$ and E_c^{VWN} are the HF exchange energy, Slater exchange functional, the Becke88 exchange functional, the Vosko–Wilk–Nusair (VWN) correlation functional, respectively. These parameters are $c_1 = 0.2$, $c_2 = 0.8$, $c_3 = 0.72$, $c_4 = 0.19$ and $c_5 = 0.81$. Besides B3LYP, we used various exchange-correlation functionals, BHandHLYP [15], PW91PW91 [16], MPW1PW91[17]. And we also examined by HF and MP2 [18], in order to elucidate dependency of J_{ab} values on computational methods.

All calculations were carried out with the use of 6-31G* basis set for ligands, and Huzinaga MIDI+pd basis set [19] for Cu^{2+} atoms using the GAUSSIAN 03 program package [20]. To confirm the effects of the diffuse function for ligands, the J_{ab} values were estimated with and without the diffuse function. As summarized in Table 1, the 6-31G* basis set gave J_{ab} values of −0.7, −0.9, −0.6 and −0.1 eV for the various separation distance of the metal–salen dimer ([**S**–Cu^{2+}–**S**]$_2$, where **S** means salen ligand), respectively, while the 6-31+G* basis set gave −0.6, −0.9, −0.6 and −0.1, respectively. The diffuse functions do not affect J_{ab} values of the [**S**–Cu^{2+}–**S**]$_2$ quantitatively, so that the 6-31G* basis set is used for estimating J_{ab} values, here.

We constructed model structures based on the X-ray structure of the metal–salen–base pair complex [8]. The structure of the metal–base pair in DNA, however, is difficult to decide whether it is the right handed or not, on the basis of experimental data, so that we assume that this structure is the right handed one. A distance between adjacent planes and rotation angle of the original

structure are decided to be 3.375 Å and 36° on B–DNA form, respectively, as illustrated in Fig. 1a. Here we call this structure "original structure".

4. Results and discussion

4.1. J_{ab} values between Cu^{2+} ions for the original structure with and without-backbones

First, the J_{ab} values between two Cu^{2+} ions are calculated for the original structure with and without-backbones (sugar–phosphate). By using those assumptions, we constructed the model system as illustrated in Figs. 1a and 2. Calculated total energies, $\langle \hat{S}^2 \rangle$ values and the J_{ab} values of models without-backbone are summarized in Table 1. Results with backbones are also summarized in Table 2.

Within the both models, the calculated energy splitting between the BS LS and the HS states is small. However the BS LS state is slightly stable and the calculated J_{ab} values are negative, indicating an anti-ferromagnetic interaction. This result agrees with experimental J_{ab} values of a Metal–DNA (M–DNA) based on a natural B–DNA ($J = -0.0483\ cm^{-1}$) [4]. The J_{ab} values of with- and without-backbone models are same. These results can be easily understood by the natural orbitals (NOs) analysis. The NOs are obtained by diagonalization of a first order density matrix as

$$\rho(r, r') = \sum n_i \{\phi_i(r)\}^* \phi_i(r'), \quad (4)$$

where n_i denotes the occupation number of NO (φ_i). The occupation number is in proportion to the overlap between α and β orbitals, so that one can estimate SOMO–SOMO overlap from the number. The overlap is calculated by $n_i - 1$ [10]. Therefore, if an occupation number of a magnetic orbital is close to 1.0, then two electrons in the orbital are almost localized on each spin site. On the other hand, n_i should be equal to 2.0 if the two spins are delocalized on two spin sites. The NOs for the BS LS state are depicted in Fig. 3. The highest occupied natural orbital (HONO) and the lowest unoccupied natural orbital (LUNO) mainly consist of $d_{x^2-y^2}$ orbitals of Cu^{2+} ions, and their occupation numbers are almost 1.0, indicating that overlap between two spins on Cu^{2+} ions are very small. In "with-backbone" model, we cannot find population on backbone atoms, and occupation number of HONO is same to that of "without-backbone" model. These results indicate that backbone does not affect SOMO–SOMO overlap. Therefore the J_{ab} values of two models are same. Also we consider solvent (water) effect by using PCM method on the original structure. The calculated J_{ab} value is $-0.8\ cm^{-1}$ and it is almost equal to non-solvent model. These results suggested that the J_{ab} value does not depend on a chemical environment by solvent.

4.2. Change in J_{ab} values with deformations

It is well known that the DNA is flickered and changed their forms such as A-, B-and Z-forms by solvent [21]. In this sense, a structural disorder of the DNA strand must be examined for the consideration of the magnetic interaction. Therefore we, next, consider three possibilities of deformations i.e. the distance, the rotation angle and the slip in *X*–*Y* plane between two monomers as illustrated in Fig. 1b–d, and examine a change in J_{ab} values with those deformations. Calculated results for each distance and rotation angle are summarized in Table 1 and 3, respectively. The range of the separated distance and rotation angle are 3.0–5.0 Å and 0–180°, respectively. The calculated J_{ab} values are small in all range of distances and angles. Interestingly, the J_{ab} values are not in proportion to the separated distance. These is a minimum around 3.375 Å. In addition, J_{ab} values do not show a periodic dependency on the rotation angle. For example, there are minima around 120° and 150°. Usually, it should be minima around 0°, 90° and 180° when the symmetry of $d_{x^2-y^2}$ orbitals of Cu^{2+} ions of adjacent planes are considered, because the J_{ab} values depends on overlap between two spin orbitals on Cu^{2+} ions. The reason of this phenomenon is originated from the twisted salen structure as explained in Section 4.4.

In order to explain the detail, the NO analyses are carried out for several angles. The occupation numbers of the BS LS state are depicted in Table 4. All of their occupation numbers for HONO and LUNO are almost 1.0 indicating overlap between two spins on Cu^{2+} ions are very small.

As explained above, it is expected that the DNA backbone is always flickered by outer environment. So, we also estimate the slipping of two monomer in *X*–*Y* plane as illustrated in Fig. 1d. In this model, separated distance and rotation angle are fixed to 3.375 Å and 36°, respectively. As summarized in Fig. 4, the J_{ab} values do not show a simple behavior because of the twisted structure of salen, but anti-ferromagnetic interaction is observed in whole region.

4.3. Dependency of the J_{ab} values on various calculation methods

It has been reported calculated J_{ab} values sometimes depend on the DFT functional sets quantitatively, but not qualitatively. Therefore, we next investigated the dependency of the J_{ab} values on calculation methods such as BHandHLYP, PW91PW91, MPW91PW91, HF and MP2. Calculated results are shown in Table 5. Although the double helix of DNA is stabilized by π–π interaction, the DFT method which does not include π–π interaction gives systematic J_{ab} values. B3LYP, BHandHLYP and MPW1PW91 functional contain 20%, 50% and 25% HF exchange, respectively. From the results, it can be seen that the J_{ab} values depend on a ratio of HF exchange, but not depend on a correlation functional. In PW91PW91 (0% HF exchange), the J_{ab} value is a weak ferromagnetic interaction for the original structure. In MP2, the absolute values of the J_{ab} are larger at a long distance as compared others methods. This result of MP2 is unreasonable because magnetic interaction should be

close to zero at a long distance. Tsuzuki et al. reported that the MP2 calculation overestimate π–π interaction such as benzene or naphthalene [22,23]. Our results also suggest the method may not be applicable to the long distance $[\mathbf{S}–Cu^{2+}–\mathbf{S}]$ dimer.

4.4. Change in the J_{ab} values for planer $[\mathbf{S}–Cu^{2+}–\mathbf{S}]$ without ethylenediamine

As described above, on the metal–salen complex structure, the dihedral angle between the planes defined by the aromatic rings

was +22° because of crosslink by ethylenediamine. If the metal–salen monomer does not have the linking en, it will be planer complex. Therefore, we examined the J_{ab} values of planer $[\mathbf{S}–Cu^{2+}–\mathbf{S}]_2$ dimer without en to elucidate the effect of the twist structure of ligand. We changed the dihedral angel into 0° by removing en from $[\mathbf{S}–Cu^{2+}–\mathbf{S}]_2$ as shown in Fig. 5. The calculated results are shown Table 6. The calculated J_{ab} values are small in all range of distances. The J_{ab} values depend on the separated distance and the anti-ferromagnetic interaction becomes stronger as the distance between two Cu ions becomes shorter. From the result, the reason that, J_{ab} values of $[\mathbf{S}–Cu^{2+}–\mathbf{S}]_2$ dimer is not in proportion to the dimer distance seems to come from the twisted structure of the ligand.

Fig. 5. Structure of $[\mathbf{S}–Cu^{2+}–\mathbf{S}]_2$ without ethylenediamine.

5. Conclusion

We theoretically investigated magnetism of Cu^{2+} bridged salen–base pairs. To our knowledge, this is the first report on the magnetism for this system. In all calculated results using B3LYP, the total energies of the HS and the BSLS states are degenerated but J_{ab} values show weak anti-ferromagnetic couplings within the examined model structures. These results agree with Metal–DNA based on natural B-DNA [4]. So, we can conclude that artificial Metal–DNA (especially this system) shows anti-ferromagnetic interaction, which is consistent with the experimental result. The J_{ab} values strongly depend on the ligand structure caused by en but not backbones. Seeman et al. reported pioneering studies of DNA nanoarchitectures. They made, for example, the self-assembly of branched DNA molecules into a two-dimensional crystal and ligated DNA molecules form interconnected rings to create a cube-like structure [24]. Using these structures, it is possible to create a new material by arranging molecules in space precisely. Assimilating Seeman's structures and the metal-base pair in DNA, it is also possible to create a new magnetic material by arranging metals with spins. From our results, it seems to be effective to design the angle of aromatic ring to control the magnetic properties.

were obtained using a JEOL JMS-AX500 mass spectrometer. The infrared spectra were measured using a Shimadzu FT-IR-8700 C. The EPR spectra were recorded by a Brucker ELEXSYS E500. The X-ray data were collected by a Rigaku MSC Mercury CCD area detector with graphite monochrometer Mo Kα radiation. The magnetic susceptibility measurements were performed using a Quantum Design SQUID magnetometer MPMS-XL.

2.2. Synthesis of 2,4-diphenylcarbonohydrazide **3**

A Schlenk tube was charged with carbonohydrazide (1.0 g, 11 mmol), finely ground K_3PO_4 (4.6 g, 22 mmol), CuI (420 mg, 2.2 mmol), *N,N′*-dimethylethylenediamine (0.47 mL, 4.4 mmol), iodobenzene (6.1 mL, 55 mmol), and dry DMF (10 mL). The mixture was stirred under argon at 60–70 °C for 24 h. The resulting brownish suspension was filtered through a Celite pad and washed with 50 mL of ethyl acetate. The combined filtrate was concentrated and the residue was purified by flash chromatography on silica gel eluting with ethyl acetate to give **3** as a yellow oil (0.571 g, 21% yield), which was crystallized from a mixture of ethyl acetate-*n*-hexane in a freezer to give beautiful pale yellow prisms. Compound **3**: m.p. 60 °C; MS (FAB^+); *m*/*z* 242 (M^+); ^1H NMR (400 MHz, $CDCl_3$): δ 7.72 (td, *J* = 7.2, 1.2 Hz, 4H), 7.14 (dd, *J* = 7.8, 1.4 Hz, 4H), 7.03 (td, *J* = 7.2, 1.2 Hz, 2H), 4.47 (s, 4H); ^{13}C NMR (75 MHz, $CDCl_3$) δ 161.79, 144.63, 128.72, 125.23, 123.36; IR (KBr, cm^{-1}): 3342 (m), 3284 (m), 3062 (w), 1652 (s), 1585 (s), 1495 (s), 1361 (s), 1305 (s), 920 (m), 692 (s); *Anal.* Calc. for $C_{13}H_{14}N_4O$: C, 64.45; H, 5.82; N, 23.13. Found: C, 64.18; H, 5.83; N, 23.28%.

2.3. Synthesis of 2-(2,4-diphenyl-3-oxoverdazyl)-5,10-diphenyl-5,10-dihydrophenazine (**VzDPP**·)

A mixture of 5,10-diphenyl-5,10-dihydrophenazine-2-carbaldehyde (100 mg, 0.27 mmol) [10], pyridinium tosylate (21 mg, 0.08 mmol), and **3** (72 mg, 0.30 mmol) in methanol (5 mL) was refluxed for 30 min. The resulting precipitates were collected by filtration to give the expected condensation product, dihydro-**VzDPP** (162 mg, 96% yield). Thus obtained dihydro-**VzDPP** (50 mg, 0.16 mmol) was dissolved in CH_2Cl_2 (5 mL). The CH_2Cl_2 solution was treated with an excess amount of PbO_2 (203 mg, 0.85 mmol) and stirred for 1 h at room temperature. The mixture was filtered and concentrated. The residue was purified by chromatography on silica gel eluting with CH_2Cl_2–*n*-hexane (1:2), to give **VzDPP**· as a red powder (41 mg, 80% yield). **VzDPP**·: m.p. 254 °C; HRMS (FAB^+); *m*/*z* Calc. for $C_{38}H_{27}N_6O$+H: 584.2325; found 584.2303 (M+H); IR (KBr, cm^{-1}): 3057 (w), 1689 (s), 1591 (s), 1489 (s); EPR; *g* = 2.0037 (a_N = 6.49, 4.41 G, a_H = 0.68, 0.36 G) in toluene at room temperature.

2.4. Synthesis of 2-(2,4-diphenyl-3-oxoverdazyl)-5,10-diphenyl-5,10-dihydrophenazine radical cation $GaCl_4^-$ salt (**VzDPP**$^{\cdot+}\cdot GaCl_4^-$)

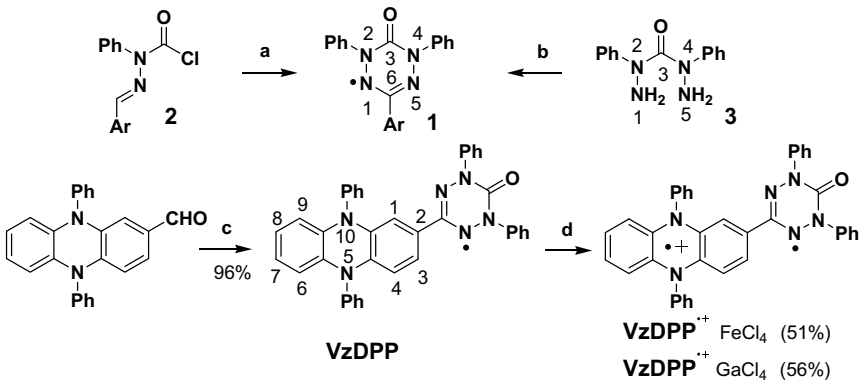
The following procedure was carried out in a glove box. To a solution of **VzDPP**· (30 mg, 0.05 mmol) in CH_2Cl_2 (5 mL), was added a solution of thianthrene$^{\cdot+}\cdot GaCl_4^-$ [11] (22 mg, 0.05 mmol) in CH_3CN (15 mL). The reaction mixture was stirred for 30 min at room temperature, filtered to remove insoluble materials, and concentrated under reduced pressure. The residue was dissolved in a minimum amount of CH_2Cl_2 (ca. 5 mL). Then, diethyl ether (20 mL) was added into the CH_2Cl_2 solution. **VzDPP**$^{\cdot+}\cdot GaCl_4^-$ was obtained as a dark red precipitate and was recrystallized from CH_2Cl_2–diethyl ether as follows: **VzDPP**$^{\cdot+}\cdot GaCl_4^-$ was dissolved in a minimum amount of CH_2Cl_2 in an uncapped small bottle. The bottle was placed in a larger capped bottle containing diethyl ether and kept at room temperature for two days. **VzDPP**$^{\cdot+}\cdot GaCl_4^-$ was obtained as dark red prisms (21 mg, 51% yield). **VzDPP**$^{\cdot+}\cdot GaCl_4^-$: m.p. 256 °C; MS (FAB^+); *m*/*z* 584 (**VzDPP**$^{\cdot+}$); MS (FAB^-); *m*/*z* 211 ($GaCl_4^-$); IR (KBr, cm^{-1}): 3076 (w), 1705 (s), 1589 (m), 1548 (m), 1485 (m); *Anal.* Calc. for $C_{38}H_{27}Cl_4GaN_6O$: C, 57.40; H, 3.42; N, 10.57. Found: C, 57.13; H, 3.67; N, 10.36%; EPR; *g* = 2.0030 in a powder form at room temperature, see Fig. 3 for the fine structures in butyronitrile at 123 K.

2.5. Synthesis of 2-(2,4-diphenyl-3-oxoverdazyl)-5,10-diphenyl-5,10-dihydrophenazine radical cation $FeCl_4^-$ salt (**VzDPP**$^{\cdot+}\cdot FeCl_4^-$)

The $FeCl_4^-$ salt was similarly prepared using thianthrene$^{\cdot+}\cdot FeCl_4^-$ [11]. **VzDPP**$^{\cdot+}\cdot FeCl_4^-$ was obtained as dark red prisms (54% yield). **VzDPP**$^{\cdot+}\cdot FeCl_4^-$: m.p. 250 °C; MS (FAB^+); *m*/*z* 584 (**VzDPP**$^{\cdot+}$); MS (FAB^-); *m*/*z* 198 ($FeCl_4^-$); IR (KBr, cm^{-1}): 3076 (w), 1703 (s), 1589 (m), 1545 (m), 1485 (m); *Anal.* Calc. for $C_{38}H_{27}Cl_4FeN_6O$: C, 58.41; H, 3.48; N, 10.76. Found: C, 58.33; H, 3.42; N, 10.64%; EPR; *g* = 2.0288 in a powder form at room temperature, see text for the fine structures in butyronitrile at 123 K.

3. Results and discussion

3.1. Syntheses of **VzDPP**· and **VzDPP**$^+\cdot MCl_4^-$ (M = Fe and Ga)



6-Aryl-2,4-diphenyl-3-oxoverdazyl derivatives **1** have generally been synthesized via 2-arylmethylidene-1-phenylhydrazinecarbonyl chloride **2** [12] (Scheme 1). Obviously, the condensation method of arylaldehyde with hitherto unknown 2,4-diphenylcarbonohydrazide **3** is much more convenient. We have therefore developed a synthetic route to **3** by applying the method of copper catalyzed amidation of aryl halides [13]. The synthesis of **3** was carried out in one step although the yield was moderate (~20%, see Section 2). Thus, neutral **VzDPP**· was synthesized through the condensation of 5,10-diphenyl-5,10-dihydrophenazine-2-carbaldehyde with **3**, followed by the oxidation with PbO_2 in CH_2Cl_2 in good yield (Scheme 1). **VzDPP**· exhibited two oxidation peaks at $E_{ox}(1)$ = +0.35 V (reversible) and $E_{ox}(2)$ = +0.90 V (irreversible) versus SCE in DMF in the presence of 0.1 M *n*-$Bu_4N^+\cdot ClO_4^-$. They can be assigned as oxidation potentials of **DPP**– and **Vz**·-moieties, respectively, by comparison with suitable model compounds (**DPP**: +0.30 V (reversible), **1** (Ar = Ph): +1.00 V (irreversible) versus SCE in DMF in the presence of 0.1 M *n*-$Bu_4N^+\cdot ClO_4^-$).

VzDPP$^{\cdot+}\cdot MCl_4^-$ (M = Fe and Ga) were obtained by the chemical oxidation of the neutral compound with thianthrene$^{\cdot+}\cdot MCl_4^-$ [11] salts as dark red prisms in moderate yields (Scheme 1).

3.2. Structures of **VzDPP**$^{\cdot+}\cdot MCl_4^-$ (M = Fe and Ga)

The molecular and packing structures of the $FeCl_4^-$ and $GaCl_4^-$ salts are very similar (see Table 1 for their crystallographic parameters). Fig. 1 shows a crystal packing structure of **VzDPP**$^{\cdot+}\cdot FeCl_4^-$ salt. There are several intermolecular short contacts within or close to the van der Waals contacts between magnetically important atoms. The **VzDPP**$^{\cdot+}$ moieties are combined by $FeCl_4^-$ in the b–c^* plane (green dotted lines (C–Cl contacts: 3.39–3.58 Å, Fig. 1I)). They are also aligned in the a^*–b plane through the intermolecular C–N contact (red dotted lines: 3.26 Å) and the C–C contact (black dotted lines: 3.29–3.50 Å), giving a ladder-type chain structure $[(\mathbf{VzDPP}^{\cdot+})_2]_n$ along the a^*-axis (Fig. 1II). The combination of these contacts makes a 3D network structure.

Quite similar contacts with similar contact-lengths were observed for **VzDPP**$^{\cdot+}\cdot GaCl_4^-$ salt (C–Cl contact: 3.39–3.59 Å, C–N contact: 3.25 Å, C–C contact: 3.28–3.49 Å).

Scheme 1. Reaction conditions: (a) $PhNHNH_2$, Et_3N in ethanol; (b) (i) ArCHO, (ii) oxidation; (c) (i) **3**, pyridinium tosylate (cat.) in methanol, (ii) PbO_2 in CH_2Cl_2; (d) thianthrene radical cation MCl_4^- (M = Fe and Ga) salts [11].

[b] $R_w = [\sum w(|F_o| - |F_c|)^2/\sum wF_o]^{1/2}$.

The magnetic interaction between **VzDPP**$^{\bullet+}$ ($S = 1$, *vide infra*) and Fe(III) ($S = 5/2$) in the above chain structure are most likely to be antiferromagnetic from the analogy of similar π–d type magnetic systems [14]. Thus, ferrimagnetic spin alignment may be expected in these π–d chain structures. However, the $[(\mathbf{VzDPP}^{\bullet+})_2]_n$ ladder chain includes several π–π type contacts, which are likely to be also antiferromagnetic. Especially, the short contacts between the carbon atom (C8, see Fig. 2 for numbering) and the nitrogen spin-center (N12 in the verdazyl moiety, see Fig. 2) would cause a sizable antiferromagnetic interaction as judged from the spin densities of **VzDPP**$^{\bullet+}$ (Fig. 2).

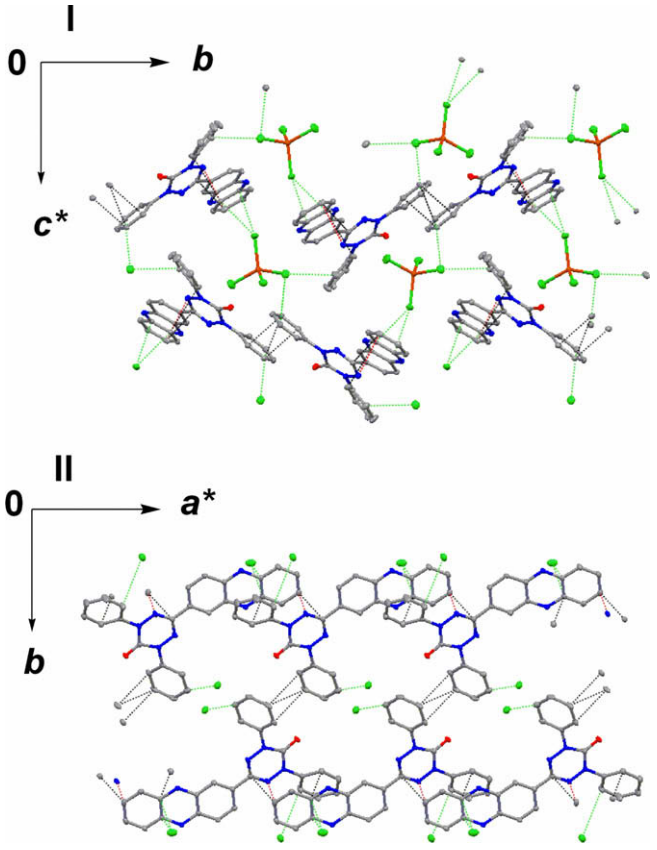

Fig. 1. Crystal packing structure of **VzDPP**$^{\bullet+} \cdot FeCl_4^-$, where intermolecular short contacts are shown by dotted lines; black: C–C contact, red: C–N contact, green: C–Cl ($FeCl_4$) contact. (I) A view projected along the a-axis. (II) Projected along the c-axis. In both views, the phenyl groups on **DPP** and all the hydrogen atoms were omitted for clarity. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3.3. EPR study and intramolecular magnetic interaction of *VzDPP*$^{\bullet+} \cdot MCl_4^-$ (M = Fe and Ga)

VzDPP$^{\bullet+} \cdot MCl_4^-$ (M = Fe and Ga) showed very similar EPR spectra in a frozen butyronitrile matrix at 123 K. Fig. 3 shows the spectrum of **VzDPP**$^{\bullet+} \cdot GaCl_4^-$. The spectrum has a characteristic feature of randomly oriented triplet pattern with the zero field parameters of $|D/hc| = 0.0112$ cm^{-1} and $|E/hc| = 0.0013$ cm^{-1} from the spectrum simulation. The weak signal due to $\Delta m_s = \pm 2$ forbidden transition was also observed in the half field region. The intensity of the weak $\Delta m_s = \pm 2$ signal linearly increased to the reciprocal temperature, which indicates either a triplet ground state or a singlet ground state with a small S–T gap. A small signal observed in the center field is due to a doublet impurity.

VzDPP$^{\bullet+} \cdot FeCl_4^-$ has similar zero field parameters of $|D/hc| = 0.0112$ cm^{-1} and $|E/hc| = 0.0015$ cm^{-1}. The signal due to Fe(III) was not observed under the conditions.

It is interesting to note that these $|D/hc|$ values are considerably larger than the nitronyl nitroxide substituted **DPP**$^{\bullet+}$ ($|D/hc| = 0.00725$ cm^{-1} in frozen butyronitrile at 123 K [9]). The larger

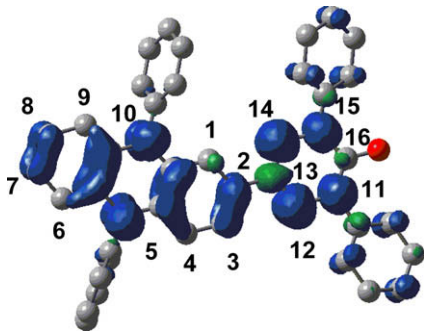

Fig. 2. Spin density map (blue: positive spin, green: negative spin) calculated at UB3LYP/6-31G* level and numbering of the atoms for **VzDPP**$^{\cdot+}$. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

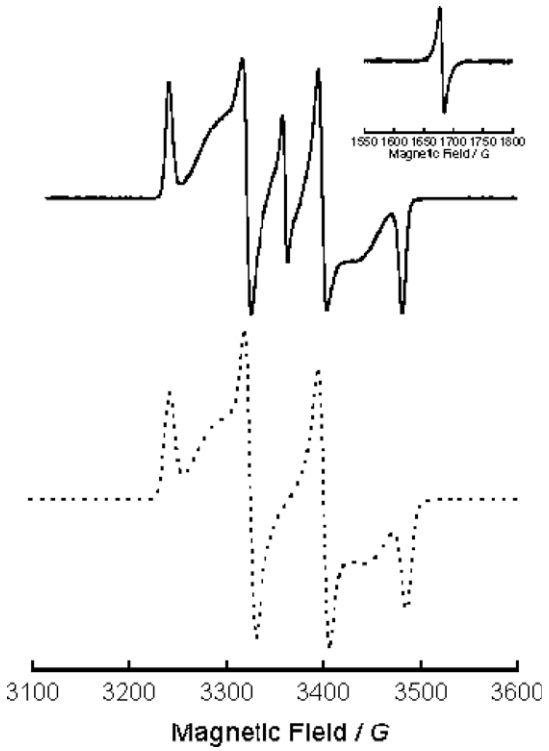

Fig. 3. EPR spectrum of **VzDPP**$^{\cdot+} \cdot GaCl_4^-$ in frozen butyronitrile matrix at 123 K (solid line: observed spectrum with $\nu_0 = 9.4277$ GHz, dotted line: simulation spectrum with parameters of $g_{xx} = 2.0034$, $g_{yy} = 2.0007$, $g_{zz} = 2.0032$, $|D/hc| = 0.0112\ cm^{-1}$, and $|E/hc| = 0.0013\ cm^{-1}$).

values for **VzDPP**$^{\cdot+} \cdot MCl_4^-$ are probably related to the higher delocalization nature of the spin densities in the verdazyl radicals (see also Fig. 2).

In order to obtain a theoretical insight into the intramolecular exchange interaction between **Vz**$^{\cdot}$ and **DPP**$^{\cdot+}$, DFT calculations were carried out using Gaussian 03 program (UB3LYP/6-31G*) [15]. The geometry of **VzDPP**$^{\cdot+}$ was taken from the X-ray structure analysis for the $GaCl_4^-$ salt. For the calculation of low-spin open-shell singlet state, the broken symmetry (BS) approach was employed [16]. The triplet state was more stable than the BS-singlet state by 0.512 kcal/mol. The exchange interaction after correction of the spin-contamination in both high- and low-spin states was estimated to be $J/k_B \sim +246$ K.

3.4. Magnetic properties of **VzDPP**$^{\cdot+} \cdot MCl_4^-$ (M = Fe and Ga)

The measurement of magnetic susceptibilities provides a clearer insight into the overall magnetic property including the intramolecular magnetic interaction between **Vz**$^{\cdot}$ and **DPP**$^{\cdot+}$. Fig. 4I shows $\chi_pT - T$ plots for **VzDPP**$^{\cdot+} \cdot GaCl_4^-$. The χ_pT values at room temperature is about 0.98 emu K mol^{-1} and almost constant in a temperature range of 200–300 K. This value is close to the theoretical value ($\chi_pT = 1.00$ emu K mol^{-1}) for the $S = 1$ state ($g = 2.0030$ from the powder EPR), indicating the intramolecular magnetic interaction between **Vz**$^{\cdot}$ and **DPP**$^{\cdot+}$ is strongly ferromagnetic ($J/k_B \geqslant +250$ K, $H = -2J\mathbf{S}_{Vz\cdot}\cdot\mathbf{S}_{DPP\cdot+}$) in accordance with the theoretical calculations for **VzDPP**$^{\cdot+}$ (*vide supra*) and the experimental result for the nitronyl nitroxide-substituted analoge [9]. The χ_pT value gradually decreased as the temperature was lowered. In the $GaCl_4$ salt, the intermolecular contacts between **VzDPP**$^{\cdot+}$ moiety and the chlorine atom ($GaCl_4^-$) would make minor contributions in the magnetic interactions because of the diamagnetic nature of Ga(III). Taking the crystal structure in consideration, the observed temperature change would be ascribed to the antiferromagnetic interaction within the $[(\mathbf{VzDPP}^{\cdot+})_2]_n$ ladder chain. The simulation based on a linear chain of $S = 1$ gave a poor result, which

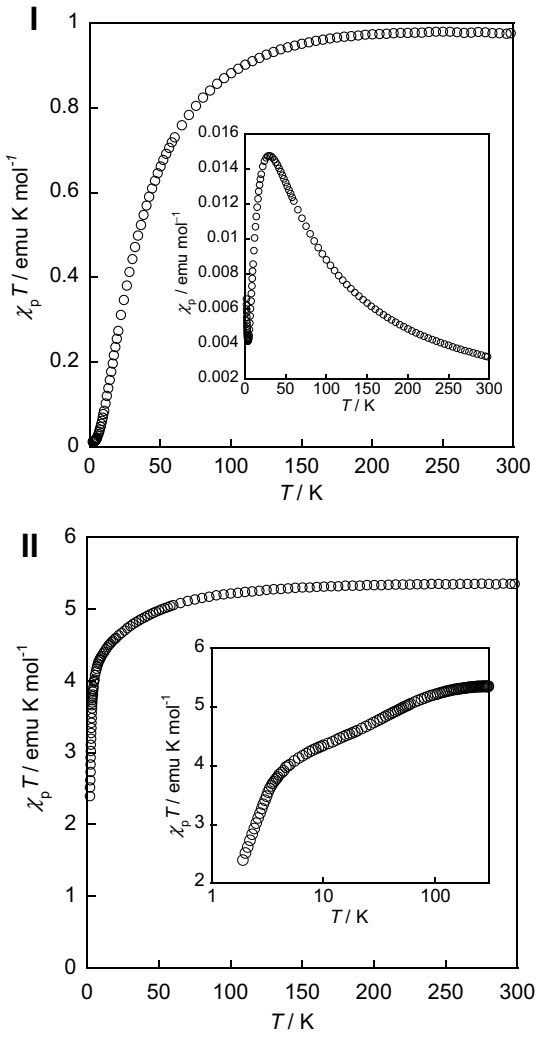

Fig. 4. Magnetic properties of **VzDPP**$^{\cdot+} \cdot MCl_4^-$ (M = Ga and Fe). (I) $\chi_pT - T$ plots for the Ga salt, inset: $\chi_p - T$ plots, (II) $\chi_pT - T$ plots for the Fe salt, inset: $\chi_pT - T$ (log scale) plots.

suggests the importance of the ladder type spin structure. The antiferromagnetic interaction was roughly estimated to be in the order of −30 K from the maximum temperature of χ_p.

The temperature dependence of χ_pT for **VzDPP**$^{\bullet+}\cdot FeCl_4^-$ is shown Fig. 4II. The χ_pT value at room temperature (χ_pT = 5.35 emu K mol^{-1}) is close to the theoretical summation of χ_pTs: 1.00 emu K mol^{-1} for **VzDPP**$^{\bullet+}$ (S = 1, g = 2.0030 from the powder EPR of **VzDPP**$^{\bullet+}\cdot GaCl_4^-$) plus 4.50 emu K mol^{-1} for Fe(III) (S = 5/2, g = 2.0288 from the powder EPR of **VzDPP**$^{\bullet+}\cdot FeCl_4^-$), indicating the presence of magnetically independent S = 1 (**VzDPP**$^{\bullet+}$) and S = 5/2 (Fe(III)) states at room temperature. χ_pT decreased and slowly approached an inflection point of ca. 4.5 emu K mol^{-1} by lowering the temperature (300 K → 10 K) and further decreased below 10 K. The value of 4.5 emu K mol^{-1} is close to that expected from only the S = 5/2 state. The decrease of χ_pT below 10 K may be attributed to the antiferromagnetic interaction between Fe(III) spins. The nearest intermolecular Fe–Fe distance is 9.14 Å. The through-space magnetic interaction with such a long distance seems to be almost impossible even at low temperature. Then, the antiferromagnetic interactions between Fe(III) spins would occur through the spin-vanishing ladder chain structures.

4. Conclusion

In order to develop a new molecular magnet based on the radical-substituted radical cation strategy, we prepared verdazyl-substituted dihydrophenazine radical cations, **VzDPP**$^{\bullet+}\cdot FeCl_4^-$ and **VzDPP**$^{\bullet+}\cdot GaCl_4^-$. The structure of **VzDPP**$^{\bullet+}$ was shown to have a large ferromagnetic interaction between **Vz**$^{\bullet}$ and **DPP**$^{\bullet+}$ ($J/k_B \sim$ ca. + 250 K). These salts had similar molecular and packing structures. Distinct features of the packing structures is (1) there are 2D type intermolecular contacts between the carbon atoms of **DPP**$^{\bullet+}$ and the chlorine atom of MCl_4^- moiety in the b–c^* plane, (2) **DPP**$^{\bullet+}$ moieties form a ladder chain structure, $[(\mathbf{VzDPP}^{\bullet+})_2]_n$ along the a^*-direction, thus the overall intermolecular contacts were shown to be in a 3D manner. The magnetic properties for these salts were clarified in the temperature range of 2–300 K. In both cases, χ_pT decreased as lowering of the temperature (300 K → 10 K), indicating an antiferromagnetic interaction. The antiferromagnetic interaction is assigned to be due to the ladder chain structure, $[(\mathbf{VzDPP}^{\bullet+})_2]_n$, and estimated to be ca. −30 K for the $GaCl_4^-$ salt. The same order of values is expected for the $FeCl_4^-$ salt from analogy of structures. For **VzDPP**$^{\bullet+}\cdot FeCl_4^-$, χ_pT decreased through the inflection point of ca. 4.5 emu K mol^{-1} around 10 K and further decreased below 10 K. No evidence of magnetic phase transition with long-range order was obtained.

Appendix A. Supplementary data

CCDC 707540 and 707541 contain the supplementary crystallographic data for $FeCl_4^-$ and $GaCl_4^-$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2008.11.002.

organization of zigzag chains in the crystal seems to be very important for the generation of the cooperative interaction network.

2. Results and discussion

Four types of calculations have been performed for the $[Fe(pyim)_2(bpy)](ClO_4)_2 \cdot 2C_2H_5OH$ system in both LS and HS states. Firstly, the calculations have been done using the X-ray defined structures (at 293 K for the HS, and at 173 K for the LS, respectively) [22]. The energy gap between two states $\Delta E = E_{HS} - E_{LS}$ has been found equal to 293 kJ/mol (per iron center). Although the calculations correctly predict the ground state, the energy gap is evidently too large, as for spin transition systems usually a value less than 100 kJ/mol is expected. Several reasons of such discrepancy can be suggested. Besides the deficiency of the method itself due to the choice of the exchange-correlation potential, several features of the experimentally studied system are neglected. In particular, the magnetic measurements show that some residual amount of the HS centers is present at 173 K. The calculations also neglect the disorder observed at both temperatures for the counter ion and solvent molecules, only the position with a maximal occupancy is used in calculations. The next step was to calculate just one polymeric chain with two counter ions and solvent molecules attached as it shown in Fig. 1, keeping interatomic distances found in the crystallographic experiment. This led to the energy gap equal to 172.3 kJ/mol demonstrating the effect of interchain interaction on this parameter essentially determining the transition temperature.

Two other calculations involved the total optimization of the crystal structure, or a partial optimization with parameters of the elementary cell fixed to their experimental values. The total optimization correctly reproduces the LS ground state with the energy gap ΔE equal to 79.3 kJ/mol. Although this value seems more reasonable than those given by single point calculations it remains still rather large. However, it has still to be corrected by the zero-energy-vibrations contribution, which diminishes the effective energy gap. The partial optimization with the elementary cell

Table 1
Comparison of some characteristic intrachain and intermolecular distances (in Å) for experimental and optimized structures.

	293 K (Exp)	HS full opt.	HS opt. fix. cell	173 K (Exp)	LS full opt.	LS opt. fix. cell

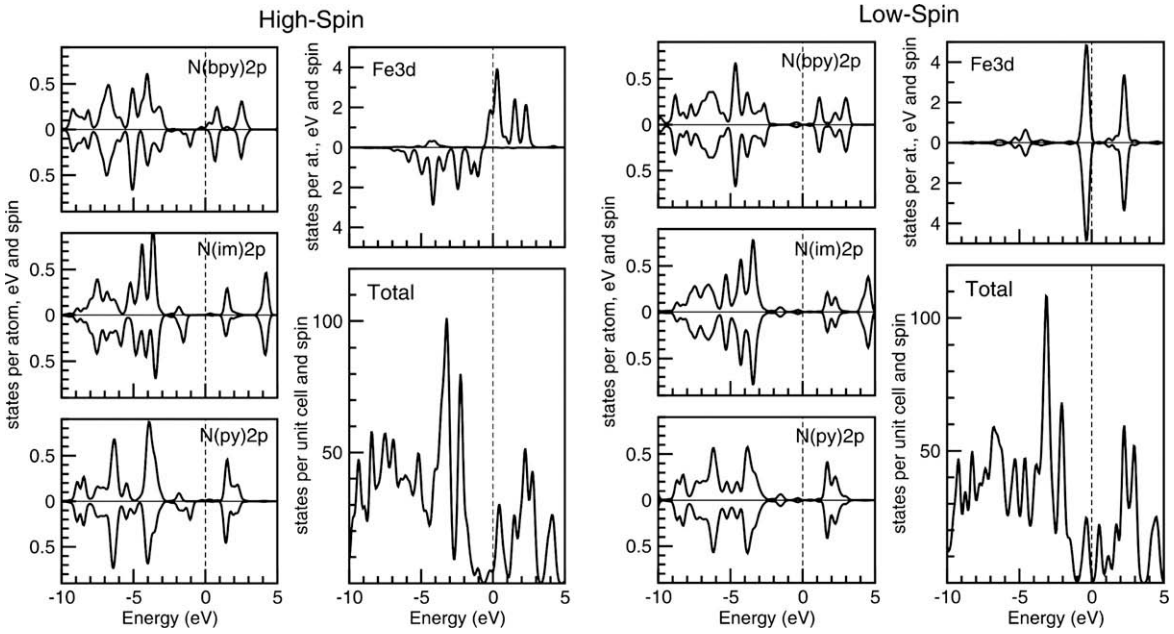

Fig. 2. Local (per Fe and N atoms) and total (per unit cell) DOS for the HS and LS states.

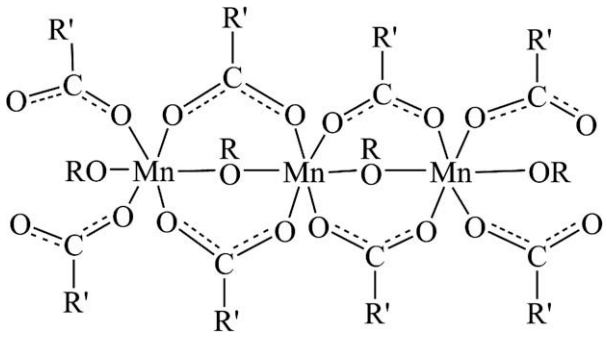
parameters fixed at their HS values results in ΔE equal to 155.2 kJ/mol. This value, intermediate between those obtained by the total optimization and by single chain calculations, shows the importance of lattice relaxation in the definition of the energy gap between two spin states. The total optimization leads to the geometry of the [FeN_6] coordination core close to the experimental one in both spin states (Table 1). The calculations reproduce the increase of metal–ligand bond lengths of about 0.2 Å in the HS state. However, the agreement for the intermolecular distances and elementary cell parameters is less satisfactory (Table 2). The calculations do not reproduce the increase of the *a* and *b* parameters upon the LS→HS transition and, consequently, the increase of the elementary cell volume. It is interesting to note the behavior of the calculated *c* parameter agrees with the X-ray data. As the polymer chains in the structure run parallel to *z*-axis, it means that the calculations correctly describe the structure along the chains, resulting in important errors in the description of the interchain space.

Fig. 2 shows partial and total densities of states (DOS) calculated for the structures with optimized chain parameters and fixed lattice vectors. In fact, the DOS for the fully optimized structures cannot be visually resolved from the present ones. The nominal electron configurations of the Fe ion can be easily read from the occupation of narrow bands, which can be identified as t_{2g} and e_g states. It is seen that the magnetization induced on nitrogen atoms of the first coordination sphere is not negligible; the hybridization of Fe3d–N2p states, very different in two spin channels, is especially well seen within 2 eV below the band gap. The structure of corresponding molecular orbitals will be discussed elsewhere.

3. Computational details

The periodic DFT calculations have been carried out using the SIESTA program [28] with only valence electrons described by basis sets of numerical localized atomic orbitals included in calculations. The generalized gradient approximation with the Perdew–Burke–Ernzerhof scheme [29] was employed for the exchange-correlation functional. Core electrons were replaced by norm-conserving pseudopotentials using the scalar-relativistic Troullier–Martins scheme [30] in the Kleinman-Bylander factorised form [31] with nonlinear core corrections. In the present work we used the molecular-dynamics technique with variable cell shape and coordinate optimization by conjugate gradients as provided within SIESTA.

4. Conclusions



In this paper we attempted to apply periodic quantum chemical DFT approaches for the description of spin crossover coordination polymers. The calculations included full geometry optimization for both spin states. We have found that computational methods are able to describe correctly the energetic order of spin multiplets and the intrachain geometry. It appears that the calculations can be used to predict polymer structures for the cases when the X-ray structures are not available. However, the possibilities of calculations are somehow limited to describe the interchain geometry. It may be due to the well-known shortcomings of DFT methods in application to weak intermolecular interactions. From this point of view, the search of new exchange-correlation functionals adapted for the description of the spin states energetics of transition metal complexes as well as weak intermolecular interactions seems highly desirable. Also, an interesting perspective can appear with calculations based on the constrained geometry optimization, when the interchain geometry is fixed. One can hope that some reliable results can be obtained even with existing functionals for a series of parent compounds. Studies of the whole family of zigzag chain spin crossover polymers [25] are currently underway.

Scheme 1. A portion of the chain structure of the $[Mn^{III}(OR)(O_2CR')_2]_n$ family of polymers.

$\{[Mn(OH)(O_2CMe)_2] \cdot 2MeCO_2H \cdot H_2O\}_n$ (**1**) was prepared as described elsewhere [9d].

Microanalyses (C, H, N) were performed by the in-house facilities of the Chemistry Department at the University of Florida. IR spectra (4000–450 cm^{-1}) were recorded on a Nicolet Nexus 670 spectrometer with samples prepared as KBr pellets. Variable-temperature dc and ac magnetic susceptibility data were collected at the University of Florida using a Quantum Design MPMS-XL SQUID susceptometer equipped with a 7 T magnet and operating in the 1.8–300 K range. Samples were embedded in solid eicosane to prevent torquing. Pascal's constants were used to estimate the diamagnetic corrections, which were subtracted from the experimental susceptibilities to give the molar paramagnetic susceptibilities (χ_M).

2.2. Compound preparation

2.2.1. $[Mn(OMe)(O_2CBu^t)_2]_n$ (**2**)

Compound **2** was synthesized following the same procedure as **1**, except that a solvent mixture of MeOH/Bu^tCO_2H was used in

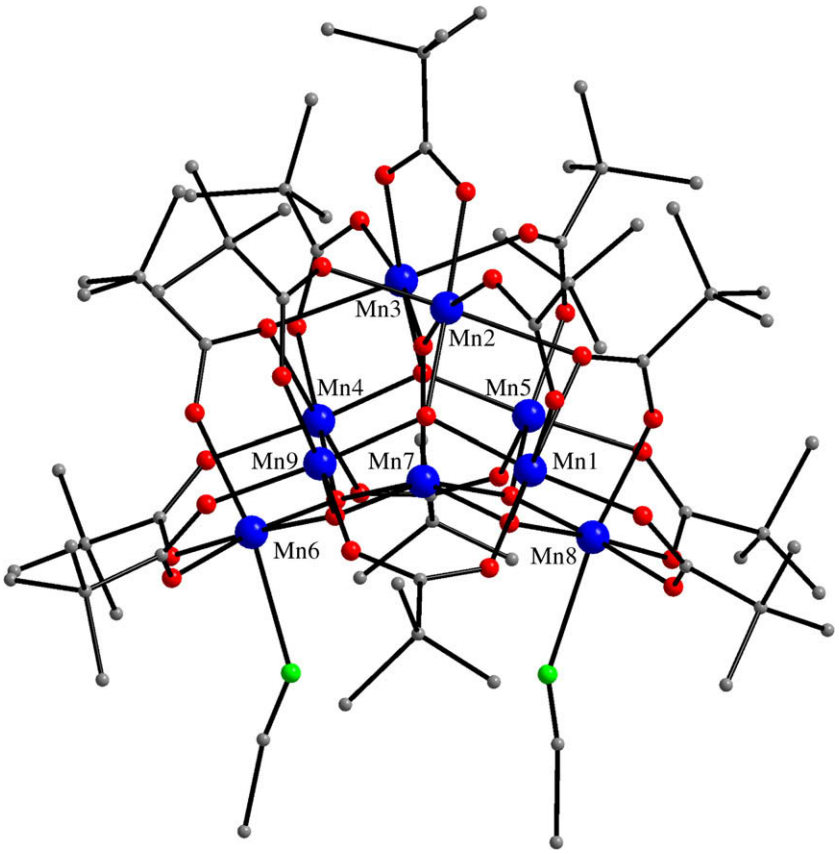

Fig. 1. Partially labeled PovRay representation of the structure of **3**, with the hydrogen atoms omitted for clarity. Color code: Mn^{III} blue, O red, N green, C grey. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

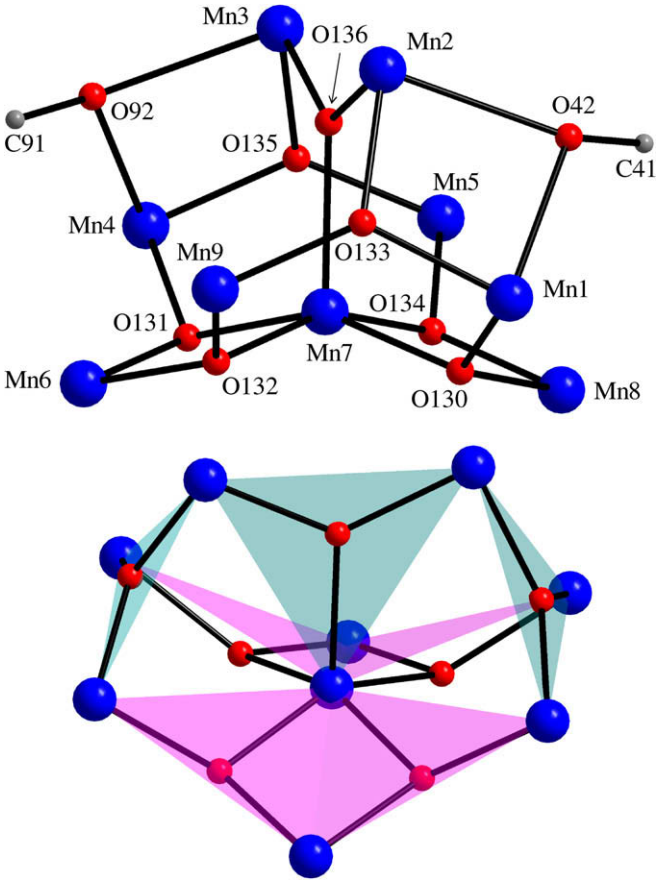

Fig. 2. (Top) PovRay representation of the labeled core of **3**; (bottom) The Mn_9 topology, emphasizing the butterfly $[Mn_4(\mu_3\text{-}O)_2]^{8+}$ and triangular $[Mn_3(\mu_3\text{-}O)]^{7+}$ subcores. Color code: Mn^{III} blue, O red, C grey.

place of H_2O/$MeCO_2H$. The identity of **2** was established by means of IR spectroscopic comparison with authentic material of **1**, and elemental analysis (C, H, N). Yield: 70 % (based on Mn). The dried sample analyzed as solvent-free. *Anal.* Calc. for $C_{11}H_{21}O_5Mn$: C, 45.84; H, 7.34; N, 0.00. Found: C, 45.84; H, 7.42; N, 0.01%. Selected IR data (KBr pellet, cm^{-1}): 2974s, 1705w, 1576s, 1549s, 1482s, 1406s, 1358s, 1226s, 1003m, 939w, 896w, 785w, 630s, 553s, 459m.

2.2.2. $[Mn_9O_7(O_2CBu^t)_{13}(MeCN)_2]$ · toluene (**3** · toluene)

Freshly prepared solid complex **2** (0.20 g, 0.70 mmol) was added to a solution composed of MeCN (25 mL) and toluene (15 mL). The resulting reddish-brown slurry was stirred overnight, during which time most of the solid dissolved, and the color of the solution changed to dark brown. A small quantity of undissolved material was removed by filtration, and the filtrate was allowed to stand undisturbed at room temperature. After 24 h, X-ray quality dark brown crystals of **3** · toluene were collected by filtration, washed with Et_2O (2×5 ml), and dried under vacuum. Yield: 60% (based on Mn). Material that had been dried under vacuum for 10–12 h and then stored in air was found to have lost the bound MeCN groups, which were replaced with H_2O molecules; thus, vacuum-dried solid analyzed as $[Mn_9O_7(O_2CBu^t)_{13}(H_2O)_2]$. *Anal.* Calc. for $C_{52}H_{121}O_{35}Mn_9$: C, 39.89; H, 6.23; N, 0.00. Found: C, 40.28; H, 6.08; N, 0.02%. IR (KBr pellet, cm^{-1}): 3853w, 3748w, 3433mb, 2969s, 2921s, 2355m, 1637m, 1558s, 1487s, 1421s, 1370s, 1229s, 1164m, 1114m, 1067mb, 903w, 788w, 692m, 625m.

[a] The underlined value is the one closest to the charge for which it was calculated. The oxidation state of a particular atom can be taken as the nearest whole number to the underlined value.

2.2.3. $[Mn_{10-x}Fe_x(OMe)_{20}(O_2CMe)_{10}]$ (**4**)

To a slurry of freshly prepared complex **1** (0.50 g, 2.00 mmol) in MeCN (25 mL)/MeOH (1 mL) was added solid $Fe(NO_3)_3 \cdot 9H_2O$ (0.10 g, 0.25 mmol). The resulting reddish-brown slurry was stirred overnight, during which time most of the solid dissolved and the color of the solution changed to dark brown. A small quantity of undissolved material was removed by filtration, and the filtrate was allowed to stand undisturbed at room temperature. After several days, only a handful of dark brown prismatic crystals of **4** had appeared, and these were devoted solely to single-crystal X-ray diffraction studies.

2.3. Single-crystal X-ray crystallography

Data for complexes **3** · toluene and **4** were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing MoKα radiation (λ = 0.71073 Å). Cell parameters were refined using up to 8192 reflections. A full sphere of data (1850 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was <1%). Absorption corrections by integration were applied based on measured indexed crystal faces. The structures were solved by direct methods in SHELXTL6 [10], and refined on F^2 using full-matrix least squares. The non-H atoms were treated anisotropically, whereas the H atoms were placed in ideal positions and refined as riding on their C atoms. Unit cell parameters and structure solution and refinement data are listed in Table 1.

For **3** · toluene, the asymmetric unit contains one Mn_9 cluster and one toluene molecule of crystallization. There are five disordered Bu^t groups, and each was refined in two parts with their site occupation factors dependently refined. A total of 1071 parameters were refined in the final cycle of refinement using 9621 reflections with $I > 2\sigma(I)$ to yield R_1 and wR_2 of 4.84 and 9.64%, respectively.

For **4**, the asymmetric unit consists of one and a half M_{10} ring located on an inversion center. All metal positions are disordered between Fe and Mn. Each position of the metal on the ring was refined with one Fe and one Mn with their site occupation factors dependently refined in the early refinement stages. All of the site occupation free variables refined to 50%, and thus they were all fixed at 50%. Each position of Fe/Mn metal atoms was constrained to maintain equivalent coordinates and displacement parameters. There are also several disordered methoxy groups where the methyl group was refined in two parts. Several electron density peaks of 2.5 electrons or less were observed around the rings and did not make chemical sense. Most likely, those are a result of ring disorder in the plane of the wheel. A total of 1266 parameters were refined in the final cycle of refinement using 13 806 reflections with $I > 2\sigma(I)$ to yield R_1 and wR_2 of 5.89 and 14.67%, respectively.

3. Results and discussion

3.1. Syntheses

Slow dissolution with stirring of $[Mn(OMe)(O_2CBu^t)_2]_n$ (**2**) in MeCN/toluene gave a dark brown solution from which was obtained $[Mn_9O_7(O_2CBu^t)_{13}(MeCN)_2]$ (**3**) as **3** · toluene in good yields (~60%). The reaction is clearly a hydrolysis involving adventitious water, causing an undoubtedly complicated structural rearrange-

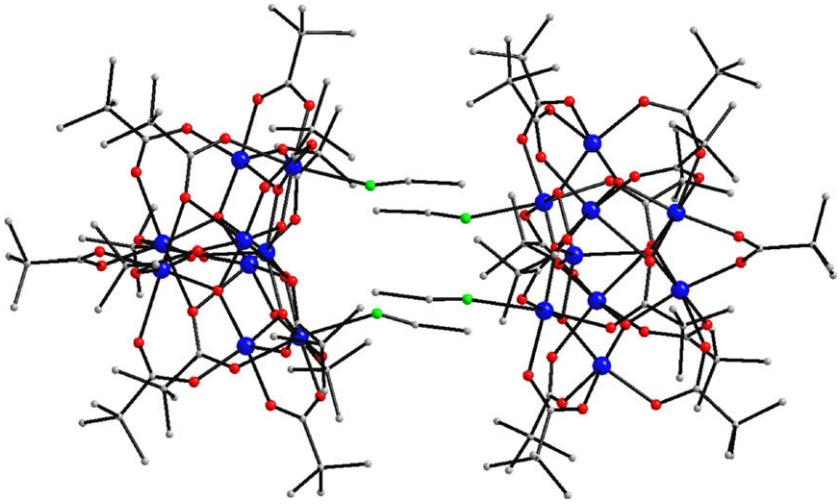

Fig. 3. PovRay representation of a pair of Mn_9 cages. Color code: Mn^{III} blue, O red, N green, C grey.

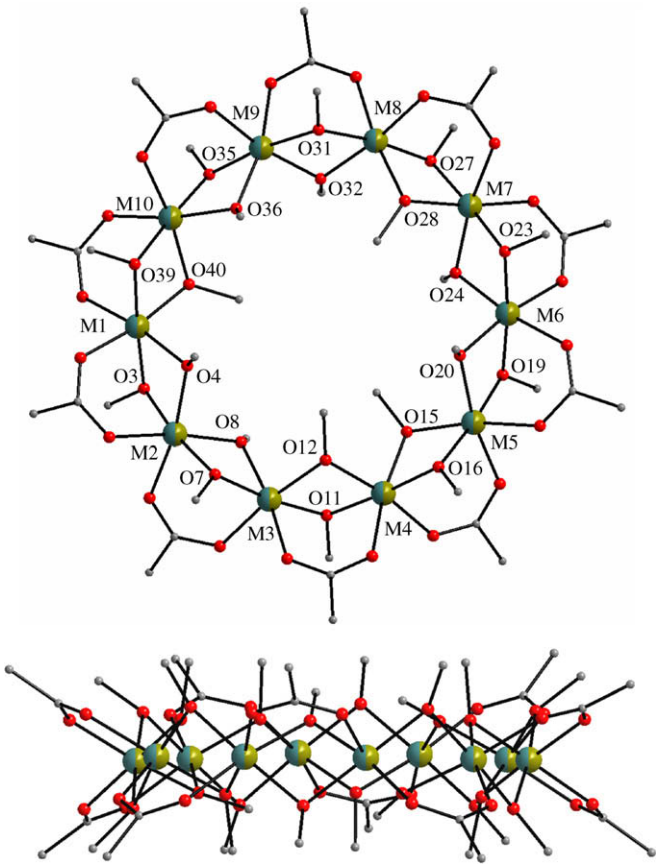

Fig. 4. (Top) Labeled PovRay representation of the structure of **4**, with the hydrogen atoms omitted for clarity; (bottom) side-view emphasizing the wheel planarity and O/M/O layered structure. Color code: M (Mn/Fe) blue/green, O red, C grey.

ment but no redox changes since the product contains only Mn^{III} atoms like the starting material **2**. The MeCN is essential for a high-yield transformation; reactions in neat toluene gave only a very low yield (~10%) of a product whose IR spectrum is almost identical with that of **3** and is assumed to be the form with two bound water molecules instead of MeCN. Changes to the exact MeCN:toluene ratio had no effect on the identity of the product, only small changes to the yield. With the identity of **3** established, we also tried similar reactions with $[Mn(OH)(O_2CMe)_2]_n$ (**1**) and, on the basis of IR spectroscopy and elemental analysis data, concluded that the product was the acetate version of **3** and thus did not study this product further. The reaction of **2** in MeCN/MeOH under various conditions yielded the known Mn_{84} complex [11], and/or non-crystalline materials difficult to characterize.

We have in the past used complex **1** as the starting material for the preparation of the heterometallic compound $[CeMn_8O_8(O_2CMe)_{12}(H_2O)_4]$ [12], and so we now also investigated the use of **1** and **2** in reactions with another 3d metal, namely iron. Thus, the reaction of **1** with $Fe(NO_3)_3 \cdot 9H_2O$ in a 8:1 ratio in MeCN/MeOH was explored. It was difficult to isolate pure products from this reaction system, and finally obtained some dark brown crystals in extremely low yields of what proved to be the decanuclear mixed-metal complex $[Mn_{10-x}Fe_x(OMe)_{20}(O_2CMe)_{10}]$ ($x < 10$) (**4**). The color of the crystalline material **4** clearly precludes assignment of all the metal ions as Fe^{III} ($x \neq 10$) since $[Fe_{10}(OMe)_{20}(O_2CMe)_{10}]$ is a known compound that has a light yellow color. On the other hand, it was also clear that this was not the completely Mn^{III} version $[Mn_{10}(OMe)_{20}(O_2CMe)_{10}]$ ($x \neq 0$). The product thus had to be mixed-metal, but the relative metal content was not possible to be accurately obtained from the refinement of the crystal structure

(vide infra). Reasons such as the similar Mn and Fe electronic densities and the complicated overall structure of **4** with a relatively large molecular weight preclude safe conclusions about the exact identity of the metal ions present. Unfortunately, not enough crystals were obtained to allow a metal analysis, and we were unable to increase the yield by varying the solvent ratio. With the identity of **4** established, we also tried to obtain the homometallic $[Mn_{10}(OMe)_{20}(O_2CMe)_{10}]$ wheel, but were unsuccessful. Reactions of **1** in pure MeOH, for example, gave only uncharacterized Mn^{II} products.

3.2. Description of structures

The molecular structure and the core of complex **3** are depicted in Figs. 1 and 2, respectively. Selected interatomic distances and angles are listed in Table 2. Complex **3** contains a $[Mn_9O_7]^{13+}$ core that can be described as two fused $[Mn_4O_2]$ butterflies (Mn1, Mn5, Mn7, Mn8, and Mn4, Mn6, Mn7, Mn9) sharing one Mn atom (Mn7). The remaining two Mn ions (Mn2 and Mn3) are connected to the fused butterfly unit through an O^{2-} ion (O136) forming a $[Mn_3O]$ triangle with Mn7. The $[Mn_3O_4]$ base of this unit (Mn6, Mn7 and Mn8) is non-planar, the Mn6–Mn7–Mn8 angle being ~145°. The metal ions are all Mn^{III}, as deduced by consideration of structural parameters and by bond valence sum (BVS) calculations (Table 3) [13]. Atoms Mn5, Mn7, and Mn9 are five-coordinate with distorted square pyramidal geometry (τ = 0.28, 0.09, and 0.35, where τ is 0 and 1 for ideal square pyramidal and trigonal bipyramidal geometries, respectively [14]), and their axial bonds [2.052(4)–2.173(3)] are significantly longer than the basal ones [1.855(3)–1.935(3)]. The remaining Mn atoms are all six-coordinate with distorted octahedral geometries, and display Jahn–Teller axial elongations. Eleven $Bu^tCO_2^-$ groups bind in the common μ-bridging mode and two in the rarer μ_3-mode, with one O atom bridging two metals. The two MeCN molecules are terminally bound to Mn6 and Mn8.

Complex **3** · toluene crystallizes in pairs, as shown in Fig. 3, in a head-to-head arrangement with the MeCN ligands interlocked and the two molecules rotated by ~90° with respect to each other to give an S_4 symmetry dimer. Compounds with a similar core to that in **3** have been previously reported [15], some containing Na^+ or K^+ ions, namely $[Mn_9Na_2O_7(O_2CPh)_{15}(MeCN)_2]$ [15c] and $[Mn_9K_2O_7(O_2CBu^t)_{15}(HO_2CBu^t)_2]$ clusters [15d], respectively; **3** is the third structurally characterized Mn_9 complex with the general formula $[Mn_9O_7(O_2CR)_{13}(L)_2]$ (R = Ph, L = terminal ligands, such as pyridine or 2,4-dimethyl-6-hydroxypyrimidine) [15a,8a].

The structure of complex **4** is shown in Fig. 4. Selected interatomic distances and angles are listed in Table 4. The structure is essentially identical to previously characterized Fe_{10} 'ferric wheels' [16] except that it is clearly a mixed-metal species. Several refinement cycles of the Mn/Fe content led to the conclusion that the compound contains both metals statically disordered about all 10 sites; thus, a general Mn_{10-x}–Fe_x (x < 10) metal content description was clearly the best fit to the observed electron density. The complex has virtual D_{5d} symmetry and comprises a near-planar (±0.003–0.040 Å) wheel of 10 octahedral metal atoms with each M_2 pair bridged by one $MeCO_2^-$ and two MeO^- groups, giving layers of O atoms above and below the M_{10} wheel (Fig. 4, bottom). The wheel has a central hole of ~3 Å diameter unoccupied by any guest molecule. The M_{10} molecules pack in the crystal on top of each other forming supramolecular nanotubular stacks parallel to the a axis, but with each molecule slightly tilted relative to this axis.

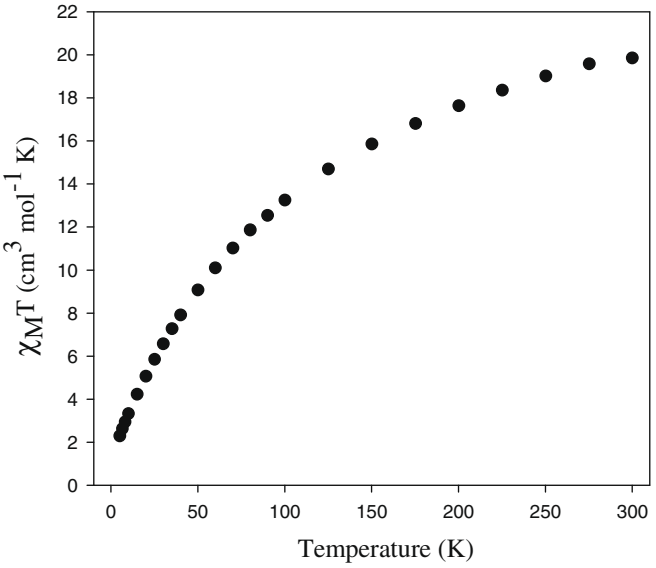

Fig. 5. $\chi_M T$ vs. T plot for complex **3**.

3.3. Magnetochemistry

Variable-temperature dc magnetic susceptibility data were collected on a powdered polycrystalline sample of **3**, restrained in eicosane, in a 1 kG (0.1 T) field and in the 5.0–300 K range. $\chi_M T$ for **3** steadily decreases from 19.86 cm^3 $Kmol^{-1}$ at 300 K to 2.29 cm^3 $Kmol^{-1}$ at 5.00 K (Fig. 5). The rate of decrease increases below ~50 K. The room temperature $\chi_M T$ value is much less than the spin-only value (g = 2.0) of 27 cm^3 $Kmol^{-1}$ for nine non-interacting Mn^{III} ions, indicating predominantly strong antiferromagnetic interactions within the molecule and a low, but possibly non-zero, ground state S value. To determine the ground state of the complex, magnetization data were collected in the magnetic field and temperature ranges 1–60 kG and 1.8–10.0 K. However, we could not get an acceptable fit using data collected over the whole field range, which is a common problem caused by low-lying excited states, especially if some have an S value greater than that of the ground state. A common solution is to only use data col-

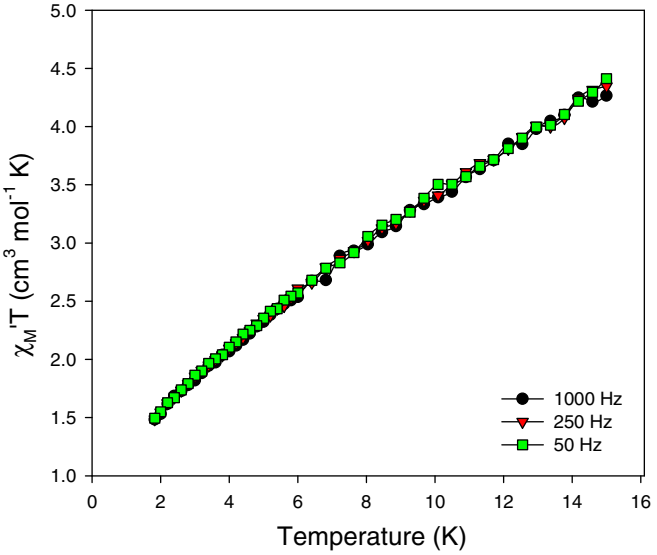

Fig. 6. Plot of the in-phase (χ'_M) ac magnetic susceptibility, as $\chi'_M T$ vs. T, in a 3.5 Oe field oscillating at the indicated frequencies for complex **3**.

lected with low fields ($\leqslant$1.0 T) [5a,5b]. However, it was still not possible to obtain a satisfactory fit assuming that only the ground state is populated in this temperature range. This suggests that the complex possesses particularly low-lying excited states that are populated, even at these relatively low temperatures.

Thus, we turned to ac susceptibility measurements in a 3.5 G ac field oscillating at frequencies in the 50–1000 Hz range. The in-phase $\chi'_M T$ vs. T data are shown in Fig. 6 and reveal several pertinent features: (i) $\chi'_M T$ for **3** decreases linearly with decreasing temperature in the whole temperature range, indicating depopulation of a high-density of low-lying excited states with spin S greater than that of the ground state, in agreement with the conclusion from the dc studies; (ii) extrapolation of the $\chi'_M T$ data to 0 K gives a value of $\sim$1 $cm^3\,Kmol^{-1}$ for **3**, indicative of an $S = 1$ ground state with $g \sim 2$. It does appear that the complex does indeed have a non-zero ground state spin, although it could be possible that there are extremely close $S = 0$, 1 and even 2 states. In any event, complex **3** clearly has a very small ground state spin. As expected, there were no out-of-phase ac signals down to 1.8 K.

4. Conclusions

The use of the carboxylate-bridged Mn^{III} polymeric compound of general formula $[Mn(OR)(O_2CR')_2]_n$ (R = H, Me; R′ = Me, Bu^t) has provided access to two new homo- and heterometallic Mn^{III}-based clusters. The homometallic Mn_9 complex **3** has a rare metal core topology, comprising adjacent $[Mn_4O_2]$ butterfly and $[Mn_3O]$ triangular subunits. The heterometallic M_{10} (M = Mn/Fe) wheel complex **4** is analogous to the known family of Fe_{10} ferric wheels, and clearly contains both Mn and Fe with a varying Mn:Fe ratio. Unfortunately, we have yet to develop a high-yield route to such mixed Mn/Fe wheels to allow us to study this point further, as well as to characterize the magnetic properties, and attempts along this direction are continuing.

2. Computational details

The theoretical study of the magnetism of the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal was performed using the First-Principles *Bottom–Up* methodology [3], which consists in the sequential application of the following four steps:

(1) Analysis of the crystal packing to locate all unique radical–radical pairs:

This analysis was done looking at the distances between spin-carrying units. The only spin-carrying units in the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal are the $CuBr_4^{2-}$ anions. All pairs of radicals having a Cu···Cu distance shorter than 10.0 Å were considered as possible candidates. Among them, only those different by symmetry were selected as the candidate pairs for the next steps.

(2) Computation of the exchange magnetic interaction (J_{AB}) for each unique radical pairs:

The J_{AB} values are obtained from the energy difference between the appropriate states computed by First-Principles methods (either ab initio [4] or DFT [5] methods). The spin-carrying units, the $CuBr_4^{2-}$ anions, are doublet radicals (the spin density is not only located on the Cu(II) atoms, which have an unpaired electron, but also on the Br atoms [6]). Therefore, only two states are possible in any AB radical pairs: one singlet and one triplet state. The value of J_{AB} for each pair is obtained as $J_{AB} = (E^S_{BS} - E_T)$, where E^T is the energy of the triplet state and E^S_{BS} the energy of the singlet state computed using the broken-symmetry approach [7,8] for a proper description of the open-shell singlet state. The values of E^S_{BS} and E^T are calculated using a neutral model which consists of two $CuBr_4^{2-}$ anions and four $(2,3\text{-dmpyH})^+$ counterions, hereafter referred as the anion$_2$cation$_4$ model. The nearest four $(2,3\text{-dmpyH})^+$ counterions to each radical pair are thus included to model the most relevant effects that the electrostatic field induces on the radical pair wavefunctions (previous studies [3] have shown that the J_{AB} computed using this model is nearly identical to that obtained using much larger subsets of point charges). The geometry of these anion$_2$cation$_4$ models is that found in the crystal for the full molecules, without geometry optimization. The previous J_{AB} expression derives from the original broken-symmetry equations when the SOMO orbitals of the two radicals show a very small overlap, which is the usual situation in through-space magnetic interactions, such as those found in the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal. Our experience indicates that in through-space magnetic interactions this expression gives results closer to the experimental values than alternative ones [9,10] where projection is used. The following form of Heisenberg Hamiltonian was used:

$$\hat{H} = -2\sum_{A,B} J_{AB}\hat{S}_A \cdot \hat{S}_B \qquad (1)$$

The E^T and E^S_{BS} energies were computed using the B3LYP functional [11,12], as it has been shown to provide J_{AB} values close to the experimental results [3,13–15]. The Ahlrich-pVDZ [16] basis set for Cu, and a 6-31+G(d) [17] basis set for the remaining atoms were used. All calculations were done using the GAUSSIAN 03 code [18].

(3) Determination of the magnetic topology of the crystal and its minimal magnetic model space:

Once the J_{AB} values are known for all unique radical pairs, one can define the magnetic topology as the network of non-negligible magnetic interactions present among the radicals of the crystal. Then, one has to look for an appropriate minimal magnetic model space, a finite set of radical centers where all J_{AB} interactions are present in a ratio as close as possible to that found in the infinite

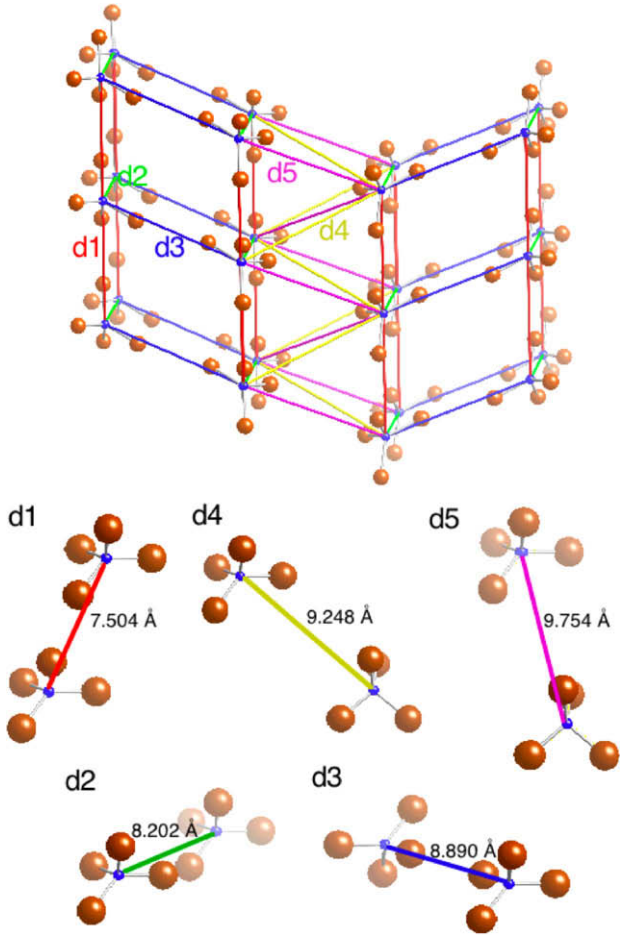

Fig. 1. Geometry of all unique $CuBr_4^{2-}$···$CuBr_4^{2-}$ radical pairs found in the 88 K crystal (only the anions are shown for an easier visualization of the crystal packing). The Cu···Cu distance (in Å) is also given for each pair. The unique pairs found in the 273 K structure are the same, although the Cu···Cu distances vary slightly (see Table 4).

crystal. When the minimal model space is extended along the three crystallographic axes it must reproduce the topology of the infinite crystal. The minimal model space will be used to compute the matrix representation of the Heisenberg Hamiltonian in Step 4 [3].

4) Calculation of the macroscopic magnetic properties of the crystal:

Once an appropriate minimal magnetic space has been found for the crystal, one can compute the matrix representation of the Heisenberg Hamiltonian Eq. (1), and then the full energy spectrum of the selected minimal magnetic model space by diagonalization of that matrix representation. For efficiency of the computer code, rather than using the Hamiltonian Eq. (1) we used the Hamiltonian:

$$\hat{H} = -2\sum_{A,B} J_{AB}\left(\hat{S}_A \cdot \hat{S}_B + \frac{1}{4}\hat{I}_{AB}\right) \qquad (2)$$

where $\hat{I}_{AB}$ is the identity operator, and $\hat{S}_A$ and $\hat{S}_B$ are the spin operators acting on radical A and B. The energy spectrum computed using the Hamiltonian in Eq. (2) presents the same differences between consecutive states than those obtained using the Hamiltonian of Eq. (1). As the macroscopic magnetic properties only depend on the energy differences between states, when using the same J_{AB} exchange values, the macroscopic properties predicted by the two Hamiltonians are the same. Since the size of the matrix representation the size of the matrix representation of the Heisenberg Hamiltonian increases with the number of doublet radical (N) centers as $N!/[(N/2)!(N/2)!]$, in practice the full diagonalization can reach up to 16 different doublet centers.

The rigorous computation of the macroscopic magnetic properties is done using the adequate Statistical Mechanics expressions [3]. When the proper minimal magnetic model space is selected, the macroscopic properties should converge as the size of the

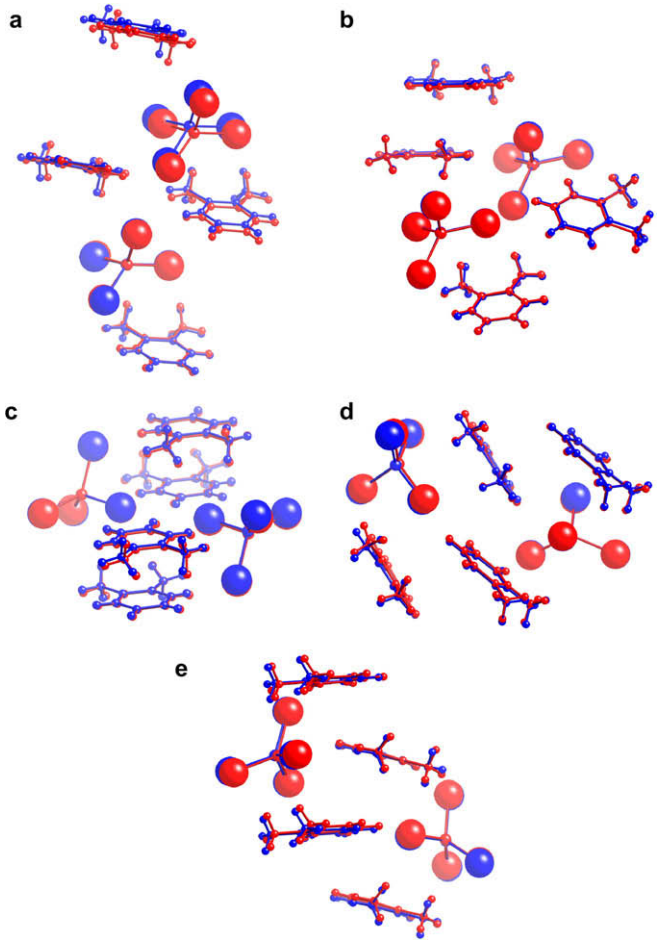

Fig. 2. Geometry of the anion$_2$cation$_4$ models employed to compute the $J(di)$ exchange interactions, for all unique pairs found in the 88 and 273 K structures of the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal (red corresponds to the 88 K structure, and blue to the 273 K structure). The pairs are identified as follows: (a) *d1*, (b) *d2*, (c) *d3*, (d) *d4* and (e) *d5*. The geometry of the pairs for the 88 K crystal are overlapped on top of the pairs for the 273 K crystal. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

minimal magnetic model space is increased, and the converged value is very close to the experimental value of the property.

The First-Principles *Bottom–Up* procedure is general and unbiased (no previous assumptions are required, as it only requires the knowledge of the crystal structure). The results obtained when using this procedure reproduce very well the available experimental data in all cases studied to date [19–25]. It is also a very powerful analytical tool, as it allows one to connect the macroscopic magnetic properties with the microscopic magnetic interactions. We also would like to mention that the First-Principles *Bottom–Up* methodology is an improvement in comparison to the usual theoretical studies of molecule-based magnets, which usually perform only the first two steps of the First-Principles *Bottom–Up* procedure.

3. Results and discussion

The 88 K crystal structure of $[(2,3\text{-dmpyH})_2CuBr_4]$ has been previously reported (see Fig. 1) [2]. The structure determined at 273 K is reported in Table 1 [1]. At both temperatures, the crystal packs in the *P2(1)/n* space group. Furthermore, experimental observation showed no evidence of a first-order crystallographic phase transition while lowering the temperature from 273 to 120 K (we are also confident that there is no change from 120 to 88 K, based on the small changes in the crystallographic parameters between these two structures). This is further demonstrated by looking at the data in Table 2, which presents the crystallographic parameters for 88, 120 and 273 K. The lattice parameters (*a, b, c* and β) show small changes between the 88 and 273 K structures while negligible changes are seen between 88 and 120 K, completely consistent with the expected thermal expansion. All unit cell axes increase their values as the temperature increases, but the change in the *b* parameter is more than twice that for the *a* and *c* parameters, whose variation is very similar.

The changes in the cell parameters do not significantly affect the intramolecular geometry of the $CuBr_4^{2-}$ radicals (these are the only spin-carrying units in these crystals). As shown in Table 4, the differences in bond lengths is less than 1%, and that in bond angles is generally smaller than 1°. The anisotropic thermal expansion of the cell parameters predominantly affects the intermolecular distance (changes up to 0.14 Å, see Table 3) and relative orientation of the molecules in the crystal, particularly the $CuBr_4^{2-}$ radicals. These changes modify the magnetic properties of the 273 K crystal relative to the 88 K crystal, as we demonstrate hereafter by doing the First-Principles *Bottom–Up* study of the 273 K structure, and comparing these results with those already published for the 88 K structure [2].

In the first step of the First-Principles *Bottom–Up* study of the 88 K crystal [2], it was concluded that only five unique $CuBr_4^{2-}\cdots CuBr_4^{2-}$ radical pairs could be magnetically relevant in this structure (hereafter identified as the *d1–d5* pairs). Only the $CuBr_4^{2-}\cdots CuBr_4^{2-}$ radical pairs were searched because they are the only spin-carrying units. A view of these radical pairs and also of their position within the crystal is shown in Fig. 1, while Table 4 collects its two most significant intermolecular distances. It is worth pointing that the five unique pairs selected in step 1 for the 273 K crystal are the same found in the 88 K crystal. Furthermore, their geometrical arrangement is similar (see Fig. 2, where the geometry of these pairs and their nearest four counterions is overlapped). However, as shown in Table 4, the intermolecular Cu···Cu and Br···Br distances between the two crystals change in a non-isotropic pattern: as the temperature is raised the intermolecular distances within all radical pairs increase, although the variation is different from pair to pair.

Only two of the five pairs found in the 88 K structure presented non-negligible $J_{AB}(di)$ values: *d1* and *d3* (this calculation is the second step of the First-Principles *Bottom–Up* study of the 88 K crystal). The situation is different for the 273 K crystal. The

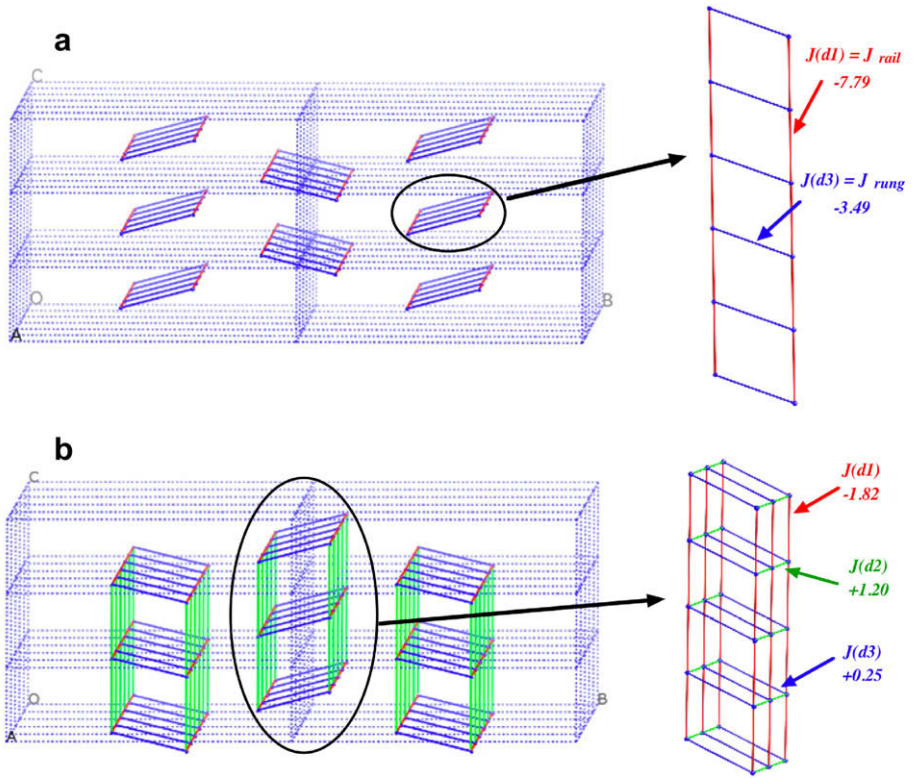

Fig. 3. Magnetic topology for the 88 K (a) and 273 K (b) structures of the $[(2,3\text{dmpyH})_2CuBr_4]$ crystal. Each spin-carrying unit has been replaced by a point site for a better visualization of the magnetic topology. The $J(di)$ values are given in wavenumber units.

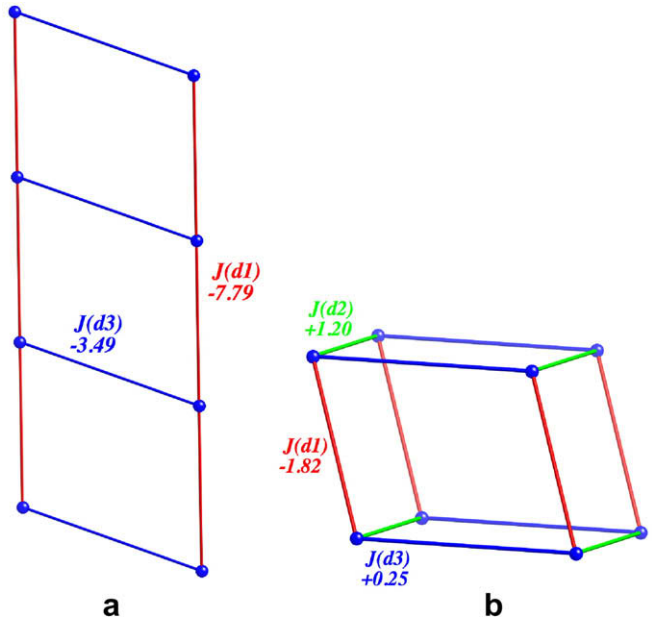

Fig. 4. Minimal magnetic model space for the (a) 88 K (8s) and (b) 273 K (4s–4s) structures of the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal.

non-isotropic thermal expansion of the crystal induces important changes when one compares the $J_{AB}(di)$ results computed on the 273 and 88 K crystals (see Table 4): (a) while only two non-negligible interactions are present in the 88 K structure, there are three non-negligible interactions in the 273 K structure ($J(d4) = 0.04\ cm^{-1}$ and $J(d5) = 0.06\ cm^{-1}$ are so small that, as will be shown below, they do not affect the computed macroscopic magnetic susceptibility curve), (b) $J_{AB}(d3)$ pair interaction changes from antiferromagnetic to ferromagnetic, and (c) the relative strength of the other $J_{AB}(di)$ pair interactions also changes.

One can now compare the magnetic topology for the 88 and 273 K structures of the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal (step 3 of the First-Principles *Bottom–Up* procedure). As shown in Fig. 3, the modifications in the $J(di)$ values give rise to a change in the magnetic topology of these crystals. At 88 K the magnetic topology is a strong-rail two-leg spin ladder ($J_{rail} = J(d1) = -7.79\ cm^{-1}$ and $J_{rung} = J(d3) = -3.49\ cm^{-1}$). At 273 K the magnetic topology can be described as planes of non-interacting bilayers, where the dominant $J(d1) = -1.82\ cm^{-1}$ and $J(d2) = +1.20\ cm^{-1}$ form a two alternating (antiferromagnetic and ferromagnetic) *ac*-planes connected by $J(d3) = -0.25\ cm^{-1}$. Only the 88 K magnetic topology is consistent with the experimental two-leg spin-ladder properties observed in the $[(2,3\text{-dmpyH})_2CuBr_4]$ crystal.

Using these two topologies one can compute the macroscopic magnetic properties for the 88 and 273 K structures (step 4 of the First-Principles *Bottom–Up* procedure). First, one has to select the proper minimal magnetic model space for both topologies. It is needed to compute the matrix representation of the Heisenberg Hamiltonian Eq. (2) and its energy spectrum. The minimal magnetic model for the two-leg spin ladder topology (88 K structure) is the 8s model shown in Fig. 4a, while for the isolated bilayer topology it is the 4s–4s model shown in Fig. 4b. Fig. 5 shows two commonly used representations of the magnetic susceptibility curve, $\chi(T)$ and $\chi T(T)$ computed using these models. The curves for the 88 and 273 K structures are very different. Only these computed using the 88 K structure reproduce the shape of the experimental curves at low temperatures. Notice also at high temperature the 88 and 273 K curves predict similar paramagnetic properties. This clearly demonstrates the importance of using the proper crystal structures in the analysis of the magnetic properties of molecule-based magnetic crystals.

Test calculations were also done on the 273 K structure using larger magnetic models. First, the effect of extending the

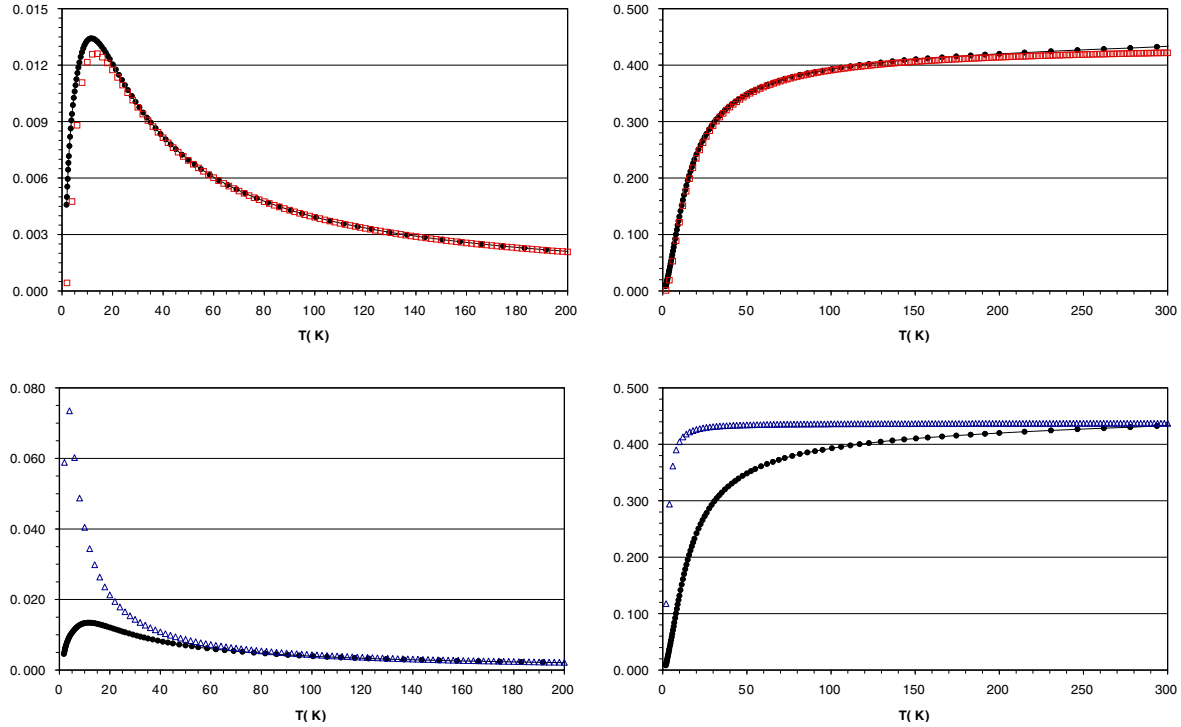

Fig. 5. *Top*: Computed $\chi(T)$ and $\chi T(T)$ curves for the 88 K structure (red) using the 8s minimal magnetic model and its comparison with the experimental curve (black); *Bottom*: Computed $\chi(T)$ and $\chi T(T)$ curves for the 273 K structure (blue) using the 4s–4s minimal magnetic model and the comparison with the experimental curve (black). Both minimal magnetic models are shown in Fig. 4. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

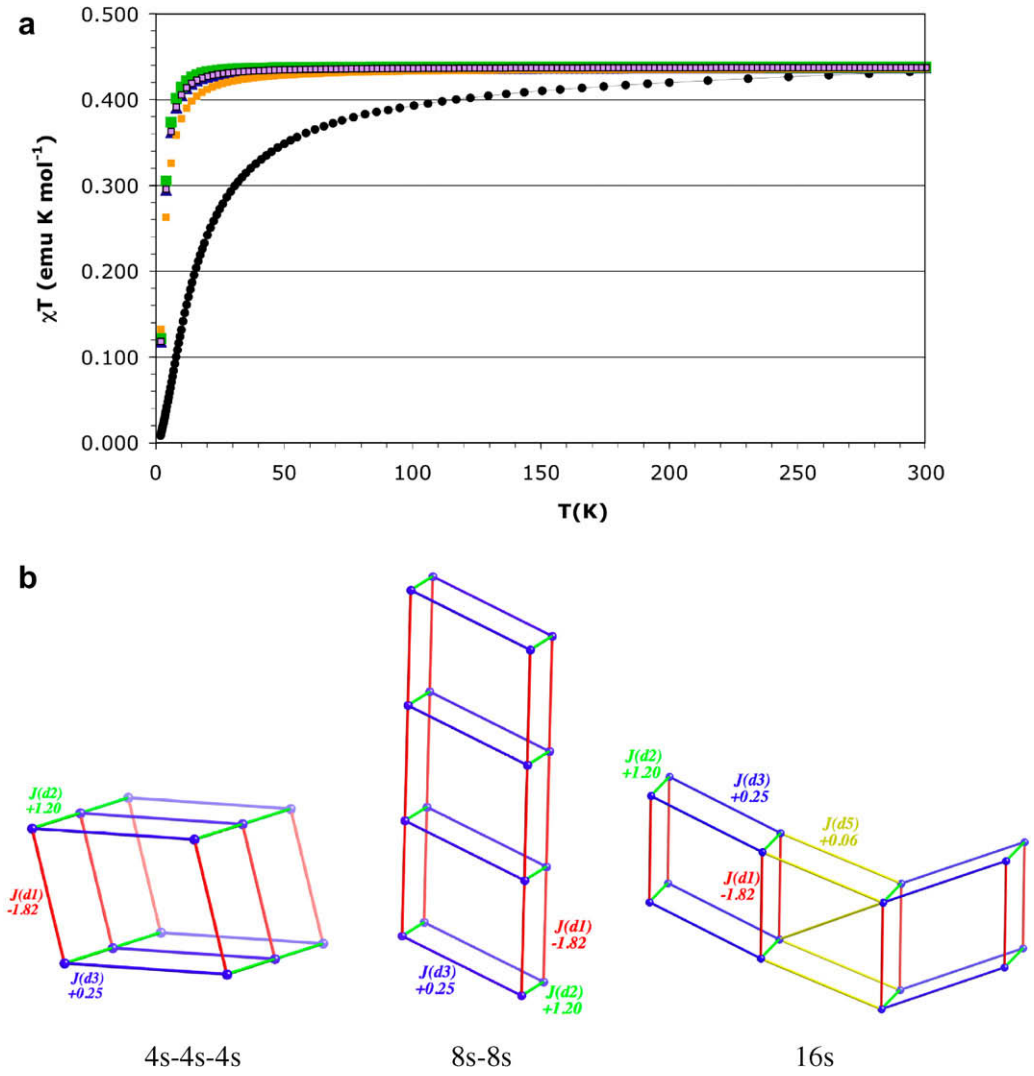

Fig. 6. (a) Magnetic susceptibility curve computed using the 4s–4s–4s (green squares), 8s–8s (orange squares) and 16s (violet squares) magnetic models. The curve obtained using the 4s–4s minimal magnetic model space is also shown for comparison (blue triangles), together with the experimental curve (black circles). (b) Magnetic models used in the calculations of the magnetic susceptibility. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

minimal magnetic model along the crystallographic axes was evaluated (see magnetic models 4s–4s–4s and 8s–8s in Fig. 6). Then, it was tested the effect of including $J(d5) = 0.06\ cm^{-1}$ in the minimal magnetic model (see 16s magnetic model in Fig. 6). In none of these cases the shape of the computed $\chi(T)$ and $\chi T(T)$ curves changed with respect to those computed using the 4s–4s minimal magnetic model space (Fig. 6). Therefore, neither the extension of the minimal magnetic model nor the inclusion of the $J(d5)$ pair interactions have any effect in the computed macroscopic properties, as expected from previous studies. In summary, the 4s–4s model of Fig. 4 is a proper minimal magnetic model space for the study of the macroscopic properties of the 273 K structure of the $[(2,3dmpyH)_2CuBr_4]$ crystal. The fact that the low temperature macroscopic properties computed using a room temperature structure differ from the experimental results at that temperature demonstrates the relevance of using low temperature crystal structures in the study of the magnetic properties at this range of temperatures.

4. Conclusions

The results of the First-Principles Bottom–Up study of the 88 and 273 K structures of the $[(2,3\text{-}dmpyH)_2CuBr_4]$ crystal (range of temperatures where no first order phase transition is observed) shows that low temperature structures have to be used in order to perform theoretical studies and analysis of the magnetic properties of this crystal at these temperatures. Small variations in the intermolecular geometrical arrangement of the $CuBr_4^{2-}$ radicals caused by the anisotropic thermal expansion induce physically relevant changes in the nature and relative importance of the microscopic J_{AB} magnetic interactions. These modifications in the J_{AB} values do not correlate directly with the distance between the bromide ions or copper ions, therefore emphasizing that intermolecular angles are also significant in the magnetic exchange between the radicals of the crystals studied here [26]. As a result of these geometrical changes, the magnetic topology of the low and room temperature structures differ. The 88 K structure is found to be a two-leg spin-ladder [$J_{rail} = J(d1) = -7.79\ cm^{-1}$ and $J_{rung} = J(d3) = -3.49\ cm^{-1}$], i.e. a 1D magnetic topology. However, the 273 K structure presents a magnetic topology consisting of non-interacting bilayers [each layer formed by $J_{intra}(d1) = -1.82\ cm^{-1}$ and $J_{intra}(d2) = +1.20\ cm^{-1}$, which are then connected by $J_{inter}(d3) = -0.25\ cm^{-1}$], i.e. a 2D magnetic topology. The macroscopic magnetic susceptibility curves computed from these two magnetic topologies are strikingly different, and only that originating from the 88 K structure reproduces the experimental curve.

All these structural and magnetic changes are a consequence of the non-isotropy of the thermal expansion. Therefore, these anisotropic changes can be a problem when studying magnetic interactions, if they are not properly accounted for. This problem does not exist when using crystal structures determined at temperatures close enough to the temperature range to be studied.

Supplementary data

CCDC 699270 contains the supplementary crystallographic data for $C_{14}H_6D_{14}N_2CuBr_4$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk

Acknowledgments

M.M.T. is grateful for grants from the NSF (IMR-0314773) toward the purchase of the MPMS SQUID, from PCISynthesis Inc. toward the purchase of the D8 Powder X-ray Diffractometer, and the Kresge Foundation toward the purchase of both. The Spanish team also thanks the Spanish Science and Education Ministry for support (Projects BQU2002-04587-C02-02 and CTQ2005-02329), the Catalan DURSI (Grants 1999SGR-00046 and 2005SGR-00036), and the computer time allocated by CESCA and BSC. Furthermore, J.J. thanks the Spanish Science and Education Ministry for the award of his Ph. D. grant.

magnetism. The natural orbital analysis was also performed to examine the alternate $d_{z^2-x^2}$ type orbital ordering. The calculated potential energy curves were discussed, from the viewpoint of the theoretical total energy in the Jahn–Teller distorted structure.

2. Theoretical background

2.1. Computational methods

The computational method employed here is UB2LYP, which is one of the hybrid-density functional theory (DFT) methods, because we concluded that B2LYP is the reliable method for the perovskite-type transition metal solids [19–21]. In hybrid-DFT method, the exchange and correlation potentials are generally defined by

$$E_{XC} = C_1E_X^{HF} + C_2E_X^{Slater} + C_3E_X^{Becke88} + C_4E_C^{VWN} + C_5E_C^{LYP} \quad (3)$$

where E_X^{HF}, E_X^{slater}, and E_X^{Becke} denote HF, Slater [22,23], and Becke [24] exchange functionals, respectively, and E_C^{VWN} and E_C^{LYP} denote the Vosko, Wilk, and Nusair (VWN) [25], and Lee, Yang, and Parr (LYP) [26] correlation functionals, respectively. The mixing coefficients (C1, C2, C3, C4 and C5) in UB2LYP is (0.5, 0.5, 0.5, 1.0 and 1,0), respectively. Tatewaki–Huzinaga MIDI [27] basis sets plus Hay's diffuse function [28] were used for copper cation and 6-31G* basis set was used for fluorine anion. All calculations were performed by GAUSSIAN 94 program package [29].

2.2. Effective exchange integrals (J_{ab})

The magnetic property in the strongly correlated perovskite-type fluorides can be investigated by Heisenberg-type spin coupling Hamiltonian [30], which is expressed as

$$\hat{H}(HB) = -2J_{ab}\mathbf{S_a}\cdot\mathbf{S_b} \quad (4)$$

where J_{ab} is the orbital-averaged effective exchange integral between the a-th and b-th spin sites with total spin operators ($\mathbf{S_a}$ and $\mathbf{S_b}$). Previously, [20,21] we concluded that the approximate spin projected scheme is one of the best method to obtain J_{ab} values for the species. The J_{ab} value under the spin projected scheme $J_{ab}^{(1)}$ can be calculated by the difference of the total energies between the highest-spin (HS) state and the lowest-spin (LS) state

$$J_{ab}^{(1)} = \frac{^{LS}E(X) - {}^{HS}E(X)}{^{HS}\langle S^2\rangle - {}^{LS}\langle S^2\rangle} \quad (5)$$

where $^{Y}E(X)$ and $^{Y}\langle s^2\rangle$ the total energy and total spin angular momentum for the spin state Y (LS and HS) by the calculation method X (X = UB2LYP), respectively. Eq. (5) can be applied not only for linear chains of dimer and trimer but also for tetranuclear ring [20,21]. On the other hand, the J_{ab} value under the spin unprojected scheme for tetranuclear ring is given by $J_{ab}^{(2)}$ (*ring*) [20,21]

$$J_{ab}^{(2)}(ring) = \frac{^{LS}E(X) - {}^{HS}E(X)}{4NS_aS_b} \quad (6)$$

where N is total number of spin sites and S_c is spin size (S_c (c = a, b)). In the tetranuclear ring (N = 4), the denominator in Eq. (6) becomes 4, where S_a and S_b are also equal to 1/2, because of spin quantum numbers of copper cation.

2.3. Natural orbital analysis

The natural orbital is determined by diagonalizing their first-order density matrices as

$$\rho(r,r') = \sum n_i\phi_i(r)\phi_i(r')^* \quad (7)$$

where n_i and ϕ_i denote the occupation number and natural orbital, respectively. On the other hand, the magnetic orbitals are expressed by the different natural orbitals,

$$\chi_i = \cos\omega\phi_i + \sin\omega\phi_i^+ \quad (8a)$$
$$\eta_i = \cos\omega\phi_i - \sin\omega\phi_i^+ \quad (8b)$$

where ω is the orbital mixing parameter, and ϕ_i and ϕ_i^+ denote the i-th bonding and corresponding antibonding natural orbitals, respectively. The natural orbital mixing, in turn, provides the magnetic broken-symmetry orbitals (χ_i and η_i) localized on different sites. The orbital overlap (T_i) between magnetic orbitals is defined to elucidate their localizability

$$T_i = \langle \chi_i | \eta_i \rangle = \cos^2 \omega - \sin^2 \omega = \cos 2\omega \quad (9)$$

The occupation numbers of the occupied bonding and antibonding natural orbitals are close to 2.0 and 0.0, respectively. On the other hand, those of the magnetic singly occupied natural orbitals (SONOs), which are close to 1.0, are given by orbital overlap as

$$n_i = 1 + T_i,\ n_i = 1 - T_i. \quad (10)$$

3. Geometric structures

Both the smaller apical Cu–F distances, and the shortened and elongated equatorial Cu–F distances are responsible for the alternate $d_{z^2-x^2}$ type orbital ordering. The two dimensional cluster models surrounded by apical and equatorial fluorine anions were constructed as shown in Figs. 3a–3d. The sites numbers are shown in Fig. 3e. The apical and equatorial Cu–F distances in K_2CuF_4 are 1.950 Å and 2.080 Å, respectively [7,11,12]. In **1** and **2**, only equatorial fluorine anions on CuF_2 layer and apical fluorine anions are taken into account, respectively. On the other hand, in **3** and **4**, both the apical and equatorial fluorine anions are taken into account. **4** has the all apical and equatorial fluorine anions, while **3** has only the equatorial fluorine anions approaching to copper cations.

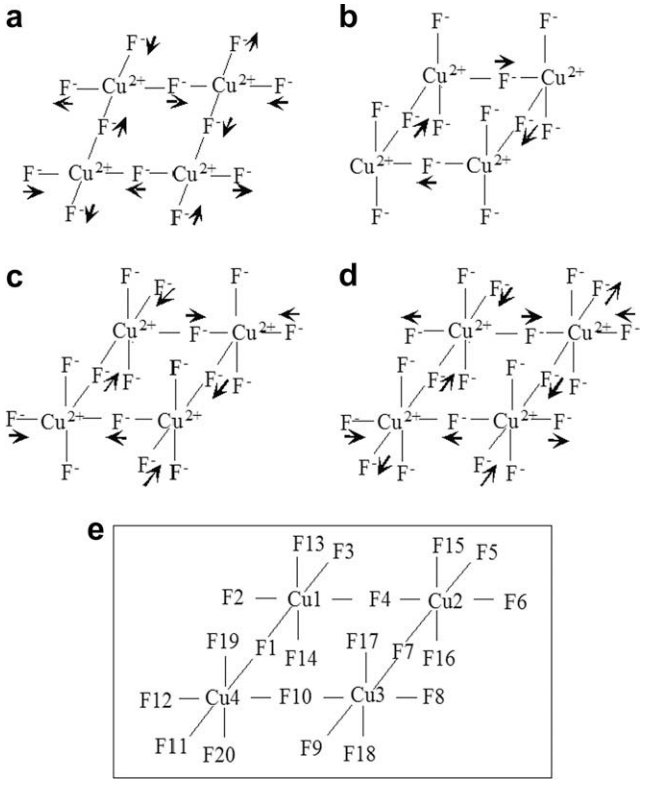

Fig. 3. The two dimensional cluster models of K_2CuF_4 and the site numbers: (a) **1**, (b) **2**, (c) **3**, (d) **4**, and (e) site numbers.

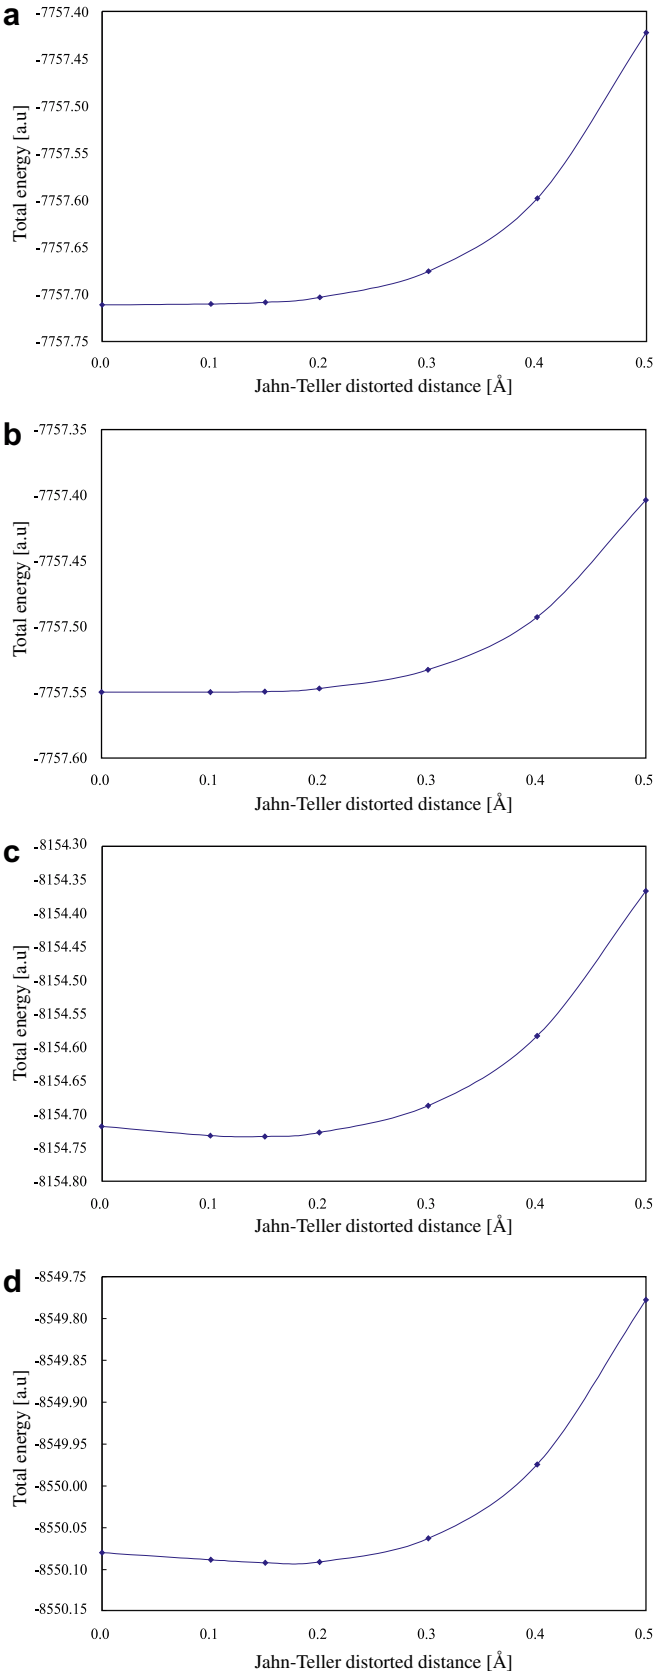

Fig. 4. The potential energy curves, changing the amplitude of Jahn–Teller distortion the equatorial fluorine anions from the initial position (q) in Q_2 mode: (a) **1**, (b) **2**, (c) **3**, and (d) **4**. (HS state, UB2LYP method).

4. Results and discussion

4.1. Potential energy curves

As shown in Fig. 4, we obtained the potential energy curves of HS state for **1**, **2**, **3**, and **4** by UB2LYP, changing the amplitude of Jahn–Teller distortion of the equatorial fluorine anions (q), while the apical fluorine anions are all fixed. Jahn–Teller distortion occurs in **3** and **4**, since the potential energy curves have the minimum points. On the other hand, no Jahn-Teller distortion occurs in **1** and **2**, since the potential energy curves are monotonous increasing.

4.2. Effective exchange integrals (J_{ab})

Table 1 shows J_{ab} values for **1**, **2**, **3**, and **4** by UB2LYP, changing the amplitude of Jahn–Teller distortion of the equatorial fluorine anions (q). As $J_{ab}^{(1)}$ values are almost equivalent with $J_{ab}^{(2)}(ring)$ values, the effect of the spin projection is small in K_2CuF_4. At q = 0.00 Å, **1**, **2** and **4** provide negative J_{ab} values, showing the antiferromagnetic interaction. On the other hand, the positive J_{ab} value for **3** at q = 0.00 Å indicates the ferromagnetic interaction. At the experimental amplitude of Jahn–Teller distortion (q = 0.15 Å) [31], J_{ab} values for **3** and **4** are 6.784 cm^{-1} and 6.162 cm^{-1}, respectively, while **1** and **2** provides negative J_{ab} values. They are well consistent with the experimental ones (5.212 $cm^{-1} \sim 7.739\ cm^{-1}$) [9–12]. Between 0.30 Å and 0.50 Å, J_{ab} values for **2** become positive. It is because the bridge-fluorine anions (F1, F4, F7 and F10) cause the alternate $d_{z^2-x^2}$ type orbital ordering without the other equatorial fluorine anions. However, the equatorial Cu–F distances are too large.

4.3. Natural orbital analysis

Fig. 5 shows the singly occupied natural orbital (SONO+1s) and their occupation numbers of HS state for **1**, **2**, **3**, and **4** by UB2LYP, at the experimental amplitude of Jahn–Teller distortion (q = 0.15 Å). J_{ab} values at q are approximately given by

$$J_{ab} \cong K_{ab} - c(T_i^q)^2 \tag{11}$$

where K_{ab}, c and T_i denote the Coulomb exchange integral, positive constant and orbital overlap between copper cations at q, respectively. J_{ab} values are negative if T_i^q values are non-negligible.

In **1** and **2**, $\mathbf{d}_z^2$ and $d_{x^2-y^2}$ orbitals exist in copper cations, respectively. However, in **3**, the alternate $d_{z^2-x^2}$ type orbital ordering occurs, where $d_{z^2-y^2}$ orbital of Cu1 (Cu3) interacts with equatorial F1 and F3, and apical F13 and F14 (equatorial F7 and F9, and apical F17 and F18), and $d_{z^2-x^2}$ orbital of Cu2 (Cu4) interacts with equatorial F4 and F6, and apical F15 and F16 (equatorial F10 and F12, and apical F19 and F20). Smaller $T_i^{0.15}$ value between $\chi_{SONO\pm1}$ and $\eta_{SONO\pm1}$ (0.002) shows the scarce orbital overlap between $d_{z^2-x^2}$ and $d_{z^2-y^2}$ orbitals. The proper ferromagnetic interactions between copper cations appear in **3**, resulting in the reasonable J_{ab} value (6.784cm^{-1}). Similarly, in **4**, $d_{z^2-y^2}$ ($d_{z^2-x^2}$) orbitals in Cu1 and Cu3 (Cu2 and Cu4) are formed. Smaller $T_i^{0.15}$ value between $\chi_{SONO\pm1}$ and $\eta_{SONO\pm1}$ (0.005) shows the scarce orbital overlap between $d_{z^2-x^2}$ and $d_{z^2-y^2}$ orbitals. The proper ferromagnetic interactions between copper cations also appear in 4, providing the reasonable J_{ab} value (6.162 cm^{-1}).

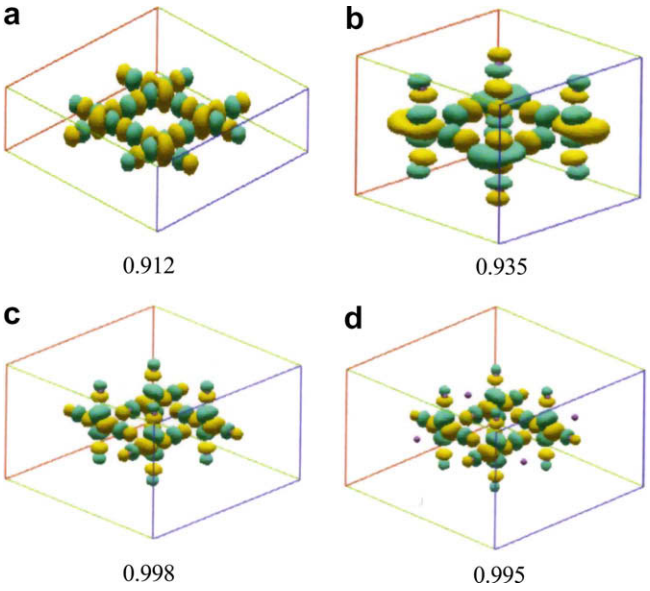

Fig. 5. The singly occupied natural orbital (SONO+1s) and the occupation numbers at the experimental amplitude of Jahn–Teller distortion: (a) **1**, (b) **2**, (c) **3**, and (d) **4** (HS state, UB2LYP method). The site numbers of back, right, front and left copper cations are Cu1, Cu2, Cu3 and Cu4, respectively.

4.4. Cooperative Jahn–Teller effect

From the viewpoint of the theoretical total energy in the Jahn–Teller distorted structure, we discuss the calculated potential energy curves. We considered only **3** and **4**, since no alternate $d_{z^2-x^2}$ type orbital ordering occurs in **1** and **2**. It is considered that the calculated potential energy curves may be expressed as the second-order polynomial by regarding q as the parameter in Eq. (2). In fact, as shown in Figs. 4c and 4d, the calculated potential energy curves of **3** and **4** are well fitted by Eq. (2), near the minimum point (0.10 Å $\sim$ 0.20 Å). Table 2 shows the calculated coefficients and amplitude of Jahn–Teller distortion (q_{calc}) in Eq. (2). The total energy is smaller by the Jahn–Teller distortion, due to the positive

Table 1

0.50	−11.08	−14.04

[a] $J_{ab}^{(1)}$ values are shown in cm^{-1}.
[b] q is shown in Å.

A values. On the other hand, the elastic energy becomes larger as the amplitude of Jahn–Teller distortion is larger, due to the positive k values. These facts explain that the minimum points are given in the calculated potential energy curves. The q_{calc} values in **3** and **4** are 0.132 Å and 0.164 Å, respectively. They are well consistent with the experimental value (q=0.15 Å) [31]. On the other hand, the potential energy curves are not fitted at the smaller and larger q values. It is because the degree of the contamination of e_g orbitals ($d_{x^2-y^2}$ and d_z^2 orbitals) differs. The third-order anharmonic term [14] describes them, which is given by

$$A'(\cos 3\theta)q^3 \tag{12}$$

where A' is the proportionality constant. This term includes the parameter of θ in Eq. (1).

In K_2CuF_4, the cooperative Jahn–Teller effect is dominative. The spin-orbit coupling is negligible, as spin angular momentum vanishes in ($d^9 t_{2g}^6 e_g^3$) configuration of copper cation. For example, when the spin angular momentum remains in the degenerated t_{2g} orbital, the quantum nature appears in the degree of freedom in orbital [32,33]. The dynamical effect, in which both the electronic and vibrational states make transitions simultaneously, is also negligible.

4.5. Effect of point charges

The cluster models adapted here are parts of K_2CuF_4. It is desirable for the cluster models to consider the effect on the rest of the crystal. Here, we estimated the J_{ab} values for the cluster models of **3** and **4** embedded in point charges. Table 3 shows $J_{ab}^{(1)}$ values for **3** and **4** with point charges by UB2LYP, changing the amplitude of Jahn–Teller distortion of the equatorial fluorine anions (q). At the experimental amplitude of Jahn–Teller distortion (q = 0.15 Å), $J_{ab}^{(1)}$ values of **3** and **4** with point charges become 5.374 cm^{-1} and 3.402 cm^{-1}, respectively. Though they are underestimated in comparison with $J_{ab}^{(1)}$ values of **3** and **4** without point charges, the difference of about 1 $cm^{-1} \sim 2$ cm^{-1} is negligible under hybrid-DFT level calculation. It is concluded that embedding of **3** and **4** in point charges has no effect on estimating the changes of the total energies and J_{ab} values. Hence, the bare cluster models of **3** and **4** can be adapted for calculation.

5. Conclusion

In this study, we examined the cooperative Jahn–Teller effect in K_2CuF_4, from the viewpoints of the potential energy curves, effective exchange integrals (J_{ab}) and the natural orbital analysis. We have concluded as follows:

1. The two dimensional cluster models under consideration of octahedral fluorine anions around copper cation reproduced the alternate $d_{z^2-x^2}$ type orbital ordering.
2. The calculated J_{ab} values showed the ferromagnetic interaction between $d_{z^2-x^2}$ and $d_{z^2-y^2}$ orbitals, and were well consistent with the experimental ones.
3. The calculated potential energy curves were well fitted with the theoretical total energy near the calculated amplitude of Jahn–Teller distortion.
4. The calculated amplitudes of Jahn–Teller distortion are also well consistent with the experimental ones.

Namely, the cluster calculation based on hybrid-DFT method provides the reasonable potential energy curves. It means that the first principle calculation enables us to estimate the amplitude of Jahn–Teller distortion theoretically. This method could be applicable for the other Jahn–Teller distorted systems.

2. Experimental

2.1. Compound preparation

All chemicals and solvents were used as received. The complex $[Mn_{12}O_{12}(O_2CCH_3)_{16}(H_2O)_4]$ (Mn_{12}-ac) was prepared as described elsewhere [14]. Mn_{12}-phn was prepared as described below. A solution of diphenylphosphinic acid (0.79 g, 3.2 mmol) in CH_2Cl_2 (80 ml) was dropped into a solution of Mn_{12}-ac (0.50 g, 0.24 mmol) in acetonitrile (50 ml) within 1 h. The solvent was evaporated under reduced pressure to complete dryness. The remaining solid was redissolved in CH_2Cl_2 (70 ml) and filtered through kieselguhr. Hexane was added and the solution was allowed to stand undisturbed at 4 °C for 12 h. The resulting black crystals were collected by filtration, washed with hexane and dried in vacuo. A crystallography sample was grown slowly from CH_2Cl_2/hexane at 4 °C and maintained in mother liquor to avoid solvent loss. Selected IR bands (ATR, cm^{-1}): 3053 (w), 1570 (m), 1541 (m), 1485 (w), 1437 (m), 1384 (m), 1332 (m), 1124 (vs), 1046 (vs), 1014 (vs), 994 (vs), 751 (m), 723 (vs), 701 (vs). MALDI-TOF-MS (m/z): 3693.2 $[Mn_{12}O_{12}(O_2PC_{12}H_{10})_{12}(O_2CCH_3)_4]^+$; 3633.8 $[Mn_{12}O_{12}(O_2PC_{12}H_{10})_{12}(O_2CCH_3)_3]^+$; 3475.7 $[Mn_{12}O_{12}(O_2PC_{12}H_{10})_{11}(O_2CCH_3)_4]^+$. Details of the synthesis and the characterization of 4-MOBCA can be found elsewhere [12].

2.2. X-ray crystallography

Crystal data of Mn_{12}-phn: $C_{314.87}H_{264}Cl_{21.55}Mn_{24}O_{92}P_{24}$, $M_r = 8345.58$, tetragonal, $I41/a$, $a = 34.7178(9)$ Å, $b = 34.7178(9)$ Å, $c = 28.8662(10)$ Å, $V = 34793.2(18)$ Å^3, $Z = 4$, brown block, ρ_{calcd} (g/cm^3) = 1.593, μ(Mo K$_\alpha$) (cm^{-1}) = 1.192, $T = 100$, empirical absorption correction, $T_{max}/T_{min} = 0.650/0.699$, 124.917 reflections collected, 18.049 unique ($R_{int} = 0.133$), $R_1 = 0.0639$, $wR_2 = 0.1610$, using 17.930 reflections with $I > 2\sigma(I)$ to refine 1067 parameters. The crystallography data collection was performed at a STOE IPDS-II diffractometer equipped with a graphite monochromated radiation source ($\lambda = 0.71073$ Å) and an image plate detection system. The selection, integration and averaging procedure of the measured reflex intensities, the determination of the unit cell by a least-squares fit of the 2Θ values, data reduction, LP correction, and the space group determination were performed using the X-Area software package delivered with the diffractometer. An empirical absorption correction method was implemented after indexing of the crystal faces. The structure was solved by direct methods (SHELXS-97) [15] and standard Fourier techniques against F^2 with a full-matrix least-squares algorithm using SHELXL-97 [15] and the WinGX (1.70) [16] software package. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and refined with a riding model.

2.3. Physical measurements

The magnetic measurements were performed by using a micro-Hall effect magnetometer to detect the magnetic dipolar field of a Mn_{12}-phn single crystal placed on top of the sensor. The field was aligned with the easy axis of magnetization using the transverse field method.

Mn_{12}-phn was deposited on the functionalized Au(1 1 1) surface via ligand exchange reaction with 4-MOBCA as described elsewhere [12]. STM and STS measurements were performed in an Omicron Multiprobe UHV system at room temperature. For the STM/STS measurements, electrochemically etched tungsten tips, flash-annealed by electron bombardment were used. The ± sign of the bias voltage denotes the voltage applied to the sample.

3. Results and discussion

Mn_{12}-phn crystallizes in the space group $I41/a$ with the two different complexes $[Mn_{12}O_{12}(O_2PC_{12}H_{10})_{12}(O_2CCH_3)_4]$ (complex **1a**) and $[Mn_{12}O_{12}(O_2PC_{12}H_{10})_{12}(O_2CCH_3)_4(H_2O)_4]$ (complex **1b**) per asymmetric unit. The structure of the $[Mn_{12}O_{12}]^{16+}$ core is similar to other Mn_{12} complexes (see Fig. 1). The central $[Mn^{IV}_4O_4]^{8+}$ cubane is surrounded by a ring of eight Mn^{III} ions that are held together via eight μ_3-O^{2-} ions. The residual free sites of the Mn^{III} ions are occupied with eight axial and four equatorial μ_2-bridging diphenylphosphinate molecules.

The axial Mn^{III}/Mn^{IV}-bridging molecules are four acetate molecules. The last four free sites of the Mn^{III} ions are occupied by four water molecules in the case of complex **1b**, in case of complex **1a** the free sites keep unoccupied. The ligand exchange reaction remains incomplete as only 12 of the 16 acetate molecules were exchanged. The first four of the equatorial acetate ligands and four of the axial acetate ligands are exchanged [17] as well as four of the equatorial acetate ligands afterwards. In this state the direct coordination sphere around the $[Mn_{12}O_{12}]^{16+}$ core is packed tightly and no further ligands can be exchanged. Only the acetate molecules are small enough to fill the free axial sites bridging the Mn^{III}/Mn^{IV} ions.

Magnetization hysteresis measurements were carried out on a well-shaped Mn_{12}-phn single crystal in the temperature range from 0.4 to 3.2 K, at a sweep rate of 1 T/min. Fig. 2a represents the temperature dependence of the hysteresis loops showing a series of steps, separated by plateaus. As the temperature is lowered, the hysteresis increases because there is a decrease in the transition rate of thermally assisted tunneling. The hysteresis loops become temperature independent below 0.6 K, demonstrating quantum tunneling at the lowest energy levels. The steps in the hysteresis loops are very sharp due to low solvent/ligand disorder in the crystals [18–20]. The field between two resonances allows an estimation of the anisotropy constant D, yielding for the difference between two steps at high fields a value of $D = 0.49$ K (assuming $g = 2$). Additional measurements were performed in the presence of a constant transverse field. The results of these measurements are presented in Fig. 2b showing oscillations of the tunneling probability at zero field as a function of the magnetic field applied approximately along the hard magnetization axis.

Fig. 3 shows STM images of Mn_{12}-phn clusters on the 4-MOBCA/Au(1 1 1) surface obtained at +2.8 V (a) and +0.4 V (b), respectively.

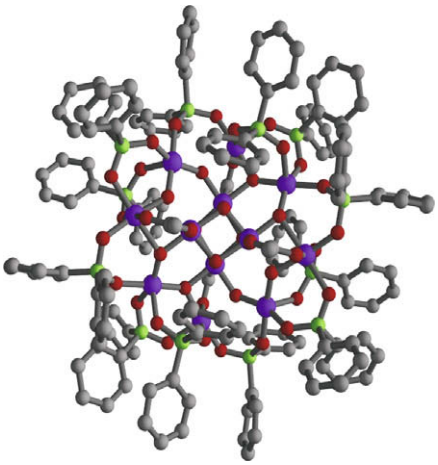

Fig. 1. The structure of Mn_{12}-phn viewed along the c-axis: Mn – violet, O – red, P – green, C – gray. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

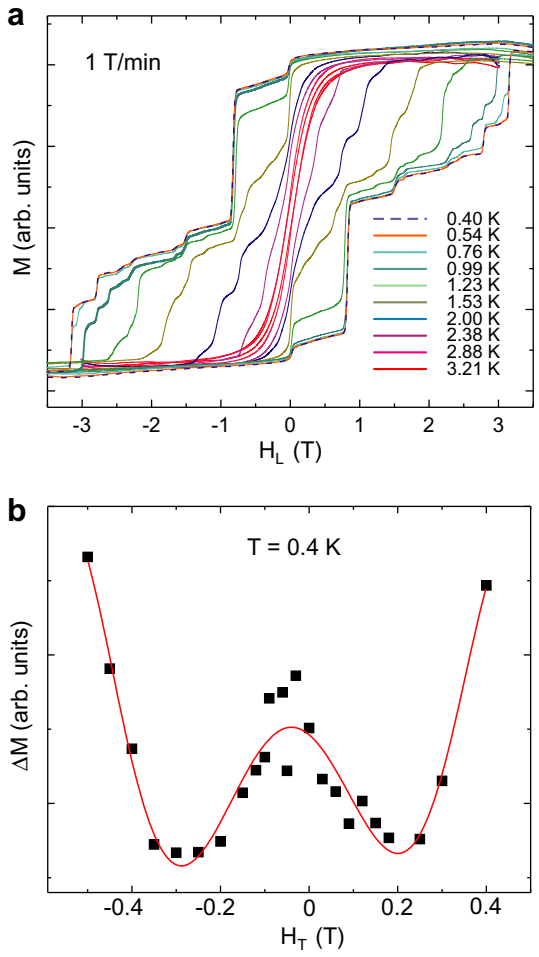

Fig. 2. (a) Hysteresis loops of a Mn_{12}-phn single crystal measured at different temperatures and a constant field sweep rate indicated in the figure. The loops display a series of steps, separated by plateaus. As the temperature is lowered, there is a decrease in the transition rate due to reduced thermally assisted tunneling. The hysteresis loops become temperature independent below 0.6 K. (b) ΔM at zero field as a function of transverse field measured at 0.4 K.

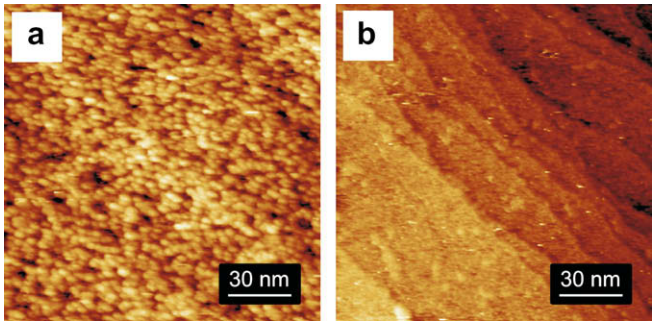

Fig. 3. 150 × 150 nm^2 STM images of Mn_{12}-phn clusters measured at +2.8 V (a) and +0.4 V (b) bias voltage. Mn_{12}-phn molecules are "invisible" for the STM tip at +0.4 V (within the conductance gap) and thus the characteristic steps of the 4-MOBCA covered Au(1 1 1) surface are visible. The two STM pictures were obtained from the same sample area.

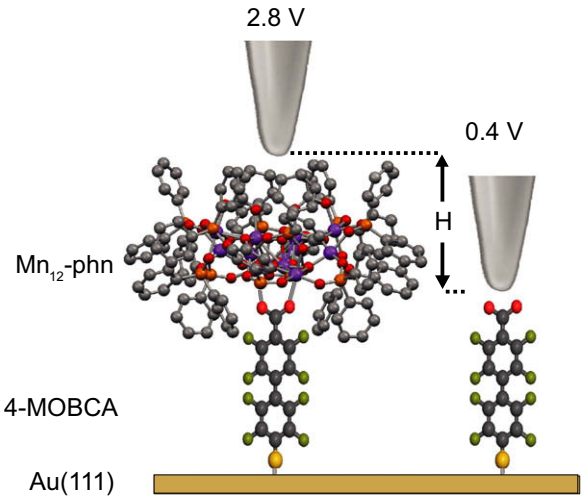

Fig. 4. Schematic representation of the *z*–*U* spectroscopy measurements on Mn_{12}-phn.

The higher bias voltage corresponds to the region of high conductance, whereas the lower value corresponds to the conductance gap region. The molecules are invisible for the STM operated at +0.4 V bias voltage, and thus the characteristic monoatomic steps of the 4-MOBCA covered Au(1 1 1) surface can be observed. At +2.8 V bias voltage the Mn_{12}-phn molecules are visible.

For the determination of molecular heights we utilized the *z*–*U* spectroscopy method described elsewhere [21,22]. The principle of *z*–*U* spectroscopy implemented in this study is shown in an idealized sketch in Fig. 4. An STM tip is brought into tunneling contact with a Mn_{12} molecule. This corresponds to a tip-molecule distance of about 0.5 nm. *z*–*U* characteristics of Mn_{12}-phn are obtained by varying the bias voltage and measuring the *z*-position of the tip. The feedback loop of the STM remains operating and a fixed set current is selected so that the tip position is altered whenever a variation of the tunneling current is detected. Since Mn_{12} molecules reveal a broad conductance gap in STS I-U measurements [12,13] no molecular states can be occupied by electrons at low bias voltage, thus the tunneling current rapidly decreases around the onset of the conductance gap. As a result, the tip is extended until the fixed set current is restored. STM images and STS spectra [22] show that this is the case for a tunneling contact with the 4-MOBCA functionalized substrate. In a previous work, [12] STS I-U spectra of 4-MOBCA also showed that the conductance is relatively low at low bias voltage. Consequently, the STM tip approaches the 4-MOBCA layer very closely and the difference *H* between the positions of (tunneling) contact with the Mn_{12} molecule and the substrate is a good estimation of the real height of the molecular layer.

Fig. 5a shows *z*–*U* spectra obtained from different Mn_{12}-phn clusters. The set current was 6.9 pA. In the *z*–*U* spectra, a distinct step is visible around 1 V, corresponding to −0.5 nm with respect to the 0 nm position for 2.8 V. The step separates two distance ranges which correspond to a tunneling contact with the Mn_{12}-phn molecule (high bias voltage) and with the 4-MOBCA functionalization layer (low bias voltage). To demonstrate that the step is not a measurement artifact, a *z*–*U* spectrum obtained from bare Au(1 1 1) in the bias voltage range between 0.4 V and 1.4 V is shown for comparison. The absolute *z* position is not directly comparable to the measurement on Mn_{12}-phn due to the different starting positions. Nonetheless, no hint of any step is visible in the *z*–*U* spectrum obtained from Au(1 1 1), clearly showing that the signatures obtained from Mn_{12}-phn are due to the molecule.

The evaluation of 40 *z*–*U* spectra obtained from Mn_{12}-phn yields an average step height of 1.4 nm with the individual step heights ranging from 1.1 to 1.7 nm. These values are in very good agreement with the diameter of the Mn_{12}-phn molecules derived from the X-ray structure, assuming random orientation and ligand exchange with 4-MOBCA. A broad spread of the measured molec-

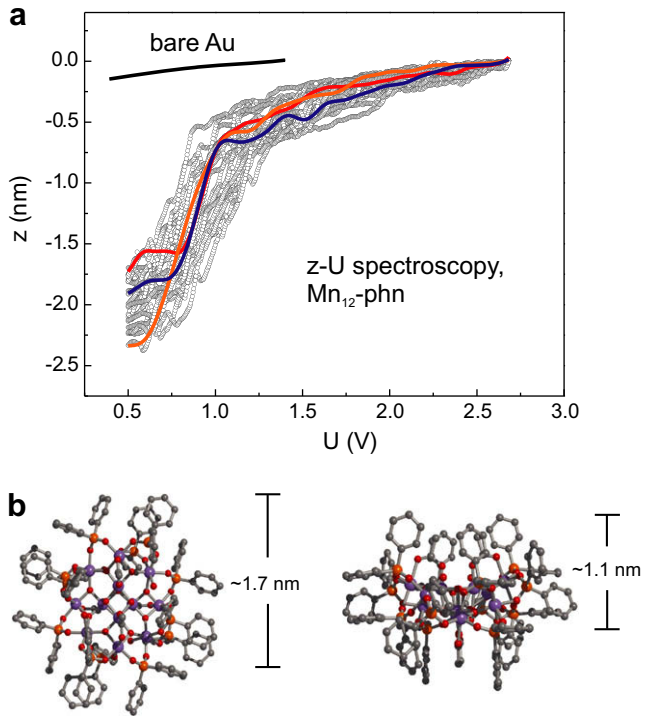

Fig. 5. (a) Representative distance–voltage characteristics obtained from different individual Mn_{12}-phn molecules (open circles) and from bare Au(111) (black line, upper corner, same scale). Three curves marked with different colors (red, orange, blue) are presented to demonstrate the different step heights. (b) Sketches of two orientations of Mn_{12}-phn molecules resulting in the minimum and maximum height values of 1.1 nm and 1.7 nm (measured with respect to the 4-MOBCA layer due to the exchange of ligands). (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

ular heights can be attributed to a random orientation of different molecules which can be explained by the equally high acidity of the diphenylphosphinic acid and of 4-MOBCA with no site-specific ligand exchange reaction being expected. The bulky diphenylphosphinate ligands effectively suppress the ligand exchange of the axial acetate ligands thus leading to the higher ligand exchange probability of the diphenylphosphinate ligands. Contrary to that, in the case of Mn_{12}-thiophenecarboxylate (Mn_{12}-th) a smaller spread of the measured molecular heights was observed. [22] Moreover, the comparison of the measured molecular heights with the structural X-ray data obtained from Mn_{12}-th single crystals indicated that the Mn_{12}-th molecules are oriented with the easy axis perpendicular to the surface. A preferred orientation was explained by a higher probability for exchange of axial ligands due to the higher acidity of 4-MOBCA compared to thiophenecarboxylate ligands. [23] Thus, we show that the substitution of the Mn_{12} ligand shell may have a major impact on the surface orientation of the Mn_{12} clusters deposited on Au, i.e. on the orientation of the easy magnetization axis. Moreover, the possibility to determine the orientation of individual Mn_{12} molecules is an important prerequisite for future well-defined magnetic field dependent cryogenic STS measurements. For such measurements, the orientation of the molecular easy magnetization axis with respect to an external magnetic field has to be known. According to the results of the *z–U* spectroscopy, the orientation can be identified by means of STS. Beyond the estimation of the real height, the *z–U* spectra also demonstrate the presence of a single Mn_{12}-phn monolayer on 4-MOBCA, thus confirming the success of the ligand exchange reaction.

4. Conclusion

The synthesis, investigation as well as surface deposition of a truly axial symmetry Mn_{12}-diphenylphosphinate (Mn_{12}-phn) single molecule magnet has been reported. Out of 16 acetate ligands encapsulating the $Mn_{12}O_{12}$ core, 12 ligands were exchanged by diphenylphosphinate in this compound. Mn_{12}-phn shows well-defined steps in the magnetic hysteresis loops indicating that the crystals possess a very high quality. A monolayer of Mn_{12}-phn was chemically grafted on a functionalized Au(111) substrate and studied by means of STM/STS. The presence of a conductance gap in Mn_{12} molecules was used for distance–voltage (*z–U*) spectroscopy that, in the present case, allows the determination of the real-space height of the molecules with high accuracy. A large spread in the measured molecular heights obtained from the *z–U* spectra indicates the absence of a preferential orientation of the Mn_{12}-phn molecular easy axis with respect to the surface which we attribute to the equally high acidity of the diphenylphosphinic acid and of 4-MOBCA. These results are compared with the data obtained from another Mn_{12} derivative containing 16 thiophenecarboxylate ligands which shows a preferential orientation of the clusters on the Au surface with the easy magnetic axis perpendicular to the surface plane. In general, we show that the substitution of the ligand shell may have a major impact on the surface orientation of Mn_{12} clusters deposited on Au, i.e. on the orientation of the easy magnetization axis. This represents a crucial step towards addressing the magnetic properties of individual Mn_{12} molecules in the future. The possibility to identify the orientation of individual molecules will allow measurements with a well-defined orientation of the easy magnetization axes with respect to an external magnetic field.

Scheme 1. The ligand H_6ipa-bhea.

documented. In this paper we report the synthesis and chemical characterization of mono- and dinuclear copper(II) complexes based on the H_6ipa-bhea ligand. The magnetic properties of the dinuclear complex will be presented and discussed on the basis of density functional theory (DFT) calculations utilizing the broken symmetry (BS) approach.

2. Experimental

2.1. Materials

N,*N*-*bis*-(pyridin-2-ylmethyl)ethylenediamine (unspenp) [18], *N*,*N*-*bis*-(2-hydroxyethyl)ethylenediamine (bhea) [15], and 2-methyl-4,6-diformylresorcinol (ipa) [11] were synthesized according to literature procedures. All other starting materials are commercially available and were used without further purification. Further abbreviations used throughout the text: H_6ipa-bhea = 4,6-*bis*-(2-(*bis*-(2-hydroxyethyl)amino)ethylimino-methyl)-2-methyl-1,3-di hydroxybenzene, H_4hyforsa-bhea = 6-(2-(*bis*-(2-hydroxyethyl) amino)ethylimino-methyl)-4-formyl-2-methyl-1, 3-dihydroxybenzene, H_2hyforsa-unspenp = 6-(2-(*bis*-(pyridin-2-ylmethyl)amino) ethylimino-methyl)-4-formyl-2- methyl-1,3-dihydroxybenzene.

2.2. Physical measurement

Melting points are given uncorrected and were determined with a VEB Analytik Dresden HMK 72/41555. NMR spectra were recorded on Bruker Avance 200 and 400 MHz spectrometers at ambient temperatures. The chemical shifts were referenced to tetramethylsilane and are reported in ppm. The infrared spectra were recorded on a Bruker IFS55/EQUINOX spectrometer. Elemental analyses were determined on a Leco CHNS/932 and a VARIO EL III elemental analyzer. Magnetic susceptibilities were obtained from a polycrystalline sample using a Quantum-Design MPMSR-5S SQUID magnetometer, measurements were conducted with an applied magnetic field of 2000 and 5000 Oe in the temperature range from 300 to 2 K (for details see Ref. [19]). The measured values of χ_M were corrected for their diamagnetic contribution.

2.3. Synthesis of the ligand

2.3.1. H_6ipa-bhea

2-Methylresorcinol (0.75 g, 4 mmol) was added to a solution of bhea (1.24 g, 8 mmol) in ethanol (50 ml) leading to a yellow solution. The reaction mixture was stirred for additional 2 h at ambient temperature. After removing the volatile components *in vacuo* at ambient temperature the ligand was obtained as a yellow solid in quantitative yield (Yield: 1.80 g). M.p. 99 °C. *Anal.* Calc. for $C_{21}H_{36}N_4O_6$: C, 57.25; H, 8.24; N, 12.72. Found: C, 57.21; H, 8.39; N, 12.59%. ^{1}H NMR (200 MHz, DMSO–d_6): δ = 1.87 (s, 3H, CH_3); 2.59 (t, 8H, ^3J = 6.2 Hz, NCH_2CH$_2$OH); 2.75 (t, 4H, ^3J = 6.2 Hz, C=NCH$_2$CH_2N); 3.41 (t, 8H, ^3J = 6.2 Hz, CH_2OH); 3.56 (t, 4H, ^3J = 6.2 Hz, C=NCH_2CH$_2$N); 4.50 (s br, 4H, CH$_2$OH); 7.21 (s, 1H, arom. 2.4. Synthesis of the complexes

2.4.1. [$Cu_2(H_4$ipa-bhea)](ClO$_4$)$_2$ (**1**)

Aqueous ammonia (2 equiv.) was added to a solution of H_6ipa-bhea (96 mg, 0.2 mmol) in methanol (3 ml). Subsequent dropwise addition of Cu(ClO$_4$)$_2$ · 6H$_2$O (162 mg, 0.4 mmol), dissolved in methanol (5 ml), initially resulted in the formation of a green precipitate, which upon complete addition fully redissolved. The resulting dark green solution was stirred for further 20 min. Slow diffusion of diethylether into this solution afforded green prisms of **1** · MeOH suitable for X-ray diffraction within two days. The crystals were filtered off and dried *in vacuo*, which leads to the loss of the solvent of crystallization (Yield: 132 mg, 79%). M.p. >280 °C. *Anal.* Calc. for $C_{21}H_{34}Cl_2Cu_2N_4O_{14}$: C, 32.99; H, 4.48; N, 7.33. Found: C, 31.95; H, 4.37; N, 6.92%. IR (KBr, cm^{-1}): 3400 s br, 2925 m, 1621 s, 1590 vs, 1447 m, 1398 m, 1272 m, 1201 s, 1142 m, 1108 vs, 1090 vs, 1060 m 715 w, 626 m.

2.4.2. [Cu(H_3hyforsa-bhea)]ClO$_4$ · 2H_2O (**2**)

H_6ipa-bhea (244 mg, 0.5 mmol), dissolved in water (5 ml), was added to a solution of Cu(ClO$_4$)$_2$ · 6 H$_2$O (410 mg, 1.1 mmol) in water (5 ml). The resulting turquoise solution was stirred for 10 min and kept undisturbed in a closed vessel. Overnight blue prisms of **2** suitable for X-ray diffraction were obtained. The bulk material was obtained by slow evaporation of the solvent at ambient temperature for additional three days. The crystals were separated by filtration, washed with a small amount of water and dried *in air* (Yield: 208 mg, 74%). M.p. >280 °C. *Anal.* Calc. for $C_{15}H_{25}ClCuN_2O_{11}$: C, 35.44; H, 4.96; N, 5.51. Found: C, 35.63; H, 4.57; N, 5.39%. IR (KBr, cm^{-1}): 3245 s br, 2926 m, 1633 vs, 1601 vs, 1559 vs, 1450 s, 1372 m, 1302 s, 1188 vs, 1121 vs, 1090 vs, 1060 s, 771 m, 730 m, 626 m.

2.4.3. [Cu(Hhyforsa-unspenp)]ClO$_4$ (**3**)

Complex **2** (145 mg, 0.3 mmol) was dissolved in methanol (10 ml) by stirring for about 30 min, resulting in a clear deep blue colored solution. Subsequently a solution of unspenp (69 mg, 0.3 mmol) in methanol (1 ml) was added accompanied by a color change to dark green. The reaction mixture was stirred for additional 5 min leading to a green precipitate and the mixture was kept overnight at ambient temperature. During this period a green microcrystalline solid was formed, which was filtered off, washed with methanol and finally redissolved in acetonitrile. Slow diffusion of diethylether into this solution afforded, within two days, green prisms of **3** suitable for X-ray diffraction. The crystals were separated by filtration and dried *in vacuo* (Yield: 129 mg, 80%). M.p. >280 °C. *Anal.* Calc. for $C_{23}H_{23}ClCuN_4O_7$: C, 48.77; H, 4.09; N, 9.89. Found: C, 48.63; H, 4.12; N, 9.85%. IR (KBr, cm^{-1}): 3357 s br, 3284 m, 2985 w, 2939 w, 2901 w, 1632 s, 1602 vs, 1542 vs, 1450 s, 1391 m, 1357 m, 1332 s, 1260 s, 1122 vs, 1108 vs, 1073 s, 1050 m, 901 w, 625 m.

2.5. X-ray crystallographic studies

X-ray measurements were carried out on a Nonius Kappa CCD diffractometer using graphite monochromated Mo Kα radiation (λ = 71.073 pm) at 183(2) K. The crystallographic data are summarized in Table 1. Data were corrected for Lorentz and polarization effects, but not for absorption effects [20]. The structures were solved by direct methods with SHELXS97 and refined by full-matrix least-squares techniques against F_o^2 using SHELXL97 [21]. For **1** · MeOH the observed systematic absences suggest either of the tetragonal space groups *Pca*2$_1$ and *Pcca*. Attempts to solve the

structure in the centrosymmetric space group were unsuccessful. This led in agreement with intensity statistics to the non-centrosymmetric orthorhombic space group $Pca2_1$ as the final choice. The refinement afforded a Flack parameter [22] of about 0.3, which changed to about 0.7 upon inversion of the parameter set. Therefore, the final structure refinement was performed by assuming racemic twinning and refining a free variable for the ratio of the two racemic components. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms in structures of **1** · MeOH and **3** were included at calculated positions with fixed thermal parameters. For the structure of **2** the carbon-bounded hydrogen atoms were placed at calculated positions with fixed thermal parameters. All protic hydrogen atoms on oxygen atoms (water, phenol, and hydroxy) were found during structure solution and refined isotropically.

2.6. Computational details

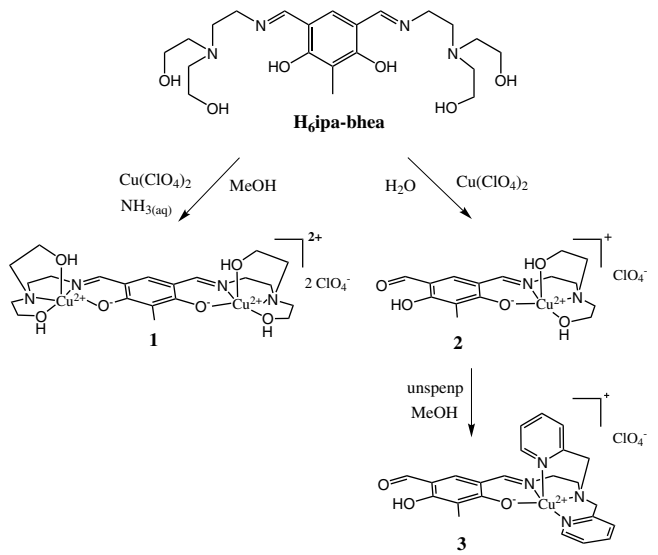
The density functional theory (DFT) according to the Kohn–Sham scheme was employed to study the magnetic properties of the complex. All-electron DFT calculations and geometry optimizations were performed with the quantum chemical program package TURBOMOLE [23]. As implemented in this program, the gradient corrected (GGA) functional BP86 [24] in combination with the resolution-of-the-identity (RI) density-fitting technique [25] and the hybrid functional B3LYP [26] were used together with the def2-TZVP basis set which is of split-valence triple-ζ quality with additional polarization functions on all atoms [27]. For structure optimization a geometry gradient norm of 3×10^{-4} hartree/bohr was used as convergence criterion.

The magnetic properties of the dinuclear complex **1** are analyzed according the phenomenological Heisenberg Hamiltonian $\hat{H} = -J\hat{S}_1\hat{S}_2$, where the coupling constant J is given by the energy difference between the relevant singlet and singlet states ($J = E_S - E_T$). Therefore, a negative value of J indicates antiferromagnetic coupling with a triplet ground state. The BS approach originally proposed by Noodleman was used to cope with the DFT inherent problem that the singlet state cannot be expressed by a single determinant [28]. In this formalism, the energy of the singlet state is computed on the basis of a single determinate of broken spin and space symmetry built up by localizing spin up and spin down electrons onto the two copper centers, which is not a spin eigenstate. Although the original formalism was based on spin projection to extract the singlet energy, it has been shown that this energy can be directly estimated from the energy of the BS solution (E_{BS}) without performing any spin projection according to [29]:

$$J = E_{BS} - E_T \quad (1)$$

This procedure is in accordance with the proposal of Perdew et al. [30], who suggested that the BS determinant is the correct solution of the Kohn–Sham equations for the singlet state. Consequently, the inclusion of Hartree–Fock (HF) type contributions, which are known to usually overestimate the relative stability of the triplet state, can improve the accuracy of the calculated values [29]. Therefore, we used the gradient corrected (GGA) functional BP86 and the hybrid functional B3LYP for comparison.

3. Results and discussion



3.1. Synthesis and characterization

The ligand H_6ipa-bhea was prepared by Schiff-base condensation of 2-methyl-4,6-diformylresorcinol (ipa) with two equivalents of *N,N-bis*-(2-hydroxyethyl)ethylenediamine (bhea). The H_6ipa-bhea ligand provides two equal pentadentate [N_2O_3] binding pockets, with a phenolate oxygen, an imine and amine nitrogen, and two oxygen atoms of the hydroxy ethyl groups as potential donors. The reaction with two equivalents of $Cu(ClO_4)_2 \cdot 6H_2O$ leads to either the expected dinuclear or a mononuclear copper(II) complex depending on the reaction conditions as illustrated in Scheme 2.

If the reaction is carried out in methanol in the presence of two equivalents aqueous ammonia the desired dinuclear copper(II) complex $[Cu_2(H_4ipa\text{-}bhea)](ClO_4)_2$ (**1**) is obtained. The compound can be isolated as green crystals of the corresponding solvent containing compound **1** · MeOH. As both phenolate groups are deprotonated, the bridging ligand coordinates the two copper(II) ions in its dianionic form.

On the other hand, the complexation reaction in water results in the partial hydrolysis of the ligand H_6ipa-bhea. Such a copper assisted ligand hydrolysis is not uncommon and reported in literature for different Schiff-base ligands during complexation reaction [31]. One of the imine side chains is hydrolyzed under addition of two equivalents of $Cu(ClO_4)_2 \cdot 6H_2O$ regenerating a free formyl group. Whereas the second binding pocket remains intact and is coordinating a copper(II) ion resulting in the formation of the mononuclear complex $[Cu(H_3hyforsa\text{-}bhea)]ClO_4 \cdot 2H_2O$ (**2**). Here the hydrolyzed ligand H_4hyforsa-bhea coordinates in its monoanionic form. Because of the excellent solubility of the byproduct, the copper(II) complex formed by the in situ generated primary tetradentate amine *N,N-bis*-(2-hydroxyethyl)ethylenediamine (bhea) and the second equivalent copper(II) perchlorate, compound **2** can be easily isolated analytical pure and in high yield. As no analytic evidence for the formation of the corresponding dinuclear complex **1** could be detected, the mononuclear complex **2** is the sole resorcinol containing product of this reaction.

As complex **2** contains a free formyl group, it should be accessible for an additional Schiff-base condensation potentially forming an unsymmetric double-Schiff-base ligand. Besides the well-known synthetic multistep and protecting group approaches to unsymmetric ligands [32], we have recently established a straightforward general synthesis of unsymmetric compartmental end-off

Scheme 2. Synthesis of copper(II) complexes with H_6ipa-bhea.

double-Schiff-base ligands based on a stepwise Schiff-base condensation of the free ligand system [33].

Following this line we reacted the mononuclear complex **2** with the tetradentate amine *N*,*N*-*bis*-(pyridin-2-ylmethyl)ethylenediamine (unspenp) in methanol. From this reaction the mononuclear complex [Cu(Hhyforsa-unspenp)]ClO_4 (**3**) could be isolated, which unexpectedly contained an altered coordination pocket for the copper(II) ion. Most likely the intended reaction takes place, but the newly generated nitrogen-rich coordination pocket has a higher affinity to coordinate the copper(II) ion and in turn the initial Schiff-base group is hydrolytically cleaved. The resulting mono-Schiff-base ligand H_2hyforsa-unspenp formed from ipa and unspenp, again contains a free formyl group and coordinates as a mono anionic ligand. Nevertheless, under appropriate conditions and/or with a suitable amine component both mononuclear complexes **2** and **3** seem to be likely candidates as metal containing building blocks for the directed synthesis towards unsymmetric homo- and heterodinuclear transition metal complexes.

All complexes were characterized by X-ray structural analysis, elemental analysis, and IR spectroscopy. The crystals of **1** · MeOH lose the co-crystallized methanol molecules upon drying whereas crystals of **2** remained intact with two water molecules per complex moiety. The IR spectrum of the ligand exhibits two strong characteristic bands at 1638 and 1588 cm^{-1}, which can be attributed to the stretching vibration of the imine moieties ($\nu_{C=N}$) and the bridging phenylene ring ($\nu_{C=C}$). Upon coordination to copper(II) ions in the dinuclear complex **1**, these bands are slightly shifted to 1621 and 1590 cm^{-1}. In both mononuclear complexes **2** and **3** the IR spectra contain an additional band in this region as a result of the $\nu_{C=O}$ stretching vibration of the formyl group. The corresponding bands are observed at 1633, 1601, and 1559 cm^{-1} in **2** and 1632, 1602, and 1542 cm^{-1} in **3**. These bands are shifted to somewhat lower frequencies due to a formation of intramolecular hydrogen bonds with the *ortho*-positioned phenol, typical for salicylaldehyde derivatives. Due to the coordination of the copper(II) ion through the second phenolate oxygen atom affecting the relevant resonances an unambiguous assignment is not possible. Moreover, for all three complexes further strong bands, broad and structured, are observed in the region at around 1100 cm^{-1} characteristic for stretching vibrations of unbound perchlorate counterions in the crystal lattice.

3.2. Description of the structures

3.2.1. [Cu_2(H_4ipa-bhea)](ClO_4)$_2$ · MeOH (**1** · MeOH)

The homodinuclear complex [Cu_2(H_4ipa-bhea)](ClO_4)$_2$ · MeOH (**1** · MeOH) crystallizes in the orthorhombic space group $Pca2_1$. The molecular structure and labeling scheme of the complex cation of **1** · MeOH is depicted in Fig. 1. Selected bond lengths and angles are listed in Table 2.

The coordination sites at both copper ions are occupied by the N_2O_3 donor sets of the doubly deprotonated [H_4ipa-bhea]$^{2-}$ ligand system. The metal centers are coordinated through the phenolate oxygen atoms O1/O4, the Schiff-base nitrogen atoms N1/N3, the amine nitrogen atoms N2/N4 as well as both hydroxy oxygen atoms O2/O5 and O3/O6. The coordination polyhedra around Cu1 can best be described as slightly distorted square pyramid with a τ value of 0.21 (τ = 0 for an ideal tetragonal pyramid, τ = 1 for an ideal trigonal bipyramid [34]). The tetragonal plane is formed by the oxygen atoms O1 and O2 as well as the nitrogen atoms N1 and N2 with bond lengths ranging from 186 to 203 pm. The copper ion is displaced from this plane by 18 pm towards the apical position, which is occupied by the oxygen atom O3 with a Cu–O distance of 226 pm. As compared to the bond lengths of the relevant equatorial donor atoms, the Cu–O3 bond length is significantly elongated, due to the typical Jahn–Teller distortion of the copper(II) ion. In contrast, the Cu2 center exhibits a distorted trigonal–pyramidal coordination environment with τ = 0.77. The trigonal plane is formed by the Schiff-base nitrogen atom N3 at a distance of 192 pm and the two weak oxygen donors O5 and O6 of the hydroxy ethyl groups at a distance of about 212 pm. The apical positions with a *trans* angle of 178° are occupied by the phenolate oxygen atom O4 and the amine nitrogen atom N4 at distances of 188 and 203 pm, respectively.

The dinuclear cation [Cu_2(H_4ipa-bhea)]$^{2+}$ of complex **1** crystallizes together with two perchlorate counterions and one methanol

molecule. The resulting hydrogen bonding for the cationic complex is depicted in Fig. 2. As the oxygen donors of the hydroxy ethyl groups are only weakly bound to the copper(II) ions, their actual coordination geometries seem to be influenced by the hydrogen bonding interactions with the methanol molecule. The relevant hydrogen bonding distances are well within the usually observed range [17,35,36]. Both perchlorate ions show a disorder of all oxygen atoms which is typical for unbounded and non-interacting tetrahedral counterions, and even not unexpected for cases with a terminal hydrogen bonding interaction like the perchlorate ion Cl1 (cf. Fig. 2) [37].

3.2.2. $[Cu(H_3hyforsa\text{-}bhea)]ClO_4 \cdot 2H_2O$ (**2**)

The molecular structure and atom labeling scheme of the complex cation $[Cu(H_3hyforsa\text{-}bhea)]^+$ is depicted in Fig. 3. The complex cation crystallizes together with one perchlorate counterion and two water molecules in the space group $P2_1/c$. One imine group of the initial double-Schiff-base ligand is hydrolyzed during complexation reaction while the second binding pocket remains intact and coordinates a copper(II) ion. The coordination geometry of the copper(II) ion is similar to the Cu1 center of complex **1**. The basal plane of the distorted square-pyramidal environment ($\tau = 0.28$) is formed by the donor atoms O1, O2, N1, and N2. The copper center is displaced from the basal plane by 15 pm towards the apical position occupied by the hydroxy oxygen atom O3. Selected bond lengths and angles are summarized in Table 3.

The phenol oxygen atom O4 remains protonated and is involved in an intramolecular hydrogen bonding interaction with the oxygen atom O5 of the free formyl group. Additional intermolecular hydrogen bonding of O5 with the oxygen atom O3 of the apical hydroxy ethyl side chain of an adjacent $[Cu(H_3hyforsa\text{-}bhea)]^+$ moiety leads to the formation of dimeric $[\{Cu(H_3hyforsa\text{-}bhea)\}_2]^{2+}$ units, as illustrated in Fig. 4. Moreover, within the dimeric units the phenylene rings are involved in π–π interactions at a distance of about

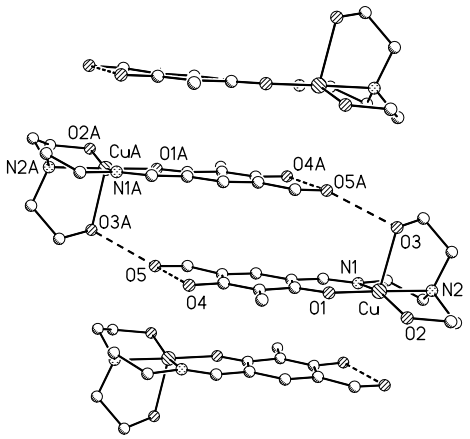

Fig. 4. Representation of the π–π stacking interactions of the complex cation $[Cu(H_3hyforsa\text{-}bhea)]^+$ of **2**. Dashed lines indicate hydrogen bonding interactions. Symmetry equivalent atoms are labeled with suffix A. Hydrogen atoms are omitted for clarity.

340 pm which is in the expected range [36,38]. Additional π–π stacking interactions with neighboring dimeric units lead to the formation of 1D chains running along the [1 0 0] direction.

These chains are further cross-linked through hydrogen bonding including both water molecules and the perchlorate counterion resulting in a 3D network depicted in Fig. 5. The water molecule O1W is involved in a hydrogen bonding network with the hydroxy group O2, the perchlorate counterion O11 and the second water molecule O2W. Furthermore, O2W is linked with the phenolate oxygen atom O1, the hydroxy group O3 and the perchlorate counterion O13. All hydrogen bonding interactions (see Fig. 5) are in the usually observed range [17,35,36]. It should be noted that the perchlorate counterion of **2** does not show any disorder, presumably due to the bridging connectivity within the hydrogen bonding network.

3.2.3. $[Cu(Hhyforsa\text{-}unspenp)]ClO_4$ (**3**)

The complex cation $[Cu(Hhyforsa\text{-}unspenp)]^+$ of complex **3** is depicted in Fig. 6. Selected bond lengths and angles are listed in Table 3. The copper center is penta-coordinated through the phenolate oxygen atom O1, the Schiff-base nitrogen atom N1, the amine nitrogen atom N2 and the two pyridine nitrogen atoms N3 and N4 of the ligand side chains. According to a distortion index of $\tau = 0.84$ the coordination environment at the copper center is best described as slightly distorted trigonal bipyramid. The trigonal plane is given by the nitrogen donor atoms N1, N3, and N4 with

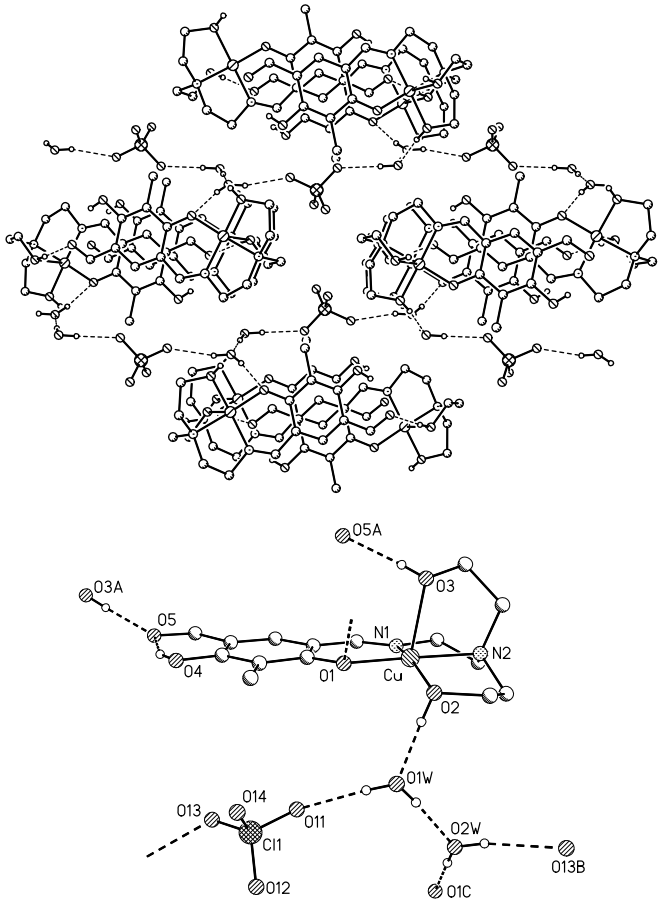

Fig. 5. Representation of the supramolecular structure of complex [Cu(H_3hyforsa-bhea)]$ClO_4 \cdot 2H_2O$ (**2**). Dashed lines indicate hydrogen bonding interactions. Symmetry equivalent atoms are labeled with the suffixes A to C. Pertinent distances (pm): O2···O1W 263, O3···O5 275, O4···O5 265, O1W···O11 288, O1W···O2W 270, O2W···O1C 295, O2W···O13B 301 pm.

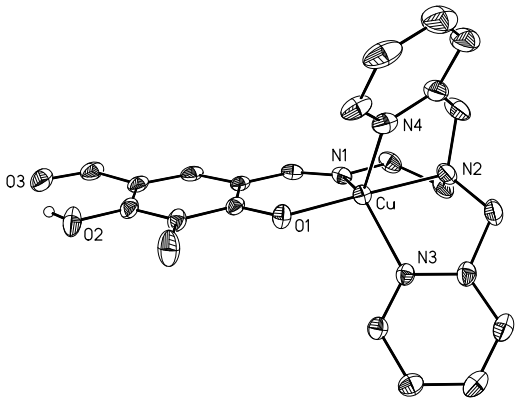

Fig. 6. Molecular structure of the complex cation of [Cu(Hhyforsa-unspenp)]ClO_4 (**3**). The carbon-bound hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at the 30% probability level.

bond lengths ranging from 196 to 215 pm. With a *trans* angle of 178° the apical positions are occupied by the phenolate oxygen atom O1 and the amine nitrogen atom N3 at distances of 189 and 204 pm, respectively. As in the case of complex **2**, the oxygen atom O3 of the free formyl group is involved in an intermolecular hydrogen bonding with the phenolic group O2.

In the crystal structure the complex cations assemble coplanar and built 1D chains via π–π stacking interactions along the [001] direction as depicted in Fig. 7. Two alternating π–π interactions are present leading to face-to-face pairs at a distance of about 360 pm which are in turn stacked with an offset along the pseudo C_2 axis at a π–π interaction distance of about 330 pm.

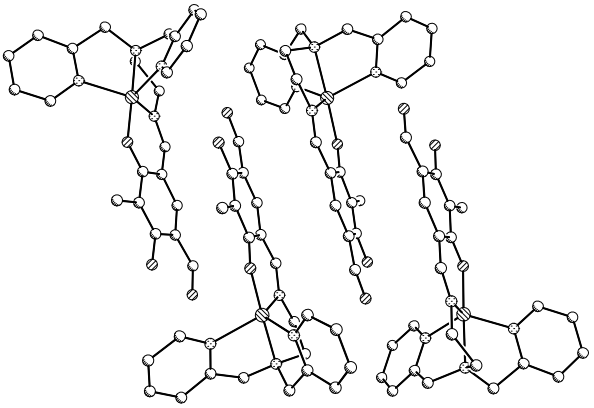

Fig. 7. Representation of the π–π stacking interactions of the complex cation $[Cu(Hhyforsa\text{-}unspenp)]^+$ of **3**. Hydrogen atoms are omitted for clarity.

4. Magnetochemistry

Variable temperature (2–300 K) magnetic susceptibility data collected on a polycrystalline sample of the dinuclear complex **1** are depicted in Fig. 8 as $\chi_M = f(T)$ and $\chi_M T = f(T)$. The experimental $\chi_M T$ value of 0.85 $cm^3\ K\ mol^{-1}$ at 300 K is in good agreement with the theoretical spin-only value expected for two independent copper(II) ions. Upon lowering the temperature $\chi_M T$ slightly decreases down to 0.74 $cm^3\ K\ mol^{-1}$ at about 50 K. Further lowering the temperature leads to a rapid decrease of $\chi_M T$ approaching values close to zero. This behavior is indicative for an antiferromagnetic exchange interaction between the two copper(II) centers with an $S = 0$ ground state mediated by the *meta*-dihydroxyphenylene bridge.

In order to interpret the magnetic properties the experimental $\chi_M T$ data has been analyzed using the Bleaney–Bowers equation for isolated dinuclear copper(II) complexes ($\hat{H} = -J\hat{S}_1\hat{S}_2$ with $S_1 = S_2 = 1/2$) [39]. The contribution of paramagnetic impurities (ρ) with $S = 1/2$ as well as the temperature independent paramagnetism (χ_{tip}) were also taken into account according to

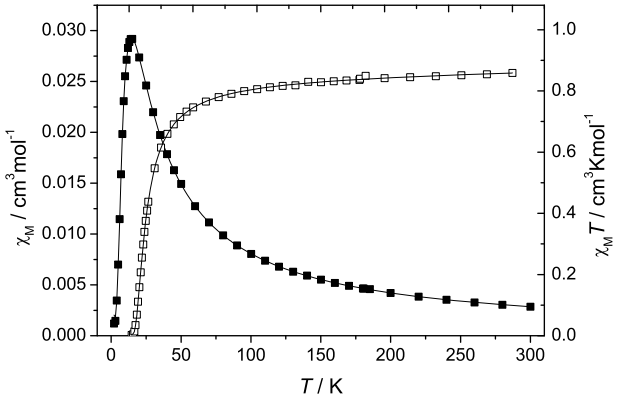

Fig. 8. Plot of the thermal dependence of χ_M (black filled squares, ■) and $\chi_M T$ (empty squares, □) for complex **1** with an applied magnetic field of 2000 Oe. The corresponding fit functions according to Eq. (2) are drawn as solid lines (for parameters see text).

$$\chi_M T = \frac{2N_A, g_{eff}^2, \beta^2}{k}\left[\frac{(1-\rho)}{[3+\exp(-J/kT)]}+\frac{\rho}{4}\right]+\chi_{tip}T \quad (2)$$

The best fit for complex **1** was obtained for the parameters $J = -16.38(4)\ cm^{-1}$, $g = 2.131(1)$, $\rho = 0.004(1)$, and $\chi_{tip} = 8.0(6)\cdot 10^{-5}\ cm^3\ mol^{-1}$ with a coefficient of determination of $r^2 = 0.99995$.

The obtained coupling constant for **1** is somewhat smaller than those observed for dinuclear copper(II) complexes with a double-Schiff-base ligands containing the same *meta*-dihydroxyphenylene-bridging unit but different carbonic acid hydrazides as amine components with J values ranging from -26 to $-28\ cm^{-1}$ [11]. There is another report describing magnetic properties of similarly bridged dinuclear copper(II) complexes with double-Schiff-base ligands of 4,6-diacetylresorcinol [12]. These complexes also show antiferromagnetic exchange interactions with reported Weiss constants θ ranging from -10 to -34 K depending on the amine component utilized. Regression of the Curie plot of **1** leads to a θ value of about -10 K, which is at the lower end of this reported range.

5. DFT calculations

In order to further elucidate the magnetic properties of the dinuclear copper(II) complex **1**, which contains a *meta*-phenylene linkage, we carried out DFT calculations, including the ligand explicitly, employing two density functionals (BP86 and B3LYP) in combination with the def2-TZVP basis set (see the Section 2 for details). The two density functionals particularly differ with respect to a special term in the functional and thus in the resulting potential, which is the so-called exact exchange admixture that has a systematic influence on the energy splittings between different spin states. While BP86 is a pure density functional with no exact exchange, 20% exact (Hartree–Fock type) exchange are introduced in the B3LYP density functional. The pure density functional BP86 was employed for structure optimization, as it can be combined with the computer-time-saving RI density-fitting technique. The structure optimization was carried out in the triplet state using the X-ray crystallographic molecular structure as a starting point.

The optimized structure is in reasonable agreement with the X-ray crystallographic structure, except for the relative orientation of the hydroxy ethyl groups of the two ligand compartments leading to a variation of the coordination geometry at the two copper centers. Therefore, the most difference with respect to the crystal structure is observed for the corresponding O–Cu–N angles and find its expression in converging τ values for the two copper centers Cu1 and Cu2 of 0.43 and 0.60, respectively (as compared to 0.21 and 0.77 for the crystal structure). This is in line with the interpretation, that the hydrogen bonding interactions in the crystal structure (cf. Fig. 2) influence the actually observed coordination geometry of the copper centers in the solid state structure.

The BS approach was utilized to calculate the singlet–triplet gap of the exchange-coupled dinuclear copper(II) complex (see Section 2). The calculations have been performed on the crystallographic structure of **1**. As expected, the exchange coupling constant $J = -90\ cm^{-1}$ calculated with the pure density functional BP86 is too large as compared to the experimental value. This is consistent with the generally observed overestimation of the stabilization of the singlet state relative to the triplet state by DFT methods. The inclusion of an appropriate amount of exact exchange is known to considerably improve the accuracy of the calculated values, with the hybrid functional B3LYP being a good choice [40]. Indeed, the calculation with the hybrid functional B3LYP yields an exchange coupling constants of $J = -19\ cm^{-1}$, which is in excellent agreement with the experimental value determined for **1**.

The magnetic orbitals as derived from the calculation of the BS state are depicted in Fig. 9. They have basically $d_{x^2-y^2}$ character with relevant contributions from the three donor atoms at each copper center which are approximately in the plane of the bridging *meta*-phenylene unit, namely the phenolate oxygen (O1/O4), the imine nitrogen (N1/N3), and the amine nitrogen atoms (N2/N4) of the H_6ipa-bhea ligand. This is somewhat surprising, as the two copper centers reveal large differences with respect to their coordination geometry (Cu1: distorted square pyramid $\tau = 0.21$; Cu2: distorted trigonal bipyramid $\tau = 0.77$). Together with the observed low contributions of the oxygen atoms of the hydroxy ethyl groups to the magnetic orbitals, this is indicative for a rather small influence of the latter on the electronic structure of the exchange-coupled dinuclear system. This is corroborated by the fact that the exchange coupling constant calculated for the optimized structure (Cu1: $\tau = 0.43$; Cu2: $\tau = 0.60$) is virtually unchanged with values of

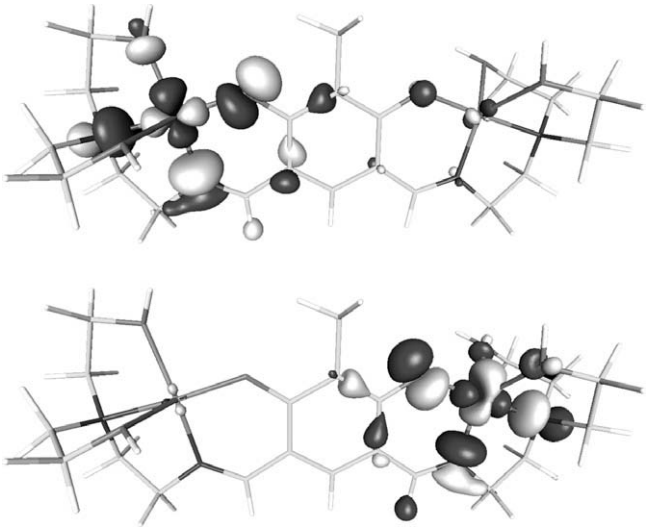

Fig. 9. Isodensity surfaces (0.05 au) of the magnetic orbitals for the Cu1 (top) and Cu2 (bottom) centers of complex **1** derived from BS calculation for the crystallographic geometry.

−96 and −21 cm^{-1} for the BP86 and B3LYP functionals, respectively.

Although the simple picture of a spin-polarization mechanism would predict a ferromagnetic ground state for a *meta*-phenylene bridged system, it has been shown by Bencini et al. that both spin-polarization and superexchange effects contribute to the overall coupling behavior in such systems [10]. In fact, for systems with the magnetic orbitals almost orthogonal to the bridging π system usually leads to an indirect spin-polarization pathway which is less effective than relevant superexchange contribution. This is consistent with the spin-density maps of the BS and triplet state depicted in Fig. 10. The spin-density population calculated for the triplet state is alternating along the bridging π system as a fingerprint of the indirect spin-polarization. Whereas for the BS state a considerable spin-delocalization into the bridging ligand is observed, which is indicative of an efficient superexchange through the *meta*-phenylene unit.

6. Conclusions

The new double-Schiff-base ligand H_6ipa-bhea was synthesized providing two *meta*-phenylene bridged pentadentate [N_2O_3] binding pockets. The reaction with copper(II) perchlorate depending on the reaction conditions leads to either the dinuclear complex [Cu_2(H_4ipa-bhea)](ClO_4)$_2$ (**1**) or the mononuclear copper(II) complex [Cu(H_3hyforsa-bhea)]$ClO_4 \cdot 2H_2O$ (**2**). In the case of **2** partial hydrolysis of the ligand is observed, leading to a complex with available salicylaldehyde like moiety providing a free formyl group for further condensation reactions. The reaction of **2** with *N,N-bis*-(pyridin-2-ylmethyl)ethylenediamine leads to the new mononuclear complex [Cu(Hhyforsa-unspenp)]ClO_4 (**3**) with a pentadentate [N_4O] binding pocket and again a salicylaldehyde moiety with free formyl group. The newly introduced nitrogen-rich binding pocket has a higher affinity towards the coordination of copper(II) ions. Under appropriate conditions together with suitable amine components both mononuclear complexes **2** and **3** seem to be likely candidates for metal containing building blocks in the directed synthesis of unsymmetric homo- and heterodinuclear transition metal complexes with gradually adjustable properties of the binding pockets. Further studies utilizing this concept for the synthesis of unsymmetric Schiff-base ligands and their homo- and heterodinuclear transition metal complexes are under investigation. Temperature-dependent magnetic measurements for complex **1** reveal antiferromagnetic exchange interactions between the two copper(II) ions through the central resorcinol bridge with an isotropic coupling constant of −16 cm^{-1}. The electronic structure of the *meta*-phenylene bridged dinuclear complex **1** has been investigated by broken symmetry DFT calculations. Due to the orthogonal orientation of the magnetic orbitals with respect to the bridging π system, which in this case by the way is independent of the actual coordination geometry of the copper centers, only an indirect spin-polarization pathway is present. Consequently, the more effective superexchange pathway through the *meta*-dihydroxyphenylene-bridging unit dominates and lead to the overall antiferromagnetic exchange coupling between the copper centers.

7. Supplementary data

CCDC 707275, 707276, and 707277 contain the supplementary crystallographic data for **1** · MeOH, **2**, and **3**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

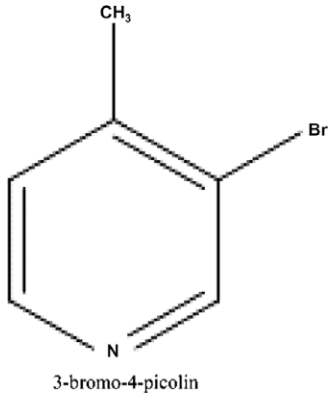
silver(I) and gold(I) compounds is the metallophilic interactions [1,5–8,11–14]. Metallophilicity is a closed-shell intermolecular interaction between silver(I) or gold(I) atoms [15]. The metallophilic interactions are comparable to hydrogen bond interactions [14,15]. In the case of gold(I) compounds, such attraction has been called an aurophilic interaction.

We report here that synthesis, crystal structures, and magnetic properties of a new bimetallic spin crossover coordination polymers with the formula $\{Fe^{II}(3\text{-bromo-4-picoline})_2[Au^{I}(CN)_2]_2\}_n$ (**1**). The new compound **1** has more complicated interactions as compared with the traditional Hofmann-like structures and interesting spin crossover behaviors.

2. Experimental



2.1. Materials

All the chemicals were purchased from commercial sources and used without any further purification.

2.2. Synthesis of the compound

2.2.1. $\{Fe^{II}(3\text{-bromo-4-picoline})_2[Au^{I}(CN)_2]_2\}_n$ (**1**)

In 10 mL of water, $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ (0.25 mmol, 98 mg) and $K[Au(CN)_2]$ (0.25 mmol, 72 mg) were dissolved. The vapor diffusion method using 3-bromo-4-picoline (Scheme 1) as a source of ligand molecules provided colorless polycrystalline crystals suitable for X-ray diffraction of **1** over a period of two days. **1**: Elemental *Anal.* Calc. for $C_{16}H_{12}Au_2FeN_6Br_2$: C, 21.40; H, 1.35; N, 9.36. Found: C, 21.54; H, 1.39; N, 9.27%. IR (nujol method, cm^{-1}):2156 (ν_{CN}).

3-bromo-4-picolin

Scheme 1. Molecular structure of the ligand.

2.3. X-ray crystal structural determinations

The crystal structure of **1** was determined using a BRUKER APEX SMART CCD area-detector diffractometer with monochromated Mo Kα radiation (λ = 0.71073 Å). The diffraction data was treated using SMART and SAINT, and absorption correction was performed using SADABS [16]. The structure was solved by using direct methods with SHELXTL [17]. All non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were generated geometrically. The low quality of crystal data of **1** at 90 K is due to the occurrence of a sharp phase transition that provokes a notable increase of the mosaicity of the crystals in the low temperature phase. Pertinent crystallographic parameters are displayed in Table 1 and selected metric parameters for the complex are presented in Table 2.

2.4. Magnetic measurements

The temperature dependence of the magnetic susceptibility of the complex in the temperature range of 2–300 K with a cooling and heating rate of 1 $Kmin^{-1}$ in a 1 kOe field was measured on a MPMS-XL Quantum Design SQUID magnetometer.

3. Results and discussion

3.1. Preparation and IR spectra

The reaction of an aqueous solution of $FeSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ containing two equivalents of $K[Au(CN)_2]$ with a vapor diffusion method using pyridine-derivative ligand, 3-bromo-4-picoline, afforded crystals of the 2D CN-bridged coordination compound $\{Fe^{II}(3\text{-bromo-4-picoline})_2[Au^{I}(CN)_2]_2\}_n$ (**1**).

The solid state IR spectra of **1** had C≡N bands at 2156 cm^{-1}, which is at a higher wavenumber than that of free $[Au(CN)_2]^-$ (2135 cm^{-1}), at room temperature. This suggests that the CN groups of $[Au(CN)2]^-$ act as bidentate bridging ligands.

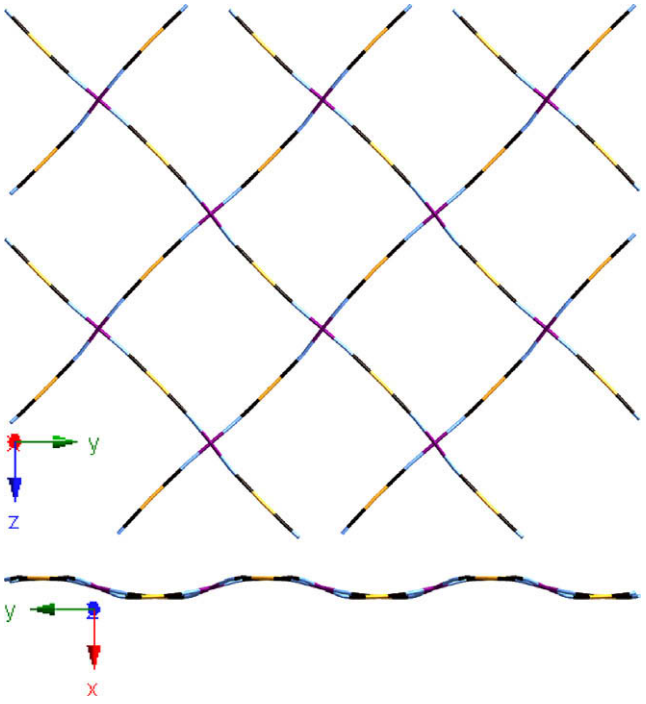

Fig. 1. The cylinder drawing, wave-shaped 2-D structure of **1** (90 K). The 2-D framework of **1** at 293 K is almost identical to that of **1** at 90 K. Consequently, we have used the same representation for these compounds. Atom code: Fe(purple), Au(yellow), N(blue), C(black). In this picture, hydrogen atoms and 3-bromo-4-picoline ligands are omitted for clarity. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

3.2. Crystal structure of **1** (293 K and 90 K)

Coordination compound **1** crystallized in the centrosymmetric space group $P2_1/c$ at 293 K and 90 K. Crystal structures of **1** (293 K) and **1** (90 K) are almost identical. Two-dimensional cyano-bridged corrugated framework of **1** is shown in Fig. 1. The two-dimensional frameworks are built-up in a stacked parallel arrangement. There is crystallographically one type of Fe^{II} ion which coordinates four N atoms from bidentate cyano substituents moiety in the equatorial positions. The complex has crystallographically two types of distinct almost linear $[Au(CN)_2]^-$ units (Fig. 2). The angles for **1** (293 K) and [**1** (90 K)] defined by C(13)–Au(1)–C(14) and C(15)–Au(2)–C(16) are 179.1(9) [178.7(13)] and 177.1(8) [176.5(14)], respectively. The pyridyl nitrogen ligation site at the two 3-bromo-4-picoline monodentated ligands coordinates in the axial positions of Fe(1) (Fig. 2). The two 3-bromo-4-picoline ligands in $[Fe^{II}(3\text{-bromo-4-picoline})_2][Au^{I}(CN)_2]$ are *transoid* conformations for Fe(1). The Fe···Fe distances in the Fe(1)–NC–Au(1)–CN–Fe(1) and Fe(1)–NC–Au(2)–CN–Fe(1) one-dimensional wave chain edges for **1** at 293 K [at 90 K] are 10.438 [10.254] and 10.450 [10.266] Å, respectively. Fe–N(1), Fe–N(2), Fe–N(3), Fe–N(4), Fe–N(5) and Fe–N(6) bond distances for **1** (293 K) and [**1** (90 K)] are 2.191(13) [2.137(18)], 2.218(16) [2.11(3)], 2.145(16) [2.05(3)], 2.180(17) [2.05(4)], 2.163(19) [2.04(3)] and 2.176(16) [2.08(3)] Å, respectively. These bond distances for **1** at 293 K and 90 K correspond to the excepted values for Fe^{II} 100% HS state and 50% HS 50% LS state respectively.

The interesting structural feature of **1** is that bilayer networks are formed by strong aurophilic interactions (Fig. 3). The Au···Au intermetallic short distances in the bilayers for **1** (293 K) and [**1** (90 K)] are 3.0455(11) [3.0098(19)] Å, less than the sum of the van der Waals radii of Au (3.32 Å). The Au···Au distance between two adjacent noninteracting layers is 7.205 Å for **1** (293 K) and

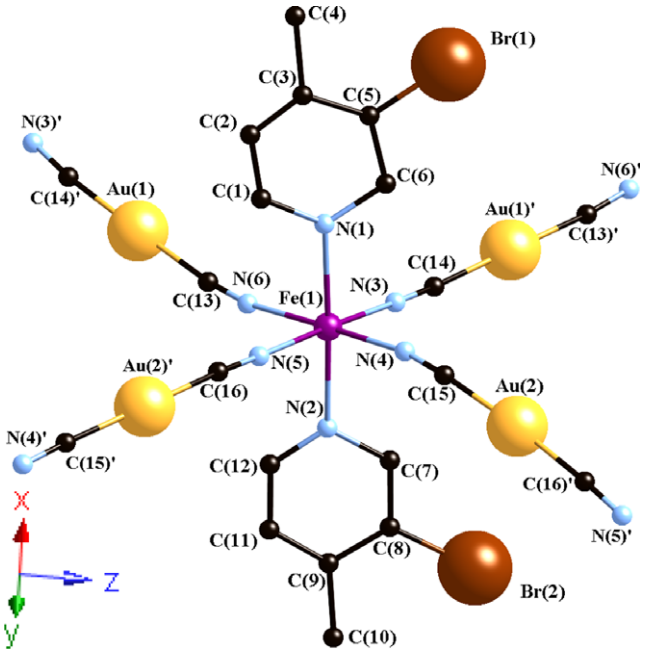

Fig. 2. Coordination structure of the Fe and Au ions in **1** (90 K) containing its asymmetric unit and atom numbering. The structure of **1** at 293 K is almost identical to that of **1** at 90 K. Consequently, we have used the same representation for these compounds. In this picture, hydrogen atoms are omitted for clarity. Atom code: Fe(purple), Au(yellow), N(blue), C(black), Br (brown). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

7.185 Å for **1** (90 K), respectively. Furthermore, intermolecular Au···Br and Br···Br distances in the complex are also significantly smaller than the sum of the van der Waals radii (3.61 and 3.90 Å) (Fig. 4). In particular, the Au(1)···Br(1) distance (3.51 Å (293 K) and 3.70 (90 K) Å) shows a strong interaction. The corresponding significant distances are gathered in Table 3.

3.3. Magnetic properties

$\chi_M T$ versus T plots, with χ_M being the molar magnetic susceptibility and T the temperature, for **1** are shown in Fig. 5. At room temperature, the magnetic behavior of the complexes **1** is characteristic of Fe(II) compounds in the high-spin state, $\chi_M T = 3.58$ and

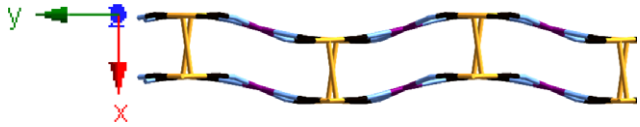

Fig. 3. Bilayer structure of **1** at 90 K with strong aurophilic interactions. In this picture, hydrogen atoms and 3-bromo-4-picoline are omitted for clarity. The structure of **1** at 293 K is almost identical to that of **1** at 90 K. Consequently, we have used the same representation for these compounds.

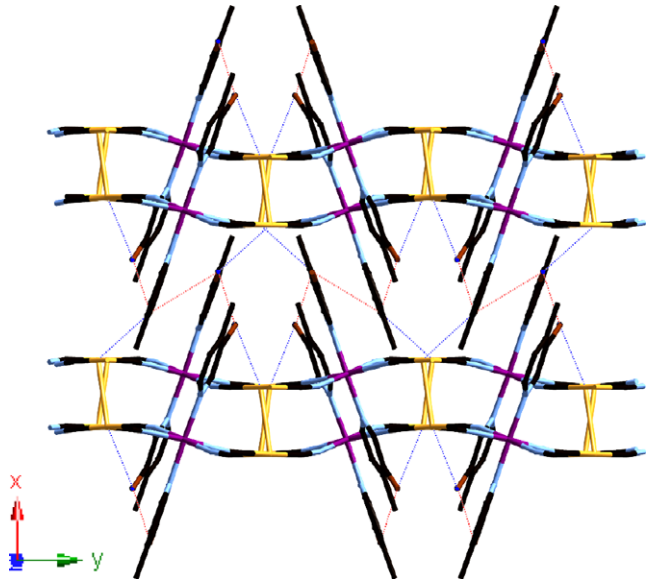

Fig. 4. Crystal packing showing the formation of a 3D supramolecular architecture by intermolecular Au···Br (blue dotted line) and Br···Br (red dotted line) interactions for **1** (90 K). In this picture, hydrogen atoms are omitted for clarity. The structure of **1** at 293 K is almost identical to that of **1** at 90 K. Consequently, we have used the same representation for these compounds. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Table 3
Selected intermolecular Au···Br and Br···Br distances for **1** (293 K and 90 K).

1 (293 K)	**1** (90 K)
Lengths (Å)	
Au(1)–Br(2):3.338	Au(1)–Br(2):3.291
Au(2)–Br(1):3.688	Au(2)–Br(1):3.590
Br(1)–Br(2):3.710	Br(1)–Br(2):3.561
Br(2)–Br(2):3.810	Br(2)–Br(2):3.757

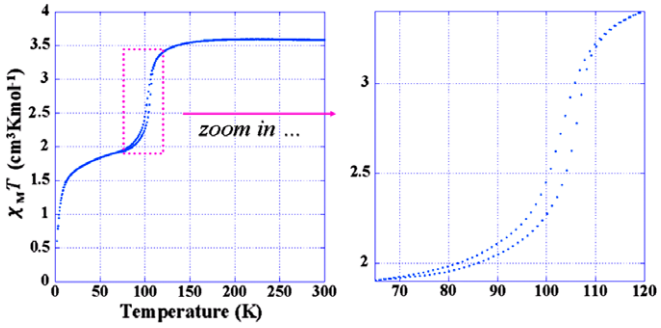

Fig. 5. Magnetic properties of **1**. $\chi_M T$ vs. T from 2 to 300 K.

the value of μ_{eff} is ($\mu_{eff} = 2.828\sqrt{(\chi_M T)}$) per one Fe^{II} ion at 300 K is 5.35 μ_B. The value for **1** is slightly higher than 4.90 ($=g\sqrt{(S(S+1))}$, $g = 2$, $S = 4/2$) that of a pure spin only system, whereas the values are similar to the μ_{eff} value at 300 K of other Hofmann-like spin crossover Fe^{II} compounds [3,4b,18b,18c]. Upon cooling, $\chi_M T$ remains almost constant down to 135 K; below this temperature, $\chi_M T$ undergoes a sharp decrease to around 50% conversion and the warming mode reveals the occurrence of a narrow hysteresis loop. The spin crossover behavior for this complex causes a reversible change of color from colorless to purple. The critical temperature for the cooling (T_c^{down}) and warming (T_c^{up}) modes are 107.3 and 110.9 K, giving an approximately 3.6 K hysteresis loop. The decrease in the value of $\chi_M T$ at lower temperatures is due to a typical behavior of zero-field splitting (ZFS) effects of the metallic Fe^{II} centers in the residual HS ($S = 2$) species.

4. Conclusions

In summary, we have prepared and characterized a new bimetallic spin crossover coordination polymer with the formula $\{Fe^{II}(3\text{-bromo-4-picoline})_2[Au^{I}(CN)_2]_2\}_n$ (**1**). The quasi-linear bidentate $[Au(CN)_2]^-$ unit connects octahedral Fe^{II} ions. As a result, these units assemble to construct huge $\{Fe^{II}_2[Au^{I}(CN)_2]_4\}$ rectangular mesh 2D network arrays which are slightly wave-shaped. The spaces between the 2D $Fe(-NCAuCN-Fe_{1/4})_4$ host frameworks are filled with the 3-bromo-4-picoline ligands. Intriguingly, these 2D layers are organized by pairs, in which strong binuclear aurophilic interactions hold the layers together. The Au···Au distance in the adjacent double layer is 3.0455(11) (293 K) and 3.0098(19) (90 K) Å. Moreover, Au···Br and Br···Br interactions would give rise to a three-dimensional supramolecular network. Similar Hofmann-like compounds $\{Fe(3\text{-Xpy})_2[M(CN)_2]_2\}$ (X = CN, F, Cl, Br, I) (M = Ag, Au) have already been reported [4c,7,18]. However, new complicated networks in **1** are unprecedented for Hofmann-like cyano-bridged coordination polymers.

From the measurements of the temperature dependence of the magnetic susceptibility, the profile of the magnetic behaviors of the complexes **1** includes a rapid 50 % spin transition with a narrow hysteresis loop. The spin crossover behavior of **1** is associated with the new complicated networks caused by Au···Au, Au···Br and Br···Br interactions.

This work shows that this new **1** may be a key material to develop Hofmann-like Fe(II) compounds, which have interesting magnetic properties such as spin-crossover phase transition and molecular magnetism.

Scheme 1. Synthesis of benzo-1,3-diselenole-2-thione derivative **6**.

reaction afforded 3,4-dibromobenzaldehyde **3** [6]. The aldehyde **3** was transformed to 2-(3,4-dibromophenyl)-1,3-dioxolane **4** to protect the formyl group for the following reactions. Poly(diselenide) **5** was prepared by the reaction between dibromo compound **4** and sodium diselenide in DMF (*N*,*N*-dimethylformamide) [7]. Reduction of polymer **5** with sodium tetrahydroborate, followed by the treatment of thiophosgene, afforded the key thione **6**.

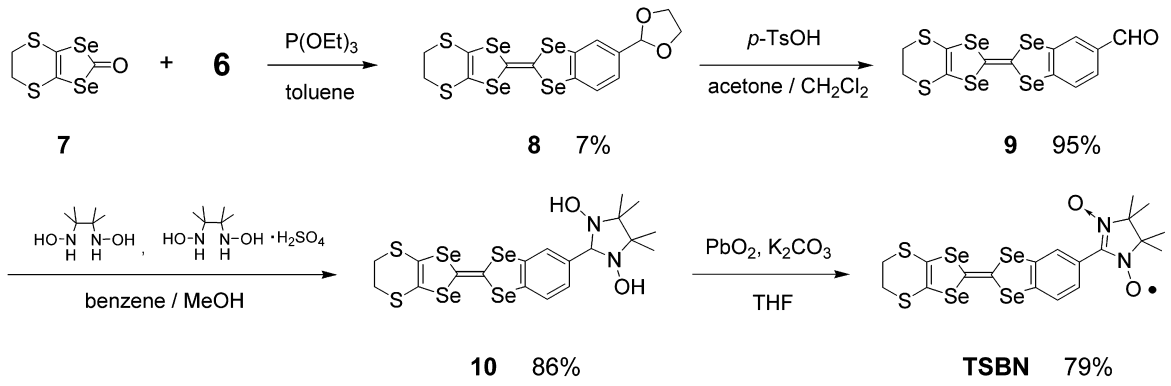
A cross-coupling reaction between thione **6** and 4,5-(ethylenedithio)-1,3-diselenole-2-one **7** was conducted in triethyl phosphite to obtain TSF-acetal derivative **8**. This acetal precursor **8** was hydrolyzed to give the formyl derivative **9**, which was reacted with 2,3-dimethyl-2,3-bis(hydroxyamino)butane in the presence of its sulfuric acid salt as a catalyst to afford cyclic bis(hydroxylamine) **10** as a radical precursor. The final product, **TSBN**, was obtained by the oxidation of precursor **10** with lead dioxide in a reasonable yield.

The ESR spectrum of **TSBN** in benzene solution showed quintet lines ($g = 2.0063$, $a_N = 0.73$ mT) which were assigned to the nitronyl nitroxide group. The magnetic susceptibility of **TSBN** was measured by a SQUID magnetometer. The temperature dependence of the χT value of sample was reproduced by the Curie–Weiss law; Curie constant and Weiss temperature were evaluated to be 0.372 emu K mol^{-1} and -0.21 K, respectively. These data supports that the radical unit is intact during the crystallization process.

2.2. Crystal structure of *TSBN*

Single crystals (black elongated plates) of **TSBN** · THF (tetrahydrofuran) were obtained by recrystallizaion from THF/hexane, and its crystal structure was determined by X-ray crystallography. The crystal data indicate that the crystal of **TSBN** · THF is isostructural to that of **ESBN** · THF. The molecular structure of neutral **TSBN** is shown in Fig. 1a. The nitronyl nitroxide plane is twisted from that of the benzoTSF with a small dihedral angle of 22.3(2)°, which suggests the presence of an effective intramolecular π–π interaction between the donor and radical sites. The crystal packing of **TSBN** is shown in Fig. 1b. The crystal of **TSBN** · THF belongs to an orthorhombic space group *Pbca*. The unit cell contains eight symmetrically related molecules, including THF. When the molecular arrangement in the crystal is viewed along the *b*-axis, short intermolecular chalcogen contacts between molecules A, B and C (related with A by the C_2 axis) are found to be 3.744(1), 3.653(1), 3.653(1) and 3.426(2) Å for Se3(A)···Se1(C), Se4(A)···Se2(B), S2(A)···Se4(B) and S2(A)···Se2(B), respectively (Fig. 2). Hence, the molecules form a sheet-like network within the *ac* plane through these intermolecular contacts, the network being separated from the adjacent ones by THF molecules and sterically-bulky radical moieties, as shown in Fig. 1b.

2.3. Electronic structure of *TSBN*



A cyclic voltammogram (CV) of **TSBN** was measured in a benzonitrile solution in the presence of 0.1 M tetrabutylammonium perchlorate as an electrolyte. Fig. 3a showed three reversible redox waves at 0.80, 0.93 and 1.13 V versus Ag/AgCl. In comparison with the redox potentials of acetal precursor **8** (0.79 and 1.05 V versus Ag/AgCl) and of phenyl nitronyl nitroxide (0.85 V versus Ag/AgCl), the first and third oxidation potentials of **TSBN** are assigned to the oxidation potentials of the TSF moiety, and the second oxidation potential of **TSBN** is assigned to the nitronyl nitroxide moiety, respectively. The one-electron oxidation of this donor radical is, therefore, considered to give rise to a reasonably stable cation diradical species.

Singly oxidized species of **TSBN** were generated by treatment with iodine in DMSO solution to show a set of ESR signals derived from a triplet species ($|D| = 2.5 \times 10^{-2}$ cm^{-1}, $|E| = 2.4 \times 10^{-3}$ cm^{-1}, $g_x = 2.0094$, $g_y = 2.0068$, $g_z = 2.0076$) at 4.2 K. The temperature dependence of signal intensity obeys the Curie law in the temperature range of 4.2–70 K, indicating that the triplet state is the ground state of **TSBN**$^{+\cdot}$.

The electronic structure of **TSBN** was calculated by DFT method (B3LYP/6-31G*), as shown in Fig. 3b. The orbital energy of SOMO(α) is lower than that of HOMO(α,β), supporting the CV data. In addition, the energy level of HOMO(α) is slightly lower than that of HOMO(β) because the β spin in HOMO is destabilized by the α spin in SOMO. The coefficients of SOMO are localized on the nitronyl nitroxide moiety, while those of HOMO are spread over the entire molecule. Due to this space-sharing nature of the relevant molecular orbitals, Hund rule in the MO level is expected to hold in the cation diradical (**TSBN**$^{+\cdot}$) which is formed by the removal of an electron from HOMO. Accordingly, **TSBN** is characterized by the spin-polarized electronic structure.

2.4. Magnetoresistance measurement of *TSBN*

Before preparing an ion-radical salt of **TSBN**, we examined a conducting property of the newly prepared **TSBN**. The conductivity of single crystal of neutral **TSBN,** measured by a four-probe method, was considerably low ($\sigma_{RT} < 10^{-9}$ S/cm). However, the neutral microcrystals of **TSBN,** which were mounted on interdigitated electrodes with a gap of 2 μm, exhibited a distinct nonlinear *I*–*V* characteristics ($I \propto V^m$,m = 11 ± 1) at 2 K, as shown in Fig. 4a. While the origin of the observed *I*–*V* characteristics is not clear at the present stage, the carrier injection into the sample from an electrode through a tunneling barrier at the boundary is conceivable as the reason for this nonlinear behavior. Such conduction behavior is known as a trapped-charge-limited conduction (TCLC), and it is frequently observed in *I*–*V* characteristics of organic EL devices [8].

Scheme 2. Synthesis of **TSBN**.

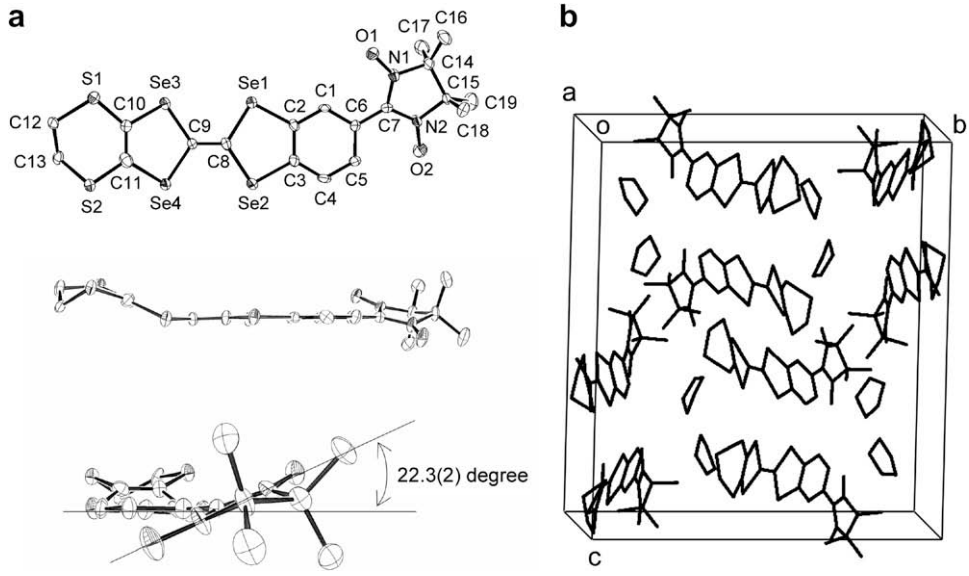


Fig. 1. (a) Ortep drawing of **TSBN** with thermal ellipsoids at the 50% probability level. Hydrogen atoms are omitted for clarity. (b) Molecular arrangement in the crystal of **TSBN**. Crystal structure of **TSBN** · THF: black elongated plate from THF/hexane, sized ca. 0.30 × 0.04 × 0.01 mm^3, $C_{23}H_{27}N_2O_3S_2Se_4$, MW = 759.43, orthorhombic, space group *Pbca* (No. 61), λ(Mo Kα) = 0.71070 Å, T = 113(2) K, a = 10.690(3), b = 21.044(5), c = 23.846(6) Å, V = 5365(2) Å^3, Z = 8, $D_{calc.}$ = 1.881 g cm^{-3}. Isotropic and anisotropic least-squares refinement (308 parameters) on 6102 merged reflections (R_{int} = 0.0648) converged at R_{all} = 0.0931 for all data; $R_1 > 2\sigma(I)$ = 0.0599 for 4370 observed data ($I > 2\sigma(I)$), GoF = 1.113.

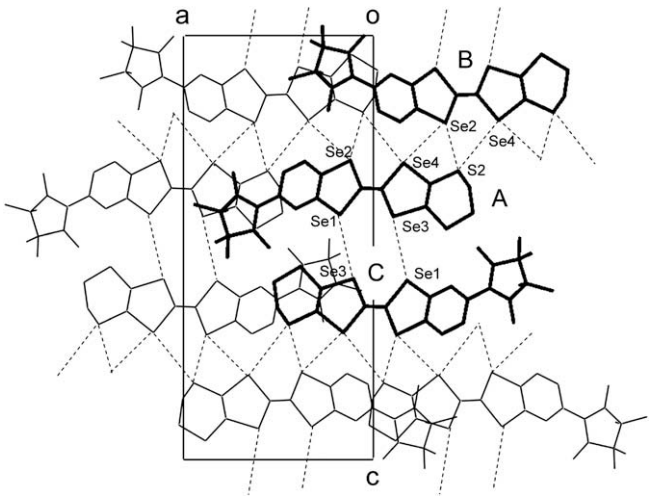

Fig. 2. The sheet-like network of **TSBN**. Molecular arrangement on the *ac* plane. THF molecules are omitted for clarity.

The magnetoresistance measurement of neutral microcrystals of **TSBN** using interdigitated electrodes was curried out with a constant bias voltage of 8 V, by applying a magnetic field between −5 and 5 T. As shown in Fig. 4b, the resistance of the sample decreased under 5 T at 2 K, exhibiting ca. −5% of the negative magnetoresistance, whereas the same sample showed ca. 1% of the positive magnetoresistance at 4 K. In contrast, acetal precursor **8** without carrying a localized spin did not exhibit the negative magnetoresistance effect in spite of showing a similar *I*-*V* characteristics. These results unequivocally suggest that the electron transportation is affected by localized spins of **TSBN** and the scattering by spins is suppressed by the application of an external magnetic field.

3. Conclusion

We have synthesized and characterized a novel TSF-based spin-polarized donor, **TSBN**. The neutral microcrystals of **TSBN** which were mounted on interdigitated electrodes showed distinct non-linear *I*–*V* characteristics at 2 K. Moreover, the sample exhibited the negative magnetoresistance (−5% at 2 K under 5 T). Therefore,

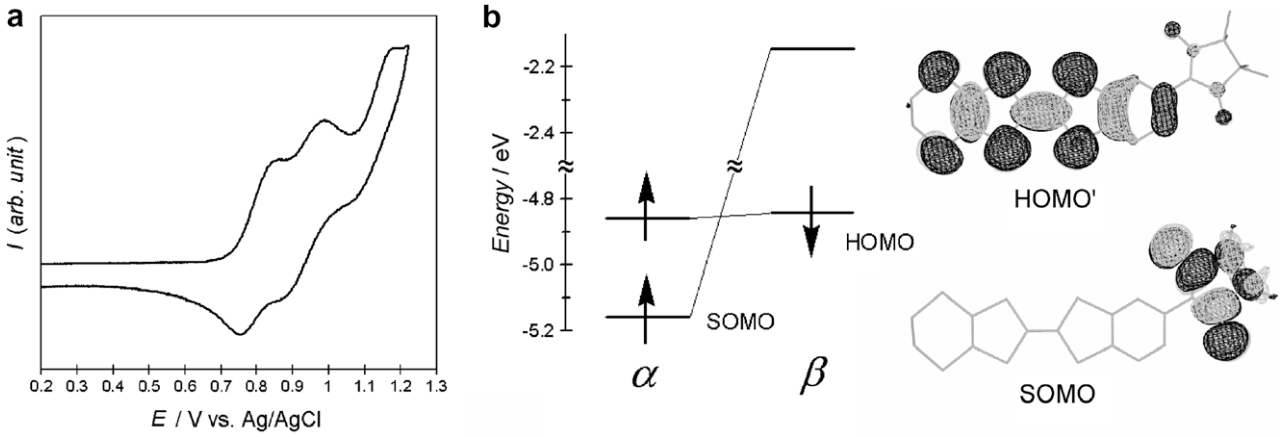

Fig. 3. (a) Cyclic voltammogram of **TSBN**. (b) Spin-polarized energy diagram of **TSBN** calculated by a DFT method (B3LYP/6-31G*). The space-sharing nature of HOMO′ and SOMO is also depicted; HOMO′ is derived from one-electron oxidation of HOMO.

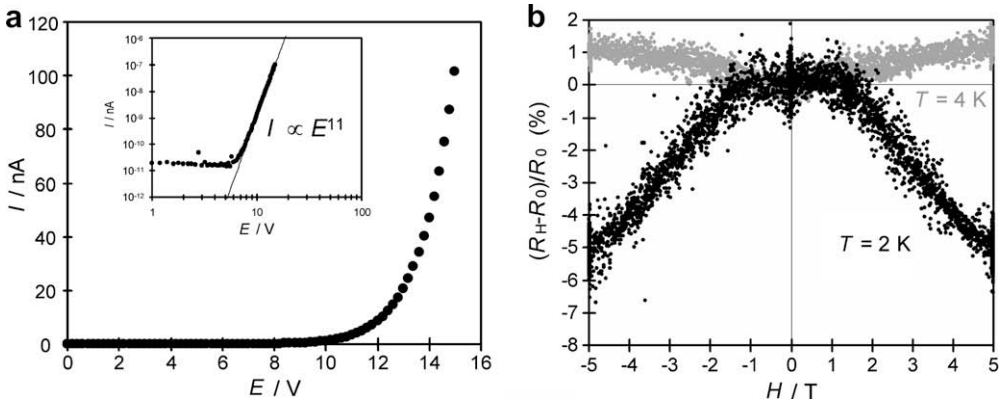

Fig. 4. (a) Nonlinear current–voltage characteristics of **TSBN** at 2 K. (b) Magnetic field dependence of magnetoresistance of **TSBN** at a bias voltage of 8 V.

TSBN would be expected to be an excellent component of an organic ferromagnetic metal, if the conductivity of an ion-radical salt is metallic.

4. Experimental

4.1. General

^{1}H NMR spectra and ^{13}C NMR spectra were recorded on a JEOL GSX-270 (270 MHz) spectrometer. The chemical shifts were reported in δ relative to tetramethylsilane (0.00 ppm). X-band ESR spectra were recorded on a JEOL JES-TE300 spectrometer. The microwave frequency was measured with an Advantest TR5212 counter, and the resonance magnetic field value was measured with the aid of a JEOL ES-FC5 NMR field meter. Elemental analyses were performed by the Center of Organic Elemental Analyses in the Department of Chemistry, Faculty of Science, The University of Tokyo. Cyclic voltammograms were recorded at room temperature with a platinum working electrode, using a BAS CV-50W Voltammetric analyzer. An Ag/AgCl electrode was used as the reference electrode. The temperature dependence of the magnetic susceptibility was measured using a Quantum Design MPMS-5XL SQUID magnetometer in a temperature range of 2–300 K. X-ray crystallographic analysis was carried out at 113 K on a Rigaku Mercury CCD X-ray diffractometer with graphite-monochromatized Mo Kα radiation (λ = 0.71070 Å; 50 kV, 250 mA). *I–V* characteristics and magnetoresistance measurement were carried out using a Quantum Design MPMS-5XL SQUID magnetometer and a Keithley 6487 picoammeter/voltage source. The geometry of the interdigitated Au electrodes with the area of 2×2 mm^2 is as follows: the thickness is 100 nm with 5 nm Ti as the adhesive layer, the gap is 2 μm, the electrode width is 2 μm. The electrodes are fabricated on a quartz substrate sized 5×10 mm^2.

Most of the reagents and solvents were purchased from Tokyo Chemicals Inc., Wako Chemicals Inc., Kanto Chemicals Inc. and Merck Inc. THF was distilled from sodium benzophenone ketyl under nitrogen atmosphere. All the other reagents were used as purchased without further purification. All reactions were monitored by thin-layer chromatography carried out on Merck 60F245 TCL plates. Column chromatography was performed on Merck Silicagel 60 with a mesh of 0.063–0.200 mm.

4.2. Synthesis

4.2.1. 5-(1,3-Dioxolan-2-yl)-1,3-benzodiselenole-2-thione (**6**)

To a suspension of selenium (5.21 g, 65.7 mmol) in 90 ml of DMF, sodium (1.85 g, 80.5 mmol) was added slowly at room temperature under nitrogen atmosphere, and the mixture was heated to 100 °C for 12 h. To the suspension, 2-(3,4-dibromophenyl)-1,3-dioxolane (**4**) (10.18 g, 33.1 mmol) in 10 ml of DMF was added, and the mixture was heated to 125 °C for 30 h. The mixture was cooled to room temperature, diluted with 100 ml of methanol, and poured into 500 ml of saturated aqueous sodium chloride.

The precipitates were filtered, washed with water and methanol, and dried *in vacuo* to afford 5.63 g of poly(diselenide) (**5**) as a orange-brown solid.

To a stirred suspension of poly(diselenide) (**5**) in 130 ml of THF and 100 ml of methanol, sodium tetrahydroborate (6.00 g, 0.159 mol) was added at 0 °C under nitrogen atmosphere. To the resultant homogeneous solution, thiophosgene (3.02 g, 26.3 mmol) was added at 0 °C under nitrogen atmosphere, and the mixture was stirred at 0 °C for 0.5 h. After the solvent was removed under reduced pressure, the residue was extracted with dichloromethane and the extract was washed with water. The separated organic layer was dried over sodium sulfate, filtered, and concentrated. The residue was purified by column chromatography (silica gel, eluent: dichloromethane-hexane (6:1)) to afford 1.21 g (10%) of **6** as a yellow solid.

^{1}H NMR (270 MHz, $CDCl_3$–TMS) δ 7.64 (d, J = 1.7 Hz, 1H), 7.52 (d, J = 8.2 Hz, 1H), 7.42 (dd, J = 1.7, 8.2 Hz, 1H), 5.82 (s, 1H), 4.15–4.01 (m, 4H). ^{13}C NMR (270 MHz, $CDCl_3$–TMS) δ 214.6, 146.4, 145.8, 137.6, 125.5, 125.0, 123.1, 102.5, 65.38. *Anal.* Calc. for $C_{10}H_8O_2SSe_2$: C, 34.30; H, 2.30. Found: C, 34.17; H, 2.38%.

*4.2.2. 2-[2-(5,6-Dihydro[1,3]diseleno[4,5-b][1,4]dithiin-2-ylidene)-1,3-benzodiselenol-5-yl]-1,3-dioxolane (**8**)*

A stirred mixture of thione-acetal **6** (0.95 g, 2.71 mmol), 4,5-(ethylenedithio)-1,3-diselenole-2-one (**7**) [9] (1.64 g, 5.43 mmol), 75 ml of triethyl phosphite and 75 ml of toluene was heated to 120 °C for 2 h under nitrogen atmosphere. After the solvent was removed under reduced pressure, the residue was suspended in 200 ml of chloroform and filtered. The solution was concentrated and subjected to column chromatography (silica gel, eluent: chloroform). The second red band gave 169 mg of red crude oil. The oil was purified by preparative GPC (eluent: chloroform) to afford 123 mg (7%) of **8** as an orange solid.

^{1}H NMR (270 MHz, $CDCl_3$–TMS) δ 7.42 (d, J = 1.7 Hz, 1H), 7.27 (d, J = 8.3 Hz, 1H), 7.23 (dd, J = 1.7, 8.3 Hz, 1H), 5.75 (s, 1H), 4.12–3.98 (m, 4H), 3.31 (s, 4H). *Anal.* Calc. for $C_{15}H_{12}O_2S_2Se_4$: C, 29.82; H, 2.00. Found: C, 29.76; H, 2.05%.

*4.2.3. 2-(5,6-Dihydro[1,3]diseleno[4,5-b][1,4]dithiin-2-ylidene)-1,3-benzodiselenol-5-carbaldehyde (**9**)*

To a solution of acetal **8** (95 mg, 0.16 mmol) in 10 ml of dichloromethane, 10 ml of acetone and small amount of *p*-toluenesulfonic acid monohydrate were added, and the mixture was stirred at room temperature for 2 h. The precipitates were filtered, washed with methanol and dried *in vacuo* to afford 84 mg (95%) of **9** as a golden brown solid.

^{1}H NMR (270 MHz, $CDCl_3$–TMS) δ 9.88 (s, 1H), 7.79 (d, J = 1.7 Hz, 1H), 7.60 (dd, J = 1.7, 8.0 Hz, 1H), 7.48 (d, J = 8.0 Hz, 1H), 3.33 (s, 4H). *Anal.* Calc. for $C_{13}H_8OS_2Se_4$: C, 27.87; H, 1.44. Found: C, 27.84; H, 1.54%.

*4.2.4. 2-[2-(5,6-Dihydro[1,3]diseleno[4,5-b][1,4]dithiin-2-ylidene)-1,3-benzodiselenol-5-yl]-4,4,5,5-tetramethylimidazolidine-1,3-diol (**10**)*

To a suspension of aldehyde **9** (70 mg, 0.13 mmol) in 42 ml of benzene-methanol (1:1), 2,3-dimethyl-2,3-bis(hydroxyamino)butane (93 mg, 0.63 mmol) and its sulfate (9 mg) were added, and the mixture was reflux for 3 days under nitrogen atmosphere. The precipitates were filtered, washed with methanol, and dried *in vacuo* to afford 74 mg (86%) of **10** as a pale orange solid.

^{1}H NMR (270 MHz, DMSO–d_6–TMS) δ 7.78 (s, 2H), 7.62 (s, 1H), 7.53 (d, J = 8.2 Hz, 1H), 7.29 (d, J = 8.2 Hz, 1H), 4.43 (s, 1H), 3.39 (s, 4H), 1.05 (s, 6H), 1.02 (s, 6H).

*4.2.5. 2-[2-(5,6-Dihydro[1,3]diseleno[4,5-b][1,4]dithiin-2-ylidene)-1,3-benzodiselenol-5-yl]-4,4,5,5-tetramethylimidazoline-3-oxide-1-oxyl (**TSBN**)*

To a stirred suspension of hydroxylamine **10** (80 mg, 0.11 mmol) in 25 ml of THF, potassium carbonate (0.7 g, 5.1 mmol) was added, and the mixture was stirred for 0.5 h. To the suspension, lead dioxide (0.7 g, 2.9 mmol) was added and vigorously stirred for 1.5 h. The reaction mixture was filtrated and the filtrate was concentrated. The residue was purified by column chromatography (silica gel, eluent: THF-hexane (1:1)) to afford 63 mg (79%) of **TSBN** as a dark green solid.

ESR (benzene) g = 2.0063, quintet, a_N = 0.728 mT (2 N). *Anal.* Calc. for $C_{19}H_{19}N_2O_2S_2Se_4 \cdot C_4H_8O$: C, 36.37; H, 3.58; N, 3.69. Found: C, 36.39; H, 3.67; N, 3.55%.
