ABSTRACT

Eight kinds of imidazolate-bridged copper(II) complexes were found to be classified into two categories from the magnetic properties. The crystal structures of $[Cu(L)(\mu\text{-im})]_n$ (Him = imidazole; L = nonane-4,6-dionate, 2,6-dimethylheptane-3,5-dionate) and $[Cu(L)(\mu\text{-im})]_4$ (L = nonane-4,6-dionate, 1-phenylbutane-1,3-dionate) were determined, to reveal that they consist of polymeric chains and tetranuclear cycles, respectively. Note that the nonane-4,6-dionate derivative gave the two phases. The Bonner–Fisher model (a one-dimensional antiferromagnetic chain model) was plausibly applied to $[Cu(L)(\mu\text{-im})]_n$ for the best fit, while a square model was to $[Cu(L)(\mu\text{-im})]_4$. The complexes with unknown crystal structures were also subjected to magnetic measurements, and the tetra- and polymeric structures could be clearly distinguished from each other by fitting the magnetic data to appropriate models. The exchange parameters were comparable for both series ($2J/k_B = -78$ to -97 K) because the structurally common bridges Cu–N(eq)–N(eq)–Cu afford comparable magnitudes of couplings.

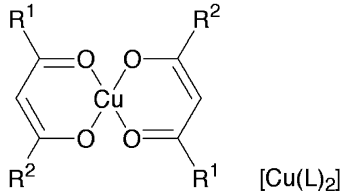
1. Introduction

Oligonuclear and polymeric copper(II) coordination compounds attract much attention in materials chemistry; for example, Kahn's magnetic material building-blocks [1], Yaghi and co-workers' metal-organic frameworks [2], and Lehn's supramolecular chemistry approach [3]. Some peculiar enzyme functions are based on oligonuclear copper clusters in laccase and ascorbate oxidase [4], where imidazolates and histidinates play a role of bridging ligands. Copper(II) imidazolate systems afford a variety of structures of self-assembled supramolecular coordination complexes, e.g., trinuclear cycles [5], tetranuclear cycles or [2 × 2] grids [6–10], discrete linear systems [11–16], polymeric chains [17,18], layers [19–21], and 3-D networks [19,22].

One of the authors (T.K.) reported imidazolate-bridged copper(II) complexes $[Cu(\beta\text{-diketonato})(\mu\text{-im})]_x$ (Him stands for imidazole) [23], but their crystal structures have not yet been reported. Generally, there are difficulties in preparing single crystals of polymeric coordination compounds, and also in characterizing compounds as infinite polymers or cyclic oligomers solely from the spectroscopic and elemental analyses. We will report here the crystal structures of $[Cu(dnbm)(\mu\text{-im})]_x$ as two phases, infinite polymer and cyclic tetramer (for structural formula, see below). Preliminary results have been reported in the previous letter [24], and the present report will further discuss the following issue. When the crystal structure analysis is unsuccessful owing to the poor crystallinity, their magnetic measurements would help prediction of crystal structures. The magnetic properties of the complexes whose crystal structures were unknown were analyzed according to the model of a polymer- or tetramer-based spin system.

2. Results



2.1. Preparation

The β-diketones (HL) employed are pentane-2,4-dione (Hacac), heptane-3,5-dione (Hdprm), nonane-4,6-dione (Hdnbm), 2,6-dimethylheptane-3,5-dione (Hdibm), 2,2,6,6-tetramethylheptane-3,5-dione (Hdpm), (1-phenylbutane-1,3-dione (Hbzac) and 1-(2-thienyl)butane-1,3-dione (Htac), and their copper(II) complexes are represented as $[Cu(L)_2]$ (Scheme 1).

Imidazolate-bridged copper(II) complexes $[Cu(L)(\mu\text{-im})]_n$ have been prepared in ethanol [23], and they were efficiently obtained in methanol as well. The reactions of $[Cu(L)_2]$ with two molar equiv. of imidazole gave polymeric complexes $[Cu(L)(\mu\text{-im})]_n$ ($[Cu(acac)(\mu\text{-im})]_n$ (**1p**), $[Cu(dprm)(\mu\text{-im})]_n$ (**2p**), $[Cu(dibm)(\mu\text{-im})]_n$ (**4p**) and $[Cu(dpm)(\mu\text{-im})]_n$ (**5p**)), and tetranuclear $[Cu(bzac)(\mu\text{-im})]_4$ (**6t**). However, $[Cu(dnbm)_2]$ gave tetranuclear $[Cu(dnbm)(\mu\text{-im})]_4$ (**3t**) instead of polymeric $[Cu(dnbm)(\mu\text{-im})]_n$ (**3p**) under these conditions. Complex $[Cu(dnbm)(\mu\text{-im})]_n$ (**3p**) was obtained by the reaction of $[Cu(dnbm)_2]$ with two molar equiv. of imidazole in ethanol. Complex $[Cu(tac)(\mu\text{-im})]_4$ (**7t**) prepared

according to the previous report [23] was used for the magnetic measurements. Here, the notation **p** and **t** denote polymeric and tetranuclear, respectively.

2.2. Molecular structures

Fig. 1 shows the molecular structure of **3p**. The complex consists of a helix, which has a dinuclear crystallographically independent unit [{Cu(dnbm)(μ-im)}$_2$] as a repeating motif. The intramolecular nearest-neighboring Cu1···Cu2 and Cu2···Cu1* distances are 5.9016(10) and 5.8973(11) Å, respectively. The Cu ions have a CuN_2O_2 coordination environment with two nitrogen atoms from two imidazolates and two oxygen atoms from a dnbm ligand. Selected geometrical parameters are summarized in Table 1. Although the geometry about the copper ions Cu1 and Cu2 is approximately square-planar, the O1–Cu1–N1, O2–Cu1–N4$^{\#}$, O3–Cu2–N3, and O4–Cu2–N2 bond angles are considerably smaller than ideal square-planar angle of 180°, being bent toward opposite directions to form a saddle structure. Namely, the coordination around the copper ions is considerably distorted from square-planar toward tetrahedral (d-SP). The Cu1 ion is located slightly above the mean basal O1–O2–N1–N4$^{\#}$ plane by 0.018(3) Å, and the Cu2 ion above the mean basal O3–O4–N2–N3 plane by 0.053(3) Å.

There are eight copper ions in a pitch along a crystallographic 4_2 screw axis in **3p**, contrary to the expectation from the cis configuration of the N–Cu–N coordination, which seems suitable for a fourfold axis involving four copper ions. It may be related to the d-SP structures at Cu1 and Cu2. The Cu1···Cu2···Cu1* angle (134.66(2)°) is considerably larger than, while the Cu2···Cu1*···Cu2* angle (89.64(2)°) is close to, the ideal right angle. The alternating irregular angles are responsible for the formation of a Cu_8-based chain and not a Cu_4-based helix or a tetrameric macrocycle.

Fig. 2 shows the molecular structure of **4p**. A dinuclear unit is crystallographically independent. A zig-zag chain structure is formed in a space group *C*2/*c*, which contains four copper units in a pitch. As the N–Cu–O angles of 150.37(15)–173.13(15)° indicate, Cu1 has an almost square planer structure (n-SP), while Cu2 has a d-SP one. The dislocations from the mean N_2O_2 planes are small (0.053(12) and 0.031(2) Å, respectively), owing to the saddle structures.

The Cu···Cu distances (5.8865(7) and 5.9239(7) Å) of **4p** are comparable with those of **3p**. The nearest-neighboring Cu···Cu···Cu angles are 102.925(10)° and 132.817(11)°, being suitable for such a zig-zag chain and quite different from that of **3p**. The steric bulkiness of peripheral substituents (*n*-propyl *versus* isopropyl) may affect the molecular packing in the crystal. Basically, the Cu–N and Cu–O distances as well as the N–Cu–N and O–Cu–O angles of **4p** are in typical ranges and just comparable to those of **3p**. Since the Cu–N bonds can rotate in solution, the geometry seems to be fixed in a suitable packing motif on crystallization. Thus, in comparison between **3p** and **4p**, the mutual geometry between neighboring units is different, which is caused by torsion around the Cu–N bonds.

We found that [Cu(dnbm)(μ-im)] has two phases, **3p** and **3t**. As Fig. 3 shows the molecular structure of **3t**, four Cu ions construct a rectangle arrangement affording a [2 × 2]-molecular grid. A half of the molecule of **3t** is crystallographically independent owing to centrosymmetry in a space group $P\bar{1}$. The intramolecular Cu1···Cu2 and Cu1···Cu2† distances are 5.8694(7) and 5.8933(10) Å, respectively. The Cu2†···Cu1···Cu2 and Cu1···Cu2···Cu1† angles are 89.951(12)° and 90.049(12)°, respectively.

As for the CuN_2O_2 coordination environments in **3t**, the O3–Cu2–N3† and O4–Cu2–N2 are much smaller than the angle of 180°, and, giving saddle-type distortion. Such an out-of-plane deformation has also been reported in the imidazolate-bridged Cu_4 macrocyle [8]. The coordination around the Cu1 ion is n-SP, while Cu2 is d-SP. This finding seems to be similar to that of the bisimidazolato copper(II) compound possessing a d-SP/n-SP–mixed tetranuclear framework. [26]. The dislocations of Cu1 and Cu2 ions are small (0.049(3) and 0.082(3) Å, respectively) from the mean basal N_2O_2 planes, owing to the saddle structures. As the side view (Fig. 3b) shows, the two basal planes are slightly canted with each other by 7.7(1)°.

Fig. 4 shows the molecular structure of **6t**. The refinement was unsatisfactory because **6t** gave only tiny crystals. Large standard deviations remained and thermal displacement factors were somewhat unrealistic for several carbon atoms. However, the *R* factors were decreased to be relatively small (ca. 0.06), and we can safely conclude that **6t** has a tetranuclear macrocyclic structure, or a molecular [2 × 2] grid, in a space group $P\bar{1}$. A dinuclear unit is crystallographically independent. The nearest-neighboring Cu···Cu···Cu angles are nearly 92° and 88°. The molecular structure of **6t** is almost identical to that of **3t** except for the peripheral substituents, and furthermore the molecular packings are also similar to each other in the comparable crystal lattices.

2.3. Magnetic properties

We measured magnetic susceptibilities (χ_{mol}) of polycrystalline specimens of the present compounds on a SQUID magnetometer. The X-ray diffraction study revealed the crystal structures of **3p**, **4p**, **3t**, and **6t**, and we will check the consistency between the structure and magnetic properties. Fig. 5a and 5b show the χ_{mol} versus *T* plots for polymeric **3p** and **4p**, respectively, on the basis of a copper(II) ion.

The χ_{mol} value of **3p** was increased on cooling from 300 K, reached a broad maximum around 60 K, and gradually decreased. This behavior clearly indicates the presence of dominant antiferromagnetic coupling. An extrapolation of the χ_{mol} curvature to 0 K seems to give a non-zero χ_m intercept. Usually such behavior is related with the infinite Heisenberg $S = 1/2$ antiferromagnetic chain, as originally predicted by Bonner and Fisher [27], and so far confirmed by many experiments [28]. Cyclic $S = 1/2$ antiferromagnetic clusters having even number of the spin sources would show null χ_{mol} at $T \rightarrow 0$ K. Thus, the non-zero χ_{mol} at $T \rightarrow 0$ K is regarded as a fingerprint of infinite chain structures. On further cooling, the χ_{mol} value of **3p** was further decreased with a turning point around 10 K. The origin of this anomaly is not clear at present, but might be explained in terms of a spin-Peierls transition [29]. Namely, a strong singlet–dimer formation takes place to reduce drastically the magnetic susceptibility. To estimate the exchange coupling within a chain, we used the data above 15 K. Assuming the

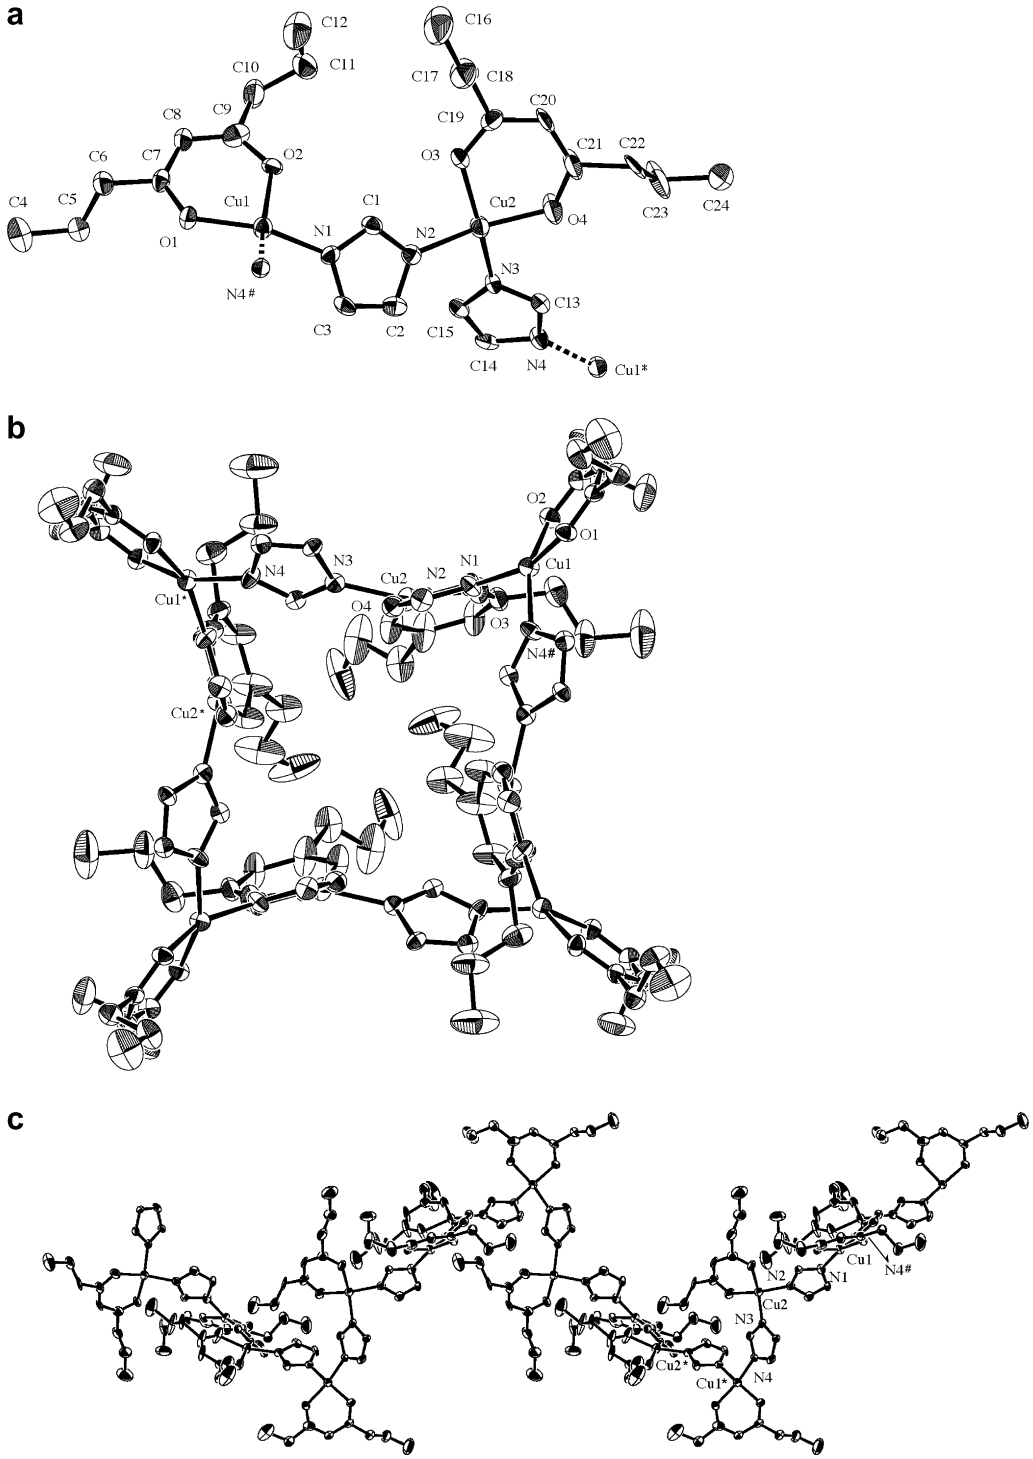

Fig. 1. X-ray crystal structure of $[Cu(dnbm)(\mu\text{-im})]_n$ (**3p**). (a) Crystallographically independent unit. Only a major conformation is shown for the C23–C24 portion. Thermal ellipsoids are drawn at the 50% probability level. Hydrogen atoms are omitted. (b) Top and (c) side views of a chain. Eight repeating units are drawn. Symmetry operation codes of $*$ and # are $-y$, $-1/2+x$, $-1/2+z$ and $1/2+y$, $-x$, $1/2+z$, respectively.

equally-spaced $S = 1/2$ magnetic chain and the Heisenberg spin Hamiltonian as $H = -\Sigma 2JS_i \cdot S_{i+1}$, we applied the following expression [27] with $x = |J|/k_BT$:

$$\chi_{mol} = \frac{N_A\mu_B^2 g^2}{k_B T}\,\frac{0.25 + 0.14995x + 0.30094x^2}{1.0 + 1.9862x + 0.68854x^2 + 6.0626x^3}. \quad (1)$$

The best fit gave $-89.8(7)$ K with $g = 2.04(2)$ for **3p**. According to the Bonner–Fisher analysis, T_{max} at which χ_{mol} shows a rounded maximum is simply related with J as expressed by Eq. (2) [27]. The χ_m peak position around 60 K for **3p** agrees well with the calculated J value:

$$k_B T_{max}/|J| = \text{ca. } 1.28. \quad (2)$$

Similarly, **4p** exhibited a Bonner–Fisher-type behavior (Fig. 5b). However, in sharp contrast to the case of **3p**, the χ_{mol} value of **4p** turned to increase again below 10 K, suggesting a slight contamination with Curie impurity. We analyzed the experimental data using the Bonner–Fisher model plus a Curie contribution (Eq. (3)).

[a] N4 is a symmetry-related equivalence with $-y, -1/2+x, -1/2+z$.
[b] N4 is a symmetry-related equivalence with $1/2-x, -1/2+y, 3/2-z$.
[c] N4 is a symmetry-related equivalence with $1-x, 2-y, -z$.

$$\chi_{mol} = \frac{N_A \mu_B^2 g^2}{k_B T} \frac{0.25 + 0.14995x + 0.30094x^2}{1.0 + 1.9862x + 0.68854x^2 + 6.062x^3} + \frac{C_{imp}}{T}. \quad (3)$$

The best fit gave $2J/k_B = -93.1(6)$ K with $g = 2.129(5)$ and $C_{imp} = 0.00695(4)$ cm^3 mol^{-1} for **4p**. The obtained J is very close to that of **3p**, despite of the different helix motives.

Although the crystal structures of **1p**, **2p**, and **5p** are unknown, we measured their magnetic susceptibility to predict the crystal structures. Fig. 6 shows the results of them. They showed a broad maximum and non-zero χ_{mol} at $T \to 0$ K. This behavior strongly suggests that they are antiferromagnetically correlated infinite chains, just like **3p** and **4p**. There also were Curie tails. The Bonner–Fisher model (i.e., Eq. (3)) was applied, giving $2J/k_B = -96(2)$ K, $g = 2.01(4)$, and $C_{imp} = 0.00725(9)$ cm^3 K mol^{-1} for **1p**, $2J/k_B = -96.9(3)$ K, $g = 2.09(2)$, and $C_{imp} = 0.0086(2)$ cm^3 K mol^{-1} for **2p**, and $2J/k_B = -85(1)$ K, $g = 2.13(2)$, and $C_{imp} = 0.00232(8)$ cm^3 K mol^{-1} for **5p**. The calculated curves well reproduced the experimental data (solid lines in Fig. 6). Thus, we assume that they would be chains.

The content of the Curie impurity varied from 0.6% to 2% depending on the specimens investigated here, but the coupling parameters are close to each other (from −85 to −97 K for **1p**–**5p**). This finding supports the assumption that the structurally common bridges Cu–N(eq)–N(eq)–Cu afford comparable magnitudes of couplings. They largely depend on the coordination sites, equatorial and axial, where the nitrogen atoms are coordinated [30].

The χ_{mol} versus T pots of tetrameric **3t** and **6t** (Fig. 7) exhibited a distinctly different feature from those of **3p** and **4p**. Namely, zero χ_{mol} values are suggested at $T \to 0$ K. As for **3t**, the χ_{mol} value increased on lowering temperature and reached a maximum around 55 K. After that the χ_{mol} value turned to decrease somewhat steeply toward $\chi_{mol} = 0$ cm^3 mol^{-1}. A Curie impurity was included, as indicated with a sharp upturn at the lowest temperature region.

A square model involving four $S = 1/2$ spins leads to the Heisenberg spin Hamiltonian as $H = -2J(S_1 \cdot S_2 + S_2 \cdot S_3 + S_3 \cdot S_4 + S_4 \cdot S_1)$. The molar magnetic susceptibility can be written as Eq. (4) [6,7,10] by applying Kambe's vector coupling method [31] and the van Vleck equation:

$$\chi_{mol} = \frac{N_A \mu_B^2 g^2}{k_B T} \frac{2 + 5\exp(2J/k_B) + \exp(-2J/k_B)}{7 + 5\exp(2J/k_B) + 3\exp(-2J/k_B) + \exp(-4J/k_B)} + \frac{C_{imp}}{T}. \quad (4)$$

A Curie impurity term was added. The experimental data of **3t** were fitted to Eq. (4) to give $2J/k_B = -81.0(2)$ K, $g = 2.061(2)$, and

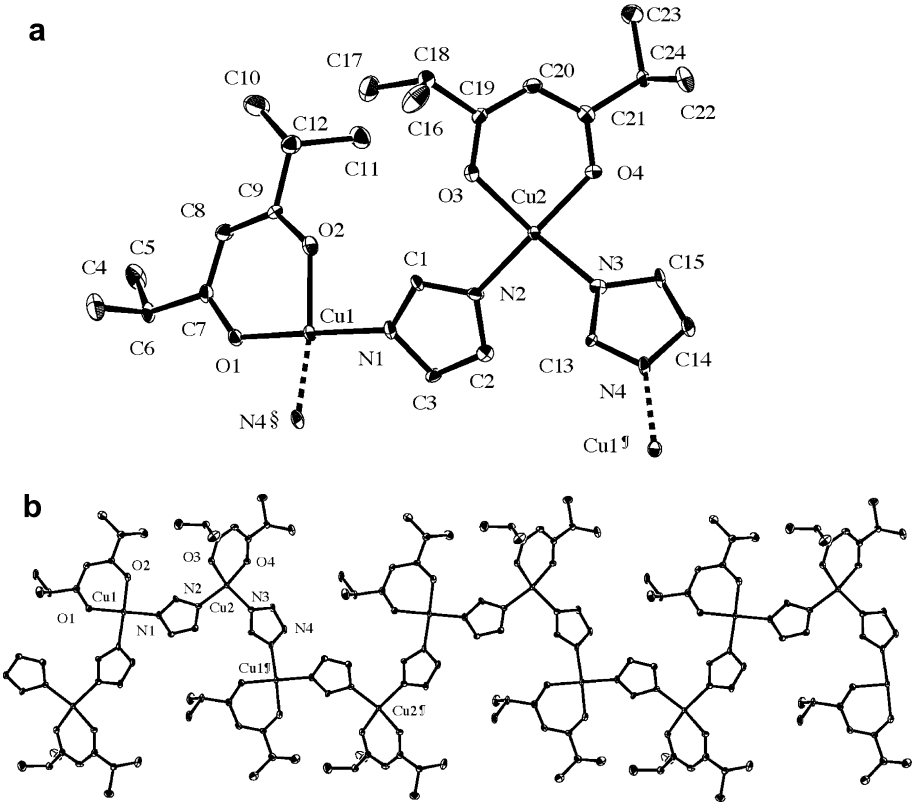

Fig. 2. X-ray crystal structure of [Cu(dibm)(μ-im)]$_n$ (**4p**). (a) Crystallographically independent unit. Thermal ellipsoids are drawn at the 50% probability level. Hydrogen atoms are omitted. (b) Side views of a chain. Six repeating units are drawn. Symmetry operation codes of § and ¶ are $1/2-x, -1/2+y, 3/2-z$, and $1/2-x, 1/2+y, 3/2-z$, respectively.

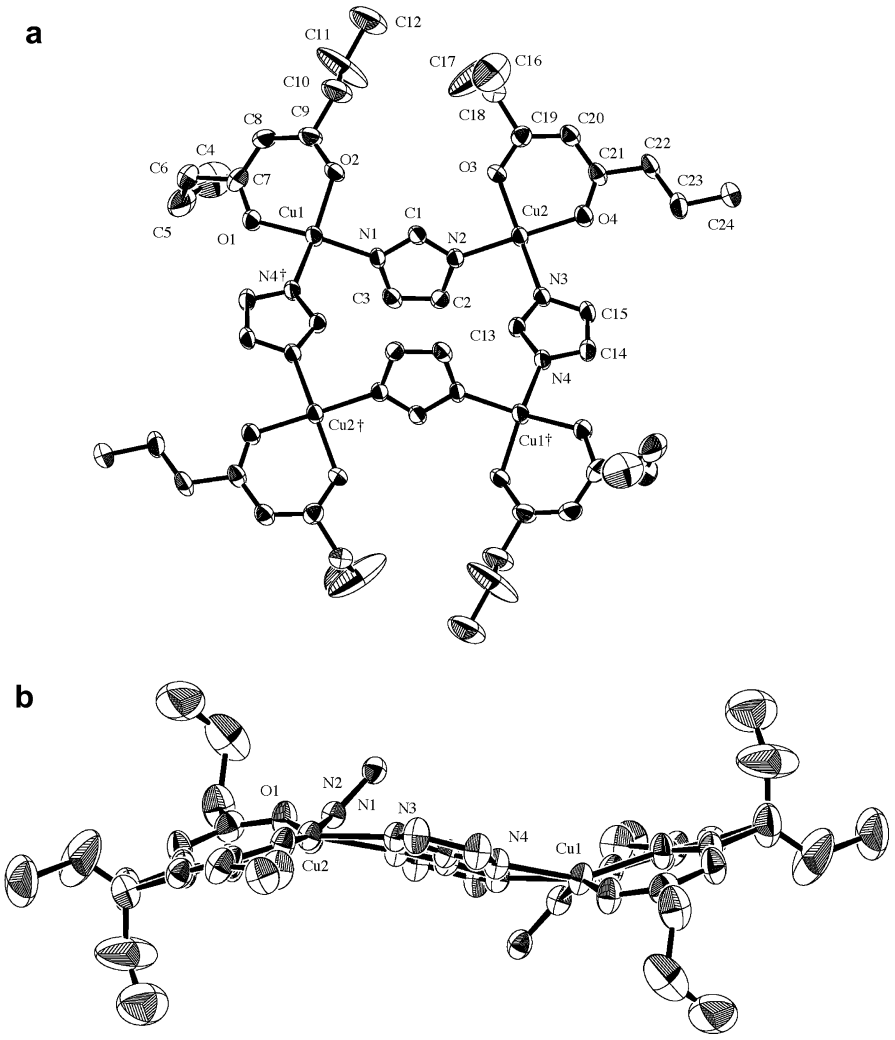

Fig. 3. X-ray crystal structure of [Cu(dnbm)(μ-im)]$_4$ (**3t**). (a) Top and (b) side views. Thermal ellipsoids are drawn at the 30% probability level. Hydrogen atoms are omitted. Symmetry operation code of † is $1-x, 2-y, -z$.

C_{imp} = 0.0203(2) cm^3 K mol^{-1}. The dotted line in Fig. 7a implies the first term in Eq. (3) after the subtraction of the Curie term. This line approaches to 0 cm^3 mol^{-1} at $T \rightarrow 0$ K.

The data of **6t** were similarly analyzed (Fig. 7b). The data on **6t** were fitted to Eq. (4) and the parameters were optimized as: $2J/k_B = -78(1)$ K, $g = 2.13(2)$, and $C_{imp} = 0.00662(8)$ cm^3 K mol^{-1}. The J value is very close to that of **3t**.

The crystal structure of **7t** is unknown, but we measured its magnetic susceptibility (Fig. 7b). The data on **7t** were also well fitted to Eq. (4) rather than Eq. (3). The molecular structure was suggested to be a square tetramer. The parameters were optimized as: $2J/k_B = -85.0(8)$ K, $g = 2.27(1)$, and $C_{imp} = 0.00230(6)$ cm^3 K mol^{-1}. The calculated curves well reproduced the experimental data. Thus, we predict that **7t** would consist of a cyclic tetramer.

3. Discussion

3.1. Synthesis

Complexation reactions of [Cu(L)$_2$] with imidazole are very sensitive to the nature of the β-diketonato ligand as well as to the reaction conditions, sometimes giving different products depending upon the solvent used. For convenience, [Cu(L)$_2$] can be classified into [Cu(L^1)$_2$], [Cu(L^2)$_2$], and [Cu(L^3)$_2$] (HL^1, HL^2, and HL^3 stand for aliphatic β-diketones, aroyl- or hetaroylacetones and fluorinated β-diketones, respectively).

The reactions of [Cu(L^1)$_2$] and [Cu(L^2)$_2$] with two molar equiv. of imidazole in methanol or ethanol gave polymeric and tetranuclear complexes ([Cu(L^1)(μ-im)]$_n$ and [Cu(L^2)(μ-im)]$_4$), respectively. The [Cu(dnbm)$_2$] case is exceptional. A mixture of [Cu(dnbm)$_2$] with two molar equiv. of imidazole gave **3t** under the same conditions. On the other hand, when a mixture solution was concentrated gradually on heating, yielding **3p** (see Section 5).

Complexation reactions of [Cu(L)$_2$] with pyrazole gave different products. The complexes [Cu(L^1)$_2$] afforded di- or tetranuclear complexes, while [Cu(L^2)$_2$] afforded pyrazolate-bridged complexes, 1:1 and/or 1:2 adducts [32]. Furthermore, [Cu(L^1)$_2$] afforded different products depending upon the solvents used. By successive addition of imidazole, [Cu(acac)$_2$] gave no isolable imidazolate complex in chloroform [25], while gave **1p** instead of the imidazolate complex in ethanol or methanol [23]. It has been reported that [Cu(L^3)$_2$] such as [Cu(hfac)$_2$] (Hhfac stands for 1,1,1,5,5,5-hexafluoropentane-2,4-dione) afforded 1:1 and/or 1:2 adducts in chloroform because of their stronger coordination ability [25].

3.2. Crystal structures

Chaudhuri et al. prepared cyclic tri- and tetranuclear copper(II) complexes [5,6], where non-substituted imidazolate was utilized

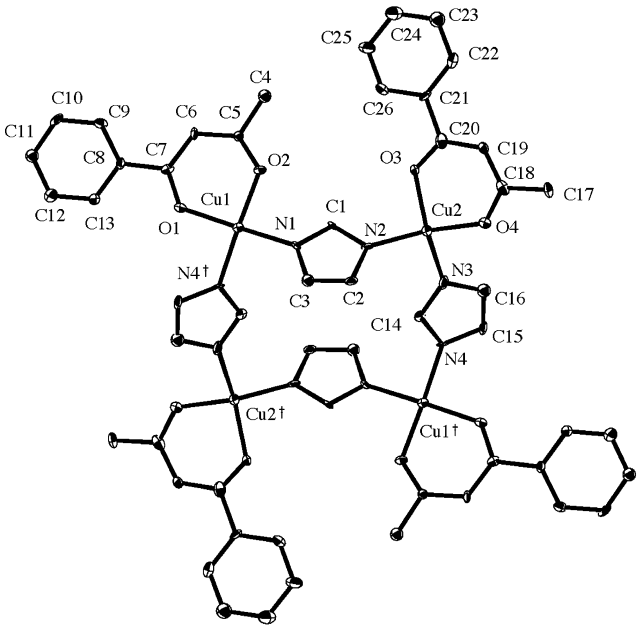

Fig. 4. X-ray crystal structure of [Cu(bzac)(μ-im)]$_4$ (**6t**). Thermal ellipsoids are drawn at the 50% probability level. Hydrogen atoms are omitted. Symmetry operation code of † is $2-x$, $1-y$, $-z$.

as a bridge; namely, $[Cu_3(tacn)_3(\mu\text{-im})_3](ClO_4)_3$ and $[Cu_4(tacn)_4(\mu\text{-im})_4](ClO_4)_4 \cdot 2H_2O$ (tacn = 1,4,7-triazacyclononane). The capping ligands are tridentate and neutral. Consequently, the copper ions were square-pyramidal. Counter ions (ClO_4^-) did not work as ligands. On the other hand, the present compounds have monoanionic β-diketonate chelates as a cap. All of the copper ions are tetra-coordinated (actually n-SP and d-SP). There is no counter anion in the crystal lattice. However, the tetranuclear skelton $[Cu_4(\mu\text{-im})_4]$ of **3t** is similar to that of $[Cu_4(tacn)_4(\mu\text{-im})_4](ClO_4)_4 \cdot 2H_2O$ [6] as well as other known tetramers [7–10].

In the present study, the capping ligands are simple β-diketonates, which occupy two equatorial sites in a cis manner. Accordingly, the imidazolate N atoms are coordinate at the rest position in a cis manner. The N(im)–Cu–N(im) angles close to 90° favors tetranuclear macrocycles. Though several imidazolate-based preorganized ligands have been utilized for development of [2 × 2] grids [6–10], the combination of commercially available copper(II) diketonates and the unsubstituted imidazolate ion is also versatile for this purpose.

3.3. Magnetic properties

The magnetic data of **1p**–**5p** were analyzed by the Bonner–Fisher model as an equally-spaced model. We have to think possible fittings to alternating-chain and rectangle models, because the crystallographic analysis indicates that there are two kinds of exchange couplings. The present analysis brought about averaged values from two independent parameters, J and αJ, where α is alternation parameter. In more precise treatment using the Heisenberg spin Hamiltonian as $H = -\Sigma(2JS2_{2i-1} \cdot S_{2i} + 2\alpha JS_{2i} \cdot S_{2i+1})$, we could adopt an alternating antiferromagnetic chain model [33]. One may imagine the singlet–triplet model [34] in case of the $\alpha = 0$ limit, and accordingly the χ_{mol} value approaches to null at $T \rightarrow 0$ K when α is close to zero. On the other hand, the χ_{mol} versus T profile appears just like the Bonner–Fisher curve when α is close to unity. The present results on **1p**–**5p** exhibited the non-zero χ_{mol} at the $T \rightarrow 0$ K limit, which guarantees that an approximation as an equally-spaced chain model is valid. Moreover, the possibility of

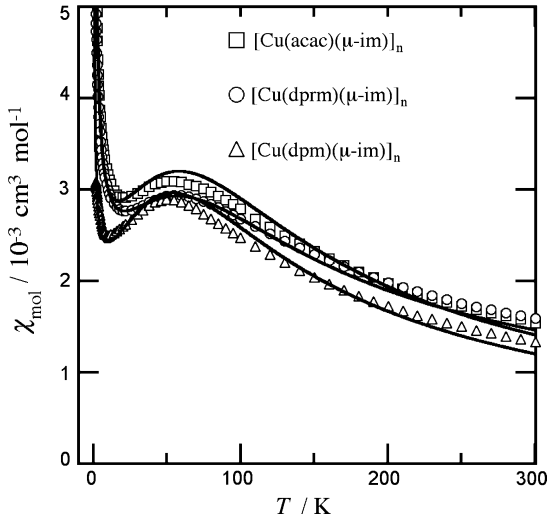

Fig. 6. Temperature dependence of molar magnetic susceptibility (χ_{mol}) for [Cu(acac)(μ-im)]$_n$ (**1p**), [Cu(dprm)(μ-im)]$_n$ (**2p**), and [Cu(dpm)(μ-im)]$_n$ (**5p**). The solid lines represent the best fit curves. See the text for the equations and parameters.

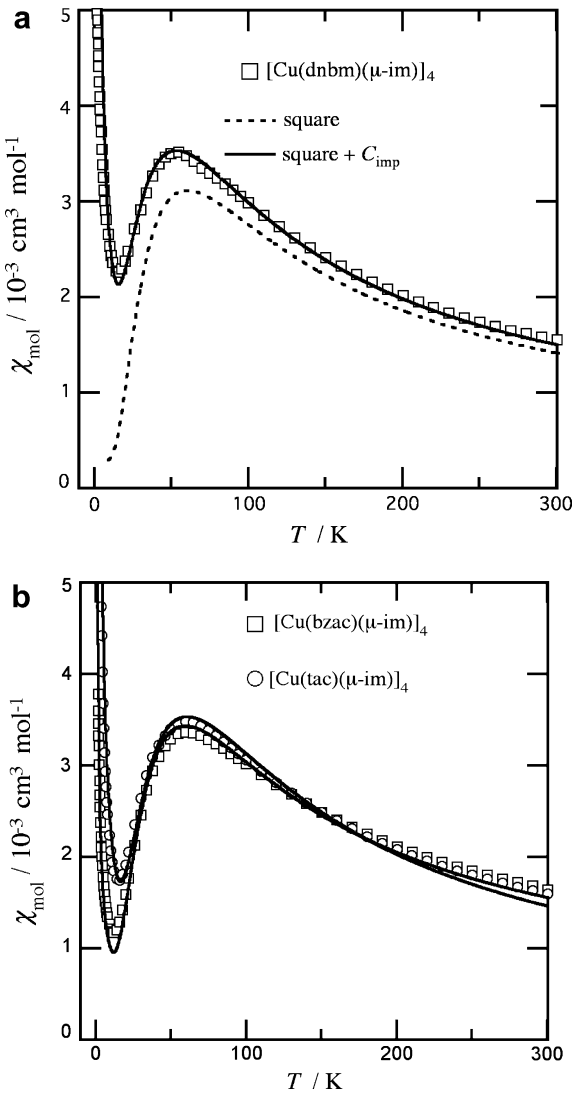

Fig. 7. Temperature dependence of χ_{mol} for (a) [Cu(dnbm)(μ-im)]$_4$ (**3t**) and (b) [Cu(bzac)(μ-im)]$_4$ (**6t**) and [Cu(tac)(μ-im)]$_4$ (**7t**). The solid and dotted lines represent the best fit curves. See the text for the equations and parameters.

the cyclic structures such as a tetramer is completely discarded. Compounds **1p**, **2p**, and **5p** consist of chains as well as **3p** and **4p**. The reports on imidazolate-bridged copper(II) chains are rare [17,18], in which the copper ions were weekly bonded with ligands in an axial manner. To our knowledge, the present work is the first characterization of one-dimensional imidazolate-bridged copper(II) chains showing appreciable antiferromagnetic couplings.

The magnetic data of **3t**, **6t**, and **7t** were analyzed by the square model as an equally-spaced model. Similarly, possibility of rectangle models deserves discussion, because the crystallographic analysis indicates that there are two crystallographic independent copper ions in a tetramer. We actually tried to fit the data of **7t** as well as **3t** and **6t** to the alternating antiferromagnetic chain model [32] and the rectangle model [7]. We eventually found that the latter analysis more likely from the better fit. Furthermore, we also found that the analysis based on the equal spacing satisfactorily reproduced the experimental results.

The structurally common bridges Cu–N$_{im}$(eq)–N$_{im}$(eq)–Cu afford comparable magnitudes of couplings. The 2J values were observed between −78 and −97 K for both the chains and cycles investigated here, and accordingly the α value should be 0.80 at the most. Hence, though an alternating parameter α should be introduced, α was found to be close to unity.

The exchange parameters for the present compounds fell in a typical range of superexchange couplings between copper(II) ions across imidazolates [5–10]. The mechanism of the superexchange coupling was previously discussed by Kolks et al. [7] and Chaudhuri et al. [6]. The σ-pathway across the nitrogen lone-pairs has been pointed out, like other diazaaromatic-bridged systems [35]. The present exchange couplings are much larger than that of imidazolate-bridged copper(II) chains having the *N*-equatorial–*N*-axial bridging motif (for example, $2J/k_B = -5.2$ K [18]).

4. Concluding remarks

The magnetic properties of **1p**–**5p**, **3t**, **6t**, and **7t** were found to be devided into two categories: the Bonner–Fisher model was plausibly applied to polymeric [Cu(L)(μ-im)]$_n$ for the best fit, while a square model to tetrameric [Cu(L)(μ-im)]$_4$. We could not determine the crystal structures of **1p**, **2p**, **5p**, and **7t** at present. It is difficult to characterize compounds as infinite polymers or cyclic oligomers solely from the spectroscopic and elemental analyses. The polymeric and tetranuclear structures could be clearly distinguished from each other by fitting the magnetic data to theoretical curves.

We utilized a simple imidazolate anion for linking several copper(II) diketonates without preorganization of the ligands. It should be noted that the combination of simple copper(II) diketonates and imidazolate ion is versatile for supramolecular chemistry.

5. Experimental

5.1. Materials

Bis(β-diketonato)copper(II) complexes employed were [Cu(acac)$_2$], [Cu(dprm)$_2$], [Cu(dnbm)$_2$], [Cu(dibm)$_2$], [Cu(dpm)$_2$] and [Cu(bzac)$_2$]. They were prepared by the reported method [23]. Imidazole (Tokyo Chemical Industry Co.) was recrystallized from light petroleum (b.p. range 30–70 °C).

The imidazolate-bridged complexes **1p**–**5p** and **6t** are previously characterized except for melting points. However, these complexes and **3t** were prepared for X-ray diffraction study and magnetic measurements according to the following method. Complex **7t** prepared by the previous report [23] was applied for magnetic measurements.

[Cu(acac)(μ-im)]$_n$ (**1p**). The complex [Cu(acac)$_2$] (103.2 mg, 0.39 mmol) was dissolved in methanol (20 ml) with two molar equiv. of imidazole (53.3 mg, 0.78 mmol). The solution was refluxed for 2 h. After standing for a few days, a violet precipitate was formed. The product was filtered, washed with a small amount of methanol, and dried *in vacuo*. The yield was 33.5 mg (37%). Mp. 182–185 °C.

[Cu(dprm)(μ-im)]$_n$ (**2p**). This complex was prepared according to a similar method to that described for **1p**. The yield was 39%. Mp. 183–186 °C.

[Cu(dnbm)(μ-im)]$_n$ (**3p**). The complex [Cu(dnbm)$_2$] (74.8 mg, 0.20 mmol) was dissolved in ethanol (15 ml) with two molar equiv. of imidazole (27.3 mg, 0.40 mmol). The solution was refluxed for 2 h and the solvent was concentrated gradually on heating. Black fine needles were formed during the concentration. They were filtered, washed with a small amount of ethanol, and dried *in vacuo*, giving 17.3 mg of **3p** (30%). Mp. 153–156 °C.

[Cu(dnbm)(μ-im)]$_4$ (**3t**). The complex [Cu(dnbm)$_2$] (74.8 mg, 0.20 mmol) was dissolved in ethanol (15 ml) with two molar equiv. of imidazole (27.3 mg, 0.40 mmol). The solution was stirred at

room temperature for 2 h, and allowed to stand at room temperature for 10 days. The resultant bluish black blocks were filtered, washed with a small amount of ethanol, and dried *in vacuo*. The yield was 10.3 mg (18%). Mp. 113–114 °C.

[Cu(dibm)(μ-im)]$_n$ (**4p**). The complex [Cu(dibm)$_2$] (50.8 mg, 0.14 mmol) was dissolved in methanol (10 ml) with two molar equiv. of imidazole (18.4 mg, 0.27 mmol). The solution was refluxed for 2 h. After standing for a few days, dark blue needles were formed. They were filtered, washed with a small amount of methanol, and dried *in vacuo*. The yield was 16.2 mg (40%). Mp. 183–185 °C.

[Cu(dpm)(μ-im)]$_n$ (**5p**). This complex was prepared by a similar method to that described for complex **1p**. The yield was 85%. Mp. >195 °C.

[Cu(bzac)(μ-im)]$_4$ (**6t**). The complex [Cu(bzac)$_2$] (100.2 mg, 0.26 mmol) was dissolved in methanol (25 ml) with two molar equiv. of imidazole (35.3 mg, 0.52 mmol). The solution was refluxed for 2 h. After standing for a few days, dark green crystals were formed. They were filtered, washed with a small amount of methanol and dried *in vacuo*. The yield was 35.1 mg (46%). Mp. 185–187 °C.

5.2. X-ray crystallographic analysis

X-Ray diffraction data of **3p, 4p, 3t**, and **6t** were collected on a Rigaku R-axis RAPID diffractometer or a Rigaku Saturn-70 CCD diffractometer with graphite monochromated MoKα radiation (λ = 0.71069 Å). The structures were directly solved by a heavy-atom method and expanded using Fourier techniques in the CRYSTALSTRUCTURE 3.8.2 program package [36]. Numerical absorption correction was used. All of the hydrogen atoms were located at calculated positions and the parameters were refined as "riding". The thermal displacement parameters of non-hydrogen atoms were refined anisotropically. Full-matrix least-squares methods were applied using all of the unique reflection data. Selected crystallographic data are listed in Table 2. Preliminary crystallographic analysis on **6t** was also performed.

5.3. Magnetic measurements

Magnetic properties of polycrystalline specimens of **1p**–**5p, 3t, 6t,** and **7t** were measured at 5000 Oe in a temperature range down to 1.8 K on a Quantum Design MPMS SQUID magnetometer. The magnetic responses were corrected with diamagnetic blank data of the sample holder measured separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants.

ABSTRACT

The reaction of the polymer $\{Co(Piv)_2\}_n$ (Piv is the pivalic acid anion) with triethylenetetramine (L^1) ($M:L^1 = 2:1$) in MeCN affords the polymeric compound $[Co_2L^1(\eta^2\text{-}Piv)_2(\mu\text{-}Piv)_2]_n$ (**1**) containing asymmetric dicobalt units coordinated by one chelate ligand L^1. The reaction of **1** with an additional amount of L^1 ($M:L^1 = 1:1$) in MeCN gives rise to the binuclear molecule $Co_2L^1{}_2(Piv)_4$ (**2**), where L^1 acts as a chelate-bridging ligand. Compounds analogous to **2** with M = Fe (**3**) were prepared by the reaction of the polymer $\{Fe(Piv)_2\}_n$ with L^1 in MeCN using the reagent ratio $M:L^1 = 1:1$. The reaction of the compound $CoL^1{}_2(Piv)_4$ (**2**) with isophthalaldehyde (L^2) produces the binuclear complex $Co_2L^3(Piv)_4$ (**4**) containing the new [2 + 2] macrocyclic ligand L^3 as a result of condensation of L^1 with L^2. All newly synthesized compounds were characterized by X-ray diffraction and magnetic measurements.

1. Introduction

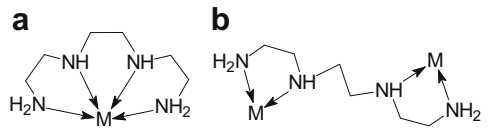
The molecular assembly of macrocyclic molecules on metal centers is typical of lanthanide species [1,2]; nevertheless, the use of d metals in these processes was also documented [3–6]. The main problem in the latter case is low solubility of the final complexes or the formation of large amounts of by-products. In our investigations, we used pivalate derivatives of different metals, which made it possible to manipulate metal complexes having good solubility in organic solvents.

To assemble a macrocycle, we chose triethylenetetramine as the starting building block and isophthalaldehyde as the cross-linking agent. Transition metal ions are known to generally form mononuclear complexes with triethylenetetramine, which is coordinated as a tetradentate chelate (Scheme 1a) [7–20]. However, triethylenetetramine can also act as a chelate-bridging ligand (Scheme 1b) [21–23].

For this reason, we made attempts to use these properties to assemble a new heterocyclic molecule from the tetraamine ligand and isophthalaldehyde, which are bound to the metal centers as mediators in this process.

2. Experimental

2.1. Synthesis



New complexes were synthesized in freshly distilled acetonitrile using the standard Schlenk techniques. The starting materials were purchased from commercial sources and were used without purification. The initial compounds $[Co(Piv)_2]_n$ and $[Fe(Piv)_2]_n$ were synthesized according to the known procedure [24,25].

$[Co_2L^1(\eta^2\text{-}Piv)_2(\mu\text{-}Piv)_2]_n$ (1). *Method A.* A mixture of $[Co(Piv)_2]_n$ (0.4 g, 1.54 mmol) and triethylenetetramine (0.11 g, 0.77 mmol) in MeCN (30 ml) was refluxed at 80 °C for 0.5 h. The resulting purple solution was kept at room temperature for 24 h. Purple needle-like crystals suitable for X-ray diffraction thus formed were collected, washed with cold MeCN, and dried under a stream of argon. The yield of **1** was 0.41 g (80%). Found: C, 46.8; H, 8.0; N, 8.5% $C_{26}H_{54}Co_2N_4O_8$ (%): C, 46.71; H, 8.14; N, 8.38. IR (KBr) ν/cm^{-1}: 3376 m, 3276 m, 2964 s, 2872 m, 1564 s, 1548 s, 1536 s, 1408 s, 1456 m, 1416 s, 1360 s, 1224 m, 1072 w, 1000 w, 964 w, 900 w, 892 w, 792 w, 604 w.

Method B. A solution of **2** (0.3 g, 0.37 mmol) in MeCN was added to $[Co(Piv)_2]_n$ (0.19 g, 0.74 mmol), and the reaction mixture was refluxed at 80 °C for 0.5 h. The resulting purple solution was filtered and kept at room temperature for 24 h. Purple needle-like crystals suitable for X-ray diffraction were collected, washed with cold MeCN, and dried under a stream of argon. The yield of **1** was

Scheme 1. Coordination modes of triethylenetetramine to the metal centers: chelate (a) and chelate-bridging (b).

0.42 g (85%). Found: C, 46.7; H, 8.0; N, 8.4% $C_{26}H_{54}Co_2N_4O_8$ (%): C, 46.71; H, 8.14; N, 8.38. IR (KBr) ν/cm^{-1}: 3376 m, 3276 m, 2964 s, 2872 m, 1564 s, 1548 s, 1536 s, 1408 s, 1456 m, 1416 s, 1360 s, 1224 m, 1072 w, 1000 w, 964 w, 900 w, 892 w, 792 w, 604 w.

$Co_2L^1{}_2(Piv)_4$ (2). *Method A*. A solution of triethylenetetramine (0.09 g, 0.62 mmol) in MeCN (5 ml) was added to a solution of **1** (0.41 g, 0.61 mmol) in MeCN (20 ml). The reaction mixture was refluxed at 80 °C for 0.5 h. The resulting dark-red solution was concentrated to 5 ml, cooled to room temperature, and allowed to stand for several hours, after which red crystals suitable for X-ray diffraction precipitated. The crystals were washed with cold MeCN and dried under a stream of argon. The yield of **2** was 0.44 g (89%). Found: C, 47.1; H, 9.0; N, 13.7% $C_{32}H_{72}Co_2N_8O_8$ (%): C, 47.17; H, 8.91; N, 13.75. IR (KBr) ν/cm^{-1}: 3752 w, 3380 w, 3276 m, 2964 s, 2948 s, 2868 m, 1668 w, 1564 s, 1480 s, 1456 m, 1404 s, 1356 s, 1224 m, 1048 w, 976 w, 884 m, 792 m, 596 w, 396 w.

Method B. A solution of triethylenetetramine (0.15 g, 1.00 mmol) in MeCN (15 ml) was added to $[Co(Piv)_2]_n$ (0.26 g, 1.00 mmol). The reaction mixture was refluxed at 80 °C for 0.5 h. The resulting dark-red solution was concentrated to 5 ml, cooled to room temperature, and allowed to stand for several hours, after which red crystals suitable for X-ray diffraction precipitated. The crystals were washed with cold MeCN and dried under a stream of argon. Found: C, 47.2; H, 8.9; N, 13.6% $C_{32}H_{72}Co_2N_8O_8$ (%): C, 47.17; H, 8.91; N, 13.75. The yield of **2** was 0.37 g (90%). IR (ν, cm^{-1}): 3752 w, 3380 w, 3276 m, 2964 s, 2948 s, 2868 m, 1668 w, 1564 s, 1480 s, 1456 m, 1404 s, 1356 s, 1224 m, 1048 w, 976 w, 884 m, 792 m, 596 w, 396 w.

$Fe_2L^1{}_2(Piv)_4$ (3). A solution of triethylenetetramine (0.04 g, 0.39 mmol) in MeCN (15 ml) was added to $[Fe(Piv)_2]_n$ (0.10 g, 0.39 mmol). The resulting colorless solution was refluxed at 80 °C for 0.5 h, concentrated to 10 ml, and kept at room temperature for 72 h. The colorless crystals that precipitated were washed with cold MeCN and dried under a stream of argon. The yield of **3** was 0.12 g (78%).

$Co_2L^3(Piv)_4$ (4). A solution of **2** (0.32 g, 0.39 mmol) and isophthalaldehyde (0.11 g, 0.80 mmol) in MeCN (20 ml) was refluxed at 80 °C for 1 h. The resulting red solution was kept at room temperature for 48 h. Pink crystals that precipitated were washed with cold MeCN and dried under a stream of argon. The yield of **4** was 20–25%. Found: C, 57.1; H, 7.7; N, 12.0%. $C_{50}H_{79}Co_2N_9O_8$ (%): C, 57.08; H, 7.57; N, 11.9. IR (KBr) ν/cm^{-1}: 3419 w, 3260 w, 3156w, 3075 w, 2958 m, 2922 m, 2864 m, 1700 w, 1643 s, 1586 s, 1570 s, 1533 s, 1482 m, 1431 m, 1401 m, 1353 m, 1304 w, 1224 m, 1176 w, 1125 w, 1018 m, 974 m, 897 m, 879 w, 807 w, 792 m, 690 w, 605 w.

2.2. Methods

Microanalyses were carried out on a Carlo Erba CHN elemental analyzer. IR spectra were recorded on a Specord M80 spectrometer in KBr pellets (4000–400 cm^{-1}). Magnetic measurements were carried out on an MPMS-5S SQUID magnetometer (Quantum Design) in the temperature range 2–300 K in a magnetic field of up to 5 kOe. The molar magnetic susceptibility χ was calculated including diamagnetic corrections. The effective magnetic moment was calculated by the formula $\mu_{eff} = (8\chi T)^{1/2}$.

2.3. X-ray data collection

The X-ray data sets for complexes **1**–**4** were collected on a Bruker AXS SMART APEX II diffractometer equipped with a CCD detector (graphite monochromator, ω scanning technique, scan step 0.3°, exposure time per frame 10 s) using a standard procedure [26]. Semi-empirical absorption corrections for all complexes were applied (min/max transmission was 0.8186/0.6628 for **1**, 0.8841/0.8497 for **2**, 0.8515/0.7373 for **3**, and 0.9690/0.9570 for **4**) [27]. The structures were solved by direct methods and using Fourier techniques and were refined by the full-matrix least squares against F^2 with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms in compounds **1**–**4** were positioned geometrically and refined using the riding model. All

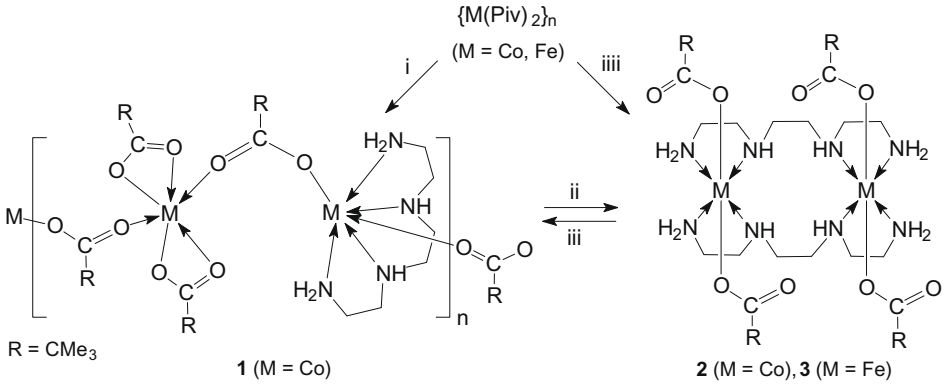
calculations were carried out with the use of the SHELX97 program package [28]. The crystallographic parameters and the refinement statistics are given in Table 1.

3. Results and discussion



3.1. Synthesis and X-ray diffraction study

In the first step, the polymer $[Co(Piv_2)]_n$ was found to react with triethylenetetramine (reagent ratio M: L^1 = 2: 1) in MeCN (80 °C) to form the new polymer $[Co_2L^1(\eta^2\text{-Piv})_2(\mu\text{-Piv})_2]_n$ (**1**) (Scheme 2).

The X-ray diffraction study showed that the polymeric chain consists of non-symmetric dicobalt units, in which the metal atoms are held together by the bridging pivalate group (Fig. 1, Table 2). The binuclear unit contains only one chelate triethylenetetramine molecule, which is bound to one cobalt atom (type a, Scheme 1), whereas the second metal center is coordinated by two chelate pivalate groups. The adjacent binuclear fragments in the polymer are also linked together by the bridging pivalate groups. Hence, each cobalt atom has a distorted octahedral environment (CoO_6 or CoN_4O_2). The hydrogen atoms of the amine groups form hydrogen bonds with the carboxylate oxygen atoms (Table 3, Fig. 1).

In the next step, the addition of L^1 to polymer **1** (reagent ratio M: L^1 = 2: 1) resulted in the formation of the binuclear molecule $Co_2L^1{}_2(Piv)_4$ (**2**) (Scheme 2). However, the addition of the initial polymer $[Co(Piv_2)]_n$ to a MeCN solution of **2** (reagent ratio **2**: $[Co(Piv_2)]_n$ = 1: 1) again initiated the formation of polymeric compound **1**. Compound **2** can also be prepared by the reaction of $[Co(Piv_2)]_n$ with L^1 in MeCN (80 °C) (reagent ratio M: L^1 = 1: 1) (Scheme 2). The iron-containing binuclear analogue $M_2L^1{}_2(Piv)_4$ (M = Fe (**3**)) was synthesized starting from $[Fe(Piv_2)]_n$ by the reaction with L^1 in MeCN (80 °C) (reagent ratio M: L^1 = 1: 1) (Scheme 2).

According to the X-ray diffraction data for **2** and **3** (Table 1), the binuclear units in both compounds have similar structures (Fig. 2). The metal(II) atoms (in two independent molecules for complex **3**)

[a] For two independent molecules.
[b] Intermolecular.

Scheme 3. Formation of the binuclear complex $[M_2L^3(Piv)_4]$ (M = Co (**4**)) [(i), MeCN, Ar, 80 °C].

are in a distorted octahedral environment formed by four nitrogen atoms of two equatorial ligands L^1 and two oxygen atoms of two axial terminal pivalate groups. In molecules **2** and **3**, the tetraamine ligands L^1 act as chelate-bridging ligands and are coordinated to the adjacent metal centers (type b, Scheme 1) *via* two M–N bonds (Table 2). In the complex molecules, hydrogen bonding is present between the carboxylate oxygen atoms and the amine protons and between the binuclear units (Table 3).

In the next step of the assembly of the macrocycle, we used isophthalaldehyde (L^2) as the cross-linking agent. Formally, the tetraamine ligands L^1 in binuclear molecule **2** are ready for condensation with L^2. The reaction of complexes **2** with L^2 in MeCN (reagent ratio M: L^2 = 1: 1) afforded the binuclear structure $M_2L^3(Piv)_4$ (M = Co (**4**)) containing the new [2 + 2] macrocyclic ligand L^3 as a condensation product of L^1 and L^2 (Scheme 3).

According to the X-ray diffraction data, the 30-membered macrocycle containing eight nitrogen atoms is the main structural unit of centrosymmetric binuclear molecule **4** (Fig. 3, Table 2). However, only six N atoms are bound to two inner Co(II) centers. The metal atoms Co(1)···Co(2) are at a nonbonded distance (Co···Co 9.242(2) Å). In addition, the Co(II) atom is coordinated by two oxygen atoms of the terminal carboxylate anions. Therefore, each cobalt atom is in a disordered tetragonal pyramidal ligand environment (Fig. 3). Hydrogen bonding is present between the

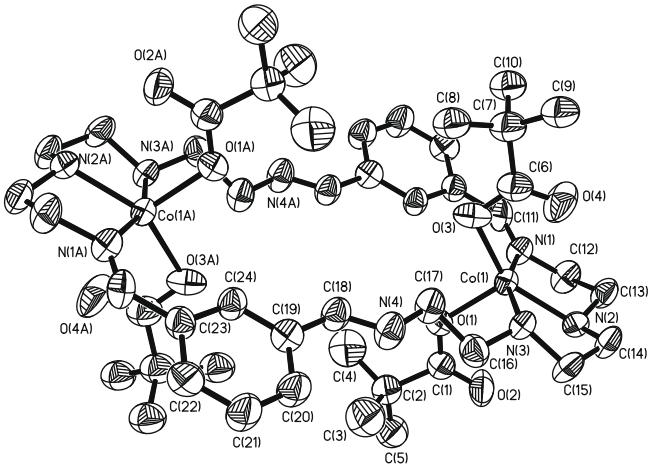

Fig. 3. Structure of the complex $Co_2L^3(Piv)_4$ (**4**).

oxygen atoms of the terminal carboxylate groups and the hydrogen atoms of the coordinated amine groups (Table 3, Fig. 4).

In the crystal structure, adjacent molecules **4** self-assemble *via* weak intermolecular hydrogen bonds between the nitrogen atoms (N(4) of the ligand L^3 and the protons of the amine groups (N(3)), which are not coordinated to the metal centers (Co···Co

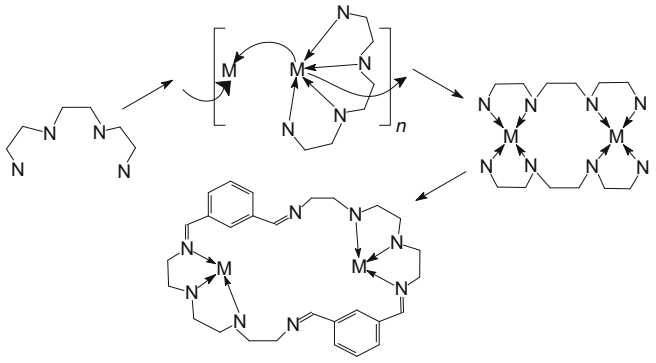
3.2. Magnetic properties



Magnetic measurements of the newly synthesized cobalt(II)-containing complexes **1**, **2**, and **4** revealed the strong temperature dependence of the magnetic moment (Fig. 5). All complexes have a similar temperature dependence of the magnetic moments. The magnetic moments μ_{eff} are 6.79 and 6.91 μ_B at 300 K and 6.30 μ_B at 325 K for complexes **1**, **2**, and **4**, respectively. The experimental effective magnetic moments are substantially larger than the theoretical pure spin value μ_{calc} = 5.48 μ_B (for two spins, $S = 3/2$, $g = 2$), which is attributed to the orbital contribution to the magnetic susceptibility typical of Co^{II} ions and the g factor >2. The magnetic moments first smoothly and then more sharply decrease with decreasing temperature and reach 4.55, 5.39, and 4.75 μ_B at 2 K for complexes **1**, **2**, and **4**, respectively. The exchange interaction parameters were estimated from the Curie–Weiss law because it is difficult to precisely calculate these parameters because of the large orbital contribution to the magnetic susceptibility typical of Co^{II} ions in an octahedral environment. Complex **1** exists as a polymeric chain, in which Co^{II} ions are coupled by exchange interactions through the bridging carboxylate anions. In the temperature range of 50–300 K, the plot $\chi^{-1}(T)$ for complex **1** follows the Curie–Weiss law ($\chi = C/(T-\theta)$) with C = 5.91 (2.955 per cobalt atom) and $\theta/k = -8.8$ K (Fig. 5, Table 4). The negative value of θ/k is indicative of the presence of antiferromagnetic exchange interactions, which are responsible for a decrease in the magnetic moment at low temperatures. For complex **2**, the Curie constant C = 6.22 and $\theta/k = -12$ K (Fig. 5, Table 4). Intramolecular interactions between the Co^{II} ions through the Co(1)–N(2)–C(13)–C(14A)–N(3A)–Co(1A) aliphatic ligand are possible. In addition, intermolecular interactions through the Co(1)–O(3)–C(6)=O(4)···H–N(4A)–Co(1A) channel can also exist. Therefore, in the solid phase, the Co^{II} ions form exchange-bound chains because of which it is impossible to analyze the magnetic properties based on the expression for the susceptibility of exchange-bound dimers. In the structure of complex **4**, there are also interactions between the Co^{II} ions of the adjacent molecules through the hydrogen bonds between the coordinated carboxylate group and the amine nitrogen atom of the ligand and between the amine nitrogen atom of the ligand and the imine nitrogen atom of the ligand belonging to the adjacent molecules. The plot χ^{-1}(T) for complex **4** follows the Curie–Weiss law (Fig. 5, Table 4).

For iron compound **3**, the temperature dependence is more complicated. In the temperature range 300–30 K, the effective magnetic moment (μ_{eff}) decreases only slightly from 7.24 to 7.20 μ_B (Fig. 5). However, at helium temperatures μ_{eff} decreases sharply to 5.06 μ_B (2 K). The magnetic moment μ_{eff} at room temperature is similar to the calculated magnetic moment for two iron(II) ($S = 2$, $g = 2$) ions (μ_{calc} = 6.93 μ_B). In the structure of **3**, as in complex **2**, there are exchange-bound chains of Fe^{II} ions, in which antiferromagnetic exchange interactions prevail (Fig. 5, Table 4).

Table 4
Calculated Curie–Weiss parameters for compound **1**–**4**.

Scheme 4. Schematic representation of the phase assembly of macrocyclic complex **4**.

To conclude, we found that binuclear complex **2** with chelate-bridging tetraamine ligands can be used as a building block to assemble macrocyclic species. The present investigation showed that the formation of the macrocyclic molecule at cobalt centers as mediators of chemical assembly proceeds in a stepwise fashion (Scheme 4).

Magnetic susceptibility data
Manganese(II) clusters
Manganese(II) cubanes

ABSTRACT

The employment of di-2-pyridyl ketone, $(py)_2CO$, in manganese(II) benzoate chemistry is reported. The syntheses, crystal structures and spectroscopic (IR, EPR) characterization are described for $[Mn^{II}_3(O_2CPh)_6\{(py)_2CO\}_2]$ (**1**), $[Mn^{II}_3(O_2CPh)_6\{(py)_2CO\}_2]\cdot 2MeCN$ (**2** · 2MeCN) and $[Mn^{II}_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]$ (**3**), where $(py)_2C(OH)O^-$ is the monoanion of the *gem*-diol form of $(py)_2CO$. Variable-temperature, magnetic susceptibility studies on **3** have also been performed. Complexes **1** and **2** · 2MeCN are linkage isomers. The trinuclear molecules of both complexes have a linear structure, with one $\eta^1{:}\eta^2{:}\mu_2$ and two *syn, syn*- $\eta^1{:}\eta^1{:}\mu_2$ $PhCO_2^-$ groups spanning each pair of Mn^{II} atoms. The terminal Mn^{II} atoms are each capped by one κ^2N,N' $(py)_2CO$ ligand in orange **1** and one κ^2N,O $(py)_2CO$ molecule in the yellow isomer **2** · 2MeCN. The molecule of **3** has a cubane topology with the Mn^{II} centers and the deprotonated oxygen atoms from the $\eta^1{:}\eta^3{:}\eta^1{:}\mu_3$ ligands occupying alternate vertices of the cube. A terminal monodentate $PhCO_2^-$ group completes a distorted octahedral coordination at each Mn^{II} atom. The IR data are discussed in terms of the coordination modes of the ligands that are present in the complexes. The X-band EPR spectra of powdered **1** and **2** at 4 K indicate that the populated spin states exhibit a zero-field splitting, while the spectrum of **3** at 18 K is consistent with the presence of magnetically interacting Mn^{II} atoms in the solid state. The magnetic properties of **3** in the 300–5 K range have been modelled with two *J* values, which reveal weak antiferromagnetic interactions within the molecule. Some suggestions have been made concerning the great stability of complex **3**.

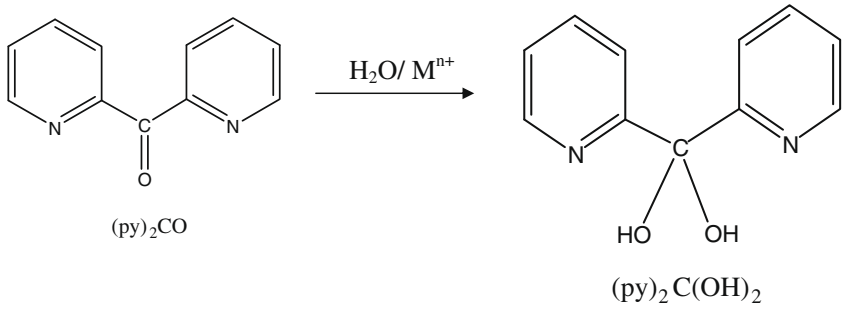
1. Introduction

Molecular Mn carboxylate cluster chemistry continues to attract intense attention from many research groups around the world. The reasons for this are many, but the two most important ones are the relevance of the chemistry of Mn to bioinorganic chemistry [1] and to the ongoing efforts to develop new routes to high-spin molecules [2] and single-molecule magnets (SMMs) [3]. SMMs are molecules that retain their magnetization below a blocking temperature (T_B) in the absence of an applied field, thus representing a molecular, "bottom up" approach to nanoscale magnets.

In this study, we have sought to extend our previous work where we had employed di-2-pyridyl ketone ($(py)_2CO$, Scheme 1) in Mn acetate reactions, and had obtained structurally interesting new complexes [4]. Due to its highly activated carbonyl group, $(py)_2CO$ is a unique ligand [5]. Water, among other nucleophiles [5,6], has been shown to add to the carbonyl group *upon coordination of the 2-pyridyl rings and/or the carbonyl oxygen* forming the ligand $\{(py)_2C(OH)_2\}$ [the *gem*-diol form of $(py)_2CO$]. Upon deprotonation, the latter can function either as mono- or dianionic ligand depending on the reaction conditions. Herein, we report the synthetic investigation of the $Mn^{II}/PhCO_2^-/(py)_2CO$ reaction system that resulted in the isolation of three manganese(II) benzoate clusters. Portions of this work have been communicated [7].



2. Experimental

2.1. General information and techniques

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received.

Scheme 1. Ligands discussed in the text. Note that $(py)_2C(OH)_2$ and its anions do not exist as free species but exist only in their respective metal complexes. M^{n+} = metal ion; n = 2, 3.

$Mn(O_2CPh)_2 \cdot 2H_2O$ was prepared as described elsewhere [8]. Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory using an EA Carlo Erba analyzer.

IR spectra (4000–400 cm^{-1}) were recorded on a Perkin–Elmer 16 PC FT-IR spectrometer with samples prepared as KBr pellets. FT-Raman spectra were recorded on a Bruker IFS 66v interferometer with a FT-Raman FRA 106 module. The compounds were excited by the 1064 nm line of a Nd:YAG laser operating at 200 mW. For each spectrum, 1000 scans were recorded and averaged. Solid state EPR spectra in the 4.2–300 K range were recorded on a Bruker ER 200D-SRC X-band spectrometer equipped with an Oxford ESR 9 cryostat. Dc magnetic measurements were carried out on a polycrystalline sample of the cubane complex (vide infra) using a Quantum Design MPMS SQUID magnetometer operating at a constant magnetic field of 0.1 T between 5.0 and 300 K. The experimental molar susceptibility was corrected for the diamagnetic contribution from the sample holder and the diamagnetic response from the sample, which was evaluated from Pascal's constants.

2.2. Compound preparation

2.2.1. $[Mn_3(O_2CPh)_6\{(py)_2CO\text{-}\kappa^2N,N'\}_2]$ (**1**), $[Mn_3(O_2CPh)_6\{(py)_2CO\text{-}\kappa^2N,O\}_2]\cdot 2MeCN$ (**2**·2MeCN) and $[Mn_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]$ (**3**) in a mixture

A colourless solution of $Mn(O_2CPh)_2\cdot 2H_2O$ (300 mg, 0.9 mmol) in freshly distilled MeCN (20 ml) was treated with solid $(py)_2CO$ (110 mg, 0.6 mmol) under mild stirring. The solid soon dissolved and the colour of the solution turned to bright yellow. Stirring was maintained for 20 min, and the solution flask was sealed and left undisturbed overnight. After several hours the solution began to afford a mixture of orange crystals of **1** and yellow crystals of **2**·2MeCN, while the colour of the solution faded to orange. One crystal from each compound was removed from the mixture and its identity was crystallographically established. The orange crystals proved to be complex **1,** while the unstable yellow crystals corresponded to complex **2**·2MeCN. After 3 days, the precipitation was judged to be complete producing more orange crystals and no yellow ones. The ratio of orange to yellow crystals was estimated to be approximately 4:1; the combined yield of the precipitated materials was about 55%. After 1 week a quantity of colourless polyhedral crystals, crystallographically identified as $[Mn_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]$ (**3**), was precipitated in 30% yield, while the supernatant mother solution was colourless. The reaction mixture was then left to slowly evaporate in the air and upon atmospheric oxidation the $(py)_2CO$-free known compound $[Mn_6O_2(O_2CPh)_{10}(MeCN)_4]$ formed as brown rectangular plates in ~10% yield (all yields are based on the total Mn content of the reaction mixture).

2.2.2. $[Mn_3(O_2CPh)_6\{(py)_2CO\text{-}\kappa^2N,N'\}_2]$ (**1**)

A colourless solution of $Mn(O_2CPh)_2\cdot 2H_2O$ (300 mg, 0.9 mmol) in freshly distilled MeCN (20 ml) was treated with solid $(py)_2CO$ (110 mg, 0.6 mmol) under mild stirring. The solid ligand soon dissolved and the colour of the solution instantly turned to bright yellow. Then a reflux condenser was attached to the reaction flask and the solution maintained under reflux for 24 hours under vigorous stirring. The colour of the solution gradually turned to orange. The reaction flask was cooled to room temperature and left undisturbed to produce orange crystals of pure **1** over a period of 3 days. The crystals were filtered, washed with Et_2O (2 × 3 ml) and dried in the air. 60% yield.

IR (KBr pellet, cm^{-1}): ν = 3062m, 2828w, 1710s, 1602s, 1560s, 1474m, 1446sh, 1432m, 1386sb, 1296m, 1258w, 1222m, 1016m, 950m, 802m, 776m, 750w, 724s, 678s, 636m. *Anal.* Calc. for $C_{64}H_{46}O_{14}N_4Mn_3$ (1259.9): C, 61.01; H, 3.69; N, 4.45. Found: C, 60.67; H, 3.55; N, 4.52%.

2.2.3. $[Mn_3(O_2CPh)_6\{(py)_2CO\text{-}\kappa^2N,O\}_2]\cdot 2MeCN$ (**2** · 2MeCN)

A colourless solution of $Mn(O_2CPh)_2\cdot 2H_2O$ (600 mg, 1.8 mmol) in freshly distilled MeCN (20 ml) was treated with solid $(py)_2CO$ (220 mg, 1.2 mmol) in small portions under gentle stirring. The solid ligand soon dissolved and the bright yellow solution obtained was left undisturbed to produce a yellow microcrystalline powder. The powder was collected after 6 h, since after that time orange crystals of **1** began to form. The yellow material was collected by filtration, washed with Et_2O (2 × 3 ml) and dried in the air. The yield was 30%. (KBr pellet, cm^{-1}): ν = 3064m, 2830w, 1640s, 1596s, 1546br, 1470m, 1430sh, 1408s, 1384sh, 1296w, 1268w, 1028m, 1016m, 978w, 772m, 724s, 678m, 640w, 615sh. The solid analyzed as solvent-free. *Anal.* Calc. for $C_{64}H_{46}O_{14}N_4Mn_3$ (1259.9): C, 61.01; H, 3.69; N, 4.45. Found: C, 60.87; H, 3.73; N, 4.40%.

2.2.4. $[Mn_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]$ (**3**)

To a colourless solution of $Mn(O_2CPh)_2\cdot 2H_2O$ (167 mg, 0.5 mmol) in "wet" CH_2Cl_2 (25 ml) was added solid $(py)_2CO$ (92 mg, 0.5 mmol). The solid soon dissolved to yield a pale yellow solution. The solution became colourless after 30 min of stirring. The solution was layered with *n*-hexane (50 ml). Slow mixing gave large, polyhedral crystals of the product after 3 days in 90% yield. The crystals were collected by filtration, washed with Et_2O (2 × 3 ml) and dried in the air. IR (KBr pellet, cm^{-1}): ν = 3416br, 1596s, 1558s, 1434m, 1390s, 1292w, 1258w, 1222m, 1016m, 950m, 774m, 726s, 680m, 662w, 636m. *Anal.* Calc. for $C_{72}H_{56}O_{16}N_8Mn_4$ (1509.0): C, 57.30; H, 3.75; N, 7.43. Found: C, 57.42; H, 3.96; N, 7.33%.

2.3. Single-crystal X-ray crystallography

A crystal of **1** was mounted in air, while crystals of **2**·2MeCN and **3** were mounted in capillary. Diffraction measurements were made

on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation. Complete crystal data and parameters for data collection and processing are listed in Table 1. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11^\circ < 2\theta < 23^\circ$. Intensity data were recorded using the θ-2θ scan method. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization corrections were applied using the Crystal Logic software package.

The structures were solved by direct methods using SHELXS-86 [9] and refined by full-matrix least-squares techniques on F^2 with SHELXL-97 [10]. For the structure of **1**, all hydrogen atoms were located by difference maps and refined isotropically. In the case of **2** · 2MeCN, all hydrogen atoms were located by difference maps and refined isotropically, except those of the MeCN solvate which were introduced at calculated positions as riding on their respective bonded atom. For the structure of **3**, all hydrogen atoms were introduced at calculated positions as riding on bonded atoms. For all three structures, all non-hydrogen atoms were refined using anisotropic thermal parameters.

3. Results and discussion

3.1. Synthetic comments

The $Mn(O_2CPh)_2{\cdot}2H_2O/(py)_2CO$ reaction system in freshly distilled MeCN is complicated. The 1.5:1 reaction gave a bright yellow solution, which upon storage in a *closed* flask gradually turned to orange within ~10 h giving a mixture of yellow and orange crystals in a visual ratio ~1:1. The orange crystals are stable in the atmosphere, whereas the yellow ones collapse rapidly giving a yellow powder. To our surprise, both dried samples gave almost identical analytical results corresponding to the empirical formula $Mn(O_2CPh)_2\{(py)_2CO\}_{0.7}$. Our curiosity increased when we looked at the IR spectra of the two samples. The spectra of the orange and yellow materials exhibit a strong band at 1710 and 1640 cm^{-1}, respectively, attributable to ν(C=O) and suggesting [11] that the ligand is present in its rare [5] ketone $(py)_2CO$ form (Scheme 1) in both compounds. Thus, we decided to collect full single-crystal, X-ray data sets for the two samples. Crystallography revealed that the orange and yellow crystals correspond to the compounds $[Mn^{II}_3(O_2CPh)_6\{(py)_2CO\text{-}\kappa^2N, N'\}_2]$ (**1**) and $[Mn^{II}_3(O_2CPh)_6\{(py)_2CO\text{-}\kappa^2N, O\}_2]{\cdot}2MeCN$ (**2**·2MeCN), respectively. Though the molecular coordination formula of the two complexes is identical, there is a major difference associated with the coordination (ligation) mode of $(py)_2CO$. In complex **1** the ligand is coordinated through the two pyridyl N atoms forming a 6-membered chelating ring, whereas in **2**·2MeCN the donor atoms of $(py)_2CO$ are the carbonyl O atom and the pyridyl N atom thus forming a 5-membered chelating ring (vide infra). With hindsight, the different coordination sphere of the external Mn^{II} atoms in the trinuclear molecules justifies the different colours of the compounds. Also the instability of the yellow crystals in the normal laboratory atmosphere is explained by the easy loss of the solvate MeCN molecules from the crystal lattice.

If the storage time of the initial reaction solution increases from several hours to ~3 days, the percentage of the orange crystals increases leading to a final visual ratio of ~4:1. At this point the yield was ~55%, based on the total available Mn. Prolonged storage (>1 week) of the initial reaction solution in a closed flask led to the slow precipitation of a third product in the form of colourless, polyhedral crystals, together with a sporadic precipitation of few orange crystals of **1,** in 30% yield (again based on the total available Mn). The colourless crystals were crystallographically shown to be $[Mn_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]$ (**3**). The Mn^{II}-mediated nucleophilic attack of H_2O [from the solvent and $Mn(O_2CPh)_2{\cdot}2H_2O$] on the carbonyl group is responsible for the formation of the *gem*-diolate(-1) ligand $(py)_2C(OH)O^-$ [5]. The electrophilic character of the carbonyl carbon atom of $(py)_2CO$ is increased by coordination of the carbonyl oxygen to Mn^{II} (direct polarization) and/or coordination of the more remote pyridyl nitrogens (induced polarization) in solution [5].

Complexes **1**, **2** · 2MeCN and **3** are not the only products from the $Mn(O_2CPh)_2{\cdot}2H_2O/(py)_2CO$ reaction system in MeCN! If the initial reaction solution- that already had led to the three manganese(II) complexes- was left to slowly evaporate in the air, its colour turned to brown and few reddish-brown rectangular plates of the known $(py)_2CO$-free, mixed valence cluster $[Mn^{II}_4Mn^{III}_2O_2(O_2CPh)_{10}(MeCN)_4]$ (**4**) [12] appeared as a by-product [12]; the yield was ~10% (based on the total available Mn). The identity of **4** was confirmed by elemental analyses, IR spectrum, and a unit cell determination and comparison with the authentic material [12]. Complex **4** contains a $\{Mn_6O_2\}^{10+}$ core that can be conveniently described as two edge-sharing Mn_4 tetrahedra at the center of each of which is a μ_4-O^{2-} group [12,13].

With the identities of **1**–**3** established, convenient syntheses of pure materials were sought under alternative reaction conditions. First, we decided to take full advantage of the fact that the colour of the solution reflects the identity of the dominant species present, i.e. the solution is yellow when the first yellow crystals of **2**·2MeCN appear and orange when the main quantity of the orange crystals of **1** form. Second, we wondered why two trinuclear products form. The answer to this question was provided by Toyama et al. who carried out excellent synthetic and NMR studies on Ru^{II}/Cl^-/DMSO/$(py)_2CO$ chemistry [14]. These researchers concluded that the κ^2N,O coordination mode of the $(py)_2CO$ ligand is *kinetically* favourable, while the κ^2N,N' mode is the *thermodynamically* stable ligation mode. Thus, when the reaction mixture in MeCN was maintained under reflux for 24 h its colour changed progressively from yellow to orange, bypassing the precipitation

of the kinetic product **2** and leading to the clean isolation of **1** in good yield (~60%), according to the chemical Eq. (1). For the isolation of **2** we employed a

$$3Mn^{II}(O_2CPh)_2\cdot 2H_2O + 2\ (py)_2CO \xrightarrow[T,24\ h]{MeCN} \underset{\text{orange } \mathbf{1}}{[Mn^{II}_3(O_2CPh)_6\{(py)_2CO\}_2]} + 6H_2O \quad (1)$$

different route. Since compound **2** is the first product that forms (evident from the bright yellow colour of the initial solution), we used nearly saturated solutions of $Mn(O_2CPh)_2\cdot 2H_2O$ and $(py)_2CO$ (1.5:1) in MeCN at room temperature, carefully mixed in order to avoid precipitation of the starting materials. After ~1 h, yellow microcrystals of **2**·2MeCN began to precipitate. The precipitation was interrupted after ~6 h, by filtering the mixture and collecting the polycrystalline material. The formation of **2** is summarized in Eq. (2). The route produced **2** in 30% yield. We could not optimize

$$3Mn^{II}(O_2CPh)_2\cdot 2H_2O + 2\ (py)_2CO \xrightarrow[RT,6\ h]{MeCN} \underset{\text{yellow } \mathbf{2}}{[Mn^{II}_3(O_2CPh)_6\{(py)_2CO\}_2]} + 6H_2O \quad (2)$$

the procedure, because after ~6 h the first crystals of **1** appeared. Once formed and isolated, the orange complex **1** does not transform into **2** in MeCN even though the reaction mixture is stirred or refluxed overnight.

The pure complex **3** was easily prepared by the 1:1 (this ratio was adopted after the crystal structure solution of this cluster) reaction between $Mn(O_2CPh)_2\cdot 2H_2O$ and $(py)_2CO$ in CH_2Cl_2 containing few drops of H_2O (<0.5 ml). The obtained colourless solution was layered with *n*-hexane to afford the product in almost quantitative yields (~90%). The formation of the tetranuclear cluster is summarized in Eq. (3). The

$$4\ Mn^{II}(O_2CPh)_2\cdot 2H_2O + 4\ (py)_2CO \xrightarrow{\text{"wet" } CH_2Cl_2} \underset{\text{colourless } \mathbf{3}}{[Mn^{II}_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]} + 4\ PhCO_2H + 4H_2O \quad (3)$$

excess benzoates act as a base facilitating the single deprotonation of the *gem*-diol form of the ligand. This reaction represents a general synthetic method for the isolation of $Mn^{II}/\{(py)_2C(OH)O^-/RCO_2^-$ cubanes irrespective of the nature of R [15]. Complex **3** is the only product that can be isolated from the $Mn(O_2CPh)_2\cdot 2H_2O/(py)_2CO$ reaction mixtures in "wet" CH_2Cl_2 even if basic and/or oxidizing conditions are applied (albeit in lower yields) stressing its great thermodynamic stability. The latter can be attributed to the formation of four intramolecular H bonds, typical for all $(py)_2C(OH)O^-/RCO_2^-$-based 3d metal cubanes; in addition, all the 12 phenyl and pyridyl rings present in the molecule of **3** interact in pairs forming intramolecular π–π stacking interaction, which also provide stability. In spite of this stability, recent results from our group indicate that complex **3** can be oxidized and hydrolyzed under very strong conditions forming mixed-valence Mn_8 and Mn_{20} clusters, fragments of which are structurally related to **3** [16].

Complexes **1** and **2** react spontaneously with H_2O and undergo partial oxidation by the atmospheric oxygen in MeCN giving a mixture of **3** and **4**, as expected. *Assuming* a 3:1 molar ratio of the products, such a reaction can be represented by the balanced Eq. (4):

$$6[\underset{\mathbf{1}\text{ or }\mathbf{2}}{Mn_3(O_2CPh)_6\{(py)_2CO\}_2}] + 13H_2O + 4MeCN + \frac{1}{2}O_2 \xrightarrow{MeCN} 3[\underset{\mathbf{3}}{Mn_4(O_2CPh)_4\{(py)_2C(OH)O\}_4}] + [\underset{\mathbf{4}}{Mn_6O_2(O_2CPh)_{10}(MeCN)_4}] + 14PhCO_2H \quad (4)$$

3.2. Vibrational spectra

The IR spectrum of **1** shows a strong band at 1710 cm^{-1}, suggesting that the organic ligand is present in its ketone form [11,17]. This mode is situated at higher wavenumber than that in the spectrum of free $(py)_2CO$ (1684 cm^{-1}), confirming the non-participation of the ketone group in coordination in complex **1**. The low wavenumber (1640 cm^{-1}) for the ν(C=O) vibration in the IR spectrum of the yellow isomer **2** is due to the carbonyl oxygen coordination. The ν(C=O) mode appears as a medium-intensity peak at 1679 and 1638 cm^{-1} in the Raman spectra of **1** and **2**, respectively. The IR spectrum of **3** does not exhibit a band in the region for the carbonyl stretching vibration as expected, with the nearest band at 1596 cm^{-1} which can be assigned as a pyridyl stretching mode [this band has also a $\nu_{as}(CO_2)$ character] raised from 1582 cm^{-1}, as observed earlier [18] upon complex formation involving hydration of $(py)_2CO$.

In the IR spectrum of **3**, the strong band at 1390 cm^{-1} is assigned to the $\nu_s(CO_2)$ mode (the corresponding Raman peak appears at 1397 cm^{-1}). The difference Δ, where $\Delta = \nu_{as}(CO_2) - \nu_s(CO_2)$, is 1596–1390 = 206 cm^{-1}; the value of this parameter is larger than that for NaO_2CPh (184 cm^{-1}), as expected [19] for the monodentate mode of carboxylate ligation. In the IR spectrum of **1** the bands at 1602 and 1560 cm^{-1} are assigned to $\nu_{as}(CO_2)$, both features undoubtedly representing two overlapping bands; the $\nu_s(CO_2)$ modes appear at 1432 and 1386 cm^{-1}. The appearance of two distinct bands for each mode reflects the presence of two different types of $PhCO_2^-$ groups in the complex (vide infra). The 1602, 1386 cm^{-1} (Δ = 216 cm^{-1}) pair are assigned [19,20] to the $\eta^1{:}\eta^2{:}\mu_2$ benzoate, while the 1560, 1432 cm^{-1} pair (Δ = 128 cm^{-1}) to the bidentate bridging ($\eta^1{:}\eta^1{:}\mu_2$) benzoates (vide infra). An analogous spectral situation is seen in **2**, with the 1596, 1384 cm^{-1} (Δ = 212 cm^{-1}) pair representing the monoatomically-bridged $\eta^1{:}\eta^2{:}\mu_2$ $PhCO_2^-$ group, and the 1546, 1408 cm^{-1} (Δ = 138 cm^{-1}) the bidentate bridging $PhCO_2^-$ ligands.

3.3. Description of structures

The molecular structures of complexes **1–3**, are depicted in Figs. 1–3. Selected interatomic distances and angles are listed in Tables 2–4.

Complex **1** crystallizes in the triclinic space group $P\bar{1}$. Its crystal structure consists of trinuclear $[Mn_3(O_2CPh)_6\{(py)_2CO\}_2]$ molecules. The central metal center [Mn(2)] is located on a crystallographic inversion center and thus the trinuclear molecule adopts a linear structure. Mn(2) is coordinated by six oxygen atoms belonging to six $PhCO_2^-$ groups. One $\eta^1{:}\eta^2{:}\mu_2$ and two *syn*, *syn*- $\eta^1{:}\eta^1{:}\mu_2$ carboxylate groups span each pair of neighbouring Mn^{II} atoms. The terminal metal ions [Mn(1), Mn(1′)] are each capped by one bidentate chelating - *N*,*N*′ (κ^2*N*,*N*′) $(py)_2CO$ ligand (Scheme 2).

The $Mn(2)O_6$ octahedron is almost perfect with the Mn(2)—O bond lengths and the *cis* O—Mn(2) —O bond angles being in the ranges 2.133(2)–2.214(2) Å and 86.8–93.2(1)°, respectively. The $Mn(1)N_2O_4$ octahedron is distorted; the main distortion arises from the acute O(6)—Mn(1)—O(7) angle [56.8(1)°]. TheMn—N and Mn—O bond lengths agree well with values expected for octahedral high-spin Mn^{II} complexes [4,17,21]. The C(6)–O(1) bond distance [1.210(6) Å] is typical for a carbon–oxygen double bond [14]. The coordination of the bridging benzoate oxygen [O(6), O(6')] is slightly pyramidal [$\sum$°O(6) = 346.2°]. The Mn(1)–O(6)–Mn(2) angle is 105.9(1)°.

The six-membered chelating ring Mn(1)NCCCN adopts a slightly boat conformation with the Mn(1) and C(6) atoms 0.032 and 0.099 Å, respectively, below the plane defined by the remaining

four atoms. The dihedral angle between the two pyridyl rings of the $(py)_2CO$ ligand is 10.0°.

Complex **2**·2MeCN crystallizes also in the triclinic space group $P\bar{1}$. Its crystal structure consists of centrosymmetric trinuclear $[Mn_3(O_2CPh)_6\{(py)_2CO\}_2]$ molecules and solvate MeCN molecules; the latter will not be further discussed. The structure of the trinuclear molecule that is present in **2**·2MeCN is similar to that present in **1**. The main differences are: (i) The termini of the $\{Mn(O_2CPh)_3Mn(O_2CPh)_3Mn\}$ unit in the former are each capped by the bidentate chelating - *N,O* (κ^2*N,O*) $(py)_2CO$ ligand (Scheme 2); (ii) the Mn(1)NO_5 octahedron in **2**·2MeCN is more distorted than the corresponding Mn(1)N_2O_4 polyhedron in **1**. For example, the average value of the three *trans* coordination angles around Mn(1) is 154.1(1)° in **2**·2MeCN compared to 161.3(1)° in **1**. The more severe distortions in the former arise from the acute O(6)–Mn(1)–O(7) angle of 57.5(1)° (such an acute angle is also present in the structure of **1**) and the five-membered chelating ring Mn(1)NCCO with a narrow N(1)–Mn(1)–O(1) angle [70.4(1)°]; and (iii) the intraligand pyridyl ring angle is considerably larger in **2**·2MeCN (49.6°) than in **1** (10.0°); this is a consequence of the different coordination modes of the ligand.

An exciting structural feature of **2**·2MeCN is the κ^2*N,O* ligation mode of $(py)_2CO$, see Scheme 2. Complex **2**·2MeCN is only the third structurally characterized example of a metal complex that contains $(py)_2CO$ in its κ^2*N,O* coordination mode; the previous two examples are complex *trans* (Cl), *cis* (S)-$[Ru^{II}Cl_2\{(py)_2CO\text{-}\kappa^2N,O\}(DMSO\text{-}S)_2]$ [14] and the organometallic compound $[(\eta^5\text{-}C_5H_5)Rh\{(py)_2CO\text{-}\kappa^2N,O\}]$ [22]. The κ^2*N,N'* mode is the familiar coordination mode of $(py)_2CO$ in complexes containing this ligand in its ketone form [5,11,14,23].

Complexes **1** and **2**·2MeCN are linkage isomers. This is the first case of true linkage isomerism in the coordination chemistry of $(py)_2CO$. Toyama et al. have recently studied the complexes *cis* (Cl), *cis* (S)-$[Ru^{II}Cl_2\{(py)_2CO\text{-}\kappa^2N,N'\}(DMSO\text{-}S)_2]$ and (the above mentioned) *trans* (Cl), *cis* (S)-$[Ru^{II}Cl_2\{(py)_2CO\text{-}\kappa^2N,O\}(DMSO\text{-}S)_2]$ [14], which can be considered as linkage isomers; however, these complexes also exhibit geometrical isomerism.

Complexes **1** and **2**·2MeCN join a small family of structurally characterized, trinuclear complexes containing the $[Mn^{II}_3(\eta^1{:}\eta^1{:}\mu_2\text{-}O_2CR)_4(\eta^1{:}\eta^2{:}\mu_2\text{-}O_2CR)_2]^0$ core [21,24]. The benzoate members of this family are listed in Table 5. Such complexes have been important in the establishment of the "carboxylate shift" concept [25]. Of the various types of metal-carboxylate binding modes,

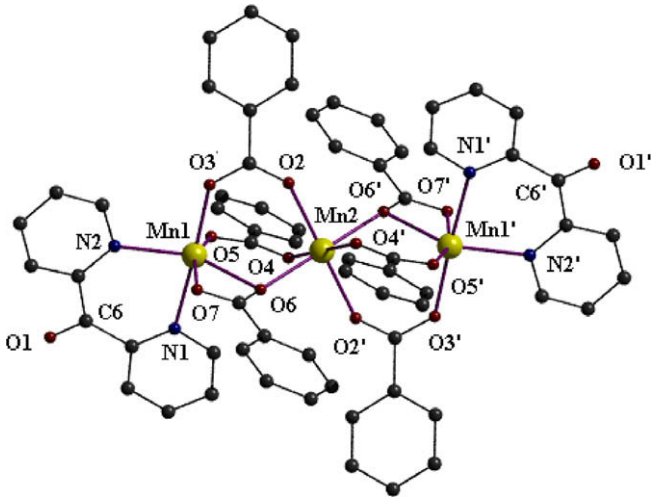

Fig. 1. Partially labeled plot of the molecular structure of complex **1**. Primes are used for symmetry related (−*x*, −*y*, −*z* +1) atoms.

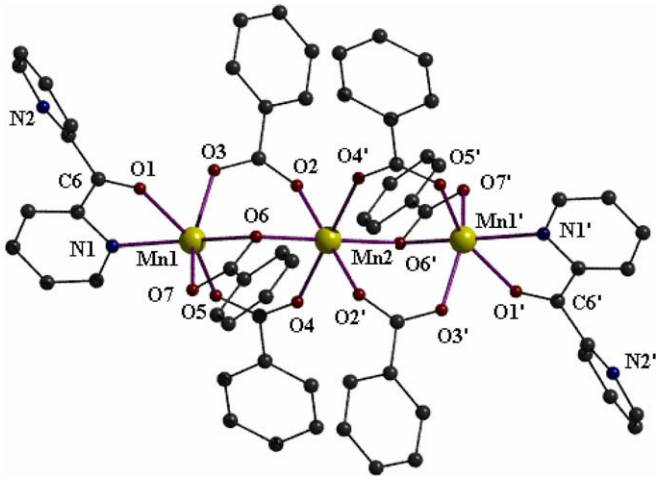

Fig. 2. Partially labeled plot of the linear trinuclear molecule present in complex **2**·2MeCN. Primes are used for symmetry related (−*x*, −*y*, −*z*) atoms.

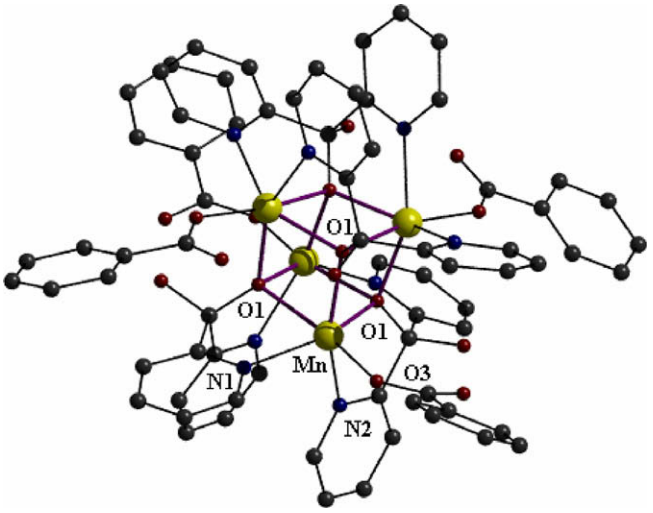

Fig. 3. Partially labeled plot of the cubane molecule present in complex **3**. Only the donor atoms of one Mn^{II} center are labeled. O(1) is the donor atom of the $(py)_2C(OH)O^-$ ligand, while O(3) is the coordinated oxygen atom of the $PhCO_2^-$ group.

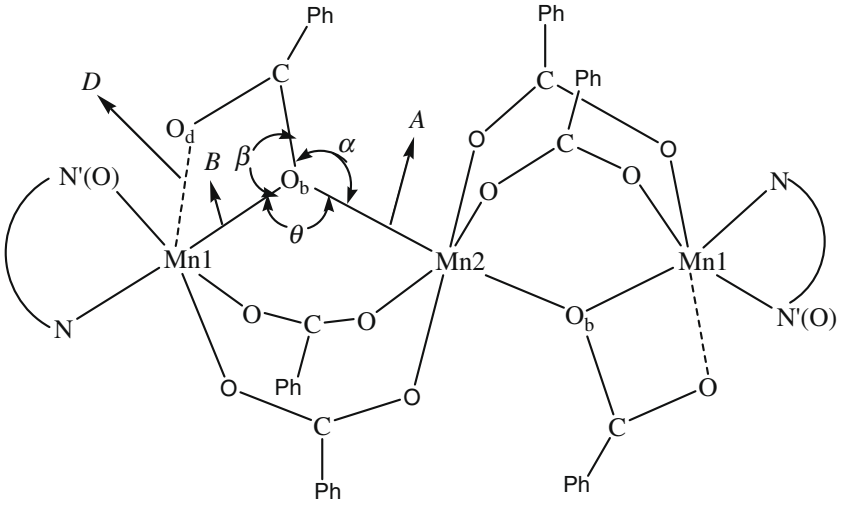
monodentate (monoatomic) bridging between metal centers offers great flexibility. Analysis [25] of the structural features of discrete complexes containing monodentate/monoatomic bridging carboxylates shows that they can be grouped into three classes, depending upon the strength of the interaction of the non-bridging, or dangling (O_d), oxygen atom [O(7) in complexes **1** and **2**·2MeCN] with one of the bridged metal ions [Mn(1) in **1** and **2**·2MeCN]. The application of this analysis to trinuclear Mn^{II} benzoate complexes is demonstrated in Scheme 3 and Table 5. The monoatomic bridging mode is postulated to be an important intermediate between the other, more common carboxylate attachment modes, based on observed variation of the geometry for monoatomic bridges in structurally characterized metal complexes. The movement from monoatomic bridging to the other binding modes has been termed the "carboxylate shift" [25]; such a shift is considered to be kinetically important in carboxylate-containing metalloproteins. Complex **2**·2MeCN is characterized by a small *D* value, $B > D$, a rather long Mn...Mn distance, a small difference between $C–O_d$ and $C–O_b$ (indicating significant delocalization of the double bond), a large tilt ($\alpha-\beta$) of the $\eta^1:\eta^2:\mu_2$ carboxylate group toward Mn(1) and the significant distortion of the coordination geometry of Mn(1). Thus, compound **2**·2MeCN has a strong interaction between Mn(1) and O_d, i.e. O(7), and can be placed in class III in Lippard's classification scheme [25]. Based on analogous arguments, complex **1** is placed in class II in the "carboxylate shift" classification scheme.

Complex **3** crystallizes in the tetragonal space group *I*-42*d*. Its structure consists of tetranuclear $[Mn_4(O_2CPh)_4\{(py)_2C(OH)O\}_4]$ molecules. The molecule of **4** lies on an inverse four-fold axis (S_4 symmetry) and the asymmetric unit contains a quarter of the cluster molecule. The tetranuclear molecule has a cubane $[Mn^{II}_4(\mu_3\text{-}OR')_4]^{4+}$ core with Mn^{II} atoms and μ_3-O atoms occupying alternate vertices. Thus, the molecule consists of two interpenetrating tetrahedra: one of four μ_3-O atoms originating from the $(py)_2C(OH)O^-$ ions and one of four Mn^{II} atoms. In addition to three μ_3-O atoms, each Mn^{II} center is coordinated to two N atoms that belong to two different $(py)_2C(OH)O^-$ ligands and to one O atom that belongs to a monodentate $PhCO_2^-$ group. Thus, the chromophore is $Mn^{II}N_2O_4$. One octahedral face of each Mn^{II} atom is occupied by the three alkoxide-type O atoms and the other consists of the remaining donor atoms.

One O atom of each $(py)_2(OH)O^-$ ligand remains protonated and unbound to the metals. The resultant monoanion functions as a κ^3N,N',O (or $\eta^1:\eta^1:\eta^3:\mu_3$) ligand forming two five-membered MnNCCO chelating rings with two different Mn^{II} atoms (these rings share a common C—O edge) and an alkoxide-type bond to a third metal ion (Scheme 2). This ligation mode is common in the coordination chemistry of hydrated di-2-pyridyl ketone [5].

The Mn_4 tetrahedron is distorted by compression along an S_4 axis and this gives four shorter Mn^{II}...Mn^{II} distances (3.353 Å) and two longer (3.445 Å). There are two types of Mn—O(alkoxide-type) bonds for each Mn^{II} atom: one bond is long (2.327 Å), whereas the two other bonds are shorter (average 2.174 Å). The cube deviates from the ideal geometry. The internal cube angles at the metal vertices (R'O–Mn–OR') average 80.2°, whereas the corresponding angles at the alkoxide corners (Mn–OR'-Mn) are considerably larger averaging 99.0°. An ideal cubane has twelve equal bond lengths and twenty four bond angles at 90°. Such an ideal situation is not encountered in practice, notably because three bonds at 90° are rarely observed at the bridging O atom. An sp^3 hybridized O atom would have three angles at 109.5°, and this may be achieved by compressing the four oxygens along the body diagonals of the cube



Scheme 2. The crystallographically established coordination modes of the ligands $(py)_2CO$ and $(py)_2C(OH)O^-$ in complexes **1–3**.

Scheme 3. The schematic structures of complexes **1** and **2** · 2MeCN showing the dangling (O_d) and bridging (O_b) oxygen atoms of the $\eta^1{:}\eta^2{:}\mu_2$ carboxylate groups of the benzoate ligands, and defining the geometry of monoatomic carboxylate-bridged polymetallic centers in relation to the "carboxylate shift" mechanism proposed by Lippard [25]; the values of the relevant structural parameters for **1** and **2** · 2MeCN and other trinuclear complexes containing the $[Mn^{II}_3(\eta^1{:}\eta^1{:}\mu_2\text{-}O_2CPh)_4(\eta^1{:}\eta^2{:}\mu_2\text{-}O_2CPh)_2]^0$ core are listed in Table 5.

(tetrahedral distortion), increasing the angles at oxygen, but concurrently decreasing the angles at the metal below 90°. The magnitude of this effect may be measured by calculating the sum of the angles at an oxygen vertex, the value for an ideal cubane being 270° and that for an sp^3 oxygen 328.5° [26]. In the case of **3**, this sum is 297.0°. The ratio of the mean O...O distance to the mean Mn...Mn distance may be also taken as a measure of the tetrahedral distortion; a value of one is expected for a perfect cube [26]. This ratio is 0.85 for **3.**

There are several secondary interactions within the cubane molecule that justify its extreme stability towards further reactivity. These are conveniently summarized in Table 6 and shown in Fig. 4. Four, symmetry related H bonds form, with the protonated O atom of the $(py)_2C(OH)O^-$ ligand as the donor and the uncoordinated O atom of the monodentate $PhCO_2^-$ group as the acceptor. In addition, the aromatic rings of the molecule stack in six pairs through π–π interactions [27]. These interactions are of two types: four interactions are between one pyridyl ring of a $(py)_2C(OH)O^-$ ligand and the aromatic ring of the $PhCO_2^-$ group and two between pyridyl rings of adjacent $(py)_2C(OH)O^-$ ligands, with the former being weaker than the latter. By contrast with its $MeCO_2^-$ analogue $[Mn_4^{II}(O_2CMe)_4\{(py)_2C(OH)O\}_4]$ [4], which lacks the four Ph...py interactions, complex **3** is thermodynamically stable being the only product from the $Mn^{II}/PhCO_2^-$ /$(py)_2CO$ system in H_2O-containing organic solvents, whereas the acetate cluster is readily oxidized and hydrolyzed to afford cluster $[Mn_{10}^{II}Mn_4^{III}O_4(O_2CMe)_{20}\{(py)_2C(OH)O\}_4]$; the structure of the latter is based on cubane subunits [4].

A few Mn^{II} cubanes containing the $[Mn_4^{II}(\mu_3\text{-}OR')_4]^{4+}$ core have been reported previously [4,17,28,29]. Complexes **1–3** join a handful of structurally characterized Mn complexes containing various forms of $(py)_2CO$ as ligands [4,28f,30].

3.4. EPR and magnetic studies

At 300 K, the X-band EPR spectra of **1** and **2**·2MeCN are very broad (more than 4000 G). At 10 K, fine structure is resolved, while at 4 K the two spectra are similar and quite complicated with resonances at $g = \sim 6.3$, ~3.4, ~2.0 and ~1.7. This indicates that the populated spin state at 4 K exhibits zero-field splitting [24b,24c]. If the ZFS effects were negligible, i.e., $|J| > |A|$ (A is the hyperfine splitting parameter), a narrow signal would be expected with g around 2. However, if the ZFS is considerable, this signal should be split into several features, and thus signals at low fields may be observed, as found here.

Variable-temperature dc magnetic susceptibility data were collected on a powdered microcrystalline sample of **3** (Fig. 5) in the temperature range 300-5 K under an applied field of 0.1 T. The room temperature $\chi_M T$ value is 16.5 $cm^3\,mol^{-1}\,K$, slightly lower than the expected value of 17.5 $cm^3\,mol^{-1}\,K$ for four $S = 5/2$ uncoupled spin carriers with $g = 2$. The $\chi_M T$ product remains practically constant down to 50 K and then decreases sharply upon further cooling, reaching a value of 5.57 $cm^3\,mol^{-1}\,K$ at 5 K. This behaviour is indicative of weak antiferromagnetic exchange interactions between the Mn^{II} centers [4,17,28d,28h]. Since the spin carriers are all d^5 Mn^{II} atoms, and therefore orbital

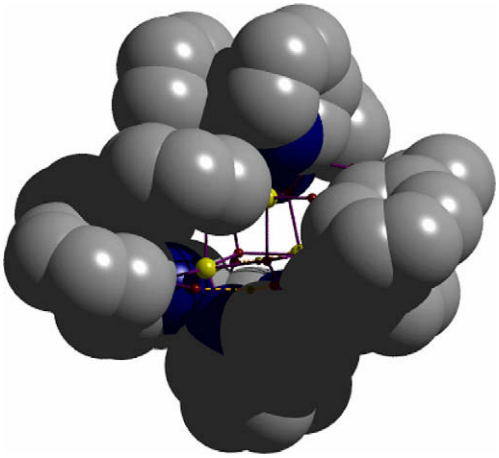

Fig. 4. The secondary intramolecular interactions of **3**. The π–π interacting pairs are shown as space-filling models, while some H bonds are depicted as dotted lines.

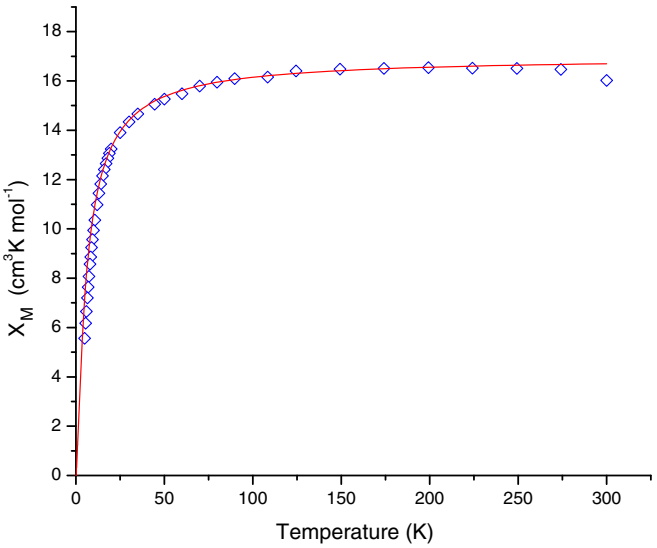
singlet (S) ions, only the isotropic part of the exchange interaction was considered.

When a symmetrical spin Hamiltonian with all coupling constants assumed to be equal was applied, the high temperature data could not be reproduced. The actual S_4 symmetry of the complex was taken into account in order to find a more accurate Hamiltonian. This suggested the use of the spin Hamiltonian given in Eq. (5). The J_1

$$H = -2J_1(S_1S_2 + S_1S_4 + S_2S_3 + S_3S_4) - 2J_2(S_1S_3 + S_2S_4) \quad (5)$$

parameter was attributed to the four shorter Mn^{II}...Mn^{II} distances of 3.353 Å with corresponding Mn–O(1)–Mn angles of 96.4 and 100.9°. The J_2 parameter was attributed to the two longer Mn^{II}...Mn^{II} distances of 3.445 Å with corresponding Mn–O(1)–Mn angles of 99.7°. The exchange interaction model used is illustrated in Scheme 4. The simulation was performed using the program MAGPACK [31]. The best fit parameters are J_1 = -0.25 cm^{-1}, J_2 = -0.10 cm^{-1} and g = 1.97. The ground state of the complex was found to be S = 0, with S = 1 and S = 2 excited states 0.6 and 1.8 cm^{-1} above the ground state, respectively. Any ZFS together with the close spacing of the S levels and their Zeeman M_S components when in an applied magnetic field, make the calculation of the magnetization, M, very difficult to achieve by use of the DS_Z^2-type spin Hamiltonians [28h]. Previous detailed studies [28c] have shown that small D values ($-0.5 \leqslant D \leqslant 0.5$ cm^{-1}) have essentially no effect on the $\chi_M T$ vs. T plots for such Mn$_4^{II}$ systems.



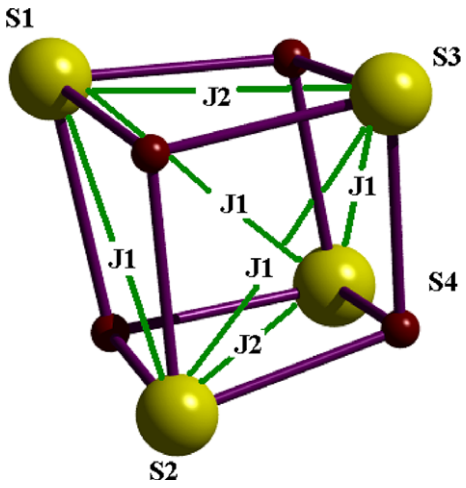


Fig. 5. Plot of $\chi_M T$ vs. T for a powdered sample of complex **3**. The solid line represents the simulation of the experimental data.

Scheme 4. Exchange interaction model used for **3**.

The weak antiferromagnetic J values for **3** are within the narrow range (from −0.10 to −4.11 cm^{-1}) reported for other cubane complexes containing the [Mn$_4^{II}$ (μ_3-OR')$_4$]$^{4+}$ core [4,17,28b,28d,28f–h,29b]. In particular, the J values are close to those (−0.10 and −0.19 cm^{-1}) of the structurally similar complex [Mn$_4^{II}$ (O_2CMe)$_4$ {(py)$_2$C(OH)O}$_4$] [4].

The X-band powder EPR spectrum of **3** at 1.8 K exhibits an almost featureless broad resonance with a $g \sim 2$-value. The broadness of the isotropic absorption is consistent with the presence of magnetically interacting Mn^{II} centers in the solid state [32].

4. Concluding comments

The present work extends the body of results that emphasize the ability of (py)$_2$CO-based ligands to form new structural types in 3d-metal chemistry. The employment of (py)$_2$CO in reactions with Mn(O_2CPh)$_2$·2H_2O has provided access to three neutral Mn^{II} complexes, two novel Mn$_3^{II}$ linkage isomers and one Mn$_4^{II}$ cubane. The trinuclear complexes are reactive and transform into the cubane cluster and a known mixed-valent, (py)$_2$CO-free Mn$_4^{II}$Mn$_2^{III}$ cluster. The intramolecular H-bonding and π–π stacking interactions that are present in the cubane are considered responsible for its great stability towards reactivity. This work demonstrates the flexibility, versatility and synthetic potential of combining (py)$_2$CO with carboxylate ligands. We currently explore synthetic methods

for isolating Mn^{II} benzoate clusters that involve the dianionic ligand $(py)_2CO_2^{2-}$ and for preparing Mn^{III} (or $Mn^{II/III}$) benzoate clusters that contain various forms of $(py)_2CO$.

Supplementary data

Crystallographic data in CIF format have been deposited at the Cambridge Crystallographic Data Center with CCDC Nos. 660964; 660965 and 660966 for **1**, **2**·2MeCN and **3**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (Fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk). DFT calculations

ABSTRACT

In the present work we report a reaction in which dimethyl sulfoxide, initially used as solvent, undergoes oxidation to form sulfate, which then participates to the formation of a linear one-dimensional copper chain. Indeed, using $[Cu(bipy)Cl_2]$, a building block largely applied in synthesis of molecular magnetic compounds, the coordination compound $[Cu(bipy)(H_2O)_2(SO_4)]_n$, where bipy = 2,2′-bipyridine was obtained. Magnetic characterization of complex shows a weak antiferromagnetic interaction between the copper(II) ions with $J = -0.53\ cm^{-1}$. DFT calculations demonstrate that the pathway for the weak antiferromagnetic interaction is through the sulfate bridge.

Dimethyl sulfoxide (DMSO) is a well-known molecule due to its important applications in chemistry and molecular biology. It is largely used as aprotic polar solvent which dissolves a large number of substances, turning it particularly useful in chemical reactions, crystallization processes, chemical analyses, biological studies and in coordination chemistry [1]. Several examples in the literature report the preparation of molecular magnetic compounds using DMSO as the reaction solvent and, in many cases, Cu(II) is the metallic ion involved. As examples, one-dimensional chain [2], two-dimensional [3], interlocked systems [4] and compounds with optical properties [5] have been described. Furthermore, DMSO can also influence the magnetic properties of crystalline compounds [6]. Synthetic chemists usually assume that DMSO is a quite inert solvent for the preparation of coordination compounds. However, when a series of building blocks for molecular magnets were prepared in our laboratories, using copper(II) chloride, diamine ligands and DMSO as the solvent, sulfate containing complexes were obtained. In spite of the large number of papers describing the ability of O_2 activation by copper complexes in solution [7] and the catalytic properties of such complexes in oxidative processes [8], no reference was found about the possibility of generating unexpected products due to DMSO oxidation.

The reaction between $[Cu(bipy)Cl_2]$ [9] and the 4,4′-sulfonyl-bis(phenylamino)bis(ethyl-2-oxoacetato) (**L01**) ligand [10] in DMSO provided needle shaped green crystals, identified as $[Cu(bipy)(H_2O)_2(SO_4)]_n$. When the reaction was carried out in the same experimental conditions, except for the absence of the **L01** ligand, the product was also obtained [11]. Under identical conditions, reactions of the similar precursors yielded one-dimensional compounds of formula $[Cu(en)(H_2O)_2(SO_4)]_n$ and $[Cu(H_2O)_2(phen)(SO_4)]_n$, where en = 1,2-ethylenediamine and phen = 1,10-phenantroline. In order to understand the origin of the sulfate ions, a spot test in the mother liquor was performed with barium chloride aqueous solution. As result, no detectable amount of sulfate ion was found, suggesting a slow formation of SO_4^{2-} due to oxidation of DMSO.

Magnetic measurements for $[Cu(bipy)(H_2O)_2(SO_4)]_n$ were performed on a Cryogenic SX-600 SQUID magnetometer in a range of 2–300 K with an applied field of 0.1 T. Diamagnetic correction was evaluated from Pascal's constants. The field dependence of the magnetization was measured in the field range 0–6 T at 1.8 K. χ_M and $1/\chi_M$ plots as a function of temperature are displayed in Fig. 1. $1/\chi_M$ can be nicely fitted to the Curie–Weiss law ($\chi_M = C/(T - \theta)$). The values obtained for Curie and Weiss constants are 0.37 emu. mol^{-1} and −0.13 K, respectively. These values are expected for an antiferromagnetic chain with a $S = 1/2$ that presents weak interactions through the SO_4^{2-} bridge [12]. Based on the structure of $[Cu(bipy)(H_2O)_2(SO_4)]_n$, we attempted to reproduce the experimental magnetic data considering a Heisenberg 1-D Hamiltonian for antiferromagnetic chains [13]

$$H = -J\sum_{i=1}^{n-1} S_{A_i} S_{A_{i+1}}$$

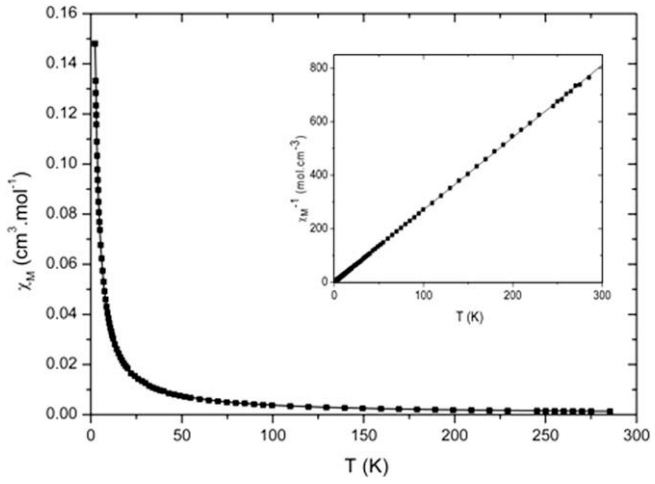

Fig. 1. Temperature dependence of χ_M of $[Cu(bipy)(H_2O)_2(SO_4)]_n$ (squares). Line corresponds to the best fit. Inset: $1/\chi_M$ data as a function of the temperature (squares) fitted to the Curie–Weiss law (line).

and

$$\chi = \frac{Ng^2\beta^2[0.25 + 0.074975x + 0.075235x^2]}{kT[1 + 0.9931x + 0.172135x^2 + 0.757825x^3]},$$

where $x = |J|/kT$.

The best fit parameters were $J = -0.53$ cm^{-1} and $g = 2.01$. Magnetic measurements as a function of the applied magnetic showed a field of 6 T is not enough to override the antiferromagnetic interactions and reach saturation, preventing the magnetization to follow a paramagnetic behavior at 1.8 K.

The crystal structure of $[Cu(bipy)(H_2O)_2(SO_4)]_n$ has been previously described [14]. In the complex the copper atom is in a distorted octahedral environment. Two nitrogen atoms of the diamine groups and two water molecules are in the equatorial plane, whereas the apical positions are occupied by two oxygen atoms of the sulfate ions. Each sulfate ion is bound to two copper ions forming a 1D chain. Each chain is connected to another one through hydrogen bonds between oxygen atoms of sulfate and hydrogen atoms of water molecules. Inspection of the crystal structure shows two pathways through which the antiferromagnetic coupling may occur (Fig. 2). The first one is through the sulfate bridge (model **a**), binding the copper atoms and the second one is through the intermolecular hydrogen bounds (model **b**). Furthermore, there is not a consensus in literature about the main pathway in which the magnetic interaction occurs [12,15]. In order to examine how magnetic orbitals could be involved in the exchange interactions, DFT calculations were performed for $[Cu(bipy)(H_2O)_2(SO_4)]_n$ in GAUSSIAN 03W program package (G03W) [16] employing the Becke's three-parameters hybrid functional (B3) [17] and the Lee-Yang-Parr's gradient-corrected correlation functional (LYP) [18] – B3LYP method. The TZVP basis set was applied for all other atoms [19]. Geometries were fully optimized under these conditions (B3LYP/TZVP). The values of the coupling constants J were obtained using the broken symmetry approach [20]. The optimized geometry is in good agreement with structural experimental parameters. For the model **a**, the magnetic orbital has a small contribution from the d_z2 orbital centered on the copper atoms and a large contribution from the π^* orbital of the sulfate bridge. The d_z2 orbital is directed to the sulfate ion in the apical positions. In this case the value obtained for the coupling constant was $J = -0.20$ cm^{-1}. In the same way as found for **a**, the magnetic orbital of **b** model presents large contributions of a π^* orbital of the sulfate bridge. However, the active orbital centered on the copper atom is a $d_x2 - {}_y2$ instead of a d_z2 one. The coupling constant calculated for model **b** is $J = -0.04$ cm^{-1}. Both models underestimate the value of the experimental coupling constant, but there is a clear difference between the magnitudes of the two calculated values. The magnetic interactions described by model **a** are closer to the experimental values than those obtained with model **b**, showing that the magnetic interaction occurs through the sulfate bridge.

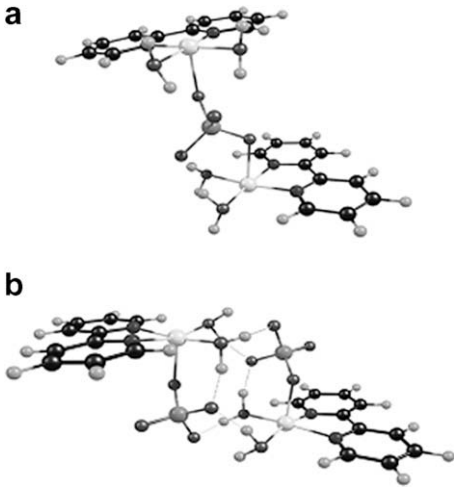

Fig. 2. Models a and b used in DFT calculations for $[Cu(bipy)(H_2O)_2(SO_4)]_n$.

As copper(II) salts and diamine ligands are ordinary reactants applied in the syntheses of molecular magnets, these results showed the possibility of obtaining undesired sub-products formation in reactions where DMSO is used as solvent. Formation of the sulfate copper chains does not depend on the nature of the organic ligands involved in the reactions. Moreover, the obtained chains are insoluble in all investigated solvents, therefore the precipitation of traces of the insoluble paramagnetic compounds can be considered as a possible contamination source which can lead to misleading interpretation of the magnetic behavior, as was recently described [21].

Tetrairon(III) complexes

ABSTRACT

Tripods of general formula R'–O–$CH_2C(CH_2OH)_3$ are excellent site-specific ligands for the preparation of functionalized Fe_4 single-molecule magnets. Herein, we describe the synthesis and characterization of two novel complexes designed to bind graphene surfaces, in which the R group consists of an alkyl spacer $–(CH_2)_n–$ (n = 6 and 10) and a terminal pyrenyl moiety. The site-specific ligand substitution on $[Fe_4(OMe)_6(dpm)_6]$ (Hdpm = dipivaloylmethane) with the new tripods has been studied with ^{2}H NMR on isotopically-enriched samples, revealing that, once formed, these clusters are stable in solution over long timescales. It was not possible to isolate the new compounds as crystalline solids, nevertheless they were chemically characterized by elemental analysis and ^{1}H NMR. The presence of the pyrenyl ending groups prompted us to investigate the effect of metal complexation on fluorescence, and a full pyrene-to-iron cluster excitation energy transfer was observed. The analysis of the magnetic behaviour revealed an S = 5 ground spin state with a negative zero-field splitting parameter D = –0.42 cm^{-1}.

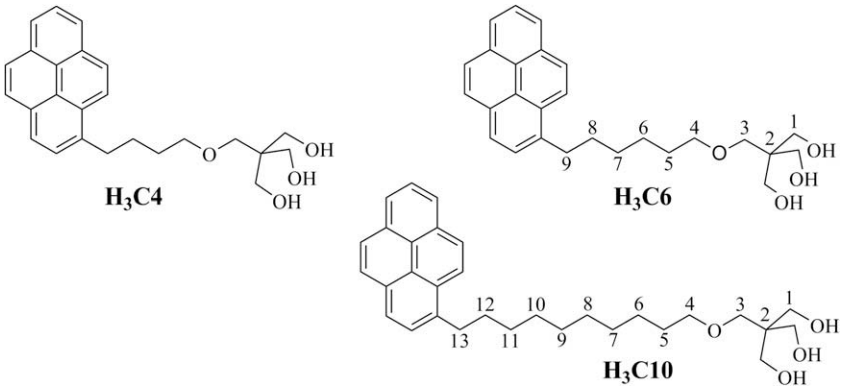
1. Introduction

Tetrairon(III) complexes with a propeller-like structure (also known as "ferric stars") are among the most appealing single-molecule magnets (SMM) for application in molecular spintronics and quantum computing [1]. Since the discovery of the archetypal tetrairon(III) SMM, the compound $[Fe_4(OMe)_6(dpm)_6]$ [2] (**1**, Hdpm = dipivaloylmethane), several derivatives have been obtained by selective replacement of the six methoxide bridges with tripods H_3L = R–$C(CH_2OH)_3$. The products of the reaction are usually obtained as pure, crystalline materials and display enhanced magnetic properties as compared with the parent compound **1**. Moreover, the R group can be chosen so as to bring additional functionalities, such as surface-binding capability [3–7]. We have recently shown that tetrairon(III) SMM can be successfully anchored to native gold surfaces by using R groups containing thioacetyl moieties, with full retention of magnetic properties [8]. In a different approach, tripods bearing a terminal double bond were reacted with H-terminated silicon substrates to give arrays of molecular receptors designed for SMM binding [7]. The first CNT-SMM hybrids (CNT = carbon nanotube) were also successfully realized by exploiting the noncovalent π-stacking interaction between pristine CNT and a Fe_4 derivative functionalized with pyrenyl units [9]. The tripodal ligand used (**H_3C4**, Scheme 1) is a derivative of pentaerythritol and comprises a short C4 alkyl spacer. In the present work we wish to describe the synthesis of two additional pyrene-functionalized SMM, **2** and **3**, bearing longer spacers (**H_3C6** and **H_3C10** in Scheme 1). The new compounds were characterized with NMR and fluorescence spectroscopy, and the magnetic properties were measured with DC magnetometry and HF-EPR spectroscopy.



2. Experimental

2.1. Materials and methods

All the chemicals were of reagent-grade quality and used as received, unless otherwise stated. Anhydrous THF and diethyl ether, predried over $CaCl_2$, were distilled from Na/benzophenone shortly before use. MeOH was carefully dried by treatment with Mg/I_2 and distilled prior to use. Anhydrous toluene, *n*-hexane, dichloromethane (DCM) and 1,2-dichloroethane (DCE) were obtained by distillation over CaH_2. Toluene and *n*-hexane were stored over Na wires, while DCM and DCE were stored over 4-Å molecular sieves in the dark.

Scheme 1. Tripodal ligands functionalized with pyrenyl moieties.

(1-Methyl-2,6,7-trioxabicyclo[2.2.2]octan-4-yl)methanol [10], 6-bromohexanoyl chloride [11], 10-bromodecanoyl chloride [12], $[Fe_4(OMe)_6(dpm)_6]$ (**1**) [3], and $[Fe_4(OMe)_6(dpm\text{-}d_{18})_6]$ (**1-*d***) [3] were synthesized according to literature procedures.

All the solutions used for NMR and fluorescence experiments were prepared with anhydrous solvents and were stored excluding any possible contamination. The NMR spectra were recorded at 302 K with a Bruker FT-DPX200 NMR spectrometer. Proton chemical shifts are reported relative to TMS, while deuteron chemical shifts are referenced to acetone-d_6, as external standard (δ = 2.16 ppm). The protons of the pyrenyl ring are abbreviated as C*H*Py. ESI Mass spectra were obtained with an ESI Waters ZQ-4000 instrument; C, H analysis was performed using a Carlo Erba EA1110 CHNS-O automatic analyser.

2.2. Synthesis of the compounds

2.2.1. 6-Bromo-1-(pyren-1-yl)hexan-1-one (*4*)

Pyrene (2.478 g, 12.25 mmol) and 6-bromohexanoyl chloride (2.180 g, 10.21 mmol) were dissolved in 29 mL of anhydrous DCE under N_2, the mixture was cooled to −10 °C and $AlCl_3$ (1.633 g, 12.25 mmol) was added portionwise in 20 min. The reaction mixture turned to a dark color and was allowed to reach room temperature slowly and stirred overnight. Excess $AlCl_3$ was quenched with crushed ice, the resulting aqueous phase was saturated with solid NaCl, 50 mL of fresh DCE were added and the layers separated. The organic phase was washed with saturated NaCl, dried over $MgSO_4$, filtered and concentrated in vacuo. The crude product was purified with column chromatography on silica gel (petroleum ether–DCM: 7:3) to yield **4** as a yellowish solid (3.014 g, 78%). ^{1}H NMR ($CDCl_3$): δ (ppm) 8.88 (d, J = 9.4 Hz, 1H, C*H*Py); 8.30–8.00 (m, 8H, C*H*Py); 3.44 (t, J = 6.7 Hz, 2H, CH_2Br); 3.21 (t, J = 7.2 Hz, 2H, CH_2CO); 2.02–1.82 (m, 4H, CH_2CH$_2$Br, CH_2CH$_2$CO); 1.68–1.52 (m, 2H, CH_2). ^{13}C NMR ($CDCl_3$): δ (ppm) 206.60 (*C*O); 129.53 (*C*HPy); 129.43 (*C*HPy); 127.05 (*C*HPy); 126.38 (*C*HPy); 126.22 (*C*HPy); 125.97 (*C*HPy); 124.75 (*C*HPy); 123.99 (*C*HPy); 42.25 (*C*H$_2$); 33.55 (*C*H$_2$); 32.65 (*C*H$_2$); 27.93 (*C*H$_2$); 23.99 (*C*H$_2$).

2.2.2. 1-(6-Bromohexyl)pyrene (*5*)

To a stirred suspension of $AlCl_3$ (0.880 g, 6.60 mmol) in 9 mL of anhydrous Et_2O under N_2, $LiAlH_4$ (6.6 mL, 1-M solution in Et_2O) was added dropwise. To the resulting milky reaction mixture, a solution of **4** (1.00 g, 2.64 mmol) in 12.5 mL of anhydrous DCM was slowly added dropwise. The reaction turned orange with a white precipitate and was stirred at room temperature for 1 h. Excess $LiAlH_4$ was quenched by careful addition of crushed ice, then 2.5-M HCl was added until acidic pH. The reaction was extracted with Et_2O (2 × 50 mL), the combined organic phases were washed with saturated NaCl, dried over $MgSO_4$, filtered and concentrated in vacuo to yield **5** as a yellow solid (0.864 g, 92%), which was used without further purification (98% + from ^{1}H NMR). ^{1}H NMR ($CDCl_3$): δ (ppm) 8.29 (d, J = 9.2 Hz, 1H, C*H*Py); 8.20–7.96 (m, 7H, C*H*Py); 7.87 (d, J = 7.8 Hz, 1H, C*H*Py); 3.42 (t, J = 6.7 Hz, 2H, CH_2Br); 3.36 (t, J = 7.7 Hz, 2H, CH_2Py); 1.97–1.81, (m, 4H, CH_2CH$_2$Br, CH_2CH$_2$Py); 1.59–1.50 (m, 4H, CH_2). ^{13}C NMR ($CDCl_3$): δ (ppm) 136.34 (*C*^{IV}Py); 130.93 (*C*^{IV}Py), 129.76 (*C*^{IV}Py); 127.51 (*C*HPy); 127.20 (*C*HPy); 127.16 (*C*HPy); 126.54 (*C*HPy); 125.77 (*C*HPy); 124.82 (*C*HPy); 124.77 (*C*HPy); 124.65 (*C*HPy); 123.39 (*C*HPy); 33.84 (*C*H$_2$); 33.40 (*C*H$_2$); 32.76 (*C*H$_2$); 31.63 (*C*H$_2$); 28.84 (*C*H$_2$); 28.09 (*C*H$_2$).

2.2.3. 2-(Hydroxymethyl)-2-((6-(pyren-1-yl)hexyloxy)methyl)-propane-1,3-diol (***H$_3$C6***)

To a stirred suspension of NaH (0.289 g, 60% w/w dispersion in mineral oil, 12.0 mmol) in 17 mL of anhydrous THF under N_2, (1-methyl-2,6,7-trioxabicyclo[2.2.2]octan-4-yl)methanol (0.193 g, 1.20 mmol) was added as a solid in one portion. The mixture was stirred at room temperature for 1 h, then a solution of **5** (0.484 g, 1.32 mmol) in 7 mL of THF was added dropwise, followed by tetrabutylammonium bromide (TBABr) (0.020 g, 0.053 mmol). The reaction was stirred at room temperature for 3 days under N_2, excess NaH was quenched with careful addition of MeOH, the solution was acidified with 2.5-M HCl until pH 1. The solvent was removed in vacuo and the crude material was purified with column chromatography on silica gel (DCM, gradient elution to DCM–MeOH: 10:1) to yield the intermediate monoacetylated product **AcH$_2$C6** (0.200 g, 0.432 mmol) and a small amount of the desired compound **H$_3$C6** (0.030 g, 6%). The monoacetylated product (0.200 g, 0.432 mmol) was dissolved in 4 mL of anhydrous MeOH, NaOMe (0.015 mL, 2.94-M solution in methanol, 0.044 mmol) was added and the mixture was stirred under N_2 for 1 day at room temperature. Finally, a drop of 2.5-M HCl was added and the solvent removed in vacuo to yield **H$_3$C6** as a light yellow solid (0.178 g, 98%).

^{1}H NMR for **AcH$_2$C6** ($CDCl_3$): δ (ppm) 8.29 (d, J = 9.4 Hz, 1H, C*H*Py); 8.20–7.95 (m, 7H, C*H*Py); 7.87 (d, J = 7.8 Hz, 1H, C*H*Py); 4.19 (s, 2H, CH_2OCO); 3.69–3.55 (m, 4H, CH_2OH); 3.43 (s, 2H, OCH_2-C^{IV}); 3.42 (t, J = 6.2 Hz, 2H, CH$_2$CH_2O); 3.36 (t, J = 7.6 Hz, 2H, CH_2Py); 2.08 (s, 3H, CH_3CO); 1.96–1.81 (m, 2H, CH_2); 1.66–1.38 (m, 6H, CH_2).

^{1}H NMR for **H$_3$C6** (DMSO-d_6): δ (ppm) 8.35–8.00 (m, 8H, C*H*Py); 7.92 (d, J = 7.9 Hz, 1H, C*H*Py); 4.15 (t, J = 5.3 Hz, 3H, O*H*); 3.39 (d, J = 5.3 Hz, 6H, CH_2OH); 3.35–3.26 (m, 6H, CH_2OCH_2, CH_2Py); 1.83–1.69 (m, 2H, CH_2); 1.55–1.25 (m, 6H, CH_2). ^{13}C NMR (DMSO-d_6): δ (ppm) 137.00 (*C*^{IV}Py); 130.85 (*C*^{IV}Py); 130.37 (*C*^{IV}Py);

129.10 (C^{IV}Py); 127.96 (C^{IV}Py); 127.39 (*C*HPy); 127.34 (*C*HPy); 127.09 (*C*HPy); 126.33 (*C*HPy); 126.01 (*C*HPy); 124.83 (*C*HPy); 124.65 (*C*HPy); 124.20 (C^{IV}Py); 123.37 (*C*HPy); 70.71 (CH_2O); 69.62 (CH_2O); 61.00 (CH_2OH); 45.43 (C^{IV}); 32.51 (CH_2); 31.46 (CH_2); 29.06 (CH_2); 28.82 (CH_2); 25.52 (CH_2).

Anal. Calc. for **H_3C6**, $C_{27}H_{32}O_4$: C, 77.11; H, 7.67. Found: C, 76.77; H, 8.01%.

2.2.4. [Fe_4(C6)$_2$(dpm)$_6$] (**2**)

To a stirred solution of **1** (0.075 g, 0.050 mmol) in 20 mL of dry toluene, **H_3C6** (0.052 g, 0.12 mmol) was added and the resulting mixture was stirred for 40 h. The solvent was carefully removed in vacuo without warming, the resulting dark orange solid was stirred with 10 mL of anhydrous *n*-hexane for 30 min, and the suspension obtained was filtered on a G4 sintered glass frit. Removal of the solvent in vacuo without warming afforded **2** as a dark orange solid (0.081 g, 75%).

Anal. Calc. for **2**·C_6H_{14}, $Fe_4O_{20}C_{126}H_{186}$: C, 67.41; H, 8.37. Found: C, 67.35; H, 8.37%.

2.2.5. 10-Bromo-1-(pyren-1-yl)decan-1-one (**6**)

Pyrene (2.430 g, 12.00 mmol) and 10-bromodecanoyl chloride (2.700 g, 10.00 mmol) were dissolved in 28 mL of anhydrous DCE under N_2, the mixture was cooled to 0 °C and $AlCl_3$ (1.600 g, 12.00 mmol) was added portionwise in 20 min. The reaction turned to a dark color and was allowed to reach room temperature slowly and stirred overnight. Excess $AlCl_3$ was quenched with crushed ice, the resulting aqueous phase was saturated with solid NaCl, 50 mL of fresh DCE were added and the layers separated. The organic layer was washed with saturated NaCl, dried over $MgSO_4$, filtered and concentrated in vacuo. The crude product was purified with column chromatography on silica gel (petroleum ether–DCM: 7:3) to yield **6** as a yellow solid (3.450 g, 83%). ^{1}H NMR ($CDCl_3$): δ (ppm) 8.88 (d, J = 9.4 Hz, 1H, *CH*Py); 8.30–7.98 (m, 8H, *CH*Py); 3.39 (t, J = 6.8 Hz, 2H, CH_2Br); 3.19 (t, J = 7.3 Hz; 2H, CH_2CO); 1.94–1.76 (m, 4H, CH_2CH_2Br, CH_2CH_2CO); 1.53–1.31 (m, 10H, CH_2). ^{13}C NMR ($CDCl_3$): δ (ppm) 205.25 (*C*O); 133.53 (C^{IV}Py); 132.91 (C^{IV}Py); 131.08 (C^{IV}Py); 130.56 (C^{IV}Py); 129.42 (*C*HPy); 129.32 (*C*HPy); 129.23 (C^{IV}Py); 127.04 (*C*HPy); 126.33 (*C*HPy); 126.15 (*C*HPy); 125.95 (*C*HPy); 125.91 (*C*HPy); 124.82 (*C*HPy); 124.35 (C^{IV}Py); 123.98 (*C*HPy); 42.63 (CH_2CO); 33.96 (CH_2Br); 32.81 (CH_2); 29.35 (CH_2); 29.25 (CH_2); 28.68 (CH_2); 28.13 (CH_2); 24.97 (CH_2).

2.2.6. 1-(10-Bromodecyl)pyrene (**7**)

To a stirred suspension of $AlCl_3$ (0.919 g, 6.90 mmol) in 9 mL of anhydrous Et_2O under N_2, $LiAlH_4$ (6.90 mL, 1-M solution in Et_2O) was added dropwise. To the resulting milky reaction mixture, a solution of **6** (1.20 g, 2.76 mmol) in 8 mL of anhydrous DCM was slowly added dropwise. The reaction turned orange with a white precipitate and was stirred at room temperature for 2 h. Excess $LiAlH_4$ was quenched by careful addition of crushed ice, then 2.5-M HCl was added until acidic pH. The reaction was extracted with Et_2O (2 × 50 mL), the combined organic phases were washed with saturated NaCl, dried over $MgSO_4$, filtered and concentrated in vacuo to yield **7** as a yellow solid (1.142 g, 98%), which was used without further purification (98% + from ^{1}H NMR). ^{1}H NMR ($CDCl_3$): δ (ppm) 8.31 (d, J = 9.4 Hz, 1H, *CH*Py); 8.21–7.97 (m, 7H, *CH*Py); 7.88 (d, J = 7.8 Hz, 1H, *CH*Py); 3.41 (t, J = 6.4 Hz, 2H, CH_2Br); 3.36 (t, J = 7.8 Hz, 2H, CH_2Py); 1,96–1.78 (m, 4H, CH_2CH_2Br, CH_2CH_2Py); 1.59–1.24 (m, 12H, CH_2). ^{13}C NMR ($CDCl_3$): δ (ppm) 137.30 (C^{IV}Py); 131.52 (C^{IV}Py); 131.00 (C^{IV}Py); 129.75 (C^{IV}Py); 129.46 (C^{IV}Py); 128.66 (C^{IV}Py); 127.57 (*C*HPy); 127.23 (*C*HPy); 127.11 (*C*HPy); 126.51 (*C*HPy); 125.76 (*C*HPy); 124.80 (*C*HPy); 124.64 (*C*HPy); 123.53 (*C*HPy); 34.00 (CH_2Br); 33.61 (CH_2); 32.88 (CH_2); 31.93 (CH_2); 29.80 (CH_2); 29.56 (CH_2); 29.52 (CH_2); 29.44 (CH_2); 28.78 (CH_2); 28.20(CH_2).

2.2.7. 2-(Hydroxymethyl)-2-((10-(pyren-1-yl)decyloxy)methyl)-propane-1,3-diol (**H_3C10**)

To a stirred suspension of NaH (0.716 g, 60% w/w dispersion in mineral oil, 17.9 mmol) in 25 mL of anhydrous THF under N_2, (1-methyl-2,6,7-trioxabicyclo[2.2.2]octan-4-yl)methanol (0.287 g, 1.79 mmol) was added as a solid portionwise. The mixture was stirred at room temperature for 1 h, then a solution of **7** (0.834 g, 1.98 mmol) in 3 mL of THF was added dropwise, followed by TBABr (0.030 g, 0.079 mmol). The reaction was stirred at room temperature for 5 days under N_2, excess NaH was quenched with careful addition of MeOH, the solution was acidified with 2.5-M HCl until pH 1. The solvent was removed in vacuo and the crude material was purified with column chromatography on silica gel (DCM, gradient elution to DCM–MeOH: 1:1) to yield the intermediate monoacetylated product **AcH_2C10** (0.486 g, 0.937 mmol) and **H_3C10** (0.243 g, 28%). Compound **AcH_2C10** (0.486 g, 0.937 mmol) was dissolved in 9 mL of anhydrous MeOH, NaOMe (0.032 mL, 2.94-M solution in methanol, 0.094 mmol) was added and the mixture was stirred under N_2 for one day at room temperature, a drop of 2.5 M HCl was added and the solvent removed in vacuo to yield **H_3C10** as a dark yellow solid (0.437 g, 99%).

^{1}H NMR for **AcH_2C10** ($CDCl_3$): δ (ppm) 8.28 (d, J = 9.4 Hz, 1H, *CH*Py); 8.18–7.94 (m, 7H, *CH*Py); 7.86 (d, J = 7.8 Hz, 1H, *CH*Py); 4.20 (s, 2H, CH_2OCO); 3.71–3.57 (m, 4H, CH_2OH); 3.43–3.29 (m, 6H, OCH_2C^{IV}, CH_2CH_2O, CH_2Py); 3.04 (br s, 2H, O*H*); 2.09 (s, 3H, CH_3CO); 1.85–1.79 (m, 2H, CH_2CH_2Py); 1.60–1.29 (m, 14H, CH_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 171.65 (*C*O); 137.32 (C^{IV}Py); 131.47 (C^{IV}Py); 130.96 (C^{IV}Py); 129.68 (C^{IV}Py); 128.61 (C^{IV}Py); 127.52 (*C*HPy); 127.21 (*C*HPy); 127.07 (*C*HPy); 126.45 (*C*HPy); 125.74 (*C*HPy); 125.08 (C^{IV}Py); 124.76 (*C*HPy); 124.59 (*C*HPy); 123.51 (*C*HPy); 72.26 (CH_2); 72.06 (CH_2); 63.67 (CH_2); 63.35 (CH_2); 53.41 (C^{IV}); 44.67 (CH_2); 33.57 (CH_2); 31.91 (CH_2); 29.80 (CH_2); 29.55 (CH_2); 29.46 (CH_2); 29.39 (CH_2); 26.06 (CH_2); 20.80 (CH_3).

^{1}H NMR for **H_3C10** (DMSO-d_6) δ (ppm) 8.28 (d, J = 9.3 Hz, 1H, *CH*Py); 8.17–7.93 (m, 7H, *CH*Py); 7.85 (d, J = 7.9 Hz, 1H, *CH*Py); 3.70 (s, 6H, CH_2OH); 3.42 (s, 2H, OCH_2C^{IV}); 3.38 (t, J = 6.6 Hz, 2H, CH_2CH_2O); 3.33 (t, J = 7.8 Hz, 2H, CH_2Py); 3.12 (br s, 3H, O*H*) 1.93–1.78 (m, 2H, CH_2); 1.60–1.28 (m, 14H, CH_2). ^{13}C NMR ($CDCl_3$) δ (ppm) 137.40 (C^{IV}Py); 131.56 (C^{IV}Py); 131.04 (C^{IV}Py); 129.78 (C^{IV}Py); 128.70 (C^{IV}Py); 127.62 (*C*HPy); 127.30 (*C*HPy); 127.15 (*C*HPy); 126.54 (*C*HPy); 125.82 (*C*HPy); 125.19 (C^{IV}Py); 124.85 (*C*HPy); 124.68 (*C*HPy); 123.60 (*C*HPy); 73.55 (CH_2O); 72.23 (CH_2O); 64.45 (CH_2OH); 44.98 (C^{IV}); 33.66 (CH_2); 32.00 (CH_2); 29.89 (CH_2); 29.63 (CH_2); 29.55 (CH_2); 29.48 (CH_2); 26.15 (CH_2).

Anal. Calc. for **H_3C10,** $C_{31}H_{40}O_4$: C, 78.11; H, 8.46. Found: C, 77.89; H, 8.76%.

2.2.8. [Fe_4(C10)$_2$(dpm)$_6$] (**3**)

To a stirred solution of **1** (0.080 g, 0.053 mmol) in 20 mL of dry toluene, **H_3C10** (0.063 g, 0.13 mmol) was added and the resulting mixture was stirred for 40 h. The solvent was carefully removed in vacuo without warming, the resulting dark orange solid was stirred with 12 mL of anhydrous *n*-hexane for 30 min, and the suspension obtained was filtered on a G4 sintered glass frit. Removal of the solvent in vacuo without warming afforded **3** as a dark orange solid (0.098 g, 81%).

Anal. Calc. for **3**·0.5C_6H_{14}, $Fe_4O_{20}C_{131}H_{195}$: C, 68.01; H, 8.50. Found: C, 67.54; H, 8.51%.

2.3. Fluorescence spectra

Fluorescence emission spectra were recorded with a Spex Jobin Yvon FluoroMax 2 spectrofluorometer, using a triangular cell and front-face irradiation. Spectral bandwidth was around 2 nm.

2.4. Magnetic measurements

DC magnetic data were recorded using a Cryogenic S600 SQUID magnetometer. The temperature dependence of the M/H ratio (assumed to correspond to the static susceptibility) was measured on 15.77- and 13.51-mg samples of **2** and **3**, respectively, in applied fields of 10 kOe from 300 to 30 K and of 1 kOe from 30 to 1.9 K to suppress saturation effects. The isothermal magnetization of the same samples was also measured at 1.9, 2.5 and 4.5 K in fields up to 50 kOe.

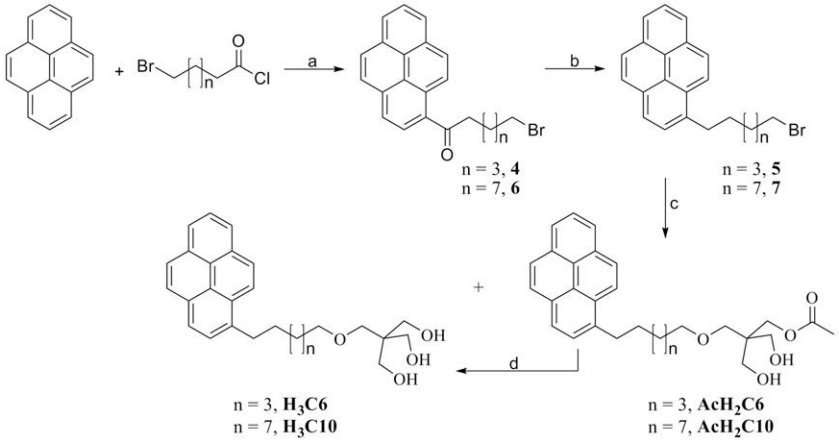
Data reduction was carried out using the following molecular weights and diamagnetic contributions (estimated from Pascal's constants): for **2**, 2244.24 and -1408×10^{-6} emu mol^{-1} (corresponding to **2**·C_6H_{14}); for **3**, 2313.37 and -1464×10^{-6} emu mol^{-1} (corresponding to **3**·0.5C_6H_{14}).

2.5. EPR spectra

High-Frequency EPR (HF-EPR) spectra were recorded at the Grenoble High Magnetic Field Laboratory on a homebuilt spectrometer working in single-pass mode, at temperatures of 5, 10 and 20 K. Gunn diodes operating at 95 or 115 GHz, equipped with a frequency doubler were used as source excitation. The amorphous samples of **2** and **3** used for the experiments were crushed using a mortar and pestle and pressed in a pellet. Spin-Hamiltonian calculations and simulation of HF-EPR spectra were carried out as described elsewhere [5]. The uncertainty in the spin-Hamiltonian parameters obtained by simulation of HF-EPR spectra is of the order of ±1 on the last significant digit.

3. Results and discussion

3.1. Synthesis



The two novel pyrenyl ligands were synthesised as shown in Scheme 2. Pyrene was acylated with the appropriate ω-bromoalkanoyl chloride through a classical Friedel-Crafts reaction [12,13]. The subsequent reduction of the carbonyl moiety was carried out in mild conditions [14] to give the corresponding 1-(ω-bromoalkyl)pyrene (**5**, **7**) in good yields without need of purification. The next step, i.e. the coupling reaction of 1-(ω-bromoalkyl)pyrene with (1-methyl-2,6,7-trioxabicyclo[2.2.2]octan-4-yl)methanol, proved not to be trivial. Literature procedures employing KOH in DMSO [15,16] lead almost exclusively to the formation of elimination by-products. Strictly anhydrous conditions with NaH as base and catalytic TBABr proved to be the most successful strategy to the desired products. Interestingly, the work-up conditions allowed to isolate both the totally deprotected tripods and the monoacetylated derivatives, which were quantitatively hydrolyzed to give the target compounds **H_3C6** and **H_3C10**.

The coordinating ability of the two new ligands was tested using ^{2}H NMR. When samples are isotopically enriched on the *t*Bu groups of dpm$^-$ ligands, the paramagnetically-shifted ^{2}H NMR signals allow to easily monitor structural changes in the tetrairon(III) core [3,5]. Toluene solutions of the deuterated complex [$Fe_4(OMe)_6$(dpm-d_{18})$_6$] (**1-*d***) showed time dependent ^{2}H NMR spectra, as previously reported for Et_2O solutions [3]. If spectra are recorded immediately after the dissolution two distinct signals appear at δ = 10.3 and at 12.7 ppm in a 91:9 ratio, which are assigned respectively to the intact tetrairon(III) species and to a magnetically uncoupled Fe(dpm) complex. After 24 h, the latter signal is largely dominant and after 6 days dpm$^-$ is present exclusively as monomeric Fe(dpm) complexes and as free ligand (δ = 0.9 ppm) (Fig. 1a).

The above-described trend is drastically affected if an excess of tripodal ligand (2.7 eq.) is added to a 1.6 mM solution of **1-*d*** in toluene (see Fig. 1b and c). The ratio between the signals at 10.3 ppm and at 12.7 ppm is 4:1 short after preparation and raises to 7:1 after 24 h. After 6 days the spectra are dominated by the resonance from intact tetrairon(III) complexes, with only very weak signals at 12.7 ppm and at 0.9 ppm. Thus, the two tripods **H_3C6** and **H_3C10** show the same coordinating ability and stabilize tetrairon(III) complexes over long timescales. Indeed, very similar spectra were obtained using the shorter-chain ligand **H_3C4**, whose tetrairon(III) complex could be isolated in crystalline form [9].

To gain further evidence, the same solutions were analysed with ESI-MS, a unique tool for the determination of the molecular mass of large and labile molecules. The ESI (+) spectra revealed signals centred at m/z = 2289 and 2401, attributable to [**2-*d*** + Na^+] and [**3-*d*** + Na^+], respectively. A remarkable agreement between the theoretical masses and the reconstructed ESI isotope patterns was found, thus confirming the ^{2}H NMR data.

Unfortunately, all attempts to isolate product clusters in crystalline form failed. The complexes were thus assembled in dry toluene solution using excess ligand, the solvent was removed in vacuo and the solid was extracted with dry *n*-hexane, since the solubility of **H_3C6** and **H_3C10** in this solvent is as low as 10^{-5} M (data obtained by UV–Vis analysis of saturated solutions). Solvent removal from the filtered extracts led to **2** and **3** as dark orange amorphous solids in good yield.

Scheme 2. Synthesis of the ligands **H_3C6** and **H_3C10**. Experimental conditions: (a) $AlCl_3$, DCE, −10 °C to room temperature, 18 h; (b) $AlCl_3$, $LiAlH_4$, Et_2O/DCM, 1–2 h room temperature; (c) (1-methyl-2,6,7-trioxabicyclo[2.2.2]octan-4-yl)methanol, NaH, THF, TBABr, 3–5 days, room temperature and (d) NaOMe, MeOH, room temperature, 1 day.

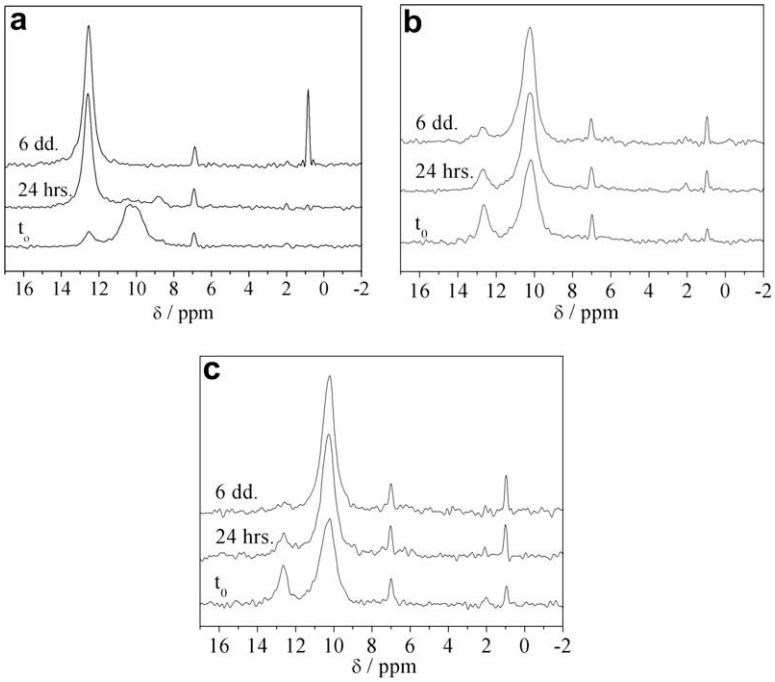


Fig. 1. Time-dependent ^{2}H NMR spectra of tetrairon(III) complexes in toluene solution at 302 K (t_0 labels freshly prepared solutions). (a) 1.57 mM solution of **1-*d***. (b) 1.55 mM solution of **1-*d*** with addition of excess tripodal ligand **H_3C6**. (c) 1.64 mM solution of **1-*d*** with addition of excess tripodal ligand **H_3C10**.

3.2. Solution characterization

Tetrairon(III) clusters with general formula $[Fe_4(L)_2(dpm)_6]$, although strongly paramagnetic, exhibit a quite distinctive ^{1}H NMR resonance arising from *t*Bu protons, whose very broad signal is observed at ca. 10.4 ppm at room temperature. The tripodal ligands L^{3-}, when coordinated, do not show any observable NMR signal from ^{1}H nuclei lying closer to the metal centers, such as C1 hydrogens and the first few CH_2 groups of alkyl substituents (refer to Scheme 1 for the atom numbering) [5]. The ^{1}H NMR spectrum of **2** in toluene-d_8 is presented in Fig. 2a. In addition to the above-mentioned *t*Bu signal, the spectrum comprises a group of broad resonances at 7.93–7.70 ppm arising from the 18 aromatic protons of the pyrenyl rings, which display unresolved hyperfine splittings. In the spectral region spanned by C1, C3, C4 and C9 hydrogens of the free ligand (δ = 3.6–3.1 ppm), a broad signal is observed at 3.3 ppm, whose integrated intensity corresponds to four protons only. This resonance is assigned to C9 protons, which lie farthest from the metal centers (see Supporting Information for the ^{1}H NMR spectrum of **H_3C10** in toluene-d_8). Integration of the broad signal at 1.72–1.33 ppm also indicates that, beside C4, additional protons of the aliphatic spacer escape NMR detection, thus lending further support to metal complexation. The longer alkyl spacer in **3** coherently affords sharper NMR resonances from pyrenyl and C13 hydrogens, as shown in Fig. 2b. Finally, traces of *n*-hexane are clearly detectable in both spectra (ca. 1.0 and 0.5 molecules per cluster for **2** and **3**, respectively).

Pyrenyl derivatives are widely used as fluorescent probe molecules for crucial applications, as chemosensors for metal ions [17], optical switches [18] and hybridization fluorescence sensors for polynucleotides [19], just to cite few. The fluorescence changes of pyrene hydroxamate derivatives due to metal ion complexation were studied in detail by Fages and coworkers. Complexation of iron(III) by a trichromophoric tripodal hydroxamate ligand was found to induce almost quantitative quenching of the fluorescence emission of the ligand [20].

The fluorescence spectra of dilute solutions of **H_3C6** and **H_3C10** (Fig. 3) in toluene show the monomer emission, patterned in five principal vibronic bands, while the broad excimer emission around 485 nm is almost not detectable, as expected for dilute solutions of pyrene derivatives. The relative intensity of peak III to peak I (see Fig. 3), known to be solvent sensitive, was found to be around

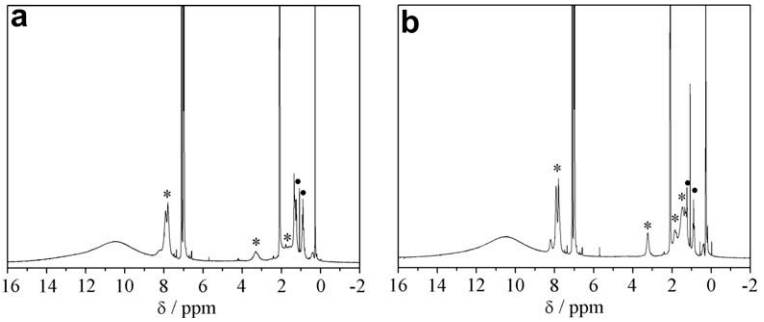

Fig. 2. ^{1}H NMR spectra of **2** (a) and **3** (b) in toluene-d_8. The signals labelled with $*$ are ascribed to tripodal ligands, while the signals marked with ● are due to traces of *n*-hexane.

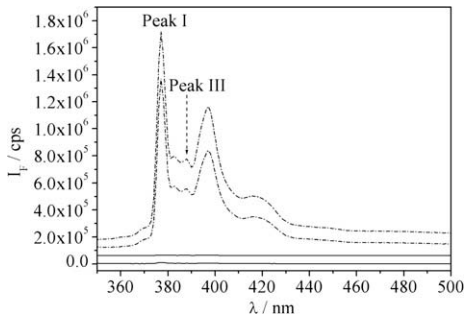

Fig. 3. Fluorescence spectra of 10^{-4} M solutions of **2** (grey, upper solid line) and **3** (black, lower solid line) in toluene. The fluorescence spectra of the free ligands **H_3C6** (grey, upper dash-dot line) and **H_3C10** (black, lower dash-dot line) are also reported for comparison at similar concentration (ligand and cluster samples were totally absorbing at λ_{exc} = 300 nm).

0.43, smaller than for toluene solutions of unsubstituted pyrene [21], but similar to the ratio found with other 1-substituted pyrene derivatives [22]. The spectra of **2** and **3** revealed a virtually complete excitation energy transfer (EET) from the S_1 state of pyrene to the chromophoric iron cluster ($\Phi_{EET} \geqslant 0.99$ for **2**, $\Phi_{EET} \sim 1$ for **3**, respectively, see Fig. 3). The residual very weak fluorescence might be attributed to traces of free ligand.

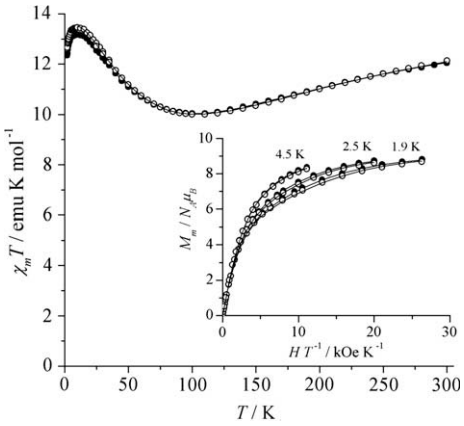

Fig. 4. DC magnetic properties of **2** (solid symbols) and **3** (void symbols). The solid lines provide the best fit to the experimental data with the following spin-Hamiltonian parameters: (for **2**) J_1 = 13.79(2) cm^{-1}, J_2 = −0.903(14) cm^{-1}, g = 1.8782(5); (for **3**) J_1 = 14.48(4) cm^{-1}, J_2 = −0.46(2) cm^{-1}, g = 1.8996(8). The inset shows isothermal magnetization data, along with the best-fit simulations obtained with (for **2**) D = −0.349(4) cm^{-1}, g = 1.852(3) and (for **3**) D = −0.386(6) cm^{-1}, g = 1.858(4). The spin-Hamiltonians used are defined in Ref. [5].

A full EET is consistent with the observation that the efficiency of quenching was independent of the length of the spacer alkyl chain.

3.3. Magnetic properties and HF-EPR spectra

The magnetic properties of **2** and **3** have been investigated using magnetic measurements and HF-EPR spectroscopy on powder samples. The $\chi_m T$ product of **2** and **3**, where χ_m is molar magnetic susceptibility and T is absolute temperature, is reported in Fig. 4 as a function of T. The overall trend is typical for tetrairon(III) propellers, the low-T increase of the magnetic moment being due to the selective population of the ground S = 5 state [3]. However, the maximum $\chi_m T$ value observed around 10 K in the two compounds is 13.2 emu K mol^{-1} (**2**) and 13.4 emu K mol^{-1} (**3**), hence ca. 10% lower than the Curie constant for an S = 5 spin state (15.0 emu K mol^{-1} with g = 2.00, as appropriate for high-spin iron(III)). The discrepancy, which exceeds the experimental accuracy of magnetic measurements, is confirmed by the unphysically low g values obtained by the quantitative analysis of $\chi_m T$ versus T and M_m versus H data (see caption to Fig. 4) using a well-established spin-Hamiltonian formalism [5]. The fit is otherwise excellent and affords spin-Hamiltonian parameters close to those observed in many other tetrairon(III) propellers [3,5]. It is likely that diamagnetic or weakly magnetic impurities arising from chemical manipulations contribute to decrease the magnetic response of the investigated samples, which are noncrystalline and difficult to purify.

Deeper insight was provided by the fine structure of the ground spin state as revealed by variable-temperature HF-EPR at 190 and 230 GHz. The spectra recorded at the higher frequency are gathered in Fig. 5, while 190-GHz spectra can be found in the Supporting Information. They are typical for high-spin species with an easy axis anisotropy [23] and can be accurately reproduced with the following spin-Hamiltonian parameters, as defined in Ref. [5]: for **2**, D = −0.421 cm^{-1}, E = 0.009 cm^{-1}, $B_4^0 = 1.8 \times 10^{-5}$ cm^{-1}; for **3**, D = −0.422 cm^{-1}, E = 0.008 cm^{-1}, $B_4^0 = 2.3 \times 10^{-5}$ cm^{-1} (S = 5 and g = 2.000 ± 0.005 throughout). Thus, the two complexes have identical magnetic anisotropy within experimental error. Furthermore, their spin-Hamiltonian parameters are typical for tetrairon(III) propellers $[Fe_4(L)_2(dpm)_6]$, in which the tripodal ligands adopt a η^2, η^2, η^2, μ_4 coordination mode [3–7].

4. Conclusion

Two novel tetrairon(III) SMM designed to bind graphene surfaces through pyrenyl groups were synthesised using new tripodal ligands with spacers of different length. Although the new compounds could not be isolated as crystalline solids suitable for X-ray diffraction studies, their molecular structure was inferred from

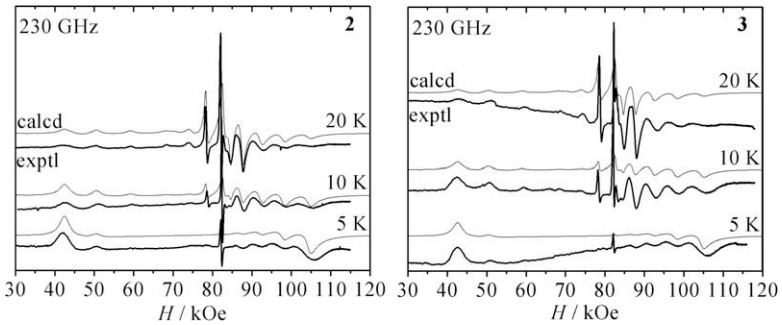

Fig. 5. HF-EPR spectra of **2** and **3** recorded at 230 GHz and at three different temperatures. The free electron resonance is found at H_0 = 82.1 kOe. The thin lines are best-fit simulations obtained with the parameters reported in the text.

^{1}H NMR and fluorescence spectra, magnetic measurements and HF-EPR. In particular, the typical ground spin state of $[Fe_4(L)_2(dpm)_6]$ complexes ($S = 5$ with a negative D parameter) was clearly revealed by HF-EPR.

Acknowledgments

We gratefully acknowledge Mr. Luca Zuppiroli (Department of Organic Chemistry, Faculty of Industrial Chemistry, University of Bologna, Italy) for ESI-MS experiments and the staff of CIGS (Centro Interdipartimentale Grandi Strumenti, University of Modena and Reggio Emilia) for assistance during ^{2}H NMR experiments.

ABSTRACT

The precursor $[Fe^{III}(L)Cl]$ (LH_2 = *N*,*N*′-bis(2′-hydroxy-benzyliden)-1,6-diamino-3-azahexane) has been prepared and Mössbauer spectroscopy assigned a high-spin ($S = 5/2$) state at room temperature. The precursor is combined with the bridging units $[Sb^V(X)_6]^-$ ($X = CN^-$, NCS^-) to yield star-shaped heptanuclear clusters $[(LFe^{III}–X)_6Sb^V]Cl_5$. The star-shaped compounds are in general high-spin systems at room temperature. On cooling to 20 K some of the iron(III) centers switch to the low-spin state as indicated by Mössbauer spectroscopy, i.e. multiple electronic transitions. While the cyano-bridged complex performs a multiple spin transition the thiocyanate-compound shows no significant population at both temperatures.

1. Introduction

The phenomenon of switching molecules is an important researchers field in various scientific disciplines. An approach is to generate multistable molecules, i.e. physically and chemically induced transition between electronic states [1]. For multinuclear compounds the spin transition is rare [1].

Our systematic approach [2–13] enabled us to apply chemical tuning on pentadentate ligand Fe(III) complexes as building units $[LFe^{III}–X]$ (L = bis(3-salicylidene aminopropyl) amine) and show multistability, e.g. multiple thermally induced transitions between low-spin (LS) $^2T(O_h)$ and high-spin (HS) $^6A(O_h)$ in various star-shaped compounds: tetranuclear [4], heptanuclear [3,5–9], nonanuclear [2,3,6–9] and dodecanuclear [10].

In the present work, we extend this approach and introduce a novel heptanuclear system. With antimony we introduce a main-group element as star-shaped center and modify the bridging units between cyanide and thiocyanate. Such pentanuclear Fe_6Sb compounds may be capable of performing six spin transitions in one cluster, e.g. between 6 and 30 unpaired electrons. Such star-shaped heptanuclear Fe_6Sb systems are potential spin crossover systems. Their high-spin to low-spin switching was investigated by Mössbauer spectroscopy.

2. Experimental

The ligand LH_2 = *N*,*N*′-bis(2′-hydroxy-benzyliden)-1,6-diamino-3-azahexane has been prepared [8]. Complexation with Fe(III) gives the used iron precursor $[Fe^{III}(L)Cl]$ (=[2,3/H/Sal-H/Fe/Cl]) (Fig. 1). The precursor is combined with the bridging central units $[Sb^V(X)_6]^-$ ($X = CN^-$, NCS^-) to yield star-shaped heptanuclear clusters $[(LFe^{III}–X)_6Sb^V]Cl_5$ (=[2,3/H/Sal-H/Fe/$Sb(X)_6$]) (see Fig. 2).

2.1. Precursor

The precursor was prepared as described in literature [8]. The dark brown powder was characterized by IR and ESI.

2.2. $[Sb^V(X)_6]^-$ ($X = CN^-$, NCS^-)

The antimony pseudohalogenides cyanides and thiocyanates were prepared with their analogous compound of antimony chloride and potassium cyanide and potassium thiocyanate in acetone under nitrogen atmosphere. The mixtures stirred for 6 days under reflux.

2.3. Heptanuclear clusters $[(LFe^{III}–X)_6Sb^V]Cl_5$ (=[2,3/H/Sal-H/Fe/$Sb(X)_6$]) ($X = CN^-$, NCS^-)

The complexes were prepared in analogy to the literature [2,8]. The reaction solution stirred for 30 min and cooled for 5 days. The products were characterized by ESI-MS, IR- and Mössbauer spectroscopy.

2.3.1. IR-spectroscopy

A conventional MIR-IR spectrometer is used at ambient temperatures.

2.3.2. Mössbauer spectroscopy

The Mössbauer spectra were recorded using constant acceleration Mössbauer spectrometers. As a source ^{57}Co in rhodium is used.

3. Results and discussion

The schematic structure of the [2,3/H/Sal-H/Fe/Sb(X)$_6$] (X = CN^-, NCS^-) complexes are heptanuclear in star-shaped geometry. The complexes are characterized by IR-spectroscopy. They show, that a stretching vibration for a typical CN-bond shifts on bridging from 2080 to above 2100 cm^{-1}. For a typical NCS-bond this effect is less pronounced on bridging from 2050 to above 2060 cm^{-1}.

As central star-element antimony was used in the oxidation-state +5. This antimony(V) is coordinated to six precursors bridged via cyanide or rhodanide. The MM+ force field structure of the $[(LFe^{III}–NC)_6Sb^V]^{5+}$ complex is shown in Fig. 3.

Fig. 4 and Table 1 show the Mössbauer spectra and data of $[(LFe^{III}–NC)_6Sb^V]Cl_5$. At room temperature a doublet is seen which is characteristic for iron(III) in the high-spin state with 66% of the area fraction. A second doublet is characteristic for iron(III) in the low-spin state. On cooling to 20 K the same two doublets are observed being characteristic for iron(III) in the low-spin and high-spin state. Some of the molecules have been converted from high-spin to the low-spin state. This is indicative for a thermally-induced spin-crossover.

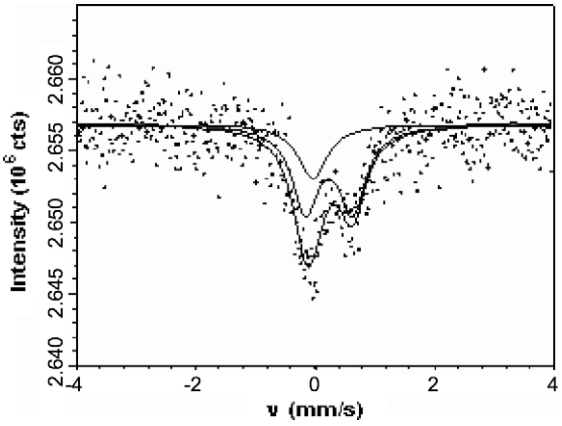

Fig. 5. Mößbauer spectra of $[(LFe^{III}–NCS)_6Sb^V]Cl_5$ measured at 300 K.

Fig. 5 shows the Mössbauer spectra of $[(LFe^{III}–NCS)_6Sb^V]Cl_5$ at room temperature. The spectra shows an asymmetric signal which is indicative for iron(III) in the high-spin state. There is no sign of iron(III) in the low-spin state. The modification of the cyano-bridge by a thiocyanate-bridge eliminates the iron(III) in the low-spin state at room temperature.

4. Conclusion

The ^{57}Fe-Mössbauer data indicate that the $[(LFe^{III}–NC)_6Sb^V]Cl_5$ show multiple spin transitions between iron(III) in the high-spin and low-spin state. Changing the bridging unit from CN^- to NCS^- all iron-centers in $[(LFe^{III}–NCS)_6Sb^V]Cl_5$ are converted to Fe(III) in the high-spin state at 300 K.

The results show that the CN-bridged compound performs molecular switching. Modification of the bridging unit from cyanide to thiocyanate keeps all units in the high-spin state at 300 K. This proves the usage of main group elements such as antimony as central atoms in switching molecules.

ABSTRACT

We report here numerical experiments, modeling and interpretations dealing with the magnetic interactions necessary for building nano-scale magnets in quasi-one-dimensional systems based on the assembling of [Mn(porphyrin)]$^+$ magnetically anisotropic *d* units and TCNE-*p*-type spin carriers. The magnetic ordering and its coupling parameter are studied by Broken Symmetry DFT calculations for various model structures, allowing for the rationalization of geometry dependence of the effective exchange. The roles of the phenyl substituent, as well as of the basis set and the DFT functional used in the computation are discussed. The intrinsic anisotropy of these systems is studied in an original manner, extracting Ligand Field and Spin Orbit parameters by combined fits to non-relativistic and relativistic DFT calculations, allowing the explicit estimation of the Zero Field Splitting parameters.

1. Introduction

The [Mn^{III}(porphyrin)]$^+$[cyanocarbon]$^-$ compounds form one of the most extensively studied families of molecular magnets [1]. The first member of the family was [MnTPP][TCNE] · *x*S [2], where (TPP = *meso*-tetraphenylporphyrinato, TCNE = tetracyanoethylene, and S = toluene). Since then a large variety of related compounds has been synthesized and characterized [3]. The manganese–porphyrin magnetic compounds are quasi-one-dimensional electron transfer salts consisting of chains of alternating metalloporphyrin electron donors and cyanocarbon electron acceptors. The adjacent spins along these chain alternate, $S_1 = 2$ on the donor and $S_2 = 1/2$ on the acceptor. This family of magnets provides the opportunity for the study of magnetic ordering because it offers a wide range of controlling factors [4]. For example the cyanocarbon bridge connecting the adjacent porphyrins can be varied to influence the intrachain interactions; different organic constituents can be added at the periphery of the porphyrin to affect the interchain interactions and, thereby, build up or reduce three-dimensional magnetic order; various solvents that may induce glassy behavior can be incorporated into the structure [4].

The mechanism for magnetic ordering proposed for the manganese–porphyrin compounds [MnTPP][TCNE] · *x*S, (S = toluene, *ortho*-xylene, and *ortho*-dichlorobenzene, etc.) is based on strong intrachain exchange, weak interchain dipole–dipole interactions and modest single-ion anisotropy all leading to canted magnetic ordering at low temperatures. The antiferromagnetic coupling (by strong kinetic superexchange of the order of 70 cm^{-1}) along the chain of unequal alternating spins leads to a 1D ferrimagnetic spin configuration [5]. Then, in the absence of superexchange pathways between the chains, the classical dipole–dipole interaction (coupling of about 10^{-3}–10^{-2} cm^{-1}) together with the onsite SIA (estimated to about 1–3 K) were proposed to produce canted magnets with critical temperatures around 10–15 K [5].

The motivation of the mechanism put forth was based on the results of fits of the dc susceptibility data to a model of alternating classical and quantum spins [6], which provided *J* of about −50 to −100 cm^{-1}, for certain [MnTPP][TCNE] · *x*S systems [5]. The fit was good in the range 50–350 K but at low temperatures deviations occurred, attributed to interchain interactions. However, an independent confirmation of the strength of the intrachain interaction and of the size of the single-ion anisotropy has been lacking.

A first theoretical approach attempted to correlate the critical temperatures with the overlap between the π^* SOMO of [TCNE]$^-$ and the d_z^2 SOMO of [Mn^{III}P]$^+$ [7]. Later on, CASSCF, CASPT2 and DFT/B3LYP calculations qualitatively reproduced the antiferromagnetic intrachain coupling and ferrimagnetic spin configuration along the chains [8]. However, it was found that the DFT techniques tend to overestimate the exchange coupling constant, while the ab initio approaches underestimate the experimental *J*s [8]. Moreover, based on the results obtained it was impossible to assign the mechanism of magnetic ordering in this family of compounds [8].

More recently, Broken Symmetry DFT studies of the manganese–porphyrin–cyanocarbon dimer provided antiferromagnetic exchange constants of different strengths, depending on the functional used [9]. In this case, all DFT results underestimated the experimental value, obtained based on the Seiden fit, best results being obtained with UDFT/B3LYP, followed by UDFT/B2LYP and UHF. A subsequent study allowed the calculation of the zero-field-splitting that showed that the TCNE coordination hardly affects the magnetic anisotropy of $[Mn^{III}P]^+$, influencing significantly only the ferrimagnetic spin alignment [10]. The method used was based on UDFT calculations with BLYP, B2LYP and B3LYP functionals, the values obtained for D being all negative (about -0.8 to $-3.3\ cm^{-1}$) suggesting Ising-like anisotropy. The transverse component, E, was found to be at least two orders of magnitude smaller than D. Again, the three functionals provided different values, best results being obtained with UDFT/B3LYP.

Given the interest in this family of quasi-1D magnetic compounds, we report here DFT numerical experiments on the exchange coupling and magnetic anisotropy in manganese–porphyrin–cyanocarbon dimers.

2. Calculations

DFT calculations were carried out with the Gaussian03 [11] and ADF [12] packages using triple zeta polarized basis sets (6-311G* and TZP, respectively). The programs and functionals were used in the estimation of exchange coupling constant via Broken Symmetry calculations [13].

The reference system consisted in an experimental structure of the manganese–tetraphenyl–porphyrin system $[Mn^{III}TPP]^+[TCNE]^-$ [14]. In constructing the model dimer we added a Li^+ ion to the terminal CN group of the $[TCNE]^-$ radical, to mimic the polarization effects of the next metal ion. Furthermore, a HCN group *trans* coordinated to Mn^{III} is a substitute for the TCNE on the other side of the continued polymer. The resulting dimer proposed as a model for $[Mn^{III}TPP]^+[TCNE]^-$ systems is $\{(HCN)[MnTPP]^+[TCNE]^-Li^+\}$, with a $S_1 = 2$ on Mn^{III} and $S_2 = 1/2$ on $[TCNE]^-$.

Further idealization was done replacing the phenyl groups with H atoms and symmetrizing the slight deviation from the tetragonal symmetry, reducing the model to simple porphyrin within D_{4h} point group. The cartesian coordinates of the $[MnP]^+$ and $[MnTPP]^+$ units are presented in the Supplementary Data.

3. Results and discussion

3.1. Broken Symmetry calculations of exchange constants

The Yamaguchi–Onishi approach [15] was used to handle the BS DFT output and calculate the exchange constant. The illustration of the Broken Symmetry calculation is shown in Fig. 1, which gives an overall positive spin in the case of the unrestricted high spin (HS) system and the segregation of α and β bulk spin densities on MnTPP and TCNE units at the proper Broken Symmetry (BS) state computed at low spin projection. In both HS and BS spin density maps we observe areas with slight spin polarization.

Table 1
Broken Symmetry calculations of the J coupling constant in $[MnP]^+[TCNE]^-$ and $[MnTPP]^+[TCNE]^-$ dimers, reflecting the role of the phenyl substituent, the basis set and the DFT functional.

System	Code	Basis	Functional	$J\ (cm^{-1})$
[MnTPP][TCNE]	G03	6-311G*	B3LYP	−72.32
[MnTPP][TCNE]	G03	6-31G*	B3LYP	−73.97
[MnTPP][TCNE]	G03	6-311G*	BP86	−153.83
[MnTPP][TCNE]	G03	6-31G*	BP86	−153.15
[MnP][TCNE]	G03	6-311G*	B3LYP	−79.55
[MnP][TCNE]	G03	6-311G*	BP86	−182.70
[MnP][TCNE]	ADF	TZP	BP86	−171.74

Since the numerical calculations are usually performed on simplified models with porphyrin instead of the substituted ligands, we studied the impact of the substituent on the computed exchange constant. We also checked the influence of the basis set and the functional used. Moreover, the Gaussian and ADF calculations allowed the comparison between the Gaussian and the Slater-type atomic basis sets. The data are summarized in Table 1.

We note that the relative small differences between the computed J parameters of the $[MnP]^+$ and the substituted $[MnTPP]^+$, suggests that the use of H atoms instead of phenyl groups is a reasonable computational simplification. The conclusion that the organic constituents added at the periphery of the porphyrin have little effect on the intrachain exchange coupling is consistent with experimental suggestions that they affect mainly the interchain interactions by keeping the chains further apart and/or providing superexchange pathways [4].

From the data in Table 1 it can be seen that, once polarization effects are included, the differences between the basis sets do not lead to significant variations of the exchange constants. The functional, however, exerts a sensible role. It can be seen that the Becke-Perdew (BP86) functional gives higher absolute values of negative J, compared with the hybrid Becke and Lee-Yang-Parr (B3LYP) method. Corroborating this with the UHF versus UB3LYP comparison showing weaker antiferromagnetic coupling in the non-correlated HF case [9] we can infer that the functional part tends to give larger antiferromagnetic part, possibly overestimating its absolute values in certain circumstances. This issue deserves further exploration and a direct comparison to experiment, in order to determine the subtle balance between the better account of dynamical correlation and problems in long range functional dependence [16].

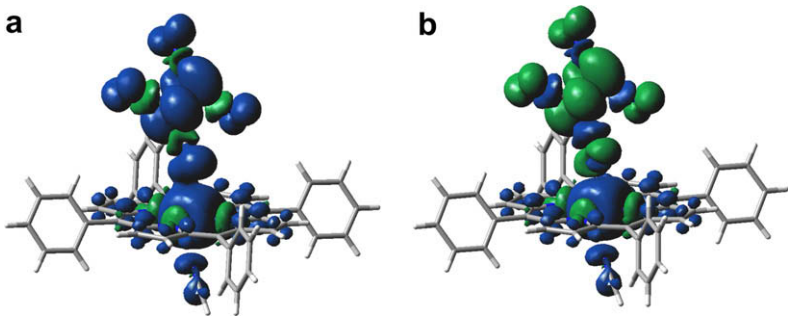

Fig. 1. The spin density isosurfaces for the [MnTPP][TCNE] system in unrestricted DFT (UB3LYP) calculations. (a) The high spin case (HS, $S_z = 5/2$) AND (b) the Broken Symmetry "low spin" configuration (BS, $S_z = 3/2$).

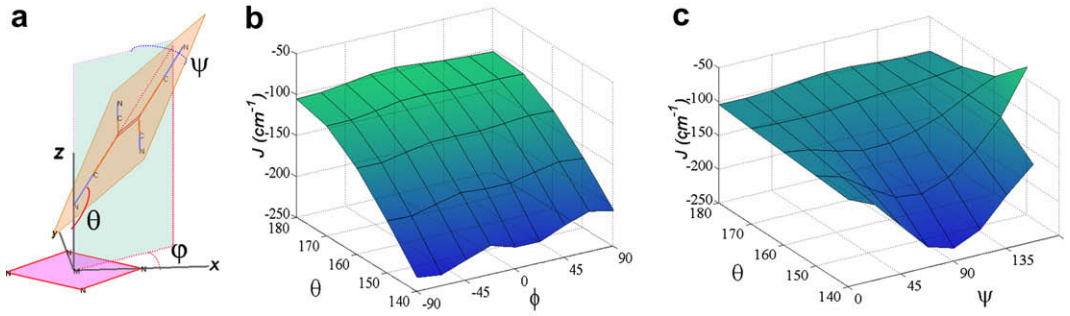

Fig. 2. (a) The geometry parameters defining the mutual orientation of the MnP and TCNE planes; (b) and (c) the dependence of computed J coupling constant ($J(\theta,\varphi)$ at $\Psi = 0$ and $J(\theta,\Psi)$ at $\varphi = 0$, respectively). The results are from Broken Symmetry (BS) BP86/6-311G* calculations with G03 code on the [MnP][TCNE] system.

Further, we studied the influence of the mutual orientation between the metal ion and the organic ligand on the strength of the exchange interaction. The important geometry parameters are shown in Fig. 2a. The orientation of the coordinating N≡C– group with respect to the metal ion is described by the angle θ, θ = Mn–N–C. The angle φ can be described either as the angle between the x axis of the porphyrin plane and the projection of the N≡C– group on that plane, or as the dihedral of a selected N(P)–Mn–N–C sequence. The angle Ψ, describes the rotation of the TCNE plane around the coordinating N≡C– group. The angle Ψ is the dihedral between the Mn–NC and TCNE planes. The Mn–NC is represented in Fig. 2a as a vertical plane, perpendicular to the porphyrin frame. At $\Psi = 0$ the TCNE plane is also perpendicular to the porphyrin.

Fig. 2b displays the dependence of the exchange coupling on θ and φ. It can be seen that the angle θ controls the σ and π overlapping, whereas the φ rotation does not change this balance, having a smaller effect. Fig. 2c presents the dependence of J on θ and Ψ. The Ψ parameter also defines the orientation of the p spin carrier with respect of the d-orbitals. At $\theta = 0$, when the NC group is aligned along the z axis, the Ψ angle does not change the balance of σ and π interaction channels. It affects only the distribution of the π effects among the yz and xz d-orbitals and since these are degenerate in the tetragonal symmetry, the Ψ dependence is not active, as is seen in the plateau of Fig. 2c. At lower values of θ, when the Ψ is about 90° the overlap between the p and the z^2 spin carriers is maximized, increasing the antiferromagnetism. At $\Psi = 0°$ or 180° the routes to z^2 are only orthogonal and, therefore, ferromagnetic. The other channels of π-type overlap, p-d_{xz} and p-d_{yz} remain antiferromagnetic, yielding in the sum the negative total J but with reduced magnitude. This explains the strong Ψ dependence in the lower θ side of Fig. 2c. A more detailed, analytical, description of these effects, realized by model fit to the computed J parametric surfaces is under construction.

3.2. Relativistic calculations and analytical modeling of magnetic anisotropy

The magnetic anisotropy is challenging to calculate, particularly in usual DFT codes, where there is no direct routine for it. An interesting and reliable approach was proposed by Yamaguchi and coworkers [17]. Their original program, GSO-ZFS, uses a wave function provided for instance by a preliminary Gaussian calculation, to compute the spin-orbit integrals and estimate the Zero Field Spitting (ZFS) by means of a perturbation scheme. The ZFS parameters obtained by the same group for $[Mn^{III}P]^+$ complexes [10] were in agreement with previous phenomenological estimations [5] and experimental values [18].

Here we approach the calculation of ZFS in the DFT frame by a different route, using results from ADF non-relativistic and relativistic calculations, followed by an appropriate handling with a Ligand Field (LF) and Spin Orbit (SO) model based on the following Hamiltonian:

$$\hat{H} = \hat{H}_{LF} + \hat{H}_{SO}. \tag{1}$$

The Ligand Field part is conveniently expressed in terms of standard tetragonal parameters Dq, Ds and Dt [19]:

$$\hat{H}_{LF} = 14Dq\sqrt{\pi}\left[Y_4^0 + \sqrt{\frac{5}{14}}(Y_4^4 + Y_4^{-4})\right] - 14Dt\sqrt{\pi}Y_4^0 - 14Ds\sqrt{\frac{\pi}{5}}Y_2^0, \tag{2}$$

where Y_l^m are the spherical harmonics, considered as operators. The energies of the d-orbitals are more transparently expressed by converting the set of Ds and Dt parameters into δ_e and δ_t

$$\delta_e = 2Ds - 6Dt, \tag{3a}$$
$$\delta_t = -Ds + 4Dt, \tag{3b}$$

which measure directly the gaps between the orbitals originating from the e_g and t_{2g} octahedral reference.

The Spin Orbit Hamiltonian in the one-electron form is:

$$\hat{H}_{SO} = \xi\hat{l}\cdot\hat{s}. \tag{4}$$

Our approach consists of the following steps:

(i.1). Non-relativistic DFT calculations provide orbital energies (Table 2) related to the LF parameters, $10Dq$, δ_e and δ_t (Table 3) by the formulas given in the second column of Table 2 and illustrated schematically on the left side of Fig. 3a.

(i.2). Relativistic DFT calculations determine molecular orbital energies (Table 4) used to evaluate the SO coupling parameter, ξ, by fitting the calculated energies with those provided by the 10 × 10 LF + SO Hamiltonian matrix (matrix A1, in the Supplementary Data) of the d spin-orbitals; the LF parame-

δ_t	1914	2003

ters used in the LF + SO Hamiltonian matrix are those obtained in the previous step; the relationships between the orbital energies are illustrated on the right side of Fig. 3a.

(i.3). The LF and SO parameters obtained from the one-electron scheme of orbital energies are further used into the full many-electron LF + SO Hamiltonian applied to the ^5D term that corresponds to the d^4 configuration of the Mn^{III} ion (Fig. 3b). The SO coupling (expressed by the 25 × 25 Hamiltonian matrix discussed in formulas A3 of the Supplementary Data) splits the ^5D term into $(2L + 1)(2S + 1) = 25$ states, which can be further grouped based on their symmetry with respect to the LF interaction (Fig. 3b).

(i.4). The lowest energy levels with the same symmetry provided by the numerical diagonalization of the 25 × 25 Hamiltonian matrix in the previous step (the five levels with $^5B_{1g}$ symmetry in Fig. 3b) are the Zero-Field-Splitted levels from where the D parameter is obtained.

The advantage of the outlined procedure resides in the direct numerical calculation of the D parameter, with no need for the perturbation expressions usually invoked to express the ZFS terms as function of LF and SO parameters. By using a direct fit of the model Hamiltonians to DFT computed molecular orbitals and having the advent of D_{4h} symmetry that simplifies the model, it is not necessary to perform the projection techniques outlined by Atanasov et al. for extracting LF [20] and SO [21] parameters from DFT calculations.

The numerical experiments were applied comparatively to the idealized square-planar $[Mn^{III}(P)]^+$ and elongated octahedron $[Mn^{III}P(NCH)_2]^+$ complexes. The $[Mn^{III}(P)]^+$ unit, without axial ligands, was taken to discriminate the contribution due to the porfirine ligand itself. The $[Mn^{III}P(NCH)_2]^+$ case is taken to mimic the magnetic anisotropy of the manganese ion embedded in the chains of $[Mn^{III}TPP]^+[TCNE]^-$. In order to keep the convenient D_{4h} symmetry, the unit was idealized taking axially placed NCH groups as surrogate for the coordinating effect of the TCNE ligands along the chain. The fit following the steps *i*.1–*i*.4 described above gives rise to LF parameters placed in the usual range of strong field ligands and significant axial magnetic anisotropy.

The relation of orbital and spectral terms and the role played by the LF and SO effects is illustrated schematically in Fig. 3a and b. In

Table 4

Fitted Spin Orbit coupling		
ξ (cm^{-1})	480.8	374.6

the ^5D term the LF part can be simply taken as reverse of the orbital (d^1) scheme, since the d^4 configuration can be interpreted as an one-hole configuration. In this way, there is no need for explicit two-electron (Racah-type) parameters, the orbital data being sufficient for the recovery of the spectral terms and magnetic anisotropy of the d^4 ion. Passing from d^1 (orbital) to the d^4 (spectral term) description the $\xi\hat{l}\cdot\hat{s}$ one-electron Spin Orbit coupling is converted into the $\lambda\hat{L}\cdot\hat{S}$ Hamiltonian when taking $\lambda = \xi/6$.

The $10Dq$ parameter (Table 3) is higher in the modeled $[Mn^{III}P(NCH)_2]^+$complex than in the $[Mn^{III}(P)]^+$ unit because of axial ligand supplementary contribution into the former. In turn, the axial LF anisotropy expressed by the δ_e parameter is higher in the $[Mn^{III}(P)]^+$ because of the absence of axial ligands. The higher LF anisotropy can be qualitatively related to the larger absolute value of the ZFS parameter modeled in the $[Mn^{III}(P)]^+$ unit, $D = -0.65\ cm^{-1}$, as compared with $D = -0.40\ cm^{-1}$ in the $[Mn^{III}P(NCH)_2]^+$. The negative sign is determined by the stabilization of the $^5B_{1g}$ as LF groundstate. Although, the absolute parameters of the ZFS might be slightly underestimated, overall, the values of the D constant are consistent with those reported previously [5,10,17].

Our approach also provides the other LF–SO driven states corresponding to the ^5D set, or in other words, the Zero Field Splitting of all the Ligand Field spectral terms. Thus, it is interesting to note that the ZFS levels of the excited $^5A_{1g}$ states are fitted with a positive parameter, $D(^5A_{1g}) = +1.77\ cm^{-1}$ for $[Mn^{III}P(NCH)_2]^+$, and $D(^5A_{1g}) = +1.07\ cm^{-1}$ for $[Mn^{III}P(NCH)_2]^+$. This result is in line with the fact that in a compressed octahedron this state becomes lowest, imposing reversed magnetic anisotropy.

4. Conclusions

We reported calculations providing the magnetic exchange and anisotropy for $[Mn^{III}(porphyrin)]^+[TCNE]^-$ systems. By means of Broken Symmetry DFT calculations we studied the role of the Mn-TCNE bonding geometry on the intrachain exchange. We demonstrated that the phenyl substituent has a small influence on the

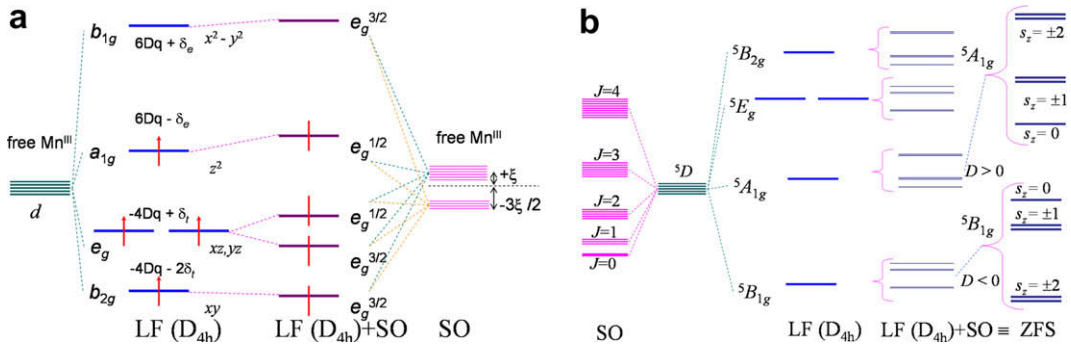

Fig. 3. The scheme of the Ligand Field (LF) + Spin Orbit effects (SO) in D_{4h} symmetry for: (a) one-electron states (*d*-orbitals) and (b) poly-electronic spectral terms of the d^4 configuration. The right extreme of the (b) panel shows the magnification of the ZFS pattern in the $^5B_{1g}$ ($D < 0$) and $^5A_{1g}$ ($D > 0$) terms.

intrachain coupling and confirmed that the values of J depend strongly on the DFT functional used. The ZFS parameters obtained by means of a combined relativistic and non-relativistic calculation are consistent with previous results, while the method proposed has the advantage of being very explicit in combining modern calculations and basic phenomenological concepts. Further exploration of the computation and modeling aspects, as well as the explicit correlation with available experimental data, make the object of future studies. The effect of the lower symmetry of the pseudo-tetragonal unit makes the object of future studies.

ABSTRACT

The broken-symmetry (BS) and multideterminant approaches to atomic oxygen (O), molecular oxygen (O_2) and iron–oxo (Fe(IV)=O) core in P450 have elucidated electronic structures of the ground triplet and excited singlet states, which indicate isoelectronic characteristics of the species. The dissociation processes of the O–O and Fe–O double bonds are also examined to clarify the radical character, namely O-atom property responsible for radical mechanism of hydroxylations of alkanes and epoxidation of alkenes. This isolobal analogy has indeed enabled us to propose possible reaction mechanisms of oxygenation reactions by the Fe(IV)=O species on the basis of available theoretical and experimental results for O and O_2. Similarly an isolobal analogy of the σ^* bond among Fe(IV)=O, dioxirane, peracids, etc. indicates the common electrophilic property for the oxygenation reactions. The small energy gaps between the high- and low-spin states of the transition structures and intermediates generated in the oxygenation reactions are found to be origins for spin crossover phenomena along the reaction pathways of these reactions.

1. Introduction

Active oxygen, oxyradicals and their metal-trapped species such as M=O, MOOH, etc. play important roles in various oxygenation reactions [1]. Past decades, electronic structures of metalloenzymes that catalyze oxygenation reactions have been extensively investigated by optical, magnetic, and many other experimental techniques [2–15]. Accumulated experimental results have elucidated a unified picture that the compound I consisted of the high-valent iron–oxo core [Fe(IV)=O] and ligand radical (•L), [(Fe(IV)=O) (•L)], is a common active species in catalase, peroxidase, P450, etc. Theoretical calculations [1] have also been performed for elucidation of electronic structure and reactivity of the compound I.

Transition-metal oxygen systems are generally characterized as strongly correlated electron systems with charge, spin, and orbital freedom [19,20]. For example, iron ions in heme enzymes exhibit valence fluctuations from divalent Fe(II) to pentavalent Fe(V) state, depending on ligand and other environment effects. The spin states of these species are variable from a low-spin singlet (diamagnetic, $S = 0$) to a high-spin (for example, sextet $S = 5/2$) state by changes in the ligand fields and other factors. Several d-orbital configurations are also feasible even in the same spin state, which results in different spatial symmetry states with near degeneracy. This is a difficult theoretical situation which often causes several computational troubles and misunderstanding in some cases.

As shown previously [1,19,20], the ground triplet and excited singlet states are not so separated in energy in the case of atomic oxygen (O), molecular oxygen (O_2) and high-valent iron–oxo [Fe(IV)=O] species as well as copper (gold)–oxo species [Cu(III)=O and Au(III)=O], as shown in Fig. 1. Isoelectronic character for these species leads to possible analogies for the reactivities among them. For example, spin crossover from $^3O_2$ to $^1O_2$ occurs in chemiluminescene reactions [through reductive activation of $^3O_2$ by complete electron transfer (efficient case) or direct bonding interaction between $^3O_2$ and a substrate (inefficient case)] [21]. The spin inversion may be equally expected for hydroxylation reactions of alkanes and epoxidation of alkenes by the Fe(IV)=O core in P450 and related synthetic model compounds [1–20].

In this paper (part XII of this series), both broken-symmetry (BS) and multideterminant (MR) methods are examined to calculate the energy levels of the ground and excited states of the isoelectronic species in Fig. 1. The relative stabilities among the

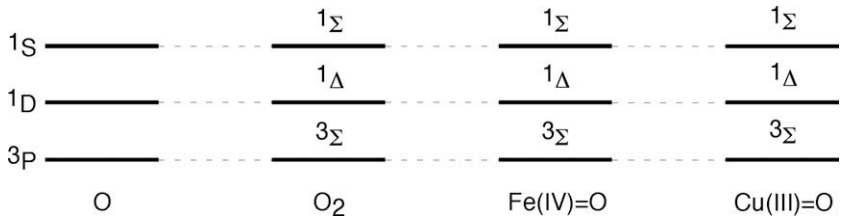

Fig. 1. The ground triplet and excited singlet states of the isoelectronic species, O, O_2, Fe(IV)=O, and Cu(III)=O.

different electronic and spin states of the Fe(IV)=O cores are analyzed from the view point of the configuration mixing of the zwitterionic (ZW) and/or charge-transfer (CT) configurations. To this end, theoretical backgrounds for the isolobal analogy are given in Section 2, and model Hamiltonians are solved analytically. The isolobal analogy provides possible reaction modes for epoxidation and hydroxylation reactions as discussed in Section 3. Finally, present computational results are discussed in relation to spin crossover phenomena in oxygenation reactions.

2. Theoretical background for the isolobal analogy

2.1. Restricted HF (RHF) and RDFT molecular orbitals of O_2 (O) and Fe(IV)=O

Here, the theoretical background for the isolobal analogy is briefly discussed. The restricted Hartree–Fock (RHF) and restricted Kohn–Sham (KS) density functional theory (RDFT) solutions are introduced in relation to the MO-theoretical description of the iron–oxo species [1]. The atomic orbitals of the fragments (O and Fe) are given by Fig. 2A. The molecular orbitals (MO) of O=O are expressed by the linear combinations of 2p-AOs (LCAO) as follows:

$$\phi(\pi_{x(y)}) = N^{-1}\{2px_1(2py_1) + 2px_2(2py_2)\} \quad (1a)$$

$$\phi(\pi^*_{x(y)}) = N^{-1}\{2px_1(2py_1) - 2px_2(2py_2)\} \quad (1b)$$

where the O–O σ-orbitals $\phi(\sigma)$ are neglected. The MOs of O=O are depicted in Fig. 2B. The orbital configurations of O_2 (O), O_2^- ($O^{\cdot-}$), and O_2^{2-} (O^{2-}) are depicted in Fig. 3B (A).

The molecular orbitals of the Fe(IV)=O are given by the LCAO approximations of the fragment AOs.

$$\phi(\pi_{x(y)}) = N^{-1}\{c_1 3dx_1(3dy_1) + c_2 2px_2(2py_2)\} \quad (2a)$$

$$\phi(\pi^*_{x(y)}) = N^{-1}\{c'_1 3dx_1(3dy_1) - c'_2 2px_2(2py_2)\} \quad (2b)$$

where c_i (i = 1, 2) denotes the LCAO coefficient. The dπ–pπ MOs of Fe(IV)=O are depicted in Fig. 2C. The orbital configurations of Fe(IV)=O, Fe(V)=O, and Fe(VI)=O are depicted in Fig. 3C and D. The energy levels of π_w and π_w^* (w = x and y) orbitals of O, O_2, and Fe(IV)=O are degenerate in energy. In this sense, these species are isolobal (or isoelectronic) [1].

The bond order (b) of O_2^m (m = 2 + ~2−) is defined by the occupation numbers of the MOs: $(\sigma)^a(\pi_x)^b(\pi_y)^c(\pi_y^*)^d(\pi_x^*)^e(\sigma^*)^f$. It is formally 3 for O_2^{2+} (m = 2+), since a = b = c = 2 and d = e = f = 0. The bond orders are, respectively, 2.5, 2.0, 1.5, and 1.0 for O_2^{1+}, O_2, O_2^-, and O_2^{2-}. Similarly, the bond order (b) for the high-valent Fe(VI)=O is 3.0 like O_2^{2+}. The b-values for Fe(V)=O, Fe(IV)=O, Fe(III)=O, and Fe(II)=O are, respectively, 2.5, 2.0, 1.5, and 1.0. The O_2 and Fe(IV)=O are isoelectronic from the view point of the bond order b = 2 as shown in Fig. 1. However, these RHF and RDFT pictures often break down because of strong electron and spin correlations described below.

2.2. Configuration interaction methods for O_2 (O) and Fe(IV)=O

As an example of the MR methods, configuration interaction methods are introduced here. As illustrated in Fig. 3, the O^{2-}, O_2^{2-}, and Fe(II)=O are regarded as the closed-shell singlet species, which are described by the single Slater determinant $|\pi_x^*\overline{\pi_x^*}\pi_y^*\overline{\pi_y^*}|$. On the other hand, the $O^{\cdot-}$, O_2^-, and Fe(V)=O species have the open-shell doublet state, for which the two configurations with the same energy are available (^{2}D state). The O, O_2, and Fe(IV)=O have the open-shell triplet ground state (Fig. 3). Since these species

have the degenerate π_x^* (p_x) and π_y^* (p_y) orbitals, two closed-shell $|\pi_x^*\overline{\pi_x^*}|$ (= Δ_{xx}) and $|\pi_y^*\overline{\pi_y^*}|$ (= Δ_{yy}) and two diradical configurations $|\pi_x^*\overline{\pi_y^*}|$ (= Δ_{xy}) and $|\overline{\pi_x^*}\pi_y^*|$ (= Δ_{yx}) can be constructed, as illustrated in Fig. 4A. The configuration interaction (CI) between the degenerated configurations provides the $^{1,3}\Sigma$ and $^1\Delta$ states, as shown in Fig. 4B. The closed-shell (zwitterionic, Δ_{xx} = ZWI and Δ_{yy} = ZWII) and diradical (Δ_{xy} = DRI and Δ_{yx} = DRII) states are spontaneously degenerate in energy at the $^1\Delta$ state of O_2 and Fe(IV)=O. On the other hand, the $^{1,3}\Sigma$ states are given by the resonant ZW and DR configurations, respectively (Fig. 4B). Thus, the isolectronic state correlation diagrams for O, O_2, and Fe(IV)=O are available, as shown in Fig. 1 [1].

2.3. BS MO approaches to dissociation process of the covalent bonds of O_2, O_2^-, and O_2^{2-}

The broken-symmetry (BS) MO method is briefly introduced here. The dianion of molecular oxygen (O_2^{2-}) has the O–O σ-bond at the equilibrium geometry (bond order = 1), since all the bonding and antibonding π orbitals are doubly occupied (π-bond order = 0). As an example, let us consider the O–O dissociation process of O_2^{2-} on the basis of the BS MO approximation. The bonding and antibonding σ MOs are given by the RHF [restricted Kohn–Sham (RKS)] method.

$$\phi(\sigma) = N^{-1}(2pz_1 - 2pz_2) \tag{3a}$$

$$\phi(\sigma^*) = N^{-1}(2pz_1 + 2pz_2) \tag{3b}$$

where N is the normalizing factor. The bonding orbital is doubly occupied near the equilibrium geometry, being responsible for the stable closed-shell covalent bond (see Fig. 3). However, the RHF (RKS) orbitals are reorganized into the different orbitals for different spins (DODS) MOs if the O–O bond length exceeds a certain limit.

$$\psi^{\pm}(\sigma) = \cos\theta\phi(\sigma) \pm \sin\theta\phi(\sigma^*) \tag{4a}$$

$$\psi^{\pm}(\sigma^*) = \mp\sin\theta\phi(\sigma) \pm \cos\theta\phi(\sigma^*) \tag{4b}$$

where θ is the orbital mixing parameter. The MO bifurcation process and BS MOs are schematically depicted in Fig. 5A. The BS MOs become the atomic orbitals at the dissociation limit ($R = \infty$).

$$\psi^+(\sigma) = \psi^-(\sigma^*) = 2pz_1 \tag{5a}$$

$$\psi^-(\sigma) = \psi^+(\sigma^*) = -2pz_2 \tag{5b}$$

Therefore, the diradical BS configuration, $|\psi^+(\sigma)(\uparrow)\overline{\psi^-(\sigma)(\downarrow)}|$ (or $|\overline{\psi^+(\sigma)(\downarrow)}\psi^-(\sigma)(\uparrow)|$), reduces to the simple valence-bond (VB) configuration, $|2pz_1\overline{2pz_2}|$ (or $|\overline{2pz_1}2pz_2|$) in the Heitler–London theory. The O–O dissociation process of O_2^{2-} is explained by the following MO-VB scheme.

$$^1[\mathrm{O\text{–}O}]^{2-} \rightarrow {}^1[\ominus\ \overset{\uparrow\ \downarrow}{\mathrm{O}\overset{\delta\bullet}{\text{----}}\bullet\delta}\ \mathrm{O}\ominus\ ] \rightarrow {}^1[{}^2(\ominus\ \mathrm{O}\bullet\uparrow) + {}^2(\downarrow\bullet\mathrm{O}\ominus)] \tag{6a}$$

where ⊖ (or –) denotes the closed-shell lone pair. The O^- radical anion is correctly generated from O_2^{2-} in the unified MO-VB scheme.

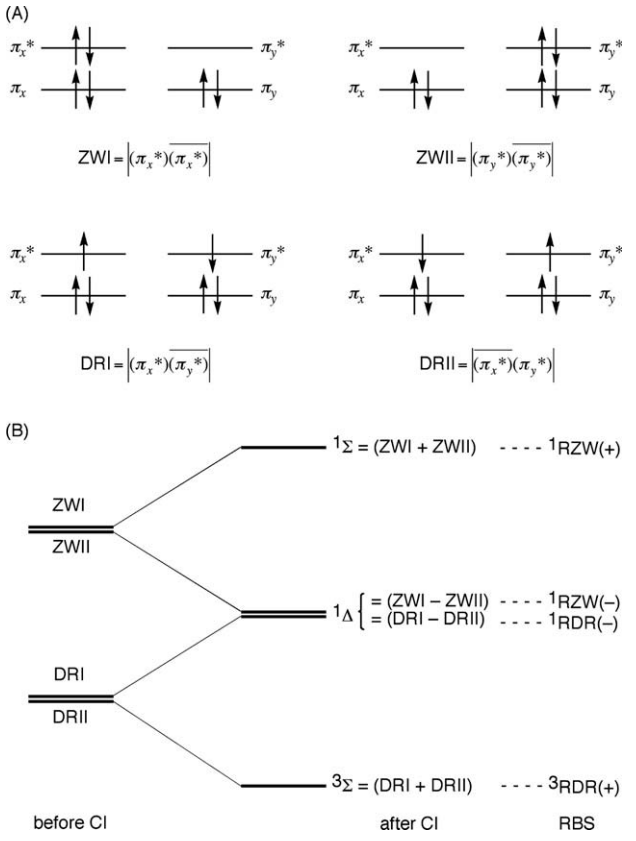

Fig. 4. (A) The orbital configurations of the diradical (DR) and zwitterionic (ZW) configurations and (B) energy levels of the DR and ZW states before and after configuration interaction (CI).

One of the π^*-orbital becomes half-occupied in the case of $O_2^{-\cdot}$ (Figs. 3 and 5). The delocalized π^*-orbital is deformed into the localized BS π^*-orbital at the O–O elongated O^-. The dissociation process of $O_2^{-\cdot}$ can be expressed by the unified MO-VB scheme as

$$^2[O{=}{=}O]^{-\cdot} \rightarrow {}^2[\uparrow \overset{\bullet}{O}\overset{\uparrow}{\delta\bullet}\cdots\overset{\downarrow}{\bullet\delta}O\ominus] \rightarrow {}^2[{}^3(\uparrow \overset{\bullet}{O}\bullet\uparrow) + {}^2(\downarrow\bullet O\ominus)] \qquad (6b)$$

The triplet O atom and doublet O anion radical are formed smoothly within the different orbitals for different spins (DODS) BS scheme. On the other hand, two π^*-orbitals are half-occupied in the case of triplet molecular oxygen ($^3O_2$). The O–O dissociation process of $^3O_2$ is given by the unified MO-VB scheme as

$$^3[O{=}{=}O] \rightarrow {}^3[\uparrow \overset{\bullet}{O}\overset{\uparrow}{\delta\bullet}\cdots\overset{\downarrow}{\bullet\delta}\overset{\bullet}{O}\uparrow] \rightarrow {}^3[{}^3(\uparrow \overset{\bullet}{O}\bullet\uparrow) + {}^1(\downarrow\bullet\overset{\bullet}{O}\uparrow)] \qquad (6c)$$

Thus, the triplet and singlet O atoms are generated at the dissociation limit under the DODS-type BS approximation, as can be easily recognized by the axial spin vector expression. However, two triplet O atoms should be generated at the ground state in this process.

To obtain correctly two ^3O atoms at the dissociation limit, the more general spin orbitals (GSO) [22] than the DODS MOs are necessary, as shown in Fig. 6. The GSO is given by the mixture of the up- and down-spins (namely, two-component spinor).

$$\varphi(\mathrm{GSO}) = \psi^+\alpha + \psi^-\beta = \begin{pmatrix}\psi^+\\ \psi^-\end{pmatrix} \qquad (7)$$

GSO permits the local spin rotation to obtain two ^3O atoms at the dissociation limit.

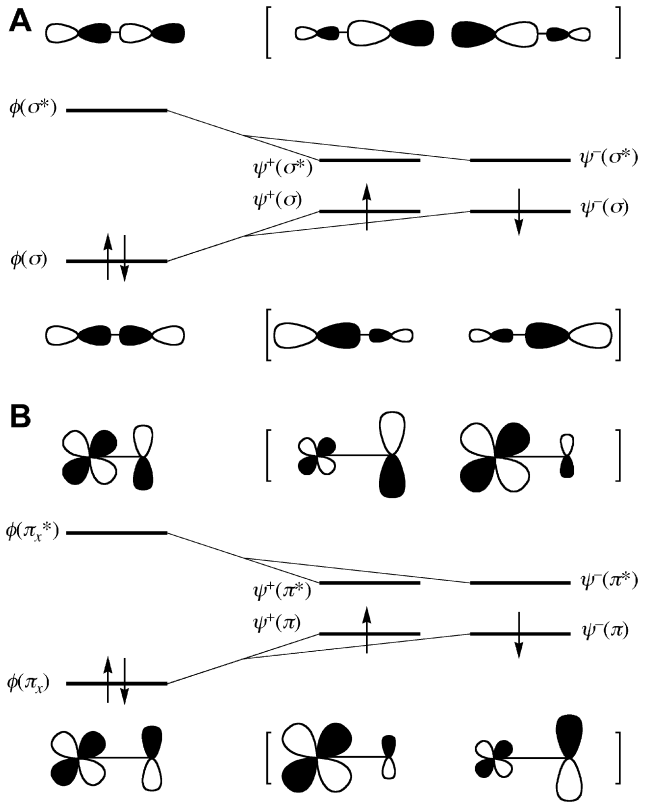

Fig. 5. Orbital correlation diagram for the dissociation process of (A) O–O σ-bond and (B) dπ–pπ bond.

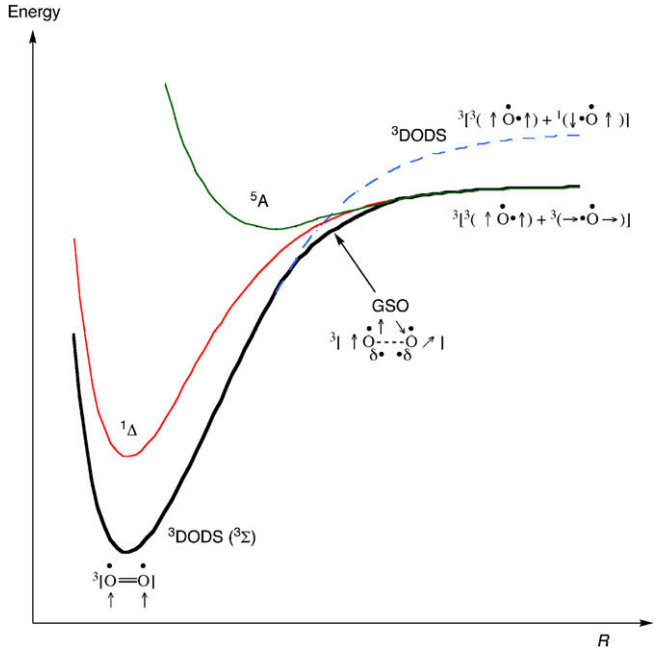

Fig. 6. The potential energy curves of the O–O dissociation process of molecular oxygen. The local spin rotation described by general spin orbital (GSO) is necessary at the intermediary stage, although the different orbitals for different spin (DODS) description is feasible at the equilibrium geometry.

$$^3[\uparrow \overset{\bullet}{O}\overset{\uparrow}{\delta\bullet}\cdots\overset{\downarrow}{\bullet\delta}\overset{\bullet}{O}\uparrow] \rightarrow {}^3[\uparrow \overset{\bullet}{O}\overset{\uparrow}{\delta\bullet}\cdots\overset{\searrow}{\bullet\delta}\overset{\bullet}{O}\nearrow] \rightarrow {}^3[{}^3(\uparrow \overset{\bullet}{O}\bullet\uparrow) + {}^3(\rightarrow\bullet\overset{\bullet}{O}\rightarrow)] \qquad (6d)$$

The detailed mathematical expression of this process by GSO has been given in our previous paper [22]. The dissociation of a covalent bond is thus described by the unified MO-VB scheme as

$$^{S}[\mathrm{MO}] \rightarrow {}^{S}[\mathrm{MO}+\mathrm{VB}] \rightarrow {}^{S}[\mathrm{VB}](S = \text{spin state}) \tag{6e}$$

The MO and VB (atomic orbital AO) pictures are useful for near equilibrium and near dissociation limit, respectively. However, the exact description of the intermediate region, [MO + VB] region, is not at all easy because of the dual character. It is noteworthy that the transition state regions of oxygenation reactions are often classified into this regime. The BS MO description is one of the simple but practical approaches even to this region, although it exhibits the so-called spin symmetry breaking. The recovery of spin symmetry from BS MO has been accompanied by the approximate spin projection (AP) scheme in this series of papers.

2.4. Resonating BS MO methods and approximate spin projection

Here, the recovery of the broken spin symmetry by the resonating BS (RBS) and approximate spin projection (AP) procedures is briefly described. The single Slater determinant is utilized in the case of the broken-symmetry (BS) MO description of the open-shell states of O_2 and Fe(IV)=O. The ground triplet state of O_2 (O) and Fe(IV)=O (namely the core of cpd II) is given by the single determinant as $|\pi_x^*(\uparrow)\pi_y^*(\uparrow)|$ ($S = 1$) or $|\pi_x^*(\downarrow)\pi_y^*(\downarrow)|$ ($S = -1$), where the weak spin polarizations (SP) of other doubly occupied MOs are neglected. The lowest-spin (LS) BS MO solutions are expressed by the DR configurations as $|\overline{\pi_x^*(\uparrow)}\pi_y^*(\downarrow)|$ ($\equiv |\psi^+(\pi_x^*)\overline{\psi^-(\pi_x^*)}|$) [$DR_a$ ($\uparrow\downarrow$), $S_z = 0$] or $|\pi_x^*(\downarrow)\overline{\pi_y^*(\uparrow)}|$ ($\equiv |\overline{\psi^+(\pi_x^*)}\psi^-(\pi_x^*)|$) [$DR_b$ ($\downarrow\uparrow$), $S_z = 0$], where the SP effects are also neglected. However, these BS DR configurations are degenerate in energy, leading to the resonating BS (RBS) states consisted of in and out of phase combinations of them, as illustrated in Fig. 7A. The RBS states are responsible for the $^1\Delta_{xy}$ and $^3\Sigma$ states, respectively. This in turn means that each BS MO configuration is nothing but a counter part of the exact $^1\Delta_{xy}$ and $^3\Sigma$ states, and therefore, its energy is given by the half sum of their energies: $E(^{LS}\mathrm{BS}) \cong [^1E(\Delta_{xy}) + {}^3E(^3\Sigma)]/2$, as illustrated in Fig. 7A. The elimination of the $^3\Sigma$ component from the ^{LS}BS configuration by the approximate spin projection procedure (AP BS) provides the projected energy for the $^1\Delta_{xy}$ state, which is close to that of the $^1\Delta_{xy}$ state by the CI (see Fig. 7A). Similarly, the elimination of the quartet component from the LS doublet BS solutions of cpd I provides the projected doublet energies (^{2}AP BS), as shown in the previous papers [1,19,20].

2.5. BS MO descriptions of metal–oxo species

Here, the broken-symmetry (BS) descriptions of the metal–oxo species are briefly examined before the detailed discussions of the iron–oxo bonds. The bonding and antibonding $\pi_{x(y)}$ MOs by the RHF(RKS) are given by the linear combination of dπ and pπ [= 2px(y)] AOs.

$$\phi(\pi_x) = c_1 3d\pi_x + c_2 2p\pi_x \tag{8a}$$
$$\phi(\pi_x^*) = c_1' 3d\pi_x - c_2' 2p\pi_x \tag{8b}$$

where the c_i (c_i') denote the LCAO coefficients. The bonding BS MOs are given by the HOMO (π_x) and LUMO (π_x^*) mixing as follows (see Fig. 5B):

$$\psi^+(\pi_x) = \cos\theta_1\phi(\pi_x) + \sin\theta_1\phi(\pi_x^*) \tag{9a}$$
$$= \cos\omega(3d\pi_x) + \sin\omega(2p\pi_x) \tag{9b}$$
$$\psi^-(\pi_x) = \cos\theta_2\phi(\pi_x) - \sin\theta_2\phi(\pi_x^*) \tag{9c}$$
$$= \cos\eta(2p\pi_x) + \sin\eta(3d\pi_x) \tag{9d}$$

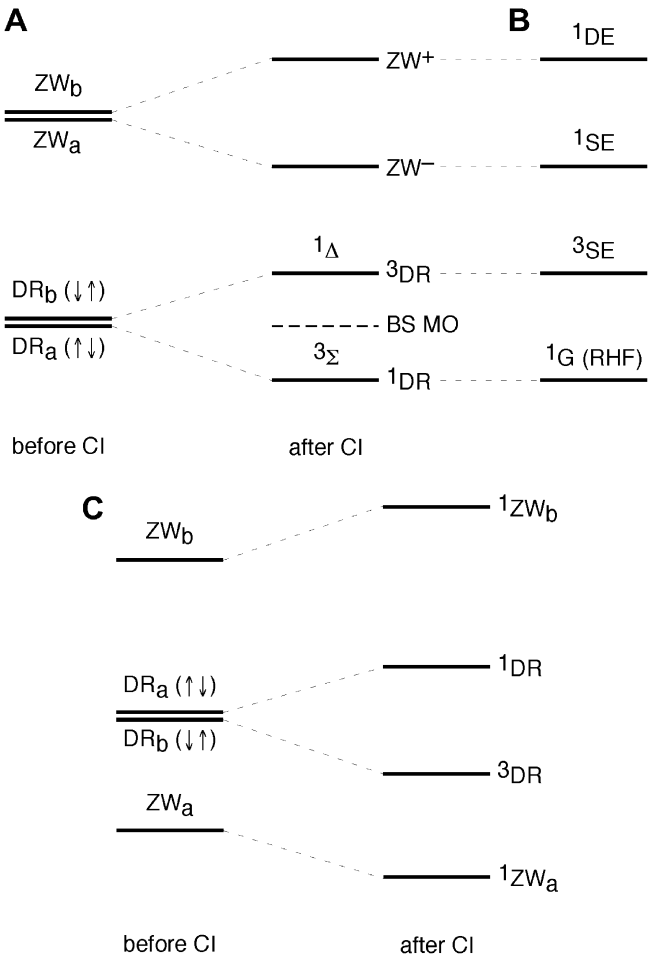

Fig. 7. (A) Energy diagrams of the DR and ZW states for the ground DR state before and after CI, (B) energy diagrams of the ground (G), single (SE) and double (D) excitation states for the closed-shell (^{1}RHF) species, and (C) energy diagrams of the DR and ZW states for the ground ZW state before and after CI.

where θ_1 (θ_2) and ω (η) are the mixing coefficients of MOs and AOs, respectively. Two parameters are necessary for the metal–oxo (M=O) bonds, since the electronegativities of the metal (M) and oxygen (O) sites are different, leading to definition of the ionicity parameter

$$y = \frac{\alpha_M - \alpha_O}{U} (\neq 0) \tag{10a}$$

where α_M and α_O denote the Coulomb integrals of M and O, respectively, and U is the effective on-site Coulomb repulsion integral ($U = U_M - U_O$) under the Hückel–Hubbard (HH) model examined previously [1,19–21]. On the other hand, the covalent bonding parameter is defined by

$$x = -\frac{\beta}{U} \tag{10b}$$

where β denotes the resonance integral for HH model. As shown previously [1], the BS HF (KS) equations can be analytically solved in the case of the HH model and LCAO coefficients of BS MOs are expressed by functions of the ionicity (y) and covalent (x) parameters.

As an example, let us consider the dissociation limit of the M–O bond for simple explanation. The two parameter theory (ω, η) in Eq. (9) can describe both diradical (DR) and zwitterionic (ZW) configurations [23]:

$$\left.\begin{aligned}\psi^{+}(\pi_x) &= 3d\pi_x(\omega=0)\\ \psi^{-}(\pi_x) &= 2p\pi_x(\eta=0)\end{aligned}\right\}(\uparrow)\,\dot{\mathrm{M}}-\dot{\mathrm{O}}\;(\downarrow)\equiv \mathrm{DR_a}\;(\uparrow\downarrow) \tag{11a}$$

$$\left.\begin{aligned}\psi^{+}(\pi_x) &= 2p\pi_x(\omega=\pi/2)\\ \psi^{-}(\pi_x) &= 2p\pi_x(\eta=0)\end{aligned}\right\}^{\oplus}\mathrm{M}-\mathrm{O}^{\ominus}\equiv \mathrm{ZW_a} \tag{11b}$$

$$\left.\begin{aligned}\psi^{+}(\pi_x) &= 3d\pi_x(\omega=0)\\ \psi^{-}(\pi_x) &= 3d\pi_x(\eta=\pi/2)\end{aligned}\right\}^{\ominus}\mathrm{M}-\mathrm{O}^{\oplus}\equiv \mathrm{ZW_b} \tag{11c}$$

This means that the M=O bond in the intermediate dissociation region is generally expressed by the mixing of DR_a (↑↓), ZW_a and ZW_b configurations in the VB (AO) CI scheme. The BS MO description (followed by AP) in (9) is, therefore, one of the practical approximations to the exact VB-CI approach to this regime.

The antibonding BS MOs are also given by the two parameters as follows (see Fig. 5).

$$\psi^{+}(\pi_x^*) = -\sin\theta_1\phi(\pi_x)+\cos\theta_1\phi(\pi_x^*) \tag{12a}$$

$$= -\sin\omega(3d\pi_x)+\cos\omega(2p\pi_x) \tag{12b}$$

$$\psi^{-}(\pi_x^*) = -\sin\theta_2\phi(\pi_x)+\cos\theta_2\phi(\pi_x^*) \tag{12c}$$

$$= -\sin\eta(2p\pi_x)+\cos\eta(3d\pi_x) \tag{12d}$$

where ± signs are determined by the orthogonality condition of BS MOs. The antibonding BS MOs are reduced to the AOs at the dissociation limit ($R=\infty$) [23].

$$\left.\begin{aligned}\psi^{+}(\pi_x^*) &= 2p\pi_x(\omega=0)\\ \psi^{-}(\pi_x^*) &= 3d\pi_x(\eta=0)\end{aligned}\right\}(\downarrow)\,\dot{\mathrm{M}}-\dot{\mathrm{O}}\;(\uparrow)\equiv \mathrm{DR_b}\;(\downarrow\uparrow) \tag{13a}$$

$$\left.\begin{aligned}\psi^{+}(\pi_x^*) &= -3d\pi_x(\omega=\pi)/2\\ \psi^{-}(\pi_x^*) &= 3d\pi_x(\eta=0)\end{aligned}\right\}^{\ominus}\mathrm{M}-\mathrm{O}^{\oplus}\equiv \mathrm{ZW_b} \tag{13b}$$

$$\left.\begin{aligned}\psi^{+}(\pi_x^*) &= 2p\pi_x(\omega=0)\\ \psi^{-}(\pi_x^*) &= -2p\pi_x(\eta=\pi/2)\end{aligned}\right\}^{\oplus}\mathrm{M}-\mathrm{O}^{\ominus}\equiv \mathrm{ZW_a} \tag{13c}$$

Thus, the doubly excited configuration $|\pi_x^*\overline{\pi_x^*}|$ (or $|\overline{\pi_x}\pi_x|$) corresponds to the DR_b (↓↑), ZW_b or ZW_a state at the dissociation limit, depending on the magnitude of the ionicity (y) and covalency (x) parameters. This means that the BS MO doubly excited (DE) states are generally expressed by the mixing of these three VB (AO) configurations.

The singly excited states are also explained by the VB (AO) CI terms at the dissociation limit:

Ⓐ $$\left|\psi^{+}(\pi_x)\overline{\psi^{-}(\pi_x^*)}\right| = \left|3d\pi_x\,\overline{3d\pi_x}\right| \quad \left(^{\ominus}\mathrm{M{-}O}^{\oplus}\equiv \mathrm{ZW_b}\right) \tag{14a}$$

$$\left|\psi^{+}(\pi_x^*)\overline{\psi^{-}(\pi_x)}\right| = \left|2p\pi_x\,\overline{2p\pi_x}\right| \quad \left(^{\oplus}\mathrm{M{-}O}^{\ominus}\equiv \mathrm{ZW_a}\right) \tag{14b}$$

Ⓑ $$\left|\psi^{+}(\pi_x)\overline{\psi^{-}(\pi_x^*)}\right| = -\left|2p\pi_x\,\overline{3d\pi_x}\right| \quad \left((\downarrow)\,\dot{\mathrm{M}}{-}\dot{\mathrm{O}}\;(\uparrow),\ \mathrm{DR_b}\;(\downarrow\uparrow)\right) \tag{15a}$$

$$\left|\psi^{+}(\pi_x^*)\overline{\psi^{-}(\pi_x)}\right| = -\left|3d\pi_x\,\overline{2p\pi_x}\right| \quad \left((\uparrow)\,\dot{\mathrm{M}}{-}\dot{\mathrm{O}}\;(\downarrow),\ \mathrm{DR_a}\;(\uparrow\downarrow)\right) \tag{15b}$$

Ⓒ $$\left|\psi^{+}(\pi_x)\overline{\psi^{-}(\pi_x^*)}\right| = -\left|3d\pi_x\,\overline{2p\pi_x}\right| \quad \left((\uparrow)\,\dot{\mathrm{M}}{-}\dot{\mathrm{O}}\;(\downarrow),\ \mathrm{DR_a}\;(\uparrow\downarrow)\right) \tag{16a}$$

$$\left|\psi^{+}(\pi_x^*)\overline{\psi^{-}(\pi_x)}\right| = -\left|2p\pi_x\,\overline{3d\pi_x}\right| \quad \left((\downarrow)\,\dot{\mathrm{M}}{-}\dot{\mathrm{O}}\;(\uparrow),\ \mathrm{DR_b}\;(\downarrow\uparrow)\right), \tag{16b}$$

where A, B, and C correspond to the parameter sets ($\omega=\eta=0$), ($\omega=\pi/2$, $\eta=0$), and ($\omega=0$, $\eta=\pi/2$), respectively. The singly excited states of diradical (DR) correspond to the zwitterionic (ZW) configurations (see Fig. 7A), whereas the singly excited states of ZW are given by the DR configurations (see Fig. 7C). Therefore, the configuration mixing (CI) of BS MO configurations provide the symmetry-adapted (SA) ground and excited states, as shown in Fig. 7. The DR state reduces to the closed-shell RHF state for nonradical species. The RHF CI scheme for the species is depicted in Fig. 7B, where the ground state (^{1}G) is well-described by ^{1}RHF and excited states are given by singly (SE) and doubly (DE) excited configurations, respectively. Further detailed descriptions of BS MO CI and related VB (AO) CI are given in our previous papers [23]. We have examined the BS MO descriptions of metal–oxo bonds (for example, Cr=O, Mn=O and Fe=O) on the basis of the unrestricted Hartree–Fock (UHF) calculations [1]. It was found that the analytical solutions of the BS UHF equations with two parameters (ω, η) are useful for qualitative understanding of the nature of labile metal–oxo bonds which are determined by subtle balances of the ionicity (y) and covalent (x) parameters. The computational results by ab initio BS UHF are also well-explained on the basis of the theoretical formula (9–16).

2.6. BS MO descriptions of iron–oxo species

The molecular orbital configuration of hyper high-valent Fe(VI)=O is expressed by the bonding orbitals in Fig. 3D. The σ, π_x, π_y orbitals of Fe(VI)=O at the equilibrium geometry ($R_{Fe-O}\leqslant 1.65$) are stable closed-shell pairs, indicating that the bond order is 3.0. This means that the Fe(VI)=O bond is regarded as singlet oxene structure with triple bond as in the case of Mn(V)=O [1]. Since the d-orbital level is deep for the high-valent Fe(X) state (X = VI–IV), the ionicity parameter (y) in Eq. (10) is not so large, leading to the formation of strong covalent bonds instead of the ionic bond. However, such a stable oxene triplet bond should not exhibit the high oxygenation reactivity. This in turn suggests that elongation of the Fe–O triple bond and/or decrease of the bond order by reduction of the Fe(VI) center are necessary for high reactivity of the Fe=O bonds.

The dissociation of Fe(VI)=O is mainly expressed by the decrease of the covalency parameter (x) [namely the resonance integral (β)]. The change of the bonding property is, therefore, expressed by the MO-VB scheme.

$$^1[\mathrm{Fe(VI)}{\equiv}\mathrm{O}] \rightarrow {}^1\left[\mathrm{Fe(IV)}\begin{matrix}\delta\bullet\uparrow\\ \delta\bullet\uparrow\end{matrix}\!\!\cdots\!\!\begin{matrix}\downarrow\bullet\delta\\ \downarrow\bullet\delta\end{matrix}\mathrm{O}\right] \rightarrow {}^1\left[{}^3\mathrm{Fe(IV)}\begin{matrix}\bullet\uparrow\\ \bullet\uparrow\end{matrix} + {}^3\left(\downarrow\dot{\mathrm{O}}\downarrow\right)\right] \tag{17}$$

The stable dπ-pπ orbitals (π_x and π_y) are reorganized into broken-symmetry (BS) orbitals in Fig. 5 in the intermediate region, where the triplet ^{3}O radical character is not negligible, as illustrated by the spin vector model. The ^{3}Fe(IV) ($S=1$) and ^{3}O ($S=-1$) fragments are generated at the dissociation limit, although the total spin state is singlet.

The antibonding π_x^* orbital is half-occupied in the case of ^{2}[Fe(V)≡≡O], where the bond order is formally 2.5. The bonding and antibonding π_x^* orbitals are deformed into the BS orbitals in Fig. 5 in the dissociation region. Therefore, the Fe–O dissociation process is expressed by the MO-VB scheme as

$$^2[\mathrm{Fe(V)}{\equiv}{\equiv}\mathrm{O}] \rightarrow {}^2\left[\mathrm{Fe(III)}\begin{matrix}\delta\bullet\uparrow\\ \downarrow\bullet\end{matrix}\!\!\cdots\!\!\begin{matrix}\downarrow\bullet\delta\\ \mathrm{O}\end{matrix}\right] \rightarrow {}^2\left[{}^2\mathrm{Fe(III)}\begin{matrix}\bullet\uparrow\\ \bullet\end{matrix} + {}^3\left(\downarrow\dot{\mathrm{O}}\downarrow\right)\right], \tag{18}$$

where triplet ^{3}O atom is generated at the dissociation limit.

The other antibonding π_y^* orbital is also half-occupied in the ^{3}[Fe(IV)=O] species with the formal bond order 2 (double bond), namely the metal–oxo bond as shown in Fig. 3C. The Fe–O dissociation process is given by the following MO-VB scheme

$$^3[\mathrm{Fe(IV)}{=}\mathrm{O}] \rightarrow {}^3\left[\mathrm{Fe(II)}\begin{matrix}\delta\bullet\uparrow\\ \delta\bullet\uparrow\end{matrix}\!\!:\!:\!:\!:\!\!\begin{matrix}\downarrow\bullet\delta\\ \downarrow\bullet\delta\end{matrix}\mathrm{O}\right] \rightarrow {}^3\left[{}^3\mathrm{Fe(II)}\begin{matrix}\bullet\uparrow\\ \bullet\uparrow\end{matrix} + {}^3\left(\downarrow\bullet\mathrm{O}\bullet\downarrow\right)\right], \tag{19}$$

where the triplet state of ^{3}Fe(II) is expressed with the atomic configuration: $^3[(\delta_{xy})^2(3d\pi x)^2(3d\pi y)^1(\sigma^*)^1]$. The spin crossover from the triplet to the quintet configuration $^5[(\delta_{xy})^1(\delta_{xy}{}^*)^1((3d\pi x)^2(3d\pi y)^1(\sigma^*)^1)$ is feasible if the exchange interaction on the Fe(II) site

is predominant. On the other hand, the local spin crossover occurs from the triplet excited state of ^{3}Fe(II) to the singlet ground state: ^{1}Fe(II) = $^1[(\delta_{xy})^2(3d\pi x)^2(3d\pi y)^2]$, under the condition that the ligand field for Fe(II) is strong enough to stabilize this closed-shell configuration. The electron transfer from Fe(II) to atomic oxygen (^{3}O) takes place if the ligand field of Fe(II) is electron donating as

$$^3[^1\mathrm{Fe(II)}\ ^3\dot{\dot{\mathrm{O}}}] \rightarrow {}^3[^2\mathrm{Fe(III)}\text{–}^2\mathrm{O}\bar{\bullet}] \rightarrow {}^3[^3\mathrm{Fe(IV)}\text{–}^1\mathrm{O}^{2-}] \quad (20)$$

where the triplet state of ^{3}Fe(IV) is expressed with $^3[(\delta_{xy})^2(3d\pi x)^1(3d\pi y)^1]$. The last oxygen dianion structure is formally proposed for the metal–oxo species, although the oxygen atom site in the structure should exhibit the nucleophilic property. Variations of the nature of iron–oxo bonds are qualitatively expressed by changes of the ionicity (y) and covalency (x) parameters in the BS MO scheme, as shown in Section 2.5. These parameters are of course subtle functions of types of ligands and substituents introduced, together with environmental effects such as solvent and protein fields in biological systems. As shown in Eqs. (17)–(20), the high-valent Fe(X)=O bonds exhibit more or less the triplet O diradical character. This is the reason why we have proposed the ^{3}O-atom model for electrophilic hydroxylation reactions by the species.

The excited singlet state $^1\Delta$ of Fe(IV)=O exhibits the dual characteristics, as illustrated in Fig. 4: one is the diradical (DR) configuration [$^1\Delta_{xy(yx)}$ state in the present paper] and the other is expressed with the zwitterionic (ZW) configuration [$^1\Delta_{xx(yy)}$]. These configurations correlate, respectively, with the diradical $^1[(2px)^1(2py)^1]$ and ionic $^1[(2px)^2(2py)^0$ or $(2px)^0(2py)^2]$ components of the excited $^1\Delta$ state of O atom. The isoelectronic analogy leads to our proposal of the ^{1}O model for hydroxylation reactions with $^1\Delta$ state of Fe(IV)=O. The $^1\Delta_{xy}$ and $^1\Delta_{xx}$ configurations of O-atom should prefer, respectively, the abstraction and insertion reactions. It is noteworthy that the mechanisms of hydroxylation reactions by ^{1,3}O atom are well understood on both experimental and theoretical grounds, as illustrated in Fig. 3 [1].

3. Discussions and concluding remark

3.1. BS calculations of metal–oxo species

The broken-symmetry (BS) calculations have been performed for transition-metal oxo species to confirm qualitative pictures presented in preceding sections [1,23]. The binding energies for the naked system, M=O (**1**), were calculated by using the BS Hartree–Fock (UHF) and hybrid density functional theory (UDFT), UB3LYP, and post UHF, namely, coupled–cluster (CC) method, UCCSD(T). The calculated binding energies for the $^2\Pi$-state of CuO are 2.69 and 2.37 eV by the UB3LYP and UCCSD(T) methods [24–29], in compatible with the experimental value (2.75 eV). The corresponding values for the $^5\Pi$-state of CrO are 4.34 and 3.71 eV, as compared with the experiment (4.41 eV). These results are not at all trivial, since the experimental binding energies can be reproduced by the less expensive BS DFT (UB3LYP) instead of time-consuming CCSD(T). The spin contamination errors in the BS approach are not so serious at least for energetics.

The BS UHF calculations [1] of the simplest model, O=M(NH_2)$_2$ (**2**) for transition-metal oxo porphyrine systems were also performed to confirm variations of the nature of the M–O bonds with changes of oxidation number (m) of transition metal ions [M = Cr(m), Mn(m), and Fe(m), m = 2–5]. It was found that the oxygen site of **2** is indeed variable from nucleophilic to electrophilic, depending on the m-value of these ions, for example [1],

$$\mathrm{Fe}(m{+}2)\mathrm{O}^{2-} \leftrightarrow \mathrm{Fe}(m{+}1)\mathrm{O}^{1-} \leftrightarrow \mathrm{Fe}(m)\mathrm{O}^{0} \leftrightarrow \mathrm{Fe}(m{-}1)\mathrm{O}^{+} \quad (21)$$

These variations are consistent with the qualitative pictures in Section 2.6. The high-valent iron–oxo species (Fe(IV)=O) often undergoes electrophilic reactions such as epoxidation of olefins. Thus, the isoelectronic analogy between O, O_2, Fe(IV)=O and Cu(III)=O in Fig. 1 is useful for qualitative understanding of electrophilic oxygenation reactions.

The BS calculations are useful for elucidation of covalent (x) and ionicity (y) parameters (in (10)) in model complexes and metalloenzymes as shown in this series of papers. In fact, the essence of the BS computational results can be extracted by using the effective Hückel–Hubbard (HH) model

$$H = \sum \alpha_i a_i^+ a_i + \sum \beta_{ij} a_i^+ b_j + \sum U_{ii} a_i^+ a_i a_i^+ a_i + \sum V_{ij} a_i^+ a_i b_j^+ b_j \quad (22)$$

where V_{ij} denotes the nearest neighbor Coulomb interaction. Several model Hamiltonians such as t(b)-J Hamiltonian [19,20] can be derived from this model. However, the BS methods are hardly applicable to several excited states, leading to the multireference (MR) approach for quantitative purpose. Several computational results based on the CAS-type approaches such as CASDFT will be shown elsewhere. These results are also expressed by the full CI scheme based on the model Hamiltonian in Eq. (22) as described in Section 2.

3.2. Isoelectronic analogy among O_2 (O) and Fe(IV)=O species

The isoelectronic analogy between O_2 and Fe(IV)=O in Fig. 1 lend support to propose common reaction intermediates in addition (epoxidation) reactions of the species to C=C double bonds, as shown in Fig. 8. A lot of our and other groups computational results on O_2 reactions [1,30,31] would be indeed transferable to understand reaction mechanisms of the Fe(IV)=O core. For example, four different intermediate [or transition structure (TS)] are conceivable, depending on the types of alkenes. The 1,4-diradical (DR) and metal DR (MDR) intermediate (or TS) are feasible for alkenes with less electron donating groups. For example, our BS calculations on the singlet oxygen ($^1O_2$) plus ethylene system indicated that 1,4-diradical (DR) mechanism was more favorable than the perepoxide (PE) mechanism [1,30]. Recent CASSCF and CASPT2 calculations on the same system [31] have concluded that perepoxide turns out to be attainable only by passing through the diradical, due to the nature of the critical points involved. Similarly our early BS calculation showed that metal 1,4-diradical (MDR) mechanism was more favorable than the metal perepoxide (MPE) mechanism [1]. Recent DFT calculations by Visser et al. also concluded the same result [32]. On the other hand, the 1,4-zwitterion (ZW) and metal ZW (MZW) species may be more stable than the DR and MDR in the case of alkenes with electron donating group. For example, the MZW for the Fe(IV)=O core may undergo the 1,2-cation shift at C=C double bond, leading to the so-called NIH shift [33]. The conversion from DR(MDR) to ZW(MZW) can be grasped with variations of the ionicity (y) and covalent (x) parameters on the theoretical grounds as shown in Section 2 [1]. The electron transfer (ET) and metal ET (MET) diradical intermediates may be generated in the case of strongly electron-rich alkenes such as dimethoxy ethylene. The MET is indeed formed in the one-electron oxidation step of phenol and amines by peroxydases with the Fe(IV)=O core, the so-called compound (cpd) I (or II) [34].

Possible mechanisms of hydroxylation reactions of alkanes are also available on the basis of the isoelectronic analogy between O and Fe(IV)=O as illustrated in Fig. 9. Both diradical (DR) and zwitterionic (ZW) mechanisms may be conceivable theoretically, depending on the strength of electron donating property of substituents introduced, though recent DFT calculations [2–21] usually favor the DR mechanism to the ZW mechanism. On the other hand, the electrophilic property of the peroxo species such as dioxirane,

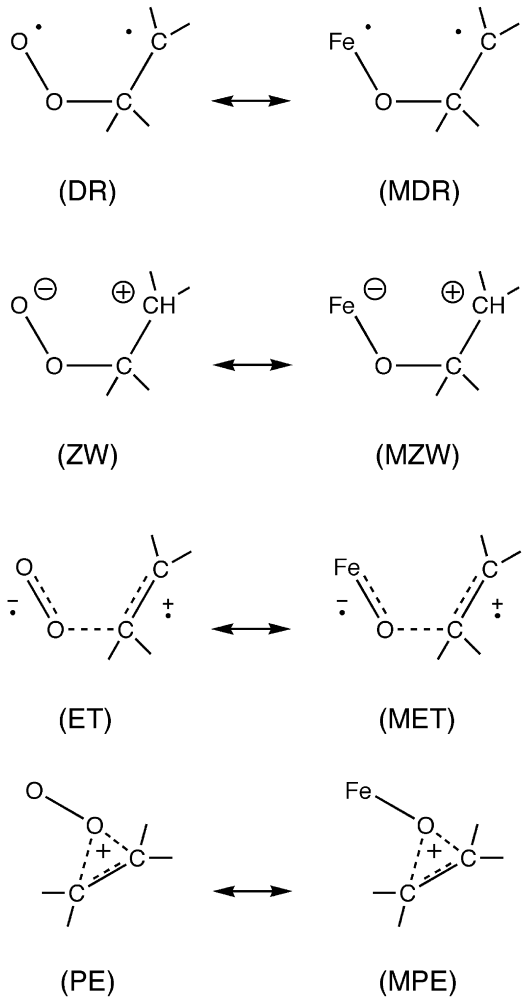

Fig. 8. Possible mechanisms of oxygen transfer reactions to alkenes on the basis of isoelectronic analogy between molecular oxygen and Fe(IV) core in P450.

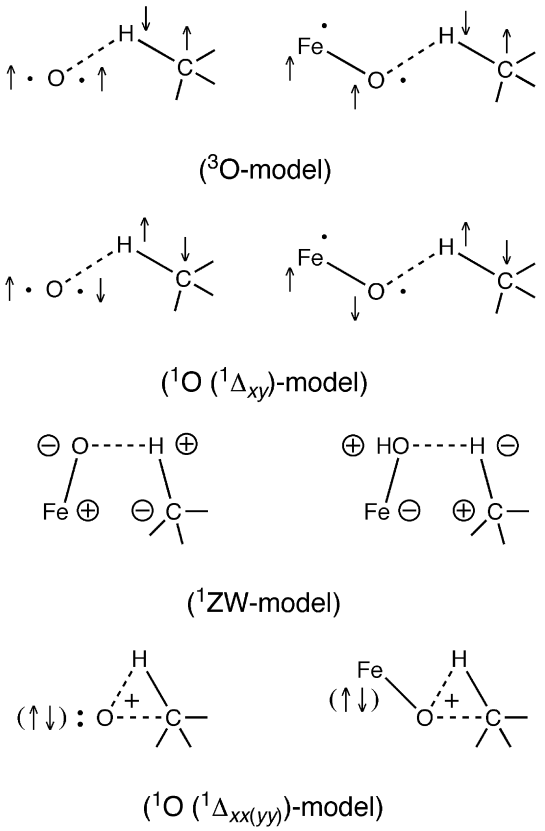

Fig. 9. Possible mechanisms of oxygen transfer reactions to alkanes on the basis of isoelectronic analogy between atomic and molecular oxygens and Fe(IV) core in P450.

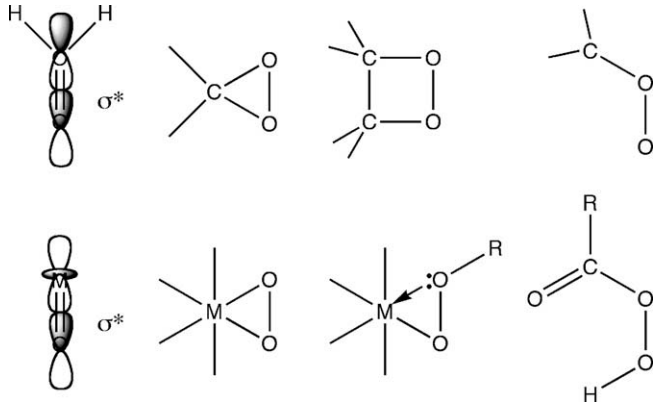

Fig. 10. Electrophilic properties of the σ* orbital of the O–O bond in several peroxides and metal oxo and metal peroxo species.

dioxetane, carbonyloxide, peracids, etc. may be understood by the existence of the lower-lying σ* orbital (LUMO) of these species as illustrated in Fig. 10. The electrophilic nature of the σ* orbital of the transition-metal oxo (M=O) species, transition-metal hydro(-alkyl)-peroxides, etc. plays an important role in several oxygenation reactions [1–20]. Thus, our BS MO analysis of metal–oxo bonds during 1985–1992 [1] has elucidated theoretical frameworks and possibilities in mechanisms of their oxygenation reaction of alkanes and alkenes, as illustrated in Figs. 8–10. The theoretical efforts in past decades have already been summarized in the review articles [1]. Recently, ab initio BS MO calculations [18–21] for realistic models including environmental effects have been extensively carried out to conclude which mechanism is more favorable than others. Such efforts are expected to elucidate reasonable mechanisms of oxygenation reactions on the theoretical grounds.

3.3. Concluding remarks

The electronic structures of the isoelectronic species, O, O_2, and Fe(IV)=O have been investigated on the basis of both broken-symmetry (BS) and multireference (MR) methods. In Section 2, the BS and MR descriptions of the ground (G) and low-lying excited states of these species were presented to elucidate the diradical (DR) and zwitterionic (ZW) characters of these states. The energy gap between the high-spin (HS) and low-spin (LS) DR states is rather small, often showing the spin crossover in the reaction pathways of oxygenation reactions [1,22]. Thus the oxygenation reactions are regarded as an interesting field for the molecular magnetism at least from the theoretical viewpoint. The reaction schemes of hydroxylation of alkanes and epoxidation of alkenes by the Fe(IV)=O core have been explained by the isolobal analogy, namely the triplet (^3O, $^3O_2$) and singlet (^1O, $^1O_2$) models, together with the electrophilic model based on the σ* orbital, for oxygenation reactions in Fig. s1 and Figs. 8–10. These models are found to be useful for qualitative understanding of ab initio DFT computational results on the Fe(IV)=O cores in model complexes and enzymes. The model Hamiltonians are also solved analytically to extract essential features of the DFT computational results.

ABSTRACT

The metal complexes with long alkyl chains $[Co(C16\text{-}terpy)_3](BF_4)_2$ (**1**) and $[Fe(C16\text{-}terpy)_2](BF_4)_2$ (**2**) were synthesized and the physical properties of the complex were characterized by magnetic susceptibility, Mössbauer spectroscopy, polarizing optical microscopy, differential scanning calorimetry, and X-ray scattering, where C16-terpy is 4′-hexadecyloxy-2,2′:6′,2″-terpyridine. Variable-temperature magnetic susceptibility measurements and/or Mössbauer studies revealed that the complex **1** exhibited unique spin transition ($T_{1/2}\downarrow$ = 217 K and $T_{1/2}\uparrow$ = 260 K) induced by structural phase transition, and the complex **2** was in the low-spin state in the temperature region of 5–400 K before the first mesophase transition. The cobalt(II) and iron(II) complexes exhibited liquid-crystal properties in the temperature range of 371–528 K and 466–556 K, respectively. After mesophase transition, the complex **1** exhibited only slight spin transition ($T_{1/2}\downarrow$ = 266 K and $T_{1/2}\uparrow$ = 279 K), and the complex **2** was in the low-spin state. The compounds with multifunction, i.e., magnetic property and liquid-crystal properties, are important in the development of molecular materials.

1. Introduction

Liquid crystals are fascinating functional materials, and are important in the field of advance materials such as electrooptic devices. Generally, liquid crystals used in the display is organic liquid crystals, organic liquid crystals are diamagnetic and can be easily oriented by an electric field. The construction of metal-containing liquid crystals (metallomesogens) has recently attracted a great deal of attention [1–7]. Metallomesogens have unpaired electron, spin, and the control of liquid crystal property used spin characters is very interesting. The investigation for magnetic liquid crystals containing rare-earth ions has been reported, because these ions often have a large magnetic anisotropy [1]. Furthermore, side chain nickel(II) polymeric compounds have been synthesized and the compounds have exhibited cooperative magnetic properties toward constructing of ferromagnets with liquid-crystal properties [3]. Therefore, liquid crystals that can be controlled by a several of external fields have been developed.

Recently, Fujigaya et al. have reported the spin-crossover (SCO) iron(II) compounds triggered by a phase transition [8], and the similar materials reported by Kimizuka et al. [9,10]. The compounds exhibit phase transition (crystal ⇆ melt)-triggered SCO behavior. Gaspar et al. have also investigated the synchronicity both transition, spin transition and solid–liquid crystal transition in iron(II) complexes [11]. Chang et al. have reported a synchronic bistability of valence tautomerism and crystal–melt phase transition [12]. Recently, we have also investigation the possibility to synchronize between the motion of the long alkyl chains and spin states [7,13–16]. Putting a metal complex cores with SCO in the liquid crystals is expected to show novel physical properties base of a synergy between magnetic and liquid crystal properties toward external stimuli.

We aim at constructing metal complexes with SCO and liquid crystal properties. Here we focused on the cobalt(II) and iron(II) compounds $[Co(C16\text{-}terpy)_3](BF_4)_2$ (**1**) and $[Fe(C16\text{-}terpy)_2](BF_4)_2$ (**2**) (C16-terpy is 4′-hexadecyloxy-2,2′:6′,2″-terpyridine) in order to develop novel metallomesogens.

2. Experimental

2.1. Synthesis

The ligand 4′-hexadecyloxy-2,2′:6′,2″-terpyridine (C16-terpy) was synthesized as follows: 2,6-bis(2-pyridyl)-4(1*H*)-pyridone (0.5 g, 2.00 mmol), K_2CO_3 (0.332 g, 3.00 mmol), and 1-bromohexadecane (0.73 g, 3.00 mmol) were mixed in DMF (50 ml). The mixture was stirred vigorously at 80 °C for one day. After cooling at r.t., the mixture was poured into ice/water. The pale purple precipitates was filtrated and washed with hot acetone and hexane. The product was dissolved in $CHCl_3$, and the solution was washed with 10% K_2CO_3 in water. The separated organic solution was dried

using anhydrous Na_2SO_4 and concentrated to give white powders; yield: (0.94 g, 97%). ^1H NMR ($CDCl_3$): δ = 8.70 (d, J = 4.0, 2H), 8.62 (d, J = 8.0, 2H), 8.01 (s, 2H), 7.85 (td, J = 8.0, 1.5, 2H), 7.32 (ddd, J = 7.5, 4.5, 1.0, 2H), 4.22 (t, J = 6.5, 2H) 1.86–1.26 (m, 28H), 0.88 (t, J = 7.0, 3H). Selected FT-IR data [ν/cm^{-1}] using KBr disk: 2919, 2848, 1582, 1469, 1446, 1407, 1359, 1202, 1030, 796.

The compound [Co(C_{16}-terpy)$_2$](BF_4)$_2$ · MeOH (**1** · **MeOH**) was synthesized as follows: the ligand C16-terpy (170 mg, 0.36 mmol) was dissolved in $CHCl_3$/MeOH (20 ml) and was added to solution of Co(BF_4)$_2$ · $6H_2O$ (60 mg, 0.18 mmol) in MeOH (10 ml). The brown orange solution was concentrated to about 10 ml, the micro crystals were filtered and recrystallized slowly from MeOH; yield: 94 mg (43%); brown orange crystals. *Anal.* Calc. for $C_{63}H_{90}O_3N_6B_2F_8Co_1$: C, 62.43; H, 7.48; N, 6.93; Co, 4.86. Found: C, 62.48; H, 7.53; N, 6.98; Co, 4.93%. The elemental analyses for **1** after removing MeOH molecules are as follows: Calc. for $C_{62}H_{86}O_2N_6B_2F_8Co_1$, C, 63.11; H, 7.35; N, 7.12; Co, 4.99. Found: C, 63.21; H, 7.42; N, 7.20; Co, 4.83%.

The iron(II) compound [Fe(C_{16}-terpy)$_2$](BF_4)$_2$ · acetone (**2** · **acetone**) was synthesized as follows: under nitrogen atmosphere, C16-terpy (300 mg, 0.633 mmol) was dissolved in $CHCl_3$/MeOH (20 ml) and was added to mixture solution of $FeCl_2$ · $4H_2O$ (63 mg, 0.317 mmol) and $NaBF_4$ (69 mg, 0.317 mmol) in $CHCl_3$/MeOH (ca. 10 cm^3). The purple solution was concentrated to about 20 ml, the micro crystals were filtered and recrystallized from Aceton/EtOH; yield: 215 mg (85%); purple needle crystals. *Anal.* Calc. for $C_{65}H_{92}Cl_2Fe_1N_6O_{11}$: C, 61.95; H, 7.36; N, 6.67; Fe, 4.43. Found: C, 62.10; H, 7.22; N, 7.10; Fe, 4.21%. The elemental analyses for **2** after removing acetone molecules are as follows: *Calc.* for $C_{62}H_{86}O_2N_6B_2F_8Fe_1$, C, 63.28; H, 7.37; N, 7.14; Fe, 4.75. Found: C, 63.19; H, 7.22; N, 7.09; Fe, 4.53%.

2.2. Physical experiments

All elemental analyses date were obtained at the Service Center of the Elemental Analysis of Organic compounds, Department of Chemistry, Kyushu University. Metal analyses were done on a Shimadzu AA-625-11 Atomic Absorption/Flame Emission Spectrometer. Infrared spectra were recorded using KBr disk with a JASCO FT-IR-410. All NMR measurements were performed on a Bruker AVANCE SERIES DPX 400 instrument operating at 400 MHz. Differential Scanning Calorimetry (DSC) thermal analysis was carried out on a SHIMADZU DSC50 differential scanning calorimeter. Optical polarized microscopy was carried out on a Nippon Chemical Industrial corporation polarization microscope OPTICAL POL with a Yanagimoto factory MODEL MP-J3 micro melting point meter. Powder X-ray diffraction (XRD) studies were performed on a Rigaku X-ray diffractometer RAD-2A with 2.0 kW Cu Kα X-ray. The magnetic susceptibilities $\chi(T)$ were measured between 5 and 400 K with a superconducting quantum interference device magnetometer (Quantum Design MPMS-5S) in an external field of 0.5 T. The Mössbauer spectrometer with a ^{57}Co/Rh source was driven in the transmission mode. The measurements at low temperature were performed with a closed-cycle helium refrigerator (Iwatani Co., Ltd.).

3. Results and discussion

Single crystals **1** · **MeOH** were isolated as MeOH adducts by slow recrystallization from MeOH solvent. Fig. 1a shows the molecular structure for **1** · **MeOH**. Each of the cobalt(II) ions are octahedrally coordinated by six nitrogen atoms in two C16-terpy ligands, i.e., an N_6 donor set. The values of the bond lengths are typical LS and HS cobalt(II) compounds. The long alkyl chains $C_{16}H_{33}O$ which forms a rod like structure are stuck out of 4′-position in the terpyridine moiety. On the other hand, the single crystal X-ray analysis was done for **2** · **acetone**. Fig. 1b shows the structure when complex **2** · **acetone** is in the low-spin state. The structure of **2** · **acetone** is similar to that of **1** · **MeOH**. The values of the bond lengths are consistent with those for typical LS iron(II) compounds.

The temperature dependence of the magnetic susceptibility for the compound **1** was measured in the form of the χ_mT versus T curve, where χ_m is the molar magnetic susceptibility and T the temperature (Fig. 2). The χ_mT value for **1** gradually decreases from 1.58 cm^3 K mol^{-1} at 400 K to 0.41 cm^3 K mol^{-1} at 226 K, and the gradually decrease of the χ_mT value shows normal thermal SCO behavior. Further cooling, the χ_mT value increases abruptly at around $T_{1/2}\downarrow$ = 217 K to 2.01 cm^3 K mol^{-1} at 206 K. The magnetic behavior shows that compound **1** exhibits spin transition from LS state to HS state on cooling. On heating, the χ_mT products undulation between 1.70 and 2.15 cm^3 K mol^{-1} in the temperature range from 5 to 251 K. On further heating, the χ_mT values abruptly dropped at around $T_{1/2}\uparrow$ = 260 K, showing the transition from HS to LS state. Then the χ_mT value gradually increases in the temperature range from 267 to 400 K. In the additional cycle, the wide thermal hysteresis loop (ΔT = 43 K) remained unchanged in the successive thermal cycle. On the other hand, Mössbauer spectrum was measured at room temperature K for the complex **2** (Fig. 3a). A doublet with *Q.S.* (quadrupole splitting) = 1.18 mm s^{-1} and *I.S.* (isomer shift) = 0.22 mm s^{-1} was observed for **2**, at 300 K, which corresponded to the LS state of iron(II) compounds. Magnetic property for the complex **2** was also followed by measurements of the molar magnetic susceptibility χ_m as a function of temperature in the temperature range of 300–570 K by using SQUID for high temperatures. The χ_mT value for the complex **2** is equal to 0.32 cm^3 K mol^{-1} over room temperature, which shows that the iron(II) ions remain in the LS state although there is some influence by impurities of a quartz pipe and quartz wool.

Liquid-crystalline properties were confirmed by differential scanning calorimetry (DSC), polarizing optical microscopy (POM),

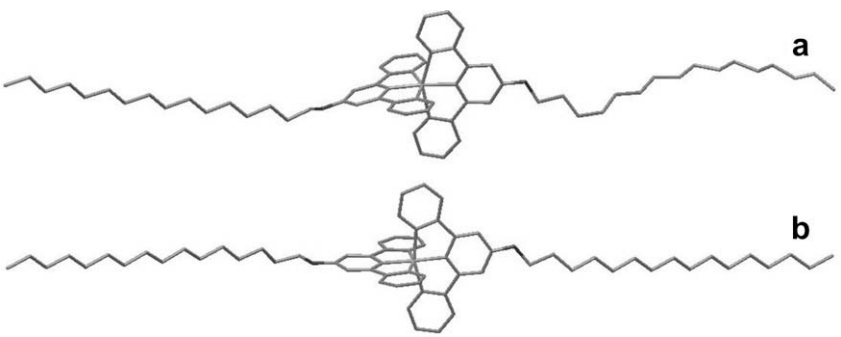

Fig. 1. Molecular structure of the cobalt(II) compound **1** · **MeOH** (a) and the iron(II) compound **2** · **acetone** (b).

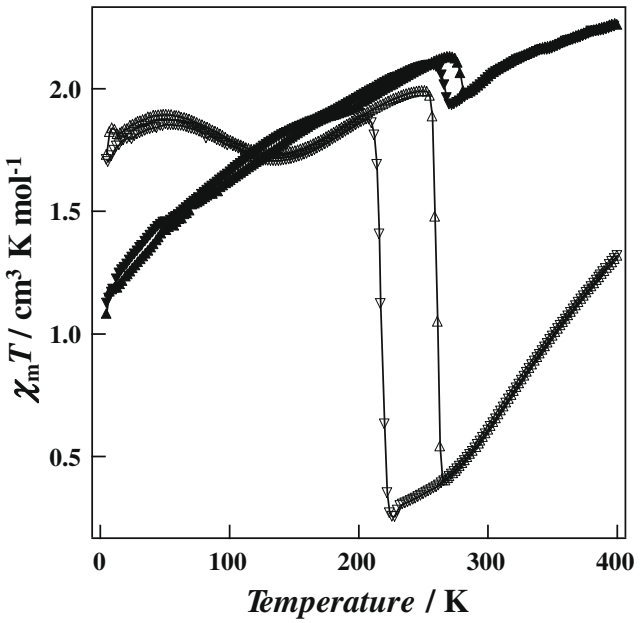

Fig. 2. $\chi_m T$ versus T plots for the complex **1**. The magnetic susceptibilities were measured on heating (△) and cooling (▽) before mesophase transition, and on heating (▲) and cooling (▼) after mesophase transition between 5 and 400 K.

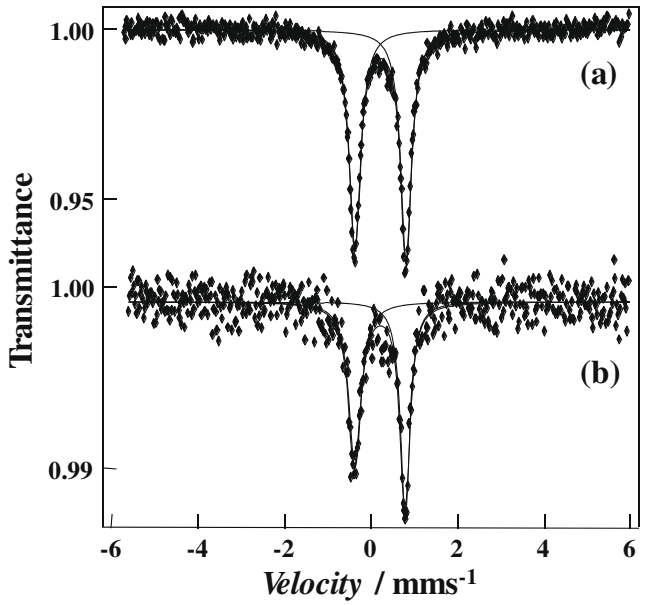

Fig. 3. Mössbauer spectra for **2** at room temperature. (a) Spectrum before mesophase transition. (b) Spectrum after mesophase transition.

and X-ray scattering (PXRD). Phase transition enthalpies were measured by carrying out DSC thermal analysis. The results are summarized in Table 1. Four peaks were observed at 371, 430, 511 and 528 K for **1**. The DSC peak (ΔH = 36.8 kJ mol^{-1}) at 371 K to a crystal-mesophase (SmE) transition, and that (ΔH = 13.7 kJ mol^{-1}) at 430 K is assigned to a SmE-SmC phase transition. Further heating, the peak at 511 K is assigned to a SmC-SmA phase transition, and that at 528 K is melting point. On the other hand, four peaks were observed at 448, 461, 466 and 556 K for **2**. Two peaks at 448 and 461 K is assigned to crystal (K_1) to crystal (K_2) and K_2 to K_3 transitions, respectively. Further heating, the peak at 466 K is assigned to K_3 to mesophase (D_{L2}) transition, and that at 556 K is melting point.

The mesophase was studied by hot-stage polarized optical microscopy, and identified as the mesophases based on the textures observed by optical microscopy for **1** and **2** (Fig. 4). Fig. 4a at 390 K, (b) at 490 K and (c) at 520 K show the texture of SmE, SmC and SmA phases, respectively. Fig. 4d at 520 K shows the texture of D_{L2} phase.

Temperature-dependent X-ray diffraction measurements were carried out to confirm this mesophase. Figs. 5 and 6 show the powder X-ray diffraction patterns of the crystal and mesophase states for the compounds **1** and **2**. A sharp reflection in the small-angle (2θ = 5.3°) with d-spacing of 16.7 Å was detected for **1** at 300 K (crystal phase). At 390 K, the peak of 2θ = 5.3° disappeared and a new peak appeared at 2θ = 4.6° (d = 19.2 Å) (SmE phase). At 490 K, the peak of 2θ = 4.6° disappeared and a new peak appeared at 2θ = 2.7° (d = 32.7 Å) (SmC phase). The peak of 2θ = 2.7° shifted to that of 2θ = 2.66° (d = 33.2 Å). The peak of 2θ = 21.5° (d = 4.1 Å) becomes broad at the same time. A sharp reflection in the small-angle (2θ = 4.7°) with d-spacing of 18.8 Å was detected for **2** at 300 K (K_1 phase). At 450 K, a new peak appeared at 2θ = 4.5° (d = 19.6 Å) (K_2 phase). At 463 K, the peak of 2θ = 4.5° shifted to that of 2θ = 4.4° (d = 20.1 Å). At 490 K, the peak of 2θ = 4.4° and 4.7° disappeared and a new peak appeared at 2θ = 2.6° (d = 34.0 Å) (D_{L2} phase).

The temperature dependence of the magnetic susceptibility for the compound **1** was measured after mesophase transition (Fig. 2).

Table 1
Phase transition temperatures and enthalpy changes for **1** and **2**.

Compound	Phase → Phase (T (K); ΔH / kJ mol^{-1})
1	K $\xrightarrow{371}$ SmE $\xrightarrow{430}$ SmC $\xrightarrow{511}$ SmA $\xrightarrow{528}$ I.L.(decomp.) [36.8] [13.7] [−] [−]
2	$K_1 \xrightarrow{448} K_2 \xrightarrow{461} K_3 \xrightarrow{466} D_{L2} \xrightarrow{556}$ I.L.(decomp.) [28.8] [4.55]

Phase nomenclature: K = crystal, SmA = smectic A mesophase, SmC = smectic C mesophase, SmE = smectic E mesophase, I.L. = isotropic liquid.

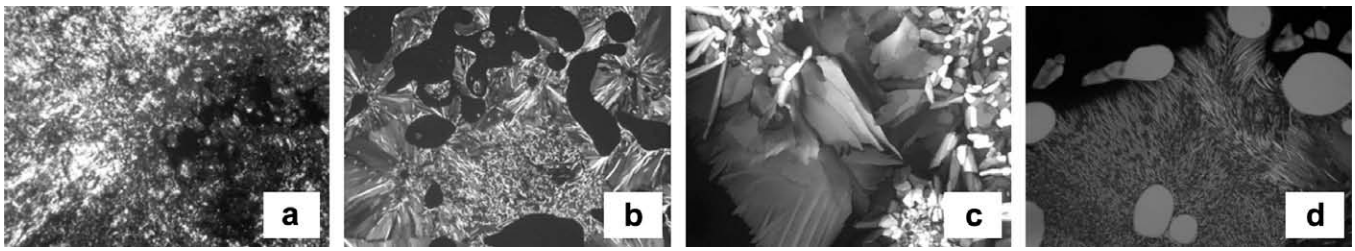

Fig. 4. Texture of the complex **1** and **2** under crossed polarizers at various temperatures. The texture (a) at 390 K is assigned to SmE phase, (b) at 490 K is assigned to SmC phase and (c) at 520 K is assigned to SmA phase for **1**. The texture (d) at 520 K is assigned to D_{L2} phase.

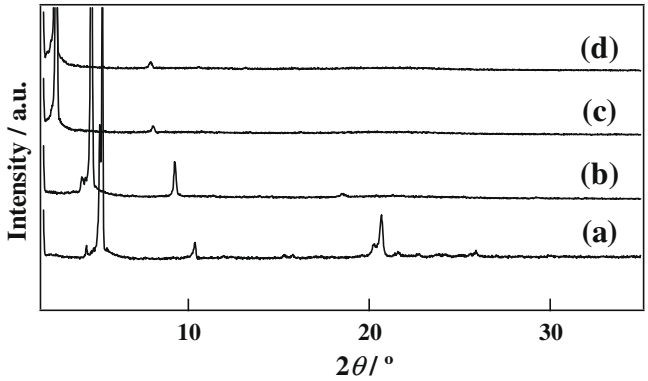

Fig. 5. Temperature dependence of powder XRD patterns for **1** (a) at 300 K, (b) at 390 K, (c) at 490 K and (d) at 520 K.

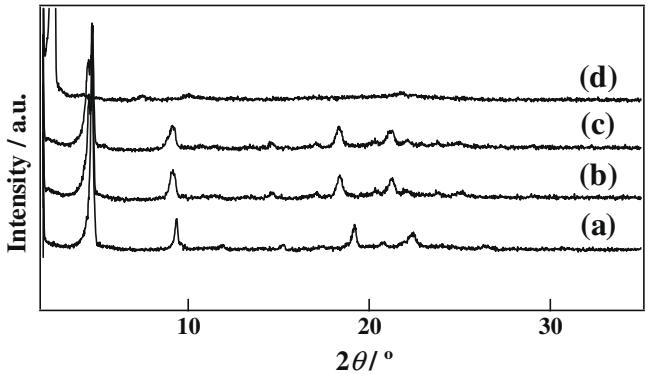

Fig. 6. Temperature dependence of powder XRD patterns for **2** (a) at 300 K, (b) at 450 K, (c) at 463 K and (d) at 500 K.

The $\chi_m T$ value for **1** gradually decreases from 2.26 cm^3 K mol^{-1} at 400 K to 1.93 cm^3 K mol^{-1} at 272 K. Further cooling, the $\chi_m T$ value slightly jump at around $T_{1/2}\downarrow$ = 266 K to 2.10 cm^3 K mol^{-1} at 256 K. The magnetic behavior shows that compound **1** exhibits slight spin transition induced by structural phase transition. On heating, the $\chi_m T$ gradually increases between 1.12 and 2.13 cm^3 K mol^{-1} in the temperature range from 5 to 271 K. On further heating, the $\chi_m T$ values slightly dropped at around $T_{1/2}\uparrow$ = 279 K. Then the $\chi_m T$ value gradually increases in the temperature range from 282 to 400 K. In the additional cycle, the wide thermal hysteresis loop (ΔT = 13 K) remained unchanged in the successive thermal cycle. The jump may be explained by increasing orientation of micro-crysytalline particles with anisotropic paramagnetic susceptibility. The magnetic results show that molecular arrangement for the complex **1** keeps condition as it is if the molecular arrangement is gathered once. On the other hand, Mössbauer spectrum was measured at room temperature K after mesophase transition for the complex **2** (Fig. 3b). A doublet with *Q.S.* (quadrupole splitting) = 1.17 mm s^{-1} and *I.S.* (isomer shift) = 0.21 mm s^{-1} was observed for **2**, at 300 K, which corresponded to the LS state of iron(II) compounds. The magnetic property for **2** is in the LS state, and both of the Mössbauer spectra give same parameters before and after mesophase transition.

4. Conclusions

The metal complexes with long alkyl chains $[Co(C16\text{-}terpy)_3](BF_4)_2$ (**1**) and $[Fe(C16\text{-}terpy)_2](BF_4)_2$ (**2**) were synthesized and the physical properties of the complex were characterized. The complex **1** exhibited unique spin transition ($T_{1/2}\downarrow$ = 217 K and $T_{1/2}\uparrow$ = 260 K) induced by structural phase transition, and the complex **2** was in the low-spin state in the temperature region of 5–400 K before the first mesophase transition. The compound **1** exhibited mesophase transitions, K to SmE at 371 K, SmE to SmC at 430 K, SmC to SmA at 511 K, and the compound **2** also exhibited mesophase transitions, K_3 to D_{L2} at 466 K. We believe that our approach, i.e., the co-occurrence of magnetic and liquid-crystal properties, can be widely applied, not only in the design of liquid-crystal materials with magnetism but also in the design of a variety of switchable molecular compounds.

ABSTRACT

Spin susceptibility of $S = 1/2$ one-dimensional antiferromagnetic Heisenberg chain $[Cu(OH)(NO_3)(pydz)]H_2O$ (pydz = pyridazine), which was difficult to be estimated from magnetic susceptibility measurements, was determined by measuring the temperature dependence of solid-state high-resolution ^{13}C MAS (magic angle spinning) NMR and by performing theoretical calculation. From fitting to theoretical formula for $S = 1/2$ one-dimensional chain model, one-dimensional intrachain exchange interaction J/k_B was estimated at 590–695 K (Hamiltonian = $J\sum S_i \cdot S_j$). We also evaluated that the ratio $\frac{k_B T_N}{J}$, which expresses a degree of one-dimensionality, is less than 3.4×10^{-3}. This result indicates that $[Cu(pydz)(OH)(NO_3)]H_2O$ has high one-dimensionality.

Low-dimensional magnetic coordination polymers have attracted much attention in recent years because of many specific properties due to enhanced quantum fluctuation. In particular, one-dimensional electron spin system is one of the most popular quantum spin systems exhibiting interesting properties such as, Haldane gap for integer spin systems or gapless spin excitation levels for half integer spin systems [1–3]. Although they have been studied for a long time and some specific properties were found, new quantum properties have been still discovered such as single chain magnet [4,5] or field-induced gap [6–8], suggesting that one-dimensional system is still developing field.

Strong magnetic interaction within one-dimensional chain system enables us to apply an ideal model of no long-range ordering to the experimental results; specific properties of one-dimensionality may be observed in higher temperature region. Coordination polymer $[Cu(OH)(NO_3)(pydz)]H_2O$ is expected to be one of the strongest $S = 1/2$ one-dimensional antiferromagnetic Heisenberg chain [9–13] by considering from its crystal structure and very small magnetic moment at room temperature [14]. There are three bridging ligands in $[Cu(OH)(NO_3)(pydz)]H_2O$, which are hydroxyl ion, nitrate ion and pyridazine between adjacent copper(II) ions as shown in Fig. 1.

It is known that hydroxyl as a ligand plays an important role to enhance magnetic interaction [15] and magnetic moment of this compound measured at room temperature, which is $1.08\mu_B$, is much smaller than about $1.9\mu_B$ of typical copper coordination polymers. These properties suggest that $[Cu(OH)(NO_3)(pydz)]H_2O$ has strong antiferromagnetic interaction.

It is difficult to determine the spin susceptibility for strong antiferromagnetic coordination polymers, because magnetic susceptibility measurement observes not only spin susceptibility χ_{spin} but also other contributions. Observed value can be written as shown in Eq (1) [16,17]:

$$\chi_{obs} = \chi_{spin} + \chi_{dia} + \chi_{TIP} + \cdots, \quad (1)$$

which includes diamagnetic component χ_{dia} and temperature independent paramagnetism χ_{TIP}, for example. When spin susceptibility is as small as other contributions due to strong antiferromagnetic interaction, spin susceptibility cannot be evaluated correctly from magnetic susceptibility measurement. In fact, spin susceptibility χ_{spin} has never been reported for $[Cu(OH)(NO_3)(pydz)]H_2O$. So we need to determine spin susceptibility from other methods. In this report, we elucidated the spin susceptibility by solid-state high-resolution NMR and theoretical calculations.

One-dimensionality is suggested by the ratio of $\frac{k_B T_N}{J}$, where J/k_B is one-dimensional intrachain exchange interaction and T_N is Neel temperature. We estimated J/k_B and upper limit of T_N from spin susceptibility determined by solid-state high-resolution NMR and magnetic susceptibility measurement, respectively. We found that $[Cu(OH)(NO_3)(pydz)]H_2O$ has very high one-dimensionality compared with other structurally one-dimensional coordination polymer [10,18].

$[Cu(OH)(NO_3)(pydz)]H_2O$ was prepared by the literature method [14]. After $Cu(NO_3)_2 3H_2O$ (0.58 g, 2.4 mmol) was dissolved

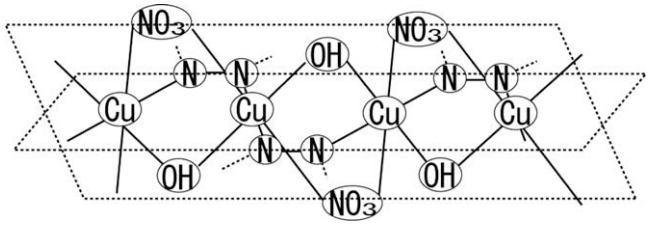

Fig. 1. Linear chains structure of $[Cu(OH)(NO_3)(pydz)]H_2O$. Nitrogen atoms coordinating to copper are from pyridazine molecule. Two planes shown by broken lines mean the planes made up with Cu–NO_3–Cu and Cu–pyridazine–Cu, respectively.

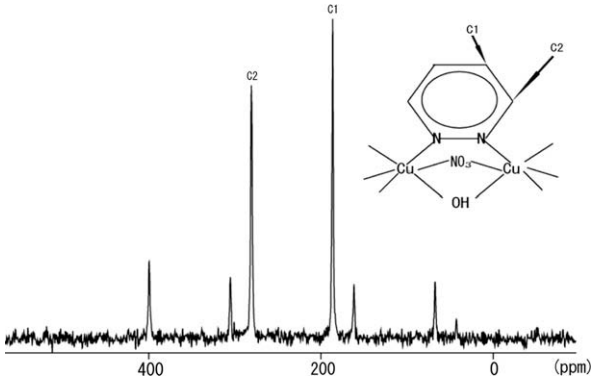

Fig. 2. ^{13}C MAS NMR spectrum of $[Cu(OD)(NO_3)(pydz\text{–}d^4)]D_2O$ at 9 kHz and room temperature. C1 and C2 are assignments of inequivalent pyridazine carbon atoms which are marked in inserted molecular diagram of $[Cu(OD)(NO_3)(pydz\text{–}d^4)]D_2O$.

in water (10 ml), pyridazine (0.174 ml, 2.4 mmol) was added with stirring the solution. The blue color of $Cu(NO_3)_2 3H_2O$ turned into dark-blue. This solution was concentrated to 2 ml by heating and ethanol (8 ml) was added. After sample was left at room temperature for 4–5 days, blue crystals formed. Elemental analysis for C, H and N showed good agreement with calculation. Anal. *Calc.* for $[Cu(OH)(NO_3)(pydz)]H_2O$: C, 19.95; H, 2.95; N, 17.45. Found: C, 20.01; H, 2.86; N, 17.66%. The powder X-ray diffraction of this complex agreed very well with previous report [14].

Solid-state high-resolution ^{13}C MAS (magic angle spinning) NMR was measured for deuterated sample $[Cu(OD)(NO_3)(pydz\text{–}d^4)]D_2O$ by spin echo pulse sequence synchronized with sample rotation and with Bruker DSX300 spectrometer at 7.03 T of external field, where resonant frequency for ^{13}C was 75.4 MHz. The spinning rate of the samples was 9 kHz. The ^{13}C NMR shift was measured from the external reference of hexamethylbenzene (carbon of methyl group: 17.17 ppm from TMS). Temperature dependence of ^{13}C NMR was measured between 190 and 420 K. Difference in temperature between thermometer of MAS probe and sample was calibrated by temperature dependence of ^{207}Pb NMR for $Pb(NO_3)_2$ [19].

Using the GAUSSIAN-98 software package, we performed UB3LYP calculation on a dimer for coordination polymer chain of $[Cu(OH)\text{-}(NO_3)(pydz)]H_2O$. As a reference, we also made calculation on a dimmer model for one-dimensional compound $[CuCl_2\text{-}(pydz)]$. Used basis set was LanL2DZ. The geometric structure of the dimer model was extracted from the crystal structure reported in a Ref. [14].

Temperature dependence of DC susceptibility was measured between 2 and 300 K in an applied magnetic field of 1 T with SQUID magnetometer (Quantum Design MPMS). Samples were put into a gelatin capsule for the measurement. Susceptibility of the gelatin capsule was also measured and was subtracted from the raw data of the sample.

Spin susceptibility can be determined indirectly by temperature dependence of NMR shift, because NMR shift depends on spin susceptibility as described as follows:

$$\delta_{para} = \frac{A}{N_A \hbar \gamma g \mu_B} \chi_{spin}, \tag{2}$$

$$\delta = \delta_{para} + \delta_{dia}, \tag{3}$$

where δ_{para} is paramagnetic shift which is caused by the Fermi contact term and dipole interaction term, A is hyperfine coupling constant (hfcc), δ_{dia} is diamagnetic chemical shift, γ is nuclear magnetogyric ratio, g is g-value and μ_B is Bohr magneton of electron spin. Although NMR is indirect method to determine spin susceptibility, it has great advantage to observe not the χ_{obs} in magnetic susceptibility measurement but the χ_{spin}. So we could determine χ_{spin} for $[Cu(OH)(NO_3)(pydz)]H_2O$ to discuss the intrachain magnetic interaction. Observed NMR shift δ is proportional to χ_{spin} and hfcc and includes temperature independent δ_{dia}. As a result, for determining spin susceptibility through NMR measurement, we need three parameters, i.e. δ, A and δ_{dia}. Fig. 2 shows ^{13}C MAS NMR spectrum at 9 kHz and room temperature for deuterated sample $[Cu(OD)(NO_3)(pydz\text{–}d^4)]D_2O$.

C1 and C2 is isotropic shift assigned to two inequivalent carbon atoms of pyridazine ligands. Assignment was confirmed by a measurement of partially deuterated pyridazine sample $[Cu(OH)\text{-}(NO_3)(pydz\text{–}d^2)]H_2O$. D-atom is bonded to C1 and H-atom is bonded to C2. When H–C1 of pyridazine is deuterated, dipolar interaction between carbon and hydrogen becomes very weak due to much smaller nuclear magnetogyric ratio of deuterium. As a result, line width of ^{13}C NMR peak becomes narrow for carbon atom bonded to deuterium atom and the C(–D) peak is concretely assigned. Narrow NMR spectrum shown in Fig. 2 is a result for fully deuterated pyridazine ligand in the complex. Peaks except for C1 and C2 are spinning side bands. Large shift from TMS was attributed to paramagnetic shift due to delocalization of lone pair electrons from copper to pyridazine ligand. Observed shifts of C1 and C2 correspond to δ in Eq. (3). Temperature dependence of δ of C1 and C2 are shown in Fig. 3.

Since the sample decomposed above 405 K and large change of NMR spectrum occurred, measurements at higher temperatures was impossible. Temperature dependence of shifts was due to a change of spin susceptibility as shown in Eq. (2). Because it was found from magnetic susceptibility measurement that magnetization decreased as temperature decreased in the range of NMR measurement, NMR shift to the lower frequency of each peak with decreasing temperature was considered to come from weakened paramagnetism. And diamagnetic chemical shift of pyridazine carbon atom locates near 150 ppm. From these behaviors of NMR shifts, it was expected that both hyperfine coupling constants and electron spin densities of carbon atoms in pyridazine ligand are positive. Additionally, in variation of shift with temperature, there are differences between C1 and C2. While shift of C1 changes only 4–5 ppm, that of C2 changes 10 ppm in the same temperature region. Because C2 is nearer to copper ion than C1, electron spin density at C2 is larger than C1 as explained later from theoretical calculation. As a result, NMR shift of C2 is influenced strongly by electron spins of copper ions more than that of C1.

From NMR measurement, we could obtain δ at each temperature. To evaluate the value of χ_{spin} of $[Cu(OH)(NO_3)(pydz)]H_2O$, we need the values of hfcc A and δ_{dia}, which could not be determined from the present NMR measurement due to the limited temperature region of the measurement without decomposition of the sample. So we attempted to use the calculated value of hfcc A and experimental value of δ_{dia} of similar one-dimensional $S = 1/2$ antiferromagnetic Heisenberg chain $[CuCl_2(pydz)]$. This compound has analogous crystal structure to the $[Cu(OH)(NO_3)(pydz)]H_2O$

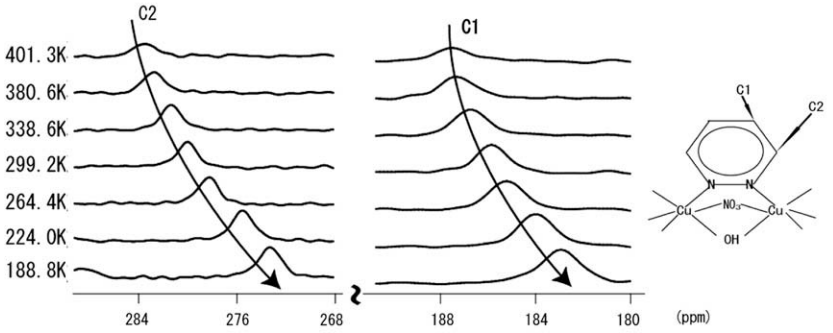

Fig. 3. Temperature dependence of ^{13}C MAS NMR spectra of [Cu(OD)(NO_3)(pydz–d^4)]D_2O between 188.8 and 401.3 K. Arrows follow temperature dependence of each peak.

[20]. Since [$CuCl_2$(pydz)] has smaller antiferromagnetic interaction than that of [Cu(OH)(NO_3)(pydz)]H_2O probably due to absence of hydroxyl bridging ligands, all the values of χ_{spin}, hfcc A and δ_{dia} can be determined by NMR and magnetic susceptibility measurements. Spin susceptibility χ_{spin} dominates the magnetic susceptibility of [$CuCl_2$(pydz)]. From the theoretical calculation based on DFT, we evaluated hfcc A of C1 and C2 both for [$CuCl_2$(pydz)] and [Cu(OH)(NO_3)(pydz)]H_2O. Table 1 shows theoretical and experimental value of hfcc A for [Cu(OH)(NO_3)(pydz)]H_2O and [$CuCl_2$-(pydz)]. Experimental value for [$CuCl_2$(pydz)] was obtained by using Eq. (2) with experimental results of ^{13}C NMR and magnetic susceptibility measurements as shown in Figs. 4–6 which were determined at first time in this work.

Table 1
Theoretical and experimental values of hfcc for [Cu(OH)(NO_3)(pydz)]H_2O and [$CuCl_2$(pydz)]. C1 and C2 mean the carbon atoms shown in Figs. 2 and 3.

	Hyperfine coupling constant (MHz)	
	C1	C2
Theoretical		
[Cu(OH)(NO_3)(pydz)]H_2O	1.3	4.4
[$CuCl_2$(pydz)]	1.7	3.1
Experimental		
[$CuCl_2$(pydz)]	2.4	3.3

For [$CuCl_2$(pydz)], theoretical hfcc values almost coincide with experimental hfcc both for C1 and C2, indicating that DFT calculation is valid. Theoretical values of hfcc of [Cu(OH)(NO_3)(pydz)]H_2O and [$CuCl_2$(pydz)] are similar to each other. This result indicates that there are similar circumstances about carbon atoms of pyridazine between the two coordination polymers, and that calculated hfcc A for [Cu(OH)(NO_3)(pydz)]H_2O and experimentally determined δ_{dia} of [$CuCl_2$(pydz)] can be used for the discussion of mag-

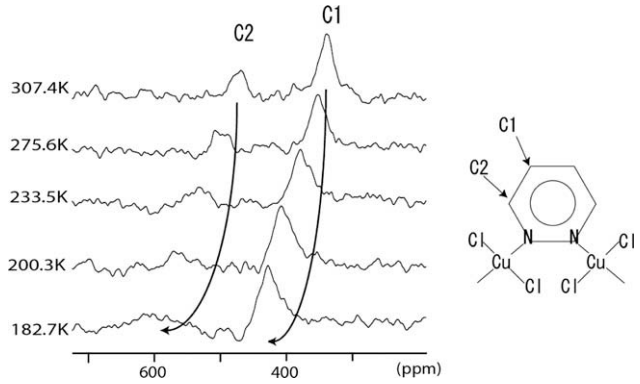

Fig. 5. Temperature dependence of ^{13}C MAS NMR spectra of [$CuCl_2$(pydz)] between 182.7 and 307.4 K. Arrows follow temperature dependence of each peak.

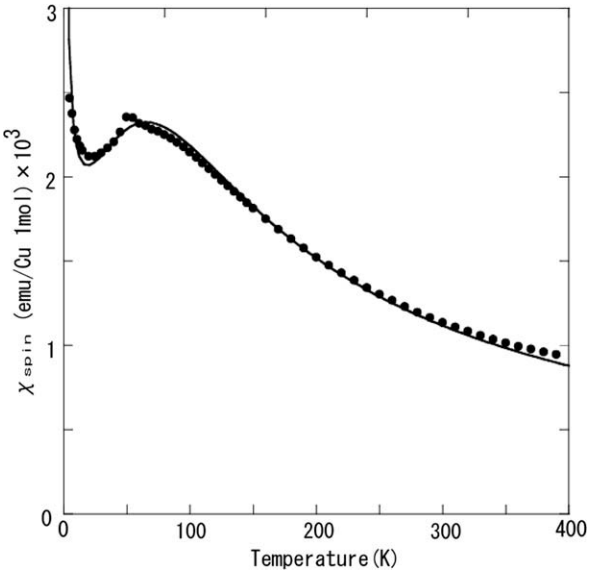

Fig. 4. Spin susceptibility of [$CuCl_2$(pydz)] from magnetic measurement. Solid curve is theoretical fit. J/k_B was estimated to 105 K.

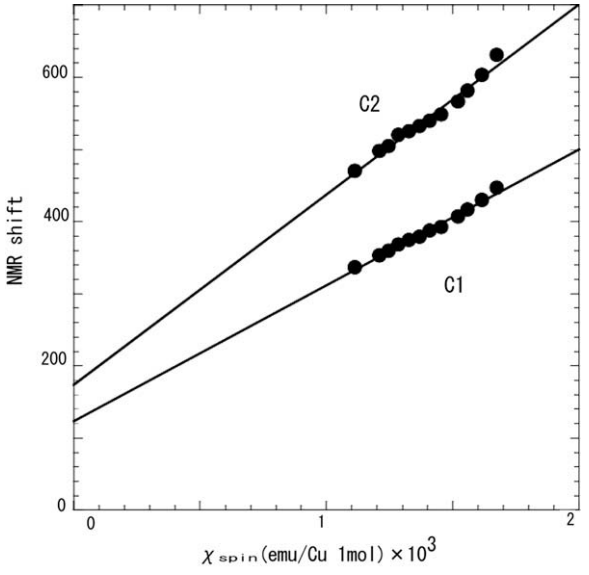

Fig. 6. Dependency of NMR shift of carbon atoms in [$CuCl_2$(pydz)] for spin susceptibility.

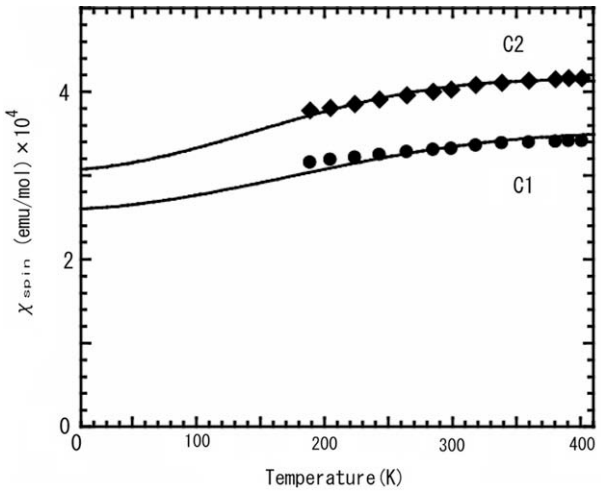

Fig. 7. Spin susceptibility of $[Cu(OH)(NO_3)(pydz)]H_2O$ obtained from NMR measurement. Closed circles and squares indicate spin susceptibility determined from each peak of C1 and C2. Solid curves represent the fit to Eq. (4).

netic interaction in a one-dimensional chain of $[Cu(OH)(NO_3)(pydz)]H_2O$. Now we have the values of hfcc A and δ_{dia} for $[Cu(OH)(NO_3)(pydz)]H_2O$ and we are able to discuss the spin susceptibility of $[Cu(OH)(NO_3)(pydz)]H_2O$.

Spin susceptibility was determined by Eq. (2). Fig. 7 shows spin susceptibility of $[Cu(OH)(NO_3)(pydz)]H_2O$ derived, as explained above.

Temperature range of plots is 188.1–401.3 K, where NMR measurement was performed. Upper plot in Fig. 7 is spin susceptibility determined from ^{13}C NMR shift of C1 and lower plot is from C2. Extrapolated solid lines were calculated based on theoretical formula called E.A.T. model [21,22], which can be written as follows:

$$\chi_{E.A.T.} = g^2\left(\frac{N\mu_B^2}{4k_B}\right)F(x)\frac{1}{T}, \tag{4}$$

$$F(x) = \frac{1 + 0.08516x + 0.23351x^2}{1 + 0.73382x + 0.13696x^2 + 0.53568x^3}, \tag{5}$$

where $x = J/k_BT$. E.A.T. model is a model that is a revision of well-known one-dimensional Bonner–Fischer model, and is superior to original model in the lower temperature region. Spin susceptibility of $[Cu(OH)(NO_3)(pydz)]H_2O$ could be fitted well by E.A.T. model. Here, g-value was fixed to 2.1 which value is often found for copper coordination polymers. As a result one-dimensional intrachain exchange interaction J/k_B was estimated to be 695 and 590 K for C1 and C2, respectively, which indicates J/k_B is 590–695 K. This result indicates that $[Cu(OH)(NO_3)(pydz)]H_2O$ has very strong antiferromagnetic intrachain interaction.

Although there are a few reports about stronger one-dimensional antiferromagnetic chain such as Sr_2CuO_3 ($J/k_B \sim 2600$ K) [9,10] and $[NiBr(chxn)_2]Br_2$ ($J/k_B = 2500$ K) [11] so far, this coordination polymer must be one of the most important antiferromagnetic chain with the strongest intrachain interaction among the copper coordination one-dimensional polymers.

Finally, we evaluated one-dimensionality of $[Cu(OH)(NO_3)(pydz)]H_2O$. One-dimensionality can be estimated from the ratio of Neel temperature T_N and J/k_B as shown in Eq. (6):

$$R = \frac{k_BT_N}{J}. \tag{6}$$

One-dimensional system, which has the smaller value of R, exhibits magnetic ordering at the lower temperature and finally approaches to the ideal one-dimensional chain that never undergoes the phase transition.

Table 2
List of J/k_B, T_N and the ratio $R = \frac{k_BT_N}{J}$ of some coordination polymers which have good one-dimensionality [9,10,13,18,23–25].

	J/k_B (K)	T_N (K)	k_BT_N/J
Sr_2CuO_3	2600	5.4	2.1×10^{-3}
$Sr_2Cu(PO_4)_2$	143	0.085	5.9×10^{-4}
$Cu(C_6H_5COO)_2 \cdot 3H_2O$	17.2	0.0008	4.7×10^{-5}
$[Cu(OH)(NO_3)(pydz)]H_2O$	590–695	<2	$<3.4 \times 10^{-3}$

In this study, we also performed magnetic susceptibility measurements down to 2 K for $[Cu(OH)(NO_3)(pydz)]H_2O$. Since no anomaly was found in the temperature range of the experiment, T_N is expected to be lower than 2 K. Tentatively, we estimated upper limit of the ratio of one-dimensionality from our experimental values, which is $R < \frac{2}{590} = 3.4 \times 10^{-3}$. Table 2 shows one-dimensional antiferromagnetic compounds found so far, together with the present compound $[Cu(OH)(NO_3)(pydz)]H_2O$.

Although Sr_2CuO_3 has the strongest intrachain interaction, one-dimensionality is inferior to other coordination polymers, which have weaker intrachain interaction than Sr_2CuO_3. In fact, $Cu(C_6H_5COO)_2 \cdot 3H_2O$ is the most ideal one-dimensional system at very low temperature, to our knowledge, though this coordination polymer exhibits only small J/k_B. The ratio $\frac{k_BT_N}{J}$ of present compound $[Cu(OH)(NO_3)(pydz)]H_2O$ is as large as Sr_2CuO_3 at least. This result indicates that $[Cu(OH)(NO_3)(pydz)]H_2O$ is a coordination polymer, that has large J/k_B and possibly better one-dimensionality with chemically tunable organic bridging ligands.

We determined NMR shift, hyperfine coupling constant, diamagnetic NMR chemical shift of pyridazine ligand of $S = 1/2$ one-dimensional antiferromagnetic Heisenberg chain $[Cu(OH)(NO_3)(pydz)]H_2O$ by using ^{13}C MAS NMR in the temperature region from about 190 to 400 K and by theoretical study based on DFT. From derived physical values, small spin susceptibility of antiferromagnetic Heisenberg chain $[Cu(OH)(NO_3)(pydz)]H_2O$ was elucidated and one-dimensional intrachain exchange interaction J/k_B was estimated to 590–695 K, which is very large among one-dimensional coordination polymers with organic ligands. We also evaluated one-dimensionality for $[Cu(OH)(NO_3)(pydz)]H_2O$ by considering the ratio $\frac{k_BT_N}{J}$ in this compound. It was estimated that the ratio $\frac{k_BT_N}{J}$ is much less than 3.4×10^{-3}. This ratio indicates that $[Cu(pydz)(OH)(NO_3)]H_2O$ has very good one-dimensionality.

Electron spin density distribution

ABSTRACT

Stable nitroxide radicals are useful to construct molecular magnetic systems. Particularly, radicals substituted by –COOH and $–CONH_2$ can be coordinated to magnetic metal ions and may be used as cladding reagents of gold nano-particles for modifying magnetism. Nitroxide molecules with unsaturated five-member ring have almost planner structure and electron spin delocalization may be expected. We determined the hyperfine coupling constants (hfcc) of ^{1}H, ^{2}H and ^{13}C of a series of nitroxide radicals with five-member ring. Experimental values of hfcc were compared with those deduced from calculations based on density functional theory. The electron spin density distribution at β position of ring was sensitive to the ring structure, although the electron spin density at β position is small compared with N–O site. Magnetic susceptibility and UV–Vis absorption spectra were also measured and discussed.

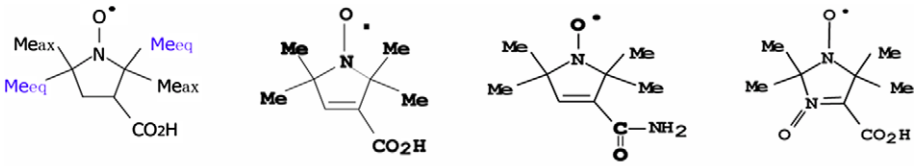
Stable organic radicals substituted by –COOH and $–CONH_2$ can be coordinated to magnetic metal ions and may be used as cladding reagents of gold nano-particles for bringing about specific magnetism. For this purpose, electron spin density distribution in the radical molecules is important. As a candidate of such organic radicals, we investigated the electron spin density distribution by paramagnetic shift of solid-state high-resolution ^{1}H, ^{2}H and ^{13}C NMR spectrum for powder crystalline samples and by calculation based on density functional theory for four radicals shown in Scheme 1, *i.e.* (**1**) 3-carboxy-2,2,5,5-tetramethyl-1-pyrrolidinyloxy, (**2**) 3-carboxy-2,5-dihydro-2,2,5,5-tetramethyl-1H-pyrrol-1-yloxy, (**3**) 3-(aminocarbonyl)-2,5-dihydro-2,2,5,5-tetramethyl-1H-pyrrol-1-yloxy, and (**4**) carboxy-2,5-dihydro-2,2,5,5-tetramethyl-1H-imidazol-1-yloxy 3-oxide.

Although it is known that major electron spin density locates on N–O site and methyl groups for stable nitroxide radicals, electron spin density distribution of other part of the molecule is important for use of these organic radicals as a building block of molecular magnetic systems. Since linkage between the organic radicals and metal ions or metal nano particles is mostly formed through this other part (–COOH, –CONH2, etc. in the present case), one of the aim of present study is to investigate the electron spin density distribution of five-member ring and functional groups, which locate opposite the N–O site. Ring structure of five-member ring radicals is chair shape (compound **1** in this paper) or almost planner (other compounds **2**–**4** in this paper), while nitroxide radicals with six member ring mostly exhibit chair shape. Then it is also the aim of this study to clarify how the planarity affects the electron spin density distribution in the five-member ring radicals by experiments and DFT calculation.

Specimens **1**, **2** and **3** were purchased from Acrōs Organics, where **4** from Aldrich and were used as obtained for experiments except ^{2}H NMR of partially deuterated (–COOD) specimen of **1**. This deuteration was performed by several times of recrystallization from CD_3OD. Guaranteed purity was 98%, 99%, 99%, and 98% for **1**, **2**, **3**, and **4**, respectively. Since it was found that compound **4** degraded and electron spin disappeared by 10–15% as described later, we only present only the result of UV–Vis absorption spectrum and DFT calculation for **4**.



Magic angle spinning (MAS) ^{1}H and ^{13}C NMR spectra were measured at 294 K with Bruker DSX300 spectrometer. Spinning rate was 25 kHz for ^{1}H and 9 kHz for ^{13}C NMR by using 2.5 and 4 mm Zirconia rotor, respectively. Temperature raise by sample spinning was corrected by chemical shift of ^{207}Pb NMR spectrum of $PbNO_3$. Hyperfine coupling constant (hfcc) at each atom of the radical molecule can be determined from isotropic shift δ_{iso} of each NMR signal, which is measured by MAS technique. The observed isotropic shift on a ppm scale consists of Fermi contact term, pseudo contact (dipolar) term, and temperature independent diamagnetic term, as follows [1–3]:

$$\delta_{iso} = \delta_{Fermi} + \delta_{pseudo} + \delta_{dia} \quad (1)$$

$$\delta_{Fermi} = \frac{\mu_B}{3k_BT} \cdot \frac{A_{Ferm}}{\gamma_{nuc}/2\pi} \left(\frac{g_{xx} + g_{yy} + g_{zz}}{3} \right) S(S+1) \quad (2)$$

Scheme 1.

$$\delta_{\text{pseudo}} = \frac{\mu_B^2}{18k_B\text{Tr}^3}[\{2g_{zz}^2 - (g_{xx}^2 + g_{yy}^2)\}(3\cos^2\theta - 1) - 3(g_{xx}^2 - g_{yy}^2)\sin^2\theta\cos 2\Omega]S(S+1) \quad (3)$$

where A_{Fermi} is the Fermi coupling constant of the relevant nucleus in the unit of herz, T is the absolute temperature, γ_{nuc} is the nuclear gyromagnetic ratio, r is the distance between electron spin and nucleus, and others have usual meanings. Eq. (3) displays a contribution from anisotropy of g value of unpaired electron spin to the observed NMR isotropic shift. The anisotropy of the g value is very small for typical nitroxide radical crystals; *e.g.* 2.00620 ± 0.0040 [4]. Thus in our case, the contribution of the pseudo contact term is estimated to be less than 0.01 MHz for r = 0.18 nm, and the pseudo contact term in Eq. (3) can be neglected in comparison with the Fermi contact term to determine the hfcc A_{nuc} (=A_{Fermi}). By using molar magnetic susceptibility χ_M, Eqs. (1) and (2) can be written by [5]:

$$\delta_{\text{iso}} = \frac{A_{\text{nuc}}}{\gamma_{\text{nuc}}/2\pi}\cdot\frac{\chi_M}{N_A g\mu_B} + \delta_{\text{dia}} \quad (4)$$

Experimentally determined hfcc A_{nuc} (=A_{Fermi}) is proportional to the electron spin density $\rho(R_{\text{nuc}})$ at the relevant nuclear position R_{nuc} as follows:

$$A_{\text{nuc}}(=A_{\text{Fermi}}) = \frac{8\pi}{3}g\mu_B\cdot\frac{\gamma_{\text{nuc}}}{2\pi}\rho(R_{\text{nuc}}) \quad (5)$$

Hyperfine coupling constant A_{nue} can be determined experimentally from Eq. (4). However, since the signal accumulation for ^{13}C NMR at natural abundance required over night acquisition or more, it was difficult to measure temperature dependence of the NMR shift δ_{iso}. Therefore, we derived hfcc A_{nue} from the data measured at 294 K. Temperature dependence of magnetic susceptibility of the powder crystalline samples were also measured and are shown in Fig. 1. Curie–Weiss fitting gave Weiss temperature θ = −8.42 K (R = 1.00), −2.31 K (R = 1.00), for **1** and **3**, respectively. Although compound **4** degraded before the measurements as mentioned above and observed $\chi_M T$ value was 0.32 at 300 K, which was considerably smaller than the expected value of 0.375, preliminary value of Weiss temperature was estimated to be very small $\theta \sim -0.1$ K.

Since antiferromagnetic interactions are small, radical spin almost behaves as Curie spin and hfcc A_{nue} can be estimated from Eq. (4) with the observed isotropic shift at 294 K by using chemical shift δ_{dia} of diamagnetic compound with similar structure.

Theoretical calculation of hyperfine coupling constants A_{nue} were performed for single molecule with UB3LYP/6–31+G(d,p) based on DFT of GAUSSIAN98 program package [6]. Molecular structure of **4**, of which the crystal structure has never been reported, was optimized by calculation with UB3LYP/6–31+G(d,p). Reported crystal structures and optimized structures were used for the calculation for **1**, **2** and **3** [7,8]. Calculated results are listed in Tables 1–4.

^{1}H and ^{13}C NMR spectra of **1** are shown in Fig. 2 together with numbering scheme of carbon atoms. Three irradiation frequencies were chosen to cover all of the signals of ^{13}C NMR spectrum. Peaks indicated by stars were assigned to spinning side bands by changing the spinning rate. Assignment of ^{1}H and ^{13}C NMR spectral lines

were based on the theoretical calculations. Assignment of hydrogen atom of –COOH was based on temperature dependent MAS ^{2}H NMR spectra of partially deuterated compound (–COOD). Powder crystalline sample of **1** is racemic and hfcc A_{nue} was calculated for the structure in a crystal of pure L-form. Comparison between the experimental values and those of calculations is indicated in Table 1. Agreement between the experimental values and calculation is fairly good except for C4, C5 and related hydrogen atoms. Calculation for hydrogen atom of –COOH also deviates from exper-

imental value. This is probably due to racemic crystal used for the measurement and hydrogen bonding between –COOH and >N–O· radical site in the crystal. Actually, temperature variation of MAS ^{2}H NMR spectrum of –COOD split into two peaks in the temperature range between 200 and 300 K, which correspond to D- and L-form in the racemic powder crystalline sample [9]. While X-ray diffraction experiment for a racemic single crystal gave an averaged structure for random mixing of D- and L-form [10], MAS ^{2}H NMR spectrum of –COOD detected slightly different local environments of –COOD···O–N (nitroxide) hydrogen bonding. Temperature variation of the two shift gave hfcc of deuterium A_D = +0.04 and +0.08 MHz, respectively. These values correspond to hfcc of respective protons A_H = +0.56 and +0.28 MHz. An average of these two values almost coincides with +0.36 MHz derived from unresolved MAS ^{1}H NMR shown in Fig. 2. In general, resolution of MAS ^{2}H NMR spectrum is much better than that of MAS ^{1}H NMR spectrum, since MAS is not efficient for dipolar coupled protons due to rapid spin diffusion during sample rotation and spin diffusion is very slow for deuteron.

We are interested in the variation of electron spin density distribution on the five-member ring by introducing double bond and hetero atom into the ring. ^{13}C NMR spectrum of **2**, which has

C=C double bond in the ring, is shown in Fig. 3. Peaks indicated by stars are spinning side bands. Calculated and experimentally determined hfcc are listed in Table 2.

Compound **3** has also C=C double bond in the ring and –$CONH_2$ group is introduced instead of –COOH of compound **2**. ^{1}H, ^{13}C NMR spectra are shown in Fig. 4. For ^{13}C NMR spectrum, peaks indicated by stars are spinning side bands. Calculated and experimentally determined hfcc are compared in Table 3.

From the NMR measurements of the three radical compounds with five-member ring **1**–**3**, we found that there is significant difference in hfcc A_{nue} of β position of the ring, *i.e.* +1.3, −0.48, and +1.56 for C5 of **1**, C3 of **2**, and C3 of **3**, respectively. Most of single occupied molecular orbital (SOMO) is composed of p(π^*) orbital of nitroxide group. Five-member ring of **1** is not planar but has chair conformation and SOMO is distributed to >CH_2 moiety via hyper-conjugation between hydrogen atoms of >CH_2 moiety and p(π^*) orbital of nitroxide group. This hyper-conjugation induces positive hfcc (+1.3 MHz) of β position. On the other hand, there exists a node of SOMO at β position of the ring of **2**. This is one of the significant differences between the two compounds. Fig. 5 illustrates differences of delocalization of SOMO among the four compounds.

To estimate experimentally the change of electronic state of these radicals, we also measured UV–Vis absorption spectra at room temperature for solutions of **1**, **3**, and **4** together with TEMPOL with six member ring of chair conformation. The experimental results are summarized in Fig. 6a. Fig. 6b indicates a good correlation between the experimental values of maximum absorption wave length and those of DFT calculation (UB3LYP/6–31+G(d,p). The π–π^* transitions appear between 200 and 300 nm. Typical n–π^* transition of nitroxide radicals can be seen between 400 and

500 nm. We also performed unrestricted ZINDO calculation with GAUSSIAN03 program, and found that the results were not good: the calculated wavelengths of the n–π^* transitions were 700–800 nm, while the observed values located 400–500 nm.

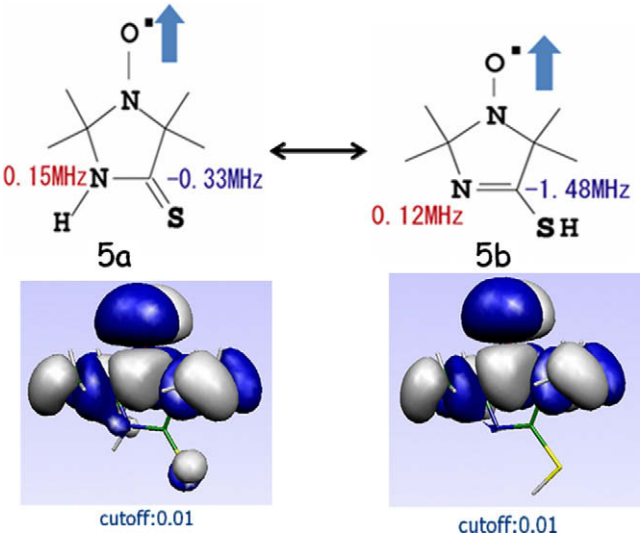

Fig. 7. Change of delocalization of SOMO between (a) thion and (b) thiol form of **5**.

In addition to these π–π^* and n–π^* transitions, relatively strong absorption was observed between 300 and 400 nm for **3** and **4**. These molecules have planar unsaturated ring structures. Since the calculation is fairly reliable as shown in Fig. 6b, an origin of this absorption band can be estimated from the calculation. One of the transitions, which contributes to this band of **4**, is 49b → 54b(SOMO) (396 nm). This transition corresponds to a dramatic change of orbital distribution as depicted in Fig. 6c. Transition of 54a(SOMO) → 55a(LUMO) locates at 365 nm, which is close to the previous transition. Optical control of transient spin density distribution with near visible light may be possible for **4**.

Synthesis of a similar radical with unsaturated five-member ring and with sulfur atom, 2,2,5,5-tetramethyl-4-thion-3-imidazoline-1-oxyl (**5a**), was reported [11–13]. This radical molecule may be changed to thiol form (**5b**) as depicted in Fig. 7 and is interesting as one of the cladding reagents for gold nano-particles for a specific magnetism. Therefore, we also tried to calculate delocalization of SOMO for the two isomers and an energy difference between them by DFT method mentioned above. Molecular structures of **5a** and **5b** were optimized by the same method as for **1**–**4**. Radical **5a** is energetically stable by 45 kJ/mol compared with **5b**. Difference of SOMO delocalization between **5a** and **5b** is depicted in Fig. 7, where numerical values shown are calculated hfcc of nitrogen and carbon atoms.

Magnetic metal complexes with these organic radicals as magnetic ligands are now under study.

ABSTRACT

A trinuclear copper(II) complex and a tetranuclear copper(II) complex that each incorporate a 9-tungstoarsenate(III) polyoxoanion ligand and several 2,2′-bipyridine (2,2′-bpy) ligands co-crystallize as the acid form: $H_4[\{Cu(2,2'\text{-bpy})\}_3(\alpha\text{-}AsW_9O_{33})] \cdot [\{Cu(2,2'\text{-bpy})_2\}\{Cu(2,2'\text{-bpy})\}_3(\alpha\text{-}AsW_9O_{33})] \cdot 38H_2O$ (**1**). Compound **1** was obtained from a hydrothermal reaction employing the trivacant lacunary polyoxometalate $[\alpha\text{-}AsW_9O_{33}]^{9-}$ as a precursor. The α-isomeric form of the parent ion is retained in both product anions. Four different coordination modes are observed for the seven copper centers, with unusual structural distortions imposed by the steric bulk of the polyanion. Intra- and intermolecular π-stacking of the 2,2′-bpy ligands are both evident. Variable temperature magnetic susceptibility, magnetization and EPR data are consistent with very weak antiferromagnetic interactions between the copper centers that are likely mediated by the π-stacking of the 2,2′-bpy ligands.

1. Introduction

Polyoxometalates (POMs) are an important class of inorganic compounds that exhibit a diverse compositional range and significant structural versatility [1]. One of the best known families of POMs are the heteropoly Keggin ions $[XM_{12}O_{40}]^{n-}$ (X = heteroatom, M = Mo and W). While a variety of main group or transition elements can act as heteroatoms in these species, the lone pair of electrons on elements such as arsenic(III) are stereoactive, preventing the formation of the closed plenary Keggin ions and instead giving rise to polyanions with more open structures, such as the trivacant lacunary Keggin ion $[\alpha\text{-}AsW_9O_{33}]^{9-}$ [2]. The exploration of these species as inorganic ligands for polynuclear complexes of other metals has afforded a number of new species. The reaction of other transition metals with $[\alpha\text{-}XW_9O_{33}]^{9-}$ (X = As(III), Sb(III) and Bi(III)) leads to polynuclear complexes with "sandwich" type structures, whereby two, three of four heterometals are "sandwiched" between two $[XW_9O_{33}]^{n-}$ POM ligands [3]. The POM $[\alpha\text{-}AsW_9O_{33}]^{9-}$ has also proved an excellent starting material for the synthesis of larger and more structurally elaborate polynuclear complexes of 3d or 4f metals including: $[K\subset\{Eu(H_2O)_2(AsW_9O_{33})\}_6]^{35-}$, $[Cs\subset\{Eu\text{-}(H_2O)_2(AsW_9O_{33})\}_4]^{23-}$, $[(CuCl)_6(AsW_9O_{33})_2]^{12-}$, $[Ce_4As_4W_{38}(H_2O)_{12}O_{136}]^{16-}$, $[Gd_6As_6W_{65}O_{229}(OH)_4(H_2O)_{12}(OAc)_2]^{38-}$ and $[Yb_{10}As_{10}W_{88}O_{308}(OH)_8(H_2O)_{28}(OAc)_4]^{40-}$ [4–7].

The functionalization of POMs with other transition metals or discrete coordination complexes is increasingly being pursued to enhance or modulate the physical properties of the POMs [8]. These species can alternatively be considered as metal complexes of inorganic POM ligands. In any case, the resulting hybrid species have considerable potential for applications as functional materials. To this end, several molecular copper complexes that feature different polyoxotungstates as inorganic ligands, in combination with the organic ligand 2,2′-bpy, have been reported: $[\{Cu(2,2'\text{-bpy})(H_2O)\}_2\{Cu(2,2'\text{-bpy})\}_2(\alpha\text{-}SbW_9O_{33})]^-$, $\{Cu(2,2'\text{-bpy})(H_2O)\}\{Cu(2,2'\text{-bpy})\}_3\{Cu(2,2'\text{-bpy})_2\}(\beta\text{-}GeW_8O_{31})]$, $[\{\{Cu(2,2'\text{-bpy})(H_2O)\}\{Cu(2,2'\text{-bpy})\}_4(\beta\text{-}GeW_9O_{34})\}_2]$ and $[\{Cu(2,2'\text{-bpy})\}_8(\beta\text{-}PW_8O_{31})2]^{2-}$ [9–11]. Similarly, the related ligand 1,10-phenathroline (phen) features in the molecular copper–tungstoarsenate(V) complex $[\{Cu\ (phen)\}_8(\beta\text{-}AsW_8O_{31})_2]^{2-}$, which has the same structure as $[\{Cu\text{-}(2,2'\text{-bpy})\}_8(\beta\text{-}PW_8O_{31})_2]^{2-}$ [12]. However, to the best of our knowledge there has been no report to date of any 3d metal complex incorporating both 2,2′-bpy and tungstoarsenate(III or V) ligands.

Herein we describe the synthesis, crystal structure and magnetic and EPR investigations of a compound comprised of the two new polynuclear complexes $[\{Cu(2,2'\text{-bpy})\}_3(\alpha\text{-}AsW_9O_{33})]^{3-}$ (**1a**) and $[\{Cu(2,2'\text{-bpy})_2\}\{Cu(2,2'\text{-bpy})\}_3(\alpha\text{-}AsW_9O_{33})]^-$ (**1b**) (Fig. 1) that co-crystallize as the acid form.

2. Experimental

2.1. Compound preparation

All manipulations were performed under aerobic conditions, using materials as received.

2.2.1. $H_4[\{Cu(2,2'\text{-}2,2'\text{-bpy})\}_3(AsW_9O_{33})] \cdot [\{Cu(2,2'\text{-bpy})_2\}\{Cu(2,2'\text{-bpy})\}_3(AsW_9O_{33})]$ (**1**)

Equimolar amounts of $Na_9[AsW_9O_{33}]$, $CuCl_2 \cdot 2H_2O$, and 2,2′-bpy (0.15 mmol of each) were added to a teflon-lined autoclave with 15 ml of 0.5 M NaOAc/AcOH buffer (pH 4.7). The mixture was heated at 438 K for 24 h and then cooled at a rate of 2 K h^{-1}. This afforded blue crystals that were suitable for single crystal X-ray diffraction and a sample for crystallography was maintained in contact with the mother liquor. The crystals were isolated by filtration, washed with cold distilled water and air dried to give a yield of *ca.* 40%. Some of the water molecules of crystallization are lost upon drying, with thermogravimetric analysis consistent with three H_2O molecules. *Anal.* Calc. for $H_4[\{Cu(2,2'\text{-bpy})\}_3(AsW_9O_{33})] \cdot [\{Cu(2,2'\text{-}2,2'\text{-bpy})_2\}\{Cu(2,2'\text{-}2,2'\text{-bpy})\}_3(AsW_9O_{33})] \cdot 3H_2O$ ($As_2C_{80}H_{74}N_{16}Cu_7O_{69}W_{18}$): W, 52.80; N, 3.58; H, 1.19; C, 16.33; Na, 0. Found: W, 49.30; N, 3.41; H, 1.53; C, 16.37; Na, 0.11%. IR. (KBr pellets, cm^{-1}): 1473(m), 1446(s), 1315(w), 1252(w), 1160(w), 1060(w), 1034(w) 1018(w), 942(vs), 885(vs), 774(vs), 729(m), 706(s), 484(w).

2.2. General and physical measurements

Infrared spectra (KBr disk) were recorded on a BioRad 175 FTIR spectrometer. Elemental analyses were performed at Chemical and Microanalytical Services, Belmont, Australia. Thermogravimetric analyses were performed on a Mettler Toledo thermal analyser. Variable temperature magnetic susceptibility and magnetization measurements were performed with a Quantum Design MPMS SQUID magnetometer equipped with a 5 T magnet. Three sets of DC magnetic susceptibility data were collected with magnetic fields of 0.01, 0.10 and 1.0 T. Pascal's constants were used to estimate the diamagnetic correction for the compound. EPR spectra were recorded on microcrystalline samples with a Bruker FT ECS-106 spectrometer.

2.3. X-ray crystallography

The intensity data of all compounds were collected on a Bruker CCD diffractometer using graphite monochromated Mo Kα radiation (λ = 0.71073 Å). Crystals were transferred directly from the mother liquor to a protective oil, which was used to prevent solvent loss. The structures were solved using direct methods and refined using a full-matrix least squares procedure based on F^2 using all data [13]. The crystallographic data are provided in Table 1.

3. Results and discussion

3.1. Syntheses

Compound **1** was obtained from the hydrothermal reaction of equimolar amounts of $Na_9[\alpha\text{-}AsW_9O_{33}]$ [2], $CuCl_2$ and 2,2′-bpy in sodium acetate buffer at 165 °C. Compound **1** could be obtained reproducibly in approximately 40% yield, based on 2,2′-bpy as the limiting reagent. Efforts to improve the yield by varying the reaction stoichiometry to better reflect the final composition of the compound were unsuccessful.

The use of the pre-formed lacunary POM $[\alpha\text{-}AsW_9O_{33}]^{9-}$ as a precursor for compound **1** is in stark contrast to the syntheses of related Cu-2,2′-bpy complexes of $[SbW_9O_{33}]^{9-}$, $[GeW_9O_{34}]^{10-}$, $[GeW_8O_{31}]^{10-}$ and $[PW_8O_{31}]^{9-}$ and the Cu-phen complex of $[AsW_8O_{31}]^{9-}$, all of which involve the hydrothermal reactions of Na_2WO_4, $CuCl_2$ and 2,2′-bpy or phen with Sb_2O_3, GeO_2, H_3PO_4 or Na_3AsO_4 [9–12]. Despite the hydrothermal conditions there is no evidence for any fragmentation or isomerization of the $[\alpha\text{-}AsW_9O_{33}]^{9-}$ starting material during the formation of compound **1**. Both fragmentation and isomerization to the β isomeric form have been observed previously during the formation of other large

complexes from reactions involving $[\alpha\text{-}AsW_9O_{33}]^{9-}$ performed at ambient temperature and pressure [6,7].

3.2. Description of structures

Single-crystal X-ray diffraction reveals that the asymmetric unit of compound **1** contains two different anionic complexes: **1a** (a trinuclear Cu complex) and **1b** (a tetranuclear Cu complex), together with water molecules. Molecules **1a** and **1b** are both derivatized $[\alpha\text{-}AsW_9O_{33}]^{9-}$ fragments. The POM fragments in each species are bound to three {Cu(2,2′-bpy)} units, with complex **1b** also incorporating a {Cu(2,2′-bpy)$_2$} unit. Selected interatomic distances associated with the coordination of the Cu centers are provided in Table 2. Two of the {Cu(2,2′-bpy)} units occupy lacunary sites of each of the POMs, with the Cu atoms bound through terminal O atoms that are terminal in the parent POM. These are Cu6 and Cu7 for **1a** and Cu3 and Cu4 for **1b**. The atoms Cu4 and Cu7 are bound to O atoms from the same edge-shared $\{W_3O_{13}\}$ triad in the POMs (Fig. 2a), while Cu3 and Cu6 are bound to O atoms from different edge-shared triads (Fig. 2b). It seems that the steric requirements of the 2,2′-bpy ligands prevent the binding of a third Cu center to the lacunary site of the trivacant POM, as the remaining {Cu(2,2′-bpy)} units coordinate to non-lacunary sites on the exterior of the POM, with Cu2 and Cu5 each binding to four bridging O atoms in **1a** and **1b**, respectively (Fig. 2c). These Cu centers bind at the interface between two edge-shared triads and are therefore each coordinated to two edge-sharing and two corner-sharing doubly bridging O atoms of the parent POM. A similar binding mode has been observed previously for two {Cu(2,2′-bpy)} units bound to $[\alpha\text{-}SbW_9O_{33}]^{9-}$ in the complex [{Cu(2,2′-bpy)(H$_2$O)}$_2${Cu(2,2′-bpy)}$_2$(α-SbW_9O_{33})] [9]. The [Cu(2,2′-bpy)$_2$]$^{2+}$ fragment in **1b** also binds to a non-lacunary site of the POM, coordinating to a terminal O atom in addition to a weak bond (2.68(2) Å) to an edge-sharing bridging O atom in the same triad (Fig. 2d). This arrangement of the Cu-2,2′-bpy fragments affords C_1 point symmetry for **1b**, while small structural distortions give rise to a deviation from ideal C_s point symmetry for **1a**.

Of the seven copper centers in compound **1**, four are four-coordinate with square planar geometries (Cu3, Cu4, Cu6 and Cu7), two are six-coordinate with distorted octahedral geometries (Cu2 and Cu5) and one is strictly five-coordinate with a long sixth Cu–O bond giving rise to an octahedrally distorted trigonal bipyramidal geometry (Cu1). Selected interatomic distances for the Cu centers are provided in Table 1. Bond valence sum calculations performed on the Cu atoms are consistent with seven divalent Cu ions [16]. The four four-coordinate Cu centers display coordination typical for square planar Cu^{II}, with Cu–O and Cu–N bond distances in the range 1.87–1.92 and 1.95–1.99 Å, respectively. The two distorted octahedral Cu centers each have N_2O_4 coordination spheres with Cu–N bond distances of 1.95–2.00 Å. Each of these centers has two Cu–O bonds of length 1.95–2.01 Å, *trans* to the Cu–N bonds. The remaining Cu–O bonds are longer, with bond distances of 2.27–2.41 Å. In addition, the *trans* O–Cu–O angles associated with these bonds are 127.1(8)° and 129.3(9)° for Cu5 and Cu2, respectively, whereas the *trans* O–Cu–N angles are in the range 172–175°. Thus this coordination geometry is best described as *cis*-distorted octahedral, with the distortion evidently due to the steric requirements of the bulky POM unit. The remaining copper center, Cu1, is strictly five-coordinate with an N_4O coordination sphere and distorted trigonal bipyramidal geometry. The atoms N2 and N4 occupy the axial sites of the trigonal bipyramid with Cu–N bond distances of 1.96(3) and 1.95(3) Å, while the atoms N1, N3 and O28 occupy the equatorial sites with Cu–N, Cu–N and Cu–O bond distances of 2.04(3), 2.14(3) and 2.07(3) Å, respectively. The O–Cu–N bond angles within the equatorial plane are 92(1)° and 147(1)°, while the N–Cu–N angle is 121(1). The atom O21 lies approximately on the equatorial plane and participates in a weak bond with Cu1 with a Cu···O separation of 2.68(2) Å. The Cu···O21 vector approximately bisects the Cu–N3 and Cu–O28 vectors, giving rise to the observed octahedral distortion to the trigonal bipyramidal coordination geometry of Cu1.

The 2,2′-bpy ligands of the copper ions that occupy the lacunary sites of the POM fragments participate in extensive intra- and intermolecular π-stacking interactions that extend along the crystallographic *a* direction (Fig. 3). These π–π interactions contract the intramolecular separation between these copper atoms to 4.36(1) and 4.45(1) Å for **1a** and **1b**, respectively. In addition intermolecular π–π interactions are also observed between pairs of 2,2′-bpy ligands coordinated to Cu1 and Cu2 centers from neighbouring molecules.

The absence of sodium cations in the X-ray structure and the very small percentage of sodium evident in the elemental analysis

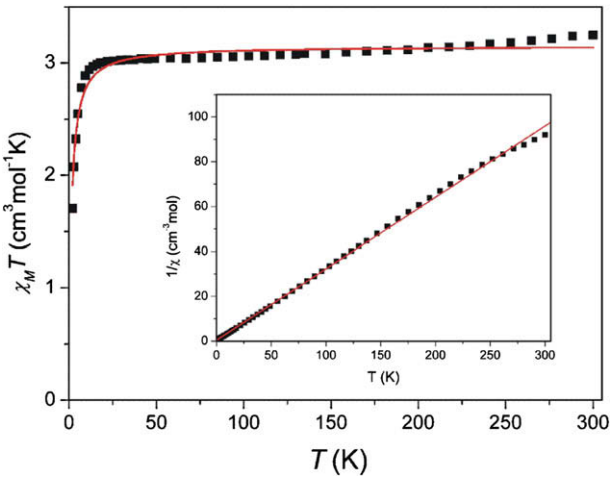

Fig. 4. Plot $\chi_M T$ vs. T for compound **1** obtained with a magnetic field of 1 T. The inset is a plot of $1/\chi_M$ vs. T and the solid line is the fit to the Curie–Weiss law as described in the text.

data imply the presence of four additional protons in compound **1a** to balance the charge of the anionic complexes. Bond valence sum calculations performed on the O atoms are consistent with all oxo rather than hydroxo ligands [14]. However, there is insufficient evidence to determine whether these acid protons are protonating the hydrate water molecules or the POM surface, with both of these protonation modes having been observed previously in POM chemistry [15].

3.3. Infrared spectroscopy

The infrared spectrum of compound **1** was recorded between 400 and 4000 cm^{-1} as a pressed KBr disk. Two regions are distinctive and useful for the identification of the compound. Four peaks that are characteristic of the 2,2′-bpy ligand are clearly evident at 1446(s), 1315(w), 1252(w) and 1160(w). These peaks have previously been employed to differentiate between the spectra of phosphotungstate POMS incorporating 2,2′-bpy and 4,4′-bpy complexes of Cu(II) [11]. In the region between 500 and 1000 cm^{-1} the peak at 942(vs) cm^{-1} can be assigned to the W=O stretching vibration and the peaks at 885(vs), 774(vs), 729(m) and 706(s) can be assigned to the different W–O–W and Cu–O–W and As–O–W stretching vibrations [17].

3.4. Magnetochemistry

Variable temperature magnetic susceptibility data were measured for compound **1** with magnetic fields of 0.01, 0.1 and 1 T and essentially superimposable data were obtained with the different fields (Fig. 4). The value of $\chi_M T$ decreases gradually from 3.25 to 3.01 cm^3 mol^{-1} K as the temperature is decreased from 300 to 20 K, before decreasing sharply to reach a value of 1.70 cm^3 mol^{-1} K at 2 K. The data between 2 and 300 K were fit to the Curie–Weiss law (inset of Fig. 4) to yield Curie and Weiss constants of 3.14 cm^3 mol^{-1} K and −1.3 K, respectively. This Curie constant is consistent with the value of 3.15 cm^3 mol^{-1} K calculated for seven non-interacting Cu^{II} ($S = 1/2$) ions with $g = 2.19$, which is within the range of $g = 2.1$–2.3 that is typical for Cu^{II} complexes [18]. This essentially Curie behavior indicates that the magnetic interactions between the Cu centers are minimal, with the small negative Weiss constant and the low temperature decrease in $\chi_M T$ consistent with very weak antiferromagnetic coupling. This is most likely intramolecular (Cu3···Cu4, Cu6···Cu7) and mediated by the π–π interactions between the 2,2′-bpy ligands in each complex [19].

The structurally related compound [{Cu(2,2′-bpy)$_2$-(H$_2$O)}$_2${Cu(2,2′-bpy)}$_2$(α-SbW$_9$O$_{33}$)]$^-$ also displays Curie–Weiss behavior in the temperature range 110–300 K [9]. Although a ferromagnetic Weiss constant is observed in this case, the origin of the apparent ferromagnetic coupling is not clear. In contrast, in the related compound [{{Cu(2,2′-bpy)(H$_2$O)}{Cu(2,2′-bpy)}$_4$(α-GeW$_9$O$_{34}$)}$_2$], a considerably stronger antiferromagnetic coupling is observed ($2J = -34.2$ cm^{-1}), which is due to the presence of μ$_3$–O bridge between two CuO$_3$N$_2$ moieties and a tungsten center [10].

Low temperature magnetization data were collected between 2 and 10 K for compound **1**. Although these data do not appear to show saturation behavior at fields up to 5 T, the magnetization at 2.0 K and 5.0 T is 6.5 BM, which is consistent with seven Cu(II) centers in compound **1**.

3.5. EPR spectroscopy

X-band EPR spectra were measured on a microcrystalline sample of compound **1** at 110 and 298 K. The room temperature spectrum features a single broad isotropic signal with an effective g value of 2.13. This g value is consistent with the value obtained from fitting the variable temperature magnetic susceptibility data. At 110 K the EPR spectrum appears to display some axial character suggestive of $g_{||} > g_{\perp}$, although a clearly defined peak associated with $g_{||}$ is not observed. This may reflect the origin of the spectrum as an average of the signals due to the seven different Cu centers in compound **1**, which includes four centers with square planar coordination geometry, two centers with *cis*-distorted octahedral geometry and one center with octahedrally distorted trigonal bipyramidal coordination (Fig. 2). Thus only limited information can be extracted from these data. These X-band EPR spectra do not provide any information about any magnetic exchange interactions between the Cu(II) centers and Q-band EPR spectroscopy would be required to probe this aspect in order to detect $\Delta M_s = 1$ and $\Delta M_s = 2$ lines arising from neighbouring Cu(II) centers [20].

4. Conclusions

In summary, an initial exploration of the potential of [α-AsW$_9$O$_{33}$]$^{9-}$ as a precursor for the hydrothermal synthesis of new POM-ligated copper complexes has afforded the first two copper complexes of tungstoarsenate and 2,2′-bpy ligands. Four different

Cu coordination geometries are observed including unusual *cis*-distorted octahedral and octahedrally distorted trigonal bipyramidal geometries, where the distortions are imposed by the steric requirements of the POM. Intra- and intermolecular π-stacking interactions between the 2,2′-bpy ligands of the Cu centers that occupy the lacunary POM sites extend along the crystallographic *a* direction. Magnetic studies indicate very weak antiferromagnetic interactions between the Cu centers that are likely mediated by these π−π interactions.

ABSTRACT

A nonmagnetic compound, $[NO_2BzPy][Cu(mnt)_2]$ (mnt^{2-} = maleonitriledithiolate; NO_2BzPy^+ = 1-(4′-nitrobenzyl)pyridinium), is isostructural with $[NO_2BzPy][Ni(mnt)_2]$, which is a quasi-1D spin system and exhibits a spin-Peierls-like transition with J = 192 K in the gapless state and spin energy gap = 738 K in the dimerization state, respectively. Further, five nonmagnetic impurity doped compounds $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0.04–0.74) were prepared, and their crystal structures as well as magnetic properties were investigated. The nonmagnetic doping causes the suppression of the spin transition with an average rate of 139(13) K/percentage of dopant concentration, and the transition collapse is estimated at around $x > 0.5$.

1. Introduction

Impurity doping of a low-dimensional magnetic system often results in non-intuitive ground states and transition behavior differing from that of the parent material [1–7]. Lots of investigations for doping magnetic impurity with different spins have been done theoretically and experimentally for the low-dimensional inorganic magnetic systems since the first inorganic spin-Peierls compound $CuGeO_3$ was discovered [1–8]. In contrast, the examples of an impurity doping on the low-dimensional molecular magnetic system are very rare [9–12] even if the molecular spin-Peierls transition compounds have been known much earlier than the inorganic one [13–15]. One of crucial reasons to cause the above-mentioned situation is that the molecular structure is usually so complicated that it is not easy to find a suitable dopant that match with the parent material in both molecular structure and valence. In our previous study, we observed a peculiar spin-Peierls-like transition in 1-(4′-nitrobenzyl)pyridinium bis(maleonitriledithiolato)nickelate (Scheme 1 and abbreviated as $[NO_2BzPy][Ni(mnt)_2]$) [12]. This compound possesses columnar stacks along c-axis with cations and anions segregated, and the regular anionic stack can be considered as a uniform magnetic chain with $S = 1/2$ since the $[Ni(mnt)_2]^-$ monoanion bears a half spin. The magnetic exchange nature is antiferromagnetic (AFM) above transition temperature, while below that a spin gap is opened with the spin chain dimerization [16]. Instead of $[Ni(mnt)_2]^-$ monoanion with nonmagnetic $[Au(mnt)_2]^-$ monoanion, the compound of $[NO_2BzPy][Au(mnt)_2]$, which is isostructural with $[NO_2BzPy][Ni(mnt)_2]$, was obtained, and the effect of nonmagnetic $[NO_2BzPy][Au(mnt)_2]$ doping in the lattice of $[NO_2BzPy][Ni(mnt)_2]$ on the spin-Peierls-type transition was further investigated [17]. The doped systems $[NO_2BzPy][Au_xNi_{1-x}(mnt)_2]$ exhibit that: (1) within an anionic stack, $[Au(mnt)_2]^-$ substituting $[Ni(mnt)_2]^-$ does not change the crystal structure of $[Ni(mnt)_2]^-$ compound, moreover, the $[Ni(mnt)_2]^-$ and $[Au(mnt)_2]^-$ anions could not be distinguished from the single-crystal structure temperatures above 10 K; (2) even though an anionic stack exhibits a disordered structural feature, the magnetic behavior does not show a random spin system characteristic in the heavier doped system ($x \geqslant 0.49$), additionally, the fits for temperature dependence of magnetic susceptibility indicated the presence of stronger AFM coupling interaction between the $[Ni(mnt)_2]^-$ anions which are separated by the nonmagnetic $[Au(mnt)_2]^-$ species; (3) the transition is suppressed by nonmagnetic doping and collapsed at around $x > 0.27$, and in a heavier doped system with $x = 0.49$, the spin gap vanishes and a gapless phase is achieved again, and this magnetic behavior resembles to the phenomena observed in inorganic spin-Peierls transition systems such as $CuGO_3$ [1–3] and $TlCuCl_3$ [4], however, the transition collapses when x value is much higher than those found in the inorganic spin-Peierls transition systems and (4) single-crystal EPR measurements and theoretical analysis for the

sample of $[NO_2BzPy][Au_{0.57}Ni_{0.43}(mnt)_2]$ disclosed the existence of intermolecular charge transfer between the adjacent $[Ni(mnt)_2]^-$ and $[Au(mnt)_2]^-$ species in an anionic stack [18].

It is well known that the structural feature of a nonmagnetic dopant strongly influence the magnetic transition behavior in a spin-Peierls system, this very important theme forms the background of the present work. The nonmagnetic compound $[NO_2BzPy][Cu(mnt)_2]$ is isostructural with the nonmagnetic compound $[NO_2BzPy][Au(mnt)_2]$ as well as the spin-Peierls-like transition compound $[NO_2BzPy][Ni(mnt)_2]$, compared with $[NO_2BzPy][Au(mnt)_2]$, the molecular geometric parameters in $[Cu(mnt)_2]^-$ species are much closer to those in $[Ni(mnt)_2]^-$ anion than $[Au(mnt)_2]^-$ species (the averaged M–S distances: d_{Au-S} = 2.3085, d_{Cu-S} = 2.1886 and d_{Ni-S} = 2.1466 Å; and the averaged ∠S—M—S bite angles: ∠S—Au—S = 90.50°, ∠S—Cu—S = 92.37° and ∠S—Ni—S = 92.44° in above-mentioned three compounds). In this contribution, we further investigate the crystal structures and magnetic properties of a series of compounds with a formula $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0–1 and it represents the molar fraction of Cu in a doped system).

2. Experimental

2.1. Preparation of compounds

$[NO_2BzPy][Ni(mnt)_2]$ and $[NO_2BzPy]_2[Cu(mnt)_2]$ were prepared according to the published procedures [16,19].

$[NO_2BzPy][Cu(mnt)_2]$: The compound $[NO_2BzPy]_2[Cu(mnt)_2]$ was oxidized by 0.75 equivalent of I_2 to afford $[NO_2BzPy][Cu(mnt)_2]$ (yield: ~72%). Single crystals suitable for X-ray structural analysis were obtained by diffusing diethyl ether into an acetonitrile solution of $[NO_2BzPy][Cu(mnt)_2]$. Elemental *Anal.* Calc. for $C_{20}H_{11}N_6O_2S_4Cu$: C, 43.0; H, 1.98; N, 15.0%. Found: C, 42.8; H, 2.04; N, 14.9%.

$[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$: Each doped compound was prepared according to the procedure employed in the literature [17], and the product is needle- or block-shaped crystals which are suitable for X-ray structural analysis. The molar ratio of $[NO_2BzPy][Ni(mnt)_2]$ to $[NO_2BzPy][Cu(mnt)_2]$ in the starting materials and the results of elemental analyses for C, H and N for $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0.04–0.74) are presented in Table 1.

2.2. Physical measurements

Elemental analyses were performed with a Perkin–Elmer 240 analytical instrument. IR spectra were recorded on Bruker Vector 22 spectrophotometer (KBr disc). The molar ratio of Ni-to-Cu for each alloy compound was determined by inductively coupled plasma-atomic emission spectrometer (ICP-AES, Atomscan Advantage, USA). Magnetic susceptibility measurement over the range of 2–350 K for each polycrystalline sample was carried out using a Quantum Design MPMS-XL superconducting quantum interference device (SQUID) magnetometer under 1.0 T.

2.3. X-ray structural analyses

Crystallographic data were collected using a Rigaku Raxis-Rapid diffractometer with Mo Kα (λ = 0.71073 Å) radiation from a graphite monochromator. Structures were solved by direct method using the SHELXL-97 software package [20]. The non-hydrogen atoms were refined anisotropically using the full-matrix least-squares method on F^2. It is similar to the $[NO_2BzPy]$-$[Au_xNi$

$_{1-x}$(mnt)$_2$] compounds that the [Cu(mnt)$_2$]$^-$ anions distribute randomly in the [Ni(mnt)$_2$]$^-$ stack for all doped crystals of [NO$_2$BzPy][Cu$_x$Ni$_{1-x}$(mnt)$_2$] at 293 K, and the occupancy factors of Cu and Ni atoms for each doped sample were defined by ICP measurement. All hydrogen atoms were placed at calculated positions (C–H = 0.930 Å for benzene or pyridine rings and 0.970 Å for methylene) and refined riding on the parent atoms with U(H) = 1.2 × U_{eq} (bonded C atom). Details of the lattice parameters, data collections, and refinements for [NO$_2$BzPy][Cu$_x$Ni$_{1-x}$(mnt)$_2$] (x = 0.04–1) at 293 K are summarized in Table 2.

3. Results and discussion

3.1. Description of crystal structures

Crystal structure of [NO$_2$BzPy][Cu(mnt)$_2$] at 293 K: This compound crystallizes in monoclinic space group *P2(1)/c*, and it is isostructural with the compounds [NO$_2$BzPy][Ni(mnt)$_2$] and [NO$_2$BzPy][Au(mnt)$_2$]. The asymmetric unit in a cell is comprised of a coupled of [Cu(mnt)$_2$]$^-$ and NO$_2$BzPy$^+$. The [Cu(mnt)$_2$]$^-$ anion possesses roughly a planar geometry (Fig. 1a), and the Cu–S lengths range from 2.1844(8) to 2.1982(8) Å, these values are close to the Ni–S lengths [2.1409(7)–2.1565(6) Å] in [NO$_2$BzPy][Ni(mnt)$_2$], and shorter than the Au–S lengths [2.303(2)–2.3153(19) Å] in [NO$_2$BzPy][Au(mnt)$_2$]. The S–Cu–S bite angles of 92.08(3)° and 92.66(3)° are also close to the S–Ni–S values

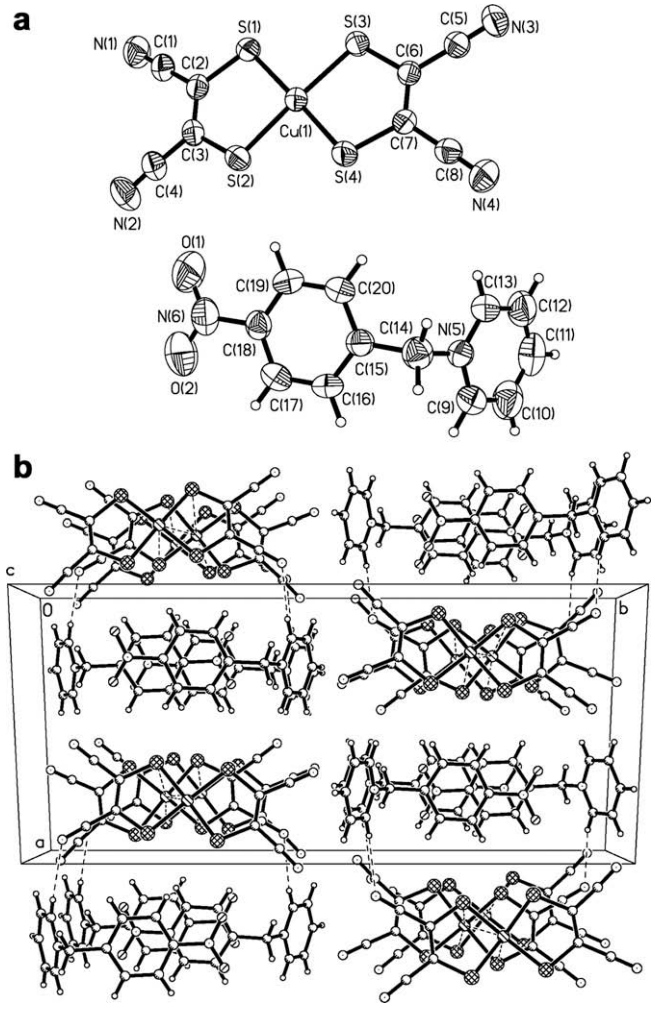

Fig. 1. (a) ORTEP view with displacement ellipsoids at 50% possibility level and (b) packing diagram of [NO$_2$BzPy][Cu(mnt)$_2$] projected along *c*-axis.

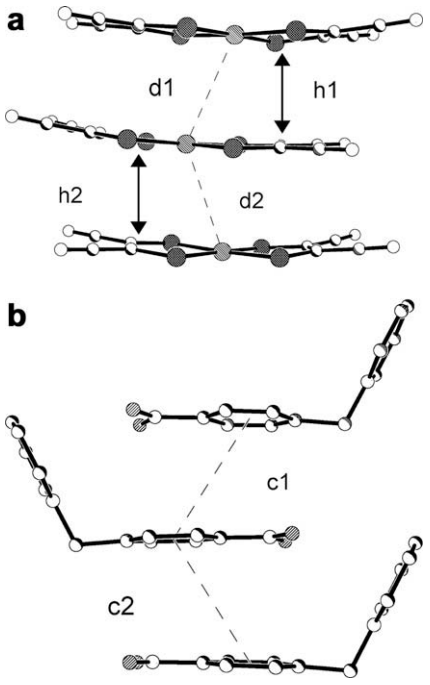

Fig. 2. (a) Distances of M···M (d_1 and d_2) and interplane between neighboring anions (h_1 and h_2) and (b) central-to-central distance between adjacent benzene rings (c_1 and c_2).

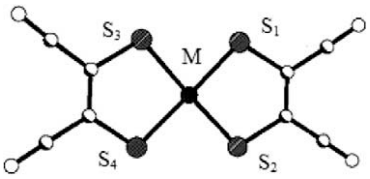
[92.32(3)° and 92.56(3)°] in [NO$_2$BzPy][Ni(mnt)$_2$]. The molecular conformation of [NO$_2$BzPy]$^+$ cation in [Cu(mnt)$_2$]$^-$ compound resembles to that in [Ni(mnt)$_2$]$^-$ compound. For example, the dihedral angles of pyridine ring and benzene ring with the reference plane C$_{Ar}$–CH$_2$–N$_{Py}$ are 88.3° and 64.8° in [Cu(mnt)$_2$]$^-$ compound versus 86.9° and 65.2° in [Ni(mnt)$_2$]$^-$ compound, respectively. The pyridine and benzene rings makes a dihedral angle of 90.2° in [NO$_2$BzPy][Cu(mnt)$_2$] and 95.0° in [NO$_2$BzPy][Ni(mnt)$_2$].



Both anions and cations form, respectively, the segregated stacks that run parallel to *c*-axis (Fig. 1b). Within anionic stacks, the face-to-face anions slid along *b*-axis and eclipse each other. The interplane distances between the adjacent [Cu(mnt)$_2$]$^-$ anions, which is defined by four coordinated S atoms, are h_1 = 3.507 and h_2 = 3.493 Å (Fig. 2a), while the adjacent Cu···Cu distances are exactly identical with d_1 = d_2 = 3.895 Å. The cationic stack is also regular with a uniform central-to-central distance of 4.280 Å between neighboring benzene rings (cf. Fig. 2b).

Crystal structures of [NO$_2$BzPy][Cu$_x$Ni$_{1-x}$(mnt)$_2$] (x = 0.04–0.74) at 293 K: As shown in Table 2, each compound with formula [NO$_2$BzPy][Cu$_x$Ni$_{1-x}$(mnt)$_2$] (x = 0.04–0.74) is isostructural to the parent compounds with very similar lattice parameters. The M–S lengths and S–M–S bite angles along with their estimated standard deviations are presented in Table 3. With the doping concentration x increases, the distances of M···M, M···S, S···S and interplanar distances between the nearest neighbors (h_1, h_2 refer to Fig. 2a) within an anionic stack change gradually and monotonically (cf. Fig. 3), and this characteristic of structural variation is distinct from the [NO$_2$BzPy][Au$_x$Ni$_{1-x}$(mnt)$_2$] systems.

3.2. Magnetic susceptibilities

The magnetic behavior of each [NO$_2$BzPy][Cu$_x$Ni$_{1-x}$(mnt)$_2$] (x = 0–1) was determined on its polycrystalline sample from 2 to 350 K. These compounds are isostructural with each other. Therefore, it is reasonable to suppose that the diamagnetism for each compound of [NO$_2$BzPy][Cu$_x$Ni$_{1-x}$(mnt)$_2$] is equal roughly to the magnetic susceptibility of [NO$_2$BzPy][Cu(mnt)$_2$]. The corrected

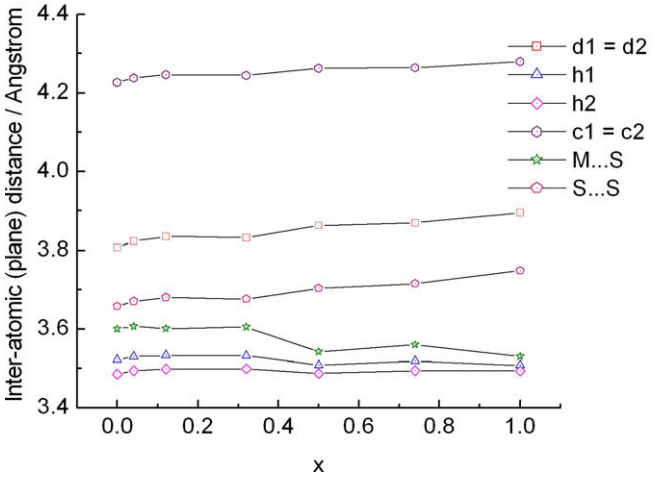

Fig. 3. Variations of interatomic and interplane distances between neighboring anions in a stack (h_1 and h_2; see Fig. 2) as x for $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0–0.74) at 293 K and $[NO_2BzPy][Ni(mnt)_2]$ at 273 K [16].

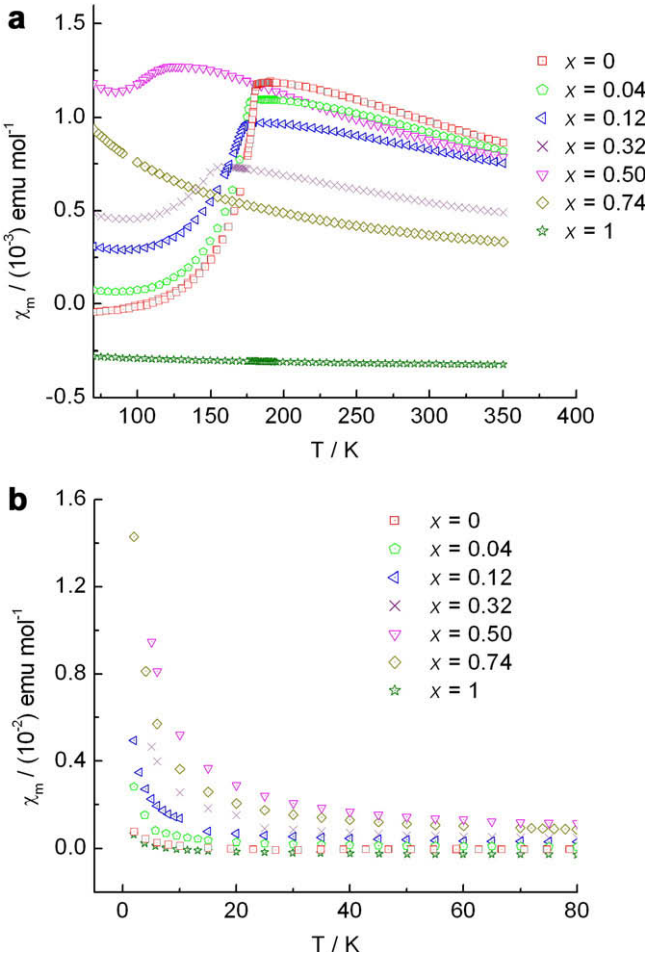

Fig. 4. Plots of $\chi_m(T)$ versus T for $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0–1) in the temperature range of (a) 70–350 K and (b) 2–80 K.

molar paramagnetic susceptibilities of $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0–0.74) as well as the nonmagnetic compound of $[NO_2BzPy][Cu(mnt)_2]$ are given in Fig. 4 as $\chi_m = f(T)$, from which it can be found that the nonmagnetic compound of $[NO_2BzPy][Cu(mnt)_2]$ clearly shows diamagnetism behavior (with negative magnetic susceptibilities).

For the parent compound of $[NO_2BzPy][Ni(mnt)_2]$ (x = 0), as reported in our previous work [16], a magnetic transition occurs around 181 K, and the phenomenology of the magnetic transition closely resembles that of a spin-Peierls transition. The spin gap with the value of 738 K in dimerized state was estimated from the fits of the magnetic susceptibility data in low temperature phase, and the magnetic exchange interaction with J/k_B = 192(3) K [17] in high temperature phase was evaluated from the analysis for magnetic susceptibility data utilizing a regular antiferromagnetic Heisenberg model for a S = ½ linear chain system [21].

As displayed in Fig. 4a and b, the nonmagnetic doping causes (1) the molar magnetic susceptibility decreasing with x value increase when x < 0.5; (2) an onset of a strong paramagnetic background in the low temperature region and (3) a damping of the spin transition. These behaviors are similar to the doped systems of $[NO_2BzPy][Au_xNi_{1-x}(mnt)_2]$ [17]. It is understandable that the nonmagnetic doping induces the strong paramagnetic background in the low temperature region for the doped sample since the antiferromagnetic spin chains of $[Ni(mnt)_2]^-$ are broken at the position of nonmagnetic dopants $[Cu(mnt)_2]^-$, moreover, the spin number in a chain should be randomly even and odd in equal probability. Therefore, the spin at the end of any odd numbered spin chain becomes uncoupled, giving a contribution to the paramagnetic susceptibility, and this contribution is dominant especially for heavily doped systems. In the doped system at x = 0.5, the broad maximum of magnetic susceptibility appears in the χ_m–T plot which is a typical characteristic of a lowered dimensionality of spin system due to the existence of short-range ordering. It is

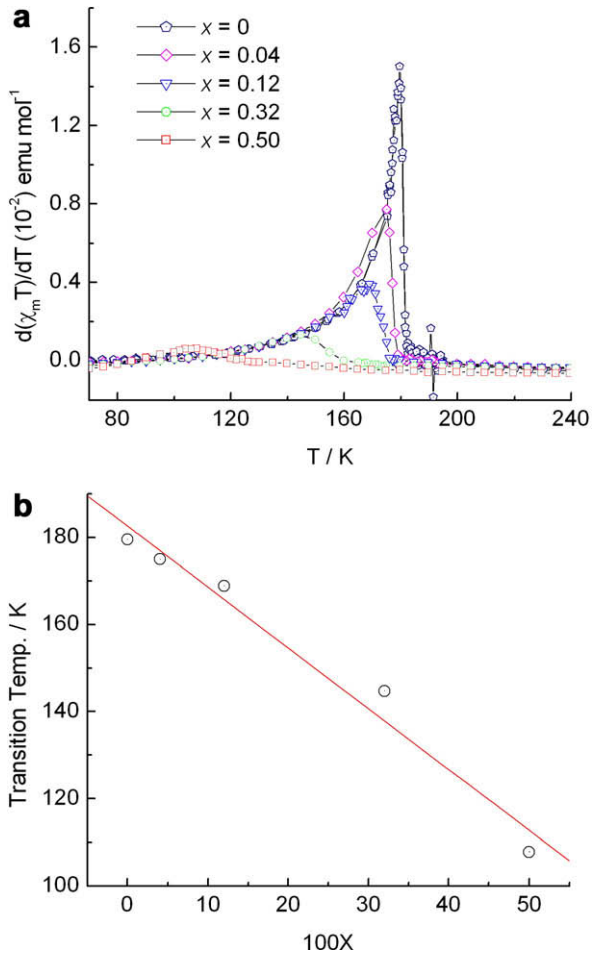

Fig. 5. (a) Plots of $d(\chi_m T)/dT$ versus T for $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0–0.5) and (b) the x dependences of T_C.

noteworthy that the transition is still observed with the χ_m value clear dropping in the χ_m–T plot even if the change is small. In the heavily doped system of x = 0.74, the shape of $\chi_m(T)$–T plot is totally different from other doped systems, in which the typical characteristic of a lowered dimensionality of spin system (with a broad maximum of magnetic susceptibility) and the magnetic transition disappear, and the temperature dependences of magnetic susceptibility exhibits a simple Curie–Weiss behavior. Fig. 5a depicts the derivative curves of $\chi_m T$ versus T for $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0–0.5) and Fig. 5b plots the corresponding x dependences of T_C, which is defined as the peak temperature in the $d(\chi_m T)/dT$–T plot. The values of $T_C(x)$ reduce linearly up to $x \leqslant 0.5$, and it is expressed as $T_C = 182(3)–139(13)x$ (K). Compared with the $[NO_2BzPy][Au_xNi_{1-x}(mnt)_2]$ system, where $T_C = 180(2)–221(12)x$ (K), the $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ system exhibits higher x value of the transition collapsing and smaller x dependence of T_C shift.

4. Conclusion

Summarily, we synthesized and characterized structurally five nonmagnetic doped compounds with a formula $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0.04–0.74), and investigated the nonmagnetic impurities effects on the spin-Peierls-like transition in a quasi-1D spin system of $[NO_2BzPy][Ni(mnt)_2]$. The nonmagnetic impurities suppress the spin-Peierls-like transition, and the transition temperature T_C reduces at an average rate of 139(13) K/percentage of nonmagnetic dopant. The transition collapse is estimated around $x > 0.5$. Compared with the $[NO_2BzPy][Au_xNi_{1-x}(mnt)_2]$ system, the $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ system shows higher x values of the transition collapsing and smaller x dependence of T_C shift, and these differences may be originate from the molecular structure distinction between $[Cu(mnt)_2]^-$ and $[Au(mnt)_2]^-$ anions, for example, the average Au–S length is around 0.15 Å longer than the average Ni–S length whereas the average Cu–S length is similar to the Ni–S distance.

Supplementary data

CCDC 705212–705217 contain the supplementary crystallographic data for each compound of $[NO_2BzPy][Cu_xNi_{1-x}(mnt)_2]$ (x = 0.04–1). These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Crystal orbital

ABSTRACT

Practical two-dimensional high-spin organic polymers are newly designed and the electronic structures are examined on the basis of the ab initio two-dimensional unrestricted Hartree–Fock crystal orbital (UHF-CO) method. The present polymers can be oxidized up to six electrons per unit cell, and it is predicted that the three-electron and six-electron oxidations per unit cell lead to the high-spin organic polymers having superdegenerate band structures originating from the characteristic non-bonding crystal orbital patterns.

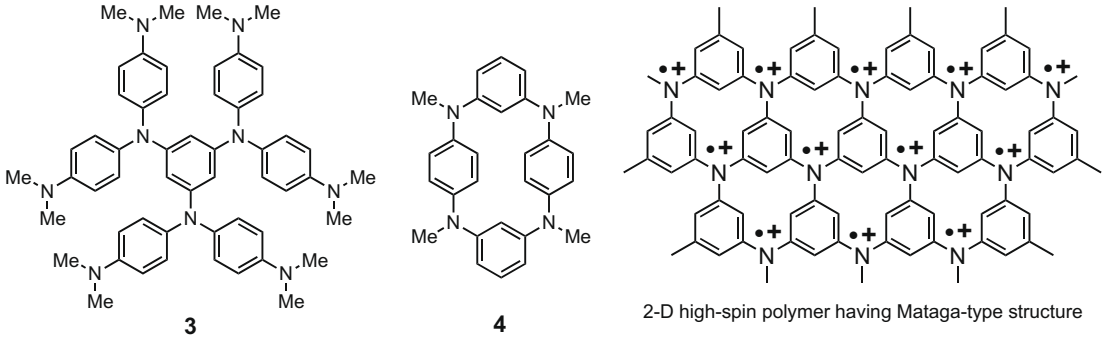
1. Introduction

Polymer-based organic ferromagnets have been attracting much attention since Mataga's proposal [1]. This is firstly because the design of such polymers is conceptually straightforward and secondly because magnetic interaction through covalent intramolecular pathway can be expected to be strong compared with that through intermolecular pathway in the known crystalline ferromagnets composed of stable radical molecules [2].

In the polymer-based approach, the entire polymer can be constructed from two units: (i) a spin-containing (SC) unit and (ii) a ferromagnetic coupling (FC) unit [3]. The concept of FC unit is equivalent to appropriate choice of spacer connecting between SC units. To date, 1,3-benzenediyl and/or 1,3,5-benzenetriyl are well-known FC units. When two SC units are connected by 1,3-benzenediyl, the resulting diradical has inevitably two nearly degenerate non-bonding molecular orbitals (NBMOs) (for example, *m*-benzoquinodimethane). These NBMOs distribute over common atoms and therefore strong exchange interactions are expected to occur between two radical spins, leading to a high-spin preference [4]. This mechanism is closely related to the Hund's rule in atomic physics. Employing several kinds of SC units, a lot of polymers and their oligomer model molecules have been investigated along this line [5,6]. However, authentic preparation of organic polymer-based ferromagnets still remains questionable [7].



On the other hand, over the past 40 years, a considerable number of theoretical studies have been made on several organic high-spin model polymers. On the analogy of the NBMOs in high-spin molecules, the concept of "superdegeneracy" has been introduced into the half-filled bands for possible ferromagnetic polymers [8,9]. Furthermore the elaborate density functional studies have been performed to give more reliable information on the electronic structures of ferromagnetic one-dimensional (1-D) polymers and dendrimers [10].

As is well-known as Mermin and Wagner's theorem, in 1-D spin systems [11], the magnetic long range order cannot be accomplished at finite temperature. Moreover, for practical application of the 1-D magnetic polymer, generation of the spinless sites due to incomplete oxidation or decomposition leads to disappearance of high-spin correlation. Hence, 2-D or 3-D spin network is indispensable to the realization of defect-tolerant high-spin polymers [2].

Recently, we have investigated the polycationic states of a series of oligoarylamines in order to prepare two-dimensional (2-D) high-spin polymers [12–17]. These stable polycationic species are found to be in their high-spin ground states, probably due to the combination of the strong FC unit (1,3,5-benzenetriyl and 1,3-benzenediyl) and the robust SC unit (semiquinone radical cation of *para*-phenylenediamine). For example, the trication of the dendritic oligoarylamine **3** has quartet ground state [13], and the dication of the macrocyclic oligoarylamine **4** has triplet ground state [14]. When we design the arylamine-based 2-D high-spin polymers, the Mataga-type polymer is inappropriate for the candidate (Scheme 1). This is because such a molecular structure does not allow the planar 2-D structure due to the sterically overcrowded molecular structure. On the other hand, polymers **1** and **2** having *meta*- and *para*-phenylene linkage make it possible to maintain planar 2-D structure (Fig. 1). Polymers **1** and **2** contain six and nine nitrogen atoms per unit cell, respectively. Hence, three-electron oxidation per unit cell of **1** leads to complete generation of semiquinone radical cation (hereafter we denote this cationic state as

Scheme 1.

1[3+]). Likely, six-electron oxidation per unit cell of **2** leads to complete generation of semiquinone radical cation (**2**[6+]). These charged polymers are of great importance for realization of the planar 2-D high-spin organic polymers. In particular, the realization of the high-spin organic polymers with the layered structures such as **1** and **2** opens the possibility of the control of their spin states by facilitating the reversible and partial inclusion and/or exclusion of the counter ions like the graphite intercalation compounds.

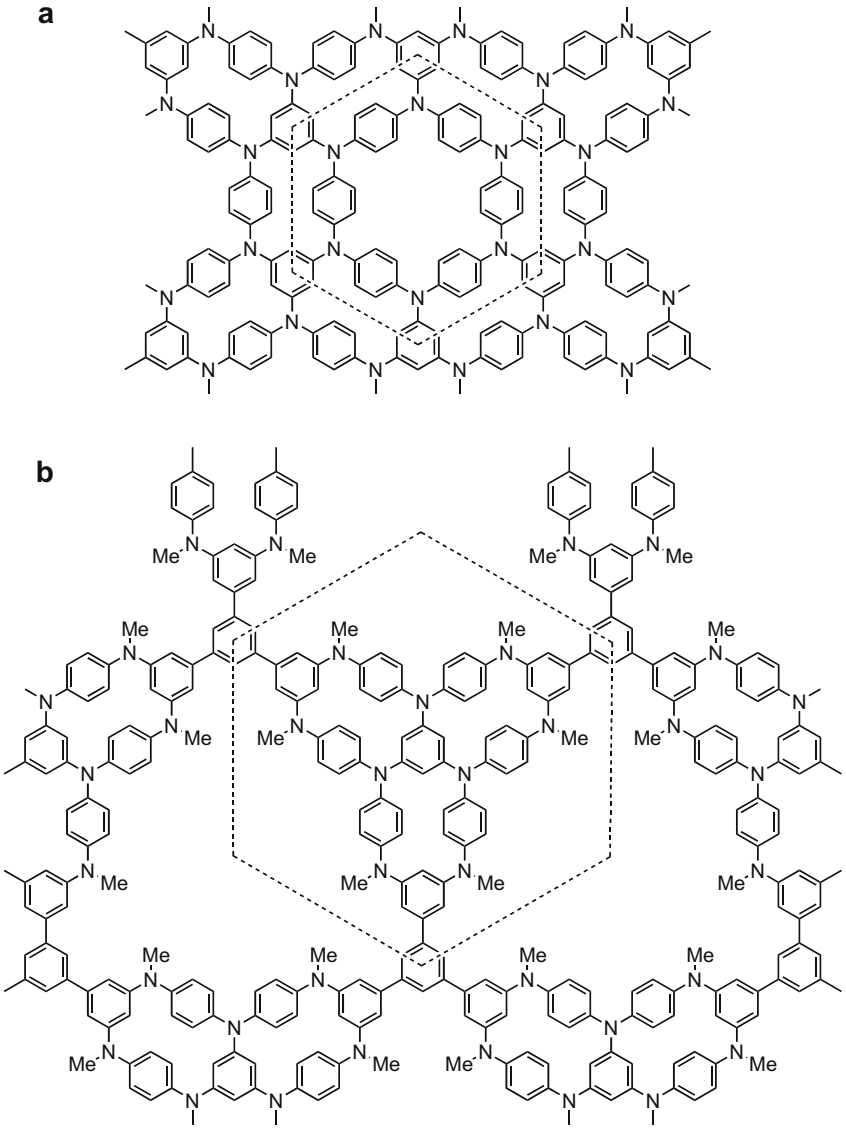

Fig. 1. Arylamine-based 2-D polymers: (a) **1** and (b) **2**. The unit cells are enclosed by broken lines.

Hence, it is worth while examining the spin electronic structures of these oxidized polymers prior to the future synthetic chemical studies.

In this paper, the newly designed 2-D magnetic polymer composed of 1,3,5-benzenetriamines as FC units and of *para*-phenylenediamines as SC units are examined on the basis of the ab initio 2-D unrestricted Hartree–Fock crystal orbital (UHF-CO) method. The aim of this study is to predict the spin electronic structures of the oxidized 2-D polymers **1**[3+], **1**[6+], **2**[3+] and **2**[6+].

2. Method of calculation

All the calculations of the novel 2-D polymers were carried out on the basis of ab initio UHF-CO method implemented in CRYSTAL98 package [18]. The 6-21G basis sets were utilized in this study [19]. To check the basis set dependency, we have performed UHF-CO calculations employing 3-21G, 4-31G and 6-31G* basis sets [19]. As a result, tendency of energy band structures remains unchanged except for the total energies.

The 2-D polymers, **1** and **2**, are classified by the layer groups belonging to a subset of the 230 space groups: $P\bar{3}1m$ for **1** and $P312$ for **2**. The unit cells for **1** and **2** correspond to the enclosed areas in Fig. 1a and b. Prior to the UHF-CO calculations, we determined the unit cell geometry by the geometry optimizations of the model clusters (Fig. 2) on the basis of the semi-empirical molecular orbital method (AM1 [20]). Several X-ray crystal structures of the arylamine molecules relating to the present molecular structure in the unit cell have been already reported [14,21–23]. The essential features from these X-ray studies are as follows: (i) all the nitrogen atoms lie in a plane and (ii) the 1,3,5-benzenetriyl rings are in the plane defined by the nitrogen atoms, while the *para*-phenylene rings are significantly canted out of the plane. The cant angle depends on the molecules studied and ranges from 40° to 80°. However, the cant angles from the reported tetraazacyclophane molecules are within 40–60°, [14,22] which are in good accordance with the values (59.0° for **1** and 47.2° for **2**) of the AM1-geometries. In the geometry optimization process, no restriction on the cant angle of *para*-phenylene rings was imposed. However, 1,3,5-benzenetriyl rings were assumed to retain coplanarity with the plane defined by the nitrogen atoms. As a result, the global planarity of the present polymers can be guaranteed by the fact that all the nitrogen atoms lie in a plane, whereas the local planarity is not guaranteed owing to canting of *para*-phenylene rings. Furthermore, the other geometrical parameters were in reasonable agreement with those of the reported X-ray structures.

Finally we performed the ab initio UHF-CO calculations for the neutral and charged states of the polymers **1** and **2** employing the above-mentioned optimized unit cells. The charged unit cell for the charged polymers must be compensated by the counter ions. In the present calculations, a uniform background charge was imposed to neutralize the charge in the unit cell [18]. Note that the same unit cell geometries were used for both the neutral and cationic states. This is because the 2-D networked structures are too rigid to be easily deformed. Actually, the DFT calculations on the tetraazacyclophane molecule demonstrated that the backbone structure in the neutral state remains unchanged even in the higher charged state [14]. Therefore, the present calculations can give qualitatively reliable results for the spin electronic structures of the polymers **1** and **2**.

3. Results and discussion

The geometries for the unit cells studied here are shown in Fig. 2. The bond lengths and angles take reasonable values in comparison with the reported X-ray structures of the related arylamine molecules [14,21–23]. The cant angles of the *para*-phenylene units in **1** and **2** are calculated to be 59.0° and 47.2°, respectively, and therefore, the π-conjugation between the 1,3,5-benzenetriyl and *para*-phenylene rings is expected to become weak compared to the hypothetical planar structures of **1** and **2** (Fig. 1).

The calculated total energies per unit cell are listed in Table 1. Apparently, the high-spin states are energetically more stable than the low-spin states for the cationic forms of **1** and **2** generated by three-electron and six-electron oxidations per unit cell. Herein it should be noted that, in the **2**[6+], all the nitrogen atoms are oxidized. In this case, it is natural that the quinoid deformation takes place and leads to diamagnetic polymers. However, this kind of deformation in the 2-D polymers is anticipated to need considerable energy compared to that in the oligomers. Therefore when the polymer **2** can be fully oxidized, **2**[6+] is highly expected to become a high-spin polymer.

The high-spin preference for the cationic states of **1** and **2** can be explained by the band structures (Fig. 3). In **1**[3+], the α-spin highest occupied crystal orbital (HOCO) bands (178–180) are less than 0.25 eV in width (Fig. 3a). These flat bands give the physical origin for the high-spin preference. On the other hand, the corre-

1	neutral	−2135.280	–	–
	+3	−2135.132	−2135.020	3.1
	+6	−2135.370	−2134.936	11.8
2	neutral	−3209.923	–	–
	+3	−3209.940	−3209.803	3.7
	+6	−3209.823	−3209.104	19.6

[a] Energy differences (in eV) between the high-spin and low-spin states. The positive value means the high-spin preference.

sponding frontier β-spin bands are broader than the α-spin bands. The broadness of the β-spin bands stems from two reasons. First, the all-*para*-phenylene linkage exists in the polymer backbone, as is apparent from the unit cell structure in Fig. 1a. Second, **1**[3+] is of partially oxidized form. Turning now to the fully oxidized **1**[6+], the α-spin HOCO bands (175–180) are less than 0.06 eV in width, and moreover, the corresponding β-spin bands are also flat, originating from the fully oxidized form (Fig. 3c). The bands become so flat that the magnetic spins will be localized considerably. Again, these narrow bands give the physical origin for the high-spin preference for **1**[6+]. More noteworthy is that the partially oxidized **2**[3+] has completely flat band structures, as shown in Fig. 3b. This contrast between **1**[3+] and **2**[3+] is explainable by inspection of the CO patterns. As shown in Fig. 4a, the α-spin HOCOs (178–180) for **1**[3+] at the Γ point are delocalized over the entire polymer backbone, whereas the α-spin HOCOs (274–276) for **2**[3+] at the Γ point are mainly localized on the triphenylbenzene rings (Fig. 4b). Consequently, the highly localized HOCOs result in the flat bands even in **2**[3+]. In addition, the orbital patterns of the HOCOs at the Γ point for **1**[3+] are formed by those of the non-bonding molecular orbitals (NBMOs) of 1,3-benzenediamine and 1,3,5-benzenetriamine (Fig. 4c and d). Consequently, the non-bonding HOCOs result in the flat bands in **2**[3+].

The α-spin HOCOs for **1**[6+] (175–180) and **2**[6+] (271–276) at the Γ point are shown in Fig. 5. In **1**[6+], the six spin-containing α-spin HOCOs are separated into non-, doubly-, and triply-degenerate COs, and these COs are quasi-degenerate (Fig. 5a). Moreover, all the HOCOs in **1**[6+] are localized more than those in **1**[3+]. On the one hand, the upper three non- and doubly-degenerate COs (274–276) in **2**[6+] lie about 2 eV above the lower three non- and doubly-degenerate COs (271–273) (Fig. 5b). Similar to the HOCOs in **2**[3+], those in **2**[6+] have also highly localized character. However, the AO coefficients are mainly distributed to the hexaphenylbenzenetriamine moieties. As a whole, it was clarified that the nature of the HO α-bands of the cationic forms of **1** and **2** are clearly constructed from the NBMOs of 1,3-benzenediamine and 1,3,5-benzenetriamine.

Let us now look at the spin density distributions for **1**[3+], **1**[6+], **2**[3+], and **2**[6+], as shown in Fig. 6. In **1**[3+] and **1**[6+], most of the spin densities concentrate on 1,3,5-benzenetriamine moieties due to the large cant angle of the *para*-phenylene rings. The spin den-

They are depicted after the expansion of the actual molecular structures onto the plane of the page. The solid and white circles show the positive and negative spin densities, respectively, and their radii are in proportion to the magnitudes of the spin density. Only the spin density larger than 0.05 is shown in this figure.

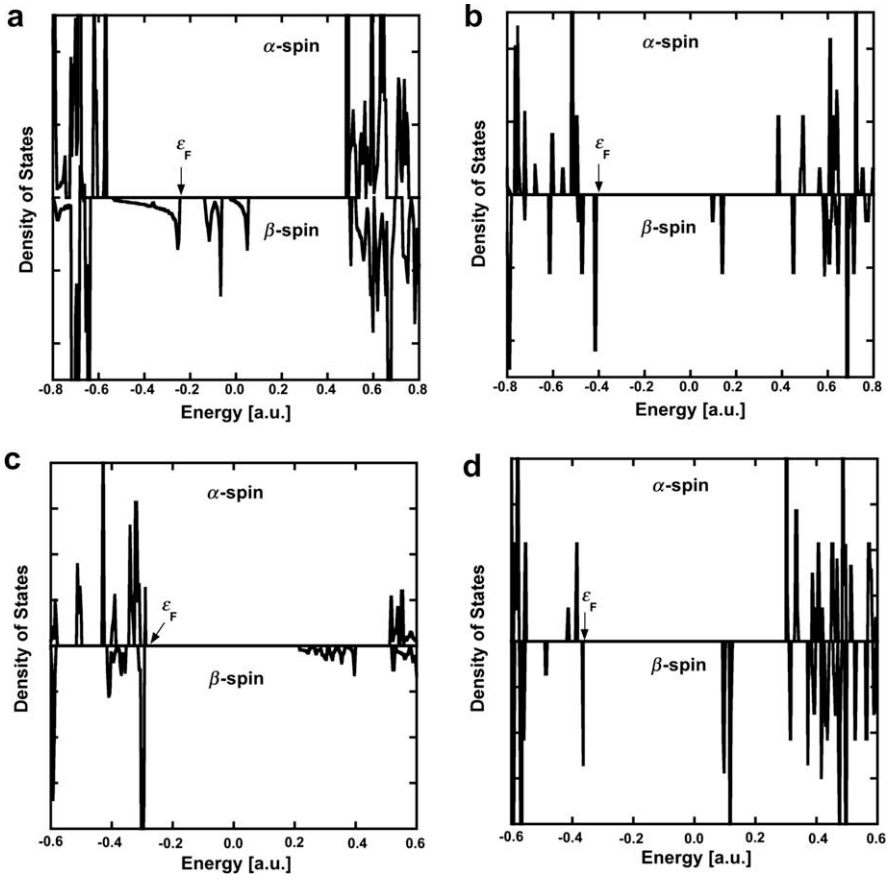

Fig. 7. The density of states for the high-spin states of (a) **1**[3+], (b) **2**[3+], (c) **1**[6+], and (d) **2**[6+]. The arrows designate the Fermi level.

sity on the nitrogen atoms increases with going from **1**[3+] to **1**[6+]. On the other hand, in **2**[6+], a considerable amount of spin flows into the *para*-phenylene rings through spin polarization effect [24], by which the positive and negative spin densities appear alternately in the two polymers. However, the spin densities on the nitrogen atoms of 1,3-benzenediamine or 1,3,5-benzenetriamine moieties are so small that we can conclude that **2**[3+] and **2**[6+] are spin localized systems.

The density of states (DOS) for **1**[3+], **1**[6+], **2**[3+], and **2**[6+] are shown in Fig. 7. From the calculated results, these high-spin polymers are expected to be insulating, because of a considerably large band gaps between the HOCO bands and the lowest unoccupied crystal orbital (LUCO) bands.

4. Conclusion

We have investigated the electronic structures of newly designed 2-D high-spin polymers **1** and **2** composed of the strong FC unit (1,3,5-benzenetriyl and 1,3-benzenediyl) and the stable SC unit (semiquinone radical cation of *para*-phenylenediamine). According to the ab initio UHF-CO calculations of cationic states of **1** and **2**, it was found that the high-spin preference is maintained in **1**[3+], **1**[6+], **2**[3+], and **2**[6+]. This indicates that the oligomer model study of **1** and **2** will be fruitful.

ABSTRACT

Three novel Mn(III) cyclam complexes, $[Mn(cyclam)(NCBH_3)_2](CF_3SO_3)$, $[Mn(cyclam)(NCBPh_3)_2](CF_3SO_3)$, and $[Mn(cyclam)(NCSe)_2](CF_3SO_3)\cdot H_2O$, have been synthesized. These complexes are in the high-spin state between 4 and 350 K, and show large zero-field splittings. The crystal structure of $[Mn(cyclam)(NCBH_3)_2](CF_3SO_3)$ was determined where the axial elongation of Mn–N bonds is found to be the largest among the homologue complexes. Ligand field in the $[Mn(cyclam)X_2]^+$ complex series was examined by angular-overlap model calculation.

© 2009 Elsevier Ltd. All rights reserved.

1. Introduction

The magnetism of Mn(III) complexes receives much attention recently because their large magnetic anisotropy serves useful pinning potentials for magnetization reversal in various nanomagnets [1] and their complicated d^4 electron configurations provide a potential for multiple bistabilities including spin-crossover and the Jahn–Teller effects [2–5].

A series of Mn(III) complexes, *trans*-$[Mn(cyclam)X_2]^+$ (cyclam = 1,4,8,11-tetraazacyclotetradecane, X^- = axial anionic ligand), has been extensively studied, focusing on the electronic structure and magnetic properties, which may take high-spin $(e_g)^1(t_{2g})^3$ or low-spin $(t_{2g})^4$ electron configurations [6–11]. Within the series, only one low-spin species is known with $X^- = CN^-$ [11], and no spin-crossover complexes are reported yet. We are interested in the stronger side of a range of axial ligand field, and obtained three novel complexes with $X^- = NCBH_3^-$ (**1**), $NCBPh_3^-$ (**2**), and $NCSe^-$ (**3**), exploring the spin-crossover boundary on the interaction parameter space. The crystal structure of *trans*-$[Mn(cyclam)(NCBH_3)_2](CF_3SO_3)$ (**1**) was solved and reported in detail. Several known complexes [8,9,11] were also prepared along with novel ones and their magnetic susceptibilities were measured aiming to determine the magnetic anisotropy parameter (uniaxial zero-field splitting parameter D) as a guide scale of axial ligand field. By applying angular-overlap model and extended Hückel molecular orbital calculations, the relation between magnetic anisotropy and electronic structure was discussed for a series of $[Mn(cyclam)X_2]^+$ complexes.

2. Experimental

Commercially available solvents and chemicals were used without further purification. The reaction procedures of **1** and **2** were carried out in ambient atmosphere. The reaction procedure of **3** was performed under an argon atmosphere using standard Schrenk technique. The complex $[Mn(cyclam)(OH_2)_2](CF_3SO_3)\cdot H_2O$ was prepared according to the literature method [8]. Elemental analyses were carried out at the Laboratory for Instrumental Analysis, Graduate School of Engineering, Osaka University. IR spectra were recorded on a JASCO FT/IR-300E.

2.1. Synthesis

2.1.1. $[Mn(cyclam)(NCBH_3)_2](CF_3SO_3)$ (**1**)

To an aqueous solution (3 mL) of $[Mn(cyclam)(OH_2)_2](CF_3SO_3)_3\cdot H_2O$ (378 mg, 0.5 mmol) was added an aqueous solution (2 mL) of $NaNCBH_3$ (62.9 mg, 1.0 mmol) at room temperature and the mixture was stirred. Sky-blue solid precipitated immediately was filtered off and dried in air (yield 135 mg, 56%). Infrared spectrum (KBr disk, cm^{-1}): 2184 (ν{C≡N}), 2350 (ν{B–H}). *Anal.* Calc. for $C_{13}H_{30}B_2F_3MnN_6O_3S$: C, 32.26; H, 6.25; N, 17.36. Found: C, 31.77; H, 6.18; N, 17.35%. For X-ray crystallographic analysis, an aqueous solution (1.5 mL) of $NaNCBH_3$ (13.1 mg, 0.21 mmol) was carefully layered on an aqueous solution (1 mL) of $[Mn(cyclam)(OH_2)_2](CF_3SO_3)_3\cdot H_2O$ (76.1 mg, 0.10 mmol) to yield sky-blue single crystals in 2 h.

2.1.2. $[Mn(cyclam)(NCBPh_3)_2](CF_3SO_3)$ (**2**)

A mixture of KCN (130 mg, 2.0 mmol) and BPh_3 (484 mg. 2.0 mmol) in ethanol (2.5 mL) at room temperature was stirred for 1 h to give a clear solution. To an aqueous solution (2 mL) of

doi:10.1016/j.poly.2009.02.013

$[Mn(cyclam)(OH_2)_2](CF_3SO_3)_3 \cdot H_2O$ (756 mg, 1.0 mmol) was added the ethanolic solution and the mixture was stirred. Immediately yellowish green solid was precipitated and filtered off. The solid was washed by ethanol, and dried in air (yield 357 mg, 38%). Infrared spectrum (KBr disk, cm^{-1}): 2171 (ν\{C≡N\}). *Anal.* Calc. for $C_{49}H_{54}B_2F_3MnN_6O_3S$: C, 62.57; H, 5.79; N, 8.93. Found: C, 62.30; H, 5.82; N, 8.98%.

2.1.3. $[Mn(cyclam)(NCSe)_2](CF_3SO_3) \cdot H_2O$ (**3**)

To a solution of KSeCN (143 mg, 0.99 mmol) in acetonitrile (10 mL) was added a solution of $[Mn(cyclam)(OH_2)_2](CF_3SO_3)_3 \cdot H_2O$ (378 mg, 0.50 mmol) in the same solvent (5 mL) at room temperature. The deep purple solution changed to a clear orange solution immediately after stirring. After 20 min, the solution was completely evaporated in vacuo. In half volume of solvent evaporated a dark-orange solid started to precipitate. The solid was washed by ethanol and dried in vacuo (yield 86.7 mg, 28%). Infrared spectrum (KBr disk, cm^{-1}): 2055 (ν\{C≡N\}). *Anal.* Calc. for $C_{13}H_{26}F_3MnN_6O_4SSe_2$: C, 24.69; H, 4.14; N, 13.29. Found: C, 24.68; H, 3.78; N, 13.23%.

2.2. X-ray structure determination

Single crystal structure determination was performed on the compound **1** at 123 K using a Rigaku RAXIS RAPID imaging-plate area detector with graphite monochromated Mo Kα radiation (λ = 0.071073 nm). The structure was solved by direct methods [12] and expanded using Fourier techniques [13]. The positions of all non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included and their positions were refined using a riding model. All calculations were performed using the CRYSTALSTRUCTURE crystallographic software package [14,15]. Detail on the data collections and refinements are summarized in Table 1.

2.3. Magnetic susceptibilities

Magnetic measurements of **1** and **2** were carried out on a Quantum Design MPMS-XL5 SQUID magnetometer equipped with reciprocating sample option (RSO) at magnetic fields of 1.0 and 5.0 T. Magnetic measurement of **3** was carried out on a Quantum Design MPMS-2 SQUID magnetometer at a field of 1.0 T. Polycrystalline samples were mounted in calibrated gelatin capsules held at the center of a polypropylene straw fixed to the end of the sample rod.

3. Results and discussion

3.1. Molecular structure of $[Mn(cyclam)(NCBH_3)_2](CF_3SO_3)$ (**1**)

Crystal structure was determined for the complex **1** which crystallizes in the non-centrosymmetric space group $P2_12_12_1$. The molecular structure is depicted in Fig. 1. The counter anion $CF_3SO_3^-$ links neighboring complex cations via weak hydrogen bonds O···H–N forming a chain structure along *c*-axis (Fig. 2).

The coordination environment around Mn(III) is elongated-octahedron type. The equatorial Mn–N distances fall in a range of 0.2004–0.2034 nm. The axial Mn–N distances are significantly longer than them, being 0.2209 and 0.2215 nm. These values are the longest among axial Mn–N distances in the hitherto-reported $[Mn(cyclam)X_2]^+$ complexes [6–11]. The Mn–N and N≡C bonds in Mn···$NCBH_3$ axial coordination are non-collinear with the Mn–N–C angle of 169.4–173.7°, which gives rise to a small deviation from tetragonal symmetry, while the axial Mn–N bond is almost normal to the equatorial N_4 plane with the tilt angle of 1.06° (Table 2).

3.2. Magnetic properties

Isofield magnetizations of **1** and **2** were measured from 2 to 350 K, and the ones of **3** were from 4 to 350 K. All the compounds showed effective magnetic moments μ_{eff} of 4.9–5.2μ_B at room temperature, which agree well with the spin-only value of 4.9μ_B (S = 2) expected for a high-spin d^4 electron configuration of Mn(III) (Fig. 3). The μ_{eff} drops observed at low temperature should be attributable to the zero-field splitting accompanying with tetragonal coordination environment, rather than to antiferromagnetic intermolecular interactions. The uniaxial zero-field splitting

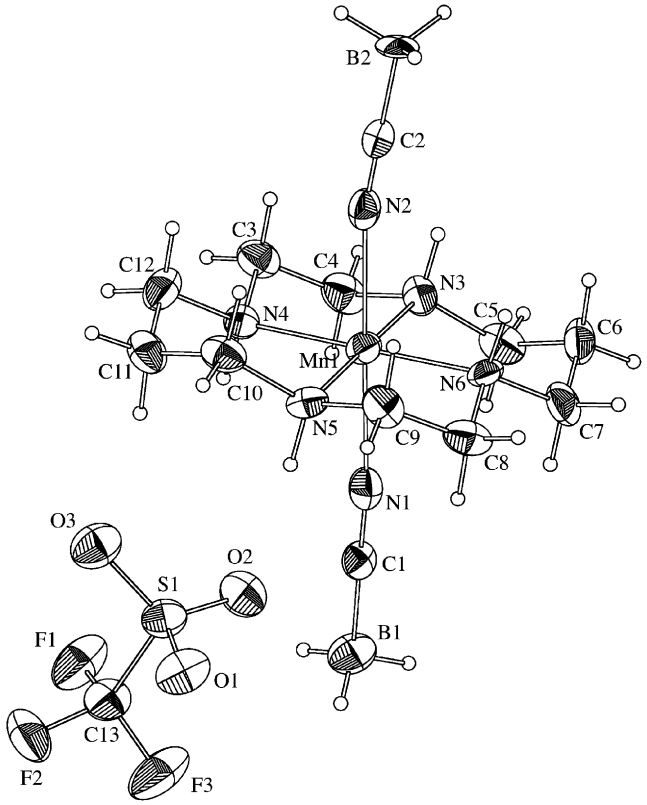

Fig. 1. Molecular structure of *trans*-$[Mn(cyclam)(NCBH_3)_2](CF_3SO_3)$ (**1**). All H atoms are shown as open circles, and thermal ellipsoids for heavier atoms are drawn at the 50% probability level.

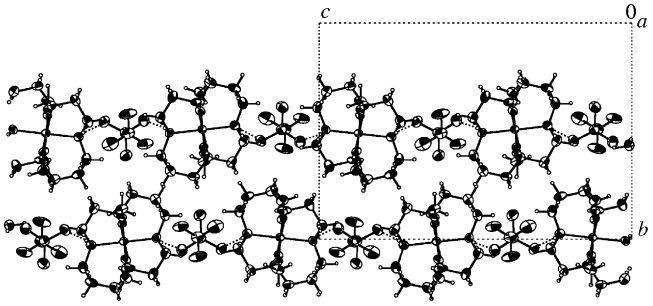

Fig. 2. Chain structure of *trans*-[Mn(cyclam)($NCBH_3$)$_2$](CF_3SO_3) with weak hydrogen bonds along *c*-axis.

parameter *D* of **1**, **2** and **3** were estimated by assuming random orientation of crystallites (Table 3).

3.3. Magnetic anisotropy analysis on the basis of AOM

Extended Hückel molecular orbital calculations [18] were made to figure out one-electron orbital energies for the complexes with X^- = Cl^-, Br^-, I^-, $NCBH_3^-$, NCO^-, NCS^-, N_3^-, CN^-, ClO_4^-, NO_3^-, and NO_2^- using their crystallographic coordinates [6–11]. The orbital energies of five d-character molecular orbitals are depicted in Fig. 4. It is obvious that the d_{z^2} orbitals are strongly affected by σ-donor character of axial ligands, while the orbital energy of the $d_{x^2-y^2}$ orbitals are dominated by the equatorial ligand cyclam and kept almost unchanged at around −8.2 eV throughout the series. Non-bonding t_{2g} orbitals found below −12 eV are slightly lifted by π-donor/acceptor character of the axial ligands, providing a single and a doubly degenerate levels. In spite that the splitting in the t_{2g} orbitals are much smaller than that in e_g orbitals, this small splitting plays an essential role in the low-spin electronic configuration under a very strong ligand field.

One-electron orbital energies obtained from extended Hückel molecular orbital calculations are useful to estimate ligand-field parameters. The angular-overlap model (AOM), instead of a conventional cubic harmonics expansion, was adopted to describe the ligand fields in [Mn(cyclam)X_2]$^+$ complexes, since it is more convenient to attribute the effect of individual ligand to the AOM parameters representing localized σ and π donors (e_σ and e_π, respectively). For an octahedral complex *trans*-[ML_4X_2] of D_{4h} symmetry, the orbital-energy relations:

$$E(x^2-y^2) = 3e_\sigma(\mathrm{L}), \quad (1)$$

$$E(z^2) = e_\sigma(\mathrm{L}) + 2e_\sigma(\mathrm{X}), \quad (2)$$

$$E(yz) = E(zx) = 2e_\pi(\mathrm{L}) + 2e_\pi(\mathrm{X}), \quad (3)$$

$$E(xy) = 4e_\pi(\mathrm{L}) \cong 0, \quad (4)$$

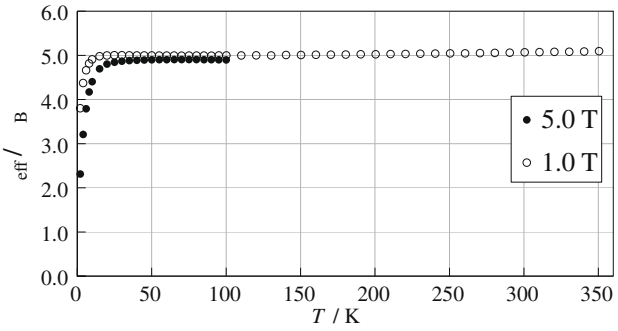

Fig. 3. The temperature dependence of effective magnetic moment of a polycrystalline sample of *trans*-[Mn(cyclam)($NCBH_3$)$_2$](CF_3SO_3) from 2 to 350 K. At temperatures lower than 50 K, the effective magnetic moment shows a drop caused by the zero-field splitting.

are known for σ-donor equatorial ligand L and σ,π-donor axial ligand X, where $E(d)$ stands for the one-electron orbital energy of d-character orbital [19]. These relations were used to extract AOM parameter values compiled in Table 4. If $e_\pi(X)$ is negative, *i.e.* $E(yz)$, $E(zx) < E(xy)$, the axial ligand behaves as a π-acceptor rather than a π-donor. In this case, the possible low-spin electronic configuration is orbitally-degenerate $\{(d_{yz})(d_{zx})\}^3(d_{xy})^1$, not $(d_{xy})^2(d_{yz})^1(d_{zx})^1$, which is subject to the Jahn–Teller instability. It may be responsible for the tilting of axial ligands observed in $X^- = CN^-$ [11].

Although there is a report that the magnetic anisotropy in the high-spin $[Mn(cyclam)I_2]^+$ complex may be dominated by MLCT excited states mixing into the high-spin $^5B_1$ ground state [20], the contribution of such low-energy MLCT excited states is very rare and reliably ignored in most of the $[Mn(cyclam)X_2]^+$ complexes. Thus, the magnetic anisotropies of them were simulated taking only d-orbitals into account. Fig. 5 shows the zero-field splitting parameter (D) of $[Mn(cyclam)X_2]^+$ series mapped on an interaction parameter plane $e_\sigma(X)$–$e_\pi(X)$, which was calculated from the longitudinal Zeeman splitting simulations based on the AOM in conjunction with typical values for Mn(III) electronic parameters: Racah's parameters $B/hc = 1140\ cm^{-1}$ and $C/B = 4.3$ [21]; spin-orbit coupling $\zeta/hc = 355\ cm^{-1}$ [19]; Stevens' orbital reduction factor $k = 0.8$ [22]; and the AOM parameter of equatorial cyclam ligands $e_\sigma(L)/hc = 10000\ cm^{-1}$. The red broken curve on the map is a spin-crossover boundary separating high-spin ($S = 2$) and low-spin ($S = 1$) region. On this map, $e_\sigma(X)$ and $e_\pi(X)$ values of several complexes summarized in Table 4 are also plotted. This map suggested that the high-spin complex **1** does not have strong enough ligand field to break Hund's rule, and the cyanohydroborate anion behaves as not a π-acceptor expected but a weak π-donor for Mn^{3+}. Given the comparison of D-value in Table 4, complexes **2** and **3** appear to be located between **1** and $[Mn(cyclam)(NCO)_2]^+$. Although the D map was obtained on the basis of rather naïve AOM model, the agreement with experimental values is satisfactory in semiquantitative level. Comparing these plots with the spin-crossover boundary curve, it is revealed that the attainment of spin-crossover Mn(III) cyclam complexes requires stronger σ-donor and π-acceptor ligands than the complexes **1**–**3** have.

4. Conclusion

The manganese(III) complexes **1**–**3** were newly prepared and found to be in the high-spin state. The magnetic measurements of them revealed very large uniaxial zero-field splittings D in **1**–**3**. The crystal structures of **1** and analogous complexes were utilized in extended Hückel and AOM calculations, providing useful information of the spin-crossover boundary of $[Mn(cyclam)X_2]^+$ series.

Supplementary data

CCDC 705754 contains the supplementary crystallographic data for complex **1**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

We performed quantum spin dynamics in anisotropic electron-spin systems to clarify the mechanism in single molecular magnets (SMM) theoretically. Usually, SMMs have large negative anisotropic D value and the large total spin angular moment (S_{total}). The splitting ground spin states in one SMM molecule are usually caused by the anisotropic terms (D and E), which become more important as well as isotropic term (J). In order to examine the effects of such anisotropic magnetic terms, model systems with large spin multiplicity of the ground state (S_{total} = 5 and 2) were treated. First, energy diagram in external magnetic field is shown, since negative D terms are responsible to the zero-field magnetic moment. Next, the quantum Liouvile approach is used for our spin dynamics simulation involving the relaxation processes of the system. Our simulations in S_{total} = 5 system successfully reproduced magnetic quantum tunneling (MQT) behavior in DC-external magnetic field. Moreover, in S_{total} = 2 system under AC-external magnetic field, frequency dependence of real (χ') and imaginary (χ'') parts of χ can be shown with Fourier transformation. Our theoretically drawn half circles in Cole-Cole plot (χ' versus χ'') will give information to many experimental studies.

1. Introduction

Recently, low-dimensional magnetic materials have been actively investigated in relation to the so-called nano-science. For example, single molecular magnets (SMM) have been interesting targets both experimentally and theoretically [1–8]. In such the novel molecules classified in zero-dimension (0D), there are many sophisticated features, which are attracting most of scientists. For example, it is reported that magnetic hysteresis in SMMs ($S_{total} \approx 10$) is appeared by using dual stable spin states, though that is caused by moving domain-wall in bulk magnetic materials ($S_{total} \approx 10^5$). Many SMMs are the molecules that have large magnetic anisotropy (D) as well as the large total spin angular moment (S_{total} (or S)). For example, famous SMM molecules: Fe8 ($Fe_8O_2(OH)_{12}(tacn)_6$, tacn = 1,4,7-triazacyclononane) [3,4], Mn12-act ($Mn_{12}(CH_3COO)_{16}(H_2O)_4]_{12}]2CH_3COOH4H_2O$) [5–7] and Mn4 ($Mn_4O_3Cl_4(O_2CEt)_3Py_3$) [8] have been reported. Both molecules possess the large spin moment (S_{total} = 10) as ground spin state and their spin structure is anisotropic. Two spin states (M = +10 and −10) for such Mn12-ac and Fe8 molecules are the most stable and energy barrier (blocking temperature: 25 K for Fe8 and 67 K for Mn12-act) between both states exist for spin-flipping. Many scientists have been synthesized many related molecules and measured chemical or physical properties. Generally speaking, SMM molecules possess remarkable properties: (1) Large spin multiplicity of the ground state, (2) anisotropic magnetization (easy axis type), (3) activation energy ΔE for the magnetization reversal (magnetic hysteresis) and (4) magnetic quantum tunneling (MQT) between sub-levels (step structure in hysteresis loop). In particular, these SMMs are expected to candidates for elemental qubit devices in quantum computers as next generation calculation machine. They have a clear advantage concerning anisotropy of the magnetic moment and long relaxation time.

In the series of our previous studies, we have studied the excitation energy transfer in aggregated systems such as dendrimer molecules, where exciton migration with exciton–phonon interaction is very important [9–13]. Our simulation achieved theoretical prediction of dynamic features in aggregated systems. The results gave much information to experimental scientists. Now we have smoothly extended the theory to spin dynamics involving spin-phonon interaction that play important roles in several types of molecular magnetism [14,15].

The relaxation processes in the spin dynamics are focused in this study. We perform spin dynamics in strongly correlated electron-spin systems in order to clarify the phase relaxation in spin

doi:10.1016/j.poly.2009.02.032

clusters. In our study, we consider the phenomenoligical relaxation parameters for the relaxation terms of the quantum Liouville equation.

Quantum spin Hamiltonian is considered in order to investigate behavior of quantum spin under external magnetic field (DC or AC). Especially, for simplified model systems for SMM molecules, anisotropic terms in Hamiltonian become important. Quantum Liouville approach with this Hamiltonian is used for the dynamics involving the relaxation processes of the system. Simple model systems (S_{total} = 5 and 2) are considered as the simplest example of SMMs.

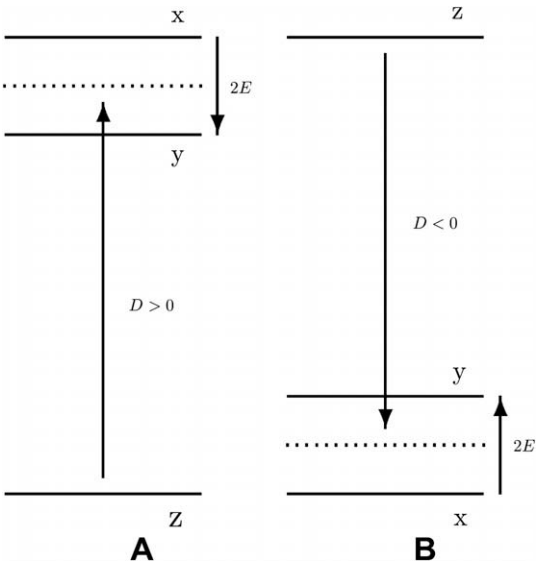

Fig. 1. The energy diagrams for anisotropic spins are shown, when the spin is on $\mathbf{u}_x$, $\mathbf{u}_y$ or $\mathbf{u}_z$ axis. Magnetic parameters D and E are called axial and transverse parameter, respectively. Two cases of positive and negative D are shown in (A) and (B), respectively, though the sign of E is not essential. Usually, single molecular magnets (SMM) have large negative D as well as the large total spin moment (S_{total} (or S)).

2. Theoretical background

2.1. Anisotropic quantum spin Hamiltonian

General spin Hamiltonian with spin-orbit coupling and external magnetic field $\mathbf{H}_0$ is defined as

$$\hat{H} = \lambda(\hat{\mathbf{L}} \cdot \hat{\mathbf{S}}) + (\hat{\mathbf{L}} + g_e\hat{\mathbf{S}})\mu_B\mathbf{H}_0 \tag{1}$$

Here, if we apply perturbation procedure and ignore higher terms, we can obtain effective Hamiltonian:

$$\hat{H}_{\text{eff}} = \langle 0|\hat{H}|0\rangle + \sum_{n\neq 0} \frac{\langle 0|\hat{H}|n\rangle\langle n|\hat{H}|0\rangle}{E_0 - E_n} \tag{2}$$

and finally,

$$\hat{H}_{\text{eff}} = \mu_B\hat{\mathbf{S}}g_e(1 - \lambda\Lambda)\mathbf{H}_0 + D\{\hat{S}_z^2 - S(S+1)/3\} + E(\hat{S}_x^2 - \hat{S}_y^2) \tag{3}$$

The tensor Λ in first term shows spatial symmetry of system and second and third terms are related to magnetic anisotropy.

Here, let us describe the zero-field splitting (ZFS) Hamiltonian of the magnetic anisotropy as

$$\hat{H}_{\text{ZFS}} = D\hat{S}_z^2 + E(\hat{S}_x^2 - \hat{S}_y^2) \tag{4}$$

under the suitable coordinates. Here, the parameter D and E are called axial and transverse parameters, and S is the total spin vector. If the ZFS tensor D can be calculated and diagonalized ($\mathbf{u}_x$, $\mathbf{u}_y$, $\mathbf{u}_z$), the diagonal elements are ordered and values D and E are defined. [16] The sign of E is not essential, since $\mathbf{u}_x$ and $\mathbf{u}_y$ can be swapped. Therefore, we ignore the sign of E in the present study. The energy diagrams for anisotropic spins are shown in Fig. 1. Magnetic properties between positive and negative D systems are different. Usually, SMMs have large negative D and large S. In Fig. 2A double well potential ($D < 0$) are depicted and each spin state ($M_S = S, S-1, \ldots, -S+1, -S$), which are illustrated in Fig. 2B as direction of magnetic field, has discrete levels. There are two ground states ($M_S = \pm S$), and the energy barrier between the two states is not zero. If the two valley states can be taken as 0 and 1, we can use as data storage units. Of course, spin transitions between each

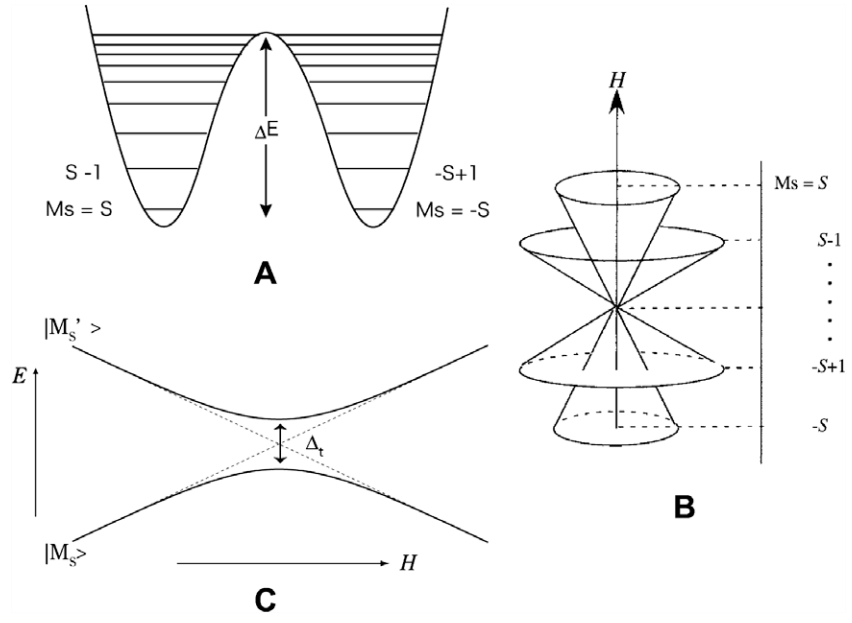

Fig. 2. (A) Double well potential ($D < 0$) are depicted. There are two ground states ($M_S = \pm S$), and the energy barrier between the two states is not zero. (B) All spin states ($M_S = S, S-1, \ldots, -S+1, -S$) are illustrated as direction of magnetic field. (C) In the non-zero E value case, tunnel splitting by the level mixing between $\mathbf{u}_x$ and $\mathbf{u}_y$ axis will occur and avoided crossing have appeared.

spin state are also very important. In the non-zero E value case, tunnel splitting by the level mixing between $\mathbf{u}_x$ and $\mathbf{u}_y$ axis will occur and avoided crossing are appeared in Fig. 2C.

Here, we append external magnetic field term into Eq. (4):

$$\hat{H}_{\mathrm{ZFC+ext}} = D\hat{S}_z^2 + E(\hat{S}_x^2 - \hat{S}_y^2) + \hat{H}_{\mathrm{ext}} \tag{5}$$

Here, direction of magnetic field $\mathbf{H}_0$ is set to apply in xz-plane and defined as

$$\hat{H}_{\mathrm{ext}} = -g_e\mu_B\mathbf{H}_0\cdot\hat{\mathbf{S}} = -g_e\mu_B H_0[\cos\theta\hat{S}_z + \sin\theta\hat{S}_x] \tag{6}$$

The parameter $\mathbf{H}_0$ is magnitude of magnetic field and θ is angle between z-axis and magnetic field.

2.2. Spin dynamics simulation with QME procedure

As a continuation of previous work, we have further examined the relaxation processes of electron spin via spin-phonon interaction. [14,15,17–19] Here, at the first step of this spin dynamics, these interactions are treated phenomenologically. Quantum master equation (QME) procedure is important in order to describe spin dynamics theoretically. In generally the time evolution of spin population ($\rho(t)$) is described by the master equation:

$$i\hbar\frac{\partial}{\partial t}\rho = [\hat{H}(t), \rho(t)] - i\Gamma\rho(t) \tag{7}$$

where the second term on the right side represents a relaxation term in the Markov approximation.

The total Hamiltonian ($\hat{H}_{\mathrm{tot}}(t)$) is expressed by the sum of the Hamiltonian ($\hat{H}_s$) for the spin parts and some interaction parts ($\hat{H}_{\mathrm{int}}$). In this study, since simulations are performed in spin systems, operator O_i is setting to spin operator S_x:

$$\hat{H}_{\mathrm{tot}} = \hat{H}_s + \sum_{i,q_i}\Omega_{q_i}c_{q_i}^{\dagger}c_{q_i} + \sum_i \hat{O}_i(\kappa_i^* c_i^{\dagger} + \kappa_i c_i) + g_e\mu_B\mathbf{H}(t)\cdot\hat{\mathbf{S}} \tag{8}$$

where the second, third and forth terms are indicate phonon parts, spin-phonon interaction and external magnetic field, respectively. For the first term ($\hat{H}_s$) we employ the anisotropic spin Hamiltonian ($\hat{H}_{\mathrm{ZFC}}$) of Eq. (4) and suitable values for both parameters D and E are set manually in our simulation.

Now we consider the ground multiplet electron-spin systems. Detailed formulation for Eq. (7) can be re-written by

$$\dot{\rho}_{\alpha\beta} = -i[\hat{H}_S + \hat{H}_{\mathrm{int}}, \rho]_{\alpha\beta} - \sum_{mn}\Gamma_{\alpha\beta;mn}\rho_{mn} \tag{9-1}$$

$$\dot{\rho}_{\alpha\alpha} = -\sum_{mn}\Gamma_{\alpha\alpha;mm}\rho_{mm} \tag{9-2}$$

In addition, the relaxation term in Eq. (7) can be considered as two types of mechanisms, i.e., population and coherent damping mechanisms. The detailed damping (Γ_{mn}) parameters in Eqs. (9-1) and (9-2) can be represented by

$$\Gamma_{\alpha\beta;mn} = \sum_k\sum_i[\delta_{n\beta}(\hat{O}_i)_{\alpha k}(\hat{O}_i)_{km}\gamma_i(\omega_{mk}) + \delta_{m\alpha}(\hat{O}_i)_{nk}(\hat{O}_i)_{k\beta}\gamma_i(\omega_{nk})] - \sum_i[(\hat{O}_i)_{\alpha m}(\hat{O}_i)_{n\beta}\gamma_i(\omega_{n\beta}) + (\hat{O}_i)_{\alpha m}(\hat{O}_i)_{n\beta}\gamma_i(\omega_{m\alpha})] \tag{10-1}$$

$$\Gamma_{\alpha\alpha;mm} = \sum_k\sum_i[\delta_{m\alpha}\{(\hat{O}_i)_{\alpha k}(\hat{O}_i)_{km} + (\hat{O}_i)_{mk}(\hat{O}_i)_{k\alpha}\}\gamma_i(\omega_{mk})] - 2\sum_i[(\hat{O}_i)_{\alpha m}(\hat{O}_i)_{m\alpha}\gamma_i(\omega_{m\alpha})] \tag{10-2}$$

Here, feeding (γ_{mn}) parameters also defined by

$$\gamma_i(\omega) = \frac{2\gamma_i^0}{1+e^{-\beta\omega}} \tag{10-3}$$

These feeding parameters are determined in a manner that the spin states relax from higher-lying to lower-lying states with the velocities, which depend on energy levels difference.

3. Results and discussion

3.1. Magnetic hysterisis and tunneling of magnetization

First, we employ spin model ($S_{\mathrm{total}} = 5$) as a simple spin cluster for SMM molecule, where for example 10-centered electro-spins with all ferromagnetic couplings are one of candidate cases. This model has 11 spin states ($2S + 1 = 11$) and each state is indicated by ($S = 5$: $M = 5,4,3,2,1,0,-1,-2,-3,-4,-5$). Fig. 3A shows the schematic energy levels of this spin systems on external magnetic field H (0–0.4 T). The spin Hamiltonian of Eq. (5) are employed and the anisotropic parameters are fixed at $D = -0.5\ \mathrm{cm}^{-1}$ and $E = 0\ \mathrm{cm}^{-1}$. In this system, the spin states $|S = 5 : M = \pm 5\rangle$ have ground energy at zero external magnetic field and split into two states under non-zero field. Each spin state is strongly influenced by magnetic field and show Zeeman splitting. In this figure, we can find several crossing points between two different spin states. If anisotropic parameter E is set to non-zero, each crossing points turn to avoided-level crossing points as shown in Fig. 2C. In such case, the tunneling of magnetization, i.e. MQT, which has been reported by experimental studies in many SMM crystals, is expected.

Thus, we set anisotoropic transverse parameter E to $0.01\ \mathrm{cm}^{-1}$ and run QME spin simulation. The simulation was performed numerically using (4,4) Runge-Kutta method by using Eqs. (9-1) and (9-2). The relaxation parameter (γ^0) for spin-phonon coupling is set to be $0.05\ \mathrm{cm}^{-1}$ and sweep rate (dH/dt) for external magnetic field is 0.01. The results of our simulation are depicted in Fig. 3B, where curvature of magnetization $-\langle S_z\rangle$ values (opposite direction to external magnetic field) is drawn to magnetic field. Static

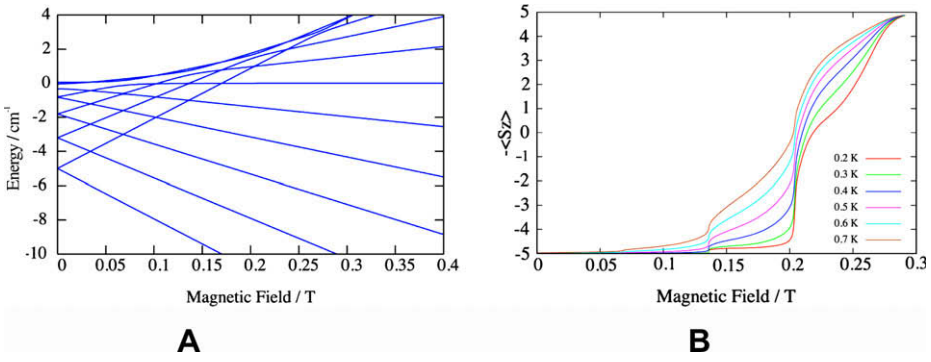

Fig. 3. We employ spin model ($S_{\mathrm{total}} = 5$) as a simple spin cluster for SMM molecule. (A) The schematic energy levels of this spin systems under external magnetic field. The spin Hamiltonian of Eq. (5) is employed and the anisotropic parameters are fixed at $D = -0.5\ \mathrm{cm}^{-1}$ and $E = 0\ \mathrm{cm}^{-1}$. (B) Anisotoropic transverse parameter E was set to be $0.01\ \mathrm{cm}^{-1}$ and run QME spin simulation. The results of our simulation are depicted in static magnetic field (DC).

magnetic fields (DC) are swept from 0 to 0.3 T and we can find out magnetization jumps at the avoided-level crossing point. The relaxation speed of magnetization increases, when magnitude of external magnetic field matches up to avoid level crossing points. Thus, step-like curvature is reproduced. External temperature is fixed to be $T = 0.2, 0.3, \ldots, 0.7$ K and we confirmed the magnetic hysteresis that magnetization at near 0 K remains even in the field being 0 T. The transition ratio between ground and excited levels in lower temperature regions becomes small, because thermal excitation ratio decreases.

3.2. AC-magnetic susceptibility and Cole-Cole plot

In previous section static (DC) external magnetic field was introduced into the system. In order to study SMM molecules concerning many interesting experimental studies, spin dynamic simulation for AC-magnetic susceptibility is also very important. Such magnetic response under the periodically driven fields depends on the frequency of the external magnetic field. Thus, frequency dependence of real (χ') and imaginary (χ'') parts of χ could be shown with Fourier transformation.

$$\chi(\omega) = \int dt e^{i\omega t}\chi(t) = \chi'(\omega) + i\chi''(\omega) \tag{11}$$

We assume that χ values can be described with linear relaxation (Debye type). Fig. 4 shows our obtained results in the case of $S_{\text{total}} = 2$, where for example four-centered electro-spins with all ferromagnetic couplings are one of candidate cases. Here, calculations for smaller S_{total} system were progressed, because the results for larger S_{total} system will be more complicated and hard to understand. Same procedure of numerical calculations depended on our QME simulation were carried out, except for alternative magnetic field in Eq. (6). The spin Hamiltonian of Eq. (5) are employed and the anisotropic parameters are fixed at $D = -0.5\ \text{cm}^{-1}$ and $E = 0\ \text{cm}^{-1}$. The relaxation parameter (γ^0) for spin-phonon coupling is $0.1\ \text{cm}^{-1}$ and amplitude of external magnetic field is 0.1 T. External temperature is fixed to be $T = 0.4, 0.5, \ldots, 2.0$ K and we can find out drastic changing of curvature of both χ' and χ'' terms. In this figure, temperature dependency is found, which implies response speeds against alternative external field will be sensitive to simulation temperature.

Moreover, let us re-plot the data in Fig. 4 into Fig. 5. Our theoretically drawn half circles in Cole-Cole plot (χ' versus χ'') will give information to experimental studies. In this figure, we can find that regular circles are realized in higher temperature case. On the other hand, in lower temperature system each circle becomes to be distorted. It is implied that divergence from linear-like decrement of spin relaxation time especially in lower temperature regions.

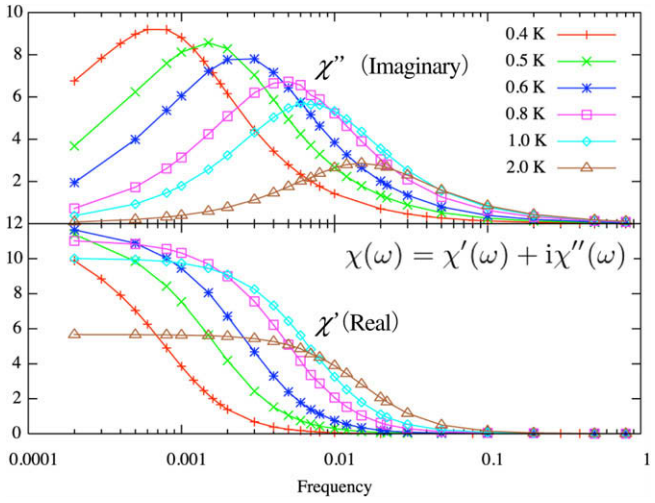

Fig. 4. Our QME simulation was carried out under AC magnetic field in Eq. (6). The anisotropic parameters are fixed at $D = -0.5\ \text{cm}^{-1}$ and $E = 0\ \text{cm}^{-1}$. AC-magnetic susceptibility in $S_{\text{total}} = 2$ system is shown, where frequency dependence of real (χ') and imaginary (χ'') parts of χ can be shown with Fourier transformation.

4. Conclusion

We have performed spin dynamics in electron-spin system using the quantum Liouville equation with the relaxation process

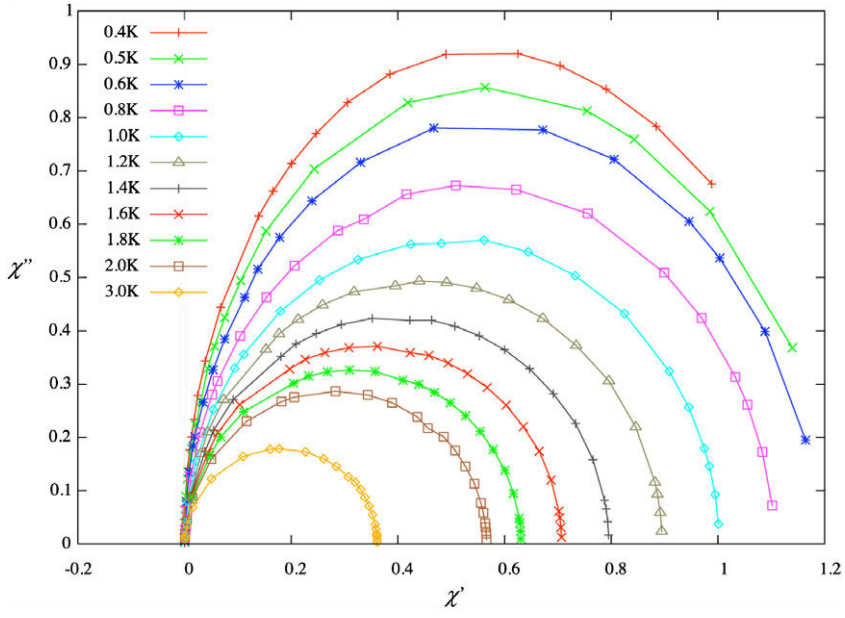

Fig. 5. The Cole-Cole (χ' versus χ'') plot, which was obtained by re-plotting the data in Fig. 4.

between spin states. These spin dynamics of the SMM-like spin system are simulated using QME approach. For the $S_{total} = 5$ spin systems, we consider the Zeeman splitting by external static magnetic field (DC). We examine the spin dynamics in variable magnitude of the external field and obtain tunneling of magnetization. Magnetic hysteresis and magnetization jump are seen in our simulation. It is worth considering our theoretical results for understanding magnetic nature of SMM molecules. For the $S_{total} = 2$ spin systems, we extend our spin dynamic simulation to that under alternative external magnetic field (AC). Our results in several temperatures are analyzed by Fourier transformation and plotted into χ', χ'' versus frequency and Cole-Cole plots. Our calculation of AC-magnetic susceptibility will give us much information of magnetic nature of SMM molecules. The relaxation processes are expected to be obedient except for lower temperature regions. Though real SMM molecules possess larger spin multiplicity of the ground state than our employing systems, our simulation will help us design newer SMMs as well as analyze the reported SMMs.

In addition to our spin dynamic simulation in this paper, we also can evaluate physical parameters by all *ab initio* MO procedures. Both *D* and *E* values in our simulation can be calculated for both model and real systems. These parameters are related to one of two terms: spin–spin dipole coupling (e.g. in organic ferromagnets) [18,20] or spin-orbit coupling (e.g. in metal complex) [16,21]. For the other parameters, i.e. *J* (Heisenberg Hamiltonian) [22], *t*, *U* (Hubbard, *t*–*J* Hamiltonian) [22] and ***d*** (Dzyaloshinskii–Moriya interaction) [16,21] have been treated theoretically in our studies. Thus, our all theoretical approach for A to Z is feasible and very unique.

In a previous report [14,15], we have discussed the superposed and entangled states of quantum systems. In this word, SMM molecules are one of good candidate of calculation and memory devices (qubit) in quantum computer. In fact, the quantum computing was realized by using seven nuclear spins by NMR technique. [23] One of the required conditions for quantum computing by the use of these systems (the magnetic moment in electron-spin or nuclear-spin, Rabi oscillation, etc.) is that the coherence time should be longer than the gating time. Efficiency of the small spin cluster in order to explore novel magnetic materials can be confirmed. This study is the first theoretical step for the rational design of quantum spin structures in SMM molecules.

Rods

ABSTRACT

The single X-ray structures of the thiosemicarbazide complexes $[Cd(NH_2CSNHNH_2)Cl_2]_n \cdot H_2O$ (**A**) and $[Cd(NH_2CSNHNH_2)_2Cl_2]_n$ (**B**) are reported. Both compounds have been found to be effective as single source precursors for the preparation of CdS nanomaterials. Thermal decomposition of the precursors in hexadecylamine (HDA) results in the formation of nanorods of different dimensions. The powder X-ray diffraction patterns of the nanodimensional materials reveal differences in the phases of the CdS synthesized from the two complexes. The particles synthesized from both precursors show quantum confinement effects in their absorption spectra, with the evidence of a broad defect emission in their photoluminescence spectra.

1. Introduction

Rods of semiconductor nanoparticles were prepared by Alivisatos et al. [1] by adding hexylphosphonic acid (HPA) in an attempt to modify crystal growth. Numerous reports on the synthesis of metal chalcogenide nanorods, including those of CdSe [2], CdTe [3] and CdS [4–7], followed. Peng et al. have studied various factors that influence the formation of particles with non-spherical morphologies for CdSe [8]. Their work suggests that the nature of the precursor, the rate of nucleation and the nature of the capping agent are all potential factors affecting particle morphology. We have recently shown that the ratio of surface area to volume [7] and feed ratios are significant parameters in the formation of these small particles [9]. In Peng's work, cadmium chalcogenide (CdE; E = S, Se) nanoparticles were synthesized using CdO and $Cd(O_2CCH_3)_2$ together with an alkylphosphonic acid. The study showed that the rod shaped particles formed in reactions with high monomer concentrations. At intermediate monomer concentrations the nanoparticles grow to give a mixture of spheres and rods. At low monomer concentrations the particles are exclusively close to spherical. There have been relatively few reports of the preparation of nanorods of CdS by colloidal routes [10–17], and such work remains of current interest.

Group IIB metal complexes of thiosemicarbazides and thiosemicarbazones have been themselves identified as compounds which have potential for applications as non-linear optic materials [18,19]. Cadmium complexes of these ligands are thermally stable with large second harmonic generation (SHG) efficiencies [20,21].

Here we report the synthesis and structure of two cadmium complexes containing the thiosemicabazide ligand, and the preparation of CdS rods via their thermal decomposition in hexadecylamine (HDA). Thiosemicarbazide has been shown to be a good ligand for a range of metals, including zinc, mercury, cadmium and nickel [22,23]. Furthermore the related bis-bromo complex is also known for cadmium [24]. This earlier work suggests that these complexes offer an excellent opportunity for the study of the effects of the ligand system on the formation of nanomaterials.

2. Experimental

2.1. Materials

Ethanol, methanol, toluene, chloroform, thiosemicarbazide (analytical grade), hexadecylamine (HDA), tri-n-octylphosphine and cadmium chloride (analytical grade) were purchased from Aldrich. All the reagents were used as purchased without further purification.

2.2. Physical measurements

Absorption spectra were measured on a Helios B UV-spectrophotometer in chloroform in a 1 cm path length cell. Photoluminescence measurements were carried out on a Horiba Fluorolog-3 (FL3-22) in chloroform with a 1 cm path length. The p-XRD data were collected on a Bruker D8 diffractometer with a Cu Kα source. TEM were recorded on a Philips CM200 microscope with a 200 kV

doi:10.1016/j.poly.2009.02.046

accelerating voltage. Samples were prepared by dispersing the particles in toluene and evaporating a droplet onto a carbon coated copper grid. X-ray diffraction single crystal data were collected with a Bruker Smart APEX CCD area detector equipped with an Oxford Cryosystem low-temperature device [25], using Mo Kα radiation and ω scans. Data were corrected for Lorentz and polarisation factors. The crystal data collection parameters are given in Table 1. Absorption corrections were applied to all data. All the structures were solved by direct methods using SHELXS-97. All the structures were completed by iterative cycles of ΔF-syntheses and full-matrix least squares refinement. All non-H atoms were refined anisotropically. In all the structures difference Fourier syntheses were employed in positioning idealised methyl-hydrogen atoms, which were assigned isotropic thermal parameters [U(H) = 1.5 Ueq(C)] and allowed to ride on their parent C-atoms [C–H 0.93 Å]. All refinements were against F^2 and used SHELXL-97 [26]. The thermal ellipsoids of the crystal structures are contoured at 50% probability.

2.3. Synthesis of the precursors

2.3.1. Synthesis of $[Cd(NH_2CSNHNH_2)Cl_2]_n{\cdot}H_2O$ (A)

$CdCl_2$ (2.5 g, 13 mmol) and thiosemicarbazide (2.5 g, 26 mmol) were each dissolved in ethanol (70 mL), and reacted. A creamy white precipitate immediately formed upon mixing, which was re-dissolved in hot methanol (100 mL) and left to cool slowly at room temperature. The flakes obtained were re-crystallised in hot water (100 mL). After 3 days, brown crystals of a flat square shape were obtained. The product contained some creamy white prismatic crystals (showed to be complex **B**, which were removed from the product by hand). The brown crystals of a flat square shape, $[Cd(NH_2CSNHNH_2)Cl_2]_n{\cdot}H_2O$ (**A**) (3.1 g) were analysed. The structure of complex **A** is shown in Fig. 1. Micro analysis: expected, C 6.3, H 2.2, N 21.9; found, C 6.2, H 2.2, N 21.0. Yield: 85%. Significant IR bands (cm^{-1}): ν(N–H) 2347, 3165, 3441; ν(C–N) 1589; ν(N–N) 1371; ν(C=S) 1049; ν(Cd–Cl) 250; ν(Cd–S) 198.

2.3.2. Synthesis of $[Cd(NH_2CSNHNH_2)_2Cl_2]_n$(**B**)

Cadmium chloride (1.1 g, 6 mmol) and thiosemicarbazide (1.1 g, 12 mmol) were each dissolved in hot ethanol (50 mL) in a 1:2 molar ratio, and reacted. A white precipitate was collected by filtration, dried under vacuum, and re-dissolved in hot methanol (100 mL). The solution was quickly filtered with suction whilst hot, which enhances the cooling rate. The supernatant formed a white precipitate, which was filtered, re-crystallised in 100 mL of water and left for approximately 2 days to crystallise, giving white prismatic crystals of $[Cd(NH_2CSNHNH_2)_2Cl_2]_n{\cdot}$(**B**) (1.5 g). The structure of complex **B** is shown in Fig. 2 and the packing diagram in Fig. 3. Micro analysis: expected, C 4.1, H 1.7, N 14.4; found, C 4.3, H 2.4, N 14.4. The materials were used as prepared [27]. Yield: 85%. Significant IR bands (cm^{-1}): ν(N–H) 2355, 3167, 3448; ν(C–N) 1592; ν(N–N) 1380; ν(C=S) 1039; ν(Cd–Cl) 257; ν(Cd–S) 201.

2.3.3. Decomposition of precursor (**A**) to nanodispersed CdS

Hexadecylamine (HDA) (4 g) was degassed at 120 °C for 30 min. The HDA was then heated to 180 °C under nitrogen. Complex **A** (0.25 g, 0.855 mmol) was suspended in tri-n-octylphosphine (4 mL) and injected into the hot HDA. The reaction was allowed to proceed for 30 min and the resultant yellow suspension was then cooled to 70 °C and the product isolated by washing with methanol (2 × 50 mL) and centrifuging. A similar procedure was used to decompose complex **B** (0.25 g, 0.684 mmol).

3. Results and discussion

3.1. Precursor structure

3.1.1. Structure of complex (**A**) $[Cd(NH_2CSNHNH_2)Cl_2]_n{\cdot}H_2O$

The structure of complex **A** (Fig. 1) is very similar to that reported by Woode et al. [28], showing only a small variation in the unit cell with a similar bonding arrangement. The compound crystallises into the monoclinic Cc space group. Complex **B** (Fig. 2), on the other hand, crystallises in the monoclinic C2/c space group. The lattice of complex **B** consists of infinite chains of $CdCl_4$ units linked into CdL_2 units via a Cd–S–Cd bridge (L is a thiosemicarbazide). The chloride ions lie almost symmetrically around the cadmium centre in the $CdCl_4$ moiety in a square planar geometry. The sulfur bridge is generated though a thiosemicarbazide ligand which lies fractionally closer to the $CdCl_4$ moiety than CdL_2 (cf 2.735(1) Å vs 2.862(1) Å). This is probably the result of the thiosemicarbazide molecules tilted orientation toward the $CdCl_4$ moiety (N(1)–S(1)–Cd(1) 86° cf 98° for Cd(2)). The CdL_2 units have the two thiosemicarbazide ligands lying in a square planer arrangement bound through both the sulfur and the nitrogen atoms. This results in a considerably shorter Cd–S bond for the chelating ligand than for the bridging ligand (Cd(2)–S(1) 2.862(1) Å cf Cd(2)–S(1) 2.589(1) Å). There are significant inter-chain and intra-chain bonding through NH–S and NH–Cl interactions (eg Cl(1)–N′(2) 3.400(3) Å; Cl(2)–N′(1) 3.234(3) Å; S(2)–N′(3) 3.582(3) Å;

S(2)–N′(2) 3.395 Å). It is interesting to note the effect of the chelation of the thiosemicarbazide ligand on the length of the Cd–S bond. In both structures chelation results in a Cd–S bond length of 2.585(3) Å, whereas the non-chelate has a bond length of 2.860(3) Å. Selected bond lengths and bond angles for both complexes are shown in Tables 2 and 3, respectively.

3.1.2. Thermal analysis of the precursors

The thermogravimetric (TGA) decomposition data for both the precursors is shown in Fig. 4. The major difference in the decomposition profiles of the two compounds is difference of *ca.* 50 °C in the major decomposition step. Complex **A** showed major decomposition at 200 °C, which is attributed to the loss of the thiosemicarbazide ligand. Complex **B** showed an initial mass loss of approximately 4.5%, which is associated with the loss of water (4.9% calculated). Thereafter, **B** showed major decomposition starting at approximately 250 °C. The decomposition of both precursors continued gradually up to about 500 °C. The difference shown by the complexes upon decomposition is most likely an effect of the structural changes, which could explain why different nanomaterials of different phases were formed. The decomposition patterns, however, seem consistent with two compounds which have very

similar structures and nominal formulae. The mechanism in which the CdS nanomaterials are formed is perhaps by the decomposition process. An overall ~50% mass loss is consistent with the formation of CdS, and it would appear that at 500 °C neither precursors approach this degree of decomposition. It does however seem likely that some $CdCl_2$ would also be formed and that the decomposition of this would require the higher temperatures. In the nanoparticle synthesis experiments the formation of $CdCl_2$ would not be a problem as it seems likely that it would be dissolved in the reaction media.

3.2. Preparation of CdS nanomaterials

The complexes were both decomposed in hexadecylamine at 180 °C for 30 min. In each case a pale yellow product was isolated. The UV absorption spectra (Fig. 5) were recorded and showed a significant blue shift in the band edge compared to that for bulk CdS (515 nm) (for materials synthesized using complex **A** the band edge was at 418 nm, and using complex **B** at 430 nm). The photoluminescence spectra (Fig. 5) both showed a large broad peak at 500 nm, which is consistent with the traps/defects in cadmium sulfide. Powder XRD of the materials showed a significant difference between the two products (Fig. 6). The product from complex **A** gave the typical hexagonal diffraction pattern (JCPDS 41–1049). However, the diffraction pattern for **B** was more difficult to interpret. On an initial examination, the pattern seems close to cubic, typified by the absence of the {1 0 2} and {1 0 3} lines. The sharp diffraction line at $2\theta = 25°$ cannot be ignored, as it is consistent with the {1 0 0} plane for the hexagonal form of CdS. The p-XRD results can be best understood in light of the morphology of the material (Figs. 7 and 8). In both cases there is a predominance of anisotropic material. Whilst the aspect ratios of the materials are approximately the same, there is a significant difference in the widths of the rods. Compound **A** gave rods with widths approaching the Bohr radius of 6.0 nm (±1.5 nm), however compound **B** results in rods with significantly smaller widths of 3.0 nm (±0.5 nm). These rod widths are consistent with the observed UV absorption spectra. Furthermore measurement of the lattice spacing of the rods leads to the conclusion that the long axis is the *c*-axis of the unit cell. If the p-XRD patterns are considered in light of this data, it may be seen that diffraction from the {1 0 0} planes will

approximate to an infinite lattice much more closely than planes with contributions from an orthogonal axis. Taking this into account one would expect to see a broadening of the {0 0 2} and {1 0 1} lines as well as the {1 1 0} and {1 1 2} lines. Furthermore the broadening of the {1 1 2} line should be greater than that for the {1 1 0} line, as is observed here in sample **A**.

4. Conclusions

Cadmium thiosemicarbazide complexes are useful precursors for the preparation of anisotropic cadmium sulfide nanomaterials. Furthermore the nature of the precursor and the ease of thermal decomposition can significantly affect the morphology of the final products.

5. Supplementary data

CCDC 602904 and 602905 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Reduction by $NaBH_4$ of the imine functions of (5,7,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradec-4-ene)-nickel(II) and -copper(II), and of their 13-ethyl-5,7,7-trimethyl-homologues, yield the nitro-substituted cyclic tetraamine cations (5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)-nickel(II) and -copper(II), $[M(neh)]^{2+}$, and (13-ethyl-5,5,7-trimethyl-homologues, $[M(nph)]^{2+}$, respectively. The nickel(II) cations form square–planar, singlet ground, state salts with poorly coordinating anions and octahedral, triplet ground state, compounds with additional ligands, *trans*-β-$[Ni(neh)A_2]$, $A^- = Cl^-$, NCS^- and *trans*-β-$[Ni(neh)A_2](ClO_4)_2$, X = NH_3, MeCN, all with nitrogen configuration III, 1*R*,4*R*,8*S*,11*S* = β. With oxalate the chain-polymeric compound *catena-trans*-β-$[Ni(neh)(\mu\text{-}C_2O_4)]_n \cdot 3n(H_2O)$ is formed. Folded macrocycle compounds *cis*-α-$[Ni(neh)(C_5H_7O_2)]ClO_4$ and *cis*-α-$[\{Ni(neh)\}_2(C_2O_4)](ClO_4)_2$ are formed with the chelates acetylacetonate and oxalate, with configuration 1*R*,4*R*,8*R*,11R = α. These react with $HClO_4$ to form metastable α-$[Ni(neh)](ClO_4)_2$ with retention of configuration. The copper(II) cations form crimson salts with poorly coordinating anions and compounds of the type β-[Cu(neh)A]ClO_4 of varying shades of blue with coordinating anions. Structures of singlet ground state square–planar nickel(II) compounds β-$[Ni(neh)](ClO_4)_2 \cdot H_2O$, β-$[Ni(neh)](ClO_4)_2$, β-$[Ni(neh)]_2[ZnCl_3(OH_2)]_2[ZnCl_4] \cdot H_2O$ and α-$[Ni(neh)](ClO_4)_2$, the triplet ground state chain-polymeric compound *catena-trans*-β-$[Ni(neh)(\mu\text{-}C_2O_4)]_n \cdot 3n(H_2O)$ and of square–pyramidal β-$[Cu(nph)Cl]ClO_4$ are reported.

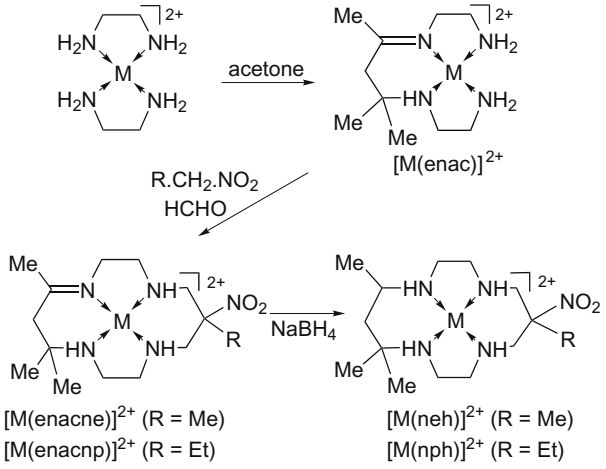
1. Introduction



Numerous metal-ion azamacrocycle compounds have been prepared by ring-closing Mannich-like reactions of the terminal primary amine groups of linear amine complexes with methanal plus a diprotic carbon acid [1–3]. Reactions with methanal plus nitroalkanes, R–CH_2–NO_2, link terminal NH_2 groups of polyamines by forming a 1,5-diaza chelate ring with 3*R*,3-nitro substituents. Complexes of linear tetraamines react to give cyclic tetraamine products with single (nitro plus alkyl) substituents and structures have been reported for the copper(II) compounds with 13–16-membered macrocyclic rings [4–8].

Metal-ion amine–imine compounds, including azamacrocycle compounds, have been prepared by condensation reactions of metal amine complexes with acetone [9]. Reactions of bis(ethane-1,2-diamine)-nickel(II) or -copper(II) with acetone yield (4,6,6-trimethyl-3,7-diazanon-3-ene-1,9-diamine)-nickel(II) or -copper(II), $[M(enac)]^{2+}$ [10,11], which react with methanal and nitroethane (or nitropropane) to yield the nitro-substituted imine–triamine azamacrocyclic cations (5,7,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradec-4-ene)-nickel(II) or -copper(II), $[M(enacne)]^{2+}$ {or from nitropropane (13-ethyl-5,7,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetradec-4-ene)-nickel(II) or -copper(II), $[M(enacnp)]^{2+}$} [12–14], see Scheme 1.

Structures have been determined for $[Ni(enacne)][ZnCl_4]$ [12], $[Cu(enacnp)(OH_2)](ClO_4)_2$ [13], $[Cu(enacnp)][Ni(CN)_4] \cdot H_2O$ [14] and $[Cu(enacne)(NCS)]ClO_4 \cdot H_2O$ [15]. The structures of $[Ni(enacne)][ZnCl_4]$, $[Cu(enacnp)(OH_2)](ClO_4)_2$ and $[Cu(enacne)(NCS)]ClO_4 \cdot H_2O$ have disorder manifest as superimposed 5,7,7-trimethyl-4-ene and 5,5,7-trimethyl-7-ene structures, with disorder of the N4 or N8 location of the imine function and of the C5 or C7 location of the *gem*-dimethyl function. This was attributed to co-crystallisation of enantiomers arising from the C13 chiral centre [12].

Scheme 1. Preparations of $[M(enac)]^{2+}$, $[M(neh)]^{2+}$ and $[M(nph)]^{2+}$, M = Ni(II), Cu(II).

In this communication, the preparations and properties of compounds of nitro-substituted cyclic tetraamines formed by the reduction of the imine functions of $[M(enacne/np)]^{2+}$ cations by $NaBH_4$ are described, and the structures of compounds of the resulting nitro-substituted cyclic tetraamines neh and nph are reported.

2. Results

Reduction by $NaBH_4$ of $[Ni(enacne)]^{2+}$, $[Ni(enacnp)]^{2+}$, $[Cu(enacne)]^{2+}$ and $[Cu(enacnp)]^{2+}$ as perchlorate salts, was studied in a variety of solvents. The imine functions were reduced leaving the nitro functions unaffected, forming the cyclic tetraamine cations $[Ni(neh)]^{2+}$, $[Ni(nph)]^{2+}$, $[Cu(neh)]^{2+}$ and $[Cu(nph)]^{2+}$ respectively, see Scheme 1.

The properties of the these cations are generally similar to those of their amine–imine analogues, $[M(enacne)]^{2+}$ and $[M(enacnp)]^{2+}$ [12–15].

The nickel(II) cations form orange coloured singlet ground state salts with poorly coordinating anions (such as perchlorate or chlorozincates) with nitrogen configurations III [16], 1*RS*,4*RS*,8*SR*,11*SR*, labeled as β. The cations coordinate additional ligands to form triplet ground state octahedrally coordinated compounds. With unidentate coordinating anions the cations form *trans*-compounds, also with configuration III, (e.g. *trans*-β-$[Ni(neh)(NCS)_2]$ and *trans*-β-$[Ni(neh)Cl_2]$). Crimson β-$[Ni(neh)(NH_3)_2](ClO_4)_2$, which separates from concentrated ammonia solution, loses the ammonia on exposure to the atmosphere. A grey–green bis(acetonitrile) adduct which crystallises from acetonitrile slowly loses the acetonitrile on exposure to the atmosphere. A grey–green-coloured chain-polymeric μ-oxalato compound, *catena*-β-$[Ni(neh)(\mu\text{-}C_2O_4)]_n \cdot 3n(H_2O)$ crystallises when oxalate is added to a neutral aqueous solution of $[Ni(neh)](ClO_4)_2$.

With the chelates oxalate and pentane-2,4-dionate the water-insoluble blue-coloured compounds *cis*-α-$[Ni(neh)(acac)]ClO_4$ and *cis*-α-$[\{Ni(neh)\}_2(C_2O_4)](ClO_4)_2$ are formed. These have the macrocycle folded with nitrogen configuration V, 1*RS*,4*RS*,8*RS*,11*RS*, labeled as α. Reaction of α-$[Ni(neh)(acac)]ClO_4$ with acid yields a solution containing metastable α-$[Ni(neh)]^{2+}$. The very slow interconversion between the nitrogen configurations in acid solution enabled preparation of metastable square–planar α-$[Ni(neh)](ClO_4)_2$. Similar reactions have been observed for other nickel(II) tetraaza macrocycle compounds [17–20].

The copper(II) cations form dark red salts with poorly coordinating anions, and with coordinating anions form compounds of various shades of blue, such as $[Cu(neh)X]ClO_4$, $X = Cl^-$, NCS^- or NO_2^-.

3. Structural studies

See Section 5.2 for crystallographic details.

Slow crystallisation of the perchlorate salt of $[Ni(neh)]^{2+}$ from water gave dark-orange coloured crystals of the monohydrate **3.1**. More rapid crystallization from water, or crystallization from organic solvents, gave light orange coloured crystals of the unhydrated salt, which has a poorly ordered structure **3.2**, which is described in the Supplementary data.

Attempts to prepare the tetrachlorozincate salt gave a product with an unusual stoichiometry, shown for structure **3.3** to have both tetrachlorozincate(II) and aqua-trichlorozincate(II) anions. The structure **3.5** is of a chain-polymeric compound with $Ni(neh)^{2+}$ cations linked by oxalate ions. The metastable square–planar compound α-$[Ni(neh)](ClO_4)_2$ is reported as structure **3.4**. The poorly ordered structure **3.6** of square–pyramidal β-$[Cu(nph)Cl]ClO_4$ is described in the Supplementary data.

3.1. The structure of 1RS,4RS,7RS,8SR,11SR,13RS-(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) perchlorate hydrate, β-$[Ni(neh)](ClO_4)_2 \cdot H_2O$

The asymmetric unit of this compound consists of two singlet ground state nickel(II) cations, four perchlorate anions and two water molecules. See Fig. 1 for a view of the asymmetric unit. The nickel(II) ions are in square–planar coordination by the four secondary amine nitrogen atoms of the cyclic tetraamine 5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane. Cation 1 has Ni1 and ring atoms N1–C14, with water molecule including O1 weakly interacting in one axial site and cation 2 has Ni2, ring atoms N21–N34 and water O2. See Fig. 2 for a view of the cation 1 and associated water molecule and Table 1 for dimensions of the cations.

The cations show small tetrahedral distortions of the N_4 donor group (r.m.s. displacements of N-atoms from the N_4 planes are ±0.043(1) Å for cation 1, with Ni1 0.0242(6) Å from the plane and ±0.047(1) Å for cation 2, with Ni2 0.0469(6) Å from the plane). The dimensions about the nickel(II) ions are normal for square–planar singlet ground state nickel(II), with all Ni–N distances similar, with mean Ni–N = 1.95(2) Å. The five-membered chelate rings

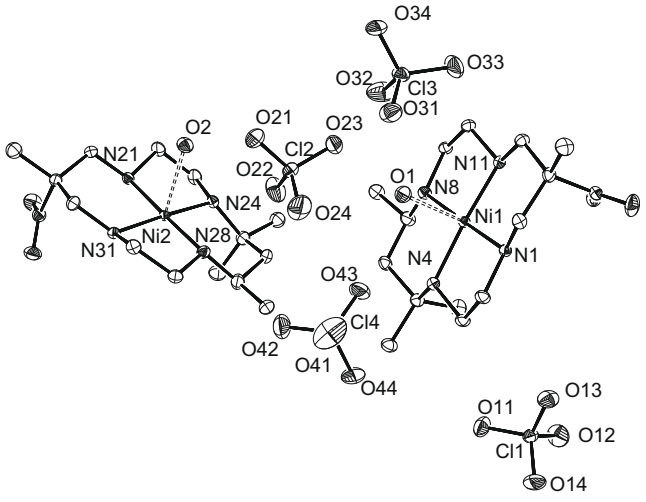

Fig. 1. The asymmetric unit for β-$[Ni(neh)](ClO_4)_2 \cdot H_2O$, drawn [30] with probability ellipsoids at the 50% confidence level, with hydrogen atoms omitted.

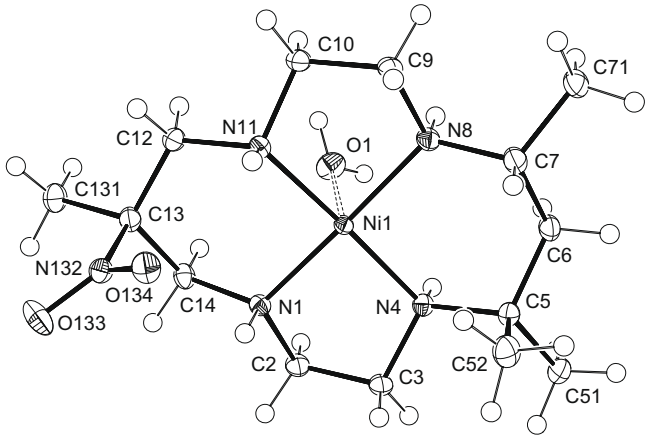

Fig. 2. The cation 1 and associated water molecule for β-[Ni(neh)]$(ClO_4)_2 \cdot H_2O$, drawn [30] as for Fig. 1, with hydrogen atoms shown as circles of arbitrary radius.

Table 1
Selected dimensions (Å, °) for β-[Ni(neh)]$(ClO_4)_2 \cdot H_2O$.

Atoms	Dimension	Atoms	Dimension
Ni1–N1	1.929(6)	Ni2–N21	1.943(5)
Ni1–N4	1.953(6)	Ni2–N24	1.949(5)
Ni1–N8	1.931(7)	Ni2–N28	1.957(6)
Ni1–N11	1.952(6)	Ni2–N31	1.954(5)
N1–Ni1–N4	87.0(3)	N21–Ni2–N24	86.4(2)
Ni1–O1	2.566(7)	Ni2–O2	2.592(7)
N1–Ni1–N8	178.2(3)	N21–Ni2–N28	179.1(2)
N1–Ni1–N11	92.0(2)	N21–Ni2–N31	94.7(2)
N4–Ni1–N8	93.6(3)	N24–Ni2–N28	92.8(2)
N4–Ni1–N11	178.0(3)	N24–Ni2–N31	178.7(2)
N8–Ni1–N11	87.5(3)	N28–Ni2–N31	86.2(2)

have asymmetric gauche conformations and the six-membered chelate rings both have chair conformations. The axially oriented C13-nitro substituent and the axial component of the C5-dimethyl group are oriented to the same side of the N_4 plane. Atomic displacements from NiN_2 chelate planes are listed in Table S1 in the Supplementary data.

The cations both have the 1*S*,4*S*,8*R*,11*R* nitrogen configuration III, usual for cyclam-like tetraamines in planar coordination, with approximate mirror symmetry (for cation 1 through C13, Ni1 and C6) apart from the axially oriented methyl substituent (C52)H_3 and nitro group (N132, O133, O134), and analogously for cation 2. The atoms C7 and C13 (and C27 and C33) are also chiral centres, C13 because of the different substitutions present at C5 and C7, with overall configuration 1*S*,4*S*,7*R*,8*R*,11*R*,13*R* for both cations.

The main difference between the two cations is in the orientation of the nitro groups, which is apparently determined by local hydrogen bonding. For cation 1 the nitro group is aligned approximately with the direction N11···C13, while for cation 2 the nitro group is aligned approximately normal to Ni2···C23 (with O131···C14 = 2.68 Å and O132···C14 = 2.75 Å).

The cations each occur as inversion related pairs in the unit cell, linked by a hydrogen bond (N1–H1···O132 ($-x$, $-y$, $-z$) or N21–H21···O232 ($-x$, $-y$, $-z$). The closest axial approach to each nickel ion is by a water molecule (including O1 for Ni1 and O2 for Ni2), on the side of the NiN_4 'plane' remote from the axial methyl and nitro groups (angles O–Ni–N range from 88.49(5) to 92.95(5)° for Ni1 and from 89.54(5) to 92.76(5)° for Ni2). The cations, anions and water molecules are linked by hydrogen bonding, listed in Table S2 of the Supplementary data. The structure shows no indication of the disorder in the location of the axial methyl substituents observed for structures **3.2, 3.3, 3.5** and **3.6.**

3.2. The structure of 1RS,4RS,7RS,8SR,11SR,13RS-(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) perchlorate, β-[Ni(neh)]$(ClO_4)_2$

Disorder of the perchlorate ions precluded a satisfactory structural solution for this compound, which is described more fully in the Supplementary data, with selected dimensions listed in Table S3 and hydrogen bonds in Table S4. The cations are similar to those of the previous compound, as shown in Fig. 1, but probably with disorder in location of the axial methyl group, arising from co-crystallisation of enantiomers. The compound unusually has three cations in the asymmetric unit, arranged in sequence in columns, as shown in Fig. 3. Poorly ordered perchlorate ions interleave with the cations, with weak axial interactions by the nickel(II) ions with perchlorate ion oxygen atoms.

3.3. The structure of bis-1RS,4RS,7RS,8SR,11SR,13RS-(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) bis(aquatrichlorozincate) tetrachlorozincate hydrate, β-[Ni(neh)]$_2$[$ZnCl_3(H_2O)$]$_2$[$ZnCl_4$] · H_2O

The asymmetric unit of this orange coloured, singlet ground state, compound contains two square–planar (tetraazamacrocycle)nickel(II) cations, labeled as for **3.1**, three anions and an independent water molecule including O1. One anion is a tetrachlorozincate(II) ion (including zinc atom Zn1 and chloride ions Cl11–Cl14) while the other two anions are aqua-trichlorozincate(II) ions (one including Zn2, water oxygen O2 and chloride ions Cl21–Cl23 and the other including Zn3, water oxygen atom O3 and partial occupancy chloride ions Cl31–Cl36). See Table 2 for dimensions and Fig. 4 for a view of the asymmetric unit.

The two cations have generally similar structures; similar to the cation shown in Fig. 1, though their environments differ. The dimensions about the nickel(II) ions are normal for square–planar singlet ground state nickel(II), with all Ni–N distances similar, with

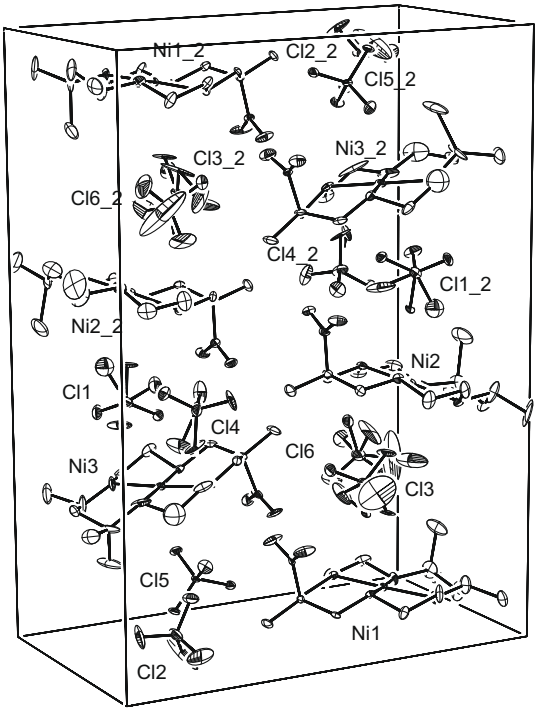

Fig. 3. View of β-[Ni(neh)]$(ClO_4)_2$ down the *b* axis of the unit cell, drawn [30] with ellipsoids at 30% probability, with hydrogen atoms omitted. The symmetry operation 2 = $-x$, $y + 1/2$, $-z$.

Table 2
Selected dimensions (Å, °) for β-[Ni(neh)]$_2$[ZnCl$_3$(H$_2$O)]$_2$[ZnCl$_4$] · H$_2$O.

Atoms	Dimension	Atoms	Dimension
Ni1–N1	1.929(6)	Ni2–N21	1.943(5)
Ni1–N4	1.953(6)	Ni2–N24	1.949(5)
Ni1–N8	1.931(7)	Ni2–N28	1.957(6)
Ni1–N11	1.952(6)	Ni2–N31	1.954(5)
N1–Ni1–N4	87.0(3)	N21–Ni2–N24	86.4(2)
N1–Ni1–N8	178.2(3)	N21–Ni2–N28	179.1(2)
N1–Ni1–N11	92.0(2)	N21–Ni2–N31	94.7(2)
N8–Ni1–N4	93.6(3)	N24–Ni2–N28	92.8(2)
N4–Ni1–N11	178.0(3)	N24–Ni2–N31	178.7(2)
N8–Ni1–N11	87.5(3)	N28–Ni2–N31	86.2(2)

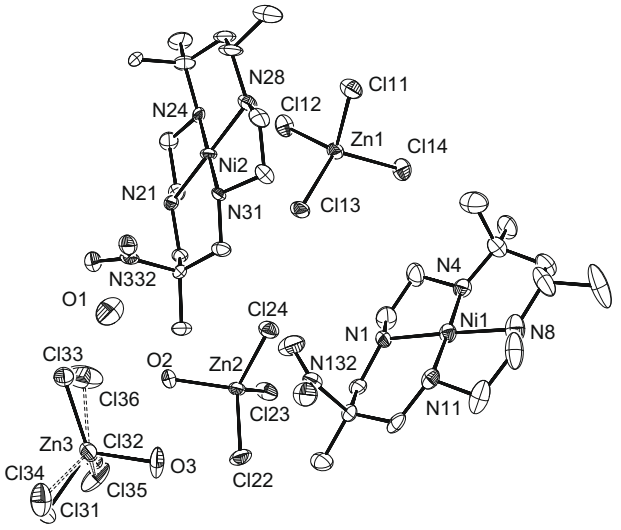

Fig. 4. The asymmetric unit for β-[Ni(neh)]$_2$[ZnCl$_3$(H$_2$O)]$_2$[ZnCl$_4$] · H$_2$O, drawn [30] as for Fig. 1.

mean Ni–N = 1.95(2) Å. The N$_4$ donor sets are near co-planar [r.m.s. displacements of N-atoms from N$_4$ planes are ±0.028(3) Å for the cation 1 and ±0.007(3) Å for the cation 2, with the Ni-atoms in-plane]. The angle between the two N$_4$ planes is 38.2(2)°. The cations have the configuration III of the coordinated nitrogen centres and a macrocycle conformation similar to that of the perchlorate salts, above, see Table S5 in the Supplementary data for displacements of atoms from the NiN$_2$ chelate planes.

When the structure was refined with an initially assumed 5,5,7-trimethyl structure of the cations then significant residual electron density was present in the axial substitution sites of both C7 and C27, while the freely refined site occupation factor (sof) of the axial methyl groups (C52)H$_3$ and (C252)H$_3$ were ca. 0.7. These residual peaks were assigned as partial occupancy axial methyl groups (C72)H$_3$ and (C272)H$_3$, as described elsewhere [12,21]. Refinement with complementary sof for (C52)H$_3$ and (C72)H$_3$, {and also C252)H$_3$ and (C272)H$_3$}, i.e. with superimposed 5,5,7-trimethyl and 5,7,7-trimethyl arrangements, led to the sof for (C52)H$_3$ of 0.70(2) and for (C72)H$_3$ of 0.30(2) for the cation 1, and with corresponding values of 0.72(2) and 0.28(2) for the cation 2.

The configuration of the major disorder component for both cations is 1*S*,4*S*,7*S*,8*R*,11*R*,13*R* and that of the minor component is 1*R*,4*R*,7*R*,8*S*,11*S*,13*S* (after renumbering as 5,5,7-trimethyl- to comply with IUPAC nomenclature) so the disorder components are enantiomers arising from the chiral centres C13 and C33, respectively.

Apart from the axial methyl group, the cations have approximate mirror symmetry through C13, C131, N15, Ni and C6 (or through C23, C231, N25, Ni2 and C26) respectively. The five-membered chelate rings have asymmetrical gauche conformations. The 13-methyl-13-nitro-substituted chelate rings have chair conformations, with the nitro substituent axially oriented. The trimethyl-substituted chelate rings also have chair conformations with the axially oriented methyl substituent oriented to the same side of the N$_4$ plane as the nitro substituent. The nitro-substituents are aligned approximately normal to the direction Ni···C13. The conformations of the macrocycles for the two cations are generally similar, but differ in detail, indicating the flexibility of these rings, with details of conformation determined by the environment.

The cations including Ni2 occur in the unit cell as inversion related pairs, with Ni2···Ni2 (−*x* + *1*, −*y* + *1*, −*z* + *1*) = 6.792(2) Å, linked by N–H···O–N inter-pair hydrogen bonds (as also observed for [Ni(enacne)][ZnCl$_4$] [12]). Close approaches of partial occupancy axial methyl substituents, C52···C72 (−*x*, −*y* + *1*, −*z* + *1*) = 2.37(2) Å, implies correlation of the site occupancies. The cations including Ni1 also occur as inversion related pairs, but the macrocycle cations are "back to back", with Ni1···Ni1 (−*x* + *1*, −*y* + *1*, −*z* + *1*) = 8.582(2) Å. There is no close interaction between the axial methyl substituents for the pairs for these cations.

The nickel(II) ions have only distant axial interactions: Ni1···Cl23 (*x*, *y* + *3/2*, −*z* + *1/2*) = 3.269(2); Ni1···Cl14 (*x*, *y* + *1/2*, −*z* + *1/2*) = 3.529(2); Ni2···Cl13 = 3.182(2) and Ni2···O333 (−*x* + *1*, −*y* + *1*, −*z* + *1*) = 3.622(5) Å.

The anions [(Zn1)Cl$_4$]$^{2-}$ and [(Zn2)Cl$_3$(OH$_2$)]$^-$ have approximately tetrahedral geometries. The anion [(Zn3)Cl$_3$(OH$_2$)]$^-$ shows disorder, which was modeled with two sets of three chloride ions, refined with complementary sof, arranged about the (Zn3)···(O3) axis, Cl31, Cl32 and Cl33 with sof = 0.75(2) and Cl34, Cl35 and Cl36 with sof = 0.25(2), with the sets rotated relatively by about 10°. There was no indication of similar disorder for the Zn2 anion. Bond lengths for the anions are in the ranges: Zn1–Cl, 2.240(2)–2.290(2); Zn2–O2, 2.022(5); Zn2–Cl, 2.230(2)–2.260(2); Zn3–O3, 2.024(6); Zn3–Cl (major components) 2.20(1)–2.284(4) Å.

The cations, anions and independent water molecule are linked by hydrogen bonds, listed in Table S6 of the Supplementary data.

3.4. The structure of 1RS,4RS,7SR,8RS,11RS,13RS-(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) perchlorate, α-[Ni(neh)](ClO$_4$)$_2$

The asymmetric unit of this orange compound consists of two (tetraazamacrocycle)nickel(II) cations, labeled as for structure **3.1**, and four perchlorate ions. The two cations have similar structures, with the nickel(II) ions in square–planar coordination by the four secondary amine nitrogen atoms of the macrocycle, the cation including Ni1 is shown in Fig. 5. The dimensions of the NiN$_4$O groups are normal for singlet ground state [Ni(tetraazamacrocycle)]$^{2+}$ cations, see Table 3. The Ni–N distances are similar, with mean value 1.932(8) Å, slightly shorter than the values for the configuration III cations of **3.1** and **3.3**. The N$_4$ donor groups show slight tetrahedral twisting, with r.m.s. displacements of ±0.066(3) Å for the N atoms and 0.014(2) Å for Ni1, with values ±0.018(3) and 0.018(2) Å for cation 2. A perchlorate ion oxygen atom interacts weakly in one axial coordination site for each cation (Ni1···O11 = 2.790(5), Ni2···O21 = 2.572(5) Å).

The cations are enantiomers, both with nitrogen configuration V of the secondary amine centres. Cation 1 has the 1*S*,4*S*,8*S*,11*S* configuration and cation 2 the 21*R*,24*R*,28*R*,31*R* configuration. This configuration is least strained for the azamacrocycle in folded coordination but is metastable in planar coordination, as it forces the macrocycle to adopt a non-optimum conformation, with the two six-membered chelate rings in twist conformations [17–20]. Displacements of atoms from the NiN$_2$ chelate planes are shown in Table 4, which should be compared with the values for the usual configuration III atomic displacements in Tables S1, S3 and S5.

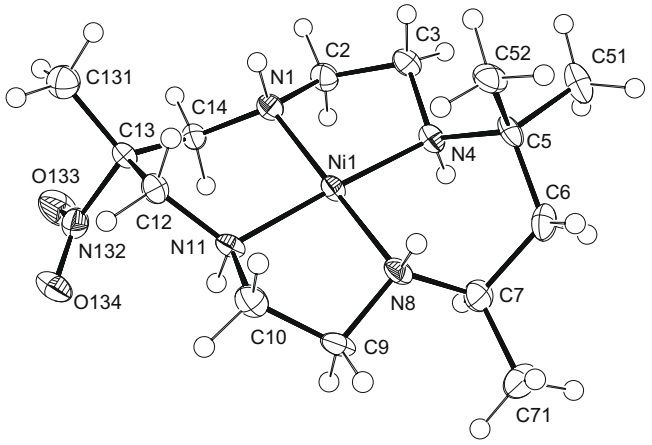

Fig. 5. The cation 1 for α-[Ni(neh)](ClO$_4$)$_2$, drawn as for Fig. 2.

Table 3
Selected dimensions for α-[Ni(neh)](ClO$_4$)$_2$.

Atoms	Distance (Å)	Atoms	Angle (°)
Ni1–N1	1.928(4)	N1–Ni1–N4	87.6(2)
Ni1–N4	1.938(4)	N1–Ni1–N8	176.8(2)
Ni1–N8	1.926(4)	N1–Ni1–N11	92.2(2)
Ni1–N11	1.932(4)	N4–Ni1–N8	93.5(2)
Ni1–O11	2.791(5)	N4–Ni1–N11	175.2(2)
Ni2–N21	1.932(4)	N8–Ni1–N11	87.0(2)
Ni2–N24	1.928(4)	N21–Ni2–N24	87.7(2)
Ni2–N28	1.926(4)	N21–Ni2–N28	176.4(2)
Ni2–N31	1.921(4)	N21–Ni2–N31	91.9(2)
Ni2–O21	2.569(5)	N24–Ni2–N28	93.3(2)
		N24–Ni2–N31	174.3(2)
		N28–Ni2–N31	87.4(2)

The conformation adopted orients the C51 and C71 methyl substituents equatorially and the C52 methyl substituent axially (and similarly for the C251, C271, C252 and C332 methyl groups), with the axially interacting perchlorate ion on the less crowded side, opposite to C52 (or C252). The C131 (C231) methyl and N132 (N332) nitro nitrogen atoms are approximately equally displaced from the NiN$_4$ plane, with the nitro groups oriented approximately normal to the Ni1···C13 (or Ni2···C133) directions. There is no indication of disorder in the location of the axial methyl substituents as observed for other [Ni(neh)]$^{2+}$ compounds.

Hydrogen bonds, which link the anions and cations, are listed in Table S7 of the Supplementary data.

3.5. The structure of catena-(bis(μ^2-oxalato-O,O')-1RS,4RS,7RS,8SR,11SR,13RS-(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II)·trihydrate, catena-trans-[β-Ni(neh)(μ-C$_2$O$_4$)]$_n$ · 3n(H$_2$O)

This pale grey–green-coloured triplet ground state compound has a chain-polymeric structure, with square–planar β-[Ni(neh)]$^{2+}$ cations linked axially by bridging bis-unidentate oxalato groups. The asymmetric unit includes one azamacrocyclic nickel(II) cation, one bridging oxalate ion and three independent water molecules, see Figs. 6 and 7. The dimensions about the nickel(II) ion, shown in Table 5, are normal for triplet ground state octahedral Ni(II). The Ni1-O1 distance is slightly shorter than the Ni1-O2^A (symmetry operation A = x + 1/2, −y + 1/2, z + 1/2) distance although O1 is on the more crowded side of the macrocycle, towards which the axially oriented methyl and nitro-substituents are oriented. The N$_4$ group is near co-planar, with r.m.s tetrahedral twisting of ±0.001(1) Å, with Ni1 displaced by 0.039(1) Å from the plane towards O1. The five-membered chelate rings have gauche conformations and the six-membered chelate rings chair

		O133–N132–O134	123.7(2)

Symmetry operation A = $x + ½ - y + 1/2$, $z + ½$.

conformations, the overall conformation being similar to those of **3.1** and **3.3**, although the Ni–N distances are appreciably longer. The nitro group is aligned approximately normal to the C13···Ni1 direction. Displacements of atoms from NiN_2 chelate planes are listed in Table S8 of the Supplementary data.

As for the chlorozincate salt, **3.3**, the axial component of the *gem*-dimethyl group is disordered over sites axial with respect to ring atoms C5 and C7. The structure was refined with complementary sof for the two sites (sof of (C52)H_3 = 0.654(5)), with the disorder attributed to the presence of the enantiomers in ca. 2:1 proportions. The disorder components have the NH–C(Me)$_2$–CH_2CH(Me)–NH chelate ring reversed, which would be expected to lead to some disorder of all the atoms of the chelate ring. Site (C51)H_3 was resolved into sites (C51A)H_3 and (C51B)H_3, which were refined with the same complementary sof.

The linked macrocycle cations have Ni1···Ni1^A = 7.378 Å, with N_4 planes inclined at 5.3(1)° and twisted relatively (torsion angles N1–N8···N8^A–N4^A = 50.6(1)° and N4–N11···N11^A–N4^A = 56.1(1)°). The torsion angle O1–C21–C22–O2 = 114.8(1)°. The NH groups, oxalate ion and water molecules are linked by hydrogen bonding, listed in Table S9 of the Supplementary data.

3.6. The structure of chloro-1RS,4RS,7RS,8SR,11SR,13RS-(13-ethyl-5,5,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)copper(II) perchlorate, β-[Cu(nph)Cl]ClO_4

This blue compound has a square–pyramidal cation with a near co-planar cyclic tetraamine N_4 group and an axially coordinated chloride ion (r.m.s. displacements from the N_4 plane are: N atoms: ±0.003(3), Cu1, 0.155(6); Cl1, 2.788(6) Å). Mean Cu–N = 2.02(1) and Cu–Cl = 2.637(3) Å, see Fig. 8. Disorder in the location of the

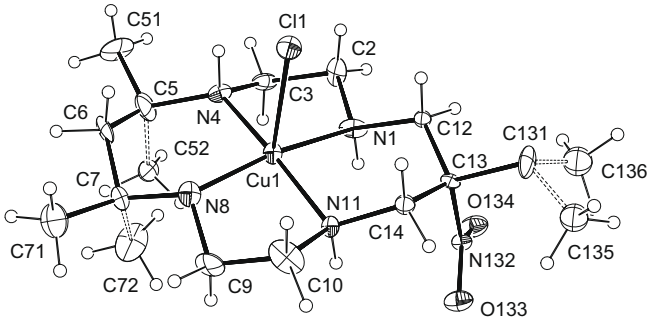

Fig. 8. The cation of β-[Cu(nph)Cl]ClO_4, drawn [30] as for Fig. 2. Sites C52, C72, C135 and C136 have partial occupancy, see text.

axial methyl substituents, methyl group of the ethyl substituent and of the perchlorate ion precluded a fully satisfactory solution of the structure, which is described more fully in the Supplementary data, with dimensions listed in Table S10.

4. Discussion

The azamacrocycle cations [M(enacne/np)]$^{2+}$, M = Ni(II) or Cu(II), are formed by a combination of two template condensations; an aldol-like reaction of bis(ethane-1,2-diamine) complexes with acetone to form the trimethyl-1-amine-3-imine linked [M(enac)]$^{2+}$ cation [9–11], and a Mannich-like reaction of [M(enac)]$^{2+}$ with methanal and the diprotic acid nitroethane to form the 2-methyl-2-nitro-1,3-diamine link [1–8]. The resulting "hybrid" macrocycle cation, [M(enacne)]$^{2+}$, combines features of the (5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetrdeca-4,11-diene)metal(II) cation, [M (*trans*[14]diene)]$^{2+}$ [9] and 6,13-dimethyl-6,13-dinitro-1,4,8,11-tetraazacyclotetrdecane)metal(II), [M(dino)]$^{2+}$ macrocyclic ligand cations [1,22]. Both [Ni(*trans*[14]-diene)]$^{2+}$ and [Ni(dino)]$^{2+}$ predominantly form singlet ground state compounds, the axially oriented methyl and nitro-substituents hindering access to the axial coordination sites of the metal ions. In contrast, the [Ni(enacne)]$^{2+}$ cation forms triplet ground state compounds, both *trans* with axially coordinated ammonia and a variety of anions and *cis* with the macrocycle folded to accommodate a chelate additional ligand [12].

The imine functions of the [Ni(*trans*-[14]diene)]$^{2+}$ and [Ni(enacne)]$^{2+}$ cations are reduced by $NaBH_4$ to form the (5,5,7,12,12,14-hexamethyl-1,4,8,11-tetraazacyclotetradecane) and (5,7,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane) cyclic tetraamine cations, respectively. The first occurs as C-*meso* and C-*rac* stereoisomers, which are readily separated for the nickel(II) cations because the C-*rac* isomer, tet*b*, has a much greater propensity to form compounds with chelate additional ligands with the macrocycle folded in the 1*RS*,4*RS*,8*RS*,11*RS* nitrogen configuration V than the C-*meso* isomer tet*a* [9]. The [M(enacne)]$^{2+}$ cations have a chiral centre at C13 so could, in principle, give rise to stereoisomeric reduction products, though for both nickel(II) and copper(II) one product was isolated, in ca. 75% yield. Appreciable amounts of tarry degraded material formed, so the potential yield of other products is small.

For all the structures of compounds of enacne/enacnp and neh/nph, as yet reported, the macrocycle is in square–planar coordination with the 1*SR*,4*SR*,8*RS*,11*RS* nitrogen configuration, III [16], which is least strained for planar coordination of cyclam-like azamacrocycles. For all these structures the nitro-substituent is axially oriented on a chair conformation chelate ring, to the same side of the "plane" as the axial component of the *gem*-dimethyl group. For [Ni(neh)]$(ClO_4)_2 \cdot H_2O$, structure **3.1**, the asymmetric unit contains two independent cations, both with the 1*S*,4*S*,7*R*,8*R*,11*R*,13*R* configuration; inversion centres ensuring chiral balance for the unit cell. It would appear that the $NaBH_4$ reduction of [Ni(enacne)]$^{2+}$ yields exclusively, or at least predominantly, the 7*RS*,13*RS* stereo-isomers.

Assessment of the stereochemistry for both the enacne and neh cations for several of the structures determined is complicated by the occurrence of disorder arising from co-crystallisation of cations with the N5-N8 trimethyl-amine-imine (enacne) or N5–N8 trimethyl-diamine (neh) chelate rings reversed. These disorder components for the enacne compounds are the 13*R* and 13*S* enantiomers, or for the neh cations the 7*R*,13*R* and 7*S*,13*S* enantiomers, typically present in ca. 0.7:0.3 proportions.

This disorder is not present for the singlet ground state perchlorate salt hydrate, structure **3.1**, but is present for the tetrachlorozincate salt, structure **3.3** (and probably also for the unhydrated

perchlorate salt, structure **3.2**) and is also present for the triplet ground state *catena*-μ-oxalato compound, structure **3.5**, which has appreciably longer Ni–N bond lengths. It is not present for the α-configuration perchlorate salt, **3.4**, which has a quite different conformation.

The same disorder phenomenon was observed for [Cu(enacne/np)]$^{2+}$ compounds [12–15] and is present for the [Cu(nph)(Cl)]ClO_4 structure **3.6**.

For the cyclic amine–imine compounds [Ni(enacne)][$ZnCl_4$], [Cu(enacnp)(OH_2)]$(ClO_4)_2$ and [Cu(enacne)(NCS)]$ClO_4{\cdot}H_2O$ this disorder leads to superposition of amine–imine chelate rings with inherently asymmetric conformations, with resulting intermediate C=N/C–N distances and apparent long C–CH_3 distances to the minor component axial methyl substituents. For the tetraamine compounds, now reported, these distances are more "normal", since reversal of the N4–N8 diamine chelate ring leads to smaller distortions in the chelate ring conformation.

As anticipated, the properties of the nickel(II) and copper(II) coordination compounds of the triamine–imine (enacne/enacnp) and tetraamine (neh/nph) azamacrocycles are generally similar. The [Ni(neh/nph)]$^{2+}$ cations exist as singlet ground state β-configuration cations in solutions in polar solvents such as water and as salts with poorly coordinating anions. The tendency of these cations to form triplet ground state *trans*-di-ligand compounds depends largely on the extent to which the axially oriented substituents "block" access to the axial coordination sites. The 'hybrid' [Ni(enacne)]$^{2+}$ cation forms such octahedrally coordinated compounds more readily than either of the 'parent' [Ni(*trans*[14]-diene)]$^{2+}$ or [Ni(dino)]$^{2+}$ cations. As examples, both [Ni(neh)]$^{2+}$and [Ni(enacne)]$^{2+}$ crystallize from water as triplet ground state compounds with chloride and thiocyanate ions, while the 'parent' cations do not. The formation of a triplet ground state bis(acetonitrile) adduct by [Ni(neh)]$(ClO_4)_2$, but not by [Ni(enacne)]$(ClO_4)_2$, may indicate that the more flexible neh ligand enables adoption of a conformation with less repulsion between the axial substituents and axially coordinated ligands. The tendency of the cations to form folded macrocycle compounds with chelates is also largely determined by interactions involving axial substituents, as exemplified by the facile formation of such species by the C-*rac* cation [Ni(tet*b*]$^{2+}$ and the resistance to such folding by the C-*meso* cation [Ni(teta)]$^{2+}$. The formation of triplet ground state α-[Ni(enacne)(O_2N)]ClO_4 but singlet ground state β-[Ni(neh)]$NO_2{\cdot}ClO_4 \cdot H_2O$ may indicate easier folding by the enacne macrocycle. Both [Ni(enacne)]$^{2+}$ and [Ni(neh)]$^{2+}$ form water-insoluble folded macrocycle compounds α-[Ni(L)(acac)]$(ClO_4)_2$ and α-[{Ni(L)}$_2(C_2O_4)$]-$(ClO_4)_2$, but it is not clear to what extent the insolubility is driving their formation. The *trans*-coordinated chain-polymer *catena-trans*-β-[Ni(neh)(μ-C_2O_4)]$_n \cdot 3n(H_2O)$ (structure **3.5**) crystallizes when oxalate is added to an aqueous solution containing [Ni(neh)]$^{2+}$. The compound is stable in aqueous solution but in the presence of perchlorate ions slowly converts to the insoluble di-nuclear bis-bidentate μ^4-oxalato compound α-[{Ni(neh)}$_2$-(C_2O_4)]$(ClO_4)_2$.

There is one other example in the Cambridge Structural Database [23] of a nickel(II) compound with an oxalato-bridged chain-polymeric structure similar to structure **3.5**; *catena*-(3,14-dimethyl-2,6,13,17-tetraazatricyclo(14.4.01.18.07.12)docosane)(μ-C_2O_4)nickel(II) dihydrate) [24], and one other with a chain-polymeric structure with the "non-bridging" oxygen atoms of the oxalate ion in bidentate coordination to another nickel(II) ion; [Ni_2(1,4,8,11-tetraazacyclotetradecane)$_2$(μ^3-C_2O_4)]$_n(ClO_4)_{2n} \cdot n(H_2O)$ [25].

Reaction with acid of the folded macrocycle α-configuration oxalato or propane-2,4-dionato compounds removes the chelate by protonation and produces a solution containing the square–planar α-configuration cation. This is metastable in acid solution but slowly in neutral and rapidly in basic solution converts to the stable β-configuration cation. These properties are similar to those observed with other nickel(II) cyclic tetraamine compounds [17–20].

The cations [Cu(neh/nph)]$^{2+}$ form dark red salts with poorly coordinating anions and compounds of varying shades of blue with coordinating anions such as Cl^-, NCS^-, NO_2^-, etc. [Cu(nph)]$(ClO_4)_2$ crystallises as the red anhydrous compound from non-aqueous solvents, but as a blue hydrate from water. Both cations form very sparingly soluble blue compounds with tetracyanonickelate(II), analogous to [Cu(nph){Ni$(CN)_4$}] $\cdot H_2O$ [14], which has trinuclear [(neh)Cu–NC–Ni$(CN)_2$–CN–Cu(neh)]$^{2+}$ cations.

The square–pyramidal structure **3.6** of β-[Cu(nph)Cl]ClO_4 has a structure similar to that of β-[Cu(neh)(NCS)]$ClO_4 \cdot H_2O$ [14], which also has disorder in the location of the axial methyl group. The displacement of the copper(II) ion from the N_4 best plane for these compounds varies with the strength of the interaction with the axial ligand, being 0.246(2) Å for [Cu(enacnp)$_2${Ni$(CN)_4$}]$^{2+}$ with strongly bound tetracyanonickelate(II), 0.205(2) Å for [Cu(enacne)(NCS)]$ClO_4{\cdot}H_2O$, 0.155(6) Å for [Cu(nph)Cl]ClO_4 and 0.143(1) Å for [Cu(enacnp)(OH_2)]$(ClO_4)_2$ [13–15].

The orientation of the nitro group appears to be determined largely by local hydrogen bonding interactions. For β-[Ni(neh)]$(ClO_4)_2 \cdot H_2O$ (cation 1), β-[Ni(neh)]$_2$[$ZnCl_3(H_2O)$]$_2$[$ZnCl_4$] $\cdot$ $0.5H_2O$, α-[Ni(neh)]$(ClO_4)_2$, β-[Ni(neh)](μ-C_2O_4)]$_n \cdot 3n(H_2O)$ and β-[Cu(nph)Cl]ClO_4, and for [Ni(enacne)][$ZnCl_4$] [12] the nitro group is aligned approximately parallel with the M···C13 direction whereas for β-[Ni(neh)]$(ClO_4)_2 \cdot H_2O$ (cation 2), the three cations of β-[Ni(neh)]$(ClO_4)_2$ and the [Cu(enacne/np)]$^{2+}$ compounds the group is aligned approximately parallel with the direction Cu···C13 [12,16].

The 13- and 14-membered nitro-substituted cyclic tetraamine copper(II) compounds (formed from linear tetraamines, methanal and nitroethane [4–8]) have the nitro group axially oriented on chair conformation chelate rings and oriented normal to the Cu···C(NO_2) direction, while the 15- and 16-membered ring compounds have the relevant chelate ring in a boat conformation with the nitro group 'parallel', with one oxygen atom weakly interacting in an axial coordination site.

5. Experimental

5.1. Preparation of compounds

The cyclic tetraamine(metal) cations, [M(neh/nph)]$^{2+}$, were prepared by $NaBH_4$ reduction of the imine functions of the triamine–imine cations, [M(enacne/np)]$^{2+}$, which were prepared as previously reported [12,13]. The tetraamine compounds are distinguishable from the triamine–imine precursor compounds by the absence of a ν(C=N) band at ca. 1655 cm^{-1} in the IR. The IR spectra of neh and nph analogues are generally indistinguishable. Bands in the "fingerprint" region arising from other species generally could not be assigned because of the complexity of the neh/nph spectrum. The nitro-substituted cyclic tetraamine cations are resistant to acid (other than nitric acid which rapidly oxidizes them) but are very slowly degraded in base.

Compounds containing perchlorate are potentially explosive and should be treated with caution.

5.1.1. *β-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) perchlorate, β-[Ni(neh)](ClO$_4$)$_2$, structures **3.1** and **3.2***

Ni(enacne)]$(ClO_4)_2$ (2 g) was dissolved in water (50 cm^3) and $NaBH_4$ (0.15 g, 1:1 mol equivalents; excess $NaBH_4$ reduces the yield of product) added, when gentle effervescence occurred and a blue–violet borohydrido complex [Ni(enacne)(BH_4)]ClO_4 formed and sometimes precipitated. The solution was left at ambient tem-

perature for 2d, while gentle effervescence occurred and any initial precipitate redissolved. The solution was filtered, acidified with perchloric acid and allowed to evaporate to small volume, while the orange product crystallised. This was filtered off, washed with ethanol and recrystallised from hot acetonitrile. A pale grey–green acetonitrile *adduct* slowly crystallised on standing (IR: ν(NH) 3286, 3208, ν(C≡N) 2307, 2277, 2253; $\nu_{asym}(NO_2)$ 1553 cm^{-1}). This adduct was filtered off and washed with cold ethanol. It slowly lost the acetonitrile on exposure to the atmosphere, though large crystals were quite persistent. The solid was boiled with ethanol, when the orange perchlorate salt crystallised. This *product* was filtered from the cold solution and recrystallised from hot water, methanol or acetone (containing a few drops of water)/propan-2-ol in ca. 75% yield. The crystallisation of the acetonitrile adduct purifies the material from any traces of unreduced [Ni(enacne)]$(ClO_4)_2$ which is much more soluble in this solvent. If the IR spectrum showed any ν(C=N) absorption at 1665 cm^{-1} then the recrystallisation from acetonitrile was repeated. *Anal.* Calc. for $C_{14}H_{31}Cl_2N_5NiO_{10}$: C, 30.1; H, 5.6; N, 12.5. Found for a sample of the anhydrous salt recrystallised from acetone/propan-2-ol: C, 30.3; H, 5.7; N, 12.6%. Spectra; IR (KBr) ν_{max} (cm^{-1}): ν(NH), 3221sh, 3194; $\nu_{as}(NO_2)$, 1552. Visible (water) λ_{max}: 462 (nm); ε: 46 mol^{-1} cm^{-1} dm^3.

Large well-formed, dark-orange crystals of the *monohydrate* (structure **3.1**) crystallised on slow evaporation from water, with water bands in the IR spectrum (KBr) ν_{max} (cm^{-1}): ν(OH), 3592, 3523; ν(NH), 3202; δ(HOH), 1637; $\nu_{as}(NO_2)$ 1556. This hydrate slowly effloresced in the atmosphere.

5.1.2. bis-β-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) tetrachlorozincate(II) bis(aquatrichlorozincate(II)) hydrate, β-[Ni(neh)]$_2$ [$ZnCl_4$][$ZnCl_3(OH_2)$] · H_2O, structure **3.3**

Zinc(II) chloride in small excess was added to a solution of [Ni(neh)]$(ClO_4)_2$ in hot 10:1 acetone: water. The orange crystalline *solid* was filtered off and recrystallised from hot water. *Anal.* Calc. for $C_{28}H_{68}Cl_{10}N_{10}Ni_2O_7Zn_3$: C, 25.4; H, 5.2; N, 10.6 Found: C, 25.1; H, 5.2; N, 10.3%. IR (KBr) ν_{max} (cm^{-1}): ν(OH), (3367, 3313)vs, br; ν(NH), 3219, 3109; δ(HOH), 1646sh, 1620; $\nu_{as}(NO_2)$, (1558,1546)s, sp.

5.1.3. α-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) perchlorate, α-[Ni(neh)]$(ClO_4)_2$, structure **3.4**

α-[Ni(neh)(acac)]ClO_4 (5.1.8, 1 g) was dissolved in acetone (10 cm^3) and aqueous perchloric acid (5 cm^3, 10%) added, when the colour changed from blue to orange. The orange *product* which crystallised as the solution evaporated was recrystallised by evaporation from acetone/propan-2-ol. The compound slowly isomerizes in solution to form the β-cation. IR (KBr) ν_{max} (cm^{-1}): ν(NH), 3203; $\nu_{as}(NO_2)$, 1558.

5.1.4. trans-β-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)(dithiocyanato-N)nickel(II), trans-β-[Ni(neh)$(NCS)_2$]

Sodium thiocyanate was added to a hot aqueous solution of [Ni(neh)]$(ClO_4)_2$. Salmon coloured crystals of the *product* were filtered from the cold solution and recrystallised from hot water. The compound is sparingly soluble in cold water, forming an orange coloured (dissociated) solution. It is soluble in a variety of polar organic solvents e.g. acetonitrile, acetone, dichloromethane, etc, forming blue–violet (associated) solutions. *Anal.* Calc. for $C_{16}H_{31}N_7NiS_2O_2$: C, 40.3; H, 6.6; N, 20.6. Found: C, 40.4; H, 6.7; N, 20.6%. IR (KBr): ν_{max} (cm^{-1}) ν(NH), ν(NH), 3300, 3233, all w; ν(NCS^-), 2061vs, sp; $\nu_{as}(NO_2)$, 1546sp.

5.1.5. trans-Dichloro-β-(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II), trans-β-[Ni(neh)Cl_2]

A few drops of concentrated hydrochloric acid was added to a hot concentrated aqueous solution of the perchlorate salt. The pale lavender coloured *product* was filtered from the cold solution and recrystallised from hot water. *Anal.* Calc. for $C_{14}H_{31}N_5Cl_2NiO_2$: C, 39.0; H, 7.2; N, 12.2. Found: C, 39.4; H, 7.3; N, 12.3%. IR (KBr): ν_{max} (cm^{-1}) ν(NH), 3279, 3223w, 3025; $\nu_{as}(NO_2)$, 1554s.

5.1.6. Catena-trans-bis(μ-oxalato-O,O′)-β-[(5,5,7,13-tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane- k^4)nickel(II)·trihydrate, catena-trans-β-[Ni(neh)(μ-C_2O_4)]$_n$·3n(H_2O), structure **3.5**

Diethylammonium oxalate (0.5 g in 5 cm^3 water) was added to a solution of [Ni(neh)Cl_2] (0.5 g in 5 cm^3 water). The pale lavender coloured *product* which slowly crystallised was filtered off and washed with a little cold water, then recrystallised from water. *Anal.* Calc. for $C_{16}H_{37}N_5NiO_7$: C, 38.3; H, 7.4; N, 13.9. Found: C, 38.5; H, 7.1; N, 13.8%. IR (KBr) ν_{max} (cm^{-1}): ν(OH), 3587, 3486; ν(NH), 3263, 3177; δ(HOH), ν_{as}(OCO), $\nu_{as}(NO_2)$ 1647, 1583vs, 1543, 1564.

Note: The compound is stable in solution in water but in the presence of perchlorate ions converts to insoluble *cis*-α-[{Ni(neh)}$_2(C_2O_4)$]$(ClO_4)_2$.

5.1.7. cis-α-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II)] nitrite·perchlorate hydrate, β-[Ni(neh]NO_2 · ClO_4 · H_2O

This orange coloured *compound* was prepared as for the thiocyanato compound, 5.14, by substituting sodium nitrite and recrystallised from water. *Anal.* Calc. for $C_{14}H_{33}ClN_6NiO_9$: C, 32.1; H, 6.4; N, 16.1. Found: C, 32.5; H, 6.2; N, 16.2%. IR (KBr) ν_{max} (cm^{-1}): ν(OH), 3437br; ν(NH), 3295w, 3258, 3204, 3087; δ(HOH), 1655; $\nu_{as}(NO_2)$, 1547sp.

5.1.8. cis-α-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)(pentane-2,4-dionato)nickel(II) perchlorate, cis-α-[Ni(neh)(acac)]ClO_4

Pentane-2,4-dione (acetylacetone), in small excess was added to a hot aqueous solution of [Ni(neh)]$(ClO_4)_2$, followed by dilute aqueous ammonia. The blue *precipitate* that formed was filtered from the cold solution, washed with water, and recrystallised from acetone/propan-2-ol. *Anal.* Calc. for $C_{19}H_{38}ClN_5NiO_8$: C, 40.8; H, 6.9; N, 12.5. Found: C, 41.2; H, 6.2; N, 12.7%. IR (KBr) ν_{max} (cm^{-1}): ν(NH), 3307w, 3275, 3261; $\nu_{as}(NO_2)$, 1547, ν($acac^-$), 1597, 1518, 1400, all sp.

5.1.9. bis-cis-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)(-oxalato)nickel(II) perchlorate, cis-α-[{Ni(neh)}$_2$(μ-C_2O_4)]$(ClO_4)_2$

(a) Oxalic acid in small excess was added to a solution of [Ni(neh)(acac)]ClO_4 in ethanol, when the sparingly soluble blue product crystallised.
(b) Sodium oxalate and dilute aqueous ammonia were added to an aqueous solution of [Ni(neh)]$(ClO_4)_2$ and the solution heated, when the product slowly crystallised.

The *product* was filtered off and washed with water, then ethanol. *Anal.* Calc. for $C_{15}H_{31}ClN_5NiO_8$: C, 35.8; H, 6.2; N, 13.9. Found: C, 35.8; H, 6.3; N, 13.5%. IR (KBr) ν_{max} (cm^{-1}): ν(NH), 3274; ν_{as}(CO), 1651vs,sp, 1598w; $\nu_{as}(NO_2)$, 1546; $\nu(CO)_{sym}$, 1307 $\nu_3(ClO_4^-)$, 1102, 1066 $\nu_4(ClO_4^-)$, 624.

5.1.10. β-(13-Ethyl-5,5,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)-nickel(II) perchlorate, β-Ni(nph)](ClO$_4$)$_2$

This orange *compound* was prepared by reduction of [Ni(enacnp)](ClO$_4$)$_2$ and purified by crystallization of the acetonitrile adduct, as for the neh homologue 5.11. *Anal.* Calc. for $C_{15}H_{33}Cl_2N_5NiO_{10}$: C, 31.4; H, 5.8; N, 12.2. Found: C, 31.7; H, 5.9; N, 12.4%.

5.1.11. (13-Ethyl-5,5,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)nickel(II) tetrachlorozincate(II) hemihydrate, [Ni(nph)][ZnCl$_4$] · 0.5H$_2$O

This orange *compound* was prepared as for the [Ni(neh)]$^{2+}$, chlorozincate salt. *Anal.* Calc. for $C_{15}H_{34}Cl_4N_5NiO_{2.5}Zn$ requires: C 30.5; H, 5.8; N, 11.8. Found: C, 30.4; H, 5.6; N, 11.8%.

5.1.12. β-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)-copper(II) perchlorate, β-[Cu(neh)](ClO$_4$)$_2$

[Cu(enacne)](ClO$_4$)$_2$ (2 g) was dissolved in acetonitrile/methanol (20 cm^3 of a 1:1 mixture). NaBH$_4$ (0.15 g. 1: 1 mol proportions, in 10 cm^3 of the same solvent mixture) was added. The solution effervesced and a dark chocolate coloured solid slowly precipitated. This slowly redissolved to leave a purple solution with a small amount of black precipitate. After ca. 24 h. the solution was filtered, acidified with dilute perchloric acid and allowed to evaporate to small volume. The crimson *product* was filtered from the cold solution, washed with ethanol and recrystallised from hot water or acetonitrile/propan-2-ol. Yield ca. 80%. Recrystallisation is ineffective in removing any traces of unreduced [Cu(enacne)](ClO$_4$)$_2$, indicated by the presence of a ν(C=N) band at ca. 1665 cm^{-1} in the IR. Precipitation and recrystallisation of [Cu(neh)Cl]ClO$_4$, 5.115, removes this contaminant and the perchlorate salt can be reformed by evaporation of an aqueous solution containing 1.1 mol proportions of perchloric acid, with a final recrystallisation from hot water. *Anal.* Calc. for $C_{14}H_{31}Cl_2CuN_5O_{10}$: C, 29.8; H, 5.5; N, 12.4. Found: C, 30.0; H, 5.3; N, 12.4%. Spectra, IR (KBr) ν_{max} (cm^{-1}): ν(NH), 3267w, 3209; ν_{as}(NO$_2$), 1551, 1540. Visible (water) λ_{max}: 514 (nm), ε 94 cm^{-1} mol^{-1} dm^3.

5.1.13. β-(5,5,7,13-Tetramethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)-copper(II) tetrachlorozincate(II), β-[Cu(neh)][ZnCl$_4$]

This red *compound* was prepared as for the nickel compound, 5.12. *Anal.* Calc. for $C_{14}H_{31}Cl_4CuN_5O_2Zn$: C, 29; H, 5.5; N, 12.2. Found: C, 29.7; H, 5.3; N, 12.2%. IR (KBr) ν_{max} (cm^{-1}): ν(NH) 3247, 3220w, 3197, 3164; ν_{as}(NO$_2$) 1548.

Table 6
Crystallographic details.

*5.1.19. Chloro-β-(13-ethyl-5,5,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetra-decane)copper(II) perchlorate, β-[Cu(nph)Cl](ClO$_4$, structure **3.6***

This blue *compound* was prepared as for the $[Cu(neh)]^{2+}$ homologue, 5.1.15. *Anal.* Calc. for $C_{15}H_{33}Cl_2CuN_5O_6$: C, 35.1; H, 6.5; N, 13.6. Found: C, 35.1; H, 6.4; N, 13.6%.

5.1.20. β-(13-Ethyl-5,5,7-trimethyl-13-nitro-1,4,8,11-tetraazacyclotetradecane)-copper(II) tetrachlorozincate hemihydrate, β-[Cu(nph)][ZnCl$_4$] · 0.5H$_2$O

This red *compound* was prepared as for the neh homologue, 5.113. *Anal.* Calc. for $C_{15}H_{34}Cl_4N_5NiO_{2.5}$: C, 30.5; H, 5.8; N, 11.9 Found: C, 30.4; H, 5.6; N, 11.8%.

5.2. Crystallography

Diffraction data was collected by using Bruker C.C.D. diffractometers [26] with graphite monochromaticized Mo Kα radiation (λ, 0.71073 Å), with phi and omega scans, and corrected for absorption [26,27]. See Table 6 for details.

The structures were solved by direct methods (SHELXS) [28] and refined on F^2 (SHELXL) [28], with anisotropic thermal parameters, except where specified. Hydrogen atoms bonded to C and N are in calculated positions, with their positions refined using a riding model with SHELXL defaults. Hydrogen atoms of water molecules were located from difference synthesis and their positions refined with DFIX (0.82 Å) constraints.

The structures with C5/C7 disorder in the location of the axial methyl groups were refined with complementary sof for these groups. For the oxalato compound 3.5 this disorder model was extended to atom C51.

Appendix A. Supplementary data

ABSTRACT

The crystal structure of copper sulfate templated by 2-methylpiperazine, $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4]\cdot H_2O$, was investigated using single crystal X-ray diffraction data. At room temperature, it crystallises in the monoclinic $P2_1/n$ space group with the following unit-cell parameters: $a = 6.9153(1)$, $b = 23.1295(3)$, $c = 10.4472(1)$ Å, $\beta = 104.227(1)^\circ$, $V = 1619.75(4)$ Å^3 and $Z = 4$. The Cu^{II} cation adopts a slightly distorted octahedral geometry, arising from four water molecules and two sulfate tetrahedra leading to the formation of $[Cu(SO_4)_2(H_2O)_4]$ units. The structure consists of isolated $[Cu(SO_4)_2(H_2O)_4]^{2-}$ anions, 2-methylpiperazinediium cations $(C_5H_{14}N_2)^{2+}$ and water molecules connected by a three-dimensional hydrogen-bond network. The thermal decomposition of the precursor, studied by thermogravimetry and temperature-dependent X-ray powder diffraction, proceeds through four stages giving rise to the copper oxide.

1. Introduction

In the past decades, a variety of organically templated metal sulfates with fascinating architectures and desirable physical properties have also attracted considerable attention [1]. A great interest has been shown in some double sulfates of trivalent metal with monovalent aliphatic ammonium cations because of their ferroelastic and ferroelectric properties [2–6]. So far, there are few data on the double sulfates of divalent transition metal cations with mono or divalent organic amines cations [7–19]. By analogy with trivalent metal sulfates showing a para-ferroelectric transition upon cooling [3–6], it was expected that such divalent metal sulfates would exhibit this feature. The use of non-centrosymmetric amine groups, instead of alkylamines, may help crystallize disordered phases at room temperature. Cation ordering at low temperature would thus provide acentric structures that are the basic condition to have ferroelectricity. In order to expand upon the emergent chemistry of templated metal sulfate, a new compound using 2-methylpiperazine as a template and copper as a transition metal has been synthesized. In this paper, we report the chemical preparation, the structural study and the thermal behavior of title compound.

2. Experimental

2.1. Synthesis

Single crystals of the compound $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4]\cdot H_2O$ were grown as follows: 1 mmol of the copper sulfate pentahydrate $CuSO_4\cdot 5H_2O$ (99%, Merck); 1 mmol of 2-methylpiperazine (98%, ACROS Organics) and 1 mmol of sulfuric acid H_2SO_4 (96%, Carlo Erba) were mixed together in a minimum amount of distilled water. The clear solutions were stirred for 15 min and allowed to stand at room temperature. After a few days, blue prismatic crystals were formed. The product was filtered off and washed with a small amount of distilled water.

2.2. Structure determination and refinement

Although in some cases beautiful crystals of macroscopic dimensions were obtained (e.g., $0.336 * 0.153 * 0.334$ mm^3), the preparation proved to be difficult. Finally smashing the crystals gave fragments suitable for analysis.

Single-crystal X-ray data of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4]\cdot H_2O$ were collected at room temperature on a Nonius Kappa CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) through the programm COLLECT [20]. Correction for Lorentz-polarisation effect, peak integration and background determination were carried out with the program DENZO [21]. Frame scaling and unit-cell parameters refinement were performed with the program SCALEPACK [21].

Analytical absorption corrections were performed by modeling the crystal faces using NUMABS [22]. The crystal structure has been solved in the monoclinic symmetry, space group $P2_1/n$ according to the automated search for space group available in WINGX [23]. Transition metal and sulfur atoms were located using direct methods with the program SHELXS-97 [24]. The oxygen atoms and the organic moiety were found from successive Fourier calculations using SHELXL-97 [25]. The aqua H atoms and those bonded to N atoms were located in a difference Fourier map and their positions and isotropic displacement parameters were refined. Within the water molecules, the O–H and H–H distances were restrained to 0.85(2) and 1.39(2) Å, respectively, so that the H–O–H angle approach the theoretical values, 105.4°. H atoms bonded to C atoms were positioned geometrically (the C–H bonds were fixed at 0.97 Å) and allowed to ride on their parent atoms. Crystallographic data and the results of the least-squares structure refinement are given in Table 1. Bond distances and angles calculated from the final atomic coordinates, as well as probable hydrogen bonds, are listed in Tables 2 and 3.

2.3. Thermal analyses

Thermogravimetric analysis for $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4]\cdot H_2O$ was carried out with a Rigaku Thermoflex instrument. The 80.82 mg powdered sample was spread evenly in a large sample holder to avoid mass effects. The TG run was performed in flowing air with a heating rate of 15° Ch^{-1} from room temperature to 900 °C. The temperature-dependent X-ray (TDXD) was performed with a D5005 powder diffractometer (Bruker AXS) using Cu Kα radiation [λ(Kα_1) = 1.5406 Å, λ(Kα_2) = 1.5444 Å] selected with a diffracted-beam graphite monochromator, and equipped with an Anton Paar HTK1200 high-temperature oven camera. The thermal decomposition of the compound was carried out in air, with a heating rate of 14.4° Ch^{-1} from ambient to 870 °C.

2.4. IR spectroscopy

All IR measurements were obtained using a Perkin Elmer 1600 FT spectrometer. Samples were diluted with spectroscopic KBr and pressed into a pellet. Scans were run over the range 400–4000 cm^{-1}.

3. Results and discussion

3.1. Description of the crystal structure of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4]\cdot H_2O$

All of the transition metal sulfates templated by amines described in the literature show similar structures. However, the arrangement of the polyhedra and the organic molecules within these structures is slightly different. Consequently, we were able to distinguish different arrangement types and space groups [26–34]. The crystal structure of the new 2-methylpiperazinediium

copper disulfate obtained her, crystallizes in the centrosymmetric space group $P2_1/n$. It consists of isolated $[Cu(SO_4)_2(H_2O)_4]^{2-}$, $(C_5H_{14}N_2)^{2+}$ and H_2O units connected by a complex hydrogen-bond network only. Fig. 1 shows a view of the structure of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$ down the crystallographic *a*-axis.

In the molecular material, the coordination polyhedra around the copper cations are slightly distorted octahedra located in a general position and coordinated by two oxygen atoms of sulfate groups at a distances $Cu–O_3 = 2.3418(11)$ and $Cu–O_7 = 2.3672(11)$ Å and four corners of water molecules (Cu–OW distances vary from 1.9509(12) to 1.9828(12) Å). The values of O–Cu–O angles are between 84.11(5) and 179.27(5)° (Table 2). The copper octahedra are separated from one to each other with a shortest metal–metal distance of Cu–Cu = 6.706 Å. Since, this intermetallic distance is shorter than those found in other compounds previously reported, e.g. $Cu–Cu_{min} = 6.953$ Å and $Co–Co_{min} = 6.803$ Å in dabco and ethylenediamine related sulfates, respectively, it can be the origin of some interesting magnetic interactions at low temperature. This result demonstrates that the structural arrangement and the distances between the metallic centers depend on the size and the shape of the amino group involved in these structures. Within a formula unit, two types of sulfate oxygen atoms are distinguished: six oxygen atoms are hydrogen bonded to water molecules or to the organic cations and two oxygen atoms bonded to Cu atom. It should be noted that the shortest S–O bond lengths are observed for oxygen atoms H-bonded to water molecules or to 2-methylpiperazinediium cations, S–O distances range from 1.4578(14) to 1.4964(12) Å. The distances and angles in the sulfate groups as quoted in Table 2 and they indicate that their shapes are slightly distorted. These geometric characteristics do not present any particularity and they are comparable to those observed in some sulfate compounds templated by others amines groups. Each Cu octahedron shares two oxygen atoms with two sulfate groups to form $[Cu(SO_4)_2(H_2O)_4]$ units. These latest are stabilized and connected together through OW–H···O hydrogen bonds giving rise to a three-dimensional inorganic framework. Fig. 2 represents one $[Cu(SO_4)_2(H_2O)_4]$ group, indicating that two oxygen atoms belonging to the sulfate groups participate in the coordination sphere of the copper atom. Indeed, each metallic octahedron is connected not only to two sulfate groups by corners sharing but also to four other sulfate tetrahedra via H-bonds: one in a bidentate manner and three others in a monodentate fashion (Fig. 3). These octahedra are linked also, via OW–H···O hydrogen bonds, to one free water molecule in a monodentate manner. This neighboring environment is different from that found in the ethylenediamine related sulfate [33], where the cobalt octahedron is surrounded only by six sulfate tetrahedra via H-bonds: two in a bidentate manner and four others in a monodentate fashion. Within the OW–H···O intermolecular H-bonds, the OW···O distances range from 2.622(2) to 2.808(2) Å and the OW–H–O angles are comprised between 151(3) and 176(2)° (Table 3). The negative charge of the inorganic part is compensated by the 2-methylpiperazinediium cations which are located on general position in the inorganic framework cavities (Fig. 1). The characteristic bond distances and angles within the protonated diamine molecule, listed in Table 2, are in agreement with those observed in other compounds containing similar amine groups [18,30,35]. Fig. 4 shows that each organic cation engages its hydrogen atoms bonded to N atoms in N–H···O hydrogen bonds. Thus, it is connected to four neighboring $[Cu(SO_4)_2(H_2O)_4]$ groups and participates in the structure cohesion. The N···O distances vary from 2.720(2) to 2.7616(2) Å and the N–H–O angles range between 160.1 and 168.9° (Table 3).

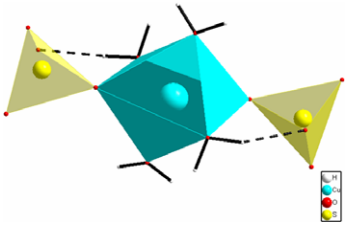

Fig. 2. The $[Cu(SO_4)_2(H_2O)_4]$ units in the structure.

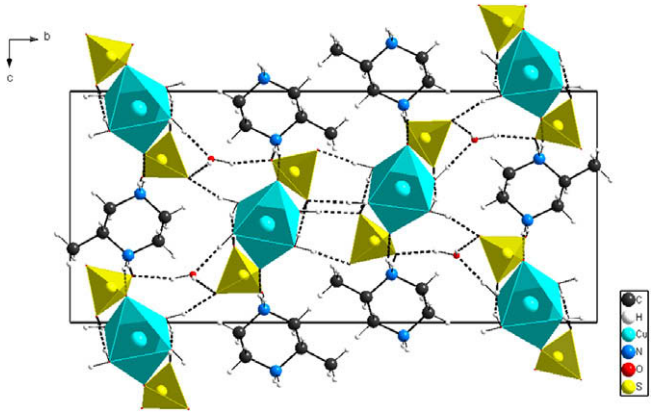

Fig. 1. View of the structure of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$ down the crystallographic *a*-axis. Hydrogen bonds are represented by dashed lines.

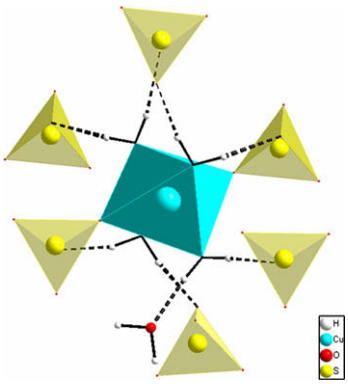

Fig. 3. Octahedron environment around the Cu atom, in the structure of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$.

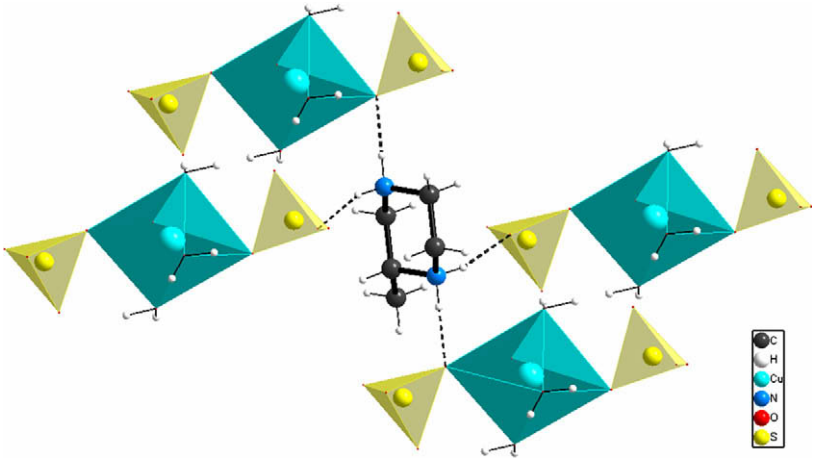

Fig. 4. H-bonds established between $(C_5H_{14}N_2)^{2+}$ and sulfate tetrahedra in the structure of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$.

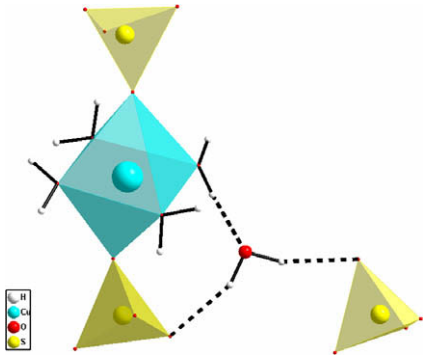

Fig. 5. H-bonds established between the free H_2O molecule, sulfate tetrahedra and copper octahedron in the structure of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$.

In the hybrid materials, the presence of free water molecules plays an important role in the cohesion of the structure [30,32] because they participate in more hydrogen bonds than the other water molecules (three hydrogen bonds for OW5, shown in Table 3). In these hydrogen-bonded interactions, the OW5···O (where OW5 plays the role of a donor) distance range from 2.805(2) to 2.808(2) Å and the OW···OW5 (where OW5 plays the role of an acceptor) distance is 2.622(2) Å. Hence, OW5 is more weakly linked than those found in other water molecules observed in the present structure. The OW5–H···O angles vary from 151(3)° to 161(2)° and OW–H···OW5 angle has the value 174(2)°. The free water molecule OW5 is surrounded by two sulfate tetrahedra and one copper octahedron; connect to each other via, OW–H···O, hydrogen bonds. It is not participating in the environment of copper. It accepts only one hydrogen bond, by one of its free electronic doublets, from the Cu octahedron, and it is donating two hydrogen bonds to two oxygen atoms of sulfate tetrahedra. The environment of the free water molecule is shown in Fig. 5.

The presence of the template in this structure is confirmed using IR spectroscopy, with C–H and N–H bonds measured at 1456 and 1610 cm^{-1}, respectively. C–H and N–H stretches are observed at 2990 and 2782 cm^{-1}, respectively. S–O and S=O stretches are centered on 1120 cm^{-1}. These data are in agreement also of the double protonation of the organic moiety.

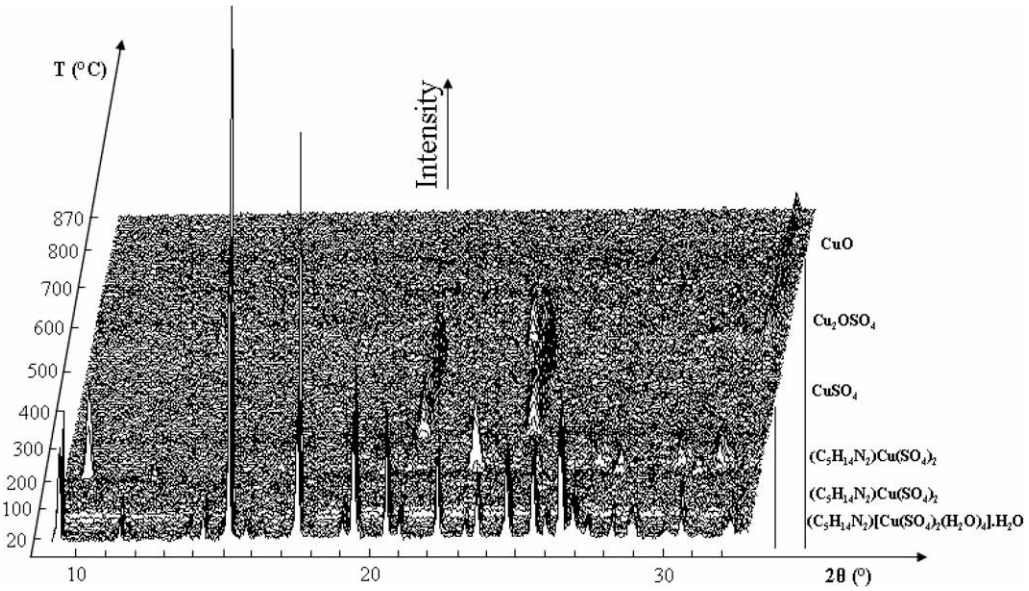

Fig. 6. TDXD plot for the decomposition of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$ in air (14.4° Ch^{-1} from 20 to 870 °C).

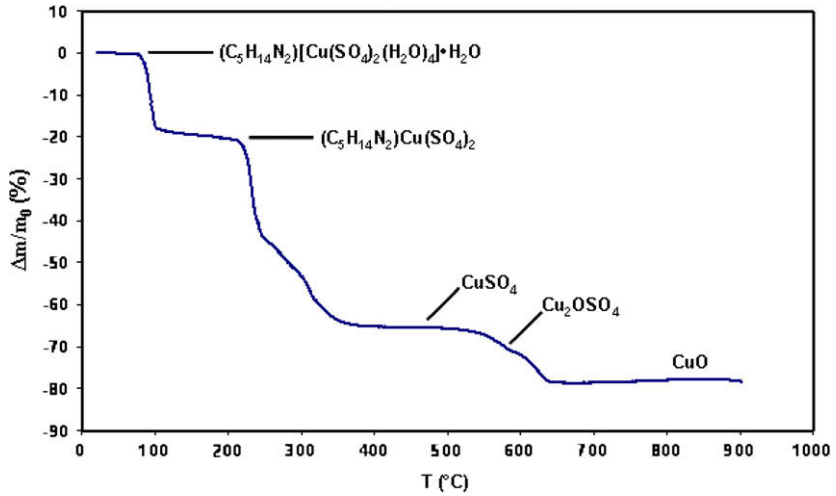

Fig. 7. TG curve for the decomposition of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$ in flowing air.

3.2. Thermal behavior of the precursors

Fig. 6 shows the successive powder patterns obtained during the thermal decomposition of $(C_5H_{14}N_2)[Cu(SO_4)_2(H_2O)_4] \cdot H_2O$, in air in the temperature range 20–870 °C. The TG curve, carried out with a heating rate of 15° Ch^{-1} between 25 and 900 °C, appears in Fig. 7. The first transformation occurs in the temperature range 71–202 °C. The weight loss of 20.7% is in agreement with the departure of five water molecules (cal. weight loss of 20.1%), thus leading to the anhydrous phase, $(C_5H_{14}N_2)Cu(SO_4)$, amorphous to X-rays (Fig. 6). At 220 °C, some diffraction lines emerge from the background. At this temperature no weight loss is observed in the TG curve. From these observations, it was concluded that the anhydrous phase crystallises. It can be noted that a similar thermal behavior has already been observed for $(C_4H_{14}N_2)[M^{II}(H_2O)_6](SO_4)_2 \cdot 4H_2O$ with M^{II} = Co and Ni templated by 1,4-butanediamine [32]. Unfortunately, high background contribution and instability of diffracted intensities did not allow further structural investigations of the compound. $(C_5H_{14}N_2)Cu(SO_4)$ is not stable and decomposes into $CuSO_4$ (weight loss 65.38%). As shown in Fig. 6, some diffraction lines appear to coexist with $CuSO_4$ in the temperature range 550–600 °C. They are attributed to Cu_2OSO_4, as also evidenced by the weight loss of 71.21% (cal. 73.29%) observed in the TG curve at the inflection point (T = 590 °C). The final transformation corresponds to the formation of copper oxide, CuO, which crystallises immediately after Cu_2OSO_4 starts to decompose.

4. Concluding remarks

The title compound templated by 2-methylpiperazine was prepared by the slow evaporation method and characterised by single crystal X-ray diffraction, powder thermodiffractometry and thermogravimetric analyses. It crystallises in the monoclinic system, space group $P2_1/n$. The structure consists of $[Cu(SO_4)_2(H_2O)_4]$ units, built from copper (II) octahedron and two sulfate tetrahedra linked by corner sharing, water molecules, and diprotonated 2-methylpiperazine cations connected together by hydrogen bonds only. The thermal decomposition of the precursors leads to amorphous and crystalline anhydrous phases, respectively. We believe that the centric crystal structure of the title compound was expected from the racemic character of the amine used in the synthesis. The use of the chiral form of this amine (S or R) would allow us to obtain possible acentric organic–inorganic salts. More extensive studies using this synthetic approach should giving rise to a new class of ferroelectrics at room temperature, stable within a wider temperature range. Additional work with XRD, dielectric and thermocurrent measurements are under way and will give more insight into the structural and the physical characteristics of these materials [36].

Appendix A. Supplementary data

CCDC 718821 contains the supplementary crystallographic data for **1**. ABSTRACT

By using Mn^{2+} and Mn^{3+} salts, and freshly extracted ovalbumin, Mn_3O_4 nanocrystals have been synthesized successfully. The X-ray diffraction results indicated that the synthesized nanoparticles have only the spinel structure without the presence of any other phase impurities. As the ovalbumin–water mixture was highly basic, the process did not require any use of base to increase the pH where hydrolysis took place. A gel formed where water soluble ovalbumin proteins served as a perfect matrix for entrapment of metal ions (Mn^{2+} and Mn^{3+}). Upon heat treatment, the dried gel precursor decomposed into nanocrystalline Mn_3O_4. The discrepancy between the crystallite size from XRD and particle size SEM analysis reveals polycrystalline nature of the synthesized particles with this route. EPR analysis of Mn_3O_4 shows a narrow and symmetric line indicating the absence of hyperfine splitting.

1. Introduction

Manganese oxides have attracted considerable interest due to their wide range of applications in catalysis, ion-exchange materials, electrochemical materials, high-density magnetic storage media, solar energy transformation and molecular adsorption [1–6]. Hausmannite, Mn_3O_4 with the spinel structure, is an important oxide which can be used as an active catalyst for the oxidation of methane and carbon monoxide [7] and the selective reduction of nitrobenzene [8] as well as electrode materials for batteries; moreover, it is an effective material to prevent air pollution and limit the emission of NO_x and volatile organic compounds from waste gases of different origins [9].

Various methods have been reported for the synthesis of Mn_3O_4 nanoparticles. Among these methods, high-temperature and hydrothermal methods are generally adopted in conventional processes for the synthesis of Mn_3O_4. Almost all oxides, hydroxides, carbonates, nitrates and sulfates of manganese can serve as precursors to produce Mn_3O_4 at about 1000 °C in air [10]. However, these processes are economically unviable. Recently, chemical bath deposition [11], sol–gel technique [12], oxidation–precipitation method [13], reflux [14] and the co precipitation method [15] have been employed to prepare Mn_3O_4. It is becoming very important to find simple and cost effective routes to synthesize Mn_3O_4 nanoparticles by application of cheap, non-toxic and environmentally friendly precursors.

Egg white proteins (ovalbumin) have various types of functional properties such as gelling, foaming, emulsification, heat setting and binding adhesion [16]. Besides the advantage of its solubility in water and its tendency to associate with metal ions in solution, egg white proteins have also been used as a binder cum gel to shape material, especially bulk and porous ceramics [17]. The use of egg white not only simplifies the process but also would provide another preference process to synthesize of nanocrystalline ceramic particles in an environmentally friendly and cheap way. Up to now, Dhara [17], Kumari et al. [18] and Maensiri et al. [19] used egg white as a water soluble polymeric matrix to produce nanocrystalline alumina, $LiMn_2O_4$ and $NiFe_2O_4$, respectively.

Hereby, we report an innovative approach for the synthesis of Mn_3O_4 based on calcination of a dried gel precursor obtained by freshly extracted ovalbumin mediated synthesis. To the best of our knowledge, this study is the first report on the synthesis of Mn_3O_4 nanocrystals using egg white.

2. Experimental

2.1. Synthesis of Mn_3O_4 nanoparticles in the presence of egg white

Mn (II) acetate dihydrate, $(Mn(ac)_2) \cdot 2H_2O$ and Mn (III) acetylacetonate, $Mn(acac)_3$, of reagent grade, were obtained from Merck. All chemicals were used without further purification. Firstly, water–egg white mixture was prepared (3:2 volume ratio). 60 ml of egg white was stirred with 40 ml deionized water with vigorously at room temperature until a homogeneous solution was obtained. Subsequently, stoichiometric amount of $Mn(ac)_2$ and

doi:10.1016/j.poly.2009.03.026

$Mn(acac)_3$ (with the molar ratio of 1:2) were added slowly into egg white–water solution. During addition of Mn salts the solution was stirred magnetically at room temperature for 2 h to obtain a clear solution. Throughout the whole process, no pH adjustment was necessary as the pH of the solution was measured as ~9. Then the yellow–orange mixed solution was evaporated by heating at 80 °C for several hours until a dried gel precursor was obtained. The dried mass was crushed into powder using a mortar and pestle and then calcined in a box-furnace at 800 °C 3 h in air.

2.2. Characterization

X-ray powder diffraction (XRD) analysis was conducted on a Huber JSODEBYEFLEX 1001 diffractometer operated at 40 kV and 35 mA using Cu Kα radiation.

Fourier transform infrared (FT-IR) spectra of the samples were recorded in transmission mode with a Perkin Elmer BX FT-IR infrared spectrometer using KBr diluted pellets in the range of 4000–400 cm^{-1}.

The thermal stability was determined by thermogravimetric analysis (TGA, Perkin Elmer Instruments model, STA 6000). The TGA thermogram was recorded for 5 mg of powder sample at a heating rate of 10 °C min in the temperature range of 30–800 °C under nitrogen atmosphere.

Scanning electron microscopy (SEM) analysis was performed, in order to investigate the microstructure of the sample, using FEI XL40 Sirion FEG Digital Scanning Microscope. Samples were coated with gold at 10 mA for 2 min prior to SEM analysis.

Transmission electron microscopy (TEM) analysis was performed using a FEI Tecnai G2 Sphera microscope. A drop of diluted sample in alcohol was dripped on the TEM grid.

A conventional X-band (f = 9.8 GHz) Bruker EMX model EPR spectrometer employing an ac magnetic field (modulation frequency: 100 kHz) modulation technique was used for magnetic characterization. Operating conditions were 20.07 mW microwave power, 15 G modulation amplitude, center field 8000 G, time constant 40.96 ms and sweep time 41.94 s with multiple accumulations to enhance the signal-to-noise ratio.

3. Results and discussion

3.1. XRD analysis

A typical XRD pattern of the as-synthesized powder is shown in Fig. 1. All diffraction peaks were indexed to the tetragonal Mn_3O_4 (which are consistent bulk value ICDD Card no. 24-0734). The lattice parameters were calculated as a = 5.76(3) and b = 9.47(1) Å using the d-spacing values and the respective (hkl) parameters. The average size of the crystallites, D_{XRD}, was estimated as 22 ± 10 nm from the diffraction pattern using the line profile fitting of Mn_3O_4 diffraction peaks as described in Wejrzanowski et al. [20] and Pielaszek [21]. The line profile, shown in Fig. 1, is fitted for 14 peaks with the following Miller indices: (101), (112), (200), (013), (211), (004), (220), (213), (204), (015), (312), (303), (321) and (224).

3.2. FT-IR analysis

FT-IR analysis was performed for the sample prepared by the calcination of the dried gel precursor and the spectrum is presented in Fig. 2. In the range of 1000–400 cm^{-1}, two main metal–oxygen bands at ~606 and 478 cm^{-1} were observed in the FT-IR spectrum which are associated with the coupling between Mn–O stretching modes of tetrahedral A- and octahedral B-sites [22,23].

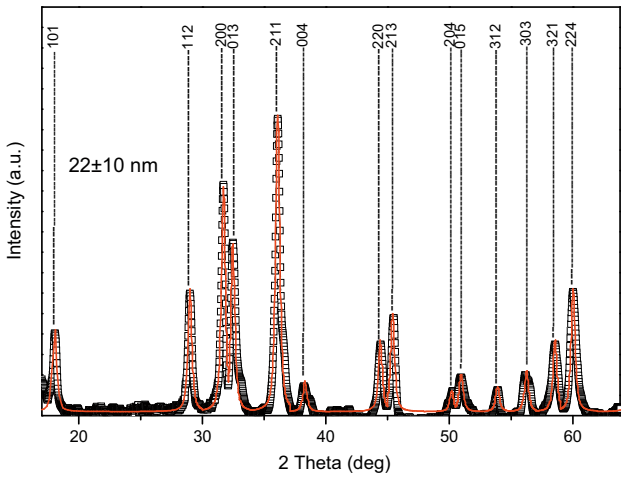

Fig. 1. XRD pattern of Mn_3O_4 particles (obtained upon calcination of dried gel precursor 800 °C) and line profile fitting.

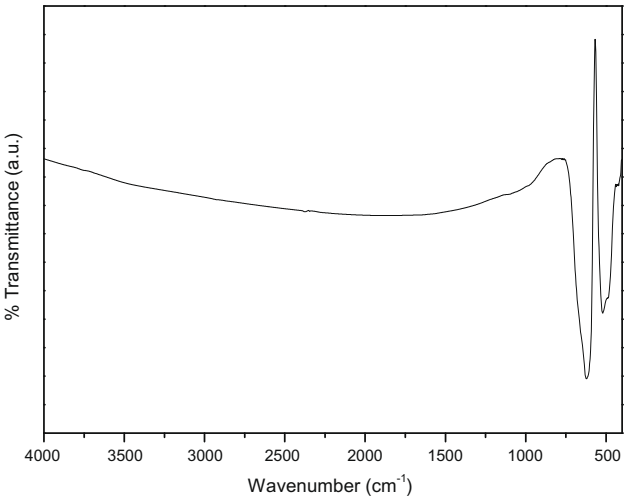

Fig. 2. FT-IR spectrum of as-synthesized Mn_3O_4 upon calcination of the dried gel precursor at 800 °C.

3.3. Thermal analysis

Thermal stability of the precursor powder and final powder has been analyzed using TGA. Thermograms for both samples are presented in Fig. 3. Calcined powder shows no weight loss, as all organic residues have been removed, that reveals the stability of obtained Mn_3O_4 nanoparticles. Precursor powder shows an overall weight loss of ~75%. According to the differential thermogram, DTG, presented in the inset of Fig. 3 there is four-step weight loss (indicated with arrows) for the precursor powder, of mainly ovalbumin, matrix the first one at <200 °C, a shoulder at ~240 °C, the most intense one at ~300 °C and a secondary shoulder one at ~450 °C. The observed thermogram perfectly matches that of pure ovalbumin reported by Kumari et al. [18] above 200 °C. Weight loss up to 200 °C is due to the adsorbed water and boiling of organic residues released from Mn salts. Weight loss around ~240 °C suggests that water molecules in albumin are strongly bonded to the protein molecules and that it takes higher energies to remove them. The considerable weight loss at ~300 °C and the shoulder at ~450 °C is due to the decomposition of proteins in ovalbumin.

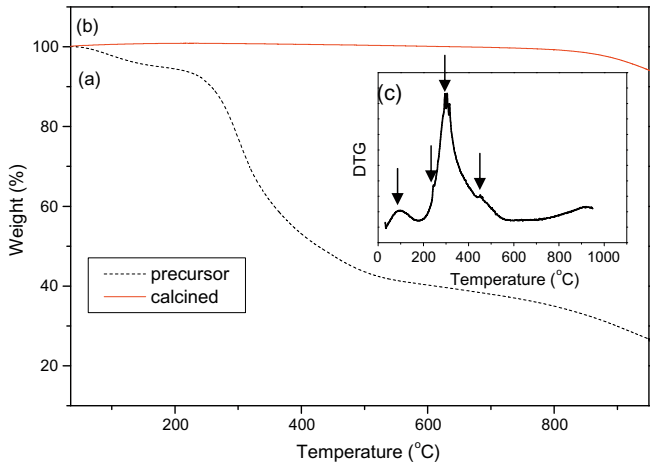

Fig. 3. TGA thermograms of (a) as-made dried gel precursor; (b) final powder after calcination of dried gel precursor; and (c) differential thermogram, DTG, of the precursor in (a).

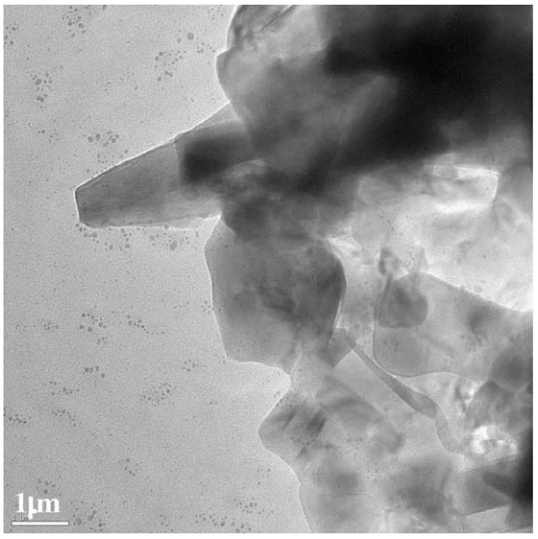

Fig. 5. TEM micrograph of Mn_3O_4 particles obtained upon calcination of the dried gel precursor at 800 °C.

3.4. SEM analysis

SEM analysis was performed to investigate the morphology of synthesized Mn_3O_4 powder and micrographs taken at different magnifications are presented in Fig. 4. Particles were observed to have various morphologies and a wide range of sizes making it difficult to assess the average size from the micrographs. Non-spherical morphology of particles with smooth surfaces suggests the shape is controlled by the entrapment in the dried gel, mainly due to the ovalbumin proteins that confines and stabilizes the metal ions in the gel. Particles with well-defined smooth surfaces are in majority with sizes ranging from ~150 nm up to ~2 μm. The particle size is much larger than the crystallite size obtained from XRD indicating the polycrystalline nature of the observed particle morphologies.

3.5. TEM analysis

Morphology of Mn_3O_4 particles were also investigated by TEM and a micrograph is presented in Fig. 5 which shows a strong agglomeration. Even though particles have lateral dimensions on the order of 1–2 μm levels, their high transparency under TEM reveals a sheet like morphology.

3.6. EPR analysis

The magnetic properties of the as-synthesized Mn_3O_4 were measured using EPR technique in X band and the resultant spectrum is presented in Fig. 6. The EPR spectrum can be used to detect Mn^{2+} and Mn^{4+}, whereas Mn^{3+} is usually not detected due to the complete splitting of the energy levels (no ground state degeneracy) [24].

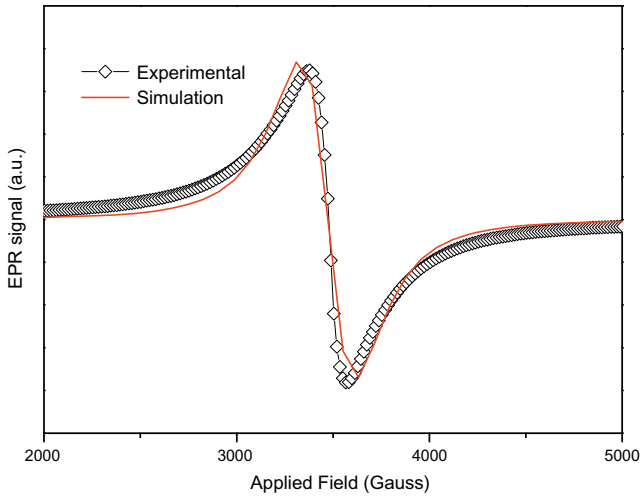

Fig. 6. First derivative of EPR signal (◇) and simulation (–) for Mn_3O_4 particles obtained upon calcination of the dried gel precursor at 800 °C.

Fig. 6 shows room temperature EPR spectrum of Mn_3O_4 including a narrow and symmetric line with its Gaussian simulation signal. The hyperfine splitting is not observed. EPR lines have a peak to peak line-width of 195 G, resonance field of 3475 G and g value

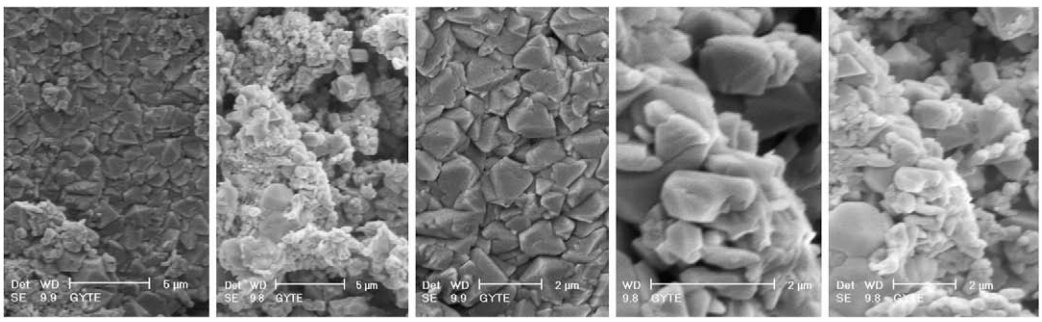

Fig. 4. SEM micrographs of Mn_3O_4 particles, obtained upon the calcination of the dried gel precursor at 800 °C, at different magnifications.

of 2.01. Srinivasan et al. [25] have reported on the temperature dependence of ΔH, Hr and g parameters of Mn_3O_4 in detail. Our results are in accordance with their room temperature observations, where ΔH, Hr and g have been reported as 405 Oe, 3170 Oe and 2.01 at 9 GHz. Huber et al. [26] suggested effective g value of the unlike spin in the exchanged–coupled system as follows:

$$g_{eff} = \frac{g_A S_A(S_A+1)N_A + g_B S_B(S_B+1)N_B}{S_A(S_A+1)N_A + S_B(S_B+1)N_B}$$

where g_A and g_B are the g values, S_A and S_B are spin moments, N_A and N_B are the relative concentrations of A and B sites, respectively. At $Mn^{+2}[Mn^{+3}]_2\ O_4$, by assuming that Mn^{+2} has $g_A = 2$ and using $S_A = 5/2$ and $S_B = 2$ are spin moments, $N_A = 1$ and $N_B = 2$ and experimental g value as $g_{eff} = 2.01$, the Mn^{+3} in B site has g value 2.02 that means unquenched orbital moment resulting unsplitted EPR line [25]. EPR spectrum and exchange coupled equation reveal the absence of hyperfine splitting in the final powder.

4. Conclusion

A novel, environment friendly route utilizing freshly extracted ovalbumin, and Mn^{2+} and Mn^{3+} salts, has been successfully used for the synthesis of Mn_3O_4 nanocrystals. High pH value of ovalbumin–water mixture self-regulated the pH for hydrolysis of metal ions. Water soluble ovalbumin proteins formed a gel and served as a matrix for entrapment of Mn^{2+} and Mn^{3+} ions. The dried gel precursors decomposed into nanocrystalline Mn_3O_4 upon calcination. Crystallite size was estimated as 22 ± 10 nm by XRD line profile fitting and particle size observed from SEM is in the range of 150 nm–2 μm. This discrepancy indicated polycrystalline nature of synthesized nanoparticles. EPR analysis showed a narrow and symmetric line indicating the absence of hyperfine splitting. Presented synthetic route is simple, cost effective, cheap and environmentally friendly that can be applied for the synthesis of other oxide systems.

Metal-hydroxo clusters

ABSTRACT

The controlled hydrolysis of lanthanoid trichloride hexahydrate (Ln = Nd, Eu, Ho) in methanol with the β-diketone ligands dibenzoylmethane and 1,3-bis(4-ethoxyphenyl)propane-1,3-dione yielded tetranuclear and pentanuclear hydroxo clusters for Eu and Ho. In contrast, performing the reaction in the presence of 1,3-bis(4-methoxyphenyl)propane-1,3-dione yielded a mononuclear complex for Nd. The compounds were structurally characterised by means of single crystal X-ray diffraction, showing that the increased bulkiness of the ligand due to the ethoxy functionalities does not affect the capability of the diketonate to stabilize the cluster core. Variable temperature dc susceptibility magnetic measurements were made on the clusters and were indicative of very weak to zero antiferromagnetic, intra-cluster coupling. Variable frequency ac data recorded at low temperatures did not show any evidence for single molecule magnet (SMM) behaviour, unlike the recent reported case of the analogue $[Dy_5(OH)_5(\mathbf{Ph_2acac})_{10}]$, where $\mathbf{Ph_2acac}^-$ is the dibenzoylmethanide ligand.

1. Introduction

Over the past decade, the hydrolysis of lanthanoid salts (LnX_3 X = Cl, I, OTf, ClO_4) performed under "controlled conditions" and in the presence of "protecting ligands", to avoid extensive formation of insoluble hydroxide species, has allowed the isolation and characterisation of a wide variety of polynuclear oxo/hydroxo clusters [1]. Although these polynuclear cages have been envisaged for some time as precursors for the preparation of novel functional materials, due to the properties associated with the f electrons of the rare earths such as luminescence [2], magnetism [3], and Lewis acidity [1f,4], very few results in this context have so far been reported. The only relevant examples reported for their application describe their catalytic activity in polymerisation and oxidation reactions [4]. By contrast, the incorporation of polynuclear lanthanoid cages into hybrid organic/inorganic polymeric networks or molecular frameworks has been successfully attempted [5]. Despite these early results, there is still little known about the chemistry and reactivity of the rare earth clusters. In all the synthetic procedures, formation of the polynuclear cage is the ultimate step and no further reactions aimed at modifying either the metal core or the encapsulating ligands have been described. As a result, questions about the stability of the clusters under specific reaction conditions or the possibility of introducing different functional groups on the outer shell in a preformed cage remain unanswered. As part of our ongoing research into obtaining functionalisable clusters, we have pursued cluster formation using β-diketonates obtained from dibenzoylmethane ($\mathbf{Ph_2acac}$H) with short chain ether groups in the *para* position of both phenyl rings. The preparation of tetranuclear and pentanuclear lanthanoid hydroxo clusters, via hydrolysis of lanthanoid chlorides with β-diketonates as ligands, is now well established [4,6]. It is also well known that less bulky ligands promote the formation of larger clusters and vice versa [6,7]. In exploring the chemistry and reactivity of rare earth oxo/hydroxo clusters, we have also probed the relationship between the overall steric bulk of the ligand and the size of the cage (in terms of number of Ln^{3+} ions) which results from this synthetic procedure. This can provide valuable information on whether small modifications to the outer shell can cause a collapse of the cage as a result of changes in the steric demand of the ligands. To achieve this goal we used an "inverse approach", i.e. firstly modifying the ligand with subsequent cluster formation. As such, methoxy and ethoxy functionalities were added in the *para* positions of both the phenyl rings of $\mathbf{Ph_2acac}$H and analogous reactions to the ones which give the unmodified $\mathbf{Ph_2acac}^-$ ligated clusters were carried out. Moreover, a detailed investigation of the magnetic properties of these polynuclear cages has been conducted, in view of their possible use as single molecule magnets (SMMs) [8]. While the

doi:10.1016/j.poly.2009.03.031

present work was in progress, a paper describing the SMM features of $[Dy_5(OH)_5(\mathbf{Ph_2acac})_{10}]$, isostructural to the Ho and Eu clusters reported in this work, has just appeared [3c]. Variable frequency ac susceptibility studies have shown that the present Ho_5 and Eu_5 clusters are essentially flat in the out-of-phase ac χ''_M versus T (2–10 K) region, with the merest hint of an increase indicating they are either not SMMs or that the blocking temperature is below 2 K. In contrast, the Dy_5 analogue showed characteristic maxima in χ''_M at ~3 K, pointing to slow relaxation of the magnetisation [3c]. The static dc magnetic susceptibilities of the present compounds show Curie–Weiss behaviour, some with plateaus in susceptibilities at low temperatures, that is indicative of weak to zero antiferromagnetic intra-cluster coupling.

2. Experimental

2.1. General procedures

Chemicals were obtained from Sigma–Aldrich and used as received. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AM 200 and AM 300 spectrometers. Chemical shifts were recorded on the δ scale and referenced to the solvent. Infrared spectra were recorded on a Perkin–Elmer 1600 Series FTIR using solid state pellets (KBr). Melting points were measured on a Stuart Scientific Melting Point Apparatus SMP3 in an open capillary and were not corrected. Elemental Analyses were performed by the Campbell Microanalytical Laboratory, Department of Chemistry, University of Otago, Dunedin, New Zealand. Crystallographic data were obtained on a Bruker X8 APEX CCD at the temperature of 123 K. The data for $[Nd(\mathbf{5})_3(DMF)_2]$ were collected on an Enraf-Nonius KAPPA CCD at the temperature of 123 K. All compounds were measured with Mo Kα radiation generated by a fine-focus sealed tube using a graphite monochromator. Scans were performed in φ and ω and 0.5° frames were recorded. All the molecular structures were solved using the program SHELXS-97 [9]. Refinement was carried out with the program SHELXL-97 against F^2 using least-square methods [9]. For the X-ray data refer to Table 3. Magnetic measurements were performed using a Quantum Design MPMS 5 Squid for dc studies and a Quantum Design PPMS instrument for ac susceptibilities, as described previously [10]. Samples of mass ~20 mg were checked for crystallite torquing anomalies, due to magnetic anisotropy, by making mulls in Vaseline and comparing to the neat powder samples. The ac frequencies employed on the PPMS machine were 10, 50, 100, 250, 500, 750, 1000, 1250, 1500 Hz with the accompanying dc (static) field of about 3 Oe.

2.2. Synthesis of methyl 4-methoxybenzoate (*1*)

Methyl 4-hydroxybenzoate (6.0 g, 40 mmol) was dissolved in dry DMF (80 ml). K_2CO_3 (16.6 g, 120 mmol) was added and the suspension was stirred for 10 min. Methyliodide (3.8 ml, 60 mmol) was then added dropwise. After stirring for 14 h, water (100 ml) and ethyl acetate (500 ml) were added. The aqueous phase was separated from the organic layer, which was washed with water (8 × 250 ml), dried over $MgSO_4$ and evaporated to dryness to yield **1** as a yellow solid. Yield: 6.42 g (97%). M.p. 51–52 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 3.84 (s, 3H, CH_3O), 3.86 (s, 3H, $COOCH_3$), 6.86–6.93 (m, 2H, 2-H, 6-H), 7.93–8.01 (m, 2H, 3-H, 5-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 51.9 ($COOCH_3$), 55.5 (CH_3O), 113.7 (C3, C5), 122.7 (C1), 131.7 (C2, C6), 163.4 (C4), 167.0 ($COOCH_3$). MS (ESI): m/z = 166.8 $[MH]^+$.

2.3. Synthesis of methyl 4-ethoxybenzoate (*2*)

Methyl 4-hydroxybenzoate (6.0 g, 40 mmol) was dissolved in dry DMF (80 ml). K_2CO_3 (19.3 g, 140 mmol) was added and the suspension was stirred for 10 min. Ethyliodide (4.8 ml, 60 mmol) was added dropwise. After stirring for 14 h, water (100 ml) and ethyl acetate (500 ml) were added. The aqueous phase was separated from the organic layer, which was washed with water (8 × 250 ml), dried over $MgSO_4$ and evaporated to dryness to yield **2** as a white solid. Yield: 6.98 g (97%). M.p. 37–38 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.43 (t, J = 7.0 Hz, 3H, CH_3CH_2O), 3.88 (s, 3H, CH_3O), 4.08 (q, J = 7.0 Hz, 2H, CH_3CH_2O), 6.88–6.92 (m, 2H, 2-H, 6-H), 7.96–8.00 (m, 2H, 3-H, 5-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.8 (CH_3CH_2O), 51.9 (CH_3O), 63.8 (CH_3CH_2O), 114.2 (C3, C5), 122.6 (C1), 131.7 (C2, C6), 162.9 (C4), 167.0 ($COOCH_3$). MS (ESI): m/z = 202.9 $[MNa]^+$, 181.2 $[MH]^+$.

2.4. Synthesis of 4-methoxycetophenone (*3*)

4-Hydroxyacetophenone (5.5 g, 40 mmol) was dissolved in dry DMF (80 ml). K_2CO_3 (18 g, 130 mmol) was added and the suspension was stirred for 10 min. Methyliodide (3.8 ml, 60 mmol) was added dropwise. After stirring for 16 h, water (100 ml) and ethyl acetate (500 ml) were added. The aqueous phase was separated from the organic layer, which was washed with water (12 × 250 ml), dried over $MgSO_4$ and evaporated to dryness to yield **3** as a pale yellow solid. Yield: 5.86 g (98%). M.p. 40–41 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 2.54 (s, 3H, CH_3), 3.87 (s, 1H, CH_3O), 6.90–6.97 (m, 2H, 3-H, 5-H), 7.90–7.97 (m, 2H, 2-H, 6-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 26.5 (CH_3), 55.6 (CH_3O), 113.8 (C3, C5), 130.5 (C1), 130.8 (C2, C6), 163.6 (C4), 196.9 ($COCH_3$). MS (ESI): m/z = 150.8 $[MH]^+$.

2.5. Synthesis of 4-ethoxy acetophenone (*4*)

4-Hydroxyacetophenone (5.5 g, 40 mmol) was dissolved in dry DMF (80 ml). K_2CO_3 (18 g, 130 mmol) was added and the suspension was stirred for 10 min. Ethyliodide (4.8 ml, 60 mmol) was added dropwise. After stirring for 16 h, water (100 ml) and ethyl acetate (500 ml) were added. The aqueous phase was separated from the organic layer, which was washed with water (12 × 250 ml), dried over $MgSO_4$ and evaporated to dryness to yield **4** as a beige solid. Yield: 5.86 g (99%). M.p. 38–39 °C. ^{1}H NMR (200 MHz, $CDCl_3$): δ = 1.44 (t, J = 7.0 Hz, 3H, CH_3CH_2O), 2.54 (s, 3H, CH_3), 4.12 (q, J = 7.0 Hz, 2H, CH_3CH_2O), 6.87–6.95 (m, 2H, 3-H, 5-H), 7.88–7.96 (m, 2H, 2-H, 6-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.8 (CH_3CH_2O), 26.4 (CH_3), 63.8 (CH_3CH_2O), 114.3 (C3, C5), 130.3 (C1), 130.7 (C2, C6), 163.0 (C4), 196.9 ($COCH_3$). MS (ESI): m/z = 186.9 $[MNa]^+$, 164.9 $[MH]^+$.

2.6. Synthesis of 1,3-bis(4-methoxyphenyl)propane-1,3-dione (*5H*)

NaH (2.0 g of 60% dispersion in mineral oil, 50 mmol) was added to a mixture of dry DMSO and anhydrous THF (1:2, 150 ml). Compounds **1** (3.3 g, 20 mmol) and **3** (2.2 g, 15 mmol) were dissolved in dry THF (20 ml) and added dropwise to the NaH-suspension while cooling with an ice bath. The brown mixture was allowed to warm up to room temperature after stirring for 1 h, and it was heated to 40 °C and stirred for 16 more h. The THF was evaporated under reduced pressure, water was added (100 ml), and the residue was neutralised with hydrochloric acid (10%) to pH 7. The mixture was then extracted with ethyl acetate (2 × 300 ml), and the combined organic layers were washed with water (10 × 250 ml), dried over $MgSO_4$, and evaporated to dryness. The crude product was recrystallised from ethanol. Compound **5**H was obtained as light brown needles. Yield: 2.22 g (52%). M.p. 119–120 °C. ^{1}H NMR (as mixture of keto and enol forms) (200 MHz, $CDCl_3$): δ = 3.87 (s, 6H, CH_3O), 4.53 (s, CH_2), 6.73 (s, 1H, CH), 6.91–7.01 (m, 4H, 3-H, 3-H, 5-H, 5-H), 7.93–8.03 (m, 4H, 2-H, 2-H, 6-H, 6-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 55.6 (CH_3O), 91.6

(COCH$_2$CO), 114.1 (C3, C3, C5, C5), 128.4 (C1, C1), 129.2 (C2, C2, C6, C6), 163.2 (C4, C4), 184.8 (CO). IR (KBr pellet): ν = 2925 (m), 2849 (m), 1604 (s), 1498 (s), 1204 (m), 120 (s), 1229 (s), 1186 (s), 1171 (s), 1116 (m), 1022 (m), 842 (m), 781 (s), 722 (m), 634 (w) cm^{-1}. MS (ESI): m/z = 307.0 [MNa]$^+$, 285.0 [MH]$^+$.

2.7. Synthesis of 1,3-bis(4-ethoxyphenyl)propane-1,3-dione (**6**H)

NaH (2.0 g of 60% dispersion in mineral oil, 50 mmol) was added to a mixture of dry DMSO and anhydrous THF (1:2, 150 ml). Compounds **2** (4.3 g, 24 mmol) and **4** (2.2 g, 20 mmol) were dissolved in dry THF (20 ml) and added dropwise to the NaH-suspension while cooling with an ice bath. The brown mixture was allowed to warm up to room temperature after stirring for 1 h and it was heated to 40 °C and stirred for 16 more h. The THF was evaporated under reduced pressure, water was added (100 ml), and the residue was neutralised with hydrochloric acid (10%) to pH 7. The mixture was extracted with ethyl acetate (2 × 300 ml) and the combined organic layers were washed with water (8 × 100 ml), dried over $MgSO_4$ and evaporated to dryness. The crude product was recrystallized from ethanol. **6**H was obtained as thin yellow plates. Yield: 4.62 g (74%). M.p. 137–138 °C. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.45 (t, J = 7.0 Hz, 6H, CH_3CH$_2$O), 4.11 (q, J = 7.0 Hz, 4H, CH$_3$CH_2O), 4.52 (s, CH$_2$), 6.72 (s, 1H, CH), 6.90–6.98 (m, 4H, 3-H, 3-H, 5-H, 5-H), 7.93–8.03 (m, 4H, 2-H, 2-H, 6-H, 6-H). ^{13}C NMR (50 MHz, $CDCl_3$): δ = 14.8 (*C*H$_3$CH$_2$O), 63.9 (CH$_3$*C*H$_2$O), 91.6 (CO*C*H$_2$CO), 114.5 (C3, C3, C5, C5), 128.2 (C1, C1), 129.2 (C2, C2, C6, C6), 162.6 (C4, C4), 196.9 (CO). IR (KBr pellet): ν = 2981 (m), 2936 (m), 2891 (m), 1604 (s), 1506 (m), 1389 (m), 1302 (m), 1254 (s), 1229 (s), 1190 (m), 1173 (s), 1120 (s), 1042 (s), 919 (m), 851 (m), 835 (w), 815 (w), 785 (s), 729 (w), 702 (w), 670 (w), 652 (w), 605 (m) cm^{-1}. MS (ESI): m/z = 335.0 [MNa]$^+$, 313.1 [MH]$^+$.

2.8. Synthesis of [Nd(**5**)$_3$(DMF)$_2$]

$NdCl_3 \cdot 6H_2O$ (0.36 g, 1.0 mmol) and **5**H (0.57 g, 2.0 mmol) were added to 50 ml methanol. Once both reagents were completely dissolved, NEt_3 (0.84 ml, 6.0 mmol) was then added dropwise. After stirring the reaction mixture for 13 h, the solvent was evaporated under reduced pressure. The solid was washed with toluene (3 × 10 ml) and then dissolved in DMF (5 ml). Green block shaped crystals were obtained by slow evaporation after 6 months. Yield (not optimised): 0.17 g (15%). *Anal.* Calc. for $C_{57}H_{59}N_2NdO_{14}$: C, 60.04; H, 5.22; N, 2.46. Found: C, 59.78; H, 5.32; N, 2.43%. IR (KBr pellet) ν: 2933 (w), 2835 (w), 1663 (w), 1641 (m), 1658 (s), 1525 (s), 148,5 (s), 1459 (s), 1430 (s), 1376 (s), 1302 (m), 1249 (s), 1217 (m), 1168 (m), 1103 (s), 1061 (w), 1022 (m), 936 (m), 842 (w), 780 (m) cm^{-1}.

2.9. Synthesis of [Eu$_4$(OH)$_2$(**Ph$_2$acac**)$_{10}$]

$EuCl_3 \cdot 6H_2O$ (0.37 g, 1.0 mmol) and **Ph$_2$acac**H (0.45 g, 2.0 mmol) were added to 50 ml methanol. Once both reagents were completely dissolved, NEt_3 (0.84 ml, 6.0 mmol) was then added dropwise. After stirring the reaction mixture for 13 h, the solvent was evaporated under reduced pressure. The residue was stirred in toluene (15 ml) and filtered. The resulting yellow solid was washed with ethanol (3 × 30 ml) and then dissolved in chloroform (5 ml). Bright yellow crystals were obtained by slow diffusion of hexane into this solution. Yield (not optimised) 0.21 g (15%). *Anal.* Calc. for $C_{150}H_{132}Eu_4O_{22}$: C, 62.24; H 4.60. Found: C, 62.32; H, 4.05%. 2.10. Synthesis of [Eu$_5$(OH)$_5$(**6**)$_{10}$]

Compound **6**H (0.62 g, 2.0 mmol) was dissolved in a mixture of methanol/THF (1:1, 50 ml), and $EuCl_3 \cdot 6H_2O$ (0.37 g, 1.0 mmol) was added. Once both reagents were completely dissolved, NEt_3 (0.84 ml, 6.0 mmol) was then added dropwise. After stirring for 16 h the solvents were evaporated and toluene (30 ml) was added to the residue. The mixture was stirred for 2 h and filtered. The toluene solution was left undisturbed to evaporate to yield yellow crystals after 1 week. Yield (not optimised): 0.24 g (28%). *Anal.* Calc. for $C_{204}H_{211}Eu_5O_{45}$: C, 59.15; H, 5.13. Found: C, 58.81; H, 5.22%. 2.11. Synthesis of [Ho$_5$(OH)$_5$(**Ph$_2$acac**)$_{10}$]

$HoCl_3 \cdot 6H_2O$ (0.38 g, 1.0 mmol) and **Ph$_2$acac**H (0.56 g, 2.5 mmol) were added to 50 ml methanol. Once both reagents were completely dissolved, NEt_3 (0.84 ml, 6.0 mmol) was added dropwise. The solution was stirred for 16 h and then evaporated to dryness under reduced pressure. The residue was stirred in toluene (15 ml) and the remaining white solid was filtered off. The filtrate was allowed to stand undisturbed at room temperature to yield yellow crystals after 5 days. Yield (not optimised): 0.10 g (16%). *Anal.* Calc. for $C_{150}H_{115}Ho_5O_{25}$: C, 57.34; H, 3.69. Found: C, 57.67; H, 3.83%. 3. Results and discussion

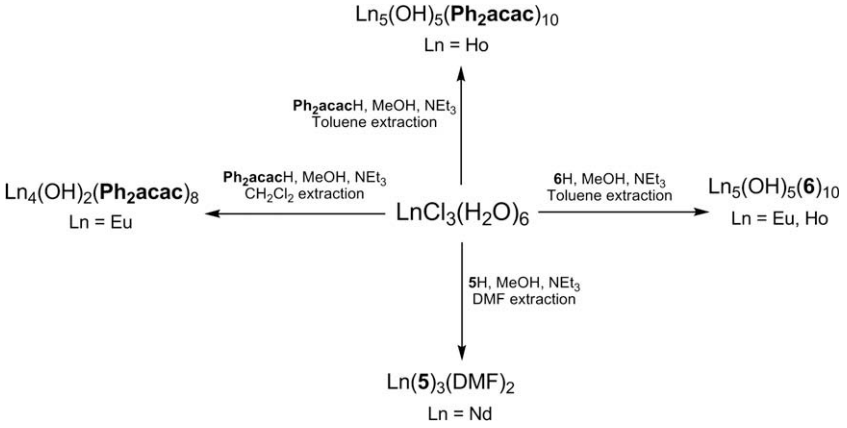
3.1. Synthesis of the functionalised ligands and preparation of the polynuclear clusters

The functionalised ligands 1,3-bis(4-methoxyphenyl)propane-1,3-dione (**5**H) and 1,3-bis(4-ethoxyphenyl)propane-1,3-dione (**6**H) were prepared in two steps, as shown in Scheme 1. First, the corresponding 4-hydroxyacetophenone and methyl 4-hydroxybenzoate precursors were treated with MeI or EtI in DMF to produce either the methoxy compounds **1** and **3** or the ethoxy functionalised compounds **2** and **4**. Subsequently, via Claisen condensation, **5**H and **6**H were obtained through coupling of **1** with **3** or **2** with **4** respectively using NaH in dry THF. Only the symmetrical versions of the β-diketones were prepared and investigated in this work.

The cluster compounds were prepared according to the literature procedure [4] by treating 1 equiv. of the corresponding hy-



Scheme 1. Synthesis of the functionalised β-diketonate ligands 5 and 6.

drated lanthanoid chloride ($LnCl_3(H_2O)_6$, Ln = Nd, Eu, Ho) with 2 equiv. of ligand (**Ph$_2$acac**H, **5**H, or **6**H) in the presence of an excess of triethylamine in methanol. When the ligands **Ph$_2$acac**H or **6**H were used, the cluster compounds were extracted with toluene or dichloromethane after complete removal of the methanol. The organic phase was then washed with water to remove any unreacted triethylamine along with residual triethylammonium chloride or lanthanoid salt. This procedure yielded the tetranuclear cluster $[Eu_4(OH)_2(\mathbf{Ph_2acac})_8]$ as well as the pentanuclear clusters $[Eu_5(OH)_5(\mathbf{6})_{10}]$ and $[Ho_5(OH)_5(\mathbf{6})_{10}]$. The reaction of the lanthanoid chlorides with **5**H yielded products with poor solubility in toluene, chlorinated solvents or alcohols. Therefore, they were dissolved in DMF and allowed to stand undisturbed. After several months, single crystals suitable for X-ray diffraction were obtained starting from $NdCl_3$ and **5**H. The structure was identified as a mononuclear complex of formula $[Nd(\mathbf{5})_3(DMF)_2]$. At present, due to the insolubility of the product, it is still unclear whether this mononuclear complex was the only species formed in the initial reaction mixture or resulted from deaggregation of a polynuclear cluster in DMF. However, previous studies on polynuclear oxo/hydroxo lanthanoid clusters have shown these cages are unstable in water but relatively stable in highly polar organic solvents such as DMF or DMSO [3d]. By comparison with these results it seems likely that the poor solubility of the complex prevents its further growth into an hydroxo cluster. A summary of the reactions attempted and the corresponding products is given in Scheme 2.

3.2. Crystallography

The tetranuclear $[Eu_4(OH)_2(\mathbf{Ph_2acac})_8]$ and the pentanuclear $[Ho_5(OH)_5(\mathbf{Ph_2acac})_{10}]$ are isostructural with previously reported clusters and will not be described in any detail within this work. Small differences in bond lengths, primarily due to the lanthanoid contraction [11], are provided in Table 1. Interestingly though, in

Scheme 2. Summary of the attempted reactions and corresponding obtained products.

Table 1
Selected bond lengths for $[Eu_4(OH)_2(\mathbf{Ph_2acac})_{10}]$ and $[Ho_5(OH)_5(\mathbf{Ph_2acac})_{10}]$.

Ligand	$[Eu_4(OH)_2(\mathbf{Ph_2acac})_{10}]$	Bond (Å)	$[Ho_5(OH)_5(\mathbf{Ph_2acac})_{10}]$	Bond (Å)
OH	Eu(1)–O(1)	2.410(4)	Ho(1)–O(1) (μ_3-OH)	2.312(4)
OH	Eu(2)–O(1)	2.343(4)	Ho(1)–O(2) (μ_4-OH)	2.560(2)

the case of Eu both tetranuclear and pentanuclear clusters are formed. It is known that bigger lanthanoids prefer tetranuclear cages where each metal cation is nonacoordinated, whereas smaller ones tend to form pentanuclear cages with octacoordinated metal ions [6]. In this respect, Eu represents the borderline of this trend.

The Nd complex [Nd(**5**)$_3$(DMF)$_2$] (Fig. 1) crystallises in the triclinic space group $P\bar{1}$. The metal is overall octacoordinated by three diketonate ligands, which all adopt a chelating configuration, and two molecules of DMF. Two of the ligands lie on a plane with the third almost perpendicular, whereas the other face of the complex is occupied by the two coordinated solvent molecules. A third molecule of DMF resides in the crystal lattice. The structure does not show any appreciable intermolecular hydrogen bonding, however, the phenyl rings of the diketonate ligands form a π-stacking network exhibiting offset face-to-face bonding with an average distance of 3.6 Å and a vertex-to-face bonding (C–H═C_6H_4 centroid 3.1 Å).

[Eu$_5$(OH)$_5$(**6**)$_{10}$], and [Ho$_5$(OH)$_5$(**6**)$_{10}$] (Fig. 2, where only the Ho cage is reported) are isostructural, showing only small differences in bond lengths between the oxygen atoms of the diketonate and hydroxo ligands due to the lanthanoid contraction passing from Eu to Ho [11] (see Table 2). The structure and geometry of the pentanuclear cage is isostructural with previously published pentanuclear clusters with dibenzoylmethanide ligands. In this case however, the presence of the ethoxy groups in the ligands lowers the symmetry and the compounds crystallise in a monoclinic space group ($C2/c$). Four toluene molecules are present in the lattice. There is no appreciable evidence of either intermolecular hydrogen bonding or π-stacking.

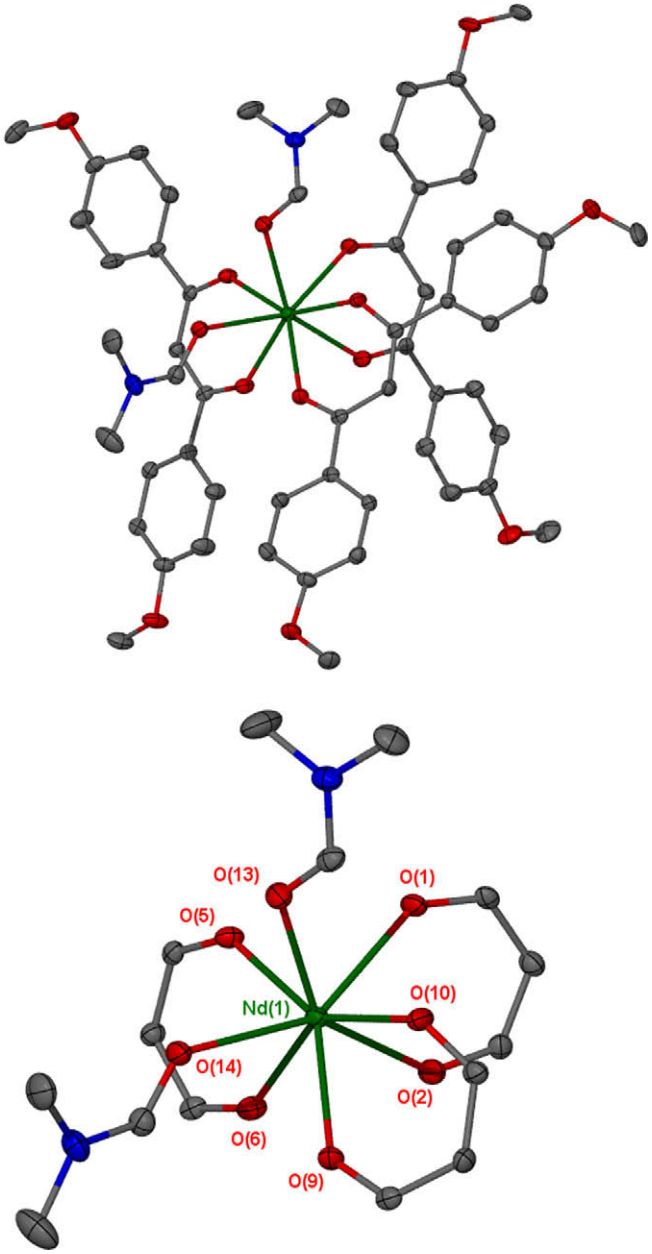

Fig. 1. X-ray crystal structure of [Nd(**5**)$_3$(DMF)$_2$] (top) and coordination environment around the Nd cation (bottom) with ellipsoids at 50% probability. Hydrogen atoms are omitted for clarity.

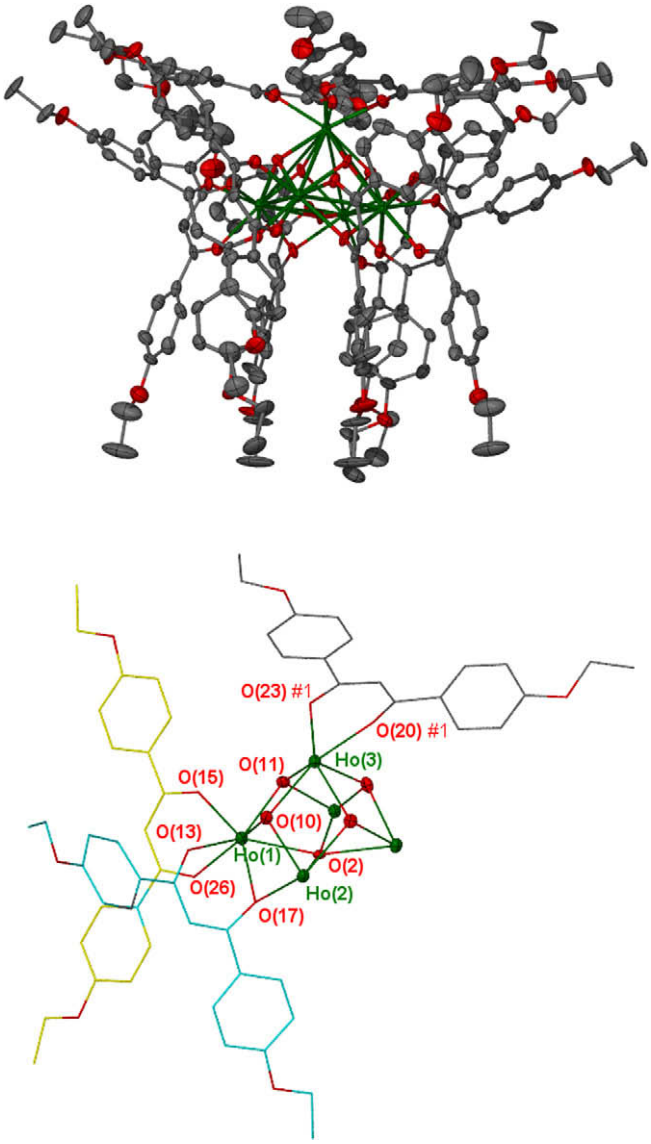

Fig. 2. X-ray crystal structure of [Ho$_5$(OH)$_5$(**6**)$_{10}$] (top) and cluster core (bottom) showing with one ligand chelating (yellow), one ligand chelating/bridging (blue) and one ligand chelating the apical holmium atom (grey). Ellipsoids at 50% probability for core atoms. Hydrogen atoms omitted for clarity, labelling only for atoms that are part of the asymmetric unit and #1 $-x, y, 1/2 - z$. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

3.3. Magnetic measurements on the cluster compounds

The plots of the dc μ_{eff} and χ_M values, per Eu_4 in $[Eu_4(OH)_2(\mathbf{Ph_2acac})_8] \cdot 2\ CHCl_3 \cdot$ hexane, are given in Fig. 3. It can be seen that the μ_{eff} values decrease gradually from 6.5 μ_B (3.25 μ_B per Eu) at 300 K to 0.75 μ_B at 2 K (0.37 μ_B per Eu). The corresponding χ_M values show a broad maximum/plateau between ~70 and 30 K, possibly due to medium strength antiferromagnetic (antiparallel) coupling of the f^6 spins. This plateau region is followed by a rapid, Curie-like increase in χ_M that commonly (in d-block clusters) originates from traces of monomeric (more strongly) paramagnetic impurities. Single ion Eu(III) compounds display μ_{eff} values at 300 K of ~3.4 μ_B, compared to a calculated value of ~3.61 μ_B obtained after consideration of ligand field and spin–orbit splitting of the ^7F free-ion ground state (to give J levels 0 ($^7F_0$ ground level), 1, 2, 3, 4, 5, 6) and thermal population of the first excited $^7F_1$ level following its splitting by first order Zeeman magnetic field effects (H), together with second order Zeeman contributions (H^2) [12,13]. Because of large spin–orbit coupling constants in f-block ions, the separation of the $^7F_0$ and $^7F_1$ levels is of the order of the Boltzmann energy kT (210 K at 300 K) and thus monomeric Eu(III) compounds will show a significant temperature dependence in μ_{eff}, with a zero value calculated at 0 K. Thus, in clusters of the present kind, sorting the spin–spin coupling from the single-ion ligand field/spin–orbit effects is not trivial. The plateau in χ_M at low temperatures might originate from a combination of second order Zeeman (TIP, temperature independent susceptibilities) single-ion effects and weak intra-cluster antiferromagnetic coupling. Very similar plots of μ_{eff} (expressed as $\chi_M T$) and χ_M, versus temperature to those given in Fig. 3 have recently been reported for tetranuclear (chain) species $[Eu_2(L^1)_2(1,10\text{-phen})_2(H_2O)_5] \cdot 3H_2O$, where L^1 is *m*-sulphophenylphosphonate, (μ_{eff} at 300 K = 3.39 μ_B, per Eu) for which antiferromagnetic coupling was suggested [2b], and in the framework structures $[Eu(benzenetricarboxylate)(H_2O)]_n$ and $\{[Eu_2(2\text{-amino-1,4-benzene-dicarboxylate})_3 \cdot (dmf)_4] \cdot 2dmf\}_n$ for which the thermal population of $^7F_1$ levels was invoked, with spin–spin coupling across the carboxylate bridges being assumed to be negligible to weak [14].

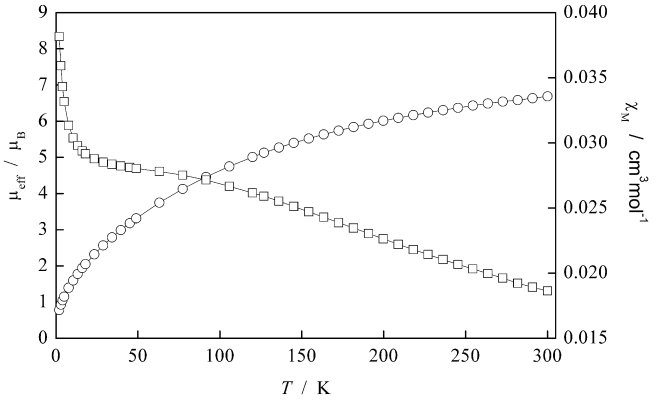

Fig. 3. Plots of molar magnetic susceptility, χ_M, per Eu_4 (squares) and effective magnetic moment, μ_{eff}, per Eu_4 (circles) for $[Eu_4(OH)_2(Ph_2acac)_8] \cdot$ hexane $\cdot$ 2chloroform. The solid lines are just guides to the eye.

The plots of μ_{eff} and χ_M, per Eu_5, versus temperature for $[Eu_5(OH)_5(\mathbf{6})_{10}] \cdot 4$ toluene are given in Fig. 4 and generally have a similar shape to those in Fig. 3, but with a higher plateau value in χ_M between 60 and 10 K, because of the extra Eu(III) centre in this

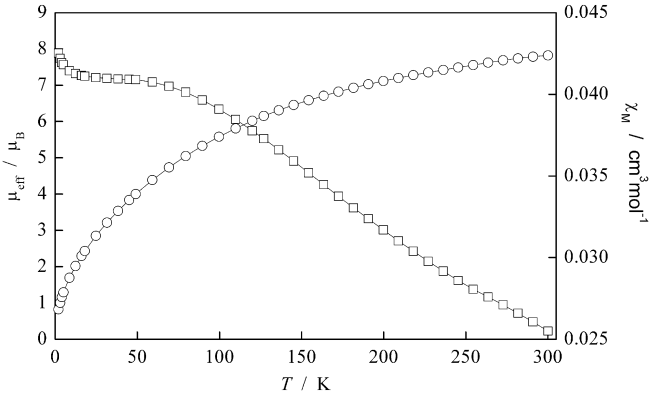

Fig. 4. Plots of molar magnetic susceptility, χ_M, per Eu_5 (squares) and effective magnetic moment, μ_{eff}, per Eu_5 (circles) for $[Eu_5(OH)_5(6)_{10}] \cdot 4$ toluene.

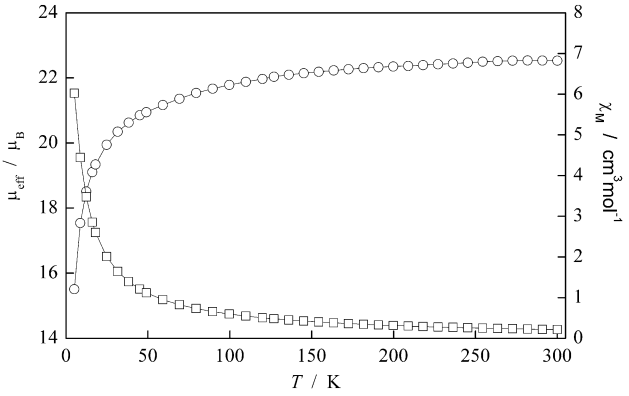

Fig. 5. Plots of molar magnetic susceptility, χ_M, per Ho_5 (squares) and effective magnetic moment, μ_{eff}, per Ho_5 (circles) for $[Ho_5(OH)_5(\mathbf{6})_{10}] \cdot 4$ toluene.

cluster. The room temperature value of μ_{eff}, per Eu, of 3.54 μ_B (7.89 μ_B, per Eu_5), is again typical of Eu(III) compounds and the temperature variation poses the same questions that were discussed for the tetranuclear compound, above, in that the ligand field/spin–orbit effects can not easily be untangled from any antiferromagnetic coupling, although the latter appears to be very weak. The Eu...Eu distances in the crystal structure, of 3.6–3.9 Å, connected by hydroxide are probably longer than the *cis*-carboxylate bridging in the benzenecarboxylate network systems [14] and similar to one of the phosphonate bridging distances (3.81 Å) in $[Eu_2(L^1)_2(1,10\text{-phen})_2(H_2O)_5] \cdot 3H_2O$ [2b]. Thus, from a chemical/structural perspective, it is difficult to predict whether spin coupling between Eu(III) centres is significant, or whether the magnetism is largely single-ion in origin. The examples cited, and the present Eu_4 and Eu_5 clusters, all show rather similar magnetic moment plots irrespective of the bridging ligands employed.

The plot of μ_{eff} and χ_M, per Ho_5, versus temperature for $[Ho_5(OH)_5(\mathbf{6})_{10}] \cdot 4$ toluene is given in Fig. 5. The μ_{eff} values gradually decrease from 22.4 μ_B at 300 K (10.01 μ_B per Ho(III)) to 15.5 μ_B at 4.2 K (6.93 μ_B per Ho(III)). The corresponding χ_M/T plot shows Curie–Weiss behaviour. The Ho(III) f^{10} configuration, with a $^5I_8$ free-ion ground state, typically leads to observed values of ~10.4 μ_B in monomeric systems, and this compares well to the calculated $g(J(J+1))^{0.5}$ value of 10.6 μ_B. Since spin–orbit coupling, second order Zeeman and ligand field effects do not influence the magnetism, as was the case in Eu(III), the decrease in μ_{eff} values with decreasing temperature strongly suggests that antiferromagnetic coupling is occurring in this cluster, via the hydroxo bridges. It is not strong enough, however, to give a maximum in χ_M, a characteristic feature of antiferromagnetic coupling, at least in d-block

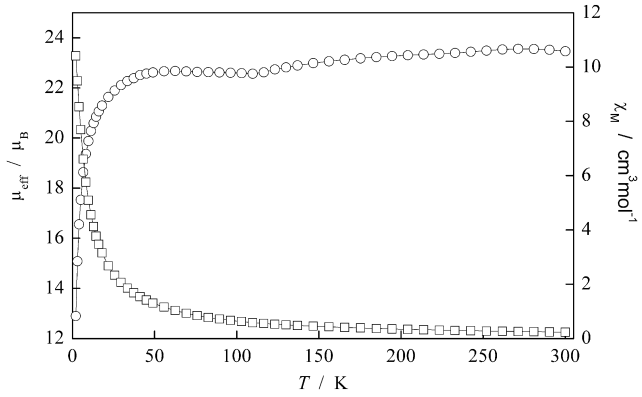

Fig. 6. Plots of molar magnetic susceptility, χ_M, per Ho_5 (squares) and effective magnetic moment, μ_{eff}, per Ho_5 (circles) for $[Ho_5(OH)_5(\mathbf{Ph_2acac})_{10}] \cdot 4$ toluene.

cluster systems. There appear to be few, if any Ho(III) clusters to make comparisons of the present data to. Some metallocrown 15-MC-5 complexes containing both Ho(III) and Cu(II), in dimeric or helical structures, show values of μ_{eff} of 10.4 μ_B at 300 K, decreasing to 7.85 μ_B at 2 K, due to the constituent f^{10} and d^1 spin centres. Exchange coupling parameters could not be obtained for such a complicated situation [15].

The magnetism plots for $[Ho_5(OH)_5(\mathbf{Ph_2acac})_{10}]$ are given in Fig. 6, and, while showing a μ_{eff} value at 300 K similar in size to that of $[Ho_5(OH)_5(\mathbf{6})_{10}] \cdot 4$ toluene, viz. 10.42 μ_B, there is an unusual but reproducible shallow dip at ~100 K, followed, below 50 K, by a rapid decrease with μ_{eff} reaching 5.72 μ_B at 2 K. Assuming that trace impurities are not present, and that there is no phase change at ~100 K, it would appear that changing the β-diketonate ligand from $\mathbf{6}^-$ to $\mathbf{Ph_2acac}^-$ leads to small differences in the magnetism and in the electronic structure of these Ho_5 clusters.

To probe for SMM behaviour in the present clusters, and in view of the very recent report of this important feature occurring, below ~3 K, in an isostructural Dy(III) cluster, $[Dy_5(OH)_5(\mathbf{Ph_2acac})_{10}]$ [3c], the latter showing dc μ_{eff} versus T plots rather like those in Fig. 6, measurements of the dynamic ac in-phase, χ'_M, and out-of-phase, χ''_M, values were made on the clusters between 10 and 2 K, in frequencies of 50–1500 Hz under a close to zero dc applied field. The temperature dependence of χ'_M was Curie–Weiss-like, as in the dc χ_M plots, while the χ''_M values remained close to zero between 10 and 2 K, with only the merest hint of frequency dependent increases at close to 2 K. This contrasts with the clear maxima, at ~3 K, observed in the χ''_M versus T plots for $[Dy_5(OH)_5(\mathbf{Ph_2acac})_{10}]$. Thus we would require facilities to measure χ''_M below 2 K, with a dc field applied to move any frequency dependent maxima above 2 K.

4. Conclusions

The reaction of functionalised β-diketones, as analogues of dibenzoylmethane bearing *para* ethoxy group, with Eu and Ho trichlorides yielded tetranuclear and pentanuclear hydroxo clusters. These structures demonstrate that the increased bulkiness of the ligand has no effect on the formation of the cluster core. On the other side, the methoxy functionalised β-diketone yielded a Nd mononuclear complex. It is still unclear whether this complex does not grow into a cluster due to its limited solubility in the reaction medium or as a cause of deaggregation in polar solvents like DMF. The magnetic studies on the present clusters of Eu(III) and Ho(III) show typical temperature dependent magnetic moment data for these ions. Any antiferromagnetic coupling, within the clusters, is very weak and the decrease in magnetic moments with decreasing temperature is largely due to thermal depopulation of Zeeman lev-

els that originate from the Eu(III) single ion energy levels formed after the free ion states have been split by ligand field and spin–orbit coupling effects. Low temperature plateaus in the molar susceptibilities of the Eu(III) clusters are probably due to second order Zeeman effects rather than to antiferromagnetic coupling. It is likely that antiferromagnetic coupling across the hydroxo bridges is occurring in the Ho(III) clusters since spin–orbit splittings and Zeeman population effects are much less applicable than in the Eu(III) analogues. While there are some hints of SMM behaviour in the Eu and Ho clusters, below 2 K, we do not see the typical maxima in the out-of-phase ac susceptibilities, at different frequencies, recently observed in a closely related pentanuclear Dy(III) cluster [3c]. In other work on large Ln(III) clusters containing different bridging groups than those employed here, some of us have realised, as in Ref. [3c], that to observe SMM features in homometallic Ln(III) species, Dy(III) ($S = 5/2$; $^6H_{15/2}$ ground state) is the lanthanide ion of choice [16]. Much more work on different lanthanoids is needed, however, to test this idea.

5. Supplementary data

CCDC 701176–701180 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via <http://www.ccdc.cam.ac.uk/conts/retrieving.html>, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgments

The authors want to thank Dr. Craig Forsyth (Monash University) and Dr. Regine Herbst-Irmer (Universität Göttingen) for the help provided regarding the crystal structures. Prof. George M. Sheldrick (Fakultät für Chemie, Universität Göttingen) is also gratefully acknowledged for Tobias Beck's student exchange program at Monash University. This work was supported by the Australian Research Council, Monash University and Bayer Schering Pharma.

Coordination polymer of zinc(II)
1,2,4-Triazole
Trimesic acid
Benzene-1,2,4,5-tetracarboxylic acid
Photoluminescence

ABSTRACT

Two coordination polymers of the formula $[Zn_5(tmaH)_4(trz)_2(H_2O)_4]$ (**1**) and $[Zn_3(bta)(trz)_2(H_2O)_4]\cdot 2H_2O$ (**2**) [$tmaH_3$ = benzene-1,3,5-tricarboxylic acid/trimesic acid, trzH = 1,2,4-triazole, $btaH_4$ = benzene-1,2,4,5-tetracarboxylic acid] have been synthesized and structurally characterized by X-ray single crystal diffraction analysis. Both complexes are 3D coordination polymers containing $[Zn_4(trz)_2]$ units connected by benzene-carboxylate anions. In particular, an undulated layer containing 6- and 18-membered rings is outlined in the network of **1**. Hydrogen bonds, involving the coordinated and lattice water molecules with carboxylate oxygen atoms, contribute to the stabilization of the networks. Their thermal stability was investigated by thermogravimetric analysis. The fluorescence spectrum of **1** features two peaks at 419 and 323 nm, originating from a π–π^* intraligand transition and LMCT, respectively. For **2** a broad band at 410 nm is assigned solely as a π–π^* intraligand transition.

1. Introduction

Metal organic frameworks (MOFs) [1–3] have been an area of increasing interest due to their topology and potential application in the field of ion exchange [4–6], catalysis [7–9], luminescence [10–12] and gas storage [13–16]. Among the variety of organic molecules used as linkers in the design of supramolecular networks, aromatic polycarboxylates (O-donor) and heterocyclic N rings are the most widely used ligands due to their rigidity in structure and flexibility in coordination modes [17–24].

Several metal organic supramolecular structures based on $tmaH_3$ [$tmaH_3$ = benzene-1,3,5-tricarboxylic acid/trimesic acid] and $btaH_4$ [benzene-1,2,4,5-tetracarboxylic], in the form of differently deprotonated anions, have been reported. The examples show an extensive application of these ligands towards transition metal ions with the aim to build architectures of high dimensionality [25–30]. Polyaza heterocycle trzH [1,2,4-triazole] and its derivatives are very interesting ligands with N-donor centers, which can produce interesting networks with novel topologies [31–37]. TrzH can function as a neutral bridging ligand to two metal sites or as a bridge between three metal centers in the azolate form (trz^-). By exploiting the ligating behavior of these two types (O- and N-donors) of ligands, interesting novel networks can be synthesized.

In this work we report the hydrothermal synthesis, structural characterization, thermal and photoluminescence properties of two new coordination complexes showing a 3D network, namely $[Zn_5(tmaH)_4(trz)_2(H_2O)_4]$ (**1**) and $[Zn_3(bta)(trz)_2(H_2O)_4]\cdot 2H_2O$ (**2**).

2. Result and discussions

2.1. Preparation of the complexes

Zinc(II) complexes **1** and **2** were obtained by reacting zinc(II)acetate and 1,2,4-triazole with benzene-1,3,5-tricarboxylic acid and benzene-1,2,4,5-tetracarboxylic acid, respectively. The pH of both of reaction mixtures were adjusted to five by adding NaOH solution. Both the isolated compounds are air-stable, less soluble in water and alcohols, but soluble in solvents with pronounced donor properties.

2.2. Structure description of *1*

An ORTEP view of the three crystallographically independent Zn(II) coordination spheres is depicted in Fig. 1 and selected bond lengths and angles are reported in Table 1. The three independent metals present different coordination environments, Zn(1) and Zn(3) having distorted tetrahedral NO_3 and N_2O_2 donor sets, respectively, neglecting a long Zn–O(carboxylate) distance of 2.271(3) Å for the latter. The Zn(1)- and Zn(3)-N(triazole) coordination bond lengths are between 2.000(3) and 2.024(3) Å, those

with O-carboxylate fall in a larger range from 1.941(2) to 2.072(2) Å. On the other hand, the Zn(2) ion, located on an inversion center, presents an octahedral O_6 chromophore, with Zn–OH_2 bond lengths of 2.159(3) and 2.063(3) Å, and Zn–O(carboxylate) distances of 2.060(2) Å. All these values are within the range usually observed for Zn(II) compounds containing five-membered azaheterocycles and benzene-carboxylate anions [38–44]. Fig. 2 shows the centrosymmetric $[Zn_4(trz)_2]$ unit and the bridging behavior of the triazolato ligand coordinating two Zn(3) ions spaced at 3.807 Å, while the Zn(1)–Zn(3) and Zn(1)–Zn(3′) distances are 6.070 and 5.956 Å, respectively. In addition, the metals are linked by carboxylate groups having sin-anti bridging behavior (intermetallic Zn(1)–Zn(2) and Zn(1)–Zn(3) distances of 5.048 and 4.353 Å). The described connections give rise to an undulated layer comprising 6- and 18-membered rings (Fig. 2). These undulated metal layers are further connected by bridging benzene-1-carboxylic-3,5-carboxylato dianions to form a 3D network (Fig. 3), which is reinforced by H-bonds involving the aquo and carboxylate oxygen atoms. Strong interactions (O–H···O distance of *ca.* 2.6 Å; Table 1S in SI) are measured for the H-bonds occurring between the carboxylic groups. Here the 1,3,5-tricarboxylate dianions show different behavior, one acts as μ_3-bridging/monocoordinating, the other as μ_3-bridging/chelating species (Fig. 1S in SI). It is interesting to note that the carboxylate groups involved in metal bridging are tilted with respect to the benzene ring by 39.6(2)° (C7/O1/O2) and 23.2(2)° (C16/O7/O8), while the other $-CO_2$ groups are almost coplanar with the ring atoms.

2.3. Structure description of **2**

The two crystallographic independent ions, Zn(1) and Zn(2), exhibit a N_2O_4 octahedral and a distorted N_2O_2 tetrahedral coordination environment, respectively. Fig. 4 depicts the crystal structure, while a selection of bond lengths and angles is collected in Table 2. The coordination bond distances of Zn(2) are almost comparable, being in the range 1.922(4) to 1.993(4) Å, the Zn(1)–O(1w), Zn(1)–N(1) and Zn(1)–O(2w) distances vary from 2.070(5) to 2.100(4) and 2.146(4) Å, respectively. The deprotonated triazole ligand bridges three metal ions forming an isosceles triangle, the base being defined by two Zn(2) ions spaced at 3.611 Å, while the two Zn(1)–Zn(2) distances are 5.993 and 6.170 Å. These values are comparable to those measured in the structure of **1**. The crystal structure can be described as being built up of – $Zn(1)(H_2O)_4$ – $[Zn(2)_2(trz)_2]$ – arrays running in the ac plane, which are linked by μ_4-tetrabenzene-carboxylate anions (Fig. 5) to form a 3D architecture. Each carboxylate group is tilted by about 54.9(4)° with respect to the phenyl ring, having one oxygen atom coordinating a metal ion and the other acting as a H-bond acceptor for an aquo ligand. The conformation assumed by the carboxylate groups is likely attained for steric reasons in order to accomplish metal coordination and H-bond interactions. The described H-bonding scheme together with interactions realized by lattice water molecules and carboxyl groups contribute to the stabilization of the overall crystal structure (O–H···O distances in the range 2.640–2.836 Å) (Table 1S in SI).

2.4. PXRD study

The simulated and measured XRD patterns of compounds **1** (Fig. 6a) and **2** (Fig. 6b) match well, indicating that the solid structures are unchanged during the crystallization process.

2.5. Thermal study

The thermal decomposition profiles for **1** and **2** are shown in Figs. 7 and 8, respectively. Compound **1** is thermally stable up to 40 °C. On further heating, the compound is dehydrated in two steps

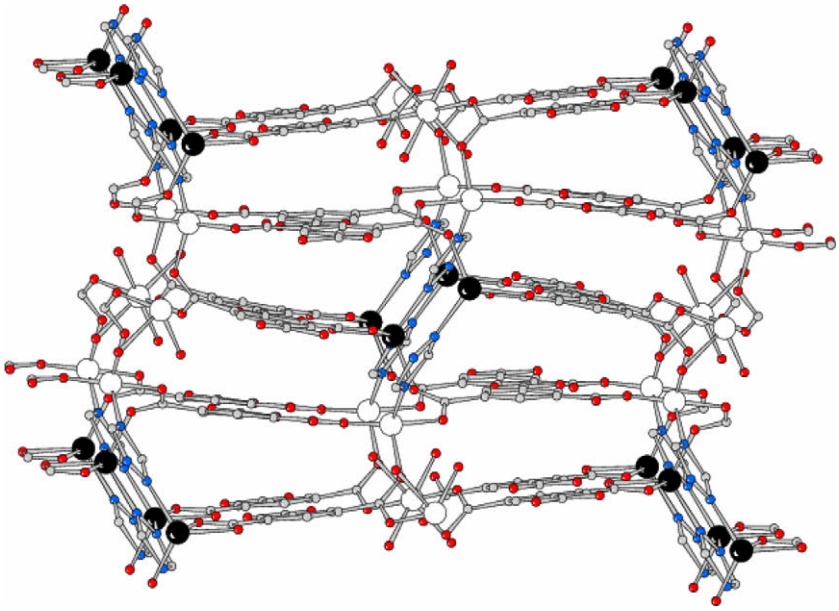

Fig. 3. 3D structure of **1** showing the bridging benzene-carboxylato anions connecting the undulated layers [Zn(3) evidenced as black spheres].

(four coordinated water molecules, mass loss *ca.* 5%, Calc. 5.2%) in the temperature range 40–250 °C. The deaquation temperature range is significant, with the presence of two types of strong hydrogen bonding of the coordinated water molecules (O–H: 2.6 and 2.8 Å). The deaquated species collapsed further upon heating as the Zn centers fail to attain a stable geometry after the removal of the coordinated water molecules. A rapid weight loss (*ca.* 9.8%, Calc. 9.9%) between 260 and 340 °C corresponds to the loss of the trz^- ligand, and sharp weight loss (*ca.* 59%, Calc. 60.8%) between 350 and 630 °C is attributed to the loss of the $tmaH^{2-}$ ligand. Compound **2** undergoes a preliminary dehydration process between 80 and 130 °C, corresponding to the loss of a total of six water molecules in two steps (mass loss *ca.* 15%, Calc. 15.6%), indicating the presence of coordinated and non-coordinated water molecules. The subsequent step between 350 and 460 °C is associated with the loss of the bta^{4-} ligand with a mass loss of *ca.* 36% (Calc. 36.2%). Finally the trz^- ligand is lost (mass loss *ca.* 19%, Calc. 19.7%) between 725 and 770 °C.

2.6. Photoluminescence study

The luminescence study of the ligands and complexes has been performed in the solid state at room temperature. The two polycarboxylates *i.e.* $tmaH_3$ and $btaH_4$, give no fluorescence response, whereas the azole trzH shows an emission band around 370 nm with $\lambda_{ex} = 300$ nm (Fig. 2S in SI). Compound **1** shows two peaks: a major peak at 323 nm and a weak emission at 419 nm when excited at 278 nm (Fig. 9). For compound **2** a bright fluorescence at 410 nm with a broad emission band has been found when the complex is excited at 320 nm (Fig. 10). During a comparison of the emission properties of the complexes with the trzH ligand, the red shifted band by 49 nm (for **1**) and 40 nm (for **2**) can be assigned as a π–π^* intraligand charge transfer of the triazole ring. On the contrary, for **1**, the 323 nm band, blue shifted by ~47 nm, can be assigned as a ligand-to-metal charge transfer (LMCT) transition. The probable reason for this is that the triazole ring is a deprotonated π-excessive system which is coordinated to the Zn(II) center by displacing one hydrogen atom. The coordination of Zn(II) with the trz^- ring decreases the electron density of the trz^- ring, which is responsible for the weakening of the strength of emission.

3. Conclusion

The reaction of the 1,2,4-triazole ligand and zinc(II) metal with aromatic polycarboxylates affords interesting polymeric architec-

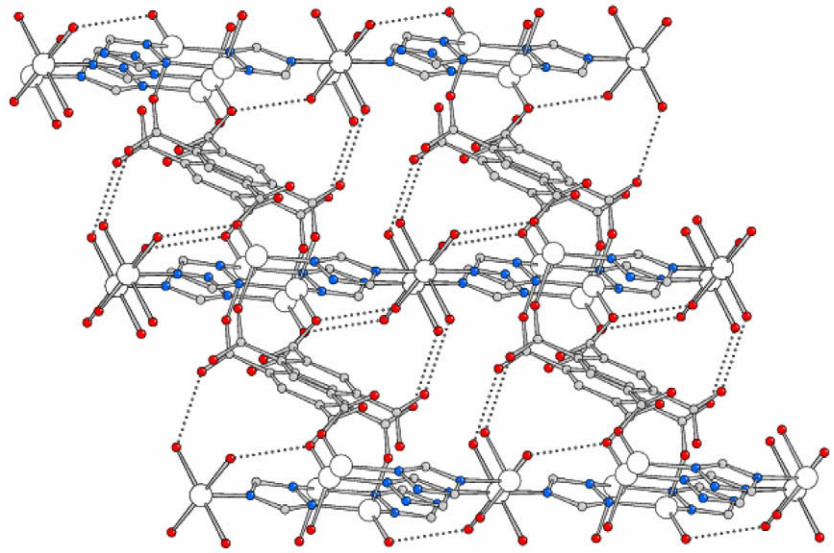

Fig. 5. 3D crystal packing of **2** viewed down the *a*-axis with H-bonds indicated (dotted lines). Guest water molecules are not shown.

tures. In this work, the combination of the 1,2,4-triazolate anion (trz^-) with the benzene-1,3,5-tricarboxylate dianion ($tmaH^{2-}$) or the fully deprotonated benzene-1,2,4,5-tetracarboxylate (bta^{4-}) with Zn(II) ions leads to two 3D coordination networks. The X-ray structural analysis of the compounds revealed that both the polymeric structures comprise centrosymmetric $[Zn_4(trz)_2]$ fragments where each triazolato ligand bridges three metal ions. In particular, an undulated layer containing 6- and 18-membered rings is outlined in the crystal structure of **1**. A photoluminescence study revealed that the red shifted band for both compounds is due to a π–π^* intraligand charge transfer of the triazole ring, while the blue shifted band in **1** is due to LMCT. The synthesis of these compounds demonstrates that the proper combination of polycarboxylates and 1,2,4-triazole derivatives is an excellent way to synthesize interesting high dimensional networks/MOFs.

4. Experimental

4.1. Materials and physical measurements

All the chemicals for the synthesis were used as received. Zinc acetate dihydrate was obtained from MERCK. Benzene-1,3,5-tricar-

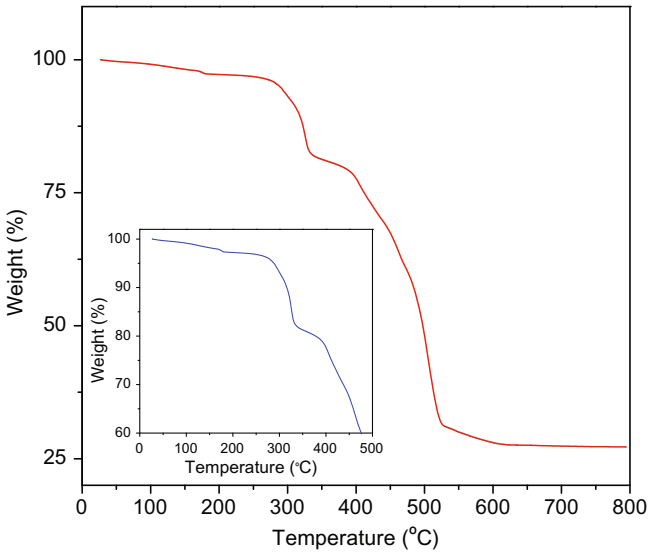

Fig. 7. TG analysis of **1** in the temperature range 25–800 °C with a heating rate of 10 °C/min under N_2 atmosphere.

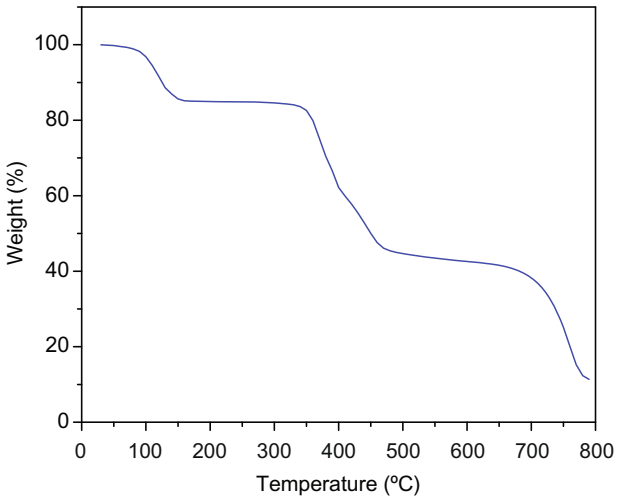

Fig. 8. TG analysis of **2** in the temperature range 25–800 °C with a heating rate of 10 °C/min under N_2 atmosphere.

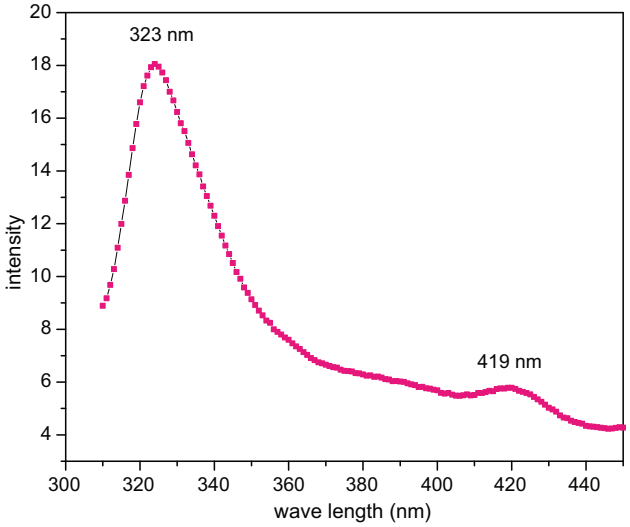

Fig. 9. Solid state emission spectra of **1** at room temperature (λ_{ex} = 278 nm).

boxylic acid, benzene-1,2,4,5-tetracarboxylic acid and 1,2,4-triazole were purchased from SIGMA–ALDRICH Inc. IR specta for **1** and **2** were recorded in a JASCO FT/IR-6200 using the ATR technique in the range 4000–400 cm^{-1}. Elemental analyses (C, H, N) were performed using a Perkin–Elmer 240C elemental analyzer. Thermogravimetric analysis (TGA) were done under nitrogen (flow rate of 20 mL min^{-1}) with a Metler Toledo (SDTA 851e) analyzer in the temperature range 25–800 °C, with a heating rate of 10 °C/min. X ray powder diffraction data were recorded on a BRUKER AXS D8 advance instrument using Cu Kα radiation. The fluorescence spectra of the ligands and compounds were measured in the solid state at room temperature using a HITACHI F-7000 spectrofluorimeter.

4.2. Synthesis of $\{[Zn_5(tmaH)_4(trz)_2(H_2O)_4]\}_n$ (**1**)

A mixture of $Zn(CH_3COOH)_2{\cdot}2H_2O$ (0.5 mmol, 0.109 g), $tmaH_3$ (0.5 mmol, 0.105 g) and trzH (0.5 mmol, 0.034 g) in a molar ratio of 1:1:1 was taken in deionized water (8 mL). The pH of the solution was adjusted to ~5 with 1(M) NaOH solution. The solution was transferred into 23 mL Teflon-lined stainless steel vessel and heated at 160 °C for 72 h. The mixture was allowed to cool to room

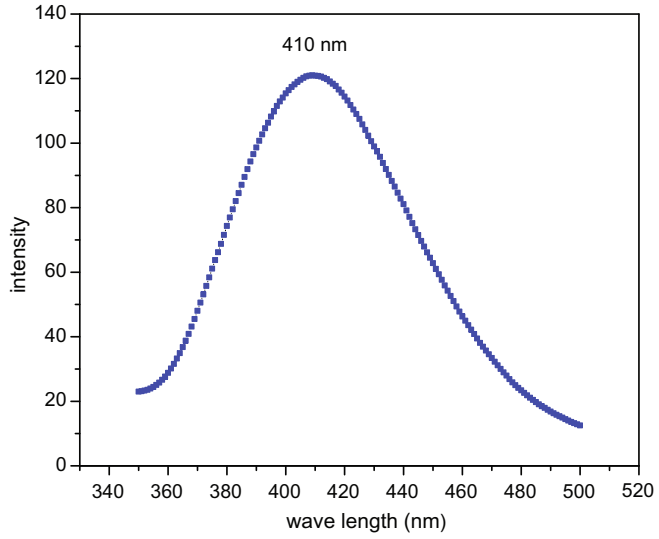

Fig. 10. Solid state emission spectra of **2** recorded at room temperature (λ_{ex} = 320 nm).

temperature and the resulting colorless needle-shaped crystals were isolated by decanting the supernatant liquid, and were washed with deionized water, ethanol and dried in air. Yield: 75%. *Anal.* Calc. for $C_{40}H_{28}N_6O_{28}Zn_5$ (1367.53): C, 35.12; H, 2.06; N, 6.14. Found: C, 35.09; H, 2.12; N, 6.20%.

4.3. Synthesis of $\{[Zn_3(bta)(trz)_2(H_2O)_4{\cdot}2H_2O]\}_n$ (**2**)

Compound **2** was prepared by a similar procedure to that described for the synthesis of **1**. The ligand $btaH_4$ (0.5 mmol, 0.127 g) was used instead of $tmaH_3$. After cooling the solution to room temperature, colorless needle-shaped crystals were isolated by filtering the supernatant liquid, and were washed with deionized water, ethanol and dried in air. Yield: 60%. *Anal.* Calc. for

4.4. IR study

The IR spectral analysis of compounds **1** and **2** shows a broad band in the region 3200–3500 cm^{-1} [ν(O–H)], suggesting the presence of H_2O molecules [45]. ν_{as}(OCO), ν_s(OCO) bands appear at ~1620, ~1424 cm^{-1} for compound **1** and ~1635, ~1455 cm^{-1} for compound **2**, respectively, indicating the carboxylate is involved in the coordination.

4.5. Crystallographic data collection and refinement

Diffraction data collections were carried out at room temperature on a Nonius DIP-1030H system, using Mo Kα radiation, λ = 0.71073 Å. Cell refinement, indexing and scaling of all the data sets were performed using the programs DENZO and SCALEPACK [46]. The structures were solved by direct methods and subsequent Fourier analyses, and refined by the full-matrix least-squares method using SHELXl97 [47] based on F^2 with all reflections. Hydrogen atoms bonded to carbon were included at calculated positions, while those of water molecules were located in a difference Fourier map and refined with distance constraints. All the calculations were performed using the WINGX System, Ver 1.70.01 [48]. Crystallographic data are given in Table 3.

ABSTRACT

A new series of nickel(II) complexes derived from symmetrical diacetyl bisaroylhydrazones [Ni(L^1-R)] and unsymmetric phenylglyoxal bisaroylhydrazones [Ni(L^2-R)] have been prepared and characterized. X-ray crystal and molecular structures of [Ni(L^1-H)], [Ni(L^1-pCH_3O)] and [Ni(L^1-pNO_2)] have been determined. In these complexes, the Ni(II) is in a distorted square planar environment and the aroylhydrazone acts as dinegative tetradentate ligand forming a 5,5,5-tricyclic chelate ring. Reaction of [Ni(L^1-R)] with aqueous ammonia afforded the paramagnetic five coordinate [Ni(L^1-R)(NH_3)] while [Ni(L^2-R)] gave the diamagnetic square planar [Ni(L^2-R)(NH_3)] complexes. Reaction of [Ni(L^1-R)] complexes with imidazole gave the corresponding paramagnetic octahedral bis(imidazole) adducts. X-ray structures of both [Ni(L^1-H)(HIm)$_2$] and [Ni(L^1-pNO_2)(HIm)$_2$] suggest a distorted octahedral structure where the bisaroylhydrazone occupies the basal plane while the two imidazoles occupy the axial sites. The molecular units are associated together forming triple stranded helical chains. With imidazole the [Ni(L^2-R)] series gave the corresponding diamagnetic mono(imidazole) [Ni(L^2-R)(HIm)] complexes, The X-ray structure of {Ni(L^2-pCH_3)(HIm)] suggest square planar arrangement around the Ni(II) where the bisaroylhydrazone acts as dinegative NNO tridentate ligand forming with the Ni(II) a 5,6-bicyclic chelate ring the fourth coordination site is occupied by imidazole nitrogen.

1. Introduction

The coordination chemistry of tridentate aroylhydrazones derived from ortho hydroxyaldehydes and ketones [1–11], 2-N-heterocyclic aldehydes and ketones [12–17], β-diketones [18–23] and α-ketomonooximes [24–28] have been extensively studied. Besides their interesting coordination chemistry, tridentate aroylhydrazones and their transition metal complexes show a wide spectrum of biological and pharmacological activities [29–34]. Less attention, however, was paid for a systematic study on the coordination chemistry of tetradentate bisaroylhydrazones derived from α-ketoaldehydes and α-diketones. Some of the diacetyl bis-aroylhydrazone nickel(II) complexes have been prepared and characterized [35–38]. In these complexes the bis aroylhydrazone ligand was found to act as a dinegative NNOO tetradentate anion where the central Ni(II) is coordinated to two imine nitrogens and the two deprotonated enolimide oxygens forming the 5,5,5-membered tricyclic chelate ring system. This mode of chelation was confirmed by X-ray structural analysis of the Ni(II) complexes with diacetyl bis(benzoylhydrazone) and bis(*p*-methoxybenzoylhydrazone) [35,37]. Moreover, square planar Ni(II) complex with diacetyl bisbenzoylhydrazone was found to act as Lewis acid and its interaction with different types of Lewis bases has been studied spectrophotometrically [39–42]. Only octahedral bis(pyridine) adduct was isolated and partially characterized [39]. Reactions with bidentate heterocyclic bases, however, proceeded with the rupture of one of the two coordinated oxygens and eventually gave the monobase adduct. The bis(aroylhydrazone) ligand acted as dinegative NNO tridentat anion, forming with the central Ni(II) a 5,5-membered bicyclic chelate ring [43]. In the present paper, we describe the synthesis and characterization of a new series of nickel(II) complexes derived from both symmetric diacetyl bis-aroylhydrazones (H_2L^1-R) (**1**, $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$, *p*-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$, *p*-$Cl{\cdot}C_6H_4$ or *p*-$NO_2{\cdot}C_6H_4$) and unsymmetric phenylglyoxal bisaroyl – hydrazones (H_2L^2-R) (**1**, $R_1 = H$, $R_2 = C_6H_5$, $R_3 = C_6H_5$, *p*-$CH_3{\cdot}C_6H_4$, *p*-$OCH_3{\cdot}C_3H_4$, *p*-$Cl{\cdot}C_6H_4$, *p*-$NO_2{\cdot}C_6H_4$). The X-ray crystal and molecular structure of [Ni(L^1-pNO_2)] has been determined and compared with the previously reported X-ray

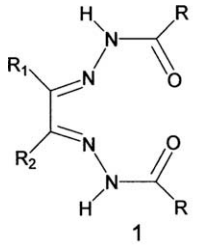
structures of [Ni(L^1-H)] and [Ni(L^1-pCH_3O)] [35,37]. The reactions of both [Ni(L^1-R)] and [Ni(L^2-R)] series with ammonia and imidazole have been also studied aiming to investigate the effect of the nature of substituents on the C–C backbone of the ligands on the reactivity of this type of nickel(II) complexes. The X-ray structures of representative bis- and monoimidazole complexes obtained, respectively, from the reaction of imidazole with [Ni(L^1-R)] and [Ni(L^2-R)] have been determined.



2. Experimental

2.1. Materials

Diacetyl and phenylglyoxal were obtained from Aldrich and used without further purification. Hydrazine hydrate (99%) (BDH), imidazole and nickel acetate tetrahydrate (BDH) were also used without further purification. Aroylhydrazines were prepared, as previously described [27], by the hydrazinolysis of aromatic carboxylic methyl esters in methanol.

2.2. Preparation of bisaroylhydrazones (*1*)

Bisaroylhydrazones were prepared as previously described by the condensation of diacetyl or phenylglyoxal with two equimolar amounts of aroylhydrazine in acidified ethanol [36]. The infrared, ultraviolet-visible and ^{1}H NMR spectral data of the prepared bisaroylhydrazones are deposited as Supplementary data.

2.3. Preparation of nickel(II) complexes

*2.3.1. Preparation of [NiL^1-R] (**2**, $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$, p-CH_3·C_6H_4, p-CH_3O·C_6H_4, p-Cl·C_6H_4 and p-NO_2·C_6H_4) and [NiL^2-R]·nH_2O (**2**, $R_1 = H$, $R_2 = C_6H_5$, R_3 = p-CH_3·C_6H_4, p-CH_3O·C_6H_4, p-Cl·C_6H_4 and p-NO_2·C_6H_4) complexes*

A hot solution of potassium hydroxide (0.02 mol) in ethanol (15 ml) was added to a suspension of the appropriate bisaroylhydrazone (**1**, $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$, p-CH_3·C_6H_4, p-CH_3O·C_6H_4, p-Cl·C_6H_4 and p-NO_2·C_6H_4; R_1 = H, $R_2 = C_6H_5$, R_3 = p-CH_3·C_6H_4, p-CH_3O·C_6H_4, p-Cl·C_6H_4 and p-NO_2·C_6H_4) (0.01 mol) in ethanol (50 ml). To the resulting yellow solution, a hot solution of nickel(II) acetate tetrahydrate (0.01 mol) in ethanol (25 ml) was added. The mixture was then refluxed, with constant stirring, for 2 h. The isolated complex was then filtered off, recrystallized from benzene and then dried under vacuum. Single crystals of [Ni(L^1-H)] and [Ni(L^1-pCH_3O)], suitable for X-ray diffraction studies were selected from the recrystallised batches, while crystals of benzene solvate [Ni(L^1-pNO_2)]·1/2C_6H_6 were isolated from the mother liquor after kept for 1 month.

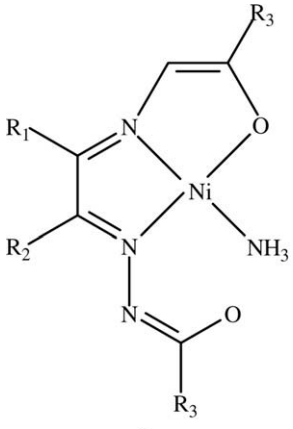
2.3.2. Preparation of [Ni(L^1-R)(NH_3)] complexes



To a hot suspension of diacetyl bis(aroylhydrazone)(**1**, R_1 = R_2 = CH_3, R_3 = p-Cl·C_6H_4 and p-NO_2·C_6H_4) (0.01 mol) in ethanol (20 ml), a hot solution of nickel(II) acetate tetrahydrate (0.01 mol) in ethanol (20 ml) was added. The resulting green mixture turned red upon treating with aqueous ammonia (3 ml of 30% ammonia solution). The red solution was then stirred for 1/2 h, during which a reddish brown precipitate separated out, was filtered off and dried in air. In the case of R_3 = C_6H_5, p-CH_3·C_6H_4 and p-CH_3O·C_6H_4 only the [Ni(L^1-R)] complexes were isolated.

[(Ni(L^1-pCl(NH_3)]. Yield: 38%. *Anal.* Calc. For $C_{18}H_{17}N_5O_2Cl_2Ni$: C, 46.50; H, 3.69; N, 15.06. Found: C, 46.88; H, 3.65; N, 14.60%. IR (KBr) (cm^{-1}): 3320m, 3246m, 3190m, ν(N–H) (NH_3); 1640s δ(N–H); 1584s, ν(C=N–N=C); 1550sh, ν(N=C–C=N). Magnetic moment (μ_{eff}, μ_β): 2.70.

2.3.5. Preparation of [Ni(L^2-R)(HIm)] (**6**, R_1 = H, $R_2 = C_6H_5$, R_3 = p-CH_3·C_6H_4, p-CH_3O·C_6H_4, p-Cl·C_6H_4 and p-NO_2·C_6H_5)

To a hot suspension of phenylglyoxal bisaroylhydrazone (0.01 mol) in acetonitrile (20 ml), a hot solution of nickel(II) acetate tetrahydrate (0.01 mol) in ethanol (20 ml) was added. The resulting green complex was then treated with a large excess of solid imidazole (0.05 mol) to give a dark red solution. The resulted solution was filtered, then evaporated to half its original volume. After cooling, the formed red crystals were filtered off.

2.4. Physical measurements

The infrared spectra were recorded on a Perkin–Elmer 1430 Data system and/or a Perkin–Elmer (FT-IR) Paragon 1000 PC spectrophotometer. Solid samples were examined as KBr discs. The ultraviolet and visible absorption spectra were recorded on V-530 UV–Vis. recording spectrophotometer, Jasco, using 10 mm quartz cells and/or a double beam ratio recording Lambada 4B Perkin–Elmer spectrophotometers. ^{1}H NMR spectra were recorded on Brucker WM 300 using tetramethylsilane (TMS) as an internal standard. Magnetic susceptibilities of powdered dried samples were recorded on a Faraday-type magnetometer using a sensitive computer controlled D-200 Cahn RG microbalance. The magnetic field applied was ~1.5 T [44]. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants.

X-ray diffraction data were collected on CrysAlis CCD, Oxford Diffraction limited, version 1.70.14 (2002), using graphite monochromated Mo Kα radiation (λ = 0.71013 Å). The structures were solved by direct method with SHELXS-97 [45]; refinement was done by full-matrix least squares on F^2 using the SHEXL-97 [45]. Drawings of the molecules were produced with ORTEP 3 [46] or PLATON [47].

3. Results and discussion

3.1. Synthesis and characterization

In ethanol, the reaction of both symmetrical diacetyl bisaroylhydrazones, (H_2L^1-R), and unsymmetrical phenylglyoxal bisaroylhydrazone (H_2L^2-R) with nickel(II) acetate tetrahydrate in the presence of KOH, respectively afforded the corresponding neutral nickel(II) chelates [Ni(L^1-R)] (**2**, $R_1 = R_2 = CH_3$ and $R_3 = C_6H_5$, *p*-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$, *p*-$Cl{\cdot}C_6H_4$, and *p*-$NO_2{\cdot}C_6H_4$) and [Ni(L^2-R)]·nH_2O (**2**, $R_1 = H$, $R_2 = C_6H_5$, $R_3 = p$-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$ or *p*-$Cl{\cdot}C_6H_4$). The IR spectra of these nickel(II) complexes lack absorption bands which could be attributed to ν(N–H), amide(I) ν(C=O) and amide (II) bands, but exhibit instead a very intense band at *ca.* 1625–1580 cm^{-1} due to ν(C=N–N=C). The ν(N=C–C=N) of the diimine residue which appears at *ca* 1610–1570 cm^{-1} in the spectra of metal free ligands are shifted to lower frequencies, 1550–1535 cm^{-1}, in the corresponding Ni(II) complexes. These spectral data suggest the deprotonation of the two amide residues of the bisaroylhydrazone ligand and the bisaroylhydrazones in these nickel(II) complexes act as dinegative N_2O_2 tetradentate ligands [35–37]. At room temperature (298 K), the prepared monoligand nickel(II) complexes [Ni(L^1-R)] and [Ni(L^2-R)]·nH_2O were found to be diamagnetic, indicating square planar arrangement with $^1A_{1g}$ ground state. The solution electronic absorption spectra (UV–Vis) of these complexes in dichloromethane are in agreement with this assignment [48]. The absorption bands at *ca* 239–282 and 321–397 nm can be related to the different L–L* transitions of the highly conjugated dinegative ligand anion. Similar to other square planar nickel(II) complexes [48], the band located around 410– 71 nm is most probably due to a LMCT transition(s), while the three absorption bands in the regions 623–658, 681–703 and 742–771 nm can be fairly attributed to the different $d(M) \rightarrow \pi^*(L)$ transitions (MLCT) [36]. The recorded spectra lack weak absorptions due to the different d–d transitions which are most probably hidden under the very intense LMCT band. The position of MLCT absorption bands in the spectra of the square planar nickel(II) complexes [Ni(L^1-R)] and [Ni(L^2-R)]·nH_2O were found to be affected by the nature of p-substituents in the aroylhydrazone residue. The energy of the MLCT bands, measured in wavenumber (cm^{-1}), can be correlated with Hammett's σ_p constant and plot of wavenumber against σ_p gave a straight line with a negative slope confirming the MLCT origin of these absorption bands.

On using aqueous ammonia, the reaction of H_2L^1-R (**1**, $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$, *p*-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$) with Ni$(CH_3COO)_2{\cdot}4H_2O$ using (1:1) molar ratio in ethanol resulted in the formation of the diamagnetic square planar neutral complexes [Ni(L^1-R] (**2**) which are identical to those isolated in the absence of aqueous ammonia.. In these reactions, aqueous ammonia acts as proton acceptor which facilitates the deprotonation of the bishydrazone ligands. However, with bishydrazones having electron withdrawing substituents (**1**, $R_1 = R_2 = CH_3$, $R_3 = p$-$Cl{\cdot}C_6H_4$ or *p*-$NO_2{\cdot}C_6H_4$), the reaction proceeded with the formation of the monoammine complexes [Ni(L^1-R)·NH_3]. The IR spectra of both [Ni(L^1-pCl)·NH_3] and [Ni(L^1-pNO_2)·NH_3] lack absorptions due to hydrazone ν(N–H), amide I ν(C=O) and amide II, implying the deprotonation of both aroylhydrazone arms. The spectra, also, show a series of bands at 3365, 3320, 3245 cm^{-1} due to the different vibration modes of coordinated NH_3, besides bands at *ca.* 1640, 1580 and 1550 cm^{-1} due to δ(N–H) of NH_3, ν(C=N–N=C) and ν(N=C–C=N) respectively. The solid complexes are paramagnetic with magnetic moments being within the range 2.60–2.70 μ_β (298 K). From the stoichiometry, infrared spectral data and magnetic measurements, a distorted square pyramidal structure can be tentatively assigned for these solid complexes, where the four donor atoms of the dinegative bishydrazone ligand are coordinated to the Ni(II) forming the equatorial plane while ammonia occupies the fifth coordination site. It seems that these complexes are stable only in the solid state. However in solution, complete deammination occurs and the solution electronic spectra of both [Ni(L^1-pCl)·NH_3] and [Ni(L^1-pNO_2)·NH_3] in dichloromethane are quite similar to those recorded for the parent square planar complexes.

The reaction of unsymmetric bisaroylhydrazones H_2L^2-R with Ni$(CH_3COO)_2{\cdot}4H_2O$ in the presence of aqueous ammonia gave the corresponding monoammine complexes of the general formula [Ni(L^2-R)·NH_3]·nH_2O. Different from [Ni(L^1-pCl)·NH_3] and [Ni(L^1-pNO_2)·NH_3] which are paramagnetic, the prepared nickel(II) complexes [Ni(L^2-R)·NH_3]·nH_2O are diamagnetic, suggesting square planar arrangement around the Ni(II) ion. The electronic absorption spectra of these complexes in dichloromethane display three absorptions due to L–L* transitions at *ca* 220, 270 and 360 nm, besides a strong LMCT absorption band at *ca* 445 nm. The spectra also display three MLCT absorption bands within the range 470–660 nm, confirming a square planar structure. In these square planar nickel(II) complexes, the bisaroylhydrazone must act as a dinegative tridentate anion while the NH_3 occupies the fourth coordination site. Thus two coordination modes **3** or **4** can be proposed for these complexes. The presence of a very intense amide I [ν(C=O)] band at 1650–1666 cm^{-1} in the IR spectra of these complexes suggest the deprotonation of the hydrazone N–H proton and structure **4** can be tentatively assigned for these complexes where the bisaroylhydrazone acts as dinegative NNO tridentate anion and is coordinated to the Ni(II) via deprotonated enolimine oxygen, imine nitrogen and deprotonated hydrazone nitrogen forming a 5,6-membered bicyclic chelate system.

In ethanol–acetonitrile mixture, the reaction of complexes [Ni(L^1-R)] complexes with excess solid imidazole (HIm) (8 equiv.) afforded the corresponding bis(imidazole) nickel(II) complexes [Ni(L^1-R)$(HIm)_2$] (**5**, $R_1 = R_2 = CH_3$, $R = C_6H_5$, *p*-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$, *p*-$Cl{\cdot}C_6H_4$ or *p*-$NO_2{\cdot}C_6H_4$). The IR spectra of these bis(imidazole) complexes display absorption bands at 3135–3115 cm^{-1} region due to ν(N–H) of the coordinated imidazole besides a series of bands at 3075–3050, 2972–2930 and 2920–2835 cm^{-1} which can be attributed to [ν(C–H) + ν(N–H)] coupled vibrations. Similar to the IR spectra of the parent square planar complexes [Ni(L^1-R)], the spectra of bis(imidazole) complexes [Ni(L^1-R)$(HIm)_2$] do not show any absorptions due to hydrazone υ(N–H) and amide I band (νC=O), but display intense bands at 1600–1575 cm^{-1} and 1555–1530 cm^{-1} due to ν(C=N–N=C) and ν(N=C–C=N), respectively, confirming the deprotonation of both hydrazone arms and the bis(aroylhydrazone) acts as a dinegative NNOO tetradentate ligand. The [Ni(L^1-R)$(HIm)_2$] complexes were found to be paramagnetic with magnetic moments (μ_{eff} = 3.15–3.50 μ_β) suggesting octahedral structure (**5**, $R_1 = R_2 = CH_3$, $R_3 = C_6H_5$, *p*-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$, *p*-$Cl{\cdot}C_6H_4$ or *p*-$NO_2{\cdot}C_6H_4$). The octahedral structure of both [Ni(L^1-H)$(HIm)_2$] and [Ni(L^1-pNO_2)$(HIm)_2$] has been confirmed by X-ray structural analysis.

Different from the reaction of [Ni(L^1-R)] (**2**) with imidazole which gave the bis(imidazole) complexes, [Ni(L^1-R)$(HIm)_2$] (**5**), the Ni(II) complexes derived from unsymmetric phenylglyoxal bishydrazones [Ni(L^2-R)]·nH_2O afforded the corresponding mono(imidazole) complexes [Ni(L^2-R)(HIm)] (**6**, $R_1 = H$, $R_2 = C_6H_5$, $R_3 = p$-$CH_3{\cdot}C_6H_4$, *p*-$CH_3O{\cdot}C_6H_4$, *p*-$Cl{\cdot}C_6H_4$ and *p*-$NO_2{\cdot}C_6H_4$). The IR spectral patterns of the mono(imidazole) complexes are more less similar to those recorded for the analogous mono(ammine) complexes and show a series of absorption bands at 3218–3131, 1660–1645, 1610–1580 cm^{-1}, respectively, due to ν(N–H) of the coordinated imidazole, amide I [ν(C=O)] of the uncoordinated

R_3-C=O residue, and ν(C=N–N=) of the deprotonated aroylhydrazone arm. The prepared mono(imidazole) complexes are diamagnetic indicating square planar arrangement around the central Ni(II) ion. The recorded electronic absorption spectra, in dichloromethane, are in agreement with this assignment.

3.2. X-ray molecular and supramolecular structures

3.2.1. Square planar nickel(II) complexes [Ni(L^1-R)] (**2**, $R_1 = R_2 = CH_3$ and $R_3 = C_6H_5$, p-CH_3O·C_6H_4, and p-NO_2·C_6H_4)

The crystal data and structural refinement parameters for [Ni(L^1-H)], [Ni(L^1-pCH_3O)] and [Ni(L^1-pNO_2)]·1/2C_6H_6 are listed in Table 1, while selected bond distances (Å) and bond angles (°) are collected in Table 2. The X-ray structures of [Ni(L^1-H)], [Ni(L^1-pCH_3O)] have been previously reported [35,37]. The X-ray structure of the newly prepared [Ni(L^1-pNO_2)] · 1/2C_6H_6 together with the atomic numbering scheme are, respectively, shown in Fig. 1. In these complexes the Ni(II) ion is in a distorted square planar environment where the bisaroylhydrazone ligand in these complexes acts as a dinegative N_2O_2 tetradentate ligand, forming the expected 5,5,5-membered tricyclic chelate ring system [35–37]. The bond distances of Ni–O1 and Ni–O2 in both [Ni(L^1-H)] and [Ni(L^1-pNO_2)], and Ni–O1 and Ni–O1# (#, $1 - x, y, -z + 1/2$) in [Ni(L^1-pCH_3O)], Table 2, are within the range 1.874–1.896 Å which are significantly higher than the range (1.83–1.86 Å) reported for square planar Ni(II) complexes with tridentate and tetradentate aroylhydrazones having, respectively, 5,6-membered bicyclic and 5,5,6-membered tricyclic chelate rings [3,5,22,21], but are comparable with the range (1.87–1.91 Å) reported for nickel(II) aroylhydrazone oxime complexes with 5,5-membered bicyclic chelate system [26]. This can be related to the steric constraints imposed by the 5,5,5- membered tricyclic chelate system. The Ni–N1 and Ni–N3 bond distance range (1.79–1.80 Å), Table 2, is relatively shorter than the range (1.82–1.84 Å) reported for square planar Ni(II) complexes derived from both mononegative tridentate and dinegative tetradentate aroylhydrazones. The observed decrease

#1 Symmetry transformations used to generate equivalent atoms: -x, y, -z + 1/2.

in both Ni–N1 and Ni–N3 bond distances may be due to appreciable (Ni–N) π-interactions usually observed in coordinated diimine systems. The bond distance ranges for C–N (imide) [C1–N2, C10–N4] (1.32–1.33 Å) and C–O [C1–O1, C10–O2] (1.29–1.32 Å) are consistent with the deprotonation of the enolimine tautomer [11,17,20,21,49]. The ligand C–N (imine) [C8–N1, C9–N3], hydrazine [N1–N2, N3–N4], C–N(imide) [C1–N2, C10–N4] and C–O [C1–O1, C10–O2] are intermediate between formal single and double bonds indicating delocalization over the 5,5,5-membered tricyclic chelate system.

The structures of these square planar Ni(II) complexes show interesting supramolecular architectures depending on the nature of substituents in the hydrazone phenyl rings. No classic hydrogen bonds are found in the crystal lattice of these complexes. However, in the unsubstituted complex [Ni(L^1-H)], two molecules are interconnected by two reciprocal C6H···O2 (C6···O2 = 3.487 Å) hydrogen bonds, forming a hydrogen bonded dimer. While in [Ni(L^1-pCH_3O)], each molecular unit is linked to four different neighboring molecular units via two pairs of reciprocal C9H···O2 (C9···O2 = 3.523 Å) hydrogen bonds giving rise to a two dimensional stepped sheet extending parallel to the ac-plane. Each molecular unit, in the stepped sheet, is stacked from both sides to two adjacent molecular units of inverted symmetry via two reciprocal edge to face CH···π interactions between the C9H*A* methyl proton and (C2–C7) phenyl π system [(CH9*A*···Cg1) = 2.816 Å, where Cg1 refers to the phenyl ring centroid] forming a one dimensional array of stacked molecular units as shown in Fig. 2. The dimensions of this CH···π interaction are consistent with those reported for other systems [50]. The Ni(II) coordination planes in this stacked array are parallel to each other and the distance between two successive planes is 3.36 Å. Both CH···O and CH···π non-covalent interactions combine to form a three dimensional network of molecular units.

In the crystal lattice of [Ni(L^1pNO$_2$)]·1/2C_6H_6, one of the nitro group oxygens (O4) is engaged in hydrogen bonding with the methyl

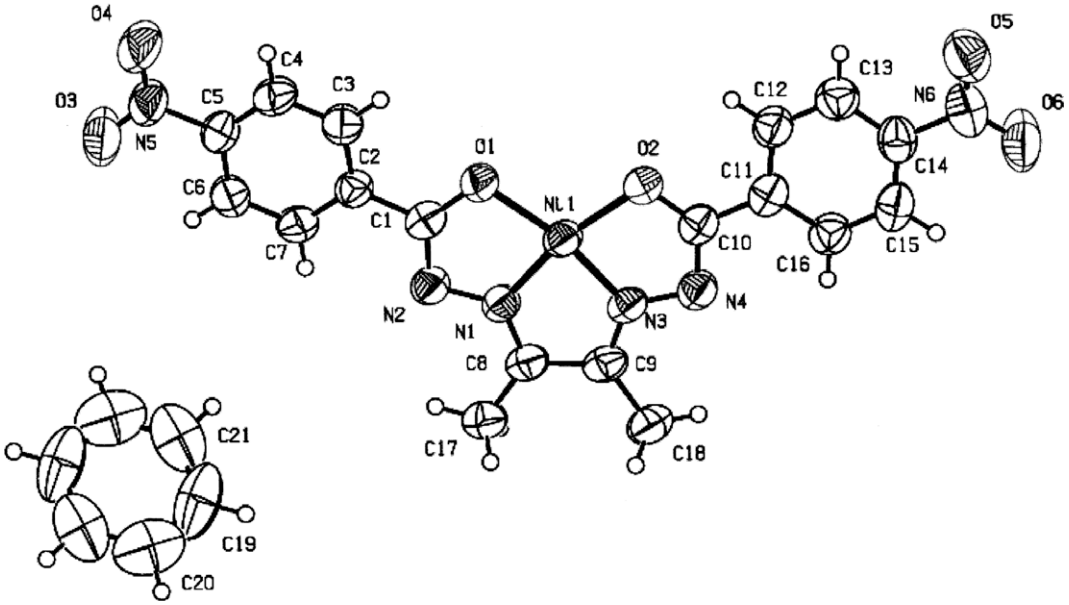

Fig. 1. ORTEP representation of [Ni(L^1-pNO$_2$)] with labeling atoms.

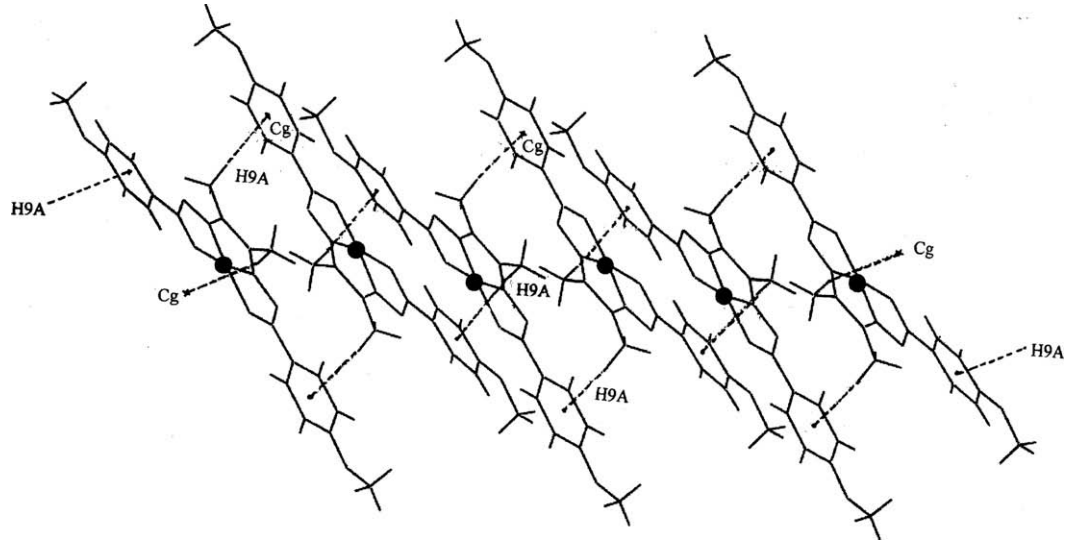

Fig. 2. CH···π non-covalent bond interactions in [Ni(L^1-pCH_3O)] complex.

proton (H17B) of the neighboring molecule (CH17B···O4, C17···O4 = 3.19 Å) giving rise to an infinite chain propagating along b axis. This chain is connected to another adjacent chain of inverted symmetry by pairs of reciprocal hydrogen bonds between the other nitro group oxygens (O3) of chain 1 and the phenyl ring H7 protons of chain 2 (C7H···O3 = 3.281 Å) forming an infinite strand of double chains as shown in Fig. 3. The parameters of (CH17B···O4) [C–H17B = 0.96 Å, H17B···O4 = 2.672 Å, C17···O4 = 3.19 Å and C17–H17B–O4 angle = 114.79°] are in the typical range reported for such interaction [51,52]. The benzene molecules in the unit cell do not show any non-covalent intermolecular interactions.

3.2.2. Bis(imidazole) and mono(imidazole) nickel(II) complexes

The crystal data and structural refinement parameters for the bis(imidazole) nickel(II) complexes, [Ni(L^1-H)$(HIm)_2$] · 1/3H_2O, [Ni(L^1-NO_2)$(HIm)_2$] and the mono(imidazole) Ni(II) complex [Ni(L^2-pCH_3)(HIm)] are, respectively, listed in Table 3. The structures of [Ni(L^1-H)$(HIm)_2$] and [Ni(L^1-NO_2)$(HIm)_2$] together with their atomic numbering scheme are, respectively, shown in Figs. 4 and 5. Selected bond distances (Å) and bond angles (°) for [Ni(L^1-H)$(HIm)_2$] · 1/3H_2O and [Ni(L^1-NO_2)$(HIm)_2$] are listed in Table 4. The crystal structure of [Ni(L^1-H)$(HIm)_2$] · 1/3H_2O consists of three crystallographically independent molecular units, namely Ni1, Ni2

and Ni3 molecular units, in addition to one water molecule while that of $[Ni(L^1\text{-}NO_2)(HIm)_2]$ consists of one type of discrete molecular units. The central Ni(II) in each of the three molecular units of $[Ni(L^1\text{-}H)(HIm)_2]\cdot 1/3H_2O$ as well as in $[Ni(L^1\text{-}NO_2)(HIm)_2]$ is six coordinate in a distorted octahedral geometry, where the dinegative bisaroylhydrazone ligand occupies the equatorial plane while the two imidazole rings are situated in the two apical positions. The bite angles in the three molecular units of $[Ni(L^1\text{-}H)(HIm)_2]\cdot 1/3H_2O$ and $[Ni(L^1\text{-}NO_2)(HIm)_2]$, Table 4, are less than 90° while the trans angles in the equatorial planes are much less than 180°. The axial angles formed between the central Ni and the coordinated imidazole nitrogens, N5–Ni–N7, N13–Ni–N15, and N21–Ni–N23, in Ni1, Ni2, and Ni3 molecular units of $[Ni(L^1\text{-}H)(HIm)_2]\cdot 1/3H_2O$ are 156.2(3)°, 154.8(3)° and 161.1(3)°, respectively, while the

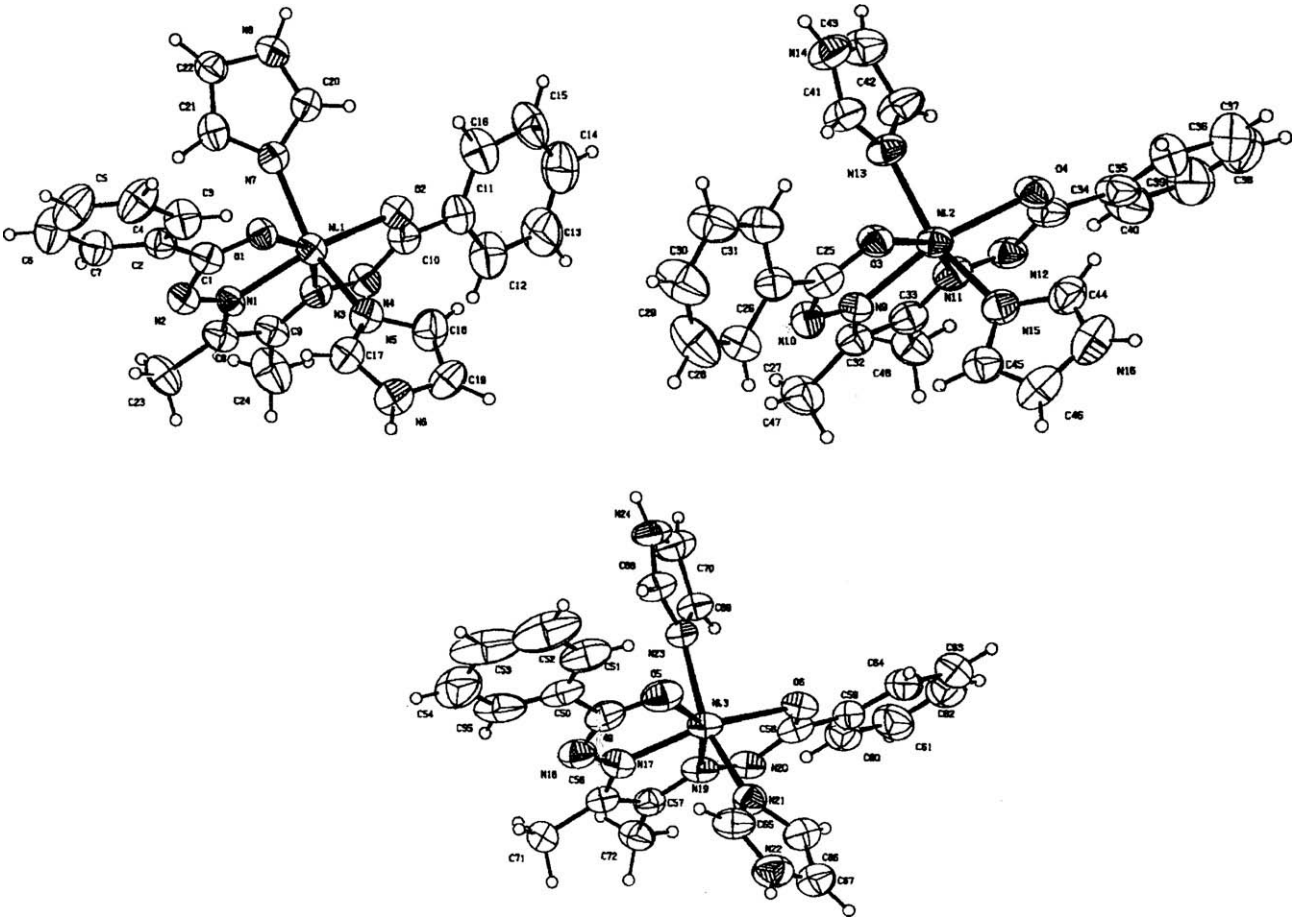

Fig. 4. ORTEP representation of the three crystallographic independent molecular units of $[Ni(L^1\text{-}H)(HIm)_2]$ with labeling atoms.

corresponding angle (N5–Ni–N7) in $[Ni(L^1\text{-}NO_2)(HIm)_2]$ is 159.09°. Hereafter, the imidazole ring in these complexes are designated by the tertiary nitrogen directly coordinated to the Ni(II).

The N–H protons of the two coordinated imidazole rings in both $[Ni(L^1\text{-}H)\cdot(HIm)_2]\cdot 1/3\ H_2O$ and $[Ni(L^1\text{-}NO_2)(HIm)_2]$ play a crucial role in their crystal packing. In $[Ni(L^1\text{-}H)\cdot(HIm)_2]\cdot 1/3\ H_2O$, the Ni1, Ni2 and Ni3 molecular units are involved in different supramolecular assemblies. The N6H proton of the N5 imidazole ring in Ni1 molecular unit is involved in intermolecular hydrogen bond formation, N6H···O1 (N6···O1 = 2.720 Å), *i*th the enolimine oxygen O1 of one adjacent Ni1 molecular unit while the other N8H proton of the N7 imidazole ring forms N8H···N2 (N8···N2 = 2.864 Å) hydrogen bond with the hydrazone N2 nitrogen of another adjacent Ni1 molecular units, giving rise to a supramolecular triple stranded helical chain (Ni1 chain) propagating along *b*-axis as shown in Fig. 6a. The Ni2 molecular units are also linked together via N16H···N10 (N16···N10 = 3.080 Å) hydrogen bonds, forming a linear chain extended along *b*-axis. In this chain, two successive Ni2 molecular units are further linked to one Ni3 molecular unit via N14H···O6 (N14···O6 = 2.934 Å) and N24H···O4 (N24···O4 = 2.75.53 Å) hydrogen bonds, respectively, thus the interconnected Ni2- and Ni3-molecular units form mono stranded helical chain (Ni2–Ni3 chain) extended parallel to the *b*-axis as shown in Fig. 6b. The Ni2–Ni3 helical chain is stabilized by CH···π interactions between the N13 imidazole C43H proton and the (C49–C54) phenyl π system, and between the phenyl (C59–C64) phenyl C63H proton and N23 imidazole π system. Similarly, the Ni3 molecular units are also linked to the adjacent Ni2 molecular units, forming another Ni2–Ni3 chain but of inverted symmetry. The Ni2–Ni3 chains are connected together by water bridges where the water H7*2* protons are involved in hydrogen bond formation with the enolimine O2 oxygens of the Ni2 molecular units while the water O7 oxygens form hydrogen bonds with the imidazole N22–H protons of Ni3 molecular units (N22H···O7, N22···O7 = 2.839 Å) of the neighboring Ni2–Ni3 chain giving rise to a two-dimensional sheet of helical chains extending parallel to *bc*-plane. In the crystal lattice of $[Ni(L^1\text{-}H)\cdot(HIm)_2]\cdot 1/3H_2O$, the Ni1 molecular units of Ni1 chains are connected from both sides to Ni2 and Ni3 molecular units by C23···N12 and C52H···C12, respectively. Thus the Ni1 chains are embedded between the two extended sheets originated from Ni2 and Ni3 molecular units.

In $[Ni(L^1\text{-}NO_2)(HIm)_2]$ the molecular units are linked together by N6H···O1 (N6···O1 = 2.763 Å) and a trifurcated hydrogen bond between N8H imidazole proton and N3 imine nitrogen (N8H···N3, N8···N3 = 2.622 Å), N4 hydrazine nitrogen (N8H···N4, N8···N4 = 2.642 Å) and N5 imidazole nitrogen (N8H···N5, N8···N5 = 2.559 Å), giving rise to a supramolecular triple stranded helical chain propagating along the *c*-axis more or less similar to Ni1 chain in $[Ni(L^1\text{-}H)(HIm)_2]\cdot 1/3H_2O$. The helical chain is further stabilized by intrachain C–H···π interactions between aromatic C16H and N7 imidazole π system [50]. In the crystal lattice of $[Ni(L^1\text{-}NO_2)(HIm)_2]$ the helical chains are linked together by CH····N non-covalent bond interactions between H23A methyl protons of one chain and N2 hydrazine nitrogen of the adjacent chain, forming a sheet of infinite

chains extended parallel to the *bc*-plane. The chains in one sheet are further interconnected to symmetry inverted chains of the adjacent sheet by C24HC···O6, C24H*A*···O5 and C21H···O5 interactions, giving rise to two dimensional arrays of helical chains.

The structure of the monoimidazole complex, [Ni(L^2-pCH_3)(HIm)], together with the atomic numbering scheme is shown in Fig. 7. Selected bond distances (Å) and bond angles (°) for [Ni(L^2-pCH_3)(HIm)] are listed in Table 5. The central nickel (II) in [Ni(L^2-pCH_3)(HIm)] is in a distorted square planar geometry, being coordinated to the imine N1 nitrogen [Ni–N1 = 1.8154(17) Å] and the deprotonated enolimide O1 oxygen [Ni–O1 = 1.8721(14) Å] of the aldehydic arm, besides the deprotonated hydrazide N3 nitrogen of the phenyl arm, forming a 5,6-membered bicyclic chelate ring. The ketoamide O2 oxygen of the phenyl arm remains uncoordinated. It is thus apparent that the bis(aroylhydrazone) molecule acts as a dinegative NNO tridentate ligand rather than the expected dinegative NNOO tetradentate ligand. The fourth coordination site is occupied by the N5 imidazole nitrogen [Ni–N5 = 1.899(17) Å]. This unexpected coordination mode can be related to the unsymmetric nature of the coordinated bis(aroylhydrazone) ligand. The imidazole N6–H proton is involved in hydrogen bond formation with the uncoordinated ketoamide O2 oxygen forming, hydrogen bonded dimer. In this dimer, the two imidazole rings are involved in π–π stacking interaction [Cg5···Cg5 = 4.102 Å]. The hydrogen

bonded dimers are linked together by two pairs of reciprocal CH···π interactions between the C12H proton of the phenylglyoxal phenyl (C11–C16) ring and the N5 imidazole π-system [C12H···Cg5 = 2.790 Å] giving rise to a linear chain propagating along b-axis. The chain of dimers is further stabilized by C9H···C7 interactions [C9···C7 = 3.569 Å]. In the crystal lattice, the hydrogen bonded dimers chain are interconnected by reciprocal C23H····C9 interactions.

ABSTRACT

μ-1,3-Acetamide or acetate bridged, symmetric and asymmetric dicopper(II) complexes *viz* $[Cu_2(P1\text{-}O^-)(NHAc^-)](ClO_4)_2$ (**1**), $[Cu_2(P2\text{-}O^-)(OAc^-)](ClO_4)_2$ (**2**) and $[Cu_2(P2'\text{-}O^-)(OAc^-)(H_2O)](ClO_4)_2$ (**3**) were synthesized by employing classic dinucleating ligands; P1-OH, P2-OH (symmetric), and P2′-OH (asymmetric) having trivial differences in their ligand frame work. Solid state structures of these complexes were determined by X-ray crystallography. In solution, they were also characterized by various spectroscopic techniques, which includes ESI-MS, FT-IR, optical, solution magnetic moment, paramagnetic ^{1}H NMR and EPR. The solution magnetic moment of these complexes at room temperature suggests a weak magnetic interaction between the two Cu(II) centers.

Published by Elsevier Ltd.

1. Introduction

Nature has specially designed many dinuclear metalloprotein active sites with carboxylate and histidine rich ligand donors located in chemically different environments around the two metal centers, an asymmetry that may also involve the coordination numbers and the geometry of the metal centers [1–4]. These two metal centers are often found in close proximity (3–4 Å) and are bridged *via* oxo, hydroxo, carboxylate or imidazolate groups, such as to allow electronic interaction, which in turn is manifested in the physical properties of the metalloenzymes and so in model complexes, such as redox potentials, optical and magnetic characteristics. One, two or three bridging groups are usually encountered, for example: one imidazolate bridge in the defense enzyme Cu–Zn superoxide dismutase, one oxygen and one carboxylate in the diiron enzyme ribonucleotide reductase B_2, one hydroxy and two carboxylates in the diiron enzyme deoxyhemerythrin. Such binuclear structures have been well recognized to play key roles in various stereo-selective and specific biological functions such as dioxygen (O_2) activation, hydroxylation of –C–H bonds, hydrolytic cleavage of peptide and phosphoesters bonds of DNA and RNA, and several others [5–8].

Consequently, the design and synthesis of such binuclear metal complexes are challenging for the stimulation of new types of co-operative binuclear activation chemistry and their implications in the magnetic and electronic interactions in such systems for the better understanding of the various physicochemical properties of the natural enzymes [9–11]. This has led to the synthesis of a number of dicopper(II) complexes with different bridging patterns including hydroxo, alkoxo, phenoxo, imidazolate or carboxylate alone or with their combinations [12–37]. These dicopper complexes are found to have weak to strong spin–coupling between the two copper centers with intriguing modulation in their proton NMR features [12,38–42]. Among them the interesting ones are the weakly coupled systems with a shorter net electronic relaxation time (τ_s) of $\sim 10^{-11}$ s.

Here, we report the synthesis and characterization of three new dicopper(II) complexes namely $[Cu_2(P1\text{-}O^-)(NHAc^-)](ClO_4)_2$ (**1**), $[Cu_2(P2\text{-}O^-)(OAc^-)](ClO_4)_2$ (**2**) and $[Cu_2(P2'\text{-}O^-)(OAc^-)(H_2O)](ClO_4)_2$ (**3**) with a combination of chemically similar (**2**) and dissimilar (**1** and **3**) coordination environments around the two copper(II) centers (Chart 1), in order to understand more about the unique features of coordination asymmetry in binuclear systems.

2. Experimental

2.1. General

All reagents were purchased from commercial sources and used without further purification. Solvents were dried and purified under nitrogen using standard methods and distilled immediately

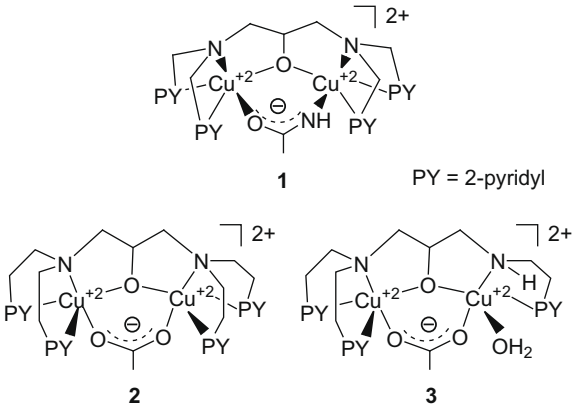

Chart 1. A representation of the binuclear copper(II) complexes **1**, **2** and **3**.

before use. Electronic spectra were measured on a Varian Cary 5E model UV–Vis–NIR spectrometer. Infrared spectra were obtained on a Shimadzu IR470 spectrometer using KBr disk/nujol mull. CHN data were obtained from Perkin–Elmer Model 2004 Series-2 CHN–S–O analyzer. Electro spray mass spectra were recorded on a Q-Tof micro hybrid quadrupole time of flight mass spectrometer. Samples are prepared in acetonitrile and were introduced into the ESI source through a syringe pump at the rate of 5 μL per min. The ESI capillary was set at 3.5 kV; the cone voltage range was 20–40 V and an average of 6–8 scans were used to observe the final spectra.

JEOL 400 or Bruker 400 spectrometers were used to record 1D spectra. Spectral width used to measure the spectra is −100–300 ppm. The carrier frequency is set at the middle of the spectral window. 1D spectra were obtained using a 90° pulse of 8–9 μs duration with 32 K data points and are the average of 1000–2000 scans. The relaxation delay used for the measurement was 0.1 s, as the rate of relaxation of the protons is of the order of ms. The shift values reported are those positive to TMS are downfield and those negative are upfield shifted. Signal assignment is partial. EPR spectra were obtained for frozen solutions of 1–2 mM concentration in DMF on a Varian E-112 spectrometer operating at X-band equipped with a liquid N_2 Dewar insert using 4 mm-OD quartz tubes at 77 K, and calibration was effected using a powder sample of 2,2-diphenyl-1-picrylhydrazyl (DPPH; $g = 2.0037$). The ligands *N,N′,N″,N‴*-tetrakis(2-pyridylmethyl)1,3-diamino-2-propanol (P1-OH), *N,N′,N″,N‴*-tetrakis(2-pyridylethyl)1,3-diamino-2-propanol (P2-OH), and *N,N′,N″*-tris(2-pyridylethyl)1,3-diamino-2-propanol (P2′-OH) were synthesized according to published procedures [43,44]. P2′-OH was obtained as a second fraction during the purification of P2-OH ligand.

Caution: Perchlorate salts of metal complexes with organic ligands are potentially explosive. Although no problems were encountered in this work, only small amounts of material should be prepared and handled with caution.

2.2. Solution magnetic moment

Room temperature magnetic moments were determined by Evans' method [45]. In a coaxial NMR tube (one tube placed in another, 5 mm OD) with the outer tube containing a known concentration of the metal complex (10–20 mM), in a deuterated solvent (acetonitrile-d_3/nitromethane-d_3) and the inner tube or capillary with only the solvent is taken. The ^{1}H NMR spectrum (0–10 ppm) of the solvent in the inner tube placed in an empty standard NMR tube was recorded and its position was fixed at its original position (e.g. CH_3CN at 1.97 ppm). Then the empty tube was replaced by the one, which contain the metal-complex solution. The spectrum of this solution and that of solvent in the inner tube were recorded simultaneously. The position of acetonitrile (solvent) for both the samples was noted. Solvent in the capillary remained at it's original position, while that in the complex shifted from its original position due to bulk susceptibility of the metal complex. The difference in the shift ($\Delta\nu$) called paramagnetic chemical shift was noted. This is related to the molar susceptibility (χ_M) (Eq. (1)) from which the magnetic moment (μ) (Eq. (2)) is calculated.

$$\chi_M = \frac{3}{4\pi}\frac{\Delta\nu}{\nu_0}\frac{1000}{c} + \chi_0 - \chi_D \quad (1)$$

where, $\Delta\nu$ = paramagnetic shift of the solvent = $\nu^{sol}_{internal} - \nu^{sol}_{external}$, ν = frequency of the NMR spectrometer, c = concentration of the metal complex used, L/mol, χ_0 = solvent susceptibility, χ_D = diamagnetic correction of the metal complex (-452.72×10^{-6} (**1**), -465.62×10^{-6} (**2**), and -416.12×10^{-6} (**3**) cgs units).

$$\mu = 2.84\sqrt{\frac{\chi_M \times T}{n}} \quad (2)$$

where χ_M = total molar susceptibility, T = temperature of measurement and n = nuclearity of the complex.

2.3. $[Cu_2(P1\text{-}O^-)(NHAc^-)](ClO_4)_2$ (**1**)

To $Cu(ClO_4)_2 \cdot 6H_2O$ (0.15 g, 0.4 mmol) in MeOH (1 mL), a mixture of P1-OH (0.1 g, 0.2 mmol) and Et_3N (25 μL, 0.2 mmol) in MeOH (3 mL) was added under N_2. Acetamide (0.013 g, 0.2 mmol) and Et_3N (25 μL, 0.2 mmol) mixture was introduced to the above solution, to obtain bluish-green precipitate. The reaction mixture was stirred for 2 h, then filtered and washed with methanol, and dried to obtain light blue precipitate as **1** (0.13 g; yield, 70%). UV–Vis (CH_3CN) [λ_{max}, nm (ε, M^{-1} cm^{-1})]: 290 (2335), 670 (135), 885 (331). IR (ν, cm^{-1}; KBr disk): 1559, 2847 (s, νCH_3CONH^-), 1098 (s, νClO_4^-). *Anal.* Calc. for $[Cu_2(P1\text{-}O^-)(NHAc^-)](ClO_4)_2$, $C_{29}H_{33}Cl_2Cu_2N_7O_{10}$: C, 41.58; H, 3.97; N, 11.71. Found: C, 41.95; H, 3.62; N, 11.14%. Magnetic moment (Evans, CD_3CN): 1.92 μ_B/Cu^{2+}. ^{1}H NMR (CD_3CN, RT, 400 MHz): δ = 256.5, 210.4, 206.3, 70.4, 68.2, 64.0, 58.9, 50.4, 43.9, 32.8, 30.0, 27.5, 27.3, 26.7, 26.2, 24.7, 24.4, 21.8, 20.9, 13.4, 10.7, 10.5, 10.3, 10.2. EPR (DMF, 90 K): $g_{\|}$ = 2.48, 2.45, $g_{\perp}$ = 2.14 and $A_{\|}$ = 125 and 140 G. Magnetic moment (Evans, CD_3CN): 1.88 μ_B/Cu^{2+}. ESI-MS: *m*/*z*, 690 (30%) $[Cu(P2'\text{-}O^-)(OAc^-)(ClO_4^-)]^+$ and *m*/2*z*, 295 (100%) $[Cu(P2'\text{-}O^-)(OAc^-)]^+$.

2.6. X-ray crystallography

Crystals of **1**, **2** and **3** were obtained by solvent evaporation from CH_3CN or CH_2Cl_2. Crystals of approximate size $0.3 \times 0.2 \times 0.2\ mm^3$ were mounted and covered with epoxy resin before data collection and data were collected at 293(2) K. Diffraction data were recorded with the $\omega/2\theta$ scan mode on a Mo Kα radiation (λ kα = 0.71073 Å). The data were corrected for absorption using *Psi*-scan. The unit cell parameters were obtained by a least squares fit of 25 reflections ($2.02° < 2\theta < 24.97°$). Complexes **1** and **2** belong to orthorhombic system, and **3** belongs to monoclinic crystal system. The unit cell parameters and information related to intensity data collection are summarized in Table 2. The structures were solved by direct methods and refined by full-matrix least squares techniques using SHELXL-97 [46] program, which provided most non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. Solvent hydrogens were located through difference Fourier Map. All other hydrogens were geometrically fixed and riding model refinement was performed. During the refinement, wR_2 was optimized according to $wR2 = [\sum[w(F_o^2 - F_c^2)2]/\sum[w(F_o^2)^2]]^{1/2}$ with $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ for $P = (F_o^2 + 2F_c^2)/3$ where, *a* and *b* as free variables, [*a* = 0.1233, 0.0467, 0.0859 and *b* = 18.93, 18.99, 6.4619 for **1**·CH_3CN, **2**·CH_3OH and **3**, respectively]. Molecular graphics were of ORTEP3 (WINGX) program [47].

3. Results and discussion

3.1. Synthesis and characterization

The dicopper complexes **1**, **2** and **3** were synthesized by straightforward methods *via* the reaction of copper(II) perchlorate with a mixture of primary and auxiliary ligands; P1-OH/P2-OH/P2′-OH, acetamide/acetic acid and 2 equivalents of Et_3N in ethanol to afford > 70% yield. They were characterized by solid state FT-IR, solution state magnetic moment (Evans measurement), optical, elemental (CHN) analysis, paramagnetic ^1H NMR, and mass spectrometry including X-ray crystal structure determination.

IR spectra of **1**, **2** and **3** display the bands expected for the counterion (ClO_4^-), and acetamide/acetate coligands (Table 1). Complex **1** shows acetamide –C=O stretch at 1559 cm^{-1} and –NH stretch at 2847 cm^{-1}. Complexes **2** and **3** show two characteristic carboxylate stretching vibrations around 1460 and 1560 cm^{-1}. A difference in ($\nu_{as} - \nu_s$) value of ~110 cm^{-1}, in agreement with the presence of a carboxylate group bridging the two copper(II) ions in μ-1,3-coordination mode [48]. All the three complexes exhibit a strong stretch around 1090 cm^{-1} corresponding to free perchlorate.

Complexes **1** and **3** exhibit very clean ESI-MS spectra in acetonitrile solvent, containing two major peaks corresponding to the monocationic and dicationic molecular species. Complex **1** shows a peak at *m*/*z* 738 (20%) corresponding to the monocationic species $[Cu_2(P1\text{-}O^-)(NHAc^-)(ClO_4^-)]^+$ and at *m*/2*z* 318.4 (100%) corresponding to the dicationic species $[Cu_2(P1\text{-}O^-)(NHAc^-)]^{2+}$ (Fig. S1). Complex **3** showed a peak at *m*/*z* 690 (30%) with the characteristic isotopic distribution attributable to $[Cu_2(P2'\text{-}O^-)(OAc^-)(ClO_4^-)]^+$ ion; besides, a major peak at *m*/2*z* 295 (100%) corresponding to $[Cu_2(P2'\text{-}O^-)(OAc^-)]^{2+}$ is also consistent with **3** (Fig. S3). FAB MS of the complex **2** showed a peak at *m*/*z* 795 (45%) corresponding to the monocation $[Cu_2(P2\text{-}O^-)(OAc^-)(ClO_4^-)]^+$ (Fig. S2). Interestingly, it also showed a peak at *m*/*z* 690 corresponding to the monocation of complex **3** $[Cu_2(P2'\text{-}O^-)(OAc^-)(ClO_4^-)]^+$ with 75% isotopic abundance indicating that the conversion of P2-OH to P2′-OH is facile.

Solution magnetic moments of **1**, **2** and **3** were measured in deuterated acetonitrile/nitromethane solvent by Evan's method [45]. The room temperature effective magnetic moment (μ_{eff}) values for **1**, **2** and **3** are 1.92, 1.93 and 1.88 μ_B/Cu^{2+}, respectively. These magnetic moment values correspond to the presence of a spin of $s = 1/2$ as like mononuclear copper(II) complexes, which in turn indicate their weak spin–spin coupling.

3.2. Electronic absorption spectroscopy

The electronic absorption spectra of **1**, **2** and **3** are shown in Fig. 1. The peak positions of the spectral components are summarized with their molar extinction coefficients in Table 1. Complex **1** has an intense low energy band maximum at 890 nm (330 $M^{-1}\,cm^{-1}$) and a well defined high energy shoulder at 670 nm (135 $M^{-1}\,cm^{-1}$), which are assigned to d_{xy},$d_{x2-y2} \rightarrow d_{z2}$ and $d_{xz,yz} \rightarrow d_{z2}$ transitions of a trigonal bipyramidal Cu(II) center with unpaired electron on the d_{z2} orbital [49]. The dicopper(II) complexes **2** and **3** display similar absorption pattern in the electronic spectra (Fig. 1). Both show a charge transfer transition, L (alkoxo) → Cu^{2+} at 355 nm (ε = ~750 $M^{-1}\,cm^{-1}$) and two d–d transitions, one at 685 nm (ε = ~300 $M^{-1}\,cm^{-1}$) region, and an-

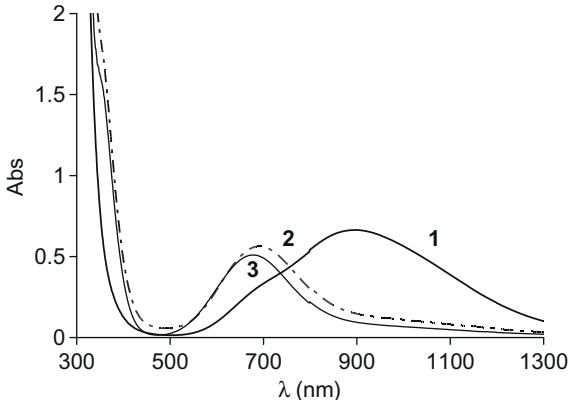

Fig. 1. The overlay of the optical spectra of **1**, **2** and **3** (2 mM in CH_3CN).

other weak low energy broad shoulder centered at 1000 nm ($\varepsilon = \sim 50\ M^{-1}\ cm^{-1}$) region. The d–d transitions of **3** are slightly shifted towards higher energy region than that of **2**. They are assigned to $d_{xz,yz,xy} \rightarrow d_{x2-y2}$ and $d_{z2} \rightarrow d_{x2-y2}$ transitions, respectively, which in turn represent the presence of square pyramidal Cu(II) centers with d_{x2-y2} orbital, holding the unpaired electron [49–51].

3.3. X-ray structures of the dicopper(II) complexes *1*, *2* and *3*

Complexes **1**, **2** and **3** were recrystallized from CH_3CN/CH_2Cl_2 solutions by solvent evaporation, and analyzed as $[Cu_2(P1\text{-}O^-)(NHAc^-)](ClO_4)_2$ (**1**), $[Cu_2(P2\text{-}O^-)(OAc^-)](ClO_4)_2$ (**2**) and $[Cu_2(P2'\text{-}O^-)(OAc^-)(H_2O)](ClO_4)_2$ (**3**), respectively from X-ray structure. Crystallographic data and selected geometric information for **1**, **2** and **3** are given in Tables 2 and 3. The structural diagrams are presented in Figs. 2–4 with the counter anions omitted for clarity. Complexes **1** and **2** crystallize in the orthorhombic space group, *Pbca* ($Z = 8$), whereas complex **3** crystallizes in the monoclinic space group, $P2_1/c$ ($Z = 4$). All are found binuclear. The copper(II) centers are doubly bridged by the alkoxo oxygen atom (O1) from the dinucleating ligand back bone and the acetamide/acetate bidentate supporting ligand from the bottom.

Table 2
Summary of crystal and refinement data for $[Cu_2(P1\text{-}O^-)(NHAc^-)](ClO_4)_2 \cdot CH_3CN$ (**1**); $[Cu_2(P2\text{-}O^-)(OAc^-)](ClO_4)_2 \cdot CH_2Cl_2$ (**2**); and $[Cu_2(P2'\text{-}O^-)(OAc^-)(H_2O)](ClO_4)_2$ (**3**).

The binuclear copper(II) centers of **1** are in distorted trigonal bipyramidal ligand environment, where a μ_2-bridging alkoxide (O1) and two pyridyl nitrogens (N2, N3 or N5, N6) from the binucleating ligand occupy the three basal coordination site and an asymmetrically *syn*, *syn*-coordinated acetamide group (O2/N7) and a tertiary amine nitrogen (N1/N4) from the ligand occupies the apical sites thereby establishing CuN_3O_2 and CuN_4O chromophores around Cu1 and Cu2, respectively (Fig. 2). The intervening bridges, alkoxide donor (O1) and acetamide donors (O2 and N7) respectively, lie on the equatorial and axial sites, anticipated to

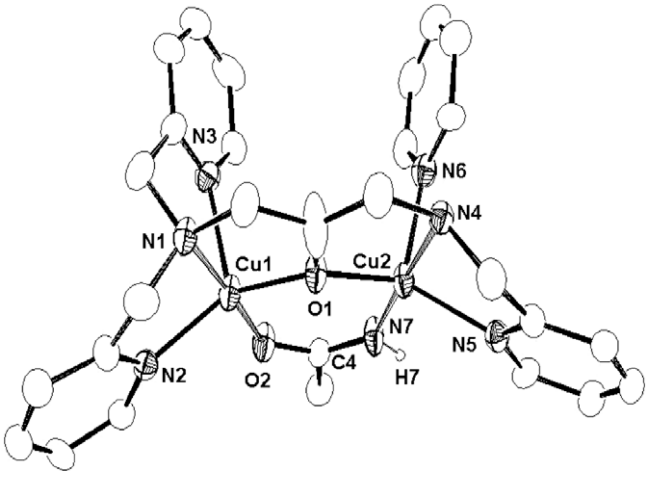

Fig. 2. X-ray structure (25% ellipsoids) of **1**.

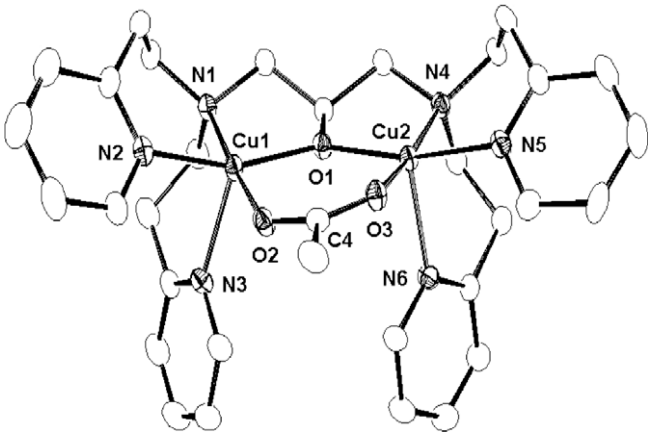

Fig. 3. X-ray structure (25% ellipsoids) of **2**.

induce weak magnetic interaction between the two copper(II) centers.

Unlike **1**, the copper(II) centers in **2** and **3** are each in a distorted square pyramidal ligand environment, where an amine nitrogen (N1/N4), a μ_2-bridging alkoxide/phenoxide (O1) and one pyridyl nitrogen (N2/N5) from the binucleating ligand and a symmetrically *syn*, *syn*-coordinated carboxylate group (O2/O3) take up the four basal coordination sites of the square plane. The apical sites are occupied by two *cis*-oriented pyridyl nitrogens (N3 and N6) from the binucleating ligand in the symmetric complex **2**. In the asymmetric complex **3**, one of the apical sites is occupied by an exogenous water oxygen atom (O4) at a distance of 2.617 Å due to the lack of another pyridyl nitrogen atom, which in turn makes the molecule asymmetric. Complex **2** has two CuN_3O_2 chromophores, and complex **3** has CuN_2O_3 and CuN_3O_2 chromophores around the copper(II) centers. Unlike complex **1**, in **2** and **3**, both the intervening bridge donors, alkoxide (O1) and acetate donors (O2 and O3) lie on the square plane.

The geometrical parameters (τ_1 and τ_2) of ~0.61 (**1**), 0.3 and 0.08 (**2**), and 0.25 and 0.005 (**3**), again indicate distorted trigonal bipyramidal and square pyramidal geometries around the copper centers, respectively [52]. The copper atoms are out of their mean planes by ~0.12 Å (**1**), ~0.18 Å (**2**), and ~0.16 Å (**3**). Dihedral angle between the trigonal and square planes containing Cu1 and Cu2 in **1**, **2** and **3** are 23.42, 21.9, and 26.47°, respectively. The two copper centers of **1**, **2** and **3** are separated by 3.41, 3.54, and 3.498 Å and make a ∠Cu1–O1–Cu2 angle of 128.0, 133.3 and 130.7°, respectively indicating an increase of ∠Cu1–O1–Cu2 angle with Cu···Cu distance. Unpredictably, complex **2** having a flexible two methylenes linker ligand P2-OH has larger Cu···Cu separation and Cu–O–Cu angle, compared to complex **1** holding a one methylene linker ligand P1-OH.

The apical Cu–N bonds in **2** and **3** are longer than the average basal Cu–N bonds by (0.25–0.30 Å) as is always observed in square pyramidal copper(II) complexes containing binucleating ligands and also the bond distances involving them are not equal pinpointing distortion of the square–pyramids. There is an asymmetry in the coordination distances around Cu1 and Cu2 in **1** due to acetamide ($NHAc^-$) bridge; also the latter seems to bridge strongly compared to acetate, which is apparent from the Cu–O and Cu–N distances (Table 3). There is no significant difference in the C–O/C–N bond distances of acetamide/acetate auxiliary bridges suggesting complete delocalization of the bridge.

Table 4 gives selected bond parameters and magnetic data of carboxylate bridged dicopper(II) complexes containing dinucleating ligand analogous to P1-OH. In such complexes, the important bond parameters (Cu···Cu separation and the Cu–O–Cu angle) that

[a] Unknown/not measured.

dictate predominantly the magnetic property depend primarily on the dinucleating ligand present and coordination geometry. Cu···Cu separation of **1**, **2** and **3** lie between 3 and 4 Å, and the same is observed for analogous carboxylate bridged dicopper(II) complexes [12,16,36,37]. The O–C–O carboxylate bond angle is quite deviated from the trigonal angle and is constantly observed above 120°.

3.4. Paramagnetic ^{1}H NMR spectroscopy of the dicopper(II) complexes *1*, *2* and *3*

Complex **1** is an unsymmetrical complex, where the auxiliary ligand acetamide induces coordination asymmetry with N_3O_2 and N_4O coordination around the two copper(II) centers. Because of this, it shows twice the number of resonances (Fig. 5) as compared to the acetate analogue $[Cu_2(P1\text{-}O^-)(OAc^-)]^{2+}$ [12]. As the molecule is asymmetric, all the protons impart individual resonances. There are totally 25 resonances, all downfield shifted. The acetamide bridged complex **1** adopts the same trigonal bipyramidal geometry, like that of the acetate bridged analogue $[Cu_2(P1\text{-}O^-)(OAc^-)]^{2+}$ and hence, the chemical shifts of various protons are comparable, except that all the signals are now doubled in number. All the methylene hydrogens are not clearly resolved to show separate signals. For convenience, the methylene pair hydrogens together are labeled as α/β. The pyridyl signals are assigned based on the acetate analogue, since their chemical shifts are not expected to be affected much because of acetamide coordination. The signals at 27.5 and 32.8 ppm are assigned to the $-CH_3$ and –NH resonances of the acetamide bridge, respectively on the basis of their integration ratio. This assignment is tentative.

The *C*2-symmetric complex $[Cu_2(P2\text{-}O^-)(OAc^-)]^{2+}$, **2** exhibits a ^{1}H NMR spectrum with signals spanning from δ 250 to −20 and most line widths are less than 100 Hz. There are 20 sharp signals. Among them, 15 signals are down-fielded and 5 are up-fielded (Fig. 6). Signal assignment for **2** is achieved using a combination of measurements: Signal integration, the proximity of the hydrogens from the metal center measured from X-ray structure and line-widths that correlates with the through bond electron delocalization (Table 5). All the methylene hydrogens are inequivalent due to their diastereotopic nature. For similar dinuclear copper complexes, the solution state Cu–H distances from T_1 measurement concord well with the solid state Cu–H distances from X-ray structure data [12,38–41]. And hence, the signals for the protons H6, Ha, H6′ and Ha′ that are very close to copper are the far downfield shifted in the NMR spectrum and are assigned in accordance with their solid state Cu–H distances. As anticipated these proton signals have broader line widths and thus short T_2 values. The methylene hydrogen (CH) and the second methylene hydrogens (CH_2) are found to have negative spin density through spin polarization, and as anticipated, they are seen in the negative region.

H5′	16.7	21	5.18	2
He′	14.9	59	3.5	2
Ha‴	14		3.52	2
He‴	13.8		3.83	2
H3′	10.4	32	5.19	2
H4	9.3	32	5.68	2
H4′	8.5	21	6.01	2
Ha″	−5.5	74	2.9	2
He″	−6.6		3.2	2
H_0	−6.8		3.18	1
Ha⁗	−11.9	263	4.05	2
He⁗	−17.7	63	4.22	2

Although the axial (H_a) and equatorial (H_e) hydrogens are the geminal methylene hydrogens, H_a is close to copper, whereas H_e is away from copper. This is due to the conformational change that causes Cu–N–C–$H_{a/e}$ dihedral angle variation, thereby M–$H_{a/e}$ distances change significantly between the axial and equatorial hydrogens. The measured dihedral angles for the different methylenes from X-ray crystal structure are *viz* H_a and H_e, 172.9 and 70°; $H_{a'}$ and $H_{e'}$, 165.7 and 75.9°; and $H_{a''}$ and $H_{e''}$, 142.7 and 99.4°. Hence, H_a's are expected to be far downfield shifted than H_e's and the same is observed as well. The spectral assignment is purely partial. Variable temperature measurements were carried out between the temperature range −251 to +348 K in CD_3NO_2 solvent. Most of the resonances except those in the diamagnetic region are temperature dependent. As the temperature increases, the signals move towards the diamagnetic region (Fig. S4). The intercepts of the various signals in the plot of chemical shifts *versus* $1/T$ (Curie plot) lie within ±20 ppm indicating that the chemical shifts are predominantly contact in origin [42].

The unsymmetrical analogue of **2** $[Cu_2(P2'\text{-}O^-)(OAc^-)(H_2O)]^{2+}$ (**3**) having the asymmetric polypodal ligand P2′-OH with one ethyl pyridyl arm on one side and two ethyl pyridyl arms on the other side gives a complicated ^{1}H NMR spectrum (Fig. 7) and notably, with the same spectral span range like **2** at 25 °C. With the

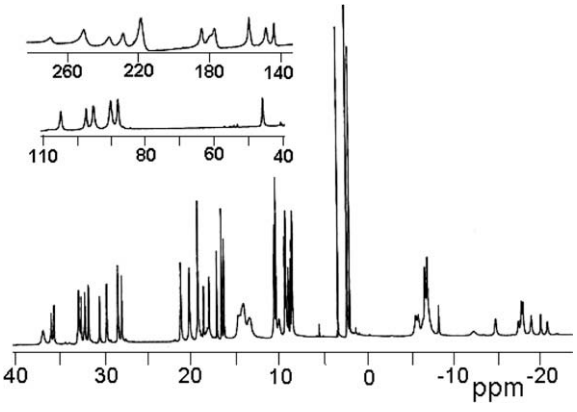

Fig. 7. A 400 MHz ^{1}H NMR spectrum of **3** in CD_3CN at RT.

unsymmetrical structure, all the hydrogens present in the molecule now become magnetically inequivalent, and hence resonances correspond to all the protons sprout up in the ^{1}H NMR spectrum. The diastereotopic methylenes are not resolved out and they show signals correspond to two inequivalent sets. All the remaining hydrogens are well resolved. Variable temperature measurements were carried out between the temperature range 258–298 K in CD_3CN (Fig. S5). Like complex **2**, here also most of the resonances except those in the diamagnetic region are temperature dependent and the spectral width narrows with increasing temperature.

3.5. EPR spectroscopy

The dicopper(II) complexes show characteristic EPR spectra (Figs. S6–S8). The X-band EPR spectra of **1**, **2** and **3** have been measured in the parallel mode and in frozen DMF glass state at LN_2 temperature and the '*g*' parameters are tabulated below (Table 1). All displayed $g_{\|} > g_{\perp}$ and $g_{\|} > 2.15$, representative of five-coordinated Cu(II) complexes with strained geometry. Complex **1** shows two overlapping four-line pattern in the $g_{\|}$ region and a pattern characteristic of tbp geometry with an average spacing of 110 G (Fig. S6). The $g_{\|}$ and $g_{\perp}$ values of **1**, 2.20 and 2.12, respectively, are well near to each other indicating their geometry is a mixture of tbp and sp. Whereas, the binuclear copper(II) complexes **2** and **3** provide a nearly axial spectra with $g_{\|} > g_{\perp}$, consistent with $d_{x^2-y^2}$ being the highest energy half-occupied molecular orbital. In addition to that, complex **2** shows a "half-field" signal (~1250 G) correspond to the forbidden $|\Delta M_s = 2|$ transition at $g = 3.90$ (Fig. S7), and is characteristic of dinuclear Cu^{2+} species with a weak magnetic coupling [53].

ABSTRACT

Five mononuclear nickel(II) complexes, *viz.* [Ni(L1)(PPh_3)] (**1**), [Ni(L2)(PPh_3)] (**2**), [Ni(L3)(PPh_3)] (**3**), [Ni(L4)(PPh_3)] (**4**) and [Ni(L5)(PPh_3)] (**5**) (where L1, L2, L3, L4 and L5 are dianions of *N*-(2-mercaptophenyl) salicylideneimine, 5-methyl-*N*-(2-mercaptophenyl)salicylideneimine, 5-chloro-*N*-(2-mercaptophenyl) salicylideneimine, 5-bromo-*N*-(2-mercaptophenyl)salicylideneimine and *N*-(2-mercaptophenyl)naphthylideneimine, respectively), have been synthesized and characterized by means of elemental analysis, electronic, IR, ^1H, ^{13}C and ^{31}P NMR spectroscopy. Single crystal X-ray analysis of two of the complexes (**1** and **5**) has revealed the presence of a square planar coordination geometry (ONSP) about nickel. The crystal structures of the complexes are stabilized by intermolecular π–π stacking between the ligands (L) and by various C–H···π interactions.

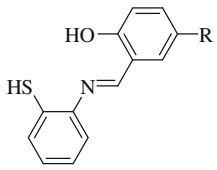
1. Introduction

The synthesis of geometrically distorted nickel(II) complexes with mixed N and S donor sets is the research interest of many groups [1]. Nickel is present in the active sites of several important classes of metalloproteins, such as 2-mercaptoethanol-inhibited urease and Ni/Fe hydrogenases [2]. The nickel coordination sphere in both of these metalloenzyme systems contains N and S donor sets. These features led to increased interest in the synthesis of nickel(II) complexes with mixed N,S donating chelates as structural and spectroscopic models of the active sites. There are many reports available for nickel(II) complexes with N,S donor ligands [3], but nickel(II) complexes containing N,S donor ligands as well as triphenylphosphine are very rare [4]. Complexes of this kind are interesting in terms of both models of the active sites and homogeneous catalysis.

In addition, *N*-(2-mercaptophenyl)salicylideneimine exhibits different kinds of coordination modes with different metal ions. It behaves as a bifunctional tridentate ligand with Tc(V), Re(V), Ru(II) and Ru(III) [5–7]. The same ligand shows monofunctional tridentate coordination with Co(II), Cu(II) and Zn(II) [8] and monofunctional bidentate coordination with Ru(I) [9]. Hence, we intend to investigate the coordination behaviour of *N*-(2-mercaptophenyl)salicylideneimine, its derivatives and *N*-(2-mercaptophenyl)naphthylideneimine with Ni(II). Here, we report square planar nickel(II) complexes of O,N,S donor ligands and triphenylphosphine. These complexes were characterized by IR, electronic and NMR spectral data. The structures of two complexes have been determined by single crystal X-ray crystallography. The general structures of the ONS Schiff base ligands used in this study are depicted in Fig. 1.

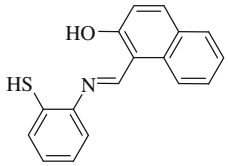
2. Experimental

2.1. Materials



All the chemicals used were of analytical grade. Solvents were purified and dried according to standard procedures [10]. $NiCl_2{\cdot}6H_2O$ was purchased from Qualigens Fine Chemicals and was used without further purification. The starting complex [$NiCl_2(PPh_3)_2$] was prepared by the reaction between $NiCl_2{\cdot}6H_2O$ and triphenylphosphine in glacial acetic acid [11]. The Schiff base ligands were prepared by the condensation between salicylaldehyde, its derivatives or 2-hydroxy-1-naphthaldehyde and *o*-aminothiophenol in ethanol [5,12].

2.2. Physical measurements



Electronic spectra were measured on a Perkin Elmer EZ 301 UV–Vis double beam spectrophotometer for CH_3CN solutions of the complexes in the 200–800 nm range. FT-IR spectra were recorded

on a Perkin Elmer Spectrum One FT-IR spectrometer as KBr pellets in the frequency range 400–4000 cm^{-1}. The C, H, N and S contents were determined by a Thermoflash EA1112 series elemental analyzer. ^1H, ^{13}C, HSQC and HMBC NMR spectra were recorded in a Bruker AMX 400 instrument using TMS as the internal standard. ^{31}P NMR spectra were recorded in a Bruker AMX 400 instrument in $CDCl_3$ with H_3PO_4 as a reference. Melting points were determined with a Khora digital melting point apparatus.

2.3. X-ray crystallography

Single crystals of **1** and **5** for X-ray diffraction studies were grown at room temperature from a dichloromethane solution by the diffusion of diethyl ether vapour. Diffraction data were collected on a Bruker SMART APEX CCD diffractometer using graphite monochromated Mo Kα radiation (λ = 0.71073 Å). The structures were solved by direct methods (SHELXS-97) [13] and refined by full-matrix least squares fitting based on F^2 using the program SHELXL-97 [14]. All non-hydrogen atoms were refined with anisotropic displacement parameters. All H atoms were located by difference Fourier syntheses and were then included in the refinement with idealized geometry riding on the atoms to which they were bonded.

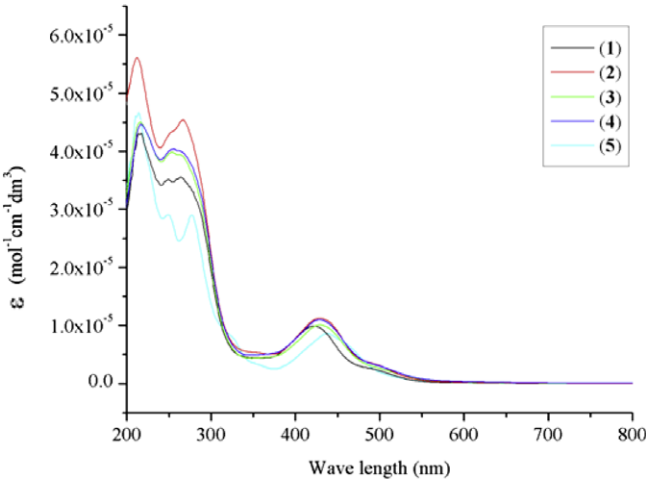

Fig. 2. Electronic spectra of the nickel(II) complexes.

2.4. Synthesis of Ni(II) complexes

All the complexes were prepared by stirring an ethanolic solution of $[NiCl_2(PPh_3)_2]$ with dichloromethane solutions of the ligands in a 1:1 molar ratio for 2 h at 25–27 °C. The resulting dark brown solutions were concentrated to approximately 3 cm^3 and cooled. Hexane (20 cm^3) was then added, whereupon the product complex separated. The brown coloured complex was filtered, washed with ethanol and then with hexane, and dried in *vacuo*. The formation of complex was checked by TLC.

$[Ni(L1)(PPh_3)]$ (**1**) is prepared from $[NiCl_2(PPh_3)_2]$ (0.5 g; 0.764 mmol) and H_2L1 (0.175 g; 0.764 mmol). Yield: 59%. *Anal*Calc.

3. Results and discussion

The reaction of equimolar ratios of the ligands (H_2L) and [$NiCl_2(PPh_3)_2$] yielded the new complexes of the general formula [Ni(L)(PPh_3)] (L = dianionic Schiff base ligand) in moderate to good yield. All the present complexes were brown in colour. They were found to be soluble in CH_2Cl_2, CH_3CN, C_6H_6, DMSO, DMF and C_2H_5OH. The analytical data for these complexes are in good agreement with the above molecular formula. In all the reactions, it has been observed that the Schiff base behaves as a bifunctional tridentate ligand by substituting one of the triphenylphosphine ligands and both the chloride ions from the starting complex.

3.1. Electronic spectra

The electronic spectra of the complexes (Fig. 2) **1**, **2**, **3** and **4** in CH_3CN showed four bands in the region 198–431 nm. The bands appearing in the region 198–267 nm have been assigned to intraligand transitions. A less intense band in range 423–431 nm corresponds to a forbidden $d \rightarrow d$ transition. Complex **5** displayed six bands in the 199–469 nm range. The extra bands are due to the additional phenyl ring present in the ligand. Four bands in the region 199–323 nm are due to intraligand transitions and two bands at 438 and 469 nm are due to forbidden $d \rightarrow d$ transitions. The same behaviour has been observed in the electronic spectra of other similar square planar nickel(II) complexes [4,15].

3.2. IR spectra

Selected IR bands of the ligands and complexes are listed in Table 1. The spectra of the ligands exhibit a strong band around 1610–1622 cm^{-1}, which is assigned to a ν(C=N) vibration. As a result of coordination, this band shifts to a lower wavenumber by *ca.* 10 cm^{-1} in the complexes [4,16]. The band in the region

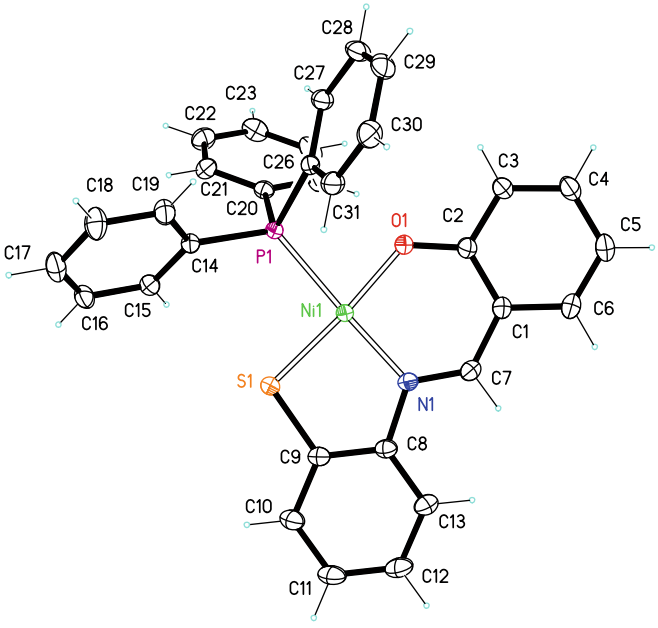

Fig. 7. Molecular structure of complex **1** showing 50% displacement ellipsoids.

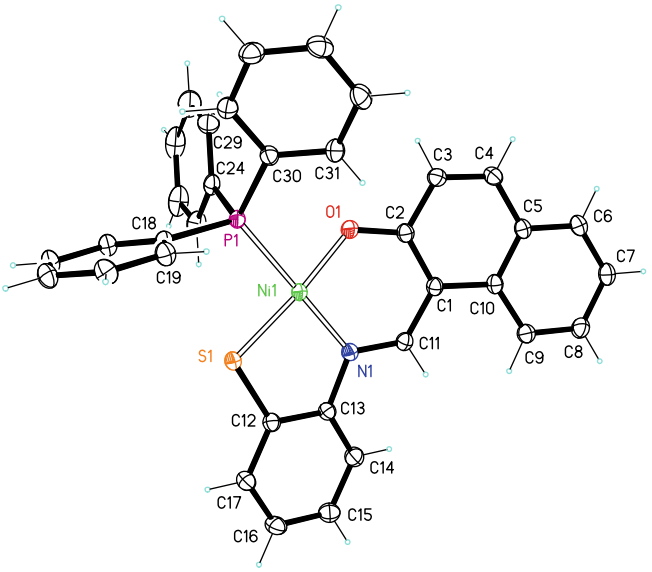

Fig. 8. Molecular structure of complex **5** showing 50% displacement ellipsoids.

1304–1323 cm^{-1}, which is assigned to phenolic ν(C–O) in the free ligand, is shifted to a higher wavenumber in the complexes, suggesting the coordination of the phenolic oxygen atom to the nickel ion [4,16]. A weak band observed in the region 753–757 cm^{-1}, corresponding to ν(C–S) in the ligands, shifts to a lower wavenumber (743–752 cm^{-1}) which supports sulfur coordination with the nickel centre [17]. The bands around 530 and 460 cm^{-1} in all the complexes are assigned to ν(Ni–O) and ν(Ni–N), respectively [18]. Bands due to triphenylphosphine also appear in the expected region [19].

3.3. NMR spectra

^{1}H, ^{13}C and ^{31}P NMR spectral data of the complexes are given in Table 2. All the nickel(II) complexes exhibit a multiplet around 6.3–8.1 ppm, which has been assigned to the protons of the phenyl groups present in triphenylphosphine and the Schiff base ligand. A doublet observed at 8.8 ppm in the complexes has been assigned to the azomethine proton (–C=N–) [20]. Complex **3** exhibits a singlet at 2.3 ppm, corresponding to methyl protons. The absence of a resonance due to phenolic and thiolato hydrogen atoms indicates the deprotonation of these groups and the Schiff bases behave as dianionic ligands. The ^{1}H NMR spectrum of **1** is depicted in Fig. 3. In the ^{13}C NMR spectra of all the complexes, azomethine carbon resonances are observed in the 151.12–154.49 ppm range. The resonances for C–S, C–N, C–O and C–P are observed in the regions 129.00–129.69, 149.32–149.99, 162.44–164.93 and 142.96–144.48 ppm, respectively [21,22]. The ^{13}C NMR and DEPT 135 spectra of **1** revealed the presence of seven different carbons (119.30, 129.00, 129.46, 143.85, 143.98, 149.82 and 163.98 ppm). This indicates that the three quaternary carbons arising from triphenylphosphine aromatic units are in different magnetic environments. The HSQC correlation spectrum of **1** (Fig. 4) establishes the connection between the imine proton (δ_H = 8.89, d, J = 10.36 Hz, 1H) and C-7 (δ_C = 154.51). The interaction of the imine proton (δ_H = 8.89, d, J = 10.36 Hz, 1H) with three quaternary carbons *viz.* C-1 (δ_C = 119.30), C-2 (δ_C = 163.98) and C-8 (δ_C = 149.82) and the methine carbon C-6 (δ_C = 134.00) has been understood from the HMBC correlation spectrum (Fig. 5). The ^{31}P NMR spectra of all the complexes exhibit a singlet around 22.3–25.2 ppm, suggesting the presence of one coordinated triphenylphosphine ligand in these nickel(II) complexes [23]. The ^{31}P NMR spectra of all the complexes are given in Fig. 6.

3.4. X-ray crystallography

The compounds **1** and **5** were structurally determined by X-ray crystallography. The crystallographic and measurement data are shown in Table 3 and representative bond lengths and bond angles are listed in Table 4. Figs. 7 and 8 present thermal ellipsoid representations of complexes **1** and **5**, respectively. In both the complexes, the nickel(II) atom is four coordinated in a square planar geometry by the Schiff base and triphenylphosphine ligands. The Schiff base acts as a tridentate ligand through the thiolato sulfur atom, the imine N and the phenolic O atom. Two units of [Ni(L1)(PPh_3)] and four units of [Ni(L5)(PPh_3)] are present in their respective unit cells. As expected for four coordinate d^8 metal complexes, the structure of **1** adopts a nearly ideal square planar geometry with O–Ni–S and N–Ni–P bond angles of 173.98(3) and 174.75(3)°, respectively [24]. The other angles around the nickel(II)

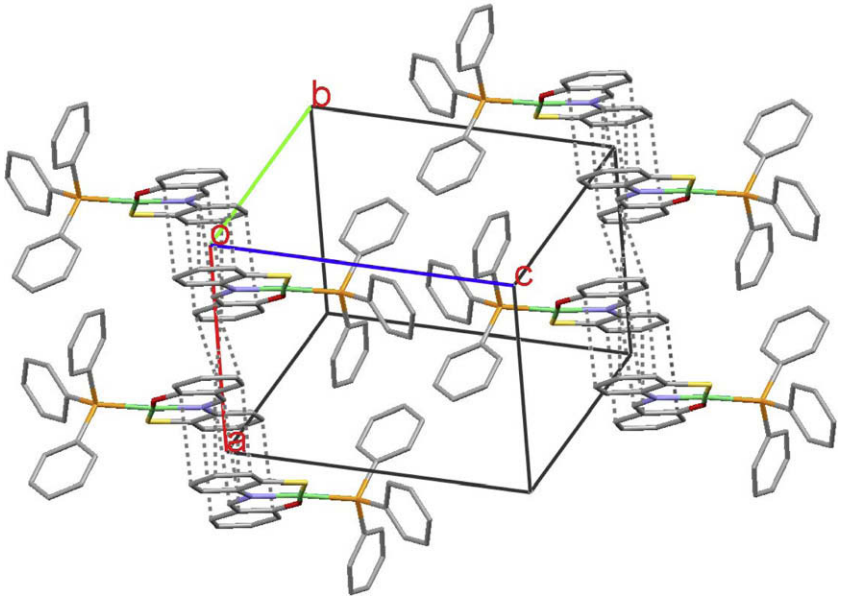

Fig. 9. Schematic drawing of the crystal packing of **1** showing the π–π stacking parallel to the *a*-axis. Hydrogen atoms are omitted.

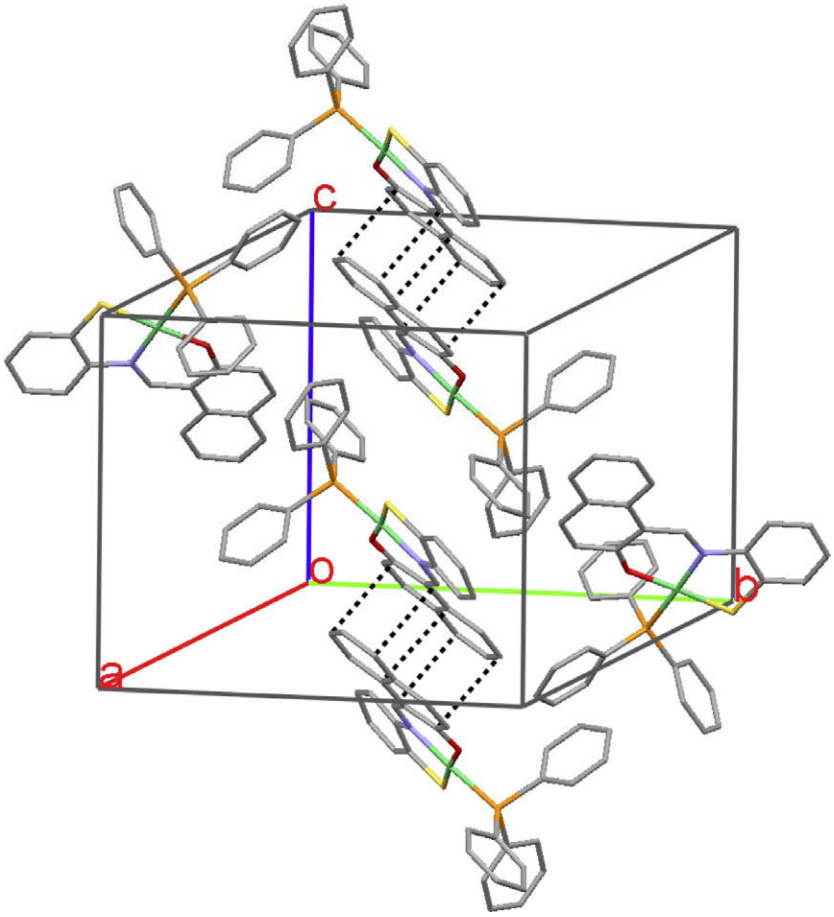

Fig. 10. Schematic drawing of the crystal packing of **5** showing the π–π stacking between pairs of complexes *via* their naphthyl moieties. Hydrogen atoms are omitted.

atom deviate slightly from the ideal value (90°), ranging from 82.58(3) to 95.37(4)°. In structure **5**, the O–Ni–S and N–Ni–P bond angles are 175.08(2) and 177.24(3)°, respectively and other angles around nickel(II) are in the range 85.10(2) to 94.34(3)°. The Ni–P, Ni–O, Ni–N and Ni–S bond distances are in the usual range in both complexes [4]. Disregarding triphenylphosphine, complex **1** is essentially planar, showing a r.m.s. deviation of 0.030 Å of the non-hydrogen atoms from a common least-squares plane, from which the P atom deviates by 0.324(1) Å. Complex **5** is distinctly more aplanar showing for the Ni(L5) moiety a r.m.s. deviation of 0.154 Å from planarity and a significant twist between the phenyl and the naphthyl residues of L5 (interplanar angle 14.15(5)°). These differences between [Ni(L1)(PPh_3)] and [Ni(L5)(PPh_3)] are attributable to differences in crystal packing and intermolecular interactions. The intermolecular interactions in [Ni(L1)(PPh_3)] are characterized by comparatively weak π–π stacks of L1, forming continuous chains along the *a*-axis (Fig. 9). In [Ni(L5)(PPh_3)], there are pairs of complexes π–π stacked via their naphthyl moieties (Fig. 10). The PPh_3 moieties in both [Ni(L1)(PPh_3)] and [Ni(L5)(PPh_3)] do not show π–π stacking but contribute by various C–H···π interactions to the coherence of the structures.

4. Conclusion

Mononuclear Ni(II) complexes of the type [Ni(L)(PPh_3)] (L = ONS donor Schiff base ligand) were prepared and characterized by NMR, IR and electronic spectroscopy. Structures of two complexes were determined by X-crystallography, which are stabilized by intermolecular π–π stacking between the ligands (L) and by various C–H···π interactions.

Supplementary data

CCDC 663130 and 653443 contain the supplementary crystallographic data for **1** and **5**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Mononuclear palladium(II) complexes containing a pyrazole-thioether ligand, with general formula *trans*-[Pd(X)$_2$(bddo)] (X = CN$^-$ (**1**), SCN$^-$ (**2**) or N$_3^-$ (**3**); bddo = 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane), have been prepared. Similar reactivity carried out with pyridine or triphenylphosphine has been assayed. When pyridine is used, a mixture of [Pd(bddo)(py)$_2$](BF$_4$)$_2$ ([**4**](BF$_4$)$_2$) and [Pd(bddo)](BF$_4$)$_2$ is obtained. When triphenylphosphine is used, only [Pd(bddo)](BF$_4$)$_2$ is obtained. The complexes have been characterised by elemental analyses, conductivity measurements, IR and NMR spectroscopies. X-ray crystal structure of *trans*-[Pd(SCN)$_2$(bddo)] (**2**) is presented. In this complex the metal atom is coordinated by the two azine nitrogen atoms of the pyrazole rings and two SCN$^-$ anions in *trans* disposition.

1. Introduction

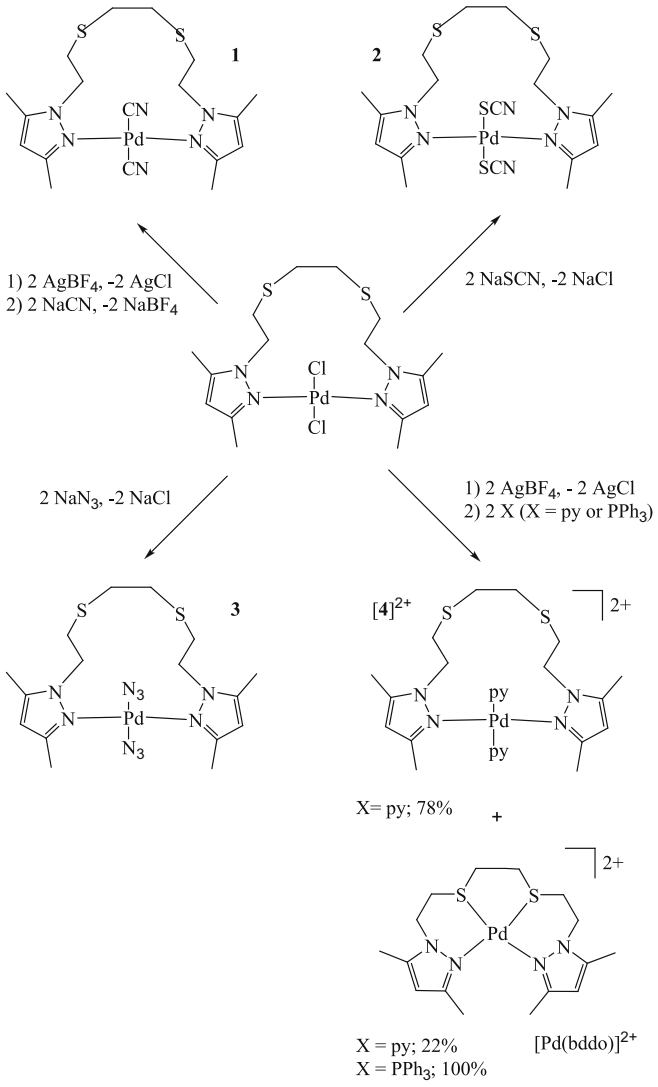
The role of ligands in coordination and organometallic chemistry does not need emphatic presentation since their fundamental importance in determining the morphology and the chemical–physical properties of the molecules. For example, a rich variety of coordination modes is observed for pyrazole hybrid ligands [1] and their complexes have been successfully employed in catalysis [2], chemotherapy [3], electrochemical reduction [4], magnetic coupling [5] and metallo-supramolecular chemistry [6].

For this reason, in our group, we have studied and reported the synthesis and characterisation of ligands combining a pyrazolyl group with some other donor groups, in particular, with S (thiol or thioether) [7] with the objective of introducing ligands with different nature in the coordination sphere of the metal.

We have investigated the reactivity of the complex [PdCl(μ-med)]$_2$ (Hmed = *N*-(2-mercaptoethyl)-3,5-dimethylpyrazole), with monodentate (pyridine, triphenylphosphine, cyanide, thiocyanate and azide) or bidentate ligands (bipyridine and bis(diphenylphosphine)ethane) [8].

Recently, we have studied the reactivity of [PdCl(bdtp)](BF$_4$) (bdtp = 1,5-bis(3,5-dimethyl-1-pyrazolyl)-3-thiapentane) with pyridine, triphenylphosphine, cyanide, thiocyanate or azide ligands, yielding the complexes [Pd(bdtp)(X)](BF$_4$)$_2$ (X = py, PPh$_3$) and [Pd(X)(bdtp)](BF$_4$) (X = CN$^-$, SCN$^-$ and N$_3^-$) [9].

In a previous paper, the synthesis and characterisation of [PdCl$_2$(bddo)] and [Pd(bddo)](BF$_4$)$_2$ (bddo = 1,8-bis(3,5-dimethyl-1-pyrazolyl)-3,6-dithiaoctane) have been presented [7a]. Here, we extend the study of the coordinative properties of bddo ligand towards Pd(II). Reaction of [PdCl$_2$(bddo)] with cyanide, thiocyanate or azide in the presence of AgBF$_4$ or NaBF$_4$ produces the complexes [Pd(X)$_2$(bddo)] (X = CN$^-$ (**1**), SCN$^-$ (**2**) and N$_3^-$ (**3**)). Reaction of [PdCl$_2$(bddo)] with pyridine yields a mixture of [Pd(bddo)(py)$_2$](BF$_4$)$_2$ ([**4**](BF$_4$)$_2$) and [Pd(bddo)](BF$_4$)$_2$. When the reaction is carried out with triphenylphosphine, [Pd(bddo)](BF$_4$)$_2$ is the only complex that is obtained (Scheme 1).



2. Results and discussion

2.1. Synthesis and spectroscopic properties of the complexes

Reaction of [PdCl$_2$(bddo)] [7a] with two equivalents of NaBF$_4$ in the presence of two equivalents of NaSCN or NaN$_3$, and in a mixture of CH$_2$Cl$_2$/MeOH (1:1), yields the complexes [Pd(X)$_2$(bddo)] (X = SCN$^-$ (**2**) or N$_3^-$ (**3**)). When identical conditions are used in an attempt to prepare the corresponding [Pd(CN)$_2$(bddo)] (**1**) complex, displacement of the bddo ligand occurs, yielding Na$_2$[Pd(CN)$_4$] [10]. A new synthetic route has been tried. Complex [Pd(bddo)(CH$_3$CN)$_2$](BF$_4$)$_2$ is formed by the reaction of [PdCl$_2$(bddo)] with two equivalents of AgBF$_4$ in a mixture of CH$_2$Cl$_2$/CH$_3$CN (2:1) at room temperature. Two equivalents of NaCN are then added to the solution of [Pd(bddo)(CH$_3$CN)$_2$](BF$_4$)$_2$, yielding [Pd(CN)$_2$(bddo)] (**1**) (Scheme 1).

Scheme 1.

When $[PdCl_2(bddo)]$ reacts with two equivalents of $AgBF_4$ in CH_2Cl_2:CH_3CN:CH_3OH (2:1:1) and then two equivalents of pyridine (py) are added, a mixture of two complexes, $[Pd(bddo)(py)_2](BF_4)_2$ (78%) ([**4**]$(BF_4)_2$) and $[Pd(bddo)](BF_4)_2$ (22%), is obtained. $[Pd(bddo)](BF_4)_2$ had already been described in a previous paper by some of the authors of this work, and its presence in the mixture has been confirmed by comparison of the ^{1}H NMR spectra. ^{1}H NMR spectrum of the mixture has also been used to determine the ratio of [**4**]$(BF_4)_2$ (δ(C–H_{pz}) = 6.18 ppm) and $[Pd(bddo)](BF_4)_2$ (δ(C–H_{pz}) = 6.26 ppm) complexes (integration of C–H_{pz} signals, see Section 4). Unfortunately, isolation of the two complexes by silica gel chromatography was unsuccessful. Recrystallisations of the mixture with different solvents have been carried out but pure products could not be obtained.

When a similar reaction is used to prepare the complex $[Pd(bddo)(PPh_3)_2](BF_4)_2$, we obtain $[Pd(bddo)](BF_4)_2$ as a pure product [7a].

Complexes **1–3** and the mixture of [**4**]$(BF_4)_2$ and $[Pd(bddo)(PPh_3)_2](BF_4)_2$ have been characterised by elemental analyses, conductivity measurements and spectroscopic methods.

The elemental analyses confirm the stoichiometries proposed for the compounds. The positive ionisation spectra (ESI(+)) of **1–3** gave peaks with m/z values at 519, 583 and 551, respectively, corresponding to {100%, ($[Pd(X)_2(bddo)] + Na)^+$)}, (X = CN^-, SCN^- and N_3^-).

The conductivity data in acetonitrile are in agreement with non-electrolytes for compounds **1–3** [11].

IR spectra of complexes **1–3** and the mixture of [**4**]$(BF_4)_2$ and $[Pd(bddo)](BF_4)_2$ are similar to that of $[PdCl_2(bddo)]$, the most characteristic bands being those attributable to the pyrazolyl group: $\nu(C{=}C)_{pz}$ and $\nu(C{=}N)_{pz}$ between 1557 and 1546 cm^{-1}. The IR spectrum of the mixture of [**4**]$(BF_4)_2$ and $[Pd(bddo)](BF_4)_2$ presents bands, attributable to [**4**]$(BF_4)_2$, that are assigned to $(\nu(C{=}C)_{ar})_{py}$ and $(\nu(C{=}N)_{ar})_{py}$ at 1601 cm^{-1}, $(\delta(C{-}H)_{oop})_{py}$ at 701 cm^{-1} and ν(B–F) at 1066 cm^{-1}. [12] The terminal CN^- groups in **1** give rise to a band at 2140 cm^{-1}, typical of monodentate cyanides [13]. Complex **2** exhibits a strong band at 2111 cm^{-1} indicative of S-bond thiocyanates [13a–c,14]. Finally, the IR spectrum of **3** displays a strong band at 2024 cm^{-1} attributable to azide groups [13a,15]. The IR spectra of the complexes in the 650–250 cm^{-1} region have also been studied. In all cases, they show bands attributable to ν(Pd–N) between 463 and 419 cm^{-1}. Moreover, bands attributable to $\nu(Pd{-}C_{cyanide})$ at 412 cm^{-1} (**1**), $\nu(Pd{-}S_{thiocyanate})$ at 342 cm^{-1} (**2**) and $\nu(Pd{-}N_{azide})$ at 473 cm^{-1} (**3**) were also assigned [13a,15].

The ^{1}H, ^{13}C{^{1}H}NMR, COSY and HSQC spectra for complexes **1–3** were recorded in $(CD_3)_2CO$ and show the signals of coordinated ligands. HSQC spectra were used to assign the protons and carbons of the $SCH_2CH_2N_{pz}$ and the SCH_2CH_2S fragments. NMR data are reported in the Section 4.

NMR spectra of compound **2** and **3** were studied in more detail. Study of the $SCH_2CH_2N_{pz}$ fragment as an AA'XX' system gave a set of coupling constants for each complex. These constants are consistent with the simulated spectra obtained with the aid of the *g* NMR program [16]. Fig. 1 shows the experimentally determined and simulated spectra of the $SCH_2CH_2N_{pz}$ and the SCH_2CH_2S fragments for **2**. In the ^{1}H NMR spectrum of complexes **2** and **3,** we observe two multiplets corresponding to one CH_2 of the $SCH_2CH_2N_{pz}$ fragment each. The two protons of each CH_2 group are isocrones but each of them presents one ^2J coupling constant with the geminal proton and two ^3J coupling constants with the vicinal protons, due to the rigidity of the bddo ligand once it is complexed (NMR data can be found in the Section 4).

The coupling constants obtained for the $SCH_2CH_2N_{pz}$ fragment of complexes **2** and **3** are comparable to those obtained for $[PdCl_2(bddo)]$ [7a]. This indicates that the bddo ligand presents the same coordination behaviour in $[PdCl_2(bddo)]$ and complexes **2** and **3**: the ligand coordinates the Pd(II) centre through the azine nitrogens of the two pyrazolyl rings and the thioether groups remain uncoordinated. This type of coordination is corroborated by the X-ray crystal structure of $[PdCl_2(bddo)]$ [7a] and complex **2** (Fig. 2).

The ^{1}H NMR spectrum of complex **1** could not be further studied due to the broadness of the signals corresponding to the $SCH_2CH_2N_{pz}$ fragment. However, the number of signals and their positions is similar to those found for $[PdCl_2(bddo)]$, and complexes **2** and **3**. This would indicate that the bddo ligand also coordinates the Pd(II) centre in **1** through the azine nitrogens of the two pyrazolyl rings.

*2.2. Description of the crystal and molecular structure of trans-$[Pd(SCN)_2(bddo)]$ (**2**)*

The structure of **2** consist of discrete *trans*-$[Pd(SCN)_2(bddo)]$ units packed according to van der Waals forces (Fig. 2). Some selected bond lengths and bond angles for this complex are listed in Table 1.

The palladium atom is coordinated by two pyrazolic nitrogens and two sulfur atoms from the thiocyanate ligands in a distorted square-planar geometry. The tetrahedral distortion can be observed in the mean separation [0.077 Å] of the atoms linked to

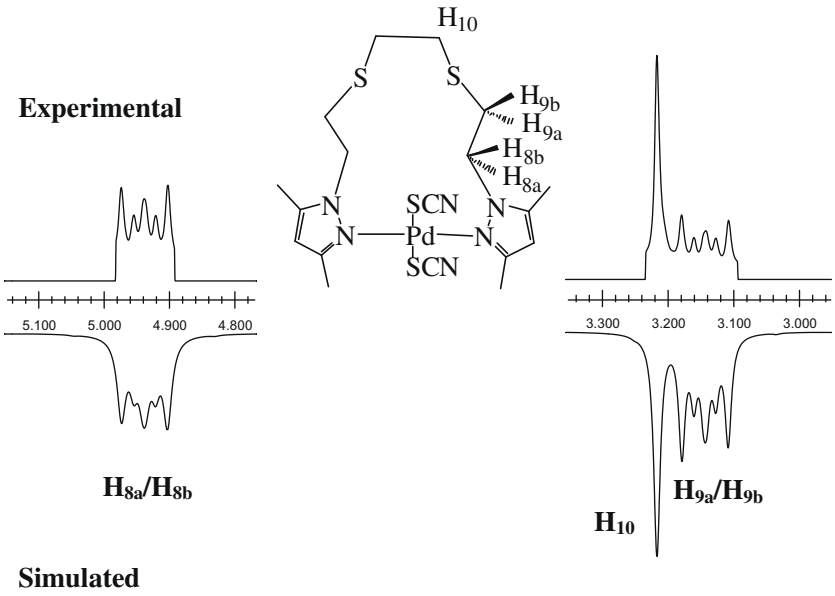

Fig. 1. The 250-MHz ^{1}H NMR and the simulated *g* NMR spectra for H_8, H_9 and H_{10} protons of the $N_{pz}CH_2CH_2S$ and SCH_2CH_2S fragments of $[Pd(SCN)_2(bddo)]$ (**2**), including the numbering of the H_8, H_9 and H_{10} protons.

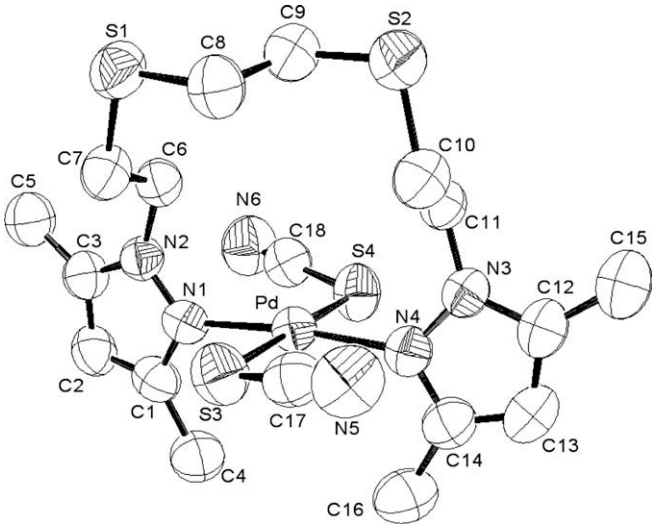

Fig. 2. ORTEP drawing of $[Pd(SCN)_2(bddo)]$ (**2**), showing all non-hydrogen atoms and the atom numbering scheme; 50% probability amplitude displacement ellipsoids are shown.

Table 1
Selected bond lengths (Å) and bond angles (°) for **2**.

Pd–N(1)	2.047(3)	Pd–S(3)	2.352(2)
Pd–N(4)	2.025(3)	Pd–S(4)	2.320(2)
N(4)–Pd–N(1)	172.67(12)	N(1)–Pd–S(4)	93.73(9)
N(4)–Pd–S(4)	85.45(10)	N(1)–Pd–S(3)	85.33(9)
N(4)–Pd–S(3)	95.34(11)	S(4)–Pd–S(3)	178.49(5)

the Pd atom in relation to the mean plane. Tetrahedral distortion of the square-planar geometry can also be observed in the angles S3–Pd–S4 and N1–Pd–N4, of 178.49(5)° and 172.67(12)°, respectively. The dihedral angle between the planes N1–Pd–S3 and N4–Pd–S4 is 7.33°. The pyrazolyl groups are *trans* to each other. The bddo ligand acts as a bidentate chelate, and form one thirteen membered ring.

The PdN_2S_2 *core* (N pyrazole and S thiocyanate) is found in three complexes in the literature [14a,17]. The Pd–N_{pz} (2.025(3) Å, 2.047(3) Å) and Pd–S_{SCN} (2.320(2) Å, 2.352(2) Å) distances are of the same order as those found in the literature for this kind of complexes. For the Pd–N_{pz} bonds, the literature describes distances between 1.979 and 2.141 Å [9], and for Pd–S_{SCN}, the described bond distances lay between 2.278 and 2.448 Å [18].

The values of the Pd–S–C angles are 104.20(18)° and 105.62(16)° for Pd–S3–C17 and Pd–S4–C18, respectively. These angles agree with the values observed for other complexes found in the literature (104.8(1)° for $[Pd(SCN)_2(HPz)_2]$ (HPz = pyrazol) [14a], 106.2(2)° for $[Pd(SCN)_2(phmPz)_2]$ (phmPz = 1-phenyl-3-methylpyrazole) [14a], 102.0(1)° for $[Pd(SCN)_2(HdmPz)_2]_n$ (HdmPz = 3,5-dimethylpyrazole) [17], 107.3° for $[Pd\{Ph_2P(CH_2)_3NMe_2\}(SCN)(NCS)]$ [19]) and 102.71(10)° for $[Pd(SCN)_2(PTA)_2](SCN)_2$ (PTA = 1,3,5-triaza-7-phosphaadamantane) [20].

The values of S–C–N angles in the thiocyanate groups are 176.5(5)° (S3–C17–N5) and 173.9(5)° (S4–C18–N6). These angles are of the same order as those found in the aforementioned complexes [17–20] and show that the thiocyanate groups are nearly linear. In addition, the bond length values of S–C (1.612(6) Å, 1.712(5) Å) and C–N (1.187(6) Å, 1.121(6) Å), indicate the dominance of the mesomeric S–C≡N form [17].

3. Conclusion

The present paper reports the reaction of the complex $[PdCl_2(bddo)]$ with cyanide, thiocianate, azide, pyridine and triphenylphosphine, in the presence of $AgBF_4$ or $NaBF_4$. In these complexes, the chlorine ligands are replaced by anionic ligands (cyanide, thiocianate, or azide) to yield the complexes *trans*-$[Pd(X)_2(bddo)]$ (X = CN^-, SCN^- and N_3^-). In these complexes, the bddo ligand shows bidentate coordination (*NN*).

When neutral ligand piridine reacts with the complex $[PdCl_2(bddo)]$, a mixture of $[Pd(bddo)(py)_2](BF_4)_2$ and $[Pd(bddo)](BF_4)_2$ complexes has been obtained. Only one complex, $[Pd(bddo)](BF_4)_2$, has been obtained when the neutral ligand is triphenylphosphine.

In summary, in these complexes, the presence of monodentate anionic ligands (CN^-, SCN^- or N_3^-) produces complexes in which the bddo ligand coordinates de Pd(II) centre in a *NN* mode. When monodentate neutral ligands (py or PPh_3) are used, the *NSSN* coor-

dination of the bddo ligand is favoured. ^{1}H NMR experiments have proven to be highly useful to determine the coordination mode of the bddo ligand in these complexes.

4. Experimental

4.1. General details

The reactions were carried out under nitrogen atmosphere using vacuum line and Schlenk techniques. All reagents were commercial grade materials and were used without further purification. Solvents were dried and distilled according to standard procedures and stored under nitrogen. Samples of $[PdCl_2(bddo)]$ were prepared as described in the literature [7a]. Elemental analyses (C, H, N, S) were carried out by the staff of Chemical Analyses Service of the Universitat Autònoma de Barcelona on a Carlo Erba CHNS EA-1108 instrument. Conductivity measurements were performed at room temperature (r.t.) in 10^{-3} M acetonitrile solution, employing a CyberScan CON 500 (Euthech instrument) conductimeter. Infrared spectra were run on a Perkin Elmer FT spectrophotometer, series 2000 cm^{-1} as KBr pellets or polyethylene films in the range 4000–250 cm^{-1}. ^{1}H, ^{13}C{^{1}H} NMR COSY and HSQC spectra were recorded on a NMR-FT Bruker AC-250 MHz spectrometer, $(CD_3)_2CO$ solution at 298 K. ^{1}H NMR and ^{13}C{^{1}H} NMR chemical shifts (δ) were determined relative to internal TMS and are given in ppm. Mass spectra were obtained with an Esquire 3000 ion-trap mass spectrometer from Bruker Daltonics.

4.2. Synthesis of the complexes

4.2.1. Synthesis of the complex $[Pd(CN)_2(bddo)]$ (**1**)

A solution of 0.21 mmol (0.040 g) of $AgBF_4$ in methanol (5 ml) was added dropwise, under vigorous stirring, to a solution of 0.10 mmol (0.050 g) of $[PdCl_2(bddo)]$ in 10 ml of CH_2Cl_2/CH_3CN (2:1). Afterwards, stirring was stopped, and AgCl was filtered off through a Celite pad. Then, a solution of 0.20 mmol (0.010 g) of NaCN dissolved in 5 ml of CH_3OH was added. The mixture was stirred for 12 h. Then, when the volume of the resultant solution was reduced to roughly 5 ml, the product precipitated as a yellow solid. This solid was filtered, washed with diethyl ether and dried under vacuum.

(Polyethylene, cm^{-1}): 440 ν(Pd–N), 412 ν(Pd–C). ^{1}H NMR ($(CD_3)_2CO$ solution, 250 Hz, 298 K) δ: 6.15 [2H, s, C*H*(pz)], 4.83 [4H, br, $N_{pz}CH_2$CH2S], 3.49 [4H, s, SCH_2CH_2S], 3.36 [4H, br, NpzCH_2CH_2S], 2.32 [6H, s, CH_3(pz)], 2.27 [6H, s, CH_3(pz)] ppm. ^{13}C{^{1}H} NMR ($(CD_3)_2CO$ solution, 63 MHz, 298 K) δ: 154.4 (pz-*C*), 143.8 (pz-*C*), 116.6 (*C*N), 105.0 (*C*H(pz)), 48.7 ($N_{pz}CH_2CH_2S$), 32.1 ($N_{pz}CH_2CH_2S$, SCH_2CH_2S), 13.6 (*C*H_3(pz)), 11.0 (*C*H_3(pz)) ppm.

4.2.2. Synthesis of the complex $[Pd(X)_2(bddo)]$ ($X = SCN^-$ (**2**), and N_3^- (**3**))

A solution of 0.40 mmol (0.032 g) of NaSCN or 0.40 mmol (0.026 g) of NaN_3 dissolved in 5 ml of CH_3OH was added to another solution of 0.19 mmol (0.100 g) of $[PdCl_2(bddo)]$ in 10 ml of CH_2Cl_2. In both cases, the colour changed from orange to red. Immediately after, 0.40 mmol (0.044 g) of $NaBF_4$ in methanol (5 ml) were added. The solutions were stirred for 12 h, and then, they were filtered through a pad of Celite. When the volumes of the resultant solutions were reduced to roughly 5 ml, the products precipitated as orange solids. These solids were filtered and dried under vacuum.

Compound ***2****:* Yield: 0.085 g (78%). ($C_{18}H_{26}N_6PdS_4$): Anal. Calc.: C, 38.53; H, 4.67; N, 14.98; S, 22.86. Found: C, 38.30; H, 4.50; N, 14.90; S, 23.05%. Coupling constants for complexes **2** and **3** were obtained with the aid of the *g* NMR program [16].

4.2.3. Reaction of $[PdCl_2(bddo)]$ with pyridine

A solution of 0.21 mmol (0.040 g) of $AgBF_4$ in methanol (5 ml) was added dropwise and with vigorous stirring to another solution of 0.10 mmol (0.053 g) of $[PdCl_2(bddo)]$ in a mixture of CH_2Cl_2/CH_3CN (2:1, 10 ml). After 5 minutes, stirring was stopped, and AgCl was filtered off through a Celite pad. Then, a solution of 0.23 mmol (0.018 g) of pyridine in dichloromethane (3 ml) was added. The solution was stirred for 12 h. When the volume of the resultant solution was reduced to roughly 5 ml, an orange solid precipitated. This solid was filtered and washed with diethyl ether, yielding a mixture of $[Pd(bddo)(py)_2](BF_4)_2$ [**4**]$(BF_4)_2$ and $[Pd(bddo)](BF_4)_2$. Isolation of the two complexes by silica gel chromatography (60 Å) or recrystallisation with different solvents was unsuccessful.

$[4](BF_4)_2$ + $[Pd(bddo)](BF_4)_2$: Yield: 0.052 g (68%) (78% [**4**]$(BF_4)_2$ + 22% [Pd(bddo)]$(BF_4)_2$). IR (KBr, cm^{-1}): 3077 ν(C–H)$_{ar}$, 2979, 2922 ν(C–H)$_{al}$, 1601 ((ν(C=C), ν(C=N))$_{py}$, 1546 (ν(C=C), ν(C=N))$_{pz}$, 1454, 1414 (δ(C=C), δ(C=N))$_{ar}$, 1066 ν(B–F), 765 (δ(C–H)$_{oop}$)$_{pz}$, 701 (δ(C–H)$_{oop}$)$_{py}$. (Polyethylene, cm^{-1}): 443, 419 ν(Pd–N). ^{1}H NMR ($(CD_3)_2CO$ solution, 250 Hz, 298 K) δ: **$[4](BF_4)_2$**, (78%): 8.87, 8.28, 7.83 [7.8H, m, Py], 6.18 [1.6H, s, C*H*(pz)], 4.55 [3.1H, m, $N_{pz}CH_2CH_2S$], 3.23 [3.1H, m, $N_{pz}CH_2CH_2S$], 3.11 [3.1H, s, S–CH_2–CH_2–S], 2.37 [4.7H, s, CH_3(pz)], 2.35 [4.7H, s, CH_3(pz)] ppm. **$[Pd(bddo)](BF_4)_2$**, (22%): 6.28 [0.4H, s, C*H*(pz)], 5.50, 5.19 [0.4H/0.4H, m, $N_{pz}CHHCH_2S$], 3.78, 3.72 [0.4H/0.4H, m, $N_{pz}CH_2CHHS$], 3.11 [0.9H, m, S–CH_2–CH_2–S], 2.52 [0.7H, s, CH_3(pz)], 1.99 [0.7H, s, CH_3(pz)] ppm. ^{13}C{^{1}H} NMR ($(CD_3)_2CO$ solution, 63 MHz, 298 K) δ: **$[4](BF_4)_2$**: 150.6 (pz-*C*), 141.4 (pz-*C*), 126.8 (Py), 107.0 (*C*H(pz)), 51.2 ($N_{pz}CH_2CH_2S$), 37.2 (SCH_2CH_2S), 33.8 ($N_{pz}CH_2CH_2S$), 14.5 (*C*H_3(pz)), 10.8 (*C*H_3(pz)) ppm. **$[Pd(bddo)](BF_4)_2$**: 152.1 (pz-*C*), 147.0 (pz-*C*), 108.9 (*C*H(pz)), 63.5 ($N_{pz}CH_2CH_2S$), 48.3 (SCH_2CH_2S), 31.4 ($N_{pz}CH_2CH_2S$), 13.2 (*C*H_3(pz)), 11.8 (*C*H_3(pz)) ppm.

Residual electron density (e Å^{-3})	0.306 and −0.640

*4.2.4. X-ray crystal structure for compound **2***

Suitable crystals for X-ray diffraction of compound **2** were obtained through crystallisation from acetonitrile-diethylether solution (1:1).

A prismatic crystal was selected and mounted on a MAR345 diffractometer with an image plate detector. Unit-cell parameters were determined from 2038 reflections (3° < θ < 31°) and refined by least-squares method. Intensities were collected with graphite monochromatized Mo Kα radiation. 30 651 reflections were measured in the range 2.63° ⩽ θ ⩽ 30.00°. About 7125 of which were non-equivalent by symmetry (R_{int} (on I) = 0.079). About 5885 reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Lorentz-polarization but no absorption corrections were made.

The structure was solved by Direct methods, using SHELXS97 computer program [21], and refined by full-matrix least-squares method with SHELXL97 computer program [22] using 30 651 reflections, (very negative intensities were not assumed). The function minimised was $\sum\omega||F_O|^2 - |F_C|^2|^2$, where $\omega = [\sigma^2(I) + (0.0414P)^2 + 0.0658P]^{-1}$ and $P = (|F_O|^2 + 2|F_C|^2)/3$. All H atoms were computed and refined, using a riding model, with an isotropic temperature factor equal to 1.2 times the equivalent temperature factor of the atom which are linked. The final $R(F)$ factor and $R_w(F^2)$ values as well as the number of parameters and other details concerning the refinement of the crystal structure are gathered in Table 2.

Supplementary data

CCDC 723189 contains the supplementary crystallographic data for complex **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Novel Ni(II), Zn(II), Co(II) and Cu(II) phthalocyanines with four peripheral 4-[methyleneoxy(18-crown-6)] groups have been synthesized via the cyclic tetramerization of 4-[{(18-crown-6)-yl}methyleneoxy]phthalonitrile and the corresponding metal salts ($NiCl_2$, $Zn(CH_3COO)_2$, $CoCl_2$ and $CuCl_2$). The thermal stabilities of the metal-free and metallophthalocyanine compounds were determined by thermogravimetric analysis. The structures of the target compounds were confirmed using elemental analysis, IR, ^{1}H-NMR, ^{13}C-NMR, UV–Vis and MS spectral data. Voltammetric and *in situ* spectroelectrochemical measurements show that while the cobalt phthalocyanine complex gives both metal-based and ring-based redox processes, the metal-free, nickel, zinc and copper phthalocyanines show only ring-based reduction and oxidation processes. An *in situ* electrocolorimetric method has been applied to investigate the color of the electro-generated anionic and cationic forms of the complexes.

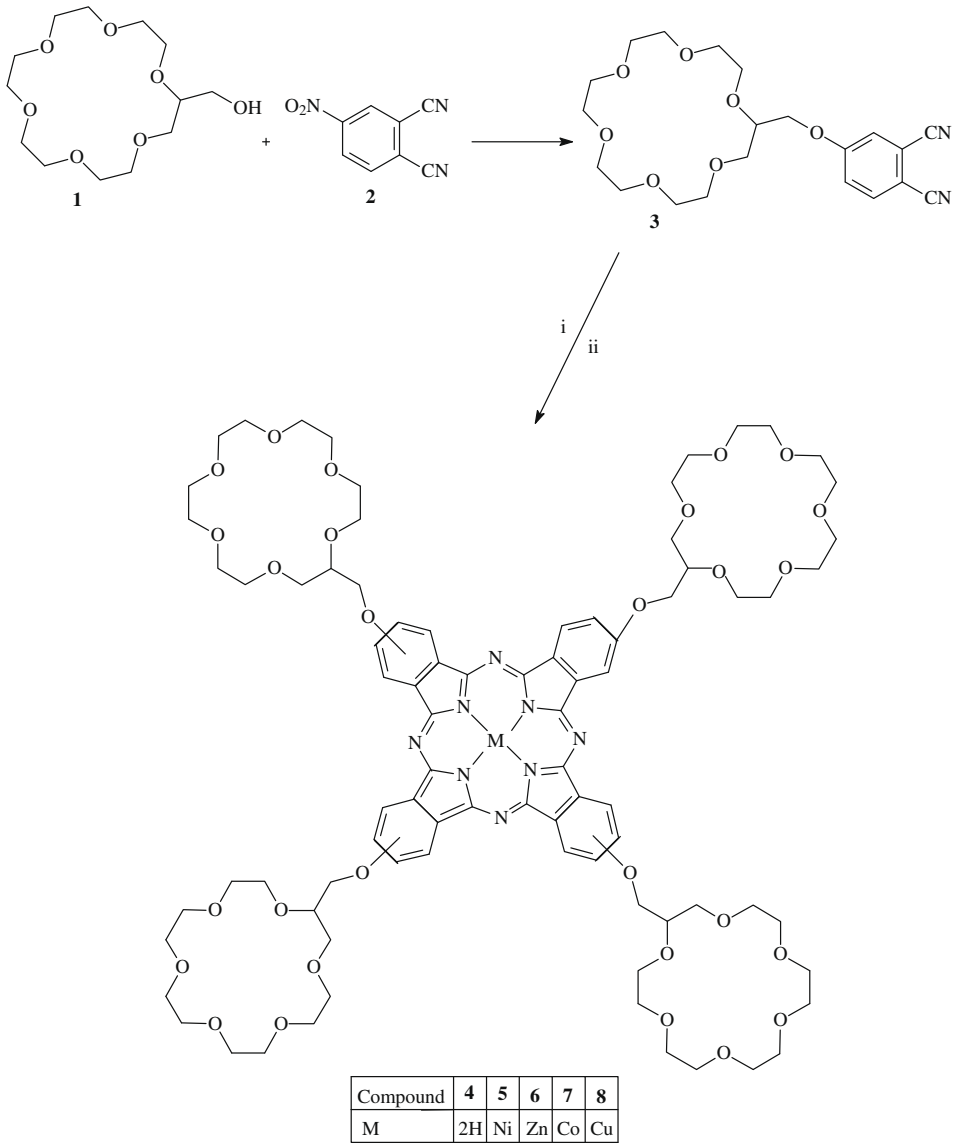
1. Introduction

The synthesis of metal-free and metallophthalocyanines has been an area of intense research activity for over 50 years [1–3]. In recent years, much effort has been dedicated to the synthesis and characterization of novel phthalocyanine derivatives having interesting electrical, optical, gas sensing and catalytic properties by making slight differences in peripheral substitution [4–7]. Remarkable progress has been made in the past decade in the use of phthalocyanine derivatives as sensitizers for photodynamic therapy of cancer [8–11]. The range of solubility of the phthalocyanines becomes very important for these applications, since many phthalocyanines are poorly soluble in organic solvents. The solubility of Pcs can be enhanced by adding different kinds of substituents, such as long chain alkyl, alkylthio or alkoxy groups at the periphery positions of the phthalocyanine ring [12–15].

Attachment of crown ether groups to the phthalocyanine ring significantly increases the solubility of phthalocyanines in many organic solvents, leading to significant advances in research such as biological modelling, homogeneous catalysis, alkaline or earth alkaline and lanthanide metal extractions [16,17].

Microwaves have been used previously for the synthesis of phthalocyanines and there is a wide range of references on the topic [18–23]. In this paper, we describe the synthesis and characterization of metal-free **4** and metallophthalocyanines **5**, **6**, **7** and **8**, containing four flexible 18-crown-6(1,4,7,10,13,16-hexaoxacyclooctadecane) moieties on the periphery through methyleneoxy bridges, by microwave irradiation. Also, we have investigated the voltammetric, *in situ* spectroelectrochemical and *in situ* electrocolorimetric responses of the metallophthalocyanines in solution to open a way to their possible electrochromic application, depending on the spectroelectrochemical and chromaticity data. It is well known that many phthalocyanine complexes show excellent electrochromic properties [24–26] both in solution and as films. Therefore, we report here the *in situ* electrocolorimetric analysis of the phthalocyanines to determine the possible electrochromic application of the complexes, because the electrocolorimetry technique provides a more precise way to define colour of the electro-generated species [27].



2. Results and discussion

2.1. Synthesis and characterizations

The synthesis of the new metal-free and metallophthalocyanines is shown in Scheme 1. The first step in the synthetic procedure was to obtain 4-[{(18-crown-6)yl}methyleneoxy] phthalonitrile (**3**). This reaction involves the nucleophilic aromatic nitro displacement of 4-nitrophthalonitrile with 2-hydroxymethyl(18-crown-6) (**1**) in the presence of K_2CO_3 as the base in dry dimethylformamide (DMF) at 50 °C [28]. Scheme 1. The synthesis of the metal-free phthalocyanine and metallophthalocyanines. (i) *n*-Pentanol, DBU. (ii) MW, 175 °C, 350 W and metal salts.

4-[{(18-crown-6)yl}methyleneoxy]phthalonitrile (**3**) into the metal-free phthalocyanine (**4**) was accomplished in *n*-pentanol in the presence of a few drops of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) as a strong base at reflux temperature under argon atmosphere. Cyclotetramerization of the dinitrile compound **3** in the presence of anhydrous metal salts [$NiCl_2$, $Zn(CH_3COO)_2$, $CoCl_2$ and $CuCl_2$] gave the desired metallophthalocyanines, **5**–**8** in 2-(dimethylamino)ethanol by microwave irradiation. Characterization of the products involved a combination of methods including FT-IR, ^{1}H NMR, elemental analysis, UV–Vis spectroscopy and mass spectroscopy.

In the IR spectra, the formation of compound **3** was clearly confirmed by the disappearance of the OH and NO_2 bands at 3338 and 1538–1355 cm^{-1} and the appearance of the C≡N band at 2229 cm^{-1}. In the ^{1}H NMR spectrum of **3**, the OH group of compound **1** disappeared, as expected. The ^{1}H NMR spectrum of **3** showed new signals at δ = 7.65 (d, 1H, Ar–H), 7.31 (s, 1H, Ar–H), 7.18 (d, 1H, Ar–H), belonging to aromatic protons. The ^{13}C NMR spectrum of **3** indicated the presence of nitrile carbon atoms in **3** at δ = 115.76 and 115.33 ppm. The mass spectrum of compound **3**, which shows a peak at m/z = 459 [M+K], supports the proposed formula for this compound.

After conversion of the dinitrile **3** to phthalocyanines **4**–**8**, the sharp C≡N vibration around 2229 cm^{-1} disappeared in the FT-IR spectra. The NH stretching absorption of the inner core of the metal-free phthalocyanine **4** was observed at 3285 cm^{-1}. The ^{1}H NMR spectrum of compound **4** indicates aromatic protons at δ 7.64, 7.27 and 7.17 ppm, and the aliphatic ether protons at δ 4.07–3.59 ppm. The NH protons of **4** could not be observed owing to the probable strong aggregation of the molecules [29]. The mass spectrum of **4** displayed the $[M]^+$ parent ion peak at m/z = 1683, which confirms the same structure. The IR spectra of metallophthalocyanines **5**–**8** are very similar. The ^{1}H-NMR spectra of complexes **5**–**6** showed almost identical chemical shifts. ^{1}H-NMR measurement of the cobalt(II) and copper(II) phthalocyanine **7**, **8** were precluded owing to their paramagnetic nature. In the mass spectra of the Ni, Zn, Co and Cu phthalocyanines, the presence of molecular ion peaks at m/z = 1741 $[M+H]^+$, 1786 $[M+K]^+$, 1740 $[M]^+$ and 1745 $[M]^+$, respectively, confirmed the proposed structures.

The thermal behaviour of the metal-free and metallophthalocyanines were investigated by thermogravimetric analysis/differential thermal analysis (TG/DTA). Although the thermal stabilities of phthalocyanines is well known, the phthalocyanine compounds are not stable above 340 °C. The initial decomposition temperature

Table 1
Thermal properties of the phthalocyanines.

Compound	M	Initial decom. temp. (°C)	Main decom. temp. (°C)
4	2H	379	409
5	Ni	376	399
6	Zn	388	419
7	Co	340	364
8	Cu	359	373

decreased in the order: **6** > **4** > **5** > **8** > **7** (Table 1). The DTA curves exhibited exothermic changes for all the phthalocyanines (**4**–**8**) in the region investigated [30].

The metal-free and metallophthalocyanines display typical electronic spectra with two strong absorption regions, one of them in the UV region at about 300–350 nm (B-band) and the other one in the visible region at 600–700 nm (Q-band) [31]. The electronic absorption spectra of the metal-free phthalocyanine (**4**), nickel(II) phthalocyanine (**5**), zinc(II) phthalocyanine (**6**) in chloroform at room temperature are shown in Fig. 1. In the UV–Vis spectrum of the metal-free derivative **4** (in $CHCl_3$) split Q-bands appeared at 707, 674 and 647 nm, while the B-bands remained at 365 and 300 nm. The UV–Vis spectra of the metallophthalocyanines **5**–**8** (in $CHCl_3$) exhibited an intense single Q-band absorption for $\pi \rightarrow \pi^*$ transitions around 677–692 nm and B-bands in the UV region around 293–383 nm [32,33].

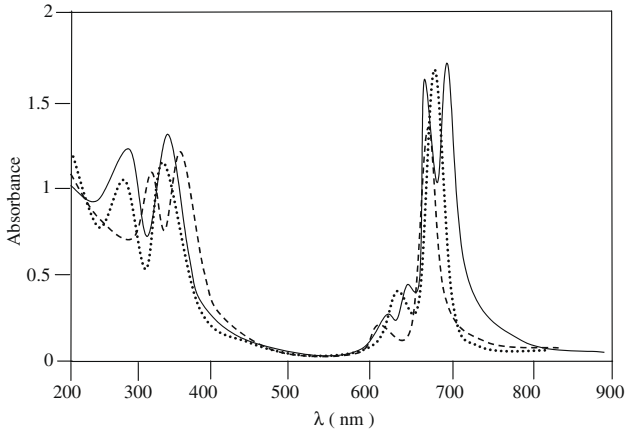

Fig. 1. UV–Vis spectra of compounds **4** (**––**), **5** (—) and **6** (···) in chloroform.

2.2. Electrochemical measurements

The solution redox properties of the complexes (**4**–**8**) were studied using cyclic voltammetry (CV) and square wave voltammetry (SWV) measurements in dichloromethane (DCM), containing 0.10 mol dm^{-3} tetrabutylammonium perchlorate (TBAP) on a Pt electrode. Table 2 lists the assignments of the redox couples, half-wave peak potentials ($E_{1/2}$) and the difference between the first oxidation and reduction processes ($\Delta E_{1/2}$). $\Delta E_{1/2}$ reflects the HOMO–LUMO gap for metal free Pcs and it is related to the HOMO–LUMO gap in MPc species. The $E_{1/2}$ values are shifted to more negative potentials when compared with the reported data for redox processes in other metallophthalocyanine complexes [31,34–42].

H_2Pc (**4**), NiPc (**5**), ZnPc (**6**) and CuPc (**8**) give very similar voltammetric responses with small potential shifts due to the different metal centers. Based on the well-known electrochemical behavior of phthalocyanine complexes, all the couples of these complexes are assigned to the phthalocyanine ring. The nature of the redox couples was also confirmed below using spectroelectrochemistry measurements. Figs. 2 and 3 illustrate the CVs of **5** and **6** as representative for MPcs having redox inactive metal centers. Both complexes give three reduction and two oxidation couples within the potential window of the DCM/TBAP electrolyte system. All complexes show an aggregation tendency in solution, so the redox couples are split into two waves due to electron transfer of aggregated and monomeric species. Diluting solutions of the complexes causes peak current of the waves assigned to the aggregated species to decrease more than that of the monomeric species, supporting existence of the aggregation-disaggregation equilibrium.

Table 2
Voltammetric data of the complexes with the related metallophthalocyanines for comparison.

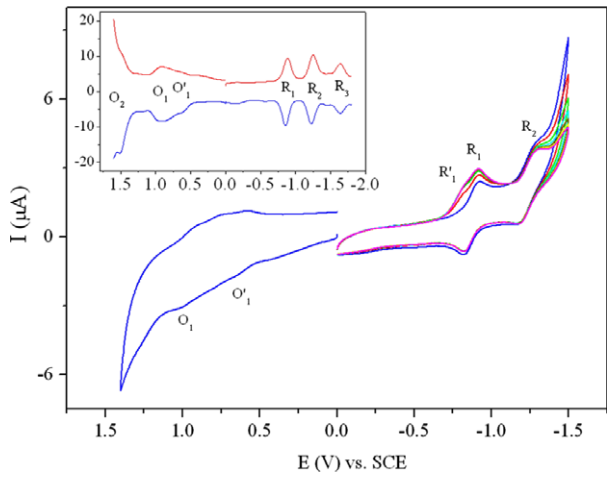

Fig. 2. Repetetive CVs of **5** recorded at 0.100 mV s^{-1} scan rate on Pt in DCM/TBAP (inset: SWVs of **5**. SWV parameters: pulse size = 100 mV; frequency:25 Hz).

Redox couples and splitting of them are illustrated by SWV scans. Switching potentials do not affect the peak character of the complex considerably. However, repetitive CV cycles affect the aggregation–disaggregation equilibriums of the complexes. In case of **6**, second split wave of the first reduction process (R′1) increases in current with repetitive CV cycles, indicating monomerization of the aggregated species under potential cycling. However, aggregation of **5** increases with repetitive CV cycles, since R′1 increases with continuous CV cycles. Aggregations of the complexes are also observed with the UV–Vis spectra during *in situ* spectroelectrochemical measurements, even at much diluted solutions, as given below.

Fig. 4 shows the CV and SWV of CoPc (**7**). Within the electrochemical window of TBAP/DCM in the CV measurements, **7** undergoes one oxidation and three reduction processes. CV and SWV analysis show that **7** also has an aggregation-disaggregation equilibria in solution, thus the redox couples split into two waves due to electron transfer of the aggregated and monomeric species. Assignments of the redox couple are confirmed by spectroelectrochemical measurements, which are given below.

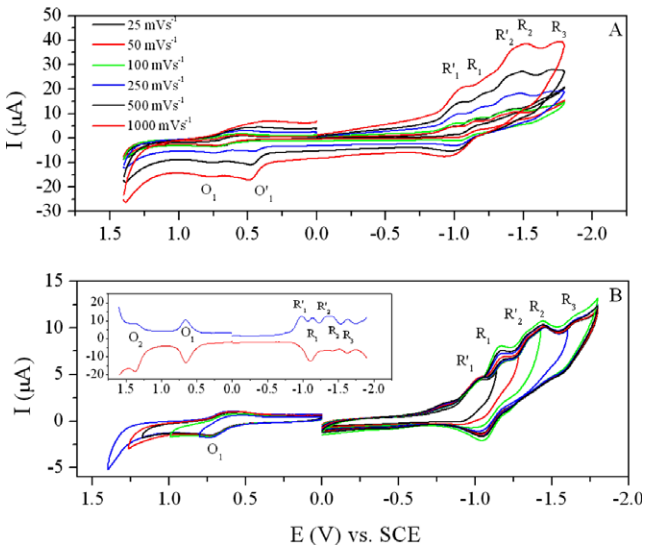

Fig. 3. (A) CVs of **6** recorded at different scan rates on Pt in DCM/TBAP. (B) CVs of **6** recorded with different switching potentials at 0.100 mV s^{-1} scan rate (inset: SWVs of **6**. SWV parameters: pulse size = 100 mV; frequency:25 Hz).

2.3. Spectroelectrochemical studies

Spectroelectrochemical studies were employed to confirm the assignments in the CVs of the complexes. The complexes **4**–**6** and **8** all have redox inactive metal centers, therefore, the *in situ* UV–Vis spectral changes indicated ligand-based characters of all the redox couples of **4**–**6** and **8**. The UV–Vis spectral chances of NiPc (**5**) are given in Fig. 5 as a representative of a MPc having a redox inactive metal center. During controlled potential reductions of **5** at −1.00 V potential application, intensity of the Q-band at 672 nm decreases without shift, while two new bands at 580 and 936 nm (charge transfer region) are recorded. At the same time, the B2-band at 374 nm increases in intensity. Observation of a band at 630 nm before and after this process indicates the presence of the aggregated species. This process gives clear isosbestic points at 335, 387, 610 and 728 nm in the spectra. These spectroscopic changes are characteristic of Pc ring reduction and confirm the CV assignment of the couple to the $[Ni^{II}Pc^{-2}]/[Ni^{II}Pc^{-3}]^{-1}$ process (Fig. 5A) [43–45]. Spectroscopic changes during controlled potential application at −1.50 V support further reduction of the monoanionic species, $[Ni^{II}Pc^{-3}]^{-1}$, to $[Ni^{II}Pc^{-4}]^{-2}$ (Fig. 5B). Decrease of the Q-band intensity without shift and observation of new bands in the charge transfer region at 490, 793 and 877 nm are characteristic of a ring reduction process. During oxidation of **5** (Fig. 5C), absorption of the Q-band decreases in intensity without shift, while new bands between 450 and 550 nm and at 748 nm appear with an increase in intensity. Clear isosbestic points were recorded at 375, 588 and 708 nm in the spectra. These changes are typical of ring-based oxidation and are assigned to the $[Ni^{II}Pc^{-2}]/[Ni^{II}Pc^{-1}]^{+1}$ processes [43–45].

The color change of the complexes during the redox processes were recorded using *in situ* colorimetric measurements. Fig. 5D gives the chromaticity diagrams of the complex **5** recorded simultaneously during the spectroelectrochemical measurements. Without any potential application, the solution of **5** is greenish blue ($x = 0.277$ and $y = 0.336$). As the potential is stepped from 0 to −1.00 V, color of the neutral **5**, $[Ni^{II}Pc^{-2}]$, starts to change and light blue color ($x = 0.268$ and $y = 0.298$) of the monoanionic form of **5**, $[Ni^{II}Pc^{-3}]^{-1}$, was obtained at the end of the first reduction. Similarly color of the dianionic species, $[Ni^{II}Pc^{-4}]^{-2}$, was recorded as light purple ($x = 0.318$ and $y = 0.316$). The monocationic species $[Ni^{II}Pc^{-1}]^{+1}$ has a reddish blue color ($x = 0.343$ and $y = 0.350$). Measurement of the *xyz* coordinates allows quantification of each color of the redox species, which is very important to decide their possible electrochromic application.

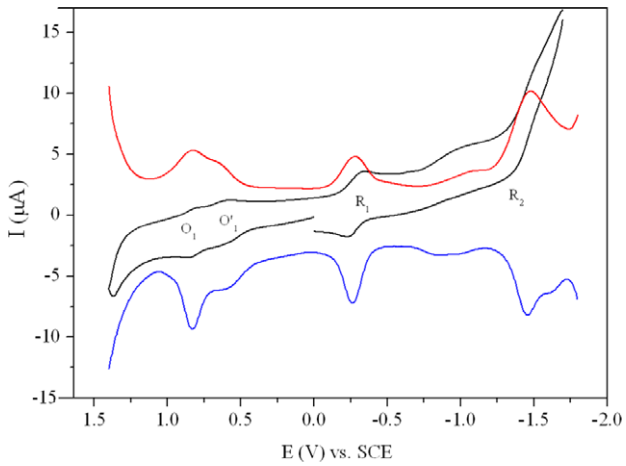

Fig. 4. CVs of **7** recorded at 0.100 mV s^{-1} scan rate on Pt in DCM/TBAP (inset: SWVs of **7**. SWV parameters: pulse size = 100 mV; frequency:25 Hz).

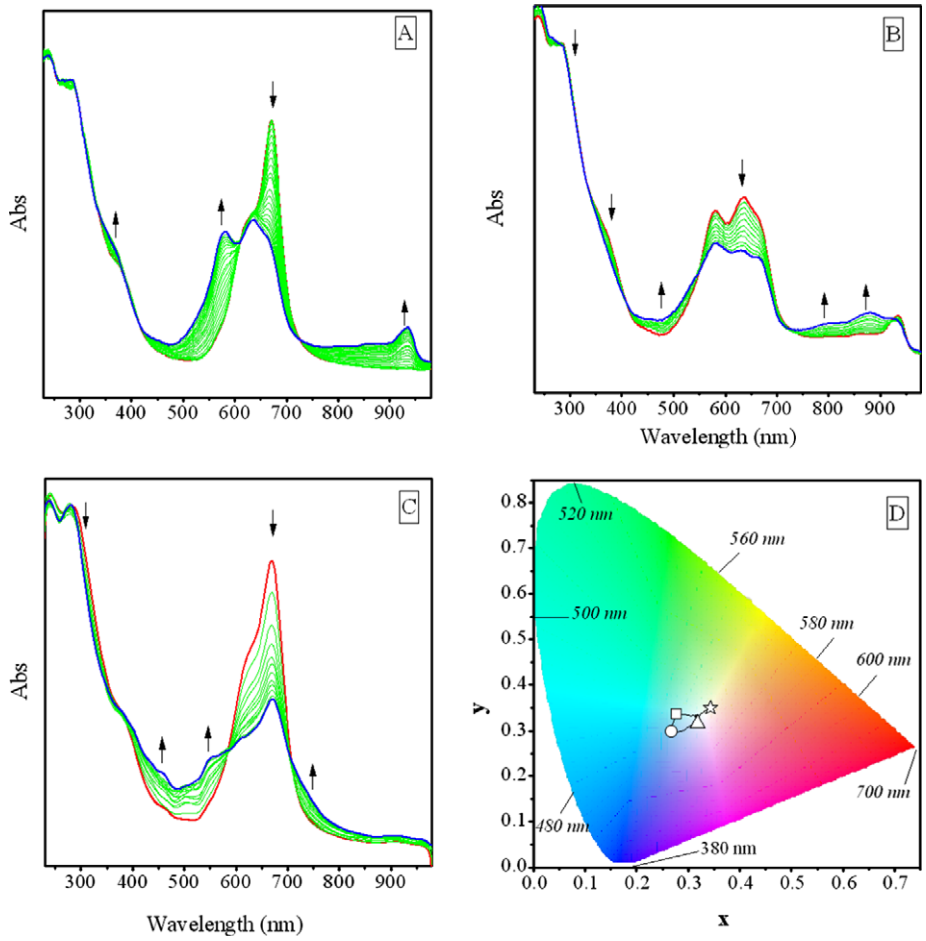

Fig. 5. *In situ* UV–Vis spectral changes of **5**. (A) E_{app} = −0.70 V. (B) E_{app} = −1.50 V. (C) E_{app} = 1.10 V. (D) Chromaticity diagram of **5** (each symbol represents the color of electrogenerated species; □ : neutral **5**, $Ni^{II}Pc^{-2}$, ○ : $Ni^{II}Pc^{-3}$, △: $Ni^{II}Pc^{-4}$, ☆ : $Ni^{II}Pc^{-}$).

Fig. 6 represents the *in situ* UV–Vis spectral changes and *in situ* recorded chromaticity diagram of CoPc (**7**) in DCM/TBAP during potential application at potentials of the redox processes. Shifting of the Q-band from 675 to 706 nm and observation of a new band at 450 nm indicate metal center reduction of **7** at −0.55 V potential application (Fig. 6A). At the same time, the B-band shifts from 297 to 307 nm with an increase in intensity. This process resulted in clear isosbestic points at 325, 388, 564 and 690 nm in the spectra. A color change from greenish blue (x = 0.254 and y = 0.340) to yellow (x = 0.382 and y = 0.433) was recorded, as shown in the chromaticity diagram (Fig. 6D). These spectroscopic data confirm our earlier assignment of the first reduction couple to $[Co^{II}Pc^{-2}]/[Co^{I}Pc^{-2}]^{1-}$. Further reduction of $[Co^{I}Pc^{-2}]^{1-}$ at −1.20 V indicates a ligand-based redox process, because the Q-band at 706 nm decreases without shift while a new broad band is recorded at 540 nm. At the same time, the B-band decreases in intensity while the band at 450 nm decreases slightly in intensity with red shifting (Fig. 6B). Clear isosbestic points were observed at 345, 400, 613 and 764 nm in the spectra. A color change from yellow to orange (x = 0.397 and y = 0.373) was recorded (Fig. 6D). These changes confirm our earlier assignment of a second reduction couple to $[Co^{I}Pc^{-2}]^{1-}/[Co^{I}Pc^{-3}]^{2-}$. Fig. 5C represents the spectral changes during the oxidation process of the complex. During 0.95 V potential application, a decrease of the Q-band at 675 nm without shift and observation of new bands at 528 and 760 nm indicate a ligand-based process and it is assigned to $[Co^{II}Pc^{-2}]/[Co^{II}Pc^{-1}]^{1+}$ [46–50]. A greenish blue color changes to light red (x = 0 .355 and y = 0.343) occurs during the oxidation process.

3. Experimental

2-Hydroxymethyl(18-crown-6) (**1**) and 4-nitrophthalonitrile (**2**) were prepared according to the reported procedures [51,52]. All reagents and solvents were of reagent grade quality and were obtained from commercial suppliers. All solvents were dried and purified as described by Perrin et al. [53]. The IR spectra were recorded on a Perkin–Elmer 1600 FT-IR Spectrophotometer, using KBr pellets or NaCl discs. ^{1}H and ^{13}C NMR spectra were recorded on a Varian Mercury 200 MHz spectrometer in $CDCl_3$, chemical shifts were reported (δ) relative to Me_4Si as an internal standard. Mass spectra were measured on a Micromass Quatro LC/ULTIMA LC-MS/MS spectrometer. The elemental analyses were performed on a Costech ECS 4010 instrument. A Seiko II Exstar 6000 thermal analyzer was used to record the DTA curves under a nitrogen atmosphere with a heating rate of 20 °C min^{-1} in the temperature range 30–900 °C using platinum crucibles. Melting points were measured on an electrothermal apparatus and are uncorrected. Optical spectra in the UV–Vis region were recorded with a Unicam UV2-100 spectrophotometer, using 1 cm pathlength cuvettes at room temperature.

3.1. Synthesis of 4-[{(18-crown-6)-yl)methyleneoxy]phthalonitrile (3)

2-Hydroxymethyl-18-crown-6 (**1**) (2.5 g, 8.49 mmol) was dissolved in anhydrous DMF (25 ml) under N_2 atmosphere, and 4-nitrophthalonitrile (**2**) (1.46 g, 8.49 mmol) was added to the solution. After stirring for 10 min, finely ground anhydrous K_2CO_3

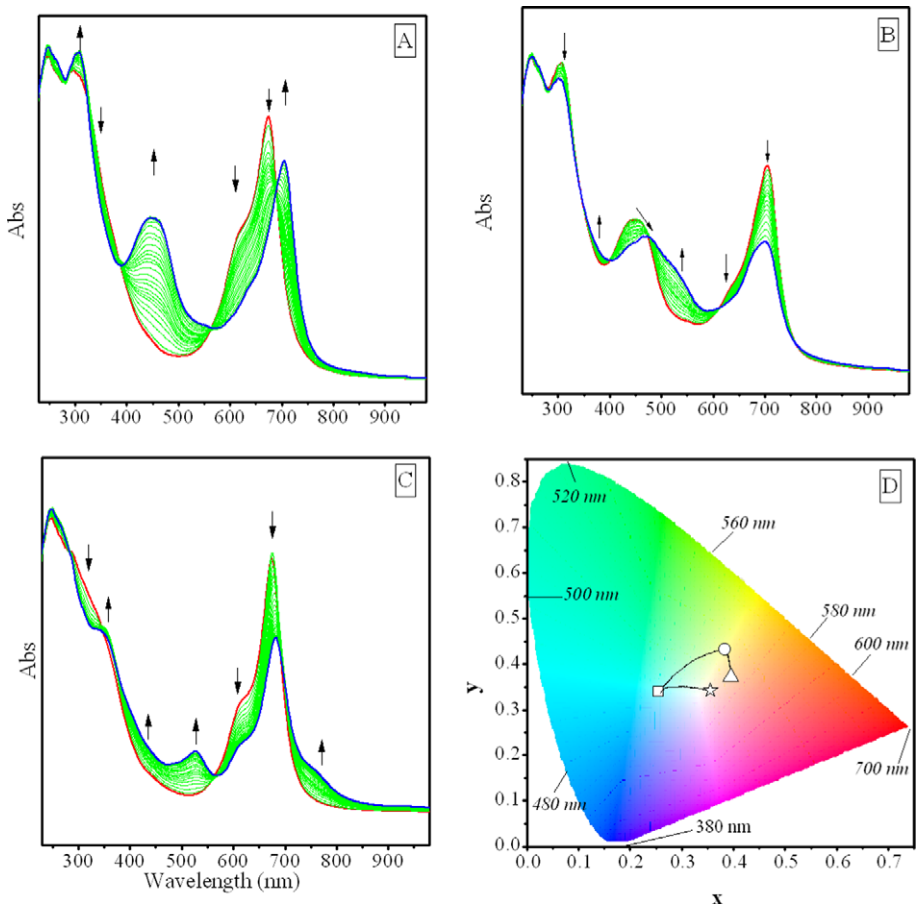

Fig. 6. *In situ* UV–Vis spectral changes of **7**. (A) E_{app} = −0.70 V. (B) E_{app} = −1.25 V. (C) E_{app} = 1.10 V. (D) Chromaticity diagram of **7** (each symbol represents the color of electrogenerated species; □ : neutral **7**, $Co^{II}Pc^{-2}$, ○ : $Co^{I}Pc^{-2}$, △ $Co^{I}Pc^{-3}$, ☆ : $Co^{II}Pc^{-}$).

(3.51 g, 25.47 mmol) was added portion-wise over 2 h, with efficient stirring. The reaction mixture was stirred under N_2 at 50 °C for 3 days. Then the solution was poured into ice-water (100 ml) and the aqueous phase was extracted with chloroform (3× 40 ml). The combined extracts were dried over anhydrous sodium sulfate. Purification of the product was accomplished by column chromatography with silica gel (eluent chloroform). 1.50 g (42%). *Anal.* Calc. for $C_{21}H_{28}N_2O_7$: C, 59.99; H, 6.71; N, 6.66. Found: C, 59.93; H, 6.74; N, 6.62%. IR (KBr tablet), ν_{max}/cm^{-1}: 3071 (Ar–H), 2923–2851 (Aliph. C–H), 2229 (C≡N), 1597, 1562, 1491, 1464, 1350, 1320, 1254, 1115, 1028, 951, 840, 525. ^{1}H NMR. ($CDCl_3$), (δ: ppm): 7.65 (d, 1H, Ar–H), 7.31 (s, 1H, Ar–H), 7.18 (d, 1H, Ar–H), 4.21 (d, 2H, CH–CH_2–O), 3.94–3.56 (m, 23H, CH_2–O). ^{13}C NMR. ($CDCl_3$), (δ: ppm): 162.11, 135.10, 119.86, 119.75, 117.21, 115.76, 115.33, 107.09, 76.41, 71.20, 70.86, 70.67, 70.49, 70.08, 69.79, 69.23. MS (ES^+), (m/z): 459 $[M+K]^+$.

3.2. Metal-free phthalocyanine (**4**)

A mixture of 4-[{(18-crown-6)-yl}methyleneoxy]phthalonitrile (**3**) (0.25 g, 0.59 mmol) and 0.59 mmol of 1.8-diazabicyclo[5.4.0]undec-7-ene (DBU) (0.4 ml) in 2.5 ml of dry n-pentanol was heated and stirred at 160 °C for 24 h under N_2. After the reaction mixture was cooled and decanted, the remaining dark green solid was dissolved in ethanol (20 ml) and precipitated by adding diethyl ether. The precipitated green solid product was filtered off, and then dried. The obtained green solid product was purified by aluminium oxide column chromatography, using only chloroform as the solvent system. Yield: 97 mg (39%). *Anal.* Calc. for $C_{84}H_{114}N_8O_{28}$: C, 59.93; H, 6.82; N, 6.65. Found: C, 59.98; H, 6.84; N, 6.69%. IR (KBr tablet) ν_{max}/cm^{-1}: 3285 (N–H), 3065 (Ar–H), 2924–2862 (Aliph. C–H), 1643, 1602, 1520, 1487, 1352, 1287, 1242, 1110, 835, 749. ^{1}H NMR. ($CDCl_3$), (δ: ppm): 7.64 (d, 4H, Ar–H), 7.27 (s, 4H, Ar–H), 7.17 (m, 4H, Ar–H), 4.07-3.59 (m, 100H, CH_2–O). UV–Vis (chloroform): λ_{max}/nm: [(10^{-5} ε dm^3 mol^{-1} cm^{-1})]: 300 (5.08), 365 (5.12), 614 (4.51), 647 (4.65), 674 (5.20), 707 (5.23). MS (ES^+), (m/z): 1683 $[M]^+$.

3.3. Nickel(II) phthalocyanine (**5**)

A mixture of 4-[{(18-crown-6)-yl}methyleneoxy]phthalonitrile (**3**) (0.25 g, 0.59 mmol), anhydrous $NiCl_2$ (19 mg, 0.15 mmol) and 2-(dimethylamino)ethanol (2.5 ml) was irradiated in a microwave oven at 175 °C, 350 W for 8 min. After cooling to room temperature the reaction mixture refluxed with ethanol to precipitate the product, which was filtered off. The green solid product was washed with hot ethanol, water, diethyl ether and dried *in vacuo*. The obtained green solid product was purified by aluminium oxide column chromatography, using only chloroform:methanol (100:2) as the solvent system. Yield: 123 mg (48%). *Anal.* Calc. for $C_{84}H_{112}N_8O_{28}Ni$: C, 57.97; H, 6.49; N, 6.44. Found: C, 57.61; H, 6.89; N, 7.01%. IR (KBr tablet) ν_{max}/cm^{-1}: 3060 (Ar–H), 2901-2875 (Aliph. C–H), 1610, 1468, 1351, 1284, 1246, 1103, 954, 834, 745. ^{1}H NMR. ($CDCl_3$), (δ:ppm): 7.70 (m, 4H, Ar–H), 7.28 (s, 4H, Ar–H), 7.21 (m, 4H, Ar–H), 4.15–3.66 (m, 100H, CH_2–O). UV–Vis (chloroform): λ_{max}/nm: [(10^{-5} ε dm^3 mol^{-1} cm^{-1})]: 332 (5.42), 383 (5.07), 608 (4.47), 677 (5.12). MS (ES^+), (m/z): 1741 $[M+H]^+$.

3.4. Zinc(II) phthalocyanine (**6**)

The same procedure as above was adopted by using compound **3** (0.25 g, 0.59 mmol), anhydrous $Zn(CH_3COO)_2$ (27 mg, 0.15 mmol) and 2-(dimethylamino)ethanol (2.5 ml). The obtained green solid product was purified by aluminium oxide column chromatography, using only chloroform:methanol (100:2) as the solvent system. Yield: 139 mg (54%). *Anal.* Calc. for $C_{84}H_{112}N_8O_{28}Zn$: C, 57.74; H, 6.46; N, 6.41. Found: C, 57.60; H, 6.71; N, 6.50%. IR (KBr tablet) ν_{max}/cm^{-1}: 3065 (Ar–H), 2910–2880 (Aliph. C–H), 1605, 1488, 1394, 1351, 1287, 1247, 1104, 956, 834, 748. ^1H NMR. ($CDCl_3$), (δ: ppm): ^1H NMR. ($CDCl_3$), (δ: ppm): 7.54 (d, 4H, Ar–H), 7.14 (s, 4H, Ar–H), 6.98 (m, 4H, Ar–H), 4.01–3.45 (m, 100H, CH_2–O). UV–Vis (chloroform): λ_{max}/nm: [(10^{-5} ε dm^3 mol^{-1} cm^{-1})]: 293 (5.06), 356 (5.07), 620 (4.62), 686 (5.21). MS (ES^+), (m/z): 1786 $[M+K]^+$.

3.5. Cobalt(II) phthalocyanine (**7**)

The same procedure as above was adopted by using compound **3** (0.25 g, 0.59 mmol), anhydrous $CoCl_2$ (19 mg, 0.15 mmol) and 2-(dimethylamino)ethanol (2.5 ml). The obtained green solid product was purified by aluminium oxide column chromatography, using only chloroform:methanol (100:2) as the solvent system. Yield: 159 mg (61%). *Anal.* Calc. for $C_{84}H_{112}N_8O_{28}Co$: C, 57.96; H, 6.49; N, 6.44. Found: C, 57.74; H, 6.79; N, 6.56%. IR (KBr tablet) ν_{max}/cm^{-1}: 3021 (Ar–H), 2905–2868 (Aliph. C–H), 1608, 1470, 1351, 1286, 1246, 1102, 956, 833, 752. UV–Vis (chloroform): λ_{max}/nm: [(10^{-5} ε dm^3 mol^{-1} cm^{-1})]: 347 (5.11), 368 (5.13), 617 (4.71), 692 (5.19). MS (ES^+), (m/z): 1740 $[M]^+$.

3.6. Copper(II) phthalocyanine (**8**)

The same procedure as above was adopted by using compound **3** (0.25 g, 0.59 mmol), anhydrous $CuCl_2$ (15 mg, 0.15 mmol) and 2-(dimethylamino)ethanol (2.5 ml). The obtained green solid product was purified by aluminium oxide column chromatography, using only chloroform:methanol (100:2) as the solvent system. Yield: 143 mg (55%). *Anal.* Calc. for $C_{84}H_{112}N_8O_{28}Cu$: C, 57.80; H, 6.47; N, 6.42. Found: C, 57.98; H, 6.83; N, 6.60%. IR (KBr tablet) ν_{max}/cm^{-1}: 3010 (Ar–H), 2900–2873 (Aliph. C–H), 1598, 1486, 1454, 1351, 1288, 1189, 1104, 955, 833. UV–Vis (chloroform): λ_{max}/nm: [(10^{-5} ε dm^3 mol^{-1} cm^{-1})]: 322 (5.03), 360 (5.05), 620 (4.62), 689 (5.08). MS (ES^+), (m/z): 1745 $[M]^+$.

3.7. Electrochemical, in situ spectroelectrochemical and in situ electrocolorimetric measurements

The electrochemical and spectroelectrochemical measurements were carried out with a Gamry Reference 600 potentiostat/galvanostat controlled by an external PC and utilizing a three-electrode configuration at 25 °C. For CV and SWV measurements, the working electrode was a Pt disc with a surface area of 0.071 cm^2. The surface of the working electrode was polished with a diamond suspension before each run. A Pt wire served as the counter electrode. A saturated calomel electrode (SCE) was employed as the reference electrode and separated from the bulk of the solution by a double bridge. Ferrocene was used as an internal reference. TBAP in DCM was employed as the supporting electrolyte at a concentration of 0.10 mol dm^{-3}. High purity N_2 was used to remove dissolved O_2 for at least 15 min prior to each run and to maintain a nitrogen blanket during the measurements. IR compensation was applied to the CV and SWV scans to minimize the potential control error.

UV–Vis absorption spectra and chromaticity diagrams were measured by an OceanOptics QE65000 diode array spectrophotometer. *In situ* spectroelectrochemical measurements were carried out by utilizing a three-electrode configuration of a thin-layer quartz spectroelectrochemical cell at 25 °C. The working electrode was Pt tulle. A Pt wire counter electrode separated by a glass bridge and a SCE reference electrode separated from the bulk of the solution by a double bridge were used.

In situ electrocolorimetric measurements, under potentiostatic control, were obtained using an OceanOptics QE65000 diode array spectrophotometer with a color measurement mode by utilizing a three-electrode configuration of a thin-layer quartz spectroelectrochemical cell. The standard illuminant A with 2° observer at constant temperature in a light booth designed to exclude external light was used. Prior to each set of measurements, background color coordinates (x, y and z values) were taken at open-circuit, using the electrolyte solution without MPc under study. During the measurements, readings were taken as a function of time under kinetic control, however only the color coordinates at the beginning and end of each redox processes were reported.

4. Conclusion

In this work, we describe the synthetic procedure and characterization of new soluble metal-free and metallophthalocyanines substituted with four flexible 18-crown-6 ether groups through methyleneoxy bridges. Also, the thermal properties of the phthalocyanines were examined by thermogravimetric analysis. Through the introduction of crown ether groups into peripheral positions of phthalocyanines, the solubility in organic solvents increased. A good solubility of phthalocyanine in organic solvents is becoming more important for technological materials. Voltammetric and spectroelectrochemical studies show that while metal free, zinc, copper and nickel phthalocyanine complexes give ligand-based, redox processes, the cobalt phthalocyanine complex gives both metal and ligand-based redox processes. Definite determination of the colors of the electro-generated anionic and cationic form of the complexes is important to decide any possible electrochromic application of the complexes. Electrochromic applications of the complexes are under investigation.

ABSTRACT

The europium complex with pyridine-2,6-dicarboxylic acid forms three-dimensional polymers in the solid state. The crystal structure of this assembly shows that europium cation is nine-coordinated and the first coordination sphere contains four water molecules. Mono(dipicolinate) structural units are interconnected by bridging carboxylate oxygens to provide a compact supramolecular structure with a high density.

1. Introduction

The Ln(III) complexes with organic ligands containing carboxylic groups are of durable interest for their usually high thermodynamic stability and peculiar magnetic and luminescent properties. Pyridine-2,6-dicarboxylic acid (dipicolinic acid, H_2DPA) is one of suitable polydentate ligands and three dipicolinate are necessary for an efficient Ln(III) coordination (coordination number 9). These $[Ln(DPA)_3]^{3-}$ complexes have been extensively studied by X-ray crystallography at the beginning of the eighties [1]. The crystal structures of tris(dipicolinato)lanthanide complexes reveal the formation of triclinic phases for Ce–Dy and hexagonal, monoclinic, and orthorhombic phases for Ho–Lu [1,2], where discrete mononuclear anionic complexes $[Ln(DPA)_3]^{3-}$ are arranged in columns and interconnected by H-bonds. The solid state structure of tris(dipicolinato)lanthanide complexes was also studied with the intention of preparing mixed lanthanide/transition metal oxides by thermal decomposition [3–5]. These complexes with saturated coordination sphere exhibit interesting luminescent properties [6,7], which can be further tuned by introducing suitable substituents on the pyridine ring [8]. In solution, the stability constants of $[Ln(DPA)_3]^{3-}$ complexes determined by potentiometry reach relatively high values ($\log \beta_{13}$ = 19–22, Ln = La–Lu) [9]. Due to a high symmetry (D_3), tris(dipicolinato)lanthanide complexes were extensively used for development of paramagnetic NMR tools for structural analysis (lanthanide shift reagents) [10–13].

In addition to $[Ln(DPA)_3]^{3-}$ complexes described above, several reports deal with unsaturated Ln(III) complexes containing two dipicolinate anions bound to the same lanthanide cation. Bis(dipicolinato)lanthanide complexes $[Ln(HDPA)(DPA)(H_2O)_2]$ were prepared systematically (Ln = La–Yb) [4,14–16], or as side products (Eu) [5]. These neutral complexes crystallise in monoclinic phases and adopt a polymeric structure, where one $Hdipic^-$ ligand is coordinated only to one metal, while the second DPA^{2-} also participates on the coordination of neighbouring metal ions through bridging carboxylate oxygens.

$Ln_2(DPA)_3$ complexes represent an intermediate structure between bis and mono(dipicolinate) complexes. While the first Ln(III) cation is coordinated by two DPA molecules forming an anionic complex, the second Ln(III) cation is coordinated by only one DPA (cationic complex). Both complexes are interconnected by carboxylate bridges to form 3D microporous coordination polymers [17].

Mono(dipicolinate) complexes $[Ln(DPA)]^+$ were characterised in solution by their stability constants [9] and by NMR [13]. However, to the best of our knowledge, no crystal structure of mono(dipicolinate) lanthanide complexes was reported. Only recently, lanthanide selenite–DPA compounds forming two-dimensional clusters were characterised by crystallography [18]. In this contribution we report on the crystal structure of europium mono(dipicolinate) complex. This unprecedented polymeric structure completes the series of Ln(III) complexes with dipicolinic acid summarised above and illustrates a high versatility of Ln(III)–DPA complexes.

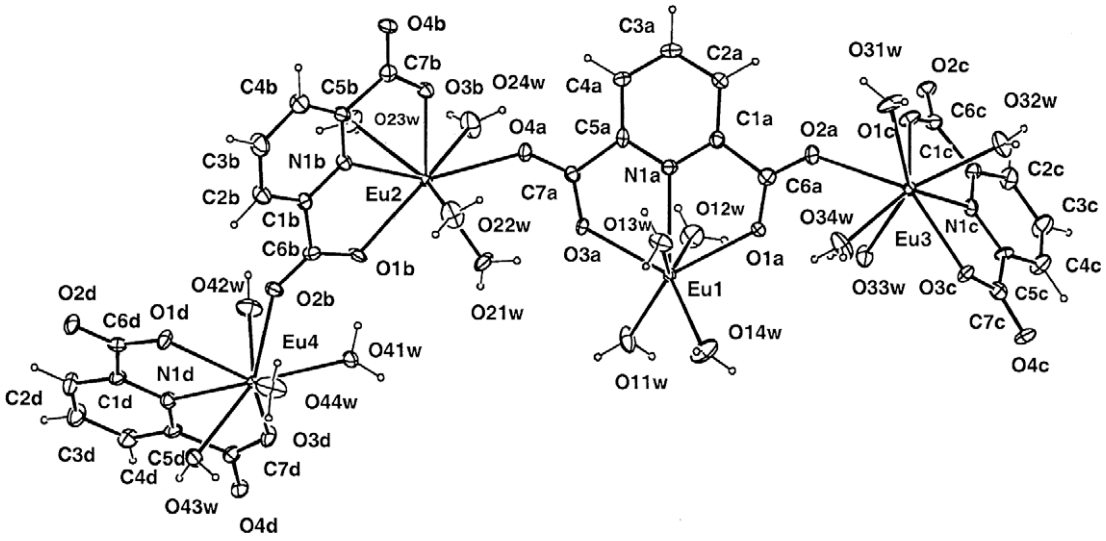

Fig. 1. The asymmetric unit of the $\{[Eu(C_7H_3NO_4)(H_2O)_4]_4(ClO_4)_4\}_\infty$ (**1**) polymer with the atom numbering.

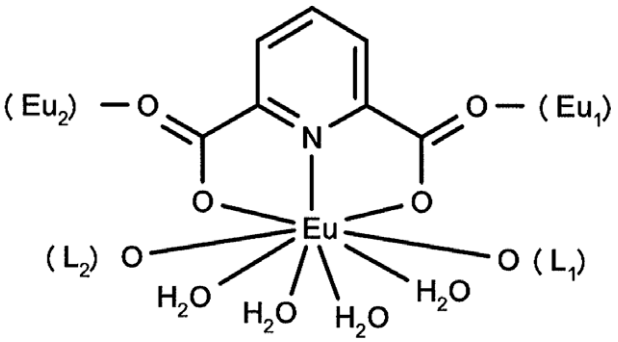
2. Experimental

2,6-Dipicolinic acid (p.a.) was purchased from Acros Organics. The europium and lanthanum perchlorate salts were prepared from the corresponding oxides (Rhodia, 99.99%) according to literature procedures [19]. Ln(III) content of solid salts was determined by complexometric titrations with Titriplex III (Merck) in the presence of urotropine and xylene orange.



2.1. X-ray crystal data of $\{[Eu(C_7H_3NO_4)(H_2O)_4]_4(ClO_4)_4\}_\infty$ (*1*)

Dipicolinic acid ($\sim 10^{-2}$ M) was dissolved in water and 1 eq of $Eu(ClO_4)_3$ was added. The X-ray quality transparent crystals were obtained by slow evaporation at room temperature. The raw data were collected at 200 K on a Stoe IPDS diffractometer with graphite monochromated Mo [Kα] radiation ($\lambda = 0.7107$ Å). The structure was solved by direct methods (SIR97) [20]. All other calculations were performed with XTAL [21] programme package. The crystallographic data and the details of structural refinements are the following: $M = 1954.4$, crystal system trigonal, space group $R\bar{3}$, $a = 28.7051(11)$ (Å), $c = 35.1997(17)$ (Å), $V = 25\,118(2)$ (Å^3), $D_c = 2.325$ g cm^{-1}, $\mu = 4.75$ mm^{-1}, $Z = 18$, $T = 150$ K, 82 855 collected reflections, 10 933 independent reflections ($R_{int} = 0.045$) and 7702 observed reflections [$F_0 > 4\sigma(F_0)$], 840 refined parameters, $R = 0.024$, $\omega R = 0.025$. The hydrogen atoms of water molecules have been observed and refined with restraints on bond lengths and bond angles and blocked in the last cycles. Two ClO_4^- are located in general positions and do not show disorder. The two other perchlorates of the asymmetric unit are located on various special positions and show large disorders.

3. Results and discussion

Upon complexation of lanthanides with DPA^{2-}, the ^{1}H NMR signal related to the aromatic protons of the free ligand ($\delta = 8.33$) disappears and the ^{1}H NMR spectrum of the Eu(III) complex in D_2O ($[Eu]_{tot}/[DPA]_{tot} = 1$) shows two separate signals with the relative peak area in the ratio 1:2. The peak splitting is compatible with the pyridine protons in C_2-symmetrical environment ($\delta_H(D_2O)$ 4.5 (1H, t), 2.6 (2H, d)). The resulting paramagnetic shift for *para* and *meta* protons can be calculated according to $\Delta^{para}_{m,p} = \delta_{dia} - \delta_{exp}$, where δ_{exp} is the chemical shift of the paramagnetic Eu(III) complex. δ_{dia} corresponds to a diamagnetic shift measured for an analogous lanthanum complex. The calculated values for the monometallic complex $[Eu(DPA)]^+$ ($\Delta^{para}_p = 3.8$; $\Delta^{para}_m = 5.6$) are in agreement with the report of Alsaadi ($\Delta^{para}_p = 3.74$; $\Delta^{para}_m = 5.6$) [13]. No signal belonging to $[Eu(DPA)_2]^-$ and $[Eu(DPA)_3]^{3-}$ complexes was identified in the spectrum.

The X-ray crystal structure shows that the Eu(III) complex with DPA^{2-} crystallises in trigonal space group ($R\bar{3}$) with the asymmetric unit composed of four $[Eu(DPA)(H_2O)_4]^+$ building blocks (Fig. 1). Each europium cation in this crystal structure is nine-coordinated by one molecule of dipicolinic acid (three coordinating atoms), two oxygens coming from the carboxylate groups of neighbouring $Eu(DPA)^+$, and four water molecules (Scheme 1). The coordination sphere of Eu(III) is best described as a distorted mono-capped square antiprismatic site, where pyridine nitrogen caps the rectangular face formed by two carbonyl oxygens and two water molecules. In the polymer, both carboxylate groups of DPA^{2-} act as

[b] Calculated with data in Ref. [3].

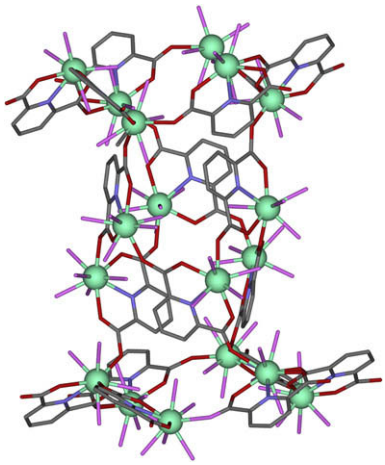

Fig. 2. Partial side view of the 3D cylinder running along the [0 0 1] direction in **1**. The hydrogens and perchlorates are omitted for clarity.

bidentate ligands with bridging functions. This binding mode advantageously increases the number of coordination bonds between Eu(III) and the DPA^{2-} ligands. The Eu–O and Eu–N distances in **1** are close to these found in Eu(III) complexes with two or three dipicolinates (Table 1). However, the average distances between Eu(III) and bridging oxygens are slightly longer than in the bis(dipicolinate)europium complex. The shortest Eu–N distances are found for tris(dipicolinates), which indicates a better encapsulation of Eu(III) in the coordination cavity. The calculated density of $\{[Eu(C_7H_3NO_4)(H_2O)_4]_4(ClO_4)_4\}_\infty$ amounts to 2.33 g cm^3. This value can be compared with 1.99 g cm^{-3} and 1.65 g cm^{-3} measured for $[Eu(HDPA)(DPA)(H_2O)_2]\cdot 4H_2O$ [5] and for $Cs_3[Eu(DPA)_3]\cdot 9H_2O$ [3], respectively. It shows that the density decreases about 0.34 g cm^{-3} per DPA^{2-} ligand bound to the Eu(III) cation.

Detailed scrutiny of the crystal structure **1** shows that the $[Eu(DPA)]^+$ complexes form the three-dimensional polymers with a cylindrical arrangement parallel to the *c* axis (Fig. 2). This supramolecular structure can be better described as an alternation of "cavities" and "tunnels" evidenced schematically in Fig. 3, (L = DPA^{2-}, the atom numbering is related to Fig. 1). The "cavities" are constituted by six monomeric units (three $Eu3L^c$ and three $Eu4L^d$) located around the $\bar{3}$ axis and represented on Fig. 4a. These "cavities" are interconnected by the "tunnels" composed of three units $Eu1L^aEu2L^b$ along a three-fold axis (Fig. 4b and c). The resulting cylindrical arrangements are further connected through $O4^c$ and $O4^d$ (oxygens located on L^c and L^d coordinated to Eu3 and Eu4, respectively), which form the bridges by coordinating the cations Eu2 and Eu1 of neighbouring cylinders (Fig. 3). The perchlorate anions are located in different general and special positions inside and outside of the cylinders formed by the complexes. Interestingly, these cylinders can be considered as monodimensional nanotunnels along the *c* axis with anions or solvent molecules sitting inside. A view of the crystal packing along the [0 0 1] direction evidencing the hexagonal "cavities" and "tunnels" is given in Fig. 5.

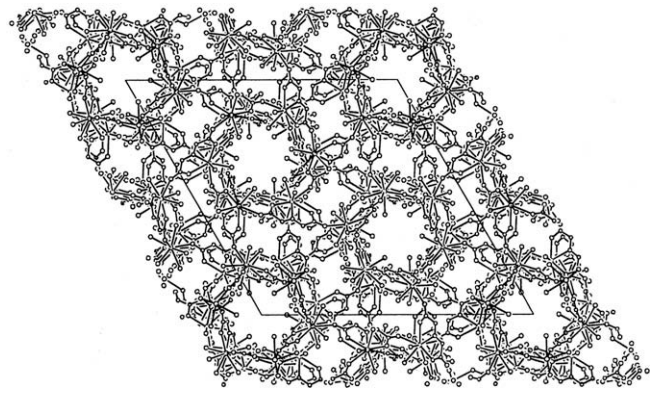

Fig. 5. View of the crystal packing of **1** along the [0 0 1] direction. The hydrogens and perchlorates are omitted for clarity.

4. Conclusion

The structure of mono(dipicolinato)europium complex in the solid state has been elucidated by X-ray crystallography. The self-assembly of $[Eu(DPA)(H_2O)_4]^+$ units leads to the formation of a peculiar polymeric network, where Eu(III) cations are nine-coordinated and all carboxylate groups of DPA^{2-} behave in a bidentate fashion. A tendency to form polymeric complexes increases along the series $[Eu(DPA)_3]^{3-}$, [Eu(HDPA)(DPA)], $Eu(DPA)]^+$ and reflects the decrease of occupancy of Eu(III) coordination sphere by chelating ligands. Although only the Eu(III) complex is presented, the formation of similar structures with remaining lanthanides is expected. However, the three-dimensional solid state arrangement is most probably not preserved in solution. This study demonstrates that unsaturated lanthanide complexes possessing carboxylic functions may be advantageously used for designing 3D metalloorganic frameworks.

ABSTRACT

A series of iron (III) containing POSS compounds, $[Bu_4N][(R)_7Si_7O_{12}FeCl]$ (R = isobutyl- (**1**), ethyl- (**2**), phenyl- (**3**), and cyclopentyl- (**4**)) were investigated as potential catalysts for aerobic oxidation of tetrahydrofuran (THF). The oxidation products for this reaction were characterized by IR, GC and GC–MS. The major oxidation product was γ-butyrolactone ($C_4H_6O_2$, GBL); while the two minor products were 2-hydroxy-THF and its tautomer, 4-hydroxybutanal. A third minor oxidative product is believed to be an isomer of dihydroxy-THF. THF free syntheses of **2**–**4** have been developed and all three compounds were characterized by elemental analysis, IR, and X-ray diffraction studies. The crystallographic data for **1**–**4** demonstrate a similar iron coordination sphere between the four compounds, but the different substitutents on the various POSS. The corresponding turnover numbers for the aerobic oxidation of THF suggest that smaller substitutents on the POSS ligands improve the stability of the catalytic species. When compared to other published catalytic iron systems, these turnover numbers appear to be the largest for the aerobic conversion of THF to GBL.

1. Introduction

Metal containing polyhedral oligomeric silsesquioxanes (POSS) have been used to model a variety of industrial catalysts consisting of silica (SiO_2) supported metals [1,2]. As a result, our laboratory has been investigating the use of POSS ligands as potential models for the Fe-ZSM-5 catalyst [3]. During this process, we synthesized and fully characterized four different iron (III)-containing POSS compounds, $[Bu_4N][(R)_7Si_7O_{12}FeCl]$ (R = isobutyl- (**1**), ethyl- (**2**), phenyl- (**3**), and cyclopentyl- (**4**)) (Fig. 1).

In the crystal structure of the isobutyl derivative (**1**) an equivalent of γ-butyrolactone ($C_4H_6O_2$, GBL) had crystallized with the complex [4]. Since GBL had not been added to the reaction mixture, we hypothesized that it was formed from the aerobic oxidation of the solvent, tetrahydrofuran (C_4H_8O, THF), during the synthesis of **1** (Reaction 1).

The aerobic oxidation of ethers, such as THF, has been facilitated by a variety of transition metal complexes [5–12]. However, oxidation of ethers using an iron containing complex is especially significant because of iron's importance in biological reactions [13,14]. We offer here our results of the controlled aerobic oxidation of THF in the presence of four different iron (III) chloro-POSS compounds (**1**–**4**) and a control of iron (III) chloro complex that does not contain the POSS, $[Bu_4N][FeCl_4]$ (**5**). In addition, we present the synthesis and structural characterization of the ethyl- (**2**) and phenyl- (**3**) derivatives, and an improved synthesis and structural characterization for the cyclopentyl- derivative (**4**) [15].

2. Experimental

2.1. Materials and instrumentation

All procedures were performed under aerobic conditions. Hexane and toluene were dried over Na and stored over 4 Å molecular sieves. Acetonitrile was dried over CaH_2 and stored over 4 Å molecular sieves. IR spectra were recorded on a Nicolet Impact 410 FTIR Spectrometer using a KBr pellet or NaCl plates. Elemental analysis was performed by Galbraith Laboratories Inc. (Knoxville, TN) using a Perkin–Elmer 240 CHN Analyzer. Gas chromatography (GC) was recorded on a GOW-MAC Series 400 Thermal Conductivity GC using a carbowax column. Gas chromatography–mass spectrometry (GC–MS) analysis was performed on an Agilent 6890 gas chromatograph coupled to a Waters GCT time-of-flight mass spectrometer using a Varian VF5-MS column (20 m, 0.18 mm i.d., 0.15 μm) programmed from 40 (1 min hold) to 300 °C at 15 °C/min) operating in 20 to 1 split injection mode (Injector T = 250 °C). The compounds were ionized via electron ionization. The X-ray diffraction data were collected under a cooled N_2 stream

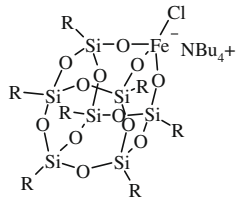

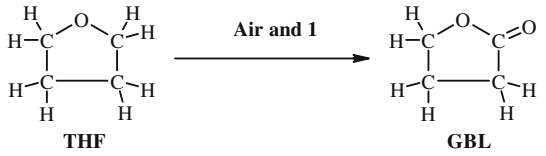

Fig. 1. Iron (III) chloro-POSS compounds, R = isobutyl- (**1**), ethyl- (**2**), phenyl- (**3**), and cyclopentyl- (**4**)

Reaction 1. Oxidation of tetrahydrofuran to γ-butyrolactone.

at 150 K on a Bruker Apex CCD diffractometer (sealed-tube Mo radiation) which is controlled via Bruker Smart software. Trisilanolethyl-POSS, $(CH_3CH_2)_7Si_7O_{12}H_3$, the trisilanolphenyl-POSS, $(C_6H_5)_7Si_7O_{12}H_3$, and the trisilanolcyclopentyl-POSS, (cyclo-$C_5H_9)_7$-$Si_7O_{12}H_3$ were all obtained from Hybrid Plastics or as a gift from Dr. Andre Lee from Michigan State University and used as received. Triethylamine, anhydrous tetrahydrofuran (THF), γ-butyrolactone (GBL), and dodecane were all obtained from Sigma–Aldrich chemical and used as received. Compound **1** was synthesized as described in the literature [16]. Compound **5** was prepared according to the literature procedure [17].

2.2. Synthesis of compound *2*

A colorless solution of the trisilanol-POSS, $(CH_3CH_2)_7Si_7O_{12}H_3$, (0.200 g, 0.336 mmol) in toluene (4.0 mL) was treated with 3 equiv. of triethylamine (141 μL, 1.01 mmol). The mixture was stirred for 5 min at room temperature before 1 equiv. of solid **5** (0.148 g, 0.336 mmol) was added. The yellow solid did not immediately dissolve. After stirring for 10 min, the solution had turned yellow and a precipitate had formed. A white precipitate was collected by filtration. The yellow filtrate was concentrated in vacuo giving a yellow oil, which was then extracted with acetonitrile. A majority of the yellow oil dissolved except for a small amount of insoluble white precipitate. These were removed by filtration, and the filtrate was concentrated in vacuo to give yellow crystalline material, which was then extracted with toluene and then concentrated in vacuo to afford a yellow powder after being dried under vacuum.

2.2.1. Compound *2*

Yield: 83.9%. *Anal.* Calc. for $C_{30}H_{71}FeClNO_{12}Si_7$ (925.81): C, 38.92; H, 7.73; N, 1.51. Found: C, 38.89; H, 7.63; N, 1.54%. IR (KBr, ν (cm^{-1})): 2967s, 2877s, 1481m, 1461m, 1415w, 1383w, 1252s, 1086vs, 940s, 881m, 753s, 696vs, 492s, 458s.

2.3. Synthesis of compounds *3* and *4*

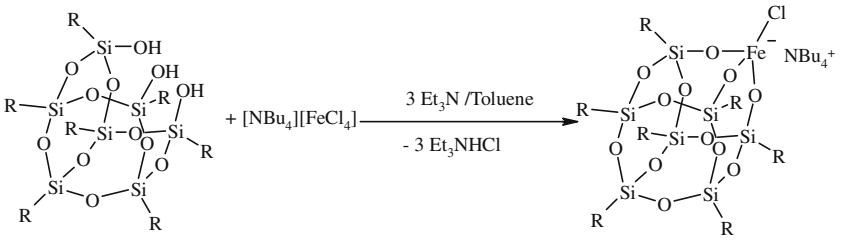
Compounds **3** and **4** were prepared following a procedure analogous to the synthesis of **2**. Similar molar quantities of the appropriate trisilanol-POSS were used, but due to their lower solubility in toluene, twice the volume of solvent was used as well as longer reaction times were necessary.

2.3.1. Compound *3*

Yield: 82.2%. *Anal.* Calc. for $C_{58}H_{71}FeClNO_{12}Si_7$ (1262.09): C, 55.19; H, 5.67; N, 1.11. Found: C, 55.12; H, 5.49; N, 1.12%. IR (KBr, ν (cm^{-1})): 3137w, 3071s, 3049s, 2965s, 2931s, 2874s, 2719w, 1961m, 1891m, 1824m, 1776m, 1593s, 1480s, 1431s, 1381s, 1068vs, 879s, 744vs, 694vs, 645s, 594m, 551s.

2.3.2. Compound *4*

Yield: 73.8%. *Anal.* Calc. for $C_{51}H_{99}FeClNO_{12}Si_7$ (1206.24): C, 50.78; H, 8.27; N, 1.16. Found: C, 50.61; H, 8.72; N, 1.26%. IR (KBr, ν (cm^{-1})): 2948vs, 2864s, 1481m, 1471m, 1454m, 1383m, 1243s, 1099vs, 1040vs, 943s, 906w, 736m, 496vs.



2.4. X-ray analysis of iron (III) chloro-POSS compounds

Crystallization of **2** from a minimum amount of toluene afforded yellow crystals of **2**. $C_{30}H_{71}ClFeNO_{12}Si_7$, M = 925.81, monoclinic space group, $P2_1/c$, a = 9.8962(5), b = 29.5660(15), c = 16.1237(8) Å, β = 90.7710(10)°, V = 4717.2(4) Å^3, Z = 4, D_{calc} = 1.302 Mg/m^3; F(0 0 0) = 1976, μ_{Mo} = 0.422 mm^{-1}; crystal dimensions: 0.32 × 0.28 × 0.25 mm. The structure was solved via direct methods. Least-squares refinement on F^2 using all reflections converged to R_{F^2} = 15.29%. One of the ethyl methylene carbons was disordered 50:50 over two sites.

Crystallization of **3** from a minimum amount of toluene afforded yellow crystals of **3**. $C_{58}H_{71}ClFeNO_{12}Si_7$–2($C_6H_5CH_3$), M = 1446.36, monoclinic space group, $P2_1/n$, a = 15.079(3), b = 20.224(4), c = 25.423(4) Å, β = 100.642(4)°, V = 7619(2) Å^3, Z = 4, D_{calc} = 1.261 Mg/m^3; F(0 0 0) = 3052, μ_{Mo} = 0.401 mm^{-1}; crystal dimensions: 0 0.22 × 0.34 × 0.35 mm. The structure was solved via direct methods. Least-squares refinement on F^2 using all reflections converged to R_{F^2} = 27.52%. There are two toluene solvate molecules per asymmetric unit which were constrained to fit approximately rigid hexagons. The crystal was very weakly diffracting which caused problems in the refinement including poorly shaped ADP's, unexpected variations in U_{eq} values, and some atypical bond lengths. These problems are noted in the checkcif report. Crystallization of **4** from a minimum amount of toluene afforded yellow crystals of **4**. $C_{51}H_{99}ClFeNO_{12}Si_7$, M = 1206.24, monoclinic space group, $P2_1/c$, a = 15.4303(16), b = 22.127(2), c = 40.539(4) Å, β = 93.408(2)°, V = 13817(2) Å^3, Z = 8, D_{calc} = 1.159 Mg/m^3; F(0 0 0) = 5192, μ_{Mo} = 0.428 mm^{-1}; crystal dimensions: 0.21 × 0.28 × 0.34 mm. The structure was solved via direct
methods. Least-squares refinement on F^2 using all reflections converged to R_{F^2} = 23.54%. Crystals diffracted very weakly which caused problems in the refinement including poorly shaped ADP's, unexpected variations in U_{eq} values, and some atypical bond lengths. These problems are noted in the checkcif report. One of the cyclopentyl groups was disordered over two 50% occupancy orientations.

2.5. Aerobic oxidation of the tetrahydrofuran

In a 10-mL micro-scale round bottom flask, 0.0500 mol% of the iron complex was dissolved in 2.00 mL of THF. The resulting solution was golden yellow. Three stacked micro-scale water condensers were added to the round bottom flask to prevent evaporation of the solvent. The mixture was stirred for 5 days at room temperature. Afterwards, the reaction mixture was analysed by infrared spectroscopy (IR) and gas chromatography (GC). Dodecane was used as an internal standard during the GC analysis, and the turnover number from four separate trials were averaged to give the reported values. On separate occasions, similar reaction mixtures were analysed by gas chromatography–

Reaction 2. THF free synthesis of **1**–**4**.

mass spectrometry (GC–MS) to determine the identities of the THF oxidation products.

3. Results and discussion

3.1. Synthesis of iron (III) chloro-POSS compounds

The conversion of THF to GBL was originally detected when **1** was synthesized and crystallized in a solution of THF under aerobic conditions [4]. A general THF free synthesis was therefore developed in order to prepare **1**–**4** (Reaction 2). The corresponding POSS trisilanol was treated with 3 equiv. of triethylamine in toluene. Although **5** was insoluble in toluene, the reaction between **5** and the POSS ligand still occurred albeit slower and with a considerable amount of stirring. After reaction times ranging from 5 to 60 min, depending on the POSS, triethyl ammonium chloride salt and a small amount of unreacted **5** were removed by filtration. The resulting yellow toluene solution was concentrated under reduced pressure to give a yellow oil, which was then extracted with acetonitrile. The trisilanol POSS ligands are insoluble in acetonitrile, while **1–4** are soluble, therefore unreacted trisilanol POSS ligand can be easily removed from the reaction mixture increasing the purity of the product. A final extraction with either hexane or toluene, depending on the product, resulted in the formation of **1–4** in relatively high yields.

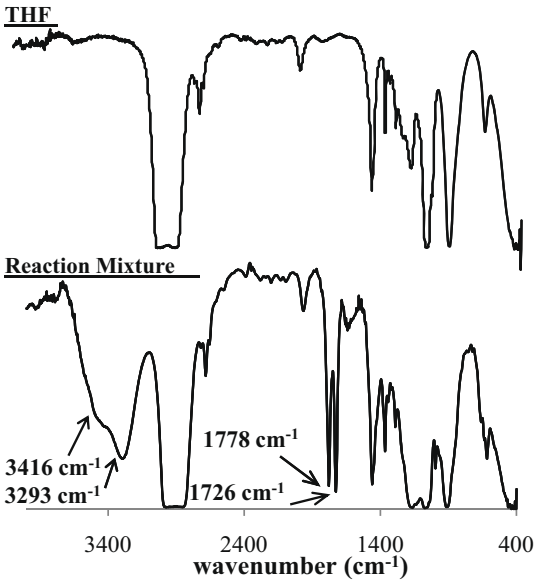


Fig. 2. Infrared spectral data of pure THF (top) and a typical reaction mixture (bottom).

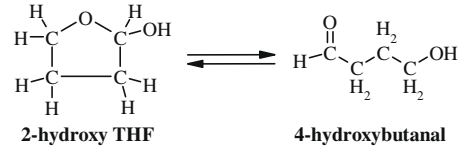

3.2. X-ray analysis of iron (III) chloro-POSS compounds

The iron (III) center in **2**–**4** all have the same coordination geometry previously observed in **1** [15,16], a distorted tetrahedral geometry composed of a single chlorine atom and three trisilanate oxygen atoms. The Fe–Cl bond distances in **1**–**4** are very similar [Fe–Cl: **1**, 2.2536(10) Å; **2**, 2.2534(5) Å, **3**, 2.227(2) Å, and **4**, 2.256(1) Å], while the average Fe–$O_{trisilanate}$ bond length of **1–4** are also very close [Fe–$O_{trisilanate}$: **1**, 1.842 (±0.008) Å; **2**, 1.84 (±0.01) Å, **3**, 1.835(±.009) Å, and **4**, 1.825(±.009) Å]. Clearly, the four complexes are structurally comparable within the coordination environment of the iron and differ only in the type and thus the size of the hydrocarbon substitutents on the POSS ligand.

3.3. Aerobic oxidation of the tetrahydrofuran

A yellow solution of 0.0500 mol% **1–5** in anhydrous THF was stirred open to the atmosphere for five days. The IR spectrum of the reaction mixtures of each sample was compared to the IR spectrum of pure THF (Fig. 2). New bands were detected that are indicative of oxidation products: a shoulder at 3416 cm^{-1}, a broad band at 3293 cm^{-1}, and two sharper bands at 1778 cm^{-1} and 1726 cm^{-1}. The peaks in the 3000 cm^{-1} range are characteristic of hydroxyl (–OH) functionality, while the peaks in the 1700 cm^{-1} range support the presence of carbonyl (C=O) groups [18]. The 1778 cm^{-1} peak is consistent with the IR of pure GBL obtained in our laboratory as well as the literature value [19].

According to the GC–MS results, GBL was confirmed as the major oxidation product for the aerobic oxidation of THF. In addition, two minor products were also detected. The more abundant of the two minor species was 2-hydroxy-THF. The shoulder at 3416 cm^{-1} in the IR also supports its presence [20]. It can undergo a ring-chain tautomerism to form 4-hydroxybutanal [21], however, the GC–MS did not detect the ring opened species (Reaction 3). In the liquid phase, however, the 1726 cm^{-1} peak in the IR is consistent with 4-hydroxybutanal [22]. Therefore, it is possible that either the gas phase equilibrium favoured the cyclic tautomer in the MS or the ring-opened form did not elute from the GC column. The third most abundant species detected by the GC–MS is believed to be a dihydroxy-THF molecule. An M^+ peak of 104 in the mass spec is consistent with a molecular formula of $C_4H_8O_3$, and the broad band at 3293 cm^{-1} in the IR would also support the presence of a second hydroxyl containing species. We were unable to definitively confirm which dihydroxy-THF isomer was present in the reaction mixture.

Reaction 3. Ring-chain tautomerism of 2-hydroxy-THF and 4-hydroxybutanal.

Table 1
Turnover numbers for THF oxidation products.

Iron (III) chloro complex	THF to GBL turnover number	Total oxidation turnover number
Isobutyl POSS (**1**)	74 (±7)	100 (±8)
Ethyl POSS (**2**)	114 (±9)	170 (±10)
Phenyl POSS (**3**)	89 (±7)	130 (±10)
Cyclopentyl POSS (**4**)	82 (±7)	120 (±9)
No POSS (**5**)	6 (±2)	14 (±3)

As of this study, it is not clear that the iron (III) chloro-POSS complexes (**1–4**) remain intact during the oxidation of THF, and are thus responsible for the catalytic conversion of THF to GBL. In our previous report [4], we showed that an equivalent of GBL co-crystallized with **1**, suggesting that **1** remains intact during the oxidation of THF. In this work, though, we were unable to isolate **1–4** from any of the THF reaction mixtures, possibly due to its low concentration. Also, the iron (III) center is paramagnetic [4], making simple spectroscopic methods for characterizing the catalytic iron species difficult. It is possible that the iron (III) chloro-POSS complexes could function as a pre-catalyst by potentially loosing the chloride ligand or reacting with water or oxygen to generate the catalytic species. As a result, we calculated turnover numbers for the THF oxidation reaction based on the initial number of moles of iron (III) in **1–5**.

Since the reaction mixture contained multiple oxidation products of THF, we calculated both the THF to GBL turnover numbers as well as the turnover numbers for the total oxidation of THF (Table 1). The iron (III) chloro-POSS complexes (**1–4**) generated between 74 and 114 equiv. of GBL per mole of iron (III), while the total number of oxidation equivalents per iron (III) ranged from 100 to 170. As a control, **5** was dissolved in THF under the same conditions and only 6 turnovers of GBL and 14 total oxidation turnovers were measured. Apparently, the POSS ligand enhances the stability of the catalytic species resulting in the higher turnover numbers. This may be a result of the POSS ligand's electron withdrawing ability, which would result in a more Lewis acidic iron center [23].

To place the iron (III) chloro-POSS system's turnover numbers in context, a review of the literature was conducted revealing only two previously published examples of the catalytic oxidation of THF to GBL by dioxygen in the presence of an iron complex. The first system used $FeCl_2{\cdot}$(1.5 THF) under a pressure of dioxygen and carbon dioxide [14]. The second system used a carboxylate-bridged diiron complex in the presence of a triarylphosphine in air-saturated THF [13]. Both systems produce multiple THF oxidation products, including GBL. Approximately 2.5 turnovers of GBL were obtained after a reaction time of about 8 days from the $FeCl_2{\cdot}$(1.5 THF) system, while the carboxylate-bridged diiron system did not report turnover numbers. Therefore, the iron (III) chloro-POSS system appears to provide the highest published THF to GBL turnovers for an iron system to date.

4. Conclusion

Clearly, the GBL observed in the crystal structure of **1** is formed by the aerobic oxidation of THF [4]. By first synthesizing the four iron (III)-containing POSS compounds (**1–4**) in toluene and then dissolving them in THF, we have demonstrated that all four complexes are capable of either catalysing this oxidation reaction or acting as pre-catalysts. The low turnover numbers observed with **5** supports that the presence of the POSS ligand significantly stabilizes the catalysts allowing for dramatically higher yields of GBL. A comparison of the turnover numbers for **1–4** also shows that by varying the substitutent on the POSS, the stability of the catalyst can be improved: the POSS with the smallest substitutent, **2,** provides the most stable catalyst.

Supplementary data

CCDC 706342, 706344 and 706343 contain the supplementary crystallographic data for **2**, **3** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Acknowledgements

We thank the University College of the Pennsylvania State University for their financial support. Special thanks go to Dr. Andre Lee (Michigan State University) for providing several samples of the trisilanol POSS and Dr. Robert Minard (Pennsylvania State University) for his assistance in obtaining and interpreting the GC–MS data.

ABSTRACT

Cobalt(II), nickel(II), copper(II) and zinc(II) complexes of 2-thiophenecarbonyl hydrazone of 3-isatin (H_2L^1) and 2-furoic hydrazones of 3-isatin (H_2L^2) and 3-(*N*-methyl)isatin (HL^3), with general composition $[M(L)_2] \cdot nX$, where X is ethanol or/and water, were synthesised and characterised. The molecular structure of HL^3 showed that it crystallised in the keto form, which is also the more abundant tautomer for the three hydrazone ligands in solution. The three ligands behave as κ^2-*O,N* donors in the cobalt(II) and zinc(II) complexes. The X-ray crystal structure of pseudotetrahedral $[Zn(HL^1)_2] \cdot 1.75MeOH$ confirmed the *O,N* coordination mode of the two monodeprotonated ligands in their keto forms. Secondary interactions of zinc ions with the O atoms of each isatin keto residue provoke a substantial distortion towards a square pyramidal form. The interaction of the isatin keto residues is stronger in the three nickel(II) complexes where the three acylhydrazones can be considered as κ^3-*O,N,O* donors.

The free ligands and their complexes were evaluated *in vitro* as antimicrobial agents against a panel of Gram positive and Gram negative bacteria, as well as, yeasts and moulds. Among the tested microorganisms, *Haemophilus influenzae* was the most sensitive strain, especially to H_2L^1 and its complexes.

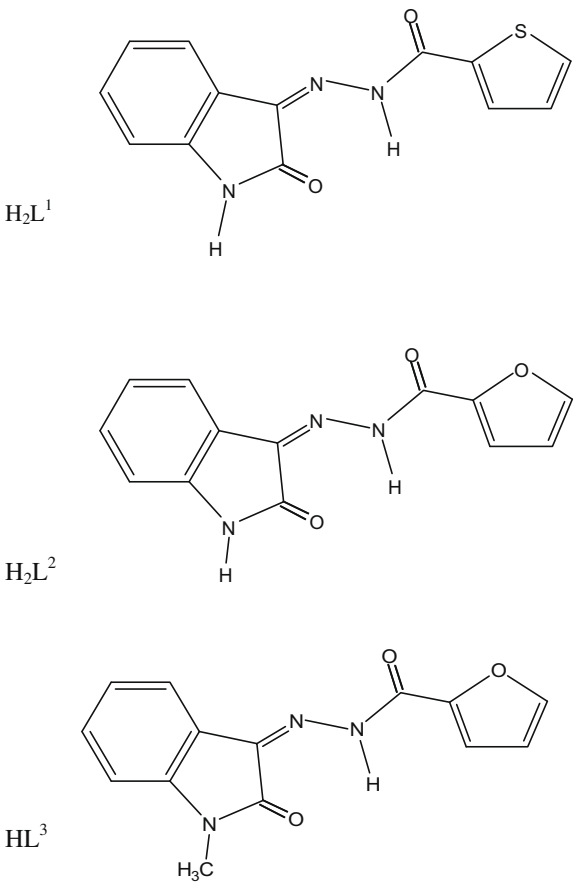
1. Introduction

Acylhydrazones are known to present a wide spectrum of biological properties, such as analgesic, anti-inflammatory, antithrombotic, antinociceptive and antiplatelet [1]. In some cases, the biological activity has been related to the chelating property of the acylhydrazones [2].

Acylhydrazones can behave as κ^2-*O,N* or κ^3-*O,N,X* ligands to form stable coordination compounds with different transition metal ions [3]. We have recently reported the interesting biological properties of cobalt(II), nickel(II), copper(II) and zinc(II) complexes of 3-isatin- and *N*-methyl-isatin-3-picolinoylhydrazone [4] as well as of 2-thiophenecarbonyl and isonicotinoyl hydrazones of 3-(*N*-methyl)isatin [5].

Following this research line, here we describe the synthesis and structural characterisation of some Co(II), Ni(II), Cu(II) and Zn(II) complexes of 2-thiophenecarbonyl hydrazone of 3-isatin, H_2L^1, 2-furoic hydrazone of 3-isatin, H_2L^2, and 2-furoic hydrazone of 3-(*N*-methyl)isatin, HL^3 (Scheme 1). Moreover, we report the antibacterial and antifungal activities of all the synthesised compounds.



2. Experimental

2.1. Materials and measurements

All reagents and solvents were of reagent grade. Elemental analyses were performed with a Carlo-Erba 1108 analyser. The nuclear magnetic resonance (NMR) spectra were recorded on a Bruker ARX-400 using dimethyl sulfoxide-d_6 (DMSO-d_6) as solvent. Infrared (IR) spectra in the 4000–400 cm^{-1} range were recorded on a Bruker V-22 spectrophotometer with the samples prepared as KBr discs. Magnetic susceptibility measurements were performed on pulverised samples at room temperature (RT) with an Alfa MSB-MK1 balance. Diffuse reflectance spectra were recorded on a Shimadzu UV-3101 PC spectrophotometer.

Scheme 1. Representations of H_2L^1, H_2L^2 and HL^3.

2.2. Synthesis of compounds

2.2.1. Synthesis of ligands

The ligands, 2-thiophenecarbonyl hydrazone of 3-isatin, H_2L^1, 2-furoic hydrazone of 3-isatin, H_2L^2, and 2-furoic hydrazone of 3-(*N*-methyl)isatin, HL^3, were obtained by refluxing an ethanol solution of isatin- or *N*-methyl-isatin and the corresponding hydrazide (2-thiophenecarboxylic or 2-furoic hydrazide), following a general procedure previously reported [6]. Powdered solids obtained by cooling were filtrated, washed with ethanol and dried under vacuum. The slow evaporation at room temperature of an ethanol solution of HL^3 led to the isolation of some crystals adequate to their study by diffraction of X-ray.

2.2.1.1. H_2L^1. Anal. Calc. for $C_{13}H_9N_3O_2S$: C, 57.7; H, 3.3; N, 15.5; S, 11.8. Found for yellow solid: C, 57.5; H, 3.3; N, 15.3; S, 12.1%. M.p. 235 °C. Yield 83%. IR (KBr, cm^{-1}, s: strong, m: medium, w: weak, sh: shoulder, br: broad, v br: very broad): ν(NH) 3421w, br, 3168m, v br, 3113w, br; ν(CO) 1732s, 1653s; ν(CN) 1593s; ν(CN) + δ(NH) 1512m. NMR δ(^{1}H, DMSO-d_6, 400 MHz, ppm, s: singlet, d: doublet, t: triplet and m: multiplet) = 11.64 (1H, s, *H*N1), 10.84 (1H, s, *H*N3), 8.17 (1H, d, *H*C13), 8.07 (1H, d, *H*C7), 8.01 (1H, d, *H*C11), 7.39 (1H, t, *H*C5), 7.26 (1H, m, *H*C12), 7.06 (1H, t, *H*C6), 6.91 (1H, d, *H*C4), NMR δ(^{13}C, DMSO-d_6, 100 MHz, ppm) = 164.50 (C9), 162.00 (C1), 143.91 (C3), 138.91 (C2), 134.90 (C11), 134.49 (C10), 133.96 (C13), 132.68 (C5), 127.64 (C12), 126.41 (C7), 121.69 (C6), 115.29 (C8), 110.54 (C4); λ (nm) = 240, 278, 324, 432.

2.2.1.2. H_2L^2. Anal. Calc. for $C_{13}H_9N_3O_3$: C, 61.2; H, 3.5; N, 16.5. Found for yellow solid: C, 61.2; H, 3.4; N, 16.4%. M.p. 266 °C. Yield 83%. 2.2.1.3. HL^3. Anal. Calc. for $C_{14}H_{11}N_3O_3$: C, 62.4; H, 4.1, N, 15.6. Found for yellow solid: C, 62.3; H, 4.1; N, 15.6%. M.p. 197 °C. Yield 62%. IR (cm^{-1}, KBr): ν(NH) 3453m, v br; ν(CO) 1713s, 1678s; ν(CN) 1606s; ν(CN) + δ(NH) 1516m. δ (^{1}H, DMSO-d_6, 400 MHz, ppm) = 13.78 (1H, s, $HO1_{enol}$), 11.55 (1H, s, *H*N1), 8.05 (1H, d, *H*C13), 7.99 (1H, d, *H*C7), 7.63 (1H, d, *H*C11), 7.49 (1H, t, *H*C5), 7.43 (1H, t, $HC5_{enol}$), 7.18 (1H, t, $HC6_{enol}$), 7.15 (1H, t, *H*C6), 7.10 (1H, d, *H*C4), 6.78 (1H, m, *H*C12), 3.23 (1H, m, H_3CN3_{enol}), 3.19 (1H, m, H_3CN3), δ(^{13}C, DMSO-d_6, 100 MHz, ppm) = 163.21 (C9), 160.93 ($C9_{enol}$), 157.10 (C1), 147.00 (C13), 146.90 ($C13_{enol}$), 145.42 (C10), 144.91 (C3), 143.65 ($C3_{enol}$), 139.80 (C2), 132.62 (C5), 131.63 ($C5_{enol}$), 125.95 (C7), 123.12 ($C6_{enol}$), 122.21 (C6), 120.54 ($C7_{enol}$), 118.94 ($C8_{enol}$), 118.73 (C11), 114.73 (C8), 112.85 ($C12_{enol}$), 112.35 (C12), 109.87 ($C4_{enol}$), 109.27 (C4), 25.92 (CN3), 25.58 ($CN3_{enol}$); λ (nm) = 238, 262, 388, 430.

2.2.2. Synthesis of complexes

Complexes were obtained by refluxing for 6–12 h an ethanol suspension of each metal acetate ($ZnAc_2$, $CuAc_2$, $NiAc_2$ and $CoAc_2$) and corresponding free ligands in a 1:2 molar ratio. The resulting suspension was stirred at room temperature for about 24–72 h. Powder solids obtained by cooling, were filtrated, washed with ethanol and dried under vacuum. After several attempts of recrystallisation of all these solids in ethanol–methanol solutions, only small single crystals of $[Zn(HL^1)_2] \cdot 1.75MeOH$ could be obtained by slow evaporation, at room temperature from a solution of $[Zn(HL^1)_2] \cdot EtOH$.

2.2.2.1. $[Zn(HL^1)_2] \cdot EtOH$. Anal. Calc. for $C_{28}H_{22}N_6O_5S_2Zn$: C, 51.6; H, 3.4; N, 12.9; S, 9.8. Found for orange solid: C, 51.3; H, 3.2; N, 12.7; S, 10.0%. M.p. >300 °C. Yield 50%. IR (KBr, cm^{-1}): ν(NH + OH) 3177w, br, 3143m, v br, 3064w; ν(CO) 1703s, 1690s; ν(CN) 1611s; ν(CN) + δ(NH) 1531m. δ(^{1}H, DMSO-d_6, 400 MHz, ppm) = 11.22 (1H, s, *H*N3), 8.24 (1H, d, *H*C7), 7.97 (1H, d, *H*C13), 7.91 (1H, d, *H*C11), 7.44 (1H, br, *H*C5), 7.24 (2H, m, *H*C6, *H*C12), 7.05 (1H, d, *H*C4), δ(^{13}C, DMSO-d_6, 100 MHz, ppm) = 173.12 (C1), 166.50 (C9), 143.11 (C3), 138.86 (C10), 135.23 (C2), 132.90 (C11), 132.34 (C5), 131.86 (C13), 128.28 (C12), 126.52 (C7), 123.07 (C6), 116.34 (C8), 111.64 (C4).

2.3. Single crystal X-ray diffraction measurements for HL^3 and $[Zn(HL^1)_2] \cdot 1.75MeOH$

The most significant crystal and refinement data for HL^3 and $[Zn(HL^1)_2] \cdot 1.75MeOH$ are summarised in Table 1. Orange prismatic single crystals of HL^3 and $[Zn(HL^1)_2] \cdot 1.75MeOH$ were mounted on a fibreglass, and their X-ray diffraction data were collected at room temperature on a Bruker CCD Smart 1000 diffractometer, employing graphite monochromated Mo Kα radiation (λ = 0.71073 Å). Data reduction was performed using the SAINT package [7], and involved corrections for Lorentz, polarisation and absorption (SADABS) effects [8]. The structures were solved by direct methods (SHELXS-97) [9], and refined by full-matrix least-squares techniques on all F^2 (SHELXL-97) [9]. In the case of HL^3, all the H atoms were introduced in calculated positions, excluding that bonded to N1, which was located in the Fourier maps. Molecular graphics were represented by ORTEP-3 for Windows [10].

Several crystals of $[Zn(HL^1)_2] \cdot 1.75MeOH$ were mounted, but data collected revealed not only severe non-merohedral twinning, but a poor diffraction ability as well. In fact, the best of these data sets only displays a θ_{max} of ca. 23°. Despite these inconveniences, the structure could be clearly solved using direct methods (SHELXS-97) [9], and even refined by standard Fourier techniques based on weighted full-matrix least-squares on F^2 (SHELXL-97) [9], with a final R_1 = 0.0974. This procedure allowed modelling with some restraints the disorder observed for some solvated methanol molecules, and for the thiophene rings of both ligand units. This latter can be described as a rotation of 180° around the pivot C atoms (C110 and C210), which leads to find two different occupation sites for the S atoms [S101 and S11′ (0.68:0.32); S201 and S21′ (0.79:0.21)], and their opposite C atoms [C111 and C11′ (0.68:0.32); C211 and C21′

(0.79:0.21)]. Non-H atoms were anisotropically treated, except C and O atoms with low occupation sites. All the H atoms were added theoretically and treated as riding on concerned atoms. In view of the data quality, a detailed analysis of the dimensions seems inadvisable and consequently, bond distances and angles should be interpreted with some caution, but the molecular structure determined for the complex appears unambiguous.

2.4. Antimicrobial activity

All the ligands and their complexes were assayed for their *in vitro* growth inhibitory activity using the twofold broth dilution technique [11]. All determinations were performed in triplicate and confirmed by three separate experiments.

Since the compounds are virtually water insoluble, samples were dissolved in dmso. In order to test final concentrations ranging from 200 to 0.15 μg/mL, further dilutions were prepared in the test media (Haemophilus Test Medium for *Haemophilus influenzae*, Mueller Hinton Broth for the remaining bacteria and Sabouraud Liquid Medium for fungi). Solvent never exceeded 1% v/v and controls containing broth media supplemented with only dmso at the same dilutions used in the experiments were found inactive. The final inoculum size was 5×10^4 bacteria/mL and 1×10^3 fungi/mL. After incubation at 37 °C for 24 h (bacteria) or at 30 °C for 48 h (fungi), the minimal inhibitory concentrations (MICs, μg/mL) were determined as the lowest concentrations of drug in the medium where no microbial growth was visible.

To evaluate the minimal bactericidal concentrations (MBCs, μg/mL) and the minimal fungicidal concentrations (MFCs, μg/mL), 100 μL from each clear sample were removed and transferred in tubes containing 1 mL of fresh medium and then incubated at 37 °C for 24 h (bacteria) and 30 °C for 48 h (fungi).

The antimicrobial activity was investigated against some Gram positive and Gram negative bacteria, as well as yeasts and moulds that are related below:

- Gram positive bacteria: *Bacillus megaterium* BGSC 7A2, *Bacillus subtilis* ATCC 6633, *Bacillus thuringiensis* var. *kurstaki* BGSC 4D1, *Sarcina lutea* ATCC 9341, *Staphylococcus aureus* ATCC 25923, *Staphylococcus epidermidis* ATCC 12228 and clinical isolates of methicillin-resistant *S. aureus*, methicillin-resistant *S. epidermidis*, *Staphylococcus haemolyticus*, *Streptococcus agalactiae*, *Streptococcus faecalis* and *Streptococcus faecium*;
- Gram negative bacteria: *Enterobacter cloacae* ATCC 23355, *Escherichia coli* SPA 27, *Proteus vulgaris* ATCC 13315, *Pseudomonas aeruginosa* ATCC 9027, *Salmonella typhimurium* ATCC 14028, *Serratia marcescens* ATCC 8100 and clinical isolates of *H. influenzae*, *Klebsiella pneumoniae* and *Proteus mirabilis*.
- Yeasts: *Candida tropicalis* ATCC 1369, *Saccharomyces cerevisiae* ATCC 9763.
- Moulds: *Aspergillus niger* ATCC 6275.

Since $[Co(HL^1)_2] \cdot H_2O$ showed antifungal activity, we expanded the test in liquid medium to other yeasts such as *Candida albicans* ATCC 10231, clinical isolates of *Candida guilliermondii*, *Candida parapsilosis* and *Cryptococcus neoformans*. Moulds including *Pseudallescheria boydii*, *Sporothrix schenkii*, some dermatophytes (*Epidermophyton floccosum*, *Microsporum gypseum*, *Trichophyton mentagrophytes*) and phytopathogenic fungi (*Alternaria tenuis* ATCC 11680, *Botrytis cinerea*, *Fusarium* sp., *Fusicladium dendriticum, Sclerotinia minor*) were also tested by the twofold agar dilution method. The dmso solution of $[Co(HL^1)_2] \cdot H_2O$ was serially diluted in Sabouraud dextrose agar to give a range of concentrations from 200 to 1.5 μg/mL. The inocula were prepared from exponentially growing cultures and were performed by applying the strains on the agar surface. Growth controls were included. The minimal inhibitory concentration (MIC) was read as the lowest concentration of the compound in the agar where no visible growth of the moulds took place after 14 days of incubation at 25 °C.

3. Results and discussion

The empirical formula of the complexes of the general type $[M(L)_2] \cdot nX$, where M = Co(II), Ni(II), Cu(II) or Zn(II) and X = ethanol, water, was calculated on the basis of C, H and N microanalysis. Excluding $[Cu(L^3)_2] \cdot 0.5H_2O$, attempts to prepare a series of complexes by reaction of metal chlorides and free ligands were unsuccessful, despite some reaction conditions such as time, temperature, pH and even molar ratios (1:1 instead of 1:2) were altered. The reason for obtaining only complexes with 1:2 (metal:ligand) molar ratio could be attributed to the two bulky terminal moieties of the ligands. According to physicochemical characterisation data the three ligands coordinated with elimination of the hydrazine proton, which is the most labile of all. This is agreement with the structure observed for $[Zn(HL^1)_2] \cdot 1.75MeOH$, characterised by X-ray diffraction.

All the obtained metal complexes were soluble in dmso and dmf, but insoluble in water and most organic solvents. Although dmso and dmf are considered coordinating solvents they did not compete in the coordination sphere with any of the three ligands. In fact, all the complexes dissolved in dmso for their study by NMR spectroscopy are stable for long periods of time.

3.1. Crystal structure of HL^3

The molecular structure of HL^3 is depicted in Fig. 1. The planarity of the ligand is expressed in the low value for the dihedral angle between the isatin and hydrazide residues. The most significant bond distances and angles are listed in Table 2. The bond distances in the acylhydrazone chain are in good agreement with others reported elsewhere (Table 3) [4,5,12]. The O1–C1 distance (about 1.217 Å) is indicative of a keto tautomer for this compound in the solid state at room temperature. The mean distance in the isatin aromatic ring is 1.394 Å which is also similar to those found in isatin 3-picolinoyl hydrazone [4].

N1–C1, N1–N2 and N2–C2 bonds display different configurations, which can be described as *Z*, *E* and *Z*, respectively. This spatial array [5] seems clearly influenced by an intramolecular bifurcated hydrogen bond [N1–H···O2 (about 2.744 Å) and N1–H···O3 (about 2.665 Å)].

3.2. Crystal structure of $[Zn(HL^1)_2] \cdot 1.75MeOH$

The most significant bond distances and angles are summarised in Tables 4 and 5, respectively. An ORTEP representation of this zin-

c(II) complex is shown in Fig. 2, with its corresponding numbering scheme.

The asymmetric unit contains a discrete molecule of the neutral complex with solvated methanol molecules that show some disorder and partial occupation sites. The molecular structure shows the coordination of two monodeprotonated ligands behaving as chelating *N*,*O*-donors. The zinc ion assumes in $[Zn(HL^1)_2] \cdot 1.75MeOH$ a geometry that could be described as pseudo-tetrahedral, with Zn–O and Zn-N bond lengths ranging 2.0–2.1 Å, what is usual for this type of ligands [4]. The geometry of the complex presents a substantial distortion towards a square pyramidal form due to weak secondary interactions between the O atoms (O102 and O202) of each isatin residue and the metal centre. The obtained Zn···O distances (about 2.55 Å) are too long to be considered as true coordinated bonds.

The spatial array of the coordinated ligand is allowed by an extended planarity, with a configuration of the N101–C101, N101–N102 and N102–C102 bonds which can be described as *Z*, *E* and *E*, respectively. Geometric parameters around C101 and C201 seem to indicate the presence of keto forms for the coordinated ligand, as occurred in HL^3 and some other related free ligands [4,5,12].

The crystal packing scheme seems supported by substantial H-bonding between the amine atoms and one of the solvated methanol molecules. In addition, some intermediate and weak π–π stacking interactions, as well as σ–π contacts can be also worthy of mention.

3.3. NMR studies

The use of two-dimensional, COSY (correlation spectroscopy), HMQC (heteronuclear multiple quantum correlation) and HMBC (heteronuclear multiple bond correlation) experiments have allowed a full assignment for H- and C-signals of free ligands and their zinc(II) complexes.

Free ligands. H_2L^1, H_2L^2 and HL^3 are mainly in keto form in DMSO-d_6 solution. In fact, we did not detect neither H- nor C-signals for the enol form of H_2L^1. However, the presence of the corresponding enol forms of H_2L^2 and HL^3 in solution is unquestionable. Thus, the keto:enol molar ratios could be assessed for about 5:1 and 4:1 in H_2L^2 and HL^3, respectively. Fig. 3 (bottom) shows the ^{13}C spectrum of H_2L^2 that illustrates the keto–enol equilibrium affecting –N(1)H–C1(O)– bonds.

In the enol form C9, C7, C5 and C3 signals are upfield shifted respect to the keto form, while C12, C8, C6 and C4 signals experiment an inverse effect. Among the observed signals for both forms, C8 and C7 are the most influenced by the keto-enol equilibrium (shifted in about 5.5 ppm). Similarly, Fig. 4 shows that the most affected H-signals are attributed to *H*C7 and *H*N(3) (shifted in about 0.5 ppm).

Comparison of ^{13}C NMR spectra of H_2L^1 and H_2L^2 allows to observe the influence of the heteroatom on the C-atom signals of furan and thiophene rings. Thus, C10 and C13 result more deshielded when the heteroatom is O than when is S, whereas for C1, C11 and C12 occurs the inverse. Similarly, the deshielding effect on H11, H12 and H13 atoms is more marked when the heteroatom is S that when is O.

Zinc complexes. Comparison of ^1H NMR spectra of zinc complexes and the corresponding free ligands allows the following observations:

(i) The absence of the signal assigned to *H*N(1) proton in the three zinc(II) complexes is indicative of the monodeprotonation of their respective ligands.
(ii) A slight downfield shift (0.2–0.4 ppm) for *H*N(3), *H*C7, *H*C6 and *H*C4 proton signals respect to their corresponding free ligands is interpreted as due to the complexation of the zinc(II) ion through N(2). This is illustrated in Fig. 4 for the H_2L^2–$[Zn(HL^2)_2] \cdot 2H_2O$ pair.
(iii) A very slight upfield shift (0.1 ppm) undergone by *H*C11 and *H*C13 proton signals is coherent with the participation of O(1) in the metal coordination.
(iv) *H*C5 and *H*C12 proton signals remained virtually unaffected upon the metal coordination.

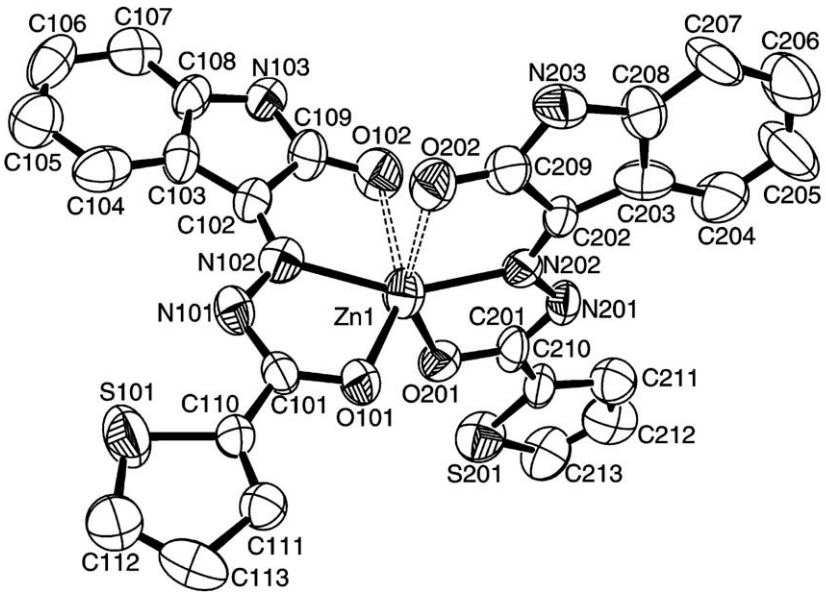

Fig. 2. ORTEP representation of [Zn(HL^1)] at 40% probability. Solvated methanol molecules, H atoms, and disordered S and C atoms of the thiophene residues with lower occupation sites have been omitted for clarity.

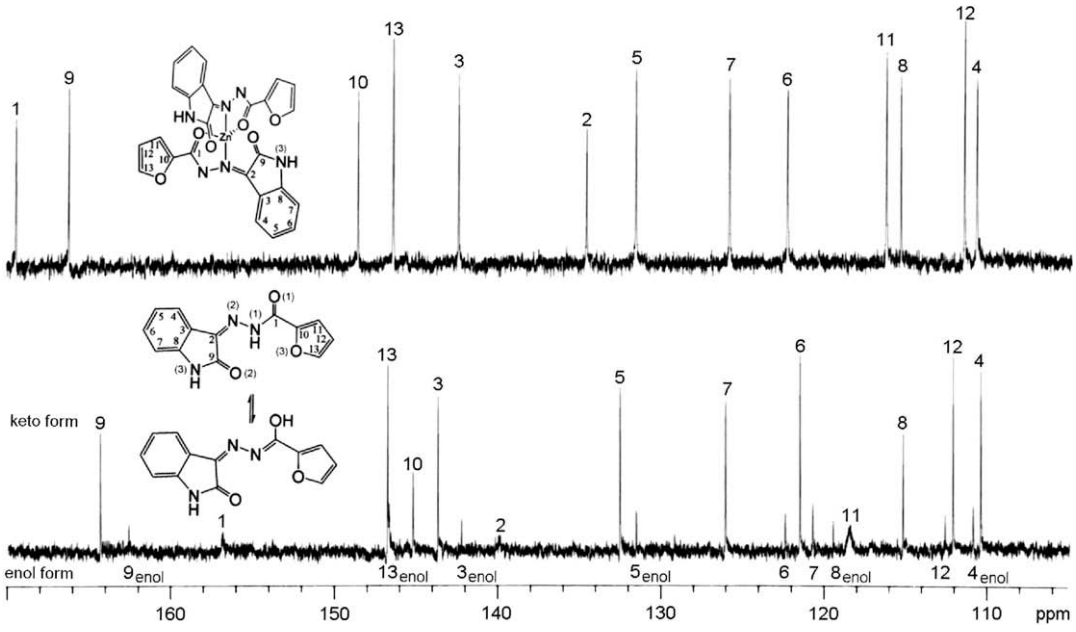

Fig. 3. ^{13}C NMR spectra of H_2L^2 (bottom) and $[Zn(HL^2)_2] \cdot 2H_2O$ (top) using DMSO-d_6 as solvent.

The comparative study of ^{13}C NMR spectra of zinc complexes and the corresponding free ligands allows us to conclude that the most affected C-signals by the complexation are those attributed to C1 (bonded to O1) and C2 (bonded to N2). In particular, C1 signal underwent a downfield shift (about 12.7 ppm) in $[Zn(HL^2)_2]\cdot 2H_2O$, while C2 signal underwent an upfield shift in the mentioned zinc complex of H_2L^2 (about 4.7 ppm). The remaining signals show shifts below 3.7 ppm, being about 2.1 ppm for C9 (bonded to O2). Based on this, the three ligands can be considered as O(1), N(2)-donors in their zinc(II) complexes, which is in agreement with that described for the molecular structure of $[Zn(HL^1)_2] \cdot 1.75$MeOH.

3.4. IR spectra

The IR spectra of the complexes showed very broad bands in the 4000–3000 cm^{-1} region, corresponding to the presence of solvent molecules (ethanol or/and water) associated through hydrogen bonds. For an accurate interpretation of the IR spectra of the Zn(II), Cu(II), Ni(II) and Co(II) complexes we used our previous reports on 3-(*N*-methyl)isatin-3-picolinoyl hydrazone [4] and 3-(*N*-methyl)isatin-2-thiophenecarbonyl hydrazone [5] complexes. Both ligands and their nickel(II) complexes were structurally characterised by X-ray diffraction. These Ni(II) complexes resulted to be octahedral (μ_{eff} = 3.1–3.2 BM) with the ligands behaving as κ^3-*O*,*N*,*O*.

In the IR spectra of all synthesised metal complexes the ν(CN) band of each ligand (1593–1609 cm^{-1}) was shifted up to 1604–1617 cm^{-1}. Additionally, a shift of the ν(CN) + δ(NH) band from 1511–1516 cm^{-1} (free ligands) up to 1517–1578 cm^{-1} was also observed. Both shifts, which include the effect provoked by the back-donation to the coordinated metal ions, express the participation of the hydrazone nitrogen atom in the coordination. The

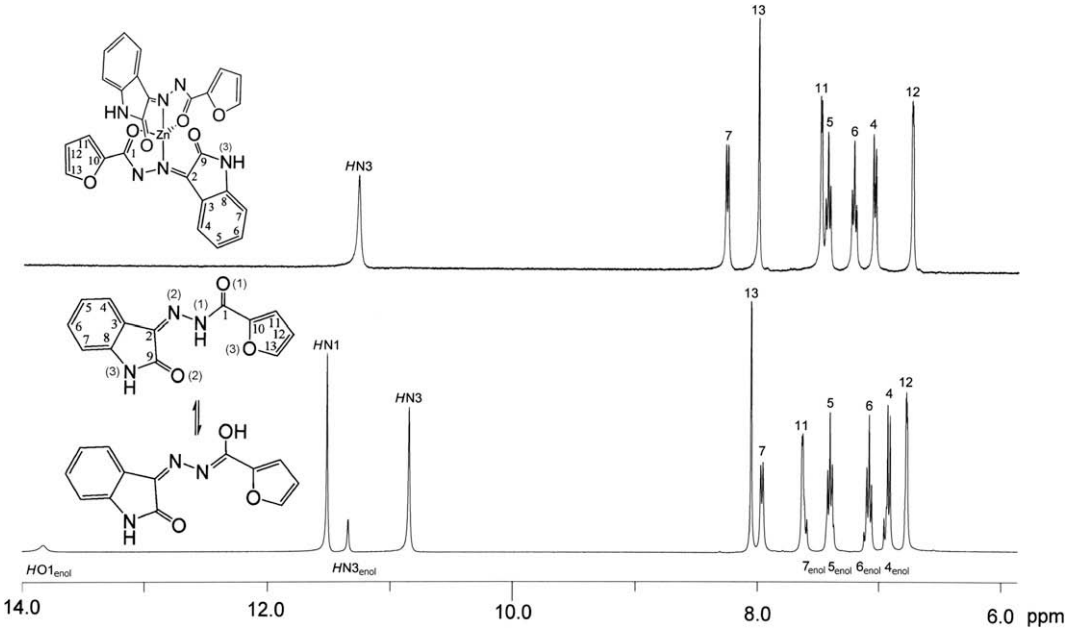

Fig. 4. ^{1}H NMR spectra of H_2L^2 (bottom) and $[Zn(HL^2)_2] \cdot 2H_2O$ (top) using DMSO-d_6 as solvent.

highest shifts were observed for the complexes of HL^3. Apparently, the methyl group substituted in the isatin ring of HL^3 provokes an electronic effect that acts contrary to the shift induced by coordination to the metal ion. Coincidently, the smallest shifts were also observed when comparing the ^{13}C NMR spectra of HL^3 and $[Zn(L^3)_2] \cdot 0.75H_2O$.

The ν(CO) band of the aliphatic carbonyl group was also analysed. The band shifted from 1732–1713 cm^{-1} (free ligands) down to 1703–1660 cm^{-1} in the complexes. Actually, two ν(CO) bands were recorded for the free ligands, with an extra one at 1678–1653 cm^{-1} since two carbonyl groups are present. The highest wavelength corresponds to aliphatic carbonyl and the lowest to the isatin carbonyl group. Upon coordination the band of this latter group overlaps with the shifted aliphatic carbonyl group band.

The three nickel(II) complexes presented the highest shift in the ν(CO) band, down to 1660–1665, a shift similar to that observed in the reported complexes with 3-(*N*-methyl)isatin-3-picolinoyl hydrazone [4] and 3-(*N*-methyl)isatin-2-thiophenecarbonyl hydrazone [5]. The nickel(II) complexes with these latter two ligands were reported to present an octahedral structure with the carbonyl isatin group also participating in the coordination, although less intensely than the aliphatic carbonyl group, according to X-ray structural analysis.

3.5. Magnetism and diffuse reflectance

The μ_{eff} values obtained for $[Ni(HL^1)_2] \cdot 0.5H_2O$, $[Ni(HL^2)_2] \cdot H_2O \cdot EtOH$ and $[Ni(L^3)_2] \cdot 0.5H_2O$ at room temperature, 3.1, 3.2 and 3.1 BM, respectively, correspond to octahedral geometries [5,13–15] with the ligands acting as κ^3-*O,N,O*, as already analysed from the IR spectra. Additionally, the diffuse reflectance spectra of $[Ni(HL^1)_2] \cdot 0.5H_2O$ (Fig. 5) and $[Ni(HL^2)_2] \cdot H_2O \cdot EtOH$ show two electronic transitions, ν_1 $[^3T_{2g}(F) \leftarrow {}^3A_{2g}(F)]$ and ν_2 $[^3T_{1g}(F) \leftarrow {}^3A_{2g}(F)]$, in the 1040–1090 and 625–690 nm ranges, respectively, characteristic for octahedral nickel(II) complexes. A similar spectrum was reported for the nickel(II) complex of 3-(*N*-methyl)isatin-2-thiophenecarbonyl hydrazone [5] with a doublet at 618 and 676 nm. This latter complex presented a octahedral distorted coordination environment with Ni–O distances at 2.059 and 2.236 Å [5]. In the $[Ni(HL^1)_2] \cdot 0.5H_2O$ spectrum (Fig. 5), the ν_2 absorption

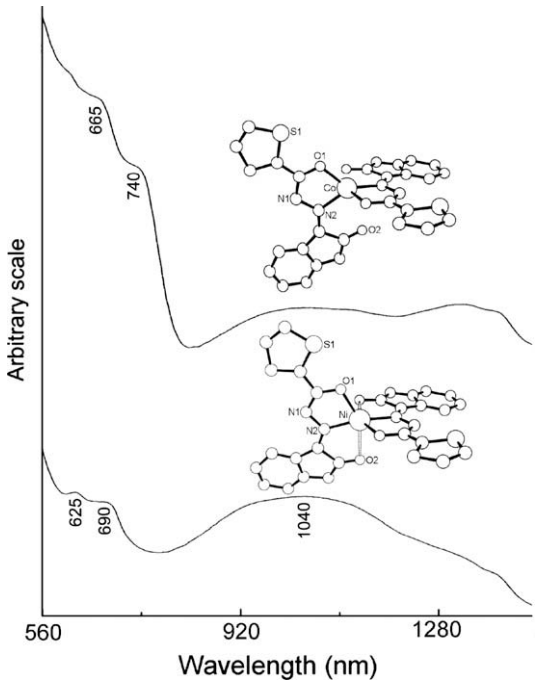

Fig. 5. Diffuse reflectance spectra (in the range 560–1460 nm) for two representative complexes $[Co(HL^1)_2] \cdot H_2O$ (top) and $[Ni(HL^1)_2] \cdot 0.5H_2O$ (bottom).

was also observed as a splitted band that can be attributed to the previously described distortion.

The μ_{eff} values of $[Co(HL^1)_2] \cdot H_2O$, $[Co(HL^2)_2] \cdot 1.5H_2O$ EtOH and $[Co(L^3)_2] \cdot 0.5H_2O$ (4.7, 4.6 and 4.6 BM, respectively) fall within the range characteristic for high spin tetrahedral cobalt(II) complexes. This is coherent with κ^3-*O,N* behaviour of the three ligands in their respective Co(II) complexes. The diffuse reflectance spectra of $[Co(HL^1)_2] \cdot H_2O$ (Fig. 5) and $[Co(L^3)_2] \cdot 0.5H_2O$ in the visible region presented the asymmetric ν_3 $^4T_1(P) \leftarrow {}^4A_2(F)$ band, characteristic of a Co(II) ion with tetrahedral geometry [5,13,16–18]. However, examination of the infrared region did not lead to an unequivocal

identification of the weak band associated with the ν_2 transition $^4T_1(F) \leftarrow {}^4A_2(F)$.

The absence of detectable bands in the 500–800 nm range for the diffuse reflectance spectrum of $[Cu(L^3)_2] \cdot 0.5H_2O$ (obscured by a strong charge-transfer band tailing) does not permit a structural proposition with certainty. However, the Jahn–Teller effect and the fact that the interaction between the metal centre and the O atom of the isatin residue is weak are arguments to dismiss a hexa-coordination. The magnetic moment values obtained for the copper(II) complexes with H_2L^1, H_2L^2 and HL^3 were 1.8, 1.9 and 2.1 BM, respectively. The relatively high value of $[Cu(L^3)_2] \cdot 0.5H_2O$ should be attributed to a distortion of the assumed square planar structure due to the steric effect induces by the methyl group substituted in the isatin ring.

3.6. Antimicrobial activity

The *in vitro* antimicrobial activity of H_2L^1, H_2L^2 and HL^3 and their metal complexes together with isatin and 2-furoic hydrazide (whose condensation gave H_2L^2), was assayed against representative Gram positive and Gram negative bacteria, yeasts and moulds (Table 6). It must be noted that the antimicrobial activity of the remaining starting compounds (*N*-methyl isatin and 2-thiophenecarboxilic acid hydrazide as well as the metal salts used in this work) has been previously reported [5] presenting low activity against the studied strains (except Zn(II) salts versus *H. influenzae*) [5]. Therefore, the values reported in Table 6 should be attributed mainly to the undissociated complexes. Moreover, dimethyl sulfoxide used as solvent did not influence the growth of the tested microorganisms.

3.6.1. Antibacterial activity

Several of the tested compounds inhibit the growth of the Gram positive bacteria listed in Table 6. Among these particular substances, $[Zn(HL^1)_2] \cdot EtOH$ and $[Zn(L^3)_2] \cdot 0.75\ H_2O$ inhibit the growth of *B. subtilis* at 25 μg/mL while $[Cu(HL^1)_2] \cdot 2.5H_2O$, $[Ni(HL^1)_2] \cdot 0.5H_2O$, $[Co(HL^1)_2] \cdot H_2O$, $[Ni(L^3)_2] \cdot 0.5H_2O$ and $[Co(L^3)_2] \cdot 0.5H_2O$ show a smaller effectiveness (MIC 50 μg/mL) against the cited microorganism. $[Zn(HL^1)_2] \cdot EtOH$ is also the most effective compound against *S. aureus* (MIC 50 μg/mL).

The compounds exhibiting MIC values $\leqslant$ 50 μg/mL against *B. subtilis* or *S. aureus* were tested against a wide variety of Gram positive bacteria including methicillin-resistant strains of *S. aureus* and *S. epidermidis*. MIC values reported in Table 7 show that complexes of H_2L^1 are effective towards almost all the tested microorganisms (MICs 12–100 μg/mL), while the effectiveness of complexes of HL^3 generally is limited to bacilli and can be qualified as modest.

Remarkably, all free ligands and their metal complexes proved to be effective in controlling the growth of Gram negative *H. influenzae* a very harmful bacterium to humans (Table 6) being the most potent agents H_2L^1 and its complexes (MICs 1.5–3 μg/mL). So, among all the tested microorganisms, *H. influenzae* appears to be the most sensitive strain. On the contrary, a poor inhibition of Gram negative *E. coli* was observed.

Ligands and complexes active against *H. influenzae* (MIC $\leqslant$ 50 μg/mL) were tested against other Gram negative bacteria as *E. cloacae*, *K. pneumoniae*, *P. mirabilis*, *P. vulgaris*, *P. aeruginosa*, *S. typhimurium* and *S. marcescens*. Only a moderate degree of inhibition against *P. vulgaris* for $[Zn(HL^1)_2] \cdot EtOH$ and $[Ni(HL^1)_2] \cdot 0.5H_2O$ at 50 μg/mL and for $[Cu(HL^1)_2] \cdot 2.5H_2O$ at 100 μg/mL was observed, whereas both ligands H_2L^1 and HL^3 and complexes $[Zn(HL^2)_2] \cdot 2H_2O$ and $[Co(L^3)_2] \cdot 0.5H_2O$ were active at 200 μg/mL.

All the active compounds exhibited bacteriostatic properties, as it is deduced from their MBC values higher than the corresponding MICs (Tables 6 and 7).

3.6.2. Antifungal activity

Of all the compounds assayed against *S. cerevisiae*, *C. tropicalis* and *A. niger* (Table 6) only $[Co(HL^1)_2] \cdot H_2O$ showed antifungal properties against the first one (MIC 100 μg/mL). MFC value higher than 200 μg/mL evidenced fungistatic activity.

To more extensively investigate the spectrum of its antifungal activity, we tested a higher number of yeasts and moulds including some dermatophytes and phytopathogenic fungi cited in epigraph 2.3. As a result, a moderate inhibitory activity was detected towards the assayed dermatophyte fungi *E. floccosum* (MIC 12 μg/mL), *T. mentagrophytes* (MIC 25 μg/mL) and *M. gypseum* (MIC 50 μg/mL), as well as towards the phytopathogenic fungi *A. tenuis* (MIC 50 μg/mL), *Botrytis cinerea* (MIC 100 μg/mL) and *S. minor* (MIC 200 μg/mL).

4. Conclusions

Three new acylhydrazone ligands and their metal complexes, $[M(L)_2] \cdot n$X, were synthesised and characterised. The X-ray molecular structure of HL^3 showed that this ligand crystallised in the keto form, which was also the more abundant tautomer for the three ligands in solution. Physicochemical studies allow to said that the three acylhydrazones coordinated as monoanionic *O*,*N*-donors to cobalt(II) and zinc(II) ions, which are tetracoordinated. In $[Zn(HL^1)_2] \cdot 1.75MeOH$ secondary interactions of the O atoms of each isatin residue with zinc(II) provokes a substantial distortion of the pseudo-tetrahedral geometry. For the nickel(II) complexes, carbonyl isatin groups of the three ligands coordinate strongly enough to consider them presenting a *O*,*N*,*O*-donor behaviour to give a distorted octahedral geometry.

The free ligands and their complexes were evaluated *in vitro* as antimicrobial agents against a panel of Gram positive and Gram negative bacteria, as well as yeasts and moulds. Among the tested microorganisms, *H. influenzae* appears to be the most sensitive strain. H_2L^1 and its metal complexes were active against Gram positive bacteria such as *B. subtilis* methicillin-susceptible and methicillin-resistant as well as *S. aureus*, being $[Zn(HL^1)_2] \cdot EtOH$, the most active compound. It must be emphasised that the studied metal complexes were more active than the free ligands and metal salts [5]. Moreover, $[Co(HL^1)_2] \cdot H_2O$ showed antifungal properties against dermatophytes and some phytopathogenic fungi.

Supplementary data

CCDC 662397 and 708535 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

This paper represents the hydrothermal synthesis of new isomorphous lanthanide–vanadium complexes with one-dimensional coordination polymers: $[Pr_2(VO_2)_2(dipic)_4(H_2O)_9] \cdot nH_2O$ with dipic = pyridine-2,6-dicarboxylic acid and $n = 7.75$. The structure determination shows a unique one-dimensional structure in which three types of chains run along the *c*-axis: the chain of positively charged praseodymium complexes bridged by a dipic ligand ($[Pr(dipic)(H_2O)_5]^+$), the chain of negatively charged, stacked vanadium complexes ($[VO_2(dipic)]^-$), and the chain of neutral praseodymium complexes with a bridged dipic ligand and a coordinating dipic ligand ($[Pr(dipic)[VO_2(dipic)](H_2O)_4]$). Such one-dimensional chains provide open channels which can accommodate water molecules. Not only accommodated water molecules but also ones coordinated to praseodymium ions were easily removed and absorbed upon heating at 200 °C and exposure of humidity at room temperature, respectively.

1. Introduction

The synthesis and assembly of metal–organic frameworks (MOFs) through coordination of metal ions with multifunctional organic ligands are one of the current interests as a new class of porous materials [1–4]. The interests in these materials span from purely academic aspects of chemistry and physics to applications such as separation, catalysis, and potential fuel gas storage [5–9].

A large number of the works have so far been done on the coordination polymers containing transition metals because of their well-defined coordination geometries which can make an artificial design of MOFs easy. On the other hand, the use of lanthanide elements for constructing MOFs is usually unsuitable and hard to control the coordination geometries of MOFs due to their high coordination numbers. Nevertheless, owing to important magnetic and luminescence properties of lanthanide elements, a growing development in the field of MOFs containing lanthanide ions have provided the wide applications of light conversion molecular devices based on a charge transfer type luminescence from antenna ligands to central lanthanide ions [10–40]. However, in most of them, only lanthanide ions are employed to construct efficient MOF structures. Incorporation of 3d transition elements into a MOF structure, thus creation of 3d–4f metal-based MOF structure, may provide us a great opportunity for constructing desirable architectures of the MOF assisted by the combination of flexible coordination manners of lanthanide ions and stereochemical preference coordination ones of transition metal ions. A few examples have been reported for 3d–4f metal-based MOFs with a 3D nanotubular coordination polymer and a 1D channel coordination polymer [14,22,26,35,38–40].

Since lanthanide ions have a high affinity for hard donor atoms and ligands such as oxygen or hybrid oxygen–nitrogen atoms, pyridine-2,6-dicarboxylic acid (dipic) which has been frequently employed in the architectures for lanthanide coordination polymers is adopted in this study as a multicarboxylate ligand. Among the 3d–4f metal-based MOFs reported so far, 3d-transition ions such as Cu^{2+}, Fe^{2+}, Mn^{2+}, and Ni^{2+} were widely used in order to build metal centers as nodes in the MOF frameworks. Vanadium(V) has a preference for tetrahedral and square-pyramidal coordination against oxygen atoms, implying a possibility to act as a multi-connected metal node in the 3D frameworks. In spite of the fact, vanadium ions have been little employed in the construction of MOFs. Here, we report a series of one-dimensional coordination polymers consisting of praseodymium(III) and vanadium(V) complexes with dipic. To our knowledge, these are the first example of 3d–4f metal-based coordination polymers containing vanadium as a 3d transition ion.

2. Experimental

2.1. Characterization

Qualitative and quantitative chemical analyses for the single crystal were undertaken by an electron probe microanalysis (EPMA) using a Shimadzu EPMA-8705. Elemental analyses for C, H, and N were carried out using Flash EA1112 microanalyzer. Thermogravimetric analysis (TG) and differential thermal analysis (DTA) were carried out at a heating rate of 5 °C min^{-1} in air using a Seiko Denshi TG-DTA 6300. The IR spectra were recorded on a Shimadzu FT-IR 4200 spectrometer using KBr disk. Magnetic susceptibility data were collected on a powdered sample with use of a SQUID magnetometer on a Quantum Design MPMS-5S. Data were corrected for diamagnetism of the ligands estimated from Pascal's constants [41].

2.2. Synthesis

$[Pr_2(VO_2)_2(dipic)_4(H_2O)_9]\cdot nH_2O$ was hydrothermally synthesized at 150 °C for 72 h in a 40 mL Teflon-lined steel autoclave under autogenous pressure. The starting solution was prepared by mixing Pr_6O_{11} (0.5 mmol), pyridine-2,6-dicarboxylate (3 mmol), V_2O_5 (1.5 mmol), and deionized water with a molar ratio of 2:1:2:1:555 (total volume, 15 mL), and its pH value was adjusted to 3.05 by hydrochloric acid. After the hydrothermal reaction, the autoclave was slowly cooled to room temperature, and plate-like crystals were produced. The yield of the compound was about 70 mol% per Pr. *Anal.* Calc. for $C_{28}H_{45.5}N_4O_{36.75}Pr_2V_2$: C, 23.85; H, 3.25; N, 3.97%. Found: C, 23.55; H, 3.15; N, 3.3%. Heavy atoms ratio by EPMA: Pr:V = 1.0:0.99.

2.3. Structural determination

Crystallographic data of the compound were collected on a Rigaku RAXIS-RAPID single crystal diffractometer equipped with an imaging plate area detector with graphite monochromated Mo Kα radiation with $\lambda = 0.71073$ Å at a temperature of 93 K. The data processing was accomplished with the Crystal Structure processing program [24]. The structure was solved by direct methods using the program SIR97 [42] and refined by full-matrix least-squares techniques against F^2 using the SHELXTL-97 crystallographic software package [43]. All non-H atoms were easily found from the difference Fourier map and refined anisotropically. The hydrogen atoms on the dipic molecules were positioned geometrically and included in the refinement as riding, whereas the hydrogen atoms on the water molecules coordinated to praseodymium ions were first geometrically fixed so that the distance of O–H in water molecules was 0.85 Å, and then in the final refinement stages were refined isotropically without constraint. On the other hand, some of hydrogen atoms on solvent-like water molecules, several oxygen atoms of which were highly disordered, were unassigned.

3. Results and discussion

The formula, $[Pr_2(VO_2)_2(dipic)_4(H_2O)_9]\cdot 7.75H_2O$, is deduced from the structural determination of single crystal, the elemental analyses, and the TG measurement. Magnetic susceptibilities of the compound were also measured in the temperature range from 5 to 300 K. The $\chi_M T$ value is equal to 3.15 $cm^3\,K\,mol^{-1}$ at room temperature, which is fairly agreement with its expected value (3.20) per chemical formulae deduced from the assumption of Pr^{3+} ion with $^3H_4$ ground state and V^{5+} ion (d^0).

3.1. Description of the crystal structure of $[Pr_2(VO_2)_2(dipic)_4(H_2O)_9]\cdot nH_2O$

Crystal data, intensity measurements, and structure refinements are summarized in Table 1. Selected bond distances are listed in Table 2. The hydrogen bonds parameters which could be assigned are shown in Table 3.

The asymmetric unit for the compound is shown in Fig. 1. There are two types of praseodymium ions. Not as understood directly by insight from Fig. 1, both of Pr1 and Pr2 have a nine-folded coordination environment. Pr1 is coordinated by two carboxylic oxygen atoms and a nitrogen atom of a dipic molecule with tridentate coordination, one of carboxylic oxygen atoms of another dipic molecule with bridging coordination, four water molecules, and finally one of oxygen atoms of a dioxovanadyl group, thus forming the nine-folded coordination environment. The coordination environment around Pr2 is almost the same as that around Pr1 except for an additional coordination of a water molecule instead of one of oxygen atoms of a dioxovanadyl group. The Pr–O(carboxylic) bond distances ranging from 2.492 to 2.497 Å for Pr1 and from 2.500 to 2.514 Å for Pr2, the Pr–N(pyridinic) bond distances of 2.594 Å for Pr1 and 2.566 Å for Pr(2), and Pr–O(water) bond distances ranging from 2.497 to 2.573 Å for Pr1 and from 2.477 to 2.532 Å for Pr2 are all comparable to those reported previously. The polyhedron of both praseodymium coordination spheres for the compound may be best described as a distorted tricapped trigonal prism, but the distortion is so remarkable. There are also two kinds of vanadium atoms in the compound. The asymmetric unit also contains two crystallographically independent vanadium atoms. V1 is a five-folded coordination by two oxo ligands and the tridentate ligand of a dipic molecule. The oxo ligands (O31 and O32) of V1 have two distinct bond distances to V1: one is a longer distance of 1.638 Å for V1–O31 which takes part in the coordination to Pr1, the other a shorter distance of 1.614 Å for V1–O32 which seems to participate in hydrogen bonding to O14W (Table 3). The situation in the coordination around V2 is somewhat different from to that around V1 because of no coordination to praseodymium central ions. The longer distance (1.626 Å) found for the O42–V2 bond is indicative for participation of hydrogen bonding although the bond was not able to be identified in the crystal structure refinement, and the short one (1.608 Å) found for the O41–V2 bond indicates the existence of V=O bond. The bond lengths and angles found in the compound are primarily similar to those observed for $[VO_2(dipic)]$ motifs previously reported [44,45]. The structure refinement finally satisfied showed 7.75 mol of water molecule in the asymmetric unit in spite of the fact that the TG measurement suggested an existence of approximately eight water molecules, as discussed in later. These water molecules are classified into two groups; one is the molecules coordinating praseodymium ions (O11W, O12W, O13W, and O14W for Pr1, and O21W, O22W, O23W, O24W, and O15W for Pr2, respectively) and the other the molecules isolated as a water of crystallization, some oxygen atoms of which are highly disordered.

The structural architecture constructed in the compound is one-dimensional, consisting of three types of chains, all running along the *c-axis* (Fig. 2). In the first type of chains containing Pr2 (Fig. 2a), a dipic molecule plays two roles; one acts as a tridentate ligand for praseodymium, the other as a bridging one for adjacent praseodymium ions through one of oxygen atoms of a carboxylic group. The $[VO_2(dipic)]$ motif of V1 is connected, as a pendant arm, with Pr1 of this chain via one of its oxo group. Formally, the chain is neutral, expressed as $[Pr(dipic)[VO_2(dipic)](H_2O)_4]$. The fundamental structure of the second type of chains containing Pr, as shown in Fig. 3b, is substantially the same as that of the first type except for no existence of $[VO_2(dipic)]$ motif, which is replaced by a water molecule. The principal unit of the chain is pos-

itively charged, expressed as $[Pr(dipic)(H_2O)_5]^+$. The third type only consisting of the $[VO_2(dipic)]^-$ units formally negatively charged is, strictly speaking, not a chain but a kind of stacking sequence of the units (Fig. 3c). The pyridine rings of dipic molecules are stacked with a decline angle of 34.7° against (001) plane. The driving force of occurrence of the stacking sequence seems to be resulted from hydrogen bonding between oxygen atoms of the oxo group and water molecules of crystallization [11,16,19,23,31,34] although the hydrogen bonding was not fully specified. Totally, the assembly of three kinds of chains running along the *c-axis* makes open cannels, where a large amount of water molecules are populated, as shown in Fig. 3.

3.2. Thermal stability

The thermal stability of the compound has been investigated using TG and powder X-ray diffraction measurements (Figs. 4 and 5). The TG, performed from room temperature to 800 °C, shows two types of major weight losses in this temperature range.

[b] x, −y + 3/2, z − 1/2.

The first weight loss initiated at about 40 °C, accompanied with endothermic heats, implying the elimination of water molecules. With a careful insight, one can observed two step weight loss processes for this region. The first step accompanying a weight loss of 10.1 wt% corresponds to the loss of eight water molecules, and the second step (12.8 wt%) corresponds to the loss of nine water molecules. On the basis of the crystal structure of the compound, it could be concluded that the first step is responsible for the elimination of the guest water molecules populated in the channel while the second step is responsible for the elimination of water molecules coordinated to praseodymium ions. On the hand, the high temperature weight loss with an initiation temperature of about 350 °C involves a complicated multi-step process. Since these steps accompany exothermic heats, this weight loss may be attributed from the elimination due to the combustion of four dipic molecules. The observed weight loss is 50.3 wt%, fairly con-

sistent with the calculated one (53.8 wt%). The powder XRD studies were performed for the as-synthesized sample, the sample heated at 200 °C for 3 h, and the samples obtained after the heated sample was kept upon exposure of 100% relative humidity for 24 h (Fig. 5). The crystalline compound becomes amorphous upon the release of water molecules by heating it at 200 °C. Such an amorphous material, however, recover its crystal structure upon the exposure of water vapor at room temperature, as shown in Fig. 5c. This result implies that the amorphous phase still has micro-porous frameworks for accommodation of water molecules. In fact, the sample which absorbs water molecules and recovers its crystal frame-

works exhibits almost the same thermal behavior in the TG measurement as that of the as-grown crystal (Fig. 6).

4. Conclusion

One-dimensional coordination polymers based on 3d–4f metal-based MOFs have been synthesized under a hydrothermal condition. XRD analysis reveals that it is crystallized in an orthorhombic crystal system. The compounds are constructed from three kinds of continuous chains, which provide open channels in the interstitials among them. Guest water molecules accommodated in the channels can be easily removed and absorbed upon heating and exposure of humidity, respectively.

ABSTRACT

Complexation of Mg^{2+}, Ca^{2+}, Zn^{2+} and Cu^{2+} with alizarin, characterized by NMR and theoretical studies (DFT, B3LYP/6-31G(*d,p*) PCM and NMR GIAO B3LYP/IGLOIII), indicated that the metal ion is attached to two hydroxyl groups in a bidentate mode. The alternative complexation in the bidentate mode, with only one hydroxyl group and a carbonyl oxygen, is less possible as it has a higher energy.

1. Introduction

Anthraquinones are one of the most important natural compounds which are applied widely in medicine as drugs [1] and antineoplastic agents [2], in industry as dyes and dye-related compounds [3], in environmentally friendly synthesis of hydrogen peroxide [4], as analytical reagents, indicators and in many other areas [5–7]. One of the most well known anthraquinones is alizarin (1,2-dihydroxy-9,10-anthraquinone) which can be isolated from plants, for example from *Radix Rubiae tinctorum* L. Its crucial feature is a strong ability to chelate ions such as calcium, zinc, magnesium and copper. Alizarin is also believed to be responsible for the biological activity of *Rubia tinctorum* extracts in nephrolithiasis, since kidney stones are composed mostly of calcium and magnesium salts [8].

On the other hand the above mentioned ions are common in biological structures. They activate chemical bonds making them more suitable to undergo various chemical reactions [9]. Calcium is a major bone component and plays an important role in transferring signals in many biochemical routes, for example the sight process or muscular contraction. Zinc activates many essential enzymes, such as alcohol dehydrogenase or the digestive enzyme carboxypeptidase, by creating a complex with the active site. The zinc ion is also an important structural component in proteins involved in nucleic acid binding [10]. Magnesium stimulates the first factor of chlorophyll photosynthesis, it is also needed to prompt the ATP moiety or DNA polymerase. The copper ion plays a role in oxidation processes [11].

Nuclear Magnetic Resonance (NMR) is a useful technique for studying the structure of chemical and biological systems, from small molecules to complicated structures such as nucleic acids and proteins. Chemical shifts and spin–spin coupling serve to recognize the molecular conformation, composition and environment of the moiety. However, the investigation and understanding of the relationships between molecular structure and measured NMR parameters can sometimes be quite difficult, and need the support of theoretical calculations.

In this work we describe the studies of alizarin and its metal complexes using the NMR technique and theoretical DFT calculations.

2. Experimental and computations details

NMR experiments were performed on commercially available alizarin and metal salts (Fluka®). In the NMR studies, the alizarin was dissolved in DMSO-d_6 at a concentration of 30 mg/6.00 ml of solvent and concentration of metal 0.195, 0.168, 0.212, 0.223 mol/dm^3 ($Mg(NO_3)_2 \cdot 6H_2O$, $Zn(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$, $Cu(NO_3)_2 \cdot 2H_2O$). The solvent was supplied from Dr Glaser AG (Basel, Switzerland). The NMR spectra were recorded at room temperature on a Bruker Avance DRX300 instrument, operating at 300.13 MHz for 1H nuclei and 75.46 MHz for 13C nuclei. The NMR spectra at the temperatures 293, 313, 333 and 353 K for the solution of alizarin and the zinc salt were recorded on a Bruker Avance AMX600 instrument operating at 600.58 MHz for 1H nuclei. Proton decoupling was achieved by power gated decoupling using

doi:10.1016/j.poly.2009.01.046

the Waltz 16 sequence. The spectra were referenced to the solvent line of DMSO (δH = 2.50 ppm quintuplet, δC = 39.43 ppm septuplet) as internal standards. NMR spectra were analyzed using the MestreC program [12].

In the theoretical study of the structure of the complex, Becke's three parameters functional approach with the Vosko et al. local correlation part and the Lee et al. non-local part, abbreviated as B3LYP, was applied [13]. The calculations of geometry were performed using the standard 6-31G(*d*,*p*) basis set [14]. The effect of the solvent of the calculated structures has been taken into account with Barone and Cossi's implementation [15]. The polarizable conductor model (CPCM) continuum solvatation method with Klamt's [16] and explicit from 4 to 6 water molecules and five DMSO molecules was applied. The NMR parameters were calculated using the coupled perturbed density functional theory (CP-DFT) method with the B3LYP functional by including the diamagnetic spin–orbit, paramagnetic spin–orbit, Fermi-contact and spin-dipolar terms [17]. This functional is believed to be in a good agreement with experimental data [18]. A IGLO III base [19] was applied to the calculations of the NMR properties for carbon, hydrogen and oxygen atoms and a standard base 6-31G(*d*) for the zinc atom. The same solvent models as employed for the geometry optimization were used in the calculation of the scalar coupling. The computations were carried out using the Gaussian 03 suite of codes [20], and the results were visualized by applying the ChemCraft package [21].

3. Results and discussions

Alizarin (1,2-dihydroxy-9,10-anthraquinone) is the one of the most popular hydroxyanthraquinones and is often selected as a model system Fig. 1.

The effect of complexation of alizarin has been studied by various techniques, such as IR, UV–Vis, NMR, MS and theoretical modelling [22–26]. Alizarin has favourable donor-centers, namely oxygen atoms from carbonyl (C=O) and hydroxyl (OH) groups [22]. They create good binding sites for divalent cations. In aqueous solution (physiological conditions), metal cations are always present in the hydrated form. The number of water molecules in the hydratation sphere of the cations amounts to 12 ± 2 water molecules for Ca^{2+} and 13 ± 2 for Mg^{2+} [27]. The most important water molecules create the first solvatation sphere and this corresponds to the coordinate number of the metal. The typical coordination number for Ca^{2+}, Mg^{2+}, Zn^{2+} and Cu^{2+} is six [9,28]. A good model for complexes of anthraquinone with metal cations must always include the hydration shell of the metal cation [29]. The hydrated metal cation may interact with the anthraquinone via its outer shell (Fig. 2a), inner shell and in bidentate fashions (Fig. 2b and c).

Our calculations have shown that the bidentate binding form is the preferred structure of alizarin complexes with metal ions (Fig. 2b and c). The one of the two structures, which is lower in energy, is seen on coordination to calcium metal (Fig. 2c). This result correlates with the conclusion about the structure of the complex proposed by Brewer [25]. The energy difference between structures b and c equals 0.85 kcal/mol (Fig. 2) for the alizarin complex with Mg^{2+}, 3.82 kcal/mol for the complex with Ca^{2+}, and 1.62 kcal/mol for the complex with Zn^{2+}. The stability of the structure shown in Fig. 2c is strengthened due to the formation of strong hydrogen bonding O–H···O=C, which is manifested by the shorter H···O distance (in the case of the calcium complex it equals 1.6 and 1.9 Å for the structures in Fig. 2c and b, respectively). In water solution at various pH values there are possibilities of other interactions to the ones analyzed above, for example the metal ion can interact with $MeOH^+$, $Me(OH)_2$ and the ligand as anthraquinone$^-$ or antraquinone-H^+. Such interactions, however, are not analyzed in this paper.

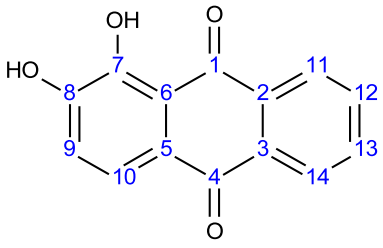

Fig. 1. The alizarin structure with the carbon atoms numbering.

The interaction between the anthraquinone and the metal may be manifested in some changes of geometry and the magnetic properties of anthraquinone. By our calculations we have found that the planarity of alizarin is not disturbed after complexation to the metal. The root mean square deviation (RMSD) from planarity for the carbon, oxygen and aromatic-hydrogen atoms is very small (in the range of 0.03 Å). However the interaction between the anthraquinone and the metal is expected to influence the chemical shifts of the nearby atoms. This change can be observed by ^{1}H NMR and ^{13}C{^{1}H} NMR techniques. (Figs. 3 and 4 and Table 1).

The ^{1}H NMR spectra for alizarin alone, and with $Mg(NO_3)_2$, $Ca(NO_3)_2$ and $Zn(NO_3)_2$ in DMSO-d_6, and the ^{1}H NMR spectra for alizarin with $Zn(NO_3)_2$ at various temperatures show small differences, lower than 0.13 ppm (Table 1), between the chemical shift for the pure and complexed alizarin. The changes of the chemical shift for the ^{13}C{^{1}H} NMR spectra are lower than 0.54 ppm. In all cases the addition of the metal salt to the solution results in upfield shifts. However there is a big change in the shape of the ^{1}H NMR signal (Figs. 3 and 4). The two hydroxyl hydrogen signals for alizarin dissolved in DMSO are wide, indicating their dynamics. The signal further to the left (12.56 ppm) was identified as the one attached to the hydroxyl group at C7. Our calculations have also shown that it should be shifted upfield with respect to the hydrogen atom of hydroxyl group at C8. When the complex is being formed, the hydrogen of the hydroxyl group at C7 becomes significantly narrowed whereas the hydrogen atom attached to the hydroxyl group at C8 becomes even wider than that in alizarin. This occures for the complexes with magnesium and zinc. In the case of the complex with calcium, the signal from the hydrogen atom of hydroxyl group at C8 is slightly narrowed but to a much smaller extent than the other one. The spectrum of the complex with copper shows very wide signals due to the paramagnetic nature of that metal. The aromatic region and proton H7 are visible in the ^{1}H NMR spectrum as broad signals and the signal from the H8 proton has disappeared, as in the case of the other complexes.

The interpretation of the above observation is as follows. Formation of the complex of alizarin with the metal in a fashion shown in Fig. 2c, i.e. by the oxygens from both hydroxyl groups, should result in weaker binding of the corresponding hydroxyl hydrogen atoms to the corresponding oxygen atoms. In fact the calculated O–H distance of the hydroxyl group is the shortest one (0.968) Å and it does not take part in the interaction with the metal ion attached to the C8 carbon atom, which is shown in structure Fig. 2a. In the structures presented in Fig. 2b and c, the distance becomes equal, 0.970 Å. Due to the above effect, the signals of the hydroxyl hydrogens atoms in the NMR spectra should be wider as they are dynamically less restricted. However the hydrogen attached to the hydroxyl group at C7 becomes trapped by the carbonyl oxygen. This effect is confirmed by the calculations which indicate the shortening of the H···O distance and lengthening of the O–H distance in the O–H···O fragment. In the presented magnesium complex (Fig. 2) the (C7)O–H distances equal 0.974, 0.997 and 1.017 Å and the (C7)OH···O distances equal 2.025,

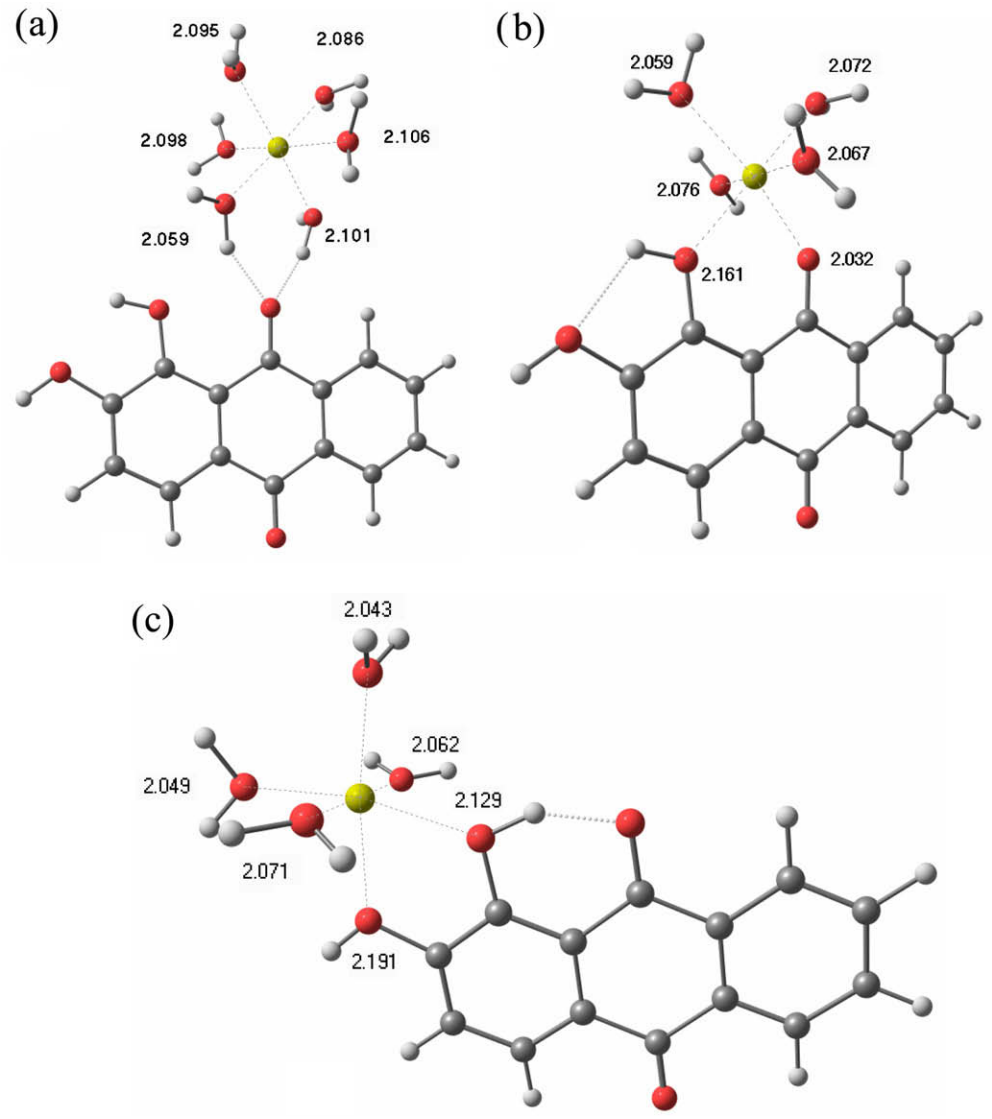

Fig. 2. Binding modes of Mg^{2+} cations to alizarine. The presented structures were optimized at the B3LYP/6-31G(*d*,*p*) level of theory with the PCM solvent model. (a) Outer-shell binding; (b) bidentate binding to oxygens from carbonyl and hydroxyl groups; (c) bidentate binding to oxygen from both hydroxyl groups.

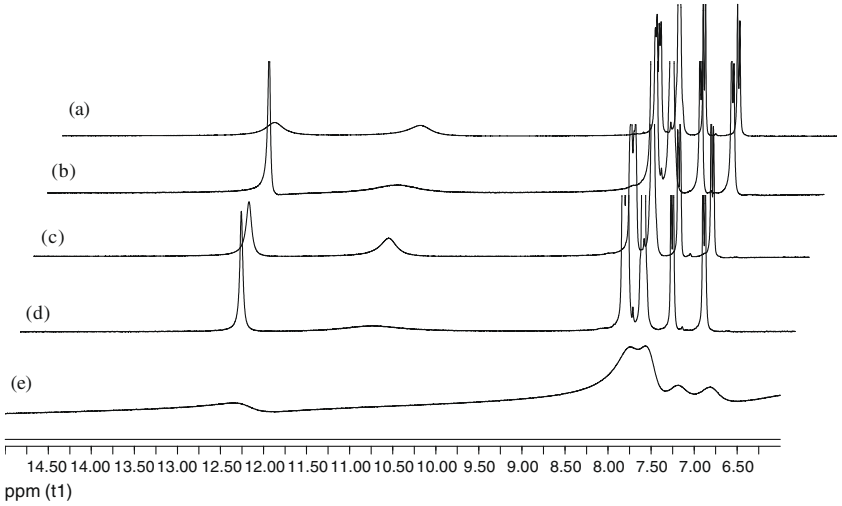

Fig. 3. The ^1H NMR spectra in DMSO-d_6 for (a) alizarin, (b) alizarin with $Mg(NO_3)_2$, (c) alizarin with $Ca(NO_3)_2$, (d) alizarin with $Zn(NO_3)_2$, (e) alizarin with $Cu(NO_3)_2$.

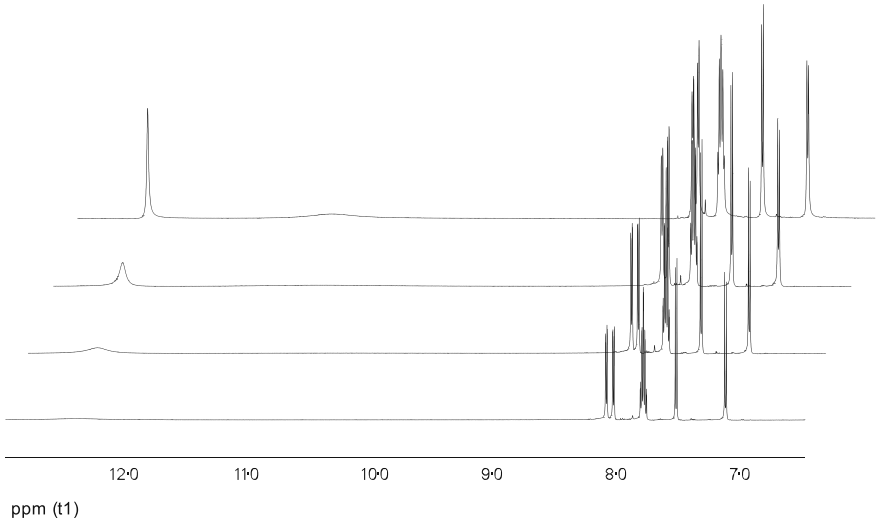

Fig. 4. The ^{1}H NMR spectra of alizarin and $Zn(NO_3)_2$ in DMSO-d_6 recorded at various temperatures (293, 313, 333 and 353 K).

Δ Indicates the difference in chemical shift between non-complexed and complexed alizarin.
Error Indicates the predicted relative percentage error theoretical versus experimental.
* The final assignment is based on the analysis of the data from theoretical calculations.
** The experimental chemical shift difference between NMR signals for alizarin and its complex and the calculated chemical shift difference between NMR signals for alizarin and its complex.
*** The structure C is analogous to the structure presented in Fig. 2c but with the zinc ion, B corresponds to Fig. 2b, also with zinc ion.

1.971 and 1.578 Å, respectively for the structures presented in Fig. 2a–c.

It finally results in restricting the freedom of the hydrogen atom at the C7 hydroxyl group and narrowing its signal in the ^{1}H NMR spectra. The phenomena described above confirms the mode of binding in the way shown in Fig. 2c, but it neglects other modes of binding.

Dimethyl sulfoxide is a strong aprotic donor solvent and it can efficiently intersolvate the d-element ions of Cu^{2+} and Zn^{2+}. The considered interaction between the metal and the DMSO molecule is: $M^{2+}\cdots O{=}S(CH_3)_2$. Models of this same interaction between the ion and solvent were researched by El-Nahas [30]. The calculation of the model with DMSO gives similar results to that where water molecules are used as the solvent. The structures for the DMSO model are presented in the Supplementary data.

Heating a mixture of alizarin with $Zn(NO_3)_2$ in DMSO (from 20 to 80 °C) results in widening of the signals corresponding to both hydrogen atoms attached to hydroxyl group, since at the elevated temperatures the dynamics of these hydrogen atoms increase. (Fig. 4) The above experiment additionally supports our previous conclusion.

Theoretically, the calculated chemical shifts strongly correlate with the calculated values. For most of the hydrogens the predicted error is within the 4–8% range and for carbon atoms it is lower than 11%. The highest value of predicted error for the proton signal of H8 (from the hydroxyl group) is 34%. The calculation of the

chemical shift for structures DB and DC (supplementary material) with the explicit influence of the –O–H8···O (solvent) hydrogen bond gives more appropriate results. The experimental chemical shift of H8 for alizarin is 10.86 ppm, and the theoretical value is 7.20 ppm, in structures DC and DB it is 11.85 and 12.47 ppm, respectively. The tendency of most experimental ($\Delta\delta$) and theoretical ($\Delta\delta^{theor}$) chemical shift differences between complexed and non-complexed alizarin is the same and it is of a positive value (Table 1). The structure of the complexes which correlates in the best way with the theoretical and experimental data is the structure in which the metal interacts in a bidentate mode to both oxygen atoms from hydroxyl groups (Fig. 1c).

4. Conclusions

Alizarin acts as a bidendate ligand on forming complexes with metal ions. From the possible structures, the one with the metal attached to two hydroxyl oxygen atoms is of lower energy. A theoretical calculation of the structure of the complex and NMR parameter analysis lead to the same conclusion.

In the ^{1}H NMR and ^{13}C{^{1}H} NMR spectra, the chemical shift difference between the free ligand and the ligand complexed to metal is too small and is not useful in studies of the mode of complexation. However the change of the shape of the signals from the hydroxyl group (O–H) is informative.

Acknowledgement

The authors thank Dr. Vladimir Synchrovsky from UCB Prague for a discussion about the solvatation model. We would also like to thank the Poznań and Wroclaw Supercomputing and Networking Centers and Academic Computer Centre in Gdansk for a generous allotment of computer time.

ABSTRACT

We have studied the effect of the substituent position in the ring, and lithium, sodium and potassium ions on the electronic structure of *o*-, *m*- and *p*-methoxybenzoic acids (anisic acids) by the use of FT-IR, FT-Raman, Ar matrix FT-IR and ^{1}H NMR methods, and *ab initio* calculations at the B3LYP/6-311++G** level of theory. Characteristic shifts of the bands in the spectra and changes in the band intensities along the metal and ligand series were observed. On the basis of the obtained results we may answer the questions: (1) do the substituents in the benzene ring influence the electronic charge distribution in the carboxylic group of anisic acids and alkali metal anisates, (2) do the metal ions affect the electronic charge distribution in the methoxy group, (3) in what way do the alkali metals affect the electronic system of *o*-, *m*- and *p*-anisic acids? The substitution of lithium, sodium and potassium ions in the carboxylic group of *o*-, *m*- and *p*-anisic acids causes changes in the values of bond lengths and angles, and in the electronic charge distribution in the carboxylic group, methoxy group and aromatic ring. The influence of alkali metals on the electronic structure of the ligands is weaker than the effect of methoxy substituents. The effect of Li, Na and K ions on the aromatic ring of the ligands is mostly noticeable in the case of the *ortho* isomer. The carboxylic and methoxy groups situated in *ortho* positions in the ring weaken the effect of the alkali metals on the electronic charge distribution in the carboxylic anion and methoxy group.

1. Introduction

Methoxybenzoic acids (anisic acids) are naturally occurring compounds and their biological activity is widely described. They are known to be important inhibitors in the growth of bacteria [1] and they influence the catalytic activity of many enzymes [2]. For example *p*-anisic acid is an inhibitor of phospholipase A_2. The crystal structure of an anisic acid – bound triple mutant of phospholipase A_2 revealed that the small molecule of anisic acid is located in the active site of the enzyme. One of the carboxylate oxygen atoms is coordinated to the calcium ion, and the second carboxylate oxygen atom is hydrogen bonded to the phenolic hydroxyl group of tyrosine (Tyr69) [3]. The biological activity of molecules is determined by their molecular structure, i.e. the kind and position of substituent and the kind of metal coordinated through the carboxylic group. There is a direct relationship between chemical structure and the biological properties of chemical compounds. For example, Maffei et al. showed that methoxy-substituted benzoic acids decrease isocitrate lyase (ICL) activity, whereas hydroxyl-substituted benzoic acids generally increase ICL activity [4]. Our studies on 3,5-dihydroxy- and 2,6-dihydroxybenzoates as well as 3,5-dichloro- and 2,6-dichlorobenzoates showed that the highest antimicrobial activity towards *Bacillus subtilis* and *Staphylococus ureus* posses alkali metal 3,5-dichlorobenzoates [5]. Among the studied complexes of *m*-iodobenzoic and pyridine-carboxylic acids with alkali metals and transition metals, the highest antimicrobial activity towards the selected microorganisms was showed by Zn *m*-iodobenzoate and Ag picolinate [6]. To better understand the mechanisms of action of chemical compounds on biological systems it is essential to carry out physico-chemical studies of model compounds. The results of this study make it possible to predict some properties of a molecule, such as reactivity, durability of complex compounds as well as the nature of the interactions of these compounds with their biological targets (e.g. receptors in the cell or important cell components) and a kinship to enzymes. From this point of view it is very important to study the effect of substituents and metals on biologically important ligands such as anisic acids [7].

In this paper we have studied the effect of metals (lithium, sodium and potassium) and the position of a methoxy substituent in the ring on the electronic system of *o*-, *m*- and *p*-anisic acids by the use of infrared (FT-IR), Raman (FT-Raman), nuclear magnetic resonance spectroscopy (^{1}H NMR) and quantum mechanical calculations (optimized structure, theoretical IR and NMR spectra, atomic charge distribution using NPA, ChelpG and MK methods).

It is worth mentioning that to our knowledge no calculations have been reported so far for alkali metal anisates and the spectroscopic data are incomplete and have mainly been performed for anisic acids.

2. Experimental

The alkali metal anisates were prepared by dissolving the appropriate weighed amount of the anisic acids in an aqueous solution of the alkali metal hydroxides in a stoichiometric ratio of 1:1. The anhydrous compounds were obtained after the evaporation the solvent on a vapour bath, and drying at 160 °C in a dryer under reduced pressure. The metal:ligand ratio is 1:1, which was proven by elementary analysis of the synthesized compounds. The results for the *o*-anisates are as follows: lithium *o*-anisate: %C = 60.01, %H = 4.32, C:H element ratio = 1.17:1; sodium *o*-anisate: %C = 55.07, %H = 4.04 (C:H = 1.14:1); potassium *o*-anisate: %C = 49.94, %H = 3.67, (C:H = 1.13:1). The results of elementary analysis for *m*-anisates: lithium *m*-anisate: %C = 60.42, %H = 4.37, (C:H = 1.16:1); sodium *m*-anisate: %C = 53.81, %H = 4.11 (C:H = 1.10:1); potassium *m*-anisate: %C = 49.96, %H = 3.80, (C:H = 1.10:1). The results of elementary analysis for *p*-anisates: lithium *p*-anisate: %C = 60.71, %H = 4.37, (C:H = 1.17:1); sodium *p*-anisate: %C = 54.57, %H = 3.98 (C:H = 1.15:1); potassium *p*-anisate: %C = 50.55, %H = 3.77, (C:H = 1.13:1). The calculated percentage composition of carbon and hydrogen atoms in anisate molecules are as follows: for lithium anisate %C = 60.78, calc.%H = 4.46; for sodium anisate %C = 55.18; %H = 4.05; for potassium anisate: %C = 50.51; %H = 3.71, (C:H = 1.14:1).

The IR spectra were recorded with an Equinox 55 spectrometer within the range 400–4000 cm^{-1}. Samples in the solid state were measured in a KBr matrix – pellets were obtained with a hydraulic press under 739 MPa pressure. Raman spectra of solid samples in capillary tubes were recorded in the range 400–4000 cm^{-1} with a FT-Raman accessory of the Perkin–Elmer system 2000. The resolution of the spectrometer was 1 cm^{-1}. Argon matrices were produced by deposition of the sample into a stream of gas onto a KBr window held at 20 K in a Displex 202 cryostat. The compound, contained in a glass tube, was heated to 333 K. During irradiation and subsequent spectral measurements, the matrix temperature was kept at 20 K. As irradiation sources, the following were used: (1) an 899 ring laser (Coherent), pumped by a Coherent Innova 300 argon laser; (2) an ILA 120 argon laser; (3) a 300 W xenon lamp (ILC). The NMR spectra in DMSO solution were recorded with a Bruker Varian Tectron 500 MHz unit at room temperature. TMS was used as an internal reference. The optimized geometries, NPA (Natural Population Analysis), ChelpG (CHarges from ELectrostatic Potentials using a Grid based method), MK (Merz–Singh–Kollman) atomic charges and IR wavenumbers were calculated at the B3LYP/6-311++G** level of theory using the Gaussian 98W program [8]. Additionally the AIM theory of Bader [9] (the theory of atoms in molecules) was used to localize bond critical points and to calculate their properties: electron densities at bond critical points (ρBCP) and electron densities at ring critical points (ρRCP). All AIM calculations were performed using the AIM2000 program [10]. The aromaticity indices (HOMA – *the harmonic oscillator model of aromaticity index*, I_6 – *the Bird's aromaticity index*, BAC – *the bond alternation coefficient*, A_j – *the first aromaticity index formulated by Julg and François*) were calculated for optimal geometrical structures of anisic acid and the anisates [11,12]. Literature structural data were used in this discussion. The average estimated standard deviation (esd) of the carbon–carbon bond lengths was less than 0.01 Å.

3. Results and discussion

3.1. Geometries of methoxybenzoic acids

The geometries of the anisic acids were calculated using the B3LYP/6-311++G** level of theory. Different conformers were taken into consideration (Fig. 1). All structures were checked by vibrational analysis (no imaginary wavenumbers) and their be-

haved as energy minima. The structure of *o*-anisic acid (Fig. 1a) is a conformer of minimum energy. The molecule is stabilized by intramolecular hydrogen bonds between the oxygen atom of the methoxy group and the hydrogen atom of the carboxylic group. The existence of hydrogen bonds was previously proven by calculations at the B3LYP/6-311++G** level in the gas phase [13] and in solutions [14,15]. The other geometries of *o*-anisic acid were also taken into account (Fig. 1b–d), but our discussion is constrained to the structure no. 1b in Fig. 1 because of the same location of the substituents as in the experimental crystal structure [16]. The conformers of *m*-anisic acid and *p*-anisic acid with the lowest energy are shown in Fig. 1e and Fig. 1f, respectively. In the case of *p*-anisic acid, the mutual position of the methoxy and carboxylic groups is similar as in the crystal structure [17]. An X-ray structure for *m*-anisic acid was not found.

Comparing the studied structures, we found quite good agreement between the calculated and experimental data (with the exception of the carboxylic and methoxy group distances and angles). The computations were done for an isolated compound, whereas in the solid state the molecules are held together by intermolecular forces, predominantly hydrogen bonds. The calculated conformers of *o*-anisic acid are shown in Fig. 2 (a – with hydrogen bonds, and b, c – without hydrogen bonds). The hydrogen bonds clearly influence the geometry of the *o*-methoxybenzoic acid molecule, especially bond lengths and angles in the carboxylic and methoxy groups. The other geometric parameters change insignificantly. The interaction between the carboxylic and methoxy groups affects the geometry of the ring. Both experimental and theoretical C1–C2, C2–C3 and C6–C1 bond lengths in *o*-anisic acid are longer than the other distances in the aromatic ring. The slight influence of the carboxylic group on the methoxy group hydrogen H7 is seen. The C8–H7 distance is shorter than the C8–H8 and C8–H9 lengths.

The optimized geometry of *m*-anisic acid at the B3LYP/6-311++G** level is displayed in Fig. 3. Almost all the bonds are of similar length, being longer than the conjugated C–C bond of the benzene ring (approximately 1.390 Å). The optimized geometrical parameters for *p*-anisic acid are given in Fig. 4a and b. Especially surprisingly is short length of the C5–C6 bond (1.370 Å).

Comparing the *ortho*, *meta* and *para* isomers of methoxybenzoic acid one may see a distinct effect of the substituents on the geometrical parameters of the molecules. The bond lengths and angles located in the neighbourhood of carboxylic and methoxy groups undergo remarkable alternations. Namely, in the 2a and 2b conformers the C6–C1, C1–C2 and C2–C3 distances are longer than the other bonds distances in the ring (both experimental and calculated data). In the *meta* isomer, the C6–C1, C2–C3, C3–C4 and C4–C5 bonds lengths are the longest in the ring. In the *para* isomer, the C6–C1, C1–C2, C3–C4 and C4–C5 distances are longer than the other C–C bonds in the aromatic ring. Moreover, the dependency between the alternation of bond lengths in the aromatic ring and the aromatic properties of molecule, which was discussed previously in our paper [18], is very interesting. The geometric criterion of aromaticity is based on the fact that the essential factor in aromaticity stabilization is the π-electron delocalization manifested in the following: planar geometry, equalization of the bond lengths and angles, and symmetry. Following this idea, geometry-based aromaticity indexes were formulated and successfully applied for the determination of the aromatic character of mono- and polycyclic compounds [19,20]. The geometrical indexes calculated on the basis of theoretical and experimental bond lengths are gathered in Table 1. The experimental [21,22] and calculated data (this paper) for the benzoic acid molecule are also included and discussed below. On the basis of the obtained indexes we could arrange the acids according to an increase in the aromatic properties of the molecules. Namely, the values of the aromaticity indexes increase

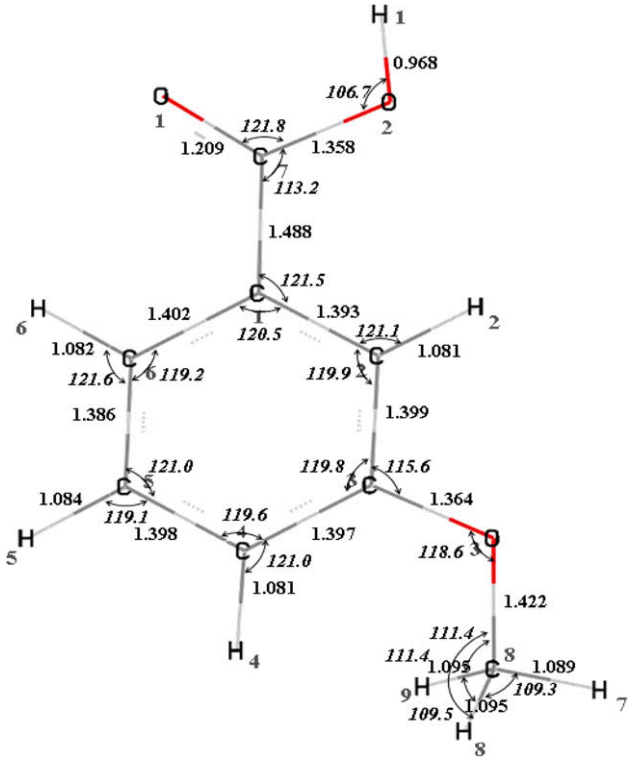

Fig. 3. Calculated bond lengths [Å] and angles [°] (italics) for *m*-anisic acid.

in the order: *o*- → *p*- → *m*- isomers, which suggests that the stabilization of the π-electron system increases in the series *o*- → *p*- → *m*- methoxybenzoic acids (the conformer of *o*-anisic acid with intramolecular hydrogen bonding was not taken into account). Moreover, the difference between the highest and the lowest values of angles between the carbon atoms in the aromatic ring, Δα(CCC), is higher for the *ortho* isomer, compared to the *meta* and *para* isomers, and the values of Δ(CC) decrease in the order as mentioned above (i.e. *o*- → *p*- → *m*-). One may see that calculation of the Δ(CC) and Δα(CCC) values are sufficient for a preliminary estimation of the aromatic properties of the studied systems. Comparing the geometrical indexes obtained for the 2a and 2b conformers of *o*-methoxybenzoic acid we may see that the presence of the intramolecular hydrogen bonds clearly stabilizes the π-electron system of the molecule. The aromaticity indexes are higher for the 2a structure (with hydrogen bonds) compared to 2b (without hydrogen bonds), and the I_6 index is even higher for the 2a structure than the *meta* isomer.

3.2. Geometries of alkali metal methoxybenzoates

The geometrical parameters for lithium, sodium and potassium *m*- and *p*-methoxybenzoates, calculated at the B3LYP/6-311++G** level, are gathered in Tables S1 and S2 (see Supplementary data). The structural data for *o*-methoxybenzoates were reported previously [7]. Comparing the effect of alkali metal ions and substituents on the structure of the ligand, one may say that the metal ions do not evoke such large changes in bond lengths and angles as the methoxy substituent in the aromatic ring. The bond lengths that change more than 0.003 Å in the series: Li → Na → K anisates are displayed in Fig. 5. The alkali metal ions mostly influence the bond lengths and angles in the carboxylic group (which is to be expected) and what is interesting is that they influence the methoxy group geometry. In the series of Li → Na → K *o*-, *m*- and *p*-methoxybenzoates, the C7–O1, C7–O2 and O3–C8 distances decrease, whereas the C1–C7 and C–O3 bond lengths extend. Moreover,

* Structures 1a and 1b are presented in Fig. 1.

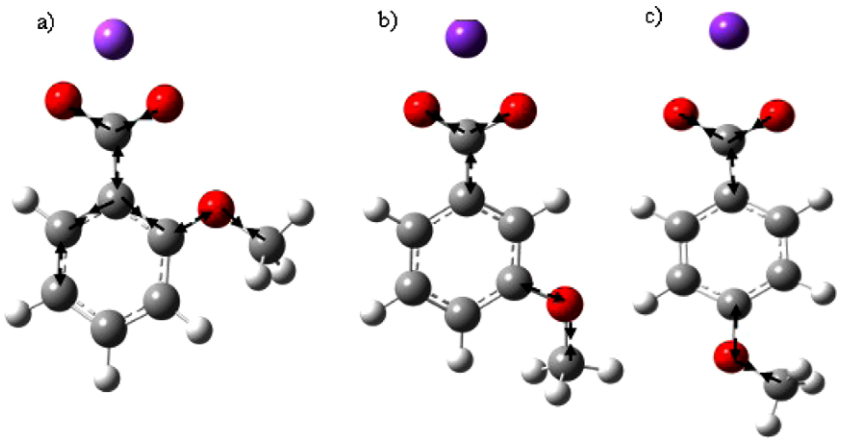

Fig. 5. The change of bond lengths more than 0.003 Å in the series: Li → Na → K (a) *o*-anisates; (b) *m*-anisates and (c) *p*-anisates. The symbols mean: ←→ an increase in bond lengths; →← a decrease in bond lengths; the colors mean: grey – carbon, white – hydrogen, red – oxygen, violet – alkali metal. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

the C6–C1–C2, C3–C4–C5, C–O3–C8, H–C–H (in the methoxy group) angles decrease, and the O1–C7–O2 angle increases along the series Li → Na → K anisates. The existence of some regular changes in the distance and angles of molecules suggests that other parameters such as atomic charges of molecules or position of wavenumbers in the IR or Raman spectra may also change regularly in the same fashion for methoxybenzoates. The biggest changes in the geometry of the ring is seen in the case of the *ortho* isomer (Fig. 5).

Similarly as was done in the case of the anisic acids, the aromaticity indexes for the anisates were calculated and gathered in Table S3. The substitution of a metal ion in the carboxylic group does not cause such evident alternations in the values of indexes, as in the case of the change of substituent in the aromatic ring. Generally, the values of indexes increase in the order: Li → Na → K methoxybenzoates, which suggests an increase in the aromatic properties of the molecules in the above series and therefore the stabilization of the π-electron system. In the case of *m*- and *p*-anisates, the values of the indexes stay almost unchanged, whereas for *o*-anisates the indexes change more clearly. This may mean that the alkali metal ions affect the electronic system of ligand to the highest degree when the substituent is in the *ortho* position in the ring and the effect is poorly observed for a *meta* position of the methoxy substituent in the ring.

3.3. Atomic charges

The calculated NPA, ChelpG and MK atomic charges for *o*-, *m*- and *p*-anisic acids and anisates are gathered in Tables S4–S6, respectively. In Table 2 the total atomic charges of the carboxylic and methoxy groups as well as the aromatic rings of studied molecules are given. The position of the substituent affects the electronic charge distribution in the ligand. Namely, the electronic charge density of the methoxy group increases in the series: *o*- → *p*- → *m*- anisic acids, in the case of the carboxylic group the charge generally increases in the order: *o*- → *m*- → *p*- (in the case of NPA charges: *o*- ∼ *m*- → *p*-), and the charge density of the ring changes along the series: *p*- → *m*- → *o*-. The lowest charge density of the methoxy and carboxylic groups, as well as the highest charge density of the ring, is observed in the case of *o*-anisic acid. This is probably caused by the so-called "ortho effect". The main part of the "ortho effect" consists of polar and steric effects which influence the acidity of the carboxylic acids [23]. A methoxy group in the *meta* position in the ring possesses electron withdrawing properties, whereas in the *para* position in the ring it is an electron donating group. When the substituent group has electron withdrawing character, the negative charge of the carboxylic group of the benzoate derivative decreases (stabilization of the carboxylic anion). On the other hand, a methoxy substituent in the *para* posi-

ρ-Electron density, $\nabla^2\rho$-Laplacian of the electron density.

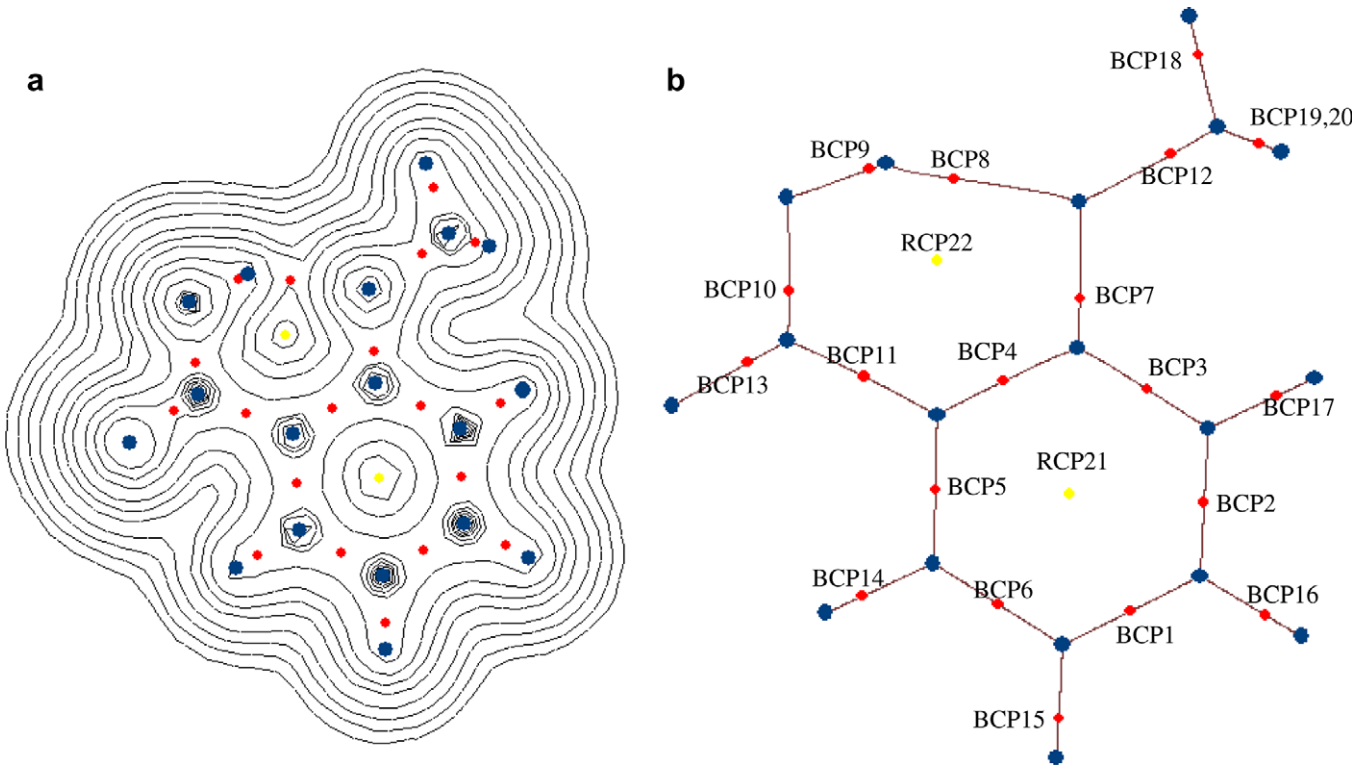

Fig. 6. (a) Contour maps of electron density for *o*-methoxybenzoic acid and (b) critical points assignment: (●) nuclear position; (●) ring critical point; (●) bond critical point.

tion is an electron donating group which causes an increase in the electronic charge distribution and destabilization of the carboxylic anion. It explains the highest electronic charge density of the methoxy and carboxylic groups in the case of *m*- and *p*-anisic acids, respectively.

Comparing the calculated atomic charges for two conformers of *o*-methoxybenzoic acid (1a – with intramolecular hydrogen bonds and 1b – without hydrogen bonds) we may notice that conformer 1a clearly possesses higher electronic charge density on the C1 (except for NPA charge) and O3 atoms, and lower electronic charge density on the H1 and O1 atoms. As a result of this, the total NPA, ChelpG and MK atomic charges of the methoxy group are lower in the case of the 1a conformer compared with the 1b conformer, and inversely – the total atomic charge of the carboxylic group is lower in the case of the 1b structure. Whereas the total atomic charge on the aromatic ring carbon atoms is slightly lower in the case of the 1a conformer. We can see that the existence of intramolecular hydrogen bonds clearly influences the electron

density in the carboxylic and methoxy groups, and therefore it influences the reactivity and properties of the molecules. To study the presence of intramolecular hydrogen bonds in *o*-methoxybenzoic acid, the Bader theory (AIM) was applied. The results of topological analysis are gathered in Table 3 and Fig. 6. The calculations prove the existence of hydrogen bonds between the oxygen atom of the methoxy group and the hydrogen atom of the carboxylic group. In general, the hydrogen bond critical points are associated with small densities and positive Laplacians [24,25]. The electron density at the H···O bond critical point is equal to 0.039926 au. According to the criterion applied in literature, the formed hydrogen bond has weak character [26]. Moreover, the intramolecular hydrogen bond strongly stabilizes the molecule by forming a six-membered quasi aromatic ring with RCP = 0.015781 au (RCP = 0.021436 au for the real aromatic ring of *o*-anisic acid).

It is worth mentioning that the NPA, ChelpG and MK atomic charges located on the C1, C2, C6, C7 and O1 atoms and on the aromatic ring carbons connected with the methoxy substituent change (i.e. increase or decrease) in the series: *o*- → *p*- → *m*- anisic acids. In the case of the C3, C8 and O3 atoms, only the NPA and MK atomic charges change in the same fashion. The calculated values of the atomic charges depend on the type of applied method. This is extremely visible in the case of the methoxy group hydrogens. Namely, the NPA atomic charges on H7, H8 and H9 atoms remain almost unchanged, but the values of the ChelpG atomic charges decrease in the series *o*- → *m*- → *p*- methoxybenzoic acids. In contrast, the values of the MK atomic charges decrease along the series *o*- → *p*- → *m*- anisic acids.

The substitution of metal ions in place of the carboxylic group hydrogen causes a decrease in the electronic charge density on the C1 atom and an increase on C2, C4, C6, O1, O2, H7, H8 and H9 atoms compared to the corresponding atomic charges calculated for the acid. The atomic charges on the other atoms change insignificantly or increase/decrease depending on the applied method. Namely, for *o*-anisates, the electronic charge density on H4 and H5 atoms increase compared to the values of the charges calculated for *o*-anisic acid; for *m*-anisates, the electronic charge density on the C7 atom decreases, whereas that on the O3 atom increases compared to the values of the charges calculated for *m*-anisic acid; for *p*-anisates, the charges on the C3, C5 and C8 atoms decrease, and on the O3 atom increases in comparison with *p*-anisic acid. The calculated total electronic charge density of the methoxy group increases in the series: acid → Li → Na → K anisates. The total electronic charge density of the carboxylic group is higher in anisate molecules than the corresponding acids and it decreases in the order: Li → Na → K anisates. The total electronic charge density of the ring increases in the series: Li → Na → K anisates (NPA method). The total electronic charge density of ring calculated for *o*- and *m*- anisates is higher than that calculated for the corresponding acids, but in the case of *p*-anisates it is lower than that for *p*-anisic acid. This tendency is displayed in Fig. 7.

3.4. Vibrational wavenumbers

Replacement of the carboxylic group hydrogen with a metal ion brings about characteristic changes in the IR and Raman spectra of the metal anisates in comparison with the spectra of the ligand. The disappearance of bands for the symmetric and asymmetric valence vibrations: stretching ν(C=O) [*o*-anisic acid: 1693 and 1669 cm^{-1} (IR), and 1639 cm^{-1} (Raman); *m*-anisic acid: 1693 cm^{-1} (IR) and 1627 cm^{-1} (Raman); *p*-anisic acid: 1686 cm^{-1} (IR)], in-plane bending β(C=O) [*m*-anisic acid: 808 cm^{-1} (IR) and 811 cm^{-1} (Raman); *p*-anisic acid: 735 cm^{-1} (IR)] as well as out-of-plane bending γ(C=O) of the carbonyl group [*o*-anisic acid: 653 (IR) and 650 (Raman) cm^{-1}; *m*-anisic acid: 580 cm^{-1} (IR) and 582 cm^{-1} (Raman); *p*-anisic acid: 548 cm^{-1} (IR)]; disappearance of stretching vibrations ν(O–H) in the range: *o*-anisic acid: 3056–2818 (IR) cm^{-1}; *m*-anisic acid: 2676–2533 cm^{-1} (IR); *p*-anisic acid: 2728–2520 cm^{-1} (IR)], deformation vibrations:β(O–H) [*o*-anisic acid: 1409 cm^{-1} (IR); *m*-anisic acid: 1417 cm^{-1} (IR); *p*-anisic acid: 1427 cm^{-1} (IR) and 1421 cm^{-1} (Raman)] and γ(O–H) [*m*-anisic acid: 935 cm^{-1} (IR); *p*-anisic acid: 928 cm^{-1} (IR)]; appearance of bands of the asymmetric and symmetric vibrations of the carboxylate anion $\nu_{as}(COO^-)$, $\nu_s(COO^-)$ as well as $\beta_{as}(COO^-)$, $\beta_s(COO^-)$, and disappearance or changes in positions and intensities of some aromatic bands are observed. The FT-IR spectra of the anisic acids are shown in Fig. 8.

Thanks to the FT-IR Argon matrix, it is possible to distinguish between hydrogen bonds present in the molecule of *o*-anisic acid. In the region of OH stretching vibrations, i.e. 3728–3358 cm^{-1} a few bands appear (see Fig. 9). The most intense band is assigned to the OH stretches of the monomer, whereas the weaker bands at 3364 and 3358 cm^{-1} correspond to associated molecules. Reva et al. have claimed that using different Ar matrix-to-sample ratios

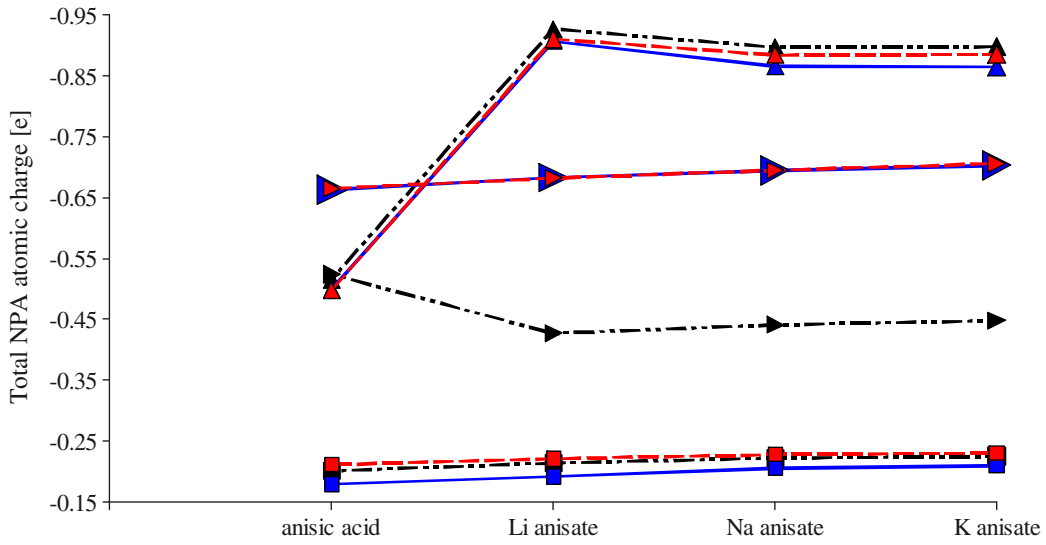

Fig. 7. The total NPA atomic charge calculated at the B3LYP/6-311++G** level for *o*-anisic acid and *o*-anisates (line: —), for *m*-anisic acid and *m*-anisates (line: - - -) as well as for *p*-anisic acid and *p*-anisates (line:). The following symbols stand for: ■ methoxy group, ► ring, ▲ carboxylic group.

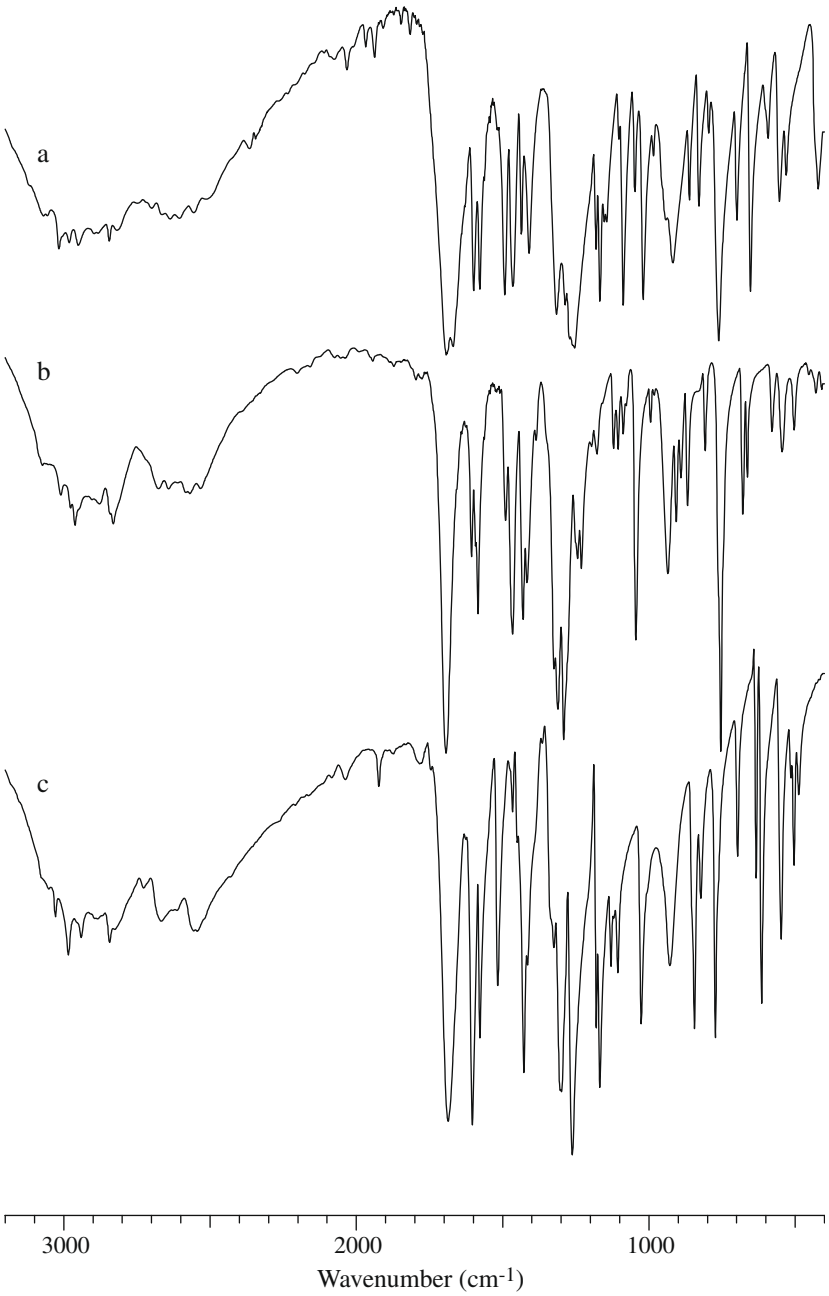

Fig. 8. The FT-IR spectra of: (a) *o*-anisic acid; (b) *m*-anisic acid; (c) *p*-anisic acid.

it is possible to study the existence of benzoic acid monomers as well as cyclic dimers with two H-bonds and linear dimers with single H-bonds [27,28]. Moreover the calculated wavenumbers showed that the formation of intramolecular hydrogen bonds in the *o*-anisic acid molecule lowers the band wavenumbers of the OH stretches. In the C═O stretching region several bands occurred in the Ar matrix IR spectra of *o*-anisic acid. The bands at 1768 and 1762 cm^{-1} are assigned to vibrations of monomers, whereas a very weak band at 1735 cm^{-1} corresponds to the vibration of a dimer. Moreover the βOH, *v*C-(OCH_3), *v*OCH_3 and γC═O vibrations are also affected by the presence of H-bonds.

The position of the substituent in the aromatic ring affects the vibrations of anisic acid molecules. In the Table 4 the selected wavenumbers of bands present in the IR and Raman spectra of anisic acids, sodium anisates as well as benzoic acid and sodium benzoate are gathered. Comparing the wavenumbers of the corresponding bands one can see that the methoxy substituent influences the electronic system of ligand to a larger extent than a metal substituted in the carboxylic group. Substitution of the methoxy group in the ring causes shifts of selected bands to over 100 cm^{-1}. Whereas substitution of metal ions in the place of the carboxylic group hydrogen of anisic acid causes displacement of the corresponding bands by a maximum of about 20 cm^{-1}. Moreover, it seems that the metal more strongly affects the electronic system of benzoic acid than anisic acid. Generally, we can see (Table 4) that more bands disappear in the IR and Raman spectra of sodium benzoate compared with the spectra of benzoic acid than occurs in the case of anisates and anisic acids. Namely, three main aromatic bands (i.e. 8a, 19a, 19b) disappear in the IR spectrum of sodium benzoate compared with the IR spectrum of the acid. Band no. 8b is absent in the Raman spectrum of the sodium salt, but it is present in the Raman spectrum of benzoic acid. The

rest of the bands are shifted toward lower or higher wavenumbers. Moreover the maximum of the band displacement amounts to 37 cm^{-1} in the IR spectra and 30 cm^{-1} in the Raman spectra (band no. 10a). This may suggest that the methoxy substituent slightly weakens the effect of the metal on the aromatic system of the ligand.

The effect of metals on the electronic system of the ligand depends on the position of the methoxy substituent in the ring. Taking into account the four main aromatic bands present in the spectra of *o*-, *m*- and *p*-anisic acids, i.e. no. 8a, 8b, 19a and 19b (a simplified interpretation of the origin of spectral bands and notation by Varsanyi [29] is used), one may observe the influence of the alkali metals on the aromatic system of the ligand. In Table 4 the spectroscopic data for the sodium salt and anisic acids are gathered, and similar dependencies occur for the lithium and potassium salts as well. Bands no. 8a (IR and Raman spectra), 8b (IR spectra), 14 (IR and Raman spectra) and 18b (IR and Raman spectra) disappear in the spectrum of Na *m*-anisate. The rest of the bands mentioned in Table 4 undergo a displacement in the spectrum of the salt toward lower wavenumbers by a maximum of 13 cm^{-1}. On the other hand, in the spectra of sodium *o*-anisate most of the bands are shifted toward higher wavenumbers compared with the corresponding bands in the spectrum of the acid (except bands no. 19b and 10a – their wavenumbers slightly decrease in the IR and Raman spectra of the salts). Moreover bands no. 4 and 6b appear in the spectra of the salt, but they are absent in the spectra of the ligand. In the case of *p*-anisate, some of the bands are shifted toward higher wavenumber, i.e. 8a (IR, R), 8b (IR), 19b (R) and 14 (IR, R), the remaining bands are shifted toward lower wavenumbers or they disappear. Bands no. 8a, 8b, 18a and 10a from the IR and Raman spectra of sodium *o*-anisate and bands no. 8b, 19b and 14 from the IR and Raman spectra of sodium *p*-anisate undergo a significant displacement (>10 cm^{-1}) compared with the spectra of the acids. This effect is stronger in the case of the *ortho* isomer. Analysis of the spectroscopic data shows that the effect of the metals on the electronic system of the ligand is different in the case of *meta*, *ortho* and *para* isomers of anisic acid. This is probably caused by different electron donating-withdrawing properties of the substituent. The methoxy substituent in the *meta* position in the ring possesses electron withdrawing character and causes a decrease in the electronic charge distribution in the ring of the salt. This is revealed in a decrease in the numbers, wavenumbers and/or intensities of the bands for metal complexes in comparison to the appropriate bands in the spectra of the ligand. It is caused by a decrease in the force constants of the bonds and polarization of the C–C and C–H bonds in the ring [18]. In the case of the *ortho* isomer, the close proximity of the methoxy and carboxy substituents plays an important role in increasing the negative charge of the ring in *o*-anisate molecules, which induces the displacement of aromatic bands toward higher wavenumbers in comparison to the corresponding bands in the spectrum of *o*-anisic acid. A methoxy substituent in the *para* position in the ring shows

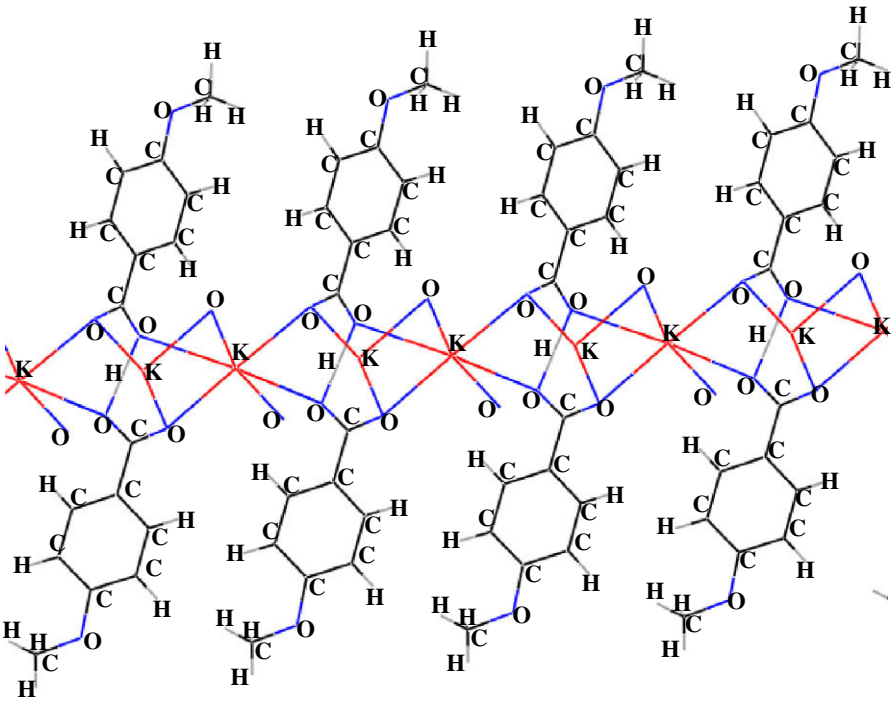

Fig. 10. Crystal structure of potassium *p*-anisate [30].

electron donating character, causing an increase in the negative charge density of the ring, and the carboxylic group as well (the negative charge density of the COO^- group is higher in the case of *p*-anisate compared to *o*-anisate and *m*-anisate, and this is described below). The effect of metals on the electronic structure of the ligand cannot be described by a simple model, the intermolecular interactions which stabilize the system should be taken into consideration as well. Comparing the theoretical and experimental data it should be kept in mind that calculations were performed for an isolated molecule, whereas in fact molecular interactions exist. In Fig. 10 the crystal structure of potassium *p*-anisate is presented. A comparison of that structure with simple calculated models (e.g. in Fig. 5) shows how big a simplification is assumed during the calculations [30].

In the IR and Raman spectra of the salts, some of the bands assigned to aromatic ring vibrations are shifted toward lower wavenumbers in the series: Li → Na → K anisates, i.e. bands no. 20a (~3070 cm^{-1}), 20b (~3025 cm^{-1}), 8b (~1605 cm^{-1}), 8a (~1590 cm^{-1}), 18a (~1100 cm^{-1}), 17b (~940 cm^{-1}), 10a (~780 cm^{-1}), 11 (~750 cm^{-1}) and 6b (~660 cm^{-1}) in the spectra of *o*-anisates; 19b (~1480 cm^{-1}), 3 (~1315 cm^{-1}), 7a (~1280 cm^{-1}), 13 (~1250 cm^{-1}), 18a (~1080 cm^{-1}), 17a (~900 cm^{-1}), 7b (~870 cm^{-1}) and 6b (~500 cm^{-1}) in the spectra of *m*-anisates; 20b (~3050 cm^{-1}), 8b (~1600 cm^{-1}), 19a (~1510 cm^{-1}), 14 (~1310 cm^{-1}), 9a (~1135 cm^{-1}), 18a (~1005 cm^{-1}) and 6a (615 cm^{-1}) in the spectra of *p*-anisates. The decrease in the wavenumbers of the aromatic bands along with the change of the complexed metal cation or ring substituent is interpreted by some authors as only an

effect of the increase in the atomic mass of the cation or the substituent. Our previous studies showed that the most important factor causing the decrease in the wavenumbers of the aromatic bands is the ionic potential of the metal ions [31–33].

The substitution of alkali metals in the carboxylic group of anisic acid causes changes in the electronic charge distribution of the methoxy group as well. It is mostly visible in the case of bands assigned to the asymmetric stretching vibrations of the methoxy group $\nu_{as}(CH_3)$ (~2980 and ~2950 cm^{-1}) (Table 5). In the spectra of anisates these bands are shifted towards lower wavenumbers (or disappear) compared with the spectra of the acids, and they clearly decrease in wavenumbers along the series: Li → Na → K. The smallest differences between the position of the bands assigned to the methoxy group vibrations are visible in the spectra of *o*-acid and its salts, for example the band attributed to $\nu_{as}(CH_3)$ appears at 2981 cm^{-1} in the spectrum of *o*-anisic acid, and at 2977 cm^{-1} in the spectra of the Li and Na *o*-anisates (there is a lack of this band in the spectrum of K *o*-anisate). Whereas, in the spectra of *m*- and *p*-anisic acids, the discussed band is located at 2961 and 2986 cm^{-1}, respectively. In the spectra of Li, Na and K *m*- and *p*-anisates, $\nu_{as}(CH_3)$ is present at 2942, 2942 and 2944 cm^{-1}, and at 2964, 2954 and 2958 cm^{-1}, respectively. In Table 6 the differences between the wavenumbers of the asymmetric and symmetric stretching and deforming vibrations of the carboxylic group are gathered. In the IR and Raman spectra of *o*-anisates, the bands of $\nu_{as}(COO^-)$ are generally located at higher wavenumbers and $\nu_s(COO^-)$ are present at lower wavenumbers compared to the corresponding bands in the spectra of *m*- and *p*-anisates. The same situation is seen in the case of $\beta_{as}(COO^-)$ and $\gamma_s(COO^-)$. As a consequence, the values of $\Delta\nu(COO^-)$ and $\Delta\beta(COO^-)$ are higher in the case of Li, Na and K *o*-anisates than *m*-, *p*-anisates. Moreover the change of metal in the series Li→Na→K causes somewhat larger changes in the value of $\Delta\nu(COO^-)$ and $\Delta\beta(COO^-)$ of *m*-anisates and *p*-anisates than *o*-anisates. Probably the carboxylic and methoxy groups situated in the *ortho* position in the ring weaken the effect of the alkali metals on the electronic charge distribution in the carboxylic anion. Additionally, one can see that in the case of alkali metal salts, the IR and Raman wavenumbers of $\Delta\nu(COO^-)$ and $\Delta\beta(COO^-)$ decrease in the series *o*- → *m*- → *p*-anisates, which according to the calculated total atomic charge indicates an increase in the negative charge density of the carboxylic group in the same series. This was previously explained by electron withdrawing and electron donating properties of the methoxy substituent situated in the *meta* and *para* position in the ring, respectively. The stabilization effect of the *ortho* position of the methoxy group has not been completely described so far and it is explained by steric and polar effects [23].

3.5. ^1H NMR spectra of anisic acid and anisates

The chemical shifts of the protons from experimental and calculated ^1H NMR spectra of anisic acid and Li, Na and K anisates are displayed in Fig. 11. In the spectra of anisates, the proton signals are shifted downfield in comparison to the corresponding signals in the spectrum of the acid. Moreover the general tendency for the decrease of chemical shift of particular protons in the series: Li → Na → K is noticeable. It points at an increase in the screening of aromatic protons as a consequence of the circular current weakening. The highest differences between the values of chemical shifts present in the spectra of acid and salts are mostly visible in the case of *ortho* isomer.

4. Conclusions

1. The substitution of lithium, sodium and potassium ions in the carboxylic group of *o*-, *m*- and *p*-anisic acids causes changes in the values of bond lengths, angles and in the electronic charge distribution in the carboxylic group, methoxy group and aromatic ring. The values of the aromaticity indexes increase in the order: *o*- → *p*- → *m*- isomers which suggests that the aromaticity of the studied systems increases in the series *o*- → *p*- → *m*- methoxybenzoic acids. The presence of intramolecular hydrogen bonds causes an increase in the aromaticity of the *o*-anisic acid molecule. The electronic charge density of the methoxy group increases in the series: *o*- → *p*- → *m*- anisic acids. In the case of the carboxylic group, the charge generally increases in the order: *o*- → *m*- → *p*-, and the charge density of the ring changes along the series: *p*- → *m*- → *o*-. Such distribution of the negative charge may be explained by the electron donating and electron withdrawing properties of the methoxy group situated in the *o*-, *m*- and *p*- position in the ring.
2. On the basis of the spectroscopic data, the values of the aromaticity indexes and the atomic charges, it was shown that the influence of the alkali metals on the electronic structure of the ligands is weaker than the effect of the methoxy substituents. The calculated total electronic charge density of the methoxy group increases in the series: acid → Li → Na → K anisates. The total electronic charge density of the carboxylic group is higher in the case of anisates than the coresponding acids, and decreases in the order: Li → Na → K anisates. The total electronic charge density of the ring increases in the series: Li → Na → K anisates (NPA method). The effect of the metals on the electronic system of the ligand depends on the position of the methoxy substituent in the ring and the electron donating-withdrawing properties of substituent. In the case of the *ortho* isomer, steric and polar effects additionally play an important part in the increase in the negative charge of the ring in *o*-anisates. On the basis of IR, Raman and ^1H NMR data it is concluded that the effect of Li, Na and K on the aromatic ring of the ligand is mostly noticeable in the case of the *ortho* isomer. The bands in vibrational spectra, which are responsible for oscillation or deformation, change their wavenumbers depending on the structure of the ligand.

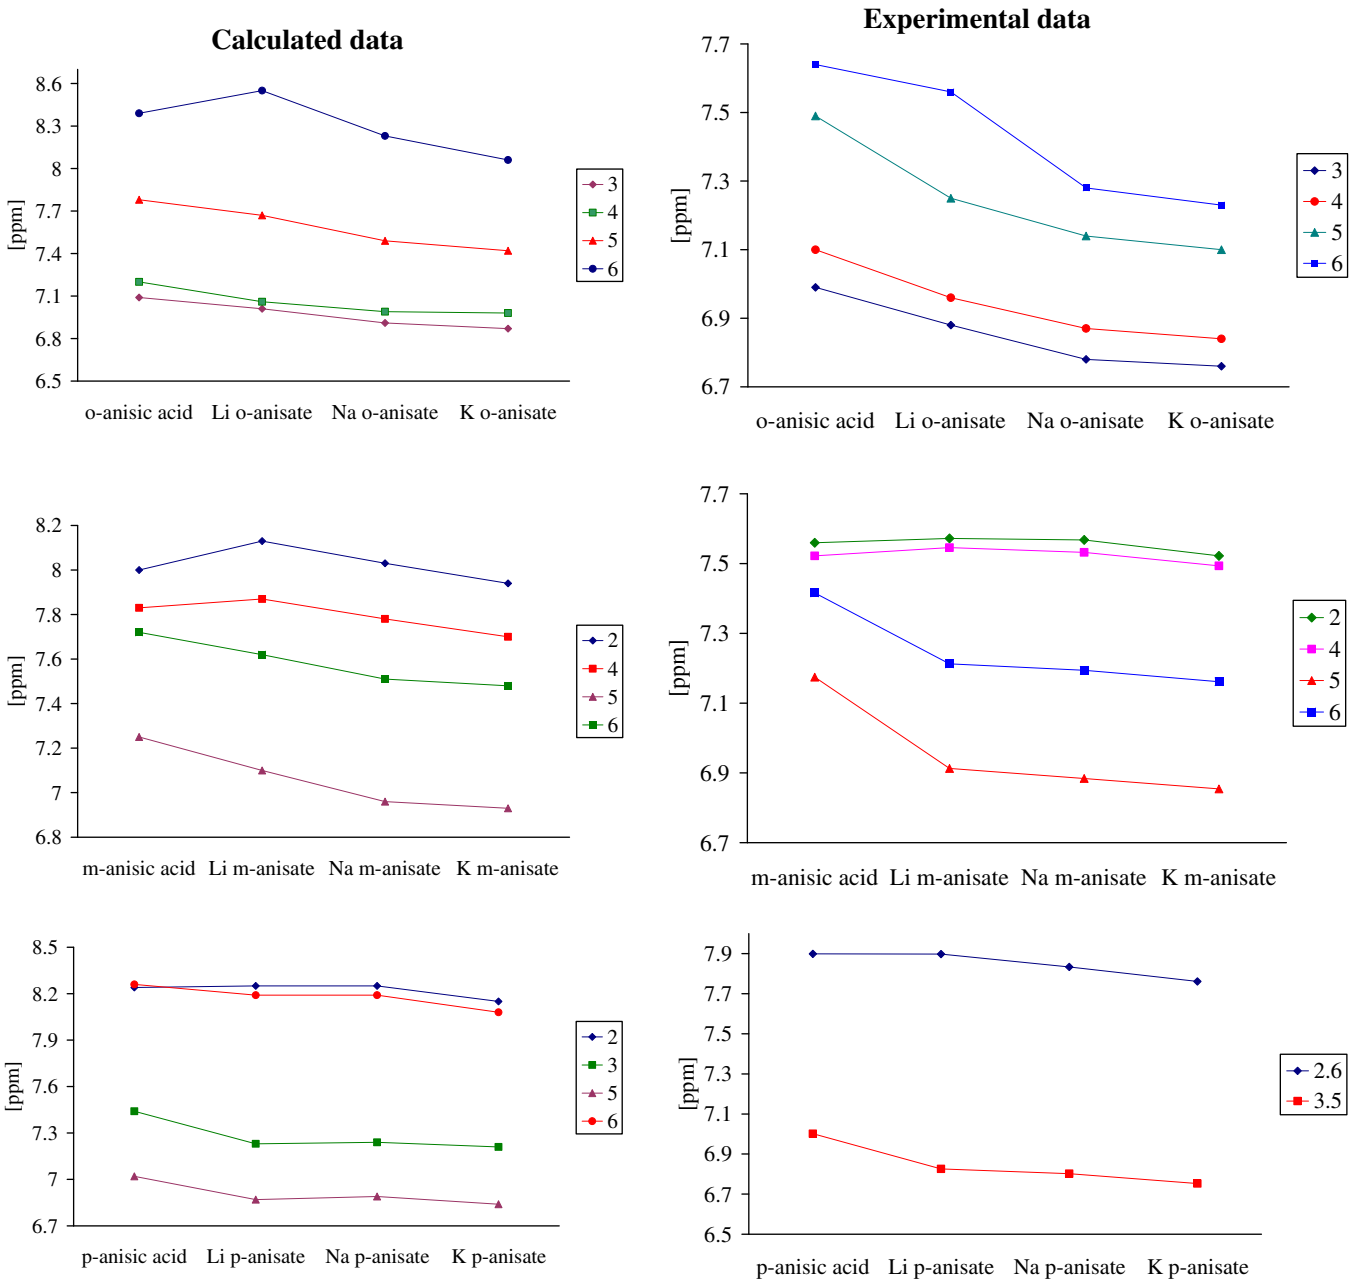

Fig. 11. The chemical shifts of protons from calculated (B3LYP/6-311++G** GIAO; TMS) and experimental ^{1}H NMR spectra of anisic acids and Li, Na and K anisates (proton numbering in Figs. 2–4).

3. It is assumed that the carboxylic and methoxy groups situated in the *ortho* position in the ring weaken the effect of alkali metals on the electronic charge distribution in the carboxylic anion and methoxy group. Additionally, one can see that the IR and Raman wavenumbers of $\Delta\nu(COO^-)$ and $\Delta\beta(COO^-)$ decrease in the series *o*– → *m*- → *p*-anisates, which according to the calculated total atomic charge indicates an increase in the negative charge density of the carboxylic group in the same series.

Oxidative cleavage
Nucleolytic efficiency

ABSTRACT

A set of copper(II) complexes of glycine and methylated glycine derivatives, $Cu(aa)_2$, consisting of C-dimethylglycine, L-alanine, *N*-dimethylglycine and sarcosine, was investigated for their DNA binding and nucleolytic properties by means of EPR and visible spectroscopy, and electrophoresis. They bind weakly to DNA with apparent binding constants in the range $1.8–2.9 \times 10^3\ M^{-1}$ with very similar orientation. No DNA cleavage is observed in the absence of exogenous agents. Copper(II) complexes of *N*-methylated derivatives bind to DNA more stereo-specifically and less strongly, and their oxidative DNA cleavage is less efficient than those of the corresponding C-methylated derivatives in the presence of hydrogen peroxide (H_2O_2) alone, or sodium ascorbate (NaHA) alone or tandem H_2O_2–NaHA. The oxidative DNA cleavage mechanism in the three systems involves a common copper(I) species. Neocuproine can inhibit DNA cleavage by these complexes.

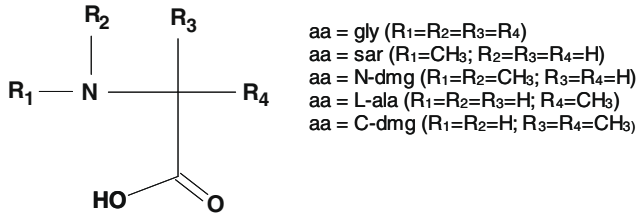
1. Introduction



Although, copper is essential to animals, it can also induce toxicity. This toxicity is due to those reactions of the redox-active copper ions which generate reactive oxygen species (ROS) via a Fenton or Haber–Weiss mechanism [1]. Copper(II), Cu^{2+}, has been implicated in many diseases such as Wilson's disease, Menkes disease, Alzheimer's disease, Parkinson's disease, prion disease, other neurodegenerative diseases and cataract [2]. ROS can be produced by Cu^{2+} in the presence of hydrogen peroxide or ascorbate anion or both hydrogen peroxide and ascorbate [1–5]. The ROS thus produced can cause damage to protein, DNA or cellular membrane. Recently, it was reported that even the antioxidant metalloenzyme, copper–zinc superoxide dismutase (Cu–Zn-SOD) could cleave DNA in the presence of hydrogen peroxide or mercaptoethanol [6].

Copper complexes with amino acids are both important biologically and interesting. Many low-molecular-weight copper complexes with amino acids and amino acid derivatives act as anti-inflammatory, antiulcer, anticonvulsant, anticancer, and/or radiation protection agents [7]. They can assume a variety of coordination geometries, from irregular square planar, distorted planar, flattened tetrahedral, and distorted square–pyramidal to distorted octahedral, as observed in their experimental crystal structures [7].

However, copper(II) ion chelated with amino acid can harm DNA by either oxidative or hydrolytic cleavage, depending on the amino acid involved [8–10]. A recent study has investigated the effects of pH, concentration of both amino acid and hydrogen peroxide, and the type of amino acids (glycine, lysine, L-alanine) on the kinetics of ·OH radicals formation from the reaction of copper(II)-amino acid mixtures with hydrogen peroxide [11]. Similar reaction is also involved in the oxidative cleavage of DNA by copper(II) complexes of *N*,*N*′-dimethylglycine and other ligands [8]. A widely accepted view of the mechanism of DNA cleavage by copper(II) complexes details the binding of the complexes to the DNA and their subsequent reaction with hydrogen peroxide to generate the ·OH radicals on site to cleave the DNA. Of relevance are the studies of the binding of copper(II) complexes of some amino acids with DNA fibers using EPR spectroscopy and the results have shown that the nature and orientation of binding of the complexes were influenced by the amino acids used (glycine, serine, threonine, lysine and arginine) [12,13]. This paper reports the effect of the number and position of methyl substituent(s) on (i) the relative quantity of hydroxyl radicals produced by the reaction of the copper(II) chelated methyl-derivatives of glycine (general structure of ligands is depicted in Scheme 1), $Cu(aa)_2$, with hydrogen peroxide, and (ii) the oxidative cleavage of DNA by these complexes in the

presence of either hydrogen peroxide or sodium ascorbate or both these exogenous reagents. In addition, the interaction of these complexes with DNA was investigated by EPR and ethidium bromide (EB) quenching assay studies.

2. Experimental

2.1. Reagents and materials

Most of the reagents were of analytical grade and were used as supplied. The pBR 322, gene ruler 1 Kb DNA ladder, ethidium bromide, loading buffer, Tris and agarose were bought from BioSyn Tech (Fermentas). Salmon testes DNA was purchased from Sigma Chemical Co. (USA). All solutions for DNA experiments were prepared with ultra-pure water from a Elga PURELAB ULTRA Bioscience water purification system with UV light accessory. The borate buffer was prepared from 0.1 M boric acid aqueous solution in which the pH was adjusted with NaOH aqueous solution till pH 8.5. The borate buffer pH 8.5 contains borate at 0.1 M. All stock solutions of H_2O_2 in water and metal complexes in borate buffer were freshly prepared daily.

2.2. Physical measurements

The C, H and N microanalysis was carried out with a Perkin Elmer 2400 CHN analyser. Infrared spectra of all compounds were recorded as KBr pellets using Perkin–Elmer FT-IR spectrometer in the frequency range 4000–400 cm^{-1}. UV–Vis spectroscopic measurement was carried out on a Perkin Elmer Lambda 40. Fluorescence measurements were performed using a Perkin–Elmer LS55 photoluminescence spectrometer. The EPR data of the copper complexes were obtained with a JEOL RE-2X spectrometer.

2.3. Synthesis of $Cu(aa)_2$ complexes

The aqua*bis*(*N*,*N*-dimethylglycinato)copper(II), Cu(N-dmg)$_2$ and *cis*-aqua*bis*(glycinato)copper(II), *cis*-Cu(gly)$_2$, complexes were synthesized by previously reported procedures [8,14]. The FTIR of Cu(N-dmg)$_2$ and *cis*-Cu(gly)$_2$ were identical with those of aqua*bis*(*N*,*N*-dimethylglycinato)copper(II) [8] and *cis*-aqua-*bis*(glycinato)copper(II) [14], respectively. The *bis*(C-dimethylglycinato)copper(II), Cu(C-dmg)$_2$, *bis*(L-alaninato)copper(II), Cu(L-ala)$_2$, and *bis*(sarcosinato)copper(II), Cu(sar)$_2$ were prepared by reacting freshly prepared copper(II) hydroxide with the respective amino acid as in the previously reported procedure [8].

2.3.1. Elemental analysis for $Cu(aa)_2$ complexes

Cu(C-dmg)$_2$: *Anal.* Calc for Cu($C_8H_{16}N_2O_4$): C, 35.88; H, 6.02; N, 10.46. Found: C, 35.91; H, 5.84; N, 10.36%. For Cu(sar)$_2$: *Anal.* Calc. for Cu($C_6H_{12}N_2O_4$)(H_2O)$_2$: C, 26.13; H, 5.85; N, 10.16. Found: C, 26.32; H, 5.66; N, 10.15%. For Cu(L-ala)$_2$: *Anal.* Calc. for Cu($C_6H_{12}N_2O_4$): C, 30.06; H, 5.05; N, 11.69. Found: C, 30.11; H, 4.88; N, 11.61%. 2.4. PNDA assay of ·OH radicals from $Cu(aa)_2 + H_2O_2$

The reactions of Cu(aa)$_2$ and copper(II) salt in borate buffer pH 8.5 with H_2O_2 were carried out merely to investigate the relative amount of hydroxyl radicals produced. The reactions were monitored at 5-min intervals over duration of 15 min. A PNDA assay was used for this purpose and the procedure has been previously described [9]. The production of ·OH radicals from the reactions of the copper nitrate and the Cu(aa)$_2$ complexes (100 μM) in borate buffer pH 8.5 with 20 μM H_2O_2 was assayed by the use of *p*-nitrodimethylaniline (PNDA) indicator (56 μM) according to a previous procedure [9]. The % bleaching of the PNDA after time *t* (minutes) was calculated by using the formula $(A_o - A_t)/A_t \times 100$, where A_o and A_t are the absorbance of the PNDA in the reaction mixture at initial time and at time *t*. Initial absorbance reading was measured within 30 s.

2.5. Preparation of DNA pellets and fibers

The DNA from salmon testes was dissolved in 20 mM NaCl to make a solution of approximately 1 mM DNA base pair concentration. Subsequently, the complex solution was added drop wise to the DNA, and stirred for approximately 12 h at 4 °C. The resulting solutions were adjusted to a pH of 8.4 with sodium hydroxide and hydrochloric acid throughout the experiments. The DNA-pellet was obtained by ultracentrifugation of the mixed solution at 60 000 rpm for 7 h. The DNA fibers were prepared from the pellet as previously reported [9].

2.6. EPR spectra

X-band (9.2 GHz) EPR spectra at ambient temperature and −150 °C were measured on a JEOL RE-2X spectrometer with 100 kHz field modulation of 0.5 mT. The magnetic field was calibrated with an NMR field meter EFM-2000 (ECHO Electronics LTD). The microwave frequency was measured on Anritsu MF2412A frequency counter. The EPR spectra were measured at different angles of Φ between the fiber axis and the static magnetic field.

2.7. DNA cleavage experiments

The reaction mixtures were prepared as follows: 1 μl of 10 μM H_2O_2 or 1 μl of 2 μM ascorbic acid were added to the mixture of 0.5 μl of supercoiled plasmid DNA pBR322 (0.25 μg/μl) and 2 μl of 500 μM copper(II) complexes or salt followed by dilution with borate buffer pH 8.5 to a total volume of 20 μl. The reactions were performed after incubating the reaction mixture at 37 °C for 2 h in the presence or/and absence of complexes or copper salt. 3 μl of 6× loading buffer was added to 20 μl of the reaction mixtures and electrophoresis was performed at 80 V for 90 min in Tris-acetate-EDTA (TAE) buffer, pH 8.1, using 1.25% agarose gel. After electrophoresis, the agarose gel was stained with ethidium bromide solution (0.5 μg/ml).

Agarose gel electrophoresis experiments were carried out on supercoiled plasmid DNA pBR322 (4.4 Kb) using a horizontal gel system. For the cleavage studies, each 20 μL sample consisted of the complex dissolved in buffer, DNA, and the required volume of additional buffer. All samples were incubated in the dark in a water-bath at a temperature of 37 °C for 2 h. For the oxidative or reductive cleavage studies, incubation of the samples was similarly carried out. The DNA cleavage profile was analyzed using 1.25%

agarose gel in a horizontal gel tank set with a running time of 2 h, at a constant voltage of 80 V. Each reaction mixture consisted of 0.5 μg/μL DNA and borate buffer pH 8.5 unless otherwise mentioned. The resultant DNA bands after the electrophoresis step for each set of experiments were stained with ethidium bromide before being photographed under UV light using a Syngene Bio Imaging system and the digital image was viewed with Gene Flash software.

For the DNA cleavage by $Cu(aa)_2$ in the presence of hydrogen peroxide alone or sodium ascorbate (NaHA) alone, mechanistic experiments were similarly carried out to test the effect of radical scavengers sodium azide (NaN_3), thiourea, tiron, and DMSO on the DNA cleavage. Neocuproine (a Cu(I)-specific chelator) was also used to test any cleavage inhibition. To identify formation of Cu(I)-intermediate species, additional spectroscopic experiments were undertaken to obtain the visible spectra of (i) CuI + neocuproine; (ii) $Cu(aa)_2 + H_2O_2$ + neocuproine; (iii) $Cu(aa)_2$ + NaHA + neocuproine. CuI and neocuproine stock solutions were prepared in methanol–water (2:1 v/v) while the $Cu(aa)_2$ were dissolved in borate buffer pH 8.5. All final reaction mixtures were obtained by topping up with borate buffer pH 8.5.

2.8. Ethidium bromide quenching assay

Calf thymus DNA (CT-DNA) was obtained from Sigma Chemical Co. (USA), and used as received. Stock solution of DNA was prepared by dissolving nucleic acids in buffer solution, stored at 4 °C more than 24 h with gentle shaking occasionally to get homogeneity, and used within 2 days. The concentrations of CT-DNA per nucleotide phosphate [DNA] were calculated according to the absorbance at 260 nm by using extinction coefficient of DNA = 6400 M^{-1} cm^{-1}.

Ethidium bromide quenching assay were performed by measuring the emission of ethidium bromide bound to DNA which shows the enhanced emission intensity due to its intercalative binding to DNA. The competitive binding of the complexes to the DNA reduces the emission intensity of ethidium bromide (EB) with either the bound complex quenching the emission or a displacement of the bound ethidium bromide from the bound to the free state. Fluorescence measurements were performed using a Perkin–Elmer LS55 photoluminescence spectrometer. All the fluorescence measurements were taken at λ_{ex} of 545 nm and λ_{em} of 600 nm at room temperature.

In this experiment, 0.32 μM ethidium bromide was added to 10 μM CT-DNA solution. After that, the mixture was incubated overnight to reach saturation condition. Varied complex concentrations in borate buffer (pH 8.5) were added to the EB-DNA solution. After the mixtures were incubated for 2 h, their fluorescence intensity was measured after each addition. The fluorescence intensities were plotted against the complex concentration to yield a curve that showed the relative extent of quenching of DNA-bound EB. The values of the apparent binding constant, K_{app}, of the $Cu(aa)_2$ complexes were calculated from the equation $K_{app,Cu(aa)_2}$ [$Cu(aa)_2$] = $K_{app,EB}$[EB], where $K_{app,EB}$ is the apparent binding constant of EB assumed to be 10^7 M^{-1}, $K_{app,Cu(aa)_2}$ is the apparent binding constant of $Cu(aa)_2$, [EB] is the concentration of EB used and [$Cu(aa)_2$] is the concentration of the $Cu(aa)_2$ at 50% quenching [15].

3. Results and discussion

3.1. DNA interaction with $Cu(aa)_2$

It is well known that DNA cleavage by copper(II) complexes involves binding of the complexes to DNA. In fact, DNA binding studies with copper(II) complexes of some amino acids have been reported [12,13]. This study attempts to investigate whether the nature of the binding of the $Cu(aa)_2$ complexes affects their nucleolytic property, and thereby help to understand the effect of the position and number of methyl substituent on the nucleolytic property of a series of copper(II) methyl-substituted glycine derivatives. Two experiments were conducted, viz. EPR study to investigate the binding of the complexes with highly oriented DNA fibers where the fiber is rotated through an angle Φ (from 0–90°) with respect to the static magnetic field, B (Fig. 1) and EB-quenching assay to find the binding strength of the $Cu(aa)_2$.

The EPR spectra of all the $Cu(aa)_2$ complexes on B-form DNA at room temperature (r.t.) are similar (Fig. 2). The intensity of the typical Cu(II) spectral peaks are maximum at $\Phi = 0°$ and decreases to zero at $\Phi = 90°$. As such, all the $Cu(aa)_2$ complexes are oriented in a similar fashion with the $g_{//}$ axis parallel to the B-DNA fiber axis. This indicates that the presence of methyl groups does not greatly alter the binding orientation of the $Cu(aa)_2$ to the DNA. However, the binding structures are still unclear and need further investigation. Nevertheless, the angular Φ dependence of the EPR spectra of B-form DNA at room temperature is more prominent for Cu(N-dmg)$_2$ and $Cu(sar)_2$, suggesting that these copper(II) complexes with *N*-methylated glycine derivatives are orientated more stereo-specifically than the other $Cu(aa)_2$ complexes (Fig. 2d and e). Freezing of the B-DNA fiber randomized the orientation of all the complexes except that of Cu(N-dmg)$_2$ (data not shown). This result implies that the hydrogen bonding of amino protons of the complexes with solvated water was randomly modulated by micro iceberg formation in the DNA fibers; the *N*-methyl groups in N-dmg protected such randomization. Therefore, there is distinct differences in the interaction of the *N*-methylated $Cu(aa)_2$ and the C-methylated $Cu(aa)_2$ with the DNA.

To investigate further the binding interaction between the $Cu(aa)_2$ and DNA, an EB-quenching assay was carried out to compare the DNA binding strength. Subsequent calculation of the apparent binding constants of the $Cu(aa)_2$ complexes from the classical Stern–Volmer equation at 50% quenching of DNA-bound EB, the order of increasing binding strength of the $Cu(aa)_2$ complexes is found to be $Cu(sar)_2$ < *cis*-$Cu(gly)_2$ < Cu(N-dmg)$_2$ < $Cu(L\text{-ala})_2$ < Cu(C-dmg)$_2$ (Table 1). The C-methylated $Cu(aa)_2$, i.e. Cu(C-dmg)$_2$ and $Cu(L\text{-ala})_2$, binds more strongly to the DNA by ~1–1.5× more than the *N*-methylated $Cu(aa)_2$, i.e. Cu(N-dmg)$_2$ and $Cu(sar)_2$. Although, not intercalators themselves, these $Cu(aa)_2$ complexes (binding constant range $1.882–2.936 \times 10^3$ M^{-1}) bind to DNA much more weakly than classical intercalators (with binding constants of the order of 10^5 M^{-1}) [16]. Those copper(II) complexes,

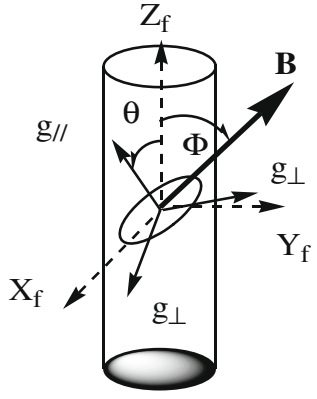

Fig. 1. The coordinate system used for the calculation of EPR line shapes. Static magnetic field **B**, DNA-fiber axes (X_f, Y_f, Z_f), and *g*-tensor axes ($g_{//}$, $g_\perp$). Φ and θ are the angles of the **B** and $g_{//}$ axes from Z_f, respectively.

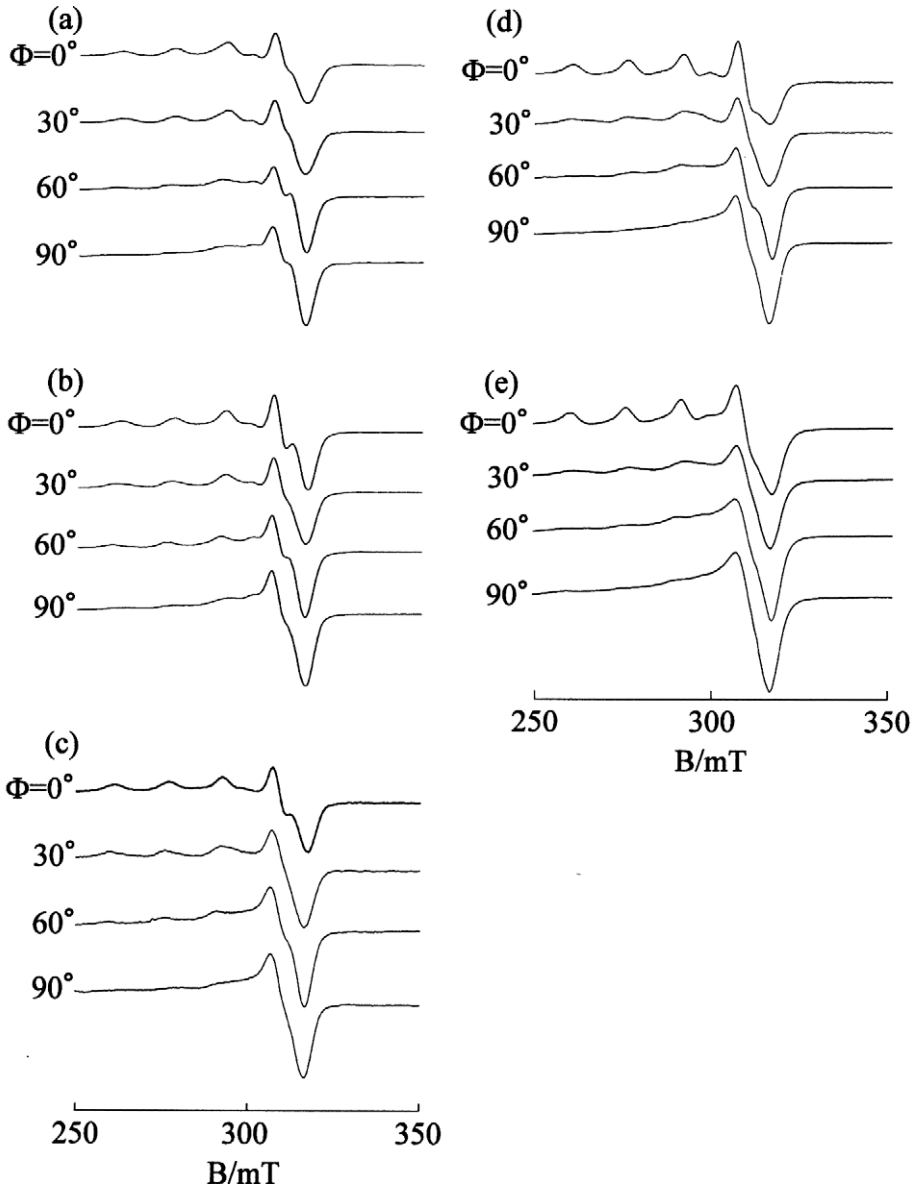

Fig. 2. EPR spectra of Cu(II) glycine derivatives on B-form DNA at r.t. (a) Cu(II)(gly):$g_{//} = 2.26$, $A_{//} = 0.0163\ cm^{-1}$; (b) Cu(II)(C-dmg)$_2$: $g_{//} = 2.25$, $A_{//} = 0.0163\ cm^{-1}$; (c) Cu(II)(L-ala)$_2$: $g_{//} = 2.26$, $A_{//} = 0.0164\ cm^{-1}$; (d) Cu(II)(N-dmg)$_2$: $g_{//} = 2.27$, $A_{//} = 0.0164\ cm^{-1}$; (e) Cu(II)(sar)$_2$: $g_{//} = 2.27$, $A_{//} = 0.0164\ cm^{-1}$.

which binds by partial intercalation, can have binding constant in the magnitude of $10^4\ M^{-1}$ [17]. Nevertheless, the binding constants of Cu(aa)$_2$ are comparable to [Cu(imda)(phen)(H$_2$O)] (K_b, $0.60 \times 10^3\ M^{-1}$; imda = iminodiacetic acid; phen = 1,10-phenanthroline) and [Cu(imda)(5,6-dmp)] (K_b, $3.9 \times 10^3\ M^{-1}$; 5,6-dmp = 5,6-dimethyl-1,10-phenanthroline) which bind to DNA by partial intercalation and groove binding, respectively [18]. The Cu(aa)$_2$ complexes are probably groove binders.

Table 1
Ethidium quenching assay results for the Cu(aa)$_2$.

Complex	Concentration at 50% quenching/μM	Binding constant/M^{-1}
Cu(C-dmg)$_2$	1090	2.936×10^3
Cu(L-ala)$_2$	1554	2.058×10^3
Cu(N-dmg)$_2$	1560	2.050×10^3
cis-Cu(gly)$_2$	1597	2.003×10^3
Cu(sar)$_2$	1770	1.882×10^3

3.2. DNA cleavage by Cu(aa)$_2$ in presence of exogenous agents

This section examines the effect of the position and number of methyl substituent of the copper(II) chelated methylated glycine derivatives, Cu(aa)$_2$, on the nucleolytic property of these complexes in the absence and presence of exogenous agents. The mono- and di-C-methylated (i.e. α-carbon) glycine complexes are Cu(L-ala)$_2$ and Cu(C-dmg)$_2$, respectively while those of the corresponding *N*-amino nitrogen methylated glycine complexes are Cu(sar)$_2$ and Cu(N-dmg)$_2$. The pH value of 8.5 for the nucleolytic experiments was selected to avoid partial dissociation of the Cu(aa)$_2$ complexes at lower pH values. No precipitation was observed in preparing stock solutions of Cu(aa)$_2$ in borate buffer at pH 8.5. To obtain distinct gel images for comparison and achieve the above objective, the concentration of the Cu(aa)$_2$ was optimised. As the Cu(aa)$_2$ complexes alone did not cleave the DNA under our experimental conditions, DNA cleavage experiments were conducted in the presence of (i) hydrogen peroxide alone, (ii) so-

dium ascorbate alone, and (iii) both hydrogen peroxide and sodium ascorbate together.

3.2.1. DNA cleavage by $Cu(aa)_2$ in presence of H_2O_2

Incubating the DNA alone or in the presence of 10 μM H_2O_2 in borate buffer at pH 8.5 for 2 h at 37 °C did not result in any degradation of DNA. About 500 μM of either $CuCl_2$ or $Cu(aa)_2$ also did not cleave DNA in the absence of 10 μM H_2O_2 under the above experimental conditions (Fig. 3). All the copper compounds can induce DNA cleavage in the presence of H_2O_2. The copper(II) complexes of the C-methylated glycine derivatives, i.e. $Cu(C\text{-}dmg)_2$ and $Cu(L\text{-}ala)_2$ (Fig. 3: lanes **11** and **14**, respectively) are better nucleolytic agents as they were able to convert all the supercoiled DNA to nicked and linear DNA. However, the copper(II) complexes of the *N*-methylated glycine derivatives, i.e. $Cu(N\text{-}dmg)_2$ and $Cu(sar)_2$, are the least efficient as some supercoiled DNA still remained uncleaved (Fig. 3: lanes **12** and **15**, respectively). The order of nucleolytic efficiency is $Cu(C\text{-}dmg)_2 > Cu(L\text{-}ala)_2 \simeq$ *cis*-$Cu(gly)_2 > Cu(N\text{-}dmg)_2 \simeq Cu(sar)_2$.

Interestingly, the $CuCl_2$(aq.) can only nick some supercoiled pBR322 (Fig. 3, lane **5**) while the $Cu(aa)_2$ complexes can induce a greater amount of DNA cleavage. This suggests chelation of each of the investigated amino acid to the copper(II) ion enhances its nucleolytic efficiency. This is unlike the tetradentate amino acid, *N*,*N*-ethylenediaminediacetic acid, which upon chelation to copper(II) ion diminished its nucleolytic efficiency [9]. This suggests bidentate amino acid chelated to copper(II) ion can cause more damage to DNA than copper(II) ion in the borate buffer solution. In conclusion, it can be said that $Cu(aa)_2$ with C-methyl substituent are better nucleolytic agents than those with *N*-methyl substituent in the presence of hydrogen peroxide.

The cause of DNA cleavage by copper(II) complexes in the presence of hydrogen peroxide has been attributed to the formation of hydroxyl radicals [19,20]. Nakajima et al. had previously proposed that the hydroxyl radical was produced by a two step reactions in a copper(II)-hydrogen peroxide system: (i) $Cu(II) + H_2O_2 \rightarrow Cu(I) + HOO^{\cdot} + H^+$; and (ii) $Cu(I) + H_2O_2 \rightarrow Cu(II) + OH^- + {}^{\cdot}OH$ [21]. The H_2O_2 has a dual function, i.e. acting initially as reducing agent and then as oxidizing agent. As expected, a hydroxyl radical scavenger, thiourea, inhibited the DNA cleavage by most of the $Cu(aa)_2$ complexes in the presence of hydrogen peroxide (Fig. 4, lanes **12–15**). The degree of inhibition apparently varies with each $Cu(aa)_2$. Unexpectedly, thiourea enhanced the DNA cleavage by $Cu(sar)_2$ (Fig. 4, lane **16**) and copper(II) ions (Fig. 4, lane **6**). As far as we know, this is the first instance of selective activation of a copper(II) complex and copper(II) ion by thiourea towards cleavage of DNA in the presence of hydrogen peroxide. We are currently investigating this further to elucidate this unusual phenomenon.

Consequently, we investigate the difference in nucleolytic efficiency of the $Cu(aa)_2$ by using a PNDA assay to compare the amount of hydroxyl radicals produced from the reaction of $Cu(aa)_2$ with hydrogen peroxide in borate buffer at pH 8.5. In the PNDA assay, the amount of bleaching of the yellow PNDA is directly proportional to the ·OH radicals produced as the reaction stoichiometric ratio of PNDA: ·OH is 1:1 [9]. As can be seen from Fig. 5, the inferred order of increasing ·OH radical production is $Cu(NO_3)_2 < Cu(sar)_2 < Cu(N\text{-}dmg)_2 <$ *cis*-$Cu(gly)_2 < Cu(L\text{-}ala)_2 < Cu(C\text{-}dmg)_2$. As the order of nucleolytic efficiency shows a similar trend, i.e. $Cu(N\text{-}dmg)_2 \simeq Cu(sar)_2 < Cu(L\text{-}ala)_2 \simeq$ *cis*-$Cu(gly)_2 < Cu(C\text{-}dmg)_2$, the nucleolytic efficiency may be attributed to the difference in the rate of ·OH radical production and the resultant amount of radicals produced. This difference in production of ·OH radicals by the $Cu(aa)_2$ complexes may be the result of a number of factors, such as steric hindrance to binding of H_2O_2 or ^-OOH due to methyl groups at the amino nitrogen, electronic effect of electron donating methyl substituent, and difference in redox property of the $Cu(aa)_2$. A previous study by Raja et al. found that the number of methyl groups and their position on the tridentate pyridylmethylethylenediamine ligands in a series of copper (II) complexes affect their DNA binding and nucleolytic efficiency [22]. Among the three complexes, two complexes were less efficient in cleaving the DNA than the third one and this was attributed to the presence of the more sterically hindered ligands in the former. Shao et al. similarly attributed the difference in the decreasing order of nucleolytic

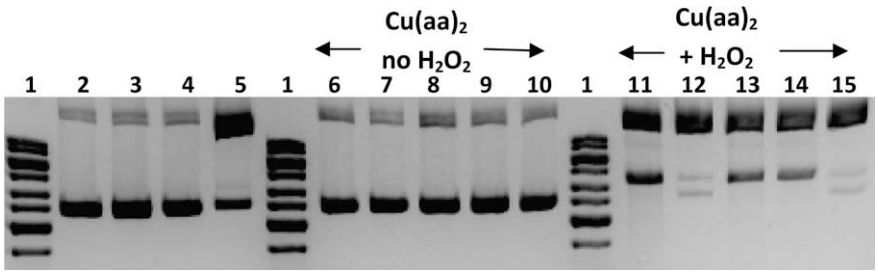

Fig. 3. Electrophoresis results of incubating pBR322 (0.5 μg/μL) with 500 μM of each $Cu(aa)_2$ complexes at 37 °C in borate buffer pH 8.5 in an oven incubator for 2 h in the absence and presence of 10 μM H_2O_2. Lanes **1** are gene ruler 1 Kb DNA ladder; lane **2**, DNA alone; lane **3**, DNA + 10 μM H_2O_2; lane **4**, DNA + 500 μM $CuCl_2$; lane **5**, DNA + 500 μM $CuCl_2$ + 10 μM H_2O_2. property of three copper(II) complexes of aminoquinoline derivatives to increasing steric hindrance of the amino-substituent of the ligands [23]. Others have also reported steric and electronic effects, enantiospecificity and reactive orientation as factors that determine the nature of the DNA binding and nucleolytic efficiency of 26 derivatives of $[Salen\text{-}Mn(III)]^+$ [24]. As for the redox factor, a recent study found that the rate of oxidation of DNA by a series of complexes based on $Ru(tpy)(bpy)O^{2+}$ (with electron-donating or -withdrawing substituent in the polypyridyl ligands) had correlation with the order of redox potentials of these complexes [25]. Thus, similar factors may affect the nucleolytic efficiency of the present $Cu(aa)_2$ complexes.

One of the mechanisms of DNA cleavage by copper(II) complexes in the presence of hydrogen peroxide involves binding of the metal complex species to the DNA and subsequent DNA cleavage by ·OH radicals produced at the binding sites [19–21,26,27]. The order of increasing binding strength of the $Cu(aa)_2$ complexes has been found to be $Cu(sar)_2$ < *cis*-$Cu(gly)_2$ < $Cu(N\text{-}dmg)_2$ < $Cu(L\text{-}ala)_2$ < $Cu(C\text{-}dmg)_2$ (Table 1, Section 3.1). The order of increasing ·OH radical production is $Cu(sar)_2$ < $Cu(N\text{-}dmg)_2$ < *cis*-$Cu(gly)_2$ < $Cu(L\text{-}ala)_2$ < $Cu(C\text{-}dmg)_2$ (Fig. 5). Thus, the greater nucleolytic efficiency of the copper(II) C-methylated glycine derivatives compared to those of *N*-methylated glycine derivatives can be attributed to both the greater binding strength of these complexes and higher ·OH radical production. Similar dependence of nucleolytic efficiency on the DNA binding strength has been observed for various series of copper(II) complexes [15,28,29].

3.3. DNA cleavage by $Cu(aa)_2$ in the presence of sodium ascorbate alone or of both sodium ascorbate and H_2O_2

The $CuCl_2$ and all the $Cu(aa)_2$ complexes do not cleave the DNA in the absence of sodium ascorbate (Fig. 6, lanes **4**, **6–10**). DNA in the presence of 2 μM of sodium ascorbate showed no DNA cleavage (Fig. 6, lane **3**). However, DNA incubated with 500 μM of $CuCl_2$ in the presence of 2 μM of sodium ascorbate could nick a small amount of supercoiled plasmid DNA (Fig. 6, lane **5**). Except for $Cu(sar)_2$, the other $Cu(aa)_2$ complexes induced more extensive nicking of the DNA. No double nicking of DNA to produce linear DNA was observed. This suggests that chelating the bidentate amino acid to the copper(II) ion normally enhanced its nucleolytic efficiency in the presence of ascorbate. By comparing the nucleolytic efficiency of the copper(II) C-methylated glycine derivatives with those of the *N*-methylated glycine derivatives, the same conclusion is again obtained as that for the DNA cleavage by $Cu(aa)_2$ in the presence of hydrogen peroxide. However, *cis*-$Cu(gly)_2$ (instead of $Cu(C\text{-}dmg)_2$) is the most efficient nucleolytic agent in the presence of sodium ascorbate as all the supercoiled DNA was converted to nicked DNA (Fig. 6, lane **13**).

The ROS scavenging experiment for the reaction of DNA with $Cu(aa)_2$ in the presence of sodium ascorbate was carried out to determine the active species responsible for DNA cleavage. No distinct DNA cleavage inhibition was detected for thiourea, sodium azide and tiron (results not shown). Thus, no detectable ·OH, singlet oxygen ($^1O_2$), and superoxide anion radical (O_2^-) is produced. The DNA cleavage by $Cu(aa)_2$ in the presence of sodium ascorbate (NaHA) may be due to the formation of ascorbyl (=ascorbate) radical as the active cleavage agent. Ascorbate is known to be a one electron donor and electron transfer results in formation of ascorbyl radical [30,31]. However, there is total inhibition of DNA cleavage by neocuprione, a Cu(I)-specific chelator (Fig. 7A). The present DNA cleavage by $Cu(aa)_2$ seems to be different from the that by $[Cu(phen)(L\text{-}threo)(H_2O)](ClO_4)$ in the presence of ascorbate where inhibition by DMSO indicated the role of ·OH radicals [32]. Additional experiment with DMSO shows no inhibition of DNA cleavage by all the $Cu(aa)_2$ (data not shown). Thus, ascorbyl radicals may be

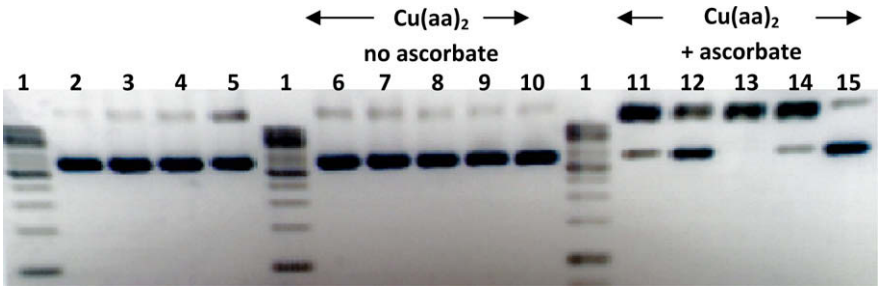

Fig. 6. Electrophoresis results of incubating pBR322 (0.5 μg/μL) with 500 μM of each $Cu(aa)_2$ complexes at 37 °C in Borate buffer pH 8.5 in an oven incubator for 2 h in the absence and presence of 2 μM sodium ascorbate. Lanes labeled **1** are gene ruler 1 Kb DNA ladder; lane **2**, DNA alone; lane **3**, DNA + 2 μM sodium ascorbate; lane **4**, DNA + 500 μM $CuCl_2$; lane **5**, DNA + 500 μM $CuCl_2$ + 2 μM sodium ascorbate. Lanes **6–10** DNA + $Cu(aa)_2$ alone: **6**, $Cu(C\text{-}dmg)_2$; **7**, $Cu(N\text{-}dmg)_2$; **8**, *cis*-$Cu(gly)_2$; **9**, $Cu(L\text{-}ala)_2$; **10**, $Cu(sar)_2$. Lanes **11–15** DNA + $Cu(aa)_2$ + 2 μM sodium ascorbate: **11**, $Cu(C\text{-}dmg)_2$; **12**, $Cu(N\text{-}dmg)_2$; **13**, *cis*-$Cu(gly)_2$; **14**, $Cu(L\text{-}ala)_2$; **15**, $Cu(sar)_2$.

the active cleaving species in the DNA cleavage by $Cu(aa)_2$ in the presence of ascorbate alone.

In the above discussion on the mechanism of DNA cleavage by (i) $Cu(aa)_2$ in the presence of H_2O_2 and (ii) $Cu(aa)_2$ in the presence of ascorbate, there seems a common and essential initial step in the process. In both cases, the Cu(II) species seems to have been reduced to the Cu(I) species. To verify this, spectroscopic experiments on the reactions of the 500 μM $Cu(aa)_2$ with (i) H_2O_2 (10 mM) in the presence of neocuproine (750 μM), and with (ii) ascorbate (200 μM) in the presence of neocuproine (250 μM), were carried out. For each $Cu(aa)_2$ tested in both series of experiments, there was appearance of a new intense band at 456 nm (Fig. 8 spectra A and B show only spectra for $Cu(L\text{-ala})_2$). The formation of the Cu(I)–neocuproine species was confirmed by comparison with the spectrum of a solution of copper(I) iodide with neocuproine which has a λ_{max} at 456 nm (Fig. 8 Spectrum C). In view of this, DNA cleavage mechanism by $Cu(aa)_2$ is likely to involve the following reactions:

$$Cu(II) + H_2O_2 \rightarrow Cu(I) + HOO^{\cdot} + H^+ \quad (1)$$

$$Cu(I) + H_2O_2 \rightarrow Cu(II) + HO^- + {}^{\cdot}OH \quad (2)$$

$$Cu(II) + AH^- \rightarrow Cu(I) + A^{\cdot -} + H^+ \quad (3)$$

where Cu(II) represents copper(II) species, Cu(I) represents copper(I) species, $HOO^{\cdot}$ represents the hydroperoxo (= hydroperoxyl) radical, AH^- is the ascorbate anion and $A^{\cdot -}$ is the ascorbyl radical. Reaction (1) is not likely to directly responsible for DNA cleavage as the hydroperoxo radicals are reported to have little or no ability to induce DNA cleavage [33]. A crucial step in the inhibition by neocuproine for the $Cu(aa)_2$–H_2O_2 system may involve the oxidatively stable Cu(I)–neocuproine species which were not oxidized by H_2O_2 [34]. Consequently, reaction (2) did not occur and no hydroxyl radicals were formed to cleave the DNA.

To investigate the inhibition of DNA cleavage by the $Cu(aa)_2$-ascorbate system by neocuproine, we monitor the various $Cu(aa)_2$–neocuproine mixtures spectroscopically and found that there was a distinct shift of the λ_{max} of the $Cu(aa)_2$ to longer wavelengths, indicating partial or total displacement of coordinated aa^- ligands by neocuproine to form a series of new species (Fig. 9 and Table 2) whose λ_{max} values are close to that of Cu(II)–neocuproine

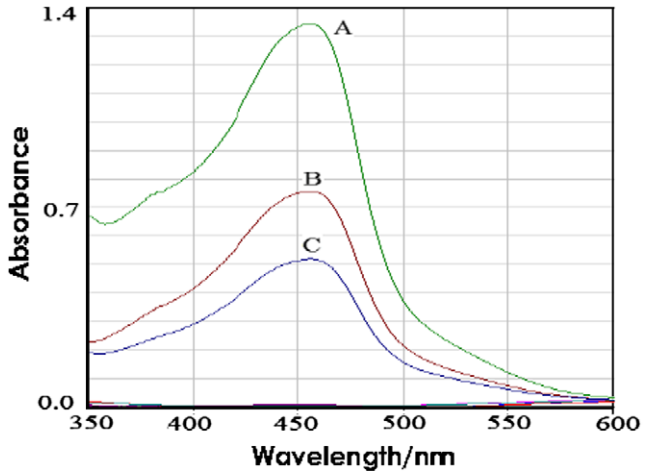

Fig. 8. Visible spectra of (A) 500 μM $Cu(L\text{-ala})_2$ in the presence of 10 mM H_2O_2 + 750 μM neocuproine; (B) 500 μM $Cu(L\text{-ala})_2$ in the presence of 200 μM NaHA + neocuproine; (C) CuI + neocuproine.

at 689 nm. Thus, the Cu(II)–neocuproine species can be formed in the DNA-$Cu(aa)_2$-NaHA mixtures in the presence of neocuproine. Inhibition of DNA cleavage cannot be directly due to formation of this Cu(II)–neocuproine species as the copper(II) oxidation state has not been reported to be stabilized. In fact, Cu(II)–neocuproine has been extensively used as an oxidizing agent for a variety of antioxidants in the CUPRAC method [35]. In fact, a blue methanolic solution of Cu(gg)(dmp) (gg = glycylglycinate; dmp = neocuproine) has been reported to eventually becomes yellow by a neocuproine-promoted reduction of Cu(II) to form the stable $Cu(I)(dmp)_2^+$ [36]. Hall et al. have reported that copper(II)–neocuproine complexes can easily be reduced to the copper(I) state and this reduction is more rapid if the solution is boiled [37]. No explanation was given for the reduction of the copper(II)–neocuproine in the absence of any reducing agent. Thus, the DNA-bound $Cu(aa)_2$ species can be converted to DNA-bound Cu(II)–neocuproine species and be still readily reduced to DNA-bound Cu(I)–neocuproine species by

	706(0.014)	689(0.046)

ascorbate to produce ascorbyl radical. However, the ascorbyl radicals may be formed further from the DNA and prevented from reaching the DNA by the Cu(I)–DNA–neocuproine complex as it was established that the initial $Cu(aa)_2$ binds very weakly to the DNA. Further investigation is needed to confirm this proposed inhibition of DNA cleavage by neocuproine in the $Cu(aa)_2$-ascorbate system.

As thus far, no comparison has been made for the use of H_2O_2 alone, sodium ascorbate (or ascorbic acid) alone, and the combination of H_2O_2 and sodium ascorbate to activate copper(II) complexes for DNA cleavage, we have done so for our series of $Cu(aa)_2$ complexes. In all cases (including the $CuCl_2$), the nucleolytic efficiency of $Cu(aa)_2$ increases in the following order in the presence of exogenous agent: sodium ascorbate < hydrogen peroxide < {hydrogen peroxide + sodium ascorbate} (Fig. 10). For the DNA cleavage by $Cu(aa)_2$ in the presence of both sodium ascorbate and H_2O_2, the order of nucleolytic efficiency is $Cu(sar)_2$ < $Cu(N\text{-}dmg)_2$ < $Cu(L\text{-}ala)_2$ < $Cu(C\text{-}dmg)_2$ < *cis*-$Cu(gly)_2$. Again the copper(II) complexes

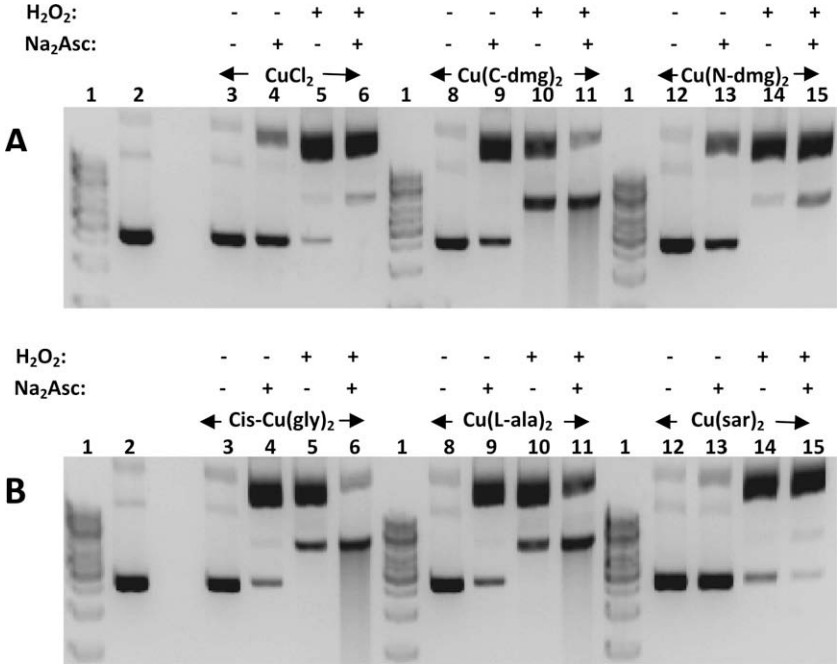

Fig. 10. Electrophoresis results of incubating pBR322 (0.5 μg/μL) with 500 μM of each $Cu(aa)_2$ complexes at 37 °C in Borate buffer pH 8.5 in an oven incubator for 2 h in the absence and presence of exogenous agents (10 μM H_2O_2; 2 μM sodium ascorbate; 10 μM H_2O_2 + 2 μM sodium ascorbate). A: $CuCl_2$, $Cu(C\text{-}dmg)_2$, $Cu(N\text{-}dmg)_2$; B: *cis*-$Cu(gly)_2$, $Cu(L\text{-}ala)_2$, $Cu(sar)_2$.

of C-methylated glycine derivatives cleave the DNA better than the copper(II) complexes of the *N*-methylated glycine derivatives. The higher DNA cleavage by $Cu(aa)_2$-NaHA-H_2O_2 system can be attributed to the more efficient production of ·OH by virtue of more Cu(I) species produced through reactions (1) and (3).

In conclusion, the $Cu(aa)_2$ complexes bind weakly to the DNA with a similar orientation. Nevertheless, the differences in binding between the copper(II) C-methylated glycine derivatives and the copper(II) *N*-methylated glycine derivatives are distinguishable. The electrophoresis results show that the nucleolytic property of the former complexes are better than that of the latter in the presence of hydrogen peroxide alone or sodium ascorbate alone or both combination of hydrogen peroxide and sodium ascorbate. For mechanism of the cleavage reaction, reduction of Cu(II) to Cu(I) species by hydrogen peroxide or ascorbate has been confirmed.

ABSTRACT

A series of cationic, half-sandwich ruthenium complexes with the general formula $[(\eta^6\text{-}p\text{-cymene})RuCl(S\cap N)]^+$, (S∩N = MeS-$C_6H_4$-2-N=CHAr, **1a–f**) have been studied by cyclic voltammetry and X-ray crystallography. The complexes **1a–e** undergo irreversible oxidations and the results are compared to related complexes. The molecular structures of **1d**[PF_6] and **1f**[PF_6] were determined by X-ray crystallography.

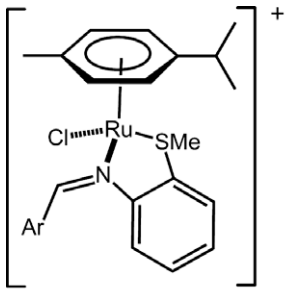
1. Introduction

Schiff bases are popular ligands in coordination chemistry due to their easy syntheses and their ability to be easily modified both sterically and electronically [1]. There are many examples of chelating Schiff base ligands that are potentially anionic, but neutral bidentate varieties are less common. Common examples are the 2-pyridylimines, $NC_5H_4CH{=}NR$, [2] and phosphinoimines derived from 2-(diphenylphosphino)benzaldehyde [3]. Recently, we have reported the synthesis and coordination chemistry of two classes of thioether-containing Schiff base ligands. One class is derived from the reaction of 2-(methylthio)aniline with aldehydes [4] and the other from the reaction of 2-(alkylthio)benzaldehydes with amines [5]. The first class of ligands, which form a five-membered chelate ring upon coordination to a metal center, has been shown to be susceptible to hydrolysis upon coordination to metal centers, while the second class with six-membered chelate rings is much more stable with respect to hydrolysis. In fact, our initial attempts to crystallize the compounds resulted in the isolation of the 2-methylthioaniline complex [4]. After several days under an ambient atmosphere, the Schiff base ligand bound to the ruthenium center completely hydrolyzes. Using X-ray crystallography, we can examine the changes in the ligand structure upon coordination to a metal center and how these changes may affect the hydrolytic stability of the Schiff bases upon coordination to the ruthenium center.

Arene ruthenium complexes are versatile compounds and have found use in catalysis [6] and medicine [7]. Investigation of the structural and electrochemical properties of η^6-arene ruthenium complexes can provide insight into their utility. There are very few reports of electrochemical studies on cationic arene ruthenium complexes [5,8]. Significant information can be obtained by investigating the effect of ligand structure on the properties of transition metal complexes.

The present work is an extension of our previous studies of $[(\eta^6\text{-}p\text{-cymene})RuCl(S\cap N)]^+$ complexes [4,5]. Herein we report the electrochemical properties and X-ray crystal structures of some η^6-*p*-cymene ruthenium complexes with our first generation of S∩N Schiff base ligands [4] and compare them to related complexes.



2. Results and discussion

2.1. Electrochemical behavior

The $[(\eta^6\text{-}p\text{-cymene})RuCl(MeSC_6H_4\text{-}2\text{-}N{=}CH\text{-}C_6H_4\text{-}p\text{-}X)]^+$ complexes **1a–e** (Scheme 1) were analyzed by cyclic voltammetry. All of the complexes show an irreversible Ru(II) to Ru(III) oxidation between 1196 and 1336 mV versus ferrocene/ferrocenium (Table 1). As expected, electron donating groups on the ligand reduce the oxidation potential while electron withdrawing groups increase the oxidation potential. To that end, complex **1d** (X = NO_2)

Scheme 1.

is the most difficult to oxidize, while complex **1b** (X = OCH_3) is the easiest. A plot of E_{pa} versus Hammett constant, σ, reveals a linear relationship (Fig. 1) with a slope of about 134 mV/σ, which is very similar to the previously reported [(η^6-*p*-cymene)RuCl(RSC_6H_4-2-CH=NAr)]$^+$complexes [5]. In fact, the oxidation potentials for **1a–e** are very near those of our previously reported complexes. All of the complexes are easier to oxidize the than the reported phosphine complex [(η^6-*p*-cymene)RuCl(dppf)]$^+$ [8b] but more difficult to oxidize than the analogous phosphine imine complex [(η^6-*p*-cymene)RuCl($Ph_2PCH_2P(Ph_2)$=NC_5F_4N)]$^+$ [8c].

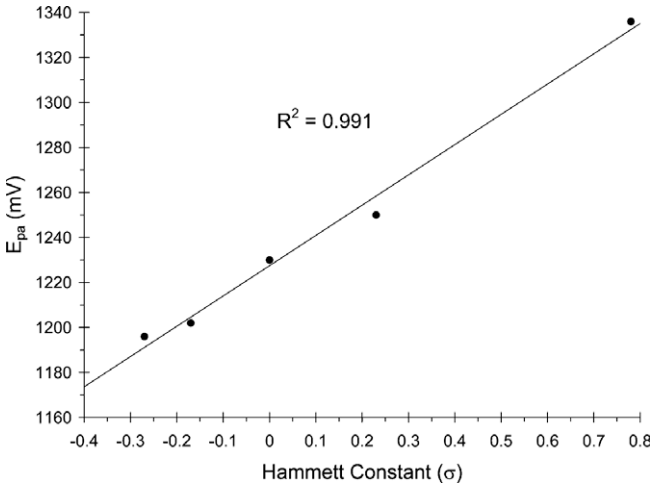

Fig. 1. A plot of E_{pa} vs. Hammett constant, σ, for the ruthenium complexes **1a–e**.

2.2. X-ray crystallographic analysis

Single crystal X-ray structure analyses were carried out for compounds **1d**[PF_6] (Fig. 2) and **1f**[PF_6] (Fig. 3). Crystallographic data are given in Table 2 and selected bond lengths (Table 3) and angles (Table 4) are also given along with relevant bond lengths and angles for the free ligand $MeSC_6H_4$-2-N=CH-3,5-$C_6H_3(OCH_3)_2$ [9]. In the ruthenium complexes, the S∩N ligands are coordinated in an η^2 fashion resulting in a five-membered ring. The complexes adopt the familiar piano stool geometry. The ruthenium atom is situated 1.688(15) and 1.6954(10) Å from the centroid of the *p*-cymene ring in **1d** and **1f**, respectively. These distances are shorter than those in the previously characterized [(η^6-*p*-cymene)RuCl(RSC_6H_4-2-CH=NAr)]$^+$complexes [5], but are in agreement with other structurally characterized cationic η^6-*p*-cymene ruthenium complexes [10]. The bond angles for the leg portion of the piano stool range from approximately 79–80° for the N(1)–Ru–S angle to approximately 91–92° for the S–Ru–Cl angle.

Looking at an overlay of the structures of **1d** and **1f** (Fig. 4) using the program Mercury [11], the two structures are very similar. The largest angle differences are the angles around the imine carbon C20 (Table 4). Another difference, which is evident in the overlay of the two structures, is the orientation of the C10–C15 benzene ring of the ligand. The angle between the mean plane of the η^6-*p*-cymene ligand and the mean plane of the C10–C15 benzene ring is 20.97(8)° in **1d** and 14.57(7)° in **1f**. The C10–C15 ring is **1f** is probably pushed further away from the arene substituent on the imine due to the increased steric bulk of the 3,5-methoxy groups. This also explains the larger S–Ru–Cl angle in **1d**, 92.09(4)°, compared to complex **1f**, 90.934(12)°.

Comparing the structure of complex **1f** with that of the free ligand $MeSC_6H_4$-2-N=CH-3,5-$C_6H_3(OCH_3)_2$ [9], the bond distances

are all very similar (Table 3). The only significant differences are in the angles of the imine and thioether portions of the compounds. The N–C20–C21 angle is about 6.9° smaller in the free ligand while the C16–N–C20 angle is about 4.5° smaller. Additionally, the imine is in the *cis* configuration when coordinated to the ruthenium center but in the *trans* configuration in the free ligand (Fig. 5). This change in imine geometry is not required for coordination (either the *cis*- or *trans*-imine could coordinate to the metal center). However, the *cis*-geometry minimizes steric interactions between the arene substituent on the imine and the metal center. The C10–S–C1 bond angle decreases by about 2.4° upon coordination of the ligand to the ruthenium center, again most likely due to increased steric repulsion from the ruthenium fragment. The decreased bond angles around C20, N, and S most likely are the reason for the slight lengthening of the bonds involving those three atoms as shown in Table 3.

Of primary interest is the bite angle of the S∩N ligands in these complexes; 80.32(8)° in **1d** and 79.18(3)° in **1f**. They are significantly smaller than the bite angles of our previously reported RSC_6H_4-2-CH=NAr, which form six-membered rings upon coordination with bite angles in the $[(\eta^6$-*p*-cymene)RuCl(RSC_6H_4-2-CH=NAr)$]^+$ complexes of 86.86(12)°–89.22(4)° (Table 5). This smaller bite angle in the MeS-C_6H_4-2-N=CHAr ligands, along with the changes in the imine bond angles and geometry, may explain the instability of complexes **1a–f** towards hydrolysis [4].

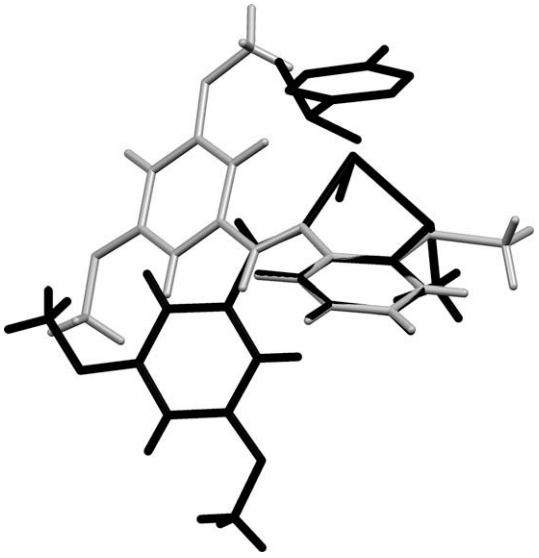

Fig. 5. Overlay of the crystal structures of complex **1f** (black) and the free ligand $MeSC_6H_4$-2-N=CH-3,5-$C_6H_3(OCH_3)_2$ (grey) generated using the program Mercury.

3. Conclusions

While the arene ruthenium complexes of our S∩N Schiff base ligands derived from 2-methylthioaniline have similar electrochemical properties to those with S∩N ligands derived from 2-(alkylthio)benzaldehydes, the decrease in bite angle may lead to more reactive metal complexes with respect to hydrolysis.

4. Experimental

4.1. General considerations

All reagents were of commercial grade and used without further purification. The ruthenium complexes were synthesized using the literature procedure [4] and their analytical and spectroscopic data are reported there. The electrochemical studies were carried out in acetonitrile using a BAS CV-50W potentiostat. A conventional three-electrode cell consisting of a platinum disk working electrode, a platinum wire auxiliary electrode and a Ag/AgCl reference electrode was used. The cyclic voltammograms were run in 0.1 M $[Bu_4N][PF_6]$ at a scan rate of 100 mV/s. The scanning limits were +0.5 to +1.9 V versus Ag/AgCl, and the ferrocene/ferrocenium couple appeared at +445 mV versus the Ag/AgCl reference. All potentials are reported versus the ferrocene/ferrocenium couple.

4.2. X-ray crystallography

Orange X-ray quality crystals of complexes **1b**$[PF_6]$ and **1f**$[PF_6]$ were isolated by layering a solution of the complex in dry 1,2-dichloroethane with dry *n*-heptane under a nitrogen atmosphere. Data were collected at Youngstown State University on a Bruker AXS SMART APEX CCD-equipped diffractometer at −173 °C using MoKα radiation (λ = 0.71073 Å) from a graphite monochromater. Cell refinement and data reduction were accomplished using SAINT+ [12]. The data were corrected for absorption through use of the SADABS procedure. See Table 2 for a summary of crystal data and X-ray collection information.

Solution and data analysis were performed using the WinGX software package [13]. The structures were solved by direct methods using the program SIR2002 [14]. The refinements were completed using the program SHELX-97 [15]. Hydrogen atoms were assigned positions based on the geometries of their attached carbons. See Table 2 for final refinement parameters.

ABSTRACT

Hybrid aerosol assisted and atmospheric pressure chemical vapour deposition methodology has been utilised to produce nanocomposite thin films of gold nanoparticles and vanadium dioxide from vanadyl acetylacetonate and auric acid. The addition of tetraoctyl ammonium bromide (TOAB) to the precursor solution gave control of the size and distribution of gold nanoparticles in the vanadium oxide matrix. These reactions led to vanadium dioxide films with reduced crystallite sizes and enhanced thermochromic properties. The films were analysed by X-ray diffraction, scanning electron microscopy and X-ray photoelectron spectroscopy. Their optical and thermochromic behaviour was also determined. This hybrid method shows great potential for the production of nanocomposite thin films with good physical properties.

1. Introduction

The production and use of nanoparticles is a major research theme worldwide [1]. Many applications of these nanoparticles will rely on their incorporation into a host matrix. The production of a nanocomposite can change the physical properties of both the host matrix and the nanoparticles. Additionally the resulting nanocomposite serves both to immobilize the nanoparticles and to render them chemically inert. Much work has focused on the production of metallic nanoparticles incorporated into a semi-conductor matrix [1–8], this has led to improvements in photocatalysis [1,9,10], photoanodes [11], and various chromatic films [12,13].

Here we describe a one step hybrid chemical vapour deposition route for producing nanocomposite thin films. Gold nanoparticles are preformed in solution using tetraoctylammonium bromide as a surfactant in methanol and transported to the reaction chamber using an aerosol. A conventional atmospheric pressure chemical vapour deposition (APCVD) reaction is used to grow the semi-conductor matrix; in this case vanadium dioxide, at the same time ensuring that gold nanoparticles are encapsulated in the growing vanadium dioxide film.

Vanadium dioxide is a material that has shown potential for use as an intelligent glazing material [14,15]. The material has a metal to semiconductor transition (MST) where there is a structural change from a higher temperature rutile structure to a lower temperature monoclinic structure [16]. This structural transition results in a change in electrical conductivity and optical properties. The monoclinic phase is a semiconductor and generally transparent to solar radiation, whereas the rutile material is metallic and reflects a wide range of solar radiation. Work has been conducted in recent years to try and reduce the transition temperature of the vanadium dioxide MST by adding dopants [17,18], of which tungsten has been the most successful dopant reducing the MST by 20–25 °C per atom % [19].

In this work, we focus on using gold nanoparticles to improve the properties of vanadium dioxide films. Gold nanoparticles have a surface plasmon resonance that is strongly absorbing, the frequency of which is strongly dependent on the dielectric properties of the host matrix as well as the size and shape of the nanoparticles [20,21]. By using nanoparticles of the right size and shape, the properties of the resulting films can be tuned. The use of auric acid and colloidal gold suspensions used in aerosol assisted chemical vapour deposition (AACVD) to produce gold nanoparticle films have been reported [22,23]. However, the use of auric acid alone led to films with a wide nanoparticle size distribution [22]. It has been shown that the use of a coordinating surfactant controlled the size and shape of the deposited gold nanoparticles [23]. Indeed gold doped vanadium dioxide composites produced using reactive ion beam sputtering followed by annealing and laser ablation have received attention as fast optical switches [24,25]. Attempts to produce gold doped vanadium dioxide films from a single source

AACVD reaction have proved futile as there appears to be an adduct reaction on mixing solutions of vanadium and gold precursors [26]. There are no cheap and easily available gold precursors for use in APCVD, there is however potentially an abundance of precursors that can be used in AACVD as the precursor limitations of APCVD do not apply [27,28], indeed previous work has reported the use of auric acid [22,23].

This hybrid technique of combining aerosol assisted and atmospheric pressure gas streams [26] has advantages over other techniques for the deposition of nanocomposites; firstly it is highly flexible, a wide variety of semiconductor metal oxides are grown using APCVD, whilst AACVD has the potential to deliver any solution of preformed nanoparticles. Secondly CVD is industrially well known and has wide application in the microelectronics and glazing industry, it has a number of established advantages such as conformal coating and good substrate adherence.

Here we show that using the hybrid technique, high quality vanadium dioxide–gold nanocomposites can be made. The use of the surfactant tetraoctylammonium bromide (TOAB) in the film formation allowed for greater control of nanoparticles.

2. Experimental

A 98% nitrogen, 2% oxygen mixture was obtained from the British Oxygen Company (BOC) and used as supplied in the plain line. Nitrogen (99.99%) was obtained from BOC and used as supplied in the bubbler lines. Coatings were obtained on SiO_2 coated float glass. Combined AA/AP CVD experiments were conducted on 150 mm × 45 mm × 3 mm pieces of glass using a flat-bed cold-walled CVD reactor. The glass was cleaned prior to use by washing with petroleum ether (60–80 °C) and isopropanol and then dried in air. A graphite block containing a Whatman cartridge heater was used to heat the glass substrate. The temperature of the substrate was monitored by a Pt–Rh thermocouple. Independent thermocouple measurements indicated that temperature gradients of up to 50 °C cm^{-1} were observable at a substrate temperature of 600 °C across the surface of the glass. The rig was designed so that four independent gas lines could be used. All gas handling lines, regulators and flow valves were made of stainless steel and were 6.5 mm internal diameter except for the inlet to the mixing chamber and the exhaust line from the apparatus that were 13 mm in diameter. In these experiments three gas lines were used. Gases came directly from a cylinder and were preheated by passing along 2 m lengths of stainless steel tubing, which were curled and inserted inside a tube furnace. The temperatures of all the gas inlet lines were monitored by Pt–Rh thermocouples and Eurotherm heat controllers.

Vanadyl acetylacetonate (99.99%) was obtained from Aldrich and used without further purification and was placed into a stainless steel bubbler. The bubbler was heated to 175 °C by a heating jacket and vanadyl acetylacetonate introduced into the gas streams by passing hot nitrogen gas through the bubbler. Auric acid (40 mg, 0.117 mmol 99.9%, obtained from Aldrich and used without further purification) was dissolved in 25 ml methanol and placed into a glass flask. In experiments using TOAB, between 1.00 and 0.06 g was added to the reaction flask and stirred for 10 min prior to the deposition experiment. An aerosol was generated at room temperature by use of a PIFCO air humidifier. Nitrogen was passed through the aerosol mist, thus forcing the aerosol particles encapsulated with precursor into the heated reaction chamber.

The two components of the system were transported using stainless steel pipes 13 mm internal diameter respectively. The pipes were attached directly to the reaction chamber of the coater. Gas flows were adjusted using suitable regulators and flow controllers. The exhaust from the reactor was vented directly into the extraction system of a fume cupboard. This deposition setup has been described in more detail previously [26]. All of the apparatus was baked out with nitrogen at 150 °C for 30 min before use. Deposition experiments were conducted by heating the horizontal-bed reactor and the bubblers to the desired temperatures before diverting the nitrogen line through the bubbler and hence to the reactor. Deposition experiments were timed by use of a stopwatch and were conducted between 30 s and 30 min in order to vary the thickness of the samples. The maximum possible deposition temperature with this equipment was 600 °C. At the end of the deposition only nitrogen was allowed to flow over the glass substrate until the substrate was sufficiently cool to handle (~60 °C). Samples were handled and stored in air. Substrate temperature for deposition was kept constant at 525 °C as this has been found to be the optimal temperature to grow monoclinic vanadium dioxide thin films from vanadyl acetylacetonate. Due to the nature of the graphite heating block there are changes in thickness that correlate with the temperature gradient across the substrate however, a highly uniform area 2 cm × 5 cm in the middle of the substrate is always observed, it is this area that is referred to when discussing the uniformity of the films.

Electron microprobe analysis was obtained on a JEOL EMA and referenced against vanadium and oxygen standards. EDAX and WDAX were conducted using a Phillips XL30 ESEM instrument. SEM images were acquired on a Jeol 6301F field emission instrument. X-ray diffraction patterns were measured on a Bruker Gadds D8 diffractometer using monochromated (Cu $K\alpha_{1+2}$) radiation in the reflection mode using a glancing incident angle of 5°. Reflectance and transmission spectra were recorded between 300 and 2500 nm on a Perkin–Elmer Lambda 950 UV–Vis spectrometer. UV–Vis spectra were obtained using a Helios double beam instrument. Raman spectra were acquired on a Renishaw Raman system 1000 using a helium–neon laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of neon. Transmittance-temperature studies were performed on a Perkin–Elmer 457 grating spectrometer set to 4000 cm^{-1}. An aluminium temperature cell controlled by RS resistive heaters, Eurotherm temperature controllers and k-type thermocouples were used to manipulate sample temperature. Sample temperature was measured using a k-type thermocouple taped directly onto the film surface. Film thickness was measured directly by scanning electron microscopy then correlated with EDAX and optical transmission data.

3. Results

Composite VO_2/Au nanoparticle films were grown by the use of hybrid aerosol assisted/atmospheric pressure CVD from [$HAuCl_4$] and tetraoctylammonium bromide (TOAB) in methanol (the aerosol component) and [$VO(acac)_2$] (the atmospheric pressure component). The films showed good surface coverage, uniformity and reproducibility. Film thickness could be easily varied by increasing or decreasing the time of deposition. In all cases at least the first 75% of the substrate is covered, similar to that observed previously with VO_2 films produced from the APCVD reaction of vanadyl acetylacetonate and with other APCVD systems such as those that produce metal oxide and metal phosphide materials [29–33]. Similarly there are changes in thickness that correlate with the temperature gradient across the substrate surface as seen previously [29–33] and a highly uniform area 2 cm × 5 cm in the middle of the substrate. The colour of the films (Table 1) could be altered substantially with a range of blues and greens being produced in contrast to the yellow/brown colour normally associated with monoclinic vanadium dioxide; this is attributed to the inclusion of gold nanoparticles in the VO_2 matrix. UV/Vis absorbance

Table 1
Summary of experimental conditions and chemical analysis. Flow conditions were constant for all experiments; Plain flow = 2 L min^{-1}, $VO(acac)_2$ Bubler flow = 4 L min^{-1} and Aerosol flow = 1 L min^{-1}.

Sample	Contents of AACVD flask	EDAX/WDAX/XRD phase	Au/V ratio	λ max in visible transmission/nm	λ max in visible reflection/nm
1	40 mg $HAuCl_4$ 1.00 g TOAB	VO_2 (m) + Au	0.52	493	495
2	40 mg $HAuCl_4$ 0.50 g TOAB	VO_2 (m) + Au	0.15	493	530
3	40 mg $HAuCl_4$ 0.25 g TOAB	VO_2 (m) + Au	0.96	566	559
4	40 mg $HAuCl_4$ 0.12 g TOAB	VO_2 (m) + Au	0.09	566	545
5	40 mg $HAuCl_4$ 0.06 g TOAB	VO_2 (m) + Au	0.29	561	596
6	40 mg $HAuCl_4$ No TOAB	VO_2 (m) + Au	0.35	570	591

spectroscopy of the gold doped films indicates that a plasmon resonance band is present; however this is very broad, ~100 nm, due to significant variation of gold nanoparticle size (Fig. 1). The strength of the band correlates strongly with the gold to vanadium ratio in the films. The addition of TOAB into the precursor flask causes a significant shift in the SPR centre (Fig. 1).

The films from the hybrid CVD reaction were also more adherent than films of vanadium dioxide or gold produced using AACVD [22,23]; they passed the Scotch tape test and could not be wiped off with a piece of towelling. The films could however, be marked with a brass or steel stylus similar to films of VO_2 produced previously [19,34,35]. The films were found to be electrically insulating

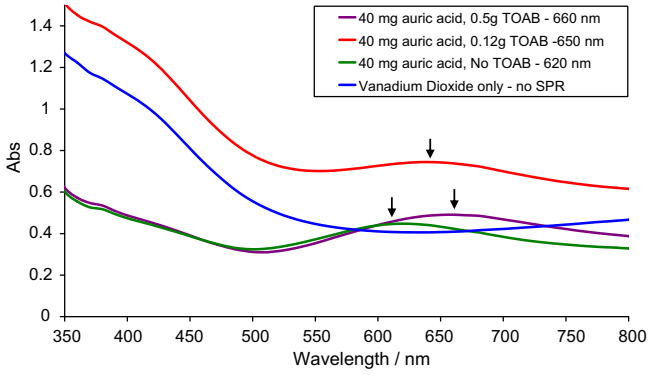

Fig. 1. UV/Vis spectroscopy and surface plasmon centres of typical samples of a VO_2/Au nanoparticle film produced using the hybrid AA/AP CVD methodology grown with TOAB and without TOAB. The arrows mark the position of the surface plasmon band resonance centre. The absorbance spectrum of a VO_2 film is included for comparison.

suggesting that the amount of gold in the films was not enough to exceed the percolation limit. Details of experimental conditions are given in Table 1.

Scanning electron microscopy (Fig. 2) of the samples indicates an island growth morphology. Typically for samples produced with TOAB (Samples 1–5) a smaller average island size of 75 nm (Fig. 2A) is seen compared with 150 nm (Fig. 2B) for those produced without.

Analysis with energy dispersive analysis of X-rays indicated that the films contained gold and vanadium (summarised in Table 1) and no contaminant, at least to the limit of detection of the methodology (around 1/2 atom % depending on the element).

Backscattered electron imaging (Fig. 3) and EDAX spot analysis indicated that gold is found amongst the crystallites on the surface, rather than segregating as independent gold crystallites as seen as a result of the sol gel process [36]. There were stark differences between the gold crystallites grown with TOAB (Fig. 3A) and those grown without (Fig. 3B). The gold crystallites in films grown with TOAB formed spherical agglomerates with a diameter in the region of 70 ± 10 nm. The gold crystallites in films grown without TOAB were very different; the crystallite agglomerates were smaller, around 40 nm diameter, and highly interconnected with no particular shape.

X-ray diffraction analysis (Fig. 4.) indicates that in all cases cubic gold and monoclinic vanadium dioxide are formed, though the films were not particularly crystalline. The films were quite thin and a large broad hump centred at 24 2θ is seen from the amorphous glass substrate. The gold crystallite size was evaluated using Scherrer equation, it was found that for samples produced with TOAB the crystallite size was 13 ± 3 nm in diameter, where as crystallites produced without the use of TOAB were smaller, measuring 8 ± 2 nm in diameter. Annealing in nitrogen at 500 °C for 2 h did

not improve the crystallinity of the VO_2 phase in the films, however peaks relating to V_2O_5 appeared in the X-ray diffraction pattern. Indeed in some cases there is some evidence of the formation of V_2O_5 in the as produced samples. This is not entirely unexpected as previous work on vanadium dioxide by APCVD has seen a similar phenomenon and has shown that surface V_2O_5 does not effect the thermochromic behaviour of the bulk film [19,34,35]. X-ray photoelectron analysis (XPS, Fig. 5A and C.) of the sample surface suggests a variety of vanadium environments due to the broadness and asymmetry of the peaks, we believe V_2O_5 to be present only at the surface; indeed, on etching only a single vanadium environment (V_{2p} at 516.8 and 523.4 eV) is observed consistent with vanadium dioxide. XPS shows that gold is found in a single metallic environment, Au_{4f} 83.6 and 87.2 eV (Fig. 5B and D), this indicates several things: there are no other detectable gold compounds present in the film, there is no un-reacted precursor on the film surface and indicates that the gold is present only as gold nanoparticles on the surface and in the bulk of the host film matrix. XPS and Raman spectroscopy were used to evaluate carbon contamination in the films; insignificant amounts of carbon, less than 1 atom%, could be detected in the bulk of the films using XPS. More carbon was detected on the surface of the films using XPS but is most likely from an external source. Raman spectroscopy produced no signal, specifically no signal from graphitic carbon (at 1000 cm^{-1}) was observed suggesting that the level of carbon is below the detection limit of this method and that the films are poor Raman scatterers possibly due to surface morphology effects.

As seen with un-doped and tungsten doped samples prepared by CVD [19,34,35] a large change in transmission is observable at 2500 nm (Fig. 6), typically 35–40% comparable with previous literature values [19,34,35]. The reflectance spectrum is different (Fig. 6) there is only a small change of around 10% on undergoing the transition. This is similar to previous examples of gold doped VO_2 films produced using this hybrid methodology [26].

All of the films show thermochromic behaviour with reduced transition temperatures compared to un-doped VO_2 single crystals (typically 66–68 °C) [16] and compared to un-doped VO_2 thin films (50–66 °C depending on the growth conditions) [35]. Typically the hysteresis width (Fig. 7) of gold doped vanadium dioxide thin films is in the range of 15–20 °C. The films produced with TOAB in (Samples 1–5) had lower transition temperatures, typically 42–45 °C, than the films without TOAB (Sample 6) where the transition temperature was in the region 50–54 °C.

4. Discussion

The hybrid aerosol assisted atmospheric pressure chemical vapour deposition reaction of vanadyl acetylacetonate and auric acid lead to the production of thin films of gold nanoparticle doped monoclinic vanadium dioxide thin films. Addition of TOAB to the precursor solution led to significant changes in the functional properties and colour of the deposited films.

The addition of gold nanoparticles into the film lead to the observation of a surface plasmon resonance band. The position of this band determines the overall colour and is dependent upon three factors: the inter-particle distance, particle size and the refractive index of the host matrix [20,21]. The refractive index of the host matrix is assumed constant between samples so the only factors that effect the surface plasmon resonance (SPR) are the size and distance between gold nanoparticles.

For films grown without TOAB the SPR centre is 620 nm, the use of 0.5 g or more TOAB in the reaction moves the SPR centre to 660 nm. Using less than 0.5 g TOAB in the reaction causes a smaller change in the SPR centre. The more TOAB used in the reaction the more profound the effect; the addition of smaller amounts of TOAB, 0.06–0.25 g, leads to a shift in the visible reflection peak from 591 to 559 nm but no significant change in the visible transmission peak. Samples produced with a larger amount of TOAB, 0.5 or 1.00 g, had profound changes in both the visible transmission and reflectance peaks and appeared blue as both the transmission and reflection peaks were shifted to ~495 nm. This is because as more gold nanoparticles agglomerates are templated (i.e. with increasing levels of TOAB) the agglomerates are more discreet and regular in size and shape (Fig. 3) and the effect of the SPR band

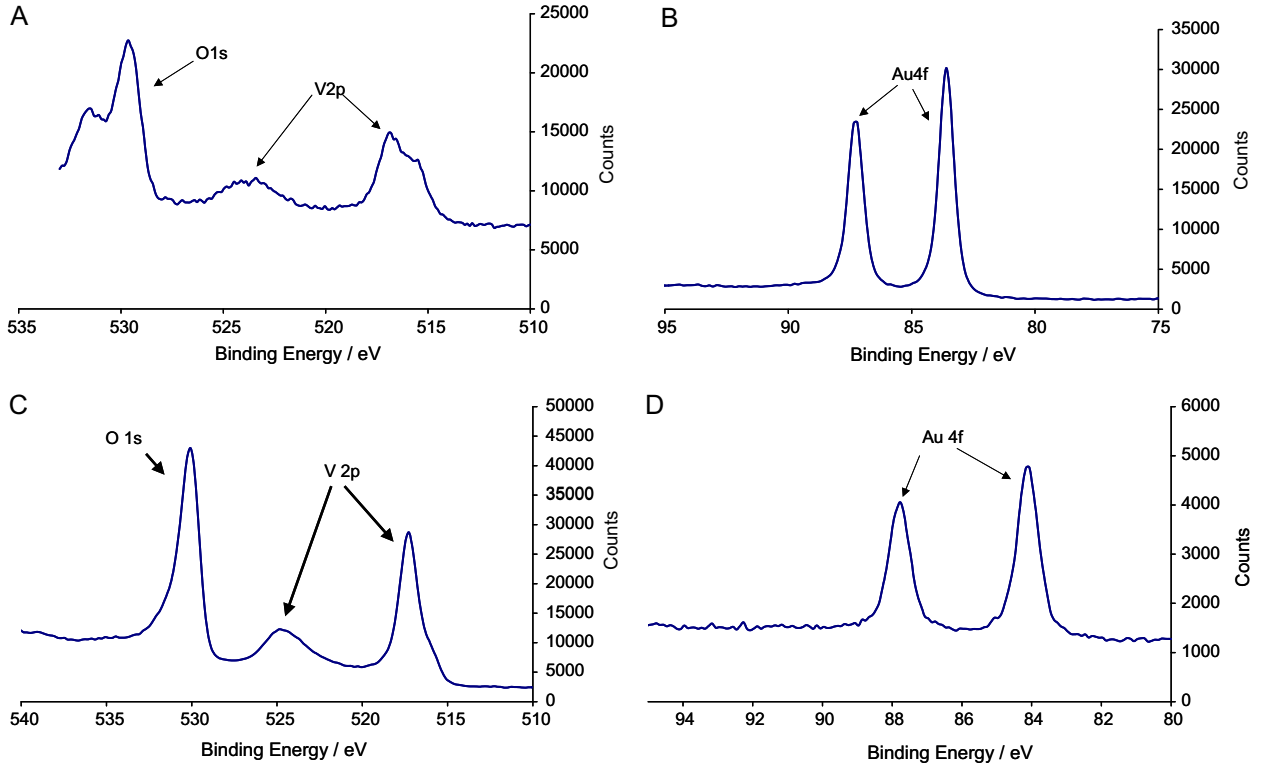

Fig. 5. X-Ray Photoelectron Spectroscopy of typical samples of a VO_2/Au nanoparticle film produced using the hybrid AA/AP CVD methodology grown (A) with TOAB vanadium and oxygen region, (B) with TOAB gold region, (C) without TOAB vanadium and oxygen region and (D) without TOAB gold region.

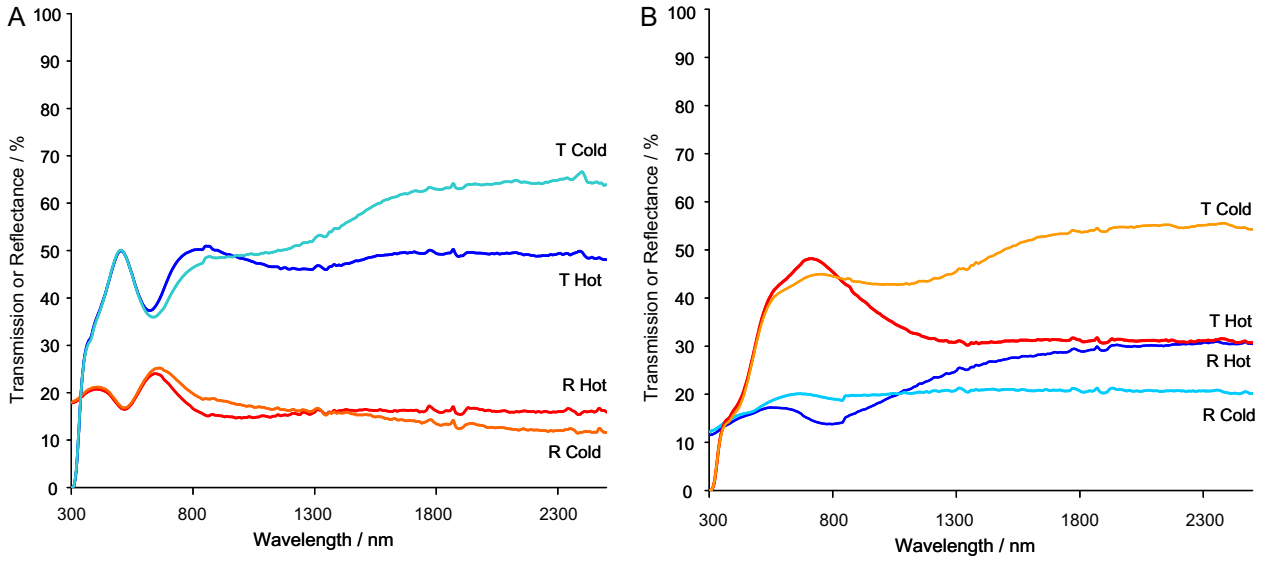

Fig. 6. Transmission and Reflection Data for typical samples of a VO_2/Au nanoparticle film produced using the hybrid AA/AP CVD methodology grown (A) with TOAB and (B) without TOAB.

is stronger. Where no TOAB or lower levels of TOAB (less than 0.25 g) were used, nanoparticle agglomerates had a wide variety of shapes and sizes and were more heavily interconnected; in these instances the effect of the SPR band is weak and there is no significant change in the colour of the films.

As mentioned in the results section the microstructure of the films is significantly altered due to the use of TOAB in the reaction; in depositions without TOAB the island size of vanadium dioxide particles is around 150 nm and there is significant interconnectivity between agglomerates (Fig. 2B), similar to that previously seen [35], whilst with the use of TOAB the agglomerate size is reduced to 75 nm and leads to a more discreet, rounded morphology. A similar effect is seen when observing the gold nanoparticles in the films using backscattered electron imaging (Fig. 3). The films produced without TOAB show a variety of gold nanoparticle shapes and sizes, significant but random agglomeration and interconnectivity. The films produced using TOAB are very different, the gold nanoparticle agglomerates are uniform in shape and size (~75 nm diameter spheres). This is due to a surfactant effect caused by the TOAB that has been seen previously [23]. It is less

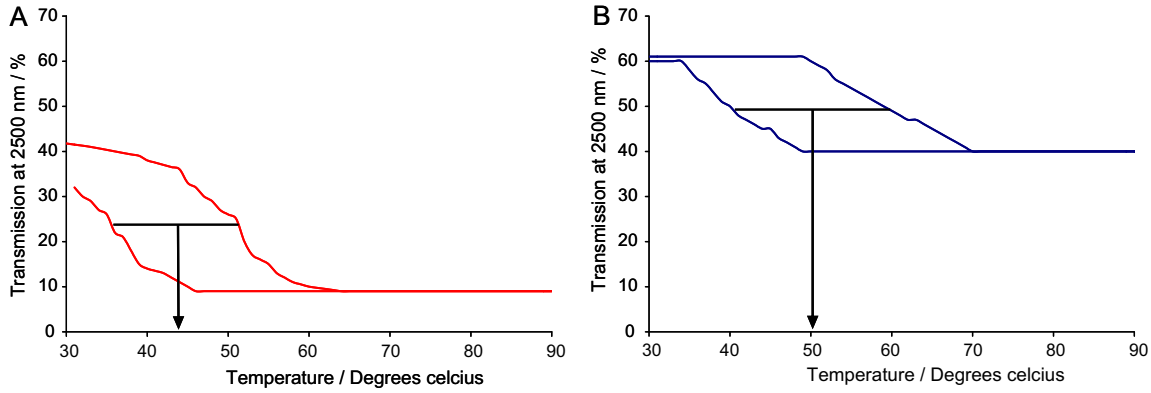

Fig. 7. Hysteresis behaviour of typical samples of a VO_2/Au nanoparticle film produced using the hybrid AA/AP CVD methodology grown of (A) with TOAB and (B) without TOAB.

expected that the use of TOAB would cause a change in the overall film morphology between films grown under otherwise identical conditions.

In all cases a large change in transmission is observable at 2500 nm (Fig. 6), typically 30–40% comparable with previous literature values [19,34,35]. The reflectance spectra show a smaller change of 10–15% (Fig. 6) on undergoing the transition. This is attributable to the metallic nature of the gold nanoparticles and the rough looking film surface (Fig. 2). Un-doped or tungsten doped films of monoclinic vanadium dioxide do not have as significant a metallic contribution to the reflectance and the change at 2500 nm on undergoing the MST is around 25% [19,20,29,34,35].

All of the films show thermochromic behaviour with reduced transition temperatures. Typically the hysteresis width (Fig. 7) of gold doped vanadium dioxide thin films is relatively wide in the range of 15–20 °C compared to 10 °C as seen with some tungsten doped samples produced by APCVD [19,34,35] and 10–15 °C seen for films produced by Sol–Gel methodology [36], though this is comparable to films of this type produced previously using the hybrid method [26]. The hysteresis width seemed to be independent of the amount of gold present in the film. Ideally the hysteresis width would be as narrow as possible in order to maximise the energy saving effect the coating would have. Hysteresis width has been attributed to several factors such as a variety of grain size [37] and or crystallographic orientation [35]. Indeed the transition temperature is reduced to ~50 °C for samples grown without the use of TOAB and to as low as 42 °C with films grown with TOAB, which is independent of the amount of gold in the films. It is likely that this reduction for the films grown without TOAB is caused by strain as a result of preferential orientation as observed previously [26,35], although this is difficult to quantify as the films are thin and poorly crystalline. The additional reduction of the transition temperature to 42 °C seen in films produced by TOAB is harder to explain. The average island size is smaller and agglomeration more, this may lead to higher strain in the films though this is difficult to evaluate in the absence of quality X-ray diffraction data. TOAB has been used previously to template gold nanoparticles in AACVD [23] causing a surfactant effect in solution before aerosol generation. The effect was to direct the size and shape of the nanoparticles. This is occurring in this instance as well and it may be that the uniform size of templated gold crystallites in the films produced with TOAB help lead to this additional reduction in transition temperature.

The use of TOAB in hybrid aerosol assisted atmospheric pressure chemical vapour deposition reactions leads to several interesting effects. There is a change in morphology of the overall film that is unexpected and can be potentially exploited to enhance the properties of the film. The gold nanoparticle agglomerates are effectively templated; we anticipate that the use of a different surfactant will lead to different size and shape nanoparticle agglomerates. It also seems that the vanadium dioxide islands are templated; to test this some depositions were performed with TOAB but no gold in the precursor flask. The resultant morphologies were very similar to those obtained here. The use of TOAB also leads to an additional reduction on the thermochromic transition temperature, this is attributed to the introduction of additional strain in the film caused by this template effect.

5. Conclusion

The use of hybrid aerosol assisted and atmospheric pressure chemical vapour deposition methodology has afforded nanocomposite thin films of a vanadium dioxide matrix hosting gold nanoparticles. This methodology is a one step process using a solution of preformed nanoparticles and shows great promise for producing other nanocomposites. The use of TOAB in these reactions adds a further level of control over the reaction product than has been previously seen using this hybrid methodology. Unexpectedly the TOAB was found to template not just the growth of gold nanoparticles incorporated in the film, but the growth of the film itself. This introduced additional strain into the film and caused a reduction in the thermochromic transition temperature.

Acknowledgments

This research was supported financially as part of the EU project TERMOGLAZE. Pilkington glass are thanked for the provision of glass substrates. IPP thanks the Wolfson trust for a merit award. RB thanks the Royal Society for a Dorothy Hodgkin fellowship. Mr. Kevin Reeves is thanked for invaluable assistance with electron microscopy. MS thanks the University of Palermo “Esperto di Nanotecnologie per i Beni Culturali” for funding.

ABSTRACT

Zinc complexes with pyrimidine-2-thionato ligands with the general formula $[Zn(RpymS)_2]$ can be easily obtained by electrochemical oxidation of a zinc anode in a cell containing an acetonitrile solution of the appropriate thione (RpymSH, R = 4,6-Me_2,5-Et; 4-CF_3 and 4,6-CF_3,Me). When 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen) were added to the cell, the corresponding adducts $[Zn(RpymS)_2L]$ were also obtained (L = bipy, phen). All of the compounds have been characterized by microanalysis, mass spectrometry, IR spectroscopy and, for compounds that were sufficiently soluble, by ^1H and ^{13}C NMR spectroscopy. The compounds $[Zn(4,6\text{-}Me_2,5\text{-}EtpymS)_2(MeOH)]$ (**4**), $[Zn(4\text{-}CF_3pymS)_2(phen)]$ (**7**) and $[Zn(4,6\text{-}CF_3,MepymS)_2(bipy)]$ (**9**) were also characterized by X-ray diffraction. The structures of all of these complexes consist of discrete molecules. In complex **4**, the pyrimidine-2-thionato acts as an S,N bidentate chelating ligand. The coordination number for Zn is five and the fifth position is occupied by an oxygen atom from a methanol molecule. In **7** and **9**, the coordination number for the metal centre is four. In these cases the thionato ligands show a monodentate behaviour, using the exocyclic sulfur to bind the zinc atom.

1. Introduction

Much of the interest in Zn–sulfur chemistry results from the potential relevance of these compounds in biological systems. Zinc complexes with N,S donors can be used as models for the study of metalloproteins and metalloenzymes [1]. In fact, the molecular structure of liver alcohol dehydrogenase (LADH) includes zinc atoms coordinated by two cysteine thiolates, a hystidine nitrogen and a water molecule [2]. In LADH, the catalytic cycle is initiated by displacement of one oxygen donor ligand molecule (water) by another (the alcohol substrate), which transiently binds to the zinc centre in LADH prior to displacement [3]. It is also well known that several alcohol dehydrogenases and thiolate alkylating enzymes contain the unusual NS_2ZnX coordination, where N represents a hystidine molecule, S a cysteinate group and X the catalytic site [4]. In the same way, many metabolic processes involve heterocyclic thiones, which have been known to play an important role in these reactions (e.g. 6-amino-2-thiouracil [5] exhibits antiviral and chemotherapeutic activity), and such activity is enhanced when they are administrated as metal complexes [6,7]. Moreover, thionato complexes derived from pyrimidine have been proposed as new chemotherapy agents [8–10] and the capability of the heterocyclic amines to act as carrier moieties [11,12] in order to react with plasma proteins led to increased interest in their metal complexes. This fact is consistent with the structural requirements for cytotoxic activity. In many cases, it seems probable that complex formation is implicated in the biological action of these pyrimidine derivatives [13]. The study of the interaction between metal ions and pyrimidine derivatives could provide a great deal of information related to the interactions of these metals with nucleic acids constituents [14]. In fact, it has been proposed that Zn(II) complexes could be directly involved in the addition of a mononucleotide to the free end of a DNA molecule [15].

Zinc complexes with ligands containing the thioamide group have also applications in many other fields and bis(N-oxopyridine-2-thionato)zinc(II), commonly known as zinc pyrithione, is an effective antifungal agent and is used as the active component of some antidandruff shampoo products [16]. Moreover, although the usual mode of binding for thioamides involves the formation of four-membered chelate rings through sulfur and nitrogen coordination [17], pyrimidine thiones and the corresponding thionatos have the potential to bind the metal ion by coordination with sulfur, nitrogen or a combination of the two [18–21]; these bindings could leave some potential donor atoms free and those positions would enhance the biological activity. When both sulfur and nitrogen atoms bind the metal centre (zinc), the N–Zn bond seems to be stronger than the S–Zn bond [22].

Scheme 1.

As part of our continued interest in the coordination chemistry of heterocyclic thione compounds, we report here the synthesis and characterization of zinc complexes with several pyrimidine-2-thionato ligands (Scheme 1). Ligands of this type are amongst the most versatile and unique in their coordination form [23], yielding complexes with unusual geometries, variable nuclearities and great structural diversity [21,24]. Moreover, the presence in these ligands of different substituents allows the possibility of investigating the influence of the nature and location of the substituents in the heterocyclic ring on the coordinative behaviour of these ligands and on the structure of the corresponding complexes. All of the compounds were obtained by using an electrochemical procedure that involves the anodic oxidation of a zinc foil in a solution of the corresponding ligand. For the synthesis of the heteroleptic complexes, 2,2′-bipyridine (bipy) or 1,10-phenanthroline (phen) were added to the cell solution.

2. Experimental

2.1. Materials and characterization

1,1,1-Trifluoro-2,4-pentanedione, thiourea, 3-ethyl-2,4-pentanedione, 1,1,1-trifluoroacetone, benzaldehyde, 4-trifluoromethylpyrimidine-2-thione; 1,10-phenanthroline and 2,2′-bipyridine are commercial products and were used as supplied. Zinc was used as a foil and washed with hydrochloric acid and brushed prior to use.

Elemental analyses were performed with a Carlo–Erba EA microanalyser. IR spectra were recorded as KBr mulls on a Bruker IFS-66 V Spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX 300 MHz instrument with $CDCl_3$ or [D_6] DMSO as solvent. Chemical shifts are given in relative to TMS as the internal standard. The mass spectra (FAB) were recorded on a Micromass Autospec spectrometer, with 3-nitrobenzyl alcohol as the matrix material.

2.2. Synthesis of [4,6-Me_2,5-EtpymSH] (**1**)

This ligand was prepared by using a synthetic route previously reported for another pyrimidine-2-thiones [25]. 3-Ethyl-2,4-pentanedione (8.92 g, 0.069 mol, 9.35 mL) was dissolved in ethanol (70 mL) and concentrated hydrochloric acid (10 mL) was added at room temperature. The mixture was stirred under argon for 30 min and a solution of thiourea (8.47 g, 0.11 mol, 1.6 equiv.) in ethanol (150 mL) was added dropwise by cannula. This mixture was heated under reflux for 24 h.

The solvent was removed by vacuum distillation and the solid was treated with 2 M NaOH (150 mL). The mixture was filtered and the solution was acidified to pH 6 with 2 M H_2SO_4 at low temperature. A yellow solid was obtained and was filtered off. This product was recrystallized from $CHCl_3$ (Yield: 6.928 g; 59.21%). *Anal.* Calc. for $C_8H_{12}N_2S$ (168.26): C, 57.11; N, 16.65; H, 7.19; S, 19.06. Found: C, 57.113; N, 16.78; H, 7.36; S, 19.04%. IR (KBr/cm^{-1}): 3100–3200 (m, br); 1650 (s), 1610 (s), 1580 (w), 1559 (m), 1450 (m), 1430 (w), 1420 (w), 1380 (w), 1350 (w), 1320 (s), 1300 (w), 1280 (w), 1220 (m), 1200 (m), 1180 (w), 1160 (m), 1150 (m), 1090 (w), 1060 (w), 1020 (m), 990 (w), 970 (m), 940 (w), 930 (w), 920 (w), 850 (w), 840 (w), 820 (w), 770 (m), 680 (m), 660 (m), 640 (w), 620 (w), 590 (w), 580 (w), 560 (w), 490 (w), 460 (m), 380 (m). ^{1}H NMR (300 MHz, $CDCl_3$): δ = 13.00 (s, 1 H, NH); 1.07 (t. 3H, H_9); 2.44 (s, 3H, C_7/$C_{7'}$) 2. 52 (q, 2H, H_8) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 171.7 (s, C_2); 165.7 (s, C_4); 165. 6 (s, C_6); 124 (s, C_5); 13.35 (s, C_7); 13.29 ($C_{7'}$); 20.6 (s, C_8); 1.43 (s, C_9) ppm. MS m/z = 169 (M^+); 335.2 (M_2^+).

2.3. Synthesis of [4,6-CF_3MepymSH] (**2**)

A slightly different method was used for the synthesis of this ligand; it was obtained by direct reaction between thiourea (2.428 g, 32 mmol) and 1,1,1-trifluoro-2,4-pentanedione (5 g, 32 mmol) in ethanol in the presence of concentrated hydrochloric acid (1 mL) as a catalyst. The mixture was heated under reflux for 2 h and the resulting dusty yellow solid was filtered off (Yield: 4.45 g; 71.8%). *Anal.* Calc. for $C_6H_5F_3N_2S$ (194.17): C, 37.11; H, 2.60; N, 14.43; S, 16.51. Found: C, 36.89; H, 2.60; N, 15.26; S, 16.08%. IR (KBr/cm^{-1}): 3100–3200 (m, br), 1615 (vs), 1590 (vs), 1440 (m), 1350 (vs), 1320 (w), 1200 (s, br), 1130 (m), 1100 (m), 1030 (w), 970 (s), 920 (m), 860 (w), 850 (m), 705 (w), 660 (w), 595 (w), 530 (m), 510 (w), 570 (m), 450 (m), 370 (w) cm^{-1}. ^{1}H NMR (300 MHz [D_6] DMSO): δ = 14.40 (s, 1 H, NH), 7.19 (s, 1 H, H_5), 2.39 (s, 3H, CH_3). ^{13}C NMR (300 MHz [D_6] DMSO) δ = 181.00 and 172.13 (s, C_2); 155.86 and 153.72 (q $^2J_{13C-19F}$ = 35 Hz, C_4); 104.89 (s, C_5); 163.61 (s, C_6); 119.27 and 119.67 (q, $^1J_{13C-19F}$ = 275 Hz, CF_3); 23.45 and 18.46 (s, CH_3) ppm. MS (FAB): m/z = 194 (M^+).

2.4. Electrochemical synthesis

The cells consisted of zinc foil (anode) and a platinum wire (cathode) in contact with the thione solution in acetonitrile. A small amount of tetraethylammonium perchlorate acted as an electrolyte. The cell can be summarized as $M_{(+)}/CH_3CN$ + RpymSH + L′/$Pt_{(-)}$. All of the syntheses were carried out at room temperature and the current intensity was kept at 10 mA. In all of the reactions hydrogen was evolved at the cathode and the yellow or orange colour of solutions faded. At the end of the reactions the solids were isolated by filtration.

Caution: Although no problem was encountered in this work, all perchlorate compounds are potentially explosive and should be handled in small quantities and with great care!

2.4.1. Synthesis of [Zn(4,6-Me_2,5-EtpymS)$_2$](H_2O) (**3**)

The electrolysis of a solution of 4,6-Me_2,5-EtpymSH (150 mg, 0.89 mmol) gave a pale yellow solution and no solid was obtained after filtration. A total of 29 mg (0.89 mmol) of zinc was dissolved from the anode. After the evaporation of the solvent at room temperature a dusty pale yellow solid was obtained (Yield: 109 mg; 44%), which was identified as [Zn(4,6-Me_2,5-EtpymS)$_2$](H_2O). *Anal.* Calc. for $C_{16}H_{24}N_4S_2ZnO$ (416.07): C, 45.99; N, 13.41; H, 5.79; S, 15.34. Found: C, 46.01; N, 13.77; H, 6.18; S, 15.03%. IR (KBr/cm^{-1}): 3500 (m, br); 2990 (m); 1550 (s), 1460 (w), 1430 (w), 1370 (m), 1350 (w), 1280 (s), 1160 (m), 1120 (w), 1070 (m), 1000 (w), 970 (w), 930 (w), 770 (w), 610 (w), 580 (m, br) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 1.39 (t, 3H, CH_3); 2.37 (s, 6H, CH_3); 2.45 (q, 2H, –CH_2–) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 21 (s, C_8); 127.85 (S, C_5); 165.4 (s, C_4/C_6); 175.0 (s, C_2) ppm. MS (FAB): m/z = 631 [Zn_2(4,6-Me_2EtpymS)$_3$]; 399 [Zn(4,6-Me_2EtpymS)$_2$]; 231 [Zn(4,6-Me_2EtpymS)]. Crystals of [Zn(4,6-Me_2,5-EtpymS)$_2$ (MeOH)](MeOH) (**4**) suitable for X-ray diffraction were obtained by recrystallization of the initial product from methanol.

2.4.2. Synthesis of [Zn(4-CF_3pymS)$_2$] (**5**)

A solution of 4-CF_3pymSH (150 mg, 0.83 mmol) in acetonitrile was electrolyzed and 17 mg (0.27 mmol) of zinc were dissolved from the anode. As the current was flowing a suspension was

obtained in the cell and the initial orange colour became pale yellow. The suspension was filtered to give a dusty pale yellow solid (Yield: 60 mg; 34%). *Anal.* Calc. for $C_{10}H_4N_4F_6S_2Zn$ (421.91): C, 28.35; N, 13.44; H, 0.95; S, 15.13. Found: C, 29.09; N, 13.22; H, 1.20; S, 14.69%. IR (KBr/cm^{-1}): 1580 (s), 1550 (vs), 1480 (m), 1460 (m), 1440 (s), 1420 (s), 1350 (vs), 1310 (s), 1290 (m), 1200 (vs), 1190 (s), 1160 (s), 1150 (s), 1130 (s), 110 (s), 1070 (w), 1050 (w), 1040 (w), 1020 (m), 1000 (w), 970 (m), 900 (w), 830 (s), 820 (s), 770 (s), 730 (s), 680 (w), 670 (s), 650 (m), 630 (m), 590 (w), 520 (w), 460 (m), 440 (w), 410 (m), 350 (m), 320 (m) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 7.25 (d, 1H, H_5); 8.49 (d, 1H, H_6) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 109.3 (s, C_5); 121.30 (q, C_7); 154.5 (q, $^2J_{13C-19F}$ = 111 Hz, C_4); 168.69 (s, C_6); 181.09 (s, C_2) ppm. The signals in the mass spectra were not identified.

2.4.3. Synthesis of [Zn(4-CF$_3$pymS)$_2$(bipy)] (**6**)

A total of 17 mg (0.27 mmol) of Zn were dissolved from the anode when the thione (150 mg, 0.83 mmol) was electrolyzed. Bipy (65 mg, 0.42 mmol) was also added to the cell solution. As the process was taking place, the initial orange solution became a dark yellow suspension. The mixture was filtered and a pale yellow dusty solid was obtained (Yield: 130 mg; 54%). *Anal.* Calc. for $C_{20}H_{12}N_6F_6S_2Zn$ (579.98): C, 41.43; N, 14.49; H, 2.09; S, 11.06. Found: C, 41.47; N, 14.66; H, 2.12; S, 11.53%. IR (KBr/cm^{-1}): 1590 (s), 1550 (vs), 1480 (m), 1460 (m), 1440 (s), 1420 (s), 1340 (vs, br), 1310 (s), 1240 (m), 1200 (vs, br), 1190 (s), 1160 (w), 1150 (w), 1140 (m), 1110 (m), 1070 (w), 1050 (w), 1040 (w), 1020 (m), 1000 (m), 970 (m), 900 (w), 830 (m), 820 (s), 770 (s), 730 (s), 680 (w), 670 (s), 650 (m), 630 (m), 590 (w), 520 (w), 460 (m), 430 (w), 410 (m), 350 (m), 320 (m) cm^{-1}. ^{1}H NMR (300 MHz [D_6] DMSO): δ = 7.31 (d, 1H, H_5); 8.76 (wide, 1H, H_6); bipy: 7.92 (d, 2H, $H_5/H_{5'}$); 8.11 (wide, 2H, $H_4/H_{4'}$); 8.55 (d, 2H, $H_3/H_{3'}$); 9.1 (d, 2H, $H_6/H_{6'}$) ppm. ^{13}C NMR (300 MHz [D_6] DMSO) δ = 114.95 (s, C_5); 162.10 (s, C_6); 148.90 (bipy $C_6/C_{6'}$) ppm. MS (FAB): m/z = 399 [Zn(4-CF$_3$pymS)(bipy)].

2.4.4. Synthesis of [Zn(4-CF$_3$pymS)$_2$(phen)] (**7**)

The result of the electrolytic process was a yellow dusty solid (Yield: 148 mg; 59%). Thione (150 mg, 0.83 mmol), phen (84 mg, 0.46 mmol) and Zn (0.22 mg) were used for this reaction. *Anal.* Calc. for $C_{22}H_{12}N_6F_6S_2Zn$ (601.98): C, 43.76; N, 13.92; H, 2.00; S, 10.62. Found: C, 44.16; N, 14.24; H, 2.02; S, 10.99%. IR (KBr/cm^{-1}): 1610 (m), 1600 (s, br), 1530 (m), 1500 (m), 1480 (w), 1430 (m), 1420 (s), 1330 (s, br), 1210 (s), 1190 (m), 1160 (w), 1140 (w), 1130 (w), 110 (m), 1090 (m), 1070 (w), 990 (w), 970 (m), 860 (w), 850 (m), 830 (m), 820 (m), 780 (w), 720 (s), 680 (w), 670 (s), 640 (m), 460 (m), 440 (w), 420 (m), 360 (m) cm^{-1}. ^{1}H NMR (300 MHz [D_6] DMSO): δ = 7.92 (d, 1H, H_5); 8.87 (d, 2H, H_6); phen: 8.09 (br, 2H, H_8/H_3); 8.29 (s, 2H, H_5/H_6); 9.01 (d, 2H, H_5/H_6); 9.11 (d, 2H, H_2/H_9) ppm. ^{13}C NMR (300 MHz [D_6] DMSO) δ = 95.3 (s, C_7); 114.9 (s, C_5); 154.45 (q, C_4); 168.08 (s, C_6); 168.67 (s, C_2); phen: 127.03 (s, C_3/C_8); 128.75 (s, C_5/C_7); 128.75 (s, C_{4a}/C_{6a}); 139.46 (s, C_4/C_6); 139.85 (s, C_{4b}/C_{6b}); 148.71 (s, C_2/C_9) ppm. MS (FAB): m/z = 425 [Zn(4-CF$_3$pymS)(phen)]. Crystals of **7** used for X-ray diffraction studies were obtained by recrystallization from ethanol.

2.4.5. Synthesis of [Zn(4,6-CF$_3$MepymS)$_2$] (**8**)

Electrolysis of an acetonitrile solution of 4,6-CF$_3$MepymSH (0.152 g, 0.78 mmol) using a zinc anode gave a pale yellow solution rather than a solid. A total of 29 mg (0.44 mmol) of Zn was dissolved from the anode. The solvent was evaporated and a dark yellow dusty solid was obtained (Yield: 62 mg; 35%). This product was identified as Zn(4,6-CF$_3$MepymS)$_2$. *Anal.* Calc. for $C_{12}H_8N_4F_6S_2Zn$ (449.94): C, 31.90; N, 12.27; H, 1.80; S, 14.21. Found: C, 32.92; N, 12.27; H, 2.40; S, 13.40%. IR (KBr/cm^{-1}): 1575 (vs), 1540 (vs), 1479 (m), 1430 (m), 1385 (vs), 1360 (m), 1270 (vs), 1220 (s), 1190 (s), 1170 (m), 1140 (s), 1110 (m), 1030 (w), 990 (w), 980 (w), 940 (w), 920 (m), 850 (s), 780 (w), 710 (s), 550 (m), 510 (w), 460 (m) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.38 (s, 3H, CH_3); 6.94 (s, 1H, H_5) ppm. ^{13}C NMR (300 MHz, $CDCl_3$) ppm: δ = 23.78 (CH_3); 111 (C_5); 169.16 (C_6); 182 (C_2). MS (FAB): m/z = 710 [Zn_2(4,6-CF$_3$MepymS)$_3$]; 451 (M^+); 257 [Zn(4,6-CF$_3$MepymS)].

2.4.6. Synthesis of [Zn(4,6-CF$_3$MepymS)$_2$(bipy)] (**9**)

Thione (200 mg, 1.03 mmol) and bipyridine (80 mg, 0.51 mmol) were initially dissolved for this synthesis. The process caused the dissolution of 46 mg (0.72 mmol) of the zinc anode. Once more, a solid was not obtained at the end of the electrolytic process but a pale yellow solution, which was slowly concentrated at room temperature to give a colourless crystalline solid. These crystals were not suitable for X-ray diffraction studies (Yield: 90 mg; 29%). The analytical data confirmed that this solid was [Zn(4,6-CF$_3$MepymS)$_2$(bipy)]. *Anal.* Calc. for $C_{22}H_{16}F_6N_6S_2Zn$ (606.01): C, 43.07; N, 13.82; H, 2.65; S, 10.55. Found: C, 43.07; N, 13.62; H, 2.53; S, 10.13%. IR (KBr/cm^{-1}): 1590 (s), 1570 (vs), 1540 (vs), 1480 (m), 1460 (m), 1440 (s), 1380 (s, br), 1360 (s), 1310 (m), 1270 (s), 1260 (s), 1220 (s), 1180 (m), 1160 (m), 1140 (s), 1120 (w), 1100 (w), 1020 (w), 1000 (w), 970 (m), 910 (m, br), 880 (w), 840 (vs), 810 (w), 770 (vs), 730 (s), 710 (vs), 650 (m), 630 (w), 550 (m), 480 (w), 460 (w), 440 (w), 410 (m), 350 (m) cm^{-1}. ^{1}H NMR (300 MHz, $CDCl_3$): δ = 2.39 (s, 3H, CH_3), 6.83 (s, 1H, H_5); bipy: 7.59 (dd, 2H, $H_5/H_{5'}$); 8.10 (dd, 2H, $H_4/H_{4'}$), 8.26 (d, 2H, $H_3/H_{3'}$), 9.00 (d, 2H, $H_6/H_{6'}$) ppm. ^{13}C NMR (300 MHz, $CDCl_3$): δ = 24.58 (s, CH_3); 109.58 (s, C_5); 121.68 (q, CF_3), 149.6 (q, $^2J_{13C-19F}$ = 91 Hz, C_4) 168.9 (s, C_6); 182 (s, C_2); 126.79 (bipy, $C_3/C_{3'}$); 140.63 (bipy $C_5/C_{5'}$) ppm. MS (FAB): m/z = 413 ([Zn(4,6-CF$_3$MepymS)(bipy)]. Crystals of **9** suitable for X-ray diffraction studies were obtained by recrystallization of the initial product from ethanol/dichloromethane.

2.4.7. Synthesis of [Zn(4,6-CF$_3$MepymS)$_2$(phen)] (**10**)

A total of 62 mg (0.97 mmol) of zinc was dissolved through electrolysis of the corresponding ligand (200 mg, 1.03 mmol). In this case, phen (62 mg, 0.97 mmol) was added to the initial solution. As the current flowed the initial yellow solution became orange in colour. Solid did not appear during the reaction and partial evaporation of the solvent at room temperature gave a dusty brown solid (Yield: 80 mg; 20%), which was identified as [Zn(4,6-CF$_3$MepymS)$_2$(phen)]. *Anal.* Calc. for $C_{24}H_{16}F_6N_6S_2Zn$ (630.01): C, 45.62; N, 13.30; H, 2.55; S, 10.15. 2.5. X-ray crystal structural determination

Intensity data sets for all compounds were collected with the use of a Smart-CCD-1000 Bruker diffractometer (Mo Kα radiation, λ = 0.71073 Å) equipped with a grafite monochromator. All crystals were measured at 293 K. The omega and phi scans technique was employed to measure intensities in all crystals. No decomposition

of the crystals happened during data collection. The intensities of all data sets were corrected for Lorentz and polarization effects. Absorption effects in all compounds were corrected using the program SADABS [26]. The crystal structures of all compounds were solved by direct methods. Crystallographic programs used for structure solution and refinement were those of SHELX 97 [27]. Scattering factors were those provided with the SHELX program system. Missing atoms were located in the difference Fourier map and included in subsequent refinement cycles. The structures were refined by full-matrix least-squares refinement on F^2, using anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms attached to carbons in the three compounds were placed geometrically and refined using a riding model, including free rotation about C–C bonds for methyl groups, with C–H distances of 0.93–0.97 Å. For all compounds, hydrogen atoms were refined with U_{iso} constrained at 1.2 (for non-methyl groups) and 1.5 (for methyl groups) times U_{eq} of the carrier C atom. Hydrogen atoms attached to oxygens (structure of complex **4**) were found and refined isotropically.

Table 1 summarizes pertinent details of the data collections and structure refinements, while Tables 2, 4 and 5 list important geometrical data for all compounds. Ortep3 [28] drawings with the numbering scheme used are shown in Figs. 1, 3 and 4.

3. Results and discussion

3.1. Preparation

Zinc complexes of general formula [Zn(RpymS)$_2$] (R = 4,6-Me_2,5-Et; 4-CF_3; 4,6-CF_3,Me) were easily prepared in reasonable yields by a simple one-step electrochemical method [29]. Mixed complexes with 2,2′-bipyridine or 1,10-phenanthroline were also obtained by addition of the corresponding coligand to the cell. The compounds are air-stable and moderately soluble in non-polar organic solvents but are soluble in dimethyl sulfoxide and *N*,*N*′-dimethylformamide.

The electrochemical efficiency, defined as the amount of metal dissolved per Faraday of charge, was in all cases close to 0.5 mol F^{-1}. This fact, together with the evolution of hydrogen at the cathode, is compatible with the occurrence of the following electrode reactions.

$$\text{Cathode}: \text{RpymSH} + e^- \rightarrow \text{RpymS}^- + 1/2\ H_2$$

$$\text{Anode}: \text{Zn} \rightarrow \text{Zn}^{2+} + 2e^-$$

$$\text{Overall}: \text{Zn} + 2\text{RpymSH} \rightarrow [\text{Zn(RpymS)}_2]$$

$$\text{Zn} + 2\text{RpymSH} + \text{L} \rightarrow [\text{Zn(RpymS)}_2\text{L}]$$

where L is 2,2′-bipyridine or 1,10-phenanthroline.

For the complexes [Zn(4,6-Me_2,5-EtpymS)$_2$(MeOH)] (**4**), [Zn(4-CF_3pymS)$_2$(phen)] (**7**) and [Zn(4,6-CF_3MepymS)$_2$(bipy)] (**9**) crystals suitable for X-ray diffraction studies were obtained.

3.2. Crystallographic studies

In all cases the crystal structure consists of discrete molecular species. This fact shows that the presence of an additional coligand inhibits the polymerization of the compound, as found by X-ray diffraction of zinc complexes with only heterocyclic thiones as ligands. For example, [Zn(pymS)$_2$] [30] and [Zn(4,6-Me_2pymS)$_2$] [31] are polymeric.

3.2.1. Crystal and molecular structure of [Zn(4,6-Me_2,5-EtpymS)$_2$(MeOH)] (**4**)

A perspective view of compound **4** is shown in Fig. 1 together with the atomic labelling scheme used. Selected bond lengths

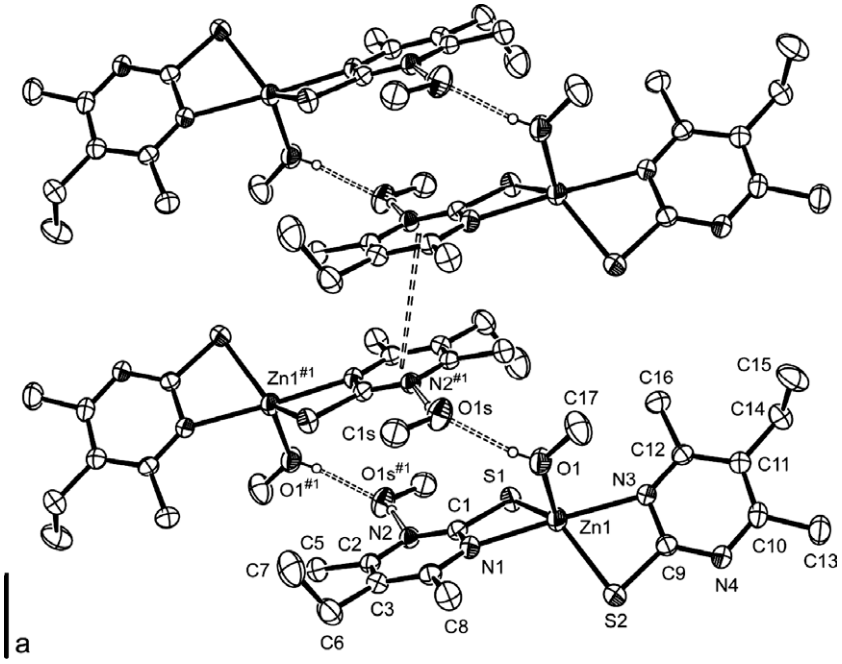

Fig. 1. Crystal structure of [Zn(4,6-Me_2,5-EtpymS)$_2$(MeOH)] (**4**) and a view of different kinds of intermolecular interactions.

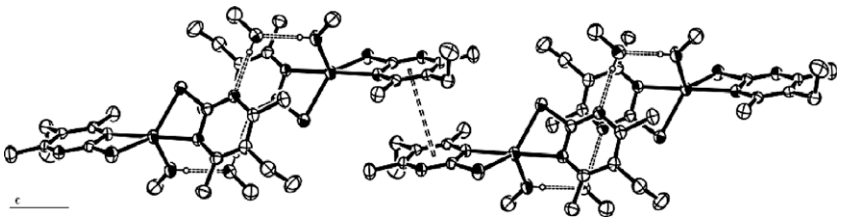

Fig. 2. A view of O–H···N interactions and π-stacking between pyrimidine rings in (**4**).

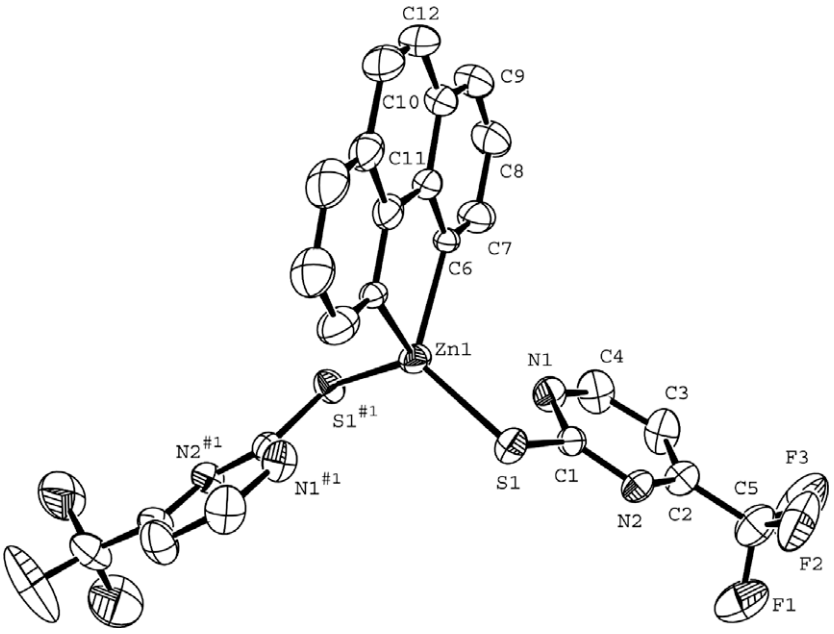

Fig. 3. Crystal structure of [Zn(4-CF_3pymS)$_2$(phen)] (**7**). The hydrogen atoms have been omitted for clarity.

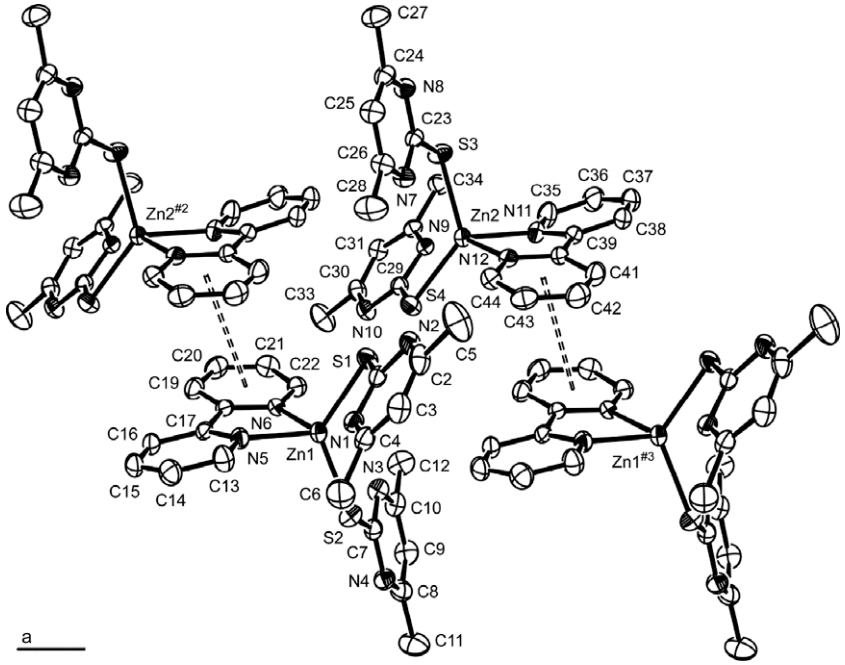

Fig. 4. Crystal structure of [Zn(4,6-CF_3MepymS)$_2$(bipy)] (**9**) and a view of π-stacking between bipyridine rings in **9**. The hydrogen atoms have been omitted for clarity.

and angles are given in Table 2. Crystallographic data are reported in Table 1.

The crystal structure consists of discrete molecular species in which the metal atom is coordinated by one methanol molecule and by two anionic pyrimidine-2-thionato ligands, which act in a bidentate manner (S,N); the other nitrogen atom of each pyrimidine-2-thionato ligand is not coordinated. Analysis of the shape-determining bond angles, using the geometrical parameter τ [$\tau = (\beta - \alpha)/60$], [32] gives a value of 0.77 and suggests that the zinc atoms are in a distorted [ZnN_2OS_2] trigonal bipyramidal environment. The nitrogen atoms are located in axial positions and the equatorial plane is described by two sulfur atoms from the pyrimidine-2-thionato ligands and the oxygen atom from the methanol molecule. The zinc atom is practically on the best plane defined by the donor atoms of the equatorial plane, with the deviation being only 0.028(1) Å. The distortion of the regular trigonal bipyramidal geometry is mainly due to the small bite of the thionato ligands, whose N(3)–Zn(1)–S(2) and N(1)–Zn(1)–S(1) chelate angles are 69.51(10)° and 69.31(10)°, respectively, which deviate significantly from 90°. These deviations produce bond angle values that are quite different from the expected ones. Thus, the N(1)–Zn(1)–S(2) and N(3)–Zn(1)–S(1) bond angles are 108.20(10) and

111.40(9)°, respectively, which are significantly different from 90° (the corresponding ideal value). However, the bond angles O(1)–Zn(1)–N(1) and O(1)–Zn(1)–N(3) [89.53(13) and 92.29(13)°] are very close to the ideal value (90°).

The angles described by atoms in equatorial positions should be close to 120°; the angles involving oxygen atoms [114.99(12)° and 113.40(12)°] are smaller than the ideal value (120°) but the S(2)–Zn(1)–S(1) bond angle is somewhat larger, 131.53(5)°. This is due to the steric requirements of the pyrimidine ligands. All of these facts do not significantly affect the N(1)–Zn(1)–N(3) bond angle [177.54(11)°], which is very close to the ideal value of 180°.

A comparison of the metal–ligand bond distances in complexes **4**, **7** and **9** shows that these are dependent on the coordination number of the metal, and this in turn depends on the monodentate or chelating nature of the thionato ligand. The Zn–S bond lengths in **4** [2.3318(19) and 2.377(2) Å] are greater than the average values [2.2892(13), 2.2929(13) and 2.3117(6) Å, respectively] found for the corresponding distances in the tetracoordinated complexes **7**, **9** and [Zn(5-CF_3pyS)$_2$(bipy)] [33] and are significantly shorter than those reported in the hexacoordinated complexes [Zn(3-CF_3pyS)$_2$(phen)] [2.5602(19) and 2.4770(19) Å] and [Zn(3-CF_3pyS)$_2$(bipy)] [2.5607(7) and 2.4781(7) Å] [33]. This fact is undoubtedly due to the coordination number in complex **4** being intermediate between four and six. However, these distances are quite similar to those found in other pentacoordinated zinc complexes that contain pyrimidine-2-thionato as a ligand; 2.347(2) and 2.369(2) Å in [Zn(4,6-Me_2pymS)$_2$(py)] [34] or 2.369(6) and 2.319(2) Å in [Zn(4,6-Me_2pymS)$_2$], [31] with the latter compound consisting of polymeric chains.

The Zn–N_{pymS} bond lengths [2.196(3) and 2.235(3) Å] are similar to those found in the above hexacoordinated complexes of zinc(II) with pyridine 2-thionato complexes [average values, 2.190(5) and 2.202(2) Å] and are also similar to those in the pentacoordinated complex [Zn(4,6-Me_2pymS)$_2$(py)] [2.241(5) Å] [34]. The fifth coordination position in this complex is occupied by a methanol molecule, which is quite usual for zinc coordination compounds [35–42]. The value for the Zn–O bond length [2.058(4) Å] is within the range reported for other pentacoordinated zinc complexes containing methanol as a solvate [1.950–2.078 Å] [36–42]. The pyrimidine portion of each thionato ligand is essentially planar, with the largest deviation from the least squares plane being 0.061(2) Å and the deviations of the sulfur atoms being 0.030(5) Å for S(1) and 0.021(5) Å for S(2) from the plane of the pyrimidine group that is bound.

3.2.2. Crystal packing and intermolecular interactions of **4**

In this complex the pyrimidine-2-thionato ligands do not exactly mimic the dianionic NS_2 environment of the zinc centre in LADH, but the presence in this complex of suitably positioned methanol molecules enables the formation of a hydrogen bond (see Fig. 1) between the alcoholic proton of the zinc-bound methanol molecule and the methanol molecule of crystallization [O(1)···O(1s) 2.617(5) Å; O(1)–H(1)···O(1s) 172(6)°]. This type of short hydrogen bonding interaction involving the zinc-bound methanol mimics the hydrogen-bonding network involving Ser_{48} in LADH [O(Ser_{48})···O(alcohol) = 2.6 Å] [43], which is responsible for the proton transfer from the active site of the enzyme to the solvent; this situation has been observed in the X-ray structures of other systems that have been used to model aspects of the active site chemistry of LADH [40,41].

Complex **4** also shows a wide variety of intra- and intermolecular interactions. For example, the molecule of crystallization involved in the aforementioned interaction with the coordinated methanol molecule also establishes an O–H···N interaction with the non-coordinated nitrogen of one of the pyrimidines of a neighbouring complex which is related to the first molecule through an inversion centre [O(1s)···N(2) 2.786(5) Å; O(1s)–H(1s)···N(2) 174(5)°]. At the same time, and due to symmetry requirements, this neighbouring complex establishes the same interactions as the original complex. In this way, associations of the type {[Zn(4,6-Me_2,5-EtpymS)$_2$(MeOH)]$_2$(MeOH)$_2$} are formed and these have an inversion centre. A view of this group is shown in Fig. 1 and the hydrogen bonding interactions are also indicated. In addition, the pyrimidine rings involved in the classical hydrogen bonding establish "parallel displaced" π-stacking interactions with equivalent rings in neighbouring groups. These interactions occur along the crystallographic *a* axis and are shown in Fig. 1. The interaction data (Table 3) show that this is a weak interaction (Cg···Cg > 3.8 Å, slip angles beta, gamma > 25°) [44]. At the same time a weaker π-stacking interaction is established between the pyrimidine rings not involved in classical hydrogen bonding. This interaction is "parallel displaced" in nature [45]. These interactions are propagated along the crystallographic *c* axis (Fig. 2). The interaction data (Table 3) show that this is a weak interaction, albeit slightly stronger than the π-stacking interaction that occurs along the *a* axis (vide supra).

3.2.3. Crystal and molecular structure of Zn[(4-CF_3pymS)$_2$(phen)] (**7**) and Zn[(4,6-CF_3MepymS)$_2$(bipy)] (**9**)

Perspective views of the molecular structures of **7** and **9** are shown in Figs. 3 and 4, respectively, together with the labelling schemes used. Crystallographic data are reported in Table 1 and a selection of bond distances and angles are given in Tables 4 and 5.

In both cases the structures consist of discrete molecular species and the difference in comparison to **4** is that in **7** and **9** the zinc atom is tetracoordinated. The metal is coordinated by one phenanthroline (**7**) or bipyridine (**9**) molecule, and by two anionic pyrimidine-2-thionato binding the metal through the sulfur atom only while the nitrogen atoms of the pyrimidine ligands are not coordinated; the distance from the nitrogen to the zinc atom is 2.855(4) Å in the phen complex and 2.778(4) and 3.224(4) Å in the bipy complex. These values are larger than those observed in other zinc complexes containing heterocyclic donor nitrogen ligands [2.085–2.291 Å] [46,47]. These distances are also significantly longer than the sum of the covalent radii of zinc and nitrogen but are in the order of the sum of the van der Waals radii (2.94 Å) [48]. Therefore, we consider that the Zn–N distances indicate a very weak contact.

The geometry around the metal atom is best described as a distorted tetrahedral [ZnS_2N_2] environment. This distortion is due to the small bite of the bipyridine, N–Zn–N = 78.30(13)°, or of the phenanthroline, N–Zn–N = 79.0(2)°, which results in secondary deviations of the other perinuclear angles from the ideal value of 109°. Thus the bond angles in these compounds are in the range 123.10(5)–78.30(13)° for the zinc environment.

There are no significant differences between the values reported for Zn–S bond lengths: 2.2819(13) and 2.2964(12) Å for the complex with bipy and 2.2929(13) Å for the phen complex. However, these distances are shorter than those reported for zinc pyridine-2-thionato complexes (hexacoordinated and pentacoordinated) and are also shorter than those found in another tetracoordinated zinc complex [2.3117(6) Å] [33].

The distances involving the metal and the nitrogen atoms of the phenanthroline [2.119(4) Å] in **7** or bipyridine [average value 2.100(3) Å] in **9** are in the expected range for zinc complexes containing this type of chelating nitrogen ligands [49]. In both compounds the Zn–N and Zn–S distances are very similar to those found in [Zn(S-*p*-tolyl)$_2$phen] [50] which in an EXAFS study has been used as a model for the zinc centre of Transcription Factor IIIA (TFIIIA) [51]; this raises the possibility that **7** and **9** might also be considered as models for this protein.

The 2,2′-bipyridine, 1,10-phenthroline and pyrimidine rings are planar [maximum deviation 0.015(3) Å]. In compound **7**, the sulfur atom is out of the plane of the pyrimidine ring to which is attached [0.081(6) Å]. However, in **9** one of the sulfur atoms, S(2), is approximately in the plane of the pyrimidine rings to which it is bound [0.006(6) Å] but S(1) is out of the plane of the pyrimidine ring to which is attached [0.1124(5) Å]. The S–C bond lengths, which are between 1.724(4) and 1.739(5) Å, are similar to those found in other complexes with pyrimidine-2-thionato derivatives, a fact that suggests that this ligand is coordinated in a form that is closer to the thionato than the thione.

*3.2.4. Crystal packing and intermolecular interactions in **7** and **9***

In the packing of compound **7**, the phenanthroline units establish π-stacking interactions between one another and these interactions occur along the *c* axis. The π-stacking interactions occur between phenanthrolines belonging to contiguous chains, which intercalate between the phenanthrolines of another chain. These interactions connect chains to one another, leading to interactions in the BC plane. Each phenanthroline unit is involved in two identical "parallel displaced" π-stacking interactions. These interactions are established between lateral rings of each phenanthroline molecule, as shown in Fig. 5 (the fluorine and hydrogen atoms not involved in the interactions have been removed for the sake of clarity). The values for these interactions (Table 3) show that the interaction is strong.

The bipyridine units in **9** establish a rather strong "parallel displaced" π-stacking interaction (Table 3) with other bipyridine units in symmetry inequivalent complexes. These interactions connect pairs of compound molecules that are arranged along the crystallographic *a* axis, as shown in Fig. 4.

3.3. IR spectroscopy

The IR spectra of the complexes do not show the band observed in the pyrimidine-2-thionato ligands at 3200–3000 cm^{-1}, which is attributed to ν(N–H) stretching. This difference in the spectra indicates that deprotonation of the NH group occurs during the electrochemical synthesis and that the ligand is coordinated in the anionic thionato form in the complex. This conclusion is also supported by the shift to lower wavenumbers of the strong bands for ν(C=C) and ν(C=N), which appear at 1600–1550 and 1570–1525 cm^{-1}, respectively, in the free ligands [52]. In the spectra of the bipy and phen complexes, in addition to the bands described above, the spectra contain bands at around 758 and 735 cm^{-1} and 1510, 850 and 730 cm^{-1}, which are typical of coordinated 2,2′-bipyridine [53] and 1,10-phenanthroline [53,54], respectively.

3.4. NMR spectroscopy

The room temperature ^{1}H NMR spectra of the complexes do not contain the signal attributable to the –NH hydrogen, which appears in the free ligand at δ = 14.40–13.00 ppm. The absence of this signal is a result of deprotonation of the ligand during the electrolytic process. The signals of all of the protons of the pyrimidine ring, methyl or methylene groups (see Section 2), are slightly shifted compared to those in the free ligands by the coordination of the pyrimidine-2-thionato ligand.

The ^{1}H NMR spectra of [Zn(RpymS)$_2$(bipy)] and [Zn(RpymS)$_2$(phen)] also show signals assignable to the hydrogens of the additional ligand. These signals undergo small shift with respect to the free ligand and these changes provide evidence for the coordination of the additional ligands to the metal atom through nitrogen atoms [55,56].

The ^{13}C NMR spectra of the complexes contain the signals for the different carbon atoms (see Section 2). The spectra of the complexes containing the ligand 4,6-CF_3MepymSH show that doubling observed in the free ligand of the signals for C_2, C_6, CF_3 and CH_3, has disappeared and this shows that, in solution, the ligand is coordinated to the metal in the thionato form only. In complexes where the –CF_3 group is a substituent in the heterocyclic ring, the signals of the corresponding carbon appear as a quadruplet because of coupling with fluorine atoms.

3.5. Mass spectrometry

All of the complexes were also characterized by mass spectrometry using the positive-ion FAB technique and 3-nitrobenzyl alcohol (NBA) as matrix. The FAB spectra of [Zn(4,6-Me_2EtpymS)$_2$], [Zn(4,6-CF_3MepymS)$_2$], and [Zn(4,6-CF_3MepymS)$_2$(phen)] show the molecular ion with the appropriate isotope distribution, as well as peaks due to the fragments generated by the loss of one of the thionato ligands. In the former case, the peak due to the loss of the 1,10-phenanthroline is also observed at m/z = 263. The peak due to the loss of one of the thionato ligands is observed in the spectra of most of the complexes.

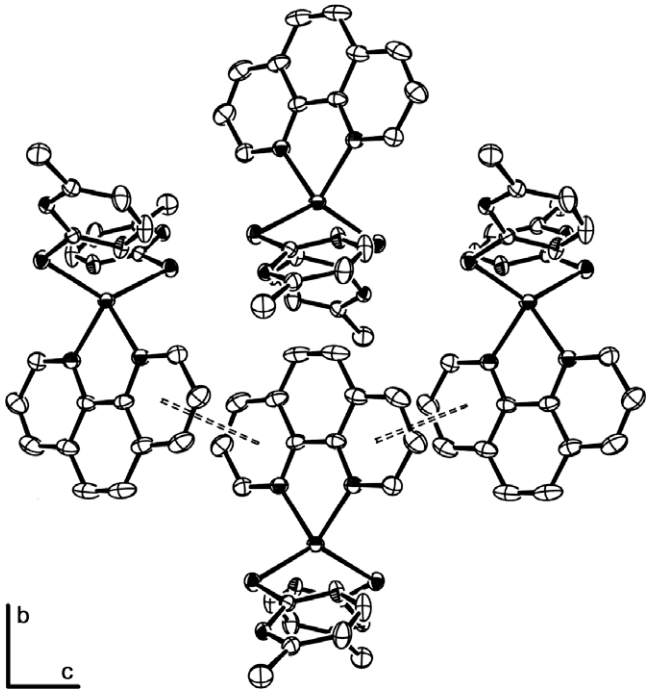

Fig. 5. A view of π stacking interactions in **7**.

4. Conclusion

In this paper, we report the electrochemical synthesis of a series of zinc complexes with pyrimidine-2-thionato derivatives as well as the synthesis of their adducts with *N,N* donors (bipy and phen). The thionato ligands differ in the nature, position and number of substituents in the heterocyclic ring.

At present we are unable to explain the different behaviour of the thionato ligands. Two different coordination modes (bidentate chelating and monodentate) are reported in this work. For Zn(4,6-Me_2,5-EtpymS)$_2$(MeOH)] the metal centre is in a ZnN_2S_2O environment, which describes a distorted bipyramidal trigonal. In the adducts with bipy and phen the zinc atom is in a highly distorted tetrahedral ZnN_2S_2 environment.

Polynuclear complexes

ABSTRACT

The synthesis, crystal structures and variable temperature magnetic investigation of three new thiocyanato-bridged copper(II) complexes with 2,2′-biimidazole (H_2bim) or 2-(2′-pyridyl)imidazole) (pyim) as coligands, $\{[Cu(H_2bim)_2][Cu(H_2bim)(NCS)_2(SCN)_{0.6667}(NO_3)_{0.3333}]_2\}\cdot 2H_2O$ (**1**), $[Cu(H_2bim)(NCS)_2]_n$ (**2**) and $[Cu(pyim)(NCS)_2]_n$ (**3**) are reported. Complex **1** contains centrosymmetric trinuclear species where central $[Cu(2)(H_2biim)_2]^{2+}$ cations and peripheral $[Cu(1)(H_2biim)(NCS)_2(SCN)]^-$ anions are linked through single end-to-end thiocyanato bridges. Complexes **2** and **3** are made up of neutral zigzag chains of copper(II) ions linked by single (**2**) and double (**3**) end-to-end thiocyanato bridges. A bidentate H_2bim ligand (**2**) or pyim (**3**) and a terminal N-thiocyanate group (**2**) complete the coordination spheres around each copper atom. The values of the intramolecular (**1**) and intrachain (**2** and **3**) copper–copper separations are 5.6143(5) (**1**), 5.6744(3) (**2**) and 6.0797(11) Å (**3**). Magnetic susceptibility measurements for **1**–**3** in the temperature range 1.9–295 K show the occurrence of weak intramolecular (**1**) and intrachain (**2** and **3**) antiferromagnetic interactions [$J = -0.10$ (**1**), -0.24 (**2**) and -0.03 cm^{-1} (**3**), the Hamiltonians used being $\hat{H} = -J(\hat{S}_1\cdot\hat{S}_2 + \hat{S}_2\cdot\hat{S}_3)$ (**1**) and $H = -J\sum_i(\hat{S}_i\cdot\hat{S}_{i+1})$ (**2** and **3**)]. The magnitude and nature of these magnetic interactions are discussed in the light of the respective structures and they are compared with those reported for related systems.

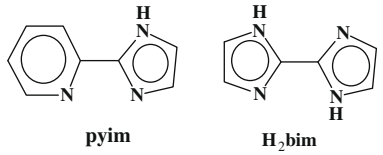
1. Introduction



Aromatic nitrogen heterocycles such as 2,2′-biimidazole (H_2bim) or 2-(2′-pyridyl)imidazole (pyim) (see Scheme 1) have in common the bidentate and bridging (under deprotonation) coordination modes in their metal complexes, the neutral character, the presence of aromatic rings that make possible the π–π stacking and their good donor character in hydrogen bonding interactions. All these characteristics are very important with regard to the development and exploration of rational synthetic strategies leading to metal-containing extended supramolecular motifs [1,2]. Concerning this last point, the hydrogen bonded 2,2′-biimidazolate transition metal complexes as a tool of crystal engineering of extended coordination compounds has illustrated the versatility and potentiality of these precursors [3]. In fact, a quite large number of discrete complexes and polymeric species based on association in one, two or three dimensions (*nD* with $n = 1$–3) with H_2bim-containing metal species has been described [2–14]. Another point to be outlined concerns the good number of studies devoted to the synthesis and biological activity of tin(IV) and platinum(II) compounds of H_2bim and its derivatives that have been published [15].

As far as the related pyim ligand is concerned, its coordination chemistry is more limited than that of H_2bim, most likely due to the fact that the yield for this molecule in the more recent preparative method is only *ca.* 33% [16]. It deserves to be noted that the first structural report of a pyim-containing metal complex was published only in 2002 and it concerned the copper(II) chain $\{[Cu(pyim)(\mu\text{-}1,5\text{-}dca)]NO_3\}_n$ (dca = dicyanamide) [17]. Since then, other structures of copper(II) [6b,18], zinc(II) [19], iron(II) [20], manganese(II) [21], vanadium(IV) [22], rhenium(III/IV) [23] and ruthenium(II) [24] complexes as well as those of two heterobimetallic compounds [25] were determined. Apart from the interest in the possibilities of the pyim ligand as a builder of supramolecular arrays through coordinative bonds and hydrogen bonding, the magneto-structural studies on the iron(II)–pyim complexes have revealed the occurrence of the spin-crossover phenomenon [16,20a]. This fact makes this ligand very appealing in research fields such as molecular magnetism and materials science.

In the context of our current magneto-structural studies on polynuclear complexes, we have investigated the complex

Scheme 1.

formation of the related H_2bim or pyim ligands with copper(II) in the presence of thiocyanate as a coligand. The trinuclear complex $\{[Cu(H_2bim)_2][Cu(H_2bim)(NCS)_2(SCN)_{0.6667}(NO_3)_{0.3333}]_2\} \cdot 2H_2O$ (**1**) and the chain compounds $[Cu(H_2bim)(NCS)_2]_n$ (**2**) and $[Cu(pyim)(NCS)_2]_n$ (**3**) were obtained and their preparation, crystal structure and magnetic properties are detailed herein.

2. Experimental

2.1. Materials

Copper(II) nitrate trihydrate and potassium thiocyanate were purchased from commercial sources and used as received. The ligands H_2bim and pyim were prepared by following previously reported methods [16,26]. Elemental analysis (C, H, N, S) were carried out by the Microanalytical Service of the Universidad Autónoma de Madrid.

2.2. Preparation of the complexes

2.2.1. $\{[Cu(H_2bim)_2][Cu(H_2bim)(NCS)_2(SCN)_{0.6667}(NO_3)_{0.3333}]_2\} \cdot 2H_2O$ (**1**) and $[Cu(H_2bim)(NCS)_2]_n$ (**2**)

Solid H_2bim (0.040 g, 0.313 mmol) was poured into an aqueous solution (150 cm^3) of $Cu(NO_3)_2 \cdot 3H_2O$ (0.150 g, 0.625 mmol) and then an aqueous solution (50 cm^3) containing KNCS (0.120 g, 1.25 mmol) was added dropwise under continuous stirring. X-ray quality deep green plate-like (**1**) and polyhedral (**2**) crystals were grown from the resulting green solution after one month by slow evaporation at room temperature. They were separated manually, washed with a small amount of cold water and dried on filter paper. The yields are 20% (**1**) and 75% (**2**). These percentages are practically interchanged when the starting Cu(II):H_2bim:NCS^- molar ratio is 1:1:2 [*ca.* 70% (**1**) and 20% (**2**)] (yields based on of the H_2bim ligand). *Anal.* Calc. for $C_{29.33}H_{28}Cu_3N_{22}O_4S_{5.33}$ (**1**): C, 31.61; H, 2.51; N, 27.66; S, 15.35. Found: C, 31.49; H, 2.46; N, 27.51; S, 15.25%. *Anal.* Calc. for $C_8H_6CuN_6S_2$ (**2**): C, 30.62; H, 1.91; N, 26.77; S, 20.44. Found: C, 30.51; H, 1.88; N, 26.70; S, 20.28%.

2.2.2. $[Cu(pyim)(NCS)_2]_n$ (**3**)

Single crystals of **3** as green polyhedra were grown by slow diffusion in an H-shaped tube of aqueous solutions containing KNCS (0.0408 g, 0.50 mmol) in one arm and a mixture of $Cu(NO_3)_2 \cdot 3H_2O$ (0.060 g, 0.25 mmol) and pyim (0.036 g, 0.25 mmol) in the other arm. The two arms were carefully filled with water and the whole was allowed to diffuse at room temperature. The crystals were collected after 20 days, they were washed with a small mount of cold water and dried on filter paper. The yield was *ca.* 80%. *Anal.* Calc. for $C_{10}H_7CuN_5S_2$ (**3**): C, 36.98; H, 2.16; N, 21.55; S, 19.75. Found: C, 36.87; H, 2.12; N, 21.20; S, 19.64%.

2.3. Physical techniques

IR spectra (4000–400 cm^{-1}) were recorded on a Bruker IF S55 spectrophotometer with samples prepared as KBr pellets. Variable-temperature (1.9–295 K) magnetic susceptibility measurements on polycrystalline samples were carried out with a Quantum Design SQUID susceptometer using an applied magnetic field of 1000 G over the whole temperature range. The complex $(NH_4)_2Mn(SO_4)_2 \cdot 6H_2O$ was used as a susceptibility standard. Diamagnetic corrections for the constituent atoms were estimated from Pascal's constants [27] as -525×10^{-6} (**1**), -147×10^{-6} (**2**) and -157×10^{-6} cm^3 mol^{-1} (**3**). A value of 60×10^{-6} cm^3 mol^{-1} was used for the temperature-independent paramagnetism of the copper(II) ion.

2.4. X-ray data collection and structure refinement

Diffraction data were collected with a Bruker-AXS SMART 2 K CCD area detector diffractometer at 293 (**1** and **2**) and 153 K (**3**). Crystal parameters and refinement results are listed in Table 1. The three structures were solved by direct methods and they were refined by full-matrix least-squares based on F^2, including all reflections. In the case of compound **1** the electron density maps

Table 1

clearly indicated that disorder is present at the site of one of the terminal thiocyanato groups. Initially, models with two orientations of the thiocyanato group were tested (S- and N-coordinated, respectively), but the residual electron density was still high, and suggested the presence of a four-atom group, rather than a rotated three-atom group as the minor component. As copper(II) nitrate had been used in the synthetic procedure, the presence of nitrate at this site would be possible. Eventually the best fit was obtained for a disordered model in which an S-coordinated thiocyanato group is present in 2/3 of the unit cells and a nitrate in 1/3 of the cells. Both disordered groups were refined as rigid groups with idealized geometry. In case of compound **3** systematic extinctions are compatible with space groups *Cc* or *C2/c*. Structure refinement in the centrosymmetric space group, with Cu on the twofold axis, revealed that a disordered model, not only for the pyim group, but also for Cu and thiocyanate, had to be invoked. After conversion to the non-centrosymmetric space group, *Cc*, refinement of an ordered model resulted. A pseudo twofold axis and a pseudo centre of symmetry are present in the structure due to the similarity and positions of the five- and six-membered rings of the pyim ligands. For all three compounds non-hydrogen atoms, except those in the disordered region of **1**, were anisotropically refined. All hydrogen atoms were clearly seen in electron difference Fourier maps. Those bound to carbon and nitrogen were included at idealized positions whereas those bound to water oxygen in **1** were included at positions found in the electron difference map, and all hydrogen atoms were refined according to the riding model.

3. Results and discussion

3.1. Synthesis and IR characterization

Compounds **1**–**3** have been obtained by reacting copper(II) nitrate and potassium thiocyanate with H_2bim (**1** and **2**) or pyim (**3**) as coligands. **1** is a trinuclear species whereas **2** and **3** are chain compounds all of them being neutral. The electroneutrality in this family is achieved by the coordination of thiocyanate either as a terminal [through the nitrogen (**1** and **2**) and sulfur (**1**)] or bridging [single (**1** and **2**) and double (**3**) end-to-end coordination mode] ligand, H_2bim and pyim adopting the bidentate coordination mode. Curiously, in the case of **1** the nitrate is also present as a terminal ligand. The low solubility in water of **1** and **2** accounts for their coprecipitation, but either compound may become the major product by modifying starting Cu(II):H_2bim:NCS^- molar ratio. In the light of previous studies of metal complexes with H_2bim or pyim as ligands [3,31], it is clear that the possibility of their deprotonation in **1**–**3** deserves to be investigated further. Most likely, this deprotonation would allow to overcome their insolubility and it would afford different species. As widely shown for the coordinated H_2bim, the release of the imidazole-hydrogen from the coordinated pyim in the presence of a base, would allow the coordination of the free imidazolate nitrogen to a metal ion to yield imidazolate-bridged polynuclear compounds. Interestingly, only a limited number of metal complexes containing deprotonated pyim is cited and their structures remain unknown [31].

Dealing with the IR spectra of **1**–**3**, the most relevant information concerns the high frequency region. The presence of the coordinated H_2bim (**1** and **2**) or pyim (**3**) is evidenced by the N–H [3130 (**1**), 3122 (**2**) and 3265 cm^{-1} (**3**)] and C–H [multiplet in the range 3100–2700 (**1** and **2**) and 3090–2750 cm^{-1} (**3**)] stretchings. It deserves to be noted that the N–H and C–H stretching vibrations of the free H_2bim and pyim molecules appear as multiplets in the region 3200–2500 cm^{-1}. The region of the ν_{CN} stretching band of the thiocyanate is very illustrative in the present family because of the shift towards higher frequency values (this band appears at 2053 cm^{-1} for the free KNCS) and the number of peaks: a triplet at 2112, 2086 and 2055 cm^{-1} for **1**, a doublet at 2116 and 2090 cm^{-1} for **2** and a strong absorption at 2115 cm^{-1} with a shoulder at 2124 cm^{-1} for **3**. According to the literature [32–35], the the ν_{CN} stretching occurs close to 2053 cm^{-1} when it exhibits the N-bonded coordination mode whereas in complexes containing the S-bonded thiocyanate, this value is near 2100 cm^{-1} and in the case of end-to-end bridging (M–NCS–M), this vibrational frequency is higher than 2100 cm^{-1}. These spectral data are in agreement with the coordination modes of the thiocyanate ligand in the crystal structures of the present series of complexes [terminal thiocyanato-N (**1** and **2**) or -S (**1**) and end-to-end bridging thiocyanato (**2** and **3**)] (see below).

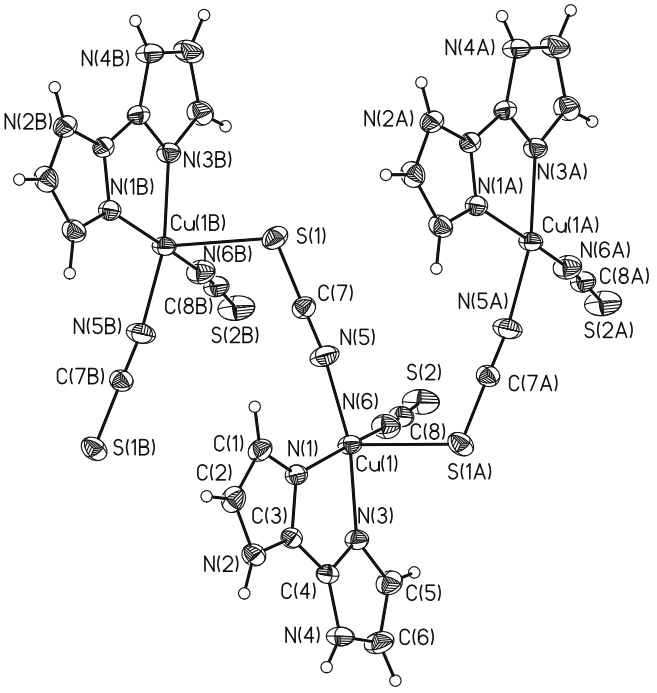

Fig. 2. Chain structure of **2**. Thermal ellipsoids are plotted at the 30% probability level. Symmetry code: (a) $x, 0.5 - y, -0.5 + z$; (b) $x, 0.5 - y, 0.5 + z$.

3.2. Description of the structures

3.2.1. $\{[Cu(H_2bim)_2][Cu(H_2bim)(NCS)_2(SCN)_{0.6667}(NO_3)_{0.3333}]_2\} \cdot 2H_2O$ (*1*)

The crystal structure of **1** is formally built of $[Cu(H_2bim)_2]^{2+}$ and $[Cu(H_2bim)(NCS)_2(SCN)]^-$ ions ($[Cu(H_2bim)(NCS)_2(NO_3)]^-$ ions in the minor site; see below) and water of hydration. One cation and two anions are connected through single end-to-end out-of-plane thiocyanato bridges to form a trinuclear entity (Fig. 1). The copper atom of the cation is situated at a crystallographic inversion

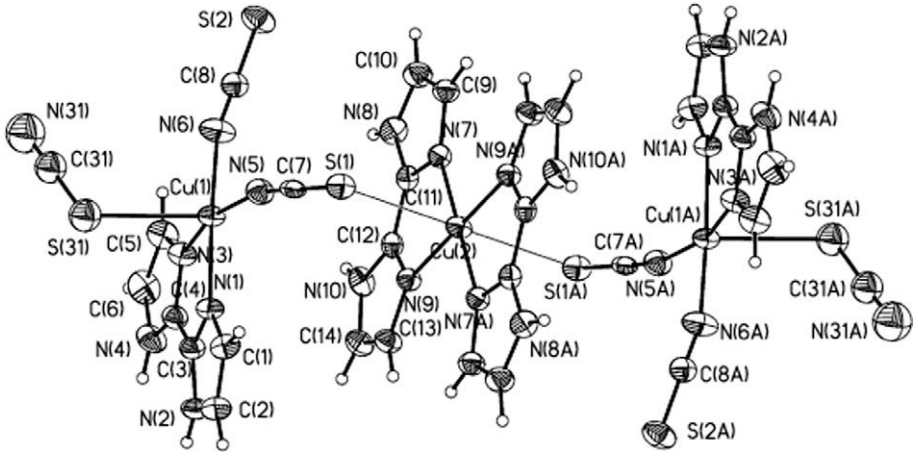

Fig. 1. The trinuclear unit in compound **1**. Only the major component of the disordered axial ligand on Cu(1) is shown. Thermal ellipsoids are plotted at the 30% probability level.

centre, and it is bound to four H_2bim nitrogen atoms in a rhombic planar arrangement [Cu(2)–N(7) = 2.025(3) Å and Cu(2)–N(9) = 2.014(3) Å]. In addition there are semi-coordinated weak axial Cu–S interactions [Cu(2)–S(1) = 3.0357(11) Å] to thiocyanato groups which are N-bound at the anion site. The copper atom of the anion [Cu(1)] has a distorted square pyramidal coordination sphere, the equatorial plane being defined by four nitrogen atoms, two from H_2bim, [Cu(1)–N(1) = 1.995(3) Å and Cu(1)–N(3) = 2.006(3) Å], one from the bridging thiocyanate [Cu(1)–N(5) = 1.942(3) Å], and one from a terminal thiocyanate [Cu(1)–N(6) = 1.944(3) Å]. The disordered thiocyanato/nitrato group resides in the apical site; the major site (occupancy 0.6667) through S-coordinated thiocyanate [Cu(1)–S(31) = 2.804(2) Å] and the minor site (occupancy 0.3333) across O-coordinated nitrate [Cu(1)–O(42) = 2.277(7) Å]. The plane of Cu(1) has a significant tetrahedral distortion, the maximum atomic deviation being 0.071 Å, and the copper atom is displaced 0.172 Å from this plane in the direction of the apical ligand. The equatorial plane of Cu(2) is exactly planar. Each of the imidazole rings is essentially planar, the dihedral angles between the two rings within a H_2bim molecule are 4.6° and 4.1°. These values compare well with that observed in the free H_2bim molecule (1.2°) [36]. The values of the inter-ring C(11)–C(12) and C(3)–C(4) bond distances of the two bidentate H_2bim ligands in **1** [1.431(5) and 1.439(5) Å, respectively] are similar to those found for the free [1.423(8) Å] [36] and coordinated biimidazole [1.447(3) and 1.442(5) Å in the complexes $[Cu(H_2bim)(C_2O_4)(H_2O)]\cdot H_2O$ and $[Cu(H_2bim)_2(H_2O)](NO_3)_2$, respectively] [6b,d]. The Cu(1)···Cu(2) distance within the trinuclear entity is 5.6143(5) Å whereas the shortest intermolecular copper–copper separation is 7.2046(6) Å [Cu(1)···Cu(2e), (e) referring to the unit cell translation $x, y-1, z$]. The neutral trinuclear units are interlinked through hydrogen bonds involving the imidazole, thiocyanate, nitrate and water molecules (see end of Table 2). To our knowledge this is the first report on a trinuclear thiocyanato-bridged copper(II) complex.

3.2.2. $[Cu(H_2bim)(NCS)_2]_n$ (**2**)

This compound features a chain structure with single out-of-plane, end-to-end thiocyanato bridges (Fig. 2). The copper atom has a distorted square pyramidal coordination sphere, the equatorial plane being defined by four nitrogen atoms, two from the chelating H_2bim group [Cu(1)–N(1) = 2.0146(14) Å, Cu(1)–N(3) = 2.0032(14) Å], one from the bridging thiocyanate group [Cu(1)–N(5) = 1.9490(16) Å], and one from the terminal thiocyanate [Cu(1)–N(6) = 1.9604(17) Å]. The sulfur atom of bridging thiocyanate resides in the apical position [Cu(1)–S(1a) = 2.6744(6) Å, (a) referring to the *c*-glide symmetry operation $x, 0.5-y, -0.5+z$]. The equatorial plane at the copper atom has a slight tetrahedral distortion (maximum atomic deviation of 0.033 Å), and the copper

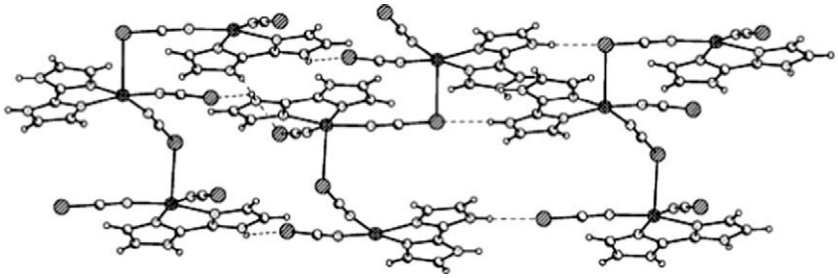

Fig. 3. Section of packing in compound **2**. Three neighbour chains are included. The N–H···S contacts listed in Table 3 are indicated by dashed lines.

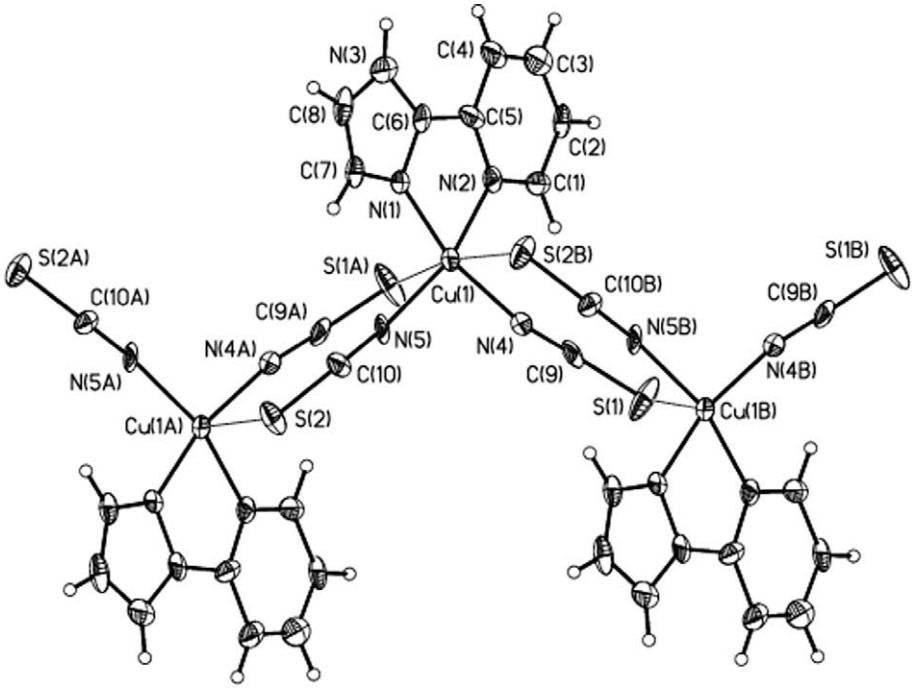

Fig. 4. Section of the chain structure in **3**. Thermal ellipsoids are plotted at the 30% probability level. Symmetry code: (a) $x, -y, -0.5+z$; (b) $x, -y, 0.5+z$.

atom is displaced by 0.188 Å from the mean equatorial plane towards the apical ligand. The individual imidazole rings are essentially planar and the dihedral angle between the two rings is 6.7°. The value of the inter-ring C(3)–C(4) bond distance of the bidentate H_2bim ligand is 1.438(2) Å. The chains are linked through weak N–H···S interactions (see end of Table 3 and Fig. 3) and van der Waals forces. The intra-chain Cu(1)···Cu(1a) distance is 5.6744(3) Å, a value which is somewhat longer then the shortest interchain metal–metal distance [5.4824(5) Å for Cu(1)··· Cu(1c); symmetry code: (c) $-x, -y, 1-z$].

3.2.3. $[Cu(pyim)(NCS)_2]_n$ (**3**)

The building block of this structure is the neutral [Cu(pyim)$(NCS)_2$] moiety with chelating pyim [Cu(1)–N(1) = 2.001(11) Å and Cu(1)–N(2) = 2.014(9) Å] and two thiocyanato nitrogen atoms [Cu(1)–N(4) = 1.925(11) Å and Cu(1)–N(5) = 1.987(10) Å)] coordinating in the equatorial plane of the copper atom. These units are connected into a chain through double, out-of-plane end-to-end thiocyanato bridges where the sulfur atoms form weak axial interactions with copper [Cu(1)–S(1a) = 3.171(3) Å and Cu(1)–S(2b) = 3.177(4) Å; (a) and (b) referring to symmetry operations $x, -y, -0.5+z$ and $x, -y, 0.5+z$, respectively] (Fig. 4). The equatorial plane of the copper atom has a pronounced tetrahedral distortion (maximum atomic deviation is 0.302 Å), the metal atom being situated close to the averaged plane (atomic deviation 0.004 Å). Each ring of the pyim ligand is essentially planar and the dihedral angle between the two rings is only 1.5°. The small deviation from planarity of the pyim molecule is in agreement with the significant double bond character of the inter-ring C(5)–C(6) bond [1.415(13) Å]. The bond distances and angles of the pyim ligand in **3** are similar to those observed in other pyim-containing copper(II) complexes [6b,17,18,25b]. Parallel chains in the crystal are linked through N–H···S and C–H···S type interactions (see end of Table 4) creating a three-dimensional network (Fig. 5). The intra-chain Cu(1)···Cu(1a) distance is 6.0797(11) Å whereas the shortest interchain metal–metal separation is 7.6758(12) Å [Cu(1)···Cu(1f); symmetry code: (f) $0.5+x, 0.5-y, 0.5+z$].

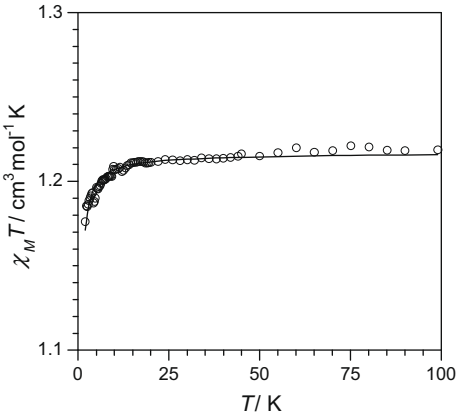

Fig. 6. Temperature dependence of the $\chi_M T$ product for **1**. The solid line is the best-fit curve through Eq. (1) (see text).

3.2.4. Magnetic properties

The thermal dependence of the $\chi_M T$ product for **1**–**3** [χ_M is the magnetic susceptibility per three (**1**) and one (**2** and **3**) copper(II) ions] is shown in Figs. 6 (**1**) and 7 (**2** and **3**). At room temperature, $\chi_M T$ is equal to 1.22 (**1**), 0.418 (**2**) and 0.407 cm^3 mol^{-1} K (**3**). These values are as expected for three (**1**) and one (**2** and **3**) magnetically isolated spin doublets. A Curie law behaviour is observed for the three compounds upon cooling from room temperature down to 90 (**2**), 15 (**1**) and 10 K (**3**). A small decrease of $\chi_M T$ is observed in the lower temperature range to reach minimum values of 0.373 (**2**), 1.175 (**1**) and 0.398 cm^3 mol^{-1} K (**3**) at 1.9 K. These features indicate the occurrence of very weak intramolecular (**1**) and intrachain (**2** and **3**) antiferromagnetic interactions.

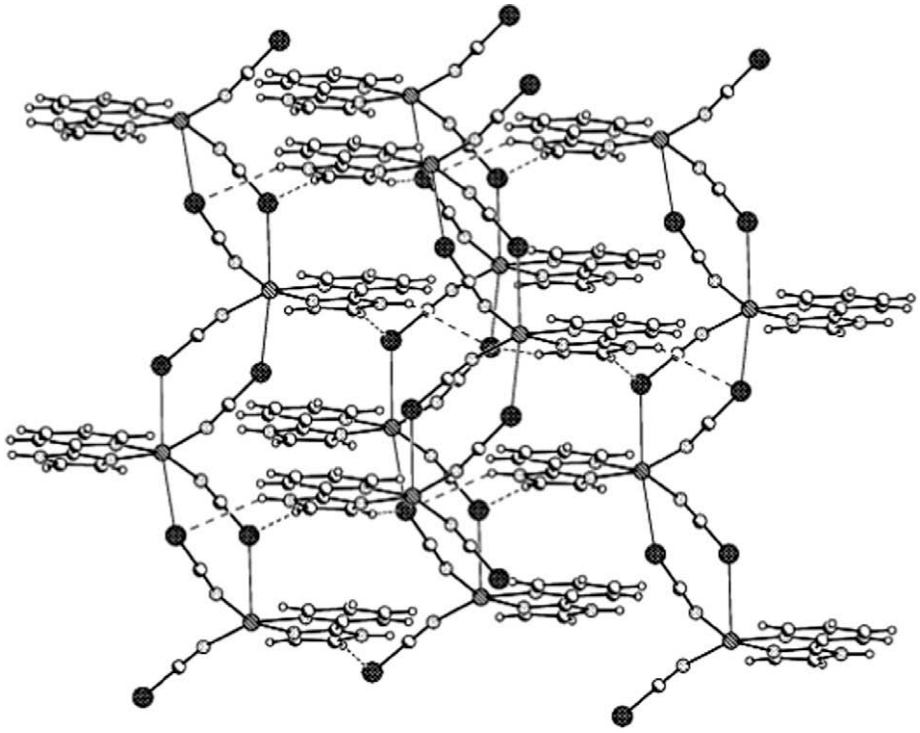

Fig. 5. Packing of chains in **3**. Four chains are shown, running vertical. N–H···S and C–H···S interactions between chains are indicated.

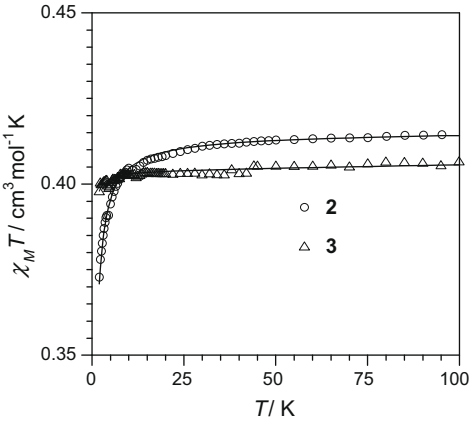

Fig. 7. Temperature dependence of the $\chi_M T$ product for **2** (△) and **3** (○). The solid lines are the best-fit curves through Eq. (2) (see text).

In agreement with the trinuclear structure of **1**, its magnetic susceptibility data were analyzed through the expression [Eq. (1)]

$$\chi_M = N\beta^2 g^2/4kT\{[1+\exp(J/kT)+10\exp(3J/2kT)]/[1+\exp(J/kT)+2\exp(3J/2kT)]\} \quad (1)$$

where N, β, g, k and T have their usual meaning and J is the exchange coupling between the peripheral and central copper(II) ions after the isotropic Hamiltonian $\hat{H} = -J[(\hat{S}_1 \cdot \hat{S}_2) + (\hat{S}_2 \cdot \hat{S}_3)]$ with $\hat{S}_1 = \hat{S}_2 = \hat{S}_3 = 1/2$. Best-fit parameters for **1** through Eq. (1) are $J = -0.10\ cm^{-1}$, $g = 2.08$ and $R = 1.1 \times 10^{-5}$ where R is the agreement factor defined as $\sum_i[(\chi_M T)_{obs(i)} - (\chi_M T)_{calc(i)}]^2/\sum_i[(\chi_M T)_{obs(i)}]^2$.

Given the one-dimensional structure of **2** and **3**, their magnetic data were analyzed through the numerical expression for a uniform chain of local spin doublets [Eq. (2)] [37]

$$\chi_M = (N\beta^2 g^2/kT)[(0.25+0.074975x+0.075235x^2)/(1.0+0.9931x+0.172135x^2+0.757825x^3)] \quad (2)$$

which is derived from the isotropic Hamiltonian $\hat{H} = -J\sum_i \hat{S}_i \cdot \hat{S}_{i+1}$ where $x = |J|/kT$ and J is the exchange coupling constant describing the magnetic interaction between the two nearest-neighbour spin doublets. Best-fit parameters through Eq. (2) leads to the following values: $J = -0.24\ cm^{-1}$, $g = 2.10$ and $R = 2.1 \times 10^{-5}$ for **2** and $J = -0.03\ cm^{-1}$, $g = 2.08$ and $R = 2.8 \times 10^{-5}$ for **3**.

The information available in the literature concerning the magnetic properties of structurally characterized single- and double-thiocyanato-bridged copper(II) complexes is quite limited and a summary of relevant magneto-structural data is listed in Table 5. One can see there that the magnetic coupling is weak and either ferro- or antiferromagnetic in nature. The observed weak antiferromagnetic couplings in **1**–**3** are hence in line with the previous magnetic data on related complexes. All these compounds have in common the end-to-end coordination mode of the thiocyanato bridge linking one equatorial position at one copper atom with the apical one of the adjacent copper. Taking our compounds as suitable examples, the weakness of the magnetic interaction can be easily understood having in mind the intramolecular (**1**) and intrachain (**2** and **3**) out-of-plane exchange pathways through the single (**1** and **2**) and double (**3**) thiocyanato bridges which

Table 5
Selected magneto-structural data for single- and double-$\mu_{1,5}$-thiocyanato-bridged copper(II) complexes.

[b] Copper environment: eo, elongated octahedral; dsq, distorted square pyramidal.
[c] Metal–metal separation through the thiocyanato bridge.
[d] Magnetic coupling.
[e] This value is obtained through a simple Bleaney–Bowers expression for two interacting spin doublets.
* Average values.

are involved. The magnetic orbital on each copper(II) ion in this series is roughly defined by the short equatorial bonds around the copper atom. Given that the spin density in the axial positions is very weak, the overlap between the two parallel magnetic orbitals is very small. Under these conditions, the exchange coupling is expected to be very weak, and either ferro- (case of accidental orthogonality which is strongly dependent on the value of the angle at the apical bridging atom) or antiferromagnetic. In spite of the long axial Cu–S bond length and the large intramolecular copper–copper separation in the complexes listed in Table 5, some of them show a significant, although weak, magnetic interaction. This must be due to the diffuse character of the sulfur orbitals. The low ability of the thiocyanato ligand to mediate magnetic interactions through the out-of-plane pathway is also comparable with that of other pseudohalide ligands such as azido and cyanato [52], and it contrasts with the greater efficiency when the thiocyanate links the equatorial positions of two adjacent copper(II) ions, as in the dinuclear complex $[Cu(Hmtpo)(H_2O)(NCS)_2]_2$ (Hmtpo = 4*H*,7*H*-5-methyl-7-oxo[1,2,4]triazolo[1,5-*a*]pyrimidine) where $J = -148.2$ cm^{-1} [53]. In this latter case, the good overlap between the coplanar magnetic orbitals of each copper(II) ion accounts for the important antiferromagetic interaction observed.

4. Conclusions

The use of the thiocyanate group in combination with the blocking imidazole type ligands H_2bim or pyim has led to the preparation of three polynuclear copper(II) complexes: a trinuclear species (**1**) and two one-dimensional compounds (**2** and **3**). Different coordination modes and a different number of thiocyanate bridges are present in this series, illustrating once more the versatility of this ligand in its coordinating behaviour and the difficulty to predict it. In the three cases, the thiocyanate adopts the end-to-end bridging mode [single (**1** and **2**) and double (**3**)] linking one equatorial position of one copper atom with an apical position at the adjacent copper. The intramolecular (**1**) and intrachain (**2** and **3**) magnetic couplings are weak and antiferromagnetic in line with the scarce data from previous magneto-structural studies on related species.

Supplementary data

CCDC 697116, 697117 and 697118 contain the supplementary crystallographic data for **1**, **2** and **3**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

The reaction of xantphos dioxide (O∩O) with the polynuclear precursor $[Ru(CO)_2Cl_2]_n$ to give the mononuclear complex $[Ru(CO)_2Cl_2(O\cap O)]$(**1**) is reported together with single crystal X-ray structure analyses of both the free ligand and the ruthenium complex. The synthesized compounds have also been characterized by elemental analyses, IR and NMR (^1H, ^{31}P and ^{13}C) spectroscopy. The ligand O∩O crystallizes with lattice water molecules in a triclinic system with space group $P\bar{1}$ whereas the complex **1** crystallizes in an orthorhombic system with space group $P2_12_12_1$. Each mononuclear unit of O∩O and **1** is stabilized in their solid state through non-covalent (C–H···O, C–H···Cl and C–H···π) interactions to develop an extended three-dimensional network structure. The complex **1** exhibits an interesting intramolecular O···O interaction between one of the P═O groups and backbone O leading to different electron donacity of two P═O groups to the metal centre.

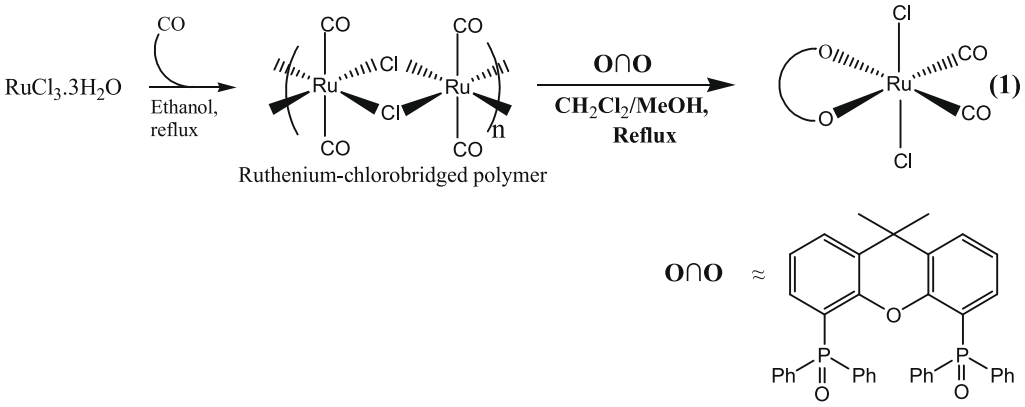
1. Introduction

The assembly of mononuclear and polynuclear organometallic complexes in the solid state is governed by a balance between non-directional close packing forces and directional interactions between metal atoms or charged groups [1]. The intermolecular interactions acting among the molecules in their solid state plays an important role to understand the solid state properties of organometallic compounds as both physical (conductivity, diffusion, magnetic susceptibility, reorientation and second harmonic generation) and chemical (solid state reactivity, racemisation, resolution) properties of a compound depend on the ways in which the molecules are organized in the crystal and on the forces which hold them together [2]. The two major types of interactions employed by chemists to engineer supramolecules with predefined dimensions (1D, 2D and 3D), are metal ligand bonding and hydrogen bonding. In addition to strong (O–H···O) and weak (C–H···O) hydrogen bonds; halogen bonds (C–X···O) and weak (C–H···π) interactions have also been well characterized and exploited to playing an important role in crystal engineering and organometallic structures [3–7]. The metallosupramolecules thus generated have attracted attention in recent years due to their applications in diverse areas such as catalysis, optoelectronics, gas storage, ion exchange, molecular recognition and magnetism [8–21]. To develop such extended network structures, an appropriate ligand should be chosen, which on complexation with metal ions forms 'supramolecular glue' resulting in polymeric network. As a part of our continuing research activity [22–26], herein we report the synthesis, structure and self-aggregation of oxygen functionalised robust backbone ditertiary phosphine like xantphos [9,9-dimethyl-4,5-bis(diphenyl phosphino)xanthene] and its ruthenium(II) carbonyl complex.



2. Results and discussion

The rigid backboned xantphos dioxide (O∩O) reacts with the polymeric precursor $[Ru(CO)_2Cl_2]_n$ in 1:1 molar ratio to afford hexa-coordinated mononuclear complex $[Ru(CO)_2Cl_2(O\cap O)]$ (**1**) (Scheme 1). The IR spectra of **1** show two equally intense ν(CO) bands at around 1973 and 2049 cm^{-1} attributing the presence of two terminal carbonyl groups only (Fig. 1). The ν(P–O) band of **1** at 1187 cm^{-1} is about 6 cm^{-1} lower than that of the free ligand (ν(P–O) = 1193 cm^{-1}) revealing the coordination to metal through O-donor. The ^{13}C NMR spectrum of **1** shows only one signal for the two non-equivalent carbonyl carbons as broad singlet at around δ 195 ppm. The ^{31}P NMR spectra of **1** exhibit only one sharp signal indicating the presence of a single isomer.

The ligand O∩O and its metal complex **1** have been structurally characterized by single crystal X-ray diffraction. The crystal information for the two compounds is summarized in Table 1. The ligand O∩O crystallizes with lattice water molecules in a triclinic system with space group $P\bar{1}$. The asymmetric unit of O∩O, shown in Fig. 2 consists of three xantphos dioxide moieties along with three disorder water molecules. The two P═O groups of each molecule form strong hydrogen bonds with one water molecule. The

average value of P═O bond length is found to be 1.48 Å (Table 2). The compound O∩O forms a three-dimensional network structure by extending infinitely via strong intermolecular C–H···O and C–H···π interactions as shown in Fig. 3. As indicated in both Figs. 3 and 4, water molecules are trapped into the network by the ligand O∩O through intermolecular hydrogen bonding by bridging each molecule of xantphos dioxide generating solvent stabilized three-dimensional network [O(3)···O(11) 2.722(3); O(1)···O(11) 2.776(2); H(49)···O(11) 2.676(1); H(63)···O(11) 2.708(2); H(47A)···O(11) 2.508(3) etc.] (Table 3). The compound loses water molecule on activating the sample at 100 °C for 1 h and this solvent loss is accompanied by the loss of transparency of the crystals. An X-ray powder diffraction analysis revealed that the solvent loss is accompanied by the loss of crystallinity, and indeed, no diffraction peaks were observed for the bulk sample.

The complex **1** crystallizes in an orthorhombic system with space group $P2_12_12_1$ where the Ru atom is situated at the centre of an octahedral environment formed by two O donors, two CO and two Cl atoms. The selected bond lengths and bond angles are presented in Table 2. The X-ray crystal structure (Fig. 5) reveals that the two Cl atoms are *trans* to each other, whereas the CO groups which are *cis* to each other are situated at the positions *trans* to two O donors. The two CO groups, two O donors and Ru metal are located in the same plane. The ligand O∩O forms a chelate (bite angle O2–Ru1–O1, 85.39) through O, O donor and forms a ten member distorted ring structure. The O1–Ru1–O2 plane is inclined by an angle 102° to the plane of the backbone of xantphos ligand. As a result of this folded structure, there appears a close intramolecular (O(1)···O(5) [2.905(4) Å, Fig. 5] interaction between the O atom of ligand backbone and one of the O atoms of P═O group of the chelating ligand. This type of O···O interaction is not commonly observed though the O–O short contact between two carbonyl groups is documented in literature [3]. The effect of the O···O interaction in **1** is reflected in CO bond order which is consistent with their corresponding Ru–C bond lengths (Table 2). The influence of O(1) *trans* to C(41) at the metal centre is less than that

Table 2

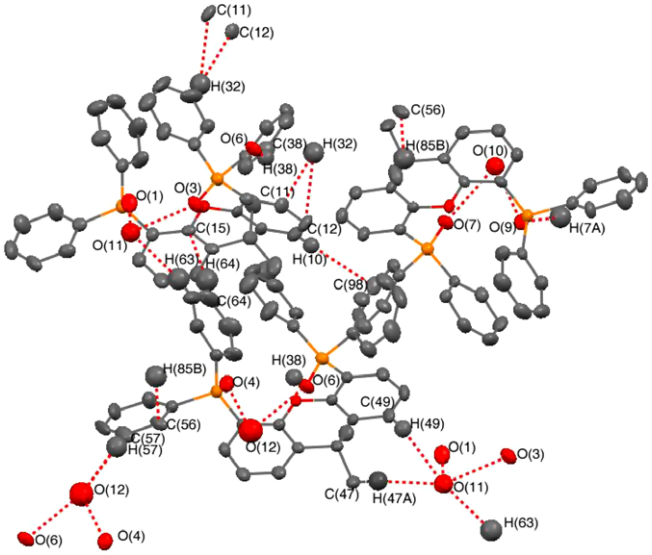

Fig. 3. Intermolecular short contacts in the molecule O∩O. All the hydrogen atoms except those involved in hydrogen bonding have been omitted for clarity.

of O(2) trans to C(42), which may be due to O(1)···O(5) interaction. Because of the weak Ru–O interaction in the former, the electron density increases on the metal centre in the latter case resulting in more dπ-electrons to the antibonding π^* orbital of the CO and hence decreases the Ru–C bond length and consequently reduces the C–O bond order (increases C–O bond length). The longer bond length of Ru1–C41 (1.931(7) Å) than Ru1–C40 (1.833(7) Å) indicates a weaker interaction in the former and is therefore likely to dissociate more easily.

The complex **1** exhibit some interesting intermolecular interactions involving shorter distances than the sum of van der Waals radii (Fig. 6). The interactions between these molecules are presented by dotted lines and summarized in Table 4. The molecules are connected by weak hydrogen bondings between H atoms of the phenyl ring of xantphos ligand and O atom of CO group (C–H···OC) and Cl atom (C–H···Cl) of the adjacent molecules [C(23)–H(23)···Cl(2) 2.763(4) Å, C(36)–H(36)···Cl(2) 2.879(4) Å, C(12)–H(12)···O(4) 2.582(7) Å and C(35)–H(35)···O(3) 2.704(6) Å]. In addition to these hydrogen bondings, intermolecular C–H···π interactions between H atoms of xantphos ligand and the phenyl ring of these molecules [C(30)–H(30)···C(33) 2.812(7) Å, C(8)–H(8)···C(24) 2.822(5) Å, and C(32)–H(32)···C(11) 2.832(8) Å] are also observed in their solid

state. All these results demonstrate the extended three-dimensional network structure as shown in Fig. 7 which exhibits high thermal stability (>300 °C). This result infers that the intermolecular interactions of one mononuclear unit of **1** with the adjacent members have a profound effect on overall thermal stability of the network.

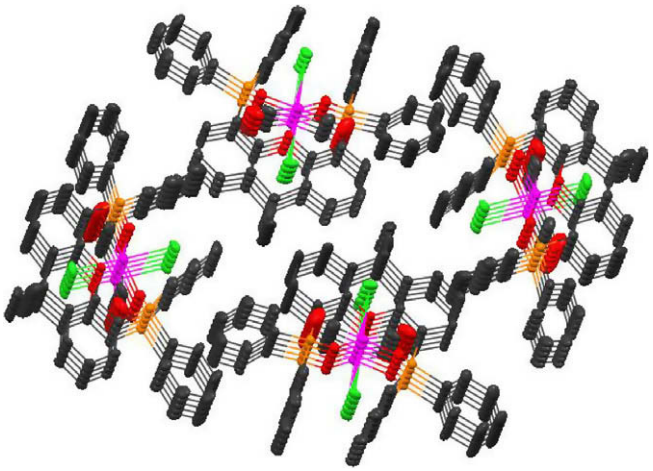

Fig. 7. 3D stacked structure of **1** stabilized by weak hydrogen bonding. Hydrogen atoms are omitted for clarity.

3. Experimental

3.1. General

All operations were carried out under nitrogen atmosphere. All solvents were distilled under N_2 prior to use. $RuCl_3 \cdot xH_2O$ was purchased from M/S Arrora Matthey Ltd., Kolkata, India. The ligand xantphos was purchased from M/S Aldrich, USA and used without further purification. H_2O_2 was obtained from Ranbaxy, New Delhi, India and estimated before use.

Elemental analyses were performed on a Perkin–Elmer 2400 elemental analyzer. IR spectra (4000–400 cm^{-1}) were recorded on KBr discs in a Perkin–Elmer system 2000 FT-IR spectrophotometer. The ^{1}H, ^{13}C and ^{31}P NMR spectra were recorded in $CDCl_3$ solution on a Bruker DPX-300 Spectrometer and chemical shifts were reported relative to $SiMe_4$ and 85% H_3PO_4 as internal and external standards, respectively. Thermal analyses of the complexes were carried out using a thermal analyzer (TA instrument, Model STD 2960 simultaneous DTA–TGA) in presence of N_2 atmosphere with a heating rate of 10 °C/min.

3.2. Synthesis of xantphos dioxide (O∩O)

The ligand xantphos dioxide was synthesized by oxidation of xantphos with H_2O_2 following the literature protocol [27].

IR (KBr, cm^{-1}): 1193 [ν(P–O)]. ^{1}H NMR ($CDCl_3$, ppm): δ 6.74–7.74 (m, 30H, Ph), 2.17 (s, 6H, CH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 153.10–124.1 (Ar), δ 32.3, 34.9 (CH_3). $^{31}P\{^{1}H\}$ NMR ($CDCl_3$, ppm): δ 30.95 [s, P(v)]. *Anal.* Calc for $C_{39}H_{32}O_3P_2$: C, 74.40; H, 5.08. Found: C, 73.98; H, 5.09%.

3.3. Synthesis of the starting complex $[Ru(CO)_2Cl_2]_n$

The starting complex $[Ru(CO)_2Cl_2]_n$ was prepared by passing CO through a refluxing solution of $RuCl_3 \cdot 3H_2O$ in ethanol for about 24 h [28–31].

3.4. Synthesis of $[Ru(CO)_2Cl_2(O\cap O)]$ (**1**)

$[Ru(CO)_2Cl_2]_n$ (0.877 mmol, 200 mg) was dissolved in methanol (10 cm^3) and xantphos dioxide (0.877 mmol, 536 mg) was dissolved in dichloromethane (10 cm^3). Both the solutions were mixed together and refluxed for 4 h. The solvent was removed and washed with diethyl ether. The resulting reddish yellow

compound was recrystallised from dichloromethane/*n*-hexane to give the complex '**1**' (640 mg, 87%)

IR (KBr, cm^{-1}): 2049, 1973 [ν(CO)]. 1187 [ν(P–O)]. ^1H NMR ($CDCl_3$, ppm): δ 6.53–7.92 (m, 30H, Ph), 1.74 (s, 3H, CH_3), 1.82 (s, 3H, CH_3). ^{13}C NMR ($CDCl_3$, ppm): δ 152.78–122.13 (Ar), δ 33.59, 34.20 (CH_3), 195.64 (CO). $^{31}P\{^1H\}$ NMR ($CDCl_3$, ppm): δ 41.96 [s, P(v)]. Anal. Calc for $C_{41}H_{32}Cl_2O_5P_2Ru$: C, 57.40; H, 3.73. Found: C, 56.85; H, 3.65%.

3.5. X-ray structural analysis

Single crystals of O∩O and **1** were grown by layering a CH_2Cl_2 solution of O∩O and **1** with *n*-hexane. The intensity data of O∩O and **1** were collected on Bruker Smart–CCD and Rigaku Saturn CCD, respectively with Mo Kα radiation (λ = 0.71073 Å). The structures were solved with SHELXS-97 [32] and refined by full-matrix least squares on F^2 using SHELXL-97 computer program [33]. Hydrogen atoms were idealized by using the riding models.

Powder XRD spectra of the compound O∩O were recorded on a Bruker AXS D8 ADVANCE from 2 to 80 °C at 4° min^{-1} with a step size of 0.02° using Cu Kα source (λ = 1.54 Å). Samples were prepared as front-coated packed powders in aluminium sample holders.

4. Conclusion

In this paper, the synthesis of ruthenium(II) carbonyl complex (**1**) containing a xantphos dioxide chelating ligand along with the structural characterization of the ligand (O∩O) and its ruthenium complex (**1**) have been carried out. The compound O∩O forms a three-dimensional network structure by extending infinitely via strong intermolecular C–H···O and C–H···π interactions by bridging each molecule of xantphos dioxide with water molecules to generate a solvent stabilized architecture. The ligand O∩O reacts with $[Ru(CO)_2Cl_2]_n$ to afford hexa-coordinated Ru(II) complex **1**, which generates three dimensional rigid network via intermolecular C–H···O, C–H···Cl and C–H···π interactions resulting in high thermal stability (>300 °C). The complex **1** exhibit an interesting intramolecular O···O interactions leading to different electron donacity of two P═O groups to the metal centre.

ABSTRACT

The present study reports the preparation and characterization of PbO nanocrystals obtained via a thermal decomposition route. The PbO nanocrystals were synthesized using lead oxalate powder as a precursor. Nanostructured products were investigated by means of XRD, TEM, FT-IR and XPS. The XRD results indicate that tetragonal phase β-PbO with a particle size of about 30–45 nm was obtained when the intermediate precipitate was calcined at 500 °C.

1. Introduction

The synthesis of nanomaterials is an increasingly active area [1,2]. Nanostructured materials have attracted the attention of researchers not only by their unique chemical and physical properties but also by their potential application in many fields, which has stimulated the search for new synthetic methods for these materials. These materials consist of small grains with sizes below 100 nm.

Lead oxide (PbO), an important industrial material, has been widely applied in storage batteries, gas sensors, pigments and paints [3,4]. PbO has two polymorphic forms and a wide band gap: red α-PbO, stable at low temperature, and yellow β-PbO, stable at high temperature [5], and the α-PbO → β-PbO phase transition occurs at about 490 °C. However, the high temperature yellow form can exist even at room temperature.

In recent years, increased attention has been focused on the synthesis of PbO nanostructures. Pan et al. [6] synthesized PbO nanowires through electron beam irradiation on PbO_2 nanobelts. Jia and Gao [7] synthesized β-PbO nanorods with diameters ranging from 40 to 120 nm and lengths up to 500 nm, via the hydrothermal method in the presence of citrate. Xia and coworkers [8] synthesized PbO by the one-step solid state reaction of a Pb(II) compound with NaOH at room temperature.

One type of method to prepare nanosized PbO is thermal decomposition. Ma et al. [9] prepared nanometer-sized PbO by pyrogenetic decomposition of lead carbonate synthesized by chemical precipitation. Jiang et al. [10] prepared PbO nanowires via calcining lead glycolate nanowires that were synthesized by heating lead acetate in ethylene glycol. Nanosized PbO particles were prepared by thermal decomposition of lead hydroxycarbonate synthesized under microwave irradiation by Yang and coworkers [11]. Chen et al. [2] prepared PbO nanocrystals by thermal decomposition of $Pb(OH)_2$.

Recently, metal coordination complexes or organometallic compounds as precursors for the preparation of inorganic nanomaterials have been widely studied as they represent an important interface between synthetic chemistry and materials science. Complexation is a popular method of modifying ligands in the original precursor solution, and carboxylic acids or their salts are the most frequently used complexing agents. Nathan et al. [12] used citric acid as a chelating agent for the preparation of NiO nanostructures to induce molecular level mixing of the dissociated metal ions dissolved in the solution. Gajbhiye et al. [13] reported that by using cobalt acetylacetonate as a precursor, Co nanoparticles with the smallest size are synthesized compared to cobalt acetate. This is because of the chelate effect in the $[Co(acac)_2]$ complex.

Considering the reaction of the chelating agent, we suggest that oxalate anions coordinated to the Pb ions in $Pb(NO_3)_2$ inhibit the agglomeration of metal cations and decrease the particle size of the PbO nanoparticles. As far as we are aware, the use of lead oxalate for the production of lead oxide nanoparticles has not been reported. Therefore, we chose lead oxalate as a lead precursor. Recently, our group reported the synthesis of metal oxide nanoparticles via thermal decomposition of a novel precursor [14–19]. Herein, we report a facile method for the synthesis of PbO nanocrystals by thermolysis of lead (II) oxalate $[Pb(O_4C_2)]$ in the coordinating solvent oleylamine and with triphenylphosphine (TPP).

2. Experiment

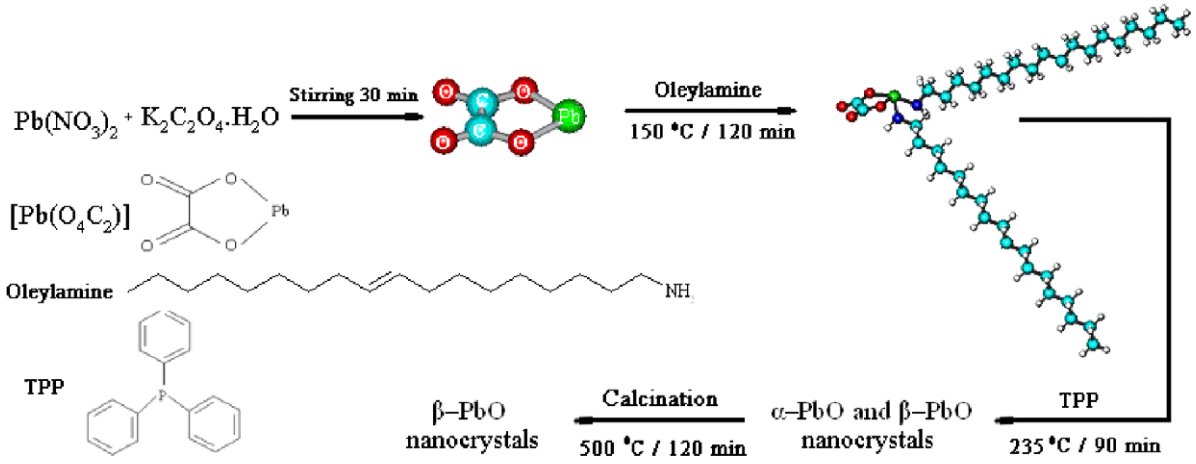
2.1. Characterization

XRD patterns were recorded by a Rigaku D-max C III, X-ray diffractometer using Ni-filtered Cu Kα radiation (λ = 1.5406 Å). Elemental analysis was obtained from a Carlo ERBA Model EA 1108 analyzer. Transmission electron microscopy (TEM) images were obtained on a Philips EM208 transmission electron microscope with an accelerating voltage of 200 kV. Fourier transform infrared (FT-IR) spectra were recorded on a Shimadzu Varian 4300 spectrophotometer in KBr pellets. X-ray photoelectron spectroscopy (XPS) of the as-prepared products was measured on an ESCA-3000 electron spectrometer with non-monochromatized Mg Kα X-ray radiation as the excitation source. Thermogravimetric analysis (TG) was carried out using a thermal gravimetric analysis instrument (Shimadzu TGA-50H) with a flow rate of 20.00 ml/min and a heating rate of 10 °C min^{-1} in air from room temperature to 500 °C.

2.2. Synthesis of lead oxalate

All the chemical reagents used in our experiments were of analytical grade and were used as received without further purification. Lead (II) oxalate, [$Pb(O_4C_2)$], as a precursor was synthesized according to this procedure: lead (II) nitrate $Pb(NO_3)_2$ (2 mmol) was dissolved in 10 ml of distilled water to form a homogeneous solution. A stoichiometric amount of potassium oxalate dissolved in an equal volume of distilled water was added dropwise to the above solution under magnetic stirring. The solution was stirred for about 30 min and a white precipitate was isolated which was washed with water and ethanol several times to remove potassium nitrate as a by-product. The white precipitate of lead oxalate was dried at 50 °C. The reaction equation of the synthesis of lead oxalate is shown in Eq. (1). The [$Pb(O_4C_2)$] was characterized by elemental analysis, FT-IR, powder X-ray diffraction (XRD) and thermogravimetric analysis (TGA). *Anal.* Calc. for [$Pb(O_4C_2)$]: C, 8.14; Pb, 70.18. Found: C, 8.07; Pb, 70.10%.

$$Pb(NO_3)_{2(aq)} + K_2C_2O_4 \cdot H_2O_{(aq)} \rightarrow [Pb(O_4C_2)]_{(s)} + 2KNO_{3(aq)} \quad (1)$$



2.3. Synthesis of PbO nanocrystals

The current synthetic procedure is a modified version of the method developed by Hyeon et al. for the synthesis of nanocrystals [20]. The synthetic pathway is shown in Scheme 1. First, the [$Pb(O_4C_2)$]–oleylamine complex was prepared by the reaction 0.5 g of [$Pb(O_4C_2)$] and 7 ml of oleylamine. The mixed solution was placed in a 50 ml two-necked distillation flask and heated up to 150 °C for 2 h. In this step, metal nuclei are formed during the heat treatment in the presence of oleylamine. In the second step, the resulting metal-complex solution was injected into 5 g of triphenylphosphine (TPP) at 235 °C. Upon heating at 235 °C, the color of the reaction solution changed from white to dark orange, which indicates the short burst of nucleation. The dark orange solution was aged at 235 °C for 90 min, and then cooled to room temperature. The light red nanocrystals were precipitated by adding excess ethanol to the solution and then they were separated by centrifugation. The final product was washed with ethanol for at least three times to remove impurities. The product could easily be re-dispersed in non-polar organic solvents, such as hexane or toluene. The synthesized nanocrystals were characterized by XRD, TEM, FT–IR and XPS.

3. Results and discussion

The TG curve of [$Pb(O_4C_2)$] is shown in Fig. 1. There is only one weight loss step in the temperature range 250–330 °C. The weight loss at 250–330 °C may be ascribed to the decomposition of the oxalate. The weight loss is about 25.00%, which is close to the theoretical value (24.39 wt%). This weight loss is due to the decomposition of lead oxalate to lead oxide because the oxidation number of the lead ions is constant during the thermal decomposition process. Fig. 2 shows the XRD patterns of the lead oxalate precursor (a), intermediate precipitate (b) and PbO nanocrystals (c). The XRD pattern of lead oxalate in Fig. 2a can be indexed to the anorthic cell reported for lead oxalate (JCPDS No. 14-0803, a = 6.091 Å, b = 6.978 Å, c = 50557 Å). No significant impurities such as KNO_3 (JCPDS No. 15-0607) were observed, which indicates that pure lead oxalate was obtained. The intermediate precipitate contains a mixture of red and yellow PbO nanocrystals (α and β) formed through the thermal decomposition of lead oxalate in the presence of oleylamine and TPP. All of the reflections of the XRD pattern in Fig. 2b can be indexed to the orthorhombic lattice of PbO (α-PbO, JCPDS No. 35-1482, marked with "*") and the tetragonal lattice of PbO (β-PbO, JCPDS No. 01-0824, "♦"). The average crystallite size (D_c) of the PbO nanocrystals is 35 nm, which was calculated using the Debey–Scherrer Eq. (2) from the major diffraction peaks of the corresponding β-PbO (1 0 1) and α-PbO (1 1 1) [21],

$$D_c = \frac{K\lambda}{\beta \cos\theta} \quad (2)$$

Scheme 1. Schematic diagram illustrating the formation of PbO nanocrystals.

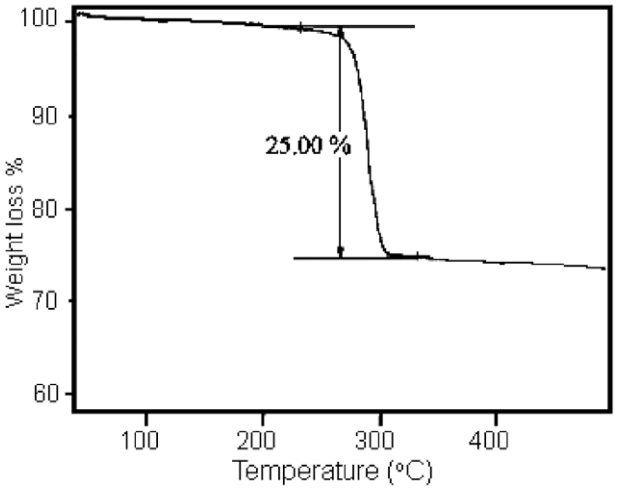


Fig. 1. TGA plot for the decomposition of the lead oxalate precursor.

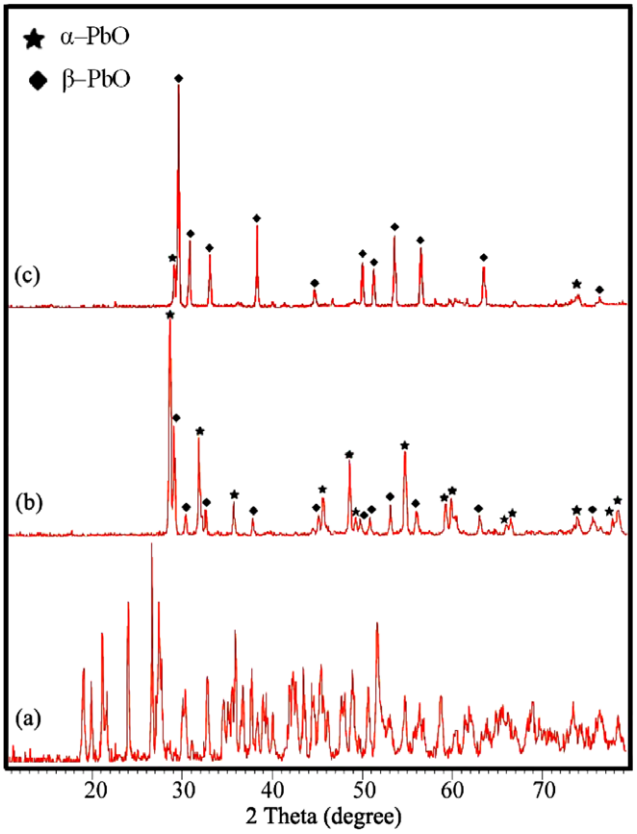

Fig. 2. XRD patterns of the obtained (a) lead oxalate precursor, (b) intermediate product (α-PbO and β-PbO) and (c) β-PbO nanocrystals.

where β is the breadth of the observed diffraction line at its half-intensity maximum, K is the so-called shape factor, which usually takes a value of about 0.9, and λ is the wavelength of the X-ray source used in the XRD. In order to change α-PbO into stable β-PbO, the intermediate precipitate was calcined at 500 °C for 2 h. The XRD pattern of β-PbO nanocrystals is shown in Fig. 2c. In this pattern, two reflection peaks of α-PbO with very low intensity are still observed, which can be removed at a higher calcination temperature but the particle size of the nanocrystals increases by increasing the temperature. The particle size of β-PbO nanocrystals calculated from the major diffraction peak of the corresponding β-PbO (1 0 1) using the Debey–Scherrer equation is 45 nm. All XRD results of the PbO nanocrystals, such as reflection peak (*h k l*), its corresponding full width at half maximum (FWHM) and theta positions, are listed in Tables 1 and 2 (Fig. 2b and c). Several peaks of the corresponding β-PbO have not been marked with *h k l* values (refer JCPDS No. 01-0824).

TEM images of β-PbO nanocrystals are shown in Fig. 3a and b. The images indicate that the PbO powder consists of nanometric particles with diameters of 30–45 nm, which is in agreement with the XRD results. The SAED pattern (Fig. 3c) indicates that the β-PbO nanocrystals are single crystals.

FT-IR spectroscopy is a useful tool to help understand the functional group behavior of any organic molecule. The infrared spectra of free TPP (a), oleylamine (b), lead oxalate (c) and β-PbO nanocrystals (d) are shown in Fig. 4. As shown in Fig. 4a, the peaks corresponding to the P–Ph stretching at 1710 cm^{-1}, the bending mode of the phenyl group γ(=CH) at 742 $cm^{-1}$and υ (benzene ring) at 697 cm^{-1} can be seen. In the IR spectrum of oleylamine (Fig. 4b) two sharp bands at 2925 and 2855 cm^{-1} are attributed to the asymmetric CH_2 stretch and the symmetric CH_2 stretch, respectively [22]. The rocking and bending mode of the methylene group $\omega(CH_2)$ is seen at 1270 cm^{-1}. The IR spectrum of $[Pb(O_4C_2)]$ is shown in Fig. 4c. The very weak broad absorption band around 3446 cm^{-1} corresponds to the ν_{O-H} stretching vibrations of water molecules [23]. This observation provides evidence for the presence of a small amount of water absorption on the surface of $Pb(O_4C_2)$ after handling. The double absorption peaks that appear at 1645 and 1610 cm^{-1} are due to the asymmetric vibrations of the carbonyl group and the absorption peaks at 1369 and 1287 cm^{-1} are assigned to $\nu_{s(C-O)+\delta(OC=O)}$ modes. Two distinct peaks at 776 and 508 cm^{-1} are attributed to the out-of-plane bending mode of water and O–C–O in-plane bending mode of oxalate, respectively [24], which indicate the formation of $[Pb(O_4C_2)]$. In the IR spectrum of lead oxalate, no peak appears at 1384 cm^{-1}, which is a typical absorbance of nitrate anions, indicating the lack of nitrate anions in the lead oxalate [25]. In the FT-IR spectrum of the β-PbO nanocrystals (Fig. 4d) a new peak appears at 451 cm^{-1}, which is assigned to the Pb–O bond.

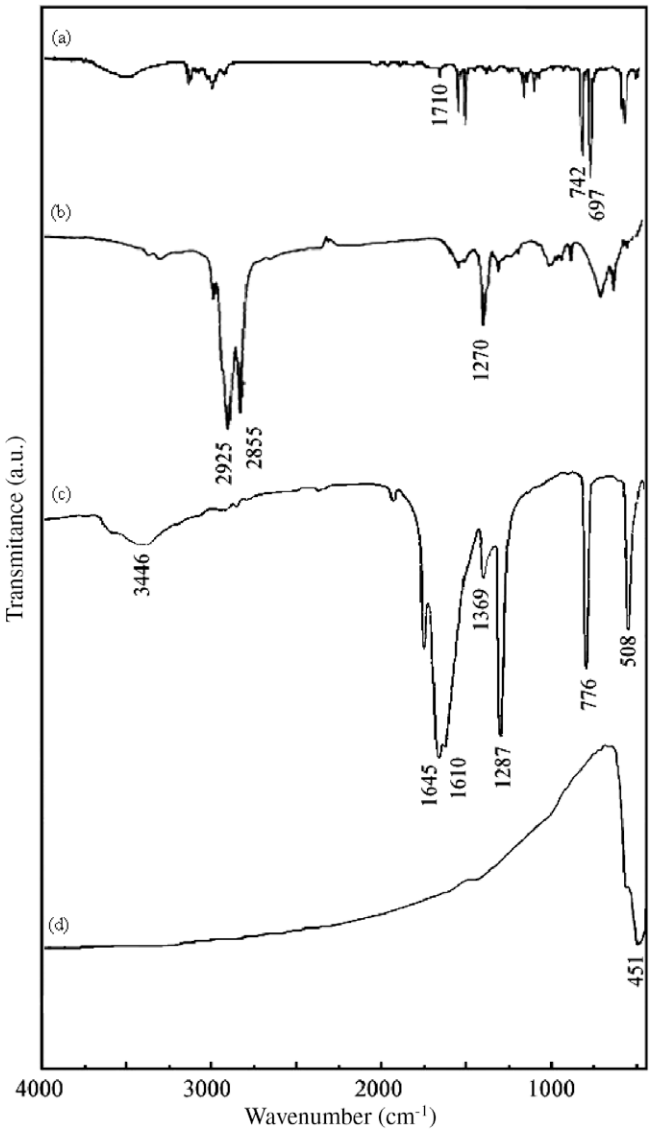

Fig. 4. FT-IR spectra of (a) TPP, (b) oleylamine (c) lead oxalate and (d) PbO nanocrystals.

In order to further prove the formation of PbO, the products were characterized by X-ray photoelectron spectroscopy (XPS). Fig. 5 shows the XPS of the as-synthesized samples. The XPS gives a binding energy of Pb 4f7/2 for the obtained product of 138.7 eV [26]. The O 1s spectrum shows a peak at 529.8 eV, approximately equal to the literature value of 530.9 eV for O 1s in PbO [2,27]. A full survey scan did not reveal any other element peaks. The results are agreeable to the data for PbO in the literature [26].

In order to prepare nanosized materials, they need to be coated with organic surfactants to prevent them from irreversible aggregation. TPP has been widely used in the synthesis of phosphine-stabilized gold or other metal nanoparticles. The phenyl groups in TPP can provide greater steric hindrance than the straight-chained alkyl groups such as tributylphosphine and trioctylphosphine, to control the size of the metal nanoparticles [28]. Lagunas et al. [29] found that Lewis bases such as trioctylphosphine oxide (TOPO) can accelerate the thermal decomposition of carbonyl species, and oleic acid plays a role of modulating the rate of decarbonylation. Oleylamine, similar to oleic acid, is chemically bonded to the surface of the metals through N atoms. TPP plus oleylamine are employed as a stabilizer to control the particle growth.

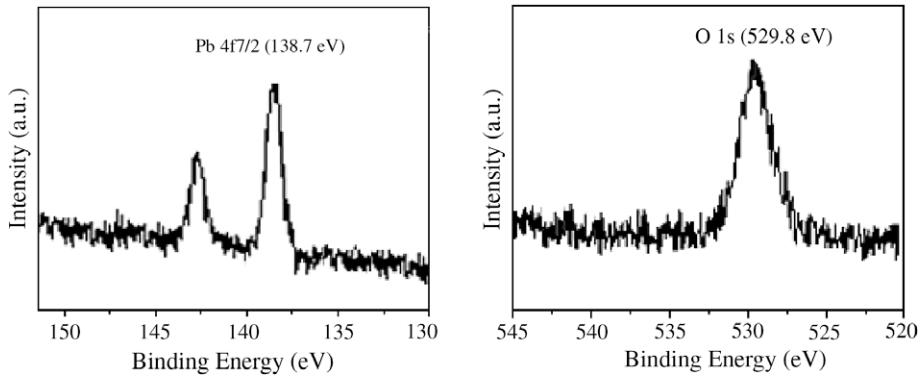

Fig. 5. XPS spectra of Pb 4f and O 1s of the PbO nanocrystals.

Table 3
Preparation of PbO nanocrystals under different conditions.

Sample	Capping agent	Temperature (°C)	Time	Product	Particles size (nm)
1		650	6 h	β-PbO	55
2	Oleylamine	150	120 min	α-PbO and [$Pb(O_4C_2)$]	45–60
3	Oleylamine + TPP	235	90 min	α-PbO and β-PbO	35
4	Oleylamine + TPP	500	120 min	β-PbO	30–45

In order to study the effect of TPP and oleylamine on the phase and particle size of PbO, different conditions were used to prepare the PbO nanoparticles (Table 3). According to previous reports, the stable phase β-PbO is obtained at high temperature [5]. Therefore, lead oxalate was calcined at 500 and 600 °C for 2 h. The XRD results showed that there is still an amount of α-PbO in the products. Although by increasing the temperature the particle size of PbO increases, a mixture of α- and β-PbO was exchanged into pure β-PbO at 650 °C. β-PbO with a particle size of about 55 nm and irregular shapes was obtained by calcining [$Pb(O_4C_2)$] at 650 °C for 6 h (sample 1). We decided to use a suitable solvent for the preparation of PbO with a small particle size at a lower temperature. So 0.5 g [$Pb(O_4C_2)$] and 5 ml oleylamine, (sample 2), were mixed and heated at 150 °C for 2 h. In this process, α-PbO and [$Pb(O_4C_2)$] with particle sizes of 45–60 nm were obtained. In order to prepare PbO nanocrystals without lead oxalate, the procedure mentioned in the experimental section including oleylamine and TPP, was carries out (sample 3). If sample 2 is compared to sample 3, it can be seen that by using of oleylamine and TPP, PbO nanocrystals (35 nm) without starting materials are obtained in a shorter time. In addition, pure β-PbO nanocrystals were obtained by calcination of sample 3 at 500 °C for 2 h (sample 4). By comparing samples 4–1, it was found that pure β-PbO with a smaller size is synthesized in the presence of TPP and oleylamine at a lower temperature and in a shorter time. After all, TPP as a Lewis base in the presence of oleylamine can accelerate the thermal decomposition of lead oxalate, so the thermal decomposition process occurs in a shorter time and nanoparticles with the smallest size are produced.

4. Conclusion

In summary, we have demonstrated the synthesis of α-PbO and β-PbO nanocrystals from lead oxalate powders via a thermal decomposition process. The controlled experimental results showed that oleylamine and triphenylphosphine (TPP) as the solvent and capping agent in the chemical process play an important role in the formation of pure products. This method is introduced as an inexpensive, fast, reproducible process for the large-scale synthesis of PbO nanocrystals.

ABSTRACT

A novel polymeric metal-free phthalocyanine (M = 2H) and its metal complexes (M = Zn, Cu, Co and Ni) were prepared by the tetramerization reaction of 3,6,9-Tris(*p*-tolylsulfonyl)-1,11-bis(3,4-dicyanophenoxy)-3,6,9-triazaundecane **5** with the appropriate materials. The electrical conductivities of the metal-free phthalocyanine and the metal complexes, measured in air, were found to be $\sim 10^{-6}$–10^{-5} S m^{-1}. The aggregation property of the zinc complex **7** was investigated with Ni^{2+}, Cu^{2+}, Co^{2+}, Pb^{2+}, Cd^{2+} and Ag^{+} cations. Thermal analysis of the polymers were done by differential scanning calorimetry (DSC) and thermal gravimetric analysis (TGA) at a heating rate of 10 °C min^{-1} under a nitrogen atmosphere. All the novel compounds were characterized by using elemental analysis, UV–Vis, FT–IR, NMR and MS spectral data and DSC, DTA/TG techniques.

1. Introduction

Phthalocyanines (Pcs) consisting of a planar macrocycle with an 18 π-electron system have been extensively studied due to their unique optical, electronic, catalytic and structural properties [1]. There has been growing interest in the use of phthalocyanines in a variety of new technological fields such as semiconductor devices [2], electrochromic display devices [3], liquid crystals [4], Langmuir–Blodgett films [5], catalysts [6], gas sensors [7–9] and as photosensitizers in photodynamic therapy of cancer [10].

Polymeric phthalocyananines are also very interesting since they belong to a class of π-conjugated semiconductor polymers, which offer a unique combination of properties. Being discovered in the 1950s, polymeric phthalocyanine remains an enigmatic material and many of its intrinsic properties are known rather insufficiently [11–13]. Polymeric phthalocyanines were mainly prepared via polycyclotetramerization reactions of bifunctional monomers such as aromatic tetracarbonitriles, various oxy-, arylenedioxy- and alkylenedioxy-bridged diphthalonitriles, and other nitriles or tetracarboxylic acid derivatives in the presence of metal salts or metals [11,12,14–16]. The electrical properties of polymeric phthalocyanines are of interest because of their conjugated structure and stability against light, heat, moisture and air. Hence polymeric phthalocyanines are suitable candidates for use as environmentally stable electrically conductive materials [14–16]. Their structural similarity to chlorophyll has also made them useful for applications in artificial solar cells [17]. The ion-binding ability of phthalocyanines containing homo- and hetero-donor atoms in peripheral substituent groups is receiving considerable attention in view of their effect on the aggregation of the molecules. After polymerization reactions, polymeric phthalocyanines will have many donor atoms and thus high metal binding ability.

Recently, several types of monomeric and polymeric phthalocyanines with various functional groups have been synthesized by our group. These phthalocycanines have peripheral substituents with several macrocyclic or podand units [15,16,18–22].

In the present work, we describe the synthesis and characterization of a novel polymeric metal-free phthalocyanine and metal complexes containing peripherally long triazadioxa derivatives which may allow the new functionalized materials to be of importance in the preparation of analytical chemicals such as new kinds of heavy metal extraction agents. We have examined the electrical conductivities of the polymers in air atmosphere. The aggregation properties of the polymer **7** and the thermal properties of all the polymers were investigated.

quinoline, sulfuric acid, hydrochloric acid, pyridine, acetone, sodium thiosulfate, acetonitrile, sodium carbonate, dioxane, *n*-hexane, lithium, glacial acetic acid, silica gel, ammonia, $MgSO_4$, $CoCl_2{\cdot}6H_2O$, $NiCl_2{\cdot}6H_2O$, $Cu(Ac)_2{\cdot}H_2O$ and $Zn(Ac)_2{\cdot}2H_2O$ were received from Merck and used as supplied. Potassium carbonate was received from Merck and used after drying in oven at 250 °C for 36 h. All organic solvents were dried and purified by the usual methods. 4-Nitrophthalonitrile was synthesized as described in the literature [23]. *N*,*N*′,*N*″-Tris(*p*-tolylsulfonyl)diethylene-triamine was synthesized according to the literature [24].

2.2. Measurements

Melting points of the compounds were determined with an electrothermal melting point apparatus and were uncorrected. ^{1}H NMR spectra were measured on a Bruker AMX 400 MHz NMR spectrometer in DMSO-d_6 with Me_4Si as an internal reference. ^{13}C NMR spectra were recorded on a Bruker AMX 100 MHz NMR spectrometer with DMSO-d_6 as the solvent and with Me_4Si as an internal reference. Transmission IR spectra of the samples were obtained on a FT–IR spectrophotometer (Shimadzu FT–IR-8201 PC) with the samples in KBr pellets. Optical spectra in the UV–Vis region were recorded with a model Shimadzu 1601 UV–Vis spectrometer using 10 mm pathlength cuvettes at room temperature. For the electrical measurements, the surfaces of the samples were covered with silver paste to form electrodes. The dielectric permittivity and AC conductivity of the samples were performed between 100 Hz and 1 MHz frequency range at room temperature by using a LCR meter (Agilent 4284A). Mass spectra were measured on a Micromass LCT Mass spectrometer. Elemental analyses were performed on a CHNS-932 LECO elemental analyzer. The metal contents of the metallophthalocyanine polymers were determined with a Unicam 929 AA spectrophotometer. Differential thermal analysis was performed on a TGA Q600 TA instrument under nitrogen (100 mL/min) atmosphere with a heating rate of 10 °C/min in the temperature range 30–700 °C. Differential scanning calorimetry (DSC) was performed on a Perkin Elmer Jade DSC under nitrogen atmosphere with a heating rate of 10 °C/min over the temperature range 50–700 °C.

2.3. Preparation of 3,6,9-Tris(p-tolylsulfonyl)-3,6,9-triazaundecane-1,11-diol (**3**)

A three-necked, round bottomed flask equipped with a mechanical stirrer and reflux condenser was charged with compound **1** (4.35 g, 7.5 mmol), ethylene carbonate (**2**) (1.5 g, 17.05 mmol) and finely powdered potassium hydroxide (0.016 g, 0.29 mmol). The stirred mixture was heated at 165 °C for 5 h under an inert nitrogen atmosphere. The reaction mixture was then allowed to cool to 90 °C, and 10 mL of ethanol was added through the condenser as rapidly as possible. 0.15 g of activated carbon was added to the solution and refluxed for 30 min. The temperature was then increased to 120 °C and the suspension was stirred for 30 min longer, and filtered through Celite. Water (10 mL) was added dropwise to the stirred solution, but no precipitate was observed. The reaction mixture was extracted with chloroform (5 × 35 mL). After drying on $MgSO_4$, the solvent was evaporated. The product **3** was a viscous brown liquid. After dissolving in toluene, the solution was kept in a refrigerator and the precipated colorless solid product that subsequently formed was filtered. The final product **3** was dried over P_2O_5 *in vacuo* at 50 °C.

Yield: 4.41 g (89%). M.p.: 104–105 °C. R_f: 0.43 (Chloroform:petroleum ether 7:3). *Anal.* Calc. $C_{29}H_{39}N_3O_8S_3$ (653.82): C, 53.27; H, 6.01; N, 6.43; S, 14.71. Found: C, 53.49; H, 6.27; N, 6.17; S, 14.94%. FT–IR (KBr, cm^{-1}): 3390 (O–H), 3068–3030 (Aromatic =CH), 2944–2882 (–CH_2–), 1599 (C=C), 1494, 1456, 1332 (SO_2), 1261, 1160 (SO_2), 1089–1001 (CH_2O–), 909, 812, 717, 645, 552. ^{1}H NMR (DMSO-d_6), δ (ppm): 7.74–7.67 (d, 6H, Ar*H*), 7.45–7.36 (d, 6H, Ar*H*), 4.87 (br. s, 2H, OH), 3.60–3.18 (m, 16H, NCH_2, OCH_2) 2.42 (s, 3H, ArCH_3), 2.40 (s, 6H, ArCH_3). ^{13}C NMR (DMSO-d_6), δ (ppm): 143.9, 143.6, 135.7, 135.4, 129.8, 127.4, 126.9 (Ar*C*), 59.9 (*C*H_2OH), 49.8, 49.3, 49.1 (*C*H_2N), 21.5 (*C*H_3), 21.3 (*C*H_3). MS (ES$^+$), *m/z*: 676.2 [M+Na]$^+$.

2.4. Preparation of 3,6,9-Tris(p-tolylsulfonyl)-1,11-bis(3,4-dicyanophenoxy)-3,6,9-triazaundecane (**5**)

3,6,9-Tris(*p*-tolylsulfonyl)-3,6,9-triazaundecane-1,11-diol (**3**) (4.41 g, 6.75 mmol) and 4-nitrophthalonitrile (**4**) (2.36 g, 13.50 mmol) were dissolved in 10 mL of dry DMF in a 100 mL three-necked flask and the mixture was stirred at room temperature under an inert atmosphere and degassed three times. Then temperature was increased to 50 °C. Finely powdered K_2CO_3 (2.83 g, 20.25 mmol) was added to the solution in eight equal potions at 30 min intervals. The reaction mixture was stirred at 50 °C for 6 days. The reaction was monitored by a thin layer chromatography ($CHCl_3$:MeOH, 7:3). At the end of this period, the mixture was cooled and poured into ice (100 g), and mixed for 4 more hours. The precipitate that formed was filtered and washed with water and EtOH. After recrystallization from MeOH, the obtained product **5** was dried over P_2O_5 in a vacuum oven at 50 °C to yield a light yellow powder.

Yield: 5.38 g (88%). M.p.: 138–139 °C. *Anal.* Calc. $C_{45}H_{43}N_7O_8S_3$ (906.06): C, 59.65; H, 4.78; N, 10.82; S, 10.62. Found: C, 59.42; H, 5.02; N, 10.60; S, 10.97%. MS (ES$^+$), *m/z*: 907.2 [M+H]$^+$, 751.1 [M-Ts]$^+$.

2.5. Preparation of polymeric metal-free phthalocyanine (**6**)

A mixture of **5** (0.906 g, 1.0 mmol), *n*-pentanol (5.0 mL) and 1,8-diazabicyclo[5,4,0] undec-7-ene (DBU) (0.15 mL, 0.16 g, 1.0 mmol) was placed in a standard Schlenk tube under nitrogen atmosphere and degassed two times. Then temperature was increased to 160 °C. The reaction mixture was stirred at 160 °C for 18 h. After the reaction mixture was cooled to room temperature, ethyl alcohol (10 mL) was added dropwise and mixed for half an hour. The dark green precipitate was filtered and washed with MeOH and diethyl ether. The dark green product **6** was dried at 50 °C under vacuum over P_2O_5.

Yield: 0.78 g (86%). M.p.: >300 °C. *Anal.* Calc. $(C_{180}H_{174}N_{28}O_{32}S_{12})_n$ (3626.25) (for (for nitrile end groups): C, 59.62; H, 4.84; N, 10.82; S, 10.61. Found: C, 53.49; H, 6.27; N, 6.17; S, 14.94%. FT–IR (KBr, cm^{-1}): 3294 (N–H), 3063 (Aromatic =CH), 2928–2866 (aliphatic CH_2), 2225 (C≡N), 1629 (C=N), 1604 (aromatic –C=C–), 1549, 1460, 1337 (SO_2), 1227 (Ar–OCH_2), 1153 (SO_2), 1087, 1035 (N–H), 810, 708, 648, 538.

2.6. Preparation of polymeric zinc and copper complexes (**7**, **8**)

A mixture of compound **5** (0.906 g, 1.0 mmol), zinc acetate dihydrate (0.114 g, 0.5 mmol) or cupric acetate monohydrate (0.100 g, 0.50 mmol) and amyl alcohol (5 mL) was put in a standard

Schlenk tube and the temperature was increased to 90 °C. DBU (0.15 mL, 1.0 mmol) was added dropwise to the suspension at the same temperature. Then the temperature was increased to 160 °C and the reaction was stirred at 160 °C for 18 h under a nitrogen atmosphere. After the reaction mixture was cooled to room temperature, ethanol (10 mL) was added and mixed for 30 min. The crude products were collected by filtration and washed with methanol, DMF, water and acetone. The final green **7** and dark green **8** products were dried under vacuum over P_2O_5 at 50 °C.

*2.6.1. Compound **7***

Yield: 0.98 g (96.1%). M.p.: >300 °C. *Anal.* Calc. $(C_{180}H_{176}N_{24}O_{40}S_{12}Zn)_n$ (3765.61): C, 57.41; H, 4.71; N, 8.93; S, 10.22; Zn, 1.74. C=O), 1645 (–C=N–), 1601 (Aromatic –C=C–), 1487, 1456, 1395, 1334 (SO_2), 1222 (Ar-OCH_2), 1155 (SO_2), 1085–1043, 940, 810, 715, 650, 543.

*2.6.2. Compound **8***

Yield: 0.92 g (91.5%). M.p.: >300 °C. *Anal.* Calc. $(C_{180}H_{176}N_{24}O_{40}S_{12}Cu)_n$ (3763.78): C, 57.44; H, 4.71; N, 8.93; S, 10.22; Cu, 1.69. Found: C, 57.72; H, 4.53, N, 9.27; S, 10.49; Cu, 1.46%. FT–IR (KBr, cm^{-1}): 3386 (imide N–H), 3064 (Aromatic =CH), 2951–2824 (CH_2), 1772 (sym. C=O), 1714 (asym. C=O), 1645 (–C=N–), 1607 (Aromatic –C=C–), 1510, 1454, 1400, 1340 (SO_2), 1229 (Ar-OCH_2), 1157 (SO_2), 1089–1018, 954, 814, 718, 646, 548.

*2.7. Preparation of polymeric cobalt and nickel complexes (**9**, **10**)*

A mixture of compound **5** (0.906 g, 1 mmol), dry quinoline (3 mL) and $CoCl_2{\cdot}6H_2O$ (0.120 g, 0.5 mmol) or $NiCl_2{\cdot}6H_2O$ (0.122 g, 0.5 mmol) was charged in a standard Schlenk tube and degassed several times with nitrogen. The reaction mixture was treated at 210–220 °C for 18 h under a nitrogen inert atmosphere. After 18 h of refluxing, the reaction mixture was cooled to room temperature and then 10 mL of ethanol was added to the mixture slowly and stirred for 30 min. The obtained green **9** and dark green **10** products were filtered off. The crude products were washed with water, MeOH and diethyl ether. The final products (**9** and **10**) were dried under vacuum over P_2O_5 at 50 °C.

*2.7.1. Compound **9***

Yield: 1.0 g (97.4%). M.p.: >300 °C. *Anal.* Calc. $(C_{180}H_{176}N_{24}O_{40}S_{12}Co)_n$ (3759.17): C, 57.51; H, 4.72; N, 8.94; S, 10.23; Co, 1.57. *2.7.2. Compound **10***

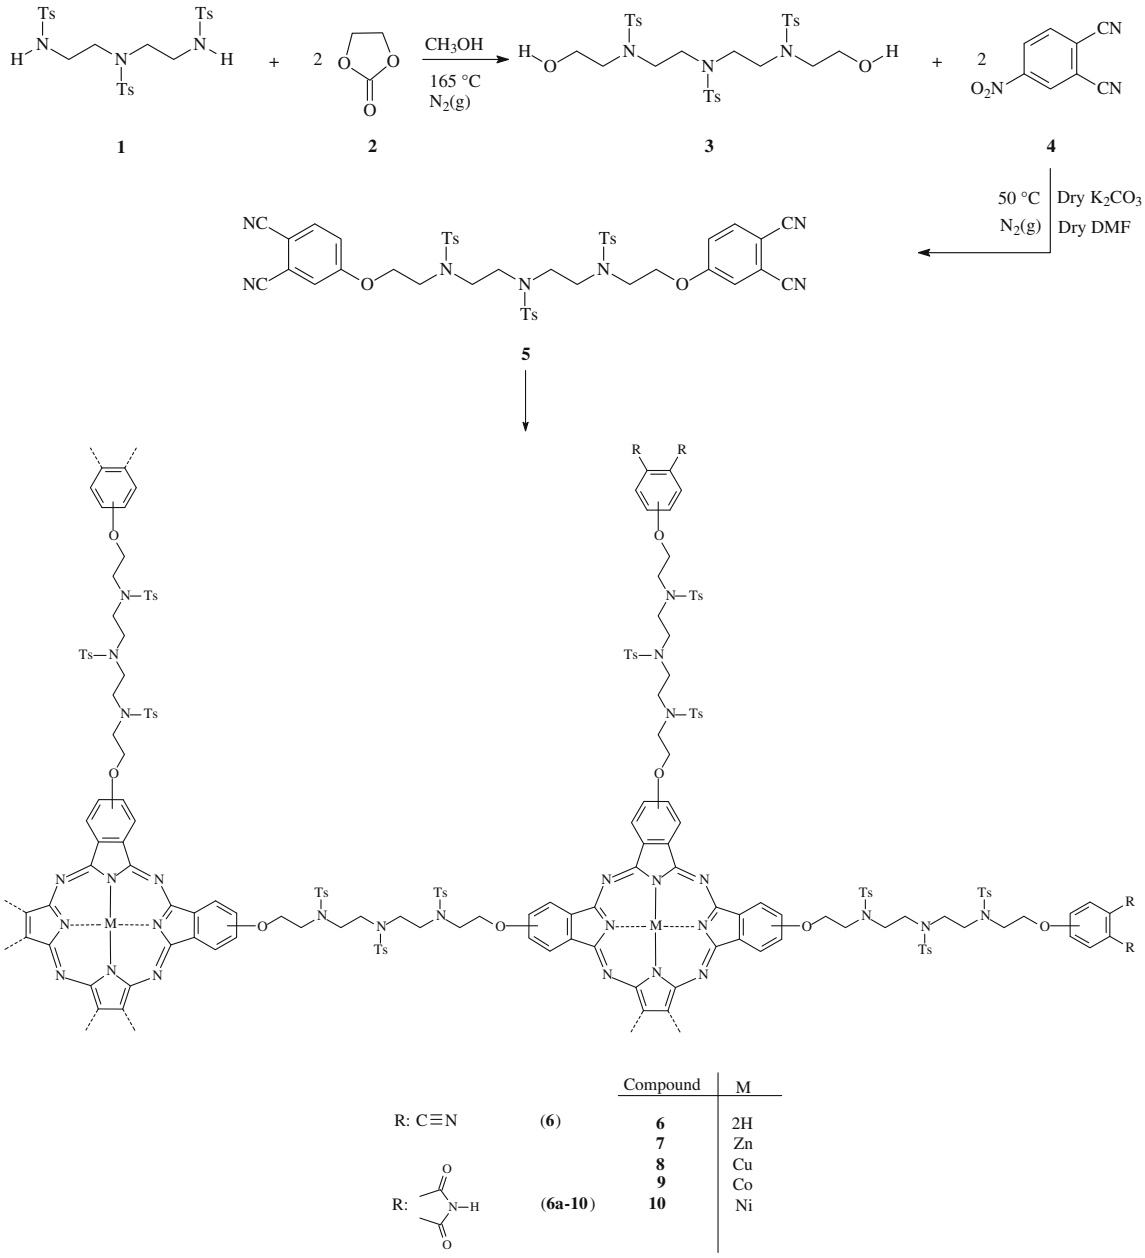
Yield: 1.01 g (98.2%). M.p.: >300 °C. *Anal.* Calc. $(C_{180}H_{176}N_{24}O_{40}S_{12}Ni)_n$ (3758.92): C, 57.52; H, 4.72; N, 8.94; S, 10.23; Ni, 1.56. Found: C, 57.81; H, 4.97; N, 9.19; S, 9.87; Ni, 1.83%. FT–IR (KBr, cm^{-1}): 3437 (imide N–H), 3053 (Aromatic =CH), 2926–2731 (CH_2), 1768 (sym. C=O), 1721 (asym. C=O), 1654 (–C=N–), 1604 (Aromatic –C=C–), 1533, 1489, 1460, 1341 (SO_2), 1234 ($ArOCH_2$), 1155 (SO_2), 1089–1020, 991, 810, 723, 651, 546.

*2.8. The conversion of cyano end groups of the polymeric metal-free phthalocyanine into imido groups (**6a**)*

A sample of compound **6** (150 mg) was dissolved in a minimum volume of H_2SO_4 (96 wt.-%) at room temperature. After 3–4 h of stirring, the reaction mixture was filtered. The filtered part was poured into excess amount of ice-water mixture. The dark green crude product was washed with distilled water until the residue washing water was neutral. Then the final product **6a** was washed with ethanol, diethyl ether and dried under vacuum over P_2O_5 at 50 °C.

Yield: 118 mg (78.7%). M.p.: >300 °C. *Anal.* Calc. $(C_{180}H_{178}N_{24}O_{40}S_{12})_n$ (3702.25) (for imide end groups): C, 58.40; H, 4.85; N, 9.08; S, 10.39. Found: C, 58.17; H, 4.59; N, 9.43; S, 10.68%. FT–IR (KBr, cm^{-1}): 3380 (imide N–H), 3275 (N–H), 3056 (Aromatic =CH), 2938–2740 (CH_2), 1774 (sym. C=O), 1720 (asym. C=O), 1627 (–C=N–), 1600 (Aromatic –C=C–), 1565, 1458, 1345 (SO_2), 1230 ($ArOCH_2$), 1163 (SO_2), 1086, 1035 (N–H), 964, 815, 730, 648, 540.

2.9. Metal analysis of the polymeric metal complexes



A sample of the polymeric metal complexes (**7**–**10**) (10 mg) was added into concentrated sulfuric acid (2.5 mL) and concentrated nitric acid (3.5 mL). The mixture was heated for 2 h at 160 °C in an oil-bath. The solution was firstly digested in conc. HCl acid solution and then diluted with deionize water (500 mL). The determination of metal ions was conducted by atomic absorption measurements.

3. Results and discussion

The synthesis of the 3,6,9-Tris(*p*-tolylsulfonyl)-3,6,9-triazaundecane-1,11-diol (**3**) was performed by starting with *N*,*N*′,*N*″-Tris(*p*-tolylsulfonyl)diethylenetriamine **1** (Scheme 1). Compound **1** was synthesized as described in the literature [24]. Elemental analysis and mass spectral data of **3** were satisfactory: 676.2 $[M+Na]^+$. Compound **3** was characterized by NMR and IR spectroscopy techniques. In the ^1H NMR (DMSO-d_6) spectrum of **3**, the NH group of **1** had disappeared, as expected, and a new signal at $\delta = 4.87$ (br. s, 2H, OH) appeared. The proton-decoupled ^{13}C NMR spectrum of **3** indicates the presence of the corresponding carbon atoms at $\delta = 59.9$ (CH_2OH) and 49.8 (CH_2N). The IR spectrum of **3** was easily verified with the disappearance of N–H and the presence of O–H stretching vibrations at 3390 cm^{-1}. The difference between the IR spectra of **3** and **1** is clear from the absence of characteristic vibrations such as N–H.

3,6,9-Tris(*p*-tolylsulfonyl)-1,11-bis(3,4-dicyanophenoxy)-3,6,9-triazaundecane (**5**) was prepared by the reaction of 4-nitrophthalonitrile and **3** in the presence of K_2CO_3 in dry DMF. Final purification of the bisphthalonitrile derivative by recrystallization afforded **5**, for which elemental analysis and ES^+ mass spectral data were satisfactory *m/z*: 907.2 $[M+H]^+$, 751.1 $[M-Ts]^+$. In the ^1H and ^{13}C NMR spectra of **5**, the OH groups of compound **3** disappeared and nitrile carbon atoms appeared as expected. The disappearance of O–H and the presence of the C≡N functional group at 2232 cm^{-1} in the IR spectrum of compound **5** confirm the formation of the desired compound **5**.

The metal-free phthalocyanine polymer **6** was synthesized by heating a mixture of **5**, DBU and amyl alcohol in a Schlenk tube. Model compound **6a**, containing phthalocyanine units and suitable imido end groups, was prepared to use its characteristic data for analysis of the polymerization degree. The cyano end groups of the metal-free phthalocyanine were converted into imido end groups by treating **6** with conc. H_2SO_4, and **6a** was obtained. The IR spectrum of polymer **6** is slightly broadened and reduced in intensity, which can be attributed to the difficulty in grinding the sample to a small particle size and the polymeric structure. The peaks at 3294 and 1035 cm^{-1} are the characteristic metal-free phthalocyanine N–H stretching and pyrrole ring vibration bands. A weak –C=N– absorption at 1629 cm^{-1} was detected. Elemental

Scheme 1. Synthesis of bisphthalonitrile **5** and polymers **6**–**10**.

[a] Intensity ratio of absorption B bands at λ = 219–334 nm and Q bands at λ = 676–888 nm ($C = 1.0 \times 10^{-4}$ g/L in H_2SO_4 and 1.0×10^{-4} g/L in pyridine).

analysis was satisfactory. In the IR spectra for **6a**, the disappearance of the peak at 2225 cm^{-1} due to the cyano groups of **6** and the appearance of new peaks at ~1774–1720 cm^{-1} due to imido groups supports the conversion of the cyano groups into imido groups.

The transition metal complexes (**7–10**) were prepared from the bisphthalonitrile compound **5** and the corresponding metal salt in the appropriate solvent (Scheme 1). The IR spectra of the metal complex polymers (**7–10**) are very similar, except for the metal-free phthalocyanine polymer **6**. The metal-free phthalocyanine polymer showed an N–H stretching band at 3294 and 1035 cm^{-1} due to the inner core [25]. These bands disappear in the spectra of the metal complex polymers. These bands are especially beneficial for characterization of metal-free phthalocyanine polymers, as there is little frequency dependence on the ring substitution and they are not overlapped by strong bisphthalonitrile monomer absorptions [14–16]. The end groups of the metal-free phthalocyanine polymer were cyano groups (2225 cm^{-1}), while the end groups of the metal complex polymers were imido groups (~1772–1714 cm^{-1}). The existence of imido groups in the case of the metal complex polymers was attributed to the presence of moisture during the work-up and the hydrated metal salts. There was little shift to longer wavelength numbers in most of the IR bands of the metal complexes with respect to the metal-free analogues [14–16,26]. The spectra of the complexes are quite complex and reveal many metal-independent ligand absorptions, and metal-N vibrations were expected to appear at 400–100 cm^{-1}, but they were not detected using KBr pellets [27]. The elemental analyses of the metal free (**6**, **6a**) and metal complex polymers (**7–10**) were satisfactory.

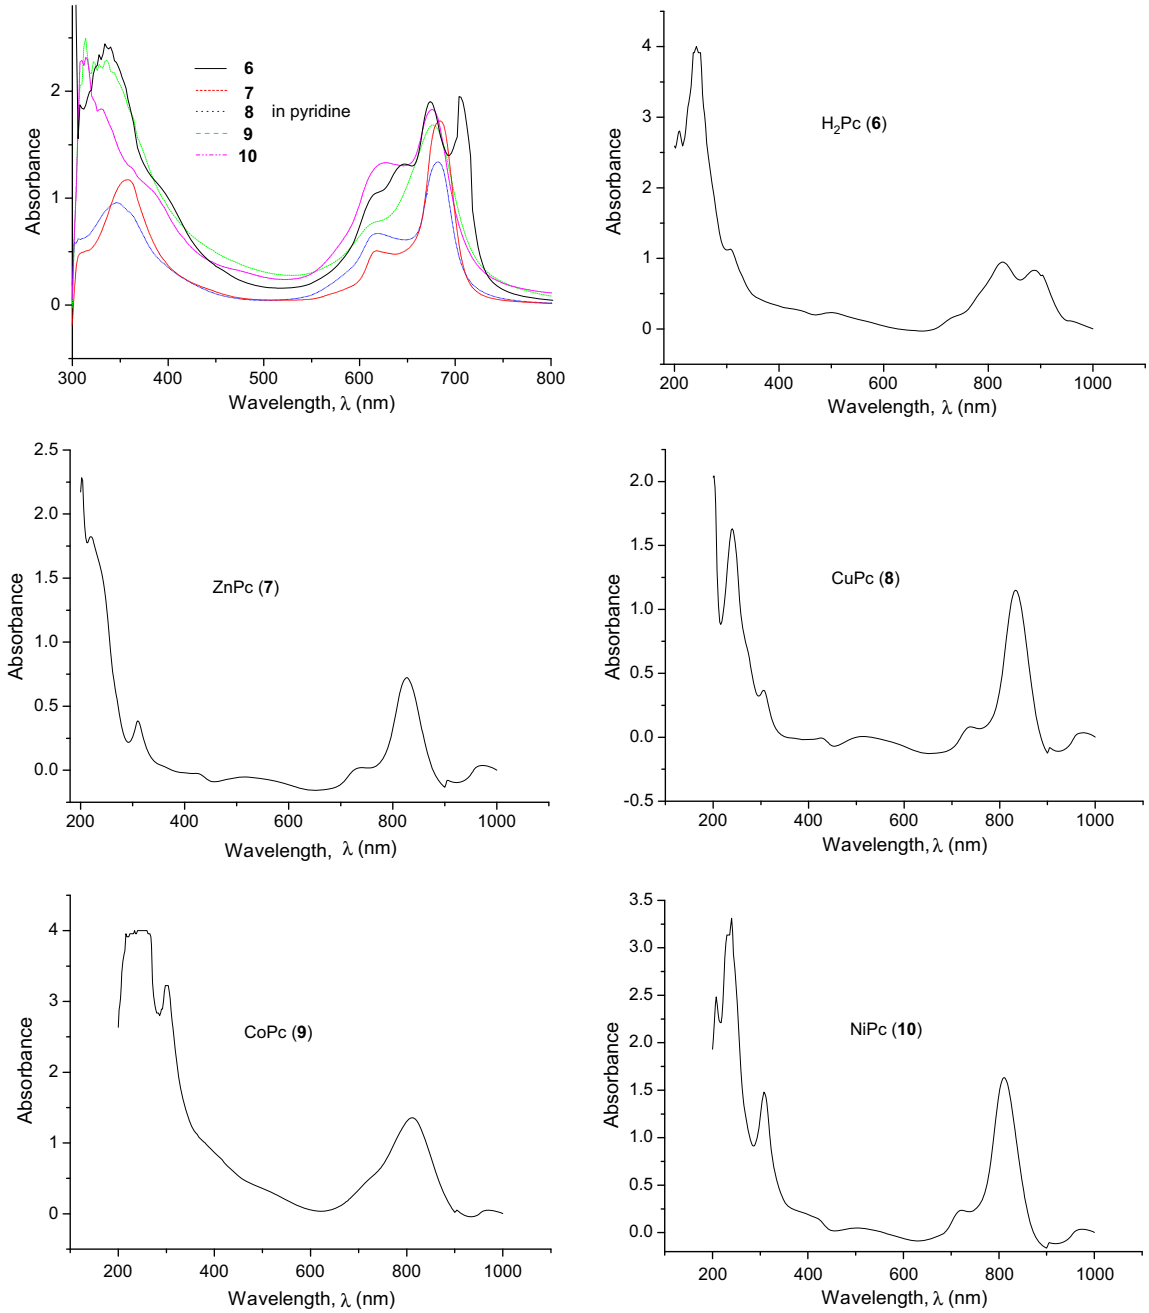

Fig. 1. UV–Vis spectra of polymers (**6–10**) in pyridine ($C = 1.0 \times 10^{-4}$ g/L) and in H_2SO_4 ($C = 1 \times 10^{-4}$ g/L).

It is very difficult to determine the molecular weight of polymeric phthalocyanines because of their poor solubility in common organic solvents. One possible procedure to determine the degree of polymerization is IR spectroscopy, by comparison of the intensity of the end cyano groups to other ring vibrations. This method has been applied to only a few cases [28,29]. We determined the degree of polymerization after converting the cyano end groups of the metal-free phthalocyanine polymer into imido end groups, due to the relatively good intensity of C=O imide groups to nitrile groups. After this, the ratios of the absorption intensities of (Ar–O–C) (etheric groups) of the polymers (~1230 cm^{-1}) to asym. C=O groups of the imides (~1714 cm^{-1}) were calculated [compound/$\log_{10} I_{1230}/I_{1714}$: **6a**/0.52, **7**/1.84, **8**/1.23, **9**/1.57, **10**/1.14]. The polymerization degrees follow the order: **7** > **9** > **8** > **10** > **6a**. On the other hand, the IR spectrum of **6** shows a low degree of polymerization due to the high intensity of the nitrile groups.

The metal-free phthalocyanine **6** and the metal complexes (**7–10**) gave the typical UV–Vis absorption spectra of phthalocyanines (Table 1). As can be seen in Table 1, there is a shoulder at the slightly higher energy side for polymeric metal-free phthalocyanine and the metal complexes. The presence of shoulders in the UV–Vis spectra of the polymers corresponds to aggregated or non-aggregated species in conc. sulfuric acid and pyridine. The metal-free phthalocyanine polymer (**6**) decomposes slowly by hydrolysis in conc. H_2SO_4, which is demonstrated by a decrease of the absorption coefficient at longer wavelengths and also the color of the solution turns from green to brown with time. However the metal complex polymers (**7–10**) were more stable in conc. sulfuric acid than the metal-free polymer and there was no color change in the case of the metal complexes even after a day. When going from organic solvents to concentrated H_2SO_4, the long-wave absorption band underwent a significant bathochromic shift, which was due to weak protonation of the phthalocyanine ring at the *meso* nitrogen atoms. The intensity of these absorptions also decreased. The UV–Vis spectrum of **6** was obtained in pyridine and conc. H_2SO_4. The electronic absorption spectra of (**6–10**) in pyridine and H_2SO_4 at room temperature are shown in Fig. 1. There was a single Q band for **7–10** while there was a split Q-band, as expected, and two strong bands in the visible region for **6** [30]. The split Q-band, which is characteristic for metal-free phthalocyanines, was observed at λ_{max} 705 and 674 nm, with shoulders at 647 and 617 nm, for (**6**) indicating the monomeric species; monomeric species with D_{2h} symmetry show two intense absorptions at around 700 nm [30,31]. On the other hand, such split-Q band absorptions are due to a $\pi\pi^*$ transition of this fully conjugated 18π electron system [32]. In the case of a H_2SO_4 solution of **6**, the primary band in the visible region was broadened and shifted to longer wavelength (182 nm). In all cases the intensities in the UV (Soret band transition) and vis (Q-band transition) spectra were $I_{UV}/I_{Vis} \leqslant 1$ (Table 1). This result can be attributed to the absence of poly(isoindolinine) co-units in all of the polymeric metal complexes (**7–10**).

UV–Vis titrations were performed with several heavy metal cations (Ni^{2+}, Cu^{2+}, Co^{2+}, Pb^{2+}, Cd^{2+}, Zn^{2+} and Ag^{+}) to investigate the metal-binding capabilities of complex **7** with triaza-dioxa long peripheral substituents. Firstly, we clarified whether methanol has any effect or not on the visible spectrum of **7**. For this purpose, different amounts of methanol were added to a solution of **7** in pyridine. There was only a little change in the intensities of the Q-bands in the visible absorption spectra of **7** with increasing the amounts of methanol, due to the increasing polarity. Then different concentrations of metal salt (e.g. $AgNO_3$, $NiCl_2{\cdot}6H_2O$, $Co(NO_3)_2{\cdot}6H_2O$, $Pb(NO_3)_2$, $Zn(CH_3COO)_2{\cdot}2H_2O$, $Cd(NO_3)_2{\cdot}4H_2O$ and $CuCl_2{\cdot}2H_2O$) solutions in methanol (1.0×10^{-4} M) were added to the solution of the zinc complex **7** in pyridine (1.0×10^{-4} g/L). When we added Ni^{2+}, Cu^{2+} and Co^{2+} solutions to the zinc complex solution, the Q band of **7** broadened and shifted to the low-wavelength region. The addition of Ni^{2+}, Cu^{2+} and Co^{2+} solutions caused a dramatic change due to aggregation in the visible spectrum of **7** (Fig. 2). The increasing interactions between the polymer chains due to the intermolecular complexation through triazadioxa peripheral units with Ni^{2+}, Cu^{2+}, Co^{2+} ions forms sandwich type complexes and causes the new absorption bands. The new bands can be attributed to the presence of dimeric and oligomeric phthalocyanine species. Further addition of Ni^{2+}, Cu^{2+} and Co^{2+} solutions caused no observable effect. On the other hand, when solutions of Pb^{2+}, Cd^{2+}, Zn^{2+} and Ag^{+} were added, the intensity of the bands at 684 and 618 nm gradually decreased without any shift and no optical change was observed (Fig. 3). The decrease in the intensity

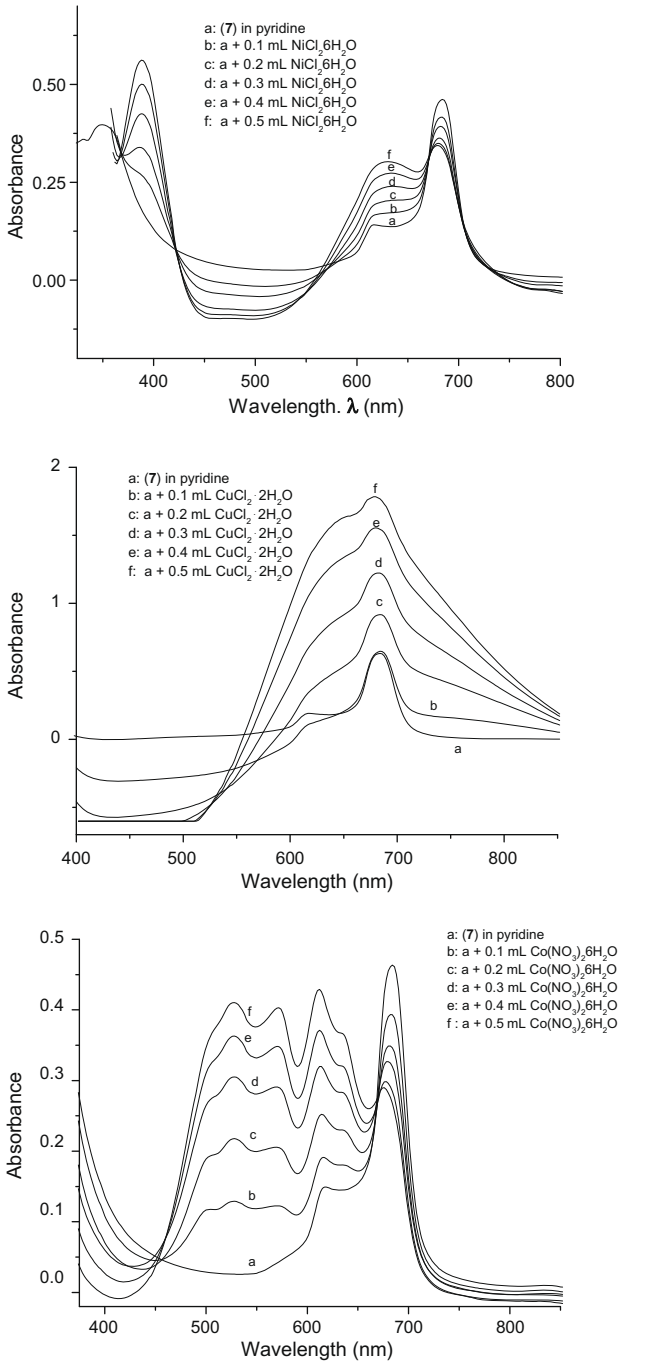

Fig. 2. Changes in the visible spectra of **7** in pyridine ($C = 1.0 \times 10^{-4}$ g/L) after the addition of $NiCl_2{\cdot}6H_2O$, $CuCl_2{\cdot}2H_2O$ and $Co(NO_3)_2{\cdot}6H_2O$ solutions in methanol ($C = 1.0 \times 10^{-4}$ M).

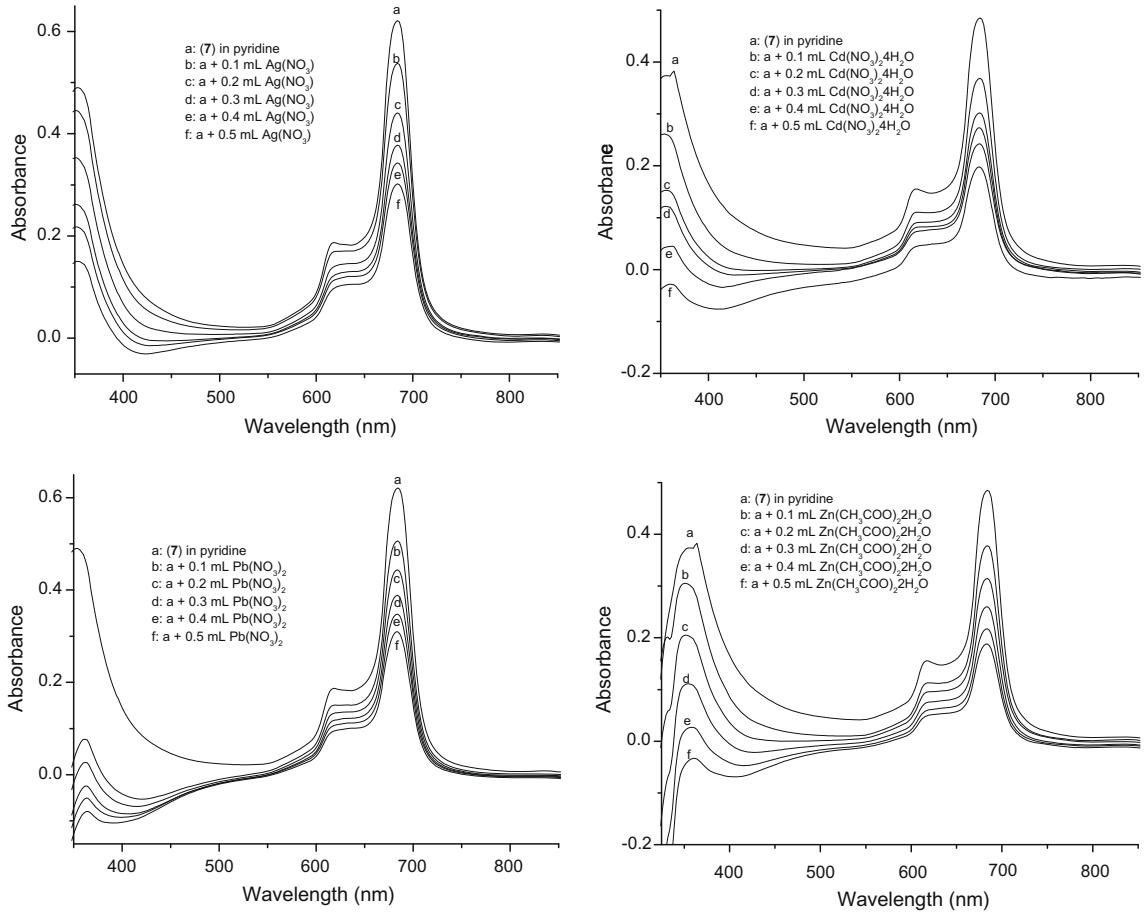

Fig. 3. Changes in the visible spectra of **7** in pyridine ($C = 1.0 \times 10^{-4}$ g/L) after the addition of $AgNO_3$, $Pb(NO_3)_2$, $Cd(NO_3)_2{\cdot}4H_2O$ and $Zn(CH_3COO)_2$ solutions in methanol ($C = 1.0 \times 10^{-4}$ M).

of the bands can be attributed to the dilution effect and the very weak or non-coordination of the N and O atoms to Pb^{2+}, Cd^{2+}, Zn^{2+} and Ag^{+} ions, thus leaving the $Pb(NO_3)_2$, $Cd(NO_3)_2{\cdot}4H_2O$, $Zn(CH_3COO)_2{\cdot}2H_2O$ and $AgNO_3$ units only loosely coordinated via oxygen and nitrogen donors.

The powder samples of the polymeric metal-free phthalocyanine and metal complexes were pressed in the form of pellets of 10 mm diameter and thickness ranging from 1 to 3 mm for AC conductivity measurements. The surfaces of the polymers were covered with silver paste to form electrodes. Then, the capacitance and the dielectric loss factor of each sample were measured between 10 kHz and 1 MHz frequency range at room temperature

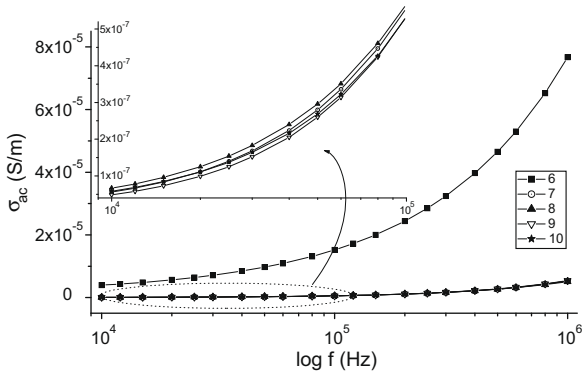

Fig. 4. The frequency versus AC conductivity of polymers (**6**–**10**) at room temperature.

Table 2
Thermal properties of the polymers.

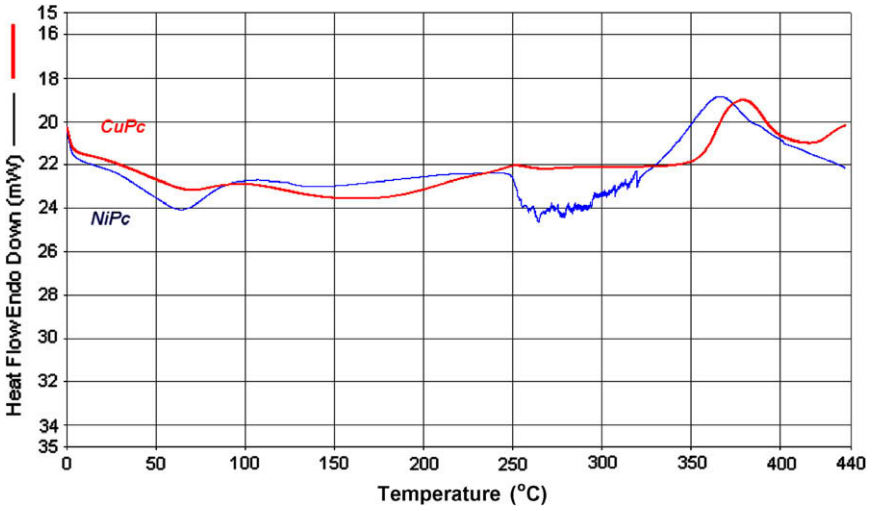

Fig. 6. DSC thermograms of CuPc (**8**) and NiPc (**10**).

by using a LCR meter (Agilent 4284A). From the measured values of the dielectric permittivity and the dielectric loss factor, the AC conductivity was calculated. The conductivity values correspond to those of semi-conductive materials encountered in most of the substituted phthalocyanine derivatives [33]. The dielectric permittivity of the samples was calculated using the relation;

$$C = \frac{\varepsilon_0 \varepsilon_r A}{d}$$

where C is the capacitance of the sample, ε_0 is the permittivity of air, A is the surface area of the sample, d is the thickness of the sample and ε_r is the dielectric permittivity of the sample. The frequency versus AC conductivity graph was plotted at room temperature and is depicted in Fig. 4. From the figure, it can be seen that the value of the AC conductivity does not show a clear variation at lower frequencies at room temperature. That is, there is no appreciable variation in AC conductivity of the polymers at low frequencies (<10^5 Hz), above 10^5 Hz, there is a rapid increase with frequency. This is in accordance with the theory of AC conduction in amorphous materials, which predicts that for polaron transport or other hopping modes, the AC conductivity will increase monotonically with the increased frequency of the applied field. The AC conductivity, dielectric permittivity, and dielectric loss can be related by the following equation;

$$\sigma_{AC} = 2\pi f \varepsilon_0 \varepsilon_r \tan\delta$$

where ε_0 is the permittivity of air, ε_r is the dielectric permittivity of the sample, f is the frequency and tan δ is the dielectric loss [34]. On the other hand, the AC conductivity of the metal-free polymer was higher than those of the metal complexes. This can be due to the oxygen-susceptible NH group of the metal-free polymer **6**. The NH groups should be partially oxidized in air. In the metal complexes, the NH groups were no longer sensitive to O_2 after complexation with transition metal ions [17].

Thermal properties of the metal-free and metal complex polymers were investigated by DSC and DTA/TG. The phthalocyanine polymers are resistant to thermal oxidation [35]. The DTA and DSC curves exhibit exothermic changes for all polymers in the region investigated [36], the curves do not show melting points. No obvious correlation between the transition metal ion in the phthalocyanine ring and the corresponding main decomposition temperatures could be established, while the initial decomposition temperature decreased in the order: **6** > **8** > **10** > **7** > **9** (Table 2). The higher stability of **6** as compared with the polymeric metal complexes (**7**–**10**) could obviously be traced to the interaction of the polar nitrile groups in the solids. DSC and DTA/TG thermograms of all the polymers can be seen in Figs. 5 and 6. The glass transitions were found as 42, 51, 50, 56 and 45 °C for **6**, **7**, **8**, **9** and **10**, respectively. All samples showed a weight loss below 200 °C, probably due to volatiles evaporation (N_2, O_2, CO_2 and H_2O) or low temperature degradation of unstable chemical fragments in the samples. At higher temperatures, between 350 and 400 °C, the main degradation step is visible, with a weight lost of about 43–54% for all samples. All the adsorbed gases and decomposed groups in the samples were identified by MS as: 17 (NH_3), 18 (H_2O), 28 (N_2), 32 (O_2) and 44 (CO_2) below 200 °C, 27 (HCN), 44 (CO_2) and 91 (toluene) above 400 °C.

4. Conclusion

We have presented the synthesis and characterization of the new bisphthalonitrile **5** and polymeric metal-free (**6**) phthalocyanine and metal complexes (**7**–**10**) with diazatrioxa peripheral units. The polymers (**6**–**10**) were prepared using a bisphthalonitrile monomer and the appropriate precursors. No obvious correlation between the transition metal ion in the phthalocyanine ring and the corresponding main decomposition temperatures could be established. The electrical conductivities of the polymeric materials measured in air at room temperature and were found to be 10^{-6}–10^{-5} S m^{-1} in air. The polymeric zinc complex **7** had a clear aggregation tendency with the addition of Ni^{2+}, Cu^{2+} and Co^{2+} solutions. On the other hand, there was no shift or optical change with the addition of Pb^{2+}, Cd^{2+}, Zn^{2+} and Ag^{+} solutions.

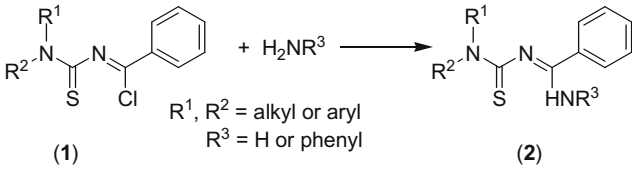
ABSTRACT

N-[(Dialkylamino)(thiocarbonyl)]benzimidoyl chlorides react with α-amino acid esters under formation of the corresponding *N*-[(dialkylamino)(thiocarbonyl)]benzamidines. Derivatives with glycine ethylester, HL(GlyOEt), cysteine methylester and S-benzyl protected cysteine ethylester, HL(S-Bzl-CysOEt), were prepared and isolated in crystalline form. The reaction with cysteine methylester yields the corresponding sulfur-bridged dimeric compound $\{HL(CysOMe)\}_2$.



Starting from $[ReOCl_3(PPh_3)_2]$, complexes of these new ligands could be obtained in two different coordination modes: monodentate coordination by only the thiourea sulfur atom or S,N,O tridentate coordination after ester hydrolysis.

1. Introduction

Besides many applications in catalysis, the coordination chemistry of rhenium is of interest with respect to potential applications as radiopharmaceuticals. The β^--emitting rhenium nuclides ^{186}Re and ^{188}Re are under investigation for use in radioimmunotherapy [1]. Furthermore, the coordination chemistry of rhenium is in many cases comparable to its lighter homologue technetium, which is the workhorse in diagnostic nuclear medicine [2]. Nevertheless, the labeling of biomolecules such as peptides or proteins with radioactive metal isotopes still remains a challenge in the development of new radiopharmaceuticals. For this purpose, ligand systems, which form stable complexes with the metal ions and can readily be used for the formation of bioconjugates are of high interest.

Since the first report about *N*-[(dialkylamino)(thiocarbonyl)]benzimidoyl chlorides (**1**) in 1982 [3,4], the coordination chemistry of many bidentate *N*-[(dialkylamino)(thiocarbonyl)]-benzamidines (**2**), which can readily be obtained by reactions of the chlorides with ammonia or aniline, with various metals like Ni, Pt, Cu, Ag, Au, Tc or Re has been extensively studied [5].

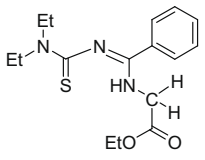
(**1**) (**2**)

Recently, we extended the chemistry of *N*-[(dialkylamino)(thiocarbonyl)]benzamidines to tridentate ligands and studied the coordination behavior of this novel ligand family with rhenium and technetium [6].

Here, we describe the synthesis and structural characterization of *N*-[(diethylamino)(thiocarbonyl)]benzamidines with glycine ester, L-cysteine ester, and some derivatives as well as their reactions with $[ReOCl_3(PPh_3)_2]$.

2. Results and discussion

2.1. Preparation of the ligands



The amino acid derivatives of **2** were prepared following the general route of Hartmann et al. [4] starting from **1** with $R^1 = R^2$ = ethyl. *N*-[(diethylamino)(thiocarbonyl)]benzimidoyl chloride was exposed to glycine ethylester or L-cysteine methylester in absolutely dry acetone at 0 °C in the presence of triethyl amine. After filtration from a colorless precipitate, which is $(NHEt_3)Cl$, the glycine derivative HL(GlyOEt) was isolated in good yields, while oxidation was observed in the case of cysteine and only the disulfide $\{HL(CysOMe)\}_2$ could be isolated. Similar reactions have been undertaken before with the amino acids leucine, valine and glycine, but the glycine derivative could not be isolated as a pure solid, and the reaction products of metal salts with the leucine and valine derivatives have not been structurally characterized [7].

The crude HL(GlyOEt) was recrystallized from $CHCl_3$, which gave slightly yellow, almost colorless crystals. The infrared spectrum of the product exhibits a strong band at 1750 cm^{-1} due to the carbonyl function of the amino acid ester, and a strong band at 3245 cm^{-1} due to the vibration of the NH group. Its ^{1}H NMR spectrum is characterized by a set of well separated quartets for the methylene protons and one triplet for each methyl group. This indicates a hindered rotation around the CN bond of the

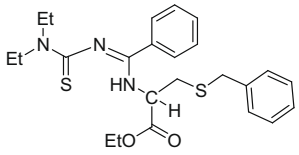
doi:10.1016/j.poly.2009.04.012



diethylamino group. The compound crystallizes in the orthorhombic space group $P2_12_12_1$ with one molecule in the asymmetric unit. The molecular structure of HL(GlyOEt) is shown in Fig. 1, selected bond lengths and angles are summarized in Table 1. The data confirm hindered rotation around the CN bonds because of mesomeric effects. The bonds N21–C2, C2–N3 and N3–C4 possess partially double bond character, as has already been reported previously for similar ligands [5].

HL(GlyOEt)

{HL(CysOMe)}$_2$

HL(S-Bzl-CysOEt)

The infrared spectrum of {HL(CysOMe)}$_2$ shows strong bands for the NH vibration at 3325 cm^{-1} and for the carbonyl group at 1740 cm^{-1}. The dimeric structure of this compound could be elucidated by X-ray crystallography (Fig. 2) and the ESI-TOF mass spectrum, which shows the molecular peak with one proton at 705 *m*/*z*. Selected bond lengths and angles are given in Table 1. The formation of a dimer is not unexpected under these reaction conditions and it should be possible to prevent this by working under completely oxygen free conditions. With regard to planed reactions with ^{188}Re and/or ^{99m}Tc under 'radiopharmaceutical reaction conditions', that means highly diluted aqueous solutions and aerobic conditions, we decided to choose another approach and protected the thiol by a benzyl group.

The reaction of benzimidoyl chloride with S-benzyl protected cysteine ethylester in the presence of triethylamine as a supporting base leads to the product HL(S-Bzl-CysOEt) in good yields. The infrared spectrum of the ligand shows clearly the stretching vibration of the NH bond at 3385 cm^{-1} and an additional band for the carbonyl group at 1725 cm^{-1}. The ^{1}H NMR spectrum of this compound also reveals the hindered rotation around the CN bonds by well separated signals for the methylene and methyl groups. Also for this compound the mesomeric effects are confirmed by X-ray crystallography. The structure is shown in Fig. 3, and the values of the selected bond lengths and angles clearly show the partial double bond character for the CN bonds C2–N21, C2–N3 and C4–N5, while the bond length of 1.288(2) Å for C3–N4 reveals a stronger double bond character.

2.2. Synthesis of the rhenium complexes

The reaction of equimolar amounts of [$ReOCl_3(PPh_3)_2$] and HL(GlyOEt) in dry acetone gave a deep green solution, from which a green powder was isolated after removal of the solvent and washing the residue with diethylether. After recrystallisation from acetonitrile/toluene, green needles were obtained, which were suitable for X-ray crystallography. The infrared spectrum of the crystalline compound reveals a medium band at 3350 cm^{-1}, which indicates that the ligand is still protonated and does mutually not coordinate via the nitrogen atom. The vibration of the Re=O double bond is found at 985 cm^{-1}. The ^{1}H NMR spectrum of the complex reveals one multiplet and one triplet for the methyl groups and

four separated signals for four different methylene groups, suggesting hindered rotation of the diethylamino group as has been discussed for the uncoordinated benzamidine. The molecular structure of the complex is shown in Fig. 4 and confirms the composition of the compound as $[ReOCl_3\{HL(GlyOEt)\}(PPh_3)]$ (**3a**) and the monodentate coordination of the ligand by the sulfur atom S1. The complex crystallizes in the monoclinic space group *C*2/*c*. The rhenium atom is coordinated octahedrally by one triphenylphosphine, three facially coordinated chloro ligands, an oxo ligand and the monodentate coordinated, neutral HL(GlyOEt). Selected bond lengths and angles are given in Table 2. They suggest some delocalization of electron density within the thiourea unit. The C=S double bond is elongated and the C–N bonds are shortened with respect to values obtained for the uncoordinated compounds and for other rhenium complexes with thiourea [8]. The monodentate coordination pattern is very unusual for this type of *N*-(dialkylamino)(thiocarbonyl)benzamidines, particularly when the

coordination behavior of the metal ions allows chelate formation. There are only a few reports about Au and Ag complexes and one Tc complex with such ligands with exclusive sulfur coordination [5f,5g,5l].

The same pattern of reactivity is found for the reaction of $[ReOCl_3(PPh_3)_2]$ with HL(S-Bzl-CysOEt) in dry acetone and the neutral rhenium(V) complex $[ReOCl_3\{HL(S\text{-}Bzl\text{-}CysOEt)\}(PPh_3)]$ (**3b**) with a monodentate coordinated HL(S-Bzl-CysOEt) ligand is formed, as is shown in Fig. 5. Selected bond lengths and angles are compared with the corresponding values of **3a** in Table 2. They suggest similar bonding situations for both compounds.

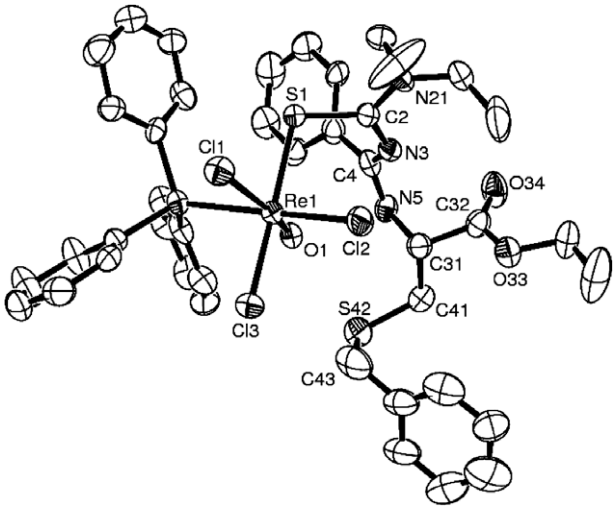

Fig. 5. Ellipsoid representation [15] of [$ReOCl_3${HL(S-BzlCysOEt)}(PPh_3)]. Thermal ellipsoids represent 50% probability. H atoms have been omitted for clarity.

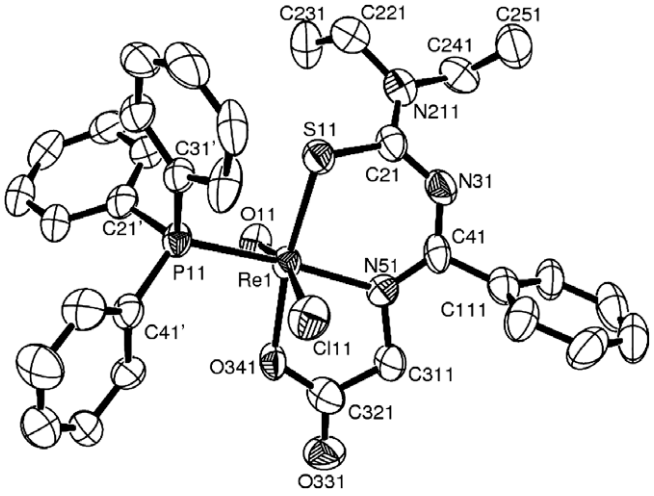

Fig. 6. Ellipsoid representation [15] of [ReOCl(LGly)(PPh_3)]. Thermal ellipsoids represent 50% probability. H atoms have been omitted for clarity.

Our attempts to deprotect the thiol groups in HL(S-Bzl-CysOEt) or **3b** by standard procedures, in order to increase the chelating power of the ligand, failed. The thiocarbonyl unit did not resist the deprotection conditions and decomposition of the non-coordinated HL(S-Bzl-CysOEt) as well as of **3b** occurred, and no defined products could be isolated. Compounds **3a** and **3b** are stable as solids and in solution of dry and aprotic solvents. Addition of water to a solution of **3a**, however, resulted in an immediate change of color from deep green to orange-red, and a compound of the composition [ReOCl{L(Gly)}(PPh_3)] (**4a**) could be isolated after removal of the solvent. Compound **4a** can also be prepared from the crude reaction mixture of the synthesis of **3a** in moderate yields, simply by the addition of some drops of water.

The infrared spectrum of **4a** indicates deprotonation of the organic ligands by the absence of an NH vibration and the band of the carbonyl group is shifted by 60 cm^{-1} with regard to the corresponding band in **3a**. This is a strong hint towards a coordination via the the oxygen atom. The ^1H NMR spectrum of this compound reveals a set of four well separated signals for the methylene protons of the diethyl group. The methyl groups are characterized by two well separated triplets, but there are no more signals of the ester group. The ready hydrolysis of the ester and the subsequent rearrangement of the coordination sphere of the rhenium atom is confirmed by the X-ray crystal structure of the product.

The compound crystallizes in the triclinic space group $P\bar{1}$ with two complex molecules and co-crystallized solvent in the asymmetric unit. Fig. 6 shows the molecular structure of **4a**, selected bond lengths and angles are summarized in Table 3. The thiocarbamoylbenzamidinate acts in the product as a doubly deprotonated, tridentate, equatorially coordinated S,N,O ligand. The rhenium atom has a distorted octahedral coordination environment with the chloro ligand *trans* to the oxo oxygen. The general bonding situation inside the chelating ligand can best be described as an extended π-system with delocalized electron density inside the chelate ring, but also including the C–N bond of the diethylamino group. The C–N bonds inside this system are almost equal as has been observed for other metal complexes with *N*-[(dialkylamino)(thiocarbonyl)]benzamidines before [5,6]. The consequence of such a bonding mode is a comparably rigid structure, which favours a planar coordination and, thus, does obviously not allow a facial coordination of $LGly^{2-}$ in the compound under study.

A similar ester hydrolysis and ligand rearrangement is observed for compound **3b**. Recrystallization of the complex from a mixture of acetone and water results in a yellow–brown solid of [ReOCl{L(S-Bzl-Cys)}(PPh_3)] (**4b**). The infrared spectrum of this compound does not show any band which can be assigned to the NH vibration which indicates deprotonation and coordination via the nitrogen atom. The band of the carbonyl function is shifted by about 50 cm^{-1} with respect to **3b**. The ^1H NMR spectrum of the product shows two triplets for the methyl groups and four multiplets for the four methylene protons of the diethylamino group, but no more signals for the ester group. The ^{31}P NMR spectrum in DMSO exhibits a peak at 23.1 ppm for coordinated triphenylphosphine.

* Values for two crystallographically independent molecules.

Ester hydrolysis during the coordination to a rhenium center has already been observed by Seifert et al. [9]. The reaction of mercaptoacetic acid ester with (Ph_4As)[$ReOCl_4$] seems to be pH-dependent. The hydrolysis of the ester group under acidic conditions was in this case faster than in neutral solution. However, Angelici et al. [10] made the observation that during the metal-catalyzed hydrolysis of ethyl valinate-*N*,*N*-diacetic acid and ethyl leucinate-*N*,*N*-diacetic acid and the forming of neutral complexes the pH value is not of importance. In our case, we could also make the latter observation. While the complexes **3** are stable in solution even after addition of HCl, the color of the solution immediately turns from green to orange–brown after addition of water. This supports the conclusion that the addition of water changes the coordination sphere of the complex (most probably by the exchange of a chloro

ligand) and the proton transfer to the ester is a secondary step. Metal catalysis is also indicated by the fact that HL(GlyOEt) and HL(S-Bzl-CysOEt) do not hydrolyze under the same conditions.. A detailed mechanism, however, cannot be formulated with the present results.

3. Conclusions

Novel ligands derived from *N*-[(diethylamino)(thiocarbonyl)]benzimidoyl chloride and α-amino acid esters can readily be prepared as stable solids. Surprisingly, they react with [$ReOCl_3(PPh_3)$] in dry acetone only as monodentate, neutral ligands via the thiocarbonyl unit. Addition of water, however, results in an immediate hydrolysis of the ester function and the formation of complexes with tridentate S,N,O ligands. This is the result of a remarkably mild, metal-induced saponification of amino acid esters and guides the way to new ligand systems of this type also for the chemistry of technetium. The metal-catalyzed hydrolysis allows the convenient synthesis of ester-protected ligand systems which are activated by the presence of the metal ion and water.

4. Experimental

[$ReOCl_3(PPh_3)_2$] [11] and $Et_2NCSNCClPh$ [3] were prepared by literature procedures. The acetone was dried over P_4O_{10} and distilled under argon.

Infrared spectra were measured as KBr pellets on a Shimadzu FTIR-spectrometer 8300. ESI-TOF mass spectra were measured on an Agilent 6210 ESI-TOF. FAB^+ mass spectra were recorded with a TSQ (Finnigan) instrument using nitrobenzyl alcohol as matrix. Elemental analyses were determined using a Heraeus (vario EL) elemental analyzer. The found hydrogen values of most of the rhenium complexes are significantly too low. This seems to be a systematic problem probably caused by some hydride formation during the combustion process and does not refer to impure samples. Reference samples have been checked by high resolution mass spectrometry. ^1H and $^{31}P\{^1H\}$ NMR spectra were taken with a JEOL 400 MHz multinuclear spectrometer.

4.1. Synthesis of HL(GlyOEt)

A solution of $Et_2NCSNCClPh$ (1 g, 4 mmol) in 20 ml of dry acetone was cooled to 0 °C and glycine ethylester hydrochlorid (560 mg, 4 mmol) was added. Triethylamine (1.5 ml, 10 mmol) dissolved in 5 ml of dry acetone was dropped to the suspension during a period of 30 min. The mixture was vigorously stirred for 3 h at room temperature and filtered from the precipitated triethylamine hydrochloride. The solvent was removed in vacuum and the residue was redissolved in 10 ml THF. After filtration from a small amount of insoluble solid, the mixture was brought to dryness again and the oily residue was dissolved in 2 ml chloroform and kept at 4 °C. The product crystallized upon standing overnight as pale yellow crystals. They were filtered off and washed with a small amount of diethylether. The obtained single crystals were suitable for X-ray crystallography. Yield: 880 mg (60%). *Anal.* Calc. for $C_{16}H_{23}N_3O_2S$: N, 13.1; C, 59.8; H, 7.2; S, 9.4. ESI-MS: *m/z* 705 $M+H^+$.

4.3. Synthesis of HL(S-Bzl-CysOEt)

The compound was prepared from $Et_2NCSNCClPh$ (258 mg, 1 mmol) and L-(S-benzyl)cysteine ethylester hydrochlorid (276 mg, 1 mmol) as described for HL(GlyOEt). The oily residue was crystallized by slow evaporation of a 1:1 (v/v) mixture of CH_2Cl_2 and MeOH. Yield: 340 mg (79%). *Anal.* Calc. for $C_{24}H_{31}N_3O_2S_2$: N, 9.2; C, 63.0; H, 6.8; S 14.0. 4.4. Synthesis of [$ReOCl_3${HL(GlyOEt)}(PPh_3)] (**3a**)

HL(GlyOEt) (66 mg, 0.2 mmol) was dissolved in 5 ml of dry acetone and added to a suspension of [$ReOCl_3(PPh_3)_2$] (166 mg, 0.2 mmol) in 15 ml of dry acetone. After heating under reflux for 6 h, the solid was completely dissolved and a dark green solution was formed. The solvent was removed to dryness under reduced pressure and the residue was treated with 20 ml diethylether and kept overnight at 4 °C. During this time, a dark green solid precipitated, which was filtered off and recrystallized from acetonitrile/toluene. Yield: 75 mg (48%). *Anal.* Calc. for $ReC_{34}H_{38}N_3O_3SPCl_3$: N, 4.7; C, 45.8; H, 4.3; S 3.6. Found: N, 5.2; C, 44.9; H, 2.8; S, 4.0%. 4.6. Synthesis of [ReOCl(LGly)(PPh_3)] (**4a**)

(a) The green solid, which was obtained as a crude product during the synthesis of **3a**, was dissolved in acetone. After addition of a few drops of water, the color of the solution immediately turned from green to orange–red. Slow evaporation of the acetone/water mixture gave orange–red crystals of X-ray quality. Yield: 36 mg (47%).

(b) Compound **3a** (90 mg, 0.1 mmol) was dissolved in acetone. A few drops of water were added to the green solution, which resulted in an immediate change of the color and forms an orange–red solution. Slow evaporation gave orange–red crystals. Yield: 39 mg (49%).

Anal. Calc. for $ReC_{32}H_{32}N_3O_3SPCl$: N, 4.9; C, 48.6; H, 2.9; S 4.0. Found: N, 4.9; C, 48.8 H, 2.9; S, 4.1%. IR (ν_{max}, cm^{-1}): 3055 (m), 2975 (m), 2930 (w), 2870 (w), 1695 (st), 1525 (st), 1435 (st), 1390 (st), 1350 (m), 1330 (m), 1275 (m), 1225 (w), 1190 (w), 1145 (w), 1075 (m), 970 (st), 930 (w), 775 (w), 750 (m), 695 (m), 530 (m), 505 (w). ^{1}H NMR (δ, DMSO-d_6): 1.15 (t, 3H, CH_3), 1.27 (t, 3H, CH_3), 3.63 (q, 2H, CH_2), 3.73 (q, 2H, CH_2), 3.75 (m, 2H, CH_2), 4.14 (q, 2H, CH_2), 4.24 (bs, 2H, CH_2), 7.38–7.63 (m, 10H, $CH_{aromatic}$), 9.86 (s, 1H, NH) ppm. ^{31}P NMR (δ, DMSO): 23.1 ppm. +ESI-MS: m/z 756 M-Cl$^+$.

4.7. Synthesis of [ReOCl{L(S-Bzl-Cys)}(PPh_3)] (**4b**)

HL(S-Bzl-CysOEt) (46 mg, 0.1 mmol) in 5 ml acetone was added to a suspension of [$ReOCl_3(PPh_3)_2$] (83 mg, 0.1 mmol) in 5 ml acetone. The reaction mixture was stirred at room temperature until the solid was completely dissolved and the solution was deep green. After addition of 5 ml H_2O, the color of the solution turned from green to yellow–orange. Slow evaporation of the solvent gave a yellow precipitate. Yield: 35 mg (37%). *Anal.* Calc. for $ReC_{42}H_{46}N_3O_3S_2PCl_3$: N, 4.5; C, 51.8; H, 4.35; S 6.9. Found: N, 4.3; C, 50.5; H, 2.7; S, 6.3 IR (ν_{max}, cm^{-1}): 3055 (m), 2975 (m), 2930 (w), 1695 (st), 1525 (st), 1435 (st), 1355 (st), 1330 (m), 1290 (w), 1255 (w), 1190 (w), 1145 (w), 1095 (m), 1070 (m), 1000 (w), 970 (m), 770 (w), 750 (w), 695 (st), 530 (m), 510 (w). ^{1}H NMR (δ, DMSO-d_6): 1.23 (t, 3H, CH_3), 1.29 (t, 3H, CH_3), 2.55 (m, 1H, CH_2), 2.75 (dd, 1H, CH_2), 3.07 (d, 1H, CH_2), 3.23 (d, 1H, CH_2), 3.56 (m, 1H, $CH_{2,\ ethyl}$), 3.91 (m, 1H, $CH_{2,\ ethyl}$), 4.04 (m, 1H, $CH_{2,\ ethyl}$), 4.26 (m, 1H, $CH_{2,\ ethyl}$), 5.04 (dd, 1H, CH), 7.01–7.70 (m, 25H, $CH_{aromatic}$) ppm. ^{31}P NMR (δ, DMSO): 23.6 ppm.

4.8. X-ray structure determinations

The intensities for the X-ray determinations were collected on a STOE IPDS automated single crystal diffractometer with Mo Kα radiation. The structures were solved by direct methods using SIR 92 [12] or Patterson SHELXS-86 [13] or SHELXS-97 [13]. Subsequent Fourier-difference map analyses gave the position of the non-hydrogen atoms. Refinement was performed using SHELXL-97 [13]. Hydrogen atom positions were calculated for idealized positions and treated with the 'riding model' option of SHELXL.

The compound **3a** crystallized with a disordered quarter molecule of toluene per asymmetric unit. Another area of diffuse electron density (counting for an overall amount of 115 electrons) was located near the center of inversion and could not be refined as discrete solvent molecules. It has therefore been removed from the electron density map by the program SQUEEZE [14] Crystal data and more details of the data collections and refinements are contained in Table 4.

Appendix A. Supplementary data

CCDC 721754, 721755, 721756, 721757 and 721758 contain the supplementary crystallographic data for HL(GlyOEt), {HL(CysOMe)}$_2$, HL((S-Bzl)CysOEt), 3a·0.25 toluene and 3b·0.5·O(C_2H_5)$_2$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

Functionalised β-diketones
Oxo-hydroxo bridges
Synthesis and structural elucidation

ABSTRACT

The reaction of $YCl_3{\cdot}6H_2O$ with *ortho*-hydroxydibenzoylmethane (HO-DBMH) in a 1:2 ratio, in methanol and in the presence of excess triethylamine as a base yielded a yellow precipitate which on crystallization from toluene or benzene /hexane afforded pale yellow block-like crystals. Single crystal X-ray diffraction of **1** revealed the formation of an interesting hexanuclear yttrium oxo-hydroxo cluster $[Y_6(O\text{-}DBM)_6(HO\text{-}DBM)_4(\mu_3\text{-}OH)_2(MeOH)_4]$; the core resembles a butterfly framework flanked by a lanthanide atom on each side. Ten phenolic β-diketone ligands are present in the cluster, which bridge the metal centers in both chelating and chelating-bridging fashions.

1. Introduction

Multinuclear metal clusters, in particular lanthanide based clusters, have generated a huge amount of interest in recent years owing to their wide ranging applications from precursors to magnetic materials to catalysis [1–13]. Traditionally, lanthanide oxo-hydroxo clusters have been synthesized either by controlled hydrolysis of air and moisture sensitive lanthanide precursors [14–16] or by slow deprotonation of the coordinated water molecules of hydration in lanthanum salts like $LnCl_3{\cdot}xH_2O$, in the presence of suitable ligands by addition of a base [17–19]. β-Diketones have been used as ligands extensively to synthesize a large number of lanthanide clusters whose solid state structures vary from tetra- to tetra decanuclear forms [17–23]. Although β-diketones have been investigated in detail for their ligating ability towards lanthanides and their solid state structures are well understood, the use of functionalized β-diketones [24] and in particular phenolic β-diketones [25,26] as ligands towards lanthanides are rare. In this paper, we present the synthesis and structural characterization of a hexanuclear cluster of yttrium and using HO-DBMH as a ligand. The single crystal X-ray characterization technique revealed the formation of a novel hexanuclear yttrium cluster, $[Y_6(O\text{-}DBM)_6(HO\text{-}DBM)_4(\mu_3\text{-}OH)_2(MeOH)_4]$ (**1**).

2. Experimental

Yttrium trichloride hexahydrate was synthesized from the corresponding oxide by neutralizing with conc. HCl, followed by evaporation to dryness. The ligand 1-(2-hydroxyphenyl)-3-phenyl-1,3-propanedione was prepared according to the literature method [27]. Triethylamine and the solvents were used as purchased from commercial sources without further purification. Elemental analyses were carried out with a FLASH EA series 1112 CHNS analyzer. IR spectra were recorded on a JASCO-5300 FT-IR spectrophotometer (using KBr pellets). The ^1H solution NMR spectrum was recorded on a BRUCKER DRX 400 instrument. Single crystal X-ray data was collected at 298(2) K on a BRUKER SMART APEX CCD area detector system [λ(Mo Kα) = 0.71073 Å] with a graphite monochromator, and the data were reduced using SAINTPLUS. The structure was solved using SHELXS-97 and refined using SHELXS-97 [28,29]. All non hydrogen atoms were refined anisotropically, except for the carbon and oxygen atom of a methanol solvent molecule (C_{81}–O_{32}) which was refined isotropically. As the solvents of crystallization, methanol and water molecules, were heavily disordered, the hydrogen atoms were not fixed for the solvents of crystallization found in **1**.

2.1. Synthesis

The ligand, 1-(2-hydroxyphenyl)-3-phenyl-1,3-propanedione (H0-DBMH) (0.470 g, 1.96 mmol) and $YCl_3{\cdot}6H_20$ (0.30 g, 0.98 mmol) were dissolved in methanol (20 ml). Triethylamine (0.39 g, 3.92 mmol) was slowly added to the above reaction mixture and stirred for 12 h at room temperature. The pale yellow precipitate that formed was filtered, washed with methanol (5 ml)

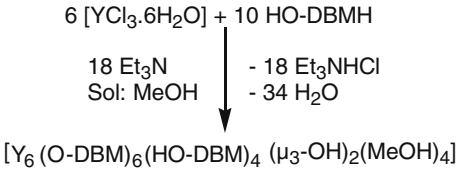
doi:10.1016/j.poly.2009.04.035



and air dried. Further the precipitate was dissolved in toluene (15 ml) and stirred for 20 min, at which point the solution was again filtered. Slow evaporation of toluene at room temperature yielded yellow crystals of **1** in 78% yield (0.39 g). The crystals lost the solvent of crystallization rapidly and turned opaque. Better quality crystals suitable for single crystal X-ray diffraction studies were obtained by slow evaporation of **1** from benzene (*Caution*: Benzene is a class A carcinogen and should be used with the proper precautions) or by a benzene/hexane diffusion method after a week. Elemental analysis for $C_{154}H_{122}O_{36}Y_6$: *Anal.* calcd. C 60.01, H 3.99; found: C 60.04, H 3.95. IR(KBr, cm^{-1}): 3580(m) (ν OH), 3057(m), 1597(s) (ν CO), 1547(w), 1516(s) (ν C–C), 1483(m), 1392(m), 1296(m), 1248(s), 1203(m), 1138(m), 1024(m), 941(m), 860(m), 756(s), 719(m), 696(m), 625(s), 584(m), 520(m). ^{1}H NMR ($CDCl_3$) δ (ppm): 2.65 (s, Me/coordinated solvent methanol), 4.54 (s, CH), 6.54–8.02 (m, Ph), 11.60 (broad peak, phenolic OH).

3. Results and discussion

The synthetic methodology used for the preparation of **1** was adopted from recent literature reports [17–19]. Hydrated yttrium chloride and the ligand, *ortho*-hydroxydibenzoylmethane (HO-DBMH) were dissolved in methanol (20 ml) in a ratio 1:2, and triethylamine (excess) was added dropwise to the stirred reaction mixture (Scheme 1). Halfway through the addition of the base, a yellow precipitate was obtained. The reaction mixture was stirred further for a period of 12 h and filtered to isolate the precipitate.

The precipitate was then washed thoroughly with methanol to remove the unreacted starting materials and the product was air dried. Pale yellow block-like crystals were obtained after a week by slow diffusion of hexane into a toluene or benzene solution of **1** at room temperature. The products were characterized by standard analytical and spectroscopic techniques. The IR spectrum of **1** shows a peak corresponding to a C–O stretch at around 1597 cm^{-1}. A broad peak at 3580 cm^{-1} can be attributed to the presence of an OH group in the product. The ^{1}H NMR spectrum of **1** in $CDCl_3$ shows a multiplet centered around 6.54–8.02 ppm, corresponding to the aromatic groups of the phenolic β-diketone ligand.

The solid state structure of **1** was established by single crystal X-ray diffraction. The crystallographic data is given in Table 1. Although we could crystallize **1** from both toluene and benzene solutions by slow diffusion of hexane at room temperature, only the crystals isolated from benzene were of sufficiently good quality for single crystal X-ray diffraction analysis, in spite of several attempts to isolate good quality crystals of **1** from toluene (*Caution*: Benzene is a class A carcinogen and should be used with the proper precautions). The neutral cluster **1** crystallises in the triclinic space group $P\bar{1}$. The core of the cluster consists of six yttrium centers connected through oxo and hydroxo bridges. A sheath of organic groups encapsulates the metal oxo-hydroxo core enabling the product to dissolve in a wide range of organic solvents like chloroform, dichloromethane, benzene and toluene. The hexanuclear metal core can be visualized in the following manner; a central butterfly core (consisting of four yttriums) flanked by a yttrium metal on each side (Fig. 1).

Scheme 1.

The yttrium atoms that make up the butterfly core are eight-coordinate and the peripheral yttriums are seven-coordinate. The central butterfly core is held together by two μ3-OH bridges, similar to the ones found in the tetranuclear structures of ytterbium and lutetium reported recently [20]. The yttrium to oxygen bond distances (2.254–2.436 Å) and the Y–O–Y bond angles (95.44–111.12°) fall in the ranges reported in the literature [17–19]. Selected bond lengths and bond angles are given in Table 2.

Ten phenolic β-diketone ligands are found coordinated to the metal centers in **1**, displaying varying modes of binding.

Six of these ligands are in the dianionic $[O–DBM]^{2-}$ form, while the other four are monoanionic $[OH–DBM]^-$. The six dianionic $[O–DBM]^{2-}$ ligands are found wrapped around the central butterfly

core, displaying both chelating and chelating-bridging modes of binding. The oxygens of the β-diketone part of the ligand chelate to the central dimeric core of the butterfly unit. Further, one of the oxygen atoms of the β-diketone part of each ligand also bridges to a third yttrium metal atom (so does the symmetry related oxygen) leading to the formation of the central butterfly framework observed in **1**. This core is linked to the peripheral metal centres through the phenoxide groups, which act as bridging ligands, leading to the formation of a hexanuclear cluster. Each of the peripheral yttrium centers are further chelated to two monoanionic OH-DBM ligands. The varying modes of binding found in **1** are depicted in Chart 1. Interestingly, other than the central metal dimer of the butterfly unit, all the other metal centers are coordinated to a methanol solvent molecule to saturate their coordination spheres.

It is of interest to mention here that a subtle change in the stoichiometry of the reactants can lead to isolation of interesting new structures in the solid-state. In a recent report, reaction of hydrated lanthanum nitrate with H0-DBMH in methanol as solvent followed by addition of triethylamine as a base in the ratio 1:3:3 has led to the isolation of mononuclear complexes of lanthanides where the phenolic part of the ligand is essentially non-coordinating [25]. In the present case, however, where the stoichiometry of the metal/ligand/base is 1:2:4, hexanuclear clusters have been isolated wherein the phenolic oxygen from the ligand acts as a bridging group in a μ-2 fashion (Chart 1). Hence a small change in the stoichiometry of the ligand and base (a slight excess) has had a dramatic change in the coordination chemistry of the ligand, leading to the isolation of a novel hexanuclear cluster. Similar observations, wherein a subtle change in the stoichiometry or the nature of solvents/base used in a reaction lead to dramatic variations in the structure of the resultant cluster, are widely reported for transition metal clusters [30,31], whereas they are a rarity in the case of rare earths. This observation opens up further interesting possibilities as far as the coordination chemistry of the ligand towards lanthanide metals is concerned.

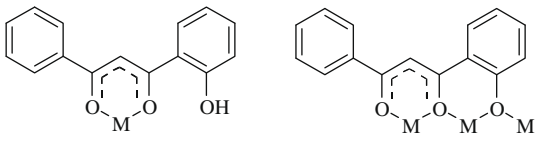

Chart 1.

4. Conclusion

We have been successful in synthesizing a hexanuclear yttrium oxo-hydroxo cluster using a phenolic β-diketone as a ligand. The hexanuclear framework reported here is quite unique and we believe that changing yttrium to other paramagnetic lanthanides, like dysprosium or gadolinium, will lead to the generation of paramagnetic lanthanide oxo-hydroxo clusters possessing interesting magnetic properties. Work is currently under progress in this direction.

Supplementary data

CCDC 721333 contains the supplementary crystallographic data for **1**. ABSTRACT

Several (azido)iridium(III) complexes having a pentamethylcyclopentadienyl (Cp^*) group, $[Cp^*Ir(N_3)_2(Ph_2Ppy\text{-}\kappa P)]$ (**1**: Ph_2Ppy = 2-diphenylphosphinopyridine), $[Cp^*Ir(N_3)(Ph_2Ppy\text{-}\kappa P,\kappa N)]CF_3SO_3$ (**2**), $[Cp^*Ir(N_3)(dmpm)]PF_6$ (**3**: dmpm = bis(dimethylphosphino)methane), $[Cp^*Ir(N_3)(Ph_2Pqn)]PF_6{\cdot}CH_3OH$ (**4**·CH_3OH: Ph_2Pqn = 8-diphenylphosphinoquinoline), and $[Cp^*Ir(N_3)(pybim)]$ (**5**: Hpybim = 2-(2-pyridyl)benzimidazole) have been prepared and their crystal structures have been analyzed by X-ray diffraction. In complex **1**, the Ph_2Ppy ligand is only coordinated via the P atom (-κP), while in **2** it acts as a bidentate ligand through the P and N atoms (-$\kappa P,\kappa N$) to form a four-membered chelate ring. Comparing the structural parameters of the chelate ring in **2** with those of a similar five-membered chelate ring formed by Ph_2Pqn in **4**, it became apparent that the angular distortion in the Ph_2Ppy-$\kappa P,\kappa N$ ring was remarkable, although the Ir–P and Ir–N bonds in the Ph_2Ppy-$\kappa P,\kappa N$ ring were not elongated very much from the corresponding bonds in the Ph_2Pqn-$\kappa P,\kappa N$ ring. In the pybim complex **5**, the five-membered chelate ring was coplanar with the pyridine and benzimidazolyl rings. With the related (azido)iridium(III) complexes analyzed previously, comparison of the structural parameters of the Ir–N_3 moiety in $[Cp^*Ir^{III}(N_3)(L\text{–}L')]^{+/0}$ complexes reveals an anomalous feature of the 2,2′-bipyridyl (bpy) complex, $[Cp^*Ir(N_3)(bpy)]PF_6$.

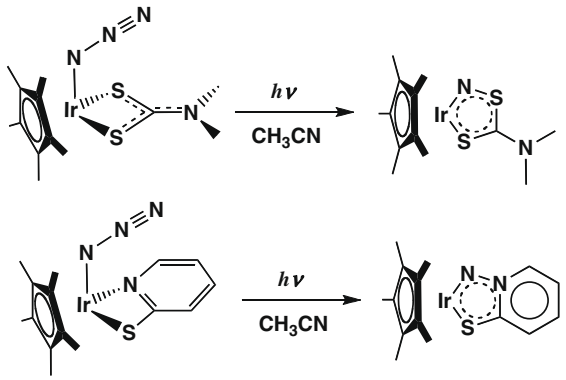
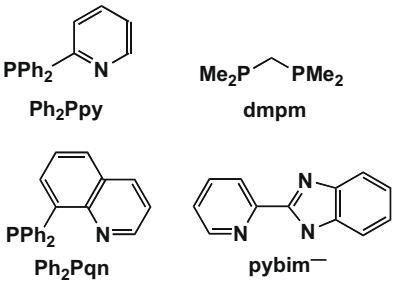
1. Introduction

Recently, the investigation of transition-metal azido complexes has been revived because they often show interesting chemical reactivities and physical properties [1–4]. For example, photolysis of some azido complexes results in higher-valent metal nitrido complexes, which have the potential for further nitrogen-atom (or imino-group) transfer reactions [2]. The *crick* reactions of azido complexes with nitriles or alkynes via 1,3-dipolar cycloaddition, which affords the corresponding tetrazolato or triazolato complexes, are also attractive for the creation of new functional compounds [3]. Furthermore, the azido-bridged dinuclear complexes or cluster compounds are of current interest in studies of supramolecular architecture and the development of molecular magnetic materials [4]. We have also investigated the photochemical reactivities of (azido)iridium(III) complexes with a $Cp^*Ir^{III}(N_3)$ ($Cp^* = \eta^5\text{-}C_5Me_5$) fragment, and found a novel nitrogen-atom insertion reaction on photolysis of $[Cp^*Ir(N_3)(R_2dtc$, 2-Spy, or 2-Sqn)] (R_2dtc^- = *N,N*-dialkyldithiocarbamate; 2-Spy^- = 2-pyridinethiolate; 2-Sqn^- = 2-quinolinethiolate) complexes (Scheme 1) [5–7]. This interesting reaction seems to be attributable to the highly strained chelate ring and the stability of the Ir–S bond of the above dithiocarbamato or thiolato ligands. On the other hand, it is also known that some Cp^*Ir^{III} complexes having phosphines or imidazolates often exhibit interesting structural features and novel reactivities [8–11]. Therefore, the related $Cp^*Ir^{III}(N_3)$ complexes bearing 2-diphenylphosphinopyridine (Ph_2Ppy), 8-diphenylphosphinoquinoline (Ph_2Pqn), bis(diphenyl- or dimethylphosphino)methane (dppm or dmpm), as well as 2-(2-pyridyl)benzimidazolate ($pybim^-$) (L–L′: Scheme 2) may be possible candidates for similar or other fascinating reactions. Here, we have prepared such complexes of $[Cp^*Ir^{III}(N_3)(L\text{–}L')]^{+/0}$, and their molecular structures and chemical reactivities were compared, together with the analogous complexes characterized previously in our group [5,7,12,13].



2. Experimental

2.1. Preparation of complexes



The diazidoiridium(III) complex, $[Cp^*Ir(N_3)_2]_2$ [12], and the phosphines, Ph_2Ppy [14] and Ph_2Pqn [15], were prepared by the literature methods. The ligands, dmpm and 2-(pyridyl)benzimidazole (Hpybim), were purchased from Aldrich Co. Ltd.

Caution! The AgN_3 resulting from the preparation of complex **2** is potentially explosive. Although we had no severe experience in our laboratory, all experiments handling the precipitated AgN_3 should be performed with the greatest care.

*2.1.1. [Cp*Ir(N$_3$)$_2$(Ph$_2$Ppy-κP)] (**1**)*

A methanol solution (6 cm^3) of Ph_2Ppy (135 mg, 0.57 mmol) was added with stirring to a solution of $[Cp^*Ir(N_3)_2]_2$ (236 mg, 0.287 mmol) in a mixture of dichloromethane and methanol (1:1, 4 cm^3), affording a yellow–brown precipitate in a few minutes. The reaction mixture was concentrated (to ca. 5 cm^3) under reduced pressure, and the resulting precipitate was collected by filtration. The crude product was washed with methanol (1 cm^3) and diethyl ether (3 cm^3), and recrystallized from a mixture of dichloromethane and methanol to give orange platelet crystals. Yield: 244 mg (63%). *Anal.* Calc. for $C_{27}H_{29}IrN_7P$: C, 48.06; H, 4.33; N, 14.53%. Found: C, 47.91; H, 4.28; N, 14.41%. ^1H NMR (CD_2Cl_2, 303 K): δ 1.44 (d, J_{HP} = 2.4 Hz, Cp*, 15H), 7.10–7.57 (m, Ph and py, 13H), 8.70 (dq, J_{HH} = 31.9 and 0.9 Hz, 6-py, 1H).

*2.1.2. [Cp*Ir(N$_3$)(Ph$_2$Ppy-κP,κN)]O$_3$SCF$_3$ (**2**)*

A methanol solution (3 cm^3) of $Ag(O_3SCF_3)$ (97 mg, 0.38 mmol) was added dropwise with stirring to an orange solution of **1** (255 mg, 0.378 mmol) in dichloromethane (2 cm^3). The mixture was stirred in the dark at room temperature for 18 h, and the resulting white precipitate (AgN_3) was filtered off. The precipitate was washed successively with acetonitrile (5 cm^3), methanol (5 cm^3) and dichloromethane (5 cm^3), and the filtrate and all washings were combined. The mixture was evaporated to dryness under reduced pressure, and the orange residue was dissolved in hot methanol (50 °C, 3 cm^3). After removal of undissolved impurities by filtration, the filtrate was allowed to stand in a refrigerator overnight, affording yellow–brown prismatic crystals. Yield: 226 mg (76%). *Anal.* Calc. for $C_{28}H_{29}F_3IrN_4O_3PS$: C, 43.02; H, 3.74; N, 7.17%. Found: C, 43.09; H, 3.79; N, 7.14%.

The corresponding PF_6 salt (**2′**) was prepared similarly using $AgPF_6$, instead of $Ag(O_3SCF_3)$.

*2.1.3. [Cp*Ir(N$_3$)(dmpm)]PF$_6$ (**3**)*

The ligand, dmpm (26 mg, 1.9 mmol) was added dropwise by syringe to a red suspension of $[Cp^*Ir(N_3)_2]_2$ (400 mg, 0.972 mmol) in methanol (10 cm^3) under a dinitrogen atmosphere. The reaction mixture was stirred at room temperature for 30 min and evaporated to dryness under reduced pressure. The residue was washed with Et_2O (10 cm^3 × 3), and then dissolved in methanol (2 cm^3) under air. A saturated methanol solution containing NH_4PF_6 (800 mg, 4.9 mmol) was added to the filtered methanol solution. The mixture was allowed to stand for 30 min to afford a pale yellow precipitate, which was collected by filtration, washed with methanol (1 cm^3) and Et_2O (3 cm^3), and dried in vacuo. The crude product was dissolved in a mixture of acetonitrile and methanol (1:1), and Et_2O vapor was diffused into the filtered solution to give yellow crystals of **3**. Yield: 432 mg (69%). *Anal.* Calc. for $C_{15}H_{29}F_6IrN_3P_3$: C, 27.69, H, 4.49; N, 6.46%. Found: C, 27.93; H, 4.47; N. 6.33%. ^1H NMR (CD_3CN, 303 K): δ 1.66 (virtual t, $^1J_{HP} + {}^3J_{HP}$ = 6.6 Hz, PMe, 6H), 1.83 (virtual t, $^1J_{HP} + {}^3J_{HP}$ = 6.2 Hz, PMe, 6H), 1.93 (s, Cp*, 15H), 3.49 (q, J_{HP} and J_{HH} = 15.9 Hz, CH_2, 1H), 4.68 (dt, J_{HP} = 15.6, J_{HH} = 10.5 Hz, CH_2, 1H).

*2.1.4. [Cp*Ir(N$_3$)(Ph$_2$Pqn)]PF$_6$ (**4**)*

Ph_2Pqn (74.8 mg, 0.239 mmol) was added to a suspension of $[Cp^*Ir(N_3)_2]_2$ (96.5 mg, 0.117 mmol) in methanol (5 cm^3), and the mixture was stirred at room temperature for 8 h. A methanol solution (3 cm^3) of NH_4PF_6 (137 mg, 0.839 mmol) was added to the resulting orange solution, affording an immediate precipitation. The precipitate was filtered off, washed with methanol (2 cm^3), and dried in vacuo. The crude product was recrystallized from acetonitrile/methanol to form orange platelet crystals. Yield: 171 mg (88%). *Anal.* Calc. for $C_{31}H_{31}F_6IrN_4P_2$: C, 44.98; H, 3.77; N, 6.77%. Found: C, 44.68; H, 3.93; N, 6.95%. ^1H NMR (CD_3CN, 303 K) δ 1.56 (d, J_{HP} = 2.4 Hz, Cp*).

*2.1.5. [Cp*Ir(pybim)(N$_3$)] (**5**)*

A methanol solution (3 cm^3) of Hpybim (46.7 mg, 0.239 mmol) and $NaOCH_3$ (13.8 mg, 0.255 mmol) was added to a suspension of $[Cp^*Ir(N_3)_2]_2$ (103.5 mg, 0.126 mmol) in a mixture of dichloromethane and methanol (2:1, 3 cm^3). The mixture was stirred at room temperature for 8 h and concentrated to ca. 1 cm^3 by a flow of dinitrogen. The resulting yellow precipitate was collected by filtration and dried in vacuo. Yield: 109.4 mg (77%). *Anal.* Calc. for $C_{22}H_{23}IrN_6$: C, 46.88; H, 4.11; N, 14.91%. Found: C, 46.50; H, 4.21; N, 14.88%. Yellowish orange platelet crystals suitable for the X-ray diffraction study were obtained from a mixture of dichloromethane and methanol.

2.2. Measurements

Proton NMR spectra were acquired on a JEOL EX270 or a Varian Mercury 300 spectrometer; chemical shifts were referenced to the residual ^1H NMR signals of the deuterated solvent and are reported versus TMS. Infrared spectra were measured on a JASCO FT/IR FT-550 spectrophotometer using Nujol mulls.

2.3. Crystallography

The X-ray diffraction data were obtained at −73(2) °C on a Rigaku R-axis rapid imaging plate detector with a graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). A suitable crystal was mounted with a cryoloop and flash-cooled by cold dinitrogen stream. Data were processed by the Process-Auto program package [16a], and absorption corrections were made by the numerical

method from the crystal shapes [16b]. The structures were solved by the direct method using SIR2004 [17a], and refined on F^2 (with all independent reflections) using SHELXL97 [17b]. All non-H atoms were refined anisotropically, and H atoms were introduced at the positions calculated theoretically and treated with riding models. For the compound **3**, the positions of the F atoms of PF_6^- were severely disordered but no satisfactory model could be found. Therefore, the reported result was an artificially distorted structure for this anion. All calculations were carried out using the CRYSTAL STRUCTURE software package [16c].

Crystal data are collected in Table 1.

3. Results and discussion

3.1. 2-Diphenylphosphinopyridine (Ph_2Ppy) complexes

Kollipara et al. have recently reported the syntheses of $[Cp^*IrCl_2(Ph_2Ppy)]$, $[Cp^*IrCl(Ph_2Ppy)_2]PF_6$ and $[Cp^*IrCl(Ph_2Ppy)]PF_6$, as well as the crystal structures of the first two complexes having monodentately P-coordinated ligands (Ph_2Ppy-κP) [18]. Similar to their synthetic procedure and to the preparative method for $[Cp^*Ir(N_3)_2(napy\text{-}\kappa N)]$ (napy = 1,8-naphthyridine) [12], a stoichiometric reaction of $[Cp^*Ir(N_3)_2]_2$ and Ph_2Ppy (1:2 mole ratio) in a mixture of dichloromethane and methanol afforded an orange crystalline product of $[Cp^*Ir(N_3)_2(Ph_2Ppy)]$ (**1**) in 63% yield.

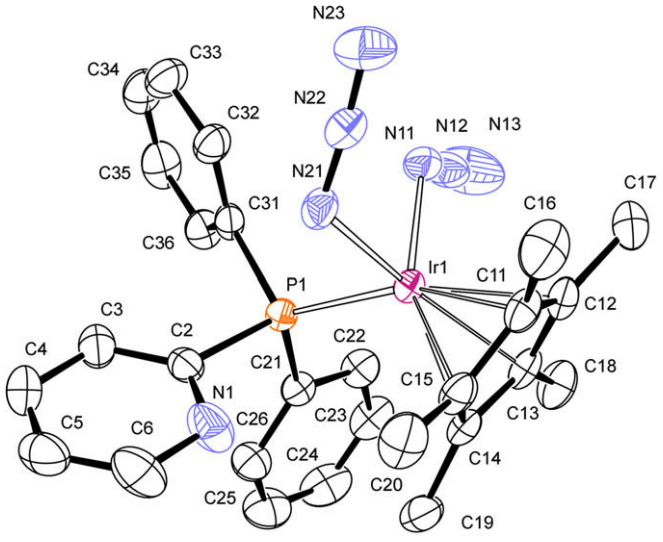

Fig. 1. An ORTEP view (50% probability level, hydrogen atoms omitted) of $[Cp^*Ir(N_3)_2(Ph_2Ppy\text{-}\kappa P)]$ (**1**).

The molecular structure of **1** determined by single-crystal X-ray analysis is illustrated in Fig. 1, which revealed the monodentate coordination mode of Ph_2Ppy through the P atom. In this analysis, three six-membered rings bound to the P atom, i.e., two phenyl and one pyridyl rings, were not distinguishable from one another, and the N atom of Ph_2Ppy could not be specified [19,20]. We tentatively assigned the N atom to the atom that was closest to Ir among the six possible atoms. Even under this assumption, the Ir1···N1 distance was 3.537(2) Å, which is far from being a bonding interaction. The structure of the "$Cp^*Ir(Ph_2Ppy)$" moiety in **1** is very similar to that in $[Cp^*IrCl_2(Ph_2Ppy\text{-}\kappa P)]$ [18]; the Ir–P bond lengths in **1** (2.3060(6) Å) and in the dichloro complex (2.299(2) Å) are comparable. Also, the "$Cp^*Ir(N_3)_2$" moiety corresponds well to that in $[Cp^*Ir(N_3)_2(napy\text{-}\kappa N)]$ [9]. The Ir–N(N_3) bonds in **1**, 2.112(3) and 2.129(2) Å, are comparable to those of the napy complex, 2.114(7) and 2.126(7) Å. The bending coordination mode and the intraligand structural parameters of the coordinated N_3^- ligands are also quite similar to those of the napy complex (see: Table 2).

The ligand, Ph_2Ppy, has the potential to form a four-membered chelate ring [21]. However, unlike the related bis(phosphino)methanes (dmpm or dppm; vide infra) and thiolates (2-Spy^- or 2-Sqn^-), a simple reaction of Ph_2Ppy with $[Cp^*Ir(N_3)_2]_2$ in a mixture of dichloromethane and methanol did not give the chelate complex. Kollipara et al. reported the formation of a chelate complex by the reaction of Ph_2Ppy and $[Cp^*IrCl_2]_2$ in methanol [18]. Here, to obtain a pure sample in high yield, we have utilized the reaction of complex **1** with a stoichiometric amount of $Ag(O_3SCF_3)$ or $AgPF_6$ for the preparation of $[Cp^*Ir(N_3)(Ph_2Ppy)](O_3SCF_3$ or $PF_6)$ (**2** or **2′**). The chelate coordination mode of Ph_2Ppy-$\kappa P,\kappa N$ was confirmed by X-ray analysis (Fig. 2). The Ir1–P1 bond length in **2** (2.3159(9) Å) is nearly the same as that in **1** (monodentately P-coordinated Ph_2Ppy complex). The Ir1–N1 bond length and the chelate bite angle of P1–Ir1–N1 in **2** are 2.125(3) Å and 67.40(8)°, respectively. These values are comparable to those in the corresponding 2-Spy complex (Ir–N = 2.111(4) Å, S–Ir–N = 67.0(1)°) [22] and 2-Sqn complex (Ir–N = 2.131(5) Å, S–Ir–N = 66.6(2)°) [7]. We expected, therefore, that the chelate Ph_2Ppy complex **2** would be stable, similar to the 2-Spy and 2-Sqn complexes. However, it was found that complex **2** was labile in acetonitrile solution.

Fig. 3 depicts the variable-temperature (−20–40 °C) ^1H NMR spectra of $[Cp^*Ir(N_3)(Ph_2Ppy)]PF_6$ (**2′**) in acetonitrile-d_3 (ca.

sh: Shoulder

0.05 mol dm^{-3}, prepared under a dinitrogen atmosphere). At 40 °C the Cp* resonance was observed as a broad signal around d 1.6. On cooling, this signal separated into two broad resonances with different intensities. At −20 °C both resonances were detected as sharp doublets at δ 1.51 and 1.64, with an intensity ratio of 4:1. The doublet resonances are indicative of the existence of an Ir–P bond, and, therefore, the two species in solution are assumed to be the chelate and the monodentately P-coordinated Ph_2Ppy complexes (Scheme 3). This results indicate that complex **2′** exists as an equilibrium mixture because of the dissociation of the Ir–N(py) bond in acetonitrile-d_3. Such a dissociation would be favorable for a N-atom insertion reaction, because the reaction of $[Cp^*Ir(N_3)(2\text{-}Spy)]$ was initiated by the photochemical cleavage of the Ir–N(py) bond [6]. However, photochemical or thermal reaction of an acetonitrile-d_3 solution of complex **2′** gave a complicated mixture of unidentified products, in which there was no lower-field shifted ^1H NMR resonance diagnostic for the two-legged piano stool structure of $Cp^*Ir^{III}(L\text{–}L')$-type complexes [5–7]. It has also been reported [23] that photolysis of $[Cp^*Ir(N_3)_2(PPh_3)]$ gave $[Cp^*Ir(H)(Ph_2PC_6H_4\text{-}\kappa P,\kappa C)]$, presumably via a "$Cp^*Ir^I(PPh_3)$" transient species formed by homoleptic cleavage of two Ir–$N(N_3)$ bonds. Thus, the present reactions might be caused by the undesirable thermal or photoreduction of the iridium(III) azido complex.

As mentioned above, the Ir–N(py) bond length and the chelate bite angle of complex **2** were comparable to those of $[Cp^*Ir(N_3)(2\text{-}Spy \text{ or } 2\text{-}Sqn)]$, while the solution behavior, i.e., the lability of the Ir–N(py) bond, was obviously different. To elucidate the reason for the different behavior from the structural point of view, we have also analyzed the crystal structures of the related complexes bearing dmpm and Ph_2Pqn.

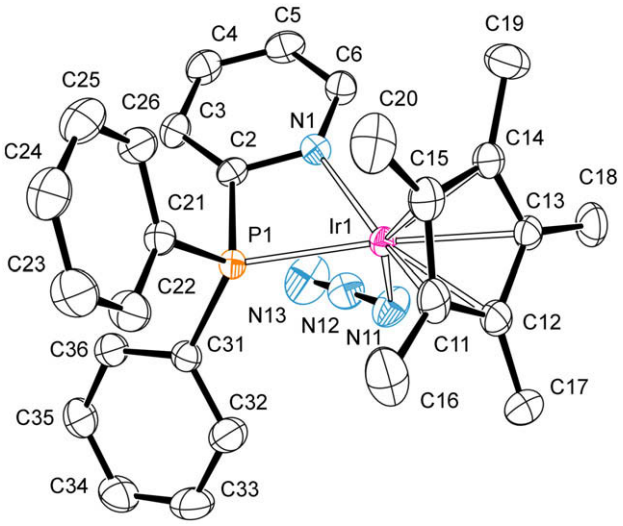

Fig. 2. An ORTEP view (50% probability level, hydrogen atoms omitted) of the cation in $[Cp^*Ir(N_3)(Ph_2Ppy\text{-}\kappa P,\kappa N)]O_3SCF_3$ (**2**).

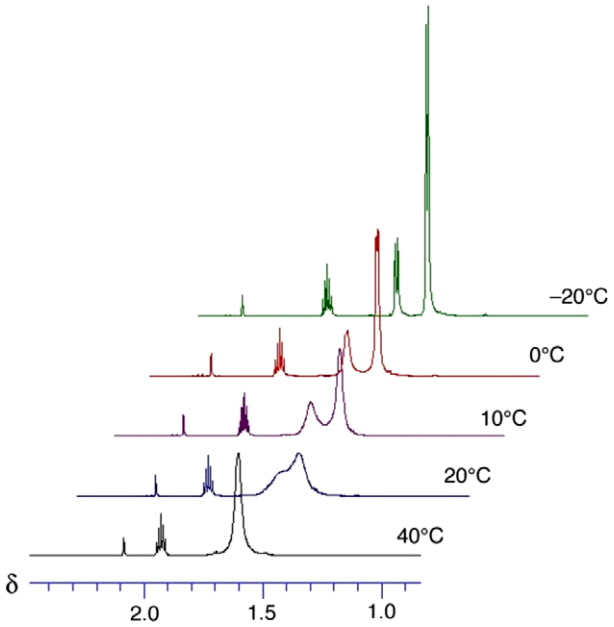
3.2. Bis(dimethylphosphino)methane (dmpm) complex

It has been reported that particular Pt^{II}–dppm complexes of the form $[Pt(CH_2X)_2(dppm\text{-}\kappa^2P,P)]$ (X = Cl, Br, or I) demonstrated a fascinating chelate-ring expansion reaction by insertion of a CH_2



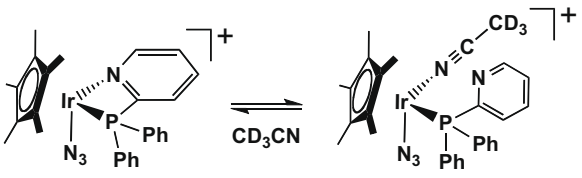


Fig. 3. Variable-temperature ^1H NMR spectra in the Cp* region of $[Cp^*Ir(N_3)(Ph_2Ppy\text{-}\kappa P,\kappa N)]PF_6$ (**2′**) in CD_3CN.

Scheme 3.

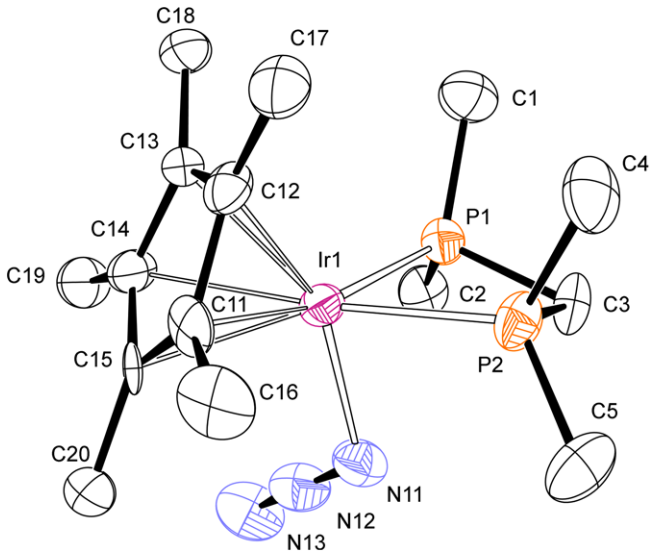

Fig. 4. An ORTEP view (50% probability level) of the cation in $[Cp^*Ir(N_3)(dmpm)]PF_6$ (**3**).

group into a Pt–P bond [24], which is somewhat related to a N-atom insertion reaction. Thus, we thought it might be interesting to investigate the structures and reactivities of the bis(phosphino)methane complexes of $[Cp^*Ir(N_3)(P–P)]PF_6$ (P–P = dppm or dmpm). These complexes were prepared in good yields by reaction of $[Cp^*Ir(N_3)_2]_2$ and the phosphines in methanol, followed by isolation of the PF_6 salts on addition of NH_4PF_6. We have also prepared the CF_3SO_3, BF_4 and BPh_4 salts of the dppm complexes, but none of them deposited suitable crystals for an X-ray diffraction study. Instead, we have determined the crystal structure of $[Cp^*Ir(N_3)(dmpm)]PF_6$ (**3**). The molecular structure with a four-membered chelate ring was confirmed, as illustrated in Fig. 4. The chelate bite angle, P1–Ir1–P2, of dmpm in complex **3** is 71.0(1)°, which is larger than those of Ph_2Ppy in complex **2**, 67.40(8)°. The Ir1–P1–C3 and Ir1–P2–C3 angles in **3** are 93.3(5) and 95.7(4)°, respectively, which are larger than the Ir1–P1–C2 angle in **2,** 85.9(1)°. These angular differences indicate clearly that the steric strain effects are more severe in the Ph_2Ppy chelate than in the dmpm chelate. It is also notable that two Ir–P bonds of complex **3** showed a large numerical deviation, Ir1–P1 2.344(4) versus Ir1–P2 2.282(3) Å, but we cannot account for this unusual feature at present.

Unlike the Ph_2Ppy chelate in complex **2**, the four-membered chelate rings in the dppm and dmpm complexes were stable in acetonitrile solution. When acetonitrile-d_3 solutions of the dppm and dmpm complexes were photolyzed by a high-pressure Hg lamp under a dinitrogen atmosphere at temperature below 0 °C, the ^1H NMR spectra of the resulting solutions indicated the formation of a complicated mixture of unidentified products. Similar to the case of Ph_2Ppy complex **2**, there was no lower-field shifted resonance diagnostic for Cp^*Ir^{III} complexes with a two legged piano stool structure. However, most of the Cp^* resonances became doublets (*cf.* the reactant complexes showed a triplet), because of coupling to the single P nucleus. This may suggest that a N-atom insertion could have taken place on photolysis.

3.3. 8-Diphenylphosphinoquinoline (Ph_2Pqn) complex

To clarify the structural features of the Ph_2Ppy chelate ring in complex **2**, the corresponding Ph_2Pqn complex was prepared and characterized by X-ray diffraction analysis for comparison. The complex, $[Cp^*Ir(N_3)(Ph_2Pqn)]PF_6$ (**4**), was obtained in nearly quantitative yield, and deposited orange prismatic crystals with a methanol molecule of crystallization, **4**·CH_3OH. The molecular structure of the cation in **4**·CH_3OH revealed by the X-ray diffraction study is shown in Fig. 5.

The chelate bite angle of Ph_2Pqn (P1–Ir1–N1) in complex **4** is 81.25(9)°, which is comparable to those in the other Ph_2Pqn complexes determined previously [21,25], but much larger than that of Ph_2Ppy in complex **2**, 67.40(8)°. The five-membered chelate ring is almost planar, and coplanar with the quinolyl ring. The deviations of atoms Ir1 and P1 from the least-square quinolyl ring plane are only 0.246(4) and 0.177(4) Å, respectively. The Ir1–P1–C8 angle in the chelate ring is 102.2(1)°, which is a little smaller than the ideal tetrahedral angle, but is normal for the coordinated phosphines. All bond angles around N1 are nearly 120°. These values indicate that the chelate coordination of Ph_2Pqn forms a strain-free planar five-membered ring. The Ir1–P1 and Ir1–N1 bond lengths in **4** are 2.294(1) and 2.115(3) Å, respectively, which are comparable to those in $[Cp^*Ir(8\text{-}Sqn)(N_3)]$ (Ir–N 2.104(3) Å), $[Cp^*IrCl(8\text{-}MeSqn)]PF_6$ (Ir–N 2.094(3) Å) [26], and the Ph_2Ppy complex **2** (vide supra). It is surprising that the Ir–P and Ir–N bonds in the highly strained four-membered Ph_2Ppy chelate ring elongate only by 0.02 and 0.01 Å, respectively, while the bond angles in the Ph_2Ppy ring show severe deviation from the ideal values: P–Ir–N 67.40(8)°, Ir–P–C 85.4(1)°, and Ir–N–C 106.3(2)°. This observation suggests that the primary reason for the dissociation of the Ir–N(py) bond of the Ph_2Ppy complex **2** in solution must be an angular strain in the four-membered chelate ring. In other words, even the bond lengths are seemingly comparable, the coordination bond in the strained chelate ring is remarkably weak and easy to dissociate in solution to relieve the steric strain.

In the crystal structure of **4**·CH_3OH, there was a stacking interaction between the quinolyl rings with a neighboring molecule, forming a dimer unit. The distance between the planes is ~3.6 Å. This stacking interaction is the most remarkable difference from the crystal structure of the Ph_2Ppy complex **2**.

3.4. 2-(2-Pyridyl)benzimidazolato (pybim) complex

In a series of studies we are investigating the molecular structures and photochemical reactivities of (azido)iridium(III) complexes containing various kinds of bidentate coligands, $[Cp^*Ir^{III}(N_3)(L–L')]^{+/0}$. Previously, we have reported the crystal

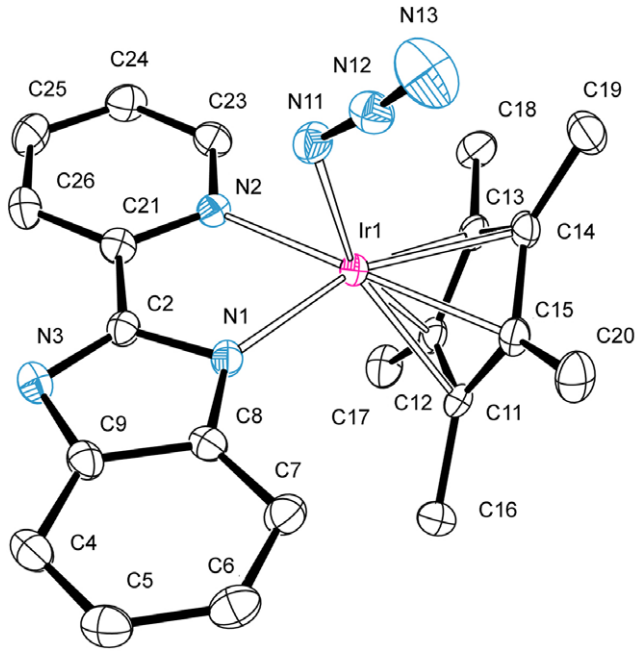

Fig. 6. An ORTEP view (50% probability level, hydrogen atoms omitted) of $[Cp^*Ir(N_3)_2(pybim)]$ (**5**).

structure of $[Cp^*Ir(N_3)(bpy)]PF_6$ [13], which showed an interesting 1,3-dipolar cycloaddition reaction in acetonitrile to form 5-methyltetrazolato complexes [20]. Furthermore, it has also been revealed that 2-pyridyl and 2-benzimidazolyl groups exhibited a different coordination behavior, at least when they were incorporated into bidentate thiolato ligands, i.e., 2-pyridinethiolate (2-Spy$^-$) and benzimidazole-2-thiolate (Hbimt$^-$) [7]. Thus, to compare directly the molecular structures between the bpy and pybim$^-$ complexes, we have prepared and characterized the pybim complex, $[Cp^*Ir(N_3)(pybim)]$ (**5**).

Complex **5** was obtained from $[Cp^*Ir(N_3)_2]_2$ and Na(pybim) as yellow–orange crystals in 77% yield. The molecular structure determined by X-ray analysis is shown in Fig. 6. As expected, the anionic pybim$^-$ ligand formed a planar five-membered chelate ring, which is coplanar with the pyridine and benzimidazolate rings. The chelate bite angle (N1–Ir1–N11) is 76.5(2)°, which is comparable to that of bpy in $[Cp^*Ir(N_3)(bpy)]PF_6$, 76.8(2)° [13]. The Ir1–N2(py) bond length in **5**, 2.139(3) Å, is longer than the Ir–N(bpy) bonds in the above bpy complex, 2.086(5) and 2.097(5) Å. The Ir–N1(bim) bond in **5** is 2.087(3) Å, which is remarkably shorter than the Ir1–N2(py) bond and comparable to the Ir–N(bim) bond length in a dinuclear 2-benzimidazolethiolato (Hbimt$^-$) complex of $[\{Cp^*Ir(N_3)\}_2(\mu\text{-Hbimt})_2]\cdot CH_3OH$, 2.098(4) Å [7]. Because the N ligator in the anionic benzimizadolate ring is more basic than that in the neutral pyridine ring, the bim-*N* donor would give a stronger σ-bonding interaction with an Ir^{III} center than the py-*N* does. When the bite angle of the ligands, N–E, are compared in $[Cp^*Ir^{III}(N_3)(N\text{–}E)]^{0/+}$ having a planar five-membered chelate ring, the angle increases in the order (N–E =) pybim$^-$ ≈ bpy < Ph_2Pqn < 8-Sqn$^-$. The same order was observed in the Ir–E bond lengths: Ir–N(pybim) 2.087(3) ≈ Ir–N(bpy) 2.092(7) < Ir–P(Ph_2Pqn) 2.294(1) < Ir–S (8-Sqn) 2.366(1) Å.

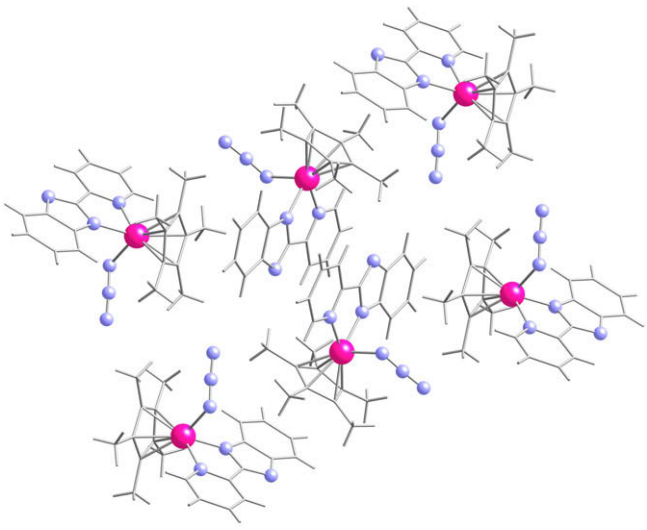

Fig. 7. A stacking diagram of the pybim complexes in the crystal.

The crystal structure of **5** exhibited a characteristic packing diagram. As seen in Fig. 7, a planar pybim ring is stacked with the other pybim ring in a neighboring molecule and a Cp* ring in another molecule. The interplanar distances between the planes are ~3.4 Å. In the crystal structure of $[Cp^*IrCl(Hpyim)]PF_6$ (Hpyim = 2-(2-pyridyl)imidazole) [9], a similar stacking interaction between a pair of Hpyim ligand planes was observed, in addition to the hydrogen-bonding interaction between the im-H group and the coordinated Cl$^-$ ligand. However, in the present complex **5** the N3 atom of the pybim ligand was free from coordination or hydrogen-bonding interaction.

3.5. Comparison of the structural parameters of the $Cp^*Ir^{III}(N_3)$ moiety

The structural parameters of the $Cp^*Ir^{III}(N_3)$ moiety in the complexes determined in the previous and present studies are collected in Table 2. The Ir–C bond lengths of the complexes analyzed previously were in the range of 2.14–2.20 Å. However, some of the Ir–C bonds in complexes **1**–**4** are slightly longer than 2.20 Å (up to 2.29 Å). A detailed examination revealed that the elongated Ir–C bonds are all *trans* to the phosphino donor group(s). Thus, it is concluded that the Ir–C bonds of the Cp* group are also affected by the strong *trans* influence of the phosphines.

The parameters associated with the Ir–N_3 moiety are very similar among the complexes listed in Table 2, except for the bpy complex of $[Cp^*Ir(N_3)(bpy)]PF_6$. Namely, in most (azido)iridium(III) complexes the Ir–N_α bond lengths are in the range 2.09–2.14 Å and the Ir–N_α–N_β bond angles are in the range 117–127°. The coordinated azido ligands are nearly linear (N_α–N_β–N_γ 174–177°), with longer N_α–N_β (1.18–1.23 Å) bonds than N_β–N_γ (1.13–1.17 Å) bonds. In contrast, in $[Cp^*Ir(N_3)(bpy)]PF_6$ all of the parameters for the Ir–N_3 moiety are outside the above ranges. In particular, the Ir–N_α bond is strikingly long at 2.230(6) Å, and the N_α–N_β bond (1.025(12) Å) is remarkably shorter than the N_β–N_γ bond (1.282(15) Å). Consistent with the differences in these structural parameters, the $\nu(N_3)$ stretching frequency of the bpy complex, 2022 cm^{-1}, is observed at a slightly lower frequency than those of the other complexes (Table 2). At this time, we cannot explain these exceptional observation for the bpy complex, but they could give an important insight into the different reactivity of the bpy complex from the others [25].

4. Conclusion

In this study, the crystal structures of five (azido)iridium(III) complexes bearing potentially bidentate ligands (L–L′) have been determined and their structural parameters have been discussed, together with those of the related complexes analyzed previously. Comparing the parameters of the four-membered chelate ring

formed by Ph_2Ppy (in complex **2**) with those of the five-membered chelate ring of the related phosphine–imine-type hybrid ligand Ph_2Pqn (in complex **4**), it became apparent that the Ph_2Ppy ring was highly strained as indicated by the smaller bond angles, but the Ir–P/N coordination bond lengths were comparable to those in the strain-free Ph_2Pqn chelate ring. Although the Ir–N bond and the Ir–N–C angle in the Ph_2Ppy complex **2** are similar to those in the 2-Spy and 2-Sqn complexes analyzed previously [6,22], complex **2** exhibits a dissociation equilibrium of the Ir–N(py) bond in acetonitrile solution.

The pybim complex showed an interesting molecular and crystal structure. The ligand, $pybim^-$, forms a planar five-membered chelate ring with an extended π-delocalized system, and the pybim plane shows a stacking interaction with the neighboring pybim and Cp^* planes to give a characteristic packing structure of the crystal. Furthermore, the Ir–N(bim) bond is shorter than the Ir–N(py) bond, because of the stronger electron-donating properties of the benzimidazole moiety.

We have also examined the photochemical and thermal reactivities of the complexes described in this study, but they showed a complicated mixture of unidentified products.

Supplementary data

CCDC 711474, 711475, 711476, 711477, and 711478 contain the supplementary crystallographic data for **1, 2**, **3**, **4**·CH_3OH, and **5**, respectively. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Thermolysis of the dinuclear compound $[Cp^*IrCl_2]_2$ (**1**) with $ClRe(CO)_5$ (**2**) leads to the formation of the confacial bioctahedral compound $Cp^*Ir(\mu\text{-}Cl)_3Re(CO)_3$ (**3**) in high yield. Whereas the substitution of the chloride ligands in **3** is observed on treatment with excess *p*-methylbenzenethiol to furnish the sulfido-bridged compound $Cp^*Ir(\mu\text{-}SC_6H_4Me\text{-}4)_3Re(CO)_3$ (**4**), **3** undergoes fragmentation upon reaction with tertiary phosphines [PPh_3 and $P(OMe)_3$] to furnish the mononuclear compounds Cp^*IrCl_2P and *fac*-$ClRe(CO)_3P_2$. Both **3** and **4** have been isolated and fully characterized in solution by IR and ^1H NMR spectroscopies, and their solid-state structures have been established by X-ray crystallography. The redox properties of **3** and **4** have been explored by cyclic voltammetry, and the results are discussed relative to extended Hückel MO calculations.

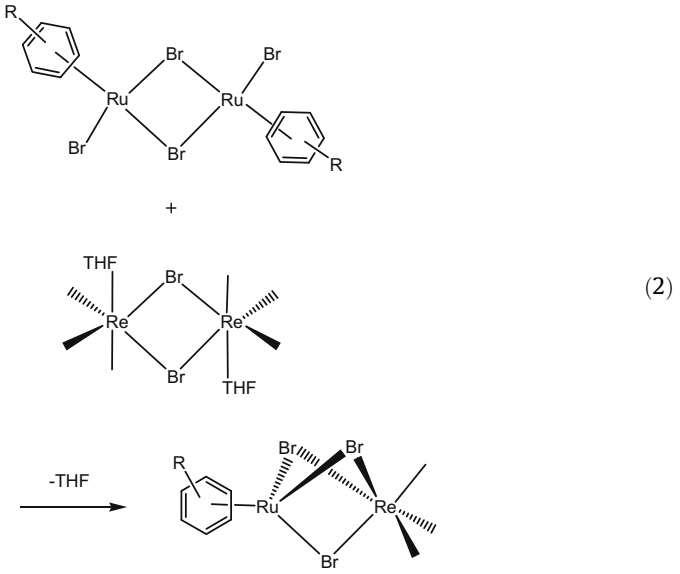
1. Introduction

The catalysis of organic reactions using dinuclear mixed-metal compounds remains under active investigation, with synergistic bimetallic participation in C–H and C–C bond activation processes promoting altered product distributions relative to the corresponding homometallic systems [1]. An undisputed paradigm of cooperative bimetallic reactivity involving alkyne coordination and insertion into a metal–hydride bond has recently been demonstrated by Adams et al. in the case of the mixed-metal compound $HOsPt(CO)_4(SnPh_3)(PBu^t_3)$. Eq. (1) shows this particular reaction, and control experiments and MO calculations confirm the fact that the platinum metal serves as the initial site for alkyne coordination, leading to a weakened Os–H bond, which in turn facilitates the ensuing alkyne insertion and formation of the vinylidene species $OsPt(CO)_4(SnPh_3)(PBu^t_3)[\mu - HC_2(H)Ph]$ [2]. The role played by heterobimetallic species in Fischer–Tropsch chemistry, alkyl and CO insertion reactions, alkyne and alkene hydrogenations, and the reversible reduction of hydronium ions to H_2 by FeNi hydrogenases continues to receive attention, and the mechanistic insight afforded by the mixed-metal species in these different reactions cannot be underscored in terms of modeling heterogeneous catalysts and biological processes [3].



(1)

Severin and co-workers have shown that heterobimetallic compounds based on a $M(\mu\text{-}X)_3M'$ architecture can serve as highly active catalyst precursors in Oppenauer-type oxidations of alcohols and atom-transfer radical addition (ATRA) reactions to alkenes [4]. Accordingly, the directed synthesis of new heterobimetallic systems is warranted if a full understanding of the cooperative synergism between dissimilar metals is to be unraveled in the above catalytic reactions. Severin has outlined several different synthetic methodologies that may be employed in the synthesis of $M(\mu\text{-}X)_3M'$ compounds, with the union of a halide-containing compound and a "lightly activated" or weakly bound solvent com-

plex providing a clean route that leads to the formation of a plethora of different M(μ-X)$_3$M′ derivatives [5]. An elegant example demonstrating this concept involves the synthesis of (η^6-arene)Ru(μ-Br)$_3$Re(CO)$_3$ (where arene = benzene, cymene, 1,3,5-Et$_3$C$_6$H$_3$) from the reaction of [(η^6-arene)RuBr$_2$]$_2$ with [ReBr(THF)(CO)$_3$]$_2$, as depicted in Eq. (2). Here the formal loss of THF and splitting of the halide bridges in the latter dimer afford the mononuclear rhenium species "BrRe(CO)$_3$" that is readily scavenged by the donating halide ligands associated with the (η^6-arene)RuBr$_2$ fragment. The driving force for this and related reactions is entropically driven, and the formation of new bridging metal–halogen bonds in the binuclear RuRe product compensates for the loss of the weakly bound THF molecules.

(2)

Recently, we reported our results on the synthesis of the chlorine-bridged compound (η^6-cymene)Ru(μ-Cl)$_3$Re(CO)$_3$ from [(η^6-cymene)RuCl$_2$]$_2$ and ClRe(CO)$_5$. Here we capitalized on known lability of the CO groups in the latter reagent to generate the unsaturated species "ClRe(CO)$_4$" under thermal and photochemical activation, which in turn reacts with the starting ruthenium dimer to furnish the observed heterobimetallic end-product [6]. The trapping of an *in situ* generated unsaturated species upon loss of CO represents an alternative protocol for the preparation of M(μ-X)$_3$M′ compounds. Herein we present our data on the synthesis and physical characterization of Cp*Ir(μ-Cl)$_3$Re(CO)$_3$ (**3**) and the corresponding sulfido-bridged product Cp*Ir(μ-SC$_6$H$_4$Me-4)$_3$Re(CO)$_3$ (**4**). Preliminary reactions between **3** and phosphine ligands support the fragmentation of the starting heterobimetallic compound to mononuclear species.

2. Experimental

2.1. General

The starting materials [Cp*IrCl$_2$]$_2$[7] and ClRe(CO)$_5$[8] used in the synthesis of **3** were prepared by established literature procedures. The chemicals IrCl$_3$·*x*H$_2$O (Engelhard), Re$_2$(CO)$_{10}$ (Pressure Chemical), and *p*-methylbenzenethiol (Aldrich) were used as received, while the pentamethylcyclopentadiene employed in the synthesis of **1** was prepared from 2-bromo-2-butenes (isomeric mixture) [9], the latter which was purchased from Aldrich. The reaction solvents were either distilled from an appropriate drying agent under argon using Schlenk techniques or obtained from an Innovative Technology solvent purification system. All distilled solvents were stored in Schlenk storage vessels equipped with high-vacuum Teflon stopcocks [10]. The combustion analysis on **3** was performed by Atlantic Microlab, Norcross, GA.

The reported IR data were recorded on a Nicolet 6700 FT-IR spectrometer, while all ^{1}H spectra were recorded at 500 MHz on a Varian VXR-500 spectrometer. The ESI-APCI mass spectrum of **4** was recorded at the UC San Diego mass spectrometry facility in the positive ionization mode.

2.2. Synthesis of Cp*Ir(μ-Cl)$_3$Re(CO)$_3$ from the thermolysis of [Cp*IrCl$_2$]$_2$ with ClRe(CO)$_5$

To 10 mg (0.013 mmol) of **1** in a 100 mL Schlenk round-bottom flask under argon flush was added 20 mL of CH$_2$Cl$_2$, followed by 9.1 mg (0.025 mmol) of **2**. The solution was then heated at reflux over night and allowed to cool to room temperature, at which time TLC analysis revealed the consumption of the latter starting material and a large spot at the origin of the TLC plate belonging to the desired compound **3**. The solvent was removed under vacuum and the residue recrystallized from a minimum amount of CH$_2$Cl$_2$/benzene to yield **3** as a golden-yellow solid in 91% yield (16 mg). IR (CH$_2$Cl$_2$): υ(CO) 2037 (s), 1919 (s, broad) cm^{-1}. ^{1}H NMR (CDCl$_3$): δ 1.90 (s, Cp*). *Anal.* Calc. for C$_{13}$H$_{15}$Cl$_3$IrO$_3$Re·1/8C$_6$H$_6$: C, 23.12; H, 2.21. Found: C, 22.87; H, 2.22%.

2.3. Synthesis of Cp*Ir(μ-SC$_6$H$_4$Me-4)$_3$Re(CO)$_3$ from **3** and *p*-methylbenzenethiol

To a 250 mL Schlenk round-bottom flask was added 50 mg (0.071 mmol) of **3**, followed by the addition of 50 mL of toluene via cannula. The slurry was stirred for several minutes to ensure complete dissolution of **3**, after which time 35 mg (0.28 mmol; slight excess) of *p*-methylbenzenethiol was added in one portion and the contents heated at reflux for 1.5 h. TLC analysis of the crude reaction solution in CH$_2$Cl$_2$/hexane (1:9) revealed the presence of the desired product **3** as a bright yellow spot at R_f = 0.86, along with a trace amount of an orange spot at R_f = 0.80 ascribed to Cp*Ir(μ-Cl)(μ-SC$_6$H$_4$Me-4)$_2$Re(CO)$_3$ and some material that remained at the origin. **3** was subsequently isolated by column chromatography over silica gel using the aforementioned mobile phase in 64% yield (44 mg). IR (CH$_2$Cl$_2$): υ(CO) 2012 (s), 1902 (s, broad) cm^{-1}. ^{1}H NMR (CDCl$_3$): δ 1.30 (s, 15 H, Cp*), 2.32 (s, 9 H, Me-4), 7.06 (d, 6 H, ^3J = 8 Hz, aryl), 7.61 (d, 6 H, ^3J = 8 Hz, aryl). ESI-MS (*m*/*z*): 988.97 [**3**+Na]$^+$, 845.01 [**3**-SC$_6$H$_4$-Me-*p*]$^+$.

2.4. X-ray crystallographic data

Single crystals of **3** and **4**·1/2CH$_2$Cl$_2$ suitable for diffraction analysis were grown from CH$_2$Cl$_2$ solutions containing each compound that had been layered with hexane. The X-ray data for **3** and **4**·1/2CH$_2$Cl$_2$ were collected on an APEX II CCD-based diffractometer at 100(2) K. The frames were integrated with the available APEX2 [11] software package using a narrow-frame algorithm, and the structures were solved and refined using the SHELXTL program package [12]. Each molecular structure was checked using PLATON [13], and all nonhydrogen atoms were refined anisotropically. The hydrogen atoms in **3** and **4**·1/2CH$_2$Cl$_2$ were assigned calculated positions and allowed to ride on the attached carbon heavy atom. The refinement for **3** converged at R = 0.0534 and R_w = 0.1575 for 3179 independent reflection with $I > 2\sigma(I)$, with convergence values for **4**·1/2CH$_2$Cl$_2$ obtained at R = 0.0181 and R_w = 0.0374 for 7729 independent reflection with $I > 2\sigma(I)$. The X-ray data and processing parameters are reported in Table 1, with selected bond distances and angles quoted in Table 2.

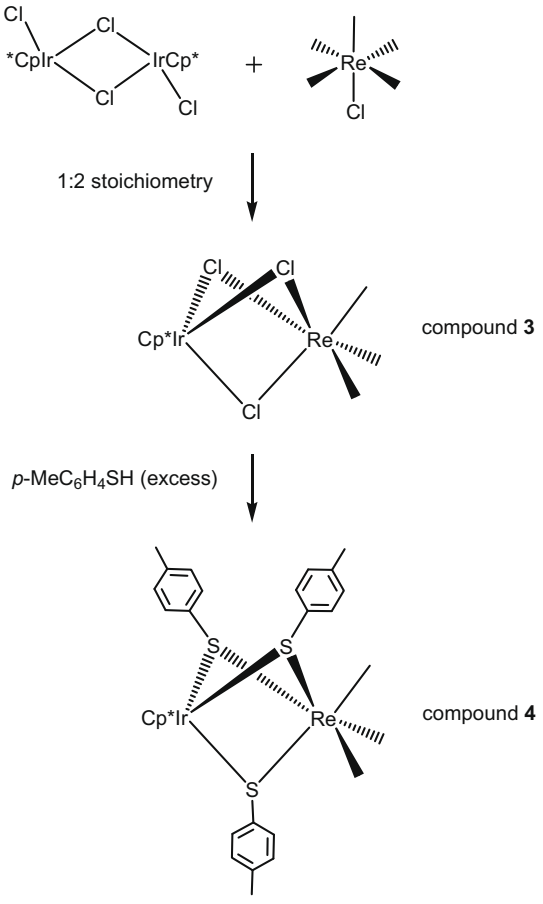
2.5. Electrochemical studies

The reported cyclic voltammetry data were recorded on a PAR Model 273 potentiostat/galvanostat, equipped with positive feedback circuitry to compensate for *i*R drop. The homemade three-electrode cell that was employed allowed the cyclic voltammograms to be recorded under oxygen- and moisture-free conditions. A platinum disk (area = 0.0079 cm^2) was utilized as the working and auxiliary electrode, and the reference electrode utilized a silver wire as a quasi-reference electrode. The reported potential data were standardized against the formal potential of the $Cp^*_2Fe/Cp^*_2Fe^+$ (internally added) redox couple, taken to have $E_{1/2} = -0.20$ V [14].



2.6. Extended Hückel MO calculations

The extended Hückel calculations reported here were carried out using the original program developed by Hoffmann and Lipscomb [15], as modified by Mealli and Proserpio [16]. The weighted H_{ij}'s contained in the program were used in the calculations, and the input Z-matrices for **3** and **4** were constructed from the available X-ray data, with the predefined CACAO packaged Cp moiety replacing the Cp* ligand in each compound and methyl groups substituted for the *p*-tolyl groups in **4**.

3. Results and discussion

3.1. Syntheses and X-ray diffraction structure of $Cp^*Ir(\mu\text{-}Cl)_3Re(CO)_3$ (**3**)

Thermolysis of **1** and **2** (equimolar in metal) in refluxing CH_2Cl_2 furnishes the new heterobimetallic compound **3**, as assessed by IR and NMR analysis of the reaction solution before formal work-up; heating **1** and **2** in either 1,2-dichloroethane or toluene also affords **3** without complications. Scheme 1 shows the reaction leading to **3**. Compound **3** could not be purified by column chromatography employing traditional supports such as silica gel and alumina because of the irreversible binding of **3** to the chromatographic sup-

Scheme 1.

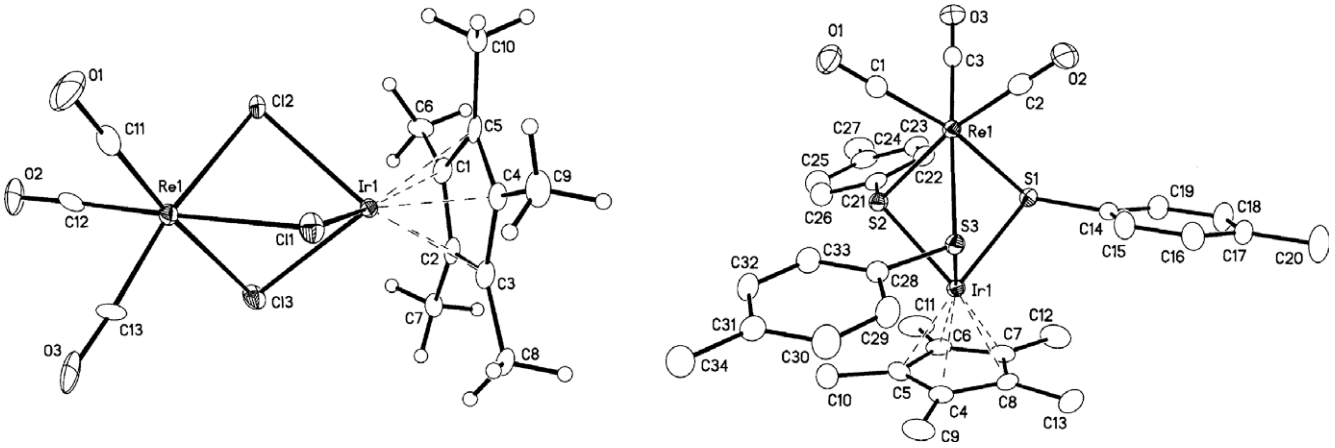


Fig. 1. Thermal ellipsoid plot of **3** (left) and **4**·1/2CH_2Cl_2 (right) showing the thermal ellipsoids at the 50% probability level. The accompanying solvent molecule in the latter structure has been omitted for clarity.

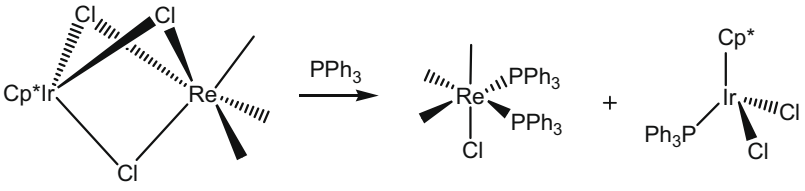
ports, necessitating the use of recrystallization in order to purify **3**. Isolated yields of **3** ranged from good to excellent and were readily achieved through recrystallization of the crude reaction material using the non-coordinating solvents CH_2Cl_2 and benzene. **3** was isolated as an air-stable golden-yellow solid, and samples of **3** maintained under argon did not exhibit any visible sign of decomposition over the course of several months; however, exposure of **3** to atmospheric moisture led to the slow decomposition of **3**. This same decomposition was noticeably accelerated by directly treating **3** with water, consistent with the reactive nature of the halide bridging ligands in related M(μ-Cl)$_3$M′ dimers and formation of hydrolysis-derived species representing a significant decomposition manifold [17].

CO dissociation in $XRe(CO)_5$ has been shown to be facile and facilitated by the ancillary halide ligand, facts experimentally established by different research groups over three decades ago [18]. Essentially quantitative yields of **3** may also be achieved by making use of the lability of the CO groups in **2** in the presence of the weak donor solvent MeCN. The *cis* labilization exerted by the chloride ligand in **2** leads to facile loss of *cis* CO groups and the *in situ* generation of the "lightly activated" compound *fac*-$ClRe(CO)_3(MeCN)_2$.[19] Moreover, the thermolysis of **2** has been kinetically studied and found to proceed by a rapid first-order process involving dissociative CO loss, exhibiting a $t_{1/2}$ ca. 25 min at 60 °C [20]. Reaction of the *in situ* generated *fac*-$ClRe(CO)_3(MeCN)_2$ with **1** then gives the desired product **3**.[1] The proposed reaction sequence was verified by a control experiment between independently synthesized *fac*-$ClRe(CO)_3(MeCN)_2$ and **1**, which afforded **3** in >90% yield. Finally, **3** may be synthesized by a photochemical route employing near-UV irradiation (366 nm). Loss of CO in **2** upon optical excitation leads to the unsaturated intermediate $ClRe(CO)_4$ [21], which in turn is free to react with **1**, followed by an accompanying redistribution of a Cp^*IrCl_2 fragment.

3 was characterized by IR and ^{1}H NMR spectroscopies, combustion analysis, and X-ray crystallography. The IR spectrum exhibits two terminal carbonyl stretching bands for the Re–CO groups at 2037 and 1919 cm^{-1} consistent with the idealized C_{3v} symmetry displayed by the $Re(CO)_3$ moiety, while the ^{1}H NMR spectrum reveals a single resonance at δ 1.90 for the Cp^* ligand. Fig. 1 shows the solid-state structure of **3** and reveals a molecular motif predicated on a triply bridged confacial bioctahedral geometry, where the three chlorines function as the common face-sharing ligands. Assuming the occupation of three coordination sites by the Cp^* ligand, each metal center in **3** is formally six-coordinate and electronically saturated according to the Effective Atomic Number (EAN) rule when the bridging chlorides are treated as 3e-donating ligands. The structure of **3** is analogous to the bromine-bridged derivative $Cp^*Ir(\mu\text{-}Br)_3Re(CO)_3$ prepared by Severin and co-workers [22], and represents the only heterobimetallic ReIr derivative containing face-sharing chlorine ligands on file with the Cambridge Structural Data Center [23]. The internuclear Re(1)···Ir(1) distance of 3.3424(8) Å in **3** precludes any significant metal–metal bonding when contrasted with the Re–Ir single-bond lengths of 2.8081(6), 2.9013(6), and 2.8519(2) Å reported for the heterobimetallic compounds $Cp^*(CO)Ir(\mu\text{-}CO)_2Re(CO)Cp^*$, $[ReIr(CO)_3Cp^*(\eta^5\text{-}7\text{-}CB_{10}H_{11}]$, and $[Cp^*Ir(PMe_3)(\mu\text{-}S)_2Re(NC_6H_3Me_2\text{-}2,6)_2]$, respectively [24]. The structural absence of a metal–metal bond in **3** has, in fact, been theoretically confirmed in related $L_3M(\mu\text{-}X)ML_3$ compounds by extended Hückel MO calculations [25]. Here the tethering of the d^6-$[CpIr]^{2+}$ and d^6-$[Re(CO)_3]^+$ fragments by three chloride ligands (Cl^-) gives rise to a filled set of low-energy d orbitals incapable of metal–metal bonding.[2] The Re–Cl distances range from 2.504(4) Å [Re(1)–Cl(1)] to 2.5123(4) Å [Re(1)–Cl(3)] and display a mean distance of 2.509 Å, while the slightly shorter Ir–Cl distances range from 2.439(4) Å [Ir(1)-Cl(1)] to 2.461(4) Å [Ir(1)–Cl(3)] and reveal a mean length of 2.484 Å. Both sets of metal–halides distances are in excellent agreement with the mean Re–Cl and Ir–Cl bond distances tabulated by Orpen et al.[26]. The remaining bond distances and angles are unremarkable and require no comment.

3.2. Syntheses and X-ray diffraction structure of $Cp^*Ir(\mu\text{-}SC_6H_4Me\text{-}4)_3Re(CO)_3$ (**4**)

Due to the interest in functionalized dendrimers and star-shaped molecules based on $M_2(\mu\text{-}SR)_3$ cores, we next explored the functionalization of **3** with *p*-methylbenzenethiol [27]. Facile substitution of the three chloride ligands in **3** by *p*-methylbenzenethiol (slight excess) is observed in refluxing toluene to afford



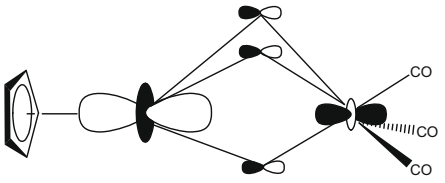
[1] A control experiment (^{1}H NMR) involving the reaction of MeCN with **1** was conducted to explore the formation of the solvated species $Cp^*IrCl_2(MeCN)$ which, in principal, could then undergo reaction with *fac*-$ClRe(CO)_3(MeCN)_2$ to furnish **3**. While no direct NMR evidence for the MeCN-induced fragmentation of **1** was observed, our data do not rule out a small equilibrium concentration (<5%) of the ligand-substitution product $Cp^*IrCl_2(MeCN)$.

[2] The formal union of two d^6-ML_3 moieties is net non-bonding because of the filled t_{2g} set of orbitals belonging to each metal. Inclusion of bridging ligands having π character does not change the situation due to the existence of the appropriate symmetry-adopted linear combination orbitals (SALCs) that negate any net bonding between the metal centers.

the sulfido-bridged compound **4** as the major product, along with a trace amount of material whose spectroscopic properties were indicative of the bis-substituted sulfido-bridged species $Cp^*Ir(\mu\text{-}Cl)(\mu\text{-}SC_6H_4Me\text{-}4)_2Re(CO)_3$. This latter material was examined for its reactivity with added *p*-methylbenzenethiol and found to give **4**. Whereas **3** was unstable with respect to chromatographic supports, **4** could be readily purified by column chromatography over silica gel. **4** was characterized in solution by IR spectroscopy, which revealed two strong υ(CO) bands at 2013 and 1902 cm^{-1} consistent with the *A* and *E* symmetry bands belonging to the *fac*-$Re(CO)_3$ moiety. The observed ca. 20 cm^{-1} shift to lower frequency of each carbonyl band in **4** vis-a-vis the υ(CO) bands in **3** is consistent with the presence of the stronger σ donating sulfido ligands in the former compound. The ^{1}H NMR spectrum of **4** exhibited two high-field resonances at δ 1.30 and 2.32 that are readily ascribed to the Cp^* and *p*-Me moieties, respectively, with the aryl hydrogens at δ 7.06 and 7.61 exhibiting a classic AX pattern having a $J/\Delta\delta$ value of 0.03. Finally, the ESI mass spectrum of **4** displayed two prominent peaks at *m/z* 988.97 and 845.01 that are attributed to a pseudo-molecular ion for [**3**+Na]$^+$ and the loss of a single sulfido ligand for [**3**-SC_6H_4-Me-*p*]$^+$, respectively, consistent with the formulated structure. The unequivocal identity of **4**, as the CH_2Cl_2 solvate, was subsequently established by X-ray diffraction analysis. The thermal ellipsoid plot of **4** in Fig. 1 establishes the presence of the three bridging sulfido groups and the local octahedral coordination about the Re(1) and Ir(1) centers. **4** is unique insomuch as it represents, to our knowledge, the first structurally characterized sulfido-bridged heterobimetallic ReIr compound exhibiting a confacial bioctahedral geometry. The overall molecular structure is identical to that of **3**, and the internuclear Re(1)···Ir(1) distance of 3.3718(7) Å is elongated by 0.030 Å compared to the corresponding distance found in **3**. The formation of **4** in near quantitative yield, along with the collective spectroscopic and mass spectral data, confirm the fact that metal redistribution to give the homometallic products $[Cp^*Ir(\mu\text{-}SR)_3IrCp^*]^+$ and $[(OC)_3Re(\mu\text{-}SR)_3Re(CO)_3]^-$ is not an important manifold in the reaction involving **3** with added thiol [28].

3.3. Reaction of **3** with tertiary phosphines

The reactivity of **3** with various phosphines was next explored by NMR spectroscopy, with the synthesis of ligand-substituted derivatives possessing an intact heterobimetallic $Ir(\mu\text{-}Cl)_3Re$ core as our targeted goal. To our knowledge, no reports exist for the reaction of such halide-bridged mixed-metal systems and phosphine donor ligands. **3** reacts rapidly with a slight excess of added PPh_3 (ca. 3.1 equiv. per **3** employed), leading to the disruption of the starting chloride-bridged dimer and formation of the known mononuclear compounds *fac*-$ClRe(CO)_3(PPh_3)_2$ and $Cp^*IrCl_2(PPh_3)$, as depicted in Eq. (3) [29]. Similar reactivity was found when an excess of $P(OMe)_3$ was employed in the reaction with **3**, with the corresponding compounds *fac*-$ClRe(CO)_3[P(OMe)_3]_2$ and Cp^*IrCl_2 $[P(OMe)_3]$ observed by NMR spectroscopy.



(3)

The reaction of **3** with the rigid bidentate phosphine 4,5-bis(diphenylphosphino)-4-cyclopenten-1,3-dione (bpcd) was also probed by ^{31}P NMR spectroscopy, given our longstanding interest in the coordination chemistry and activation of this particular ligand by polynuclear metal clusters [30]. As in the above reactions with monodentate phosphines, rapid fragmentation of **3** is observed upon treatment with a measured amount of bpcd (1:2 ratio), with new ^{31}P resonances recorded at δ 22.28 and −26.91 that are readily assignable to the known chelated rhenium compound *fac*-$ClRe(CO)_3$(bpcd) (cf.: δ 22.29) and the ionic compound [Cp^*IrCl(bpcd)][Cl], respectively [31,32]. The latter product is assumed to derive from chloride loss upon ring-closure of the pendent phosphine in the intermediate species $Cp^*IrCl_2(\eta^1\text{-bpcd})$. Having established the lability of **3** in phosphine-promoted fragmentation reactions, further substitution studies were abandoned.

3.4. Redox properties and MO data for **3** and **4**

The electrochemical properties of **3** and **4** were next investigated the cyclic voltammetry at platinum electrodes in THF at room temperature using 0.2 M TBAP as the supporting electrolyte. The CV of **3** when examined at a scan rate of 250 mV/s over the potential range of 1.5 to −1.5 V revealed a diffusion-controlled irreversible oxidation at $E_p^a = 1.42$ V [33]. The nature of the orbital associated with this oxidation wave in **3** was established by MO analysis of the model complex $CpIr(\mu\text{-}Cl)_3Re(CO)_3$ at the extended Hückel level. The energy level of the HOMO in **3** was computed to be −11.52 eV by extended Hückel MO calculations, and the HOMO is best described as an antibonding Re–Ir orbital that is largely iridium based and formed from the overlap of metal d_{z2} and chlorine p_z orbitals, as depicted below.[3] The general orbital composition of the HOMO in **3** is similar to the a_2" HOMO reported by Hoffmann and co-workers for a series of homobimetallic $L_3M(\mu\text{-}X)_3ML_3$ compounds [25,34]. Finally, the computed Mulliken reduced overlap population (ROP) of −0.095 between the two metal centers in **3** reinforces the absence of any net bonding between the two metal centers.

HOMO (-11.52 eV)

[3] The HOMO in the model compound $CpIr(\mu\text{-}Cl)_3Re(CO)_3$ consists of significant atomic contributions from the iridium (84%) and rhenium (4%) centers, and the three bridging chlorines (collectively 8%). Here the three in-phase linear combination of p_z chlorine orbitals are situated antisymmetric relative to a twofold rotation axis defined by the metal atoms.

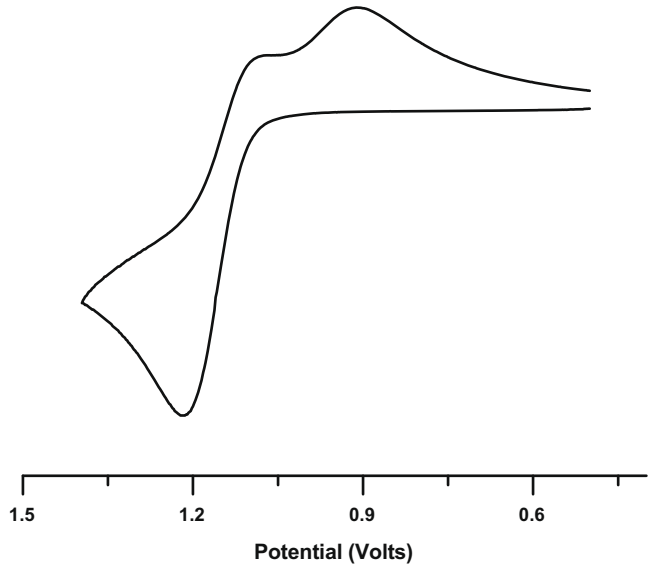


Fig. 2. Anodic scan cyclic voltammogram of **4** (ca. 10^{-3} M) in THF containing 0.2 M TBAP at 0.25 V/s at room temperature.

Examination of **4** by CV, in a manner identical to that of **3**, also revealed the presence of an irreversible oxidation wave at $E_p^a = 1.22$ V, in addition to a return cathodic wave at $E_p^c = 0.74$ V as depicted in Fig. 2. The redox behavior for **4** is not unlike the irreversible oxidation properties displayed by several tris(sulfido)-bridged Ru_2 and Rh_2 compounds prepared by Chérioux et al. [35] The identity of the HOMO in **4** was verified by extended Hückel MO calculations on the model compound $CpIr(\mu\text{-}SMe)_3Re(CO)_3$, where an energy of −11.51 eV was computed and an orbital composition analogous to **3** found.[4] The ROP value of −0.071 computed for the Ir and Re centers in $CpIr(\mu\text{-}SMe)_3Re(CO)_3$ is consistent with a structure where the bridging sulfido ligands act as simple tethering agents and do not promote metal–metal bonding.

4. Conclusions

The syntheses, X-ray diffraction structures, and electrochemical properties of the new mixed-metal compounds **3** and **4** have been presented and discussed. Whereas the halide-bridged compound **3** exhibits fragmentation upon reaction with phosphine ligands, treatment of **3** with added *p*-methylbenzenethiol furnishes the corresponding sulfido-bridged ReIr heterobimetallic compound **4**. Future work will probe the sequential metathesis of the chlorine ligands in **3** with suitable hydride and alkyl reagents in connection with our chemical and catalytic interests on the cooperative activation and formation of C–H and C–C bonds at structurally defined bimetallic ensembles.

Supplementary data

CCDC 709012 and 709013 contain the supplementary crystallographic data for **3** and **4**·1/2CH_2Cl_2. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

[4] The atomic orbital contributions to the antibonding HOMO in $CpIr(\mu\text{-}SMe)_3Re(CO)_3$ consist of Ir (80%) and Re (3%) d_{z^2} character and sulfur (collectively 15%) p_z character.

Acknowledgment

Generous and continued financial support from the Robert A. Welch Foundation (Grant B-1093-MGR) is much appreciated.

ABSTRACT

Reaction of *N*(4)-phenyl-2-formylpyridine thiosemicarbazone (H2Fo4Ph), *N*(4)-phenyl-2-acetylpyridine thiosemicarbazone (H2Ac4Ph) and *N*(4)-phenyl-2-benzoylpyridine thiosemicarbazone (H2Bz4Ph) with gallium nitrate gave $[Ga(H2Fo4Ph)_2](NO_3)_3$ (**1**), $[Ga(2Ac4Ph)_2]NO_3$ (**2**) and $[Ga(2Bz4Ph)_2]NO_3$ (**3**). In all complexes coordination of the thiosemicarbazone via the N_{py}–N–S chelating system occurs. In **1** the thiosemicarbazone acts as a neutral ligand while in **2** and **3** the ligand is anionic. Upon slow diffusion of **2** in DMSO $[Ga(2Ac4Ph)_2]NO_3{\cdot}DMSO$ (**2a**) was formed. The crystal structure of **2a** was determined. Upon coordination the antibacterial activity of both gallium and thiosemicarbazones against *Pseudomonas aeruginosa* significantly increases.

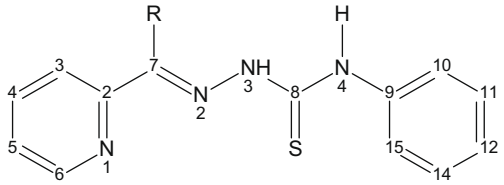
1. Introduction

Indiscriminate antibiotic use both in humans and animals results in the emergence of resistance to several drugs, as in the case of clinical isolates of the bacterium *Pseudomonas aeruginosa* and other microorganisms [1,2]. New agents are needed because conventional antibiotics generally work poorly in chronic infections. A key factor accounting for this is that the infecting organisms live in biofilms, surface-associated bacterial communities encased in a polymeric matrix. Physiological changes inherent to biofilm growth make bacteria resistant to killing by the immune system and antibiotics [2].

Iron metabolism is a major vulnerability for infecting bacteria. In fact, in almost all pathogens, Fe is essential for growth and the functioning of key enzymes, and is required in various metabolic and DNA-synthetic pathways. Free Fe levels are extremely low *in vivo* due to multiple host defenses that sequester Fe, and this is a potent restriction to both acute and chronic infection [2]. The chemical behavior of gallium(III) is close to that of iron(III), in terms of its electric charge, ion diameter, and coordination number. Many biological systems are unable to distinguish gallium(III) from iron(III) [2,3]. Ga can disrupt Fe-dependent processes because, unlike iron(III), gallium(III) cannot be reduced, and sequential oxidation and reduction are critical for many of Fe's biological functions [2]. The literature reports the use of Ga as a strategy to disrupt bacterial Fe metabolism in *P. aeruginosa*. Ga was able to inhibit *P. aeruginosa* growth and prevent biofilm formation, and showed bactericidal activity [2].



Coordination of gallium(III) to organic ligands could improve the antimicrobial action of Ga by increasing its lipophilicity and bioavailability [4]. In addition, by the use of appropriate ligands, metal–ligand synergism could occur.

Thiosemicarbazones and their metal complexes present wide pharmacological versatility and their applications as antitumoral, antiviral and antimicrobial agents have been extensively investigated [5]. Although, thiosemicarbazones are well known for their ability to form complexes with iron(II) and iron(III), the literature reports few works on their complexes with gallium(III) [6,7].

In previous works we demonstrated that coordination to copper(II) could be a strategy for antimicrobial dose reduction of *N*(4)-tolyl- thiosemicarbazones derived from 2-formylpyridine, 2-acetylpyridine and 2-benzoylpyridine [8,9]. In this work we investigated the effect of coordination to gallium(III) on the antibacterial activity of *N*(4)-phenyl-2-formylpyridine thiosemicarbazone (H2Fo4Ph), *N*(4)-phenyl-2-acetylpyridine thiosemicarbazone (H2Ac4Ph) and *N*(4)-phenyl-2-benzoylpyridine thiosemicarbazone (H2Bz4Ph) (see Fig. 1) against the *gram*-negative bacilli *P. aeruginosa*. Since Ga proved to exhibit antibacterial activity against *P. aeruginosa* [2], the effect of coordination with thiosemicarbazones on the antimicrobial activity of Ga has been evaluated as well. To our knowledge this is the first investigation on the antibacterial activity of Ga complexes with thiosemicarbazones.

R = H (in H2Fo4Ph), CH_3 (in H2Ac4Ph) or Ph (in H2Bz4Ph)

Fig. 1. Generic representation for *N*(4)-phenyl-2-pyridine-derived thiosemicarbazones.

2. Experimental

2.1. Materials and measurements

All common chemicals were purchased from Aldrich and used without further purification. The thiosemicarbazones were prepared according to standard procedures [10].

Partial elemental analyses were performed on a Perkin Elmer CHN 2400 analyzer. An YSI model 31 conductivity bridge was employed for molar conductivity measurements. Infrared spectra were recorded on a Perkin Elmer FT-IR Spectrum GX spectrometer using nujol mulls between CsI plates. NMR spectra were obtained with a Bruker DPX-200 Avance (200 MHz) spectrometer using DMSO-d_6 as the solvent and TMS as internal reference.

2.2. Synthesis of gallium(III) complexes with N(4)-phenyl-2-formylpyridine thiosemicarbazone, N(4)-phenyl-2-acetylpyridine thiosemicarbazone and N(4)-phenyl-2-benzoylpyridine thiosemicarbazone

The gallium(III) complexes were obtained by refluxing, for 3 h, an ethanol solution (25 mL) of the desired thiosemicarbazone (2 mmol) with gallium nitrate in 2:1 ligand-to-metal molar ratio. The resulting solids were filtered off then washed with ethanol followed by diethyl ether, and dried *in vacuo*.

2.2.1. Bis[N(4)-phenyl-2-formylpyridinethiosemicarbazone]-gallium(III) nitrate [Ga(H2Fo4Ph)$_2$](NO$_3$)$_3$ (**1**)

Yellow solid. *Anal.* Calc. for $C_{26}H_{24}GaN_{11}O_9S_2$: C, 40.64; H, 3.15; N, 20.05. Found: C, 40.98; H, 3.21; N, 20.25%. FW: 768.39 g mol^{-1}. IR (CsI/nujol, cm^{-1}): ν(C=N) 1608, ν(C=S) 760, ν(NO$_3$) 1421, 1320, ρ(py) 613, ν(Ga–N$_{azometh.}$) 441, ν(Ga–S) 320, ν(Ga–N$_{py}$) 232. ^{1}H RMN [200 MHz, DMSO-d_6, δ (ppm)] main signals: 12.52 [s, 1H, N(3)H]; 10.47 [s, 1H, N(4)H]; 8.82 [d, 1H, H(6)]; 8.55 [d, 1H, H(3)]; 8.38 [t, 1H, H(4)]; 8.24 [s, 1H, H(7)]; 7.82 [t, 1H, H(5)]. ^{13}C RMN [200 MHz, DMSO-d_6, δ (ppm)] main signals: 176.7 [C(8)=S]; 148.4 [C(2)]; 144.7 [C(6)]; 143.1 [C(4)]; 138.5 [C(9)]; 135.6 [C(7)=N]; 125.7 [C(5)]; 124.3 [C(3)]. Λ_M = 190.94 Ω^{-1} cm^2 mol^{-1} in DMF. Yield 69%.

Yellow solid. *Anal.* Calc. for $C_{28}H_{26}GaN_9O_3S_2$: C, 50.16; H, 3.91; N, 18.80. Found: C, 50.13; H, 3.75; N, 18.50%. FW: 670.42 g mol^{-1}. IR (CsI/nujol, cm^{-1}): ν(C=N) 1600, ν(C=S) 764, ν(NO$_3$) 1424, 1332, ρ(py) 621, ν(Ga–N$_{azometh.}$) 443, 438, ν(Ga–S) 343, 339, ν(Ga–N$_{py}$) 216. ^{1}H RMN [200 MHz, DMSO-d_6, δ (ppm)] main signals: 10.25 [s, 1H, N(4)H]; 8.36 [d, 1H, H(6)]; 8.11 [d, 1H, H(3)]; 8.30 [dt, 1H, H(4)]; 8.11 [d, 1H, H(3)] 7.68 [t, 1H, H(5)]; 2.95 [s, 3H, H(15)]. ^{13}C RMN [200 MHz, DMSO-d_6, δ (ppm)] main signals: 171.5 [C(8)=S]; 151.1 [C(2)]; 145.1 [C(6)]; 144.6 [C(7)=N]; 142.8 [C(4)]; 142.4 [C(3)]; 139.5 [C(9)]; 128.3 [C(5)]; 125.2 [C(3)]. Λ_M = 75.57 Ω^{-1} cm^2 mol^{-1} in DMF. Yield 78%.

2.2.3. Bis[N(4)-phenyl-2-benzoylpyridinethiosemicarbazonato]-gallium(III) nitrate [Ga(2Bz4Ph)$_2$]NO$_3$ (**3**)

Orange solid. *Anal.* Calc. for $C_{38}H_{30}GaN_9O_3S_2$: C, 57.44; H, 3.81; N, 15.87. Found: C, 57.48; H, 3.84; N, 16.12%. FW: 794.56 g mol^{-1}. IR (CsI/nujol, cm^{-1}): ν(C=N) 1597, ν(C=S) 760, ν(NO$_3$) 1423, 1331, ρ(py) 616, ν(Ga–N$_{azometh.}$) 437, 432, ν(Ga–S) 344, 337, ν(Ga–N$_{py}$) 205. ^{1}H RMN [200 MHz, DMSO-d_6, δ (ppm)] main signals: 10.43 [s, 1H, N(4)H]; 8.34 [d, 1H, H(6)]; 8.25 [t, 1H, H(4)]; 7.71 [d, 1H, H(3)]; 7.57 [d, 1H, H(5)] 7.68 [t, 1H, H(5)]; 2.95 [s, 3H, H(15)]. ^{13}C RMN [200 MHz, DMSO-d_6, δ (ppm)] main signals: 172.3 [C(8)=S]; 149.1 [C(2)]; 145.2 [C(6)]; 144.7 [C(7)=N]; 142.7 [C(4)]; 142.4 [C(3)]; 139.2 [C(9)]; 130.7 [C(5)]; 126.2 [C(3)]. Λ_M = 50.78 Ω^{-1} cm^2 mol^{-1} in DMF. Yield 73%.

As shown by crystal structure determinations (see Section 3.3) upon dissolution of complex **2** in DMSO conversion to bis[*N*(4)-phenyl-2-acetylpyridine thiosemicarbazonato]gallium(III) nitrate DMSO solvate, [Ga(2Ac4Ph)$_2$]NO$_3$·DMSO (**2a**) occurred.

2.3. Crystallography

Data were obtained at 120 K with Mo Kα radiation by means of the Enraf Nonius KappaCCD area detector diffractometer of the EPSRC crystallographic service, based at the University of Southampton. Data collection was carried out under the control of the program COLLECT [11] and data reduction and unit cell refinement

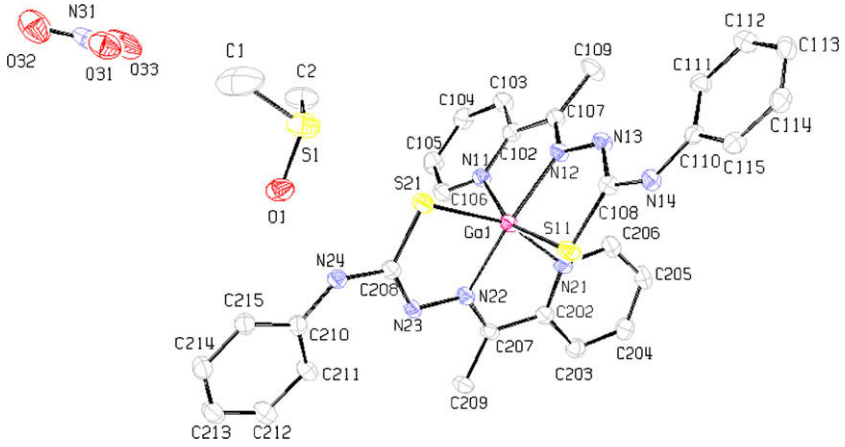

Fig. 2. Atom arrangement and atom numbering scheme for molecule of [Ga(2Ac4Ph)$_2$]NO$_3$·DMSO (**2a**). For purposes of clarity, the hydrogen atoms have been omitted. Probability ellipsoids are drawn at the 50% level. Hydrogens on nitrogens are drawn as spheres of arbitrary radii.

were achieved with the COLLECT [11] and DENZO programs [12]. The program ORTEP-3 for Windows [13] was used in the preparation of Fig. 2 and SHELXL-97 [14] and PLATON [15] in the calculation of molecular geometry. The structure was solved by direct methods using SHELXS-97 [16] and fully refined by means of the program SHELXL-97 [14]. Difference map peaks provided positions for the hydrogen atoms of the NH groups for which the coordinates, along with isotropic displacement parameters, were fully refined. All other hydrogen atoms were placed initially in calculated positions. Crystal data and structure refinement details are listed in Table 1.

2.4. Antibacterial activity

Antibacterial activity was evaluated by minimum inhibitory concentration (MIC) using the macro dilution test [17–20]. *P. aeruginosa* (ATCC 27853) stored in Brain Heart Infusion (BHI) broth was subcultured for testing in the same medium and grown at 37 °C. Then the bacterial cells were suspended, according to the McFarland protocol in saline solution [19], to produce a suspension of about 10^5 CFU mL^{-1} (colony-forming units per mL). Serial dilutions of the test compounds, previously dissolved in dimethyl sulfoxide (DMSO), were prepared in test tubes to final concentrations of 512, 256, 128, 64, 32, 16, 8, 4, 2, and 1 μg mL^{-1}; 100 μL of a 24-h-old-inoculum was added to each tube. The MIC, defined as the lowest concentration of the test compound which inhibits the visible growth after 20 h, was determined visually after incubation for 20 h at 37 °C. Tests using tetracycline hydrochloride and DMSO as controls were carried out in parallel. All tests were performed in triplicate with full agreement between results.

3. Results and discussion

Microanalyses and molar conductivity data suggest the formation of $[Ga(H2Fo4Ph)_2](NO_3)_3$ (**1**), $[Ga(2Ac4Ph)_2]NO_3$ (**2**) and $[Ga(2Bz4Ph)_2]NO_3$ (**3**). In complex **1** the thiosemicarbazone acts as a neutral ligand while in **2** and **3** it is attached to the metal centre in the anionic form.

3.1. Infrared Spectra

The vibrations attributed to ν(C=N) at 1600–1588 cm^{-1} in the spectra of the free thiosemicarbazones shift to 1608–1597 cm^{-1} in the spectra of the complexes, in agreement with coordination via the azomethine nitrogen [8–10,21].

The ν(C=S) absorption is observed at 774 cm^{-1} in the spectrum of H2Fo4Ph. This absorption shifts to 760 cm^{-1} in the spectrum of **1**, according to coordination of a thione sulfur. In the spectra of H2Ac4Ph and H2Bz4Ph the ν(C=S) absorption is found at 801 and 798 cm^{-1}, respectively, and it shifts to 764 and 760 cm^{-1} in the spectra of **2** and **3**, in agreement with coordination of a thiolate sulfur [21,22].

The in-plane deformation mode of the pyridine ring at 599–583 cm^{-1} in the spectra of the uncomplexed thiosemicarbazones shifts to 621–613 cm^{-1} in complexes **1–3**, suggesting coordination of the hetero-aromatic nitrogen [21–23].

Absorptions at 1424–1421 cm^{-1} and 1331–1320 cm^{-1} were attributed to vibrations of the nitrate group as counter-ion in the spectra of all complexes [24]. New absorptions at 443–432 cm^{-1}, 344–337 cm^{-1} and 240–205 cm^{-1} were attributed to ν(Ga–N), ν(Ga–S) and ν(Ga–N_{py}), respectively [6].

Hence, the infrared data suggest coordination of the thiosemicarbazones via the N_{py}–N–S chelating system in the all cases.

3.2. NMR Spectra

The ^{1}H and ^{13}C NMR assignments for the gallium(III) complexes in DMSO-d_6 are reported in Section 2.2. The ^{1}H resonances were attributed based on chemical shifts, multiplicities and coupling constants. The carbon type (C, CH) was determined by using DEPT135 experiments. The assignments of the protonated carbons were made by 2D heteronuclear-correlated experiments (HMQC) using delay values which correspond to ^1J(C, H).

In the ^{1}H NMR spectra of the free thiosemicarbazones the signals of N(3)–H were found in the δ 13.14–10.63 range. Only one signal of N(3)–H at δ 12.07 and at δ 10.67 was found for H2Fo4Ph and H2Ac4Ph, respectively, which is consistent with hydrogen bonding to the oxygen of DMSO and with the presence of the thiosemicarbazones in the *E* configuration [10]. The lower frequency signal for the acetyl derivative is probably due to the gamma gauche effect of the methyl group attached to C7 which makes N(3)–H less acidic [25]. Two signals at δ 10.63 and δ 13.14 were observed for H2Bz4Ph, suggesting the presence of the *E* and *Z* configurational isomers, respectively. In the first N(3)–H is hydrogen-bonded to DMSO and in the second N(3)–H is hydrogen-bonded to the hetero-aromatic nitrogen [10]. Again the gamma gauche effect of the phenyl group makes N(3)–H of the phenyl derivative less acidic in comparison to that of the formyl thiosemicarbazone [25].

In the ^{1}H NMR spectra of the gallium(III) complexes only one signal was observed for each hydrogen. In **1** the signal for N(3)–H at δ 12.52 indicates that the thiosemicarbazone remains protonated after coordination. The absence of the signal for N(3)–H in the spectra of **2** and **3** is in agreement with the presence of an anionic thiosemicarbazone in both cases. Upon coordination with formation of complexes **1–3** the pyridine hydrogens undergo significant shifts, indicating complexation through the hetero-aromatic nitrogen [10,21].

In the ^{13}C NMR spectrum the signals of C(7)=N and the pyridine carbons shift significantly upon coordination and formation of **1–3**, in accordance with complexation through the imine nitrogen and the hetero-aromatic nitrogen. The C(8)=S signal undergoes a small shift after formation of **1**, in accordance with the coordination of a thione sulfur. Upon formation of complexes **2** and **3** significant shifts were observed for the signals of C(8)=S, in accordance with coordination of a thiolate sulfur. The NMR data suggest tridentate

Table 2
Selected Bond lengths (Å) and angles (°) for $[Ga(2Ac4Ph)_2]NO_3{\cdot}DMSO$ (**2a**).

N(11)–Ga(1)–S(21)	93.4(1)	N(21)–Ga(1)–S(11)	91.6(1)
N(12)–Ga(1)–N(21)	92.4(1)	N(22)–Ga(1)–N(11)	96.3(1)
N(11)–Ga(1)–N(21)	85.5(1)	N(22)–Ga(1)–N(12)	168.0(1)
S(11)–Ga(1)–S(21)	96.75(4)		

coordination through the N_{py}–N–S system in all cases. Hence, in complexes **1–3** the thiosemicarbazone adopts the *E* configuration [10,21,22].

3.3. X-ray Crystallography

Attempts to crystallize complex **2** from DMSO solution led to the isolation of $[Ga(2Ac4Ph)_2]NO_3{\cdot}DMSO$ (**2a**). The atom arrangements and atom numbering scheme for molecule **2a** are shown in Fig. 2. Selected geometric parameters are listed in Table 2.

In **2a** the gallium(III) cation is in a distorted octahedral environment. The sulfur atoms are in a *cis* arrangement, with a S(11)–Ga–S(21) angle of 96.75(4)° and *trans* to the pyridinyl nitrogen atoms. Distortion from an ideal octahedral arrangement mainly arises from the small N–Ga–N and N–Ga–S chelate bite angles, which are very close to 80° (see Table 2).

The free thiosemicarbazone crystallizes in the *EE* conformation [26]. A twisting of approximately 180° in the N3–C8 bond of the thiosemicarbazone to match the steric requirements of tridentate coordination was evidenced. Therefore, in complex **2a** the ligand adopts the *EZ* conformation. Hence some angles undergo significant changes on complexation. The C8–N3–N2 angle goes from 118.89° in H2Ac4Ph [26] to 113.4(3)° and 113.6(3)° in **2a**; N3–C8–S1 goes from 119.68° in H2Ac4Ph [26] to 126.6(3)° and 126.7(3)° in **2a**.

Table 3
Hydrogen bonding parameters (Å,°) for $[Ga(2Ac4Ph)_2]NO_3{\cdot}DMSO$ (**2a**).

D–H···A	D–H	H···A	D···A	D–H···A
N(14)–H(14)–O(1)^{i}	0.896(14)	2.005(15)	2.873(4)	163(4)
N(24)–H(24)–O(1)	0.900(14)	2.051(16)	2.931(5)	166(4)

Symmetry operations: *i*: 1/2 + *x*, 1/2-*y*, -*z*.

There is a slight shortening of the bond distance between Ga and the imine nitrogen (2.058(3) and 2.048(3) Å) compared to the distance between Ga and the hetero-aromatic nitrogen (2.122(3) and 2.127(3) Å). Similar feature was observed in the gallium complex with 2-acetylpyridine *N*(4)-dimethylthiosemicarbazone, with Ga–N_{imine} bond distances (2.033(2) and 2.038(2) Å) longer than the Ga–N_{py} bond distances (2.131(2) and 2.114(2) Å) [6]. By contrast, in the case of the complex with acetylpyrazine *N*,*N*-dimethylthiosemicarbazone the Ga–N_{py} bond distances (2.036(2) and 2.037(2) Å) are shorter than the Ga–N_{imine} bond distances (2.141(2) and 2.164(2)Å) [7].

The expected lengthening of the C8–S1 bonds from 1.677 Å in H2Ac4Ph [26] to 1.743(4) and 1.747(4) Å in **2a**, and shortening of the N3–C8 bonds from 1.358 Å in H2Ac4Ph [26] to 1.327(5) and 1.322(5) Å in **2a** were observed. Therefore the C8–S1 bond changes from a double to a predominantly single bond whereas N3–C8 acquires some double bond character.

Of interest, DMSO solvate is hydrogen bonded via oxygen to N(14)–H(14)^{i} and N(24)–H(24). Details are listed in Table 3 (see Fig. 3) [symmetry code: *i*: 1/2 + *x*, 1/2 − y, −z].

3.4. Antibacterial activity

Table 4 lists the minimum inhibitory concentration (MIC) against the growth of *P. aeruginosa* (ATCC 27853) for the thiosemicarbazones and their gallium(III) complexes, together with values obtained for tetracycline hydrochloride as positive control, and for gallium nitrate.

The values of MIC were 736 μM (H2Fo4Ph), 269 μM (H2Ac4Ph) and 111 μM (H2Bz4Ph), indicating that the C7-substituent affects the antibacterial activity. Gallium nitrate showed a poor effect in the studied strain. Upon coordination to gallium(III) a significant increase in the activities of both Ga (up to fifteen fold) and the thiosemicarbazones (up to ten-fold) was observed, with values of MIC

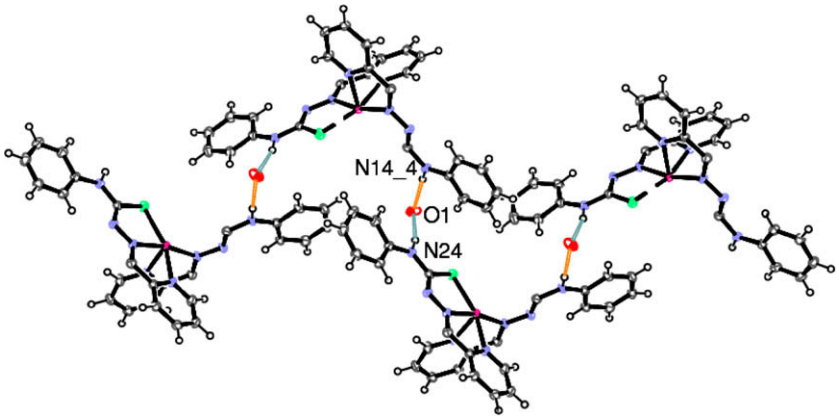

Fig. 3. Hydrogen bonding of $[Ga(2Ac4Ph)_2]NO_3{\cdot}DMSO$ (**2a**) formed by solvent molecule and N–Hs. For purposes of clarity, anion and methyl carbons of cation were omitted.

Table 4
Minimum Inhibitory Concentration (MIC) against *P. aeruginosa* ATCC 27853 for *N*(4)-phenyl-2-formylpyridine thiosemicarbazone (H2Fo4Ph), *N*(4)-phenyl-2-acethylpyridine thiosemicarbazone (H2Ac4Ph) and *N*(4)-phenyl-2-benzoylpyridine thiosemicarbazone (H2Bz4Ph), their gallium(III) complexes, gallium nitrate and tetracycline hydrochloride.

Compounds	MIC (μmol L^{-1})
H2Fo4Ph	736
$[Ga(H2Fo4Ph)_2](NO_3)_3$ (**1**)	75
H2Ac4Ph	269
$[Ga(2Ac4Ph)_2]NO_3$ (**2**)	42
H2Bz4Ph	111
$[Ga(2Bz4Ph)_2]NO_3$ (**3**)	47
Gallium nitrate	667
Tetracycline hydrochloride	24

in the 75–42 μM range for complexes **1–3**, which were of the same order of magnitude as the value of MIC determined for tetracycline.

As already mentioned, Ga has been used as a strategy to disrupt bacterial Fe metabolism in *P. aeruginosa* [2]. In the present case the activity of Ga was substantially enhanced upon coordination to the thiosemicarbazones. Therefore the thiosemicarbazones were probably able to successfully deliver the metal to the bacterial cell. Changes of lipophilicity upon complexation could explain such effect. Metal-ligand synergism could also occur particularly in the cases of complexes **2** and **3**.

4. Conclusions

The foregoing results suggest that coordination of Ga to thiosemicarbazones could be an interesting strategy for enhancing both metal and ligand activities and that thiosemicarbazones could function as vehicles for increasing Ga bioavailability. Moreover, since thiosemicarbazones are in general poorly active against *gram*-negative bacteria [5], coordination to Ga could be an efficient strategy to broaden their spectrum of antibacterial action.

Supplementary data

CCDC 701075 contains the supplementary crystallographic data for **2a**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

The β-aminovinylketone ligands $CH_3C(NH_2)CHC(O)CH_3$ (**1**) and $CH_3C(NHCH_3)CHC(O)CH_3$ (**2**) were synthesized from 2,4-pentandione by amination with a water solution of the appropriate amine in toluene at room temperature. The reactions of **1** and **2** with the $PdCl_2$ salt in amine medium gave the volatile chelate metal complexes $Pd[CH_3C(NH)CHC(O)CH_3]_2$ (**3**) and $Pd[CH_3C(NCH_3)CHC(O)CH_3]_2$ (**4**). The obtained compounds were identified by elemental analysis, ^1H and ^{13}C NMR, IR-spectroscopy and were characterized by TGA and a single-crystal X-ray diffraction study. In compounds **3** and **4**, the Pd atom has a square coordination environment Pd O_2N_2.

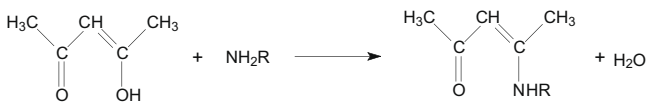
1. Introduction



An important practical implementation of volatile metal compounds concerns the preparation of metal films by the chemical vapor deposition method (MO CVD) [1–3]. Volatile molecular β-diketonates and β-ketoiminates of palladium(II) are the most adequate precursors for the preparation of palladium films [4,5]. β-Ketoimine is an analogue of β-diketone with one oxygen atom substituted by an NH- or NR-group. Metal β-diketonates and β-ketoiminates, having the same substituents in the ligand, possess similar volatility [6]. The first offer, however, an advantage over the latter because of the lower oxygen content in the molecule which decreases the substrate oxidation process upon the preparation of a metal film. Besides, replacing two oxygen atoms in the chelate with nitrogen improves the thermal stability of the complexes compared to the O–O-chelate analogues [7], and this renders them the most suitable for application in CVD. Metal ketoiminates, however, have been studied and applied to a lesser degree than metal diketonates because of the hampered availability of β-ketoimines compared to β-diketones. Upon the synthesis of metal complexes with these ligands, ketoimines need to be prevented from undergoing saponification. Unlike Pd(II) β-diketonates, which are rather well studied and reported in [8–11], Pd complexes based on enamineketones are less studied. Structural studies of fluorinated Pd(II) β-ketoiminates are known in the literature [5,7,12]. The synthesis of the palladium β-ketoiminate, $Pd(ki)_2$, is given in Ref. [13]. A crystallographic study performed in Ref. [14] suggests that this compound is isostructural to the complexes $Cu(ki)_2$ and $Ni(ki)_2$. The complete solution of the crystal structure of $Pd(ki)_2$ is unavailable in the literature and in Structure Databases to date.

This paper reports the synthesis, properties and structures of two β-aminovinylketones: 4-amino-3-penten-2-one – $CH_3C(NH_2)$-$CHC(O)CH_3$ (Hki) (**1**) and 4-methylamino-3-penten-2-one – $CH_3C(NHCH_3)CHC(O)CH_3$ (Hmki) (**2**), as well as of two volatile Pd(II) complexes with these ligands: $Pd[CH_3C(NH)CHC(O)CH_3]_2$, $Pd(ki)_2$ (**3**) and a new complex $Pd[CH_3C(NCH_3)CHC(O)CH_3]_2$, $Pd(mki)_2$ (**4**). The crystal structures of compounds **1**–**4** are studied for the first time.

2. Results and discussion

2.1. Synthesis and structural characterization of *1* and *2*

There are many techniques for the synthesis of β-aminovinylketones, including the condensation of β-diketones with amines [15–18]. To prepare the ligands, we have used a simple method [19]. The ligands 4-amino-3-penten-2-on (**1**) and 4-methylamino-3-penten-2-on (**2**) were obtained from 2,4-pentandione (Hacac) following the scheme:

where R = H (**1**), CH_3 (**2**).

doi:10.1016/j.poly.2009.02.043

A mixture of acetylacetone (Hacac) with a concentrated aqueous amine solution, and toluene in a 1:1:1 volume ratio was used. This mixture was stirred in a closed vessel for 12 h. The enaminoketones, isolated from toluene, were purified by sublimation in a vacuum. This procedure allowed us to obtain the (N,O)-ligands **1** and **2** in a high yield. Chemical analysis confirmed the presence of one nitrogen atom in each of the ligands. With the general similarity of the IR spectra of enaminoketones, the spectrum of **1** shows a strong wide band over the 3334 cm^{-1} range, which is associated with valence ν(N–H) vibrations [20].

The synthesized β-aminovinylketones, 4-amino-3-penten-2-one (**1**) and 4-methylamino-3-penten-2-one (**2**), may be represented as three tautomeric structures, similar to that we discussed earlier for 2,2,6,6-tetramethyl-3-amino-4-hepten-5-one [21] with an oxygen in the ketone or enol form. The ^1H and ^{13}C NMR spectra of solutions of **1** and **2** in $CDCl_3$ unambiguously reveal that the given compounds, as all other enaminoketones, exist in the solution predominantly in the carbonyl form [16]. Also we assume the formation of an intramolecular hydrogen bond between the proton of the RNH-group and the oxygen atom (Fig. 1). In the ^1H NMR spectra, the broad signal near 10 ppm corresponds to this hydrogen atom of the (RN···H···O–) moiety.

An X-ray structure study revealed that the ligand Hki (**1**) has a molecular structure, which consists of isolated molecules (Fig. 2a). In the structure, there are two crystallographically independent molecules of approximately the same geometry. Not taking into account the hydrogen atoms of the methyl groups, the molecules are planar to within 0.02 Å and the angle between the normals to the planes of two independent molecules is 50.8°. The average length of the O–C bonds (1.256 Å) is less than that of the N–C bonds (1.326 Å) by 0.07 Å. The difference in the corresponding values of C–C_γ is no more than 0.03 Å, and the average value of the terminal C–C_{Methyl} bonds is 1.501 Å. The deviations of the bond angles on the carbon atoms from 120° are no more than 3.6°. The molecules are linked by N–H···O bonds with N···O and H···O equal to 2.86 and 1.95 Å, respectively.

The compound Hmki (**2**) crystallizes as colorless transparent plates, which tend to twin, resulting in the high *R*-value. Structure **2** is of the molecular type and is built up of ligand hydrogen-bonded molecules (Fig. 2b). The molecule is practically planar, since all non-hydrogen atoms are located in the same plane to within 0.013 Å. The O–C bond length (1.247 Å) is shorter than that of N–C (1.337 Å) by 0.09 Å; the corresponding C–C bonds are 1.396 Å and the C(1)–C(3)–C(4) bond angle is 124.5°. The terminal C–C and N–C bonds are 1.512 and 1.454 Å, respectively. In the structure, the molecules are hydrogen-bonded into planar centrosymmetric dimers, which form the (1 2 1) layers with d = 3.44 Å, and the N–H···O bonds are 2.99 (2.28) Å.

2.2. Synthesis and structure characterization of $Pd[CH_3C(NH)CHC(O)CH_3]_2$ (**3**) and $Pd[CH_3C(NCH_3)CHC(O)CH_3]_2$ (**4**)

For the synthesis of the β-ketoiminate complexes $Pd(ki)_2$ (**3**) and $Pd(mki)_2$ (**4**), we have used a new procedure based on the interaction between the $PdCl_2$ salt and the ligand HL (where HL is Hki (**1**) or Hmki (**2**)) in the corresponding amine medium, according to the following scheme:

$$PdCl_2 \xrightarrow{\text{excess } NH_2R\ (solv)} [Pd(NH_2R)_4]Cl_2 \xrightarrow{+2HL,\ pH\ 8-9} PdL_2,$$

where R = H or CH_3.

The reaction occurs via an intermediate stage, with the formation of the colorless $[Pd(NH_2R)_4]Cl_2$ complex, which subsequently reacts with the ligand. The intermediate complex is stable only in alkaline media and is readily converted into the sparingly soluble *trans*-$[Pd(NH_2R)_2Cl_2]$ at the lower pH of the solution. Therefore for the chelate of the palladium complex to be obtained in high yield, the reaction conditions should rule out the formation of the sparingly soluble $[Pd(NH_2R)_2Cl_2]$, whose precipitation withdraws the palladium from the reaction and lowers the yield of the target product.

The IR spectrum of complex **3** shows a band for the N–H vibrations at 3284 cm^{-1} [20]. The lack of this band in the spectrum of compound **4** confirms indirectly the presence of the N–CH_3 bond in this compound. This data and elemental analyses results confirm the successful preparation of the palladium complexes **3** and **4**.

The structure of the complex $Pd(ki)_2$ (**3**) is of the molecular type and comprises the isolated complexes, shown in Fig. 3. There are two crystallographically independent complexes with similar structures. The Pd(1) complex lies on a two-fold axis, and the Pd(2) complex has 2 2 2 symmetry. The O and N atoms are statistically located in the same position with 0.5 occupancy that is, the complexes are simultaneously *cis*- and *trans*-isomers. The Pd–O (N)

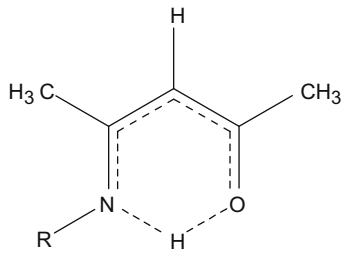

Fig. 1. Supposed tautomeric form of enaminoketones in solution (R = H, CH_3).

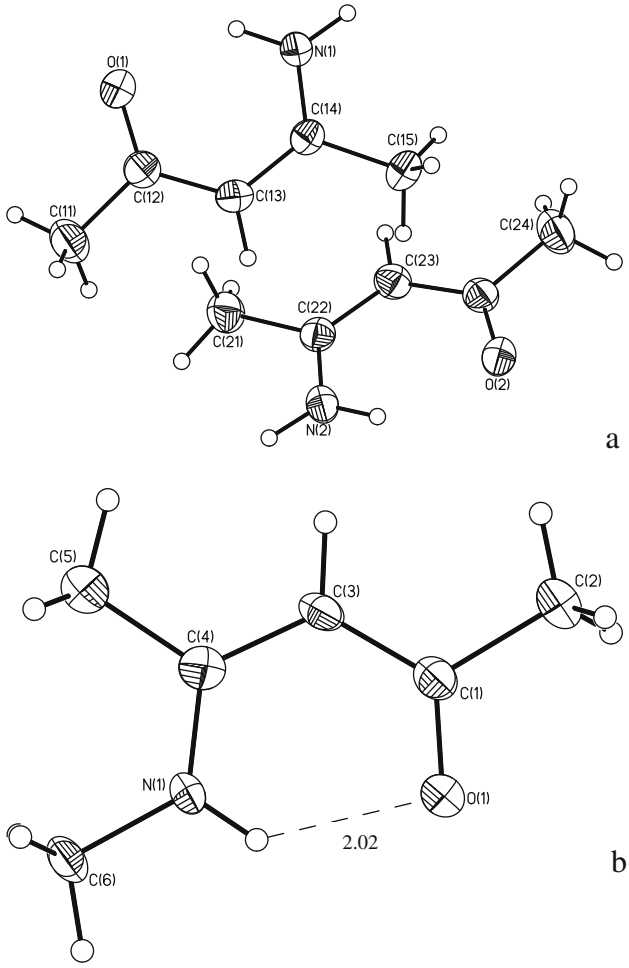

Fig. 2. ORTEP drawing of enaminoketone molecules: a – **1**, b – **2**.

bond lengths are similar, within the measuring error, with an average value of 1.984 Å, and the average value of the chelate O–Pd–N angles is 92.8°. In metal cycles, the average values of the O (N)–C, C–C_γ and C–C_{Methyl} bonds are 1.305, 1.389 and1.506 Å, respectively. The angles of bending of the cycles along the O (N)···O (N) line are no more than 1.9°, hence the molecules in the complexes, except the terminal hydrogen atoms, are practically planar, to within 0.073 Å. The angle between the normals to the planes of the two independent palladium complexes is 58.8°. Fig. 5a shows the general packing of the molecules along the *z*-axis. In the structure, the molecules of the complexes are packed into one-dimensional associates (ribbons), as if located on the 6_3 pseudoaxes with Pd···Pd distances of 5.67 and 5.74 Å. Such ribbons form the (0 1 1) layers with $d = 7.52$ Å. The intermolecular interactions between the layers are determined by the H···H contacts over the 2.37–2.63 Å range.

In the Pd(mki)$_2$ complex (**4**), the Pd atom has a square coordination of two oxygen and two nitrogen atoms (Fig. 4). The difference between the Pd–O (1.972 Å) and Pd–N (2.041 Å) bond lengths is 0.07 Å and the chelate O–Pd–N angle is 92.4°. In the metal cycles, the N–C and O–C bonds are practically equal, and the C–C and C–C_γ bonds differ by 0.07 Å. The molecule of the complex, not taking into account the hydrogen atoms, is planar to within 0.03 Å, and the angle of bending of the metal cycles along the O···N line is 4.6°. The C–C_{Methyl} and N–C_{Methyl} separations are 1.51 and 1.47 Å, respectively. Fig. 5b shows the molecule packing in the crystal along the *a*-axis. All the complexes are identically oriented and packed along the *x*-axis with a minimal Pd···Pd distance of 6.077 Å (the "*a*" parameter). We can also isolate the $(\bar{1}\,\bar{1}\,1)$ layers in the complexes with the interlayer distance $d = 3.59$ Å. The hydrogen atoms of the methyl groups alone emerge at the outer surfaces of the layers, and the molecule skeleton of the non-hydrogen atoms lies fully in the layer plane. The shortest contacts to the methyl groups of the neighboring complexes, which complete the Pd coordination, are Pd···C (H) 4.10 (2.92) Å.

*2.3. Thermogravimetric study (TG) of Pd[$CH_3C(NH)CHC(O)CH_3$]$_2$ (**3**) and Pd[$CH_3C(NCH_3)CHC(O)CH_3$]$_2$ (**4**)*

The TG study was performed under a helium flow up to 350 °C. To perform a comparative analysis of the volatility and thermal stability of the Pd(ki)$_2$ (**3**) and Pd(mki)$_2$ (**4**) complexes and the comparison with the (O,O)-chelate analogue, the TG curves for the Pd complex with acetylacetone, Pd(acac)$_2$, obtained under the same conditions, are given in Fig. 6. Among the considered palladium(II) complexes, complex **4** is the most volatile. A loss of the mass of this complex through sublimation is only ~90% owing to partial decomposition. This is also true for the other ketoiminate complex **3**, with a significant thermal stability but lesser volatility as compared to its O,O chelate analogue, Pd(acac)$_2$. The thermal

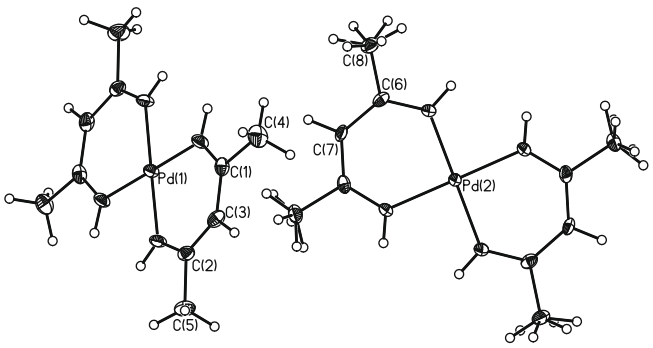

Fig. 3. The structure of the palladium(II) β-ketoiminate complexes in compound **3**.

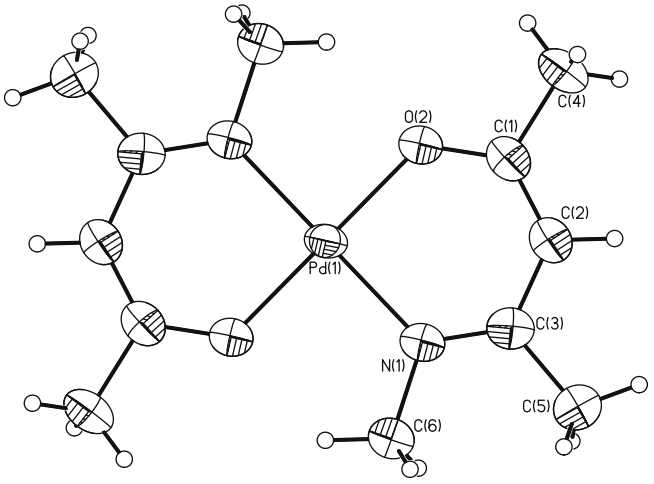

Fig. 4. ORTEP drawing of the palladium (II) β-methylketoiminate (**4**).

analysis of the Pd ketoiminates showed that replacing the NH group with the NCH_3 group in the chelate significantly increased the volatility of Pd(mki)$_2$ (**4**).

3. Concluding remarks

The ligands $CH_3C(NH_2)CHC(O)CH_3$ (**1**) and $CH_3C(NHCH_3)CHC(O)CH_3$ (**2**) were synthesized from 2,4-pentandione by amination with a water solution of the appropriate amine in toluene at room temperature. Pd[$CH_3C(NH)CHC(O)CH_3$]$_2$ (**3**) and Pd[$CH_3C(NCH_3)CHC(O)CH_3$]$_2$ (**4**) have been synthesized in water amine solutions. The obtained compounds have been identified by elemental analysis, ^{1}H and ^{13}C NMR, IR-spectroscopy, and were characterized by TGA and a single-crystal X-ray diffraction study. A crystallographic analysis has shown that metal complexes (**3**) are isostructural to β-ketoiminate complexes of Cu(II) and Ni(II).

4. Experimental

4.1. General considerations

Hacac (2,4-pentandione) of 99% purity (Merck) was used without pretreatment. Commercially available $PdCl_2$, aqueous ammonia and methylamine of adequate purity were used. The synthesis of Hki (**1**) and Hmki (**2**) was carried out according to Ref. [19].

Ligands **1** and **2**, and complexes Pd(ki)$_2$ (**3**), Pd(mki)$_2$ (**4**) and Pd(acac)$_2$ have been purified by vacuum sublimation in a gradient tube oven ($P \sim 10^{-2}$ Torr, $T = 50$–250 °C). Elemental analysis was performed with a Carlo-Erba 1106 (Italy) device. Infrared spectra were measured in KBr pellets, with the use of a Scimitar FTS2000 spectrometer. NMR spectra were recorded on a Bruker MSL300 spectrometer; chemical shifts were referenced to the proton impurity of the NMR solvent (^{1}H) or to the NMR solvent (^{13}C). The thermal analysis was performed in an Ar flow at a heating rate of 10 K/min (~1–3 mg samples) using a NETZSCH TG 209 F1 device.

X-ray intensity data were collected on a Bruker X8Apex CCD diffractometer at 150 K using standard techniques (ω- and φ-scans of narrow frames) and corrected for absorption effects (SADABS). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 using the SHELX97 program set (Bruker AXS Inc., 2004) [22]. Crystallographic data and details of single-crystal diffraction experiments for compounds **1**–**4** are given in Table 1. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms of CH_3 groups were calculated by geometrical methods. Selected bond lengths and angles are in Tables 2 and 3.

4.2. Synthesis of $CH_3C(NH_2)CHC(O)CH_3$ ligand (*1*)

About 10 ml of acetylacetone, 10 ml of toluene, and 10 ml of 25% aqueous solution of ammonia were cooled to 5 °C and were mixed. The reaction mixture was kept in the closed vessel at room temperature for 12 h. Then the aqueous layer was isolated and washed with 25 ml toluene twice. The toluene solutions were combined, evaporated to 20 ml, and cooled to 0–5 °C. The white ketoimine precipitate, resulting from the cooled solution, was filtered off. A small amount of ketoimine was also isolated upon the evaporation. The crude product was separated on a rotary evaporator and recrystallized from heptane after cooling in a refrigerator. White crystals of pure ligand were obtained after sublimation in a vacuum (T = 150 °C, $P = 10^{-2}$ Torr). Yield ~ 60%. *Anal.* Calc. for C_5H_9NO: C, 60.58; H, 9.15; N, 14.13. Found: C, 60.39; H, 9.53; N, 14.45%.

^1H and ^{13}C NMR spectra in $CDCl_3$ solution indicate that the compound exists in the ketone form, giving a structure with an intramolecular hydrogen bond, shown in Fig. 1. ^1H NMR (300 MHz, 25 °C, ppm): 1.89 [s, $(CH_3)CN$]; 2.02 [s, $(CH_3)CO$]; 4.97 (s, CH); 5.0 (br, s, HNH); 9.7 (br, s, HNH–O). ^{13}C NMR{^1H} (75.4 MHz, 25 °C, ppm): 22.8 [s, $(CH_3)CN$]; 29.8 [s, $(CH_3)CO$]; 96.4 (s, CH); 160.7 (s, C–N); 196.9 (s, C=O).

IR (cm^{-1}): 3334 (vs), 3174 (vs), 2972 (s), 2907 (m), 2922 (m), 1619 (vs), 1537 (vs), 1414 (s), 1356 (s), 1290 (vs), 1196 (s), 1106 (m), 1019 (m), 989 (m), 931 (w), 896 (m), 749 (m), 629 (s), 554 (vw), 483 (vw), 396 (w). M.p.: 43–44 °C.

4.3. Synthesis of $CH_3C(HNCH_3)CHC(O)CH_3$ ligand (*2*)

Ligand **2** was prepared according to the above described procedure from acetylacetone (10 ml), toluene (10 ml) and a saturated 25% aqueous solution of methylamine (10 ml). The reagents were cooled to 5 °C and poured together with stirring. Then all the procedures for ligand **1** were followed. The crude product was separated on a rotary evaporator and recrystallized from heptane after cooling in a refrigerator. White crystals were obtained after sublimation in a vacuum (T = 120 °C, $P = 10^{-2}$ Torr). Yield ~ 80%. *Anal.* Calc. for $C_6H_{11}NO$: C, 63.68; H, 9.80; N, 12.38. Found: C, 63.46; H, 9.51; N, 12.61%.

^1H and ^{13}C NMR spectra in $CDCl_3$ solution indicate that the compound exists in the ketone form, giving a structure with intramolecular hydrogen bonds as shown in Fig. 1. ^1H NMR (300 MHz, 25 °C, ppm): 1.89 [s, $(CH_3)CN$]; 1.94 [s, $(CH_3)CO$]; 2.92 [d, $(CH_3)NH$, $^4J_{HH}$ = 5.3]; 4.91 (s, CH); 10.65 [br, s, $(CH_3)NH$–O]. ^{13}C NMR{^1H} (75.4 MHz, 25 °C, ppm): 19.2 [s, $(CH_3)CN$]; 29.3 [s, $(CH_3)CO$]; 29.9 [s, $(CH_3)N$]; 95.8 (s, CH); 164.0 (s, C–N); 195.1 (s, C=O).

IR (cm^{-1}): 3165 (vw), 3076 (vw), 2995 (vw), 2937 (vw), 1612 (vs), 1569 (vs), 1521 (s), 1461 (m), 1436 (s), 1352 (s), 1293 (vs), 1195 (m), 1071 (s), 1015 (m), 968 (m), 930 (w), 823 (s), 731 (s), 648 (w), 555 (vw), 532 (w), 393 (w). M.p.: 39–40 °C.

4.4. Synthesis of $Pd[CH_3C(NH)CHC(O)CH_3]_2$ (*3*)

A $PdCl_2$ sample (1 g, 5.6 mmol) was placed in an ammonia solution (25 ml of water and 25 ml of concentrated ammonia solution) and heated on a water bath until the salt completely dissolved and a colorless solution was obtained (the pH should be kept at a highly alkaline level). Then, ligand **1** (2.22 g, 22.4 mmol) dissolved in water (20 ml) was added to the solution. The pH of the reaction mixture decreases with the reaction time. The chelate complex $Pd(ki)_2$ (**3**) started to form slowly at pH 8–9, and the reaction was continued for at least 5 h. The precipitate was filtered off, washed with water, dried in air, and dissolved in benzene. The product isolated from benzene was purified by vacuum sublimation (T = 200 °C, $P = 10^{-2}$ Torr). Yield 1.1 g (65%). The $Pd(ki)_2$ complex is a yellow crystalline powder. The compound begins to decompose slowly at 245 °C. *Anal.* Calc. for $C_{10}H_{16}N_2O_2Pd$: C, 39.68; H, 5.33; N, 9.26. Found: C, 39.52; H, 5.18; N, 9.45%.

4.5. Synthesis of $Pd[CH_3C(NCH_3)CHC(O)CH_3]_2$ (**4**)

This complex was prepared according to the above described procedure for complex (**3**) from $PdCl_2$ (1 g, 5.6 mmol) and ligand **2** (2.54 g, 22.4 mmol) in 20 ml water. The yield of the sublimed product was 1.3 g (70%). The $Pd(mki)_2$ complex is a pale yellow crystalline powder. The compound begins to decompose slowly at 195 °C. *Anal.* Calc. for $C_{12}H_{20}N_2O_2Pd$: C, 43.58; H, 6.10; N, 8.47. Found: C, 43.37; H, 6.24; N, 8.24%.

^1H and $^{13}C\{^1H\}$ NMR spectra in $CDCl_3$ indicate that compound **4** exists in solution mainly as one of the two possible isomers, but the second one forms slowly in the solution on standing. ^1H NMR (300 MHz, 25 °C, ppm): 1.89 [s, $(CH_3)CN$]; 1.94 [s, $(CH_3)CO$]; 2.99 [s, $(CH_3)N$]; 4.83 (s, CH). ^{13}C NMR$\{^1H\}$ (75.4 MHz, 25 °C, ppm): 22.3 [s, $(CH_3)CN$]; 24.2 [s, $(CH_3)CO$]; 36.7 [s, $(CH_3)N$]; 99.2 (s, CH); 164,4 (s, C–N); 173.6 (s, C═O).

IR(cm^{-1}): 3356 (vw), 2991 (vw), 2910 (vw), 1591(s), 1573 (s), 1513 (vs), 1459 (s), 1391 (vs), 1273 (m), 1223 (m), 1134 (w), 1021 (m), 1004 (m), 951 (m), 862 (vw), 757 (m), 731 (w), 693 (vw), 653 (vw), 615 (vw), 467 (w), 405 (vw).

ABSTRACT

Two new bis(diphenylphosphino)isopropylphenylamines, $(PPh_2)_2N\text{-}C_6H_4\text{-}CH(CH_3)_2$, having the isopropyl substituent at the carbon atom 2 (**1**) or 4 (**2**), were prepared by the aminolysis of chlorodiphenylphosphine with isopropyl substituted aniline at the *ortho*- or *para*-position, respectively, under anaerobic conditions. Oxidation of **1** and **2** with either aqueous hydrogen peroxide, elemental sulfur or grey selenium in thf gave the corresponding oxides, sulfides and selenides $(Ph_2P{=}E)_2N\text{-}C_6H_4\text{-}CH(CH_3)_2$, where E = O, S or Se, respectively. The palladium and platinum complexes $[M\{(Ph_2P)_2N\text{-}C_6H_4\text{-}CH(CH_3)_2\}Cl_2]$ (M = Pd, Pt) and the copper complex $[Cu\{(Ph_2P)_2N\text{-}C_6H_4\text{-}CH(CH_3)_2\}_2]PF_6$ were isolated from the reaction of the bis(phosphino)anilines with $MCl_2(cod)$ or $[Cu(CH_3CN)_4]PF_6$, respectively. The new compounds were characterized by NMR, IR spectroscopy and elemental analysis. Furthermore, the solid-state structures of two representative complexes were determined using single crystal X-ray diffraction analysis. The compounds of palladium (**1d**) and platinum (**1e**), both mononuclear complexes, crystallize in the monoclinic $P2_1/c$ space group. In both compounds the metal ion has a distorted square–planar coordination geometry. The structural properties of complexes **1d** and **1e** in the solid state are very similar. The palladium complexes were also tested for their catalytic activities in C–C coupling reactions.

1. Introduction

Tertiary phosphines have long been used in the design and synthesis of transition metal complexes with catalytic properties [1–3], especially with late transition metals like nickel, rhodium, ruthenium, palladium and platinum [4] that can be used as highly active catalysts in industrially important reactions such as allylic alkylation [5–8], amination [9–11], the Heck reaction [12–20], Suzuki coupling [21–25], hydroformylation [26–29], and hydrogenation of olefins [30–33]. In particular, palladium complexes containing phosphine ligands serve as highly active catalysts for the straightforward formation of carbon–carbon bonds [34–37]. Compounds containing phosphorus–nitrogen direct bonds have been known for many years and their chemistry has been of considerable interest because of their applications in increasingly diverse fields [38,39]. The applications of chelating bis(phosphino)amine ligands is widespread in organometallic chemistry and in homogeneous catalysis as these ligands can be used for fine tuning the activity and selectivity of the catalyst [40]. A variety of PNP and related diphosphine ligands, specially in combination with Cr(III) compounds, were reported to be very active and efficient catalysts for ethylene tri- and tetramerization [41–44]. Bis(phosphino)amines display their versatility by exhibiting different coordination behavior when the donor–acceptor properties are altered by incorporating a substituent at the ligand backbone [45]. Synthesis and coordination chemistry of bis(phosphino)anilines have also been studied in some detail [46,47]. It has been shown that coordination of bis(phosphino)anilines to transition metal ions occurs mainly via the phosphorus centers due to the low basicity of the amine nitrogen, attributable to the P–N π interaction between the phosphorus d_π and nitrogen p_π orbitals [48].

Herein, we report the synthesis of two new bis(diphenylphosphino)anilines by the aminolysis of chlorodiphenylphosphine with isopropyl substituted aniline at the *ortho*- or *para*-positions and the corresponding oxides, sulfides and selenides as well as their complexes with selected transition metal ions (Cu^+, Pd^{2+} and Pt^{2+}). The

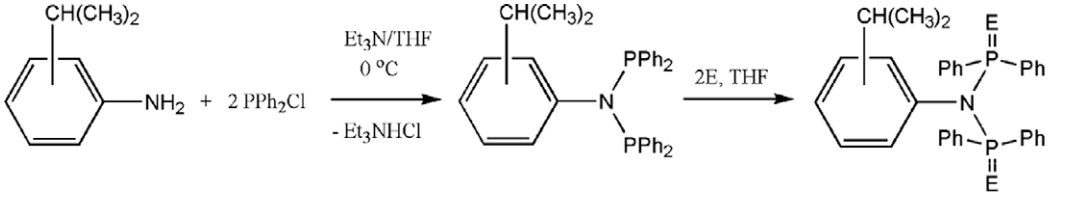
doi:10.1016/j.poly.2009.04.033

compounds were isolated from the reaction mixture by crystallization and fully characterized using elemental analysis, FT-IR, multinuclear NMR spectroscopy. The solid-state structures of two of the products were established by single crystal X-ray diffraction analyses. We also report on the catalytic activities of the palladium(II) complexes as pre-catalysts in the Heck and Suzuki coupling reactions.

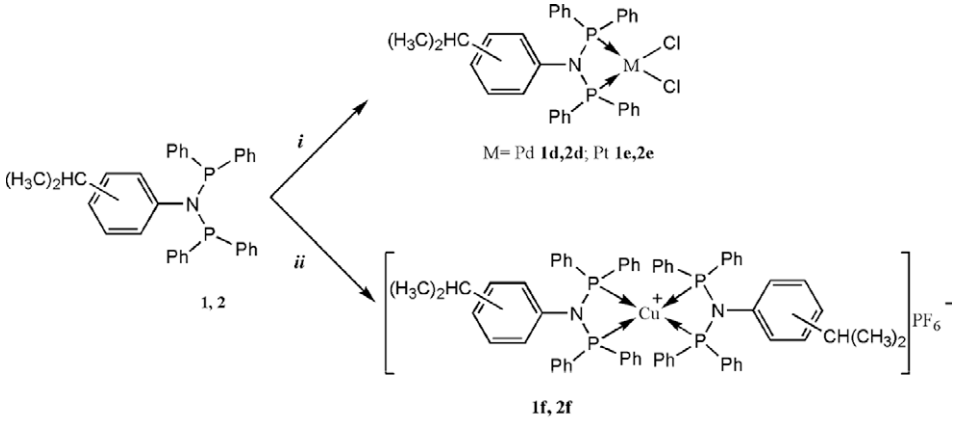
2. Results and discussion

2.1. Synthesis and characterization



N,*N*-bis(diphenylphosphino)isopropylanilines $(PPh_2)_2N$-C_6H_4-$CH(CH_3)_2$, having the isopropyl substituent at the carbon 2 (**1**) or 4 (**2**) were easily prepared from the reaction of *o*-H_2N-C_6H_4-$CH(CH_3)_2$ or *p*-H_2N-C_6H_4-$CH(CH_3)_2$, respectively, with two equivalents of chlorodiphenylphosphine in the presence of triethylamine in thf solution at 0 °C (Scheme 1). Although the existence of compound **1** has been reported by Killian et al., neither the experimental procedure for the preparation nor characterization data is available [49]. Hence, the synthesis and full characterization of compound **1** will be reported herein for the first time. Compounds **1** and **2** were isolated as white solids in high yields (87% and 85%, respectively) under anaerobic conditions. Attempts to prepare *N*,*N*-bis(diphenylphosphino)-2,6-diisopropylaniline did not succeed, may be due to the steric repulsion between the two isopropyl groups and phenyl rings of the phosphine.

In the ^{1}H NMR spectra, both **1** and **2** show multiplets for the aromatic H-atoms in the regions 6.75–7.53 and 6.58–7.39 ppm, respectively. The CH signal of the isopropyl group is at 2.99 ppm for **1** and 2.76 ppm for **2**. The methyl groups of the isopropyl substituent give doublets at 0.75 and 1.15 ppm for **1** and **2**, respectively. The ^{31}P–{^{1}H} NMR spectra of **1** and **2** show a single resonance at 62.2 and 68.5 ppm, respectively, in line with the values previously observed for similar compounds [50,51]. The ^{13}C NMR spectra of the compounds give four signals for the phenyl carbon atoms, two signals for the isopropyl groups, and six or four signals for the aniline ring in **1** or **2**, respectively.



Oxidation of **1** and **2** with aqueous hydrogen peroxide or elemental sulfur or selenium in thf gave the corresponding oxides (**1a**, **2a**), sulfides (**1b**, **2b**), and selenides (**1c**, **2c**), respectively (Scheme 1).

Oxidation of both **1** and **2** using aqueous H_2O_2 was very rapid even at ambient temperature. However, the reaction with elemental sulfur or selenium had to be carried out at elevated temperatures, as expected because elemental sulfur and selenium are weaker oxidizing agents than hydrogen peroxide, especially towards phosphorus atoms with bulky phenyl groups [52–55]. The ^{31}P–{^{1}H} NMR spectra display one singlet for each of **1a** and **2a** (23.9 and 24.2 ppm) and **1b** and **2b** (68.5 and 68.9 ppm), suggesting that the two phosphorus atoms are chemically equivalent in these compounds. The ^{31}P NMR signals of **1c** and **2c** are also singlets, but they are accompanied by selenium satellites at 67.8 ppm ($^1J(^{31}P–^{77}Se) = 787$ Hz) and 67.3 ppm ($^1J(^{31}P–^{77}Se) = 792$ Hz), respectively.

In the reaction of [M(cod)Cl_2] (M = Pd, Pt; cod = 1,5-cyclooctadiene) with one equivalent of **1** or **2** in thf solution, cod is replaced by *N*,*N*-bis(diphenylphosphino)isopropylaniline as a bidentate ligand, yielding the respective [M{$(Ph_2P)_2N$-C_6H_4-$CH(CH_3)_2$}Cl_2] complexes **1d**, **2d**, **1e**, **2e** (M = Pd, Pt, respectively). The reaction of $[Cu(CH_3CN)_4]PF_6$ with two equivalents of **1** or **2** gives the expected complexes [Cu{$(Ph_2P)_2N$-C_6H_4-$CH(CH_3)_2$}$_2$]PF_6 **1f** or **2f**, respectively. Both reactions are summarized in Scheme 2. The ^{31}P–{^{1}H} NMR spectra of **1d** and **2d** exhibit a single resonance at 37.9 and 38.5 ppm, respectively, which are within the range expected for structurally similar complexes [56–58]. The phosphorus reso-

nances of **1d** and **2d** are shifted to lower frequencies by ca. 24 and 30 ppm, respectively, compared to the free ligands. The $^{31}P\text{–}\{^1H\}$ NMR spectra of complexes **1e** and **2e** show a singlet at δ 23.6 and 20.5 ppm, respectively, accompanied by platinum satellites. The large $^1J(^{135}Pt\text{–}^{31}P)$ coupling constants of 3325 and 3310 Hz for **1e** and **2e**, respectively, are indicative of a *cis* arrangement of phosphines around a platinum(II) center [59]. The $^{31}P\text{–}\{^1H\}$ NMR chemical shifts of **1f** and **2f** are also within the expected range, 89.4 and 87.6 ppm, respectively, for structurally similar complexes [43,54,60,61]. The phosphorus resonances of complexes **1f** and **2f** show a coordination shift to higher frequencies by ca. 27 and 19 ppm, respectively, compared to those of the free ligands.

Single crystals of $[Pd\{(Ph_2P)_2N\text{-}C_6H_4\text{-}2\text{-}CH(CH_3)_2\}Cl_2]$ (**1d**) and $[Pt\{(Ph_2P)_2N\text{-}C_6H_4\text{-}2\text{-}CH(CH_3)_2\}Cl_2]$ (**1e**) suitable for X-ray diffraction studies were obtained by slow diffusion of diethylether into a solution of the complexes in dichloromethane. Both complexes were crystallized as 1:1 solvent adducts and the crystallographic data of $[Pd\{(Ph_2P)_2N\text{-}C_6H_4\text{-}2\text{-}CH(CH_3)_2\}Cl_2]\cdot(C_2H_5)_2O$ and $[Pt\{(Ph_2P)_2N\text{-}C_6H_4\text{-}2\text{-}CH(CH_3)_2\}Cl_2]\cdot(C_2H_5)_2O$ are listed in Tables 1 and 2 for **1d** and **1e**. A perspective view of the molecules is given in Fig. 1.

These two crystal structures are isomorphous. The key bond lengths and angles of complexes **1d** and **1e** in the solid state are very similar, with minimal structural differences due to the relocation of the isopropyl groups. The coordination geometry around the Pd and Pt atoms is distorted square–planar, involving two P and two Cl atoms. In the coordination environment, the Pd–P and Pt–P bond lengths are 2.2045(11)–2.2068(10) and 2.1925(12)–2.1936(12) Å, respectively. The Pd–Cl and Pt–Cl coordination bond lengths are 2.3600(11)–2.3553(11) and 2.3462(13)–2.3510(13) Å, respectively. The coordination bond lengths of the Pt atom are slightly smaller than the Pd atom. The palladium(II) complex **1d** and the platinum(II) complex **1e** have coordination angles around the Pd and Pt atoms in the range 71.93(4)–96.96(5)° and 72.52(4)–97.36(5)°, respectively. Despite the difference of the two metal atoms, the P–Pd–P angle and P–Pt–P angles are close to each other (71.93(4)° and 72.52(4)°, respectively). The fact that these angles are much smaller than the ideal value of 90° in a regular square planar geometry can be attributed to the strain in the diphosphine ligands: the bite distance in these ligands is obviously small. Indeed, the P1···P2 distances are 2.5908(14) Å for Pd complex and 2.5942(16) Å for Pt complex. The Pd and Pt atoms are at distance of 0.0538(3) and

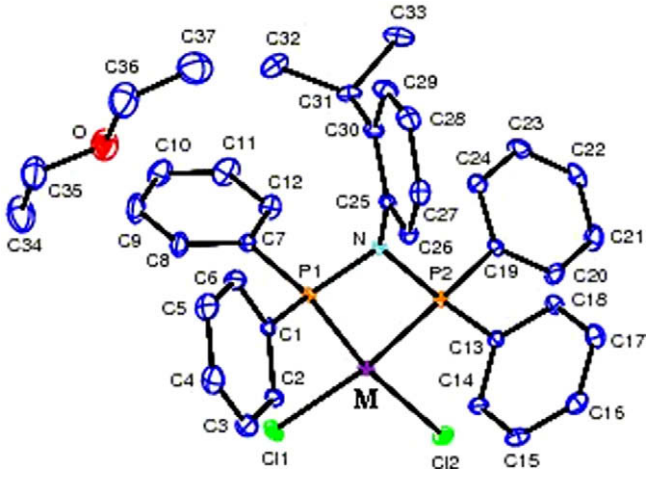

Fig. 1. ORTEP drawing of the compounds **1d** and **1e** with the atomic numbering scheme. H atoms have been omitted for clarity, where M = Pd and Pt, respectively.

0.0341(3) Å, respectively from the basal plane defined by the atoms Cl1, Cl2, P1, P2.

The P–N bond distances of palladium complex **1d** [1.722(3) and 1.710(3) Å] are very similar to those of platinum complex **1e** [1.724(4) and 1.719(4) Å]. They are within the expected ranges in comparison to similar structures [52–54,58]. The aromatic rings in the molecules, as expected, have the usual bond lengths and angles.

It is interesting to note that compounds **1d** and **1e** crystallized under similar conditions, both forming 1:1 adduct with solvent molecules. To get information about the conformation of the complexes **1d** and **1e**, dihedral angles between the neighboring square planes in the molecule were calculated with PARST [62]. Some dihedral angles between the planes around the coordination sphere and phenyl rings (Fig. 2) are given in Table 3. The title molecule is not planar but the phenyl rings are essentially planar.

2.2. The Heck coupling reactions

The palladium complexes **1d** and **2d** were tested as catalysts in one of the most important C–C bond forming processes in synthetic organic chemistry, known as the Heck reaction, the palladium-catalyzed coupling of aryl/vinyl halides with olefins [63,64]. After optimizing the reaction conditions, we carried out the coupling reactions of several substrates with styrene. We found that the use of 0.01 mmol of palladium complexes (**1d** and **2d**) with two equivalents of K_2CO_3 in dioxane at 85 °C led to the best conversion. A control experiment indicated that the coupling reaction does not occur in the absence of **1d** or **2d**. Under these optimum conditions, a wide range of arylbromides bearing electron-donating or electron-withdrawing groups (*p*-bromoacetophenone, *p*-bromobenzaldehyde, *p*-bromobenzene, *p*-bromoanisole and *p*-bromotoluene) react with styrene giving the coupled products in high yields (Table 4).

2.3. The Suzuki coupling reactions

The palladium complexes **1d** and **2d** were tested as catalysts in the Suzuki reaction of aryl/vinyl halides with boronic acid, which is one of the most efficient methods for C–C bond formation [65]. Following optimization experiments, we found that the use of 0.01 mmol of the palladium complexes (**1d** and **2d**) with Cs_2CO_3 as the base at 75 °C in dioxane appeared to provide the highest yield. We initially tested the catalytic activity of the complexes (**1d** and **2d**) for the coupling of *p*-bromoacetophenone with phenylboronic acid and the control experiments showed that the coupling reaction does not occur in the absence of the catalyst. Under these conditions, *p*-bromoacetophenone, *p*-bromobenzaldehyde, *p*-bromobenzene, *p*-bromoanisole and *p*-bromotoluene react cleanly with phenylboronic acid giving high yields of the products (Table 5).

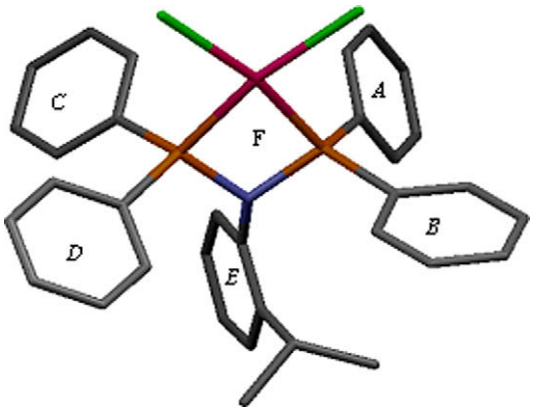

Fig. 2. Conformation of the compounds **1d** and **1e**.

Table 3
Dihedral angles between defined planes of the compounds **1d** and **1e**.

Plane 1	Plane 2	Dihedral angle (°) **1d**	Dihedral angle (°) **1e**
P1/M/P2	Cl1/M/Cl2	3.69(5)	2.31(4)
P1/M/P2	P1/N/P2	6.6(2)	6.7(2)
A	B	61.3(2)	59.9(2)
C	D	64.2(2)	64.9(2)
E	F	77.1(1)	77.1(1)

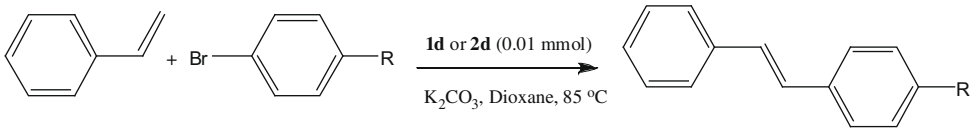
Notes: Planes A–F are involving the atoms as given (Fig. 2): A: C1/C2/C3/C4/C5/C6, B: C7/C8/C9/C10/C11/C12, C: C13/C14/C15/C16/C17/C18, D: C19/C20/C21/C22/C23/C24, E: C25/C26/C27/C28/C29/C30, F: Pt/P1/N/P2. M = Pd, Pt.

3. Experimental

All reactions and manipulations were performed under argon atmosphere using standard Schlenk techniques unless otherwise stated. Ph_2PCl, 2-isopropylaniline and 4-isopropylaniline were purchased from Fluka and were used as received. Solvents were dried using the appropriate reagents and distilled prior to use. The starting materials $[MCl_2(cod)]$ (M = Pd, Pt, cod = 1,5-cyclooctadiene) [66,67] and $[Cu(CH_3CN)_4]PF_6$ [68] were prepared according to the literature procedures. Infrared spectra were recorded from KBr pellets in the range 4000–400 cm^{-1} on a Mattson 1000 ATI UNICAM FT-IR spectrometer. NMR spectra were recorded on a Bruker AC 400 spectrometer (400.1 MHz for ^1H, 100.6 MHz for ^{13}C, and 162.0 MHz ^{31}P). Microanalysis was carried out on a Fisons EA 1108 CHNS-O instrument. GC analyses were performed on a HP 6890 N Gas Chromatograph equipped with a capillary column (5% biphenyl, 95% dimethylsiloxane) (30 m × 0.32 mm × 0.25 μm).

3.1. General procedure for the synthesis of N,N-bis(diphenylphosphino) isopropylanilines $[(Ph_2P)_2N\text{-}(C_6H_4)\text{-}CH(CH_3)_2]$ (**1**, **2**)

Ph_2PCl (1.63 g, 7.40 mmol) was added slowly to a solution of 2- or 4-isopropylaniline (0.50 g, 3.70 mmol) and Et_3N (0.75 g, 7.40 mmol) in thf (20 mL) at 0 °C. The resulting white suspension was stirred for 1 h and precipitated triethylamine hydrochloride was removed by filtration through a sintered Schlenk tube. The solution was evaporated to dryness under reduced pressure and white solids of **1** or **2** were obtained.



3.1.1. N, N-bis(diphenylphosphino)-2-isopropylaniline $[(Ph_2P)_2N\text{-}(C_6H_4)\text{-}2\text{-}CH(CH_3)_2]$ (**1**)

Yield: 1.62 g, 87%; M.p. 129–131 °C; ^1H NMR (400 MHz, [D]$CHCl_3$, 25 °C, TMS): 6.75–7.53(m, 24H, Ar–H), 2.99(m, 1H, $CH(CH_3)_2$, 0.75(d, ^3J(H–H) = 6.4 Hz, 6H, –$CH(CH_3)_2$); ^{13}C NMR (100 MHz, [D]$CHCl_3$, 25 °C, TMS): 146.3, 139.7, 134.9, 132.5, 131.4, 130.5, 128.5, 127.8, 126.6, 125.8 (C_{arm}); 27.5 (–$CH(CH_3)_2$); 23.6 (–$CH(CH_3)_2$); $^{31}P\{^1H\}$ NMR (162 MHz, [D]$CHCl_3$, 25 °C, 85% H_3PO_4): 62.2 (s); IR (KBr pellet, ν cm^{-1}): 901 (PNP), 1432 (PPh); Elemental *Anal.* Calc. for $C_{33}H_{31}NP_2$: C, 78.71; H, 6.21; N, 2.78. Found: C, 78.46; H, 5.97; N, 2.59%.

3.1.2. N, N-bis(diphenylphosphino)-4-isopropylaniline $[(Ph_2P)_2N\text{-}(C_6H_4)\text{-}4\text{-}CH(CH_3)_2]$ (**2**)

Yield: 1.58 g, 85%; M.p. 103–105 °C; ^1H NMR (400 MHz, [D]$CHCl_3$, 25 °C, TMS): 6.58–7.39(m, 24H, Ar–H), 2.76(m, 1H, $CH(CH_3)_2$, 1.15(d, ^3J(H–H) = 7.2 Hz, 6H, –$CH(CH_3)_2$); ^{13}C NMR (100 MHz, [D]$CHCl_3$, 25 °C, TMS): 145.8, 139.6, 133.3, 131.3, 128.9, 128.5, 127.9, 126.2 (C_{arm}); 33.5 (–$CH(CH_3)_2$); 24.0 (–$CH(CH_3)_2$); $^{31}P\{^1H\}$ NMR (162 MHz, [D]$CHCl_3$, 25 °C, 85%

H_3PO_4): 68.5 (s); IR (KBr pellet, ν cm^{-1}): 906 (PNP), 1438 (PPh); Elemental *Anal.* Calc. for $C_{33}H_{31}NP_2$: C, 78.71; H, 6.21; N, 2.78. Found: C, 78.62; H, 6.02; N, 2.64%.

3.2. General procedure for the synthesis of the chalcogenides

3.2.1. N,N-bis(diphenyloxophosphino)isopropylanilines [$(Ph_2P(O))_2N$-(C_6H_4)-$CH(CH_3)_2$] (**1a**, **2a**)

A thf solution (10 mL) of *N*,*N*-bis(diphenylphosphino)isopropyl aniline (0.20 g, 0.40 mmol) and aqueous H_2O_2 (30% w/w, 0.08 mL) was stirred for 2 h at room temperature. The solution was filtered through Celite to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (10 mL) gave **1a** and **2a** as white solids which were collected by suction filtration.

3.2.2. N,N-bis(diphenyloxophosphino)-2-isopropylaniline [$(Ph_2P(O))_2N$-(C_6H_4)-2-$CH(CH_3)_2$] (**1a**)

Yield: 0.16 g, 75%; M.p. 202–204 °C; ^{1}H NMR (400 MHz, [D]$CHCl_3$, 25 °C, TMS): 6.98–7.71(m, 24H, Ar–H), 3.59(m, 1H, C*H*$(CH_3)_2$), 0.65(d, ^3J(H–H) = 6.4 Hz, 6H, –CH(C*H*$_3)_2$); ^{13}C NMR (100 MHz, [D]$CHCl_3$, 25 °C, TMS): 149.2, 134.6, 134.2, 133.1, 132.6, 132.2, 131.9, 128.3, 127.7, 125.9 (C_{arm}); 27.8 (–*C*H$(CH_3)_2$); 23.9 (–CH$(CH_3)_2$). ^{31}P–{^{1}H} NMR (162 MHz, [D]$CHCl_3$, 25 °C, 85% H_3PO_4): 23.9 (s); IR (KBr pellet, ν cm^{-1}): 908 (PNP), 1448 (PPh), 1216 (PO); Elemental *Anal.* Calc. for $C_{33}H_{31}NO_2P_2$: C, 74.01; H, 5.83; N, 2.62. Found: C, 73.81; H, 5.72; N, 2.46%.

3.2.3. N,N-bis(diphenyloxophosphino)-4-isopropylaniline [$(Ph_2P(O))_2N$-(C_6H_4)-4-$CH(CH_3)_2$] (**2a**)

Yield: 0.18 g, 85%; M.p. 124–126 °C; ^{1}H NMR (400 MHz, [D]$CHCl_3$, 25 °C, TMS): 6.97–7.81(m, 24H, Ar–H), 3.56(m, 1H, C*H*$(CH_3)_2$), 0.75(s, 6H, –CH(C*H*$_3)_2$); ^{13}C NMR (100 MHz, [D]$CHCl_3$, 25 °C, TMS): 149.3, 134.1, 133.2, 132.6, 131.6, 128.5, 127.8, 125.6 (C_{arm}); 27.8 (–*C*H$(CH_3)_2$); 24.1 (–CH$(CH_3)_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]$CHCl_3$, 25 °C, 85% H_3PO_4): 24.2 (s); IR (KBr pellet, ν cm^{-1}): 910 (PNP), 1446 (PPh), 1199 (PO); Elemental *Anal.* Calc. for $C_{33}H_{31}NO_2P_2$: C, 74.01; H, 5.83; N, 2.62. Found: C, 73.67; H, 5.48; N, 2.43%.

3.2.4. N,N-bis(diphenylthiophosphino)isopropylanilines [$(Ph_2P(S))_2N$-(C_6H_4)-$CH(CH_3)_2$] (**1b**, **2b**)

To a solution of **1** or **2** (0.20 g, 0.40 mmol) in thf (10 mL), S_8 (0.025 g, 0.80 mmol) was added and this mixture was refluxed

for 4 h. The solution was filtered through Celite while hot to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (15 mL) gave **1b** and **2b** as light yellow solids which were collected by suction filtration.

*3.2.5. N,N-bis(diphenylthiophosphino)-2-isopropylaniline [(Ph$_2$P(S))$_2$N-(C$_6$H$_4$)-2-CH(CH$_3$)$_2$] (**1b**)*

Yield: 0.17 g, 75%; M.p. 149–151 °C; ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.90–8.05(m, 24H, Ar–H), 3.54(m, 1H, C*H*(CH$_3$)$_2$), 0.69(d, ^3J(H–H) = 6.8 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 151.0, 136.5, 134.7, 134.0, 133.7, 132.2, 131.3, 128.4, 127.4, 125.0 (C$_{arm}$); 28.3 (–*C*H(CH$_3$)$_2$); 24.6 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 68.5 (s); IR (KBr pellet, ν cm^{-1}): 905 (PNP), 1440 (PPh), 650 (PS); Elemental *Anal.* Calc. for C$_{33}$H$_{31}$NS$_2$P$_2$: C, 69.82; H, 5.50; N, 2.47. Found: C, 69.61; H, 5.31; N, 2.38%.

*3.2.6. N,N-bis(diphenylthiophosphino)-4-isopropylaniline [(Ph$_2$P(S))$_2$N-(C$_6$H$_4$)-4-CH(CH$_3$)$_2$] (**2b**)*

Yield: 0.19 g, 84%: M.p. 189–191 °C; ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.72–8.10(m, 24H, Ar–H), 2.59(m, 1H, C*H*(CH$_3$)$_2$), 0.99(s, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 147.8, 136.1, 133.6, 132.9, 132.4, 131.3, 127.5, 125.9 (C$_{arm}$); 33.4 (–*C*H(CH$_3$)$_2$); 23.7 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 68.9 (s); IR (KBr pellet, ν cm^{-1}): 906 (PNP), 1446 (PPh), 694 (PS); Elemental *Anal.* Calc. for C$_{33}$H$_{31}$NS$_2$P$_2$: C, 69.82; H, 5.50; N, 2.47. Found: C, 69.68; H, 5.36; N, 2.36%.

*3.2.7. N,N-bis(diphenylselenophosphino)isopropylanilines [(Ph$_2$P(Se))$_2$N-(C$_6$H$_4$)-CH(CH$_3$)$_2$] (**1c**, **2c**)*

Grey Se (0.063 g, 0.8 mmol) was added to a solution of **1** or **2** (0.20 g, 0.40 mmol) in thf (10 mL) and this mixture was refluxed for 1 h. The solution was filtered through Celite while hot to remove a small amount of insoluble material. The filtrate was concentrated in vacuo to ca. 1–2 mL and addition of *n*-hexane (15 mL) gave **1c** and **2c** as light yellow solids which were collected by suction filtration.

*3.2.8. N,N-bis(diphenylselenophosphino)-2-isopropylaniline [(Ph$_2$P(Se))$_2$N-(C$_6$H$_4$)-2-CH(CH$_3$)$_2$] (**1c**)*

Yield: 0.21 g, 80%; M.p. 240–242 °C; ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.88–8.04(m, 24H, Ar–H), 3.53(m, 1H, C*H*(CH$_3$)$_2$), 0.70(d, ^3J(H–H) = 6.8 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 151.2, 136.8, 134.6, 134.4, 132.8, 131.6, 130.5, 127.8, 127.5, 125.0 (C$_{arm}$); 28.4 (–*C*H(CH$_3$)$_2$); 24.9 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 67.8, J(PSe) = 786.6 Hz; IR (KBr pellet, ν cm^{-1}): 891 (PNP), 1438 (PPh), 563 (PSe); Elemental *Anal.* Calc. for C$_{33}$H$_{31}$NSe$_2$P$_2$: C, 59.92; H, 4.72; N, 2.12. Found: C, 59.62; H, 4.43; N, 2.01%.

*3.2.9. N,N-bis(diphenylselenophosphino)-4-isopropylaniline [(Ph$_2$P(Se))$_2$N-(C$_6$H$_4$)-4-CH(CH$_3$)$_2$] (**2c**)*

Yield: 0.22 g, 84%: M.p. >300 °C (dec.); ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.71–8.15(m, 24H, Ar–H), 2.60(m, 1H, C*H*(CH$_3$)$_2$), 1.00(d, ^3J(H–H) = 6.8 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 147.6, 136.0, 134.3, 133.4, 132.8, 131.4, 127.5, 125.9 (C$_{arm}$); 33.4 (–*C*H(CH$_3$)$_2$); 23.6 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 67.3, J(PSe) = 792 Hz; IR (KBr pellet, ν cm^{-1}): 917 (PNP), 1446 (PPh), 542 (PSe); Elemental *Anal.* Cal. for C$_{33}$H$_{31}$NSe$_2$P$_2$: C, 59.92; H, 4.72; N, 2.12. Found: C, 59.72; H, 4.57; N, 1.98%.

3.3. General procedure for the synthesis of the complexes

*3.3.1. Dichloro{N,N-bis(diphenylphosphino)isopropylaniline}palladium(II) (**1d**, **2d**)*

A solution of [PdCl$_2$(cod)] (0.227 g, 0.795 mmol) and **1** or **2** (0.40 g, 0.795 mmol) in thf (20 mL) was stirred for 2 h. The volume was concentrated in vacuum to ca. 1–2 mL and addition of diethyl ether (15 mL) gave **1d** and **2d** as yellow solids which were collected by suction filtration and dried in vacuum.

*3.3.2. Dichloro{N,N-bis(diphenylphosphino)-2-isopropylaniline} palladium(II) (**1d**)*

Yield: 0.44 g, 81%; M.p. 249–251 °C; ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.78–7.85(m, 24H, Ar–H), 2.57(m, 1H, C*H*(CH$_3$)$_2$), 0.31(d, ^3J(H–H) = 6.4 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 147.4, 136.4, 134.8, 134.4, 132.4, 130.6, 130.4, 129.9, 128.6, 126.6 (C$_{arm}$); 28.7 (–*C*H(CH$_3$)$_2$); 23.8 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 37.9 (s); IR (KBr pellet, ν cm^{-1}): 890 (PNP), 1438 (PPh); Elemental *Anal.* Calc. for C$_{33}$H$_{31}$NP$_2$PdCl$_2$: C, 58.21; H, 4.59; N, 2.06. Found: C, 57.94; H, 4.43; N, 1.83%.

*3.3.3. Dichloro{N,N-bis(diphenylphosphino)-4-isopropylaniline} palladium(II) (**2d**)*

Yield: 0.48 g, 89%; M.p. 250–252 °C; ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.79–7.85(m, 24H, Ar–H), 2.58(m, 1H, C*H*(CH$_3$)$_2$), 0.3(d, ^3J(H–H) = 6.0 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 147.3, 138.1, 134.8, 134.4, 132.1, 130.0, 128.7, 126.6 (C$_{arm}$); 28.9 (–*C*H(CH$_3$)$_2$); 23.8 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 38.5 (s); IR (KBr pellet, ν cm^{-1}): 892 (PNP), 1447 (PPh); Elemental *Anal.* Calc. for C$_{33}$H$_{31}$NP$_2$PdCl$_2$: C, 58.21; H, 4.59; N, 2.06. Found: C, 57.84; H, 4.37; N, 1.93%.

*3.3.4. Dichloro{N,N-bis(diphenylphosphino)isopropylaniline} platinum(II) (**1e**, **2e**)*

A solution of [PtCl$_2$(cod)] (0.298 g, 0.795 mmol) and **1** or **2** (0.40 g, 0.795 mmol) in thf (20 mL) was stirred for 2 h. The volume was concentrated in vacuum to ca. 1–2 mL and addition of diethyl ether (15 mL) gave **1e** and **2e** as white solids which were collected by suction filtration and dried in vacuum.

*3.3.5. Dichloro{N,N-bis(diphenylphosphino)-2-isopropylaniline} platinum(II) (**1e**)*

Yield: 0.52 g, 85%; M.p. 294–296 °C; ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.75–7.81(m, 24H, Ar–H), 2.63(m, 1H, C*H*(CH$_3$)$_2$), 0.30(d, ^3J(H–H) = 6.8 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 147.7, 139.3, 134.6, 134.2, 132.2, 130.6, 130.2, 129.8, 127.4, 126.4 (C$_{arm}$); 28.9 (–*C*H(CH$_3$)$_2$); 23.8 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 23.6, J(PtP) = 3325 Hz; IR (KBr pellet, ν cm^{-1}): 893 (PNP), 1440 (PPh); Elemental *Anal.* Calc. for C$_{33}$H$_{31}$NP$_2$PtCl$_2$: C, 51.51; H, 4.06; N, 1.82. Found: C, 51.24; H, 3.82; N, 1.69%.

*3.3.6. Dichloro{N,N-bis(diphenylphosphino)-4-isopropylaniline} platinum(II) (**2e**)*

Yield: 0.55 g, 90%; M.p. >250 °C (dec.); ^{1}H NMR (400 MHz, [D]CHCl$_3$, 25 °C, TMS): 6.40–7.81(m, 24H, Ar–H), 2.66(m, 1H, C*H*(CH$_3$)$_2$), 0.31(d, ^3J(H–H) = 6.8 Hz, 6H, –CH(C*H*$_3$)$_2$); ^{13}C NMR (100 MHz, [D]CHCl$_3$, 25 °C, TMS): 147.0, 137.6, 134.3, 133.1, 132.2, 130.1, 128.0, 126.6 (C$_{arm}$); 30.8 (–*C*H (CH$_3$)$_2$); 25.6 (–CH(*C*H$_3$)$_2$); ^{31}P–{^{1}H} NMR (162 MHz, [D]CHCl$_3$, 25 °C, 85% H$_3$PO$_4$): 20.5, J(PtP): 3310 Hz; IR (KBr pellet, ν cm^{-1}): 892 (PNP),

1438 (PPh); Elemental *Anal.* Calc. for $C_{33}H_{31}NP_2PtCl_2$: C, 51.51; H, 4.06; N, 1.82. Found: C, 51.29; H, 3.94; N, 1.73%.

3.3.7. Bis[N,N-bis(diphenylphosphino)isopropylaniline]copper(I) hexafluorophosphates (**1f**, **2f**)

To a solution of $[Cu(CH_3CN)_4]PF_6$ (0.148 g, 0.398 mmol) in thf (15 mL) was added compound **1** or **2** (0.40 g, 0.795 mmol), and the resulting solution was stirred for 1 h. The volume was concentrated in vacuum to ca. 1–2 mL and addition of diethyl ether (15 mL) gave **1f** and **2f** as white solids which were collected by suction filtration and dried in vacuum.

3.3.8. Bis[N,N-bis(diphenylphosphino)-2-isopropylaniline]copper(I) hexafluorophosphate (**1f**)

Yield: 0.41 g, 85%; M.p. 179–181 °C; ^{1}H NMR (400 MHz, [D]$CHCl_3$, 25 °C, TMS): 7.11–7.57(m, 24H, ArH), 2.60(m, 1H, C*H*$(CH_3)_2$), 0.10(d, ^3J(H–H):6.4 Hz, 6H, –$CH(CH_3)_2$); No ^{13}C NMR spectrum was obtained due to the low solubility of the complex in all common solvents; ^{31}P–{^{1}H} NMR (162 MHz, [D]$CHCl_3$, 25 °C, 85% H_3PO_4): 89.4, PF_6: −144.3, $J(PF_6)$ = 712 Hz; IR (KBr pellet, ν cm^{-1}): 898 (PNP), 1446 (PPh); Elemental *Anal.* Calc. for $C_{66}H_{62}N_2P_5F_6Cu$: C, 65.21; H, 5.14; N, 2.30. Found: C, 64.96; H, 4.95; N, 2.18%.

3.3.9. Bis[N,N-bis(diphenylphosphino)-4-isopropylaniline]copper(I) hexafluorophosphate (**2f**)

Yield: 0.38 g, 79%; M.p. 181–183 °C; ^{1}H NMR (400 MHz, [D]$CHCl_3$, 25 °C, TMS): 6.77–7.52(m, 24H, ArH), 2.72(br, 1H, C*H*$(CH_3)_2$), 1.10(s, 6H, –$CH(CH_3)_2$); No ^{13}C NMR spectrum was obtained due to the low solubility of the complex in all common solvents; ^{31}P–{^{1}H} NMR (162 MHz, [D]$CHCl_3$, 25 °C, 85% H_3PO_4): 87.6, PF_6: −144.3, $J(PF_6)$ = 712 Hz; IR (KBr pellet, ν cm^{-1}): 908 (PNP), 1439 (PPh); Elemental *Anal.* Calc. for $C_{66}H_{62}N_2P_5F_6Cu$: C, 65.21; H, 5.14; N, 2.30. Found: C, 65.02; H, 4.97; N, 2.19%.

3.4. General procedure for the Heck coupling reaction

Heck coupling reactions were conducted as follows: the bisphosphinoamine–palladium complexes (**1d** or **2d**) (0.01 mmol), arylbromide (1.0 mmol), styrene (1.5 mmol), K_2CO_3 (2.0 mmol) and 1,4-dioxane (3 mL) were placed in a Schlenk tube and the mixture was heated to 85 °C for 1.5 h. The progress of the reaction was monitored by GC. Upon completion, the mixture was cooled, and the product extracted with ethyl acetate/hexane (1:5), filtered through a pad of silica gel with copious washing, concentrated and purified by flash chromatography on silica gel. The purity of the compounds was checked by NMR and GC, and yields are based on arylbromide.

3.5. General procedure for the Suzuki coupling reaction

Suzuki coupling reactions were conducted as follows: the bisphosphinoamine–palladium complexes (**1d** or **2d**) (0.01 mmol), arylbromide (1.0 mmol), phenylboronic acid (1.5 mmol), Cs_2CO_3 (2.0 mmol) and 1,4-dioxane (3 mL) were placed in a small Schlenk tube and the mixture was heated at 75 °C for 1 h. The progress of the reaction was monitored by GC. Upon completion, the mixture was cooled, the product extracted with ethyl acetate/hexane (1:5), filtered through a pad of silica gel with copious washing, concentrated and purified by flash chromatography on silica gel. The purity of the compounds was checked by NMR and GC, and yields are based on arylbromide.

3.6. X-ray diffraction structure analyses

To determine the crystal structures of **1d** and **1e**, X-ray diffraction data were collected at room temperature using an Enraf-nonius CAD4 diffractometer with graphite monochromated Mo Kα radiation using the $w/2\theta$ scan mode. The lattice parameters and their estimated standard deviations were determined from a least-squares analysis using 25 centered reflections in the range 9.86–17.99° for the Pd complex and 10.15-17.98° for the Pt complex by using CAD4 Express [69]. Data reduction was carried out using XCAD 4 [70]. The structures were solved by the direct method using the solution program SHELXS97 and refined on F_0^2 using SHELXS97 [71]. In both complexes, all non-hydrogen atoms were refined, first with isotropic and then with anisotropic thermal parameters by full matrix least squares. The hydrogen atom of the CH group in the 2-isopropyl aniline ligand was taken from a difference Fourier map. All other hydrogen atoms were positioned geometrically with C–H = 0.93, 0.97 and 0.96 Å for aromatic, methylene and methyl H, and constrained to ride on their parent atoms, with $U_{iso}(H) = xU_{eq}(C)$, where $x = 1.5$ for methyl H, and $x = 1.2$ for others H atoms. Results of the X-ray structure determination are given in Tables 1–3 for **1d** and **1e**, and the ORTEP [72] drawings of the molecules are shown in Fig. 1.

4. Conclusion

In conclusion, two new bis(diphenylphosphino)amines and their oxides, sulfides and selenides have been prepared. In addition, both compounds show similar coordination properties towards Cu, Pd and Pt. The Pd complexes exhibit high catalytic activity in the Heck and Suzuki cross-coupling reactions. The procedure for carrying out the catalytic reactions is quite simple and efficient towards various aryl bromides and does not require an induction period. Based on these findings, it can be postulated that **1d** and **2d** offer some distinctive advantages in the C–C coupling reactions compared to other palladium/aminophosphine systems [20,50,55,64].

5. Supplementary data

CCDC 694356 and 69455 contain the supplementary crystallographic data for **1d** and **1e**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Manganese(II) complexes of [18]py_2N_4: 3,6,14,17,23,24-hexaazatricyclo[17.3.1.1^{8,12}]tetracosa-1(23),2,6,8(24),9,11,13,17,19,21-decane; [20]py_2N_4: 3,7,15,19,25,26-hexaazatricyclo[19.3.1.1^{9,13}]hexacosa-1(25),2,7,9(26),10,12,14,19,21,23-decaene; Bzo_2[18]py_2N_4: 3,10,18,25,31,32-hexaazapentacyclo[25.3.1.1.^{12,16}.0^{4,9}.0^{19,24}]dotriaconta 1(31),2,4(9),5,7,10,12(32),13,15,17,19,21,23,25,29-hexadecane and Bzo_2[18]py_2N_4: 2,10,16,24,30,32-hexaazapentacyclo[23.3.1.1^{4,8}.1^{1,1,15}1^{18,22}otriaconta-1(29),2,4,6,8(32),9,11,13,15(31),16,18(30),19,21,23,25,27-hexadecane have been encapsulated in the nanopores of zeolite-Y by the template condensation reaction. Mn(II) complexes with macrocyclic ligand were entrapped in the nanocavity of zeolite-Y by a two-step process in the liquid phase: (i) the adsorption of [bis(diamine)manganese(II)]; [Mn(diamine)$_2$]$^{2+}$@NaY; in the supercages of the zeolite, and (ii) in situ condensation of the manganese(II) precursor complex with 2,6-diacetylpyridine. The new complex nanoparticles entrapped in the nanoreactor of zeolite-Y have been characterized by FT-IR, diffuse reflectance (DRS), X-ray photoelectron (XPS), thermal analysis, UV–Vis spectroscopic techniques, X-ray diffraction (XRD) and elemental analysis as well as by nitrogen adsorption.

1. Introduction

Complex nanoparticles entrapped in the nanoreactors of zeolite-Y are fascinating class of materials, which have attracted wide spread attention in basic science as well as in technology development. Zeolites are endowed with a unique physical and chemical characterization, which offers opportunities to manipulate active sites microenvironment. They are even compared with the catalytic antibodies and metallo-enzymes and hence they are often referred to as zeozymes [1]. Some of the prominent physical characteristics of zeolites are their ruggedness to temperature and pressure and their ability to recognize, discriminate and organize molecules with less than 0.1 nm levels precision at the active sites [2]. Moreover, non-corrosive, environmentally friendly and economically viable nature of the zeolite-catalyzed reactions have provided the opportunity for the development of various industrial processes such as fluid catalytic cracking, hydrocracking, isomerization and oxidation.

Zeolites are crystalline aluminosilicates whose internal voids are formed by cavities and channels of strictly regular dimensions and of different sizes and shapes. In particular, the pore structure of Y zeolite consists of almost spherical 1.3 nm cavities interconnected tetrahedrally through smaller apertures of 0.74 nm diameter. The metal complex can be easily accommodated inside the supercages of Y zeolite [3–19]. The large internal surface area and void volumes with extremely narrow pore size distribution as well as functional centres homogeneously dispersed over the surface make nanoporous solids highly active materials. Over the last decades, there has been a dramatic increase in the synthesis, characterization and application of novel nanoporous materials [20].

In this paper, I report the synthesis and characterization of manganese(II) complexes of 18- and 20-membered hexaaza macrocyclic ligand; [18]py_2N_4: 3,6,14,17,23,24-hexaazatricyclo[17.3.1.1^{8,12}]tetracosa-1(23),2,6,8(24),9,11,13,17,19,21-decane; [20]py_2N_4: 3,7,15,19,25,26-hexaazatricyclo[19.3.1.1^{9,13}]hexacosa-1(25),2,7,9(26),10,12,14,19,21,23-decaene; Bzo_2[18]py_2N_4 : 3,10,18,25,31,32-hexaazapentacyclo[25.3.1.1.^{12,16}.0^{4,9}.0^{19,24}]dotriaconta 1(31),2,4(9),5,7,10,12(32),13,15,17,19,21,23,25,29-hexadecane; Bzo_2[18]py_2N_4: 2,10,16,24,30,32-hexaazapentacyclo[23.3.1.1^{4,8}.1^{1,1,15}1^{18,22}otriaconta-1(29),2,4,6,8(32),9,11,13,15(31),16,18(30),19,21,23,25,27-hexadecane; encapsulated within the nanopores of zeolite-Y by the template condensation of 2,6-diacetylpyridine and [bis(diamine)manganese(II)]; [Mn([18]py_2N_4)]$^{2+}$@NaY, [Mn([20]

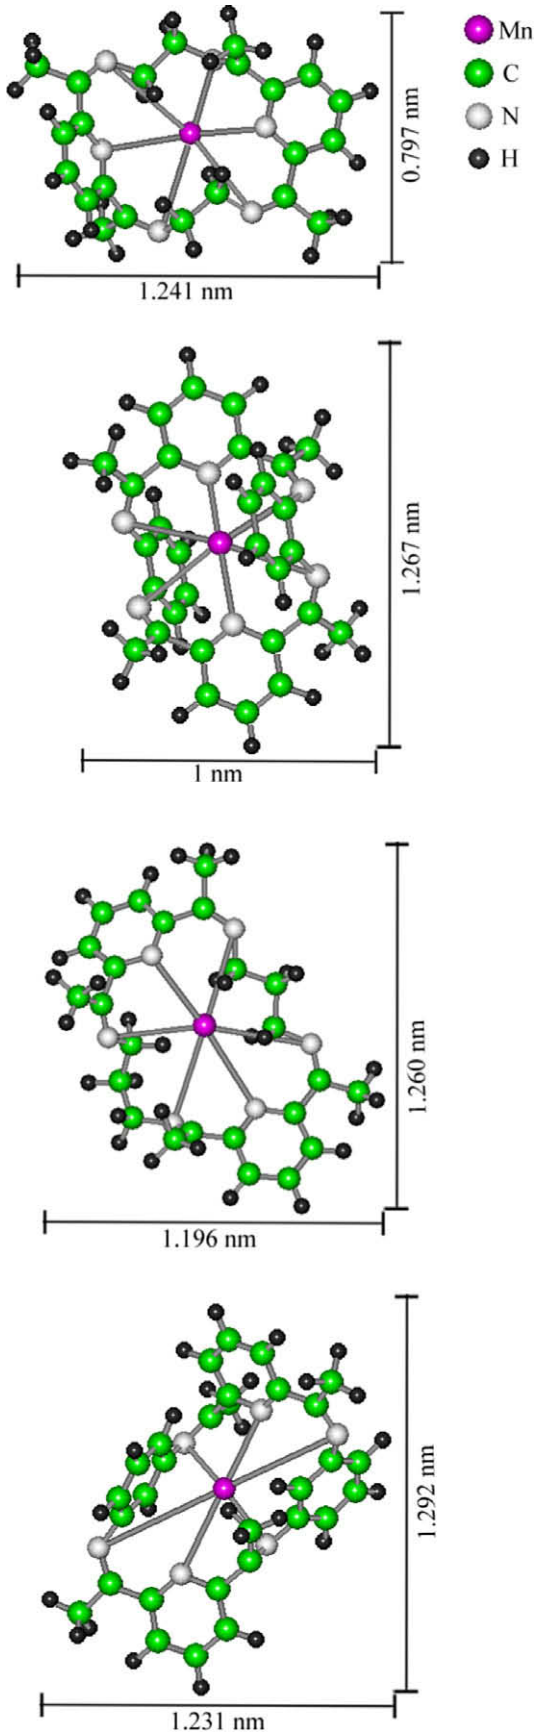
$py_2N_4)]^{2+}$@NaY, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$@NaY and $[Mn(Bzo_2[20]$-$py_2N_4)]^{2+}$@NaY; shown in Schemes 1 and 2.

2. Experimental

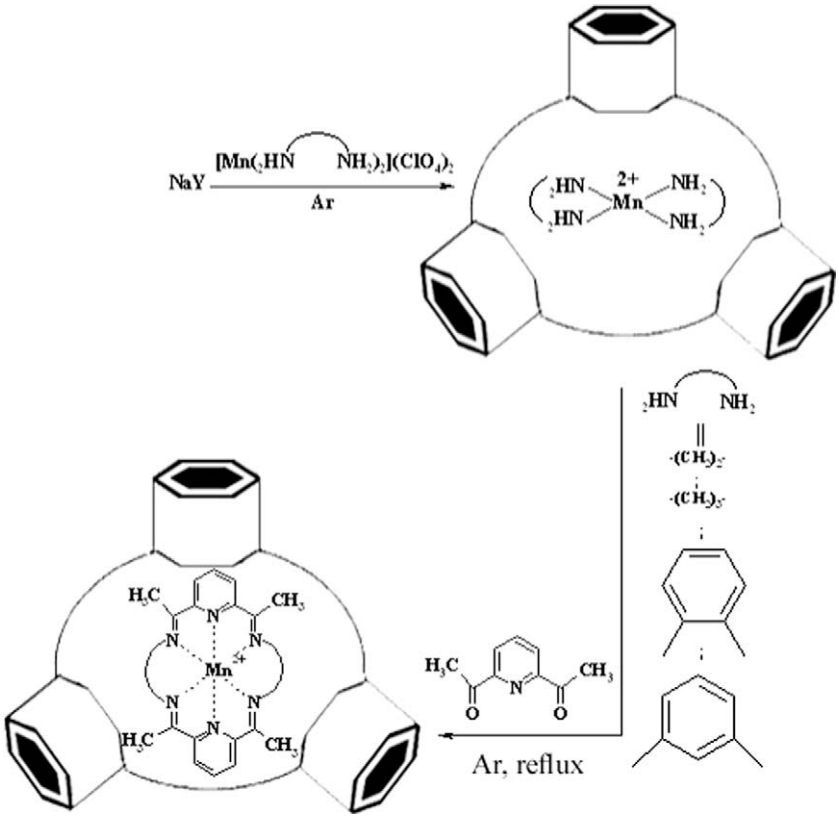
2.1. Chemical and starting materials

Caution: Although no problems were encountered during the course of this work, attention is drawn to the potentially explosive nature of perchlorates.



2,6-Diacetylpyridine, 1,2-diaminoethane, 1,3-diaminepropane, 1,2-diaminobenzene, 1,3-diaminobenzene, $MnCl_2{\cdot}6H_2O$ and $LiClO_4{\cdot}3H_2O$ were commercial products obtained from Alfa and Aldrich, and were used without further purifications. The solvents used were of reagent grade and were purified by usual methods. NaY with the Si:Al ratio of 2.53 was purchased from Aldrich (Lot No. 67812). The complex "$[Mn(diamine)_2](ClO_4)_2$" was prepared according to a similar reported procedure [21]. Hexaaza macrocyclic ligands ($[18]py_2N_4$, $[20]py_2N_4$, $Bzo_2[18]py_2N_4$ and $Bzo_2[20]$-py_2N_4) were prepared by following the procedures reported in Ref. [22].

2.2. Physical measurements



FT-IR spectra were recorded on Shimadzu Varian 4300 spectrophotometer in KBr pellets. The electronic spectra of the neat complexes were taken on a Shimadzu UV–Vis scanning spectrometer (Model 2101 PC). Diffuse reflectance spectra (DRS) were registered on a Shimadzu UV/3101 PC spectrophotometer in the range 1500–200 nm, using MgO as a reference. The elemental analysis (carbon, hydrogen and nitrogen) of the materials was obtained from Carlo ERBA Model EA 1108 analyzer. XRD patterns were recorded by a Rigaku D-max C III, X-ray diffractometer using Ni-filtered Cu Kα radiation. Nitrogen adsorption measurements were performed at 77 K using a Coulter Ofeisorb 100CX instrument. The samples were degassed at 150 °C until a vacuum better than 10^{-3} Pa was obtained. Micropore volumes were determined by the *t*-method, a "monolayer equivalent area" was calculated from the micropore volume [23,24]. The amounts of metallocomplexes encapsulated in zeolite matrix were determined by the elemental analysis and by subtracting the amount of metallocomplex left in the solutions after the synthesis of the materials as determined by UV–Vis spectroscopy, from the amount taken for the synthesis. Atomic absorption spectra (AAS) were recorded on a Perkin–Elmer 4100–1319 Spectrophotometer using a flame approach, after acid (HF) dissolution of the known amounts of the zeolitic material and SiO_2 was determined by gravimetric analysis. XPS (small area X-ray photoelectron spectroscopy) data were recorded with the PHI-5702 Multi-Technique System, Power Source by Mg Kα line and Ag 3d5/2 FWHM 6 0.48 eV. Thermogravimetric-differential thermal analysis (TG-DTA) was carried out using a thermal gravimetric analysis instrument (Shimadzu TGA-50H) with a flow rate of 20.0 mL min^{-1} and a heating rate of 10 °C min^{-1}. FAB mass spectra were recorded on a Kratos MS50TC spectrometer. Distance for as-prepared complexes was calculated by HyperChem (HyperChem is an exceptional molecular modelling programme).

2.3. Preparation of $[Mn([18]py_2N_4)]^{2+}$, $[Mn([20]py_2N_4)]^{2+}$, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$ and $[Mn(Bzo_2[20]py_2N_4)]^{2+}$

To a stirred methanol solution (500 ml) of $[Mn(diamine)_2]$-$(ClO_4)_2$ (42.07 mmol; diamine = 1,2-diaminoethane (2.53 g), 1,3-diaminopropane (3.11 g), 1,2-diaminobenzene (4.54 g) or 1,3-diaminobenzene (4.54 g)) was slowly added 2,6-diacetylpyridine (13.69 g, 84.20 mmol) under nitrogen atmosphere. The mixture was heated at reflux for 12 h until a dark yellow solution resulted.

Scheme 1. 18- and 20-membered hexaaza macrocyclic manganese(II) complexes.

Scheme 2. Encapsulation manganese(II) complex nanoparticles of 18- and 20-membered hexaaza macrocyclic within nanoreactors of zeolite-Y.

The solution was cooled to room temperature and was filtered to remove manganese hydroxide. Excess perchloric acid or lithium perchlorate dissolved in methanol was added to the filtrate, and the mixture was kept in the refrigerator until a deep yellow solid was formed. The deep yellow solid was filtered, washed with diethyl ether and air-dried. The products were crystallized from hot methanol.

2.4. Preparation of $[Mn(diamine)_2]^{2+}$@NaY

To a stirred methanol solution of NaY (4 g) was added 0.37 g of [bis(diamine)manganese(II)] perchlorate (diamine = 1,2-diaminoethane, 1,3-diaminopropane, 1,2-diaminobenzene or 1,3-diaminobenzene) suspended in 100 ml of methanol and was then refluxed for 8 h under Ar atmosphere. The light yellow solid consisting of $[Mn(diamine)_2]^{2+}$ denoted as $[Mn(diamine)_2]^{2+}$@NaY was collected by filtration, washed with ethanol. The resulted zeolites were Soxhlet extracted with ethanol (for 4 h) and then with chloroform (for 3 h) to remove excess unreacted diamine and any Mn(II) complexes adsorbed onto the external surface of the zeolite crystallites. The resulting light yellow solids were dried at 60 °C under vacuum for 24 h.

2.5. Preparation of complex nanoparticles entrapped in the nanopores of zeolite-Y

To a stirred methanol suspension (100 ml) of $[Mn(diamine)_2]^{2+}$@NaY (2 g) was slowly added 2,6-diacetylpyridine (under Ar atmosphere). The mixture was heated under reflux condition for 24 h until a pale yellow suspension resulted. The solution was filtered and the resulting zeolites were Soxhlet extracted with chloroform (for 4 h) and then with ethanol (for 4 h) to remove excess unreacted products from amine–ketone condensation and any manganese(II) complexes adsorbed onto the external surface of the zeolite crystallites. The resulting pale yellow solids were dried at 70 °C under vacuum for 12 h. The remaining [bis(diamine)manganese(II)] ions in zeolite were removed by exchanging with aqueous 0.1 M NaCl solutions. The stability of the encapsulated complex nanoparticles was checked after the reaction by UV–Vis and possible leaching of the complex was investigated by UV–Vis in the reaction solution after filtration of the zeolite. The amounts of Mn(II) complexes encapsulated in zeolite matrix were determined by the elemental analysis and by subtracting the amount of Mn(II) complex left in the solutions after the synthesis of the materials as determined by UV–Vis spectroscopy, from the amount taken for the synthesis.

3. Results and discussion

Hexaaza macrocyclic manganese(II) complexes were prepared by reacting 2 equiv. of 2,6-diacetylpyridine and 1 equiv. of $[Mn(diamine)_2]^{2+}$ (Scheme 1). It was observed that the 18- and 20-membered hexaaza macrocyclic product obtained from the reaction was largely affected by the molar ratio of the reactants. The complexes are soluble in dimethylformamide (DMF) and dimethylsulfoxide (DMSO), but are insoluble in common organic solvents and water. They are thermally stable up to ~250 °C. The complexes are extremely stable in the solid state and in solution and are relatively stable against ligand dissociation even in highly acidic solutions. The analytical data of the metal chelates are given in Table 1, which show that chelates may be represented by the formula $[Mn([18]py_2N_4)](ClO_4)_2$, $[Mn([20]py_2N_4)](ClO_4)_2$, $[Mn(Bzo_2[18]py_2N_4)](ClO_4)_2$ and $[Mn(Bzo_2[20]py_2N_4)](ClO_4)_2$. The measurements of molar conductance in DMF show that these chelates are 1:2 electrolytes. The tests for anions are positive directly without decomposing the chelates showing their presence outside

[a] In acetonitrile solutions.

the coordination sphere. The molecular formulae of the complexes have been assigned on the basis of the results of their elemental analyses and the molecular ion peaks in the mass spectra (Table 1).

Synthesis of hexaaza manganese(II) complex nanoparticles encapsulated in the nanocavity of zeolite-Y involves two steps: (i) exchange of $[Mn(diamine)_2]^{2+}$ (diamine = 1,2-diaminoethane, 1,3-diaminopropane, 1,2-diaminobenzene or 1,3-diaminobenzene) ions with NaY in methanol solution and (ii) reaction of $[Mn(diamine)_2]^{2+}$@NaY with excess 2,6-diacetylpyridine in methanol where 2,6-diacetylpyridine slowly enters into the nanocavity of zeolite-Y due to its template nature and interacts with [bis(diamine)manganese(II)] ions. Soxhlet extraction using ethanol and chloroform finally purified the impure complexes. The remaining uncomplexed metal ions in zeolite were removed by exchanging with an aqueous 0.01 M NaCl solution. As one extra anionic ligand would be required to balance the overall charges on the Mn(II), Cl^- of NaCl used during exchanged process fulfills this requirement. Thus, the formula of manganese(II) complex may be written as $[Mn([18]py_2N_4)]^{2+}$@NaY, $[Mn([20]py_2N_4)]^{2+}$@NaY, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$@NaY, $[Mn(Bzo_2[20]py_2N_4)]^{2+}$@NaY. The percentage of metal contents determined before and after encapsulation by inductively coupled plasma (ICP) along with their expected formula is presented in Table 2. As crude mass was extracted with methanol, the metal ion content found after encapsulation is only due to the presence of metal complexes in the nanopores of the zeolite-Y. The molecular formulae of the complex nanoparticles are based on the neat complexes $[Mn([18]py_2N_4)]^{2+}$, $[Mn([20]py_2N_4)]^{2+}$, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$ and $[Mn(Bzo_2[20]py_2N_4)]^{2+}$Y which have also been prepared and characterized.

The C, H, N analysis results of the neat manganese(II) complex nanoparticles showed close similarity to the theoretical values. The molecular formulae of the hexaaza complexes have been assigned on the basis of the results of their elemental analyses. A preliminary identification of the metal complexes was made on the basis of their IR spectra, which exhibited no bands characteristic of free primary amine, thus supporting the proposed macrocyclic

skeleton (Scheme 1). The manganese contents of the materials were estimated by dissolving the known amounts of the materials in conc. HCl and from these solutions, the manganese contents were estimated by using atomic absorption spectrometry (AAS). The chemical compositions (Tables 1 and 2) confirmed the purity and stoichiometry of the neat and encapsulated complexes. The chemical analyses of the samples revealed the presence of organic matter with a C/N ratio roughly similar to that for neat complexes. In Table 2 the mol ratios Si/Al obtained by chemical analysis for zeolites are presented. The Si and Al contents in Mn(II)@NaY and the nanocomposite materials were almost in the same ratio as in the parent zeolite. This indicates little changes in the zeolite framework due to the absence of de-alumination in metal ion exchange. The parent NaY zeolite has Si/Al molar ratio of 2.53 which corresponds to a unit cell formula $[Na_{56}[(AlO_2)_{56}(SiO_2)_{136}]$. The unit cell formula of metal-exchanged zeolites showed a manganese dispersion of 11.4 moles per unit cell $(Na_{33.8}Mn_{11.4}[(AlO_2)_{56}(SiO_2)_{136}].n\text{-}H_2O)$. The analytical data of each complex indicated Mn:C:N molar ratios almost close to those calculated for the mononuclear structure. The excess amount of un-reacted complex can be removed with NaCl solution.

The IR spectra of all the complexes do not exhibit any bands in the region at *ca.* 3400–3200 cm^{-1}, which is the characteristic frequency of the free $-NH_2$ group. There is no absorption ~1600–1700 cm^{-1} due to the free carbonyl group [25]. The absence of stretching and bending vibrations of the (C–O) group at *ca.* 1525 and 1280 cm^{-1} substantiates the absence of this group [26]. The strong bands appearing as doubles at *ca.* 1610–1640 cm^{-1} may be assigned to υ(C=N) vibrations and point towards the coordinated azomethine groups [27,28]. Therefore, it is clear from the IR spectra that both the NH_2 groups of diamine have condensed with both the carbonyl groups of 2,6-diacetylpyridine to give rise to an N_6 arrangement of four azomethines and two pyridine nitrogen atoms equally suitable for coordination. 2,6-Disubstituted pyridine derivatives show various bands at *ca.* 1585–1615, 1570–1590, 1455–1490 and at *ca.* 1440–1445 cm^{-1} can be assigned to four υ(C=C) skeletal frequencies and designated as bands I, II, III and IV of pyridine rings, respectively [27–29]. The spectra also exhibit a ring breathing mode at *ca.* 990 cm^{-1}, an out-of-plane (C–H) deformation at *ca.* 800 cm^{-1}, an in-plane (C–C) deformation at *ca.* 615 cm^{-1} and an out-of-plane (C–C) deformation at *ca.* 405 cm^{-1}, respectively. The two strong bands at *ca.* 785 and 740 cm^{-1} are assigned to γ(C–H) and ø(C–C) vibrations [30], respectively.

The spectra of the chelates exhibit a downward shift in the location of bands I, II, III and IV. The bands at *ca.* 990 cm^{-1} disappear and are replaced by a band at *ca.* 1015–1025 cm^{-1}.The band assigned γ(C–C) splits into two at *ca.* 725 and 740 cm^{-1}, while γ(C–H) appears at *ca.* 785 cm^{-1} as a single band. These changes point towards the involvement of the pyridine nitrogen in coordination. Furthermore, the bands assignable to an in-plane (C–C) deformation (~605 cm^{-1}) and an out-of-plane (C–C) deformation (~410 cm^{-1}) undergo an upward shift to 15–20 cm^{-1} in the spectra of chelates, which is consistent with the coordination of pyridine-nitrogen to the metal atom [31]. This mode of coordination is further supported by the far-IR spectra of complexes. In the spectra of complexes under study, a strong band at *ca.* 1615 cm^{-1} with a shoulder at *ca.* 1610 cm^{-1} may be assigned to symmetric and anti-symmetric stretching modes of the azomethine linkage [32] and the frequency concerned with the υ(C=N) stretching mode shifted to a lower range by 2–5 cm^{-1}, with a marginal loss of the intensity of the band. This lowering may be taken as an indication of the coordination of the nitrogen of the azomethine group to the metal atom [33]. The appearance of one band at *ca.* 1080 and 625 cm^{-1} assignable to Cl_4^- stretching and bending modes, respectively, is found in the perchlorate complexes of manganese(II). The position of these bands is compatible with the ionic perchlorate group [34].

The far-IR spectra of the complexes show various bands in various regions assignable to pyridine ring and metal-nitrogen vibrations. The spectra of the complexes derived from 2,6-diacetylpyridine and diamine show bands at *ca.* 415 and 600 cm^{-1}, assignable to (C–C) out-of-plane and (C–C) in-plane deformations. The vibrations suffer significant shift towards higher frequencies and support pyridine-nitrogen coordination to the metal atom [35]. The spectra also exhibit various bands in the region at *ca.* 260-280 cm^{-1}. In this region the various vibrations observed are at *ca.* 260–270, 265–274 and 275–280 cm^{-1} and these may be assigned to υ(Mn–py) stretching vibrations, respectively [36]. The far-IR spectra also show various bands at *ca.* 430–495 cm^{-1}, which implies $\upsilon_{(Mn-N)}$ (azomethine) vibrational modes and confirms the involvement of the azomethine nitrogen.

IR spectroscopy provided information on the integrity of the encapsulated complexes, as well as the crystallinity of the host zeolite. The IR bands of all encapsulated complexes were weak due to their low concentration in the zeolite. Mn(II) complexes encapsulated in the zeolite cages did not show any significant shift in C=N stretching modes. I did not notice any appreciable changes in the frequencies of Mn complexes after incorporation into zeolite matrix. The major FT-IR bands of the encapsulated complexes are tabulated in Table 2. All metal complexes encapsulated zeolites exhibit band around 1140, 1035, 960, 780 and 740 cm^{-1} due to zeolite framework. No significant broadening or shift of the structure-sensitive zeolite vibrations at 1130 cm^{-1} (due to the asymmetric T–O stretch) on encapsulation of metal complexes indicates that there is no significant expansion of the zeolite nanocavities or dealumination during the encapsulation process. This further indicates that the structure of metal complexes fit nicely within the cavity of the zeolite.

The magnetic moment measurements of the manganese(II) complexes at room temperature are in the range 5.93–6.01 BM (Table 1), corresponding to five unpaired electrons. Electronic spectra of Mn(II) complexes exhibit four weak intensity absorption bands, in the range 560 nm (ε = 47 l mol^{-1} cm^{-1}), 400 nm (ε = 50 l mol^{-1} cm^{-1}), 344 nm (ε = 65 l mol^{-1} cm^{-1}) and 312 nm (ε = 160 l mol^{-1} cm^{-1}). These bands may be assigned to the transitions: $^6A_1g \rightarrow {}^4T_1g$ (^4G), $^6A_1g \rightarrow {}^4Eg$, ^4A_1g (^4G), $^6A_1g \rightarrow {}^4Eg$ (^4D) and $^6A1\,g \rightarrow {}^4T_1g$ (^4P), respectively (Table 1). When the complex

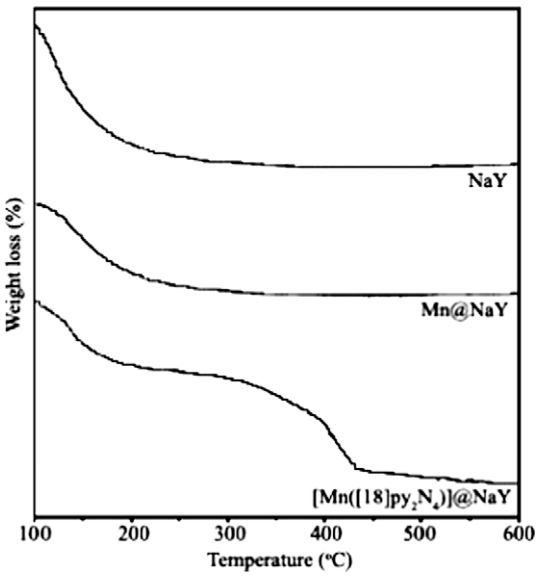

Fig. 1. TGA profiles of NaY, Mn@NaY and $[Mn([18]py_2N_4)]^{2+}$@NaY.

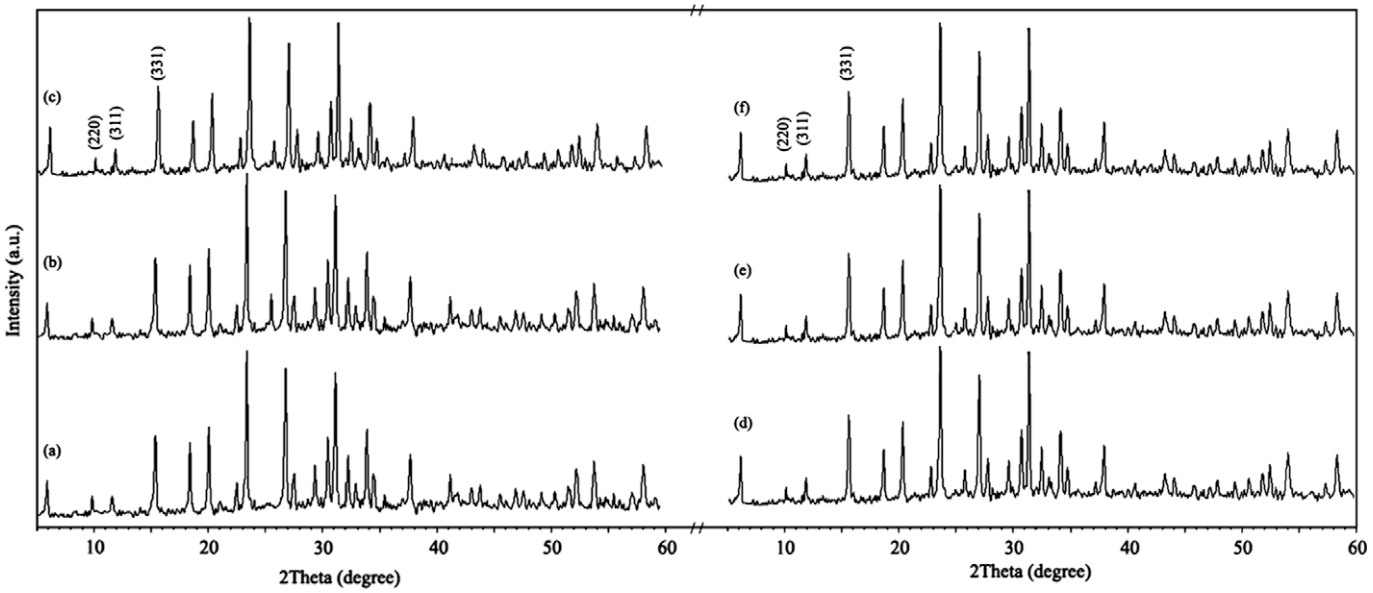

Fig. 2. XRD patterns of (a) NaY, (b) Mn@NaY, (c) $[Mn([18]py_2N_4)]^{2+}$@NaY, (d) $[Mn([20]py_2N_4)]^{2+}$@NaY, (e) $[Mn(Bzo_2[18]py_2N_4)]^{2+}$@NaY, (f) $[Mn(Bzo_2[20]py_2N_4)]^{2+}$@NaY.

nanoparticles were encapsulated in zeolite-Y, the d ↔ d band shifted again to the higher energy side. The stability of the complexes increases apparently when they are encapsulated in zeolite-Y. The position of the d ↔ d band corresponds to a octahedral geometry for macrocyclic manganese(II) complex nanoparticles [37].

The TGA profile of one of the representative nanocomposite material, $[Mn([18]py_2N_4)]^{2+}$@NaY is given in Fig. 1. The thermal decomposition of all these materials occurs in two steps. The endothermic loss in the first step starts shortly after increasing the temperature above 150 °C and continues until the loss of all intrazeolite water. The exothermic loss in the two steps, as expected, occurs in a wide temperature range (200–500 °C) and is due to the slow decomposition of the chelating ligand. A very small weight percentage loss indicates the presence of only small amount of metal complex insertion in the cavity of the zeolite. This is in agreement with the low percentage of metal content estimated by atomic absorption spectrometer. As shown in Fig. 1, the decomposition of encapsulated complexes occurred at high temperature, so the encapsulated complexes are stable than the neat complexes [38–41].

The X-ray powder diffraction (XRD) patterns of NaY, Mn(II)@-NaY and encapsulated complexes along with simple complexes "$[Mn([18]py_2N_4)]^{2+}$" were recorded at 2θ values between 5° and 60° to study the crystallinity and to ensure encapsulation (Fig. 2). The XRD patterns of manganese exchanged zeolite and their respective encapsulated complexes are essentially similar to that of NaY, though a slight change in the intensity of the bands has been noticed. The relative peak intensities of the 220, 311 and

					289.5, 289.1		402.3		

[a] Amount of the elements determined by XPS analysis of the samples.

331 reflections have been thought to be correlated to the locations of cations. In zeolite-Y, the order of peak intensity is in the order: $I_{331} \gg I_{220} > I_{311}$, while in encapsulated complexes, the order of peak intensity became $I_{331} \gg I_{311} > I_{220}$. The difference indicates that the ion-exchanged Mn^{2+}, which substitutes at the location of Na^{+}, undergoes rearrangement during complexation. These observations indicate that the framework of the zeolite has not undergone any significant structural changes during the incorporation of the materials, i.e. the crystallinity of zeolite-Y is preserved during encapsulation. This clearly suggests the presence of metal complexes in zeolite matrix. X-ray diffraction indicated that zeolites with good crystallinity can be obtained during the encapsulation of manganese(II) complexes by the template condensation reaction.

The surface area and pore volume of the materials are presented in Table 3. The encapsulation of $[Mn([18]py_2N_4)]^{2+}$, $[Mn([20]py_2N_4)]^{2+}$, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$ and $[Mn(Bzo_2[20]py_2N_4)]^{2+}$ complexes in zeolite reduced the adsorption capacity and the surface area of the zeolite. The lowering of the pore volume and surface area indicated the presence of complexes ($[Mn([18]py_2N_4)]^{2+}$, $[Mn([20]py_2N_4)]^{2+}$, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$, $[Mn(Bzo_2[20]py_2N_4)]^{2+}$) within the zeolite nanocages and not on the external surface.

The presence of the complex in NaY was supported by XPS analysis. All modified NaY samples revealed the presence of oxygen, sodium, silicon and aluminum from the zeolite lattice in their XPS resolution spectra. The bands typical of the Mn(II)–py_2N_4 complex, scarcely visible because of their low loading, were identified in the Mn $2p_{3/2}$ and N 1s region. The bulk (Table 1) and the surface Si/Al (Table 4) atomic ratios of NaY and of modified samples were similar, which indicates that dealumination does not occur during the encapsulation procedure. The binding energies of the elements detected by XPS are summarized in Table 4. The most intense bands identified are due to the zeolite structure, in the Si 2p region a band at 103.5 eV typical for Si atoms with different chemical environments, such as SiO_4 and terminal Si–OH groups. In the Al 2p region a band at 75.1 eV from the tetrahedral AlO_4 groups and a symmetrical large band at 531.0 eV from the O 1s region, and finally a band in the Na 1s region at 1072.6 eV were also observed (Table 4).

As seen from Table 4, the amount of surface manganese is very similar to the that of bulk manganese content (Table 1), which suggests that the Mn(II)–py_2N_4 complexes are homogeneously distributed throughout the NaY crystals. The medium binding energy values for Mn 2p3/2 are different before and after encapsulation, which indicates the change in environment of the manganese upon coordination with the py_2N_4 ligand. Before coordination the medium binding energy of Mn 2p3/2 value was 639.9 eV (Mn(II)@NaY) and after the complex encapsulation the value is 640.5 eV, $[Mn([18]py_2N_4)]^{2+}$@NaY; 640.3 eV, $[Mn([20]py_2N_4)]^{2+}$@NaY; 640.6 eV, $[Mn(Bzo_2[18]py_2N_4)]^{2+}$@NaY and 640.4 eV, $[Mn(Bzo_2[20]py_2N_4)]^{2+}$@NaY (Table 4). These results confirm the same manganese coordination sphere for the complex when free or encapsulated within NaY zeolite and that the host matrix environment does not affect the valence state of the metal atom of the complex.

The high resolution C 1s spectrum of encapsulated complexes shows an asymmetric band centred at 285.0 eV that can be deconvoluted into three individual bands (Table 4). The three bands at high energy were also observed in the starting material and are presumably due to the presence of some contamination. The band at 289.0 eV is attributed to the aromatic carbons of the py_2N_4 ligand. The encapsulated complexes and the free complex samples exhibit a band centred at 400.1 and 402.3 eV in the N 1s region, due to the contribution of nitrogen atoms of the ligand (Fig. 3).

Fig. 3 shows the Mn 2p core levels of neat and encapsulated complexes. Manganese remains in the 2+ oxidation state in both

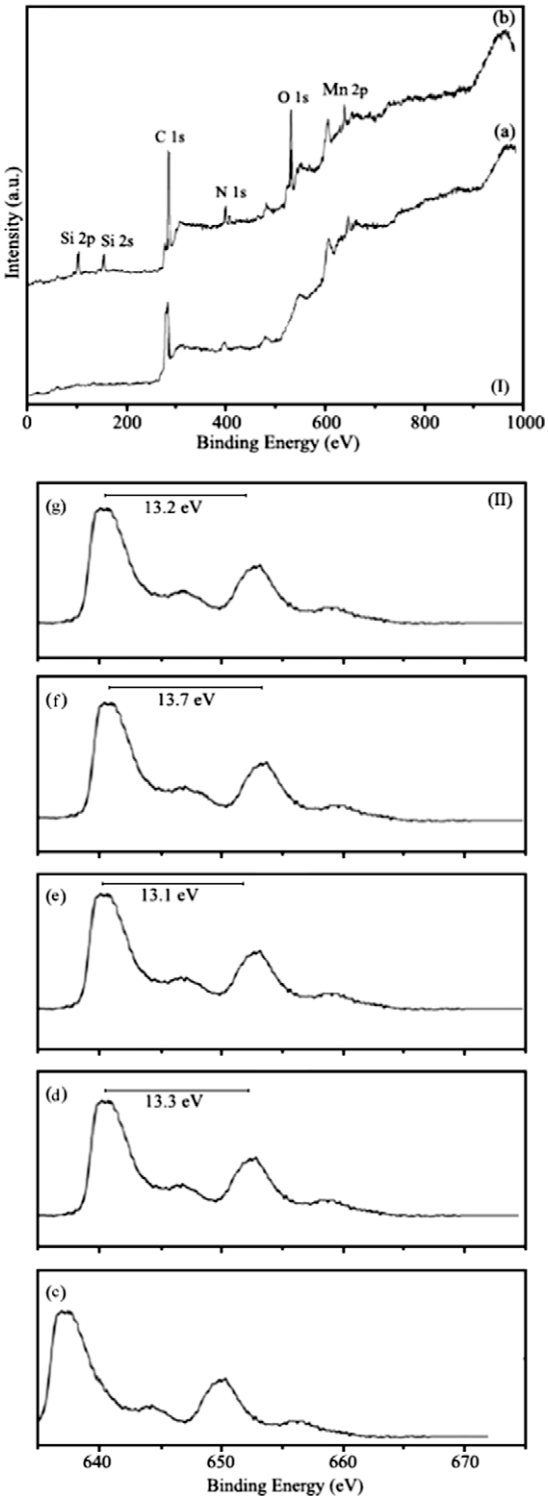

Fig. 3. XPS spectra of (I) (a), $[Mn([18]py_2N_4)](ClO_4)_2$; (b), $[Mn([18]py_2N_4)]^{2+}$@NaY. (II) XPS Mn 2p2/3 of (c), $[Mn([18]py_2N_4)](ClO_4)_2$; (d), $[Mn([18]py_2N_4)]^{2+}$@NaY; (e), $[Mn([20]py_2N_4)]^{2+}$@NaY; (f), $[Mn(Bzo_2[18]py_2N_4)]^{2+}$@NaY; (g), $[Mn(Bzo_2[20]py_2N_4)]^{2+}$@NaY.

the neat and encapsulated complexes and it matches well with the reported values for similar systems [42]. There is a strong increase in satellite intensity for Mn 2p levels and a large energy gap (13.1–13.7 eV) between them is observed from encapsulated complex, which results in higher stability than in neat complex. Table 4 lists out the relevant parameters for Mn complexes.

4. Conclusion

The octahedral hexaaza complex nanoparticles; [Mn-([18]py_2N_4)]$^{2+}$, [Mn([20]py_2N_4)]$^{2+}$, [Mn(Bzo_2[18]py_2N_4)]$^{2+}$ and [Mn(Bzo_2[20]py_2N_4)]$^{2+}$; have been encapsulated in the nanocavity of zeolite by template condensation between pre-entrapped; [bis(diamine)manganese(II)] (diamine = 1,2-diaminoethane, 1,3-diaminopropane, 1,2-diaminobenzene, 1,3-diaminobenzene), [Mn(N–N)$_2$]$^{2+}$@NaY; complexes with 2,6-diacetylpyridine. This strategy appears to be effective for the encapsulated of Mn(II) complexes with 18- and 20-membered hexaaza macrocycle ligands derived from [Mn(N–N)$_2$]$^{2+}$@NaY, as template condensation in the nanocavity is still possible and no unreacted [Mn(N–N)$_2$]$^{2+}$ ions were detected. Furthermore, the spectroscopic data suggest that the encapsulated complex nanoparticle experience very little distortion in the supercage and that the chemical ligation to the zeolite surface is minimal.

ABSTRACT

In this work the study of Calf Thymus DNA interaction with several Cu(L-dipeptide) complexes was reported. The binding stoichiometry (Cu(mmol)/DNAmol base) was determined and in an attempt to clarify the binding mode, EPR and CD experiments were performed. All the studied complexes interacted with DNA, in a more selective way than $[Cu(H_2O)_6]^{2+}$, being the [Cu(ala-phe)] the complex with the highest interaction. The EPR experiments suggested that the monomeric species formed in solution were coordinated through a nitrogen atom of the DNA bases (inner-sphere binding) and the CD studies showed structural changes upon the DNA–complex interaction. Besides, the ratio Cu(mmol)/DNAmol base obtained by the binding stoichiometry experiments was close to that found by EPR and CD determinations. The effect on cell proliferation determined by the crystal violet bioassay on UMR106 rat osteosarcoma-derived cells showed that the [Cu(ala-phe)] complex exerted an antiproliferative action against this tumor line.

1. Introduction

The interaction of metal complexes with nucleic acids and their constituents has been a subject of interest in bioinorganic chemistry, especially since the discovery of cisplatin and their analogues. These studies have been useful for the development and the comprehension of the activity of new chemotherapeutic agents designed for the treatment of numerous diseases [1–3]. Many of these chemotherapeutic agents act by inhibition of the synthesis of the deoxyribonucleic acid (DNA), a natural target due to its predominant role in cellular replication. One way to achieve this inhibition is by direct DNA binding in either a noncovalent interaction by intercalation, groove-face binding or external electrostatic binding or a covalent interaction due to an outer-sphere or inner-sphere binding and (or consecutive) strand breakage [4,5].

In particular, in the search for new drugs the proposal that complexes based on essential metals may be less toxic than those with non essential ones led to the study of copper based drugs, some of them having an important cytotoxic effect [6–8]. Consequently, active copper compounds and their interaction with DNA have attracted great interest [5,9–11]. These studies have mostly used methods that focus on changes in the DNA structure as electronic absorption titration, fluorescence spectroscopy, viscosity measurements and circular dichroism, among others. For instance, chemotherapeutic copper complexes with polypyridil ligands showed an important interaction with DNA as intercalators as determined by UV–Vis and circular dichroism (CD) spectroscopies and viscosity [3]. Moreover, Sarkar's group studied the DNA interaction of Cu(II) complexes with piroxicam and meloxicam (anti-inflammatory drugs) which exhibited anticancer activity by UV–Vis and circular dichroism (CD) spectroscopies. They showed that their complexes bind strongly to DNA-backbone possibly with intercalation [12].

On the other hand, there is much less work using methods based on properties related to the metal ion. In this area relevant studies were performed by Chikira's group that provided information on the binding of copper complexes with amino acids or peptides to DNA fibers by electronic paramagnetic resonance (EPR) [13–20].

As a part of our research on metal-based drugs we have studied several copper complexes with oligopeptides as potential antitumoral agents encouraged by the antecedents in the literature [21,22]. In particular, we have synthesized and structurally characterized in solid state and in water solution a series of copper complexes with dipeptides [23–30] and analysed their magnetic interactions [31,32].

Due to these previously reported antecedents and with the aim of obtaining structural information about the interaction of DNA with copper-dipeptide complexes we explored changes in the environment of the copper ion and in the DNA upon coordination.

doi:10.1016/j.poly.2009.04.029

In particular, the study of the DNA interaction with several Cu(L-dipeptide) complexes previously characterized by our research group was performed. Several dipeptides commercially available were selected in an effort to include ligands with inverted sequences of aminoacids and to cover a series containing aminoacids with different sizes. The aim of this selection was to perform a screening that provides structural information useful for biggest systems. Firstly, the direct quantification of the amount of copper bound to the DNA (binding stoichiometry) was measured. Secondly, EPR experiments were made with the complex that presented the best binding stoichiometry and with two complexes that presented medium interaction, in order to test whether there was any change in the Cu(II) coordination sphere when binding to the DNA. CD technique was used to explore the distortion introduced in the DNA structure upon binding with complexes or the distortion in the Cu(dipeptide) complexes.

Besides, to evaluate potential pharmacological activity of the complexes, a cell proliferation assay on UMR106 rat osteosarcoma-derived cells was performed.

2. Materials and methods

2.1. Synthesis of the complexes and analytical characterization

The copper (II) complexes with L-dipetides (SIGMA) ala-ala, ala-val, ala-ile, ala-leu, ala-thr, ala-phe, ala-tyr, phe-ala, phe-leu, phe-phe, val-phe, val-gly were obtained and characterized as described previously [26,27,29,30].

Table 1 summarizes the stoichiometry and analytical data for the Cu(II) complexes. Elemental analysis was performed with a CARLO ERBA EA 1108 equipment.

2.2. Spectroscopic measurements

Electronic absorption spectra of aqueous solution samples were recorded on a Milton Roy Spectronic 3000 spectrophotometer, using 1-cm path length quartz cells.

The copper concentration was measured by atomic absorption spectroscopy using a Perkin–Elmer 5000 instrument, with a Photron lamp for copper analysis, at 325 nm with air/acetylene flame.

X-band (9.5 GHz) EPR measurements were carried out on frozen aqueous solutions using a Varian E109 spectrometer and cavity with 100 kHz field modulation. The measurements were performed at N_2 liquid temperature. The *g*-values were obtained from spectral simulations using the QPOW program [33].

The CD spectra were recorded using a Jasco 720 instrument in a 1-cm path length quartz cell, in the 200–300 nm range.

2.3. Determination of the stoichiometry of the interaction Cu(II)dipeptide–DNA

The technique used in order to determine the stoichiometry of the interaction of the complexes with DNA was adapted from Mahnken et al. [34]. An aqueous solution of Calf Thymus DNA (SIGMA) (c.a. 1.7 mg/mL, 1 mL) was allowed to react with an aqueous solution of Cu-dipeptide (c.a. 1 mM, 1 mL) for 24 h at 37 °C.

The DNA was precipitated afterwards by addition of absolute ethanol (4 mL) and an aqueous solution of NaCl (2 M, 0.2 mL), and it was centrifuged (30 min at 50 rpm). The supernatant was discarded. The precipitate was dissolved in 2 mL of H_2O. This process was repeated three times. DNA and copper concentrations were monitored in the final solution. DNA concentration was determined at 260 nm using $\varepsilon_M = 6000\ M^{-1}\ cm^{-1}$. Copper concentration was measured by atomic absorption spectroscopy as described in Section 2.1. The solubility of the complexes was checked in the conditions of the precipitation of the DNA. The interaction was expressed as the ratio: Cu(mmol)/DNA(mol base).

2.4. Cu(II)dipeptide–DNA binding: characterization by EPR measurements

The EPR spectra of an aqueous solution of Calf Thymus DNA (SIGMA, 2.45 mg/mL) in presence of increasing amounts of copper complexes were recorded. The dilution scheme for each Cu(II) complex covered a 10–500 μM range, while the concentration of the DNA solution varied from 500 to 700 μM in DNA bases (pH 7). After each addition of copper complex the mixture was allowed to mix for 15 min at room temperature and then an aliquot was frozen at N_2 liquid temperature in order to register the EPR spectrum.

2.5. Cu(II)dipeptide–DNA binding: characterization by CD measurements

The CD spectra of an aqueous solution of Calf Thymus DNA (SIGMA) in presence of increasing amounts of copper complexes were recorded. The dilution scheme for each Cu(II) complex covered a 0.5–5 μM range, while the concentration of the DNA solution (DNA concentration was determined at 260 nm using $\varepsilon_M = 6000$) remained approximately constant at 50 μM in DNA bases (pH 7). As the data were obtained in excess of DNA, the total molar concentration remained nearly constant in all the spectra of each complex. This enabled us to perform a Job analysis of the data at 218 nm in order to estimate a binding constant for DNA–[Cu-peptide] [35].

Table 1
Stoichiometry, code and analytical data for the Cu(II) complexes.

Complex code	Complex stoichiometry	%C		%N		%H	
		Calc.	Exp.	Calc.	Exp.	Calc.	Exp.
1	$[Cu(ala\text{-}ala)]\cdot 2H_2O$	27.93	27.57	10.86	10.41	5.40	4.89

11	[Cu(val-phe)]	51.60	51.96	8.60	8.71	5.57	6.01
12	[Cu(val-gly)]	35.67	35.92	11.88	11.96	5.13	5.58

2.6. Cell proliferation assay

Due to the fact that [Cu(ala-phe)] presented the higher interaction with DNA, it was selected to study the antiproliferative activity. The effect of the copper salt and [Cu(ala-phe)] complex over the cell proliferation was study in a model of osteoblastic tumoral UMR106 cells.

UMR106 rat osteosarcoma-derived cells were grown in DMEM supplemented with 100 U/ml penicillin, 100 μg/ml streptomycin and 10% (v/v) serum bovine fetal (FBS) at 37 °C, 5% CO_2. When 70–80% confluence was reached, cells were subcultured using 0.1% trypsin 1 mM EDTA in Ca^{2+}–Mg^{2+} free phosphate buffered saline (PBS) (11 mM KH_2PO_4, 26 mM Na_2HPO_4, 115 mM NaCl, pH: 7.4). For experiments, cells were grown in 24-well plates. When cells reached 70% confluence, the monolayers were washed twice with DMEM and were incubated in different conditions according to the experiment.

A mitogenic bioassay was carried out as described by Okajima with some modifications [36].

Briefly, cells were grown in 48-well plates. When cells reached 60% confluence, the monolayers were washed twice with serum-free DMEM and were incubated with different concentrations of $CuSO_4$ or Cu-complex. The monolayers were washed with PBS buffer and fixed with 5% glutaraldehyde/PBS at room temperature for 10 min. Then, they were stained with 0.5% crystal violet/25% methanol for 10 min. After that, the dye solution was discarded and the plate was washed with water and dried. The dye taken up by the cells was extracted using 0.5 ml/well 0.1 M glycine/HCl buffer, pH 3.0/30% methanol and transferred to test tubes. Absorbance was read at 540 nm after a convenient sample dilution [37].

3. Results and discussion

3.1. Determination of the stoichiometry of the interaction Cu(II)dipeptide–DNA

The results of the binding stoichiometry of Cu(II)dipeptide–DNA are shown in Table 2. As shown in Table 2, the stoichiometry of binding depends on the complex, from what it is possible to assume that it is the Cu(II)dipeptide complex, and not only the free copper ion that interacts with DNA. The $[Cu(H_2O)_6]^{2+}$ complex interacts with DNA at a higher extent (>150 (mmol)/DNA(mol base)), probably in a less selective way interacting also with phosphate groups due to the positive charge.

All the studied complexes showed interaction, in a lower, and possibly more selective way than Cu(II) aqua ion. The extent of the interaction depended on the dipeptide ligand. The [Cu(ala-phe)] complex presented the highest binding stoichiometry while the rest of the series [Cu(ala-X)] (X = different aminoacids) showed significantly lower values. Besides, the interaction of [Cu(phe-ala)] was almost four times smaller than that of the [Cu(ala-phe)]. It might be possible that the phenyl ring (without substituents) in the second aminoacid is important in the interaction when the first aminoacid is alanine. Another observation is that in the complexes with a voluminous first aminoacid in the dipeptide ligand the interaction with DNA seems to be disfavoured. This is the case of [Cu(phe-ala)], [Cu(phe-leu)], [Cu(phe-phe)], [Cu(val-phe)] and Cu(-val-gly)].

Based on these results, [Cu(ala-phe)] that presented the best binding stoichiometry and [Cu(ala-val)] and [Cu(val-phe)] that presented medium interaction, were chosen for carrying out EPR and CD experiments with the aim to obtain structural information of the interaction.

Table 2
Binding stoichiometry expressed as Cu(mmol)/DNA(mol base).

Complex number	Complex stoichiometry	Cu(mmol)/ DNA(mol base)
1	$[Cu(ala\text{-}ala)]\cdot 2H_2O$	11
2[a]	[Cu(ala-val)][a]	9
3[a]	[Cu(ala-ile)][a]	14
4	$[Cu_3(ala\text{-}leu)_3(H_2O)_3(CO_3)]\cdot PF_6\cdot H_2O$	20
5	$[Cu(ala\text{-}thr)]\cdot {}^1/_2H_2O$	14
6[a]	[Cu(ala-phe)][a]	42
7	$[Cu(ala\text{-}tyr)]\cdot H_2O$	10
8	$[[Cu(phe\text{-}ala)]\cdot {}^1/_2H_2O$	11
9[a]	[Cu(phe-leu)][a]	13
10[a]	[Cu(phe-phe)][a]	2
11	[Cu(val-phe)]	8
12	[Cu(val-gly)]	10

[a] Previously reported [38].

3.2. Cu(II)dipeptide–DNA binding: EPR measurements

EPR experiments were carried out with solutions of the complexes [Cu(ala-phe)], [Cu(ala-val)], and [Cu(val-phe)]. Moreover, EPR spectra of DNA solution in presence of increasing concentrations of the Cu-dipeptide complexes were also recorded (see Section 2.3). The Fig. 1 shows the EPR spectra of a solution of free [Cu(ala-phe)] and solutions of this complex in presence of DNA at various mmol Cu(ala-phe)/mol bases DNA ratios. Besides, the spectral simulations are included in Fig. 1. Similar results were obtained studying the spectra of [Cu(ala-val)], and [Cu(val-phe)] in presence of DNA.

[Cu(ala-phe)] (Fig. 1A) in frozen solution presented an EPR spectrum characteristic of coupled Cu(II) ions with a single resonance around $g \sim 2$ ($H \sim 310$ mT) [30,39,40] whereas the spectrum of the Cu(ala-phe) complex with DNA at low mmol Cu(ala-phe)/DNA mol bases ratios (Fig. 1B) is the typical spectrum of

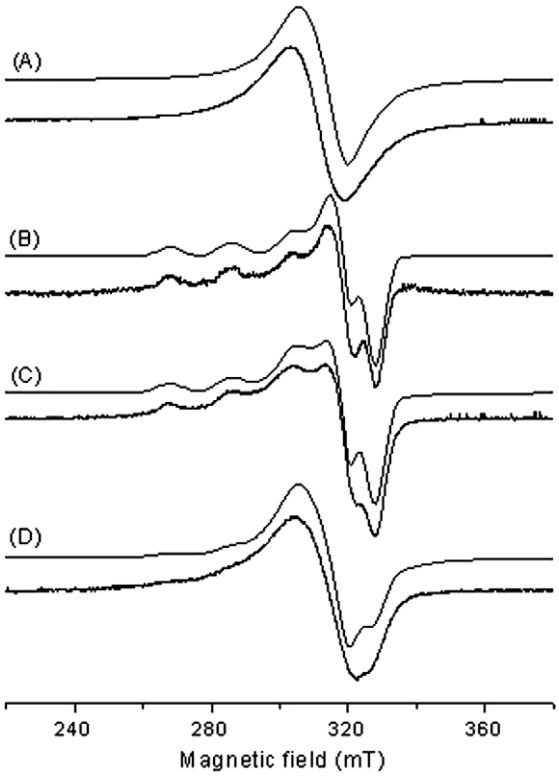

Fig. 1. Experimental (lower trace) and simulated (upper trace) X-band EPR spectra of a frozen solution of: (A) [Cu(ala-phe)] and [Cu(ala-phe)] in presence of DNA at (B) 30, (C) 110, and (D) 500 mmol Cu(ala-phe)/DNA mol bases.

monomeric Cu(II) complexes where the four hyperfine lines arising from the interaction of the $S = 1/2$ electron spin with the $I = 3/2$ copper nucleus are observed. This result showed that, at low Cu-dipeptide per DNA ratios (low copper complex levels), the magnetically coupled structure of the Cu-dipeptide complex is lost due to the coordination of the Cu-dipeptide monomer with the DNA molecule. The g values obtained from simulations of the spectrum at low mmol Cu(ala-phe)/mol bases DNA are: $g_{//} = 2.217$, $g_{\perp} = 2.048$, $A_{//} = 550$ MHz and $A_{\perp} = 35$ MHz.

With the aim to obtain structural information Peisach's proposal was used [19,41]. The magnitude of $A_{//}$ and $g_{//}$ was interpolated in the Peisach graph and the nature of the coordinating atoms in the equatorial plane was assigned. Our $A_{//}$ and $g_{//}$ values are similar to those reported for Cu(II) coordinated through three N atoms and one O atom (N3O).

Fig. 2 shows the Cu(II) environment in solution as presented in our previous work [38].

As shown in Fig. 2, in the free complex Cu(II) is coordinated through two N atoms and two O atoms in the equatorial plane. After the interaction with DNA, the EPR spectra suggest that the copper ion is equatorially coordinated through three N atoms and one O atom. This behaviour would show that one O atom from the copper environment is replaced by one N from a DNA base (inner-sphere binding).

When the Cu-dipeptide per DNA ratios increases (Fig. 1C and D) a spectrum of coupled Cu(II) ions appears superposed to the monomeric signal. The spectra in Figs. 1C and D could only be satisfactorily simulated when two spectral components were included in the fitting protocol using the QPOW program: the spectrum of the polymeric species (Cu(ala-phe) alone) and the spectrum of the monomeric specie (Cu(ala-phe) bonded to DNA), described above.

The existence of two spectral components supports the hypothesis that the DNA is able to bind only a small amount of Cu(dipeptide), and the remaining Cu(dipeptide) exists as free complex in solution (not coordinated to the DNA).

3.3. Cu(II)dipeptide–DNA binding: characterization by CD measurements

Circular dichroism experiments were carried out with [Cu(ala-phe)], [Cu(ala-val)] and [Cu(val-phe)] in (a) copper complex solutions and (b) copper complex solutions in presence of DNA. The aim of these experiments was to confirm the interaction and determine whether the DNA or the Cu(dipeptide) complex experimented structural changes due to the Cu(dipeptide)–DNA interaction.

(a) The spectra of aqueous solutions of the Cu(dipeptide) complexes were registered at increasing concentrations. As an example, the inset of Fig. 3 shows the spectra of Cu(ala-phe) complex. As expected, the ellipticity at 218 nm (maximum wavelength) linearly increases with the concentration, as shown Fig. 3, with a molar ellipticity of 765 M^{-1} cm^{-1}. Similar results were obtained for the complex [Cu(val-phe)] (molar ellipticity at 218 nm: 1190 M^{-1} cm^{-1}) while complex [Cu(ala-val)] does not show any significant ellipticity at 218 nm (15 M^{-1} cm^{-1}).

(b) The spectra of a DNA solution in presence of increasing concentrations of Cu(dipeptide) complexes were registered. Fig. 4 shows the spectra obtained for the [Cu(ala-phe)]–DNA system. Similar results were obtained with the [Cu(val-phe)] complex.

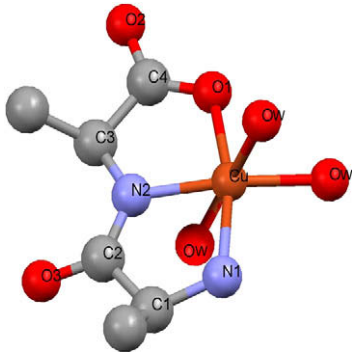

Fig. 2. Scheme of the Cu(II) environment of the Cu-dipeptide complexes in solution.

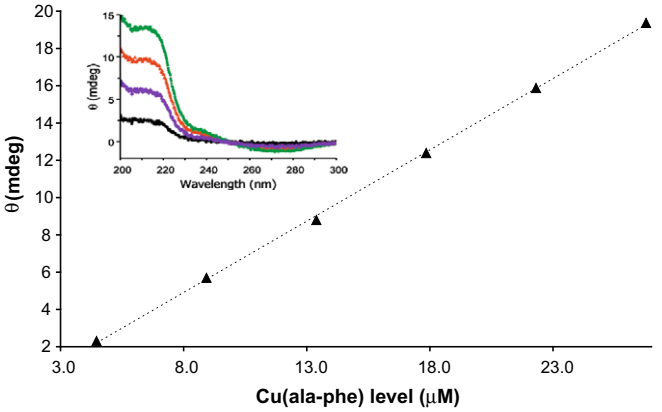

Fig. 3. Ellipticity of [Cu(ala-phe)] at 218 nm *vs.* concentration. Inset: CD spectra of [Cu(ala-phe)].

Fig. 4 presents the ellipticity of the system at 218 nm *versus* [Cu(ala-phe)] concentration.

It can be observed that the ellipticity at 218 nm does not increase linearly with the [Cu(ala-phe)] concentration, as would be expected if there were no interaction between the [Cu(ala-phe)] complex and the DNA. At low Cu(dipeptide) concentration (that is, low mmol [Cu(ala-phe)]/mol bases DNA ratio) the ellipticity almost does not increase with the increment of the Cu(dipeptide) concentration. As the ratio is increased, the ellipticity increases, showing a molar ellipticity similar to that of the free Cu(dipeptide) complex. This may be explained considering that at low mmol

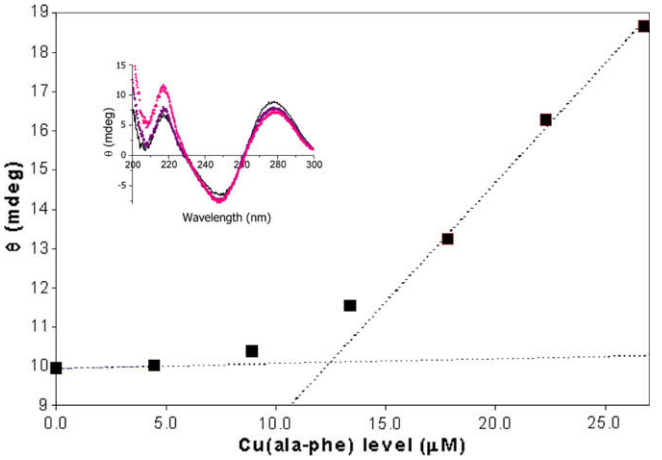

Fig. 4. Ellipticity of the [Cu(ala-phe)]-DNA system at 218 nm *vs.* [Cu(ala-phe)] concentration. Inset: selected CD spectra of DNA and DNA in presence of [Cu(ala-phe)] (with mmol [Cu(ala-phe)]/mol bases DNA ratios from 5 to 55).

[Cu(ala-phe)]/mol bases DNA ratio all the Cu(dipeptide) complex added is bonded to the DNA. The coordination with DNA induces structural changes with the consequently quenching of the complex ellipticity. As the mmol Cu(dipeptide)/mol bases DNA ratio is increased, the DNA is not more able to bind the Cu(dipeptide) complex, therefore the system behaves as if there were no interaction between the excess of Cu(dipeptide) complex and the DNA. In the Cu(dipeptide) concentration range of 8.9–13.4 μM (where we observed the slope change), the Cu(mmol)/DNA(mol base) ratio is 18–32 mmol Cu/DNA (mol base). Although the binding stoichiometry presented in Section 3.1 (42 Cu(mmol)/DNA(mol base)) is not included in this range it is still comparable and supports the proposal of the DNA saturation.

In the case of the [Cu(ala-val)] complex the results are different from the previous ones, as shown in Fig. 5.

As the complex has a very low molar ellipticity at 218 nm, the ellipticity of a solution of DNA with increasing concentrations of [Cu(ala-val)] should slightly increase at this wavelength. On the contrary, a decrease in the signal at 218 nm was observed. This result shows that the molar ellipticity of the DNA decreases in presence of [Cu(ala-val)], as previously reported for metallic complexes which bind to DNA [41]. This behaviour suggests a structural change in the DNA. It is possible that in the case of the complex [Cu(ala-phe)] there is also a decrease in the molar ellipticity of the DNA, which is masked by the decrease in the ellipticity of the complex bounded to the DNA.

In relation to the binding constant, the obtained values for [Cu(ala-phe)] and [Cu(val-phe)] were 1.2×10^4 and $5.9 \times 10^3\ M^{-1}$, respectively. These results are of the same order that the corresponding ones for complexes with biological activity reported in the bibliography [42,43].

The spectra of [Cu(ala-val)] does not show enough differences to estimate a binding constant.

3.4. Cell proliferation assay

The obtained results are shown in Fig. 6. As can be seen from the figure, at concentrations lower than 50 μM, the complex do not exert any inhibition on cell proliferation since no differences *versus* basal results could be observed. At higher doses, the complexes and the copper salt caused different inhibition of cell growth in a dose response manner. [Cu(ala-phe)] showed the greatest cell proliferation inhibition at the highest concentration (500 μM) where 45% cell survival could be detected when the osteosarcoma cells were incubated with this complex.

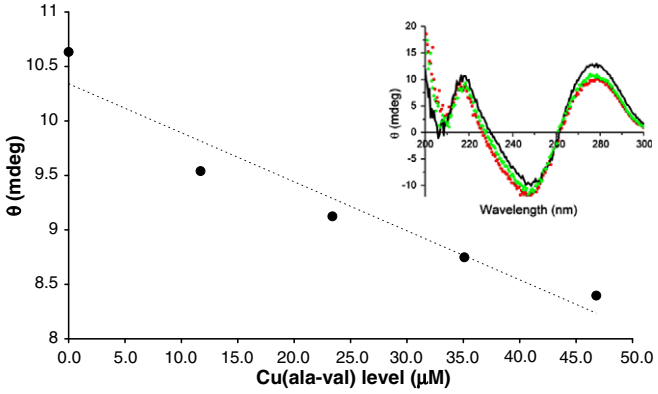

Fig. 5. Ellipticity of the [Cu(ala-val)]/DNA system at 218 nm *vs.* [Cu(ala-val)] concentration. Inset: selected CD spectra of DNA and DNA in presence of [Cu(ala-val)] (with mmol Cu(ala-val)/mol bases DNA ratios from 20 to 100).

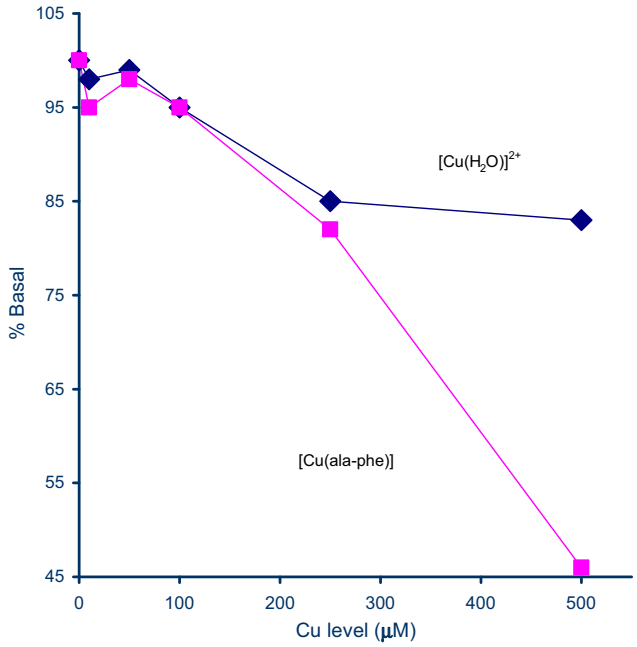

Fig. 6. Cell proliferation experiments with UMR106 after the treatment with [Cu(ala-phe)] and copper salt.

4. Conclusions

This work provided information about the interaction of a series of Cu(dipeptide) complexes with Calf Thymus DNA using different methodologies. All the studied complexes showed interaction, in a lower, and possibly more selective way than Cu(II) aqua ion. The extent of the interaction depended on the dipeptide ligand.

Interestingly, the EPR and CD studies suggested that the DNA binds a fixed amount of the Cu(dipetide) complex (which is coordinated to the bases of the DNA) up to saturation. Moreover, the systems start to show saturation at a mmol Cu(dipeptide)/mol bases DNA ratio close to that obtained in the binding stoichiometry values.

The inhibitory effect caused by [Cu(ala-phe)] on cell proliferation in the cultures of UMR106 osteoblasts is encouraging for future studies on the bioactivity of this complex with other tumoral cell lines since it may have potential application as antitumoral agent.

Optical properties

ABSTRACT

In this work, we present the synthesis and optical study of the binuclear zinc(II) macrocyclic complexes, derived from 4-methyl-2,6-diformylphenol and 1,2-diaminobenzene (H_2L). Two zinc macrocyclic complexes with different anions were prepared and characterized: $[Zn_2LCl_2]\cdot H_2O$ (**1**) and $[Zn_2L](NO_3)_2$ (**2**).

The complexes are emissive, both in the solid state and in solution at room temperature. Spectroscopic properties of the macrocyclic complexes were investigated using stationary and time resolved methods in solutions of dimethylsulfoxide (DMSO), and in solid state. DMSO solutions show two emission bands centered at 480 and 521 nm for complex (**1**), and at 527 nm with a shoulder at 480 nm for (**2**). The emission spectra of these compounds in solid state show a red shifted band, presenting the maxima at 565 nm for (**1**) and 575 nm for (**2**). The emission lifetimes for these compounds are very short, viz. 650 and 480 ps for macrocycles (**1**) and (**2**), respectively.

1. Introduction

The rich chemistry of complexes of dicompartmental ligands binding two metals has been applied to the investigation of magnetic exchange interactions between these centres, the stabilisation of mixed valence species and the activation of small molecules [1–7]. Besides, macrocycles derived from 4-methyl-2,6-diformylphenol and 1,2-diaminobenzene are studied since they show a high electronic delocalisation due to the planar structure that they present.

Luminescent metal complexes are gaining significant attention as sensors and probes in view of their applications in light emitting diodes (LEDs), biomedical analyses, fluorescence imaging and possibly in cancer phototherapy [8]. For example, metal complexes are promising luminescent materials for their applications as LEDs, owing to their ability to enhance, shift and quench luminescent emission of organic ligands by metal coordination. Many polynuclear zinc(II) compounds exhibit promising luminescent properties, especially those with ligands containing heteroaromatic rings, since the metal centres enhance the fluorescence of the aromatic moieties. Therefore, they are currently of interest in the development of fluorescent materials [9–11].

The zinc(II) macrocyclic complexes, derived from 4-methyl-2,6-diformylphenol and 1,2-diaminobenzene were prepared and characterized. We herein report an optical study of the binuclear macrocyclic compounds shown in Scheme 1.

2. Experimental

The reagents and solvents employed were used as received without further purification. Elemental analyses (C,H,N) were determined with a Perkin–Elmer elemental analyzer. The percentage of zinc was determined by atomic absorption with a Perkin–Elmer equipment, model 1100B. The FT-IR spectra were recorded from KBr pellets in the range 4000–400 cm^{-1} on a Bruker-IFS 28 spectrophotometer. The low frequency region, from 400–200 cm^{-1}, was recorded on a Bruker Vector 22 spectrophotometer. Micro-Raman spectra for (**1**) and (**2**) were recorded on Renishaw systems 2000, using laser excitation at 785 nm. All measurements were made in a back-scattering geometry, using a spatial resolution of 1 μm^2; the laser beam had circular polarization and laser powers of 10%. Single point spectra were recorded with 10 s accumulation times. In order to reduce the high fluorescence showed by the zinc macrocyclic complexes, the sample was deposited over a glass covered with gold nanoparticles in terms to get an enhanced Raman signal. The diffuse reflectance UV–Vis spectra were recorded using a Perkin–Elmer Lambda 20 UV–Vis spectrophotometer equipped with a Labsphere RSA-PE-20 diffuse reflectance

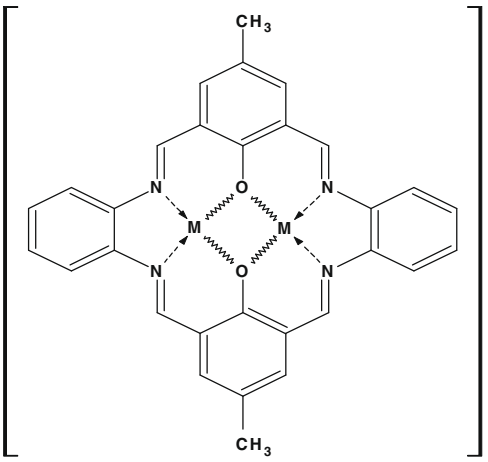
accessory. Magnesium oxide was used as reference and the spectra were recorded in the range 1.5–6.0 eV at room temperature. Reflectance measurements were converted to absorption spectra using the Kubelka–Munk function $F(R_\infty)$. Solution absorption spectra were recorded on a Unicam-UV3 spectrophotometer.

Solution fluorescence spectra in DMSO were performed on a Spex Fluorolog 2τ2 spectrophotometer. Fluorescence lifetime measurements were performed using Time-Correlated Single Photon Counting (TCSPC) technique [12]. Approximately 100 femtosecond excitation pulses with tunable wavelength (360–470 nm) were generated by doubling the fundamental frequency of a modelocked Ti:sapphire laser (Spectraphysics Tsunami) pulses in β-barium borate crystal. The laser repetition rate was reduced to 2 MHz by a home-made acousto-optical pulse picker in order to avoid saturation of the chromophore. TCSPC system is equipped with an ultrafast microchannel plate photomultiplier tube detector (Hamamatsu R3809U-51) and an electronics board (Becker and Hickl SPC-630), and has instrument response time less than 50 ps. Triggering signal for the TCSPC board was generated by sending a small fraction of the laser beam onto a fast (400 MHz bandwidth) Si photodiode (Thorlabs Inc.). Fluorescence signal was dispersed in Acton Research SPC-300 monochromator after passing through a pump blocking, long wavelength-pass, autofluorescence-free, interference filter (Omega Filters, ALP series). The monochromator is equipped with a CCD camera (Roper Scientific PIXIS-400B) allowing for monitoring of the fluorescence spectrum. Fluorescence transients were not deconvolved with the instrument response function since their characteristic time-constants were much longer than the width of the system response to the excitation pulse.

Emission spectra in solid state at room temperature were recorded using a Perkin–Elmer LS55 UV/Visible spectrometer. The solid sample were prepared by mixing the complexes with an inert silicone, and deposited on a quartz sample slice.



Thermogravimetric analyses (TGA) were performed from room temperature to 800 °C, under argon with a heating rate of 10 °C min^{-1}, using a Netzsch thermogravimetric analyzer, model 209-F1.

2.1. Synthesis of the partially reduced macrocyclic ligand derived from 4-methyl-2,6-diformylphenol and 1,2-diaminobenzene. (H_2L': 7,16-dihydroxy-6′,13′-dimethyl-1,4,10,13-tetraaza-tetrabenzo[2,3-a;6,7,8-f,a;11,12-a;15,16,17-f,a]cyclooctadeca-2,6,9,11,15,18-hexaene)

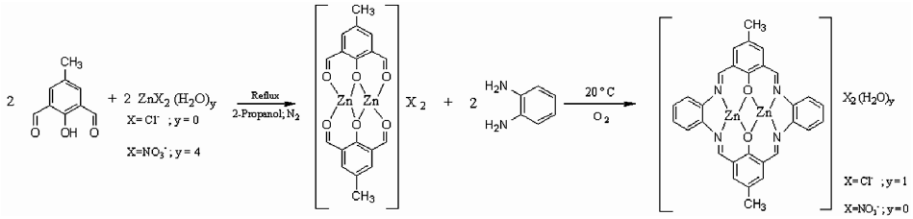
The template reaction, using Mg^{2+} or H^+ ions as template agents, was done by reacting under reflux 2-hydroxy-5-methyl-1,3-benzenedicarbaldehyde with 1,2-diaminobenzene in boiling methanol. The isolated macrocyclic ligand (**H_2L'**) was the partially reduced amino-imine compound, which was characterized by elemental analyses, ^{1}H NMR and FT-IR spectroscopy. The tetraimine ligand was not obtained with these synthetic conditions. *Anal.* Calc for H_2L' ($C_{30}H_{28}N_4O_2$): C, 75.61; N, 11.76; H, 5.92. Found: C, 74.55; N, 11.61; H, 5.97%. ^{1}H NMR: s: 2.31 (6H, methyl); d: 4.42 (4H, methylene); s: 6.32 (2H, amine); m: 6.75–7.27 (12H, aromatic); s: 8.60 (2H, azomethine); s: 13.5 ppm (2H, OH). FT-IR: ν_{N-H} = 3406 cm^{-1}; $\nu_{C=N}$ = 1617 cm^{-1}.

2.2. Synthesis of $M_2LX_2{\cdot}nH_2O$ (H_2L: 7,16-dihydroxy-6′,13′-dimethyl-1,4,10,13-tetraaza-tetrabenzo[2,3-a;6,7,8-f,a;11,12-a;15,16,17-f,a]cyclooctadeca-2,4,6,9,11,13,15,18-octaene); M = Zn(II), X = Cl (1); X = NO_3 (2)

The synthesis of the zinc(II) tetraimine macrocyclic compounds was achieved in a step by step synthesis. Initially 2-hydroxy-5-methyl-1,3-benzenedicarbaldehyde (1.84 mmol, 0.300 g) was refluxed for 3 h with $MX_2{\cdot}nH_2O$ (1.84 mmol, 0.250 g for X = Cl^- or 0.480 g for X = NO_3^-) in 2-propanol (40 mL), under an inert atmosphere (N_2). The dinuclear metal aldehydate complex was formed, and was used as the precursor for the formation of the macrocyclic compound. 1,2-Diaminobenzene (1.84 mmol, 0.199 g) dissolved in 2-propanol (10 mL) was added drop by drop to the 2-propanol solution of the precursor, and was left at ambient temperature with stirring for 90 min.; the macrocyclic complex $M_2LX_2{\cdot}nH_2O$ precipitated as a brick-red solid. The solid was first washed with acetone and then with methanol, and the purity was verified by column chromatography. *Anal.* Calc. for (**1**) ($C_{30}H_{24}N_4O_3Cl_2Zn_2$): C, 52.20; N, 8.12; H, 3.50; Zn, 18.95. Found: C, 52.6; N, 8.0; H, 3.7, Zn, 18.6%. *Anal.* Calc. for (**2**) ($C_{30}H_{22}N_6O_8Zn_2$): C, 49.68; N, 11.59; H, 3.06; Zn, 18.04. Found: C, 49.8; N, 11.2; H, 3.2; Zn, 18.1%.

1=Zn(II), Cl^- 2=Zn(II), NO_3^-

Scheme 1.



The zinc(II) macrocyclic complexes (**1**) and (**2**) were also synthesized by an alternative synthetic route, which involves a solvent free mechanochemical synthesis. Complexes (**1**) and (**2**) were obtained without any applied heating. The metal salts (2 mmol) and 2-hydroxy-5-methyl-1,3-benzenedicarbaldehyde (2 mmol) were mixed by grinding in a porcelain mortar for 10 min, till a strong yellow color of the solid was observed. Later, 1,2-diaminobenzene (2 mmol) was added to the reacting mixture, and this was also ground; a brick-red solid was obtained within a few minutes. The analyses gave the same percentage values, and the infrared spectra presented the same absorption bands as those obtained for the complexes synthesized by the traditional procedure.

3. Results and discussion

3.1. Syntheses

The reaction of dicarbonyl compounds with diamines is much more complicated than the simple Schiff condensation of mono carbonyl compounds with amines [13]. Moreover, the Schiff condensation with macrocyclic closure is usually obtained by a template reaction, in which metal ions [14] or anions of protic acids [15] are used as template agents. The introduction of a template agent is the most reliable method to prevent the formation of oligomers, and assures the presence of the macrocyclic compound.

In order to avoid the abnormal condensation of 2,6-diformyl-4-methylphenol with 1,2-diaminobenzene, accompanied with the reduction of two *trans* C=N double bonds of the macrocycle [16], the aldehydate dinuclear complex was formed, before the diamine was added. The final template formation of the dinuclear zinc(II) macrocyclic complexes was done in the presence of oxygen, in order to avoid any further reduction process (see Scheme 2).

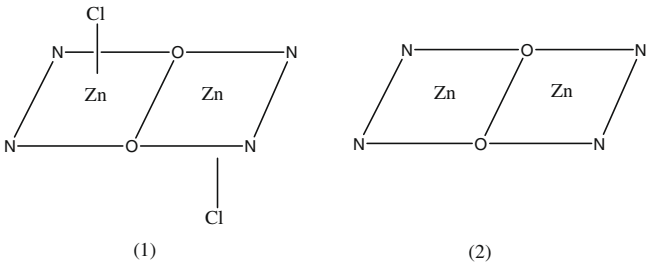
Scheme 2.

3.2. Thermogravimetric analyses

Thermal behaviour of the $[Zn_2LCl_2]\cdot H_2O$ macrocyclic complex (**1**) shows a weight loss in several steps. At 115 °C an experimental weight loss of 2.6% is found and it can be associated with the weight loss of one water molecule (calculated value is 2.6%). The temperature at which the water molecule is lost in (**1**) permits to infer that it is not coordinated to the metal ion. There is a second weight loss at 335 °C which corresponds to 9.8%; this correlates well with the calculated value for the loss of two chlorides, with a weight loss of 10%. Above this temperature a gradual loss of weight is recorded, associated with the thermal decomposition of the sample (Fig. 1Sa).

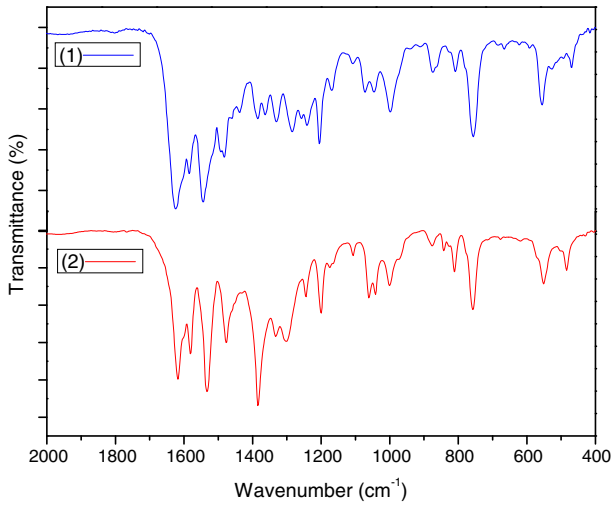
In the case of the nitrate complex $[Zn_2L](NO_3)_2$ (**2**) the thermal behaviour is characterized by a weight loss at 430 °C, corresponding to a 15.9%, which correlates with the loss of two nitrate ions (calculated value is 17.1%). The weight loss above 430 °C is associated with the thermal decomposition of the sample (Fig. 1Sb).

No single crystals of compounds (**1**) and (**2**), suitable for X-ray diffraction were obtained. Due to the low solubility of these macrocyclic compounds in most of the organic solvents, the ^{1}H NMR spectra were recorded in DMSO-d^6. However, the recorded spectra presented low resolution, which precluded the assignment of the signals. Therefore the proposed structures of the two complexes are written considering the above information. The proposed geometry around the zinc ion can be defined as square base pyramid for (**1**) and square planar for (**2**) (see Scheme 3).



Literature data shows that for zinc, the most common coordination numbers are five and six. Several N_2O_2X pentacoordinated zinc(II) complexes are found in the literature, where the apical position of the first coordination sphere is occupied by a chlorine atom [17–20]. An example of a pentacoordinated zinc(II) species with a monodentate nitrate ligand is given by Tandon et al. [21] Even though the zinc square planar compounds are scarce, literature data show that square planar zinc(II) complexes can be found for Schiff base species with a N_2O_2 first coordination sphere [22–25].

3.3. Spectroscopy



3.3.1. Infrared and Raman spectra

Fig. 1 shows the infrared and Raman spectra for (**1**) and (**2**). The IR spectra of both macrocyclic complexes show the fundamental vibration bands of the ligand; the stretching bands corresponding to νC=N appear at 1623 and 1618 cm^{-1}, the stretching vibration of νC=C at 1544 and 1535 cm^{-1}, νC–O$_{Ph}$ at 1330 and 1298 cm^{-1}, and the bending vibration of aromatic rings νC–H at 755 and 758 cm^{-1} for (**1**) and (**2**), respectively [26]. Furthermore, the macrocyclic complex $[Zn_2L](NO_3)_2$ presents a sharp and intense band at 1384 cm^{-1}, which corresponds to a ionic nitrate ion. When the nitrate ion is coordinated to a zinc ion, the infrared spectrum presents an absorption band at ca. 1750 cm^{-1}, band which is absent in the spectrum of the studied macrocyclic complex, suggesting the ionic nature of the nitrate ion.

On the other hand, the absence in the spectrum of the band around 1700 cm^{-1}, characteristic of the carbonyl group indicates the formation of the macrocyclic complex [27], which is in agree-

Scheme 3.

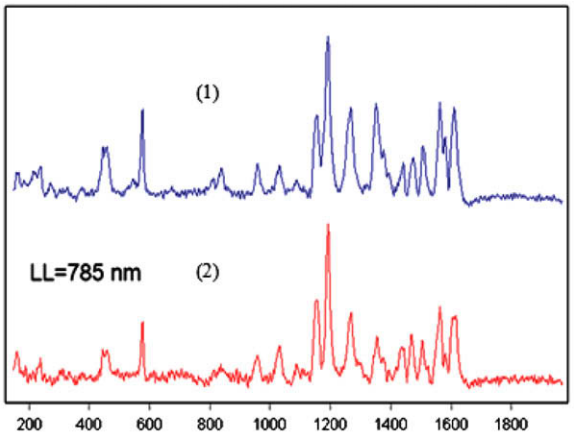


Fig. 1. Above: FT-IR Spectra of macrocyclic complexes, $[Zn_2LCl_2]\cdot H_2O$ (**1**), $[Zn_2L](NO_3)_2$ (**2**); below: Raman spectra, $[Zn_2LCl_2]\cdot H_2O$ (**1**) and $[Zn_2L](NO_3)_2$ (**2**).

ment with similar published data for these types of macrocyclic complexes.

Micro-Raman measurements are shown in Table 1. Characteristic fundamental vibrational modes observed in the Raman spectrum between 1000 and 1600 cm^{-1} are frequently used to study morphological structure. The measured samples show the typical C–H bending, C=C ring stretching and C=N bands for all complexes in this region, confirming the FT-IR assignments. Between 200 and 600 cm^{-1}, Zn–O, Zn–N stretching bands and some macrocycle and ring deformations appear, which are not well defined in the FT-IR spectra. Complex (**1**) presents a band at 285 cm^{-1} which can be assigned to the M–Cl stretching mode, while in the spectrum of complex (**2**) this band is absent [28,29].

3.3.2. Electronic spectra

The visible spectra of macrocyclic compounds (**1**) and (**2**) are depicted in Fig. 2. The absorption spectra of these dinuclear compounds in pure dimethylsulfoxide solution show two transitions at 422 nm ($1.7 \times 10^4\ M^{-1}\ cm^{-1}$) and 450 nm ($1.5 \times 10^4\ M^{-1}\ cm^{-1}$) for (**1**) and 416 nm ($2.9 \times 10^4\ M^{-1}\ cm^{-1}$) and 450 nm ($2.0 \times 10^4\ M^{-1}\ cm^{-1}$) for (**2**) in the visible region (Fig. 2a). The absorption bands, centred approximately at 420 and 450 nm for the zinc complexes may be assigned to the spin allowed MLCT $d \rightarrow \pi^*$ transition [26d], due to the relatively high extinction coefficient.

If the spectra are recorded in a mixture of DMSO:H_2O (3:2), changes are observed in the shape of the spectra, reaching a similar pattern for both complexes (Fig. 2b). This effect can be attributed to a change in the first coordination sphere of the complex cations (Scheme 4). In DMSO solution it is possible to propose that the chloride ions are acting as ligands, inside of the first coordination sphere for (**1**), while the nitrate anions are simple counterions for (**2**) and do not form part of the first coordination sphere (Scheme 4a). When a mixture of DMSO:H_2O is used, the water molecules are able to promote the substitution of the coordinated chloride ions, achieving both complexes a similar first coordination sphere (Scheme 4b).

The diffuse reflectance spectrum for (**1**) is shown in Fig. S2. This $[Zn_2LCl_2]\cdot H_2O$ macrocycle possesses an optical band gap of 2.1 eV, which is identical with the one corresponding to (**2**), and can be associated to the metal to ligand charge transfer process.

Scheme 4.

The complexes are emissive both in the solid state and in solution at room temperature (RT). Spectroscopic properties of the macrocyclic complexes were investigated using stationary and time resolved methods in solutions of dimethylsulfoxide (DMSO) and in solid state. When the DMSO solutions of the macrocyclic complexes (**1**) and (**2**) are irradiated with a wavelength of 422 and 420 nm, respectively, a green emission can be observed with bands centred at 480 and 521 nm for complex (**1**), and at 527 nm with a shoulder at 480 nm for (**2**) (Fig. 3). It can be observed that

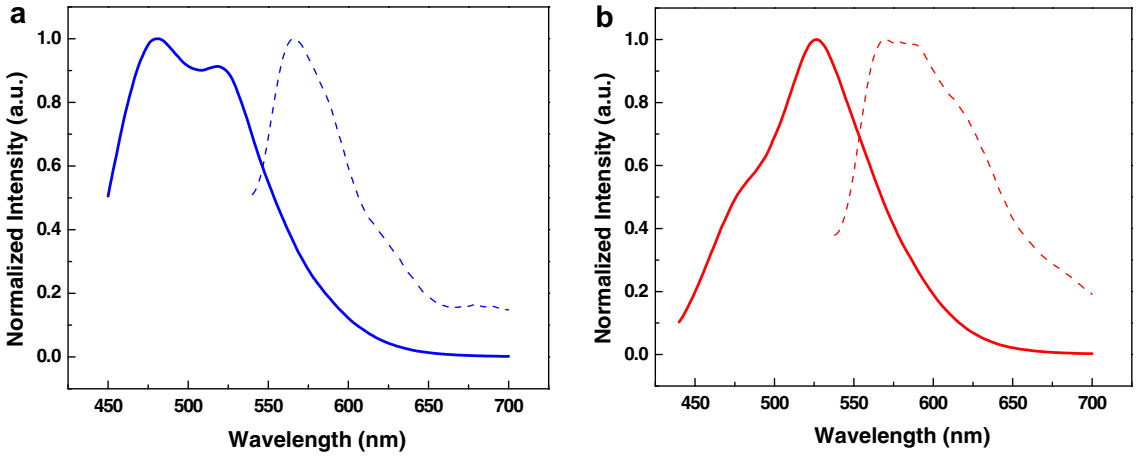

Fig. 3. Emission spectra of the macrocycles in DMSO solution (——) and solid state (– – – –). (a) $[Zn_2LCl_2]\cdot H_2O$ (**1**); (b) $[Zn_2L](NO_3)_2$ (**2**).

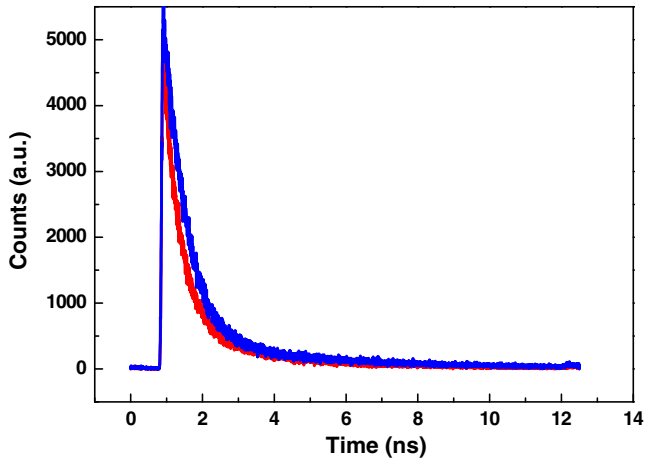

Fig. 4. Time resolved emission decay for $[Zn_2LCl_2]\cdot H_2O$, (**1**) (blue line) and $[Zn_2L](NO_3)_2$, (**2**) (red line) in DMSO solution at 545 and 550 nm, respectively, following excitation at 425 nm. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

macrocyclic complex (**1**) shows the highest energy of emission. The fluorescent emission may originate from the metal to ligand emission excited state. The emission is broad and structureless, which rules out a ligand centred nature of the emission, which would induce prominent vibrational structure, and makes it consistent with a charge transfer nature of the excited state [30].

The solid-state photoluminiscent spectra of the macrocyclic complexes (**1**) and (**2**) are depicted in Fig. 3. The emission spectra of these compounds in solid state compared with those in DMSO solutions show a red shifted band at 565 nm (**1**) and 575 nm (**2**). Red shifting of emission maxima can be observed for most fluorescent compounds in the solid state, probably due to π–π stacking of the aromatic rings in the molecules [31]. Comparing the solution with the solid emission spectra, it is possible to infer that the solvent destroys the π–π interactions, and thus the energy of the transition is increased in solution.

Time-resolved luminescent measurements allowed us to follow the intensity of the emission of the macrocycle after a laser excitation pulse at 425 nm. Fig. 4 shows the monoexponential intensity decays for the emission of the zinc macrocycles. The emission wavelengths used were chosen in order to minimize the signal–noise ratio. The emission lifetimes for these compounds are very short, viz. 650 and 480 ps for macrocycles (**1**) and (**2**), respectively. The lifetime difference could be explained in terms of the different coordination sphere for both macrocycles (see Scheme 4). Longer lifetimes have been reported for similar binuclear zinc macrocycles; however the involved transitions were assigned to a ligand centred emission [32] or from an excited state centred on the acceptor in a donor–acceptor system [33].

4. Conclusions

Two zinc macrocyclic complexes with different anions were prepared and characterized: $[Zn_2LCl_2]\cdot H_2O$ (**1**) and $[Zn_2L](NO_3)_2$ (**2**).

The infrared, Raman and electronic spectroscopic data were used to define the coordination of the anions; the chloride ions inside the first coordination sphere for (**1**) and the nitrate ions as simple counteranions for (**2**). The influence of the first coordination sphere on the fluorescent properties was shown to be important, being the emission lifetime for (**1**) longer than for (**2**).

Due to fact that the title compounds present emission at 500 nm, being thermally stable and insoluble in several solvents, they might be promising candidates for further applications as green light emitting materials.

ABSTRACT

At ambient temperature, the complex [Ni(OAc)(**PNP^{tBu}**)]OTf has one independent molecule in the asymmetric unit of the crystal structure with very large anisotropic displacement parameters. During cooling a fully reversible solid–solid phase transition occurs at a discrete temperature in the range 210–230 K. The low-temperature phase has six independent, well ordered molecules in the asymmetric unit. The $P2_1/a$ space group symmetry of the high-temperature phase changes to $P2_1/n$ for the low-temperature phase and the *c*-axis increases by a factor of six. The acetate ligand is shown to be coordinated in a η^1-fashion through one of the oxygen atoms, with the sterically encumbered, tridentate **PNP^{tBu}** ligand completing the square planar geometry around the Ni^{II} ion. The synthesis and full characterization of the complex is reported.

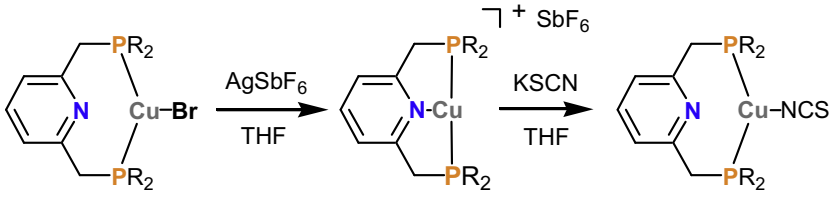
1. Introduction

Crystal structures with more than one independent molecule of the same species in the asymmetric unit ($Z' > 1$) are a curiosity for several decades and still relatively rare. There are interesting discussions still ongoing about the origin of this phenomenon [1]. Obviously, crystallization temperature and kinetics play an important role as well as the crystallization conditions (from solution by cooling or solvent evaporation, from the melt, or from the gas phase by sublimation). The central question under discussion is, whether a compound packed in a crystal structure with $Z' > 1$ should always have a more stable polymorph with $Z' = 1$, which only has to be sought.

Not only crystallization can lead to structures with $Z' > 1$, such structures can also be the result of solid–solid phase transitions. Here, the high Z' structures are frequently the ordered low-temperature phase, while the high-temperature phase with a lower Z' value shows signs of large thermal motion or disorder. The α-phase of the trivalent metal acetylacetonates $M^{III}(acac)_3$ of manganese [2], aluminum [3] and chromium [4] are isostructural at room temperature with $Z' = 1$, but at low-temperature they show different symmetries with $Z' = 2$, 3, or 6. Other examples are the divalent crown ether complexes $[M^{II}(H_2O)_2(15\text{-crown-}5)](NO_3)_2$, where Z' depends on the metal as well as on the measurement temperature [5].

The high Z' structure after a phase transition that is presented in this publication was found in an organometallic compound of a late transition metal. These compounds containing tridentate, pincer ligands continue to attract major attention [6]. Most examples of such ligands formally exist as monoanionic frameworks [7], but more recently neutral analogues have also gained interest [8]. Amidst that class of ligands, those derived from 2,6-lutidine have been studied intensely, in part because of the non-innocent character of the ligand framework, which has allowed for unusual cooperativity of the metal and the ligand, in particular for both fundamental coordination chemistry studies [9] and catalytic applications [10] (Scheme 1).

Recently, we applied the neutral (pseudo-)pincer ligand **PNP^{tBu}** [11] to construct a number of Cu^{I} complexes, wherein the potentially tridentate ligand but rather acted as a flexidentate ligand with hemilabile coordination of the pyridine N-atom [12]. More recently, we decided to explore the non-innocent character of the PNP-backbone in combination with its coordination to Ni^{II} and were able to selectively synthesize several thiolate and alkyl complexes [13]. During these investigations, we required the corresponding Ni(**PNP^{tBu}**)-acetato complex as a potential starting material.



2. Experimental

2.1. General

Solvents were purified by established procedures. Starting materials were purchased from commercial sources and used as

Scheme 1. Hemilabile coordination of the pyridine N-atom of **PNP^{tBu}** whilst coordinated to Cu^{I}.

received. IR spectra (ATR reflectance mode) were recorded with a Nicolet Avatar 360 FT-IR, NMR spectra were recorded with a Varian 200 spectrometer at room temperature (^{1}H: 200 MHz, ^{13}C: 50 MHz, ^{31}P: 80 MHz) and calibrated to the residual proton and carbon signals of the solvent (^{1}H) or an external solution of 85% aqueous H_3PO_4 (^{31}P{^{1}H}). **PNP^{tBu}** was synthesized according to a literature procedure [11,12].

2.2. Synthesis of complex *1*, *[Ni(PNP^{tBu})(OAc)]OTf*

To a solution of **PNP^{tBu}** (395.5 mg, 1.00 mmol) in THF/CH_2Cl_2 (1:1 v/v; 80 mL) was added $Ni(OAc)_2 \cdot 4H_2O$ (248.8 mg, 1.00 mmol), together with NaOTf (172.1 mg, 1.00 mmol) and 4 Å molecular sieves. The resultant orange-red suspension was stirred for 16 h before being filtered. After removal of solvent *in vacuo*, recrystallization of the red solid yielded orange-red crystals by slow diffusion of pentane into a THF-solution (476.9 mg, 0.72 mmol, 72%). ^{31}P NMR (80.9 MHz, acetone-d_6): δ 49.1. ^{1}H NMR (200 MHz, acetone-d_6): δ 7.99 (t, J_1 = 7.0 Hz, 1H, *p*-ArH), 7.56 (d, J_1 = 7.0 Hz, 2H, *m*-ArH), 3.91 (m, 4H, –CH_2–), 1.76 (s, OCOCH_3), 1.57 (vt, J_1 = 7.0 Hz, 36H, ^{t}Bu). IR (ATR, cm^{-1}): *v* 1631, 1604, 1566, 1467.

2.3. X-ray crystal structure determinations

The crystal structures of **1a** and **1b** were determined on the same crystal. Intensities were measured on a Nonius KappaCCD diffractometer with rotating anode (graphite monochromator, λ = 0.71073 Å). Integration was performed with Eval15 [14] (structure **1a**) or Eval14 [15] (structure **1b**). For **1a** a non-reduced setting of the cell parameters was used for comparison with **1b**. The program SADABS [16] was used for absorption correction and scaling. The structures were solved with Direct Methods using the program SHELXS-97 [17] and refined with SHELXL-97 [17] against F^2 of all reflections. Non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were introduced in calculated positions and refined with a riding model. The orientations of the methyl groups were refined successfully. Geometry calculations and checking for higher symmetry was performed with the PLATON program [18]. Further details are given in Table 1.

2.4. Temperature dependent unit cell determinations

The temperature dependent unit cell determinations were performed on a Nonius KappaCCD diffractometer with a different crystal than the collection of the complete datasets for the structure determination. To minimize apparatus errors, the CCD detector was kept fixed during the experiment. The Phi/Phi–Chi routine was used to obtain accurate positions of the reflections [19] and the cell parameters were re-determined after every temperature change and refined with the program PEAKREF [20]. The crystal was cooled from 290 to 110 K in steps of 20 K with a rate of 360 K/h and then warmed up to 290 K with the same steps and rate. The orientation matrix of the low-temperature phase was taken as starting point for all unit cell determinations.

3. Results and discussion

3.1. Synthesis

Complex **1** is prepared in a straightforward manner by the stoichiometric reaction of $Ni(OAc)_2 \cdot 4H_2O$ and **PNP^{tBu}** in CH_2Cl_2, together with one equiv NaOTf and 4 Å molecular sieves, as a red solid. The ^{31}P NMR spectrum showed a singlet at δ 49.1, while the presence of the acetate co-ligand was corroborated by virtue of a triplet at δ 1.76 in the ^{1}H NMR spectrum. The IR spectrum showed bands at *v* 1631 and 1467 cm^{-1} for the acetato fragment, together with two bands at 1604 and 1566 cm^{-1} for the coordinated **PNP^{tBu}** ligand. Recrystallization from THF-pentane yielded orange-red single crystals (Scheme 2).

3.2. Molecular structure

The molecular structure of **1** is discussed on the basis of **1b**, which is a well ordered structure, while **1a** shows signs of disorder. The Ni^{II} center is four coordinated with a slightly distorted square

Scheme 2. Synthesis of complex **1** starting from commercially available 2,6-lutidine.

Table 2
Selected bond lengths (Å), angles and torsion angles (°) for **1a** at 240 K and the six independent molecules of **1b** at 110 K.

planar geometry with cis angles between 86.23(9)° and 97.29(7)° in **1b** (Table 2). The coordination environment is formed by the neutral **PNP^{tBu}** ligand and one oxygen atom of the anionic carboxylate ligand leading to an overall single positive charge of the complex (Fig. 1). The second oxygen of the carboxylate is not coordinated (the Ni–O2 distances are 3.059(2)–3.223(2) Å in **1b**). The five atoms of the metal coordination plane are nearly coplanar with the pyridine ring with interplanar angles of 9.36(12)–11.24(13)° in **1b**. This is in contrast with the bent shape of the corresponding cationic three-coordinated Cu^{I} complexes [12], where the interplanar angles are between 34.40(11)° and 44.09(7)°. The P–Ni–P angles in **1b** are between 170.30(4)° and 173.23(4)°, which is much higher than in corresponding second- or third row square planar complexes with **PNP^{tBu}**. This reflects the direct influence of the ionic radius and the flexibility range of the ligand skeleton.

The overall single positive charge of the metal complex is balanced by a non-coordinated triflate anion per formula unit. The shortest intermolecular distance of a triflate oxygen to a nickel center in **1b** is 6.017(3) Å, but there are weak intermolecular C–H···O and C–H···F interactions with the triflate as acceptor. The corresponding C···O and C···F distances are 3.173(5)–3.564(4) and 3.204(4)-3.453(5) Å, respectively, with C–H···O and C–H···F angles of 124–170° and 124–154°.

The main difference between the molecular structures of **1a** at 240 K and **1b** at 110 K are the displacement ellipsoids. A rigid-body analysis of the metal complex in **1a** using the program THMA11 [21]

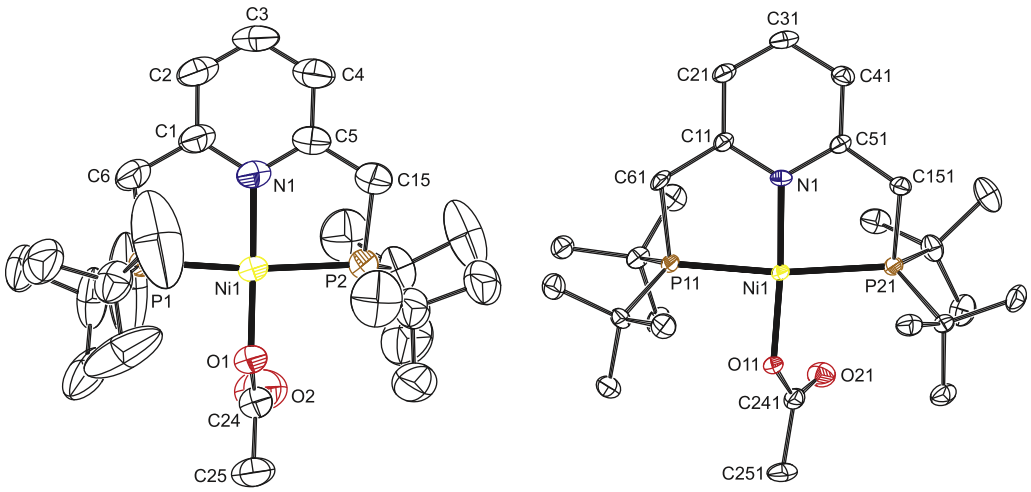

Fig. 1. Displacement ellipsoid plots of **1a** at 240 K (left) and one of the six independent molecules of **1b** at 110 K (right), drawn at the 50% probability level. Hydrogen atoms and triflate anions are omitted for clarity.

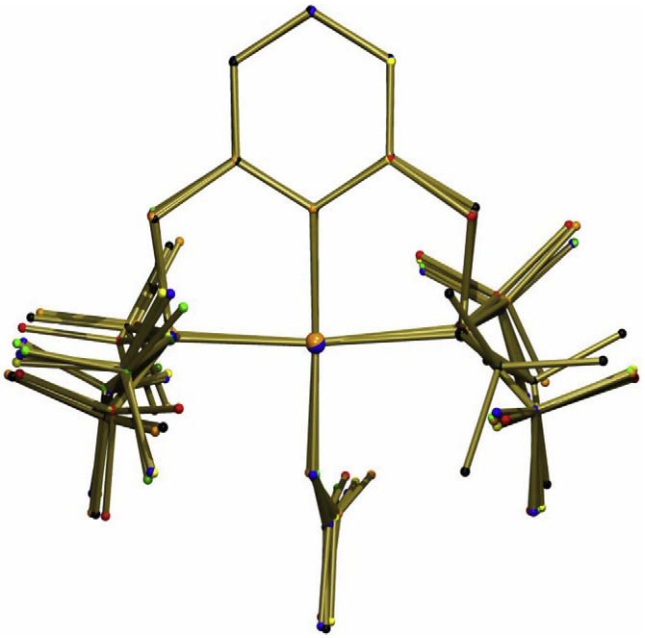

Fig. 2. Quaternion fit [24] of the six independent molecules in **1b** based on the atoms of the metal coordination environment and the pyridine ring. The calculation was performed with the program PLATON [18].

results in a very high R value of 0.554 [$R = (\Sigma(U_{obs} - U_{calc})^2/\Sigma(U_{obs})^2)^{1/2}$], which indicates that the displacement parameters of the molecule cannot be described with a rigid body model. The largest deviations from the rigid body model are in the *tert*-butyl groups at P1 (Fig. S1 [23], Supplementary data). Large deviations are also observed in the *tert*-butyl groups at P2, the benzylic carbon C6, and the non-coordinated acetate oxygen O2. The rigid body fit of the six independent molecules of **1b** is significantly better with R values between 0.213 and 0.363.

The main differences between the six independent molecules in **1b** are the orientations of the *tert*-butyl groups at phosphorus P1 (Fig. 2). These differences correspond to the large displacement ellipsoids in **1a**, which contains only one independent molecule in the asymmetric unit and can thus be considered as disordered average structure of **1b**. The puckering of the five-membered chelate rings in **1b** also differs: in four molecules the N–C–C–P torsion angles have an equal sign, in two molecules they have an opposite sign. In other words: four molecules have a local twofold symmetry, two molecules have a local mirror symmetry. Both of these different puckering modes are rather common in metal pincer complexes [22] and the change between local twofold and local mirror symmetry obviously has only a small energy barrier.

3.3. Symmetry change during the phase transition

Crystal structure **1a** at 240 K is described in a non-reduced setting of the cell parameters in space group $P2_1/a$, which is a non-standard setting of $P2_1/c$. This setting simplifies the comparison with **1b** at 110 K. The reduction of the cell parameters of **1a** can be obtained by applying transformation matrix $\mathbf{T_1} = (-1, 0, -2/0, -1, 0/0, 0, 1)$, which keeps the space group $P2_1/a$.

Applying transformation matrix $\mathbf{T_2} = (0, 0, 1/-2, 0, -3/0, -1, 0)$ with a determinant of 2 on **1a** will generate a C-centered pseudo-orthorhombic cell with $\alpha = \beta = 90°$ and $\gamma = 90.122(1)°$, but the associated orthorhombic Laue symmetry is not fulfilled by the reflection intensities ($R_{int} = 0.546$). No indications for pseudo-orthorhombic twinning were detected during data integration or structure refinement.

If transformation matrix $\mathbf{T_3} = (1, 0, 0/0, 1, 0/0, 0, 6)$ with a determinant of 6 is applied on the cell parameters of **1a**, the low-temperature cell of **1b** is generated. The corresponding operation with respect to the symmetry operations and the atomic coordinates involves matrix $\tilde{\mathbf{T}}_3^{-1} = (1, 0, 0/0, 1, 0/0, 0, 1/6)$. Before the application of $\tilde{\mathbf{T}}_3^{-1}$ the unit cell, symmetry operations and atomic coordinates must be expanded in c-direction by a factor of 6 resulting in 24 symmetry operations. After the application of $\tilde{\mathbf{T}}_3^{-1}$ only four symmetry operations have translational components of 0 and ½, consistent with space group $P2_1/n$ (space group of **1b**). The other 20 symmetry operations have translational components of 1/6 and 1/3 and do not belong to $P2_1/n$. By structural changes related to the phase transition these 20 symmetry operations become only approximate.

The phase transition keeps the point group (in German: "*Kristallklasse*") intact and only changes the translation symmetry. It can therefore be classified as *klassengleich*. Projections of the molecular packing of **1a** and **1b** in the crystal are depicted in Fig. 3. The crystal structure consists of alternating layers of

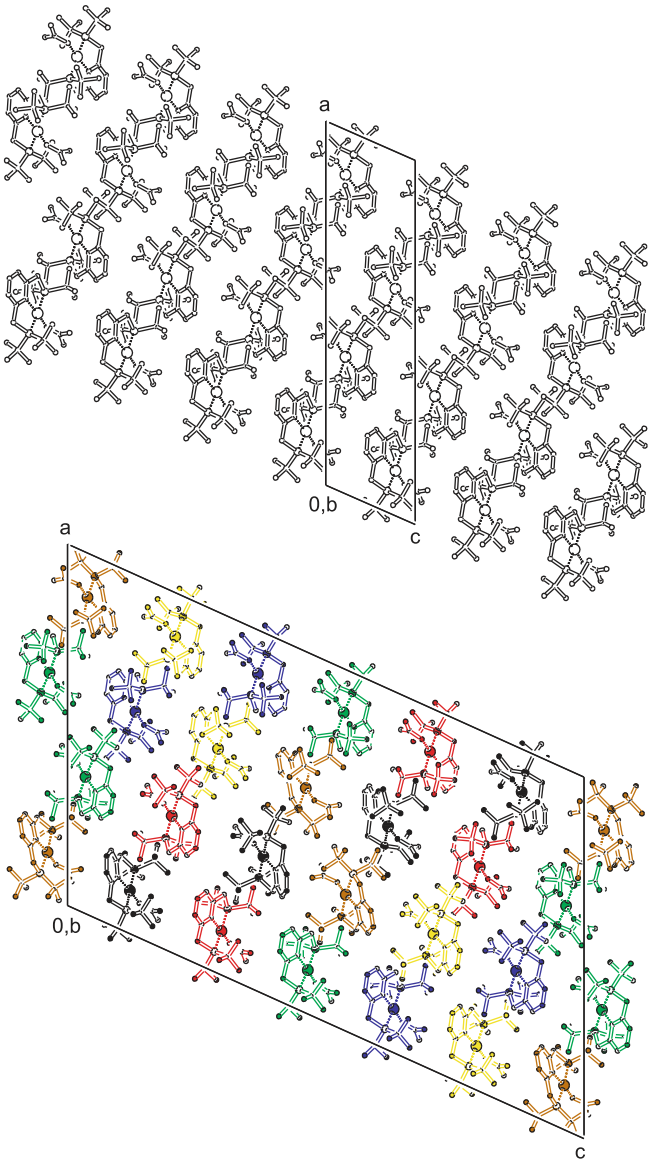

Fig. 3. Packing in the crystals of **1a** at 240 K (top) and **1b** at 110 K (bottom). View along the crystallographic b-axis. Independent molecules are drawn in different colors. Hydrogen atoms and triflate anions are omitted for clarity.

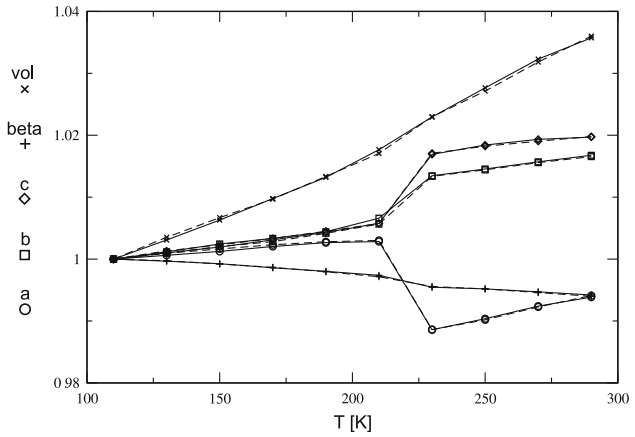

Fig. 4. Temperature dependence of the unit cell parameters normalized to those at 110 K. In the range 230-290 K the values of the *c*-axis were multiplied by a factor of 6. This multiplication was also taken into account for the calculation of the volume. The cooling curves are drawn as straight lines, the warming curves as dashed lines. Between 110 and 210 K and between 230 and 290 K the behavior is assumed linear. The lines between 210 and 230 K only indicate the discontinuity; the exact temperature of the phase change was not determined.

[Ni(OAc)(**PNP^{tBu}**)] cations and triflate anions parallel to the (2, 0, −1) plane (**1a**) or the (1, 0, −3) plane (**1b**). The only noteworthy intermolecular interactions are the above mentioned C–H···O and C–H···F bonds.

3.4. Temperature dependent unit cell parameters

The unit cell parameters of **1** have been determined by cooling from 290 to 110 K and warming up again to 290 K (see Section 2). The behavior is linear between 290 and 230 K, has a discontinuity between 230 and 210 K and then again linear between 210 and 110 K (Fig. 4). We assume that a phase transition occurs at a discrete temperature in the range between 230 and 210 K. The temperature of 240 K for the data collection of **1a** was chosen above this discontinuity in order to obtain the pure high-temperature phase.

1b at 110 K has a higher density (1.432 g/cm^3) than **1a** at 240 K (1.390 g/cm^3), which is a consequence of the discontinuity in the volume curve (Fig. 4); extrapolations of the volume of **1b** to 240 K would result in a density of 1.406 and 1.407 g/cm^3 for the cooling and warming curves, respectively. The better packing in **1b** can also be seen in the packing index [25] of 69.6%, compared to 66.9% in **1a**. In the case of polymorphic compounds with large Z' it has been discussed that the structures should be metastable [1], which would mean a relatively low density. In the present case of a disorder–order phase transition the density of the high Z' structure is higher than in the low Z' structure. The phase transition in **1** is fully reversible, as can be seen by comparing the cooling and the warming curves (Fig. 4).

For all unit cell changes in the ranges 290–230 and 210–110 K strain tensors have been calculated in the (Cartesian) crystal-physical coordinate system [26]. All eigenvalues of the tensors are positive in these temperature ranges, which means a triaxial positive thermal expansion.

3.5. Crystal defects of the low-temperature phase

The X-ray reflections of **1a** at 240 K have a normal profile (Fig. S2, Supplementary data) and a relatively small mosaicity of 0.25° has been assumed for the integration of the intensities. The crystal is well aligned in the center of the X-ray beam. After cooling to 110 K (**1b**) the reflections were found to be split. This splitting of the reflections is best described by two orientation matrices, which are related by a 0.42° rotation about a non-crystallographic axis. Additionally, both crystal fragments are no longer in the center of the X-ray beam. Integration of the intensity was performed with Eval14 [15] using a large enough contour around the split peak and summing all intensity within the contour based on the *background-peak-background* method. If the crystal is warmed to 240 K again, the splitting of the peaks disappears and the structure refined from these data is identical to **1a**.

3.6. Description of the low-temperature phase as modulated structure

In Fig. 2 the six independent molecules of **1b** were fitted on each other, taking into account the molecular geometry and ignoring the packing of the molecules in the crystal. The packing can be seen, if the transformation matrix $\mathbf{T_3}^{-1}$ is applied to the cell parameters and $\tilde{\mathbf{T}}_3$ to the coordinates of **1b** (Fig. S3, Supplementary data). Here, the deviations not only concern the conformations of the *tert*-butyl groups but affect all atoms and these deviations are very large. The Ni-atoms differ by up to 1.29 Å, the P-atoms up to 1.27 Å, the N-atoms up to 1.44 Å. The largest difference is between equivalent atoms of C18 and C22 in *tert*-butyl groups with 2.51 and 2.50 Å, respectively.

This very strong modulation of the atomic positions can also be seen in the intensity statistics of the reflections (Table S1, Supplementary data). While the substructure reflections with $l = 6n$, which correspond to **1a** at 240 K, are significantly stronger, the superstructure reflections with $l = 6n \pm m$, which are absent in **1a**, are still very strong due to the very strong modulation.

As a consequence of this intensity statistics the refinement of **1b** as a commensurate modulated structure in the four-dimensional space group $P2_1/a(\alpha 0 \gamma)0s$ appears not advisable. For such a refinement the reflections would have to be re-indexed with a six times smaller *c*-axis and a *q*-vector = 0, 0, 1/6.

The superstructure refinement in the three-dimensional space group $P2_1/a$ presented in this study is very stable. The data/parameter ratio is 14.7 and there are no correlation matrix elements larger than 0.608.

4. Conclusions

The free energy of a crystal has contributions from enthalpy and entropy [27]. On a qualitative level it can be stated that disorder increases the contribution of the entropy, while an optimal packing increases the contribution of the enthalpy. In many cases of solid–solid phase transitions the high-temperature phase shows signs of disorder and the low-temperature phase is well ordered [28]. In nearly all cases the high-temperature phase has higher symmetry, which is broken during cooling.

The present results confirm these simple theories, but it interesting to see how large the changes are, as well in the molecular conformation as in the crystal packing. Differences up to 2.51 Å are found between equivalent positions of non-hydrogen atoms of the six independent molecules of **1b** as a consequence of different puckering of the chelate-rings. From these huge changes we may conclude that the model of the average structure of **1a** is only approximate and does not cover all disorder features of this structure. The large structural changes during the phase transition will cause enormous stress, which is the probable reason for the crystal defects observed in the X-ray diffraction images of **1b**.

ABSTRACT

A series of Co^{II}, Ni^{II}, and Cu^{II} complexes with *trans*-1-(2-pyridyl)-2-(4-pyridyl)ethylene (bpe) and various polycarboxyl co-ligands have been prepared under general condition and characterized by IR, elemental analysis, and TG-DTA techniques. Single-crystal X-ray diffraction indicates that these complexes display multifarious binuclear, 1-D, and 2-D coordination motifs in virtue of the bridging polycarboxyl building blocks, in which the bpe ligand uniformly adopts the unidentate coordination by using its 4-pyridyl group. Remarkably, higher-dimensional extended networks are further formed with the aid of additional secondary interactions based on bpe (such as H-bonding and π–π stacking). These results demonstrate that bpe is a reliable bifunctional tecton to construct diverse supramolecular architectures *via* synergistic effect of multiple intermolecular interactions.

1. Introduction

The development of metallosupramolecular complexes based on crystal engineering strategy is of significant success in recent years, which provides a rational junction between aesthetics of the crystalline materials and their physicochemical properties [1–8]. From the viewpoint of supramolecular chemistry, the information of a predesigned ligand could be read by the metal ion in the assembled process according to the coordination algorithm to define the primary architecture [9–13]. Moreover, the secondary intermolecular non-covalent interactions such as H-bonding and aromatic stacking do play a key role in structural assembly [14–19], which however are difficult to control at the present time. In this regard, dipyridyl- and polycarboxyl-type ligands have been illustrated to be reliable building blocks for the construction of such metallosupramolecular systems [20–22].

In this context, we have demonstrated that *trans*-1-(2-pyridyl)-2-(4-pyridyl)ethylene (bpe) is a potential bifunctional ligand [23] to be readily involved in different intermolecular interactions due to the distinct steric effect of the terminal pyridyl groups. Generally, the 4-pyridyl ring prefers to coordinate with the metal ion, whereas the 2-pyridyl group has a tendency to serve as the H-bonding acceptor. Significantly, this characteristic can be applied to direct the photocycloaddition of such metallosupramolecular complexes in solid state to give new coordination species [24]. As a continuation of our efforts on this interesting project, we will describe herein the preparation, crystal structures, and thermal properties of five Co^{II}, Ni^{II}, and Cu^{II} complexes constructed from bpe and different aromatic polycarboxyl co-ligands (see Chart 1) such as benzene-1,3,5-tricarboxylic acid (H_3btc), benzene-1,2,4,5-tetracarboxylic acid (H_4btec), isophthalic acid (H_2ip), and terephthalic acid (H_2tp). The results undoubtedly reveal that structural diversity of these supramolecular solids is dominated by the interplay of both coordinative and multiple secondary interactions.

2. Experimental

2.1. Materials and general methods

All reagents and solvents were commercially available and used as received. Fourier transform (FT) IR spectra (KBr pellets) were recorded on an AVATAR-370 (Nicolet) spectrometer. Elemental analyses were carried out on a CE-440 (Leemanlabs) analyzer. Thermogravimetric and differential thermal analysis experiments were performed in the temperature range of 25–800 °C (heating rate: 10 °C/min) on a Rigaku standard TG-DTA analyzer under N_2 atmosphere with an empty Al_2O_3 crucible as the reference.

2.2. Synthesis of complexes **1**–**5**

2.2.1. $[Co(Hbtc)(bpe)_2]_n$ (**1**)

A CH_3OH (10 mL) solution of H_3btc (21 mg, 0.1 mmol) was mixed with an aqueous solution (10 mL) of $Co(NO_3)_2{\cdot}6H_2O$

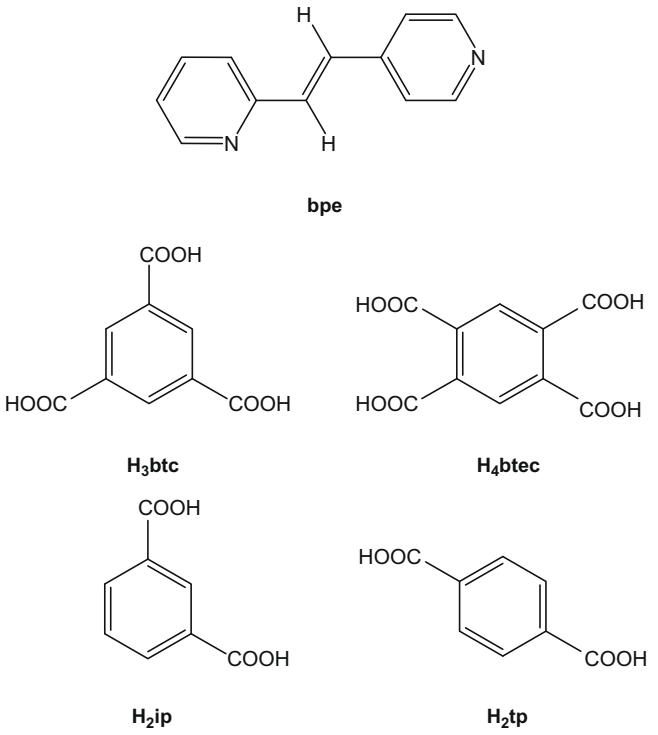

Chart 1.

(29 mg, 0.1 mmol) under stirring, to which a CH_3OH (5 mL) solution of bpe (18 mg, 0.1 mmol) was added. The resulting solution was filtered and left to stand under ambient condition. Red lamellar crystals of **1** suitable for X-ray diffraction were obtained upon slow evaporation of the solvents after a period of two weeks in 48% yield (15 mg, based on bpe). *Anal.* Calc. for $C_{33}H_{24}CoN_4O_6$: C, 62.76; H, 3.83; N, 8.87%. Found: C, 62.91; H, 3.74; N, 9.03%. IR (cm^{-1}): 3425b, 1691m, 1614vs, 1560s, 1432s, 1376s, 1220w, 1103w, 967m, 815m, 767m, 721m, 546m.

2.2.2. $[Co_2(btec)(bpe)_2(H_2O)_8](CH_3OH)_2(H_2O)_4$ (**2**)

The same synthetic method as that for **1** was used except that H_3btc was replaced by H_4btec (25 mg, 0.1 mmol), producing red block crystals of **2** in 58% yield (29 mg, based on bpe). *Anal.* Calc. for $C_{36}H_{54}Co_2N_4O_{22}$: C, 42.70; H, 5.37; N, 5.53%. Found: C, 42.43; H, 5.18; N, 5.41%. IR (cm^{-1}): 3416b, 1611vs, 1561vs, 1377s, 1139w, 1013m, 816m, 684w, 541m.

2.2.3. $[Ni(ip)(bpe)_2(H_2O)_2]_2(CH_3OH)(H_2O)_3$ (**3**)

The same synthetic method as that for **1** was used except that $Co(NO_3)_2{\cdot}6H_2O$ and H_3btc were replaced by $Ni(ClO_4)_2{\cdot}6H_2O$ (37 mg, 0.1 mmol) and H_2ip (17 mg, 0.1 mmol), respectively. Blue prism crystals of **3** were obtained in 51% yield (17 mg, based on bpe). *Anal.* Calc. for $C_{65}H_{66}Ni_2N_8O_{16}$: C, 58.58; H, 4.99; N, 8.41%. Found: C, 58.73; H, 5.15; N, 8.30%. IR (cm^{-1}): 3419b, 1610vs, 1546vs, 1472m, 1433s, 1386vs, 1221m, 1151w, 1073w, 1021m, 970w, 818m, 747s, 713m, 658w, 546m.

2.2.4. $\{[Ni(tp)(bpe)_2(H_2O)_2](CH_3OH)(H_2O)_2\}_n$ (**4**)

The same synthetic method as that for **1** was used except that $Co(NO_3)_2{\cdot}6H_2O$ and H_3btc were replaced by $Ni(ClO_4)_2{\cdot}6H_2O$ (37 mg, 0.1 mmol) and H_2tp (17 mg, 0.1 mmol), respectively. Green block crystals of **4** were produced in 43% yield (15 mg, based on bpe). *Anal.* Calc. for $C_{33}H_{36}NiN_4O_9$: C, 57.33; H, 5.25; N, 8.10%. Found: C, 57.53; H, 5.12; N, 8.23%. IR (cm^{-1}): 3414b, 1667w, 1593vs, 1497w, 1428m, 1379vs, 1153w, 1098w, 977m, 881m, 808m, 751s, 676w, 551s.

2.2.5. $\{[Cu(ip)(bpe)_2](H_2O)_4\}_n$ (**5**)

The same synthetic procedure as that for **1** was used except that $Co(NO_3)_2{\cdot}6H_2O$ and H_3btc were replaced by $Cu(ClO_4)_2{\cdot}6H_2O$ (37 mg, 0.1 mmol) and H_2ip (17 mg, 0.1 mmol), respectively. Green block crystals of **5** were produced in 45% yield (15 mg, based on bpe). *Anal.* Calc. for $C_{32}H_{32}CuN_4O_8$: C, 57.87; H, 4.86; N, 8.44%. Found: C: 57.58; H, 4.68; N, 8.76%. IR (cm^{-1}): 3427b, 1619vs, 1560s, 1367vs, 1221w, 1080w, 969w, 818m, 752m, 544m.

2.3. X-ray crystallography

Single-crystal X-ray diffraction data for **1**–**5** were collected on a Bruker Apex II CCD diffractometer at 296(2) K with Mo Kα radiation (λ = 0.71073 Å). There was no evidence of crystal decay during data collection. Semi-empirical absorption corrections were applied using SADABS and the program SAINT was used for integration of the diffraction profiles [25]. The structures were solved by direct methods using the SHELXS program of the SHELXTL package and refined with SHELXL [26]. The final refinement was performed by full-matrix least-squares methods on F^2 with anisotropic thermal parameters for all non-H atoms. In general, hydrogen atoms attached to carbon were generated geometrically with assigned isotropic thermal

Symmetry codes for **1**: A = $-x+1, -y+1, -z$; B = $x-1, y, z$; for **2**: A = $-x+1, -y+1, -z+1$; for **3**: A = $-x+3/2, -y+1/2, -z+2$; for **4**: A = $-x+1, -y+1, -z$; for **5**: A = $x, -y+1/2, z-1/2$; B = $-x+1, y-1/2, -z+1/2$. The symmetry codes also correspond to those in Fig. 1a to Fig. 5a.

parameters, and those of oxygen were first located in difference Fourier syntheses and then treated as riding. Notably, most of hydrogen atoms of the lattice methanol and water in **3–5** were not located. One bpe ligand in **3** was treated by using a disorder model with the central —CH=CH— fragment adopting two different locations. Further details for crystallographic data and refinement conditions are listed in Table 1. Selected bond distances and angles are shown in Table 2 and hydrogen bonding geometries are listed in Table 3.

3. Results and discussion

3.1. Synthesis and general characterization

All complexes described here were similarly prepared by direct assembly of the ligands with the corresponding metal salt in water–methanol at ambient condition. In each case, an approximate metal/ligand composition of 1: 1: 1 (M: bpe: H_3btc/H_4btec/H_2ip/H_2tp) was utilized for the starting materials. However, the resulting complexes are found to have the stoichiometric ratios of 2: 2: 1 for **2** and 1: 2: 1 for others in order to achieve the charge balance. The compositions of all complexes were confirmed by microanalysis, IR, and X-ray single-crystal diffraction techniques. As for the IR spectra, the broad bands centered at *ca.* 3400 cm^{-1} indicate the O—H stretching of carboxyl (for **1**) or solvents (for **2–5**). In the IR spectra of **2–5**, the absence of characteristic absorption bands of carboxyl suggests the complete deprotonation of the polycarboxyl ligands. As a result, the antisymmetric and symmetric stretching vibrations of carboxylate appear in the range of 1593–1619 and 1367–1386 cm^{-1}, respectively. It should be noted that the coexistence of both carboxyl and carboxylate groups is observed in **1**, with the characteristic IR absorption peaks occurring at 1691, 1614, and 1376 cm^{-1}, respectively.

3.2. Structural analysis of *1–5*

3.2.1. $[Co(Hbtc)(bpe)_2]_n$ (*1*)

In complex **1**, each Co^{II} ion is six-coordinated and exhibits a distorted octahedral geometry (see Fig. 1a), in which four oxygen donors from three different Hbtc anions constitute the equatorial plane and a pair of nitrogen atoms from two bpe ligands occupy the axial sites with the N2–Co1–N3 angle of 175.5(2)°. For benzene-1,3,5-tricarboxylic acid, two carboxyl groups thereof are deprotonated and bind to Co^{II} in chelating and bridging modes, respectively. Thus, the Hbtc anionic components interlink the Co^{II} centers to result in a 1-D coordination motif along [1 0 0] with dimeric $[Co(COO)]_2$ subunits, in which the Co···Co separation is 4.174(1) Å. As expected, the bpe ligands serve as unidentate terminals using their 4-pyridyl nitrogen donors and decorate the 1-D patterns along two sides as pendants (see Fig. 1b). Notably, each uncoordinated 2-pyridyl N1 atom of bpe is hydrogen bonded to the carboxyl group of Hbtc and such interchain O5–H5···N1 interactions extend the 1-D arrays into a 2-D layered network (see Fig. 1c and Table 3). Moreover, such layers are arranged in an interdigitated fashion to result in a 3-D supramolecular architecture, which is sustained by interlayer aromatic stacking interactions be-

tween the bpe components (see Fig. 1d and Table 4). Very small interspace is found in this structure with a volume of 80.9 $Å^3$ (5.5% of the unit cell volume).

3.2.2. $[Co_2(btec)(bpe)_2(H_2O)_8](CH_3OH)_2(H_2O)_4$ (**2**)

The replacement of H_3btc with H_4btec in the reaction process leads to the formation of a distinct dinuclear complex **2**. Each Co^{II} center in **2** is surrounded by one N atom of bpe, one O atom of btec, and four aqua molecules, forming a distorted octahedron with the axial O1–Co1–N1 angle of 173.74(7)°. Interestingly, the fully deprotonated btec anion links two adjacent Co^{II} ions (Co···Co = 11.619(7) Å) by using two unidentate carboxylate groups to constitute a centrosymmetric binuclear entity (see Fig. 2a). These binuclear motifs are further extended by multiple O–H···O bonds between the water ligands and carboxylate groups (O5–H5A···O4, O6–H6A···O3, O6–H6B···O3, O7–H7A···O1, and O8–H8B···O2, see Table 3 for details) to result in a 2-D network (see Fig. 2b). In addition, each "free" 2-pyridyl nitrogen of bpe is also hydrogen bonded to the water ligand to afford an intralayer O5–H5B···N2 interaction. Further investigation of the crystal pack-

(c) Packing diagram of **3** viewed along [0 0 1].

ing indicates that these 2-D patterns adopt a similar interdigitated packing to that in **1** with the presence of significant interlayer π–π stacking interactions (see Fig. 2c and Table 4). Furthermore, the included lattice water and methanol molecules are found to interact with the 2-D motifs by means of multiple O–H···O bonds such as O7–H7B···O9, O8–H8A···O10, O9–H9···O4, O10–H10A···O11, and O11–H11B···O5 (see Table 3 for details), which consolidate the 3-D supramolecular lattice of **2**.

3.2.3. *[Ni(ip)(bpe)$_2$(H$_2$O)$_2$]$_2$(CH$_3$OH)(H$_2$O)$_3$* (**3**)

In the structure of **3**, each octahedral Ni^{II} ion is six-coordinated by four O atoms from two ip and two aqua ligands as well as a pair of N atoms from the terminal bpe ligands (Fig. 3a). Two symmetry related Ni^{II} centers are doubly bridged by the ip ligands (Ni···Ni = 7.779(1) Å) to result in a bimetallic macrocyclic motif decorated by four unidentate bpe pendants, which is different from the linear binuclear array of **2**. Both carboxylate groups of ip are unidentate and as a result, intramolecular O5–H5A···O2 and O6–H6A···O4 bonds are found between the aqua ligands and uncoordinated carboxylate oxygen atoms. Significantly, the binuclear complexes are linked *via* O6–H6B···O6 interactions to afford 1-D zigzag arrays and each lattice water molecule of O7 serves as a trifurcate bridging (O5–H5B···O7, O7–H7A···O4, and O7–H7B···O5, see Table 3 for details) to interconnect the 1-D arrays, resulting in a 3-D reticular framework (see Fig. 3b). In this open network,

the void cavities are mostly occupied by the protrudent bpe ligands in a staggered fashion and thus, only small channels constituted by the bpe ligands are found (395.3 Å^3, 6.0% of the unit cell volume) to accommodate the lattice water guests (see Fig. 3c). The methanol solvents are located within the interstice between the water molecules of O5, O6, and O7. Even now, very small potential solvent-accessible void (113.4 Å^3, 1.7% of the unit cell volume) is found for the overall 3-D lattice. It should be noted that each uncoordinated 2-pyridyl N2 atom of bpe is hydrogen bonded to the included lattice water of O9 (N···O = 2.840 Å) and no aromatic stacking interaction is observed in this case.

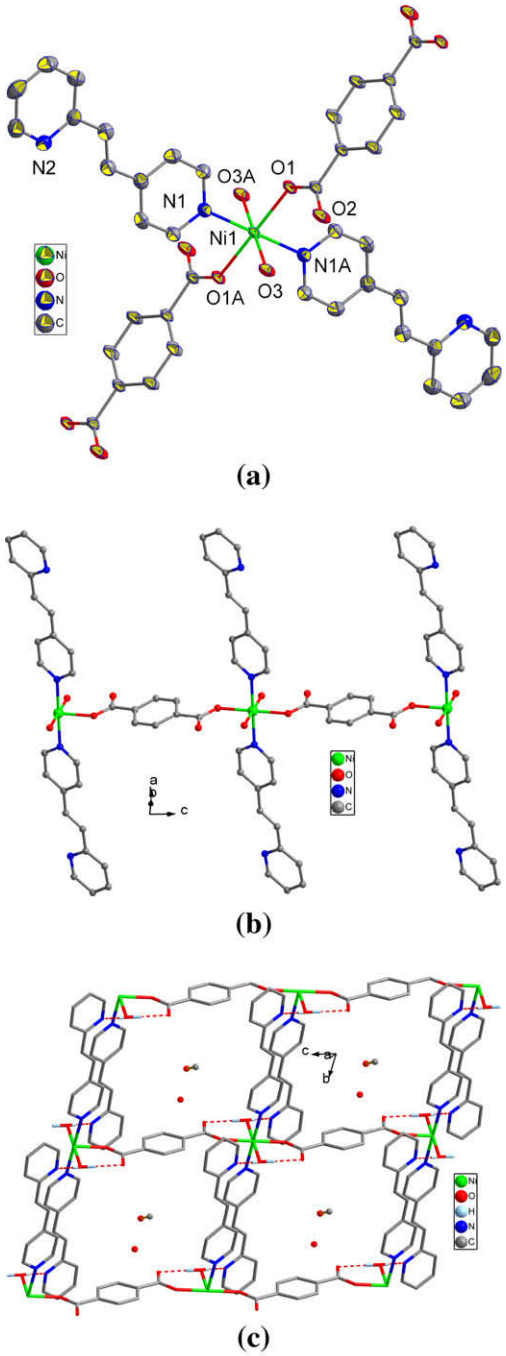

Fig. 4. (a) A portion view of **4** showing the coordination geometry of Ni^{II}. Displacement ellipsoids are drawn at the 30% probability level. (b) 1-D fishbone-like coordination motif in **4**. (c) A perspective view of the layered network in **4** with the inclusion of lattice solvents.

*3.2.4. $\{[Ni(tp)(bpe)_2(H_2O)_2](CH_3OH)(H_2O)_2\}_n$ (**4**)*

Each Ni^{II} ion in **4** lying at the inversion center is ligated by two unidentate carboxylate oxygen atoms, two 4-pyridyl nitrogen donors as well as a pair of water molecules to compose a NiN_2O_4 octahedral sphere (Fig. 4a). As a result, the adjacent Ni^{II} ions are connected by the tp dianionic bridges to afford a 1-D linear chain along [0 0 1] with the Ni···Ni distance of 11.310(2) Å, which is also decorated by bpe at both sides in an approximately perpendicular mode to result in a fishbone-like motif (see Fig. 4b). Intrachain O3–H3B···O2 bond between the water ligand and adjacent uncoordinated carboxylate oxygen is found. And of further importance, interchain O3–H3A···N2 contacts (see Table 3 for details) between the water ligands and 2-pyridyl N atoms further extend the 1-D arrays into a 2-D supramolecular layer along the *bc* plane, within

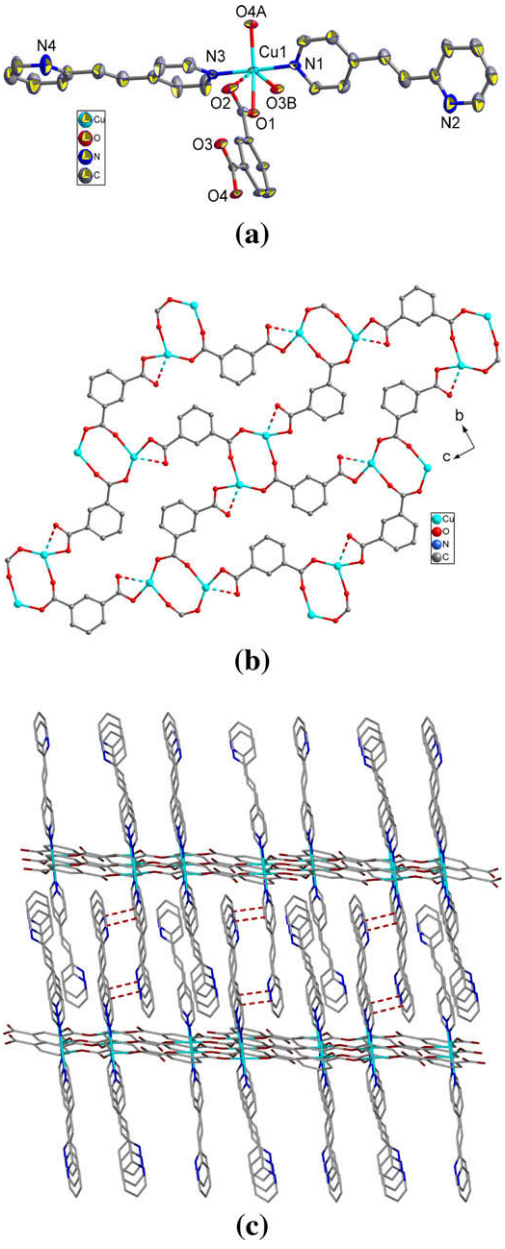

Fig. 5. (a) A portion view of **5** showing the coordination geometry of Cu^{II}. Displacement ellipsoids are drawn at the 30% probability level. (b) 2-D coordination sheet in **5** (the bpe ligands are omitted for clarity). (c) Packing diagram of **5** viewed along [0 1 0], showing interlayer π–π stacking as brown broken lines (the lattice water molecules are omitted for clarity).

which the lattice water and methanol molecules are included (see Fig. 4c). These 2-D arrays show a parallel packing mode along the [1 0 0] direction and no aromatic stacking interaction is found in this structure, which has very small solvent-accessible areas with a volume of 60.7 Å^3 (6.5% of the unit cell volume).

3.2.5. $\{[Cu(ip)(bpe)_2](H_2O)_4\}_n$ (**5**)

As depicted in Fig. 5a, each Cu^{II} ion in **5** is surrounded by three carboxylate oxygen donors from different ip and two 4-pyridyl nitrogen atoms from two bpe. The local coordination sphere of Cu^{II} can be described as a distorted square-pyramid with the τ value of 0.33 [27], in which the axial site is occupied by O3B. In addition, there exists a weak Cu1···O2 contact with the distance of 2.757(5) Å. Each ip ligand is coordinated to three Cu^{II} ions *via* the carboxylate groups and in this way, the adjacent Cu^{II} centers are connected by the bridging ip ligands to form a 2-D sheet (see Fig. 5b). In this 2-D pattern, each Cu^{II} center and ip ligand can be regarded as the equivalent three-connecting nodes to result in a 4.8^2 topology (**fes** net) [28]. On the other hand, if the bimetallic $[Cu_2(COO)_2]$ subunits (Cu···Cu = 4.459(2) Å) are considered as nodes, such a 2-D motif can be simplified to a familiar 4^4 topology (**sql** net). As expected, the bpe pendants around the 2-D arrays facilitate their interdigitated stacking mode and the resulting 3-D supramolecular lattice is sustained by interlayer aromatic stacking contacts (see Fig. 5c and Table 4) between the pyridyl rings of bpe. Furthermore, the lattice water molecules are located within the interlayer voids with the formation of water···water interactions and there also exist secondary contacts such as N2···O7 (2.816 Å) and N4···O8 (3.074 Å) between the 2-pyridyl nitrogen of bpe and lattice water.

3.3. Structural assembly of **1**–**5** via multiple supramolecular interactions

It is noteworthy that high-dimensional supramolecular assembly may be rationally designed *via* synergistic effect of multiple intermolecular interactions. In the structures of **1**–**5**, a variety of coordination motifs from discrete dinuclear species (for **2** and **3**) to infinite 1-D (for **1** and **4**) and 2-D (for **5**) arrays are formed. This structural discrepancy can be ascribed to the different bridging functions of the polycarboxyl building blocks (e.g. **1** versus **2** or **3** versus **4**) as well as the coordination tendencies of the metal ions (e.g. **3** versus **5**). On the other hand, all bpe ligands in these complexes are uniformly unidentate coordination by using the 4-pyridyl nitrogen and serve as the end-capping segments to decorate the coordination motifs. Of further importance, the coordination-unfavored 2-pyridyl group of bpe is always involved in the formation of O–H···N bonds with carboxyl (for **1**) or water (for **2**–**5**). Additionally, aromatic stacking interactions (see Table 4) are also observed between the pyridyl groups of bpe in complexes **1**, **2**, and **5**. Moreover, the solvent molecules especially water show the H-bonding activity in most of these structures. As a result, a variety of supramolecular networks that display distinct propagating and packing features are constructed under the regulation of both coordinative and secondary interactions. This investigation further confirms that the application of a bifunctional tecton (such as bpe here) is a practicable approach for the assembly of supramolecular coordination solids.

3.4. Thermal stability of complexes **1**–**5**

All complexes are air stable and their thermal stability was investigated by thermogravimetric (TG) and differential thermal analysis (DTA) experiments (see Fig. S1 in Supplementary Information for TG-DTA curves). Complex **1** is thermally stable to 228 °C, where the weight loss occurs and ends at 443 °C. Accordingly, an intensive exothermic peak is observed at 421 °C in DTA. The TG curve of **2** shows the first weight loss of 14.03% (calculated: 13.44%) from 59 to 118 °C, corresponding to the exclusion of all lattice aqua and methanol molecules (an endothermic peak at 94 °C in DTA). The residual coordination framework starts to decompose until heating to 216 °C and ends at 407 °C with an endothermic and an exothermic peaks at 243 and 408 °C in DTA. The resulting residue holds a weight of 24.07% of the total sample and seems to be $CoCO_3$ (calculated: 23.49%). In the TG curve of **3**, the weight loss of 5.54% in the range of 96–145 °C indicates the elimination of all lattice solvents (calculated: 6.45%) with an endothermic peak at 116 °C in DTA. Pyrolysis of the residuary component occurs upon heating to 169 °C and stops at 476 °C with two exothermic peaks at 380 and 447 °C in the DTA curve. As for **4**, the first weight loss of 12.51% in the TG curve (41–168 °C) suggests the release of all lattice solvents and one coordination water (calculated: 12.44%). Accordingly, an endothermic peak is found at 73 °C in DTA. Decomposition of the residual framework supervenes upon further heating to 191 °C and ends at 596 °C with an exothermic peak at 429 °C in DTA. The final residual solid has a weight of 11.00% of the total sample and seems to be nickel oxide (calculated: 10.80%). The TG curve of **5** displays a weight loss of 2.90% from room temperature to 133 °C, corresponding to the release of one lattice aqua molecule (calculated: 2.71%) with an endothermic peak at 78 °C in DTA. Upon further heating to 188 °C, a series of weight losses are observed in the TG curve, which end at 473 °C (three exothermic peaks at 262, 287, and 458 °C in DTA).

4. Conclusion

In this work, five novel metallosupramolecular complexes based on a bifunctional tecton bpe and different polycarboxyl co-ligands are presented. These complexes display discrete (dinuclear), 1-D, and 2-D coordination patterns through the polycarboxyl linkers, which are further extended in virtue of the predictable secondary interactions based on bpe to form diverse high-dimensional architectures. That is to say, the synergistic effect of multiple intermolecular contacts (coordination force as well as H-bonding and aromatic stacking) is critical to direct such network materials. These results provide further insights into the design and assembly of crystalline supramolecular solids and more systematic studies on this perspective are ongoing.

ABSTRACT

Deep blue tetrachloronickelate(II) salts of 1-alkyl-3-methylimidazolium cations $[C_n mim]^+$ with intermediate chain lengths (n = 5, 7, 8 and an n = 4/6 mixture) have been prepared from imidazolium chlorides and $NiCl_2$. They are liquid at ambient temperatures (ca. 20 °C) and above, and display viscosities and thermal stability comparable to related $[BF_4]^-$ compounds. The similarities may reflect the compensating effects of the dinegative charge of the $[NiCl_4]^{2-}$ ion and its larger size.

1. Introduction

In the past several decades, the chemistry of room temperature ionic liquids (RTILs) has expanded markedly as these compounds have become better understood and more broadly applied in academic and commercial settings [1]. Their unique properties, including large liquid temperature ranges, negligible vapor pressure, and adjustable viscosity and basicity, have stimulated uses as 'designer solvents' [2–4], in electrochemistry [5–7], and in catalysis [8]. A substantial part of their attractiveness stems from the discovery of air- and moisture-stable RTILs with main group anions such as $[PF_6]^-$ [9], $[BF_4]^-$ [10], $[(CF_3SO_2)_2N]^-$ [11], and $[CF_3SO_2]^-$ [11]. Metal-containing anions from across the periodic table have also been incorporated into ionic liquids, and they also can possess air- and moisture-stability; among these are zinc, tin, and iron-containing $[MCl_x]^-$ anions associated with various choline-derived cations [12]. In comparison with commonly used main group monoanions, metal-containing anions offer the possibility of more highly charged species (e.g., $[LnX_6]^{3-}$) [13] and additional variations in geometries (e.g., tetrahedral and square planar $[MX_4]^{2-}$ species) [14–16].

Nickel-based anions have a long history of use in ionic liquids. Osteryoung investigated the solubility of $NiCl_2$ in chloroaluminate melts, and determined that the predominant nickel containing species was $[NiCl_4]^{2-}$, although several additional ions were also detected [17]. Imidazolium-based Ni-containing salts $[C_n mim]_2[NiCl_4]$ (n = 2 (mp = 92–93 °C) [18]; 4 (mp = 55–58 °C) [15]; 12–18 (mp = 50–75 °C) [19]) were later prepared by other workers; crystal structures for the compounds with n = 2 and 4 demonstrated the existence of extensive cation-anion hydrogen-bonding. Pyridinium-based Ni-containing salts $[C_n py]_2[NiCl_4]$ (n = 12, 14, 16, 18) were investigated by Seddon and coworkers, who found all of them to be mesogenic solids with melting points ranging from 80–88 °C [19]. Abbott found that a choline-derived nickel chloride salt had a melting point above 100 °C [12]; it thus falls outside the conventional definition of RTILs (mp < 100 °C) [20].

In a search for nickel-containing ionic liquids that would be fluid at ambient temperatures (ca. $\geqslant$ 20 °C), and which might be useful in film formation or electrochemical applications [5], we have investigated the use of imidizolium cations with pendant alkyl chains of intermediate length, roughly C_5–C_{10}. This region has been previously identified as one in which compounds with low melting points are often found, as the hydrogen bonding that contributes to the high melting points of $[C_{(n \leqslant 4)}mim]$-based RTILs is disrupted, but the dispersion forces between longer chains that cause $[C_{(n \geqslant 10)}mim]$-based compounds to exhibit mesogenic characteristics have yet to become dominant [9,10].

In this work we outline the synthesis of several imidazolium RTILs that incorporate tetrachloronickelate anions and are liquid at 25 °C. The composition, viscosity and thermal behavior of these compounds was investigated.

2. Results and discussion

2.1. Synthesis of compounds

The mixture of the alkyl imidazolium chlorides with hydrated nickel(II) chloride results in dark blue liquids containing the $[NiCl_4]^{2-}$ anion (Eq. (1)).

$$2[C_n\text{mim}]\text{Cl} + \text{NiCl}_2(\text{H}_2\text{O})_6 \rightarrow 2[C_n\text{mim}]_2[\text{NiCl}_4] + 6\text{H}_2\text{O} \quad (1)$$

The water can be removed by heating under vacuum. When $n = 5$, the originally mobile liquid forms an opaque aqua-colored gel after several days at room temperature. When $n = 7$ or 8, or for the mixed cation species with $n = 4$, $n = 6$, the compounds remain transparent blue liquids indefinitely. The previously described $[C_2\text{mim}]^+$ and $[C_4\text{mim}]^+$ salts of $[\text{NiCl}_4]^{2-}$, in contrast, have melting points of 92–93 °C [18] and 56 °C [15], respectively [21]. The salts reported here are hygroscopic, and deliberate addition of water causes them to turn green, but the blue color will be regenerated on heating under vacuum.

2.2. Viscosity measurements

The viscosities of the nickelate salts were measured from 23–60 °C (the exact range varied with the cation), and the available viscosities closest to 25, 30 and 40 °C are given in Table 1. Not surprisingly, the two longer-chained salts with $[C_7\text{mim}]^+$ and $[C_8\text{mim}]^+$ cations have higher viscosities at a given temperature than do those with shorter chains; e.g., the viscosity of the $[C_8\text{mim}]^+$ salt is between 40% and 60% greater than for the $[C_5\text{mim}]^+$ analogue. Below 30 °C, the viscosity of the mixed $[C_4\text{mim}][C_6\text{mim}][\text{NiCl}_4]$ species (which could be considered to have an "average" chain length of C_5) tracks closely with that of the single-chained $[C_5\text{mim}]_2[\text{NiCl}_4]$ salt. Above that temperature, the viscosities start to diverge, and values for the mixed imidazolium salt stay roughly 15% below that of the single. The effect of mixed cations on the viscosities of ionic liquids is not well studied (cf. the relative rarity of viscosity measurements in systems with mixed anions [12,22,23]), so that it is not clear how typical the behavior of $[C_4\text{mim}][C_6\text{mim}][\text{NiCl}_4]$ is.

Table 1
Representative values for substituted imidazolium $[\text{NiCl}_4]^{2-}$, $[\text{PF}_6]^-$, $[\text{BF}_4]^-$ salts.

Ionic liquid	T (°C)	η (cP)	Ref.
$[C_5\text{mim}]_2[\text{NiCl}_4]$	24.9	125	This work
$[C_5\text{mim}]_2[\text{NiCl}_4]$	30.2	76	This work
$[C_5\text{mim}]_2[\text{NiCl}_4]$	40.2	33	This work
$[C_7\text{mim}]_2[\text{NiCl}_4]$	26.3	178	This work
$[C_7\text{mim}]_2[\text{NiCl}_4]$	30.1	116	This work
$[C_7\text{mim}]2[\text{NiCl}_4]$	40.0	49	This work
$[C_8\text{mim}]2[\text{NiCl}_4]$	27.7	144	This work
$[C_8\text{mim}]2[\text{NiCl}_4]$	30.2	109	This work
$[C_8\text{mim}]2[\text{NiCl}_4]$	40.0	50	This work
$[C_8\text{mim}][\text{PF}_6]$	30	452	[24]
$[C_8\text{mim}][\text{BF4}]$	30	82	[25]
$[C_4\text{mim}][C_6\text{mim}][\text{NiCl}_4]$	25.1	122	This work
$[C_4\text{mim}][C_6\text{mim}][\text{NiCl}_4]$	30.0	70	This work
$[C_4\text{mim}][C_6\text{mim}][\text{NiCl}_4]$	40.0	30	This work
$[C_4\text{mim}][\text{PF}_6]$	30	204	[24]
$[C_4\text{mim}][\text{BF}_4]$	30	91.4	[24]
$[C_6\text{mim}][\text{PF}_6]$	30	363	[24]
$[C_6\text{mim}][\text{BF}_4]$	30	177	[24]

Although the data are still limited, at similar temperatures the $[\text{NiCl}_4]^{2-}$ salts appear to have viscosities considerably less than that observed for $[\text{PF}_6]^-$ salts, and similar to or slightly greater than $[\text{BF}_4]^-$ salts [24,25]. The last point is somewhat surprising, considering that the dianionic charge on the $[\text{NiCl}_4]^{2-}$ ion might be expected to strengthen coulombic attractions and hence to increase viscosity. On the other hand, the larger size of $[\text{NiCl}_4]^{2-}$ compared to $[\text{BF}_4]^-$ (with effective radii of ca. 2.9 Å versus 2.1 Å, respectively) [26] should weaken such interactions, and serve as a compensating influence. It is worth noting that the viscosity of the mixed $[C_4\text{mim}][C_6\text{mim}][\text{NiCl}_4]$ salt is comparable to that of $[C_4\text{mim}]_2[\text{BF}_4]$, underscoring the potential viscosity lowering ability of mixed cations.

Plots of the complete data sets (Fig. 1) indicate slightly non-Arrhenius behavior for the ionic liquids at higher temperatures. Nevertheless, a fit of the data to an Arrhenius-like equation that expresses the energy of activation for viscous flow (Eq. (2)),

$$\eta = \eta_0 e^{E_\eta/RT} \quad (2)$$

for which E_η is the energy of action for viscous flow, and η_0 is a constant, is very good for all four liquids ($r^2 > 0.99$). The E_η values (Table 2) cluster around 65–69 kJ mol^{-1}, without an obvious correlation with the chain length. These are near the value of 55.7 kJ mol^{-1} determined for the RTIL [choline][Zn_2Cl_5] [12], but are roughly four times higher than the average of 17 ± 3 kJ mol^{-1} found for various RTILs with more common anions ($[\text{BF}_4]^-$, $[\text{PF}_6]^-$, $[\text{Tf}_2\text{N}]^-$, $[\text{Tf}_2\text{C}]^-$), even when the cations are hydroxy-substituted, and thus capable of engaging in hydrogen bonding [27].

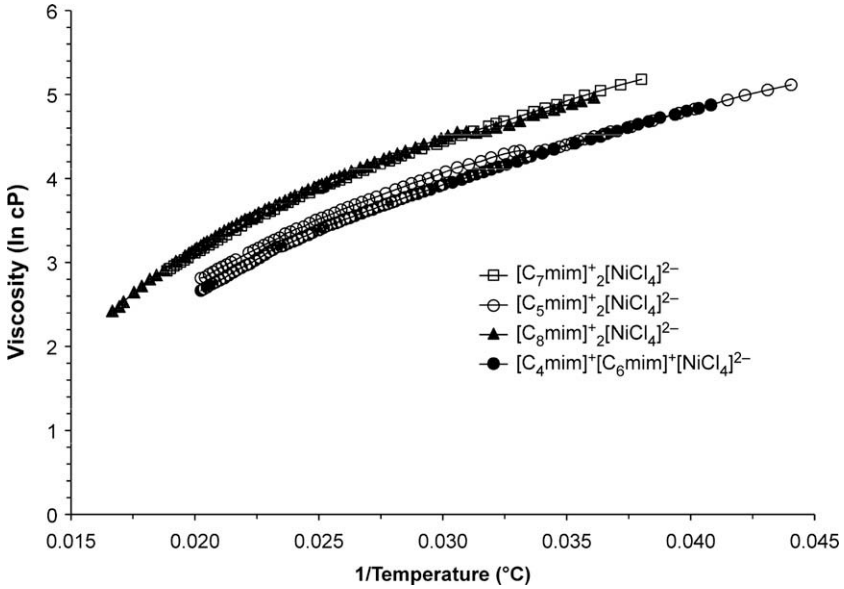

Fig. 1. Viscosity of imidazolium $[\text{NiCl}_4]^{2-}$ salts as a function of temperature.

Table 2
Energy of activation for viscous flow of tetrachloronickelate salts.

Compound	$E\eta$ (kJ mol^{-1})	r^2
$[C_5mim]_2[NiCl_4]$	65.6	0.997
$[C_7mim]_2[NiCl_4]$	67.8	0.998
$[C_8mim]_2[NiCl_4]$	64.6	0.995
$[C_4mim][C_6mim][NiCl_4]$	68.7	0.996

2.3. Thermal behavior

The thermal stabilities of imidazolium salts have been studied under various conditions, and have been found to have more dependence on anion type than cation size [24]. The three single-chain $[C_nmim]_2[NiCl_4]$ salts were investigated with scanning TGA, and all were found to decompose in a similar, multistep manner. A TGA scan for $[C_7mim]_2[NiCl_4]$ is presented in Fig. 2. Onset of decomposition (2% weight loss) under N_2 occurs just above 300 °C, and approximately two-thirds of the mass is gone by 430 °C, which corresponds to the loss of both imidazolium cations. Such volatilization temperatures are typical for imidazolium salts [28], but determination of the exact temperature and rate at which decomposition occurs is a non-trivial matter [29]. With imidazolium salts, whether decomposition occurs in a single or in multiple steps varies with the anion; $[C_1mim][PF_6]$ decomposes in a single step, for example, but $[C_1mim][BF_4]$ (like the tetrachloronickelate liquids) does so in several steps [30].

Continued heating of $[C_7mim]_2[NiCl_4]$ eventually leads to a constant weight near 690 °C, with a residual mass of 14%. This value does not correspond to the presence of completely reduced nickel or nickel chloride alone. To investigate this point further, a sample of $[C_7mim]_2[NiCl_4]$ was placed in a tube furnace at 700 °C for 1 h under N_2. After the sample cooled, powder XRD analysis on the resulting metallic-appearing film indicated the presence of both elemental nickel and $NiCl_2$; given this information, the residual weight in the TGA experiment corresponds to a Ni:$NiCl_2$ ratio of 3:1. Other modifications to the anion could make the decomposition to nickel alone more likely [31].

2.4. Conclusions

The strategy of using imidiazolium cations with intermediate chain lengths to produce ambient temperature ionic liquids is successful with $[NiCl_4]^{2-}$ anions. Despite the latters' dinegative charge, the viscosity and thermal properties of the resulting liquids are similar to related $[BF_4]^-$-based species. The nickelate-based liquids could provide useful substrates for electrochemical studies and metal deposition reactions.

3. Experimental

3.1. General considerations

Organic and inorganic starting materials were reagent grade from Acros or Strem Chemical and used as received. The preparation of 1-butyl-3-methylimidazolium chloride ($[C_4mim]Cl$), 1-pentyl-3-methylimidazolium chloride ($[C_5mim]Cl$), 1-hexyl-3-methylimidazolium chloride ($[C_6mim]Cl$), 1-heptyl-3-methylimidazolium chloride ($[C_7mim]Cl$), and 1-octyl-3-methylimidazolium chloride ($[C_8mim]Cl$) followed literature procedures [32].

Viscosity data were obtained on a Cambridge Applied Systems Viscolab 400 Viscometer fitted with heating tape. All thermal measurements were carried out on an Instrument Specialist TGA-1000 instrument. Elemental analyses were performed by the University of Illinois Microanalytical Laboratory, Desert Analytics (Tucson, AZ), or at the Micro-Mass Facility, University of California, Berkeley (Berkeley, CA).

3.2. Preparation of bis(1-pentyl-3-methylimidazolium) tetrachloronickelate(II), $[C_5mim]_2[NiCl_4]$

1-Pentyl-3-methylimidazolium chloride (5.26 g, 27.9 mmol) and $NiCl_2(H_2O)_6$ (3.31 g, 13.9 mmol) were placed in a 50 mL round bottom flask equipped with a magnetic stirring bar. The flask was flushed with N_2 and the reaction was allowed to stir at 80 °C for 18 h. The reaction was removed from heat and allowed to cool to room temperature. The solution was dried under vacuum at 95 °C to afford a dark blue liquid (6.24 g, 88%). *Anal.* Calc. for $C_{18}H_{34}Cl_4N_4Ni$: C, 42.64; H, 6.76; N, 11.05. Found: C, 39.31; H, 6.38; N, 10.19%. Although individual percentage values are low, the C:H:N values are in nearly exact molar ratios (18.0:34.8:4.0), suggesting that combustion was incomplete.

3.3. Preparation of bis(1-heptyl-3-methylimidazolium) tetrachloronickelate(II), $[C_7mim]_2[NiCl_4]$

1-Heptyl-3-methylimidazolium chloride (4.29 g, 19.8 mmol) and $NiCl_2(H_2O)_6$ (2.35 g, 9.89 mmol) were placed in a 100 mL

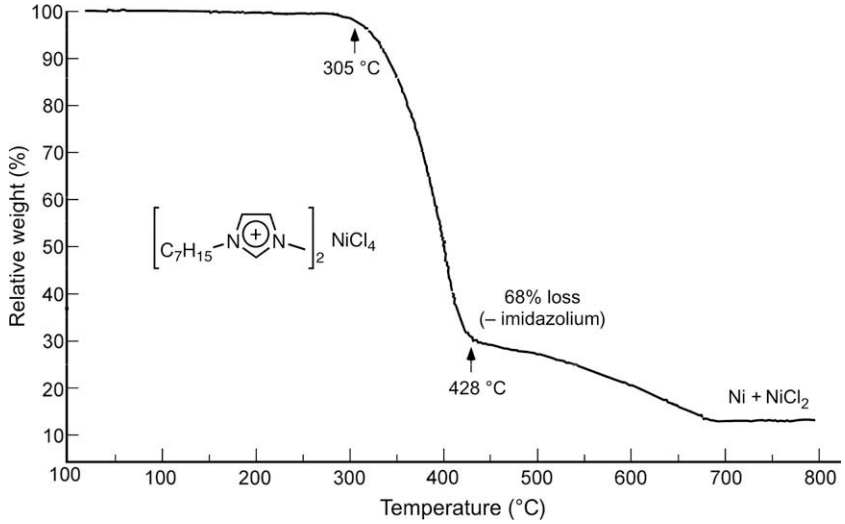

Fig. 2. Thermal behavior of $[C_7mim]_2[NiCl_4]$ under N_2 (20° min^{-1}). The arrow at 305 °C marks the decomposition onset.

round bottom flask equipped with a magnetic stirring bar. The flask was flushed with N_2 and the reaction was allowed to stir at 80 °C for 17 h. The reaction was removed from heat and allowed to cool to room temperature. The solution was dried under vacuum at 95 °C to afford a dark blue liquid (4.65 g, 83%). *Anal.* Calc. for $C_{22}H_{42}Cl_4N_4Ni$: C, 46.93; H, 7.52; N, 9.95. Found: C, 46.04; H, 7.57; N, 9.80%.

3.4. Preparation of bis(1-octyl-3-methylimidazolium) tetrachloronickelate(II), $[C_8mim]_2[NiCl_4]$

1-Octyl-3-methylimidazolium chloride (4.54 g, 19.7 mmol) and $NiCl_2(H_2O)_6$ (2.34 g, 9.84 mmol) were placed in a 100 mL round bottom flask equipped with a magnetic stirring bar. The flask was flushed with N_2 and the reaction was allowed to stir at 90 °C for 9 h. The reaction was removed from heat and allowed to cool to room temperature. The solution was dried under vacuum at 90 °C for 2 h to afford a dark blue liquid (5.17 g, 89%). *Anal.* Calc. for $C_{24}H_{46}Cl_4N_4Ni$: C, 48.72; H, 7.84; N, 9.48. Found: C, 47.91; H, 7.90; N, 9.38%.

3.5. Preparation of (1-butyl-3-methylimidazolium)(1-hexyl-3-methylimidazolium) tetrachloronickelate(II), $[C_4mim][C_6mim][NiCl_4]$

1-Butyl-3-methylimidazolium chloride (2.25 g, 12.9 mmol), 1-hexyl-3-methylimidazolium chloride (2.61 g, 12.9 mmol), and $NiCl_2(H_2O)_6$ (3.06 g, 12.9 mmol) were placed in a 100 mL round bottom flask equipped with a magnetic stirring bar. The flask was flushed with N_2 and the reaction was allowed to stir at 90 °C for 23 h. The reaction was removed from heat and allowed to cool to room temperature. The solution was dried under vacuum at 100 °C to afford a dark blue liquid (5.97 g, 91%).

ABSTRACT

The preparation and crystal structures of four *ortho*-carboranyl-nitrogen compounds, PhCb^{o}N=N(C_6H_4Me-4) (**1**), PhCb^{o}NHNH(C_6H_4Me-4) (**2**), MeCb^{o}NHNHPh (**3**) and PhCb^{o}NHOH (**4**) (Cb^o = 1,2-$C_2B_{10}H_{10}$; nitrogen groups at cage carbon C1, Ph or Me at C2), the last as a 1,4-dioxane solvate, are reported. Comparisons of their structures with those of other *ortho*-carboranyl-nitrogen systems studied earlier reveal further correlations between their cage C–C and *exo*-C–N bond distances and bond orders. Substituent orientations and bond distances (cage C1–C2, *exo*-C1–N) in RCb^{o}NHR″ systems (R = Ph or Me at C2) are consistent with dative π-bonding from a nitrogen lone pair into the cage carbon *p*-AO otherwise responsible for cage C1–C2 σ bonding. Their C1–C2 bond distances are remarkably sensitive to the planar (sp^2) or pyramidal (sp^3) nature of the NHR″ group. The N=O and N=NR′ residues in RCb^{o}X prefer to be orientated in plane with the cage C1–C2 in contrast to the RCb^{o}NHR″ systems. Correlations between their cage C–C and *exo*-C–N bond distances and the ^{11}B NMR chemical shifts of their antipodal boron atoms reflect the π-bonding characteristics of the nitrogen substituent.

1. Introduction

The remarkable capacity of π-donor substituents, attached to carbon atoms of an *ortho*-carborane C_2B_{10} cage, to influence cage C1–C2 bond lengths was first detected some two decades ago [1] with the structural characterisation of the proton sponge salt of the anion PhCb^{o}O$^-$, (Cb^o = 1,2-$C_2B_{10}H_{10}$; O$^-$ at cage carbon C1, Ph at C2) followed by many related studies [2,3–7] on *ortho*-carboranes containing thiolato and phosphino groups. However, this area has only recently been documented systematically by experimental and computational studies on systems RCb^{o}X and XCb^{o}X in which X is a potential π-donor such as NH_2, OH, SH or anions derived therefrom by deprotonation [8,9]. *Exo*-C=X π-bonding in these systems between the cage carbon atom and substituent X involves a tangentially oriented *p*-AO on carbon that would otherwise be involved in cage bonding, and C1–C2 bond lengthening will occur if the *p*-AO used for *exo*-C=X π-bonding is the *p*-AO that in *ortho*-carborane itself is involved in C1–C2 σ-bonding (AO = atomic orbital; Fig. 1).

The extent to which the cage C1–C2 bond is affected by *exo* π-bonding will therefore depend on the orientation of the substituent in the *exo*-CN systems explored here. Though many *ortho*-carborane derivatives with *exo*-C–N bonds are known, only three structural studies have been carried out elsewhere to our knowledge: the first was on a rhenium complex ^{i}PrCb^{o}N$_2$Re(CO)$_4$ [10], which contains a 6-membered –Re–N=N–C–B–H– ring in which the metal atom is attached to one nitrogen atom and to a boron-attached hydrogen; the second was on a hydrazocarborane, HCb^{o}NRNHR (R = $CO_2{}^t$Bu) [11], which contains an intramolecular cage C–H···O hydrogen bond [12]; and the third was on a zirconium complex, PhN$_3$Cb^{o}ZrCp$_2$ [13], which contains a 3-membered ZrN_2 ring. All three systems thus contain intramolecular interactions that influence the orientation about nitrogen at C1 with respect to the cage C1–C2 bond.

In 2004, we reported the crystal structures of PhCb^{o}NH$_2$ and the adduct PhCb^{o}NH$_2$·OP(NMe$_2$)$_3$ which revealed six independent molecules with C1–C2 bond distances ranging between 1.74 and 1.85 Å [8]. We also reported improved syntheses of *ortho*-carborane nitroso derivatives RCb^{o}NO and dicarboranylamines (RCb^o)$_2$NH (R = Ph, Me) and discussed their structures, which in the case of the secondary amines (and amides [(RCb^o)$_2$N]$^-$ derived therefrom) showed significant cage distortion (C1–C2 bond lengthening) attributable to *exo*-C=N π-bonding [14–16]. To supplement these studies, we have carried out a synthetic, spectroscopic, structural and computational investigation of the compounds

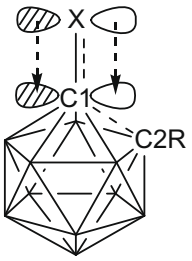

Fig. 1. Orbitals involved in the *exo* π-bonding for RCb^{o}X where X is a π-donating group and R is not a donor group.

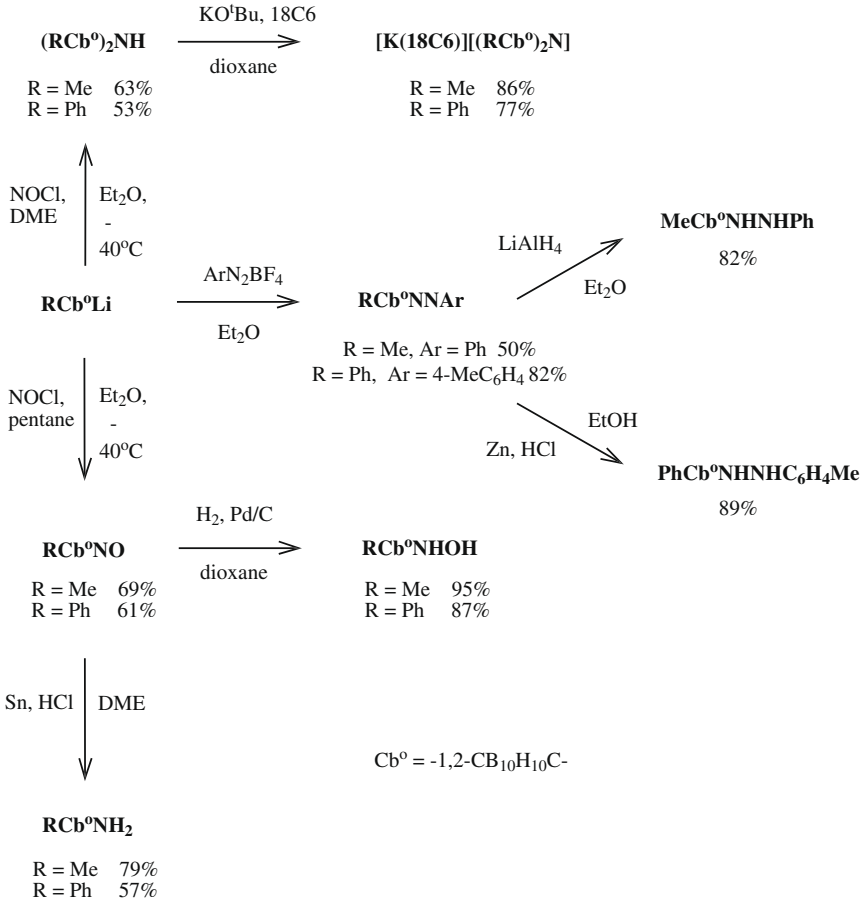
RCb^{o}X (R = Ph, Me; X = NNR′, NHNHR′, NHOH; R′ = Ph or C_6H_4Me-4), and further spectroscopic and computational studies on systems with X = NH_2, NO, NHCb^{o}R and [NCb^{o}R]$^-$, which have revealed hitherto unremarked characteristics and trends in *ortho*-carborane systems RCb^{o}X containing *exo*-CN units, which we report here.

2. Results and discussion

In this section, we outline the synthetic procedures used to prepare the new compounds, and describe their structures. We then explore the structural, bonding and spectroscopic characteristics of *ortho*-carboranyl-nitrogen systems RCb^{o}N═O, RCb^{o}N═NR′ and RCb^{o}NHR′′ in general, including both the new systems and those previously characterised [8,14]. We also compare the structural and bonding relationships of these 3D pseudoaromatic cages with 2D aromatic ring analogues.

2.1. Synthetic aspects



Scheme 1 summarises the experimental procedures used for the syntheses of the carboranes investigated in this definitive study. Synthetic methods that have not been reported in our earlier papers [8,14] are described in detail in Section 4. The azocarboranes were synthesised using a reported literature procedure [17]. The reductions of the nitroso-carboranes RCb^{o}NO with hydrogen using a palladium/carbon catalyst gave the known [18,19] hydroxylamines RCb^{o}NHOH in high yields. High-yield reductions of the azocarboranes RCb^{o}NNAr to the hydrazines RCb^{o}NHNHAr were carried out here using the reducing agents $LiAlH_4$ and Zn/HCl.

2.2. Structural aspects: new experimentally determined structures

2.2.1. The azo-carborane PhCb^{o}N$_2$(C_6H_4Me-4) (**1**) and hydrazo-carboranes PhCb^{o}NHNH(C_6H_4Me-4) (**2**) and MeCb^{o}NHNHPh (**3**)

The crystal structures of these three compounds were determined by X-ray diffraction (for details, see Section 4). Their molecular structures are illustrated in Figs. 2 and 3.

The structures of the azo-carborane (**1**) and its hydrazo analogue (**2**) (Fig. 2) are similar, differing significantly, and as expected, only in the bond lengths and angles in the region of their –N═N– and –N(H)N(H)– units. Their NN links, at 1.250(2) in (**1**) and 1.409(2) Å in (**2**), are of normal length for double and single bonds, respectively, between nitrogen atoms. The CNN bond angles, at both ends of the N(1)–N(2) links, appear not to differ between the two ends (implying that the link to the carboranyl residue resembles that to the aryl group in both **1** and **2**) nor between **1** and **2**, suggesting both **1** and **2** contain sp^2-hybridised

Scheme 1. Routes to carboranyl-nitrogen derivatives.

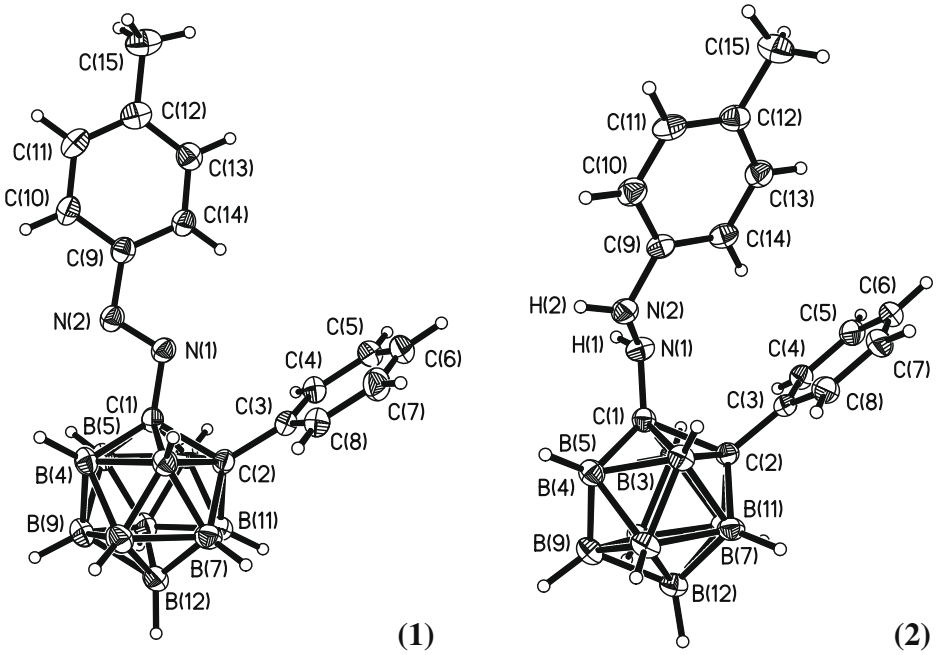


Fig. 2. Molecular structures of PhCb^{o}N$_2$C$_6$H$_4$Me (**1**) and PhCb^{o}NHNHC$_6$H$_4$Me (**2**). Selected bond distances (Å) and angles (°) for (**1**): N(1)–N(2) 1.250(2); N(2)–C(9) 1.428(3); C(2)–C(3) 1.509(3); N(1)–N(2)–C(9) 112.88(15); N(1)–N(2)–C(9)–C(14) 15.3(3). For (**2**): N(1)–N(2) 1.409(2); N(2)–C(9) 1.421(3); C(2)–C(3) 1.497(3); N(1)–N(2)–C(9) 115.73(16); N(1)–N(2)–C(9)–C(14) −25.7(3).

nitrogen atoms. In both **1** and **2**, the phenyl substituent on C(2) lies in a plane roughly perpendicular to the N(1)–C(1)–C(2) plane, as would be expected not only on steric grounds (to keep it away from the substituent on C(1)), but also as this is the orientation that optimises π-donation from ring to cage and causes *ca.* 0.03 Å C1–C2 bond lengthening [20–23].

The orientations of the azo and hydrazo substituents on C(1), however, differ significantly. In **1**, the azo N(1)–N(2)–C(9) unit lies in the N(1)–C(1)–C(2) plane, as in the nitroso carborane PhCb^{o}NO studied previously [14]. In **2**, the hydrazo N(1)–N(2)–C(9) unit is twisted out of the C(1)–C(2)–C(3) plane, clearly not on steric grounds, but to an extent that significantly ensures that the lone pair on N(1) lies in that plane. The view of **2** in Fig. 2 shows the *ortho* hydrogen atom on C(14) lying over, and attracted to, the π-cloud of the phenyl group on C(2), with an H···centroid distance of 2.65 Å, and this attraction is likely to be responsible for the orientation of the tolyl group.

The molecular structure of compound **3**, MeCb^{o}NHNHPh, shown in Fig. 3, differs from that of **2** in the orientation of the aryl-hydrazo group, away from the methyl substituent on C(2). However, the local geometry about N(1) resembles that in **2** in ensuring that the lone pair on N(1) lies in the N(1)–C(1)–C(2) plane.

2.2.2. The hydroxylamino-carborane PhCb^{o}NHOH (*4*)

The molecular structure of this compound (Fig. 4) was determined by single-crystal studies on a dioxane hemisolvate of composition PhCb^{o}NHOH·0.5dioxane. The orientations of both substituents on the carborane cage were found to resemble those already discussed for compounds **2** and **3**, and are in line with those found previously for PhCb^{o}NH$_2$ [8]. The phenyl group in **4** lies roughly perpendicular to the N(1)–C(1)–C(2) plane, and the HNOH

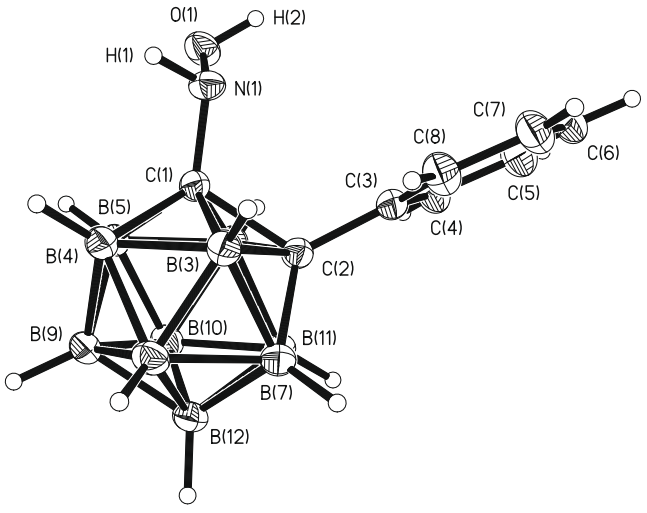

Fig. 4. Molecular structure of PhCb^{o}NHOH (**4**). The dioxane molecule in the crystal structure is not shown. Selected bond distances (Å): N(1)–O(1) 1.435(2); C(2)–C(3) 1.506(3).

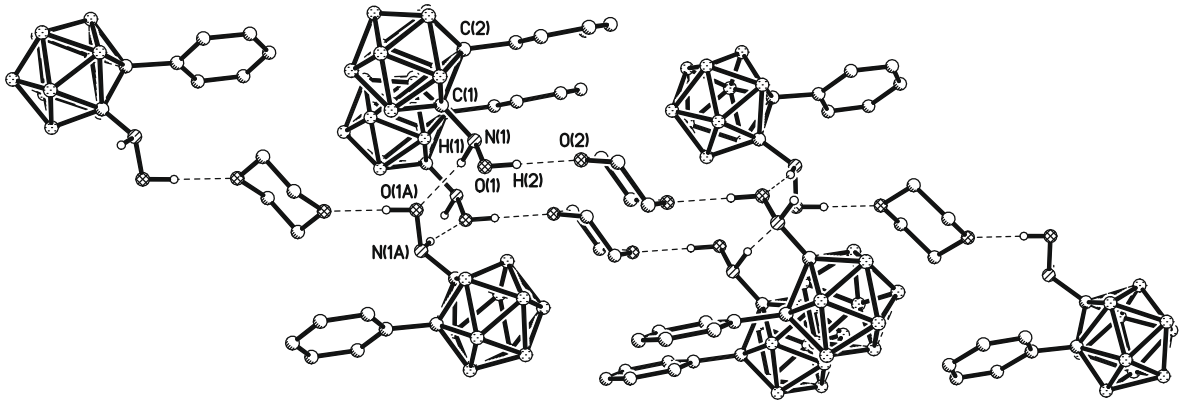

Fig. 5. Supramolecular structure of PhCb^{o}NHOH·0.5dioxane. Selected intermolecular distances (Å) and angles (°): O(1)···O(2) 2.752(2), N(1)···O(1A) 3.209(2), O(1)–H(2)···O(2) 177(3), N(1)–H(1)···O(1A) 167(2). [O(1A) is generated from O(1) by screw-axis symmetry].

unit is oriented away from the phenyl group, like the HNNHR unit in **2**, implying that the lone pair on the nitrogen lies in the N(1)–C(1)–C(2) plane. In the crystal structure, intermolecular N–H···O hydrogen-bonding interactions between the hydroxylamino units link the molecules into (PhCb^{o}NHOH)$_n$ chains, which in turn are interlinked by N–OH···O hydrogen bonds to both oxygen atoms of the dioxane molecules (Fig. 5).

2.3. Structural aspects: general characteristics of RCb^{o}N systems

The structures of the four compounds **1**–**4** described above, together with the four in our previous paper [14] [PhCb^{o}NO, (PhCb^o)$_2$NH, (MeCb^o)$_2$NH and the anion (PhCb^o)$_2$N$^-$] and the amine PhCb^{o}NH$_2$ characterised earlier [8], provide a useful data bank from which to deduce some common characteristics of *ortho*-carboranyl-nitrogen systems. These include preferred orientations of the *exo*-nitrogen substituent with respect to the carborane cage, and systematic complementary trends in their *exo*-C(1)–N(1) and cage C(1)–C(2) bond distances; as the former shorten, the latter lengthen.

The compounds we have studied are of two formula types, RCb^{o}NHR″ and RCb^{o}N=Z. Their structures are shown in Figs. 6 and 7. The nitroso- and azo-carboranes PhCb^{o}N=O and PhCb^{o}N=N(C$_6$H$_4$Me-4) are of the latter type [14]. All of the other compounds are of the former type, including the anion (PhCb^o)$_2$N$^-$ in which the lone pair left on deprotonation of the parent amine can be regarded as occupying the site vacated by proton.

Figs. 6 and 7 show the NHR″ and N=Z units in their preferred orientations about the *exo*-C(1)–N(1) bond with respect to the carborane cage, with the substituents R″ or Z leaning away from the substituent R (Ph or Me) on the other cage carbon atom C(2). This orientation not only minimises steric non-bonding repulsive interactions between the groups on C(1) and C(2), but aligns the lone pair of electrons on the *exo*-nitrogen atom on C(1) in the C(2)–C(1)–N(1) plane for RCb^{o}NHR″, the alignment best suited for dative π-bonding from the nitrogen lone pair into the *p*-AO on C(1) responsible for cage C(1)–C(2) σ-bonding, as shown in Fig. 6.

The extent to which *exo*-dative C=N π-bonding donation from the NHR″ group occurs (and whether it does so at the expense of cage C(1)–C(2) σ-bonding) can be inferred from the experimental C(1)–C(2) and C(1)–N(1) distances in Table 1, in which compounds are listed in the order of their increasing cage C(1)–C(2) distances, which matches the sequence of decreasing C(1)–N(1) distances. Table 1 includes also torsion angles C(2)–C(1)–N(1)–Z/R″, which reveal that these compounds show some departures from the preferred orientations shown in Figs. 6 and 7; bond angles C(2)–C(1)–N(1), which show expected deviations from a normal angle of 121.7° for an *exo*-bond on a regular icosahedron; and the C(1)–N(1)–Z/R″ bond angles at nitrogen, which for species RCb^{o}NHR″ would be 120° for an ideal trigonal planar coordination at nitrogen (sp^2) and 109° for pyramidal nitrogen (sp^3). The data in Table 1 include the four distinct molecules of PhCb^{o}NH$_2$ in the asymmetric unit of the crystal structure and for the two distinct molecules of this same species in its hydrogen-bonded adduct with hexamethylphosphoramide, PhCb^{o}NH$_2$·HMPA [8].

The range over which cage C(1)–C(2) bond distances vary in Table 1 (1.677(2)–1.995(3) Å, i.e. 0.32 Å) is more than twice the range over which *exo*-C=N distances vary (1.490(2)–1.345(4) Å i.e. 0.15 Å), because the former are fractional-order bonds becoming progressively weaker as the table is descended, whereas the latter

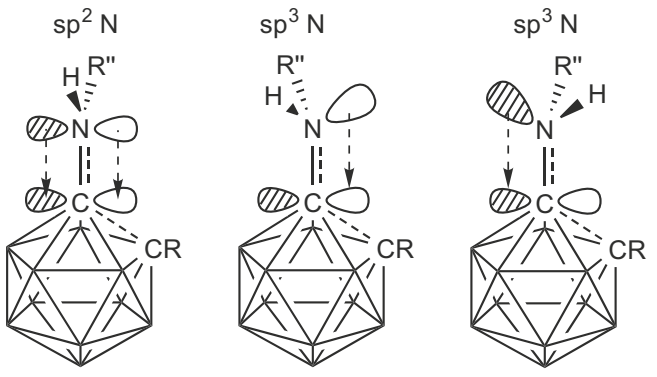

Fig. 6. Preferred orientations in RCb^{o}NHR″ systems. The cage acts as a π-acceptor.

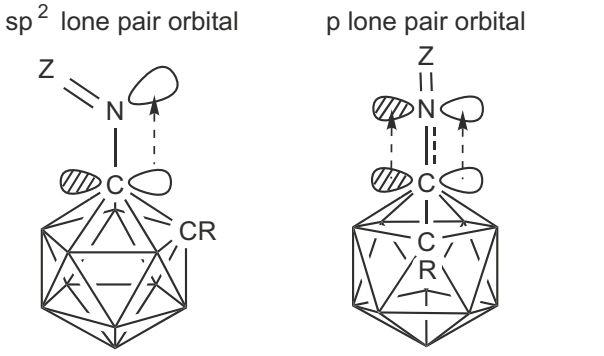

Fig. 7. Preferred orientation in RCb^{o}N=Z systems (Z = O, NR′). The cage *may* act as a π-donor.

Table 1
X-ray-determined trends: the optimum torsion angle C(2)–C(1)–N(1)–Z/R′′ to align the p-orbital lone pair of sp^2-hybridised nitrogen with the cage C(1)–C(2) bond is 90° for compounds RCb^{o}NHR′′, and to align the sp^2-orbital lone pair of sp^2-hybridised nitrogen with the cage C(1)–C(2) bond is 180° for compounds RCb^{o}N=Z. HMPA = OP(NMe$_2$)$_3$.

range in bond order from single to multiple. To aid comparison within the series, AM1 calculations have been carried out using the atomic coordinates determined by X-ray diffraction, without further optimisation. Selected bond distances and orders, with corresponding σ and π contributions, are given in Table 2.

The data in Table 2 show the correlation between the cage C(1)–C(2) and *exo*-C(1)–N(1) bond orders expected from their lengths. The bond orders of the cage C···C bonds decrease as those of the *exo*-C(1)–N(1) bonds increase. The range over which the C(1)–C(2) bond orders vary (from 0.61 in PhCb^{o}NO to 0.24 in the anion (PhCb^o)$_2$N$^-$) is comparable to that over which the *exo*-C(1)–N bond orders vary (from 0.92 to 1.30), and is itself worthy of comment. Because icosahedral carborane clusters are held together by only 13 skeletal electron pairs spread around their 30 edge 'bonds', the average cage edge bond order will be 0.43 (13/30). The cage carbon–carbon bond in *ortho*-carborane HCb^{o}H itself has an order some 50% in excess of this because the carbon atoms are more electronegative than their boron neighbours and so attract a greater share of the electrons available. The data in Table 2 show that the cage C(1)–C(2) bond order has been reduced to about this average icosahedral value of 0.43 in the amine PhCb^{o}NH$_2$, and to roughly half this value in the anion (PhCb^o)$_2$N$^-$.

In our discussion of bond lengths and bond order so far, we have concentrated on the cage C(1)–C(2) and *exo*-C(1)–N(1) bonds. This is because these are the only bonds in these systems PhCb^{o}X whose lengths and orders change significantly and systematically with X, as illustrated by the data in Table 3, which lists the experimental lengths of all the 2-centre links in the immediate environment of C(1); Fig. 8 illustrates that pentagonal pyramidal environment. From Table 3 it is clear that, although there are minor variations between compounds in the measured lengths of C(1)–B(3/6), C(1)–B(4,5), C(2)–B(3,6), B(3,6)–B(4,5) and B(4)–B(5), these variations cannot be regarded as systematic or significant.

However, on closer inspection, the C1–C2 bond lengths determined cannot simply be explained by the orientation of the π-donating groups. For example, the two compounds **2** and **3** contain similar C1–C2 bond lengths of *ca.* 1.77 Å even though it is generally accepted that the phenyl group lengthens the bond by *ca.* 0.03–0.05 Å compared to the methyl group due to the steric and/or electronic effect(s) of the former [24,25]. The difference of 0.04 Å for the C1–C2 bond lengths in **2** and **4** is significant even though the orientations of the nitrogen groups are similar. There are six distinct PhCb^{o}NH$_2$ molecular geometries experimentally determined, with C1–C2 bond lengths ranging from 1.745 to 1.853 Å (see Table 1) – a difference of 0.11 Å, which cannot be explained solely by the orientation of the amine group.

2.4. Structural aspects: computational studies

Optimised geometries of carboranes at the MP2/6-31G* level of theory have been shown to be in excellent agreement with experimental geometries determined by gas-phase electron diffraction

[28–30] and X-ray crystallography [8,12,20,31,32]. Earlier, we had carried out computations on model geometries of HCb^{o}X with π-donor groups (X = OH, NH^-, NH_2 and CH_2^-) to investigate the effect of orientation of these groups on the C1–C2 bond length; in these computations a planar configuration (sp^2) was assumed for NH_2 [8]. The effect of a pyramidal form (sp^3) at a nitrogen π-donor group on the C1–C2 bond or the effect of π-acceptor groups on the cage geometry had not been investigated previously. Here, data for the systems HCb^{o}X where X = N═O, N═NH, NHOH, NH_2 and $NHNH_2$ in various possible orientations (indicated by their torsion angles) are listed in Table 4. The pyramidal or planar configurations of the nitrogen atom N1 attached to C1 for NHR″ groups were also examined.

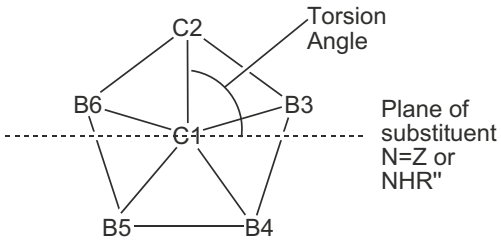

Fig. 8. The pentagonal pyramidal environment about C1.

The model carboranes with Π-acceptor groups, NO and NNH, prefer to be oriented in plane (0° and 180°) with the C1–C2 bond, as opposed to being oriented perpendicular to the C1–C2 bond, with an energy difference of *ca.* 4 kcal mol^{-1} (Fig. 8). The reasons for a slight preference for 0° orientations over 180° orientations in these models are cage C–H···X bond interactions [12]. Energetically, the hydroxylamino (NHOH) group clearly favours the pyramidal form (sp^3 N) over the planar form (sp^2 N) irrespective of the orientation. There is no strong preference for one orientation over another for the NHOH group. The substituents NO, NNH and NHOH (with sp^3 N) have little orientational influence on the *ortho*-carborane cage geometry.

By contrast, the models containing the NH_2 groups are similar in energy irrespective of whether the nitrogen atom N1 is planar (sp^2) or pyramidal (sp^3) in configuration (Fig. 7). However, the 90° orientations are energetically favourable and are expected for a π-donor group –NHR″ to be oriented to align the donor p-orbital with the C1–C2 bond for maximum overlap. The model HCb^oNH_2 has four geometries within a range of 2.9 kcal mol^{-1} in energy but their C1–C2 bond distances vary from 1.623 to 1.713 Å, a difference of 0.09 Å, attributable to the orientations and the sp^2 or sp^3 configuration about the nitrogen atom. Similar observations are found for the model carborane containing the $NHNH_2$ group.

Table 4
Selected bond lengths (Å) and energies of MP2-optimised geometries of HCb^{o}X where torsion angles for C2–C1–N–Z/R″ are fixed at 0, 90 and 180° (a = N–H away from C1, t = N–H towards C1).

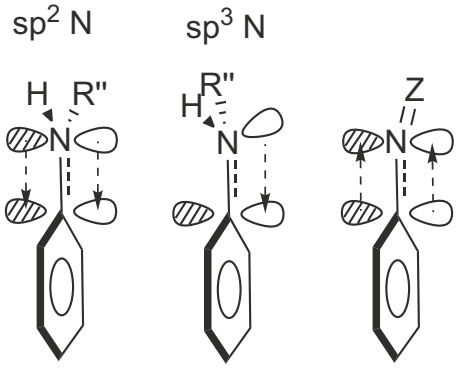

Fig. 9. Preferred orientations in PhNHR′′ and PhN=Z systems.

There are parallels here between carborane chemistry and aromatic ring chemistry, where substituents that can act as π-donors or π-acceptors adopt orientations that maximise interaction with the π-system of the aromatic ring (Fig. 9) provided that steric factors do not rule out the preferred orientations of substituents NO, NNH, NHOH, NH_2 and $NHNH_2$ when attached to a benzene ring. Selected bond distances and relative energies from computational data on these benzene derivatives for the two orientations, planar (0°) and perpendicular (90°), at the MP2/6-31G* level of theory are listed in Table 5. For the acceptor groups NO and NNH, the coplanar form is energetically preferred over the perpendicular form by 8.9 and 5.1 kcal mol^{-1}, respectively, but the orientation has little influence on the ring geometries [33]. The NHOH group strongly favours the pyramidal (sp^3) configuration over the planar (sp^2) form energetically, but small energy and geometry differences between the two orientations are found for the sp^3 form. The amino NH_2 group does not have a strong energetic preference for the sp^2 or sp^3 form but has a notable orientational effect on the C–N bond, with distances of 1.381 Å for the sp^2 N geometry in plane with the C1–C2 bond (0°) and 1.435 Å for the sp^3 N geometry perpendicular to the C1–C2 bond (90°) [34]. The ring geometry, however, remains largely unaffected by the C–N bond variations. The orientation of the $NHNH_2$ group has a similar effect on the geometry and energies as the orientation of the NH_2 group. Preferred orientations determined computationally for PhNNH and $PhNHNH_2$ are in accord with the orientations of the aromatic rings in the experimental structures for **1**, **2** and **3**.

The geometries of PhCb^{o}X and MeCb^{o}X were also computed at the MP2/6-31G* level of theory. Comparisons shown in Table 6 reveal very good agreements between the selected geometric parameters for optimised and experimental geometries in all cases. The NHR′′ groups, as discussed for the model carboranes, are particularly intriguing: the sp^3 N form is more stable than the sp^2 N form in these groups. However, for the NH_2 group the energy difference between the geometries containing sp^3 N and sp^2 N groups is small (less than 3 kcal mol^{-1}), which indicates that both forms could coexist in the solid and solution states where intermolecular interactions come into play. The computed C1–C2 distances of 1.743 and 1.813 Å for the sp^3 N and sp^2 N PhCb^oNH_2 geometries, respectively, and their energies, are in broad agreement with the observation of six distinct PhCb^oNH_2 molecules with C(1)–C(2) bond distances of 1.745–1.853 Å (see Table 1) in the crystal structure.

For compounds with NHNHR′ groups, **2** and **3**, the relative energies between their sp^3 N and sp^2 N geometries are slightly larger at *ca.* 4.0 kcal mol^{-1}, but comparison of the bond parameters of experimental geometries with sp^3 N optimised geometries are poor. The experimental geometry for **3** is in much better agreement with the sp^2 N optimised geometry of MeCb^{o}NHNHPh, whereas the experimental geometry for **2** lies between the two optimised geometries (sp^2 N and sp^3 N) of PhCb^o$NHNHC_6H_4Me$. As for PhCb^oNH_2, these geometries depend on intermolecular interactions such as crystal packing forces. This subtle difference in the sp^2/sp^3 N character results in similar C1–C2 bond distances found experimentally for **2** and **3**. The pyramidal sp^3 N form is clearly favoured in energy for the PhCb^{o}NHOH geometry and in accord with the experimental geometry found for **4**.

The optimised and experimental geometries for the dicarboranylamines (PhCb^o)$_2$NH and (MeCb^o)$_2$NH are in excellent agreement and their planar nitrogen atoms are clearly sp^2 in character. Optimised geometries for some methyl analogues, where no experimental structures were determined, reveal geometries and trends similar to the experimental and optimised geometries for the phenyl analogues.

2.5. Experimental and computed NMR trends

The ^{11}B NMR spectra of polyhedral borane clusters such as carboranes provide a rich source of information provided that signals can be assigned with confidence. At the simplest level, the number of different boron sites in a molecule, deduced from the number of resonances, helps identify isomers. Of more importance in the present context is the 'antipodal effect' in icosahedral carborane chemistry [35–39], whereby the NMR shift of the boron atom directly opposite a substituted cage carbon atom is sensitive to the nature of the substituent. In *ortho*-carborane derivatives RCb^{o}X, bearing substituents X and R on carbon atoms 1 and 2, respectively, the resonances of the atoms opposite (B12 and B9, respectively) respond to the corresponding substituent, particularly if that substituent is a π-donor [2,8]. For the present series of compounds RCb^{o}X, where X is a nitrogen π-donor, the antipodal shift is expected to be related to the degree of *exo* π-bonding, and hence to *exo*-C1–N1 and cage C1–C2 bond lengths.

For such a comparison to be made the ^{11}B NMR shift for the antipodal atom (^{11}B δ-B12) must be reliably assigned. Although the two peaks corresponding to B9 and B12 are readily identified from the peak intensities it is impossible to assign each unambiguously without assumptions being made. One of these peaks appears at approximately the same shift in all compounds. This therefore can be assigned to B9, antipodal to the Ph or Me group in PhCb^{o}X and MeCb^{o}X, respectively. This peak would be expected to change little in these series of compounds as the substituent on C2, i.e. the Me or Ph group, remains unchanged. ^{11}B NMR shifts for B9 and B12 have been assigned on this basis (see Table 7).

[a] Computed shifts for sp^3 geometry.
[b] Computed shifts averaged for both sp^2 and sp^3 geometries.
[c] Observed values in CD_3CN.

The antipodal shift increases as π-bonding increases, displayed by the graph of the B12 shift vs experimental C–N bond lengths (Fig. 10). This is in agreement with previous work showing that such shifts are related to electron donation to the cluster. Hence the ^{11}B NMR data give an indication of degree of *exo* π-bonding and this can be used to assess such effects in compounds which have not been structurally characterised.

The shifts of the BH protons revealed by ^{1}H{^{11}B} NMR can be assigned using ^{1}H–^{11}B HETCOR or ^{1}H{^{11}B selective} experiments. The ^{1}H shifts of the hydrogen atoms bonded to the antipodal boron show the same relationship with the C–N bond length as the ^{11}B shifts of B12, decreasing frequency of the antipodal hydrogen with increased π-bonding to the cage suggesting increased shielding. The ^{13}C shifts of the cage carbon atoms C1 and C2, however, are

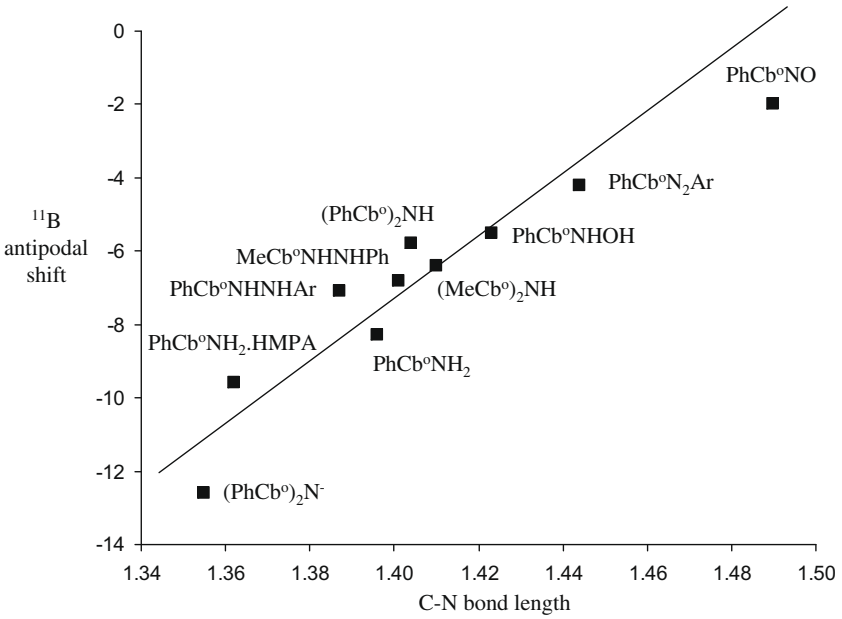

Fig. 10. Correlation between the observed ^{11}B shift of B12 (ppm) and the experimental C(1)–N(1) bond length (Å).

not simply related to the *exo*-C–N π-bonding effects. Calculated NMR chemical shifts on MP2-optimised geometries are in very good agreement with observed shifts and trends as shown in Table 7.

3. Conclusions

In this paper we have reported the crystallographically derived molecular structures and ^{11}B, ^{13}C and ^{1}H NMR spectra of four new *ortho*-carboranyl-nitrogen compounds PhCb^{o}N=N(*p*-tolyl) (**1**), PhCb^{o}NHNH(*p*-tolyl) (**2**), MeCb^{o}NHNHPh (**3**) and PhCb^{o}NHOH (**4**) (Cb^o = 1,2-$C_2B_{10}H_{10}$). Together with other carboranyl-nitrogen systems RCb^{o}X reported earlier, these provide a useful data bank from which the general structural, bonding and NMR characteristics of such systems can be discerned. Their structures show how dative *exo*-C=N *p*-bonding from the substituent to the cage is reflected in shortening of the *exo*-C–N bond (as it gains multiple character) and lengthening of the cage C1–C2 bond (as it loses bond order) to an extent that reflects the π-donor power of the substituent, the orientation of the CN group and the sp^2 or sp^3 character of the nitrogen atom for the NHR″ group, which are seen from computational studies to be important. The ^{11}B NMR chemical shift of the boron atom antipodal to the substituent also provides a guide to the π-donor power of X.

4. Experimental

All air-sensitive manipulations were carried out under dry, oxygen-free N_2. Stirring refers to use of a magnetic stirrer. Hexanes were distilled over Na. 1,2-Dimethoxyethane (DME) was dried by reflux and distillation over potassium; ether refers to diethyl ether dried, where appropriate, over sodium. Ether solutions were dried over magnesium sulfate and evaporated near room temperature. 1-Methyl-*ortho*-carborane [41] and 1-phenyl-*ortho*-carborane [42] were prepared by literature methods and dried by sublimation at 0.01 mm Hg. 1-Nitroso-2-methyl-*ortho*-carborane and 1-nitroso-2-phenyl-*ortho*-carborane were made as described elsewhere [14]. Benzenediazonium tetrafluoroborate and 4-methylbenzenediazonium tetrafluoroborate salts were made using a general literature method [43].

Melting points were measured in capillary tubes with an Electrothermal 9200 heating block. Infrared spectra were recorded from KBr discs on Perkin–Elmer 1600 series FTIR or Perkin–Elmer 1720X FTIR spectrometers and ultraviolet spectra with a Shimadzu UV 1201. Elemental carbon, hydrogen and nitrogen analyses were performed using Exeter Analytical CE-440 or Carlo Erba Strumentazione EA Model 1106 instruments. Mass spectra (MS) were recorded on a VG Micromass 7070E instrument under EI conditions at 70 eV. Values of M show the isotope range $^{10}B_n$ to $^{11}B_n$ including a ^{13}C contribution if observed. NMR spectra were measured using Varian Unity-300 (^{1}H, ^{11}B, ^{13}C), Bruker AM250 (^{1}H, ^{13}C), Bruker Avance 400 (^{1}H, ^{11}B, ^{13}C) and/or Varian Inova 500 (^{1}H, ^{11}B) instruments. All chemical shifts are reported in δ (ppm) and coupling constants in Hz. ^{1}H NMR spectra were referenced to residual protio impurity in the solvent ($CDCl_3$, 7.26 ppm). ^{13}C NMR spectra were referenced to the solvent resonance ($CDCl_3$, 77.0 ppm). ^{11}B NMR spectra were referenced externally to $Et_2O{\cdot}BF_3$, δ = 0.0 ppm. Peak assignments of cage boron and hydrogen atoms were determined with the aid of 2D ^{11}B{^{1}H}–^{11}B{^{1}H} COSY, selective ^{1}H{^{11}B} and ^{1}H–^{11}B correlation spectra.

4.1. Preparation of azocarboranes (modification of a reported [17] method)

A solution of the substituted lithiocarborane was prepared by the addition of butyllithium (5.05 ml, 2.5 M in hexanes) to a solution of the starting carborane (0.0127 mol) in diethyl ether (100 ml) at 0 °C. The solution was warmed to ambient temperature with stirring for 30 min. The diazonium salt was added as a solid over a period of 30 min and stirred overnight to give a cloudy red solution. Water was added and the organic layer was separated and washed with water. The organic layer was dried and evaporated to leave a brown residue. This was recrystallised from hexane to give orange crystals of the azocarborane.

1-Methyl-2-phenylazo-*ortho*-carborane, 1.78 g (50%), M.p. 122.5–123.5 °C (lit. [17] 121–122 °C). *Anal.* Calc. for $C_9H_{18}B_{10}N_2$: C, 41.2; H, 6.9; N, 10.7. Found: C, 41.1; H, 7.0; N, 10.6%. 4.2. Preparation of hydrazocarboranes

Lithium aluminium hydride, $LiAlH_4$, (0.3 g, 8 mmol), was added to a solution of 1-methyl-2-phenylazo-*ortho*-carborane (0.50 g, 1.91 mmol) in diethyl ether (20 ml) and the mixture stirred for 20 h. Wet diethyl ether was added, followed by water (10 ml) and dilute HCl until the cloudy solution became clear. The organic layer was washed with water (2 × 50 ml), dried and evaporated to leave a pale yellow solid. This was recrystallised from hot hexane to yield colourless crystals of 1-methyl-2-phenylhydrazo-*ortho*-carborane (0.41 g, 82%). M.p. 142–144 °C (lit. [17] 143–144 °C). *Anal.* Calc. for $C_9H_{20}B_{10}N_2$: C, 40.9; H, 7.6; N, 10.3. Found: C, 40.7; H, 7.8; N, 10.3%. MS (EI$^+$, *m*/*z*) [M]$^+$ 260–267; 264 (100); IR ν_{max} (KBr) [cm^{-1}]: 3360, 3322 (NH), 3125 (phenyl CH), 2933 (methyl CH), 2615s, 2580s, 2559s (BH), 1601, 1497, 1454m, 1251m, 1019m, 754s, 696 m. $^1H\{^{11}B\}$ NMR ($CDCl_3$), δ: 7.24 (t, $^3J_{HH}$ 7 Hz, 2H, *meta* C_6H_5), 6.90 (t, $^3J_{HH}$ 7 Hz, 1H, *para* C_6H_5), 6.85 (d, $^3J_{HH}$ 8 Hz, 2H, *ortho* C_6H_5), 5.68 (s, 1H, NH), 4.89 (s, 1H, NH), 2.52 (s, 2H, H8,10), 2.23 (s, 3H, BH), 2.16 (s, 3H, BH), 2.09 (s, 3H, CH_3), 2.05 (s, 2H, BH); $^{11}B\{^1H\}$ NMR ($CDCl_3$), δ: −6.1 (1B, B9), −7.1 (1B, B12), −11.0 (4B), −11.8 (4B); ^{13}C NMR ($CDCl_3$), δ: 147.3 (C_6H_5 *ipso*), 129.3 (d, $^1J_{CH}$ 158 Hz, C_6H_5), 121.0 (d, $^1J_{CH}$ 160 Hz, C_6H_5), 113.0 (d of t, $^1J_{CH}$ 156 Hz, C_6H_5), 96.7 (C1), 80.9 (C2), 22.1 (q, $^1J_{CH}$ 130 Hz, CH_3).

The compound 1-phenyl-2-(4-methylphenyl)azo-*ortho*-carborane (0.73 g) was dissolved in 20 ml of ethanol. Zinc dust (3.5 g) was added and 20 ml conc HCl added dropwise. The solution was stirred overnight, becoming colourless. It was poured into water (200 ml), giving a white precipitate. The solid was extracted with diethyl ether (3 × 50 ml). The organic layer was washed with water, dried and evaporated. The residue was recrystallised from hexane to give pale yellow crystals of 1-phenyl-2-(4-methylphenyl)hydrazo-*ortho*-carborane (0.65 g, 89%). M.p. 148–149.5 °C. *Anal.* Calc. for $C_{15}H_{24}B_{10}N_2$: C, 52.8; H, 7.0; N, 8.2. Found: C, 53.0; H, 7.0; N, 8.1%. MS (EI$^+$, *m*/*z*) [M]$^+$ 336–343; 340 (100); IR ν_{max} (KBr) [cm^{-1}]: 3312s (NH), 3120, 3105 (aryl CH), 2950 (methyl CH), 2663s, 2628s, 2550s (BH), 1514s, 1262m, 814s, 689s. $^1H\{^{11}B\}$ NMR ($CDCl_3$), δ: 7.69 (d, $^3J_{HH}$ 8 Hz, 2H, *ortho* C_6H_5), 7.53 (t, $^3J_{HH}$ 8 Hz, 1H, *para* C_6H_5), 7.40 (t, $^3J_{HH}$ 8 Hz, 2H, *meta* C_6H_5), 6.82 (d, $^3J_{HH}$ 8 Hz, 2H, *meta* C_6H_4Me), 6.17 (d, $^3J_{HH}$ 8 Hz, 2H, *ortho* C_6H_4Me), 5.28 (br,s, 1H, NH), 4.83 (s, 1H, N*H*Ar), 2.83 (s, 2H, H3,6), 2.59 (s, 2H, BH), 2.41 (s, 3H, BH incl H9), 2.32 (s, 1H, H12), 2.21 (s, 3H, CH_3), 2.14 (s, 2H, H8,10); $^{11}B\{^1H\}$ NMR ($CDCl_3$), δ: −3.9 (1B, B9), −6.8 (1B, B12), −10.6 (4B), −12.6 (4B); $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 144.9 (*C*–CH_3), 131.8, 129.5, 128.8 (aryl CH); 131.0 (*ipso* C_6H_5), 130.5 (*para* C_6H_5), 130.1 (C–N), 112.5 (*C*HCN), 102.3 (C1), 90.0 (C2), 20.4 (CH_3).

4.3. Preparation of carboranylhydroxylamines

The methyl nitrosocarborane (0.22 g) was dissolved in 10 ml of *p*-dioxane, 5% Pd/C (40 mg) added and the solution degassed by a freeze-pump–thaw process. Hydrogen was admitted and its uptake measured using a standard hydrogenation apparatus. Twenty-five milliliters of hydrogen was consumed over a period of 6 h. The solution was filtered and evaporated to leave a white solid (210 mg, 95%), M.p. 253–255 °C (lit. [19] 256–258 °C). *Anal.* Calc. for $C_{15}H_{24}B_{10}N_2$: C, 19.1; H, 7.9; N, 7.4. Found: C, 19.4; H, 8.1; N, 6.2%. MS (EI$^+$, *m*/*z*) [M]$^+$ 185–192; 189 (100); IR ν_{max} (KBr) [cm^{-1}]: 3340, 3290 (NH,OH), 2914 (methyl CH), 2579s (BH), 1254s, 1116s, 1080m, 870s. $^1H\{^{11}B\}$ NMR ($CDCl_3$), δ: 5.94 (s, 1H, NH), 5.39 (s, 1H, OH), 2.46 (s, 2H, H3,6), 2.24 (s, 3H, BH), 2.22 (s, 1H, BH), 2.18 (s, 2H, BH), 2.05 (s, 2H, H8,10), 2.02 (s, 3H, CH_3); $^{11}B\{^1H\}$ NMR ($CDCl_3$), δ: −6.1 (2B, B9,12), −10.9 (4B), −11.7 (4B); $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 94.5 (C1), 78.6 (C2), 21.6 (CH_3).

A larger-scale preparation was used for the phenyl analogue to afford 3.37 g (87%) from 3.86 g of the nitroso compound, M.p. 95–96 °C, (lit. [18] 98–99 °C). *Anal.* Calc. for $C_{15}H_{24}B_{10}N_2$: C, 38.2; H, 7.2; N, 5.4. Found: C, 38.3; H, 6.8; N, 5.6%. MS (EI$^+$, *m*/*z*) [M]$^+$ 247–255; 251 (100); IR ν_{max} (KBr) [cm^{-1}]: 3532, 3463, 3280 (NH,OH), 3061 (phenyl CH), 2574s (BH), 1493m, 1446s, 1071s, 1003s, 689s. $^1H\{^{11}B\}$ NMR ($CDCl_3$), δ: 7.70 (d, 2H, *ortho* C_6H_5), 7.47 (t, 1H, *para* C_6H_5), 7.40 (t, 2H, *meta* C_6H_5), 5.69 (s, 1H, NH), 5.09 (s, 1H, OH), 2.83 (s, 2H, H3,6), 2.53 (s, 2H, BH), 2.42 (s, 3H, BH), 2.38 (s, 1H, H12), 2.17 (s, 2H, H8,10); $^{11}B\{^1H\}$ NMR ($CDCl_3$), δ: −3.8 (1B, B9), −5.7 (1B, B12), −10.6 (4B), −12.1 (4B); $^{13}C\{^1H\}$ NMR ($CDCl_3$), δ: 131.3, 130.8 (para C), 130.0 (ipso C), 129.1, 98.4 (C1), 86.5 (C2).

4.4. Preparation of methyl-ortho-carboranyl amine

The compound 1-nitroso-2-methyl-*ortho*-carborane (1.50 g) was dissolved in dimethoxyethane (25 ml) and tin powder (1.50 g) was added. Concentrated HCl (25 ml) was added dropwise and the solution stirred for 15 min, after which time the blue colour had disappeared. The solution was heated to reflux for 3 h, cooled to room temperature and diluted with diethyl ether (100 ml). The solution was washed with water (3 × 50 ml), dried and evaporated. The white residue was sublimed to yield 1-amino-2-methyl-*ortho*-carborane (1.10 g, 79%), M.p. 301–302 °C (lit. [19] 302–303 °C). *Anal.* Calc. for $C_3H_{15}B_{10}N$: C, 20.8; H, 8.7; N, 8.1. Found C, 20.9; H, 9.0; N, 7.1%. MS (EI): M, 169–176 ($C_3H_{15}B_{10}N$ = 173). I.R. (cm^{-1}): 3306, 3219br (NH), 2939w (methyl CH), 2671s, 2634s, 2602s, 2580s (BH), 1491m, 1451m, 1221m, 1079s, 1026m, 1002m, 864m, 809m, 764s, 700s. $^1H\{^{11}B\}$ NMR ($CDCl_3$): 3.00 (2H, s, H4,5), 2.99 (2H, NH_2), 2.41 (2H, H7,11), 2.20 (1H, H9), 2.04 (3H, CH_3), 2.02 (2H, H3,6), 1.98 (1H, H12), 1.95 (2H, H8,10), ^{11}B NMR ($CDCl_3$): −5.5 (1B, d, B9), −9.4 (1B, d, B12), −9.8 (2B, d, B4,5), −10.6 (4B, d, B3,6,7,11), −12.5 (2B, d, B8,10). $^{13}C\{^1H\}$ NMR ($CDCl_3$): 91.1 (C1), 78.9 (C2), 21.1 (CH_3).

4.5. Crystal structure determinations

Crystals of the compounds **1**–**4** were examined on Bruker SMART (**3**) and Stoe STADI4 (**1**, **2**, **4**) diffractometers with Mo Kα radiation (λ = 0.71073 Å; Cu Kα with λ = 1.54184 Å for **1**) at 160 K. Crystal data and other information are given in Table 8. Standard methods and software were employed, including refine-

ment on all F^2 values [44]; no absorption corrections were applied, and no structural disorder was found.

5. Computational

AM1 [45,46] calculations were carried out on crystallographically determined geometries using MOPAC2002 (Version 2.40) within the CACHE 6.1 program for Windows [47]. *Ab initio* computations were carried out with the GAUSSIAN 03 package [48]. All model geometries of HCb^{o}X and PhX with fixed torsion angles for C2–C1–N–R/X listed in Tables 4 and 5, respectively, were optimised initially at the HF/6-31G* level of theory followed by the MP2/6-31G* level of theory. The geometries of PhCb^{o}X and MeCb^{o}X listed in Table 6 were optimised at the HF/6-31G* level of theory either with no symmetry constraints (and confirmed by frequency calculations to be a true minimum) or with the nitrogen atom N1 constrained to a planar configuration. These geometries were then optimised at the MP2/6-31G* level of theory.

Calculated NMR shifts at the GIAO-B3LYP/6-311G* level were obtained from these MP2-optimised geometries. Theoretical ^{11}B chemical shifts at the GIAO-B3LYP/6-311G*//MP2/6-31G* level were referenced to B_2H_6 (16.6 ppm [49]) and converted to the usual $BF_3{\cdot}OEt_2$ scale: $\delta(^{11}B) = 102.83 - \sigma(^{11}B)$. The ^{13}C and ^{1}H chemical shifts were referenced to TMS: $\delta(^{13}C) = 179.81 - \sigma(^{13}C)$; $\delta(^1H) = 32.28 - \sigma(^1H)$. Agreements between observed and calculated (B3LYP/6-311G*//MP2/6-31G* level) ^{11}B and ^{13}C NMR shifts generated from optimised geometries are generally very good for carboranes [50–54]. Agreements between observed and calculated ^{1}H NMR shifts in carboranes are often not as good due to a narrow ppm range (*ca.* 12 ppm) and substantial solvent effects on ^{1}H shift measurements [40].

Supplementary data

CCDC 704893, 704894, 704895 and 704896 contain the supplementary crystallographic data for **1**, **2**, **3** and **4**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

X-ray crystal structure

ABSTRACT

The nitrate and perchlorate Ni(II) complexes of the stereo-isomeric hexazamacrocyclic ligands L^1(3,6,14,17,23,24-hexaazatricyclo[17.3.1.18,12]tetracosa-1(23),8,10,12(24),19,21-hexaene,2,7,13,18-tetramethyl) and L^2 (3,7,15,19,25,26-hexaazatricyclo[19.3.1.19,13]hexacosa-1(25),9,11,13(26),21,23-hexaene,2,8,14,20-tetramethyl) derived from 2,6-diacetylpyridine have been synthesized and characterized by microanalysis, LSI-MS, conductivity measurements, IR, UV–Vis spectroscopy and magnetic studies. Crystal structures of $L^1{\cdot}2H_2O$ as well as of the complexes $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$ have been determined. The X-ray studies show the presence of mononuclear endomacrocyclic complexes with the metal ion coordinated to all the nitrogen donor atoms from the macrocyclic framework in a N6 core. The geometry around the metal ions can be described as distorted octahedral. The nitrate and perchlorate anions do not coordinate to the metal ions, but they are involved in intermolecular interactions through hydrogen bonds to the amine groups of the macrocyclic ligands.

1. Introduction

Azamacrocyclic ligands have been extensively investigated during the past decades [1] mainly due their ability to form complexes with different metal ions or anionic species [2–6] with considerable potential in areas such as catalysis, modelling of metalloenzyme activity, molecular recognition [7]. The presence of pyridine groups in the macrocyclic framework offering the possibility of obtain highly stable metal complexes have been the subject of numerous investigations in recent years [8–10]. The cavity size, the rigidity and the donor type of the macrocycle is important in governing the host–guest interactions and the selectivity of metal ions [11,12].

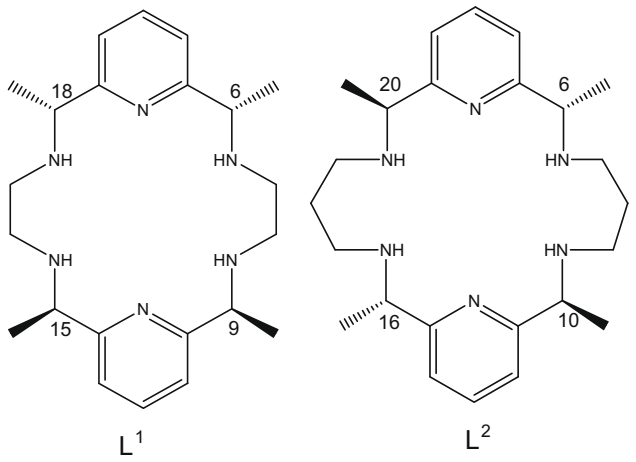
This paper is an extension of the investigation of our research group about the structure–function relationships in the complexation behavior of transitional and post-transitional metal ions with azamacrocyclic ligands derived from 2,6-diformylpyridine or 2,6-diacetylpyridine and different diamine moieties [13–18]. In this case, we have tried to explore if the variety of the size of the macrocyclic framework can be adequate for the coordination of more than one metal ions into the macrocyclic cavity, giving rise to di- or polynuclear endomacrocyclic complexes.

In this way, we present the nitrate and perchlorate Ni(II) complexes with two different reduced hexaazamacrocycle ligands: the hexaaza 18-membered (L^1) and the hexaaza 20-membered (L^2) (Scheme 1). The intermolecular interactions through hydrogen bonds between the nitrate and perchlorate counter ions and amine groups in crystal structures are also studied.

2. Experimental

2.1. Chemical and starting materials

2,6-Diacetylpyridine, 1,2-ethanediamine, 1,3-diaminepropane, barium(II) chloride dihydrated and nickel(II) hydrated nitrate and perchlorate salts were commercial products obtained from Alfa and Aldrich, and were used without further purifications. The solvents used were of reagent grade and purified by usual methods.



Caution: Although no problems were encountered during the course of this work, attention is drawn to the potentially explosive nature of perchlorates.

2.2. Synthesis of macrocyclic ligands

The ligands L^1 and L^2 were obtained following the method described previously [17,18] by sodium borohydride reduction of

the result of a barium(II) template condensation of 2,6-diacetylpyridine and 1,2-ethanediamine (L^1) or 1,3-diaminepropane (L^2).

2.3. Synthesis of metal complexes – general procedure

The reactions were carried out in 1:1 metal:ligand molar ratio in all cases. The appropriate metal salt (0.25 mmol) was dissolved in acetonitrile (10 ml) and added to a stirred solution of the macrocyclic ligand (0.25 mmol) in acetonitrile (20 ml). The solution was stirred for 2 h and concentrated in a rotary evaporator until *ca.* 5–6 ml. The products obtained were filtered off, dried and recrystallized in acetonitrile.

2.4. Physical measurements

Elemental analyses were performed in a Carlo–Erba EA microanalyser. Infra-red spectra were recorded as KBr discs on a Bruker IFS-66 V spectrophotometer. LSI-MS were recorded using a Micromass Autospec spectrometer with 3-nitrobenzyl alcohol as the matrix. Conductivity measurements were carried out in 10^{-3} mol dm^{-3} acetonitrile solutions at 20 °C using a WTW LF3 conductivimeter. Solid state electronic spectra were recorded on a Hitachi 4-3200 spectrophotometer using $MgCO_3$ as reference. Magnetic studies were determined at 298 K on a vibration sample magnetometer (VSM) Digital Measurement System 1660 with a magnetic field of 5000 G.

2.5. X-ray data collection, structure determination and refinement

The details of the X-ray crystal structure solution and refinement are given in Table 1. Measurements were made on a MACH3 Enraf Nonius for $L^1{\cdot}2H_2O$ and on a Bruker SMART CCD Area Detector for $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$. All data were corrected for Lorentz and polarization effects. For $L^1{\cdot}2H_2O$ a semi-empirical absorption correction (φ-scan) was made [19], whilst an empirical absorption correction was applied for $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$ [20]. Complex scattering factors were taken from the program package SHELXTL[1]. The structures were solved by direct methods, which revealed the position of all non-hydrogen atoms. All the structures were refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters for all non-hydrogen atoms [21]. Hydrogen atoms were included in calculated positions and refined in riding mode for $[NiL^1](ClO_4)_2$ and located on a difference electron density map and refined with isotropic displacement parameters for $L^1{\cdot}2H_2O$ and $[NiL^2](NO_3)_2$.

3. Results and discussion

The ligands L^1 and L^2 have been obtained by reduction of the tetraiminic barium(II) complexes, giving an isomeric mixture of the corresponding saturated macrocycle. Previously, we also reported the X-ray data of the nitrate salt of the diprotonated 6S,9S,15R,18R-*meso* form of the ligand L^1 [17].

In this case, the crude isomeric mixture of the protonated ligand L^1 was treated with a water solution of NaOH, extracted with chloroform and recrystallised in acetonitrile to give crystals suitable for X-ray diffraction of the 6S,9S,15S,18S-*meso* form of the ligand, $L^1{\cdot}2H_2O$.

The molecular structure of $L^1{\cdot}2H_2O$ together with the atomic numbering scheme adopted and selected bond distances and angles are shown in Fig. 1. The X-ray data are listed in Table 1. The structure does not differ much from that previously found for $[H_2L^1](NO_3)_2{\cdot}3H_2O$.

The crystal belongs to the triclinic $P\bar{1}$ space group with bond lengths and angles falling within the normal ranges. The asymmetric unit is comprised by two independent half molecules of the ligand. As in the protonated $[H_2L^1](NO_3)_2{\cdot}3H_2O$, the macrocyclic ligand has a markedly stepped conformation and the four amine nitrogen atoms of each molecule are coplanar, but in this case the pyridine rings are parallel-dihedral angle of 28.73° in $[H_2L^1](NO_3)_2{\cdot}3H_2O^-$ and the dihedral angle between the plane containing one of the pyridine ring and the plane determined by the four aliphatic nitrogen atoms is 61.18° for one molecule and 55.96° for the other −61.2° in $[H_2L^1](NO_3)_2{\cdot}3H_2O$. No intra- or intermolecular π,π-stacking interactions between pyridine rings have been observed in the structure, but some intermolecular interactions through hydrogen bonds between amine groups and water molecules are present in the crystal lattice: [O2W–H2W···N3_$1 = 1.995(1) Å; 168.8(1)°] ($1 $-x + 1$, $-y + 1$, $-z + 1$);

The coordination ability of the hexaazamacrocyclic ligands L^1 and L^2 towards hydrated nitrate and perchlorate salts of Ni(II) in 1:1 metal:ligand molar ratio was studied.

The complexes $[NiL^1](NO_3)_2$ and $[NiL^1](ClO_4)_2$ were synthesized starting from the 6S,9S,15R,18R-*meso* form of the ligand L^1. However, $[NiL^2](NO_3)_2$ and $[NiL^2](ClO_4)_2$, were obtained starting from the isomeric mixture of L^2. All the complexes have been characterized by microanalysis, LSI-MS, conductivity measurements, IR, UV–Vis spectroscopy and magnetic studies. The complexes $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$ were also characterized by X-ray diffraction.

3.1. Crystal structures of metal complexes

By slow concentration of an acetonitrile solution of the corresponding complexes, crystals suitable for X-ray diffraction of $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$ were obtained.

One and a half structurally similar $[NiL^1]^{2+}$ cations, together with three perchlorate anions are present in the asymmetric unit of the crystal structure of $[NiL^1](ClO_4)_2$. The atomic numbering scheme adopted of one of $[NiL^1]^{2+}$ cations, together with selected bond distances and angles is shown in Fig. 2a. X-ray data are listed in Table 1.

The Ni(II) ion is sited in the middle of the macrocyclic cavity, endomacrocyclic coordinated in a distorted octahedral geometry with a N6 core arising from coordination by the six donor nitrogen atoms from the macrocyclic framework. The equatorial plane can be considered by the amine nitrogen atoms [N2–N3–N5–N6, rms 0.474, for Ni(1) and N8–N9–N8#–N9#, rms 0.478 for Ni(2)], with the Ni(II) atoms at 0.0059 and 0.0114 Å from that planes, respectively. The axial positions are occupied by the pyridine nitrogen atoms (N1 and N4 atoms for Ni1 and N7, N10 for Ni2).

The structure shows a 'twist-wrap' conformation, typical of this kind of ligand, where the macrocycle adopts a helical shape with

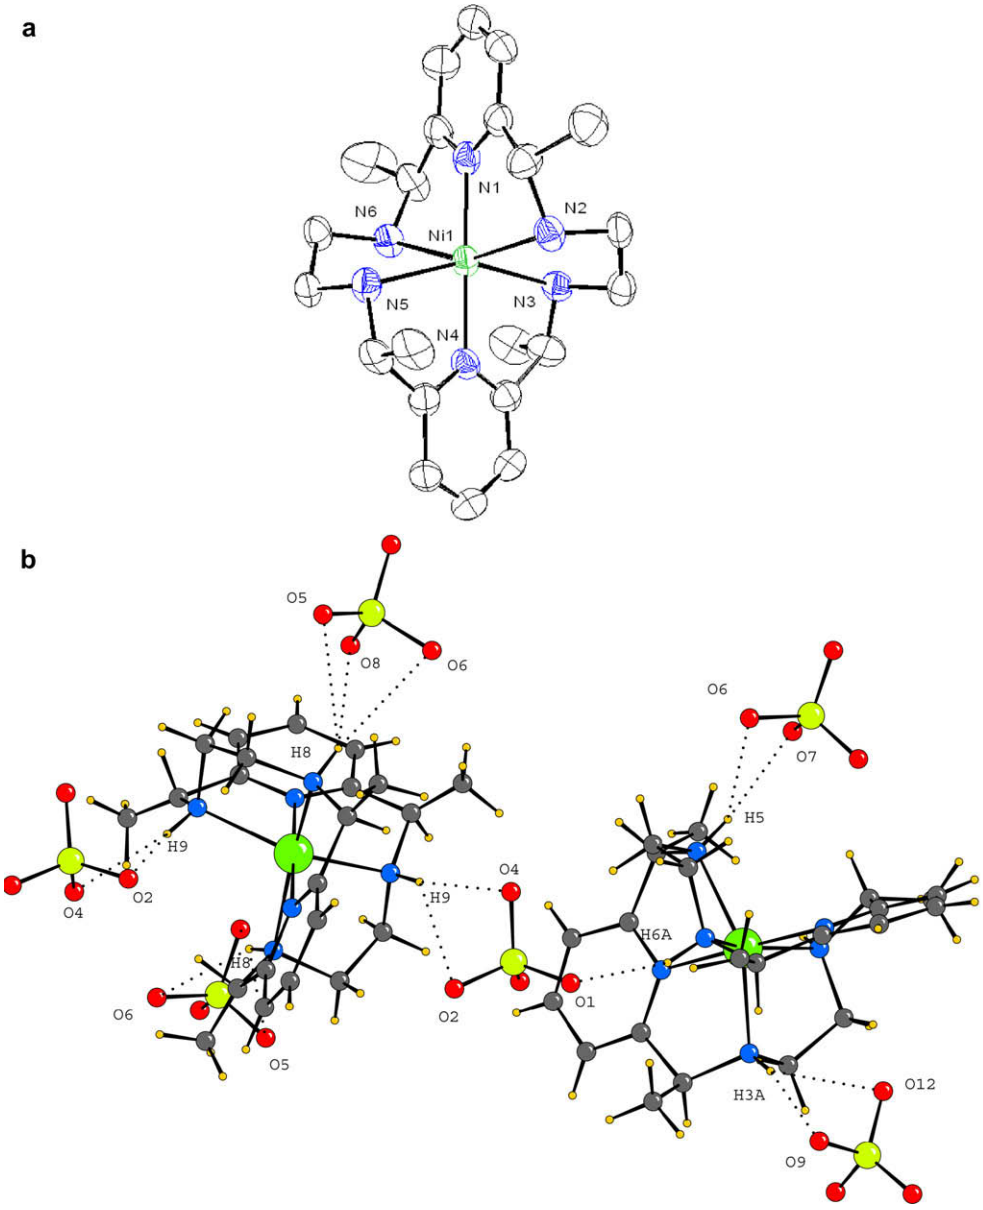

Fig. 2. (a) Crystal structure of $[NiL^1]^{2+}$ cation. Selected bond lengths (Å) and angles (°): N(1)—Ni(1) 2.016(8); N(2)—Ni(1) 2.147(7); N(3)—Ni(1) 2.144(8); N(4)—Ni(1) 2.005(8); N(5)—Ni(1) 2.171(8); N(6)—Ni(1)2.110(8); N(4)—Ni(1)—N(1) 178.5(3); N(4)—Ni(1)—N(6) 102.7(3); N(1)—Ni(1)—N(6) 76.8(3); N(4)—Ni(1)—N(3) 77.3(3); N(1)—Ni(1)—N(3) 101.4(3); N(6)—Ni(1)—N(3) 101.7(3); N(4)—Ni(1)—N(2) 102.7(3); N(1)—Ni(1)—N(2) 77.7(3); N(6)—Ni(1)—N(2) 154.6(3); N(3)—Ni(1)—N(2) 83.5(3); N(4)—Ni(1)—N(5) 77.0(3); N(1)—Ni(1)—N(5) 104.4(3); N(6)—Ni(1)—N(5) 83.6(3); N(3)—Ni(1)—N(5) 154.3(3); N(2)—Ni(1)—N(5) 102.6(3). (b) Crystal lattice structure of $[NiL^1](ClO_4)_2$ complex showing some intermolecular hydrogen bonding between perchlorate anions and amine groups.

the two pyridine rings oriented at 67.43° and 69.88° relative to each other for Ni1 and Ni2, respectively. The angle between the pyridinic nitrogen atoms and the metal ion [N1–Ni1–N4, 178.5(3)° for Ni1 and N7–Ni1–N10 180.00(9)° for Ni2], shows that the macrocycle is not folded.

The pyridine groups provide the shortest bond to the Ni(II) atoms [2.016(8) and 2.005(8) Å for Ni1; 2.006(11) and 2.046(12) Å for Ni2]. The bond lengths of the secondary amine groups are in the range 2.171(8)–2.110(8) Å for Ni1 and 2.152(8)–2.127(8) Å for Ni2, not markedly different from those reported previously with similar macrocyclic ligands [22,23]. The perchlorate ions are not coordinated to the metal centers, but they are involved in intermolecular interactions through hydrogen bonds with some of the amine groups of the macrocyclic ligand (Fig. 2b): [N5–H5···O6 = 2.918(10) Å; 126(1)°], [N5–H5···O7 = 2.207(10) Å; 173(1)°], [N8–H8···O5 = 2.822(10) Å; 124(1)°], [N8–H8···O6 = 2.741(10) Å; 153(1)°], [N8–H8···O8 = 2.485(10) Å; 151(1)°], [N9–H9···O2 = 2.984(10) Å; 141(1)°], [N9–H9···O3 = 2.843(10) Å; 127(1)°], [N9–H9···O4 = 2.324(10) Å; 167(1)°], [N6–H6A···O1 = 2.238(10) Å; 150(1)°], [N2–H2A···O10_$1 = 2.666(20) Å; 150(1)°], [N2–H2A···O11_$1 = 2.397(10) Å; 142(1)°], [N3–H3A···O12_$2 = 2.490(20) Å; 142(1)°], [N3–H3A···O9_$2 = 2.684(20) Å; 170(1)°], [N3–H3A···O10_$2 = 2.787(20) Å; 128(1)°]. $1 $x - 1, +y, +z$; $2 $-x + 1, -y + 1/2 + 1, +z - 1/2$.

The reaction between the isomer mixture of L^2 with $Ni(NO_3)_2 \cdot 6H_2O$ gave rise to adequate crystals for X-ray studies. The solution of the crystal structure reveals the presence of a Ni(II) nitrate complex of the 6R,10R,16R,20R-*meso* form of the ligand L^2. The molecular X-ray structure of $[NiL^2](NO_3)_2$ with the atomic numbering scheme adopted, together with selected bond distances and angles is shown in Fig. 3a. The details of the X-ray crystal structure solution and refinement are given in Table 1. The

asymmetric unity is consistent with the cation $[NiL^2]^{2+}$ and two well-separated nitrate anions. The X-ray analysis confirms the presence of mononuclear endomacrocyclic complex, where the metal ion is also six coordinated by all the donor nitrogen atoms from the macrocyclic backbone, in a distorted octahedral geometry. The equatorial plane can be also formed by the amine nitrogen atoms [N2–N3–N5–N6, rms 0.4131] and the distance between the nickel ion and that plane is 0.0056 Å. The axial positions are occupied by the pyridine nitrogen atoms, N1 and N4.

The structure also shows a 'twist-wrap' conformation with the two pyridine rings oriented at 88° relative to each other. The angle between the pyridinic nitrogen atoms and the metal ion [N1–Ni–N4, 178.38(14)°], shows that the macrocycle is not folded.

The pyridine groups also provide the shortest bond to the Ni atom [2.029(3) and 2.022(3) Å]. The bond lengths of the secondary amine groups vary from 2.126(4) to 2.145(3) Å, not markedly different from that described above for $[NiL^1](ClO_4)_2$. The nitrate ions are not coordinated to the metal center, but they are involved in intermolecular interactions through hydrogen bonds with the amine nitrogen atoms (Fig. 3b): [N2–H2N···O6N = 2.904(1) Å; 174(1)°], [N3–H3N···O1N = 3.057(1) Å; 156(1)°], [N3–H3N···O3N = 3.344(1) Å; 147(1)°], [N5–H5N···N2N = 3.640(1) Å; 154(1)°], [N5–H5N···O5N = 3.060(1) Å; 164(1)°], [N5–H5N···O6N = 3.486 (1) Å; 136(1)°], [N6–H6N···O3N = 2.939(1) Å; 175(1)°].

Inter- or intramolecular π,π-stacking interactions between the pyridine rings are not observed.

3.2. Spectroscopic and magnetic studies

Elemental analysis are consistent with the presence of mononuclear Ni(II) complex in all cases.

The IR spectra of the complexes (KBr discs) show that the ν(C=N) vibration band of the pyridine groups are shifted to higher wavenumber than in the free ligand suggesting the coordination to the metal atom [24]. The secondary amine stretches around 3300 cm^{-1} in the free ligands are shifted suggesting also the coordination to the metal ion. The IR spectra of the nitrate and perchlorate complexes feature absorptions attributable to ionic nitrate (1383 cm^{-1}) and perchlorate (1100 cm^{-1}). The lack of splitting of these bands indicates that there is no coordination of these groups

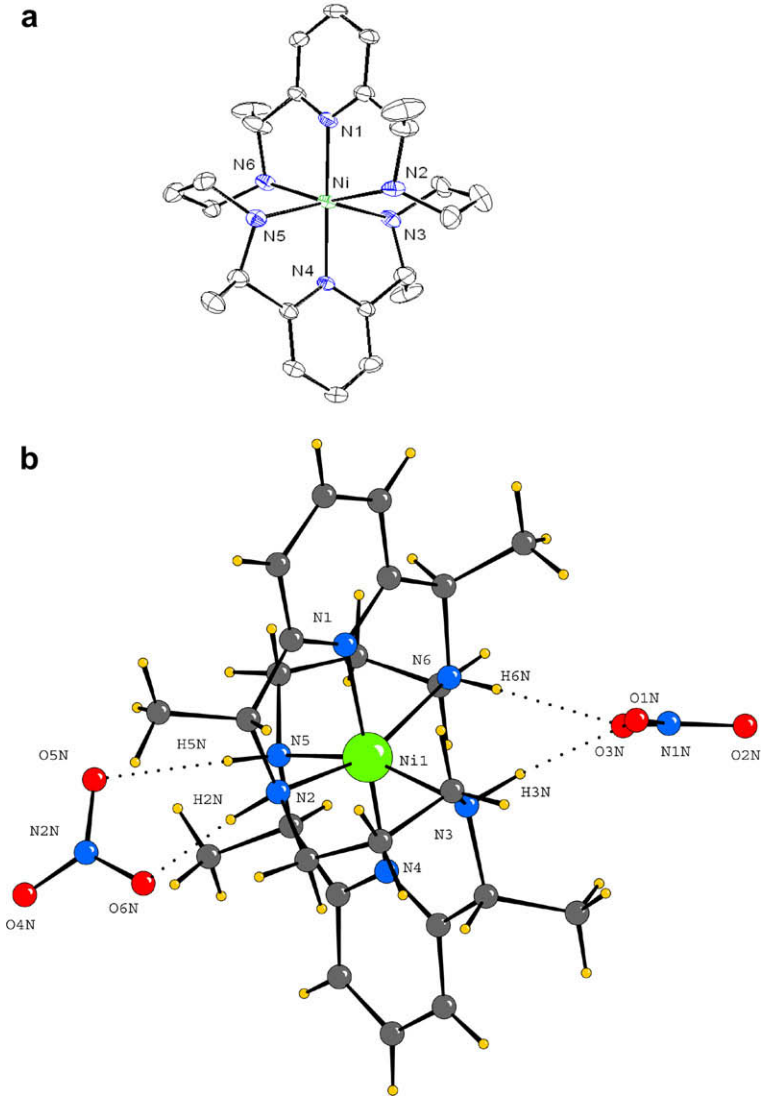

Fig. 3. (a) Crystal structure of $[NiL^2]^{2+}$ cation. Selected bond lengths (Å) and angles (°): Ni—N(4) 2.022(3); Ni—N(1) 2.029(3); Ni—N(2) 2.126(4); Ni—N(5) 2.142(3); Ni—N(6) 2.142(4); Ni—N(3) 2.145(3); N(4)—Ni—N(1) 178.38(14); N(4)—Ni—N(2) 98.70(16); N(1)—Ni—N(2) 79.90(15); N(4)—Ni—N(5) 78.89(12); N(1)—Ni—N(5) 100.36(13); N(2)—Ni—N(5) 94.22(15); N(4)—Ni—N(6) 103.26(16); N(1)—Ni—N(6) 78.14(15); N(2)—Ni—N(6) 158.04(13); N(5)—Ni—N(6) 90.30(15); N(4)—Ni—N(3) 78.65(12); N(1)—Ni—N(3) 102.12(13); N(2)—Ni—N(3) 90.38(15); N(5)—Ni—N(3) 157.51(13); N(6)—Ni—N(3) 93.62(16). (b) Crystal lattice structure of $[NiL^2](NO_3)_2$ complex showing some intermolecular hydrogen bonding between nitrate anions and amine groups.

to the metal centers as has been demonstrated by the X-ray analysis of $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$ [25,26].

Also, molar conductivity data, measured at room temperature using acetonitrile as solvent, showed the presence of ionic counterions, since they are in the range reported in that solvent for 2:1 [27].

The LSI mass spectra of the complexes show peaks according to the mononuclear nature of the complexes.

The reflectance spectra of all complexes show three bands at *ca.* 9804 (ν_1), 16502 (ν_2) and 28571 cm^{-1} (ν_3). These bands are attributable to the $^3T_{2g} \leftarrow {}^3T_{2g}$, $^3T_{1g}(F) \leftarrow {}^3T_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3T_{2g}$ transitions, respectively, and are indicative of octahedral Ni(II) compounds [28,29].

The value of the room temperature magnetic moments of the compounds [3.1 – 3.3 B.M.] lies within the range usually observed for octahedral Ni(II) complexes [30].

4. Conclusion

The nitrate and perchlorate Ni(II) complexes of the potential neutral hexadentate N_6 donor macrocyclic ligands, L^1 and L^2, have been synthesized in acetonitrile. The crystal structure of $L^1{\cdot}2H_2O$ as well as of $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$ complexes have been also determined. All the complexes are mononuclear with the metal ion endomacrocyclicly coordinated by the six donor nitrogen atoms from the macrocyclic framework in a N6 core. The coordination geometry can be considered as distorted octahedral. The nitrate and perchlorate anions are no coordinated to the metal ions, but both anions are involved in intermolecular interactions through hydrogen bond with some amine groups of the ligands.

5. Supplementary data

CCDC 728059, 728060 and 728061 contain the supplementary crystallographic data for $L^1{\cdot}2H_2O$, $[NiL^1](ClO_4)_2$ and $[NiL^2](NO_3)_2$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

The paper presents a combined experimental and computational study of novel rhenium(III) complexes with the picolinate ligand – $[ReCl_2(pic)(PPh_3)_2]$ (**1**) and $[ReBr_2(pic)(PPh_3)_2]$ (**2**). Both complexes **1** and **2** have been characterised spectroscopically and structurally (by single-crystal X-ray diffraction). Complex **1** has been additionally studied by magnetic measurement. The magnetic behavior is characteristic of a mononuclear d^4 low-spin octahedral Re(III) complex ($^3T_{1g}$ ground state) and arises because of the large spin–orbit coupling ($\zeta = 2500\ cm^{-1}$), which gives a diamagnetic ground state. DFT and time-dependent (TD)DFT calculations have been carried out for complex **1**, and UV–vis spectra of the $[ReX_2(pic)(PPh_3)_2]$ compounds have been discussed on this basis.

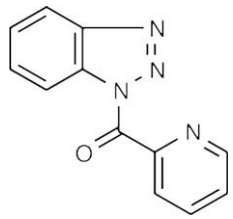
1. Introduction

The coordination chemistry of rhenium is a field of current growing interest from various viewpoints. The attention of scientists concentrates on synthetic aspects, structural, physicochemical properties and reactivity, as well as on topics with an applied character such as the development of radiotherapeutic cancer agents, nitrogen fixation and catalysis [1]. The ^{186}Re (1.07 MeV β-emitter, $t_{1/2}$ 90 h) and ^{188}Re (2.12 MeV β-emitter, $t_{1/2}$ 17 h) isotopes are among the most attractive isotopes for applications in targeted radionuclide therapy [2,3].

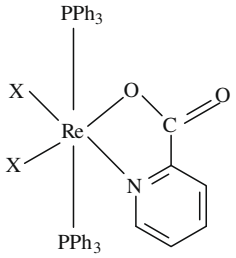
Diazenido and dinitrogen rhenium complexes are important in view of their significance in the field of nitrogen fixation [4–6]. Methyltrioxorhenium is one of the most versatile catalysts for olefin oxidation reactions, aldehyde olefination and olefin metathesis [7,8]. The *mer, trans*-$[ReOCl_3(PPh_3)_2]$ and its derivatives catalyze the oxidation of sulfides to sulfoxides, thiols to disulfides and catalyze oxygen-transfer from sulfoxides to phosphines [8]. The $[ReOCl_2(O–N)(PPh_3)]$ chelates with pyridinecarboxylate ligands exhibit a remarkable catalytic activity for the conversion of ethane to a mixture of propionic and acetic acids in a single-pot process [9]. The $[CH_3ReO(pic)_2]$ complex is an active precursor in olefin oxidation and forms epoxides in a two-phase H_2O_2–H_2O/CH_2Cl_2 system [10].

Generally, chelation of nitrogenous π-acidic ligands to Re^VO facilitates the oxygen atom transfer to oxophilic substrates *via* electron withdrawal from the metal [11]. In this context, the design, synthesis and reactivity of oxorhenium complexes has become the aim of several laboratories, including ours.



Previously, we investigated the reactivity of $[ReOX_3(EPh_3)_2]$ (X = Cl, Br; E = P or As) oxorhenium(V) species towards 1,10-phenanthroline and 5,6-diphenyl-3-(2-pyridyl)-1,2,4-trazine. The products of these reactions include both Re(V) oxocomplexes – $[ReOCl_3(phen)]$ and Re(III) compounds – $[ReCl_2(phen)(PPh_3)_2](ReO_4)\cdot\frac{1}{2}H_2O$, $[ReCl_3(OPPh_3)(dppt)]$ [12,13]. In this report we focus on the examination of the reactions of $[ReOX_3(PPh_3)_2]$ with 1-(2-pyridylcarbonyl)benzotriazole. Potentially, 1-(2-pyridylcarbonyl)benzotriazole can bind to the metal center ion *via* one of two modes: either through the two nitrogen atoms located in the pyridine and triazole rings or through one pyridyl nitrogen and the carbonyl oxygen (Scheme 1).

The reactions of $[ReOX_3(PPh_3)_2]$ with 1-(2-pyridylcarbonyl)benzotriazole lead to novel Re(III) $[ReX_2(pic)(PPh_3)_2]$ complexes (Scheme 2).



The 1-(2-pyridylcarbonyl)benzotriazole hydrolyzes in the reaction with $[ReOX_3(PPh_3)_2]$, and the formed picolinic acid coordinates to the rhenium ion. With much higher yield, however,

Scheme 1. Structure of 1-(2-pyridylcarbonyl)benzotriazole.

Scheme 2. Structure of $[ReCl_2(pic)(PPh_3)_2]$; X = Cl for **1** and X = Br for **2**.

$[ReCl_2(pic)(PPh_3)_2]$ (**1**) and $[ReBr_2(pic)(PPh_3)_2]$ (**2**) were isolated from the reactions of $[ReOX_3(PPh_3)_2]$ with picolinic acid in the presence of PPh_3 in ethanol.

The molecular orbital diagram of **1** has been calculated with the density functional theory (DFT) method. Currently the density functional theory (DFT) is commonly used to examine the electronic structure of transition metal complexes. It meets with the requirements of being accurate, easy to use and fast enough to allow the study of relatively large molecules of transition metal complexes [14]. The electronic spectrum of **1** has been discussed on the basis of the time-dependent DFT calculations. Recent studies have supported the TDDFT method to be applicable for open- and closed-shell 5d-metal complexes (including rhenium complexes), giving good assignments of the experimental spectra [15–17].

2. Experimental

2.1. General procedure

The reagents used in the syntheses were commercially available and were used without further purification. The $[ReOX_3(PPh_3)_2]$ complexes were prepared according to the literature methods [18]. IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–vis 8500 in the range 1000–180 nm in acetonitrile solution. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer. The ^1H NMR spectrum was obtained in d_6-DMSO using a Bruker Avance 400 spectrometer.

2.2. Preparation of $[ReCl_2(pic)(PPh_3)_2]$ (**1**)

2.2.1. Method A

$[ReOCl_3(PPh_3)_2]$ (0.50 g, 0.6 mmol) was added to 1-(2-pyridylcarbonyl)benzotriazole (0.135 g, 0.6 mmol) in ethanol (100 ml) and the reaction mixture was refluxed for 4 h. The resulting reaction mixture was reduced in volume to ~10 ml and allowed to cool to room temperature. An orange crystalline precipitate of **1** was filtered off and dried in air. Yield 55%.

2.2.2. Method B

$ReOCl_3(PPh_3)_2$] (0.50 g, 0.6 mmol) was added to picolinic acid (0.075 g, 0.61 mmol) and PPh_3 (0.30 g, 1.15 mmol) in ethanol (100 ml) and the reaction mixture was refluxed for 4 h. The resulting reaction mixture was reduced in volume to ~10 ml and allowed to cool to room temperature. An orange crystalline precipitate of **1** was filtered off and dried in air. Yield 80%.

IR (KBr; ν/cm^{-1}): 1697 (vs) ν_{asymCO_2}; 1616 (m) and 1596 (w) ν_{CN} and $\nu_{C=C}$; 1288(s) ν_{asymCO_2}.

2.3. Preparation of $[ReBr_2(pic)(PPh_3)_2]$ (**2**)

A procedure similar to that for $[ReCl_2(pic)(PPh_3)_2]$ was used with $[ReOBr_3(PPh_3)_2]$ (0.50 g, 0.52 mmol) and 1-(2-pyridylcarbonyl)benzotriazole (0.12 g, 0.53 mmol) in method A, and $[ReOBr_3(PPh_3)_2]$ (0.50 g, 0.52 mmol), picolinic acid (0.068 g, 0.55 mmol) and PPh_3 (0.29 g, 1.10 mmol) in method B.

IR (KBr; ν/cm^{-1}): 1684 (vs) ν_{asymCO_2}; 1608 (m) and 1586 (w) ν_{CN} and $\nu_{C=C}$; 1281(s) ν_{asymCO_2}.

Anal. Calc. for $C_{42}H_{34}Br_2NO_2P_2Re$: C, 50.82; H, 3.45; N, 1.41%. Found: C, 50.59; H, 3.32; N, 1.34%.

2.4. Crystal structure determination and refinement

The X-ray intensity data of **1** and **2** were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector and graphite monochromated Mo Kα radiation (λ = 0.71073 Å) at room temperature. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and absorption corrections [19] were applied. The structures were solved by the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique. The hydrogen atoms were treated as "riding" on their parent carbon atoms and assigned isotropic temperature factors equal to 1.2 times the value of equivalent temperature factor of the parent atom. SHELXS97 [20], SHELXL97 [21] and SHELXTL [22] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.5. Computational details

The gas phase geometry of **1** was optimized without any symmetry restrictions in the singlet and triplet ground-states with the DFT method using the hybrid B3LYP functional of GAUSSIAN-03 [23–25]. The calculations were performed using the ECP basis set LANL2DZ [26] with an additional *d* and *f* function with the exponent α = 0.3811 and α = 2.033 [27] for rhenium and the standard 6-31G basis set for the other atoms. For chloride, oxygen, nitrogen and phosphorous atoms, diffuse and polarization functions were added [28–33]. The vibrations in the calculated vibrational spectrum of **1** were real, thus the geometry corresponds to a true energy minimum.

The electronic spectrum of **1** was calculated with the TDDFT method, and the solvent effect (acetonitrile) was simulated using the polarizable continuum model with the integral equation formalism (IEF-PCM) [34–37].

2.6. Magnetic measurement

Magnetic measurements of **1** in the temperature range 1.8–300 K were performed using a Quantum Design SQUID-based MPMSXL-5-tpe magnetometer. The superconducting magnet was generally operated at a field strength ranging from 0 to 5 T.

Measurements were made at a magnetic field of 0.5 T. Corrections are based on subtracting the sample-holder signal and the contribution χ_D estimated from Pascal constants equals -499×10^{-6} cm^{3}mol^{-1} for complex **1**. The effective magnetic moment was calculated from the equation, $\mu_{eff} = 2.83(\chi_M T)^{1/2}$ (*B.M.*).

3. Results and discussion

The $[ReCl_2(pic)(PPh_3)_2]$ (**1**) and $[ReBr_2(pic)(PPh_3)_2]$ (**2**) complexes were first isolated from the reactions of $[ReOX_3(PPh_3)_2]$ (X = Cl or Br) with 1-(2-pyridylcarbonyl)benzotriazole in ethanol. Although mechanism of the reaction has not been examined in detail, two reaction courses can be supposed.

The first one is thought to occur *via* reduction of $[ReOX_3(PPh_3)_2]$ by triphenylphosphine and coordination of 1-(2-pyridylcarbonyl)benzotriazole to the Re(III) center. After the coordination of 1-(2-pyridylcarbonyl)benzotriazole to the Re(III) ion, hydrolysis of 1-(2-pyridylcarbonyl)benzotriazole occurs and the picolinic acid formed coordinates to the Re(III) ion to give $[ReCl_2(pic)(PPh_3)_2]$, whereas the benzotriazole remains uncoordinated. The oxygen atom transfer is believed to proceed *via* initial nucleophilic attack on the Re≡O π^* orbitals, and many instances of formation of phosphine oxides from Re^VO and tertiary phosphines can be given [11,38,39]. The starting oxo complex is synthesised using a large excess of triphenylphosphine and it can be impure with PPh_3. The $[ReCl_3(L\text{-}L)(PPh_3)]$ complex with coordinated 1-(2-pyridylcarbonyl)benzotriazole (L-L) has not been isolated from the reaction, but many instances of the formation of $[ReCl_3(L\text{-}L)(PPh_3)]$ in related syntheses can be given [11,38,39].

The second probable reaction model involves hydrolysis of 1-(2-pyridylcarbonyl)benzotriazole, coordination of the picolinate ligand to Re(V), formation of $[ReOCl_2(pic)(PPh_3)_2]$ and subsequent reduction of $[ReOCl_2(pic)(PPh_3)_2]$ to $[ReCl_3(pic)(PPh_3)_2]$. The low yield of $[ReX_2(pic)(PPh_3)_2]$ in the reactions of $[ReOX_3(PPh_3)_2]$ with 1-(2-pyridylcarbonyl)benzotriazole results from an insufficient amount of PPh_3.

With a much higher yield, compounds **1** and **2** were isolated from the reactions of $[ReOX_3(PPh_3)_2]$ with picolinic acid in the presence of PPh_3. In this case, similar reaction models can be postulated. The more probable one seems to involve coordination of the picolinate ligand to Re(V), formation of $[ReOCl_2(pic)(PPh_3)_2]$ and subsequent reduction of $[ReOCl_2(pic)(PPh_3)_2]$ to $[ReCl_3(pic)(PPh_3)_2]$. It has been previously proven that $[ReOCl_3(PPh_3)_2]$ easily reacts with picolinic acid to give $[ReOCl_2(pic)(PPh_3)]$ [9]. However, the other reaction course involving reduction of Re(V) to Re(III) followed by coordination of picolinate ion to the Re(III) is also possible.

The IR spectra of **1** and **2** show features comparable to those of mononuclear picolinato species [40]. The bands assigned to $\nu_{sym}(CO_2)$ and $\nu_{as}(CO_2)$ appear at 1697 and 1288 cm^{-1} for **1**, and 1984 and 1281 cm^{-1} for **2**. The value of $\Delta\nu(CO_2) = \nu_{as}(CO_2) - \nu_s(CO_2)$, equal to ≈400 cm^{-1} for the $[ReX_2(pic)(PPh_3)_2]$ compounds, confirms a unidentate coordination mode of the carboxylate group. Characteristic bands corresponding to the ν(CN) and ν(C=C) modes of the *pic* ligand appear in the range 1620–1550 cm^{-1} [41]. The absence of the strong ν(Re=O) band at ~980 cm^{-1} is a clear indication that there is no oxo-Re(V) starting material left in the samples of **1** and **2**.

The proton spectrum of **1** shows features comparable to those of mononuclear Re(III) with tertiary phosphines. The ^{1}H NMR signals of **1** are relatively narrow due to short electron-spin relaxation time of the Re(III) center, but the signals are spread over the ppm range [42]. The *ortho* protons of two PPh_3 coordinated molecules appear as a doublet at 12.02 ppm, and they are downfield from the *meta* and *para* protons (8.5–8.7 ppm). The three protons of the picolinate ion appear as a triplet at 10.15 ppm and two doublets at 7.13 and 6.81 ppm, respectively.

3.1. Crystal structures

A definite proof for the structure is provided by the X-ray diffraction results. The crystallographic data of the complexes **1** and **2** are summarized in Table 1. The $[ReX_2(pic)(PPh_3)_2]$ complexes are isostructural, crystallise in the orthorhombic Abm2 space group (No. 39) with rhenium, halogen and all the picolinate anion atoms located on the special position *c* with site symmetry m. Thus both the polyhedron $ReCl_2NO$ base and picolinate anion are planar by symmetry.

The short intra- and intermolecular contacts, which can be classified as weak hydrogen bonds [43,44], are gathered in Table 2. The

Table 2
Hydrogen bonds for **1** and **2**.

D–H···A	D–H	H···A	D···A	D–H···A
1

C(23)–H(23)···Br(1)#3	0.93	2.77	3.488(6)	135.1

Symmetry transformations used to generate equivalent atoms: #1 −1 + *x*, *y*, *z*; #2 −*x*, *y*, 1/2 + *z*; #3 1−*x*, *y*, 1/2 + *z*.

hydrogen bonding scheme in the both structures is similar due to the isostructurality, however, in **2** some more short contacts exist due to the larger radius of the Br atom. The planar, in the range of experimental error, phenyl rings of the PPh_3 ligands are inclined at 62.4(3), 71.3(3), 81.5(3)° in **1** and at 61.23(3), 71.98(4), 81.25(3)° in **2**. The O–C═O bonds of the carboxylate groups show significant delocalization in both structures (the C(24)–O(1) distances are 1.264(18) and 1.292(8) Å, and the C(24)–O(2) distances are 1.22(2) and 1.248(9) Å, respectively, in **1** and **2**).

The molecular structure of **1** is presented in Fig. 1, and selected bond distances and angles of **1** and **2** are collected in Tables 3 and 4, respectively. The $[ReX_2(pic)(PPh_3)_2]$ complexes show a distorted octahedral geometry about Re with bidentate N,O donors of the picolinato ligand, two halide ions arranged in *cis* geometry and two PPh_3 molecules in *trans* arrangement.

The bond lengths and angles of **1** and **2** do not differ significantly from the expected values for related mononuclear rhenium complexes [9]. The Re–Cl(1) bond *trans* to N is far longer than the Re–Cl(2) bond *trans* to O, indicating a *structural trans* effect of the pyridine ring.

3.2. Magnetic properties

The magnetic properties of **1**, in the form μ_{eff} versus T (μ_{eff} is the effective magnetic moment) is shown in Fig. 2. The rhenium(III) complex shows a room temperature magnetic moment of 1.68 B.M. The magnetic moment of the solid is temperature dependent between 300 and 1.8 K and the value of the $\chi_M T$ product decreases on lowering the temperature. This behavior is characteristic of mononuclear d^4 low-spin pseudo-octahedral Re(III) complexes ($^3T_{1g}$ ground state) [45–54] and arises because of the large spin–orbit coupling ($\zeta = 2500\ cm^{-1}$ [55]), which gives a diamagnetic ground state. It seems that at room temperature, in accordance

LUMO+5	−0.811	$\pi^*(PPh_3)$	−0.891	$\pi^*(PPh_3)$

with Boltzmann's distribution, the higher magnetic state is populated, and it is depopulated with temperature lowering, and a decrease of the magnetic moment is observed.

The magnetization indicates a value of only 0.001 B.M. at 5 T. The magnetization of the sample confirms that the ground state is diamagnetic and the rhenium(III) compound is of a very high purity.

3.3. Geometry optimisation

The gas phase geometry of **1** was optimized in the triplet and singlet states using the DFT method with the B3LYP functional. The total energy of the triplet state is 5.8 kcal/mol smaller in comparison with the singlet state. The optimized geometric parameters of the triplet state are gathered in Table 3. Generally, the predicted bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations. The largest differences are found for the Re–Cl bond distances. This may come from the basis sets which are approximated to a certain extent or may indicate the influence of the crystal packing on the values of the experimental bond lengths. The theoretical calculations do not consider the effects of chemical environment. However, a similar elongation of the rhenium–chlorine bond lengths (up to 0.25 Å) in the B3LYP with different basis sets has been found in other rhenium–chlorine complexes [56].

3.4. Molecular orbitals

The energies and characters of several of the highest occupied and lowest unoccupied molecular orbitals of **1** are presented in Table 5. Among the highest occupied MOs of **1**, the largest numbers constitute π orbitals of the phenyl rings with a contribution from the Cl atoms. The three highest molecular orbitals with α-spin can be represented as a combination of π^*_{Re-Cl} and π_{pic}, with predominant involvement of the former component. The HOMO orbital, with β-spin, has the same character. The LUMO+1 and LUMO+3 β orbitals of **1** are also to a large extent formed by rhenium d_π atomic orbitals (d_{xz}, d_{yz} or d_{xy}). Among the lowest unoccupied MOs of **1**, the most are constituted of π^* orbitals of the *pic* and phenyl rings. The

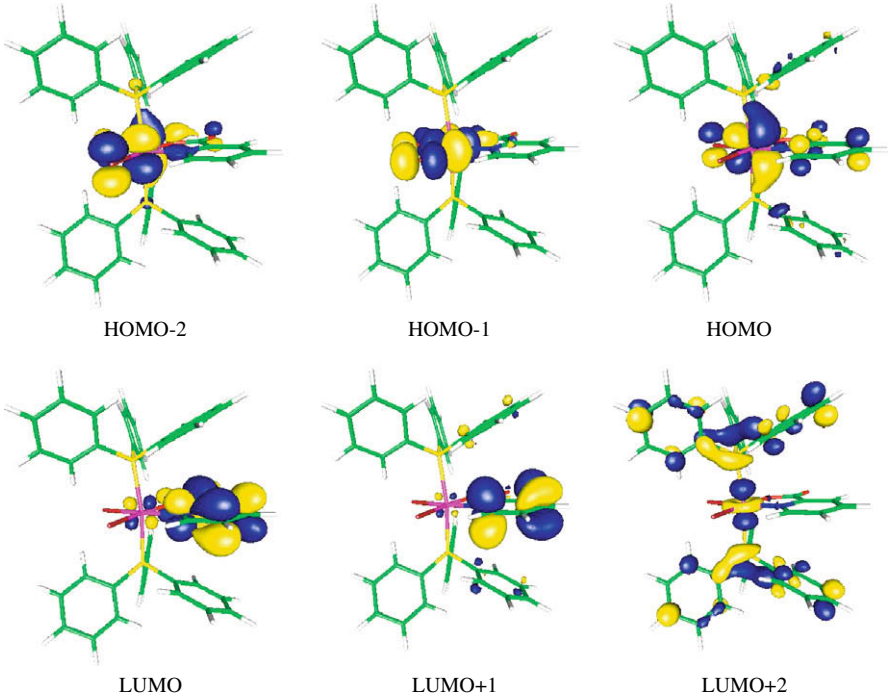

Fig. 3. The selected HOMO and LUMO orbitals with α-spin for **1**.

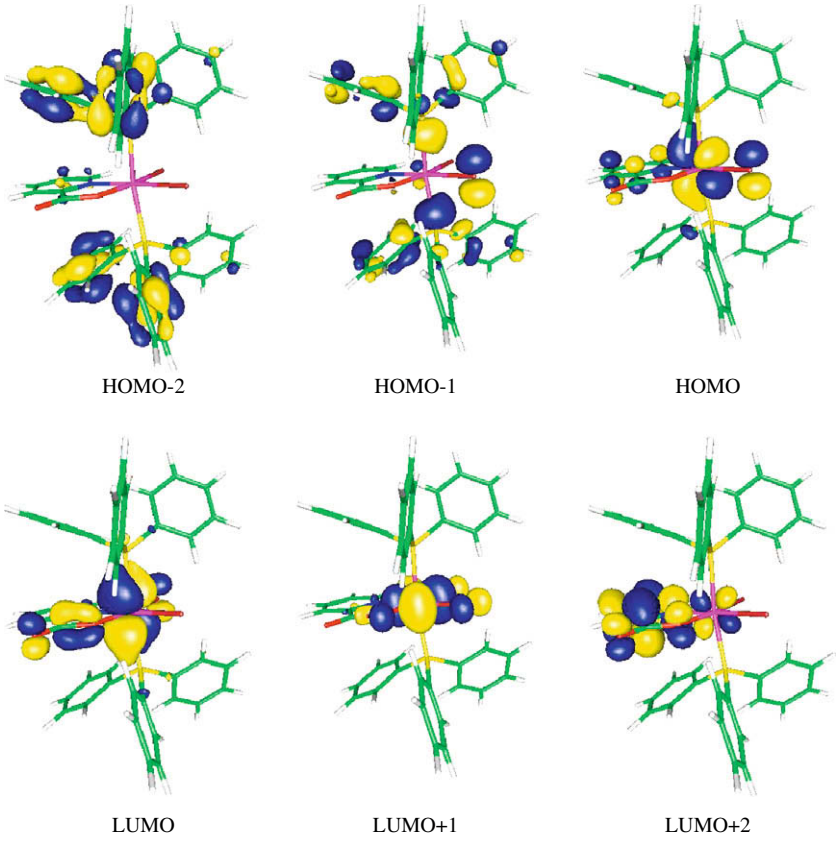

Fig. 4. The selected HOMO and LUMO orbitals with β-spin for **1**.

LUMO and LUMO+1 with α-spin and LUMO+2 and LUMO+3 with β-spin have π^*(pic) character. The π^* phenyl ring orbitals of the triphenylphosphine ligands participate in the higher unoccupied orbitals. The contours of the selected occupied and unoccupied molecular orbitals of **1** with α-spin and β-spin are presented in Figs. 3 and 4, respectively.

3.5. Electronic spectra

The experimental and calculated electronic spectra of **1** are presented in Fig. 5. Each calculated transition is represented by a gaussian function $y = ce^{-bx^2}$ with the height (c) equal to the oscillator strength and b equal to 0.04 nm^{-2}. The electronic spectrum of **2** is very similar in terms of the position, intensity and shape of the bands in the whole region 1000–180 nm; with maxima at 514.1, 458.8, 341.4, 251.5 and 201.7 nm.

Table 6 presents the most important spin-allowed triplet–triplet electronic transitions calculated with the TDDFT method, assigned to the observed absorption bands of **1**. For the high energy part of the spectrum, only transitions with oscillator strengths larger than 0.020 are listed in Table 6. The investigated complex is of a large size; the numbers of basis functions are equal to 832. The calculated electron transitions (1 1 0) do not comprise all the experimental absorption bands; the UV–vis spectrum was calculated to ~270 nm. Thus the shortest wavelength experimental bands of **1** are not assigned to the calculated transitions; some additional intraligand and interligand transitions are expected to be found at higher energies in the calculations for **1**.

The assignment of the calculated orbital excitations to the experimental bands was based on an overview of the contour plots and relative energy to the HOMO and LUMO involved in the electronic transitions.

In the 350–600 nm region, complex **1** displays multiple transitions of moderate intensity in the form of peaks and shoulders.

The low-energy absorption band of **1** originates from the transitions between HOMO-1, HOMO, LUMO and LUMO+2 with β-spin. As can be seen from Fig. 4, the β HOMO−1 is composed of ligand (chloride and triphenylphosphine) orbitals, β HOMO is delocalized on the central ion and ligands, and β LUMO and β LUMO+2 are

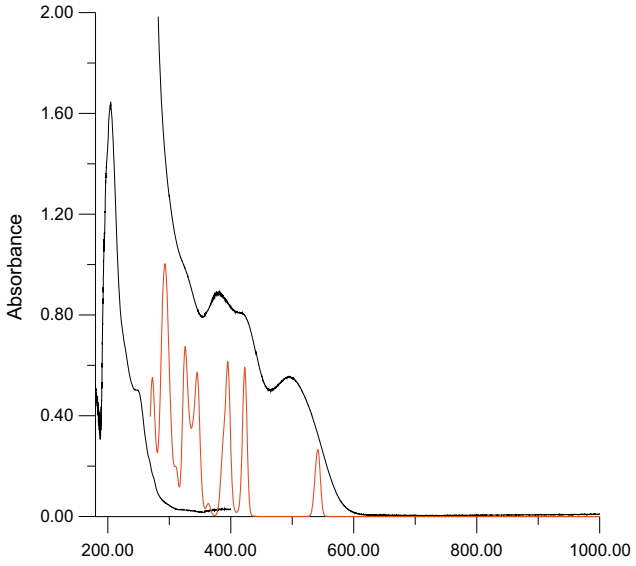

Fig. 5. The experimental (black) and calculated (red) electronic absorption spectra of a solution of **1** in acetonitrile. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

Table 6

					204.8 (6.05) 270 000

ε – Molar absorption coefficient [$dm^3\ mol^{-1}\ cm^{-1}$].
f – Oscillator strength.
H – Highest occupied molecular orbital.
L – Lowest unoccupied molecular orbital.

formed from d_{Re} orbitals and π^*-bonding orbitals of the picolinate ligand. Accordingly, these transitions can be seen as delocalized MLLCT (*Metal–Ligand-to-Ligand CT*) transitions.

The transitions assigned to the experimental bands at 427.7 and 379.3 nm can be seen as mixed Re → π*(pic) (*Metal–Ligand Charge Transfer*; *LMCT*) and π(Cl)/π(pic) → π*(pic) (*Ligand–Ligand Charge Transfer*; *LLCT*) transitions. The experimental absorption band at 328.2 nm is mainly attributed to the d/π(Cl)/π(pic) → d/π*(PPh_3) transition, whereas the transitions assigned to the experimental band at 247.9 are mainly of *LLCT* character.

4. Conclusions

This work is an extension of our previous research on the reactivity of [$ReOX_3(PPh_3)_2$] towards N–O and N–N chelating ligands. 1-(2-Pyridylcarbonyl)benzotriazole does not coordinate to the rhenium ion. Hydrolysis of 1-(2-pyridylcarbonyl)benzotriazole in the reaction with the oxo-complexes occurs and picolinic acid binds to the Re center to give the [$ReX_2(pic)(PPh_3)_2$] complexes (X = Cl, Br). The studied compounds were synthesized for the first time. Their structures were definitively proven by X-ray diffraction measurements and confirmed by spectroscopic analysis. The magnetic measurements, NMR and UV–vis studies confirm that the [$ReX_2(pic)(PPh_3)_2$] complexes are typical mononuclear d^4 low-spin octahedral Re(III) complexes. In the visible region the [$ReX_2(pic)(PPh_3)_2$] complexes display multiple transitions of moderate intensity in the form of peaks and shoulders. The TDDFT/PCM calculations show that these transitions can be seen as delocalized MLLCT (Metal–Ligand-to-Ligand CT) transitions.

Supplementary data

CCDC 724894 and 724895 contain the supplementary crystallographic data for $C_{42}H_{34}Cl_2NO_2P_2Re$ and $C_{42}H_{34}Br_2NO_2P_2Re$. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

The reactions of $K_3[Cu(CN)_4]$, 3-acetylpyridine (3-Acpy) or 4-acetylpyridine (4-Acpy) in the presence of Me_3SnCl in H_2O/acetonitrile media at room temperature afford the 3D-supramolecular coordination polymers $(SCPs)_\infty{}^3[Cu_2CN(\mu\text{-}CN)\cdot(3\text{-}Acpy)_2]$ **1** and $_\infty{}^3[Cu_2CN(\mu\text{-}CN)\cdot(4\text{-}Acpy)_2]$ **2**. The structures of **1** and **2** consist of Cu_2CN building blocks which are connected by CN groups, forming 1D-zig-zag chains. Each chain is bonded to another chain by hydrogen bonding into a 2D-layer, which is further stacked in an interwoven mode by π–π stacking interactions and hydrogen bonds in **1** and **2**, as well as Cu···Cu interactions in **1**, to create supramolecular 3D-network structures. The high dimensional topologies of **1** and **2** result mainly from extensive hydrogen bonding and π–π stacking. The long wavelength absorption band at 400–420 nm in the electronic spectra of **1** and **2** is assigned to a CT from copper(I) to the Acpy ligand. Compound **2** exhibits strong luminescence at 485 and 527 nm, corresponding to MLCT and metal-centered transitions, respectively.

1. Introduction

There has been much interest in recent years in the design and synthesis of supramolecular coordination polymers, due to their intriguing structural motifs and potential applications in luminescence, conduction, magnetism, ion exchange, gas adsorption, catalysis and biology [1–19]. Recent work has focused on the copper(I) cyanide system because of the known versatility of $Cu(CN)_n$ structural motifs in accommodating various ligands, and Cu(I) compounds have rich fluorescent properties [20–25]. In addition, copper(I) cyanide has shown promise in the assembly of a zeolitic-type framework [26–29] and as a precursor in the synthesis of $YBa_2Cu_3O_{7-x}$ superconductors [30].

The structure and properties of a number of copper(I) cyanide coordination polymers containing nitrogen bases have been reported previously [20,21,31–39]. However, a limited number of copper(I) cyanide coordination polymers incorporating unidentate pyridine bases have been studied [40–42]. $[CuCN(py)_2]$ and $[(CuCN)_2(2\text{-}mpy)_2]$ are single-stranded polymers, with successive copper atoms linked by single linear cyanide bridges with four- or three-coordinate $\mu_2Cu(CN)_2$ or $\mu Cu(CN)_2$ copper environments [40–42]. Also, $[(CuCN)_2(4\text{-}mpy)_3]$ is a one dimensional polymer containing the familiar linear polymeric –Cu(CN)Cu(CN)Cu(CN)– array in which the Cu(1) atom has one pyridine base attached and the Cu(2) atom has two base nitrogen atoms. On the other hand, $[Cu_2(CN)(IN)(HIN)]_n$ (IN: isonicotinate) is based on fused chair-shaped $[Cu_6(\mu\text{-}HIN)_2(\mu\text{-}(IN)_2(\mu\text{-}(CN)_2]$ hexagons, which form a triple interpenetrated 2D-ligand to metal coordinative bonding network and simultaneously a triple interpenetrated 3D-hydrogen bonding network [43].

Extending the previous essays, Cu(I)CN:3/4Acpy adducts have been crystallized from a H_2O/CH_3CN solution containing Me_3SnCl. Acetylpyridine compounds can be considered as versatile ligands for the construction of novel metal–organic frameworks. The *N*-pyridinic and the acetyl groups should allow not only multiple metal coordination, but also supramolecular interactions via hydrogen bonding. Two distinct complexes have been obtained for which single crystals have been isolated and subjected to single crystal X-ray studies.

2. Experimental

All chemicals and solvents used in this study were of analytical grade, supplied by Aldrich or Merck and were used as received, except $K_3[Cu(CN)_4]$ which was prepared in the laboratory according to the literature [44,45]. Microanalyses (C, H, N) were carried out with a Perkin Elmer 2400 automatic elemental analyzer. The IR spectra were recorded on a Perkin Elmer 1430 Ratio Recording Infrared Spectrophotometer as KBr discs. Electronic absorption spectra as solid matrices were measured on a Shimadzu (UV-310PC) spectrometer. Fluorescent spectra as solid matrices were measured with a Perkin Elmer (LS 50 B) spectrometer.

2.1. Synthesis of $[(CuCN)_2{\cdot}(L)_2]$ [L = 3-Acpy, 4-Acpy] (**1**, **2**)

A solution of 90 mg (0.3 mmol) of $K_3[Cu(CN)_4]$ in 30 mL H_2O was added, under gentle stirring, to a solution of 189 mg (0.95 mmol) of Me_3SnCl in 10 mL H_2O and 0.1 mL (0.916 mmol) of 3-acetylpyridine (3-Acpy) (for **1**) or 4-acetylpyridine (4-Acpy) (for **2**) in 20 mL acetonitrile, and after one week yellow needle or yellow prismatic crystals started growing from the initially clear solution. After filtration, washing with a small cold quantity of H_2O and acetonitrile and over night drying, about 40 mg (75% referred to $K_3[Cu(CN)_4]$) of yellow crystals **1** or about 50 mg (83.3% referred to $K_3[Cu(CN)_4]$) of yellow crystals **2** were obtained. All attempts for the synthesis of **1** and **2** at room temperature in the absence of Me_3SnCl were unsuccessful.

Anal. Calc. for **1** ($C_{16}H_{14}N_4O_2Cu_2$): C, 45.5; H, 3.3; N, 13.2. Found: C, 45.2; H, 3.1; N, 13.1%.

Anal. Calc. for **2** ($C_{16}H_{14}N_4O_2Cu_2$): C, 45.5; H, 3.3; N, 13.2. Found: C, 45.2; H, 3.2; N, 13.1%.

2.2. Single crystal structure determination

Structural measurements for **1** and **2** were performed on a Kappa CCd Enraf Nonius FR 90 four cycle geniometer with graphite monochromatic Mo Kα radiation {[λ Mo Kα] = 0.71073 Å} at 25 ± 2 °C. All structures were resolved using direct methods and all of the non-hydrogen atoms were located from the initial solution or from subsequent electron density difference maps during the initial stages of the refinement. After locating all of the non-hydrogen atoms in each structure, the models were refined against F^2, first using isotropic and finally using anisotropic thermal displacement parameters. The positions of the hydrogen atoms were then calculated and refined isotropically, and then the final cycle of refinements was performed. The cyano groups of all structures were ordered unless otherwise stated. Crystallographic data for **1** and **2** are summarized in Table 1. Selected bond distances and bond angles are given in Tables 2 and 4. The C13 and N11 atoms of the two bridging cyanide groups in **2** are centrosymmetric and were modelled as disordered over a pair of sites of equal occupancy. The disorder of these cyano groups in the asymmetric unit of **2** reflects the observation that *Rw* remains constant upon adopting a C atom or N atom at these sites.

3. Results and discussion

The room temperature reactions of the ternary adducts $K_3[Cu(CN)_4]$, Me_3SnCl and L (L = (3-Acpy) or (4-Acpy)) afford yellow crystals of the tin free $[Cu_2(CN)_2{\cdot}(3\text{-Acpy})_2]$, **1** and $[Cu_2(CN)_2{\cdot}(4\text{-Acpy})_2]$, **2**. There are two abnormal features in these reactions: they proceed at room temperature producing significant amounts of single-phase products and they result exclusively in the formation of the tin free assemblies **1** and **2**, in spite of the presence of Me_3SnCl to produce, as was expected, zeolitic-type SCP. The room temperature products of **1** and **2** can be considered as novel SCPs that may be compared with those prepared by hydrothermal reactions for $[Cu_2(CN)_2{\cdot}L]$ [46–48] or otherwise with those prepared recently by using atmospheric aqueous reflux reactions, $[Cu_2(CN)_2{\cdot}(L)]$ and $[(CuCN)_3{\cdot}(L)]$ [49]. Such room temperature reactions avoid the substantial drawbacks of hydrothermal syntheses (including small reaction scales, modest yields and mixed products) or the open reflux reactions (including long time and relatively high temperature). On the other hand, in the absence of Me_3SnCl, the reaction does not proceed and consequently no product is formed under the used experimental conditions. The presence of Me_3SnCl seems to be essential for the reaction to proceed thermodynamically at room temperature, a point which needs further investigation. However, it is known that the Me_3SnCl molecule has a weak Sn···Cl bond, since the non-polar trimethyltin(IV) units are bridged to the chlorine atoms by unequal, and relatively large, (2.430 and 3.269 Å) distances [50]. In this case, one might suggest that this may cause decomposition of the tetrahedral $[Cu(CN)_4]^{-3}$ anion to different $(Cu)_n(CN)_m$ fragments which are readily assembled with the other reactants in solution to produce the thermodynamically more stable SCP. The Me_3SnCl may form, in this case, the more stable Me_3SnCN, since the Sn–C or the Sn–N bond distances of the ordered C–N–Sn–N–C or even N–C–Sn–C–N chains are in the range of 2.49 ± 0.02 Å [51], or it may form the $(Me_3Sn)_2$ dimer. Nevertheless, it is quite clear that Me_3SnCl plays an important role in the formation of the different topologies of the SCPs of Cu(I)CN and heterocyclic ligands [52].

3.1. Crystal structure of $[Cu_2(CN)_2{\cdot}(3\text{-Acpy})_2]$, **1**

The asymmetric unit of **1** comprises half of the formula unit, it involves one crystallographically distinct copper(I) atom, which has an identical symmetry operation, one ordered cyanide group and one 3-Acpy ligand (Fig. 1). The X-ray analysis reveals that the structure of **1** displays a 1D-extended corrugated chain of $(CuCN)_n$ with the 3-Acpy ligand attached to every Cu atom (Fig. 2). The coordination geometry of the Cu(1) atom can be described as distorted trigonal planar, and it is coordinated by two cyano groups (N–Cu1–C) and one 3-Acpy ligand. The angles of

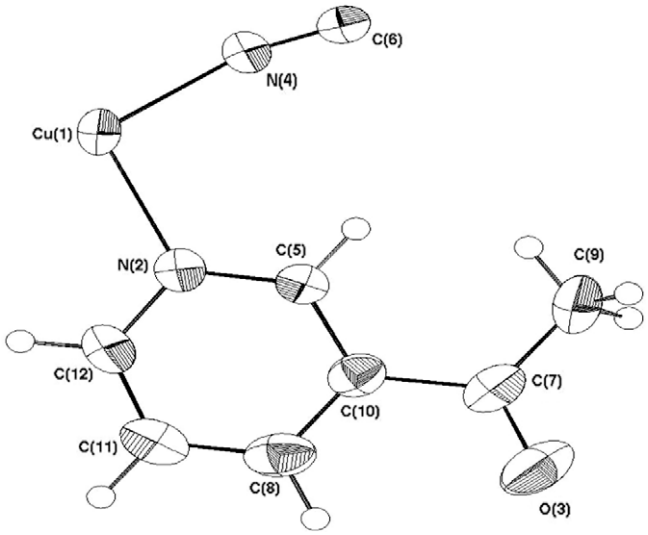

Fig. 1. An ORTEP plot showing the asymmetric unit of **1** with the atom labelling scheme.

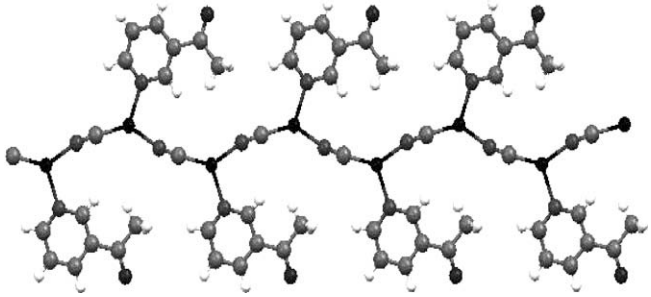

Fig. 2. A 1D-extended chain of CuCN in **1** along the *a*-axis.

the trigonal structure deviate largely from 120° (Table 2) due to the pyramidalization of the trigonal structure around the Cu atom which is caused by close Cu–C6 (2.791 Å), Cu–N4 (3.024 Å) or Cu–Cu (2.959 Å) contacts. Alternatively, the structure of **1** can be considered to consist of Cu_2CN building blocks which are connected by the CN group forming a one dimensional zig-zag chain with the 3-Acpy ligands, which are nearly parallel (ca: 1.19°), located above and below the chain. This one dimensional zig-zag chain is bonded to another chain by hydrogen bonds between the oxygen atoms of 3-Acpy in one chain and the hydrogen atoms of 3-Acpy in another chain, organizing these chains into a two dimensional layer (O3–H11 = 2.512 Å) (Fig. 3).

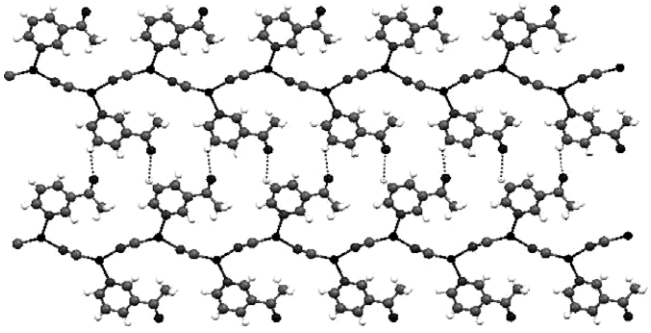

Fig. 3. A view of the hydrogen bonds between two adjacent chains along the *b*-axis in **1**.

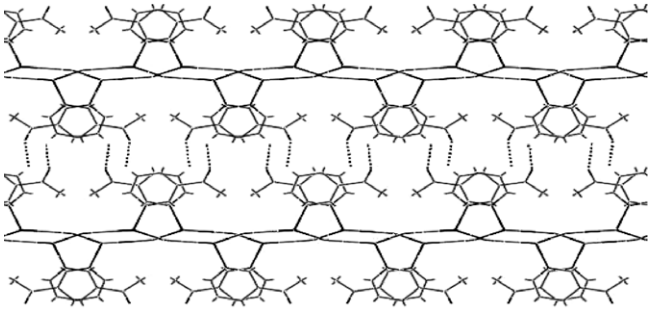

Fig. 4. A packing diagram of **1** showing π–π stacking and hydrogen bonds along the *c*-axis.

Table 3
Hydrogen bond lengths (Å) and bond angles (°) in **1**.

N4–H9A	3.154(2)	C9–H9A···N4	116.68
O3–H8^{ii}	3.127(3)	C8–H8^{ii}···O3	102.58
N4–H9C	2.934(2)	C9–H9C···N4	136.26
O3–H8^{i}	2.888(2)	C8–H8^{i}···O3	114.33
N4–H5	2.714(2)	C5–H5···N4	116.08
O3–H11^{i}	2.512(3)	C11–H11^{i}···O3	131.00

Symmetry codes: (i) $-1-x,1/2+y,3/2-z$; (ii) $-x,1-y,-z$.

The two dimensional layers of **1** are close packed in a parallel fashion along the *c*-axis, while the 3-Acpy planes are stacked in an interwoven mode along the *c*-axis (Fig. 4) causing π–π stacking interactions (ca: 3.58 Å) [53]. In addition, hydrogen bonds between the layers, ca: 2.513–3.127 Å (Table 3) create a supramolecular 3D-network structure containing channels with separation distances in the range 2.959–4.906 Å (Fig. 5). These corrugated layers are also stacked along the *b*-axis, and they are interconnected mainly by Cu–Cu interactions; Cu–Cu = 2.959 Å [54–58], and metal–π interactions between the Cu ions from one chain and the pyridine rings from the adjacent layer; 2.791 Å. In view of the recent discussions of cuprophilic interactions [49,59–61], one might suggest that the weak Cu–Cu interaction seems to be realistic according to a detailed quantum chemical study focused on pairs of $Cu^{I}XY$ systems, as experimentally determined Cu–Cu distances of convincing examples in favour of cuprophilic attraction are usually longer than 2.70 Å, [59–61]. Thus, the value of 2.959 Å falls within the range of cuprophilic interactions. All these interactions, especially hydrogen bonds and the cuprophilic interaction, play an important role in constructing the 3D-network structure of **1**.

3.2. Crystal structure of $[Cu_2(CN)_2{\cdot}(4\text{-Acpy})_2]$, **2**

The structure of the organotin-free product **2** seems to be different from the prototype compound **1**. The asymmetric unit of **2** involves not only two copper centers, Cu(1) and Cu(2), and two cyanide groups, but also two organic ligands; 4-Acpy (Fig. 6). One 4-Acpy (N3,O4) ligand is coordinated to Cu1 while the other

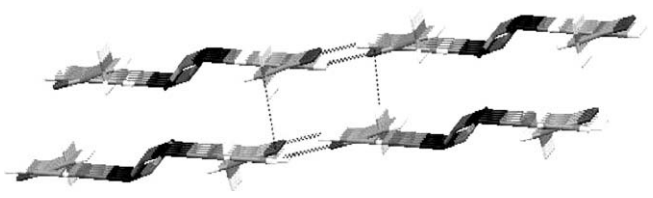

Fig. 5. A packing diagram showing the hydrogen bonds and channels in **1** along the *b*-axis.

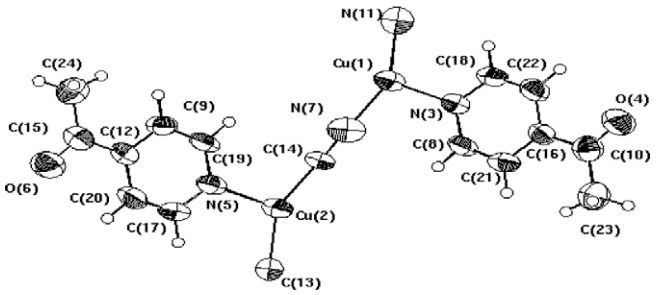

Fig. 6. An ORTEP plot showing the asymmetric unit of **2** with the atom labelling scheme.

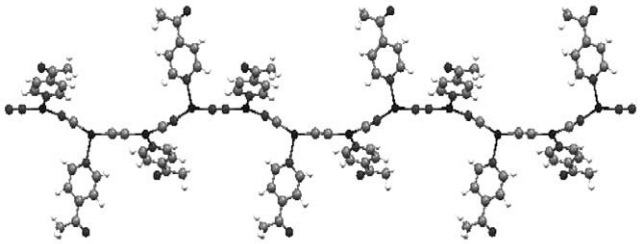

Fig. 7. 1D-puckered chain of 2 in the ac-plane with the 4-Acpy ligands tilted out of the plane on both sides of the chain by 66.48°.

4-Acpy (N5,O6) is coordinated to Cu2 in a unique fashion in that the two ligands have two different planes with an angle equal to 66.48° (Fig. 7). The cyanide group (C14N7) is ordered, exhibiting a Cu–C distance of 1.853 Å and Cu–N distance of 1.896 Å, while the other cyanide group (C13N11) is disordered (Table 4).

Each of Cu1 and Cu2 is coordinated to two cyanide groups and one 4-Acpy ligand, forming a distorted trigonal configuration. Three coordination is a characteristic feature not only of Cu(I) cyanide structures such as $KCu(CN)_2$ [62], $NaCu(CN)_2{\cdot}2H_2O$ [63] and $K[Cu_2(CN)_3]{\cdot}H_2O$ [64], but also of cyanohalides [65] and cyano amine structures [66]. The angles of the trigonal structure deviate largely from 120° (Table 4) due to the pyramidalization of the trigonal structure around the Cu atoms, which is caused by close Cu–C or Cu–N contacts in the range 2.991–3.039 Å (Table 4).

The structure of **2** consists of Cu_2CN building blocks which are connected by CN groups forming a 1D-puckered chain, while the 4-Acpy ligands intermingle on both sides of the chain in a unique way (Fig. 7). The lengths of the Cu1–N3 and Cu2–N5 bonds are

2.105 and 2.099 Å, respectively which are in the usual range reported for the prototype compounds [40–42]. Alternatively the structure can be viewed as two N11–Cu1–N7–C14–Cu2 sub-building blocks connected by the disordered cyanide group (C13–N13), forming the main building blocks of the structure **2**, along with two 4-Acpy ligands located on both sides of the chain. On the other hand, the shape of the puckered chain looks like a fan with four arms that have two different lengths, 6.404 and 8.697 Å. This main building block can propagate along the *b*-axis via hydrogen bondings where the repeating main building blocks are connected by the O4···H24C bond; 2.717 Å, O6···H23C bond; 2.704 Å, O6···H24B bond; 2.628 Å, and O4···H23B bond; 2.617 Å (Fig. 8, Table 5) and along the *a*-axis via the second disordered cyanide group forming a 2D-network structure. Alternatively, the main building block forms down the projection of the *c*-axis zig-zag $(CuCN)_4$ chain with two 4-Acpy ligands above the chain while the other two 4-Acpy ligands are locate underneath the chain, creating a cavity with dimensions of 9.659 × 12.725 Å, which is capable of accommodating two 4-Acpy ligands of another building block (Fig. 9). It is worth mentioning that there are no kinds of interactions; hydrogen bonding or π–π stacking, between the fragments of the main

s = strong, m = medium, w = weak.

building blocks. However, in spite of the shape of the structure of the main building blocks down the projection of the *c*-axis looking like a circle, it forms an open framework at the methyl groups along any other axes. The distance between two Cu1 atoms in this presented circle is 13.47 Å. The extended structure of **2** is interwoven, creating polygon structures which connect the main building blocks, forming a 3D-network structure. This polygon structure is formed via the O4 and O6 atoms which form hydrogen bonds with the hydrogen atoms of the pyridine ring (H8, H19), and of the acetyl groups, O4···H19 = 2.673 Å, O6···H8 = 2.681 Å, O6···H24B = 2.628 Å, as well as Cu(I) contacts; Cu2–C13 = 3.014 Å (Table 5). It worth mentioning that there is no Cu–Cu interaction, since the shortest Cu–Cu distances are Cu2–Cu2 = 5.828 Å, Cu1–Cu2 = 6.967 Å and Cu1–Cu1 = 8.541 Å, while the distance between the chains along the *a*-axis are Cu1–Cu2 = 11.264 Å, C14–C14 = 10.386 Å and N7–N7 = 11.703 Å.

3.3. Infrared spectra of *1* and *2*

The IR spectra of **1** and **2** exhibit bands characteristic of the $(CuCN)_n$ fragment and the unidentate ligand; (3-Acpy, 4-Acpy) (Table 6). The bands at 3035–3093, 3000, 2921, 1415–1420, 653–697 and 779–758 cm^{-1} are attributed to $\nu_{CH(arom.)}$, $\nu_{CH(aliph.)}$, δ_{CH} and γ_{CH} of the Acpy ligands in the IR spectra of **1** and **2**, respectively. These bands are shifted to lower wavenumbers than the vibrational frequencies of the free ligands due to the formation of hydrogen bonds between the hydrogen atoms of the ligands and the other donor sites of the $(CuCN)_n$ fragment [67]. On the other hand, the bands at 1583–1601, 1551 and 1477–1486 cm^{-1} are attributed to $\nu_{C=N}$ and $\nu_{C=C}$ of Acpy ligands in **1** and **2**, respectively. These bands exhibit small shifts to lower wavenumbers compared to those of the free Acpy ligands, supporting the coordination of 3-Acpy and 4-Acpy to the Cu(I) sites.

Also, the IR spectra of **1** and **2** show a strong band at 1683–1698 cm^{-1} which can be assigned to $\nu_{C=O}$. This band is shifted to a lower wavenumber than the vibration frequency of the carbonyl group of the free ligands due to the formation of hydrogen bonds.

It is worth mentioning that the $\nu_{C\equiv N}$ bond of **1** and **2** is different from that of $K_3[Cu(CN)_4]$, which is potentially used as one of the adducts for forming **1** and **2**. The $\nu_{C\equiv N}$ band of $K_3[Cu(CN)_4]$ appears at 2081 cm^{-1}. It is obvious that the structures of **1** and **2** are quite different from that of $K_3[Cu(CN)_4]$, but it does contain the $(CuCN)_n$ fragment. The presence of two $\nu_{C\equiv N}$ IR absorption bands in the spectrum of **2** at 2126 and 2041 cm^{-1} supports the presence of two different cyanide groups; one is ordered while the other is disordered. On the other hand, the presence of only one $\nu_{C\equiv N}$ IR absorption band in the spectrum of **1** at 2112 cm^{-1} supports the presence of one ordered cyanide group.

It is worth mentioning that **1** and **2** are associated with non-linearly bridging cyanide groups as their stretching frequencies lie close to that of the genuine salt [68,69].

3.4. Electronic absorption and emission spectra of *1* and *2*

The electronic absorption spectra of **1** and **2** display absorption bands for 3-Acpy and 4-Acpy at 260–280, 300–310 and 400–420 nm. The band at 260 nm corresponds to the $^1L_b \leftarrow {}^1A$ transition in pyridine, which resembles that of benzene. The band at 280 nm is due to the π–π^* transitions within the acetyl moiety. On the other hand, the band observed at 310 and 300 nm in the spectra of **1** and **2,** respectively, can be assigned to n–π^* transitions of the acetyl moiety. The long wavelength absorption band at 400–420 nm can be assigned to a CT from the copper(I) to the Acpy ligand. The band is red shifted on going from **1** to **2**. The emission spectra of free 3-Acpy and 4-Acpy do not show any emission bands under the used experimental conditions, however, **2** exhibits strong luminescence at 485 and 527 nm (Fig. 10). The high energy emission band is due to a metal-to-ligand charge transfer (MLCT), where the electron is transferred from the Cu(I) center to the unoccupied π^*–orbital of the 4-Acpy ligand, while the low-energy emission may be ascribed to metal-centered transitions of the type $3d^{10} \rightarrow 3d^9\,4s^1$ and $3d^{10} \rightarrow 3d^9\,4p^1$ on the Cu(I) center. Compound **1** does not exhibit any luminescence properties under the used experimental conditions.

4. Discussion

These results reinforce the observation that the cyanide group is an effective bridging ligand which can link together two copper centers; μ_2-1,2-CN. The cyanide group is a popular bridging ligand for the construction of the solid state structures, and appears to be a potentially useful synthon for crystal engineering to obtain supramolecular materials with valuable physical and chemical properties. In spite of the fact that **1** and **2** are tin free compounds, the presence of Me_3SnCl has an important role for the synthesis of copper(I) cyanide SCPs at room temperature, since such SCPs are usually produced by solvothermal reactions. Supramolecular coordination polymers with the same composition do not necessary have the same structure. In spite of the stoichiometry of **1** and **2**

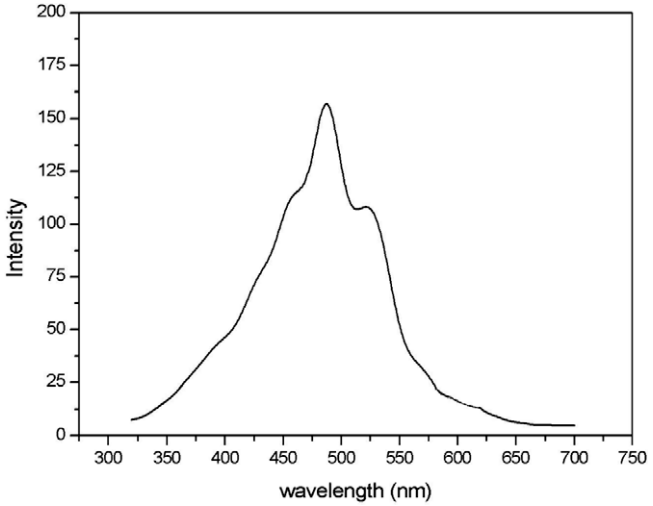

Fig. 10. Solid-state emission spectrum of **2** upon excitation at 350 nm.

being the same, the 3D-network of **1** is created by hydrogen bonding, π–π stacking and Cu···Cu interactions while the 2D-layers of **2** form a non-interpenetrating 3D-network via hydrogen bonging. The acetyl group plays an essential role in the formation of hydrogen bonding to generate 3D-network structures. For comparison, substituted pyridine adducts of copper(I) cyanide have shown considerable capacity for steric control of the coordination environment of copper by variation of the substitution pattern of the base [40–42]. The arrays of $[CuCN(py)_2]$, $[(CuCN)_2(2\text{-mpy})_2]$ and $[(CuCN)_2(4\text{-mpy})_3]$ are low dimensional single-stranded polymers, comprising a sequence of copper(I) atoms linked by single end-coordinated cyanides, with one or two pyridine ligands appended, with associated copper atom coordination numbers of three or four. No hydrogen bonds are observed in these polymers. On the other hand, replacing the methyl group by an acid group affords the three dimensional interpenetrated $[Cu_2(CN)(IN)(HIN)]_n$ polymer. 2D-layers are formed by interpenetrated $[Cu_6(CN)_2(C_6H_4\text{-}NO_2)_2(C_6H_4NO_2H)_2]$ hexagons stacked by short hydrogen bonds. Each independent 2D-network is hydrogen bonded to only one of the three independent networks of an adjacent layer, to give a 3D-supramolecular architecture. Cuprophilic interactions and π–π stacking are avoided in the network, leaving the combination of coordination and hydrogen bonds to be responsible for the formation of the triple interpenetrated 3D supramolecular material with relatively high thermal stability [43]. In the structures of **1** and **2**, the acetyl groups are also capable of creating 3D-networks via hydrogen bonding. Thus, it is clear that the organic ligands may be introduced as structural components of composite inorganic–organic materials and used to propagate high dimensional-topologies. In this case the hydrogen bonds play an essential role in constructing 3D-topologies exhibiting more flexible networks which should open a very concrete way to porous materials.

Supplementary data

CCDC 191302 and 191303 contain the supplementary crystallographic data for **1** and **2**. These data can be obtained free of charge via http://www.ccdc.cam.ac.uk/conts/retrieving.html, or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (+44) 1223-336-033; or e-mail: deposit@ccdc.cam.ac.uk.

ABSTRACT

Crystals of monoaxially coordinated T-shaped and H-shaped supramolecular zinc(II) phthalocyaninato complexes with pyrazine are obtained. In both types of molecules the central Zn atom of ZnPc complexes with pyrazine exhibits 4 + 1 coordination. The Zn atom is equatorially coordinated by four isoindole N atoms of Pc macrocycle and axially by N atom of pyrazine molecule. The interaction of the central Zn atom of ZnPc with the axial N atom of pyrazine leads to a deviation of Zn from the centre of cavity by 0.371(2) Å in the T-shaped complex and by 0.296(2) Å in the H-shaped complex. Thermogravimetric analysis of the crystals exhibits three slopes down, corresponding to the loss in succession of solvated pyrazine molecules, than the loss of ligated pyrazine molecules from the T-shaped complex and the finally the loss of the bridged pyrazine molecule from the H-shaped complex. Finally the thermal processing leads to the β-ZnPc as residue. The UV–Vis spectrum taken in solution shows the batochromic shift in the polar solvent like α-chloronaphthalene in relation to the spectrum in non-polar solvent like benzene.

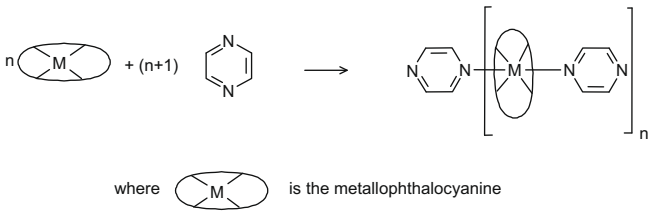
1. Introduction

The syntheses of the metallophthalocyaninate complexes and studies of their properties are still of interest since compounds of this family exhibit many technologically important features [1–4]. One of the useful methods of the MPc's functionalization is their transformative or non-transformative recrystallization in organic solvents. For many MPc's including the zinc phthalocyanine too, the complexes, formed with solvents composed of monodentate N-donating molecules, are well studied and also their single crystal X-ray structures are known [5–10]. This is not so good in the case of the potentially N-bidentately additive molecules like pyrazine (pyz).

The first experimental results on the products of the metallophthalocyanines recrystallization in pyrazine were published just for the ZnPc–pyz system 40 years ago [13]. For this binary system the existence of the only one uniform new phase, with the 2(ZnPc):3(pyz) molar composition was established. However its crystalline structure reminded unexplored.

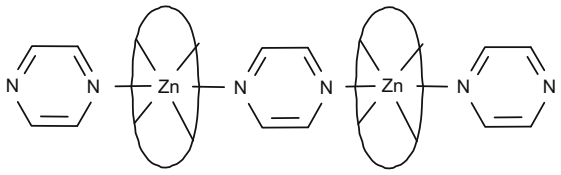
Later, Hanack and coworkers [12–15] published various experimental results for Fe(II), Co(II) and Ru(II) phthalocyanine systems with pyz. These experiments have shown that depending on the processing conditions used, the FePc, or CoPc or RhPc can form two kinds of compounds with pyrazine, composed appropriately of monomeric or linearly polymerized, pyrazine bridged, molecules. For monomers as well as for polymers the central M(II) ion of MPc complexes exhibits the 4 + 2 coordination, i.e. it is equatorially coordinated by four N-isoindole atoms of the Pc macroring and bis-axially coordinated by two pyz units. It corresponds with the experimentally determined M(II)Pc:pyz units relations, being 1:2 for monomers and close approximately to 1:1 for polymers. The formation of the polymer illustrates Scheme 1.

We are supposing however, that the 2ZnPc:3pyz composition of the crystalline phase cannot be composed of the uniform molecules formed from ZnPc and pyz molecules arranged and connected in such a simple way as shown in Scheme 2.



This statement may be supported by the literature data concerning the coordinativity of the zinc ion being in the ZnN_4 chromophore, which indicate that only monoaxial coordination of the relative ZnPc complex with pyz should be expected [10,16]. If so, the ZnPc should at the most be able to form only two different units with pyz as shown in Scheme 3.

In consequence the 2ZnPc:3pyz crystalline phase, independently if it is composed of one kind of such units, or both of them, requires the presence of the additive pyz units in the solid-state. Besides it means that in the ZnPc–pyz system, in contrast to the FePc or CoPc-pyz systems, the polymerization should not be possible.



To revise the idea, and in particular to verify how the building blocks of the 2ZnPc:3pyz phase are arranged in the solid state we decided to obtain the crystalline sample of the 2ZnPc:3pyz phase, as well as to investigate the role of pyrazine in controlling the solid-state supramolecular chemistry of ZnPc and the crystal growth.

2. Experimental

2.1. Preparation and growing of the crystals

The ZnPc and pyz (both obtained from Aldrich), taken at the weight proportion 1:10, were mixed together and next portioned on to the samples, of ca. 1.5 g in mass each. The individual samples were degassed and sealed off in the glass ampoule, ca. 10 cm in length. Next, each of the ampoules was annealed at selected temperature by one-two days in a slightly inclined position.

2.1.1. 2(ZnPc):3(pyz), phase I

The annealing of ampoules at the temperature between the range of 70–150 °C leads to formation of the 2(ZnPc):3(pyz) crystalline phase I. When in the suspension the crystals of phase I were clearly seen, the inclination of the ampoule was reversed and the ampoule was heated again. This allowed to flow off the excessive pyz liquids away from the crystals, which were remained in the opposite part of the ampoule. The samples made of the crystalline phase I were controlled by X-ray dispersive spectroscopic and X-ray powder diffraction methods. The results were in agreement with the experimental data reported earlier [11]. However, the violet single crystals suitable for the X-ray single crystal analysis were selected from the sample processed at 110 °C. The ampoules processed at 70, 90 or 150 °C gave microcrystalline product of phase I. enable to obtain the crystals since the crystals of ZnPc:pyz = 2:3 are stable.

2.1.2. β-ZnPc, phase II

When the samples of the ZnPc/pyz mixture were processed at 190 °C or higher temperature, the effective behaviour of pyz is no longer as ligating but as transporting medium. In the result above the suspension in the free ampoule volume, the violet well developed prysmatic β-ZnPc crystals are growing (Fig. 1). For one of such single crystals the X-ray diffraction data were collected, giving the high quality structural data.

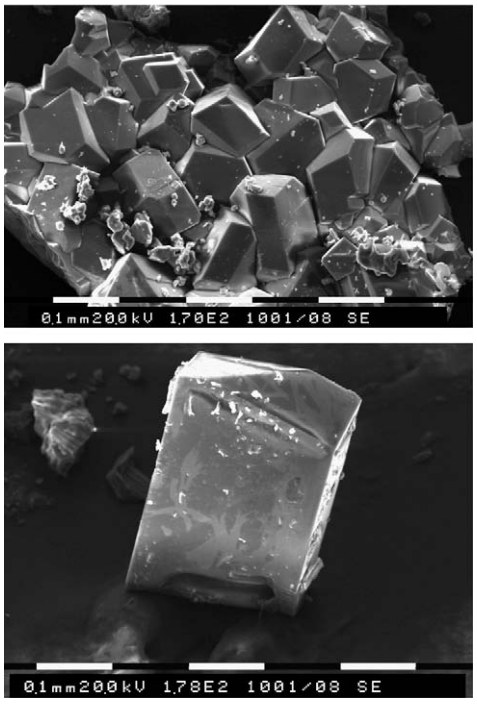

Fig. 1. Crystals of β-ZnPc obtained at 190 °C in the ZnPc-pyrazine system.

2.2. UV–Vis spectroscopic measurements

Measurements of the electronic spectra were carried out at room temperature using a Varian Cary 5E UV–Vis–NIR spectrometer. The UV–Vis spectra were recorded for the phase I as well as for the phase II in polar (α-chloronaphthalene, DMF) and non-polar solvents (benzene, cyclohexane) in 0.5 cm quartz cell.

2.3. Thermal measurements

Thermal analysis was carried out on a Lines L81 thermobalance apparatus with Pt crucibles. Powdered Al_2O_3 has been used as a reference. The measurements have been performed under static air atmosphere on heating from room temperature to 300 °C at the heating rate of 5 °C min^{-1}.

2.4. X-ray powder diffraction measurements

The purified started metallophthalocyanines as well as the rest of the samples left after thermogravimetric analyses were measured on a STOE powder diffractometer equipped with a linear position detector (PSD) [17] using Cu $K\alpha_1$ radiation (λ = 1.540562 Å) at room temperature.

2.5. X-ray data collection and structure determination

A violet single crystal of 2(ZnPc):3(pyz) having edges of 0.34 × 0.27 × 0.22 mm was measured on a KUMA KM-4 CCD diffractometer with graphite monochromatized Mo Kα (λ = 0.71073 Å) radiation at room temperature. The final unit cell parameters were refined by least-squares methods on the basis of 2342 reflections. 32203 reflections (14111 independent, 8608

[a] $R = \Sigma||F_o| - ||F_c||/\Sigma F_o$.
[b] $wR = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma wF_o^4\}^{1/2}$; $w^{-1} = [\sigma^2(F_o^2) + (0.0296P)^2]$ where $P = (F_o^2 + 2F_c^2)/3$.

observed with $I > 2\sigma(I)$, $R_{int} = 0.037$) were measured up to 56.3° in 2θ covering over 98% of the Ewald sphere. Data collections were made using the CRYSALIS CCD program [18], integration and scaling of the reflections were performed with CRYSALIS Red program [18]. Face-indexed absorption corrections were carried out using the SHELXTL program [19]. The structure was solved by direct methods using the SHELXS-97 and refined using the SHELXL-97 program [20]. Fourier maps gave the positions of the zinc(II) and most of the nitrogen and carbon atoms of the phthalocyaninato rings. The remaining atoms were located from difference Fourier synthesis. The hydrogen atoms of the phenyl rings were located from the $\Delta\rho$ maps and in final cycles of calculations they were refined with riding model. The H atoms of the solvated pyrazine molecules were set isotropic with thermal parameters 20% greater than the equivalent isotropic displacement parameter of the carbon atom. The final differences Fourier map showed no peaks of chemical significance. The largest peaks on the final $\Delta\rho$ map were +0.56 and −0.49 e Å^{-3}. Details of the data collection parameters, crystallographic data and final agreement parameters are collected in Table 1.

3. Results and discussion

3.1. Synthesis and equilibrium in solution

When the procedure described in the Section 2.1 is carried out in the temperature range of 90–150 °C the crystalline product has always the 2(ZnPc):3(pyz) composition. However, the single crystals suitable for the full X-ray analysis were obtained when the ampoule was processed at 110 °C. At this temperature the prolonged heating enable to obtained crystals of ZnPc:pyz = 2:3 composition that are stable (Fig. 2). When the ampoule containing the crystalline 2(ZnPc):3(pyz) product was prolonged heated at 190 °C or at higher temperature, the 2(ZnPc):3(pyz) crystals appear decomposed, since the Zn–N(pyz) bond become broken liberating the pyrazine molecules. Simultaneously the liberated ZnPc molecules interact with each other initialising the growth of the pure β-ZnPc crystals, which after prolonged heating leads to the well-developed good quality prismatic crystals (Fig. 1). When the ampoule with the β-ZnPc crystals was heated again at the temperature between 90 and 150 °C, the pyrazine interacts with the β-ZnPc forming

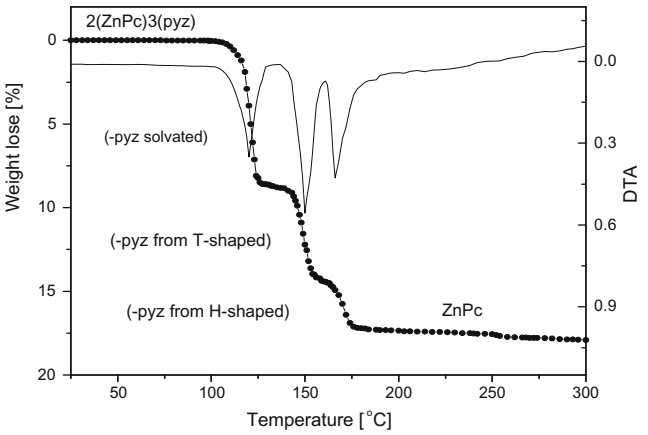

Fig. 2. Thermograms for the crystalline phase of 2(ZnPc):3(pyz). Speed rate 5 °C min^{-1}.

again the 2(ZnPc):3(pyz) crystals. Thus the formation of the solid-state supramolecular crystalline 2(ZnPc):3(pyz) phase is reversible and can be controlled by the annealing temperature. The 2(ZnPc):3(pyz) crystals are relatively soluble in 1-chloronaphthalene, quinoline, pyridine and other N-donating solvents, and slightly soluble in benzene, DMSO and CH_2Cl_2. Contact of 2(ZnPc):3(pyz) crystals with dilute acids lead to the demetallation, yielding metal-free phthalocyanine (H_2Pc) in the α-form, which was identified by X-ray powder diffraction method [21].

3.2. Thermal measurement and analysis

The obtained crystalline 2(ZnPc):3(pyz) phase is relatively stable up to about 120 °C (Fig. 2). Above this temperature the solvated pyrazine molecules are released (weight loss ~8.5%) yielding a mixture of the H- and T-shaped supramolecular complexes. These complexes loss the ligated pyrazine at ~150 and ~170 °C. First, at lower temperature (150 °C), the T-shaped complex losses the ligated pyrazine molecule, and next, at temperature higher by about 20 °C, the H-shaped complex releases the bridged pyrazine molecule, since the respective weight losses are ~5.7% and ~2.8%. The calculated weight losses for the thermal decomposition of the 2(ZnPc):3(pyz) phase are: 8.60% (solvated pyz), 14.33% (solvated + ligated pyz in the T-shaped complex) and 17.19% (solvated + ligated T-shaped + bridged H-shaped complexes) and they are in agreement with the experimental results (Fig. 2). The thermogravimetric experiment clearly shows that the H-shaped supramolecular complex is more stable than the T-shaped complex. Although, the axial Zn–$N_{(pyz)}$ bond in the T-shaped complex is stronger (2.178(2) Å) than in the H-shaped complex (2.207(2) Å), due to the bridging effect the H-shaped complex is more stable. The differential thermal curve indicates three distinct endothermic deflection peaks appearing during thermal decomposition of the 2(ZnPc):3(pyz) crystals. The thermal decomposition of the 2(ZnPc):3(pyz) phase leads to the β-ZnPc as was identified by the X-ray powder diffraction method. The TG analysis is fully consistent with the preparation procedure which shows that the 2(ZnPc):3(pyz) crystalline phase can be obtained only at the middle temperature range of 70–150 °C. However, the good quality single crystals suitable for the X-ray analysis were obtained at 110 °C, below the first steep of decomposition (see Fig. 2).

3.3. Stereochemistry and supramolecular arrangement

A single X-ray analysis of the 2(ZnPc):3(pyz) crystal revealed the formation of a supramolecular structure. The crystal of the

phase I is built up of two different types of supramolecular complexes and the pyrazine as solvent molecules. One of them is H-shaped supramolecular complex and the second one is T-shaped. In both types of the supramolecular ZnPc-derivatives the Zn(II) atom exhibits the 4 + 1 coordination. It is equatorially coordinated by four isoindole N atoms of Pc macrocycle and axially by the N-ring atom of ligated pyrazine molecule. In the H-shaped complex both N-ring atoms of pyrazine molecule are ligated to two ZnPc molecules. Thus in the H-shaped complex the pyrazine molecule is a bridging molecule developing the centrosymmetric supramolecular dimeric structure (Fig. 3a). In T-shaped ZnPc complex the pyrazine molecule coordinates only one ZnPc molecule (Fig. 3b). In both supramolecular complexes each Zn(II) center is pentacoordinated forming a distorted square pyramid. The phthalocyaninate(2-) macroring in both supramolecular ZnPc-complexes, H-shaped and T-shaped, is not strictly planar due to the interactions of the Zn-center with axial pyz molecule. Interaction between the N-ring atom of pyz molecule, with a lone-pair of electrons, and positively charged Zn(II)-center of ZnPc molecules leads to deviation of Zn(II) from the N_4-isoindole plane by 0.296(2) Å in the H-shaped supramolecular dimeric complex and by 0.371(2) Å in the T-shaped monomer. As a result of the interaction of Zn(II) with the axially ligated pyrazine molecule, the planar Pc ligand as found in the β-ZnPc adopts a saucer shaped form in the T-shaped complex, while in the H-shaped supramolecular dimeric complex the two isoindole rings of Pc on the diagonal are bent upward and the other two are bent downward in respect to the N_4-isoindole plane. Thus in the H-shaped supramolecular complex the Pc rings exhibit approximately the S_4 symmetry. In the T-shaped complex the greatest deviations of the non-H atoms from the N_4-isoindole plane are observed for the outermost carbon atoms: C3B-C6B, 0.167(2)–0.275(2) Å; C11B-C14B, 0.209(2)–0.295(2) Å; C19B-C22B, 0.106(2)–0.247(2) Å and C27B-C30B, 0.141(2)–0.215(2) Å, while in the H-shaped the greatest upward deviations are observed for C5 and C6 (0.123(2) and 0.141(2) Å) and for C20 and C21 (0.258(2) and 0.295(2) Å) while the downward deviations are observed for C13 and C14 (−0.047(2) and −0.112(2) Å) and for C28 and C29 (−0.179(2) and −0.176(2) Å). In both supramolecular complexes the greatest deviations of the carbon atoms from the N_4-isoindole plane of Pc ring correlate well with the orientation of the bridged (in H-shaped) or axially ligated (in T-shaped) pyrazine molecule, which is almost perpendicular to the N_4-isoindole plane of respective Pc rings (84.8(1)° in H-shaped and 87.2(1)° in the T-shaped). The pyrazine ring is oriented by the H atoms in the orto position in relation to N atoms of the isoindole rings showing the greatest deviation from the N_4-isoindole plane of Pc ring. The equatorial Zn–N bonds in the H-shaped supramolecular complex ranging from 1.997(2) to 2.005(2) Å are slightly shorter than those in the T-shaped complex (2.009(2)–2.012(2) Å), while the opposite relation is observed in the axial Zn–N(pyz) bonds, longer in H-shaped and shorter in T-shaped (Table 2). Thus the interaction of pyrazine molecule with one ZnPc molecule with the formation of T-shaped complex is stronger than the interaction with two ZnPc molecules with the formation of the H-shaped supramolecular complex. The strength of the axial Zn–N(pyz) interaction is also evidenced by the displacement of Zn(II) from the N_4-isoindole plane of Pc ring. The displacement values of Zn(II) in these H- and T-shaped complexes are in the normal range observed in the 4 + 1 coordinated ZnPc-derivatives [10,22–26]. In the H-shaped supramolecular complex the Pc rings are parallel to each other and are separated by a distance of 7.763(3) Å (the N_4–N_4 distance).

The arrangement of the H- and T-shaped supramolecules in the crystal is mainly determined by the π–π interactions between the aromatic Pc macrorings. Strong π–π interaction is common feature in the structures of phthalocyanine and its metal complexes, and determines their crystal structures. The π–π interactions also play an important role in association of metallophthalocyanines in solution [27,28]. The H-shaped supramolecules are arranged in the back-to-back fashion forming stacks almost parallel to [1 0 0] direction with the distance of 3.341(2) Å between the N_4-planes

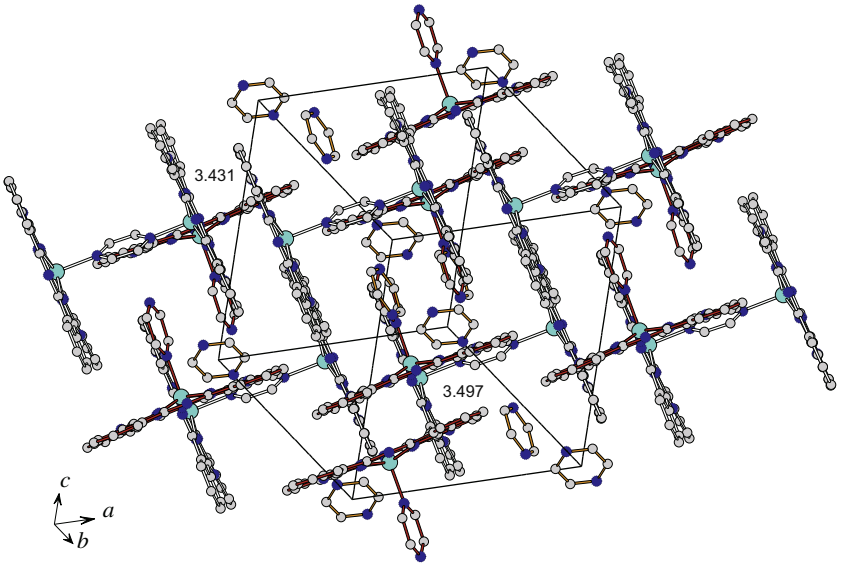

Fig. 4. View of the arrangement of H- and T-shaped molecules in the unit cell.

of Pc macrorings. The T-shaped molecules are also arranged in the back-to-back fashion with the distance between the N_4-planes of 3.497(2) Å. The back-to-back oriented T-shaped molecules form layers parallel to (0 2 0) crystallographic plane, while the H-shaped supramolecules form layers almost parallel to (0 0 2) crystallographic plane (Fig. 4). Thus the overlap of the Pc ligands in the solid state of the phase I is characteristic of the (4 + 1)-Zn-phthalocyaninate complexes. Scheidt and Lee examined the overlap in neutral, structurally characterized metal-porphyrinate complexes and discovered that the distribution of the lateral shift of the ligands is trimodal rather than continuous [29]. The values appear to be ~1.5 Å for clusters with strong π–π overlap, at ~3.5 Å with intermediate π–π overlap and at ~6.5 Å with weak overlap. The back-to-back overlap, in this crystal with distances of 3.341(2) Å in H-shaped and 3.397(2) Å in T-shaped supramolecular ZnPc-complexes, represents an intermediate interaction between the π-aromatic Pc-ligands. However, owing to the saucer-shape of Pc ligand in T-shaped complex or diagonally deformed up and downward in H-shaped, the mean inter-planar separation between the back-to-back overlapped dimers (~3.28 Å in H-shaped and 3.37 Å in T-shaped) is nearly midway between the sum of the C-atom van der Waals radii of the π ring system (~3.4 Å) and the distance at which the steric interactions between the π ring system becomes predominantly repulsive (~3.08 Å) [30]. Thus the π–π stabilization of the solid state arrangement is evident and the π–π interactions play important role in the supramolecular arrangement and the packing pattern. Both back-to-back oriented H-shaped and T-shaped supramolecular complexes in the crystal are almost perpendicular, the N_4-planes of Pc rings of the H-shaped complex form an angles of 93.7(1)° with the N_4-plane of Pc of the T-shaped complex. The pyrazine molecules are located in the holes between the mutually arranged H- and T-shaped molecules. One of them is located around an inversion center at the origin of the unit cell and is almost parallel to (0 0 1) crystallographic plane, while to other pyrazine molecule is located between the Pc rings of the H-shaped molecule and is almost parallel to the Pc rings (the dihedral angle of pyrazine plane and plane of Pc ring is equal to ~17.5°). Since in H-shaped complex the Pc rings are apart by 7.767(3) Å, the pyrazine molecules are located between the phenyl rings (C18–C23/$C2^i$–$C7^i$ and C2–C7/$C18^i$–$C23^i$, $i = 1 - x, 2 - y, 1 - z$), while between the other phenyl rings (C10–C15/$C25^i$–$C30^i$ and $C10^i$–$C15^i$/C25–C30) is located the coordinated pyrazine molecule of the T-shaped complex. This arrangement of the H- and T-shaped molecules and the pyrazine solvated molecules indicates that besides the π–π interactions between the back-to-back oriented H-shaped and T-shaped supramolecular units, the π–π interactions between the solvated pyrazine molecules and the phenyl rings of Pc macrorings are also significant factor stabilising the supramolecular arrangement and the crystal packing.

3.4. UV–Vis spectroscopy

To investigate further the structure of the 2(ZnPc):3(pyz) species in solution, the electronic absorption spectra in polar and non-polar solvents were recorded. The absorption spectra of the 2:3 complexes in both polar (1-chloronaphthalene) and non-polar solvents (benzene) are very similar (Fig. 5) and characterize the ZnPc with a single pyz in axial position. They both show characteristic well-developed intense Q band, assigned from HOMO (A_{1a} ground state) to LUMO (E_u, the first excited state) transition, and the broad B-Soret band, and they are in agreement with the spectrum of ZnPc published by A.B.P. Lever [31]. As can be seen from Fig. 5 the spectra exhibit characteristic splitting of the Q band due to the vibronic coupling in the excited state, which was well

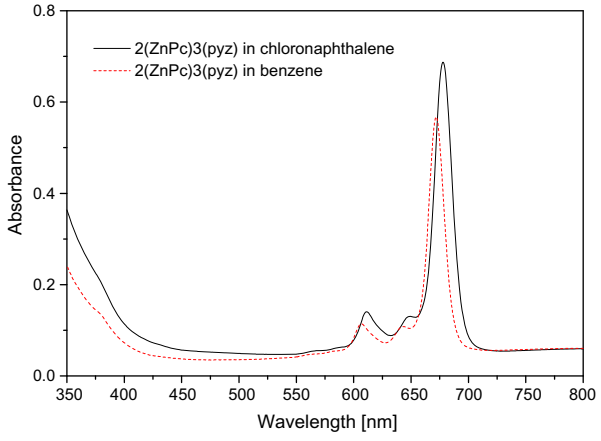

Fig. 5. Electronic absorption spectra of 2(ZnPc):3(pyz) in chloronaphthalene (solid line) and in benzene (doted line).

described in the literature [32–35]. However, the spectrum taken in benzene is blue shifted (~10 nm) in the relation to that taken in α-chloronaphthalene. The difference in the wavelength of the absorption in benzene or in α-chloronaphthalene is a consequence of different solvents (solvent effect). A similar correlation is observed in other polar and non-polar solvents. What seems also important, we did not notice any time dependence of the spectra, as it was in the cause of iron phthalocyanine–pyz system [14].

4. Conclusion

The experiment performed with the ZnPc–pyz system confirms a presence of the stable supramolecular 2(ZnPc):3(pyz) phase in which the three various molecules, ZnPc(pyz), $(ZnPc)_2$(pyz) and pyz constitute the solid-state phase. The results indicate also on the peculiar feature of the zinc cation, which being in the essentially planar ZnN_4 moiety, is capable to only monoaxial coordination of the electron donating ligand molecules. It is also interesting, that the high quality ZnPc crystals can be grown when in the ZnPc–pyz system the annealing temperature is set to the value exceeding the ZnN_4–Npyz attraction force, roughly 200 °C.

ABSTRACT

The bimetallic $[Ni_2(H_2L2)_2](ClO_4)_4$ (**1**), $[Ni_2(HL2)(H_2L2)](ClO_4)_3$ (**2**) and $[Zn_2(H_2L2)_2](BF_4)_4$ (**3**) complexes (H_2L2 = N',N'^2-bis[(1*E*)-1-(2-pyridyl)ethylidene]propanedihydrazide) were synthesized and characterized. The structure of complexes (**1**) and (**2**) was established by X-ray analysis. NMR spectroscopy was used for the characterization of complex (**3**). The complexes (**1**) and (**2**) were obtained from the same synthetic reaction and two crystal types of these complexes have been isolated during the fractional crystallization process.

In complex (**1**) each Ni(II) ion is coordinated with two NNO donor atom sets from two H_2L2 ligands forming an octahedral geometry. Similarly, in complex (**2**) the octahedral geometry of each Ni(II) ion is attained by coordination of two NNO donor atom sets, one from the neutral and the other from the mono-anionic form of the ligand. The antimicrobial activity of the ligand and complexes is also presented.

1. Introduction

For the past years one line of our research has been dedicated to complexes of polydentate dihydrazone ligands with adjacent coordination pockets, predominantly condensation derivatives of 2-acetylpyridine and oxalic or malonic acid dihydrazide [1,2]. Dihydrazone type ligands display a versatile behavior in metal coordination. Occupation of all possible coordination sites depends on the nature of the central metal atom, conformational flexibility of the ligand as well as on the presence of other species capable to compete for coordination pockets. Oxalic dihydrazide based ligands, like N',N'^2-bis[(1*E*)-1-(2-pyridyl)ethylidene]ethanedihydrazide (H_2L1, Scheme 1a), are capable to bind more than one metal center. In the reaction with $Cu(AcO)_2{\cdot}H_2O$ binuclear complex with L1 was obtained [3], where the ligand in its *transoid* orientation binds two metal centers through oxamido type bridges in bis-tridentate mode. With $Ni(BF_4)_2{\cdot}6H_2O$ formation of tetranuclear complex, with fully occupied coordination sites of HL1, is favoured [4]. However, use of $Ni(AcO)_2{\cdot}4H_2O$ afforded formation of neutral mononuclear Ni(II) complex where L1 in its *cisoid* orientation is coordinated as tetradentate via only the nitrogen atoms, with no involvement of the central oxalic fragment [3]. On the other hand, it was shown that H_2L1 is hydrolytically unstable, which is not so uncommon for ligands derived from condensation reactions. Decomposition of H_2L1 by hydrolysis at the hydrazide moiety occurs in a reaction with $Cu(NO_3)_2{\cdot}3H_2O$ or $Cu(ClO_4)_2{\cdot}6H_2O$ in aqueous methanol, affording formation of the binuclear Cu(II) complex with 2-acetylpyridine hydrazone in which oxalate ion bridges two metal centers [5]. Similarly, hydrolysis of H_2L1 takes place in the reaction with $Fe(ClO_4)_3{\cdot}6H_2O$ in water with concomitant reduction of Fe(III) to Fe(II) by oxalic fragment affording formation of mononuclear Fe(II) complex with 2-acetylpyridine hydrazone [1]. In contrast, with structurally similar dihydrazone ligand, N',N'^2-bis[(1*E*)-1-(2-pyridyl)ethylidene]propanedihydrazide (H_2L2, Scheme 1b), which is more flexible in comparison to H_2L1, the hydrolysis does not take place. In mononuclear octahedral Fe(III) complex, H_2L2 is coordinated through nitrogen atoms from both coordination pockets [1], while it binds two metal centers in bis-tridentate fashion in Cd(II) complex [2].

Oxalic and malonic based dihydrazones and their complexes showed versatile biological activities [2,6]. Evaluation of cytotoxic activity of H_2L1 and H_2L2 on HeLa (human cervix carcinoma cells) and B16 (murine melanoma) tumor cell lines showed that these ligands were more active in comparison to other acyl hydrazones of 2-acetylpyridine [6], while heptacoordinated binuclear Cd(II)

Scheme 1.

complex with H_2L2 showed cytotoxic activity in low micromolar range [2].

As a continuation of the investigation of coordination behavior of flexible 2-acetylpyridine based dihydrazone ligands, the present work reports synthesis and characterization of Ni(II) and Zn(II) complexes with H_2L2 and evaluation of the biological activity of the synthesized compounds.

2. Experimental

2.1. General remarks

2-Acetylpyridine (99+%), malonic acid dihydrazide (97%), Ni-$(ClO_4)_2{\cdot}6H_2O$ (purum p.a. $\geq$ 98.0%), and $Zn(BF_4)_2{\cdot}6H_2O$ were obtained from Aldrich. All solvents (ethanol, *N*,*N*-dimethylformamide, diethyl ether, acetonitrile, dimethyl sulfoxide) were reagent grade and used without further purification. IR spectra were recorded on the Perkin–Elmer FT-IR 1725X spectrometer using the KBr-pellet technique in the region 4000–400 cm^{-1}. Electronic absorption spectra were recorded on a GBC UV–visible Cintra 6 Spectrometer. The NMR spectra were performed on Bruker Avance 500 equipped with broad-band direct probe. All spectra were measured at 298 K. The Zn(II)–H_2L2 complex was characterized on the basis of NMR spectroscopy results: 1D (^1H, ^{13}C), 2D COSY (Correlation Spectroscopy) and 2D ROESY (Rotational Frame Nuclear Overhauser Effect Spectroscopy) spectra, as well as 2D ^1H–^{13}C heteronuclear correlation spectra. Chemical shifts are given on δ scale relative to tetramethylsilane (TMS) as internal standard for ^1H and ^{13}C.

2.2. Synthesis of N′,N′²-bis[(1E)-1-(2-pyridyl)ethylidene]propanedihydrazide (H_2L2)

The ligand H_2L2 was prepared as described previously [1] by condensation reaction of 2-acetylpyridine and malonic acid dihydrazide in water with a few drops of conc. HCl (pH $\sim$ 4.5). IR (KBr-pellet, cm^{-1}): 3190 (w), 3089 (w), 3006 (w), 1662 (vs), 1626 (m), 1580 (s), 1460 (m), 1430 (m), 1378 (m), 1227 (m), 1152 (m), 1084 (w), 991 (w), 784 (s), 726 (s), 662 (m), 623 (m), 560 (m), 483 (m), 404 (m). ^1H NMR (500.26 MHz, DMSO-d_6): δ = 2.32 (s, 6H, H–C8═H–C12), 4.09 (s, 2H, H–C10), 7.33 (t, 2H, H–C5═H–C17, ^3J = 5.0 Hz, ^3J = 1.5 Hz), 7.58 (dt, 2H, H–C4═H–C16, ^3J = 7.5 Hz, ^3J = 1.5 Hz), 7.97 (d, 2H, H–C3═H–C15, ^3J = 7.5 Hz), 8.56 (d, 2H, H–C6═H–C18, ^3J = 5.0 Hz), 10.86 (bs, 2H, H–N3═H–N4). ^{13}C NMR (125.79 MHz, DMSO-d_6): δ = 11.93 (C8═C12), 40.70 (C10), 119.79 (C6═C18), 123.79 (C5═C17), 136.20 (C4═C16), 148.56 (C3═C15), 155.00 (C9═C11), 163.88 (C2═C14), 170.31 (C7═C13).

2.3. Synthesis of Ni(II) complexes with H_2L2 ligand

Into a solution of $Ni(ClO_4)_2{\cdot}6H_2O$ (0.22 g, 0.59 mmol) in EtOH (20 mL), the ligand H_2L2 (0.20 g, 0.59 mmol) was added. After refluxing the suspension for 1 h, an olive-green precipitate was filtered off and washed with cold EtOH and ether. The precipitate was dissolved in DMSO and after two days of slow diffusion of EtOH vapour, green crystals of complex **(1)** were obtained, and taken out of the solution. Seven days later, from the same mother liquid, after slow diffusion of EtOH vapour, brown crystals of complex **(2)** were obtained. The crystals of **(1)** and **(2)** were separated by fractional crystallization. Both crystals were unstable in air. X-ray diffraction measurements for **(1)** and **(2)** were performed on crystals mounted in a LithoLoop immediately after taking from the mother liquid and flash-cooled on a diffractometer.

(1): After filtration, green crystals were washed with cold water and ethanol, and dried in vacuo. The data listed below reflects the product obtained after drying. IR (KBr-pellet, cm^{-1}): 3105 (w), 3000 (w), 2921 (w), 2742 (w), 1629 (w), 1599 (s), 1538 (s), 1472 (m), 1362 (m), 1219 (m), 1171 (m), 1077 (vs), 1001 (vs), 954 (s), 779 (s), 744 (m), 694 (m), 619 (vs), 570 (m), 519 (m), 461 (m), 414 (w).

(2): After filtration, brown crystals were washed with cold water and ethanol, and dried in vacuo. The data listed below reflects the product obtained after drying. IR (KBr-pellet, cm^{-1}): 3106 (w), 2925 (w), 2745 (w), 1598 (s), 1541 (s), 1511 (vs), 1464 (s), 1374 (s), 1263 (w), 1221 (s), 1174 (m), 1071 (vs), 1003 (vs), 952 (s), 780 (s), 745 (m), 705 (m), 618 (vs), 569 (s), 519 (s), 460 (s), 414 (m).

2.4. Synthesis of Zn(II) complex with H_2L2 ligand

Into the solution of $Zn(BF_4)_2{\cdot}6H_2O$ (0.20 g, 0.59 mmol) in EtOH (20 mL), the ligand H_2L2 (0.20 g, 0.59 mmol) was added. After refluxing the suspension for 1 h, a white precipitate was separated, filtered off and washed with cold EtOH and ether. The precipitate was dissolved in DMSO and after two days of slow diffusion of EtOH vapour, white crystals of complex **(3)** were obtained. The crystals were unstable in air, therefore the data listed below reflects the product obtained after washing crystals of **(3)** with cold water and ethanol, and drying in vacuo. IR (KBr-pellet, cm^{-1}):

3442 (w), 3268 (w), 1631 (m), 1600 (s), 1525 (s), 1475 (m), 1444 (w), 1352 (m), 1209 (s), 1184 (m), 1106 (s), 1025 (vs), 784 (s), 748 (w), 692 (w), 666 (w), 640 (w), 590 (w), 562 (m), 517 (m), 454 (m), 410 (m). ^{1}H NMR (500.26 MHz, DMSO-d_6): δ = 2.32 (s, 6H, H–C8=H–C12), 4.00 (s, 2H, H–C10), 7.34 (t, 2H, H–C4=H–C16, ^3J = 7.5 Hz), 7.36 (t, 2H, H–C5=H–C17, ^3J = 5.0 Hz), 8.03 (d, 2H, H–C6=H–C18, ^3J = 5.0 Hz), 8.57 (d, 2H, H–C3=H–C15, ^3J = 7.5 Hz), 11.02 (bs, 2H, H–N3=H–N4). ^{13}C NMR (125.79 MHz, DMSO-d_6): δ = 12.16 (C8=C12), 40.96 (C10), 120.09 (C3=C15), 124.06 (C5=C17), 136.46 (C4=C16), 148.59 (C6=C18), 154.83 (C9=C11), 163.88 (C2=C14), 170.42 (C7=C13).

2.5. X-ray analysis

For X-ray measurements the crystals were mounted in a loop containing some amount of solvent and flash-cooled on a diffractometer to 130 (**1**) and 100 (**2**) K. The intensity data were measured with a KM4CCD kappa-geometry diffractometer using graphite monochromated Mo Kα radiation (λ = 0.71073 Å) [7] and the temperature of the samples was controlled with an Oxford Instruments Cryosystem cold-nitrogen-gas blower. The intensity data were corrected for Lp effects as well as for absorption [7]. The structures were solved by direct methods using SHELXS97 [8] and refined by least-squares techniques with SHELXL97 [8]. In (**1**) all hydrogen atoms have been placed at calculated positions, including the ethanol hydrogen, the location of which was made possible by the use of the AFIX 147 instruction of SHELXL [8]. In (**2**) only hydrogen atoms connected to carbon atoms have been placed at calculated positions, while those attached to the nitrogen atoms have been located on subsequent difference Fourier maps. In (**2**) only three out of four possible N–H hydrogens (belonging to two crystallographically independent ligands) have been located, which could be interpreted as an indication of the partial deprotonation of one of the two ligands. That the absence of the hydrogen atom in the vicinity of N33 was not accidental was further confirmed by a detailed analysis of the complex geometry and intermolecular interactions (*vide infra*).

During the process of the crystal structure refinement the H atom positions were refined in a so called "riding model" with constraints on the C–H, N–H and O–H bond lengths and isotropic displacement parameters. Both crystal structures contain significant amount of solvent (DMSO, ethanol, diethyl ether) molecules, which together with perchlorate anions are the source of severe crystal disorder.

In (**1**) only the complex cation, one perchlorate group, two DMSO molecules and one ethanol molecule were readily discernable; the remainder of the structure appeared considerably disordered, which included three out of four perchlorate anions as well as DMSO and ethanol solvent molecules. The disordered parts of the structure were refined with restraints on 1,2 and 1,3 distances (DFIX instructions). The disorder model for two of the perchlorate groups was such that two sites were identified for one of the perchlorate oxygen atoms (i.e. O11 and O11a, and O13 and O13a). These perchlorate anions were refined with positional restraints and with anisotropic displacement parameters for all but the disordered oxygen atoms. The remaining perchlorate anion was highly disordered with all four oxygen atoms occupying three different sites with 0.53, 0.25 and 0.22 occupancy ratio. All its oxygen atoms were refined isotropically. Two disordered DMSO molecules were also refined isotropically. At the final stages of the structure solution it appeared evident that the investigated crystal contains, besides four perchlorate anions, four DMSO molecules and an ethanol molecule, some other solvent molecules not easily recognizable. All these molecules were situated in-between cationic layers, roughly parallel to the (1 0 0) lattice planes. Eventually, we have modeled this residual electron density as coming from a half of a DMSO molecule and a fraction of an ethanol molecule but the molecules were so disordered that numerous attempts to resolve multiple sites were unsuccessful. Therefore, we have removed these molecules from the model and used the SQUEEZE [9] program to account for the presence of these solvent molecules. The atom list does not contain the atoms of the residual solvent molecules.

The model of the crystal structure of (**2**) that came out from the numerous attempts to account for the presence of the residual electron density, contained in the asymmetric unit one bimetallic cluster, three perchlorate groups, three DMSO molecules and severely disordered ethanol and/or diethyl ether molecules. The solvent molecules concentrated in channels and hydrogen bonded to the complex cations. One of the three DMSO molecules was disordered with two methyl groups occupying three sites with 0.86, 0.82 and 0.32 occupancies. The disorder of ethanol and diethyl ether solvent molecules could not be properly modeled, therefore these molecules were removed from the atom list and the program SQUEEZE [9] was used to account for their presence. Again the contribution of these additional solvent molecules has been treated by the SQUEEZE program [9] globally, hence the atom list does not contain atoms constituting these remaining solvent molecules.

Siemens computer graphics program [10] was used to prepare Figs. 1 and 2. The crystal data for (**1**) and (**2**) and the parameters of data collection are summarized in Table 1.

2.6. Antimicrobial activity

All the synthesized compounds were screened for their antibacterial activity against gram positive bacteria *Staphylococcus aureus* ATCC 25923, *Micrococcus lysodeikticus* ATCC 4698, *Bacillus subtilis* ATCC 6633 and gram negative bacteria *Escherichia coli* ATCC 35218 *in vitro* using cup plate agar diffusion method. Solid medium used for this study was the nutrient agar (Torlak, Belgrade), pH 7.3. The medium was autoclaved for 15 min. The suspension of a bacterial culture in sterile isotonic saline solution (0.5 mL) was added to 10 mL of agar which was melted and cooled. Agar was poured onto the sterile petri dishes with a swirling motion to form an agar layer of uniform thickness. The plate was left undisturbed until the agar solidified. Small wells (8 mm in diameter) were punched in agar layer. The solutions of synthesized compounds (1 mg/100 μL of DMSO and 100 μL DMSO for control) were poured into the wells. The amount of standard antibiotic was 10 μg/disk. The zones of inhibition were measured in mm after incubation at 37 °C for 24 h. Antifungal activity was determined in the same way as antibacterial activity on Sabouraud dextrose agar (Torlak, Belgrade; pH

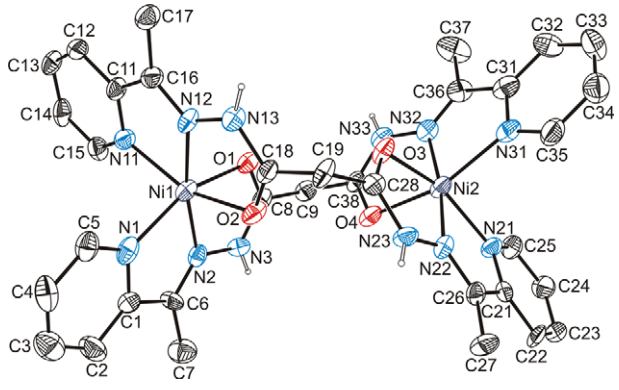

Fig. 1. View of the bimetallic complex cation of (**1**). Displacement ellipsoids drawn at 40% probability level. For clarity, hydrogen atoms bonded to carbon atoms have been omitted. The hydrogen atoms attached to the nitrogen atoms have been displayed to illustrate the neutral (uncharged) form of the malonic acid dihydrazide ligand.

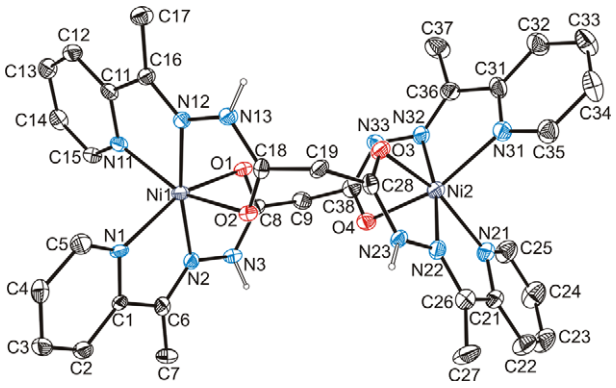

Fig. 2. View of the bimetallic complex cation of (**2**). Displacement ellipsoids drawn at 40% probability level. For clarity, hydrogen atoms bonded to carbon atoms have been omitted. The hydrogen atoms attached to the nitrogen atoms have been displayed to illustrate the monodeprotonated (monoanionic) form of the malonic acid dihydrazide ligand.

5.6) against the *Candida albicans* strain ATCC 24433. The amount of standard antimicotic was 10 μg/disk.

3. Results and discussion

3.1. General

By the fractional crystallization from DMSO/EtOH solution of the precipitate, obtained in the reaction of H_2L2 with $Ni(ClO_4)_2\cdot 6H_2O$ in EtOH, two different Ni(II) complexes were separated as green **(1)** and brown **(2)** crystals. Both crystals lose crystalline form when exposed to air, the brown ones being more stable. Complex **(2)** is soluble in MeCN, DMF and DMSO already at room temperature, and partially soluble in hot MeOH. When complex **(1)** is dissolved in either MeCN, DMF or DMSO the color of the solution almost instantly changes from green to brown. Furthermore, from the solution obtained by dissolution of green crystals, both complexes of Ni(II), green and brown ones, were obtained. The complex (**1**) crystallized first. The proposed mechanism for the formation of complex (**2**) starting from complex (**1**) is given in Eq. (1). As mentioned above, upon dissolution of complex **(1)** in DMSO the color of the solution rapidly changed from green to brown. The electronic absorption spectrum of this brown solution is practically the same in the shape and position of the absorption maximum as that of complex **(2)** (Supplementary data Fig. S1). This supports the assumption that complex **(1)** easily converts into the more stable complex **(2)**. The three spin allowed absorption bands ($^3A_{2g} \rightarrow {}^3T_{2g}(F)$; $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$) are expected for Ni(II) complexes when the noncubic field components are small compared with the approximately cubic field components. However, in the electronic absorption spectrum of complex **(2)** only one asymmetric band occurs in the near infrared region at 854 nm. The absorption bands that are expected to appear in the visible and UV region are most probably masked with more intense charge transfer bands or by transitions within the ligands.

By the reaction of $Zn(BF_4)_2\cdot 6H_2O$ and H_2L2 ligand Zn(II) complex, which forms unstable white crystals soluble in MeCN, DMF and DMSO, was obtained.

$$\begin{aligned} &[Ni_2(H_2L2)_2]^{4+} \leftrightarrows [Ni_2(H_2L2)(solvent)]^{4+} + H_2L2 \\ &2H_2L2 \leftrightarrows HL2^- + H_3L2^+ \\ &[Ni_2(H_2L2)(solvent)]^{4+} + HL2^- \leftrightarrows [Ni_2(HL2)(H_2L2)]^{3+} \end{aligned} \quad (1)$$

3.2. Description of the crystal structures

The ligand H_2L2 used in the synthesis of complexes (**1**) and (**2**) contains eight donor atoms: six nitrogens and two oxygens. It has the ability to coordinate in a neutral, mono or dianionic form. Views of the cationic moieties of complexes (**1**) and (**2**) are shown in Figs. 1 and 2, respectively, and Ni(II) coordination geometry is listed in Table 2. As can be seen from these Figures, cationic moieties in both complexes are binuclear. Each complex cation is built of two ligands, each acting as bis tridentate (N_2O) bridging two metal centers. This results in octahedral environment around each Ni(II) center. The planes formed by the five atoms constituting the two O,N,N-chelates coordinated to one metal center are mutually perpendicular with dihedral angles of 83.6 and 82.5° in (**1**), and 83.7, and 85.6° in (**2**). The intramolecular Ni···Ni distance in (**1**) equal to 6.029(1) Å is quite long, with twelve bond connections between the metal centers. The corresponding distance in (**2**) is only slightly shorter and amounts to 5.983(1) Å. What differs the two complex cations is the form of the ligands. While in (**1**) both ligand molecules are present in a neutral form, so the total charge of the complex cation is balanced by four perchlorate groups, in (**2**) one of the ligands is present in a neutral and one in a monoanionic (singly deprotonated) form, so the charge of this complex cation in balanced by three perchlorate groups. Structural arguments for this finding are as follows. Inspection of bond lengths and angles (Table 2) reveals that in complex (**2**) they are different around and in the vicinity of the N33 nitrogen atom, and the coordinated oxygen atom O4 than around the other nitrogen and oxygen atoms. Of the four Ni–O bonds three are nearly identical, with the mean value 2.11(2) Å and one (Ni–O4) is by 0.05 Å shorter, indicating coordination to the deprotonated enolic oxygen. Moreover, the valence angle on the unprotonated nitrogen N33 amounts to 108.4(3)°, while the mean of the other three angles is 113.4(2)°, the difference being 5.0°. Differences in other bond lengths within the three protonated (average values) and one unprotonated O,N chelate ring in complex cation (**2**) range from 0.011 Å (for N–N bonds) to 0.030 Å (for C–O bonds). Differences in valence angles spread from 0.5° (for N–Ni–O angles) to 4.3° (for O–C–N angles). Further support for the presence of one deprotonated ligand in the complex cation (**2**) comes from the inspection of the hydrogen bonding pattern (Table 3). It reveals that the environment of N33 nitrogen is different from the environment of the remaining nitrogen atoms (N3, N13, N23) of which each acts as strong hydrogen bond donor to three different DMSO molecules.

The average Ni–N and Ni–O bonds in (**1**) amount to 2.04 (5) and 2.108(5) Å. The shortest coordinate bond is to the central nitrogen atom (N2, N12, N22, N32). As a rule, the coordinate bonds to the oxygen atoms are longer than to the nitrogen atoms. Strong

hydrogen-bonding interactions exist between oxygen atoms belonging to the four DMSO molecules and the protonated nitrogen atoms (N3, N13, N23 and N33). These H-bonding interactions are summarized in Table 3.

3.3. Spectroscopic characterization

In the IR spectrum of the ligand H_2L2 the most intense band is amide band I [ν(C=O)] at 1662 cm^{-1}, and the band of ν(C=N) at 1580 cm^{-1} is also prominent. In the spectra of complexes (**1**) and (**2**) relative intensities and positions of the bands ν(C=O) and ν(C=N) are different. In the spectrum of (**1**) ν(C=O) is at the lower wave number (1629 cm^{-1}) and becomes weaker than the band ν(C=N) at 1599 cm^{-1}. In the spectrum of complex (**2**) the intensity of the carbonyl band is even weaker, so that it becomes a shouder on the ν(C=N) band. This is a consequence of deprotonation of the hydrazide nitrogen, so that, due to electron delocalization, C=O bond acquires partial single bond character, and the C–N bond partial double bond character. This is in accordance with shorter C–N bond length in the complex (**2**) in comparison to the corresponding bond lengths in part of complex (**2**) in which deprotonation did not occur. The most intense band in both complexes (**1**) and (**2**) is the band corresponding to perchlorate anion, at 1077 cm^{-1} and 1071 cm^{-1} in (**1**) and (**2**), respectively. In the Zn(II) complex (**3**) there is the same pattern of bands as in complex (**1**). In the spectrum of (**3**), the most intense band is at 1025 cm^{-1} due to tetrafluoroborate anion.

Preliminary X-ray results of the highly solvated Zn(II)–H_2L2 complex showed the coordination number six of dinuclear Zn(II) complex. However, ^{1}H NMR spectrum of the Zn complex in DMSO-d_6 solution indicates dissociation of the complex affording the free ligand and the dinuclear Zn complex, with one molecule of the ligand bridging two Zn atoms, the remaining coordination sites being occupied by solvent molecules. This conclusion is based on two series of signals in the ratio 1:1, one corresponding to the free ligand, and the other to the coordinated ligand. In the complex itself there are no prominent changes of chemical shifts upon complexation. It is noteworthy that hydrazide moieties are not deprotonated (signal at 11.02 ppm).

3.4. Antimicrobial activity evaluation

The results of the determination of antimicrobial activity of the ligand, the complexes (**2**) and (**3**), as well as the simple metal salts are presented in Table 4. The complex (**3**) showed activity against all tested microorganisms, while complex (**2**) was active against some strains of Gram positive bacteria only.

4. Conclusion

It was demonstrated that the investigated ligand forms unstable, highly solvated bimetallic complexes with Ni(II) cations. Two crystal types of these complexes have been isolated during the fractional crystallization process. They differ in both the crystal color and the stability. The less stable green crystals convert slowly to brown crystals while being kept in the solution. Once taken from the solution they decompose rapidly. It was shown that the apparent changes in crystal color signal a process of deprotonation of the hydrazide derived ligand and a consequent loss of a perchlorate anion.

The studied complexes (**2**) and (**3**) showed antimicrobial activity.

ABSTRACT

Solution equilibrium studies on the Cu(II)–polyamine–methionine ternary systems (polyamine: ethylenediamine (en), diethylenetriamine (dien), N,N,N′,N″,N″-pentamethyldiethylenetriamine (Me_5dien)) have been performed by pH-potentiometry, UV–Vis spectrophotometry and EPR methods. The obtained results suggest the formation of the mixed-ligand complexes with $[Cu(A)(Met)]^+$ stoichiometry in all studied systems. Our spectroscopic results indicate the tetragonal geometry for $[Cu(en)(Met)]^+$, the geometry slightly deviated from square pyramidal for $[Cu(dien)(Met)]^+$ and strongly deviated from square pyramidal towards trigonal bipyramidal for the $[Cu(Me_5dien)(Met)]^+$ species. The coordination modes in these mixed-ligand complexes are discussed.

1. Introduction

From 20 natural amino acids, which are the building blocks of proteins, eight are essential and cannot be produced by the human body, among them is methionine. Containing sulphur, it helps to prevent disorder of the hair, skin and nails, to lower the cholesterol levels by increasing the liver's production of lecithin and to reduce fat build-up in the liver and body [1].

On the other hand, the ferrocenylmethyl substituted L-methionine (together with L-asparagine) derived ligands and their copper(II) complexes [2,3] receive attention as owing to their redox properties, as electrochemical sensor design, and due to their ability to coordinate weakly Cu(II) at axial position through thioether group.

Chakravarty and coworkers [4–10] are involved in the development of the chemistry of non-porphyrinic low molecular weight copper-based complexes as new photoactive DNA cleaving agents. They [11] showed that although the amino acid (A) or heterocyclic base (B) are individually cleavage inactive, their ternary copper(II) complexes "A–Cu(II)–B" revealed efficient photoinduced DNA cleavage ability. One of them is the ternary copper(II) complex containing L-methionine as a photosensitizer and N,N-donor planar phenanthroline bases as DNA groove binders. They were observing a dramatic shift of the photoactive wavelength to the PDT window on complexation of L-methionine to the d^9-copper(II) ion.

The investigation of sulfur atom containing ligands for copper complexes receives attention from bioinorganic chemistry as well as coordination chemistry. Cysteine–thiolate–copper interactions are important in electron-transfer protein centers [12] and sulfide–copper interactions as a Cu_4–S cluster occur in the enzyme nitrous oxide reductase [13,14]. Thioether methionine–copper interactions occur in the type 1 "blue" electron-transfer proteins [15,16] but also at the active site of certain monooxygenases which effect substrate C–H bond activation and oxygenation chemistry. Thus, an area of research interest is to shed further light on copper redox chemistry in the presence of thioether groups (as models for protein methionine residues) directed toward oxidative chemistry, i.e., emphasizing Cu^+/O_2 or Cu^{2+}/H_2O_2 reactions (but this problem is out of the scope of our interest).

The important role of mixed-ligand complexes in different systems is beyond question. Thus, these types of complexes are our continuous inspiration to assemble data on formation, stability and structure and on the mutual influence of two ligands derived

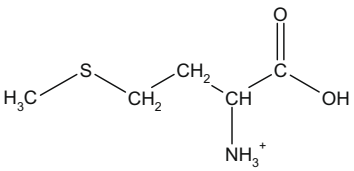
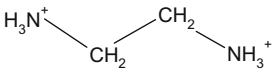
from amino acids (hydroxamic acids) or amino acids and different polyamines bound to the same metal ion [17–26], (selected papers). In this paper we report the results of the studies on molecular structures and reactivity of the mixed-ligand copper(II) complexes of simple polyamines and methionine.

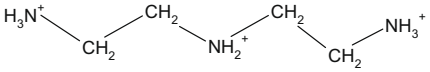
2. Experimental

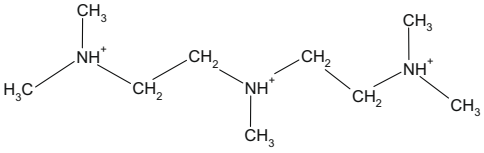
2.1. Materials

Ethylenediamine dihydrochloride (en 2HCl) and diethylenetriamine (dien) were purchased from Sigma–Aldrich Chemical Co, N,N,N′,N″,N″-pentamethyldiethylenetriamine (Me_5dien) from Fluka and D,L-methionine was obtained from Reanal (Hungary). All ligands were of analytical grade and were used without further purification. The exact concentrations of the ligand stock solutions used for potentiometric measurements were determined by the Gran's method [27]. Copper(II) chloride solution was purchased from Merck as a Titrisol concentrate for the preparation of standard solutions. The concentration of the metal ion stock solution was standardized by complexometric ethylenediaminetetraacetate (EDTA) titration. Carbonate-free potassium hydroxide solution (the titrant) was prepared and standardized against a standard potassium hydrogen phthalate solution. All solutions were prepared with deionized water. The formulae of the fully protonated form of the ligands used in this study are shown in Scheme 1.









2.2. Potentiometric measurements

The stability constants of the proton and copper(II) complexes were determined by pH-metric titration of 5 cm^3 samples in aqueous solutions. All the measurements were carried out at 0.2 mol dm^{-3} ionic strength (KCl) and 25.0 ± 0.1 °C using a constant-temperature water-bath. The titrations were performed with carbonate-free KOH solution of known concentration (ca. 0.2 mol dm^{-3}) under argon atmosphere over the pH range 2.0 ≈ 11.0 or until precipitation occurred. For the binary systems the ligand concentration was 4×10^{-3} or 8×10^{-3} mol dm^{-3} (because of precipitation the ligand concentration for the Cu^{2+}–Met system was 1, 2 or 4×10^{-4} mol dm^{-3}). The metal ion to ligand ratios were 1:1, 1:2, 1:4 and 1:8.

For the ternary systems the ratios of copper(II):en/dien/Me_5dien:Met were 1:1:1, 1:1:2, 1:2:1 and 1:2:2. Titrations were made on samples containing the copper(II) ion at 4×10^{-3} mol dm^{-3} prepared from $CuCl_2$ salt. The values of stability constants of the complexes formed in the binary systems were kept constant during calculating the potentiometric data of the ternary systems.

The pH-metric titrations were carried out with a Radelkis Op-208/1 instrument equipped with a combination pH electrode (SINGLE PORE, Hamilton) and an ABU-80 autoburette (Radiometer).The electrode system was calibrated by periodic titrations of HCl solution (7.5×10^{-3} mol dm^{-3} in KCl) against standard KOH solution as described earlier [26]. The pH-metric results were used to establish the stoichiometry of the species and to calculate the stability constants of the species formed in the ternary systems. The equilibrium calculations were performed by the HYPERQUAD 2006 computer program [28]. The reported standard deviations were calculated by assuming random errors.

The charges of the complexes have been omitted in the text and tables. However, for clarity, it should be mentioned here that the fully deprotonated form of amino acid (Met) is L^- while the amines (en), (dien) or (Me_5dien) are neutral.

Ligands	Abreviation
 D,L-methionine	$[H_2L]^+$
 ethylenediamine	$[H_2\text{-en}]^{2+}$
 dietylenotriamina	$[H_3\text{-dien}]^{3+}$
 N,N,N',N'',N''-pentamethyldiethylenetriamine	$[H_3\text{-}Me_5\text{dien}]^{3+}$

Scheme 1.

2.3. UV/Vis spectroscopy

A BECKMAN DU68 spectrophotometer and 2-cm quartz cells were used to record the electronic absorption spectra in the visible range at room temperature. The spectra were recorded digitally (0.5 nm step) in the range of 200–900 nm. The metal ion concentration prepared from $CuCl_2$ salt was 4×10^{-3} mol dm^{-3} for Vis and 1×10^{-4} mol dm^{-3} for UV. For the ternary systems copper(II):en:Met, copper(II):dien:Met and copper(II):Me_5dien:Met the concentration ratios were 1:2:1, 1:1:2 and 1:2:1, respectively. The concentration ratios of the reagents were chosen in order to achieve as high as possible concentration of the mixed-ligand species and to get the lowest concentration of the [Cu(Met)$_2$] species that precipitates in the solution. The measurements were carried out in water at different pH values, using 1, 2 or 3 cm path length quartz cuvettes. The net ligand-field absorption band of each mixed-ligand species was extracted from the absorption spectra applying the procedure described in Ref. [20].

2.4. EPR spectroscopy

Electron paramagnetic resonance (EPR) spectra were performed on a Bruker 300E X-band spectrophotometer equipped with a Bruker NMR gaussmeter ER 035M and a Hewlett–Packard frequency counter HP 5350B at 77 K in water/ethyleneglycol (4:1 v/v) solution. The EPR parameters were calculated by computer simulation of the experimental spectra using Bruker's WIN-EPR SIMFONIA Software Version 1.25. The metal ion concentration and the metal ion to ligands molar ratios were the same as those used in the electronic absorption spectra.

3. Results and discussion

3.1. Acidity of the ligands and Cu^{2+}-complexation for the binary systems

The values of the protonation constants for the studied ligands and the stability constants of the complexes formed in the binary systems were re-determined under the same experimental conditions as those applied for the ternary systems. The obtained results for the ligands [19,22,25,29] and for the binary systems Cu^{2+}–en [30–32], Cu^{2+}–dien [20,22], Cu^{2+}–Me_5dien [23,29,30] and Cu^{2+}–Met [19,30,33–35] are in good agreement with the literature data.

The fully protonated form of en contains two dissociable protons (H_2L^{2+}), one at each amino group $-NH_3^+$, while dien and Me_5dien (H_3L^{3+}) are able to release three protons in the whole pH range. Met (H_2L^+) has two dissociable protons that dissociate off the ligand in the measurable pH range. The carboxylic function is depro-

Table 1
Cumulative formation constants (logβ), derived equilibrium constants (log K) and characteristic parameters for the stability of complexes formed in the ternary systems Cu^{2+}–amine (en, dien or Me_5dien)–D,L-methionine at 25 °C and I = 0.2 mol dm^{-3} (KCl). (Charges are omitted for simplicity).

tonated in the acidic pH range, whereas the amino group dissociates in the basic solution [19].

In the Cu^{2+}–Met system the complexation process starts at pH 2.5. $[Cu(Met)]^+$ is predominant species in the solution in the pH range about 4–5. A further increase in pH leads to the $[Cu(Met)_2]$ complex formation. This is accompanied by the changes in d–d transition energies. The values of λ_{max} received at the maximum concentration of the $[Cu(Met)]^+$ (700 nm) and $[Cu(Met)_2]$ (λ_{max} = 623 nm) species are very similar to these found for $[Cu(\alpha\text{-ala})]^+$ (690 nm) and $[Cu(\alpha\text{-ala})_2]$ (λ_{max} = 618 nm), respectively [36]. Furthermore, the EPR parameters of the spectra observed for the $[Cu(Met)]^+$ species at pH 3.3 in the liquid and frozen solution are close to those observed for $[Cu(\alpha\text{-ala})]^+$ at pH 4.68 (Table 2). This data indicate that the amino nitrogen atom and the carboxylate oxygen are the major binding sites in both species $[Cu(\alpha\text{-ala})]^+$ and $[Cu(Met)]^+$. Such coordination mode without the involvement of the thioether sulfur of Met in the coordination to the copper(II) ions was also postulated on the basis of the IR spectra [35]. Although there is a wide range of studies focused on Cu^{2+} binding to a variety of peptides containing methionyl residue that revealed the possibility of S–Cu^{2+} interaction [24,37–39], methionine itself was reported to act as a tridentate ligand for copper(II) ions only at low temperatures and at low pH values [40].

3.2. Cu^{2+}-complexation for the ternary systems

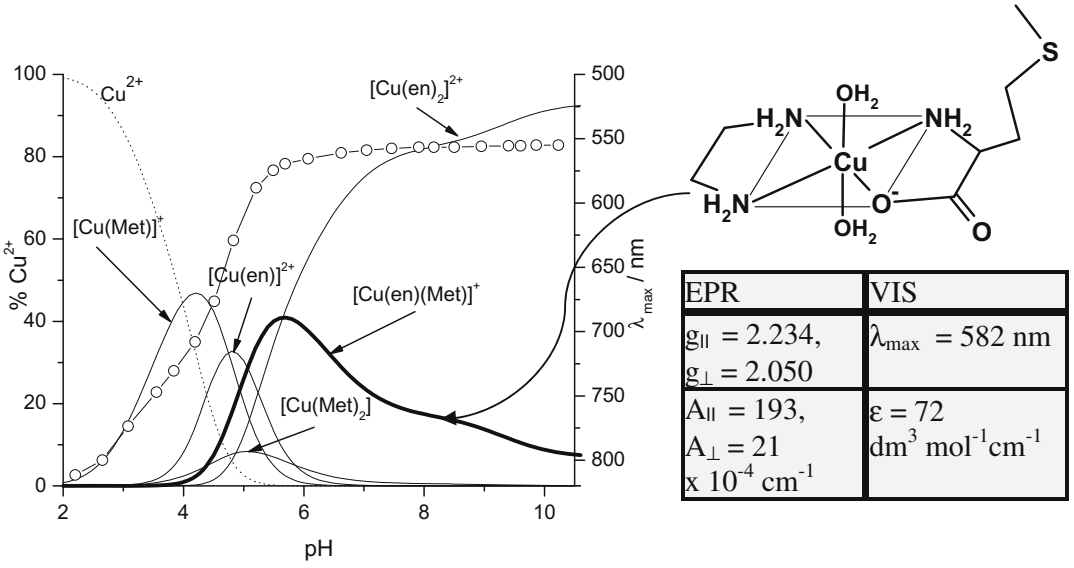
The four-component equilibria can be described as:

$$pM + q(A) + r(Met) + sH \rightleftharpoons M_p(A)_q(Met)_rH_s$$

where *p*, *q*, *r* and *s* are the stoichiometric coefficients corresponding to the metal ion, Cu^{2+}, A (A = en, dien or Me_5dien), Met, and H, respectively; charges are omitted for simplicity.

The overall formation constants are defined as:

$$\beta_{pqrs} = [M_p(A)_q(Met)_rH_s]/[M]^p[(A)]^q[(Met)]^r[H]^s$$



The equilibrium models for ternary systems and corresponding stability constants giving the best fits of the pH-metric titration curves are presented in Table 1. According to these data, only one type of mixed-ligand species with stoichiometry $[Cu(A)Met]^+$ is formed in all ternary systems.

The binding strength between Met and copper(II) ions in the presence of polyamine can be evaluated from the computed values β_{pqrs} according to the equation: $\log K_{Cu(A)Met} = \log\beta_{Cu(A)Met} - \log\beta_{Cu(A)}$ (Table 1 row 2). The derived equilibrium constant, $K_{Cu(A)Met}$, shows how tightly Met is bound to the simple $[Cu(A)]^{2+}$ complex. Similarly as it was observed for the ternary systems of the same polyamines and L-histidine in copper(II) solution, the stepwise stability constants of the mixed-ligand species involving tridentate dien and Me_5dien are much lower than for the species containing bidentate en [41].
