With the discovery of the dynamic polarisation of nuclei[119-121] (the Overhauser–Abragam effect) Fremy's salt unexpectedly acquired exceptionally important practical value[122-129]. The Overhauser effect, which forms the basis of the double nuclear–electron resonance method, allows the hyperfine structure of EPR spectra of extremely dilute solutions of free radicals to be investigated in weak magnetic fields, where the usual EPR method is insufficiently sensitive.

Aqueous solutions of Fremy's salt are now being used both in the USSR and abroad for the construction of highly sensitive nuclear precession magnetometers[125-128].

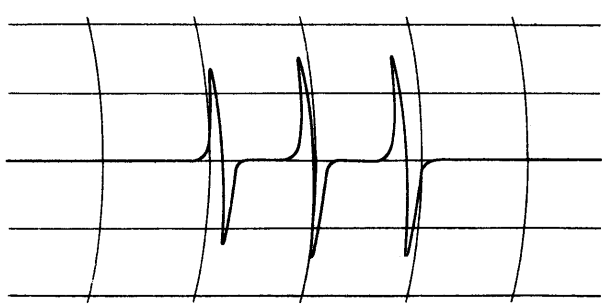

Fig. 2. The EPR spectrum of a chloroform solution of Fremy's salt.

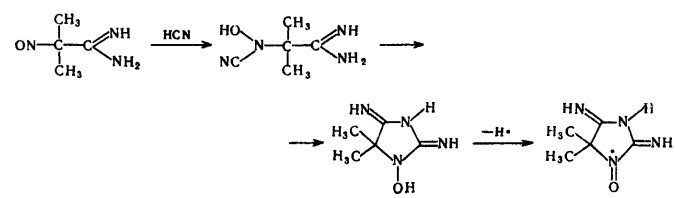
Fremy's salt has found an important application as the working material in "Maser" type devices[129] and also for studying the nature of molecular motion and the microstructure of liquids[130] by the spin-echo method[131,132].

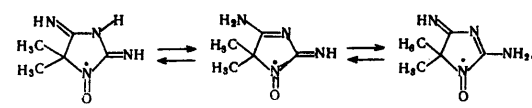
4. NITROXIDES

The paramagnetic compounds of this class are often called in the literature free radicals of quadrivalent nitrogen. The first organic radical of quadrivalent nitrogen was obtained in 1901 by Piloty and Schwerin[133] by the scheme:



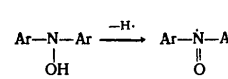
It is a brick-red substance, known as porphyrexide¶, which is reminiscent of nitrogen dioxide and Fremy's salts in its chemical properties. Moreover, porphyrexide readily displaces chlorine from hydrochloric acid, reacts with nitric acid, with alkalis, and also with chlorine to give mono- and di-chloroporphyrexides[134]. The possibility that some of these reactions take place without use of the free valency is not ruled out. Unfortunately neither the structure nor the paramagnetism of the porphyrexide derivatives was established.

Later magnetic susceptibility[135] and EPR spectroscopic studies[136,137] confirmed the free-radical nature of porphyrexide as a nitrogen(IV) compound. The EPR spectrum of porphyrexide is a triplet with a separation of 10 Oe between components, but the hyperfine structure of the components of the triplet has not been interpreted unambiguously. Hausser assumes[138] that the complexity of the hyperfine structure can be explained by the existence of an equilibrium between a few valence-tautomeric† forms in porphyrexide solutions:



In all the tautomeric structures of porphyrexide the bond between the nitrogen and the oxygen is semipolar or donor, which undoubtedly corresponds to a lower (stable) energy level due to possible formation of a conjugated diene or triene system of bonds by which the unpaired electron may be delocalised.

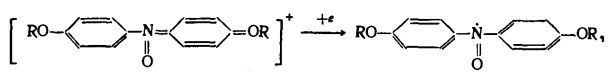
The individual diaryl nitroxides can be sufficiently reliably obtained by one of three methods — by careful oxidation of the diaryl hydroxylamines[139]:



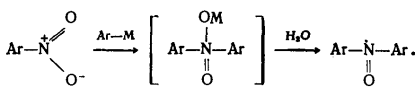
¶ Because its colour is similar to that of murexide (ammonium purpurate).

† [sic]. The author means tautomerism, not valency-tautomerism (Ed. of Translation).

by single-electron reduction of corresponding alkoxyl derivatives of the oxides of diarylammonium salts with perchloric acid [140]:



and by the action of organometallic compounds on nitro-compounds [141]:



The radicals of this class are red, crystalline compounds, stable in air. An important property of these substances is their ability to retain paramagnetism even at very low temperatures (-60°C).

The high stability of aromatic nitroxides permits their detection in a different type of oxidising system which includes aromatic amines,

Hoskins [142] observed the EPR spectrum of diphenyl nitroxide on passing oxygen through a hot mixture of toluene, alcoholic alkali, and diphenylamine. The catalytic oxidation of solutions of aromatic derivatives of naphthylamine, methylaniline, aniline, and phenothiazine also led to the appearance of corresponding EPR signals [143]. Apparently, stable nitroxides can be obtained from a large number of aromatic amines and are widely used as antioxidants and polymerisation inhibitors. EPR has been used to study the oxidation of many aromatic amines in the liquid phase [144,145]. However, it must be borne in mind that the EPR spectrum does not always give unambiguous information about the chemical structure of the oxidation product.

The preparation of the pure free radicals of this class is known to be difficult, which explains why only a few diaryl nitroxides have been isolated in the free state during the last fifty years (Table 1).

The stability of the diaryl nitroxides depends on various factors, including the electronic and steric effects of the substituents, the overall symmetry of the chemical species, the nature of the crystal lattice of the material, etc.

Of the three possible structures for diphenyl nitroxide, the first and last correspond to the maximal gain in energy due to conjugation of the nitrogen–oxygen bond with the aromatic system:

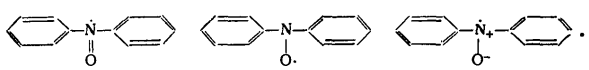


TABLE 1. Individual diarylnitroxides

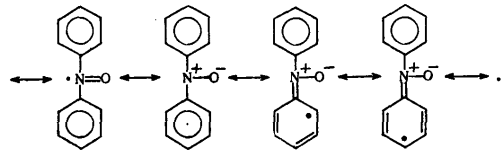
The hyperfine structure of the EPR spectrum of diphenyl nitroxide [172] showed that it can be described with the aid of several electronic structures of covalent and ionic type, the relative contribution of which depends on the polar properties of the medium.



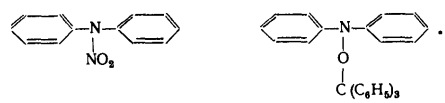
The hyperfine structure of the EPR spectrum of diphenyl nitroxide (Fig. 3) consists of three groups of lines due to the splitting of the level of the unpaired electron at the nitrogen nucleus. Each group is divided into a large number of components owing to delocalisation of the unpaired electron by the π-orbital system of the aromatic nuclei and its interaction with the protons [173].

An analysis of the spectroscopic parameters shows that ~40% of the spin density is at the nitrogen atom, 30% at the oxygen, and 30% at the *ortho*- and *para*-positions of the aromatic nuclei [153].

The dipole moments [155,174], the intensity of the colour, and the reactivity of the homologues and derivatives of diphenylnitroxide are consistent with these conclusions.

Wieland and his many students [175] have made the outstanding contributions to the study of the reactivity of diaryl nitroxides.

Aromatic nitroxides rapidly combine at the nitrogen and oxygen with nitrogen(II) oxide and triphenylmethane to form the corresponding derivatives [139]:



The principal interest lies in the reaction of diphenyl nitroxide with nitrogen dioxide, which leads to the formation of a new free radical, 4,4′-dinitrodiphenylnitroxide [147,176]:

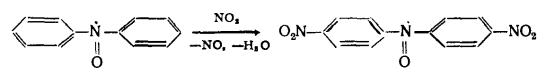


Fig. 3. The EPR spectrum of a benzene solution of diphenyl nitroxide.

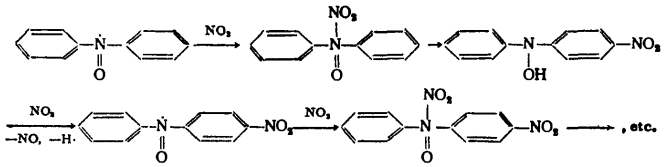
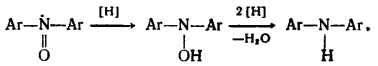
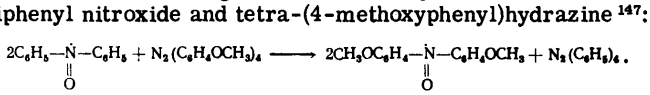
Wieland and Roth[146] demonstrated the complexity of this reaction, which takes place through a series of successive stages‡:



Nitroxides are readily reduced by hydrogen iodide, zinc dust, hydrazine, tin(II) chloride, sulphurous acid, hydrogen sulphide, and hydrogen in the presence of hydrogenation catalysts:



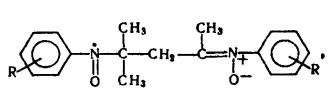
An unusual exchange reaction takes place between diphenyl nitroxide and tetra-(4-methoxyphenyl)hydrazine[147]:



A similar exchange reaction was observed by Möbius and Schneider[177] between 2,2-diphenyl-1-picrylhydrazyl and the peroxide radical[177].

In recent years much attention has been paid to the study of isotropic hyperfine structure parameters of the EPR spectra of diaryl nitroxides. Usually the liquid solutions of these radicals at concentrations $< 10^{-3}$ M show, in addition to the nitrogen triplet, a rich hyperfine structure due to the delocalisation of the unpaired electron at the aromatic nuclei and its reaction with the various *ortho*- and *para*-substituents[157]. For example, the EPR spectrum of bis-(4-methoxy-2,6-dimethylphenyl) nitroxide (Fig. 4) consits of three groups of lines reflecting the interaction of the unpaired electron with the nitrogen nucleus (a_N = = 10 ± 0.3 Oe). Each group has hyperfine structure components with a binomial distribution of intensities due to the splitting of the electronic levels at the 12 protons of the methyl groups and 4 *meta*-protons of the aromatic ring (a_H = 0.8 ± 0.1 Oe). Hence the splitting of the level of the unpaired electron at the methyl groups of the aromatic nuclei serves as a direct experimental proof of the phenomenon of hyperconjugation. Fig. 5 shows the scheme of the interaction of the π-orbital system containing an unpaired electron with the protons of the methyl group.

A special class of aromatic nitroxides is formed by the radicals in which the nitrogen–oxygen group is conjugated with only one aromatic nucleus. A long-known representative of this group is the so-called Banfield and Kenyon's radical, which can be obtained by oxidation of the condensation product of acetone and phenylhydroxylamine[178,179]. Several individual compounds of this class have been described[180,181]:



where R = H, *o*-CH_3, *m*-CH_3, *p*-CH_3, *m*-F, *p*-F, *m*-Cl, *p*-Cl, *m*-Br, *p*-Br, *m*-NO_2.

‡ Analogous reactions can apparently also occur with porphyrexide, mentioned earlier.

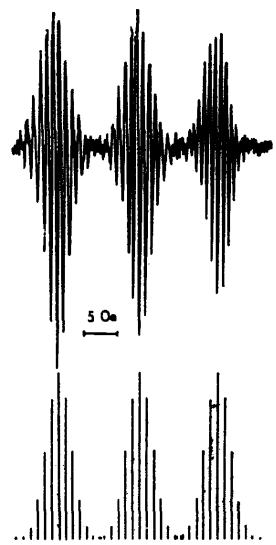


Fig. 4. The EPR spectrum of a benzene solution of bis-(4-methoxy-2,6-dimethylphenyl) nitroxide, with the theoretically calculated spectrum (below).

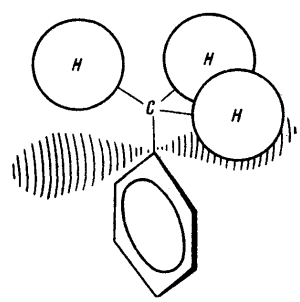

Fig. 5. Scheme of the overlap of the electron clouds of the hydrogen atoms of the methyl group with the π-orbital of the aromatic ring.

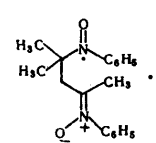
The well-resolved EPR spectrum of the Banfield and Kenyon radical was obtained with an oxygen-free tetrahydrofuran solution of the substance. Each of the three quadruplets of the hyperfine spectrum is split into seven lines with a non-binomial distribution of the intensities (Fig. 6).

Detailed analysis of the spectrum showed hyperfine interaction of the unpaired electron with the most removed methyl group, which conformationally can approach closely to the aromatic nucleus containing the unpaired electron[182]:



The other radicals in the series which are known as individual compounds include *trans*-decalyl phenyl nitroxide (I),[183–186] t-butyl 2,6-dimethoxyphenyl nitroxide (II),[141] and 2,6-dimethoxyphenyl 1,1-dimethylbenzyl nitroxide (III).[141] All these substances are obtained by the action

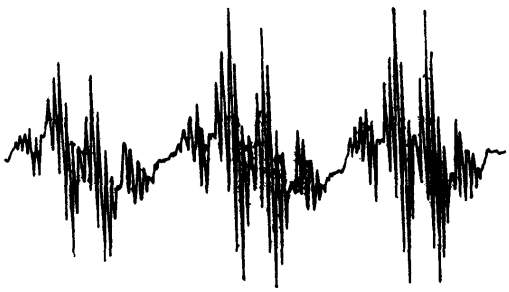


Fig. 6. Hyperfine structure of the EPR spectrum of the tetrahydrofuran solution of the Banfield and Kenyon radical.

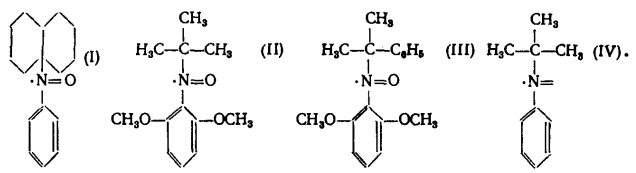
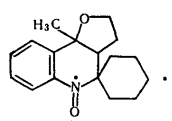
of organometallic compounds on the corresponding nitroso- or nitro-compounds:



(I) m.p. 83°C; (II) m.p. 101–102.5°C; (III) m.p. 77–78°C; (IV) —

Attempts to isolate from solution the individual compound t-butyl phenyl nitroxide (IV) were unsuccessful [141,187,188], despite its obvious structural similarity with (I)–(III).

A large number of aliphatic–aromatic nitroxides is known in solution, but there is not always sufficient basis for ascribing to them a definite structure [189,190]. Many stable nitroxides of the hydrogenated quinoline series were first studied in solution by Razuvaev and coworkers [191,192], but only one individual radical of this class has been obtained pure [193].

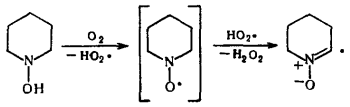


m.p. 101–101.5°C

The hyperfine structure of the EPR spectrum of this radical is a noniplet with ratio of intensities 1 : 2 : 1 : 1 : 2 : : 1 : 1 : 2 : 1, due to the splitting of each component of the nitrogen triplet (a_N = 11.8 Oe) into three lines by the interaction of the unpaired electron with the two protons at positions 6 and 8 of the aromatic ring (a_H = 2.9 Oe).

5. IMINOXYLS

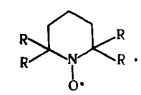
Free iminoxyl radicals§ is the name given to compounds of oxygen(I), which are formed as intermediates in the oxidation of secondary saturated amines [194] and hydroxylamines, for example,



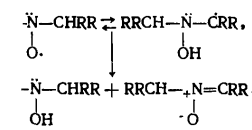
§ This term emphasises the genetic connection of iminoxyls with other radicals of oxygen(I), for example, with hydroxyl (H—O·), alkoxyl (R—O·), and aroxyl (Ar—O·). The terms "amine oxide", "nitroxide", and "aminoxy-radical" are less convenient, as they do not reflect the free-radical nature of these species and contradict the rules for the official nomenclature of organic compounds.

In contrast with the nitroxides it is essential that the NO group of the iminoxyls does not participate in the formation of a conjugated system of multiple bonds, and therefore that the unpaired electron apparently remains localised on the oxygen to a considerable extent.

The existence of free iminoxyls in solutions was first postulated by Rogers and coworkers [195,196]. Rogers assumed that free iminoxyls not possessing α-hydrogen atoms should be stable free radicals. For example, the iminoxyl of piperidine is unstable, but those completely alkylated in positions 2 and 6 of the heterocycle should be stable:



Apparently the substituents R can be not only organic residues, as it is important that the iminoxyls should not be capable of tautomeric conversions of the type:



Lebedev and Kazarnovskii obtained the simplest free radicals of this class by the oxidation of 2,2,6,6-tetramethylpiperidine [197]. The EPR spectrum of this radical in benzene is a triplet with a hyperfine splitting constant of ~ 15.6 Oe [198,199]. Samitov and Lebedev [200] ascribe the anisotropy of the spectrum to contributions from different quantum states in the sublevels of the hyperfine structure and the influence of the quadrupole moment of the nitrogen nucleus [200].

By analysing the parameters $\psi^2(O)$, a_N, and a_H of the EPR spectra of solutions of free iminoxyls in benzene, obtained by oxidising a series of secondary amines and hydroxylamines [201,202], Coppinger and Swalen concluded that the most plausible electronic structure of these radicals corresponds to the formulae:

Hence the valence state of the nitrogen atom, similar to the analogous state of nitrogen in substituted hydroxylamines [66], corresponds to the formula:

$$N[(1s)^2\ (2s+\delta 2p)^2\ (2p+\delta' 2s)^2\ (2p+\delta'' 2s)].$$

The $(2p+\delta' 2s)$ atomic orbitals, being equivalent, should form localised bonding orbitals with the hybrid sp^3-orbitals of the carbon atoms. The $N(2p+\delta'' 2s)$ atomic orbital will overlap with the corresponding orbital of the oxygen atom, forming a third localised orbital.

The EPR spectrum of dialkyliminoxyls in solutions exhibit hyperfine structure due to the interaction of the spin of the unpaired electron with the nuclear spins of the nitrogen atom and the hydrogen atoms adjacent to it (Fig. 7). Table 2 gives the main parameters of the hyperfine structure in the EPR spectra of the free iminoxyls in dilute benzene solutions.

The hyperfine splitting from the nitrogen and hydrogen nuclei is explained by the principal state of the radical's

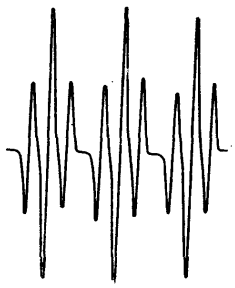


Fig. 7. Hyperfine structure of the EPR spectrum of a benzene solution of di-s--butyl iminoxyl.

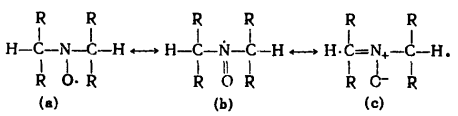
TABLE 2. Fundamental parameters of the EPR spectra of free iminoxyls [201].

Formula	a_N	a_H	Number of components	Formula	a_N	a_H	Number of components
$(CH_3CH_2)_2NO$	15.5	10.6	15	$(CH_3CH_2CH)_2NO$	15.4	4.1	9
$(CH_3CH_2CH_2)_2NO$	15.5	10.6	15	CH_3			
$(CH_3CH_2CH_2CH_2)_2NO$	15.7	10.5	15	$(C_6H_5CH_2)_2NO$	15.6	9.5	15
CH_3				$(CH_2{=}CH{-}CH_2)_2NO$	15.5	9.3	15
$(CH_3CH)_2NO$	16.0	4.7	9	$CH_2CH_2CH_2CH_2CH_2NO$	15.4	11.7	15

being capable of representation with the participation of a few valence-isomeric structures [203,204]:



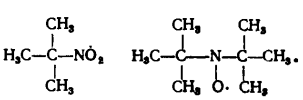
Closely related to the dialkyliminoxyls is a class of labile alkylidene iminoxides of the general formula:

The first radical of this type was observed on subjecting single-crystal dimethyl glyoxime to γ-radiation [205-207].

Many alkylidene iminoxyls were studied in liquid solutions by a flow method [208], using cerium ammonium nitrate [209] and lead tetra-acetate [210] as oxidants.

Most alkylidene iminoxyls are extremely unstable and in the liquid phase many of them have a lifetime measured in fractions of a second, therefore none of the compounds of this class can be obtained in the pure state.

In 1961 Hoffmann and coworkers, using Maki's method [211], observed two EPR spectra (Fig. 8) during the polarographic reduction of 1,1-dimethyl-1-nitroethane, one of these spectra showing the appearance of an unstable anion-radical, and the other belonging to the stable di-t-butyl iminoxyl [212,213]:



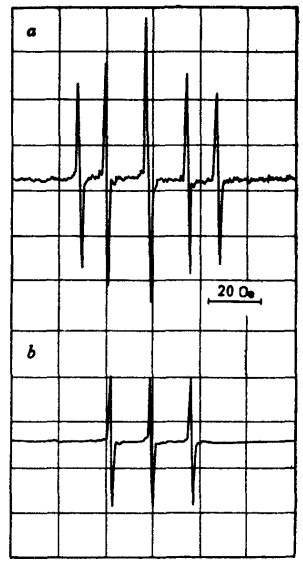


Fig. 8. EPR spectra:
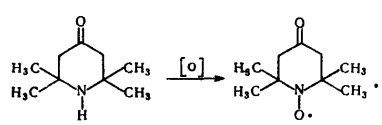
a) mixture of the anion radical of 1,1-dimethyl--1-nitroethane and di-t-butyl iminoxyl; *b*) di-t--butyl iminoxyl (in 1,2-dimethoxyethane).

Di-t-butyl iminoxyl, obtained pure in the reaction of 1,1-dimethyl-1-nitroethane with sodium, is a red liquid, stable in air up to 120°C. [214,215] It is interesting that in the well-resolved hyperfine structure of the EPR spectrum of this radical in addition to three fundamental lines a system doublets — satellites of low intensity — can be observed owing to the interaction of the unpaired electron with the nuclei of the ^{13}C carbon isotope of the methyl groups [216].

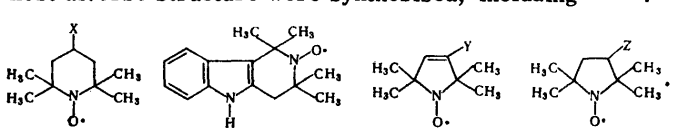
On heating a solution of phorone with a mixture of ammonium nitrate, sodium hydroxide, Trilon B, hydrogen peroxide, and sodium tungstate [217] Razuvaev and coworkers observed that for a few weeks this solution gave a triplet signal which they assumed to belong to a stable radical of triacetonamine formed in the solution [218].

Using preparative thin-layer chromatography on aluminium oxide to separate the paramagnetic mixture, Neiman and coworkers actually separated pure crystalline 2,2,6,6--tetramethyl-4-oxo-piperidine 1-oxide [219].

A new iminoxyl was obtained in high yield by the direct catalytic oxidation of triacetonamine [220]:



Within a short time many individual iminoxyls of the most diverse structure were synthesised, including [221-225]:



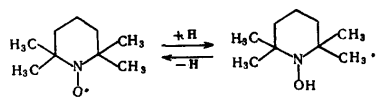
All the free radicals of this series exhibit a singlet when pure, but in solutions they have triplet EPR spectra with a hyperfine splitting constant of ~ 15.5 Oe.

In addition to the ultraviolet, infrared, and EPR spectra, the volatility[226], heat of combustion, and dipole moments of the simplest free iminoxyls have been studied[227].

It is significant that the increase in dipole moment in a free radical, compared with the corresponding hydroxylamine, can in the first approximation be explained by the interaction of the unshared electron pair of the nitrogen atom with the partly free p-orbital atom of the oxygen. Displacement of one of the electrons of the unshared pair of the nitrogen atom to the oxygen atom brings both an increase in the dipole moment of the nitrogen–oxygen bond, and the appearance of spin density at the nitrogen atom:

Comparison of the dipole moments of the radicals and of the corresponding hydroxylamines allowed the distribution of the spin density of the unpaired electron at the N–O bond to be evaluated approximately. The spin density was 27% at the nitrogen atom and 73% at the oxygen atom. Hence the most probable structure of the free iminoxyls is evidently the Coppinger structure[201].

The reduction of free radicals at a mercury dropping electrode[228], hydrogenation[229], and reaction with an alcoholic solution of phenylhydrazine[230] or with an acid solution of a substituted p-phenylenediamine[231] – all these processes lead to the formation of the corresponding substituted hydroxyalamines:

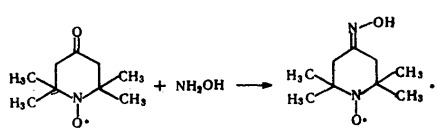


Free iminoxyls readily react with alkyl radicals, which can be used for inhibiting chain radical processes[232–236].

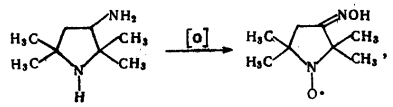
Hence all the free radical reactions of iminoxyls which have been studied proceed exclusively with formation of oxygen derivatives of substituted hydroxylamines, which is also some proof of the predominant localisation of the unpaired electron at the oxygen atom in accordance with the Coppinger structure[201]. However, no proof yet exists that such reactions cannot be accompanied by redistribution of the electron density on the approach of the attacking reagent.

The most notable property of free radicals of this series is their reactions without use of the free valency. This type of reaction can undoubtedly be assumed in various types of chemical and biological systems, especially with high-molecular weight compounds. Nevertheless an unambiguous demonstration that radicals react without participation of the unpaired electron is not available.

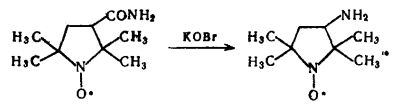
In 1962, Neiman and coworkers first gave an unambiguous proof of the reaction of stable iminoxyls without use of the free valency[237,238], for example¶:



The discovery and organised study of all the possible reactions of iminoxyl radicals without use of the free valency[239–242] defined the limits of its usefulness and this reaction was made a reliable instrument for the synthesis of previously inaccessible free radicals. As an example, it was impossible to obtain an amine radical by oxidising aminopyrrolidine,

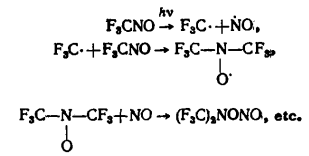


whereas a reaction which did not involve the free valency readily led to the desired product[243]:



Free iminoxyl radicals very soon acquired great popularity and became the object of steady attention from chemists, physicists, and biologists[244–249].

A study appeared in 1957 which showed that the photochemical decomposition of trifluoronitrosomethane leads to the intermediate formation of bis(trifluoromethyl)-iminoxyl radicals, the existence of which can be judged from their conversion products[250].



Perfluorinated iminoxyl radicals were observed by the EPR method during the polymerisation† of perfluoroethylene in the presence of trifluoronitrosomethane[251] (Fig. 9).

Free bis(trifluoromethyl)nitroxyl was obtained in 1964 by the action of silver oxide on bis(trifluoromethyl)hydroxylamine[253]:

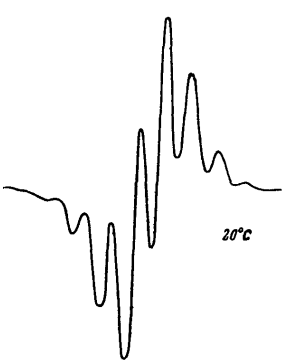


Fig. 9. EPR spectrum of the perfluoroiminoxyl radical.

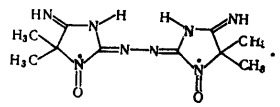
¶ We must remember that Fremy's salt reacts with hydroxylamine by use of the free valency[110].

† Almost simultaneously the hypothesis was propounded that the initiation of the copolymerisation of trifluoronitrosomethane and fluoroalkenes takes place by an anionic mechanism[252].

The same radical was recently obtained pure by a group of Soviet scientists [254,255] who made a detailed study of its properties. It is a violet-pink gas, which readily condenses to a diamagnetic dimer containing ~ 1.5% of the free radical. From the electronic structure of this radical it apparently occupies a position intermediate between the iminoxyls and Fremy's salt.

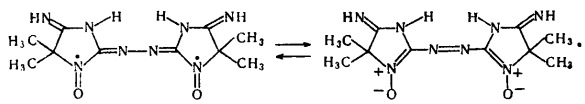
6. INDIVIDUAL POLYRADICALS

As long ago as 1903, Piloty and Vogel, by the reaction of porphyrexide with hydrazine and then with potassium cyanoferrate(III), first obtained a dark blue crystalline compound, which they called porphyrindine [256]:

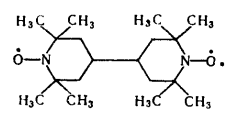


The free-radical nature of this substance was subsequently reliably established by measurement of its magnetic susceptibility [257].

The diamagnetic principal state of porphyrindine is in thermodynamic equilibrium with the excited paramagnetic state which lies only a little higher. This equilibrium shifts in favour of the paramagnetic state on raising the temperature [258]:

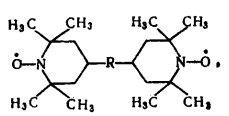


The first representative of the kinetically stable biradicals of the iminoxyl class was obtained during the oxidation of 2,2,2′,2′,6,6,6′,6′,-octamethyl-4,4′-bipiperidyl [259]:



During the study of this substance the discovery was made of the extremely interesting phenomenon of conformational electronic exchange, which is shown in the quintuplet nature of the EPR spectrum (Fig. 10).

To show the mechanism of the interaction of the unpaired electron with the nuclear spins of both nitrogen atoms a series of individual biradicals of diverse chemical structure was synthesised [260]:



where R = OCOO, NHCONH, $OCOC_6H_4COO$, $OCONH[CH_2]_6$. .NHCOO, or $OCO[CH_2]_nCOO$ (n = 0–8). The main method of preparation of the biradicals was by reaction of radicals without use of the free valency. It was found that the effectiveness of the conformational spin–spin interaction is determined not only by the length but also by the flexibility

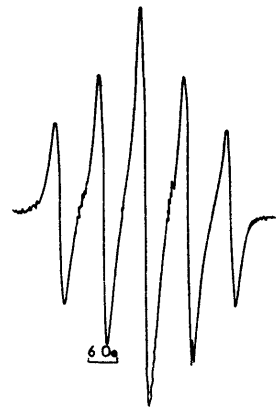


Fig. 10. Hyperfine structure of the EPR spectrum of the first kinetically stable bis--iminoxyl (chloroform solution).

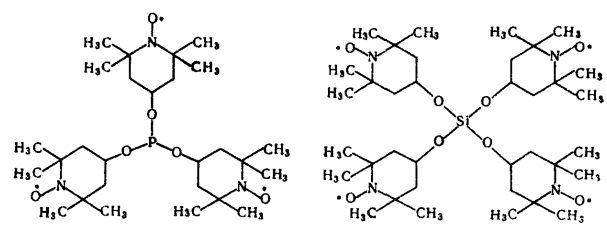
of the bonding chain R, for example, on replacing a polymethylene bridge by p-phenylene, the effect disappeared and the EPR spectrum again became a triplet‡.

A study of free biradicals of the iminoxyl class by the EPR method at different temperatures and in various solvents showed that spin–spin exchange interaction takes place during conformational collisions of two paramagnetic fragments of bis-iminoxyl [266].

A reaction without use of the free valency was successfully used in the syntheses of the first individual free tri- and tetra-radicals of the iminoxyl type [267,268], for example:



The EPR spectra of the triradicals are septets of lines due to the interaction of unpaired electrons with the magnetic moments of three nitrogen nuclei, and for the quadriradicals there are nine components with a separation of ~ 4 Oe between them.

The study of the exchange interaction in polyradicals at different temperatures showed that there is only paired interaction with the neighbouring paramagnetic fragments and during this all the spins of the polyradicals participate in the electronic exchange. In this way instances were first discovered in which the number of unpaired electrons participating in the exchange exceeds two. This brings about the successive transfer of the excitation from one spin to another through the paired collisions. Here we encounter the unusual "memory" of the electron, which is capable of giving information about excitation with a definite rate along the chain of paramagnetic fragments [269].

‡ The EPR spectra of triarymethyl biradicals [261–265] are not significantly different from the analogous spectra of free triarylmethyls.

REACTIONS OF EPOXYALKANES TAKING PLACE WITH EXPANSION OF THE OXIRAN RING

L. N. Grobov, A. P. Sineokov, and V. S. Etlis

CONTENTS

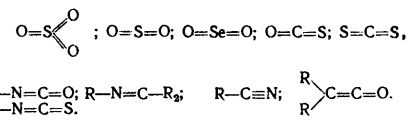
1. Introduction 671
2. Reactions with SO_3, SO_2, and SeO_2 671
3. Reactions with carbonyl sulphide and carbon disulphide 672
4. Reactions of epoxyalkanes with isocyanates 673
5. Reactions of epoxyalkanes with compounds containing $\rangle C{=}N-$, $-C{\equiv}N$, or $\rangle C{=}C{=}O$ groups 674
6. Reactions of epoxyalkanes with isothiocyanates 675

1. INTRODUCTION

Epoxyalkanes are known to be very reactive; their many reactions have been adequately studied and described in the literature [1-4]. Most of the reactions of epoxyalkanes are accompanied by opening of the epoxide ring. Reactions accompanied by enlargement of the ring have been much less studied. The best known among these reactions are the dimerisation of the oxides and the reaction of the oxides with aldehydes and ketones, leading to the production of dioxolans.

The reactions of the oxides with carbon dioxide, leading to cyclic esters of carbonic acid, have also been studied. This process has been carried out on an industrial scale. The alkylene carbonates obtained find application in organic synthesis, as a solvent and for the production of polymers. The methods of making alkylene carbonates, their properties, and applications have been reviewed [5,6].

Cyclic products have now been obtained by the reaction of oxides with certain other compounds containing multiple bonds. Such compounds are:



2. REACTIONS WITH SO_3, SO_2, AND SeO_2

The epoxyalkanes react with the anhydrides of some inorganic acids to form cyclic esters.

Thus ethylene sulphate was obtained by the reaction of sulphur trioxide with ethylene oxide in dioxan. It is suggested that initially a coordination compound of sulphur trioxide with ethylene oxide is formed, which then rearranges into the ester [7]:

1,4-Oxathian can be used instead of dioxan [8]. Cyclic alkylene sulphates with 2–6 carbon atoms are obtained by the reaction of corresponding epoxyalkanes with sulphur trioxide in the gas phase at 140°. Sometimes the reagents are diluted with inert gas. 0.1–7.5 moles sulphur trioxide per mole oxide are taken. The cyclic alkylene sulphates formed are removed from the reaction mixture by sublimation [9].

The addition of sulphur dioxide to epoxyalkanes has been studied in greater detail. When sulphur dioxide is passed into ethylene oxide at below 0°, a molecular compound of composition $C_2H_4OSO_2$ is formed [10]. It is used for sterilising soil, as its boiling point is about 20 deg above that of its components.

To obtain ethylene sulphite the reaction is carried out at a higher temperature, either without a catalyst or in the presence of various catalysts. When a catalyst is not used, the ethylene oxide and sulphur dioxide are mixed in the liquid phase and heated under pressure to 140°. The patent states that the reaction is almost complete [11].

Pyridine, amines, amides, phosphines [12], and also quaternary ammonium bases [13,14] have been proposed for use as catalysts in this process.

The polymers of ethylene sulphite formed in the presence of catalysts depolymerise on heating at 140–150°.[13,15] Propylene sulphite can also be obtained by the thermal decomposition of the polysulphite but poly(cyclohex-1,2-ylene sulphite) does not give a monomeric product but forms cyclohexanediol and cyclopentanecarbaldehyde.

The decomposition of polysulphites can also take place under the action of atmospheric oxygen, peroxides, and hydroperoxides, and also under the action of ultraviolet light even at room temperature. By initiating depolymerisation in this way, cyclohex-1,2-ylene sulphite was also obtained from the corresponding polysulphite[16].

The method can be used for making cyclic sulphites which are otherwise unobtainable. For example, 3-hydroxypropylene sulphite, previously unobtainable by other methods, was made by direct reaction of glycidol [2,3-epoxypropan-1-ol (Ed. of Translation)] with sulphur dioxide[14].

To increase the yield of ethylene sulphite, it is recommended that the reaction of ethylene oxide with sulphur dioxide should be carried out in ethylene sulphite or in a mixture of ethylene sulphite and its polymer[17].

Activated carbon, aluminium oxide, zinc chloride, copper(II) chloride, chromium(III) chloride, manganese(II) sulphate, and phosphates at 120–150° can also be used as catalysts for the reaction of ethylene oxide with sulphur dioxide. When active carbon is used (140–160°), dioxan is formed as well as ethylene sulphite (in 1:1 ratio)[18].

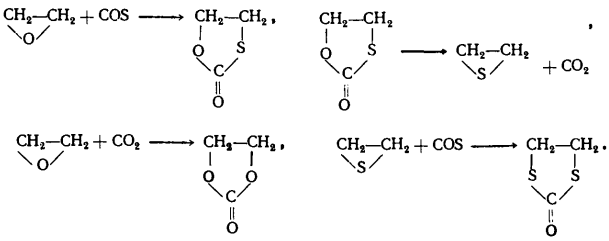
Dioxan is also formed in the thermal decomposition of poly(ethylene sulphite) obtained in the presence of salts of quaternary ammonium bases. Acetaldehyde and water are produced at the same time[14].

Another proposal for making cyclic sulphites is to pass gaseous epoxyalkanes with sulphur dioxide (molar ratio 1:2) under pressure over a catalyst at 200°. The pressure is chosen so that the reaction product is volatilised from the catalyst together with the unreacted reagents. The catalyst can be activated carbon, treated with alkali or silver nitrate and then alkali. Sulphur-resistant catalysts are also used, for example, nickel and/or tungsten sulphides. The cyclic ester is condensed from the effluent gas. Another possibility is to condense the ester product together with the unreacted substances and then separate the mixture by distillation[19]. von Woerden gives other methods of preparing cyclic sulphites and their properties[20].

In the presence of tetraethylammonium bromide, selenium dioxide also adds on to some epoxyalkanes to form cyclic esters of selenous acid[21]. The product of the reaction between selenium dioxide and 1,2-epoxycyclohexane could not be isolated pure. With trimethylene oxide a linear polymeric ester of selenous acid is apparently formed.

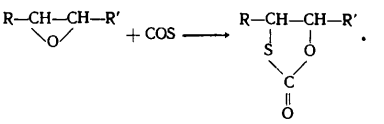
3. REACTIONS WITH CARBONYL SULPHIDE AND CARBON DISULPHIDE

The reactions of the sulphur analogues of carbon dioxide, carbonyl sulphide, and carbon disulphide with epoxyalkanes and the properties of products have been much less studied. At 150° under pressure in the presence of trimethylamine, ethylene oxide and carbonyl sulphide form a copolymer of ethylene *OS*-thiocarbonate and ethylene sulphide[22]; in the presence of tetraethylammonium bromide two products are formed: ethylene carbonate and ethylene *SS*-dithiocarbonate[23,24]. To explain their formation the following scheme has been suggested:



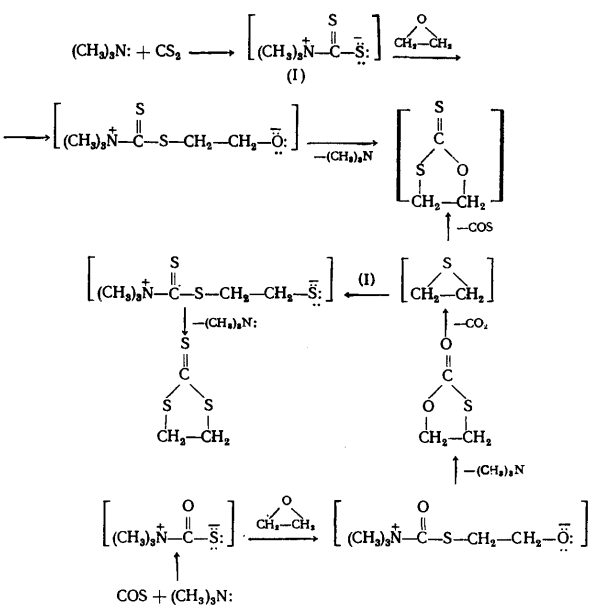
It has been shown that ethylene *OS*-monothiocarbonate in the presence of ethylene oxide and crystalline tetraethylammonium bromide actually decomposes into ethylene sulphide and carbon dioxide at 40–50°.[25]

In the reactions of propylene oxide, 3-chloro-1,2-epoxypropane[23,24], 1-chloro-2,3-epoxybutane, and 1,2-dichloro-3,4-epoxybutane with carbonyl sulphide only one product is formed, by the scheme:



Cyclohex-1,2-ylene oxide and symmetrical oxides such as 2,3-epoxybutane and 1,4-dichloro-2,3-epoxybutane do not react with carbonyl sulphide[26].

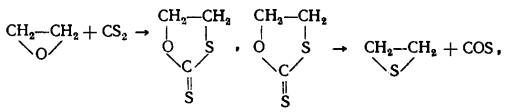
Carbon disulphide also reacts with epoxyalkanes with ring enlargement. In this way Durden and coworkers[27,28] obtained several alkylene trithiocarbonates. The reaction was carried out in the liquid phase under pressure of nitrogen with excess of the epoxyalkane. The maximal yield of ethylene trithiocarbonate was obtained at a carbon disulphide : ethylene oxide molar ratio of 1 : 2.5 and the presence of 0.5 mole % trimethylamine. Carbon dioxide and carbonyl sulphide are formed as side-products, the amount of carbon dioxide formed increasing with decrease in the carbon disulphide : alkene oxide ratio:

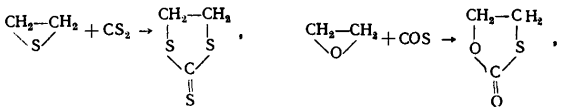


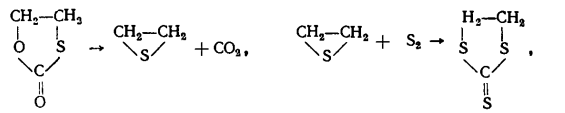
Ethylene sulphide, the intermediate formation of which is postulated in this mechanism, was not isolated from the reaction products.

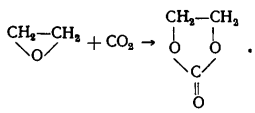
By the same method the authors obtained propylene trithiocarbonate, cyclohex-1,2-ylene trithiocarbonate, phenylethylene trithiocarbonate, and 4-cyanocyclohex-1,2-ylene trithiocarbonate.

The reaction proceeds differently when an equimolar ratio of the reactants is used. Ethylene oxide and carbon disulphide then form a mixture of ethylene trithiocarbonate and ethylene carbonate in the molar ratio 2:1.[29] Their formation can be represented by the scheme:[30]



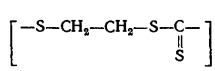




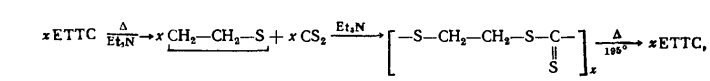


The absence of ethylene dithiocarbonate from the products, although it could be obtained by the reaction of the carbonyl sulphide formed in the process with the ethylene sulphide, suggests that the rate of reaction of the latter with carbon disulphide is much greater than the rate of reaction with carbonyl sulphide.

In connection with the proposed scheme of reaction, the authors made a detailed study of the reaction of ethylene sulphide with carbon disulphide. The reaction proceeded in the presence of triethylamine as catalyst. Temperature was found to greatly affect this reaction. Whereas ethylene trithiocarbonate is the sole product at 100°, at 25° it was accompanied by 37% of a copolymer of ethylene sulphide and carbon disulphide, of composition:



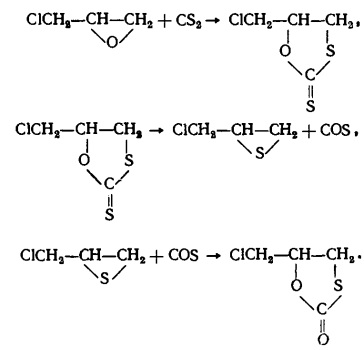
At 195–200° this copolymer decomposes, with formation of ethylene trithiocarbonate. All this can be represented by the scheme[29]:



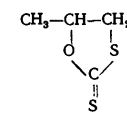
in which ETTC represents ethylene trithiocarbonate.

The decomposition of the ethylene dithiocarbonate obtained initially, which takes place in the presence of hydrogen peroxide and tetraethylammonium bromide, was also confirmed experimentally[31].

3-Chloropropylene *OS*-monothiocarbonate and 3-chloro-1,2-epithiopropane are formed in the reaction of 3-chloro-1,2-epoxypropane with carbon disulphide. Their formation can be represented by the following series of reactions:

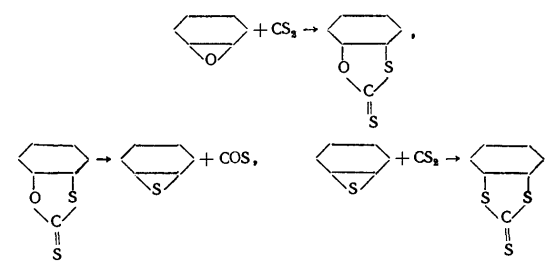


OS-Propylene dithiocarbonate



was obtained as the main product of the reaction of propene with carbonyl sulphide. A little ethylene sulphide was also isolated.

Cyclohex-1,2-ylene trithiocarbonate, a little *OS*-cyclohex-1,2-ylene dithiocarbonate, and carbonyl sulphide are formed in the reaction of 1,2-epoxycyclohexane with carbon disulphide:



For the reactions of alkylene thiocarbonates see Refs. 32–52.

4. REACTIONS OF EPOXYALKANES WITH ISOCYANATES

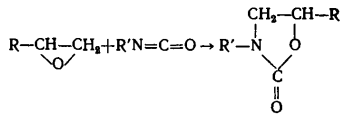
Ethylene oxide, propylene oxide, 2-phenyloxiran, and 3-chloro-1,2-epoxypropane bring about the trimerisation of isocyanates. Thus tri(phenyl isocyanate) was obtained by the reaction of ethylene oxide with phenyl isocyanate at room temperature and at 100°.[53] The trimerisation of isocyanates is accelerated in the presence of tertiary amines[54–57].

The catalytic action of oxides in the presence of bases is probably due to the formation of the bipolar ion

the existence of which has been shown experimentally[58].

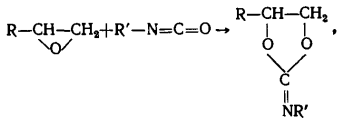
Substituted oxazolid-2-ones were obtained in high yield in the reaction of isocyanates with epoxyalkanes in the presence of tetraethylammonium bromide or potassium iodide

in dioxan, dimethylformamide, or acetonitrile at 150–200°:[54]

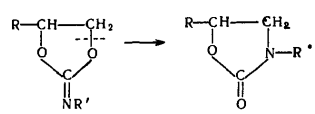


Oxazolid-2-ones were also obtained by the reaction of phenyl isocyanate and epoxides without a solvent at 180–200°.[59–61] Pyridine, tribenzylamine, zinc chloride, lithium chloride, iron(III) chloride, disodium phthalate, alkali, and lead naphthenate act as catalysts for the reaction. Carbonates or sulphites of 1,2-diols, and also cyclic carbonates of α-hydroxy-acids and their sulphite and nitrite analogues[59,61,62], can be used instead of epoxides in the reaction with isocyanates, when they decompose on heating to form the epoxyalkanes. Under the stated conditions, the 3,5-disubstituted oxazolid-2-ones are always formed, as the opening of the epoxide or carbonate ring takes place at the unsubstituted carbon atom[61]. 3-Phenyloxazolid-2-ones were isolated in high yield by the reaction of ethylene carbonate with isocyanate at 130–160° in the presence of *N*-methylmorpholine[63].

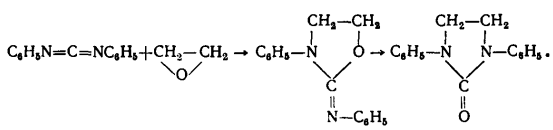
From the above, it follows that reactions between isocyanates and epoxides take place at the N=C bond of the isocyanate. However, Gulbins and Hamann[64,65] showed, by a detailed investigation of this reaction, that the first stage is the addition of the epoxyalkane at the C=O bond of the isocyanate with the intermediate formation of 2-phenylamino-1,3-dioxolane:



which under the conditions of the reaction rearranges into an oxazolid-2-one. This was demonstrated with the aid of a counter-synthesis. 2-Phenylamino-1,3-dioxolan was obtained from phenylimidocarbonyl dichloride and disodium glycollate, and on heating at 200° in the presence of lithium chloride it rearranged to an oxazolidone. A similar reaction takes place at 100° under the action of aluminium chloride[66]. The rearrangement takes place in such a way that the dioxolane ring is broken between the oxygen atom and the unsubstituted CH_2 group:

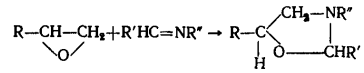


In their structure and reactivity carbodi-imides are reminiscent of isocyanates, therefore their reaction with epoxides or alkylene carbonates in the presence of lithium chloride or pyridine at 200° would be expected to yield substituted imino-oxazolidines. However, instead of these products cyclic ureas, derivatives of imidazolid-2-one, are isolated. As Gulbins and Hamann have shown[65], here initially an imino-oxazolidine is formed, which is converted into 1,3-diphenylimidazolid-2-one by breaking of the C–O bond:



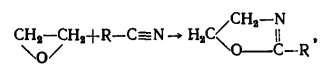
5. REACTIONS OF EPOXYALKANES WITH COMPOUNDS CONTAINING THE GROUPS >C=N–, –C≡N, OR >C=C=O

The reaction of epoxyalkanes with compounds containing >C=N– and –C≡N bonds were investigated by Oda and coworkers[67,68]. Ethylene oxide, propylene oxide, and 3-chloro-1,2-epoxypropane add on to Schiff bases in the presence of tin(IV) chloride (5–10 mole %), to form oxazolidines:



The reactions were carried out in carbon tetrachloride at 10–20°. *N*-t-Butylazomethine reacts with epoxyalkanes with a moderate yield in the absence of catalysts, which can be attributed to its high nucleophilic nature. The use of boron trifluoride as catalyst led to a fall in the yield.

The expected oxazolines



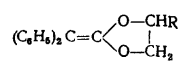
where R = CH_3, $(CH_3)_2CH$, $C_6H_5CH_2$, or CH_2=CH, were isolated from the reaction of epoxyalkanes with nitriles[68].

The reaction was carried out in concentrated sulphuric acid at 5–10°. The existence of side-reactions necessitated the use of a twofold excess of the epoxide, but the yield of the total product was very low (up to 21%). Two isomeric oxazolines were obtained from propylene oxide and acetonitrile. The preferential opening of the epoxide ring at the secondary carbon atom suggests an S_N1 mechanism, which includes the attack of the nitrile on the carbonium ion, and that leads to the opening of the ring of the protonated epoxide.

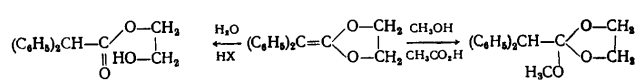
Diphenylacetonitrile reacts with ethylene and propylene oxides in the presence of sodium amide to form imidolactones[65].

In the presence of the >C=C=O system of bonds in ketenes the formation of reaction products with epoxides at both the C=C and the C=O bond can be expected.

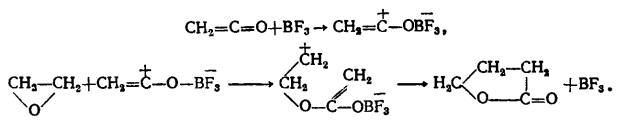
Diphenylketen forms cyclic acetals of diphenylketen on reaction with styrene oxide [phenyloxiran (Ed. of Translation)], γ-phenoxypropylene oxide, ethylene carbonate, and propylene carbonate at 180–200° in the presence of lithium chloride[65]:



The infrared spectra of the compounds obtained show a strong absorption band at 6.05 μm (1653 cm^{-1}) due to the C=C double bond; the absorption band of the carbonyl group was not observed. The structure of the acetals was confirmed by the formation of the ortho-ester of diphenylacetic acid on reaction of the acetal from diphenylketen and ethylene oxide with methanol in the presence of acetic acid, and also by the formation of 2-hydroxyethyl diphenylacetate on hydrolysis:



Hence it was shown that diphenylketen reacts with epoxides at the C=O bond. The rearrangement of the acetal into a γ-lactone was not observed. In contrast to this, Oda and coworkers[70] showed that aliphatic and aromatic α-oxides react with keten in the presence of boron trifluoride–diethyl ether at the C=C bond to form γ-lactones:

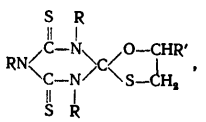


Lactones are obtained in ~ 10% yield on passing keten into an ethereal solution of an epoxide in the presence of 5 mole % boron trifluoride–diethyl ether at 5–50°. In this way, ethylene oxide, 1,2-epoxypropane, styrene oxide, and 3-chloro-1,2-epoxypropane gave respectively γ-butyrolactone, γ-valerolactone, γ-phenyl-γ-butyrolactone, and γ-chloromethyl-γ-butyrolactone.

6. REACTIONS OF EPOXYALKANES WITH ISOTHIOCYANATES

The reaction of epoxyalkanes with the nearest sulphur analogues of the isocyanates — the isothiocyanates — is quite unique.

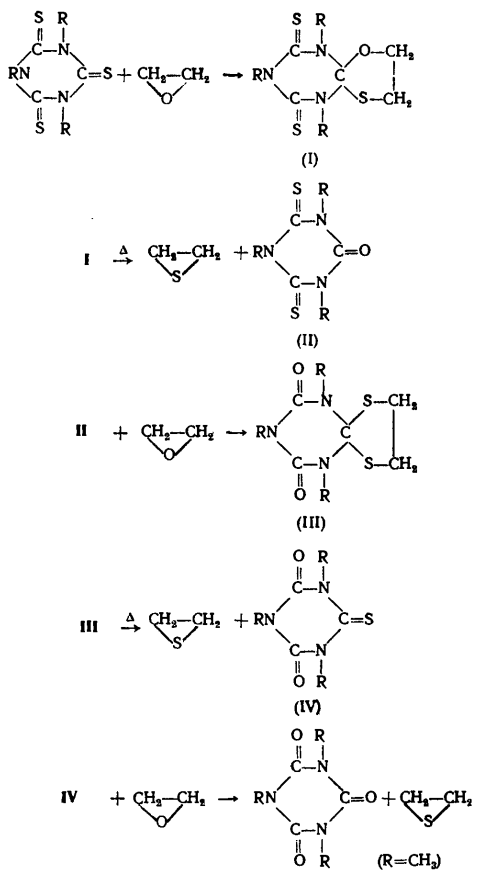
The simplest isothiocyanate, methyl isothiocyanate, reacts with ethylene oxide in the presence of tetraethylammonium bromide to form hexahydro-1,3,5-trimethyltriazine-2,6-dithione-4-spiro-2′-(1,3-oxathiolan):[71]



where R = CH_3 and R′ = H.

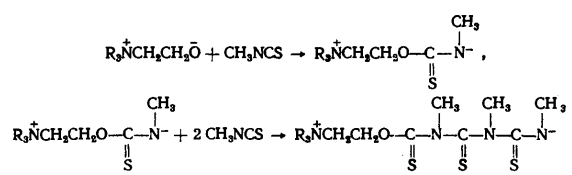
When this compound is heated to 200° in dioxan it decomposes with liberation of ethylene sulphide and trimethyl dithioisocyanurate; oxidation of it with nitric acid led to trimethyl isocyanurate. It was shown that the formation of a spiro-compound proceeds through the formation of the trimethyl ester of trithioisocyanuric acid, which then reacts at the C=S bond with the ethylene oxide[72]. Trimethyl trithioisocyanurate was obtained by trimerisation of methyl isothiocyanate in a solution of the oxides in the presence of catalytic amounts of triethylamine or pyridine, An analogous reaction also takes place in a solution of triethylamine in the presence of catalytic amounts of epoxyalkanes, that is, the latter in conjunction with tertiary amines bring about trimerisation of the methyl isothiocyanate. The reaction does not take place in the absence of the oxides.

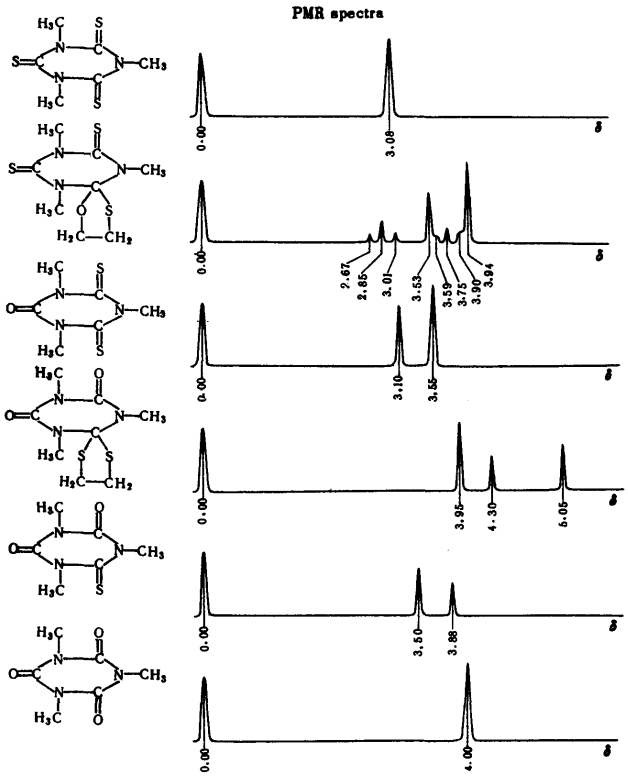
The liberated trimethyltrithioisocyanurate reacts with ethylene oxide, propylene oxide, and 3-chloro-1,2-epoxypropane in the presence of tetraethylammonium bromide to form the corresponding spiro-compounds, which when heated to 200° decompose into alkylene sulphide and trimethyl dithioisocyanurate[72]. On the reaction of propylene oxide with methyl isothiocyanate, the trimer of methyl isothiocyanate is obtained in addition to the spiro-compound; increasing the duration of the reaction leads to the production of only one spiro-compound[72]. This once again confirms that in the reactions with epoxyalkanes the methyl isothiocyanate is first trimerised and then the trimer reacts with the alkylene oxide at the C=S bond. The decomposition product of the spiro-compounds, trimethyl dithioisocyanurate, also reacts with ethylene oxide at the C=S bond to form a new spiro-compound which when heated to 200° liberates ethylene sulphide and trimethyl monothioisocyanurate. The latter reacts with ethylene oxide to give first a spiro-compound and then trimethyl isocyanurate. Hence, on starting from trimethyl trithioisocyanurate, trimethyl isocyanurate was obtained, that is, complete replacement of sulphur by oxygen took place under the action of ethylene oxide[72]:



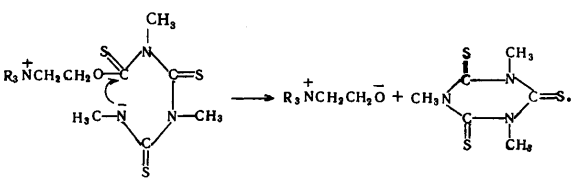
The structure of all the compounds obtained was confirmed by use of PMR spectroscopy (Figure).[73] It can be assumed that the mechanism of formation of trimethyl trithioisocyanurate and the spiro-compound is analogous to the reaction of the trimerisation of isocyanates. A bipolar ion acts as catalyst[58]:

The ion formed adds on to the N=C bond of the isothiocyanate to form a nitrogen anion, which continues the chain growth up to the stage of the trimer:



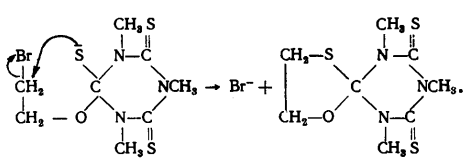


Then the ring closes with release of the original catalyst:

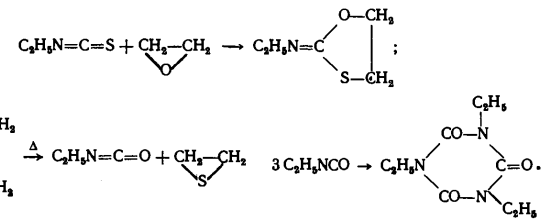


In the presence of tetraethylammonium bromide the anion acts as catalyst:

which catalyses the trimerisation of methyl isothiocyanate. The trimethyl trithioisocyanurate obtained is attacked by the anion at the C=S bond, leading to an anion with a negative charge at the sulphur atom, which closes into a ring by displacing a bromide anion:

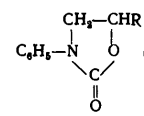


The nearest homologue of methyl isothiocyanate, ethyl isothiocyanate, reacts with ethylene oxide in the presence of tetraethylammonium bromide somewhat differently. In addition to the spiro-compound, triethyl isocyanurate [75] and ethylene sulphide were isolated from the reaction mass; their formation can be represented as follows:

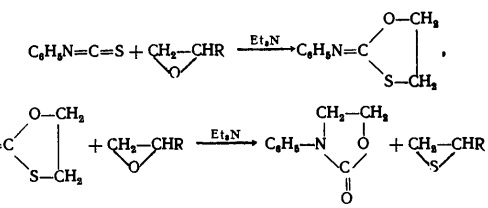


Epoxyalkanes in conjunction with basic compounds are known to bring about trimerisation of isocyanates [54]. Here the trimerisation proceeds under the influence of the sulphur analogue of ethylene oxide — ethylene sulphide — and traces of triethylamine.

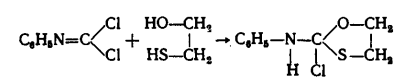
Phenyl isothiocyanate reacts with epoxyalkanes in the presence of triethylamine to form compounds which do not contain sulphur — 3-phenyloxazolid-2-ones [74]:



where R = H, CH_3, or CH_2Cl. The scheme for obtaining oxazolid-2-ones can be represented as follows:



The 2-phenylimino-1-thio-3-oxolan which is formed as an intermediate readily reacts with the epoxyalkane giving an oxazolidone and the corresponding epithioalkane. The possibility of such a reaction taking place is confirmed by the fact that 2-phenylimino-1-thio-3-oxolan is formed from phenylimidocarbonyl dichloride and mercaptoethanol in the presence of triethylamine [75]; ethylene oxide converts the product into 3-phenyloxazolid-2-one. On using pyridine as an acceptor for the hydrogen chloride the above reaction between phenylimidocarbonyl dichloride and mercaptoethanol leads to the production of 2-chloro-2-phenylamino-1-thio--3-oxolan:



which also reacts with ethylene oxide, to form 3-phenyloxazolid-2-one [76]. The reaction probably takes place through the stage of formation of 2-phenylimino-1-thio--3-oxolan.

Hence in the reaction of epoxyalkanes with isothiocyanates, the epoxide opens the C=S bond in the N=C=S system of double bonds.

1. INTRODUCTION

When a molecule of an organic compound absorbs a quantum of light, it undergoes transition from the ground electronic state to an excited state. The nature of the electronic transitions in the molecule may be explained by means of the somewhat modified Jablonski diagram shown in Fig. 1.[2] For most compounds the ground state of the molecule S_0 is the singlet state, in which the total spin of the orbital electrons (s) is equal to zero, and the multiplicity, denoted by the quantity $2s + 1$, is unity. Electronic transitions from S_0 to excited singlet levels S_1, S_2, etc., without change of spin orientation, are much more probable than transitions with change in multiplicity; generally speaking, the latter are forbidden. According to present interpretations[3], a molecule at a high excited singlet level, S_2, S_3 etc., passes to a lower S_1 level in $\sim 10^{-13}$ s without emission of radiation, where it remains for 10^{-7}–10^{-9} s. The molecule may pass from the S_1 level to the S_0 ground level either without or with the emission of light (fluorescence).

The molecule may also pass from the excited singlet level to a lower triplet level T, for which the resultant spin of the electrons is unity, and the multiplicity is 3.[4,5] A transition from the triplet level to the ground state with a change in multiplicity is forbidden; the molecule therefore remains in the triplet state much longer than in the singlet excited state. A spontaneous transition from the triplet to the ground state may be accompanied by the emission of light (phosphorescence). Compared with fluorescence, phosphorescence is marked by a longer decay period (up to several seconds) and by a displacement towards the long-wave region of the spectrum.

The excited molecules may undergo various unimolecular chemical conversions or enter into chemical reactions with other molecules.

† A previous review dealt with intermolecular energy transfer in the radiolysis of solutions of organic compounds[1].

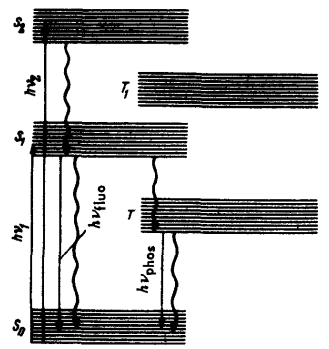

Fig. 1. Scheme of electronic transitions in an organic molecule. The straight arrows correspond to transitions with absorption or radiation of light. The wavy arrows correspond to transitions without radiation.

In multicomponent systems the excited molecules of one component may transfer energy to molecules of another component. The special features of intermolecular energy transfer are largely due to the large number of the excited molecules that take part in it. Energy transfer may occur at singlet levels:

$$A^{S_1} + B^{S_0} \rightarrow A^{S_0} + B^{S_1}.$$

A^{S_1} and B^{S_1} are excited singlet molecules of the energy donor and acceptor, A^{S_0} and B^{S_0} are donor and acceptor molecules at the ground singlet level. This process is called singlet-singlet energy transfer.

If the energy is transferred from the triplet level of the molecule A to the molecule B according to the scheme:

$$A^{T} + B^{S_0} \rightarrow A^{S_0} + B^{T},$$

the process is called energy transfer at triplet levels or triplet-triplet transfer.

The molecules B^{S_1} and B^{T} formed as a result of energy transfer may be deactivated with the emission of luminescent light. This phenomenon is called sensitized fluorescence or sensitized phosphorescence. If the molecules of A are also capable of showing luminescence, quenching of the glow due to the energy of the donor will also be observed.

As a result of energy transfer, chemical conversion of the acceptor may be sensitized or the photochemical reaction of the donor may be inhibited.

It is generally considered that for energy transfer to occur, the level of the excited donor molecule, from which transfer takes place, should be higher than the excited level of the acceptor molecule.

The transfer of energy between singlet levels in solution may occur not only at a direct diffusion approach of the interacting molecules, but also at distances greatly exceeding the kinetic radii of the molecules. In the latter case, the greater the overlap of the fluorescence spectrum of the donor and the absorption spectrum of the acceptor, the greater will be the effectiveness of the transfer. Förster[6] and Galanin and Frank[7] explained the phenomenon of long-range action in singlet-singlet energy transfer in solution by dipole-dipole interactions of the excited donor molecule with the acceptor molecule. These authors

showed that the probability of the "resonance" transfer of energy (W) is determined by the expression:

$$W = \frac{1}{\tau}\left(\frac{R_0}{R}\right)^6,$$

where τ is the lifetime of the excited energy-donor molecules, R is the distance between the interacting molecules, and R_0 is the so-called critical radius of resonance interaction, which is determined by the optical properties of the system, particularly by the oscillator strengths and the area of overlap of the emission spectrum of the donor and the absorption spectrum of the acceptor.

The transfer of energy at triplet levels was first observed by Terenin and Ermolaev[8] in investigating the phosphorescence of a solid solution of naphthalene sensitized with benzaldehyde or benzophenone under the action of light of wavelength 365 nm absorbed by the donor molecules (naphthalene is virtually transparent in this spectral region). The triplet level of naphthalene is lower, and the singlet level higher, than the corresponding levels of benzaldehyde and benzophenone. In this connection the transfer of energy to naphthalene can only take place at the triplet levels.

In liquid solutions, triplet-triplet energy transfer was first discovered by Bäckström and Sandros[9], who studied the quenching of biacetyl phosphorescence by aromatic compounds with triplet levels lower than the triplet level of biacetyl. These workers showed that the rate of energy transfer at triplet levels is close to the value determined by the rate of diffusional encounter of the interacting molecules.

Aromatic compounds containing carbonyl groups are frequently used as energy donors in triplet-triplet transfer[10]. This is because these compounds have high triplet levels and low singlet levels. Moreover, when electronically excited, these compounds show a high probability (frequently close to unity[11,12]) of passing to the triplet state because of the strong spin-orbital interaction in $n \rightarrow \pi^*$ transitions[3].

The most reliable results on triplet-triplet energy transfer in liquid solutions have been obtained by Porter and Wilkinson[13] by the method of flash photolysis. Essentially, this method consists in producing a high concentration of intermediate particles — radicals or triplet molecules — in solution by means of short-duration light impulses of high intensity; the optical absorption of these particles is determined by means of a "sounding" beam. Flash photolysis may be used to determine both the absorption spectrum of the intermediate particles and the change in their concentration with time.

Using this method, Porter and Wilkinson were able to follow the change in the rate of disappearance of the triplet states of a number of aromatic compounds (energy donors) in the presence of acceptor additives. In some instances they were also able to observe triplet acceptor molecules that arose as a result of energy transfer. The absolute rates of triplet-triplet energy transfer were determined and were found to be close to the diffusion rates, in agreement with the results of Bäckström and Sandros[9].

At present, the mechanism of energy transfer at triplet levels is not quite clear. Terenin and Ermolaev[14,15] consider that the transfer proceeds by an exchange-resonance mechanism[16]. This mechanism requires overlapping of the electronic shells of the interacting molecules, which is in agreement with the diffusion mechanism of energy transfer in solutions.

At low acceptor concentrations, the intermolecular energy transfer competes with the spontaneous deactivation of the excited donor molecules. If the energy transfer is regarded as a bimolecular process, the dependence of the quantum yield on the acceptor concentration can be expressed by simple equations. For the quantum yield (γ) of sensitized processes (luminescence or chemical decomposition) the equation has the form:

$$\frac{\gamma}{\gamma_{lim}} = \frac{k_{AB}\tau\,[B]}{1 + k_{AB}\tau\,[B]}, \qquad (1)$$

where γ_{lim} is the limiting quantum yield of the sensitized process at sufficiently high concentrations of B, when there is no spontaneous deactivation of the excited molecules of A; k_{AB} is the rate constant for energy transfer; and τ is the lifetime of excited molecules of A.

If the acceptor is a quencher, the quantum yield for luminescence or chemical decomposition of the donor is determined by the Stern–Volmer equation:

$$\frac{\gamma}{\gamma_0} = \frac{1}{1 + k_{AB}\tau\,[B]}, \qquad (2)$$

where γ_0 is the quantum yield in the absence of quencher.

Although these equations have been derived from the simplest kinetic considerations and are semiempirical, in many instances they are nevertheless in good agreement with experimental results. The product $k_{AB}\tau$, which is determined from the dependence of the quantum yield on the concentration of B, is a measure of the effectiveness of the transfer of excitation energy.

The information presented in this section is sufficient for an understanding of the material on specific photochemical reactions discussed below. Detailed analyses of the problem of intermolecular energy transfer during luminescence may be found in a number of publications[10,17–22].

In the present review, problems of energy migration in biologically important systems[19–23] are not considered, nor are papers on the migration of energy in photochemical reactions in the gas phase and in solid and vitreous media.

The data in a number of papers considered in the review do not allow an unambiguous conclusion to be drawn as to the mechanism of energy transfer; for this reason, it would obviously not be expedient to classify the material on the basis of transfer mechanism. It is arranged according to the type of chemical reaction accompanying the energy transfer.

2. SENSITIZED PHOTODECOMPOSITION

a. Halogeno-Substituted Hydrocarbons

One of the first papers on sensitized photolysis of organic compounds was that of West and Paul[24], published in 1932; they studied the photolysis of solutions of ethyl iodide in hexane and benzene under the action of light of wavelength 254–280 nm (maximum radiation in 261 nm region). Unlike hexane, benzene is not transparent in the 261 nm region, and a considerable portion of the light is absorbed by the solvent in benzene solutions. In particular, with a solution of concentration 0.03 M, benzene absorbs 180 times as much light as ethyl iodide. However, the quantum yield for the photodecomposition of ethyl iodide in such a solution is virtually the same as that for

the photolysis of a 0.03 M solution in hexane, in which light is only absorbed by the ethyl iodide. To explain these results, the authors suggested that excited benzene molecules may transfer energy to ethyl iodide molecules, which decompose into free radicals.

Later, West and Fitelson[25] showed that the sensitized decomposition of ethyl iodide may also occur in such solvents as methyl iodide, hydrogen sulphide, and chlorobenzene, the first two solvents themselves decomposing under the action of light. The transfer of energy to ethyl iodide appears to compete with the decomposition of excited molecules of these solvents.

To explain the mechanism of energy transfer in these reactions, West and Miller[26] compared the kinetics of the naphthalene-sensitized photodecomposition of ethyl iodide in hexane with the kinetics of the quenching of naphthalene fluorescence.

The rate of decomposition of ethyl iodide under the action of light of wavelength 313 nm, which only excites naphthalene, is proportional to the amount of light absorbed. The additivity of the spectral changes that occur when solutions of naphthalene and ethyl iodide are mixed clearly indicates that there is no appreciable complex formation in the unexcited state. Thus, the decomposition of ethyl iodide is the result of transfer of excitation energy. With an ethyl iodide concentration of less than 0.01 M, the quantum yield of the decomposition obeys Eqn. (1); $\gamma_{lim} = 0.3$ agrees with the quantum yield for the decomposition that occurs when light acts directly on ethyl iodide, that is, all the light energy absorbed by naphthalene is transferred to the ethyl iodide. Under these conditions $k_{AB}\tau \simeq 10^3$ litre mole^{-1}.

The quenching of naphthalene fluorescence by ethyl iodide follows the Stern–Volmer law. However, here $k_{AB}\tau = 180$ litre mole^{-1}. The authors explain the difference in the effectiveness of energy transfer obtained from data on fluorescence and data on photolysis on the assumption that the photodecomposition of ethyl iodide is brought about by the transfer of energy, not only from the fluorescing level of the naphthalene molecule, but also from the excited level from which the molecule does not fluoresce. This is probably a triplet level, although the authors themselves put forward no suggestions as to its nature. This is due to the fact that the paper by West and Miller appeared before Terenin[4], and then Lewis and Kasha[5], developed an interpretation of the triplet excitation levels and their roles in photochemical reactions.

Ethyl iodide weakly absorbs light of wavelength 313 nm; for this reason, only ethyl iodide molecules at high vibrational levels absorb light of this wavelength and pass to the excited electronic state, which here is a repulsive state.

However, in the presence of naphthalene and with ethyl iodide concentrations greater than 0.01 M, all the energy of light of wavelength 313 nm absorbed by naphthalene is transferred by ethyl iodide molecules. Evidently, ethyl iodide molecules in the lower vibrational levels can receive energy quanta from naphthalene molecules of a size such that they would remain virtually unabsorbed under the direct action of light. The explanation of this effect given by West and Miller is illustrated schematically in Fig. 2. Curve *1* is the potential curve of ethyl iodide in the ground state; the shape of the curve should not change appreciably in collisions between unexcited molecules of naphthalene (N) and ethyl iodide (Et–I), since there is little interaction between these; *2* is the repulsion curve of ethyl iodide. The energy of the configuration formed when a molecule of

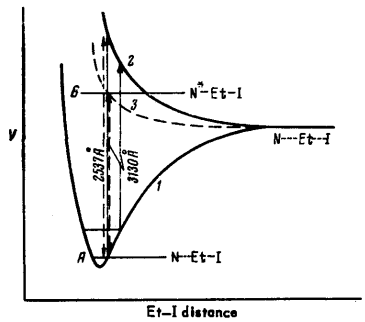

Fig. 2. Mechanism of photosensitized decomposition of ethyl iodide.

ethyl iodide collides with an excited naphthalene molecule (curve *3*) will be less than the energy of (EtI)*, if there is appreciable interaction between the excited naphthalene molecules (N*) and ethyl iodide. Accordingly, the sensitized decomposition of ethyl iodide requires less energy than that required under the direct action of light.

Wilkinson[27] studied the sensitized photodecomposition of solutions of 1-iodonaphthalene in the presence of various sensitizers under the action of light of wavelength 365 nm, for which iodonaphthalene is virtually transparent. The photodecomposition of iodonaphthalene occurs in the presence of additives (acetophenone, benzophenone, anthraquinone, 2-acetonaphthone), the triplet level of which lies above the corresponding naphthalene level, and it does not occur when the triplet level of the additive (anthracene) is lower than that of iodonaphthalene. The reaction probably proceeds by the transfer of energy between the triplet levels.

Kallmann-Oster and Kallmann[28], who studied the concentration dependence of free radical yields in the photolysis and radiolysis of carbon tetrachloride solutions in benzene, concluded that the sensitized photodecomposition of carbon tetrachloride is the result of transfer of energy from benzene to CCl_4‡. The rate of formation of free radicals was determined with the aid of the free-radical acceptor 1,1-diphenyl-2-picrylhydrazyl (DPPH). The concentrations of DPPH and CCl_4 were such that the direct action of light ($\lambda = 254$ nm) on these compounds could be neglected. The rate of formation of free radicals in photolysis reaches a limiting value at CCl_4 concentrations of about 10^{-2} M, and it decreases in the presence of additions of the organic luminophores, fluoranthene, *p*-terphenyl, and phenylbiphenylyloxadiazole. The authors consider that energy transfer occurs at low excited singlet levels. Van Dusen and Hamill[29], who studied the photolysis ($\lambda = 254$ nm) of mixtures of benzene with carbon tetrachloride, ethyl iodide, chloroform, and other chlorides over a wide concentration range, consider that sensitized photodecomposition of chlorides is associated with transfer of energy from benzene at the triplet levels.

Semeluk and Unger[30], who studied the benzene-sensitized photodecomposition of chloroform in the gas phase,

‡ We have already discussed in detail the problem of energy transfer in the radiolysis of solutions containing CCl_4 and other halogeno-substituted hydrocarbons[1]. See also Van Dusen and Hamill[29].

also consider that decomposition of chloroform is due to triplet-triplet energy transfer from benzene to chloroform.

When the sensitizing additive itself undergoes chemical change, it is difficult to decide whether the photochemical reaction is due to the transfer of energy from this additive and subsequent reaction of acceptor decomposition products with the additive, or to the immediate entry of excited additive molecules into photochemical reaction with the other compound. Thus, Bowen and Rohatgi[31] found that when light acts on anthracene (A) dissolved in carbon tetrachloride, recombination products of $^{\cdot}ACl_4$ and $^{\cdot}CCl_3$ radicals are formed. They consider that the latter radicals are formed by abstraction of a Cl$^{\cdot}$ atom from CCl_4 by excited anthracene.

To find the nature of the excited anthracene molecules which react with carbon tetrachloride, Kusuhara and Hardwick[32] compared the rate of this reaction for anthracene under the direct action of light with that for anthracene excited by energy transfer from coronene. It was first shown by flash photolysis that energy is transferred from coronene to anthracene at triplet levels. The relative concentrations of triplet molecules produced by direct action and as a result of energy transfer were also evaluated. Comparison showed that the rates of the direct and sensitized reactions are proportional to the concentrations of triplet anthracene molecules. Bagdasar'yan[33,34] observed an increase in the rate of initiation of photopolymerization of various vinyl monomers (styrene, α-methylstyrene, allyl acetate, isoprene, chloroprene) in the presence of CCl_4; he considers this to be due to the removal of Cl$^{\cdot}$ atoms from CCl_4 by excited monomer molecules. Robb and coworkers obtained analogous results in a study of the photochemical telomerization of styrene and methyl methacrylate with CCl_3Br.[35,36]

b. Some Other Readily Decomposable Compounds

Organic peroxides, hydroperoxides, azo- and diazo-compounds, disulphides, and some other compounds are readily decomposed in solution under the action of light, and some are also decomposed by heating; for this reason, they are frequently used as sources of free radicals in the initiation of chemical reactions[37,38]. Because of the readiness with which these compounds are decomposed when electronically excited, they may be used as very sensitive acceptors in sensitized reactions.

Luner and Szwarc irradiated dilute benzene solutions of acetyl peroxide with light of wavelength 254 nm, which is absorbed virtually by benzene alone, and they observed sensitized decomposition of the peroxide[39]. Sensitized decomposition of the peroxide also occurs in iso-octane in the presence of anthracene or naphthacene under the action of light of wavelength 265 nm, which is absorbed by these hydrocarbons.

Krongauz and Bagdasar'yan[40], and later Vasil'ev and Krongauz[41,42], made a detailed study of the solvent-sensitized radiolysis and photolysis of benzoyl peroxide in benzene and in toluene. Luminophore additives (anthracene, phenanthrene, *p*-terphenyl, etc.) reduce the yield in the sensitized decomposition of benzoyl peroxide. At the same time, benzoyl peroxide quenches the solvent-sensitized fluorescence of these luminophores. They suggested that the same excited states of the solvent molecules participate in the transfer of energy both to the peroxide and to the luminophore, and they obtained concordant values of the constants for energy transfer from the solvent to the additives; these values were calculated from data on the sensitized fluorescence of the luminophores and the sensitized decomposition of peroxide in three-component solutions (solvent–benzoyl peroxide–luminophore). In sensitized fluorescence, the energy transfer occurs at singlet excitation levels. Thus, the decomposition of benzoyl peroxide also appears to be due to singlet-singlet energy transfer. Subsequently, an attempt was made to give a more detailed elucidation of the mechanism of energy transfer in these systems[43-45]. It was shown that energy transfer occurs at a distance exceeding the kinetic radii of the molecules, but the effectiveness of the transfer largely depends on the rate of diffusion of the molecules in the solution.

The sensitized photodecomposition of benzoyl peroxide resulting from the transfer of energy from the luminophores to the peroxide has also been studied. This process leads to quenching of the luminophore phosphorescence, which also indicates singlet-singlet energy transfer. However, here the rate constant for the transfer is much lower than with sensitization by a solvent and it is in satisfactory agreement with the hypothesis that energy is transferred by diffusion approach of the molecules to a distance equal to the kinetic radii.

Kardash and Krongauz[46] compared the kinetics of the naphthalene-sensitized photodecomposition of propionyl peroxide in benzene under the action of light of wavelength 313 nm (which is absorbed only by naphthalene) with the kinetics of the photolysis of solutions of naphthylpropionyl peroxide; they showed that naphthylpropionyl peroxide decomposes by a bimolecular mechanism. With peroxide concentrations less than 5×10^{-3} M, the quantum yield tends to zero. In the low-concentration region, the concentration dependence of the quantum yield for the photodecomposition of naphthylpropionyl peroxide is similar to the same dependence for a 2:1 mixture of naphthalene and propionyl peroxide. It appears that excited molecules of naphthylpropionyl peroxide can transfer energy directly to the peroxide groups of other molecules.

Überreiter and Bruns[47] studied the fluorenone-sensitized photodecomposition of tetralin hydroperoxide in chlorobenzene under the action of light of wavelength greater than 365 nm. At concentrations less than 5×10^{-3} M, the rate of decomposition of tetralin hydroperoxide is proportional to the hydroperoxide concentration. The sensitized decomposition of the hydroperoxide is due to energy transfer between triplet levels; the formation of hydrogen bonds between the donor and acceptor plays an important part in this transfer. The authors consider that this is confirmed by the failure of fluorenone to sensitize the photodecomposition of benzoyl peroxide, with which it does not form hydrogen bonds. The rate of hydroperoxide photodecomposition depends linearly on the square root of the fluorenone concentration; this appears to be related to the mutual deactivation of two triplet fluorenone molecules.

In a study of the so-called "delayed fluorescence" of a number of aromatic luminophores in solution, Parker and Hatchard observed similar interaction between two triplet molecules with the formation of excited and unexcited singlet molecules[48]:

$$A^T + A^T \longrightarrow A^{S_1} + A^{S_0}.$$

The benzophenone-sensitized photodecomposition of diazomethane into methylene and nitrogen is an interesting example of a reaction resulting from energy transfer at

triplet levels. When light acts directly on diazomethane[49,50] dissolved in cyclohexene, or when diazomethane is decomposed by heat, a mixture of norcarane and methylcyclohexenes is formed, as a result of the reaction of cyclohexene with methylene, which appears to occur in the singlet state. In the photodecomposition of diazomethane sensitized by benzophenone (as noted above, on photoexcitation benzophenone passes virtually completely into the triplet state), norcarane is mainly formed. This appears to be related to the triplet state of the methylene in this case. Methylene formed by the direct photolysis of diazomethane in octane reacts with *cis*- or *trans*-but-2-ene to give the corresponding *cis*- or *trans*-dimethylcyclopropane. At the same time, when diazomethane undergoes sensitized photodecomposition, a mixture of *cis*- and *trans*-dimethylcyclopropane is always formed. The intermediate formed by the addition of the triplet methylene to butene can probably undergo internal rotation before cyclization.

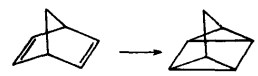
Hammond and coworkers have shown that, with the use of energy transfer at triplet levels, it is possible to induce sensitized photodecomposition of ethyl pyruvate into acetaldehyde and carbon monoxide with a much higher quantum yield than that obtained in the direct photolysis of this α-keto-ester[51]. They used benzophenone as an energy donor. The energy transfer is evidently very effective in this instance, since small additions of ethyl pyruvate (0.05 M) completely suppress the photoreduction of benzophenone to benzohydrol, which proceeds through the triplet state of benzophenone (see Section 6). β-Acetonaphthone, the triplet level of which (59 kcal mole^{-1} [52]) is considerably lower than the triplet level of ethyl pyruvate, does not sensitize the photodecomposition of this compound.

Berman and coworkers[53] have studied the ketone-sensitized photochemical decarbonylation of aldehydes, such as ethylenehexanal, heptanal, octanal, etc. Benzophenone, acetophenone, their chloro- and methoxy-derivatives, and 2-octanone, which have excitation triplet levels of about 70–75 kcal mole^{-1}, sensitize the photodecomposition, but acetophenone is ineffective, as with ethyl pyruvate. 2-Ethylenehexanal inhibits the photoreduction of benzophenone in propan-2-ol. The ratio of the rate constant for the transfer of energy from benzophenone to the aldehyde to the rate constant for the photoreduction is 70. It is interesting that for the inhibition by naphthalene of the photoreduction of benzophenone by alcohol this ratio is $\sim 3 \times 10^3$.[54]

3. SENSITIZED INTRAMOLECULAR REARRANGEMENTS

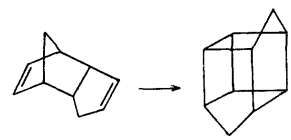
The first investigation of sensitized chemical reactions in solution was described in a paper published in 1931 by Weigert and Pruckner[55]. This dealt with the conversion of *o*-nitrobenzaldehyde into *o*-nitrobenzoic acid, photosensitized by acetone. When light of wavelength 313 nm acts on 0.05–2% solutions of *o*-nitrobenzaldehyde, the quantum yield for the rearrangement of aldehyde to acid ($\sim$ 0.5) is almost independent of concentration, although in a 2% solution the aldehyde absorbs three times as much light as acetone, but at 0.05% concentration, acetone accounts for 90% of all the light absorbed by the solution. Evidently all the energy absorbed by the acetone is transferred to the aldehyde.

In some instances sensitized reactions proceed with a higher quantum yield than the same reactions under the direct action of light. Thus, Hammond and coworkers[56] showed that the photochemical rearrangement of norbornadiene to quadricyclene:



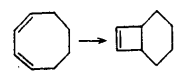
gives a much higher quantum yield when sensitized by such compounds as acetone, acetophenone, and benzophenone than the same reaction under the direct action of light[57].

Schenck and Steinmetz[58] showed that endodicyclopentadiene isomerizes to pentacyclo[5,2,1,$0^{2,6}$,$0^{3,9}$,$0^{4,8}$]-decane:



in the presence of acetone with a greater yield than that obtained under the direct action of light.

The photochemical isomerization of 1,3-cyclo-octadiene to Δ^7-bicyclo[4,2,0]octene[59]



can also be sensitized in the presence of benzophenone[60].

In all the intramolecular rearrangement reactions enumerated above ketones were used as sensitizers; as mentioned above, the probability of ketones passing into the triplet state when subjected to photoexcitation is very high. The rearrangements also appear to proceed through the triplet state. This may explain the higher quantum yields in the sensitized reactions, which, in contrast to the unsensitized reactions, appear to be a consequence of triplet-triplet energy transfer.

4. SENSITIZED *cis–trans* ISOMERIZATION

cis–trans isomerization relative to the ethylenic bond usually proceeds readily under the action of light[61]. Lewis and coworkers were the first to make a detailed study of photochemical isomerization; they studied the photoisomerization of stilbene in liquid and solid solutions[62]. Because of the stability of both its isomers, the substantial differences in their optical properties, and the high quantum yield in the *cis–trans* conversion, stilbene has also been frequently used in later investigations into the reaction mechanism of direct and sensitized isomerization. Lewis and coworkers compared data on absorption and fluorescence spectra and on quantum yields of the isomerization and concluded that when light is absorbed each isomer passes into its excited electronic level. Transition to the other isomeric form occurs by degradation of the electronic excitation to vibrational excitation, the energy of which is sufficient for rotation of groups in the molecule.

In subsequent papers[63–65], this picture was given concrete expression in accordance with Mulliken's ideas[66,67] on the excited state of ethylene and its derivatives. When the ethylene molecule is excited, the parallel position of the π-orbitals of the C=C bond ceases to be the position most favoured energetically and the orbitals are twisted through an angle of 90°. The triplet state then becomes

more stable than the singlet state. According to Dyck and McClure[63], because of conjugation of the ethylene bond with the phenyl rings in stilbene, a strictly perpendicular position of the π-orbitals in the excited state is not necessarily the most favourable position[63]. However, in the triplet state there must be much less restriction to rotation of groups about the ethylenic bond. A curious feature of the photoisomerization of *trans*-stilbene is the low activation energy of ~ 2 kcal mole^{-1}.[68,69] Stegemeyer suggests that a potential barrier separates the triplet states of *trans*- and *cis*-stilbene[68]. However, a number of other workers consider that this barrier exists in the transition of *trans*--stilbene from the first excited singlet state to the triplet state[63,69,70].

Investigation of the sensitized isomerization of stilbene has confirmed the view that *cis–trans* isomerization proceeds through the triplet state[71,72]. Hammond and coworkers[71] used acetophenone, benzophenone, and anthraquinone as additives in sensitizing the isomerization of stilbene in solution; the triplet levels of these compounds are higher than the triplet level of *cis*- and *trans*-stilbene[71]. In the sensitized reaction, the ratio of the concentration of the *cis*-isomer to that of the *trans*-isomer in a state of photo--equilibrium was found to be $[cis]_{equil}/[trans]_{equil} \simeq 1.5$. For direct isomerization under the action of light, $[cis]_{equil}/[trans]_{equil} \simeq 11$. The ratio of the absorption coefficient of the *trans*-isomer to that of the *cis*-isomer in the 313 nm region is 7.2. These workers consider that if the absorption coefficients were identical, triplet molecules of *cis*- and *trans*-stilbene would be formed at the same rate. In the photoequilibrium state, the ratio $[cis]_{equil}/[trans]_{equil}$ for the direct action of light would then be $11/7.2 \simeq 1.5$, that is, the same value as in sensitized isomerization. In the authors' opinion, this indicates that isomerization proceeds through the triplet state. Malkin and Fischer[69] determined the product of the rate constant for energy transfer from benzophenone to *trans*-stilbene and the lifetime of the benzophenone triplet molecules as $k_{AB}\tau = 2 \times 10^3$ litre mole^{-1}. Assuming that k_{AB} is determined by the diffusion rate (in methylcyclohexane $k_{AB} \simeq 3 \times 10^9$ litre mole^{-1} s^{-1}), they obtained $\tau = 5 \times 10^{-7}$ s. These workers also showed that *trans*-stilbene passes from the triplet state to the lower singlet level of the *trans*- or *cis*--form with about the same probability.

Hammond and coworkers obtained results of particular interest on the sensitized photoisomerization of stilbene, pent-2-ene, 1,2-dichloroethylene, 1,2-diphenylpropene, piperylene, and ethyl maleate–ethyl fumarate in the presence of energy-donor additives with triplet levels lower than the triplet levels of the acceptors[73–76]. The authors explain the occurrence of reaction in this instance by the possibility of "non-vertical" energy transfer to the triplet levels of the energy acceptors which correspond to the already "twisted" position of the groups in the molecule relative to the double bond. Here it is assumed that the triplet level of such a twisted molecule is lower than the triplet level to which the molecule passes when the position of the atoms is unchanged in accordance with the Franck–Condon principle (vertical transitions).

By plotting $[cis]_{equil}/[trans]_{equil}$ for the isomerizing acceptors against the energy of the triplet level of the sensitizers (E_T), Hammond and coworkers obtained peculiar "spectra"[76]. Fig. 3 shows an example of such a spectrum for stilbene. To interpret this spectrum, the authors put forward a scheme for the arrangement of the triplet levels of stilbene (Fig. 4). All the sensitizers with triplet

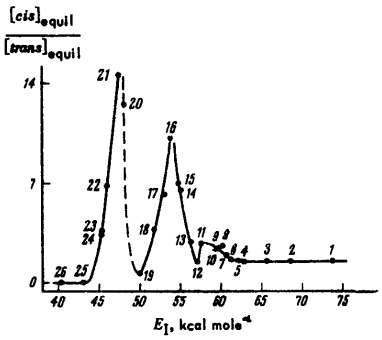


Fig. 3. Sensitized photoiosomerization of stilbene. Dependence of $[cis]_{equil}/[trans]_{equil}$ on the position of the triplet level of sensitizers:
1) acetophenone; 2) benzophenone; 3) thioxanthone; 4) anthraquinone; 5) flavone; 6) Michler's ketone; 7) 4-acetylbiphenyl; 8) 2-naphthyl phenyl ketone; 9) naphthalene-2-carbaldehyde; 10) 2-acetonaphthone; 11) 1-naphthyl phenyl ketone; 12) 1,4-naphthoquinone; 13) 1-naphthalene-1-carbaldehyde; 14) biacetyl; 15) penta-2,3-dione; 16) benzyl; 17) fluorenone; 18) duroquinone; 19) benzoquinone; 2) pyrene; 21) 1,2-benzanthracene; 22) benzanthrone; 23) acridine; 24) 3-acetylpyrene; 25) eosin; 26) 9,10-dibromoanthracene.

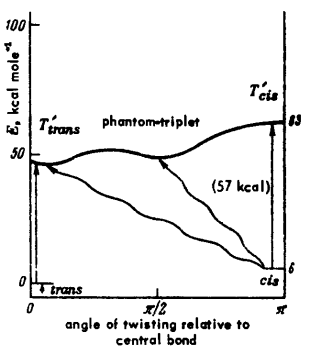

Fig. 4. Potential energy of rotation of stilbene in triplet state.

levels higher than the triplet levels of both stilbene isomers, that is, higher than 63 kcal mole^{-1}, probably give rise to vertical transitions to the triplet levels of both isomers. The ratio $[cis]_{equil}/[trans]_{equil}$ is then ~ 1.5. As the triplet levels of the sensitizers are reduced, the rate of energy transfer to *cis*-stilbene, the triplet level of which is higher than the corresponding level of *trans*-stilbene, apparently decreases faster than the rate of energy transfer to *trans*-stilbene. This leads to an increase in the ratio $[cis]_{equil}/[trans]_{equil}$.

However, at the 57 kcal mole^{-1} point (sensitizer: 1,4--naphthaquinone) corresponding to the O–O transition of *cis*-stilbene from the unexcited singlet state to the triplet state, a distinct minimum is observed (exact resonance). The second maximum (benzyl) corresponds to passage through the resonance condition for the vertical transition of *trans*-stilbene to the triplet level. The subsequent

minimum and maximum are due to non-vertical transitions to the corresponding triplet levels of twisted molecules. Finally, eosin and dibromoanthracene, in which E_T is less than 45 kcal mole^{-1}, can produce non-vertical transition and isomerization of *cis*-stilbene only, since the unexcited singlet level of the latter is 6 kcal mole^{-1} higher than in *trans*-stilbene. Similar spectra are also obtained for other acceptors that undergo isomerization.

Krongauz used the sensitized *trans–cis* isomerization of stilbene to study the triplet molecules of benzene in the liquid phase[77]. When dilute solutions of *trans*-stilbene in benzene are irradiated by light of wavelength 254 nm, which is absorbed almost entirely by the benzene alone, the stilbene is isomerized. In the concentration range studied (10^{-5} to 10^{-3} M), stilbene does not change the luminescence of benzene, that is, it does not deactivate the singlet excited benzene molecules. Energy transfer appears to take place between triplet levels. The lifetime of triplet benzene molecules ($\sim 10^{-6}$ s) and the lower limit of their quantum yield (0.1) were evaluated.

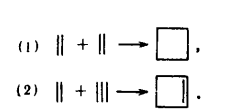
An important feature of this sensitization reaction is that the quantum yield for the isomerization of *trans*-stilbene is inversely proportional to the square root of the intensity of light absorption. This dependence is explained by the fact that the incident light is absorbed in a thin layer of solvent (half the light of wavelength 254 nm is absorbed by a benzene layer about 2.7×10^{-3} cm thick). The transfer of energy from benzene to stilbene also occurs in this layer, which leads to high stationary concentrations of triplet molecules in the thin layer and promotes the possible bimolecular deactivation of these molecules. By analogy with delayed fluorescence, it may be supposed that, when two triplet molecules of *trans*-stilbene interact, excited and unexcited singlet molecules are formed. On the basis of this explanation, the lifetime of *trans*-stilbene in the triplet state was found to be about 10^{-3} s.

Krongauz later used the sensitized isomerization of stilbene as a method of investigating triplet molecules in a liquid with the object of demonstrating the participation of triplet monomer molecules in the initiation of the photopolymerization of methyl methacrylate[78]. Bagdasar'yan suggested this mechanism for the photoinitiation of the polymerization of vinyl monomers[79]. When light of wavelength 254–265 nm acts on dilute solutions of *trans*-stilbene in methyl methacrylate, solvent-sensitized isomerization of the stilbene occurs. At the same time *trans*-stilbene inhibits the photopolymerization of methyl methacrylate, but has no effect on polymerization initiated by material initiators. Since the isomerization of stilbene is caused by energy transfer at triplet levels, it has been concluded that triplet monomer molecules participate in the initiation of photopolymerization.

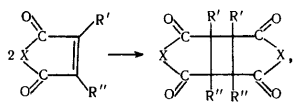
5. SENSITIZED DIMERIZATION AND POLYMERIZATION OF UNSATURATED COMPOUNDS

Bäckström and Sandros[9] studied the triplet-triplet transfer of energy from biacetyl to anthracene and found that, in addition to the quenching of the biacetyl fluorescene, a dimer of anthracene was formed.

Schenck and Steinmetz used sensitized dimerization for the synthesis of a large number of cyclobutane and cyclobutene derivatives[60,80,81]. The formation of cyclodimers by the interaction of two identical, or different, molecules containing C=C or C≡C bonds may be represented by the following scheme:



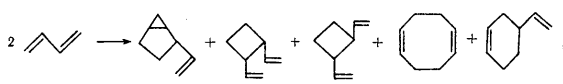
Various aldehydes, ketones, quinones, quinoid dyes, etc. have been used as sensitizers. The sensitization method has been used for the cyclodimerization of indene, coumarin, butadiene, etc., and also for reactions of the following type:



where R = H, CH_3; X = O, NH, N–C_6H_5, or N–C_6H_{11}. Many of these reactions do not occur under the direct action of light. Examples of sensitized reactions in which two different molecules interact include numerous reactions of the anhydrides of maleic and dimethylmaleic acids with benzene, thiophen, cyclohexene, chloro-derivatives of ethylene, furan, butyne, etc. Many of these reactions are recommended for preparative purposes.

After an examination of the mechanism of sensitization, Schenck and Steinmetz were inclined to favour the hypothesis that in many instances there is no transfer of energy but that intermediate biradical addition products are formed[60,82].

In dimerization reactions that occur under the direct action of light, a whole range of isomeric products is generally formed. On the other hand, sensitized reactions usually give a considerably lower number of isomers. For example, five different isomers are formed in the direct photodimerization of butadiene,



but in the sensitized reaction only the last three isomers are formed[56]. The ratios of the amounts of isomers formed depend on the nature of the sensitizer. In the cyclodimerization of isoprene, the distribution of dimerization products also depends on the nature of the sensitizer[83].

In the case of butadiene and isoprene, the ratio of the amounts of dimerization products is determined by the position of the triplet level of the sensitizer; the corresponding relationships form characteristic spectra with a minimum in the region $E_T \simeq 50$ kcal mole^{-1}.[108] The concept of sensitization of non-vertical transitions has been used in the interpretation of these spectra, and it has also been applied to sensitized *cis–trans* isomerizations. Hammond and coworkers[108] have put forward a number of objections to the view of Schenck and Steinmetz that sensitized dimerization proceeds through a stage in which intermediate biradical addition products are formed.

Norrish and coworkers have studied the sensitized photopolymerization of styrene[84,85]. The aromatic hydrocarbons anthracene, pyrene, and chrysene were used as sensitizers that absorb active light. It was shown by the flash photolysis method that additions of styrene (0.3–1.5 M) deactivate the triplet states of anthracene in solution. It was concluded that triplet molecules of anthracene

initiate the photopolymerization of styrene. The results of Norrish and coworkers do not lead unequivocally to this conclusion, since styrene can also effectively deactivate molecules in the singlet excited state[86].

The photoinitiation of polymerization of vinyl monomers by excited molecules of dye additives has been investigated[87-90]. Some workers consider that initiation is preceded by transfer of energy from the additive to the monomer[87]; others consider that polymerization is initiated by triplet molecules of the additive itself[85,88,90]. Solution of the problem is further complicated, because some additives enter into copolymerization or chain-transfer reactions with polymer radicals[78,85].

We are not, of course, here concerned with those reactions in which additive molecules are converted, as a result of decomposition or some other chemical reaction, into radicals that initiate polymerization. We shall only mention the example of sensitized decomposition of a radical initiator of polymerization which has been investigated by Überreiter and Sorge[87]. These workers carried out the photopolymerization of styrene in the simultaneoues presence of the two additives, Neutral Red and benzoyl peroxide, and they found that the dye (as an energy donor) sensitizes decomposition of the peroxide and thus accelerates photopolymerization.

6. OXIDATION–REDUCTION REACTIONS

The intermolecular transfer of energy has been used to elucidate the nature of excited states that participate in various photochemical oxidation–reduction reactions of organic compounds. The photochemical reactions of alcohols with quinones is an important example of these[91].

The photoreduction of benzophenone by alcohols, which was first carried out by Ciamician and Silber[92], proceeds with a high quantum yield and is used as a method for the preparation of benzopinacol. The process appears to occur according to the following scheme[93]:

$$(C_6H_5)_2CO + h\nu \longrightarrow (C_6H_5)_2CO^*,$$
$$(C_6H_5)_2CO^* + R_2CHOH \rightarrow (C_6H_5)_2\dot{C}OH + R\dot{C}OH,$$
$$R_2\dot{C}OH + (C_6H_5)_2CO \rightarrow R_2CO + (C_6H_5)_2\dot{C}OH,$$
$$2\,(C_6H_5)_2\dot{C}OH \rightarrow (C_6H_5)_2{-}\underset{\displaystyle OH}{\overset{\displaystyle |}{C}}{-}\underset{\displaystyle OH}{\overset{\displaystyle |}{C}}{-}(C_6H_5)_2.$$

States corresponding to $n \rightarrow \pi^*$ transitions appear to be the active excited states of carbonyl-containing compounds in these reactions[94].

Hammond and coworkers[12,95] found that the product of the rate constant for the interaction of excited benzophenone molecules with benzohydrol in benzene solution and the lifetime of the excited benzophenone molecules, $k_r\tau$, is about 20 litre mole^{-1}. Assuming that the maximal value of k_r is about 2×10^9 litre mole^{-1} s^{-1} (if the process is determined by the diffusion rate) these workers obtained a minimum value of 10^{-8} s for τ. In their opinion, the lifetime of the excited benzophenone molecules in the excited singlet state does not exceed 10^{-10} s, and they therefore concluded that triplet molecules take part in the reaction. The introduction of paramagnetic additives, such as oxygen and iron dipivaloylmethide, reduces the rate of reduction of benzophenone; this rate decrease is connected with the deactivation of the triplet state of benzophenone by these compounds. The more precise values of $k_r = 5 \times 10^6$ litre mole^{-1} s^{-1} and $\tau = 4 \times 10^{-6}$ s have been derived from kinetic results on the quenching of benzophenone triplet molecules by oxygen and the iron chelate.

Moore and Ketchum showed that naphthalene is about as effective in reducing the rate of reaction of benzophenone with benzohydrol as are the paramagnetic additives[96]. Naphthalene affects the photoreduction of benzophenone by propan-2-ol in the same way[54]. Since naphthalene is diamagnetic, and its first excited singlet level is higher than the corresponding level of benzophenone, the inhibiting effect of naphthalene is explained by the transfer of energy from benzophenone to naphthalene at triplet levels (see Section 1).

Later, Hammond and Leermakers showed that 2-acetophenone, piperylene, azulene, cyclo-octatetraene, biacetyl, and a number of other compounds that have triplet levels lower than the triplet level of benzophenone are about as effective as naphthalene in inhibiting the photoreduction of benzophenone[97]. These workers consider that this confirms the hypothesis that the rate of triplet-triplet energy transfer in these systems is controlled by diffusion, that is, energy is transferred in each collision of an excited benzophenone molecule with an acceptor molecule.

Using data on the kinetics of the benzophenone-sensitized phosphorescence of benzene solutions of biacetyl, Bäckström and Sandros[98] found that for benzophenone τ is about 2×10^{-6} s; it was assumed that the rate constant for triplet-triplet energy transfer, which is controlled by diffusion, is 1×10^{10} litre mole^{-1} s^{-1}. When propan-2-ol is used as a solvent, quenching of the phosphorescence occurs, evidently because of a reaction between the benzophenone and the alcohol; the lifetime of triplet benzophenone molecules is then reduced to 5.7×10^{-8} s.

The results obtained by Porter and coworkers by flash photolysis provide a direct proof that the triplet state participates in the reduction of benzophenone to benzpinacol[99,100]; it was shown by this method that the intermediates formed in the photolysis of benzophenone in benzene in the presence of propan-2-ol are ketyl radicals, $(Ph)_2{=}C{-}OH$. When naphthalene is added to the solution, the absorption band corresponding to the ketyl radicals disappears, and a new band characteristic of triplet naphthalene molecules appears[101]; virtually no benzpinacol is then formed. The lifetime of triplet benzophenone molecules in propan-2-ol, calculated from data on the kinetics of benzophenone consumption in the presence of naphthalene, is 6×10^{-8} s, which is in good agreement with the results of Bäckström and Sandros.

As in the reaction with benzophenone, the photochemical reaction between quinones and alcohols leads to the removal of hydrogen atoms from the alcohol and reduction of the quinone[102,103]. The following is a possible reaction scheme[104]:

$$Q + h\nu \rightarrow Q^*,$$
$$Q^* + R_2CHOH \rightarrow Q\dot{H} + R_2\dot{C}OH,$$
$$Q\dot{H} + R_2CHOH \rightarrow QH_2 + R_2\dot{C}OH,$$
$$2Q\dot{H} \rightarrow Q + QH_2,$$
$$2R_2\dot{C}OH \rightarrow R_2CO + R_2CHOH,$$

where Q is the quinone molecule and QH* is a semiquinone radical.

Obviously, the nature of the active excited state may differ in different quinones.

Bridge and Porter, who used the method of flash photolysis to study the intermediate particles formed in the photoexcitation of duroquinone in various solvents, showed that the disappearance of quinone triplet molecules and the formation of the semiquinone radical are independent processes that proceed at different rates [105]. From this it was concluded that the reduction of duroquinone proceeds through the excited singlet state. At the same time, the photoreduction of anthraquinone by propan-2-ol is greatly retarded in the presence of anthracene or naphthalene and it does not change in the presence of biphenyl [27]. The triplet levels of the first two hydrocarbons are lower, and that of the third is higher, than the corresponding anthraquinone level. For this reason, the inhibiting action of these additives is due to the transfer of energy from the anthraquinone triplet level, which appears to be the photochemically active level in this reaction.

In the presence of oxygen the mechanism of oxidation–reduction reactions may undergo substantial change [21]; oxygen itself then plays the part of the oxidant, and it is sensitized by the components that absorb light. In many instances (see, for example, Karyakin [106]), the reactions proceed through a stage in which intermediate peroxide compounds are formed. It is possible, however, that even here energy transfer from the sensitizer to oxygen is of considerable importance. Thus, Porter and Windsor [107] proposed the following scheme, which includes energy transfer, to explain the photo-oxidation of hydrocarbons by oxygen sensitized by anthracene:

$$A^T + O_2^T \rightarrow A^{S_0} + O_2^S,$$
$$O_2^S + RH \rightarrow R^{\cdot} + HO_2^{\cdot},$$
$$R^{\cdot} + O_2 \rightarrow RO_2^{\cdot},$$

where O_2^T is the triplet ground state of oxygen and O_2^S is an excited singlet state.

---o0o---

The material discussed in this review shows that the phenomenon of intermolecular transfer of excitation energy plays an important part in photochemical reactions of organic compounds in solution. In many instances the redistribution of the primarily absorbed light energy between the components of the solution considerably changes the course of the photochemical reaction. In particular, some reactions that proceed very slowly or not at all under the direct action of light can be induced by energy transfer from sensitized additives.

Sensitization and inhibition effects in photochemical reactions produced by intermolecular energy transfer are frequently used to elucidate the nature of excited states resulting from the action of light. An important advantage of sensitized photochemical reactions is their "cumulativeness", or their capacity to accumulate changes in the acceptor molecules that occur with the transfer of energy. This allows investigation of systems that are difficult to study by the luminescence method because of small quantum yields of the excited molecules under examination.

CONTENTS

I. Introduction 687

II. Preparation of chelate compounds in optically active forms 688

III. The use of spectropolarimetry and polarimetry in the study of chelate compounds 688

1. Study of redox reactions, racemisation, and substitution in chelates 688
2. Quantitative polarimetric determination of metals and ligands in chelates 689
3. Study of chelate formation and the nature of the bonding in chelates 689
4. Study of the phenomenon of stereospecificity in the chemistry of chelates 690
5. The configuration of chelate compounds 691

I. INTRODUCTION

The exceptional sensitivity of optical rotation to various types of reaction (structural changes, intermolecular interaction, etc.) and the unique nature of the properties of optically active compounds is leading to the broad extension of

studies of this phenomenon in the most varied branches of chemistry, particularly in the chemistry of chelate† compounds. It is known, for example, that many complex processes which take place in living organisms with the participation of metals include the formation of optically active compounds.

Optically active chelate compounds, which can be studied by spectropolarimetry, have in recent years been the object of a large number of studies. For a long time the spectropolarimetric method did not find extensive application because of the lack of available reliable instruments. About 1955 this difficulty was overcome by the production of the Rudolph spectropolarimeter [2]. Analogous instruments have been produced comparatively recently in the USSR. [3,4]

The foundations of the spectropolarimetric method in Russia were laid by Chugaev in the early nineteen-hundreds, in the period of the completion of the theory of the structure of organic compounds. Chugaev set himself the task of establishing the relationship between the optical activity of a substance and its chemical structure [5]. At that time it was customary to relate optical activity to an asymmetric carbon atom.

Optical activity is not a property of an individual atom, but is a property of the asymmetric molecule as a whole. As a result of the unsymmetric arrangement of the ligands around the central metal atom, it was possible to separate optical isomers of chelate compounds of nickel $[Ni(bipy)_3]X_2 . yH_2O$, where bipy represents bipyridyl [6]; cobalt(III) with Schiff bases, 1,8-diamino-3,6-dithiaoctane, etc. [7-11]; ruthenium, $[Ru(bipy)_3]Cl_2 . 6H_2O$; [12] osmium, $[OsCl_2(bipy)_2]Cl_2 . 3H_2O$; [13] iron(III) with 8-(2-pyridylmethyleneamino)quinoline [14]; zinc with 8-quinoline-5-sulphonic acid [15]; chromium [16]; platinum [17,18]; and many others.

A large number of optically active chelate compounds, exhibiting rotatory power due to an optically active ligand, the asymmetry of the molecule as a whole, or the combined influence of both these factors, have now been prepared and studied. Since review papers on optically active chelate compounds cover chiefly material up to 1958, [19-22] our aim was to systematise the literature on the chemistry of optically active chelate compounds chiefly for the period 1959–1964 and also to outline the main tasks and problems which are being solved by the spectropolarimetric method.

II. PREPARATION OF CHELATE COMPOUNDS IN OPTICALLY ACTIVE FORMS

The preparation of chelates in optically active forms is the primary problem in the chemistry of chelate compounds. As noted above, chelate compounds may exhibit optical activity as a result of the presence in the molecule of a ligand which has been prepared beforehand in optically active form. In a number of instances, however, the ligand may not contain an asymmetric centre, and the molecule as a whole becomes asymmetric after the formation of the chelate. It thus becomes necessary to separate the optical isomers of the previously-prepared chelate compound. This problem is extremely complex and its solution is directly related to the specific nature and properties of the chelate compounds.

Two main methods are used for the resolution of chelate compounds. The first method is based on the chemical reaction of optically-resolving agents with the chelate molecules, which should either be ionic or contain some functional group. In this the resolution involves the formation of diastereoisomers, which are then separated by fractional crystallisation, extraction, or chromatography. The most widely used optically active resolving agents are tartaric acid [23,24], (+)-nitrocamphor [16], antimony oxide (+)-tartrate [13,14,25], arsenic oxide (+)-tartrate [26], etc.

The resolution of some ionic chelate compounds — for example, tris-1,10-phenanthrolineruthenium(II) perchlorate — was achieved owing to the difference in the solubility of their antipodes in the presence of optically active additions (*d*-bromocamphorsulphonate) [27,28]. Recently optically active chelate compounds have been successfully used for resolving ionic chelates [29-32].

The second method of resolution, applied chiefly to "neutral" compounds, that is, compounds which are not ionic and contain no functional groups, is based on the selective adsorption of the chelates on quartz, starch, lactose, and other adsorbents. The resolution of (±)-Cr(HFA), where HFA is the fluoro-derivative of acetylacetone, has been carried out successfully by gas chromatography on quartz [33].

Chelate compounds of copper and nickel with β-keto--imines have been resolved by chromatography on D-lactose [34]. The same adsorbent gave satisfactory results in the resolution of oxobis-[4,4'-(propylenedi-imino)di-(2--pentanone)vanadium(IV). [35] Alumina treated with (+)-tartaric acid can be used as well as quartz for the resolution of Cr^{3+} and Co^{3+} acetylacetonates [36]. An interesting paper by Ferroni and Cini [37] describes the use of crystals of sodium *d*- and *l*-chlorate for the resolution of bis(benzoylacetonato)beryllium(II).

Recently, selective adsorption has also been used for the resolution of ionic chelates. Thus Dwyer and coworkers [38,39], in a study of compounds of the type $[Co(\pm)pn_2en]Cl_3$, $[Co(\pm)pnen_2]Cl_3$, $[Co(\pm)pn]Cl_3$, etc., where en represents ethylenediamine and pn propylenediamine, resolved the products on a cellulose column.

Other methods and reagents which are proving effective for the resolution of chelates are equally interesting. Harada and Fox [40] resolved the copper complex of aspartic acid by the introduction of a seed crystal of the optically active chelate. Interesting data have also been published [41] on the resolution of chelates by diffusion in liquids with asymmetric molecules.

Attempts to find new reagents and methods for the resolution of chelate compounds, particularly the search for new adsorbents, naturally deserve constant attention.

III. THE USE OF SPECTROPOLARIMETRY AND POLARIMETRY FOR THE STUDY OF CHELATE COMPOUNDS

1. Study of Redox Reactions, Racemisation, and Substitution in Chelates

Measurements of the rate of change of the optical rotation were used by Dwyer and Gyarfas [42] in a study of the dynamic equilibrium between the oxidised and reduced forms of the ions $Os(bipy)_3^{2+}$ and $Os(bipy)_3^{3+}$. This work was continued and refined by Eichler and Wahl [43], who studied

† We use the term "chelate" to describe metallocyclic compounds, in which the metal–ligand bonds may be different in character. A more detailed discussion of nomenclature has been published [1].

the rate of electron exchange in $Fe(phen)_3^{2+}-Fe(phen)_3^{3+}$, where phen = phenanthroline, and $Os(bipy)_3^{2+}-Os(bipy)_3^{3+}$ systems from the change in optical rotation and by using isotopic tracers.

Dwyer and Sargeson[44] described the measurement of the rate of electron transfer from the change in the dispersion of the rotation of the $Coen_3^{2+}-Coen_3^{3+}$ system. A detailed study of rates of electron transfer was made by Im and Busch[45,46], who divided the systems studied into two categories. The first consists of systems in which the absolute configuration is not preserved on electron transfer. As an example, the dependence of the racemisation of ethylenediaminetetra-acetatocobaltate(III) on temperature, pH, and concentration was studied. The hexadentate complex d-$[Co^{III}EDTA]^-$, where EDTA represents ethylenediaminetetra-acetate, undergoes racemisation at 100°, 90°, 85°, and 74° and the racemisation is catalysed by $[Co^{II}EDTA]^{2-}$ ions. We thus have two processes

$$d\text{-}[Co^{III}EDTA]^- \rightleftharpoons l\text{-}[Co^{III}EDTA]^-,$$

$$d\text{-}[Co^{III}EDTA]^- + [Co^{II}EDTA]^{2-} \rightleftharpoons [Co^{II}EDTA]^{2-} + l\text{-}[Co^{III}EDTA]^-.$$

The second category consists of systems in which the absolute configuration is preserved on racemisation, for example, 1,2-propylenediaminetetra-acetatocobaltate(III).

Racemisation of the ionic complex $[Coen_3]^{3+}$ in the presence of active carbon takes place as a result of a redox reaction[47]. By making use of electron exchange and the difference in the solubilities of the diastereoisomers of the tris(ethylenediamine)cobalt(III) ion, Busch[48] increased considerably the yield in the resolution of this ion.

The spectropolarimetric method has also been used successfully to measure the rate of exchange of the free ligand 1,2-propylenediaminetetra-acetic acid (PDTA) with its complex[49]:

$$[M(+)PDTA]^{4-} + l\text{-}PDTA \rightleftarrows [M\,l\text{-}PDTA]^{4-} + d\text{-}PDTA,$$

where M = Cu, Ni, Co, etc. It is obvious that the rotation falls to zero when half of the ligand has reacted.

The problem of racemisation is related to the problem of electron exchange and ligand exchange in chelate compounds. Redox reactions are one factor responsible for the racemisation of chelate compounds. This phenomenon has been examined in detail by Lewis and Wilkins[22] and in a number of recent papers. It has been established that the racemisation of certain compounds, for example, *cis*-chloroaquobis(ethylenediamine)cobalt(III)[50,51] and *cis*-bis(oxalato)diaquochromate(III),[52] takes place as a result of the isomerisation of the optically active *cis*-compound into the symmetrical *trans*-compound. In other examples the racemisation is brought about by dissociation of the chelate. For example, the tris(acetylacetonato)silicon cation undergoes racemisation as a result of degradation by hydrolysis[53]. Dissociation is responsible for the racemisation of a large number of nickel chelates with phenanthroline and bipyridyl[28,44-56]. Brown and Ingold[57] used polarimetry to study the kinetics of the replacement of chloride ions in the *cis*-dichlorobis(ethylenediamine)cobalt(III) ion.

An important problem concerns the behaviour of chelate compounds in various chemical reactions, particularly substitution. In a number of instances spectropolarimetry makes it possible to establish whether the reaction involves the chelates themselves or free ligands liberated as a result of dissociation of the chelate. Study of the bromination and diazo-coupling of optically active catechol-arsenic(IV) chelates[58] showed no significant change in optical activity and configuration, from which it was concluded that the reaction involves the chelates themselves.

Preservation of the optical activity is also observed in electrophilic substitution (chlorination, bromination, nitration, etc.) in optically active tris(acetylacetonato)-compounds of Cr^{III}, Co^{III}, and Rh^{III}.[59] Thus the chelate compound reacts as a single aromatic system, since otherwise, racemic products would have been obtained after the reactions.

2. Quantitative Polarimetric Determination of Metals and Ligands in Chelates

The use of polarimetry for the quantitative determination of optically active natural products is well known. This method can also be used, however, for the quantitative determination of optically inactive compounds. In 1957, Freegarde[60] determined the metal ions Ag^+ and Fe^{3+} by means of the optically active reagent (+)-tartaric acid. Freegarde measured the rotation of a (+)-tartaric acid solution before and after the addition of a weighed specimen of the substance, which formed a precipitate with the optically active reagent.

Complex formation by molybdic acid with maleic and tartaric acids, mannitol, sorbitol, and other compounds has been used for the polarimetric determination of the latter in the presence of various other optically active compounds[61].

Haas and Faber[62] used (+)-tartaric acid for the quantitative determination of molybdenum by a polarimetric method. The ability of the Cu^{2+} ion to form a complex with L-(+)-histidine has been used for the spectropolarimetric determination of the metal ion and the optically active ligand[63].

3. Study of Chelate Formation and the Nature of the Bonding in Chelates

The study of optical activity assists in the deeper penetration into the essential features of the processes taking place on chelate formation and in the investigation of very slight molecular changes which cannot be observed by other methods.

By studying the optical rotatory power of L-propylenediamine in the presence of different quantities of metal ions (Zn^{2+}, Cd^{2+}, Hg^{2+}, or Ag^+) it is possible to gain information on chelate formation from the change in rotation. The optical activity of L-propylenediamine remains unchanged in the presence of Ba^{2+} and Mg^{2+} ions, apparently due to the absence of chelate formation[64].

Larsson[65] used polarimetry to study various outer-sphere complexes of (+)-tris(ethylenediamine)cobalt(III). It is a familiar fact that change in the composition of the second coordination sphere of complexes of transition metals (sulphate, chloride, etc. ions) does not produce marked changes in the absorption spectra, whereas the optical rotation of the ionic complexes depends to a marked extent on the nature of the counter-ion. Larsson measured the optical rotation of (+)-$[Coen_3]^{3+}$ in aqueous solutions with gradual increase in the concentration of sulphate,

thiosulphate, fluoride, chloride, and perchlorate ions, and observed a rotation minimum in the first two instances, indicating the formation of outer-sphere complexes.

A change in the dispersion of the rotation was also observed when optically inactive ions were added to (-)-*cis*-oxalatobis(ethylenediamine)cobalt(III) and (-)-tris(ethylenediamine)chromium(III) ions[66]. A polarimetric study of the conditions of the reaction of orthotellurate with (+)-tartrate established that a compound with 1:1 composition is obtained[67]. Polarimetric study of the Th^{4+}–tartaric acid system led to the conclusion that a stable chelate compound with the 1:1 composition is formed[68]. In analogous fashion, Chinese authors[69] established the existence of a cobalt tartrate with 1:1 composition by observing the change in the rotatory power, absorption coefficient, and refraction of the system.

The study of optical activity helps to solve the problem of the nature of the bonding in chelate compounds[70]. For example, the lack of success in attempts to resolve tris-(oxalato)manganates and tris(oxalato)ferrates[71] may be attributed to ionic bonding between the metal and the coordinated groups in these chelate compounds. In compounds which can be obtained in optically active form, these bonds are covalent.

4. Study of the Phenomenon of Stereospecificity in the Chemistry of Chelates

The phenomenon of stereospecificity has been observed in the study of optically active chelate compounds. This problem has been examined in a number of monographs[20-22] and reviews[72-76].

The problem of stereospecificity is related to the chemistry of mixed chelate compounds, in which different ligands are coordinated around the central metal atom. Mixed chelate formation is fairly common among ionic chelates and there is no need to deal specially with this question[77-80]. It may be noted that mixed tris-bidentate chelate compounds can be prepared by three methods: by adding ligands to the bis- or mono-chelate, by replacing ligands in tris-chelates, or by direct preparation. These compounds have been the subject of many studies[26,81].

The preparation of mixed chelates presents no obstacles so long as optically inactive ligands are dealt with. The preparation of chelates containing optically active ligands introduces the effect of stereospecificity, as a result of which some possible isomers (*Dlld*, *Ldll*, etc.) of these compounds are obtained in very small yield or not at all. Thus in the reaction of racemic propylenediamine (pn) with platinum(IV) chloride, Smirnoff[82] was able to obtain only two compounds *D*-$[Pt(L\text{-}pn)_3]^{4+}$ and *L*-$[Pt(D\text{-}pn)_3]^{4+}$.

Bailar and his coworkers[83] found that mixed isomers are probably formed, but undergo disproportionation with the formation of the products which were isolated by Smirnoff. The similar formation of a limited number of isomers of tris-(*trans*-1,2-diaminocyclopentane)cobalt(III) by Jaeger and Blumendal[84], who consider that two or more of the ligands in the chelate compound usually have the same configuration, that the chelate exists in a single configuration, and its sign of rotation may be the same as or opposite to that of the ligand.

Subsequent studies refuted this opinion to some extent. Lifschitz[85], for example, prepared tris-(D-alanine)-cobalt(III), from which two α-forms *Dddd* and *Lddd* and one β-form were isolated. The fact that the two α-forms have equal stabilities suggests that the stereospecific effect is not very strong in amino-acid chelates. Bailar and coworkers[86,87] found that the carbonatobis-(L-propylenediamine)cobalt(III) ion exists in both *D*- and *L*-forms, and that the configuration of its salt depends on the method of crystallisation. Another paper[88] reports the existence of both the (+)-tartratobis-(L-propylenediamine)cobalt(III) and (-)-tartratobis-(L-propylenediamine)cobalt(III) ions, but the stabilities of these isomers are different.

Extensive studies of the phenomenon of stereospecificity have been made by Dwyer and coworkers. Ionic chelates of Co^{III} with D- and L-propylenediamine (*Dlll* and *Lddd*) have been prepared and the equilibria between the isomers *Dddd* ⇌ *Lddd* and *Dlll* ⇌ *Llll* have been studied[89]. Analogous isomers of Pt^{IV} were prepared[90]. An attempt to prepare chelates with mixed ligands by the reaction of dichlorobis(ethylenediamine)cobalt(III) chloride with L-propylenediamine was unsuccessful and gave a mixture of the chlorides $[Coen_3]Cl_3$ and $[Co(L\text{-}pn)_3]Cl_3$.[91] The reaction of tetrachloro(L-propylenediamine)platinum(IV) and tetrachloro(ethylenediamine)platinum(IV) with ethylenediamine and D-propylenediamine, however, led to the preparation and resolution of the mixed chelates $[Pten_2(L\text{-}pn)]Cl_4$, $[Pt(L\text{-}pn)_2en]Cl_4$, and $[Pt(D\text{-}pn)_2(L\text{-}pn)]Cl_4$. It was pointed out that unsuccessful attempts to isolate mixed chelates are apparently due not to differences in the stabilities of the chelates but to the establishment of an equilibrium between all possible isomers in the course of the reaction. This led to the isolation of the thermodynamically more stable isomers $[Pt(L\text{-}pn)_3]Cl_4$ and $[Pt(D\text{-}pn)_3]Cl_4$, which predominate in the mixture, whereas the small quantities of the mixed isomers could not be detected. It was suggested that the equilibrium is established either as a result of the formation of intermediate 7- or 8-covalent chelates, or as a result of the catalytic influence of small quantities of Co^{II} and Pt^{II} chelates. Recently, Dwyer and coworkers[93] described the preparation of a mixture of isomers, from which the following were separated by chromatography on a cellulose column: *L*-$[Co(-)pn_3]Cl_3$, *L*-$[Co(-)pn_2en]Cl_3$, *L*-$[Co(-)pnen_2]Cl_3$, *D*-$[Co(-)pn_3]Cl_3$, *D*-$[Co(-)pn_2en][ClO_4)_3$, and *D*-$[Co(-)pnen_2](ClO_4)_3$. It is considered that the degree of stereospecificity of the chelates is a property chiefly of the ligands and may vary from almost zero, for sodium bis(oxalato)-L-propylenediaminecobaltate(III)[94] to the almost complete stereospecificity of the chelates with propylenediaminetetra-acetic acid[95].

Partial stereospecificity was observed in a study of cobalt(III) chelates with 4-methyl-1,8-bis(salicylideneamino)-3,6-dithiaoctane[25]. It was established that the dextrorotatory isomer of the ligand gives chiefly the laevorotatory form of the chelate (85%), whereas the laevorotatory isomer gives the dextrorotatory form of the chelate. In a continuation of their study of stereospecificity, Dwyer and coworkers[38] recently described the isolation of various mixed chelates of Co^{III} with propylenediamine and gave the equilibrium constants for the systems

$$D\text{-}[Co(+)pn_3]^{3+} \cdot L(Co(-)pn_3]^{3+}/D[Co(+)pn_2(-)pn]^{3+} \times L[Co(-)pn_2(+)pn]^{3+}=1.0$$
$$D\text{-}[Co(+)pn_2(-)pn]^{3+}/L[Co(+)pn_2(-)pn]^{3+}=2.4$$
$$D\text{-}[Co(+)pn(-)pn_2]^{3+} \cdot L=[Co(-)pn(+)pn_2]^{3+}/D[Co(-)pn_3]^{3+} \cdot L=[Co(+)pn_3]^{3+}=6.1.$$

The stability of the isomers and their relative concentration in the mixture were explained on the basis of the possible conformations of the propylenediamine ring.

As well as being of purely theoretical importance, the phenomenon of stereospecificity has found practical appli-

cation. Bailar and coworkers[83] suggested that if the reaction between an optically active chelate and an excess of a racemic coordinating substance is selective, that is, if the chelate can accept only one optically active isomer from the racemate, resolution of the racemic ligand should be observed. The first experiments did not give satisfactory results, however. Later[88], partial resolution of racemic tartaric acid was achieved by heating the cobalt chelate $[Co(L\text{-}pn)_2(rac\text{-}tart)]Cl$ in aqueous solution with an excess of L-propylenediamine. The latter replaces the (-)-tartrate ion in the chelate, whereas the (+)-tartrate ion is much more firmly held in the coordination sphere, proving that the configurations of (+)-tartaric acid and L-propylenediamine are identical. Partial resolution of racemic mixtures of organic acids (tartaric, α-chloropropionic, and lactic) was achieved using the carbonatobis(L-propylenediamine)cobalt(III) ion[96]. In all instances the dextrorotatory form of the acid enters the coordination sphere more readily than the laevorotatory form, and this leads to resolution. This reaction can also be used to determine the configuration of optically active acids. An attempt to resolve racemic tartaric acid by the reaction of its silver salt with *trans*-dichlorobis[(-)-stilbenediamine]-cobalt(III) nitrate was unsuccessful[97], however.

Sarma and Bailar[98] described the partial resolution of diamines, amino-acids, and dibasic acids by coordination with an optically active chelate. Stereospecificity has also been used successfully to prepare optically active chelate compounds[29,99,100]. For example, when (±)-$[Co(EDTA)]^-$ is treated with L-propylenediamine, the amine reacts with (-)-$[Co(EDTA)]^-$, leading to partial resolution of the chelate. Stereospecific reactions were recently used to prepare optically active forms of propylenediamine[101] and propylenediaminetetra-acetic acid[102].

The phenomenon of stereospecificity in non-ionic optically active chelate compounds of the bis-[*o*-(α-phenylethyliminomethyl)phenolato]copper type was studied by Terent'ev and coworkers[103]. In a study of the possibility of preparing chelates with irregularly paired ligands, in which the metal atom would be combined with two different molecules of a Schiff base ligand, it was established that for the systems studied the compounds with regularly paired ligands are favoured energetically.

A mixture of (-)-*o*-(α-phenylethyliminomethyl)phenol and (+)-*o*-(α-phenylethyliminomethyl)phenol in the presence of an excess of one of the forms was taken for the original ligands, and the chelate formation was carried out with copper and nickel; it was concluded that the products are always the compounds in which the metal is coordinated to ligands with one configuration, to give chelates with regularly paired ligands (*ll* or *dd*). An interesting feature is that these compounds can be formed by crystallisation of the double crystal-racemates *ll*×*dd*. This intramolecular racemisation leads to separation of a racemic fraction of the ligand in the form of the chelate, and the remaining uncombined fraction of the ligand is enriched in one of the optically active forms (*l* or *d*) taken in excess. This makes it possible to carry out the further purification of incompletely resolved amines and to obtain them in optically pure form.

5. The Configuration of Chelate Compounds

The study of optical rotatory power assists in the solution of the problem of the three-dimensional structure of a number of chelate compounds. In some instances the production of optical activity can be explained if it is assumed, following Werner[104], that the chelate compounds of elements with a coordination number of 6 have an octahedral structure whereas compounds with coordination number 4 have a tetrahedral or square-planar structure. Thus to explain the optical activity of *meso*-stilbenediamineisobutylenediamineplatinum chloride, Mills and Quibell[105] suggested that the bonds have a planar arrangement, since only then is the molecule asymmetric. With tetrahedral arrangement of the bonds, a plane of symmetry appears, so that the optical activity disappears.

The tetrahedral configuration of some beryllium chelates was confirmed by the successful resolution of their optically active isomers. Burgess and Lowry[106] observed the existence of optical isomers for benzoylcamphor complexes of beryllium, whose solutions exhibit mutarotation. This phenomenon was attributed to the gradual disappearance of the optical activity associated with the beryllium atom, which is the centre of the asymmetry.

Mills and Cotts[107] studied chelate compounds of beryllium, copper, and zinc with benzoylpyruvic acid; the optical isomers were separated using strychnine and brucine. They obtained an optically active solution almost free from alkaloid, but this rapidly underwent racemisation. Bis-(benzoylacetonato)beryllium, resolved by Busch and Bailar[108] by shaking a benzene solution of the chelate with optically active quartz powder, was found to be more stable.

The partial resolution of the tris(oxalato)germanate(IV) ion[109] proves the octahedral arrangement of the bonds in this ion and their covalent character. The successful resolution of bis(*o*-diethylphosphinophenyldiethylarsine)-copper(I) indicates that this compound has tetrahedral configuration[110]. The tris(biguanidine)-chelates of Co^{III} and Cr^{III}, like the tris(ethylenediamine)-chelates, have an octahedral configuration in which there are no elements of symmetry, and this was confirmed by separation of their optical isomers[23]. Ramaiah and coworkers[35] suggested that the five-coordinate chelate oxobis-[4,4′-(propylene-di-imino)di-(2-pentanone)]vanadium(IV) has a plane-pyramidal structure. In this instance the compound should exist in the form of optical isomers, and this was in fact proved. The partial resolution of the optical isomers of the β-keto-imine chelates of copper and nickel by a chromatographic method confirms that these compounds have tetrahedral configuration[34]. These and other examples[111,112] confirm that the existence of optical isomers provides a means of investigating the configuration of chelate compounds.

An important problem which has recently attracted the attention of research workers[113] is the determination of the absolute configuration of optically active chelates. A very important step in this direction was taken by Japanese scientists[114], who used X-ray diffraction methods to determine the absolute configuration of the *D*-(+)-$Coen_3^{3+}$ ion.

Later, Ballard and coworkers[115] proposed a new criterion for establishing absolute configuration, based on the sign of the optical rotatory power of the chelate in the long-wave range of the spectrum and on the sign of the rotatory power of the ligand[116]. Saito and coworkers gave data on the determination of the absolute configuration of the $[CoCl_2(L\text{-}pn)_2]^+$ [117] and *L*-$[Co(L\text{-}pn)_3]^{3+}$ [118] ions. The determination of the absolute configuration of some chelates is important since it makes possible the rapid determination of the configuration of many other analogous

compounds by comparison of their absorption spectra and rotatory dispersion curves. Japanese authors [119-122] have pointed out that if two optically active chelate compounds have similar bond character and hence similar stabilities, the sign of the Cotton effect should depend only on the absolute configuration. Compounds with the same absolute configuration should give Cotton effects with the same sign. This comparison of the rotatory dispersion curves of chelate compounds with known and unknown configurations has been used [24,36,76,123,124] to determine the configuration of chelates.

Optically active quartz and various other solids are being used successfully for the resolution of chelate compounds [37]. Bailar [125] has pointed out that if it were possible to show that a relationship exists between the configuration of quartz and the configuration of the isomer which is adsorbed by it, this would provide a simple method for determining the configuration of optically active substances.

The configuration of non-ionic optically active chelate compounds was discussed by Pfeiffer [126]. In a study of the rotatory dispersion curves for a number of chelates based on salicylaldehyde and various optically active amines and diamines and containing optically active formylcamphor, Pfeiffer reached the following conclusions.

1. The Cotton effect is shown by optically active chelate compounds of this type in the visible range of the spectrum only when a chromophoric metal atom is present.

2. As far as the manifestation of the Cotton effect is concerned, dicyclic and tricyclic compounds are in principle equivalent.

3. The position of the asymmetric carbon atom relative to the metal atom in the compounds studied plays no significant part in the manifestation of the Cotton effect.

Since the rotatory dispersion curve shows an anomalous shape when a metal is added to a Schiff base, it was concluded that in addition to the asymmetric carbon atom there should be another centre of asymmetry — the metal atom — and that it is the latter which produces the Cotton effect. From this Pfeiffer concluded that the chelates considered have tetrahedral configuration. Chelate compounds of the same type but containing no asymmetric carbon atom have planar configuration. Pfeiffer considered that the vicinal effect cannot be responsible for the Cotton effect. In an analysis of this work by Pfeiffer, Martell and Calvin [20] consider the rejection of the vicinal effect to be premature. The vicinal effect is apparently responsible for the anomalous shape of the rotatory dispersion curves. Evidence against tetrahedral configuration for these compounds is also provided by the fact that they could not be separated into optical isomers with respect to the central metal atom.

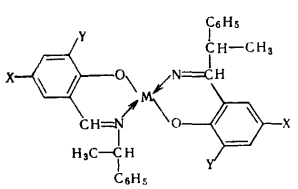
Thus Pfeiffer, on the basis of the normal rotatory dispersion curve for the nickel–formylcamphor complex, concluded that this chelate has square-planar configuration [126]. Later, however, French and Corbett [127] recorded the ultraviolet spectrum and rotatory dispersion curve and found that the rotatory dispersion curve shows a maximum at $\lambda = 3162$ Å, due to the absorption band of the nickel centre in the molecule. Measurement of the magnetic susceptibility of this compound in the solid state and in methanol solution shows that it is paramagnetic. On the basis of the data obtained, it was concluded that the nickel–formylcamphor complex has tetrahedral configuration. Subsequent study [128] of the absorption spectra, rotatory dispersion, and magnetic susceptibility of bis(formylcamphor)ethylenediaminenickel led to the conclusion that this compound has planar configuration in the solid state, but that in methanol solution, under the influence of the asymmetric centre present, equilibrium is established between the two configurations: planar and tetrahedral.

From these data it can be seen that the mere presence or absence of the Cotton effect does not provide proof for tetrahedral or planar configurations respectively in chelate compounds. In these compounds the central metal atom is a chromophore which reacts with the asymmetric centre in the molecule. The absorption band corresponding to the metal atom is optically active and a Cotton effect appears in this range of the spectrum.

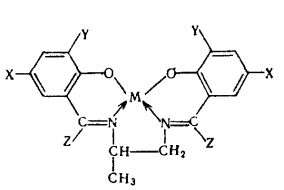
Lifschitz [129] in a study of the rotatory dispersion of chelate compounds, examined the question of the relationships which should exist between the chromophore and an optically active centre for production of the Cotton effect. He considers that in compounds containing optically active coordinated groups, a Cotton effect in the range of the absorption band of the central metal atom is observed only when the asymmetric atom is a member of a ring formed through the central atom by means of "inner-complex bonding (that is, where the metal atom is attached to the organic molecule by means of a principal valency and a subsidiary valency)". Lifschitz emphasises the difference in the behaviour of the copper and nickel chelates. Thus the compounds of $[Cu(L\text{-}pn)_2]^{2+}$ give an anomalous rotatory dispersion curve, whereas the compounds of $[Ni(L\text{-}pn)_2]^{2+}$ give a normal curve. Lifschitz considers that for the nickel chelate it is necessary to assume a symmetrical structure in which the rotation is due entirely to the optically active propylenediamine molecules present. The unique behaviour of copper is attributed to the possibility of partial asymmetric synthesis.

A review by Mat'ë [130] gives several examples from the literature which have been attributed to partial asymmetric synthesis, and points out that in every instance where a complex capable of existing in two enantiomorphic forms is obtained, it is necessary to investigate carefully whether the Cotton effect arises from a bond between an active molecule and the central atom or is due to partial asymmetric synthesis.

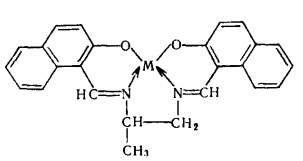
Recent papers by Terent'ev and coworkers [131-133] give the results of spectropolarimetric studies of chelates with structures A, B, C, D, and E, with optically active *o*-hydroxyaldimines and *o*-hydroxyketimines.



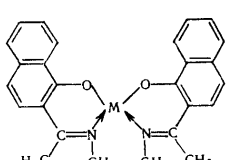
(A) X = H, Cl, Br, NO_2; Y = OCH_3, H; M = Cu, Ni, Co



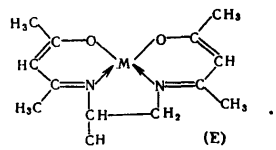
(B) X = H, Cl, Br, NO_2; Y = OCH_3, H; Z = CH_3, H; M = Cu, Ni, Co



(C)



(D)



(E)

On the basis of a comparison of the rotatory dispersion curves for these compounds, it was concluded that non-vicinal (distant) substituents (X, Y) in the chelates have little influence on the rotatory dispersion. The introduction of a vicinal substituent ($Z = CH_3$) in the metal-containing ring on going from the hydroxyaldimine derivatives to the hydroxyketimine derivatives, however, leads to a sharp increase in the absolute values of the molecular rotation without altering significantly the nature of the rotation, due to the difference in the degree of coplanarity of the chelate compounds.

Although spectrophotometry has been unable to record these fine changes in molecular structure, the conclusions reached on the basis of spectropolarimetric studies have been confirmed by data from the EPR spectra[134].

---o0o---

It can be seen from the foregoing that the use of polarimetry and spectropolarimetry in the study of optically active chelate compounds opens up promising possibilities. The high sensitivity of these methods makes it possible in a number of instances to record fine changes in a molecule, difficult to detect by other methods.

The possibilities of the spectropolarimetric method in the chemistry of optically active chelate compounds are far from being exhausted, however. The increase observed every year in the number of studies in this field and the isolation of new chelates in optically active form enable us to hope that new properties and phenomena making it possible to reach a deeper understanding of the chemistry of optically active chelate compounds will be discovered and studied.

I. INTRODUCTION

Modern ideas on the molecular structure of organic compounds are to a large extent linked with the study of physical properties, such as absorption spectra in all regions from the ultraviolet to the microwave, dipole moments, atomic and electronic polarisation, etc. In the last two decades a new method for investigating organic compounds — molecular mass spectrometry — has been developed; this deals with the interaction of molecules and electrons. The overall relative probability of the formation of various ions that arise when a molecule is bombarded with slow (20–70 eV) electrons is characteristic of the stability of the molecule, and, what is very important for the organic chemist, of its structure, since the possible rupture of a given bond depends mainly on the distribution of electron density.

The formation of mass spectra is generally considered from the point of view of the Franck–Condon principle[1], according to which the first act in any inelastic collision between an electron and a molecule is electronic excitation of the latter, which occurs as an electronic transition while the distance between nuclei remains unchanged. In the inelastic collision of an ionising electron with a molecule, one of the valence electrons is removed and a molecular ion corresponding to the molecular weight and empirical formula of the compound is formed. Electrons acting on the molecule in the ion source of the mass spectrometer usually possess energy of several tens of electron volts; therefore, in the bombardment of polyatomic molecules, in addition to ionisation, decomposition of molecular ions occurs with rupture of C–C and C–H bonds and the formation of ionic fragments, which may also decompose in turn. This multiplicity of processes is responsible for the complexity of the mass spectra of polyatomic molecules with their multiplicity of lines.

The stability of organic molecules to electron impact is characterised by the probability of decomposition of molecular ions[2], W_Z, and is determined by the ratio of the number of molecular ions (I_{mol}) to the number of fragmentation ions (ΣI_{frag}): $W_Z = \Sigma I_{frag}/(I_{mol} + \Sigma I_{frag})$. The value of $W_M = (1 - W_Z)$ determines the stability of the molecule to electron impact.

This ratio, in turn, reflects the rate of decomposition of the molecular ion; since the time between the formation of ions and their detection is usually 10^{-5} s, the absence of particular molecular-ion peaks in the mass spectrum indicates that these ions have a short life. The rate of decomposition of the molecular ion is a function of the energy acquired by the ion during its formation; when the energy of the ionising electrons falls to a value close to the ionisation potential of the molecule, the proportion of molecular ions is increased in relation to that of fragmentation ions.

The ionisability of molecules and radicals formed in the rupture of chemical bonds is characterised by what is termed complete ionisation, which represents the quantity of ions formed by unit quantity of the compound[3]. It is determined by the sum of the intensities of all the peaks in the spectrum multiplied by the coefficient of sensitivity of the strongest peak; the latter is expressed in units of ion current referred to unit pressure.

In addition to the ions formed by simple rupture of bonds, the mass spectra of nearly all molecules containing more than two carbon atoms show the presence of ions that are produced as a result of rearrangement of atoms at the moment of dissociation. Rearrangements with migration of a hydrogen atom are observed very frequently[4]. The activation energy of rearrangements in ions is low and commensurable with the activation energy of rearrangements in neutral molecules; accordingly, rearrangements in the molecular ion proceed comparatively easily[3]. With hydrocarbons the difference in activation energies of various rearrangements is very small, and therefore competing reactions lead to the formation of diverse fragments.

Although the number of carbon and hydrogen atoms in the ion can be readily established, the question as to which of the hydrogen atoms has separated with a given fragment can only be decided by a study of the mass spectra of isotopically "labelled" compounds[6,7]. Information on the structure of ionised fragments can also be obtained by measuring the energy changes in the reactions that occur and by studying metastable transitions.

All the ions formed in the primary step of interaction of the electrons with the molecule† may be divided into three groups: (1) stable ions, with insufficient excitation energy for decomposition before detection; (2) unstable ions, with sufficient energy for decomposition before they leave the ion source; and (3) metastable ions of intermediate energy[8]. The latter, which decompose after acceleration (but before deflection by the magnetic field), are generally focussed with the production of "false" peaks corresponding to ions of "non-integral" mass. The relationship between the apparent mass of the metastable ion, m^*, the mass of the initial ion before dissociation, m_0, and the mass of the fragmentation ion is expressed by the equation $m^* = m^2/m_0$. The metastable ions are "witnesses" of a given stage of the decomposition process, and they can be used to decide the question of the probable routes of dissociative ionisation.

Temperature is one of the other factors that affect the distribution of intensities in mass spectra. An increase in the temperature of a gas increases the vibrational energy of the molecules and in this way changes the probability of formation of various ions in the mass spectrum of the compound under examination. The most reliable studies on the temperature dependence of mass spectra indicate that there are different changes in intensity of the peaks of various ions[9-12]. The intensity of a molecular-ion peak always decreases with increase in temperature; the peaks of fragmentation ions can increase, decrease, or pass through a maximum; the intensity of ion peaks due to the end products of dissociative ionisation increases with increasing temperature. The value of the complete ionisation depends little, or not at all, on change of temperature.

The variety of phenomena that occur on the interaction of complex molecules with electrons is not limited to those mentioned above. We thought it expedient to consider only those phenomena and characteristics that reflect the specific features of dissociative ionisation processes.

Any examination of the present state of the theory of molecular mass spectrometry from the point of view of the organic chemist must take into account the fact that none of the current views allows quantitative predication of the intensity distribution in the mass spectrum of a complex organic compound of known formula. Therefore, in addition to work designed to set up a quantitative theory of the formation of mass spectra, based on studies of primary and secondary acts in the ionisation of complex molecules, research work is also needed to establish correlations between the structures of organic compounds and their mass spectra. The study of regularities in the mass spectra of organic compounds, and of the relationship between structure and intensity distribution, brings us nearer a solution of the problem of determining a structure from the results of mass-spectrometric analysis. The establishment of different kinds of empirical rules will provide the basis for the development of methods of identification and of qualitative and quantitative analysis.

The methods of molecular mass spectrometry are widely used to study various classes of organic compounds, but their greatest analytical use has been in the hydrocarbon field. However, despite the large number of published papers on the subject, up to now there has been no general systematic summary of the regularities in the mass spectra of hydrocarbons with different degrees of unsaturation. The present review is an attempt, in some measure, to fill this gap.

II. PARAFFIN HYDROCARBONS

The most intense peaks in the mass spectra of hydrocarbons correspond to ions of odd mass number[13] with an even number of electrons, $C_2H_5^+$, $C_3H_7^+$, $C_4H_7^+$, $C_4H_9^+$, etc. The absence from paraffin molecules of groupings that either are stable to electron impact, or produce considerable weakening of certain single bonds, makes it difficult to establish correlations; usually, the primary decomposition process is clear only for branched molecules.

Bloom and coworkers[14], and also Mohler and coworkers[15], studied the mass spectra of octane and nonane isomers and extended the regularities they discovered to all paraffin hydrocarbons. They showed that the most probable processes are those in which the fragmentation ions $C_3H_7^+$ and $C_4H_9^+$ are formed. Molecules with ethyl, propyl, and isopropyl groups readily eliminate these ions, the ion produced corresponding to the mass of the remaining part of the molecule. In most instances, hydrocarbons with a terminal tertiary butyl group give similar spectra, the maximum peak corresponding to $C_4H_9^+$ ions.

In many instances the configuration of the carbon atoms in the hydrocarbon ions can be determined by examining the energetics of the process without the use of labelled compounds[16]. A study of the potentials at which the $C_2H_5^+$, $C_3H_7^+$, and $C_5H_{11}^+$ ions appear‡ in the mass spectra of the normal paraffin hydrocarbons[17] C_5H_{12} and C_8H_{18} has shown that propyl, butyl, and pentyl ions have the secondary structure, but the free radicals formed with them usually have the primary structure, and only sometimes the secondary. The stability of the $C_3H_7^+$ ion, which is encountered in considerable quantities in the mass spectra of all paraffin hydrocarbons, appears to be associated with its cyclopropenyl structure, that is, with the presence of a protonated cyclopropane ring[18]. This conclusion was further supported by the work of Stevenson[7], who established that, in the mass spectra of [1-^{13}C]propane and [2-^{13}C]propane, the relative intensities of the peaks for the fragmentation ions $C_1H_x^+$ and $C_2H_x^+$ are identical; this indicates that the carbon atoms are indistinguishable in the molecular ion $C_3H_8^+$, from which these fragments are formed. Urch also showed that with ionisation by electron impact there is a change in the symmetry of the neutral molecule[19].

Of 80 mass spectra of alicyclic C_2–C_{12} hydrocarbons presented in the catalogue of the American Petroleum Institute[20], only two (those of ethane and 3,4-dimethylhexane) show the formation of more intense peaks of the

† The primary processes also include electron capture and the formation of negative ions. However, since these processes are not typical of hydrocarbons, we shall not consider them here.

‡ The adiabatic ionisation potential of a molecule or atom is theoretically defined as the energy required for the removal of an electron from a neutral particle in the ground state with the formation of a molecular or atomic ion, also in the ground state. The ionisation potential determined by the electron-impact method is, in most instances, the so-called "vertical potential", which exceeds the adiabatic potential by the energy of vibration at excitation of the ion; this is due to the difference in the equilibrium configurations of the nuclei in the molecule and in the molecular ion. The term "appearance potential" applies to those instances of ion formation in which dissociation accompanies ionisation; the appearance potential corresponds to the minimal energy for the production of fragmentation ions.

fragmentation ions $C_2H_4^+$ and $C_4H_8^+$, with an odd number of electrons. Intense peaks of $C_nH_{2n}^+$ ions, the formation of which was related to the elimination of groups with tertiary carbon atoms and the migration of hydrogen, have also been observed in the mass spectra of some dodecanes[21].

The formation of ions which isomerise is not generally typical of paraffin hydrocarbons, but in some instances, for example, in the dissociative ionisation of neohexane, the formation of $C_3H_7^+$ ions must entail rupture of two C–C bonds and migration of a hydrogen atom. These considerations are also valid for the $C_2H_5^+$ ion in the spectrum[22] of isobutane $(CH_3)_3CH$. Analysis of the mass spectra of deuterated hydrocarbons also indicates that migration occurs. For example, $(CH_2D)^+$ and $(CHD_2)^+$ ions are present in the mass spectrum of 1,1,1-trideuteroethane[17].

Several hypotheses have been advanced to explain the specificity of decomposition of complex molecules, including hydrocarbon molecules. An attempt to solve this problem based on the concept of the distribution of the electron density of single bonds[23] led to disagreement with the experimentally observed distribution of intensities, particularly for C_3 and C_4 ions of long-chain molecules[24,25]. Nor were positive results obtained when bond energies for the initial molecule were used to calculate mass spectra; the appearance of very high peaks coreesponding to ions with a small number of carbon atoms could not be explained[26,27].

The quasi-equilibrium theory of mass spectra[28,29] allows the calculation of intensities in the mass spectra of paraffin hydrocarbons containing not more than five carbon atoms. Satisfactory results were obtained in the calculation of mass spectra of low-molecular ethers, alcohols, etc.[30–34] In the investigation of large molecules, a discordance was observed between theory and experiment, particularly in the region where the ionising electrons have low energies; most of the fragments are then formed by direct dissociation on electron impact. The normal paraffins C_nH_{2n+2} from C_6 to C_{30} have been used as models to explain the factors which give rise to the anomalous (from the standpoint of statistical theory) decomposition of molecules on electron impact[35]. Treatment of the mass spectra of these compounds showed that the yield of heavy ions (with the number of carbon atoms in the ion $m \geq 15$) does not depend on m and n as such, but is determined only by $(n - m)$, that is, by the size of the neutral fragment. For low values (3–15) of m, the yield of ions depends on both n and m.

Ryhage and coworkers[36] examined the mass spectra of the labelled paraffin hydrocarbon $CD_3-[CH_2]_{24}-CD_3$ and concluded that fragmentation ions are formed from the central portion of a saturated chain, since the C_2-C_5 fragmentation ions contained no deuterium. Theoretical investigation of the dissociation of molecular ions of normal paraffins has shown[37] that fragmentation ions are formed as a result of competing successive decomposition steps; each ion decomposes in such a way that no charged fragments are formed with less than half the initial number of carbon atoms.

Gur'ev and coworkers[38,39], who studied the mass spectra of [5-^{13}C]-n-nonane, suggested that fragmentation ions are formed by "shedding" of a charged part of the molecule in the region of electron impact, the C–C bonds being ruptured at equal distances from the point of impact. The complete set of probabilities of the mass spectra of an infinitely large molecule appear at each point of collision (independently of the size of the molecule); if the rupture of one of the bonds should take place "outside the limits" of the molecule, only one bond is broken and a smaller fragment is formed. Potapov and coworkers[40,41] studied the probability curves for the appearance of various ions, which give an indication of the mechanism by which ions are formed, and they showed that C_nH_{2n+1} ions are formed from n-octane and n-nonane by simple rupture of one C–C bond to give an ion and a radical. The formation of ions accompanied by the production of many neutral fragments is less favoured energetically. Examination of the mechanism of formation of $C_nH_{2n}^+$ ions, in particular $C_3H_6^+$ ions, led to the conclusion that rupture of two C–C bonds and union of the terminal parts of the hydrocarbon chain take place in a synchronous step. Comparison of the mass spectra obtained in electron and ion collisions[42] showed that dissociation of the ions occurs some time after the moment of excitation, and the relative decomposition probabilities depend to a small extent on mass and type of neutral particle with which collision occurs[43].

To establish the role of different mechanisms for the formation of the commonest ions, $C_3H_7^+$ and $C_4H_9^+$, in the mass spectra of long-chain paraffins, Beynon and coworkers studied [4-^{13}C]-n-eicosane and [1-^{13}C]-n-heptadecane and examined the degree of enrichment of fragmentation ions with heavy carbon[44]. The following hypothetical routes of formation of ions were considered: (1) simple rupture of one carbon–carbon bond in the molecular ion with the formation of an ion and a neutral fragment; (2) rearrangement of the molecular ion to a protonated ring structure; (3) complete "disintegration" of the carbon–carbon skeleton before the formation of fragments; (4) removal of any given number of adjacent carbon atoms from a (linear) molecular ion; (5) decomposition of a molecular ion with simple rupture of the carbon–carbon double bond, followed by rearrangement of the fragmentation ion to a ring structure and further fragmentation by Scheme (2); (6) simple bond rupture with subsequent removal of C_2H_4 fragments.

The validity of these hypotheses was tested by comparing experimental and calculated curves reflecting the proportion of unlabelled and labelled fragmentation ions with a different number of carbon atoms. The results showed that ions with a small number of carbon atoms are generally not formed by simple rupture of the carbon chain. On the other hand, rupture of one C–C bond is characteristic for larger ions. Further decomposition occurs mainly by successive removal of C_2 ions. The hypothesis that a ring structure is formed directly from a molecular ion is not in agreement with experimental results obtained with heavy fragments. The best agreement between the experimental and theoretical curves was obtained with mechanism (5); it was assumed, from steric considerations, that the rings usually contain five or six carbon atoms.

The specificity of dissociative ionisation of paraffins with a normal, or not too branched, chain is reflected in the nature of the distribution curve: the maximum corresponds to $C_3H_x^+$ ions, which are formed with the highest probability, irrespective of the length of the paraffin chain (Fig. 1). When the chain contains quaternary carbon atoms, a second maximum appears. Thus, investigation of the mass spectra of isomeric tetradecanes with the methyl side group in different positions showed that secondary maxima appear, owing to the rupture of a bond at the tertiary carbon atom[45,46].

The degree of decomposition of the paraffin molecule that occurs when it interacts with ionising electrons depends

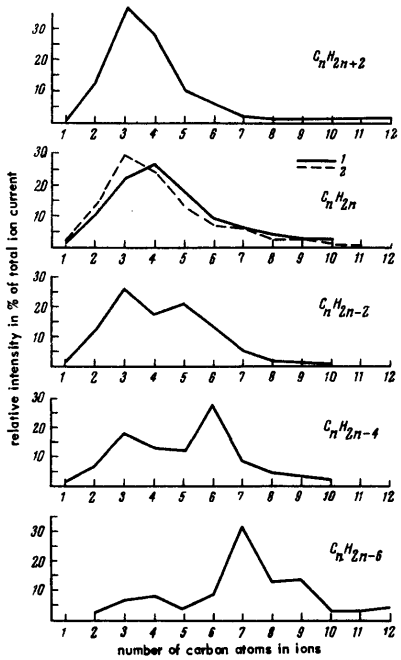

Fig. 1. Distribution curves of intensities against number of carbon atoms in ions for different hydrocarbon groups
1) naphthene; 2) monoalkene.

on the branching of the carbon skeleton: Bloom and coworkers analysed the spectra of 18 octane isomers and showed that the most intense molecular-ion peak is observed in the mass spectrum of the normal isomer[14]. Examination of the spectra of the tetradecanes[45,46] and the hexadecanes[47] showed a similar picture. The intensity of the molecular-ion peak decreases with increase in molecular weight; a more rapid rate of decrease is shown by branched paraffins than by the normal isomers. The peak intensities of the molecular ions of C_6–C_{12} hydrocarbons are, with some exceptions, 3–6% of the maximum. Further increase in molecular weight leads to virtually complete disappearance of the molecular-ion peaks in the spectra of branched paraffins[48]. Gur'ev examined the mass spectra of normal paraffins and showed that the dependence of the fraction of molecular ions on molecular size is well represented by an exponential curve[49]. Polyakova and coworkers[50] studied the mass spectra of normal paraffins on different instruments, and showed that, in all instances, the sensitivity coefficients of the molecular-ion peaks are a function of molecular weight. However, the nature of the dependence, which is represented by an interpolation formula, varies somewhat from one instrument to another.

III. NAPHTHENE HYDROCARBONS

In many ways the dissociative ionisation of naphthene hydrocarbons is similar to the process observed when electrons interact with paraffin molecules.

Unlike paraffins, naphthene hydrocarbons have intense molecular-ion peaks; for C_6–C_{11} isomers, the mean intensity of the molecular-ion peaks is 18.5% of the maximum.

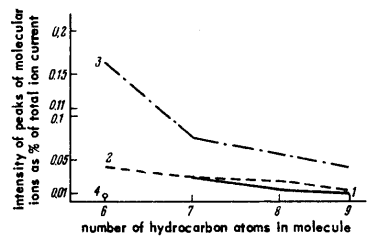

Fig. 2. Stability of $C_nH_{2n}^+$ molecular ions to electron impact:
1) monoalkenes; 2) five-membered naphthenes; 3) six-membered naphthenes; 4) ethylcyclobutane.

The stability of naphthene hydrocarbons to electron impact is greater than that of paraffins, and it does not change so sharply as the number of carbon atoms in the molecule increases. However, hydrocarbons with the empirical formula C_nH_{2n} differ in their resistance to electron impact. Fig. 2 shows the intensities of the molecular-ion peaks relative to the complete ion current in the mass spectra of monoalkenes and naphthene hydrocarbons with five- and six-membered rings. The figures representing the degree of decomposition of monoalkenes and cyclopentane hydrocarbons are very close (curves *1* and *2*), but the figures for cyclohexane hydrocarbons (curve *3*) indicate that these are much more stable to electron impact.

Several qualitative relationships between the structure of the initial molecule and the intensity of the molecular-ion peaks in the mass spectra of naphthene hydrocarbons can be established: (1) the molecular peaks of hydrocarbons with a five-membered ring are, as a rule, less intense than the corresponding peaks of naphthenes with a six-membered ring; (2) *gem*-disubstituted hydrocarbons have the lowest molecular peaks; (3) with few exceptions, hydrocarbons with a branched group attached to the ring have a lower molecular peak than hydrocarbons with an unbranched group having the same number of carbon atoms.

In comparison with paraffins the dissociative ionisation of naphthene hydrocarbons is associated with a much greater probability of processes in which a hydrogen atom migrates. As a result, so-called "pseudomolecular" fragmentation ions are produced with the same mass as true molecular ions from a homologue of lower molecular weight.

Stevenson[51], who studied the mass spectra of five-membered naphthene hydrocarbons, showed that, under electron impact, the excited molecular ion rearranges to the corresponding alkene ion, which undergoes further dissociation. For example, when methylcyclopentane labelled with ^{13}C dissociates, the methyl group is not removed directly, but a number of successive reactions occur that lead to the formation of methyl and other, heavier fragmentation ions. Energy calculations also show that $C_5H_9^+$ ions, which are formed by the decomposition of cyclopentane hydrocarbons, correspond to alkenes with some excess energy[52]. Analysis of the mass spectra of labelled cyclohexane, methylcyclohexane, ethylcyclopentane, and methylcyclopentane[53] has shown that, for methylcyclopentane, the ^{13}C atom may appear on the $C_5H_9^+$ or the CH_3^+ ions with equal probability; consequently, on ionisation the ring is ruptured at the substituent and the open chain then dissociates.

With methylcyclohexane, the CH_3 group is removed only from the side-chain. CH_3 and C_2H_5 groups removed from molecular ions of ethylcyclopentane and methylcyclopentane are only partly derived from the side-chain. With methylcyclohexane and methylcyclopentane, C_2H_4 groups are detached mainly from the ring, and with ethylcyclopentane exclusively from the ring. The heats of formation of $C_6H_{11}^+$ ions from cyclohexane and methylcyclohexane undoubtedly show that dissociative ionisation of hydrocarbons of this type gives an ion with a cyclic and not the alkene structure which occurs with cyclopentane hydrocarbons. The differences in behaviour of cyclopentane and cyclohexane hydrocarbons on electron impact is in accord with the stereochemistry of alicyclic compounds[54]. The presence of CH_3^+ ions in the mass spectrum of cyclobutane also points to the possibility of isomerisation to a structure of the type $(CH_3-CH-CH_2-CH_2)^+$,[55] the formation of which is associated with ring cleavage and migration of a hydrogen atom to one of the end carbon atoms. The likelihood of this process has been confirmed by a study of deuterated cyclobutane. Isomerisation of the molecular ion of naphthene hydrocarbons competes with the process in which two bonds of the naphthene ring are ruptured and a stable radical or molecule is formed, and possibly also with the process in which a group attached to the ring is removed. The probability of these processes depends on the structure of the ring and on the nature of the substituent[56-58].

The effect of stereoisomerism on the distribution of intensities in mass spectra was observed in a study of 1,2-, 1,3-, and 1,4-dimethyl cyclohexanes[59,60]. The spectra of the *cis*- and *trans*-isomers differed materially in the number of $(M - 15)^+$ ions§. Thus, the probability of removal of a methyl group from 1,2-dimethylcyclohexane was 35% greater for the *trans*-isomers; with 1,3-dimethylcyclohexane, it was 20% greater for the *cis*-isomer; and with 1,4-dimethylcyclohexane, it was 7% greater for the *trans*-isomer.

Special features in the molecular structure of naphthene hydrocarbons are also reflected in the distribution curve of ion intensities according to the number of carbon atoms[61]. In the dissociative ionisation of five- and six-membered naphthene hydrocarbons, roughly equal amounts of $C_3H_x^+$ and $C_4H_x^+$ ions are formed, but the amount of $C_5H_x^+$ ions formed differs significantly; the proportion of these ions formed from cyclopentane hydrocarbons is 2 to 2.4 times that formed from cyclohexane hydrocarbons

IV. MONOALKENE HYDROCARBONS

The interpretation of the mass spectra of monoalkene hydrocarbons is very complicated. The probability of the decomposition of paraffin hydrocarbons is mainly determined by the size of the molecule and the nature of the branching, but the direction of dissociative ionisation of monoalkene hydrocarbons is affected by the position of the double bond and by its interaction with nucleophilic methyl groups.

The increased resistance to electron impact of monoalkene molecules compared with alkanes means that in the mass spectra of monoalkenes the molecular ions give fairly intense peaks. The intensities for C_6-C_{12} hydrocarbons vary, as a rule, between 20% and 30% of the maximal peak, and sometimes they may even exceed 40%; only a small number of isomers have molecular-ion peaks with intensities less than 10% of the maximal.

The most intense peaks of fragmentation ions in the spectra of monoalkenes are formed, as a rule, by the rupture of the bond in the β-position to the double bond. The probability of this process increases when one or two methyl groups are attached to the carbon atom in the α--position to the double bond, and when a hydrogen atom migrates. Rupture of the bond in the α-position to the double bond, which is frequently accompanied by migration of a hydrogen atom, competes with this process. A double bond nearer the centre of the molecule is more likely to undergo decomposition[62]. However, in this case decomposition also occurs at the β-bond; two decomposition routes are therefore possible, and the predominance of one over the other is determined by the presence or absence of branching and by the position of the branching when it is present.

The migration of hydrogen is of great importance in the dissociative ionisation of monoalkenes; this migration leads to the formation of "pseudomolecular" ions, which are identical with molecular ions of lower members of the homologous series.

The formation of $(M - 15)^+$ ions is also typical, particularly in those instances in which the methyl group is attached at the β-position to the multiple bond. Thus, this process leads to the formation of an intense $C_5H_9^+$ peak (91.3% of the maximal) in the spectrum of 4-methylpent-2--ene. The probability of removing a methyl group is increased when several methyl groups are in the β-position to the double bond.

The intensity of ion peaks associated with rupture of the β-bond largely depends on the structure of the alkyl group and can be evaluated quantitatively in some instances. The results of calculations presented in Fig. 3 show that the probability of forming ions of mass 57 is about 6 times as great for the tertiary butyl group as for the normal butyl group. When the butyl group is in the α-position to the double bond, the peak intensity of ions of mass 57 sharply decreases. However, as for β-bond rupture, the greatest intensity is shown by the ion peak corresponding to a charged group with a tertiary carbon atom.

The same regularities have been established (less clearly, however) for hydrocarbons containing propyl and isopropyl groups. The maximal peaks corresponding to removal and formation of the $C_3H_7^+$ ion are associated with a structure containing this ion in the β-position to the double bond. The dependence of the intensity of ions of mass 43 on the structure of the propyl group and its position relative to the double bond is illustrated by the graph in Fig. 3. Normal alk-1-enes that form "paraffin-type" fragments in considerable quantity, and in particular, fragments corresponding to ions of mass 43, have not been considered.

The selectivity of dissociative ionisation of monoalkenes is reflected not only in the preferential formation of $C_nH_{2n-1}^+$ ions but also in the distribution of intensities according to the number of carbon atoms in the ions. The nature of the distribution curves is related to differences in the molecular structure of the isomers and depends on the position of the double bond in the structure of the carbon skeleton[63]. Alkenes with a normal carbon chain (Fig. 4) have one maximum on the distribution curve, corresponding to $C_3H_x^+$ ions for alk-1-enes and -3-enes, and to $C_4H_x^+$ ions for alk-2-enes and -4-enes. The shape of

§ M denotes the mass of the molecular ion.

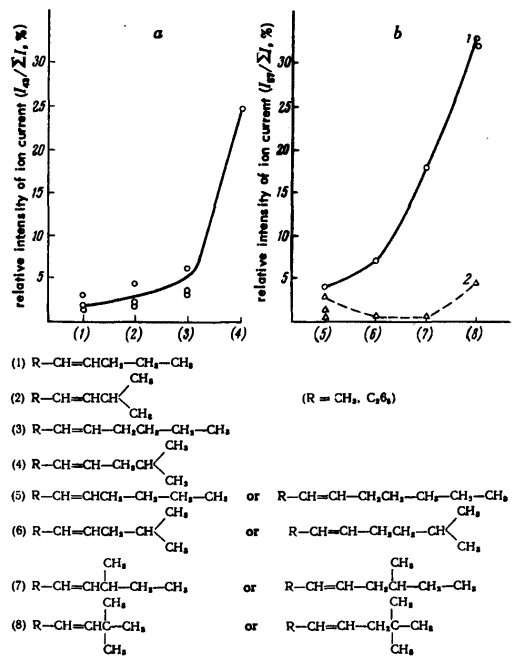

Fig. 3. Effect of structure and position of alkyl group on intensity of formation of ions of mass 43 (*a*) and 57 (*b*):
1) rupture of β-bond; 2) rupture of α-bond.

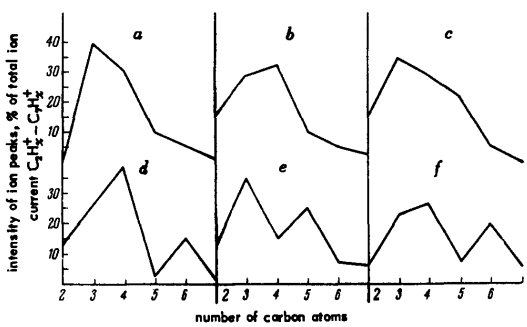

Fig. 4. Distribution of intensities against number of carbon atoms in ions for different types of monoalkenes.

the distribution curve changes as the degree of branching of the carbon skeleton increases; the formation of about equal amounts of $C_3H_x^+$, $C_4H_x^+$, and $C_5H_x^+$ ions is characteristic of mono- and di-substituted alk-1-enes (Fig. 4*c*). In addition to a maximum for $C_4H_x^+$ ions, the distribution curves of trimethylalk-1-enes show a second maximum, corresponding to $C_6H_x^+$ ions. Monomethylalk-2-enes and -3-enes show two maxima, $C_3H_x^+$ and $C_5H_x^+$. The maxima of dimethyl- and trimethylalk-2-enes correspond to $C_4H_x^+$ and $C_6H_x^+$ ions.

For a long time it was accepted that geometric isomerism of monoalkenes had no effect on the nature of the mass spectrum[64,65]. Later work showed the possibility of identifying *cis*- and *trans*-butylenes[66]. Investigation of geometric isomers showed that the differences in the mass spectra of isomers become more marked as the ionising energy of the electrons decreases, because near the ionisation threshold the greater internal energy of the *cis*-isomers compared with the *trans*-isomers facilitates dissociation[67]. This is confirmed by the values of the ionisation potentials, which are lower for the *trans*-isomers than for the *cis*-isomers[68]. Similar conclusions can be drawn from the work of Natalis[69], who showed that, when monoalkenes of the type R–CH=CHR′ (where R and R′ are methyl, ethyl, secondary propyl, or t-butyl groups), the ratio of the intensities of the molecular-ion peaks for *trans*- and *cis*-isomers increases as the size of the group increases[69]. This effect is due to liberation of excess energy on isomerisation of the *cis*-isomer with a larger alkyl radical, which promotes more rapid decomposition of the ion formed.

Arbuzov and coworkers[70] studied the mass spectra of Δ^3-carene oxide (α- and β-forms), camphene oxide, and β-pinene oxide at electron-ionising energies of 50 and 9 eV, and showed that stereoisomerism has an important effect on the course of dissociative isomerisation of these molecules, changing the probability of even very "energy-consuming" processes.

Using an MX1304 mass spectrometer, the authors studied the mass spectra of the *cis*- and *trans*-isomers of pent-2-ene: at 70 eV the distribution curves for both isomers are virtually identical; at 20 eV the quantity of ions containing five carbon atoms is about 20% greater for *trans*-pent-2-ene than for *cis*-pent-2-ene, which allows identification of these isomers.

The problem of the probability of rupture of the C–H bond has been considered[71,72]. When ethylene is ionised by monochromatised electrons, $C_2H_3^+$ ions are formed; the considerable yield of ions in this process is due to the relatively low ionisation potential of the C_2H_3 radical (9.55 eV). Study of the mass spectra of molecules of propene and its deuterated derivatives, CH_2CHCH_3, CH_3CDCH_2, CH_3CHCD_2, and CD_3CHCH_2, has shown that $C_3H_5^+$ ions are formed with equal probability from propene and from CH_3CDCH_2. Thus, in dissociative ionisation the C–H (or C–D) bond is ruptured at the central carbon atom. To elucidate the mechanism of dissociative ionisation of ethylene, the mass spectra of this compound were investigated at electron energies of 10–70 eV; tetrafluoroethylene was examined in the same way[73]. It is suggested that a number of peculiarities in the mass spectra may be explained by a difference in charge distribution in molecular ions.

V. UNSATURATED C_nH_{2n-2} HYDROCARBONS

All hydrocarbons of this group with a normal carbon skeleton readily ionise on electron impact. Conjugated diene hydrocarbons are somewhat more stable. Complete ionisation is little affected by the mutual arrangement of the multiple bonds; different isomers form about the same number of ions per unit quantity of compound[14].

The structure of the carbon skeleton, in combination with the position of the multiple bonds, has a much greater effect on the character of the distribution of the ion intensities in the mass spectrum.

1. 2,3- and 3,4-Diene Hydrocarbons

In the mass spectra of 3,4-dienes (octa-3,4-diene, 7-methylocta-3,4-diene, deca-3,4-diene[74]), the greatest

intensity is shown by the peak of $C_5H_7^+$ ions, which are formed on rupture of the bond in the α-position to the allene group, accompanied by elimination of a larger group. In addition, the excited molecular ion decomposes simultaneously at two C–C bonds with the formation of $C_3H_x^+$ ions. Of the ions of this type, the most intense are $C_3H_3^+$ and $C_3H_5^+$, that is, those ions with a conjugated or a cyclopropenyl structure[22].

The general nature of mass spectra of 2,3-dienes is similar to that of 3,4-dienes; the curve showing the distribution of intensity against the number of carbon atoms in the ions also has two maxima, corresponding to the $C_3H_x^+$ and $C_5H_x^+$ ions. However, the maximal intensity in the spectrum is shown not by the peak of $C_5H_7^+$ ions but by the peak of $C_5H_8^+$ ions, which are formed by decomposition of a molecular ion at the β-bond, accompanied by migration of hydrogen.

Some information on the mechanism of formation of the most intense ions in the spectrum can be obtained by examining the curves showing the effectiveness of ionisation¶. Curves for the probability of appearance of ions of mass 67, which are of maximal intensity in the spectrum of 3,4-dienes, show that changes in the intensity of the ion current as a function of electron energy can be represented virtually by a single general curve[74]; this appears to indicate that this ion is formed by the same mechanism from different 3,4-dienes. For octa-3,4-diene, 7-methylocta-3,4-diene, and deca-3,4-diene, the appearance potentials are within the range 11.6–11.9 eV. The appearance potentials of ions of mass 68, corresponding to the maximal peaks in the spectra of octa-2,3-diene and 7-methylocta-2,3-diene, are 9.2 and 9.9 eV respectively. The appearance potentials of ions of mass 67 are considerably higher, at 13.8 and 12.7 eV.[74] It would appear that the penta-1,3-diene structure can be ascribed to $C_5H_8^+$ ions formed by rupture of a β-bond accompanied by migration of hydrogen. This hypothesis is confirmed by the values of the heats of formation — 9.64 eV for the penta-1,3-diene molecular ion, and 9.68 eV for $C_5H_8^+$ ions.

The mass spectrum of 7,7-dimethylocta-3,4-diene differs markedly from the spectra of other representatives of this series[74]; its intensity distribution curve shows only one maximum, corresponding to $C_4H_x^+$ ions. The peak of $C_4H_9^+$ ions shows the maximal intensity. An explanation of the anomalous dissociation of 7,7-dimethylocta-3,4-diene is probably to be sought in the different ways various atomic groupings can affect the electron-density distribution in the molecule. The ease with which the $C_4H_9^+$ ion is formed may be due to polarisation of the C–C bond on interaction with electrons of a molecule containing a tertiary butyl group. The formation of a tertiary butyl ion is favoured by energy considerations, since the corresponding decomposition of the initial molecular ion is either exothermic or thermoneutral. Similar specificity in the decomposition of 7,7-dimethylocta-3,4-diene is in agreement with the known relationship[75], according to which the extent of removal of alkyl groups on electron impact increases linearly in the sequence: normal, iso-, and tertiary alkyl groups. This tendency, which is more pronounced in compounds with a permanent dipole, can also be traced in the

¶ In determinations on the mass spectrometer of ionisation and appearance potentials, the change in ion current is recorded as a function of the energy of the ionising electrons; what is termed an ionisation effectiveness or probability curve is then obtained, from which the ionisation potential is determined by some method.

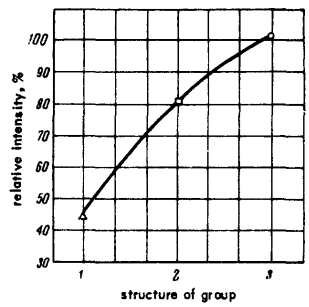

Fig. 5. Probability of decomposition at β-bond in 3,4-diene hydrocarbons:
1) normal structure; 2) iso-structure;
3) tertiary.

3,4-diene series. When a β-bond in 7,7-dimethylocta-3,4-diene is broken, $C_4H_x^+$ ions are formed. When the same bond is broken in 7-methylocta-3,4-diene, $C_3H_x^+$ and $C_2H_x^+$ ions are formed. Fig. 5 shows how the decomposition probability changes from the normal to the tertiary alkyl group. The $C_4H_9^+$ ion, which has the greatest probability of formation in the mass spectrum of 7,7-dimethylocta-3,4-diene shows the lowest appearance potential, 11.7 eV, in comparison with the ions $C_3H_5^+$, $C_3H_7^+$, and $C_5H_8^+$, for which the potentials are 15.0, 13.5, and 12.6 eV respectively.

Investigation of the mass spectra of 2,2-dimethyldeca-3,4-diene, 2,2,7,7-tetramethylocta-3,4-diene, and 4,4-dimethylpent-1-ene has permitted elucidation of the effect on dissociative ionisation of the structure of the butyl group at the β-carbon atom[76]. In the mass spectra of these hydrocarbons, the greatest intensity is shown by ion peaks formed by decomposition of a molecular ion into a butyl radical and a fragmentation ion containing multiple bonds. For 2,2-dimethyldeca-3,4-diene and 2,2,7,7-tetramethylocta-3,4-diene, the relevant ions are $C_4H_9^+$ and $C_8H_{13}^+$; for 7,7-dimethylocta-3,4-diene, $C_4H_9^+$ and $C_6H_9^+$; and for 4,4-dimethylpent-1-ene, $C_4H_9^+$ and $C_3H_7^+$. The $C_4H_9^+$ ion evidently corresponds to the butyl group in the β-position to the double bond. The probability of forming this ion, which is determined by the structure of the group, can be characterised by the ratio of the height of the $C_4H_9^+$-ion peak to the full ion current and by the dependence of this quantity on the relative weight of the tertiary butyl group in the molecule (Fig. 6). The intensity of formation of the $C_4H_9^+$ ion is a linear function of the relative weight of the t-butyl group (in the β-position to the double bond) in the molecule. It is noteworthy that the monoalkenes are also subject to this relationship (point *4* on Fig. 6). The probability that a positive charge will be found on one of the two fragments formed when the molecular ion decomposes is determined by the structure of the butyl group. The greater the relative weight of the tertiary butyl group, the greater will be the intensity of the peak of the $C_4H_9^+$ ion in comparison with the $(M - 57)^+$ ion. Thus, for 2,2,7,7-tetramethylocta-3,4-diene and 7,7-dimethylocta-3,4-diene, dissociative ionisation proceeds mainly with rupture of the β-bond between the t-butyl group and the allene grouping to give the ions $C_4H_9^+$, $C_8H_{13}^+$, and $C_6H_9^+$ respectively. The two latter ions appear to serve as sources of ions of mass 95, 81, 67, and 39, which are formed by elimination of methylene radicals. In the mass spectra of 2,2-dimethyldeca-3,4-diene, successive decomposition processes, together with rearrangements, play a much more important part than does rupture

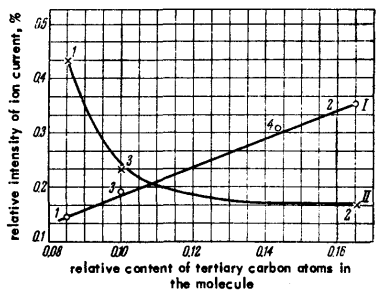

Fig. 6. Relationship between the structure of the butyl groups and the probability of formation of $C_4H_9^+$ ions. I) $I_{57}/\Sigma I_j$; II) I_{57}/I ($M = 57$): 1) 2,2-dimethyldeca-3,4-diene; 2) 2,2,7,7-tetramethylocta-3,4-diene; 3) 7,7-dimethylocta-3,4-diene; 4) dimethylpent-1-ene.

of the $C_4H_9-C_8H_{13}$ bond. The peaks of rearrangement ions of empirical formula C_nH_{2n-2} are very intense; the ions $C_5H_8^+$, $C_6H_{10}^+$ and $C_8H_{14}^+$ are stabilised with the migration of hydrogen. When the electron-ionising energy is reduced from 70 to 20 eV, the selectivity of decomposition greatly increases, and the quantitative ratio of the characteristic ions changes somewhat. In the mass spectrum of 2,2-dimethyldeca-3,4-diene, at electron energies of 70 eV, the probability of finding a positive charge on the $C_4H_x^+$ ions was 2.6 times greater than that for $C_8H_x^+$ ions. At 50 eV these values are fairly close, and at 20 eV the intensity of $C_8H_x^+$ ions is 1.6 times that of $C_4H_x^+$ ions. For 2,2,7,7-tetramethylocta-3,4-diene, reduction of the electron-ionising energy from 70 to 30 eV leads to a relative increase in the number of $C_8H_x^+$ ions compared with the number of $C_4H_x^+$ ions, but the intensity of the latter changes very little.

The structure of the $C_4H_9^+$ ions formed in the dissociative ionisation of the β-bond in 2,2-dimethyldeca-3,4-diene and 2,2,7,7-tetramethylocta-3,4-diene can be deduced by comparing the heats of formation of these compounds[76]. The $C_4H_9^+$ ions must obviously have a different structure, while the C_8H_{13} radicals are probably identical.

The heats of formation† of $C_8H_{13}^+$ ions were 9.10 and 9.00 eV. This suggested that the C_8H_{13} radicals produced when $C_4H_9^+$ ions are formed have the same heats of formation. It thus become possible to evaluate the difference in heats of formation of $C_4H_9^+$ ions, which was found to be 0.55 eV. A similar difference (0.56 eV) was observed in the heats of formation of the $C_4H_9^+$ ions produced by dissociative ionisation of iso- and n-butanes[78]. The existence of this difference shows that the $C_4H_9^+$ ions formed by electron impact differ in structure from one another in the same way as the groups forming part of the molecule under examination.

2. Conjugated Dienes

On electron impact, conjugated diene hydrocarbons with a normal or slightly branched chain of carbon atoms behave in the same way as alkenes and mainly from $C_3H_x^+$ and $C_5H_x^+$ ions. The mass spectra of conjugated diene hydrocarbons with a t-alkyl group at the double bond, such as:

$(CH_3)_3C-CH=CH-CH=CH_2$	(C_8H_{14})
$(CH_3)_2(C_2H_5)C-CH=CH-CH=CH_2$	(C_9H_{16})
$(CH_3)(C_2H_5)_2C-CH=CH-CH=CH_2$	$(C_{10}H_{18})$
$(C_2H_5)_3C-CH=CH-CH=CH_2$	$(C_{11}H_{20})$

are different[79].

In this series of compounds, stability to electron impact decreases with increase in molecular weight; the intensity of the molecular-ion peak decreases by a factor of 5 when the number of carbon atoms in the molecule increases from 8 to 11. Complete ionisation is also a function of molecular weight and increases from 1.18 for C_8H_{14} to 2.74 for $C_{11}H_{20}$‡. A similar dependence was also observed with other types of hydrocarbons[80].

The main decomposition routes of molecular ions are similar for the hydrocarbons that have been examined, but the intensity of fragmentation ions depends on the ratio of methyl and ethyl groups near the tertiary carbon atom. In dissociative ionisation, alkyl or alkenyl groups, or ethylene molecules, are successively eliminated. At first, a methyl group (from C_8H_{14}), or an ethyl group (from other hydrocarbons) appears to be removed from the molecular ion. The maximal intensity in the mass spectra of the hydrocarbons C_8H_{14}, C_9H_{16}, and $C_{10}H_{18}$ is shown by the peaks of ions of mass 95, 109, and 123, that is, $(M-15)^+$ and $(M-29)^+$. These ions can decompose in turn to form smaller fragments. In the dissociation of $C_{11}H_{20}^+$, an ethyl group is eliminated and an ion of mass 123 is formed, which on further decomposition gives an ion of mass 81, corresponding to the maximal peak in the spectrum. The scheme in Fig. 7 illustrates the suggested routes of dissociative ionisation. This sequence of decomposition reactions has been confirmed by the presence of metastable ions.

VI. UNSATURATED C_nH_{2n-4} HYDROCARBONS

This homologous series includes enyne and triene hydrocarbons containing conjugates and unconjugated double and triple bonds[81,82].

The first member of the enyne series, vinylacetylene, is highly resistant to electron impact. The molecular-ion peak shows the greatest intensity in the mass spectrum of this compound. The most abundant fragmentation ions are formed by rupture of the C–H bond. Fragmentation ions produced by decomposition at the carbon–carbon bond are not characteristic of vinylacetylene. Appreciable decomposition at this bond only occurs when an ion of mass 26 is formed.

The introduction of a methyl group into the vinylacetylene molecule at any position somewhat lowers the stability of the molecular ion, but this ion retains its maximal intensity. Thus, the probability of decomposition of vinylacetylene is 60%, compared with 80% for methylvinylacetylene, isopropenylacetylene, and n-propenylacetylene. The probability of rupture of the molecule at a C–H bond is very high and about equal for all isomers, probably because of the formation of ions of mass 65, stabilised by conjugation. Normal hydrocarbons differ from isopropenylacetylene in showing a much more intense peak for ions of

† The heats of formation of allene hydrocarbons were calculated on the basis of the additivity of the thermodynamic functions of the structural groupings that make up the molecule[77].

‡ Complete ionisation was determined relative to benzene.

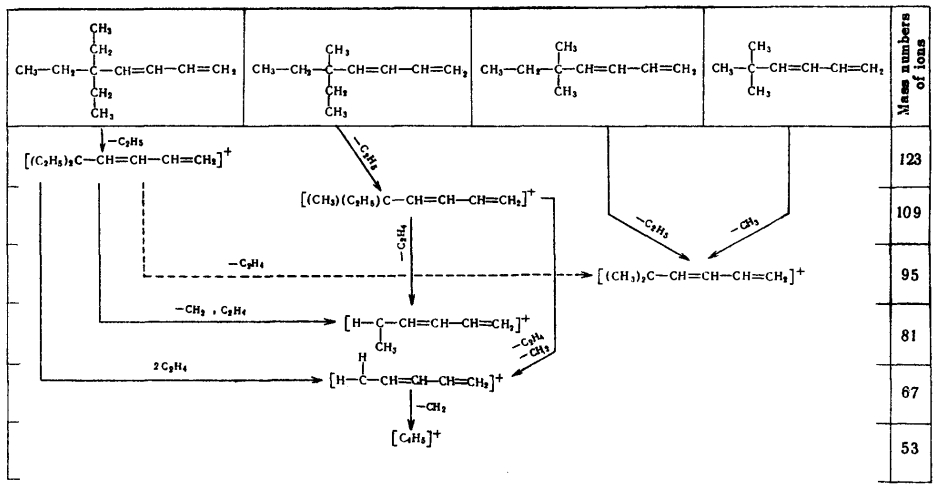

Fig. 7. Scheme of dissociative ionisation of diene hydrocarbons with a tertiary alkyl group at the multiple bond. The dotted line indicates decomposition routes not confirmed by metastable transitions. The figures correspond to the masses of the fragmentation ions.

mass 63. These ions may be produced by the following scheme:

$$C_5H_6^+ \rightarrow C_5H_5^+ \rightarrow C_3H_3^+ + (H_2).$$

Decomposition of the molecule at the bond between the methyl group and the vinylacetylene system occurs to a small extent (15–25%) with all isomers except propynylacetylene. The spectra of all the isomers show a very intense ion of mass 39, the appearance of which is due to rupture of a single C–C bond and loss of hydrogen:

$$C_5H_6^+ \rightarrow C_3H_5^+ \rightarrow C_3H_3^+.$$

The $C_3H_3^+$ ion may also be produced when a molecule decomposes at the triple bond, but its appearance in the spectrum of the branched-chain isomer, and also in the spectra of piperylene and isoprene, indicates that the first hypothesis is more likely to be correct. Examination of the spectra of the methyl derivatives of vinylacetylene shows that introduction of a methyl group adjacent to the triple bond is the factor that has the greatest effect on the stability of the molecular ion.

Investigation of the mass spectra of alkyl derivatives of vinylacetylene of higher molecular weight(pent-1-en-3-yne, hex-1-en-3-yne, oct-1-en-3-yne, and dec-1-en-3-yne) shows[82] that, as the size of the alkyl group increases, the intensity of the molecular-ion peak falls to 1.9% (in the spectrum of dec-1-en-3-yne), but the probability of decomposition increases to 99.5%. The preferential formation of two types of ions, $C_3H_x^+$ and $C_6H_x^+$ is characteristic of all the representatives of the alkylvinylacetylenes studies; these ions correspond to two maxima on the intensity distribution curves of the ions. The $C_3H_3^+$ ions appear to be formed by different mechanisms; in vinylmethylacetylene the ion of mass 39 is produced by simple rupture of a C–C bond, but for other homologues the formation of this ion is associated with the rupture of other carbon–carbon bonds of different stability and with the migration of hydrogen. This hypothesis is confirmed by the values of the appearance potential of the $C_3H_3^+$ ion[82], which are directly proportional to the size of the alkyl radical and vary from 13.0 for vinylmethylacetylene to 18.4 eV for vinylhexylacetylene. The mass spectra of vinylacetylene shows considerable abundance of ions of the type $C_nH_{2n-5}^+$, $C_nH_{2n-7}^+$, and $C_nH_{2n-4}^+$; these are produced by rearrangements in which hydrogen migrates. A specific feature of dissociation, due to the presence of conjugated bonds in the molecule, is that the carbon–carbon bond in the γ-position to the conjugated system in molecules of higher vinylacetylene homologues is the most stable to electron impact. In thermal conversions the β-bond is the least stable.

The introduction of the t-butyl group as a substituent at the double or triple bond in enyne hydrocarbons(2,2-dimethylhex-5-en-3-yne, 2-t-butylbut-1-en-3-yne, 2,2,5-trimethylhex-5-en-3-yne, 2,2-dimethylhept-6-en-3-yne, and 2-t-butylhex-1-en-3-yne)[83] materially alters the intensity distribution of the ions in the mass spectra.

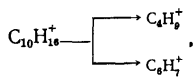
The maximum for $C_3H_x^+$ ions is less sharp because of more intense formation of $C_4H_x^+$ ions, and the maximum for $C_6H_x^+$ ions is affected by the intense formation of $C_7H_x^+$ ions. The maximal peaks in the mass spectra of C_8H_{12} and C_9H_{14} hydrocarbons correspond to ions that are produced by elimination of one methyl group from the molecular ion. This process leads to the formation of $C_7H_9^+$ ions from C_8H_{12} hydrocarbons, and $C_8H_{11}^+$ ions from C_9H_{14} hydrocarbons. In addition, an important part is played by reactions in which hydrogen and methylene groups are eliminated; as a result, the ions $C_7H_7^+$, $C_8H_8^+$, $C_6H_5^+$, etc. appear in the spectra.

The observed analogies suggest the existence of a general mechanism for the formation of fragmentation ions; this may be represented by the following scheme, which includes all ions with an intensity greater than 20% of the maximal:

$$C_8H_{12}^+ \xrightarrow{-CH_3} C_7H_9^+(100\%) \xrightarrow{-2H} C_7H_7^+(50\%) \xrightarrow{-C_2H_2} C_5H_5^+(20\%) \xrightarrow{-C_2H_2} C_3H_3^+(40\text{–}90\%),$$
$$C_7H_7^+ \xrightarrow{-CH_2} C_6H_5^+(75\%) \xrightarrow{-C_2H_2} C_4H_3^+(30\%)$$

$$C_9H_{14}^+ \xrightarrow{-CH_3} C_8H_{11}^+(100\%) \xrightarrow{-2H} C_8H_9^+(25\%) \xrightarrow{-CH_2} C_7H_7^+(30\text{–}90\%) \xrightarrow{-C_2H_2} C_5H_5^+(25\%),$$
$$C_7H_7^+ \xrightarrow{-CH_2} C_6H_5^+(25\text{–}45\%)$$

It follows from this scheme that the formation of $C_4H_9^+$ ions plays an important part only for compounds containing a t-butyl group at the double bond in the β-position to the triple bond; elimination of the t-butyl group is then favoured by the presence of an alkyl substituent in the acetylene grouping. The intensities of the peaks of $C_4H_9^+$ ions in the spectrum of 2-t-butylbut-1-en-3-yne (C_8H_{12}) and 2-t-butylhex-1-en-3-yne ($C_{10}H_{16}$) are 38.2 and 99.6% respectively. Decomposition of the latter compound may be represented as follows:



Any of the fragments formed may carry a positive charge with equal probability. Some stages of the hypothetical successive reactions have been confirmed by the presence of metastable ions in the peaks of the mass spectra. Thus, the mass spectrum of

$$(CH_3)_3C{-}C \equiv C{-}CH_2{-}CH{=}CH_2,$$

indicates the presence of an ion with an apparent mass of 46.6; this corresponds to the following reaction:

$$C_7H_7^+ \rightarrow C_5H_5^+ + C_2H_2.$$

Similar processes have also been observed in the dissociative ionisation of alkylbenzenes[84,85,86], cycloheptatriene[87], and spiro[2,4]cycloheptadiene[88]. Ions of mass 91 have been assigned the cyclic tropylium structure, the decomposition of which has been shown by mass spectra of samples labelled with ^{13}C and by energy calculations, to occur by the successive elimination of acetylene molecules.

Definite conclusions on the reactivity of organic compounds can be drawn from a comparison of the ionisation potentials for molecular ion formation. Vinylacetylene (9.9 eV) and isopropenylacetylene (10.1 eV) are the most difficult to ionise. Lengthening of the normal carbon chain adjacent to the triple bond reduces the ionisation potential to 9.4 eV (vinylmethylacetylene), and adjacent to the double bond, to 8.5 eV (propenylacetylene). Thus, the ionisation potentials of molecules change according to the position of the methyl group. It would be interesting to compare these results with those on the kinetics of reactions of vinylacetylenes that proceed by an ionic mechanism. However, information of this kind is not available in the literature.

VII. HYDROCARBONS OF THE GENERAL FORMULA C_nH_{2n-6}

This group includes hydrocarbons with an open chain containing conjugated and unconjugated double and triple bond, cyclic dienes with an unsaturated alkyl group in the side-chain, as well as benzene and its homologues.

Generally, isomeric hydrocarbons show a similar distribution of intensities in their mass spectra. However, the spectra of initial representatives of homologous series of highly unsaturated hydrocarbons, such as the C_nH_{2n-6} series, show considerable differences, which are associated with structural features[89]. In the first place, the stability of the molecule to electron impact varies in the same way as do, for example, the stabilities of the isomeric C_5H_6 enyne hydrocarbons. In the mass spectra of hexa-1,3-diyne, hexa-2,4-diyne, hexa-1,5-dien-3-yne, and benzene, the relative stability of the molecule, in the same way as the full ion current, depends largely on the structure of the initial C_6H_6 hydrocarbon. The benzene molecule is the most stable. Ethyldiacetylene is 20% less stable than benzene and 30% less stable than the isomeric dimethyldiacetylene. However, the molecular-ion peak is the maximal peak in the spectrum of all four compounds.

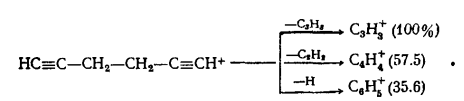
The ion-intensity distribution curves of all the C_6H_6 hydrocarbons investigated have two maxima, corresponding to the $C_6H_x^+$ and $C_4H_x^+$ ions[89]. The $C_6H_x^+$ group includes fragmentation ions from $(M-1)^+$ to $(M-5)^+$ in addition to molecular ions. The $(M-1)^+$ and $(M-4)^+$ ions are the most intense ions in the ethyldiacetylene spectrum. The $C_4H_x^+$ group includes ions formed from the parent ion by removal of two carbon atoms and different numbers of hydrogen atoms. Most of the ions of this group are capable of rearranging and are formed by the rupture of more than one C–C bond.

The removal on electron impact of one carbon atom with the formation of $C_5H_x^+$ ions is a process characteristic only of ethyldiacetylene. The peak of rearrangement ions of mass 64, corresponding in empirical formula to methyldiacetylene, shows the highest intensity in this group. The ability of the ethyldiacetylene molecular ion to dissociate with the formation of $C_5H_x^+$ ions appears to be related to the fact that this is the only hydrocarbon of those considered that can give fragments with rupture of a (less stable) bond in the β-position to the conjugated system.

Reduction of the energy of ionising electrons seriously affects the distribution of intensities only at energies lower than 30 eV. Near the ionisation threshold, differences in the spectra of ethyldiacetylene, divinylacetylene, and benzene are levelled out. It has been shown that the ionisation potentials of ethylacetylene, divinylacetylene, and benzene are quite similar.

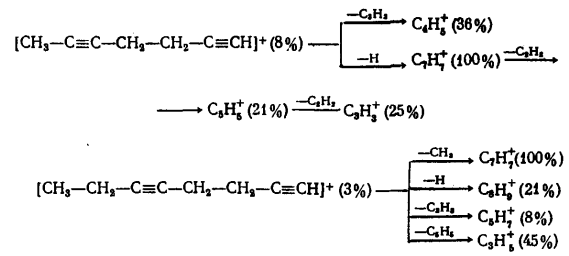
1. 1,5-Unconjugated Diynes

Because of the absence of conjugation, hexa-1,5-diyne, hepta-1,5-diyne, and octa-1,5-diyne are relatively unstable to electron impact[90]. The main decomposition route, the formation of fragmentation ions by cleavage of the molecular ion at the bond in the β-position to the acetylene grouping, may be represented by the following schemes:



In the mass spectra of methyl- and ethyl-dipropargyl, the maximum intensity is shown by peaks of $C_7H_7^+$ fragmentation ions. The molecular-ion peaks are low (8.2 and 2.6% of the maximum). The $C_7H_7^+$ ions appear to be produced by rupture of an outer β-bond, with elimination of hydrogen or a methyl group. These ions may have a cyclic "tropylium" structure. They decompose further according to the general scheme (with elimination of acetylene molecules). In this respect, the mass spectra of 1,5-diynes

are very similar to the spectra of the isomeric C_nH_{2n-6} hydrocarbons with conjugated multiple bonds.



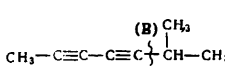
The decomposition of molecular ions of methyl- and ethyl-dipropargyl hydrocarbons at an inner β-bond occurs to only a slight extent, if at all. The spectrum of methyldipropargyl shows a peak corresponding to the $C_4H_5^+$ ion, which may in fact be produced in this way, but the presence of a peak of a metastable ion of mass 30.8 (0.2%) indicates that this ion is formed, at least partly, by the reaction $C_7H_7^+ \rightarrow C_4H_5^+ + C_2H_2$. The relative content of the analogous $C_5H_7^+$ ion in the ethyldipropargyl spectrum is small. The $C_5H_5^+$ ion in the ethyldipropargyl spectrum is formed mainly by the transition $C_8H_9^+ \rightarrow C_5H_5^+$ as is indicated by the presence of a metastable ion of mass 40.3. As a result of these reactions, the curves for the distribution of intensities show three maxima for hexa-1,5-diyne (corresponding to the ions $C_3H_x^+$, $C_4H_x^+$, and $C_6H_x^+$), two maxima for hepta-1,5-diyne ($C_4H_x^+$ and $C_7H_x^+$), and three maxima for octa-1,5-diyne ($C_3H_x^+$, $C_5H_x^+$, and $C_7H_x^+$). The low intensity of rearrangement ions in comparison with isomers containing conjugated bonds is a particular feature of the spectra of 1,5-diynes.

2. 2,4-Conjugated Diynes

The effect of conjugation on the behaviour of molecules under electron impact can be studied on the mass spectra of 2,4-diyne hydrocarbons[91] and of the alkenylvinylacetylenes[92]. It has been shown above that, in the spectra of hexa-2,4-diyne and in the spectra of the remaining isomers, the maximal intensity is exhibited by the peak of the molecular ion, which is inferior only to the benzene ion in its stability. With 6-methyl- and 6,6-dimethyl-hepta-3,4-diyne, decomposition of the molecular ion begins to play a much greater part; stability to electron impact decreases steadily from 30.9% for hexa-2,4-diyne to 5.9% for 6,6-dimethylhepta-2,4-diyne. The diversity of dissociative ionisation processes is reflected in the distribution of intensities. The curve of intensity distribution has two maxima, corresponding to the $C_4H_x^+$ and $C_6H_x^+$ ions. The maxima of the hydrocarbons C_8H_{10} and C_9H_{12} are displaced by one carbon atom.

The relatively low proportion of $C_3H_3^+$ ions is noteworthy and indicates that the probability of rupture of the central bond (A) in hexa-2,4-diyne is 3.7%:

In the spectra of hexa-2,4-diyne homologues, the $C_3H_3^+$ ion can be formed in a different way, namely, by rupture of the bond (B) and removal of hydrogen atoms from the propyl group.



This process results in some increase in the probability of the formation of the $C_3H_3^+$ ion; the peak intensity of ions of mass 39 becomes 7.9% of the full ion current; the proportion of $C_3H_3^+$ ions in the spectrum of 6,6-dimethylhepta-2,4-diyne relative to the full ion current is the same (7.4%). Removal of a methyl group, which is necessary for this process, meets with no difficulties, in so far as it is associated with rupture of a carbon–carbon bond in the β-position to the multiple bond.

It is very difficult to interpret the mechanism of formation of $C_4H_x^+$ ions, which are probably formed by removal of two methyl groups and migration of hydrogen atoms to a fragment with conjugated bonds. The ions $C_5H_x^+$, $C_7H_x^+$, $C_6H_x^+$, and $C_8H_x^+$ also appear to be formed by processes in which extensive isomerisation occurs. The first stage is probably effected by rupture of a bond in the β-position to the triple bond, and removal from the molecular ion of a methyl group derived from an isopropyl or t-butyl group, with the formation of $C_7H_x^+$ and $C_8H_x^+$ ions.

3. Alkenylvinylacetylenes

The mass spectra of the isomeric alkenylvinylacetylenes (C_7H_8), propenyl-, isopropenyl-, and allyl-vinylacetylene, show a similar distribution of intensities[92]. The maximal peak corresponds to the $C_7H_7^+$ ion; ions of mass 65 and 63 are also formed in large quantities. The probability, W_z, of decomposition of the parent ions depends on the structure of the alkenyl group (Fig. 8). Isopropenylvinylacetylene (W_M = 16.4%) is the most stable to electron impact. The intensity of the $C_7H_7^+$ ion peak is 18.3%, and the total proportion of fragmentation ions is 84.6%. The allylvinylacetylene molecular ion undergoes somewhat more extensive conversion (W_z = 81.2%); the proportion of $C_7H_7^+$ ions is 32.1%. Of the three isomers studied, propenylvinylacetylene undergoes the most extensive decomposition (W_z = 92.3%), but the quantity of ions of mass 91 and 65 is 1.9 and 2.4 times greater respectively than for isopropenylvinylacetylene.

Crotylvinylacetylene and its isomer, allylisopropenylacetylene, mainly dissociate in the same way as C_7H_8 hydrocarbons; the maximal intensity in their spectra is shown by the $C_7H_7^+$ ion peak; the stabilities of the parent ions are 9.8 and 7.7% respectively.

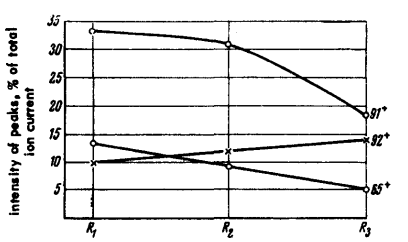


Fig. 8. Effect of structure of alkenyl group on probability of formation of molecular and fragmentation ions: R_1 = (CH_3–CH=CH–); R_2 = (CH_2=CH_2–CH_2–); R_3 = (–C(=CH_2)–CH_3).

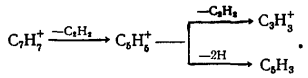
Comparison of the mass spectra of dienyne hydrocarbons with the spectra of aromatic hydrocarbons, cycloheptadiene[84,87], and alkyl vinylacetylenes[81], not only indicates certain analogies in the distribution of ion intensities, but also suggests the existence of a general mechanism for the formation of separate typical ions. Evidently, in many instances in which the hydrocarbon molecule contains seven or more carbon atoms, the carbon skeleton rearranges to a seven-membered ring, and this excited ion acts as the main source of other fragmentation ions.

It may be assumed that when dienyne hydrocarbons dissociate the $C_7H_7^+$ ion formed acquires the structure of the tropylium ion, which may then undergo cleavage according to the following scheme:



Since all seven hydrocarbon atoms of the tropylium ion are equivalent, acetylene may be eliminated in several ways, which considerably increases the probability of this process. The above-mentioned scheme for the decomposition of the $C_7H_7^+$ ion formed by the dienyne hydrocarbons C_7H_8 and C_8H_{10} is confirmed by the presence in the spectra of these hydrocarbons of a metastable ion of mass 46.6 (intensity 0.5%).

The general scheme of dissociative ionisation becomes somewhat more complicated in higher members of the series (Fig. 9). At the first stage of decomposition, a methyl group is removed, and the most intense peak in the spectrum is formed ($C_8H_9^+$ ion); the position of the methyl group does not materially affect the peak intensity of these ions. Other fragmentation ions appear to be formed by removal of acetylene molecules, methylene groups, and hydrogen from the $C_8H_9^+$ ion.

Since fragmentation ions in the mass spectra of C_7–C_9-dienyne hydrocarbons are formed by a common mechanism, it may be that in the dissociation of $C_8H_9^+$ ions the carbon skeleton also rearranges to a seven-membered ring. These conclusions are in good agreement with the results of a study of the mass spectrum of tetrahydronaphthalene[93], in which the ions $C_8H_8^+$ and $C_7H_7^+$ are formed from the molecular ion $C_{10}H_{12}^+$ by elimination of C_2H_4 and C_3H_5 respectively. A cyclic structure can be ascribed to the ions $C_8H_8^+$ and $C_7H_7^+$ — that of cyclo-octatetraene to the first, and that of tropylium to the second.

The cyclic structure of ions in the gas phase, particularly of the tropylium ion, may explain the absence of material differences in the mass spectra of the isomers of dienyne hydrocarbons and the similarities of these spectra to the spectra of hydrocarbons of other groups, such as alkylbenzenes, cycloheptatriene, and styrene, and also to the spectra of compounds other than hydrocarbons.

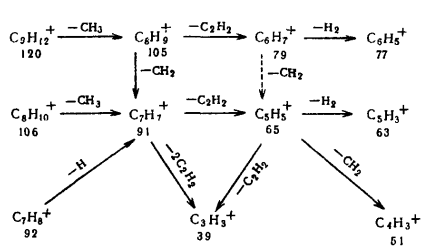


Fig. 9. Scheme of dissociative ionisation of dienyne hydrocarbons.

4. Alkylbenzenes

The most marked effects of conjugation on dissociative ionisation are shown by benzene and its homologues.

Benzene and its homologues are highly resistant to electron impact; the stability, which is 33% for benzene, decreases somewhat with increasing molecular weight, but it remains fairly high, averaging about 10% of the total ion current.

The alkylbenzenes dissociate mainly by rupture of the bond in the β-position to the benzene ring. The process includes the removal of a hydrogen atom from toluene, or from the alkyl group of other homologues, and the formation of a phenylalkyl ion. Sometimes, rupture of the β-bond is accompanied by migration of hydrogen with the formation of an alkylbenzene ion and an alkene.

Other things being equal, the mode of decomposition of the alkylbenzene molecule depends on the size and chain length of the alkyl groups attached to the benzene nucleus[84]. The main dissociation products of monoalkylbenzenes are ions formed by rupture of the side-chain at the β-bond. The size and chain length of the substituents at the α-carbon atom also affect the distribution of intensities.

Alkylbenzenes with the structure PhC(X)(Y)Z have been used in studies on the main modes of decomposition[84]. If X and Y = H, and Z is a group larger than the methyl group, rupture of the Y–C bond is accompanied by migration of hydrogen to the ion containing the ring. The probability of this migration, which is measured by the ratio of the heights of the ion peaks for masses 91 and 92, increases with increasing chain length. If X = H, and Y and Z are groups larger than the methyl group, appreciable peaks corresponding to the rupture of single bonds appear, and, for normal groups, the intensity of these peaks is directly proportional to the number of carbon atoms in the groups lost. If X and Y are methyl groups and Z is any alkyl group, significant peaks corresponding to ions of mass 91 are observed.

The probability of dissociation at an α-bond also varies with the substituent groups at the α-carbon atom. Branching at the α-carbon atom favours rupture at the α-bond.

Rylander and Meyerson[85], and also Hanuš[87], showed that the formation of the most intense ions in the mass spectra of alkylbenzenes is associated not only with migration of hydrogen, but also in many instances with rearrangement of the carbon skeleton. Detailed study of the mass spectra of deuterated toluenes shows the the probability of removing any of the hydrogen atoms from the molecule is the same. It may therefore be assumed that the carbon skeleton of the molecular ion rearranges, and all the carbon atoms become equivalent[94,95]. Various phenomena observed when alkylbenzenes interact with electrons, and not hitherto explained, become clear if it is assumed that in dissociative ionisation one of the most intense ions in the spectra of these compounds ($C_7H_7^+$) isomerises to the highly stable tropylium ion[96]. This hypothesis explains the stabilisation of the phenyl ion when the first methyl group is introduced into benzene by rearrangement of the benzenoid ion to the symmetrical, stable tropylium ion.

The introduction of a second methyl group does not change the fundamental structure of the ion and therefore has no effect on its stability. The existence of the tropylium ion also explains the identical distribution of intensities in the mass spectra of *o*-, *m*-, and *p*-dialkylbenzene isomers.

In the dissociation of polyalkylbenzenes, most of the ions are formed by rupture of a β-bond (with the exception of examples in which the side-chains consist of methyl or ethyl groups). As the number of side-chains increases, so does the number of bonds and therefore the number of possible characteristic peaks. Rupture at the β-bond in some chains, and at the α-bond in others, can lead to appreciable formation of peaks of ions of mass 91. Dialkylbenzenes with two groups larger than the methyl group behave differently. Dissociation occurs preferentially at the centre of the longest side chain with the greatest amount of branching at the α-carbon atom. If all the side-chains are short (for example, methyl groups), rupture at the α-bond predominates over β-rupture. The maximal peak for the polymethylbenzenes usually corresponds to $(M - 15)^+$ ions. With polyethylbenzenes, two competing processes that depend on structure are observed; these lead to the formation of about equal amounts of $(M - 15)^+$ and $(M - 29)^+$ ions.

The isomeric polyalkylbenzenes, which differ only in the position of the side-chains in the ring, generally have similar spectra. The intensity distribution of the ions obtained by electron bombardment does not permit the *ortho*-, *para*-, and *meta*-positions to be distinguished.

Notwithstanding some differences in the behaviour of the polyalkylbenzenes, their mass spectra have much in common, in particular these spectra show the preferential formation of ions of mass 77, 78, 91, 92, 105, 106, 119, 120, 133, 134, 147, 148, 161, and 162; on an average these ions make up 60% of the total ion current. The spectra of all polyalkylbenzenes show the presence of ions of mass 77, 78, and 79, and also of ions of mass 91, 92, 93, 105, 106, and 107, which are formed by rupture of the side chains at α- and β-bonds. The peaks of these ions are the most specific for establishing a relationship between structure and spectra. A clearly-defined system for the identification of 34 alkylbenzenes containing up to 24 carbon atoms in the side-chain has been worked out on the basis of mass spectra[84].

We shall not deal with polycyclic aromatic hydrocarbons. It should be noted, however, that as the number of condensed rings in the molecule increases the stability to electron impact increases, and W_M is a linear function of the ratio of the numbers of carbon and hydrogen atoms in compounds with different numbers of rings[97].

---o0o---

Examination of the mass spectra of hydrocarbons of different homologous series has shown that, as the degree of unsaturation increases, large fragmentation ions tend to be stabilised, and this is reflected in the distribution of ion intensities (Fig. 1).[98] The distribution curve of alkanes and monoalkenes shows a single well-defined maximum, corresponding to $C_3H_x^+$ ions. A study by Coggeshall[99] of the mass spectra of alkane and alk-1-ene hydrocarbons showed that the proportion of ions containing the same number of carbon atoms (m) in relation to the full ion current has a maximum in the region where $m = 3-4$, the maximum of the alkene curve being displaced towards larger values of m.

One maximum, corresponding to $C_5H_x^+$ ions, also appears on the distribution curve of C_nH_{2n-2} ions. For enyne hydrocarbons (C_nH_{2n-4}), the second maximum is displaced in the direction of ions of greater mass ($C_6H_x^+$). $C_7H_x^+$ ions show a high intensity in the spectra of the alkenylvinylacetylene hydrocarbons (C_nH_{2n-6}). Fig. 10 illustrates this tendency towards reduced formation of ions of relatively low mass as the degree of unsaturation of the hydrocarbons increases.

This tendency is not confined to hydrocarbons; it is also shown by a number of cyclic fluoro-compounds[100].

The observed displacement of maxima on the distribution curves towards heavier ions appears to be related to the possibility of stabilisation of these ions as conjugated or cyclic structures, and it is no doubt also associated with processes in which rearrangements occur[98]. $C_3H_3^+$ ions play the main part in the formation of the first maximum, corresponding to $C_3H_x^+$ ions; in the formation of the second maximum in the spectrum of C_nH_{2n-2} hydrocarbons, corresponding to $C_5H_x^+$ ions, the main part is played by $C_5H_5^+$ and $C_5H_7^+$ ions and by C_5H_8. In dissociative ionisation of 3,4-dienes, the $C_5H_7^+$ ion may acquire the stable structure of the cyclopentyl ion, but in the case of 2,3-dienes stabilisation occurs by transfer of hydrogen to give the $C_5H_8^+$ ion. Curves showing the effectiveness of ionisation indicate that the processes that lead to the formation of $C_5H_7^+$ and $C_5H_8^+$ ions are quite general[74].

The main $C_6H_x^+$ ions in the mass spectra of C_nH_{2n-4} hydrocarbons are $C_6H_5^+$ and $C_6H_7^+$. These ions are also characteristic of the first members of homologous series of the general formula C_nH_{2n-6}.

Attempts have been made to obtain an idea of the structure of the $C_6H_x^+$ ion from an examination of the mass spectra of benzene and its open-chain isomers[89,90,101]. The appearance potentials of fragmentation ions and their enthalpies of formation indicate isomerisation of the excited molecular ion of benzene to a structure of the type:

$$(CH_2{=}CH{-}CH{=}CH{-}C{=}CH)^+.$$

The heat of isomerisation corresponds to the excited electronic state of the benzene ion (10.3 eV) observed by the photoionisation method. The molecular ion $C_6H_6^+$, which has a linear structure with a conjugated system of multiple bonds, dissociates in turn to form the fragmentation ions $C_6H_5^+$ and $C_6H_4^+$, which are also linear in their ground states. The high degree of unsaturation of the ions $C_6H_6^+$, $C_6H_5^+$, and $C_6H_4^+$ is responsible for the high probability of processes in which hydrogen migrates and $C_6H_7^+$ ions are formed; these

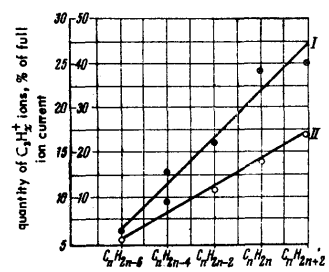

Fig. 10. Selectivity of dissociation of different types of hydrocarbons C_8 (*I*) and C_{10} (*II*).

ions are present in the spectra of vinylalkylacetylenes to the extent of 30–40% of the total ion current. Similar processes probably give rise to the formation of ions of mass 77, 78, and 79 in the mass spectra of some alkylbenzenes[102].

Dienynes and the isomeric alkylbenzenes show maxima on the distribution curves corresponding to $C_3H_x^+$ and $C_5H_x^+$ ions that are characteristic of highly unsaturated compounds; moreover, the isomeric C_7H_8 and C_8H_{10} hydrocarbons, such as toluene, ethylbenzene, and xylene, have a third maximum for $C_7H_x^+$ ions. For C_9H_{12} hydrocarbons, this maximum is displaced in the direction of the heavier $C_8H_x^+$ ions.

To obtain a more precise idea of the structure of rearranged ions produced in the dissociative ionisation of highly unsaturated compounds, the authors determined the potentials at which $C_3H_3^+$, $C_5H_5^+$, and $C_7H_7^+$ ions were produced from alkyl- and alkenyl-vinylacetylenes. Using these potentials and the known heats of formation of the molecules, they were able to calculate the heats of formation of the ions, decide between different possible ionic structures, and establish the mechanism by which these are formed. The heats of formation of $C_3H_3^+$ ions obtained from different hydrocarbons are close to one another (292–294 kcal mole^{-1}); it is possible that $C_3H_3^+$ ions acquire a cyclic structure, which can be assigned to them in the same way as to quasiaromatic systems[95]. Within the limits of experimental error, the heats of formation obtained for $C_7H_7^+$ ions coincide with the heat of formation of the tropylium ion (238–240 kcal mole^{-1})[86], which undoubtedly indicates that these ions have a cyclic structure.

Study of the mass spectra of toluene and its isomers, cycloheptatriene, spiro[2,4]hepta-1,3-diene, bicyclo[2,2,1]-hepta-2,5-diene[103], and 7d-cycloheptatriene[104] has shown that always the intermediate excited particle produced by dissociative ionisation is the tropylium ion, $C_7H_7^+$, from which other fragmentation ions are formed:

$$C_7H_8^+ \rightarrow C_7H_7^+ \rightarrow C_5H_5^+ \rightarrow C_3H_3^+ \text{ and } C_7H_8^+ \rightarrow C_5H_6^+.$$

The cyclic structure of ions in the gas phase, in particular the structure of the tropylium ion and its homologues, explains the absence of substantial differences between the mass spectra of isomers of dienyne hydrocarbons and also the analogies of these spectra to the spectra of alkylbenzenes, cycloheptatriene, and some compounds other than hydrocarbons.

Examination of the mass spectra of hydrocarbons containing different numbers of multiple bonds in the molecule shows that the quantity of ions produced by rearrangement increases with the number of multiple bonds in the molecule[98,105]. In other words, rearrangement ions in the mass spectra of hydrocarbons are characteristic of the degree of unsaturation and may be used for the qualitative and quantitative analysis of hydrocarbons.

A characterististic such as complete ionisation is directly related to the structure of hydrocarbons and their degree of unsaturation, and it can be used in the quantitative evaluation of interactions of ionising electrons with molecules. The available experimental results clearly prove that any attempt to express the relative ionisation cross-section of molecules as the sum of the cross-sections of the atoms would not reflect the true situation.

It has been shown that different isomers of many types of highly branched hydrocarbons containing multiple bonds differ in their complete ionisation potentials, which is probably due to wide differences in the electron-density distribution of the molecules. Thus, Table 1 gives the values for complete ionisation (relative to benzene) of isomeric diene hydrocarbons.

TABLE 1.

C_9H_{14}	Complete ionisation	$C_{10}H_{18}$	Complete ionisation
$(CH_3)_3C'-CH=CH-CH=CH_2$	1.18	$H_3C-H_2C-HC=C=CH-CH_2-CH_2-CH_2-CH_3$	1.81
$CH_3-CH=CH-CH_2-CH_2-CH_3$	1.40	$H_3C-CH_2-HC=C=CH-CH_3-C(CH_3)_2$	1.81
CH_2-CH_3			
$H_3C-HC=C=CH-CH_2-CH_2-CH_2-CH_3$	1.87	$CH_3(C_2H_5)_2C-CH=CH-CH=CH_2$	2.19

Complete ionisation is certainly not always directly related to molecular weight. In the alkylbenzene homologous series, complete ionisation is a linear function of the number of carbon atoms in the molecule, but the converse is true of 1,5-diynes, as is shown by the figures in Table 2.

At present there is no explanation of this effect, and the problem remains to be solved.

The establishment of empirical relationships between the structure of the molecule and its mass spectrum leads to the elucidation of the general principles that govern dissociative ionisation. Although the apparatus necessary for the quantitative calculation of mass spectra of individual compounds is not available, quantitative characteristics common to types of compounds can be calculated. In this connection, the use of curves showing the distribution of intensities against the number of carbon atoms in ions has proved very fruitful. Since the position of the maxima on the curves is determined by the value of z in the formula C_nH_{2n+z}, it is possible to establish the composition of a homologous series of ions specific to the hydrocarbon groups whose spectra are unknown[106]. On the other hand, the curves reflect special features in the molecular structure of isomers; this has been used as a basis for the determination of cyclopentane and cyclohexane hydrocarbons in complex mixtures, and for the identification of types of monoalkenes[61,63].

Mathematical treatment of the relationship between the characteristic intensity and the degree of unsaturation of different types of hydrocarbons has permitted the calculation of the corresponding mass-spectrometric coefficients for naphthene hydrocarbons with different numbers of condensed rings in the molecule. As a result, the lack of experimental calibration coefficients has been no hindrance to the development of methods of determining paraffins and naphthenes present in high-boiling petroleum fractions[107,108].

TABLE 2.

Number of carbon atoms in molecule	Complete ionisation	
	alkylbenzenes	1,5-diyne hydrocarbons
6	1	1
7	1.4	0.92
8	1.8	0.78

Correlations in the mass spectra of hydrocarbons have also been used in a new method of analysis, chromato--mass-spectrometry, developed by Tal'roze and co-workers[109-115].

These workers studied the problem of the minimum amount of mass-spectrometric information necessary for the unambiguous identification of individual compounds. It was shown that any individual compound reaching the mass spectrometer from the chromatograph can be identified with a high degree of probability, provided that two types of ratios of mass-spectrometric peaks are known in the 39-45 range of mass numbers. This enabled a mass spectrometer of low dispersion and resolving power to be used. The above authors have developed methods for the analysis of hydrocarbons and their derivatives by chromato-mass--spectrometry.

RUSSIAN CHEMICAL REVIEWS
Uspekhi Khimii

October 1966

SEMEN ISAAKOVICH VOL'FKOVICH

Dear Semen Isaakovich,

The Editorial Board of the Journal "Uspekhi Khimii" send you their heartfelt greetings on the occasion of your jubilee. As a member of the Editorial Board of this journal from the day of its foundation, you have rendered an enormous service to the journal and its readers. Your work in the field of chemistry and chemical engineering and, in particular, in the development of the manufacture of mineral fertilisers, is of great importance for the national economy of our country. We believe that your energy and your capacity for work will ensure that the fields which you will develop in the future will enrich both science and industry.

Your work on the training of chemists has gained general respect.

We wish you good health, many happy days, and even greater creative successes.

U.D.C. 631.8:631.816

STUDIES IN THE CHEMISTRY AND TECHNOLOGY OF MINERAL FERTILISERS IN THE USSR

A. A. Ionass, L. V. Vladimirov, and S. Ya. Shpunt

The progress in the chemistry and technology of the products of the basic chemical industry has been stimulated in recent years in all highly developed countries by the rapid growth of the application of chemistry to agriculture and the continuous increase of the requirements of many other branches of the national economy. The considerable increase in the manufacture and application of mineral fertilisers (by a factor of five in fifty years) has led to qualitative changes in the technological methods for their preparation, has greatly extended the range of fertilisers available and the industrial raw materials pool, and has led to great intensification of theoretical and practical research. A considerable contribution to the development

of the chemistry and technology of mineral fertilisers, acids, and salts, has been made by the Fertilisers, Insecticides, and Fungicides Institute, founded soon after the October Revolution on the initiative of Ya. V. Samoilov, E. V. Britske, and D. N. Pryanishnikov. In this Institute fundamental research has been carried out, which ensured the creation in the USSR of a large-scale mineral fertilisers industry and its raw materials base and had led to the determination of the requirement for effectiveness and the conditions of application of fertilisers in agriculture. Extensive and creative studies have been made by the Institute in the chemistry and technology of sulphuric, nitric, phosphoric, and hydrofluoric acids, insecticides, fungicides, and herbicides.

Semen Isaakovich Vol'fkovich, who celebrated his 70th birthday on the 23rd October 1966, has been one of the principal scientific leaders of this large collective of chemists, engineers, and other specialists over a period of more than 40 years (he set up his own school). Extensive studies, which led to the development of new ways of manufacturing phosphorus fertilisers and a whole series of advanced processes for the preparation of potassium, nitrogen, boron, and complex fertilisers, have been made by Vol'fkovich and his coworkers and students. They have done much work on the chemistry and technology of the compounds of fluorine, sulphur, selenium, and rare earths, and certain organic compounds. The work of Vol'fkovich and coworkers on the chemistry and technology of phosphorus and its compounds has been of the greatest importance. He began with the study of the production of phosphorus by the reduction, in an electric furnace, of phosphates naturally occurring in the USSR, which served as the starting point of many years of further investigations by planning and production engineers, and then passed on to the study and development of other thermal reactions involving the processing of phosphates by their interaction with alkali metal salts and treatment with water vapour. An extensive and detailed cycle of investigations was devoted to the development of the processing of phosphates by their interaction with sulphuric, nitric, and hydrochloric acids.

The physicochemical studies of equilibrium systems and the kinetics of the decomposition of natural phosphates, particularly closely related to the methods of manufacture of fertilisers from the raw materials available in the USSR and the complex utilisation of the latter, have proved very important in the development and progress of the processes described above.

A large proportion of the phosphate deposits prospected up to 1927 in the USSR were of lower quality than the North African, American, and island phosphorites. During the first years of the industrialisation of our national economy, Soviet superphosphate factories encountered many difficulties in the processing of inferior local phosphorites, while in 1930 further difficulties were encountered in the transition to a new type of raw material (new throughout the world and not just in the USSR) — the Khibinsk apatite concentrate. The Khibinsk deposit of apatites and nephelin ores huge and unique as regards composition and properties, differs significantly from the African and American phosphates used up to that time. This difference required a more extensive study of the structure of apatite and the reactions involved in its processing.

Together with Berlin[1-10] and other coworkers, Vol'fkovich studied the kinetics of the decomposition of fluoroapatite and other minerals associated with it, which led to the decision to enrich the ore, and optimum conditions were established for the conversion of the apatite concentrate into superphosphate. This process involves two main stages:

$$Ca_5F(PO_4)_3 + 5H_2SO_4 + 2.5H_2O = 3H_3PO_4 + 5(CaSO_4 \cdot 0.5H_2O) + HF,$$

$$Ca_5F(PO_4)_3 + 7H_3PO_4 + 5H_2O = 5[Ca(H_2PO_4)_2] \cdot H_2O + HF.$$

The first stage takes place in the reactor and is completed in the presence of a large excess of sulphuric acid over the stoichiometric amount required for the preparation of $Ca(H_2PO_4)_2$, the process being localised in the surface layer of the initial phosphate particles. In this stage calcium sulphate is precipitated as the hemihydrate. The second stage begins at a temperature in excess of 110°C and under these conditions the hemihydrate is converted into the anhydrous anhydrite. Despite the negative conclusions of a number of foreign specialists, studies in the laboratory and in factories under operating conditions established not only the possibility but the advantage of the processing of the apatite concentrates which made it possible to apply the technological scheme for the manufacture of superphosphate thus developed in all Soviet and certain foreign undertakings.

The development of the mineral fertilisers industry in the USSR made urgent a more profound study of the raw material, and the development of new technological methods for its processing. As early as 1927–1928 the decision was taken at the Fertilisers, Insecticides, and Fungicides Institute to obtain concentrated fertilisers and to develop a new method of the acid processing of phosphates. Vol'fkovich, Kamzolkin, and others[11-13] studied the complex processing of phosphates designed to prepare concentrated fertilisers, ammonium phosphates, and double and enriched superphosphate, with simultaneous synthesis of nitrogen fertilisers. The method consisted essentially in the decomposition of phosphate by mixtures of sulphuric acid and ammonium sulphate which led to economy in the use of sulphuric acid and higher purity of phosphoric acid obtained from interior phosphorites contaminated with iron and aluminium oxides. The "phosphogypsum" thus obtained is decomposed with ammonia and carbonic acid or ammonium carbonate, yielding ammonium sulphate and calcium carbonate. The ammonium sulphate is recovered in the process involving extraction with phosphoric acid, which is neutralised by ammonia or is used to decompose natural phosphate. The extraction of phosphoric acid and its neutralisation by ammonia have been studied in detail at the Fertilisers, Insecticides, and Fungicides Institute, and have been used in industry: the preparation of ammonium sulphate from phosphogypsum was tested under pilot plant conditions.

The studies carried out by Belopol'skii, Taperova, Shpunt, and others[14-16] on the kinetics of the decomposition and the solubility of the hydrates of calcium sulphate and its phase transformations in the system $CaO-P_2O_5-SO_3-H_2O$ served as a basis for the manufacture of phosphoric acid and superphosphate. The studies showed that within this system $CaSO_4.2H_2O$, $CaSO_4.0.5H_2O$, and $CaSO_4$ are formed. $CaSO_4.2H_2O$ is the principal component of phosphogypsum, obtained in the manufacture of phosphoric acid; it is the metastable component of the system and since the induction period in its conversion is very long, it is stable within the limits of the manufacturing cycle.

The studies of the solubilities of calcium sulphate hydrates in aqueous phosphoric acid were made at 25° and 80°C. It was shown that anhydrite is the least soluble and hence the only stable solid phase at 80°C.

The relative stabilities of gypsum and the hemihydrate vary with the concentration of phosphoric acid. At concentrations less than 33% P_2O_5 the dihydrate is less soluble and is therefore more stable than the hemihydrate. The opposite behaviour is found at concentrations in excess of 33% P_2O_5. The solubility curves for gypsum and the hemihydrate intersect at a P_2O_5 concentration of 33% at 80°C. These conditions correspond to the reaction

$$CaSO_4 \cdot 2H_2O \rightleftarrows CaSO_4 \cdot 0.5\,H_2O.$$

The system $CaSO_4$–H_3PO_4–H_2O was studied at 25°C and phosphoric acid concentrations between 0 and 63% P_2O_5. It was shown that, at all phosphoric acid concentrations, the first solid phase precipitated at 25°C and 80°C is the hemihydrate, which is rapidly hydrated to gypsum at low concentrations (9–20% P_2O_5). The study of the solubility of calcium sulphate hydrates at 25°C showed that there are two intersections of the solubility curves. The first intersection is at 33.7% P_2O_5, gypsum being the solid phase; above 33.25% anhydrite is the stable phase. At a concentration of 49% P_2O_5 the solubility curve for gypsum intersects the solubility curve for the hemihydrate. Under these equilibrium conditions gypsum and the hemihydrate are metastable, being converted into anhydrite. Thus the reactions of calcium sulphate in phosphoric acid at 25°C are as follows:

Below 33.75% P_2O_5 in solution	Between 33.75 and 49.0% P_2O_5 in solution	Above 49.0% P_2O_5 in solution
$CaSO_4 \cdot {}^1/_2 H_2O$	$CaSO_4 \cdot {}^1/_2 H_2O$	$CaSO_4 \cdot 2H_2O$
↓	↓	↓
$CaSO_4$	$CaSO_4 \cdot 2H_2O$	$CaSO_4 \cdot {}^1/_2 H_2O$
↓	↓	↓
$CaSO_4 \cdot 2H_2O$	$CaSO_4$	$CaSO_4$

The studies showed that at 80°C the only stable solid phase is anhydrite. At 25°C the stable phases are anhydrite above 33.75% P_2O_5 and gypsum below this concentration. The hemihydrate is metastable at all phosphoric acid concentrations. In solutions with concentrations between 33.75% and 49% P_2O_5 gypsum is more stable than the hemihydrate, while above 49% P_2O_5 the opposite relation obtains. In these studies the kinetics of the transformations of various calcium sulphate hydrates were also investigated, which made it possible to construct a polythermal induction period isochrone diagram [to determine the temperature variation of the compositions corresponding to constant induction periods? (Ed. of Translation)], on the basis of which it was suggested that concentrated phosphoric acid be prepared with elimination of calcium sulphate in the form of anhydrite.

The most important chemical-technological factor in the manufacture of phosphoric acid is the formation and elimination of calcium sulphate. The form, particle size, and homogeneity of the calcium sulphate formed and the presence of impurities in the acid have a decisive influence on the separation of the sulphate from phosphoric acid, which is achieved by means of filters of various design and decanting devices; impurities also affect the conditions and degree of washing of the precipitate and hence the extraction coefficient of the phosphoric acid.

Until physicochemical analysis led to the elucidation of the details of the crystallisation of various forms and modifications of calcium sulphate in the manufacture of phosphoric acid by its extraction from phosphorites with sulphuric acid, it was difficult to ensure the formation, in the manufacturing process, of large phosphogypsum crystals which could be easily filtered. On the basis of physicochemical studies, Vol'fkovich, Voskresenskii, and others [17-20] carried out technological investigations of the crystallisation of phosphogypsum, in which they determined the conditions for the formation of highly crystalline, and hence easy to filter, calcium sulphate deposits, which enabled a highly effective technological scheme to be developed. On the basis of these data, factories have been planned and constructed in which phosphoric acid is manufactured to this day by the sulphuric acid decomposition method (Voskresensk, Vinnitsa, Volkhovsk, Krasnoural'sk, and other factories).

In view of the intense development of the industrial synthesis of ammonia and nitric acid, Vol'fkovich undertook as early as the 1930's the development of processes for nitric acid decomposition of phosphates. The advantage of these processes consists in the manifold utilisation of the reacting phosphate and nitric acid, the energy of the reaction being used at the same time for the decomposition of the phosphate. Whereas in the manufacture of phosphoric acid and concentrated fertilisers by sulphuric acid and hydrochloric acid decomposition, phosphogypsum and calcium chloride are formed as the respective waste products, which leads to considerable industrial difficulties, in the processing of phosphates by nitric acid there is no waste. Vol'fkovich, Loginova, and Belopol'skii [21-26] elucidated the physicochemical and chemical-technological conditions for the processing of natural phosphates with nitric acid, with manifold utilisation of the raw material (phosphorus, fluorine, and rare earths).

Over a period of several years, Vol'fkovich and his coworkers investigated the chemistry and various modifications of the process using different types of raw material native to the USSR, which led them to propose original technological schemes. These schemes are based on the decomposition of fluoroapatite, the main component of natural phosphates:

$$Ca_5F(PO_4)_3 + 10HNO_3 = 3H_3PO_4 + 5Ca(NO_3)_2 + HF. \quad (1)$$

In the processing of natural phosphates the oxides of iron, aluminium, potassium, and sodium and silicic acid pass into solution in addition to nitric, phosphoric, and hydrofluoric acids; in the processing of the Khibinsk apatite lanthanides also dissolve. Vol'fkovich suggested that the solution prepared by reaction (1) be converted into concentrated and complex fertilisers [25]. One of the modifications of the process proposed and developed together with Loginova consisted in the cooling of the solution (extract) as a result of which calcium nitrate crystallised out and could be separated, which ensured that on further neutralisation with ammonia solution the phosphates were obtained in partially or completely soluble form (depending on the temperature to which the solution was cooled). Calcium nitrate may be used as such or converted by treatment with ammonia and carbonic acid into ammonium nitrate or decomposed by heating into calcium oxide and nitrogen oxides, which are returned to the manufacturing cycle. The isolation of calcium sulphate from solution with the aid of ammonium sulphate was also investigated. On neutralisation with ammonia solution, ammonium phosphate or its mixture with dicalcium phosphate are formed by the reactions

$$H_3PO_4 + NH_3 = NH_4H_2PO_4, \quad (2)$$

or

$$3H_3PO_4 + 1.5\,Ca(NO_3)_2 + 4.5\,NH_3 = 1.5\,NH_4H_2PO_4 + 1.5\,CaHPO_4 + 3NH_4NO_3. \quad (3)$$

Following the addition of ammonium sulphate to the solution and neutralisation with ammonia, the overall reaction is

$$H_3PO_4+Ca(NO_3)_2+(NH_4)_2SO_4+NH_3+2H_2O=CaSO_4\cdot 2H_2O+NH_4H_2PO_4+2NH_4NO_3. \quad (4)$$

Calcium sulphate (gypsum) can be separated and then treated with carbonic acid and ammonia to yield ammonium sulphate which is returned to the process [reaction (4)].

On addition of potassium chloride or sulphate to the reaction mixture, a ternary fertiliser (Nitrophoskas), containing 52% of nutrient materials (N, P_2O_5, and K_2O), is obtained. In their study of the nitric acid decomposition of phosphates, much attention was given to the investigation of the system $CaO-P_2O_5-N_2O_5-H_2O$ [26] at 25° and 50°C. Table 1 presents data characterising the compositions of the liquid and solid phases at the nodal points of the isotherms[26]. The results obtained permitted a technological analysis of the nitric acid decomposition of phosphates, the determination of the theoretical proportions of the reactants, and the calculation of the limiting yields and the concentrations of the intermediate and final products formed in the process.

The method of nitric acid decomposition of phosphates proposed by Vol'fkovich eliminates the formation of waste in the manufacturing process by including stages in which stepwise neutralisation of the nitric acid extract is carried out by sodium, calcium, or ammonium salts, fluoride and rare earths being precipitated. The latter cannot be recovered in the sulphuric acid processing of phosphates.

Various methods of nitric acid processing of phosphates developed in the laboratories of the Fertilisers, Insecticides, and Fungicides Institute have been applied on the industrial scale in the experimental workshop of the Dneprodzerzhinsk nitrogen mineral fertilisers factory. Margolis, Dubovitskii, Glazova, and others participated in these studies[27,28].

TABLE 1.

Nodal points of the isotherms.

Designation of point (see Ref. 26)	Solution: wt.% CaO	wt.% P_2O_5	wt.% N_2O_5	moles per 1000 moles of H_2O: CaO	moles per 1000 moles of H_2O: P_2O_5	moles per 1000 moles of H_2O: N_2O_5	Solid phase
				25°C isotherm

D	25.95	—	51.23	265.2	—	374.3	$Ca(NO_3)_2\cdot 2H_2O + Ca(NO)_2$

In the concentration range investigated the isotherms are characterised by the saturation fields of the following stable phosphates and nitrates:

	25°	50°
Phosphates	$CaHPO_4$ $Ca(H_2PO_4)_2\cdot H_2O$	$CaHPO_4$ $Ca(H_2PO_4)_2\cdot H_2O$
Nitrates	$Ca(NO_3)_2\cdot 4H_2O$ $Ca(NO_3)_2\cdot 3H_2O$ $Ca(NO_3)_2\cdot 2H_2O$	$Ca(NO_3)_2\cdot 2H_2O$ $Ca(NO_3)_2$

At the present time there are in the USSR two factories in which modified methods of nitric acid processing of phosphates are used, and two further factories are planned. Apart from the advantages of the use of nitric acid mentioned above, owing to the absence of waste and the twofold utilisation of the acid, for the decomposition of phosphates and as a component of the fertiliser, these manufacturing schemes can be employed in the processing of inferior iron-containing phosphorites.

The studies carried out under the direction of Vol'fkovich and Belopol'skii by the scientific team at the Fertilisers, Insecticides, and Fungicides Institute on the decomposition of natural sodium sulphate with ammonia and carbonic acid with production of sodium carbonate and ammonia sulphate are of theoretical and technical interest. This process is of particular interest in the USSR where there are large deposits of natural sulphate (Kara-Bogaz-Gol, the Aral sea, and others). The manufacture of sodium carbonate and ammonium sulphate from mirabilite consists in the double decomposition of sodium sulphate and ammonium bicarbonate:

$$Na_2SO_4+2NH_4HCO_3 \rightleftarrows (NH_4)_2SO_4+2NaHCO_3.$$

The 15°, 7°, 0°, -5°, -5.9°, -10°, and -17°C isotherms for the system $Na_2SO_4-NH_4HCO_3-H_2O$ were investigated[29-31] in order to set up a rational physicochemical basis for the development of a method of converting sodium sulphate into sodium carbonate and ammonium sulphate. The diagrams obtained in the study of the appropriate systems were used for practical calculations. Graphical calculation revealed the possibility of separating sodium and ammonium sulphates by freezing out. Combination of freezing and evaporation allows, in theory, the separation to be taken to completion, 100% utilisation of the initial sodium sulphate being thereby achieved (up to 95–97% in practice).

The physicochemical study of the carbonisation of aqueous ammonia solutions of sodium sulphate by Bolopol'skii and Urusov[32] permitted the calculation, on the basis of the equilibrium diagrams, of the optimum proportions of the reactants, the latter being confirmed by direct experiments on the carbonisation of aqueous ammonia solutions of sodium sulphate. Extensive experimental data yielded comparative coefficients characterising the course of the carbonisation in various zones of the carbonisation column and allowed an approach to the determination of the conditions which should be taken into account in the design of the usual Solvay columns to ensure the successful carbonisation of ammonia–sulphate solutions in the latter. To optimise the conditions of this process, Belopol'skii and Shpunt[33] investigated the partial pressure of ammonia, carbon dioxide, and water over ammonia–sulphate and ammonia–chloride solutions.

Semi-industrial and industrial experiments on the carbonisation of ammonia–sulphate solutions using appropriate apparatus[34] demonstrated the usefulness of the sodium carbonate column in the carbonisation of such solutions and yielded data required for the design and exploitation of apparatus for carbonisation, filtration, and calcination in the ammonia–sodium carbonate manufacture based on sodium sulphate.

Comparative technical and economic calculations indicate high economic efficiency of the process, which is a consequence of the manifold utilisation of the raw material and the absence of waste in the manufacturing process. The latter can be introduced for the processing of sodium sulphate (mirabilite from the Kara-Bogaz deposit and others).

To avoid the loss of sulphuric acid and the consumption of large amounts of electrical energy in the processing of phosphates, Vol'fkovich, Postnikov, Illarionov, Ionass, and Remen[35-38] investigated and developed a new hydrothermal process for the conversion of natural phosphates into fertilisers and fodder for animal husbandry. The process yields a highly concentrated mineral fodder additive containing up to 90% of useful substances, including about 40% P_2O_5 and 50% CaO, essential for the nutrition of animals. To obtain information about the reactions occurring in the hydrothermal processing of phosphates, it was necessary to investigate the systems $CaO-P_2O_5$ and $CaO-SiO_2-P_2O_5$. These systems have been the subjects of numerous investigations by Bredig et al.[39], Trömmel[40], and Barrete and McCoughey[41], who discovered the principal compounds formed under given conditions and established the regions of their existence. However, in these studies the system $CaO-P_2O_5-SiO_2$ was not investigated adequately in the range of low silica concentrations, and this region is of great importance for the hydrothermal processing of natural phosphates developed by Vol'fkovich and coworkers. Evseeva, Luzhnaya, and others[42] investigated the system at low concentrations of SiO_2 and showed that under these conditions the principal phase is $Ca_3P_2O_8$, which has a very small region of stability.

Until recently the mechanism of the hydrothermal process of natural phosphates remained obscure. The solution of this problem is not only of theoretical but also of practical importance for the industrial application of the process. In order to establish its mechanism[43], measurements were made of the heats of formation of hydroxoapatite and fluoroapatite and also the heat of decomposition of the Khibinsk apatite concentrate. The heat of formation of fluoroapatite is 3269 kcal mole^{-1} and that of hydroxoapatite 3211.9 kcal mole^{-1}. The heat of replacement of fluorine by a hydroxy-group in the reaction between fluoroapatite and water has been calculated from these quantities as 44.24 kcal.

On the basis of their own and literature data[44], these authors calculated the enthalpy differences and the entropies for hydroxoapatite (HA), fluoroapatite (FA), and water vapour in the temperature range 1000–1800°K, and also the thermodynamic functions and equilibrium constants for the reaction

$$Ca_{10}F_2(PO_4)_6+2H_2O \rightleftarrows Ca_{10}(OH)_2(PO_4)_6+2HF.$$

These quantities are listed in Tables 2 and 3.

TABLE 2. Enthalpy differences and entropies for hydroxoapatite fluoroapatite, and water vapour.

T, °K	$(H_T^\circ - H_{298.16}^\circ)$			S_T°		
	HA	FA	H_2O	HA	FA	H_2O

TABLE 3. Thermodynamic functions and equilibrium constants for the reaction*.

$10^4/T$	$T_1^\circ K$	ΔH	ΔS	$\log K_e$	$\log K_e^1$	K_e^1
1	1000	48.166	43.430	−9.4929	−4.7465	0.0000179
0.76863	1300	50.591	40.084	−6.7396	−3.3698	0.000427
0.62500	1600	55.734	37.084	−5.1834	−2.5918	0.00250
0.57143	1750	56.163	34.876	−4.3561	−2.1780	0.00664
0.55560	1800	56.602	34.129	−4.1444	−2.0722	0.00847

* $K_e^1 = \sqrt{K_e} = P_{HF}/P_{H_2O}$.

For 1000° and 1300°K, literature data for higher temperatures were used, the enthalpy difference for fluoroapatite being calculated from the equation

$$(H_T - H_{298.16}) = 226.04\,T + 14.44 \times 10^{-3}T^2 + 48.82 \times 10^5 T^{-1} - 85\,050,$$

and for hydroxoapatite from the equation

$$H_T - H_{298.16} = 228.52\,T + 19.81 \times 10^{-3}T^2 + 50.00 \times 10^5 T^{-1} - 86\,670.$$

The enthalpy differences for water at 1000°, 1300°, and 1750°K were taken from Waggaman[45], while the values at 1600° and 1800°K were calculated from the equation

$$H_T - H_{298.16} = \int_{298.16}^{T} C_p dT.$$

The equilibrium constants K_e and K_e^1 confirm that the partial pressures of hydrogen fluoride in equilibrium with water vapour are very low. Thus, if it is assumed that, on isomorphous replacement of a fluoride ion by a hydroxide ion a new phase is formed, the reaction must be localised in the high-temperature zone (near the flame in the rotating furnace). If the process took place according to the mechanism indicated, involving the conversion of the fluoroapatite phase into the hydroxoapatite phase, then at 1375°C there would be no loss of fluorine. However, laboratory and then factory experiments showed that at this temperature fluorine is evolved, albeit slowly, and therefore there is a possibility of the formation of a phase of variable composition — fluorohydroxoapatite. Direct determination of the heat of decomposition confirms this hypothesis. Thus experiments show that the mechanism of the process can be represented by the following equations:

$$(1)\ Ca_{10}F_2(PO_4)_6+H_2O=Ca_{10}F(OH)(PO_4)_6+HF,$$

$$(2)\ Ca_{10}F(OH)(PO_4)_6+H_2O=Ca_{10}(OH)_2(PO_4)_6+HF,$$

$$(3)\ Ca_{10}(OH)_2(PO_4)_6=2Ca_3(PO_4)_2+Ca_4P_2O_9+H_2O.$$

Since the apatite concentrate contains only a small amount of silica, up to 2% of sand is added to it; in the presence of silica the reaction takes place as follows:

$$2\,Ca_5OH(PO_4)_3+\frac{1}{3}SiO_2=3Ca_3(PO_4)_3+\frac{1}{2}Ca_2SiO_4+H_2O.$$

In a general form the hydrothermal decomposition of apatite may be represented by the reaction

$$n\,Ca_{10}F_2(PO_4)_6+m\,SiO_2+H_2O=10\,nCaO\cdot 3nP_2O_5\cdot mSiO_2+2HF.$$

This process was investigated, under Vol'fkovich's direction, by Ionass, Remen, and others using the apatite concentrate and phosphorites from other deposits (Kara-Tau, Egor'evskoe deposit, Volgo-Vyatskoe deposit, and others[46]). Above it was shown that, by virtue of its low fluorine content and the absence of harmful impurities (lead and arsenic), the product obtained by this method, defluorinated phosphate, may be used not only as a fertiliser but also as a mineral calcium–phosphorus food additive for animals.

The hydrothermal processing of natural phosphates has been investigated under laboratory and semi-industrial conditions [47-53]. Two technological methods, applicable to different phosphate raw materials, have been developed. In the method developed for natural phosphates, not containing impurities and characterised by high temperatures of the onset of deformation and fusion, defluorination takes place in the solid phase. The main component of the apparatus used in this technological method is a rotating tubular furnace; to enhance the efficiency of the furnace, a process involving the granulation of the charge using phosphoric acid was developed.

The technological method for natural phosphates with impurities and low deformation and fusion temperature characteristics is based on the processing of the natural phosphate in the melt. Highly efficient cyclone furnaces were used in the fusion. The results were applied in industry. At the present time this process is being used in the Sumsk factory.

Recently Vol'fkovich has carried out interesting work at Moscow University and the Fertilisers, Insecticides, and Fungicides Institute on the problems of the chemistry and technology of dehydrated phosphates. The dehydrated phosphates (poly- and meta-phosphates) of ammonium and potassium are more concentrated in nutrient element content than the orthophosphate salts and may be used as highly effective concentrated fertilisers. Some of these salts are polymers which, depending on the physicochemical conditions, may be obtained in various polymeric modifications differing in composition and properties.

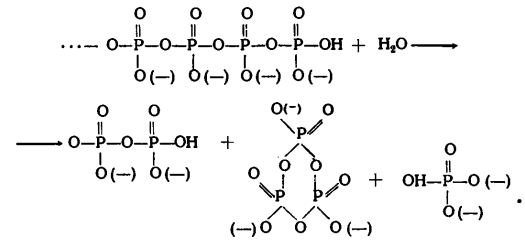
Vol'fkovich, Kubasova, Cherepanova, and others [54-56] investigated the methods for the preparation of potassium metaphosphate involving the reaction of polyphosphoric acids with potassium salts and thermal dehydration of acid salts of orthophosphoric acid; at the same time the structure and the physicochemical properties of the products were studied. A technological method, subsequently tested on a semi-industrial scale, was developed on the basis of laboratory experiments and a thermographic study of the dehydration of KH_2PO_4 to $(KPO_3)_n$, and also of the intermediates obtained in the decomposition of potassium chloride by orthophosphoric acid. Chemical and X-ray diffraction studies established the effect of small amounts of certain metal oxides on the structure of potassium metaphosphate. The relation between the structural characteristics of the specimens obtained and their solubility in water was determined.

Potassium polyphosphates obtained from polyphosphoric acids consist of a mixture of phosphates with a degree of condensation equivalent to several tens of phosphorus atoms in the chain. In contrast to high-molecular potassium polymetaphosphates of the composition $(KPO_3)_n$, these products exhibit high solubility in water and are therefore more completely and rapidly assimilated by plants.

Metal ammonium phosphates constitute an interesting class of compounds which are of practical importance. Vol'fkovich suggested that they be used as fertilisers. These compounds contain three nutrient elements — nitrogen, phosphorus, and the metal, and behave as concentrated fertilisers. They include magnesium, copper, manganese, and iron ammonium phosphates. They contain nitrogen in a sparingly soluble form. Some of the metal ammonium phosphates, in particular the aluminium and iron ammonium phosphates, can be used as insoluble fire-resistant materials. The idea that the metal ammonium phosphates be used as fire-resistant materials is due to Vol'fkovich and coworkers [57,58]. Later it was developed by his coworkers and applied in practice.

A number of Vol'kovich's studies dealt with the chemistry and technology of ammonium orthophosphates and polyphosphates. As early as the 1920's, the system $(NH_4)_2O-P_2O_5-SO_3-H_2O$ was investigated [59] and data necessary for the manufacture of Ammo-Phos were obtained. Aluminium phosphates are of very great theoretical and practical importance: since they contain two plant nutrient elements, they are widely used as concentrated and complex fertilisers. Dehydrated poly- and meta-phosphates are distinguished by a high content of nutrient elements and can be employed not only as fertilisers but also as components of wetting agents in certain bakery and technical chemical products. Dehydrated phosphates can be produced by direct reaction of P_2O_5 and NH_3, but the investigations of Britske and others showed that the formation of imido- and amido-groups is possible in this process.

In a study directed by Vol'fkovich, Kubasova [60] investigated the formation of dehydrated phosphates based on polyphosphoric acids; she investigated both the physicochemical properties and the structure of the compounds. The structure of the dehydrated phosphates was studied by X-ray diffraction analysis, infrared spectroscopy, thermography, chromatography, and other methods. These experiments showed that all water-soluble ammonium polyphosphates, obtained by the dehydration of monoammonium phosphate at 350°C, are amorphous to X-rays; an increase of the dehydration temperature results in the formation of sparingly soluble polyphosphates with crystalline as well as vitreous structures. The determination of the interplanar spacings in these crystals yielded values close to the lattice parameters of the kurrol sodium salt. The formation of the isotropic water-soluble modification is associated with the formation of ammonium phosphate glasses having the metaphosphate composition. To establish the nature of the P–O–P bond in the water-soluble ammonium polyphosphates, a study was made of their hydrolysis. These investigations showed that the hydrolysis of ammonium polyphosphates is similar to that of the polyphosphates of other cations and consists in the splitting of P–O–P bonds at the ends of long chains and the formation of trimetaphosphate rings, with a constant ratio $(P_3O_9):(PO_4) = 1:1$, by the following mechanism:



In this hydrolytic mechanism there are two OH groups for each trimeta- or ortho-phosphate group, of which only one is titrated at pH 8, namely the newly formed OH group at the end of the residual polyphosphate chain.

This mechanism suggests that the anions of the water-soluble ammonium polyphosphates have a linear chain structure, and this applies to all chain-type polyphosphates with a degree of condensation greater than five. The degree of dehydration and the average number of atoms in the chain were determined by the analysis of the terminal

functional groups by potentiometric titration. The infrared spectra of ammonium polyphosphates showed that, depending on the dehydration temperature, there is a decrease of the intensity of the bands characterising the P–OH bond upon condensation and an increase in the length of the polyphosphate chains. A technological method for the preparation of ammonium phosphates was developed on the basis of the experimental data.

Vol'fkovich and Urusov made a physicochemical study of the dehydration of ammonium orthophosphates and showed that ammonium metaphosphate may be prepared by heating the ortho-salt in an atmosphere of ammonia[61]. Vol'fkovich's studies on the synthesis of phosphoramidic and phosphorimidic acids are also of interest; according to Sokolov's agrochemical and vegetative experiments, some of these compounds are effective fertilisers which are not bound by the soil[62].

The rapid development of urea manufacture and the prospective manufacture of polyphosphoric acid open up new possibilities for the preparation of highly concentrated urea polyphosphate fertilisers which are of great interest for the mineral fertilisers industry. To develop their synthesis, Vol'fkovich and Chekhovskikh[63] made a physicochemical study of the system urea–polyphosphoric acid. This study was based on thermal and crystal-optical methods and visual observations over a range of temperatures. The molecular ratio of H_2O to P_2O_5 in the poly-acid was found to be 2.67 at a concentration of 74.5% P_2O_5 and 2.4 at 76% P_2O_5. These studies showed that in the system urea–polyphosphoric acid with R = 2.67 a 1 : 1 urea–polyphosphoric acid compound is formed. This compound melts congruently at 117.8–118°C and forms a eutectic with urea at 68°C and 64.5 mole % of urea and a peritectic with a second compound (2 : 1) which melts incongruently at 46°C. Polyphosphoric acid with R = 2.67 forms solid solutions, also with a eutectic corresponding to 15 mole % of urea. In the system urea–polyphosphoric acid with R = 2.462 a single 1 : 1 compound, melting congruently at 113°C, is also formed. This compound gives rise to a eutectic with urea at 74.8°C and 60 mole % of urea. The reaction between urea and polyphosphoric acids at a 1 : 1 molar ratio gave products containing 16.9–17.1% N and 51.6–52% P_2O_5, which may be used as fertilisers.

Vol'fkovich was the first Soviet scientist to investigate and apply industrially the electrothermal preparation of phosphorus from low-quality phosphorites native to the USSR [64,65] and he also made a series of studies [66–68] on the trapping and utilisation of fluorine-containing waste gases produced in natural phosphate processing, as a result of which the superphosphate factories of the Soviet Union have since produced a number of fluoride and fluorosilicate salts. In recent years he developed, together with members of the Fertilisers, Insecticides, and Fungicides Institute and factory workers, a synthesis of hydrofluoric acid from the gases evolved in phosphate mineral fertiliser factories. Vol'fkovich pioneered in the USSR the manufacture of hydrofluoric acid and fluoride salts from fluorspar. He and his coworkers were the first to investigate and develop methods of preparation of boric acid from borosilicate ores (datolites) and other materials [69–71], which until then had never been used as raw materials.

He made an extensive series of laboratory studies on the physicochemical conditions for the modification and improvement of the physical properties of ammonium nitrate[72,73], the preparation of ammonium sulphate from gypsum[74], and the reaction of sulphur dioxide with ammonia. He also carried out experiments on the chemical processing of potassium salts native to the USSR into chlorine-free potassium sulphate, phosphate, and nitrate fertilisers[74].

A characteristic feature of all of Vol'fkovich's research is endeavour to arrive at a manifold solution of the problem, permitting an almost complete utilisation of the available power and raw materials, and also to apply in chemical and technological research the facilities of modern technology and advanced methods of physical and physicochemical analysis. In his studies, he employed widely thermal, X-ray diffraction, spectroscopic, crystal-optical, chromatographic, isotopic, and other methods of research. To investigate the physical means of influencing chemical reactions, he has employed almost all the known advanced procedures, in particular those involving high-temperature catalytic processes in a fluidised bed and cyclone reactors.

Vol'fkovich proposed several substances (as well as methods for their manufacture) for the protection of plants and animals from pests and disease, and recommended a number of antiseptics for the protection of wood and certain organic materials from rot and decay. Vol'fkovich and coworkers synthesised a number of organic and organometallic substances. The relevent reactions include the synthesis of organophosphorus compounds by the interaction of phenol[75] with phosphorus and of phosphorus pentoxide with aluminium phenoxides[76], the preparation of melamine phosphates[77], the polycondensation of urea with various organic and inorganic compounds, the radiolysis of tetrachloroethylene and hexachlorobutadiene, and others[78]. Vol'fkovich is the author of the first technological method for the chemical manufacture of potassium chloride from Solikamsk potassium salts[79].

III. Alkylation and acylation of polynitro-compounds 728

I. INTRODUCTION

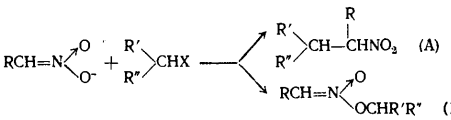
In recent years the scale of the studies on the chemistry of aliphatic nitro-compounds has been steadily increasing. Among the wide variety of the reactions which have attracted the attention of numerous investigators the alkylation and acylation of nitro-compounds merit attention. In the first place these reactions are of considerable theoretical interest since it is here that the dual reactivity of nitro-compounds is shown in a particularly pronounced form. Furthermore, they have attracted the attention of investigators for a long time as a method for preparing various nitro-derivatives and a wide variety of carbonyl compounds. However, despite the large number of studies on this problem, the available data have not been reviewed so far. The aim of the present review is to collect and compare the literature data on the alkylation and acylation of nitro-compounds with nitro-groups at saturated carbon atoms.

In the first section of the review the work done on the alkylation and acylation of mononitro-compounds, i.e. compounds with not more than one nitro-group at a single carbon atom, is considered. The second part deals with polynitro--compounds with several nitro-groups at a single carbon atom.

II. ALKYLATION AND ACYLATION OF MONONITRO--COMPOUNDS

1. Alkylation of *C*-Halogeno-Derivatives

In the alkylation of nitro-compounds their salts are employed as a rule. Consequently anions are actually involved in the reaction. Since the anions of nitro-compounds have two reaction centres (the oxygen of the nitro-group and the carbon bound to the latter), two modes of alkylation of nitro-compounds may be expected:



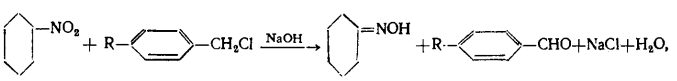
In the first case (*C*-alkylation) nitro-compounds are formed (A) while in the second case (*O*-alkylation) the products should be nitronic esters (B). As will be shown later, nitronic esters are as a rule unstable to heat and break down into a carbonyl compound and an oxime:

i.e. the breakdown of the ester involves intramolecular oxidation–reduction and ultimately the nitro-compound is reduced to the oxime and the halogeno-derivative is oxidised to the corresponding carbonyl compound.

The alkylation of mononitro-compounds has been studied in greatest detail in reactions with various halides of the benzyl type. In almost all cases such reactions results in alkylation of the oxygen only. Thus in the reactions with various *p*-substituted benzyl halides the sodium salt of 2-nitropropane yields only the corresponding benzaldehydes (in yields of 68–77%) and acetone oxime, i.e. the breakdown products of nitronic esters [1] †

where R = CH_3, Br, CH_3CO, CH_3OCO, CN, CF_3, $\overset{+}{N}(CH_3)_3I^-$.

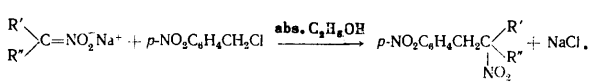
Similar results were obtained in the reactions of benzyl chloride with the potassium salt of 2-nitropropane [3], with the sodium salts of phenylnitromethane [4] and phenylnitroacetonitrile [4], and also with nitrocyclohexane [5]. The authors proposed the last reaction as a method for the preparation of alicyclic oximes and carbonyl compounds:



where R = H and CH_3.

The reaction of the silver salt of phenylnitroacetonitrile with benzyl chloride also gives an *O*-alkylation product [6].

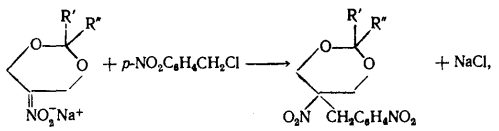
Among benzyl halides, *p*-nitrobenzyl chloride occupies an exceptional position, since, in contrast to all other benzyl halides, it alkylates alkali metal salts of nitroalkanes (nitroethane, 1- and 2-nitropropane, 1- and 2-nitrobutane, nitrocyclohexane, and nitrocyclopentane) almost exclusively at a carbon atom with formation of *p*-nitrophenyl-substituted nitroalkanes in yields between 30 and 60%: [7]



It is necessary to use a considerable excess of the nitroalkane, since otherwise polyalkylation products are formed [for example 1,1-bis-(*p*-nitrobenzyl)nitroethane may form from nitroethane [8]].

† The authors recommended this reaction as a general method for the synthesis of substituted benzaldehydes (see also Ref. 2).

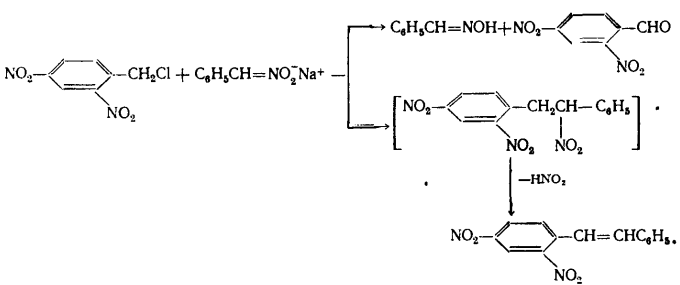
p-Nitrobenzyl chloride can also be successfully used for the *C*-alkylation of derivatives of 5-nitro-1,3-dioxan[9]:



where R′ = H and R″ = C_6H_5 (a) or R′ = R″ = CH_3 (b). In the reaction of this halide with the sodium salt of phenylnitromethane both *C*- and *O*-alkylation take place[4]. The mercury salt of phenylnitromethane does not enter into a similar reaction[4].

When *p*-nitrobenzyl halides are allowed to react with salts (sodium and silver) of phenylnitroacetonitrile, only the oxygen is alkylated[4]. It has been stated that *o*-nitrobenzyl chloride gives bis-(*o*-nitrobenzyl)nitromethane on reacting with the sodium salt of nitromethane[10], but the yield has not been given.

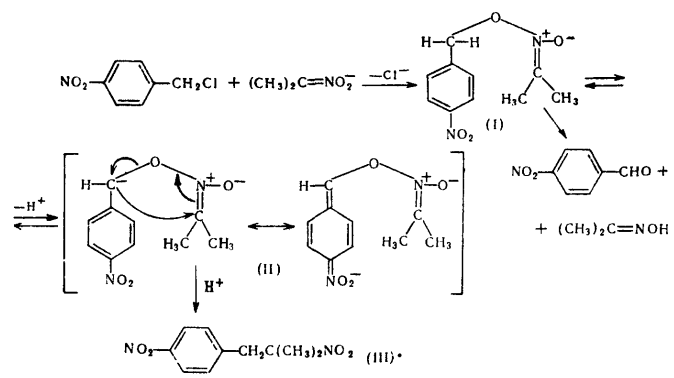
2,4-Dinitrobenzyl chloride and the sodium salt of phenylnitromethane yield both *O*- and *C*-derivatives. However, in the latter case, the product is unstable and breaks down to give 2,4-dinitrostilbene[4]:



C-Alkylation takes place in the reaction of 2,4-dinitrobenzyl chloride with the sodium salt of 2-nitropropane (yield 33%)[11].

The above data show that in the alkylation of the salts of nitroalkanes with benzyl halides it is virtually only *p*-nitrobenzyl chloride that gives products of alkylation exclusively at the carbon atom; in all the remaining cases *O*-alkylated derivatives are almost the only products. This is seen particularly clearly in the following example: in the reaction of the sodium salt of 2-nitropropane with nitro-substituted benzyl chlorides the *para*-isomer gives only *C*-alkylated products (yield 83%), the *ortho*-isomer gives products corresponding to 46% *C*-alkylation and 30% *O*-alkylation, while the *meta*-isomer and the unsubstituted benzyl chloride give rise to *O*-alkylation alone (in 73% yield)[11].

The study of the kinetics of the reaction of the lithium salt of 2-nitropropane with *o*-, *m*-, and *p*-nitrobenzyl chlorides (in ethanol at 30°) showed that the reaction is of the second order and its rate is approximately the same as that of the reaction of potassium iodide (in acetone) with the same halides[11]. Hass and Bender[11] put forward the following mechanism for the reaction of the salts of nitroalkanes with benzyl halides: both in *O*- and in *C*-alkylation the initial stage is alkylation of the oxygen with formation of the nitronic ester (I) which then either breaks down into an aldehyde and an oxime or ionises to give a resonance-stabilised carbanion (II). As a result of intramolecular rearrangement the latter then yields the *C*-alkylation product (III):



The presence of a nitro-group in the *para*-position of the benzyl ring greatly facilitates the removal of a proton from compound (I) and thereby leads to complete conversion of (I) into (II), i.e. ultimately to *C*-alkylation.

However, this mechanism does not explain why the mode of alkylation depends on the nature of the group being substituted in the *p*-nitrobenzyl system. Thus Kornblum and coworkers[12,13] showed that in the reaction of the lithium salt of 2-nitropropane with various *p*-nitrobenzyl derivatives the ratio of the products of *C*- and *O*-alkylation varies sharply with the group being substituted (see Table).

Another argument against the mechanism of Hass and Bender[11] was adduced by Boyd and Kelly[14], who showed that in the *C*-alkylation of nitro-compounds with allyl halides there is no allyl rearrangement which would have to take place if Hass and Bender's hypothesis of the initial formation of *O*-alkylation products and their subsequent rearrangement to *C*-alkylation products were correct.

Recently Kornblum and coworkers[15] suggested a new alkylation mechanism to account for the specificity of the reactions of nitroalkane salts with *p*-nitrobenzyl derivatives. They believe that, whereas *O*-alkylation involves the usual nucleophilic substitution at the oxygen atom of the

TABLE. Mode of reaction of p-$NO_2C_6H_4CH_2X$ with the lithium salt of 2-nitropropane (in dimethylformamide at -16°) depending on the nature of X.[12,13]

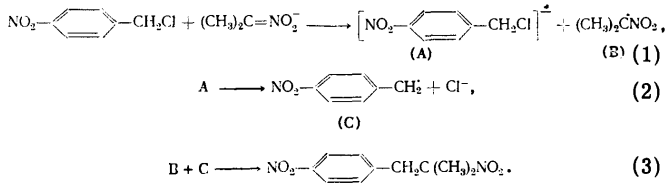
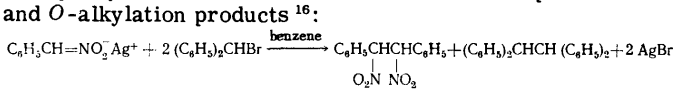
nitro-group, *C*-alkylation is a more complex anionic-radical process:



In this mechanism the first stage of the reaction consists in the transfer of an electron from the nitroalkane anion to the aromatic system [Eqn. (1)], this being followed by the loss of a chloride ion by the radical-anion (A) [Eqn. (2)] and the recombination of the two radicals (B) and (C) [Eqn. (3)].

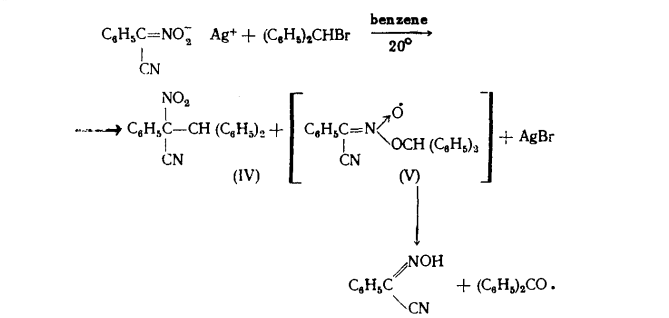
This hypothesis is based on the study of alkylation kinetics [15] (the slight increase of the rate of *C*-alkylation on going from *p*-nitrobenzyl chloride to the bromide and then the iodide, which is untypical for an S_N2-process) and was confirmed by the detection of radical-anions in the reaction mixture (by the ESR method).

The reactions of mononitro-compounds with α-phenyl substituted benzyl halides and with di- and tri-phenyl halogenomethanes are more complex. Thus in the reaction of the silver salt of phenylnitromethane with diphenylbromomethane, 1,2-diphenyl-1,2-dinitroethane and the symmetrical tetraphenylethane are obtained instead of the expected *C*- and *O*-alkylation products [16]:

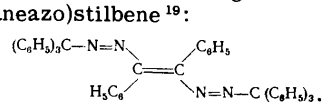


The authors believe that the unstable silver salt of phenylnitromethane breaks down with formation of diphenyldinitroethane and silver, the latter reacting with the initial bromide to give tetraphenylethane.

The reaction of the silver salt of phenylnitroacetonitrile gives, although in low yield, the *C*-alkylation product — triphenylnitropropionitrile (IV). [17] However, it was shown subsequently [18] that the principal mode of this reaction is *O*-alkylation with formation of the nitronic ester (V) which decomposes into α-isonitrosobenzyl cyanide and benzophenone:

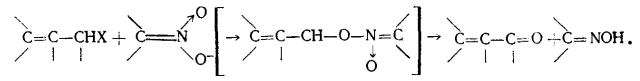


The reaction of triphenylchloromethane with the mercury salt of phenylnitromethane gives the *C*-alkylation product, 1,1,1,2-tetraphenyl-2-nitroethane, in 33–40% yield [4,17]. The reaction of triphenylchloromethane with the silver salt of phenylnitroacetonitrile is much more complex [17,19]. Initially it was believed that the *C*-alkylation product is formed [17], but later it was shown that the reaction gives rise to αα′-bis-(triphenylmethaneazo)stilbene [19]:



In addition, it proved possible to isolate triphenylmethyl isocyanate and a compound of unknown structure [19] with the empirical formula $C_{14}H_{11}N_{13}O$.

Halides of the allyl type, whose reactivity is similar to that of benzyl halides, alkylate mononitro-compounds at the oxygen atom as a rule. Thus the reaction of alkali metal salts of nitroalkanes with a series of allyl halides of different structures containing one or two allylic halogen atoms, gives rise to αβ-unsaturated mono- and di-aldehydes or ketones as a result of the breakdown of the intermediate nitronic esters [20]:



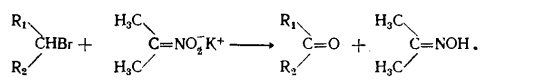
Both primary and secondary nitroalkanes and primary and secondary allyl bromides and chlorides may be used in the reaction (best results were obtained with the salts of 2-nitropropane [20] and nitrocyclohexane [21]). This reaction serves as a basis for the preparative synthesis of unsaturated aldehydes, for example citral and its homologues [21,22], which are used in the manufacture of perfumes.

O-Alkylation is also achieved with the aid of a cyclic halide of the allyl type, 3-bromocyclohexene, which reacts with the sodium salt of 2-nitropropane with formation of an unsaturated ketone (cyclohexenone) and acetone oxime [23]. Another product is cyclohexadiene (formed by the dehydrohalogenation of the initial bromide).

Mononitro-compounds have been alkylated at the carbon atom by allyl halide in only a few cases. Thus the reaction of the salts of nitroacetic and nitromalonic esters with allyl halides gives small yields (10–30%) of the corresponding *C*-derivatives [14] ‡:

where R = H and C_2H_5OCO and R′ = H and CH_3.

Many investigators have studied the alkylation of various mononitro-compounds with alkyl halides. In almost all cases the oxygen atom was alkylated with formation of nitronic esters (sometimes isolated in a pure form) or their decomposition products. The potassium salt of 2-nitropropane reacts with various alkyl halides (undecyl and dodecyl bromide, 1-piperonyl-2-bromoethane, and others) with formation of aldehydes and acetone oxime [3]:

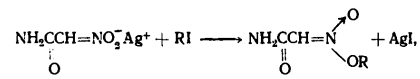


The corresponding oxime is also formed in the reaction of the sodium salt of 1,1,2-triphenyl-2-nitroethane with methyl iodide [25]. When the potassium salt of 9-nitrofluorene reacts with alkyl halides, fluorenone oxime is formed and also the corresponding aldehyde, ketone, or olefin, depending on the nature of the halide (primary, secondary, or tertiary) [26]. Similar results were obtained with the silver salt of 2-bromo-9-nitrofluorene [27].

The reaction of the sodium salt of phenyl- and *p*-bromophenylnitromethane with methyl iodide is unusual, the products being stilbene (or 4,4′-dibromostilbene) and

‡ In a paper published in 1873 [24] an attempt to synthesise 4-nitropent-1-ene from the potassium salt of nitroethane and allyl iodide is described; however, the reaction product was not identified.

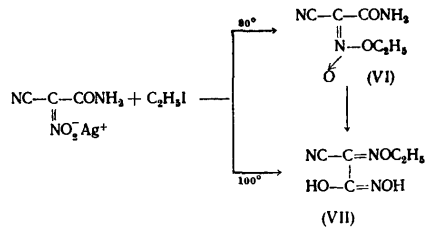
benzaldehyde[26]. The reaction of the sodium salt of phenylnitromethane with t-butyl bromide gives only the free phenylnitromethane[26]. In many cases stable nitronic esters, resulting from *O*-alkylation, can be isolated when alkyl halides react with salts of mononitro-compounds. Such esters were obtained, for example, in the reaction of the silver salt of nitroacetamide with various alkyl iodides[28,29]:



where R = CH_3, C_2H_5, n-C_3H_7, and iso-C_5H_{11}. The silver salt of the diamide of nitromalonic acid does not enter into a similar reaction[30].

When the silver salt of phenylnitroacetonitrile reacts with methyl iodide, it is possible to isolate a relatively stable nitronic ester[6,31]; in another study only the decomposition product of this ester, an oxime, was obtained[32]. The results of the reaction of *p*-bromophenylnitroacetonitrile were similar[33].

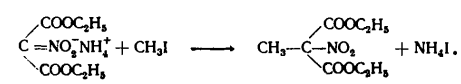
The reaction of the silver salt of fulminic acid (cyanonitroacetamide) with ethyl iodide also gives a nitronic ester (VI),[34] or, at a higher temperature, its rearrangement product (VII):[35,36]



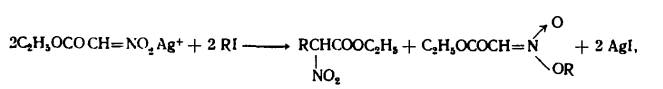
(VII)

A stable nitronic ester was obtained from the silver salt of 3-methyl-4-nitro-5-iso-oxazolone and ethyl iodide[37].

Only a few examples of *C*-alkylation of mononitro-compounds with alkyl halides are known. Thus α-methyl-α--nitromalonic ester is formed in the reaction between methyl iodide and ammonium nitromalonate[38]:

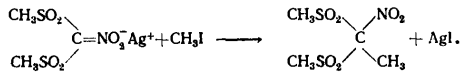


However, when ethyl iodide is used, let alone other alkyl halides, the reaction proceeds with considerable difficulty[39]. The reaction of the sodium salt of 2-chloro-2-nitroethanol with methyl iodide also yields a *C*-alkylation product[40] — 2-chloro-2-nitro-1-propanol (yield not stated)[40]. The silver salt of nitroacetic ester reacts with alkyl iodides with formation of both *O*- and *C*-alkylation products (the yield of the latter is 20–25%)[41]:



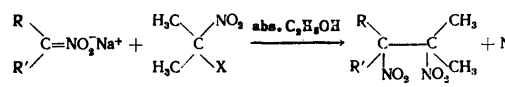
where R = CH_3 and C_2H_5. Alkyl bromides do not enter into this reaction[41].

There exist also patent data on the preparation of *C*-derivatives by the alkylation of nitromalonic ester with alkyl halides and also other alkylating agents (sulphites, sulphonates, and others), but the details of the experimental procedure are not indicated[42]. Backer[43] mentions the *C*-alkylation of the silver salt of bis(methylsulphonyl)nitromethane with methyl iodide but the yield of the product was very low:



It is also interesting that the reaction of 1-(*p*-nitrophenyl)--2-bromoethane with the sodium salt of 2-nitropropane results in alkylation at the carbon atom with formation of 3-methyl-3-nitro-1-(*p*-nitrophenyl)butane (yield 54%)[11].

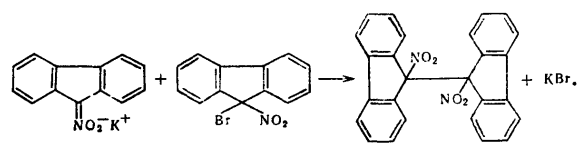
Seigle and Hass[44,45] showed that the reaction of alkali metal salts of secondary nitroalkanes with halogenonitro--compounds in which the halogen and the nitro-group are attached to the same carbon atom yields vicinal dinitroalkanes:



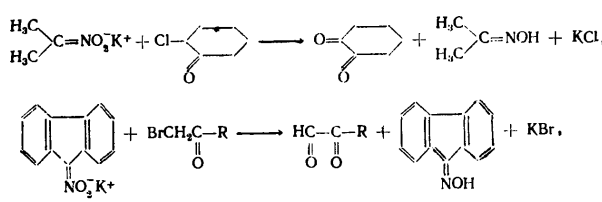
where R and R′ = CH_3, C_2H_5, and $-(CH_2)_5-$, and X = Cl, Br, and I. The yields of the *C*-alkylation products are 10% for the chloride, 20–30% for the bromide, and 43% for the iodide§.

Primary nitro-compounds do not enter into this reaction as a rule[44]; however, Nenitzescu and Isacescu[26] succeeded in obtaining 1,2-diphenyl-1,2-dinitroethane by allowing the sodium salt of phenylnitromethane to react with phenyliodonitromethane. The salts of *p*-bromo- and *p*-methyl--phenylnitromethanes do not react with this iodide[26].

The potassium salt of 9-nitrofluorene reacts with 9-bromo-9-nitrofluorene to give 1,2-di(biphenylene)-1,2--dinitroethane[26]:



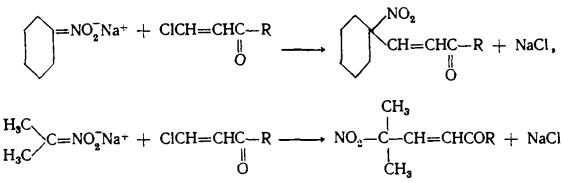
Of the other halogeno-derivatives which react with mononitro-compounds, halogeno-ketones should be mentioned. Thus the reaction of the potassium salt of 2-nitropropane with 2-chlorocyclohexanone[3] gave 1,2-cyclohexadione, while the reaction of the potassium salt of 9-nitrofluorene with bromoacetone and ω-bromoacetophenone resulted in the formation of methyl- and phenyl-glyoxal respectively (in yields of 85–95%) and fluorenone oxime[47]:



where R = CH_3 and C_6H_5.

§ Later it was shown that the yield of nitroalkanes depends significantly on the purity of the initial nitro-compounds: thus when pure 2-nitropropane is used, it is possible to increase the yield of 2,3-dimethyl-2,3-dinitrobutane to 50% for the chloride and to 80% for the bromide[46].

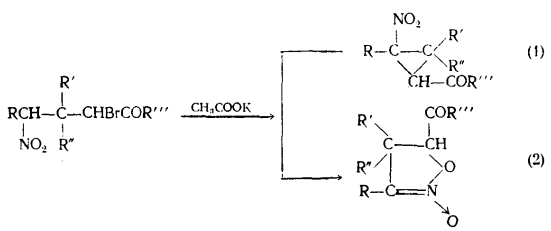
Only rather unusual halogeno-ketones, such as β-chlorovinyl ketones, alkylate nitro-compounds at the carbon atom, and even then as a rule with low yields[48-50]:



where R = CH_3, C_2H_5, n-C_3H_7, C_6H_5, p-$CH_3C_6H_4$, p-ClC_6H_4, and p-BrC_6H_4.

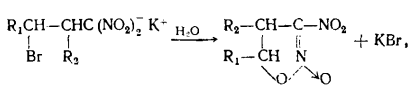
An attempt to condense the potassium salt of nitroethane with iodoacetic ester was unsuccessful[51]. Chloroacetic ester reacted with the potassium salt of 9-nitrofluorene to give fluorenone oxime and ethyl glyoxylate[26].

An unusual type of alkylation of nitro-compounds has been described in a number of papers of Kohler, Smith, and others. They showed that, when compounds of the type RCH(NO_2)CR'R"CHBrCOR'", containing a halogen in the γ-position with respect to the nitro-group and in the α-position with respect to the carbonyl, are heated with potassium acetate, intramolecular alkylation takes place with formation of either cyclopropane derivatives (*C*-alkylation)[52-58] or isoxazoline oxides (*O*-alkylation)[59-64]:



The formation of nitrocyclopropanes [reaction (1)] occurs only when primary nitro-compounds are used (R = H); secondary nitro-compounds give only the *O*-alkylation products [reaction (2)].[62]

Tartakovskii et al. showed recently[65] that, when two nitro-groups are present in the γ-position with respect to halogen, only *O*-alkylation takes place, *N*-oxides of nitroisoxazolines being formed¶:



where R_1 = H and CH_3OCO, R_2 = H, CH_3, and C_6H_5, and R_1-R_2 = -$(CH_2)_3$- and -$(CH_2)_4$-.

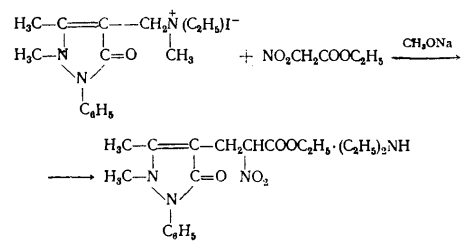
2. Alkylation with Mannich Bases and Quaternary Ammonium Bases

Alkylation with Mannich bases is known to take place according to one of two mechanisms (see, for example, Hellman and Opitz[67]): the so-called "elimination-addition" mechanism or the nucleophilic substitution mechanism.

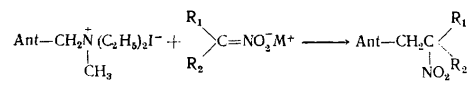
All tertiary Mannich bases with even only one labile hydrogen atom in the β-position with respect to the nitrogen (or the vinylogues of such bases) alkylate according to the first of the above mechanisms, which comprises two stages: (a) elimination of the amine from the Mannich base with formation of an unsaturated compound and (b) the Michael addition of the component to be alkylated to the unsaturated compound.

In the present review we shall consider the alkylation of mononitro-compounds only by Mannich bases which are incapable of alkylation by the above mechanism, i.e. those that react according to the nucleophilic substitution mechanism. This reaction is successful only in those cases where quaternary ammonium salts of Mannich bases incapable of undergoing deamination are used, since after removal of the tertiary amine, the bases form a carbonium ion stabilised by electron delocalisation and capable of reacting with the anion of the nitro-compound to be alkylated[67].

For example, 2-nitropropane is not alkylated by dimethyl-(β-nitroisobutyl)amine[68]. Also there is no alkylation when nitroacetic ester reacts with the tertiary Mannich base derived from antipyrine[69]†. On the other hand, when a quaternary salt, the methiodide of diethylaminomethylantipyrine, is used, nitroacetic ester can be alkylated with a 48% yield[71]:

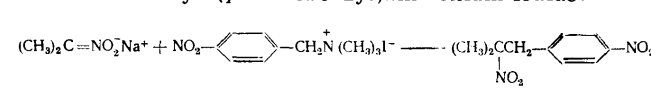


The alkylation of the potassium salt of the anilide of nitroacetic ester[71] and the sodium salt of nitromalonic ester takes place similarly[69]:



where R_1 = H and R_2 = $CONHC_6H_5$ or R_1 = R_2 = $COOC_2H_5$; M = Na and K, and Ant = antipyrine residue. The methiodide of 1-dimethylamino-2-methyl-2-nitropropane (Mannich base derived from nitropropane) proved to be unsuitable for *C*-alkylation of nitro-compounds[68].

Several examples of related reactions, the alkylation of the salts of mononitro-compounds with quaternary ammonium bases, have been described. Thus Schechter and Kaplan[72] obtained a 63% yield of the corresponding *C*-alkylation products by allowing the sodium salt of 2-nitropropane to react with trimethyl-(p-nitrobenzyl)ammonium iodide:

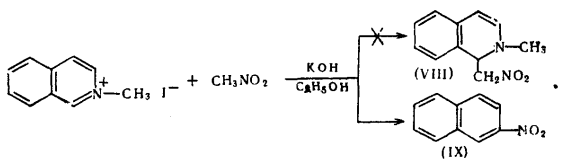


In the absence of the p-nitro-group in the phenyl ring, only benzaldehyde is formed[72], i.e. only *O*-alkylation takes place.

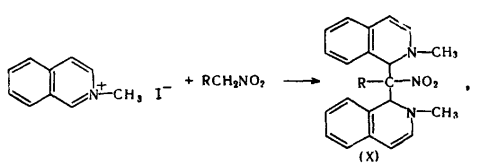
¶ A recent communication[66] described the conversion of the potassium salt of β-bromoethyl dinitroacetate, on boiling in acetone, into αα-dinitro-γ-butyrolacetone, i.e. intramolecular *C*-alkylation with formation of a five-membered ring takes place.

† The assertion by Dornow and Thies[70] that alkylation does occur in this case proved to be incorrect; in fact only the salt of one of the initial reaction components is formed[69].

The reaction of nitroalkanes with quaternary quinolinium and isoquinolinium salts is unusual. When nitromethane reacts with the methiodide of isoquinoline, 2-nitronaphthalene (IX) is obtained instead of the expected product (VIII):[73]

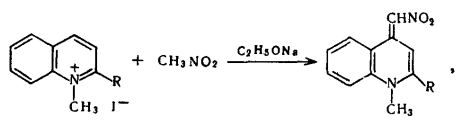


Under similar conditions nitroethane and 1-nitropropane give only bis-[1-(2'-methyl-1',2'-dihydroisoquinolyl)]-nitroalkanes (X):[73]



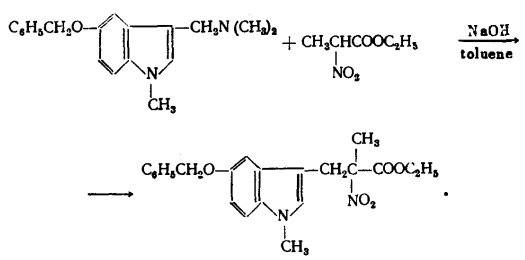
where R = CH_3 and C_2H_5. In addition to compound (IX), nitromethane also gives a small compound of compound (X) (R = H).[73]

The reaction of nitromethane with quinolinium or 2-methylquinolinium methiodide takes place in a different manner — with formation of 1-methyl-4-nitromethylenequinolanes:

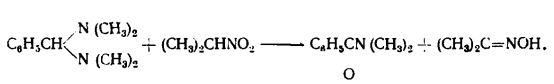


where R = H and CH_3. The reaction does not occur when a substituent is present in position 4 of the quinoline ring[74].

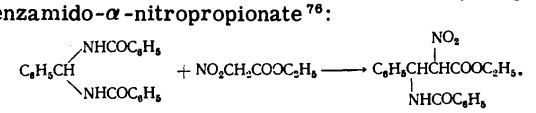
Only one example of the alkylation of nitro-compounds with a tertiary Mannich base (incapable of being deaminated), of the *N*-methylgramine series, is known. When 5-benzyloxy-1-methylgramine reacts with nitropropionic ester in the presence of sodium hydroxide, the desired alkylation product is formed in 14% yield[75]:



In this section it is also appropriate to mention the alkylation of mononitro-compounds with *N*-substituted benzylidenebisamines. Thus *NN'*-benzylidenebisdimethylamine reacts with 2-nitropropane to give a mixture of benzoic acid dimethylamide and acetone oxime[3]:

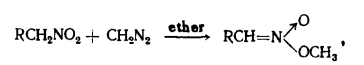


The author explains this reaction by the decomposition of the nitronic ester formed as an intermediate as a result of *O*-alkylation. Similar results were also obtained with benzylidenebispiperidine[3]. On the other hand, the reaction of nitroacetic ester with *NN'*-benzylidenebisbenzamide results only in *C*-alkylation with formation of ethyl β-phenyl-β-benzamido-α-nitropropionate[76]:



3. Alkylation with Other Alkylating Agents

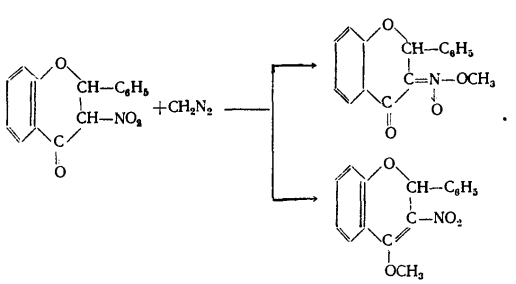
Apart from the alkylating agents enumerated above, a number of others are used in reactions with mononitro-compounds (diazomethane, dimethyl sulphate, olefin oxides, and others). With a few exceptions, the alkylation always involves the formation of nitronic esters or products of their further reaction. Thus a number of workers have shown[77,78,80,81] that diazomethane can be successfully used for the *O*-alkylation of nitro-compounds. Arndt and Rose[77], who studied the behaviour of nitro-compounds of different types in the reaction with diazomethane, concluded that the more acidic is the nitro-compound the more readily it is alkylated by diazomethane:



where R = C_6H_5, *p*-BrC_6H_4, C_6H_5CO, C_2H_5OCO, *p*-$CH_3C_6H_4SO_2$, etc.

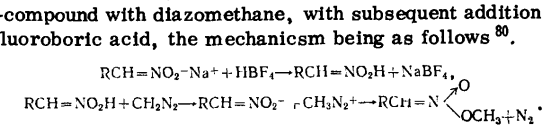
While phenylnitromethane reacts with diazomethane over a period of three days, the reaction with nitroacetic ester is completed in 2 h and that with nitromalonic ester is practically instantaneous. The reaction of diazomethane with *aci*-nitro-compounds is even faster than with true nitro-compounds[77].

It has recently been shown that the cyclic α-nitro-ketone 3-nitroflavanone is readily alkylated by diazomethane[78], yielding a mixture of two products — a nitronic ester and the ester of the enol form of the initial ketone:

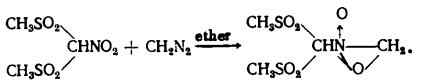


It is noteworthy that the nitro-compounds which are relatively weak acids (for example, nitromethane[79] and 1-phenyl-3-nitropropane[80]) do not enter into this reaction‡.

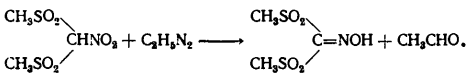
‡ The difficulty of alkylating compounds of this kind, which is probably due to the low rate of proton transfer from the nitro-compound to diazomethane, can be overcome by treating a salt of the nitro-compound with diazomethane, with subsequent addition of tetrafluoroboric acid, the mechanicsm being as follows[80].



The reaction of diazomethane with bis(methylsulphonyl)-nitromethane also results in *O*-alkylation with formation (in quantitative yield) of a nitronic ester which, according to the author, is the *N*-oxide of *N*-[bis(methylsulphonyl)-methyl]epoxymethyleneimine [81]:

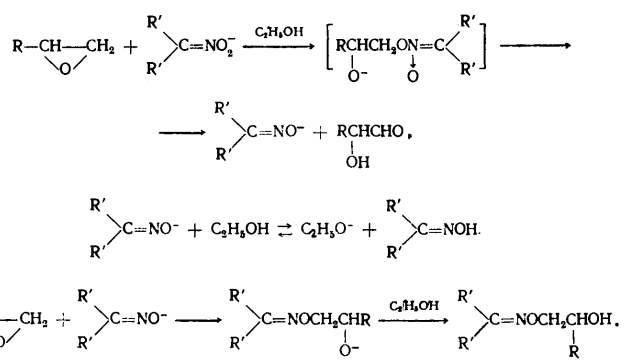


After the reaction of bis(methylsulphonyl)nitromethane with diazoethane, the same investigator [81] was able to isolate only the decomposition products of the *O*-nitronic ester — bis(methylsulphonyl)isonitrosomethane and acetaldehyde:



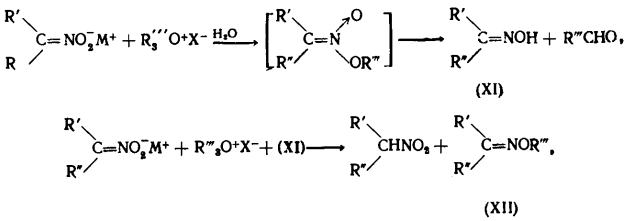
A nitronic ester is also formed when phenylnitromethane (in the form of the sodium salt) is alkylated with dimethyl sulphate [77,82]. The reaction of dimethyl sulphate with the potassium salt of 9-nitrofluorene is similar [83]: it yields a nitronic ester which decomposes to fluorenone oxime and formaldehyde on raising the temperature.

Bachman and Hokama [84] introduced into the reaction with nitroalkanes various olefin oxides (ethylene, propene, and styrene oxides) in an alkaline medium (in the presence of lithium alkoxide) and obtained only the oximes and the oxime ethers whose formation they regard as due to *O*-alkylation followed by decomposition of the reaction products into the carbonyl compounds and the oxime:



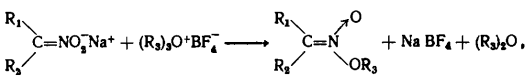
In another study on the alkylation of nitro-compounds by olefin oxides [85] the latter were introduced into the reaction with various mononitroalkanes in pyridine solution. The reactions are very complex, the corresponding γ-nitro--alcohols (*C*-alkylation products) either not forming at all or their yield not exceeding several per cent. The main products are 1-(2′-hydroxyalkyl)pyridinium nitrites and 3,4,5-trimethoxyisoxazole from primary nitroalkanes, while secondary nitroalkanes give in addition vicinal dinitroalkanes, ketones, and ketone oximes.

The reaction of the salts of mononitro-compounds with rather unusual alkylating agents such as trialkyloxonium salts has been investigated in fair detail. Thus Donaruma [86] allowed salts of nitrocyclohexane, nitrocyclopentane, and 2-nitropropane to react with trialkyloxonium fluoroborates, chloroferrates, and chloroaluminates, and in all cases observed the formation of *O*-alkylation products — oximes (XI) and the *O*-alkylated oximes (XII) (ethers):



where R′ and R″ = $-(CH_2)_4-$, $-(CH_2)_5-$, and CH_3, R‴ = = CH_3 and C_2H_5, X = BF_4, $FeCl_4$, and $AlCl_4$, and M = Na and K. The best yields of oximes (50–80%) and their ethers (20–35%) are obtained when trialkyloxonium fluoroborates are used, particularly when R‴ = C_2H_5; triethyloxonium chloroferrate and chloroaluminate react to a much smaller extent, due to side-processes (in particular due to the formation of sparingly soluble iron and aluminium salts of the nitroalkanes by double decomposition with ferric chloride and aluminium chloride, the salts being precipitated during the alkylation).

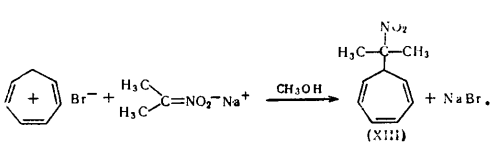
Quite recently Kornblum and Brown [80,87] used the reaction with trimethyl- and triethyl-oxonium fluoroborates to prepare nitronic esters from many aliphatic and aliphatic–aromatic mononitro-compounds:



where R_1 = CH_3, n-C_3H_7, *p*-BrC_6H_4, and *p*-$NO_2C_6H_4$, R_2 = = H and CH_3, and R_3 = CH_3 and C_2H_5. The reaction was carried out in methylene chloride at 0°, the yield of the esters being very high (80–95%). It is noteworthy that the nitronic esters from purely aliphatic nitro-compounds had not been isolated before this study.

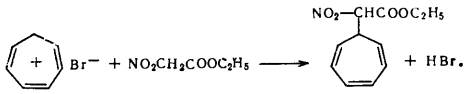
There are patent data on the alkylation of salts of primary or secondary aliphatic and alicyclic nitro-compounds with alcohols and phenols in neutral or acid media [88], the reaction resulting in *O*-alkylation with formation of oximes. The reaction can also be carried out in the presence of ammonia, amines, or ammonium salts.

Interesting results were obtained in the alkylation of nitro-compounds with tropylium bromide. Thus by allowing tropylium bromide to react with the sodium salt of 2-nitropropane, Bersohn [23] obtained a high yield (68%) of the *C*-alkylation product — 1-(dimethylnitromethyl)cyclohepta--2,4,6-triene (XIII):

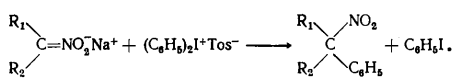


He believes [23] that initially the *O*-alkylation product forms and then readily dissociates into the initial ions with subsequent formation of the thermodynamically stable *C*-alkylation product. This process is much faster than the usual breakdown of nitronic esters into the oxime and the carbonyl compound and therefore the *C*-alkylation derivative gradually accumulates: *O*-alkylation products were not detected in this reaction.

The alkylation of nitroacetic ester with tropylium bromide takes place in exactly the same way, the only product being ethyl cycloheptatrienylnitroacetate[89]:

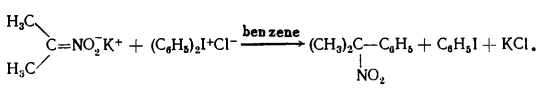


Yet another case of *C*-alkylation (more precisely arylation) of nitro-compounds was described recently by Kornblum and Taylor[90]: by allowing salts of primary and secondary nitroalkanes to react with diphenyliodonium toluenesulphonate in dimethylformamide, they obtained a good yield (55–70%) of the corresponding phenylnitroalkanes:



where $R_1 = CH_3$, $n\text{-}C_3H_7$, and $n\text{-}C_7H_{15}$, $R_2 = H$ and CH_3, and $R_1\text{–}R_2 = -(CH_2)_5-$.

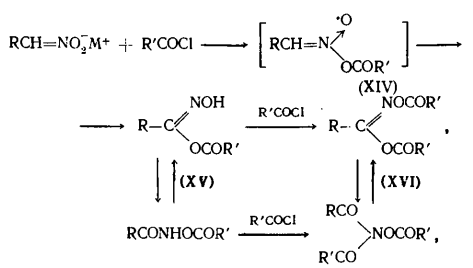
It proved impossible to make the potassium salt of phenylnitromethane undergo a similar reaction[91]. Diphenyliodonium chloride can be used successfully instead of the toluenesulphonate; the potassium salt of 2-nitropropane is then converted into 2-phenyl-2-nitropropane in 63% yield[92]:



4. Acylation of Mononitro-Compounds

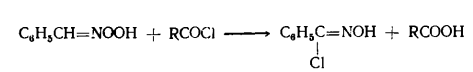
Much less attention has been given in the literature to the acylation of mononitro-compounds than to their alkylation. However, here too various acylating agents have been investigated — acyl halides, acid anhydrides, ketene, acyl cyanides, and others. In almost all cases *O*-acylation takes place exclusively with formation of nitronic acid anhydrides which then as a rule undergo further reactions.

The acylation of mononitro-compounds by acyl halides has been studied in greatest detail. Thus the reactions of salts of primary nitroalkanes with acetyl chloride and benzoyl chloride yield various acylhydroxamic acids, (XV) and (XVI), the products of the rearrangement of the anhydrides (XIV) and subsequent repeated acylation[93–95]:



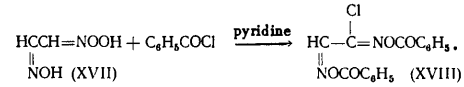
where R = H and CH_3 and R′ = CH_3 and C_6H_5.

Similar results were obtained in the acylation of the sodium salts of arylnitromethanes[83,96,97]. The acylation of *aci*-phenylnitromethane yields the chloride of benzohydroxamic acid[83]:

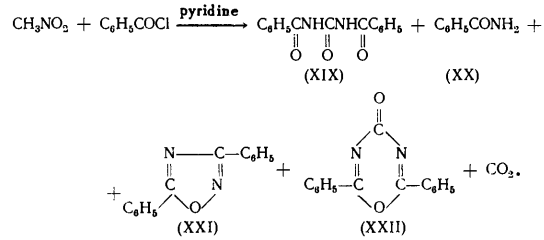


where R = CH_3 and C_6H_5. In many cases no products could be identified after the reaction of primary nitroalkanes with acyl halides[98–100].

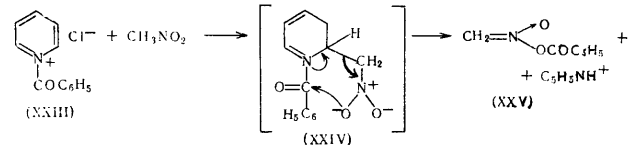
The acylation of primary mononitro-compounds by acid chlorides in pyridine solution is unusual. Thus in the reaction of phenylnitromethane and ω-nitroacetophenone with benzoyl chloride in pyridine the main product is in both cases dibenzohydroxamic acid ($C_6H_5CONHOCOC_6H_5$).[101] On the other hand, when *aci*-phenylnitromethane is used in a similar reaction, the product is the chloride of benzoylbenzohydroxamic acid ($C_6H_5CCl{=}NOCOC_6H_5$).[102] Under the same conditions methazonic acid (XVII) gives dibenzoylchloroglyoxime (XVIII):[102]



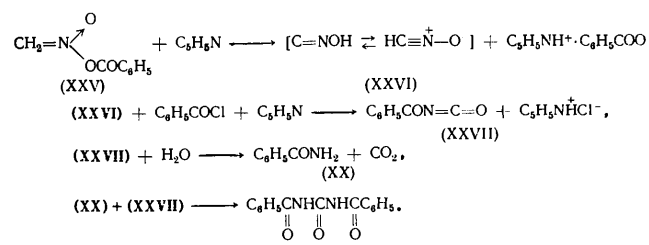
The reaction of benzoyl chloride with nitromethane in pyridine solution is much more complex[101]. It proceeds with evolution of carbon dioxide and the formation of *NN′*-dibenzoylurea (XIX) as the main product; in addition benzamide (XX), benzonitrile, 3,5-diphenyl-1,2,4-oxadiazole (XXI), and a substance with the empirical formula $C_{15}H_{10}N_2O_2$, possibly 2,6-diphenyl-4-oxo-1,3,5-oxadiazine (XXII), were isolated from the reaction mixture:



The authors of this investigation believe that in this case the acylating agent is benzoylpyridinium chloride (XXIII) which initially combines with nitromethane to give an intermediate (XXIV), and the latter then decomposes into the mixed anhydride (XXV):



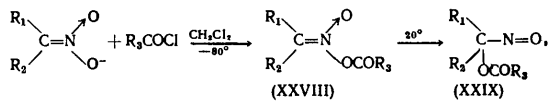
To account for the formation of *NN′*-dibenzoylurea (XIX), the authors proposed further the following mechanism:



The reasons for the formation of the other products are obscure. It is interesting that, on replacing pyridine by quinoline or dimethylaniline, not even traces of compound (XIX) are formed[101].

The acylation of secondary mononitro-compounds by acyl halides has been investigated in greatest detail by White and

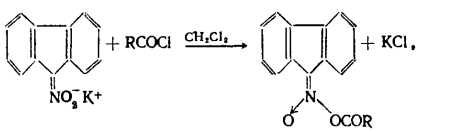
Considine [103,104]. They found that the initial products of the reactions of salts of secondary nitroalkanes with acid chlorides are the anhydrides (XXVIII), as in the case of other mononitro-compounds. On raising the temperature of the reaction mixture, a pale blue colour gradually appears, due to the extremely ready isomerisation of the nitronic anhydrides to nitrosoacyloxy-compounds (XXIX) [104] §:



(XXVIII) (XXIX)

where R_1 and R_2 = CH_3, C_6H_5, and $-(CH_2)_5-$ and R_3 = CH_3, C_6H_5, and p-$NO_2C_6H_4$. The authors were unable to obtain C-acylation products; judging from the infrared spectra, the latter are formed in amounts smaller than 1%.

In some cases on acylating secondary nitro-compounds with acyl halides it proved possible to isolate stable nitronic esters. Thus Nenitzescu and Isacescu [83] obtained O-acetyl and O-benzoyl-9-*aci*-nitrofluorenes (XXX) by allowing the potassium salt of 9-nitrofluorene to react with acetyl and benzoyl chlorides respectively:



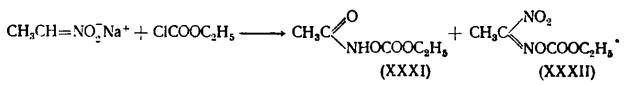
(XXX)

where R = CH_3 and C_6H_5. Subsequently White and Considine [103] confirmed the structure of compound (XXX) (R = = C_6H_5).

Another interesting case of the formation of a stable nitronic anhydride has been described by Thurston and Shriner [6]: when the sodium or silver salt of phenylnitroacetonitrile was treated with benzoyl chloride, O-benzoyl-*aci*-nitrophenylacetonitrile was obtained:

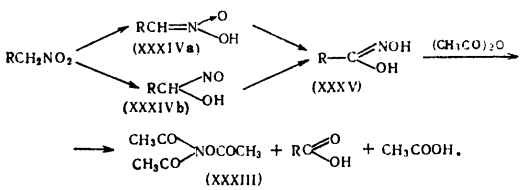
where M = Na and Ag. The authors demonstrated the structure of the product and thereby disproved the assertion of Wieland and Höchtlen [17] that they isolated the C-benzoyl derivative in a similar reaction with benzoyl bromide¶. According to Foster's data [107], the reaction of 1-nitrobornane with benzoyl chloride also yields a stable nitronic anhydride, but the product was not characterised.

The use of the ethyl ester chlorocarbonic acid as the acylating agent has been as a rule unsuccessful — no products have been identified [98,100]. In only one case, in the acylation of the sodium salt of nitroethane, Nef [94] and then Jones [95] succeeded in isolating ethoxycarbonylacetohydroxamic (XXXI) and ethoxycarbonylethylnitrolic (XXXII) acids:



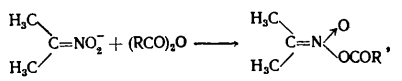
(XXXI) (XXXII)

Several papers describe the acylation of mononitro-compounds by acid anhydrides. On heating mononitroalkanes (nitromethane, nitroethane, 1-nitropropane, and phenylnitromethane) with acetic anhydride in the presence of sodium acetate or pyridine, Urbański [108] obtained in all cases only triacetylhydroxylamine (XXXIII). He believes that initially the nitro-compounds isomerise to the *aci*-form (XXXIVa) or nitrosohydroxy-compounds (XXXIVb) and then to hydroxamic acids (XXXV); the latter then undergo cleavage and acetolysis with formation of compound (XXXIII) and carboxylic acids:



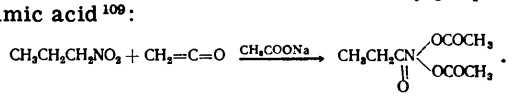
(XXXIVa) (XXXIVb) (XXXV) (XXXIII)

Quite different results were obtained in the reaction of acid anhydrides with secondary nitroalkanes. Thus acetic and propionic anhydrides react with 2-nitropropane (in toluene in the presence of potassium acetate) or its sodium salt (in ethereal suspension) to give relatively stable nitronic anhydrides [105] †:

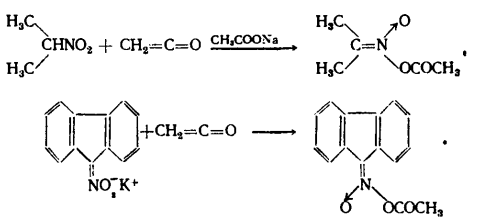


where R = CH_3 and C_2H_5. Unlike acetic or propionic anhydride, benzoic anhydride is completely inert under analogous conditions [105].

When keten is used as the acylating agent, the nature of the reaction products also depends on whether the initial nitro-compound is primary or secondary. Thus 1-nitropropane reacts with keten to form *NN*-diacetylpropiohydroxamic acid [109]:



Phenylnitromethane behaves similarly, its sole reaction product being acetylbenzohydroxamic acid [83]. In contrast to the primary nitro-compounds, the secondary compounds yield nitronic anhydrides on reacting with keten [83,109]:



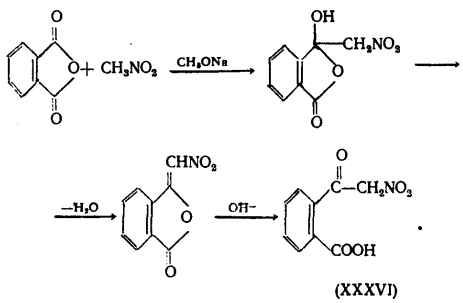
Thus in all the cases enumerated above O-acylation occurred. Only a few examples of acylation at the carbon atom with formation of α-nitroketones are described in the literature. In the study of the reaction of nitromethane with phthalic anhydride in the presence of sodium methoxide, Gabriel [110] obtained a very low yield of 2-nitroacetylbenzoic acid (XXXVI). He believes that the first stage of the process involves the addition of nitromethane

§ In another study it was shown that, in the reaction between the sodium salt of 2-nitropropane and benzoyl chloride in ether (in the form of suspension), only benzoic acid is formed even under anhydrous conditions [105].

¶ White and Considine [104] showed that, contrary to the data of Wislicenus and Pfeilsticker [106], the formation of the C-acylation product, 1-benzoyl-3-nitroindene, in the reaction of the potassium salt of 3-nitroindene with benzoyl chloride is also unlikely.

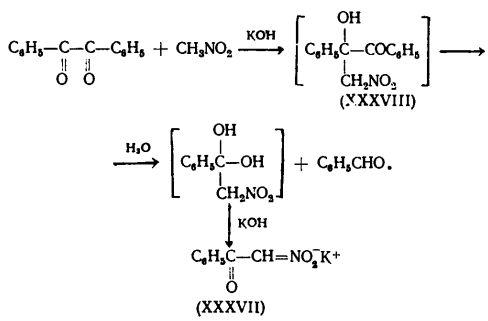
† This was subsequently confirmed by Urbański and Gurzyńska [109].

to the carbonyl double bond of the anhydride with subsequent elimination of a water molecule and hydrolysis:



(XXXVI)

In another study Yakubovich [111] treated nitromethane with benzil in the presence of twice the required amount of potassium hydroxide and obtained the potassium salt of ω-nitroacetophenone (XXXVII) and a whole series of other products. In his view, initially nitromethane adds to one of the carbonyls and then the addition product (XXXVIII) is cleaved to (XXXVII):



(XXXVII)

Nevertheless, it proved impossible to isolate compound (XXXVIII) as an intermediate; on the other hand, in the reaction between nitromethane and diacetyl an addition product of this type is formed smoothly.

In 1959 Bachman and Hokama [112,113] developed a general method for the synthesis of α-nitroketones by the *C*-acylation of primary nitroalkanes. They showed that *C*-acylation products will form only when rather unusual acylating agents, such as acyl cyanides, are employed:

$$RCH{=}NO_2^-M^+ + R'COCN \longrightarrow \underset{\displaystyle NO_2}{\overset{\displaystyle |}{R'COCHR}} + MCN,$$

where R = H, CH_3, and n-C_3H_7, R′ = CH_3 and C_6H_5, and M = Na and Li. The yields are 30–70%. When secondary nitroalkanes and used, α-nitroketones do not form. The lithium salts of nitroalkanes give better results than the sodium salts. t-Butyl alcohol, pyridine, and tetrahydrofuran are used as solvents. *O*-acylation products were never observed.

The authors offer the following explanation for this sharp difference in the behaviour (with respect to the salts of nitro-compounds) of acyl halides and acid anhydrides, on the one hand, and acyl cyanides, on the other. In the first case the reactions are so fast that thermodynamic equilibrium is not attained and *O*-acylation takes place, since the transition state then has a lower energy of formation than in *C*-acylation (by virtue of the higher electronegativity of oxygen compared with carbon). The reaction with acyl cyanides is much slower, equilibrium is attained, and the thermodynamic stability of the final products begins to play a decisive role; the latter is known to be always higher in the case of *C*-acyl derivatives [114].

III. ALKYLATION AND ACYLATION OF POLYNITRO--COMPOUNDS

In contrast to mononitro-compounds, whose alkylation has been the subject of a fairly large number of studies, the number of known examples of the alkylation of polynitro--compounds is much smaller. Thus in 1899 Hantzsch and Rinckenberger [115] obtained 1,1,1-trinitroethane by allowing the silver salt of nitroform to react with methyl iodide in ether:

$$C(NO_2)_3^-Ag^+ + CH_3I \longrightarrow CH_3C(NO_2)_3 + AgI.$$

The authors note that the potassium salt of nitroform does not enter into a similar reaction‡. They also state [115] that the reaction of the silver salt of nitroform with iodine cyanide gives trinitroacetonitrile:

$$C(NO_2)_3^-Ag^+ + ICN \longrightarrow (NO_2)_3C{-}CN + AgI.$$

Somewhat later Hantzsch and Caldwell [117] established that, when the silver salt of nitroform is allowed to react with methyl iodide at -75°, the initial step is the formation of the addition product $C(NO_2)_3Ag.2CH_3I$, which on raising the temperature is converted into trinitroethane in non--polar solvents. In the presence of hydroxyl-containing solvents (for example alcohols) this complex yields only the free nitroform. On the other hand, the reaction of the silver salt of nitroform with methyl iodide in aqueous, alcoholic, or ethereal solution gives only trinitroethane and traces of nitroform. The authors explain these results by postulating that in solution the silver salt reacts in the ionic form yielding the more stable *C*-alkylation product (trinitroethane); on the other hand, its addition product with methyl iodide reacts intramolecularly, forming the methyl ester $(NO_2)_2C{=}NO{-}OCH_3$. The latter, being unstable in a non-polar medium, isomerises to trinitroethane and in the presence of water hydrolyses to nitroform [117,118].

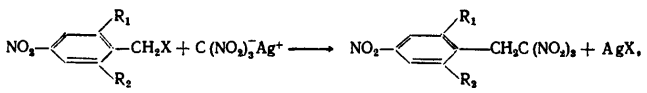
The same workers showed that the silver salt of nitroform reacts with ethyl iodide [117], benzyl iodide [115,117], allyl iodide [117], and bromoacetic ester [115], but no products were identified§. An attempt to make monochloromethyl ether [120] and triphenylchloromethane [17,120] react with the silver salt of nitroform was also unsuccessful, the reason being (according to the authors) that the water of crystallisation, which is always present in the molecule of the silver salt, hydrolyses the above halogeno-derivatives faster than they can react.

Meisenheimer and Schwarz [120] and Hantzsch [121] showed that bromonitroform and iodonitroform do not react with the silver salt of nitroform. In 1947 a paper was published, describing the alkylation of the silver salt of nitroform with various substituted benzyl halides [122] [*p*-nitrobenzyl bromide, 2,4,6-trinitrobenzyl iodide, *p*-di(iodomethyl)benzene, 1,3-di(iodomethyl)-5-nitrobenzene, and

‡ According to a recent communication [116], on carrying out the reaction in acetone, it proved possible to obtain 1,1,1-trinitroethane from the potassium salt of nitroform and methyl iodide (yield not indicated).

§ According to patent data [119], 4,4,4-trinitrobut-1-ene forms on reaction between the silver salt of nitroform and allyl bromide (in ether).

1,3,5-tri(iodomethyl)benzene], the products being the corresponding trinitroethyl derivatives of benzene, for example



where R_1 and R_2 = H and NO_2 and X = Br and I. The reactions were carried out in ether. The authors noted that in all cases they also observed the formation of unstable coloured oils (probably *O*-alkylation products), which decomposed with evolution of nitrogen oxides.

In 1952 an American patent [123] described the preparation of 1,1,1,2- and 1,1,1,3-tetranitropropane by the reaction of the silver salt of nitroform (in boiling ether) with the corresponding halogenonitro-compounds — 1-bromo-1-nitro- and 1-bromo-2-nitro-ethane. However, the patent gives no experimental details and the yields of the products are not stated.

In 1963 Hammond et al. [124] described the alkylation of the silver salt of nitroform with various halogeno-derivatives. The reaction in acetonitrile solution was studied in greatest detail. The authors showed that primary straight-chain alkyl iodides and also allyl bromide and iodide give the corresponding *C*-alkylation products in yields of 30–60%:

$$C(NO_2)_3^-Ag^+ + RX \xrightarrow{CH_3CN} RC(NO_2)_3 + AgX,$$

where R = n-alkyl and $CH_2{=}CHCH_2$ and X = I and Br. Secondary and cyclic alkyl halides and propargyl bromide, 1,3-di-iodopropane, and 1,4-dibromobutyne yield a complex mixture of products which could not be identified¶; allyl chloride, 1-bromo-2,4-dinitrobenzene, and 1-iodo-2-nitrobenzene do not react at all. When α-halogeno-acids are used, the corresponding nitrates are formed instead of the expected products, as a result of the substitution of the halogen by the nitrate group. The authors explain the failure of the above syntheses by the *O*-alkylation of the silver salt of nitroform under these conditions with formation of unstable nitronic esters:

The latter decompose with liberation of nitrate ions. The authors believe that another possible pathway involving the formation of nitrates, the gradual decomposition of the silver salt of nitroform to yield nitrate ions, is unlikely.

They also showed [124] that in the reaction of the silver salt of nitroform with chloromethyl ether and bromomethyl acetate the only product is trinitroethanol whose formation can be explained by the condensation of nitroform with formaldehyde, produced by the decomposition of the initial α-halogeno-ethers. The reaction of t-butyl bromide gave only *N*-t-butylacetamide — the product of the reaction of the halide with the solvent (acetonitrile). Hammond et al. [124] showed that the use of other solvents in the alkylation of the silver salt of nitroform (methyl and ethyl acetate, methyl and ethyl formate, acetone, ethanol, benzene) does not increase the yield compared with that obtained in acetonitrile, but the reactions are much faster. In contrast to the system in acetonitrile, in methyl acetate they were able to achieve the reaction of the silver salt with epi-iodohydrin and β-methylallyl bromide, the products, 4,4,4-trinitro-1,2-epoxybutane and 2-methyl-4,4,4-trinitrobut-1-ene, being obtained in yields of 19 and 27% respectively [124].

The study of the kinetics of the reaction of the silver salt of nitroform with methyl iodide in acetonitrile at 25.5° showed that the reaction is of third order overall, i.e. the silver cation participates as an electrophilic catalyst forming an ion pair in the transition state [124]:

$$C(NO_2)_3^- + R{-}I + Ag^+ \rightarrow (NO_2)_3C^-R^+IAg.$$

Thus the reaction is simultaneously of both S_N1- and S_N2-type.

Recently Tartakovskii et al. [126] showed that, when nitroform is treated with diazomethane, *O*-alkylation occurs with the formation of an unstable, very reactive nitronic ester.

Only a few papers have been published on the alkylation of salts of 1,1-dinitroalkanes (mainly silver salts). Duden [127] showed in 1893 that the silver salt of dinitromethane reacts with methyl iodide and ethyl iodide (in the absence of solvent) with the formation of the expected 1,1-dinitroalkanes:

$$HC(NO_2)_2^-Ag^+ + RI \rightarrow RCH(NO_2)_2 + AgI,$$

where R = CH_3 and C_2H_5. The author notes that the reactions are far from smooth, the products containing a considerable amount of unstable oils, which decompose even on slight heating.

In 1894 Nef [100] found that, when the silver salt of 1,1-dinitroethane reacts with methyl and ethyl iodide, the expected 2,2-dinitropropane formed only in the first case and even then in a low yield. The main products of the reaction were ethylnitrolic acid and the corresponding aldehyde (formaldehyde or acetaldehyde) and also free 1,1-dinitroethane. The author explains the formation of these products by the preferential *O*-alkylation of the silver salt of dinitroethane, resulting in the nitronic ester (XXXIX) which is unstable to heat and decomposes to ethylnitrolic acid (XL) and an aldehyde:

where R = H and CH_3.

A quite recent publication described the phenylation, at the carbon atom, of the potassium salts of 1,1-dinitroethane and 1,1-dinitropropane with diphenyliodonium toluenesulphonate [91]:

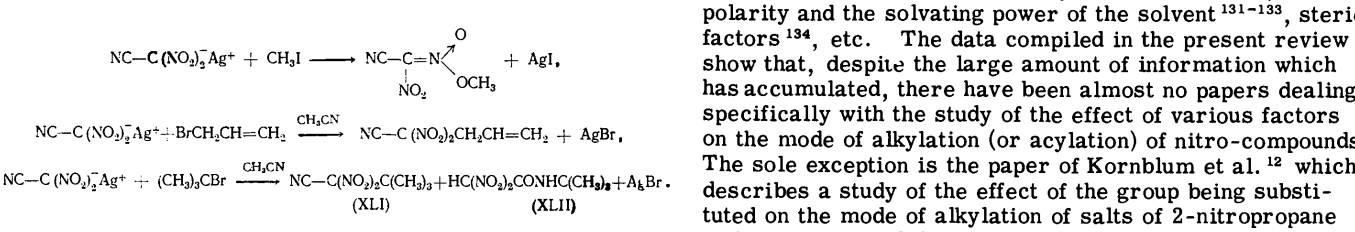
$$RCH_2C(NO_2)_2^-K^+ + (C_6H_5)_2I^+Tos^- \xrightarrow{t\text{-}C_4H_9OH} RCH_2C(NO_2)_2C_6H_5 + C_6H_5I + KTos,$$

where R = H and CH_3. The reaction is carried out in boiling t-butyl alcohol, the yields of 1-phenyl-1,1-dinitroalkanes being 67–68%. The authors note that, when dimethylformamide is used as the reaction medium, the desired products are formed in yields less than 5%, the principal product being nitrobenzene. The attempt to use the potassium salt of phenyldinitromethane in a similar reaction was unsuccessful.

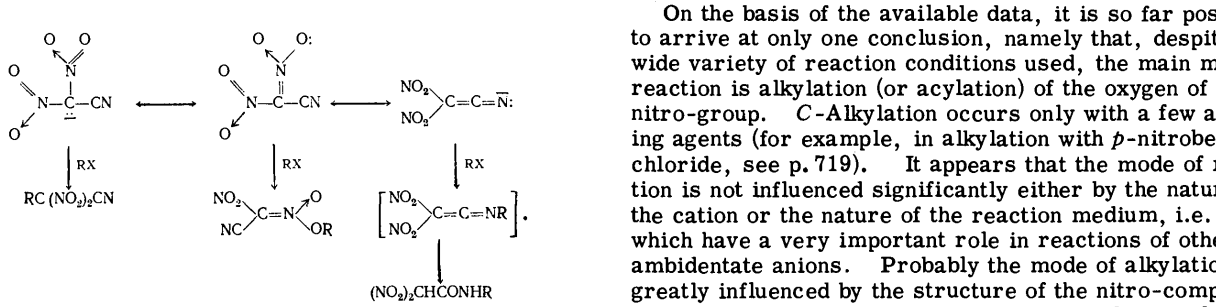
Unusual results were obtained in the alkylation of the silver salt of dinitroacetonitrile [124,128]. As a rule no identifiable products can be obtained in reactions of this kind. Only with methyl iodide, t-butyl bromide, and allyl bromide is the reaction relatively successful; with methyl iodide, only *O*-alkylation takes place (a stable methyl ether forms in 58% yield), the reaction with allyl bromide gives the *C*-alkylation product (yield 35%), while in the reaction

¶ According to patent data [125], 1,1,1,6,6,6-hexanitrohex-3-yne can be obtained by the reaction of the silver salt of nitroform with 1,4-dibromobut-2-yne in methyl acetate.

with t-butyl bromide a mixture of *C*- and *N*-alkylation products is formed [compounds (XLI) and (XLII) respectively, in yields of 17 and 18%]:



The authors' explanation of the results is that, being "polydentate" (i.e. having several reaction centres), the anion of dinitroacetonitrile can be alkylated in one of three ways, yielding *C*-, *O*-, or *N*-alkyl derivatives:



These results clearly contradict the generally accepted theory of Kornblum et al.[129] according to which the closer is the transition state in nucleophilic substitution reactions to a carbonium ion, the greater the probability of the formation of a bond with the most electronegative atom of the polydentate anion (in the anion of dinitroacetonitrile such atoms are the oxygen of the nitro-group and the nitrogen of the cyano-group). Allyl bromide and t-butyl bromide are known to form carbonium ions much more readily than methyl iodide (the fact that t-butyl bromide reacts with the silver salt of dinitroacetonitrile as a carbonium ion is demonstrated by the formation of the same products in the analogous reaction of t-butyl alcohol[128]). Nevertheless, *C*-alkylation takes place with allyl and t-butyl bromides. The authors explain this as follows: the transition state in these reactions, involving the participation of large planar ions, is sterically facilitated and therefore when two ions approach one another there is a greater probability of the formation of a bond with the geometric centre of the charge density of the dinitroacetonitrile anion (i.e. with the carbon atom) than with an individual electronegative atom (oxygen or nitrogen)[124,128].

There are no publications dealing with the acylation of polynitro-compounds, only isolated, negative data being available. Thus Hantzsch and Rinckenberger[115] noted that it is impossible to achieve the reaction of the silver salt of nitroform with chlorocarbonic ester. The use of acyl halides as acylating agents in reactions with the silver salt of nitroform (in acetonitrile) only results in the formation of the corresponding carboxylic acids[124].

---o0o---

The data presented in this review show that alkylation and acylation reactions are typical and perhaps the most distinctive examples of the dual reactivity of nitro-compounds. The mode of alkylation (or acylation) of ambidentate anions (i.e. anions with two reaction centres), to which the anions of nitro-compounds belong, is known to be influenced by a number of factors: the nature of the cation[129], the heterogeneity or homogeneity of the medium[130], the polarity and the solvating power of the solvent[131-133], steric factors[134], etc. The data compiled in the present review show that, despite the large amount of information which has accumulated, there have been almost no papers dealing specifically with the study of the effect of various factors on the mode of alkylation (or acylation) of nitro-compounds. The sole exception is the paper of Kornblum et al.[12] which describes a study of the effect of the group being substituted on the mode of alkylation of salts of 2-nitropropane with *p*-nitrobenzyl derivatives. For this reason, systematic studies in this field are necessary to elucidate the influence of the structure and reaction conditions on the mode of alkylation of nitro-compounds.

On the basis of the available data, it is so far possible to arrive at only one conclusion, namely that, despite the wide variety of reaction conditions used, the main mode of reaction is alkylation (or acylation) of the oxygen of the nitro-group. *C*-Alkylation occurs only with a few alkylating agents (for example, in alkylation with *p*-nitrobenzyl chloride, see p. 719). It appears that the mode of reaction is not influenced significantly either by the nature of the cation or the nature of the reaction medium, i.e. factors which have a very important role in reactions of other ambidentate anions. Probably the mode of alkylation is greatly influenced by the structure of the nitro-compound itself. Thus salts of phenylnitroacetonitrile are always acylated at the oxygen only, even with *p*-nitrobenzyl chloride[4], which as a rule alkylates mononitro-compounds at the carbon atom.

After the manuscript had been sent to the editors, a number of papers with a direct bearing on the present topic have been published and we decided it was necessary to consider them if only briefly.

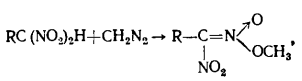
1. Mononitro-compounds. The work of Teuber and Glosauer[135], who succeeded in obtaining the corresponding *C*-alkylation products by treating the sodium salts of 2-nitropropane and nitrocyclohexane with *o*-nitrobenzyl chloride, is noteworthy. There has also been an interesting communication[136] according to which the reaction of triphenylchloromethane with the sodium salt of nitrocamphor gives a stable nitronic ester (in 44% yield) — an *O*-alkylation product. In another study[137] the intermediate stages of the reaction of triphenylchloromethane with the silver salt of phenylnitroacetonitrile were investigated (c.f. Ref. 19).

Polyanskaya et al.[138] state that in the reaction of nitroacetic ester with alkyl halides in the presence of amines (for example triethylamine), esters of α-nitroalkanecarboxylic acids are formed, i.e. alkylation at the carbon atom takes place. A few more examples of *C*-alkylation of 2-nitropropane (in the form of the sodium salt) with β-chlorovinyl ketones have been described by Belyaev and Shamanovskaya[139].

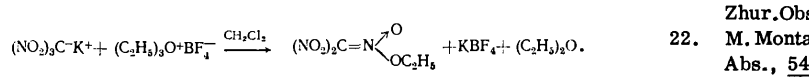
Two papers describe interesting cases of intramolecular *C*-alkylation of mononitro-compounds. Thus on treatment of 1-iodo-3-nitropropane with lithium amide in liquid ammonia, nitrocyclopropane forms in high yield (87%).[140] Etheredge[141] found that a bridge nitro-compound, 1-nitrobicyclo[3,2,1]octane, forms in 19% yield in the reaction of 2-(3-nitrocyclohexyl)ethyl toluenesulphonate with sodium hydride in dimethylformamide.

2. Polynitro-compounds. Here mention must be made in the first place of the work of Tartakovskii and

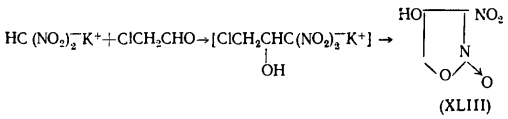
coworkers on the preparation of *O*-methyl derivatives of dinitromethane [142] and nitroform [143] (see also Ref. 126) by the action of diazomethane in benzene on dinitromethane and nitroform respectively:



where R = H and NO_2. The same workers obtained [143] the *O*-ethyl derivative of nitroform by alkylating the potassium salt of nitroform with triethyloxonium fluoroborate:



In another paper [144] they describe the synthesis of a cyclic nitronic ester (XLIII) by the intramolecular *O*-alkylation of the potassium salt of 1-chloro-3,3-dinitro-2-propanol — an intermediate in the reaction between the potassium salt of dinitromethane and chloroacetaldehyde:

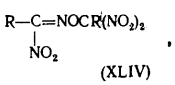


(XLIII)

Recently Ungnade and Kissinger [145] described two examples of *C*-alkylation (in yields of 80–90%) of salts of 2,2-dinitroethyl alkyl ethers with methyl iodide:

where R = CH_3 and $ClCH_2CH$.

Ustynyuk et al.[146] studied the action of various acylating agents (acid chlorides and anhydrides and acetyl nitrate) on salts of 1,1-dinitroethane and 1,1-dinitropropane and established that in all cases the reactions result in the formation of self-condensation products of the initial dinitroalkanes (XLIV) (in yields of 30–50%):



(XLIV)

where R = CH_3 and C_2H_5. The structure of compound (XLIV) was confirmed by spectroscopic methods [147].

I. INTRODUCTION

When arylphosphoranes of the type $(Ar)_3P=CR'R''$ are allowed to act upon carbonyl compounds in the well-known Wittig reaction[1-4], various olefins with double bonds in specified positions may be obtained. This reaction has found wide application in practical organic synthesis. However, it has important limitations. Aldehydes with strongly electron-donor substituents near the reaction centre do not enter into this reaction[5]; phosphoranes containing electron-acceptor groups, for example CN, $COOC_2H_5$, etc., do not as a rule react with ketones under the usual conditions[6,7]. Attempts have been made to overcome these difficulties, for example by heating the components for many hours at 100–170° in sealed tubes[8], by carrying out the reaction in high-boiling solvents, etc.[9,10] However, severe reaction conditions of this kind have an unfavourable effect on the yields of unsaturated compounds and in many cases are altogether inadmissible. It has recently been observed[11,12] that benzoic acid catalyses the reaction of ethoxycarbonylethylenetriphenylphosphorane with ketones, but the region of applicability of this catalytic effect has not yet been determined.

However, perhaps the most important disadvantage of the Wittig reaction consists in the difficulty of isolating in the majority of cases the unsaturated product. In this connection development and modification of the Wittig reaction is of considerable interest.

In 1958 Horner and coworkers[13-20] discovered the P(O)-activated olefin synthesis in which olefins and their derivatives with various functional groups are obtained by the reaction of aldehydes and ketones with organophosphorus compounds containing the $P(O)-CH_2$ group. Phosphonate salts, phosphonate esters, and phosphine oxides have been suggested as P(O)-activated reagents for olefin synthesis. The formation of unsaturated compounds by P(O)-activated synthesis can be represented by the reaction

$$R'-CO-R''+R_2P(O)-CH_2-R'''\rightarrow R'R''C=CHR'''+R_2P(O)OH.$$

The use of P(O)-activated reagents for olefin synthesis has a number of advantages over the Wittig reaction. Such reagents are more reactive with respect to carbonyl compounds, in particular ketones, since they are more nucleophilic than phosphoranes. In a special study Horner and coworkers[21] compared olefin synthesis using P(O)-activated reagents with olefin synthesis using phosphoranes in the Wittig reaction, and showed that, in the presence of the competing reactions of $(C_6H_5)_3P=CH-C_6H_5$ and $(C_6H_5)_2P(O)-CH_2-C_6H_5$ with carbonyl compounds in proportions of 1:1:1, the olefin $C_6H_5-CH=CRR'$ forms preferentially from benzyldiphenylphosphine oxide. The isolation of olefins in P(O)-activated synthesis is much simpler, since the unsaturated compounds produced can be readily separated from the highly water-soluble alkali metal salts of alkylphosphoric acids, while in the Wittig reactions special procedures must be used to separate the olefin from triphenylphosphine oxide. Finally, compared with the Wittig reagents (phosphoranes), the reagents for P(O)-activated olefin synthesis are more readily accessible, since they can be obtained relatively simply by the well-known reactions of Arbuzov, Michaelis–Becker, and others.

Like the Wittig reactions, P(O)-activated olefin synthesis makes it possible to increase the length of the carbon chain and introduce C=C bonds in specified positions. The yields of the unsaturated compounds are usually much higher than in the Wittig reaction.

The present article reviews the publications concerned with P(O)-activated olefin synthesis.

II. REAGENTS FOR P(O)-ACTIVATED OLEFIN SYNTHESIS

The methods for the preparation of organophosphorus compounds containing the $P(O)-CH_2$ group, which is essential for P(O)-activated olefin synthesis, have been thoroughly developed and the chemical properties of these compounds have been investigated fairly completely. There exist many reviews and monographs on this problem (see, for example, Refs. 22–33).

The reagents usually employed for P(O)-activated olefin synthesis are esters (most often ethyl) of phosphonic acids $(RO)_2P(O)-CH_2-R'$ (R' may be an aliphatic or an aromatic radical or any functional group) and esters of β-oxophosphonic acids $(RO)_2P(O)-CH_2-CO-R'$ (R' is an alkyl or aryl residue). In many cases alkyldiphenylphosphine oxides, and in particular benzyldiphenylphosphine oxide, proved to be satisfactory reagents for this synthesis[34]. Phosphonoacetic ester, first obtained by Arbuzov and Dunin[35] in 1914, is very often used in P(O)-activated olefin synthesis; the method of synthesis of this ester was improved in subsequent work[36-40]. To introduce two ethylene bonds, reagents for P(O)-activated diolefin synthesis, containing two P(O) groups, are used. The substances which have become important for these purposes are the tetraethyl esters of bisphosphonic acids, $(C_2H_5O)_2P(O)-(CH_2)_n-P(O)(OC_2H_5)_2$ (n = 1–8) and $(C_2H_5O)_2P(O)-CH_2-X-CH_2-P(O)(OC_2H_5)_2$ (X is one or several vinylene groups or benzene rings), and also the very readily available so-called "dioxide" $(C_6H_5)_2P(O)-CH_2-P(O)(C_6H_5)_2$.[41,42]

The most important method for synthesising phosphonic esters is the Arbuzov reaction[43-46], discovered in 1905, which is known as the "Arbuzov rearrangement":

$$(RO)_3P+R'—Hal \rightarrow (RO)_2P(O)—R'+R—Hal \quad (Hal=Cl, Br, I).$$

The possibilities of the Arbuzov reaction have been by no means exhausted. New papers continue to appear in which organophosphorus compounds suitable for P(O)-activated olefin synthesis are described[47,48]. It should be noted that the limitations which may arise when the Arbuzov reaction is applied to α-halogeno-carbonyl compounds in connection with the so-called Perkow reaction or rearrangement[49-59] (see Lichtentahler's review[60]) are unimportant in the preparation of valuable reagents for P(O)-activated olefin synthesis in which the methylene group is between the P(O) and carbonyl groups. In 1965 Arbuzov and coworkers[61] established that the reactions of diphenylphosphinous acid with chloroacetone yield mixtures containing predominantly β-oxophosphonic esters together with unsaturated phosphate esters. On the other hand with ω-bromoacetophenone, the Arbuzov reaction takes place almost exclusively with good yields of diphenylphenylacylphosphine oxide which is a valuable reagent for P(O)-activated olefin synthesis. According to the communication of Imaev and coworkers[62], dialkylphosphonoacetophenones having the general formula $(RO)_2P(O)-CH_2-CO-C_6H_5$ (R = CH_3 and $n-C_3H_7-C_8H_{17}$) can be obtained, in high yield, by the Arbuzov reaction from ω-bromoacetophenone and a number of phosphite tri-esters (except the ethyl ester). Since the reaction of α-halogeno-aldehydes with trialkyl phosphites gives virtually no normal products of the Arbuzov reaction[60], Razumov and Moskva[63] used the acetal of bromoacetaldehyde to prepare phosphonoacetaldehyde in 70% yield:

$$CH_2Br—CH(OC_2H_5)_2+(C_2H_5O)_3P \rightarrow C_2H_5Br+$$

$$+(C_2H_5O)_2P(O)—CH_2—CH(OC_2H_5)_2 \xrightarrow[HCl]{H_2O} 2C_2H_5OH+(C_2H_5O)_2P(O)—CH_2—CHO.$$

The Michaelis–Becker reaction[64] is of practical importance for the synthesis of reagents for P(O)-activated olefin synthesis; it is based on the reaction of alkali metal salts of phosphite di-esters with organic compounds containing reactive halogen atoms:

$$(RO)_2P(O)Na+R'—Hal \rightarrow (RO)_2P(O)—R'+NaHal \quad (Hal=Cl, Br, I).$$

The applicability of the Michaelis–Becker method is somewhat reduced as a result of a number of side-reactions. In particular the reaction with α-halogeno-carbonyl compounds is as a rule anomalous, since esters of epoxyphosphonic acid are formed preferentially[65,66]. The method developed by Normant and coworkers[67] for the preparation of phosphonates containing a carbonyl group, by the reaction of sodium diethyl phosphite with ethers derived from the enols of α-halogeno-carbonyl compounds, is of interest in this connection. The ethers are readily obtained by the pyrolysis of α-halogeno-diacetals. The resulting normal products of the Michaelis–Becker reaction are converted after hydrolysis into β-diethylphosphonocarbonyl compounds:

$$R—CH_2—C(OR')_2—CH_2—X \rightarrow R'—OH+R—CH=C(OR')—CH_2—X \rightarrow$$
$$\xrightarrow[NaX]{+(C_2H_5O)_2P(O)Na} R—CH=C(OR')—CH_2—P(O)(OC_2H_5)_2 \rightarrow$$
$$\xrightarrow[-R'—OH]{+H_2O} (C_2H_5O)_2P(O)—CH_2—CO—CH_2—R.$$

A number of β-oxophosphonic esters have been prepared by this method[68].

The third fundamentally important method for the preparation of organophosphorus compounds of various complexity containing $P(O)-CH_2$ groups consists in the addition of dialkylphosphorous acids and acid esters of alkyl- and aryl-phosphonous acids to ethylenic hydrocarbons and their various derivatives. This method has been proposed and largely developed by Pudovik and coworkers; data concerning the preparation of many compounds suitable for P(O)-activated olefin synthesis are presented in Pudovik's review[26]. Subsequently a number of papers were published with data on the synthesis of organophosphorus compounds of this kind using unsaturated compounds[69-75].

The hydrogen atoms in the methylene group of organophosphorous compounds containing the $P(O)-CH_2$ unit are reactive. This reactivity is due to the effect of the adjacent P(O) group involving the semipolar phosphorus–oxygen bond[76-79], with the negative charge located on the oxygen atom, i.e. $\rangle P=O \leftrightarrow P^+-O^-$. Since 1929 Arbuzov showed[80,81] that the hydrogen atoms of the methylene group in phosphonoacetic and alkylphosphonic esters, etc. are similar to those in acetoacetic ester, being readily replaced by alkali metals. In some cases the hydrogen atoms of the methylene group are so reactive that on reacting with a Grignard reagent they cause the evolution of the hydrocarbon and form an organophosphorus–magnesium compound[82]; the reaction with phenyl-lithium is similar[13] and in the Chugaev–Tserevitinov [Zerevitinov] reaction the evolution of active hydrogen reaches quantitative yields[15]. The mobility of the hydrogen atoms of the methylene group is also revealed in Claisen condensation with carboxylic acid esters[15,83,84], in condensation of the crotonic acid type with aldehydes[42,85,86], and in addition reactions to double carbon–carbon bonds in electrophilic unsaturated compounds[26].

III. MECHANISM OF P(O)-ACTIVATED OLEFIN SYNTHESIS

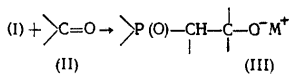
In practice the P(O)-activated olefin synthesis is carried out under mild conditions, often with slight and brief heating of the initial reactants in a suitable solvent (dimethylformamide, 1,2-dimethoxyethylene, cyclohexane, benzene, toluene). It has been found that in ether and anisole the olefin yields are low, while in chlorobenzene the reaction virtually does not occur at all[20]. Usually the condensing reagent and then the carbonyl component are added to a solution of a P(O)-activated reagent for olefin synthesis. At the end of the reaction the mixture is treated with water which dissolves the phosphonate salts, the olefins being isolated from the organic layer.

In a special investigation devoted to the study of the mechanism of the P(O)-activated olefin synthesis, Horner and coworkers[20] concluded that the reaction involves three stages, from each of which it is possible to isolate and characterise the intermediate products in some cases. In the first stage the reactive hydrogen atom of the methylene group of the P(O)-activated reagent is replaced by a metal to give a *C*-metallated compound (I):

$$\rangle P(O)—\underset{|}{CH_2}+M^+ \rightarrow \rangle P(O)—\underset{|}{\bar{C}H}M^+ + {}^1/_2H_2 \quad (M=Li, Na, K).$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad (I)$$

When alkali metal hydrides, amides, or alkoxides and metal alkyls or metal aryls are used as metallating agents, hydrogen, ammonia, alcohols, or hydrocarbons are evolved respectively. In the second stage compound (I), which behaves as a usual organometallic compound, reacts with the

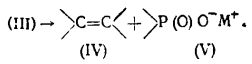
carbonyl compound (II) to form a β-hydroxy-derivative (III) of the P(O)-compound:



(II) (III)

Cases of this type of condensation in which compounds of type (III) were isolated, have been described[87-93].

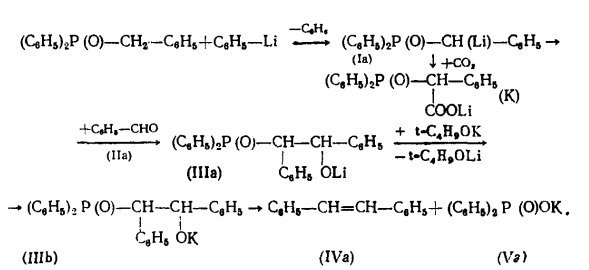
In the third stage compound (III) decomposes into an olefin (IV) and a phosphorus-containing acid anion (V):



(IV) (V)

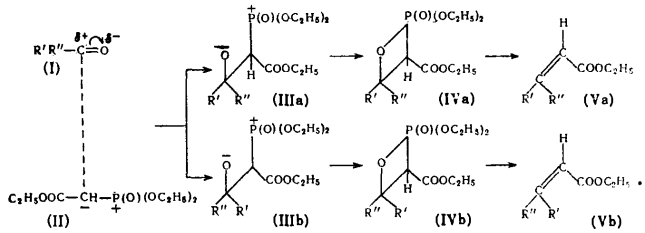
The third stage is due to the characteristic high affinity of phosphorus for organic oxygen (carbonyl oxygen)[94,95]. On the basis of the available data concerning the mechanism of the Wittig reaction between alkylidenephosphoranes and carbonyl compounds[2,3], the similarity of this reaction to P(O)-activated olefin synthesis, and the similarity of the electronic structures of P(O)-activated reagents for such synthesis, Wadsworth and Emmons[96] proposed a mechanism for P(O)-activated olefin synthesis similar to that described above.

The stages of the P(O)-activated olefin synthesis described above are to some extent hypothetical, since in most cases the intermediate compounds (I) and (III) cannot be isolated or identified. The stability of the metallated compound (I) and the hydroxy-derivative (II) of the P(O)-compound has been found to depend significantly on the nature of the alkali metal. When lithium metallating agents are used, compound (I) can be identified and compound (III) can be isolated[15,19]. Using the synthesis of stilbene as an example, Horner and coworkers[15] showed that stilbene forms in the reaction between benzyldiphenylphosphine oxide and benzaldehyde in the presence of lithium-, sodium-, and potassium-containing condensing agents. When sodium or potassium derivatives are used, the intermediates (I) and (III) cannot be detected. However, in the presence of phenyl-lithium the *C*-lithium compound (Ia) formed in the first stage was identified by its reaction with carbonic acid which yields a carboxylic acid (K). In the second stage of the reaction [after the addition of benzaldehyde to a solution of compound (Ia)] the β-hydroxy derivative (IIIa) of the P(O)-compound was isolated; on heating in toluene with potassium t-butoxide, it was converted into stilbene (IVa) and a salt of diphenylphosphinic acid (Va). It is assumed that the lithium compound (IIIa) is initially converted into an unstable potassium derivative (IIIb) which then decomposes into substances (IVa) and (Va). This can be represented as follows:



(IIIb) (IVa) (Va)

Yanovskaya and Kucherov[9] studied the stereochemistry of P(O)-activated olefin synthesis and established, on the basis of numerous experimental data, that the reaction of, for example, aldehydes with diethyl ethoxycarbonylmethylphosphonate is stereospecific and yields only the *trans*-isomers. Later these workers showed that sterically hindered ketones virtually do not enter into this reaction. Sterically unhindered ketones form with P(O)-activated reagents for olefin synthesis mixtures of *cis*- and *trans*-isomers. The absence of stereospecificity is the principal difference between the behaviour of aldehydes and ketones in this reaction. This can be explained in terms of the latest data on the mechanism of the Wittig reaction[97-100] and Yanovskaya and Kucherov's interpretation[9] of the stereospecificity of the formation of unsaturated compounds from phosphoranes and aldehydes and ketones. In P(O)-activated olefin synthesis, the formation of geometrical isomers can be represented by the scheme given below. As in the Wittig reaction, the nucleophilic attack by the carbon atom of the P(O)-activated reagent (II) for olefin synthesis on the carbon atom of the carbonyl compound (I) can result in the formation of *cis*- and *trans*-betaines (IIIa) and (IIIb) which lead to *cis*- and *trans*-olefins (Va) and (Vb) via the cyclic transition states (IVa) and (IVb):



(I) (II) (IIIa) (IIIb) (IVa) (IVb) (Va) (Vb)

In conformity with Cramm's rule[101], with aldehydes (R′ = H) the formation of the betaine (IIIb) occurs preferentially, which results in *trans*-olefins. With ketones having unbranched R′ and R″ radicals, the formation of (IIIa) and (IIIb) is equally likely, which implies an equal probability of the formation of the *cis*- and *trans*-isomers.

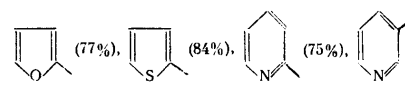
IV. SYNTHESIS OF OLEFINS

The main application of the method of P(O)-activated olefin synthesis has been to prepare olefins of various complexities with aromatic substituents and some of their heterocyclic analogues and also unsaturated acids and their derivatives.

1. Mono-Olefins and Their Hydrocarbon Derivatives

Stilbene and its analogues are obtained on condensation of carbonyl compounds with various condensing agents and P(O)-activated reagents for olefin synthesis. Stilbene, 2-stilbazole, 2-styrylfuran, and 2-styrylthiophen are obtained most simply on slight and brief heating of benzaldehyde or the corresponding heterocyclic aldehyde with diethyl benzylphosphonate in dimethylformamide in the presence of sodium methoxide[102]:

where Ar = C_6H_5 (yield 85%),



(here and below R = C_2H_5).

3-Stilbazole was obtained in the same way [15,20]. Stilbene can be synthesised in high yields also by the condensation of benzaldehyde with benzyldiphenylphosphine oxide [15,18], and if instead of benzaldehyde acetophenone is used, the product is α-methylstilbene [15]. By selecting suitable reactants with various substituents in the benzene rings, it is possible to obtain stilbenes with substituents in specified positions, for example [20]:

$$(RO)(C_6H_5)P(O)-CH_2-C_6H_4OCH_3\text{-}p + p\text{-}ClC_6H_4-CHO \longrightarrow (RO)(C_6H_5)P(O)OH + p\text{-}CH_3OC_6H_4-CH=CH-C_6H_4Cl\text{-}p.$$

Horne and coworkers [16,18] described two interesting methods for the preparation of stilbenes and their analogues by P(O)-activated olefin synthesis. In the first method triphenylphosphine oxide is heated in succession with sodium hydride and an aromatic aldehyde. This results in the formation of an olefin, benzene, and sodium diphenylphosphinate:

$$2(C_6H_5)_3P=O + 2NaH + 2Ar-CHO \longrightarrow Ar-CH=CH-Ar + 2(C_6H_5)_2PO_2Na + C_6H_6,$$

where Ar = C_6H_5, p-ClC_6H_4, α-$C_{10}H_7$, 9-$C_{14}H_{11}$ (from anthracene-9-aldehyde). If benzophenone is used instead of aldehydes, the product is tetraphenylethylene [17].

It was established that the olefin forms in stages. Initially when triphenylphosphine oxide is fused with sodium hydride (at about 200°), the products are benzene and sodium diphenylphosphine oxide (I), which then reacts with the added aldehyde, yielding the alkoxide of (α-hydroxybenzyl)diphenylphosphine oxide (II). The latter reacts with compound (I) and gives sodium diphenylphosphinate and a C-metallated derivative of benzyldiphenylphosphine oxide (III). Finally, compound (III) reacts with a second molecule of the aldehyde to form the olefin and a second molecule of sodium diphenylphosphinate. The reactions can be expressed as follows:

$$(C_6H_5)_3P=O + NaH \longrightarrow C_6H_6 + (C_6H_5)_2P(O)Na, \quad (I)$$
$$(I) + Ar-CHO \rightleftarrows (C_6H_5)_2P(O)CH(ONa)-Ar, \quad (II)$$
$$(I) + (II) \longrightarrow (C_6H_5)_2P(O)ONa + (C_6H_5)_2P(O)CH(Na)-Ar, \quad (III)$$
$$(III) + Ar-CHO \longrightarrow (C_6H_5)_2P(O)ONa + Ar-CH=CH-Ar.$$

In the second method stilbenes are obtained on auto-oxidation of derivatives of phosphine oxides or phosphonic esters. For example, benzyldiphenylphosphine oxide in benzene solution is mixed or shaken with potassium t-butoxide in an atmosphere of oxygen, the reaction mixture is then treated with water, and stilbene is isolated from the benzene layer. In general, stilbene synthesis can be represented thus:

$$2(C_6H_5)_2P(O)-CH_2-Ar + t\text{-}C_4H_9OK \xrightarrow{O_2} Ar-CH=CH-Ar + 2(C_6H_5)_2P(O)OK + t\text{-}C_4H_9OH,$$

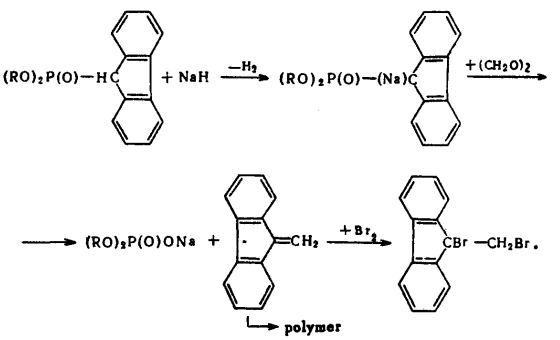
where Ar = C_6H_5, 3,4-$Cl_2C_6H_3$, and α-$C_{10}H_7$ (yield about 90%).

The study of this reaction showed [18] that the first stage involves the formation of a C-metallated phosphine oxide which is readily oxidised by molecular oxygen to a hydroxy-derivative, like the usual organometallic compounds. It is assumed that the oxidation goes via a stage in which a peroxy-compound is formed. As already mentioned, O-metallated oxides of α-hydroxyphosphines can break down reversibly into a phosphinic acid salt and a carbonyl compound [17], which immediately reacts with the C-metallated derivative of phosphine oxide to give the final reaction product — the olefin and the phosphinic acid salt. The various stages of the process can be represented in the following way:

$$(C_6H_5)_2P(O)-CH_2-Ar + t\text{-}C_4H_9OK \longrightarrow t\text{-}C_4H_9OH + (C_6H_5)P(O)CH(K)-Ar \xrightarrow{+O_2} (C_6H_5)_2P(O)-CH(O-OK)-Ar \xrightarrow{+(C_6H_5)_2P(O)CH(K)-Ar} 2(C_6H_5)_2P(O)-CH(OK)-Ar \rightleftarrows 2(C_6H_5)_2P(O)K + 2Ar-CHO,$$
$$(C_6H_5)_2P(O)-CH(K)-Ar + Ar-CHO \longrightarrow Ar-CH=CH-Ar + (C_6H_5)_2P(O)OK.$$

It has been found that, when lithium-containing metallating agents are used, it is possible to isolate O-lithium hydroxy-derivatives, which are stable unlike the O-sodium or O-potassium derivatives, since they have a lower affinity for carbonyl oxygen.

Apart from stilbenes, mono-olefins such as 1,1-diphenylethylene [13], 1-methyl-2,2-diphenylethylene [13,15], 2,2-diphenyl-1-n-propylethylene, 1-ethyl-1-methyl-2-phenylethylene [15], benzylidenecyclohexane [15,20], and triphenylethylene [13,15,18,29,96] have been obtained by the P(O)-activated synthesis. An interesting case of the P(O)-activated synthesis of mono-olefins is the reaction of diethyl fluorenylphosphonate with paraformaldehyde in the presence of sodium hydride [96]:



Since the resulting 9-methylenefluorene rapidly polymerises (particularly in the absence of solvent), the olefin formed is converted into the dibromo-derivative without being isolated first.

2. Diene and Polyene Hydrocarbons

P(O)-activated olefin synthesis has been successfully used to prepare unsaturated compounds containing two and more multiple carbon-carbon bonds. On combining together in the condensation process P(O)-activated reagents for mono- and di-olefin synthesis with mono- or di-carbonyl compounds, olefins with various degrees of unsaturation are obtained. Thus the reaction of diethyl benzylphosphonate with cinnamaldehyde yields 1,4-diphenylbuta-1,3-diene [20,96] and the reaction of benzyldiphenylphosphine with benzil gives 1,2,3,4-tetraphenylbuta-1,3-diene: [15]

$$(RO)_2P(O)-CH_2-C_6H_5 + C_6H_5-CH=CH-CHO \xrightarrow{t\text{-}C_4H_9OK} (RO)_2P(O)OK + C_6H_5-CH=CH-CH=CH-C_6H_5\ (80\%),$$
$$2(C_6H_5)_2P(O)-CH_2-C_6H_5 + C_6H_5-CO-CO-C_6H_5 \xrightarrow[(\text{or NaH})]{t\text{-}C_4H_9OK} 2(C_6H_5)_2P(O)OK + C_6H_5-CH=C(C_6H_5)-C(C_6H_5)=CH-C_6H_5\ (50\%).$$

Phenyl-substituted polyenes with a conjugated system of double bonds are formed when bis-P(O)-activated reagents for olefin synthesis and aliphatic-atomatic aldehydes or

ketones are used in the reaction. For example, 1,10-diphenyldeca-1,3,5,7,9-pentaene and 1,1,6,6-tetraphenylhexatriene are formed in the following process [20]:

$$(RO)_2P(O)-CH_2-CH=CH-CH_2-P(O)(OR)_2 + C_6H_5-CH=CH-CHO \longrightarrow$$
$$\xrightarrow{t\text{-}C_4H_9OK} C_6H_5-\overset{(A)}{(CH=CH)_3}-C_6H_5 + 2(RO)_2P(O)OK,$$
$$(A) + (C_6H_5)_2C=O \longrightarrow (C_6H_5)_2C=CH-CH=CH-CH=C(C_6H_5)_2 + 2(RO)_2P(O)OH.$$

Aliphatic–aromatic dienes with methylene bridges which interrupt the conjugation chain are obtained when the oxides of n-alkylene-$\alpha\omega$-bisdiphenylphosphines are condensed with carbonyl compounds. For example [20]:

$$(C_6H_5)_2P(O)-(CH_2)_n-P(O)(C_6H_5)_2 + 2(C_6H_5)_2C=O \xrightarrow{t\text{-}C_4H_9OK}$$
$$\longrightarrow 2(C_6H_5)_2P(O)OK + (C_6H_5)_2C=CH-(CH_2)_{n-2}-CH=C(C_6H_5)_2 \quad (n=2, 4, 6).$$

The P(O)-activated synthesis has proved particularly valuable for the preparation of olefins such as distyryls [20], which are difficult to prepare otherwise and which have found application recently as light-protective media, as stabilisers for polymers and polyolefins, and as optical bleaching agents for high-molecular compounds. Thus the condensation of tetraethyl (*p*-phenylenedimethylene)-bisphosphonate (TEPP) with various aldehydes and ketones in dimethylformamide in the presence of sodium methoxide [103] or potassium t-butoxide [20] gives distyryls of various complexity in yields of 65–90%:

$$(RO)_2P(O)-CH_2-C_6H_4-CH_2-P(O)(OR)_2 + 2R'R''C=O \rightarrow$$
$$\rightarrow 2(RO)_2P(O)OH + R'R''C=HC-C_6H_4-CH=CR'R'',$$

where R′ = H and R″ = C_6H_5, R′ = H and R″ = *p*-$O_2NC_6H_4$, R′ = H and R″ = *p*-$(CH_3)_2NC_6H_4$, R′ = H and R″ = *p*-C_6H_5–C_6H_4,

R′ = H and R″ =  , R′ = H and R″ =  , R′ = R″ =  ,

1,4-Distyryl is also obtained on condensing TEPP with terephthalic aldehyde, and the reaction of the same bis-P(O)-activated reagent for olefin synthesis with cinnamaldehyde gives an 84% yield of 1,4-di-(4-phenylbutadienyl)-benzene [20,96]. The same olefin is also the product of the condensation of cinnamaldehyde and (*p*-phenylenedimethylene)bis(diphenylphosphine oxide) [20]:

$$(RO)_2P(O)-CH_2-C_6H_4-CH_2-P(O)(OR)_2 + 2C_6H_5-CH=CH-CHO \rightarrow$$
$$\rightarrow 2(RO)_2P(O)OH + C_6H_5-(CH=CH)_2-C_6H_4-(CH=CH)_2-C_6H_5.$$

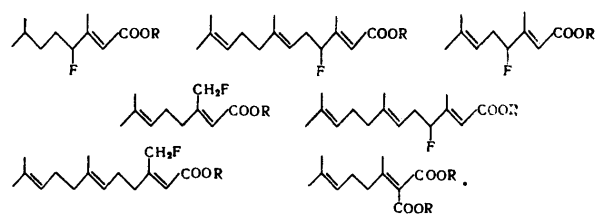
3. Synthesis of Aliphatic and Aliphatic-Aromatic Unsaturated Acids

P(O)-Activated olefin synthesis is a good method for preparing derivatives of unsaturated aliphatic and aliphatic-aromatic acids. This method has been used to synthesise quite a large number of esters and nitriles of $\alpha\beta$-unsaturated acids. The readily available (diethyl phosphono)acetic ester is usually employed as the P(O)-activated reagent for this type of olefin synthesis. The reaction is carried out in a suitable solvent (dimethylformamide, toluene, and others) in the presence of condensing agents (alkali metal alkoxides, metallic sodium, etc.). The reaction can be represented in the following general form:

$$(RO)_2P(O)-CH_2-COOR + R'R''C=O \rightarrow R'R''C=CH-COOR + (RO)_2P(O)OH.$$

The Table gives the yields of the esters prepared in this way.

The P(O)-activated olefin synthesis with participation of phosphonoacetic ester and $\alpha\beta$-unsaturated ketones containing atoms or groups of atoms with pronounced electron-acceptor properties takes place particularly smoothly. Ketones of this kind have yielded a number of ethyl esters of γ-fluoro-substituted and other $\alpha\beta$-unsaturated acids [11]. For example:



Wadsworth and Emmons [96] proposed a simple method for the preparation of esters of α-substituted $\alpha\beta$-unsaturated acids in which a number of consecutive reactions are carried out in a single apparatus without isolating the intermediates. Phosphonoacetic ester in solution in 1,2-dimethoxyethylene

TABLE. Ethyl esters of $\alpha\beta$-unsaturated acids (R′R″C=CH–COOR) obtained from aldehydes and ketones by P(O)-activated olefin synthesis.

is successively metallated with sodium hydride, the resulting alkyl derivative is metallated again and finally condensed with the carbonyl compound. The preparation of the ester of α-n-butylacrylic acid (yield 60%), for example, can be described thus:

$$(RO)_2P(O)-CH_2-COOR + NaH \xrightarrow{-H_2} (RO)_2P(O)-CH(Na)-COOR \rightarrow$$

$$\xrightarrow[-NaBr]{+R'-Br} (RO)_2P(O)-CHR'-COOR \xrightarrow[-H_2]{+NaH} (RO)_2P(O)-CR'(Na)-COOR \longrightarrow$$

$$\xrightarrow{+CH_2=O} (RO)_2P(O)ONa + CH_2=C(R')-COOR \quad (R' = n\text{-}C_4H_9).$$

If after the first metallation stage bromine is introduced into the reaction mixture instead of an alkyl halide, the final reaction product is the ester of an α-bromo-αβ-unsaturated acid. For example, α-bromo-β-isopropylacrylic acid is obtained in this way (yield 65%):

$$(RO)_2P(O)-CH(Na)-COOR + Br_2 \rightarrow NaBr + (RO)_2P(O)-CH(Br)-COOR \longrightarrow$$

$$\xrightarrow{+NaH,\ (CH_3)_2CH-CHO} (CH_3)_2C=C(Br)-COOR + (RO)_2P(O)ONa.$$

If instead of bromine, iodine is used and the resulting iodophosphonate is further metallated and then condensed with a carbonyl compound, acetylene derivatives are obtained. For example, ethyl phenylpropiolate can be synthesised in this way (yield about 60%):

$$(RO_2)P(O)CHI-COOR + 2NaH + C_6H_5-CHO \rightarrow$$

$$\rightarrow C_6H_5-C\equiv C-COOR + H_2 + NaI + (RO)_2P(O)ONa.$$

The carbonyl groups of ketens can take part in P(O)-activated olefin synthesis as well as those of aldehydes and ketones. Under the conditions described above, (diethyl phosphono)acetic ester reacts with ethyl(phenyl)keten to give 1-ethoxycarbonyl-3-ethyl-3-phenylallene[96]:

$$(RO)_2P(O)-CH_2-COOR + NaH + C_6H_5(C_2H_5)C=C=O \rightarrow$$

$$\rightarrow H_2 + (RO)_2PO_2Na + C_6H_5(C_2H_5)C=C=CH-COOR.$$

Under these conditions ethyl levulinate reacts via its ketone group with (diethyl phosphono)acetic ester, forming 1,2-diethoxycarbonyl-2-methylbut-1-ene in good yield:

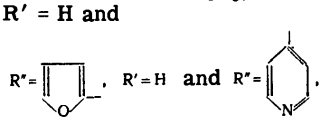
$$(RO)_2P(O)-CH_2-COOR + CH_3-CO-CH_2-CH_2-COOR + NaH \rightarrow$$

$$\rightarrow H_2 + CH_3-CH=C(COOR)-CH_2-CH_2-COOR + (RO)_2P(O)ONa.$$

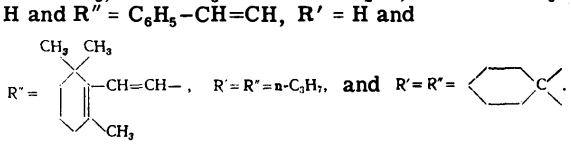
P(O)-Activated olefin synthesis has also proved valuable for the preparation of αβ-unsaturated acid nitriles which have recently become important in organic synthesis as intermediates in the synthesis of dyes, pharmaceutical preparations, and others. The nitriles are synthesised by condensing carbonyl compounds with the readily available diethyl ester of cyanomethylphosphonic acid. The following nitriles of αβ-unsaturated acids have been obtained in this way[96,103-105]:

$$(RO)_2P(O)-CH_2-CN + R'R''C=O \rightarrow R'R''C=CH-CN + (RO)_2P(O)OH,$$

where R' = R'' = H, R' = H and R'' = CH_3, R' = H and R'' = $CH_2=C(CH_3)$, R' = H and R'' = C_6H_5, R' = H and R'' = 2,6-$Cl_2C_6H_3$, R' = H and



R' = R'' = CH_3, R' = CH_3 and R'' = CH_2Cl, R' = R'' = C_6H_5, R' = H and R'' = C_6H_5–CH=CH, R' = H and



It has been found that the yields of the nitriles are quite satisfactory (60–80%) and the reaction takes place under mild conditions (at 20–50°) in various solvents (alcohols, toluene, xylene, dioxan, dimethylformamide) in the presence of different condensing agents (alkali metal hydroxides and alkoxides, the amides of alkali and alkaline-earth metals, and organic bases).

4. Isoprenoids and Compounds Related to Natural Substances

P(O)-Activated olefin synthesis can be used to prepare αβ-unsaturated carbonyl compounds. Thus the condensation of the ethyl acetal of (diethyl phosphono)acetaldehyde with benzaldehyde gives the diacetal of cinnamaldehyde which is smoothly hydrolysed to cinnamaldehyde itself[104]:

$$(RO)_2P(O)-CH_2-CH(OC_2H_5)_2 + C_6H_5-CHO + NaH \rightarrow$$

$$\rightarrow H_2 + (RO)_2P(O)ONa + C_6H_5-CH=CH-CH(OC_2H_5)_2 \xrightarrow[H^+]{H_2O} C_6H_5-CH=CH-CHO + 2C_2H_5OH.$$

The acetal $(RO)_2CH-CH_2-C(CH_3)=CH-COOR$ was obtained similarly[108] from phosphonoacetic ester and the diethyl acetal of acetoacetaldehyde.

Pommer[112] showed that P(O)-activated olefin synthesis gives better results in the preparation of carotenoids and related compounds than the Wittig olefin synthesis. Thus the synthesis of the dimethyl ester of crocetin (VI) takes place via a series of consecutive reactions, two of which are P(O)-activated condensations involving olefin synthesis. For this purpose, the tetraethyl ester of but-2-ene-1,4-diphosphonic acid (I) (yield 90%) is first prepared from 1,4-dichlorobut-2-ene and triethyl phosphite by the Arbuzov reaction and then condensed with two moles of methylglyoxal acetal (II). The resulting bisacetal of the C_{10} aldehyde (III) is hydrolysed to the C_{10} aldehyde (IV) itself. The latter is then condensed with the diethyl ester of 3-methoxycarbonylbut-2-enylphosphonic acid (V)† [the ester (V) is obtained by the Arbuzov reaction from the methyl ester of γ-bromotiglic acid and triethyl phosphite] to give the ester of crocetin (VI); the general mechanism of the synthesis can be represented by the following reactions:

$$(RO)_2P(O)-CH_2-CH=CH-CH_2P(O)(OR)_2 + 2(RO)_2CH-C(=O)-CH_3 \rightarrow$$

(I) (II)

$$\xrightarrow{2CH_3ONa} 2(RO)_2P(O)ONa + (RO)_2CH-C(CH_3)=CH-CH=CH-CH=C(CH_3)-CH(OR)_2 \longrightarrow$$

(III)

$$\xrightarrow[HCl]{H_2O} 4C_2H_5OH + O=CH-C(CH_3)=CH-CH=CH-CH=C(CH_3)-CH=O \quad (IV).$$

$$(IV) + 2H_3COOC-C(CH_3)=CH-CH_2-P(O)(OR)_2 \xrightarrow{+2CH_3ONa}$$

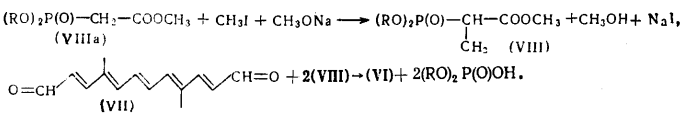
(V)

$$\longrightarrow 2(RO)_2P(O)ONa + H_3COOC\text{–}(CH=CH)_5\text{–}COOCH_3 \quad (VI).$$

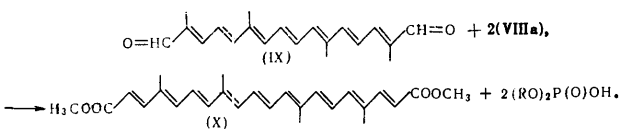
The same derivative of crocetin (VI) is obtained on condensing the C_{14} dialdehyde (VII) with the diethyl ester of α-methoxycarbonylethylphosphonic acid (VIII) which in turn is obtained by methylating the ester (VIIIa). Thus this method of the

† The C_{10} diol $CH_2OH-C(CH_3)=CH-CH=CH-CH=C(CH_3)-CH_2OH$ was obtained similarly from compound (I) and hydroxyacetone[112].

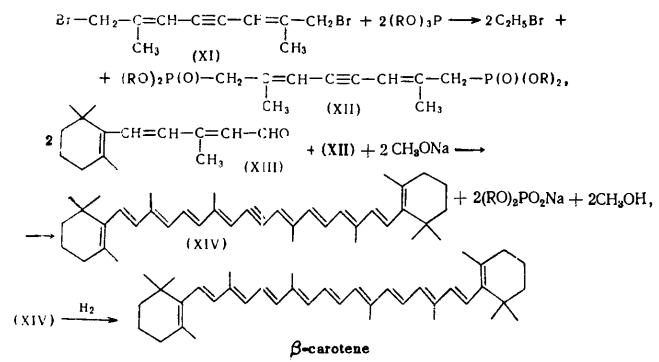
preparation of the diester (VI) can be described as follows:



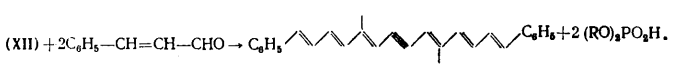
Similarly the condensation of the C_{20} dialdehyde (IX) with the ester (VIIIa) gave methylbixin (X):



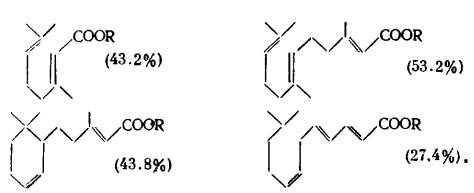
β-Carotene, the most important and most widely distributed plant pigment, was also prepared by P(O)-activated olefin synthesis. Pommer showed [112] that this method of synthesising β-carotene is superior, as regards the small number of stages and the availability of the starting materials, to all earlier procedures, including that involving the Wittig reaction [3]. The diethyl ester of 2,7-dimethylocta-2,6--dien-4-yne-1,8-diphosphonic acid (XII), prepared by the Arbuzov reaction from 1,8-dibromo-2,7-dimethylocta-2,6--dien-4-yne (XI) and triethyl phosphite, is condensed with two moles of β-ionylideneacetaldehyde (XIII) in the presence of sodium methoxide. The resulting 15,15'-dehydro--β-carotene (XIV) is smoothly converted into β-carotene after partial hydrogenation:



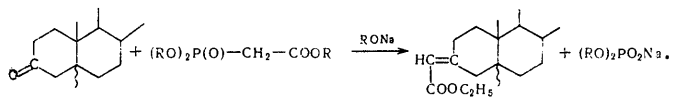
The ester (XII) reacts with cinnamaldehyde [113] by the usual mechanism of P(O)-activated olefin synthesis to yield the isoprenoid olefin 5,10-dimethyl-1,14-diphenyltetradeca-1,3,5,9,11,13-hexaen-7-yne:



By condensing phosphonoacetic ester with methylheptenone, geranylacetone, α-ionone, and α-dihydroionone in dimethylformamide in the presence of sodium methoxide, Kovalev et al. [108] obtained a number of esters of isoprenoid acids (yields are given in brackets):



The use of P(O)-activated olefin synthesis in the steroid series appears to be promising. The work of Bose and coworkers shows that 3-oxosteroids react via the carbonyl group with phosphonoacetic ester to form ethoxycarbonylmethylene derivatives [114]:



The data compiled in the present review on the methods of preparation, properties, and applications of P(O)-activated reagents for olefin synthesis show that this new method permits relatively simple preparation of unsaturated compounds with a specified structure; the compounds may belong to different classes and may be of various complexity. It is noteworthy that the possibilities of P(O)-activated olefin synthesis have been by no means exhausted as regards application to syntheses involving many organic compounds with carbonyl groups. There is no doubt that further studies in this field will yield new results of value for organic synthesis.

I. INTRODUCTION

Recently a new field of study has arisen in the chemistry of monomers, associated with the synthesis of optically active polymeric substances. Their synthesis and the study of their properties are of great theoretical and practical interest. From the theoretical standpoint, asymmetric synthesis of polymers constitutes a higher type of control of stereoregularity, compared with the synthesis of the usual regular crystalline polymers. It represents a further advance in the control of the synthesis of macromolecular materials. The synthesis of optically active polymers has introduced into polymer chemistry a new parameter — the specific rotation of polymers which is due to the presence of uncompensated asymmetry and constitutes the overall stereochemical result of the reaction. The studies of the changes in the optical rotation of the polymer as a function of polymerisation conditions makes it possible to establish the relation between the specific rotation, structural regularity, and the molecular weight of the polymer. Investigation of the optical activity of the degradation products of optically active polymers can reveal the steric relations which obtain between the monomer, the catalytic system, and the polymer.

On the other hand, successful synthesis of optically active polymers in the presence of small amounts of an asymmetric cocatalyst constitutes a first approximation to the modelling of processes in nature, where protein molecules are formed in the presence of small amounts of highly specific enzymes as a result of a series of complex consecutive reactions.

Since optically active polymers and oligomers have highly specific structures, they may prove important as components of very selective catalysts in polymerisation and polycondensation processes and they may also be used in the asymmetric synthesis of small molecules, as model systems in the study of biocatalysis, and as adsorbents for the separation of racemic mixtures.

Optically active polymers prepared from optically active monomers exhibit improved mechanical properties and thermal stability compared with polymers synthesised from the analogous racemic monomers, which is of undoubted practical interest. In recent years optically active polymers have been increasingly attracting the attention of investigators. This interest was stimulated, on the one hand, by the study of the structural features of proteins and nucleic acids in solutions and, on the other hand, by the advances in stereospecific polymerisation. Up to 1956 there were only seven papers on optically active polymers, while in 1961 alone about thirty publications appeared, including a number of reviews [1-4].

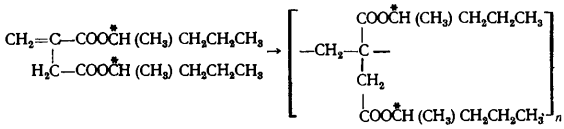
There exist three fundamental approaches to the study of optically active polymers. One of them is associated with the determination of the laws governing the asymmetric synthesis of macromolecular substances, the second deals with the study of the properties of optically active polymers, and finally, the third is concerned with the application of optically active labels in experiments designed to solve a wide range of problems in polymerisation chemistry: elucidation of the nature of active centres in catalytic systems, the conformation of macromolecules in solution, the microtactic properties of chains, the polymerisation kinetics, etc.

The author has attempted to elucidate mainly the first and the last of these problems. She wished to demonstrate the wide variety of possible uses of the optically active label; by virtue of its simplicity and availability, the procedure based on such labelling will undoubtedly form part of the arsenal of the methods available in polymer chemistry.

II. SYNTHESIS OF OPTICALLY ACTIVE POLYMERS FROM OPTICALLY ACTIVE MONOMERS AND THEIR PROPERTIES

There is nothing new in the polymerisation of optically active polymers compared with the usual stereospecific polymerisation apart from the use of the optically active monomers themselves. The resulting polymer is optically active only if the reaction does not involve the asymmetric centres of the molecule and hence racemisation does not take place.

In 1896 Walden[5] achieved the polymerisation of the optically active ester of itaconic acid, in which the asymmetric carbon atoms are located in the ester groups:



The optical rotation of the polymer is of the same order of magnitude as that of the monomer.

1. Optical Activity of High-Molecular Compounds

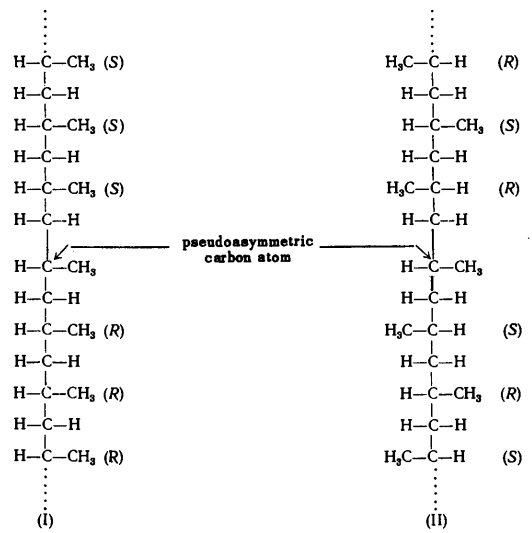
The optical activity of polymers is usually expressed in terms of the specific rotation $[\alpha]$ and the molar rotation $[M]$ which are defined by the following formulae:

$$[\alpha] = \frac{\alpha \cdot 100}{l \cdot c}; \quad [M] = [\alpha] \cdot \frac{M}{100},$$

where α is the measured angle of optical rotation (in degrees), l the thickness of the layer of substance (in decimeters), c the concentration of the solute (in grammes per 100 ml of solution), and M the molecular weight of the polymer unit.

It should be borne in mind that the observed optical activity is a fairly complex sum of contributions due to different factors. The principal factors are as follows: optically active side groups, the primary structure determined by the covalent bonds in the chain or the configuration of the macromolecule, and the secondary structure (or chain conformation) determined by steric, non-valence interaction of the side-group.

Consideration of the chain of stereoregular polymers of the vinyl type $(-CH_2-CHR-)_n$ readily shows that, owing to the stereochemical characteristics of the asymmetric carbon atom in the main chain, the primary structures in both iso- and syndio-tactic polymers are symmetrical and cannot contribute to the optical rotation of the polymer. Indeed the chain of the syndiotactic polymer (II) formed by a regularly alternating sequence of (*R*)- and (*S*)-configurations of the asymmetric atoms† is internally compensated. In the case of the isotactic sequence of chain units (I) the asymmetry of the carbon atoms in -CHR- groups is due to the differences in the lengths of the segments of the polymeric chain joined to them. Since the immediate environment of the asymmetric atoms in each -CHR- group (apart from those nearest to the ends of the chain) is almost symmetrical, such polymers have numerous symmetry planes and are therefore optically inactive.

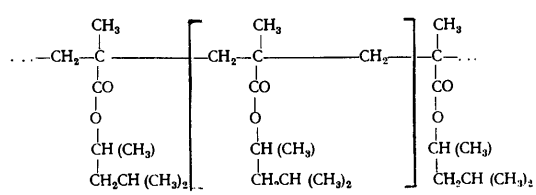


An atactic polymer formed by randomly alternating (*R*)- and (*S*)-asymmetric centres constitutes a random "meso-form" which cannot possess optical activity.

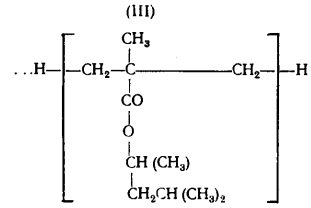
Thus comparison of the optical activities of polymer solutions with the rotation of the monomers or model compounds makes it possible, in principle, to determine the conformational contribution to the rotation and to assess on this basis the nature of the secondary structure of the macromolecule in the solution.

2. The Use of Optically Active Monomers in the Determination of the Conformation of Macromolecules in Solution

The first attempt to analyse the rotatory power of polymers was made by Arcus and West[6], who compared the optical activity of the polymers of 1,3-dimethylbutyl (+)-methacrylate (III) with the activity of the model compound 1,3-dimethylbutyl pivalate (IV). The algebraic difference between the molar rotations of the polymer and the model compound proved to be negative and equal to one third of the rotation of the model compound. The authors suggested that the observed change in rotation is associated with the presence of helical sections in the macromolecules in solution:



(III)



(IV)

† For the nomenclature, see E. L. Eliel, "Stereochemistry of Carbon Compounds" (Translated into Russian), Izd. Mir, Moscow, 1965 [McGraw-Hill, 1962].

Natta and coworkers[7] showed that in the crystalline regions all isotactic polyolefins exist in the form of rigid right- and left-hand helices. In the polymerisation of olefins without optically active side-groups, the amount of different enantiomorphic forms of the helices is the same and therefore the polymer as a whole is optically inactive. On the other hand, if the polymer is crystallised under conditions which favour the preferential formation of a particular type of helix, such structures acquire optical activity[8]. Dissolution of a crystalline polymer results in the breakdown of long, well formed helices. It has been demonstrated experimentally[9] and theoretically[10] that small sections with helical conformations persist also in solution, i.e. the one-dimensional short-range order in the macromolecules in solution is in most cases similar to the one-dimensional long-range order in the crystalline state. The maintenance of one-dimensional long-range order in a free macromolecule requires the presence of intramolecular forces capable of resisting the disorienting effect of thermal motion. In polypeptides such forces are the hydrogen bonds between the repeating CO and NH groups which ensure a rigid helical structure of the macromolecules in solution[11]. The forces of steric repulsion between groups cannot by themselves fix rigidly the position of the units of the main chain and prevent the macromolecule from rolling up into a randomly twisted spherical structure.

In their study of poly-α-olefins with optically active side-groups, Pino[12-15], Bailey[16], and Nozakura[17] found that the polymers had a considerably higher optical activity than the monomers (Table 1). The absolute magnitude of the molar optical activity of the isotactic fractions of the polymers is more than ten times greater than the molecular rotation of the analogous low-molecular compounds. The sign of the optical activity of the poly-α-olefins investigated is determined by the absolute configuration of the asymmetric carbon atom of the monomer: all the polymers of (*S*)-α-olefins exhibit positive rotation while the polymers of (*R*)-α-olefins exhibit negative rotation. Goodman and Abe[18-20] observed a similar increase, compared with the monomers, in the optical activity of polymers based on aldehydes and containing the same optically active substituents as the poly-α-olefins discussed above. Very interesting results were also obtained by Ciardelli at al.[21], who reduced the optically active poly-4-methylhex-1-yne with $[\alpha]_D = +2.0°$ to poly-4-methylhexene with $[\alpha]_D = +178°$.

TABLE 1. Comparison of the optical activities of model saturated hydrocarbons with the optical activities of atactic and isotactic fractions of certain poly-α-olefins.*

Low-molecular saturated hydrocarbons	$[M]_D^{25}$	Polymer	$[M]_D^{25}$ amorphous or very weakly crystalline fraction	$[M]_D^{25}$ highly crystalline fraction
(*S*)-2,3-dimethylpentane	−11.4	poly-(*S*)-3-methylpent-1-ene	+29.4	+161
(*S*)-2,4-dimethylhexane	+21.3	poly-(*S*)-4-methylhex-1-ene	+116	+288
(*S*)-2,5-dimethylheptane	+11.7	poly-(*S*)-5-methylhept-1-ene	+13.1	+68*
(*S*)-3-methyloctane	+13.3	poly-(*S*)-6-methyloct-1-ene	+12.8	+20*
(*S*)-2,6-dimethyloctane	+14.4	poly-(*R*)-3,7-dimethyloct-1-ene	−20.6	−154

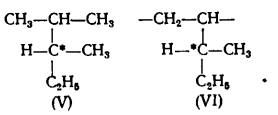
* These data refer to the most isotactic of the soluble fractions.

Pino and coworkers explain the very high optical activities of the poly-α-olefins on the basis of the above hypothesis that there is a helical short-range order in the macromolecules of isotactic polymers. When isotactic poly-α-olefins are formed, left- and right-hand helices are not energetically equivalent, since different sets of conformations of the side-group and different energies of these conformations correspond to a particular configuration of the asymmetric carbon atom in the substituent in the right-hand and left-hand helices and therefore one of the helical forms predominates in the polymers. Calculation of the molar rotation of polymers carried out in one of Pino's studies[14] by Brewster's semiempirical method[22] showed that the sign of the observed optical activity is consistent with the sign of the optical activity calculated for the helical conformation which is associated with the greatest number of rotational isomers in the side-group, i.e. has the smallest free energy.

In view of the approximate nature of the calculations by Brewster's method, the authors were unable to decide finally whether the agreement between the calculated and observed values of $[M]$ is fortuitous or real.

Birnshtein and Luizi[23] made a theoretical study of the conformational structure of the optically active poly-α--hydrocarbons which had been investigated by Pino. They showed that in macromolecules where short-range order extends over several monomer units even a small difference in the free energies of the right- and left-hand helices is sufficient to ensure that the helical conformation of lower energy predominates in the statistically twisted chains.

To elucidate the reasons for the higher optical rotation of polymers, we shall consider, from the standpoint of the conformations, the conversion of a model low-molecular optically active hydrocarbon (V) into a polymeric chain (VI):



(V) (VI)

In low-molecular hydrocarbons the number of possible conformations is fairly large and the magnitude of optical rotation is determined by the algebraic sum of positive and negative conformational rotational contributions which are of a similar value[22]. On conversion to the high-molecular compound at least one of the monomer conformations is "frozen". As a result, the equilibrium constants governing the relative amounts of dextro- and laevo-rotatory conformations in isotactic polymers and low-molecular saturated hydrocarbons differ significantly. The chromophore system of the polymer is the same as that of the monomer. The only chromophore group in these compounds is the C–H bond at the asymmetric carbon atom in the side-group. The maximum number of units in frozen conformations occurs in a helical structure, since the latter corresponds to minimum free energy.

Thus the high values of the optical rotation of poly-α--olefins are associated with the formation of preferred conformations (rigorous steric requirements) at the asymmetric atoms of the side-groups which leads to the formation of left- or right-hand helices. Pino's hypothesis does not contradict the explanation of the high values of the rotation of polymers, compared with the low-molecular

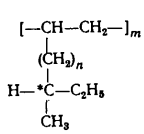
compounds, put forward by Goodman and Abe[20], who believe that the conformational rigidity of polymeric chains is due to the excess of one type of *gauche*-conformation over the others for a given isotactic sequence.

It is interesting to compare the characteristic features of the optical rotation of poly-α-olefins with the rotation of synthetic polypeptides. By virtue of the asymmetry of the helical structure itself, polypeptides, which are present in solution in a spiral conformation, behave optically as a single absorbing system and make a special "helical" contribution to the overall rotation. The optical rotary dispersion of polypeptides in solvents which do not cause appreciable breakdown of hydrogen bonds does not obey Drude's single-term equation[24] but is described by more complex expressions. The factors which influence the conformation of polypeptides (solvent, temperature, concentration of polymer, etc.) also cause a change in the optical rotation of their solutions.

In contrast to polypeptides, the optical rotatory dispersion of polyhydrocarbons in the wavelength range accessible to measurement does obey Drude's simple equation. The concentration[15] of the polymer and the solvent have little effect on the optical rotation. It is noteworthy that the temperature coefficients $\Delta[M]/\Delta T$ for polyhydrocarbons are fairly large (between -0.2 and -0.65) and depend on the stereoregularity of the fractions: they are larger for crystalline structures than for the less regular fractions.

This difference in the behaviour of the optical rotation of these two classes of "helical" polymers can be explained by the fact that the only chromophore group in polyhydrocarbons is the C–H bond at the asymmetric carbon atom in the side-group, whereas in polypeptides the chromophore system of the CO–NH unit linked by hydrogen bonds is located in the main chain. Naturally the factors which influence the stability of the hydrogen bonds in polypeptides cannot affect the conformational composition of optically active poly-α-olefins.

The optical activity of poly-α-olefins depends significantly on their stereoregularity, which is also consistent with the hypothesis of the helical structure of the polymers in solution. Comparison of the optical rotation of the most stereoregular fractions of polymers with the general formula (VII),



(VII),

where n = 0, 1, 2, and 3 shows that the molar rotation is very high for poly-(*S*)-3-methylpent-1-ene (n = 0), reaches a maximum for poly-(*S*)-4-methylhex-1-ene (n = 1), but falls appreciably in the case of higher homologues (Table 1).

Thus the study of the optical activity of polymers in solution is a very sensitive qualitative method, whereby it is possible to demonstrate whether or not sections of the helical structure of isotactic macromolecules persist in solution. Probably the secondary structure of the polymer itself influences the stereoregularity in the course of further polymerisation. Thus in the polymerisation of α-amino-acids such "stereoregulating" influence may arise on formation of an α-helix in which the isotactic distribution is preferred to the atactic distribution as a result of the better steric accommodation of the R-groups in the repeating structural unit *CHR–CONH.

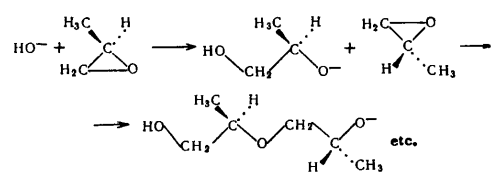
It has been shown experimentally that addition of the D-isomer in the polymerisation of the anhydride of γ-benzyl-*N*-carboxy-L-glutamic acid[11], catalysed by sodium hydroxide, decreases sharply both the rate and degree of polymerisation. This can be explained by the difficulty of incorporation of the D-isomer of the amino-acid as a unit in the growing α-helix formed from the L-amino-acid. In fact the decrease in rate is so considerable that it suggests not only that the unnatural amino-acid fails to be incorporated in the polymer chain but also that the growing chain is partially blocked on encountering the "foreign" monomer. Minoru[25] synthesised polymers by esterifying poly(vinyl alcohol) with an optically active acylamino-acid and determined the dependence of the optical activity on the degree of polymerisation and esterification. He found that the optical activity attained on introduction of a single optically active residue into the side-chain of the polymer is almost constant and independent of the degree of polymerisation and esterification of poly(vinyl alcohol).

In his study of the copolymers of styrene and (-)-menthyl acrylate, Schulz[4] found a rigorous proportionality between the optical activity and the content of the optically active component. This led him to the conclusion that there is no mutual influence of the asymmetric units in the chain. Thus the rotation of polymers and copolymers present as randomly twisted structures in solution may be used to determine their analytical composition.

The synthesis of optically active polymers containing asymmetric non-carbon atoms is of considerable interest. The only study in this field is the synthesis of the optically active poly-(+)-vinylphenyl-α-naphthylsilane achieved by Davydova et al.[26]; unfortunately the properties of the polymer are not described.

3. Polymerisation of Optically Active Propylene Oxide

One of the most thoroughly investigated optically active polymers is poly(propylene oxide) which was synthesised by Price et al. in 1956.[27] They showed that the polymerisation of the L-enantiomorph of propylene oxide takes place by an S_N2 mechanism in the presence of potassium hydroxide, first hydroxide and then alkoxide ions behaving as nucleophilic agents:



The reaction results in the formation of a fully crystalline isotactic polymer. In the presence of ferric chloride, however, a mixture of optically active crystalline and inactive amorphous polymers is obtained. Thus in the polymerisation in the presence of potassium hydroxide asymmetry is preserved to a high degree, while ferric chloride causes partial racemisation which is due to the rupture of the bond between the asymmetric carbon atom and oxygen.

Studies on the stereospecific polymerisation of propylene oxide and the relations between the type and structure of heterogeneous catalysts and the properties of the resulting polymers are of considerable interest. In this case an optically active label can also prove useful. The preservation or loss of optical activity on polymerisation of different enantiomorphs, the variation of the stereoregularity of the resulting polymers with the optical "purity" of the monomer, and also the relative rates of polymerisation of racemic and optically active propylene oxide permit the solution of a number of problems associated with the mechanism of stereoregulation (including the site where the epoxide ring is ruptured), with the chemical and stereochemical homogeneity of the active centres of the catalyst, etc.

The possible difference in the rates of polymerisation of racemic and optically active monomers was first pointed out by Kulkarni and Morawetz[28] in the polymerisation of methacryloyl and acryloyl derivatives of certain amino-acids (alanine and glutamic acid). However, a difference in the rates of polymerisation was actually observed in only one case: methacryloyl-DL-glutamic acid polymerised in the presence of benzoyl peroxide at a rate which was smaller by 5.6% than that of the polymerisation of the optically active compound.

Krylov and Livshits[29] made a theoretical analysis of the relative rates of polymerisation of the racemic monomers and the corresponding optically active compounds assuming different orders of the reaction with respect to the monomer. They demonstrated convincingly that in the stereospecific polymerisation of propylene oxide in the presence of magnesium oxide or oxalate as catalysts both enantiomorphs polymerise at the same rate which, for a first-order reaction, is twice as high as in the polymerisation of the racemate. This shows that, as was to be expected, the catalyst contains stereochemically indistinguishable centres.

To elucidate the mechanism of the asymmetrically induced polymerisation of propylene oxide on dialkylzinc–alcohol catalysts, Tsuruta et al.[30] studied the polymerisation of the monomer with different proportions of the D- and L-enantiomorphs. For comparison, the D- and L-enantiomorphs of propylene oxide were copolymerised in the presence of potassium hydroxide which is known to be a non-stereospecific catalyst. It was found that the plot of $[\alpha]_D$ for the polymer against $[\alpha]_D$ for the initial monomer is linear, both for the diethylzinc–methanol system and for potassium hydroxide. In both cases the rotation of the unreacted monomer was equal to that of the initial monomer regardless of the degree of polymerisation. To account for these results, the authors suggested that the catalytic system diethylzinc–alcohol contains two types of catalytic centre (D and L), but this cannot be regarded as evident even under the condition that "the racemisation which may occur when the monomer is incorporated in the polymer chain in the presence of the organozinc catalyst is of the same extent as in the presence of potassium hydroxide". It is interesting that the acetone-insoluble crystalline fraction of the polymer obtained on the organozinc catalyst has a higher value of $[\alpha]_D$ than the unfractionated polymer, while the soluble fraction has a lower value. The authors attribute this phenomenon to the preferential incorporation of the D-enantiomorph of propylene oxide in the crystalline polymer, so that its proportion is higher than in the initial monomer, but this is inconsistent with the hypothesis of the symmetrical distribution of the catalytic D- and L-centres.

Optically active polymers have also been obtained from propylene lactide[31], propyleneimine[32], conidine[33], and substituted caprolactams[34,35].

4. Effect of the Microtactic Structure of Macromolecules on the Optical Rotation of the Polymers

The use of optically active monomers gives rise to the possibility of a new approach to the study of the microstructure of the resulting polymers. Studies in this field have been begun recently by Schulz and Hilpert[36] who obtained a number of (-)-poly(bornyl acrylates) under conditions of radical and ionic polymerisation and investigated the curves representing the variation of the optical rotatory dispersion (ORD curves) of the polymers. Previously ORD curves were used mainly to observe the increase in the optical rotation of the polymers in the short-wavelength part of the spectrum, this serving as an indication of asymmetric synthesis of the macromolecules[37,38]. However, these curves can also provide useful information about the microstructure of the optically active polymers.

Klabunovskii et al.[39] used the data of Arcus and West[6] to find the constants A and λ_0 in the Drude equation. We may recall that the Drude equation is

$$[\alpha]_\lambda = \frac{A}{\lambda^2 - \lambda_0^2},$$

where λ_0 is the wavelength corresponding to the optically active electronic transition, λ the actual wavelength used, A the rotational constant proportional to the rotatory power associated with the transition, and to $(n^2 + 2)/3$, where n is the refractive index of the solvent.

It was shown that variation of the duration of the reaction, polymerisation temperature, and the molecular weight of (+)- and (-)-poly(1,3-dimethylbutyl methacrylates) changes slightly the rotational constant A but has no effect on λ_0. The radical initiator used has almost no influence on A and λ_0.

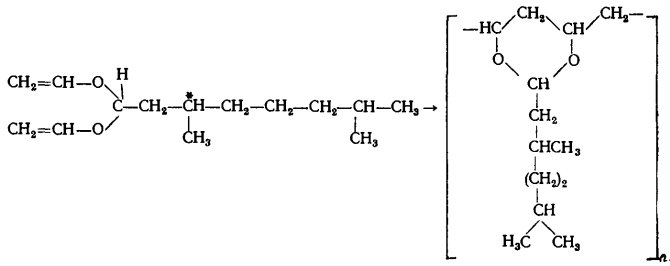
The spectropolarimetric method has been used to study the structure of polymers obtained by radical and anionic polymerisation of (+)-2-methylbutyl methacrylate[39]. It was found that λ_0 for polymers is close to the value for the monomer (about 190 nm). The values of A for the polymers obtained by radical and anionic mechanisms are significantly different and consistent with the data of Arcus and West[6].

However, Klabunovskii et al.[39] arrived at the incorrect conclusion that the stereoregularity of the polymer obtained by the radical mechanism is higher than that of the polymer obtained in the presence of a Grignard reagent. This was shown by Japanese investigators[40] in infrared and NMR spectroscopic studies of poly(methacrylic acid) obtained by the hydrolysis of the corresponding esters. By a similar treatment of ORD curves for propylene oxide polymers synthesised from L- and D-enantiomorphs in chloroform and methanol, Livshits[41] showed that the experimental curves are described by the Drude single-term equation. Polymers with greater stereoregularity give rise to higher values of A, determined by the optical activity at the sodium D-line.

The experimental data available at the present time are inadequate for the determination of the variation of the parameters defining the ORD curves as a function of the

stereoregularity of the polymers. To obtain more accurate values of the optical rotation, a correction for the dispersion of the refractive index of the medium must be applied to the observed specific rotation $[\alpha]$. Then the differences in the value of A should be consistent with the differences in the overall rotatory power associated with the optically active electronic transitions in polymers of various stereoregularities.

Abe and Goodman[42] showed that, depending on the method of polymerisation of the divinyl acetal of (+)-3,7-dimethyloctanal, the sign of the optical rotation of the resulting polymers can change:



A low-molecular polymer with optical activity close to that of the monomer and the model compound diethyl acetal of (*R*)(+)-citronellal was obtained by radical polymerisation. Cationic polymerisation in the presence of boron trifluoride–ether or aluminium chloride–ether gives solid high-molecular products with rotation of the opposite sign in the same solvent. It is interesting that the optical rotation of these polymers, like that of the (-)-poly(propylene oxide), decreases on going from benzene to chloroform solutions.

The authors attribute the difference in the rotation of substituted polydioxans to the different stereoregularity of the polymers. In this case it is reasonable to expect that the polymer obtained by the cationic mechanism has the greater stereoregularity.

The converse is also true, namely that polymers with the same chain microstructure should have the same optical rotation. Schulz[4] found that the optical activity of polyacrylates obtained by the radical mechanism and under the action of γ-radiation at -8° is the same. On this basis, he arrived at the incorrect conclusion that the polymerisation of acrylic acid esters in the amorphous, vitreous state under the action of γ-radiation involves a radical mechanism. Here the equality of the optical rotations of the polymers implies only that the microtactic structure of the chains is the same and that in both cases the polarisation is probably equally non-specific.

5. The Use of the Optically Active Label in the Study of Polymerisation Kinetics

In their study of the radical polymerisation of optically active (+)-s-butyl β-chloro(β-bromo)acrylates and vinyl (-)-β-phenylbutyrate in 1940, Marvel et al.[43] observed that the polymers have rotations which differ from those of the initial monomers by 9–12°. This difference was used to study the polymerisation kinetics.

Klabunovskii et al.[44] used a polarimetric method to study the kinetics of the radical polymerisation of the optically active esters of methacrylic and itaconic acids. The polarimetric study of polymerisation kinetics in homogeneous solutions may prove of value in certain cases, provided that the specific rotations of the monomer and the polymer differ appreciably.

III. SYNTHESIS OF OPTICALLY ACTIVE POLYMERS FROM OPTICALLY INACTIVE MONOMERS

1. The Concept of the Asymmetric Synthesis of Macromolecules

The asymmetric synthesis of macromolecules implies that in polymerisation induced by asymmetric agents there is either a selection of one enantiomorph from a monomer which consists of a racemic mixture and a fixation of these configurations in the polymer chain or formation of new asymmetric centres with a definite configuration on dissociation of a double bond or ring opening and their fixation in the macromolecular chain.

As in the case of low-molecular substances, asymmetric synthesis or asymmetric induction‡ of macromolecules can be divided into absolute and partial. By absolute asymmetric synthesis, the present author understands the synthesis of optically active substance in the absence of other optically active chemical agents (for example, under the action of circularly polarised light). Asymmetric syntheses involving the participation of auxiliary optically active substances are called partial asymmetric syntheses.

Together with partial asymmetric synthesis, in which new asymmetric centres are induced by asymmetric agents, it is also necessary to distinguish asymmetric kinetic separation. The latter term means preferential conversion or decomposition in a given reaction of one of the components of a racemic mixture because this component is formed or reacts more rapidly than the other. This follows from the fact that the two transition states are diastereoisomeric, their free energies of formation being different.

In connection with the polymerisation of racemic monomers, this means that, in the presence of optically active catalysts, preferential formation of one of the following two enantiomorphic chains is possible:

$$(R+S)\xrightarrow[\text{catalyst}]{\text{optically active}}\text{or}\ \begin{matrix}RRRR\ \ldots\\ SSSS\ \ldots\end{matrix}.$$

The unreacted monomer becomes enriched in the enantiomorph of the opposite sign to that incorporated in the chain. This type of polymerisation is called stereoelective[45].

When a racemic monomer is copolymerised with one of the enantiomorphs of another monomer, two chains can be formed, one of which contains only monomers in the (*R*)-configuration and the other only monomers in the (*S*)-configuration, i.e. a copolymer (*RRR*'...) and a homopolymer (*SSS*...) are formed:

$$(R+S)+R'\text{–}\begin{matrix}\nearrow RRR'R'R'RR\ \ldots\\ \searrow SSSSS\ \ldots\end{matrix}.$$

‡ There is no agreement in the literature concerning the use of these terms. In the present review they will be used to indicate the formation of both a new asymmetric atom and asymmetric molecular chains under conditions in which two stereoisomers are formed in unequal amounts.

This unusual type of copolymerisation is called stereoelective copolymerisation[45]. Stereoselective polymerisation must be distinguished from stereoelective polymerisation; the former consists in the polymerisation of racemic monomers in the presence of symmetrical catalysts with separation of the enantiomorphs during polymerisation and the formation of two enantiomorphic chains:

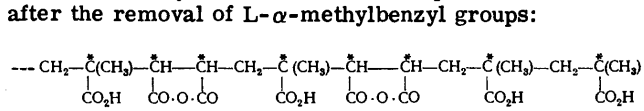
$$(R+S)\begin{cases}\nearrow RRRR\ldots\\ \searrow SSS\ldots\end{cases}$$

2. Asymmetric Synthesis of Macromolecules

Only one unsuccessful attempt to achieve absolute asymmetric synthesis, in the photo-polymerisation of styrene and copolymerisation of styrene with maleic anhydride under the action of polarised β-radiation[46], has been described. One of the possible ways of achieving partial asymmetric synthesis consists in the polymerisation of a monomer, which is optically active due to a substituent, with subsequent removal of the optically active side-groups from the final polymer. The question then arises how the optically active side-groups of the monomer influence the stereospecificity of the polymerisation. If the optically active monomer is the first unit of the growing chain, the next unit can add on either in the iso-position (DDD- or LLL-, where D and L represent the configurations of the asymmetric carbon atoms in the main chain) or in the syndio-position (DLD- or LDL-). The adducts of the monomer and the initiating radical or ion are no longer enantiomorphs but diastereoisomers, the rates of formation of which are always different. Thus the presence of optically active groups in the monomer gives rise to the potential possibility of the formation of a polymer with an optically active main chain. Whether or not the polymer or copolymer is optically active after the removal of the optically active side-groups depends on the symmetry or asymmetry of the chain formed. This problem was discussed in detail in section I, where it was shown that the primary structures of vinyl polymers are symmetrical. The secondary structure also becomes symmetrical after the removal of the optically active groups.

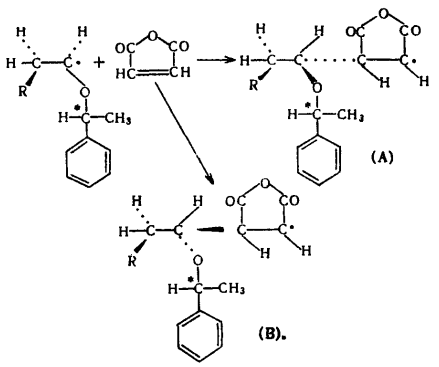
The numerous attempts to prepare optically active polymers in this way proved to be unsuccessful. Thus homopolymerisation of (+)-fluorobutyl *p*-vinylbenzoate[47], (+)-*o*-(s-butylthiomethyl)styrene[48], and (-)-1-phenylethyl methacrylate[49] and the copolymerisation of (+)-*o*-(s-butylthiomethyl)styrene with methyl methacrylate[48], followed by the removal of the optically active groups, yielded optically inactive products.

The simplest possibility of asymmetric induction is the copolymerisation of any optically active monomer with a second monomer, a disubstituted olefin, in which asymmetric carbon atoms can arise during the reaction. The copolymerisation of a usual vinyl monomer with a disubstituted olefin gives rise to three asymmetric atoms with four different substituents in its immediate vicinity. Using an optically active comonomer, it is possible to control the configuration of the induced asymmetric atoms. Thus using radical initiation, Beredjick and Schuerch[49] obtained a copolymer of L-α-methylbenzyl methacrylate and maleic anhydride which exhibited positive rotation after the removal of L-α-methylbenzyl groups:



Schmitt and Schuerch[50] obtained a laevorotatory copolymer (28.5°) by the free-radical copolymerisation of maleic anhydride with L-α-methylbenzyl vinyl ether.

The mechanism of asymmetric induction can be represented as follows:



Immediately after the first step involving the addition of two comonomers two diastereoisomeric radicals (A) and (B) are formed regardless of the configuration of the asymmetric carbon atom in the side-chain of the active component. For this reason, the rates of their formation (and further growth) must be different. During polymerisation one of the configurations of the induced asymmetric atoms is formed in excess and the corresponding copolymer exhibits optical activity even after the removal of the asymmetric side-groups. The attempt to achieve asymmetric synthesis with the aid of optically active acyl peroxides resulted in the formation of optically inactive polymers[51]. Frisch et al.[52] demonstrated theoretically that under the conditions chosen the effect of the asymmetric catalyst weakens after several chain-growth steps and therefore the specific rotation of the polymer decreases with increase in the degree of polymerisation. The situation is different in those cases where in each chain-growth step the asymmetric agent is near the growing end. This type of selection of the monomer with a specified configuration, as it approaches the growing end of the polymer chain, can be achieved by selective adsorption of the monomer on the surface or the formation of asymmetric complexes. Thus a surface or complexing agents are very important for asymmetric synthesis.

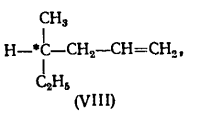
In their study of the theoretical aspects of asymmetric synthesis, Frisch et al.[52] analysed two different modes of asymmetric induction. In the first hypothesis (hypothesis of asymmetric initiation) it is assumed that the asymmetric agent influences only the first addition step and induces the formation of D-enantiomorphs with a probability different from that of the formation of the L-enantiomorphs. After the first addition step the probability of the persistance of the D- and L-configurations is the same, $k_{DD} = k_{LL}$ but $k_{DD} \neq k_{DL}$, where k_{DD}, k_{LL}, and k_{DL} are the rates of formation of the sequences DD, LL, and DL. In this case the optical activity of the polymer is inversely proportional to chain length and tends to zero for polymers with a high molecular weight.

The second hypothesis (hypothesis of asymmetric growth) postulates chain growth such that in each growth step the probability of addition in a given sequence is different from that in another sequence ($k_{DD} \neq k_{LL}$). The optical activity is independent of molecular weight and directly

proportional to the degree of asymmetric induction transmitted by the catalytic system. Qualitatively asymmetric induction should be most effective when the difference in the size of the substituents at the asymmetric centre of the molecule is large and the induced centre is as close as possible to the one already present.

3. Polymerisation of Racemic Monomers on Optically Active Catalysts

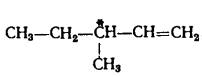
To assess the first hypothesis of asymmetric induction, Pino[53] studied the polymerisation of racemic 4-methylhex-1-ene (VIII),



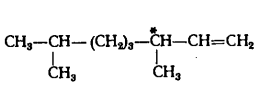
(VIII)

on a complex catalyst (based on titanium tri- and tetrachloride and optically active organometallic compounds) and compared the optical activities of the resulting polymers with the optical activity of certain polypropylene and polystyrene fractions prepared in the presence of the same catalysts. In the case of polypropylene and polystyrene only low-molecular fractions proved to be active, the optical activity decreasing rapidly with increasing molecular weight of the fraction. The optical activity of the low-molecular polymers of 4-methylhex-1-ene was much higher than that of the styrene and propylene polymers but smaller by a factor of 10–100 than the value for the optically active poly-(*S*)-4-methylhex-1-ene. The unreacted monomer proved to be inactive. The most likely explanation of the low activity of the polymers is that the optically active alkyl group of the catalyst or the first monomer unit do not determine the type of enantiomorph selected preferentially for the construction of the macromolecule, i.e. both monomer enantiomorphs are polymerised at almost the same rate. At the same time the optical activity of poly-4-methylhex-1-ene fractions obtained in the presence of catalysts based on the optically active zinc alkyl Zn(iso-C_5H_{11})$_2$ and titanium tetrachloride proved to be very high. Probably here the optical activity is not determined solely by that of the catalyst group but also by the asymmetric induction due to the first monomer unit.

The chemical structure of the monomer has a significant effect on the type of asymmetric induction. Thus in the polymerisation of racemic 3-methylpent-1-ene (IX) and 3,7-dimethyloct-1-ene (X)[54],



(IX)



(X)

where the asymmetric carbon atoms are in the α-position relative to the double bond, on the catalytic system comprising titanium tetrachloride and di[(*S*)-2-methylbutyl]zinc, polymers with considerable optical activity are formed. The optical activity of the polymer fraction increases with increasing molecular weight and melting point of the fraction, i.e. the findings are typical of asymmetric chain growth. When the degree of polymerisation of both monomers (IX) and (X) was between 7 and 22%, the unreacted monomer had appreciable optical activity. The sign of the rotation of the monomer showed that in this case the monomer enantiomorph having the same absolute configuration as the (*S*)-2-methylbutyl groups of the catalytic system was mainly incorporated in the chain. The ratios of the rates of polymerisation of the two enantiomorphs were calculated from the optical activity of the unreacted monomer and the percentage polymerisation of the monomer. It was found that the monomer with the (*S*)-configuration of the asymmetric carbon atom in the side-group polymerises 1.2–1.7 faster than the corresponding (*R*)-monomer.

The sign of the rotation of the polymers is consistent with that predicted on the basis of the absolute configuration of the preferentially polymerised monomer enantiomorph. Thus the considerable differences observed in the polymerisation of racemic 4-methylhex-1-ene, 3-methylpent-1-ene, and 3,7-dimethyloct-1-ene confirm the importance of the effect of the monomer structure on the stereospecificity of polymerisation. It may be concluded that the catalytic system titanium tetrachloride + di[(*S*)-2-methylbutyl]zinc is capable of polymerising electively one enantiomorph of a racemic α-olefin with the asymmetric carbon atom in the α-position relative to the double bond, but the electivity of this catalyst is extremely low when the asymmetric atom is in the β-position.

The stereoelectivity of the catalytic system depends also on the bond between the metal and the optically active group in the organometallic component[45]. Thus in the polymerisation of 3,7-dimethyloct-1-ene appreciable stereoelectivity is observed only with the organozinc compound [the ratio of the rates of polymerisation of the enantiomorphs in the presence of the zinc catalyst is 1.22; in the presence of organoaluminium and organoindium compounds no appreciable differences in the rates of polymerisation of (*R*)- and (*S*)-enantiomorphs are observed]. The author's explanation is that among all the organometallic compounds only the organozinc compound exchanges slowly its alkyl radical for the monomer.

In the study of the crystal structures of the polymers obtained from optically active and racemic α-olefins it was observed that the structures of poly-3-methylpent-1-enes and poly-4-methylhex-1-enes[14] are identical, but the structure of poly-(*S*)-5-methylhept-1-ene[13] is different from that of its racemic analogue. The structural identity of the polymers of (*S*)-4-methylhex-1-ene and the racemic 4-methylhex-1-ene confirms the theoretical prediction that the polymer formed from the racemic monomer is not a random copolymer of the two enantiomorphic monomers but is a mixture of two types of macromolecules. This was demonstrated by the chromatographic separation of the racemic polymer (fraction soluble in ether) on optically active poly-(*S*)-3-methylpent-1-ene[55]. On elution with ether several polymer fractions were isolated, the first having a molar rotation $[M]_D = -17.5°$ and the last being dextrorotatory with $[M]_D = +62.5°$. This study provides one of the most important demonstrations of the stereoselective polymerisation of a racemic monomer. In addition, the possibility of such separation of a polymer implies that in the isotactic growth of each macromolecule stereospecific catalysts can select preferentially one of the enantiomorphic forms of the racemic monomer, even when the asymmetric carbon atom is not directly linked to the double bond of the monomer.

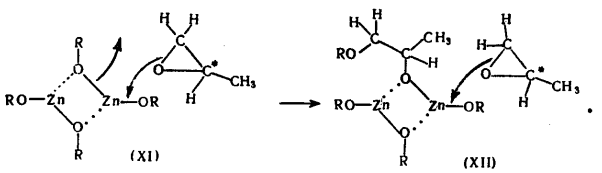
The identity of the crystal structures of the polymers obtained from different enantiomorphs and racemates of propylene oxide[27] and 2-methylbutanal[18] also indicates the stereoselectivity of the polymerisation of these monomers.

This is demonstrated directly by the successful separation of crystalline poly[(±)-propylene oxide][56] on poly[(-)menthyl glycidyl ether] into two fractions with $[\alpha]_D^{15} = -6.7° \pm 1.7°$ and $[\alpha]_D^{15} = +6.4° \pm 1.1°$.

Inoue et al.[57] described the synthesis of optically active poly(propylene oxide) using the racemic monomer and diethylzinc with optically active cocatalysts [(-)-menthol, (-)-borneol]. The optical "purity" of the polymers, determined from the specific rotation, was not more than 20%.

The occurrence of asymmetric induction was confirmed[58] by the isolation from the reaction mixture of the optically active unreacted monomer, the sign of whose rotation was opposite to that of the rotation of the monomer, preferentially incorporated into the polymer chain. It was found that, when (+)-borneol is used as the cocatalyst, L-(+)--propylene oxide is preferentially incorporated into the polymer chain.

Having analysed the optical rotations of the polymer and the unreacted monomer, Inoue et al.[59] concluded that the rotatory power of the polymer formed on the diethylzinc–(+)-borneol system is due to the preferential polymerisation of the L-enantiomorph of propylene oxide. In the initiation step propylene oxide molecules are coordinated to the catalyst, which is a cyclic dimer (XI), and are then incorporated at the site of the rupture of the Zn–O bond[60]. Chain growth proceeds according to the mechanism



(XI) (XII)

When the catalyst does not have asymmetric centres, k_{iL} should be equal to k_{iD} and the reaction should yield a mixture of polymeric molecules with a definite symmetrical distribution of tacticity in which the proportions of the L- and D-monomeric units in the chain range from 100% L to 100% D. If the catalyst contains optically active groups, the rate constant k_{iL} will differ from k_{iD}. For the system diethylzinc–(+)-borneol, $k_{iL} > k_{iD}$ and therefore L-monomeric units predominate in the polymer; also $k_{LL} > k_{LD}$. This example confirms the hypothesis of asymmetric growth.

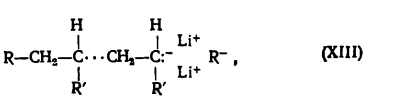
Stereoelective polymerisation of racemic propylene oxide was also achieved by Livshits and Krylov[61] on a heterogeneous stereospecific catalyst — magnesium D-tartrate. Interesting results were obtained by Furukawa and coworkers[62] in the polymerisation of racemic propylene oxide on Pruitt and Baggett's catalyst[63], prepared by the partial hydrolysis of the ferric chloride complex of propylene oxide in the presence of D-bornyl ethyl ether. The unreacted monomer was enriched in the L-enantiomorph of propylene oxide; however, the polymer did not show optical activity although it was a mixture of the crystalline isotactic fraction with a small proportion of amorphous polymer.

Observations of fundamental importance were also made in the study of the adsorption of racemic propylene oxide on an asymmetric catalytic system at a low temperature (under conditions where there is no polymerisation). After being added to the catalyst, the racemic monomer was distilled off in a vacuum. After that triethylamine was added to the residue and the volatile products were again distilled. Measurements of the optical activity showed that the propylene oxide in the first distillate was enriched in the L-monomer and in the second distillate in the D--monomer. Kinetic study of the reaction showed that the observed ratio of the D- and L-enantiomorphs of propylene oxide in the adsorbed monomer is consistent with the ratio of the rates of polymerisation of the enantiomorphs on the given catalytic system. On this basis, it was concluded that the chain growth consists of two stages, adsorption (coordination) and ring opening, and that the inequality of the rates of polymerisation of the enantiomorphs of propylene oxide is mainly due to the difference in the rate of adsorption. However, a final explanation of the lack of optical activity of the polymer was not obtained.

The polymerisation of the *N*-carboxy-anhydride of D- and L-alanine[64] in the presence of a number of asymmetric catalysts [(+)-borneol, (-)-menthol, $Al(C_2H_5)_3$–(+)-borneol, etc.] gave optically active water-soluble polyalanine fractions. Matsuura et al.[65] attempted to carry out the asymmetrically induced copolymerisation of propylene oxide and a cyclic anhydride with an asymmetric carbon atom (the anhydride of 3-phenyl-Δ_4-tetrahydrophthalic acid) on the diethylzinc–(+)-borneol catalytic system. To elucidate the possibility of the asymmetric selection of one or both monomers in the copolymerisation, measurements were made of the optical activity of the unreacted propylene oxide and the anhydride and also the hydrolysis products of the polyester which had regularly alternating propylene glycol–dicarboxylic acid ester units. It was found that the unreacted anhydride (in the form of ester) has positive rotation and the dicarboxylic acid negative rotation, while the unreacted propylene oxide and propylene glycol are optically inactive. The authors suppose that the preferential selection of one of the enantiomorphs of the anhydride is due to the specificity of the catalytic centres to a greater extent than to the "asymmetrising" influence of the preceding propylene oxide unit.

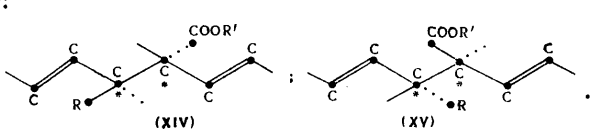
4. Asymmetric Synthesis of Polymers from Monomers without Asymmetric Centres

The preparation of optically active polymers from monomers without asymmetric centres was a considerable advance in the field of asymmetric synthesis. The polymerisation of dienes and monomers of the vinyl and acrylic types can be stereoregulated by using as catalysts lithium or sodium alkyls or aryls in a homogeneous solution. In such cases the end of the growing chain is an ionic quadrupole[66] of the type



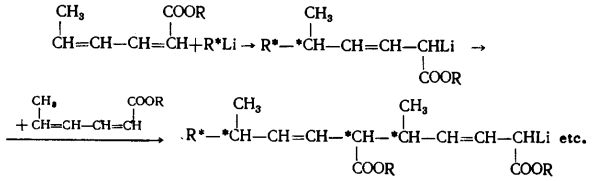
(XIII)

rather than an ion pair. The ionic quadrupole forms a complex with the monomer molecule and controls its incorporation into the growing chain. The polymerisation of dienes substituted in positions 1 and 4, in which on partial dissociation of double bonds two asymmetric carbon atoms arise simultaneously in each unit, was achieved in this way:



(XIV) (XV)

An example is the polymerisation of the esters of sorbic acid and its derivatives and of styrylacrylic acid in the presence of an optically active catalyst — methylbutyl-lithium[67] (Table 2). The polymerisation of sorbic acid esters proceeds according to the following mechanism:



The optically active group of the catalyst plays the role of the "asymmetrising" agent which effects asymmetric induction in the formation of the first asymmetric centre in the chain. Subsequently this function is assumed by the polymer chain whose end forms part of the catalytic complex during the growth process. The catalytic complex ensures the selective incorporation in the chain of units having the 1,4-*trans*-configuration and induces the formation of one of the enantiomorphic forms of the macromolecule.

It must be emphasised that both stereospecific polymerisation and asymmetric synthesis in the presence of anionic homogeneous catalysts are carried out at as low temperatures as possible (between -20° and -80°) at which the number of possible conformations of the monomer molecules is greatly reduced and the monomer–catalyst complexes are more stable. In such cases it is to be expected that the conformation of the terminal groups or of the first monomer unit will influence the configuration of the subsequent monomer units. Reduction of temperature significantly increases the stereospecificity of asymmetric synthesis also in the case of small molecules.

When the polymer was decomposed by oxidative cleavage of the double bond, optically active di- and tri-carboxylic acids were isolated, which means that the optical activity of the polymers is of a configurational type, i.e. it is related to the presence of asymmetric carbon atoms in the main chain. This method makes it possible to determine the optical "purity" of polymers, provided that oxidation is not accompanied by partial racemisation of the acids.

In the presence of racemic lithium alkyls a polymer consisting of a mixture of two enantiomorphic forms is obtained. This polymer is optically inactive.

TABLE 2. Unsaturated esters used as monomers in asymmetric syntheses.

Monomer	Formula of the monomer and the corresponding monomeric unit
Esters of β-vinylacrylic acid (penta-dienoic acid)	$CH_2=CH-CH=CH-COOR$ → $\sim CH_2-CH=CH-\overset{*}{C}H(COOR)-CH_2-CH=CH-\overset{*}{C}H(COOR)\sim$
Esters of sorbic acid (hexa-2,4-dienoic acid)	$CH_3CH=CH-CH=CHCOOR$ → $\sim (CH_3)\overset{*}{C}H-CH=CH-\overset{*}{C}H(COOR)-\overset{*}{C}H(CH_3)-CH=CH-\overset{*}{C}H(COOR)\sim$
Esters of β-styrylacrylic acid (5-phenyl-pentadienoic acid)	$C_6H_5CH=CH-CH=CHCOOR$ → $\sim \overset{*}{C}H(C_6H_5)CH=CH-\overset{*}{C}H(COOR)\cdot\overset{*}{C}H(C_6H_5)\cdot CH=CH\cdot\overset{*}{C}H(COOR)\sim$ (R = methyl and butyl)

A further advance was the use of a cocatalyst as the "asymmetrising" agent instead of the catalyst itself. This was done in the polymerisation of sorbic acid esters in the presence of an inactive catalyst and ethyl (-)-menthyl ether as an optically active additive[68]. This gave an optically active polymer with the same specific rotation as that obtained in the presence of an optically active lithium alkyl.

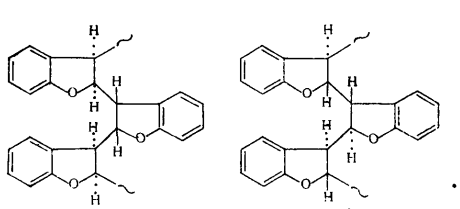
The original studies on the stereospecific polymerisation of *trans*-penta-1,3-diene using an optically active label were carried out by Natta and Porri[69]. This monomer gives rise to two types of crystalline polymer with 1,4--units. The polymerisation of the diolefin in the presence of an organometallic homogeneous catalyst yields a syndiotactic *cis*-1,4-polymer without optical activity as a result of internal compensation, while on a heterogeneous catalyst (based on vanadium trichloride and optically active tri--isopentylaluminium) the product was an optically isotactic *trans*-1,4-polymer.

Systematic study of the optical activity of the polymers obtained under different conditions in the presence of various catalysts can provide useful information about the reaction mechanism and in particular about the structure of the stereoblock-copolymers.

Another study of the same workers and Valenti[70] dealt with the elucidation of the nature of the active centres on heterogeneous Ziegler catalysts. A comparison was made of the capacities of two types of optically active catalysts of the coordination type to induce asymmetry in isotactic poly-*cis*-penta-1,4-diene: (1) (+)-tri-(2-methylbutyl)-aluminium and tetrabutoxytitanium; (2) triethylaluminium and (-)-tetramethoxytitanium. It was found that the polymers obtained in the first catalytic system were optically inactive, while polymers of both low and high molecular weight synthesised in the presence of the second catalyst did show optical activity. Thus asymmetric induction can be explained by supposing that, before being incorporated in the polymer chain, the monomer is coordinated to the organotitanium component whose asymmetric group influences the configuration of the asymmetric carbon atom in the monomer about to be incorporated.

Aliev and Krentsel'[71] achieved the asymmetric polymerisation of *trans*-1-phenylbuta-1,3-diene using two catalysts — (*R*)(+)-2-methylbutyl-lithium and a complex of n-butyl-lithium with (-)-menthylethanol. In the polymerisation with (*R*)(+)-2-methylbutyl-lithium asymmetric initiation took place, while in the presence of the optically active cocatalyst the polymerisation proceeded by the mechanism involving asymmetric chain growth. The degree of asymmetric induction was characterised by the rotational constant *A*, and it was shown that this quantity varies with the method and conditions of polymerisation.

The preparation of optically active polybenzofuran was a considerable advance in the field of asymmetric synthesis of macromolecules[72,73]:



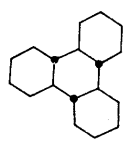
Di-isotactic polybenzofuran was obtained on the cationic catalyst $Al(C_2H_5)Cl_2$ in the presence of optically active co-catalysts: (-)-β-phenylalanine, (+)-β-phenylalanine, (-)-brucine, and others.

The polymerisation of benzofuran involving the opening of the double bond in the heterocyclic ring results in the formation of two possible diastereoisomeric units: *threo*- and *erythro*-di-isotactic units. Since polybenzofuran was not obtained in the crystalline state, the type and conformation of the chain could not be determined. However, the observed optical activity of the polymers indicates the presence of chains or sections of chains having the *erythro*- or *threo*-di-isotactic structure, since only these, among the simplest and most probable structures, would give rise to enantiomorphic chains. In *erythro*- and *threo*-di-isotactic structures all the carbon atoms in the chain are asymmetric and internally non-compensated.

The asymmetric carbon atoms of polybenzofuran exhibit an unusual type of asymmetry and cannot be assigned to the *R* or the *S* type in the nomenclature of Cahn et al.[74], whereby the configuration of the asymmetric carbon atom is established using the rule of the seniority of substituents. Indeed the carbon atom in the polybenzofuran chain in the α-position relative to the oxygen atom is linked to hydrogen, oxygen, and two carbon atoms, which are identical but belong to two different rings. A similar situation obtains also for the β-carbon atom.

To determine the seniority of the apparently identical substituents in the polycyclic compound, Farina and Bressan[75] introduced a new rule, which can be formulated as follows: if two substituents in a polycyclic compound belonging to different rings are identical in accordance with previous rules, the substituent belonging to the same ring as the given asymmetric atom is senior to the substituent linked to the external ring (the *endo*-substituent is senior to the *exo*-substituent).

We may note that a new stereochemical rule is general for polycyclic compounds (both low- and high-molecular) with the above type of asymmetry. For example, the absolute configuration of the isomers of perhydrophenylene[76], which has six asymmetric carbon atoms with a type of asymmetry similar to that found in polybenzofuran, was established on the basis of this rule:



(*R*)-*trans*-*anti*-*trans*-*anti*-*trans*-perhydrophenylene.

Best results were obtained in the asymmetric polymerisation of benzofuran using the system aluminium chloride–(-)-β-phenylalanine (component ratio 3 : 1).[75] During the polymerisation the catalyst, cocatalyst, and the end of the growing chain form part of the catalytic complex which effects asymmetric induction in each fundamental chain-growth step. In contrast to polysorbates, at the end of the reaction the macromolecules do not contain chemically combined components of the catalyst.

The product $[\alpha]n$, where n is the degree of polymerisation and $[\alpha]$ the specific rotation of a single monomeric unit, is proportional to the number of monomeric units, with rotation of a given sign, present in excess. If the hypothesis of asymmetric growth is valid, the relation between $[\alpha]n$ and n should be linear, while in the case of asymmetric initiation the relation should be represented by a curve tending to a limit.

On the other hand the quantity $W[\alpha]$, where W is the total weight of polymer per mole of catalyst, represents the total contribution of asymmetric synthesis in the polymerisation reaction. The study of the variation of $W[\alpha]$ with the amount of initiator in the polymerisation of benzofuran in the presence of aluminium chloride and (+)- and (-)-β-alanine showed that $[\alpha]$ decreases and $W[\alpha]$ tends to a limit, which confirms the hypothesis of asymmetric initiation. However, it is possible that during the polymerisation the counterion is racemised. The mechanism based on this hypothesis can explain both asymmetric growth and the disappearance of asymmetric induction, caused by the alteration in the counterion during the polymerisation process.

Schmitt and Schuerch[77] studied the cationic polymerisation of a number of unsaturated compounds: 4,5-dihydro-2-methylfuran, indene, α-angelica lactone, and cyanocyclopentene in the presence of boron fluoride and different additives, namely (-)-α-methylbenzyl alcohol, toluenesulphonyl-L-valine, and (+)-camphor. The resulting polymers contained asymmetric carbon atoms in the main chain but did not show optical activity. Examination of the molecular models of these polymers showed that in all cases syndiotactic structures are formed, which explains the absence of optical activity.

Thus we see that asymmetric synthesis of macromolecules can be achieved using the same methods of stereoregulation as in the usual stereospecific polymerisation (heterogeneous catalysis with anionic initiation for polyhydrocarbons, ionic initiation in solution at a low temperature for sorbic acid esters, benzofuran, and propylene oxide).

IV. MODIFICATION OF OPTICALLY INACTIVE POLYMERS BY LOW-MOLECULAR OPTICALLY ACTIVE COMPOUNDS

One of the methods for the preparation of optically active polymers is modification of optically inactive polymers by optically active low-molecular compounds. Thus a number of optically active polymeric salts were obtained by allowing optically active acids and bases to act upon optically inactive polyelectrolytes[4,78]. Comparison of two specimens of polyacrylic acid, obtained by the polymerisation of the monomer[79] and the hydrolysis of the anhydride of polyacrylic acid[80], shows that they are completely identical as regards infrared spectroscopic data and the content of carboxy-groups. At the same time the specific rotations of their salts with the optically active alkaloid quinine are different[4]. Probably the difference is due to the different microtactic structures of the initial polyacrylic acids. Thus the optically active label proved to be the most sensitive method for the detection of a difference in the microstructure of a polyelectrolyte.

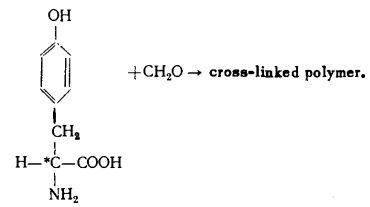
V. PREPARATION OF OPTICALLY ACTIVE POLYMERS BY POLYCONDENSATION

In principle the polycondensation method does not provide a possibility of inducing the formation of new asymmetric centres in monomers — it can only alter the environment of the already existing asymmetric atoms. There

remain two possibilities — one can use optically active monomers (pairs of monomers) or one can carry out asymmetric stereoelective polycondensation during which the optically active component incorporates selectively into the polymer chain one of the enantiomorphs of the other component which is present as a racemate:

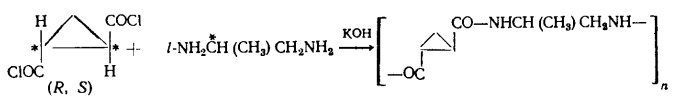
$$R + (R' + S') \rightarrow RR'RR'RR'RR' \ldots\ldots$$
$$\text{or } RS'RS'RS'RS' \ldots\ldots$$

Losse and coworkers[81] obtained an optically active cross-linked polymer by the polycondensation of L-tyrosine with formaldehyde:



This product is insoluble in organic solvents and it is impossible to determine its rotation. It exhibits ion-exchange properties and may be used for the separation of racemates by virtue of its asymmetric carbon atoms. The use of synthetic optically active polymers for the separation of racemates has also been described by other workers[82,84]. Other examples of the synthesis of optically active polymers by polycondensation may be adduced.[85,92] The greatest interest attaches to the synthesis of polycondensation polymers by kinetic racemate separation. Several examples of successful separation of low-molecular racemic compounds by this method are described in the literature. Markwald and Meth[93] described the separation of racemic mandelic acid in the formation of its (-)-menthylamide; Markwald and McKenzie[94] achieved the separation of the same acid in its esterification with (-)-menthol and (-)-borneol.

An attempt to carry out a reaction of a similar type under polycondensation conditions was made for the first time by Topchieva et al.[95], who investigated the system (-)-propylenediamine–racemic *trans*-cyclopropane-1,2-dicarboxylic acid dichloride (containing two asymmetric centres in the molecule). The optically active polymer was synthesised by interfacial polycondensation:



In order to determine whether or not one of the enantiomorphs of *trans*-cyclopropane-1,2-dicarboxylic acid is selected kinetically, a study was made of the optical activity of the acid which failed to undergo polycondensation and the acid isolated after hydrolysis of the polymer. In both cases the optical activity proved to be zero. Control experiments demonstrated that the absence of optical activity in the acid specimens is not due to secondary racemisation processes. Thus it was established that the selection effect does not occur. Application of the usual methods of stereospecific polymerisation, reaction carried out at low temperatures, in the presence of complexing agents, and on the surface of adsorbents, also failed to give the expected results[96]. Probably further advances in the study of such a system (optically active diamine–racemic acid chloride) will involve the study of the microstructure of the polyamide which may throw light on the specific features of this reaction.

VI. OPTICALLY ACTIVE POLYMERS AS CATALYSTS

One of the most interesting applications of optically active polymers is their use as catalysts. Enzymes, which consist of proteins, i.e. optically active polymers of α-amino-acids, constitute a notable example of highly specific catalysts of chemical reactions in living organisms under very mild conditions. The catalysts employed in chemistry are only effective under more severe conditions and show little specificity.

The chemical composition of proteins does not explain this superiority of enzymes over synthetic catalysts. It is known that the groups in the side-chains of proteins (thiol, imidazole, indole, and others) can behave as catalysts in some cases, but their catalytic activity is very low. The problem arises how these groups acquire such exceptional properties when they are incorporated into the composition of a giant protein molecule.

In the attempts to find the answer to this question a number of model reactions using low-molecular compounds as analogues of enzymic systems have been discovered. The mechanisms put forward for these reactions are based on the concepts of electron density and steric hindrance adopted in organic chemistry. Probably, for a more profound understanding of model reactions, it will be of interest to use high-molecular compounds with functional groups, which are closer analogues of enzymes than low-molecular compounds.

In the light of what has been said above, the importance of the new technique based on the use of optically active polymers as catalysts of chemical reactions becomes clear.

Two ways of employing optically active polymers may be distinguished: (1) in the stereospecific catalysis of reactions involving low-molecular compounds; (2) in catalytic stereospecific synthesis of high-molecular compounds. Both these cases are realised in nature with the aid of enzymes and can also be achieved *in vitro*. It is known that enzymes acting upon substrates containing an asymmetric carbon atom usually attack only one of the two enantiomorphs[97]. The specificity of this type is as a rule absolute, i.e. the enzyme is completely incapable of reacting with the other enantiomorph. This notable property of enzymes was used by Pasteur for the separation of racemic mixtures.

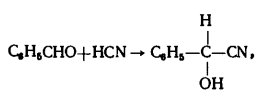
On the other hand, if the substrates consists of symmetrical molecules and the product contains an asymmetric carbon atom, then a symmetric synthesis under the influence of an enzyme results in the formation of only one enantiomorph. Thus the reduction of pyruvate in the presence of L-lactic dehydrogenase gives only L-lactate, while the product of the same reaction catalysed by another dehydrogenase is D-lactate[97].

Apart from the type of stereospecificity mentioned above, there exists yet another, namely the possibility of different behaviour of chemically identical groups in *meso*-compounds. Thus in the reaction

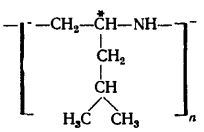
$$Cx_2yz \rightarrow Cx'xyz$$

(where primed letters denote groups attached to the carbon atom) the enzyme may act only on one of the two chemically indistinguishable x-groups. This is proved by the formation of only one enantiomorph of the asymmetric compound $Cx'xyz$. Such specificity has been observed with enzymes of the tricarboxylic acid cycle which are involved in the formation and breakdown of citric acid[98].

The generally accepted treatment of the specificity of enzymes is based on the classical "template" or "key in lock" model proposed by Fischer, Erlich, and others. In this model part of the surface of the enzyme molecule is regarded as a three-dimensional mould of a certain part of the substrate molecule. In other words, the surface of the substrate molecule is from the beginning, before reaction, complementary to the surface of the enzyme molecule. Recently the requirement of steric correspondence, which is a characteristic feature of the "template" hypothesis, has been supplemented by the "flexible" enzyme postulate, i.e. the possibility of inducing changes in the protein structure of the enzyme[99]. At the present time only one study has been made in which a synthetic optically active polymer has been successfully used as a catalyst for the asymmetric synthesis of low-molecular compounds. Tsuboyama[100] studied the synthesis of benzaldehyde cyanohydrin,



in the presence of optically active polyisobutylethyleneimine (PIBI):



The cyanohydrin synthesis involves the nucleophilic addition of the CN^- group to the carbonyl carbon atom and is catalysed by bases. On the one hand, the optically active polymer plays the role of a base which facilitates the dissociation of hydrocyanic acid and, on the other hand, by virtue of the steric effect of the isobutyl group of the polymer adjacent to the amino-group, the transition state is fixed so that the CN^- group can attack the carbonyl oxygen only in a particular direction relative to the isobutyl group.

Compared with other optically active polymeric bases, PIBI ensures the highest yield of an optically active product of the reaction (about 20%). The author concluded that the spiral structure of the polymer has a significant influence on the asymmetric synthesis.

In connection with Tsuboyama's results, it is interesting to investigate the relation between catalytic activity and the conformation of the polymer in solution and its molecular weight. Such data would bring us closer to an understanding of the nature of the "active centre" in a given catalytic system.

Another, more interesting approach involves the asymmetric synthesis of polymers in the presence of already existing optically active polymers. This problem is particularly important, since all natural biopolymers (proteins and nucleic acid) are synthesised in the living organism with the aid of appropriate optically active matrices. The attempts to achieve similar reactions with synthetic polymers have been unsuccessful. Thus in the synthesis of a polymer from racemic propylene oxide in the presence of optically active poly-(L-propylene oxide)[101] the product had a considerable optical activity even at low conversions but the activity was fully accounted for by the optically active seeding material.

Considerable advances in this field have been made by the achievement of enzymic syntheses of nucleic acids *in vitro* in the presence of templates. These include the Kornberg reaction[102] in which DNA has been synthesised on a DNA template in the presence of a universal enzyme (DNA-polymerase) from four monomeric nucleoside triphosphates; the product is a chemical copy of the primer. The catalyst in this reaction is a complex of the enzyme and the template, the former ensuring the formation of phosphodiester links, while the template is responsible for a specific sequence of the nucleosides in the reaction product.

Apart from the synthesis of DNA from all four monomeric units, Kornberg's enzyme gives the copolymer poly(A+T) on addition to a mixture of adenosine and thymidine triphosphates[103]. Without the primer the reaction is initially very slow with an induction period of several hours. After that the polymer formed initially itself serves as a template, i.e. the reaction proceeds autocatalytically. The high-molecular reaction product is a regularly alternating copolymer ATAT...

When Kornberg's enzyme is allowed to act on a mixture of monomers containing guanosine and cytidine only[103], the result is different: the products are equal amounts of the homopolymers polyguanosine and polycytidine, which form double helices by complex formation.

Apart from its template function (replication), DNA is also capable of acting as a primer for chain growth. The lower limit of the length of the primer molecule is equivalent to three nucleosides. The minimum length of the template molecule required for replication is equivalent to about twenty nucleosides. The template and primer functions may be superimposed.

Weiss and Nakamoto[104] discovered a new enzymic reaction involving the replication of RNA on DNA which behaves as a template. Enzymic systems have also been found in which polymeric RNA is synthesised from nucleoside triphosphates on an RNA (and not DNA) template[105].

The non-enzymic syntheses of polysaccharides, polynucleotides, and nucleic acids on templates are of considerable interest[106]. Thus the polymerisation of uridine monophosphate is accelerated by a factor of more than ten in the presence of polyadenylic acid. The introduction of polyarginine also accelerates the synthesis of polyuridylic acid. However, the addition of polyuridylic acid itself does not affect the reaction. The very important conclusion that there exists a mutual relation between the template acting as the catalyst and the monomer follows from

these experiments. Apparently a necessary condition which must be fulfilled in order that the polymer introduced into the reaction behaves as a template is the complementarity of the monomeric unit of the polymer and the monomeric substrate (uridine–adenine).

We shall now consider the problem of the asymmetric synthesis of polymers on templates. In this case complementarity presupposes also a correspondence between the absolute configurations of the asymmetric carbon atoms of the template and the monomeric units of the growing chain. For polymerisation to occur, the polymeric template should possess, in addition to adsorption capacity, the ability to initiate the reaction, and if this condition is not fulfilled a catalyst must be added to the reaction mixture.

The study of the adsorption of polymers from solutions on solid polymers (or association of different types of polymers) may be important for the choice of the polymeric template. Possibly, adsorbability (or capacity for association) may eventually be used as a measure of complementarity.

The problems of the adsorption of polymers on polymers are far from being elucidated. However, it is known that polymers of low molecular weight exhibit highest adsorbability. In addition, it has been observed in the chromatographic separation of isotactic poly-(*R*, *S*)-4-methylhex-1-ene [55] that adsorption interaction occurs between polymers with the same absolute configuration of the asymmetric carbon atoms and not on the principle of quasi-racemate formation.

The results obtained in the polymerisation of benzofuran [107, 108], although without direct bearing on the problem of the template role of polymers, merit attention. Farina et al. found [108] that, when benzofuran is polymerised at relatively low monomer concentrations, the resulting polymer has initially a relatively low optical activity which rapidly increases with the degree of polymerisation to a maximum, and then falls slowly.

The study of the optical activity of polymers synthesised in the presence of previously prepared optically active and inactive polybenzofurans led to the hypothesis of the autocatalytic effect of polybenzofuran on asymmetric synthesis. It is interesting that the autocatalytic effect is independent of both the sign and magnitude of the optical activity of the added polymer. The sign of the optical activity of the polymer synthesised depends only on the sign of the optical activity of the asymmetric initiator employed (the sign of the optical activity of the polymer is the same as that of the optical activity of phenylalanine), while the specific optical activity is very high even at low conversions and virtually identical in many of the cases investigated.

On the basis of their results, the authors claim that autocatalysis must be attributed not to a steric effect but to a chemical effect associated with the presence of the polymer in solution. They believe that, as a result of the presence of oxygen atoms of the ether type, polybenzofuran can behave as a Lewis base in relation to aluminium chloride and can in consequence modify the structure of the conjugate ion.

---o0o---

The studies on optically active polymers have only begun. The considerable theoretical importance of the problems of the asymmetric synthesis of macromolecules and also the wide variety of the possible uses of an optically active label in the investigation of polymerisation processes undoubtedly merit the attention of investigators in the field of polymer chemistry, and the relevant questions require further development.

III. Deuterium exchange in cyclopropane and cyclobutane 759

I. INTRODUCTION

The study of the deuterium–hydrogen exchange in hydrocarbons began soon after deuterium had become available for use in chemical research[1]. The reason for the interest in these reactions is that they can be used to elucidate the mechanisms of various processes, in the first place of hydrogenation–dehydrogenation reactions, and also the nature of the interaction between hydrocarbon molecules and the surface of a solid catalyst. The existence of a relation between the mechanisms of hydrogenation and isotope-exchange reactions has been pointed out frequently[2-4]. Fairly complete reviews of the catalytic isotope-exchange reactions of hydrocarbons have been given by Anderson[5] and Kemball[6]. In the present review we have attempted to examine the special problem of the deuterium–hydrogen exchange in cycloalkanes, which is extremely important both theoretically and practically.

Studies in this field began with the work of Horrex and Polanyi[7], who, in addition to investigating the exchange between cyclohexane and heavy water in the presence of a platinum catalyst, also observed the interaction of gaseous deuterium with cyclohexane. These workers together with Greenhalgh[8] made a more detailed study of the kinetics of the exchange between cyclohexane and deuterium oxide and gaseous deuterium over platinum deposited on glass fibre, determined the activation energy, and put forward certain hypotheses concerning the reaction mechanism. Farkas and Farkas[9,10] also investigated the exchange between a number of hydrocarbons, including cyclohexane, and deuterium over platinised platinum. Balandin and coworkers observed deuterium exchange with cyclohexane on platinum and on chromium oxide catalysts[11].

However, a distinctive feature of all the above investigations is that only the total amount of deuterium which had undergone exchange was determined. However, the main problem in the elucidation of the reaction mechanism is the determination of the amounts of products with different degrees of substitution, i.e. the distribution, which became possible only after the application of mass-spectrometric methods of analysis[12-14]. A large part of the investigations in this field have been made using evaporated metallic films as catalysts. This is because they have a number of advantages, such as high purity, high activity, and the convenience of working in a high vacuum, which was pointed out by Beeck and coworkers[15,16], who studied in detail the catalytic and adsorption properties of such films. At the same time the preparation of deposited films with reproducible properties involves considerable difficulties[17-23]. The problem of the relation between the catalytic properties of films and massive catalysts is of considerable importance. Burwell et al.[24] found that the deuterium exchange in a number of saturated cyclic hydrocarbons on evaporated palladium films and on the Pd/Al_2O_3 catalyst takes place by the same mechanism. Anderson et al.[17] demonstrated by electron diffraction that in the cases which they investigated the films have the same crystal structure as the massive metal. However, a number of workers adhere to a different view, namely that the properties of film and reduced catalysts are different[25-27]. In particular, differences have been noted between the lattice constants, electronic work functions, and the electrical conductivities of these catalysts[28-30]. These results are consistent with the data of Hightower and Kemball[31], who found that the behaviour of platinum films and deposited platinum catalysts in the reaction between *p*-xylene and deuterium is fundamentally different.

II. DEUTERIUM EXCHANGE IN CYCLOHEXANE, CYCLOPENTANE, AND THEIR DERIVATIVES

1. Reactions on Metallic Catalysts

One of the theories of hydrogen atom exchange with saturated hydrocarbons was developed by Anderson and Kemball[13,14]. Later their ideas were used to explain the reactions in cycloalkenes[32]. According to Anderson and Kemball, the first stage of the exchange is adsorption of the hydrocarbon with formation of a radical adsorbed on one metal atom and a hydrogen atom adsorbed on a second metal atom. On desorption the radical combines with a deuterium atom which had been adsorbed on a neighbouring metal atom and therefore one hydrogen atom in the hydrocarbon is replaced by a deuterium atom (the so-called simple exchange). This involves the preferential formation of monosubstituted products, polysubstituted products being formed when simple exchange is repeated. This type of exchange has a characteristic form of the probability curve for the distribution of the deuterated products, the concentration of those with a high number of deuterium atoms in the molecule falling sharply. This exchange is typical, in the first place, for reactions of methane and hydrocarbons containing isolated methyl groups linked to quaternary carbon atoms, and for reactions of cycloalkanes on oxide catalysts.

In the reactions on metals the so-called multiple exchange is more characteristic of cycloalkanes. In this type of exchange the molecule is initially adsorbed via two carbon atoms. Then one of the C–M bonds (where M is a metal atom) of the "diadsorbed" cycloalkane breaks and the deuterium adsorbed on a neighbouring metal atom adds on. There is a definite probability that the "monoadsorbed" cycloalkane thus formed again undergoes two-point adsorption in a manner such that the C–M bond is formed at the next carbon atom. When this process is continued, the cyclic molecule as it were "rolls" over the surface. The nature of the distribution of the deuterium-exchange products[13] led Anderson and Kemball to the conclusion that

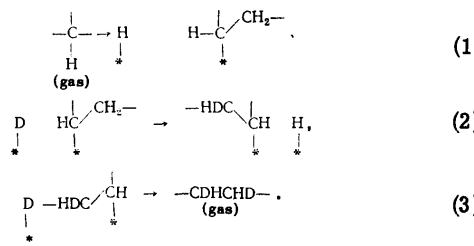
hydrogen atoms can be divided into two groups, those in the first group undergoing exchange more readily than those in the second. In the case of cyclopentane it is quite evident that such groups can only be hydrogen atoms lying on different sides of the plane of the ring. In cyclohexane such classification of hydrogen atoms is not unique but here too examination of the molecular model shows that each group consists of three axial and three equatorial atoms located on one side of the ring (cyclohexane in the "chair" conformation). According to Anderson and Kemball, the exchange of the six hydrogen atoms in the second group is possible only after the molecule turns over on the surface and its opposite side becomes adjacent to the latter. After this, the exchange takes place by the "rolling" method already described. If the possibility of complete desorption of the molecule and its subsequent readsorption via the other side of the ring is disregarded, the turning over of the cyclopentane molecule can only occur via the formation of a second C–M bond, after the rupture of one of these bonds, by a carbon atom already involved in one such bond (adsorption of the $\alpha\alpha$ type[24]). The molecule is then equally likely to lie on the surface on either side. In cyclohexane there is also another possibility — two-point adsorption of the type $\alpha\beta$ in which C–M bonds are formed by two neighbouring equatorial atoms belonging to different groups.

The complex distribution of the products of the deuterium exchange led Anderson and Kemball to the conclusion that two processes can take place simultaneously, one of which is responsible mainly for products with a high deuterium content and the other is responsible for the remaining products. Anderson and Kemball associate these processes with the presence of surfaces having different catalytic activities. On oriented films, where all the crystals are arranged preferentially with the same face directed outward, the distribution is simpler[13].

The model proposed by Anderson and Kemball permits a mathematical calculation of the contents of various deuterium exchange products. However, Hayakawa and Sugiura[33] believe that the hypothesis of the simultaneous occurrence of two processes by no means always leads to agreement between the theoretical and experimental results. Anderson and Kemball suggest that the geometrical disposition of the atoms on the surface is not significant, provided that the distances between the metal atoms lie within a fairly wide range, from 2.4 to 3.1 Å, since any inconsistency between the interatomic distances in the molecule and on the surface is compensated by a change in the C–M distance or slight twisting about the C–C bond. Thus in their view the specificity of metals is not associated with their geometry but with the different contributions of the various adsorption–desorption processes which occur on them. This view does not explain the high specificity of metals in exchange of a particular type. Furthermore, it has been shown that the distribution of the products of the deuterium exchange with cyclohexane on platinum, palladium, and nickel, which have a crystal lattice of the A1 type, is quite different from the distribution in the exchange on tungsten, molybdenum, and iron, which have a lattice of the A2 type[34,35]. The deuterium exchange in cyclohexane on germanium and silicon films is more likely to be of the simple type[36].

Hayakawa and Sugiura[33,37], who studied the deuterium exchange in cyclohexane on evaporated molybdenum and tungsten films, raised a number of objections to the explanation proposed by Anderson and Kemball. They believe that there is no hindrance to the turning over of the molecule and therefore the distribution curve should not exhibit any discontinuities. This was confirmed by their experiments. However, they agree that the exchange involves the rolling of the molecule over the surface. In their view the uniformity of the distribution (i.e. the ease of the transition of the exchange interaction from one side of the ring to the other) ensures firstly two-point adsorption of two equatorial atoms belonging to different groups and secondly the readsorption of the desorbed deuterated products. The second factor can play a significant role only at high extents of reaction, since at low extents of reaction the fraction of molecules which have participated in the exchange twice is $y^2/2$, where y is the total fraction of the molecules which have undergone exchange[6]. However, the high isotope dilution by light hydrogen in their experiments unfortunately limits somewhat the validity of their conclusions. Furthermore, the two catalysts which they investigated are very similar in properties and have a crystal lattice of the same type (A2).

The mechanism proposed by Anderson and Kemball was adopted and developed by Burwell and coworkers[24,38–41], who considered the stereochemical aspect of the reactions. They believe that the exchange takes place via the following stages[38] (the asterisk denotes the catalyst):



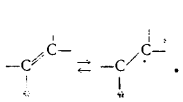
(1)

(2)

(3)

Frequent repetition of stage (2) leads to the formation of highly deuterated products. It is readily seen that this stage is analogous to "rolling" in the mechanism of Anderson and Kemball.

It is known that cyclopentane and hence also the intermediate compound adsorbed at two points may be present in a unique conformation. In this molecule all the hydrogen atoms on one side of the ring lie in pairs in one plane, i.e. they are eclipsed. Thus during the exchange cyclopentane must necessarily form compounds in the eclipsed conformation adsorbed at two points. It has been concluded[24] that, since the mode of distribution and the course of the exchange in cyclohexane and cyclopentane are similar, the intermediates must also be similar and that means that in the case of cyclohexane they are in the eclipsed conformation too. Hence it follows that the "boat" form must be assumed for the adsorbed cyclohexane molecule, since only this conformation gives rise to neighbouring eclipsed hydrogen atoms in cyclohexane. This in fact accounts for the discontinuity in the distribution curve after half the atoms have undergone exchange. Burwell believes[40] that, for the reaction to extend to the other side of the ring, an intermediate compound of the following type must form:



It is readily seen that here a second C–M bond can form on either side of the ring.

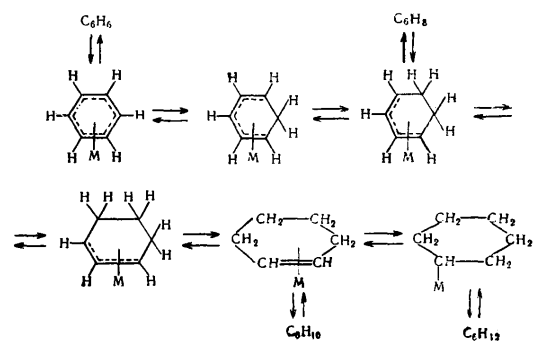
The situation is different in higher cyclic hydrocarbons. Starting with cycloheptane, not only *cis*- but also *trans*--hydrogen atoms may be in the eclipsed conformation, although with some strain in the latter case. In cyclo-octane the formation of the eclipsed conformation in the *trans*--position does not involve any strain. Evidently in such molecules exchange can extend without any hindrance to the other side of the molecule and the distribution curve should not show discontinuities. This view is confirmed by the experimental data of Burwell and coworkers[24]. Whereas the distribution curves for cyclopentane and cyclohexane show distinct peaks corresponding to penta- and hexa-substituted products respectively, in cycloheptane the peak is very small and in cyclo-octane it is virtually absent.

The conclusions of Anderson and Kemball are consistent with the temperature variation of the distribution of the deuterium-exchange products of cyclopentane over palladium found by Burwell et al.[24] They observed a gradual decrease of the maximum corresponding to $C_5H_5D_5$ as the temperature increased from 50° to 170°. Some of their results were obtained for cyclohexane over nickel[38].

The available experimental data demonstrate convincingly the possibility of interpreting the deuterium-exchange mechanism in saturated cyclic hydrocarbons from the standpoint of the multiplet theory of catalysis. Indeed the higher content of hexa-substituted deuteriocyclohexanes in the exchange on metallic catalysts of the platinum group can be explained by models in which the ring lies flat on the surface, in conformity with the sextet mechanism[34,35,42]. The authors of the present review observed[43] that the behaviour of cyclopentane in exchange on metals is quite analogous to that of cyclohexane. The doublet–sextet mechanism, developed by Kazanskii, Liberman, and Plate[44,45], which also requires a planar disposition of the molecule on the surface of the catalyst, was adopted to account for this phenomenon. Thus the higher content of the deuterium--exchange products having the composition $C_nH_nD_n$ can be attributed to the simultaneous exchange of all the hydrogen atoms on the side of the ring turned towards the surface. Evidently, with a planar disposition of the molecule on the surface, cycloalkane molecules with a number of deuterium atoms other than n can also form. This occurs, for example, when the desorption of the cycloalkanes from the surface is rapid, so that the adsorbed molecule has sufficient time to exchange only part of the hydrogen atoms before returning to the space above the adsorbent. Secondary adsorption of partially deuterated molecules can result in the formation of products in which more than half of the hydrogen atoms have been replaced by deuterium. However, the relatively slight excess of molecules having the composition $C_nH_nD_n$ over other exchange products[34,43] suggests that reactions involving two mechanisms, doublet and sextet (or doublet–sextet) take place simultaneously, their superposition yielding the observed distribution[35]. Evidently the sextet mechanism can obtain only on metals which allow a structural correspondence between their crystal lattice and the six-membered ring of the hydrocarbon molecule[42]. Similar hypotheses concerning the superposition of simultaneous processes have been made earlier[13,46]. Anderson and Kemball[13] do not reject the possibility of a doublet mechanism. It is noteworthy that their mechanism and the doublet model of the multiplet theory are not mutually contradictory.

So far we did not concern ourselves with the nature of the bond between the hydrocarbon molecule and the surface of the catalyst. Rooney, Gault, and Kemball[47,48] put forward the hypothesis [and supported it by evidence from experiments on deuterium exchange in various (polymethyl)cycloalkanes on deposited metallic films] that π-complexes are formed as intermediate surface compounds. Essentially the hypothesis is as follows. The usual type of bond between a chemisorbed hydrocarbon molecule and the metal surface is a σ-bond which involves an sp^3-hybridised carbon atom. However, when the molecule contains three or more adjacent non-quaternary carbon atoms there is a possibility of sp^2-hybridisation and delocalisation of p-electrons resulting in the formation of molecular orbitals which arise by the combination of the p-orbitals of the carbon with the unfilled surface d-orbitals of the metal[49]. The energy consumed in the change of hybridisation is compensated by the stability of the bond formed and the delocalisation of π-electrons. Thus the intermediate compound forms a π-bond with the metal similar to that which obtains in ferrocene. As a result of sp^2-hybridisation, the molecule becomes planar and one or other of its two sides turns towards the surface. The metals investigated[48] can be arranged in the following sequence as regards their capacity to form intermediate compounds with π-bonds: Pd > Pt > Ni > Rh.

Developing these ideas, Rooney suggested[50] that during deuterium exchange in cycloalkanes there is a possibility of the formation of three intermediate compounds: initially a σ-bonded alkyl is formed, which is then converted into a π-bonded olefin after the removal of a hydrogen atom (in this process there is $\alpha\beta$-exchange on one side of the plane of the ring), this being followed by the conversion of the olefin into a π-allyl intermediate compound (or a compound with a still more delocalised π-bond). Accordingly, aromatic hydrocarbons and 1,3-dienes are chemisorbed directly as π-bonded complexes. Rooney[50] explained many of the reactions of cyclic hydrocarbons in terms of the mechanism shown below: hydrogenation, dehydrogenation, disproportionation, isotope exchange, and *cis–trans* isomerisation.



Subsequently Rooney emphasised the role of the olefinic π-bond, counterbalanced by the σ-bonds of the intermediate compounds[51]. The problem of intermediate π-complexes in heterogeneous catalysis has been examined in the review of Bond and Wells[52], mainly in connection with unsaturated compounds. The hypothesis of the formation of a planar sp^2-hybridised intermediate compound linked to the surface via a π-bond bears an interesting analogy to the multiplet theory of catalysis, where it is assumed that in the adsorption of cyclohexane on metal catalysts a sextet multiplet complex lying flat on the surface is formed during the dehydrogenation of cyclohexane[42]. Although the molecule forms a π-bond with only one surface atom, this does not

exclude the specificity of the various metals and in particular the effect of geometric factors. The specificity of metals may be due to the relative ease of formation of σ- and π-intermediates. Furthermore, the mode of crystal packing can control the nature of the orbitals in individual metal atoms involved in the formation of the π-bond. In this connection, it may be supposed that the above sextet mechanism of the exchange is associated with the formation of an intermediate π-complex, while the doublet mechanism corresponds to the formation of two σ-bonds with the surface.

This is the general outline of the explanations of the deuterium exchange in cycloalkanes on metals available at the present time. The kinetics of these reactions have been considered to some extent in many of the publications quoted [13,37,38,48]. The kinetic equations obtained are not always the same but they have a certain common feature. Usually the rate of exchange is represented by

$$\omega \propto p_{C_6H_{12}}^{n} \cdot p_{D_2}^{-m},$$

with $n \simeq 1$ and $m = 0.6-1$. Thus deuterium inhibits the exchange [5]. Ravoire [53] made a special examination of the kinetics of deuterium exchange in cyclohexane under static conditions over platinum deposited on activated charcoal, and found that the reaction order and the apparent activation energy can vary on heating above 100°.

2. Reactions on Oxide Catalysts

In the first study of deuterium exchange in cyclic hydrocarbons over chromium oxide [11] it was shown that the reactions on oxide catalysts differ significantly from those on metals. It follows from what has been said above that multiple exchange reactions play a decisive role in deuterium exchange on evaporated metal films. In contrast, on oxide catalysts simple exchange predominates. In this type of exchange each adsorption step involves the exchange of only one hydrogen atom, the molecule being subsequently desorbed, so that species with a low deuterium content are the main products. The activation energy for deuterium exchange on oxide catalysts is as a rule much higher than on metals.

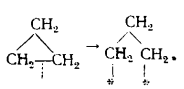
Deuterium exchange in cycloalkanes, mainly cyclohexane, has been investigated on chromium oxide [46,54,55], chromium oxide deposited on alumina [56], and on rare-earth oxides [57-59]. It was shown that the rate of isotope exchange is much higher than the rate of dehydrogenation under comparable conditions [56]. Burwell and coworkers [46] found that, in addition to simple exchange, multiple exchange takes place to a slight extent on chromium oxide (1-2% of the total exchange) and probably also a special type of exchange responsible for the increased content of products with two and three deuterium atoms per molecule. It is suggested that simple exchange involves the interaction between the cycloalkane adsorbed at only one point and a deuterium atom adsorbed at an adjacent site. The hydrocarbon radical may be linked to a chromium atom and the hydrogen to an oxygen atom, the corresponding intermediate product resembling somewhat a carbanion. Burwell attributes the multiple exchange which takes place to a slight extent on chromium oxide to the formation on the surface of an olefin or a π-allyl complex which also incorporates a chromium atom. In view of certain unusual features of the exchange, Burwell and Littlewood [55] suggested that two types of active site are present on the surface of chromium oxide.

Gadzhi-Kasumov, Isagulyants, and ourselves [60,61] arrived at a similar conclusion in a study of the relative extents of deuterium exchange with and dehydrogenation of cyclohexane when the two reactions take place simultaneously on chromium oxide. In these experiments it was found that the degree of dehydrogenation increases steadily with temperature, while the extent of exchange passes through a maximum. It is interesting that, although deuterium exchange in cyclic hydrocarbons is mainly of theoretical interest, it can also acquire some practical value, since this process has been proposed for the enrichment of hydrogen with deuterium [62-64].

III. DEUTERIUM EXCHANGE IN CYCLOPROPANE AND CYCLOBUTANE

Data on the first two, simplest representatives of the cycloalkane series, cyclopropane and cyclobutane, should prove of value for the elucidation of the mechanism of deuterium exchange in these hydrocarbons. Cyclopropane and cyclobutane are somewhat untypical in the series of cyclic hydrocarbons, because of the high Bayer strain in their rings, which reaches 10 kcal per C-C bond in cyclopropane. This excess energy in the molecule can give rise to hydrogenolysis at the same time as deuterium exchange. However, the probability of hydrogenolysis depends to a very great extent on the reaction conditions and primarily on the choice of catalyst. Thus in the reaction of cyclopropane with deuterium in the presence of platinum [65-67], palladium [66,68], rhodium [66,69], and iridium [69] deposited on pumice at temperatures between 0° and 200° cyclopropane is almost completely converted into n-propane. At the same time on an evaporated rhodium film at -100° the exchange and deuterium addition take place at comparable rates [13]; on the other hand, on the chromium oxide catalyst hydrogenolysis becomes appreciable only above 75° and particularly above 100°, while at lower temperatures it does not occur at all [46,54]. The distribution of the exchange products on the chromium oxide catalysts is consistent with the laws of probability — multiple exchange does not take place [54]. In view of the inadequacy of the data for reactions on an evaporated film [13], it is unfortunately impossible to arrive at definite conclusions concerning the mode of distribution. As shown above, under the conditions used for this reaction by Bond and Turkevich [65] and Bond and Addy [66-69], cyclopropane is almost completely decyclised and the main products are n-propanes with 7 and 8 deuterium atoms per molecule.

Since in this case the course of the exchange for cyclopropane and n-propane is almost the same, the reaction mechanisms are probably also identical. Ring opening evidently takes place in the first stage of the adsorption of cyclopropane (this is the rate-limiting stage):



It is noteworthy that under comparable conditions cyclopropane undergoes exchange faster than other cyclic hydrocarbons.

It is apparently more convenient to study deuterium exchange in cyclobutane in view of its greater stability to hydrogenolysis [70]. For example, experiments on the catalytic hydrogenation of ethylcyclobutane showed [71] that the

hydrogenolysis of this compound does not begin until 150°. Despite this, the study of deuterium exchange in cyclobutane itself was undertaken only recently [72]. Until then only derivatives had been investigated — ethylcyclobutane [39,46,54] and 1,1-dimethylcyclobutane [50]. The isotope exchange in ethylcyclobutane on a chromium oxide catalyst at 200–235° yielded a complete set of products containing between 1 and 12 deuterium atoms and also a small amount of products with masses 1–4 units greater than the molecular weight of the fully deuterated ethylcyclobutane [54]. This evidently indicates partial ring opening. The distribution of the deuterium exchange products is consistent with the predominance of simple exchange. Multiple exchange occurs to a comparatively slight extent. In the exchange on an evaporated nickel film partial hydrogenolysis is also observed, but the exchange itself is of the multiple type [39].

It is interesting that in the reaction of 1,1-dimethylcyclobutane on a palladium film only four hydrogen atoms undergo exchange. Rooney [50] attributes this to the fact that for cyclobutane deformation of intermediate $\alpha\beta$-compounds of the olefin type adsorbed on two sites should be hindered, since cyclobutene is less stable than cycloalkanes with larger rings. The formation of an intermediate π-bonded compound of the allyl type is also hindered due to the strain which it must entail in the cyclobutane ring. In the investigation mentioned above, the deuterium exchange with 1,1-dimethylcyclobutane was performed at 68°. An increase of temperature to 150° caused selective cracking to 2,2-dimethylbutane.

Savin and coworkers [72] showed that the reaction of cyclobutane itself with deuterium on evaporated platinum, palladium, nickel, tungsten, and molybdenum films at temperatures between 0° and 171° involves vigorous multiple exchange on all the metals except palladium. It was found that, regardless of the type of the crystal lattice of the metal on which the exchange takes place, the distribution curve for the deuterated products does not show a discontinuity between $C_4H_4D_4$ and $C_4H_3D_5$. This is consistent with the structural postulates of the multiplet theory, according to which there is no structural correspondence between the above metals and the cyclobutane molecule and hence there is no possibility of a process in which initially hydrogen atoms on one side of the ring plane are exchanged and then those on the other side. At the same time, these data contradict the stereochemical hypotheses of Burwell, described above, since according to the latter the distribution curve should have a certain intermediate maximum corresponding to cyclobutane which has undergone exchange to an extent of 50%. It has been pointed out [72] that the exchange in cyclobutane is accompanied by partial hydrogenolysis, which is most intense on nickel. However, this process was slower than the exchange and for short contact times it had relatively little effect on the distribution. Hydrogenolysis was not observed over platinum.

---o0o---

The study of deuterium–hydrogen exchange constitutes an effective method for determining the mechanism of the interaction between cycloalkanes and the surface of the catalyst. Direct comparison of hydrogenation and deuterium exchange is of particular interest, since it permits a more profound understanding of the mechanisms of these processes. The growing number of studies on these and related problems is clear evidence of the interest which they have for workers in the field of catalysis.

I. REVIEW OF PUBLISHED EXPERIMENTAL WORK

1. Kinetic Laws

The physical and chemical properties of semiconductor surfaces, so important in semiconductor technology and in catalysis, are controlled essentially by chemisorption processes taking place on the surface. For this reason, the study of chemisorption on semiconductors has attracted a great deal of interest.

In order to clarify the fundamental mechanism of chemisorption, it is important to investigate the kinetics of the process. The basic characteristic is the variation of the amount adsorbed q with time t at constant temperature:

the kinetic isotherm $q = q(t)$. Kinetic isotherms are established under two types of experimental conditions: at constant pressure and at constant volume.

Usually, adsorption is fast at the very beginning of the chemisorption process (during the first minute, say), and the kinetics have been inadequately investigated in this region because of the experimental difficulties involved. This stage is followed by a slower one, whose kinetics are usually measured and reported as chemisorption kinetics. However, the chemical interaction between a gas and an adsorbent, whose initial stage is studied in chemisorption, is not confined to this stage. Chemisorption, particularly at high temperatures, can be followed by processes which affect the bulk of the adsorbent: e.g. penetration of adsorbed species into the bulk of the adsorbent, diffusion of metal in stoichiometric excess (in the case of oxide or sulphide semiconductors) from the bulk phase to the surface. In the chemisorption of oxygen on oxides this process is equivalent to growth of the crystal lattice of the adsorbent. Thus, it is important to distinguish, in experimental studies of chemisorption, between chemisorption proper and subsequent stages of sorption. This has not always been done.

The kinetics of the majority of chemisorption processes are described by the Roginskii–Zel'dovich equation[1,2]

$$dq/dt = a\exp(-\alpha q), \tag{1a}$$

where a and α are constants ($a > 0$, $\alpha > 0$). In its integrated form the equation is

$$q(t) = (1/\alpha)\ln(1 + t/t_0), \tag{1b}$$

where $t_0 = 1/a\alpha$.

Eqn. (1) was used by Roginskii and Zel'dovich[3] to describe the kinetics of the chemisorption of CO on MnO_2. Taylor and Thon[4] showed that the equation could be applied to a large number of experimental results. The constants a and α are determined as follows. One chooses a value of t_0 such that the plot of q against $\ln(1 + t/t_0)$ is linear, and from the slope of this plot α is obtained. Knowing α and t_0, we can then arrive at the value of a. We can see from Eqn. (1a) that a corresponds to the initial rate of adsorption: $a = (dq/dt)_{t=0}$. However, if we determine the initial rate of adsorption from the amount of material adsorbed during the first unit of time (i.e. as rapidly as possible after the onset of adsorption), we obtain a value much greater than a found from Eqn. (1b). This is evidence for the existence of a fast initial stage of chemisorption.

The constants a and α depend on T and P as follows: (1) on raising T, α decreases, but a, on the other hand, increases with an activation energy of about 10 kcal mole^{-1}; (2) at constant T, α tends to increase slightly as P decreases, and a increases approximately as $P^{0.8}$. Taylor and Thon conclude that in the slow stage of chemisorption described by Eqn. (1) the kinetics are relatively insensitive to the mass-action effect of the gas, and are determined mainly by changes taking place in the adsorbent.

The Table, reproduced from Stone's book, illustrates the application of Eqn. (1) to chemisorption processes, but does not claim to be comprehensive.

It should be noted that Eqn. (1) formally describes any process in which the height of the potential barrier opposing a change in some quantity is linearly related to the change in that quantity. Thus Eqn. (1) could describe not only the chemisorption stage but also any subsequent absorption stage, although it does not follow that in a kinetic isotherm consisting of two intersecting Roginskii–Zel'dovich straight lines of different slope the second line necessarily denotes some process other than chemisorption.

TABLE. Chemisorption processes conforming to the Roginskii–Zel'dovich equation.

Gas	Adsorbent	Gas	Adsorbent
H_2	Cr_2O_3	CO	MnO_2
	$ZnO\cdot Cr_2O_3$		NiO
	$\alpha MnO\cdot Cr_2O_3$	O_2	$CaO\cdot Cr_2O_3$
	ZnO		NiO
	NiO		CoO

Chemisorption involving the adsorption of more than one layer, and conforming to Eqn. (1), has been observed[5-7] in the adsorption of oxygen on thin films of oxides deposited on the appropriate metal. Engell and Hauffe[8] quote an example of the penetration of oxygen into the NiO lattice, conforming to Eqn. (1), after a chemisorption stage described by the same equation but with a different slope. Parravano and Boudart have pointed out[9] that processes such as bulk and surface diffusion can also follow a logarithmic law. It follows that a wide variety of mechanisms of gas absorption can remain concealed in Eqn. (1).

Although many chemisorption processes are described by the Roginskii–Zel'dovich equation, cases are known in which chemisorption proceeds according to some other kinetic law. Thus, Enikeev and coworkers[10-13] have shown that, when the electron work function of the adsorbent is logarithmically related to the coverage of the surface, a power law is obtained:

$$dq/dt = aq^b, \tag{2a}$$

where a and b are constants ($a > 0$, $b > 0$), or alternatively

$$q(t) = a't^{b'}. \tag{2b}$$

Examples of this behaviour include O_2 on NiO, C_3H_7OH on ZnO, and O_2 on ZnO containing Li_2O. Eqn. (2b) is called the Bangham equation, and has been used by Bangham and coworkers[14,15] to describe the adsorption kinetics of CO_2 and NH_3 on glass.

Thuillier[16] observed, in his study of the chemisorption of oxygen on ZnO, a rate process conforming to the equation

$$dq/dt = a\exp(-\alpha q^2) \tag{3}$$

(a and α constant), which had been put forward by Aigrain and Dugas[17] and Germain[18]. According to Roland and Schuttler[19], Eqn. (3) also describes the kinetics of oxygen chemisorption on TiO_2 (rutile).

2. Reversibility and Irreversibility of Adsorption

Even the earliest studies of chemisorption had revealed the existence of different forms of the bond between the chemisorbate and the surface of the adsorbent. It was found that the whole adsorbate could not always be removed completely from the surface if desorption was carried out at the same temperature as adsorption. Higher desorption temperatures increase the amount of adsorbate removed from the surface, but occasionally the species which is desorbed beyond a certain temperature is not the same as

that which had been adsorbed. This was observed by Garner and Kingman[20,21] during their study of the adsorption of hydrogen and carbon monoxide on $ZnO.Cr_2O_3$. These workers concluded that two types of adsorption are possible on oxides: "reversible" adsorption, when the adsorbate can be desorbed in its original chemical form, and "irreversible" adsorption, when the opposite is true. However, the measured heats of adsorption, which were found to lie in the range of 10–30 kcal $mole^{-1}$, show that even in the case of "reversible" chemisorption we are dealing with chemical rather than physical adsorption.

The presence of two forms of chemisorption was later demonstrated by many workers. The two forms are often termed the weak and the strong form of chemisorption. The relative amounts of the two forms under comparable conditions depend on the temperature at which adsorption is allowed to proceed. Thus, hydrogen adsorbed on zinc oxide below 100° is readily desorbed, whereas at temperatures higher than 100° strong adsorption is observed[22]. The adsorption of hydrogen on ZnO was studied also by Keier and Roginskii[23,24], who found that above 100° an appreciable fraction of the hydrogen is strongly adsorbed and can only be removed from the surface in the form of water by heating the specimen above 500°. The adsorption of carbon monoxide on ZnO shows similar features: several workers[25-27] found that CO which has been adsorbed at room temperature can be desorbed unchanged, whereas above 150° the adsorption is irreversible. A weak adsorption of oxygen on ZnO at room temperature was reported by Putseiko and Terenin[28] and Enikeev et al.[10]; Keier[29] demonstrated the presence of "weak" adsorption at temperatures between 20° and 100°, and "strong" adsorption above 100°. The different forms of chemisorption of oxygen on zinc oxide were investigated also by Barry and Stone[30,31], who concluded that the predominant chemisorbed species at room temperature is O^- whereas above 300° the predominant form is O^{2-}, "stabilised by the diffusion of interstitial zinc towards the surface". The chemisorption of both unsaturated (ethylene, propene) and saturated (propane) hydrocarbons on metal oxides was investigated by Margolis[32]. A definite fraction of the adsorbed hydrocarbon (not more than 10%) is strongly bound to the surface, and can be removed only by baking in oxygen.

The ratio between the weak and the strong form of chemisorption is affected not only by temperature but also by the nature of the adsorbed gas and of the adsorbent. Thus, according to Keier and Kutseva[33] the amount of strongly bound CO_2 on nickel oxide (NiO) is no more than 2.5–3% of a monolayer, whereas oxygen and acetylene are strongly adsorbed, and can only be desorbed from the surface in negligibly small amounts.

Not surprisingly, the difference between the two forms of chemisorption springs from differences in heat of adsorption. Garner and coworkers showed[34] that the fraction of CO and H_2 which is reversibly adsorbed at room temperature varies from oxide to oxide. Thus, CO adsorption on ZnO at room temperature is completely reversible. The heats of adsorption vary between 12 and 20 kcal $mole^{-1}$. On other oxides, such as Mn_2O_3 and $Mn_2O_3.Cr_2O_3$, the heats of adsorption are higher and the chemisorption is irreversible.

Margolis showed[32] that, by introducing various amounts of impurity into the adsorbent, both the adsorption capacity and the ratio between the strong and the weak form of chemisorption can be controlled. Thus, in the adsorption of propene on magnesium chromite ($MgO.Cr_2O_3$) the proportion of the strong form is as follows: 3% in the absence of additives, 10% in the presence of 1% of added Na_2SiO_3, 25% in the presence of 2% Na_2SiO_3, and 50% of the total adsorption in the presence of 3% Na_2SiO_3.

It should be noted that any reference to two forms of chemisorption underlines the existence of different types of bond between the chemisorbed species and the surface. A more detailed study of these forms may reveal the presence of yet more types of bond.

3. Change in Electrical Conductivity and Work Function of the Adsorbent During Adsorption

The strong and the weak form of chemisorption differ in their effect on the electrical conductivity σ of the adsorbent. According to Morrison[35] and Kubokawa and Toyama[36], the weak adsorption of H_2 on ZnO, which takes place below 100°, has no effect on the electrical conductivity, whereas the strong, high-temperature adsorption increases the conductivity. The temperature beyond which adsorption begins to have an effect on σ depends on the method of preparation of the adsorbent. The activation energy for high-temperature adsorption is about twice as large as the activation energy for low-temperature adsorption. The effects on σ of the weak and the strong hydrogen chemisorption on nickel oxide are qualitatively similar to the above[37,38].

Keier's results[29] on the adsorption of ethanol on ZnO are very interesting: adsorption proceeds almost instantaneously at room temperature, and a coverage of 80–85% of a monolayer is obtained in 15–45 s. The conductivity of the adsorbent (pressed discs of ZnO) does not change during adsorption up to a complete monolayer; only after 20 min, when adsorption has gone to completion, does σ begin to increase. The increase then continues for a very long time. At 100° the adsorption of ethanol produces changes in σ two orders of magnitude higher than at 20°. The greater part of the adsorbed alcohol can be removed from the surface by heating at 450°: under these conditions ~ 50% of a monolayer is desorbed unchanged, whilst the remainder undergoes changes and emerges from the surface as CO_2 (and in part as ethylene).

The variation of the work function φ with surface coverage has been examined by Enikeev and others[10-13]. It was found that the sign of the surface charge is determined essentially by the nature of the adsorbed molecule. Changes in work function (for different gases on different semiconductors) span a fairly wide range of values: from tens of millielectron-volts to 0.7–0.9 eV. In some cases these changes are reversible, in others they are irreversible and slow to develop. The adsorption capacity, and also the dependence of φ on coverage, are related to the type of chemisorption: as a rule, the extent of adsorption of a gas is lower for exhaustive (or depletive) chemisorption than for enrichment (or cumulative) chemisorption. In the former case coverages seldom exceed 1–10% of a monolayer, and φ varies linearly with coverage. In the latter case the ultimate coverage can approach a monolayer (O_2 on NiO, C_3H_7OH on ZnO), but φ varies logarithmically with coverage.

It should be noted that a change in φ as a result of adsorption does not necessarily prove that the adsorption is chemical in character. Physical adsorption of dipolar molecules with a large enough dipole can also produce a sizeable change in φ. Such appears to be the case[10] in the adsorption of isopropyl alcohol (C_3H_7OH) on zinc oxide at 20°.

If the dipole moment of the adsorbed molecules is small, the change in φ is a measure of the bending of the energy bands at the surface of the semiconductor, and therefore also of the potential difference between the surface and the bulk. In some cases it has been shown[11] that the change in work function ($\Delta\varphi$) is equal to the change in activation energy for chemisorption (ΔE).

Simultaneous observations of the adsorption kinetics and of the kinetics of the resulting changes in the electronic properties of the semiconductor adsorbent are particularly interesting. Unfortunately, very few investigations of this type have been reported. The kinetics of changes in σ following oxygen adsorption on thin layers of oxides have been examined in a series of papers by Gray, Garner, and their coworkers[37,39], but the experiments did not include simultaneous adsorption measurements. The extent of adsorption was inferred by an indirect method: by assuming that the conductivity was proportional to the square root of the coverage.

Litovchenko and coworkers[40] arrived at the following conclusion from their study of time-changes in φ accompanying the adsorption of oxygen on germanium: "immediately after adsorption the work function φ does not change, i.e. the adsorbed molecules attach themselves to the surface in an effectively neutral state, and gradually undergo charge transfer, which in turn modifies the bending of the bands at the surface".

Enikeev has made a detailed study of the kinetics of changes in φ in conjunction with the kinetics of oxygen chemisorption on manganese dioxide[12,41]. He identifies three stages in the take-up of oxygen: the first stage consists in almost instantaneous adsorption, proceeding without activation energy. Surface coverages are very low (up to 10^{11} cm^{-2}), and the work function increases sharply by 0.20–0.25 eV. The second, and relatively slow, stage is described by the logarithmic Roginskii–Zel'dovich isotherm, Eqn. (1), both as regards coverage and work function. The latter increases linearly with the coverage, which can reach $3-6 \times 10^{12}$ cm^{-2}. Above 100° a new mechanism involving absorption of oxygen by the lattice can be observed. This gives rise to the third and slowest stage. The increase in work function during this stage is minimal.

To conclude this section on experimental studies of the kinetics of chemisorption, we must point out that, in spite of the large number of published papers (see, for example, the review article by Low[2]), very few of these have dealt with simultaneous observations of the rate of gas absorption and of kinetics of changes in the electronic characteristics of the adsorbent (such as the electron work function or the electrical conductivity). Yet, only by combining simple adsorption measurements with electronic measurements can we hope to characterise unambiguously chemisorption phenomena.

II. REVIEW OF THEORETICAL WORK

1. Difference in Approach Between the Boundary Layer Theory and the Electronic Theory of Chemisorption

The origin of the electronic theory of chemisorption on semiconductors goes back to 1947 (F. F. Vol'kenshtein). The results obtained by Vol'kenshtein and his coworkers have been published as a monograph[42]. In 1952 the electronic aspects of chemisorption on semiconductors began to attract attention in many countries: Hauffe and coworkers in West Germany, Weisz in the USA, Germain in France, etc. This work is known under the name of boundary layer theory (Randschichttheorie der Adsorption). It should be noted that until recently the kinetics of chemisorption have been practically ignored in the context of the electronic theory, most of the work being confined to equilibrium aspects of the adsorption problem.

Before proceeding to a discussion of specific contributions to the boundary layer theory (in so far as they relate to the kinetics of chemisorption), we shall dwell upon some characteristic features of the approach of the boundary layer theory to chemisorption problems in general and to the kinetic aspects in particular[8,18,43–48].

Firstly, according to the boundary layer theory a localised surface level within the forbidden gap of the semiconductor (corresponding) to a chemisorbed species) exists only in so far as it is occupied (by an electron in the case of an acceptor level or by a hole in the case of a donor level). In other words, transition to the chemically adsorbed state does not give rise to a level which, as commonly understood, can be either occupied or empty: the resulting level is by definition occupied. The localised surface levels used in the boundary layer theory to represent chemisorbed species cannot be unoccupied. Hence, during adsorption the rate of appearance of chemisorbed species can be identified with the rate of capture of electrons (or holes) by the surface levels rather than with the rate of appearance of these levels: as many chemisorbed particles appear in unit time as there are levels which can become occupied during the same time. Similarly, during desorption the rate of disappearance of chemisorbed species from the surface is identified with the rate at which electrons (or holes) can be set free from the corresponding levels.

In contrast, we note that in the electronic theory[42] the chemisorption of a species generates a localised surface level in the forbidden gap of the semiconductor which can be either free or occupied. In the former case the chemisorbed particle is in the state termed a "weak" bond; in the latter case, when a free electron (or hole) of the semiconductor becomes localised in the level, the bond between the species and the lattice of the adsorbent is stronger and the chemisorbed species is in the state termed a "strong" bond. The relative numbers of the two states (or of the two types of bond) are determined, for a given position of the surface chemisorption level, by the position of the Fermi level at the surface. The chemisorption level will be occupied by an electron (or hole) with practically unit probability only if it is located sufficiently far below or above the surface Fermi level (depending on whether we are dealing with an acceptor level or a donor level). In this case the treatment is formally the same as that of the boundary layer theory (for problems of adsorption equilibrium).

Secondly, most of the work on the boundary layer theory assumes that physical adsorption is invariably involved as a first stage necessarily preceding chemisorption. The physically adsorbed state undergoes a transition to a state in which the species is chemisorbed. The idea of physical adsorption in the boundary layer theory effectively takes the place of the idea of a "weak" form of chemisorption on which the electronic theory relies. We should also note that, as Vol'kenshtein[42] points out on p. 19 of his monograph, the electronic state leading to physical adsorption cannot produce chemical adsorption, and vice versa, so

that transition from physical to chemical adsorption necessarily involves transition of the system to a different electronic state.

One of Hauffe's papers[44] discusses a scheme in which chemisorption (of acceptor species) occurs in the absence of a physical adsorption stage: species are chemisorbed from the gas phase on to surface traps ready to receive an electron and produced by some mechanism other than adsorption. These traps are represented by some localised level in the forbidden gap. Unoccupied traps of this type take part in the act of chemisorption with the status of reactants: their concentration appears as one of the factors in the expression for the rate of adsorption. The act of chemisorption itself is, so to speak, trimolecular: it involves an unoccupied surface trap, a gas species, and an electron from the adsorbent, which is captured from the valence band if the adsorption takes place on a p-type semiconductor or from the conduction band in the case of adsorption on an n-type semiconductor. The nature of the traps is left vague: "they can have various physicochemical origins: for example, they can be physically adsorbed species". We would make the following comment on the statement that physically adsorbed species can generate localised levels in the forbidden gap of a semiconductor. It is well known[42] that the effect of physically adsorbed species on the energy spectrum of the electrons in the adsorbent is confined to a small perturbation. Hence, if such species generate localised levels they must be fairly shallow ones[49].

Hauffe's statement appears to be logical, because it ignores the "weak" bond: this is characteristic of all papers on the boundary layer theory. In fact, if the "weak" bond is effectively absent, we have two alternatives Either we operate with adsorption levels which exist only in so far as they are occupied by electrons (for the case of acceptor species), which "makes nonsense of the very concept of a localised level as a level free to accept or emit electrons",[42] or else we ascribe to physically adsorbed species the property of always generating localised levels whose occupancy is treated as a transition to the state of chemical adsorption, which can hardly be correct.

In view of the different approaches of the boundary layer and of the electronic theory of chemisorption, and also because recent papers within the scope of the electronic theory and dealing with kinetics are not mentioned in Vol'kenshtein's book[42], we shall discuss these papers separately in Section III of the present review.

2. The Boundary Layer Theory

The chemisorption of an acceptor gas was treated by Hauffe as follows[44]. (We shall use, however, the terminology adopted in the electronic theory)[42].

(a) Chemisorption on a p-type semiconductor is a reaction involving a species A from the gas phase and a surface trap B not occupied by an electron. The species A, on becoming adsorbed in the empty trap, "emits a hole into the valence band" (in Hauffe's words):

$$A+BL \rightarrow ABeL+pL,$$

where L denotes the lattice, and eL and pL are an electron and a hole in the lattice respectively. The reverse reaction gives rise to desorption. The energy relationships are summarised in Fig. 1, where B is the trapping level, AB the level of the adsorbed species, FF the Fermi level,

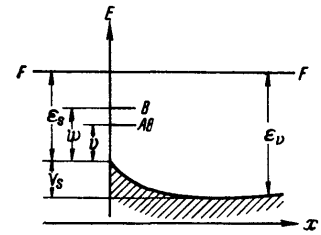

Fig. 1.

and w and v are the distances from the edge of the valence band to the trap level and to the level of the adsorbed species respectively. The overall rate of chemisorption is expressed in the form

$$dN_A/dt = k_1 P N_B (1-\eta_B)\alpha - K_2 N_A p_s.$$

Here N_A is the surface concentration of chemisorbed A species, P the pressure of adsorbed gas, N_B the surface concentration of traps, $(1 - \eta_B)$ the probability of the trap being empty, α the probability of thermal emission of a hole from the species A into the valence band, and p_S the concentration of holes just below the surface.

The following expressions are inserted for $1 - \eta_B$, p_s, and α:

$$\begin{cases} 1-\eta_B = \left(1+\exp\left[\frac{\varepsilon_s - w}{kT}\right)\right]^{-1} & (4a) \\ p_s = C_p \exp\left(-\frac{\varepsilon_s}{kT}\right), & (4b) \\ \alpha = \alpha_0 \exp\left(-\frac{v}{kT}\right), & (4c) \end{cases}$$

whence

$$\frac{dN_A}{dt} = k_1\alpha_0 \exp\left(-\frac{v}{kT}\right)\cdot\left[1+\exp\left(\frac{\varepsilon_s - w}{kT}\right)\right]^{-1}\cdot N_B P - k_2 C_p \exp\left(-\frac{\varepsilon_s}{kT}\right)\cdot N_A. \quad (5)$$

By letting dN_A/dt vanish, it is possible to determine the amount adsorbed at equilibrium; the kinetic equation (5) itself cannot be solved. At the beginning of chemisorption, when the rate of desorption is small, we can ignore the second term on the right-hand side of Eqn. (5).

If

$$\exp\left(\frac{\varepsilon_s - w}{kT}\right) \gg 1,$$

i.e. $1 - \eta_B \ll 1$, or in other words if the surface traps which play the part of adsorption centres are almost fully occupied by electrons, we obtain the following expression for the initial rate of adsorption:

$$\frac{dN_A}{dt} = k_1\alpha_0 N_B P \exp\left[-\frac{\varepsilon_s - (w-v)}{kT}\right].$$

It is not easy to see why chemisorption should require a collision between an impinging particle (species) and an

empty trap with simultaneous capture of a valence band electron by the trap, and why a collision between a particle from the gas phase and a trap already occupied by an electron (i.e. a trap in which an electron had previously become localised) should not be accompanied by chemisorption.

(b) Chemisorption on an n-type semiconductor is treated as a reaction between an empty surface trap BL, a species from the gas phase A, and a free electron from the conduction band eL:

$$A + BL + eL \rightarrow ABeL.$$

Desorption is described by the reverse reaction. The energy relationships are shown in Fig. 2, where w and v now denote the distances from the bottom of the conduction band to the trap level and to the level of the adsorbed species respectively. The equation for the net rate of chemisorption is given in the form

$$\frac{dN_A}{dt} = k_1 P N_B (1 - \eta_B) n_s - k_2 N_A \beta,$$

where

$$1 - \eta_B = \left[1 + \exp\left(\frac{w - \varepsilon_s}{kT}\right)\right]^{-1}, \quad (6a)$$

$$n_s = C_n \exp\left(-\frac{\varepsilon_s}{kT}\right). \quad (6b)$$

$$\beta = \beta_0 \exp\left(-\frac{v - w}{kT}\right). \quad (6c)$$

Here n_S is the concentration of free electrons just below the surface. Hauffe also assumes that

$$k_1 = k_0 \exp\frac{w}{kT}. \quad (6d)$$

The discussion then follows the same lines as for the case of chemisorption on a p-type semiconductor.

We should note that formula (6d) is equivalent to assuming that the rate of filling of the surface traps by electrons from the conduction band increases exponentially with their depth below the conduction band, a hypothesis which is in no way substantiated. Expression (6c), on the other hand, stated that, when a chemisorbed species is desorbed, the electron which was captured by this species is released to an adsorption centre (trap) and not to the conduction band.

Again, it is not clear why a three-body collision should be a prerequisite of chemisorption (impinging gas particle + + empty trap + free lattice electron), and why chemisorption cannot occur at a trap already filled by an electron.

In the discussion of the chemisorption of CO and H_2 on NiO (a p-type semiconductor), the first stage is assumed to be physical adsorption[45]:

$$CO + L \rightarrow CO \cdot L, \quad (7a)$$

where CO·L denotes a physically adsorbed molecule of CO.

The second stage is the transition from the physically adsorbed to the chemisorbed state:

$$CO \cdot L + pL \rightarrow COpL, \quad (7b)$$

where pL is a hole and COpL is a chemisorbed, positively charged CO molecule.

The rate of the first stage (7a) is given as

$$\frac{dN^0_{CO}}{dt} = k_1 P_{CO} - k_1' N^0_{CO} - k_2 N^0_{CO} p_s + k_2' N^+_{CO} \gamma.$$

Here N^0_{CO} and N^+_{CO} denote the surface concentrations of physically and chemically adsorbed CO molecules respectively, P_{CO} is the partial pressure of CO, and p_S the concentration of holes in the layer just below the surface.

The rate of the second stage (7b) is expressed in the form

$$\frac{dN^0_{CO}}{dt} = k_2 N^0_{CO} p_s - k_2' N^+_{CO} \gamma, \quad (8)$$

where (see Fig. 3)

$$p_s = C_p \exp\left(-\frac{\varepsilon_s}{kT}\right),$$

$$\gamma = \gamma_0 \exp\left(-\frac{v}{kT}\right).$$

Assuming that equilibrium between the physically adsorbed molecules and the gas phase is maintained at all times, Eqn. (8) takes the form

$$\frac{dN^+_{CO}}{dt} = k_3 P_{CO} \exp\left(-\frac{\varepsilon_s}{kT}\right) - k_3' N^+_{CO} \exp\left(-\frac{v}{kT}\right). \quad (9)$$

Eqn. (9) cannot be solved. From the condition $dN^+_{CO}/dt = 0$, we find the concentration of chemisorbed CO molecules corresponding to adsorption equilibrium.

Thus, Hauffe's work has been aimed at obtaining adsorption isotherms from the kinetic equations which were formulated, and not at solving these equations in order to characterise the kinetics of chemisorption. We must also point out that according to Hauffe the adsorption level undergoes charge transfer with the conduction band only in the

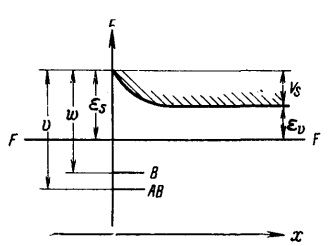

Fig. 2.

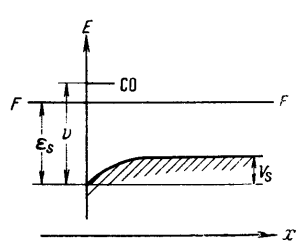

Fig. 3.

case of an n-type semiconductor and with the valence band only in the case of a p-type semiconductor. This implies that the adsorption level must be located near the conduction band for an n-type semiconductor and near the valence band for a p-type semiconductor. This hypothesis is groundless, since the position of the adsorption level in the energy spectrum depends on the nature of the chemisorbed species and on the nature of the lattice, but certainly not on the conductivity type of the semiconductor.

3. Kinetic Model of Chemisorption

Germain has discussed[18,46] what he calls a kinetic model of chemisorption. A molecule held on the surface by van der Waals forces is assumed[18] to give rise to a localised level A in the forbidden gap of the semiconductor (see Fig. 4). For concreteness, the level is assumed to be of the acceptor type. Partly ionised donors are present on the surface (level D):

$$DL \rightleftarrows DpL + eL. \qquad (10a)$$

An electron, donated by the surface donor to the conduction band, is captured from this band by the adsorption level A. As a result, the physically adsorbed A molecule is converted into an A^- ion and passes into the chemisorbed state:

$$A \cdot L + eL \rightarrow AeL. \qquad (10b)$$

Thus, chemisorption results from the consecutive transitions (10a) and (10b), and can be visualised as

$$DL + A \cdot L \rightarrow DpL + AeL. \qquad (10c)$$

It is assumed that the rate of chemisorption is equal to the rate of ionisation of the surface donors D, whose activation energy is taken to be equal to $\varphi - \chi$. The rate of adsorption is expressed in the form

$$\frac{dN_A^-}{dt} = k_1 P_A \exp\left(-\frac{\varphi - \chi}{kT}\right), \qquad (11)$$

where P_A is the pressure of the gas being adsorbed and N_A^- the surface concentration of chemisorbed species (i.e. of A^- ions), with $\varphi = \varphi(N_A^-)$. The rate of desorption is equated to the rate of the reverse reaction (10b), and is written in the form

$$-\frac{dN_A^-}{dt} = k_2 N_A^- \exp\left(-\frac{v - \chi}{kT}\right).$$

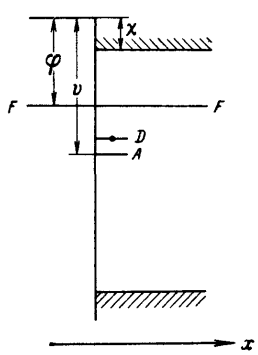

Fig. 4.

(It is evident from Fig. 4 that the difference $v - \chi$ is equal to the depth of the adsorption level below the conduction band.)

The condition of equal rates of adsorption and desorption defines the adsorption isotherm in an implicit form. At the beginning of the chemisorption process the rate is given by Eqn. (11). For small values of N_A^-, it is assumed that

$$\varphi = \varphi_0 + a(N_A^-)^2,$$

so that, taking (12) into account, Eqn. (11) becomes

$$\frac{dN_A^-}{dt} = C \exp[-a(N_A^-)^2],$$

where C and a are constants ($C > 0$, $a > 0$).

However, if a positively ionised surface donor D^+ appears on the surface for every newly produced, negative, chemisorbed A^- ion [see Eqn. (10c)], the surface charge (and therefore also the value of φ) should stay constant during chemisorption, which is of course not the case.

In Germain's[46] work the rate of adsorption is not related to the rate of ionisation of a surface impurity, but is assumed proportional to the pressure (which is taken to be constant) and, for chemisorption of the acceptor type, to the concentration n_S of free electrons in the plane of the adsorbent surface. Here $n_S \propto \exp(V_S/kT)$, so that

$$\frac{dN_A^-}{dt} = \lambda \exp\left(-\frac{V_s}{kT}\right). \qquad (12)$$

The author points out that if V_S is linearly related to N_A^- Eqn. (12) reverts to the Roginskii–Zel'dovich kinetic equation (1a), but if

$$V_s = V_s^0 - kT \ln[1 - (N_A^-)/(N_A^-)_{max}] \qquad (13)$$

the kinetic isotherm of Langmuir is obtained:

$$N_A^- = (N_A^-)_{max}[1 - \exp(-\alpha t)].$$

A similar expression for the rate of chemisorption is given by Weisz[47]: the rate of adsorption (of an acceptor gas) is proportional to the flux density of free electrons directed from the bulk towards the surface of the semiconductor, i.e. to the product of their surface concentration, their mobility, and the potential gradient at the surface.

Lastly, we shall discuss the work of Jantsch[48]. According to his model, a species landing on the surface from the gas phase is physically adsorbed and wanders on the surface until it is enabled to undergo charge transfer with the adsorbent at some surface defect. It is then converted into an ion, and this brings about the transition from the physically adsorbed to the chemisorbed state.

Furthermore, direct desorption of a chemisorbed species is considered to be very unlikely, such species disappearing from the surface only through transition to the physically adsorbed state. The kinetics of chemisorption are given by the equation

$$dN/dt = g - f. \qquad (14)$$

Here N is the surface concentration of chemisorbed species, g the increment of N per unit time resulting from transitions from the physically to the chemically adsorbed state, and f the decrement of N caused by the reverse process.

The expression for f is written in the form

$$f = N/\tau, \qquad (15a)$$

where τ is the average lifetime of a species in the chemisorbed state, and the expression for g is of the form

$$g = (\sigma z + N/\tau)w, \qquad (15b)$$

where z is the number of collisions of gas molecules with 1 cm² of the surface per second and w the probability of finding an adsorbed species in the chemisorbed state. The quantities τ, z, σ, and w are constant. We should note that the factor $(\sigma z + N/\tau)$ in Eqn. (15b) obviously expresses the increase in the concentration of physically adsorbed species per unit time. Expressing g in the form of Eqn. (15b) is equivalent to assuming that the rates of physical and chemical adsorption are in the ratio of $1 : w$. This hypothesis (whose justification is not clear) excludes the concentration of physically adsorbed species from (15b).

By inserting into Eqn. (14) the expressions (15a) and (15b) and integrating we can arrive at the Langmuir kinetic isotherm:

$$N(t) = \alpha[1 - \exp(-\beta t)],$$

where

$$\alpha = \sigma z \tau w/(1 - w); \qquad \beta = (1 - w)/\tau.$$

Thus, all the (theoretical) papers on the kinetics of chemisorption at semiconductor surfaces considered here have the following characteristic feature in common: they treat chemical adsorption as a charged form of adsorption. The possibility of a chemical bond between an electrically neutral gas molecule and the adsorbent lattice is completely ignored. This neglect of the neutral form of chemisorption is characteristic of the boundary layer theory, and can be taken to be its most serious defect.

It can be shown[42] that desorption of species directly from the charged state is much less probable than desorption of neutral species, and therefore exchange between the chemisorbate and the gas phase occurs almost entirely via the neutral form of chemisorption. On the other hand, the transition of a chemisorbed species from the neutral to the charged state can be the rate-limiting step in a number of reactions occurring at a semiconductor surface. Garrett[50] used this approach in his theoretical study of the rate of a reaction involving the mechanism

$$\mathrm{AeL} + \mathrm{DpL} \rightarrow \mathrm{ADL},$$

where A is an acceptor species and D is a donor species.

We should note, however, that in many of the papers discussed above physical adsorption is identified with the neutral form of chemisorption to a greater or lesser extent. This is specially true of the work of Germain[18], in which the function of the neutral form of chemisorption is wholly ascribed to a state which Germain terms physical adsorption.

III. THE ELECTRONIC THEORY OF CHEMISORPTION

1. Role of the Electronic Factor in the Kinetics of Chemisorption on a Homogeneous Surface

In the last three subsections of this article we shall discuss the role of the electronic factor in the kinetics of chemisorption on semiconductors from the standpoint of the electronic theory. We shall assume that chemisorbed species can exist at the surface either in an electrically neutral or in a charged state (corresponding to the "weak" and the "strong" surface bond respectively), and that transitions between the two states are possible. To make the discussion more concrete, we shall confine ourselves to the adsorption of acceptor species.

Let us examine the kinetics of chemisorption on a uniform surface[51], at constant temperature T and pressure P. Let N^0 and N^- be the surface concentrations of chemisorbed species in the neutral and in the charged states respectively. Assuming that only the species present on the surface in the neutral state can be desorbed, whereas the charged species do not undergo exchange in any way with the gas phase, we can write

$$\left.\begin{aligned} dN^0/dt &= (a_1 - a_2) - [(b_1 + b_4) - (b_2 + b_3)] \\ dN^-/dt &= (b_1 + b_4) - (b_2 + b_3) \end{aligned}\right\} \qquad (16)$$

where

$$\left.\begin{aligned} a_1 &= \alpha_1 P(N^* - N) & a_2 &= \alpha_2 N^0 \exp(-q^0/kT), \\ b_1 &= \beta_1 n_s N^0, & b_2 &= \beta_2 N^- \exp(-v/kT), \\ b_3 &= \beta_3 p_s N^-, & b_4 &= \beta_4 N^0 \exp[-(u - v)kT], \end{aligned}\right\} \qquad (17)$$

and

$$\alpha_1 = \varkappa/N^* \sqrt{2\pi MkT}, \quad \varkappa = \varkappa_0 \exp(-E_0/kT). \qquad (18)$$

Here a_1 and a_2 are the numbers of species adsorbed and desorbed per second from 1 cm² of the surface, b_1, b_2, b_3, and b_4 are the numbers of corresponding electronic transitions per cm² of the surface per second (see Fig. 5); N^* is the surface concentration of adsorption centres, i.e. the maximum number of species which can be adsorbed on 1 cm², q^0 is the energy required to detach a neutral species from the surface (the energy of the "weak" bond), M the mass of the adsorbed species, $\varkappa$ the capture probability of a species by the surface, E_0 the activation energy attending the formation of a "weak" bond, and n_S and p_S are the concentrations of free electrons and holes in the plane of the adsorbing surface (at $x = 0$); the significance of the quantities v and u is clear from Fig. 5.

We shall also use the symbols

$$\left.\begin{aligned} 1/\tau &= \alpha_2 \exp(-q^0/kT), \\ 1/\tau^0 &= \beta_1 n_s + \beta_4 \exp[-(u - v)/kT], \\ 1/\tau^- &= \beta_3 p_s + \beta_2 \exp(-v/kT), \end{aligned}\right\} \qquad (19)$$

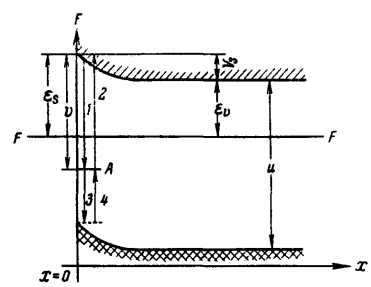

Fig. 5.

Note that $1/\tau$ defines the probability (per unit time) of desorption of a species; $1/\tau^0$ and $1/\tau^-$ are the probabilities of charging and discharging a chemisorbed species respectively. In other words, τ is the mean lifetime of a species in the adsorbed state, τ^0 and τ^- are the mean lifetimes of a chemisorbed species in the neutral and charged states respectively.

At low coverages, when

$$N \ll N^*, \tag{20}$$

the system of equations (16) can be written, using Eqns. (17)–(20), in the form

$$\left.\begin{aligned} \frac{dN^0}{dt} &= \frac{N^0_\infty - N^0}{\tau} - \left(\frac{N^0}{\tau^0} - \frac{N^-}{\tau^-}\right), \\ \frac{dN^-}{dt} &= \frac{N^0}{\tau^0} - \frac{N^-}{\tau^-}, \end{aligned}\right\} \tag{21}$$

where $N^0_\infty = N^0(\infty)$. We have made use of the fact that at $t = \infty$ we have $a_1 = a_2$, whence $\alpha_1 PN^* = N^0_\infty/\tau$.

Assuming that electronic quasi-equilibrium exists in the bulk of the semiconductor (i.e. that the distribution of free electrons and holes is approximately the equilibrium distribution corresponding to the instantaneous value of the surface charge), and that the electron and hole gases are non-degenerate, we can use equilibrium Boltzmann expressions for n_s and p_s. Under these conditions τ^0 and τ^- turn out to be functions of N^-.

If we solve the simultaneous equations (21) for constant τ^0 and τ^-, i.e. ignoring changes in the bending of the bands during chemisorption, we can analyse the kinetics of adsorption and desorption, and then proceed to show that the main features of the kinetics thus obtained do not alter appreciably when allowance is made for changes in the bending of the bands.

If electronic equilibrium exists at the surface at any given instant, t, the relative extents of the neutral and of the charged forms of chemisorption at that instant can be calculated by the well-known formulae of Fermi statistics:

$$\left.\begin{aligned} \eta^-(t) &= \frac{N^-(t)}{N(t)} = \left[1 + \exp\frac{\varepsilon_s(t) - v}{kT}\right]^{-1}, \\ \eta^0(t) &= \frac{N^0(t)}{N(t)} = \left[1 + \exp\frac{v - \varepsilon_s(t)}{kT}\right]^{-1}, \end{aligned}\right\} \tag{22}$$

where ϵ_S is the depth below the bottom of the conduction band of the Fermi level at the surface (see Fig. 5).

According to the relative values of the characteristic times τ, τ^0, and τ^-, electronic equilibrium can be preserved or destroyed during adsorption and desorption. The former regime (adsorption or desorption in which electronic equilibrium is maintained) is observed when

$$\tau^0, \tau^- \ll \tau. \tag{23a}$$

In this case (case *a*) the establishment of electronic equilibrium is fast in comparison with the establishment of adsorption equilibrium. Electronic equilibrium at the surface is set up long before adsorption equilibrium, and is maintained at all times. The second regime (case *b*) exists when adsorption or desorption causes a perturbation of the electronic equilibrium, i.e. when

$$\tau \ll \tau^0, \tau^-. \tag{23b}$$

In this case adsorption occurs in two distinguishable stages: first, equilibrium between the neutral form and the gas phase is rapidly set up, and then, in a second stage, the charged form appears whilst the concentration of neutral species remains stationary.

Either of these two limiting cases can occur in practice, depending on the nature of the adsorbent and of the adsorbate.

On the assumption that τ^0, τ^- = const, the kinetics of chemisorption after a short initial period take the form of the Langmuir equation. If allowance is made for the change in the bending of the bands during chemisorption, the kinetic isotherms usually depart from the Langmuir form. As long as electronic equilibrium is maintained, the departures from Langmuir kinetics appear only in the region close to adsorption equilibrium, whereas in the absence of electronic equilibrium these departures manifest themselves long before adsorption equilibrium is reached. Combining the two equations (21), we obtain

$$\frac{dN}{dt} = \frac{N^0_\infty - N^0}{\tau}, \tag{24}$$

whence it is evident that, as long as $N^0 \ll N^0_\infty$, the function $N(t)$ increases approximately as $N^0_\infty t/\tau$, as required by Langmuir kinetics, in the region far from adsorption equilibrium. In the case of electronic equilibrium the conditions $N^0 \simeq N^0_\infty$ necessarily implies that we are approaching adsorption equilibrium. When electronic equilibrium is disturbed, however, N^0 becomes comparable with N^0_∞ long before adsorption equilibrium is established.

The dependence of the activation energy for adsorption upon electronic parameters such as ϵ_v, V_S, and ϵ_S is quite different for the two cases *a* and *b*. If condition (23a) applies, then in the region far from adsorption equilibrium the activation energy is in general independent of the electronic parameters. This is evident from Eqn. (24), since when $N^0 \ll N^0_\infty$ we have

$$\frac{dN}{dt} = \frac{N^0_\infty}{\tau} = \alpha_1 PN^* = k\exp\left(-\frac{E_0}{kT}\right).$$

This situation obtains even if the charged form of chemisorption predominates in the adsorbate, so that the rate of adsorption is practically the same as the rate of generation of the charged form. This is not surprising if we remember that the rate of appearance of charged species (acceptors) is proportional not only to n_S but also to the concentration of unoccupied levels, i.e. the extent of the neutral form of chemisorption. It turns out that, if electronic equilibrium is maintained during adsorption and the chemisorbate is predominantly in the charged form, then the larger n_S the lower is the concentration of unoccupied levels at any instant: the net result is that the rate of appearance of charged species (and hence the rate of adsorption) becomes independent of n_S, i.e. of the position of the Fermi level.

The situation is quite different when electronic equilibrium is disturbed [case (23b)]. In the second stage, when the neutral species have reached equilibrium with the gas phase and the charged form of chemisorbate is being produced, the activation energy for adsorption includes the term ϵ_S. Under these conditions we are far from adsorption equilibrium. The rate of adsorption is given by the expression

$$dN/dt = k_0 \exp(-\varepsilon_s/kT).$$

It can be shown that this formula remains valid even when changes in band bending during adsorption are allowed for. By inserting various alternative forms of the function $\epsilon_S = \epsilon_S(N)$, we obtain various kinetic isotherms not of a non-Langmuir form. The following relationships have been observed experimentally[13]:

$$\varepsilon_s = AN + B \text{ and } \varepsilon_s = A' \ln N + B'.$$

The form of the function $\epsilon_S = \epsilon_S(N)$ has been studied theoretically by Kuznetsov[52].

2. Partial Irreversibility of Chemisorption on Semiconductors

It is well known that desorption at the temperature of the adsorption experiment does not always remove the whole of the chemisorbate from the surface. This phenomenon is termed partial irreversibility of chemisorption. We shall consider here two possible mechanisms[53,54].

The first mechanism stems directly from the model of desorption proposed for the case where electronic equilibrium is disturbed. Thus, in case *b* [see condition (23b)] the desorption of charged species lags very considerably behind the desorption of neutral species: after a time of the order of τ practically all the neutral species have left the surface, whereas the desorption of charged species is protracted over a much longer time interval, of the order of τ^-. An important consideration here is that τ^- can be very large: values of the order of 10^4–10^5 s have been computed. In this case the duration of a practical desorption experiment can be small compared with τ^-, i.e. with the time needed to remove the charged species, and hence also with the time needed for complete desorption of the chemisorbate. In these circumstances we shall be able to observe, in practice, only the desorption of the neutral form, and the charged form will appear to be almost irreversibly bound to the surface. We should note that if we abandon the assumption that only a small fraction of the adsorption centres is occupied [see Eqn. (20)], then the time for complete adsorption is found to be much less than the time for complete desorption.

The second mechanism consists in the reaction between the chemisorbate and an impurity present in the bulk of the semiconductor. For example, in the chemisorption of oxygen on ZnO the ionised interstitial zinc Zn_i^+ arriving at the surface from the bulk can react as follows with a charged, chemisorbed oxygen atom O_a^-:

$$Zn_i^+ + O_a^- \rightarrow Zn^{2+}O^{2-}.$$

This process is equivalent to an irreversible addition to the crystal lattice resulting from oxidation of the zinc in excess of stoichiometry. Many authors[30,35,45,55] have discussed the role of processes of bulk impurity extraction in chemisorption.

The most characteristic difference between the two mechanisms is that the irreversibility associated with the first is only "apparent": if desorption is allowed to proceed for a long enough time the charged form of chemisorbate ion will also be removed from the surface. On the other hand, the irreversibility associated with lattice addition can be regarded as "true" irreversibility. Furthermore, "apparent" irreversibility effects can be expected only at not too high temperatures, since τ^- falls off rapidly with increase of temperature. On the other hand, the "true" irreversibility mechanism requires a high enough mobility of the reacting impurity, and should therefore be undetectable at low temperatures, its contribution increasing sharply with increase of temperature.

Many experimental observations can be accounted for by either of these two mechanisms (for example, the large extent and large irreversibility of the adsorption of oxygen on ZnO specimens with a high content of interstitial zinc, which does not affect, however, the initial rate of desorption[30]). Therefore, it is interesting to distinguish experimentally between these two mechanisms of irreversible adsorption and to identify the mechanism which is operative under some particular experimental conditions. We shall now consider the appropriate criteria, making the following assumptions: the reaction is so slow that the equilibrium (Boltzmann) distribution of the reacting impurity in the bulk of the solid is not disturbed; chemisorption (or, more precisely, the appearance of charged species on the surface) is fast in comparison with the diffusion of the reacting impurity towards the surface; the amount of impurity removed is small in comparison with the total amount of reacting impurity in the crystal.

Based on these assumptions, the following criteria for distinguishing experimentally between "true" and "apparent" irreversibility have been obtained.

1. Let N_r and N_i stand for the reversible and the irreversible contributions to the chemisorption respectively. "Apparent" and "true" irreversibility lead to different relationships, other conditions being equal, between the ratio N_i/N_r and the bending of the bands at the surface (V_S).

In the case of "apparent" irreversibility

$$N_i/N_r \propto \exp(-V_s/kT),$$

whereas if the irreversibility is "true" and the charged form of chemisorption predominates, the expression becomes

$$N_i/N_r \propto \exp(+V_s/kT),$$

or, if the neutral form predominates in the case of "true" irreversibility,

$$N_i/N_r = \text{const}.$$

2. The kinetics of the change in the electron work function (φ) and in electrical conductivity (σ) of the adsorbent are different in the two cases. In the case of "apparent" irreversibility we should find partial irreversibility of φ (since the neutral species are desorbed, the charged species remain on the surface, and both contribute to the change in φ) and complete irreversibility of σ (since σ is determined only by the concentration of charged species, which remain on the surface, see curves *2* of Fig. 6). However, if the chemisorption is "truly" irreversible, we should observe complete reversibility of both these quantities (curve *1* of Fig. 6). In this case, both neutral and charged species are removed from the surface, since the absorption of charged species by an impurity is equivalent to their removal from the surface as regards their effect on φ and σ. Thus, direct adsorption measurements are necessary in order to identify true irreversibility.

Of course, the above statements are correct only if the surface reaction does not influence too strongly the spectrum of surface states due to causes other than adsorption.

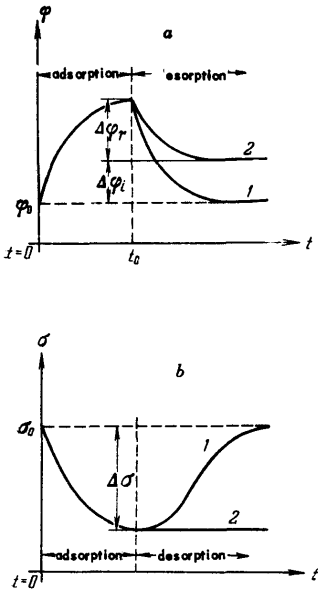

Fig. 6.

We should also remember the assumption that the impurity is effectively inexhaustible, so that ϵ_v remains constant.

An "apparent" irreversibility mechanism is evidently involved in the adsorption of oxygen on TiO_2 at room temperature: this is shown by the changes in φ and σ during desorption recently reported by Figurovskaya[56]. A "true" irreversibility mechanism can be observed at temperatures as low as 350° on zinc oxide, as reported by Glemza and Kokes[57], who made a combined study at this temperature of the adsorption of oxygen on ZnO and of the kinetics of changes in σ.

3. Electronic Aspects of the Inhomogeneity of the Adsorbent Surface

The idea of inhomogeneity in the adsorbent surface arose from attempts to explain the large fund of experimental data which do not fit into the simple model of adsorption phenomena developed by Langmuir. The theory of adsorption and catalysis at inhomogeneous surfaces, due mainly to Roginskii's school[58,59], assumes that different portions of the surface differ in their adsorption properties: their adsorption parameters (such as the heat of adsorption and the activation energy) are not the same everywhere, but each element of area shows simple (Langmuir) behaviour. Surface inhomogeneity is characterised by a definite distribution function of the elements of area with respect to activation energy and heat of adsorption.

It should be noted that the universality of the initial Langmuir model is lost[60] when allowance is made for the electronic processes taking place at the surface during chemisorption. In the electronic theory of chemisorption the adsorption and kinetic laws are not, generally speaking, of the Langmuir type, even for a uniform surface and in the total absence of direct interaction between chemisorbed species. This is because in the treatment of the adsorbent–adsorbate system as a unified quantum-mechanical system the species are "made aware" of each other through the electron gas of the adsorbent. Thus, the concept of inhomogeneity is only an additional cause for departure from the Langmuir laws.

We shall attempt here to deal with the case where the initial adsorption behaviour of the homogeneous elements of surface is non-Langmuir. In other words, the contribution of chemisorption to the surface charge is assumed small, and therefore the variation of ϵ_S with N is ignored. Only in this case can the inhomogeneity of the adsorbent surface be characterised by a distribution function specific to the surface itself: in the more general case the "distribution function" is a characteristic of the combined adsorbent–adsorbate system[60]. This approximation is equivalent to separating the effects of surface inhomogeneity and surface charging during chemisorption[61,62].

The basic problem facing the theory of adsorption and catalysis at inhomogeneous surfaces is to clarify the physical significance of the distribution function by which the theory operates. The question is: why do the different elements of surface show different activation energies or heats of adsorption? According to the ideas of the electronic theory, the adsorption properties of any part of the surface are determined by the electronic state of the system, i.e. by the position of the Fermi level in that particular element of area. Therefore, any mechanism causing the position of the Fermi level (relative to the energy bands) to vary from point to point on the surface can serve as a physical basis for surface inhomogeneity. In particular, inhomogeneity can result from uneven distribution of impurities in the bulk and at the surface of a semiconductor (even when we are dealing with impurities of a single kind). In practice, the topography of the Fermi level at the surface, i.e. its position with respect to the energy bands, is uniquely determined (as a function of position along the surface) by the distribution of impurities in the semiconductor. We must stress that the impurity in question can be one not directly involved in chemisorption (i.e. not playing a direct part in the act of chemisorption). For example, it may be an impurity located in the bulk phase. The concept of an impurity uniformly distributed in a semiconductor, widely adopted in theoretical papers, is of course greatly idealised. The inhomogeneity of the electronic properties f a semiconductor surface is a well-known fact[63–65].

As an illustration of what has been said, we shall consider the adsorption isotherm, which for a uniform surface is of the form

$$N/N^* = \theta = [1 + (b_0/P)\exp(-q/kT)]^{-1}, \qquad (25)$$

where, according to Vol'kenshtein[42],

$$q = q^0 - kT\ln\eta^0(\varepsilon_s).$$

Obviously, surface inhomogeneity implies that different areas will have different values of q. It is with respect to this quantity that averaging is carried out in the theory of adsorption at inhomogeneous surfaces. All the distribution functions which are compared with experimental adsorption isotherms in the theory are, in fact, distribution functions with respect to q. As long as we remain within the boundaries of Langmuir's molecular-kinetic model, i.e. as long as we ignore the electronic processes attending chemisorption, we have $\eta^0 = 1$, and therefore the quantity $q = q^0$ has the significance of a bond energy between the

chemisorbed species and the surface. Under these conditions the isotherm (25) is indistinguishable from the familiar Langmuir isotherm

$$N/N^* = \theta = (1 + b/P)^{-1},$$

where

$$b = b_0 \exp(-q^0/kT),$$

and any inhomogeneity results from local differences in the energy q^0 between the chemisorbed species and the surface, and can therefore be characterised by a distribution function with respect to q^0.

In the electronic theory of chemisorption differences in bond energy q^0 are not excluded, but they do not play the major role. Local differences in the position of the Fermi level ϵ_S are also possible. This will give rise to differences in the value of q for different elements of the surface, even if the bond energy q^0 is the same everywhere. In this case the surface inhomogeneity will be characterised by a distribution function with respect to ϵ_S.

In order to apply to an inhomogeneous surface a kinetic isotherm obtained for a uniform surface, some sort of averaging over a parameter of the equation is necessary. It can be shown that local differences in the part of the activation energy E_0 which does not depend on electronic parameters (i.e. differences in the capture probability of a species by the surface) do not cause departures from the Langmuir form of the kinetic isotherm (at low coverages). Non-Langmuir isotherms can be obtained in two ways, either by assuming local differences in the position of the Fermi level or by assuming local differences in the energy needed to remove a neutral species from the surface. Differences in ϵ_S may or may not lead to non-Langmuir kinetic isotherms, depending on the relative values of the time--constants τ, τ^0, and τ^-, and also on the position of the local chemisorption level with respect to the surface Fermi level. An important consideration is that if adsorption (of acceptor species) occurs under conditions such that electronic equilibrium is not maintained, and only the conduction band takes part in electron transfer processes at the surface, non-Langmuir kinetics can arise after some initial time interval only from differences in surface charge, i.e. from the fact that the kinetic isotherm was not of the Langmuir form even for a homogeneous surface. If the kinetic isotherm in this case is of the Langmuir type, i.e. of the form

$$N = A[1 - \exp(-kt)],$$

the coefficient k depends only on the position of the level associated with the chemisorbed species relative to the energy bands, and hence no averaging process can alter N.

It is clear that the role of the electronic factor in the kinetics of chemisorption on semiconductors is radically different according to whether electronic equilibrium is or is not maintained; the most characteristic kinetic features, established experimentally, are indeed those which refer to the case of disturbed electronic equilibrium. These include: (1) the non-Langmuir character of the kinetic isotherms, whose shape is determined, as shown by the work of Enikeev, Margolis, Roginskii, Rufov, and others, by the form of the function $\epsilon_S = \epsilon_S(N)$, i.e. by the way in which the work function varies with coverage; (2) the dependence upon electronic parameters of the activation energy for adsorption. Thus, the assumption that electronic equilibrium is maintained during chemisorption is far from always being justified, and is not a theoretical necessity.

Further progress in the study of kinetics, and therefore also of chemisorption on semiconductors, must await new investigations, particularly experimental ones, of the kinetics of chemisorption (in the usual meaning of the word) coupled with a study of the accompanying changes in the electronic state of the adsorbent and of the species held on its surface.

I. INTRODUCTION

Polymers with conjugated bonds occupy a central place in an interesting new class of compounds, that of organic semiconductors, which includes also low-molecular-weight one-component compounds with conjugated bonds (for example, condensed aromatic systems, dyes, etc.), individual charge-transfer complexes, some biological materials such as proteins, and charcoals. The intensive research devoted to these polymers, which were first synthesised as recently as the late 1950's,[1-4] has aroused wide interest in the problem and has created a borderline science: the physics and chemistry of organic semiconductors†. The main attraction of polymers in this context is the fact that their chemical configuration and their structure can be modified as required, thus providing an unlimited number of materials on which to study the nature of the specific properties of organic semiconductors and the modification of these properties in a desired direction.

In recent years, many reviews and monographs have been written on the methods of preparation[24-27] and on the properties[13-17,21,28-37] of semiconducting polymers. It is now recognised that polymers with conjugated bonds, like organic semiconductors of other classes, have a specific type of electronic and atomic structure which gives rise to a combination of properties uncommon in organic compounds: a special electrical and magnetic behaviour, high thermal stability, low solubility, reactivity of a specific kind (in particular, catalytic activity‡), etc. In the present review, which includes all work published up to January

† Progress in the study of organic semiconductors of various classes has been discussed in a number of books and reviews[5-23].

‡ Papers on the catalytic properties of semiconducting polymers, already fairly numerous, will not be considered here because of lack of space. See, for example, Refs. 38–43 and also p.778.

1966 (and a few more recent papers), we shall be primarily concerned with the electrical, magnetic, and structural studies of polymers with conjugated bonds of the classes listed below.

CARBO-CHAIN POLYMERS

A. With Acyclic or Alicyclic Conjugation Chain

1. Polyvinylene ("polyacetylene"), prepared by dehydrochlorination of poly(vinyl chlorides) (PVC),[1,44-55] dehydration of poly(vinyl alcohols) (PVA),[56-62] polymerisation of acetylene[63,64] and polycondensation of acetaldehyde[65,66].

2. Substituted polyvinylenes: poly(phenylacetylene)[2,3,65,67-75] and others[38,39,64-66,76-90].

3. Polyacetylene (poly-yne): $-[C\equiv C]_n-$ or $=[C=C]_n=$.[61,91-93]

4. Poly(cyclopentadiene)[95-97].

B. With Aromatic Rings in the Conjugation Chain

1. Polyphenylene[64,67,71,98-101], polyphenylene–polyvinylenes[102,103], and block copolymers of polyphenylene[98,104,105].

2. "Polybenzenes", polynaphthalenes, and other polyacenes[64,87,97,106,107].

3. Poly(arylenequinones)[67,108-111].

4. Polyarylene-polyacetylenes with triple bonds in the conjugation chain[39,61,91,112-124].

HETERO-CHAIN POLYMERS

1. Containing nitrogen in the conjugated chain: poly(acrylonitrile)§ (PAN)[41,48,78,125-147] and other polynitriles[66,132,148-159], paracyanogen[132], poly(azophenylenes)[67,99,105,160-167,217,392,393], poly(Schiff bases)[132,168-177], polyazines[175,178-180], poly(aryleneamines)[181-185], poly(aminoquinones)[186-188], poly(azoarylenequinones)[189], polytriazines[67,190], polypyridines[191-196], polypyrrole¶[197,198], poly(tetracyanoethylene)[155,199-201], aniline black[172,202,203] and others[49,196,204-210].

2. Containing oxygen in the conjugated chain: polyxanthenes or poly(acenequinone) radicals[48,100,172,208,211-216] and others[16,48,50,124,178,180,217,218].

3. Containing sulphur in the conjugated chain[107,178,180,208,217,219,220].

Various chelate polymers¶ with N, O, and S atoms in the conjugation chain have also been investigated (see, for example, Refs. 221–224).

§ The system of conjugated bonds and the semiconducting properties appear only after heat treatment.

¶ It must be emphasised that these polymers retain their specific electrical and magnetic properties even when the continuous conjugated chain in the molecule is interrupted by bridges of the hetero-atoms or by other groups ($-CH_2-$, $-SO_2-$, biphenylene, etc.): see next column and p. 776.

CHELATE POLYMERS (POLYCOORDINATION COMPOUNDS)

This group includes the poly(phthalocyanines)[225-232], poly(tetracyanoethylenes)[97,200,233-243], polyferrocenes[17,67,208,156,216,244-249], and others[58,67,112,186,221-224,250-268]. These polymers are based on chelate complexes of both transition metals (Cu, Fe, Co, Ni, Mn, etc.) and non-transition metals (Mg, Zn, Cd, Hg).

OTHER TYPES OF SEMICONDUCTING ORGANIC POLYMERS

1. Products of the radiation–thermal treatment of polyethylene[269-279] and poly(acrylonitrile)[131,280].

2. Compositions including polymers and metallic powders[231,281-288].

3. Complexes formed by various polymers with halogens[74,174,185,197,198,205,211,289-294] and with other organic substances[51,295,296], with organic molecules[185,290,295,297,298], and also with O_2.[74,195,198,275]

II. SPECIFIC PROPERTIES OF SEMICONDUCTING POLYMERS

1. Chemical Structure of the Molecule and Structure of the Material

The electronic properties of solid organic compounds able to crystallise only in the form of molecular lattices are determined, on the one hand, by the properties of the separate molecules and, on the other hand, by the way in which these molecules are packed and by their mutual interactions, i.e. by the parameters of the solid as a whole. It is best to consider these two factors separately.

From the point of view of the chemical structure of the molecule, the principal feature common to all semiconducting polymers is a system of conjugated π-bonds. The properties of such a system reveal themselves: (1) in the colour of the material, which becomes deeper as the degree of conjugation in the molecule increases (and can become black, for example after heating to 400°)[3,45,59,64,72,121,122,177,299] and less intense when the conjugation is perturbed[45,122,123,125,180]; (2) in the infrared spectra (appearance of new characteristic bands[49,59,60,83,91,93,129,239,299,301] and sharp increase in background absorption[98,239,248,302,303]); (3) in the u.v. spectra (development of strong characteristic absorption[133,134,167,242]) and in the fluorescence spectra[69,304-306]; (5) in the electrical properties (see Section II, 2).

However, recent work has shown that the earlier views, according to which the molecule of a semiconducting polymer can be visualised as a one-dimensional crystal with an uninterrupted system of conjugated π-bonds[30,307], are incorrect. There is abundant evidence for this statement. The usual sequence of colour changes of polymers subjected to heating and irradiation (yellow to brown) is not what we would expect from a gradual increase in length of the conjugated system (yellow, red, purple, blue)[52]. Heating of the polymers does not give rise to a clear long-wave shift of the absorption maximum in the u.v. spectra, but only increases the intensity near the long-wave edge of the band[133,134,242]. Heat-treated poly(methyl vinyl ketone)[300], unlike PAN[299], does not show a long-wave shift in the infrared spectrum. The electrical properties are not seriously

impaired[81,122,124,164,165,175,176,178,180,184] when the conjugation in a polymeric chain is destroyed by introducing bridging groups such as CH_2, O, N, and the biphenylene grouping, whose rings have been shown by NMR not to be coplanar[99]. Finally, it is clear from the fluorescence spectra that an increase in molecular weight is not accompanied by an increase in the length of the conjugated system[69], and the ESR spectra, which sometimes show a hyperfine structure for solutions[49,185], indicate that the unpaired electron is delocalised only over 2–7 monomer units[56,68,74,128].

It follows that the continuous conjugated chain in semiconducting synthetic polymers is usually of limited length (probably only a few monomer units). Whatever the cause of this phenomenon† we must conclude that the minimum length of uninterrupted conjugated system of π-bonds needed to give rise to the specific electronic properties of the polymers is no greater than the size of the conjugated systems in low-molecular-weight one-component compounds and in individual charge-transfer complexes. This conclusion is an argument for the general similarity of the electronic nature of all organic semiconductors.

Before proceeding to a discussion of the solid-state structure of semiconducting polymers, we must stress the fact that this structure is composed of oligomeric molecules. Thus, most workers have been unable to obtain a molecular weight higher than 3000, or a degree of polymerisation in excess of 10.[2,83,120,122,160,185,194,195,308,309] According to Berlin[15,160,309], this "oligomericity" is due to a gradual deactivation of the radicals with increasing length of conjugated chain, arising from the increasing delocalisasation of the unpaired electron. However, not all polymerisation processes involve radicals [for example, the dehydration of poly(vinyl alcohol), the dehydrochlorination of poly(vinyl chloride), "onium" polymerisation], and we can therefore envisage gradual deactivation of any reaction centre — not just free radicals — or focus attention on the decrease of the solubility of the product with increasing degree of polymerisation[308], particularly since polymers with conjugated bonds are prone to association in solution (anomalous viscosity).

Because of their low molecular weight, semiconducting polymers can exist not only in the amorphous state but also as crystals with a molecular lattice‡[61,122,135]. Intermolecular interactions in this type of lattice are fairly weak on the whole, as shown by the poor electrical conductivity of the crystalline polymers and also by the instability of the lattice towards heating: the oligomer usually becomes amorphous even at 200–300°,[57,59,60,122,161,310] although some increase in crystallinity can be observed in the initial stages (below 200°)[57,59,310,311].

However, stable local formations exist within the weak lattice, as evidenced by the ESR signal in solution[3,49,68,83,105,195,306,312], from which we can deduce that the concentration of unpaired spins has not changed[3,68,195], by the anomalous viscosity at high dilutions[135,160–162,184,190,195,313], and by the identity of the electronic spectra in the solid state and in solution, all of which have been observed for charge-transfer complexes based on polymers[293]. The nature of these stable formations is discussed tentatively in Section III.

The ease with which the molecular lattice of polymers collapses on heating is due not only to the instability of lattices of this type but also to the fact that a specific amorphous structure is produced[47,59,61,98,122,175,181] in which interaction between π-electron systems and the polar groups of oligomeric molecules can readily occur. This is apparent both from the observed chemical processes[59,60,129,133,134,146,170,299,300] and from the electrical and magnetic properties discussed in Section II, 2 and II, 3. The overall conclusion from the available data is that the specific structure of semiconducting polymers is due to regions with a relatively large number of conjugated bonds (usually, systems of condensed aromatic rings) separated by disordered regions in which the conjugation is weak[47,85,122,128,135,145,191,200,227,237,242,269,270,275] (see p. 780).

Heating to high temperatures (upwards of 500–600°) produces a gradual increase in the size of the conjugated regions and slowly raises the degree of order of the structure[47,59,123,144,146,147,275,314,315], i.e. it makes the properties of the polymers closer to those of charcoals. Of course, crosslinking processes and the formation of a three-dimensional structure can be rather slow[78,120,316]. In particular, a correlation has been found[61,91–93,314,317] between the structure of the pyrolysis products and the structure of the monomer unit in the starting molecules, and it has been shown that carbons can be obtained with a chain (poly-yne or cumulene) rather than a floor-block structure.

It will be clear from the subsequent discussion that, in order to understand the general features of the behaviour of semiconducting polymers, we need to make allowance for the interplay of the two factors considered here: the chemistructure of the molecule and the structural ordering of the material[124,165,175].

2. Electrical Properties

The electrical characteristics of polymers with conjugated bonds can vary widely: from those of dielectrics (as in the case of low-molecular-weight organic semiconductors and weak charge-transfer complexes) to those of semimetals (as in the case of strong charge-transfer complexes and carbons). Values of the electrical conductivity σ vary from 10^{-15} to $10^{2}\ \Omega^{-1}\ cm^{-1}$; the activation energy for conduction E_σ varies from 2 to 0.01 eV§. The variation of σ with reciprocal temperature is typically that expected for a semiconductor: the electrical conductivity increases exponentially with temperature T according to the law

$$\sigma = \sigma_0 e^{-E_\sigma/kT}.$$

The absence of polarisation effects during the passage of current is evidence that the conductivity is electronic rather than ionic[57,58,111,172,198,201,214,272,295]¶. The electrical properties are strongly influenced by the adsorption of oxygen[78,85,122,127,135,176,198,229,247,248,259,290]† and other substances[48,51,57,181,197,198,205,225,259,270], and also by

† In all probability, it is due partly to the low degree of polymerisation characteristic of polymers with conjugated bonds (see below) and partly to spontaneous disturbances occurring during the synthesis of the conjugated system.

‡ Some observations suggesting a correlation between the degree of crystallinity and the structure of the molecule have been reported[61,122,165,175]. It is interesting to note also that some degree of preferential orientation of the macromolecules can be induced in weakly crystalline polymers by pressure or by stretching[57,128,130].

§ For a number of polymers, semimetal characteristics have been reported[132,172] ($E_\sigma \leq 0$).

¶ Some workers discuss the possibility of ionic conduction[54,111,129,201,272,312], although polarisation effects do not necessarily imply an ionic mechanism[111].

† However, oxygen effects are often absent[57,68,154,178,179,181].

pressure [177,215,294,318], illumination (see p. 777), and irradiation [131,272,319]. When the resistance is not too high, surface conduction does not appear to distort the results [57,135,217]. But some workers point out that measurements with d.c. do not give a sufficiently complete picture of the electronic properties of polymers [200,237]. Nevertheless, the main conclusions derived from measurements with a.c. [144,200,201, 233,237,238,243,268,269,271,277] and with d.c. (see Section IV) are identical, and the results obtained by d.c. and a.c. measurements of the conductivity of poly(phthalocyanines) [230] are indistinguishable: we can therefore accept the d.c. method (which has been used in the vast majority of investigations of organic semiconductors) as entirely correct. Since the exact mechanisms of electrical conduction are not yet fully understood (see Sections IV and V), we cannot unequivocally ascribe the breaks often observed in the linear plots of $\log\sigma$ against $1/T$ to transition from impurity conduction to intrinsic conduction, particularly since Pohl's calculations for poly(acenequinone) radicals [172,214] would appear to exclude the possibility of impurity conduction by extraneous contamination. In general, with systems as inhomogeneous as polydisperse conjugated polymers it is hardly meaningful to talk of intrinsic conduction, and the term "impurity conduction" [145,277] can only refer to the presence in these polymers (excluding high-temperature polymers) of molecules or regions with a degree of conjugation sufficient to ensure appreciable ionisation at ordinary temperatures, the fraction of the total mass involved being small. Ohm's law has often been found to hold up to 10^3–10^4 V cm^{-1} in studies of semiconducting polymers [169,179,201], although departures are occasionally reported [64,214] at quite small fields of the order of 10–100 V cm^{-1}.

The sign of the current carriers (from measurements of thermo-e.m.f.) can be either positive or negative. However, oxygen always affects the thermo-e.m.f. in the positive direction [127,135,136,154,229,269], and it is at least possible that the current carriers, in contrast to the early views on organic semiconductors [5], consist largely of electrons (as indicated by most of the measurements in a vacuum), conduction by positive holes being the result of O_2 adsorption. It is interesting to note, however, that it has been possible to realise a true p–n junction in some polymers [271,320].

The electrical properties of polymers are determined by two factors: the structure of the molecule and the structure of the material. As regards molecular parameters, the necessary condition for semiconductivity in organic substances is the presence of a system of conjugated π-bonds in the molecule. As the number of π-electrons increases, we expect a decrease in ionisation potential, an increase in electron affinity [75], and an increase in polarisability, as has been established in a series of low-molecular-weight compounds with condensed rings [142]. In the case of polymers, this leads to improved electrical characteristics as the number of conjugated multiple or aromatic bonds in the polymer chain increases [45,59,61,129,133 134,167,177,214,221,253,257], and to the opposite effect when the conjugation is disturbed by lack of coplanarity of the aromatic rings [81,122,124,175,184,217,253] or by introducing into the conjugated chain aliphatic bridges, oxygen bridges, or sulphur bridges [122,124,164,165,175,176,178,180,217,319]. Pohl [172] observed an increase in conductivity with the number of aromatic π-bonds in poly(acenequinone) radicals, analogous to Eley and Parfitt's‡ rule for low-molecular-weight organic compounds [7,321,322]. Another analogy with low-molecular-weight conjugated systems — the increase in electrical conductivity§ following the introduction of nitrogen atoms into the conjugated chain [30,171,192,196,230] — is explained by the easier delocalisation of the π-electrons and also by the increased polarity of the molecules (see p. 780). The conjugated π-electron system ensures high values of the dielectric constant [29] and of the polarisability [323]. The structure of the molecule can influence the electrical properties also through changes in intermolecular interactions: introduction of side-substituents degrades the conductivity [108,110,217,228], and greater flexibility of the chain improves the electrical conductivity by facilitating intermolecular contacts [165,180,249,324].

The dependence of the electrical properties on the structure of the polymer as a whole is made evident, for example, by the improvement resulting from more ordered packing of the molecules [63,232,238] and by the effect of pressure cycling [128,130,144], both of which are attributed to changes in the properties of the intermolecular barriers [128,130,232]. On the other hand, instances have also been reported [59,61,122,175] of a decrease in resistance with decrease of the degree of crystallinity, associated with the lack of coplanarity of neighbouring condensed rings in the crystalline polymers [175] or with the break-down of the molecular crystal lattice [122]¶. On occasions, the degree of order has no particular influence on the electrical properties [57,59,178,295]. This masking of the role of the structure can be ascribed, on the one hand, to the well established competition between ordering in the material and conjugation within the molecule [165,180] and, on the other hand, to the effect of adsorbed gases.

On the question of the relative roles of order and conjugation, it is clear that greater flexibility of the molecular chains must result in closer packing and in conditions more favourable to intermolecular electron transitions, which determine the electrical properties of organic semiconductors (see Section IV). However, the introduction into the conjugated chain of groupings conducive to greater flexibility (in particular, methylene links) destroys the conjugation within the molecule and hampers the loosening of electrons. Thus, we find that single $-CH_2-$ groups introduced into the conjugated chain may increase the degree of crystallinity and improve the electrical properties by assisting intermolecular transfer, whereas longer links such as $-CH_2CH_2-$ degrade the electrical properties by lowering the degree of conjugation in spite of the fact that the degree of order is even higher [165,180]. The fact that the electrical properties are not improved indefinitely by increasing the number of double bonds in the polyene chain of a series of compounds [325,326] is further evidence that intermolecular electron transfer is the limiting stage in the conduction process.

Changes in electrical properties associated with adsorption can be identified by their reversibility.

‡ However, the electrical conductivity is reported to remain constant [64] in the series polybenzene–polynaphthalene–polyanthracene.

§ An increased conductance with partial removal of nitrogen from the polymer has been observed with poly(copper phthalocyanine) [230], but under these conditions the structure probably suffers considerable change. Weiss and coworkers [196] assume that an improvement in electrical conductivity due to nitrogen can be expected only when all the nitrogen groups exhibit either purely acceptor or purely donor properties.

¶ We should note that the more crystalline polymers are usually found to be poorer conductors than the amorphous polymers [61,122, 168,175].

Adsorption effects have been demonstrated, in particular, by measurements after heating *in vacuo* [78,127,130,135,136,247,248]. Some workers have been able to ascribe changes in conductivity to a specific adsorbate: O_2,[64,78,85,176,198,229,230,259,269] H_2O,[57,181,225,239] and ethylene [196,198]. The adsorption of O_2 was found, in most cases, to increase both the resistance and the activation energy for conduction in both *n*-type and *p*-type polymers† [64,78,85,176,198,229,259], as had been previously observed with dyes. The effect of O_2 decreases with increasing temperature of preliminary heat-treatment, and the electrical properties of polymers heated above 600–800° are no longer influenced by O_2 adsorption [85,269]. Since these effects are independent of the conductivity type of the material, we can assume, by analogy with the effect of iodine adsorption on the electrical properties of polymers [198,270,271], that O_2 acts by altering the conditions for electron transfer between highly conjugated regions rather than by affecting the concentration of current carriers [85,270,271] (see also p. 778 and 779)‡.

Occasionally, however, the reversibility of adsorption effects is highly hindered [248], and in many cases changes in electrical conductance arise from the evolution of volatile bulk impurities rather than from surface desorption: the process becomes irreversible even though no structural rearrangements are involved [129,184,227]. Some workers even hold the extreme view [78,129,136,248] that in pyrolytic materials any observed activation energy for conduction significantly different from zero must be associated with adsorption processes only, and not with the true electronic nature of the polymers. However, many workers have unambiguously related changes in electrical conductivity to reversible and irreversible structural changes rather than to adsorption [47,59,61,63,122,128,130,175,225,238,269].

Heat-treatment of the polymers breaks down the molecular crystals and leads to the formation of a specific structure with a low degree of order (see p. 775): this can cause an improvement in electrical properties even at relatively low temperatures (200–400°) by favouring growth of polyconjugated regions and by strengthening their mutual interactions [47,59,61,85,121,123,157,176]. However, in the early stages of heat-treatment (up to 200–300°) this disordering process often produces an irreversible increase§ in resistance [58,110,111,133,172,179,249], sometimes even despite a concurrent increase in the conjugation within the molecule [144].

It is interesting to note that the absolute values of the thermo-e.m.f. decrease irreversibly with increase of heat-treatment temperature [127,140,145,176,272], in keeping with the general tendency for the thermo-e.m.f. to fall as the electrical conductivity rises [129,184,227,328,329].

It follows from the above considerations that a very long conjugated chain in the molecule and long-range order (or crystallinity) in the structure of the polymer are far from being essential to the development of semiconducting properties. However, a recent theoretical investigation by Little [330] has shown that a new and astonishing physical phenomenon, superconductivity at ordinary temperatures, should appear if both these conditions are satisfied (namely, the creation of a stereoregular polymer in which specially chosen substituents maintain the excited state in an ideal polyene chain, coupled with the arrangement of the molecules in a specific type of long-range order.

Some groups of semiconducting polymers show still further peculiarities in their electrical properties. In particular, the behaviour of chelate polymers is determined by factors common to all organic semiconductors (electrical characteristics superior to those of the monomer [254], influence of the ligands [221,253], exchange interactions [224]), but it is also determined by the nature of the metal [221,224,253,254,264,265,267], although the role of this factor is sometimes a minor one [138].

Many polymers with conjugated bonds show photoelectric activity [83,87,114–117,121,133,167,169,179,214,224,259,276,331–333], generally similar to the well characterised phenomena in other classes of organic semiconductors [83,116,117,169]. In most cases the photoconductivity has been shown to be electronic in origin [83,114,117]. Some anomalies have also been observed, for example, the quenching of photoconductivity by oxygen in a *p*-type semiconductor [114,116] and polarisation phenomena [169]. Unfortunately, only a few polymers show appreciable photoeffects [116].

Other characteristic features of the electrical behaviour of semiconducting polymers will be discussed in the context of conduction mechanisms (Section IV). At this stage we shall only mention the compensation effect (linear relation between E_σ and $\log\sigma_0$) observed in a number of polymers [29,64,67,167,267,334,335], low-molecular conjugated systems [67,323,325], charge-transfer complexes [7,67], and dielectrics [336,337]. According to Tal'roze and Blyumenfel'd [334,335], this relationship is characteristic only of poor semiconductors, and should not be obeyed by low-resistance polymers [121,126].

3. Static Magnetic Susceptibility and Broad-Line ESR

Many polymers with conjugated bonds show large positive values of magnetic susceptibility [104,121,160–162,184,187,190,244,246,249,303,338–340], a dependence of the susceptibility on the field [121,161,162,181,244,246,249,312,340], and saturation at relatively low fields [249,312], i.e. the properties of an antiferromagnetic below the Néel temperature [181,312]. The susceptibility increases with temperature of heat-treatment [121,181,249]. These phenomena, which have been termed "pseudoferromagnetism", usually disappear in solution [312,341], as does also the broad (hundreds of oersteds) ESR signal¶ (occasionally observed [118,187,199,227,312,342]), which becomes even broader at low temperatures and frequently corresponds to an unacceptably high number of paramagnetic centres (up to 10^{22} per gramme, or upwards of 10 per monomer unit)[342]. Similar effects have been reported for nucleic acids and their complexes with proteins [338,343,344]. It was pointed out that the compensation effect in electrical conduction should not occur in substances showing these properties [334,335].

Attempts were immediately made to relate this unusual behaviour of organic substances to the specific features of conjugated polymeric systems: in particular, to the collective interactions arising in π-electron systems of this type as a result of a particular ordered structure [29,312], or to the formation of charge-transfer complexes [338,341]. However,

† With *p*-type polyethylene subjected to radiation–thermal treatment, the specific resistance ρ and E_σ were both found to decrease [269] in the presence of O_2.

‡ Myl'nikov [259] explains the suppression of dark conduction and photoconduction caused by O_2 adsorption on a *p*-type polymer by postulating that oxygen gives rise to carrier recombination centres on the surface.

§ The increase in resistance is sometimes due to removal of impurities by the heat-treatment [129,184,227].

¶ Instances have been reported, however, in which the positive susceptibility [339] and the broad ESR signal [342] persist in solution.

Dorfman has suggested that these properties cannot be ascribed to organic structures[345,346], and must be due to contamination (by iron compounds, in particular), as has on occasions been demonstrated experimentally[203,347,348]. On the other hand, and in keeping with the view that these phenomena are not trivial in origin, positive susceptibility has been observed for polymers prepared under high-purity conditions[162,181], and the concentration of ferromagnetic impurity present has been shown to be clearly insufficient to explain the observed effects[341,349]. Hence, Blyumenfel'd believes[349] that, although the specific pseudoferromagnetic behaviour of organic compounds is associated with the presence of iron, nevertheless it is due either to a special state of the system, in which all five $3d$-electrons of the Fe^{3+} ion take part in domain formation (as in a new type of ferrite), or alternatively the behaviour is due to specific exchange interactions between the paramagnetic iron ions through the conjugated organic structure. The question of whether the static paramagnetism and the broad ESR lines are trivial in origin is still not finally settled (in contrast to the nature of the narrow ESR signal, see Section III).

The magnetic susceptibility method is used in the study of chelate polymers with paramagnetic ions to establish the structure of the chelate link[22,252,255,256] and to reveal exchange interactions through the conjugated system[224]. In the latter case, use is made also of changes in the ESR signal for chelates with metals whose ions give resonance absorption[224,263].

4. Narrow-Line ESR

Practically all polymers with conjugated bonds give a characteristic narrow ESR signal either as prepared or after further heat-treatment. As with other classes of organic semiconductors, the absorption line is a singlet†, characterised by a g-factor close to the free-electron value ($g \simeq 2.00$), of small width (ΔH from 0.5 to 15, and rarely up to 50 oersteds), and with a relatively high concentration of unpaired spins ($N \simeq 10^{16}$–10^{21} per gramme, or 1 spin per 10–10^6 molecules)‡. The temperature dependence of the signal intensity usually follows Curie's law[3,112,143,161,162,182,183,190,198,251,273], although temperature-independent signals have been reported[68,250,269]§. The width of the signal does not vary with the measurement temperature[56,112,198,251]. The signal invariably persists when the material is dissolved[3,56,68,74,83,105,185,306,312]¶, and in many cases the shape remains unchanged and the intensity decreases in proportion when the solution is diluted[3,68,74,195].

The ESR signal suffers irreversible changes as a result of heat-treatment of the polymers. The concentration of unpaired spins N increases with temperature[3,105,160,162,170,182,205,246] up to a maximum at 600–700° (for measurements made in a vacuum)[47,269,273] and then gradually falls as the temperature is raised still further, but the signal is not completely lost at 900° and even above 1000°,[85,273,275]. The line width ΔH retains its original value of 4–8 oersteds up to heat-treatment temperatures of 400–500°,[47,85,269] but it goes through a minimum (for the case of vacuum measurements) at 500–700° which can be as low as 0.5 oersted, and further increase in pyrolysis temperature broadens the signal (upwards of 10 oersteds).

Oxygen does not usually affect the ESR signal of polymers which have not been heated above 300–400°,[85,269] but a decrease in N is occasionally observed even for low-temperature specimens[44,103,203]. After heating above 300°, oxygen is found to have an effect on ΔH: measurements in air do not show a minimum and ΔH remains constant up to heat-treatment temperatures of 500–600°, beyond which the line becomes wider (as in the vacuum measurements)[47,85,123,205,269]. Bakh and coworkers[269,275] consider that the minimum in ΔH observed after heat-treatment at 500–700° is only apparent, and due to inadequate pumping off of O_2, since after thorough degassing ΔH has its minimum value (0.5 oersted) even for the lowest baking temperatures. Line broadening in the presence of oxygen probably arises from the local magnetic fields generated by the adsorbed O_2 molecules, which alter the value of the g-factor for different regions[279]. The effect of O_2 on the concentration N of unpaired spins becomes appreciable after heating the polymer above 500°, and produces a slight shift of the maximum towards lower heat-treatment temperatures (500–600° instead of 600–700°)† and a sharp decrease in N at higher temperatures. In polymers heated to 650–800° the ESR signal vanishes when measured in air[47,85,121,269], whereas with samples heated at higher temperatures[275] and some other polymeric samples[74] (measurements *in vacuo*) there is an increase in N on admitting O_2, due to the formation of charge-transfer complexes with oxygen (see p. 780). All these changes in the ESR signal are similar, on the whole, to the phenomena observed in charcoals[12]. We should stress that the differences between carbons and heat-treated polymers are arbitrary in a number of respects (see, for example, Ubbelohde[22]), and therefore it is quite likely that the ESR signal found in low-temperature charcoals is often caused not by broken bonds[12,351] but by the factors which operate in polymers with conjugated bonds and other organic semiconductors (see Sections IV and V).

The shape of the ESR line can vary from the Gaussian to the Lorentz form, depending on the conditions of pre-treatment of the polymer, the measurement temperature, and adsorption[56,68,74,123,153,195,198,269,273,275,279,293]. For low-temperature samples and low measurement temperatures the signal is of Gaussian or intermediate form, but, on raising the heat-treatment or the measurement temperature, the line gradually acquires Lorentz character[123,153,269,275]. This is consistent with stronger exchange interactions between the paramagnetic centres as the number and size of the conjugated regions are increased. Adsorbed oxygen enhances the Lorentz character of the signal by contributing to electron exchange[195,296], in keeping with the strong influence of O_2 on the electrical conductivity of low-temperature polymers[95,269] and with the analogous effect of iodine adsorption[198,270,271].

In most cases the ESR signal is a symmetric singlet, but occasionally some asymmetry is reported: with low-

† Double, or more complex, signals have been observed[105,109,161,164,190], and ascribed to isolated radicals[105]. After heating, the signal becomes a normal singlet. Hyperfine structure is sometimes revealed by measurements in solutions[56,185].

‡ Chelate polymers can give an ESR signal either because of the presence of a paramagnetic metal ion (broad line) or for reasons common to all organic semiconductors (narrow line)[224,245,250,251].

§ A decrease in the concentration of unpaired spins on cooling the polymer has been reported only once[198], and ascribed to the formation of a stable charge-transfer complex with iodine, or to the iron polychelate complex[250].

¶ Reversible loss of signal on dissolution has been reported for aniline black[203] and for polymeric charge-transfer complexes[293], as commonly observed with low-molecular organic semiconductors[350]

† Under some conditions the maximum in N can be found at very much lower temperatures[121,191].

-temperature polymers, the asymmetry arises from the ready saturation[44,56,227,279,293,306,352] due to the large spin--lattice relaxation time (10^{-4}–10^{-5} s),[49,352] but, with the highly conducting, high-temperature polymers, the asymmetry is associated with the skin effect or with the asymmetry of the g-factor[273,275]. Saturation is less marked after adsorption of oxygen[68,74,279,293] which favours spin–lattice interaction.

The ESR signal in polymers is very interesting from the point of view of their catalytic activity, since it has been possible in some cases to demonstrate a direct correlation between catalysis and the concentration of unpaired spins[39–41]. In this connection we should mention a series of papers by Berlin and coworkers on the so called local activation[41,353–356]. According to this concept, the paramagnetic centres present in compounds with conjugated bonds, and responsible for the special magnetic behaviour of materials of this type‡, excite (or activate) the neighbouring molecules and thus give rise to catalytic activity, fluorescence, dark conduction and photoconduction, and other specific properties of organic semiconductors. The mechanism of this effect evidently involves perturbation of the electronic shells of the system under the influence of the local magnetic centres, and consequently an increased probability of reaction occurring via the excited triplet state, i.e. with a lower activation energy[354,356].

III. NATURE OF THE NARROW-LINE ESR

Generally speaking, the following basic factors, which can cause the appearance of an ESR signal in organic structures of the type under discussion, are significant: (a) inorganic paramagnetic impurities; (b) organic radicals, arising either in the course of polymerisation ("trapped radicals") or during thermal degradation of the polymers ("broken bonds"); (c) stabilised double radicals, formed by the Berlin mechanism (see below); (d) the transition of molecules to the triplet state, whose level can be so low in highly conjugated systems as to be readily populated even at room temperature ($^3E_1 \simeq kT$), or even become the ground state ($^3E_1 < kT$); (e) the appearance of polar states as a result of charge-transfer processes — in particular, the formation of charge-transfer complexes; (f) the signal from quasi-free current carriers.

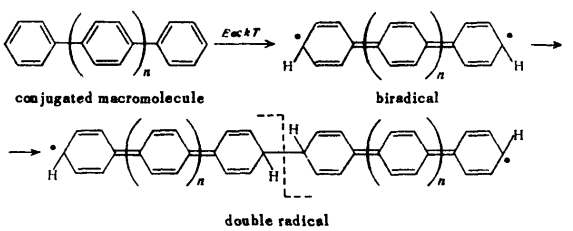
The narrow ESR signal in polymers was originally assigned to the properties of an individual highly conjugated molecule[24,29,228], and ascribed to a specific phenomenon (the appearance of some measure of unpaired character in the π-electron system at a particular stage of conjugation[29,63,245]). This interpretation is consistent with the narrowness of the line, with the dependence of the signal on the degree of conjugation in the molecule[45,84,123,176,191,306,352], with the correlation between changes in N and colour[23,175], and with the fact that the signal persists in solutions. However, many contradictions were soon discovered. Although instances of monotonic variation of the concentration N of unpaired spins with molecular weight were reported[191,207], in other cases there was no correlation between these parameters[56,84]. The observed proportionality between N and the molecular weight[68,74] cannot be reconciled on the basis of the above ideas with the fact that the length of the conjugated system does not increase with molecular weight[69]. The limited degree of delocalisation, which extends over no more than 2–7 monomer units[56,68,74,123], has been demonstrated on numerous occasions.

Furthermore, the character of the observed ESR signal did not provide an explanation of the appearance of paramagnetic centres in terms of other possible mechanisms of intramolecular excitation: either by thermal activation of the singlet–triplet transition (since the intensity varies according to Curie's law, i.e. N is independent of temperature) or due to the fact that the triplet state becomes the ground state (since the concentration of paramagnetic centres is always less than one per molecule)§.

This situation has given rise to suspicions that the ESR signal in polymers is due to impurities. However, as in the case of low-molecular organic semiconductors, we can dismiss trivial paramagnetic contaminations because: (a) all paramagnetic ions give a signal of significantly greater width[357]¶; (b) there is no analogy among inorganic para- and ferro-magnetics to irreversible temperature changes in the signal (see p. 778); (c) the signal often appears only after heating[48,168,170,323] or low-temperature carbonisation[306,340,352]; (d) the behaviour of the signal can be correlated with the colour of the material and with conjugation in the molecule[45,84,122,123,191]; (e) the signal is strongly affected by adsorption of O_2 and other substances.

At the moment, only two approaches offer a satisfactory treatment of the basic features of the paramagnetic behaviour of polymers with conjugated bonds and other organic semiconductors: Berlin's ideas on stable double radicals and the concept of charge transfer proposed by Blyumenfel'd and Benderskii.

According to the views of Berlin[15,49,84,162,359], centres which appear in the fractions of highest molecular weight are responsible for the ESR signal. Macromolecules in which a sufficient degree of conjugation is achieved (irrespectively of whether the polymerisation mechanism was radical, ionic, or molecular) can pass into the triplet state even at ordinary temperatures. The interaction between two or several such excited biradicals, termed quasi-radical polymerisation, gives a stable double radical according to the scheme



The unpaired electrons of this double radical do not interact, and do not recombine, because a mutually coplanar arrangement of the individual conjugated blocks is sterically impossible. The resulting molecular paramagnetic centres are additionally stabilised by the formation of charge-transfer complexes between the double radical and the neighbouring molecules: this, in turn, favours the excitation of these molecules to the triplet state by the local-activation mechanism (see p. 779). This explanation of the paramagnetism of polymers with conjugated bonds

‡ The nature of the paramagnetic centres is discussed in Section III.

§ This is true also of the ESR signal ascribed to the triplet state of nitrogen[182,183].

¶ Even in chelate compounds in which exchange interactions take place through organic structures[358].

evidently lacks generality, since an ESR signal can be observed also in systems where the formation of extensive conjugation chains is improbable† [122].

The hypothesis that the ESR signal in organic semiconductors is due to polar states involving charge transfer was put forward and developed in a series of papers by Blyumenfel'd and Benderskii [68,69,306,360,361]. At present, these ideas perhaps offer a more satisfactory explanation of the peculiarities of the ESR signal of low-temperature polymers [75,83,85,122,123,162,196,198,203,205,293] and of other classes of organic semiconductors [12,309,359,362,363]. According to this model, the low ionisation potential of conjugated systems assists the formation of local centres of the radical-ion type in the solid structure. The charge transfer which accompanies the appearance of these localised polar states can occur either between two neighbouring molecules, when the charge transfer is assisted by the shorter intermolecular distance, and the resulting charge-transfer complex is treated as a structural defect of the lattice, or it can involve charge capture by more remote molecules, traps, crystal defects, etc. ‡

The formation of polar states involving charge transfer is assisted by: (1) the presence of a sufficiently extensive conjugated π-electron system, which ensures high polarisability and ready ionisation of the molecules; (2) polydispersity, which produces differences in electron affinity and ionisation potential between the molecules; (3) polarity of the molecules, and in particular the presence of nitrogen atoms (which also increases the electronic heterogeneity of the system); (4) disorder and structural defects in the material as a whole, which provide the best conditions for local interactions between molecules and for the formation of traps. In the case of polymers, a special role is played by polydisperseness (as pointed out by Dulov [122] and Boguslavskii [200]), and by disorder, as evidenced by the fact that amorphous polymers are often better semiconductors than crystalline polymers [61,122,168,175]. This approach explains the contradictions pointed out on p. 779, since the formation of polar states is determined both by properties of the molecule (conjugation), and also factors less easy to characterise, such as polydispersity and structural disorder.

It should be noted that in some cases the ESR signal can arise from well known, alternative causes. In particular, the ESR signal resulting from charge-transfer complexes formed by electron transfer between a compound with conjugated bonds and an adsorbed molecule of oxygen [74,195,198,275,362,364-366] or some other molecule (see p. 774) has been specially discussed by various workers. The ESR signals sometimes observed from common radicals formed during the synthesis and trapped in the polymer structure, or from radicals of the broken bond type appearing, for example, during thermal breakdown of the polymer [105,273,367], are easily distinguished by their behaviour, since they should disappear irreversibly on dissolution or moderate heating.

In many cases (for example, in polymers heated above 900° [273] or even at lower temperatures [143]) a narrow ESR signal caused by the current carriers can be detected, similar to the signal observed in individual low-molecular charge-transfer complexes with strong binding [368-370]. Benderskii and others were able to isolate a narrow signal from photo-induced carriers in dyes, and showed that its behaviour differs from that of the broader signal associated with local paramagnetic centres [371].

IV. ELECTRICAL CONDUCTION MECHANISM

A clear description of the current-carrying processes in organic semiconductors, and particularly in polymers, is perhaps the most serious outstanding problem in the study of these interesting materials. Any mechanism proposed must explain a number of specific features of the electronic behaviour of these compounds which are now well established. The following are the most important peculiarities.

1. Electronic inhomogeneity. Measurements by various methods (a.c. measurements [200,237,243,269], studies of current noise [141] and of the effect of the adsorption of iodine [161] and of air [135], and other investigations [47,122,227,242,275]) lead to the firm conclusion that all polymers consist of discrete conducting regions (very probably, strongly conjugated or condensed regions) separated by poorly conducting (dielectric) regions evidently consisting of a disordered structure of polymer molecules (see p. 775, 776).

2. Nature of the reversible temperature dependence of the thermo-e.m.f. In most cases the thermoelectric power α is either practically independent of temperature [100,125,127,132,143,145,176,200,214,231,269,270,272] or increases at higher temperatures [100,143,145,154,176,212,229]. This suggests that the temperature variation of α and σ is the result of a change in carrier mobility at constant carrier concentration, since theory predicts a weak (logarithmic) increase of α with temperature for this type of mechanism (degenerate conductor) [14,328]:

$$\alpha = \frac{k}{e}\left[A + \ln \frac{2(2\pi m^* kT)^{3/2}}{h^3 n}\right],$$

where A is a constant which depends on the electron scattering mechanism, m^* and n are the effective mass and the concentration of the current carriers respectively, k and h are Boltzmann's and Planck's constants, and T is the absolute temperature.

When the changes in α and σ with temperature arise mainly from an exponential increase in the carrier concentration, the theory requires that α decreases with increase in temperature, in direct proportion to $1/T$: [14,328]

$$\alpha = \frac{k}{e}\left(A' + \frac{E_\sigma}{kT}\right).$$

Some polymers have shown a decrease of α with temperature [64,132,143,145,154,170,172] but the observed effect is not usually large enough to justify ascribing it to the influence of carrier concentration [64,145,172].

3. Very low mobility of charge carriers. Attempted measurements of the carrier mobility in polymers from the Hall effect have usually proved unsuccessful [48,140,157,200,225,229]. This suggests that the mobility does not exceed 0.005–0.01 $cm^2 V^{-1} s^{-1}$. Only in two cases have

† Also, a recent tentative calculation [75] shows, that the degree of polymerisation achieved (in particular) in poly(phenylacetylene) is apparently sufficient to allow transition of the molecule to the triplet state.

‡ Complexes involving partial charge-transfer can be formed [288]. Localised centres of this type do not, of course, give an ESR signal.

these measurements given positive results: poly(acenequinone) radicals gave the very low value [172,216] 0.04 $cm^2 \times \times V^{-1} s^{-1}$, and an unexpectedly high mobility (2.5–10 $cm^2 \times \times V^{-1} s^{-1}$) was observed in poly(copper phthalocyanine). However, the Hall effect measurement for the latter polymer could not be reproduced§ [225,229], and a measurement of mobility from the effect of O_2 adsorption on σ gave very much lower values [229]. Low mobility values in the polymers have been deduced also from ESR data (10^{-1}–10^{-3} $cm^2 V^{-1} s^{-1}$, [64,68,172,372]) from a.c. measurements (10^{-3}–10^{-5} $cm^2 V^{-1} s^{-1}$, [271]) and from calculations based on the band model (10^{-2}–10^{-7} $cm^2 V^{-1} s^{-1}$ [100,145,201,214]). Evidently, higher mobilities can be obtained only when the influence of the dielectric interlayers is eliminated: values of 1.4–100 $cm^2 V^{-1} s^{-1}$ have been reported [229,230,271,273,284,373]. Positive holes are usually found to be more mobile than electrons [100,140,201,208], but calculations sometimes yield the opposite result [261]. The concentrations of current carriers corresponding to the low mobilities listed above amount to 10^{12}–10^{17} cm^{-3}. [172,201,214,216,230,372]

All these special features are best explained in terms of the hopping mechanism of conduction [14,16,17,125,127,128,145,200,214,237,238,243,318], according to which current is obtained by activated hops of the carriers, over the dielectric barriers created by the disordered (non-conjugated) structures, from one polyconjugated region to the next. Under these conditions, a rise in temperature does not alter the number of effective carriers present in the polyconjugated regions (provided of course that irreversible pyrolytic processes are excluded), but it increases the probability of a jump, i.e. the mobility. As shown by the theoretical work of Klinger [374] and of Lang and Firsov [375], the hopping mechanism is the most probable in materials of low carrier mobility, in which the current is carried by small polarons and difficulties arise in the measurement of the Hall effect. This mechanism explains also the characteristic temperature variation of α of the majority of polymers, and the results obtained, in measurements with a.c. [200,237,238], with stretching and compression of a heat-treated polymer [128].

According to the band mechanism [117,154,172,328], the intermolecular π-electron interactions give rise to a conduction band which is common to the whole volume of the polymer, and in which the concentration of carriers depends on the energy needed to extract an electron from the π-conjugated system and transfer it to the quasi-free, conducting state. In other words, the carrier concentration is determined by the width of the forbidden gap, and increases with temperature. From the point of view of the band theory, a low mobility is the result of narrow bands (large effective carrier mass). However, this mechanism is inapplicable to the majority of polymers because it is inconsistent with the temperature variation of α [64,71,100,125,127,132,143,145,176,212,214,229,231,269,270,272] and with the extremely low mobility, corresponding to an improbably small mean free path (less than 1 Å) [17,140,214,230] and to unacceptably large effective masses of carriers [140]. Furthermore, the band model is particularly improbable for polymeric materials, which usually lack a crystalline structure [376] (although calculation has shown [377,378] that strict ordering is probably unnecessary to give rise to an electronic band structure in polymers). Nevertheless, there are cases, such as when the mobility is greater than 1 $cm^2 V^{-1} s^{-1}$, or when α decreases with temperature (see below for the strong carrier–carrier interaction which sometimes arises under these conditions, giving rise to pseudometallic conduction [372]), and also in photoconduction processes [48], where the band mechanism can be applied with some reservations [143,183]¶.

The tunnel mechanism [7,64,78,135,136,158,232,248] assumes that the true activation energy for conduction E_σ (ignoring the effects of adsorption, cross-linking, etc.) is determined by the energy needed to transfer an electron to an excited level in the molecule, so that E_σ in polymers with conjugated bonds should be small and tend to vanish as the degree of conjugation in the macromolecule is increased. The magnitude of the conductivity is limited by the probability of non-activated intermolecular tunnelling of the electrons, which is itself largely determined by the thickness and shape of the intermolecular barriers. The effectiveness of tunnelling transitions is proportional to the concentration of electrons in excited levels, itself an exponentially increasing function of temperature. With polymers, in contrast to low-molecular organic semiconductors and individual charge-transfer complexes [14], it is difficult to confirm the correctness of the tunnel mechanism by comparing E_σ with optical data [98,99], but is has been done [64]. Some workers [232] have postulated a tunnel mechanism on the grounds that the experimentally observed curve of activation energy *versus* the degree of crystallinity (which determines the shape of the barriers) agreed with the calculated curve. Others, however, have adopted this mechanism without sufficiently convincing evidence [78,135,136,248]. The tunnel mechanism seems hardly likely to be generally applicable to polymers with conjugated bonds, because the objections raised against it, even in the context of low-molecular organic semiconductors (to which it can be applied with much better justification [376,383]), are very cogent in the case of polymers, in particular, the much lower probability of the tunnel mechanism than of the hopping mechanism in substances with a low carrier mobility [375]. It is also interesting that the very small activation energies for carrier generation within the conjugated region (0.1 eV approximately) have been confirmed experimentally by a.c. measurements [268], but these same measurements have shown that the rate of the d.c. conduction process is limited by a stage attended by a considerable activation energy (of the order of 1.0 eV), i.e. probably by barrier jumps between conjugated regions.

Thus, the hopping mechanism appears to be the most plausible for the majority of typical polymeric semiconductors†. However, in some groups of polymers the electrical conduction is known to arise by different mechanisms. In particular, when the mobility exceeds 10 $cm^2 V^{-1} s^{-1}$ (i.e. for high-temperature samples [85,273], for compositions

§ The high mobilities in this case can probably be ascribed to the participation of the *d*-orbitals of the copper atom under favourable steric disposition of the molecules, as has been demonstrated for the monomeric copper phthalocyanine [266].

¶ It may not be out of place to point out that recent Hall effect and conductivity measurements on inorganic semiconductors (NiO and CoO) have shown that the band model is applicable to these oxides [379,380], although the hopping mechanism had been previously postulated on account of their low mobility [381]. Some recent calculations [382] of a number of electrical parameters of organic semiconductors have given grounds for retaining the band concepts for systems of this type.

† An alternative view, recently put forward, is that the electrical behaviour of semiconducting polymers is determined by the superposition of two activated processes: changes in the concentration of current carriers and changes in their mobility [175,242], as had already been proposed for organic semiconductors of low molecular weight [383,384].

with a high metal content[231], or when strong charge-transfer complexes are formed with polymers[271]), and also when α is found to decrease steeply with temperature[132], the electrical conduction is probably quasi-metallic as a result of strong electronic interactions in the polymer. Under these conditions the carrier concentration can be appreciably higher than normal (up to 10^{19} cm^{-3}).[143,273]

The chelate polymers form another special group, in which metal ions play an essential role. The specific features of the electrical properties of polychelates have been explained by invoking the ligand field theory[254], the resonance of structures involving a metal[265], or (by analogy with ferrites) a mechanism in which the electronic jumps depend on the variable valence of a metal ion[265].

V. RELATIONSHIP BETWEEN ELECTRICAL AND MAGNETIC PHENOMENA AND GENERAL THEORIES OF SPECIFIC EFFECTS IN ORGANIC SEMICONDUCTORS

A superficial comparison might lead to the conclusion that in general there is no correlation between the electrical conductivity σ and the paramagnetism of polymers with conjugated bonds. In the first instance, the irreversible temperature changes in σ and in the concentration of unpaired spins N, which occur during pyrolysis, are different (except after low-temperature heating, when the changes are in the same sense): σ increases continuously, whereas N goes through a maximum (see p. 777 and 778). But even when the changes are monotonic, an increase in σ by many orders of magnitude corresponds to an increase in N by a factor of only several tens or hundreds[64,122,214]. Secondly, the reversible temperature variation of the width of the ESR signal, in accordance with Curie's law, suggests that N stays constant, whereas σ has a positive temperature coefficient (see p. 775 and 778). Thirdly, in most cases N is greater than n (the concentration of current carriers)[64,143,214,273]. (See also Tobin's calculation[372] based on the results of Hatano and coworkers[63]; see p. 778 and 780.)

However, a deeper study of the problem reveals a correlation between the electrical and magnetic properties.

(a) Despite the fact that in most cases there is no quantitative correspondence between N and n (i.e. that the ESR signal is not, in fact, given by the current carriers), a distinct correlation is very often observed between changes in N and changes in electrical properties on heating in the low-temperature region[85,170,205,227,269], during chemical reactions[45,111], as the degree of crystallinity is increased[63], on changing the extent of conjugation[64,122,177], and for photo-induced electrical and paramagnetic characteristics[52,69]. In some groups of related polymers a direct proportionality between N and $\log\sigma$ has even been observed[122,214].

(b) The existence of a close association between the semiconductor properties and the ESR signal is suggested also: firstly, by the temperature independence of both N (Curie's law) and n[143,273] (see p. 780), and, secondly, by the success achieved in explaining the electrical behaviour of polymers by applying the ideas of polar states and charge-transfer complexes (see p 779) and of local activity centres (p. 778). The studies of polymers treated with halogens[174,198,205,211,289] provide the best example of this, since in every case the authors were able to correlate the improvement in electrical characteristics with the formation of charge-transfer complexes. The same conclusion probably applies in every other reported case of decrease in resistance and in activation energy E_σ following introduction of halogens[17,261,290] or metal salts[48,51] into the polymers. Karpacheva[174] obtained a direct demonstration that the maximum concentration of paramagnetic centres in the bromine and iodine complexes of polymeric Schiff's bases occurs at the same composition as the minimum activation energy for conduction E_σ and minimum resistance. A monotonic increase in photoelectric activity with concentration of paramagnetic centres was observed in a study of the local activation effect[69,356,385]. Further evidence for a close link between electrical conductivity and charge-transfer complexes is provided by the decrease in E_σ with increasing polarity of the molecules[314] (see p. 780).

(c) In polymers which have been heated to sufficiently high temperatures the concentration n of current carriers can become equal to the concentration N of unpaired spins[143,274]. Under these conditions the strong electronic interactions give rise to quasi-metallic conduction (see p. 781), and the ESR signal is obviously produced by the conduction electrons[143,273]‡. On further raising the pyrolysis temperature, the increasingly strong electronic interactions can lower the effective concentration of unpaired spins (and even cause the ESR signal to disappear altogether, see p. 778), so that N becomes smaller than n.

Thus, we are forced to the conclusion that the electrical and magnetic properties of polymers are by their very nature closely interrelated, although the relationship is a complex one, and can be masked by various subsidiary phenomena.

Not surprisingly, in view of the fact that comparison of the properties of other groups of organic semiconductors has led to a similar conclusion[361,368,369,385,386], attempts have recently been made to evolve generalised theories of the electrical and magnetic effects in organic semiconductors. We refer first and foremost to Blyumenfel'd and Benderskii's[360,361,378] theory of polar states already mentioned above (p. 779), which is primarily concerned with the formation and dissociation processes of local paramagnetic centres, and to Pohl's ion–exciton model[17], which deals mainly with the mechanism of current transport§. The local activation concept developed by Berlin and coworkers also aims to unify the nature of electrical and magnetic phenomena in organic semiconductors, and has already been mentioned on p. 778 and 779.

Blyumenfel'd and Benderskii consider that the electrical and magnetic properties of organic semiconductors are determined by the activation energy of a polar state within the crystal, i.e. by the concentration and also by the nature of the local paramagnetic centres, consisting of defects in the crystal structure. Generation of charge carriers

‡ This mechanism of the generation of an ESR signal is similar to that demonstrated by Wagoner for high-temperature charcoals[386], but our polymers (unlike the latter materials) show a strong variation of signal intensity (i.e. of N) with O_2 adsorption, which has no effect, however, on the electrical conductivity[85,269]. Hence, it is doubtful whether the ESR signal in polymers which have been heated only a little above 800° is in fact caused by conduction electrons. These considerations have led to the suggestion[85] that electrical conductivity arises not only from unpaired electrons, but also from delocalised, strongly interacting electrons (or holes) which do not give an ESR signal.

§ Pohl's discussion deals specifically with ionic conduction, but his arguments are equally applicable to current transport by electrons and holes, which has been proved to exist in organic semiconductors (see p.775 and Ref. 5).

occurs by dissociation of the polar state by the normal exciton mechanisms[8,387]. For very weak intermolecular interactions, the levels of the polar states lie well above the ground state of the system, and therefore the concentration of polar (paramagnetic) centres is very small and the materials should be diamagnetic and insulating. In compounds of this type, which includes low-molecular organic semiconductors and possibly also poorly conducting polymers, the ESR signal can arise only from charge-transfer complexes, formed by the reaction between molecules of the main constituent and easily ionised non-paramagnetic impurities (in particular, high-molecular fractions). As the interactions in the solid become stronger, the levels of the polar states shift downwards, with an increase in the concentration of intrinsic paramagnetic centres able to generate an ESR signal as a result of electronic transitions between molecules of the matrix. In these compounds (among which we classify some strong, individual charge-transfer complexes and many highly conducting polymers) we expect to find a relationship between electrical and paramagnetic characteristics. When the intermolecular bonds are strong enough, the levels of the polar states can become practically indistinguishable from the unexcited level, and in this case the paramagnetic state becomes the ground state of the system. Substances of this kind should exhibit a characteristically temperature-independent paramagnetism and high conductivity, like the better individual charge-transfer complexes based on tetracyanoquinodimethane[389]. However, when the levels of the polar states are shifted even lower, the radical-ions formed by electron transfer can behave as independent paramagnetic centres (Curie's law), and the resistance should rise again (as in ionic crystals); this situation may exist in the charge-transfer complexes involving halogenoquinones[388,390]¶. Unfortunately, the theory of polar states, though it offers a satisfactory description of the paramagnetism of organic semiconductors, does not underline sufficiently the specific aspects of the conduction mechanism, since it examines charge transfer essentially from the standpoint of the exciton band model.

According to Pohl, whose approach is based on the concept of ion pairs[391], the molecules of an organic semiconductor form chains (or groups) of ion–exciton complexes of the type $(M^+M^-)\ (M^+M^-)\ \ldots\ (M^+M^-)_x$ in which electronic excitation and electron transfer are greatly facilitated by the strong exciton–exciton and ion–exciton interactions. Hence the steady-state concentration of excited electrons in the system can be quite high, and this will increase the probability of electron exchange between these polymeric forms of excitons by the activated jump mechanism. On the whole, this model describes satisfactorily the special features of the electrical behaviour of organic semiconductors, but unfortunately Pohl does not consider the concrete mechanisms of intermolecular interactions in molecules of various types, nor does he accord special attention to the properties of exciton–ion complexes as paramagnetic centres in organic semiconductors.

Although the nature of the special electrical, magnetic, catalytic, and other properties of organic semiconductors is still far from clear, there can be no doubt that in the last few years this class of organic compounds has attracted exceptional interest from physicists and theoretical chemists. Thus, we may hope that the next few years will witness the appearance of a unified theory of the electronic effects in organic semiconductors, which will make it possible to understand the true nature of the specific properties of these remarkable compounds and to control those properties by rational methods.

---o0o---

The above review of the experimental results for and of the theoretical models of semiconducting polymers, in conjunction with published work on other groups of organic semiconductors which could not be discussed here, justifies the following conclusions.

1. All organic semiconductors (polymers with conjugated bonds, one-component conjugated systems of low molecular weight, charge-transfer complexes, biological materials, and charcoals) have in common a group of special properties which distinguishes them from most of the ordinary organic compounds: this is particularly true of their electrical, magnetic, catalytic, and also some other characteristics.

2. The peculiar behaviour of organic semiconductors arises, on the one hand, from the presence of conjugated π-bond systems in their molecules, and, on the other hand, from specific features of the solid-state structure of these compounds (in the case of polymers the presence of electrically conducting highly conjugated regions separated by dielectric layers).

3. Although a unified interpretation of the nature of the paramagnetism in organic semiconductors is still lacking, we can now assert that the most common cause of a narrow ESR signal in these materials is the presence of paramagnetic polar states (in particular, charge-transfer complexes) whose formation is very considerably assisted by the properties of the system of conjugated π-bonds. A special case is provided by charge-transfer complexes involving adsorbed molecules of oxygen, or charge-transfer complexes into which molecules of halogens or of some other materials have been introduced.

4. The most satisfactory explanation of the special electrical behaviour of organic semiconductors relies on the activated hopping mechanism, although in some cases (compounds of low molecular weight, and individual charge-transfer complexes) the band model also can be applied.

5. The problem of the basic common origin of electrical and paramagnetic phenomena in organic semiconductors is not finally settled, but in many instances we have convincing proof of a correlation between these properties, and some of the theoretical concepts already put forward may lead to a unified explanation of the special electrical and magnetic behaviour of organic semiconductors.

¶ Admittedly, it becomes difficult in the latter case (level of polar states below ground level) to explain the fact that the experimentally determined concentration of the paramagnetic form in organic semiconductors is almost invariably less than 100%.

CHEMISTRY OF DIFLUORAMINE

A. V. Fokin and Yu. M. Kosyrev

CONTENTS

1. Introduction 791

2. Physical properties and structure of the difluoramine molecule 792

3. Methods of making difluoramine 793

4. Chemical properties and reactivity of difluoramine 795

5. Explosive properties of difluoramine 801

1. INTRODUCTION

Until recently there had been very little investigation of difluoramine HNF_2. The main publications about it [1-3] related predominantly to its physical properties and to the history of the methods of its preparation, whereas its chemical properties remained almost uninvestigated, owing to the extreme hazard in working with it.

Of the three theoretically conceivable compounds in the series of fluoro-substituted ammonias only two are known at present: nitrogen trifluoride NF_3 and difluoramine HNF_2. The physical and chemical properties of nitrogen trifluoride are sufficiently well known [1-3]. The fluorine–nitrogen bond in NF_3 has a polar character, which determines the shift in the electron density towards the base of the regular pyramid with the nitrogen atom at the apex and the fluorine atoms in the base. It is also generally known that the ammonia molecule is extremely nucleophilic, owing to the unshared pair of electrons at the nitrogen atom. As the hydrogen atoms in it are replaced by fluorine atoms, an ever-increasing deficit in electron density is produced at the nitrogen atom (in compensation for which the electron lone pair of the nitrogen should play an ever-increasing part). Hence owing to the powerful inductive influence of the fluorine atoms there is a significant deactivation of this electron pair, increasing with the degree of substitution, and a sharp fall in the basic properties of the fluoro-substituted ammonias. This deactivation should be maximal in the nitrogen trifluoride molecule.

The same distribution of electron density along each nitrogen–fluorine bond in the NF_3 molecule and the almost complete absence of nucleophilic properties at the nitrogen atom confers on nitrogen trifluoride a high chemical inertness at temperatures up to 300–400° and explains the exclusively homolytic cleavage of the bonds under more intensive thermal action. Therefore all the reactions in which nitrogen trifluoride is at present known to participate are usually pyrolytic and have a radical character.

A feature of the structure of the difluoramine molecule gives it a reactivity which indicates the high degree of polarisation of the nitrogen–hydrogen bond $\overset{\delta+}{H}-\overset{\delta-}{N}F_2$, which under suitable conditions is capable of heterolysis with the formation of the difluoramide anion NF_2^-.

If the tervalent nitrogen atom in the ammonia molecule is considered to be in a reduced state and the tervalent nitrogen atom in nitrogen trifluoride is in an oxidised state, then the difluoramine molecule undergoes both oxidation and reduction.

Hence the difluoramine molecule, by allotting a rather active long pair of electrons to the nitrogen atom and with a hydrogen atom capable of loss as a proton, exhibits an amphoteric nature. The presence in it of an N–H bond capable of being oxidised, and of an N–F bond capable of being reduced, confers on it the dual character of reactivity in redox changes. The combination of such a variety of properties is usually responsible for the diversity of the chemical reactions in which difluoramine participates.

2. PHYSICAL PROPERTIES AND STRUCTURE OF THE DIFLUORAMINE MOLECULE

Difluoramine is a colourless gas with a characteristic sharp odour, reminiscent of the odour of nitrogen oxides, liquefying below -23° into a transparent, colourless, mobile liquid. The most important physical properties of difluoramine have been studied recently by Lawton and Weber [4,5] and by Kennedy and Colburn [6].

The microwave spectra of difluoramine and deuterated difluoramine have been investigated [7]. The HNF_2 molecule is characterised by the following parameters [7]:

length of nitrogen–fluorine bond	$r_{N-F} = 1.400 \pm 0.002$ Å,
length of nitrogen–hydrogen bond	$r_{N-H} = 1.026 \pm 0.002$ Å,
F–N–F bond angle	102.9°,
H–N–F bond angle	99.8° ± 0.2°.

The difluoramine molecule is thus an irregular triangular pyramid with the nitrogen atom at the apex.

The dissociation energy of the nitrogen–hydrogen bond in difluoramine $D(F_2N-H)$ is 72.5 kcal. [8]

The dipole moment of the HNF_2 molecule is 1.93 D, and its vector is directed at an angle of 19° to the direction of the nitrogen–hydrogen bond. This agrees well with the hypothesis of polarisation of the nitrogen–hydrogen bond and the tendency of difluoramine to dissociate according to the equation:

$$HNF_2 \rightleftharpoons H^+ + NF_2^-.$$

The infrared spectrum of gaseous difluoramine in the region 250–4000 cm^{-1} has been investigated; it includes strong doublets at 7.0, 7.8, and 10.2 μm and a triplet at 11.2 μm. [3]

The proton-NMR spectrum consists of a triplet, as should follow from proton spin–spin interaction with the two equivalent fluorine nuclei. The centre of the triplet is displaced by ~ 6 Hz to the side of fields of greater intensity in relation to benzene. The spin–spin splitting corresponds to ~ 24 Hz.

The ^{19}F-NMR spectrum consists of two broad bands arising from the spin–spin interaction of the fluorine nuclei with the proton. The peak of this doublet, which corresponds to a greater field strength, is located in the region 2100 Hz to the side of fields of lower intensity relative to trifluoroacetonitrile [3,6].

The mass spectra of difluoramine have also been studied in detail [4,6].

The anomalously high boiling point of difluoramine (-23.6°) compared with the value which could be expected starting from the boiling point of ammonia (-33.4°) and nitrogen trifluoride (-129°), the high dipole moment of the HNF_2 molecule, and other data given in Table 1 undoubtedly show that in the condensed phase difluoramine is a strongly associated liquid.

The difluoramine molecule is amphoteric and is capable of complex formation through hydrogen bonds with alkali metal fluorides [11–13] and Lewis basicity with several aprotic acids [14]. It is reasonable to assume that association

TABLE 1. Some properties of ammonia and several of its fluoro-derivatives.

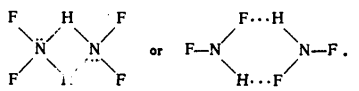
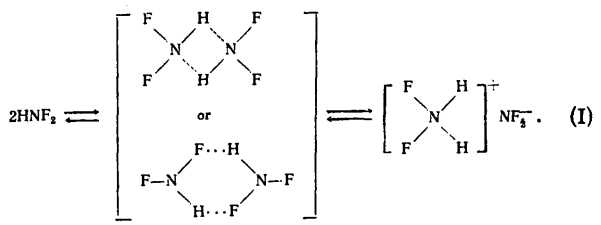
Solubility in water	very good	soluble	—	insoluble

in the liquid phase is effected by the formation of a hydrogen-bonded dimer, whose presence in solid difluoramine was shown by Craig by infrared spectroscopy [14]:



It is not ruled out that such an associate-dimer of difluoramine plays the part of an activated complex characterising the four- or six-membered transition state in equilibrium:



Difluoramine is rather readily soluble in several polar solvents, for example, in water [5,9,15,16] and, despite one assertion [2], is stable in deoxygenated aqueous and sulphuric acid solutions. Heating these solutions or non-hermetic storage leads to almost quantitative desorption of the difluoramine from them.

Preparations of 0.15 M solutions of difluoramine in 0.1 M sulphuric acid have been described [5]. On heating aqueous solutions acidified with sulphuric, nitric, phosphoric, sulphurous, or other mineral acids it can be completely expelled from them [15,17]. For example, the quantitative liberation of ~ 6.6 g HNF_2 from its solution in 100 ml 5% H_2SO_4 on heating the latter at 90° for 30 min has been described.

Difluoramine is sparingly soluble in concentrated sulphuric acid at reduced pressure and room temperature [18]. This property is utilised for its quantitative separation in preparation from triphenylmethyldifluoramine (tritylfluoramine). For example, by vacuum treatment 0.053 g HNF_2 was completely extracted from its solution in 10 ml concentrated sulphuric acid.

The solubility of difluoramine in dimethyl, ethyl methyl, diethyl, di-isopropyl, and dibutyl ethers; methylal [diethoxymethane]; dimethoxyethane; anisole; tetrahydrofuran; tetrahydropyran; and ethylene oxide has been investigated [5,19]; it forms homogeneous solutions with these solvents over a rather wide range of ratios. Solutions containing up to 10 parts by weight were obtained for dimethyl and diethyl ethers and ethylene oxide, up to 5.8 parts by weight for methylal, and 5.2 parts by weight HNF_2 for dimethoxyethane per part by weight of solvent.

The solutions of difluoramine in ethers are quite stable over a rather wide range of temperature and were patented as mono-component and two-component liquid rocket propellents [15,19]. A mixture of dimethyl ether and difluoramine, for example, is stable at from -142° to room temperature. The order of mixing of the ethers with difluoramine and also the state of aggregation of the components of the mixture (except solid) are unimportant, but the rate of mixing should be rather slow, as there is a considerable exothermic effect during mixing. All the mixtures exhibit a marked negative departure from Raoult's law, which once again confirms the hypothesis concerning the association of difluoramine in the liquid phase.

The solutions of difluoramine in dimethyl ether, diethyl ether, and ethylene oxide have been studied most thoroughly [5]. It has been found that these ethers form molecular addition compounds with difluoramine in the ratio 1 : 1, giving the composition $R_2O.HNF_2$. However, at room temperature these addition products are completely dissociated into their constituent molecules.

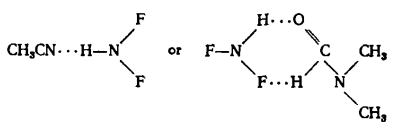
The solubility of difluoramine in methanol, ethanol, acetonitrile, dimethylformamide, and dimethyl sulphoxide has also been investigated [20]. It has been shown that equimolecular solutions of difluoramine in these solvents, like the solutions in ethers and ethylene oxide [5], behave as equilibrium systems of the form:

$$HNF_2 + X \underset{+\Delta}{\overset{-\Delta}{\rightleftharpoons}} X \cdot HNF_2$$

where X = H_2O, CH_3OH, C_2H_5OH, CH_3CN, $(CH_3)_2NCHO$, or $(CH_3)_2SO$, for which a fall in temperature favours a shift in the equilibrium to the right.

The stability of the complexes formed (adducts) depends on the nature of X. The most stable complexes are with dimethylformamide and dimethyl sulphoxide, whereas the complexes with water are distinguished by insignificant stability.

Infrared spectroscopy has shown that the complex formation in these examples is brought about by the formation of intermolecular hydrogen bonds, for example:



with the force of association falling in the sequence:

$$HNF_2 \cdot (CH_3)_2NCHO \sim HNF_2 \cdot (CH_3)_2SO > HNF_2 \cdot CH_3OH > HNF_2 \cdot H_2O$$

For some of these systems the equilibrium state is characterised as follows:

$$\ln K_{p_{HNF_2 \cdot CH_3OH}} = -\frac{4143.2}{T} + 23.22, \qquad \Delta H = 8.24 \text{ kcal mole}^{-1},$$

$$\ln K_{p_{HNF_2 \cdot CH_3CN}} = -\frac{6538.2}{T} + 31.464, \qquad \Delta H = 13.02 \text{ kcal mole}^{-1},$$

where $K_p = p^2/4$.

TABLE 2. Properties of some molecular adducts of difluoramine [5].

Ether	B.p., °C extrapolation	H_{vap}, kcal mole^{-1}	Trouton constant	Dependence of vapour pressure on temperature, $\log p_{mmHg}$ =
Dimethyl	0	7.66	28.1	$-1674/T+9.005$
Diethyl	36	7.41	24.0	$-1619/T+8.124$
Ethylene oxide	22	6.92	23.5	$-1512/T+8.015$

The examples quoted of the reversible complex formation by difluoramine with water and various organic compounds undoubtedly show that its tendency to intermolecular interaction by the formation of hydrogen bonds is one of the most important prerequisites for understanding the character of the reactivity of this compound. In this, the difluoramine molecule can evidently act either as an acceptor (through the hydrogen atom) or as a donor (through the nitrogen or fluorine atoms).

3. METHODS OF MAKING DIFLUORAMINE

Despite Ruff and Staub's claim [21,22] to have made difluoramine by the electrolysis of fused ammonium hydrogen fluoride, it is quite clear [1-3] that this compound was first obtained by Kennedy and Colburn [6] in 1959. In studying the pyrolysis of nitrogen trifluoride over arsenic in the presence of water vapour with the aim of preparing tetrafluorohydrazine, they found [6] that at 250–300° a little difluoramine is formed in addition to N_2F_4.

It is impossible to support the suggestion [6] that the appearance of HNF_2 in this process is due to the intermediate formation of arsine. The oxidative nature of the interaction of nitrogen trifluoride with arsenic and of tetrafluorohydrazine with arsine [23] obviously excludes the possibility of the formation under these conditions of such a strong reductant as arsine. Most probably difluoramine is formed as a result of the difluoramine radicals which are produced in large amounts in the defluorination of nitrogen trifluoride by arsenic:

$$NF_3 + As \xrightarrow{300^\circ} {}^\cdot NF_2 + AsF_3,$$

reacting directly with water molecules:

$${}^\cdot NF_2 + HOH \longrightarrow HNF_2 + {}^\cdot OH.$$

The great ability of the difluoramine radical to detach a hydrogen atom, a reaction which is essentially an oxidation:

$$H^\cdot + {}^\cdot NF_2 \longrightarrow [H^+ + NF_2^-] \longrightarrow HNF_2,$$

forms the basis of a group of methods for obtaining difluoramine [23]. Thus, on heating mixtures of tetrafluorohydrazine with arsine in an autoclave (1 h at 50–60°), difluoramine can be obtained in 52% yield:

$$N_2F_4 + AsH_3 \longrightarrow HNF_2.$$

The reaction of tetrafluorohydrazine with thiols also leads to the formation of difluoramine:

$$2RSH + N_2F_4 \longrightarrow 2HNF_2 + R{-}S{-}S{-}R.$$

As a result of the reaction of tetrafluorohydrazine with thiophenol at 50° in a glass reactor, difluoramine is formed in 75% yield, whereas in reaction with butanethiol in a stainless steel autoclave it is obtained in only 9% yield.

In all these instances it was very difficult preparatively to isolate the difluoramine from the gaseous reaction mass and this was done by fractional condensation of the products in a vacuum with a series of traps at -80° and below.

One variety of this group of methods is the preparation of difluoramine by heating a mixture of tetrafluorohydrazine and acetaldehyde to 150° : [24]

$$CH_3CHO + N_2F_4 \xrightarrow{150^\circ} CH_3CONF_2 + HNF_2.$$

Evidently there is an unbranched chain reaction in which $^{\cdot}NF_2$ radicals play the initiating role:

(1) $$N_2F_4 \rightleftharpoons 2{}^{\cdot}NF_2,$$

(2) $$RCHO + {}^{\cdot}NF_2 \longrightarrow R\dot{C}O + HNF_2,$$

(3) $$R\dot{C}O + N_2F_4 \longrightarrow RCONF_2 + \dot{N}F_2, \text{ etc.}$$
$$(^{\cdot}NF_2)$$

This is the more probable in that the last stage has been successfully brought about after the homolytic photolysis of biacetyl in an atmosphere of tetrafluorohydrazine[24]:

$$CH_3COCOCH_3 \xrightarrow[N_2F_4]{h\nu} 2CH_3CONF_2.$$

We think that it is not accidental that not a single instance of the formation of difluoramine in the action of tetrahydrofluorohydrazine on alcohols, carboxylic acids, or amines has yet been described, though these compounds have labile hydrogen. Furthermore, it is known[16] that the action of tetrafluorohydrazine on dimethylamine at 80° for 2 h in the gas phase leads only to the production of small amounts of methyl azide, diazomethane, and azomethane and does not give difluoramine, and the action of chlorodifluoramine on an excess of dimethylamine in ethereal solution leads to quantitative formation of tetrafluorohydrazine and dimethylammonium chloride.

On the other hand, Grzechowiak and coworkers have reported that heating certain alkanes[8] or acetone[26] with tetrafluorohydrazine leads to the removal by the $^{\cdot}NF_2$ radical of a hydrogen atom from the alkane and the formation of difluoramine and the corresponding alkyldifluoramines:

$$RH + {}^{\cdot}NF_2 \longrightarrow R^{\cdot} + HNF_2,$$
$$R^{\cdot} + N_2F_4 \longrightarrow RNF_2,$$
$$(^{\cdot}NF_2)$$

where R = CH_3COCH_2 or a hydrocarbon radical.

The authors evidently did not succeed in isolating alkyldifluoramines in the pure state, since under the conditions of the reaction they decompose into a complex mixture of resinous products.

Bumgardner[26] observed the formation of alkyl-, alkenyl-, and alkynyl-difluoramines in the photochemical reaction between tetrafluorohydrazine and certain saturated and unsaturated hydrocarbons:

$$2CH_4 + 2N_2F_4 \xrightarrow[30\ min]{h\nu} 2CH_3NF_2 + 2N_2F_2 + 2HF \quad (50\%),$$

$$CH_3CH{=}CHCH_3 \xrightarrow[h\nu]{N_2F_4} CH_3CH{=}CHCH_2NF_2 + CH_3CHFCH(NF_2)CH_3 \quad (74\%),$$

$$CH_3C{\equiv}CCH_3 + N_2F_4 \xrightarrow{h\nu} \begin{cases} CH_3C{\equiv}CCH_2NF_2 \\ CH_3CF_2C(=NF)CH_3, \\ CH_3CF{=}C(NF_2)CH_3 \end{cases}$$

Chromatographic analysis of the products of the reaction on Chromosorb impregnated with silicone oil showed the absence of difluoramine from them. The initiating role in this process on account of the loss of the hydrogen atom from the hydrocarbon was ascribed by Bumgardner solely to a fluorine atom formed in the decomposition of the excited radical $^{\cdot}NF_2$†:

$$^{\cdot}NF_2 + h\nu \longrightarrow [{}^{\cdot}NF_2^*] \longrightarrow F^{\cdot} + F\dot{N},$$
$$RH + F^{\cdot} \longrightarrow R^{\cdot} + HF.$$

† Bumgardner believed the reaction to be initiated by F· (instead of $^{\cdot}NF_2^*$) as no HNF_2 or bisdifluoramino-compounds are observed (Ed. of Translation).

However, considering the ease with which difluoramine in contact with solid materials undergoes dehydrofluorination to form fluorazene [or fluoronitrene (Ed. of Translation)], then giving difluorodiazine [dinitrogen difluoride (Ed. of Translation)][5]:

$$HNF_2 \longrightarrow HF + \dot{N}F,$$
$$2\dot{N}F \longrightarrow N_2F_2,$$

and the probability that this change can occur in the chromatographic column, then once again the chromatographic data cannot be considered completely adequate for concluding the absence of difluoramine from this process due to the removal of a hydrogen atom by the radical $^{\cdot}NF_2$.

These facts show that the formation of difluoramine can be expected in by no means all instances of the interaction of tetrafluorohydrazine with substances bearing a labile hydrogen, as has been stated[2], but only when the substance is capable of easily losing not a proton, but an atom of hydrogen, which subsequently recombines with the $^{\cdot}NF_2$ radical.

Until recently the most acceptable method for making difluoramine[4] consisted in the action of elemental fluorine diluted with nitrogen on urea at 0°. Other investigators[5,27] have often used this method. It provides difluoramine in yields which, although moderate (up to 30% on the fluorine used[5]), are evidently sufficiently stable. Taking into account that the *NN*-difluorourea being formed in this process in high yield can be almost quantitatively decomposed on heating its aqueous solutions to 90° with sulphuric acid according to the equation[15,17,27]:

$$2NH_2CONF_2 + 2H_2O + H_2SO_4 \longrightarrow 2CO_2 + 2HNF_2 + (NH_4)_2SO_4,$$

the overall practical yield of difluoramine should be considered to be considerably higher.

In a modification of this method[11] it is proposed to isolate difluoramine from the liquid which is obtained by the fluorination of urea after Lawton and Weber in a single stage by acidifying it with sulphuric acid. With this reaction a continuous process for the production of difluoramine becomes possible[15].

To obtain difluoramine by acidic hydrolytic decomposition it is possible to use the products of the fluorination of biuret, aminoguanidine, diaminourea, 5-aminotetrazole, guanidinium chloride[28], and also almost any derivative of the type:

$$RR'NCXNF_2,$$

where R and R′ can be aryl, nitroaryl, or alkyl; and X is a sulphur or oxygen atom or an NH group. These products are readily obtainable according to the equation[15]:

$$RR'NCXNH_2 + 2F_2 \longrightarrow RR'NCXNF_2 + 2HF.$$

Evidently the ability of *NN*-difluoroamido-derivatives to give difluoramine when aqueous solutions of acids act on them is one of the most important features of the reactivity of this class of compound. Mono- and di-*N*-fluorocarbamates are formed in good yield in the fluorination of alkyl carbamates with elemental fluorine in water or acetonitrile[29]:

$$H_2NCOOR \xrightarrow[H_2O \text{ or } CH_3CN]{F_2} [FHNCOOR] \xrightarrow{F_2} F_2NCOOR,$$

where R = methyl, ethyl, n-propyl, isopropyl, or n-butyl.

Like *NN*-difluorourea, the esters of *NN*-difluorocarbamic acid give difluoramine quantitatively on heating with aqueous solutions of acids:

$$F_2NCOOR \xrightarrow{H_3O^+} HNF_2 + CO_2 + ROH.$$

Difluoramine can be obtained in good yield by hydrolysis of *NN*-difluoroaminocarbonyl fluoride[30], obtained in the ultraviolet irradiation of a mixture of carbon monoxide and tetrafluorohydrazine:

(1) $$CO + N_2F_4 \xrightarrow{h\nu} F_2NCOF + COF_2 + CO_2 + NF_3,$$

(2) $$F_2NCOF + H_2O \longrightarrow HNF_2 + HF + CO_2.$$

Difluoroaminocarbonyl fluoride is hydrolysed immediately even by the action of traces of moisture; therefore on reacting with other substances in aqueous solution it behaves like difluoramine[4-6,9,11], for example:

$$2F_2NCOF + 8OH^- \longrightarrow N_2F_2 + 2CO_3^{2-} + 4F^- + 4H_2O \text{ (see Refs. 9 and 11),}$$

$$F_2NCOF + 6I^- + 5H_3O^+ \longrightarrow 2I_3^- + NH_4^+ + 3HF + 4H_2O + CO_2 \text{ (see Refs. 4 and 5).}$$

Difluoramine can be made in good yield by acid hydrolytic decomposition of *NN*-difluorosulphonyl diamide[31], which can be obtained by the fluorination of an aqueous solution of sulphonyl diamide with fluorine below -5°:

$$2F_2 + H_2NSO_2NH_2 \longrightarrow 2HF + F_2NSO_2NH_2,$$
$$F_2NSO_2NH_2 + H_2O \xrightarrow[t^\circ]{H^+} HNF_2 + HOSO_2NH_2.$$

Acidification may be effected with phosphoric or sulphuric acid of a concentration not above 1 *N*: the use of concentrated sulphuric acid is said to decrease the yield of difluoramine and increase that of tetrafluorohydrazine.

Difluoramine can be obtained just as successfully by the acid hydrolysis of some complexes of *NN*-difluorosulphonyl diamide, for example:

$$(C_6H_5)_3PO \cdot H_2NSO_2NF_2,$$

complexes which, unlike *NN*-difluorosulphonyl diamide, can be isolated pure.

The "sulphamide" method of obtaining difluoramine can be considered to be more preferable than the "carbamide", since in the final stage it does not give any gaseous products other than difluoramine, whereas in the preparation from *NN*-difluorourea it is liberated from solution as an equimolecular mixture with carbon dioxide, the separation of which presents known preparative difficulties.

The attempt to bring about the preparation of difluoramide by the vapour-phase fluorination of ammonia with elemental fluorine[32] cannot be considered successful, since this results in the formation of a complex, difficultly separable mixture of reaction products:

$$NH_3 + F_2 \longrightarrow NF_3 + N_2F_4 + HNF_2 + N_2F_2 + NH_4F.$$

A small quantity of difluoramine in a high degree of purity under laboratory conditions can be easily obtained by the decomposition of trityldifluoramine with concentrated sulphuric acid at room temperature[18]:

$$(C_6H_5)_3CNF_2 + H_2SO_4 \longrightarrow HNF_2 + (C_6H_5)_3C^+ \cdot HSO_4^- \xrightarrow{H_2O} (C_6H_5)_3COH + H_2SO_4.$$

The method ensures a 99% yield of almost pure difluoramine, which in combination with the relative accessibility of trityldifluoramine makes it extremely attractive. Trityldifluoramine in turn can be readily made from trityl chloride by reaction with tetrafluorohydrazine in the presence of mercury[18]. However, the method is of little use for technical purposes, since (as an example) 0.30 g (0.001 M) trityldifluoramine were spent in decomposition and a total of 23 cm^3 gaseous difluoramine was obtained.

The use of concentrated sulphuric acid does not prevent the quantitative formation and isolation of difluoramine and does not result in a redox reaction with the formation of tetrafluorohydrazine, as happens in the decomposition of *NN*-difluorosulphonyl amide or its complexes[31]. Probably the reason for the contradiction in these two observations lies in the different temperature conditions.

The ability of trityldifluoramine to give difluoramine with concentrated sulphuric acid is still unique among the difluoroaminoalkane series. The action of sulphuric acid on ethyl, t-isobutyl, n-butyl-, and s-butyl-*NN*-difluoramines does not lead to the formation of difluoramine[33]: these reactions are considered in detail in Section 4.

Mention must also be made of a single instance of the formation of difluoramine: ethanol acts on *NN*-difluoroacetamide to give the products ethyl acetate and difluoramine[24]:

$$CH_3CONF_2 + HOC_2H_5 \longrightarrow CH_3COOC_2H_5 + HNF_2.$$

This example, like the many instances of the hydrolytic instability of the *NN*-difluoroamido-derivatives described above, suggests that they possess the properties of acid halides and that the NF_2 group has a pseudo-halogen character.

4. CHEMICAL PROPERTIES AND REACTIVITY OF DIFLUORAMINE

It is desirable to start the review of the chemical properties of difluoramine by considering its capability for complex formation with different reagents.

The amphoteric nature of the HNF_2 molecule enables difluoramine to form coordination complexes either through the acceptor properties of the hydrogen atom or through the donor ability of the nitrogen and fluorine atoms, which have sufficiently active lone electron pairs.

In investigating the interaction of a series of organic and inorganic difluoramine derivatives of the type XNF_2, including some alkyldifluoramines, difluoramine, chlorodifluoramine, and nitrogen trifluoride, with such Lewis acids as BF_3, BCl_3, PF_5, and SO_2, Craig[14] found that the reactivity of these difluoramine derivatives is determined mainly by the donor properties of the nitrogen atom, which has a lone pair of electrons.

The activity of this pair depends directly on the electronegativity of the substituents X at the nitrogen atom. The greater the electronegativity of X, the greater the deficiency of electron density which is formed at the nitrogen atom and the greater the extent to which the lone pair of electrons takes part in the compensation of this deficit, the more the electron-donor properties of the molecule appear, and their Lewis basicity falls.

Craig showed experimentally that the basic properties of the compounds of type XNF_2 fall in the sequence:

$$C_6H_5NF_2 > CH_3NF_2 \sim CD_3NF_2 > HNF_2 > ClNF_2 > N_2F_4 \sim CF_3NF_2 \sim NF_3.$$

The most stable complexes of the type $HNF_2.A$, where A is a Lewis acid, are formed by difluoramine with BF_3, BCl_3, and SO_2. When these complexes, which are quite stable at low temperatures (< -78°), are heated they either

undergo irreversible changes – for example, $HNF_2.BCl_3$, which decomposes to give chlorodifluoramine [34]:

$$BCl_3 \cdot HNF_2 \longrightarrow ClNF_2 + BF_3 + HCl + BCl_3,$$

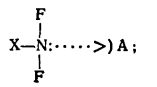
– or form equilibrium systems:

$$HNF_2.A(solid) \rightleftharpoons HNF_2(gas) + A(gas).$$

On the basis of kinetic measurements, Craig found the enthalpies of the processes and the equations which describe the temperature dependence of the pressure in the system (see Table 3).

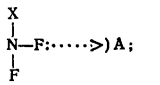
In investigating the mechanism of formation of complexes of difluoramine derivatives of the type $X-NF_2$ with Lewis acids, Craig started from the assumption of four theoretically conceivable possibilities for complex formation, due to:

(a) donor-acceptor interaction of the partners with participation of the lone pair of electrons of the nitrogen atom:

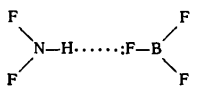


(II)

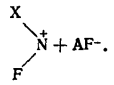
(b) donor-acceptor interaction of the partners with participation of the lone pair of electrons of the fluorine atoms, that is, by the formation of "fluorine bridges":



(c) hydrogen bonds between the hydrogen atom of the difluoramine and a nucleophilic atom of the Lewis acid:



(d) the formation of ions:

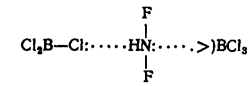


From infrared investigations Craig concluded that structure (II) best corresponds to the entire set of experimental results he obtained.

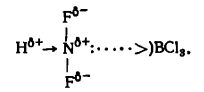
The absence from both the liquid and solid phases of difluoramine of association between the partner molecules of complex formation due to $XFN \rightarrow F \ldots A$ fluorine bridges [14] indicates greater activity by the lone pair of electrons at the nitrogen atom than by that at a fluorine atom.

Hence, although also acting as a weak base, difluoramine is capable of forming donor-acceptor bonds. The complexes thus formed are probably capable of sometimes acting as activated complexes, the formation of which can follow irreversible reactions between donor and acceptor atoms (for example, in the formation of $ClNF_2$).

According to Craig, the initial stage in the formation of chlorodifluoramine from difluoramine and boron trichloride is either the formation of a hydrogen bond:



or simple weakening of the NH bond, owing to a decrease in the electron density at the nitrogen atom:



Craig's results about the capability of difluoramine to give complexes with Lewis acids disagree with the statement of Lawton and Weber [5], who formulated their conclusions without reference to temperature interval. Craig's careful investigation showed that Lawton and Weber's conclusion about the absence of complex formation between difluoramine and Lewis acids can be correct apparently only at temperatures above 0°.

The activating role of the complex formation stage between difluoramine derivatives and Lewis acids is also shown in the dehydrofluorinations of alkyldifluoramines with BF_3, BCl_3, and PF_5. [14]

According to Craig, the first stage of the process here is the formation of complexes of the type $RNF_2.BX_3$, where R = CH_3 or C_2H_5, and X = F or Cl:

$$R'CH_2NF_2 + BX_3 \rightleftharpoons R'CH_2NF_2 \cdot BX_3, \quad \text{(III)}$$

$$R'CH_2NF_2 \cdot BX_3 \longrightarrow R'CH{=}NF + HF + BX_3,$$

$$R'CH{=}NF + BX_3 \rightleftharpoons R'CH{=}NF \cdot BX_3,$$

$$R'CH{=}NF \cdot BX_3 \longrightarrow R'C{\equiv}N + HF + BX_3. \quad \text{(IV)}$$

In citing this scheme of dehydrofluorination and unambigously considering that complex formation is brought about by the lone electron pair of the nitrogen atom, Craig contradicts some of his own observations and conclusions. The infrared spectra of the complexes of the alkyldifluoramines with Lewis acids, according to Craig's own statement, are quite complex and he did not succeed in interpreting them with sufficient certainty. In assuming that the complexes have the structure $RF_2N:BX_3$ he relied to a great extent on argument by analogy, and not on the infrared spectroscopic data.

The ease with which the complexes of the alkyldifluoramines with Lewis acids undergo irreversible decomposition with loss of hydrogen fluoride from the alkyldifluoramine molecule and the absence of a capacity for dehydrofluorination from the complexes of these Lewis acids with difluoramine enables the following propositions to be advanced.

Where difluoramine is concerned, the complexes with Lewis acids are, as Craig has shown sufficiently conclusively, formed by the lone electron pair of the nitrogen atom, but the dissociation of these complexes at elevated temperatures leads to the establishment of the reversible equilibrium considered above (with the exception of the special example of that with boron trichloride).

According to Craig's own results, the complexes of methyldifluoramine and ethyldifluoramine with boron halides and phosphorus pentafluoride are stable at temperatures below -100° and at higher temperatures "decompose irreversibly"

TABLE 3. Some characteristics of the equilibria $HNF_2.A(solid) \rightleftharpoons HNF_2(gas) + A(gas)$.

A	Expression for $\ln K_{equil}$	ΔH, kcal mole^{-1}	Note
BF_3	$-\frac{10566}{T} + 54286$	20.97	$K_p = \frac{p^2}{4}$
SO_2	$-\frac{6291.2}{T} + 35978$	12.50	

with the formation of hydrogen fluoride and the corresponding nitrile. Hence the use in Eqns. (III) and (IV) of the equilibrium sign between the left and right sides is incorrect. It is more logical to assume that in the alkyldifluoramines, when R is a hydrocarbon radical, owing to the electron donor properties of the latter the electron density at the nitrogen atom rises, as Craig observed, which naturally activates the lone electron pair at the nitrogen atom and also favours an increase in the Lewis basicity of the fluorine atom:

$$R\rightarrow\overset{\cdot\cdot}{N}F\rightarrow F:.$$

Together with steric hindrance which the alkyl radical of the Lewis acid molecule inevitably creates in its tendency to bind the lone pair of electrons of the nitrogen atom, this circumstance apparently leads to the formation of alkyldifluoramine complexes, due to fluoride bridges:

$$RCH_2\rightarrow\underset{F}{N}\rightarrow F:+)\,BF_3\longrightarrow RCH_2{-}NF{-}F:)\,BF_3,$$

and not due to the lone pair of electrons of the nitrogen atom, as occurs with difluoramine.

The decomposition of this complex when the temperature is raised leads to loss of a fluorine as a BF_4^- ion from the Lewis acid:

$$RCH_2{-}FN\,|{:}F{:}BF_3\rightarrow RCH_2{-}\overset{+}{N}F+BF_4^-.$$

The cation which is formed is stabilised by the elimination of a proton and conversion into a molecule of an *N*-fluoroimine:

$$R{-}\overset{H}{\underset{H}{C}}{-}\overset{+}{N}F\longrightarrow RCH{=}NF+H^+.$$

Subsequently, this process is repeated using hydrogen atoms at the α carbon atom, leading eventually to the formation of nitriles. The presence of hydrogen atoms at the carbon atom next to the difluoramine group is evidently proof of the condition of dehydrofluorination of the alkyldifluoramines by the Lewis acids, so that trifluoromethyldifluoramine, for example, is only very weakly associated with boron halides and no chemical reaction occurs between them [14].

The above treatment of the mechanism of dehydrofluorination is confirmed by Baum's results [33]. By studying the interaction of certain alkyldifluoramines with concentrated sulphuric acid and boron trifluoride, he showed that the process passes through the stage of formation of an *N*-fluoroiminium ion owing to the initial loss of a fluoride ion from the molecule of the difluoramine derivative:

$$R'CH_2NF_2+H_2SO_4\longrightarrow\left[RCH{=}\overset{+}{N}\begin{matrix}H\\F\end{matrix}\right]\cdot HSO_4^-+HF.$$

When R' = CH_3, Baum observed the intermediate stabilisation of the *N*-fluoroiminium ion by conversion into a molecule of an *N*-fluoroimine, which, on undergoing further dehydrofluorination by the same mechanism, was converted finally into acetonitrile:

$$\left[CH_3CH{=}\overset{+}{N}\begin{matrix}H\\F\end{matrix}\right]\xrightarrow{-H^+}CH_3CH{=}NF\xrightarrow{-HF}CH_3C{\equiv}N.$$

Baum also observed the formation of an *N*-fluoroiminium ion in other examples. When the number of carbon atoms in the radical exceeded two, a rearrangement occurred instead:

$$(CH_3)_3CNF_2+BF_3\longrightarrow\left[\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!C\!=\!\overset{+}{N}\!<\!\begin{matrix}F\\CH_3\end{matrix}\right]\cdot BF_4^-,$$

$$C_3H_7CH_2NF_2\xrightarrow{H_2SO_4}\left[CH_2{=}\overset{+}{N}\begin{matrix}F\\C_3H_7\end{matrix}\right],$$

$$C_2H_5(CH_3)CHNF_2\xrightarrow{H_2SO_4}\left[CH_3CH{=}\overset{+}{N}\begin{matrix}F\\C_2H_5\end{matrix}\right].$$

It is also necessary to note that complex formation with Lewis acids should bring about a redistribution of the electron density in the molecule of the difluoramine derivative in the direction of its depletion at the atoms which do not participate in complex formation and increase at the atom responsible for the formation of the complex. Consequently the formation of complexes with alkyldifluoramines due to the electron lone pair of the nitrogen atom should be not facilitated, but hindered by the loss of the fluoride ion, that is, dehydrofluorination, and on the contrary, complex formation due to a fluorine bridge should promote this process, as Craig also observed.

If difluoramine could form complexes with Lewis acids through fluorine bridges, then it is probable that the ready formation of fluorazene and subsequently difluorodiazine also, would be observed, which is not so:

$$HNF_2+BF_3\longrightarrow\underset{F}{\overset{H}{>}}N\rightarrow F:)\,BF_3\longrightarrow\overset{+}{H}NF+BF_4^-,$$

$$H\rightarrow\overset{+}{N}F\longrightarrow\overset{+}{H}+\dot{N}F\longrightarrow N_2F_2$$

The complex formation by difluoramine with alkali metal fluorides, established by Lawton and coworkers [11], is well known. These investigators found that potassium, rubidium, and caesium fluorides (with an activity rising from potassium to caesium) form with difluoramine molecular complexes of 1 : 1 composition, $MF.HNF_2$ (similar to the complexes of difluoramine with the dialkyl ethers [5,19]), which decompose at even low temperatures to form the two isomers of difluorodiazine and hydrogen fluoride:

$$MF+HNF_2\longrightarrow MF\cdot HNF_2\longrightarrow MF\cdot HF+\tfrac{1}{2}N_2F_2.$$

On the basis of this reaction they have patented [35] what is perhaps the simplest and most convenient of the known methods for obtaining N_2F_2, in which the difluorodiazine is formed in almost quantitative yield and almost without impurities.

The activity of the alkali metal fluorides in this reaction rises in the sequence:

$$LiF\ll NaF<KF<RbF<CsF.$$

Careful investigation by the same authors [11] of the ability of metal fluorides to form complexes with difluoramine showed that NaF, CaF_2, and NiF_2 do not form complexes with difluoramine at -80° and below, but the complexes $KF.HNF_2$ and $RbF.HNF_2$ dissociate reversibly at elevated temperatures (from -60° to -30°). The equilibria for complexes with potassium and rubidium fluorides are characterised by the data given in Table 4.

The complex $CsF.HNF_2$ readily exploded at elevated temperatures; therefore none of the investigators has studied it in detail [11,13].

TABLE 4. Some characteristics of the equilibria[11] $MF.HNF_2(solid) \rightleftharpoons MF(solid) + HNF_2(gas)$.

MF	Expression for $\log K_{equil}$	ΔH, kcal mole^{-1}
KF	$-\frac{1467}{T}+7784$	6.7
RbF	$-\frac{2166}{T}+10338$	9.9

Dubb and coworkers have made a detailed study of the structure of the complexes $MF.HNF_2$ by infrared spectroscopy[13]. They found that potassium and rubidium fluorides form complexes with difluoramine mainly by hydrogen bonds set up between the hydrogen atom of the difluoramine molecule and the nucleophilic atom of the fluorine atom of the alkali metal fluoride (complex of type A):

$$M^+F^- \cdots \overset{\delta+}{H}—\overset{\delta-}{NF_2}.$$

Such a structure for the complexes of difluoramine with the alkali metal fluorides agrees well with the above series [11,35] for their relative tendencies to complex formation; it can also be taken as the series for the relative nucleophilicity of the fluorine atom in the fluorides, or the series for increasing electropositivity of the alkali metals.

Dubb and coworkers[13] consider that the explosive nature of the complex of caesium fluoride with difluoramine is due to the formation of the difluoramide anion NF_2^- in the complex, the existence of which they have demonstrated quite thoroughly. They think that caesium fluoride forms two types of complexes with difluoramine, one of which is identical in structure with the complexes which are formed by potassium and rubidium fluorides (type A) and the other is an ionic complex (type B): $Cs^+FH.NF_2^-$, which is responsible for the explosive nature of the adduct.

Unfortunately the authors were unable to obtain quantitative relations between the forms A and B. Possibly the explosive nature of this complex is due not only to the existence of form B, but also to the energy effect of the change of the adduct from form A to form B, that is, by the heat of the reaction:

$$\underset{\text{form A}}{Cs^+F^-\cdots\overset{\delta+}{H}—\overset{\delta-}{NF_2}} \xrightarrow{t^\circ} \underset{\text{form B}}{Cs^+\cdot HF\cdot NF_2^-} + Q.$$

For the complexes with potassium and rubidium fluorides, because of the lower electropositivities of the potassium and rubidium atoms compared with the caesium atom the nucleophilicity of the fluorine atom is insufficient for the realisation of the transformation of form A into form B.

Lawton and coworkers[11] found that the dehydrofluorination of difluoramine with formation of N_2F_2 isomers can be successfully effected also by aqueous solutions of potassium fluoride.

Thus when a 25% aqueous solution of potassium fluoride with pH 8.6 is used at room temperature, difluorodiazine can be obtained in 75% yield. The authors express the process by the equation:

$$2F^- + 2HNF_2 \longrightarrow 2HF_2^- + N_2F_2.$$

When the nucleophile is not F^- but OH^- in the form of standard buffer solutions with pH 8.0 and 9.0, difluorodiazine is formed in 25% yield.

There is a basis for supposing that this equation can be considered as the overall expression for a difluorodiazine formation process from difluoramine of at least four stages in which the nucleophilic attack:

$$B: + \overset{\delta+}{H}—\overset{\delta-}{NF_2} \longrightarrow B: \cdots HNF_2,$$

is equivalent to the formation of a type A complex in the solid phase as a result of this attack, that is, the formation of the anion NF_2^-:

$$B:\cdots H—NF_2 \longrightarrow NF_2^- + B\cdot H^+,$$

is equivalent to the transformation of a type A complex into a type B complex, with the sole difference that in the solid phase the latter is rigidly fixed, but in water it is completely dissociated into its constituent ions. Subsequent decomposition of the difluoroamide anion leads to the formation of difluorodiazine:

$$F\leftarrow\bar{N}F \longrightarrow F^- + \dot{N}F,$$

$$(\text{or } M^+ + F—\bar{N}F \longrightarrow M^+\cdots F—\bar{N}F \longrightarrow MF + \dot{N}F),$$

$$2\dot{N}F \longrightarrow N_2F_2.$$

Here M^+ is an alkali metal cation, for example potassium, etc., and B^- an anion, for example F^-, OH^-, etc.

Such a treatment is the more firmly based in that the existence of the NF_2^- anion in aqueous solutions was shown quite distinctly first by Word and Wright[36] and then by Martin[9] in their electrochemical and polarographic investigations. The latter also showed that the stability of aqueous buffer solutions of difluoramine falls with rise in temperature and pH and the decomposition products are difluorodiazine and nitrogen monoxide, the appearance of which should precede the formation of fluorazene $\dot{N}F$ due to the destruction of the anion NF_2^-:

$$NF_2^- \longrightarrow F^- + \dot{N}F.$$

Johnson[37] made analogous observations on the decomposition of aqueous solutions of *NN*-difluorourea by aqueous alkalis below 0°, when he obtained difluorodiazine, tetrafluorohydrazine, dinitrogen monoxide, etc. By using ^{15}N-labelled urea he showed that difluorodiazine is formed by an intermolecular process, the decomposition of the difluoroamide anion playing an important part:

$$NF_2^- \longrightarrow NF + F^-,$$
$$NF + NF \longrightarrow N_2F_2,$$
$$NF + NF_2^- \longrightarrow N_2F_2 + F^-,$$
$$NF + H_2NCONF_2 \longrightarrow N_2F_2 + CO_2 + NH_4^+ + F^-$$

The facts of the formation of fluorazene or fluoronitrene $\dot{N}F$ were discussed both in the investigations of the decomposition of the electron-excited radical $^*NF_2$ [26,33,38-41] and also in studying the reaction of difluoramine with primary and secondary amines [40,42,43], which we will discuss below.

The promoting action of alkali metal fluorides (potassium, rubidium) in the chlorination of difluoramine by elemental chlorine is also known[12]:

$$MF:\cdots \overset{\delta+}{H}\rightarrow\overset{\delta-}{NF_2} + Cl_2 \longrightarrow ClNF_2 + MF\cdot HCl.$$

Complexes of difluoramine with alkali metal fluorides, just like the complexes with Lewis acids, can evidently play the part of activated precursors in the reaction of the difluoramine.

These facts show that the polarisation of the nitrogen–hydrogen bond in the difluoramine molecule is sufficiently

strong for the hydrogen atom in it to be capable not only of complex formation with certain nucleophilic reagents due to hydrogen bonds, but also to be lost as a proton, so that difluoramine in aqueous solutions is a weak acid[9,36], but one which does not give salts with silver and copper nitrates even in alkaline media[5].

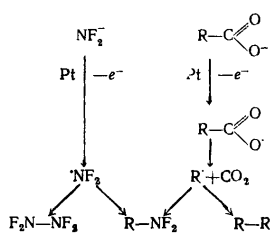
As well as complex formation, and often because of it in more complex reactions, difluoramine is capable of entering into a whole series of redox reactions.

The tendency of difluoramine (or more precisely, the difluoramide ion) to be oxidised is most clearly seen in the electrochemical preparation of tetrafluorohydrazine from it[36], when the process is localised at the stage of transfer of one electron from the anion to the platinum electrode:

$$NF_2^- \xrightarrow[\text{Pt anode}]{-e^-} \cdot NF_2.$$

Further oxidation in the electrochemical process seems impossible, thanks to the ready recombination of the difluoramine radicals to give the stable tetrafluorohydrazine molecule[36], which slowly leaves the electrolyte. This process was investigated in detail by Word and Wright[36]. It was found that the oxidation of difluoramine is possible only in acidified solutions (perchloric, sulphuric, or acetic acids) and is essentially inhibited by the presence of an oxide film on the electrode surface.

The electrochemical oxidation of difluoramine at a platinum anode can be successfully combined with the electrochemical (anodic) generation of free radicals[36]. Here, in the vicinity of the electrode, various radicals are formed in ratios which depend on the concentrations of the initial substances, and the recombination of which leads to the formation of organic difluoramine derivatives:



In the electrolysis of aqueous solutions of difluoramine in acetic, propionic, or completely deuterated acetic acids in the presence of sodium acetate, yields not below 60% of the methyl-, ethyl-, and trideuteromethyl-difluoramines were obtained in this way.

The chemical oxidation of difluoramine to tetrafluorohydrazine is easily effected by the action on aqueous solutions of HNF_2 of such oxidants as bromine, perchloryl fluoride, and oxygen[5], and also by iron(III).[9] However, the oxidation of difluoramine by an excess of oxygen-containing oxidants goes further and nitrogen oxides appear among the reaction products.

The oxidation of difluoramine to tetrafluorohydrazine with iron(III) or electrochemically seemed so effective that these processes were recommended by the authors as the best means for obtaining completely pure N_2F_4 in high yields ($\lesssim$ 70%[9,35]).

The electrochemical reduction of difluoramine at a dropping mercury electrode at various pH was first studied by Martin[9] polarographically: the reduction of difluoramine proceeds only in acid medium at potentials more negative than -1.0 V relative to the standard calomel electrode. He established that in aqueous solutions there is a single-stage, four-electron process.

Subsequently Ward and coworkers[20] showed that the electrochemical reduction of difluoramine at a dropping mercury electrode in water, methanol, ethanol, acetonitrile, dimethylformamide, and dimethyl sulphoxide goes to ammonia at potentials from -1.23 to -1.64 V relative to the standard calomel electrode, depending on the nature of the solvent and base electrolyte, for which various perchlorates were used:

$$HNF_2 + 4e^- + 2H^+ \longrightarrow NH_3 + 2F^-.$$

The authors proposed a mechanism for this process and considered the influence of solvation on the half-wave potential for the reduction of difluoramine.

The typical and most studied example of the chemical reduction of difluoramine is its reaction with acidified aqueous solutions of hydrogen iodide and potassium iodide, which goes instantly and quantitatively according to the equation[4,5]:

$$HNF_2 + 4HI = 2I_2 + NH_4F + HF,$$

and is therefore used analytically for the quantitative determination of difluoramine. Nitrogenous products of the reaction (other than ammonia) are not formed in this reaction.

The capacity of the difluoramine molecule for both oxidation and reduction evidently governs its ready disproportionation under the action of various agents, according to the equation[4,5]:

$$5HNF_2 \longrightarrow 2N_2F_4 + NH_4F + HF.$$

The process is catalysed by various solid substances, among which copper, stainless steel, urea, and lithium hydride[5] can be singled out for special activity, the reaction often going explosively.

The reaction between difluoramine and hydrogen chloride in the gas phase evidently proceeds by the same mechanism[16,44]

$$3HNF_2 + 3HCl \longrightarrow 2ClNF_2 + NH_4Cl + 2HF,$$

as does that between difluoramine and carbonyl dichloride[5]:

$$3HNF_2 + COCl_2 \longrightarrow 2ClNF_2 + \text{side products}.$$

The temperature interval 100–200° is optimal for the last reaction, but even at a high temperature tens of hours are needed for the reaction. Thus at 110° $>$ 40 h are needed to complete the reaction, and at 200° $\lesssim$ 6 h. It is emphasised[44] that the ratio of reagents must be in accordance with the above equation. The use of an excess of carbonyl dichloride favours the completion of the reaction and increases the yield of chlorodifluoramine.

The authors note[5] that despite the production of chlorodifluoramine by this means in 80% yield, the reaction is not always reproducible and is accompanied by the formation of tetrafluorohydrazine. Although the mechanism of this reaction remains unexplained, it is suggested that in the first stage hydrogen chloride is formed, which on being further contacted with difluoramine forms chlorodifluoramine by the above equation for gas-phase reaction.

The liquid-phase modification of the reaction of difluoramine with hydrogen chloride is important in practical respects[16]; it makes it easy to obtain chlorodifluoramine in yields of up to 67%. The ability of difluoramine to form complexes with water sharply reduces the explosion hazard

of the process. The reaction is carried out in aqueous solution using an alkali metal chloride and elemental chlorine, and undoubtedly proceeds by an ionic mechanism in which the decisive role belongs to the difluoramide ion on the one hand, and to chlorine or a residue of hypochlorous acid on the other:

$$NF_2^- + Cl_2 \longrightarrow ClNF_2 + Cl^-, \text{ or}$$
$$NF_2^- + OCl^- \longrightarrow ClNF_2 + O^{2-}.$$

This is the more correct in that the reaction of aqueous solutions of hypochlorous acid and sodium hypochlorite with *NN*-difluorosulphonyl diamide react quite vigorously even in the cold and this is accompanied by the formation of chlorodifluoramine in 71% yield[31]:

$$H_2N{-}SO_2{-}NF_2 + ClO^- \longrightarrow ClNF_2 + \bar{O}SO_2NH_2.$$

An analogous reaction has been described[15] in which aqueous solutions of sodium hypochlorite react with aqueous solutions of *NN*-difluorourea, when the oxidation products are chlorodifluoramine and tetrafluorohydrazine:

$$H_2N{-}CO{-}NF_2 + ClO^- \longrightarrow ClNF_2 + N_2F_4.$$

There is also an example[29] of the production of dichlorofluoramine and chlorodifluoramine by the oxidation of mono- and di-*N*-fluoroalkyl carbamates by aqueous solutions of sodium hypochlorite:

$$FHN{-}COOR \xrightarrow[H_2O]{NaClO} \left[\begin{array}{c} F \\ \diagdown \\ N{-}COOR \\ \diagup \\ Cl \end{array}\right] \xrightarrow{NaClO} Cl_2NF,$$

$$F_2N{-}COOR \xrightarrow[0-5^\circ]{NaClO} ClNF_2 + R{-}COONa.$$

Most of the known reactions of difluoramine cited above are reactions with inorganic substances. For almost all of these, reaction at high rates under conditions which favour the formation of the difluoramide anion are characteristic.

Considering difluoramine as a possible raw material for the preparation of various nitrogen fluorides it is easy to note that to obtain the desired result it is not always necessary to isolate the free difluoramine in a pure form. Either pure difluoramine or its aqueous solutions can be used for this purpose with the same success, and so also can aqueous solutions of difluoramine derivatives in which the NF_2 group has the character of an acid halide. On this basis, tetrafluorohydrazine, difluorodiazine, and chlorodifluoramine can be prepared with high yields.

There are only two examples of the interaction of difluoramine with organic compounds. Stevens and Freeman found[17] that gaseous difluoramine with solutions of alkyl or aryl nitroso-compounds in a mixture of pyridine and methylene chloride (15 : 75 ml) at 0–20° gave the corresponding alkyl- or aryl-*N'*-fluorodi-imide *N*-oxides:

$$RNO + HNF_2 \xrightarrow[0-20^\circ]{\text{pyridine} + CH_2Cl_2} R{-}\overset{\uparrow O}{N}{=}NF.$$

This reaction has been carried out on a series of nitroso--compounds, where R = phenyl; *o*-, *m*-, and *p*-tolyl; *o*- and *p*-chlorophenyl; *p*-bromophenyl; *p*-nitrophenyl; t-butyl; 2-nitro-2-propyl; 2-chloro-2-propyl; trifluoromethyl; benzyl; 2-phenylethyl; and cyclohexyl.

Simultaneously Stevens and Freeman showed that the same result can be obtained when gaseous tetrafluorohydrazine is used instead of difluoramine to react with solutions of nitroso-compounds in methylene dichloride, chlorobenzene, or carbon tetrachloride.

The last circumstance, with the known fact of tetrafluorohydrazine formation during the action of pyridine on difluoramine[5], led the authors to conclude that in both instances the formation of *N'*-fluorodi-imide *N*-oxides occurs by the very same mechanism proposed earlier by Frazer and coworkers[45] who effected a gas-phase photochemical reaction between trifluoronitrosomethane and tetrafluorohydrazine and first isolated trifluoromethyl--*N'*-fluorodi-imide *N*-oxide:

$$CF_3{-}\overset{\uparrow O}{N}{=}NF$$

Bumgardner and coworkers[42] showed that difluoramine, when condensed in a glass apparatus with an excess of an aromatic or aliphatic primary or secondary amine, deaminates the latter and gives the corresponding alkanes:

$$3RNH_2 + HNF_2 \longrightarrow 2RNH_2{\cdot}HF + N_2 + R{-}H.$$

The yield of RH reaches 77%.

With some secondary amines the reactions are:

$$\begin{array}{l} CH_2 \\ \diagup \\ NH \\ \diagdown \\ CH_2 \end{array} + HNF_2 \longrightarrow 2HF + N_2 + CH_2{=}CH_2, \qquad 80\%$$

$$\begin{array}{l} CH_2{-}CH_2 \\ | \quad\quad | \\ CH_2{-}NH \end{array} + HNF_2 \longrightarrow 2HF + N_2 + \begin{array}{l} CH_2 \\ \diagup \quad \diagdown \\ CH_2 \quad\quad CH_2 \end{array}, \qquad 40\%$$

$$(C_6H_5{-}CH_2)_2NH + HNF_2 \longrightarrow 2HF + N_2 + C_6H_5CH_2CH_2C_6H_5. \qquad 53\%$$

The authors explain the reaction with primary amines by the intermediate formation of a mono-substituted di-imide RN=NH. They consider that initially the amine promotes the α-elimination of hydrogen fluoride by the difluoramine, with formation of fluorazene:

$$RNH_2 + HNF_2 \longrightarrow RNH_2{\cdot}HF + \dot{N}F.$$

The electrophilic fluorazene in the excess of amine attacks the latter to form monosubstituted di-imide:

$$RNH_2 + \dot{N}F \longrightarrow RN{=}NH + HF,$$

which, by eliminating the nitrogen, gives an alkane, or by acting as a "trap" for the fluorazene, eliminates hydrogen fluoride and gives an alkyl azide, which was also found among the reaction products:

$$R{-}\dot{N}{=}\dot{N}{-}H + \dot{N}F$$
$$RH + N_2 \qquad RN_3 + HF.$$

With t-butylamine only ammonia and 2-methylpro-1-ene were found in the reaction products; they are formed also by the action of hydrogen chloride on this amine, which the authors take to be evidence of the acidic nature of difluoramine in relation to the amines.

Bumgardner and Freeman investigated the same reaction with certain allyl- and cyclopropylcarbinyl-amines‡ [43]. Here they observed some novelty in the reaction due rather to the unsaturated nature of the hydrocarbon radicals than to the specific effects introduced by the difluoramine. As in the previous investigation, difluoramine mainly acted as a deaminating agent.

‡ Sic. Diallyl-, allyl-, crotyl-, and 1-cyclopropylethyl-amine were studied (Ed. of Translation).

The summary of the facts given in the present review covers those reactions of difluoramine which were known up to the end of 1966. There is no doubt that the diverse reaction capabilities of difluoramine have hardly been investigated, for completely understandable reasons; in relation to different organic substances it will have many unexpected and interesting reactions, which will give a deeper understanding of the nature of this extremely interesting compound and enable the nature of the processes in which it takes part to be formulated more reliably.

5. EXPLOSIVE PROPERTIES OF DIFLUORAMINE

All the authors cited in this review without exception consider it their duty to warn readers about the extreme hazard of working with nitrogen fluorides in general and with difluoramine in particular. This danger consists in the fact that independently of the state of aggregation, difluoramine tends to spontaneous explosive decomposition for unknown reasons. Mixtures of difluoramine, like other nitrogen fluorides, with the vapours of organic substances also form explosive hazards. It is difficult to state which of the states of aggregation of difluoramine is the most dangerous but there are many indications that difluoramine itself is particularly dangerous in the solid form.

Lawton and Weber[5] note that: "... Difluoramine is extremely shock sensitive as a liquid, and even more so as a solid. The liquid is at least as detonable as nitroglycerine. The solid will detonate spontaneously when a large quantity is frozen by liquid nitrogen".

In special experiments Lawton and Weber observed over ten instances of explosion following condensation of difluoramine in quantities of 50 mg or less by liquid nitrogen, that is, at temperatures of ~ -196°. The explosions took place in the first few seconds after the trap with the difluoramine was removed from the bath of liquid nitrogen. However, they were successful more than 100 times in condensing without explosion more than 1 g difluoramine at -142° with a melting methylcyclohexane bath.

All the investigators think that at temperatures down to -142° difluoramine is comparatively harmless; they are all unanimous in the inadmissability of cooling it below this temperature and categorically forbid the use of liquefied gases (particularly liquid nitrogen) as cooling agents.

It has also been maintained[16,19] that aqueous solutions of difluoramine[16] or its solutions in ethers[19] have considerably less tendency to explode and are comparatively harmless. Nevertheless, Word and Wright[36] observed some instances of the explosion of electrolysers when the space above the aqueous electrolyte containing dissolved difluoramine communicated freely with the atmosphere. When the free space was purged with dry inert gas, they succeeded in subsequently avoiding the troubles associated with the explosion of the cells. Apparently there is also a hazard from explosions on contact of the purge gas from concentrated solutions of difluoramine with the air.

The reason for the high tendency of difluoramine to spontaneous explosive decomposition probably lies in the wholly amphoteric nature of its molecule and the dual nature of its reactivity to redox interaction. This opens a path to intermolecular disproportionation, which is also accompanied by such highly exothermic processes as the formation of hydrogen fluoride, elemental nitrogen, and nitrogen trifluoride. The activation of this process is apparently very small and can be greatly reduced by the catalytic action of various solid substances. The initial impulse can be produced either inside the system by effective catalysis, or externally by an action of accidental origin. Subsequent processes probably develop autothermically and possibly also autocatalytically.

Instances of the remarkable explosive decomposition of difluoramine after cooling below -196° should be placed in a special category. Undoubtedly such behaviour of difluoramine is connected with some energetic effects which take place inside or on the surface of the crystals of solid difluoramine. It is not ruled out that the reason for this phenomenon lies in the ionic structure of the crystal lattice of solid HNF_2, although Craig[14] also did not succeed in observing any essential difference in the infrared spectra of gaseous and solid difluoramine at -196°.

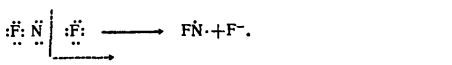
Here infrared spectroscopy cannot give the necessary information for a categorical decision as to the absence of ionisation from solid difluoramine. Just the fact of the similarity of the absorption frequencies for gaseous and solid difluoramine in the infrared region cannot serve as sufficient proof of the absence of a change of difluoramine into an ionic state at ~ -196°. One of the explanations of this important phenomenon can be a useful subsequent approach, which follows logically from the discussion in Section 2 of the present review.

In the liquid state equilibrium (I) is apparently almost wholly displaced to the left, that is, to the side of the molecular form of the dimer. The rigid fixation of the ions NF_2^- and $[H_2NF_2]^+$ at the nodes of the crystal lattice which is a consequence of deep cooling rules out the possibility of a change of the ionic form of the dimer into the molecular form and greatly facilitates the displacement of equilibrium (I) to the right. This change, under a suitable regime of cooling and crystallisation (which is evidently realised at -196° and below, but more correctly in attaining these temperatures) ends the almost complete fixation of the difluoramine as an ionic dimer. On raising the temperature the change of the difluoramine into the liquid state should be accompanied by intensive association of the ions into the molecular form of the dimer with a perceptible thermal effect.

The energy liberated is evidently sufficient to surmount the low activation barrier and start the process of rapid autothermal (possibly, also autocatalytic) decomposition of difluoramine, which is explosive in nature.

The many statements of various authors on the instability of the difluoroamide anion and the ease with which it decomposes into fluoronitrene and the fluoride anion have been given above. In all the instances of such decomposition conditions were created for suppressing the dissociation of difluoramine with formation of the NF_2^- ion (increase in the pH of the aqueous difluoramine solutions above 7, heating them, the action of ionising complex-forming agents, such as potassium fluoride, rubidium fluoride, and especially caesium fluoride, etc.). Therefore there are grounds for assuming that explosion in the processes in which difluoramine participates (because of the explosive decomposition of the latter) should be expected in those instances when conditions are created for the formation of high concentrations of difluoramido-anions in the absence of conditions for their recombination into stable molecules of the $X-NF_2$ type, in which the X–N bond will have a more covalent character than the H–N bond in difluoramine.

The NF_2^- ion is a species limitingly saturated with electrons, which should stimulate its tendency to stabilisation, leading to a decrease in this saturation, by the elimination of a fluoride anion:



Depending upon the conditions (the presence or absence of solvents and catalysts) the temperature, the difluoramine concentration, pH of the medium or basicity of the reagent, etc.) the process can proceed either quietly (for example, in aqueous alkaline solutions or under the action of potassium and rubidium fluorides) or explosively (for example, in pure difluoramine or upon reaction with caesium fluoride).

It cannot be excluded that the existence of the difluoramide anion for a sufficiently prolonged period outside the molecule of difluoramine, adducts, transition states, etc. (that is, not in a bound state) is impossible in general.

CONTENTS

1. Acidity scale for aqueous solutions of strong acids 803
2. Indicators for measuring acidity functions 805
3. Values of H_0 for aqueous solutions of strong acids and oleum 807
4. Accuracy of measurements of H_0 812
5. Physical significance of the concept of "acidity of the medium" 813
6. Relation between the acidity of the medium and the thermodynamic activity of water 814

1. ACIDITY SCALE FOR AQUEOUS SOLUTIONS OF STRONG ACIDS

In investigating the kinetics of chemical processes in a homogeneous solution it is necessary to take into account the influence of the solvent on the thermodynamic properties of the reactants. The properties of the medium are of particular importance in chemical reactions taking place in aqueous solutions of strong acids and bases. The great tendency to form hydrogen bonds and the higher concentration of ions in such solutions promotes the formation of various complexes and ions with participation of the reagents.

In kinetic equations for liquid-phase processes allowance is made for the effect of the medium on the thermodynamic properties of the reagents, intermediates, and activated complex by the use of activity coefficients. In solutions of acids and bases, the reagents are usually ionised. In most instances the ionised form exhibits a greater reactivity than the un-ionised form. The catalytic action of an acid or base in such instances consists in the conversion of the reagent into an ionised form. The possibility of the chemical process occurring at the moment of collision of the reagent with a proton, hydroxide ion, or molecules of undissociated acids and bases is also not ruled out. The kinetic equation for a chemical reaction will be the same for processes in which the species capable of reaction are ions formed in the interaction of the reagent with an acid or base (if the relative concentration of the ions is small) and for processes in which the rate-limiting state occurs during the collisions of the reagent molecules with protons or hydroxide ions.

We will consider the chemical reaction for the conversion of substance M into Q taking place in an acid medium. The process is first order with respect to M. It is assumed that the ionised form MH^+ is reactive. The MH^+ concentration is low in comparison with that of M. The rate of reaction W is expressed by Eqn. (1):

$$W = \frac{dC_Q}{dt} = k\frac{a^*}{f^*} = k'\frac{a_M a_{H^+}}{f^*} = k'\frac{C_M a_{H^+} f_M}{f^*}. \qquad (1)$$

$$\frac{W}{C_M} = k_{eff} = k' a_{H^+}\frac{f_M}{f^*},$$

where a^*, a_M, and a_{H^+} are the activities of the activated complex, the reacting substance M, and the proton respectively; C_M is the concentration of M; f^* and f_M are the activity coefficients of the activated complex and substance M.

According to Eqn. (1) the change in k_{eff} is connected with change in the quantity $a_{H^+}(f_M/f_{MH^+})$. In aqueous solutions of strong acids the protons are present as hydroxonium ions; therefore the activity of protons a_{H^+} must be expressed in terms of the concentration of hydroxonium ions $C_{H_3O^+}$ and the activity coefficient of the protons f_{H^+}:

$$a_{H^+}\frac{f_M}{f^*} = C_{H_3O^+} f_M \frac{f_{H^+}}{f^*}.$$

The experimentally observed proportionality between k_{eff} and the concentration of hydroxonium ions $C_{H_3O^+}$ in extremely dilute solutions of acids is connected with the constancy of the ratio $f_M f_{H^+}/f^*$.

In concentrated aqueous solutions of strong acids k_{eff} rises more sharply than the hydroxonium ion concentration; this is connected with an increase in the ratio $f_M f_{H^+}/f^*$. Consequently, to predict how the catalytic activity of an acid medium varies with change in the acid concentration it is necessary to know how the quantity $a_{H^+}(f_M/f^*)$ varies. The activity coefficient of the un-ionised form f_M can be measured. The activity coefficients f_{H^+} and f^* cannot be measured experimentally in isolation. Here assumptions must be made which allow measurable quantities to be introduced into the kinetic equation. When an activated complex is formed from a molecule of the reagent and a proton, then in composition and charge it corresponds to the ionised form of the reagent. Therefore it can be taken that as the composition of the medium is varied the activity coefficients of the activated species f^* and of the protonised form f_{MH^+} will change similarly. On making this assumption, f^* in Eqn. (1) can be replaced by f_{MH^+}.

$$k_{eff} = k' a_{H^+}\frac{f_M}{f_{MH^+}}.$$

The change in the catalytic activity of the acid medium is determined by the activity of the protons a_{H^+} and by the ratio of the activity coefficients of the un-ionised and ionised forms of the reagent. The proton activity a_{H^+} is determined by the properties of the medium. The activity coefficients f_M and f_{MH^+} reflect the properties of the reagent M dissolved in the acid. The quantity $a_{H^+}(f_M/f_{MH^+})$ also characterises the ratio of the concentrations of the protonated and unprotonated forms of the substance dissolved in the acid.

We will use k_{BH^+} to denote the equilibrium constant for the ionisation of substance B, expressed in terms of activity:

$$B + H^+ \rightleftharpoons BH^+,$$

$$k_{BH^+} = \frac{a_B a_{H^+}}{a_{BH^+}} = \frac{C_B a_{H^+} f_B}{C_{BH^+} f_{BH^+}}.$$

Hammett has proposed[1] that in concentrated aqueous solutions of strong acids the change in the ratio f_B/f_{BH^+} is determined by the properties of the acid medium and is independent of the chemical nature of the substance. Hence according to Hammett the following equality holds for solutions of substances (for example, M, B, C, and D):

$$\frac{f_M}{f_{MH^+}} = \frac{f_B}{f_{BH^+}} = \frac{f_C}{f_{CH^+}} = \frac{f_D}{f_{DH^+}}.$$

If Hammett's hypothesis is correct, then it becomes possible to find a quantitative characteristic for the ionising ability of acid media. Kinetic and indicator methods can be used for this purpose.

To obtain a quantitative measure of the catalytic activity of the acid medium by the kinetic method it is necessary to study the kinetics of some process over the required concentration range of the solution of the acid. A simple unimolecular chemical reaction for which the ionisation mechanism and rate-determining steps have been established in detail should be chosen for this purpose. It is desirable that the degree of ionisation of the reagent should be negligible over the whole concentration range of the acid, that is, the reagent should be almost wholly in its un-ionised form. When on going from dilute to concentrated solutions of a strong acid the mechanism of the process and also the activation energy and preexponential factor of the rate-determining step remain unchanged, the rate constant of such a process could serve as a quantitative measure of the catalytic activity of the acid media. The problem is to select a chemical process for which the rate constant at constant temperature would change by 12–14 orders of magnitude on changing the acid concentration.

Modern techniques of kinetic investigation allow processes to be studied where the rate constant varies only by 4–5 orders of magnitude at constant temperature. It is therefore necessary to choose several reagents with different reactivities. However, there is then no certainty that the reagents chosen as the models ionise by the same mechanism and that in all instances the mechanism of the rate-limiting step is the same.

A quantitative measure of the ionising ability of aqueous solutions of strong acids over a wide range of concentrations can be obtained using the indicator method proposed by Hantzsch[2] and worked out in detail by Hammett. By indicator is meant a chemical substance which is ionised in solutions of acids and bases, the un-ionised and ionised forms of which have different absorption spectra. An indicator should be chemically stable in the medium being investigated.

The concentrations of the ionised and un-ionised forms of the indicators are determined spectrometrically.

The simplest type of ionisation is protonation. This is an acid–base process, as a result of which base B is converted into acid BH^+, Eqn. (2). With a rather large number of substances ionisation finishes at the protonation stage.

In the ionisation of alcohols and organic acids, the ionised form can be dehydrated:

$$\left.\begin{aligned} &BOH + HA \rightleftharpoons BOH_2^+ + A^- \\ &BOH_2^+ \rightleftharpoons B^+ + H_2O \end{aligned}\right\} \qquad (3)$$

The protonated form BH^+ and also the cations B^+ which are formed in the dehydration of the ions BOH_2^+ can form ion pairs:

$$\left.\begin{aligned} &BH^+ + A^- \rightleftharpoons BH^+.A^- \\ &B^+ + A^- \rightleftharpoons B^+A^- \end{aligned}\right\} \qquad (4)$$

The possibility of the reagent forming a specific complex with some acid or with the solvent cannot be excluded. The ionisation mechanism is determined by the chemical structure of the reagent and by the properties of the medium.

Naturally, in studying the ionising ability of a medium by some mechanism indicators must be chosen which ionise by the same mechanism. To establish an acidity scale, Hammett selected a series of indicators which are mainly derivatives of the nitroanilines. The ionisation of these indicators proceeds by Eqn. (2). Such indicators are termed simple. Hammett took the equilibrium constant of process (2), K_{BH^+} as a measure of the strength of the base. The negative logarithm of the quantity K_{BH^+} is denoted by pK_{BH^+}:

$$pK_{BH^+} = -\log K_{BH^+}.$$

K_{BH^+} for strong bases is small and pK_{BH^+} is positive. The weaker are the basic properties of the substance, the greater the value of K_{BH^+} and the more negative the value of pK_{BH^+}.

Hammett proposed that the quantity $a_{H^+}(f_B/f_{BH^+})$ be termed the acidity of the medium. This is denoted by the symbol h_0 and its negative logarithm is termed the acidity function and given the symbol H_0:

$$h_0 = a_{H^+}\frac{f_B}{f_{BH^+}}; \qquad H_0 = -\log h_0.$$

On taking logarithms of Eqn. (2) for the constant K_{BH^+} and replacing $-\log K_{BH^+}$ by pK_{BH^+} and $-\log a_{H^+}(f_B/f_{BH^+})$ by H_0, we obtain an equation which relates the acidity function of the medium to the ratio of the concentrations of the ionised and un-ionised forms of the indicators:

$$H_0 = pK_{BH^+} + \log\frac{C_B}{C_{BH^+}}. \qquad (5)$$

If the acidity of the medium is known it is possible to calculate the basicity constant and the ratio of the concentrations of the base and the conjugate acid form of the substance. Hence to measure the acidity function of the medium by the use of some indicator it is necessary to know its basicity constant (K_{BH^+}) and the ratio of the concentrations of the un-ionised and ionised forms (C_B/C_{BH^+}) in the given medium. The concentrations C_B and C_{BH^+} are usually measured spectrophotometrically or colorimetrically. A single indicator can be used to investigate a medium whose acidity function changes within the limits of 2–3 units, which corresponds to a change in the C_B/C_{BH^+} ratio from 30–10 to 0.1–0.03. To investigate a medium with a wider range of acidities, several indicators must be used.

Infinite dilution of an aqueous solution of a strong acid is selected as the standard state for the scale. In an infinitely dilute aqueous solution the activity coefficients f_B and f_{BH^+} are taken to be unity and the thermodynamic activity of the protons is taken as numerically equal to the hydroxonium ion concentration. In such solutions the acidity of the medium equals the hydrogen ion concentration, and H_0 equals the pH.

The essence of the indicator method of measuring H_0 consists in determining pK_{BH^+} and the values of C_B/C_{BH^+} of the indicators in the medium of unknown acidity. At first it is necessary to find the values of pK_{BH^+} for the indicators, which are strong bases, for which the quantity C_B/C_{BH^+} can be determined in extremely dilute solutions of acids, where $h_0 = C_{H_3O^+}$. For example, aminoazobenzene (which we will denote by the symbol B) is already appreciably ionised in 10^{-4} m HCl† and almost completely so in 0.024 m HCl. From the dependence of $\log(C_B/C_{BH^+})$ for aminoazobenzene on the concentration of the acid in the range of C_{HCl}, its pK_{BH^+} is calculated by Eqn. (5). Another indicator is chosen for the determination of the acidity of more concentrated solutions of hydrochloric acid, for example, benzeneazodiphenylamine, which is a weaker base than aminoazobenzene. This indicator (which we will denote by the symbol C) is only partly ionised in 1×10^{-4}–2×10^{-2} m HCl and is completely ionised in more concentrated solutions, where $-\log C_{H_3O^+}$ is no longer equal to the pH.

We will compare the logarithms of the ratios of the concentrations of the un-ionised and ionised forms for the two indicators mentioned above (for example, B and C) in the same solution of acid:

$$-\log a_{H^+} = pK_{BH^+} + \log\frac{C_B}{C_{BH^+}} + \log\frac{f_B}{f_{BH^+}} = pK_{CH^+} + \log\frac{C_C}{C_{CH^+}} + \log\frac{f_C}{f_{CH^+}},$$

or

$$pK_{BH^+} - pK_{CH^+} = \log\frac{C_C}{C_{CH^+}} - \log\frac{C_B}{C_{CH^+}} + \log\frac{f_C f_{BH^+}}{f_{CH^+} f_B}.$$

† Here and subsequently the symbol m denotes the molality of the solution [in the translation, *m* is employed as the symbol for the molality and m as the abbreviation for the unit of molality, as usual (Ed. of Translation)].

When

$$\frac{f_C f_{BH^+}}{f_{CH^+} f_B} = 0,$$

it becomes possible to determine pK_{CH^+} of the indicator C, provided pK_{BH^+} of another indicator B and the quantities C_B/C_{BH^+} and C_C/C_{CH^+} in the same medium are known.

$$pK_{BH^+} - pK_{CH^+} = \log \frac{C_C}{C_{CH^+}} - \log \frac{C_B}{C_{BH^+}}. \quad (6)$$

Since pK_{BH^+} of aminoazobenzene is determined in extremely dilute solutions‡, where $H_0 = pH = -\log m_{H_3O}$, then Eqn. (6) can be used to calculate pK_{CH^+} of the less basic indicator, for example, benzeneazodiphenylamine. By determining pK_{CH^+} by Eqn. (5), the acidity of solutions of stronger acids can be calculated where the ratio of the concentrations of the un-ionised and ionised forms of benzeneazodiphenylamine can be measured with good accuracy. To measure H_0 of more concentrated solutions, an indicator D is chosen which exhibits an even lower basicity but partly overlaps the region of acid concentrations where the indicator C is still incompletely ionised. pK_{DH^+} of the indicator and H_0 for the acid solutions are calculated as described above.

Hence by means of several indicators the acidity function is measured over a wide range of concentrations of aqueous solutions of strong acids. For example, to measure the acidity function of the $HCl-H_2O$ system from dilute solutions to 16 M HCl, it is necessary to use seven or eight indicators, and to measure H_0 of the $H_2SO_4-H_2O$ system from dilute solutions to 100% H_2SO_4 10–12 indicators are required.

2. INDICATORS FOR MEASURING ACIDITY FUNCTIONS

Table 1 gives the indicators used for measuring acidity functions and the values of their pK_{BH^+}. The ionisation of such indicators involves the addition of a proton. In acid media the indicator is present in two equilibrium forms: un-ionised and ionised.

Cryoscopic and electrical conductivity results are usually used to establish the ionisation mechanism. 100% sulphuric acid acts as an ionising solvent. The indicators chosen by Hammett for measuring H_0 were investigated cryoscopically by Hammett and coworkers[6] and also by other authors[7]; the latter[7] also investigated the electrical conductivity of the solutions. The value of the van't Hoff i factor for simple indicators is near or equal to 2. On this basis it is concluded that when these substances ionise two species are formed:

$$B + H_2SO_4 \rightleftharpoons BH^+ + HSO_4^-. \quad (7)$$

This conclusion does not seem unambigous. The i factor being 2 only signifies that in 100% sulphuric acid and in H_2SO_4 solutions with low water and sulphur trioxide concentrations (sulphuric acid only slightly diluted with water and with a low oleum concentration) the substance ionises according to Eqn. (7). On the basis of this fact it is impossible to maintain that the indicator is present solely as an ionised and an un-ionised form also in more dilute aqueous solutions of sulphuric acid, when the concentration of HSO_4^- anions is high. In 100% sulphuric acid§ the HSO_4^- ions are formed as a result of autoprotolysis:

$$2H_2SO_4 \rightleftharpoons H_3SO_4^+ + HSO_4^-,$$

and their concentration is not high. For example, at 25° the concentration of HSO_4^- anions in 100% H_2SO_4 is $\sim 3 \times \times 10^{-2}$ M.[8,9] In 78–80% H_2SO_4 the concentration of HSO_4^- anions is 10.6 M at 25°.[10,11]

The possibility of the ion pairs $BH^+.HSO_4^-$ being formed in solutions of acids where there is a high concentration of anions is not ruled out:

$$BH^+ + HSO_4^- \rightleftharpoons BH^+.HSO_4^-.$$

In this instance the dissolved indicator or reagent will now be present in the acid solution as the equilibrium forms: un-ionised form, protonised form, and ion pair. When the indicators form ion pairs over some range of acid concentrations then they can be used for measurements of H_0 only if it is possible to determine the concentrations of all

TABLE 1*.

Values of pK_{BH^+} of acid indicators (at 22–26°)

Indicator	pK_{BH^+} in $HCl-H_2O$	pK_{BH^+} in $HBr-H_2O$	pK_{BH^+} in $HClO_4-H_2O$	pK_{BH^+} in $H_2SO_4-H_2O$	pK_{BH^+} in HNO_3-H_2O	pK_{BH^+} in $P_2O_5-H_2O$

2,4-Dichloro-6-nitroaniline	−3.07	−3.14	

* The errors in the determination of the pK_{BH^+} of the indicators are not given in Table 1, as this problem receives detailed discussion in Section 4. Pyrocatecholsulphonic acid is used as an indicator for determining the acidity of aqueous solutions of hydrochloric acid in the presence of ions of copper(I) chloride[4] at 20–80°. New information has been published recently[5] on the values of pK_{BH^+} for *p*-nitroaniline at elevated temperatures: at 30°, 40°, 50°, and 60°, it is 0.96, 0.9, 0.83, and 0.77 respectively.

‡ Before Paul's work[3], pK_{BH^+} for strong bases were determined by comparison of $\log (C_B/C_{BH^+})$ with the logarithm of the mean ionic activity $a_\pm$. When f_B is constant in very dilute solutions of acids the activity coefficient of the ionised form f_{BH^+} changes according to the Debye–Hückel law. Therefore it is correct to compare $\log (C_B/C_{BH^+})$ with the H_3O^+ ion concentration. Then the electrostatic contributions to f_{H^+} and f_{BH^+} are reduced.

§ Here and subsequently weight percentages of acids are given.

three forms separately. However, this is a rather difficult task. The spectrophotometric method in such instances is inapplicable since the free ions and ion pairs have similar absorption spectra.

It can be reliably stated that during the ionisation of indicators chosen for the measurement of acidity function free ions are formed in dilute solutions of strong acids and close to 100% H_2SO_4, where the concentration of anions is low. As for the region of moderate acid concentrations, where the anion concentration is high, there is still no direct proof of the absence of the ion pairs $BH^+.HSO_4^-$ from such solutions, but there are certain facts which can serve as indirect evidence that the measurable ratio C_B/C_{BH^+} for the indicators characterises the acidity of the medium h_0. The unimolecular reaction selected must be one which can be investigated in both concentrated and dilute solutions of the acid, for example, sulphuric acid, which encompass 7–8 units of the H_0 scale (from +1 to -7 units). The degree of the ionisation of the reagent should be negligible ($C_{BH^+} \ll C_B$) over the whole H_0 range being investigated. When k_{eff}/h_0 = const for all the solutions, this will be proof that in both concentrated and dilute solutions of the acid the mechanism of ionisation is the same.

As already mentioned, it is difficult to select a unimolecular chemical reaction for which the dependence of k_{eff} on H_0 can be studied over such a wide H_0 range under the condition $C_{BH^+} \ll C_B$. Nevertheless a single example can be given: the hydrolysis of β-propiolactone in sulphuric acid. This hydrolysis¶ has been studied in aqueous solutions of sulphuric acid from dilute solutions to 65% H_2SO_4. At 25°, k_{eff} increases in proportion to the acidity of the medium [13]. It is interesting to investigate a similar reaction over a wider range of acid concentrations. For this purpose it would be possible to select the exchange of hydrogen for deuterium and the subjects of the investigation could be the very indicators which are used to measure H_0. There are also considerations based on the method of measurement of the quantity C_B/C_{BH^+}. The un-ionised forms of nitroaniline indicators absorb, and the ionised forms do not absorb, in the visible region of the spectrum. The concentration of the un-ionised form C_B is determined from the intensity of the colour of the indicator solution in the visible region of the spectrum. The concentration of the ionised form C_{BH^+} is determined as the difference between the total concentration of the indicator and C_B.

The formation of ion pairs cannot be deduced from the measurements of the C_B/C_{BH^+} ratio when salt formation starts under conditions where the indicator is present almost entirely as the ionised form. When the salt-formation constant is such that ion pairs are formed in solutions with a low degree of protonation, it is impossible to determine C_B/C_{BH^+} from the change in the colour of the solution.

The problem of possible ion pair formation in the ionisation of acid–base indicators in concentrated acids requires detailed investigation. It is especially important to show the possibility of ion-pair formation in sulphuric acid solutions containing from 65 to 90% H_2SO_4 and in aqueous solutions of nitric acid with >60% HNO_3. Not all the substances which are used to measure H_0 satisfy the requirements applicable to indicators.

In concentrated solutions of sulphuric acid benzalacetophenone is unstable and undergoes isomerisation [14]. It is also unstable in polyphosphoric acid solutions [15]. Anthraquinone has several absorption bands in the visible and ultraviolet regions of the spectrum. On changing the acid concentration, in addition to the change in its degree of ionisation there is a displacement of the absorption maximum. Owing to the shift in the absorption maxima of *p*-nitrodiphenylamine and anthraquinone it is impossible to determine their degree of ionisation accurately.

Benzalacetophenone, anthraquinone, and *p*-nitrodiphenylamine are unsuitable for measuring the acidity of the medium. With *N*-substituted nitroanilines the concentration of the un-ionised form in aqueous solutions of sulphuric [16] and nitric [17] acids — and also in solutions of sulphuric acid in acetic acid [18] — falls anomalously. It can be assumed that in these materials ion pairs are formed during ionisation as well as the protonated species†.

As already mentioned above, a spectrophotometric method is now used for determining the concentrations of the ionised and un-ionised forms of indicators. The degree of ionisation of the indicator is most frequently determined by measuring the absorption coefficient at a single wavelength which is convenient for measurements. With the indicators of the nitroaniline series the absorption intensity is measured at some wavelength in the visible region of the spectrum. When the change in the spectrum of an indicator on raising the acid concentration is due not just to the appearance of an ionised form but also to a change in the optical properties of the medium, then it is difficult to judge the degree of ionisation of the indicator from the optical density of the solution. Usually in measurements of H_0 of acids the applicability of Beer's law is verified for particular wavelengths and during this the indicator concentration is varied over wide limits in solutions with the same acid concentration. The absorption coefficient for some form (ionised or un-ionised) is determined in solutions of acid with such an acidity that one of the forms is almost absent. In calculating C_B and C_{BH^+} it is assumed that the absorption coefficient of the forms B and BH^+ does does not depend on the composition of the medium in the range of acid concentrations at which the measurements are made. To avoid any possible effect when the medium is changed, the absorption coefficient of the un-ionised form is determined in acid solutions in which the ratio $C_B/C_{BH^+} \simeq 100$, and the absorption coefficient of the ionised form in solutions with $C_B/C_{BH^+} \simeq 0.01$. There are occasions when the change in the degree of ionisation of the indicator is not the only reason for a change in the spectrum. An example of this is the spectrum of 6-bromo-2,4-nitroaniline in sulphuric acid solutions [19]. This indicator has maximum absorption at 360 nm, due to the un-ionised form. In solutions of sulphuric acid with <67% H_2SO_4, the indicator is almost completely in the un-ionised form. In more concentrated solutions of the acid the intensity of the absorption maximum decreases (Fig. 1). The absorption coefficient also decreases at longer wavelengths. The position of the absorption maximum is almost unchanged in the interval 59–98% H_2SO_4, where ionisation of this substance takes place. When the absorption coefficients of the ionised and

¶ The hydrolysis of β-propiolactone has a complex mechanism. As Long and coworkers have shown [12], the experimentally observable rate constant is the sum of the rate constants of a non-catalytic and a catalytic process. Here we are considering the dependence of the rate constant of the catalytic process of hydrolysis on the acidity of the medium. This process is unimolecular.

† Possibly, in the ionisation of *N*-substituted nitroanilines, Hammett's hypothesis of the equality of the ratios of the activity coefficients of the un-ionised and ionised forms is not satisfied.

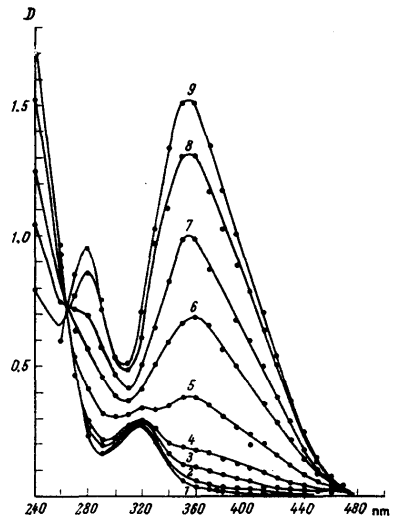

Fig. 1. Absorption spectra of 6-bromo-2,4-dinitroaniline in aqueous solutions of sulphuric acid with concentrations from 58.86 to 98.21%, from Vinnik and coworkers[19]. The optical densities D were obtained for the same indicator concentration. H_2SO_4 concentrations, %: 1) 98.21; 2) 88.07; 3) 85.24; 4) 82.72; 5) 79.93; 6) 77.5; 7) 75.36; 8) 72.18; 9) 58.96.

un-ionised forms for different wavelengths do not depend on the concentration of the acid, then the change in the observed absorption coefficients should be due only to the change in the degree of ionisation of the indicator. In this instance the same values of C_B/C_{BH^+} should be obtained for all wavelengths. As the data of Table 2 show, the values of C_B/C_{BH^+} for 6-bromo-2,4-dinitroaniline in a particular medium depend on the wavelength chosen for the measurements. The explanation is that a change in the observed absorption coefficients for different wavelengths is due not only to the change in the C_B/C_{BH^+} ratio but also to the change in the absorption coefficients of the individual dual forms of the indicator. Such an effect is also observed for 2,4-dichloro-6-nitroaniline, and it is even more prominent with p-nitrodiphenylamine[20]. With o-nitroaniline, 2,4-dinitroaniline, 2,4,6-trinitroaniline, and p-nitroaniline at 25° the ratio C_B/C_{BH^+} is almost independent of the wavelength at $\lambda > \lambda_{max}$.[19]

In solutions of 2,4-dinitroaniline in concentrated phosphoric and polyphosphoric acids[15], there is a slight displacement of the absorption maximum and the absorptivity of this indicator varies under conditions where there is still no appreciable ionisation.

The concentration of a substance is characterised by the area under the curve plotted as absorption intensity against frequency. Therefore in measuring the acidity of a medium by the indicator method, even in instances where the absorption maximum of the indicator is not displaced by changing the acid concentration, integral intensities should be used. The measurement of integral intensities is rather laborious and is not always feasible. When there is the above-mentioned complication, the values of $\log(C_B/C_{BH^+})$ obtained from the intensity for maximum absorption agree with the values obtained from the area under the curve from the absorption maximum towards longer wavelengths. This is shown by the example of 6-bromo-2,4-dinitroaniline and 5-chloro-2-nitroaniline[19], where there is hardly any displacement of the absorption maximum. Table 2 gives the values of C_B/C_{BH^+} for 6-bromo-2,4-dinitroaniline calculated for different wavelengths and from the area under the absorption curve, taken from Vinnik and coworkers[19].

When it is impossible to use integral intensities in determining the indicator ratio C_B/C_{BH^+} then it is desirable to measure the intensity at the absorption maximum.

3. VALUES OF H_0 FOR AQUEOUS SOLUTIONS OF STRONG ACIDS AND OLEUM

The problems which related to the quantitative characteristic of acid media were discussed in detail in Shatenshtein's monograph[2]. Paul and Long[21] published a thorough review of work on the acidity of aqueous and non-aqueous solutions of acids in 1957, and subsequently papers appeared in which the values of H_0 were refined and the acidities of new solutions were measured. The present review only gives values of the acidity function for aqueous solutions of strong acids and oleum.

a. Sulphuric Acid

The acidity function of sulphuric acid was first measured in work by Hammett and Deyrup[1] published in 1932. The results of these authors for the region from dilute solutions up to 68% H_2SO_4 were repeatedly confirmed in later investigations[20,22,23], but the acidity function for more concentrated solutions was determined[1] with greater error, as the indicators used were benzalacetophenone and anthraquinone, which do not satisfy the requirements applicable for indicators. The indicators used by Jorgenson and Hartter[24] to measure the acidity function of sulphuric acid solutions

from 65 to 90% H_2SO_4 were: 2,6-dinitroaniline, 4-chloro--2,6-dinitroaniline, 2-bromo-4,6-dinitroaniline, 3-methyl--2,4,6-trinitroaniline, 3-chloro-2,4,6-trinitroaniline, and 3-bromo-2,4,6-trinitroaniline. For the same acid concentration range the observed difference in $\log(C_B/C_{BH^+})$ was satisfactorily constant between 2,4-dinitroaniline and 2,6-dinitroaniline, and also between 2,6-dinitroaniline and 4-chloro-2,6-dinitroaniline.

The data on the ionisation of 6-bromo-2,4-dinitroaniline obtained by Vinnik and coworkers [19] differ somewhat from those of Jorgenson and Hartter [24]. As we determined [19] the value of C_B/C_{BH^+} from the area under the absorption curve, these results are naturally more accurate. The acidity of acid solutions with >90% H_2SO_4 can be measured by using 3-methyl-2,4,6-trinitroaniline, 2,4,6-trinitroaniline, and *p*-nitrotoluene [25]. Jorgenson and Hartter [24] also propose 3-bromo-2,4,6-trinitroaniline and 3-chloro-2,4,6-trinitroaniline for this purpose. As the acid concentration is raised, the C_B/C_{BH^+} ratio for 3-bromo-2,4,6-trinitroaniline and 3-chloro-2,4,6-trinitroaniline falls more sharply than would be expected by the acidity of the medium measured by 3-methyl-2,4,6-trinitroaniline (from Jorgenson and Hartter's results [24]) and 2,4,6-trinitroaniline‡ (Vinnik and Ryabov [9]); the reason for this is still not clear. Possibly it is connected with errors in the measurements, or with the quantity $f_B f_{CH^+}/f_{BH^+} f_C$ not being constant for these substances.

Table 3 gives published [19] values of H_0 at 25° for aqueous solutions of sulphuric acid. The acidity function for sulphuric acid at elevated temperatures was measured by Gel'bshtein and coworkers [22] by a photometric method. Table 4 gives their results for the interval from 4% H_2SO_4 to 54% H_2SO_4 (the measurements were made with *p*-nitroaniline, *o*-nitroaniline, 4-chloro-2-nitroaniline, and 2,4-dichloro-6-nitroaniline). The H_0 for more concentrated solutions of sulphuric acids are not given here for the following reasons. In addition to the indicators mentioned, 2,4-dinitroaniline (from 60.2 to 73.4% H_2SO_4), 6-bromo-2,4-dinitroaniline (from 78.0 to 89.5% H_2SO_4), and 2,4,6-trinitroaniline (from 97.1 to 99.6% H_2SO_4) were used [22]. pK_{BH^+} for the last two indicators cannot be determined by comparing $\log(C_B/C_{BH^+})$ since the acidity has not been measured by another indicator in the chosen ranges of H_2SO_4 concentrations. The ionisation regions of 2,4-dichloro-6-nitroaniline and 2,4-dinitroaniline overlap in the range 60.2–64% H_2SO_4. However, it is impossible to determine pK_{BH^+} for the latter indicator since the difference in $\log(C_B/C_{BH^+})$ for these substances depends significantly on the acid concentration.

TABLE 3. Acidity function of sulphuric acid at 25°.

* In calculating H_0 for 40°, 60°, and 80° it was assumed that the quantity pK_{BH^+} for *p*-nitroaniline in sulphuric acid is the same as that in hydrochloric acid. The pK_{BH^+} for the other indicators were determined as usual. The values of pK_{BH^+} are given in Table 1.

b. Solutions of SO_3 in Sulphuric Acid

The acidity function of oleum has been measured by Brand and coworkers [25,26] and by Vinnik and coworkers [9]. In solutions with up to 36% SO_3 the following can serve as indicators: *p*-nitrotoluene, *p*-chloronitrobenzene, *p*-fluoronitrobenzene, *p*-bromonitrobenzene, *p*-butylnitrobenzene, *m*-nitrotoluene, and nitrobenzene. 2,4-Dinitrotoluene and the *m*-nitroanilinium ion [26] (addition of a second proton to *m*-nitroaniline) ionise in more concentrated solutions. Trinitrobenzene and 2,4,6-trinitrotoluene ionise only 20–30% in 65% oleum [26]. Table 5 gives values of H_0 for oleum solutions at 25°. There is no doubt that in dilute oleum the ionisation of the aforementioned indicators consists in the addition of a proton. In concentrated oleum the activity of sulphur trioxide rises sharply and the latter can be attached to the indicator as an aprotic acid. The indicator method for measuring acidity does not distinguish between protonation and ionisation by addition of an aprotic acid.

TABLE 5. Acidity function of oleum at 25°.

SO_3, %	$-H_0$	SO_3, %	$-H_0$	SO_3, %	$-H_0$

2.0	12.62	10.0	13.21	32	13.98
2.5	12.68	12.0	13.31	36	14.13

‡ The data on the ionisation of 2,4,6-trinitroaniline obtained by Jorgenson and Hartter [24] differ considerably from those of Vinnik and Ryabova [9].

More precise information about the ionisation mechanism of indicators in concentrated oleum could be obtained by studying the dependence of the rate of deuterium exchange with the hydrogen of the aromatic ring for the indicator (type RNO_2). It should be noted that in dilute oleum there is a marked rise in acidity with increase in SO_3 concentration. In more concentrated solutions the acidity of the medium increases in proportion to the activity of the sulphur trioxide.

c. Hydrochloric and Hydrobromic Acids

Hammett and Paul[27] measured the acidity function of aqueous solutions of hydrogen chloride from dilute solutions to 20% HCl, and their results were confirmed in later investigations[3,28]. The acidity function of more concentrated solutions has been measured[29,30]. The following indicators were used: aminoazobenzene; benzeneazodiphenylamine, *p*-nitroaniline, *o*-nitroaniline, 4-chloro-2-nitroaniline, 5-chloro-2-nitroaniline, *p*-nitrodiphenylamine, 2,4-dichloro-6-nitroaniline, and 2,4-dinitroaniline. In solutions of acid where indicators with similar values of pK_{BH^+} overlap, a constant difference in $\log(C_B/C_{BH^+})$ for these indicators is observed satisfactorily.

Table 6 shows values of H_0 for aqueous solutions of HCl at 22–26°. Table 7 gives values of the acidity function for hydrochloric acid at 40°, 60°, and 80°, from Gel'bshtein and coworkers[28].

The acidity function of solutions of hydrobromic acid[30] at 25° was measured with the indicators: *p*-nitroaniline, *o*-nitroaniline, 5-chloro-2-nitroaniline, 2,4-dichloro-6-nitroaniline, and 2,4-dinitroaniline (Table 8).

d. Perchloric Acid

The acidity function of aqueous solutions of perchloric acid from 6% $HClO_4$ to 63.9% $HClO_4$ was measured by Hammett and Deyrup[1], using *p*-nitroaniline, *o*-nitroaniline, 4-chloro-2-nitroaniline, 2,4-dichloro-6-nitroaniline, 2,4-dinitroaniline, and *p*-nitroazobenzene. The last indicator overlaps with 4-chloro-2-nitroaniline and 2,4-dichloro-6-nitroaniline. However, it is impossible to calculate its pK_{BH^+} since the difference in $\log(C_B/C_{BH^+})$ for *p*-nitroazobenzene and other indicators changes with the concentration of the acid. Bonner and Lockhart[31] measured the acidity function of concentrated solutions (from 49.6 to 71.3% $HClO_4$) with 2,4-dinitroaniline and 2,4-dinitro-1-naphthylamine. For the same solutions of the acid the values of $\log(C_B/C_{BH^+})$ in these works differ by 0.25–0.28 units. The reason for this difference is still difficult to explain. In recent work by Yates and Wai[32] the acidity of aqueous solutions of perchloric acid at 25° was measured again over the range 4.9 to 78.6% $HClO_4$ using the indicators: *o*-nitroaniline, 4-chloro-2-nitroaniline, 2,5-dichloro-4-nitroaniline, 2-chloro-6-nitroaniline, 2,6-dichloro-4-nitroaniline, 2,4-dinitroaniline, 2,6-dinitroaniline, 4-chloro-2,6-dinitroaniline, 2-bromo-4,6-dinitroaniline, 3-methyl-2,4,6-trinitroaniline, and 3-bromo-2,4,6-trinitroaniline. The Hammett relation is observed by all the indicators mentioned. The results[32] for dilute solutions differ from the earlier data[1]. For example, the values of $\log(C_B/C_{BH^+})$

* Gel'bshtein and coworkers[28] determined the pK_{BH^+} of *p*-nitroaniline by a comparison of $\log(C_B/C_{BH^+})$ with the logarithm of the mean ionic activity $\log a_\pm$. In compiling this table, pK_{BH^+} for *p*-nitroaniline was calculated by comparison of $\log(C_B/C_{BH^+})$ with C_{HCl} in the interval 0.04–0.099 m. The pK_{BH^+} of *o*-nitroaniline and of 4-chloro-2-nitroaniline were determined in the usual way.

8.0	−0.20	35	−2.09		

* In calculating H_0, Vinnik and coworkers[30] used the values of the pK_{BH^+} for indicators given by Hammett and Paul[27]. In compiling this table, the pK_{BH^+} were calculated by comparing the values of $\log(C_B/C_{BH^+})$ for two indicators in the same solution. The pK_{BH^+} of *p*-nitroaniline were calculated by the formula:

$$pK_{BH^+} = -\log(C_B/C_{BH^+}) - \log m_{H_3O^+}$$

for the range of HBr concentrations 3.34×10^{-2}–0.158 m.

for *o*-nitroaniline for the same acid concentrations do not agree. According to Hammett and Paul the pK_{BH^+} of *o*-nitroaniline is more negative by 0.1 unit and the pK_{BH^+} of *p*-chloronitroaniline by 0.05 unit. Possibly this disagreement is connected with measurement errors. The results of Bonner and Lockhart and of Yates and Wai on the ionisation of these indicators agree satisfactorily. To obtain reliable values of pK_{BH^+} for the indicators it is necessary to assume information about the ionisation of strong bases which ionise in solutions where $H_0 = \log m_{H_3O^+}$. For this purpose *p*-nitroaniline can be used. The ionisation of this indicator has been measured[1] in rather concentrated solutions of perchloric acid ($C_{BH^+}/C_B > 10$). Unfortunately this indicator was not employed in the last investigations. Hammett and Deyrup[1] used a colorimeter and the other investigators[31,32] spectrophotometers, so that the results of the later works should be preferred. Table 9 gives the values of the acidity functions of aqueous solutions of perchloric acid.

e. Nitric Acid

In dilute aqueous solutions, nitric, phosphoric, methanesulphonic, and hydrofluoric acids are weak acids. However, concentrated solutions of these acids exhibit considerable catalytic activity in acid–base processes. An appreciable rise in the acidity of the medium is also observed in such solutions.

The acidity function for dilute and moderately concentrated solutions of nitric acid (up to 37.5% HNO_3) was measured by Hammett and Paul[27], using *p*-nitroaniline, *o*-nitroaniline, and 4-chloro-2-nitroaniline. Dawber and Wyatt[17] measured the acidity over a wide range of concentrations from 0.12 to 99.4% HNO_3. In measuring the acidity of concentrated aqueous solutions of nitric acid, difficulties arose over the choice of indicators, owing to their instability in such media. For example, in acid solutions with >65% HNO_3, 2,4-dinitroaniline, *N*-methyl-2,4-dinitroaniline, 4-methyl-2,6-dinitroaniline, 4-chloro-2,6-dinitroaniline, 4-dinitrodiphenylamine, and 2,4-dinitrodiphenylamine react with the acid. In solutions with >37% HNO_3, they used 2,6-dichloro-4-nitroaniline, 2,4-dichloro-6-nitroaniline, *NN*-dimethyl-2,4,6-trinitroaniline, and 4,4′-dinitrodiphenylamine. The value of pK_{BH^+} of *p*-nitroaniline was determined by the equation

$$pK_{BH^+} = \log \frac{C_{BH^+}}{C_B} - \log m_{H_3O^+},$$

pK_{BH^+} for the other indicators, except *NN*-dimethyl-2,4,6-trinitroaniline, being determined as usual. The difference in $\log(C_B/C_{BH^+})$ for two indicators in the interval of their overlap agrees with a satisfactory constancy. *NN*-Dimethyl-2,4,6-trinitroaniline ionises to an appreciable extent, starting from 71.2% HNO_3. In more dilute solutions 2,4-dichloro-6-nitroaniline was used for the measurements. However, it was used for acidity measurements only up to 64.5% HNO_3 and therefore it is impossible to determine the pK_{BH^+} of *NN*-dimethyl-2,4,6-trinitroaniline in the usual way. The authors[17] assumed that at the same value of $\log(C_B/C_{BH^+})$ there should be the same value of H_0 in aqueous solutions of sulphuric and nitric acids. The acidity for the range 64.5–83.7% HNO_3 was examined for comparison of C_B/C_{BH^+} for *NN*-dimethyl-2,4,6-trinitroaniline in solutions of nitric and sulphuric acids. As already mentioned the indicator ratio for this substance changes anomalously in sulphuric acid. When allowance is made for this, there are grounds for assuming, as the authors themselves did[17], that for solutions with >64.5% HNO_3 there are still no reliable values for H_0. In the range 83.7–99.4% HNO_3 4,4′-dinitrodiphenylamine was used. The change in H_0 can be calculated from the change in its $\log(C_B/C_{BH^+})$ (see Table 10). To determine its pK_{BH^+} it is necessary to find indicators with the aid of which H_0 can be determined in the range 60–90% HNO_3.

Table 11 gives the values of H_0 for the HNO_3–H_2O system.

f. Phosphoric Acid and Polyphosphoric Acids

Heilbronner and Weber[33] measured the acidity function at 20° of aqueous solutions of phosphoric acid containing 0.6–85.5% H_3PO_4. The acidity function of such solutions and of more concentrated solutions at 20° and higher temperatures have been measured[28,34]. Downing and Pearson[15] measured the acidity function of solutions of polyphosphoric acids. There were no experimental difficulties

in using the indicator method for work with dilute solutions of phosphoric acid but they did arise in measuring the acidity of concentrated solutions of P_2O_5 in water and especially in polyphosphoric acids. As is known, solutions of P_2O_5 in orthophosphoric acid, and also aqueous solutions of phosphorus pentoxide in water, close in composition to H_3PO_4, consist of mixtures of orthophosphoric, pyrophosphoric, and polyphosphoric acids[35]. Possibly, owing to the slow establishment of equilibrium different investigators worked with the same specified content of P_2O_5 in water but differing in the composition of the individual components. This can explain much of the disagreement in the values of H_0. To measure the acidity function of the P_2O_5–H_2O system, *p*-nitroaniline, *o*-nitroaniline, 4-chloro-2-nitroaniline, 5-chloro-2-nitroaniline, *p*-nitrophenylamine, 2,4-dichloro-6-nitroaniline, 2,4-dinitroaniline, and 6-bromo-2,4-dinitroaniline were used. With 2,4-dinitroaniline there is a weak displacement of the absorption maximum[15], a shift which depends on the P_2O_5 concentration. While there is still no appreciable degree of ionisation in the solutions there is a significant change in the absorptivity of 2,4-dinitroaniline and because of this it is difficult to determine accurately the absorptivity of its un-ionised form. Table 12 gives the values of H_0 at 20° for solutions of P_2O_5 in water from published data[15,28,34]. The acidity function of solutions with from 43.45 to 72.85% P_2O_5 has been measured with 2,4-dichloro-6-nitroaniline colorimetrically[34] and with 2,4-dinitroaniline spectrophotometrically[15]. The results practically agree. The value of pK_{BH^+} for 2,4-dichloro-6-nitroaniline in phosphoric acid is -3.02 (in sulphuric acid pK_{BH^+} = -3.28; in hydrochloric acid, pK_{BH^+} = -3.33), and pK_{BH^+} of 2,4-dinitroaniline is -4.96 (in sulphuric acid pK_{BH^+} = -4.45; in hydrochloric acid pK_{BH^+} = -4.58). The reason for such a great difference in pK_{BH^+} is still difficult to explain.

g. Hydrofluoric Acid

The acidity function of solutions of hydrofluoric acid was measured by Bell and coworkers[36] from dilute solutions to 43% HF. The indicators used were: *p*-nitroaniline, *o*-nitroaniline, and 4-chloro-2-nitroaniline. The acidity function for more concentrated solutions (right up to 100% HF) was measured by Kilpatrick and coworkers[37], who worked with optical cells made from polyfluorochloroethylene with sapphire windows. The measurements were made with *p*-nitrodiphenylamine (39.6–48.7% HF), 4-methyl-2,6-dinitroaniline (55.3% HF), 6-bromo-2,4-dinitroaniline (61.4–71% HF), anthraquinone (80.9–100% HF), and 2,4,6-trinitroaniline (98.13–100% HF). Unfortunately in this work solutions were chosen which do not ensure an overlap of indicators with similar pK_{BH^+}. Therefore it is impossible to determine the pK_{BH^+} of the indicators in this particular medium. The authors of this work[37] used values of pK_{BH^+} for aqueous solutions of sulphuric acid and because of this the values they give are approximate. Judging from their results dilute solutions of water in liquid hydrogen fluoride have an acidity close to that of dilute solutions of water in sulphuric acid. This is evident from the values of C_B/C_{BH^+} for 2,4,6-trinitroaniline (see Table 13).

Table 14 gives values of H_0 for solutions of hydrogen fluoride in water over the range 2–42.7% HF, after Bell and coworkers[36].

h. Methanesulphonic Acid CH_3SO_3H

The acidity of aqueous solutions of methanesulphonic acid at 25° in the range 0–100% was measured by Bascombe and Bell[20]. No appreciable change in the ratio C_B/C_{BH^+} with wavelength is observed for the indicators listed below. The acidity was measured: from 3 to 13.9% acid with *p*-nitroaniline; from 17 to 21.9% with *o*-nitroaniline, from 25.5 to 54.5% acid with 4-chloro-2-nitroaniline, and from 61.5 to 80.6% acid with 2,4-dichloro-6-nitroaniline. The last range of acid concentrations partly overlaps with 4-methyl-2,6-dinitroaniline, the ionisation of which was measured in 74.9–85.2% acid. In 88.9–100% acid the C_B/C_{BH^+} ratio was measured for 6-bromo-2,4-dinitroaniline. To calculate H_0 the authors assumed that for *p*-nitroaniline, *o*-nitroaniline, and 4-chloro-2-nitroaniline, pK_{BH^+} in methanesulphonic acid is the same as in hydrochloric and sulphuric acids.

The values of pK_{BH^+} of 2,4-dichloro-6-nitroaniline and 6-bromo-2,4-dinitroaniline were calculated by extrapolation. It appeared that here pK_{BH^+} for these substances greatly differs from the values for sulphuric acid obtained by direct measurements. As pK_{BH^+} were not determined by overlap of the same ranges of acid concentrations for different indicators the values of H_0 for the methanesulphonic acid–water system (Table 15) must be considered only approximate. These results show that concentrated aqueous solutions of methanesulphonic acid exhibit strongly acid properties.

i. Solutions of DCl and D_2SO_4 in D_2O

In some kinetic investigations solutions of acids in deuterium oxide D_2O are used. It is therefore necessary to have information about the values of H_0 for such systems. Högfeldt and Bigeleisen[38] measured the acidity function for solutions of DCl in D_2O for the range 10^{-4}–1 M DCl and of D_2SO_4 in D_2O for the range 10^{-4}–12 M D_2SO_4 at 22° ± 2°. Fourteen indicators were used for the measurements. It appeared that at the same molarity of the acid the acidity function was the same (within the limits of error of the measurements) for solutions of HCl in H_2O and DCl in D_2O (from 10^{-4} to 1 M) and for solutions of H_2SO_4 in H_2O and of D_2SO_4 in D_2O (from 10^{-1} to 12 M). The acidity was not measured for more concentrated solutions of the acids in D_2O.

pK_{BH^+} for solutions in D_2O is greater than for solutions in H_2O. pK_{BH^+} in D_2O is greater than in water for aminoazobenzene, *m*-nitroaniline, 2,4-dichloroaniline, benzeneazodiphenylamine, *p*-nitroaniline, diphenylamine, *o*-nitroaniline, and 4-chloro-2-nitroaniline by 0.5–0.6 unit; for *p*-nitrodiphenylamine, by 0.27 unit; and for 2,4-dichloro-6-nitroaniline, 2,4-dinitroaniline, and 4-methyl-2,6-dinitroaniline by almost 0.4 unit.

4. ACCURACY OF MEASUREMENTS OF H_0

In the measurements of acidity function there are the following sources of error: (a) the determination of the concentration of the acid; (b) the determination of the indicator ratio C_B/C_{BH^+}; (c) the determination of the value of pK_{BH^+} for the indicator.

Usually, the concentration of aqueous solutions of strong acids is determined either by alkalimetric titration or by electrical conductivity. The electrical conductivity method[39] is used mainly for determining the concentration of sulphuric acid in solutions with >99% H_2SO_4. In alkalimetric titration the error does not exceed 0.1–0.05%. On altering the concentration of strong acids by 1% the acidity function changes by 0.1–0.15 unit in moderately concentrated and by 0.3 unit in extremely dilute solutions. Hence the error in measuring the acid concentration introduces 0.02–0.03 unit into the error in H_0. In measuring H_0 for sulphuric acid in the range 99.5–100% where H_0 changes by 0.3–0.5 unit per 0.1% acid, the error due to the inaccuracy in determining the H_2SO_4 concentration does not exceed 5×10^{-3}–0.01 unit. In this region the accuracy of determining the concentration by electrical conductivity is ±0.001%. In using spectrophotometry H_0 is frequently determined with an accuracy of ±0.01–0.02 unit[29]. However, in some instances an accuracy of ±0.003 is attained, when C_B/C_{BH^+} is determined at several wavelengths[9].

A more significant error is the measurement of the pK_{BH^+} of indicators. This quantity depends on the quantity of indicator used to measure H_0 of the solutions in which the indicator concerned ionises. The error in determining pK_{BH^+} of the first indicator (the strongest base) is made up of the errors in determining the concentration of the acid and $\log(C_B/C_{BH^+})$, since pK_{BH^+} is calculated by the equation:

$$(pK_{BH^+})_1 = -\log C_{H_3O^+} + \log \frac{C_B}{C_{BH^+}}.$$

The error $\Delta(pK_{BH^+})_1 = \pm(0.03-0.04)$ unit.

The quantity pK_{BH^+} of the second indicator, which is a rather weak base, is determined by the equation:

$$(pK_{BH^+})_2 = (pK_{BH^+})_1 + \log\left(\frac{C_B}{C_{BH^+}}\right)_2 - \log\frac{C_B}{(C_{BH^+})_1},$$

$$\Delta(pK_{BH^+})_2 = \Delta(pK_{BH^+})_1 + 2\Delta\log\frac{C_B}{C_{BH^+}} \simeq \pm(0.05-0.08)\text{ unit.}$$

For the third indicator:

$$\Delta(pK_{BH^+})_3 = \Delta(pK_{BH^+})_2 + 2\Delta\log\left(\frac{C_B}{C_{BH^+}}\right).$$

The error $(pK_{BH^+})_3$ amounts to ±(0.07–0.12) unit. The error in determining the pK_{BH^+} of subsequent indicators will be increased by ±(0.02–0.04) unit. The error in H_0 is the sum of the errors in pK_{BH^+}, $\log(C_B/C_{BH^+})$, and the acid concentration. When, for example, three indicators are needed to measure H_0 in a particular solution, then ΔH_0 = = ±(0.08–0.13) unit. When there are nine indicators, ΔH_0 = = ±(0.17–0.34) unit. This number of indicators is required in measuring the acidity of sulphuric acid from extremely dilute solutions to 100% H_2SO_4, where H_0 changes by 12–13 units. In practice in kinetic investigations narrower intervals are used, amounting to 3–5 units of the H_0 scale. In such an instance there is essentially no absolute error in the value of H_0 and the difference in the errors in measuring H_0 for the start and end of the interval. For the mentioned interval of 3–5 units, the error amounts to ±(0.08–0.13) unit), which is fully acceptable for kinetic investigations§. Table 1 does not give the errors in measurements for each indicator separately. The errors can be evaluated from what has been stated above. The stated experimental errors are also not given in the tables listing H_0 for acids. In dilute solutions the accuracy of these quantities is greater in dilute solutions than in concentrated. In each specific instance the error in H_0 is readily evaluated.

§ The errors in determining H_0 were calculated for instances when Hammett's hypothesis of an equality in the ratio of the coefficients for un-ionised and ionised forms of the substance is strictly obeyed.

5. PHYSICAL SIGNIFICANCE OF THE CONCEPT OF "ACIDITY OF THE MEDIUM"

The increase in the acidity of the medium $a_{H^+}(f_B/f_{BH^+})$ as the concentration of the acid in the solution is raised can be related to the change in the concentration of protons C_{H^+}, the activity coefficient of the protons f_{H^+}, and the ratio of the activity coefficients f_B/f_{BH^+} of the indicator. Since the energy of interaction of a proton with water is ~ 200 kcal $\times$ $\times$ mole^{-1}, the concentration of free protons in aqueous solutions of acids is vanishingly small; the protons are present as hydroxonium ions H_3O^+. It is therefore necessary to relate the acidity of aqueous solutions with the properties of H_3O^+ ions and with the f_B/f_{BH^+} ratio.

In aqueous solutions of acids, hydroxonium ions and molecules of the undissociated acids HA, which are in equilibrium with one another, can donate protons:

$$HA + H_2O \rightleftharpoons H_3O^+ + A^-. \qquad (8)$$

The ionisation of substance B can be expressed by the equations:

$$B + H_3O^+ \rightleftharpoons BH^+ + H_2O, \qquad (9)$$

$$B + HA \rightleftharpoons BH^+ + A^-. \qquad (10)$$

When the ionisation of B is represented by Eqns. (9) or (10) then the acidity is expressed thus:

$$h_0 = a_{H^+}\frac{f_B}{f_{BH^+}} = \frac{a_{H_3O^+}}{a_{H_2O}}\frac{f_B}{f_{BH^+}}; \qquad h_0 = \frac{1}{K_4}\frac{a_{HA}}{a_{A^-}}\frac{f_B}{f_{BH^+}},$$

where K_4 is the equilibrium constant for the ionisation of the acid by Eqn. (8):

$$K_4 = \frac{a_{HA}\,a_{H_2O}}{a_{A^-}\,a_{H_3O^+}}.$$

In non-aqueous solutions the ionisation of acids involves the transfer of a proton from the acid HA to the solvent molecule. In alcoholic solutions, alkoxonium ions ROH_2^+ are formed; in ethereal solutions, the ions $RR'O^+H$. In pure acids the ions are formed during autoprotolysis:

$$2HA \rightleftharpoons A^- + H_2A^+.$$

The acidity of the non-aqueous solutions should be related to the properties of the ions of type ROH_2^+, $RR'O^+H$, and H_2A^+ and to the ratio f_B/f_{BH^+} of the indicators used to measure H_0. It is well known that even highly concentrated aqueous solutions of hydrochloric acid [40,41] are completely dissociated. Perchloric acid [42,43] is also completely dissociated in aqueous solutions of moderate concentration (up to 6 M). The concentration of hydroxonium ions in such solutions equals the total concentration of the acid. In concentrated aqueous solutions of sulphuric [10,11] and nitric [44] acids there is incomplete dissociation. The concentration of H_3O^+ ions, anions, and undissociated HA molecules in such solutions can be determined from the Raman spectra, by infrared spectra, and by the NMR method. Acids such as phopshoric and hydrofluoric are weakly dissociated even in dilute aqueous solutions.

It is easy to conclude that the acidity of concentrated solutions increases much more strongly than the concentration of H_3O^+ ions. For solutions with completely dissociated acids with a range of concentrations of 1–10 M, $C_{H_3O^+}$ increases tenfold, and the acidity of the medium by a few orders of magnitude. Evidently the chief reason for the change in H_0 is not the change in $C_{H_3O^+}$, but the change in activity coefficients. The activity coefficients of individual ions, in principle, cannot be measured by thermodynamic methods. The acidity h_0 includes the activity coefficient of the un-ionised form of the indicator f_B, which can be measured indirectly.

The demonstration of the dependence of f_B for indicators on the acid concentration allows us to understand the physical significance of acidity h_0.

Until recently information about the dependence of f_B for indicators on the concentration of strong acids was limited solely to aqueous solutions of sulphuric acid. Figs. 2 and 3 show the dependence of f_B for certain indicators on sulphuric acid concentration from published data [45-47]. In dilute solutions the activity coefficients of the un-ionised form f_B are almost constant. On increasing the acid concentration the quantities f_B for various indicators change differently for different indicators. For *o*-nitroaniline, f_B remains constant almost up to 25% H_2SO_4, and then falls.

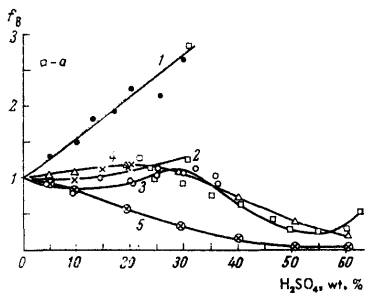

Fig. 2. Dependence of the activity coefficients f_B of the un-ionised form of the indicators on sulphuric acid concentration:
1) diphenylamine; 2) *p*-nitroaniline; 3) *o*-nitroaniline; 4) 2,6-dichloro-4-nitroaniline;
5) 2,4,6-trinitroaniline; □ experiments on the distribution of the substance between two phases; other experiments, by solubility.

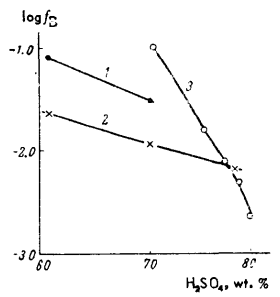

Fig. 3. Dependence of the activity coefficients f_B of the un-ionised form of the indicators on the sulphuric acid concentration:
1) 2,4-dinitroaniline; 2) 2,4,6-trinitroaniline; 3) *p*-benzoylbiphenyl. For *p*-benzoylbiphenyl instead of f_B we give the quantity $(1 + h_0/k_{BH^+})/S$ which is proportional to f_B. In this, S is the solubility of the substance in acid of the specified concentration.

For 2,4-dinitroaniline and 2,4,6-trinitroaniline there is only a decrease in f_B with increasing acid concentration, and the degrees of change of f_B are different. With *p*-nitroaniline, f_B remains constant at first and then rises slowly. With diphenylamine there is a rise in f_B, starting from dilute acid solutions. For these indicators Hammett's hypothesis of the equality of the ratios of activity coefficients of the ionised and un-ionised forms of the indicator is satisfied:

$$\frac{f_B}{f_{BH^+}} = \frac{f_C}{f_{CH^+}} = \frac{f_D}{f_{DH^+}}. \qquad (11)$$

In the general example this ratio should depend on the composition of the solution. Assume that on going from a dilute solution of sulphuric acid to solution N this ratio changes m times, and the coefficients f_B, f_C, and f_D change b, c, and d times respectively. Then:

$$f_{BH^+} = \frac{b}{m}; \quad f_{CH^+} = \frac{c}{m}; \quad f_{DH^+} = \frac{d}{m}.$$

Hammett's relationship is also observed during the ionisation of an already protonated base[48] and during the protonisation of anions, for example, of picric acid[50,51]:

$$\frac{f_B}{f_{BH^+}} = \frac{f_{BH^+}}{f_{BH_2^{2+}}} = \frac{f_{A^-}}{f_{AH}},$$

where f_{AH} and f_{A^-} are the activity coefficients of the acid and its anion. When in solution N we have $f_B = b$ and $f_{AH} = a$, then:

$$f_{BH_2^{2+}} = \frac{b}{m^2} \text{ and } f_{A^-} = ma.$$

Consequently, when the value of relationship (11) depends on the solution composition, then in comparison with the activity coefficient of the un-ionised form, the activity coefficient of the singly-charged positive ion changes $1/m$ times; that of a doubly-charged positive ion $1/m^2$ times, and that of a singly-charged negative ion, m times.

An activity coefficient characterises the change in free energy of the substance. When relationship (11) depends on the composition of the solvent, then it can be taken that the change in free energy of the ion is the sum of two parts. One part (ΔF_1) equals the change in free energy of the un-ionised species; the other part (ΔF_2) is determined solely by the charge of the ion and does not depend on its structure and chemical composition. The substances for which relationship (11) is observed are usually large polyatomic molecules. In solutions with a high concentration of ions they are polarised. The substances investigated for which Hammett's hypothesis is obeyed contain such functional groups as amino, nitro, carbonyl, etc. On the basis of what has been said above, it is to be expected that the addition of a proton to various functional groups has the same effect on the activity coefficient of the ionised molecule. Moreover, in substances with such functional groups there is a marked change in the activity coefficient f_B with change in the acid concentration. In this connection it can be assumed that these particular groups are mainly responsible for the change in the activity coefficient of the un-ionised molecules. Undoubtedly, the acquisition of a charge is reflected in the properties of all the molecules as a whole, and in particular of the atoms of the functional group bearing the charge. When the contribution of the charge to the free energy of the ionised molecule is large then it significantly changes the properties of all the atoms of the molecule and in particular the atoms of the charged functional group. Here it is difficult to suggest that the change in free energy represents the sum of two independent terms, as it should be were f_B/f_{BH^+} dependent on the solution composition. When the effect of the charge is small, then the change in free energy of the ion can be expressed as the sum ($\Delta F_1 + \Delta F_2$) and the contribution of the charge ΔF_2 to this sum can be neglected.

Hence we come to the conclusion[46] that the ratio f_B/f_{BH^+} is independent of the solvent composition and equals unity, as is assumed for dilute aqueous solutions.

The acidity of the medium equals the activity of the protons $h_0 = a_{H^+}$.

Rybkin and Shevchenko[52] measured the compensating effect of the cell for aqueous solutions of hydrogen chloride and of solutions of HCl in water saturated with surface-active acids (hexanoic and enanthic) and alcohols (heptyl and nonyl). The compensating effects of the cell of type:

$$\underset{(I)}{H_2 \mid \text{acid} \mid} \text{ air } \underset{(II)}{\mid \text{acid} \mid H_2},$$

depend considerably on the state of the surface of the investigated (I) and standard (II) solutions. The surface adsorption potential of hydrogen chloride in aqueous solutions is suppressed by additions of pentanol[49]. Surface-active substances are added to balance the surface properties of the solutions. Since their solubility is not high it can be considered that they do not change the acidity of the test solutions. In solutions saturated with surface-active alcohols there is satisfactory agreement of the measured values of $\log a_{H^+}$ with the acidity function H_0. These experiments also show the independence of f_B/f_{BH^+} on the concentration of a strong acid in aqueous solution. The view that the ratio f_B/f_{BH^+} is constant in aqueous solutions of strong acids was expressed by Gutbezahl and Grunwald[53] in 1953. It is evident that the equality of the acidity of the medium and the activity of the protons does not mean in the least that in all instances Hammett's relationship should be observed. An example of the non-observance of this relation was given on p. 806. Hammett's relation is also not observed in instances when the ionic and un-ionised forms differ significantly in their structure, as happens in the ionisation of cyanocarboxylic acids[50].

6. RELATION BETWEEN THE ACIDITY OF THE MEDIUM AND THE THERMODYNAMIC ACTIVITY OF WATER

In aqueous solutions in which strong acids are completely ionised, there are anions and water molecules in addition to the hydroxonium ions. In such systems the properties of the H_3O^+ ions are determined by the properties of water and the anions A^-. If the conclusion about the independence of the ratio f_B/f_{BH^+} and the acid concentration is correct, then:

$$h_0 = \frac{1}{K_4}\frac{a_{HA}}{a_{A^-}} = \frac{a_{HA}}{K_4 C_{A^-} f_{A^-}}, \qquad (12)$$

where C_{A^-} is the concentration of the anions and f_{A^-} the activity coefficient of the anions of the acid.

For hydrochloric, hydrobromic, perchloric, and nitric acids the standard state is chosen in such a way that the constant K_4 equals unity. For these acids:

$$h_0 = \frac{a_{HA}}{C_{A^-} f_{A^-}}. \qquad (13)$$

Hydrochloric[40,41] and perchloric[42] acids are completely dissociated even in highly concentrated aqueous solutions

and the concentration of the anions equals the total concentration of the acid. Apparently, hydrobromic acid is also completely dissociated in concentrated solutions. It is well known that a molecule of water combined with a proton is spectroscopically distinct from the remaining molecules of water in aqueous solution[54]. Molecules of water entering into the solvate sheaths of the anions and H_3O^+ ions apparently differ little from the remaining water molecules present in the solution. To the first approximation it can be assumed that the concentration of water molecules in an aqueous solution equals the difference between the stoichiometric concentration of water and the concentration of H_3O^+ ions. Therefore it is sensible to compare the values of f_A- for solutions with the same molality. The activity coefficients of the anions can be calculated by Eqn. (13).

To calculate the activity coefficient f_A- for solutions of nitric acid in water, allowance must be made for the degree of dissociation of the acid. The degree of dissociation of HNO_3 in water is taken from Young and coworkers[44]. In dilute solutions of sulphuric acid there are SO_4^{2-} and HSO_4^- anions. The standard state for solutions of H_2SO_4 in water is chosen in such a way that the activity coefficients of the H_3O^+ ions and SO_4^{2-} anions equal unity in extremely dilute solutions. In concentrated solutions of the acid the SO_4^{2-} concentration is low[10,11] and the ionised acid is present as HSO_4^- anions. Then the equilibrium constant K_4 does not equal unity. For sulphuric acid the product $K_4 f_A$- can be calculated. Table 16 gives the activity of the anions of aqueous solutions: from 0.1 m to 12 m for HCl and HBr, from 0.5 m to 12 m for $HClO_4$, from 0.1 m to 10 m for HNO_3, and the values of $K_4 f_{HSO_4^-}$ for sulphuric acid solutions in the range 0.5–12 m.

As Fig. 4 shows, in the range from 1 m to 9 m the change in the acidity function H_0 is almost the same for aqueous solutions of HCl, HBr, $HClO_4$, and H_2SO_4¶. Since the activities of the anions change differently in this range it can be concluded that the change in $h_0/C_{H_3O^+}$ is connected with a change in the solvation of the hydroxonium ion and not with a change in a_A-.

With a decrease in the number of water molecules adjacent to one hydroxonium ion, the acidity rises. The

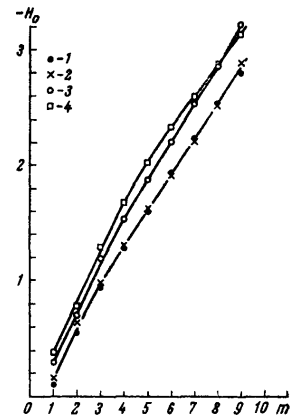

Fig. 4. Dependence of H_0 on the molar [presumably molal [Ed. of Translation)] concentration m of the strong acids: 1) HCl; 2) HBr; 3) $HClO_4$; 4) H_2SO_4.

activity of water in the solution is connected with the properties of the hydroxonium ion and the anion. In those instances where the activity of the anions change similarly for a change in the concentration of the acids it can be expected that at the same values of the activity of water a_{H_2O} the values of the acidity will be almost the same†. Table 17 gives the values of H_0 at the same activities of water. For solutions of sulphuric (from 11 to 57.8% H_2SO_4) and perchloric (from 11.3 to 54.6% $HClO_4$) acids, where the activity of water changes from 0.85 to 0.20, there are almost the same values of H_0 at the same activities of water.

Starting from solutions in which the activity of water < 0.45 the acidity of the medium for HCl, HBr, $HClO_4$, and H_2SO_4 is almost the same for the same values of a_{H_2O}. In such solutions the activities of the anions differ significantly. The activity coefficients of the ClO_4^- and HSO_4^- anions rise considerably and those of Cl^- and Br^- remain

¶ This first received attention from Bascombe and Bell[59].

† Wyatt[60] and Högfeldt[61] have compared values of H_0 and a_{H_2O} for various acids.

* The activities of water a_{H_2O} in acids were taken from published data: sulphuric acid[57]; hydrochloric acid[41]; hydrobromic acid[41]; perchloric acid[58]; nitric acid[58]; phosphoric acid[62].

almost constant. This suggests that in solutions with >8–9 m acid the change in the activity of the anion is weakly reflected in the change in the activity of water. On the other hand, even a slight decrease in the activity of water in concentrated solutions of acid is linked with a significant increase in the activity coefficient of the oxygen-containing anions ClO_4^- and HSO_4^-. On comparing solutions of strongly and weakly dissociated acids with the same activities of water, the acidity is much less for weak acids than for strong acids. For example, for solutions with a water activity of 0.2, the acidity function for strong acids is $H_0 = -4.25$, for nitric acid $H_0 = -3.78$, and for phosphoric acid $H_0 = -3.13$. This can be explained by the strong hydration of the undissociated molecules of a weak acid.

It is interesting to note that in the dissolution of anhydrous hydrogen chloride in concentrated phosphoric acid containing 80% H_3PO_4, the acidity of the medium rises as the concentration of water in the solution decreases. At the same time the activity of the Cl^- anion remains almost constant[63]. A slight change in the activity coefficients of Cl^- in aqueous solutions and in solutions in phosphoric acid and also of Br^- in aqueous solutions shows the slight solvating ability of these ions.

In sulphuric acid solutions with >94% H_2SO_4‡, there is a relation found by Brand[25]:

$$-\log\frac{C_{H_2SO_4}}{C_{HSO_4^-}} + \log k = H_0, \qquad (14)$$

where k is a constant.

‡ It has been assumed[25,64] that in sulphuric acid with > 90% H_2SO_4, all the water is present as H_3O^+:

$$H_2SO_4 + H_2O \rightleftharpoons H_3O^+ + HSO_4^-.$$

The concentration of the undissociated H_2SO_4 molecules was calculated as the difference between the initial concentrations of acid and water. Then Eqn. (14) is correct in the range 90–99% H_2SO_4. However, from the spectroscopic data[11], it follows that in solutions where the acid concentration is < 94%, the concentration of HSO_4^- anions is less than the concentration of water in the initial acid.

In such solutions the change in activity of the sulphuric acid equals the change in the mole fraction of the undissociated molecules in solution. When the concentration of the anions in Eqn. (14) is expressed by mole fraction, then it is found that $f_{HSO_4^-}$ is constant in the range from 94 to 99% H_2SO_4. In solutions where the H_2SO_4 concentration <94%, considerable numbers of ion pairs are present in equilibrium with the H_2SO_4 molecules[11].

The chemical shifts of the NMR protons reflect the change in the acidity of the medium. The chemical shifts of the NMR protons depend on the nature and concentration of the acids[65]. The acidity function and also the value of $\log(h_0 a_{H_2O})$ for hydrochloric, perchloric, sulphuric, and nitric acids are linearly related to the chemical shift σ. However, the slope of the straight line in the coordinates: $[H_0; \sigma]$ or $[\log(h_0 a_{H_2O}); \sigma]$ depends on the nature of the anion. It changes in the following sequence: $HClO_4 > HCl > H_2SO_4 > > HNO_3$.

As mentioned above, the change in the activity of the anion has little effect on the acidity h_0. The existence of a relation between proton shift and the nature of the anion at the same values of H_0 is evidence of the considerable effect of the anion on the screening of the proton in aqueous solutions.

TAUTOMERIC TRANSFORMATIONS OF PHENOLS

V. V. Ershov and G. A. Nikiforov

CONTENTS

1. Introduction 817
2. Tautomerism of phenols 818
3. Tautomerism of nitrosophenols 823
4. Tautomerism of azophenols 825
5. Equilibrium phenol–quinonoid transformations of *p*-substituted phenols 827

1. INTRODUCTION

Problems of the tautomerism of organic compounds are at present of interest to many research workers[1]. Even in the most familiar type of tautomerism (keto–enol tautomerism) there are little-studied relationships and phenomena, in particular the tautomerism of phenolic compounds. These transformations aroused the interest of research workers at an early date, but the systematic study of this interesting phenomenon was made possible only by the development of modern physical methods for studying organic compounds.

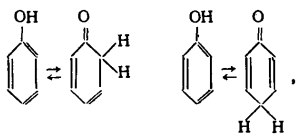
In keto–enol tautomeric transformations of organic compounds, the tautomerism of hydroxyaromatic compounds occupies a special place, since the phenomenon is accompanied by breakdown of the aromatic bond system. The present paper summarises results concerning the actual phenomenon of tautomerism in the phenol series, and also some reactions of substituted phenols (for example, salt formation), as a result of which equilibrium is established between the aromatic (phenolic) and quinonoid or quinolide†

† We apply the term "quinolide", as distinct from "quinonoid" in the description of bond systems, to cyclohexadienones in which the carbon atom in the *ortho*- or *para*-position relative to the carbonyl group is joined by ordinary (not double) bonds to two substituents.

(cyclohexadienone) bond systems. This review does not deal with the reactions of phenols in which substances with a quinolide structure are obtained merely as intermediates or are formed irreversibly by the action of electrophilic and radical reagents on substituted phenols. Reactions of the last type (phenol–dienone bond rearrangement) were reviewed in detail earlier[2]. Since we shall restrict ourselves to the regular features of equilibrium transformations in the phenol series, we shall naturally not consider processes associated with the phenomenon of mesomerism in phenolic compounds, since this is of independent interest.

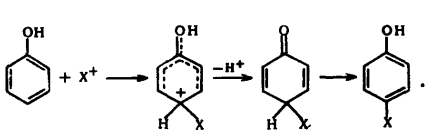
2. TAUTOMERISM OF PHENOLS

The possibility of tautomeric transformation of phenols into compounds with an *ortho*- or *para*-quinolide bond system (cyclohexadienones)



(I) (II)

is usually regarded[3,4] as a specific case of keto–enol tautomerism. Support for this view is provided by certain features which the phenomena have in common. A phenol molecule containing a hydroxyl group and a bond of aromatic type (with electron content very close to that of a double bond) should be converted into an alicyclic carbonyl compound. In reality, however, this does not take place in the simplest phenols, since the equilibrium is displaced completely towards the phenolic (enol) form. This is in fact the chief characteristic of the phenol ⇌ cyclohexadienone tautomerism which we are considering. Moreover, if it is assumed that the conversion of phenol into the cyclohexadienone with the *para*-quinolide structure (II) is energetically more favourable, phenol–dienone tautomerism, unlike keto–enol tautomerism, will not have the characteristic of a triad tautomeric transformation. Thus its mechanism should differ slightly from that of ordinary keto–enol tautomerism. Unfortunately, the question of the mechanism of phenol–dienone tautomerism remains open. Its mechanism should apparently be close to that of electrophilic substitution, which in the phenol series has characteristic features[5] associated with the intermediate formation of dienone systems of types (I) or (II). According to the mechanism at present accepted for electrophilic substitution in the phenol series (see for example Nenitzescu[6]) the first stage in the substitution is the formation of the benzonium ion (III), which is readily stabilised by the removal of a proton from the hydroxyl group with the formation of an intermediate neutral quinolide compound (IV), which rapidly isomerises into a substituted phenol. Thus for most monohydric phenols the formation of cyclohexadienone structures is possible only at the moment of reaction under the influence of an electrophilic reagent‡:



(III) (IV)

‡ See the earlier review[2] for more details.

Obviously, if it is assumed that X = H, we shall be dealing with the typical keto–enol tautomerism of phenol itself. Analogous considerations can be applied to the *ortho*-quinolide tautomer. In these transformations, however, the exact mechanism of the transformation of the dienone (IV) into the phenol has not been studied; this is directly related to the tautomerism of phenols. The question of the mechanism of phenol–dienone tautomerism is of considerable practical importance, since examples[7-9] have been described (without reference to mechanism) of the irreversible transformation of certain *para*-quinolide compounds of type (IV) into the corresponding phenols§. Moreover, even where phenol–dienone tautomerism is possible (for example, anthrol ⇌ anthrone) almost no discussion of the mechanism of these transformations has been published.

Thus all the characteristic features of phenol–dienone tautomerism are related to the extreme stability of the phenolic (enol) form. This stability is extremely regular, despite the fact that comparison of the two bond systems

shows that the formation of the carbonyl group is energetically much more favourable (by 18.6 kcal mole^{-1})[11] than that of the enol group. The possibility of partial enolisation arises, however, even in acetoacetic ester, chiefly as a result of the gain in the energy of delocalisation with another carbonyl group. In the phenol–cyclohexadienone system which we are considering, however, the gain in resonance energy (the energy of aromatic delocalisation, which for benzene amounts to ~ 36 kcal mole^{-1}[12,13]) is much greater than the energy required for enolisation of the carbonyl group, so that the aromatic bond system becomes the most favoured. Thus the simplest phenols exist in only one form and there is no possibility of tautomerism in these compounds. This conclusion is confirmed by all the chemical and physical properties of the simplest phenols. It thus becomes evident that the manifestation of phenol–dienone tautomerism is possible only when there are additional factors leading in some way to a decrease in the difference between the energies of enolisation and aromatic conjugation. The most important such factors are the following.

1. Increase in the number of hydroxyl groups in the aromatic nucleus. Here tautomerism is possible because the energy of aromatic delocalisation must compensate the energy of enolisation of not one but several carbonyl groups.

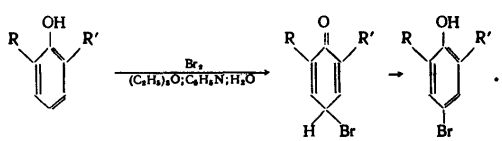
2. Formation of phenoxide ions. In the equilibrium transformation involving a phenoxide anion there is no need to expend energy on the removal of a proton, and this naturally makes the equilibrium system more labile. Moreover, the fact that the aromatic ring is always involved in the redistribution of the negative charge in the phenoxide ion should facilitate to a considerable extent the production of the carbonyl form.

§ Recently, de la Mare in a private communication[10] suggested that under the conditions of acid or base catalysis the transformation of the dienone (IV) into the substituted phenol involves initially the attachment of a proton from the solvent to the carbonyl oxygen of the dienone, followed by the removal of a proton from the *gem*-position. The mechanism may be different, however, in a spontaneous transformation.

3. Decrease in the energy of aromatic delocalisation in the phenol ring as a result of its condensation with other aromatic systems.

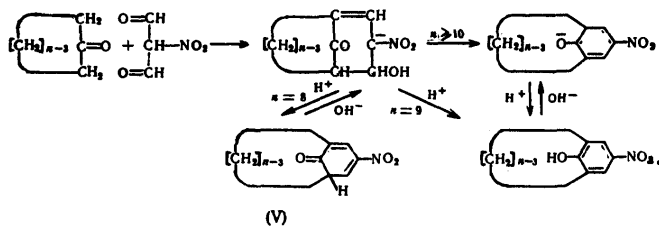
4. The introduction, into the *ortho*- or *para*-position of the phenol, of groups exhibiting a marked negative conjugation effect. Here a decrease in the energy of aromatic delocalisation takes place as a result of conjugation of the ring with the group under consideration; this may lead to a redistribution of the electron density in the molecule with the formation of a quinonoid (but not quinolide) bond system. This leads to the possibility of a slightly different tautomeric transformation of the phenol molecule, in which an electronegative group takes part in the transfer of a proton from the phenolic hydroxyl (for example, the tautomerism of nitrosophenols).

Tautomerism in phenolic compounds arises most readily when a phenolic aromatic ring is influenced simultaneously by several of the above factors. Here, the tautomerism conditions (influence of temperature and the medium) and steric phenomena are naturally of considerable importance. In the tautomerism of phenols the spatial factor (as in classical keto–enol tautomerism [14]) leads to an increase in the stability of the keto-form and retards its rearrangement into the phenol. A similar influence is shown to some extent by the steric factor even in mononuclear polyhydric phenols. For example, in the bromination of 2,6-dialkylphenols in the presence of substances exhibiting proton-accepting properties, bromo-*p*-quinolide compounds were isolated in the individual state; these isomerised spontaneously into the corresponding *p*-bromophenols [7,8]:



The lifetime of these quinolide compounds depends to a significant extent on the steric hindrance around the carbonyl group, and at 20° amounts to ten days for R = R′ = $= C(CH_3)_3$, or 4 h for R = R′ = $CH(CH_3)_2$; for R = R′ = CH_3 the bromoquinolide compounds exist only in dilute solutions and isomerise instantly into the bromophenol when attempts are made to isolate them. Stabilisation of a cyclohexadienone structure as a result of screening of the carbonyl group by t-butyl groups was also described by Kharasch [9], who by the recombination of 2,6-di-t-butylphenoxyl radicals obtained a bis-*p*-quinolide compound which readily isomerised into 3,3′,5,5′-tetra-t-butyl-4,4′-dihydroxybiphenyl.

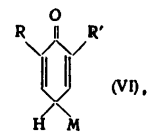
Prelog [15,16] described another type of steric influence on the stability of a cyclohexadienone having a hydrogen atom as one of the *gem*-substituents. By condensing cyclononanone with nitromalonic aldehyde followed by acidification of the reaction mixture, he obtained the dicyclic dienone (V), which is an isomeric keto-form of the corresponding nitrophenol. The dienone (V) is extremely stable and isomerisation into the phenol is prevented by the rigidity of the structure, which does not allow the formation of a double (or in this example aromatic) bond at the head of the dicyclic bridge, in accordance with Bredt's rule [17]. When the cyclic ketone is enlarged by one methylene group, however, the condensation product is converted into the nitrophenol on analogous treatment, and with further increase in the dimensions of the ring the anion of the corresponding phenol is obtained immediately in the reaction mixture:



(V)

While dealing with stabilisation of the carbonyl form by the steric factor, we should point out that for a prolonged period one could find in the literature the unrefuted opinion, put forward in 1911 by Mayer [18], that tautomerism was possible in 3,4-di-t-butylphenol because of the marked steric hindrance in the *o*-di-t-butylbenzene system [19]. This phenol was prepared in 1964, however, and it was shown to exist only in the usual phenolic form [20].

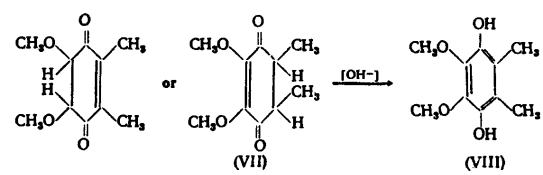
The influence of the steric effect is also seen in the formation of salts by phenols showing steric hindrance¶; some authors [21,22] on the basis of the chemical properties, have assigned the quinolide structure (VI) to these compounds in the solid state. In solution, these metal derivatives have been assigned [23,24] the structure of a levelled (ambident) ion. Treatment of these solutions with alkyl halides leads to the attachment of the alkyl residue to the phenol in the *para*-position. The quantity of C-isomer depends on the steric hindrance created by the *ortho*-alkyl groups and the magnitude of the entering alkyl group:



(VI),

where M = K, Na, or Li. Analogous reactions with these salts are undergone by benzoyl chloride [25], acrylonitrile [22,25], ethylene oxide [21], and a number of other compounds [21].

As already noted, increase in the number of hydroxyl groups in the aromatic nucleus, as a result of a decrease in the difference between the stabilisation energies of the keto- and enol forms [26], should favour tautomerism and this should be reflected in the properties and reactivity of polyhydric phenols. The individual existence of the keto-form should then be possible even when the influence of the steric effect is smaller. For example, the antibiotic gliorosein (VII), according to chemical and spectroscopic data, is an isomeric keto-form of the corresponding substituted hydroquinone (VIII), into which it can be readily converted in the presence of basic substances [27]:

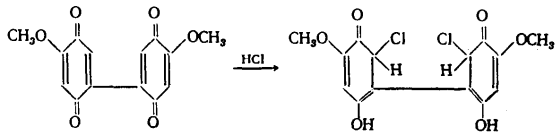


(VII) (VIII)

The formation of a similar diketo-form was also observed in the addition of hydrogen bromide to 2,6-dimethoxyquinone [28]. An analogous ketone (IX) was also obtained [29,30] in

¶ In 2,6-di-t-alkylphenols the screening of the phenolic hydroxyl is so great that these phenols do not dissolve in alcoholic solutions of alkalis and do not form salts under ordinary conditions. Salts of these phenols can be formed only by treating them with alkali metals in benzene or liquid ammonia.

the biphenyl series by the addition of hydrogen chloride to the diquinone (X). This ketone could not be enolised, however, since on recrystallisation it decomposes to the original components:



(X) (IX)

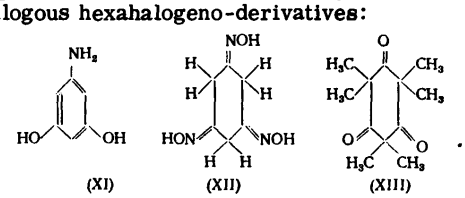
Here we see a general property of the keto-forms of substituted hydroquinones, whose stabilisation into quinonoid compounds with the removal of a molecule of an inorganic substance takes place more readily than the transformation into isomeric hydroquinones. This characteristic has been most extensively studied for compounds of the naphthalene series (see p. 823).

A large amount of material on the chemical properties and reactivity of polyhydric phenols indicates the possibility that many of these compounds react in a tautomeric keto-form. Thus resorcinol, like $\alpha\beta$-dicarbonyl compounds, is readily reduced by sodium amalgam to cyclohexane-1,3-dione[31].

The behaviour of phenols, containing different numbers of hydroxyl groups, in their reactions with ammonia is also characteristic. The replacement of the phenolic hydroxyl group in a monohydric phenol by an amino-group takes place with difficulty and under very severe conditions (350–450°, 50–60 atm), whereas with resorcinol this reaction takes place fairly readily at ~ 200°,[32] and phloroglucinol is converted almost quantitatively into 5-aminoresorcinol (XI) at room temperature in alcoholic ammonia solution[33,34]. These reactions evidently take place by the same mechanism as the action of ammonia on carbonyl compounds capable of undergoing prototropic transformations[35].

Finally, the reaction of phloroglucinol with hydroxylamine is extremely specific. As early as 1886, Bayer[36], in a study of this reaction, isolated a compound to which he assigned the structure of the cyclic trioxime (XII). Much later (1956) the structure of this substance was confirmed by spectroscopic methods[37]. Its infrared spectra show bands corresponding to the absorption of the –C=N group (1653 cm^{-1}), and the ultraviolet spectrum does not contain the maximum due to aromatic absorption.

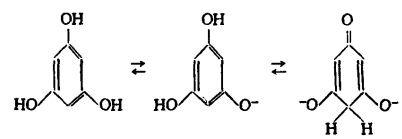
Unusual behaviour is shown by phloroglucinol and resorcinol[38-45] on alkylation by alkyl halides in aqueous alkali. Thus methylation by methyl iodide in the presence of potassium hydroxide gives a mixture of *O*- and *C*-methyl derivatives, and with an excess of methyl iodide the hexamethyl derivative (XIII) can be obtained from phloroglucinol[40-44,46-48]. A more detailed study[49] of this reaction for the example of 2,4,6-trihydroxyacetophenone showed that the composition of the mixture of final products depends to a marked extent on the concentration of alkali in the solution. This reaction resembles the alkylation of metallic derivatives of acetoacetic ester. Chlorination[50,51] and bromination[52,53] of phloroglucinol with an excess of halogenating agent also gives analogous hexahalogeno-derivatives:



(XI) (XII) (XIII)

On the other hand, there are reactions in which phloroglucinol behaves as a typical phenol: it gives the triacetate with acetyl chloride, and it is methylated by diazomethane with the formation of the trimethyl ether[54,55].

Thus the chemical properties of polyhydric phenols, in particular phloroglucinol, indicate that the compounds may react in both the keto- and enol forms. Tautomerism in phloroglucinol has not been observed directly, however. The Raman[56], ultraviolet, and infrared[37] spectra indicate that phloroglucinol consists exclusively of trihydroxybenzene both in solution and in the solid state. Naturally, here it might be assumed that phloroglucinol contains in equilibrium extremely small quantities of the keto-form, which are not detected by the methods used. It is more probable, however, that the dual reactivity of phloroglucinol is due to the tautomeric transformation of its anion, since all the reactions confirming the existence of the keto-form of phloroglucinol generally take place in the presence of bases. The existence of the phloroglucinyl oxide anion in the tautomeric keto-form can now be taken as proved, so that the question of the tautomerism of phloroglucinol reduces to the tautomerism of its anion; the most stable keto-form should be the doubly-charged phloroglucinyl oxide anion:



According to a number of authors[57-61], evidence for this is provided by the appearance of a maximum in the 250 nm region, characteristic of *para*-quinolide compounds, in the ultraviolet spectrum of an alkaline solution of phloroglucinol. Formation of this structure is also indicated by the sharp increase in the second dissociation constant of phloroglucinol compared with other polyhydric phenols (Table 1).

Finally, the existence of the doubly-charged phloroglucinyl oxide anion in the keto-form was proved most convincingly by proton magnetic resonance[63]. The PMR spectrum of aqueous phloroglucinol solution shows a single maximum corresponding to aromatic protons (τ = 3.95), which is displaced slightly when one mole of alkali is added (τ = 3.98). The addition of a second mole, however, produces sharp changes in the spectrum: the maximum due to the aromatic protons disappears, with the production of two new peaks; one of these (τ = 4.97) corresponds to protons associated with an alkene double bond, and the other (τ = = 7.00) corresponds to the protons of a methylene group. The chemical shift of the observed peaks is insensitive to change in concentration and temperature. These observations indicate the existence of a doubly-charged anion in the form of an alicyclic isomer, and according to the infrared

TABLE 1. Dissociation constants of polyhydroxyphenols[62]

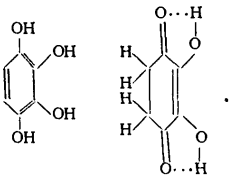
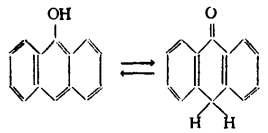
spectra[63] this structure is preserved in the disodium salt of phloroglucinol in the solid state. It thus follows that un-ionised phloroglucinol and singly-charged and doubly--charged ionic forms are present in equilibrium, and pure tautomerism between two forms of the doubly-charged anion is not observed. The formation of the doubly-charged phloroglucinyl oxide anion is apparently accompanied by simultaneous rearrangement of the aromatic bond system into a dienone system; this is extremely characteristic of the ionisation of certain substituted phenols (see p. 828).

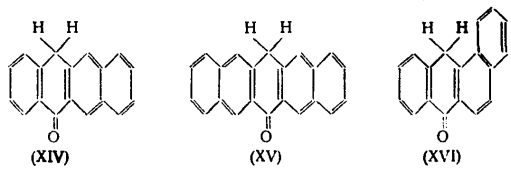
As a result of the introduction of another hydroxyl group into the aromatic ring, 1,2,3,4-tetrahydroxybenzene can exist in two individual isomeric forms[64,65]. Under appropriate conditions the isomers can be converted into one another, but there is no reversible equilibrium between them. Here the stability of the keto-form is influenced not only by the above energetic features, but also by intramolecular hydrogen bonds formed as a result of the favourable mutual arrangement of the hydroxyl and keto-groups (see p. 822).



The above published data indicate that in the mononuclear phenol series (mono-, di-, and poly-hydric), actual tautomerism, as a mobile equilibrium, does not exist. This state of affairs is not preserved, however, on going to the hydroxyl derivatives of polycondensed aromatic systems. Even in naphthols the symmetrical character of the π-electron cloud is disturbed, and this naturally leads to a decrease in the aromaticity of the phenolic ring. Approximate quantum-mechanical calculation shows that the 1–2 bonds of naphthalene are closer to double bonds than the bonds in benzene, and also that the 1,2,3,4-system of naphthalene is similar to some extent to the buta-1,3-diene system and to an even greater extent to the 1,4-diphenylbuta--1,3-diene system[66]. Thus the energy used in enolisation is compensated to a smaller extent by the energy of aromatic delocalisation in the naphthol series than in mononuclear hydroxyaromatic compounds. As a result, in the naphthalene series, even the monohydric hydroxyl derivatives exhibit the properties of the tautomeric keto-form in their chemical reactions. Thus β-naphthol is readily reduced to β-tetralone[67,68], undergoes bromination with the formation of derivatives of the keto-form with *gem*-substituents in the α-position[69], etc. As in phloroglucinol, however, tautomerism is not observed directly in the naphthols. In monohydric phenols tautomerism becomes possible only when the phenol ring is condensed with two aromatic nuclei. Thus in unsubstituted anthracene the energy of aromatic delocalisation is slightly greater than the sum of the energy of conjugation of two isolated aromatic rings[70], but when a hydroxyl group is introduced into the *meso*-position of anthracene, this excess delocalisation energy cannot completely compensate the enolisation energy. As a result, 9-hydroxyanthracene (anthrol) is able to undergo reversible conversion into the corresponding ketone (anthrone) in which the two isolated aromatic rings are conjugated with the carbonyl group, leading to an even greater increase in the stability of the keto-form:



Thus the appearance of tautomerism in a phenolic compound indicates a decrease in the aromaticity of the ring attached to the hydroxyl group. This is readily seen on going from phenol to other monohydroxy-derivatives of polycondensed aromatic compounds. The more extensive the polynuclear aromatic system, the greater the probability of conversion of the enol form into the keto-form, and the greater the stability of the keto-form. Thus the keto-form of hydroxynaphthacene (XIV) shows only a slight tendency to undergo enolisation, and the phenolic form of the pentacenes (XV) is unknown[4]:

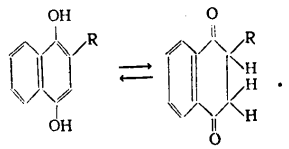


An attempt to bring about the isomerisation of (XV) in the usual way by heating in concentrated sodium hydroxide was unsuccessful. The isomer of hydroxynaphthacene — benzanthrol (XVI) — however, exists in both forms, which can be readily separated[71].

Of the above possible tautomeric transformations, the tautomerism of anthrol has been most studied. This is at present perhaps the simplest monohydroxyaromatic compound for which two isomeric forms are known to exist in equilibrium. As early as 1911, Mayer[18] found that the anthrol–anthrone equilibrium can exist in the absence of catalysts. A more detailed study[72] showed that in alcohol, 9-anthrone is enolised to the extent of only 11.5%. Slow cooling leads to crystallisation of the non-enolised product, but on rapid cooling the mixture contains crystals of 9-anthrol. The two forms are distinguished by their chemical properties. The keto-form shows a relatively low activity in the absence of catalysts bringing about enolisation. Heating in 10% sodium hydroxide for 10 min in a current of nitrogen with subsequent acidification leads to complete enolisation of anthrone. The reverse isomerisation takes place, however, when the resulting 9-anthrol is dissolved in ether, alcohol, or dioxan[73]. Alkylation of 9-anthrone by benzyl chloride in the presence of alkali gives 10,10-dibenzyl-9-anthrone. Hydrolysis of 9-benzyl--10-benzyloxyanthracene by treatment with hydrochloric acid leads to rapid isomerisation of the resulting 10-benzyl--9-anthrol into the corresponding anthrone[74]. Kinetic studies of the isomerisation of anthrol into anthrone showed that this reaction is of first order, the activation energy and rate of isomerisation depending to a marked extent on the solvent[75].

On going to polyhydroxy-derivatives of condensed hydrocarbons, all the above features are shown even more clearly, and the possibility of tautomeric transformations arises in dihydroxynaphthalenes containing both hydroxyl groups in the same ring, particularly if on formation of the keto-form the carbonyl groups are further stabilised by conjugation with the other aromatic ring. These changes were studied in

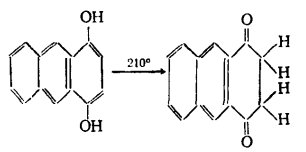
most detail by Thomson[4,76-80]. 1,4-Dihydroxynaphthalene (R = H) and 1,4-dihydroxy-2-methylnaphthalene (R = CH_3) on fusion (~ 200°) form equilibrium mixtures containing 10% of the diketo-forms (XVIII):[76,81,82]



(XVII) (XVIII)

Under ordinary conditions, however, both the dienol (XVII) and the diketone (XVIII) are stable compounds, and equilibrium between them does not exist. According to Braude's data[83], in the titration of the hydroquinone (XVII) with cerium sulphate in petroleum ether solution at 130°, the titre decreases gradually to a definite limit. Tautomeric equilibrium is evidently established under these conditions also. The reverse conversion of the diketone (XVIII) into the dienol (XVII) takes place when the diketone is dissolved in cold alkali and the resulting solution is acidified. Spectroscopic studies[76] showed that under ordinary conditions the diketone (XVIII) undergoes no structural changes in solution or in the solid state.

In the anthracene series the ability of 1,4-dihydroxy--derivatives to undergo conversion into the diketo-form is even greater, and this is naturally associated with a further decrease in the aromaticity of the phenolic ring. Thus on fusion (210°) 1,4-dihydroxyanthracene (XX) is converted in 50% yield into the corresponding 1,2,3,4-tetrahydro-1,4--diketoanthracene (XIX):[78]



(XX) (XIX)

Here the diketone is more stable than the dienol. The diketone can be converted into the dienol by dissolving in dilute alkali. Analogous properties are shown by 1,4-dihydroxy-9,10-diphenylanthracene[84]. The equilibrium 9,10-dihydroxyanthracene–anthraquinol system is also well known[85].

The stability of the diketo-forms of the 1,4-dihydroxy--derivatives of polycondensed compounds which we have considered increases appreciably when hydroxyl groups are introduced into the α-position of a neighbouring aromatic ring. This increased stability is due to the production of an intramolecular hydrogen bond in the keto-form as a result of the favourable spatial arrangement of the hydroxyl and carbonyl groups. In these compounds, the energy of aromatic delocalisation compensates not only the energy of enolisation of the two carbonyl groups, but also the additional energy of rupture of the hydrogen bond, and this should naturally decrease the stability of the enol form and displace the equilibrium (relative to the 1,4-dihydroxy-derivatives) towards the diketone[78,86] (see Table 2). The representatives of this series which have been most studied

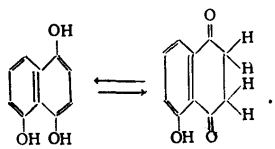
are 1,2,5-trihydroxynaphthalene (α-hydrojuglone) and its 2-methyl homologue[76,77] †:



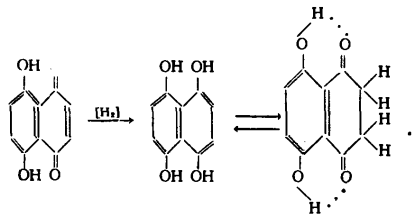
(XXI) (XXII)

The isomers (XXI) and (XXII) may exist in the equilibrium state in aqueous solution. The structures of both substances have been confirmed by spectroscopic data[76,87].

These regular features are shown even more clearly by 1,4,5,8-tetrahydroxynaphthalene, for which the conversion into the keto-form is accompanied by the production of two intramolecular hydrogen bonds. Accordingly, its keto--form (β-hydronaphthazarin) becomes more stable and this is naturally reflected in the properties of this compound.

† The diketone (XXII) — β-hydrojuglone — is present as glucosides in walnut extracts. Under the conditions of its extraction (boiling aqueous solution) it is partly converted into the enol--form — α-hydrojuglone[76].

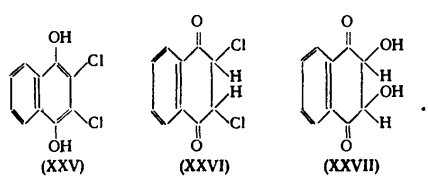
Thus 1,4,5,8-tetrahydroxynaphthalene (α-hydronaphthazarin) (XXIII), formed by the reduction of naphthazarin, is converted almost quantitatively under the conditions of the reaction into the isomeric β-hydronaphthazarin (XXIV):[88]



(XXIII) (XXIV)

The diketo-structure of β-hydronaphthazarin was proved by chemical methods[76,88]. Analogous behaviour is shown by the product of the reduction of quinizarin — leuco-quinizarin (1,2,3,4-tetrahydro-9,10-dihydroxy-1,4-diketoanthracene)[86,89]. The influence of the number of hydroxyl groups on tautomerism in the hydroxynaphthalene series is illustrated in Table 2.

A unique place in the 1,4-dihydroxynaphthalene series is occupied by compounds containing substituents (Hal, OH, SH, SO_3Na, etc.) capable of being removed. Here there are no reversible tautomeric transformations between the isomers, despite the fact that these compounds may exist in the individual state in both keto- and phenolic forms. These phenols are not converted into the diketones on fusion, since they usually decompose at elevated temperatures. On the other hand, the keto-forms, instead of enolising, are more readily converted into a quinonoid system with the removal of a molecule of an inorganic substance. Typical representatives of this type of compound are the isomeric 2,3-dichloro-1,4-dihydroxynaphthalene (XXV) and the dichlorodihydronaphthoquinone (XXVI). The latter readily loses a molecule of hydrogen chloride and is converted into 2-chloro-1,4-naphthoquinone[79].

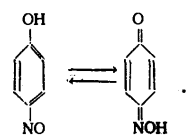


(XXV) (XXVI) (XXVII)

The keto-forms of these dihydroxynaphthalenes are in turn often obtained as a result of 1,2-addition to naphthoquinones[90-92]. Certain substituted diketones of the naphthalene series are nevertheless able to undergo irreversible enolisation — for example, (XVII) — but in these instances the reaction in this direction always competes with that involving elimination[93]. The individual properties of these compounds have been examined by Thomson[4].

3. TAUTOMERISM OF NITROSOPHENOLS

The introduction of electronegative substituents into the *ortho*- and *para*-positions of a phenol brings about a redistribution of the electron density in the molecule, leading to a decrease in the energy of aromatic conjugation and appreciable polarisation of the hydrogen–oxygen bond in the hydroxyl group. This facilitates the removal of hydrogen as a proton and leads to the appearance of keto–enol tautomerism. These features should be shown to the greatest extent in the nitrosophenol molecule, since the nitroso-group exhibits the greatest negative conjugation effect. Moreover, a distinguishing characteristic of the nitroso-group is its ability to combine with a proton using the unshared pair of electrons of the oxygen atom, with the formation of a hydroxyimino-group; this in turn should lead to additional stabilisation of the carbonyl form of the nitrosophenol as a result of the formation of a quinonoid system of conjugated bonds. Thus in the example which we are considering, there is on the one hand a decrease in the energy of aromatic conjugation in the phenolic form as a result of the presence of the nitroso-group and on the other hand an increase in the energy of enolisation of the carbonyl group, which is further stabilised by quinonoid conjugation. The final result of these two factors, operating in the same direction, is that in the nitrosophenol series the benzenoid (phenolic) form is less favoured than its isomeric quinone oxime form. Calculations by Jaffe[94] using the molecular orbital method showed that for 4-nitrosophenol the quinonoid state is favoured relative to the phenolic form to the extent of 4.6 kcal mole^{-1}. Experimental data published up to the present confirm that nitrosophenols exist chiefly in the quinonoid form. As a result, nitrosophenol $\rightleftharpoons$ quinone oxime tautomerism exhibits certain characteristic features compared with phenol–dienone tautomerism, particularly the marked sensitivity of the equilibrium to the medium, and the specific influence of substituents in the benzene ring:



Since in *o*-nitrosophenols an intramolecular hydrogen bond is formed, inevitably producing an additional influence on the characteristic features of the tautomeric equilibrium, we shall consider first the tautomerism of *p*-nitrosophenols.

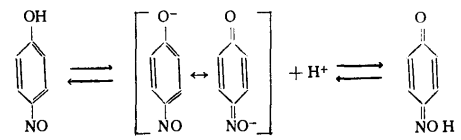
Facts indicating the tautomeric properties of *p*-nitrosophenol have been known for a long time. Bayer[95] as early as 1874, and later Goldsmidt[96], found that *p*-benzoquinone monoxime, formed by the reaction of *p*-benzoquinone with hydroxylamine, is identical in all respects to *p*-nitrosophenol obtained by the direct nitrosylation of phenol. It was found that in oxidation and reduction this compound behaves as a nitroso-compound, whereas on treatment with hydroxylamine it gives the quinone dioxime, that is, it reacts in the quinonoid form.

These data indicated the possibility of the reversible interconversion of *p*-nitrosophenol and *p*-benzoquinone monoxime. The first attempts to investigate the regular features of this transformation were undertaken using chemical methods[97-105] but no definite conclusions could be reached. The results obtained merely indicated the existence of a tautomeric equilibrium between the phenolic and

quinonoid forms. Thus it was shown that the phenolic form of nitrosophenols is converted into the quinonoid form by heating in the presence of acids [100,105] or by acidifying their alkaline solutions [106]. The two isomeric forms of the nitrosophenols give identical silver salts, which on treatment with methyl iodide give the methyl ethers of the benzoquinone oximes [102]. An analogous product is formed by the reaction of nitrosophenols with methyl sulphate in alkaline medium [102]. On the other hand, an attempt, using *p*-nitrophenylhydrazine, to determine the concentration of the quinonoid isomer in the products of the nitrosylation of phenol was unsuccessful, since all the nitrosophenol was converted into the corresponding *p*-nitrophenylhydrazone [102]. The reaction with diazomethane was found to be more suitable; diazomethane reacts with nitrosophenol in ether solution to give two products: glyoxime *NN'*-di-4-methoxyphenyl ether and benzoquinone 4-oxime *O*-methyl ether [104]. The results obtained could not be used, however, to determine the ratio of the tautomeric forms of the nitrosophenol. By 1930–1932 the opinion had been formed, on the basis of the above properties, that nitrosophenols exist chiefly in the phenolic form in the crystalline state and in inert solvents. Thus chemical methods proved unsuitable for the determination of the composition of tautomeric mixtures of nitrosophenols. The solution of these problems was made possible only by the application of spectroscopic methods, which without disturbing the equilibrium in the system, allowed its qualitative composition to be determined unambiguously and some information on its quantitative composition to be given.

The absorption spectrum of the products of the nitrosylation of phenols was first obtained by Hartley [107]. By comparing the spectrum of the products of the nitrosylation of phenol with the spectrum of *p*-nitrosoaniline, he established that the chief component of the mixture in ether solution is the quinonoid form. Baly [108], who repeated these studies, however, put forward the opposite opinion. This problem was later studied by Anderson [109]. By studying the absorption spectra of *p*-nitrosophenol in ether solution and comparing the results obtained with the spectra of the methyl ethers of the two isomeric forms of *p*-nitrosophenol, he showed that under these conditions the equilibrium mixture consists of approximately 70% quinone oxime and 30% nitrosophenol. Analogous results were obtained for solutions of nitrosophenol in dioxan, chloroform, and absolute alcohol. The most recent studies [110] of the infrared spectra of dilute solutions of *p*-nitrosophenol in carbon tetrachloride confirmed these data. When ultraviolet spectroscopy was applied to the study of the tautomerism of 2- and 3-substituted nitrosophenols, determination of the position of the maximum characteristic of the pure nitroso-form was found to be very difficult, since the equilibrium is generally displaced towards the quinonoid form and the more intense band due to the latter masks the band due to the nitroso--form. In this connection, the correctness of the interpretation of spectroscopic data in the determination of the characteristic features of the tautomerism of substituted nitrosophenols has been discussed [99,109,111,112].

The further development of spectroscopic methods has made it possible to return to this question and to solve the problem of determining the changes in the absorption spectra of the phenolic and quinonoid forms of nitrosophenols, irrespective of the number and nature of substituents [113]. In particular, detailed study of the spectroscopic properties of the products of the nitrosylation of phenol led a group of French workers [113-117] to recognise the existence of a three--component mixture in the tautomerism of nitrosophenols: the nitrosophenol, the quinone oxime, and an intermediate ionised form — the ambident ion‡:



Thus in the tautomerism of nitrosophenols, as in keto–enol tautomerism [1], the two forms first give up a proton with the formation of the same anion in each instance.

The use of spectroscopic methods has made it possible to establish the dependence of the equilibrium in a nitrosophenol–quinone oxime system on the nature of the solvent, the pH of the medium, and the position and nature of the substituents. In an aqueous medium, the above system of reversible transformations is considerably simplified and usually consists of two components. Moreover, under these conditions the tautomeric systems are extremely sensitive to changes in the pH of the medium only in the range from 3 to 7, and are independent of pH outside this range [112]. This phenomenon is associated with the ionisation of the two tautomers. In a strongly acidic medium (pH < 3), the ionisation should be suppressed, leading to a displacement of the equilibrium in one direction and the existence of only one neutral form, exhibiting the lowest acidity. In a strongly acidic medium this will in fact be the quinone oxime form. Similarly, in an alkaline medium (pH > 7) the un-ionised forms do not exist and in accordance with the total ionisation the intensity of the absorption becomes almost constant [112].

In a study of the ultraviolet spectra of aqueous solutions of unsubstituted *p*-nitrosophenol, the presence of two components (ionic and quinone oxime forms) in the system was confirmed by the existence of an isosbestic point [119]. These spectra were also used to calculate the dissociation constant of the oxime form ($pK = 6.21 \pm 0.03$); this quantity was also determined by conductimetric and potentiometric titration [119].

In neutral solvents, nitrosophenols exist in all three equilibrium forms, the quantity of ionic form increasing sharply with increase in the polarity of the solvent (ether, alcohol, water). The quantity of nitroso-form decreases and the proportion of oxime form increases in the same order [115].

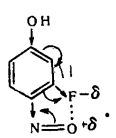
The introduction of alkyl substituents in the 2-position of the aromatic nucleus also increases the displacement of the entire system towards the quinonoid form. Thus in alcoholic solution, *p*-nitrosophenol and 3-methyl-4-nitrosophenol give maxima corresponding to all three forms (nitrosophenol, oxime, and ionic) with the oxime form predominating, whereas the introduction of alkyl substituents in the

‡ The *p*-nitrosophenol–quinone oxime tautomeric mixture was recently analysed by paper chromatography [118]. On the basis of the agreement between the calculated and experimental R_M values $\left(R_M = \log\left[\frac{1}{R_F} - 1\right]\right)$, it was assumed that the tautomeric mixture consists chiefly of nitrosophenol together with a small percentage of the oxime. No allowance was made, however, for the existence of the anionic form or for the exceptionally marked dependence of this equilibrium on the nature of the medium.

2-position leads to the disappearance or sharp decrease in the quantity of the nitroso-form in the equilibrium system [115]. Increase in the steric hindrance at the hydroxyl group, created by branched alkyl substituents, produces a completely quinonoid system — alcoholic solutions of these compounds contain only the oxime form [115]. This relationship has been studied in most detail by Finch [120] for 2,6-dialkylnitrosophenols where Alk = CH_3, C_2H_5, $CH(CH_3)_2$, or $C(CH_3)_3$. The opposite relationship is observed when the alkyl substituents are introduced into the 3,5-positions of the nitrosophenol. In this instance there is an increase in the proportion of the phenolic form in the tautomeric equilibrium in the order Alk = CH_3, C_2H_5, $CH(CH_3)_2$, and $C(CH_3)_3$. Branched substituents in the 3,5-positions apparently create additional steric hindrance to the conversion of the nitroso-form into the oxime form, and this naturally leads to an increase in the proportion of the benzenoid form [120].

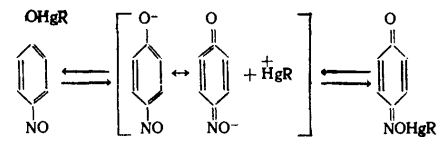
An analogous relationship is observed for the halogeno--derivatives of nitrosophenols. Thus the introduction of halogen into the 2-position of the aromatic nucleus displaces the equilibrium towards the oxime form [116]. An alcoholic solution of 2,6-dichlorobenzoquinone oxime contains only the oxime form with a small quantity of the ionised form. The same is observed for the corresponding bromo-derivatives [117]. The introduction of halogen into the 3-position, however, leads to a decrease in the proportion of the quinone oxime form in the equilibrium [115]

A unique position among halogeno-derivatives of *p*-nitrosophenols is occupied by 3-fluoro-4-nitrosophenol. This phenol cannot be converted into the isomeric 3-fluorobenzoquinone oxime. When its alkaline solution is heated and then acidified, the nitroso-form is precipitated unchanged [106]. This phenol also exists only in the nitroso--form in acidic and neutral media, irrespective of the nature of the solvent [121]. Spectroscopic studies [106] of 3-fluoro-4-nitrosophenol indicate extensive polarisation of the nitroso-group, leading to the formation of a partly bipolar structure, which by interaction of the fields may form a characteristic five-membered ring. With this bipolar structure, the oxygen atom of the nitroso-group is apparently unable to combine with a proton from the medium:



The regular features of the tautomeric equilibrium are not altered significantly on going from *p*-nitrosophenol to 4-nitrosonaphth-1-ol. With this also, the oxime form predominates in polar solvents [122], the ionic form predominates in alkaline medium [123], and the oxime form predominates in the solid state [124].

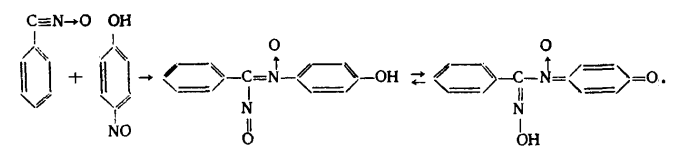
Tautomerism is also shown by the alkylmercury derivatives of *p*-nitrosophenols. In a study of the infrared spectra of these compounds, Nesmeyanov and Kravtsov [125] found that the intensity of the band due to the nitroso-group shows a definite relationship to the nature of the solvent and is independent of the concentration of substance. Since the infrared spectra indicate that in the solid state the alkylmercury derivatives of nitrosophenols have the quinone oxime structure, the observed phenomenon must be due to the existence of a tautomeric equilibrium with the intermediate formation of a common anion:



This feature is also shown by nitrosophenols with substituents in the ring, the introduction of alkyl substituents in the 2-position leading to a decrease in the concentration of the nitroso-form of the alkylmercury derivative in the solution.

An interesting feature is that interconversion of the isomers is also possible for the *O*-acetyl derivatives of nitrosophenols. For example, *O*-acetylnitrosophenol is converted quantitatively into the more stable *O*-acetylbenzoquinone oxime on recrystallisation [116].

Among other nitrosophenol derivatives, the possibility of tautomerism is observed in the products of the condensation of nitrosophenols with the oximes of certain nitriles; the 4-nitrosophenol derivative exists chiefly in the phenolic form, whereas the 1-nitrosonaphth-2-ol derivative exists in the quinonoid form [126]:

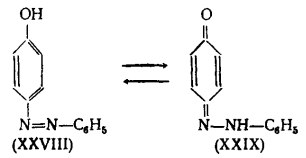


The regular features of the tautomerism of nitrosophenols are slightly different for the *ortho*-isomers. This is due to the existence [127] in these substances of an intramolecular hydrogen bond which has a fairly strong stabilising action on the nitroso-group, so that the energetic relationships between the phenolic and quinonoid (here, *ortho*--quinonoid) structures is altered slightly and the benzenoid form of the nitrosophenol is preferred. The ultraviolet spectra [127] show that *o*-nitrosophenol exists only in the phenolic form in non-polar solvents. The introduction of substituents exhibiting positive conjugation effects into the *para*-position relative to the nitroso-group, however, facilitates the rearrangement of the nitroso-group into the oxime group. Thus 2-nitroso-5-methoxyphenol and 2-nitroso--5-dimethylaminophenol [127] exist in solution in the form of tautomeric mixtures; the quinonoid form predominates, and its concentration increases with increase in the polarity of the solvent. These spectroscopic data agree with certain chemical properties. In particular, the crystallisation of 2-nitroso-5-methoxyphenol [128] from ethanol and benzene gives crystals with different appearance and melting points. These were assumed to be two tautomeric forms. With the *o*-nitrosophenols of the naphthalene series (1-nitrosonaphth-2-ol and 2-nitrosonaphth-1-ol) there is tautomeric equilibrium with the nitroso-form predominating [129].

4. TAUTOMERISM OF AZOPHENOLS

The azo-coupling of phenols, together with the data obtained by Zincke [130], who showed that hydroxyazo-compounds with analogous structure are formed by the action of arylhydrazines on the corresponding quinones, indicated the

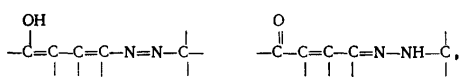
possibility of tautomeric equilibrium between azophenols and quinone arylhydrazones. A number of authors [131-138] suggested that this equilibrium is an ordinary prototropic transformation with migration of a proton between the nitrogen atom and the phenolic oxygen. This transformation is accompanied by rearrangement of the benzenoid bond system into a quinonoid system or by the opposite rearrangement of the quinonoid system into the benzenoid system:



(XXVIII) (XXIX)

The first studies of this tautomerism by chemical methods were carried out in 1929, when Borshe and coworkers [139] used dinitrophenylhydrazine to isolate the hydrazone form (XXIX) as the dihydrazone from the tautomeric mixture. The results obtained were not conclusive, since the dihydrazone can be formed directly from the monohydrazone by heating in acidic medium. Attempts to prove the existence of tautomerism in the azophenol series by chemical methods include the use of the reaction with cyclopentadiene, which according to the diene synthesis scheme gives the products of the addition to the quinonoid ring of the hydrazone form [140]. Direct confirmation of tautomerism in the azophenol series by isolation of both tautomeric forms from the equilibrium mixture has not been obtained. Only the use of spectroscopic methods made it possible to study effectively the regular features of the tautomerism of azophenols [141-152]. The successful solution of this problem was greatly assisted by the distinct separation of the spectroscopic characteristics of these tautomeric forms in the ultraviolet range.

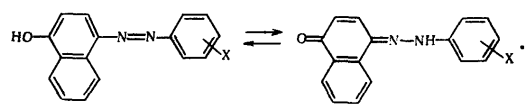
The energetic relationships for the formation of the two forms (azophenol and quinone hydrazone) facilitate tautomerism to a greater extent than in the unsubstituted phenols. Summation of the bond energies of the systems



gives 432 kcal mole^{-1} for the enol-form and 456 kcal mole^{-1} for the keto-form, that is, the formation of the keto-form is favoured to the extent of 24 kcal mole^{-1}. Thus the energy of enolisation of the carbonyl form (particularly with allowance for the quinonoid conjugation) of the azophenols is much greater than the energy of enolisation required in the formation of unsubstituted phenols, leading to a lower stability of the aromatic system. Hence the factors determining the appearance of tautomerism in the phenol series (see p. 818) should be shown even more clearly in the azophenols. The accumulation of aromatic rings condensed with the azophenol nucleus does in fact lead to more rapid conversion of the phenols into the isomeric quinonoid compounds. Thus in the solid state, compounds of the benzene series exist in the benzenoid form, whereas derivatives of the naphthalene and anthracene series exist only in the quinonoid form [149]. In solutions this change is more regular [150,153]. For example, 4-phenylazophenol always exists in only one form and exhibits a single absorption maximum (343 nm) corresponding to the azo-form, whereas 4-phenylazonaphth-1-ol and 4-phenylazoanthr-1-ol show maxima corresponding to the azophenol form (392 and 442 nm respectively) and the quinone hydrazone form (475 and 506 nm). Finally, 9-phenylazoanthr--10-ol shows only one maximum in the ultraviolet range, corresponding to the quinone hydrazone form [151]. Thus among the *p*-azophenols which we have considered, tautomeric equilibrium is found only in the derivatives of 4-azonaphthols and related compounds.

The influence of the nature of the substituents on the tautomerism of azophenols is also shown extremely clearly. Here, all the regular features characteristic of the tautomerism of phenolic compounds are preserved. The introduction of electron-accepting substituents into the molecule leads to an increase in the concentration of the keto-form, whereas the presence of electron-donating substituents facilitates the production of aromatic properties in the ring and displaces the equilibrium towards the phenolic structure. It should be noted that tautomerism is found only in the phenyl(or aryl)azophenols, but not in alkylazophenols. This is due to the fact that the phenylazo-group produces a greater displacement of electrons into the aromatic ring of the phenol, facilitating the removal of a proton and conversion into the carbonyl form. A similar influence is shown by the introduction of substituents into the phenyl nucleus of the hydrazone.

All the regular features of the influence of substituents on the tautomeric equilibrium have been studied for 4-azonaphth-1-ol derivatives:



The data [154-156] in Table 3 show the influence of substituents in the phenyl ring of the hydrazone on the tautomeric azophenol ⇌ quinone hydrazone system. The ratio of the extinctions ($\epsilon_{hydrazo}/\epsilon_{azo}$) indicates approximately the proportions of the tautomers in the equilibrium mixture. Electron-donating substituents decrease this ratio, that is, they decrease the proportion of hydrazo-form, whereas electron--accepting substituents increase this ratio. A characteristic feature is that the introduction of substituents in the 2-position usually increases the proportion of the hydrazone tautomer to a much greater extent than the introduction of an analogous group in the 4-position. This anomaly is related to the possibility of intramolecular hydrogen bond formation. Thus the introduction of a carboxyl group in the 2-position [157] stabilises the hydrazone form as a result of the formation of an intramolecular hydrogen bond. Maximal stability of the keto-form, as expected, is shown by the 2,4-dinitrophenylhydrazones. Here the negative conjugation effect of the substituent in the phenol molecule

TABLE 3. Influence of substituents on the tautomerism of azonaphthols.

Substituent X	4-Arylazonaphth-1-ol $\epsilon_{hydrazo}/\epsilon_{azo}$	1-Arylazonaphth-2-ol $\epsilon_{hydrazo}/\epsilon_{azo}$	Substituent X	4-Arylazonaphth-1-ol $\epsilon_{hydrazo}/\epsilon_{azo}$	1-Arylazonaphth-2-ol $\epsilon_{hydrazo}/\epsilon_{azo}$
4'-NH_2	—	0.17	3'-OCH_3	0.89	1.41
4'-OH	—	0.40	3'-Cl	1.50	—
4'-OCH_3	0.22	0.45	3'-NO_2	1.90	2.0

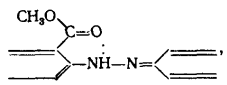
4'-$COOCH_3$	2.0	—	2'-$COOCH_3$	2.0	—

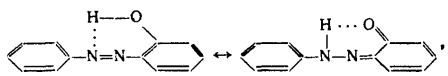
increases to such an extent that tautomerism is possible in mononuclear azophenols [140].

In the 4-phenylazonaphth-1-ol series, the NH and OH groups present in the hydrazo- and azo-tautomeric forms, are able to form hydrogen bonds with the solvent. Since these bonds have different strengths, the tautomers may be stabilised by these bonds to different extents. Moreover, substituents in the 2-position of the benzene ring will also influence the strength of the hydrogen bonding with the solvent, either by the formation of intramolecular hydrogen bonds of the type



or by creating steric hindrance to the formation of an intermolecular hydrogen bond. The influence of solvents on the tautomeric equilibrium has also been studied [148] for 4-phenylazonaphth-1-ols. For the 3′- and 4′-substituted compounds the concentration of the hydrazone tautomer increases with increase in the polarity of the solvent in the order: hexane < benzene < chloroform < 50% ethanol < < CH_3COOH. The picture is complicated considerably in the presence of 2-substituents capable of forming intramolecular hydrogen bonds (Cl, OCH_3, etc.). The proportion of hydrazo-form is smaller in polar solvents (water, ethanol, CH_3COOH) than in hexane, benzene, and chloroform. An explanation for this anomaly is apparently to be found in the competition between intramolecular and intermolecular hydrogen bond formation.

In the tautomerism of *o*-azophenols, the energetic relationships favour the formation of the carbonyl form to an even greater extent, again as a result of the production of an intramolecular hydrogen bond. As a result of this additional factor, tautomeric equilibrium is established between two isomeric forms even in solutions of 2-phenylazophenol [150]. It should be recognised that in *o*-phenylazophenol and *o*-phenylazonaphthols, intramolecular hydrogen bonding should also be shown by the phenolic form. It was first assumed [136,137,158,159] that these substances do not exhibit tautomeric properties, for the presence of the intramolecular hydrogen bond leads to the production of a mesomeric hybrid of the type:



that is, a delocalised hydrogen bond should be formed. Later spectroscopic studies [148,155,160] showed, however, that the system contains both isomers and that the intramolecular hydrogen bond is essentially static, leading to polarisation of the molecule and facilitating tautomerism.

The action of the other factors influencing the tautomeric equilibrium of *o*-azophenols is the same as that for *p*-azophenols. Table 3 gives data characterising the influence of the nature and position of substituents for 1-phenylazonaphth-2-ol. The effect differs little from those observed in the *para*-derivatives. The introduction of electron-donating substituents again displaces the equilibrium towards the azo-form and the introduction of electron-accepting substituents displaces it towards the hydrazo-form [155,156].

Table 4 gives data showing the influence of solvent on the equilibrium system for 1-(4-methoxy-3,5-dimethylphenylazo)naphth-2-ol and compares the results with those

TABLE 4. Influence of solvent on the equilibrium for 1-(4-methoxy-3,5-dimethylphenylazo)-naphth-2-ol.

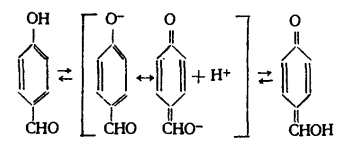
for the equilibrium constants (C_{enol}/C_{ketone}) for acetoacetic ester and acetylacetone [155]. There is a complete analogy in the influence of the substituents (Table 4). In all series the keto-structures are present in higher concentration in the more polar solvents.

5. EQUILIBRIUM PHENOL–QUINONOID TRANSFORMATIONS OF *p*-SUBSTITUTED PHENOLS

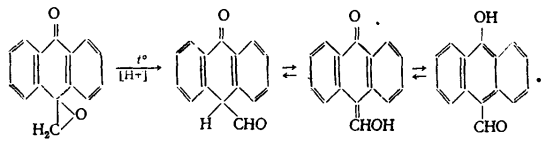
As already noted, the presence of electron-accepting groups in a phenol molecule should facilitate phenol–quinonoid tautomerism. In principle, this property may be shown by any phenol containing carbonyl, carboxyl, carbalkoxyl, nitrile, nitro- and other analogous groups in the *para*-position and, to a lesser extent, in the *ortho*-position. For example, for *p*-hydroxybenzaldehyde this transformation might be represented by the following equilibrium:



The displacement of the electrons in the aromatic ring under the influence of the negative conjugation effects of these substituents is generally insufficient, however, for the formation of a compound with a quinonoid bond system. Usually, this transformation requires the additional influence of other factors on the phenol molecule. The greatest influence in this direction is shown by steric hindrance, the decrease in the aromaticity of the phenol nucleus in condensed systems, and binding of the phenolic hydrogen by the medium. In the last, reversible equilibrium between the neutral phenolic form and a quinonoid anion may be established.

Published data show that the existence of the above tautomeric systems is possible. Thus study of the rearrangement of the epoxide of 9-methylene-10-anthrone [161,162] gave a yellow-orange substance with m.p. 206–208°, which according to the method of preparation and analysis should be 9-formyl-10-anthrone. The high acidity of the product (its strength is close to that of benzoic acid) indicates, however,

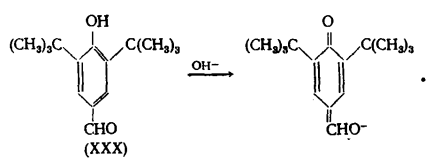
that it is present in equilibrium with the hydroxy-forms 9-formyl-10-anthrol and 9-hydroxymethylene-10-anthrone.



The existence of this ternary equilibrium was also confirmed by chemical and spectroscopic methods [162].

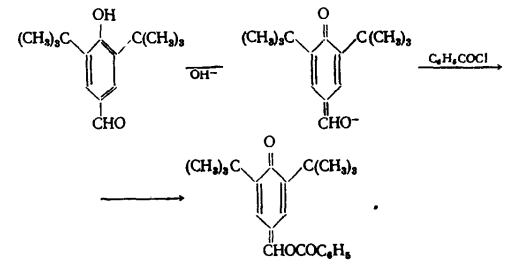
On going to the benzene series, it is difficult to reach definite conclusions regarding the tautomerism of hydroxybenzaldehyde. Thus Bartel [163], in a polarographic study of *p*-hydroxybenzaldehyde at pH 5.4–7.2 detected two polarographic waves similar to dissociation waves. These could not be attributed to ionised and un-ionised forms of the aldehyde, however, since the dissociation of *p*-hydroxybenzaldehyde in this pH range is too small. Even in a strongly alkaline medium, only neutral molecules are depolarised at the cathode. The existence of two waves might be attributed to tautomerism, but the absence of direct experimental data makes this suggestion extremely hypothetical.

The greatest quantity of material has appeared in connection with the study of the properties of phenols exhibiting steric hindrance. This is not surprising, in view of the general tendency for 2,6-disubstituted phenols and their derivatives to form stable quinonoid or quinolide structures [164–166]. The most typical compound in this respect is 3,5-di-t-butyl-4-hydroxybenzaldehyde (XXX), which exhibits extremely specific properties in an alkaline medium. Thus unlike the unsubstituted 2,6-di-t-butylphenol, it dissolves readily in alkalis, and this can be attributed only to the formation of a phenoxide ion in the isomeric dienone–enolate form. Careful neutralisation of alkaline solutions of this aldehyde leads to the quantitative separation of the aldehyde form [167]:



Spectroscopic studies [167,168] of alkaline solutions of (XXX) also indicate formation of the enolate form. When the aldehyde (XXX) is dissolved in alkalis, the absorption maximum in the ultraviolet spectrum (λ_{max} = 290 nm) is displaced towards longer wavelengths (λ_{max} = 370 nm). Absorption in this range is characteristic [169] of certain quinone methides and alkoxy-derivatives of quinone methides, with analogous structure. The infrared spectrum of an alkaline solution of (XXX) does not contain the band corresponding to an aromatic aldehyde, but shows an absorption band characteristic of conjugated carbonyl in quinone methide compounds, usually observed as an averaged band at 1618 cm^{-1} or split to form a doublet [170,171] in the region of 1610–1630 cm^{-1}. Finally, isolation of the sodium salt of 3,5-di-t-butyl-4-hydroxybenzaldehyde in crystalline form [167] showed that this compound also gives only the quinonoid bond system.

The quinonoid structure of the salt of the benzaldehyde (XXX) is also confirmed by chemical reactions. When the finely ground salt is heated in dry hexane with benzoyl chloride in a current of inert gas, the only product is 2,6-di-t-butylbenzoylhydroxyquinone methide [167]. The reaction with an alkaline solution of the benzaldehyde is analogous [168]:



These properties of 3,5-di-t-butyl-4-hydroxybenzaldehyde cannot be related to typical tautomerism, since in this example, as for phloroglucinol (see p. 820), the equilibrium apparently involves the un-ionised phenolic form and the dienone–enolate anion, whose formation is due to the transfer of the negative charge to the *p*-substituent from the strongly polarised π-electron bond.

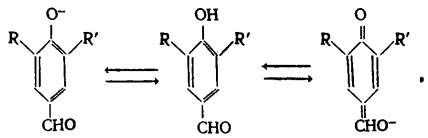
Properties analogous to those of 3,5-di-t-butyl-4-hydroxybenzaldehyde are shown by certain other 3,5-dialkyl-4-hydroxybenzaldehydes. Nikiforov and Ershov [167] recently studied the influence of alkyl substituents on the equilibrium between these aldehydes and their salts. The infrared spectra of solid specimens showed that the salts of 3,5-di-t-butyl-4-hydroxybenzaldehyde (XXX; R = R′ = CMe_3), 4-hydroxy-3,5-di-isopropylbenzaldehyde (XXXI; R = R′ = $CHMe_2$), and 5-t-butyl-4-hydroxy-3-methylbenzaldehyde (XXXII; R = CH_3, R′ = CMe_3) have a quinonoid structure, whereas salts of *p*-hydroxybenzaldehyde (XXXIV; R = = R′ = H) and 4-hydroxy-3,5-dimethylbenzaldehyde (XXXIII; R = R′ = CH_3) exist in the phenoxide form. Salts of the aldehydes (XXX), (XXXI), and (XXXII) in solution naturally may not have the classical quinonoid structure, since the distribution of the negative charge should be influenced significantly by the solvation of the entire molecule as a whole. There is no doubt, however, that the structure of these anions is close to the quinonoid structure, and this is responsible in particular for the ready solubility of these aldehydes in aqueous alkalis. This conclusion is confirmed by the ultraviolet spectra of the alkaline solutions and also by the equilibrium constants for the formation of the salts of 3,5-dialkyl-4-hydroxybenzaldehydes (Table 5).

For 3,5-dialkyl-4-hydroxybenzaldehydes exhibiting steric hindrance, the value of the constant is smaller and decreases monotonically with decrease in the steric hindrance at the phenolic hydroxyl, but it subsequently increases sharply on

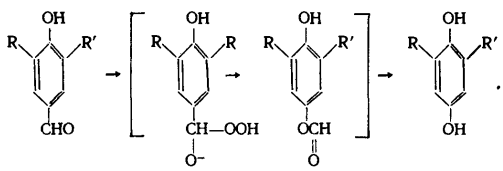
TABLE 5. Ultraviolet spectra and ionisation constants of 4-hydroxybenzaldehydes.

Compound No.	4-Hydroxy-3,5-dialkylbenzaldehyde	Ultraviolet spectra λ_{max} neutral	Ultraviolet spectra λ_{max} alkaline	Ultraviolet spectra Δλ	$10^9 K$
XXX	3,5-di-t-butyl	290	367	77	4.21
XXXI	3,5-di-isopropyl	290	356	66	3.80
XXXII	3-methyl-5-t-butyl	290	358	68	2.51
XXXIII	3,5-dimethyl	289	351	62	8.51
XXXIV	4-hydroxybenzaldehyde	285	336	51	11.48

going to the aldehyde with methyl substituents and the unsubstituted *p*-hydroxybenzaldehyde, and increases further



in the reverse order. For phenols as a whole, a decrease in dissociation constant with increase in the steric hindrance at the phenolic hydroxyl is characteristic. An analogous phenomenon is also observed in the formation of phenoxide salts of the hydroxyaldehydes (XXXIII) and (XXXIV), but the observed reverse relationship in compounds (XXX)–(XXXII) is due to the fact that the steric factor facilitates the phenol–dienone bond rearrangement and hence facilitates the formation of the quinonoid anion. These conclusions agree with data obtained from the infrared spectra of salts of *p*-hydroxybenzaldehydes and are confirmed by certain chemical reactions of these compounds, taking place in alkaline medium [172]. The most characteristic in this respect is Dakin's reaction. According to the mechanism accepted at present [173,174], this reaction passes through a stage involving the addition of hydrogen peroxide to the carbonyl group:



In practice, a marked decrease in the reaction rate is observed for hydroxyaldehydes with bulky alkyl substituents [172]. This is apparently due to the fact that these hydroxyaldehydes in alkaline medium (the conditions of Dakin's reaction) exist chiefly in the quinonoid–enolate form.

The influence of steric hindrance at the phenolic hydroxyl on the ease of formation of the quinonoid bond system has been followed most thoroughly in a study of the equilibrium between hydroxyphenyldiazonium salts and quinonediazides [174,175]:

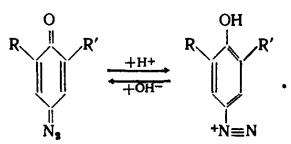


TABLE 6. Influence of substituents on the equilibrium conversion of quinone diazides into diazonium salts.

2,6-Dialkyl-p-quinone diazide	pK
p-Quinone diazide	3.19
2,6-Dimethyl	2.83
2-Methyl-6-t-butyl	2.72
2,6-Di-isopropyl	2.76
2,6-Di-t-butyl	1.65

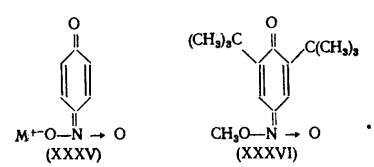
TABLE 7. Influence of *para*-substituents on the displacement of the absorption maximum in the ultraviolet spectrum of 4-substituted 2,6-di-t-butylphenols.

R	2,6-Di-t-butyl-4-R-phenol			R	2,6-Di-t-butyl-4-R-phenol		
	neutral, λ_{max}	alkaline, λ_{max}	$\Delta\lambda$		neutral, λ_{max}	alkaline, λ_{max}	$\Delta\lambda$
$C(CH_3)_3$	223	251	28	$COOC_2H_5$	261	324	63
CH_3	222	250	28	$COCH_3$	284	363	79
H	214	244	30	CN	252	307	55
Br	226	257	31	CHO	293	370	77
$CONH_2$	258	321	63	NO_2	325	450	125

The data [175] in Table 6 show that with increase in the steric hindrance at the phenolic hydroxyl, the equilibrium is displaced towards the formation of the quinonoid bond system, so that conversion of the quinonediazide into the diazonium salt requires an increasingly acidic medium. A characteristic feature is that the stability of the quinonediazides in the solid state increases in the same order [176].

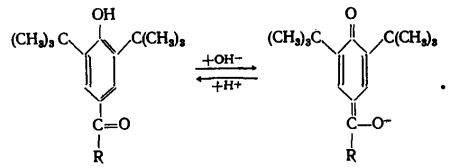
Since *o*-t-alkyl groups favour the formation of the quinonoid system to the greatest extent, a spectrophotometric study was made of the influence of various substituents on the behaviour of 4-substituted 2,6-di-t-butylphenols in alkaline medium [177,178]. The magnitude of the bathochromic shift (Table 7), which provides a criterion of the formation of a quinonoid system, increases with increase in the negative conjugation effect of the substituent, and differs considerably from the shift produced on the formation of ordinary phenoxide ions. In these examples we must naturally have in mind only the preferential location of the negative charge on the *para*-substituent. For phenols which do not contain alkyl substituents in the *ortho*-positions, the corresponding values of $\Delta\lambda$ are smaller, indicating greater delocalisation of the electron density throughout the molecule as a whole.

The greatest difference in absorption in alkaline medium is shown by 2,6-di-t-butyl-4-nitrophenol. The possibility of the reverse conversion of the neutral phenolic form of nitrophenols into the ionised quinonoid *aci*-form is also confirmed by certain chemical data. Thus *p*-nitrophenol salts which have been isolated are assigned the structure (XXXV): [179-181]

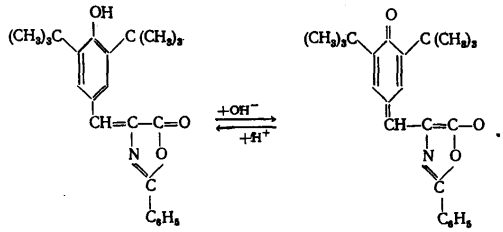


Methylation of 2,6-di-t-butyl-4-nitrophenol [177] gave a compound to which, on the basis of its chemical properties and spectroscopic data, was assigned the ether structure (XXXVI). It should be noted that in the methylation of 2,6-di-t-butyl-4-cyanophenol, only the normal *O*-methyl ether was isolated. The difference evidently excludes the influence of steric hindrance on the direction of the methylation of this nitrophenol. Finally, early papers [182] describe the methyl ether of the quinonoid form of *o*-nitrophenol. Unfortunately, the problems of reversible transformations in the nitrophenol series have as yet been insufficiently studied, so that no conclusions can be reached regarding the tautomeric transformation of nitrophenols.

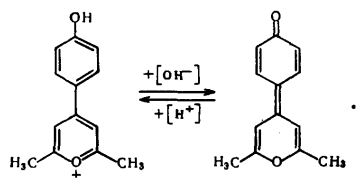
Spectroscopic data and the anomalous solubility in alkalis indicate [170,178,183] the existence of an equilibrium in the formation of salts of 4-benzoyl-, 4-cyano-, and 4-carbethoxy--2,6-di-t-butylphenols.



An analogous phenomenon is apparently observed in the formation of salts of 4-(3,5-di-t-butyl-4-hydroxybenzylidene)-2-phenyl-5-oxazolone [184]:

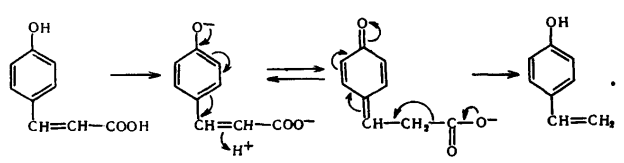


Very interesting behaviour in alkaline medium is shown by certain pyrylium salts containing phenolic substituents in the 4-position. Here the formation of the phenoxide ion should give a compound with a bipolar structure, with opposite charges on the oxygen atoms, established by the quinonoid conjugation extending over both rings [185].

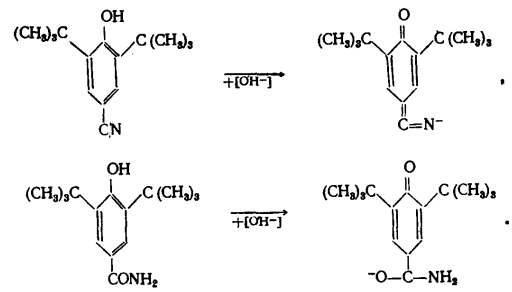


4-Substituted phenols on the whole show a distinct tendency to form a quinonoid bond system in reactions involving these substituents. These transformations are generally not tautomeric, however, but are related to the equilibrium between the ionised and un-ionised substance. Such transformations apparently explain the influence of the steric factor, facilitating formation of the quinonoid system, on the decarboxylation of *p*-hydroxycinnamic acids [186], the hydrolysis of *p*-hydroxybenzamides and nitriles [187], and the hydrolysis of the corresponding *N*-benzoyltyrosines and *N*-benzoyltyramines [188], taking place in alkaline medium.

In weakly alkaline solution, *p*-hydroxycinnamic acid is decarboxylated fairly rapidly, the reaction rate decreasing at pH < 9. This phenomenon can be attributed to the fact that protonation of the doubly-charged anion produces a quinonoid structure, which undergoes rapid decarboxylation:



The maximum corresponding to aromatic absorption in the ultraviolet spectrum of *p*-hydroxycinnamic acid in alkaline medium is displaced by 35 nm (310 nm → 345 nm), and this may indicate the presence of the quinonoid anion. This displacement is twice as large for 3,5-di-t-butyl-4-hydroxycinnamic acid (70 nm); the alkaline solution acquires a yellow colour, which disappears on acidification. The doubly-charged anion of this acid evidently exists in the quinonoid form. Its decarboxylation at pH 8.5 is 2.5 times faster than that of unsubstituted *p*-hydroxycinnamic acid [186]. An approximately analogous influence of the steric factor is observed in the hydrolysis of the amides and nitriles of the corresponding benzoic acids. Table 8 gives the rates of hydrolysis [187] of the benzamides and benzonitriles in alkaline medium. Comparison of the rates shows that the hydrolysis of 4-hydroxybenzamides and nitriles is 30 times faster than hydrolysis of their 4-hydroxy-3,5-di-t-butyl analogues. The rate of hydrolysis increases sharply for the 4-methoxy-derivatives. These facts are in good agreement with the assumption that an anion with the quinonoid structure exists under the conditions of the reaction:



The hydrolysis of *N*-benzoyltyrosines and *N*-benzoyltyramines is more complex [188]. These compounds are of interest since it is possible to establish a dienone structure with the formation of spirocyclic systems. Here again, the influence of the steric effect is clearly shown. Thus the rate of hydrolysis of 3,5-di-t-butyl-*N*-benzoyltyrosine is about half the rate of hydrolysis of *N*-benzoyltyrosine, and the corresponding rates for substituted and unsubstituted benzoyltyramines differ by a factor of 7.

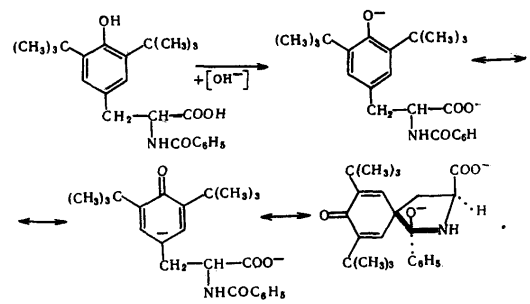


TABLE 8. Rate constants for the hydrolysis of benzamides and benzonitriles.

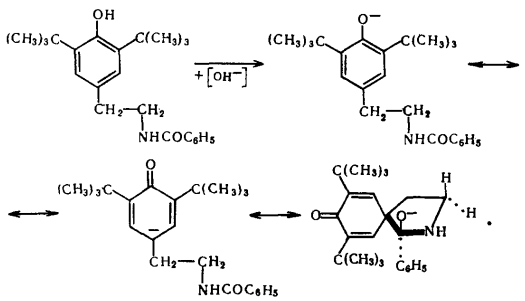
Compound		$10^6 K$, min^{-1}
Benzamides	4-hydroxy	63
	4-methoxy	963
	4-hydroxy-3,5-di-t-butyl	2
	4-methoxy-3,5-di-t-butyl	505
Benzonitriles	4-hydroxy	125
	4-methoxy	3000
	4-hydroxy-3,5-di-t-butyl	4
	4-methoxy-3,5-di-t-butyl	2000

The formation of a labile spirodienone should decrease the concentration of the *N*-benzoyl derivative, suitable for attack by an external base. The ratio of the rates shows that this factor increases in the tyramine series, since the formation of the spirodienone is then favoured to a greater extent in the hydrolysis of *N*-benzoyltyrosines:



---oOo---

Tautomeric transformations in the phenol series are extremely interesting, since the phenomenon of tautomerism, which is widely encountered in organic chemistry, is here associated with the breakdown of an aromatic bond system. On the other hand, the questions examined above may also be useful for an understanding of many of the transformations of phenols and their derivatives, of definite practical importance. Unfortunately, most work on the tautomerism of phenolic compounds is chiefly qualitative in character. The investigation of strict quantitative relationships governing this phenomenon will undoubtedly be of considerable interest.

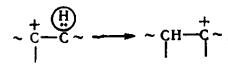
ANOMALOUS POLYMERISATION OF SOME VINYL MONOMERS

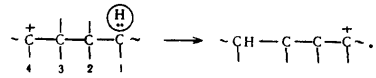
N. D. Prishchepa, Yu. Ya. Gol'dfarb, and B. A. Krentsel'

The problem of the regulation of the chain structure of polymers has always attracted the attention of many investigators. The discovery of stereospecific polymerisation was a great step forward in this direction. One of the interesting possibilities of regulating the chemical structure of macromolecules consists in changing the structure of the monomeric unit during the course of the polymerisation. This process, usually termed conversion or isomerisation polymerisation, results in the growth of the polymeric chain with simultaneous migration of a labile hydrogen atom or group of atoms.

Until now the most characteristic examples of anomalous polymerisation were observed mainly in cationic polymerisations, which are accompanied by the migration of a hydride ion [1]:



The hydride ion can migrate not only to neighbouring carbon atoms but also to those more distant:



Some authors [2,3] think that the transfer of hydrogen should be sequential: 1–2, 2–3, 3–4, etc.; others [4–6], that the migration takes place directly: 1–3, 1–4, etc.

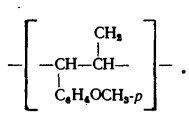
It is noteworthy that hydride transfer reactions have long been known in organic chemistry. Thus, to explain isomerisation, alkylation, cracking, and other reactions, many schemes involving intramolecular or intermolecular migration of hydrogen have been proposed [7–16].

The first suggestions about the possibility of hydrogen migration in polymerisation were made by Staudinger and Dreher [17] in 1935 in studying the polymerisation of β-methylstyrene and acetone. They performed the polymerisation in the presence of tin(IV) chloride and boron trifluoride in toluene at temperatures from 0° to -78° and suggested that polymerisation does not proceed in the usual way but with migration of a labile hydrogen of the methyl group, that is, 1,3-polymerisation occurs:

$$C_6H_5CH{=}CHCH_3 \rightarrow -C_6H_5CHCH_2CH_2 \longrightarrow -(C_6H_5CHCH_2CH_2-)_n.$$

Ozonation and pyrolysis were used to determine the structure of the polymers. Ozonation did not give results. β-Methylstyrene and acetone, and a little 1,4-diphenylbutadiene and 1,4-di-(*p*-methoxyphenyl)butadiene were detected in the products from pyrolysis at 300°.

The presence of these compounds in the pyrolysis products is attributed to the initial macromolecules having contained structures formed as a result of anomalous polymerisation. Later, a group of Hungarian scientists verified Staudinger and Dreher's results [18]. They polymerised anethole in benzene solution in the presence of tin(IV) chloride and titanium(IV) chloride at room temperature. On investigating the product, they concluded that the polyanethole had the general structure:



On comparing the results of the work of Staudinger and the Hungarian scientists, it is obvious that the conditions of the experiments were not identical; Staudinger carried out the polymerisation at low catalyst concentrations; the Hungarians studied the polymerisation at room temperature with high catalyst concentrations.

Italian scientists investigated the polymerisation of anethole in the presence of aluminium chloride, titanium(IV)

TABLE 1. Polymerisation of anethole on boron trifluoride.

Temperature, °C	Solvent	Degree of polymerisation	No. of C–CH_3 groups present in one molecule	Proportion of 1,2-structure in polymer, %
+15	ether	5.6	3.2	57
+15	ether	5.9	3.7	63
+15	dioxan	4.4	2.7	64
0	ether	7.1	5.5	77
−15	ether	8.3	6.9	83
−77	ether	9.4	7.6	81
−77	petroleum ether	11.2	9.8	87

chloride, and boron trifluoride at various temperatures [19,20]. By using the molecular weight of the polymers and the chemically determined number of CH_3–C groups in the molecule [20], the authors showed the presence of a 1,3-structure in polyanethole. Table 1 shows that a rise in temperature favours 1,3-polymerisation (correspondingly, the proportion of 1,2-structure in the chain decreases).

Kennedy [21] repeated the experiments on the polymerisation of β-methylstyrene and concluded, from the infrared spectra of the polymer obtained in methyl chloride in the presence of aluminium chloride at -60°, that it has the ordinary structure:

$$-\left[\begin{array}{l} \quad\quad CH_3 \\ -CH-CH- \\ \quad | \\ \quad C_6H_5 \end{array}\right]-.$$

Hence the contradictory results do not allow a definite conclusion to be drawn concerning the nature of the polymerisation of β-methylstyrene and anethole.

In 1955, the attention of our laboratory was drawn to the fact that in poly-(2-methylprop-1-ene) (polyisobutylene) obtained on a Ziegler catalyst the ratio of the number of CH_2 groups differed from the ratio of these groups in ordinary poly-(2-methylprop-1-ene): [22]

$$CH_2{=}C(CH_3)_2 \rightarrow -CH_2C(CH_3)_2CH_2C(CH_3)_2-, \quad (1)$$

usual structure of poly-(2-methylprop-1-ene)

$$CH_2{=}C(CH_3)_2 \rightarrow -CH_2CH(CH_3)CH_2CH_2CH(CH_3)CH_2-. \quad (2)$$

anomalous structure of poly-(2-methylprop-1-ene)

This observation could be interpreted as the polymerisation of 2-methylprop-1-ene on the triethylaluminium + + titanium(IV) chloride catalytic system yielding an anomalous polymer due to hydrogen migration. Because of this a detailed study of the polymerisation of 2-methylprop-1--ene was undertaken. The task was to find conditions under which the migration rate of the labile hydrogen atom would be commensurate with the rate of the ordinary vinyl polymerisation.

Infrared spectroscopy and an analysis of molecular weight distribution were used to determine the structure of the poly-(2-methylprop-1-ene). [23]

The usual method of studying polymers on the ultracentrifuge — from the development of sedimentation diagrams — seemed inapplicable to the poly-(2-methylprop--1-ene)s synthesised; therefore a method was used which allowed the mean molecular weight of any soluble polymers to be determined directly by analysis of the distributed concentrations in the solid layer of a sedimentation cell during the period before the sedimentation equilibrium was established [24].

The sedimentation measurements were made in a large oil ultracentrifuge at 30 000 rev min^{-1}. The molecular weight distribution curves for specimens of poly-(2-methylprop-1-ene) were constructed by use of the weight average M_w and the z-average M_z molecular weights and some model function [25] (see Fig. 1 and Table 2). The correct choice of model function was confirmed for four specimens by a series of experiments which included the measurement of the molecular weights of the specimens by hydrodynamic properties: sedimentation coefficients, diffusion coefficients, and characteristic viscosity [25]. The distribution function of one of the specimens (1) differed significantly from those of the others. It is noteworthy that this specimen was obtained at an Al/Ti ratio of 5 : 1, that is, when the infrared spectra indicate the formation of anomalous structural fragments in the poly-(2-methylprop-1-ene). The infrared spectra showed that an increase in the number of CH_2 groups increases with increased Al/Ti ratios. This indicates the commencement of parts of a new structure of the poly-(2-methylprop-1-ene), where the CH_3/CH_2 ratio is < 2, Eqn. (2), whereas in the ordinary poly-(2-methylprop-1-ene) it equals 2, (Eqn. (1).

Hence two independent physical methods showed the presence of anomalous structural groupings in specimens of poly-(2-methylprop-1-ene) obtained with an excess of trialkylaluminium in the catalyst.

The formation of such structures was observed at ratios Al/Ti > 3. The polymers obtained at other ratios of the components of the catalytic system have the ordinary structure. This has also been shown by American investigators [26], who did not observe an anomalous structure in

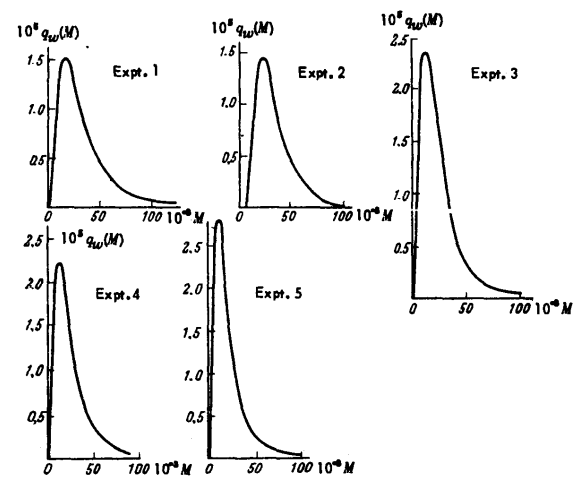


Fig. 1. Molecular weight distribution curves for poly-(2-methylprop-1-ene).

TABLE 2. Functions of the molecular weight distribution of poly--(2-methylprop-1-ene).

Specimen	M_z	M_w	M_n	M_e	$M_{SD_{sm}}$	$M_s[\eta]$	M_z/M_w	β	$10^5 g_w(M_e)$
1	60600	36600	22000	16500	37100	40000	1.66	1.02	2.51

the poly-(2-methylprop-1-ene) which they obtained on a Ziegler catalyst at ratios of Al/Ti = 2 or less.

After the publication of a paper on the conversion polymerisation of 2-methylprop-1-ene[22] attention was directed to the possibility of carrying out the 1,3-polymerisation of propene[27]. It was suggested that, depending on the reaction conditions and the catalyst used, the polymerisation can be directed to the formation of a 1,2-structure, Eqn.(3); a 1,3-structure, Eqn.(4); or their mixture, Eqn.(5):

$$CH_2{=}CH(CH_3) + [Cat] \rightarrow \sim CH_2CH(CH_3)\ldots[Cat], \quad (3)$$

$$\sim CH_2{-}\overset{\oplus}{C}H \ldots [Cat] \longleftrightarrow \sim CH_2{-}CH_2{-}CH_2\ldots[Cat], \quad (4)$$

$$\sim (CH_2)_nCH(CH_3)\,CH_2\,(CH_2)_nCH(CH_3)\,CH_2{\sim}. \quad (5)$$

The realisation of such an anomalous polymerisation of propene, as well being of exceptional scientific value, is of great practical interest, since with its aid a single monomer (propene) can yield a series of polyalkenes of different structure and properties. The recently published investigation of the 1,3-polymerisation of propene and study of the properties of the polymer obtained therefore merits attention[28].

The polymerisation was carried out in the presence of the catalytic system VCl_4.Fe(acetylacetonate) + $Al(C_2H_5)_3$. Infrared spectroscopy was used to identify the structure of the polymers. It was found that the degree of migration of hydrogen during polymerisation depends on the solvent. When the polymerisation is carried out in n-heptane, a polymer with the usual 1,2-structure is obtained. In benzene and its derivatives a polymer is obtained with the structure of a copolymer of ethylene and propene. An increase in the pressure and temperature of the reaction brought about an increase in the amount of copolymer. Polyethylene was obtained from propene when the polymerisation was carried out in dichloroethane. The X-ray diagram of the product showed that it has a crystal structure similar to that of polyethylene.

The conversion polymerisation of 3-methylbut-1-ene has been studied most[29,30]. The polymerisation was performed at low temperatures in ethyl chloride solution; aluminium chloride was used as catalyst. The polymer was obtained as colourless crystals, m.p. 55°, with molecular weight ~ 55 000. The infrared and NMR spectra of this polymer differed from those obtained from the polymer produced on a Ziegler catalyst. The authors proposed the following polymerisation mechanism: the cation attacks the molecule of the monomer, forming a secondary carbonium ion:

$$K^+ + CH_2{=}CH(CH(CH_3)_2) \rightarrow K{-}CH_2{-}\overset{+}{C}H(CH(CH_3)_2).$$

The labile hydrogen at the tertiary carbon atom migrates to the secondary carbonium ion as a hydride ion, during which process an energetically favoured tertiary carbonium ion is formed:

$$K{-}CH_2{-}\overset{+}{C}H(CH(CH_3)_2) \rightarrow K{-}CH_2{-}CH_2 + CH_2{=}CH(CH(CH_3)_2) \rightarrow$$

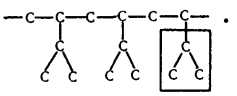
$$\rightarrow K{-}CH_2{-}CH_2{-}C(CH_3)_2{-}CH_2{-}\overset{+}{C}H(CH(CH_3)_2) \rightarrow K{-}CH_2{-}CH_2{-}C(CH_3)_2{-}CH_2{-}CH_2{-}\overset{+}{C}(CH_3)_2, \text{ etc.}$$

For a more convincing proof of the presence of the anomalous structure in the polymer synthesised on aluminium chloride the normal poly-(3-methylbut-1-ene) was synthesised by directed 1,2-polymerisation of isoprene with subsequent hydrogenation[31]:

$$CH_2{=}CH(C(CH_3){=}CH_2) \rightarrow -(-CH_2{-}CH(C(CH_3){=}CH_2)-)_n- \xrightarrow{+H_2} -(-CH_2{-}CH(CH(CH_3)_2)-)_n-.$$

The NMR spectrum of this product agreed with that of poly-(3-methylbut-1-ene) obtained on Ziegler catalyst and differed from that of poly-(3-methylbut-1-ene) synthesised on cationic catalysts. The relative proportions of anomalous and ordinary structures were determined by pyrolysis of the polymer with subsequent quantitative analysis of the gaseous products by gas chromatography and investigation of the liquid products of the pyrolysis by infrared spectroscopy. Analysis of the gaseous pyrolysis products of an isotactic polymer obtained on a Ziegler catalyst and of a hydrogenated 3,4-polyisoprene showed concentrations of 65.4 and 66.7 mole % C_3 fragments, which are formed only in the ordinary polymerisation of 3-methylbut-1-ene:

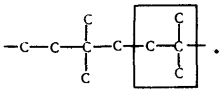
1,2-polymer



C_3 fragments

In the pyrolysis of anomalous poly-(3-methylbut-1-ene), synthesised in the presence of cationic catalysts at -96°, only 20.7 mole % C_3 fragments and 30 mole % 2-methylprop-1-ene C_4 fragments are formed:

1,3-polymer



C_4 fragments

The proportions of 2-methylprop-1-ene fraction in the pyrolysis of an isotactic polymer and of hydrogenated polyisoprene are 9.1 and 5.3 mole % respectively. Evidently the ratio of the amounts of C_3 and C_4 fragments depends on the presence in the polymer of ordinary and anomalous structures.

The amount of 1,3-structure in polymers obtained on cationic catalysts at temperatures from -78° to -96° reaches 70%. The infrared spectra of the liquid pyrolysis products of poly-(3-methylbut-1-ene) confirm the gas chromatographic results.

Additional proof of the presence of a 1,3-structure in poly-(3-methylbut-1-ene) is obtained in the polymerisation of 1,1-dimethylcyclopropane on aluminium bromide[32]:

$$CH_2{<}C(CH_3)_2{<}CH_2 \rightarrow -(-CH_2CH_2C(CH_3)_2-)-.$$

The infrared spectrum of the polymer thus obtained agrees completely with the spectrum of anomalous poly-(3-methylbut-1-ene).

Edwards and Chamberlain investigated the migration of hydride ion in the polymerisation of methylalk-1-enes of the type:

$$CH_2{=}CH{-}(CH_2)_m{-}\overset{\oplus}{C}H(CH_3)_2,$$

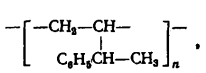
on cationic catalysts[33] and found that for $m = 0$ — for 3-methylbut-1-ene — 1,3-polymerisation proceeds throughout the entire temperature range studied (from 0° to -73°). For $m = 1$, the transfer path of the hydride ion is longer; therefore polymerisation at 0° leads to the production of only an insignificant amount of the 1,4-polymer. However, on lowering the temperature to -73° 1,4-polymerisation predominates.

For $m = 2$ and 0°, 1,5-polymerisation is almost absent; at -73°, <50% of the 1,5-polymer is formed. This shows that at lower temperature the migration of hydride ion is easier than ordinary vinyl polymerisation. Apparently, as the temperature is raised the growth rate increases more rapidly than the hydride ion migration rate, and consequently the growth activation energy is greater than the hydride ion migration activation energy.

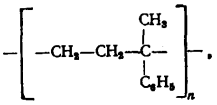
Somewhat in contradiction to Edwards and Chamberlain's results is the work of Goodrich and coworkers[34], in which it was shown that a low temperature is not necessary for the anomalous polymerisation of 4-methylpent-1-ene. These authors carried out the polymerisation in the temperature range from 0° to 60° in n-heptane solution; as catalyst, they used certain derivatives of transition metals and alkylaluminium halides.

The principal results of the workers cited above[29-33] were recently confirmed again[35]. The structure of poly-(3-methylbut-1-ene), poly-(4-methylpent-1-ene), and poly-(6-methylhept-1-ene), obtained in polymerisation on Friedel–Crafts catalysts in ethyl chloride and heptane at temperatures from 0° to -78° was studied. An anomalous structure was present in all these polymers and it was found that the ratio of anomalous structure to ordinary: (1) is independent of the type of catalyst; (2) increases with the dielectric constant of the solvent; (3) increases at lower temperatures.

Mention must also be made of work[36] on the polymerisation of 3-phenylbut-1-ene. When this compound is polymerised in ethyl chloride solution at -78° in the presence of aluminium chloride, in addition to the polymer of expected structure:

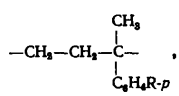


a polymer with the 1,3-structure:



is obtained in 56% yield. The structure of the polymer was determined with the aid of NMR and infrared spectra.

It is interesting that according to the infrared spectrum the polymer contains mono- and di-substituted benzene rings:



where R = H or $CH_3-CH-CH-CH_3$ (with C_6H_5 on the second CH), that is, alkylation of the benzene ring takes place in addition to the anomalous polymerisation. However, during alkylation the isomerisation of the secondary and the (energetically more favourable) tertiary carbonium ions does not take place. The authors explain this by the fact that under certain conditions the rate of alkylation of the benzene ring can be greater than the rate of rearrangement.

From certain other monomers which are apparently capable of polymerisation with migration of a hydride ion, mention may be made of the compounds of type:

$$\text{cyclo-}C_6H_{11}[CH_2]_nCH{=}CH_2 \text{ and cyclo-}C_5H_9[CH_2]_nCH{=}CH_2.$$

These substances have similar structure fragments to compounds of the 3-methylbut-1-ene type and therefore should be capable of anomalous polymerisation. The anomalous polymerisation of these cyclic monomers makes possible the introduction into the polymeric chain of the cyclohexyl or cyclopentyl ring, which should markedly change the properties of the polymer. Ketley and Ehrig[37] studied the polymerisation of such a type of monomer. The infrared spectra of poly(vinylcycloalkanes) and poly(allylcycloalkanes) obtained on Ziegler–Natta catalysts showed that the polymers have the normal structure (Fig. 2).

The absorption bands characteristic of different sequences of methylene groups for the polymers obtained on Friedel–Crafts catalysts are shown in Table 3. The presence of absorption bands characteristic of the groups

$$-(-CH_2-CH_2-)- \text{ and } -(-CH_2-CH_2-CH_2-)-,$$

which belong respectively to poly(vinylcyclohexane) and poly(allylcyclohexane) (Fig. 3), obtained on cationic catalysts and the absence of these bands from the spectra of the polymers obtained on Ziegler–Natta catalysts, shows that in polymerisation on cationic catalysts hydrogen migration

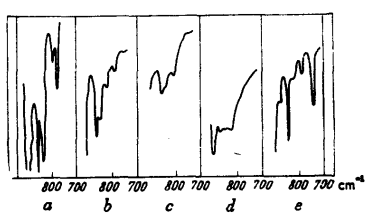


Fig. 2. Infrared spectra of polymers obtained on Ziegler–Natta catalysts:

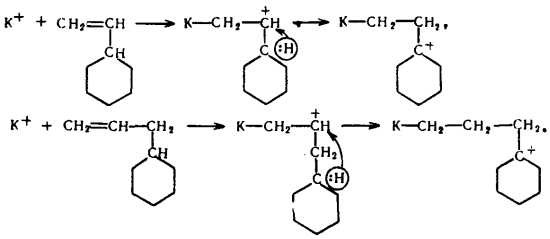
e) 5-cyclohexylpent-1-ene.

takes place, leading to the formation of anomalous polymers:



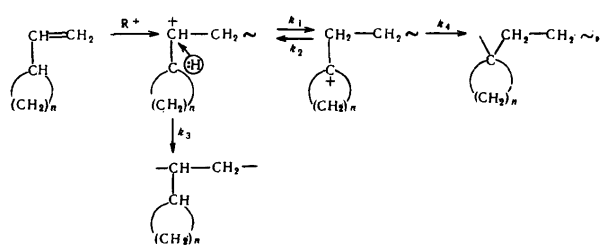
The strong absorption band at 721 cm^{-1} in poly-(5-cyclohexylpent-1-ene) obtained on cationic catalysts supports the structure:

$$-CH_2CH_2CH_2CH_2CH_2C_6H_{10}-.$$

Poly-(5-cyclohexylpent-1-ene) obtained on a Ziegler–Natta type catalyst has an absorption band at 730 cm^{-1}, which corresponds to

$$-(-CH_2-CH_2-CH_2-)-$$

in the lateral cyclohexylpropyl groups. Poly(vinylcyclopentane) obtained on cationic catalysts does not have an absorption band in the range 740–745 cm^{-1}. Hence it can be concluded that this is an ordinary 1,2-polymer. The fact that isomerisation polymerisation takes place with vinylcyclohexane, whereas for vinylcyclopentane there is the usual 1,2-polymerisation, is rather unexpected. The authors propose the following scheme of polymerisation of this type of monomer:



where k_3 should be approximately the same for cyclohexyl and cyclopentyl compounds. It can therefore be assumed that the ion formed initially during the polymerisation of vinylcyclopentane is not isomerised. When it is subjected to isomerisation then the carbonium ion which is formed is less active than in vinylcyclohexane.

The 750 cm^{-1} absorption band in the infrared spectrum of poly(allylcyclopentane) obtained on a Friedel–Crafts catalyst corresponds most likely to the $-(CH_2-CH_2-)$ groups, and not $-(CH_2-CH_2-CH_2)-$. Therefore the anomalous structure of this polymer can be represented as $-CH_2CH_2CH(C_5H_9)-$. The chain growth of poly(allylcyclopentane) will proceed with greater probability with the participation of a secondary carbonium ion situated close to the ring.

Simultaneously with Ketley and Ehrig's work appeared that of Kennedy and coworkers, which was also devoted to an investigation of the anomalous polymerisation of vinylcyclohexane[38]. The polymerisation of vinylcyclohexane was studied from -144° to +7° (catalyst, $AlCl_3$; the solvent, ethyl chloride) and from 60° to 85° (catalyst, $AlEt_3 + TiCl_4$; solvent, n-heptane). From the infrared and NMR spectra, the authors concluded that the 1,3-structure predominates in polymers obtained on aluminium chloride at temperatures below -100°. The melting points of poly(vinylcyclohexane)s containing chains with an anomalous structure were considerably lower (70–120°) than those of polymers with a 1,2-structure (200°).

The results suggest that isomerisation polymerisation of both 3-methylbut-1-ene and vinylcycloalkanes depends on the ability of the corresponding hydrogen atom to migrate, the stability of the tertiary carbonium ion formed, and its activity with respect to the monomer molecules.

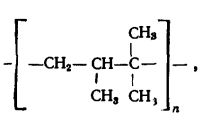
It must be noted that in addition to the communications devoted to polymerisation with hydride ion migration there are some reports of the possibility of migration of other groups or atoms. One of the first of these was made by Meier[39], who advanced the possibility of the migration of a methyl group in the polymerisation of 3,3-dimethylbut-1-ene:

$$CH_2{=}CHC(CH_3)_3 \xrightarrow{+A} \bar{A}\cdot CH_2\overset{+}{C}HC(CH_3)_3 \longrightarrow \bar{A}\cdot CH_2CH(CH_3)\overset{+}{C}(CH_3)_2 \longrightarrow \text{polymer.}$$

However, he did not produce experimental proof of the proposed scheme.

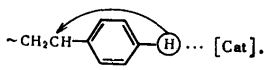
Edwards and Chamberlain suggested that in view of the similarity in the structures of 3-methylbut-1-ene and 3,3-dimethylbut-1-ene, polymerisation by migration of a methyl group (analogous to the hydrogen atom in 3-methylbut-1-ene) could be expected[33]. However, they did not succeed in obtaining a 1,3-polymer in the polymerisation of 3,3-dimethylbut-1-ene in the presence of aluminium chloride at 0°. The authors attributed their failure to steric hindrance.

Kennedy and coworkers repeated this work[40] and suggested that the reason for Edwards and Chamberlain's failure is the high rate of chain breaking after the migration of the methyl group. The authors assumed that the reaction of chain transfer or breaking requires a greater activation energy than isomerisation and growth and therefore the migration of the methyl group will take place more readily at a lower temperature. When the polymerisation of 3,3-dimethylbut-1-ene was carried out in the temperature range from -30° to -130° a trimer of 3,3-dimethylbut-1-ene was obtained. Polymerisation at a lower temperature (-130°) led to the production of an amorphous polymer. On the basis of the infrared and NMR spectra, Kennedy and coworkers proposed the following structure for this polymer:



that is, it can be assumed that in the polymerisation at -130°, migration of the methyl group precedes the growth

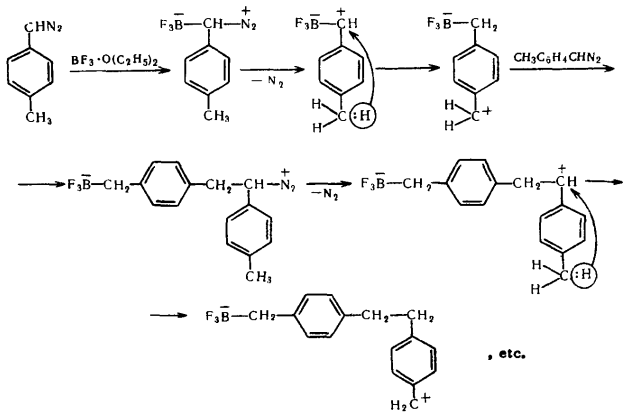
reaction, forming the energetically more favourable tertiary carbonium ion. The possibility of anomalous polymerisation of styrene with inclusion of the benzene ring in the main polymeric chain has been suggested[27]:



The first experimental proof of this hypothesis was obtained in our laboratory[41]. In the polymerisation of styrene on the system $AlEt_3$ + $VOCl_3$ a polymer was obtained from which a small fraction insoluble in benzene, with m.p. 310–315°, could be isolated. An absorption band with maximum 809 cm^{-1} was observed in the infrared spectrum of this polystyrene; it is characteristic for the 1,4-disubstituted benzene ring.

It was suggested that in the polymerisation of styrene transfer of an active centre in the *ortho*- or *para*-position to the vinyl group occurs. During this reaction the benzene or quinonoid structures are included in the main chain of the polymeric molecule. However, later investigations showed that such a possibility is ruled out.

Korshak and coworkers[42] obtained polymers including benzene rings by a somewhat unusual route. They observed that in the decomposition of phenyldiazomethane in the presence of $BF_3.O(C_2H_5)_2$ a polymer containing methylene and phenylene groups in the main chain is formed. The authors explained this fact by the partial isomerisation of phenyldiazomethane during polymerisation. The study of the infrared and NMR spectra of polymers obtained during the decomposition of 4-methylphenyldiazomethane in the presence of $BF_3.O(C_2H_5)_2$ showed the high concentration of methylene groups in the polymer. The conclusion was drawn that in the decomposition of 4-methylphenyldiazomethane formation of a polymer containing methylene and phenylene groups takes place. A mechanism for the polymerisation is proposed in which the transfer of a hydride ion to the cation being formed is realised:



In some instances the realisation of anomalous addition can have practical value. An example of this has already been mentioned — the production of copolymers of ethylene and propene as a result of the conversion polymerisation of propene.

It is possible that a way will be found of carrying out the conversion polymerisation in those instances where the direct synthesis of the polymer from the monomer by ordinary means is impossible, for example, with poly(vinyl alcohol). The conversion polymerisation of acetaldehyde can in principle lead to the direct formation of polyvinyl alcohol:

$$CH_3CHO \rightarrow -CH_2-CH(OH)-.$$

β-ELIMINATION IN THE β-SUBSTITUTED PROPIONIC ACID SERIES

P. F. Butskus and G. I. Denis

CONTENTS

1. β-Substituted propionic acids 839
2. Esters of β-substituted propionic acids 840
3. Amides of β-substituted propionic acids 841
4. Nitriles of β-substituted propionic acids 841
5. Alkylations with the aid of β-substituted propionic acids and their derivatives 843
6. Mechanism of β-eliminations 844

It has long been known that β-substituted propionic acids and their derivatives have a tendency to undergo β-elimination:

$$ACH_2CH_2X \rightarrow AH + CH_2{=}CHX$$

where A = halogen, HO, RO, RS, RSO_2, H_2N, RNH, or $(R)_2N$, etc., and X = COOH, COOR, $CONH_2$, or CN.

These reactions are of both theoretical and practical interest. However, up to recently information on this subject had not been summarised. The present review covers factual information on the β-elimination of β-substituted propionic acids, their esters, amides, and nitriles.

1. β-SUBSTITUTED PROPIONIC ACIDS

β-Halogenopropionic acids are converted into acrylic acid by distillation[1]; by heating under pressure[2] or under vacuum[3]; by heating in the presence of activated charcoal[3] or aluminium oxide[4]; by boiling with water[5] or with aqueous solutions of alkalis[5-11]; and by the action of sodium carbonate[11], lead oxide[11-13] or carbonate[12], alkali metal alkoxides[6], sodium acrylate[14], or diethylaniline[9,10]. Several attempts to synthesise β-alanine and its methyl ester from β-bromopropionic acid led to the preparation of acrylic acid[15]. When β-iodopropionic acid is treated with an excess of silver oxide, a polymer of acrylic acid is formed[16-18].

In 1862 Beilstein noted[12] that, when salts of β-hydroxypropionic acid are heated to 200–250°, salts of acrylic and diacrylic acid are formed. Later this reaction was also observed by Wislicenus[13,19]. Acrylic acid is formed when β-hydroxypropionic acid is heated to boiling, or when the acid itself, or its salts, is distilled with sulphuric acid[12,13,19-22]. When β-hydroxypropionic acid is evaporated with hydrochloric acid, a polymer of acrylic acid is formed[16-18]. Acrylic acid is obtained from a mixture of β-hydroxypropionic acid, diacrylic acid, and acrylic acid polymer[23], and also from 2-hydroxypropiononitrile[24-28].

At 190–225°, and in the presence of alkali or alkaline-earth salts of the same acids, β-alkoxypropionic acids (containing C_1 to C_{17} alkoxy-groups) give acrylic acid in good yield[29]. When β-ethoxypropionic acid is heated in the presence of *p*-toluenesulphonic acid and hydroquinone, a mixture of acrylic acid and its ethyl ester is formed[30,31]. According to the patent literature, 2-dicarboxydiethyl ether gives acrylic acid when it is treated in the gas phase at 150–185° with activated charcoal soaked in phosphoric acid[32]. In an alkaline medium, β-carboxyethyl esters of monohydric and dihydric phenols give decarboxyethylation products[33-38]. When heated for a short time to 180–190° in the presence of hydroquinone, β-acetoxypropionic acid decomposes according to the following reaction[39]:

$$CH_3COOCH_2CH_2COOH \rightarrow CH_3COOH + CH_2{=}CHCOOH.$$

The yield of acrylic acid is 77%. The removal of the β-carboxyethyl group in esters of phosphoric acid[40-43] has been studied. Methods of synthesising α- and β-substituted acrylic acids from α- and β-substituted β-hydroxypropionic acids and their esters at the hydroxy-group have been developed[44-59].

When 2-carboxyethyl aryl sulphones are boiled with 10% sodium hydroxide, cleavage occurs according to the following scheme[60]:

$$ArSO_2CH_2CH_2COOH \rightarrow ArSO_2H + CH_2{=}CHCOOH.$$

Mulder[61] observed that β-aminopropionic acid decomposes into acrylic acid and ammonia when it is heated to about the melting point. β-Diethylaminopropionic acid decomposes in the same way (160°):[62]

$$(C_2H_5)_2NCH_2CH_2COOH \rightarrow (C_2H_5)_2NH + CH_2{=}CHCOOH.$$

When heated to its melting point, the betaine of β-trimethylaminopropionic acid gives ammonium acrylate[63]. The decarboxyethylation of *N*-(2-carboxyethyl)-α-amino-acids has been studied[34]. Heating of 2,2'-dicarboxydiethylamine with phthalic anhydride leads to the formation of *N*-(2-carboxyethyl)phthalimide and acrylic acid in quantitative yield[64].

Attempts to cyclise *N*-(2-carboxyethyl)-*N*-acycl-*p*-anisidines to the corresponding quinolones led to decarboxyethylation[65]. When *N*-(2-naphthyl)-β-aminopropionic acid is heated for 2–3 min at 220°, 1-naphthylamine and acrylic acid are formed[66].

According to Rodionov and coworkers [67], when β-(2-naphthyl)-β-(3-phenylureido)propionic acid is heated with dilute hydrochloric acid, instead of cyclising to the corresponding dihydrouracil, it sometimes forms β-(2-naphthyl)acrylic acid. An attempt to obtain 1-methyl-4-naphthyl-2-thiodihydrouracil from β-(methylamino)-β-(2-naphthyl)propionic acid by heating the latter with potassium thiocyanate in the presence of hydrochloric acid was not successful; β-(2-naphthyl)acrylic acid was the only product isolated from the reaction mixture. In some instances, the cyclisation of β-alkyl- and β-aryl-β-guanidinopropionic acids leads to the elimination of guanidine and the formation of an αβ-unsaturated acid [67,68]. An attempt has been made to synthesise β-(2-thienyl)-β-alanine by the acid hydrolysis of 6-(2-thienyl)dihydrouracil, but β-(2-thienyl)acrylic acid was obtained instead of the amino-acid [69].

When the products of *NN*-dicarboxyethylation of benzenesulphonamide [70], *p*-toluenesulphonamide [71], and sulphanilamide [72] are heated with a 10% aqueous solution of potassium hydroxide, one of the 2-carboxyethyl groups is removed and *N*-monocarboxyethyl derivatives of aryl sulphonamides are formed in 60 and 86% yield:

$$ArSO_2N(CH_2CH_2COOH)_2 \rightarrow ArSO_2NHCH_2CH_2COOH + CH_2{=}CHCOOH.$$

Quantitative elimination of the 2-carboxyethyl group is achieved by treating an alkaline solution of β-indol-1-ylpropionic acid with water vapour superheated to 250–270°. [73] Later this process was observed under analogous conditions by other workers [74]. If water vapour superheated to 280° is passed for 30–40 min through a solution of 1,3-di-(2-carboxyethyl)indole in 50% potassium hydroxide, β-indol-3-ylpropionic acid is formed in 82% yield [75]. 1,3-Di-(2-carboxyethyl)-2-methylindole behaves in the same way under these conditions [75], the yield of its *N*-decarboxyethylated product being 80%. From the foregoing it is clear that the 2-carboxyethyl group can be eliminated if it occurs at the 1-position in indole, but it is stable if it occurs at the 3-position [73–78].

When distilled under reduced pressure, β-indazolylpropionic acid decomposes with the formation of indazole and acrylic acid [79]. Efros and Porai-Koshits obtained benzimidazole by heating β-carboxyethylated benzimidazole with aqueous solutions of acids or alkalis [80]. They were not, however, able to remove the 2-carboxyethyl group from carboxyethylated 2-methylbenzimidazole. When derivatives of pyridine containing a 2-carboxyethyl group at the ring-nitrogen atom are heated above the melting point, or treated with aqueous sodium hydroxide solution, they decompose with the formation of pyridine, 2- and 3-hydroxy-, 2-amino- and 4-methyl-2-amino-pyridines, and also acrylic acid [35,81–83].

Pyrolysis of, or the action of concentrated aqueous sodium hydroxide on, *N*-(2-carboxyethyl)pyrid-2-one gives the decarboxyethylation product and acrylic acid [84]. Attempts to convert some substituted *N*-(2-carboxyethyl)-4-keto-1,2,3,4-tetrahydroquinolines into the corresponding *N*-ethyl-4-keto-1,2,3,4-tetrahydroquinolines have not been successful; decarboxyethylation occurred under all experimental conditions instead of the expected decarboxylation [85].

There are also other references to decarboxyethylation [35,86–93], and to the removal of one aryl group from ββ β-triaryl-substituted propionic acids [94–96]. The bond of the 2-carboxyethyl group with the silicon atom is stronger than the bond of other alkyl groups with this atom [97–100].

2. ESTERS OF β-SUBSTITUTED PROPIONIC ACIDS

Esters of acrylic acid are formed from esters of β-halogenopropionic acids by distilling the latter with concentrated sulphuric [101,102] or phosphoric acid [101]; by heating them with aqueous [103] or alcoholic [103,104] solutions of alkali; by heating them with anhydrous sodium carbonate [102], diethylaniline [8,9], quinoline [105,106], activated charcoal [107], zinc chloride [3,101,108], barium phosphate [101,107], or aluminium oxide [4]. Acrylates are formed from the methyl and ethyl esters of β-hydroxypropionic acid when these are distilled over alkali acetates [109], or heated in the gas phase over silica gel [110], or silicon dioxide saturated with concentrated sulphuric acid [111]. They can also be obtained in yields of up to 90% from the amide [112] and the nitrile [24,25,112–119] of β-hydroxypropionic acid.

Methyl acrylate is obtained in 50% yield from methyl β-methoxypropionate by passing the latter into concentrated sulphuric acid containing an inhibitor at 200°. [120] A similar process proceeds in the gas phase over catalysts [30,121–125]. Ethyl acrylate is obtained from ethyl β-ethoxypropionate [121,126–128]. Acrylates are formed from the esters of oxy-3,3′-dipropionic acid by the action of dilute sulphuric [129] or phosphoric [32] acid, or anhydrous zinc chloride [129] at an elevated temperature. When heated with sodium hydroxide [33], or 2-amino-, [35], or 4-methyl-2-aminopyridines [81], esters of β-aryloxy propionic acid give the corresponding monohydric and dihydric phenols. On being heated with anhydrous potassium carbonate at 100°, ethyl β-hydroxypropionate having the hydroxyl group esterified with *p*-toluenesulphonic acid decomposes almost quantitatively according to the following scheme [130]:

$$p\text{-}CH_3C_6H_4SO_2OCH_2CH_2COOC_2H_5 \rightarrow p\text{-}CH_3C_6H_4SO_2OH + CH_2{=}CHCOOC_2H_5.$$

Acrylates are also obtained from esters of β-acyloxypropionic acids [131–133].

The action of picric acid on ethyl β-hydroxy-β-(*p*-aminophenyl)propionate gives the picrate of *p*-aminocinnamic acid [134].

When esters of 2-carboxyethyl aryl sulphones are boiled with a 10% aqueous solution of sodium hydroxide, arylsulphinic acids are formed [60]:

$$ArSO_2CH_2CH_2COOR \rightarrow ArSO_2H.$$

It has been shown that a state of mobile equilibrium is established when ethyl acrylate reacts with ammonia [135]:

$$CH_2{=}CHCOOC_2H_5 \underset{-NH_3}{\overset{+NH_3}{\rightleftharpoons}} NH_2CH_2CH_2COOC_2H_5 \underset{+NH_3}{\overset{-NH_3}{\rightleftharpoons}}$$

$$\underset{+NH_3}{\overset{-NH_3}{\rightleftharpoons}} NH(CH_2CH_2COOC_2H_5)_2 \underset{+NH_3}{\overset{-NH_3}{\rightleftharpoons}} N(CH_2CH_2COOC_2H_5)_3.$$

Other investigators have also observed that, when ammonia and amines react with acrylates, a varied mixture of compounds is obtained [136,137]. Dry distillation of the ethyl ester of β-alanine leads to the formation of ethyl acrylate [138]. When ethyl β-(diethylamino)propionate is distilled, it slowly decomposes into diethylamine and ethyl acrylate [139]; its salts decompose more readily; for example, the hydriodide begins to decompose even at 100°, and at 165° this process is instantaneous [62].

When phthalic anhydride is heated with di-[2-(ethoxycarbonyl)ethyl]amine, *N*-[2-(ethoxycarbonyl)ethyl]phthalimide is formed in 75% yield [64]. Ethyl acrylate is formed by heating tri(ethoxycarbonyl)triethylamine [138,140,141], *N*-benzyl- and *N*-benzoyl-di(ethoxycarbonyl)diethylamines [140,141], or by treating ethyl (1-piperidyl)propionate with cyanogen bromide by Braun's method [142]. Oxidation of the addition product of ethyl acrylate and pyrazole gives pyrazole itself [143].

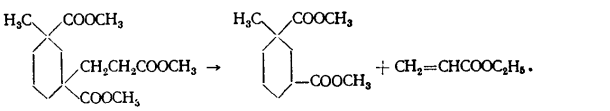
The preparation of an ester of β-(methylamino)-β-phenylpropionic acid is accompanied by the formation of the ester of cinnamic acid [144].

The decomposition products obtained by heating methyl β-(dimethylamino)propionate at 180–185° include acrylic acid. When the methiodide of this ester is heated with alkalis, it decomposes quantitatively into acrylic acid and trimethylamine [63]. When diesters of *NN*-di-(2-carboxyethyl)aryl sulphonamides are heated with 10% aqueous potassium hydroxide, they react according to the following scheme [70-62,92,93]:

$$ArSO_2N(CH_2CH_2COOR)_2 \rightarrow ArSO_2NHCH_2CH_2COOH.$$

The decomposition products obtained in the esterification of *NN*-di-(2-cyanoethyl)-α-amino-acids with hydrogen chloride in ethanol contain *N*-monocarboxyethyl derivatives and ethyl acrylate [145].

Other papers reporting the formation of acrylates from esters of β-substituted propionic acids have also been published [42,65,146-149]. In some reactions a carbon–carbon bond is broken [150,151], for example:



3. AMIDES OF β-SUBSTITUTED PROPIONIC ACIDS

Acrylamide is obtained in yields up to 80–96% from the amides of β-chloro-, [152] β-hydroxy-, [152] β-alkoxy-, [152,153] and β-(dialkylamino)-propionic acids [152,154]; it is also obtained by the following reaction [152,155]:

$$NH_4SO_3OCH_2CH_2CONH_2 \rightarrow CH_2{=}CHCONH_2 + NH_4HSO_4.$$

The $-CH_2CH_2CONH_2$ group, when located on the nitrogen atom of the pyrrole ring, is also eliminated under certain conditions [156]. Boiling of amides of β-aryloxypropionic acids [33] and amides of 2-carboxyethyl aryl sulphones [60] in aqueous sodium hydroxide gives the corresponding phenols and arylsulphinic acids:

$$ArOCH_2CH_2CONH_2 \rightarrow ArOH,$$
$$ArSO_2CH_2CH_2CONH_2 \rightarrow ArSO_2H.$$

The removal of the 2-carbamoylethyl group from esters of phosphoric acid has been studied [40,41,43].

NN-Disubstituted acrylamides are obtained from the corresponding amino-acid amides (but not anilides) by heating the latter to 180–220°, [136,137,154] for example:

$$(C_2H_5)_2NCH_2CH_2CON(C_2H_5)_2 \rightarrow (C_2H_5)_2NH + CH_2{=}CHCON(C_2H_5)_2.$$

The piperidide of β-piperidylpropionic acid cannot be separated, as it spontaneously decomposes with the formation of the piperidide of acrylic acid [136]:

$$2C_5H_{11}N + CH_2{=}CHCOOCH_3 \rightarrow C_5H_{10}N{-}CH_2CH_2CO{-}NC_5H_{10} \rightarrow$$
$$\rightarrow C_5H_{11}N + CH_2{=}CHCONC_5H_{10}.$$

It is noteworthy that when the diamides of *NN*-di-(2-carboxyethyl)aryl sulphonamides are heated with 10% aqueous sodium hydroxide solution, the corresponding monoacids are obtained in 60–76% yield, and not the expected diacids [70-72,92,93]:

$$ArSO_2N(CH_2CH_2CONH_2)_2 \rightarrow ArSO_2NHCH_2CH_2COOH.$$

When the diamide of *NN*-di-(2-carboxyethyl)benzenesulphonamide is heated with a 10% aqueous solutions of ammonia, *N*-(2-carboxyethyl)benzenesulphonamide is obtained in 70% yield; under these conditions, the *NN*-dicarboxyethyl derivative remains unchanged [70].

As Rodionov and Kiseleva [157] have shown, when *N*-benzoyl-β-phenyl-β-alanine is treated with acetic anhydride, cyclisation to the tetrahydropyrimidine derivative is accompanied by the formation of considerable amounts of benzamide and cinnamide:

$$C_6H_5CH(NHCOC_6H_5)CH_2CONH_2 \rightarrow C_6H_5CH{=}CHCONH_2 + C_6H_5CONH_2.$$

Cinnamic acid has been separated from the reaction mixture obtained by the action of acetic anhydride on the amide of *N*-ethoxycarbonyl-β-phenyl-β-alanine. Rodionov and Yavorskaya [144] have shown that, when β-phenyl-β-(*N*-benzoyl-*N*-methylamino)propionamide is heated with oxalic acid, the main reactior product is cinnamide. When *N* benzoyl-β-piperonyl-β-alanine is heated with thionyl chloride, followed by treatment with ammonia, β-piperonylacrylic acid is formed [158]. Under the same conditions, *N*-benzoyl-β-(1-naphthyl)-β-alanine gives β-(1-naphthyl)acrylamide [159]. Cyclisation of the amides of *N*-methoxycarbonyl-, *N*-acetyl-, and *N*-benzoyl-β-piperonyl-β-alanines gives β-piperonylacrylic acid in addition to the corresponding tetrahydropyrimidines [158]. The dehydrobromination of amides of β-substituted propionic acids has also been studied [160-162].

The pyrolysis of 2-carbamoylethyl hydrogen sulphate [155] and of β-alkoxypropionamides [163,164], leading respectively to the formation of acrylic acid and its nitrile, have been reported. The reaction of 2-carbamoylethyl hydrogen sulphate with alcohols gives the corresponding acrylates [165].

4. NITRILES OF β-SUBSTITUTED PROPIONIC ACIDS

Acrylonitrile is formed in 75–80% yield when β-halogenopropiononitriles are treated with ammonia [166], potassium carbonate [167], alkali hydroxides [168-171], sodium cyanide [172], tertiary aliphatic [166,168-171] and primary aromatic [166,173] amines, and also some heterocyclic bases [166,174]. One of the main methods of preparing acrylonitrile is the dehydration of β-hydroxypropiononitrile [175].

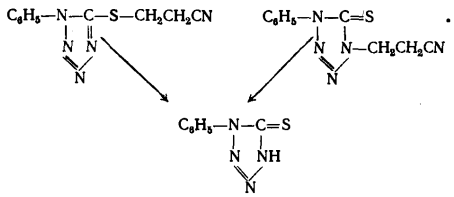
Decyanoethylation of β-alkoxypropiononitriles occurs when these compounds are subjected to reduction [176-180], hydrolysis [181-183], hydration [184] or pyrolysis [185], or when they are treated with organomagnesium compounds [186]. The same reaction occurs on reduction [187,188], hydrolysis [189], and pyrolysis [185] of bis-(2-cyanoethyl) ether, when it is heated in the presence of sodium formate [190] or with an aqueous solution of ammonia [183]. An attempt to cyclise the dicyanoethylation product of decan-1,10-diol to the corresponding iminonitrile by Ziegler's method was not successful, decan-1,10-diol being formed again in 90% yield [191]. When cleavage of the bond between the 2-cyanoethyl group and the oxygen atom occurred, the following were observed amongst the products of cyanoethylation: diethylene glycols [192]; poly(vinyl alcohol) [193,194]; some monosaccharides [195] and polysaccharides [196,197]; alicyclic [198], aromatic [178,199], and heterocyclic [200] alcohols; and phenols [35,36,81,176,185,201-207]. The product of the interaction of acrylonitrile with benzaldehyde in an alkaline medium eliminates acrylonitrile [208]. Other instances are also known of the breaking of the bond of the 2-cyanoethyl group with an oxygen atom in acid [185,209] and alkaline [175,187,209-214] media. Alkaline agents act as catalysts accelerating both the direct cyanoethylation of alcohols and the reverse reaction [215].

In the preparation of acrylonitrile from 2-hydroxypropiononitrile, the latter is sometimes esterified and the acrylonitrile is eliminated catalytically or thermally [175,216-222]. For example:

$$CH_3COOCH_2CH_2CN \rightarrow CH_3COOH + CH_2=CHCN,$$
$$p\text{-}CH_3C_6H_4SO_2OCH_2CH_2CN \rightarrow p\text{-}CH_3C_6H_4SO_3OH + CH_2=CHCN.$$

The removal of the 2-cyanoethyl group from phosphoric acid esters has been studied [40-43,223-245].

Decyanoethylation is observed when β-alkylthiopropiononitriles are hydrolysed by alkali [246], or when they are treated with organomagnesium compounds [247]; decyanoethylation also occurs when bis-2-cyanoethyl sulphide is reduced by Vyshnegradskiĭ's method [187]. Sulphones containing a cyanoethyl group are unstable in an alkaline medium and are readily decomposed by dilute alkali at room temperature to give acrylonitrile [60,248]. In the cyanoethylation of 1-phenyltetrazoline-5-thione, facile decyanoethylation of *S*- and *N*-isomers was observed [249]:



Many investigators [188,211,250-257] have studied the mobile equilibrium in the cyanoethylation of ammonia with acrylonitrile and have established the proportions of products of mono-, di-, and tri-cyanoethylation in relation to the reaction procedure and the proportions of the initial compounds. The products of this reaction undergo decyanoethylation on storage [250], when heated [211,252,258], on catalytic reduction [188,254], and when treated with ammonia [252,255,259]. Di-(2-cyanoethyl)-amine gives *N*-(2-cyanoethyl)acetamide [253] with acetic anhydride; with phthalic anhydride at 200° it gives cyanoethylated phthalimide [64]; and with perylene-3,4,9,10-tetracarboxylic acid at 230° it gives the dicyanoethylated di-imide of this acid [260,261]. When di-(2-cyanoethyl)amine reacts with chlorotriphenylmethane, a molecule of acrylonitrile is eliminated [262].

As is well known, hydrazine hydrate reacts vigorously with acrylonitrile, adding four molecules of the latter. However, when this product of the tetracyanoethylation of hydrazine is distilled under a high vacuum, it loses two molecules of acrylonitrile and is converted into a mixture of isomers of dicyanoethylated hydrazine [211]. Dibenzoyl-(2-cyanoethyl)hydrazine is formed by the action of benzoyl chloride on *unsym*-di-(2-cyanoethyl)hydrazine [263]. Kost and coworkers observed that, when (2-cyanoethyl)hydrazine is heated with mesityl oxide, 3,5,5-trimethylpyrazoline and acrylonitrile are formed [264]. It is known that *N*-cyanoethylated hydrazones undergo decyanoethylation in an alkaline medium [265], as do dicyanoethylated guanidines on cyclisation [266].

The decyanoethylation of some *N*-substituted β-aminopropiononitriles on distillation indicates the weakness of the bond between the cyanoethyl group and the nitrogen atom [250,254,267-270]. When the product of cyanoethylation of *N*-methyldodecylamine is heated for several hours at 250-275°, it decomposes almost quantitatively into the initial amine and acrylonitrile [271,272]:

$$CH_3(CH_2)_{11}N(CH_3)CH_2CH_2CN \rightarrow CH_3(CH_2)_{11}NHCH_3 + CH_2=CHCN.$$

When dicyanoethylated ethylenedinitramine is heated with aqueous alkali, the initial nitramine is formed in 82% yield [273]:

Decyanoethylation is observed when some β-alkylaminopropiononitriles are heated in the presence of water; it is also brought about by catalytic hydrogenation [275], by hydrolysis in an acid medium [276], and by other reactions [277,278].

On being heated, β-(diethylamino)propiononitrile decomposes into diethylammonium chloride and acrylonitrile [279,280]. Quaternary ammonium salts obtained from β-(dialkylamino)-propiononitriles smoothly eliminate acrylonitrile on pyrolysis [168,281]; in the presence of alkalis the reaction is rapid even at 100°. The yields of acrylonitrile and amines are as high as 90-95%. When the product of cyanoethylation of 2-amino-2-methylpropan-1-ol is alkylated with ethyl iodide, acrylonitrile separates [282]:

$$HOCH_2C(CH_3)_2NHCH_2CH_2CN + C_2H_5I \rightarrow HOCH_2C(CH_3)_2NHC_2H_5HI + CH_2=CHCN.$$

Methylation of β-(benzylamino)propiononitrile with a mixture of formaldehyde and formic acid gives *NN*-dimethylbenzylamine in 38% yield [283]:

$$C_6H_5CH_2NHCH_2CH_2CN + 2CH_2O + 2HCOOH \rightarrow$$
$$\rightarrow C_6H_5CH_2N(CH_3)_2 + CH_2=CHCN + 2CO_2 + 2H_2O.$$

Under the same conditions, the products of monocyanoethylation of tetramethylenediamine and hexamethylenediamine are converted into the corresponding tetramethyl derivatives of the diamines [284].

When the products of dicyanoethylation of a number of carboxylic acid amides are heated, especially in the presence of basic agents, *N*-monocyanoethylated amides are formed [35,64,70-72,81,92,93,250,285-293]:

$$RCON(CH_2CH_2CN)_2 \rightarrow RCONHCH_2CH_2CN + CH_2=CHCN,$$
$$RSO_2N(CH_2CH_2CN)_2 \rightarrow RSO_2NHCH_2CH_2CN + CH_2=CHCN.$$

Alkaline hydrolysis of *NN*-dicyanoethylated sulphonamides gives the corresponding *N*-monocarboxyethylated derivatives in yields up to 90%. [70-72,92,93,285,294-296]

$$RSO_2N(CH_2CH_2CN)_2 \rightarrow RSO_2NHCH_2CH_2COOH.$$

Under these conditions arylsulphonamides containing aryl and cyanoethyl groups at the nitrogen atom lose the cyanoethyl group [297]. Decyanoethylation may occur in the synthesis of *N*-cyanoethylated polyamides [298].

Recently, great attention has been paid to the decyanoethylation of the products of *N*-mono- and *NN*-di-cyanoethylation of amino-acids and their derivatives [35,81,145,205-207,250,278,299-313]. When two cyanoethyl groups are attached to a nitrogen atom, the first is removed more readily, and under milder conditions, than the second. By a suitable choice of reaction conditions, either one or two groups can be removed from the dicyanoethylation products. Some reactions of *N*-mono- and *NN*-di-cyanoethylated α-amino-acids, such as hydrolysis and cyclisation, are accompanied by decyanoethylation.

Some investigators [314] consider that the cyanoethyl group may be eliminated from dicyanoethylated aromatic amines, when these are cyclised. Decyanoethylation products have also been observed after the decomposition of β-arylaminopropiononitriles in acid or alkaline media [167,250,315-319].

Some derivatives of *N*-(2-cyanoethyl)pyrrole lose the cyanoethyl group when they are heated with sodium ethylate in absolute ethanol at 150°. When β-(5-ethoxycarbonyl-3--formyl-2,4-dimethylpyrrol-1-yl)propiononitrile is reduced by Kishner's method, 2,3,4-trimethylpyrrole is formed[156].

When heated in a vacuum to 250°, 1,3-di-(2-cyanoethyl)-indole eliminates acrylonitrile, giving a quantitative yield of 3-(2-cyanoethyl)indole, which is not decomposed by distillation in vacuum[73]. When heated with a concentrated solution of potassium hydroxide, *N*-(2-cyanoethyl)indole is hydrolysed to the corresponding acid; the decyanoethylation product, indole, is also formed in 10% yield. Under similar conditions, some derivatives of *N*-(2-cyanoethyl)-indole also give the corresponding indole derivatives[74,320]. Under certain conditions *N*-(2-cyanoethyl)indole can form indoline and acrylonitrile[321,322]. Heating of cyanoethylated benzimidazole with aqueous solutions of acids or alkalis leads to benzimidazole[80], and when 5-amino-1-(2-cyanoethyl)tetrazole is heated with aqueous barium hydroxide, 5-aminotetrazole is formed[323]. Pyrolysis of 1-(2-cyanoethyl)-6-methylpyrid-2-one gives 6-methylpyrid-2-one and acrylonitrile[324].

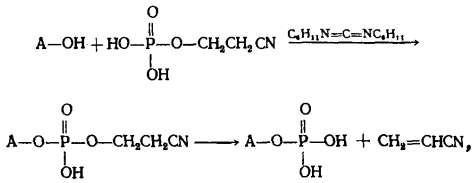
The cyanoethylation products of the following compounds have been decyanoethylated: pyrrolidine[325], derivatives of pyrazole[326,327], piperidine[251,278,325], morpholine[254], anabasine[328], phenothiazine[329,330], its benzo-derivative[331] and oxidation product[332], phenoxazine[331], phenoselenazine[333], tetrahydroharmine[334,335], 2-hydroxyquinoxaline[366], isocyanuric acid[337], dihydrobenzthiopyranoindole[339], and pteridine derivatives[339]. Attempts to remove the cyanoethyl group from 1-(2-cyanoethyl)-1,2,3,4-tetrahydro-4-ketoquinoline by means of bases have been unsuccessful. However, when this compound is treated with a mixture of concentrated hydrochloric acid and an excess of acetic anhydride, 1-acetyl-1,2,3,4-tetrahydro-4-ketoquinoline is obtained[314].

The bond between the 2-cyanoethyl group and the phosphorus atom has been studied in the mono-, di-, and tri-cyanoethylation products of phosphine, and also in their *P*-substituted derivatives. Although Rauhut and coworkers[340] were unable to remove the cyanoethyl group from the compounds mentioned above, other workers[341-344] have shown that *P*-cyanoethylated compounds can be decyanoethylated.

Halides of tri(2-cyanoethyl)tin are obtained by the action of halogens on tetra-(2-cyanoethyl)tin; under certain conditions the nitrile group is hydrolysed and two cyanoethyl groups are eliminated[345].

If a carbon–carbon bond is formed in cyanoethylation, it is usually very difficult to remove the 2-cyanoethyl group[250,346-348]. Under certain conditions, succinic acid dinitrile (the product of cyanoethylation of hydrocyanic acid) decomposes into hydrocyanic acid and acrylonitrile[211,349-351], the latter being obtained in up to 94% yield. Alkaline hydrolysis of tricyanoethylated nitromethane gives γ-ketopimelic acid, and a molecule of acrylonitrile is eliminated[211]. Some *C*-cyanoethylated compounds eliminate the cyanoethyl group under the conditions of the Fischer reaction[352].

Because acrylonitrile is readily eliminated from β-substituted propiononitriles, the 2-cyanoethyl group can be used as a protective group. It was used in this way for the cross--linking of two pyrazole nuclei by means of a methylene bridge attached to the 4-positions of both rings[326,327]; it has also been used in the synthesis of secondary amines[271,272], peptides[353], and monoesters of phosphoric acid[245]. 2-Cyanoethyl phosphate has been widely used in the synthesis of phosphate esters[223-243]. When the diesters of phosphoric acid formed are treated with mild alkali (barium hydroxide or 3 *N* aqueous lithium hydroxide at 100° for 15 min), acrylonitrile is eliminated and the monoester is formed. This method of phosphorylation is used in the synthesis of a number of nucleotides:



where A is a nucleoside residue.

Attempts have been made to use acrylonitrile for blocking sulphydryl groups of proteins[306,354]. The reaction in which *NN*-dicyanoethylated products are decyanoethylated has been used as the basis of a method for synthesising some *N*-monocyanoethylated compounds that are difficult or impossible to obtain by direct cyanoethylation with acrylonitrile[71,92,93,250,301].

5. ALKYLATIONS WITH THE AID OF β-SUBSTITUTED PROPIONIC ACIDS AND THEIR DERIVATIVES

The readiness with which β-elimination occurs in the β-substituted propionic acid series suggests that many alkylations carried out with the aid of β-substituted propionic acids and their derivatives proceed through a stage in which unsaturated compounds — acrylic acid, its ester, amide, or nitrile — are formed. This has been confirmed by studies of the mechanism and kinetics of these reactions[167,168,171,173,213,279,280,318,319,355-357].

When β-(methylthio)propionic acid is treated with hydrochloric acid, it forms di-(2-carboxyethyl) sulphide and dimethyl sulphide[358]. Under similar conditions, the hydrolysis of the methyl esters of β-(methylthio)- and β-(ethylthio)-propionic acids proceeds in the same way[358,359]; methanethiol and ethanethiol can be obtained by alkaline hydrolysis of these esters. When ethyl β-(methylamino)-propionate is heated to 130–140°, *NN*-bis-(2-ethoxycarbonylethyl)methylamine is formed[360]:

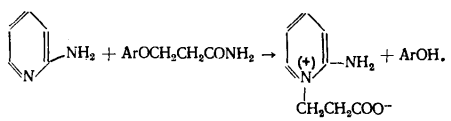
$$2\,CH_3NHCH_2CH_2COOC_2H_5 \rightarrow CH_3N(CH_2CH_2COOC_2H_5)_2 + CH_3NH_2.$$

When 2-carbamoylethyl hydrogen sulphate reacts with aliphatic and heterocyclic amines, carbamoylethylation of the amines takes place[155]. The amide of *N*-(2-carboxyethyl)-*p*-toluidine is formed when the following compounds are heated with *p*-toluidine in water at 100°; the amides of β-(alkylamino)- and β-aryloxy-propionic acids; the amides of *N*-mono-(2-carboxyethyl)-α-amino-acids and the diamides of *NN*-di-(2-carboxyethyl)-α-amino-acids; analogous derivatives of β-alanine; and sulphones containing the 2-carbamoylethyl group[60,361-363].

$$p\text{-}CH_3C_6H_4NH_2 + RCH_2CH_2CONH_2 \rightarrow p\text{-}CH_3C_6H_4NHCH_2CH_2CONH_2 + RH.$$

The products that have been obtained by the reaction of 2-carbamoylethyl hydrogen sulphate with alcohols and

phenols include acrylic acid, β-alkoxy- and β-aryloxy--propionic acids and the esters of these [165]. β-Arylpropionamides react with α-amino- [35] and γ-methyl-α-amino--pyrimidines [81] according to the following scheme:



It is interesting that when the 2-cyanoethyl ether of 2-naphthol is heated in benzene in the presence of alkali, the 2-cyanoethyl group is transferred from the oxygen atom to a carbon atom and 1-(2-cyanoethyl)-2-naphthol is formed [202,364,365]. An analogous reaction occurs with doubly cyanoethylated resorcinol [202]. When 1-phenyltetrazoline--5-thione is cyanoethylated, the *S*-isomer is converted to the *N*-isomer [249]. Attempts to transfer the cyanoethyl group in the indole ring from the nitrogen to the β-position have not been successful [75].

When diethylene glycol [192], acetamide [211], arylsulphamides [70,72,92,93,366], α-amino-acids [304,307,311], and phenylacetonitrile [348] are heated with their dicyanoethylation products, the 2-cyanoethyl groups are redistributed, and monocyanoethylated derivatives are formed, for example:

$$ArSO_2NH_2 + ArSO_2N(CH_2CH_2CN)_2 \rightarrow 2\,ArSO_2NHCH_2CH_2CN,$$
$$C_6H_5CH_2CN + C_6H_5C(CN)(CH_2CH_2CN)_2 \rightarrow 2\,C_6H_5CH(CN)CH_2CH_2CN.$$

Acetophenone with its tricyanoethylated derivatives gives mono- and di-cyanoethylation products [348]. When *unsym*--di-(2-cyanoethyl)hydrazine is treated with phenylisocyanate, a certain amount of *sym*-di-(2-cyanoethyl)hydrazine derivative is formed [367].

The occurrence of mobile equilibrium and reversibility in cyanoethylations is particularly well exemplified by the reaction of acrylonitrile with alcohols [175,210-212,250,368]. When β-alkoxypropiononitriles are heated or set aside with aliphatic or aliphatic–aromatic alcohols in the presence of alkalis or alkoxides, transcyanoethylation occurs [213,250,369,370]:

$$ROCH_2CH_2CN + R'OH \rightarrow R'OCH_2CH_2CN + ROH.$$

β-Alkoxypropiononitriles behave in the same way under the conditions of Vyshnegradskii's reaction [187]. Some β-alkoxypropiononitriles are used as cyanoethylating agents [35,81,182 201,202,213,250,371-377]. Bis-(2-cyanoethyl) ether has been used for the cyanoethylation of hydrogen sulphide [378], thiols and thiophenols [379], ketones [380], and aromatic amines [201,374]. 2-Cyanoethyl esters have been used for the cyanoethylation of aliphatic amines [381], benzene [219,382], resorcinol (in the nucleus) [383], pyrrole [384], and piperidine [385]. Much work has been done on *N*-substituted β-aminopropiononitriles as agents for the cyanoethylation of alcohols [168,371], malonic ester [376], triethyl phosphite [386], dimedone [387], aliphatic [371] and aromatic [167,201,206,279,280,373,388-391] amines, indole [73], piperidine [371], 9,10-dihydrophenanthridine [392], morpholine [376], pyrazolines [393], and pyrazolones [394]. β-Halogeno- [250] and β-hydroxy-propiononitriles [250] are used as cyanoethylation agents, as are also some products of the cyanoethylation of nitrogen-containing heterocyclic bases [250,388].

With the exception of *C*-cyanoethylated compounds, other β-substituted propiononitriles (β-halogeno-, β-alkoxy-, β-aryloxy-, and β-alkylamino-propiononitriles, *S*-cyanoethylated compounds, *N*-mono- and *NN*-di-cyanoethylated amino-acids, *NN*-dicyanoethylated arylsulphamides, cyanoethylation products of peptides and proteins) react with aromatic amines in water at 100° to form decyanoethylation and transcyanoethylation products [70-72,90-93,167,201,202,205-207 213,250,279,280,302-304,318,319,335,355,356,373,374,388-391,395]:

$$XCH_2CH_2CN + ArNH_2 \rightarrow ArNHCH_2CH_2CN + XH,$$

where X = halogen, RO, ArO, RS, ArS, $ArSO_2$, RNH, $(R)_2N$, HOOCCH(R)NH, etc. The reaction of β-substituted propiononitriles with 2-amino- [35] and 4-methyl-2-amino-pyridines [81] has been studied.

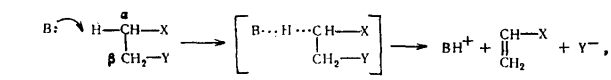
Products of the cyanoethylation of alcohols and aliphatic amines have been used instead of acrylonitrile in the reaction with phenylhydrazine for the synthesis of 3-amino-1--phenylpyrazoline [396]. The reaction of β-(dimethylamino)-propiononitrile with *p*-tolylhydrazine proceeds in the same way [397].

The use of β-substituted propiononitriles as cyanoethylating agents sometimes makes it possible to obtain cyanoethylated compounds when acrylonitrile cannot be used or when it gives low yields [250].

6. MECHANISM OF β-ELIMINATIONS

In most of the papers cited in this review, β-elimination was not the object of the investigation, but was only observed in studies on other problems. There are only a few papers in which some conclusions have been drawn as to possible reaction mechanisms or in which reaction kinetics have been studied [40,171,213,250,274,280,318,319,355-359]. These scattered data may be used, together with the general principles of the mechanisms of elimination reactions [398-401], to set up an approximate scheme of possible mechanisms for the reactions considered here.

The most important and the most widely studied class of β-elimination reactions in the β-substituted propionic acid series is that in which cleavage occurs under the action of basic agents. These reactions appear to proceed by a bimolecular elimination mechanism (*E*2) with an "*E*1 with B-like" transition state, in which rupture of the C–H bond precedes elimination of the β-substituent:

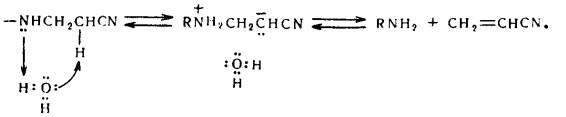


where X = COOH, COOR, $CONH_2$, CN; and Y = halogen, RO, ArO, AcO, H_2PO_3O, $(R)_2N$, $(R)_3N^+$, etc. However, it can happen that, under favourable conditions (low basicity of the agent B, low activating effect of the group X, and the presence in the β-position of substituents that facilitate rupture of the C–Y bond), there is a change to a synchronous or even *E*1-like bimolecular elimination mechanism [401].

The activating effect of the group X on the rate of elimination decreases in the order CN > $CONH_2$ > COOH, COOR. The particular ease with which decyanoethylation occurs in comparison with the removal of the 2-carboxyethyl, 2-carbamoylethyl, and 2-alkoxycarbonylethyl groups appears to be due to the high negative inductive effect (-*I*) of the nitrile group.

The scheme proposed by Bekhli [280] for the cleavage of β-dialkylaminopropiononitriles by a monomolecular mechanism (*E*1) does not appear to be valid. It was later shown that this reaction does not take place in the absence of basic agents [213]. It is also known that ammonium salts have little tendency to undergo cleavage by an *E*1 mechanism [401].

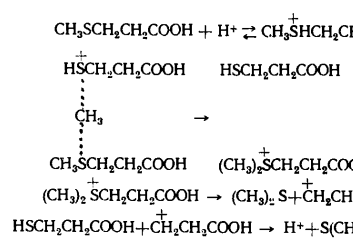
To explain the catalytic effect of water on the decyanoethylation of β-alkylaminopropiononitriles, a scheme has been proposed in which the water molecules act as a "proton carrier"[274]:



However, it is most probable that an $E2$ mechanism also operates here.

The scheme for nucleophilic bimolecular elimination does not appear to cover β-elimination reactions of β-hydroxy-, β-alkoxy-, β-aryloxy-, β-acyloxy-, and β-mercapto--propionic acids and their derivatives in an acid medium. The elimination may proceed through an oxonium ion. However, because of the lack of experimental results, it is not possible to advance a more detailed mechanism.

Challenger and coworkers have described a very interesting reaction of this type[358,359]. They observed that, when β-methylthiopropionic acid or its methyl ester is boiled with 6 N hydrochloric acid, extensive cleavage occurs with the formation of dimethyl sulphide and di-(2-carboxyethyl) sulphide. They propose the following mechanism for this reaction, which they have confirmed by numerous experimental results:



Up to now numerous pyrolytic cleavage reactions of β-halogeno-, β-hydroxy-, β-alkoxy, and β-acyloxy-propionic acids, and their esters, amides, and nitriles have not been studied at all. It may be supposed that they proceed by an "intramolecular elimination" (E_i) mechanism with a cyclic transition state, or by a radical mechanism similar to that of other pyrolytic eliminations[401]. However, cleavage of β-substituted propionic acids and their derivatives occurs at 150–250°, that is, at a temperature 100–200 deg lower than the temperature required for pyrolysis of the simplest alkyl halides, alcohols, and esters. This is probably due to the greater ease with which a hydrogen atom is eliminated from the propionic acids, arising from the effects of the carboxyl, ester, amide, and nitrile groups.

In conclusion it should be noted that at present it is still not possible to explain all the regularities and isolated anomalies of β-elimination. For example, the present review does not consider possible causes of the greater mobility of one 2-cyanoethyl group in the products of NN-dicyanoethylation, the effect of the β-substituent on ease of cleavage, isolated cases of carbon–carbon bond rupture, etc. More serious experimental work is required, with the use of physicochemical methods and kinetics studies, for the elucidation of the mechanism of β-elimination in the β-substituted propionic acid series.

GIBBERELLINS

N. Ya. Grigor'eva and V.F. Kucherov

CONTENTS

I. Gibberellins — natural phytohormones 850

II. Structure and chemical features of the gibberellins 851

III. Biogenesis of the gibberellins and their place among other natural polycyclic compounds 857

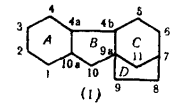
IV. Approach to an explanation of the mechanism of action of the gibberellins on higher plants 859

This review is devoted to the gibberellins — a new class of natural compound, the ever increasing interest in which is due to their high physiological activity as phytohormones.

The present article will be concerned with the chemical and biochemical aspects of the problem of the gibberellins. For a detailed analysis of the various physiological changes which can be observed in higher plants under the action of gibberellins, the reader is referred to several papers which have appeared in Soviet scientific literature [1-8].

I. GIBBERELLINS — NATURAL PHYTOHORMONES

The gibberellins, tetracyclic carboxylic acids, the structure of which is based on the hydrocarbon gibbane (I), were discovered by Japanese scientists investigating the reasons for the "bakanae" disease of rice ("foolish seedling disease"):



(I)

As long ago as 1898, Hori[9] established that the hypertrophic growth of the vegetative organs of rice seedlings which is typical of "bakanae" is caused by a fungus, the conidial stage of which was later named *Fusarium moniliforme* Sheld., the ascomycetous stage being named *Gibberella fujikuroi* Saw. In 1926, Kurosawa showed[10] that a similar physiological effect was produced by treating the seedlings with a culture medium of the fungus, free from mycelia, and in 1938 Yabuta and Sumiki[11] isolated as a crystalline material the active principles of the culture liquid of *Gibberella f.*, which they named gibberellin A and gibberellin B.

Subsequently the Japanese biochemists intensively studied the chemical structure and physiological properties of the preparations isolated, but their work only became known outside Japan in the 'fifties, when it gave an impetus to the development of studies in the field of gibberellins in other countries.

The first success in these investigations was the development of methods for the chromatographic purification of the crude preparation of gibberellin, which allowed Curtis and Cross[12] and also Stodola and coworkers[13] to isolate a pure substance with a high physiological activity, which was named gibberellic acid (GAc) or gibberellin A_3 (GA_3). The methods of fermentation and isolation which were developed out of Cross and Stodola's studies formed the basis of the industrial method of making GAc and made it an available substance[14,15]. Somewhat later, two other pure, physiologically active substances were isolated from the crude gibberellin preparation: gibberellins A_1[16-18] and A_2[17-19] (GA_1 and GA_2)†, and from the culture liquid of new strains of *Gibberella f.* the gibberellins A_4 (GA_4)[19-21], A_7 (GA_7)[22], A_9 (GA_9)[22], and A_{10} (GA_{10})[23] were obtained (see Table 1).

† The numbering of the first three gibberellins is determined by the order of their elution from columns during chromatography on a Celite 545 : Norite A mixture (1 : 1). The numbering of the other gibberellins (see below) was determined by the sequence in which they were isolated from natural sources.

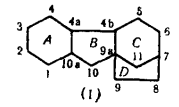
For a detailed analysis of the various physiological changes which can be observed in higher plants under the action of gibberellins, the reader is referred to several papers which have appeared in Soviet scientific literature [1-8].

I. GIBBERELLINS — NATURAL PHYTOHORMONES

The gibberellins, tetracyclic carboxylic acids, the structure of which is based on the hydrocarbon gibbane (I), were discovered by Japanese scientists investigating the reasons for the "bakanae" disease of rice ("foolish seedling disease"):



(I)

As long ago as 1898, Hori[9] established that the hypertrophic growth of the vegetative organs of rice seedlings which is typical of "bakanae" is caused by a fungus, the conidial stage of which was later named *Fusarium moniliforme* Sheld., the ascomycetous stage being named *Gibberella fujikuroi* Saw. In 1926, Kurosawa showed[10] that a similar physiological effect was produced by treating the seedlings with a culture medium of the fungus, free from mycelia, and in 1938 Yabuta and Sumiki[11] isolated as a crystalline material the active principles of the culture liquid of *Gibberella f.*, which they named gibberellin A and gibberellin B.

Subsequently the Japanese biochemists intensively studied the chemical structure and physiological properties of the preparations isolated, but their work only became known outside Japan in the 'fifties, when it gave an impetus to the development of studies in the field of gibberellins in other countries.

The first success in these investigations was the development of methods for the chromatographic purification of the crude preparation of gibberellin, which allowed Curtis and Cross[12] and also Stodola and coworkers[13] to isolate a pure substance with a high physiological activity, which was named gibberellic acid (GAc) or gibberellin A_3 (GA_3). The methods of fermentation and isolation which were developed out of Cross and Stodola's studies formed the basis of the industrial method of making GAc and made it an available substance[14,15]. Somewhat later, two other pure, physiologically active substances were isolated from the crude gibberellin preparation: gibberellins A_1[16-18] and A_2[17-19] (GA_1 and GA_2)†, and from the culture liquid of new strains of *Gibberella f.* the gibberellins A_4 (GA_4)[19-21], A_7 (GA_7)[22], A_9 (GA_9)[22], and A_{10} (GA_{10})[23] were obtained (see Table 1).

† The numbering of the first three gibberellins is determined by the order of their elution from columns during chromatography on a Celite 545 : Norite A mixture (1 : 1). The numbering of the other gibberellins (see below) was determined by the sequence in which they were isolated from natural sources.

TABLE 1. Physicochemical properties of the C_{19} gibberellins.

Name	Structural formula	M.p., °C	$[\alpha]_D$* (°C)	M.p. of methyl ester	$[\alpha]_D$ (°C) of methyl ester	pKa (25°) from Ref. 33	Ref.
Gibberellin A_1		255	+36 (20)	234	+46 (20)	3.97	16
Gibberellin A_2		235 255**	+11,7 (20)	190	+25 (26)	4.09	16,18,19
Gibberellin A_3 (gibberellic acid)		233	+92 (20)	209	+75 (20)	4.21	12,16
Gibberellin A_4		216 255**	−3 (20)	175	0±3 (20)	4.21	21
Gibberellin A_5		260	−77 (22)	191	—	4.09	30
Gibberellin A_6		206	−20 (26)	136	—	4.03	35
Gibberellin A_7		169 202**	+20 (24)	152 168**	+33 (23)	4.11	22
Gibberellin A_8		210	+13 (23)	221 231**	+14.8 (23)	4.04	35
Gibberellin A_9		208	−22 (22)	136	−15 (17)	4.26	22
Gibberellin A_{10}		245	+3	157	—	—	23

* Measured in ethanol for GA_1, GA_3, GA_7, and GA_9 and in methanol for GA_2, GA_5, GA_6, and GA_8.

** Polymorphic modifications.

The initial assignment of all these new substances to the gibberellin group was based on their common source in nature and the similarity of their spectra and physiological action on higher plants. Many investigations published in the 'fifties showed that the gibberellins are able to interfere actively in almost all the growth and development processes of plants. Thus, treatment with gibberellins stops the hibernation of seeds and stimulates their germination, accelerates the growth of seedlings, and "heals" the dwarf form of growth of dwarf mutants of higher plants. The last property is not possessed by any known chemical preparation. The ability of gibberellins to influence the photoperiodic reaction of flowering plants (long-day plants flower under short-day conditions after treatment with gibberellins) and their ability to alter the action of low temperatures (plants which need vernalisation flower normally and bear fruit without vernalisation after treatment with gibberellins) is extremely characteristic and specific.

Generalisation of the experimental results on the physiological activity of gibberellins led Chailakhyan[2,24] and, independently, Brian[25,26] to a hypothesis about the phytohormonal nature of the gibberellins. According to this hypothesis, the higher plants are capable of producing substances similar in properties to the gibberellins of fungal manufacture. These substances (endogenic gibberellins) play an important part in regulating the normal growth and the development of plants, and a shortage of them in the plant organism is responsible for the appearance of mutants with a dwarf form of growth, and also for the inability of plants which need vernalisation or a long day to develop normally in the absence of the appropriate external conditions.

Convincing confirmation of this hypothesis was given by recent investigations which showed that extracts of the epigeal parts of higher plants exhibit a gibberellin-like physiological activity and the substances present in them are almost indistinguishable from the fungal gibberellins in paper chromatography[4,27,28]. The chromatography of such extracts on a mixture of Celite 545 and Norite A permitted the separation — in addition to the known GA_1,[29-32] GA_3,[34,35] GA_4, and GA_7[23] — of three new individual substances: gibberellins A_5 (GA_5),[30,34] A_6 (GA_6),[35] and A_8 (GA_8)[35] (see also Table 1), the physiological activity of which is close to the activity of the fungal gibberellins‡.

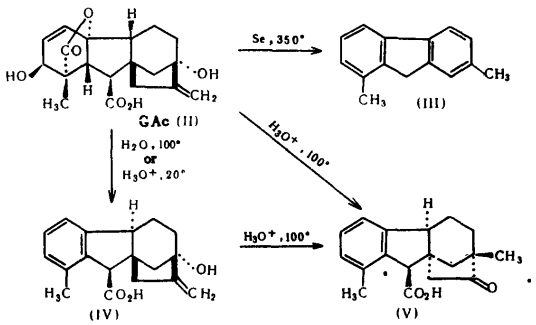
II. STRUCTURE AND CHEMICAL FEATURES OF THE GIBBERELLINS

In parallel with the work on the isolation of new gibberellins and study of the spectrum of their physiological activity, the investigation of the chemical structure of the compounds isolated was undertaken on a wide front. It was started by a group of Japanese chemists headed by Sumiki[41-46], who developed methods of degrading the gibberellins. However, up to 1955 these investigators worked with a preparation of gibberellin A, which was shown subsequently to be a mixture of GA_1, GA_2, and GA_3, therefore the characteristics which they obtained for the degradation products and also several conclusions about their structure needed checking. This task was completed by a group of English chemists headed by Cross, Grove, and McMillan, and as a result of their work the structure of the gibberellins which is now generally accepted was established and the peculiarities of the chemical conversions of this new class of natural compound were revealed.

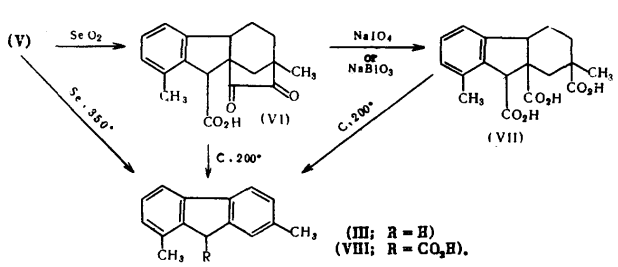
‡ Note that as well as the gibberellins substances more polar than the gibberellins and which exhibit gibberellin-like physiological activity were also separated chromatographically from the tissues of higher plants[36-40]. It was initially suggested that such substances are peptide complexes[36] or glucosides[37] of the known gibberellins and this received confirmation in the work of Sembdner and coworkers[38]. They showed that the highly polar neutral substance which they isolated from bean seeds is converted under acid hydrolysis conditions into a physiologically active organic acid comparable in polarity with known gibberellins. In addition to this acid, at least two other substances of carbohydrate type and three of peptide type were observed in the hydrolysate. Similar results were obtained by Sembdner and Schreiber[40] in studying tobacco seed gibberellins and also by Maksimov and coworkers in studying kale [*Brassica oleracea* var. *acephala* DC (Ed. of Translation)] gibberellins[36].

The key substance in the investigations to establish the structure of the gibberellins was GAc§, which is readily accessible. In this connection it is necessary to dwell in detail on the methods of determining the structure of GAc, particularly as the elucidation of the structure of this complex and very labile substance can serve as a good illustration of the enormous possibilities of contemporary organic chemistry and of the fruitfulness of a combination of chemical and physicochemical methods in studying natural products.

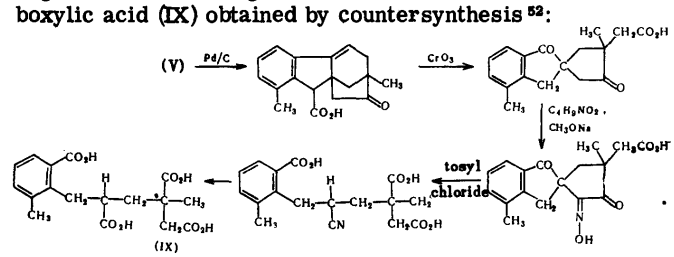
On the basis of the results of elemental and functional analyses, molecular weight determinations, and ultraviolet and infrared spectroscopic data, it was established that GAc has the empirical formula $C_{19}H_{22}O_6$, and is a tetracyclic, doubly-unsaturated dihydroxylactone-acid containing a methyl and a terminal methylene group[48]. It was shown that dehydrogenation of GAc with selenium at 350° [49] leads to 1,7-dimethylfluorene (III), which is evidence of the presence of the dimethylfluorene nucleus in its molecule. Subsequent stages of the work were connected with the revealing of the structure of the two main products of the degradation of GAc under acid conditions — allogibberic (IV) and gibberic (V) acids:



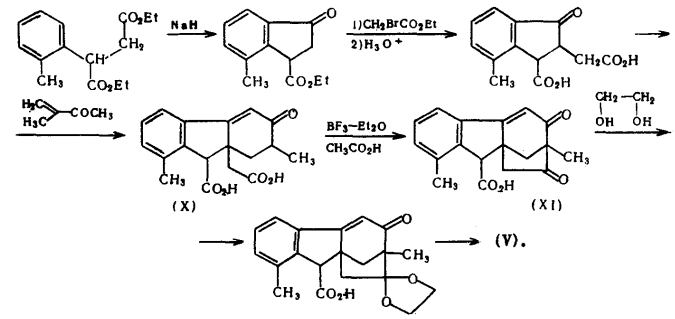
The analytical and spectroscopic data indicated that gibberic acid (V) is a tetracyclic dimethyl-substituted keto-acid of empirical formula $C_{18}H_{20}O_3$, in the skeleton of which there are an aromatic ring and a cyclopentane ring bearing a carbonyl group. The oxidation of gibberic acid with selenium dioxide leads to gibberdionic acid (VI) which under the action of sodium bismuthate or periodate is readily converted into a tricarboxylic acid (VII). The dehydrogenation of the latter, like the dehydrogenation of gibberic acid itself with selenium at 350°, leads to 1,7-dimethylfluorene (III):



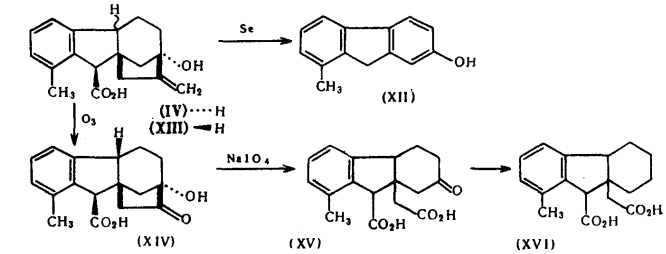
From these results it was concluded that the dehydrogenation of gibberic acid with selenium takes place without rearrangement of the skeleton and is accompanied by the breaking of the $-CH_2-CO-$ bridge connected to the flurorene nucleus at two quaternary carbon atoms. These facts, in conjunction with the formation of 1,7-dimethylfluorene-9-carboxylic acid (VIII) on the dehydrogenation of methyl gibberdionate, allowed gibberic acid to be given formula (V).[48,50] Its correctness was confirmed[51] by the oxidative degradation according to the scheme below to a tetracarboxylic acid (IX) obtained by countersynthesis[52]:



The final work in establishing the structure of gibberic acid was its synthesis, effected in 1960 by Loewenthal and Malhotra[53] by the scheme given below. The most interesting stage in this synthesis was the cyclisation (X) → (XI) in acetic acid in the presence of boron trifluoride–diethyl ether which enabled the tetracyclic diketo-acid (XI) to be obtained in ~ 80% yield:



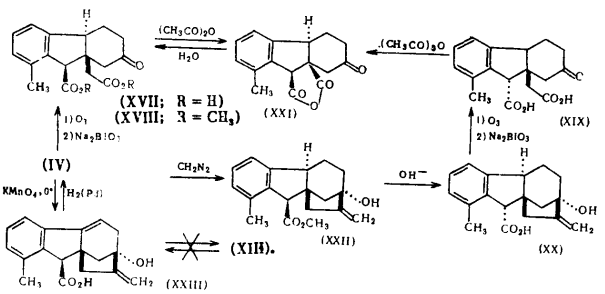
The other product of the degradation of GAc — allogibberic acid (IV) — is a tetracyclic carboxylic acid containing an aromatic ring, a tertiary hydroxyl group, and a terminal methylene group situated at the five-membered ring[48,50]. Since the dehydrogenation of allogibberic acid with selenium leads to 1-methylfluoren-7-ol (XII),[54] and when it is heated with dilute acids gibberic acid is formed (V), allogibberic acid was given formula (IV), and this was then confirmed by oxidative degradation as follows[52]:



As is seen from this scheme, the ozonation of epiallogibberic acid (XIII) — the epimer of (IV) at the $C_{(4b)}$ hydrogen atom — leads to the norketone (XIV) which in accordance with its α-ketol structure is readily cleaved by the action of sodium periodate or bismuthate. The reduction of the ketodicarboxylic acid (XV) thus obtained by the Kishner method leads to an acid (XVI), the structure of which was confirmed by countersynthesis[55,56]. A study of the stereochemistry of the conversions of the oxidative degradation products of allogibberic acid allowed its relative

§ In the fermentation of *Gibberella f.*, up to 1 g GAc,[47] 12 mg GA_1,[16] 0.3 mg GA_4,[21] 25 mg GA_7,[22] and 3–4 mg GA_9[22] are isolated from 1 litre of culture liquid. 2 mg GA_1,[28] 1 mg GA_5,[30] 8 mg GA_6,[35] and 16 mg GA_8[35] are isolated on extracting 1 kg of *Phaseolus multiflorus* seeds.

configuration to be found[57]. This problem was solved after the elucidation of the configuration of the carboxylic group at $C_{(10)}$ relative to the ethylene bridge at $C_{(7)}$–$C_{(9a)}$ and also the stereochemistry of the junction of rings *B* and *C*. The first part of the problem was solved by studying the formation of anhydrides by the dicarboxylic acids (XVII) and (XIX), which are epimeric at $C_{(10)}$ and were obtained in the oxidative degradation of allogibberic acid (IV) and its $C_{(10)}$ epimer (XX):



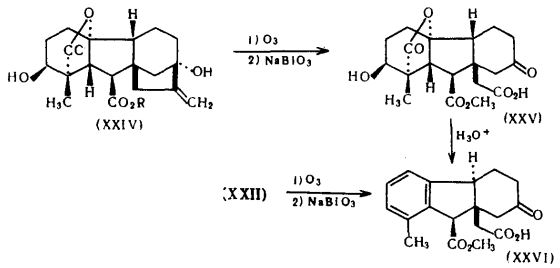
On heating with acetic anhydride, both isomeric acids give the same *cis*-anhydride (XXI), the saponification of which with water leads only to the *cis*-acid (XVII). Since this acid was identical with the degradation product of allogibberic acid (IV) the safe conclusion was drawn that in the latter there is a *cis* arrangement of the $C_{(10)}$ carboxyl group and the ethylene bridge.

The stereochemistry of the junction of the rings *B* and *C* was found by studying the stereochemistry of the hydrogenation of dehydroallogibberic acid (XXIII), formed on treating allogibberic acid (IV) with an aqueous solution of potassium permanganate at 0°. It is well known that in the catalytic hydrogenation of a double bond the addition of hydrogen proceeds from the least hindered side of the molecule. Therefore the formation of allogibberic acid (IV), uncontaminated with epiallogibberic acid (XIII) in the catalytic hydrogenation of acid (XXIII) indicated the *trans*-orientation of the hydrogen atom at $C_{(4b)}$ relative to the ethylene bridge and relative to the carboxyl group at $C_{(10)}$.

Analogous conversions in the gibberic acid (V) series showed that its carboxyl group is *trans*-oriented relative to the ethylene bridge and that rings *B*/*C* are *cis*-fused[41].

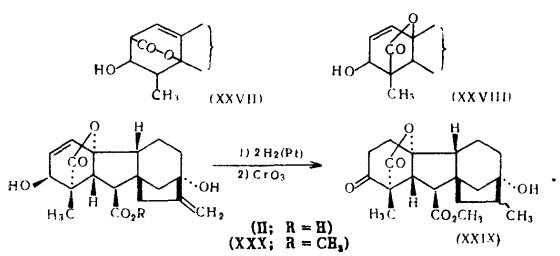
The examination of the chemical conversions still did not give the possibility of establishing the absolute configuration of gibberic and allogibberic acids. To solve this problem the method of optical rotatory dispersion was applied. With its aid Klyne[21,59], and independently of him Stork and Newman[58], showed that gibberic acid has the (7-*R*, 9a-*R*, 10-*R*)- and allogibberic acid the (7-*S*, 9a-*S*, 10-*R*)-configuration. However, this method did not allow the absolute configuration of the $C_{(4b)}$ asymmetric centre to be determined reliably, since it appeared that the rotatory dispersion curves of the compounds epimeric at $C_{(4b)}$ of this series are almost identical[59]. The problem was solved by using the method of circular dichroism, with the aid of which the (4b-*S*) absolute configuration of both acids was established[60].

The elucidation of the structure of gibberic and allogibberic acids allowed the next step to be taken in the proof of the structure of gibberellic acid — to introduce the hypothesis that the structure of rings *B*, *C*, and *D* in allogibberic and gibberellic acids is identical[61]. Confirmation of this was obtained by studying the oxidative degradation of the methyl ester of GA_1 (XXIV; R = CH_3) — the dihydro-derivative of the methyl ester of GAc. The ozonation of (XXIV) and the subsequent treatment of the resulting norketone with sodium bismuthate leads to the ester (XXV). On treatment with mineral acid the latter is converted into ester (XXVI) — the oxidative degradation product of methyl allogibberate (XXII)[61,62]:



The conclusion about the identity of the absolute configuration of rings *B*, *C*, and *D* in allogibberic and gibberellic acids, made in the same work on the basis of the optical rotatory dispersion results, seemed, however, inaccurate (see above). Use of the method of circular dichroism[60] showed that the absolute configurations of the centres $C_{(7)}$, $C_{(9)}$, and $C_{(10)}$ in these acids are identical but those of the $C_{(4b)}$ centre are contrary, that is, the system of rings *B*, *C*, and *D* in GAc has the (4b-*R*, 7-*S*, 9a-*S*, 10-*R*) absolute configuration.

The most complex step in determining the structure of GAc was elucidating the structure of ring *A*, for which in 1958 Japanese chemists proposed the partial formula (XXVII), [63] and English chemists formula (XXVIII) [64]:



Many conversions of GAc carried out by both groups of investigators showed that the (XXVIII) was the more probable formula. The final choice in its favour was made, however, only after employing the NMR method[65,66], which showed that GAc contains a hydrogen atom at $C_{(10a)}$ and four olefinic protons. Later, formula (XXVIII) was also confirmed by X-ray diffraction[60,67].

Many difficulties were encountered in proving the configuration of ring *A* of gibberellic acid. In 1959 Cross and coworkers[68] proposed formula (II) for GAc, in which the $C_{(2)}$ hydroxyl, which is readily epimerised by the action of 0.01 *N* alkali, was given the axial β configuration and the *A*/*B* ring junction was given the so-called *trans*-unnatural¶ (4a-α, 10a-β) configuration. The correctness of this formula was confirmed by nuclear magnetic resonance studies which showed the *trans*-fusion of the *A*/*B* rings in gibberellic acid. It was also demonstrated that ketone (XXIX) obtained by hydrogenation of the methyl ester of GAc (XXX) and subsequent oxidation of the OH group at $C_{(2)}$ exhibits a

¶ The name arises from the fact that most natural terpenes and steroids exhibit the antipodal fusion of rings *A* and *B*.

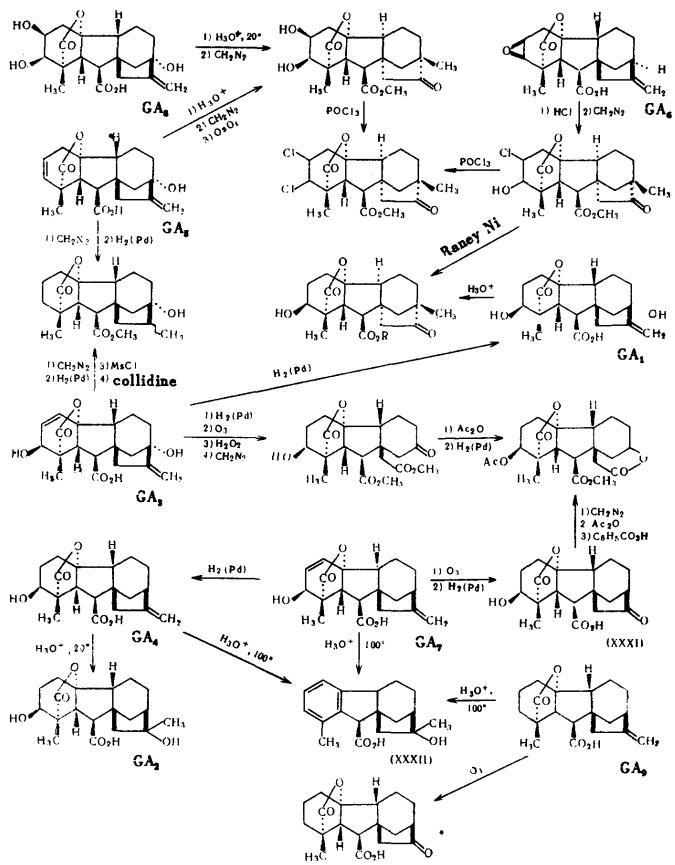
negative Cotton effect. This allowed, by application of the Octant Rule, a conclusion to be drawn about the β configuration of the hydrogen atom at $C_{(10a)}$.

In 1960 the Hudson–Klyne Lactone Rule[69] was applied to determine the stereochemistry of ring *A* of gibberellic acid; it enabled a decision to be made concerning the configuration of the lactone rings on the basis of the change in sign of the molecular rotation accompanying the opening of this ring. Stork and Newman[70] compared the changes in molecular rotation observable in the opening of steroid lactones with an α-configuration of the lactone ring on the one hand and of gibberellic acid on the other and concluded there was α-orientation of the lactone ring in GAc. Somewhat later Whalley and coworkers[71] investigated the regularities in the change in molecular rotation of lactones of the diterpene series with α- and β-configurations of the lactone ring and by applying the results obtained to the GAc system they concluded that a β-orientated lactone ring is present in ring *A* of GAc. However, this conclusion could not be considered to be firmly based as in both instances compounds with "natural" (that is, opposite to gibberellin) fused *A/B* rings were taken for comparison. The other chemical papers of 1960–1962 also did not give an unambiguous solution to the problem although detailed investigation of the stereochemistry of ring *A* made by Grove and coworkers[72] yielded a weighty argument in support of formula (II). Conclusive confirmation of it was obtained by X-ray diffraction[60] which demonstrated the α-orientated lactone ring in GAc.

Hence the structure of gibberellic acid is now reliably proved. It is expressed by formula (II) in complete agreement with which are the data obtained in studying the path of its biosynthesis.

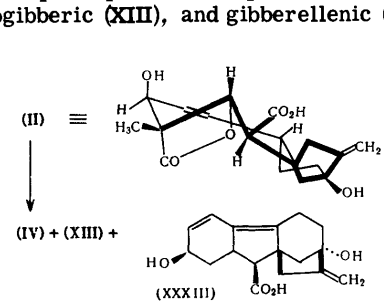
The structure of the other gibberellins† was found by referring them to the derivatives and degradation products of GAc.[19,21,22,30,35] It transpired that one group of gibberellins (GA_1, GA_5, GA_6, and GA_8) differ from GAc only in certain modifications of ring *A*. On treatment with hot solutions of mineral acids the gibberellins of this group are converted into gibberellic acid (V). The gibberellins of the other group (GA_2, GA_4, GA_7, and GA_9) differ from GAc more significantly. They do not contain a hydroxyl group at $C_{(7)}$ and thanks to this on ozonation they form norketones — for example, (XXXI) — which neither sodium bismuthate nor sodium iodate can cleave. Under the action of hot solutions of mineral acids the gibberellins of this group give aromatic acids — for example, (XXXII). The only change which occurs in the system of rings *C* and *D* during this treatment is the hydration of the terminal methylene group.

The chemical reactions which allow the structure of all the C_{19}-gibberellins at present known to be demonstrated are given schematically below:



During the elucidation of the structure of the gibberellins a series of chemical reactions was observed which are characteristic for these polycyclic compounds. We will consider the most interesting of them in detail.

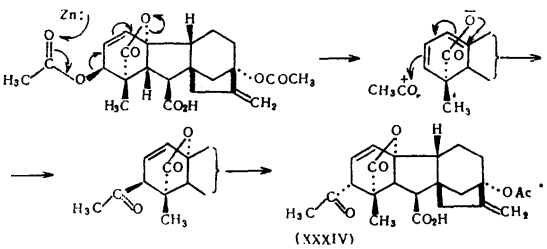
1. As mentioned above, gibberellins are extremely labile compounds, which undergo changes in aqueous solutions even at room temperatures. In this the most reactive centres of their molecules are the lactone ring, the $C_{(2)}$ hydroxyl group, and the $C_{(4b)}$ hydrogen. The opening of the lactone ring, which is accompanied by the formation of polyene and partly aromatised compounds, proceeds especially readily in gibberellins with a double bond in ring *A* (GA_3 and GA_7). In aqueous solutions it is observed even at room temperature. At elevated temperatures the process is complicated by epimerisation of the hydrogen atom at $C_{(4b)}$ and the principal reaction products are allogibberic (IV), epiallogibberic (XIII), and gibberellenic (XXXIII) acids:



The ease of formation of acids (IV) and (XXXIII) is due to the stereochemistry of the gibberellin molecules. According to the X-ray analyses[60], ring *C* of the gibberellins has a boat-shaped conformation, thanks to which there

† While this review was being prepared for publication Cross and Norton[108] isolated, from the culture liquid of *Gibberella f.*, a group of C_{20} di- and tri-carboxylic acids which are biogenetic precursors of the gibberellins. They proposed to name these compounds C_{20}-gibberellins. For more detailed information about these compounds see p. 858. The same authors reported[23,108] the isolation of a new C_{19} gibberellin, giberellin A_{11}; however, information concerning its structure and physicochemical properties has not been published yet.

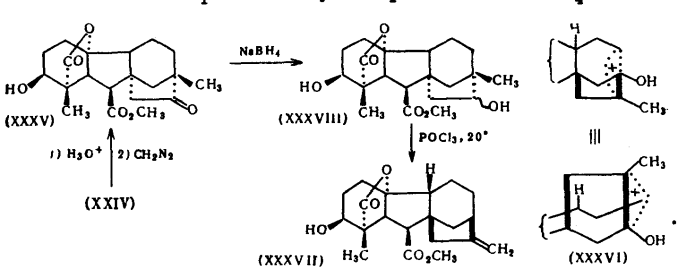
is considerable interaction of the spatially close axial hydrogen atom at $C_{(4b)}$ and carboxyl group at $C_{(10)}$ and with the ethylene bridge. Therefore the processes of epimerisation and dehydrogenation at $C_{(4b)}$, which remove this interaction, are energetically favourable. The instability of the lactone ring of gibberellins A_3 and A_7 is also due to steric reasons: the allyl lactone grouping formed by participation of the quaternary $C_{(4a)}$ atom is considerably strained and in consequence is readily opened under the influence of even such weak acids as the gibberellins themselves. The lability of the lactone ring of the gibberellins introduces several significant limitations into the chemistry of these compounds. For example, it is impossible to change from the compounds of the gibberellic acid series to the corresponding 7-deoxy-compounds with the aid of zinc and acetic acid anhydride. As McMillan and coworkers showed[73], under these conditions formation of an acetyl derivative (XXXIV) occurs, probably by the following mechanism:



2. Under conditions of catalytic hydrogenation under neutral and acid solvents the lactone ring of the gibberellins undergoes partial hydrogenolysis. The proportion of hydrogenolysis products in the reaction mixture is especially high for GA_3 and GA_7.[74-78]

3. The treatment of gibberellins containing a hydroxyl group at $C_{(7)}$ with hot dilute solutions of acids is accompanied — in addition to the opening of the lactone ring considered above and the epimerisation at $C_{(4b)}$ — by rearrangement of the carbon skeleton of rings *B*, *C*, and *D*, leading to gibberic acid (V).

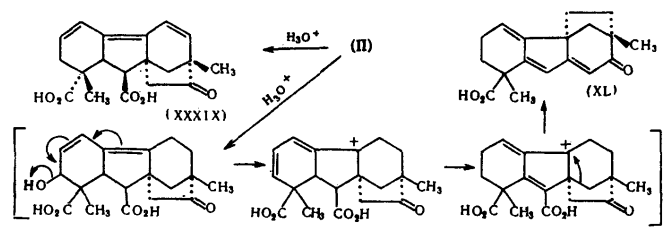
For gibberellins with a saturated ring *A* such a rearrangement takes place more readily than the opening of the lactone ring, so that it is possible to go, for example, from GA_1 (XXIV; R = H) to the ketone (XXXV). An analogous rearrangement is known for other natural compounds containing a fragment similar to rings *C* and *D* of the gibberellins (the diterpenes of the phyllocladene group, the diterpene alkaloids of the atisine group, etc.; see below). Its mechanism was studied in detail by Grove and Mulholland[57] and also by Birch and coworkers[79] who showed by the tracer method that a conversion analogous to the formation of (V) from GAc takes place by the mechanism of the Wagner–Meerwein rearrangement through a non-classical ion (XXXVI). This rearrangement of the gibberellin skeleton was used by Cross and coworkers[80] for going from derivatives of GA_1 to 7-deoxy-compounds of the GA_4 series:



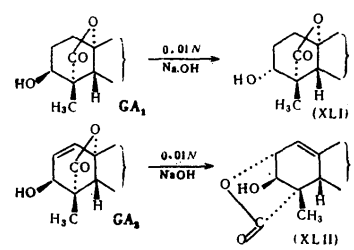
As the scheme shows, the methyl ester of GA_4 (XXXVII) was obtained by these investigators from the methyl ester of GA_1 (XXIV; R = CH_3) as the result of a double Wagner–Meerwein rearrangement: (XXIV) → (XXXV), (XXXVIII) → → (XXXVII). The low yield in this reaction is attributed to steric causes: on converting (XXXVIII) into (XXXVII) — in distinction from the conversion of (XXIV) into (XXXV) — the chair form of ring *C* becomes boat-shaped.

It is interesting to note that in gibberellins which do not contain a hydroxyl group at $C_{(7)}$ such a rearrangement is not observed. Under the conditions considered these compounds undergo only hydration of the terminal methylene group (see p. 854).

When gibberellins with an unsaturated ring *A* (GA_3, GA_7) are treated with an alcoholic solution of sulphuric acid, rearrangement of the carbon skeleton also occurs. However, unlike the reaction in an aqueous medium, the action of alcoholic sulphuric acid on these gibberellins is not accompanied by aromatisation of ring *A* and the main products of the reaction are the acids (XXXIX) and (XL)‡. A mechanism proposed for the formation of (XXXIX) includes a single, and that for the formation of (XL) a double, Wagner–Meerwein conversion[81] in accordance with the scheme:



4. Under weakly alkaline conditions the most "vulnerable" place of the gibberellins is again ring *A*. Treatment of the gibberellins possessing a saturated ring *A* (for example, GA_1) with 0.01 *N* NaOH is accompanied by epimerisation of the hydroxyl group at $C_{(2)}$ and leads to the lactone (XLI). Under similar conditions the gibberellins with an unsaturated ring *A* (GA_3 and GA_7) undergo an allyl rearrangement[82] and give lactones of type (XLII), which contain, like the original gibberellins, a hydroxyl group at $C_{(2)}$§:

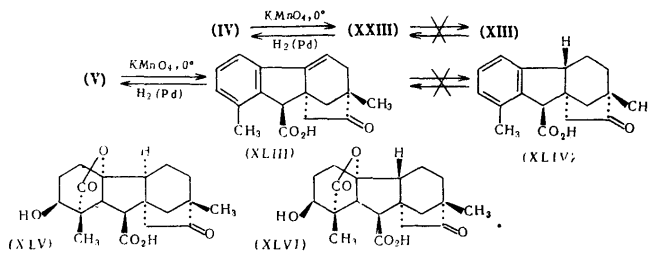


5. The complex stereochemistry of the gibberellins suggests that they should exhibit a variety of reactions of the free groups. As a rule, the information about such

‡ Note that the formation of (XXXIX) and (XL) is connected with the appearance of a dark red coloration accompanied by a blue fluorescence which is observed during the treatment of GA_3 and GA_7 with alcoholic solutions of sulphuric acid.

§ Note that epimerisation at $C_{(2)}$ and the conversion of (II) into (XLII) are accompanied by complete loss of physiological activity.

reactions is still very limited. As an example may be mentioned the difference in reactivity of compounds which are epimeric at $C_{(4b)}$, those studied in greatest detail being the degradation products of GAc containing an aromatic ring *A*.



Thus it has been found that allogibberic (IV) and gibberic (V) acids, for which the hydrogen atom at $C_{(4b)}$ has *trans*-orientation relative to the carboxyl group at $C_{(10)}$, are readily dehydrogenated under the action of potassium permanganate and even at 0° give the corresponding dehydro-acids (XXIII) and (XLIII). Contrary to this, the epimeric acids (XIII) and (XLIV), in which the hydrogen atom at $C_{(4b)}$ has *cis*-orientation relative to the carboxyl group at $C_{(10)}$, are stable to the action of potassium permanganate at 0° and do not form dehydro-acids (XXIII) and (XLIII) on hydrogenation.

The interaction of the carboxyl group at $C_{(10)}$ with the $C_{(4b)}$ hydrogen atom which is *cis*-oriented in relation to it is also apparent in the NMR spectra. Thus whereas in the spectrum of methyl gibberellate the signal of the proton at $C_{(4b)}$ is at $\tau = 7.7$, and in the norketone (XLV) it is at $\tau = 7.61$, in the norketone (XLVI) it occurs at $\tau = 7.2$.[59]

Yet another example of the sterically adjacent groups in the gibberellin molecule is provided by the interaction of the Δ^2 double bond and the carbonyl group of the lactone ring in GA_5 and its derivatives, which can be observed from the appearance of an anomalous absorption peak in the ultraviolet spectra of the corresponding compounds[30].

In examining the chemical features of the gibberellins it is impossible to avoid discussing the methods of analysing mixtures of these compounds of great structural similarity, particularly as these methods now form the basis for the identification of new gibberellin-like substances.

Although the first gibberellins were isolated as pure compounds by chromatography on columns packed with Celite 545 as long ago as the 'fifties, a reliable method of complete analysis of their mixtures did not exist until recently. The use of paper chromatography for this purpose allowed GA_8 and GA_9 to be determined reliably, but it was impossible to separate GA_1–GA_3 mixtures, or GA_4 and GA_7, by this method, although many chromatographic systems were tried[18,22,34,83,84]. Table 2 gives the R_f values of the gibberellins in the most convenient systems of solvents.

Satisfactory separation of a mixture of GA_1 and GA_3 was achieved by using centrifugal paper chromatography[85], and also thin-layer chromatography on aluminium oxide[85] and silica gel[86,87].

McMillan and Suter[88] made a complete analysis of a mixture of gibberellins by comparing the results of chromatography in a thin layer of silica gel G and kieselguhr G (see Table 3).

TABLE 4. Fluorescence of the gibberellins on thin-layer chromatograms.

Gibberellin	Colour of the fluorescing spot	Induction period of fluorescence, min	Gibberellin	Colour of the fluorescing spot	Induction period of fluorescence, min
GA_1	blue	30—40	GA_6	blue	10—20
GA_2	purple	4—8	GA_7	yellow	1—2
GA_3	blue-green	1—3	GA_8	blue	10—20
GA_4	purple	4—8	GA_9	purple	4—8
GA_5	blue	10—20			

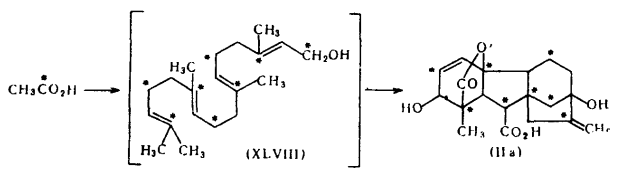
During thin-layer chromatography the gibberellins are observed by treatment of the plate with sulphuric acid and then heating. Spots which fluoresce in ultraviolet light appear, the colour and conditions of appearance of which (see Table 4) are important characteristics of the gibberellins[32].

This method allowed Jones and coworkers[31,32,87] to identify the known gibberellins in plant tissues at negligibly low concentrations (3–5 γ kg^{-1}).

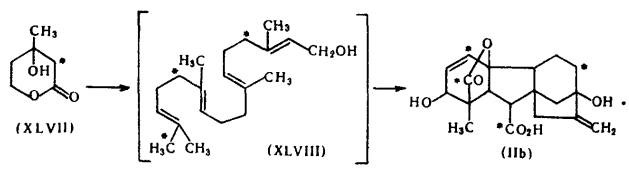
A rapid and reliable analysis of mixtures of the known gibberellins can be made also by gas–liquid chromatography[89]. Finally, very recently it was shown[90] that fragmentation mass spectrometry can be used for the analysis of mixtures and identification of individual gibberellins.

III. BIOGENESIS OF THE GIBBERELLINS AND THEIR PLACE AMONG OTHER NATURAL POLYCYCLIC COMPOUNDS

Even before the final elucidation of the structure of the gibberellins the study of the biosynthesis paths of GAc with the enzyme systems of *Gibberella fujikuroi* had begun. The first investigation of this problem was published by Birch and coworkers[91] who suggested that GAc is built by the fungus by the normal path of biosynthesis of cyclic diterpenes¶, that is, from molecules of acetic acid or the most characteristic precursor of the terpenes — mevalonolactone (XLVII). During this, the structural units are linked in accordance with the Ruzicka isoprene rule (by the head-to-tail principle), and the synthesis proceeds through a stage of formation of a normal acyclic precursor of the geranylgeraniol diterpenes (XLVIII). Cyclisation and slight transformation of the latter leads to GAc. This hypothesis could be easily checked by the use of labelled atoms. Actually, if it is true, then in GAc synthesised by fungi on a culture medium containing $^{14}CH_3CO_2H$, or mevalonolactone with ^{14}C in the $C_{(2)}$ position, the ^{14}C tracers should be distributed according to formulae (IIa) and (IIb):



(XLVIII) (IIa)

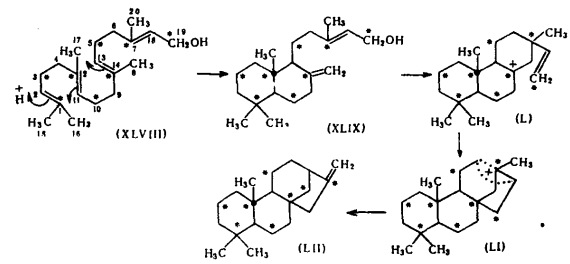


(XLVII) (XLVIII) (IIb)

Birch and his coworkers succeeded in showing that the tracer distribution corresponds strictly with the prediction.

Very recently[95], it was shown experimentally that the incubation of radioactive geranylgeraniol with *Gibberella f.* does not lead to the formation of radioactive gibberellic acid, and the precursor of the gibberellins is, as might have been expected, not this diterpene itself, but its pyrophosphate.

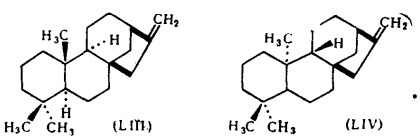
A detailed study of the reactions leading from the acyclic precursor of type (XLVIII) to GAc was not carried out in this work of Birch. However, it was assumed that the first stage in this conversion is the anti-*trans*-cyclisation at the Δ^{11} double bond to form a bicyclic product (XLIX) in which rings *A*/*B* are *trans*-fused. Subsequently there is the stage of dehydration of (XLIX) accompanied by closure of ring *C* and the formation of a carbonium ion (L), in which attack of the double bond by the cationic centre at $C_{(14)}$ passes through the stage of the non-classical ion (LI) to the tetracyclic precursor (LII):



(XLVIII) (XLIX) (L) (LII) (LI)

The first confirmation of this hypothesis was obtained even in the work of Birch and coworkers[91], since the distribution of the radioactive tracers in rings *C* and *D* of the gibberellic acid which is formed during fermentation in the presence of labelled acetic acid agreed well with the proposed scheme — compare formulae (LII) and (IIa).

Developing this hypothesis concerning the biogenesis of the gibberellins, Birch and Winter[96] suggested that the tetracyclic precursor of GAc of type (LII) is the well-studied diterpene phyllocladene (LIII).[97] However, their attempt to convert phyllocladene into GAc with the aid of the enzyme systems of *Gibberella f.* were unsuccessful: on incubation with phyllocladene labelled with ^{14}C, the fungus produced only non-radioactive GAc. In the light of contemporary ideas about the stereochemistry of the gibberellins this result does not seem unexpected, since phyllocladene exhibits the "natural" configuration at the fusion sites of rings *A* and *B*, contrary to the gibberellin configuration:



(LIII) (LIV)

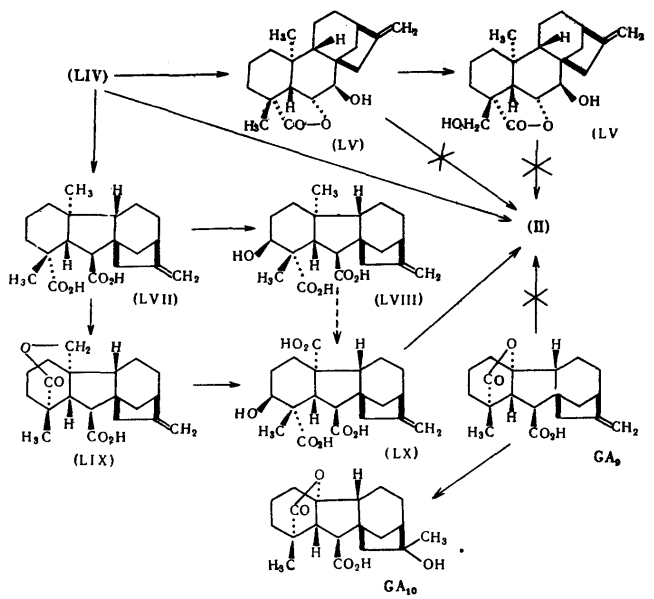
The true tetracyclic precursor of the gibberellins was found by Cross and coworkers[23,98] who showed that the culture liquid of *Gibberella f.* contains a tetracyclic diterpene (-)-kaurene (LIV),[99,100] which is easily converted into GAc under the action of fungal enzymic systems.

Extensive work carried out by the Cross group on the identification of the metabolites of various strains of *Gibberella f.* under different fermentation conditions[23,101–104] allowed the sequence of biosynthetic stages leading from kaurene to GAc to be noted. Until the publication of the results of these investigations it was thought[91,105] that the contraction of the six-membered ring *B* on going from the tetracyclic precursor to GAc precedes the introduction of the oxygen-containing functions into this ring. However, experimental verification showed[23] that neither hydroxykaurenolide (LV) nor dihydroxykaurenolide (LVI), which are isolated from the culture liquid of *Gibberella f.*, are converted by the fungus into GAc†.

¶ A discussion of the biosynthesis paths of the cyclic terpenes goes beyond the bounds of the present review. The reader should consult Refs. 92–94.

† GA_9 is also not a precursor of GAc. With the aid of the method of labelled atoms it was shown that under fermentation conditions GA_9 is converted into a new gibberellin, GA_{10}.[106]

Cross and his coworkers assume that the contraction of ring *B* is brought about in unoxidised kaurene, which is converted by acids (LVII)–(LX) into gibberellic acid:



A detailed investigation of these last stages in the biosynthesis of GAc is now being made in Cross's laboratory. In the latest communications from this laboratory [107] the isolation of the acids (LVII)–(LX) from the *Gibberella f.* culture liquid has been described, and also the conversion of acid (LVII) labelled with ^{14}C at the $C_{(8)}$ methylene group into gibberellic acid (II) and the acid (LX). In both compounds the radioactive marker was found only in the terminal methylene group. On the basis of the results, Cross and Norton propose to call the acids (LVII), (LX), and (LVIII) — which are precursors of the gibberellins and exhibit gibberellin-like physiological activity — gibberellins A_{12}, A_{13}, and A_{14} respectively [108] (see Table 5). These compounds therefore disclose a new group of C_{20} gibberellins, which differ markedly from the C_{19} gibberellins considered above in the structure of ring *A*.

The investigation of the biosynthesis paths for the gibberellins in the tissues of higher plants has started only very recently. West and coworkers [95] have shown that in the incubation of a cell-fluid-free homogenate of endosperm nuclei of wild cucumber with [2-^{14}C]mevalonolactone, radioactive (-)-kaurene and (-)-kauren-19-ol are synthesised, which are converted by the enzymic systems of *Gibberella f.* into gibberellins. Hence it is quite probable that in plant tissues also the gibberellins are synthesised from (-)-kaurene.

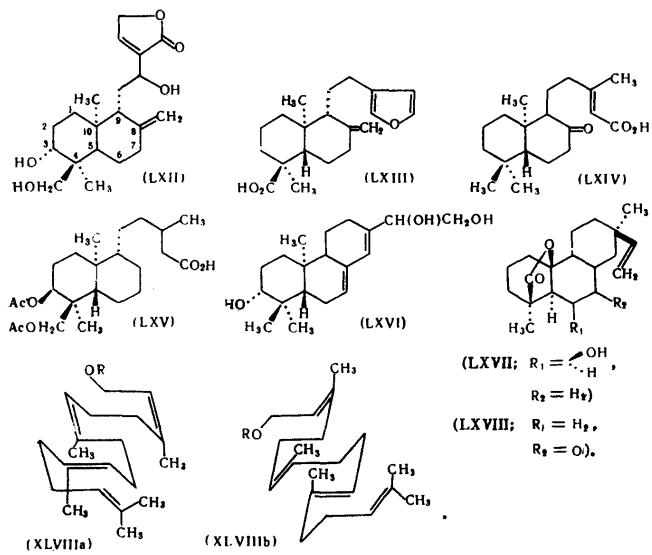
Some interesting work has been done by Lang and coworkers [109]. On incubating *Gibberella f.* with the diterpene steviol (LXI) these investigators detected the radioactive tracer in the mixture of gibberellins synthesised by the fungus. Careful chromatography of this mixture established that the tracer is concentrated in a zone free from known gibberellins but exhibiting high gibberellin-like activity.

A study of the biogenesis of the gibberellins allows us to understand the place of this unique polycyclic system among the natural compounds.

TABLE 5. Physicochemical properties of C_{20} gibberellins.

Name	Structural formula	M.p., °C	$[\alpha]_D$ (°C) n alcohol	M.p. of methyl ester, °C
Gibberellin A_{12}		245		liquid
Gibberellin A_{13}		194	—48(17)	117
Gibberellin A_{14}		232	—73	liquid

As is well known, geranylgeranyl pyrophosphate, an acyclic precursor of GAc, forms the start of a large group of natural diterpenes, which consequently are also the nearest biogenetic relatives of the gibberellins. When the cyclisation of geranylgeranyl pyrophosphate is interrupted at the stage of the GAc precursor of type (XLIX) (see p. 857), then bicyclic diterpenes are formed. In this, the transformation of the general precursor can mask the relationship of the compounds which are formed, leading to such different structures as andrographolide (LXII) [110], polyalthic (LXIII) [111], copalic (LXIV) [112], and eperuic (LXV) [113] acids‡.

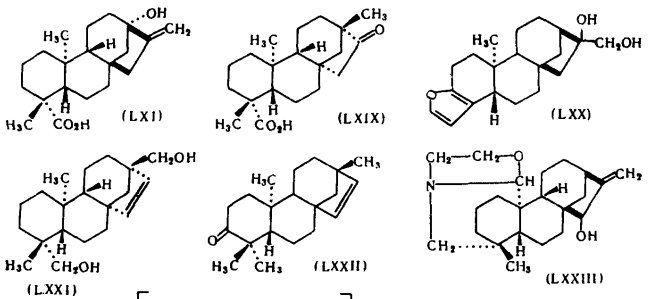


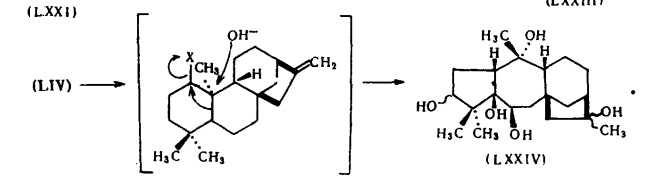
When the cyclisation of geranylgeranyl pyrophosphate is broken off at the stage of the precursor of type (L) then tricyclic diterpenes are formed. Further transformations of the precursor lead here to such substances as darutigenol (LXVI) [115], rosololactone (LXVII) [116], and rosenonolactone (LXVIII) [116,117]. Compounds (LXII)–(LXVI), like the gibberellins, possess an "unnatural" configuration of the *A/B* ring fusion and are formed, apparently, in the cyclisation of geranylgeranyl pyrophosphate in the same

‡ The configuration of these compounds at $C_{(8)}$ does not agree with the contemporary views on the stereochemistry of the diterpenes and requires verification [114]. The results of the verification have not yet been published.

"unnatural" conformation (XLVIIIa), which leads also to GAc. The lactones themselves (LXVII) and (LXVIII) have the 5α-, 10β-configuration§ usual for most terpenoids, and consequently are formed by cyclisation of geranylgeranyl pyrophosphate into conformation (XLVIIIc) antipodal to that which leads to the gibberellins. Therefore, despite the generality of the structural elements of ring *A*, lactones (LXVII) and (LXVIII) are biogenetically further from the gibberellins than darutigenol or andrographolide.

The cyclisation of geranylgeranyl pyrophosphate can lead, finally, also to a tetracyclic precursor of type (LII), to give initially the diterpenes of the phyllocladene group and their simplest derivatives. Among those closest structurally to the gibberellins there are many compounds in which the stereochemistry of the fusion of the rings *A*, *B*, and *C* is identical with the stereochemistry of the corresponding centres in GAc. Such compounds include kaurene (LIV), steviol (LXI) [118], isosteviol (LXIX) [181], cafestol (LXX) [113], beyerol (LXXI) [119], and stachenone (LXXII) [120]:





The biosynthetic transformations of the tetracyclic diterpenes can lead also to such natural compounds as the alkaloids of the atisine group — compare, for example, garryfoline (LXXIII) [121] — and the grayanotoxins — compare, for example, grayanotoxin A (LXXIV) [122]. The last is of special interest as according to its structure it can be formed from the tetracyclic precursor of the gibberellins by rearrangement of the *A*/*B* ring system by a mechanism close to the mechanism for contraction of ring *B* in the gibberellins.

IV. APPROACH TO AN EXPLANATION OF THE MECHANISM OF ACTION OF THE GIBBERELLINS ON HIGHER PLANTS

The proof of the phytohormonal nature of the gibberellins and the detailed study of the spectrum of their physiological activity (see pp. 850, 851) led in turn to the problem of explaining the mechanism of action of the gibberellins on the higher plants.

Systematic investigations in this field started only seven or eight years ago and have proceeded in two main directions: (1) study of the effect of gibberellins on the exchange of substances and the activity of the enzymic systems; (2) study of the interaction of gibberellins with other plant growth regulators.

§ Steroid numbering.

Even in the first studies devoted to investigating the influence of gibberellins on the morphological features of plants it was shown that the operation of gibberellic acid is accompanied by an increase in the dry weight of the epigeal parts of plants with only slight change (sometimes even a decrease) in the weight of the roots. Hence the growth stimulation under the influence of GAc depends not only on an increase in the general assimilation but also a redistribution of the plant material to the benefit of the epigeal part [123]. Detailed study of the changes in the exchange of substances of the epigeal parts of plants brought about by GAc allowed observation of an intensification of the photochemical [1,123,124] and dark [124] fixation of carbon and also of the stimulation of the processes of water supply in plants [125], transpiration processes [125], and processes for the biosynthesis of protein and RNA [125-128]. A large volume of material has been published about the effect of GAc on the biosynthesis of chlorophyll. As is well known, one of the distinctive features of plants treated with GAc is chlorosis However, a combination of treatment with GAc and a greater supply of mineral supplements prevents chlorosis [123]. From these results, and also from determinations of the percentage of chlorophyll in digitalis [129] and buckwheat [130] plants it followed that GAc does not suppress the biosynthesis of chlorophyll. This conclusion does not contradict the results on the reduction in the percentage of chlorophyll in the dry residue of lettuce [131], and pea [132] seedlings and also in the leaves of flowering plants [133], since when there is a sharp change in the weight of dry substance of plants under the influence of GAc it would be more correct to determine not the change in the percentage of chlorophyll in the dry residue but the change in its total quantity which can be made by the given organ of the plant.

However, the most characteristic feature of the change in materials exchange in plants under the action of GAc is the intensification of phosphorus–carbohydrate exchange. Studies by many investigators have shown that treatment with GAc brings about the utilisation of stored carbohydrates in the plants: the processes of phosphorolysis of starch and cellulose are intensified, and there is a significant increase in the level of monosaccharides [123,127,128,134-138]. The most active utilisation of stored substances under the influence of GAc occurs in germinating seeds. Detailed information on this process was obtained by studying the interaction of GAc with enzymic systems responsible for the splitting of the higher sugars. The principal objects of investigation were germinating barley seeds in which Hayashi and coworkers [139,140] observed as long ago as 1940 a sharp rise in activity of α-amylase. Subsequent work [141-146] confirmed this and also showed that, in addition to α-amylase, GAc is capable of activating other hydrolytic enzymes which participate in the splitting of starch and cellulose: diastase [147], β-amylase [141,146,148], cellulose [142], and phosphorylase [135].

In 1960 Paleg [149] showed experimentally that the activation of the α-amylase of barley grains under the influence of GAc is due to an intensification of the biosynthesis of this enzyme. Further investigation [150] established that GAc initiates the synthesis of α-amylase and the splitting of starch in seeds which have lost the ability to utilise the stored substances as a result of the removal of the germ or of γ irradiation. The results obtained enabled Paleg to develop a hypothesis that the apparatus for the control at the start of the hydrolytic processes in seeds and consequently at the start of germination is present in the germ and includes an endogenic gibberellin, which is an initiator of the biosynthesis of hydrolytic enzymes.

These studies of Paleg explained the first principles of the ability of gibberellins to interrupt the rest period of the seed and to stimulate its germination. Unfortunately, the problem of the nature of other aspects of the physiological activity of gibberellins is much less clear.

For example, despite many investigations, the problem of the mechanism of the acceleration of the growth of seedlings and the "healing" of the dwarf mutants of higher plants under the influence of gibberellins is still not solved. It has been shown reliably [1,8] that the enhanced growth after treatment with GAc stems from an increase in the cell elongation and an acceleration of their division, but the mechanism of the influence of GAc on each of these processes is not clear. To explain the action of gibberellins on the cell elongation several hypotheses have been propounded which explain the physiological activity of the gibberellins by including them in a scheme for the exchange of indolylacetic acid and other heteroauxins. The experimental basis for these hypotheses was the observation of many instances in which the level of the endogenic heteroauxins was raised [151-153] and the activity of indolylacetic acid oxidase was suppressed [154-156] after treatment of plants with gibberellins and also of the facts of the synergism of auxins and gibberellins [157-161] in their action on the plant. On the basis of these facts Galston and Warburg [162] suggested that the gibberellins are stimulators of the biosynthesis of polyphenols, which are capable of inhibiting indolylacetic acid oxidase, and consequently of raising the level of the endogenic heteroauxins in the plants. According to Galston and Warburg's hypothesis, a direct consequence of this is an intensification of cell elongation — a characteristic reaction of plants to auxins.

However, the above hypothesis is contradicted by many experimental results, including those of Kato [163] and of Brian and Hemming [164], who observed a marked difference in the reactions of the higher plants to gibberellins and heteroauxins (see Table 6).

Better agreement with the experimental results was shown by the hypothesis of Brian and Hemming [157], according to which the intensification of growth under the influence of GAc is explained by the ability of the gibberellins to suppress the biosynthesis of the polyphenolic inhibitors of the heteroauxins. Hence according to this hypothesis, just as with the Galston–Warburg hypothesis, the reason for the physiological activity of the gibberellins lay in an increase in the level of the endogenic heteroauxins, but the absence of the activity of the gibberellins in certain biosyntheses characteristic for heteroauxins was explained by the absence of the inhibitor for the auxins. However, this hypothesis also did not explain all the facts, particularly the ability of gibberellins to act in the dark and also to be cumulative in action on plants with superoptimal (inhibiting) quantities of heteroauxins.

TABLE 6. Main difference between heteroauxins and gibberellins.

Bio-test	Auxin	Gibberellin
Transport polar	+	−
Promote root initiation	+	−
Inhibit root elongation	+	−
Delay leaf abscission	+	−
Inhibit lateral buds	+	−
Induce callus formation	+	−
Promote growth of intact plants, especially of drawf mutants	−	+
Promote seed germination and breaking of dormacy	−	+
Substitute for vernalisation	−	+
Promote flowering in long-day plants under unfavourable light conditions	−	+

In recent years the main sense of the above hypotheses — the ability of the gibberellins to stimulate the biosynthesis of polyphenols — has been demonstrated experimentally by Netherlands chemists [165] by the example of ferulic, caffeic, and chlorogenic acids. However, they put forward quite another interpretation of the results obtained. Since ferulic acid can serve as the starting point for the biosynthesis of lignin, these investigators suggested, and then demonstrated by experiment, that gibberellins stimulate the biosynthesis of lignin. And since lignin plays the part of a material which strengthens the bond between cellulose fibres and gives the cell wall strength and elasticity, these investigators consider that the gibberellins play a part independent of the other growth regulators in the cell growth process: by stimulating the biosynthesis of lignin they are able to facilitate the densification of the cell walls and give them the optimal mechanical properties.

French investigators [166] also had a separate viewpoint about the action (independently of other hormones) of the gibberellins on plant growth, making clear the synergism of the auxins and gibberellins by their ability to combine with a single enzyme having two active centres, so that the adsorption of one hormone facilitates the adsorption of the other.

The stimulation of the biosynthesis of polyphenols under the influence of gibberellins can also be the key to understanding the action of these substances on the photoperiodic reaction of plants.

Actually, in recent investigations [167,168] there have been observations that the light regime has a considerable effect on the activity of oxidising enzymes taking part in the respiration processes of plants. It appeared that long-day conditions activate the so-called terminal oxidases which contain heavy metals and are capable of being poisoned by poisons of the potassium cyanide and sodium azide type (for example, polyphenoloxidase and ascorbinase), but short-day conditions activate residual respiration oxidases (including peroxidases). As it was also found reliably [167,168] that the activation of polyphenoloxidase in a long day is due to the improvement in the supply of this enzyme by polyphenols, it is easy to see that the ability of gibberellins to stimulate the biosynthesis of polyphenols can be the biochemical basis for their action on a long-day plant under short-day conditions.

---oOo---

Summing up all the results of the investigations in the field of the chemistry and biochemistry of gibberellins which have been considered, something must be said about the future development of this field of bio-organic chemistry.

Whereas in the 'fifties the central task of the problem of the gibberellins was the establishment of the structure of this group of natural compounds and revealing the spectrum of their physiological activity, the centre of investigation has now shifted to the field of studies of the biogenesis of the gibberellins and the mechanism of their action on the plant. In this connection there is great interest in studying the metabolism of GAc in plants, and also the isolation and study of the structure of new endogenic growth regulators which exhibit gibberellin-like physiological activity, but differ in properties from the known gibberellins [38,169-172].

A considerable part in future investigations of the problem of gibberellins will evidently be played by work on the full synthesis of these compounds and their chemical conversions [173-176], since in this way it is possible to find not only the connection between structural and physiological activity in this group of compounds but also to observe new forms of biological activity of gibberellin-like substances.

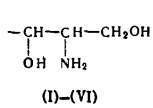
IV. Biological properties 873
1. Immunological properties 873
2. Biological activity of sphingosine and cerebrosides 874
3. Neurophysiological role of gangliosides 874

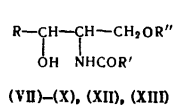
The present review considers lipids that are grouped together under the name glycosphingolipids. In addition to structural similarities, these compounds have at least one property in common in that they are capable of taking part in specific immunological reactions, the study of which may open a new approach to the understanding of the fine structural differences in animal and human tissues in normal and pathological states.

I. NOMENCLATURE

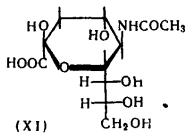
The term "sphingolipoids" was proposed by Carter to denote those lipids that contain the aliphatic amino-glycol sphingosine (I).[1] This term may now be extended to natural derivatives of dihydrosphingosine (II), C_{20}-sphingosine (III), and C_{20}-dihydrosphingosine (IV), which are found together with derivatives of sphingosine (I) in animal tissue, and also to the compounds phytosphingosine (V) and dehydrophytosphingosine (VI) and their C_{20}-homologues, which have been isolated from plants.



(I)–(VI)



(VII)–(X), (XII), (XIII)



(XI)

I, R = $CH_3[CH_2]_{12}CH{=}CH-$
II, R = $CH_3[CH_2]_{14}-$
III, R = $CH_3[CH_2]_{14}CH{=}CH-$
IV, R = $CH_3[CH_2]_{16}-$
V, R = $CH_3[CH_2]_{13}CH(OH)-$
VI, R = $CH_3[CH_2]_{11}CH{=}CHCH(OH)-$

VII, R′ = hexose
VIII, R′ = hexose–SO_3H
IX, R′ = oligosaccharide
X, R′ = oligosaccharide–hexosamine
XII, R′ = oligosaccharide–sialic acids
XIII, R′ = oligosaccharide–hexosamines–sialic acids
R as in compounds (I)–(VI)
R′ fatty acid residue

We shall apply the term "glycosphingolipids" to the group of sphingolipids that contain carbohydrates in addition to the sphingosines, (I)–(VI). In the present review we shall consider the glycosphingolipids of animal origin, that is, mainly derivatives of the sphingolipids (I)–(IV)† (Scheme 1).

The simplest representatives of this group, the cerebrosides (VIII), are monoglycosides of *N*-acetylsphingosines (ceramides).

The sulphatides or cerebroside sulphates (VIII) are sulphate esters of the cerebrosides.

The ceramide-oligohexosides (IX) are derivatives of the ceramides that contain oligosaccharides with simple hexoses as components. The name "cytosides" has also been proposed for ceramide disaccharides.

The globosides (X) are hetero-oligosaccharides of the ceramides containing hexosamines in addition to the simplest monoses; if the hetero-oligosaccharides contain sialic acids (XI) instead of hexosamines, they are termed "hematosides" (XII).

The sialic acids (XI) include all the acylated neuraminic acids[3], being, as it were, products of the aldol condensation of *N*-acylmannosamine and pyruvic acid.

The term "gangliosides" (XIII) is applied to derivatives of sphingosine containing fatty acids, monoses, hexosamines, and sialic acids.

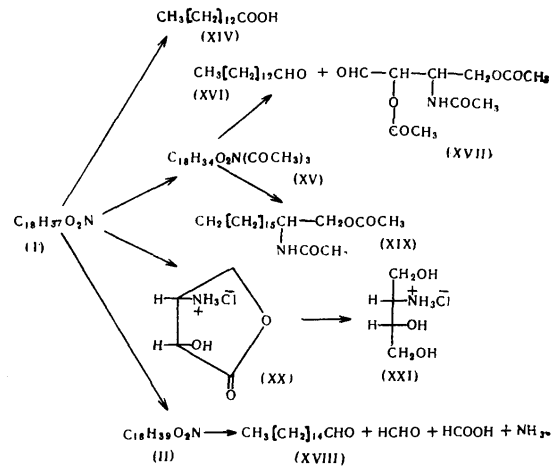
II. STRUCTURE AND DISTRIBUTION

1. Sphingosines

Sphingosine (I) was first isolated from brain lipids by Thudichum in 1901.[4] It was soon shown that it was an amino-diol with a double bond at the 4–5-position in a long hydrocarbon chain[5,6].

Oxidation of sphingosine (I) with chromic acid gave myristic acid (XIV),[7] and ozonolysis of triacetylsphingosine (XV) gave myristaldehyde (XVI) and a triacetylaminotetrose (XVII),[8] the structure of which was established by Cater[9,10] (Scheme 1)

Scheme 1



Two molecules of periodic acid are required for the oxidation of dihydrosphingosine (II) to palmitaldehyde (XVIII), formaldehyde, ammonia, and formic acid. When the triacetate (XV) was hydrogenated in the presence of platinum, the diacetate of 1-hydroxy-2-amino-octadecane (sphingine) (XIX) was formed as a result of hydrogenolysis of the 3-acetoxy-group, which indicates that one of the hydroxyl groups of sphingosine (I) is in the allyl position[11].

The D-configuration at the $C_{(2)}$ atom of sphingosine was established almost simultaneously by two methods. Carter and Humiston[11] made a comparative study of changes in optical rotation on dilution with water of dioxan or acetic acid solutions of *N*-benzoyl-α-aminostearic acid; the latter compound is isolated in the oxidation of *N*-benzoylsphingine, which is obtained from sphingosine triacetate (XV), and of *N*-acyl derivatives of known L- and D-amino-acids.

Kiss[12] converted sphingosine (I) by ozonisation into 3-amino-2-hydroxybutyrolactone hydrochloride (XX), which he then reduced to laevorotatory D-*erythro*-2-aminobutane-1,3,4-triol (XXI) (see Scheme 1).

The configuration at the $C_{(3)}$ atom was established by synthesis of the *threo*- and *erythro*-isomers of dihydrosphingosine (II)[13] (see pp. 868–869). The infrared spectrum of sphingosine (I) contains a band at 10.3 μm, indicating a *trans* double bond[14,15]. Total synthesis finally confirmed the structure of sphingosine (I) as D-(+)-*erythro*-*trans*-2-amino-1,3-dihydroxyoctadec-4-ene.

Dihydrosphingosine (II), which is identical with the hydrogenation product of sphingosine (I), was first discovered in the larvae of cat tapeworms[16], and it was soon also isolated[17,18] from the cerebroside fraction of the spinal cord and, in smaller amounts, from cow brain.

In recent years new amino-diols of animal origin, C_{20}-sphingosine (III) and C_{20}-dihydrosphingosine (IV), have been isolated. C_{20}-sphingosine (III) was first discovered by a group of Yugoslav biochemists in the brains of cows and horses[19,20]. The mixture of natural amino-diols was oxidised with chromic acid, and the methyl esters of the acids obtained were subjected to gas–liquid chromatography; it was shown that these contained methyl myristate and methyl palmitate, while methyl stearate was found in the products of oxidation and methylation of the dihydro-compounds. Recently, a rapid method was proposed for

† Recently Karlsson reported for the first time that derivatives of phytosphingosines (V) occur in animal and human tissues[2].

the determination of sphingolipid bases by gas–liquid chromatography of their trimethylsilyl derivatives[21].

The C_{20}-sphingosine (III), termed "icosisphingosine"[22], has also been found as the main component in a mixture of bases obtained by acid hydrolysis of a mucolipid[23,24] from ox brain and also of gangliosides from human brain[25].

Gas–liquid chromatography of a mixture of methyl esters of fatty acids obtained by periodate cleavage at the $C_{(2)}$–$C_{(3)}$ bond of the sphingosine fraction of human-brain gangliosides showed the presence of C_{20}-dihydrosphingosine (IV).[25] It was isolated by preparative paper chromatography of the mixture of dinitrophenyl derivatives of sphingosines obtained from human brain, cow brain, or human hair[26]. The ganglioside fraction of the brain consists of two-thirds C_{20}-sphingosines (III, IV) and one-third C_{18}-sphingosines (I, II) with about 10% of dihydro-compounds (II, IV).[27]

2. Cerebrosides

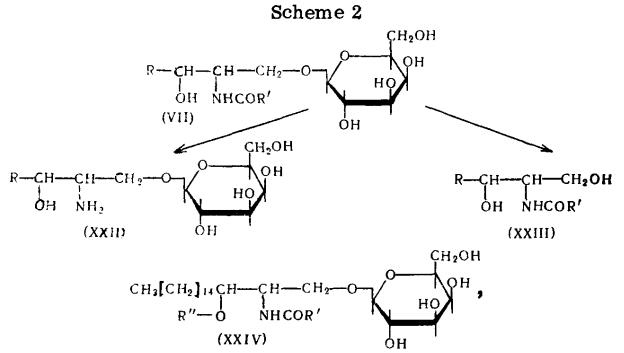
The first two cerebrosides — phrenosin and cerasine — were discovered by Thudichum in his study of the composition of the brain[28]. Later Klenk isolated two more cerebrosides, nervon and oxynervon[29,30]. These four cerebrosides differ from one another in their fatty acid components. Phrenosin contains cerebronic acid, $CH_3[CH_2]_{21}$–CHOH–COOH, cerasine contains lignocerinic acid, $CH_3[CH_2]_{22}COOH$, nervon contains nervonic (*cis*-tetracos-15-enoic) acid, and oxynervon contains hydroxynervonic acid. Cerebrosides containing other fatty acids are also known[31,32].

Repeated thin-layer chromatography has been used to separate a mixture of cerebrosides isolated from human spinal cords into 12 components containing different fatty acid residues[33]. Gas–liquid chromatography of the methyl esters of acids obtained by the hydrolytic cleavage of human brain cerebrosides indicates that these contain even-numbered and odd-numbered, saturated and unsaturated acids, as well as α-hydroxy-acids, with an unbranched chain and with from 14 to 26 carbon atoms[34].

The cerebrosides from normal human and animal brains contain galactose. In some anomalous conditions, in particular in lipidosis (Gaucher's disease), glucocerebroside accumulates in the human spleen[35,36]; it is also present, though in much smaller amounts, in the healthy human spleen[37].

The structure of cerebrosides has been established. When selectively hydrolysed, they are converted into sphingosine galactoside (psychosine) (XXII), and, under other conditions, into an *N*-acylsphingosine (ceramide) (XXIII)[28,29] (Scheme 2).

Scheme 2



where R = $CH_3[CH_2]_{12}CH{=}CH-$, R′ is a fatty acid residue, and R″ = $C_nH_{n+1}CH{=}CH-$.

Psychosine (XXII) is not reduced by the usual reagents for the aldehyde group; it is therefore a glycoside. Exhaustive methylation of cerebrosides (VII) and subsequent hydrolysis give 2,3,4,6-tetramethylgalactose, which indicates that these compounds contain a 1,5-pyranose ring[38,39].

When hexa-acetylphrenosin, or triacetylsphingosine (XV), is subjected to hydrogenolysis on platinum followed by hydrolysis, sphingine and acetic acid are formed[40], which means that the galactose is linked through the primary hydroxyl group of the ceramide. The β-configuration of the glycoside bond has been demonstrated by total stereospecific synthesis of some cerebrosides (see p. 872).

Using thin-layer chromatography on the cerebroside fraction of brain, Kochetkov and coworkers isolated a small quantity of a galactocerebroside with a greater R_f value than that of the classical cerebrosides[41]. The infrared spectrum and its behaviour on alkaline and acid hydrolysis indicated that this compound contains more than 90% of dihydrosphingosine, and that an alkenyl ether group is linked to the second hydroxyl group. The new compound was named sphingoplasmalogen (XXIV).[42]

3. Sulphatides

Thudichum detected sulphur in brain cerebrosides[28]. In 1933 Blix isolated the sulphatide (VIII) as the potassium salt from normal human brain (20–25% of total cerebrosides)[43]. The sulphatide contained fatty acids (mainly cerebronic), galactose, sphingosine, and a sulphuric acid residue. The sulphatides (VIII) can be separated from the cerebrosides (VII) by chromatography on diethylaminoethylcellulose[44].

Gas–liquid chromatography has shown that the composition of the sulphatides from grey and white matter of the human brain is similar to the fatty acid composition of the cerebrosides isolated from the same tissues, but the sulphatides contain smaller amounts of hydroxy-acids[45].

Yatzkewitz[46], using column chromatography on paper, separated sulphatides from human brain containing cerebronic, lignocerinic, and nervonic acids. Two sulphatides of rat brain isolated by Bakke and Cornatzer probably correspond to the sulphate esters of cerasine and phrenosin[47,48].

Thannhauser and Boncoddo[49], who methylated the cerebroside sulphate of cow brain and studied the products of subsequent hydrolysis by paper chromatography, showed that in this compound the sulpho-group is linked to the first hydroxyl group of galactose at $C_{(6)}$. However, re-investigation of the same sulphatide by exhaustive methylation in dimethylformamide, followed by methanolysis and gas–liquid chromatography of the methylated sugars, showed that methyl-2,4,6-trimethylgalactoside[50] was present, and not 2,3,4-trimethylgalactoside[49]. The absorption at 820 cm^{-1} (C–O–S vibrations) corresponds to the equatorial position of the $-OSO_3H$ group[51], which for the $C_{(1)}$ conformation of galactopyranose occurs when the $-OSO_3H$ group is in the 6-position or the 3-position. Obviously the sulphato-group is linked to the hydroxyl group at the $C_{(3)}$ atom of galactose, and Thannhauser and Boncoddo[49] were misled by the closeness of the R_f values obtained in the paper chromatography of the trimethylgalactoses.

On the basis of infrared spectra and a study of the methylation products, Hakomori and coworkers[52] confirmed the cerebroside 3′-sulphate structure; they also

isolated a complex sulphatide consisting of cerebroside 3′- and 6′-sulphates, which may be linked together as a diester of sulphuric acid.

4. Ceramide-Oligohexosides

Using chromatography on silicic acid of chloroform–methanol extracts, Rapport and coworkers[53] isolated the simplest ceramide-oligohexoside (IX) from human epidermal carcinoma, and they named it cytolipin H.[54,55] Compounds of similar structure have been separated from ox spleen[56,57], human spleen[37], horse erythrocytes[58], human erythrocytes[50], and human kidney tissue[59,60].

Cytolipin H is a mixture of ceramide β-lactosides in which sphingosine is linked by an amide bond with lignoceric [tetracosanoic], palmitic, behenic [docosanoic], or (to a lesser degree) another higher fatty acid[61]. The fatty acid composition of the compound was elucidated by paper chromatography and gas–liquid chromatography.

Analysis of the products of acid hydrolysis of cytolipin H with the aid of paper chromatography showed that the carbohydrate portion of the molecule contains glucose and galactose in equimolecular amounts. The configuration of the carbohydrate residue was established by an immunochemical method in which the reaction of cytolipin H with antibodies is inhibited by the addition of simple carbohydrates[54] (see p. 873). Total synthesis confirmed its structure (see p. 873) as a D-*erythro*-*N*-acylsphingosine 1-*O*-β-lactoside.

Other ceramide oligohexosides (IX), galactosyl-(1→4)--galactosylceramide and galactosyl-(1→4)-galactosyl--(1→4)-glucosylceramide[60], have been isolated from human spleens[37], kidneys[59], and erythrocytes[62], and from cow kidneys, cow's milk[63], and horse kidneys.

5. Globosides

It has been shown by a study of the products of moderate acid hydrolysis, oxidation with periodic acid, and exhaustive methylation in dimethylformamide that globoside, the main glycolipid of human erythrocytes[58,64], is *N*-acetylgalactosaminyl-(1→6)-galactosyl-(1→4)-galactosyl-(1→4)--glucosyl-(1→1)-*N*-lignocerylsphingosine.

A compound similar in structure to the globoside from erythrocytes has been isolated from human kidneys by Rapport and coworkers[66] and also by Makita and coworkers[67], and shown to be *N*-acetylgalactosaminyl)-(1→3)-galactosyl--(1→4)-galactosyl-(1→4)-glucosyl-(1→1)-ceramide[59]. Globosides have also been obtained by silica-gel fractionation of methanol–ether extracts of sheep and guinea-pig erythrocytes[62].

Recently a glycosphingolipid was isolated[68] from cancer tissue which appears to be formally a globoside, but which differs from known compounds of this type in that it has a high content of glucosamine (9–10%) and a fucose 6-desoxyhexoside (8.5–9.5%). The ratio glucose : galactose : fucose is 1 : 2.3 : 1.2. This is the main component of water-soluble glycolipids of human adenocarcinomate. Attempts to obtain the same globoside containing fucose from normal tissues were unsuccessful.

6. Hematosides

The hematoside *N*-acetylneuraminyl-(2→3)-galactosyl--(1→4)-glucosyl-(1→1)-*N*-acylsphingosine was isolated from the erythrocyte stroma of dogs, cats, and horses by Yamakawa and Suzsuki[69], and later by Klenk and Padberg[70]. Its sialic acid[71,72] is easily eliminated[73] by the action of a specific hydrolytic enzyme, neuraminidase (or sialidase), isolated from *Vibrio cholerae*.

A hematoside that probably contains two molecules of galactose and no glucose has been separated from human brain[74–76]. A more complex hematoside containing four molecules of neutral hexose and two molecules of sialic acids per molecule of ceramide has recently been isolated from hog brain[77].

7. Gangliosides

Gangliosides were first discovered in 1925 by Landsteiner and Levene[78] in extract of horse kidney, but it was not until 1942 that Klenk[79] isolated the relatively pure compound from the human cerebral cortex; it contains sphingosine, glucose, galactose, galactosamine, *N*-acetylneuraminic acid, and higher fatty acids (mainly stearic acid) in equimolecular proportions[80,81].

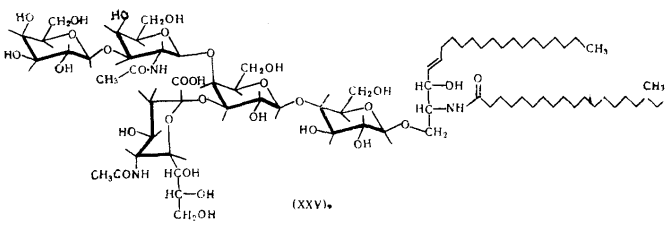
It was later shown that many gangliosides differing in composition and structure occur in nature. The fatty acid composition of brain gangliosides was studied by gas–liquid chromatography of the methyl esters obtained by saponification of the gangliosides[82–86]. Stearic acid was present to the extent of 72 to 96%; apart from this the other main acids in gangliosides are linear saturated C_{20}, C_{22}, and C_{24} acids.

The structure of the carbohydrate portion of the monosialoganglioside isolated from human brain (which in Svennerholm's nomenclature is denoted G_{M1}[87]) was determined by the collaborative work of several laboratories[88–91]. Moderate acid hydrolysis of G_{M1} gives the two disaccharides *O*-α-*N*-acetyl-D-galactosaminyl-(1→3)-galactose and *O*-β-D-galactopyranosyl-(1→3)-2-acetamido-2-desoxy-D--galactose[92].

On acetolysis with a mixture of acetic acid and acetic anhydride containing a little sulphuric acid[93], this ganglioside gives a ganglio-*N*-tetrose: galactosyl-(1→3)-*N*--acetylgalactosaminyl-(1→4)-galactosyl-(1→4)-glucose; two ganglio-*N*-trioses: galactosyl-(1→3)-*N*-acetylgalactosaminyl-(1→4)-galactose and *N*-acetylgalactosaminyl--(1→4)-galactosyl-(1→4)-glucose; two ganglio-*N*-bioses: galactosyl-(1→3)-*N*-acetylgalactosamine and *N*-acetylgalactosaminyl-(1→4)-galactose; and a lactose: galactosyl--(1→4)-glucose, the structure of which was established by periodate oxidation followed by reduction with potassium tetrahydroborate. The following saccharides containing *N*-acetylneuraminic acid were also isolated: sialyl-(2→3)--galactose, sialyl-(2→3)-galactosyl-(1→4)-glucose, sialylganglio-*N*-trioses, and a sialylganglio-*N*-tetrose. The structure of these compounds was determined by the enzyme method, which is based on the known relationship between the rate of enzymatic elimination of sialic acid and its location.

As has been shown by the periodate oxidation of methylsphingosine, obtained by exhaustive methylation of the ganglioside G_{M1}, the carbohydrate portion of this compound is linked through the primary hydroxyl group of sphingosine[88].

The structure of the ganglioside G_{M1} thus corresponds to formula (XXV); this structure was recently re-confirmed by periodate oxidation[94].



(XXV).

Another monosialoganglioside, G_{M2},[90] has also been isolated; normal human brain contains 3–5% of this compound, but much larger amounts are found in the brains of persons that have died of the infantile form of the hereditary "Tay-Sachs'" disease. For structure determination, the ganglioside G_{M2} was cleaved by acid hydrolysis to acylsphingosine saccharides and free sugars, which were then analysed quantitatively and characterised[90,95] (see Scheme 3).

Two disialogangliosides (G_{D1a} and G_{D1b}) and a trisialoganglioside (G_{T1a})[88,90,95,96] isolated from human brain are quantitatively cleaved by sialidase to give the monosialoganglioside G_{M1}. G_{D1a} is hydrolysed much more rapidly than G_{D1b}; G_{T1a} is first converted into G_{D1b} (with a little G_{D1a}), and then to G_{M1}. Hydrolysis of G_{T1a} with 0.01 *N* hydrochloric acid at 100° gives equal amounts of G_{D1a} and G_{D1b}. Since it is known that sialyl-(2→6)-lactose is hydrolysed more slowly by sialidase than sialyl-(2→3)-lactose, it may be supposed[95] that in G_{D1a} the second sialic acid molecule is linked with the $C_{(3)}$ atom of the end galactose, in G_{D1b} it is linked with the $C_{(6)}$ atom of the same galactose residue, and in G_{T1a} both hydroxyl groups are replaced.

Johnson and McCluer[94], using the method of periodate oxidation, studied the structure of yet another group of polysialogangliosides similar in structure to G_{M1} (see Scheme 3).

Oxidation of one galactose residue in the disialoganglioside G_{D1c} (according to Svennerholm's nomenclature; 3-G according to the present authors) shows that the end galactose residue is not replaced; destruction of only one molecule of *N*-acetylneuraminic acid and the stability of the second molecule indicate that the two sialic acid molecules are linked by a (2→8) bond[98–100]. Kuhn and Wiegandt isolated such a disialoganglioside[101].

The requirement of 6 moles of periodic acid for the complete oxidation of the trisialoganglioside G_{T1b}[94] is explained by the elimination of 2 moles of *N*-acetylneuraminic acid and 1 mole of galactose, and the formation of the disialoganglioside G_{D1c} as an intermediate under the action of sialidase shows that G_{T1b} also contains a (2→8)-sialic acid dimer. It can be shown by cleavage with 2 moles of periodic acid that the end galactose is not replaced, and the third mole of *N*-acetylneuraminic acid is not linked to this galactose (as in G_{D1a}), but possibly to the $C_{(6)}$ atom of *N*-acetylgalactosamine, but further evidence is needed to confirm this.

The trisialoganglioside G_{T1c}, isolated by Kuhn and Wiegandt[101] (G_{IV} according to the authors), differs in the position of the third *N*-acetylneuraminic acid residue. It is possible that the fourth sialic acid residue in $G_{Tet.1}$ (G_V according to Kuhn), which was isolated with G_{T1c}, is linked to the $C_{(6)}$ atom of the *N*-acetylgalactosamine in the same way as the third residue in G_{T1b} (see Scheme 3).

$G_{Tet.1}$	NAcHa [2 ↑ 6] NAcHa[2→3]gal[1→3]galNHAc[1→4]gal[1→4]glu[1→1]–R [3 ↑ 2] NAcHa[2→8]NAcHa

* gal = galactose; galNHAc = *N*-acetylgalactosamine; glu = = glucose; NAcHa = *N*-acetylneuraminic acid; R = ceramide.

Recently preparative thin-layer chromatography has been used to separate brain gangliosides, and a mixture of trisialogangliosides was obtained in which the ratios hexose : ceramide and galactose : glucose were 3 : 1, which could correspond to a content of 25% of galactose ganglioside with no glucose in this mixture[102].

Kuhn and Wiegandt[103], using chromatography on kieselguhr, isolated a new ganglioside from erythrocytes and milk of long-horned cattle; this contains glucosamine instead of galactosamine and is readily cleaved by employing neuraminidase[103]. Examination of enzymatic and acid hydrolysis and by ozonisation[104] showed that it may be similar to the ganglioside isolated previously from erythrocyte stroma[105].

In a study of substances that determine blood-group specificity[106] (see p. 873), two gangliosides were separated that contain galactosamine, glucosamine, galactose, glucose, sialic acid, fucose, and sphingosine residues; they differ in fatty acid composition and show a sphingosine : glucose : : sialic acid ratio of 2 : 1 : 1.

The molecular weight of gangliosides varies between 1500 and 3000. However, in aqueous solutions they may form micelles [74] with an aggregate weight of 250 000; some workers [107] consider these to be high-molecular compounds in which hundreds of structural components of ordinary gangliosides are combined [108].

In an aqueous medium, the micelle must be oriented in such a way that the neuraminic acid residues are on its surface so as to be able to associate with water molecules, but the lipid part of the molecule is screened inside. According to Klenk and Gielen [74], in organic solutions the micelle must be, as it were, turned inside out, with the hydrophilic neuraminic acid residues concealed behind a barrier of sphingosine carbohydrate residues and fatty acids.

Howard and Burton [109] put forward the hypothesis of van der Waals interaction between the hydrophobic residues in the micelle. Thus, for example, sphingosine ganglioside No. 1 may be drawn into association with the fatty acid chain of ganglioside No. 2, the sphingosine of which will be associated with the fatty acid chain of ganglioside No. 3, and so on. This means that kinetic liberation of one hydrophobic chain need not lead to dissolution of the ganglioside molecule, since the other hydrophobic chain will still be "entrapped" in the micelle.

Non-ionic and non-covalent bonds of this kind may occur in such heterogeneous micelle-like structure as cell membranes and subcellular particles consisting of lipids and proteins.

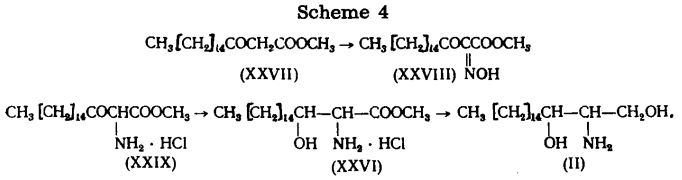
III. SYNTHETIC STUDIES

1. Synthesis of Dihydrosphingosine

Syntheses of sphingosine (I), dihydrosphingosine (II), and some sphingolipids, which have been carried out to finally establish the structure of these compounds, have advanced the development of biological studies, which require considerable quantities of the individual compounds.

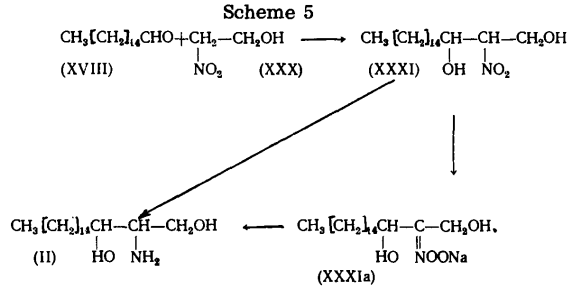
In 1947, Carter and coworkers [110] proposed a synthesis of dihydrosphingosine through methyl α-amino-β-hydroxystearate (**XXVI**), and in 1951 Gregory and Malkin [111] synthesised a mixture of racemates of dihydrosphingosine (II) from methyl 3-ketostearate (**XXVII**) by nitrosation [112] followed by stepwise reduction of the oxime (**XXVIII**), at first with palladium on charcoal in the presence of 2 moles of hydrochloric acid, then on platinum oxide, and finally with lithium tetrahydroaluminate (**XXVIII**) → (**XXIX**) → (**XXVI**) → → (II) (Scheme 4).

Scheme 4



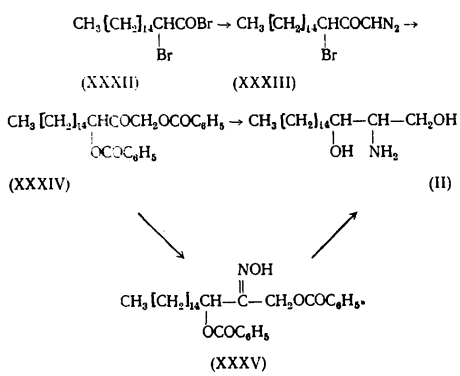
In the same year, Grob and coworkers [113] described a synthesis of a mixture of racemates of dihydrosphingosine (II): palmitaldehyde (**XVIII**) was condensed with nitroethanol (**XXX**) in the presence of sodium hydroxide, with subsequent reduction of the nitro-diol (**XXXI**) on Raney nickel (see Scheme 5); the *threo*-isomer (IIb) predominated in the mixture obtained. The total yield of dihydrosphingosine (IIa, b) was increased from 10.5 to 44% by using sodium methoxide as a condensing agent [114], separating the intermediate salt of the *aci*-form of the nitro-diol (**XXXIa**), and carrying out the reduction on platinum oxide.

Scheme 5



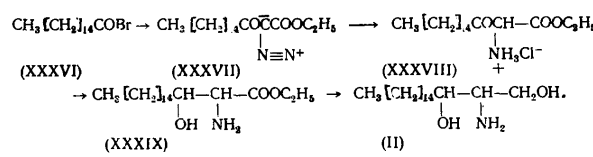
A group of Yugoslav investigators [115] has described a synthesis of a mixture of racemates of (II) in which 2-bromoheptadecanoyl bromide (**XXXII**) is condensed with diazomethane; the 3-bromo-1-diazodecan-2-one (**XXXIII**) is treated with silver benzoate and benzoic acid and the keto-diester (**XXXIV**) obtained is subjected to reductive amination on Raney nickel; alternatively, the oxime (**XXXV**), obtained from (**XXXIV**), is reduced with lithium tetrahydroaluminate (see Scheme 6).

Scheme 6



A synthesis of dihydrosphingosine (II) from the more accessible palmitic acid has also been described [116]: palmitoyl bromide (**XXXVI**) is condensed with diazoacetoacetic ester, and the 2-diazopalmitoylacetic ester (**XXXVII**) is reduced in steps, first by hydrogenation on palladium and then with sodium tetrahydroborate and lithium tetrahydroaluminate (**XXXVII**) → (**XXXVIII**) → (**XXXIX**) → (IIa, b) (see Scheme 7).

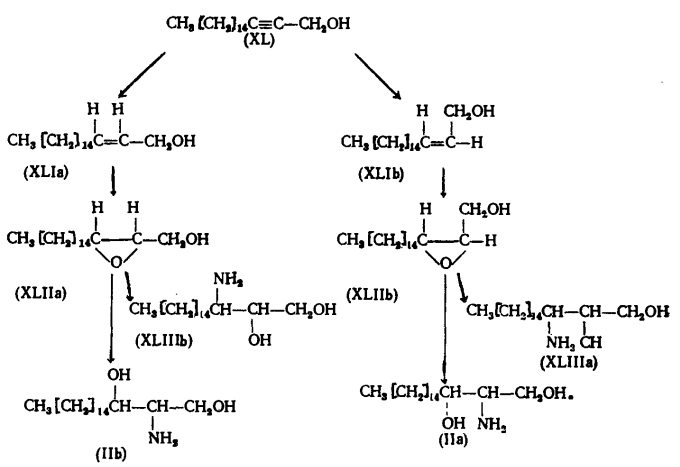
Scheme 7



A general defect of the syntheses described above is that they are not stereospecific; moreover, no methods of separating the diastereoisomers of (II) which are formed have been worked out.

The problem of the stereochemistry of sphingosine (I) at the carbon atoms $C_{(2)}$ and $C_{(3)}$ has been solved by stereospecific synthesis of the *erythro*- (IIa) and *threo*- (IIb) isomers of dihydrosphingosine [117,118]. Catalytic hydrogenation of 1-hydroxyoctadec-2-yne (XL) gives *cis*-1-hydroxyoctadecene (XLIa), but chemical reduction gives the *trans*-compound (XLIb); oxidation of the product with peroxyphthalic acid gives the corresponding *cis*- or *trans*-epoxide (XLIIa, b) Ring opening of the epoxides (XLII) with ammonia is accompanied by inversion of configuration and leads to *threo*- (IIb) and *erythro*- (IIa) dihydrosphingosines. Small quantities of the isomeric amino-diols (XLIIIa, b) are formed at the same time (see Scheme 8).

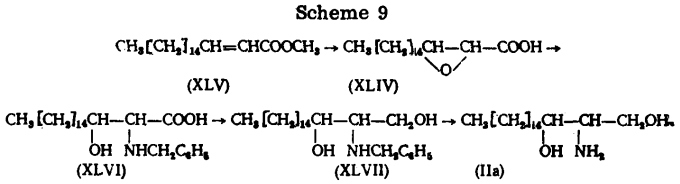
Scheme 8



At the same time, Carter and coworkers [13] synthesised D-(+)-, L-(-)-*erythro*, and DL-*threo*-dihydrosphingosines (IIa, b) by reduction of the corresponding *erythro*- and *threo*-α-amino-β-hydroxystearates [119] (XXVa, b) and separation of DL-*erythro*-dihydrosphingosine (IIa) into the antipodes as L-glutamates [120]. This work completed investivations to establish the structure of sphingosine (I).

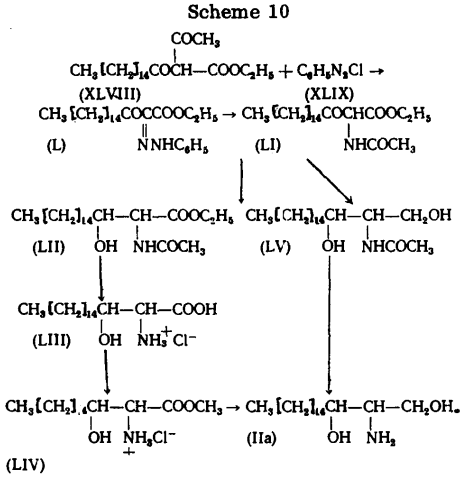
The great diversity of methods already proposed did not reduce the interest of chemists in developing new and more effective methods for the synthesis of dihydrosphingosine (II). Still another stereospecific synthesis of *erythro*-dihydrosphingosine (IIa) was described in 1964.[121] The reaction of *trans*-2,3-epoxystearic acid (XLIV), [122,123] obtained by epoxidation and subsequent saponification of methyl *trans*-octadec-2-enoate (XLV), with benzylamine leads to the formation of DL-*erythro*-2-benzylamino-3-hydroxystearic acid (XLVI). When the methyl ester (XLVI) was reduced with lithium tetrahydroaluminate and then hydrogenolysed, DL-*erythro*-dihydrosphingosine (IIa) was formed, (XLVI) → (XLVII) → (IIa) (see Scheme 9).

Scheme 9



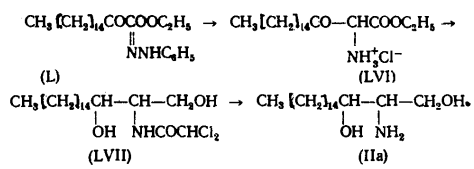
In developing a synthesis of sphingosine (see this page), Shapiro and coworkers also worked out a synthesis of (IIa). [124] Ethyl palimitoylacetoacetate (XLVIII) was condensed by Japp and Klingemann's method [125] with phenyldiazonium chloride (XLIX), and the product was hydrolysed to give the phenylhydrazone (L), which was then reduced with zinc and acetic acid in the presence of acetic anhydride to give ethyl 2-acetamido-3-ketostearate (LI). Reduction of (LI) with sodium tetrahydroborate gave an unseparable mixture of *erythro*- and *threo*-racemates (LII), which were converted into dihydrosphingosine (II) by saponification followed by esterification and reduction with lithium tetrahydroaluminate: (LII) → (LIII) → (LIV) → (IIa); the *erythro*-isomer of (II) was separated as the tribenzoate. It is more convenient to prepare (IIa) in two stages by reduction of (LI) with lithium tetrahydroaluminate to give *erythro*-*N*-acetyl-2-amino-1,3-dihydroxyoctadecane (LV), which is then hydrolysed (see Scheme 10).

Scheme 10



However, when the scale of the synthesis is increased, the yield of (IIa) decreases considerably because of the resistance of the amide (LV) to hydrolysis. For this reason, Shapiro and Sheradsky [126] later modified the method. Reduction of the phenylhydrazone (L) with zinc and aqueous 97% acetic acid leads to the keto-ester (LVI), which is separated as the hydrochloride. After this latter compound has been reduced with lithium tetrahydroaluminate, the mixture of isomers obtained is treated with methyl dichloroacetate [127], and *erythro*-*N*-dichloroacetyldihydrosphingosine (LVII) is separated; this is easily hydrolysed to *erythro*-dihydrosphingosine (IIa) (see Scheme 11). The second synthesis of dihydrosphingosine appears to be very efficient.

Scheme 11



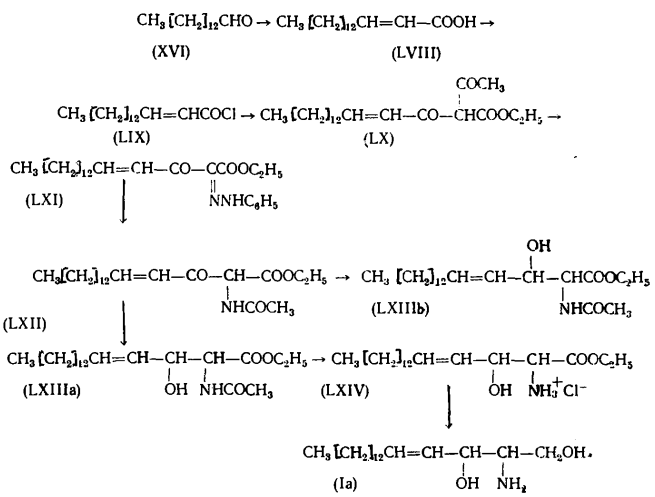
2. Synthesis of Sphingosine

There are two main schemes for the synthesis of sphingosine; these were first developed at almost the same time in the laboratories of Shapiro [128] and Grob [129].

In Shapiro's synthesis (Scheme 12), Knoevenagel–Doebner condensation of myristaldehyde (XVI) with malonic acid in the presence of piperidine gives *trans*-hexadec-2-enoic

acid (LVIII), from which the unstable *trans*-hexadec-2--enoyl chloride (LIX) is obtained by reaction with thionyl chloride.

Scheme 12



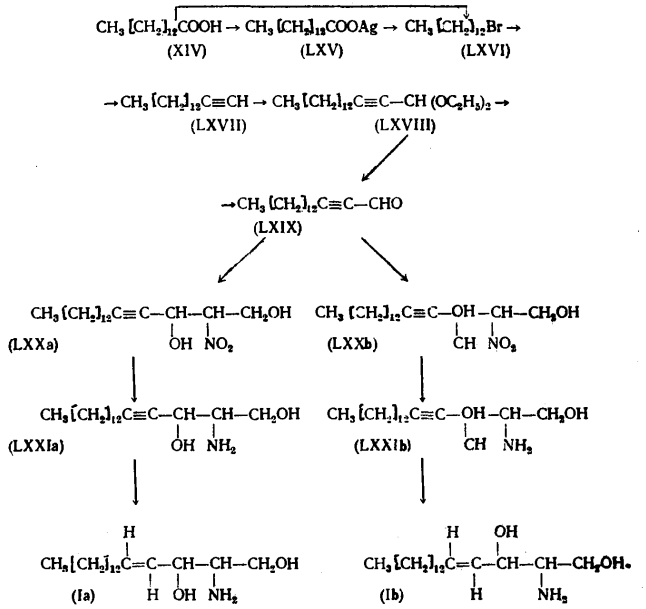
Condensation of the acid chloride (LIX) with ethyl acetoacetate gives ethyl 2-acetyl-3-keto-octadec-4-enoate (LX), which undergoes the Japp–Klingemann reaction with phenyldiazonium chloride under rigorously controlled conditions to give the phenylhydrazone (LXI). Reduction of the latter to the acetamidoester (LXII) with zinc and acetic acid, followed by selective reduction with sodium tetrahydroborate leads to a mixture of diastereomeric alcohols (LXIIIa, b), from which only the *erythro*-isomer (LXIIIa) can be crystallised. When (LXIIIa) is deacetylated with dilute hydrochloric acid in dioxan, the hydrochloride of *erythro*-ethyl 2-amino-3-hydroxyoctadec-4-enoate (LXIV) is formed in relatively low yield, which is due to partial conversion of (LXIV) to the *threo*-isomer. Reduction of (LXIV) with lithium tetrahydroaluminate leads to racemic *erythro*--sphingosine (Ia). The total yield of the latter is about 4%, calculated on the myristaldehyde (XVI).

The relatively accessible myristic acid (XIV) is the starting material in Grob and Gadient's synthesis (Scheme 13) of sphingosine, in which silver myristate (LXV) is converted into tridecyl bromide (LXVI) by the Hunsdiecker–Borodine reaction, or by direct bromination in the presence of red mercury(II) oxide [130] according to the method worked out by the present authors. Condensation of tridecyl bromide with sodium acetylide in liquid ammonia gives pentadec-1--yne (LXVII); this is converted by Iotsich's reaction with orthoformic acid into the diethylacetal of hexadec-2-yn-1--al (LXVIII), which is then hydrolysed to the aldehyde (LXIX). When this is condensed with nitroethanol in the presence of potassium carbonate, a mixture of *erythro*- and *threo*--1,3-dihydroxy-2-nitro-octadec-4-ynes (LXXa, b) is formed; the pure *threo*- (LXXb) and *erythro*- (LXXa) isomers are separated by fractional crystallisation.

Reduction of the nitrodiols (LXX) with zinc and hydrochloric acid leads to a mixture of *erythro*- and *threo*--1,3-dihydroxy-2-amino-octadec-4-ynes (LXXIa, b); *erythro*- and *threo*-sphingosines (Ia, b) are obtained by subsequent reduction of the triple bond with lithium tetrahydroaluminate. The overall yield of *erythro*-sphingosine, calculated on myristic acid (XIV) is about 7%; *threo*--sphingosine (Ib) is obtained at the same time in a yield of about 9%. The *cis*-isomers of sphingosine can be obtained by reducing the aminodiols (LXXI) on $Pd/CaCO_3$.

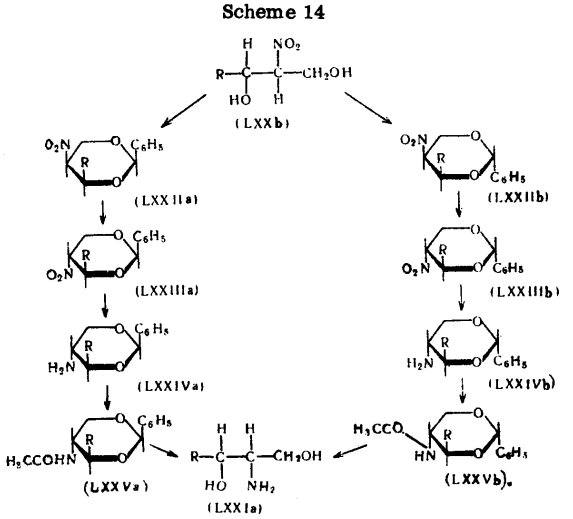
Thus, the more efficient synthesis of Grob opens the way to the preparation of all the possible spatial isomers of sphingosine, which are of great interest in biological studies.

Scheme 13



Because the unnatural *threo*-isomer (Ib) predominates in the latter synthesis, Grob and Gadient proposed a method for the *threo*–*erythro*-isomerisation of sphingosine [129]. For this purpose a mixture of two intermediate cyclic benzal derivatives (LXXIIa, b) is prepared, these being formed in a ratio of 5 : 1 in the reaction of *threo*-1,3-dihydroxy-2--nitro-octadec-4-yne (LXXb) with benzaldehyde in the presence of zinc chloride (Scheme 14; R = $CH_3[CH_2]_{12}C{\equiv}C-$).

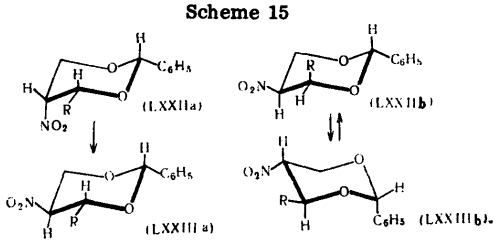
Scheme 14



The cyclic acetals (LXXIIa, b) differ in the orientation of the phenyl group in the 2-position of the 1,3-dioxan ring. Treatment of (LXXIIa) with sodium ethoxide in ethanol results in virtually complete conversion into the epimer (LXXIIIa), and when this reaction is carried out with (LXXIIb), an equilibrium mixture is formed containing the epimer (LXXIIIb) and the starting (LXXIIb) in the ratio 3 : 2.

This kind of difference in the equilibrium position is explained by the greater stability of the most favoured completely equatorial conformation (LXXIIIa) in comparison with (LXXIIa) and the approximately identical stabilities of (LXXIIb) and (LXXIIIb) (Scheme 15).

Scheme 15



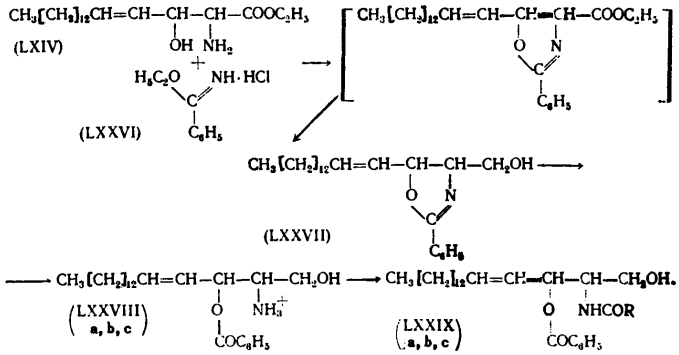
When (LXXIII) is reduced with aluminium amalgam, the amines (LXXIV) are formed, and on acetylation these give *erythro*-5-acetamido-4-(pentadec-1-ynyl)-2-phenyl-*m*-dioxans (LXXVa, b) (see Scheme 14); hydrolysis of the latter gives *erythro*-2-amino-1,3-dihydroxyoctadec-4-yne (LXXIa). The large number of stages and the long time required for some stages are disadvantages of the method. Because of these disadvantages, the present authors have worked out a new method for the *threo–erythro*-isomerisation of sphingosine, the main features of which are described in the following Section.

Grob's method has been successfully used for the synthesis of C_{20}-*erythro*-sphingosine (III) [131] and C_{20}-*erythro*-dihydrosphingosine (IV) [132] and their stereoisomers, which have been isolated in recent years; it has also been used for the synthesis of a number of long-chain amino-diols, homologues of sphingosine [133].

3. Methods of Synthesis of Glycosphingolipids

Natural sphingolipids, in particular glycosphingolipids, contain a free allyl hydroxyl group, and it is desirable that this group should be temporarily blocked during the synthesis [134–137]. With sphingosines (I) as starting materials, this blocking is difficult because of the presence in these bases of a complex system of active centres of similar reactivity in conjunction with an ethylene bond, which makes allyl rearrangements possible. The first important advance was made by Shapiro and coworkers on the basis of their sphingosine synthesis, in which the intermediate *erythro*-ester (LXIV) has a potential primary sphingosine hydroxyl group in a latent form as an ester grouping. Condensation of the *erythro*-ester (LXIV) with ethyl iminobenzoate hydrochloride (LXXVI)‡ and subsequent reduction of the ester group with lithium tetrahydroaluminate gives the oxazoline (LXXVII) (Scheme 16).

Scheme 16



When the oxazoline (LXXVII) is treated with dilute sulphuric acid in tetrahydrofuran, *erythro*-3-*O*-benzoylsphingosine (LXXVIIIa) is formed.

Using *L*- and *D*-tartaric acids, Shapiro [137] separated the sulphate (LXXVIIIa) into antipodes by way of L-*erythro*-3-*O*-benzoylsphingosine *L*-tartrate (LXXVIIIb) and D-*erythro*-3-*O*-benzoylsphingosine *D*-tartrate (LXXVIIIc). Acylation of the sulphate (LXXVIIIa) or the tartrates (LXXVIIIb, c) with a fatty-acid chloride in the presence of sodium acetate–acetic acid buffer leads to DL-, L-, and D-*erythro*-*N*-acyl-3-*O*-benzoylsphingosines (LXXIXa, b, c) respectively; these are then used for the direct synthesis of sphingolipids.

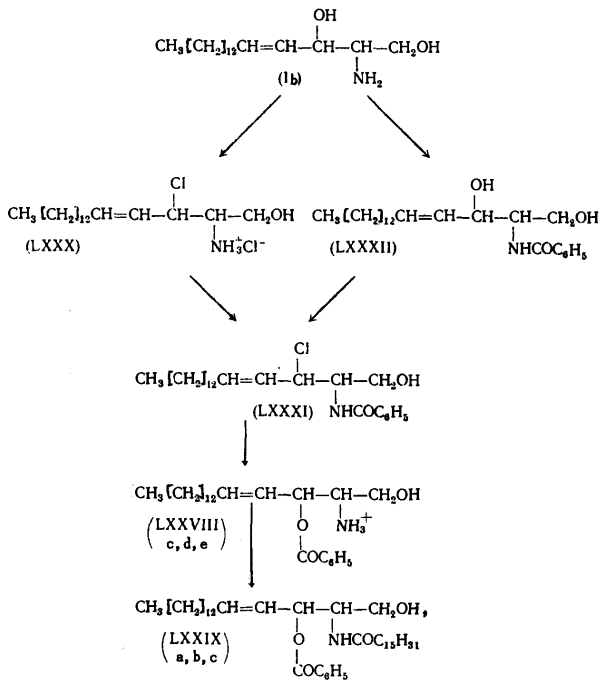
We have developed another method [138] of protecting the allyl hydroxyl group with simultaneous *threo–erythro*-isomerisation; this enables natural derivatives of *erythro*-sphingosine to be prepared from its threo-form (Ib), which is preferentially formed in Grob's synthesis. When a salt of *threo*-sphingosine (Ib) (Scheme 17) reacts with thionyl chloride in chloroform at 20°, *threo-trans*-2-amino-3-chloro-1-hydroxyoctadec-4-ene (LXXX) is formed, and on *N*-benzoylation with benzoic anhydride in the presence of sodium hydrogen carbonate this gives *threo-trans*-2-benzamido-3-chloro-1-hydroxyoctadec-4-ene (LXXXI).

The latter can also be obtained by chlorinating *threo*-*N*-benzoylsphingosine (LXXXII), that is, by changing the order of the stages. It is interesting to note that appreciable quantities of the oxazaline (LXXVII), which is an intermediate in the syntheses of sphingolipids by the Shapiro method (see Scheme 16), is not formed here. Apparently its formation is not favoured energetically [139].

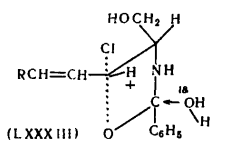
When the β-chloroamide (LXXXI) was heated in aqueous tetrahydrofuran, *erythro*-3-*O*-benzoylsphingosine (LXXVIIId) was obtained; this compound can be used in directed syntheses of sphingolipids. Measurement by amperometric titration of the amount of chloride ions liberated has shown that the reaction is an equilibrium process. It was shown by a special experiment with water containing heavy oxygen [140] that the reaction probably proceeds through a hypothetical transition state (LXXXIII); the regenerated oxygen function of *erythro*-3-*O*-benzoylsphingosinium (LXXVIIId) chloride is formed from the oxygen of the carbonyl group,

‡ Better termed α-ethoxybenzylideniminium chloride (Ed. of (Translation).

Scheme 17



but the carbonyl function of the ester grouping in (LXXIIId) is built up with the participation of oxygen from the water.

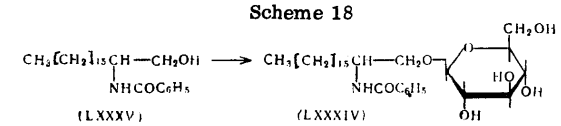


In this example [141,142], separation into antipodes is effected by allowing the chloride (LXXVIIId) to react with the monosilver salt of *D*-tartaric acid [143], followed by fractional crystallisation of the *D*-tartrates of D- and L-*erythro*-3-*O*-benzoylsphingosines (LXXVIIIc, e) formed. Palmitoylation of the chloride (LXXVIIId) or the tartrates (LXXVIIIc, e) leads to DL-, D-, and L-*erythro*-3-*O*-benzoyl-*N*-palmitoylsphingosines (LXXIXa, b, c), identical with the corresponding compounds obtained by Shapiro's method.

4. Synthesis of Cerebrosides and Psychosine

The history of synthetic studies in the glycosphingolipid field begins in 1957, when Prostenik and Krvavica [144] described the synthesis of 1-β-D-glucopyranosyl-*DL*- and 1-β-D-glucopyranosyl-*L*-benzoylsphingine (LXXXIV), in which *N*-benzoyl-*DL*-sphingine or *N*-benzoyl-*L*-sphingine (LXXXV) reacts with α-benzobromoglucose in the presence of mercury cyanide in nitromethane, the reaction product being subsequently saponified with sodium methoxide [145] (Scheme 18).

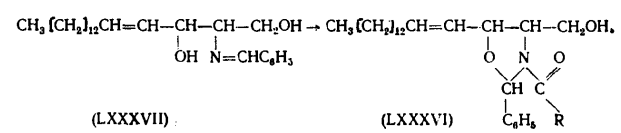
Scheme 18



Kiss was the first to synthesise the dihydrocerebroside [146,147]; he treated dihydro-*N*-tetracosanoylsphingosine with α-acetobromogalactose, and the mixture of α- and β-galactosides, formed as penta-acetates, was subsequently anomerised with titanium tetrachloride. On the basis of this synthesis it was concluded that dihydrocerasine, obtained by hydrogenation of natural cerasine or neurone, has the α-configuration, since it was found to be identical with the synthetic α-galactoside of dihydroceramide (m.p. 186°, $[\alpha]_D$ = +5.31°). In subsequent studies, Shapiro and Flowers [135] showed that this result was incorrect.

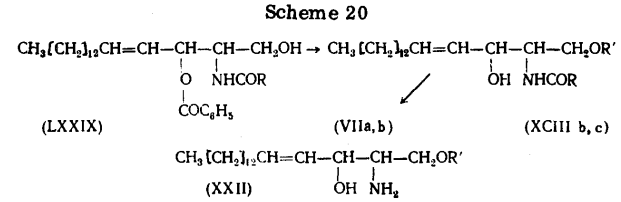
Attempts by Weiss [136] to prepare glycosides of the substituted oxazolidine (LXXXVI), which is obtained by alkylation of *N*-benzylidenesphingosine (LXXXVII) (see Scheme 19), were unsuccessful, as were the attempts of Shapiro to prepare a glycoside of the oxazolidine (LXXVII) (see Scheme 16); these failures were because of the extremely low reactivity of the hydroxyl group in these compounds, and also because of the sensitivity to alkali of the small amounts of glycoside formed.

Scheme 19



Shapiro and Flowers [135] were the first to synthesise cerebrosides (VII) from protected ceramides (LXXIX) obtained by the method described in the previous Section. Condensation of benzoylceramides (LXXIX) with α-acetobromogalactose or α-acetobromoglucose in the presence of mercury cyanide and subsequent saponification of the protecting groups leads to β-D-galacto- and β-D-gluco-cerebrosides (VII) (Scheme 20), identical in physical properties (infrared spectrum and $[\alpha]_D$) with natural cerasine and phrenosine, and with the cerebroside that is stored in the human spleen in Gaucher's disease.

Scheme 20

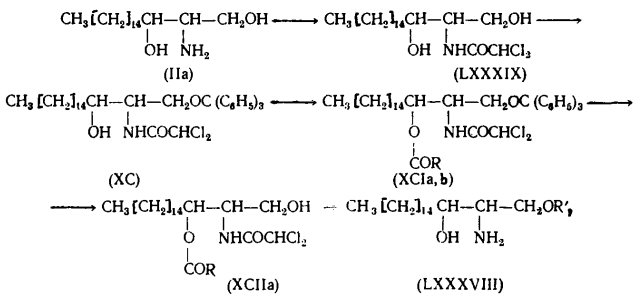


VIIa, R′ = $CH_3[CH_2]_{22}$, R′ = glucose; VIIb, R = Cl_2CH, R′ = galactose;
XXII, R′ = galactose; XCIIIb, R = $CH_3[CH_2]_{22}$, R′ = lactose;
XCIIIc, R = $CH_3[CH_2]_{14}$, R′ = lactose.

Shapiro and coworkers [137] have also described the preparation of psychosine (XXII) — a precursor of cerebrosides in biosynthesis [148] — and its dihydro-derivative (LXXXVIII), which is of interest in biosynthetic studies, particularly the synthesis of cerebrosides labelled in the fatty acid residue. The dichloroacetyl group was found to be the best group for the temporary protection of the amine function in psychosine (XXII) and dihydropsychosine (LXXXVIII). Psychosine (XXII) is obtained in the same way as the cerebrosides (VII) (see Scheme 20), the dichloroacetamide (VIIb) formed being hydrolysed by boiling with barium hydroxide.

A new method was worked out for the synthesis of dihydropsychosine (LXXXVIII) (see Scheme 21).

Scheme 21



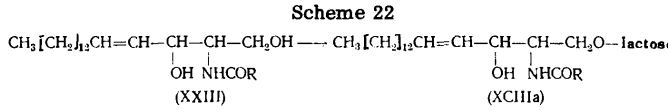
where (a) R = $-C_6H_5NO_2$-*p*; (b) R = C_6H_5; (c) R′ = glucose.

When dihydrosphingosine (IIa) reacts with methyldichloroacetate, the amide (LXXXIX) is formed; the primary hydroxyl group of this compound is temporarily tritylated and the secondary hydroxyl group is then *p*-nitrobenzoylated, (LXXXIX) → (XC) → (XCIa), since the benzoyl derivative (XCIb) is difficult to purify. Removal of the trityl protecting group with dilute acetic acid leads to the dichloroacetamido-ester (XCIIa), which is converted into dihydropsychosine (LXXXVIII) in the usual way. Later it was pointed out [149] that natural derivatives of *erythro*-sphingosine could be synthesised by this new method (see Scheme 21). This is particularly interesting since it provides a shorter synthetic route from natural *erythro*-sphingosine to the sphingolipids.

5. Synthesis of Cytolipin H

Schram and coworkers [150] synthesised the lactoside (XCIIIa), which is similar in structure to cytolipin H, using as a starting material ceramide (XXIII) obtained by enzymatic hydrolysis [151] of sphingomyelin from ox heart (Scheme 22). The infrared spectra of the lactoside (XCIIIa) and cytolipin H are almost identical, but their specific rotations differ ($[\alpha]_D$ = +2.1° and -10.8° respectively).

Scheme 22



In 1964 a synthesis of 1-*O*-β-D- and 1-*O*-β-DL-lactosyl-*N*-lignocerylsphingosines (XCIIIb) was described [152], but experimental details were not published; the method used was that developed by Shapiro for the preparation of cerebrosides (see Scheme 20). The lactoside (XCIIIb) was found to be identical in physicochemical and serological properties with cytolipin H. The work of Schram [150] has been subjected to critical examination. In particular, the probable ambiguity in lactoside formation by the unprotected ceramide (XXIII) has been pointed out; this has been related to the increased angle of rotation of the lactoside (XCIIIa).

The lactosides of *erythro*-*N*-palmitoylsphingosine (XCIIIc) and its *threo*-isomer, which are similar in structure to cytolipin H, have been prepared independently by the present authors [141,142], using the new method of synthesising sphingolipids described above [138] (see Scheme 20).

IV. BIOLOGICAL PROPERTIES

1. Immunological Properties

Recent studies in connection with the cancer problem have shown that there are significant differences in structure and biochemical composition between normal cells and tumour cells; these differences result from malignant degeneration of the tissues [153].

It has now been shown that all glycosphingolipids have the properties of organ-specific and tissue-specific haptens [154]. It is possible that glycosphingolipids, occurring as they do in membranes, participate in immunological control of cell growth [155].

Rapport and Graf made an extensive study of glycosphingolipid haptens. Using the method of complement fixation, they were the first to show that the individual lipid hapten isolated from human epidermoid carcinoma, cytolipin H, is a tissue-specific substance in a number of malignant neoplasms, such as carcinoma of the lungs, spinal cord, kidneys, and throat; Hodgkin's granuloma; bone sarcoma; lymphosarcoma; myelogenic leukaemia; and malignant melanoma. On the other hand, cytolipin H does not react with antiserum against carcinoma of the rectum or colon or epidermoid carcinoma [53,156]. Large quantities of this compound occur in the spleen of cancer patients, and small quantities occur in their livers, but none has been detected in the kidney tissues.

Repeated attempts to prepare antibodies that react with lipid extracts of cancer tissue by injecting tissue fractions of normal organs have been unsuccessful. This indicates that cytolipin H is present in only insignificant amounts, if at all, in normal organs [157]. However, Japanese biochemists [37,50,59,60] have isolated a number of glycosphingolipids, especially lactosylceramides, from various organs, including kidneys from healthy human subjects.

Immunological examination of dihydrocytolipin H, [57] and also of synthetic D- and DL-*erythro*-lactosyl-*N*-lignocerylsphingosines [158], has shown that the presence of a double bond and optical activity in the lipid part of the molecule are not essential for the immunological activity of cytolipin H. However, a change in the structure of the carbohydrate part of the molecule leads to loss of activity [159]. Rapport therefore concluded that the immunological specificity of glycosphingolipid haptens, and particularly of cytolipin H, depends, largely if not entirely, on the structure of the carbohydrate part of the molecule [61], and he has recently confirmed this conclusion [66]. The lipid residues only play a part in the localisation of the hapten in the cell membrane.

Schram and coworkers [150] accepted this point of view too readily; they thought that lactosides of any aliphatic or aromatic alcohols must behave in the same way as cytolipin H in the complement fixation reaction.

Attempts to immunise rabbits with cytolipin H, even in the presence of pure auxiliary lipids — lecithin and cholesterol — proved unsuccessful. Specific antibodies were obtained when immunisation was carried out with a mixture of cytolipin H and total tissue lipids.

The simplest glycosphingolipid, galactocerebroside [159,160], is an organ-specific lipid of brain [161]. The antiserum obtained by immunisation of rabbits with fractions of human and cow brain is active in the complement-binding reaction with galactocerebroside [160] in the presence of auxiliary

lipids, but it does not react with glucocerebroside or with cytolipin H.

The globoside isolated from human kidney and named cytolipin K is an organ-specific kidney hapten [66]. Forssman's hapten from sheep erythrocytes also contains sugar, fatty acid, and sphingosine residues characteristic of glycosphingolipids [61].

Yokoyama and coworkers [162] have proposed a useful method for the preparation of antiganglioside sera. When immunisation was effected with gangliosides deposited on the surface of erythrocytes, a high antibody titre was obtained. The specificity of the antiganglioside antibodies was demonstrated by the haemagglutination reaction, which is scarcely observed with erythrocytes covered with asialogangliosides.

In common with some other compounds, brain gangliosides inhibit the haemagglutination reaction with antibodies against Rhesus-positive erythrocytes [163], which indicates that gangliosides and blood-group antigen are immunologically similar [164]. However, antiganglioside serum does not react with Rhesus-positive erythrocytes in the haemagglutination test. This appears to be a reflection of fine structural differences between the ganglioside and the antigen determinant (possibly a complex lipopolysaccharide [165]) of Rhesus-positive human erythrocytes.

Two ganglioside-like compounds have also been separated from human erythrocytes [105], which, in addition to mucopolysaccharides [166], are substances characteristic of blood group A. These substances differ in physicochemical properties and in composition from the human erythrocyte globosides to which the group activity of the human blood groups A, B, O, and AB is ascribed [167]. Here the activity appears to be due to the presence of active mucopolysaccharides as impurities in the preparations.

In accordance with the classical method of diazo-fixation of Landsteiner [169], the reaction of diazotised *N*-*p*-aminobenzoyldihydropsychosine with proteins [168] gives artificial antigens. Immunochemical analysis by the precipitation method showed that the antiserum obtained by immunisation with such artificial albuminolipid antigens contains at least two types of antibody, antidihydropsychosine and antialbumin antibodies. However, the question to what extent antibodies obtained in this way will be complementary to natural glycosphingolipid haptens remains open.

2. Biological Activity of Sphingosine and Cerebrosides

The high-molecular-weight lipoprotein enzyme thromboplastin catalyses one of the stages in the complex process of blood coagulation [170]. The anticoagulant activity of sphingosine [171,172] is associated with its antithromboplastic [173] (that is, antienzyme) activity. This was first demonstrated in chicken plasma [174].

The use of comparatively small quantities of sphingosine in the presence of a lipid blood-coagulation activator has no inhibiting effect, but, if sphingosine is first incubated with chick blood plasma and the lipid activator is then added, the rate of coagulation is greatly increased compared with that using the lipid activator alone.

Thus, the way in which sphingosine acts depends on its concentration, on the concentration of lipid activator, and on the individual properties of the plasma. Synthetic *erythro*- and *threo*-dihydrosphingosines were found to be weaker coagulation inhibitors than sphingosine; *N*-benzoyldihydrosphingosine and triacetylsphingosine are entirely inactive. Synthetic homologues of sphingosine show the greatest activity when the chain contains 17–18 carbon atoms [133]. The presence of a double bond, free hydroxy- and amino-groups, and a long hydrocarbon chain are therefore necessary for anticoagulant activity [174].

When cerebrosides are introduced into the human organism or into experimental animals, more cholesterol is excreted with the faeces and the level of cholesterol in the blood is reduced [175]. The mechanism of this process is still unknown.

3. Neurophysiological Role of Gangliosides

Recently a number of workers have noted the important part played by the sialic acid components of gangliosides.

Van Heyningen showed in vitro experiments [176] that the gangliosides of ox brain are receptors for tetanus toxin [177], and also for such drugs as strychnine, brucine, and thebaine, which have similar neurophysiological activity [178]. The fixing power of the gangliosides is proportional to the number of sialic acid residues present in the molecule, but it also depends on the structure of the whole carbohydrate part of the molecule [179]. For example, hematosides isolated from horse brain or horse erythrocytes, which do not contain hexosamine, and the ganglioside that accumulates in the spleens of patients with "Tay-Sachs'" disease are virtually inactive [178].

The fixation of tetanus toxin by gangliosides is strictly specific for this toxin, and the non-specific inactivation of diphtheria and staphylococcal toxins by these compounds, which has been noted by North and Doery [180,181] has nothing in common with the fixation of tetanus toxin; this toxin is not inactivated at all [176]. Gangliosides also interact with serotonin, tryptophan, and related compounds, but not with γ-aminobutyric acid, β-hydroxybutyric acid, histamine, adrenaline, or noradrenaline [178].

The process by which the tetanus toxin is fixed by the ganglioside receptor in nerve tissue is directly related to the mechanism of action of the toxin. This is confirmed by the high specificity, and also by the fact that the gangliosides and the synapses inhibited by the toxin are found in the grey matter of the human brain.

The reaction of gangliosides with bacterial endotoxin that produces fever leading to disorders of the heat-regulating function of the body has also been described [182].

It may be that the reaction of the ganglioside with the toxin or with the drugs mentioned above is the first step that leads to the biochemical attack on which the pharmacological action of these compounds is based. On the other hand, the receptor may be responsible for adsorption of the toxin at the infection sites, and for its localisation in the nerve cells with subsequent centripetal transfer along the nerve columns to the site of activity in the brain or spinal cord. However, none of these hypotheses can be accepted without reservation.

Brain gangliosides are mainly associated with fractions of subcellular particles [183], which have an affinity with basic proteins [184], especially with microsoma [185] and, to a lesser degree, with mitochondria. They are readily extracted from brain tissues, but when added to a suspension of subcellular fractions of basic proteins, for example,

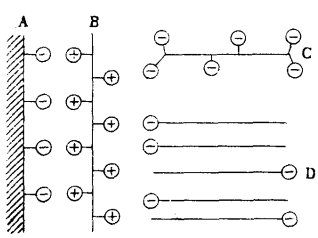
protamine, the gangliosides cannot be separated [142]. Evidently the natural gangliosides, which are acid components of lipid-rich membranes that participate in active cation transport, are linked to the basic proteins by ionic forces. This accounts for the opposite effects of these proteins and gangliosides on the excitability of the brain.

The normal brain exhibits continuous electrical and metabolic activity, which can be stimulated, particularly by electrical impulses [187]. Isolated brain tissue in a suitable nutrient solution can breathe and respond to electrical stimuli by showing increased assimilation of glucose and oxygen [188]. When such a system is cooled to 0°, the respiratory response to electrical stimulation is only 15% of the maximal reaction of normal tissue, but this response increases to 52–80% when 60–120 μg per mg of gangliosides is added. Evidently, when the tissue is cooled, the histones — which are basic proteins linked with ribonucleic acid in cell nuclei — lose their capacity of forming nucleohistone gel [184]. They separate from the RNA and migrate out of the nuclei, blocking the acid sections of the membranes. This stops reversible transfer of potassium ions in cerebral tissue after stimulation. Added gangliosides associate with these basic proteins and neutralise their activity [189-192].

Inhibition of brain excitability by protamines occurs in the same way as when cooling is applied, and it is abolished by gangliosides in exactly the same way.

Ordinary acid reagents cannot replace gangliosides. Neither *N*-acetylneuraminic acid nor L-glutamic acid restores excitability. Monoacid compounds, which cannot form aggregates, can only neutralise the basic groups of protamine, but this is not sufficient to restore excitability, which is associated with the presence of acid groups on the external surface of the membrane (see Scheme 23). On the other hand, polyacid compounds such as sialomucopolysaccharides, chondroitin sulphate, poly-L-glutamic acid, the aromatic hexasulphonic acid suramin, or micellar aggregates of such compounds as lecithin, phosphatidylethanolamine, sphingomyelin, and phosphatidylserine — compounds of widely different structure — all behave like gangliosides [193].

Scheme 23



Hypothetical interaction between acid areas of tissue (A), basic proteins (B), and polyacid molecules (C), or micellar aggregates (D).

This activity of gangliosides is higher than the activity of all other compounds and it increases with the number of sialic acid residues in the ganglioside. It is noteworthy that gangliosides restore the excitability of brain tissue and they are present in concentrations close to the critical concentration for the formation of micelles. Individual molecules of gangliosides probably first react with tissues that bind protamines, and then they combine to form micelles.

A similar explanation has been advanced for the metachromatic properties of gangliosides [194], that is, the capacity to form associations with suitable basic dyes (for example, Toluidine Blue or Pyocyanine [195]) that differ in colour from the dye itself [196]. This effect is due to association of the dye molecules with suitably arranged acid groups of the compounds being dyed [197]. A molecule of thiazine dye appears to combine with the acid groups of micellar gangliosides as a result of ionic forces, and it then undergoes association, due to secondary forces, with the formation of metachromatic dimers and polymers. The effect disappears in organic solvents, apparently because of a change in the structure of the ganglioside micelle, sialic acid residues being removed from the surface of the sphere, and also because of interaction of the dye and the solvent, which destroys the metachromatic aggregate. Because it can react with gangliosides, protamine also inhibits the metachromatic reaction with Toluidine Blue.

Using a histochemical method based on metachromatic reactions, Koenig [198] studied the localisation of the gangliosides in the nerve system, and he showed that the glycolipoprotein cytoplasmprotein granules (the so-called synaptic vesicles) containing acetylcholine [199] are also rich in gangliosides. In this connection, Burton and coworkers [109,200] put forward the hypothesis that gangliosides play a part in the transmission of nerve impulses through synapses in accordance with the concepts of a neuro-humoral mechanism [109,200]. At present, however, these concepts have given way to the idea [201] that acetylcholine functions in a uniform manner in synaptic connections and conducting axon membranes.

From the foregoing it is clear that gangliosides play an essential part in neurophysiological processes, but our knowledge in this field is still very unsatisfactory.

Further extension of our ideas on the significance of glycosphingolipids in biological systems will probably be mainly determined by the development of biochemical, biophysical, and synthetic work in this field. The problems that now have to be solved are concerned not only with the elucidation of the primary structure of new, hitherto unknown, types of glycosphingolipids, but also with establishing the actual shapes of these compounds in three-dimensional space, that is, of the forms in which they carry out their biological functions.

---o0o---

While this manuscript was being prepared for the press, interesting reviews appeared on the chemistry of gangliosides [202], and sulphatides [203], and on methods of analysis of glycolipids [204], in addition to a review article on the immunochemical properties of glycolipids [205]. Further studies have led to the isolation of a number of new sphingosine bases from animal tissues [206-208]. Thus, twenty compounds of this type are known already; these differ in chain length, number of hydroxyl groups, and degree of unsaturation. A number of new glycosphingolipids have been isolated, including *O*-acylcerebrosides from ox brain [209], and also gangliosides from human brain [210,211], leucocytes [212], and placenta [213].

THE STUDY OF ELEMENTARY CHEMICAL REACTIONS BY THE MOLECULAR BEAM METHOD

V. B. Leonas

CONTENTS

I. Introduction 879

II. Technical realisation and interpretation of experiments with molecular beams 881

III. Main results of the study of chemical reactions in intersecting beams 885

I. INTRODUCTION

In 1955 a paper[1] was published, demonstrating convincingly for the first time the real possibility of studying chemical reactions accompanying the collision of the molecules of two intersecting beams. It is no exaggeration to say that the publication of this paper opened up a new stage in studies of the mechanism of bimolecular gas reactions and originated a new line of research.

This review examines the present position and some immediate prospects in the use of intersecting molecular beams to study the mechanism of bimolecular gas reactions.

Section I gives a general picture of the molecular beam method, presents some theoretical concepts used in the examination of kinetic problems within the framework of collision theory, and finally discusses the analogy between collisions leading to chemical changes and those responsible for ordinary transfer phenomena in gases.

Section II, after a brief discussion of the experimental technique, describes the chief methods used in the analysis and interpretation of the experimental data.

The concluding Section III is devoted to a detailed examination of the chief experimental results obtained by molecular beam studies of some bimolecular chemical reactions.

Most chemical processes are complex multistage reactions, and only a relatively small proportion correspond to single-stage elementary reactions. It is obvious, however, that each stage in a complex process can in a certain sense be regarded as an elementary reaction, and study of the elementary reactions can in principle lead to a better understanding of the characteristic features of the process as a whole. This explains why in chemical kinetics there is great interest in the study of elementary chemical reactions, of which bimolecular reactions form the most commonly encountered class. The subsequent discussion deals chiefly with these reactions.

One of the main tasks in chemical kinetics is to determine the principal conditions (energetic, configurational, etc.) which must be satisfied by molecules if a chemical reaction is to take place between them. This must be regarded as the fundamental problem, since the frequency with which these conditions are realised in molecular collisions influences the rate of the process and at the same time is comparatively readily determined by familiar methods within the framework of equilibrium statistics, whose applicability is generally assumed.

On the other hand, if the equilibrium approximation is inapplicable, the problem of finding the perturbed distribution functions will also include in the initial stage the determination of the chief microscopic conditions for reaction to take place on collision of the molecules.

The classical methods of kinetic studies[2] cannot take us beyond the limits of the phenomenological Arrhenius equation, leaving to the research worker a considerable degree of freedom in the interpretation of the intimate details of the mechanism of the reaction being studied. Since the activation energy and the steric factor are found by effective statistical averaging over a large number of energy

states and the corresponding collision parameters, these characteristics are insufficient for a complete understanding of the elementary act in a chemical change. Thus there is no guarantee even that theories which provide an obviously correct description of reaction rates are based on correct original hypotheses regarding the mechanism of the elementary process.

This situation makes it extremely desirable to develop and use kinetic methods which are free from this uncertainty. The molecular beam method[3] satisfies these requirements, since, in addition to specifying the translational energy of the colliding particles, it also permits the selection of definite internal stages. In the ideal case it enables a chemical reaction to be conducted with complete control of the energy states and even of the orientations of the reacting molecules.

The molecular beam method is based on the use of a beam of atoms or molecules, produced by a suitable method, as a subject for study, either immediately after its production (in this case the particles of the beam "carry" information on the thermodynamic and physicochemical state of the gas in the formation region) or after the beam has been acted on in some way. The nature of the action on the particles of the beam and the methods used may vary: in all cases — irradiation with a beam of light, reflection from a solid surface, the action of electric or magnetic fields, collision with particles of another beam, etc. — we obtain information on the effects produced by the action. The importance of the molecular beam method in chemical studies is that it is possible in an experiment to record the direct effect of a fairly exactly localised interaction between particles capable of undergoing reaction, so that the effect is not obscured by side reactions or, as is often the case in chemical processes, competing reactions. It is thus possible to isolate an elementary process and to study it over a wide range of controlled collision energies; the localisation of the collision region effectively frees the reaction from the influence of the walls of the reaction vessel. A fairly detailed discussion of the possible applications of the molecular beam method can be found in recent reviews[3-5], and this makes it possible to restrict the present review to a discussion of studies of bimolecular gas reactions.

The ideal arrangement for an experiment to study chemical interaction between molecules corresponds to the use of two intersecting collimated beams homogeneous with respect to velocity, or of one such beam passing through a layer of relatively immobile molecules in a bombarded target. In these cases the emission of the reaction products can be observed within a very narrow range of angles about a certain direction determined by the kinematic conditions to be examined below.

The quantity of reaction products makes it possible to determine the reaction probability or cross-section, and variation of the velocities and internal energies of the particles permits the dependence of the cross-section on these parameters to be found. The position of the maximum and the width of the angular distribution of the products enable in some cases conclusions to be drawn regarding the nature of the distribution between the products of the energy liberated in the reaction, or conclusions regarding the lifetime of the intermediate complex. It is also possible to determine directly the internal energy of the reaction products and the spectrum of their velocities. Thus the extent to which the equilibrium distribution is broken down by the chemical reaction can be established. The reaction products can in turn be used as a beam for secondary scattering.

These are the basic possibilities of the molecular beam method. The level of experimental technique employed does not always permit us to realise them completely. As will be subsequently seen, however, even partial utilisation of these possibilities has enabled us to observe reaction-mechanism details which are quite inaccessible by ordinary methods. The continuous development of experimental technique in the last ten years is bringing these experiments closer to the ideal.

What is the relationship between the microcharacteristics of a chemical reaction (cross-section, threshold energy), determined in experiments with intersecting beams (the same characteristics are obtained in the theoretical analysis of elementary processes), and parameters such as, for example, the rate constant and the activation energy? This question is part of the more general question of the relationship between the microscopic and the macroscopic properties of gaseous systems. It is useful to follow this relationship and to recognise the main assumptions necessary for unambiguous conversion from one set of parameters to the other. Following Eliason and Hirschfelder[6], let us consider a reaction of the type A + B → C + D, taking place in a gas exhibiting a certain distribution of translational and internal energies. By analogy with the analysis of transport in a gas (there is an extremely sound basis for this analogy), it is convenient to regard particles with different internal states (characterised symbolically by the quantum numbers i, j, k, and l) as separate components. This approach is further justified by the fact that intuition suggests that the reactivity should depend on the internal state of the collision partners.

The partial rate of a reaction of the type $A_i + B_j \rightarrow C_k + D_l$ is given by the usual relationship

$$\left(-\frac{dn_{A_i}}{dt}\right)_{jkl} = k_{ij}^{kl}(T)\, n_{A_i} n_{B_j}, \qquad (1)$$

where n_{A_i} and n_{B_j} are the densities of the molecules A_i and B_j, and $k_{ij}^{kl}(T)$ is the partial rate constant. The overall rate of the chemical reaction (A + B → C + D) measured in kinetic experiments will then be the sum of the partial rates:

$$\left(-\frac{dn_A}{dt}\right) = \sum_{ij}\sum_{kl} k_{ij}^{kl}(T)\, n_{A_i} n_{B_j}. \qquad (2)$$

From kinetic theory, equating the partial reaction rate to the number of collisions leading to reaction[2], we can readily obtain the following relationship in the classical approximation

$$k_{ij}^{kl} = \iiiint f_{A_i} f_{B_j} \overline{I}_{ij}^{kl}(E, \theta\varphi)\, g_{ij} \sin\theta\, d\theta\, d\varphi\, dv_{A_i}\, dv_{B_j}, \qquad (3)$$

where f_{A_i} and f_{B_j} are the normalised distribution functions for the velocities $\mathbf{v}_{A_i}$ and $\mathbf{v}_{B_j}$, and $\overline{I}_{ij}^{kl}(E, \theta, \varphi)$ is the differential cross-section for the collision of molecules in states i and j with relative energy E, leading to the formation of product molecules in states k and l, moving at angles θ and φ to the direction of the relative initial velocity g_{ij}. Since in expression (3) only $\overline{I}_{ij}^{kl}(E, \theta, \varphi)$ depends on the angles θ and φ, we can, by integrating with respect to the angles, obtain a new quantity $C_{ij}^{kl}(E)$ — the so-called total reaction cross-section

$$C_{ij}^{kl} = \iint \overline{I}_{ij}^{kl}(E, \theta, \varphi) \sin\theta\, d\theta\, d\varphi. \qquad (4)$$

In principle, these two quantities (C_{ij}^{kl} and $\overline{I}_{ij}^{kl}$) represent the final results of both theoretical (quantum-mechanical or classical) calculations and experiments with intersecting beams.

The relationship between these microscopic characteristics and the reaction rate (2) is conveniently followed from the diagram[6] (Fig. 1). If the quantity $P_{ij}^{kl}(E, b, \eta, \theta, \varphi, K)$ is the probability that the collision of molecules of types A_i and B_j (involving the formation of a quasi-molecule with a set of quantum numbers K), with initial impact parameter b, azimuthal angle η, and relative energy E, will lead to the production of molecules C_k and D_l, moving at angles of θ and φ in the [coordinate] system of the centre of mass, the diagram shows the possible routes from the quantity $P_{ij}^{kl}(E, b, \eta, \theta, \varphi, K)$ to the rate constant for the reaction $A + B \rightarrow C + D$. It can be seen from Fig. 1 that in the first stage the corresponding averaging can be carried out in three ways — with respect to the values of K, the initial parameters b and η, and the final parameters θ and φ — each arrow in the diagram representing the successive procedure of averaging with respect to the quantities which are not present in the argument to which the arrow points (the use of arrows is of fundamental significance, since movement in the opposite direction is generally associated with ambiguity). This ambiguity is the main obstacle to verification of the correctness of the original theoretical models by means of ordinary kinetic data. The limited nature of the information on reaction mechanism contained in the averaged quantity $k(T)$ is thus fairly obvious.

The value of the molecular beam method when applied to chemical problems is related to the possibility of studying the mechanisms of the elementary processes corresponding to the lower branches of the diagram in Fig. 1. The unique achievements of the method are that the results obtained on the one hand stimulate the theoretical solution of the problem of the elementary act in a chemical transformation and on the other create the necessary basis for solution of the statistical problem of determining the perturbations of the equilibrium distribution function resulting from the chemical process. The particular solution of the statistical problem for the non-equilibrium situation is associated with the names of Chapman and Enskog, who examined the phenomenon of molecular transport in gases.

There is a very close analogy between the description of the rate of a chemical reaction in a gas and the description of transport phenomena (i.e. viscosity, thermal conductivity, diffusion, etc.)[7]. Before the publication of the well-known studies by Chapman and Enskog[8], the study of transport phenomena was of a particularly phenomenological character, whose defects have become especially clear in recent years. Within the framework of this approach it was almost impossible to predict the behaviour of a substance under conditions differing from those under which the experiment was carried out. The requirements of the technique, which penetrated into a range of temperatures which could not be reproduced in laboratory equipment, emphasised still further the limited nature of this approach (the situation was aggravated by the possibility of dissociation of the gas at high temperatures).

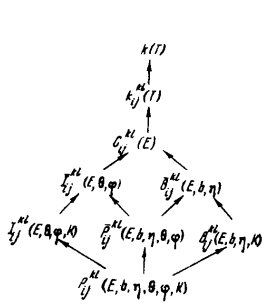

Fig. 1. Diagram illustrating the relationship between the microscopic and the macroscopic characteristics of a chemical transformation.

Chapman and Enskog reduced the description of transport phenomena in monatomic gases to a single basis — the intermolecular forces — and, for a known law of variation in these forces with distance, the determination of the kinetic coefficients became a comparatively simple computational problem. In this way the emphasis in the study of the kinetic properties of gases is being transferred to the problem of determining intermolecular forces[9]. It is extremely tempting to arrive at a similar situation in chemical problems; the immense number of possible collision partners and the limited range of attainable temperatures in this case also lead quite naturally to the necessity for finding a single basis for the description of the phenomena of chemical interaction. In this sense the transition-state theory plays a part which is in some ways analogous to the microscopic approach to the description of transport phenomena. Within the range of applicability of the corresponding approximations, the kinetics of a chemical reaction to a considerable extent reduces to a simple (from the physical viewpoint) basis — the intermolecular forces between the approaching particles. Although in the case of chemical kinetics it cannot yet be said that the main emphasis of research should be transferred entirely to the study of intermolecular forces, there is no doubt that, for reactions with a high energy threshold, studies at this level will be fruitful. Until recently, the only and insufficiently reliable source of information on intermolecular forces for chemically interacting partners was the so-called semi-empirical method of Eyring. The use of the molecular beam method combined with fast computers is opening up another source of such information. This possibility is of great promise and is discussed in Section III.

II. TECHNICAL REALISATION AND INTERPRETATION OF EXPERIMENTS WITH MOLECULAR BEAMS

Since a recent paper[3] described in detail the present state of the experimental technique of the molecular beam method, we shall restrict ourselves to an examination of certain fundamental elements of the technique of working with intersecting beams and the most recent achievements in this field.

As noted above, the chief advantage of the molecular beam method is that it permits control of the energies of the interacting molecules. The only method for isolating particles with a fixed velocity from the beam is by using mechanical selectors[3]. When both beams consist of particles with a fixed velocity, however, there is a sharp decrease in the intensity of the recording signal of the reaction products, and the situation is aggravated by the need to synchronise the arrival of the particles in the region where the beams intersect. At present, therefore, the use of selectors is restricted to one of the beams[10], and quantitative allowance can be made for the scatter thus preserved in the relative collision energies, by analysing the velocities of the products by means of a second velocity

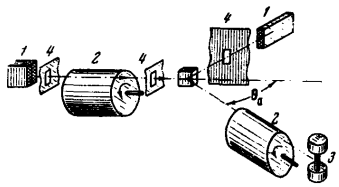

Fig. 2. Diagram of a typical experimental assembly for studying chemical reactions in intersecting beams with thermal velocities:
1) beam sources; 2) mechanical selectors for isolating particles with a given velocity; 3) movable receiver for recording both elastically scattered molecules and reaction products; 4) collimating slits.

selector. This modification must at present be regarded as representing the best arrangement for an experiment with intersecting beams (Fig. 2).

A simple method for ensuring that the collisions being studied involve beams of particles with fixed velocities is to use beams of relatively high energy (10–1000 eV), passing through a gas target, whose molecules can be regarded as virtually stationary. High-energy beams are usually produced[3] by neutralising ion beams which have been brought to fixed velocities electrostatically. An assembly has been described[11] for obtaining fast beams of almost any active atoms, radicals, or molecules in the energy range 600–4000 eV. A typical example of the use of high-energy ion beams can be found in a study[12] of the reaction $N_2^+ + D_2 \rightarrow N_2D^+ + D$.

The number of reactions which can be studied at present is limited by the necessity of ensuring that the particles of the intersecting beams have a relative collision energy greater than the energy thresholds of the reaction. Another restriction is imposed by the method of recording. The most widely used product detector is the differential surface-ionisation detector[1]. The use of this phenomenon for recording obviously limits the possible reaction products to compounds containing alkali-metal atoms. Thus the reactions which have been most extensively studied are those in which one of the partners is potassium, caesium, or rubidium (or, less satisfactorily, lithium or sodium).

This restriction can be overcome by using universal ionisation detectors[3], in which the molecules being studied are ionised by electron impact. Positive ions can be collected by a collector and measured by standard methods. A recently proposed modification[13] uses neutralisation of the space charge in a diode by the positive ions. When ionisation by electron impact is used, the possibility of dissociation must be borne in mind. Partial allowance for this effect can be made by mass-spectrometric observation of the products.

The universality of ionisation detectors is also a weakness, since the total recording signal is influenced not only by the reaction products but also by the residual gases and particles which have undergone elastic scattering. The influence of the residual-gas background in a laboratory apparatus cannot always be eliminated by improving the vacuum conditions; an effective method of reducing this effect is to modulate the beam and record only the modulated component of the detector current[3]. There still remains, however, the difficulty of recording the products in the region of the "shadow" of the original beam, since it is impossible to separate the currents from the elastically scattered molecules and possible reaction products. This difficulty can be overcome by fitting the receiver with an additional mass filter. A device for selecting ions according to mass can be constructed using either a static magnetic field[14] or the high-frequency electrostatic field of a quadrupole lens[15]. Analysers of the time-of-flight and radio-frequency types also have certain advantages, but when these are used it is more difficult to eliminate the influence of the residual-gas background. The most convenient for these purposes are analysers of the quadrupole type[15,16], which have a high transparency (low ion loss), effective resolution over a wide range of mass numbers and small size. Thus an instrument has been described[16] which makes it possible to record simultaneously ion currents differing by 8 orders of magnitude. These possibilities are of particular interest in connection with the prospects provided by the use of so-called gas-dynamic sources of molecular beams[3], with which beams of heavy molecules having high velocities can be obtained; these, however, contain a certain quantity of light "runaway" gas (H_2).

Interesting possibilities related to the problems examined here are provided by making use of the action of electric and magnetic fields on the beams. The simplest involves the use of an inhomogeneous magnetic field to separate a mixed beam of original atoms and product molecules in the region of the "shadow". The original beam usually comprises paramagnetic alkali-metal atoms; the product molecules are generally diamagnetic, so that, when the mixed beam is passed through an inhomogeneous field, the deflection of the atoms makes it possible to achieve spatial separation of these components. As a result, the receiver is able to record them separately. This method has been used by Herm et al.[17]; in some cases analogous results can be obtained by velocity analysis of the mixed beam using a mechanical selector.

It is more tempting[18,19] to use an inhomogeneous electric field to analyse the rotational states of the reaction products. For a substitution reaction with a marked change in the reduced mass, the initial orbital angular momentum will be converted into the internal angular momentum of the product molecule. As a result of the law of conservation of angular momentum, the rotation is polarised, since the internal momentum vector of the product molecules will coincide with the vector of the initial orbital momentum, perpendicular to the vector of the initial relative velocity. The polarisation will have a marked influence on the deflection of the molecules in an inhomogeneous electric field. Thus analysis of the rotational state of the products makes it possible to establish the influence of the initial orbital momentum on the probability of reaction on collision, i.e. to determine which orbital momenta (impact parameters) make the main contribution to the reaction cross-section. This analysis may allow[19] separation of the vibrational and rotational components of the internal energy of the products.

Let us now examine qualitatively the methods for treating the information obtained in experiments with molecular beams. The primary information obtained in an experiment is the angular distribution of the reaction products, the dependence of the yield of products (total or differential) on the relative collision energy of the particles in the beam, and finally the velocity spectrum of the products moving in a given direction. This primary information must be

interpreted on the basis of various models. In addition to direct recording of the reaction products, study of the elastic scattering of the particles of intersecting beams is also of considerable interest for obtaining the characteristics of a chemical reaction. Thus is due to the fact that the "entry" sections of the potential-energy surface of the reaction for elastic and "inelastic" scattering are the same with adiabatic reactions. Qualitative examination of the characteristic features of elastic scattering is necessary for an understanding of the material which will be presented subsequently.

The dependence on distance of the potential energy of the interaction between two spherically symmetrical particles is often described by a potential of the form

$$V(r) = \frac{\epsilon}{1-6/\alpha}\left\{\frac{6}{\alpha}\exp\left[\alpha\left(1-\frac{r}{r_m}\right)\right]-\left(\frac{r_m}{r}\right)^6\right\}, \qquad (5)$$

where α is a parameter which makes it possible to vary the steepness of the repulsive part of the potential curve, and the significance of ϵ and r_m is clear from Fig. 3. The curve in Fig. 3 is in some cases conveniently divided into two sections — a monotonic section which can be approximated by a function of the form $V(r) = K/r^n$, and corresponds to repulsion (it defines the interaction of particles with kinetic energy $E \gg \epsilon$), and a non-monotonic section — the latter being the region of the minimum on the curve (significant for energies $E \simeq \epsilon$).

From the elementary theory of scattering[20] it is known that for particles of fixed energy the scattering angle χ depends on the impact parameter b (the smallest distance between the centres of the moving particles in the absence of interaction) and the interaction energy for distances close to that of nearest approach of the interacting particles r_0. In contrast to the case of monotonic potentials, the dependence of the angle of deflection χ on the impact parameter for non-monotonic potentials (with a minimum, see Fig. 3) is ambiguous: equal angles χ may correspond to different values of b. A typical dependence in this case is represented by the curve in Fig. 4*a* (this gives the dependence of χ on b^2, which is proportional to the cross-section of scattering at angles greater than χ). The qualitative characteristics of the experimentally observed angular distribution of the scattered particles can be obtained[21] from the curve in Fig. 4*a* by assuming that the number of particles scattered at a given angle is proportional to the quantity $db^2/d\chi = 2\sigma_T \sin\chi$. From the χ–b^2 relationship we can by differentiation readily obtain the dependence of $db^2/d\psi$ on χ (Fig. 4*b*). Although $db^2/d\chi$ and χ in Fig. 4*b* have different signs, the sense of $db^2/d\chi$ is positive, and under the actual

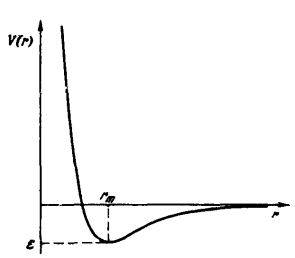

Fig. 3. Typical potential curve for the intermolecular interaction of spherically symmetrical particles.

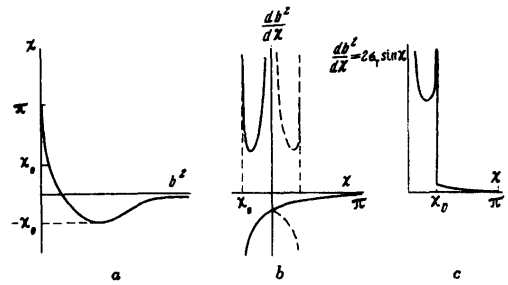

Fig. 4. Construction of the picture of elastic scattering for the interaction described by the potential shown in Fig. 3.

conditions of an experiment it is impossible to distinguish deflections to the right and to the left. Thus the observed scattering picture will correspond to Fig. 4*c*, obtained by transferring the curves (Fig. 4*b*) into the first quadrant, changing the sign, and combining the absolute values of the ordinates of the curves. The right-hand monotonic portion (Fig. 4*c*) corresponds to scattering by the repulsive forces. To study these forces it is most convenient to use the elastic scattering of fast beams of atoms and molecules[22]. Information on these forces is of interest, for example, in connection with the problem of the retardation of fast particles and their transformation into hot atoms.

An extremely useful characteristic of the scattering curve is the emission close to the angle χ_0 (it can be seen from Fig. 4*a* to be linked with the presence of the minimum on the potential curve), which is called the rainbow effect, the angle χ_0 being termed the rainbow angle. The magnitude of this angle, determined by experiment, makes it possible to find unambiguously the depth ϵ of the potential curve (Fig. 3). For non-spherical systems the position of χ_0 depends on the mutual orientation of the molecules. Firsov's discussion[21] was purely classical; quantum-mechanical treatment of this problem[23], without altering the qualitative form of the scattering curve, shifts the position of the rainbow angle slightly to the left of that shown in Fig. 4*c* and smooths out the breaks on the scattering curve. On the basis of the quantitative theory[23] it is now possible to determine from the experimental scattering curves the parameters of the potential curve for the interaction, given in a particular analytical form.

For chemical interaction, analysis of the elastic-scattering picture makes it possible to fix the distortions of the scattering curve produced by chemical effects. The magnitude of this distortion can be used[10] to find the probability of the reaction, defined by the relationship

$$P(\chi, E) = \frac{\sigma_{th}(\chi, E) - \sigma_{exp}(\chi, E)}{\sigma_{th}(\chi, E)},$$

where E and χ are the energy and angle of deflection in the [coordinate] system of the centre of mass, and σ_{th} and σ_{exp} the theoretical and experimental values of the differential cross-section of scattering of molecules with energy E at an angle χ. The value of σ_{th} can be calculated from the known potential or by using the parameters of the interaction potential, found from the initial part of the scattering curve, unperturbed by chemical reaction (Fig. 4*c*), on the assumption that this potential is also applicable to those distances of approach at which chemical reaction is possible. It is thus possible to determine the approach distances corresponding to a probability $P(\chi, E)$ different from zero,

i.e. corresponding to the development of chemical reaction, and also the dependence of P on E. It should, however, be noted that the total reaction cross-sections found from $P(\chi, E)$ are greater by a factor of 5–50 than those calculated from the total product flux. An attempt has been made[24] to analyse the possible reasons for this discrepancy, and it has been shown that the rapid descent observed on the experimental scattering curve in the range of large angles can be explained on the basis of an interaction potential in the form of a curve with two minima (the ordinary van der Waals minimum and a "chemical" minimum).

The elastic-scattering curve observed when two beams intersect can be predicted for a known potential for the intermolecular forces. In the absence of a solution to the corresponding dynamic problem, a picture of the angular scattering of the reaction products cannot be constructed in such simple fashion. Nevertheless, in some cases the laws of the conservation of energy and momentum can be used to predict the form of the distribution. Let us examine qualitatively the scheme for this calculation[25], noting that by varying its parameters (for example the dependence of the reaction cross-section on the energy) until the theoretical and experimental curves coincide, it is possible to determine the values of these parameters. Let us assume first for simplicity that the transformation taking place on collision corresponds to a hypothetical addition reaction A + B → AB, whose probability for one collision is unity (we shall not deal here with the reality of these transformations). In this case it is clear that, as a result of the law of conservation of momentum, after the "adhesion" of the particles, the complex AB in a laboratory system of coordinates will move along the vector of the velocity of the mass centre. Thus the form of the observed angular distribution of the complexes would correspond to the law governing the distribution of the vectors of the rate of movement of the mass centres of the colliding particles, and the magnitude of the beam currents would be determined by the cross-section of collision. The direction of the vector is determined by the rule for combining the particle velocity vectors $\mathbf{v}_A$ and $\mathbf{v}_B$ (Fig. 5*a*), so that the distribution of the velocity vectors of the centres of mass will depend exclusively on the distribution of the magnitudes and directions of the initial velocities of the particles in the intersecting beams. For two collimated beams with uniform velocities, the resulting distribution of the products would be needle-shaped. For collimated beams intersecting at right angles, with Maxwell velocity distribution, the distribution will be bell-shaped (Fig. 5*b*) and related unambiguously (within the limits of the assumptions made) to the bell-shaped form of the Maxwell distribution.

If the beams are poorly collimated, the form of the angular distribution will also be influenced by the scatter of the initial directions of the velocities. Anticipating a little, we may note that the indefinite nature of the interpretation, associated with poor collimation of the beam, reduces slightly the value of the information contained in the angular distribution of the products. In recent work, therefore, considerable attention is paid to the analysis of the perturbations of the elastic-scattering curve resulting from chemical interaction. If reaction does not take place at every collision (for example if the cross-section of the reaction depends on the energy), it is clear that the above bell-shaped distribution of the products will be slightly deformed by this relationship.

For the more real process A + B → C + D the distribution of the products will also depend on the masses of the products and the energy liberated in the reaction. Let us examine the simplest features of the decomposition — the formation of two product particles — in more detail[20], since a quantitative analysis of the internal energy of the products can often be carried out on the basis of only one form of angular distribution of the products.

In the system of the centre of mass, the total momentum of the system A–B is zero, and the scattering in this system will take place in such a way that the total momentum remains unchanged. In the diagram in Fig. 6, the elastic scattering corresponds to rotation of a vector of constant magnitude $\mathbf{v}'_A - \mathbf{v}'_B$, and the ends of the velocity vectors of the scattered particles for different angles of scattering lie on circles A and B with radii $\mathbf{v}'_A$ and $\mathbf{v}'_B$. With inelastic scattering the speeds of the particles of the complex AB, which decomposes in the reaction, depend on the initial kinetic energy and the energy liberated in the reaction, and also on the masses of the products C and D. If all directions of scattering of the reaction products are equally probable (this is characteristic of long-lived complexes), the ends of the velocity vectors of the products will lie on circles C and D (the C-circle is not shown) of the velocity diagram in Fig. 6, with radii $\mathbf{v}'_C$ and $\mathbf{v}'_D$ (in the three-dimensional case these circles will be represented by spheres). The directions of motion of the scattered particles in an l-system (laboratory system of coordinates) are determined by the vectors $C + \mathbf{v}'_C$ and $C + \mathbf{v}'_D$, so that products of type D will be observed within a cone whose generating lines are tangents to the D-circle of the diagram in Fig. 6. From Fig. 6 it can be seen (neglecting possible anisotropy of scattering) that the condition for the creation of a preferential direction in the recording of the products is a low rate of recoil $\mathbf{v}'_D$ compared with the speed of the mass centre of C; otherwise, the distribution will be spread out widely in space. The isotropic nature of the scattering of the products in the c-system (the system

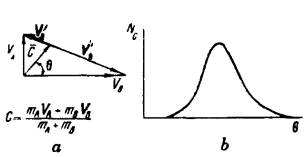

Fig. 5. *a*) Kinematic diagram giving the relationship between velocities in the laboratory coordinate system and the system of the centre of mass; *b*) form of angular distribution of the products.

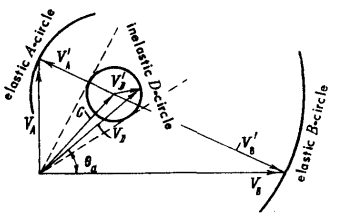

Fig. 6. Kinematic diagram describing qualitatively the main features of the emission of products in the decomposition of the quasi-molecular complex.

of the centre of mass) will be influenced to a marked extent by the lifetime of the complex AB; for schemes with a single simple scattering there should obviously be a preferential direction of scattering for the products.

Returning to Fig. 6, we can see that for isotropic scattering of the products, the compensation of the addition and subtraction of the velocities of recoil from the velocity of the mass centre causes the mean or most probable velocity measured in the l-system to coincide with the latter. For anisotropic decomposition with recoil backwards (relative to $\mathbf{v}'_B$) the velocities in the l-system will be lower than the velocity of the centre of mass, and for recoil forwards they will be higher. Thus by measuring directly the velocities of the product molecules, it is possible to solve the problem of the isotropy of scattering, i.e. the type of reaction mechanism, and also to determine the heat of the reaction $Q = E_1 - E$.

The heat of reaction Q, which is taken to equal the change in the relative kinetic energy, can be expressed

$$Q = \Delta D + \Delta E_{\text{int}},$$

where ΔD is the difference in the energies of bond rupture between reactants and product, and ΔE_{int} the difference in the internal energies of the particles in the initial and the final states. If E is the initial relative energy, the rate of recoil v'_D can be written, from the condition of conservation of energy, in the form

$$v'_D = \left[\frac{2(E+Q)}{M_D(1+M_D/M_C)}\right]^{1/2}.$$

For large positive values of Q, the speed v'_D is high, and the width of the recorded angular distribution of the products will increase considerably; on the other hand, if for a large value of ΔD the experiment reveals a narrow peak in the distribution of the products, this may provide a direct indication of a marked change in the internal energy state of the products ($\Delta D \simeq |\Delta E_{\text{int}}|$).

The value of Q can be effectively decreased only by transfer of part or all of the energy ΔD to internal degrees of freedom of the products. The nature of the angular distribution of the products is more readily used, for quantitative estimation of the fraction of ΔD transferred to internal degrees of freedom, under definite kinematic conditions, in particular for small changes in the reduced mass of the products $\mu_1 = M_C M_D/(M_C + M_D)$ relative to that of the reagents $\mu = M_A M_B/(M_A + M_B)$. In this sense, the reaction K + HBr → KBr + H, which has been studied in most detail, is inconvenient for energetic analysis, since the width of the angular distribution of the products will be strongly influenced not only by Q but also by non-uniformity of the initial velocities. On the other hand, in the reaction $K + CH_3I \rightarrow KI + CH_3$, for example, these two effects are separate because of the displacement of the maximum in the product distribution from the direction of the vector of the most probable velocity of the mass centre and because of the anisotropy of the decomposition itself. The method of kinematic estimation[26] described below in Section III, while clear and effective, was used because of the imperfect nature of the experimental technique employed; it should be noted that machine calculation[27] has revealed considerable ambiguity in these estimations. Direct determination of the velocities of the products using a selector makes it possible to solve the same problem more accurately for any kinematic conditions.

In addition to the above mechanism of adhesion with subsequent isotropic decomposition of the quasi-molecule AB, use is also made of the concepts of ricochet and stripping mechanisms of interaction on collision, taken from the theory of nuclear reactions. In the first case an atom colliding with a molecule as it were ricochets, carrying away an atom from the latter. The characteristic feature of the stripping mechanism is that the colliding atom and the atom removed by it from the molecule move in a direction which coincides with the initial direction of the colliding atom. An important aspect in stripping is that the interaction of the colliding atom with the target atom takes place as though the other atoms in the molecule were not present.

These two mechanisms, unlike the first, are characterised by the existence of a correlation between the directions of the initial and final relative velocities; the products as it were "remember" the initial state. Stripping chemical reactions take place at large impact parameters, so that they have extremely large cross-sections. On the other hand, ricochet collision is possible only when the particles approach close to one another, so that the cross-sections are much smaller than those for stripping.

In this examination no allowance has been made for the angular momentum of the interacting particles. The total angular momentum (orbital plus internal) of the system should be conserved, and this will influence both the angular distribution of the products and the nature of the redistribution of the internal energies, and also the actual probability of the reaction. For reactions in which the orbital momenta of the products and reactants are much greater than the internal momenta, the direction of the relative velocity will be preserved in determining the form of the distribution curve. For a significant change in the reduced mass of the products relative to the original (e.g. a decrease, as in the case of K–HBr), because the total angular momentum is conserved, the initial energy of orbital motion will be converted chiefly into energy of rotational excitation of the products. With increase in the rate of relative motion and hence in the orbital momentum, increase in the rotational excitation of the products may lead for this system to a decrease in the probability of reaction[10]. A complete analysis of the experimental data should therefore include allowance for the influence of angular momentum.

The experimental data obtained correspond to the laboratory system of coordinates, whereas it is more natural to carry out the theoretical analysis in the centre-of-mass system. Interpretation of the data obtained is thus possible if they are converted to the latter system. This problem usually consists of two parts — conversion from the angles giving the position of the detector in the l-system to the angles in the c-system, and conversion of the beam currents measured in the given detector positions into the differential cross-sections. These procedures have been examined in detail elsewhere[28,29].

III. MAIN RESULTS OF THE STUDY OF CHEMICAL REACTIONS IN INTERSECTING BEAMS

To provide a general picture of the results of the study of chemical reactions using intersecting beams, the Table summarises information on studies of this type, with an indication of the extent to which specific reactions have been studied. It can be seen from the Table that most attention has been paid to the study of substitution in HBr, HCl, CH_3I, and HI molecules, and exchange reactions of the type $H_2 + D \rightarrow HD + H$. For a considerable proportion of the reactions given in the Table, the data are scanty, and these reactions will be specially studied in the future.

TABLE.

Reagents	Observed product	Chief results	Remarks	Ref.
K–HBr	KBr	the total reaction cross-section, its dependence on the collision energy, and the threshold energy of the reaction were measured, and the energy state of the reaction products was analysed. The vibrational and rotational energies of the products were determined	the Cs, Rb–HBr systems have been studied	1, 10, 19, 32, 33, 42, 46
K–HCl K–HI	KCl KI	the total cross-section and its dependence on the collision energy were measured, as also the threshold energy of the reaction	data for the K–HCl system were obtained from observations of the elastic scattering	31
K–$C_nH_{2n+1}I$	KI	the total reaction cross-section was estimated (n = 1, 2). Kinematic analysis established that the greater part of the energy of reaction appears as excitation of internal degrees of freedom of the products. Anisotropy in the emission of the products was established. A numerical analysis was made of the dynamics of collision (n = 1, 2)	analogous studies were made with isopropyl, n-propyl, and n-butyl alcohols as reactants	26, 34, 41, 47, 48
K–CH_3Br	KBr	the total cross-section and the threshold of the reaction were determined	data were obtained from observations of elastic scattering	30
K–Br_2 K–I_2 K–ICl K–IBr	KBr KI KCl KBr	the total cross-sections were estimated. It was concluded that the reaction takes place by a stripping mechanism. A kinematic analysis was made of the energy state of the products. The internal energy of the products was measured directly for the K–Br_2 system	analogous results were obtained when K was replaced by Rb or Cs	17, 33, 35, 37, 43, 46, 49, 50
K–CCl_4 K–CH_2I_2	KCl KI	preliminary study indicates the possibility of a stripping mechanism	analogous results were obtained when K was replaced by Cs	17, 43
Rb–SCl_2	RbCl	a stripping mechanism was established for the reaction. Kinematic analysis indicates marked excitation of the reaction products		43
K–$SnCl_4$ K–PBr_3	KCl KBr	preliminary analysis indicates a reaction mechanism intermediate between stripping and complex formation		
H–D_2 D–H_2	HD	the differential reaction cross-sections were estimated. Suggestions were made regarding the mechanism. Numerical calculations of the dynamics of collision were carried out		38–40, 45
N_2^+–D_2	N_2D^+	the total reaction cross-sections were found over a wide range of energies		12
K–SnI_4			distortion of the elastic-scattering curve was noted for the K–SnI_4, $HgBr_2$, HgI_2, and $HgCl_2$ systems. Suggestions were made regarding the possible influence of chemical reactions	44, 51

1. Reactions of the Type K + HX → KX + H

Substitution has been studied in most detail for X = Br; study of this reaction by the molecular beam method was begun as early as 1955.[1] The first results [1] were later refined[10,31], and we shall restrict ourselves to an examination of the later data. Beck et al.[10] studied the chemical interaction accompanying the intersection of a beam of atoms (K) with fixed velocities and a beam of molecules (HBr) with a Maxwell distribution of velocities. The experimental arrangement was similar to that shown in Fig. 2 and the chief results were as follows. (i) The magnitude and nature of the dependence of the total reaction cross-section on the collision energy E were found, and the energy threshold of the reaction was determined. (ii) The data obtained in the study of the elastic scattering were used to determine the dependence of the probability of the reaction on the impact parameter b or the energy of interaction at the distance of closest approach r_0, this energy being related unambiguously to the impact parameter. (iii) A qualitative explanation was obtained for the experimentally observed dependence of the probability of the reaction on the initial collision energy for a fixed value of r_0.

In the discussion of the method used in the theoretical calculation of the angular distribution of the products it was pointed out that this distribution is determined by that of the initial velocity vectors and by the dependence of the reaction cross-section on the relative collision energy.

It might seem that in this experiment, in which the law governing the distribution of velocities in the beams is known, it should be possible, by comparing the theoretical and experimental distribution curves for the products, to determine the unknown energy dependence of the reaction cross-section. It is found in practice, however, that the distribution of the magnitudes and directions of the relative velocities depends not only on temperature but also on the divergence of the HBr beam. The energy dependence of the cross-section is therefore different for different initial assumptions regarding the divergence of the beam. This ambiguity reduces slightly the value of the information associated with the form of the angular distribution; moreover, it provides another illustration of the limitations of methods using a broad spectrum of initial states (in this case relative energies) of the interacting particles. In the work cited[10,31], a different method was selected for determining the required dependence. For different velocities of the beam of K atoms, the measured product current at the maximum was equated to the maximum on the theoretical curve calculated for the divergence which gave the best agreement between experimental and calculated distribution curves. An energy of 2 kcal $mole^{-1}$ was chosen for the normalisation of the calculated and experimental values of the product current.

The final results of the use of this procedure are shown in Fig. 7; here curves A and C correspond to different assumptions regarding the divergency of the beam of HBr

molecules. The experimental points correspond to different measurements and to selection of the most accurate assumption regarding the divergence of the HBr beam. Although the errors in the determination of the energy corresponding to a given value of the cross-section are fairly large, the shape of the curve, even close to the threshold, can be taken as close to curve D (Fig. 7) calculated for the usual solid-sphere model with a threshold energy $E^* = 0.15$ kcal × × mole^{-1}. The exact value of the threshold energy cannot be determined from these data, but it can hardly be greater than 0.4 kcal mole^{-1}. The slightly indefinite nature of the values obtained in this way can be reduced if we utilise for the analysis the results of a study of the elastic scattering of the same partners. The chief features of elastic scattering have been discussed above (Fig. 4), and for complex molecules this discussion is applicable in the approximation corresponding to spherically symmetrical pair interaction.

In the examination of the elastic scattering of reactive particles having a reaction threshold energy E^*, it is possible in principle to compare a certain limiting scattering angle: for large angles of deflection the elastic-scattering curve is distorted as a result of the partial disappearance of HBr molecules by chemical reaction. The experimental scattering curve in the range of angles smaller than the limiting angle can be used to determine the parameters of the interaction potential; from the latter we can then calculate the curve for purely elastic scattering in the range of angles greater than the limiting angle. Theoretical determination of the limiting angle is difficult, and in the work cited[10] it was determined by the *a priori* condition that the probability $P(\chi, E)$ differed from zero; this rather arbitrary choice was justified by the fact that the results obtained showed little dependence on the magnitude of this angle.

From the definition of probability introduced above, the experimental and theoretical scattering curves can be used to find the dependence of $P(\chi, E)$ on the impact parameter or the related energy of interaction for the distance of closest approach $V(r_0)$. Fig. 8 shows the dependence of the probability $P(\chi, E)$ on the energy $V(r_0)$ for five values of the initial energy of the beam of K atoms. In the energy range $0.2 < V(r_0) < 1.2$ kcal mole^{-1}, the probability curves are clearly separated; at higher values of $V(r_0)$ the experimental errors blur this relationship. The asymptotic values of the probability remain less than unity, and this can be taken as an indication that the steric factor is not equal to unity. For the reaction considered, however, it

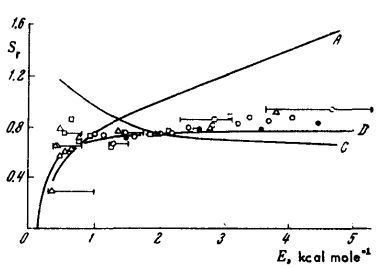

Fig. 7. Experimental dependence of the total cross-section S_r of the reaction K + HBr → KBr + H on the collision energy, and the theoretical curves calculated for various conditions (see text).

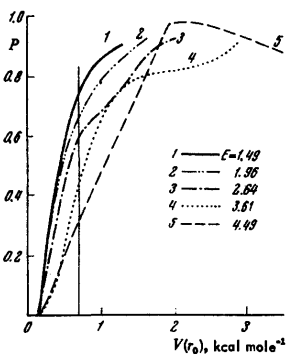

Fig. 8. Experimental dependence of the probability of the reaction K + HBr → KBr + H on the energy of interaction at the point of closest approach for various initial collision energies E.

may be stated that at $b < 2.7$ Å (or for values of $V(r_0) > > 1.2$ kcal mole^{-1}), almost all collisions lead to reaction.

By making use of the expression

$$S_p = 2\pi \int_0^\infty P(\chi, E)\, b\, db = 2\pi \int_0^\pi (\sigma_r - \sigma_s) \sin\chi\, d\chi,$$

we can find the total cross-section of the reaction S_r for a given relative energy E. Comparison of the S_r–E relationship (the solid circles in Fig. 7) with that obtained on the basis of the procedure described above shows good agreement. The absolute values of the cross-sections show less satisfactory agreement, but this can be attributed to the divergence of the beam of HBr molecules. In this way an absolute value of 34 Å^2 is found for the total cross-section of the reaction with an energy of $E = 2.6$ kcal mole^{-1}.

From the results in Fig. 8 it follows that the reaction probability, whose values correspond to the points of intersection of the curves with the normal to the abscissa, decreases with increase in the relative energy for a fixed distance of closest approach r_0. This effect has been interpreted[10] on the basis of the law of conservation of angular momentum. As a result of the marked change in reduced mass ($\mu_1 \ll \mu$), the final orbital momentum is small, and the condition of conservation of total momentum requires a considerable increase in the internal momentum of the KBr molecule. Thus with increase in the initial rate (or relative energy) there is an increase in the internal momentum (and rotational energy) of the KBr molecule, whereas the proportion of the energy corresponding to translational and vibrational degrees of freedom will decrease. It is known from statistical theory that decrease in the phase volume corresponding to these degrees of freedom should lead to a decrease in the probability of reaction. This probability is evidently zero for those initial energies and the orbital momentum for which, as a result of the conservation conditions, the whole of the final energy is equal to the rotational energy. This condition makes it possible, by extrapolation of the data in Fig. 8, to find independently an extremely important parameter (r_m) of the intermolecular interaction potential.

The conservation laws do not permit definite conclusions to be reached regarding the redistribution of the initial kinetic energy and the energy of reaction ΔD. However, direct measurement of the most probable velocities of the

KBr molecules, by means of a velocity selector [32], made it possible to establish fairly precisely how the energy is distributed between the translational and the internal degrees of freedom of the products. This most probable velocity was found, over a wide range of angles of observation, to be slightly greater than the most probable value of C. On the basis of the arguments examined above, this indicates unambiguously that the KBr is emitted predominantly forwards in the c-system (i.e. in the direction of the vector $\mathbf{v}'_K$).

Since the beam of K atoms has a fixed velocity (the beam of HBr molecules has a velocity distribution close to the Maxwell distribution), the geometric locus of the ends of possible velocity vectors of the mass centre will be the normal to the v_K axis at the point $v = m_K V_K/(m_K + m_{HBr})$ (see Fig. 9). When points on this straight line are used to construct circles with radii corresponding to different values of the heat of reaction Q (≥ 0.1 kcal mole^{-1}), the points of intersection of the possible velocity vectors $\mathbf{v}'_{KBr}$ with these circles, for decompositions involving forward emission of the KBr molecules (at an angle of 0° in the c-system), are found to lie on the almost straight vertical lines, corresponding to different values of Q, shown in Fig. 9*b*. The range of possible values of Q is not too great, from -1.85 kcal mole^{-1} for an endothermic reaction with total transfer of the energy to internal degrees of freedom (zero recoil velocity) up to 5 kcal mole^{-1} for the total transfer of the energy of reaction ΔD to the translational energy of the products. We can therefore restrict ourselves to a small number of vertical straight lines (Fig. 9*b* shows only the straight lines for $Q \geq 0$). We can plot on this diagram the measured most probable velocities of the KBr molecules for different angles of observation θ_a, and draw a smooth curve through these points (the values of the probable velocities given earlier [32] have since been slightly corrected [33]). It can then be seen from Fig. 9*b* that this curve intersects the vector of the most probable relative velocity at a point through which the line for $Q = 0.5$ kcal mole^{-1} also passes; hence the most probable exothermic heat of reaction is ~ 0.5 kcal mole^{-1}, and almost all the energy of reaction is used up in internal excitation of the products (the reaction can be regarded as thermoneutral). It has thus been possible to confirm by direct experiment the long-discussed assumption that reactions involving alkali-metal atoms and halogens lead to transfer of the greater part of the energy of reaction into internal degrees of freedom.

The reactions for substituents X = Cl (slightly endothermic reaction) or I were studied by Ackerman et al. [31] on the assembly described by Beck et al. [10] The total cross-sections of the reactions for $E = 2$ kcal mole^{-1} were found to be 28 Å^2 for K–HI and 3.9 Å^2 for K–HCl.

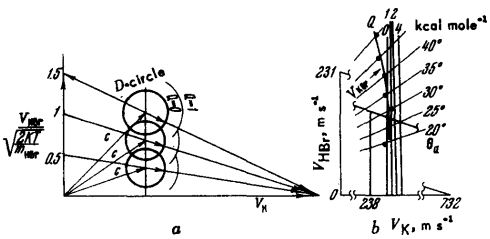

Fig. 9. Kinematic scale diagram for determining the internal energy of the products of the reaction K + HBr → KBr + H.

A method analogous to that described above was used to find the dependence of the probability of reaction on $V(r_0)$, the interaction energy at the point of closest approach. For the K–HCl system the threshold value $V_n(r_0) = 0.55 \pm \pm 0.1$ kcal mole^{-1} was clearly fixed. The plot of this dependence shows two additional breaks. Since their positions are given by the expression $V_n(r_0) + v(\hbar\nu)$, they may be due to the formation of products in different vibrational states ($v = 1$ and 2). For the K–HI system the behaviour of the probability function is quite different: it shows a sharp ascent beginning from a threshold energy $V_n(r_0) = 0.2$ kcal × × mole^{-1}, after which there is no dependence on $V(r_0)$ and only a weak dependence on E. No significant energy dependence of the total reaction cross-section has been found for either system.

2. Reactions of the Type K + $C_nH_{2n+1}I$ → KI + C_nH_{2n+1}.

Reactions of this type, unlike those examined above, are characterised by a comparatively small change in the reduced mass. This feature makes it possible, even for two beams which do not have fixed velocities, to make a quantitative analysis of the energies of the products and to establish anisotropy in their emission. A typical picture of the angular distribution of the products for the K–CH_3I system is shown in Fig. 10 (the curves correspond to two different experiments and the broken line gives the calculated curve). A rough estimate of the total cross-section of reaction gives for the K–CH_3I system the value 35 Å^2. Variation of the source temperature for the beam of K atoms indicated [26] that the activation energy of this reaction is small and does not exceed 0.3 kcal mole^{-1}.

Detailed kinematic analysis of the K–CH_3I system [26] gives interesting results. For a molecule of the product KI, the recoil velocity in the c-system may have different directions and magnitudes determined by the relationship

$$v'_{KI} = \left[\frac{M_{CH_3}}{M_{KI}}\,\frac{2(E+Q)}{M_{KI}+M_{CH_3}}\right]^{1/2}.$$

The ends of the possible recoil velocity vectors in the planar case (Fig. 10) lie on circles with radius v'_{KI}. In the scale diagram in Fig. 10 these circles are shown for various values of Q up to 25 kcal mole^{-1} (the difference in the energies of rupture of the C–I and K–I bonds). It can be seen from Fig. 10 that large values of Q (>5) correspond to recoil velocities close to or greater than the velocity of the centre

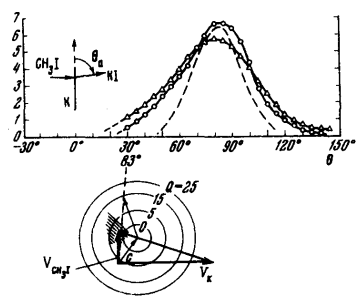

Fig. 10. Angular distribution of the products of the reaction K + CH_3I → KI + CH_3 and kinematic diagram explaining the marked internal excitation of the products.

of mass C. Thus, whereas for $Q = 0$ the range of possible appearance angles of KI lies between 40° and 70°, we find that for $Q = 6$ kcal mole^{-1} KI can be observed for any angle in the l-system. It can thus be seen from the diagram that the observed maximum in the product current for the angle $\theta_a = 83°$ in the l-system can be attributed only to the result of anisotropic emission with recoil of KI molecules backwards ("ricochet"), i.e. in the opposite direction to the velocity of the K atoms (in the c-system). When allowance is made for the cylindrical symmetry of the emission with respect to the relative velocity vector (Fig. 10), it is found that the observed current in the region of the maximum yield of products can be realised only for values of Q not exceeding 5 kcal mole^{-1}, so that ~ 80% of the energy of reaction is used up in excitation of the products.

A more accurate estimate is possible when a mechanical selector is used. Analogous results are also obtained when the number of carbon atoms $n = 2$, and also when K atoms are replaced by Cs or Rb.[26] For systems containing propyl or butyl groups it was found that the radical group has no steric influence (equal reaction cross-sections) and that the final kinetic energy of the products decreases with increase in the mass of the radical group.

For reactions involving alkyl halides, a comparison has recently been made of the calculated (by means of an electronic computer) and experimental angular distributions of the reaction products. Support has been obtained for the qualitative conclusions and quantitative estimations discussed above, but it follows from the calculations that the experimental data can be described satisfactorily with a slightly greater scatter in the values of Q and χ than appeared earlier. This ambiguity is associated with the absence of velocity selection[34].

Study of the K–CH_3Br system[30] using a beam of K atoms of fixed velocity shows that the dependence of P on E for a fixed value of r_0 is opposite to that observed for the K–HBr system (Fig. 9). The reaction probability P does not exceed 0.8, and increases sharply from 0 to this value at a threshold energy $V_n(r_0) = 0.25$ kcal mole^{-1}.

3. Reactions of the Type $X_2 + A \rightarrow XA + X$

The reactions of this type which have been studied, with X = halogen and A = alkali-metal atom are given in the Table. For the Cs–Br_2 system, the elastic-scattering curve does not show a rainbow peak, and the curve descends rapidly even in the range of relatively small angles; these distortions of the scattering curve clearly indicate a high value for the reaction cross-section[35]. In contrast to the systems examined earlier, comparison of the forms of the calculated and experimental curves for the angular distribution of the products shows considerable divergence: in particular, there is a marked difference in the positions of the maxima on these curves. This lack of agreement can be eliminated by making the theoretical calculation on the assumption that the Cs atom interacts only with one Br atom and that the bond between the atoms in the molecule can be neglected (impulse approximation). This impulse scheme corresponds to abandonment of the model which assumes the formation of a complex or composite molecule. As usual, the spectrum of possible recoil velocities of the products is determined by the heat of reaction and the initial energy E; estimates[35] show that, if the final kinetic energy is, for example, $2.2E$, the reaction products are "smeared" over a solid angle of 4π. Since the experiments revealed a narrow distribution peak at $\theta_a = 8$, it must be concluded that not more than 0.5–1 kcal mole^{-1} is transferred to the translational energy of the products and that all the remaining available energy (~ 99% of ΔD) is used up in internal excitation of the CsBr.

The agreement between the experimental curve and the results of the calculation according to the impulse mechanism also leads to the conclusion that this reaction corresponds to the class of reactions of the stripping type. Indications of this mechanism were obtained for analogous systems[36] using beams of K, Rb, and Cs and of Br_2, I_2, ICl, and IBr which did not have fixed velocities. Estimation of the total reaction cross-section for these systems leads to values of the order of 100 Å^2. For these systems the reactions are strongly exothermic (ΔD = 40–50 kcal × × mole^{-1}), but the final kinetic energy of the greater part of the products (in the region of the intensity peak), e.g. in reactions involving Br_2 and I_2 molecules, does not exceed ~ 1 kcal mole^{-1}. Thus the products have a high vibrational excitation (the rotational energy is restricted by the conservation of angular momentum). Direct measurements of the velocities of the products using a selector, carried out recently[33,37] for the K–Br_2 system, show that the spectrum of internal energies of the KBr molecules is extremely broad, extending from 4 to 17 kcal mole^{-1}. Moreover, it may be concluded from the experimental results that the angular distribution of the products in the c-system corresponds to their emission forwards within a cone having an angle of divergence of ~ 30°.

Marked internal excitation of the products takes place also with the Cs–ICl and Cs–IBr systems; here, in the estimation of the vibrational excitation, allowance must be made also for the possibility of reactions leading to products of the type CsI or CsCl (the detector will not distinguish, for example, CsI and CsBr molecules). The high reaction cross-sections and the predominant emission of the products forwards (in the direction of motion of the alkali-metal atom) in these systems again indicates that the reaction takes place by a stripping mechanism.

4. The Reactions $H_2 + D \rightarrow HD + H$ and $D_2 + H \rightarrow HD + D$

Even the first results of a study of these reactions are of considerable interest[38,39], in connection with the possibility of comparing the experimental data with theoretical analysis. The most detailed information was obtained by Datz and Taylor[38], who compared theoretical and experimental angular distribution curves for the products HD (Fig. 11). The section of the curve shown by the broken line in Fig. 11 corresponds to extrapolation of the experimental points into the range, inaccessible to measurement, of the "shadow" of the beam of D, containing a small but significant quantity of HD, The calculated angular distribution of the velocity vectors of the centres of mass is shown by the solid curve and the points correspond to different experiments.

The slight (10–15°) symmetrical broadening of the experimental curve in comparison with the theoretical curve (Fig. 11) can be explained in two ways. It may result either from formation of a short-lived linear complex or from strong excitation of the molecules of the products. A scheme of phase detection[38] makes it possible to estimate the times of flight or the velocities of the HD molecules; this estimate is incompatible with the second possibility, so that there is greater justification for the assumption that a short-lived

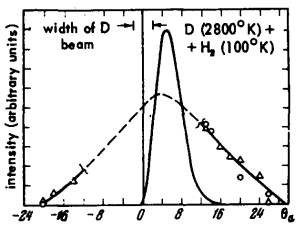

Fig. 11. Angular distribution of the products of the isotopic substitution $H_2 + D \rightarrow HD + H$ (the broken line gives the extrapolation of the experimental points and the solid curve gives the results of the theoretical calculation).

complex is formed, leading to the appearance of non-excited products. The experimental data for these reactions are as yet scanty and unreliable, but numerical analysis of the dynamics of the collisions of the D and H_2 molecules [40] also shows that for this system the direct-interaction scheme is preferable to the collision-complex model.

5. Numerical Methods

To conclude this review of experimental studies of chemical interaction in intersecting beams with thermal velocities, we must consider another extremely promising approach which makes use of fast computers for model calculations on elementary reactions. This approach is of interest in two respects: firstly, it reveals certain details of the mechanism of a chemical transformation inaccessible to present-day experimental technique and shows possible directions for subsequent experiments; and secondly, it will supplement the semi-empirical method for determining potential-energy surfaces.

Numerical methods have been used [40,41] to analyse the dynamics of collisions leading to the reactions $CH_3I + K \rightarrow$ $\rightarrow KI + CH_3$ and $H_2 + D \rightarrow HD + H$. The method involves essentially direct integration of the equations of motion for the approaching atoms and molecules, i.e. exact calculation of the classical trajectories of motion of three or more atoms. By tracing the trajectories of individual parties with time, it is possuble to pick out those which correspond to the appearance of a new combined state and hence determine the reaction cross-section. By varying the parameters of the calculation, we can find the most favourable conditions for the reaction. In the specific case of the $K-CH_3I$ system, the calculations are simplified by assuming that the methyl group behaves approximately as a separate structureless particle with the same mass, the potential of whose interaction with the I atom is the same as that for CH_3. The classical collision trajectories of these partners are computed for different initial conditions, and the familiar Monte Carlo method is used to obtain results averaged over the real distributions of the impact parameters, orientations, and vibration phases [45]. Experiments with intersecting beams permit direct comparison with the results of the calculations, and if correspondence is observed for some results, it maybe expected that other theoretical results, which cannot be directly compared with experimental data (because the latter are not available), are also applicable. On the other hand, by comparing the corresponding results of calculations and experiments and subsequently achieving better agreement, we can readily refine the form of the potential-energy surface.

One may ask to what extent we are justified in describing the motion of atoms in a chemical interaction by classical equations of motion. A number of factors indicate that this is possible — the large masses of the particles, the adiabatic nature of the chemical transformation, the many-quantum nature of the process of bond rupture in the original molecule and of bond formation in the product molecule, etc.

The quantum-mechanical treatment of elementary chemical processes is at present in its early stages. This, together with the considerable mathematical difficulties encountered in the quantum calculations, forces us to use a classical treatment in those cases where it is justified. In the final analysis, justification for the classical description must be provided by agreement between experimental data and calculations.

In particular, for the $K-CH_3I$ system [41], numerical calculation leads to agreement between the available data and makes it possible to find the lifetime of the complexes formed in a collision, their configuration, and a number of other relevant details. An interesting conclusion, following from the results of experiments and calculations on the dynamics of the collisions for the simplest reacting systems (e.g. $K-CH_3I$ and H_2-D), is that the reaction takes place in a short time interval, corresponding to the transit time in the interaction range. Numerical calculations have not as yet given any indication of the formation of the quasi-molecular complexes (albeit short-lived) used in the transition-state theory.

---o0o---

The above discussion leads to the following conclusions.

Use of the molecular beam method to study elementary chemical reactions (and also processes of energy exchange for internal degrees of freedom and interaction with a solid surface) gives valuable information on important details of reaction mechanisms.

The intensive development of experimental technique is leading to a continuous increase in the volume of information which can be obtained in experiments with molecular beams. We now have the real possibility of controlling not only the initial state of the reagents — the molecules of the intersecting beams — but also the final energy state of the reaction products. Further extension of these studies is possible by making use of the latest achievements in the production of intense beams with electron-volt energies and methods for their detection.

The possibility of using this method to study the internal energy state of reaction products is of intrinsic value in connection with the problem of stimulated radiation.

Comparison of experimental data with numerical calculations of the dynamics of collisions accompanied by chemical transformation may give information on the properties of potential-energy surfaces and supplement the semi-empirical method for their determination. The numerical method also makes it possible to reveal a number of details of the chemical interaction which cannot be determined experimentally (the lifetime of the complex, its configuration, etc.) and stimulates the organisation of new experiments to detect the effects predicted by the calculation.

The study of reactions accompanying the intersection of beams whose molecules have been excited beforehand is of considerable interest. These studies are most conveniently carried out by the molecular beam method.

The results obtained up to the present and the observed general trend towards an extension of these studies indicate the need for the rapid introduction and extensive utilisation of this method in the appropriate research organisations of the Soviet Union.

THE ELECTROCHEMICAL PROPERTIES OF MOLYBDENUM AND TUNGSTEN

E.F.Sperenskaya, V.E.Mertsalova, and I.I.Kulev

CONTENTS

1. Potentials of redox systems 892
2. Composition and spectrophotometry of complex compounds 894
3. Electrolysis of solutions 895
4. Reduction with metals and amalgams 897
5. Polarography 898

Molybdenum and tungsten find widespread application in the manufacture of high-grade steels, electrical engineering electroplating, and other fields. These metals play an important part in improving processes of chemical technology, where they are employed as catalysts. Their compounds will probably also find application in semiconductor technology. The preparation of the metals in an extremely pure state therefore acquires great significance. Electrochemical methods occupy a prominent place in solving this problem. At the same time, it becomes necessary to determine traces of molybdenum and tungsten in various materials and industrial products. Electrochemical methods of analysis have an important role in this connection also.

A systematic account of the large amount of published information which has accumulated on the electrochemistry of molybdenum and tungsten will considerably ease the labour of researach workers in this field.

1. POTENTIALS OF REDOX SYSTEMS

The peculiar structure of the electron shells of molybdenum and tungsten is responsible for the variety of types of compounds, in which the metals exhibit a valency varying from two to six. Compounds with hydrogen, which are so typical of elements of the sulphur subgroup, are unknown with molybdenum and tungsten[1]. These metals form a series of redox systems, characterised by definite potentials. Owing, however, to the instability of several compounds in aqueous solution, the redox potentials of these systems have not been evaluated. In particular, no data have been published for the systems M^{V}/M^{IV}, M^{IV}/M^{III}, and M^{III}/M^{II} in aqueous solution. Quadrivalent compounds of molybdenum and tungsten are extremely unstable in aqueous solution, undergoing disproportionation with the formation of trebly charged and quintuply charged ions.

The potentials of other redox systems have been studied quite thoroughly. Thermodynamic calculations of potentials yield the values[2,3]

Mo^{III}/Mo_{solid} – 0.20 V; Mo^{V}/Mo^{III} ~ 0.0 V;

WO_4^{2-}/W_{solid} ~ –1.1 V; W^{III}/W_{solid} > –0.05 V;

WO_3/W^{III} < –0.05 V; WO_3/WO^{3+} + 0.26 V.

Careful measurements of the potentials of various systems containing molybdenum were made by Foerster and his coworkers[4], a selection of whose results is given in Table 1.

Table 1 shows the potential of the Mo^{VI}/Mo^{V} system depends on the relative concentrations of oxidised and reduced forms. This relationship should be consistent with the formula

$$\varphi = \varphi_0 + 0.058 \log \frac{[M^{VI}]\,[H^+]^2}{[M^{V}]}, \quad (1)$$

in conformity with the potential-determining process

$$MO_2Cl_3^- + 2H^+ + 2Cl^- + e \rightarrow MOCl_5^{2-} + H_2O. \quad (2)$$

The measured potentials differ somewhat from those calculated theoretically by means of Eqn. (1). The theoretical shift in potential produced by doubling the hydrochloric acid concentration should be $0.058 \times 2 \log 2 = 0.035$ V. The changes in potential found experimentally on passing from 2 *N* to 4 *N* and 8 *N* HCl were respectively 0.039 V and 0.190 V. The potentials of this system in 4 *N* and 8 *N* HCl should be +0.628 V and +0.663 V.

The discrepancy between theoretical and experimental values was attributed partly to variation in the activity of hydrochloric acid with change in its concentration. On the other hand, these workers postulated the formation of more stable chloride complexes of quinquevalent molybdenum, which would have inevitably produced a positive shift in the potential with increase in concentration of the chloride ion.

The normal oxidation potential of this system was found to be +0.400 V.[3] The material of the indicator electrode (platinum, iridium, gold) had practically no effect on the potential.

The potential of the Mo^{V}/Mo^{III} system was calculated by means of the equation

$$\varphi = \varphi_0 + 0.029 \log \frac{[Mo^{V}]\,[H^+]^2}{[Mo^{III}]}, \quad (3)$$

in conformity with the reaction

$$MoO^{3+} + 2H^+ + 2e \rightleftarrows Mo^{3+} + H_2O. \quad (4)$$

The data in Table 2 show that the potentials of this system are more negative than those of the previous system. The

3:97	2	+0.054
1:9	2	+0.054

same features were observed in the variation of the potential with the concentration ratio of oxidised and reduced forms, and also with the concentration of hydrochloric acid.

Doubling the hydrochloric acid concentration should produce a shift in potential of $0.029 \times 2 \log 2 = 0.017$ V. For a concentration ratio of 100 between oxidised and reduced forms, the corresponding potentials should be +0.205 V (4 N HCl) and +0.232 V (8 N HCl). The measured values were more positive, +0.258 and +0.322 V. Thus the changes in potential accompanying increase in concentration of hydrochloric acid considerably exceeded the theoretical values.

The redox potentials of systems involving molybdenum had been measured by Chilesotti[5] before Foerster's investigations. The measurements were made in the titration of tervalent molybdenum with potassium permanganate. The results obtained by the two workers differ considerably.

The Mo^{VI}/Mo^{V} system has been studied also by other workers[6,7], who explained the variation in potential with the concentration of hydrochloric acid not only by the influence of the hydrogen-ion concentration but also by the occurrence of two different forms of quinquevalent molybdenum.

Syrokomskii studied the potentials of redox systems as functions of the concentrations of complexing agents[8,9]. He showed the effect of the concentration of the anions PO_4^{3-}, $C_2O_4^{2-}$, and $C_4H_4O_6^{2-}$ on the potential, which becomes more negative on addition of the complexing agent. The shift in potential produced by the different anions varies in the above sequence.

The effect of thiocyanate on the redox potential of the Mo^{VI}/Mo^{V} system was studied by Tarayan and Ekimyan[10], who found that the potential becomes more positive with increase in the thiocyanate concentration.

The potential of the W^{VI}/W^{V} system was first measured by Collenberg and Guthe[11], who obtained a value of +0.26 V, differing from that calculated by means of Eqn. (1). The experimental results have been reproduced by Chernikhov and Goryushina[12,13] in the potentiometric titration of sexivalent tungsten with bivalent chromium. Some lack of reproducibility in the potentials of systems containing quinquevalent tungsten has been explained by its rapid oxidation in air. According to some workers[14], however, solutions of quinquevalent tungsten are stable, and can be employed as working solutions in oxidimetric titration. A systematic study of the redox potentials of tungsten systems in hydrochloric acid solutions has been made by Geyer and Henze[15,16], some of whose results are listed in Table 3.

Tungsten was obtained in lower states of oxidation by electrolysis with platinum, mercury, and amalgamated

TABLE 3. Potentials (on standard hydrogen scale) of redox systems in hydrochloric-acid solutions.

W^{VI}/W^{V} ratio	Potential, V		W^{V}/W^{III} ratio	Potential, V	
	12.5	8.0		12.5	9.5
90:10	+0.42	+0.29	90:10	+0.13	+0.03
50:50	+0.36	+0.20	50:50	+0.05	−0.03
10:90	+0.37	+0.16	10:90	−0.02	−0.11

lead electrodes. With a platinum electrode (at a cathodic current density of 0.01–0.3 A cm^{-2}) quinquevalent tungsten was obtained. A sharp jump in potential occurred only when the quinquevalent state was reached. The subsequent conversion of W^{V} into W^{III} was not accompanied by a sharp change in potential. In phosphate solutions reduction occurred with difficulty to quinquevalent tungsten.

In contrast to molybdenum, the potential of the W^{V}/W^{III} system was calculated on the basis of

$$2WOCl_6^{2-} + 4H^+ + 4e \rightleftarrows W_2Cl_9^{3-} + 2H_2O + Cl^-, \quad (5)$$

as the potential-determining process. Consequently the equation

$$\varphi = \varphi_0 + 0{,}029 \log \frac{[W^V][H^+]^4}{[W_2Cl_9^{3-}]}, \quad (6)$$

was used for the calculations.

It is evident from Eqn. (6) that variation in the hydrogen-ion concentration should have a more marked effect on the potential than in the case of the analogous molybdenum system. Measurements of potential for these systems containing different concentrations of hydrochloric acid show that the potential shifts to more positive values with increase in the hydrogen-ion concentration, but no exact relationship is observed. The potentials of both systems are affected by the concentration ratio of oxidised to reduced forms.

Nevertheless, the total concentration of oxidised and reduced forms has hardly any effect on the potential. Addition of phosphoric acid makes the potential more negative[17]. Oxalic acid and other organic complexing agents have the opposite effect. The potentials of the redox systems were not studied in alkaline solutions owing to hydrolysis of the salts with the formation of precipitates. However, the potential of the $W(CN)_8^{3-}/W(CN)_8^{4-}$ system was measured in the presence of potassium cyanide, and found to be +0.57 V. Several authors regard the presence of W^{IV} in these solutions as certain[2,18].

Methods for the oxidimetric determination of molybdenum and tungsten have been developed on the basis of potential measurements in redox systems containing these elements[12,13,19–27].

The potential of metallic molybdenum in solutions of various electrolytes has been measured by Akimov[28], Shatalov[29], and others. A characteristic feature of Akimov's results (Table 4) is their dependence on the previous mechanical treatment of the electrode surface: an electrode having an uncleaned surface shows far more positive potentials than does an electrode which has first been cleaned. This indicates the presence of oxide films on the electrode surface.

The influence of the nature of the electrolyte on the potential is most probably linked in some way with the formation of oxide films. In conformity with this, the potentials are more positive in acid than in alkaline solutions

(dissolution of the film). With time the potential in an alkaline solution becomes more positive, obviously owing to the accumulation of alkali-insoluble oxidation products of molybdenum.

Shatalov[29] considers the concentration of hydrogen ions to be the main potential-determining factor in the case of molybdenum. Potential measurements over the pH range 1–8 have shown a linear relation, which can be expressed by the empirical formula

$$\varphi = \frac{0.35}{0.40} - 0.045\,\mathrm{pH}.$$

Table 5 gives results obtained by Shatalov[29] for the dependence of the potential on the nature of the anion. The results resemble those in Table 4. Chloride and hydroxide ions exert the greatest depolarising effect on molybdenum.

Kruger and Kahlenberg[30] have studied the potentials of molybdenum in solutions of various electrolytes saturated with inert gases (Table 6). It is difficult to compare Table 6 with Table 5 because of differences in the electrolyte concentrations. However, comparison of certain data (for KOH and HCl) indicates considerable negative shifts in potential when a solution is saturated with an inert gas. The reason for these shifts is obscure.

A similar variation in the potential with the nature and concentration of the anion has been obtained by several workers for tungsten[28,29,31-33], results of Korner[31] and Shatalov[29] being listed in Tables 7 and 8 respectively. Table 7 shows the depolarising action of anions on the potential. In the presence of chloride, bromide, iodide, and cyanide ions the potential becomes more negative. A considerable negative shift in the potential is observed also in ammoniacal and alkaline solutions. Shatalov's results (Table 8), obtained for tungsten in the same solutions, differ somewhat from those of Korner. The difference is most probably explained by some irreproducibility in the surface state of the tungsten electrode.

The dependence of the tungsten potential on the pH of the solution was studied by Holven[34]. In view of the direct interdependence of these properties, tungsten was recommended as an indicator electrode for the determination of pH[35].

2. COMPOSITION AND SPECTROPHOTOMETRY OF COMPLEX COMPOUNDS

A vast literature exists[36-76] on the composition of compounds formed by sexivalent molybdenum and tungsten with inorganic and organic reagents. The composition is greatly

dependent on the nature and concentration of the ligand. Thus the compound $H_2Mo_4O_{13}$ is assumed[36] to be present in dilute hydrochloric acid solutions. With increasing concentration of the acid, the cationic form $HMo_2O_6^+$ is produced. Further increase in the concentration of hydrochloric acid to 5–6 *N* promotes formation of the complex MoO_2Cl_2 by the reaction

$$HMo_2O_5^+ + 3H^+ + 4Cl^- \rightarrow 2MoO_2Cl_2 + 2H_2O.$$

The formulae WCl_6, $WOCl_4$, and WO_2Cl_2 have been attributed[11,77] to the chloride complexes of sexivalent tungsten. In aqueous solution the complexes are unstable, undergoing hydrolysis to form a precipitate of tunstic acid. The chloride complexes of sexivalent molybdenum and tungsten have their maximum light absorption in the ultraviolet. The complex $H^+[MoO_3.H_2SO_4]$ can be formed in sulphuric-acid solution.

Numerous heteropolyacids of molybdenum and tungsten are known, and a fair amount of information has been published[37-39, 50-53] on their composition and structure. The composition of the heteropolycompounds is represented by the general formula $H_3[El^1(M_3O_{10})_4]nH_2O$ or $H_4[El^2(M_3O_{10})_4].nH_2O$, where El^1 = P, As, Sb, etc. and El^2 = Si, Ge, Sn, etc.

Sexivalent molybdenum and tungsten form many complex compounds with organic reagents. Some of these are brightly coloured, and are used for the absorptiometric determination of molybdenum. In several cases the composition of the compounds which are formed has not been established[40-48, 54-76].

The chloride complexes of quinquevalent tungsten possess a blue colour and their maximum absorption lies in the range 600–700 nm. These compounds, and the corresponding molybdenum derivatives, are stable to the action of atmospheric oxygen[78]. The composition of the chloride complexes of quinquevalent tungsten has not been adequately studied[79-81].

In contrast to W^V, the chloride complexes of Mo^V exist in two forms — monomeric (> 7 *N* HCl) and dimeric (< < 2.5 *N* HCl) — which coexist in equilibrium in the intermediate range (2.5–7 *N* HCl).[46,78,82-87] However, as Babko points out[82], the composition of the chloride complexes of Mo^V and their equilibrium conditions have not been established at concentrations of hydrochloric acid of 3–6 *N*. The compounds $M_2[MoOCl_5]$, where M is an alkali metal, have been isolated from solutions of concentrated hydrochloric acid. According to this author[82], quinquevalent molybdenum does not form stable chloride complexes in solutions of dilute hydrochloric acid, but is most probably present as the cation MoO_2^+. As the concentration of hydrochloric acid increases, the cation MoO^{3+} is formed:

$$MoO_2^+ + 2H^+ \rightleftarrows MoO^{3+} + H_2O.$$

Further increase in the concentration of the acid results in the formation of the complexes $MoOCl^{2+}$, $MoOCl_2^+$, and $MoOCl_3$.

Many investigations have been made of the conditions of formation and the composition of the thiocyanate complexes of molybdenum and tungsten[88-127]. Several workers assume that the thiocyanate complex of tungsten is represented by the formula $W(CNS)_5$, while other results indicate that the tungsten is tervalent[121], the formula of the complex being WOCNS. Maximum light absorption occurs at 400 nm. Contradictory views are held on the valency of molybdenum in the thiocyanate complex: Maas[90] and Krauskopf[91] state that molybdenum is tervalent in such compounds, Markle[93] regards it as quadrivalent, and finally Sand[92] considers it to be quinquevalent. Babko's investigations[94,95], together with those of other workers[99], indicate that molybdenum is quinquevalent in this compound, whose composition corresponds to the formula $Mo(CNS)_5$ (λ_{max} = 420 nm).

There are indications of the existence of halide complexes of quadrivalent tungsten and molybdenum[128] having the formulae MCl_4, $MBrCl_3$, etc., which are unstable in aqueous solution.

The halide complexes of tervalent tungsten[129] and molybdenum[130-133] have been studied the most thoroughly. Various authors state that tervalent molybdenum exists in two forms — green and red — in hydrochloric-acid solution. The green form is produced in dilute hydrochloric acid. Some workers have therefore assumed that it corresponds to the cation Mo^{3+} or MoO^+, and that the red form, which is present in concentrated solutions of hydrochloric acid, represents the anion $MoCl_6^{3-}$. Other workers[131] regard the occurrence of two forms of tervalent molybdenum as due to *cis–trans* isomerism of a complex having the same composition $MoOCl.4H_2O$ or $[MoCl_2(H_2O)_4]^+$.

The green form is unstable, being converted into the red form by increasing the acidity or raising the temperature. A characteristic property of tervalent molybdenum is its comparatively ready oxidation by hydrogen ions to yield quinquevalent molybdenum. As a consequence, aqueous solutions of tervalent molybdenum are unstable. Spectrophotometry of the solutions confirms the presence of two forms: the $D-\lambda$ curves exhibit two absorption maxima, at 420 and 520 nm (7 *N* HCl).[132,133]. Dilution of the solution results in a shift in the maximum to shorter wavelengths, which corresponds to a change in composition of the complexes, with the ultimate formation of tervalent molybdenum hydroxide.

The chloride complexes of tervalent tungsten also exist as two forms — $H_5W_3Cl_{14}$ and $H_3W_2Cl_9$ — with absorption maxima in the region of 515 and 462 nm (red and yellow respectively). According to other workers[129], however, the occurrence of two forms of tervalent tungsten is due, as in the case of molybdenum, to *cis–trans* isomerism.

Tungsten and molybdenum blues constitute a peculiar group of compounds[134-139], whose exact composition has not been established.

3. ELECTROLYSIS OF SOLUTIONS

The first work on the electrolytic reduction of sexivalent molybdenum was done by Gahn[140]. This work was qualitative in character, as were investigations by other workers[141-145]. In particular Grotthus[141], who reduced sexivalent molybdenum in sulphuric-acid solution, noted the appearance of blue oxides of molybdenum on the cathode, metallic molybdenum not being isolated. The first attempt to isolate metallic molybdenum by electrolysis with a mercury cathode was made by Férée[146], who used a current density of 5 A cm^{-2} in the cold. The reduced molybdenum dissolved in the mercury to form an amalgam. Later Meyer[147,148] obtained molybdenum amalgam by the electrolysis of sulphuric-acid solutions. This work was repeated by Russell[149] and by Bock[150], who found the optimum conditions

(1–1.5 N H_2SO_4, cathodic c.d. 0.6 A cm^{-2}) for the quantitative deposition of molybdenum. Electrolysis with a mercury cathode was used for the quantitative separation of molybdenum from several elements which do not form amalgams. Electrolysis with solid cathodes, on the other hand, proved useful for the quantitative isolation of molybdenum as the oxide Mo_2O_3 [151,152] with subsequent quantitative determination.

Detailed investigations of the electrolytic reduction of sexivalent molybdenum were made by Chilesotti[5,130,153] and by Foerster[4,154], who studied the effect of several factors — the material of the electrode, the nature and concentration of the electrolyte, the current density, etc.

Chilesotti's results showed that the current efficiency is close to 100% at not very high current densities (0.047 A cm^{-2}), but it falls considerably with increase in current density. The variation in current efficiency with the concentration of hydrochloric acid is irregular: the efficiency decreases on passing from 9N to 6N HCl, and then increases again on passing to more dilute solutions of the acid. The time variation in the current efficiency shows considerable irregular fluctuations. The initial decrease in efficiency is most probably associated with the formation of insoluble products on the mercury surface, which lower the hydrogen overpotential. Chilesotti explained the subsequent rise in the curve by the formation of molybdenum amalgam. The process was accelerated by raising the temperature, the current efficiency being increased. The maximum current efficiency was observed on a lead electrode; values of the same order were obtained on mercury and platinum electrodes.

Chilesotti regarded the high current efficiency on lead as possibly due to the discharge of lead ions which had passed into solution under the influence of an oxidant (molybdenum). During electrolysis with platinum, mercury, and iridium cathodes, the cathode potential became more negative, reaching 0.40 V. No change in potential was observed on tin and lead cathodes.

It follows from the above survey that metallic molybdenum was not deposited when solutions were electrolysed with solid electrodes. However, a series of papers have shown that metallic molybdenum can be deposited in the presence of added iron, nickel, or cobalt salts[155–161]. The additives are usually regarded as depolarising the discharge of Mo^{VI} by forming an alloy on the cathode. Furthermore, the hydrogen overpotential on the alloy is greater than that on pure molybdenum, which also favours the process. According to Ernest and Holt[161], the mechanism of the electrode reaction is

$$M^{2+} + 2e \rightarrow M^{\circ},$$
$$MoO_4^{2-} + 4H_2O + ne \rightarrow Mo(OH)_{6-n} + (2+n)\,OH^-,$$
$$Mo(OH)_{6-n} + (6-n)\,H + M \rightarrow MMo + (6-n)\,H_2O,$$

where n = 1–3. This scheme is seen to involve the participation of atomic hydrogen in the reduction of Mo^{VI}.

Many workers have investigated the electrolytic reduction of W^{VI}. One of the first papers on the electrolysis of tungsten[162] contains a brief mention of the possibility of obtaining an amalgam by electrolysing acid solutions of tungstates containing hydrofluoric acid. This possibility has been confirmed in later work[163]. Leiser[163] made a systematic investigation of the electrolytic reduction of W^{VI} with platinum and lead cathodes, nickel being used as anode. In all cases sparingly soluble blue products were formed, whose composition could not be established. The current efficiency was low, not exceeding 3%.

A broad investigation was made by Rosenheim[164], who used phosphoric, arsenic, and organic acids ($H_2C_2O_4$, $H_2C_4H_4O_6$) as complexing agents. Lead, platinum, mercury, and zinc were examined as cathodes. Reduction took place in stages. From the colour changes occurring in the solution (blue, brown, cerise), this worker concluded that quinquevalent, quadrivalent, and tervalent tungsten was formed. Neither changing the current density nor varying the temperature resulted in further reduction. Collenberg[165,166] showed that, when a mercury cathode was used, the current efficiency did not exceed 24%, and fell sharply with time. It increased slightly with decrease in the current density. Reduction took place at negative values of the cathode potential. Thus at a current density of 0.016 A cm^{-2} the initial potential was -0.70 V, and at 0.004 A cm^{-2} it was close to zero.

Tervalent tungsten was obtained as the final product of reduction on mercury, lead, and tin cathodes. The current efficiency was far smaller on a mercury cathode than on lead.

Rosenheim suggested the following mechanism of reduction

$$\left.\begin{aligned} W^{VI} + e &\rightarrow W^{V} \\ W^{V} + 2e &\rightarrow W^{III} \\ W^{V} + e &\rightarrow W^{IV} \end{aligned}\right\}.$$

On a platinum cathode the final reduction product is merely quinquevalent tungsten.

It must be noted that molybdenum and tungsten redox systems, although reversible in the equilibrium state, are appreciably polarised during electrolytic reduction[154,169]. This is presumably due to the formation of insoluble films on the electrode surface.

Neumann and Richter[167] investigated cyanide solutions of tungsten, and attempted to deposit the metal on a mercury cathode, but were unsuccessful. However, Jackson et al.[168] confirmed Feree's preparation[162] of tungsten amalgam, and pointed out that no acid other than hydrofluoric should be present in the solution. The optimum acid concentration was 4.6 N HF, and the current density 0.60–1 A cm^{-2}.

As with molybdenum, metallic tungsten is not deposited from aqueous solution on solid cathodes. However, it has been deposited from solutions in organic solvents[170,171].

The need for tungsten coatings of high corrosion resistance led to comprehensive investigations of the conditions for the deposition of metallic tungsten from aqueous solution. The problem was first solved by Fink[172]. The tungsten deposits obtained were dense, bright, and stable to the action not only of hydrochloric and sulphuric acids but even of nitric acid. Holt[173] proposed an alkaline electrolyte for this purpose. In the cold a deposit of tungsten oxides was obtained from an alkaline solution. At 85° the cathode became covered with a silver-white film of metallic tungsten. The current efficiency was ~ 1%, which diminished with increase in current density, the optimum value of which was 0.1 A cm^{-2}. Phosphate solutions also were useful for the deposition of metallic tungsten, but the weight of the deposit did not exceed 0.0077 g.

Holt showed[174-176] that metallic tungsten can be deposited from aqueous solution only if the solution contains traces of iron (0.001 g per 75 ml of solution). The cathode deposit contains up to 35% of iron. The quality of the cathode deposit is equally affected by raising or lowering the concentration of iron in the solution: in both cases oxides of varying composition, not metallic tungsten, are deposited.

Nickel, cobalt, and copper have also been proposed[177-179] as impurities promoting the deposition of metallic tungsten. The tungsten content of the cathode deposit did not exceed 50%. In later work Holt[180] has examined aluminium, beryllium, zinc, manganese, tin, cadmium, etc. as additives, and other workers[181-185] have also investigated this problem.

The mechanism by which the additives exert their effect has not yet been elucidated. Various views have been expressed[180,186-188].

1. The discharge of W^{VI} involves two alternating processes at the cathode:

$$(a)\ M^{n+} + 2e \rightarrow M^{\circ},$$
$$(b)\ WO_4^{2-} + 8H^+ + 6e \rightarrow W^{\circ} + H_2O.$$

Reaction (*a*) continues until the surface is completely covered with a thin layer of the impurity metal, which then catalyses the discharge of W^{VI} ions, reaction (*a*) giving way to reaction (*b*). Thus the processes alternate. The hydrogen overpotential is lower on the pure metals (iron, cobalt, nickel) than on their alloys with tungsten.[180,186,188,189].

2. An alloy is formed by the discharge of mixed complexes of tungsten with the impurity metal. Holt[186] used a polarographic method to test this hypothesis. He found that the half-wave potential of the second reduction wave of nickel (-2.02 V) is displaced to more positive values (-1.67 V) in the presence of tungsten. In his opinion this indicates the discharge of a mixed complex of nickel and tungsten.

3. A layer of impurity metal deposited on the cathode promotes formation of an active form of hydrogen, which reduces the W^{VI}. The theory that several compounds are hydrogenated by atomic hydrogen formed on the cathode surface is supported by Kobozev[190-193]. It has been shown[194] that tungsten trioxide placed a short distance from the cathode surface acquires a blue colour as a result of its reduction by atomic hydrogen emitted from the mercury surface. However, Bagotskii and Iofa state[195] that the trioxide is not reduced when not in immediate contact with the cathode, which they explain by the direct reduction of WO_3 to W_2O_5:

$$2WO_3 + 2H^+ + 2e \rightarrow W_2O_5 + H_2O.$$

4. Depolarisation of the discharge of W^{VI} is due to the formation of an alloy of tungsten with the impurity metal, a view supported by Solov'eva and Vagramyan[187], who reject the theory that the metals are deposited layer by layer. If this did occur, fluctuations should be observed in the cathode potential, but these are not in fact observed.

The electrolytic oxidation of tungsten passes through the stage of formation WO_2, W_2O_5, and WO_3.[196,197]

Several papers have appeared[198-200] on the electrolysis of non-aqueous solutions and of melts of tungsten salts, but these fall outside the scope of the present review.

4. REDUCTION WITH METALS AND AMALGAMS

Reducing agents of various strengths have been used for the non-electrolytic reduction of sexivalent molybdenum[201-223] and tungsten[224-253]. Such electronegative metals as lead, cadmium, and zinc were used as reducing agents in the early work. Reduction with zinc was first employed by Pisani[201] and by Pfordten[224]. This method has subsequently been tried by a number of investigators[202,203,211,225-231].

Tervalent molybdenum and tungsten were obtained as the final products. Reduction involved the successive formation of quadrivalent and quinquevalent molybdenum and tungsten. Some workers did not achieve a definite degree of reduction[203-205].

More recently[206,207] metallic aluminium has been used as reductant. According to Riegel and Schwartz[206] reduction in 2 *N* HCl or 1.25 M H_2SO_4 solution first yields orange quinquevalent molybdenum and then green tervalent molybdenum. When this work was checked[207], it was actually found that reduction extended only to the quinquevalent state. However, further reduction is achieved by adding a tin(II) salt. The mechanism of the process was assumed[207] to be

$$Mo^{VI} + Sn^{II} \rightarrow Mo^{IV} + Sn^{IV}, \quad (1)$$

$$Mo^{IV} \rightarrow Mo^{V} + Mo^{III}, \quad (2)$$

$$Mo^{V} + Sn^{II} \rightarrow \begin{matrix} Mo^{III} + Sn^{IV} \\ Mo^{IV} \end{matrix}. \quad (3)$$

Reaction (3) takes place after Mo^{VI} has been completely converted into Mo^{V}.

Electropositive metals such as silver and mercury have also been studied[208-212] as reducing agents, reductors filled with the freshly deposited metals being used. Furman[212] observed the quantitative conversion of sexivalent into tervalent molybdenum in solutions in concentrated hydrochloric acid. In more dilute (1.5–3.5 *N*) acid only quinquevalent molybdenum was formed. Silver had a similar effect. Holtje and Geyer[205] found results for the reduction of molybdenum(VI) by mercury and silver to be reproducible and reliable. Reduction of W^{VI} with silver and mercury in concentrated hydrochloric acid[248-250] yields W^{V}. A method based on preliminary reduction of Mo^{VI} and W^{VI} with silver has been used for the quantitative determination of molybdenum and tungsten in iron–molybdenum, iron–tungsten, and iron–molybdenum–tungsten alloys[253].

Someya's work[217,232,236] was based on the use of liquid amalgams as reducing agents, and during subsequent years many workers have studied the reduction of Mo^{VI} and W^{VI} with amalgams[213-223,233-235,237-252].

Bismuth amalgam reduces Mo^{VI} to the tervalent or the quinquevalent state depending on the acidity of the solution[217]. Sexivalent tungsten is reduced to W^{V} only in concentrated hydrochloric acid.

The amalgams of lead, tin, cadmium, and zinc reduce molybdenum and tungsten quantitatively to the tervalent state[223,234]. According to other workers, however, quadrivalent tungsten is formed on reduction with cadmium amalgam[235] and with metallic cadmium[17]. The reduction of tungsten is prevented by the presence of phosphates and fluorides[237]. Different authors have divergent opinions on the degree of reduction of W^{VI} by lead amalgam. Thus

Someya[236], Holt[237], Babko[238], and Vlasak[239] state that at 60° lead amalgam converts W^{VI} into W^{III}. According to Polotebnova[240], however, lead reduces W^{VI} to W^{IV}. The lack of agreement among the results may be due to differences in the temperature conditions.

Most authors tend to regard the method based on preliminary reduction of tungsten followed by oxidimetric titration as unsuitable for quantitative purposes. Nevertheless, the method has recently been applied to the analysis of steel[245].

Work has been done on the reduction of W^{VI} by lead, zinc, and sodium amalgams in non-aqueous solution[247]. Zinc amalgam effects complete reduction to W^{III}, lead amalgam to W^{IV}, and sodium amalgam reduces W^{VI} incompletely to W^{IV}.

5. POLAROGRAPHY

Several papers have been published on the polarographic reduction of molybdenum[254-291] and tungsten[292-312] at a dropping mercury cathode. The first work in this field was done by Uhl[254], who effected reduction in nitric-acid solutions, using lactic and oxalic acids as complexing agents. The Mo^{VI} polarograms comprised two waves having half-wave potentials of -0.35 and -0.50 V (relative to the saturated calomel electrode, s.c.e.). The proportionality of the height of the first wave to the concentration of molybdenum formed the basis of a method for the quantitative determination of molybdenum and phosphorus. Stern[255] applied Uhl's method to the analysis of biological materials, and obtained two waves with half-wave potentials of -0.40 and -1.20 V. A well defined pH dependence of the wave heights was observed. The wave height is strictly proportional to the molybdenum concentration only within a narrow range of the latter[256], and hence the polarographic determination of molybdenum with nitric acid as supporting electrolyte is not very promising. According to Gokhshtein[257] the reduction of molybdenum in nitric-acid solution is complicated by polymerisation phenomena. He suggested phosphoric acid as supporting electrolyte for the polarographic determination of molybdenum.

Stackelberg et al.[258] found that sharp molybdenum waves are obtained in sulphuric acid, whose concentration should be a least 18 *N*. Molybdenum gives one wave with a potential of -0.26 V. The wave height is proportional to the molybdenum concentration, which also permits the method to be used for quantitative analysis[259]. A detailed investigation of the process occurring in aqueous sulphuric acid has been made by Kolthoff[260].

As Stackelberg points out[258], the molybdenum reduction wave appears also in aqueous hydrochloric acid. According to him, however, it corresponds to the reduction not of molybdenum but of mercuric chloride resulting from the oxidation of metallic mercury by molybdic acid.

Kanevskii and Shvartsburd[261] obtained cathodic waves of Mo^{VI} in 88–90 vol.% phosphoric acid. A method was worked out for determining molybdenum in ores containing 0.005–50%.

Molybdophosphoric heteropolyacid undergoes reduction in phosphoric acid solution. The polarography of heteropolyacids of molybdenum — molybdosilicic, molybdogermanic, etc. acids — has formed the subject of several recent papers. Grasshoff and Hahn[262-265] state that, when these acids are reduced at a dropping mercury cathode, tervalent and quinquevalent molybdenum is formed. They find that the wave heights depend on the acid concentration.

A few papers have been published on the polarography of the lower states of oxidation of molybdenum. In particular, Deshmukh[266] has studied the reduction of quinquevalent molybdenum, a solution of which he obtained by reduction with hydrazine. The polarogram obtained with sulphuric acid as supporting electrolyte consisted of two waves, which he regarded as due to stepwise reduction to quadrivalent and tervalent molybdenum. The half-wave potentials are greatly dependent on the acidity of the solution, becoming more positive with increasing acidity.

Meits[267] obtained polarograms in a citrate buffer solution. Sexivalent molybdenum gives a single wave with a half-wave potential of -0.927 V. Tungsten is not reduced under these conditions, so that the method can be used for the quantitative determination of molybdenum in the presence of tungsten. This worker assumes that reduction involves the formation of quadrivalent molybdenum. Parry and Yakubik[268] consider that polarographic reduction in tartrate solutions yields tervalent and quinquevalent molybdenum. A similar opinion is held by Pecsok and Parkhurst[269]. Pantani[270] has made a polarographic investigation of the citrate, oxalate, and tartrate complexes.

Complexone III has also been proposed as complexing agent[271-273], and it masks the interfering effect of tungsten. Ammonium fluoride has been proposed for a similar purpose[274].

Sinyakova and Glinkina[275] obtained two Mo^{VI} reduction waves (with half-wave potentials of -0.27 V and -0.73 V) using acetic acid as supporting electrolyte. With increasing concentration of the acid, the second wave disappears, while the half-wave potential of the first wave becomes more positive. Two sharp waves are obtained also in a solution containing Complexone III. The half-wave potentials depend on the pH. The reduction of molybdenum takes place also in neutral medium (ammonium oxalate), but the shape of the wave depends on the concentration of the supporting electrolyte[276].

With mixed supporting electrolytes ($HCl + HClO_4$, $HCl + H_2O_2$) catalytic polarographic currents have been observed. Thus Jones[277], while reducing Mo^{VI} with a supporting electrolyte comprising 0.75 M H_2SO_4 + 1 M $HClO_4$, observed a catalytic wave due to reoxidation of tervalent to quadrivalent molybdenum by the perchloric acid, the half-wave potential being -0.21 V.

Holten[278] used this supporting electrolyte for the quantitative determination of molybdenum in minerals and ores. The method proved convenient in the analysis of titanium alloys[279]. Tungsten does not interfere with the determination.

The catalytic reaction in perchloric-acid solutions has been studied by Rechnitz and Laitinen[280], who found that the rate of the process depends on several factors, in particular on the concentrations of molybdenum and perchloric acid.

Sinyakova and Glinkina[281] explained the appearance of a catalytic current in solutions of perchloric acid containing Mo^{VI} by the reoxidation of quadrivalent to quinquevalent molybdenum by the perchloric acid. To confirm this hypothesis they recorded polarograms of molybdenum which had been prepared by reducing sexivalent molybdenum by iron(II) sulphate, with perchloric acid as supporiing electrolyte. The polarogram comprised one wave having a

half-wave potential corresponding to the second Mo^{VI} wave in the same supporting electrolyte. Tervalent molybdenum gave a small wave having a more negative half-wave potential‡.

Haight[282-284] also believes that quadrivalent molybdenum catalyses the reduction of perchloric acid. Catalytic currents representing the reduction of perchlorates and nitrates are used for the polarographic determination of molybdenum[285,286].

Kolthoff and Parry[287] obtained catalytic currents with $HCl-H_2O_2$ supporting electrolytes. The current was proportional to the concentration of Mo^{VI} and hydrogen peroxide. According to these workers, the MoO_4^{2-} ion forms a peroxo-compound MoO_5^{2-}, which is then reduced at the dropping mercury cathode to MoO_4^{2-}:

$$MoO_5^{2-} + 2H^+ + 2e \rightarrow MoO_4^{2-} + H_2O.$$

Vlček[288] assumes that the Mo^{VI} polarographic currents in concentrated sulphuric-acid solution are also catalytic in character, being due to reoxidation of Mo^{V} to Mo^{VI} by the sulphuric acid.

In addition to the acid and neutral supporting electrolytes mentioned above, those of basic character have also been suggested[289] for the reduction of molybdenum.

Polarography has been used to study the composition of the citrate, tartrate, and phosphate complexes of molybdenum, with perchloric and nitric acids as supporting electrolytes[290]. Thus various supporting electrolytes have been used in studying the polarographic reduction of Mo^{VI} in order to find conditions which are of practical convenience for its quantitative determination.

In several of these papers suggestions have been made concerning the mechanism of the process. However, different authors hold contradictory views on this topic, which suggests that insufficient study has been made of the polarographic reduction of molybdenum[291]. This applies equally to catalytic processes.

Little study has been made of the mechanism of the electrolytic reduction of molybdenum with a large mercury cathode and its reduction by amalgams.

Relatively little work has been done on the polarographic reduction of tungsten. Stackelberg[292] found that W^{VI} is not reduced at a dropping mercury cathode in neutral and alkaline solutions, whereas in concentrated hydrochloric-acid solutions it gives a wave having a half-wave potential of -0.42 V. A sharp wave appears also in the presence of phosphoric acid. This workers does not indicate the degree of reduction of the tungsten to which this process corresponds.

Lingane and Small[293] made a detailed investigation of the polarographic reduction of W^{VI} in concentrated hydrochloric acid. The degree of reduction of the tungsten was determined coulometrically or by titration with potassium iodate solution. They also used electrolysis with a mercury cathode at a controlled potential to elucidate the mechanism of the process. The individual forms of reduced tungsten were identified spectrophotometrically. These workers found that in 12 *N* HCl the tungsten(VI) gives two waves, the first beginning at zero applied e.m.f., and the second wave having a half-wave potential of -0.56 V (s.c.e.). In less concentrated solutions the potential of the second wave becomes more negative. From the ratio of the constants for the diffusion currents of first and second waves it was concluded[293] that reduction extends to the quinquevalent and tervalent states respectively. The coulometric measurements at the corresponding potentials (-0.40 and -0.67 V) and titration with iodate support this view.

Laitinen et al.[294] studied the polarographic behaviour of W^{VI} in hydrochloric-acid solutions containing perchloric acid and lithium chloride. The half-wave potential and the number of electrons involved in the reaction were determined from the slope of the linear plot of $\log [i/(id - i)]$ against the electrode potential. These workers consider[294] that quinquevalent and tervalent tungsten is formed during the polarographic process. However, they do not exclude the possibility of the formation of quadrivalent tungsten, since the reverse process passes through this stage. A catalytic current due to reduction of the perchlorate ion was observed on a portion of the first wave in these solutions. Laitinen and Ziegler[295] explained the appearance of the catalytic current by reoxidation of the quinquevalent tungsten ion, formed during polarography, by perchloric acid. The catalytic current is large, and depends not only on the concentration of W^{VI} but also on the concentrations of hydrochloric and perchloric acids. A catalytic current has been observed also in the polarography of solutions containing hydrogen peroxide. Kolthoff and Parry[287] established that the magnitude of the catalytic current depends on the concentrations of tungsten(VI), hydrogen peroxide, and acid. The maximum catalytic current was observed in sulphuric-acid solution. These workers tend to think that the variation in the catalytic current with change in acid concentration is due to different degrees of polymerisation of the tungsten(VI).

The catalytic current is suppressed by the presence of complexing agents in the solution, and this effect has been used to determine the composition of the oxalate complexes[296].

Souchay[297,298] studied the polarographic reduction of sexivalent tungsten in solutions of various inorganic complexing agents (PO_4^{3-}, AsO_4^{3-}, GeO_3^{2-}, SeO_3^{2-}, BO_3^{3-}, etc.). Other authors have discussed the mechanism of this process[299,300].

Souchay[301] has recently studied the polarographic reduction of metatungstates in aqueous hydrochloric and sulphuric acids. Electrolysis using a mercury cathode, combined with spectrophotometry, suggests a stepwise reduction of W^{VI} to W^{V} and W^{III} in concentrated acid solutions. In dilute solutions of the acids three or more waves appear. The half-wave potentials and the wave heights depend on the acid concentration. Souchay attributes this to different degrees of polymerisation of the metatungstate and hence to variation in the number of electrons taken up by each molecule, which he regards as fluctuating between 21 and 36.

A polarographic method has been used in several investigations to determine the composition of complexes[302,303]. According to Pantani and Desideri[304] W^{VI} gives a well defined wave in solutions of phosphoric acid ($> 4\,N$). In dilute solutions the polarograms consist of three or more waves. These workers assume that reduction extends to

‡ The method employed by these workers is incorrect: (1) they do not exclude the effect if iron and cadmium on the polarograms; and (2) mixing Mo^{III} with perchloric acid before polarography should result in the instantaneous oxidation of the former by the ClO_4^- ions. An intermediate reduction product of perchloric acid, chlorine, will then appear in the solution.

the quinquevalent state. The occurrence of more than one wave, however, they attribute to variation in the diffusion coefficient of large complex molecules with increase in the acid concentration.

Two waves are present in the reduction of sexivalent tungsten from hydrochloric-acid solutions containing ammonium thiocyanate, their appearance being explained by successive reduction of the chloride and the thiocyanate complexes[305].

In the presence of organic complexing agents (oxalic, tartaric, citric acids, etc.), too, W^{VI} is reduced at a dropping mercury electrode in acid solutions[306-310]. The wave heights vary with the acid concentration. The optimum pH depends on the nature of the complexing agent.

A method based on the use of concentrated hydrochloric acid as supporting electrolyte has been recommended for the analysis of steels, alloys, etc.[292,311,312].

The published information shows that the mechanism of the polarographic reduction of sexivalent molybdenum and tungsten has not yet been thoroughly elucidated. Therefore no indication is given in reference works as to the degree of reduction of tungsten. The point is reflected in the treatise by Krykova et al.[291]

I. INTRODUCTION

Natural crystalline aluminosilicates (zeolites, molecular sieves) were shown in 1915 to have catalytic properties.

Catalysts for cracking, oxidation, and other reactions (both inorganic and organic), based on these materials, were subsequently patented [1], but initially they did not find wide practical use.

Advances in the field of zeolite synthesis, mainly in the period 1940–1950, have revealed new potentialities for these materials. Dozens of zeolites with enhanced adsorption properties and thermal stability were prepared, including some which have no natural counterpart. The production of types A and X synthetic zeolites on a semi-industrial scale [2] began in 1954: since then, these zeolites have achieved wide popularity as sorbents for drying, purification, and separation [3,4]. However, their catalytic properties have been very little studied [5], in spite of their great potential importance, which arises from the striking specificity of their properties, making possible the solution of many practical and theoretical problems in catalysis. The combination of a well-defined crystalline structure with uniform pores of molecular dimensions enables highly selective catalysts to be prepared [6–8]. By using zeolites with orifices (leading to voids within the crystals) of the correct size, we can localise reactions on the outer surface of the catalyst and eliminate the influence of internal diffusion. The aluminium in crystalline alumina–silica zeolites always has tetrahedral coordination. (This applies to the cationic forms: three-coordinated aluminium is also present in decationated modifications.) The excess negative charge of the aluminium–silicon–oxygen skeleton is compensated by cations of different elements (when first synthesised, zeolites are usually in the sodium form). These cations can be exchanged for equivalent amounts of other cations, giving rise to various ion-exchanged modifications with a range of different catalytic properties. Multifunctional multicomponent catalysts, obtained by introducing various catalytically active components into the voids of zeolites, have enhanced stability, arising either from hindered migration of the metal or from some kind of compound formation through the orifices of molecular dimensions [9] by which the voids are interconnected.

By virtue of their high chemical stability (particularly in organic media), and of their thermal stability, zeolites can be used at high temperatures, and are easily regenerated. In this respect they are superior to organic cationic ion-exchange resins, whose thermal stability is still limited [10] to 160–190°, whereas zeolites are stable up to 800° and above.

In recent years, zeolites in which some of the AlO_4 and SiO_4 tetrahedra are replaced by structural units containing Ge, Ga, Be, Mg, Cr, and other elements have been synthesised by isomorphous substitution. A comparison of the catalytic properties of these zeolites with those of the corresponding cationic forms of alumina–silica zeolites will provide valuable evidence on the relative contributions of the cationic and the anionic parts (sites) of the zeolites to their catalytic activity, and will reveal new ways of varying and controlling the properties of zeolite catalysts.

Research carried out during the past few years has led to the development of new, highly active catalysts, some of which have already found industrial application, whilst others are undergoing trials. The following new industrial catalysts — Durabead 5, a cracking catalyst almost 100 times as active as amorphous alumina–silica catalysts, the cracking catalyst [11] XZ-15, and also the isomerisation catalyst MB-5390 (SK-100) for n-alkanes, showing enhanced stability towards water and sulphur, and enabling reactions to proceed at temperatures 60–80 deg lower than existing bifunctional catalysts of the metal–acidic oxide type [12] — have been developed in the USA. In addition to their high activity and selectivity, these catalysts are remarkably stable towards impurities in the crude materials, particularly sulphur and nitrogen compounds, and heavy metals, which usually poison catalysts of other types.

These special features of zeolite catalysts are their most promising characteristics, and are the reason for the increasing scientific and practical interest in these materials.

II. GENERAL INFORMATION ON ZEOLITES, AND ON SOME OF THEIR PHYSICOCHEMICAL PROPERTIES

Most of the synthetic zeolites, like all natural zeolites, are aluminosilicates†. These compounds can have a fibrous structure, a layer structure, or a three-dimensional (skeletal) structure. Zeolites with a layer structure are thermally unstable, and possess only moderate adsorption properties. The most valuable crystalline alumina–silica zeolites from the point of view of adsorption and catalysis are those with a stable three-dimensional skeleton, and the following discussion will be mainly confined to zeolites of this type.

Approximately forty natural zeolites have been described so far, but the total number of synthetic zeolites exceeds fifty [18]. The most interesting of these are the zeolites of types A, X, Y, L, S, P, E, mordenite, and others. Their general empirical formula can be written

$$M_{2/n}O \cdot Al_2O_3 \cdot x\,SiO_2 \cdot y\,H_2O,$$

where n is the valency of the metal cation M, while x is the SiO_2/Al_2O_3 molar ratio, and y is the number of moles of water. The value of x determines the structure and the properties of the zeolites. Thus, in a type A zeolite x is close to 2.0, in a type X zeolite it varies from 2.2 to 3.0, in a type Y zeolite from 3.1 to 5.0 [18] (or to 6.0 according to other workers [8]), and in a synthetic mordenite values as high as 10 have been reported [19–21]. The zeolite lattice consists of SiO_4 and AlO_4 tetrahedra. As we have already pointed out, the aluminium–oxygen and silicon–oxygen tetrahedra in zeolites can be replaced by tetrahedra of other ions, e.g. P^{5+}, Ga^{3+}, $Ge^{4\pm}$, etc. These tetrahedra arrange themselves so as to form polyhedra. Thus, 8 tetrahedra can form a cube, 12 can form a hexagonal prism, and 24 can form a cubic octahedron. The unit cells of the zeolites are formed by the packing of these polyhedra. Voids appear between and within the polyhedra: these are interconnected by oxygen rings (orifices). The cross-sectional areas of these voids (pores) and orifices are of molecular dimensions, and are strictly constant for each type of zeolite. This property of zeolites accounts for their exceptionally high selectivity in adsorption and catalytic processes: whether or not the voids within the crystal are accessible to adsorbed molecules

† Zeolites in which aluminium has been replaced by gallium [13,14] or chromium [15,16], and the silicon by germanium [13], beryllium, or magnesium [17], have been synthesised and investigated. Their importance from the point of view of catalysis will be discussed below.

depends on the size of the latter (critical diameter). The sizes of the large voids and of their interconnecting orifices are set out in Table 1 for various zeolite samples. More detailed discussions of zeolite structure[3,4,22-30] and of the critical diameters of molecules[22] have been published.

The adsorption properties of zeolites become apparent only after dehydration, because the voids in the crystals are filled with water molecules during preparation. Zeolitic water can be removed from the crystals by heating to 300–350°, which does not affect the crystal lattice structure of most zeolites. The ease of dehydration depends on the ion-exchange form of the zeolite. Thus, the calcium form is considerably more resistant to dehydration than is the sodium form[29]. However, zeolites retain small amounts of water even after treatment at 500°. Table 2 lists the water losses reported[31] for some zeolites on heating from 500° to 1000°.

After dehydration, zeolites have a high adsorption capacity. The combined volume of the voids can amount to 50% of the total volume of the crystals[23]. An important property of the zeolite lattice is its high thermal stability. Thus, NaA zeolite is stable up to 700°, and NaX up to 750–800°. The thermal stability of zeolites increases with increasing silicon content[32], and for samples of a given type it is strongly dependent on the nature of the cation, increasing with the radius of the latter[33,34]. As noted above, the cations which compensate the negative charges of the AlO_4^- tetrahedra can undergo ion exchange. The character of the exchange process is determined by the nature, size, and charge of the cations, and by the structure type of the zeolite[35-41]. Cation exchange takes place most effectively in an alkaline medium[42]. Large cations show an ion-sieve effect, which affects the extent and the rate of exchange[35,36,43]. The long-range order of the zeolite crystal lattice is sometimes disrupted by cation exchange. This effect is very sensitive to the pH of the solution in which the exchange is taking place: many zeolites, such as types A and X, lose their structure in acid media (below pH 5). The stability of the structure is also a function of the extent of ion exchange.

The presence of mobile cations in zeolites gives rise to electrical conductivity[23,44,45], the activation energies for conduction and the resistivities being less than in other types of crystal.

TABLE 1. Diameters of large voids and of their interconnecting orifices in some zeolites.

Zeolite	LiA	NaA	KA	CaA	NaX (NaY)	CaX (CaY)	CaM*	H–M
Diameter of large void, Å	12	11–12	11	11	11–13	11–13	7**	7
Size of orifices, Å	4.4	4.0	3.3	5.0	~9	~8	4	6.6

* CaM and H–M are the calcium and the hydrogen forms of synthetic mordenite.

** Length of large channel.

TABLE 2. Thermogravimetry of some zeolites.

Zeolite	NaX	MgX	NaY	MgY	CaY	SrY	BaY
Degree of exchange, %	—	70	—	72	72	77	77
Water lost on heating from 500° to 1000°, wt. %	0.27	1.04	0.14	0.88	0.88	0.45	0.25

As well as the various cationic forms, the hydrogen and the decationated forms of molecular sieves are of great importance in catalysis. These modifications have a high catalytic activity[19-21,46], are more stable towards acids than the cationic forms[47], and show some other specific properties. Replacement of a cation by a proton by ion exchange in an acid medium is possible only with high-silica zeolites, such as mordenite[27]: most other zeolites decompose under these conditions. Barrer suggested the use of the ammonium form[48], which undergoes a reaction giving rise to the H-zeolite when heated in oxygen:

$$4(-O^- \ldots NH_4^+) + 3O_2 \rightarrow 4(-O^- \ldots H^+) + 6H_2O + 2N_2.$$

The hydrogen zeolite can be prepared from the ammonium form also by decomposition under vacuum baking conditions[49]:

$$NH_4X = H-X + NH_3 \text{ (X is the anionic skeleton of the zeolite).}$$

Treatment of silver zeolites with aqueous solutions containing H^+ ions to replace the Ag^+ ions and anions to precipitate the silver going into solution also produces the hydrogen forms[48,50]. An aqueous solution of pyridine hydrochloride[50] can be used. In practice, H-forms are most frequently prepared from the ammonium zeolites. The hydrogen (or protonated[23]) modification has the characteristic lattice of the starting zeolite, but it has more open channels than the cationic modifications. The hydrogen form is unstable at high temperatures, and is converted into the decationated form[46] by further dehydration. Under these conditions the crystal lattice of some zeolites is disintegrated, depending on the extent of exchange. Thus, the structure of zeolite X does not break down if the exchange of Na^+ by NH_4^+ is limited[51] to 30%. With a type A zeolite, decationation is possible only up to 10%, whereas with a type Y zeolite up to 90% can be achieved[51]. Zeolites can be decationated also by electrodialysis[17]. It must be stressed that the nature of the decationated form of crystalline aluminosilicates has not been definitely established. We can only report[46] that three-coordinated aluminium atoms (Lewis-acid regions) and unpaired electron spins are present in decationated samples of zeolite Y.

III. PREPARATION OF ZEOLITE CATALYSTS

Zeolite catalysts are prepared mainly by three methods — (1) ion exchange, (2) impregnation, and (3) introduction of the catalytic component during synthesis (crystallisation) of the zeolite.

The exchange of sodium cations in prepared samples of zeolites by cations of other elements (or by H^+) and the decationation of these samples have been discussed above. These treatments yield various cationic forms (or the decationated form), possessing, as has already been said, different catalytic properties. These modifications can be treated as one of the types of zeolite catalyst.

Cation exchange can be used also to introduce metals into the zeolite structure. However, the method is restricted to elements whose cations can be reduced to the metal (by hydrogen or by alkali metals). For example, nickel-exchanged zeolite (or a zeolite containing complex cations) can be reduced by hydrogen to atomic nickel[9] at high temperature (~ 500°). In addition to nickel atoms, protons are also formed, which compensate the negative charges of the alumina–silica skeleton in place of the nickel ions:

$$[AlO_4]_2^- Ni^{2+} + H_2 \rightarrow 2Ni^0 + 2[AlO_4]^- H^+.$$

The form in which the protons exist has not been accurately established: they may enter the structure as hydroxyls. Partial decationation of the zeolite by removal of water from the hydrogen form, produced as an intermediate, is also not excluded. The result is a zeolite containing deposited metal, or, as it is called, a metal-loaded zeolite [9,52-55]. Many types of these catalysts, containing metallic phases of most of the transition elements, can be prepared. Zeolites can be loaded with metals also by adsorption of appropriate volatile or soluble compounds, organic or inorganic, of the metals on the dehydrated zeolites, followed by thermal decomposition of the compounds. The latter should decompose with deposition of the metals at temperatures below the stability threshold of the crystal lattice. The following compounds can be used — carbonyls or hydrogen carbonyls (Fe, Co, Ni, Cr, Mo, W, Mn, Re), acetylacetonates (Cr, Cu, Ag, Au), halides (Ti, Hf, Zr), alkyl derivatives, and other organometallic compounds — and the preparation and use of a number of loaded molecular sieves have been described in the patent literature [56-63]. Oxidation of the metal (e.g. Zn or Cd) in a loaded zeolite in air or oxygen produces a zeolite loaded with the metal oxide.

In some cases, introduction (or deposition) of the catalytic agent after the zeolite crystals have been prepared is unsuitable. Thus, platinum cannot be introduced by ion exchange into a CaA zeolite having 5-Å orifices, because the available platinum compounds have low pH-values and are liable to disrupt the zeolite structure, while the cations of neutral platinum ammines are larger than 5 Å. In this case the catalytically active agent is conveniently introduced at the stage of preparation (crystallisation) of the zeolite [64].

The catalytic agent can also be deposited on the zeolite particles as an external coating [65]. In multicomponent contact materials the catalytic functions of the zeolite may either combine with those of the added component or disappear. Therefore, in spite of the fact that the properties of zeolites can vary according to the conditions of application and treatment, it is probably useful to differentiate between catalysts in which the zeolites act as inert carriers for the active components and polyfunctional catalysts in which the zeolite substrate performs a specific function.

Problems of catalyst activation are closely bound up with catalyst preparation. Obviously, no single method of processing can be generally applicable to all catalysts. We can only stress the fact that removal of the water from the catalysts (albeit partial) is essential in every case, since only then are the zeolites able to adsorb molecules in their intracrystalline voids, which are the main site of reactions on zeolite catalysts. The conditions, rate, and extent of dehydration depend on the particular catalyst and on the particular process.

IV. APPLICATIONS OF ZEOLITE CATALYSTS

The first reports of the use of synthetic zeolites as catalysts were published [46,66,67] in 1960. In the following years the properties of contact materials based on various cationic forms of zeolites (types A, X, Y, mordenite, etc.) were investigated in a number of reactions, the catalysts being used both individually and in admixture, and also with additions of catalytically active metals and their compounds. These reactions, and the specific features of the zeolite catalysts, will be discussed in the following subsections.

1. Catalytic Properties of Purely Synthetic Zeolites

Weisz and Frilette [67] discovered that NaX and CaX zeolites are more active towards the cracking of n-decane at 470° than are the standard alumina–silica catalysts containing 10% of Al_2O_3. The calcium form of the zeolite was more active than the sodium form, and gave products similar to those obtained in the presence of the alumina–silica catalyst. In contrast, the products obtained on NaX contained no iso-compounds, but double the quantity of alkenes instead. Furthermore, NaX was inactive towards the dealkylation of cumene even at 510°, whereas CaX was a powerful catalyst for this reaction even at 465°. The latter material also brought about the conversion of α-pinene into camphene, but this did not occur on NaX. To account for these results, the authors suggested [68] that the reactions proceed by different mechanisms on these catalysts — by a radical mechanism on NaX, and by a carbonium ion mechanism in the presence of CaX.

The influence of the degree of exchange of Na^+ by Ca^{2+} in a type X zeolite on the catalytic activity towards the cracking of n-decane has been investigated [69]. It was shown that the activity increases with decrease in the Na_2O content of the zeolite, but it was pointed out that the deactivating effect of sodium is less marked in zeolite catalysts than in the alumina–silica catalyst.

The CaX zeolite is much less active [70] towards the cracking of cumene than is an alumina–silica catalyst of the Houdry type, but the course of the reaction is the same. Cumene was found to be adsorbed approximately twice as strongly as benzene on the CaX zeolite, whereas on alumina–silica catalysts the adsorption coefficients are nearly the same [70].

The cracking of cumene has been used as a model reaction in many studies of the catalytic activity of synthetic zeolites [31,51,71-76].

Tsitsishvili and his coworkers [71] investigated the activity of NaX, CaX, and HX zeolites, and concluded that the reaction on these catalysts was sterically hindered.

Topchieva and her coworkers [72-74] studied the catalytic activity of synthetic X and Y zeolites, and found that NaX had negligible activity: replacement of Na^+ ions by Ca^{2+} increases the activity in proportion to the extent of exchange. There was also an appreciable increase in activity on increasing the SiO_2/Al_2O_3 ratio in the zeolite. The highest rate constant was obtained with decationated samples of the Y zeolite. The authors did not observe significant adsorption of propene on the zeolites, which suggests that propene cannot inhibit the cracking of cumene on these catalysts, whereas it is known to inhibit the reaction on amorphous alumina–silica catalysts. Hence, they concluded [72,74] that the kinetic mechanism of cumene cracking is probably different on the two types of catalyst.

The adsorption of quinoline on zeolites was examined [73] in order to throw light on the nature of the active centres. With decationated samples of zeolite Y the activity initially decreased in proportion to the amount of quinoline adsorbed, and remained constant thereafter. This trend in the activity of decationated zeolites led the authors to postulate the existence of at least two types of active centre on the surface — aprotic centres, associated with aluminium atoms in the tervalent state, and AlO_4 tetrahedra.

Schwab and Sieb [75] showed that the activation energy for cumene cracking of the cationic forms of zeolite X examined

(Mg^{2+}, Ca^{2+}, Cd^{2+}, Zn^{2+}, Mn^{2+}) passes through a minimum as Na^+ is gradually replaced by the bivalent cation (with the exception of Cd^{2+}, with which the activation energy increases continuously). The authors' explanation is that at high degrees of exchange the replacement occurs in deep layers of the zeolite, which are not accessible to the cumene. These results are somewhat unexpected: after a certain amount of exchange, one would have expected the activation energy to remain constant.

Among the univalent cationic modifications of zeolite X (the Li, Na, K, and Rb forms), the lithium form is the most active towards cumene cracking[76] at 500°, and is comparable to an industrial alumina–silica catalyst. The authors[76] point out the proportionality between catalytic activity and the force field of the cation, and suggest that the cations act as active centres in the zeolites.

Rabo and his coworkers[31] report that the activity of Y zeolites (SiO_2/Al_2O_3 = 5) in the cracking of cumene increases in the sequence NaY < BaY < SrY < CaY ≃ MgY ≃ ≃ BeY, i.e. in the opposite order to the radii of the corresponding cations. Thus, a direct link exists between catalytic activity and the polarising power of the cations, which increases with decrease in their radius.

The activity of the centres in decationated type Y zeolites varies[51], being highest in the samples containing the greatest number of decationated regions. The authors account for the non-equivalence of the centres by three factors — (1) the presence in the zeolites of three types of crystallographically different sites for the Na^+ ions, and probably also for the decationated sites, (2) interaction between the centres, determined by the proximity of the sites, and (3) the presence of three-coordinated unsaturated aluminium centres, in addition to AlO_4^- tetrahedra, in decationated zeolites. The same workers have shown[77] that irradiation of decationated zeolites lowers the activation energy for the cracking of cumene.

The hydrogen form of synthetic mordenite has a high catalytic activity for hydrocarbon cracking[78–81]. The fission capabilities of this catalyst in the cracking of n-decane[78] are similar to those of CaX zeolite[67]. Synthetic mordenite in the H-form cracks gas oil, n-heptane, 2,4-dimethylpentane, and methylcyclohexane faster than does the commercial alumina–silica catalyst[81], giving a higher proportion of light and branched hydrocarbons among the products. Natural mordenite, previously treated with acid and converted into the hydrogen form, becomes active in cracking, alkylation, and isomerisation reactions at relatively low temperatures[82,83]. For example, the cracking of n-hexane occurs at a temperature as low as 200° with formation of saturated compounds, and benzene is converted into toluene and ethylbenzene[83] at 400°. Butane and cyclohexane rapidly isomerise to isobutane and methylcyclopentane respectively at ~ 200°, and the authors stress the fact that under these conditions deactivation of the catalyst is very slow. Thus, at 260° and under atmospheric pressure, cyclohexane (in a stream of helium) is 11.5% converted into the isomer and 0.9% into side-products. None of these reactions occurs on amorphous alumina–silica catalysts under the stated conditions. The authors conclude that acid mordenite is more closely similar to $AlCl_3$ promoted with HCl than to an amorphous alumina–silica catalyst[83].

Some interesting features of the cracking of alkanes on synthetic zeolites have been observed[84–88]. In the presence of CaA zeolite, n-dodecane decomposed without formation of cyclic compounds, which did, however, form on NaX and CaX. The reaction products obtained in the presence of CaA also contained very small amounts of branched hydrocarbons[84]. Both dehydrocyclisation and isomerisation reactions take place in the voids of the CaA molecular sieve, but because of the small size of the orifices the resulting hydrocarbons cannot escape from the voids and undergo further transformations[85,86].

Many workers have demonstrated the high activity towards hydrocarbon cracking of the rare-earth cationic forms of zeolites X and Y and of mixed metal–acid crystalline aluminosilicates[89–96]. These catalysts, in which some of the Na^+ ions have been replaced by H^+ and some by multivalent cations (Ca^{2+}, Mn^{2+}, rare-earth elements, etc.), show enhanced activity, high selectivity, and good stability[89]; they are used in the preparation of the new industrial cracking catalyst[11,89] Durabead 5.

As was mentioned above, zeolites can also catalyse many reactions besides cracking. Their polymerisation properties were the first to be observed, because these became apparent (as "parasitic" catalytic activity) when the zeolites were used for drying alkenes. Molecular sieves can be arranged in the following sequence of catalytic activity for the polymerisation of propene[97–99]: CaX > > NaX > CaA > NaA > KA = 0. The reactivity of alkenes increases iin the sequence $CH_2{:}CH_2 < CH_3.CH{:}CH_2 <$ $< (CH_3)_2C{:}CH_2$, which is consistent with the reactivities of alkenes towards an acidic catalyst in ionic polymerisation. The composition of the polymerisation products (e.g. of propene) is also similar to the composition of the products obtained when phosphoric acid on kieselguhr is used as the catalyst. Norton[97–99] suggests that the action of zeolites in the polymerisation process is bound up with the presence of acidic regions in these materials.

The polymerisation of gaseous and liquid (low-boiling) C_2–C_6 monoalkenes on crystalline alumina–silica catalysts has been proposed[100] as a method for the production of high-octane fuels for reciprocating internal-combustion engines. In the presence of CaA zeolite, isobutene polymerises even at room temperature and atmospheric pressure to give a product containing 90 vol.% of the trimer and 10 vol.% of the dimer[101].

Crystalline aluminosilicates can also catalyse isomerisation of the double bond in alkenes[102–104]. Thus, but-1-ene on CaA zeolite, at atmospheric pressure and a temperature of 80°, undergoes 71% conversion into but-2-ene, and at 220° the yield of but-2-ene reaches 85%; 2-methylbut-1-ene is 88% converted into 2-methylbut-2-ene at 100°.[103] The activity of zeolites towards the isomerisation of alkenes is increased by γ-irradiation[77,102]. The high (up to 73%) and stable (unaffected by operation for 24 h) catalytic activity of CaA zeolite in the isomerisation of 2-methylpent-1-ene is particularly interesting[104].

Alkanes and cyclic hydrocarbons also can be isomerised on synthetic zeolites. Thus, NaX catalyses[105] the conversion of cyclopropane into propene. Cyclohexane is converted into methylcyclopentane on CaX zeolite, the yield being increased by recycling[106]. Zeolites of types X and Y in their bivalent cationic forms promote the isomerisation of n-alkanes[31].

Synthetic zeolites catalyse also the conversion of alcohols. Depending on the nature of the catalyst and on the experimental conditions, alcohols are converted into ethers[107–110] or alkenes[76,78,83,90,97,107,109,111–115], or alternatively they undergo mainly dehydrogenation with formation of carbonyl compounds[16,57]. Ethers are obtained when

the zeolite used has fairly large pores, at low temperatures, and with relatively high flow rates. Dehydrogenation of alcohols was observed on type A zeolites containing chromium introduced by isomorphous substitution[16]. In every other case the alcohols suffered dehydration with the formation of alkenes. The process is sometimes complicated by side reactions, such as polymerisation and isomerisation of the double bond and of the skeleton of the resulting alkenes, hydrogenation with formation of alkanes, etc. For the dehydration of propan-2-ol[71], the zeolites can be arranged in the series HX > NaX > CaA. The reaction took place[71] at temperatures below 250° on the NaX sample, even though Frilette and Munns[114] were unable to observe any reaction even at 300°. This discrepancy may have been caused by the use[71] of a contaminated or partly hydrolysed zeolite. However, it has been reported that the NaX zeolite dehydrates alcohol in the presence of carbon dioxide. The active centres are said[114] to result from the chemisorption of CO_2 on the zeolite. A similar promoting effect of carbon dioxide on zeolite catalysts has been observed also in the cracking of alkanes, alkenes, aromatic and naphthenic hydrocarbons, and their mixtures, in the isomerisation and polymerisation of alkenes, in the polymerisation of terpenes, and in a number of other reactions[110].

The dehydration of various alcohols on NaX and CaX zeolites has been investigated[111,112]. On NaX the chain length and the amount of chain branching do not affect the degree of conversion of the alcohols: pentanol, 3-methylbutan-1-ol, and nonanol are dehydrated to the extent of 53–56% at 275° and a space velocity of 4 h^{-1}. On CaX the conversion of pentan-1-ol was significantly higher than on NaX, but the products contained a large proportion of saturated hydrocarbons (mainly isopentane), increasing rapidly with temperature, whilst the yield of pentenes decreased. Furthermore, isomerisation of the skeleton and cracking were much more extensive on this catalyst than on NaX.

The CaY zeolite (SiO_2/Al_2O_3 = 3.4) has a high activity towards the dehydration of C_2–C_4 aliphatic alcohols and cyclohexanol[109]. All the normal primary alcohols were completely converted into the corresponding alkenes on this catalyst at 250°. Cyclohexanol was dehydrated smoothly and selectively: 68% of cyclohexene was obtained even at 150°, and at 170° the reaction was quantitative. With n-butanol and isobutanol, the resulting alkenes underwent extensive polymerisation under the experimental conditions[109].

The zeolites CaX and CaY showed remarkable behaviour in the dehydration of t-butyl alcohol[115]. The fully anhydrous zeolites had very low activity, which increased, however, as the water content of the catalyst was increased. The highest activity was observed with samples containing one water molecule per cation in the unit cell. Promotion by water was reported also in the cracking of n-hexane on the rare-earth cationic form of type Y zeolite[116]. These observations should help to elucidate the mechanism by which zeolite catalysts operate.

According to the patent literature[117], molecular sieves show high selectivity and thermal stability as catalysts for the hydration of ethylene oxide to ethylene glycol.

Several papers have been published on the use of synthetic zeolites as alkylation catalysts. A patent suggests various cationic forms of the X zeolite for the alkylation of aromatic hydrocarbons by alkenes[118]. There is evidence[8] that, unlike the conventional acidic alkylation catalysts, which rapidly lose their activity in the presence of sulphur and oxygen compounds, zeolites show a high activity in the presence of these impurities even without added metallic cocatalysts. It is pointed out that thiophens and phenols can be alkylated rapidly and with good selectivity on these catalysts[7,8]. Minachev and his coworkers[119–127] studied the reactions of aromatic hydrocarbons with alkenes and alcohols in the presence of X and Y zeolites of different compositions produced in the Soviet Union and also in the presence of synthetic mordenite. They found[120,121] that the activity of zeolites of similar structure (X and Y) in the alkylation of benzene by propene at atmospheric pressure increases with increase in the SiO_2 content. They also suggested[120] that, as in the case of amorphous alumina–silica catalysts, an optimum Al_2O_3 content should exist in zeolites. A comparative study of the behaviour of the calcium forms of Y zeolite obtained from NaY by exchange with calcium chloride, nitrate, and acetate led the authors to conclude[121] that the nature of the anion of the salt has practically no effect on the activity of the catalyst. It is the cation which plays the key role in determining the catalytic activity of zeolites[121,125,127].

It is evident from Table 3 that NaY zeolite has negligible activity towards alkylation under the stated conditions: only by raising the temperature to 400° and by decreasing the flow rate of the reaction mixture to one-third of its value could the yield of cumene be raised[121] to 10%. Bivalent and tervalent cationic forms are very active, the activity of these zeolites varying monotonically with the polarising effect of the cation: the greater the charge on the cation and the smaller its radius, the higher is the polarising effect of the cation and the more active is the catalyst. The bivalent modifications with comparable degrees of cation exchange can be arranged in the series BaY < SrY < CaY ≃ CdY ≃ MgY. The tervalent cationic forms are more active (on the basis of a single cation in the unit cell) than samples with bivalent cations, but they are less stable[125]. The activities of the pure crystalline aluminosilicates of the rare-earth elements with similar degrees of exchange are practically identical (Table 3).

TABLE 3. Alkylation of benzene by propene* at 250° on various cationic forms of Y zeolite[121,127] having SiO_2/Al_2O_3 = = 4.2, with feed rate of mixture 10.2 moles $litre^{-1}$ h^{-1} (0.6 h^{-1} with respect to C_6H_6) and C_6H_6/C_3H_6 = 2.5 : 1 (molar).

Thus there is no need to use pure compounds for the preparation of rare-earth catalysts: a contact material having approximately the same activity and selectivity can be prepared from a mixture of salts of composition similar to that of the technical mixtures of rare-earth metal chlorides [127], which makes these catalysts much more readily available. The highest yield of monopropylbenzenes (containing 93–98% of cumene) is obtained with the decationated zeolite DY. An industrial amorphous alumina–silica cracking catalyst is less effective by factors of 1.5–3.5 than zeolites with sufficiently wide orifices leading to crystal voids [120,121].

The extent of exchange of sodium ions by multivalent cations also has a marked influence on the activity and selectivity of zeolite catalysts towards alkylation [121,125,127]. The yields of monopropylbenzenes and all other alkylbenzenes increase as the proportion of Na^+ ions exchanged is increased, but not uniformly: this suggests that the cation sites in the zeolite are not equivalent. Thus, in the case of calcium [121,125], samples with degrees of exchange up to 40–45% have a low activity (Fig. 1); at around 50% exchange we observe a sharp discontinuity in the increase in activity, and the conversion of propene approaches 100%: with further replacement of Na^+ by Ca^{2+} the yields of cumene and alkylbenzenes increase much more slowly, and the yield of polyisopropylbenzenes drops as a result of the change in the selectivity of the catalyst. A similar state of affairs has been reported [127] for Nd^{3+} cations, the only difference being that the neodymium zeolites exhibited considerable activity at 20–30% lower degrees of exchange of the Na^+ ions than in the corresponding calcium zeolites. This is probably due to the higher affinity of the Nd^{3+} cations (as compared with the Ca^{2+} ions) for the catalytically active regions of the zeolite, and to the greater polarising effect of the tervalent cations [127]. The use of zeolites with a high degree of exchange allows the reactions to proceed under milder conditions, and leads to improved catalyst stability. Thus, the temperature had to be raised by 150 deg to obtain the same yield from an NdY zeolite of 21% degree of exchange as from a catalyst containing three times that amount of rare-earth elements [127].

The alkylation of benzene by ethylene and by some alcohols [121,124], and of homologues of benzene by ethylene and by propene [121,124,126], has been investigated. The results

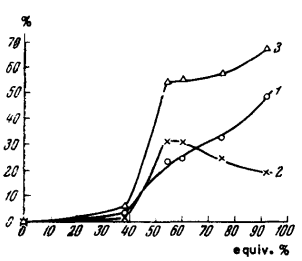

Fig. 1. Influence of the degree of exchange of Na^+ by Ca^{2+} (abscissa), at 250° with a feed rate of the mixture of 10.2 moles $litre^{-1}$ h^{-1} (0.6 h^{-1} with respect to C_6H_6) and a molar ratio of $C_6H_6 : C_3H_6$ = = 2.5, on the yield of products of the alkylation of benzene by propene (ordinate):
1) cumene; 2) polyisopropylbenzenes; 3) alkylbenzenes (monoisopropylbenzenes + polyisopropylbenzenes).

of experiments made under the optimum conditions are given in Table 4. The yields of products are calculated on the basis of the alkenes (or alcohols) used in the reaction. In the absence of alkenes, homologues of benzene undergo disproportionation of their alkyl groups on CaY zeolite [121].

Hydrogen sulphide is oxidised to sulphur on NaX zeolite [66]. It has been found [128] to react with oxygen in the voids of zeolites, to give products which vary according to the experimental conditions and to the nature of the catalyst. Hydrogen sulphide is oxidised to sulphur trioxide at 100° on an NaA molecular sieve and at 200° on a CaX zeolite. Zeolites catalyse the vapour-phase reaction between methyl propionate and formaldehyde with formation of methyl methacrylate [129], and the condensation of organosilicon compounds [130]. Finally, it has been shown [51] that the decationated form of zeolite Y can catalyse the hydrogen–deuterium reaction. The activity of the catalysts can be increased by previous irradiation [77].

2. Zeolites as Carriers of Active Components

Under certain conditions, the zeolite substrate does not show any catalytic properties, but its adsorption properties can nevertheless have a profound effect on the activity, selectivity, and stability of catalysts. Hydrogenation is one of the most important applications of catalysts of this type. Thus, the hydrogenation of acetone to propan-2-ol has been achieved [60] on a nickel-loaded zeolite, and the selective hydrogenation of acetylene to ethylene [131] on a copper–zeolite catalyst.

Many workers [132] have examined the properties of nickel–zeolite catalysts in hydrogenations involving unsaturated hydrocarbons. A 3.8% Ni–NaA sample, prepared by cation exchange, showed high selectivity: n-octene was hydrogenated to the extent of 81.5%, whilst isoalkenes and benzene suffered practically no hydrogenation at all. The explanation is that the latter cannot penetrate to the inner voids of the zeolite, and contact the nickel. On the other

hand, a 5.8% Ni–NaA catalyst prepared by deposition effected 66.6% hydrogenation of benzene at 180°. The degree of conversion of alkylbenzenes was considerably lower (30–36%). Cyclohexene was not hydrogenated on the latter catalyst, but suffered irreversible catalytic changes (87%), whilst on a nickel-free zeolite it remained unchanged[132].

Several investigations of the hydrogenation of aromatic hydrocarbons on zeolites containing platinum-group metals have been published[7,8,63,123]. Minachev and his coworkers[123] showed that these catalysts can be arranged in the sequence

$$0.5\%\ Rh/CaY > 0.5\%\ Ir/CaY > 0.5\%\ Pd/CaY.$$

as regards their activity towards the hydrogenation of benzene. Increasing the SiO_2/Al_2O_3 ratio in the zeolite has no effect on the activity of the catalysts. Equally unimportant is the nature of the cation (Na^+ or Ca^{2+}) in the zeolite. This statement applies only up to a definite temperature, because with rise in temperature hydrogenation may be accompanied by hydroisomerisation of benzene to methylcyclopentane[123]. Under milder experimental conditions, the nature of the cation may have a significant effect[8].

As Table 5 shows, diethylbenzene is hydrogenated almost quantitatively on both palladium–zeolite catalysts at 30 atm pressure. At and below 18 atm, the sample prepared from CaY zeolite is the more active. The high selectivity and the stable activity of these catalysts are stressed[8]. Zeolite catalysts show a greater selectivity than the conventional hydrogenation contact materials towards the hydrogenation of oils of high molecular weight[133].

The unusually high stability of zeolite catalysts towards sulphur-containing catalyst poisons is of great practical importance. Thus, acetylene was almost fully hydrogenated to ethane in the presence of hydrogen sulphide, and the catalysts (containing nickel or palladium) suffered no loss of activity for several hours[8].

Hydrodesulphurisation is another reaction in which loaded zeolite catalysts are used. A hydrorefining catalyst with enhanced activity is obtained[134] by introducing cobalt as a cation into the zeolite and then impregnating the product with molybdenum oxide (MoO_3). Zeolite catalysts[8] containing small amounts of a noble metal make possible the hydrodesulphurisation of crude products having appreciably higher final boiling points than with conventional hydrofining catalysts.

Metal–zeolite catalysts have been studied also in the hydrodealkylation of alkylbenzenes[135–137]. Thus, 51.8 mole% of benzene was obtained[135] at 550° from a mixture of toluene and hydrogen (molar ratio H_2 : CH = 20) in the presence of zeolite Y containing 0.5 wt.% of platinum. The ease with which methyl groups can be removed is stated[137] to decrease in the sequence cumene > ethylbenzene > toluene, whilst the extent of hydrogenolysis of the aromatic ring increases in the same order. Addition of 0.5% of sodium to an Ni–CaA catalyst lowered the extent of hydrogenation and hydrogenolysis of the aromatic ring, and left its activity towards hydrodealkylation unaffected in the case of toluene but lowered it in the case of cumene and ethylbenzene.

TABLE 5. Hydrogenation of aromatic hydrocarbons on metal–zeolite catalysts[8].

Hydrocarbon	Diethylbenzene						Benzene

Several workers have examined the possibility of using zeolites as dehydrogenation catalysts for n-alkanes[59,84,85,87,88]. Zeolite X containing 1.95 wt.% of chromium is recommended[59] as a catalyst for the dehydrogenation of propane. Galich et al. studied the activity of catalysts, prepared from zeolites A and X, towards the dehydrogenation of n-hexane[85,87,77] and n-heptane[87], and found that the activity for these particular reactions was low[88]. The unmodified zeolites caused mainly cracking of the initial hydrocarbons, but catalysts containing Cr_2O_3 were selective for dehydrogenation. The selectivity of the contact materials was improved by adding iron and chromium oxides to the zeolites, and also by replacing sodium and calcium by nickel, cobalt, zinc, chromium, and copper cations, and by protons. The catalysts prepared from type A zeolites, which hinder the passage of aromatic hydrocarbons and isoalkanes into the product phase, were more selective than those prepared from type X zeolites. In every case the catalytic activity depended on the adsorption properties of the zeolites and of their modifications, irrespective of the method of preparation[88].

Zeolites can also be used as the basis of oxidation catalysts: thus, crystalline aluminosilicates loaded with copper, silver, or gold catalyse the oxidation of ethylene to ethylene oxide[56], and a zeolite containing TiO_2 catalyses the vapour-phase oxidation of anthracene to anthraquinone[58]. A zinc-loaded zeolite has been proposed as a catalyst for the synthesis of methanol[52], and zeolites containing metals of the iron subgroup (Fe, Co, Ni) have been proposed as contact materials for the synthesis of ammonia, the Fischer–Tropsch synthesis, and other processes[60]. Cadmium oxide on a zeolite promotes the dehydrogenation of alcohols[57].

3. Multifunctional Multicomponent Zeolite Catalysts

These are, perhaps, the catalysts of greatest practical importance, for they are used in the isomerisation of n-alkanes, hydrocracking, reforming, and various other processes, which account for the bulk of the high-tonnage production in the catalytic processing of petroleum hydrocarbons.

The high activity of zeolite catalysts in the isomerisation of n-pentane and n-hexane was recognised[46] in 1960. The zeolites examined included those of types X (SiO_2/Al_2O_3 = = 2.5) and type Y (SiO_2/Al_2O_3 = 5) in various cationic forms, containing 0.5 wt.% of platinum or palladium, and it was found that samples containing univalent cations are practically inactive. Catalysts based on the decationated and on the multivalent cationic forms of type Y zeolite were extremely active. They gave not only isomers containing a tertiary carbon atom, but also quite large amounts (11–15%) of 2,2-dimethylbutane. However, catalysts prepared from zeolites containing cations of valency 3 or higher were less selective than those with bivalent cations, and in some cases the activity fell off rapidly. Catalysts based on NaX and CaX zeolites showed practically no isomerisation activity, while decationated amorphous alumina–silica had a lower activity than DY and CaY. Studies of the effect of ion exchange showed that increasing the degree of exchange enhances the activity of the samples and allows the

reactions to proceed at lower temperatures[46]. The new isomerisation catalyst MB-5390 for the conversion of n-pentane, n-hexane, and their mixtures was developed from this work: it combines the advantages of the high-temperature (370–455°) catalysts, which give a high yield of isomers, with those of catalysts working at low temperatures (23–205°), which offer a longer useful life[12]. The activity of this catalyst did not fall off after 2000 h operation. Furthermore, the catalyst was insensitive to water and sulphur (at concentrations < 0.001%). It was subsequently shown[138] that a catalyst more resistant to sulphur is obtained if platinum is introduced into CaY zeolite by ion exchange rather than by the normal impregnation method.

Minachev and his coworkers[62,122,123,139-141] examined the properties of X and Y zeolites produced in the Soviet Union, of varying SiO_2/Al_2O_3 ratios, and containing metals of Group VIII of the Periodic Table (Pt, Pd, Ir, Rh, Ni). Some of their results are presented in Table 6. The sodium forms of the zeolites gave inactive catalysts, whereas the calcium and the decationated forms gave highly active catalysts. Contact materials based on zeolites having $SiO_2/Al_2O_3 = 4.2$ were more active than materials in which this ratio was 2.5 or 3.4.[123,141] By increasing the ratio of silica to alumina in the zeolite it was possible to raise considerably the yield of isomeric hexanes (including 2,2-dimethylbutane), and to lower the reaction temperature. The platinum and the palladium catalysts (0.5 wt.%) had similar activities, but on the rhodium and iridium catalysts hydrocracking of the initial hydrocarbons took place in addition to isomerisation of n-alkanes. Thus, on a 0.5% Rh/CaY catalyst ($SiO_2/Al_2O_3 = 3.4$) at 390° and 30 atm, with a space velocity of 1 h^{-1} and a molar ratio of $H_2/n\text{-}C_6H_{14}$ = = 3.2, the quantities of isomeric hexanes and hydrocracking products were 25.8% and 21.9% respectively, whereas on the analogous iridium catalyst at 310° they became[123,139,141] 6.3% and 26.2%. Varying the concentration of palladium in the zeolite from 0.25 to 1 wt.% had little effect on the activity of the catalyst.

The isomerisation of cyclohexane followed the same pattern as the transformations of n-alkanes[141].

TABLE 6. Isomerisation and hydroisomerisation of hydrocarbons on zeolites containing Group VIII metals[141] (30 atm; space velocity 1 h^{-1}, molar ratio $H_2/CH = 3.2$).

Catalyst	SiO_2/Al_2O_3	t, °C	Yield of isomers, wt.%	Hydrocracking products, wt.%

* Space velocity = 0.5 h^{-1}, $H_2/C_6H_6 = 5$.

The hydroisomerisation of benzene gave higher yields (up to 67.3%) of methylcyclopentane than could be obtained by the conversion of cyclohexane. In addition to benzene and the isomeric cycloalkanes cyclohexane was also present among the reaction products. The rhodium and particularly the iridium catalysts again showed a high activity towards hydrocracking: at 320° the former gave 16.9% and the latter ~ 60% of hydrocracking products, whilst hydroisomerisation occurred only to the extent of 12% and 5.8% respectively.

A comparison of zeolitic and conventional bifunctional isomerisation (hydroisomerisation) catalysts showed that the former are in many cases more active than the latter[141]. A given degree of conversion of hydrocarbons can be achieved on zeolite catalysts at temperatures 50–100 deg lower than on other bifunctional catalysts. Moreover, the former offer good selectivity and high stability[141]. Lastly, a metal–zeolite catalyst does not require promoters such as HCl or HF, which are normally introduced into the Al_2O_3 or added to the crude material. All these observations confirm that zeolite catalysts are superior to those currently used in industry for isomerisation reactions.

Some metal–zeolite catalysts, such as the rhodium and the iridium zeolites, show a high activity towards the hydrocracking of hydrocarbons under certain conditions[141]. These properties are found also in catalysts prepared from the rare-earth cationic forms of zeolites and the oxides or sulphides of metals in Groups VI and VIII of the Periodic Table[142,143]. Hydrocracking of high-boiling hydrocarbons can be realised also on zeolites containing metals of Group VIII.[144,145].

Zeolite reforming catalysts also have valuable properties[7,8,146,147]. Unlike platinum reforming catalysts, they are relatively insensitive to the presence of nitrogen bases in the crude material. Thus, they are unaffected for 150 h by up to 200 p.p.m. of nitrogen (in the form of quinoline) in the fraction undergoing reforming[8].

V. SELECTIVITY OF ZEOLITE CATALYSTS

Data on the use of zeolite catalysts show that the main factors determining their activity are the nature and the degree of exchange of the cation in the zeolite, the structure of the zeolite lattice, the value of the SiO_2/Al_2O_3 ratio, and the sizes of the reactant and product molecules relative to the orifices in the zeolite. Allowance for these factors enables us to make a rational choice of zeolite catalysts having the properties required for specific reactions. Other conditions being the same, the relationship between the size of the molecules and the size of the orifices leading to voids in the zeolite is particularly important. Thus[64], n-hexane (critical diameter 4.9 Å) and 3-methylpentane (5.9 Å) are not cracked on zeolite NaA, in which the orifice size is 4 Å. On CaA zeolite (5 Å), only n-hexane is converted, while 3-methylpentane cannot gain access to the voids in the zeolite and does not react under the same conditions. When a mixture of n-hexane, 2-methylpentane, and 3-methylpentane is cracked on CaA zeolite, only the straight-chain hydrocarbon is converted. It is evident from these results that zeolites show high selectivity in respect of the size and shape of molecules, and that the active centres in zeolite catalysts are mostly located within the crystal voids. The term "intracrystalline catalysis"[64,67,68,78] originated from this effect. The intracrystalline nature of catalysis by zeolites is revealed

also by other examples. Thus, n-butanol is dehydrated to the same extent (~ 60%) at 260° on CaX zeolite (~ 8 Å) and on CaA zeolite[64]. But the degree of conversion of isobutanol (critical diameter > 5 Å) at the same temperature is 85% on CaX zeolite, and less than 2% on CaA. A similar state of affairs has been observed with s-butyl alcohol: this compound was 82% dehydrated on CaX at 130°, whereas no reaction occurred on CaA. However, on raising the temperature to 210° the compound was 45% dehydrated. This shows that, according to the conditions and to the reactivity of the molecules, the reaction can occur also on the outer surface of zeolites, although this surface accounts for only 3–5% of the total surface area. The same workers[64] have selectively hydrogenated propene (in an equimolecular mixture with isobutene) on a 0.31% Pt/CaA catalyst. At 343° and under atmospheric pressure the only product of the reaction was propane (yield ~ 70%), in spite of the fact that the two alkenes have identical reactivities towards hydrogenation. It should be noted that n-alkenes (propene, but-1-ene) could be hydrogenated even at 25°. Experiments with single alkenes showed that the active centres of the platinum are not accessible to the isoalkene, which explains why the latter was not hydrogenated.

A great deal of work has been done on the selectivity of zeolite catalysts[85,90,106,107,122,148–151]. The dehydration of ethanol on CaA zeolite gave mainly ethylene, whereas the chief product of the reaction on CaX under comparable conditions was ether[107]. Selective oxidation of n-alkanes mixed with isomers can be effected[148,150].

Individual molecules which penetrate into the pores of zeolite catalysts can be converted into different substances. Some of these can escape from the pores, but others remain trapped. When this happens, the reaction follows an unexpected path, leading exclusively to the formation of some definite products. Thus, it has been shown[85] that aromatic hydrocarbons are formed in the voids of CaA zeolite, but because of their size they cannot escape from the catalyst crystals and undergo further reactions to give condensation products and carbon. The nature of these products and of the carbon deposits has been investigated[86].

Some examples of the molecular-sieve selectivity of zeolite catalysts, taken from the papers by Minachev and his coworkers[121,122,141], are given in Table 7.

However, the molecular-sieve selectivity of zeolites is not always apparent. For example, the hydration of ethylene oxide (4.2 Å) an NaA zeolite (4 Å) gives ethylene glycol and polyethylene glycol[67]. In this case the pore size does not determine the selectivity, and the reaction takes place on the outer surface of the crystal (in the secondary pore structure). Moreover, the selectivity of zeolite catalysts is not determined exclusively by the relative size of the reactants and the zeolite orifices. According to Borunova and her coworkers[132], a 7.8% Ni/NaX catalyst prepared by ion exchange affords complete hydrogenation of n-octene, whilst benzene is only 5% hydrogenated, in spite of the fact that the hydrogenation of benzene is known[152] to reach 100% on catalysts comprising 4% or more of nickel deposited on carriers.

The zeolite structure can also affect in some cases the reaction mechanism. Thus the channel structure of synthetic mordenite (H form) used as a cracking catalyst is thought[81] to enable reactant molecules to contact several acidic active centres at the same time, which may explain the high isomerisation activity of this material, resulting in a high content of branched hydrocarbons in the cracking products. The long pores in mordenite also favour a more prolonged contact between the reactant and the active surface, resulting in cracking to simpler molecules than with amorphous alumina–silica catalysts.

Thus, geometric factors in catalysis on zeolites combine with the molecular-sieve properties of these materials, which often determine not only whether or not a reaction can occur, but also the nature of the reaction and the type of products formed.

VI. OPERATING MECHANISM OF ZEOLITE CATALYSTS

Crystalline zeolitic aluminosilicates are similar to amorphous aluminosilicates, and catalyse many reactions which are accelerated by the usual aluminosilicates. The activity of zeolites is often higher than that of aluminosilicates, and increases with the SiO_2/Al_2O_3 ratio in the crystal lattice, although the cation-exchange capacity decreases. In natural clays, on the other hand, we find a relation between the cation-exchange capacity and the catalytic activity in cracking reactions[153].

TABLE 7. Selectivity of zeolite catalysts.

Catalyst	Diameter of orifices in zeolite, Å	Reaction	Conditions: temp.	Conditions: pressure, atm	Conditions: space velocity, h^{-1}	Critical diameter of molecules, Å: reactant	Critical diameter of molecules, Å: product	Yield of products, %

* Molar ratio $C_6H_6/C_3H_6 = 2.5$.

** The SiO_2/Al_2O_3 ratio in this zeolite was 3.4; in the other cases the ratio was 4.5.

The hydrogen (and decationated) form of a molecular sieve behaves as a solid polymeric acid, and accelerates reactions to which a carbonium-ion mechanism can be assigned. The cationic forms of zeolites, on the other hand, show a different behaviour. Thus, CaX is similar to alumina–silica catalysts in its ability to dealkylate cumene, in its preferential cracking of alkenes as compared with alkanes, and in its tendency to give large amounts of branched hydrocarbons. In contrast, NaX gives cracking products similar to those obtained on pure silica or by thermal cracking. Evidently, the replacement of Na^+ by Ca^{2+} ions in a zeolite of a given structure (X) and of constant SiO_2/Al_2O_3 ratio brings about a marked change in the properties of the catalyst. It is thought that the reaction follows a radical mechanism on NaX and a carbonium-ion mechanism on CaX.[68] Another experimental fact is the uneven change in activity of the catalysts on increasing the degree of exchange of Na^+ in the zeolite by multivalent cations[61,46,121,125,127]. A promoting effect of water and of carbon dioxide on zeolite catalysts has been reported[110,114-116], and also the high stability of these catalysts towards impurity poisons in the crude materials[8,89].

One of the earliest hypotheses aimed at describing the mechanism by which zeolite catalysts operate was put forward by Rabo and his coworkers[46], who suggested that the active centres in zeolites are negatively charged AlO_4 tetrahedra. Their conclusion followed from the fact that catalysts based on the decationated form and on the bivalent cationic forms of Y zeolites have identical activities, whereas catalysts based on X zeolites have low activities. On this model, the sodium form of zeolites is inactive in the isomerisation of n-alkanes because the univalent cation fully balances the charge on the AlO_4^- tetrahedron (whatever the SiO_2/Al_2O_3 ratio in the zeolite). Replacement of Na^+ by Ca^{2+} (i.e. of a univalent by a bivalent cation) in the structure of the X zeolite does not affect the activity of the catalyst because the Ca^{2+} ion is symmetrically located with respect to two neighbouring AlO_4^- tetrahedra, and their negative charges are fully compensated (since the Si/Al ratio in an X zeolite is ~ 1.2, i.e. close to unity). In Y zeolites, on the other hand, the Si/Al ratio is twice as large as in type X, and the Ca^{2+} ions are assumed to be located unsymmetrically with respect to neighbouring tetrahedra, so that the binding energy of the cation to one of the AlO_4^- tetrahedra is low. (In planar models the distance between AlO_4^- tetrahedra increases from 2.6 Å to 5.2 Å on passing from zeolite X to zeolite Y.) The result of this dislocation of the bivalent cation is that one of the AlO_4 tetrahedra carries a negative charge, which the authors identify with an active centre.

The high activity of zeolites in which Na^+ has been replaced by a cation of valency greater than two is explained in a similar way. It is assumed that the isomerisation involves a carbonium-ion mechanism, but how the negatively charged AlO_4^- tetrahedron can induce this reaction is not made clear. As regards the cations in the zeolite, Rabo et al.[46] point to the almost complete lack of catalytic activity in catalysts containing univalent cations and to the very low activity of multivalent cationic forms of zeolites in which the Si/Al ratio is low, i.e. in which the cation density is high, and conclude that these cations contribute little or nothing to the catalytic activity of zeolites. However, this statement conflicts with experimental results showing that in a number of reactions there is a significant difference in the catalytic behaviour of the various cationic forms of zeolites. Furthermore, the possibility of varying the catalytic properties of a given crystal merely by changing the cation was found to be a typical feature of zeolites which is, as Weisz pointed out[68], unique of its kind. The nature of the cation affects the stability as well as the activity of the catalysts[46]. Also, the sodium form of type X zeolites is active in cracking, alcohol dehydration, alkene polymerisation, etc., but CaX zeolite has even greater activity in these reactions. Lastly, the originators of the above hypothesis[46] did not take account of the three-dimensional structure of zeolites, but used a simplified two-dimensional model, which could not provide sufficiently accurate values of the distance between neighbouring AlO_4^- tetrahedra (and therefore also between cations).

Because of all these facts, Pickert, Rabo, and their coworkers subsequently put forward a new model[31] according to which the catalytically active sites in zeolite catalysts are cations having a low degree of coordination to the structural oxygen ions. The activities of various cationic forms of X and Y zeolites were examined in relation to the cracking and the isomerisation of n-hexane and to the cracking of cumene. It was found that the catalytic activity of the zeolite modifications obtained by ion exchange was a function of the charge, size, and environment of the cations. The parts played by the nature of the cations and by the degree of exchange were explained in terms of the lattice structure of zeolites X and Y. In the model for the structure of these zeolites shown in Fig. 2 the solid circles denote two types of cation site, identified by X-ray diffraction analysis of a single crystal of faujasite, which is similar to the synthetic zeolites X and Y.[31] The measured average population of the S_I sites is approximately unity, while that of the S_{II} sites is about one-half. Bivalent cations at sites on an internal surface of the zeolite have only threefold coordination to oxygen ions, whereas at S_I sites between oxygen rings the cations have sixfold coordination to oxygen ions. The charge of a bivalent cation at an S_I site is fully neutralised by the negative charges of the AlO_4^- tetrahedra to which the cation is bound. On the other hand, the charge of a cation at an S_{II} site is only half neutralised. Hence, the electrostatic fields surrounding bivalent cations at the two types of site are different. Calculation shows[31] that the field strength around the cations at S_{II} sites is higher than the value needed to cause considerable shifts in the bonding electrons of the adsorbed molecules. (A field in excess of 1 V $Å^{-1}$ is sufficient to induce a large electronic

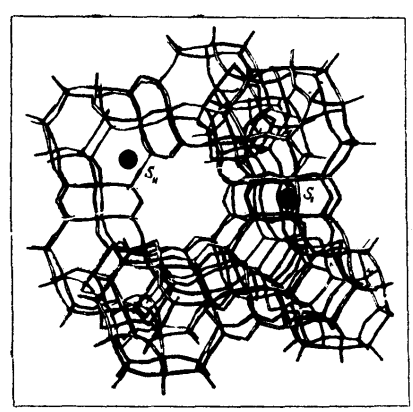

Fig. 2. Structure of the aluminosilicate framework of X and Y zeolite catalysts with two types of cation site.

shift, and in a CaY zeolite the field at these sites is greater than 6 V Å^{-1}.) It is suggested that, under the influence of the field of a cation in the zeolite, a C–H bond in an n-alkane molecule becomes polarised in the direction $C^{+}H^{-}$, which leads to the formation of a carbonium ion and to isomerisation[31]. This mechanism does not require physical removal of a hydride ion (H^{-}) with formation of an actual carbonium ion. However, the reactivity of the molecules does increase with the field strength.

The non-uniform change in the activity of a zeolite catalyst with degree of exchange of Na^{+} by bivalent (or multivalent) cations is a consequence of the non-equivalence of the cation sites. Cations at S_I sites are the first to undergo ion exchange, and most of these sites become filled with bivalent cations before the latter can begin to replace Na^{+} ions at the catalytically active S_{II} sites. In this way the authors[31] explain why a marked increase in the catalytic activity of a Y zeolite occurs only beyond about the 45–50% level of exchange. With further increase in the degree of exchange the activity of the zeolite catalyst begins to increase faster than linearly.

This model satisfactorily explains most of the experimental results. However, the difference in activity between X and Y zeolites is not convincingly explained, since according to the authors' own calculations the field strength at S_{II} sites in CaX zeolite is lower than in CaY by only 0.7 V Å^{-1}. This marginal difference can hardly account for the large difference between the two zeolites, as the authors themselves point out. They consider that, in order to resolve this inconsistency, the model must be refined, and more accurate calculations made, with fewer simplifying assumptions[31].

These views on the nature of the active centres in zeolites attracted a number of objections during the discussion at the Third International Congress on Catalysis[116]. Hirschler suggested that the activity of crystalline zeolites is due to sites akin to Brønsted acid sites, as has been postulated for amorphous alumina–silica catalysts. These sites are due to the presence in the zeolite of water, which is retained even after heating to 500° (see Table 2). This worker notes a similarity in properties between crystalline and amorphous aluminosilicates. Thus, ions of the alkali and alkaline-earth elements deactivate both the hydrogen (or decationated) form of zeolites and amorphous aluminosilicates, the poisoning effect of alkali-metal cations being considerably greater than that of alkaline-earth cations. According to Hirschler[116], the activity of both crystalline and amorphous aluminosilicates varies monotonically with their acidity.

However, important differences in behaviour between zeolites and amorphous alumina–silicas are frequently observed. For example, the hydrogen form of natural mordenite is more similar, as a catalyst, to $AlCl_3$ promoted by HCl than to an amorphous aluminosilicate[83] (see p. 907). Also, there is no direct relationship between the amount of water retained by the zeolite and the catalytic activity. Thus, MgX is less active than MgY towards the cracking of cumene and the isomerisation of alkanes, although it retains a greater proportion of water after being heated to 500° (Table 2). Hence, Rabo et al. believe[31] that the contribution of protonated sites to the carbonium-ion activity of zeolites is insignificant, for the presence of water is interpreted as a potential source of such sites.

According to Plank[116], the rare-earth cationic form of zeolite Y, when dehydrated at 650°, has very low activity towards the cracking of hexane at 204°, but treatment with water increases the activity of the catalyst many thousands of times at the same temperature. He suggests that the activity of the zeolite by water involves the reaction

$$Re^{3+} + H_2O \rightleftarrows Re(OH)^{2+} + H^{+},$$

(where Re^{3+} is a rare-earth cation), the protonated catalyst being the active form, while the salt form is inactive. The present writers[120] have expressed a similar view. The difference in stability between various catalysts based on cationic forms of zeolites X and Y has been explained[116] by the different stabilities of the zeolites HX and HY. The main function of the multivalent cations then consists in controlling the distribution and hence the stability of the acidic (H^{+}) sites: the principal difference between crystalline zeolites and amorphous aluminosilicates lies in the geometry of the acidic sites.

We must not ignore the presence of water in zeolites, since its promoting effect on zeolite catalysts is well known (in particular, towards the dehydration of t-butyl alcohol[115]). However, the "hydrolysis" mechanism described above does not appear to be generally applicable. Many experimental facts are difficult to explain from that point of view — e.g. the irregular variation in the activity of zeolites with the degree of exchange of the cations, the considerable activity of univalent cationic forms in certain reactions, etc.

Schwab and Sieb[75] have developed the so-called "two-centre" theory in order to explain the catalytic activity of zeolites. According to this theory, a reaction (such as cracking) can take place only if the catalyst contains, in addition to acidic centres, also negatively charged centres (Lewis bases). The fact that *p*-cymene is converted more readily than is cumene is claimed as evidence in favour of the hypothesis. Indeed, the presence of an electron-donor substituent (the CH_3 group) *para* to the isopropyl group causes a significant increase in the total negative charge on the nuclear carbon atom to which the isopropyl group is attached. This may result in a lowering of the activation energy for cracking, irrespective of the particular catalyst used. This theory has not been developed in detail.

Zeolites subjected to isomorphous replacement have given interesting results. Ermolenko and Pansevich-Kolyada[16] have shown that dehydration is the only reaction which ethanol undergoes on NaA zeolite. Deposition of chromic oxide (from potassium chromate) on an industrial NaA zeolite gave a catalyst which again led predominantly to dehydration. Similar behaviour was found with a sample of $Cr(OH)_3$ + NaA, prepared by mixing the zeolite with freshly prepared chromic hydroxide washed free from alkali, although this material contained 15.7% of Cr_2O_3. In contrast, a zeolite preparation in which the chromium had been introduced by isomorphous replacement caused the reaction to go mainly in the direction of dehydrogenation, with formation of acetaldehyde. The same behaviour was observed with an amorphous chromosilicate free from aluminium. However, some zeolites with isomorphous replacement, in which the SiO_2 content and the total content of Al_2O_3 and Cr_2O_3 were similar to those in NaA, proved to be catalysts of mixed type and gave approximately equal amounts of hydrogen and ethylene. These results suggest that lattice tetrahedra also can take part in some reactions. Unfortunately, the authors did not examine the behaviour of CrA zeolite prepared by ion exchange: this would have made the situation clearer.

Panchenkov and his coworkers [154] have developed some interesting ideas on the mechanism of the action of aluminosilicate catalysts. They suggest that catalysis on these materials involves reversible changes, under the influence of a reactant molecule, in the coordination of a metal ion in the crystal lattice, from a lower to a higher value. The most active centre is aluminium in fourfold coordination. The greater activity of zeolites may simply be due to the fact that the aluminium is exclusively four-coordinated, whereas in amorphous aluminosilicates the coordination number may vary (4, 5, 6, 8).

7. Dependence of rate of interaction of isocyanates with alcohols on the structure of the alcohol 921
8. Catalysis in the reaction of isocyanates with alcohols 922

1. INTRODUCTION

Research workers and technologists have recently been showing great interest in the reactions of isocyanates with alcohols and other compounds containing "active" hydrogen. The reason is that these processes underlie the preparation of several present-day chemical products [1-3].

The reaction of the isocyanate NCO group with an alcoholic hydroxyl is an act of chain propagation in the synthesis of polyurethanes, and has therefore been studied rather more thoroughly than other reactions of isocyanates. In contrast to many known reactions involving nucleophilic addition, however, investigation of the reactions of isocyanates is only in its initial stages.

A few reviews have been published [1,4] on the reactions of isocyanates, but fresh results make it necessary to re-examine several accepted ideas. Furthermore, many aspects of the kinetics and mechanism of these reactions are not yet clear, and demand new quantitative investigations.

2. STRUCTURE OF ISOCYANATES AND SOME OF THEIR PROPERTIES

The nature of the reactions undergone by isocyanates and their mechanism are largely determined by the structure of the NCO group and the distribution of electron density in the isocyanate molecule.

The isocyanate group NCO has a linear structure [5-7]. The angle between the R–N and N–C bonds in isocyanates RNCO varies with the nature of the group R. [5-8] There is probably no appreciable conjugation between the R and NCO groups in alkyl isocyanates, as is indicated, for example, by the low energy barrier of 49 ± 3 cal mole^{-1} to rotation of the methyl group in methyl isocyanate [6]. Thermochemical calculations suggest that the conjugation energy in isocyanates is small. According to Pauling [9] it does not exceed 7 kcal mole^{-1} in methyl and ethyl isocyanates. New data on the heats of combustion of isocyanates [10] and on the mean bond energies [11] yield a conjugation energy close to zero for methyl, ethyl, and phenyl isocyanates. This is understandable when it is remembered that the N=C and C=O π-bonds in the –N=C=O group are formed by carbon by means of p_y- and p_z-electrons, and are located in perpendicular planes. Nevertheless, the N=C and C=O interatomic distances in methyl isocyanate and isocyanic acid, measured by an electron diffraction method [5], indicate that these bonds are stronger than ordinary double bonds.

Table 1 shows that isocyanates RCNO possess large dipole moments, to which a substantial contribution is made by the NCO group. The fact that the dipole moment decreases† on passing from alkyl isocyanates to HNCO, i.e. with increase in the $R(\delta^+)-N(\delta^-)$ dipole from μ_{CN} = = 0.61 D to μ_{HN} = 1.42 D, [15] indicates that the sign of the moment of the NCO group is opposite to that of the R⇌N bond. Hence the nitrogen atom in the NCO group can be assumed to be more negative than the oxygen atom. This view is supported also by the increase in dipole moment on passing from isocyanates to isothiocyanates, which can be interpreted as resulting from replacing the oxygen atom in NCO by the less electronegative sulphur (according to Pauling [9] the electronegativities of oxygen and sulphur are 1.4 and 0.4 eV respectively).

The chemical behaviour of isocyanates agrees most completely with a distribution of charge and electron density in the NCO group represented by conjugation of the valency structures (I)–(III) [6,9]

$$\underset{\text{(II)}}{R-\ddot{\overline{N}}-\overline{\ddot{C}}=\ddot{O}:} \longleftrightarrow \underset{\text{(I)}}{R-N=C=O} \longleftrightarrow \underset{\text{(III)}}{R-\ddot{N}=\overset{+}{\ddot{C}}-\ddot{\overline{O}}:}.$$

TABLE 1. Dipole moments μ of some isocyanates and isothiocyanates.

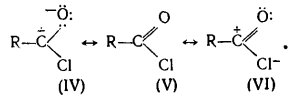
Compound	HNCO	CH_3NCO	C_2H_5NCO	C_4H_9NCO	HNCS	CH_3NCS	C_2H_5NCS	C_4H_9NCS
μ, D	1.59 [12]	2.81 [6]	2.81 [13]	2.3 [13]	1.72 [14]	3.18 [13]	3.31 [13]	3.0 [13]

† The decrease in the dipole moment of RNCO and RNCS when the alkyl radical is replaced by hydrogen is larger than would follow from vectorial addition of the dipoles [6].

TABLE 2. Rates of reaction of phenyl isocyanate with various compounds in toluene at 80° [17].

Compound	$10^4 k$, litre × mole^{-1} s^{-1}	Relative rate	Compound	$10^4 k$, litre × mole^{-1} s^{-1}	Relative rate
Butan-1-ol	30	1500	Butyric acid	2	100
Water	6	300	Butyranilide	0.3	15
Diphenylurea	2	100	Ethyl phenylcarbamate	0.02	1

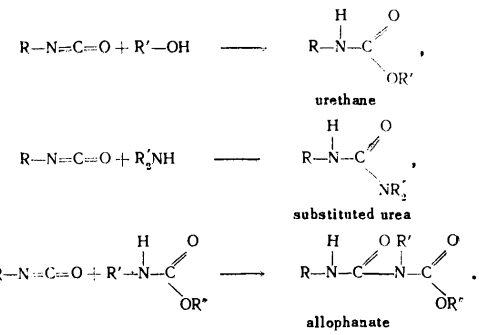
The carbon of the NCO group is a strong acceptor, resembling in several of its properties the carbon of an acid chloride — structures (IV)–(VI)



(IV) (V) (VI)

The nitrogen and the oxygen in the NCO group generally carry a negative charge, and possess electron-donor properties. This group is therefore subject to both nucleophilic and electrophilic attacks.

In most cases isocyanates behave as electrophilic reagents. Their most typical reactions are nucleophilic additions involving substances containing oxygen and nitrogen, e.g.



urethane

substituted urea

allophanate

Few thermodynamic data are available on additions to isocyanates. We can mention only the paper by Lovering and Laidler [16], who measured the heats of reaction of certain aryl isocyanates with butyl alcohols.

In the absence of catalysts, the reactivity of different nucleophilic compounds towards an isocyanate usually varies in the sequence

$$RNH_2 > ROH > H_2O > C_6H_5OH > RSH > RCOOH,$$

the sequence for amines being

$$R_2NH > RNH_2 > NH_3 > C_6H_5NH_2,$$

and that for nitrogen-containing compounds

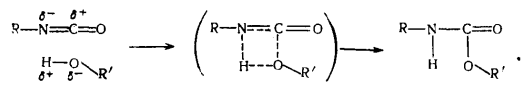
$$\underset{\text{amine}}{RNHR'} > \underset{\text{urea}}{RNHCONHR'} > \underset{\text{amide}}{RNHCOR'} > \underset{\text{urethane}}{RNHCOOR'}.$$

Numerical values of the relative rates are given in Table 2.

3. KINETICS OF THE REACTION OF ISOCYANATES WITH ALCOHOLS

The interaction of isocyanates with alcohols has been more thoroughly studied than other reactions, but even in this case the mechanism is still far from clear. Several possible reaction schemes are now being discussed in the literature, a common feature being the assumed nucleophilic attack by the alcohol or other reagent on the NCO group of the isocyanate. Non-catalytic nucleophilic addition of an alcohol to an isocyanate can be imagined as occurring in several ways. Analogous schemes may be suggested for the reactions of thiols as well as of isothiocyanates.

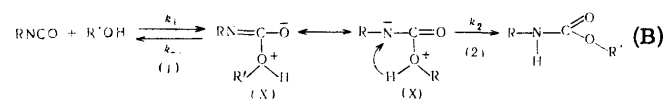
(A) Direct addition of R'OH to RNCO with the formation of a four-membered activated complex [18–20]:



(A)

Preliminary coordination corresponding to the relative arrangement of molecules in the activated complex is inherent in the formation of solvates. This mechanism is supported by the large negative entropies of activation in the non-catalytic reactions of isocyanates with alcohols [16]: in the reaction of *p*-chlorophenyl isocyanate with methanol in heptane [21], for example, $\Delta S^{\neq} = -44.5$ e.u. with $E = 8.2$ kcal mole^{-1}.

(B) Preliminary reversible addition with formation of an intermediate complex (X) of ionic structure by the scheme accepted for the reactions of other carbonyl compounds [22,23], and its subsequent unimolecular conversion into the urethane by prototropic rearrangement:



(B)

This scheme resembles that proposed by Zahradník [24] for the reactions of isothiocyanates with the hydroxide ion in aqueous–dioxan and aqueous–alcoholic solutions. The large positive values of the parameter ρ in the Hammett equation (see Section 5) observed in the reactions of isocyanates and isothiocyanates support mechanism (B) provided that (*a*) the rate of the process is limited by the nucleophilic attack (1), or (*b*) reaction (1) is rapid and reversible, the equilibrium constant increasing with increase in the electrophilic character of the substituent in group R (e.g. in phenyl).

Schemes (A) and (B) are indistinguishable by formal kinetic criteria. In both cases the reaction velocity is described by the second-order equation

$$-dC_{RNCO}/dt = kC_{RNCO}C_{R'OH}. \qquad (3)$$

For scheme (A) we have $k = k_{true}$. For scheme (B) with (*a*) $k_1 C_{R'OH} \ll k_{-1}, k_2$, we have $k = k_1 k_2/(k_{-1} + k_2)$, or in the limit, when $k_2 \gg k_1$, we find that $k = k_1$; or with (*b*) $k_1 C_{R'OH} \gg k_2$ (equilibrium), we obtain $k = Kk_2$, where K is the equilibrium constant for stage (1).

(C) Formation of the addition product X in the first stage, as in scheme (B), and its conversion into the urethane by a bimolecular reaction with a second R'OH molecule:

$$\begin{aligned} RNCO + R'OH &\underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} X, \\ X + R'OH &\xrightarrow{k_2} RNHCOOR'. \end{aligned} \qquad (C)$$

Scheme (C) was suggested by Baker and his coworkers [25,26] to explain the increase, observed under certain conditions, in the second-order rate constant with the alcohol content of the mixture. In fact, with $k_1 C_{R'OH} \ll k_{-1}, k_2$, when the

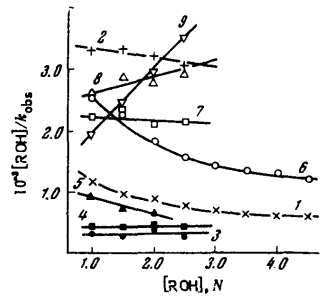


Fig. 1. Reactions of phenyl isocyanate with alcohols and glycols:
1) ethanol; 2) 2-ethoxyethanol; 3) trimethylene glycol; 4) tetramethylene glycol; 5) hexamethylene glycol; 6) ethylene glycol; 7) diethylene glycol; 8) triethylene glycol; 9) tetraethylene glycol[27].

method of quasi-stationarity with respect to the intermediate product is applicable, we have for the rate of the process, in conformity with scheme (C), the equation

$$-dC_{RNCO}/dt = \\ = k_2 C_{RNCO} C^2_{R'OH}/(k_{-1} + k_2 C_{R'OH}). \quad (4)$$

Consequently, if we start from Eqn. (3) in analysing the rate of the process, the "second-order constant" observed here will be the apparent parameter

$$k_{obs} = k_2 C_{R'OH}/(k_{-1} + k_2 C_{R'OH}). \quad (5)$$

Many facts have now been accumulated to indicate that in most cases the second-order relation is strictly satisfied up to considerable extents of conversion in reactions of both monomeric and polymeric compounds[21,27]. There are also data which in several instances do not support Baker's mechanism. Thus Robertson[28], in a kinetic study of the reaction of phenyl isocyanate with a series of alcohols and glycols, has obtained results which in most cases are not described by Eqn. (5): i.e. a linear relationship between C_{ROH}/k and C_{ROH} having a positive slope is not observed (Fig. 1).

4. EFFECT OF THE PROPERTIES OF THE MEDIUM ON THE REACTION OF ISOCYANATES WITH ALCOHOLS

The dependence of the second-order rate constant on the concentration of alcohol in certain solvents, which has been observed by several authors, is probably associated not so much with "catalysis" by the alcohol as with the change in polar and other properties of the medium. Together with Tiger[29,30] we have established, for example, that the rate constant for the reaction of phenyl isocyanate with methanol is increased by increasing the concentration of the alcohol in dioxan solution. However, a similar increase in the rate constant is observed if the concentration of the polar dichloroethane is increased while the alcohol concentration is kept constant. Since a linear relation between the logarithm of the rate constant and Kirkwood's function $(\epsilon - 1)/(2\epsilon + 1)$ (where ϵ is the dielectric constant of the medium) is maintained in both cases, it may be concluded that it is the increase in polarity of the medium produced by adding the alcohol and the dichloroethane which is responsible for the increase in the reaction rate constant. The fact that reaction velocity increases with increase in the dielectric constant of the medium is indicated also by kinetic data on the reaction of hexamethylene di-isocyanate with alcohols in the sequence of solvents[31] toluene < *o*-chlorobenzene < nitrobenzene.

Thus the conclusion reached by Ephraim et al.[32], that increase in polarity of the medium results in suppression of the reaction, is incorrect. It is probable that, apart from polarity, specific interaction between solvent molecules and the alcohol and isocyanate molecules plays an important part in the action of the solvent on the reaction velocity. Such interaction usually results in deactivation of the reactant molecules. For example, a weakly polar solvent, which undergoes no specific interaction with the reactants, is able to accelerate the reaction. Thus, according to data obtained together with Tiger[29,30], the reaction of phenyl isocyanate with methanol becomes more rapid with increasing proportion of heptane in a mixed heptane–dioxan solvent, although the dielectric constant of the system is unchanged.

5. DEPENDENCE OF RATE OF REACTION ON STRUCTURE OF ISOCYANATE

The activity of the isocyanate group is fundamentally affected by the structure of the radical R in the RNCO molecule. In conformity with the electronic structure of NCO discussed above, electron-attracting radicals will increase the fractional positive charge on the carbon, and electron-donating radicals will diminish it.

Aromatic isocyanates are usually more active than aliphatic and aralkyl isocyanates[33]. However, results obtained by different workers yield quantitative comparisons of their reactivities which show significant differences. In the case of reaction with n-butanol in the presence of triethylamine in toluene at 37°, for example, the rate constants k' and k'' (for the first and second isocyanate groups respectively in a di-isocyanate) are[34] 330×10^{-4} and 28×10^{-4} litre mole^{-1} s^{-1} for 4-methyl-1,3-phenylene di-isocyanate, while the corresponding rate constants for hexamethylene di-isocyanate are 0.83×10^{-4} and 0.42×10^{-4} litre mole^{-1} s^{-1}. In the case of reaction with a polyethylene glycol adipate at 100° we have[35] $k = 36 \times 10^{-4}$ litre mole^{-1} s^{-1} and $E = 11$ kcal mole^{-1} for the above methylphenylene di-isocyanate, compared with values of 8.3×10^{-4} litre mole^{-1} s^{-1} and 11 kcal mole^{-1} for hexamethylene di-isocyanate.

The work of Sato[27] and of Greenshields et al.[31] shows that, at high degrees of conversion, the kinetics of the reaction of alkyl or alkylene isocyanates with alcohols diverges appreciably from a bimolecular law, owing to the greater sensitivity of the rate of the process to the catalytic effect of the urethane. In the view of the latter workers[31], the kinetics of the interation of hexamethylene di-isocyanate with butan-2-ol and with polyethylene glycol in toluene are described by the equation

$$dx/dt = \alpha(a-x)(b-x)^2 + \beta(a-x)(b-x)x, \quad (6)$$

where x is the instantaneous concentration of the urethane, a and b are the initial concentrations of the isocyanate and the alcohol respectively, and α and β are constants.

In the case of aryl isocyanates the introduction of substituents into the benzene ring changes the activity of the

NCO group. On substitution of phenyl isocyanate the reaction velocity varies in conformity with the Hammett equation [37]

$$\log(k_{subst}/k_0) = \rho\sigma, \quad (7)$$

where k_0 and k_{subst} are the rate constants for the unsubstituted and the substituted phenyl isocyanate, σ is a parameter characteristic of the substituent, and ρ is a parameter characteristic of the type of reaction and its sensitivity to the action of the substituent. The results of different authors [38,39] indicate that ρ = 1.69–1.98. It is interesting that ρ = 1.7 for substituted isothiocyanates [40]. A positive value of ρ indicates that the reaction is accelerated by the introduction of electron-attracting substituents.

Values of σ for NCO and urethane groups, like those of ρ, have not yet been determined sufficiently accurately for calculation of the reaction velocity of individual NCO groups in substituted and multifunctional isocyanates. Table 3 gives the values of σ obtained from a comparison of the reaction velocities of isocyanates with alcohols. It includes for comparison values of σ for other substituents from Hammett's data.

No results have been published on the effect of *ortho*--substituents on the activity of aryl isocyanates. This effect can be estimated by means of the Taft equation [37]. Furthermore, values of ρ usually change with variation in the temperature and in the solvent, and without a knowledge of these it is impossible to calculate the rate constants for substituted isocyanates. Results obtained by us together with Tiger [29,30], for example, indicate that the parameter ρ = 3.3 for the uncatalysed reaction of substituted phenyl isocyanates with methanol in heptane, this value falling on addition of dioxan to the heptane, and reaching 2.6 in pure dioxan.

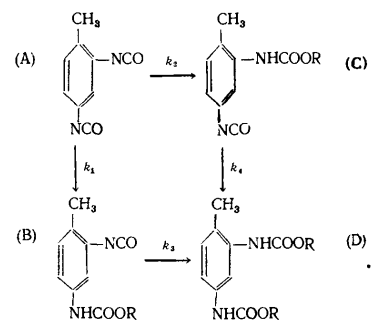
6. KINETIC FEATURES OF THE REACTION OF DI-ISOCYANATES WITH ALCOHOLS

The possibility of calculating in advance the rate constant, for interaction with an alcohol, of each of the NCO groups in a di-isocyanate is not only of theoretical but also of great practical importance. The unequal reactivities of the two NCO groups has a fundamental effect on the kinetics of the formation of the polyurethane, its average molecular weight, and the character of the molecular-weight distribution [41]. This appears especially clearly in one of the most widely used technical products — a mixture of 2- and 4-methyl-1,3-phenylene di-isocyanates.

The difference in reactivity between the NCO groups should be especially marked in 4-methyl-1,3-phenylene di--isocyanate, since the group in position 1 is not "blocked" by the methyl substituent, it is activated by the isocyanate group in position 3, and the second NCO group reacts mainly only when substitution by the urethane group has already occurred in position 1. Consequently the numerous published values for k' and k'' in di-isocyanates actually represent in the former case (k') mainly the reactivity of the first, most active NCO group in the di-isocyanate, and k'' (indirectly) the reactivity of an isocyanate group which is now present in an alkoxycarbonylaminophenyl isocyanate, not in a di-isocyanate. After reaction of the more active NCO group in position 1 in 4-methyl-1,3-phenylene di-isocyanate, for example, the NCO group in position 3 is now accompanied by a new *meta*-substituent — the urethane group — and the parameter σ changed from ~ 0.43 to close to zero. With ρ = 2, this corresponds, as follows from the Hammett equation, to an almost tenfold increase in the rate constant, which can by no means be neglected, as is done by Ferstandig and Scherrer [33].

The use above of the terms "mainly" and "indirectly" is not accidental. The point is that calculation of the rate constants from two linear sections in the anamorphoses of the kinetic curves, as is done by the authors of almost all existing papers, is sometimes not altogether correct, and frequently altogether incorrect. Let us consider this in greater detail.

If we carry out the reaction of 4-methyl-1,3-phenylene di-isocyanate with excess of an alcohol ROH, we must distinguish four pseudounimolecular reactions:



The variation in the total concentration of isocyanate groups [NCO] = 2[A] + [B] + [C] can be represented by the equation

$$[NCO] = [A]_0\left\{2e^{-(k_1+k_2)t} + \frac{k_1}{k_3-k_1-k_2}\left[e^{-(k_1+k_2)t} - e^{-k_3t}\right] + \frac{k_2}{k_4-k_1-k_2}\left[e^{-(k_1+k_2)t} - e^{-k_4t}\right]\right\}. \quad (8)$$

Brock [39] used the Hammett equation to estimate the ratios between k_1–k_4, and adopted the values $k_2 = 0.34k_1$, $k_3 = 0.0745k_1$, and $k_4 = 0.219k_1$. Putting $k_1 = 0.01$, he plotted by means of the above equation the time variation in the concentrations of the compounds A, B, and C and in the total concentration of isocyanate groups. When log [NCO] is plotted against t, an anamorphosis is actually obtained consisting of two linear sections, from which the apparent rate constants k' and k'', which do not correspond to the true values k_1 and k_2, can be found. In fact values of k' = = 0.0053 and k'' = 0.001 were obtained, instead of the values $k_1 = 0.01$ and $k_2 = 0.034$ originally introduced into the calculation.

Values of the constants and their ratios, obtained by different authors under closely similar conditions, often differ substantially from one another. Table 4 gives rate constants for reaction of the two NCO groups in 4-methyl--1,3-phenylene di-isocyanate with alcohols. The data of

Morton and Deisz [42] differ markedly from those obtained by Tazuma under similar conditions. The constants k' and k'', calculated by Burkus and Eckert [34] from a simple two-stage scheme using Frost's improved method [43] in the case of the unsymmetrical 4-methyl-1,3-phenylene di-isocyanate, are composite quantities, which do not reflect the reactivities of the two NCO groups.

With rise in temperature the difference in reactivity of the NCO groups in a di-isocyanate and the urethane–isocyanate is usually smoothed out, and the break in the anamorphosis of the kinetic curve disappears. This occurs earlier the less marked the inductive or steric interaction between the two reaction centres in the di-isocyanate. Even with 4-methyl-1,3-phenylene di-isocyanate the anamorphosis of the kinetic curve has no breaks at 100°. In the case of diphenylmethane *pp'*-di-isocyanate the anamorphosis has no break up to 70% conversion even at 30°. [1]

It is quite clear that constants for the individual stages in such multistage consecutive and parallel reactions as those of unsymmetrical di- and tri-isocyanates can be obtained only by means of electronic computers. An example is provided by the work of Ferstandig and Scherrer [33], who give a series of reliable values of the constants for several symmetrical aryl and aralkyl di-isocyanates.

7. DEPENDENCE OF RATE OF INTERACTION OF ISOCYANATES WITH ALCOHOLS ON THE STRUCTURE OF THE ALCOHOL

The activity of an alcohol depends both on the position of the hydroxyl and on the presence of substituents in the molecule. Available data are unsystematic and frequently contradictory. However, it has been firmly established that primary hydroxy-groups are more active than secondary hydroxyls. According to Lovering and Laidler [16], for example, the observed rate constants for the reactions of phenyl isocyanate with n-C_4H_9OH, iso-C_4H_9OH, and s-C_4H_9OH in alcohol at 25° are respectively 4.6 × 10^{-4}, 3.0 × 10^{-4}, and 1.44 × 10^{-4} litre mole^{-1} s^{-1}. Dyer et al.[44] obtained values of 4.4 × 10^{-4} and 1.4 × 10^{-4} litre mole^{-1} s^{-1} for the reaction rate constants of phenyl isocyanate with n-C_4H_9OH and s-C_4H_9OH in xylene at 25°.

The rate constants for the reaction of methylphenylene di-isocyanate with glycols at 40° are 0.4 × 10^{-4} and 0.78 × × 10^{-4} litre mole^{-1} s^{-1} for polyoxypropylene glycol and polyoxyethylene glycol [45].

t-Butyl alcohol reacts still more slowly. Thus according to Baker [25,26] the rate constants for the reaction of phenyl isocyanate in dibutyl ether at 20° with the series of alcohols CH_3OH, C_2H_5OH, $CH_3CH(OH)CH_3$, and t-C_4H_9OH are (0.28, 0.48, 0.23, and 0.008) × 10^{-4} litre mole^{-1} s^{-1}.

However, the difference in rates is especially large for the catalysed reactions. According to Wissman et al.[45], for example, the rate constants for the reactions of methylphenylene di-isocyanate with glycols at 40° in the presence of 0.005% of dibutyltin dilaurate are 0.87 × 10^{-4} and 27.1 × 10^{-4} litre mole^{-1} s^{-1} for polyoxypropylene glycol and polyoxyethylene glycol.

Both the absolute rates of reaction of primary and secondary alcohols with isocyanates and their ratio depend on the nature and concentration of the catalyst. Data for a series of alcohols with phenyl isocyanate in toluene solution show (Table 5) that dibutyltin dilaurate has a particularly strong effect in increasing the difference in reaction velocity between primary and secondary hydroxy-groups. It is interesting that with polyoxypropylene glycol two stages can be observed, with constants k_{prim} and k_{sec}, characterising interaction of phenyl isocyanate with the primary and the secondary hydroxyls of the diol respectively [47]. However, it is difficult to assume that the investigators were able to separate quantitatively these two stages of the reaction. Both constants are evidently effective values.

The reactivity of a molecule is diminished by the introduction of electron-attracting substituents, owing both to a decrease in the basic character of the oxygen of the hydroxy-group and to the appearance of steric hindrance. Thus the following rate constants have been determined for the reaction of 3,3-dinitropentamethylene di-isocyanate with alcohols in dimethylformamide at 30° [48]

	k, litre mole^{-1} s^{-1}
Propane-1,3-diol	3×10^{-4}
3,3-Dinitropentane-1,5-diol	0.29×10^{-4}
2,2-Dinitropropane-1,3-diol	0.064×10^{-4}

Detailed investigations of the reactions of nitro-alcohols with phenyl isocyanate have recently been made by Solodova [49] (Table 6). The change in reactivity on passing from primary to tertiary alcohols is found [49] to be less marked with nitro-alcohols (Table 7), which is attributed to steric causes. Since the nitro-alcohols already contain "bulky" nitro-groups, which cause strong steric blocking of the hydroxyls, the introduction of alkyl groups (in the case of secondary and tertiary alcohols) has less effect on the activity of the alcohol.

Introduction of a methoxy-group into an alcohol molecule enhances its activity in comparison with a methyl or an ethyl group. For the reaction of 4-methyl-1,3-phenylene di-isocyanate in ethyl acetate at 78°, for example, the rate constants with 2-methyl-2-nitropropane-1,3-diol and with 2-hydroxymethyl[methoxymethyl(?)]-2-nitropropane-1,3-diol are respectively 14.6×10^{-4} and 40.0×10^{-4} litre × × mole^{-1} s^{-1}.

The chain lengths of polymeric diols have an extremely important effect on the reactivity of their terminal groups. Although very little information has been published on this topic, the available data suggest that the degree of polymerisation has a slight effect on the rate constant [28,36,45,50] (Table 8). At low degrees of polymerisation, when the length of the glycol chain is 3–6 monomer units, some variation in the rate constant with the number of units is observed. However, the fact that the type of variation depends on the concentration of the diol (Table 9) suggests rather that the ratio between terminal groups and groups in the chain influences the properties of the medium, and hence the reaction velocity.

The degree of multifunctionality of polyols has little effect on the rate constant per equivalent (Table 10).

8. CATALYSIS IN THE REACTION OF ISOCYANATES WITH ALCOHOLS

The question of the mechanism of catalysis in reactions of isocyanates with alcohols is closely interlinked with the problem of the mechanism of catalysis in reactions of other carbonyl compounds [22] on the one hand, and with the activation of alcohols and other hydroxyl compounds [51] on the other. However, apart from the extremely interesting and little studied theoretical aspects of catalysis in the former reactions, the problem is also of great practical importance.

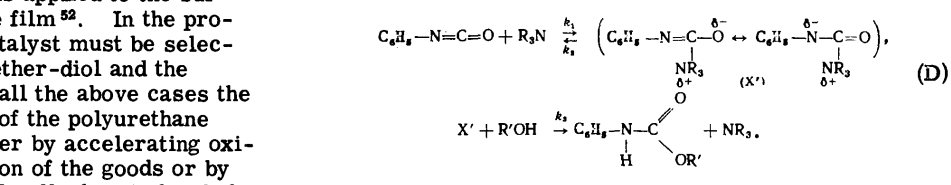
In the choice of industrial catalysts for the manufacture of polyester–urethane rubbers, the requirements which they have to meet depend on the character of the process and its technology. In the moulding of articles directly from the polymer mass, for example, it is necessary that it should retain its plasticity and mobility for a certain time after the reactants have been mixed, and then be converted quite rapidly into the completely vulcanised polyurethane rubber [1]. The requirements are the same in the application of polyurethane films and lacquers: the mixture must remain "lively" from the instant of mixing of the polyol and the di-isocyanate until it is applied to the surface, and then set rapidly to a stable film [52]. In the production of polyurethane foams the catalyst must be selective towards the di-isocyanate–polyether-diol and the di-isocyanate–water reactions. In all the above cases the catalysts should not promote ageing of the polyurethane rubbers obtained with their aid, either by accelerating oxidative degradation or photodegradation of the goods or by catalysing the formation of additional, allophanate bonds by interaction with traces of unchanged isocyanate.

From the above, far from complete list of the varied requirements to be met by the catalysts it is evident that a rational choice thereof can be made only on the basis of systematic combined investigations of the kinetics, the mechanism, and the chemistry of their action. Only a few quantitative studies have been published on the nature and action of catalysts for the reactions of isocyanates.

Although a large number of catalysts have been described, the problem of the mechanism of catalysis, i.e. of why a catalyst enhances the activity of a reactant molecule, remains unsolved. Its solution is complicated by the fact that compounds belonging to different classes, and frequently having directly opposite properties, catalyse the reactions of isocyanates with alcohols. The catalysis of the reactions of isocyanates has several features in common with that of reactions of certain carbonyl compounds, e.g. acid chlorides, anhydrides, esters, etc. In the present case, however, peculiarities are present associated both with the structure of the NCO group and with the fact that in all the above cases nucleophilic substitution is involved, whereas nucleophilic addition occurs in the reactions of isocyanates. Like the hydrolysis and the alcoholysis of certain carbonyl compounds, the reactions of isocyanates are accelerated by bases [53,54]. They are typically catalysed by organic compounds of metals [4], which is less characteristic of carbonyl compounds, but nevertheless has been described in the literature [55]. Acid catalysis, which is very widespread with esters and amides, is not very effective with isocyanates, which makes them akin to acid chlorides. This is apparently associated in both cases with the weak basic character of the compounds. As in the case of acylation with acid chlorides and anhydrides, the addition of alcohols to isocyanates is accelerated by tertiary amines [4,56,57].

Many authors explain the action of a catalyst by the occurrence of complex formation, but it is not sufficient to assume that a catalyst forms a complex with one of the reactants. It is not even sufficient to establish that a complex is in fact formed: many cases are known in which the complexes observed do not take part in the reaction. It is necessary to show that the reaction velocity is proportional to the concentration of a complex formed by the catalyst with one of the reactants. To understand the action of a catalyst, it is very important to ascertain why formation of a particular complex results in enhanced reactivity of a reactant molecule. Catalysts of amine type have been studied the most thoroughly. However, the mechanism by which they catalyse the reaction of isocyanates with alcohols is still not clear.

The possibility that the amine activated both the isocyanate molecule [25,26,58,59] and the molecule of the hydroxyl compound [60–62] has been discussed since the first quantitative work on catalysis [25,26]. In the first case a scheme (D) was proposed [25,26] in conformity with existing views on the catalysis by amines of nucleophilic substitution reactions at a carbonyl group [22]



(D)

As in the case of the catalysis of acylation by acid chlorides [57], it may be supposed that the appearance of the extremely strong electron-attracting substituent $^{+}NR_3$‡ substantially increases the deficiency of electron density on the carbon, while a new electron-donor centre appears. Both factors favour subsequent addition of an alcohol molecule to the complex X″.

The scheme (D) led to the rate equation

$$-dC_{RNCO}/dt = \frac{k_1 k_3 C_{R'OH} C_{RNCO} C_{NR_3}}{k_2 + k_3 C_{R'OH}}, \qquad (9)$$

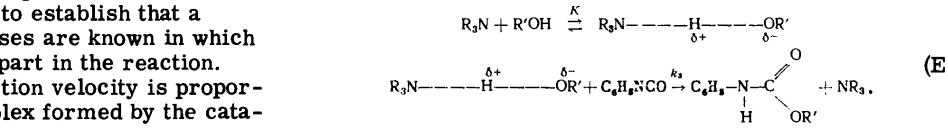
based on the hypothesis of a steady state with respect to the intermediate complex, consumption of the complex being more rapid than its formation. Some authors consider [25,26,58] that the correctness of scheme (D) is confirmed by the fact that the kinetic data give linear plots of $1/k_{cat}$ against $C_{R'OH}$ in conformity with Eqn. (9), where $k_{cat} = k_1 k_3/(k_2 + k_3 C_{R'OH})$ is the catalytic rate constant in the equation for the observed rate constant

$$k_{obs} = k_0 + k_{cat} C_{NR_3}, \qquad (10)$$

k_0 being the rate constant for the uncatalysed reaction. An equation similar to (9) can be obtained also on the hypothesis that equilibrium in the formation of the complex is established rapidly, whereas consumption of the complex is slow

$$-dC_{RNCO}/dt = \frac{K k_3 C_{R'OH} C_{RNCO} C_{NR_3}}{1 + K C_{R'OH}}. \qquad (9')$$

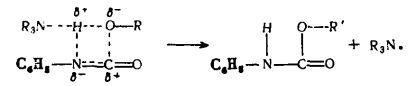
On the basis of scheme (D), however, the slope of the above linear plot should be independent of the nature of the alcohol in both cases, which is not in fact so [25,26]. The sole piece of work [63] in which a complex resembling the postulated intermediate product X′ was supposed to have been detected by infrared spectroscopy proved to be erroneous [47,62]. A fresh discussion has now appeared in the literature of a mechanism of catalysis by amines involving formation of an amine–alcohol complex [62], which then reacts slowly with the isocyanate (scheme E)



(E)

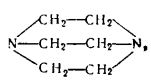
‡ For example, the value of σ^* for $^{+}N(CH_3)_3$ is +5.3, compared with +3.9 and +3.1 for NO_2 and F [37].

The latter reaction may involve formation of a four-membered activated complex[62], e.g.



The kinetic equation for mechanism (E) is identical with Eqn. (9). On the basis of formal kinetic data, therefore, no choice can be made between the two mechanisms. Mechanism (E) is supported by the fact that various amines can form hydrogen bonds with compounds containing OH and SH groups[51,62,64,65]. Formation of such complexes substantially polarises the OH and SH bonds, which is shown in an increase in the dipole moments, the polarisation increasing monotonically with the basic strength of the amine[51]. The formation of hydrogen bonds quite often increases the reactivity of compounds containing hydroxy-groups[66].

Until recently the absence of a direct correlation between the basic strength of an amine and its catalytic activity told against scheme (E). Although increasing basic strength of the amine is usually accompanied by enhancement of catalytic activity, several cases are known in which a feebly basic amine is highly active, and conversely. A linear relationship has been found[59] between the rate constant for the reaction of phenyl isocyanate with 2-ethylhexanol in benzene and the pK_a values of a series of amines. With pentamethylguanidine and 1,4-diazabicyclo[2,2,2]octane (triethylenediamine), however, the rates are respectively an order of magnitude smaller than, and five times as great as, would be expected from their basic strengths. The high catalytic activity of triethylenediamine is connected with its structure



which makes both nitrogen atoms accessible to attack by the isocyanate.

On the other hand, diethylaniline, which has similar basic strength, possesses practically no activity, because the nitrogen atom is strongly screened by the ethyl groups. A similar discrepancy between the basic strength of an amine and its catalytic activity is observed in the catalysis of acylations with acid chlorides[57]. Special experiments have shown that an important part is played in these cases by steric hindrance to the approach of the amine catalyst to the acid chloride. It has been shown[59], however, that the activity of amines with respect to the polymerisation of phenyl isocyanate varies strictly in the sequence of their basic strengths (Table 11), which suggests that steric hindrance to the approach of an amine to the isocyanate is absent. If an amine–isocyanate complex is actually the active complex formed in the first stage of the catalytic reaction (scheme D), steric hindrance should arise only when the alcohol attacks the complex molecule.

According to Flynn and Nenortas[59] mechanism (E) is not consistent with the increase in the isotope effect, with increasing basic strength of the amine, observed in the reaction of phenyl isocyanate with 2-ethylhexanol. These workers consider that, if such a mechanism were operative, increase in basic strength of the amine should be accompanied by an increase in the "detachment" of hydrogen from the alcohol, which should diminish the role of the isotope effect, in contradiction to the results obtained§.

All comparisons between the activity of an amine catalyst and its basic character have been based on the value of pK_a in aqueous solution as a measure of basic strength, although the reaction is carried out in non-aqueous media. Transfer from one solvent to another may change not only the absolute basic strength but also the sequence of amines with respect to this property[68]. In fact, from a comparison of the rate of the catalysed reaction between phenyl isocyanate and 2-ethylhexanol in ethyl acetate, Farkas and Strohm[62] found a correlation between the rate constant k_{cat} and the parameter $E_{\frac{1}{2}}$¶, characterising the basic strength of an amine in this non-aqueous solvent (Table 12). Therefore these workers[62], in agreement with the results of other investigations[60,61], give their preference to scheme (E) in catalysis by amines. It is evident from Table 12 that there is no correlation between k_{cat} and pK_a.

It is interesting that, when an isocyanate reacts with 2-mercaptoethanol, the uncatalysed reaction yields only the *O*-urethane, the *S*-urethane being formed when an amine catalyst is introduced into the reaction medium:

The explanation given[60] for this fact is that the amine interacts preferentially with the more acidic SH group to form intermediate compounds of the type $R_3N\ldots H{-}SCH_2CH_2OH$, with subsequent ionisation of the mercaptoalkanol. Since

TABLE 11. Relative activity of a series of amines in the polymerisation of phenyl isocyanate and in the formation of a urethane in the reaction of phenyl isocyanate with 2-ethylhexanol and the isotope effect in the latter reaction compared with the basic strength of the amine[59].

Amine	pK_a	Catalytic activity in: polymerisation	Catalytic activity in: urethane formation	k^H_{cat}/k^D_{cat}

TABLE 12. Comparison of catalytic activity, pK_a value, and basicity in ethyl acetate ($E_{\frac{1}{2}}$) for a series of amines in the reaction of phenyl isocyanate with 2-ethylhexanol[62].

Amine	k_{cat}, g mole^{-1} s^{-1}	Relative activity	pK_a	$E_{\frac{1}{2}}$
Triethylenediamine	5600	1	8.60	124
2-Methyl-1,4-diazabicyclo[2,2,2]octane	5130	0.92	8.86	168
Triethylamine	500	0.19	10.64	186
N-Ethylmorpholine	315	0.05	7.15	291

§ The arguments of Flynn and Nenortas are by no means self-evident. In the reaction of tritiated and light water with triphenylsilane catalysed by bases, for example, the increase in basic strength on passing from pyridine to aqueous–alcoholic alkali results in an increase in k^H_{cat}/k^D_{cat} by a factor of 2.3[67].

¶ According to Hall[69] the basic strength of an amine in a non-aqueous medium is measured by the position of the point of inflection on the curve for potentiometric titration with perchloric acid (72% $HClO_4$ in dioxan), expressed in millivolts — $E_{\frac{1}{2}}$.

$HOCH_2CH_2S^-$ is more basic than $HSCH_2CH_2OH$, reaction in the presence of a catalyst yields the *S*-urethane.

It must be noted that the concept of catalysis as a result of activation of an OH or SH bond by hydrogen bonding leaves it obscure why only amines and a few oxygen compounds which do not possess a high donor ability — tetrahydrofuran, dioxan, and ethers — should exhibit catalytic properties. In the relationship between the basicity constants of substances and their capacity for hydrogen bonding there is usually no qualitative difference between nitrogen and oxygen compounds[70], which simply arrange themselves one after the other in the sequence of their basic strengths. Nevertheless, transfer from hydrocarbon solvents to ethers, dioxan, and tetrahydrofuran[28] is accompanied by a sharp drop in reaction velocity, which is clearly caused by the formation of hydrogen bonds.

Organometallic compounds and metal salts have recently begun to be widely used as catalysts for the reactions of isocyanates. They include, for example, alkyl carboxylates and alkyl halides of Sn^{IV} (dibutyltin diacetate, dibutyltin dichloride, etc.); octanoates, stearates, and naphthenates of Cr^{III}, Ni^{II}, Zn^{II}, Bi^{III}, Fe^{III}, Sn^{II}, etc.; and acetylacetonates of Fe^{III}, Pb^{II}, Cu^{II}, Mn^{III}, Co^{II}, etc. A quite full analysis of published data will be found in papers by Farkas and Mills[4] and by Robins[71]. Table 13 gives for comparison the relative catalytic activities of two typical catalysts of different classes.

Organometallic compounds are more active by factors of 10^2–10^4 than amine catalysts of average activity. Although a large number of organometallic catalysts have been described[72–74], there is as yet no generally accepted view of the nature of their catalytic action. Again, the possibility has been discussed that a complex may be formed with the isocyanate[75], with the alcohol[76], and with both components[71,72,77]. Results have been published on the changes undergone by the spectral characteristics of isocyanates and alcohols when metal-containing catalysts are added to the system. For example, cobalt stearate[77] and cobalt octanoate[75] form with phenyl isocyanate complexes which are apparent in the infrared and ultraviolet spectra. Moreover, the catalytic activity of cobalt octanoate increases when it is kept mixed with phenyl isocyanate in toluene for 20 min or longer[75], which suggests the slow formation of an active product.

Recent results indicate[78] that tin compounds containing the Sn–O bond, e.g. R_3SnOR', readily add on to isocyanates and isothiocyanates to form carbamates containing tin:

$$(C_4H_9)_3SnOCH_3 + C_6H_5{-}N{=}C{=}O \rightarrow (C_4H_9)_3Sn{-}N(C_6H_5){-}COOCH_3.$$

Bloodworth and Davies suggest a mechanism of catalysis by organotin compounds of the reaction between isocyanates and alcohols, based on the fact that the above compounds readily react with alcohols to form urethanes. In the first stage any tin(IV) compound gives with an alcohol R'OH or phenol present in the system a tin alkoxide R_3SnOR'. This is followed by the reactions

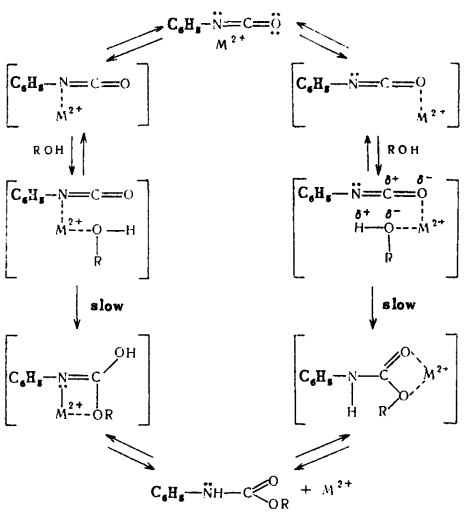
$$R_3SnOR' + C_6H_5{-}N{=}C{=}O \rightarrow R_3SnN(C_6H_5)COOR',$$
$$R_3SnN(C_6H_5)COOR' + R'OH \rightarrow R_3SnOR' + C_6H_5NHCOOR'.$$

However, the absence of quantitative data, on the basis of which the rates of known catalytic reactions could have been compared with those of the reactions suggested by these workers[78], makes it impossible either to accept or to reject this mechanism.

Observations have been made also on the activating effect of a metal-containing catalyst on the alcoholic component of the reaction mixture. For example, Blagonravova et al.[76] found that preliminary treatment of 2-hydroxyethyl adipate with zinc oxide or an acetate of this or several other metals activates the diol by forming an alkoxide. The sequence of activities is as shown in Table 14.

Complex formation between an organometallic catalyst and an alcohol is indicated also by an examination of the proton magnetic resonance spectra. According to Frisch et al.[47] 0.05–0.855 M dibutyltin dilaurate produces a substantial chemical shift (δ from 2.56 to 3.99 p.p.m.) of the hydroxyl proton in 1-methoxypropan-2-ol dissolved (0.54 M) in carbon tetrachloride, the value of δ being proportional to the concentration of tin(IV). Zabrodin and ourselves[79] have obtained similar results from an investigation of the proton resonance spectra of solutions of methanol in carbon tetrachloride in the presence of di-n-butyltin diacetate and dilaurate.

Several authors have concluded[71,72,77] that the active species is a ternary equilibrium complex containing the catalyst, the isocyanate, and the alcohol. Robins[71] puts forward two schemes for the formation of an active ternary complex of this type, of which scheme (F) applies to simple alcohols:



(F)

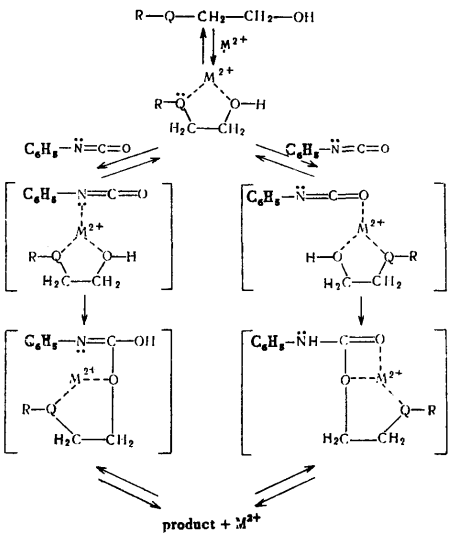
TABLE 13. Comparison of activities of triethylamine and di-n-butyltin diacetate as catalysts in the reaction of phenyl isocyanate with methanol in dioxan as solvent (Ref. 4, p. 421).

Catalyst	Concn., mole %	$10^4 k$, litre mole^{-1} s^{-1}
No catalyst	—	0.51
Triethylamine	1	6.7
Di-n-butyltin diacetate	0.009	118.0

TABLE 14. Comparison of catalytic activities of acetates of various metals[76].

Acetate	Activity	Acetate	Activity
K	3.45	Cu	0.90
Na	2.49	Ca	0.64
Co	1.20	Mg	0.53
Zn	1.00		

When the alcohol contains an "active" donor group Q in the α-, β-, or γ-position with respect to the hydroxy-group, the scheme of the reaction appears as follows:



(G)

In effect, neither mechanism is based on any strict evidence, but merely on general considerations relating to the structure of the reactants and on qualitative data on the activities of a series of catalysts, containing metal atoms or ions, towards isocyanates and alcohols of various structures.

In conformity with the above schemes, Robins formulates the following requirements to be satisfied by an organometallic catalyst: (*a*) it must possess some minimum capacity for complex formation in order that an adequate concentration of the ternary complex shall be maintained; (*b*) it should not suppress the nucleophilic character of the alcoholic oxygen, at any rate not sufficiently to make the reaction improbable; and (*c*) it should not yield with the reaction products a stable complex, which would make departure of the metal ion from the reaction zone improbable.

To obtain quantitative data on the alcohol–isocyanate reaction catalysed by tin(IV) compounds, we have recently made a detailed kinetic study of the reaction between methanol and *p*-chlorophenyl isocyanate in heptane in the presence of a series of tin compounds (di-n-butyltin diacetate, dilaurate, and dichloride)[79-82]. The rate of the catalytic reaction was shown (Fig. 2) to be proportional to the concentration of the alcohol–catalyst complex, which was determined independently by a spectroscopic method. Experiments on the thermodynamics of complex formation showed it to be an equimolecular complex. The equilibrium constant, heat of reaction, and entropy of complex formation were determined.

The equation for the reaction, deduced on the assumption that the equilibrium

$$Sn^{IV} + ROH \overset{K}{\rightleftharpoons} ROH \cdot Sn^{IV} \qquad (11)$$

was established, with a slow bimolecular interaction between the complex and the isocyanate

$$ROH \cdot Sn^{IV} + R'NCO \xrightarrow{k} R'NHCOOR + Sn^{IV}, \qquad (12)$$

satisfactorily reproduces the kinetic data obtained over wide ranges of temperature and concentration:

$$w_{cat} = k_{cat} C_{R'NCO} C_{Sn^{IV}}, \qquad (13)$$

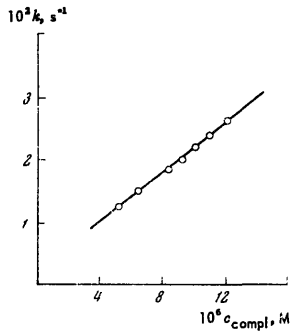


Fig. 2. Dependence of rate constant for the reaction of *p*-chlorophenyl isocyanate with methanol in heptane in the presence of di-n-butyltin dilaurate at 25° on the concentration of the alcohol–catalyst complex.

where w_{cat} is the rate of the catalytic reaction, and

$$k_{cat} = C_{ROH} k K / (1 + K C_{ROH}). \qquad (14)$$

It is seen from Eqn. (14) that both k and K can be evaluated from a plot of $1/k_{cat}$ against $1/C_{ROH}$. The complex formation constants K found from the kinetic data agree, within the limits of experimental error, with those measured directly. Values of k and K are listed in Table 15.

From the temperature dependence of k and K, values were obtained of $E = 6.7 \pm 0.5$ kcal mole^{-1} and $\Delta S^{\neq} = -23.7$ cal mole^{-1} deg^{-1}, and also the heat and the entropy of complex formation $\Delta H_{compl} = -1.3 \pm 0.5$ kcal mole^{-1} and $\Delta S_{compl} = -3.2 \pm 1.0$ cal mole^{-1} deg^{-1}. Within the limits of experimental error, the latter two values are close to the corresponding values, -0.9 ± 0.5 kcal mole^{-1} and -1.2 ± 1.0 cal mole^{-1} deg^{-1}, found directly from spectrophotometric data on complex formation between dibutyltin dilaurate and methanol.

The results obtained show that introduction of a catalyst increases the rate constant for the step involving interaction between isocyanate and alcohol, by a factor of about 10^6 in comparison with the uncatalysed reaction. Comparison of the kinetic parameters for the uncatalysed and the catalysed reactions of *p*-chlorophenyl isocyanate with methanol shows that decrease in the activation energy from $E_{uncat} = 8.2$ kcal mole^{-1} to $E_{cat} = 6.7$ kcal mole^{-1} results in an increase in rate by a factor of about 10, the main acceleration of the process (by a factor of 10^5) being a result of a sharp decrease in the negative entropy of activation from $\Delta S^{\neq}_{uncat} = -44.5$ cal mole^{-1} deg^{-1} to $\Delta S^{\neq} = -23.7$ cal $\times$ $\times$ mole^{-1} deg^{-1}: i.e. the structural requirements when the reactants approach one another in the reaction step become less rigorous. Since in our experiments the reaction medium was n-heptane, solvation phenomena played little part in the variation in $\Delta S^{\neq}$, everything being determined by the structure of the activated complex. In the uncatalysed reaction, in which a four-membered activated complex is formed in a single step, rigid limitations are imposed on the mutual disposal of isocyanate and alcohol molecules, which is reflected in the large negative entropy of activation.

Table 15 shows that the constant K, determined from kinetic data, did not change on passing from *p*-chlorophenyl to phenyl and *m*-chlorophenyl isocyanates. This provides further confirmation that only the alcohol is involved in the complex formation which is active in catalysis.

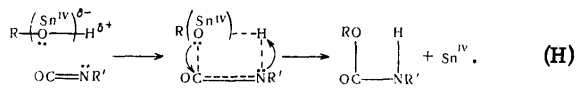
TABLE 15. Temperature dependence of k and K for various phenyl isocyanates.

T, °K	$10^3 k$, litre mole^{-1} × ×s^{-1} p-chlorophenyl	K, litre mole^{-1} p-chlorophenyl	K, litre mole^{-1} phenyl	K, litre mole^{-1} m-chlorophenyl
25	1.26	5.9	5.9	5 6
35	1.76	5.5	—	—
45	2.56	5.1	—	—

Since a specific feature of quadrivalent tin compounds is their ability to form donor–acceptor complexes, it may be supposed that the active intermediate product in the catalytic reaction between isocyanate and alcohol is formed by vacant 5*d*-orbitals of the tin and the lone pair of electrons on the basic oxygen of the alcohol. Apparently the main result of interaction between alcohol and organotin catalyst which accelerates the reaction is a change in properties of the hydroxy-group: firstly, the dipole moment of the bond is increased by the redistribution of electron density accompanying complex formation, and such redistribution can be a consequence not only of the formation of an O–Sn bond but also of the presence of conjugation between vacant 5*d*-shells of the tin and a free pair of 2*s*-electrons of the alcoholic oxygen not involved in formation of the O–Sn bond; secondly, the OH bond is lengthened by the diminution in the density of the cloud of valency electrons.

It is still too early to specify the mechanism of the reaction between the alcohol–catalyst complex and the isocyanate, but two probable routes can be imagined for the interaction.

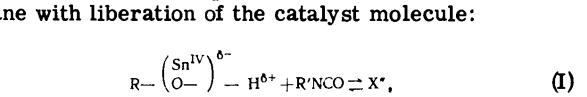
1. Reaction takes place in a single step with simultaneous transfer of a lone pair of electrons from the isocyanate nitrogen atom to the alcoholic proton and from the alcoholic oxygen to the isocyanate carbon[18–20]:



(H)

With this reaction mechanism, lengthening the OH bond and bringing it close to the C=N bond length in the isocyanate group (1.18 Å) should substantially facilitate formation of the four-membered activated complex and lower the absolute value of the negative entropy of activation.

2. Reaction takes place in stages. In the first stage the isocyanate is attacked by the alcoholic proton in the complex with formation of an intermediate product X″, which is ionic or polar in nature. The bond thus formed results in substantial activation of the carbonyl carbon in the product X″ by the appearance on it of a deficiency of electron density, and hence a fractional positive charge. The alcoholic oxygen is still firmly bound to the tin of the catalyst. In the second stage, as a result of detachment of the alcoholic oxygen from the tin and its transfer to the carbon of the isocyanate, which has already added on a proton, the intermediate product X″ is converted into a urethane with liberation of the catalyst molecule:



(I)

With such a two-stage mechanism, involving the intermediate formation of linear activated complexes, the entropy of activation should be considerably less negative than in the case of the uncatalysed reaction.

It is as yet difficult to tell which of these schemes operates during the reaction. However, examination of either of them leads to the extremely interesting conclusion that the reaction rate constant depends on the equilibrium constant of the intermediate complex. In the above cases the reactivity of the alcoholic hydrogen should increase with the stability of the complex. On the other hand, increase in its stability will diminish the nucleophilic character of the oxygen, and thereby diminish its reactivity towards the isocyanate carbon. If these views on the reaction mechanism are correct, both a considerable increase in stability of the complex and a considerable decrease should lower the rate constant of the catalytic reaction. The most active catalysts should be those which form complexes of optimum stability, characterised by definite values of the equilibrium constant.

The presence of a maximum in the activities of the series of catalysts investigated (Fig. 3) provides still further support for our hypothesis on the nature of the catalytic effect of organotin compounds in reactions between isocyanates and alcohols.

Complex formation between an organotin compound and an alcohol results in increased mobility of the hydroxyl hydrogen and an enhancement of its electrophilic activity towards the NCO group.

In the case of a catalytic reaction of this type, a change in the mechanism of addition is apparently to be expected, from nucleophilic to electrophilic. Such a change should be accompanied by a decrease in the absolute magnitude of the parameter $\rho > 0$ in the Hammett equation on passing from the non-catalytic to the catalytic reaction. Fig. 4 shows the dependence of $\log(k/k_0)$ on σ for a series of substituted phenyl isocyanates. It is seen that actually the value of $\rho = 0.9$ for the reaction catalysed by di-n-butyltin dilaurate, which is significantly less than the value of 3.3 for the uncatalysed reaction. The sign of ρ may be expected to change on passing to stronger acceptors.

An important but very little studied problem in the reactions of isocyanates is that of acid–base catalysis. Almost

1) uncatalysed reaction; 2) in the presence of di-n-butyltin dilaurate.

all known papers on the influence of acids and bases on the reactions of isocyanates are cited in the review by Farkas and Mills[4]. The lack of quantitative data makes it difficult to give soundly based judgments on the mechanism. The most complete qualitative picture of the effect of acids and bases on the reactions of isocyanates has been described by Heiss et al.[53] These workers showed that the reaction is accelerated by the addition of basic reagents, including sodium and potassium hydroxides, sodium phenoxides, trisodium phosphate, benzyltrimethylammonium hydroxide, etc. The retarding action of small additions of acids to previously "purified" polyetherdiols is apparently merely the result of neutralisation of remaining traces of bases. The correctness of this view was demonstrated by the fact that, with reagents which had been completely freed from alkali, e.g. ethylene glycol and cyclohexanol, addition of acid produced no observable retarding effect. With higher concentrations (> μ-equiv. g^{-1} oligomer) a slight accelerating effect is observed.

The boron trifluoride–ether complex also slightly accelerates the reaction of butanol with phenyl isocyanate. Sharp intensification of the catalytic action of boron trifluoride[48] and of zinc chloride[49] occurs on passing to nitro-alcohols, and this can be understood on the basis of the mechanism (H)–(I) suggested above: the strong acceptor boron trifluoride yields with butanol such a stable complex that it is difficult to transfer the combined oxygen to the isocyanate by reaction (12). The substantial decrease in basic strength on passing to nitro-alcohols produces an alcohol–catalyst complex of diminished stability and "moves" the reaction system into a region of higher catalytic activity (cf. Fig. 3). The same applies also to zinc chloride.

The catalytic action of alkalis on the reaction of an alcohol with an isocyanate can again consist either in activation of the OH bond of the alcohol by inducing a hydrogen bond

$$ROH + OH^- \rightleftarrows \overset{\delta-}{RO}\text{–}H \ldots \overset{\delta-}{OH},$$

or even in formation of an alkoxide ion

$$ROH + OH^- \rightleftarrows RO^- + H_2O.$$

Activation of the isocyanate group is also possible, with formation of an intermediate ion Y^- analogous to the ion suggested by Zahradník[24] for isothiocyanates:

$$RNCO + OH^- \rightleftarrows R\bar{N}\text{–}C(=O)(OH) \leftrightarrow RN{=}C(O^-)(OH) \quad (Y^-),$$

followed by an addition–substitution reaction occurring either in one stage

$$Y^- + ROH \rightarrow R\text{–}\overset{\delta+}{H}\text{---}\overset{\delta-}{O}R\text{–}N\text{–}C{=}O \rightarrow R\text{–}N(H)\text{–}C(OR){=}O + OH^-.$$

or in two stages with formation of an intermediate ion Z^-

$$Y^- + ROH \rightarrow RNH\text{–}C(OR)(O^-) \rightarrow RNH\text{–}C(OR){=}O + OH^-.$$

The study of catalysis by strong acids is complicated by the occurrence of secondary addition reactions. Sulphuric acid, for example, forms derivatives of sulphamic acids with isocyanates[83], carbon dioxide being evolved. It can definitely be stated, however, that an alcohol is so much more basic than an isocyanate that, at low acid concentrations, only the protonated form of the alcohol ROH_2^+ will be present even in non-aqueous solvents. Protonation of RNCO will be practically completely absent. It may therefore be supposed that, under the conditions described in the literature[4,53], alkyloxonium ions will constitute the active form.

In the range of acidities in which RNCO begins to be protonated, practically the whole of the alcohol will be in the ionic form. It is still possible, however, that the formation of small amounts of extremely active intermediate protonated forms of the isocyanate U^+ will result in acceleration of the reaction:

$$H^+ + R\text{–}NCO \rightleftarrows \begin{cases} RNH\text{–}\overset{+}{C}{=}O \\ RN{=}\overset{+}{C}\text{–}OH \end{cases} \quad (U^+),$$

$$U^+ + R'OH \longrightarrow RNHCOOR' + H^+.$$

Since only unprotonated alcohol molecules should take part in the latter reaction, and their concentration will fall with increase in acidity, an extremal dependence of the reaction velocity on the acidity of the medium should be observed, and should be found at higher acid concentrations the less basic the alcohol. In the case of acid-catalysed reactions, protonation of the isocyanate will be favoured by a substituent of nucleophilic character adjacent to the NCO group and in the ring of the phenyl isocyanate.

FLUORIDES OF HIGH OXIDISING POWER AND THEIR APPLICATION TO THE PREPARATION OF ORGANIC FLUORINE COMPOUNDS

N.I.Gubkina, S.V.Sokolov, and E.I.Krylov

CONTENTS

I. Introduction 930
II. Higher fluorides of transition metals 931
1. Higher fluorides of lanthanides 931
2. Higher fluorides of uranium, neptunium, and plutonium 931
3. Higher fluorides of the vanadium subgroup 932
4. Fluorides of chromium, molybdenum, and tungsten 932
5. Fluorides of manganese and rhenium 932
6. Simple and complex fluorides of the iron subgroup 933
7. Higher fluorides of the platinium metals 934
8. Higher fluorides of copper, silver, gold, and mercury 935
III. Higher fluorides of elements in the main subgroups of the Periodic System 936
1. Higher fluorides of thallium, lead, antimony, and bismuth 936
2. Fluorides of the oxygen subgroup 936
3. Simple and complex halogen fluorides 937
4. Fluorine compounds of the inert gases 938

I. INTRODUCTION

The extraordinarily high reactivity of elementary fluorine, together with the chemical properties of organic fluorine compounds, make methods for synthesising the latter fundamentally different from those for obtaining other halogen derivatives. All methods of preparing organic fluorine compounds can be divided into four broad groups.

The first group comprises reactions of organic compounds with elementary fluorine or with fluorides of high oxidising power. These reactions are essentially oxidations, taking place by a radical mechanism, and involving either replacement of hydrogen (or halogen) by fluorine or addition of fluorine to a multiple bond.

The second group is formed by reactions involving the exchange of other halogens for fluorine by means of hydrogen fluoride or a metal fluoride possessing no oxidising power (potassium fluoride, antimony trifluoride).

In the third group of reactions functional groupings containing oxygen, sulphur, or nitrogen are exchanged for fluorine by interaction with sulphur tetrafluoride, by the Schiemann reaction, and by other methods.

The fourth group can be regarded as including the numerous reactions in which groupings containing fluorine are introduced into organic compounds containing no fluorine, by the scheme

$$R_H - X + R_F Z \rightarrow R_H - R_F + XZ,$$
$$R_{H(\text{or } F)} - CH = CH_2 + R_F - X \rightarrow R_H - \underset{\displaystyle X}{\underset{|}{CH}} - CH_2 - R_F.$$

The present review will cover only reagents which effect reactions of the first group, i.e. fluorides which oxidise organic compounds to organofluorine compounds. Attention will be paid primarily, not to summarising the extensive literature on the most important fluorinating agents (AgF_2, CoF_3), but to elucidating the theoretical possibility of using fluorides for this purpose as a function of the chemical properties of the element concerned and its position in the Periodic System. Higher fluorides of the transition metals and of certain elements in the main subgroups of the Periodic System are of great practical importance (in the atomic industry, as oxidants in rocket technology). Information on the fluorides of interest to us will be reported in the sequence in which the elements are arranged among groups of the Periodic System (the elements capable of forming fluorides having high oxidising power are V, Cr, Mn, Tc, Re, Ru, Os, Ni, Pd, Pt, Cu, Ag, Au, Hg, Tl, Pb, Sb, Bi, O, Po, Cl, Br, I, At, Kr, Xe, Rn, Ce, Pr, Nd, Tb, Dy, U, and Pu).

The oxidising power of these fluorides is extremely varied, and cannot yet be estimated quantitatively in any way. Considerable interest should attach, in connection with the assessment of the oxidising power of ElF_x, to the energy of formation of the El–F bonds, but unfortunately knowledge of these bond energies and of their orders is very far from what could be desired. Yet even in such a simple molecule as F_2 the order of the F–F bond is less than unity, which entails an abnormally low bond energy. The reason for such anomaly in this case has been analysed in detail by the molecular orbital method[1]. Some elements are not at all readily available, and therefore have been insufficiently investigated; while others, although readily available, have higher fluorides which cannot be purified, so that their study is difficult. The highly corrosive nature of some fluorides, which attack even polytetrafluoroethylene and platinum, make it impossible to study them by the usual methods. In this paper the assignment of some fluorides to the category of oxidising agents is made on the basis of their chemical properties, often studied quite superficially, and in some cases only on the basis of general considerations regarding their reactivity. Nevertheless, we feel that future quantitative results will hardly seriously contradict our purely qualitative considerations.

Fluorides of high oxidising power show increased stability and lower oxidising power on complex formation, which makes it possible to obtain fluorides in which the metals exhibit an abnormally high valency (Ni^{4+}, Cu^{4+}).

II. HIGHER FLUORIDES OF TRANSITION METALS

Incomplete electron levels become filled in the atoms of transition metals, which comprise elements of atomic numbers 21–30, 39–40, and 57–90 (lanthanum, lanthanides, and the series of elements from Hf to Hg), together with 89–104 (Ac, Th, Pu, U, etc.). Transition metals can utilise the electronic levels *d* (and *f* in the lanthanides and actinides) for chemical bond formation.

Fluorides of high oxidising power occur among quadrivalent derivatives of cerium, praseodymium, terbium, and dysprosium in the lanthanide subgroup of Group III in the Periodic System, and are represented by the hexafluorides of uranium, neptunium, and plutonium in the actinide subgroup.

Whereas in the vanadium subgroup only vanadium pentafluoride possesses high oxidising power, and in the zinc subgroup only mercury difluoride, in the case of chromium, manganese, iron, cobalt, nickel, and copper subgroups only iron gives no fluoride of high oxidising power.

1. Higher Fluorides of Lanthanides

The appearance in lanthanides of 4*f*-electrons, at energy levels close to those of 5*d*-electrons, makes it possible for some lanthanides to yield more or less stable quadrivalent derivatives. The stability of the quadrivalent state diminishes with increase in the number of *f*-electrons, but after $4f^7$-electrons have accumulated in gadolinium, the possibility of forming a relatively unstable quadrivalent state reappears with terbium and to some extent dysprosium.

Cerium and terbium tetrafluorides are obtained by fluorinating the trifluorides with elementary fluorine at high temperatures[2,3]. There are indications that cerium tetrafluoride can be obtained also from the trichloride[4] or the dioxide[5]. Data have been published on the lattice structures of CeF_4 and TbF_4 and on the partial pressures of fluorine over these compounds at high temperatures[3,6].

When heated in air, cerium and terbium tetrafluorides are converted into oxides. The fluorides are unchanged by cold water[2,3], but react quite rapidly even in acidified solutions of aluminium nitrate with the evolution of gaseous oxygen, TbF_4 reacting slowly even in the absence of acid[3].

Fowler used CeF_4 for the vapour-phase fluorination of hydrocarbons with the aim of obtaining perfluorinated products. Since CeF_4 was less reactive than CoF_3, fewer carbon–carbon bonds underwent cleavage, so that more viscous products of higher boiling point were obtained[9]. In the opinion of Fowler and Anderson, CeF_4 is to be preferred to other fluorinating agents if the carbon skeleton is to be obtained unchanged in vapour-phase fluorination over the temperature range 150–450°. There are indications of the use of CeF_4 to obtain partly fluorinated organic compounds[5], and of the addition of fluorine to double bonds in chlorinated alkenes by means of CeF_4.[5] The chlorine in saturated chlorofluorocarbons can be replaced under the influence of CeF_4.[5] Cerium tetrafluoride is employed for the liquid-phase stabilisation of fluorinated oils in the presence of elementary fluorine[5].

It has not yet proved possible to prepare tetrafluorides of other lanthanides[3,10,11], although it has been predicted[12] that praseodymium tetrafluoride will be relatively stable.

Fluoro-complexes are known of quadrivalent cerium[13] and praseodymium[14,15] of general formulae A_2BF_6 and A_3BF_7 (where A = Na, K, Rb, and Cs and B = Ce, Pr), and the compounds $NaPrF_5$,[16] Cs_3TbF_7,[18] Cs_3DyF_7, and Cs_3NdF_7 [18] have also been obtained. In all cases the stability of the complexes increases in the sequence Na → K → Rb → Cs. The lattice parameters and the magnetic suceptibilities of these complexes have been measured[13,14]. All these complexes have been prepared by fluorinating a mixture of salts[16] or a mixture of chlorides and the corresponding oxides[13–15,17] at high temperatures. The cerium complexes are colourless and comparatively stable, and begin to react only gradually with water and hydrochloric acid. They oxidise acidified solutions of potassium iodide; concentrated sodium hydroxide solution decomposes the complexes, with precipitation of $CeO_2.xH_2O$.[13] The colourless praseodymium complexes are reduced by water with gas evolution, and are even decomposed by moist air[14]. As was to be expected, the colourless complex of quadrivalent terbium is somewhat more stable, and does not break down in moist air, but it oxidises boiling hydrochloric acid with the evolution of chlorine. Concentrated NaOH solution decomposes Cs_3TbF_7.[17] Study of the magnetic properties and the elementary composition has proved the existence of the complexes Cs_3NdF_7 and Cs_3DyF_7.[18] The yellow complexes of Nd^{4+} and Dy^{4+} liberate iodine from acidified potassium iodide solution[18].

2. Higher Fluorides of Uranium, Neptunium, and Plutonium

The fact that 5*f*-electrons are considerably more readily removed than are the 4*f*-electrons of lanthanides makes the achievement of high valencies a characteristic feature of actinides. Thus the most stable state of thorium is quadrivalent, protactinium reaches the quinquevalent state, and uranium, neptunium, plutonium, and americium are characterised by sexivalent states. As the number of 5*f*-electrons rises, their tendency to form high valency bonds falls, and the higher valency states become less stable. Thus whereas uranium hexafluoride is fairly stable, although it is a strongly oxidising compound, plutonium hexafluoride is considerably less stable, and exhibits extremely high oxidising power, while americium hexafluoride has not yet been obtained[19]. The immense practical value of the fluorides of uranium and plutonium has resulted in an extensive literature on this question[20–22]. We shall therefore confine ourselves to a brief comparison of the properties of the hexafluorides of uranium, neptunium, and plutonium, and discuss their reactions with organic compounds. The ability of uranium hexafluoride to react with all the usual organic compounds, and the need to produce resistant materials, led to the synthesis of polytetrafluoroethylene, polychlorotrifluoroethylene, and perfluorinated oils, and was the principal reason for the vigorous development of organofluorine chemistry.

Uranium hexafluoride is a moderately strong oxidant, and can be prepared, without the use of elementary fluorine or fluorides of halogens, cobalt, or silver, by the reaction[23]

$$2UF_4+O_2=UF_6+UO_2F_2.$$

Neptunium hexafluoride[24] and especially plutonium hexafluoride[24–27] are stronger oxidising agents. Thus the latter fluorinates bromine trifluoride to bromine pentafluoride[24,27], whereas uranium hexafluoride can be obtained by treating uranium compounds with bromine trifluoride[23].

Plutonium hexafluoride readily fluorinates uranium derivatives to the hexafluoride[27]. Neptunium hexafluoride occupies an intermediate position, only partly converting bromine trifluoride into the pentafluoride[24]. All the hexafluorides are immediately hydrolysed by water, but no evolution of oxygen or oxygen difluoride was observed[28,29]. Uranium hexafluoride reacts vigorously with most organic compounds (aliphatic and aromatic hydrocarbons, alcohols, and ethers) with the evolution of hydrogen fluoride and the formation of partly carbonised substances of indeterminate composition, the uranium being converted into its tetrafluoride or oxide fluoride. Trichloroethylene instantaneously reduces uranium hexafluoride to the tetrafluoride, being converted into a mixture of compounds containing chlorine and fluorine, formed by reactions involving addition, substitution, polymerisation, and decomposition[30].

At 100–200° uranium hexafluoride is rapidly and quantitatively reduced by carbon tetrachloride to uranium tetrafluoride[31]:

$$UF_6+2CCl_4 \rightarrow UF_4+Cl_2+2CCl_3F.$$

This reaction has been carefully studied for its practical application[31]. Experiments with different proportions of the reactants showed that chlorotrifluoromethane predominated when a slight excess of carbon tetrachloride was used, whereas more trichlorofluoromethane was obtained with a large excess.

When uranium hexafluoride is dissolved in 1,1,2,2,-tetrafluoroethane, reaction becomes appreciable only after a few days. The relative stability of this solution permitted its use to study several reactions of uranium hexafluoride with ammonia and with arsenic trifluoride[20]. A solution of uranium hexafluoride in tetrachloroethane is still more stable[20]. This solution takes a few weeks to decompose, and can be used for the recrystallisation of uranium hexafluoride. On the other hand, tetrachloro-1,2-difluoroethane reacts with uranium hexafluoride quite rapidly, with the evolution of a gas which is obviously dichlorodifluoromethane[20].

Uranium hexafluoride reacts with partly fluorinated hydrocarbons, replacing the hydrogen by fluorine atoms, but is completely inert towards perfluorinated hydrocarbons and chlorofluorocarbons, which are used in various operations with the hexafluoride. On prolonged heating, amorphous carbon reduces uranium hexafluoride to the tetrafluoride, with the formation of carbon tetrafluoride and other simple fluorocarbons. The hexafluoride is insoluble in carbon disulphide, and reacts relatively slowly; with moist carbon disulphide, fluorides of sulphur are formed. Uranium hexafluoride does not interact with carbon dioxide or with mercury dicyanide[20].

Plutonium hexafluoride reacts with most organic compounds still more vigorously, but perfluorinated hydrocarbons do not interact with it, too[27].

3. Higher Fluorides of the Vanadium Subgroup

Elements of this subgroup are characterised by the presence of relatively few *d*-electrons, whose energy levels are close to those of the valency *sp*-electrons. This results in participation by the *d*-electrons in the formation of valency bonds, as a result of which the elements of the vanadium subgroup exhibit a stable higher valency of +5. With increase in atomic number the mobility of the *d*-electrons increases; this tends to stabilise the higher valency of the element. In the series vanadium–niobium–tantalum the larger the positive charge on the nucleus the more weakly are the outer electrons bound to the nucleus, the lower is the ionisation potential for detachment of the corresponding electrons, and the greater the tendency of the element to form compounds corresponding to its maximum valency. The higher fluorides of elements of this group are oxidants, their oxidising power diminishing down the group.

Vanadium pentafluoride is formed by the action of fluorine on the metal at 300°,[32] by the action of chlorine trifluoride, bromine trifluoride, or iodine pentafluoride on vanadium pentoxide[33], or by the thermal disproportionation of vanadium tetrafluoride at 650°.[32] It is a relatively weak oxidising agent, but can exchange fluorine for oxygen in inorganic compounds and for other halogens in carbon tetrahalides[34,35]. There are indications that vanadium pentafluoride reacts with ether and with toluene, but the structure of the products has not been elucidated[32]. It forms salts with ammonia and with pyridine[36]. Niobium and tantalum pentafluorides are less active as oxidising agents[35].

4. Fluorides of Chromium, Molybdenum, and Tungsten

For a long time chromium hexafluoride was not identified. Fowler and his coworkers tried to obtain higher fluorides of chromium by the interaction of fluorine with chromium trichloride and chromium sesquioxide in order to study their ability to fluorinate organic compounds, but only a mixture of volatile and non-volatile fluorides was obtained, which could not be investigated because of experimental difficulties[37]. Bright red chromium pentafluoride[39] has recently been obtained, together with a small quantity of lemon-yellow chromium hexafluoride[38], by treating chromium powder with fluorine in a nickel bomb at 200 atm and 400°.[38] The yield of the hexafluoride is increased by adding manganese powder and raising the pressure to 350 atm. Chromium hexafluoride rapidly decomposes into the pentafluoride and fluorine at temperatures as low as -100° to -80°.[38]

Molybdenum and tungsten hexafluorides, in contrast, are readily available, but exhibit relatively weak oxidising properties and have no fluorinating action[40,41]: with organic compounds they form complexes.

5. Fluorides of Manganese and Rhenium

The presence of a large number of *d*-electrons enables elements in this subgroup to exhibit various valencies (+2, +3, +4, +6, and +7), the higher valencies becoming more stable from manganese to rhenium. Manganese forms a trifluoride and a tetrafluoride. The former has been well studied, and has found practical application as an extremely effective fluorinating agent (though milder than cobalt trifluoride) for organic compounds. Manganese trifluoride is used for the preparation of perfluorinated compounds under roughly similar conditions to cobalt trifluoride, the latter being more suitable for the fluorination of products of low boiling point, whereas manganese trifluoride is more useful for high-boiling compounds, since at high temperatures it causes less cleavage of carbon–carbon bonds, though the resulting product is probably incompletely fluorinated[42–45].

Wine-red manganese trifluoride is formed by treating manganese or its salts with fluorine at 250° or by treating

manganese iodate with bromine trifluoride and heating the product to 200°.[46] The extremely active manganese tetrafluoride is obtained under more severe conditions, by fluorinating simple salts ($MnCl_2$, MnF_2, $MnSO_4$,[47] MnF_3[48]) with elementary fluorine at 400–550°. The tetrafluoride is an amorphous powder, which is fairly stable at room temperature[48].

Manganese tetrafluoride is undoubtedly more reactive than the trifluoride. The latter is decomposed by water, whereas the tetrafluoride ignites spontaneously on contact with water. The trifluoride reacts with benzene, alcohol, chloroform, ether, and turpentine only when heated to 100° and above[49]. A flash of light is seen when the tetrafluoride reacts with dry petroleum ether at room temperature[47].

Quadrivalent manganese gives two series of complex fluorides — A_2MnF_6[50–52] and $AMnF_5$[50,52] (where A = Li, Na, K, Rb, Cs) — of which the brick-red compounds of the type $AMnF_5$ are the more reactive. These complex fluorides are obtained by fluorinating salts of the type $AMn^{2+}F_3$[52] or a mixture of the simple salts[48], e.g.

$$LiF+MnF_2 \xrightarrow[350°]{F_2} LiMnF_5.$$

Potassium pentafluoromanganate can be prepared by the action of bromine trifluoride on potassium permanganate with subsequent removal of excess bromine trifluoride under vacuum at 20°.[50] It is formed also by the reaction[50]

$$4KMnO_4+10SeF_4=4KMnF_5+10SeOF_2+3O_2.$$

Pentafluoromanganates are hydrolysed by water, and form brownish-black precipitates with dilute alkalis; in air they gradually decompose. Hydrogen reduces them at 250–275°: lithium pentafluoromanganate is reduced even at 150–200°, whereas the caesium salt is incompletely reduced[52].

Technetium and rhenium give the reactive fluorine compounds technetium hexafluoride[57], rhenium hexafluoride[54,55], and rhenium heptafluoride[56,57]. The volatile hexafluorides of technetium and rhenium are formed by reaction of the metal powders with fluorine (at 400° and 420° respectively), rhenium hexafluoride being obtained also by treating powdered rhenium with chlorine trifluoride at 300°.[55] On further treatment with fluorine, 1 mole of rhenium hexafluoride absorbs a further 0.5 mole of fluorine, to give the less volatile heptafluoride[56], which is probably thermally stable[57]. The infrared spectra of technetium and rhenium hexafluorides have been recorded, and the principal thermodynamic constants obtained[53,57]. All three higher fluorides are sensitive to moisture, but can be stored in a dry Pyrex glass vessel at room temperature for a long time[53,57]. Hydrolysis of technetium hexafluoride in the presence of sodium hydroxide gives a black precipitate, which dissolves on the addition of hydrogen peroxide[53]. Its behaviour is analogous to that of rhenium hexafluoride, which disproportionates on hydrolysis, giving insoluble rhenium dioxide, rhenic acid $HReO_4^-$, and hydrogen fluoride[54].

Rhenium hexafluoride is a vigorous oxidising agent, being reduced to the tetrafluoride by hydrogen at 200°, sulphur dioxide at 400°, and carbon monoxide at 300°.[54] With alkali metals it forms complexes of the type A_2ReF_8, which are readily hydrolysed by water[58].

6. Simple and Complex Fluorides of the Iron Subgroup

Since a group of five *d*-electrons is especially stable, iron(III) fluoride does not exhibit oxidising properties[59], and dissociates only at 1000° and 15 mm in a stream of nitrogen, being converted into iron(II) fluoride[60]. Cobalt, like iron, forms both a difluoride and a trifluoride, but, in contrast to iron(III) fluoride, cobalt(III) fluoride is a strong oxidising agent.

Cobalt trifluoride can be obtained by the action of fluorine on cobalt(II) fluoride or chloride at 150°.[61] It is a pale brown powder, whose physical properties and structure have been studied in detail[61]. It dissociates appreciably into cobalt(II) fluoride and fluorine in a stream of carbon dioxide at 250°–300°, and is completely dissociated at 350°. Reaction of cobalt trifluoride with water, aqueous acids, and aqueous alkalis is accompanied by very vigorous evolution of oxygen[61]. Cobalt trifluoride is widely used for the fluorination of organic compounds with the aim of preparing perfluorinated hydrocarbons. Its use for the fluorination of hydrocarbons containing about 1–20 carbon atoms has been described.

Compounds of higher molecular weight can also be fluorinated, although very considerable difficulties are involved. The fluorination of compounds containing oxygen[62] and nitrogen[63–66] has been described, but the yields are relatively low. Fluorination with cobalt trifluoride can be effected over the range 150–400° both in the vapour phase and in inert liquid perfluorinated solvents. The manufacture of perfluorinated oils for the gas-diffusion enrichment of uranium by means of cobalt trifluoride was suggested in the USA in 1941, although the cost of manufacture was extremely high. Fluorination with cobalt trifluoride has been described in detail[67,68].

The complex K_3CoF_6 was first obtained by the anodic oxidation of cobalt(II) fluoride dissolved in hydrofluoric acid, with subsequent treatment of the resulting $CoF_3.3\frac{1}{2}H_2O$ with solid potassium fluoride at -10°.[69] The corresponding ammonium complex cannot be obtained by this method[70].

Klemm and his coworkers suggested several dry methods. The first was based on the fluorination of mixtures of cobalt(II) chloride and salts containing the cation present in the final product[71], e.g.

$$3KCl+CoCl_2 \xrightarrow{F_2} K_3CoF_6.$$

The second method consists in fluorinating with dilute fluorine a complex salt containing no fluorine; for example, K_3CoF_6 can be obtained from $K_3Co(CN)_6$.[72,73] Hoppe and Klemm have reported the use of this method to prepare complexes A_3CoF_6, where A = Li, Na, K, Rb, Cs,[72,73] Ag,[74] Ba.[75] An attempt to obtain $LaCoF_6$ by fluorinating $LaCo(CN)_6$ was unsuccessful[75].

The pure A_3CoF_6 compounds possess strong oxidising properties, being decomposed by water with the separation of a black deposit and the evolution of oxygen. With aqueous perchloric acid they evolve a gas and form a bivalent cobalt salt. These complexes oxidise hydrochloric acid and acidified potassium iodide solution[74].

The previously described[71] compound K_3CoF_7 proved[72] to have the formula K_3CoF_6. At the present time only one complex of quadrivalent cobalt is known: when Cs_2CoCl_4[72] or $Cs_2Co(SO_4)_2.6H_2O$ is fluorinated, a brownish-yellow complex Cs_2CoF_6 is obtained[72,74]. The quadrivalent cobalt compound is less stable than Cs_3CoF_6.[74] Reactions of tervalent and quadrivalent cobalt complexes with organic compounds have not been studied. The physical properties of the complexes have been described[72–76].

The higher fluorides of nickel NiF_3 and NiF_4 have not yet been described, but their complex compounds of the types A_3NiF_6 and A_2NiF_6 are known.

Higher fluorides of nickel are interesting in view of their possible occurrence in electrochemical fluorination. The electrochemical fluorination of organic compounds containing oxygen, nitrogen, or sulphur is effected by passing a direct current through their solutions in anhydrous hydrogen fluoride. When nickel electrodes are used, a voltage of ~5 V is applied to the electrolytic cell, and fluorination is accompanied by relatively little cleavage of carbon–carbon bonds. Electrochemical fluorination is undoubtedly an anodic process. It has been suggested that the higher complex fluorides of nickel are active fluorine carriers[77]. This view finds indirect confirmation in the chemistry of quadrivalent nickel complexes.

The violet complex K_3NiF_6 is formed by the fluorination of a 1 : 3 mixture of potassium chloride with nickel sulphate[78] or nickel chloride[71] in a mixture of fluorine and carbon dioxide at 320°. The corresponding sodium complex is obtained similarly (from sodium chloride or bromate and nickel sulphate). Fluorination of a mixture of ACl (where A = K, Rb, Cs) and $NiCl_2$ occurs still more readily, even at 275°, diamagnetic red complexes A_2NiF_6 being obtained[71,79].

The complex K_2NiF_6 reacts very violently with water, a gas being evolved whose odour recalls that of ozone (OF_2 ?). It is relatively stable in dry air, and does not react when heated with hydrocarbons, aniline, dimethylaniline, or acetic anhydride, but reacts vigorously with acidic substances such as acetic and decanoic acids, phenol, and sulphuric and hydrochloric acids, being converted into greyish-green nickel(II) chloride:.

$$2A{-}H + K_2NiF_6 \rightarrow [H_2NiF_6] + 2KA \rightarrow NiF_2 + 2HF + 2F.$$

It is possible that similar processes occur also in electrochemical fluorination:

1. $Ni + F^- \xrightarrow{-2e} NiF_2$,
2. $NiF_2 + 2F^- + 2NR_3^HH^+ \xrightarrow{-ne} (NR_3^H)_2NiF_6$,
3. $(NR_3^H)_2NiF_6 + nF^- \xrightarrow[-nH_2]{-ne} (NR_3^F)_2NiF_6$,
4. $(NR_3^F)_2NiF_6 + 2NR_3^HH^+ \rightarrow (NR_3^H)_2NiF_6 + NR_3^F + H^+$,
5. $(NR_3)_2NiF_6 \xrightarrow[\text{off}]{\text{current}} (NR_3)_2NiF_4 + F_2$,

   $(NR_3)_2NiF_4 + 2HF \rightleftarrows NiF_2 + 2(NR_3^H)^+F^-$.

Such a mechanism is supported by the fact that, in spite of repeated attempts, electrochemical fluorination can be accomplished only at nickel anodes, except with a considerably higher overpotential at Monel-metal anodes[80]. Still further evidence in support of this mechanism is provided by the diminished yields which one of us has observed, and the decrease in stability of electrochemical fluorination, when anodes of low-grade nickel are used[81].

7. Higher Fluorides of the Platinum Metals

Among the light platinum metals, hexafluorides have been obtained of ruthenium and rhodium. Powdered ruthenium and rhodium explode in fluorine[82,83]. Ruthenium hexafluoride is a dark brown solid melting at 54°.[82] It is less volatile than the corresponding molybdenum and technetium compounds. It reacts rapidly with Pyrex glass, and to a less extent with quartz. Ruthenium hexafluoride can be stored in a nickel vessel without decomposition for a long time[82].

Rhodium hexafluoride is a black substance (the vapour being reddish-brown), resembling ruthenium hexafluoride. It breaks down into fluorine and a lower fluoride even at room temperature[83]:

$$RhF_6 \rightarrow RhF_5 + \frac{1}{2}F_2.$$

Both ruthenium and rhodium hexafluorides are extremely reactive substances: they form complexes with xenon[84,85] analogous to $XePtF_6$.[86] The infrared spectra of these hexafluorides have been recorded, and their structure has been studied[82,83].

Ruthenium pentafluoride is formed from the elements at 300°[87] and when ruthenium dioxide is treated with fluorine or with bromine pentafluoride[88]. The dark green compound[87,89] fumes strongly in the air, and reacts violently with water, being converted into a black lower oxide of ruthenium[87]. Ruthenium pentafluoride is a vigorous oxidising and fluorinating agent, iodine being oxidised to iodine pentafluoride at 160°, and sulphur to sulphur hexafluoride at 0°. At high temperatures it converts copper and silver into fluorides, and oxidises hydrogen chloride to chlorine, but it reacts only slightly with dry benzene and toluene. The reactive complexes $ARuF_6$ evolve oxygen on interaction with water[87].

Ruthenium tetrafluoride has been obtained by reducing the pentafluoride with iodine in iodine pentafluoride solution[90]. It is a non-volatile yellow solid, which blackens in moist air, and reacts violently with water, being converted into ruthenium dioxide.

Rhodium tetrafluoride is obtained by the action of fluorine on rhodium, its trichloride, or its trifluoride at 500° or by dissolving rhodium tribromide in bromine trifluoride and then evaporating off the latter. It is a hygroscopic powder, which oxidises hydrochloric acid to chlorine; it does not react with ether or carbon tetrachloride at room temperature[91]. Complexes A_2RhF_6, which are sensitive to moisture, being violently decomposed by water with the evolution of gases, have been prepared[91].

Palladium trifluoride is obtained by the action of fluorine on the dichloride[92], the di-iodide[93], or palladium[94], or by decomposing $PdF_3.BrF_3$ in a vacuum at 200°.[92] It is a hygroscopic black powder, which evolves oxygen on contact with cold water, oxidises hydrogen chloride to chlorine, and reacts vigorously when heated with iodine, sulphur, phosphorus, carbon, sodium, magnesium, aluminium, or iron[88]. Complex fluorides of quadrivalent palladium A_2PdF_6 are known. The complexes are sensitive to moisture, decompose rapidly, and blacken in moist air[92,95].

A diminution in the stability of the higher valencies with increasing number of *d*-electrons is very characteristic of Group VIII in the Periodic System. This applies to all properties. Thus, in the iron family, iron trifluoride does not exhibit oxidising properties, cobalt trifluoride is an extremely strong oxidising agent, and nickel trifluoride (and tetrafluoride) have not been prepared, but from the properties of their complexes, appear to be extraordinarily strong oxidants. A similar increase in oxidising power from left to right is characteristic also of the higher fluorides of the platinum metals.

More than fifty years ago Ruff and his coworkers described the preparation, identification, and properties of three fluorides — OsF_4, OsF_6, and OsF_8 — of osmium[96]. But when the reaction of elementary fluorine with heated

osmium was reinvestigated, a single volatile reaction product was obtained, and was identified as osmium hexafluoride[97]. This compound is hydrolysed by aqueous alkali with the evolution of heat and a gas smelling like ozone, and it oxidises water to oxygen[24,97]. Osmium hexafluoride is reduced by a deficiency of iodine in iodine pentafluoride solution[98]. The reaction begins at room temperature, and terminates at 50° according to the equation

$$10OsF_6+I_2 \rightarrow 10OsF_5+2IF_5.$$

The yield is quantitative. Osmium hexafluoride undergoes a similar transformation under the influence of ultraviolet radiation[98].

Golden-yellow iridium hexafluoride is obtained by the action of fluorine on iridium at 260°; it melts at 44.4° and boils at 53°.[99] Iridium hexafluoride is an extremely strong oxidising agent, reacting with hydrogen, sulphur, phosphorus, and halogens. It fluorinates even chlorine. It attacks glass even at room temperature, and fluorinates many metals, including platinum. Iridium hexafluoride oxidises water with the evolution of a gas smelling of ozone[24,99], and is reduced by carbon tetrachloride and by petroleum ether even in the cold. It is relatively stable in quartz, and does not decompose in the latter even at 400°.[99] The extraordinary reactivity of iridium hexafluoride is indicated also by its ability to fluorinate silver chloride. Polytetrafluoroethylene evolves carbon tetrafluoride on interaction with iridium hexafluoride[100].

In contrast to osmium, iridium forms complex fluorides of the type $AIrF_6$, which are strong oxidising agents. Hexafluoroiridates evolve oxygen on reaction with water, and are rapidly decomposed by moist air[99]. The extremely strong oxidant $IrOF_4$ is decomposed by water with the evolution of oxygen[99].

Platinum tetrafluoride decomposes with the evolution of fluorine when strongly heated[101]. The hexafluoride has recently been obtained[102,103] by the combustion of platinum in fluorine under the influence of an electric spark discharge; it is probably the strongest of all known fluorinating agents[24,26,103]. When stored in glass platinum hexafluoride, like neptunium and plutonium hexafluorides, undergoes photochemical decomposition[24]. It is unstable, undergoing rapid and complete decomposition at 280°.[24] It converts solid products of the radiolysis of neptunium and plutonium hexafluorides into the hexafluorides, although the yield is not high[24,103].

Platinum hexafluoride readily fluorinates bromine trifluoride to the pentafluoride at room temperature[103], reacts violently with metallic uranium to form the hexafluoride, and decomposes water with the evolution of oxygen[24]. The brownish-red platinum hexafluoride vapour oxidises molecular oxygen to a complex of the unusual type $O_2^+PtF_6^-$.[104] Since the first ionisation potential of oxygen $O_2 \rightarrow O_2^+$ is 12.2 eV, which is higher than that of xenon (12.13 eV), it was suggested that formation of xenon hexafluoroplatinate

$$Xe+PtF_6 \rightarrow Xe^+PtF_6^-,$$

was possible. In fact, this method has been used to obtain the first chemical compound of xenon, which is orange in colour, is stable at 20°, and sublimes in a vacuum[86]. It is readily hydrolysed by water:

$$2XePtF_6+6H_2O \rightarrow 2Xe+O_2+2PtO_2+12HF.$$

8. Higher Fluorides of Copper, Silver, Gold, and Mercury

Copper forms a stable difluoride, which is devoid of oxidising power[105]. Copper trifluoride has not been described, although it may be involved as a fluorine carrier in the catalytic fluorination of organic compounds by elementary fluorine on copper gauze[106,107].

A complex K_3CuF_6 is formed[71] by the action of fluorine on a mixture of copper(II) and potassium chlorides at 250°. This substance is vigorously decomposed by water with the evolution of an unidentified gas (either O_2, O_3, or OF_2)[71]. Complexes A_3CuF_6 (A = Rb, Cs) are known[18]. Complexes of tervalent copper may be expected to exhibit interesting fluorinating properties.

Silver difluoride is one of the most thoroughly studied and widely used fluorinating agents. Treatment of silver or its salts with fluorine at 150–250° yields the black modification of the difluoride. The yellow modification can be obtained by fluorinating silver with chlorine trifluoride. The properties of silver difluoride have been studied in some detail[108].

Silver difluoride is widely used for the fluorination of organic compounds, being a more powerful fluorinating agent than is cobalt trifluoride[109]. It fluorinates carbon monoxide to carbonyl fluoride[110], and converts hydrocarbons and halogenated derivatives into perfluorohydrocarbons. Silver difluoride has the advantage over cobalt trifluoride in fluorinating chloro-derivatives, but, because of the poorer free-flowing properties of the powder and its more corrosive nature, it is inferior to the latter in the vapour-phase fluorination of hydrocarbons[111]. It has been reported that organic disulphides are selectively fluorinated by silver difluoride to derivatives of sulphur tetrafluoride, great prospects thus being opened up in the synthesis of organofluorine compounds. A special investigation has shown that silver difluoride is irreplaceable for this purpose[112]. This compound probably plays an extremely favourable role in the catalytic fluorination of organic compounds on a silvered wire[113].

Complex compounds based on the unknown silver trifluoride have been described[114-117]. Compounds of the type $AAgF_4$ (A = K, Cs) and $BaAgF_5$ react violently with water; at 200° $BaAgF_5$ is converted into the more stable compound $BaAgF_4$, fluorine being eliminated[117]. X-Ray examination has shown that compounds which had been regarded as $CsAgF_6$ and $CsAuF_6$ did not in fact have this structure[117].

Gold trifluoride has been obtained, by fluorinating gold with fluorine or with bromine trifluoride, as an orange powder, which decomposes at 500°. It is a strong fluorinating agent, reacting violently with water. It ignites organic compounds even at room temperature, and reacts smoothly with carbon tetrachloride at 40°.[114,118] Gold trifluoride probably has a favourable influence on the catalytic fluorination of organic compounds on a gold-plated copper wire[119].

A series of complex fluorides of the type $AAuF_4$ (A = Na, K, Cs, Ag) has been obtained by fluorinating the chloroaurates with elementary fluorine or by the reaction of gold trifluoride in bromine trifluoride with the metal fluorides. The complex $AgAuF_4$ does not react with carbon tetrachloride, but it is reduced by benzene, and reacts violently with cold water[114,118].

Mercuric fluoride has long been used as a reagent. It is a hygroscopic white substance of melting point 645°, which immediately becomes yellow in the air[120]. Its preparation has been described[120-122]. Mercury difluoride is used for the replacement of other halogens by fluorine, but at temperatures above 100° it mildly fluorinates hydrocarbons[120,123]. An interesting property is its ability to add on to fluorinated compounds containing multiple bonds (azomethines[124], alkenes[125,126]), so that it can be used for synthetic purposes according to the scheme[124]

$$CF_3N{=}CF_2 + HgF_2 \rightarrow (CF_3)_2NHgN(CF_3)_2 \xrightarrow{Br_2} (CF_3)_2NBr \xrightarrow{CF_2{=}CF_2} (CF_3)_2NCF_2CF_2Br.$$

III. HIGHER FLUORIDES OF ELEMENTS IN THE MAIN SUBGROUPS OF THE PERIODIC SYSTEM

In the following subgroups a high oxidising power is exhibited by the fluorides of tervalent thallium, quadrivalent lead, quinquevalent antimony and bismuth, oxygen, and sexivalent polonium, as well as all halogen fluorides. The fluorides of the inert gases which have recently been described must probably be included among fluorides of high oxidising power.

1. Higher Fluorides of Thallium, Lead, Antimony, and Bismuth

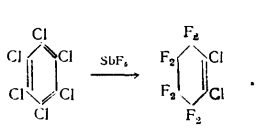
Thallium trifluoride can be obtained in several ways — by treating the oxide with fluorine at 300°,[127] or with bromine trifluoride[122] or sulphur tetrafluoride[121], by the action of chlorine trifluoride on metallic thallium[127], and by the interaction of thallium iodate with bromine trifluoride[122] — and is a white solid which darkens in moist air, being instantaneously hydrolysed by water with the formation of a black precipitate of the hydroxide

$$TlF_3 + 3H_2O \rightarrow Tl(OH)_3 + 3HF,$$

this giving the oxide Tl_2O_3 on being heated[122]. Thallium trifluoride does not react with liquid ammonia, but paraffin, benzene, and chloroform do interact with it, fluorination perhaps occurring here[127].

Lead tetrafluoride is obtained by fluorinating the difluoride with fluorine at 300°.[128] It consists of colourless crystals, which darken in the air owing to hydrolysis, and melt at around 600°.[128] Lead tetrafluoride vigorously fluorinates hydrocarbons in both liquid and vapour phases[129-131]. In practice, however, it is very difficult to use, since a eutectic mixture, containing about 60% PbF_2 + 40% PbF_4, attacks the reaction vessel[131]. The use has been reported of a mixture of lead dioxide, lead tetra-acetate, and anhydrous hydrogen fluoride[132] or of lead dioxide and sulphur tetrafluoride[133] in an autoclave, for adding fluorine at the double bond of halogenated alkenes.

Fluorides of tervalent and quinquevalent antimony are widely used in the exchange of other halogens for fluorine (the Swarts reaction)[134]. However, antimony pentafluoride is capable not only of exchanging chlorine for fluorine but also of adding fluorine to the double bond in chlorinated aromatic and unsaturated compounds[135,136]:



Antimony pentafluoride can be obtained from the pentachloride and anhydrous hydrogen fluoride or from the trifluoride and fluorine. It forms a hydrate $SbF_5.2H_2O$, as well as complexes which are stable in aqueous solution[137].

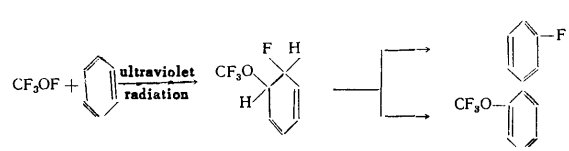
Bismuth pentafluoride is a stronger oxidising agent than is antimony pentafluoride. It reacts vigorously with water, a gas smelling of ozone being evolved[138,139], and reacts readily with paraffin oil, which is not blackened[139]. Its successful use for the synthesis of perfluorohydrocarbons has been reported[140]. However, the practical application of bismuth pentafluoride is made difficult by the complexity of its preparation, which involves passing fluorine over bismuth trifluoride at 450–500°. At this temperature the pentafluoride sublimes into the cooled part of the reaction vessel as long white needles, which instantly become yellow on contact with the air[138,139]. The yield of bismuth pentafluoride is low, obviously owing to its decomposition in the gaseous state[138]. Bismuth pentafluoride converts uranium tetrafluoride and oxide into uranium hexafluoride, and bromine into bromine trifluoride, which itself is converted into bromine pentafluoride[139].

The complex hexafluorobismuthates $ABiF_6$ are hygroscopic, and are decomposed even by 40% hydrofluoric acid[138]. Bismuth pentoxide reacts with the 40% acid with the evolution of a gas smelling of ozone. The resulting solution possesses extremely strong oxidising properties[138].

2. Fluorides of the Oxygen Subgroup

Oxygen forms with fluorine the difluoride OF_2 and several fluorides — O_2F_2, O_3F_2, and O_4F_2 — which are richer in oxygen[141]. Compounds of fluorine and oxygen with other elements are also known, such as trifluoromethyl hypofluorite CF_3OF,[141,142] fluorine nitrate NO_3F, fluorine perchlorate $ClFO_4$,[141] and compounds of the type XO_3F, where X = Cl, Br, I.[143] The oxygen fluorides are extremely strong oxidising agents even at low temperatures, and are employed in rocket technology[144-146]. Until recently oxygen difluoride has not been used for the synthesis of organofluorine compounds. When it interacts with benzene[147] and primary aliphatic amines[148], oxygen-containing products (quinones[147] and nitroso-compounds[148]) are isolated. Reaction with alkenes and alkynes yields α-fluoro-ketones, fluorohydrins, and $\alpha\alpha$-difluoro-ketones[149].

The readily available trifluoromethyl hypofluorite[141,142] adds quantitatively to the double bonds of alkenes[150-152]. It reacts slowly with benzene according to the equation[152]



Under the influence of ultraviolet radiation the hypofluorite reacts with methane[152]:

$$CF_3OF + CH_4 \xrightarrow[\text{radiation}]{\text{ultraviolet}} COF_2 + CH_3F + HF.$$

Among this group the most suitable for use for the preparation of organofluorine compounds is fluorine chlorate, which can be prepared by the action of fluorine on cooled potassium chlorate[153], by heating perchlorates or perchloric acid with excess of fluorosulphuric acid at a high temperature[154], or by treating them with a mixture of this acid and antimony pentafluoride at room temperature[155]. Fluorine

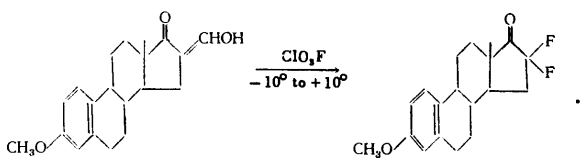
chlorate is a colourless substance melting at -110° and boiling at -46°.[153]. When heated it decomposes[156]:

$$2ClFO_3 = 2ClF + 3O_2.$$

Fluorine chlorate is able to replace the hydrogen atoms in reactive methylene groups[157,158], e.g. [157]

$$p\text{-}BrC_6H_4COCH_2COC_6H_4\text{—}Br\text{-}p \xrightarrow[\text{pyridine}]{ClO_3F,\ -10^\circ \text{ to } +10^\circ} p\text{-}BrC_6H_4COCF_2COC_6H_4\text{—}Br\text{-}p.$$

When this reagent is passed into an alcoholic solution of the sodium derivative of diethyl malonate, diethyl difluoromalonate is obtained[158]. Fluorine chlorate is employed for the fluorination of steroids[159-161], e.g. [161]



A method has recently been proposed for preparing *o*- and *p*-fluorophenols by treating the phenols with fluorine chlorate[162].

Sulphur tetrafluoride is used at the present time for replacing oxygen-containing groups by fluorine[163]. The hexafluoride is extremely stable[164]. The hexafluorides of selenium and tellurium do not exhibit oxidising properties[164].

It was earlier predicted that polonium would form a compound analogous to the Group VI hexafluorides SF_6, SeF_6, MoF_6, WF_6, and UF_6. However, no volatile compound was obtained when polonium-210 was heated in fluorine or when it was treated with liquid bromine trifluoride[26,165,166]. Treatment of polonium-208 with fluorine gave a volatile polonium fluoride, which underwent subsequent breakdown (chemical or radioactive). Perhaps its reactivity explains the lack of success of earlier attempts to prepare a volatile polonium compound[167].

3. Simple and Complex Halogen Fluorides

The halogen fluorides are extremely reactive substances, which can be arranged in the seq' ence of diminishing reactivity

$$F_2 > ClF_3 > BrF_5 > IF_7 > FCl > ,rF_3 > IF_5 > BrF^{168}.$$

Their reactions with many organic substances are very vigorous and may become explosive in character, so that the success of an experiment depends on the appropriate choice of technique.

Chlorine trifluoride, bromine trifluoride, and iodine pentafluoride are the most important as fluorinating agents, and possess several great advantages over both elementary fluorine and higher fluorides of metals. Firstly, they are liquid over quite a wide range of temperatures close to the normal, so that they can be more easily stored and used than can fluorine. Secondly, they do not leave any solid residues of the type of cobalt difluoride or silver fluoride after use, so that they are equally suitable for vapour-phase and for liquid-phase processes. Hitherto, however, the use of halogen fluorides has not been very widespread. The reasons are that they are too reactive and also that they usually introduce into the molecule not only fluorine but also, depending on the fluoride used, chlorine, bromine, or even iodine[169]. Sometimes this property is specially utilised; thus a mixture of halogens and halogen fluorides is an efficient source of halogen monofluorides in reactions with alkenes[170-172]:

$$IF_5 + 2I_2 = 5IF,$$

$$\overset{\delta+}{C}F_2{=}\overset{\delta-}{C}F\text{—}CF_3 + \overset{\delta+}{I}\,\overset{\delta-}{F} \rightarrow CF_3CFICF_3.$$

Iodine pentafluoride reacts with most organic compounds quite violently, sometimes even with ignition and evolution of hydrogen fluoride. However, insufficient study has been made either of the products or of the conditions of the reaction. Nevertheless, it is known that fluorobenzene is formed by reaction with benzene in the presence of the fluorides of arsenic and antimony[173].

The interaction of carbon tetrahalides with iodine pentafluoride has been described in detail[174], and the fluorination of carbon disulphide and carbonyl chloride with iodine pentafluoride has been studied[174]. Emeleus and Haszeldine obtained pentafluoroiodoethane from tetraiodoethylene and this pentafluoride[174].

Iodine heptafluoride is considerably more reactive than the pentafluoride. Although little work has been done on its reactions with organic substances, it is known to react with benzene in the presence of arsenic and antimony fluorides, yielding fluorobenzene[173].

Bromine trifluoride reacts explosively with the usual organic compounds. It can be successfully used for the partial replacement of other halogens by fluorine in polyhalogenated compounds, and for addition to multiple bonds in hexachlorobenzene, hexabromobenzene, and pentachlorotrifluoromethylbenzene[175,176]. However, this involves the addition to the double bonds not only of fluorine but also to some extent of bromine, obviously because the highly reactive bromine monofluoride is formed as an intermediate product. Bromine trifluoride can probably be used also for the fluorination of compounds containing some hydrogen; at least in the presence of boron trifluoride it replaces hydrogen in nitrobenzene by fluorine[173]. Selective fluorination of the nitrile group and the keto-group by bromine trifluoride in the presence of hydrogen fluoride or iodine pentafluoride at -15° has been reported[177,178]. Thus acetonitrile is converted into 1,1,1-trifluoroethane in yields of 70–90%. Under the same conditions acetone is converted into 2,2-difluoropropane in good yield (90%), but ketones of more complicated structure undergo cleavage.

Few data are available on the reactions of bromine pentafluoride. In the presence of phosphorus pentafluoride at low temperatures, for example, it converts bromobenzene into *p*-bromofluorobenzene[173].

Chlorine monofluoride is a very reactive gas, which sets fire to organic compounds. However, it can act on highly halogenated hydrocarbons, saturating double bonds and replacing hydrogen and part of the chlorine by fluorine[179].

Technical chlorine trifluoride is widely used in atomic and rocket technology[180]. In the absence of appropriate precautions, the interaction of this compound with the usual organic compounds is accompanied by explosion.

The reaction of benzene with chlorine trifluoride in polyfluorinated solvents[173] or carbon tetrachloride[181,182] in the presence of salts of various elements or of halogens as catalysts leads at low temperatures to the formation of fluoro- and chloro-benzenes[181,182], accompanied by low

yields of products involving addition of halogens to the ring carbon atoms[181,182]. Under the same conditions chlorobenzene gives *ortho*- and *para*-substitution products. Liquid-phase fluorination probably has an electrophilic mechanism[181,183]:

$$ClF_3+2CoF_2 \rightarrow 2CoF_3+ClF,$$
$$ClF_3+CoF_3 \rightarrow F^+ + CoF_4^- + ClF.$$

The vapour-phase halogenation of benzene with chlorine trifluoride, which is a free-radical process, yields a complex mixture of chlorofluorocyclohexanes[183,184]:

$$ClF_3 \rightarrow ClF+2F^{\cdot},$$
$$ClF \rightarrow Cl^{\cdot}+F^{\cdot},$$
$$C_6H_6 \xrightarrow{Cl^{\cdot},F^{\cdot}} C_6H_xCl_yF_z\ (x+y+z)=12.$$

Besides highly halogenated cyclohexanes, the mixture also contains chloro- and chlorofluoro-benzenes.

The liquid-phase halogenation of hexachlorobenzene with excess of chlorine trifluoride involves a chain of additions and vinyl and allyl substitutions leading to the formation of chlorofluorocyclohexenes $C_6F_nCl_{10-n}$ (n = 4–6). A very large excess (400%) yields chlorofluorocyclohexanes $C_6F_nCl_{12-n}$ (n = 5–7)[185].

Most of the information on the reactions of chlorine trifluoride with organic substances will be found in the patent literature, the investigations being aimed at obtaining greases and oils. Without going into details, we can summarise the results by stating that highly fluorinated chlorofluorohydrocarbons can be obtained by selecting appropriate conditions, but that, because of steric hindrance due to the massive chlorine atoms, replacement of the hydrogen is not complete[183,184], so that the products of the chlorofluorination are less stable, both thermally and chemically, than oils obtained in other ways.

A higher degree of replacement of hydrogen, and at the same time of chlorine, can be obtained in the presence of antimony salts, which obviously promote substitution of chlorine by fluorine, and thereby diminish the steric hindrance to replacement of the remaining hydrogen atoms[186]. More stable products are obtained by treating perchlorinated unsaturated and aromatic compounds[175,176,185,187].

The fluorination of carbon or coal, both by fluorine itself and by halogen fluorides, is of intrinsic interest. When fluorine, a mixture of fluorine and chlorine, or chlorine trifluoride is passed, diluted with nitrogen, through graphite or wood charcoal at temperatures between 160° and 660°, various perfluoro- or polychlorofluoro-carbons containing one or more carbon atoms are formed. Similar results are obtained with other halogen fluorides. The use of coal makes it possible to obtain products of far higher molecular weight and oils which distil between 100° at 1 atm and 250° at 20 mm.[188]

All halogen fluorides form complexes with metal fluorides. Such complexes can be obtained by two main methods — (1) direct mixing of the initial components[189,190], e.g.

$$AF + BrF_3 \rightarrow ABrF_4;$$

or (2) fluorination of metal halides with fluorine at high temperatures[191–195]

$$ABr \xrightarrow[t^\circ]{F_2} ABrF_4.$$

Complex halogen fluorides can also be prepared by treating iodates[122], chlorates[196], and metals (gold)[114] with bromine trifluoride. Iodine pentafluoride and the complex KIF_6 are obtained by the action of sulphur tetrafluoride on potassium iodate[197].

At the present time the following compounds are known

$$ACIF_4\ (A=K, Rb, Cs, Ag);\ RbClF_6,$$
$$ABrF_4\left(A=K, Rb, Cs, \frac{Ba}{2}\right);\ RbBrF_6;$$
$$AIF_4\ (A=K, Rb, Cs);\ AIF_6\ (A=Rb, Cs).$$

These complexes react violently with water, evolving oxygen, liberate iodine from potassium iodide solution[189,191,193,198], and oxidise nickel(II) salts to the quadrivalent state[191,193,198]. All the complexes obtained are milder halogenating agents than the corresponding halogen fluorides. The reactivity of the complex depends on the nature of the cation present in the outer sphere. Thus whereas under normal conditions $KBrF_4$ does not react with acetone, dioxan, or carbon tetrachloride, $AgBrF_4$ and $BaBr_2F_8$ ignite ether, acetone, petrol, and dioxan, but do not react with carbon tetrachloride. Bromine trifluoride not only ignites acetone and dioxan but also reacts violently with carbon tetrachloride[189]. The thermal stability of the complex halogen fluorides is increased by replacing the potassium cation by rubidium, and especially by caesium, while the violence of the reaction with water increases from iodine derivatives to those of bromine and chlorine[194].

The infrared spectra of the complex halogen fluorides have been recorded[194], their magnetic susceptibilities have been measured[194], and the structure of these interesting compounds has been discussed[199]. The fact that they exhibit a wide range of fluorinating activity makes them extremely promising materials for the synthesis of various organofluorine compounds.

In the electrochemical fluorination of salts of various amines it has been noted that bromide and iodide (but not chloride) anions have a favourable effect on the yield of perfluorinated products. The presence of iodine can be readily detected in fluorinated iodides from the characteristic colour, both in the electrolyte and in the perfluorinated raw material. The favourable effect of bromine and iodine may perhaps be explained by the mild fluorinating action of the complexes formed by organic bases with halogen fluorides.

4. Fluorine Compounds of the Inert Gases

As early as 1933 Pauling predicted the existence of KrF_6, XeF_6, and XeF_8. The first such compound, xenon hexafluoroplatinate, was obtained by oxidising xenon with platinum hexafluoride[86]. Four fluorides of xenon — XeF_2, XeF_4, XeF_6, and XeF_8 — have now been prepared[200,201].

Xenon difluoride is a colourless substance, which forms crystals reaching several millimetres in size. It melts at 140°, and can be supercooled to 50° without solidifying[201]. It is stable at room temperature, and can be stored in nickel or quartz vessels for several months. Xenon difluoride can be kept for a long time in sealed glass tubes at the temperature of solid carbon dioxide, but at room temperature it is slowly decomposed, even in the dark, by interacting with the glass. It reacts vigorously with methanol, and slowly with water. In solutions of alkalis and dilute acids it is decomposed, not especially violently, and it liberates iodine from acidified [potassium iodide] solution; it decomposes in dry paraffin[201], and dissolves in anhydrous hydrogen fluoride without decomposition. At

400° it is completely reduced by hydrogen to xenon and hydrogen fluoride[201].

Xenon tetrafluoride exists as colourless crystals melting at 114°.[201] It readily sublimes in a vacuum as large colourless crystals. Xenon tetrafluoride remains unchanged under vacuum in nickel or Pyrex glass for a month[200,201]. It attacks glass with the formation of silicon tetrafluoride and oxygen. Its mixtures with sugar or sulphur explode similarly to those with potassium chlorate. When deposited on paper or cotton wool, dry xenon tetrafluoride explodes on being heated; after it has become moist in the air, it instantly chars paper, and frequently it may even ignite spontaneously[201].

Xenon tetrafluoride fumes in the air, being hydrolysed to $Xe(OH)_4$, and dissolves in water, glacial acetic acid, and concentrated nitric and sulphuric acids; it reacts with acetic acid or acetic anhydride to give a crystalline substance, possibly xenon acetate. Cyclopentadiene, tetrahydrofuran, dioxan, and ethanol ignite under the influence of xenon tetrafluoride. Petrol dissolves it, and acetone reacts with it. Xenon tetrafluoride neither dissolves in nor reacts with carbon disulphide, carbon tetrachloride, dimethylformamide, diethyl ether, cyclohexane, and perfluoroheptane[201]. It oxidises metallic platinum to the tetrafluoride[201].

Xenon hexafluoride is a colourless crystalline substance of melting point 47.7° ± 0.2°;[201] it is stable at room temperature, and can be kept in a nickel vessel without decomposition for a week. Samples which have been sealed in quartz react slowly with the latter to give a colourless transparent liquid[202]. It dissolves in anhydrous hydrogen fluoride[202], the resulting solutions, unlike those of the difluoride and the tetrafluoride, possessing a high electrical conductivity, perhaps as a result of dissociation into the ions XeF_5^+ and HF_2^-. Hydrogen at room temperature and mercury at 100° reduce xenon hexafluoride to elementary xenon[201].

Xenon tetrafluoride and hexafluoride are hydrolysed according to the equations[203]

$$XeF_2 + H_2O \rightarrow Xe + 0.5\,O_2 + 2\,HF,$$
$$3XeF_4 + 6\,H_2O \rightarrow XeO_3 + 2Xe + 1.5\,O_2 + 12\,HF,$$
$$XeF_6 + 3\,H_2O \rightarrow XeO_3 + 6\,HF.$$

Alkaline hydrolysis of xenon hexafluoride yields xenic acid[201]. With boron trifluoride and arsenic pentafluoride at room temperature xenon hexafluoride forms addition products[201].

Xenon octafluoride has recently been synthesised in a sealed tube at room temperature. It is an unstable pale yellow gas which, when cooled in liquid nitrogen, is converted into a yellow solid[201,204].

The fluorides of xenon are of interest for the selective fluorination of alkenes, which can be effected in the vapour phase at room temperature. The xenon which is formed can be easily separated from the reaction product[205]. The reactivity of the fluorides increases with the proportion of fluorine in the molecule. Thus xenon hexafluoride, the most reactive of those studied, causes cleavage of the perfluoropropene molecule with the formation of hexafluoroethane and carbon tetrafluoride, whereas xenon difluoride does not react even after six days. The reaction with the tetrafluoride is represented by the equation

$$XeF_4 + 2\,CF_3CF{=}CF_2 \rightarrow 2\,CF_3CF_2CF_3 + Xe.$$

An interesting rearrangement takes place in the reaction of the xenon fluorides with aliphatic alkenes. Ethylene reacts with xenon difluoride and tetrafluoride at room temperature to form 1,1- and 1,2-difluoroethanes in 35% and 45% yield respectively. With propene, however, these fluorides give 1,1-difluoropropane as the main product (65%):

$$\left.\begin{matrix}XeF_2\\XeF_4\end{matrix}\right\} + \begin{matrix}CH_2{=}CH_2 \rightarrow CH_2FCH_2F + CH_3CHF_2 + Xe,\\CH_3CH{=}CH_2 \rightarrow CH_3CH_2CHF_2 + Xe.\end{matrix}$$

The relative instability of 1,2-difluoroethane and the enhanced stability of 1,1-difluoroethane suggest that the products formed initially isomerise under the reaction conditions into *gem*-difluorides. Furthermore, hydrogen fluoride is detected in the reaction mixture when the fluorides react with propene, which indicates partial fluorination of the methyl (allyl) group[205].

An unknown fluoride of radon RnF_x has been synthesised from the elements at 400°.[200,201] It is more stable and less volatile than xenon tetrafluoride. It is also reduced by hydrogen less vigorously than is the latter: at 200° the radon fluoride is stable in hydrogen, but at 500° and a hydrogen pressure of 800 mm it is completely reduced in 15 min.[200]

Krypton difluoride has now been obtained[206], by photochemical interaction of the elements mixed with argon[201] and by the action of a silent discharge on a mixture of the elements at low pressures (~20 mm) and temperatures (-183°)[206]. The difluoride is a crystalline substance which sublimes at temperatures considerably below 0°. It is kept in a dry Pyrex glass or polychlorotrifluoroethylene container at the temperature of solid carbon dioxide. It undergoes spontaneous decomposition at room temperature.

Hydrolysis of krypton difluoride is analogous to that of xenon difluoride[206]:

$$KrF_2 + H_2O \rightarrow Kr + 0.5\,O_2 + 2\,HF.$$

Hydrolysis is rapid also in acid solution, in contrast to xenon difluoride, which can exist in acid solution for a long time. Krypton difluoride reacts with antimony pentafluoride at -20° to form the compound $KrF_2.SbF_5$, this salt being more stable and less volatile than the difluoride itself. The complex is analogous to the salt $XeF_2.SbF_5$.[201,206]

---o0o---

All fluorides of high oxidising power can be divided into five groups according to their oxidising activity. Assignment to one group or another is based on general chemical properties, and the boundaries between the groups are to some extent arbitrary.

I	II	III	IV	V
NiF_4, NiF_3 CoF_4 CuF_3 AgF_3 OsF_6 NdF_4 DyF_4 PdF_4	$ClF_3 > BrF_3 > IF_7 > ClF$ $PtF_6 > PuF_6$ RuF_6, $NpF_6 > BrF_5$ RhF_6, $IrF_6 > BrF_5$ $CrF_6 > MnF_4$ XeF_6 OsF_6	$AuF_3 > AgF_2 > CoF_3$ BiF_5 BrF_3 RuF_5 UF_6 $XeF_6 > XeF_4$ KrF_2	MnF_3 $PbF_4 > CeF_4$ PdF_3 RuF_4 RhF_4 IF_5 CrF_5 TlF_3 TbF_4 TcF_6 XeF_2 CF_3OF $FClO_3$	VF_5 SbF_5 HgF_2

The first group comprises higher fluorides which, because of their high reactivity and thermodynamic instability, have not yet been obtained in the free state, although they exist as complex derivatives. The second group includes fluorides possessing very high fluorinating power, being capable of fluorinating halides to halogen fluorides, and all other elements to higher fluorides; they ignite organic compounds even at room temperature. The third group contains fluorides which are capable of displacing chlorine from hydrochloric acid and oxygen (sometimes as ozone or oxygen difluoride) from water, and reacting with organic compounds to replace hydrogen by fluorine atoms; these fluorides may ignite on contact with some organic compounds at room temperature. The fourth group is represented by fluorides possessing moderate reactivity, although capable of replacing hydrogen by fluorine atoms. The fifth group comprises fluorides which, while being oxidising agents, are incapable of substituting fluorine for hydrogen in organic compounds, but are able in isolated cases to add fluorine to multiple bonds. In some cases the relative activities of the fluorides within the groups are known.

I. INTRODUCTION

New oxidants, possessing a wide range of action and great selectivity, have been discovered in recent years, among them being nickel peroxide[1], manganese(III) acetate[2], osmium tetroxide, the chromium trioxide–pyridine complex[3], selenium dioxide[4], etc. An important place in this series is occupied by active manganese dioxide, which since 1948 has found wide application for the oxidation of various classes of substances, especially unstable natural

compounds containing a hydroxy-group. Manganese dioxide exists in several crystalline forms[5], some of them being encountered in minerals.

Since the discovery by Ball et al.[6] of the method of selectively oxidising the polyene alcohol vitamin A_1 with specially prepared manganese dioxide, this oxidant has attracted the attention of a large number of research workers. The selective action of active manganese dioxide and the mild reaction conditions make this reagent very convenient for the oxidation of labile polyene and polyenyne alcohols, steroids, and vitamins. Whereas manganese dioxide was presented in the earlier paper as a specific reagent for the oxidation of $\alpha\beta$-unsaturated hydroxy-compounds, subsequent investigations have considerably extended the limits to its possible application.

Hitherto the method of oxidation with manganese dioxide has been presented in isolated papers and incomplete reviews[7-11], covering by no means all the experimental results. The aim of the present review is to systematise the main investigations in this field, attention being paid to oxidation with active manganese dioxide in neutral medium.

II. TYPES OF MANGANESE DIOXIDE AND METHODS OF PREPARATION

Following Ball's discovery, quite contradictory information appeared in the literature on the oxidation of alcohols by manganese dioxide. Thus Ball[6] and Turner[12] were unable to oxidise benzyl alcohol, whereas Harfenist[13] and Highet[14] obtained benzaldehyde in excellent yields under the same conditions. It can readily be seen that the reason for such discrepancies in the results is the varying oxidising power of the numerous modifications of manganese dioxide. The type of the manganese dioxide is determined primarily by the mode of preparation. Unfortunately, it is difficult to obtain a dioxide of standard activity which might serve as a criterion for comparing the oxidising efficiency of all its varieties. For a correct choice of oxidant and reaction conditions it is probably important to find the way in which the crystal structure influences the oxidising power. Many papers have been published[15-19] on the crystal lattice of the various modifications of manganese dioxide, but little attention has been paid to the effect of the fine structure of this reagent on its oxidising properties. In some cases[20] an analogy has been noted between depolarising and oxidising activities.

The crystal structure of manganese dioxide has been studied by electron diffraction, X-ray diffraction, and electron microscopy. The X-ray pattern of manganese dioxide powder was found to have changed quite markedly after oxidation, but the change disappeared after six repetitions of the reaction. The oxidising power of manganese dioxide is almost independent of crystal size, although microcrystalline forms exhibit a higher initial rate of oxidation. Detailed data on the correlation between the effectiveness and the lattice structure of the manganese dioxides could not be obtained. It was found empirically that the more active forms comprise those obtained by oxidising manganese sulphate with potassium permanganate in alkaline medium[21], the γ-dioxide obtained by treating the permanganate with concentrated hydrochloric acid[22], and colloidal manganese dioxide[23].

Several methods have now been worked out for the preparation of active forms of manganese dioxide. Among all the forms which have been described, those prepared by the methods of Attenburrow (ACC†)[21] and of Rosenkranz (RSM)[24] have become most widely accepted and used. The first of these methods consists in the interaction of hot (80–90°) solutions of potassium permanganate and manganese(II) sulphate in the presence of caustic soda. The precipitate is separated, washed with distilled water, and dried at 100–120°. The activity of such a dioxide is not diminished by carrying out the synthesis under acid conditions[25] or after washing with dilute nitric acid. Ball, Goodwin, and Morton[6] prepared manganese dioxide (BGM) by the interaction of potassium permanganate and manganese(II) sulphate in neutral medium at room temperature. The activity of the BGM dioxide is somewhat lower than that of the RSM form prepared from the same reactants but at 80–90°. The oxidising activity of the latter is increased by washing it with 15% nitric acid[24]. Good results were obtained with manganese dioxide prepared by the pyrolysis of manganese(II) salts[13,26]. It is noteworthy that each form of active dioxide exhibits specific features in the oxidation of various classes of compounds[27].

Gritter and Wallace[26] consider that the forms of the dioxide prepared from potassium or barium permanganate and also from manganese chromate possess the highest activity. They suggest that oxidation is accelerated by the presence of traces of potassium permanganate or of higher oxides of manganese, included in the crystal lattice or adsorbed on the surface of the manganese dioxide. The decrease in activity of the ACC dioxide produced by washing with organic solvents is explained by the desorption of impurities from the surface. However, the results of X-ray examination and the ineffectiveness of the addition of small quantities of potassium permanganate to the manganese dioxide during the oxidation contradict these hypotheses. This conclusion is inconsistent also with the high activity of certain oxidants prepared by the pyrolysis of manganese(II) salts, which excludes any catalytic effect due to contamination with potassium permanganate. Neither naturally occurring forms of manganese dioxide nor the commercial product possess appreciable oxidising power in neutral medium. Gritter[26] made a comparative study of the activities of a series of dioxides by oxidising benzyl alcohol with the five most widely used forms, and showed that the oxidising power falls in the sequence

$$MnO_2: BGM^{24} > ACC^{21} > HBL^{15} > GW^{26}.$$

III. REACTION CONDITIONS

In the oxidation of alcohols to the corresponding carbonyl compounds this method may be preferred to Oppenauer's method[29]. The reaction is conducted under a great variety of conditions — with different solvents, over a fairly wide temperature range, in air and in nitrogen, and with the components present in various proportions — the starting material being in most cases shaken at room temperature with the finely ground dioxide in an inert solvent, or a

† For brevity and convenience the various forms of manganese dioxide will henceforward be denoted by the initial letters of the surnames of the authors who have published the methods of preparation.

solution being slowly passed through a column filled with the oxidant[30]. The time required for completion of the reaction varies from 10 min to 10 days and longer depending on several factors, among them being the activity of the dioxide, the solvent, the temperature of the reaction, the substance to be oxidised, and the relative proportions of the components.

1. Solvent

It has been found empirically that in many cases the rate and the direction of the reaction are affected by the choice of solvent. Many workers have noted the deactivating effect of certain solvents on manganese dioxide. Polar solvents, which are strongly adsorbed on the surface of the active dioxide, lower the activity of the oxidant. These include primarily aliphatic, especially tertiary, alcohols. Acetone and ethyl acetate also deactivate the oxidant, but considerably more slowly; in this case the activity of the manganese dioxide is easily restored by drying in a vacuum. Gritter[28] determined the rate of oxidation of unsaturated alcohols by manganese dioxide in various solvents, and showed that the fall in the rate of oxidation of alcohols in the sequence — petroleum ether > carbon tetrachloride > benzene — corresponds to an increase in the affinity of solvent and dioxide: benzene forms the most stable "complex" with the active centres on the surface, which prevents contact between oxidant and alcohol molecule. The solvent has been found to have a strong influence on the yields of the oxidation products, sometimes even changing the direction of the reaction. Thus Morton[6] showed that vitamin A in petroleum ether is converted almost quantitatively into retinene, whereas in diethyl ether it forms anhydrovitamin A. The solvents most widely used for oxidation in the cold are light petroleum ether, saturated hydrocarbons (pentane, hexane, cyclohexane), ethers, and acetone; ethyl acetate, dimethylformamide, acetonitrile, dimethyl sulphoxide, etc. are also used. The same solvents are employed, as well as water and pyridine, for reactions at high temperatures.

2. Time and Temperature of Reaction

The time and the temperature of the reaction depend on the activity of the manganese dioxide, the material to be oxidised, and the relative proportions of the components. The duration of oxidation at room temperatures varies within wide limits: whereas the transformation of $\alpha\beta$-unsaturated alcohols is usually complete at room temperature after a few minutes[31], the oxidation of alkylanilines[32] and the formation of steroid dienones[33] occupy 16–24 h. In order to shorten the reaction time, oxidation is frequently conducted at an elevated temperature in the boiling solvent, the water formed sometimes being removed by azeotropic distillation. The rate of the reaction and the time at which it is complete can be assessed qualitatively from the liberation of water. Raising the temperature to 70–120° markedly shortens the reaction time, but the yields, the purity of the product, and the selectivity of action of the oxidant are diminished. In some cases, especially when carbon–carbon bonds undergo cleavage during the oxidation, the reaction is complete at 80–100° after 10–20 h.[34,35] When the reaction is conducted at room temperature, vigorous agitation is necessary for maximum contact of the material with the surface of the dioxide in order to avoid local overheating.

3. Proportions of Reactants and Mode of Action of Active Manganese Dioxide

The oxidation of organic compounds in neutral solvents by active manganese dioxide is a heterogeneous reaction[6], so that the quantity of oxidant used is greatly dependent on the particle size of the dioxide. The particle size normally employed is 80–200 mesh. It is as yet impossible to determine theoretically, on the basis of known facts, the quantity of oxidant required. The ratio of substance to reagent usually varies within the range 1 : 5–20 by weight, and in some cases the excess of oxidant is increased to 1 : 50. The optimum proportions for the oxidation of $\alpha\beta$-unsaturated alcohols are 1 : 10 at room temperature, and 1 : 4–6 on boiling. In the opinion of many authors the ease of oxidation depends on the adsorbability of the given compound on the manganese dioxide. Ball et al.[6] consider this reaction to occur in three stages — adsorption of the substance from solution on the oxidant, oxidation, and desorption of the reaction product into the solution — from which it may be expected that more saturated compounds, which are more poorly adsorbed on the surface of the dioxide, should react at a lower rate. Results obtained by Harfenist[13] are fully consistent with Ball's conclusions. They showed that alcohols can be arranged in the sequence — conjugated polyene carbinols, benzyl and furfuryl alcohols, and vinyl- and ethynyl-carbinols — according to their ease of oxidation. However, the degree of adsorption is hardly the sole factor determining the reaction velocity.

Harfenist noted an interesting peculiarity in the oxidation of benzyl alcohols: the reaction does not usually go to completion, the product always being contaminated with the initial carbinol. In his view a permanent equilibrium is established at the surface of the dioxide between the starting material and the reaction product. Therefore oxidation proceeds successfully until a certain point is reached, at which the quantity of carbonyl compound formed attains a critical value, i.e. a concentration at which the final product begins to displace molecules of the initial alcohol from the dioxide surface. Henbest and Thomas[32] showed that only a small proportion of the oxygen in the manganese dioxide is consumed during oxidation. In their opinion water, bound to the manganese dioxide surface in the form of free hydroxyls, takes part in this reaction. Evans[8] points out that hydrated manganese dioxides contain available oxygen, the quantity of which has diminished by the theoretical amount after oxidation. The relative quantity of available oxygen in the various types of dioxide decreases in the sequence

$$MnO_2: GW > HBL > RSM > BGM > ACC.$$

The above sequence does not correspond to that based on the efficiencies of these forms of manganese dioxide in oxidising $\alpha\beta$-unsaturated alcohols. Consequently there is no direct link between the quantity of oxygen available in a sample of manganese dioxide and its oxidising power. If, however, we examine the dependence of rate of oxidation on the percentage contamination with other oxides of manganese, we find that the oxidising activity increases as the purity of the dioxide diminishes, the ACC dioxide forming an exception. Gritter[28] suggested that oxidising power is affected by the nature of the impurities present, especially cationic impurities. In his view, successful oxidation requires the presence on the manganese dioxide surface of centres of diminished electron density, capable of attracting the electron-rich oxygen of the alcoholic hydroxyl. The reaction velocity is determined by the number and type of these active centres.

The mechanism of oxidation by manganese dioxide has not yet been completely elucidated, and therefore the proposed schemes frequently contradict the experimental facts. Some investigators consider that compounds capable of forming more stable carbonium ions are more readily oxidised, but most authors deny the intermediate formation of a carbonium ion. Pratt[36] noted that the rate of oxidation of alcohols $C_6H_5CH(OH)-R$ increases roughly sevenfold as the radical R is varied in the sequence

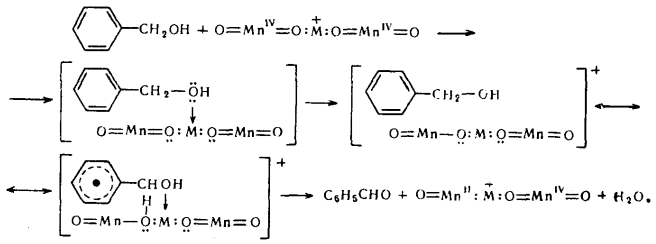
$$-\underset{\displaystyle CH_3}{\overset{\displaystyle |}{CH}}-C_6H_5;\ -\underset{\displaystyle CH_3}{\overset{\displaystyle |}{CH}}-CH_3;\ -CH_2C_6H_5;\ -CH_3;\ H;\ -C_6H_5;\ -CH=CH-C_6H_5;\ -COC_6H_5.$$

Replacement of the hydrogen atoms in the methyl group by radicals leads to a successive decrease in the rate of oxidation. Branched radicals probably cause steric hindrance to adsorption of the oxidisable molecule on the surface of the active dioxide. Nevertheless, these substituents govern the stability of the free radicals. A change in structure of the substituents which increases the stability of the free radical is accompanied by an increase in reaction velocity. Thus primary aliphatic alcohols are oxidised more slowly than secondary alcohols, and the latter in turn more slowly than phenylmethanols.

The free-radical mechanism suggested by Pratt[36-38] for the oxidation of organic compounds by manganese dioxide, combined with the adsorption theory, is probably the most successful in explaining the general features of the oxidation:

$$R_2CHOH + O{=}Mn^{IV}{=}O \rightarrow R_2\dot{C}OH + HO{-}Mn^{III}{=}O \rightarrow$$
$$\rightarrow R_2\dot{C}{-}\acute{O} + HO{-}Mn^{II}{-}OH \rightarrow R_2CO + MnO + H_2O.$$

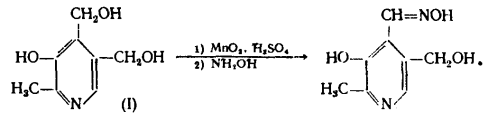
According to Gritter[28], in the course of the reaction the oxidisable substance forms a complex with the dioxide, ions of other metals, present as impurities in the oxidant, being involved in its formation:



An analogy can be traced between the oxidation of alcohols by manganese dioxide and the autoxidation of hydrocarbons in the presence of metal oxides, where similar complexes are probably formed[38].

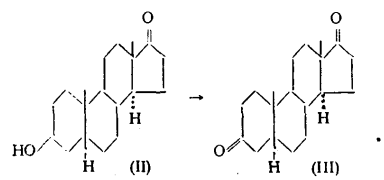
IV. OXIDATION OF ALCOHOLS

The oxidation of primary aliphatic alcohols with manganese dioxide in an acid medium was studied as early as the nineteenth century by Liebig[39], who converted ethanol into acetaldehyde with pyrolusite in sulphuric acid. β-Chloroacrylaldehyde[40], fluoroacetaldehyde[41,42], and several other aliphatic and aromatic carbonyl compounds have been obtained under similar conditions. The use has been described of manganese dioxide in acid medium for the oxidation of derivatives of vitamin A,[50] pyridoxol (I), and similar compounds[23,43-49]:

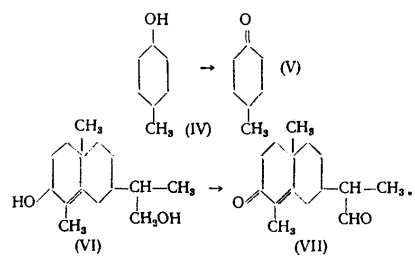


1. Oxidation of Saturated Alcohols in Neutral Medium

Comparison of the relative rates of oxidation of various types of alcohols shows that saturated alcohols are oxidised with great difficulty, while alcohols in which the hydroxyl is activated by a double or a triple bond, a system of conjugated bonds, an aromatic ring, or a carbonyl group are oxidised considerably more readily. The early work showed that neutral manganese dioxide (BGM) is inert towards primary and secondary aliphatic alcohols at room temperature. However, it was subsequently found that saturated alcohols can be oxidised to good yields of the corresponding aldehydes and ketones. In the oxidation with alkaline manganese dioxide (ACC) of ethanol, propan-2-ol, and isobutanol the yields of the carbonyl compounds reach 50%.[35] Gritter and Wallace[26] oxidised propan-1-ol and propan-2-ol under similar conditions, and obtained yields of 78% and 92% respectively. According to these workers, a long time or a high temperature is required for the reaction. The successful oxidation of saturated carbinols necessitates a large excess of the dioxide, as well as careful selection of the solvent[51]. For example, 3β-hydroxyandrostan-17-one (II) and its epimer when stirred in hexane or acetonitrile with ACC manganese dioxide for a day are converted into androstane-3,17-dione (III) in 99% yield:



Methylcyclohexanol (IV) in acetonitrile gives a 71% yield of 4-methylcyclohexanone (V):

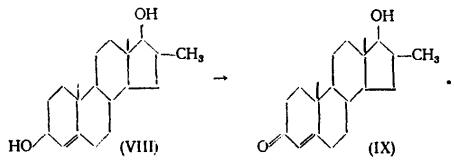


The analogue of α-santonin (VI)[52] is oxidised by manganese dioxide to the keto-aldehyde (VII).

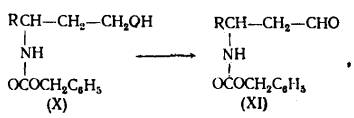
Thus the successful oxidation of saturated carbinols of various classes requires careful choice of reaction conditions and the form of the active dioxide. By means of active manganese dioxide it has proved possible to effect the oxidation of steroid alcohols[53], derivatives of gibberellic acid[54,55], alkaloids[56-59], cyclopropylmethanols[60], derivatives of tetrahydropyran-2- and -4-ols[14], bicyclo[3,3,0]-octanol[61], and other complex hydroxylated compounds[51,62-65].

The different positions of hydroxy-groups in polyols often permits selective oxidation of the hydroxyls[66-69]. A

clear example of such specific oxidation is provided by the preparation of 17α-hydroxy-16-methyl-13α,14β-androst--4-en-3-one (IX) from the corresponding 3,17-diol (VIII):[66]



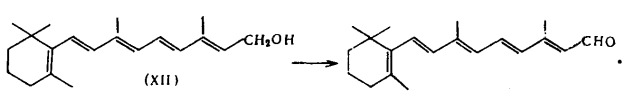
Here it is only the allylic hydroxyl which undergoes oxidation. Amino-alcohols and their benzyloxycarbonyl derivatives (X) are oxidised by the alkaline dioxide (ACC) with the formation of amino-aldehydes (XI):[70]



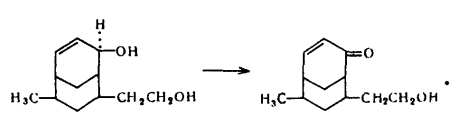
where R = C_6H_5, p-$CH_3OC_6H_4$.

2. Oxidation of αβ-Unsaturated Alcohols

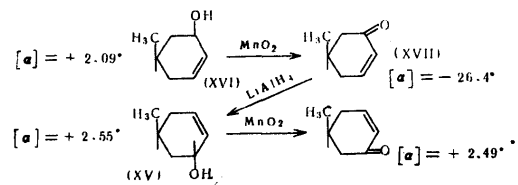
The first organic compound to be oxidised with active manganese dioxide in neutral medium was vitamin A_1 (XII), which contains a pentaene conjugated bond system and an allylic hydroxyl:



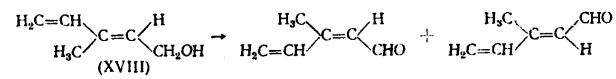
This work formed the start of a broad investigation into the oxidation of various unsaturated carbinols by manganese dioxide. During the following four or five years active manganese dioxide became firmly established as a convenient and efficient oxidant for the conversion of primary and secondary αβ-unsaturated alcohols into the corresponding carbonyl compounds. Detailed investigations of this reaction revealed certain relations between the structure and the ease of oxidation of the alcohols. Successful oxidation was found to require that the multiple bond in the unsaturated compounds should be located in the α-position with respect to the oxidisable hydroxyl. A break in conjugation sharply increases the inertness of the alcohols towards manganese dioxide. An example is provided by the oxidation of glycols containing only one allylic hydroxyl. Thus *cis*-8-2′-hydroxyethyl-6-methylbicyclo[3,3,1]non-3--en-2-ol (XIII) on treatment with active manganese dioxide gives only one oxidation product, 8-2′-hydroxyethyl-6--methylbicyclo[3,3,1]non-3-en-2-one (XIV):[71]



A characteristic feature of this reaction is the insensitivity of the carbon skeleton of unsaturated alcohols to the action of active manganese dioxide. In none of the work was cleavage of carbon–carbon bonds, change in the carbon skeleton, or allyl rearrangement noted, although these are so characteristic of many oxidations. However, some substances undergo stereochemical changes during oxidation. Cases have been reported[72] in which the angle of rotation of certain optically active alcohols changes on oxidation. The sign of rotation remains unchanged on treatment of (+)-*trans*-5-methylcyclohex-2-enol (XV) with manganese dioxide, whereas the (+)-*cis*-form (XVI) yields the *cis*--methylcyclohexenone (XVII), whose angle of rotation has the opposite sign:

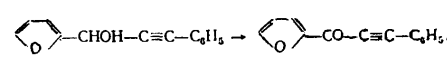


Sometimes the geometric configuration of the molecule changes during the reaction, with rearrangement of *cis*- and *trans*-substituents. Robeson[73] detected no change in the geometry of the molecule during oxidation of the geometric isomers of vitamin A_1 to the corresponding vitamin A aldehydes. Similar results were obtained by Wendler and Slates[74] in the oxidation of the *cis*- and *trans*-isomers of 2-ionylidene-ethanols. However, Boehm et al.[75,76] have observed *cis–trans* isomerisation in the transformation of pentadienols and pentenynols: *cis*-penta-2,4-dienol is oxidised by active manganese dioxide in pentane without geometric changes, whereas the *trans*-carbinol (XVIII) forms on oxidation a mixture of *cis*- and *trans*-isomers in the proportions 1 : 4:



Unsaturated alcohols containing one or more multiple bonds are very sensitive to oxidation by active manganese dioxide. This can be regarded as a classic method of synthesising unsaturated aldehydes and ketones, especially with the extremely labile naturally occurring polyene alcohols. Alcohols containing a double bond in the α-position to the hydroxy-group are oxidised by manganese dioxide to give a high yield of the corresponding carbonyl compounds, examples of this reaction being provided by the oxidation of allyl[26] and cinnamyl[36] alcohols to acrylaldehyde and cinnamaldehyde respectively. Good results have been obtained both with primary alcohols containing one double bond[77–82] or one triple bond[83] and with secondary alcohols[84–86]. The oxidation of prop-2-ynol (XIX) in the presence of diethylamine[87] gives the aminoacrylaldehyde (XX):

Alcohols in which the hydroxyl is activated by two multiple bonds[88–98] or by a multiple bond and an aromatic ring[99–102] are readily oxidised. Similarly, 1-fur-2′-yl--3-phenylprop-2-ynol (XXI) is converted into a high yield of 1-fur-2′-yl-3-phenylprop-2-ynone (XXII):[99]



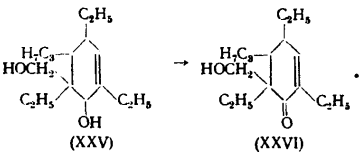
Active manganese dioxide has proved indispensable for the selective oxidation of such unstable compounds as the highly unsaturated polyene and polyenyne carbinols[103–114].

Thus treatment of dodec-2-ene-4,6,8,10-tetraynol (XXIII) with manganese dioxide gives dodec-2-ene-4,6,8,10-tetraynal (XXIV):[103]

$$CH_3-(C\equiv C)_4-CH=CH-CH_2OH \rightarrow CH_3-(C\equiv C)_4-CH=CH-CHO.$$
(XXIII) (XXIV)

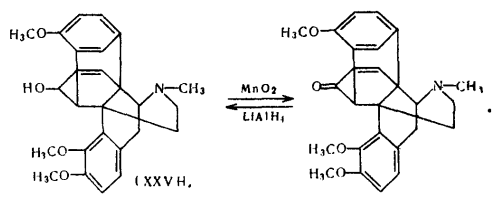
6-Methyl-8-phenylocta-3,5,7-trien-2-ol reacts similarly[104].

This method has been successfully applied to the oxidation of unsaturated cyclic carbinols[115-127]:



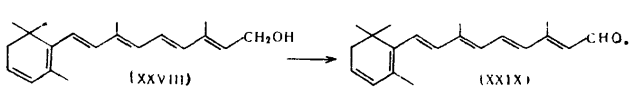
(XXV) (XXVI)

The cyclohexenone (XXVI) is obtained in 80% yield by oxidation of the corresponding alcohol (XXV) in cyclohexane at 20°.[115] Active manganese dioxide has been used for the oxidation of hydroxy-groups in certain alkaloids and other natural products[128-140]. This has enabled their structure to be established, e.g. in the case of flavothebaone (XXVII):[129]



(XXVII)

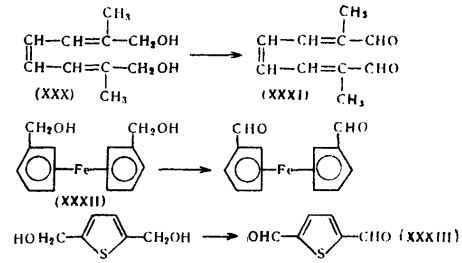
The exceptionally mild action of the active dioxide has enabled it to be used for the preparation of difficultly accessible carbonyl derivatives of vitamin A. In this case none of the known oxidants gave positive results. Numerous papers have been published on the synthesis of the corresponding aldehyde from vitamin A_1,[6,30,141] α- and β-ionylideneacetaldehydes[142-145], and β-ionone[146] by means of manganese dioxide in inert solvents at room temperature. A similar conversion is characteristic also of vitamin A_2 (XXVIII), which is readily oxidised to the aldehyde (XXIX),[147-149] and also of 8,9-dehydrovitamin A,[21] neovitamin A,[150] and several other similar compounds[151-155]:



(XXVIII) (XXIX)

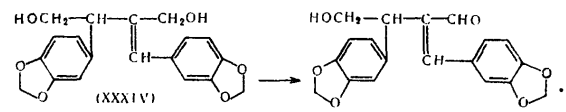
Vitamin A_1 aldehyde has been prepared also from vitamin A_1[156] and β-carotene[157] by oxidation with air in the presence of manganese dioxide. The use of these methods has enabled a convenient and cheap process to be developed for obtaining vitamin A aldehyde identical with the product isolated from the retina.

In the oxidation of polyols several reactions are possible, involving one or more hydroxyls depending on their degree of activation by multiple bonds, or accompanied by cleavage of skeletal carbon bonds (under more severe conditions). Special interest attaches to the synthesis of polyene and aromatic dialdehydes and diketones[158-172]. An example is provided by the oxidation of 2,7-dimethylocta-2,4,6-triene-1,8-diol (XXX)[164] in 94% yield to the corresponding dialdehyde (XXXI), of 1,1′-bishydroxymethylferrocene (XXXII),[171] and of 2,5-bishydroxymethylthiophen (XXXIII):[172]



(XXX) (XXXI) (XXXII) (XXXIII).

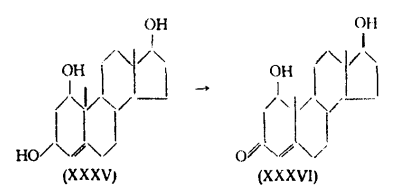
Glycols in which the hydroxy-groups are activated to different extents behave somewhat differently. Thus several publications have indicated the possibility of oxidising only an allylic type of hydroxyl[173-175]. A break in the chain of conjugation in an unsaturated bond system, even by only one carbon atom, for example, as in (XXXIV),[173] markedly decreases the rate of oxidation:



(XXXIV)

Barakat et al.[35] were able to obtain benzil and *pp′*-dimethoxybenzil in good yields from the corresponding α-hydroxy-ketones. This work also showed that ethylene glycol, glycerol, mannitol, and inositol are oxidised to carbon dioxide and water when boiled with an aqueous suspension of active manganese dioxide. The oxidation of hydroxy-acids is also anomalous: reaction is very rapid, and is accompanied by the evolution of carbon dioxide, aldehydes and ketones being formed containing one fewer carbon atoms than in the initial acid. Under milder conditions esters of hydroxy-acids undergo the usual type of oxidation[176-179].

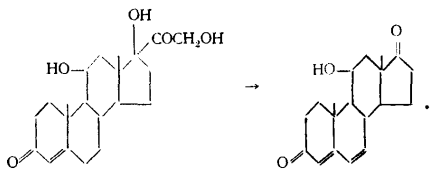
The specificity of the action of active manganese dioxide has enabled it to be used for the oxidation of several steroid hydroxy-compounds[180-203]. The reaction goes mainly by the usual route, with conversion of only an allylic hydroxyl. Androst-4-ene-1β,3β,17β-triol (XXXV) is oxidised, in propan-2-ol at room temperature, to 1β,17β-dihydroxyandrost-4-en-3-one (XXXVI):[180]



(XXXV) (XXXVI)

It is advisable to conduct the reaction at room temperature in order to ensure that the structure of the molecule shall be preserved. Otherwise, oxidation of the hydroxyl may be accompanied by dehydrogenation of the olefinic to a diene system, migration of double bonds[204-208], and even rupture of carbon–carbon bonds.

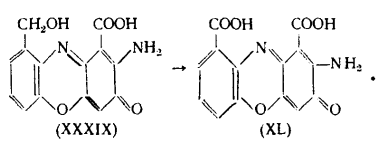
Special interest attaches to the oxidation of steroid 5-en-3β-ols, which in hot benzene are converted into 4,6-dienones[33], whereas in dimethylformamide or pyridine at 20° they give 4-en-3-ones, although the rate of reaction is not very high[51]. This extends the possibilities of synthesis of steroid products. Manganese dioxide in boiling chloroform splits off the side-chain in dihydroxy-acetonyl steroid alcohols to give 17-oxosteroids[34]. Hydrocortisone (XXXVII) is converted into 11β-hydroxyandrosta-4,6--diene-3,17-dione (XXXVIII):[209]



(XXXVII) (XXXVIII)

3. Oxidation of Aromatic Alcohols

The oxidation of benzyl alcohols and similar compounds by active manganese dioxide has been studied in some detail. As already mentioned, this oxidant has been regarded as ineffective for these alcohols. These views have now been completely refuted, and manganese dioxide has become widely used in the synthesis of aromatic aldehydes and ketones. Turner[12] was able to effect the mild oxidation of diphenylmethanol, xanthen-9-ol, furoin, 1-1'-naphthylethanol, tetrahydrophenanthren-1-ol, and several other alcohols. During recent years the successful oxidation has been accomplished of substituted benzyl alcohols[210-215], 2- and 4-hydroxymethylindoles[216,217], hydroxymethylferrocene[218], triazolylmethanols[219], secondary phenylmethanols[220,221], 1-thienylethanol[222], 1-furylalkanols[83], 2-hydroxyarylalkylbenzimidazoles[223], 4-pyranylmethanols[224], etc. The oxidation of benzyl alcohols usually goes readily, and stops at the carbonyl stage. Only one example has been reported in which the corresponding acid could be isolated as the main product: 2-amino-9-hydroxymethyl-3-oxophenoxazine-1-carboxylic acid (XXXIX), with manganese dioxide in chloroform at room temperature, gives the dicarboxylic acid (XL) as the sole product[225]:

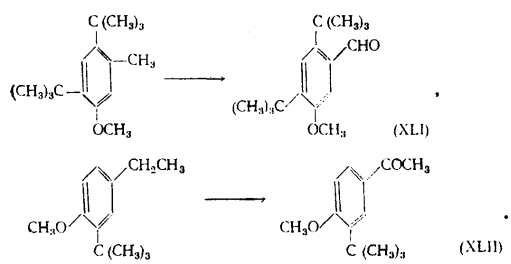


(XXXIX) (XL)

Insufficient study has hitherto been made of the mechanism of the oxidation of benzyl alcohols and similar compounds. Pratt[36] established that electron-acceptor properties of *para*-substituents in phenylmethanols have considerably less effect on their rate of oxidation than would have been expected on the hypothesis of a carbonium-ion mechanism. Moreover, Gritter and Wallace[28] have shown that methyl, methoxyl, and nitro-groups in the *ortho*-, *meta*, and *para*--positions always increase the rate of oxidation of the phenylmethanols in comparison with that of unsubstituted benzyl alcohol. This phenomenon is explained by a free-radical mechanism for the reaction. The insignificant effect of the nature of substituents becomes understandable, for radical reactions are accelerated by both electron-acceptor and electron-donor substituents. This mechanism is confirmed by the decrease in the rate of oxidation produced by the addition of diphenylamine. In a study of the oxidation of the alcohols $C_6H_5CH(OH)-R$ (where R = H, Alk, C_6H_5, $C_6H_5CH_2$, $C_6H_5CH{:}CH$, C_6H_5CO, etc.), Pratt explained the differences in the rates of oxidation of the α-substituted benzyl alcohols as due to two effects — the steric effect of substituents capable of preventing rapid adsorption of the alcohol on the surface of the active manganese dioxide, and the effect of the stabilisation of free radicals formed in the first stage of oxidation. Similar results were obtained by Gritter.

V. OXIDATION OF HYDROCARBONS

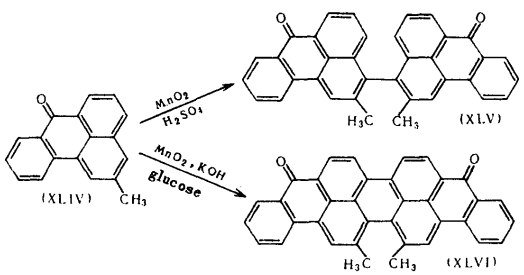
For a long time a great deal of attention has been paid in the chemical literature to the problem of the oxidation of alkylbenzenes. Among oxidising agents used for this reaction an important place is occupied by natural manganese dioxide, pyrolusite. In all cases oxidation is found to involve only the alkyl substituent in the benzene ring. Thus Fel'dman[226] heated 2,4-dichlorotoluene in the presence of pyrolusite and 58% sulphuric acid at 80° for 16–19 h, and obtained an 80% yield of 2,4-dichlorobenzoic acid, whereas *p*-nitrotoluene gives *p*-nitrobenzoic acid[227]. Alkylpyridines undergo similar oxidation[228]. When toluene is nitrated with a mixture of sulphuric and nitric acids in the presence of manganese dioxide, a mixture of *p*-nitrotoluene and 2,4-dinitrobenzaldehyde is formed[229]. It has been suggested[230] that terephthalic acid can be prepared by the oxidation of *p*-cymene with manganese dioxide in sulphuric acid. Thus the aromatic ring and certain functional substituents remain unchanged during the reaction, whereas a methyl group is converted into carbonyl or carboxyl depending on the conditions. The reaction conditions can be so chosen that oxidation is halted at the carbonyl stage. Lifshits[231] obtained a mixture of benzyl alcohol and benzaldehyde by the interaction of toluene and manganese dioxide in the presence of sulphuric acid. Carpenter et al.[232] were able to oxidise substituted methyl- and ethyl-benzenes to the corresponding benzaldehyde (XLI) and acetophenone (XLII) respectively:



Recently Hüttel and Christ[233] have proposed a new method for synthesising αβ-unsaturated carbonyl compounds (XLIII) by oxidising palladium dichloride–alkene complexes with various reagents, including manganese dioxide in an acid medium:

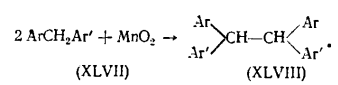
Manganese dioxide is used also for the oxidative dimerisation and even polymerisation of aromatic hydrocarbons. Travkin[234] heated 2-naphthol with manganese dioxide at

260° for 3 h, and obtained a quantitative yield of binaphthyl-2,2′-diol. Oxidation[235] of 2-methylmesobenzanthrone (XLIV) with manganese dioxide in sulphuric acid at 0–5° gives a 78% yield of 2,2′-dimethyl-3,3′-bibenzanthryl-7,7′-dione (XLV), whereas in alkaline medium containing glucose the product is 16,17-dimethylviolanthrone (XLVI):



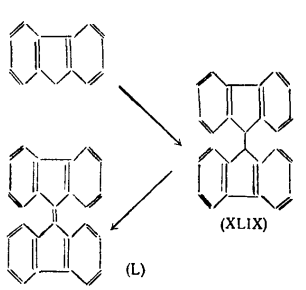
A convenient method for synthesising *p*-polyphenyls from benzene has been worked out by Kowacic[236]: the polyphenyls are formed by the action of manganese dioxide, copper(II) chloride, lead dioxide, and other oxidising agents in the presence of catalytic quantities of aluminium chloride.

The oxidative dimerisation of diarylmethanes (XLVII) by active manganese dioxide in neutral medium can be regarded as the same type of reaction[37]:



Three types of product — (1) tetra-arylethanes (XLVIII), (2) tetra-arylethylenes, or (3) diaryl ketones — may be formed depending on the conditions. Pratt made a detailed study of this process, and found it to be a general reaction with all symmetrical and unsymmetrical diarylmethanes, the rate of the reaction and the yield of tetra-arylethylenes depending on the electronic properties of the aryl ring.

The oxidation of *pp*′-dinitrodiphenylmethane, fluorene, and xanthen in a mixture of benzene and biphenyl at 211° is accompanied by the liberation of double the theoretical quantity of water. This suggests that, in the course of oxidation, tetra-arylethanes are dehydrogenated to the corresponding ethylenes, which were isolated in 15–30% yields. In order to demonstrate the formation of tetra-arylethylenes at the expense of tetra-arylethanes, 9,9′-bifluorenyl (XLIX) was converted into a 75% yield of 9,9′-bifluorenylidene (L) by the same method:



In view of the great stability of diarylmethane radicals, Pratt suggested a free-radical mechanism of oxidation:

$$Ar_2CH_2 + O{=}Mn{=}O \rightarrow Ar_2\dot{C}H + HO{-}Mn{=}O, \quad (1)$$

$$Ar_2CH_2 + HO{-}Mn{=}O \rightarrow Ar_2\dot{C}H + HO{-}MnOH, \quad (2)$$

$$2\,Ar_2\dot{C}H \rightarrow Ar_2CH{-}CH{\cdot}Ar_2. \quad (3)$$

This scheme is confirmed by the increase in rate of oxidation in the sequence — diphenylmethane, 1-benzylnaphthalene, *p*-benzylbiphenyl, di-*p*-biphenylylmethane — which corresponds to increasing stability of the corresponding free radicals. Dehydrogenation of tetra-arylethanes to the ethylenes may pass through analogous stages. Good yields of the former were obtained by stirring with a fourfold excess of manganese dioxide by weight in a 20 : 1 biphenyl–benzene mixture at 211°. The yields of tetra-arylethanes diminish with fall in temperature, although the theoretical quantity of water is liberated.

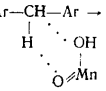
Simultaneous formation of diaryl ketones was also noted, their yields increasing with fall in temperature and increase in the quantity of active dioxide. The corresponding diarylmethanols are probably intermediate products in the oxidation of diarylmethanes to diaryl ketones. Manganese dioxide is normally used for the abstraction of hydrogen atoms, the oxidation of hydrocarbons to ketones representing a rare though not unique case of the introduction of oxygen into the carbon skeleton[227]. A possible source of hydroxy-groups is hydrated manganese dioxide, on whose surface hydroxyls are present as free radicals or as HO–Mn=O. The reaction can then be written

$$Ar_2\dot{C}H + HO{-}Mn{=}O \rightarrow Ar_2CHOH + MnO. \quad (4)$$

Reaction (4) together with reaction (1) explains the increased yield of ketones when the solvent is not distilled off during the reaction and when the latter is conducted at lower temperatures, since active manganese dioxide is rapidly dehydrated during the azeotropic distillation of water and solvent, which diminishes the possibility of attack by a hydroxyl on the free radical. At the same time, a reaction in which water and solvent are distilled off promotes the desorption and recombination of radicals, i.e. reaction (3). Thus

$$Ar_2\dot{C}H + HOMnO \rightarrow Ar_2CHOH + MnO,$$

$$Ar{-}CH{-}Ar \rightarrow Ar{-}CHOH{-}Ar + MnO,$$



$$Ar_2CHOH \rightarrow Ar_2CO + H_2O.$$

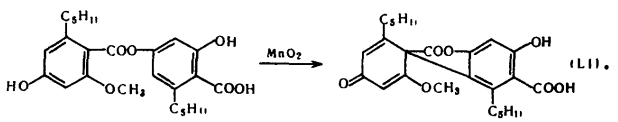
The above mechanism is confirmed by the oxidation of diphenylmethane with manganese dioxide which has first been dehydrated by being boiled in toluene. When the hydrocarbon is oxidised with this dioxide in the absence of solvent, the yield of benzophenone falls from 74% to 2%. Since the dioxide undergoes still greater dehydration in reaction with a solvent at high temperatures, it follows that in this case practically no ketone will be formed.

VI. OXIDATION OF PHENOLS

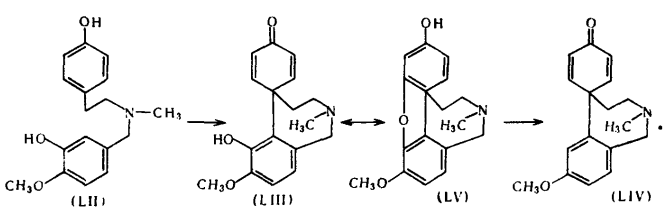
In recent years several successful syntheses, involving the oxidative linking of phenols, have been made of important natural products from readily available and inexpensive substances[238-241]. This method is based on the free-radical coupling of certain phenol derivatives, the reaction

being regarded as analogous to biochemical processes occurring in the living cell. Various oxidants convert phenols into mono- or di-radicals, which can then react intramolecularly or dimerise, new carbon–carbon, carbon–nitrogen, or carbon–oxygen bonds being formed. Active manganese dioxide occupies a special place[241] among the numerous oxidising systems (lead dioxide, potassium hexacyanoferrate(III), hydrogen peroxide, etc.) employed for this purpose.

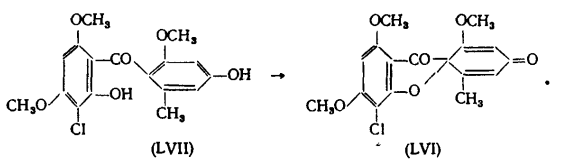
Scott and Davidson[242,243] have synthesised picrolichenic acid (LI), previously isolated from *Pertusaria amara*:



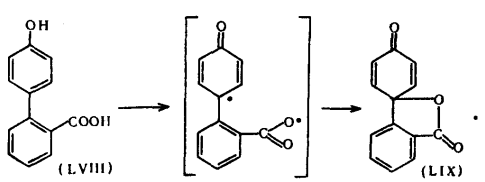
Under similar conditions Barton and Kirby[244,245] have obtained from *p*-hydroxy-*N*-(3-hydroxy-4-methoxybenzyl)-*N*-methylphenethylamine (LII) the alkaloid galanthamine (LIII), which can be further oxidised via (LV) to narwedine (LIV):[246,247]



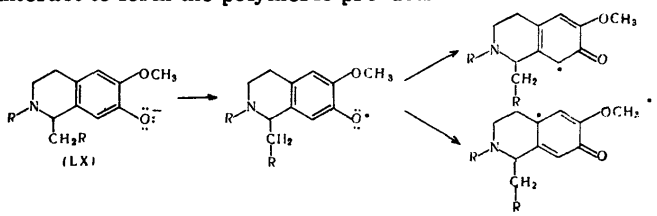
Several morphine alkaloids[248] and geodin[241] have been synthesised by a similar scheme. A new carbon–carbon bond is formed also in the oxidation of bisphenols[249]. In other cases the oxidative coupling of phenols leads to the formation of a carbon–oxygen bond. This can be seen in the synthesis of depsidone and diploicin[250,251] and of dehydrogriseofulvin (LVI)[252,253] from 3-chloro-2,4′-dihydroxy-2′,4,6-trimethoxy-6′-methylbenzophenone (LVII):



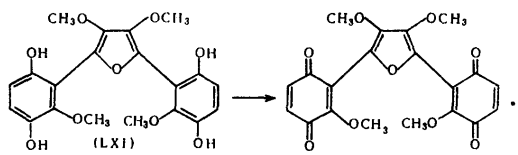
Oxidation of 4′-hydroxybiphenyl-2-carboxylic acid (LVIII) with manganese dioxide in ether[254] gives a 25% yield of phthalan-1-spiro-1′-cyclohexadiene-3,4′-dione (LIX):



Interaction of phenolic tetrahydroisoquinoline bases with active manganese dioxide at room temperature results in formation of the isoquinoline system[241,255]. At higher temperatures hydrogen is detached from the hydroxyl with formation of polymeric products. The phenoxide ion (LX) is converted into a mixture of radicals having their unpaired electron on the oxygen atom or in the *ortho*- or *para*-positions of the cyclohexadiene ring, and these radicals then interact to form the polymeric products[256,257].

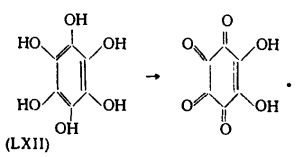


Oxidation of the mono- and di-adducts of 3,4-dimethoxyfuran with acetylbenzoquinone (LXI) involves conversion of the 2,5-dihydroxyphenyl into *p*-quinonoid substituents[258]:



These reactions have been used for the purification of industrial waste waters from *p*-t-butylphenol, bishydroxyphenylpropane, and other phenols[259].

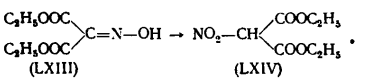
The oxidation of phenols with manganese dioxide in acid and alkaline media has been known for a long time. As early as the nineteenth century Clark[260] oxidised quinol to *p*-benzoquinone with manganese dioxide in sulphuric acid. The most interesting of recent investigations is that by Fatiadi[261] on the oxidation of benzenehexaol (hexahydroxybenzene) (LXII) with a specially prepared highly active dioxide in alkaline medium:



VII. OXIDATION OF AMINES

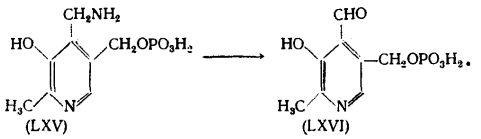
An important field for the application of active manganese dioxide is the oxidation of various amino-compounds. This reaction occurs in several ways, and covers a wide range of compounds containing nitrogen. Their interaction with manganese dioxide may involve oxidation of alkyl groups, cleavage of carbon–carbon bonds, and dehydrogenation of carbon–carbon and carbon–nitrogen bonds. The process may be either unimolecular or bimolecular.

The oxidation of amino-compounds with manganese dioxide in acid medium is widely used for the synthesis of various classes of compounds. An example is provided by the oxidation of aniline with the natural dioxide in acid medium to form *p*-benzoquinone[262]. In dilute acetic acid the oxime (LXIII) is readily converted into the nitro-compound (LXIV):[263]



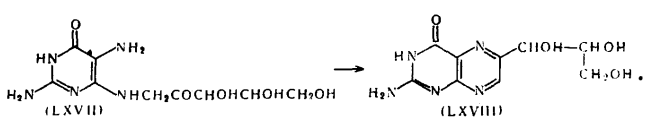
3-(2-Piperidyl)pyridine (anabasine) on oxidation with manganese dioxide in sulphuric acid gives a 45% yield of nicotinic acid[264]. Isonicotinic acid has been obtained by the oxidation of 4-ethylpyridine[228] and 4-methylpyridine[265].

When pyridoxamine (LXV) is subjected to prolonged heating with manganese dioxide in water containing sulphuric or phosphoric acid[45,266], the aminomethyl group is converted into an aldehyde group (LXVI):



(LXV) (LXVI)

Among recent work mention must be made of the paper by Lagowski and Forrest[267] describing the preparation of 2-amino-3,4-dihydro-4-oxo-6-(L-*erythro*-1,2,3-trihydroxypropyl)pteridine (LXVIII) by oxidation of the 1-pyrimidinylamino-1-deoxypentulose (LXVII):



(LXVII) (LXVIII)

In 1955 Highet and Wildman[14] accomplished the oxidation of benzylamine, *N*-methylbenzylamine, and *N*-methylpiperonylamine with manganese dioxide in chloroform. The infrared spectrum of the oxidation product of benzylamine was almost identical with that of hydrobenzamide, which confirms the intermediate formation of the imine (LXIX):

$$R{-}CH_2NH{-}CH_3 \rightarrow R{-}CH{=}N{-}CH_3.$$

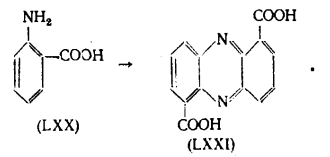
(LXIX).

Tertiary amines do not undergo this reaction, which was subsequently extended to anilines, *N*-alkylanilines, hydrazines, and hydrazones of carbonyl-containing compounds.

Great attention has been paid to the oxidation of various ring-substituted anilines to azobenzenes. Various oxidising agents — including per-acids[268], diacetoxyiodobenzene[269], sodium borate[270], lead tetra-acetate[271], etc. — have previously been used for this purpose. The simplicity of the oxidation procedure and the availability of manganese dioxide have made this method the most widely used in the synthesis of azobenzenes. Barakat et al.[35] investigated the oxidation of aniline, *o*- and *p*-chloroanilines, *p*-toluidine, 1- and 2-naphthylamines, and also *o*-, *p*-, and *m*-nitroanilines with alkaline manganese dioxide in petroleum ether. Aniline and methyl- and chloro-anilines gave the corresponding azobenzenes in excellent yields.

Wheeler and Gonsalez[272] derived several general rules from a study of the oxidation with active manganese dioxide of a series of ring-substituted anilines. One of their main conclusions was that the electronic character of the substituent has no appreciable effect on the reaction velocity or the yield of the oxidation product, although a slight electronic effect is nevertheless present. Thus *para*-substituted anilines react somewhat faster than other isomers. In a series of halogenoanilines the rate of oxidation falls in the sequence F > Cl > Br > I. 3,5-Dichloro- and 2,6-dimethoxy-anilines react normally, as does 3-chloro--4,6-dimethoxyaniline. However, several substituted nitroanilines — 2-iodo-4-nitro-, 2,6-di-iodo-4-nitro-, and 2-methyl-5-nitro-anilines — do not react with manganese dioxide. This cannot be explained by the electronic effects of the substituents, for in some cases the nitro-group facilitates oxidation. One possible explanation is that the nitro-group itself may be adsorbed on the surface of the manganese dioxide, and thereby prevent oxidation of the amino-group. Therefore 3,5-dichloro-4-nitroaniline, in which adsorption of the nitro-group is impeded by the neighbouring chlorine atoms, forms the azobenzene to a slight extent, whereas 3,5-dichloro-2-nitroaniline, in which the electronic effect of the chlorine atoms is the same as in the 4-nitro-isomer, is completely incapable of being oxidised.

Carboxyl resembles the nitro-group in having an unfavourable effect. The diminished polarity of the carboxyl in ethyl *p*-aminobenzoate, and the consequently diminished adsorbability of carboxyl on the manganese dioxide surface, make it possible to obtain a low yield of diethyl azobenzene--*pp'*-dicarboxylate. It has recently been found[273] that anthranilic acid (LXX) is oxidised in low yields to phenazine-1,6-dicarboxylic acid (LXXI):



(LXX) (LXXI)

The relatively minor influence of the nature of the substituents in the oxidation of amines can be regarded as an indication that this reaction has a free-radical mechanism. The formation of free radicals as intermediate products in the oxidation of amines has been suggested by Henbest and Stafford[274]. It must not be overlooked, however, that adsorption phenomena may mask the influence of the electronic structure of substituents in the actual oxidising step. Thus the oxidation of primary aromatic amines is a bimolecular adsorption dehydrogenation of the amino-group.

This idea has been developed by Pratt and McGovern[38], who have studied the oxidation of *N*-benzylanilines (LXXII) to benzylideneanilines (LXXIII):

$$X{-}C_6H_4CH_2NH{-}C_6H_4{-}X' \xrightarrow{MnO_2} X{-}C_6H_4CH{=}N{-}C_6H_4{-}X'.$$

(LXXII) (LXXIII)

Since an important part is played by the adsorption of anilines on the surface of the manganese dioxide, *ortho*-substituted benzylanilines react more slowly than the *para*-substituted isomers, and the *o*-methoxy-derivatives are oxidised far more slowly than the *o*-methylated compounds, since the former contain a more bulky substituent. Furthermore, the rate of oxidation of benzylanilines is independent of the electronic characteristics of the substituents.

Hydrazobenzenes (LXXIV) are extremely readily dehydrogenated to azobenzenes (LXXV) in high yields:

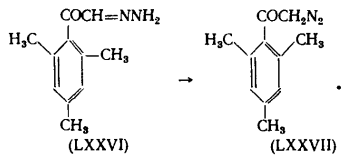
$$X{-}C_6H_4{-}NH{-}NH{-}C_6H_4{-}X \rightarrow X{-}C_6H_4N{=}N{-}C_6H_4X.$$

(LXXIV) (LXXV)

The rate of this oxidation is hardly affected at all by substituents.

The oxidation of hydrazones of carbonyl compounds by manganese dioxide represents a unimolecular dehydrogenation of the amino-group. Barakat showed that the active dioxide is able to oxidise hydrazones of ketones to azines. The appearance of a violet colour in the solution suggests formation of a diazo-compound as an intermediate stage in the oxidation. Schroeter[275] reported that active manganese dioxide oxidised hydrazones of substituted benzophenones to diazo-derivatives, though in lower yields than with oxidation by silver oxide. The dihydrazone of dibenzoylbenzene is converted under these conditions into a bisdiazo--compound[276,277]. Morrison and Danishefsky[278] used alkaline manganese dioxide to prepare diazo-ketones from

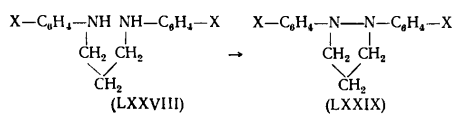
monohydrazones of diketones and keto-aldehydes. Mesitylglyoxal hydrazone (LXXVI) when shaken with the active dioxide forms diazomethyl mesityl ketone (LXXVII):



(LXXVI) (LXXVII)

Diekmann[279] obtained by means of manganese dioxide a 55% yield of bisphenylsulphonyldiazomethane from the hydrazone of bisphenylsulphonylformaldehyde. A similar reaction has been described with dihydrazones[280], where it is probable that diazo-compounds are also intermediate products[281]. Phenylhydrazides of acids form, with manganese dioxide in dilute acetic acid, aromatic hydrocarbons[282,283], while methylhydrazine in the presence of alkali forms ethane[284].

The oxidation of trimethylenediamines also consists in the oxidative dehydrogenation of the two amino-groups with subsequent intramolecular cyclisation to a pyrazoline. Wittig[285] obtained from *NN'*-diphenyltrimethylenediamine a 31% yield of 1,2-diphenylpyrazolidine. A more detailed study of this reaction has been made by Daniels and Martin[286], who found that the oxidation depends to a considerable extent on the type of active dioxide used. The conversion was investigated of a large number of 1,3-bisarylaminopropanes (LXXVIII) into the corresponding 1,2-diarylpyrazolidines (LXXIX):



(LXXVIII) (LXXIX)

In the case of *NN'*-di-*p*-methoxyphenyltrimethylenediamine the product is *pp'*-dimethoxyazobenzene[287]. Nevertheless, the corresponding ethoxy-derivative reacts normally, with formation of a pyrazolidine ring. *NN'*-Dialkyltrimethylenediamines do not undergo this reaction.

N-Alkylanilines undergo a different type of reaction with active manganese dioxide, alkyl and methylene groups in the amines being involved. Henbest et al.[32,288] studied the oxidation of *N*-alkyl- and *NN*-dialkyl-anilines with a large excess of manganese dioxide (ratio of reactants 1 : 50–100), and showed that three types of reactions could occur in this case — (*a*) formation of an amide

$$\rangle N{-}CH_3 \rightarrow \rangle N{-}CHO;$$

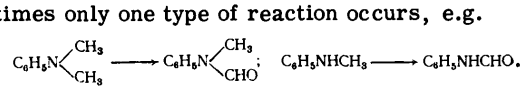
(*b*) dealkylation with formation of an aliphatic aldehyde

$$\rangle N{-}CH_2R \rightarrow \rangle NH + RCHO;$$

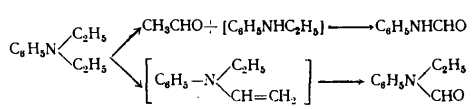
(*c*) dehydrogenation at an alkyl C–C bond followed by cleavage of the resulting enamine

$$\rangle N{-}CH_2CH_2R \rightarrow \left[\rangle N{-}CH{=}CH{-}R\right] \rightarrow \rangle NCHO + RCHO.$$

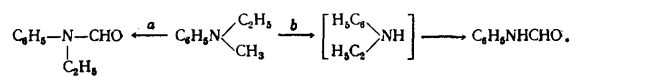
Sometimes only one type of reaction occurs, e.g.



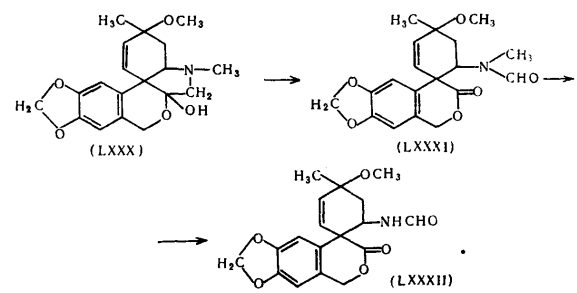
With diethylaniline the course of the reaction is more complicated:



Enamines are readily cleaved by manganese dioxide, as has been shown by the oxidation of *NN*-dibenzylstyrylamine to *NN*-dibenzylformamide[288], and also in the oxidation of sporidesmin[289] with a freshly prepared active dioxide. Introduction of a *p*-methyl group was found to facilitate the reaction, whereas a *p*-nitro-group impeded it. Small quantities of azobenzenes are formed as side-products in the oxidation of *N*-ethyl-*N*-methyl- and *NN*-diethyl-anilines. *N*-Ethyl-*N*-methylaniline yields both *N*-ethylformanilide and formanilide itself:

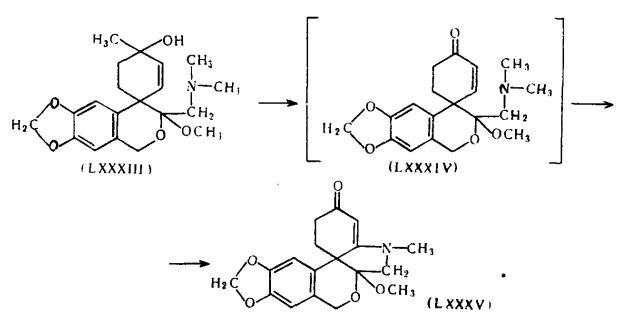


1,4-Diphenylpiperazine forms *NN'*-diformyl-*NN'*-diphenylethylenediamine, the process consisting in oxidative cleavage of a carbon–carbon single bond. This reaction is of great importance, for it represents the only known method of converting ethylenediamines into *N*-formyl derivatives. It has been used for the oxidation of tazettine to tazettamide, and of dihydrotazettine to dihydrotazettamide[290], and also in analytical practice for the determination of ethyl groups in diethylamino-compounds[291]. Japanese workers[292,293] have been able to isolate from oxidation of the alkaloid tazettine (LXXX), besides tazettamide (LXXXI), products of further oxidation, including *N*-desmethyltazettamide (LXXXII):



(LXXX) (LXXXI) (LXXXII)

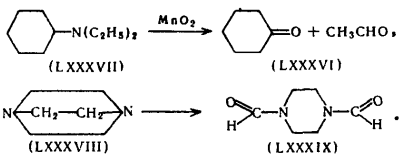
It is interesting that oxidation of a similar dimethylamino-derivative (LXXXIII)[294] produces, instead of the expected cyclohexenone (LXXXIV), oxidative elimination of one *N*-methyl group with cyclisation to dihydro-*O*-methyltazettinone (LXXXV):



(LXXXIII) (LXXXIV) (LXXXV)

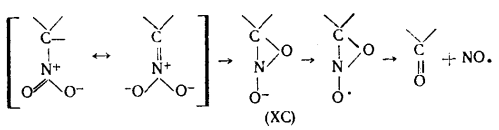
In some cases oxidation with manganese dioxide does not affect a dimethylamino-group[295]. With dialkylbenzylamines[296] the reaction consists in oxidation of the methylene group of the benzyl radical with detachment of the amino-group, various yields of benzaldehyde being formed in all cases. Tribenzylamine reacts very slowly, probably owing to steric hindrance to adsorption on the surface of the dioxide. Dialkylcyclohexylamines are transformed in good

yields into cyclohexanone (LXXXVI), the diethyl derivative (LXXXVII) being oxidised also at the ethyl group to form acetaldehyde[288]. Triethyleneamine (LXXXVIII) is oxidised with cleavage of a C–C bond to 1,4-diformylpiperazine (LXXXIX):

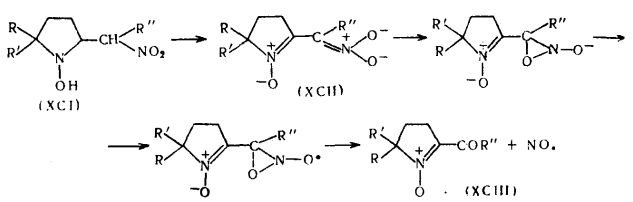


Active manganese dioxide has been successfully used for dehydrogenation at a carbon–nitrogen bond in nitrogen heterocycles. Thus tetrahydroquinazoline derivatives are converted into good yields of the corresponding dihydroquinazolines[297], and similarly pyrrolidine into pyrroline derivatives[298].

The oxidative elimination of nitric oxide from nitro-compounds represents a special case of the use of active manganese dioxide. The literature contains examples of analogous reactions in the presence of per-acids and quinones. Thus Jones[299] showed that 4-nitro-2,6-diphenylphenol when heated with an oxidising agent loses nitric oxide and is converted in good yield into 2,6-diphenyl-1,4-benzoquinone. Such reactions are regarded as taking place according to the following scheme



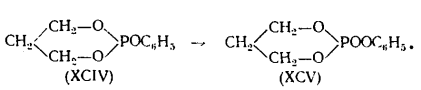
The oxaziran ring (XC), which is formed when a C=N double bond is present, breaks down to form a carbonyl compound and nitric oxide. Bowering et al.[300] have shown that a similar reaction is possible with 2-nitroalkylhydroxylamines:



Ethyl 1-hydroxy-2-methyl-5-(1-nitroethyl)pyrrolidine-2-carboxylate (XCI; R = $COOC_2H_5$, R′ = R″ = CH_3) is oxidised to the pyrroline anion (XCII), which is then converted according to the above scheme into the *N*-hydroxypyrroline (XCIII). The reaction takes place in petroleum ether at room temperature and lasts 4–6 h.

VIII. OXIDATION OF OTHER CLASSES OF COMPOUNDS

Active manganese dioxide is a good oxidising agent for tervalent phosphorus compounds. This reaction was first used for the conversion of triphenylphosphine into triphenylphosphine oxide[35]. Phenyl trimethylene phosphite (XCIV), obtained by reaction of triphenyl phosphite with trimethylene glycol, gives when shaken with manganese dioxide a 56% yield of the corresponding phosphate (XCV):[301]



Kabachnik and his coworkers have described the oxidation by means of active manganese dioxide of tertiary vinylphosphines[302], dibutyl-2-piperidinoethylphosphine, and dibutyl 2-piperidinoethyl phosphite to the corresponding oxides[303]. They have also studied the oxidation of vinyl-, allyl-, and vinylphenyl-phosphonous esters[304]. In all these cases reaction takes place readily, to give high yields without the formation of side-products.

Edwards and Stenlake[305] successfully used manganese dioxide for the oxidation of alkyl sulphides, and a paper has recently been published on the oxidation of various thiols with this oxidant[306].

Several papers have been published on the action of manganese dioxide on carbohydrates[307,308] — aldohexoses (galactose, ribose, erythrose, etc.), ketoses (inosose, fructose), disaccharides (sophorose, maltose, cellobiose, and melibiose). The oxidation of aldohexoses involves mainly elimination of $C_{(1)}$ with formation of the corresponding aldopentoses. These are accompanied by a certain quantity of epimerisation products and a mixture of C_{6-3} acids. Results of the oxidation of 3-*O*-methyl-D-glucose and of rhamnose indicate that this reaction may be of preparative value, e.g. for the synthesis of *O*-methylpentoses or deoxypentoses. Disaccharides react similarly: hexosylhexoses give hexosylpentoses. Interesting results have been obtained for the oxidation of D-fructose[309]: the manganese dioxide reacts with the carbonyl group adjacent to the first carbon atom of D-fructose with the formation of the 2-oxo-D-arabinoaldohexose, but with inadequate selectivity.

Manganese dioxide has been used in aqueous medium for the oxidation of derivatives of nucleic acids and similar compounds. Thymidine 5′-phosphate[310], adenine, 6-methylaminopurine, guanine, and 9-ethylguanine[311] have been subjected to oxidation. The latter compounds are oxidised fairly rapidly, products of the degradation of the purine ring — urea, alkylureas, guanidine, biuret, etc. — being formed. Purine nucleosides — adenosine and guanosine — are oxidised rather more slowly. Pyrimidine nucleosides — uridine, cytidine, and thymidine — remain unchanged during the same conditions.

The present review shows that during recent years active manganese dioxide in its various modifications has been finding ever wider use for numerous reactions of an oxidising character involving diverse classes of organic compounds.
